1): apparently, **2a** is not reactive enough. Formation of the desired isomer **3** dominated over that of **4** by the ratio 4:1. The same ratio of isomers was obtained with zinc chloride-ether[5a] (No. 2); although this reaction was carried out at −40°C, some of the product decomposed at longer reaction times. We therefore activated the allylic alcohol by trifluoroacetylation to afford **2b** and found that prenylation was feasible in refluxing dichloromethane (No. 3). Interestingly, on lowering the temperature to 25°C prenylation was more regioselective; formation of **3** was preferred still more (**3**:**4** = 89:11; No. 4). The total isolated yield of **3** + **4** was 73%. Products arising from attack of the tertiary allylic terminus on **1a** were not detected.

We found, however, that tertiary alkyl groups can be introduced into furans by a different method, *i. e.* by reaction with 4-methyl-2-oxo-3-pentenenitrile **5**[7] in the presence of aluminum chloride in benzene (Scheme 1). This reagent is

Scheme 1. Tertiary alkylation of **1a, b** with 4-methyl-2-oxo-3-pentenenitrile 5 in the presence of $AlCl_3$.

more regioselective than the prenylation reagent; the ratio **6a**:**7a** was 94:6. Compound **6a**, which is of the *cis*-jasmone type, has an interesting herbal, sweet, floral odor. **6a** and **6b** have also been reduced to the corresponding alcohols **9a** and **9b**.

The introduction of *functionalized* tertiary alkyl groups into furans by our second procedure goes beyond the recently described introduction of the simple *t*-butyl group[8]. Clearly, decomposition and polymerization need no longer be the necessary result of electrophilic alkylations of furans such as **1a**, **b**. Finally, regioselective control has been achieved both with respect to the site of attack in furan and also with respect to the ambident electrophile.

## Cercosporin, a Singlet Oxygen Generator**

By *Diane C. Dobrowolski* and *Christopher S. Foote**

*Dedicated to Prof. Günther O. Schenck on the occasion of his 70th birthday*

The photodynamic fungal pigment cercosporin **1**[1] is a nonspecific toxin which kills plant cells *in vitro* in the presence of light by lipid peroxidation[2, 3a]. The requirement for light, the cercosporin-sensitized formation of the characteristic $^1O_2$ oxidation product of cholesterol (the 5α-hydroperoxide), and the inhibition of the effects of cercosporin by β-carotene and other $^1O_2$ quenchers suggest that the mechanism of action involves production of $^1O_2$ sensitized by **1**[3]. We now report direct evidence for $^1O_2$ formation by observation of the characteristic $^1O_2$-luminescence at 1270 nm sensitized by cercosporin. This is the first time that a plant photodynamic sensitizer has been shown unequivocally to produce singlet oxygen. The quantum yield of $^1O_2$ formation is large: 0.81 ± 0.07 (95% confidence level).

R = $CH_2CHOHCH_3$

Samples of **1** ($1.0 \times 10^{-4}$ M, $A_{532} = 1.25$) or meso-porphyrin IX dimethyl ester **2** ($3.0 \times 10^{-4}$ M, $A_{532} = 1.15$) in $C_6D_6$ were irradiated with a Nd:YAG laser ($\lambda = 532$ nm)[6]. Luminescence was detected with a germanium photodiode[4]. The luminescence intensity at 1270 nm was the same in air or oxygen for both sensitizers, indicating that triplet states alone are involved in $^1O_2$ formation. The lifetime of the luminescence at 1270 nm (617 μs) and its quenching on addi-

[**] Chemistry of Singlet Oxygen, Part 46. This work was supported by NSF grant CHE 80-20140. We thank Dr. *M. E. Daub* for helpful discussions and a sample of cercosporin.—Part 45: J.-J. Liang, C.-L. Gu, M. L. Kacher, C. S. Foote, *J. Am. Chem. Soc. 105* (1983) 4717.

tion of 2,3-dimethyl-2-butene further confirmed its identity as $^1O_2$.

After correction for differing sensitizer optical densities, the maximum intensities of **1**- and **2**-sensitized $^1O_2$ luminescence were compared. Since the quantum yield of triplet formation from **2** is 0.81[5], and this state is efficiently quenched by oxygen to form $^1O_2$[5], the absolute quantum yield of cercosporin-sensitized formation of $^1O_2$ could be determined. Based on four independent determinations, the relative ratio of luminescence produced from **2** to that produced from **1** was found to be $1.01 \pm 0.04$. Two separate determinations of the relative rates of photooxygenation of 2-methyl-2-pentene in benzene sensitized by **2** and **1** gave the ratio $1.00 \pm 0.12$. Both ratios indicate that the quantum yield of formation of $^1O_2$ sensitized by **1** is $0.81 \pm 0.07$.

This large quantum yield strongly supports the suggestion that singlet oxygen is the toxic agent in host plants. This is a striking example of the use of a chemical mechanism by a parasite to gain an "environmental advantage".

[6] Cercosporin was provided by Dr. *M. E. Daub*, Michigan State University. Its structure and purity were confirmed by comparison of the absorption and NMR spectra with published data[1]. 2-Methyl-2-pentene (Aldrich) was purified by column chromatography on basic $Al_2O_3$. $C_6H_6$ (Mallinckrodt) was distilled from $P_2O_5$ immediately before use. **2** (Sigma) and $C_6H_6$ (Cambridge Isotope Laboratories) were used as received.—The apparatus used to observe $^1O_2$ luminescence has been described previously [4].

## Synthesis and Structure of a Linearly *anti*-Annelated Tetracycloundecane. A Potential Precursor for a Coriolin Synthesis

By *Martin Demuth**, *Antonio Cánovas*, *Eva Weigt*, *Carl Krüger*, and *Yi-Hung Tsay*

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

We recently presented a widely applicable concept for the synthesis of cyclopentanoid natural products based on the utilization of tricyclo[3.3.0.0$^{2,8}$]octan-3-one **1** as central optically active building block[1,2]. Scheme 1 outlines the strategy (AB+C principle) now chosen by us for the preparation of the tetracycloundecanes **9** and **12**, which are potential precursors for the synthesis of coriolins[1]. The most important step in the sequence involves the previously only indirectly demonstrated[3] *anti*-annelation of a third five-membered ring to **1**. The desired *anti*-configuration of the rings A and C in **13** could be confirmed by an X-ray structure analysis.

Scheme 1. a: NaH, MeI, tetrahydrofuran, 50 °C. b: 3-chloro-2-methylpropene, KBr, tBuOK, tBuOH, toluene, 80°C. c: $OsO_4$, $NaIO_4$, dioxane, $H_2O$, room temperature. d: Nafion-TMS (perfluorinated trimethylsilyl sulfonate resin), toluene, 80°C. e: AcOAg, $I_2$, toluene, room temperature. f: 1,5-diazabicyclo[4.3.0]non-5-ene, toluene, room temperature. g: tBuOK, tBuOH, toluene, 80°C, 5 min. h: as g but 12 h or TosOH cat., $CH_3OH$, room temperature. i: iodotrimethylsilane, $CH_2Cl_2$, room temperature. The numbering in **10**—**13** is that generally employed in coriolin chemistry.

The alkylation **2**→**3** proceeds in 86% yield and just as selectively as the preceding methylation **1**→**2**[2,3]. Oxidative degradation (**3**→**4**; 82%) and subsequent isomerization **4**→**5** (60%)[4] afforded a suitable starting material for further functionalization of ring A. The Prévost addition of acetyl hypoiodate to the double bond of **5** yields **6** and **7** with equally high selectivity (10 : 1) as has already been observed in an analogous case[1,3]. After re-formation of the three-membered ring (**6**→**8**; 77%, annelation of the ring C

(**8**→**9**, **11**) was achieved with potassium *tert*-butoxide in *tert*-butyl alcohol and toluene at 80°C. Interruption of this reaction after 5 min permitted isolation of the primary aldol product **9**; the end product after 12 h was the pentacyclic ether **11** (93%). The labile primary product **9** readily cyclizes to **11** in the presence of traces of bases or acids, the presumed intermediary enone **10** not being detectable (for model considerations cf. [1]). Since **9** and **10** proved to be of no synthetic value we searched for a stable derivative having basically similar features and which is readily accessible from **11**. To avoid the undesired internal ether formation, it seemed desirable that C10 be either *exo*-substituted with oxygen or bear a readily modifiable group not containing oxygen. The latter variant could be achieved by treatment of **11** with iodotrimethylsilane (TMSI)[5]; this afforded the crystalline diiodo compound **13** as major product (64%) (Fig. 1). Re-formation of the three-membered

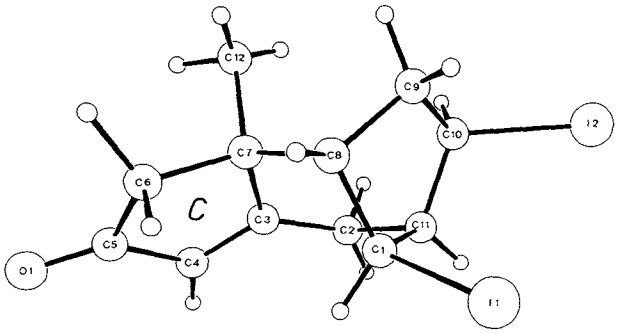

Fig. 1. Structure of the diiodo compound **13** in the crystal. $a=7.789(1)$, $b=13.772(3)$, $c=14.293(1)$ Å, $\alpha=64.51(1)$, $\beta=89.353(7)$, $\gamma=73.98(1)°$, $V=1319.90$ Å, $\rho_{calc}=2.154$ g cm$^{-3}$, $Mo_{K\alpha}$, $\mu=46.9$ cm$^{-1}$, $Z=4$, space group $P\bar{1}$, 5960 reflections, 5010 observed (2σ), 271 refined parameters, $R=0.0565$, $R_w=0.696$. ring (→ **12**; 72%) was accomplished by reaction of **13** with diazabicyclo[4.3.0]non-5-ene; thus a stable *anti*-annelated tetracycloundecane with appropriate ring A substitution was prepared for the first time. As initial step of the ring-opening **11**→**13** we postulate cleavage of the ether by $S_N2$ substitution with iodide at C10 and concomitant formation of the enone (→ **12**). The opening of the cyclopropane ring of **12** taking place in the second step does not occur at C11, but, because of steric interaction with the 10-*exo* iodide, selectively at C1. As has also been found in other examples, the iodide addition at C1 occurs with inversion[4].

## Synthesis and Structure Determination of $[(PEt_3)RhC_2B_9H_{10}]_2$— A Binuclear Rhodacarborane Containing Four Bonds Between Two Icosahedra**

By *Paul E. Behnken, Carolyn B. Knobler,* and *M. Frederick Hawthorne**

In the course of our studies of the homogeneous catalysis of olefin hydrogenation by *closo*-3,3-$(PPh_3)_2$-3-(H)-3,1,2-$RhC_2B_9H_{11}$ **1**[1], we characterized and reported the molecular structure of $[(PPh_3)RhC_2B_9H_{11}]_2$ **2**[2], a binuclear (phosphane)rhodacarborane complex formed by formal loss of $H_2$ and two phosphane ligands from two molecules of **1**. Of interest were the Rh—H—B interactions supporting the Rh—Rh bond and the stereospecificity of their formation. The two terminal B—H bonds involved in the Rh—H—B interactions determine a specific stereoisomer: of the six possibilities only **2** is observed with both enantiomers present in the unit cell.

In an attempt to further probe the nature of these interactions, cyclooctadiene(triethylphosphane)rhodium(I) chloride was allowed to react with $Cs_2[7\text{-}(7'\text{-}7',8'\text{-}C_2B_9H_{11})\text{-}7,8\text{-}C_2B_9H_{11}]$ **3**[3] (15 h reflux) to produce a dark blue compound **4** in 16% yield.

Crystals of **4** (Fig. 1) contain two icosahedral rhodacarborane fragments joined symmetrically at three vertices. Carbon atoms C1 and C1′ are covalently bonded as in the

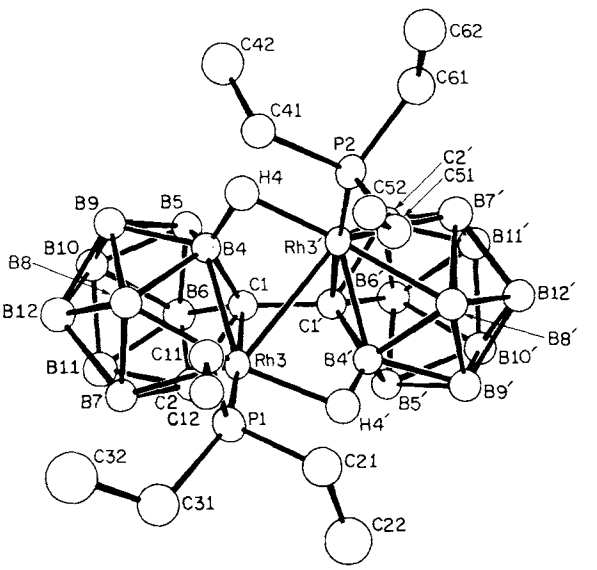

Fig. 1. ORTEP projection of the binuclear rhodium complex $[(Et_3P)RhC_2B_9H_{10}]_2$ **4**. H atoms other than those involved in bridging are omitted for clarity. For details of the crystal structure analysis ($R_w=0.036$), see Supplement.

Department of Chemistry and Biochemistry,
University of California
Los Angeles, CA 90024 (USA)

[**] This work was supported by the U. S. National Science Foundation.

carborane precursor. Each $C_2B_9$ fragment sequesters a rhodium vertex, (Rh3 and Rh3′) with a Rh–Rh distance of 2.725(1) Å, in the range of a Rh–Rh single bond[4] and comparable to that of 2.763(1) Å in **2**.

The Rh–Rh bond is further supported by two Rh–H–B three-center interactions between Rh3, H4′, B4′ and Rh3′, H4, B4 with Rh–B distances of 2.306(7) and 2.323(7) Å, respectively. The Rh–H distances are 1.92(7) Å for Rh3–H4′ and 1.85(7) Å for Rh3′–H4. These distances are comparable to those observed in **2**.

The molecule **4** has $C_2$ symmetry with the axis of rotation bisecting the Rh3–Rh3′ and C1–C1′ bonds. Unlike the asymmetric structure of **2**, the symmetry in **4** is attributed to the C1–C1′ bond which limits the Rh–H–B interactions to the B4 and B4′ vertices adjacent to C1 and C1′, respectively.

Interestingly, the carborane ligand **3** is diastereomeric by virtue of the asymmetry of the $C_2B_9H_{11}$ fragment. The mirror-plane symmetry of each carborane fragment is destroyed by substitution at one of the carbon vertices, and the carborane precursor **3** contains two chemically distinct isomers, detectable by $^{11}$B-NMR spectroscopy, which differ in the configuration of one $C_2B_9H_{11}$ moiety. The $^{31}$P-NMR spectrum of chromatographed **4** contains resonances attributable to **4** ($\delta = 34.4$, $J_{P-Rh} = 173$ Hz) as well as those of an unsymmetrical compound ($\delta = 32.3$, $J_{P-Rh} = 177$ Hz; $\delta = 29.2$, $J_{P-Rh} = 149$, $^3J_{P-P} = 6.6$ Hz) derived from the diastereomeric carborane ligand containing icosahedral fragments of opposite configuration. A hypothetical structure of the unsymmetric isomer structurally analogous to **4** would contain a Rh–H–C as well as a Rh–H–B interaction. Inversion of one $C_2B_9H_{11}$ fragment maintaining the C1–C1′ and Rh3–Rh3′ bonds would result in an interaction between C2 and Rh3′. Interactions of this type have been characterized structurally[5].

## Pentacarbonylrhenium Complexes with Thiazylamide Ligands**

By *Gabriele Hartmann, Rüdiger Mews**, and *George M. Sheldrick*

Whereas *N,N′*-dialkylsulfurdiimides R–NSN–R′ **1** and *N,N*-dialkyl(thionitroso)amines RR′N–NS **2** have been known for some time, *N,N*-dialkyl(thiazyl)amides NS–NRR′ **3**, which are isomeric to both classes of compounds, could not previously be detected. **1**[5] and **2**[6] can be incorporated into transition-metal complexes by ligand exchange. Complexes having thiazylamides as ligands are accessible by substitution of fluorine in thiazylfluoride coordinated to a transition metal. The cation $[Re(CO)_5(NSF)]^+$, which is also highly stable in solution, has proved to be particularly suitable for reactions of this type[9]:

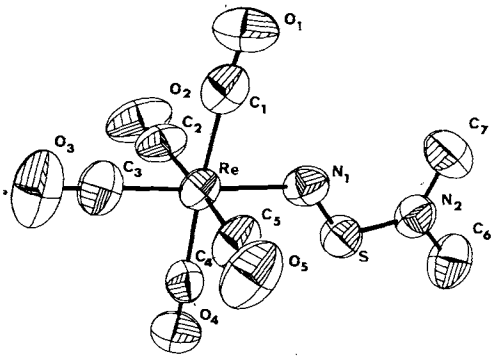
$$\underset{\mathbf{4}}{[(OC)_5Re(NSF)]^+}\ AsF_6^- + \underset{\mathbf{5}}{Me_3SiNMe_2} \xrightarrow[SO_2]{-30\,^\circ C} \underset{\mathbf{6}}{[(OC)_5Re(NSNMe_2)]^+}AsF_6^- + Me_3SiF \qquad (1)$$

$$\mathbf{4} + \underset{\mathbf{7}}{(Me_3Si)_2NMe} \xrightarrow[SO_2]{-30\,^\circ C} \left\{\left[(OC)_5Re\left(NSN\begin{matrix}Me\\SiMe_3\end{matrix}\right)\right]^+ AsF_6^-\right\}_{\mathbf{8}} + Me_3SiF$$

$$\mathbf{8} + \mathbf{4} \longrightarrow \left[(OC)_5Re\left(NS\text{–}\underset{Me}{N}\text{–}SN\right)Re(CO)_5\right]^{2+}_{\mathbf{9}}(AsF_6^-)_2 + Me_3SiF \qquad (2)$$

At −30 °C in liquid $SO_2$, reaction (1) leads quantitatively to **6**, in which the structure of the starting complex **4** is retained. Side reactions occur at higher temperatures. In reaction (2) **4** reacts analogously with the bisilylated amine **7** at −30 °C. The product **8**, which cannot be isolated pure, reacts with excess **4** to afford a dinuclear complex **9**, which contains the methylbis(thiazyl)amide as bridging ligand. If **4** and **7** are only present in the molar ratio 1 : 1, the $AsF_6^-$ anion attacks the cation in **8** (above −15 °C) to form products that have not yet been unequivocally identified.

The X-ray crystal structure of the complex cation in **6** (Fig. 1) was determined on single crystals obtained from acetone/*n*-pentane.



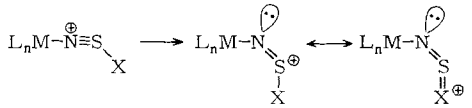


Fig. 1. Crystal structure of the mononuclear cation $[Re(CO)_5(NSNMe_2)]^+$ in **6**. All atoms (apart from H) are represented by 50% probability vibrational ellipsoids (50% location probability). **6** crystallizes in the orthorhombic system, Pbca, $a = 1136.8(4)$, $b = 2497.6(6)$, $c = 1139.8(4)$ pm, $Z = 8$, $\mu = 9.84$ mm$^{-1}$ ($Mo_{K\alpha}$). Structure determination from diffractometer data using the Patterson method. Refinement using absorption- and extinction-corrected structure factors from 2173 reflections [$F > 4\sigma(F)$] to $R = 0.044$.

The bond lengths N1–S (144.7 pm) and S–N2 (158.1 pm) characterize the novel ligands as thiazylamide, and the Re–N1 distance (216.1 pm) corresponds to that of a single bond. The M–N–S angle of 130° in **6** is considerably smaller than that in complexes of other thiazyl derivatives ($[M(NSF)_6]^{2+}$: M = Co[8a] 170.5°, M = Ni[8b] 168.6°; $[Ni\{N\text{-}SON(CF_3)_2\}_6]^{2+}$[10] 161.7°); the N1–S distances in these other complexes are somewhat shorter (140–144 pm). The

contraction of the angle and the increase in the N1–S distance can be accounted for by an increase in $sp^2$ character of the coordinating nitrogen atom:

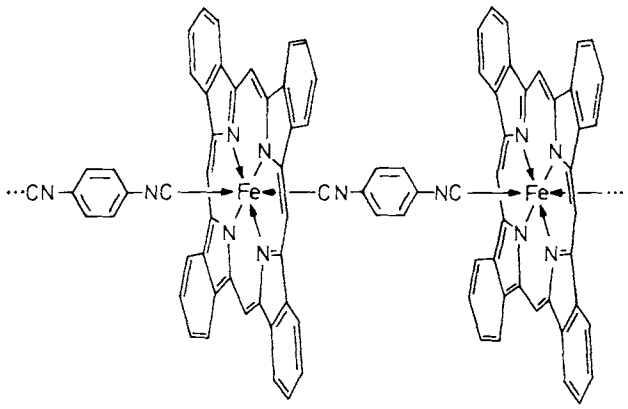
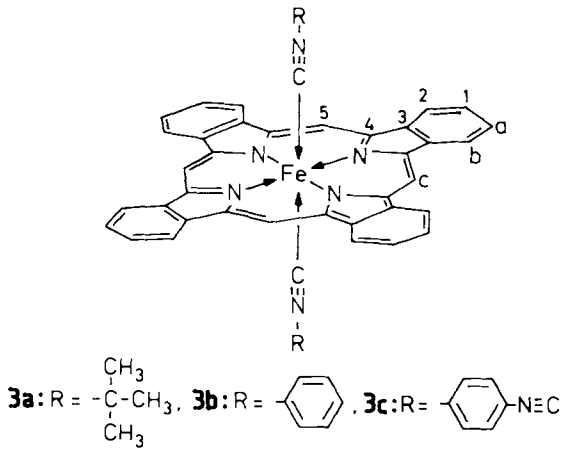
## Preparation and Properties of Tetrabenzoporphyrinatoiron(II) and Its Isocyanide Complexes



By *Konrad Fischer* and *Michael Hanack**

In contrast to hexacoordinated bisaxially bridged phthalocyaninato-transition metal compounds[1], the corresponding tetrabenzoporphyrinato (tbp) complexes have so far been the subject of very few investigations. Bisaxially bridged (tbp)M compounds should exhibit interesting properties—*e.g.* high electrical conductivity.



We were able to prepare tetrabenzoporphyrinatoiron(II) **1**, for the first time, by thermal cleavage of the axial pyridine ligand (180 °C, vacuum) from the known[8] bis(pyridine)tetrabenzoporphyrinatoiron(II) **4**, which, however, was

obtained *via* a new route. $H_2$tbp reacts with pentacarbonyliron or iron(II) acetate in an anthracene melt to give almost quantitative yields of **1**, which was isolated as (tbp)Fe(py)$_2$ from the crude product by Soxhlet extraction with pyridine. **1** can be converted by reaction with isocyanides into the monomeric derivatives (tbp)Fe(CNR)$_2$ **3** and by reaction with 1,4-diisocyanobenzene (dib) into the polymeric derivative [(tbp)Fe(dib)]$_n$ **2**. For the reaction leading to the monomeric isocyanide complexes **3a** and **3b**, merely excess ligand suffices as solvent, whereas for the reaction furnishing **3c** and its polymer **2**, anhydrous chloroform was found to be the best solvent. The complexes **1**, **2** and **3** were characterized by elemental, differential thermal, and thermogravimetric analysis, as well as by UV/VIS, IR, and $^1$H-NMR spectroscopy.

**2**

The bands occurring at 690, 718, 1190, 1212, 1440 and 1480 cm$^{-1}$ in the IR spectrum of **4** are no longer observable in the spectrum of **1**, while the rest of the absorptions remain unchanged. Owing to the solubility of **1** in pyridine leading to formation of **4**, both the $^1$H-NMR as well as $^{13}$C-NMR spectra could be measured in [$D_5$]-pyridine. The $^{13}$C-NMR data ($C^1$: $\delta = 127.2$, $C^2$: 121.8, $C^3$: 139.6, $C^4$: 144.7, $C^5$: 95.0) are in agreement with the values found for **5**[3c].

The complex **3a** obtained from **1** and *tert*-butyl isocyanide is not stable in solution but partially dissociates into its components; after addition of excess isocyanide, the $^1$H-NMR signal of the *tert*-butyl group of the coordinated ligand can also be observed: owing to the diamagnetic ring current of the macrocycle it is shifted upfield by about $\Delta\delta = 2.25$ compared to the signal of the free ligand. The spectrum of pure monomeric **3c** can likewise only be measured in presence of excess ligand, since, otherwise, partial double cleavage leads to formation of the dimer and oligomers, which are also soluble in $CDCl_3$; the signal of the α-proton of the bridge ligand is shifted about $\Delta\delta = 2.57$, that of the β-proton about $\Delta\delta = 1.11$ upfield. Unlike **3a** and **3c**, **3b** can be investigated $^1$H-NMR spectroscopically

without addition of free phenyl isocyanide; the same upfield shift is found for the α- and β-protons as in **3c**.

A characteristic feature of each of the IR spectra of the isocyanide complexes is the very intense $\nu$(CN) band. In the case of **3a** it appears in the same region as for the free ligand; *i.e.* π-bonding becomes increasingly more significant over pure σ-bonding in these complexes compared to the analogous phthalocyaninatoiron(II) compounds. As expected, the mesomeric ligands dib and CNPh exhibit even stronger π-acceptor behavior, as evidenced by the shift of the CN stretching vibration frequency by, respectively, 20 and 30 $cm^{-1}$ to lower energy. On proceeding from the monomer **3c** to the polymer **2**, $\nu$(CN) shifts a further 10 $cm^{-1}$ to lower energy, and the bands at 700, 1190 and 1595 $cm^{-1}$ are absent; otherwise only a few intensities change.

The pyridine complex **4** has an electrical conductivity of $\sigma_{RT} = 2 \times 10^{-9}$ S·cm$^{-1}$ (powder pellet, 1 kbar). In the case of "ligand-free" **1** it increases similarly as in the case of **2**, which is polymerized by dib bridges, *i.e.* it increases by three orders of magnitude to $2 \times 10^{-6}$ S·cm$^{-1}$. **1** and **2** can be oxidatively doped with two equivalents of iodine in benzene suspension. The compounds (tbp)Fe$I_{1.5}$ and $[(tbp)Fe(dib)I_{1.7}]_n$ are formed which have electrical conductivities of $\sigma_{RT} = 2 \times 10^{-2}$ and $9 \times 10^{-3}$ S·cm$^{-1}$, respectively, and are stable up to 120 °C. Thus, the electrical conductivity of (tbp)Fe$I_{1.5}$ is an order of magnitude higher than that of the corresponding phthalocyaninato-Fe$^{II}$ compound[11].

## $[Me_3Si(py)]^{\oplus}X^{\ominus}$ (X = Br, I): X-Ray Structural Analysis of the 1:1-Adducts of Bromo- or Iodotrimethylsilane and Pyridine

By *Karl Hensen**, *Thomas Zengerly*, *Peter Pickel*, and *Gerhard Klebe*

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*

As Lewis acids, silicon halides and their alkyl derivatives react with tertiary organic nitrogen bases such as pyridine, bipyridine, or trialkylamines in nonpolar solvents to afford, in general, sparingly soluble addition compounds[1]. In contrast to the numerous 1:2-adducts, $Me_2SiBr_2$, $Me_3SiBr$[2a], $Me_2SiI_2$, and $Me_3SiI$[2b] give only 1:1-adducts with pyridine. All of the compounds are readily hydrolyzable. Previously, only $SiF_4 \cdot 2$py has been studied by X-ray crystallography[3a]. In this compound the silicon atom has a slightly distorted octahedral coordination and the pyridine rings are *trans*-orientated.

In the 1:1-adduct of germanium tetrachloride and trimethylamine the amine ligand occupies an axial position in the trigonal-bipyramidal complex[3d].

We have now succeeded in growing suitable crystals of the 1:1-pyridine adducts of $Me_3SiBr$ (m.p. ≈ 27 °C) and $Me_3SiI$ (m.p. > 100 °C) by sublimation in glass capillaries, and have investigated the structures in the solid state.

These compounds do not occur as increased coordination complexes, rather the Lewis base displaces a halide ion from the first coordination sphere of the silicon atom, and ionic structures $[Me_3Si(py)]^{\oplus}X^{\ominus}$ occur in the solid state (cf. Fig. 1). The Si–Br and Si–I distances of 4.359 and 4.559 Å, respectively, are *ca.* 0.5 Å longer than the sum of the van der Waals' radii of the atoms concerned[4] and more *ca.* 2 Å longer than the sum of the covalent radii[4a].

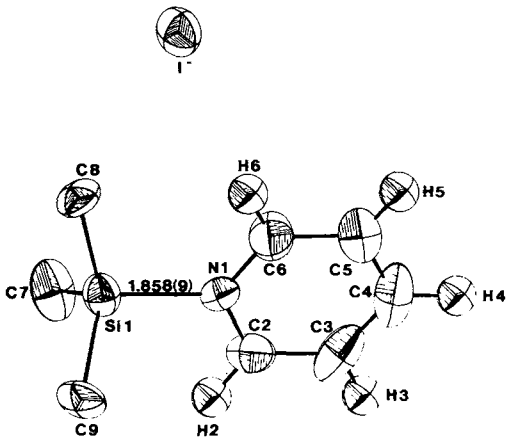

Fig. 1. ORTEP representation of the asymmetric moiety $[(CH_3)_3Si(py)]^{\oplus}I^{\ominus}$: $P2_1/c$, $a = 8.288(2)$, $b = 10.997(2)$, $c = 13.538(4)$ Å, $\beta = 110.80(2)°$, $Z = 4$; 2020 reflections, $R_w = 0.040$; Si–N 1.858(9) Å.—$[(CH_3)_3Si(py)]^{\oplus}Br^{\ominus}$: $P2_1/c$, $a = 12.008(4)$, $b = 7.206(2)$, $c = 13.518(4)$ Å, $\beta = 111.47(3)°$, $Z = 4$; 1630 reflections, $R_w = 0.076$; Si–N 1.856(7) Å.—Further details on the crystal structure investigations can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50506, the names of the authors, and the journal citation.

The CSiC angles are up to ca. 6° greater, and the CSiN angles ca. 6° smaller, than the ideal tetrahedral angle, *i.e.* considerable distorsion to trigonal pyramidal structures occurs. Within the standard deviation, the pyridine ring is planar.

Notable is the Si–N distance of 1.86(1) Å. All the previously studied compounds with tetracoordinated silicon exhibit shorter Si–N distances (mainly *ca.* 1.75 Å)[5a,b]. Comparison with corresponding cations is not possible since the structures discussed here represent the first examples of this type. *Sheldrick et al.* found a similar Si–N distance of 1.857(4) Å in a pentacoordinated silicon compound[5b]; all other increased coordination silicon compounds have values longer than 1.91 Å[3,5c,d]. The Si–C distances correspond to normal single bond values.

The formation of ionic structures apparently favors 1:1-compounds of halosilanes and pyridine in the solid state. Hence, the melting-point diagram of the system $Me_3SiCl$-pyridine[2a] gives no information about formation of an adduct. Presumably ionic structures also occur in the adducts of bromo- or iodotrimethylsilane and hexamethylphosphoric triamide (HMPT) investigated by *Chojnowski et al.*[5f]; in contrast, even with HMPT, which is a stronger Lewis base than pyridine[5g], chlorotrimethylsilane does not form a solid adduct at room temperature.

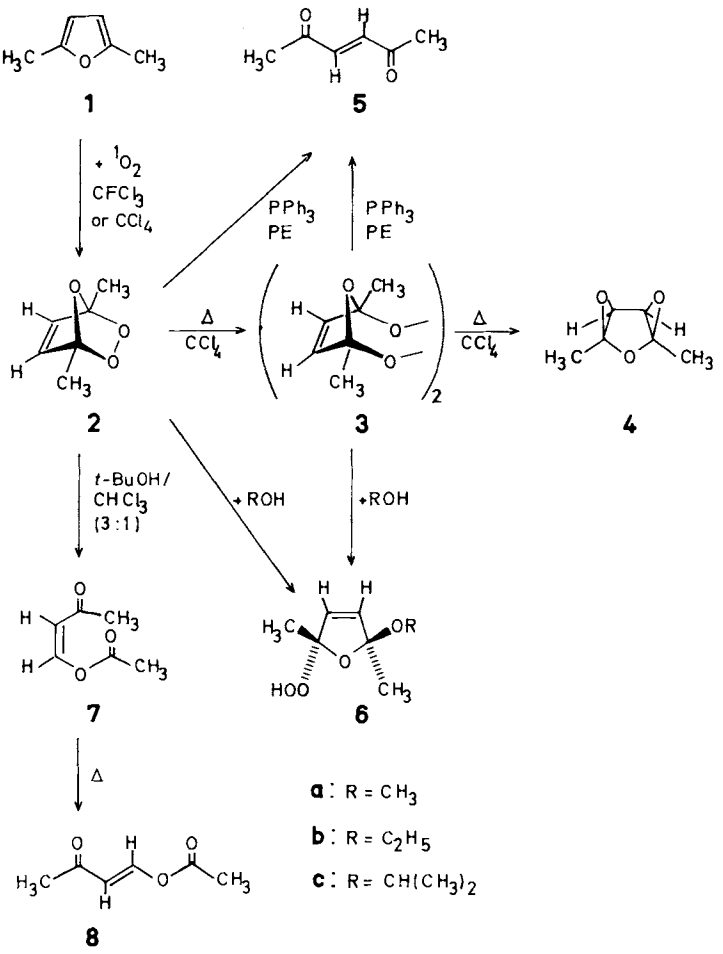
## [4+2]-Cycloaddition of Singlet Oxygen to 2,5-Dimethylfuran: Isolation and Reactions of the Monomeric and Dimeric Endoperoxides**



By *Klaus Gollnick** and *Axel Griesbeck*

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

The endoperoxide **2**, postulated by *G. O. Schenck et al.*[1] to be the primary product of the photosensitized oxygenation of 2,5-dimethylfuran **1**, has not yet been isolated. Here, we report the first isolation of monomeric **2**. **2** was obtained by tetraphenylporphin-photosensitized oxygenation (singlet oxygen reaction) of **1** in Freon 11 ($CFCl_3$) at room temperature, followed by removal of the solvent *in vacuo* and distillation of the residue at 5 °C/$10^{-3}$ torr into a cold trap at −78 °C[2a,b]. Solvent-free **2** always gives rise to explosions if handled in amounts greater than *ca.* 100 mg; however, in inert solvents like benzene or $CCl_4$ at room temperature it slowly *dimerizes* to the previously observed[1] **3**[2c], but at 55–60 °C the reaction is fast and quantitative[3]. If the temperature is raised further, the *cis*-bisepoxide **4**[2d], so far observed only in solution[4b], is obtained together with polymeric material (*ca.* 4:1).

Solutions of the *monomeric* endoperoxide **2** and the *dimeric* endoperoxide **3** in benzene or $CCl_4$ are reduced by triphenylphosphane in petroleum ether (PE) to give diketone **5**[2e] and triphenylphosphane oxide. Only one of the two possible *cis-trans* isomeric alkoxy hydroperoxides (presumably the *trans* isomer) **6a–c**[2f] is formed if **2** is dissolved in methanol, ethanol, or isopropanol, respectively, as indicated by the proton-decoupled $^{13}C$-NMR spectra of **6a** and **6b**. Alkoxy hydroperoxides **6a–c** may be prepared directly by reaction of $^1O_2$ with **1** in the corresponding alcohol, as has been known for some time for **6a**[1]. Interestingly, the same alkoxy hydroperoxides are obtained if the *dimeric* endoperoxide **3** is dissolved in these alcohols, probably *via* trapping of the *monomeric* endoperoxide **2** that may be in equilibrium with **3**.

*tert*-Butyl alcohol does not add to endoperoxide **2**; instead, **2** rearranges to the previously unknown *cis*-3-oxo-1-butenyl acetate **7**[2g] in *t*BuOH/$CHCl_3$ (3:1). **7**, which rearranges to the *trans* isomer **8**[2h,5] on heating, is also synthesized directly *via* reaction of $^1O_2$ with **1** in *t*-BuOH/$CHCl_3$ (3:1). Addition of *t*-butyl alcohol to **2** is sterically hindered and replaced here by a Baeyer-Villiger-type reaction in which vinyl group migration is preferred over methyl group migration[6].

[6] I. Saito, A. Nakata, T. Matsuura, *Tetrahedron Lett. 22* (1981) 1697 found that the endoperoxide of 1,3-di-*tert*-butylisobenzofuran underwent an analogous rearrangement of the Baeyer-Villiger type.

## $[\{(C_6H_{15}N_3)Fe\}_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2+}$, a Dinuclear Iron(III) Complex with a Metazidohemerythrin-Type Structure**

By *Karl Wieghardt*, Klaus Pohl,* and *Walter Gebert*

Hemerythrins are iron-containing, $O_2$-transporting proteins; the methemerythrins are formed by redox reaction $2Fe^{II}/O_2 \rightarrow 2Fe^{III}/O_2^{2-}$ and replacement of the coordinated peroxide by other ligands ($N_3^-$, $OH^-$, $H_2O$)[1a]. The coordination geometry of the four dinuclear $Fe^{III}$ structural units was determined by magnetic[1b] and UV spectroscopic[1c] measurements, by EXAFS investigations[1d], and by X-ray structure analyses of metaquo-[2a] and metazidohemerythrin[2b] (cf. **1**). Dinuclear $Fe^{III}$-complexes with this type of structure (an angular oxo-bridge and two carboxylato-bridges) have so far never been reported in the literature[2b].

**1**

Hydrolysis of the monomeric neutral complex (tacn)$FeCl_3$ (tacn = 1,4,7-triazacyclononane) in aqueous ammonium acetate solution and addition of NaI leads to precipitation of orange-brown crystals of the composition

$[(C_6H_{15}N_3)_2Fe_2O(CH_3CO_2)_2]I_2 \cdot 0.5\,NaI \cdot 3\,H_2O$ **2**[3].

The X-ray structure analysis of **2** shows that a dinuclear complex is formed (Fig. 1). The two $Fe^{III}$ centers are each surrounded by a distorted octahedral array of one *fac*-coordinated triamine, one μ-oxo ligand and two almost symmetrical μ-acetato ligands. This corresponds to the structure type **1** of the protein metazidohemerythrin[2b]. The Fe—O distances of the oxo-bridge (178(1) pm) are shorter than those of the acetato-bridges (203(2) pm); they indicate considerable π-bonding[4]. The Fe—N bonds *trans* to the O-atom of the oxo-bridge are somewhat longer (221(2) pm) than those *trans* to the O-atoms of the acetato-bridges (216(1) pm). This suggests a *trans*-effect of the oxo-bridge. The Fe...Fe distance (306.4(5) pm) is markedly shorter than has been found in all previous structural investigations on methemerythrin[1,2]; interpretation of the EXAFS measurements[1d] gives an Fe...Fe distance of 349(8) pm, whereas the Fe—O distance thus determined for the oxo-bridge (180 pm) is in very good agreement with our data.

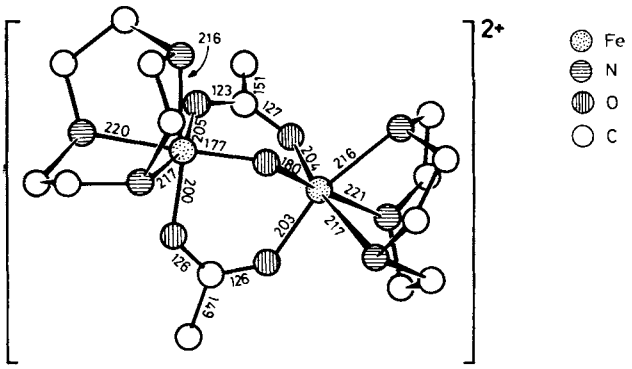

Fig. 1. Structure of the complex cation in the salt **2** (distances in pm with average standard deviation of 2 pm). Fe...Fe distance 306.4(5) pm; FeOFe angle 118.3(5)°. Space group $P2_1/c$, $a = 1323.4(7)$, $b = 1754.5(6)$, $c = 1525.0(4)$ pm, $\beta = 114.23(3)°$, $Z = 4$; 6050 independent reflections ($I > 3\sigma(I)$), $R = 0.062$. Further details of the crystal structure investigation are available on request from the Fachinformation Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen on quoting the depository number CSD 50477, the names of the authors, and full citation of the journal.

The $Fe^{III}$ centers in **2** are coupled antiferromagnetically (temperature-dependent effective magnetic moment of 0.89 $\mu_B$ at 100 K and 1.84 $\mu_B$ at 283 K per $Fe^{III}$ center). This is in good agreement with the magnetic behavior of metaquohemerythrin[1b], for which antiferromagnetic coupling of two high-spin $Fe^{III}$ centers is assumed. The UV/VIS spectrum of **2** [286 nm ($\varepsilon = 2.5 \times 10^3$ L mol$^{-1}$ cm$^{-1}$ per Fe-atom) 412 (sh), 450 (350), 484 (sh), 711 (19)] is similar to that of metazidohemerythrin. An FeOFe-vibration is observed at 730 cm$^{-1}$ in **2**.

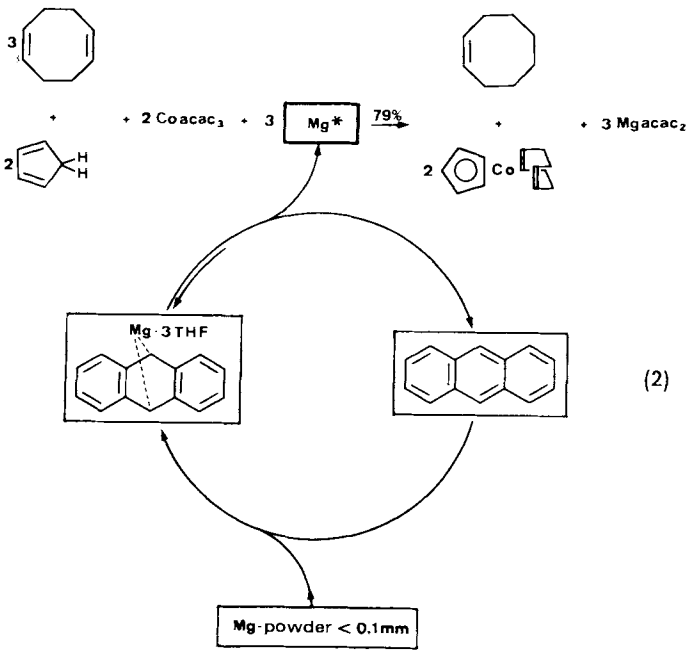
# "Organically Solvated" Magnesium for the Synthesis of Transition-Metal Complexes and Catalysts

By *Helmut Bönnemann*, Borislav Bogdanović*, Rainer Brinkmann, Da-Wei He,* and *Bernd Spliethoff*

The method that has proved most useful for the synthesis of the species in the title is the reaction of transition-metal salts with reducing agents in the presence of suitable ligands[1]. The most suitable reducing agent is magnesium metal[2a], whose reactivity strongly depends on the size and purity of its active surface[2b]. Although numerous attempts have been made to improve the activity of elemental magnesium by additives[2c], no generally applicable method for the preparation of transition-metal complexes using magnesium as reducing agent has so far been reported in the literature.

Starting from the observation[3] that addition of a catalytic amount of anthracene to magnesium powder in tetrahydrofuran (THF) produces a highly reactive organically solvated magnesium (equilibrium (1)), we have worked out a simple preparative route to transition-metal complexes which for the first time allows magnesium powder to be used for the reductive synthesis of all preparatively important compounds of this type[4].



(1)

The reaction cycle depicted in (2) illustrates the catalytic function of the anthracene in the activation of magnesium powder: the hydrocarbon first reacts with the alkaline earth metal in THF to give a sparingly soluble adduct (for the structure cf. [3c]). The adduct formation is reversible[3b], *i.e.* in the equilibrium quasi-atomic magnesium is continually produced in solution. This means that the anthracene is acting as a phase-transfer catalyst[5]. The highly active magnesium so formed reacts exothermally with the transition-metal salt, which in the presence of electron donors is converted into the corresponding complex.

Cobalt salts, 1,5-cyclooctadiene (COD) and cyclopentadiene derivatives react smoothly to give, in one step, $\eta^5$-cyclopentadienylcobalt half-sandwich complexes which are of importance as catalysts for the synthesis of pyridines from alkynes and nitriles[6]. An excess of COD takes up the active hydrogen from the cyclopentadiene to give cyclooctene.

Decisive for the success of the synthesis is that the catalyst continually supplies highly reactive magnesium. One of the main advantages of this direct synthesis of transition-metal complexes using anthracene-activated magnesium is its extraordinary variability. Thus, we have so far also been able to prepare metallocenes ($Cp_2V$, $Cp_2Fe$, $Cp_2Co$), $\eta^3$-allyl complexes of Co and Ni, olefinmetal(0) compounds ($Ni(COD)_2$, $Pt(COD)_2$, $Mo(butadiene)_3$), as well as phosphane complexes ($Pd(PPh_3)_4$, $Ni(C_2H_4)[P(OC_6H_4Me)_3]_2$). All these species are active catalysts for organic reactions.

*Typical Procedure:* Magnesium powder (7.2 g, 300 mmol; particle size $<0.1$ mm) is treated in an inert atmosphere (argon) with 1.1 g (6.2 mmol) anthracene, 300 mL THF (purified over $NaAlEt_4/LiAlH_4$) and 0.1 mL methyl iodide. On stirring at 23 °C a yellow-green solution is formed, from which orange colored anthracenemagnesium separates in *ca.* 1—2 h. The mixture is subjected to an ultrasonic bath treatment for 3 h and heated with stirring to 65 °C. After addition of 27.0 g (250 mmol) COD and 7.3 g (111 mmol) monomeric cyclopentadiene, the source of heat is removed and solid cobalt(III) acetylacetonate (35.6 g, 100 mmol) is added portionwise to the continually stirred solution over 15 min, whereby the solution vigorously boils. After cooling to 20 °C and filtration through a G3 glass frit, the clear filtrate is evaporated to dryness in a high vacuum. The residue is taken up in 500 mL pentane and the solution filtered once again through a G3 glass frit. The complex (COD)CoCp crystallizes from the clear solution at $-80$ °C. The orange-brown crystals are washed with cold pentane and dried *in vacuo*; yield 18.4 g (79.1%).

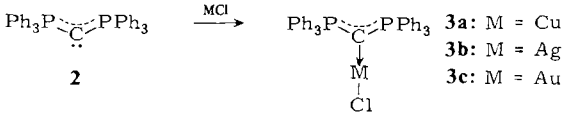
# Coinage Metal Complexes of Hexaphenylcarbodiphosphorane—Organometallic Compounds with Coordination Number 2

By *Hubert Schmidbaur**, *Christian E. Zybill*, *Gerhard Müller*, and *Carl Krüger*

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*



In organometallic compounds with gold in the oxidation state +1 the coordination number never as a rule exceeds 2, whereas with the lighter "coinage metals" this lower coordination number is exceptionally rare[1]. Among the few structurally characterized copper compounds with simple aliphatic ligands we find, besides the (trimethylsilylmethyl)copper(I) tetramer[2], also the dinuclear ylide complex **1a**[3a], in which two linear $CH_2CuCH_2$ groups are arranged parallel to each other. The corresponding silver and gold compounds **1b** and **1c**, respectively, have an analogous structure[3b].

**1a**: M = Cu
**1b**: M = Ag
**1c**: M = Au

We now report on the synthesis of coinage metal complexes of the double ylide[4] hexaphenylcarbodiphosphorane **2**, in which the strictly linear twofold coordination is ensured in all cases by the specific (especially steric) effect of the new ligand, even although the second ligand is a halide capable of functioning as a donor.

Suspensions of anhydrous CuCl or AgCl in tetrahydrofuran rapidly clarify on addition of a solution of **2** in the same solvent, and the reaction products **3a** and **3b**, respectively, crystallize from the mixtures on cooling. For the preparation of **3c** it is more advantageous to use (CO)AuCl as starting material, with removal of CO.

**2**

**3a**: M = Cu
**3b**: M = Ag
**3c**: M = Au

None of the three products[5a] is sensitive to air, and all are thermally stable up to *ca.* 200°C. Solutions of **3a**, **3b** and **3c** in $CD_2Cl_2$ show $^{31}P\{^1H\}$-NMR singlet signals at $\delta = 16.5$, 16.5, and 13.7, respectively. In the $^{13}C$-NMR spectra the signal of the ylidic C-atom is not observable; the phenyl signals conform to expectation [*e.g.* **3b**: $\delta = 132.6$, AA'X, $N = 95.7$ Hz, C-1; 127.9(4.9), C-2; 132.3, br, C-3; 130.8(4.9), C-4].

The X-ray structure analysis of **3a** shows[5b] that discrete molecules are present in the crystal, between which there are no unusually short contacts (Fig. 1). The ligand arrangement at the copper atom is practically linear with Cl–Cu–C1 = 178.2(1)°, while that at the ylidic carbon atom (C1) is trigonal planar. C1 is only 0.056 Å outside of the CuP1P2 plane, whereas the chlorine atom lies, within the standard deviation, in the plane (Fig. 2). The angles P1–C1–Cu and P2–C1–Cu, however, are very different

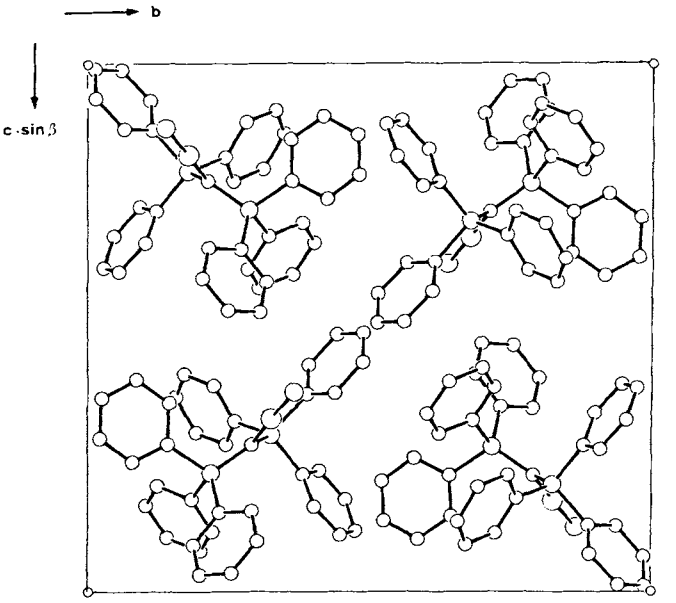


Fig. 1. Projection of a section from the crystal lattice of the copper complex **3a**.

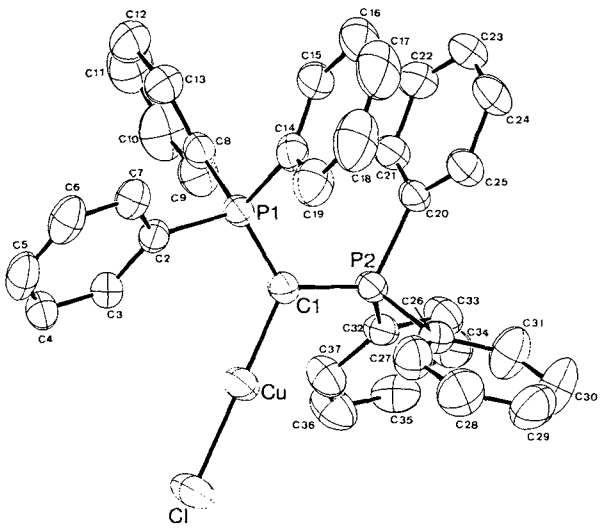
(122.1(1) and 113.7(1)°, respectively); P1–C1–P2 is 123.8(1)° and is thus smaller than the corresponding angle in **2**. The especially interesting C1–Cu distance of 1.906(2) Å corresponds to a Cu–C($sp^2$) bond, as also exists, for example, in the bis(mesityl)copper(1–) ion (1.915(9) Å[6a]).



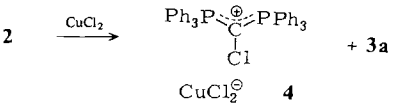


Fig. 2. Molecular structure of **3a** in the crystal [5b]. Some bond distances and angles are given in the text.

The compounds **3** are especially suitable for the synthesis of further lower coordinated organometallic derivatives.

Reaction of anhydrous $CuCl_2$ with **2** does not lead to $Cu^{II}$ coordination compounds but to reduction of the copper and oxidative halogenation of the carbodiphosphorane to give the salt **4**[5a] [$\delta(P) = 26.8$, s; $\delta(PCP) = 192$, t, $^2J(^{13}P^{13}C) = 113.3$ Hz[6b]; $\nu(CuCl_2) = 385$ cm$^{-1}$].

Prof. Dr. C. Krüger, Dr. G. Müller
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (Germany)

This behavior of **2** is in complete contrast to that of the simple ylides, which under comparable conditions undergo oxidative coupling to give bisphosphonium salts[6c].

## $(FMe_2Si)_2CF_2$: Synthesis and Reactions**

By *Gerhard Fritz** and *Heinz Bauer*

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*

The synthesis and reactive behavior of organosilicon compounds containing $CF_2$ groups have to our knowledge never been described in the literature. Reports have appeared, however, on NMR investigations of perfluoroalkylsilanes[1a] obtained by reaction of $CF_3I$ with $SiF_2$[1b].

*C*-Fluorinated carbasilanes are of interest in view of the known reactions of *C*-chlorinated compounds such as $(Cl_3Si)_2CCl_2$[2a] or $(Cl_2Si-CCl_2)_3$[2b]; *e.g.*, lithiation of the $CCl_2$ group in $(Cl_2Si-CCl_2)_3$ leads to ring contraction and ring opening[2b], and in the case of $ClMe_2Si(Me_3Si)CCl_2$ to ring closure with formation of a 2,4-disilabicyclo[1.1.0]butane[2c].

[*] Prof. Dr. G. Fritz, H. Bauer
Institut für Anorganische Chemie der Universität
Postfach 6380, D-7500 Karlsruhe 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Insertion of the carbene $CF_2$, generated by thermolysis of $Me_3SnCF_3$[3a], into the SiSi bond of $(FMe_2Si)_2$[3b] leads according to

$$FMe_2Si-SiMe_2F + :CF_2 \longrightarrow \underset{\mathbf{1}}{FMe_2Si-CF_2-SiMe_2F}$$

to formation of the new compound **1**, which we were able to isolate from the reaction mixture by gas chromatography[4]. At room temperature, and in the absence of air and moisture, **1** is a stable, colorless liquid, b.p. 161.6°C (extrapolated from the vapor pressure curve).

Unlike the corresponding *C*-chlorinated carbasilanes, **1** reacts with MeMgCl or MeLi, even at low temperatures, not with *C*-metalation but with *Si*-alkylation to give the products **2** and **3**[4]. Reaction of **1** with PhMgBr or PhLi analogously yields the phenyl derivatives **4** and **5**. That is, neither a CF- nor a CSi-cleavage takes place. Reaction of **1** with $LiAlH_4$ leads, depending upon the molar ratio, to **6** and **7**[4]. In all cases the $CF_2$ group remains inert.

It is well known that *C*-chlorinated carbasilanes cleave the SiP bond in silylphosphanes with formation of the ylide[5a]. Thus, $(Cl_3Si)_2CCl_2$ reacts with $Me_3Si-PMe_2$ to give $(Cl_3Si)_2C=PMe_2Cl$. The $CF_2$ group in **1** is also capable of undergoing this reaction, as is shown by the formation of the ylide **8**.

$$\underset{\mathbf{1}}{(FMe_2Si)_2CF_2} \xrightarrow[-\,Me_3SiF]{+\,Me_3SiPMe_2} \underset{\mathbf{9}}{\{(FMe_2Si)_2CF-PMe_2\}}$$

$$\underset{\mathbf{8}}{(FMe_2Si)_2C=PMe_2-PMe_2} \xleftarrow[-\,Me_3SiF]{+\,Me_3SiPMe_2} \underset{\mathbf{10}}{\{(FMe_2Si)_2C=PMe_2F\}}$$

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0909-0730 $ 02.50/0 

The intermediate **9** immediately rearranges to **10**. The reactions of **1** and **10** correspond to those of the analogous chloro compounds[5b], but take place only at elevated temperatures[4]. The reactivity of the $CF_2$ group can be attributed to the formation of the energetically favorable SiF bond.

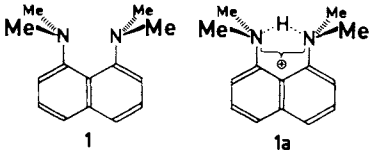
[3] a) E. Hengge, S. Waldhör, *Monatsh. Chem. 105* (1974) 671; K. G. Sharp, P. A. Sutor, *J. Am. Chem. Soc. 99* (1977) 8046; b) H. C. Clark, C. J. Willis, *ibid. 82* (1960) 1888; H. D. Kaesz, J. R. Philipps, F. G. A. Stone, *ibid. 82* (1960) 6229.



[4] Experimental: For the synthesis of **1**, a mixture of 6.1 g (26 mmol) of $Me_3SnCF_3$ and 4.0 g (26 mmol) of $(FMe_2Si)_2$ was heated in a sealed glass ampule (100 mL) at 160 °C for 3 d. After opening the ampule, the volatile reaction products were condensed in a cold trap (−196 °C). In addition to components that are gaseous at room temperature ($CHF_3$, $F_2C{=}CF_2$, $Me_2SiF_2$, $Me_3SiF$; total 0.06 g), liquid (**1**, $Me_4Si_2F_2$, $SnMe_4$, $Me_3SiF$; total 5.31 g) and solid ($Me_3SnF$; 4.7 g) components are also obtained. The liquid components can be separated gas chromatographically (column packing: silica gel with 5% SE 52, 120 °C, 0.4—0.6 bar, He), the yield of **1** being *ca.* 76%.—For the reaction of **1** (500 mg) in tetrahydrofuran with MeLi (1—2 M solution), the mixture prepared at −50 °C is warmed slowly to 20 °C; after separation of LiF there remain NMR spectroscopically pure Si-methylation products. The reactions with MeMgCl, PhMgBr, PhLi, and $LiAlH_4$ (in $Et_2O$) are carried out analogously; however, in the case of the phenyl compounds the temperature must be raised to 50 °C. For the reaction of **1** with $Me_3SiPMe_2$ the mixture must be heated in benzene for at least 6 h at 75 °C to initiate the reaction; consequently, compounds other than **8** are formed, especially $P_2Me_4$. The corresponding reaction of $(ClMe_2Si)_2CCl_2$ already takes place at 25 °C.

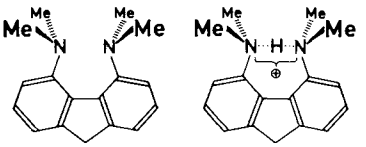
## 4,5-Bis(dimethylamino)fluorene, a New "Proton Sponge"



By *Heinz A. Staab**, *Thomas Saupe*, and *Claus Krieger*

According to *Alder et al.*[1], 1,8-bis(dimethylamino)naphthalene **1** ("proton sponge"[2]) is several orders of magnitude more basic than normal aromatic amines (**1**: $pK_a = 12.34$; *N,N*-dimethylaniline: $pK_a = 5.1$). This unusual basicity of **1** has been ascribed to the steric interaction of the two *peri*-dimethylamino groups and to the formation of a very strong N···H···N hydrogen bond in monoprotonated **1a**[1,3]. The search for similar "proton sponges" has previously been confined primarily to a variation of the 1,8-diaminonaphthalene system of **1** by substitution[4].

**1** **1a**

A model estimation shows, however, that the steric factors to which the specific basicity of **1** was attributed should be even more pronounced in 4,5-bis(dimethylamino)fluorene **2**: Based on the structures of naphthalene and fluorene, and assuming planarity for **1** and **2** with $C_{Aryl}-N$ bond lengths of 140 pm[3c], a significantly shorter N···N distance (231 pm) is derived for **2** than for **1** (245 pm). Corresponding steric interactions between the $Me_2N$ groups should likewise be preserved if the N···N distance in **2** is increased by deviations of the $C_{Aryl}-N$ bonds to opposite sides of the aromatic plane, as shown for **1** by X-ray structure analysis[3c]. A further difference between **1** and **2** should exist insofar as in the latter the lone pairs of electrons of the two nitrogen atoms, more so than in **1**, should be directed towards each other along the N···N connecting line. Therefore, in contrast to **1a** (N···H···N angle: *ca.* 140°)[3a], an approximately linear hydrogen bond was expected for monoprotonated **2a**.

**2** **2a**

4,5-Diaminofluorene[5a], by analogy to a procedure described for the synthesis of **1**[5b], was methylated with dimethyl sulfate (sodium hydride, tetrahydrofuran, 6 h reflux) to afford **2**[6] (m.p. = 69—69.5 °C) which, despite considerable steric hindrance, was obtained in 80% yield.

With perchloric acid, **2** forms **2a** · perchlorate[6] (m.p. = 295—296 °C, dec.); with excess perchloric acid double protonation of **2** was not observed. In the $^1$H-NMR spectrum of **2a** · perchlorate (360 MHz, [$D_6$]dimethyl sulfoxide) the four methyl groups of **2a** give rise to a singlet at $\delta = 3.19$, which through coupling to the proton of the hydrogen bond is split into a doublet with $J = 2.03$ Hz; a significantly higher coupling constant than is observed for **1a** · perchlorate[6] ($J = 1.92$ Hz). Compared to **2**, all fluorene protons of **2a** are shifted to higher $\delta$-values due to the positive charge on the nitrogen atoms. The proton of the hydrogen bond gives a strongly down-field shifted, broad singlet at $\delta = 18.25$.

The stronger basicity of **2** in comparison to **1** was shown by simple deprotonation experiments: Addition of **1a** · perchlorate to a solution containing an equimolar amount of **2** in [$D_6$]dimethyl sulfoxide gave rise to $^1$H-NMR signals of **1**, and those of **2** became correspondingly weaker. Integration of the signals of the $Me_2N$-protons (**1**: $\delta = 2.73$; **2**: $\delta = 2.62$; **1a**: $\delta = 3.11$; **2a**: $\delta = 3.19$; 360 MHz) in the equilibrium mixture indicates a **1**/**2**-ratio of *ca.* 4:1 (at 33 °C). Thus, **2** is able to deprotonate **1a**. On the basis of the $pK_a$ value of **1**, a $pK_a$ of *ca.* 13.5 is estimated for **2**.

An X-ray structure analysis of **2a** · perchlorate indicated that **2a** has $C_2$ symmetry and that the $C_2$ axis (in the direction of the crystallographic *b* axis) passes through C(9) and the midpoint of C(4A)–C(4A′) in the fluorene plane. **2a** and the perchlorate anions are stacked alternatingly along *b*. The atoms C(4) and C(4′) deviate by 10 pm from the mean plane of the remaining carbon atoms of the fluorene framework; the nitrogen atoms lie on opposite sides of this plane and deviate from it by 23 pm. The bond angles at nitrogen indicate that with inclusion of the hydrogen bond the bonds at the two nitrogens are arranged tetrahedrally. As expected, the N···N distance of 262.6(2) pm is very

short; in contrast to **1a**, the N···H···N hydrogen bond is almost linear (178°).

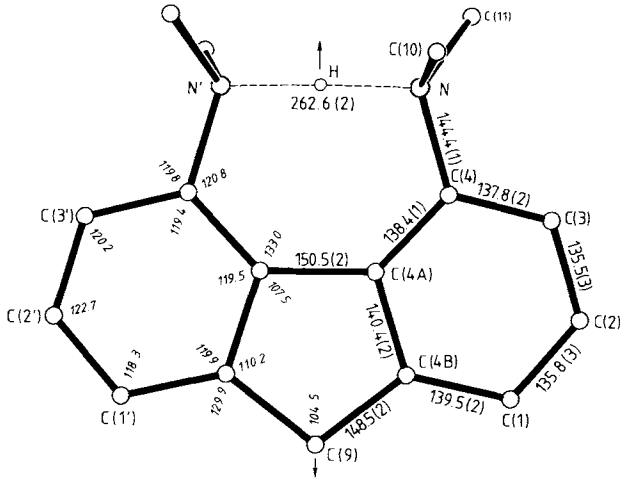

Fig. 1. Crystal structure of the **2a**-moiety of **2a**-perchlorate; view onto the fluorene plane: $a=843.7(1)$, $b=2554.5(2)$, $c=829.2(1)$ pm, $\beta=102.12(2)°$; space group C2/c, $Z=4$; 2206 measured, 1212 observed reflections; $R=0.061$. C(4)–N–C(10): 110.9; C(4)–N–C(11): 114.4; C(10)–N–C(11): 109.4; C(4)–N···N 105.0; C(10)–N···N: 107.0; C(11)–N···N: 109.8°. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50498, the names of the authors, and the journal citation.

Comparison of **1a** and **2a** clearly demonstrates the influence of steric factors on the N···H···N hydrogen bond. From the dependence found here for the 4,5-bis(dimethylamino) derivatives of 9,10-dihydrophenanthrene and—if accessible—of phenanthrene, interesting "proton sponge" properties may be expected.

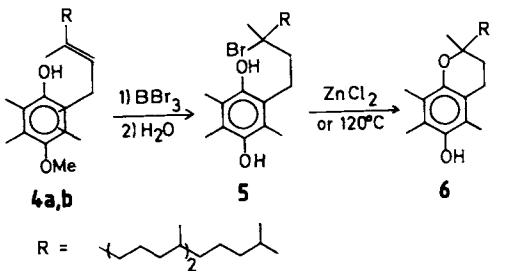
## A Carbene-Complex Route to Vitamin E**



By *Karl Heinz Dötz** and *Werner Kuhn*

Alkyne, carbonyl, and unsaturated carbene ligands can cyclize in the coordination sphere of chromium(0) to afford metal-coordinated arenes[1,3]. Following the use of this type of reaction for the synthesis of compounds in the vitamin K series[5], we have turned our attention to vitamin E.

The carbene complex pentacarbonyl[(*E*)-1-methoxy-2-methyl-2-butenylidene]chromium **1** reacts with (*E*)-6,10,14,18-tetramethyl-5-nonadecen-2-yne (methylphytylacetylene) **2** to yield the metal-coordinated hydroquinone derivative **3** as the isomeric mixture **a** : **b** = 70 : 30, which can be separated by column chromatography on silica gel. The tricarbonylchromium residue can be cleaved at room temperature using CO under pressure: in this way the hexacarbonylchromium required for preparation of the carbene complex **1** is re-formed.

In order to be able to use both hydroquinone isomers (**4a** and **4b**) for the cyclization to the chroman framework, the 4-position is demethylated using boron tribromide[10]; hydrobromination of the allyl function to afford **5** occurs

simultaneously. The subsequent condensation step occurs, as is well-known, with Lewis acids such as anhydrous zinc chloride[11]. More advantageous, however, proved to be the thermally induced ring closure which leads practically quantitatively to α-tocopherol (vitamin E) **6**.

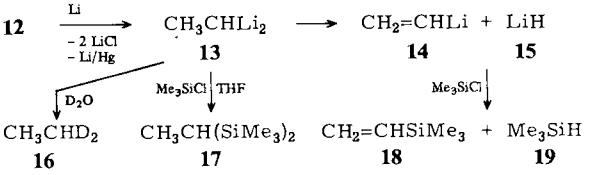
## 1,1-Dilithioethane**

By *Adalbert Maercker**, *Manfred Theis*, *Alexander J. Kos*, and *Paul von Ragué Schleyer*

Until now, dilithiomethane **5** was the only known geminal dilithioalkane. It was first obtained by *West* and *Rochow*[1a] from dibromomethane **2** and lithium in 6% yield. The yield was improved by *Lagow et al.*[1b] using a specially devised apparatus; however, mixtures of polylithio compounds were always formed that could not be separated. The best synthesis of **5** is the pyrolysis of salt-free methyllithium **4** described by *Ziegler et al.*[1c], but, unfortunately, this method does not lend itself to the preparation of higher dilithioalkanes.



We have now found that the reaction of bis(iodomercurio)methane **6**[2] with lithium powder gives access to **5**; the method also permits the synthesis of higher 1,1-dilithioalkanes for the first time. 1,1-Bis(chloromercurio)ethane **12**, which is accessible by two routes, serves as starting material for the preparation of 1,1-dilithioethane **13**. Rather than starting from vinyl bromide **7**[3a], **12** can be obtained more straightforwardly from 1,1-dichloroethane **9**. This synthesis was elaborated from a known method[3b].

**12** reacts in diethyl ether at room temperature with lithium powder (2 h, molar ratio ≈ 1:20) to afford a black suspension. Immediate addition of this suspension, which consists of 1,1-dilithioethane **13**, lithium chloride, and lithium amalgam, to $D_2O$ gives pure 1,1-dideuterioethane **16**, in almost quantitative yield, and mercury[4].

The starting material **12** or possible intermediates, such as ethylmercury chloride or diethylmercury, do not react with lithium under these conditions of hydrolysis. Treatment of **13** directly after its preparation with chlorotrimethylsilane/tetrahydrofuran (*ca.* 1:1) (reaction time 24 h at room temperature) gives 1,1-bis(trimethylsilyl)ethane **17** (30%) in addition to trimethylsilane **19** (15%) and reduction products of trimethylvinylsilane **18**. This suggests partial decomposition of **13** into vinyllithium **14** and lithium hydride **15**.

If the reaction product from **12** and lithium is first filtered off and refluxed with chlorotrimethylsilane in the absence of solvent, exclusively **18** and **19** are formed. Under these conditions **18** is not reduced, although lithium was present in considerable excess. As no organolithium compounds were detectable in the filtrate, **13** must have decomposed by loss of lithium hydride only after filtration since, as is well-known, vinyllithium is soluble in diethyl ether. In contrast to 1,1-dilithioethane **13**, dilithiomethane **5** decomposes slowly into lithium hydride **15** and lithium acetylide[1c], since a 1,2-elimination of lithium hydride is not possible.

The dilithio compound **5** can be obtained free of lithium amalgam if **6** is allowed to react with excess *tert*-butyllithium in hexane instead of with lithium powder. In contrast, 1,1-dilithioethane **13** is not accessible by this route: vinyllithium **14** immediately forms.

The thermodynamic stability and structure of **13** can be discussed by considering hypothetical gas phase monomers, which can be satisfactorily described by *ab initio* calculations at the 3—21 G basis set level[5].

**13** is destabilized relative to ethyllithium **20** due to the presence of the second lithium atom, as revealed by the following formal disproportionation:

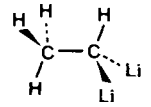
$$\underset{\mathbf{20}}{2CH_3CH_2Li} \longrightarrow \underset{\mathbf{13}}{CH_3CHLi_2} + C_2H_6 \qquad 6.1\ \text{kcal/mol}$$

The methyl group, which destabilizes ethyl- relative to methyllithium, also has an unfavorable effect in **13**[6a]:

$$\underset{\mathbf{5}}{CH_2Li_2} + C_2H_6 \longrightarrow \underset{\mathbf{13}}{CH_3CHLi_2} + CH_4 \qquad 12.4\ \text{kcal/mol}$$

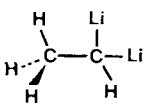
The difficulties experienced in the preparation of **13** can, in part, be attributed to this destabilizing effect. Because of lithium-hydrogen interactions, which lead to a partially double-bridged structure, the isomeric 1,2-dilithioethane **21** is much lower in energy[6b]:

$$\underset{\mathbf{13}}{CH_3CHLi_2} \longrightarrow \underset{\mathbf{21}}{LiCH_2CH_2Li} \qquad -17.6\ \text{kcal/mol}$$



At room temperature **13** decomposes quantitatively within 8 h to afford lithium hydride and vinyllithium. It has been suggested that this reaction proceeds *via* a vinyllithium-lithium hydride complex **22**, which is more stable than the monomers **14** and **15**[6c]:

$$\underset{\mathbf{14}}{CH_2{=}CHLi} + \underset{\mathbf{15}}{LiH} \longrightarrow \underset{\mathbf{22}}{CH_2{=}CHLi_2H} \qquad -51.0\ \text{kcal/mol}$$



**13** and **21** are less stable than **22** by 47.5 and 29.8 kcal/mol, respectively.

13a

13b

21

22

The structure of **13** optimized using the 3–21 G basis set is "classical" and exhibits no special Li···H or Li··Li interactions. The C–Li bond in **13a** (2.007 Å) is calculated to be only slightly shorter than that in ethyllithium **20** (2.017 Å), the length of the C–C bond is 1.581 and 1.563 Å, respectively. In addition, the energy difference between the staggered and eclipsed conformations of **13** also suggests no special Li···H interaction.

The 1,1-dilithioethane conformer **13b** is only 1.1 kcal/mol less stable than **13a** and displays a strong Li···H interaction. **13b** could, therefore, be an intermediate arising from elimination of LiH.

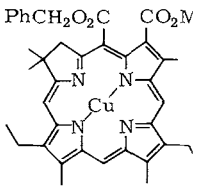
## Novel Methods for Demetalating Tetrapyrrolic Metallo-Macrocycles**



By *Alan R. Battersby*, Keith Jones,* and *Roger J. Snow*

Many natural tetrapyrrolic pigments occur as complexes with metal ions; this applies to most porphyrins, chlorins, bacteriochlorins, and corrins[1,2]. In addition, several synthetic routes to such macrocyclic systems generate metallo-complexes, *e.g.*, the $Cu^{II}$-promoted cyclization of dimethyl-*a,c*-biladienes, which is very effective for the synthesis of $Cu^{II}$-porphyrins[3]. Often it is desirable to eliminate the metal ion from the metallo-complexes in order to release the sequestering organic macrocycle in its free form: this is normally achieved by treating the metallo-complex with protic acids[4]. Removal of the metal ion in this way from the porphyrin complexes may be facile as, for example, with $Zn^{II}$ and $Mg^{II}$; however, in other cases demetalation may be difficult, and examples are common where either repetitive treatment with strong acids or forcing conditions such as dissolution in 100% sulfuric acid are necessary[4]. Clearly, these methods would cause difficulties if the macrocycle carries sensitive groups. Accordingly, we sought methods which might achieve rapid, relatively mild demetalation.

We reasoned that a promising approach would be to combine a protic acid with a reagent expected to precipitate or complex the liberated metal ion. This led to trifluoroacetic acid (TFA) with either 1,2-ethanedithiol or 1,3-propanedithiol as the preferred reagents; a solution of $H_2S$ in TFA is also effective but, in the cases studied so far, reacts more slowly.

6

**1**, M = $Cu^{II}$
**2**, M = H, H
**3**, M = $Ni^{II}$
**4**, M = $Cu^{II}$
**5**, M = H, H

Typical conditions for demetalation are as follows: The $Cu^{II}$-complex **1** (25 mg) of octaethylporphyrin (OEP) was treated at *ca.* 20°C in TFA (5 mL) with 1,2-ethanedithiol (40 µL); demetalation was complete in < 10 min as shown by UV/VIS spectroscopy; the reaction mixture was diluted with chloroform, shaken with 1 M sodium hydroxide, and the product from the chloroform layer was chromatographed to give pure OEP **2** in 97% yield. Increasing the quantity of thiol accelerated still further the demetalation. Use of 1,3-propanedithiol (10 µL for 1 mL TFA) also led to essentially quantitative removal of copper, in 25 min. The alternative method involved suspending $Cu^{II}$-OEP **1** (5 mg) in TFA (2 mL) through which $H_2S$ was bubbled for 2 min and then sealing the flask. Demetalation was complete in 1.5 h.

The nickel porphyrin **3** was also successfully demetalated, the only difference being the slightly slower rate of reaction with the thiols; the times for completion under the same conditions as used above were 20 min (1,2-ethanedithiol), 35 min (1,3-propanedithiol), and 1 h ($H_2S$). The complete removal of $Ni^{II}$ using these methods contrasts with the results using protic acids. Treatment of $Ni^{II}$-OEP **3** (1 mg) with neat TFA (1 mL) gave 50% demetalation after 15 min and 70% after 1 h, this being unchanged after 6 h. Similarly, TFA-$H_2SO_4$ gave 70% demetalation after 10 min and the same value after 1 h. Clearly an equilibrium is reached which is displaced by the thiols or $H_2S$[5].

Finally, the $Cu^{II}$-chlorins[6] **4** and **6** were demetalated essentially quantitatively using TFA-$H_2S$. For example, **4** (5 mg) in TFA (6 mL) was saturated with $H_2S$ and the mixture kept at *ca.* 20°C for 18 h; work-up and chromatography gave the metal-free chlorin **5** in 71% isolated yield.

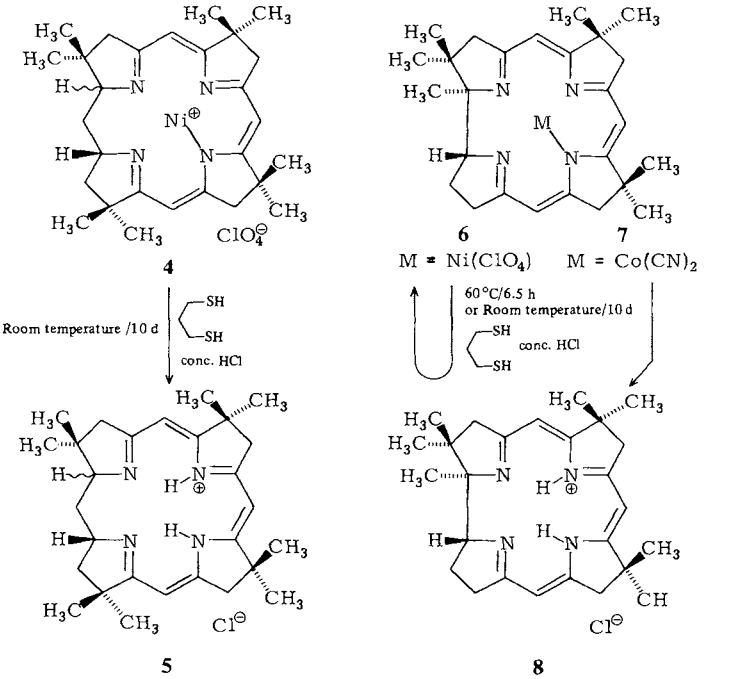
## Acid-Catalyzed Demetalation of Nickel-Hydrocorphin and Cobalt-Corrin Complexes with 1,3-Propanedithiol**



By *Norman J. Lewis, Andreas Pfaltz,* and *Albert Eschenmoser**

In investigating the chemistry of the hydrocorphinol→corrin rearrangement, we attempted to obtain the metal-free ligand system of the 20-keto-tetrahydrocorphin **2** by demetalation of the nickel(II) hydrocorphinate **1**[1] (see Scheme 1) in order to examine the possibility of A/D ring contraction. Both acids and cyanide ion were unsuccessful in effecting such a decomplexation, *e.g.*, treatment of **1** with KCN in degassed methanol at 100°C left the nickel complex essentially unchanged even after several hours[2]. Attempts at decomplexation with strong acids gave either starting material or complex mixtures of products. In striking contrast was the result obtained with 1,3-propanedithiol, which *Battersby et al.*[3] had used to decomplex a nickel-isobacteriochlorinate: By allowing **1** to stand for several days in (degassed) concentrated hydrochloric acid in the presence of excess 1,3-propanedithiol, we obtained the metal-free (crystalline) dithioketal **3** in 60% yield. The target compound **2** was then produced by acid-catalyzed transacetalization.

Subsequently, we carried out decomplexation experiments with 1,3-propanedithiol in the corrin series, where demetalation of nickel and cobalt complexes had not been achieved without destruction of the ligand system (cf. lit. in [3] and Scheme 2). Conditions which decomplexed the nickel(II)*tetrahydrocorphinate* **4**[4] cleanly to the free ligand **5** (UV/VIS) left the nickel(II) *corrinate* **6**[4] unchanged, even at 60°C. *In contrast, the cobalt(III) corrin complex* **7**[4] *was smoothly decomplexed with 1,3-propanedithiol.* The metal-free corrin, isolated in 83% yield as the crystalline hydrochloride **8**, was characterized by UV/VIS (Fig. 1), fluorescence, $^1$H-NMR, and mass spectroscopy. Among the reaction conditions that effected smooth demetalation of **7** (but not of **6**), were the following: 1,2-ethanedithiol instead of 1,3-propanedithiol or (!) 1-propanethiol in degassed $CHCl_3$ (but not $CH_3OH$) containing HCl (g), at room temperature for 5 days. This is remarkable in view of the vigorous conditions used to prepare the cobalt complex **7** from its 15-cyano derivative in over 85% yield[4] (40 h, 230°C, degassed 0.1 N hydrochloric acid).

Scheme 1. a) **1** (20 mg) in 10 mL conc. HCl + 0.1 mL 1,3-propanedithiol degassed in sealed tube, RT, 11 d in the dark; worked-up with 0.1 N $HClO_4$, short-column chromatography on silica gel (1% $NaClO_4$), $CH_2Cl_2$/ether (10:1); **3**: red crystals from $CH_2Cl_2/CH_3COOCH_3$, m.p. = 283°C, yield 60%.—b) **3** (10 mg) in 5 mL diisopropyl ketone/conc. HCl (1:1) degassed in sealed tube, RT, 2 d in the dark; worked-up with 0.1 N $HClO_4$, short-column chromatography on silica gel (1% $NaClO_4$), $CH_2Cl_2$/ether (10:1); **2**: red crystals from $CH_2Cl_2/CH_3COOCH_3$/hexane, m.p. = 174°C, yield *ca.* 30% (not optimized).

Scheme 2. a) **7** (25 mg) in 12 mL conc. HCl + 0.1 mL (≈*ca.* 20 molar equiv.) 1,3-propanedithiol degassed in sealed tube, heated 6.5 h, 60°C. **8**: dark orange crystals from $CH_2Cl_2/CH_3COOC_2H_5$ under argon, m.p. > 165°C (decomp.), yield 83%.

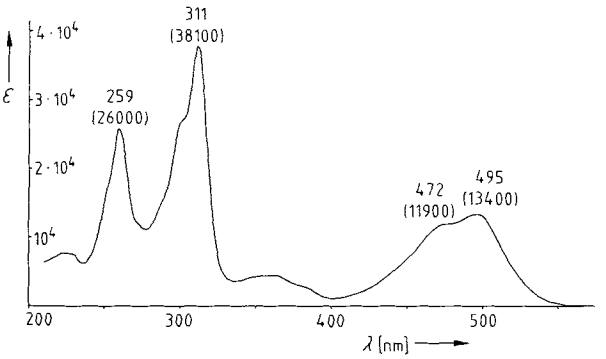

Fig. 1. UV/VIS spectrum of **8** in $CH_3OH$. $c = 4.55 \times 10^{-5}$ M. $\lambda_{max} = 259$ ($\varepsilon = 26000$), 286 (sh, 14000), 300 (sh, 27000), 311 (38100), 346 (sh, 4200), 360 (4400), 384 (2600), 472 (sh, 11900), 495 (13400) nm.

The differing behavior of the nickel(II) complexes **4** and **6**, whose ligand systems have similar chromophores but dissimilar carbon-nitrogen skeletons, presents further evidence that the corrin system is sterically a better ligand for $Ni^{2+}$ than hydroporphinoid systems[5]. The difference in the behavior of the nickel and cobalt corrin complexes corresponds to a known trend in the chemistry of the two transition metal ions (Co(III) is likely to be reduced to Co(II) before decomplexation). Moreover, the decomplexation of a cobalt corrin complex is a *novum*, which promotes the original synthesis of corrin complexes *via* A/B ring closure[4c] to a synthesis of metal-free corrins (see, however, [6]).

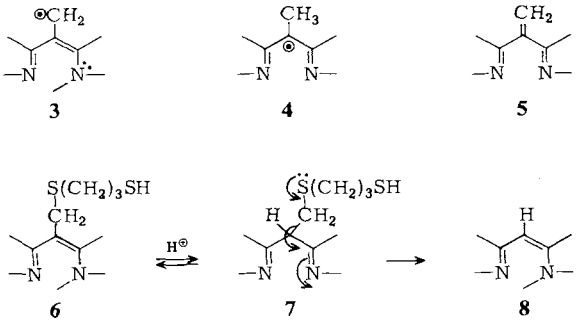
## 5,15-Bisnorcobester: an Unexpected Mode of Formation**

By *Norman J. Lewis, Rolf Nussberger, Bernhard Kräutler,* and *Albert Eschenmoser**

The decomplexation of a cobalt(III) corrin complex[1], led us to also attempt a demetalation in the vitamin $B_{12}$ series. This was not successful, but in the course of our attempts we discovered a remarkable reaction of the cobester (heptamethylcobyrinate) **1**[2].

Scheme 1. a) **1** (20.00 mg) in 20 mL $CHCl_3$, satd. at 0 °C with HCl(g) (ca. 1 wt-%) + 0.2 mL $CCl_4$ + 0.1 mL 1,3-propanedithiol, degassed (−190 °C, 2×) and sealed in an ampule (0.5 torr), heated for 4.5 d at 100 °C. Crude product methanolyzed at 65 °C in 30 mL $CH_3OH$/7 vol-% $H_2SO_4$, under argon, 2 d (reconstitution of the methoxycarbonyl groups). Chromatography on silica gel and (3×) crystallization ($CH_3CO_2CH_3$/hexane), m.p. = 114 °C, yield 56% (experimental details in R. Nussberger, Disseration ETH Zürich, in preparation).



Reaction of 1,3-propanedithiol in concentrated hydrochloric acid with cobester resulted in complex (water soluble) product mixtures with considerable loss of chromophore, but without any indication of demetalation. *Anhydrous* reaction conditions (1,3-propanedithiol + HCl(g) in $CHCl_3$, exlusion of air) led to cobalt(II)-corrinoids. Use of drastic reaction conditions (100 °C, 4 d) led to a particularly interesting result: after reoxidation of the reaction mixture with KCN/air ($Co^{II} \rightarrow Co^{III}$) and chromatographic purification of the products, a fraction with the hypsochromically

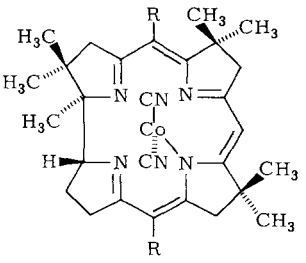
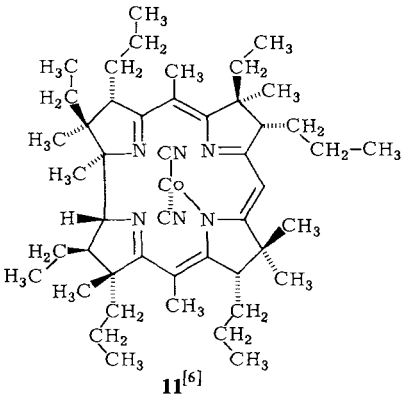
shifted UV/VIS spectrum of the chromophore of 5,15-bisnorcobester **2**[3] was observed. The reaction is only reproducible in the presence of small amounts of $CCl_4$. Under optimized conditions (Scheme 1) the didemethylation proceeds almost quantitatively (UV/VIS spectroscopy). The crystalline product (56%) had identical UV/VIS, CD, IR, $^1H$- and $^{13}C$-NMR, as well as mass spectra (fast-atom bombardement technique) as a sample of a (1:1) crystallizate of 13α- and 13β-5,15-bisnorcobester **2** (spectra shown in[3]) obtained earlier in this laboratory by total synthesis[3a,b].



**3** **4** **5**



**6** **7** **8**

The demethylation of cobester has precedence in the $KMnO_4$ oxidation of the *meso*-methyl groups of $B_{12}$ derivatives to carboxyl functions, observed by *Rapp et al.*[3d]. Diastereomerically pure 5,15-bisnorcobester[3a,b], obtained (in 4% overall yield) from this source upon decarboxylation and methanolysis, served as a reference compound in the vitamin $B_{12}$ synthesis[3b,c]. The demethylation **1**→**2** is also likely to proceed by oxidative attack on the *meso*-methyl groups and may lead *via* (stabilized) radicals of type **3** and/or **4** to a dehydrocorrinoid intermediate of type **5**, electrophilic at the *exo*-methylidene carbon. Addition of $CCl_4$ to the reaction mixture seems to ensure the formation of the necessary oxidizing agent. The hypothetical dealkylation scheme **6**→**7**→**8** corresponds to a reversal of the thiomethylation which served to introduce the *meso*-methyl groups in the cobyric acid synthesis[3b,c,4]. An alternative, stepwise procedure for the demethylation of cobester to 5,15-bisnorcobester is described by *Nussbaumer* and *Arigoni*[5].

**9**, R = H[1]
**10**, R = $CH_3$[4]

**11**[6]

When cobester was subjected to the reaction conditions shown in Scheme 1 *but without addition of $CCl_4$*, neither demethylation nor demetalation occured. After methanolysis and chromatography, cobester was recovered in 70% yield as a crystalline 13α,β-mixture. The discrepancy between cobester and the heptamethylcorrin **9**[1] in their decomplexation behavior is not caused by the two *meso*-methyl groups: the nonamethylcorrin complex **10**[4] is demetalated as easily as **9** by 1,3-propanedithiol (conc. HCl, 60 °C, 7 h or $CHCl_3$/HCl, 20 °C, 3 d). Neither is the discrepancy a consequence of the methoxycarbonyl groups of cobester, since we found that *Gossauer*'s corrin complex **11**[6] also resisted demetalation (1,3-propanedithiol in $CHCl_3$, *without $CCl_4$*, HCl, 70 °C, 1 month). These findings support the view that the additional substituents of the natural corrinoids compared to **9** or **10** hamper the transient protrusion of the nitrogen atoms from the coordination plane during decomplexation. The challenge to find a preparative route for demetalation of vitamin $B_{12}$ and its derivatives still remains.

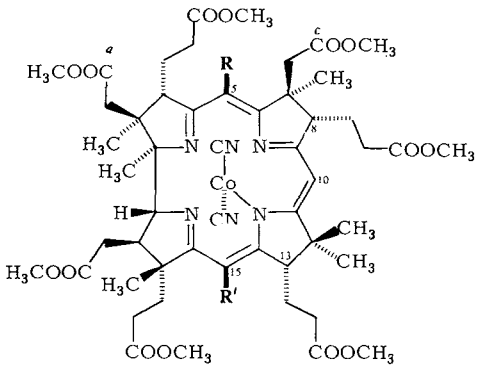
## A Simple Route to 5-Nor, 15-Nor-, and 5,15-Bisnorcobesters**



By *Cornelius Nussbaumer* and *Duilio Arigoni**

Derivatives of vitamin $B_{12}$ lacking methyl groups at positions 5 and 15 have played an important role in the total synthesis of the vitamin[1]; they are or interest in connection with current investigations on the biosynthesis of naturally occurring corrins and studies on the mode of action of the $B_{12}$-coenzyme. Diasteromerically pure 5,15-bisnorcobester **2** has been prepared previously from the 5,15-diacids, which are formed in low yield on oxidation of $B_{12}$-derivatives with $KMnO_4$[1c,d]; an unexpected mode of formation of **2** in a (1:1)-mixture with its 13β-epimer is re-

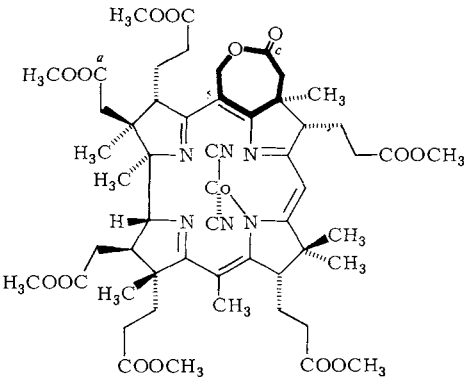
[**] We are grateful to Sandoz AG, Basel, for financial support and to Prof. *H. H. Inhoffen* for a generous gift of cobester.

ported by *Lewis et al.*[2]. Here we describe a stepwise efficient new procedure for converting **1** into **2**, which, in addition, is also a route to the two mononor-derivatives **3** and **4**.



| | R | R' | UV/VIS λ[nm] (α-band, MeOH) |
|---|---|---|---|
| **1** | $CH_3$ | $CH_3$ | 582 |
| **2** | H | H | 561 |
| **3** | H | $CH_3$ | 572 |
| **4** | $CH_3$ | H | 569 |
| **5** | $CH_2OH$ | $CH_3$ | 576 |
| **6** | $CH_3$ | $CH_2OH$ | 575 |
| **7** | $CH_2OH$ | $CH_2OH$ | 571 |
| **8** | $CH_2OCH_3$ | $CH_2OCH_3$ | 570 |

Treatment of cobester **1** with $Pb(OAc)_4$ (3 eq. of a $2.4 \times 10^{-2}$ M solution in benzene, 24 h, RT) generated a mixture of labile acetoxymethyl compounds, mild hydrolysis of which (acetone/$H_2O$ 1:10, trace $CH_3COOH$, 4 h, RT), followed by purification, gave the two monohydroxylated derivatives **5** (11%) and **6** (31%) as well as the 5,15-bishydroxymethyl compound **7** (46%), all in crystalline form. Reaction of **1** with 5 equivalents of the reagent (40 h, RT) and subsequent methanolysis (2 h reflux) of the crude product afforded the crystalline 5,15-bismethoxymethyl compound **8** in 75% yield after chromatographic purification. Use of excess $Pb(OAc)_4$ in boiling benzene caused additional oxidation at C-8 and gave a mixture from which on methanolysis variable amounts of **8** and of the corresponding *c*,8-lactone could be isolated. In contrast to a previous report[3], no products arising from electrophilic attack of the reagent at C-10 of the substrate could be detected.

On treatment with zinc in acetic acid at room temperature each of the three hydroxylated compounds **5**—**7** was reduced cleanly to the starting material **1**. An initial assignment of the structures of the two isomeric compounds **5** and **6** was made by carrying out the reduction in $CH_3COOD$ and comparing the $^1H$- and $^{13}C$-NMR spectra of the resulting regiospecifically monodeuterated cobester samples with the spectra of the unlabeled material, which have been analyzed in detail[4a, b]. Conclusive evidence corroborating these assignments was provided by the facile transformation (acetone/0.1 M phosphate buffer 1:10, pH 8, 4 h, RT) of **6** into the seven-membered lactone **9**, which could be reduced with Zn in acetic acid to the known cobester-*c*-acid. A similar tendency towards lactone formation was also observed for **7**, whereas the 15-hydroxymethyl derivative **6** was unaffected under the same reaction conditions.

**9**

Smooth elimination of the two hydroxymethyl groups of **7** was achieved by using Dowex® 50 W as catalyst[5]. After chromatographic separation, the desired product **2** was isolated in crystalline form (70%); according to the $^1H$- and $^{13}C$-NMR analyses, contamination by the 13β-epimer did not exceed 10%. Extension of the same procedure to the monohydroxylated compounds **5** and **6** afforded in good yields the 5-norcobester **3** and the 15-norcobester **4**, respectively, both crystalline and free from diastereomeric impurities. Similar 5-nor- and 15-nor-compounds had been prepared previously by more involved and less efficient routes[1c, d], and their structures assigned tentatively from spectroscopic data. The established structures of **3** and **4** now provide a basis for unambiguous correlations.

**Contemporary Heterocyclic Chemistry: Syntheses, Reactions and Applications.** By *G. R. Newkome* and *W. W. Paudler*. John Wiley – Sons, Chichester 1982. x, 422 pp., bound, £ 30.80.

To present such a complex subject as heterocyclic chemistry in a 422 page monograph is not the simplest of tasks. The authors' aim is to cover heterocyclic chemistry with particular emphasis on heteroarene chemistry.

The subject is divided into π-excessive and π-deficient heteroarenes, according to the classical concept of *Adrien Albert*, in order to allow its presentation as an entity. After a (too brief) introduction to the nomenclature, a subject which requires particular care because of the "arbitrary growth" in several areas, the basic concept of this volume is presented including MO calculations, dipole moment and NMR studies (some tables showing electronic densities, dipole moments, $^{1}$H-, $^{13}$C-, and $^{15}$N-NMR data, p$K_a$ values, UV data, bond lengths and MS fragmentation schemes of customary heterocycles are collected at the end of the volume). The main part of the book consists of a discussion of the five-membered π-excessive and the six-membered π-deficient heteroarenes, together with their benzo-annelated analogues and derivatives, to which ten and nine chapters, respectively, are devoted. Successful classical methods and modern developments are always dealt with side by side. A great deal of space is devoted to the [2+1]- and the [4+2]-cycloadditions and to the additions of singlet oxygen to five-membered heteroarenes and the subsequent reactions. Alongside pyridine, the six-membered heterocycles treated are the pyridazines, pyrimidines (significantly under-represented in comparison to their importance), pyrazines, triazines, tetrazines and their benzo derivatives.

Further chapters deal with $S_N$ and $S_E$ reactions as well as radical reactions and photochemical transformations. Among the nucleophilic reactions described in detail are the $E_A$ (heteroaryne) and the ANRORC mechanisms. They are followed by photoinduced valence isomerizations, "ring scrambling" and [4+4]-dimerizations of pyridines, pyrazines and pyrimidines. Each class of compound has a chapter on natural products and (a few) pharmaceutically important compounds, devoted to it.

Heterocondensed heteroarenes are treated in a chapter of their own. There then follows a comprehensive treatment of mesoionic heterocycles (sydnones, munchnones, 1,3-oxazolium-5-olates, 1,3-oxathioliumolates, 1,3-diazoliumolates and amides, 1,2,3,4-tetrazolium-5-thiolates) and their manifold, synthetic potential. Particular attention is paid to the three- and four-membered heterocycles; it is noticeable that the photochemical C–C cleavage of epoxides to carbonyl ylides is not mentioned. Finally, two chapters are concerned with some classical azepine, (benzo)diazepine and thiepin syntheses, together with methods of producing some azocines and diheterocines; however, the recently successful cycloaddition-ring enlargement reactions are practically ignored.

References up to 1980 are included; the principal sources quoted are monographs and review articles. Half of the citations come from the last two decades. In spite of this, one searches in vain for notions such as intramolecular cycloadditions, frontier orbitals, or regio- and enantioselectivity. The literature citations are listed at the end of each chapter which is irksome during intensive study. The formulas often look awkward because of the greatly varying bond lengths sometimes used. Better quality is to be expected in a monograph of this price class.

Altogether this lucidly constructed monograph takes its place between a text book and a progress report and guarantees, in an exemplary fashion, the chemistry student, the chemist in research and in industry, as well as the scientist of neighboring disciplines, an excellent and speedy introduction to current chapters of modern heterocyclic chemistry by means of a clear conception and ample literature citation. This book can be warmly recommended to all in industry or university who are concerned with the chemistry of heteroarenes.

und Biochemie der Universität Bonn

**Non-formal Kinetics.** By *R. Schmid* and *V. N. Sapunov*. Verlag Chemie, Weinheim 1982. xi, 199 pp., bound, DM 98.00.

The authors first introduce the reaction kinetic method with the aid of simple examples. Elementary quantities, such as the reaction rate constant or the half-life, are described in terms of the concentration-time curve, invariances I and II are also defined with the aid of linear transformations. Starting from these simplest cases and *via* parallel and series reactions, ever more complex, kinetic systems are treated. The kinetics of simple, catalyzed reactions are the starting point for the analysis of complicated, catalyzed reaction paths, particularly with reference to biochemical applications.

In the second part of the book the authors introduce a method of analysis of complex kinetics on the basis of the kinetic techniques described, which proceeds largely without assumptions. Invariances I and II, described at the beginning of the book, afford an opportunity to obtain preliminary information. The differentiated form of the rate-time curve plays a central role in the further analysis. A procedure is described that allows a numerical expression for the kinetic equations to be formulated by repeated correction of the rate-time diagram, even in the case of fractional orders of reaction and for catalyzed reactions. The development of reaction mechanisms from the equations so discribed is discussed.

Following the actual, kinetic analysis there is a chapter concerning the influence of temperature on the rate constant. The Arrhenius equation and the Eyring equation are compared and discussed in terms of the transition state theory. Further chapters treat the influence of pressure, of the solvent (with emphasis on empirical scales of polarity) and of substituents. The appendix is concerned with free enthalpy relationships and with the Exner analysis for the determination of isokinetic relationships.

The book is useful both to the advanced student and to the experienced practitioner, since it offers the one a summary of kinetic methods and the other a wealth of useful details, which is systematized. The mathematical relationships in kinetic statements are clearly and distinctly formulated. The derivation of the Bodenstein principle might be mentioned as an example. The effect of errors in measurement on the results of kinetic measurements is perhaps treated too briefly; but it may be that this lies outside the

scope of the book. Even in the future, intuition will have to play its part in the elucidation of complex reactions. However, the authors have succeeded in systematizing, for practical application, the available, kinetic methods. This book will enrich anyone who is concerned with reaction mechanisms.

# Adventures and Excursions in Bioassay: The Stepping Stones to Prostacyclin (Nobel Lecture)**

By John R. Vane*

Physiology has spawned many biological sciences, amongst them my own field of pharmacology. No man has made a more important contribution to the fields of physiology and pharmacology than *Sir Henry Dale* (1875–1968, Nobel Laureate in Physiology or Medicine in 1936). *Dale* had a great influence not only on British pharmacology in general but also on my own scientific endeavours. Indeed, I can put forward a strong case for considering myself as one of *Dale*'s scientific grandchildren. My early days as a pharmacologist were influenced not only by *Dale* himself but also by his own school of colleagues, including *Burn*, *Gaddum* and *von Euler*. It was *Burn* who taught me the principles and practice of bioassay. Some of *Gaddum*'s first publications were on the development of specific and sensitive methods for biological assay, and he maintained a deep interest in this subject for the rest of his life[1]. In 1964 he said "the pharmacologist has been a 'jack of all trades' borrowing from physiology, biochemistry, pathology, microbiology and statistics—but he has developed one technique of his own, and that is the technique of bioassay"[2].

Expensive, powerful and sophisticated chemical methods, such as gas chromatography and mass spectrometry, have been developed and perfected for detection and quantification of prostaglandins (PGs) and related substances. One should not forget, however, that starting with the discovery and isolation of prostaglandins by *von Euler*[3a]; see also text of the Nobel lecture by *Bergström*[3b]), biological techniques and bioassay have contributed very substantially to the development of the field. Bioassay has provided crucial information on the role of the lungs in the removal of circulating prostaglandins[4], the participation of prostaglandins in inflammatory reactions[5,6], the contribution of prostaglandins to the autoregulation and maintenance of blood flow to the kidney[7–9], the inhibitory effect of aspirin-like drugs on the biosynthesis of prostaglandins[10–12], the mediation of pyrogen fever by prostaglandins[13], and the release of rabbit aorta-contracting substance (RCS; now identified as thromboxane $A_2$, $TXA_2$) from lungs during anaphylaxis[14,15]. Moreover, in 1976 bioassay made possible the discovery of PGX, now renamed prostacyclin ($PGI_2$), the latest member of the prostaglandin family[16–19]. Indeed, it is doubtful whether the biological significance of any of the unstable products of arachidonic acid metabolism would have been recognised without bioassay techniques. With extraordinary simplicity and convenience, by its very nature, bioassay distinguishes between the important biologically active compounds and their closely related but biologically unimportant metabolites.

In this review I shall discuss the development of the cascade superfusion bioassay technique and some of the discoveries and concepts which arose from its application, leading up to the discovery and development of prostacyclin. The effects of prostacyclin in man and its clinical assessment (another application of bioassay) will also be discussed.

## 1. Cascade Superfusion Bioassay

### 1.1. Development

Most uses of bioassay involving smooth muscle demand high sensitivity and specificity. These aspects have been achieved first, by limiting the volume of fluid bathing the isolated tissue and second, by using an assay organ sensitive to, and relatively specific for, the test substances under study. Further specificity can be achieved by using a combination of several tissues which present a characteristic pattern of response to the test substance or substances. This takes advantage of the principle of parallel pharmacological assay, regarded by *Gaddum*[20] as strong evidence for the identity of a compound.

*Magnus*[21] introduced the idea of suspending an isolated portion of smooth muscle in a chamber containing a nutrient fluid and measuring changes in tissue tone. The organ baths used today are modified versions of that used by *Dale*[22]. *Gaddum*[23] applied the experimental design developed by *Finkleman*[24] to the assay of minute amounts of biologically active substances. He called his technique "superfusion" in contrast to perfusion. This consisted of bathing an assay tissue with a stream of fluid which was momentarily stopped at the moment of addition of the test substance. *Vane*[25] introduced the idea of superfusing several tissues in cascade (generally up to six, arranged in two banks; Fig. 1). Besides being useful for the parallel assay of individually injected samples, this arrangement also allows parallel analysis of the active components present in a fluid stream (most commonly Krebs' solution) taken from the outflow of a perfused organ.

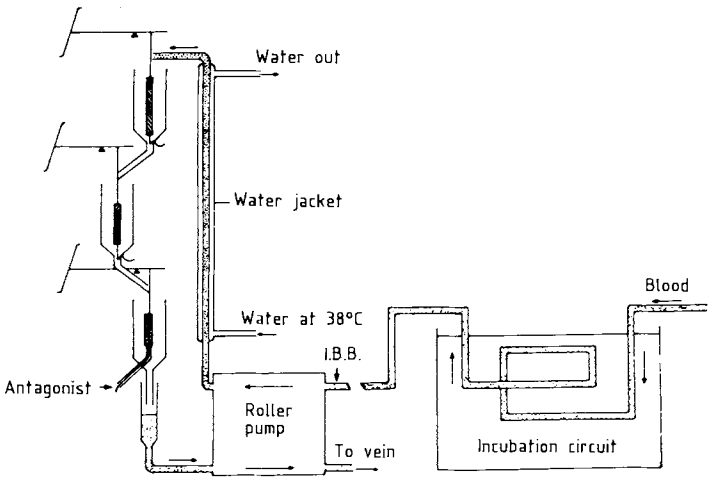

Fig. 1. Diagram of the blood-bathed organ technique. Blood is continuously withdrawn from a convenient blood vessel by a roller pump, kept at 37°C by a water jacket and then allowed to superfuse a series of isolated organs, the longitudinal movements of which are recorded. The blood is then collected in a reservoir and returned to the animal. In some experiments the blood flows through a length of silicone tubing in a water bath (incubating circuit) before superfusing the isolated tissues. Drugs can be applied directly to the isolated tissues by infusions or injections into the bathing blood (I.B.B.) or with a time delay into the incubating circuit (from *Vane* [33], by permission of the *Br. J. Pharmacol.*).

Another innovation introduced by *Vane*[25] was to use blood as the superfusion medium (the blood-bathed organ technique). The anaesthetised animal is heparinised and blood is continuously removed at a constant rate of 10—15 mL/min (dogs, cats and rabbits). Lower rates can be used from guinea pigs[26]. The blood (either from a vein or from an artery) superfuses the assay tissues and is then returned by gravity to a large vein.

Plainly, when perfusate from an organ or blood from an animal is used for superfusion, substances can reach the assay tissues within a few seconds of generation or release. This element of "instantaneity" is an important aspect of cascade superfusion bioassay in that it detects the biological activity of chemically unstable compounds whose activity would otherwise be lost in an extraction process. Another important feature of the method is that it gives the maximum opportunity for serendipity. The dynamic nature of the assay also allows the measurement of inactivation of an infused substance across a particular vascular bed. Further modifications of the bioassay technique have been developed by *Collier*[27], *Ferreira* and *Souza Costa*[28] and *Gryglewski et al.*[29].

### 1.2. Choice of Bioassay Tissues

It is usually possible to find a piece of smooth muscle which is particularly sensitive to the hormone under investigation and relatively insensitive to other substances. Indeed, think of any part of the body and you can be sure that the pharmacologist has cut it out, put it into an isolated organ bath, or perfused its vessels in order to study the effects of drugs. For bioassay, segments of the gastrointestinal tract or spirally cut strips of vascular tissue have mainly been used. Such procedures are the backbone not only of bioassay but also of classical pharmacology.

Figure 2 depicts the reactions of some superfused isolated tissues to various endogenous substances in concentrations likely to be found in circulating blood. It should be remembered that when blood is used as the superfusing medium, some smooth muscle preparations (but not others) exhibit an increased resting tone often lasting for the

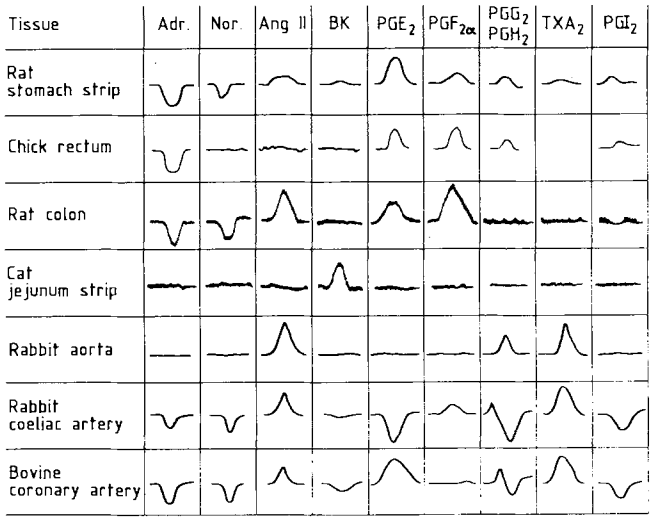

Fig. 2. Diagram showing the reactions of some blood-bathed organs to various endogenous substances in concentrations of 0.1—5.0 ng/mL. The actions of the catecholamines, 5-hydroxytryptamine and histamine can be abolished by treatment with suitable blocking agents (Adr = adrenaline, Nor = noradrenaline, Ang = angiotensin, BK = bradykinin).

duration of the experiment. Such increased tone reduces sensitivity to substances which cause contraction but increases sensitivity to those which induce relaxation.

For detection of the classical prostaglandins, the most useful combination of assay tissues is the rat stomach strip, rat colon, and chick rectum. For PG endoperoxides and later for prostacyclin, vascular tissues were added such as strips of coeliac or mesenteric artery[30]. Strips of bovine coronary artery[31] were especially useful for they contracted to $PGE_2$ but relaxed to prostacyclin (Fig. 2).

The specificity of a bioassay can be increased still further by the use of antagonists. For instance, contractions of the rat stomach strip induced by 5-hydroxytryptamine can be abolished by a specific antagonist such as methysergide, thereby leaving the preparation more specifically sensitive to the prostaglandins. The rat colon is relaxed by catecholamines but contracted by angiotensin II; when both are present in the superfusion fluid, the catecholamines reduce the contraction produced by angiotensin. This unwanted interference is prevented by blocking the actions of catecholamines with a β-receptor antagonist. When blood is used as the superfusion fluid, the antagonist can be perfused through the closed lumen (Fig. 1) of, say, the rat colon[32] thus localising the blocking agent to the assay tissue and minimising its effects on the whole animal. For a detailed discussion of the limitations of the cascade superfusion bioassay technique, the reader is referred to *Vane*[33] and to *Moncada, Ferreira* and *Vane*[34].

### 1.3. Measurement of Substances by Cascade Superfusion Bioassay

The technique is well suited for measuring substances released into the circulation, such as catecholamines or angiotensin II, and also for determining the fate of substances released or infused into different parts of the circulation.

#### *1.3.1. Release of Substances in Response to Stimuli*

Release of catecholamines from the adrenal medulla can be detected and quantitated by use of a rat stomach strip and chick rectum. This technique was used to demonstrate that circulating catecholamines appeared to play little or no part in arterial baroreceptor reflexes[25] and also that catecholamines are released into the circulation during anaphylaxis[35]. Of the substances released during the anaphylactic reaction, histamine, bradykinin and slow reacting substance in anaphylaxis (SRS-A) will all in turn release adrenaline when injected intravenously, although there may be species differences in the mechanisms of action and in the sensitivity of the adrenal medulla[36–38].

An early use of the blood-bathed organ technique was to show the sequential release of angiotensin II and catecholamines during haemorrhage[39]. Release of bradykinin into the blood stream by the intravenous injection of kallikrein or by contact of the blood with glass was easily demonstrated[40] but we consistently failed to demonstrate with this technique the endogenous release of bradykinin by physiological manipulation. However, circulating kinins were demonstrated during hypotension due to haemorrhage in the dog and the concentrations detected in the bloodstream were sufficient to lower a normal blood pressure[41].

#### *1.3.2. Inactivation of Circulating Vasoactive Substances*

By comparing the effects on the blood-bathed assay organs of infusions of a substance over several minutes into a particular vascular bed with the effects of similar infusions given into the effluent of the vascular bed, it is possible to assay the percentage of the substance disappearing in one circulation through that vascular bed (Fig. 3). This technique allowed the demonstration of the inactivation of several vasoactive substances as they passed through vascular beds such as the hind legs, the liver and the lungs.

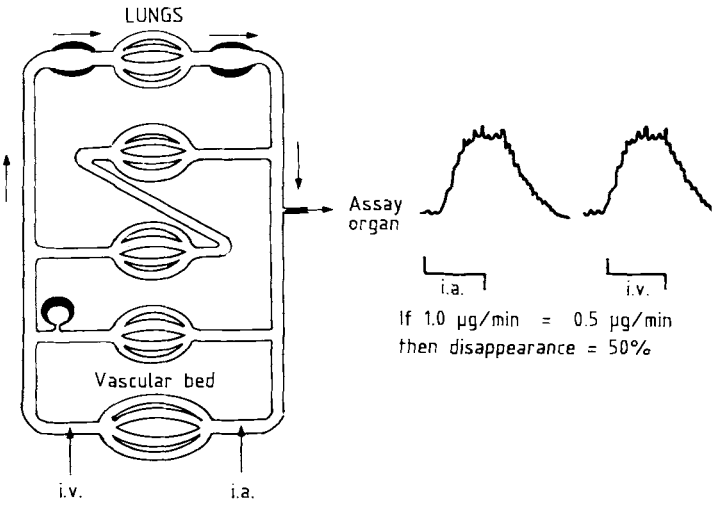

Fig. 3. Diagram showing principle of bioassay of the degree of disappearance across a vascular bed. The differences in responses of the blood-bathed organs to infusions made intraarterially (i.a.) or intravenously (i.v.) represent the degree of removal of the substance in one passage through the vascular bed.

Angiotensin II, for example, is unaffected by passage through the pulmonary circulation, either *in vivo* or in isolated lungs of all species studied, including rats, dogs, guinea pigs, cats and man (for review see *Bakhle* and *Vane*[42]). However, the same substance is substantially inactivated (50—70%) in one passage through peripheral vascular beds such as the liver, the kidneys and the hind legs[43].

We also studied the fate of adrenaline and noradrenaline and found in both cats and dogs that 70—95% of an intraarterial infusion of adrenaline or noradrenaline disappeared in one passage through the hindquarters. The lungs, however, inactivated up to 30% of an infusion of noradrenaline without interfering with the passage of adrenaline[44,45].

Bradykinin is fairly rapidly destroyed in blood and has a half-life in the blood stream of cat or dog of about 17 seconds. *Ferreira* and *Vane*[46] showed that, whereas the liver inactivated about 50%, the lungs inactivated about 80% of the bradykinin infusion.

It was observations such as these that drew our attention to the metabolic and pharmacokinetic function of the pul-

monary circulation. The selectivity of the pulmonary inactivation mechanism is strikingly demonstrated by the way in which the lungs inactivate bradykinin, but allow other peptides such as eledoisin, substance P, physalaemin, vasopressin and oxytocin to pass through without change[42].

The metabolism of prostaglandins in the pulmonary circulation *in vivo* was first studied by *Vane et al.*[4,47] who showed that almost all of an infusion of $PGE_1$, $PGE_2$ or $PGF_{2\alpha}$ was inactivated in one passage through the lungs. *McGiff et al.*[48] confirmed that $PGE_1$ and $PGE_2$ were avidly removed by dog lung *in vivo* but further showed that $PGA_1$ and $PGA_2$ survived the passage through the lungs without change. Thus, within this very closely related group of substances, the inactivation process can distinguish between the individual members. Interestingly, after the discovery of prostacyclin, we also found[49] that prostacyclin (unlike $PGE_2$, see Fig. 4) survived passage through

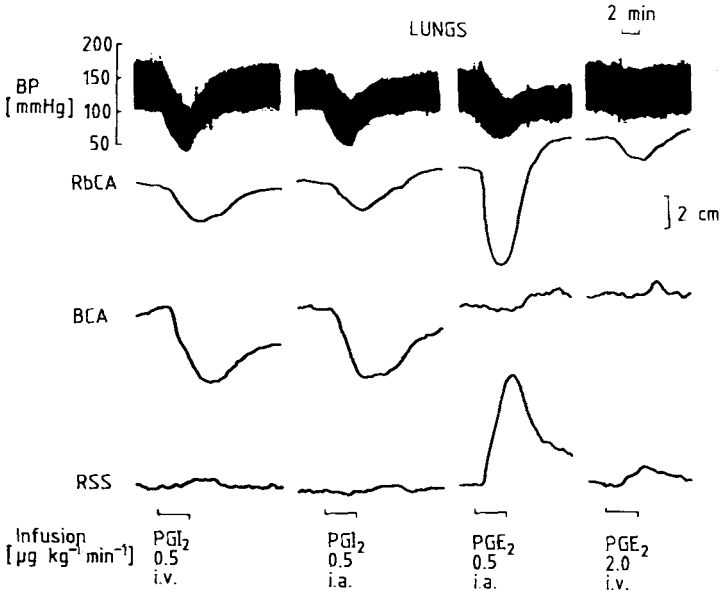

Fig. 4. Passage of prostacyclin ($PGI_2$) and prostaglandin $E_2$ ($PGE_2$) across the lungs. Spiral strips of rabbit coeliac artery (RbCA), bovine coronary artery (BCA) and rat stomach strip (RSS) were bathed in arterial blood from a dog. $PGI_2$ infused intravenously (i.v.) caused similar effects on the bioassay tissues and blood pressure (BP) as infusion into the root of the aorta (i.a.), indicating that $PGI_2$ did not disappear across the lungs. In contrast, much more than 75% of $PGE_2$ was inactivated in passage through the pulmonary circulation (see *Dusting, Moncada* and *Vane*, 1978 [49], by permission of the *Br. J. Pharmacol.*).

the pulmonary circulation without change. In other vascular beds, the inactivation of prostacyclin in a single passage (50—70%) was comparable to that of $PGE_2$. Thus, the hindquarters, and particularly the liver, removed some of the prostacyclin which reaches those beds.

Overall, the inactivation of prostacyclin in one circulation was about 50%, giving a metabolic half-life of one circulation time (30s) as compared with the chemical half-life of 2—3 min. The inactivation mechanisms for $PGE_2$ and prostacyclin[50] are similarly dependent on prostaglandin 15-hydroxydehydrogenase (PGDH). However, the disappearance of prostaglandins in the pulmonary circulation depends on two mechanisms, namely uptake and attack by the enzyme PGDH, so our results suggested that prostacyclin is not a substrate for the PG uptake mechanism.

From the differential removal of vasoactive hormones by the pulmonary circulation we proposed that they could be divided into at least two types—"local" and "circulating" hormones. The local hormones are those which are largely removed by the lungs and if they have a physiological function, it is probably localised at or near to the site of release. It is intriguing to think that venous blood may be full of potent, as yet unidentified, chemicals released by peripheral vascular beds but removed by the lungs before they can cause effects in the arterial circulation. Interestingly, in 1970, *Gryglewski* and *Vane* described the release of an unidentified substance into the venous blood after infusion of isoprenaline into the hind legs of dogs[51]. The pattern of activity of this substance on the blood-bathed assay tissues was unlike that of any prostaglandin known at that time, but it can now be clearly identified as prostacyclin.

Circulating hormones are those which pass through the lungs, either unchanged (adrenaline, histamine, vasopressin, prostacyclin) or with an actual increase in activity. One such demonstration of an increase in activity on passage through the pulmonary circulation was associated with the renin-angiotensin system. We showed[52] that, contrary to popular belief, conversion of angiotensin I into angiotensin II did not take place in the bloodstream, but was largely accomplished in the pulmonary circulation. This was demonstrated both *in vivo*[52–54] and *in vitro* (Fig. 5).

### 1.3.3. *Our Studies of Substances Released during Anaphylaxis*

*Piper* and *Vane*[14,55,56] investigated the release of mediators from perfused lungs isolated from sensitised guinea pigs. We found, as expected, that there was a large release of histamine when the lungs were challenged with antigen.

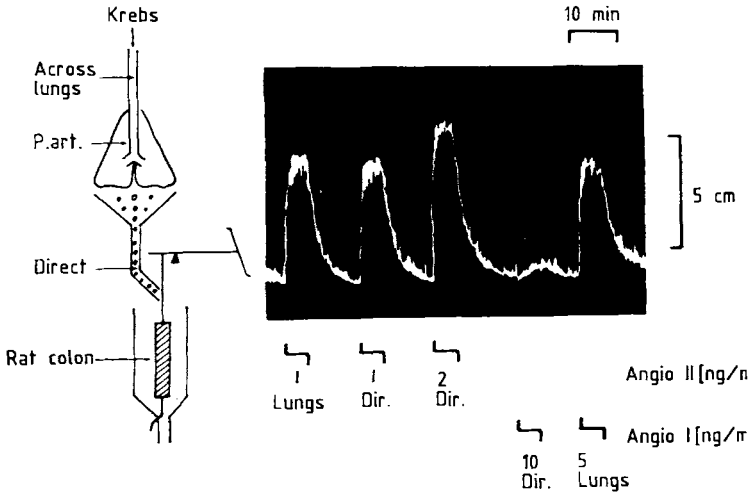

Fig. 5. Increased activity of angiotensin I when passed through guinea pig isolated lungs. The diagram on the left shows the experimental procedure (Krebs = Krebs solution, P. art. = pulmonary artery). Infusions of angiotensin II (Angio II) through the lungs or direct to the rat colon (Dir.) gave the same response of the rat colon, showing that there was no destruction in the lungs. An infusion of angiotensin I (Angio I) at 10 ng/mL direct to the rat colon gave a minimal response, but when half this concentration (5 ng/mL) was infused through the lungs there was a much greater contraction of the rat colon (after *Vane* [33], by permission of the *Br. J. Pharmacol.*).

As also expected, we found a release of SRS-A. However, we were excited at that time to find the release of three other substances which had not previously been associated with anaphylaxis (Fig. 6). We detected the release of prostaglandin-like substances with our bioassay systems and were later able to show by thin layer chromatography that prostaglandins $E_2$ and $F_{2\alpha}$ were present in the effluent. Even more exciting was the detection of the release of a previously undescribed substance which caused a strong contraction of strips of rabbit aorta and which we called, because of this effect "rabbit aorta contracting substance" or RCS. Two properties of RCS intrigued us. First, it was chemically unstable and if we introduced a delay coil of a few minutes before the lung effluent reached the assay tissues the activity had disappeared, although that of histamine, $PGE_2$, $PGF_{2\alpha}$ and SRS-A was still present. Second, we found that the release of RCS during anaphylaxis was selectively prevented by aspirin and other similar compounds. *Piper* and *Vane*[14] postulated that RCS may be involved in causing those symptoms which aspirin relieves. Isolated lungs also released prostaglandins into the perfusate when particles ($\leq 120\ \mu m$) were infused into the pulmonary artery[57].

At this time we were also becoming interested in prostaglandin release from other tissues. Mammalian cells of all types disgorge prostaglandins at the slightest provocation, but the tissue content of prostaglandins is very low compared with the release. This is well illustrated in the dog spleen, from which less than 1 μg (or 7 ng per g wet weight) can be extracted; however, the spleen can release up to 10 μg of prostaglandin (assayed as $PGE_2$) per minute when it is stimulated. *Horton et al.*[58] were the first to demonstrate that $PGE_2$ was released into splenic venous blood following splenic nerve stimulation in the dog. We became interested in the characteristics of this release and further showed that the output ($PGE_2$ and $PGF_{2\alpha}$) was associated with contraction of the spleen, for it could be induced by adrenaline and prevented by α-adrenoreceptor antagonists. Interestingly, as in the lungs, we found that prostaglandins were released by the spleen in response to infusions of particles[59].

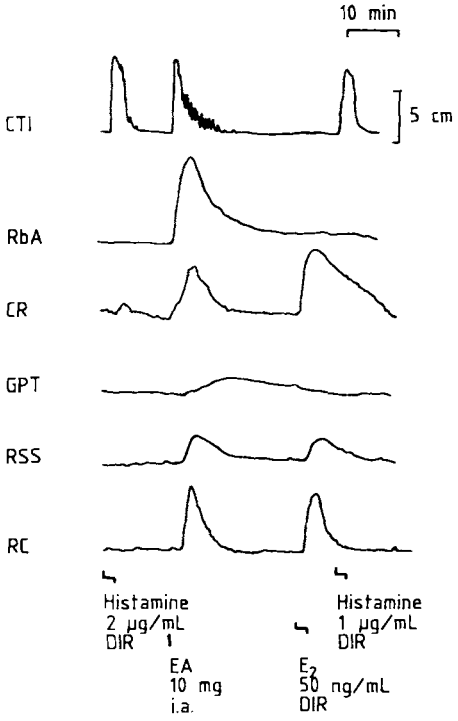

Fig. 6. Release of mediators from isolated lungs of sensitized guinea pigs. The lungs were perfused through the pulmonary artery with Krebs' solution and the effluent superfused a cat terminal ileum (CTI), rabbit aorta spiral strip (RbA), chick rectum (CR), guinea pig trachea (GPT), rat stomach strip (RSS) and rat colon (RC). All tissues except CTI were blocked with antagonists to 5HT, catecholamines and histamine. Infusions of histamine (2 μg and 1 μg/mL) DIR) and of prostaglandin $E_2$ ($E_2$, 50 ng/mL DIR) directly to the assay tissues demonstrated the selective sensitivity of the assay system. Anaphylaxis was induced in the lungs by injecting ovalbumen intraarterially (EA 10 mg I.A.). Contractions of CTI demonstrated release of histamine, RbA release of RCS, GPT release of SRS-A and CR, RSS and RC release of prostaglandins (*Piper* and *Vane* in [163], by permission of Churchill Livingstone).

## 2. Aspirin and Prostaglandin Biosynthesis

In research there is always a "climate" of experience which acts as a background to important discoveries. I have tried to indicate the "climate" in our laboratory at The Royal College of Surgeons of England around the year 1970. We had a major interest in the release and fate of vasoactive hormones and were pursuing this with especial reference to the lungs. We had discovered RCS as an unstable substance released from lungs during anaphylaxis and we knew that its release was inhibited by aspirin and other aspirin-like drugs. We had become interested in the prostaglandins and had come to the idea that any tissue which was distorted or disturbed or traumatised would release prostaglandins. In this context, it seemed to me that each distention of the lungs might cause a prostaglandin release which could help to adjust the regional pulmonary blood flow. Indeed, the idea that a prostaglandin release might be important in controlling regional blood flow in the lungs had also been suggested by *Liljestrand*[60]. With over-distention, any prostaglandins released might be detected in the arterial blood stream. I started a series of experiments using the blood-bathed organ technique to test this hypothesis. In anaesthetised dogs it was easy to show that when they were hyperventilated, there was an output into the arterial blood from the pulmonary circulation of an RCS-like substance and of $PGE_2$ and $PGF_{2\alpha}$ (*Vane*, unpublished). It was at this time that I was impressed by the effects of an infusion of aspirin into the hyperventilated dog, for not only was the associated hypotension reduced, but there was also a strong inhibition of the prostaglandin release. It was this experiment that led me to the idea (over a weekend) that aspirin might be interfering with prostaglandin biosynthesis. On the Monday morning I said to *Sergio Ferreira* and *Priscilla Piper* "I think I know how aspirin works" and set about doing an experiment. *Anggard* and *Samuelsson*[61] had described a preparation of guinea pig lungs in which a crude cell-free homogenate was used to convert arachidonic acid into $PGE_2$ and $PGF_{2\alpha}$. Although I was inexperienced in working with biochemical techniques, for I have always believed in using whole animals or organs whenever possible, I homogenised some guinea pig lungs, spun off the cell debris, divided the su-

pernatant into test-tubes, added arachidonic acid and measured by bioassay the amounts of $PGE_2$ and $PGF_{2\alpha}$ formed. To some of the tubes was added aspirin, indomethacin or morphine. By the end of that day I was convinced that aspirin and indomethacin (but not morphine) strongly inhibited the formation of prostaglandins from arachidonic acid (see Fig. 7).

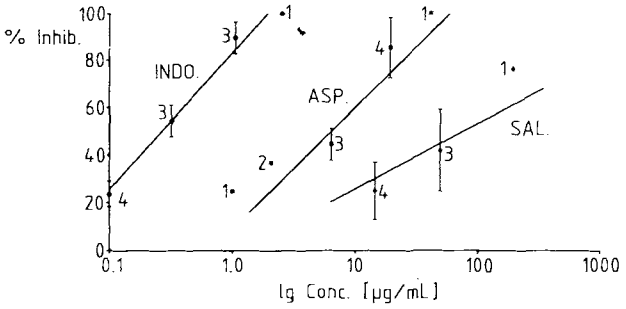

Fig. 7. Concentration (µg/mL) of indomethacin (INDO.), aspirin (ASP.) and salicylate (SAL.) plotted on a log scale against the percentage inhibition of prostaglandin synthesis (assayed as $PGF_{2\alpha}$ on rat colons). The lines are those calculated for best fit. Numbers by the points indicate number of experiments. When three or more estimates were averaged, the standard error of the mean is shown (from *Vane* [10], by permission of *Nature*).

During the time that I was confirming and extending this first experiment, *Ferreira* and *Moncada*[12] began to study the effects of aspirin and indomethacin on prostaglandin release from the spleen (Fig. 8). Independently of

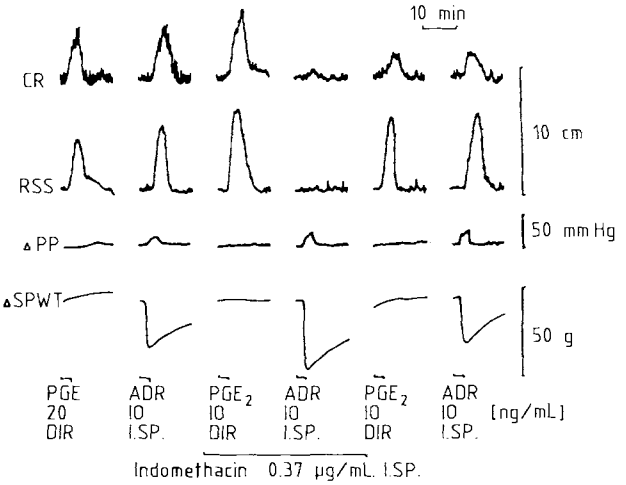

Fig. 8. A spleen from a dog was perfused with Krebs'-dextran solution at a rate of 20 mL/min. A continuous sample (10 mL/min) of the splenic outflow, with antagonists to histamine, 5HT and catecholamines added, was used to superfuse the assay tissues. The figure shows the effects of prostaglandins on a chick rectum (CR; top) and a rat stomach strip (RSS). The next two tracings (bottom) show changes in perfusion pressure (ΔPP) and spleen weight (ΔSP, WT). Except when infused into the spleen indomethacin was added to the splenic outflow to give a concentration of 0.37 µg/mL. The first panel shows contractions of CR and RSS induced by prostaglandin $E_2$ (20 ng/mL DIR). Next an adrenaline infusion into the spleen (ADR 10 ng/mL I. SP) induced a rise in perfusion pressure, a fall in spleen weight and an output of prostaglandins equivalent to $PGE_2$ at about 20 ng/mL. Indomethacin (0.37 µg/mL) was then infused into the spleen. During the next 25 min the assay tissues relaxed (not shown) and were then more sensitive to $PGE_2$ (10 ng/mL DIR). Adrenaline (40 min after start of indomethacin) now caused a greater increase in perfusion pressure, a greater decrease in spleen weight, but no output of prostaglandin. After stopping the indomethacin infusion into the spleen, the reactivity of the assay tissues gradually decreased and the output of prostaglandin induced by adrenaline infusion into the spleen gradually returned. The adrenaline stimulation shown was made 70 min after stopping the indomethacin (from *Ferreira, Moncada* and *Vane* [12], by permission of *Nature*).

these observations, *Smith* and *Willis* were using platelets to measure the effects of aspirin on prostaglandin formation. The results of these three studies were published simultaneously in 1971[10–12]. *Vane*[10] developed the hypothesis that this biochemical intervention in prostaglandin formation by the aspirin-like drugs is the basis of their therapeutic action.

An explanation of the therapeutic action of aspirin and its congeners had long been sought in terms of inhibition of a specific enzyme or biological function. Although these drugs inhibited a wide variety of enzymic reactions *in vitro*, no convincing relationship could be established between such inhibition and their known anti-inflammatory, antipyretic and analgesic actions. This was largely because of the high concentrations needed for enzyme inhibition. At the time we discovered that aspirin-like drugs inhibited the biosynthesis of prostaglandins in low concentrations, there was some evidence that the prostaglandins participated in the pathogenesis of inflammation and fever, and this reinforced the suggestion that inhibition of prostaglandin biosynthesis could explain the clinical action of these drugs. In the years which have elapsed since the original observations, a considerable body of evidence has accumulated which supports this hypothesis. Our knowledge about the inflammatory process has also increased, and the way in which prostaglandins participate in this process has been considerably clarified.

Inhibition of prostaglandin biosynthesis is a property peculiar to the aspirin-like drugs, since many otherwise pharmacologically active agents are inactive against this enzyme system, including the opiates, antihistamines, α- and β-adrenoreceptor blocking agents and antagonists of acetylcholine and 5HT. The anti-inflammatory steroids are also inactive against this enzyme although they can reduce prostaglandin production by inhibition of phospholipase $A_2$ (for review see *Flower, Blackwell, DiRosa* and *Parente*[62]).

Any hypothesis which purports to explain the action of a drug in terms of an anti-enzyme action must satisfy at least two basic criteria. First, the free concentrations achieved in plasma during therapy must be sufficient to inhibit the enzyme in question. Second, there must be a reasonable correlation between the level of anti-enzyme activity and the therapeutic potency. Clearly, there is abundant evidence to show that both these criteria are satisfied and there is also good evidence that therapeutic dosage reduces prostaglandin biosynthesis in man (for review, see *Vane, Flower* and *Salmon*[63]).

## 3. Prostacyclin

### 3.1. The Advent of the Prostaglandin Endoperoxides and the Discovery of Prostacyclin

The isolation of the prostaglandin endoperoxides by *Samuelsson et al.* in the early 1970's was a major step forward in prostaglandin research (see text of the Nobel lecture by *Samuelsson*[64]). The demonstration that the endoperoxides caused platelet aggregation and that they were transformed in platelets to $TXA_2$ led us and others to the con-

clusion that most of the activity associated with RCS was due to $TXA_2$[65a,b] (Fig. 9).

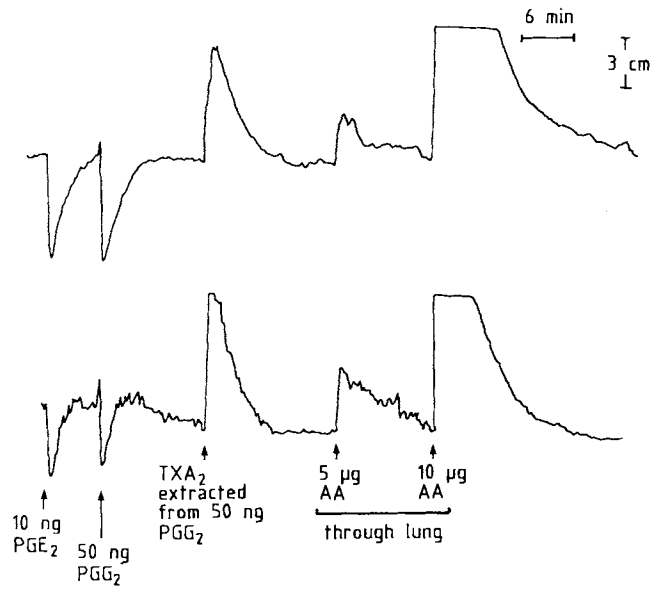

Fig. 9. Rabbit coeliac (above) and mesenteric (below) artery strips were superfused with the outflow of a pair of guinea pig lungs perfused with Krebs' solution at 10 mL/min. Prostaglandin $E_2$ (10 ng) relaxes the two tissues as does $PGG_2$. Thromboxane $A_2$ generated from 50 ng $PGG_2$ produced a contraction. Challenge of the lungs with arachidonic acid (AA 5 and 10 µg) produces a dose-dependent release of $TXA_2$-like material (from *Moncada* and *Vane* [65b], by permission of Academic Press).

From *Samuelsson*'s work we knew that $TXA_2$ could be released by platelets. We isolated the enzyme from the "microsomal" fraction of platelets and showed by our bioassay techniques that endoperoxides, when incubated with this fraction (even at 0°C), were rapidly transformed into $TXA_2$ which potently contracted rabbit aorta and induced platelet aggregation. This enzyme, which we called "thromboxane synthetase"[66,67] is now an important therapeutic target for the development of compounds with antithrombotic potential.

*Moncada, Gryglewski* and *Bunting* then began to look at other tissues to determine whether they also could generate $TXA_2$. To do this, they took microsomal fractions of several different tissues and measured, again with the superfusion cascade bioassay, formation of either the classical stable prostaglandins $E_2$ and $F_{2\alpha}$, or of $TXA_2$. It was *Moncada*'s suggestion that we should look into the biosynthetic system of vascular tissue, since vascular endothelium and platelets might share some structural features. Indeed, after several weeks of work we found that microsomal fractions of pig aorta incubated with the endoperoxide did not generate classical prostaglandins even though the endoperoxide activity (measured as RCS) disappeared. We eventually came to the conclusion that the endoperoxide was being transformed into an unknown prostaglandin and began to refer to this substance as PGX. By using recently-developed bioassay tissues such as the rabbit coeliac and mesenteric arteries[30] we were able to distinguish between the endoperoxides (which have a biphasic effect) and PGX (which has a relaxing effect). Importantly, PGX, in contrast to $TXA_2$, inhibited the clumping of platelets. Like $TXA_2$, it was also unstable, with a half-life of two minutes at 37°C. Boiling the solution for 15 seconds destroyed all measured activity.

The first paper on PGX was published by *Moncada, Gryglewski, Bunting* and *Vane* in *Nature* in October 1976[16]. Although the structure was then unknown, many of the characteristics of PGX were described, together with some important concepts. PGX was different from the other products of PG endoperoxides, and its biological activity on isolated tissues, its instability and its potent anti-aggregatory activity distinguished it from $PGD_2$, $PGE_2$, $PGF_{2\alpha}$, $TXA_2$ and $TXB_2$. PGX relaxed strips of rabbit mesenteric and coeliac arteries, but contracted rat stomach strip, chick rectum, guinea pig tracheal chain and guinea pig ileum, although its contractile potency on these tissues was less than that of the classical prostaglandins. The rat colon was not contracted by PGX: indeed, spontaneous movement was decreased.

In this first paper, the transformation of the PG endoperoxides by platelets to $TXA_2$, which caused platelet aggregation and vascular contraction, was contrasted with their transformation by blood vessel microsomes to PGX, which had potent anti-aggregatory properties and relaxed vascular strips. Thus, the concept was suggested that a balance between the amounts of $TXA_2$ formed by platelets and PGX formed by blood vessel walls might be critical for thrombus formation. Indeed, in the light of the discovery of this anti-thrombotic property associated with arterial walls, we recalled the pre-*Lister* vitalistic view that in some way the arteries kept the blood fluid.

We also developed the concept that platelets attempting to stick to vessels may release endoperoxides which are then used by the blood vessel wall to generate PGX, thus limiting or preventing further platelet clumping. We also suggested that plaque formation on the arterial wall could hinder access of platelet endoperoxides to the PGX generating system. These important properties and concepts are now well established and developed (for review, see *Moncada* and *Vane*[68]).

The structure of PGX was established through a collaborative research programme between scientists at the Upjohn Company in Kalamazoo and The Wellcome Foundation Ltd. in Beckenham[19]. This also led to the first chemical syntheses of the substance which was renamed prostacyclin ($PGI_2$)[19,69].

There is now a plethora of names for prostacyclin. The IUPAC name is 5-[(1*S*,3*Z*,5*R*,6*R*,7*R*)-7-hydroxy-6-[(1*E*,3*S*)-3-hydroxy-1-octenyl]-2-oxabicyclo[3.3.0]oct-3-ylidene]pentanoic acid. As a freeze-dried pharmaceutical preparation, the approved name is Epoprostenol, and the trade names are Flolan (Wellcome) and Cyclo-prostin (Upjohn). To maintain consistency in the scientific literature, the trivial name, prostacyclin, should be used whenever possible.

### 3.2. The Formation and Properties of Prostacyclin

Prostacyclin is the main product of arachidonic acid in all vascular tissues so far tested, including those of man (Fig. 10). The ability of the large vessel wall to synthesise prostacyclin is greatest at the intimal surface and progressively decreases toward the adventitia[70]. Culture of cells

from vessel walls also shows that endothelial cells are the most active producers of prostacyclin[71,72].

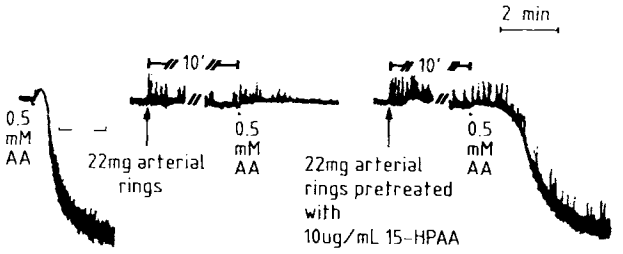

Fig. 10. Inhibition of platelet aggregation by rings of human vascular tissue. Cut rings (15–30 mg), when incubated at 37°C in human platelet rich plasma (P.R.P.) for 10 min, inhibited the aggregation produced by 0.5 mmol arachidonic acid (AA). When the rings were pretreated by incubation with 15 hydroperoxyarachidonic acid (15-HPAA) (10 μg/mL) for 5 min at 22°C, and then added to the P.R.P., aggregation was once more observed after addition of 0.5 mmol AA (from *Moncada, Higgs* and *Vane* [164], by permission of *The Lancet*).

Prostacyclin relaxes isolated vascular strips and is a strong hypotensive agent through vasodilation of all vascular beds studied, including the pulmonary and cerebral circulations (for review, see *Moncada* and *Vane*[73]). Several authors have suggested that prostacyclin generation participates in or accounts for functional hyperaemia[74,75].

Prostacyclin is the most potent endogenous inhibitor of platelet aggregation yet discovered. This effect is short-lasting *in vivo*, disappearing within 30 minutes of cessation of intravenous administration. Prostacyclin disperses platelet aggregates *in vitro*[16,76] and in the circulation of man[77]. Moreover, it inhibits thrombus formation in models using the carotid artery of the rabbit[76] and the coronary artery of the dog[78], protects against sudden death (thought to be due to platelet clumping) induced by intravenous arachidonic acid in rabbits[79], and inhibits platelet aggregation in pial venules of the mouse when applied locally[80].

Prostacyclin inhibits platelet aggregation by stimulating adenylate cyclase, leading to an increase in cAMP levels in the platelets[81,82]. In this respect prostacyclin is much more potent than either $PGE_1$ or $PGD_2$ and its effect is longer-lasting. In contrast to $TXA_2$, prostacyclin enhances $Ca^{2+}$ sequestration in platelet membranes[83]. Moreover, inhibitory effects on platelet phospholipase[84,85] and platelet cyclo-oxygenase[86] have been described. All these effects are related to its ability to increase cAMP in platelets. Prostacyclin, by inhibiting several steps in the activation of the arachidonic acid metabolic cascade, exerts an overall control of platelet aggregability.

Prostacyclin increases cAMP levels in cells other than platelets (for review, see *Moncada*[87]), raising the possibility that in these cells a balance with the thromboxane system exerts a homeostatic control of cell behaviour similar to that observed in platelets. Thus, the prostacyclin/$TXA_2$ system may have wider biological significance in cell regulation. An example is that prostacyclin inhibits white cell adherence to the vessel wall[88,89], to nylon fibres, and to endothelial monolayers *in vitro*[90]. Prostacyclin increases cAMP in the endothelial cell itself, suggesting a negative feedback control for prostacyclin production by the endothelium[91–93].

One of the functional characteristics of the intact vascular endothelium is its non-reactivity to platelets; clearly, prostacyclin generation could contribute to this thromboresistance. Moreover, prostacyclin inhibits platelet aggregation (platelet-platelet interaction) at much lower concentrations than those needed to inhibit adhesion (platelet-collagen interaction)[94]. Thus, prostacyclin may permit platelets to stick to vascular tissue and to interact with it, so allowing platelets to participate in the repair of a damaged vessel wall while at the same time preventing or limiting thrombus formation.

### 3.3. Prostacyclin and Cytoprotection

In addition to its well-known vasodilating and anti-aggregating actions, prostacyclin shares with other prostaglandins a "cytoprotective activity", as yet not clearly defined. This activity has usually been studied on gastric ulcers[95]. We have suggested[68,96] that this third property may be important in explaining certain therapeutic effects of prostacyclin. For instance, in models of myocardial infarction, prostacyclin reduces infarct size[97–99], arrhythmias[100], oxygen demand[99], and enzyme release from infarcted areas[101]. In sheep, prostacyclin protected the lungs against injury induced by endotoxin[102]. There was also a beneficial effect in endotoxin shock in the dog[103] and cat[104], where prostacyclin improves splanchnic blood flow and reduces the formation and release of lysosomal hydrolases. The effects of hypoxic damage in the isolated perfused liver of the cat are also substantially reduced by prostacyclin[105]. Canine livers can be preserved *ex vivo* for up to 48 hours and then successfully transplanted using a combination of refrigeration, Sacks' solution and prostacyclin[106].

All these effects could be related to a result obtained recently by *Moncada et al.*[107]. The addition of prostacyclin to platelets during their separation from blood and subsequent washing substantially improves their immediate functionality *in vitro*. In addition, whereas platelets normally are functional for about 6 h, when prepared with the addition of prostacyclin they remain functional for more than 72 h[107]. This extended viability of platelets *in vitro* is not accompanied by a prolonged increase in levels of cAMP, thus separating the effect from the classical anti-aggregating activity[108]. Interestingly, there has been a study demonstrating a dissociation between anti-aggregating and cytoprotective effects of a prostacyclin analogue in a model of acute myocardial ischaemia[109].

All these results suggest that some of the therapeutic effects of prostacyclin might be related to this cytoprotective effect and point to even wider indications for prostacyclin in cell or tissue preservation *in vivo* and *in vitro*.

### 3.4. Prostacyclin and Atherosclerosis

Lipid peroxides, such as 15-hydroperoxy arachidonic acid (15-HPAA), are potent and selective inhibitors of

prostacyclin generation by vessel wall microsomes or by fresh vascular tissue (see Fig. 10)[17, 18, 110, 111]. There are high concentrations of lipid peroxides in advanced atherosclerotic lesions[112]. Lipid peroxidation induced by free radical formation occurs in vitamin E deficiency, the ageing process, and perhaps also in hyperlipidaemia accompanying atherosclerosis[113]. Accumulation of lipid peroxides in atheromatous plaques could predispose to thrombus formation by inhibiting generation of prostacyclin by the vessel wall without reducing $TXA_2$ production by platelets. Moreover, platelet aggregation is induced by 15-HPAA and this aggregation is not inhibited by adenosine or $PGE_1$[114]. Human atheromatous plaques do not produce prostacyclin[115, 116]. In normal rabbits the production of prostacyclin by the luminal surface of the aorta is abolished by de-endothelialisation and slowly recovers with re-endothelialisation over a period of about 70 days. However, the recovery of prostacyclin formation did not occur in rabbits made moderately hypercholesterolaemic by diet[117]. These results suggest that it would be worth exploring whether attempts to reduce lipid peroxide formation by inhibiting peroxidation influence the development of atherosclerosis and arterial thrombosis. Vitamin E acts as an antioxidant and perhaps its empirical use in arterial disease in the past[118–120] had, in fact, a biochemical rationale. For discussion of the implication of prostacyclin and $TXA_2$ in diseases other than atherosclerosis see *Moncada* and *Vane*[68].

### 3.5. Clinical Applications of Prostacyclin

Prostacyclin is available as a stable freeze-dried preparation (Epoprostenol) for administration to man. Intravenous infusion of prostacyclin in healthy volunteers leads to a dose-related inhibition of platelet aggregation, dispersal of circulating platelet aggregates, arteriolar vasodilatation, increases in skin temperature, facial flushing and sometimes headache[87, 121]. Infusion of prostacyclin into patients susceptible to migraine or cluster headache induces, in most cases, a headache different from those usually experienced[122].

Extracorporeal circulation of blood brings it into contact with artificial surfaces which cannot generate prostacyclin. In the course of such procedures thrombocytopaenia and loss of platelet haemostatic function occur and make an important contribution to the bleeding problems following charcoal haemoperfusion and prolonged cardiopulmonary bypass in man. Formation of microemboli during cardiopulmonary bypass may also contribute to the cerebral complications which sometimes follow this procedure. Platelet damage and thrombocytopaenia were prevented by prostacyclin both in animal models of extracorporeal circulation[87, 121] and in man.

In patients with fulminant hepatic failure undergoing charcoal haemoperfusion[123], prostacyclin infusion prevented the fall in platelet count and elevation of β-thromboglobulin seen in the control patients. *Gimson et al.*[124] have made almost 200 charcoal haemoperfusions on a daily basis using prostacyclin for platelet protection in the treatment of 76 patients with fulminant hepatic failure. Remarkable survival rates (65%) were obtained in the 31 patients who had been referred early and in whom the serial haemoperfusions were started whilst the signs of grade III encephalopathy were still apparent (not rousable but may or may not respond to painful stimuli). The authors thought that this was probably the major factor in the improved survival rate, a reflection of the better biocompatibility of the system because prostacyclin was used, allowing the patients to be treated at an earlier stage. In the group treated later, with Grade IV encephalopathy already present, 20% survived, so that the overall survival rate from the 76 patients was 38%. These results (especially those treated early) compare favourably with a survival rate of 15% in patients under standard intensive care measures.

Several double-blind clinical trials of prostacyclin in cardiopulmonary bypass have been published[125–131]. The treatment groups showed a preservation of platelet number and function, with a reduction in the blood loss in the first 18 hours after operation. In the trial by *Longmore et al.*[130] the blood loss was halved. In that by *Walker et al.*[129], filters were used and the formation of platelet aggregates on the filters from the placebo group contrasted strikingly with the lack of platelet adhesion to those from patients treated with prostacyclin (Fig. 11). The heparin-sparing effect of prostacyclin was confirmed and the vasodilator effects were not troublesome; indeed, *Noback et al.*[131] suggest that these effects may be utilised in controlling intra-bypass hypertension. Clearly, the use of prostacyclin or an analogue should allow improvements in the methodology of extracorporeal circulations.

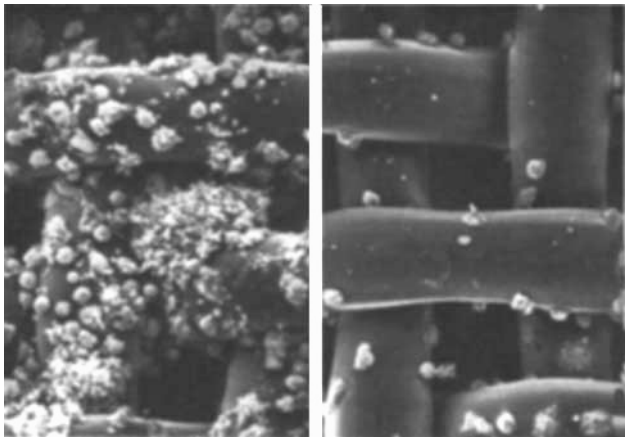

Fig. 11. Electron micrographs of the downstream face of filters taken from the arterial lines of cardio-pulmonary bypass operations in man. The left-hand picture (patient receiving placebo) shows formation of platelet aggregates, some clogging the pores ($40 \pm 5$ μ) of the filter. The right-hand picture (patient receiving prostacyclin) shows lack of platelet adhesion. The few cells sticking to the filter are leucocytes (Electron micrographs kindly provided by Dr. *N. Read* and Mr. *P. J. Astbury*, Wellcome Research Laboratories).

Therapeutic assessment of prostacyclin is still in its infancy with many trials in progress. The results are, therefore, still preliminary, but nevertheless they point the way to conditions in which prostacyclin therapy may be useful. In open trials, prostacyclin was of benefit to patients with peripheral vascular disease both through relief of ischaemic pain and improved ulcer healing[132–137]. Placebo controlled blind trials are now in progress and the results of the first to be analysed[138] are encouraging. In the 13

patients infused intravenously for 4 days with placebo, 3 showed reduction in rest pain at 5 days, 2 at 1 month and 1 at 6 months. After 6 months, 3 had died and 5 others had received surgical intervention. Of those 15 patients who were infused with prostacyclin for 4 days (average 7 ng/kg/min intravenously), at 5 days, all had reduction in rest pain. At 1 month, 9 still showed a substantial improvement, which was also evident in 7 patients at 6 months. By this time, two other patients in the group had received surgical intervention and one had died. *Zygulska-Mach et al.*[139] infused prostacyclin into 3 patients with sudden blockage of central retinal veins. Improvement was observed in those two patients who were treated within the first 48 hours.

Prostacyclin also induces long-lasting improvements in Raynaud's phenomenon. Intravenous infusion of the drug for 72 hours produced striking reductions in the frequency, duration and severity of the disease in 21 of 24 patients. The improvement lasted for a mean of 9–10 weeks, and in 3 patients subjective improvement was still reported 6 months after the infusion. Pain relief was a striking feature, presumably associated with the increased blood flow as indicated by increased temperature of the hands and fingers[140]. *Belch et al.*[141] have also reported successful treatment in 4 out of 5 patients, and a double-blind clinical trial[142] has now confirmed these results in Raynaud's phenomenon. There was an overall improvement still present at 6 weeks in 6 of 7 patients receiving prostacyclin, but only in 1 of 7 receiving placebo. The prostacyclin patients had a significant fall in the number and duration of attacks over the 6 weeks period post infusion, whereas there was no change in the placebo group.

*Gryglewski et al.* in Cracow, who first demonstrated the beneficial effects of infusion of prostacyclin in ischaemic disease of the legs, have now obtained dramatic improvements following prostacyclin infusion in 10 patients with ischaemic stroke[143]. Patients with transient ischaemic attacks and haemorrhagic stroke were excluded. With prostacyclin treatment there was a reversal of symptoms strikingly sooner in all 10 patients than could have been expected and in 6 patients during the first 6 hour infusion. One patient died 2 weeks later of a second stroke, but the other 9 have maintained return of function for (so far) up to 6 months.

Prostacyclin has been successfully used in a few cases of pulmonary hypertension and is more effective than $PGE_1$[144–146]. Single case studies have suggested that prostacyclin may be useful in the treatment of patent ductus arteriosus[147] and pre-eclamptic toxaemia[148].

Beneficial effects of intravenous infusion of prostacyclin were obtained in 9 patients with severe congestive heart failure refractory to digitalis and diuretics[149]. Mean pulmonary and systemic pressures and vascular resistances were reduced, and heart rate, cardiac index and stroke index were all increased during the infusion, with facial flushing as the only side effect.

*Bergman et al.*[150] gave an intravenous infusion of prostacyclin to patients with coronary artery disease with no deleterious effects. Heart rate and cardiac index were increased, and mean blood pressure, as well as systemic and pulmonary resistance all fell. Mean atrial pacing time to angina rose from 142 to 241 seconds. The authors concluded that acute administration of prostacyclin was beneficial in angina pectoris, having effects similar to those of the short-acting nitrates. In 5 patients with coronary artery disease, prostacyclin was safely infused directly into diseased coronary arteries[151] and there was a beneficial effect of intravenous prostacyclin infusions in patients with unstable angina[137]. However, prostacyclin had no effect on the number, severity and duration of ischaemic episodes in 8 of 9 patients with variant angina, although consistent relief was seen in the ninth patient[152].

A prostacyclin deficiency has been reported in thrombotic thrombocytopaenic purpura (TTP)[153]. Infusion of prostacyclin into two patients with TTP did not produce an increase in circulating platelet count[153, 154]. However, *FitzGerald et al.*[155] have reported an increase in platelet count and an improvement in the neurological status of one such patient during 18 days of prostacyclin infusion. They were sufficiently encouraged to conclude that the controlled evaluation of prostacyclin in TTP was warranted.

Infusion of prostacyclin protects transplanted kidneys from hyperimmune rejection in dogs[156] and is also protective in patients with chronic renal transplant rejection[157].

Clearly, there are many clinical conditions which may respond to prostacyclin treatment and its place (or that of chemically stable analogues) in therapeutics will be defined in the next few years. Some of these conditions are pre-eclamptic toxaemia[158], haemolytic uraemic syndrome[159], peptic ulceration[160], the thrombotic complications associated with transplant rejection[156], the prevention of tumour metastasis[161] and the treatment of pulmonary embolism[162].

*Over the years I have had a remarkably talented and productive group of colleagues. They have come from many parts of the world, including Australia (Greg Dusting, Bob Hodge), Belgium (Arnold Herman), Brazil (Sergio Ferreira), Great Britain (Mick Bakhle, Rod Flower, Gerry and Annie Higgs, John Hughes, Robert Lowe, Priscilla Piper, John Salmon, Ivor Williams), Holland (Franz Nijkamp), Honduras (Salvador Moncada), Italy (Domenico Regoli), Poland (Krystyna Herbaczynska-Cedro, Richard Gryglewski, Janina Staszewska-Barczak), Singapore (Kevin Ng), and the United States (Jim Aiken, Alan Block, Nobby Gilmore, Jack McGiff, Phil Needleman). Some of these have returned to my laboratory several times. Others have started as technicians and are still with me as Ph.D.'s. All (and many others) have contributed to the work which I have described. In particular, the discovery of prostacyclin was made in the Prostaglandin Research Department of the Wellcome Research Laboratories under the direction of Dr. Salvador Moncada and with the co-operation of Richard Gryglewski and Stuart Bunting. The further pre-clinical development of prostacyclin in our laboratories was also largely directed by Dr. Salvador Moncada. I would like to thank all of these friends and colleagues for their help and collaboration over the years. Their participation in the work described in this article is gratefully acknowledged.*

*I would also like to thank Mrs. A. Higgs and Mrs. A. Skinner for their help in the preparation of this manuscript.*

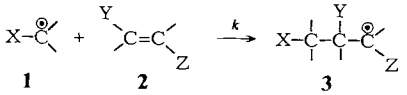
# Formation of CC Bonds by Addition of Free Radicals to Alkenes

**By Bernd Giese***

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*



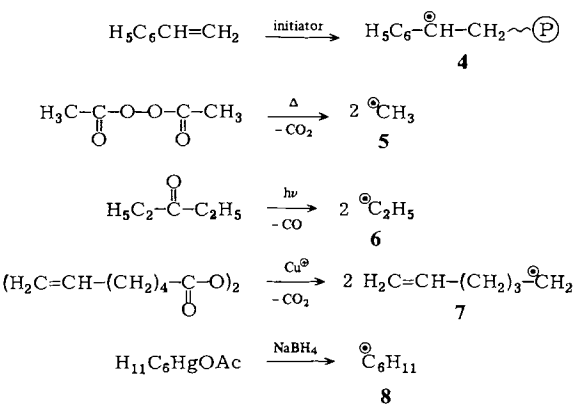
There are many reactions in which CC bonds are formed by addition of free radicals to alkenes. Information about the mechanism is important for the synthesis of specific target molecules. The rate of addition of alkyl radicals to alkenes is controlled by steric and polar effects. The stabilities of the educts and products are of only limited importance, since the transition states for these exothermic reactions occur very early on the reaction coordinate. Variations in reactivity and selectivity can be described using frontier orbital theory: for nucleophilic radicals the dominant interactions are those between SOMO's and LUMO's, and for electrophilic radicals those between SOMO's and HOMO's. The large differences in the steric effects of α- and β-substituents of alkenes can be explained by postulating an unsymmetrical transition state—the radical approaches one of the C atoms preferentially. Regio- and stereoselectivities can be predicted and are determined, in general, by steric effects.

## 1. Introduction

In recent years increasing use has been made of free radical reactions in the synthesis of organic compounds[1]. This development was made possible by mechanistic studies in which the influence of substituents on the reactivity and selectivity of free radicals was established. The most important industrial application of free radical chemistry in organic synthesis is radical-induced polymerization. This reaction involves the synthesis of a carbon skeleton by addition of alkyl radicals to alkenes. The synthesis of tailor-made polymers requires that their mechanism of formation be known: studies of the influence of substituents on the addition of alkyl radicals to alkenes were, therefore, carried out very early[2]. The development of new methods of measurement and theories has led to such advances in this area that the influence of substituents at the alkene and at the radical center on reactivity, regioselectivity, and stereoselectivity is to a large extent understood.

## 2. Influence of Substituents on the Rate of Addition of Free Radicals to Alkenes

The rates of addition of free radicals to alkenes are determined, on the one hand, by the substituents X at the radical **1** and, on the other, by the substituents Y and Z at the alkene **2**.



**1** **2** **3**

The alkene substituents Y and Z affect the rate of formation of the radical adduct **3** in very different ways. In order to distinguish between these substituents the group Y, which is bound to the carbon atom of the alkene **2** that is attacked by the radical, is denoted as the α-substituent and the neighboring group Z as the β-substituent. These substituents then exert α- and β-effects, respectively.

### 2.1. The β-Effect of Alkene Substituents

Almost forty years ago *Mayo, Lewis,* and *Walling et al.*[2,3] concluded from an analysis of free radical copolymerizations that the rate of addition of polymeric benzyl radicals **4** to monomers increases when the alkenes bear electron-withdrawing substituents. *Szwarc et al.*[4] came to the same conclusion in studies of competition kinetics using methyl radicals **5** generated from diacetyl peroxide. *James et al.*[5] determined the relative reactivities of ethyl radicals **6**, formed on photolysis of diethyl ketone. *Minisci et al.*[6] used metal salts to liberate the primary radical **7** from, for example, diacyl peroxides and to measure its relative and absolute reactivities towards alkenes. *Giese*[7] used cyclohexyl radicals **8**, formed by reaction of alkylmercury salts and $NaBH_4$, to determine the influence of substituents on the rate of addition.

**4** **5** **6** **7** **8**

The relative rates of addition of the alkyl radicals **4**—**8** to monosubstituted alkenes **9**, which are attacked to more than 98% at the terminal group, are summarized in Table 1[2-8].

Table 1 shows that the rate of addition of radicals **4**—**8** increases with the electron-withdrawing ability of the sub-

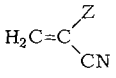
[a] Extrapolated from the Hammett relationship.

stituent Z at the alkene **9**. Thus, the rate of addition of the cyclohexyl radical **8** at 20°C increases by almost four orders of magnitude when the reaction is carried out using acrolein instead of 1-hexene. This substituent effect decreases at higher temperatures or if primary radicals (*e.g.* **5**—**7**) are used.



A similar increase in the rate of addition is caused by the presence of electron-withdrawing substituents Z in the substituted styrenes **11**, methyl acrylates **12**, and acrylonitriles **13** (Table 2)[7].

**11**

**12**

**13**

Table 2. Influence of the substituents **Z** on the rate of addition of cyclohexyl radicals **8** to styrenes **11**, methyl acrylates **12** and acrylonitriles **13** at 20°C.

| Alkenes **11–13** Z | $k_{rel}$ for the addition to alkenes **11** | **12** | **13** |
|---|---|---|---|
| CN | 66 | 310 | |
| $CO_2CH_3$ | 6.4 | 150 | 310 |
| $CF_3$ | | 40 | |
| Cl | | 12 | 31 |
| $SeC_6H_5$ | | 9.9 | |
| $CH_2Cl$ | | 7.7 | |
| $C_6H_5$ | 0.51 | 6.4 | 66 |
| $SC(CH_3)_3$ | | 5.6 | |
| $CH_2CO_2C_2H_5$ | | 1.4 | |
| H | 0.15 | ≡1.0 | 3.6 |
| $CH_3$ | 0.14 | 0.75 | 2.0 |
| $C(CH_3)_3$ | | 0.26 | 0.9 |
| $OC_2H_5$ | | | 0.5 |
| $OCH_3$ | | 0.16 | |
| Morpholino | | | 2.5 |

Plots of the relative reactivities of the cyclohexyl radical **8** from Tables 1 and 2 against $\sigma^-$ and $\sigma$-values[10], respectively, give straight lines with correlation coefficients of 0.91—0.99. The $\rho$-values calculated from the gradients lie between 3.1 and 3.8 at 20°C[8,9].

The positive sign of these $\rho$-values indicates that alkyl radicals are nucleophilic. This is remarkable since the attacking radical **1** has an electron septet which forms an octet upon generation of the adduct radical **3**. This apparent contradiction is resolved by frontier orbital theory (see Section 3).

The widest substituent variation was carried out with the methyl acrylates **12**. Figure 1 shows that there is a good correlation between the relative reactivities of **12** and the Hammett $\sigma$-values for Z. Neither radical-stabilizing substituents such as the phenyl group or a combination of captodative substituents[11] (*e.g.* $OCH_3$ and $CO_2CH_3$) nor the bulky $C(CH_3)_3$ group lead to an appreciable deviation from the straight line.

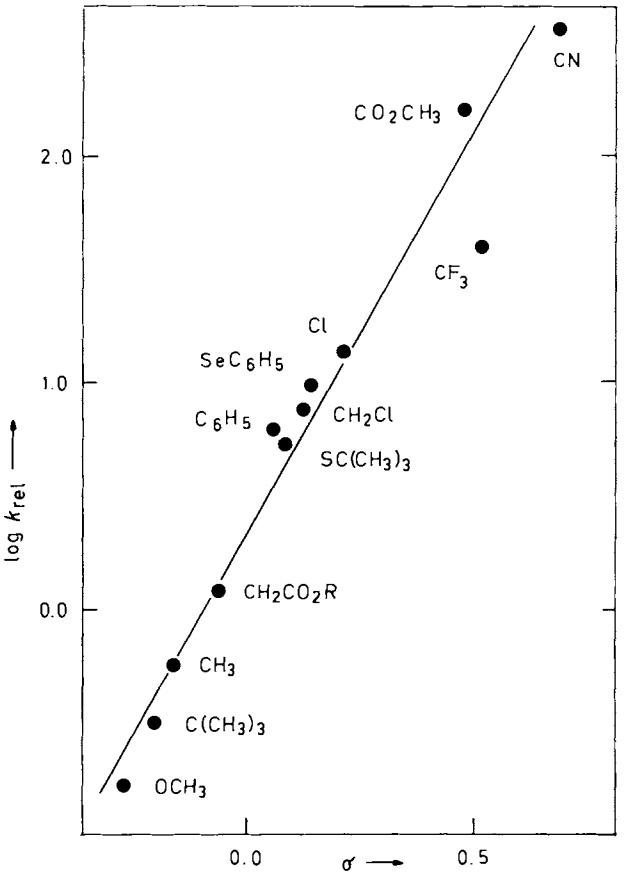


Fig. 1. Correlation of the relative reactivities of the cyclohexyl radical **8** with Hammett $\sigma$-parameters for substituents Z in methyl acrylates **12**. R = $C_2H_5$.

However, an increasing influence of the radical-stabilizing phenyl effect is observed on proceeding from the styrenes **11** ($k_{C_6H_5}/k_H = 3.4$) *via* the methyl acrylates **12** ($k_{C_6H_5}/k_H = 6.4$) and acrylonitriles **13** ($k_{C_6H_5}/k_H = 18$) to the monosubstituted alkenes **9** ($k_{C_6H_5}/k_H = 67$). This cannot be due solely to the differences in the $\rho$-values. The increasing influence of the phenyl group is probably partly due to an increase in the planarity of the $\pi$-system when the size of the geminal substituents decreases. This interpretation is supported by the fact that *trans*-substituted alkenes react faster with cyclohexyl radicals than do *cis*-substituted alkenes, and that this effect increases with increasing repulsive interaction between the vicinal substituents (Table 3)[12].

The methyl radical **5** showed a similar rate variation[13]. The unusually high reactivity of maleic anhydride is also certainly mainly due to the planarity of this *cis*-alkene[14].

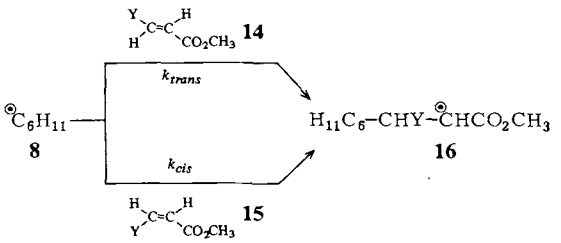

Table 3. Influence of the substituents Y on the rate ratio ($k_{trans}/k_{cis}$) for addition of cyclohexyl radicals **8** to *trans*- and *cis*-acrylic esters **14** and **15** at 20°C.

| Alkenes **14** and **15** Y | $k_{trans}/k_{cis}$ |
|---|---|
| H | 1.0 |
| CN | 1.4 |
| $CH_3$ | 1.4 |
| Cl | 1.6 |
| $C_6H_5$ | 5.0 |
| $CO_2CH_3$ | 10 |

The phenyl effect reaches its largest value ($k_{C_6H_5}/k_H = 67$) in monosubstituted alkenes **9**[8]. However, cyclohexyl radicals react 34 times faster with acrolein than with styrene at 20°C (Table 1), although free radicals are less stabilized by carbonyl groups than by phenyl substituents[15]. Thus, radical-stabilizing effects are much less important than polar effects.

The slight rate-reducing effect of bulky β-substituents is also very surprising. Thus, at 20°C the rate of addition of cyclohexyl radicals **8** decreases only by a factor of 2.2 and 2.9, respectively, when the substituent $Z = CH_3$ in acrylonitriles **13** or methylacrylates **12** is replaced by $Z = C(CH_3)_3$ (Table 2)[8, 16]. The shielding of the alkenes **12** and **13** in reactions with the cyclohexyl radical is even smaller than these values suggest, since the diminution in rate is partly caused by the electron-releasing effect and partly by the twisting of the π-system due to the repulsive interaction of the geminal substituents.

To sum up: *Substituents at the carbon atom of the alkene that is not attacked (β-substituents) exert, on the whole, only polar effects on the rate of addition of free radicals.* Radical-stabilizing and space-filling β-substituents influence the rate of addition only slightly.

### 2.2. The α-Effect of Alkene Substituents

That substituents at the vinylic carbon atom undergoing attack (α-substituents) and at the neighboring carbon atom (β-substituents) of the alkene have markedly different effects is shown by comparison of the rates of addition of cyclohexyl radicals **8** to acrylic esters **12** and **14**. Whereas 2-substituted acrylic esters **12** are attacked solely at the methylene group, addition occurs at both vinylic carbon atoms of the esters **14**. Analysis of the product mixtures allows the determination of the $k_\alpha$ value, which is statistically corrected[*] for $Y = CO_2CH_3$[9, 12] (cf. also Table 11).

[*] Since the fumaric ester has two equivalent olefinic C atoms, the rate constants are divided by 2.

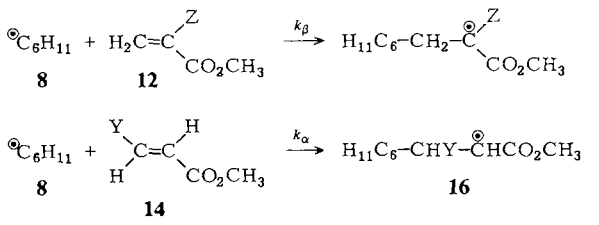

Table 4. Comparison of the relative rates $k_\beta$ and $k_\alpha$ for the addition of cyclohexyl radicals **8** to acrylic esters **12** and **14** at 20°C.

| Alkenes **12** and **14** Z or Y | $k_\beta$ | $k_\alpha$ | $k_\beta/k_\alpha$ |
|---|---|---|---|
| CN | 310 | 6.0 | 51 |
| $CO_2CH_3$ | 150 | 5.0 | 30 |
| Cl | 10 | 0.067 | 149 |
| $C_6H_5$ | 6.4 | 0.009 | 710 |
| H | ≡1.0 | ≡1.0 | 1.0 |
| $CH_3$ | 0.7 | 0.011 | 64 |

Table 4 shows that for a given substituent $k_\alpha$ is always smaller than $k_\beta$. The order of the α-effect is also completely different from that of the β-effect, so that no correlation can be made between $\log k_\alpha$ and $\sigma^-$ or σ-values. This is because substituents Y at the vinylic carbon atom of **14** undergoing attack sterically hinder the approach of free radicals. To quantify this steric effect, alkyl groups of differing steric demands were introduced into the acrylic esters **12** and **14**[12, 16]. A *tert*-butyl substituent at the vinylic carbon of alkene **12** that is not attacked (β-substituent,

Table 5. Influence of alkyl substituents Z or Y on the relative rates $k_\beta$ and $k_\alpha$ for the addition of cyclohexyl radicals **8** to acrylic esters **12** and. **14** at 20°C.

| Alkenes **12** and **14** Z or Y | $10^3\ k_\beta$ | $10^3\ k_\alpha$ | $k_\beta/k_\alpha$ |
|---|---|---|---|
| H | ≡1000 | ≡1000 | 1.0 |
| $CH_3$ | 710 | 11 | 65 |
| $C_2H_5$ | 550 | 6.6 | 83 |
| $i$-$C_3H_7$ | 430 | 1.5 | 290 |
| $t$-$C_4H_9$ | 240 | 0.05 | 4800 |

$Z = t\text{-}C_4H_9$) decreases the reaction rate of cyclohexyl radicals only by a factor of 4.2; however, the same substituent variation at the vinylic carbon atom of **14** that is attacked (α-substituent, $Y = t\text{-}C_4H_9$) decreases the rate by a factor of 20000 (Table 5). In contrast to the small steric β-effects, the steric α-effects are thus very large. This is also shown by the different slopes ($\delta = 0.28$ and 1.4, respectively) of the correlation lines in Figure 2, in which the relative reactivities are plotted against the Taft steric parameters $E_S$[10] for the substituents Z and Y.

If the alkyl groups are replaced by substituents which exhibit completely different polar effects, the polar α-effects can be determined from the deviations from the steric correlation. The $E_S$ values for Y = Cl and CN are known. After correction for the steric interactions, polar α-effects of 4.3 for Cl and 92 for CN are obtained from the rate constants. A comparison with the influence of β-substituents shows that the polar α-effects are somewhat smaller than the polar β-effects (Table 6).

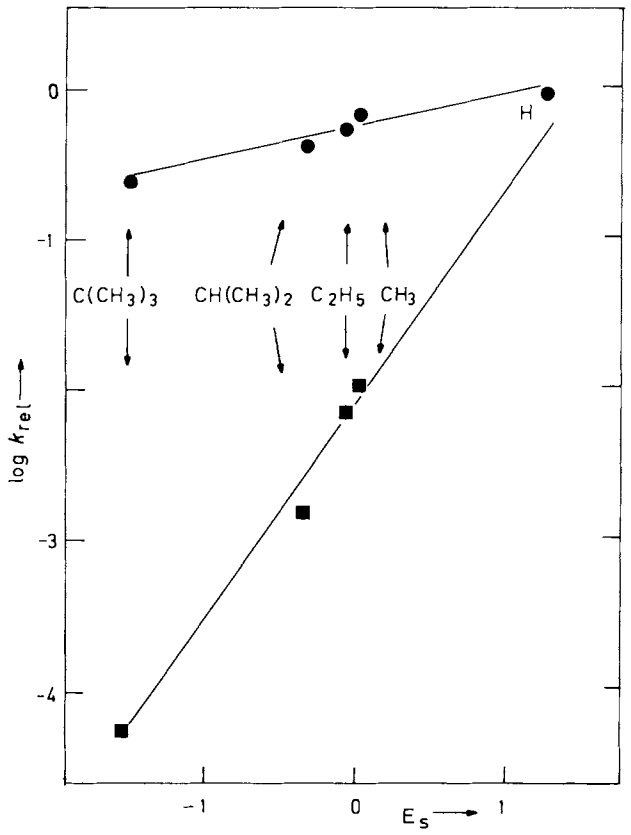

Fig. 2. Correlation between the relative reactivities of the cyclohexyl radical **8** at 20°C and the Taft $E_S$ parameters for substituents Z (●) and Y (■) in alkenes **12** and **14**.

The α-substituents Y are bonded to carbon atoms which change their hybridization from $sp^2$ to $sp^3$ during the reaction. Thus, the influence of Y on the stability of the alkenes[17] is removed during formation of the CC bond. If this hybridization change makes itself felt in the transition state for the free radical addition reaction, an α-phenyl substituent should exert a further rate-reducing effect in addition to the steric one. The phenyl group of the cinnamic ester **14** ($Y=C_6H_5$) retards the rate of addition of cyclohexyl radicals **8** to the α-carbon atom by a factor of 110[18]. Thus, the addition occurs 1.4 and 6.7 times faster than at the α-carbon atom of the ethyl- and isopropyl-substituted acrylic esters **14**, respectively ($Y=C_2H_5$ and *i*-$C_3H_7$, respectively). Since the steric effect of the phenyl group lies between that of the ethyl and isopropyl groups, and the rate-increasing polar β-effect of the phenyl group in the acrylic esters **12** is 6.4, it follows that the alkene-stabilizing effect of a phenyl group has almost no influence on the rate of addition.

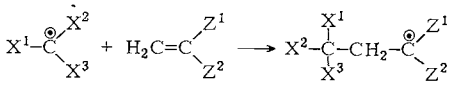

Table 6. Comparison of the polar β- and α-effects for addition of cyclohexyl radicals **8** to acrylic esters **12** and **14** at 20°C.

| Alkenes **12** and **14** Z or Y | Polar contribution to the rate of addition $k_\beta$ | $k_\alpha$ | $k_\beta/k_\alpha$ |
|---|---|---|---|
| H | ≡1.0 | ≡1.0 | 1.0 |
| Cl | 12 | 4.3 | 2.8 |
| CN | 310 | 92 | 3.4 |

To sum up: *Substituents at that carbon atom of the alkene which is attacked (α-substituents) exert both polar and steric effects on the rate of addition of free radicals.* The polar α-effect is somewhat smaller than the polar β-effect. Alkene-stabilizing substituents exert no additional effect on the rate of addition.

### 2.3. The Effect of Radical Substituents

Radical substituents also influence the rate of addition in a characteristic manner. Thus, *Minisci et al.*[19] and *Roberts et al.*[20] observed that alkyl groups X increase the reactivity of radicals **17** in addition reactions with the electron-deficient alkenes **9** and **18** (Table 7).

**17** **18**

Table 7. Influence of the substituents X on the rate of addition of radical **17** to alkenes $H_2C=CHZ$ **9**.

| Radicals **17** $X^1$ | $X^2$ | $X^3$ | Alkenes **9** Z | $k$ [L·mol$^{-1}$·s$^{-1}$] | $T$ [°C] |
|---|---|---|---|---|---|
| H | H | H | $PO(OEt)_2$ | $2.5\cdot10^3$ | −40 |
| $CH_3$ | H | H | $PO(OEt)_2$ | $2.6\cdot10^3$ | −40 |
| *n*-$C_3H_7$ | H | H | $PO(OEt)_2$ | $5.0\cdot10^3$ | −40 |
| $CH_3O$ | H | H | $PO(OEt)_2$ | $6.8\cdot10^3$ | −40 |
| $CH_3$ | $CH_3$ | H | $PO(OEt)_2$ | $1.2\cdot10^4$ | −40 |
| $CH_3$ | $CH_3$ | $CH_3$ | $PO(OEt)_2$ | $5.9\cdot10^4$ | −40 |
| *n*-$C_6H_{13}$ | H | H | CN | $5.9\cdot10^5$ | 0 |
| $CH_3$ | $CH_3$ | H | CN | $4.3\cdot10^6$ | 0 |
| OAc | $CH_3$ | H | CN | $1.1\cdot10^5$ | 25 |
| CN | alkyl | H | CN | $10^2$–$10^3$ | 25 |

The diethyl vinylphosphonate **9** ($Z=PO(OEt)_2$) reacts 24 times faster with *tert*-butyl than with methyl radicals, and acrylonitrile **9** (Z=CN) 7.5 times faster with isopropyl than with 1-heptyl radicals (Table 7). This increase in the reactivity of the radicals with the number of alkyl substituents X is remarkable since, at the same time, the stability of the reacting radicals **17** increases and that of the newly formed σ-bond decreases[15]. Thus, for these relatively small alkyl substituents the polar effects, which increase the nucleophilicity of the radical with increasing number of alkyl groups at the radical center, are apparently more important than the substituent effects on the stability of the radicals. Alkoxy substituents, which are more strongly electron-releasing than alkyl groups, further increase the reactivity of the radicals in addition reactions with electron-deficient alkenes (Table 7)[20]. In contrast, electron-attracting substituents such as X=OAc[21] or X=CN[22] decrease the rate of addition of free radicals **17** to acrylonitriles (Table 7). It is interesting to note that the reactivity and selectivity of the radicals **17** change in the same sense[23]. On proceeding from the primary 1-hexyl *via* the secondary cyclohexyl to the *tert*-butyl radical, the ρ-value for addition to acrylic esters **12** increases from 2.4 to 3.1 to 4.1[9,24], and in the fumaric esters series from 2.2 to 2.5 to 2.9[25]. A primary, alkoxy-substituted radical is just as selective as the *tert*-butyl radical[25], and a tertiary, acyl-

oxy-substituted radical just as selective as the primary 1-hexyl radical[24].

The nucleophilic reactivity and the nucleophilic selectivity of radicals **17** are thus influenced in the same sense by substituents. An explanation for this proportionality between reactivity and selectivity, which contradicts the classical reactivity-selectivity principle[26], is provided by frontier orbital theory (Section 3).

Strongly electron-withdrawing substituents can even reverse the polarity of the radicals. Thus, *Boldt et al.*[27] have shown that the reactivity of the dicyanomethyl radical increases when electron-releasing alkyl groups are introduced into alkenes. *Tedder*[28] demonstrated in very detailed studies the electrophilic properties of perfluoroalkyl and trichloromethyl radicals. For these species the rate of addition is increased by an electron-releasing methyl group and decreased by an electron-withdrawing trifluoromethyl substituent at the alkene (Table 8)[30]. This influence of substituents on the polarity of the radicals, which can lead to a change from nucleophilic to electrophilic behavior, is of paramount importance for copolymerization[31].

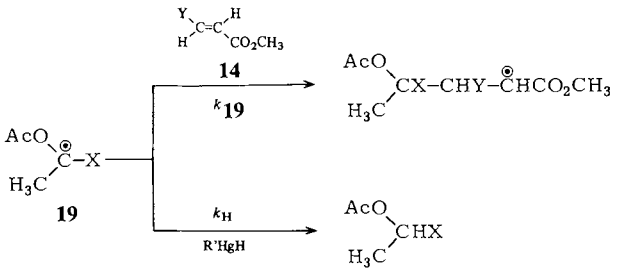

Table 8. Influence of β-substituents Z on the relative rates of addition of electrophilic radicals to alkenes **18**.

| Alkenes **18** | | $k_{rel}$ for addition of the radicals | | |
|---|---|---|---|---|
| $Z^1$ | $Z^2$ | $\overset{\oplus}{C}F_3$ (164 °C) | $\overset{\oplus}{C}F(CF_3)_2$ (164 °C) | $\overset{\oplus}{C}H(CN)_2$ (28 °C) |
| $CF_3$ | H | 0.4 | 0.13 | |
| H | H | ≡1.0 | ≡1.0 | |
| $CH_3$ | H | 2.3 | 5.6 | ≡1.0 |
| $CH_3$ | $n$-$C_3H_7$ | | | 16 |

Substituents X exert not only polar but also steric effects on the reactivity and selectivity of the radicals. The influence of the size of the group X can be studied in radicals of type **19**, which in competition with addition to the alkene **14** react with the alkylmercury hydride formed as intermediate[32]. Since hydrogen abstraction is much less dependent on the size of the substituents X than the addition to alkenes[32,33], the selectivity data in Table 9 reflect the influence of the steric variations on the reactivity of the radicals **19** in additions.

However, the influence of X on the H-abstraction cannot be completely neglected, so that the steric effect on the rate variation is even larger than that on the selectivity variation (Table 9). Substitution of a $CH_3$ by a $C(CH_3)_3$ group in the radical **19** thus decreases the rate of addition to fumaric ester by a factor of *at least* 260. As is to be expected, the steric effect is larger for reactions of fumaric esters than for those of acrylic esters, since the latter are attacked at the less shielded, unsubstituted methylene group.

Just as for the α- and β-alkene substituents Y and Z, respectively, the stabilizing influence of a radical substituent X has but little effect on the rate of addition. Thus alkyl and alkoxy substituents increase the reactivity of the radicals (Table 7), although they also stabilize them to a small extent[15]. A phenyl substituent, however, decreases the rate of addition. It can be shown from polymerization experiments, for example, that benzyl radicals react almost as slowly with acrylonitrile as do electrophilic, nitrile-substituted radicals[31]. The mesomeric stabilizing effect of a phenyl group thus retards the rate of addition of radicals to acrylonitrile just as strongly as the polar effect of a nitrile substituent.

**a**: X = $CH_3$; **b**: X = $i$-$C_3H_7$; **c**: X = $t$-$C_4H_9$

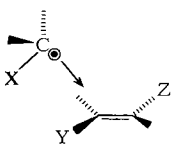

Table 9. Steric effects of alkyl groups on the selectivity ($k_{19}/k_H$) of radicals **19** at 20°C.

| Radicals **19** X | Alkenes **14** Y | Selectivity $10^3 \cdot k_{19}/k_H$ |
|---|---|---|
| $CH_3$ | H | ≡1000 |
| $i$-$C_3H_7$ | H | 250 |
| $t$-$C_4H_9$ | H | 50 |
| $CH_3$ | $CO_2CH_3$ | ≡1000 |
| $i$-$C_3H_7$ | $CO_2CH_3$ | 110 |
| $t$-$C_4H_9$ | $CO_2CH_3$ | 3.8 |

To sum up: *Substituents at the radical center exert polar and steric effects on the rate of addition to alkenes.* Radical-stabilizing substituents have comparatively little influence: only substituents which exert a strong stabilizing effect, such as X = $C_6H_5$, reduce the rate of addition.

## 3. The Reaction Mechanism

Additions of alkyl radicals to alkenes are strongly exothermic, since a σ-bond is formed and a π-bond is broken[34]. According to the Hammond postulate[35], the transition states should lie very early on the reaction coordinate, so that bond making and breaking are not far advanced. This is supported by the measured enthalpies of activation, which lie generally between 3 and 8 kcal/mol[36], and by theoretical calculations, according to which the distance between the methyl radical and ethylene in the transition state is *ca.* 230 pm[37]. All calculations favor an unsymmetrical transition state **20** in which the distances between the attacking radical and the two vinylic carbon atoms of the alkene are unequal[37,38]. There is no evidence that bridged radicals ("non-classical radicals"), whose existence has been discussed for addition reactions involving hetero radicals[39], are formed. An unsymmetrical transition state **20** readily explains the difference in the steric α- and β-effects summarized in Table 5. The distance between the β-alkene substituent Z and the radical is so large in the transition state that steric effects cannot become effective. The α-substituent Y is, however, oriented towards the attacking radical and thus exerts repulsive forces. The steric effects of the α-

**20**

alkene substituent Y and the radical substituent X are of similar magnitude (see Tables 5 and 9). This unsymmetrical transition state is also the reason for the favored formation of five-membered rings in intramolecular free radical additions[40].

The existence of early transition states and the absence of steric β-effects led us to expect that the polar effects in free radical additions can be described in terms of frontier orbital theory. To a first approximation, this theory states that the energy differences between the highest occupied molecular orbitals (HOMO's) and the lowest unoccupied molecular orbitals (LUMO's) of the reacting species are decisive in determining rate variations[41]. The smaller the energy difference between these frontier orbitals, the larger is the stabilizing effect when the reactants approach one another. The frontier orbital of a free radical is the SOMO (singly occupied molecular orbital). Thus, the interaction between the SOMO of the free radical and the LUMO and HOMO of the alkene should play a decisive role in the interpretation and prediction of polar effects[41] (Fig. 3).

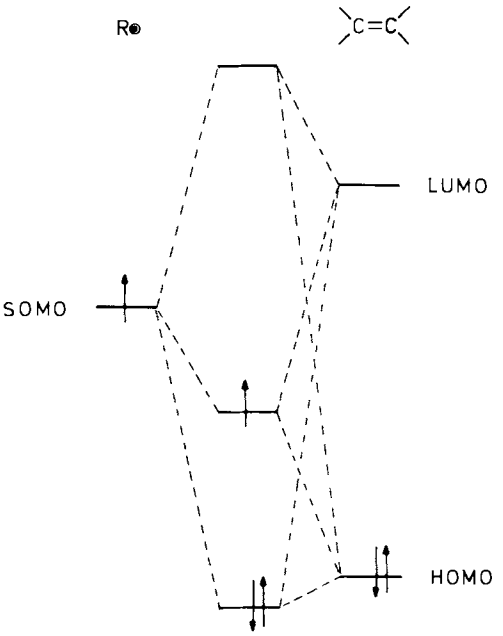

Fig. 3. Interaction between the SOMO of a free radical and the HOMO and LUMO of an alkene.

The SOMO-LUMO interaction is decisive in reactions of alkyl radicals containing electron-donating groups, which increase the energy of the SOMO[42]. The incorporation of electron-withdrawing substituents into the alkene decreases the SOMO-LUMO energy difference, and thus increases the rate of addition of the free radicals. This explains the nucleophilicity of alkyl radicals: their nucleophilic reactivity increases when electron-donating substituents are incorporated into the radical, since these decrease the SOMO-LUMO energy difference. Thus, the *tert*-butyl radical reacts more rapidly with electron-deficient alkenes than does a secondary or a primary radical (Table 7).

The variation of reactivity and selectivity in the same sense can also be understood on the basis of frontier orbital theory. The SOMO-LUMO energy difference is small for a *tert*-butyl radical, so that variation of the substituents at the alkene exerts a large effect. In comparison, the SOMO-LUMO energy difference is larger for the primary 1-hexyl radical, and, hence, the same variation of substituents at the alkene has less influence on the rate of addition. The *tert*-butyl radical is, thus, not only more reactive, but also more selective than the primary hexyl radical.

Strongly electron-withdrawing substituents decrease the SOMO energy of the radical to such an extent that the SOMO-HOMO interaction becomes dominant[43]. The radicals then lose their nucleophilic properties and become electrophilic. This change is expressed below the isokinetic temperature[44] in the form of negative ρ-values, which are typical of nitrogen-, oxygen-, and sulfur-centered radicals[45]. Just as in the carbene series[46], free radicals also exhibit nucleophilic and electrophilic behavior. Which property dominates is determined by the SOMO-HOMO and SOMO-LUMO energy differences and, thus, by the substituents at the radical center and at the alkene.

This interpretation of the polar effects is valid not only for β-substituents but also, when the steric interactions are taken into account, for α-substituents. Both electron-withdrawing α- and β-substituents lower the LUMO energies of alkenes; however, electron-withdrawing α-substituents appear to exert somewhat smaller effects than β-substituents (see Table 6). This is because not only the energies of the frontier orbitals but also the coefficients of the corresponding atomic orbitals are of importance in the interaction[41]. The rate of a reaction involving bond formation between two atoms increases with the orbital coefficients of these atoms. For the LUMOs of alkenes electron-withdrawing substituents decrease the orbital coefficients at a substituted α-carbon atom and increase those at an unsubstituted β-carbon atom[41]. Thus, the polar α-effect of electron-withdrawing groups is smaller than their β-effect (Table 6).

The LUMO of alkynes lies higher, and the HOMO lower, than in alkenes[47]. The interaction between the SOMO of the free radical and the frontier orbitals of the π-system is smaller for alkynes than for alkenes. Hence, both nucleophilic[48] and electrophilic[49] radicals react faster with alkenes **2** than with alkynes **21** (Table 10).

In contrast to free radicals, nucleophiles with non-bonding electron pairs attack triple bonds faster than double

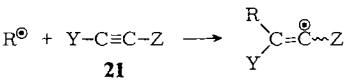

Table 10. Ratio of reactivities of alkenes **2** and alkynes **21** ($k_{alkene}/k_{alkyne}$) for additions involving nucleophilic and electrophilic radicals.

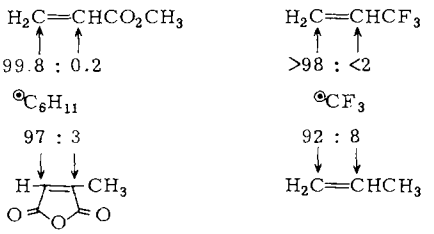
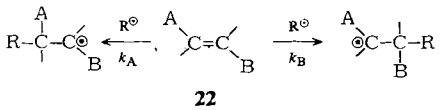
| Alkenes **2** | Alkynes **21** | $k_{Alkene}/k_{alkyne}$ for the radicals | | | |
|---|---|---|---|---|---|
| Y | Z | $\overset{\odot}{C}(CH_3)_3$ (20°C) | $\overset{\odot}{C}_6H_{11}$ (20°C) | $\overset{\odot}{C}F_3$ (164°C) | $\overset{\odot}{C}F_3$ (65°C) |
| H | H | | | 2.4 | 12 |
| H | $CH_3$ | | | | 24 |
| H | $CO_2CH_3$ | | 3.0 | | |
| H | $CF_3$ | | | 2.0 | |
| H | $C_6H_5$ | | 3.5 | | 36 |
| $CH_3$ | $CH_3$ | | | | 94 |
| $CO_2CH_3$ | $CO_2CH_3$ | 2.5 | | | |



bonds. The transition states of these reactions lie so late on the reaction coordinate that the rate of addition is determined by the rehybridization of the resulting carbanion rather than by the interactions of the frontier orbitals[50]. Competition experiments using the alkyne/alkene system can, thus, be used to distinguish between free radical and ionic nucleophilicity[48,50].

To sum up: *The transition states for addition of alkyl radicals to alkenes lie so early on the reaction coordinate that the polar substituent effects can be described in terms of frontier orbital theory. The unsymmetric transition state explains the absence of steric β-effects.*



## 4. Selectivity Effects

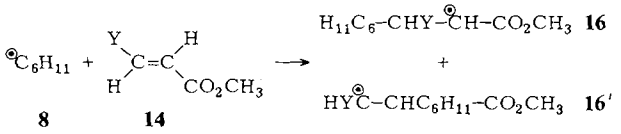
### 4.1. Regioselectivity

Free radicals preferentially attack the less-substituted carbon atoms of alkenes. Thus, the electron-donating methyl group in methylmaleic anhydride directs attack by cyclohexyl radicals **8** to the non-methylated vinylic carbon atom[51]. The electron-withdrawing ester group in methyl acrylate has a similar influence on the regioselectivity[16]. The same substituent influence is also observed for attack by electrophilic radicals, as shown by *Haszeldine et al.*[52] and *Tedder et al.*[28,53] in detailed studies involving fluorine-containing free radicals.

*Walling*[54], *Rüchardt*[55] and *Tedder et al.*[28,29,53] pointed out the dominant influence of steric parameters on the regioselectivity of free radical addition[56]. However, many textbooks explain the favored addition at the less-substituted vinylic carbon atom in terms of the differences in stabilities of the newly formed radical centers. This argument is not convincing, since when the alkene substituents are varied the stabilities of the radicals formed play only a minor role in determining the rate of free radical addition to alkenes (Section 2).

**22**

The regioselectivity for attack by radicals $R^{\odot}$ at alkene **22** is equal to $k_A:k_B$. The rate constants $k_A$ and $k_B$ are determined by the α-effect of the substituent A plus the β-effect of the substituent B and by the β-effect of A plus the α-effect of B, respectively. Since α- and β-substituents exert polar effects of similar magnitude, $k_A:k_B$ reflects to a first approximation only the differences in the steric effects of the substituents A and B. The regioselectivity of the addition of cyclohexyl radicals **8** to the acrylic esters **14** makes this clear (Table 11)[16].



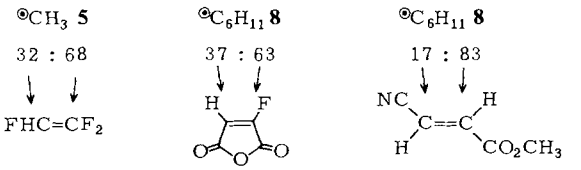


Table 11. Influence of the substituents Y on the regioselectivity of addition of cyclohexyl radicals **8** to acrylic esters **14**.

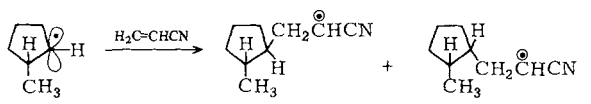
| Alkenes **14** Y | Regioselectivity **16** : **16'** | **16/16'** |
|---|---|---|
| H | 99.8 : 0.2 | 499 |
| $CH_3$ | 92 : 8 | 11.5 |
| $C_2H_5$ | 88 : 12 | 7.3 |
| $i$-$C_3H_7$ | 75 : 25 | 3 |
| $t$-$C_4H_9$ | 20 : 80 | 0.25 |

The tendency of free radicals to attack the ester-substituted vinylic carbon atom of **14** increases with the bulkiness of Y, leading to formation of **16'** Whereas the unsubstituted acrylic ester (Y = H) reacts almost solely at the methylene group to afford **16**, the *tert*-butyl-substituted acrylic ester (Y = $t$-$C_4H_9$) is attacked predominantly at the ester-substituted vinylic carbon atom. The variation in regioselectivity from 499 to 0.25 compares well with the variation of the rate ratio $k_\beta:k_\alpha$ (Table 5). Thus, the regioselectivity changes on proceeding from Y = H *via* $CH_3$, $C_2H_5$, and $i$-$C_3H_7$ to $t$-$C_4H_9$ in the acrylic esters **14** (Table 11) by factors of 43, 68, 166, and 2000, respectively. The ratios of the steric β- and α-effects ($k_\beta/k_\alpha$, see Table 5) increase in a similar manner by factors of 65, 83, 290, and 4800. As expected, the regioselectivity decreases somewhat with increasing temperature[57] and on changing to the more reactive phenyl radical[58].

The addition of free radicals to alkenes proceeds highly regioselectively when the difference in the steric bulk of the groups at the vinylic carbon atoms is large. Since all substituents are larger than hydrogen, free radicals preferentially attack the less-substituted carbon atom of alkenes. Fluorine is almost the same size as hydrogen[10], and the regioselectivity for free radical addition to fluorine-substituted alkenes is in fact often small. Trifluoroethylene[28] and fluoromaleic anhydride[59] are even preferentially attacked at the more highly substituted vinylic carbon atom.

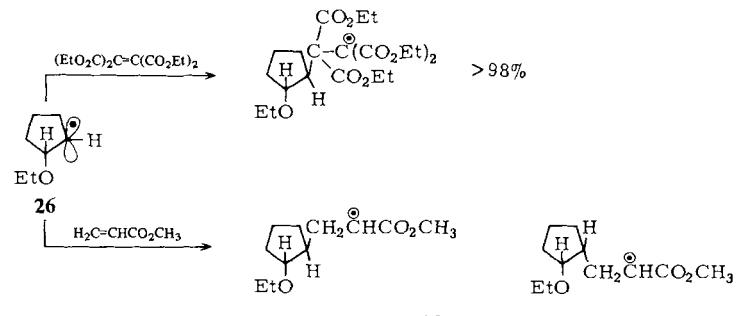


This reversal of the regioselectivity is probably due to an increase of the LUMO coefficient at the α-carbon caused by the mesomerically electron-donating[60] fluorine atom[61]. Electron-withdrawing substituents, however, increase the LUMO coefficients at the β-carbon atom. This

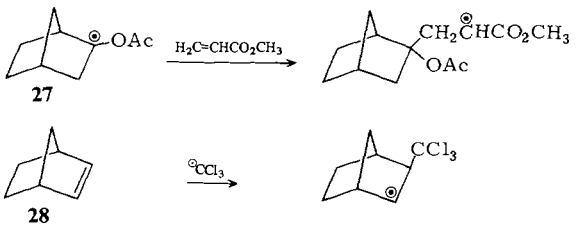
explains the preferential attack of the cyclohexyl radical **8** at the ester-substituted carbon atom of methyl-3-nitriloacrylate[12]. Sterically, an ester group hinders α-attack of the free radical somewhat more than a nitrile substituent; however, this is more than compensated for by the increase of the β-coefficient caused by the cyano group, which is a more effective electron acceptor than the ester substituent.

To sum up: *The regioselectivity is mainly determined by steric effects.* An exact prediction of the regioselectivity requires that the difference between the polar α- and β-effects be taken into account.

### 4.2. Stereoselectivity



The rate of addition of free radicals to alkenes depends on the steric effects of the substituents at the radical center and at the alkene (Section 2). When the two lobes of the orbitals containing the p-electrons in radicals or alkenes are shielded to a different extent, free radical addition occurs with a stereoselectivity corresponding to the difference in the steric substituent effects. Thus, the radical **23** reacts with acrylonitrile to give a 92:8 mixture of the adduct radicals **24** and **25**[62].

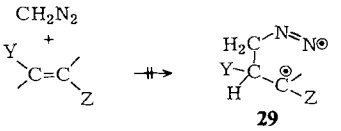


**23** **24** 92 : 8 **25**

One side of the singly occupied p-orbital of **23** is shielded by a neighboring methyl group and a hydrogen atom, and the other side only by two hydrogen atoms. This difference should correspond approximately to the steric substituent effect on the rate of addition which occurs on proceeding from the methyl-substituted radical **19a** to the isopropyl- or *tert*-butyl-substituted radicals **19b** and **19c**, respectively. The 12:1 stereoselectivity of radical **23** does, in fact, lie between the rate effects for the addition of the radicals **19a—c** to acrylic esters (Table 9); $k_{19a}:k_{19b}$ is 4:1 and $k_{19a}:k_{19c}$ 20:1.

Table 9 shows that the steric substituent effects of the radicals are amplified when the alkene is substituted at the carbon atom which is attacked. Thus, the observations that the radical **26** is attacked by the tetrasubstituted alkene exclusively *trans* to the ethoxy group[62], whereas methyl acrylate reacts with noticeably lower selectivity[63], correspond to the expected behavior.

The reactions of the norbornyl radical **27**[33] and of norbornene **28**[64] show that bulky substituents at free radical centers and at alkenes exert similar effects. In both cases, *exo*-addition occurs to more than 98%, although in **27** the p-electron of the free radical and in **28** the π-electrons of the alkene are shielded to different extents.



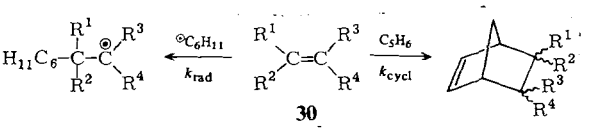
## 5. Applications

### 5.1. Studies of Reaction Mechanisms

In studies of reaction mechanisms, the questions as to whether an intermediate is involved and, if so, whether it is a free radical must often be resolved. Here, information regarding the substituent effects on the rate and selectivity of the addition of free radicals to alkenes can be useful.

Thus, comparison of the rates of additions of the cyclohexyl radical **8** and of cycloadditions of diazomethane[65] shows that the reactivity and regioselectivity of these reactions are influenced in a completely different way by alkene substituents: this suggests that the diradical **29** is not involved in the cycloaddition.

The difference between the "one-bond reactivity" of free radical additions and the "two-bond reactivity" of one-step cycloadditions makes itself felt in a highly characteristic way when substituents are introduced successively into alkenes (Table 12).



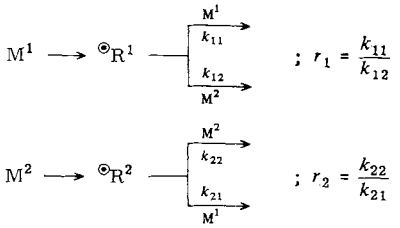


Table 12. Influence of the substituents $R^1$–$R^4$ on the rates of addition of cyclohexyl radicals **8** ($k_{rad}$) and of cycloaddition of cyclopentadiene ($k_{cycl}$) to alkenes **30** at 20°C.

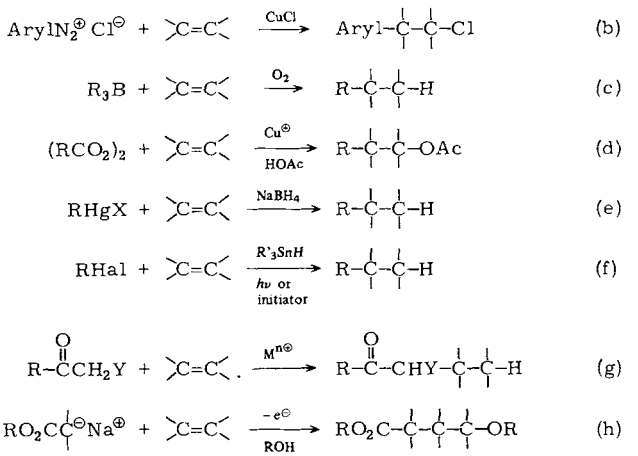
| Alkenes **30** | | | | $k_{rad}$ | $k_{cycl}$ |
|---|---|---|---|---|---|
| $R^1$ | $R^2$ | $R^3$ | $R^4$ | | |
| H | H | H | $CO_2CH_3$ | ≡1.0 | |
| $CO_2CH_3$ | H | H | $CO_2CH_3$ | 6.2 | |
| H | H | $CO_2CH_3$ | $CO_2CH_3$ | 150 | |
| H | $CO_2C_2H_5$ | $CO_2C_2H_5$ | $CO_2C_2H_5$ | 25 | |
| $CO_2C_2H_5$ | $CO_2C_2H_5$ | $CO_2C_2H_5$ | $CO_2C_2H_5$ | 1.1 | |
| H | H | H | CN | | ≡1.0 |
| CN | H | H | CN | | 78 |
| H | H | CN | CN | | 43500 |
| H | CN | CN | CN | | 460000 |
| CN | CN | CN | CN | | 4150000 |

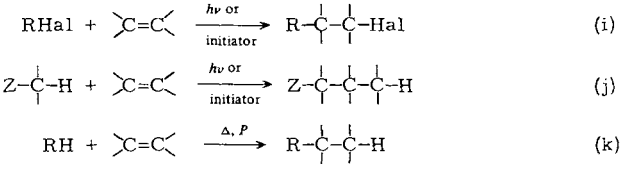
Whereas the rate of cycloaddition of cyclopentadiene increases with the number of electron-withdrawing substituents at the alkene[67], the rate of addition of the cyclohexyl radical passes through a maximum[18]; the 1,1-disubstituted alkene reacts fastest with cyclohexyl radicals **8**. Due to steric α-effects, substituents at the vinylic carbon atom which is attacked influence the rate of free radical addition to such an extent that the alkene **30**, with four ester groups, does not react faster than the monosubstituted acrylic ester[18]. In contrast, the rate of one-step cycloaddition[68] with cyclopentadiene is markedly increased by introduction of electron-withdrawing substituents at both vinylic carbon atoms. However, the validity of this comparison is diminished by the fact that ester groups exert larger vicinal, and also geminal, effects than do nitrile groups.

### 5.2. Free Radical Polymerization

In free radical polymerizations, carbon chains are formed by addition of alkyl radicals to alkenes. Thus, substituent effects which direct radical additions are of prime importance for free radical polymerization. If two monomers $M^1$ and $M^2$ which give rise to the polymer radicals $^{\odot}R^1$ and $^{\odot}R^2$ are copolymerized, the copolymerization parameters $r_1$ and $r_2$ and the $Q_j$ and $e_j$ values in the Alfrey-Price relationship (a)[69] can be correlated with the rates of addition of cyclohexyl radicals to alkenes[70].

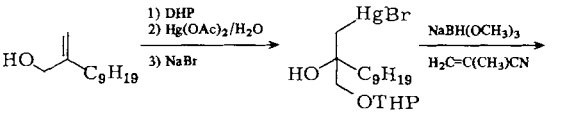


$$k_{ij} = P_i \cdot Q_j \cdot e^{-e_i \cdot e_j} \qquad \text{(a)}$$

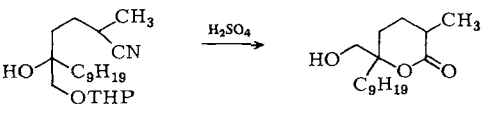


In this way, the polymerization parameters $r$ can be determined without carrying out polymerization experiments. It is also possible to measure $Q_j$ and $e_j$ values for alkenes when one of the $r$ values tends to zero. Thus, the $Q_j$ and $e_j$ values of methyl α-trifluoromethylacrylate **12** ($Z=CF_3$), which is of interest as a photoresist, cannot be measured in free radical copolymerization experiments with methyl methacrylate **12** ($Z=CH_3$) since $r_1=0$[71]. However, the $Q_j$ and $e_j$ values for **12** ($Z=CF_3$) can be calculated from the correlation between the reactivities of cyclohexyl radicals (Table 2) and the polymerization parameters of alkenes as given by equation (a)[70] using the known value of $r_2$ of 2.36: the values thus obtained are 0.74 and 2.50, respectively[72].

### 5.3. Syntheses involving CC Bond Formation

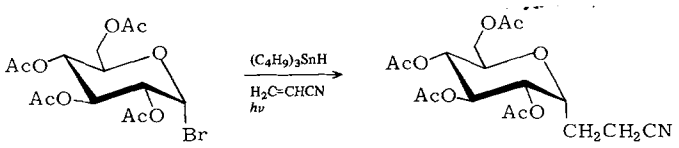


Information about the effects of substituents on the reactivity and selectivity of free radical additions can be used to predict yields and product ratios in syntheses involving the formation of CC bonds by addition of free radicals to alkenes. Examples of such syntheses are the Meerwein reaction[73] of diazonium salts (b); the Brown reaction[74] involving trialkylboranes (c); the copper-catalyzed Minisci reaction (d)[6,75]; reductive alkylation involving alkylmercury salts (e)[7,33,76] or alkyl halides (f)[77,78]; the metal salt-catalyzed reactions of carbonyl-, nitrile- or alkoxycarbonyl-substituted alkanes (g)[79]; and, to a lesser extent, the electrochemical reaction (h) involving carbanions[80].

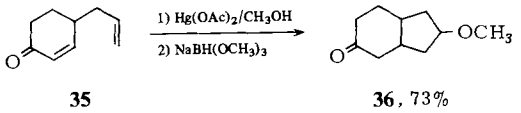


A number of halogenated hydrocarbons (i)[81] or compounds with weak CH bonds (j)[82] can add thermally or photochemically to alkenes; these reactions involve free radicals. As a final example, even the addition of unactivated hydrocarbons to alkenes (k) at high temperatures and pressures can proceed *via* free radicals[57,83].

A few examples will demonstrate the wide range of possibilities offered by these methods. *Kozikowski et al.*[84] prepared the antibiotic malyngolide **32** in only a few steps from the allylic alcohol **31**: solvomercuration, reductive addition to methacrylonitrile, and, finally, solvolysis. The 1:1 mixture of diastereomers obtained could be separated by chromatography (DHP: dihydropyran, THP: tetrahydropyranyl).

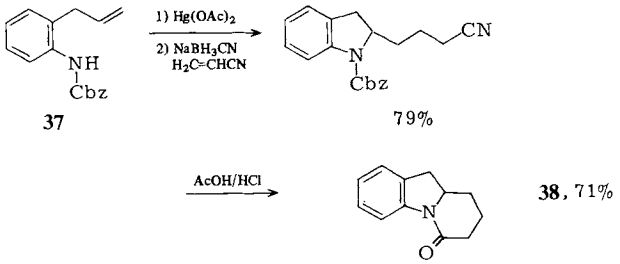


**31** 45%



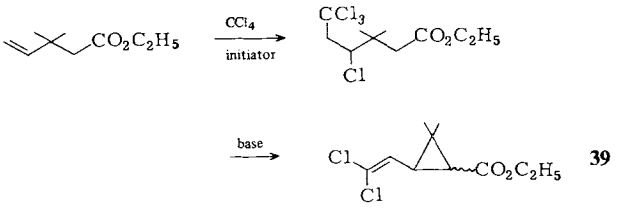
49% **32**

The exclusive formation of the 3-(α-*C*-glucopyranosyl)propionitrile **34** in the reaction of the glucosyl bromide **33** with acrylonitrile and tributyltin hydride[78] indicates that CC bond formation involving free radicals can proceed with a high degree of stereoselectivity.



**33** **34**, 72%

*Danishefsky et al.*[85] used an intramolecular addition to carry out CC bond formation in the synthesis of the bicyclic ketone **36** from diene **35**.



**35** **36**, 73%

However, the two cyclization steps to benzo[*b*]indolizidinone **38** precede or follow the radical reaction[86] (Cbz = benzyloxycarbonyl).

**37** 79% **38**, 71%

Electrophilic radicals have also been used in the synthesis of target molecules, as is demonstrated by several syntheses of ethyl permethrinate **39**[87].

**39**

## 6. Perspectives

The effects of substituents at the radical and at the alkene on the reactivity and selectivity of addition of free radicals to alkenes are, in general, known and predictable. Their description in terms of frontier orbital theory (Section 3) suggests that there should exist not only nucleophilic and electrophilic but also ambiphilic radicals[88], for which there will be no linear correlation between the σ-parameters of the substituents at the alkene and the free radical reactivity. Instead, the equally important interactions between the free radical SOMO and the LUMO and HOMO of the alkene will lead to a parabolic curve when free radical reactivity is plotted against the substituent parameters, just as has been described for cycloadditions[68,69]. Studies of the homolytic arylation of arenes[90] have provided evidence that free radical reactivity is increased both by electron-withdrawing and by electron-donating substituents at the π-system. However, the transition states in these reactions are so late that the stability of the product radicals is also of importance. In contrast, free radical addition to alkenes, a reaction involving early transition states, should be suitable for demonstrating the existence of ambiphilic radicals.

Recently, metal-catalyzed reactions of alkyl halides and alkenes have opened up new possibilities for the formation of CC bonds[91]. It is still unclear whether these syntheses involve free radicals. Comparison of the reactivity and selectivity with the data in Tables 1–11 could provide an answer to this question.

The correlation between free radical reactivities and copolymerization parameters (Section 5.2) indicates that *r*-, *Q*- and *e*-values will in the future be carried out to an increasing extent *via* direct measurement of the rates of addition of free radicals to alkenes. Studies of the "penultimate unit" effect[92] (*i.e.* the influence of substituents which are not attached to the radical center) are particularly interesting in this connection.

Finally, use of free radical chemistry for the synthesis of carbon skeletons (Section 5.3) enriches the potential of preparative organic chemistry. Specific syntheses involving free radicals require detailed knowledge of the reaction mechanism. In addition, the radicals should react *via* a chain mechanism, and, hence, be continually trapped and regenerated. Both these preconditions are fulfilled in the addition of free radicals to alkenes. Because of the high chemoselectivity of alkyl radicals (with which carbonyl, hydroxy, and halogen substituents do not interfere), free radical reactions could be particularly suitable for the synthesis of polyfunctional molecules such as carbohydrates[78,93].

*Our own work in this area was made possible by the generous support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie and by the dedicated efforts of my co-workers, whose names are to be found in the literature references. I wish, in addition, to express my grateful thanks to the Karl Winnacker Foundation.*

# Raw Materials and Energy: A Challenge for Polymer Research**

**By Klaus Weissermel* and Harald Cherdron***

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

The substantial rapid growth of synthetic polymers—plastics, man-made fibers, films, rubbers, and coatings—which continued unabated over many years, suffered a severe setback for the first time in 1973–1974 followed by another in 1980. A major cause of these reverses was the changed situation with respect to raw materials and energy. For industrial polymer research, in particular, this presents a fresh challenge with considerably changed priorities. The individual ways of meeting this challenge are highlighted and illustrated by examples: the search for alternative raw material sources for monomers; the development of economic methods for the production and processing of polymers; the recycling of polymers; and finally the development of new raw material-saving and energy-saving technologies based on the use of polymers. In the future, the applications of polymers to new technologies such as communication- and information-systems or biotechnology will join the traditional uses. But the efforts required in research and development to achieve this demand wide-ranging interdisciplinary cooperation on an even greater scale than hitherto.

## 1. The Current Situation Regarding Raw Materials and Energy

With some 85% of all primary chemicals currently used for the manufacture of polymers whose organic constituents are almost completely based on petroleum and/or natural gas, it is understandable that all the problems of availability and pricing are felt especially keenly in the polymer production sector. Thus, the two oil crises were reflected not only in the reduced demand for the primary chemicals ethylene, propene, and BTX aromatics, but, parallel to this, also in the world consumption of synthetic organic polymers in the years following 1973 and 1979 (Fig. 1).

After rapid growth, annual consumption of polymers reached 50 million t by 1974, and then, after the decline in 1975, climbed to the highest level so far of 66 million t in 1979; only to fall back sharply again in 1981.

There can be little doubt that the squandering of petroleum and natural gas for energy generation ought to be reduced[1] in favor of upgrading them into higher grade

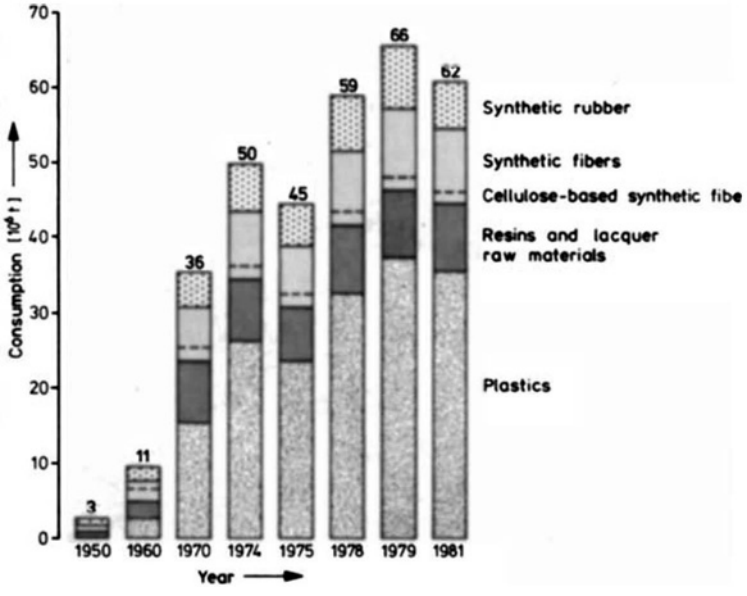

Fig. 1. World consumption of synthetic polymers in million t from 1950—1981 (excluding East block countries and China).

products, especially for use in the polymer sector. This poses three questions for polymer research and development and also sets new tasks:

- In the foreseeable future is there a possibility of finding sources of raw materials other than petroleum to ensure that the demand for monomers is met?
- In what way can polymer production and processing participate in saving raw materials and energy?
- Can the development of special polymers make a contribution to technologies that economize on raw materials and energy?

These three questions will be discussed in the following sections of this article.

## 2. Alternative Sources of Raw Materials for Monomers

The limited availability and continuing high price of petroleum raises the question as to whether it will continue to occupy the leading role as a highly important basis for chemical products. The answer to this should be given in the first place by the energy producers, as the major users of petroleum: the requirements in the transport, industrial, electricity generation, and domestic sectors currently account for approximately 89–94% of total petroleum consumption. The only alternative source of energy at present is nuclear energy, which is technically fully developed. The substitution potential of a nuclear reactor the size of the Biblis reactor is shown in Figure 2.

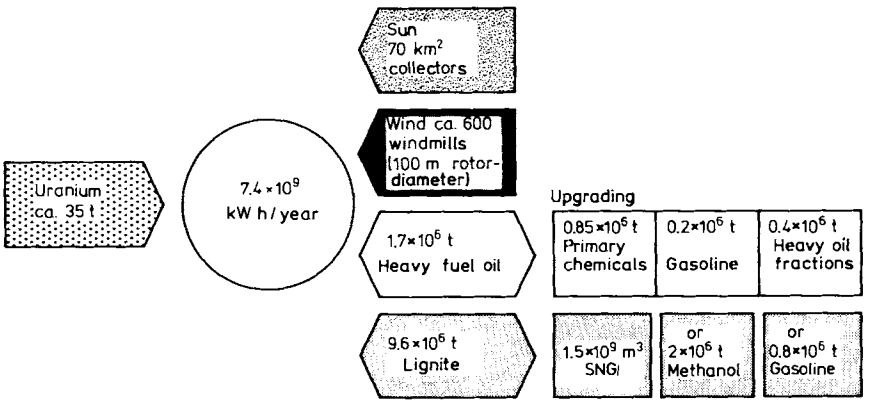

Fig. 2. Substitution potential of a 1200 megawatt nuclear power station [1a]. SNG = synthesis gas.

For electricity generation, such a nuclear power station is equivalent to an oil-fired power station with an annual consumption of 1.7 million t of fuel oil or a coal-fired power station with an annual consumption of 9.6 million t of lignite. This comparison shows how nuclear energy can be a direct or indirect replacement for oil, gas, or coal in the energy sector.

Furthermore, a nuclear power station has an effective output equivalent to 70 $km^2$ of solar collectors or 600 windmills with rotor diameters of 100 meters.

Nuclear energy could, therefore, provide an appreciable relief for the supply of energy and thus help to decelerate the wasteful exploitation of fossil fuels. These would thus become available for the more useful task of manufacturing high-grade products.

Coal and biomass as possible alternative raw materials for chemical upgrading pose fresh problems compared to petroleum as far as production of specific monomers is concerned.

### 2.1. Coal as a Source of Raw Materials

On the long term, coal and, especially, lignite will gain in importance for the chemical industry.

Compared with the outlay involved in the processing of petroleum and natural gas, all coal upgrading processes are many times more complicated and, thus, many times more expensive. For technological, economic, and ecological reasons, entry into the field of coal upgrading will very probably be gained *via* coal gasification. Lignite is the easiest to gasify and is the least expensive type of coal. Hence, synthesis gas ($CO+H_2$) produced from lignite has the greatest likelihood of becoming an economic reality in the foreseeable future.

In this context, the processing sequence "coal—synthesis gas—methanol—acetic acid—derived products" is the most tried and tested and the easiest to justify economically. In the medium term, this coal basis might also increase in significance for formaldehyde, *e.g.* for the manufacture of polyacetals and thermosets. On the other hand, the much studied catalytic conversion of ethanol into ethylene is far from being economically viable, as also is the step for the conversion of synthesis gas into polyethylene (Fig. 3).

The capital expenditure and gross requirement on raw materials for the production of 1 million t of ethylene increase steadily from ethane through naphtha to heavy fuel oil. However, the cost of raw materials and increase in capital expenditure first begin to escalate when the switch is made to coal. The reason for this is that petroleum and natural gas have a far more favorable (*i.e.* higher) hydrogen : carbon ratio than coal. Although this ratio is not of vital importance for the generation of thermal energy, process heat, or electricity, it is essential in upgrading to primary chemicals and gasoline. Only by the use of substantial quantities of energy by further consumption of lignite

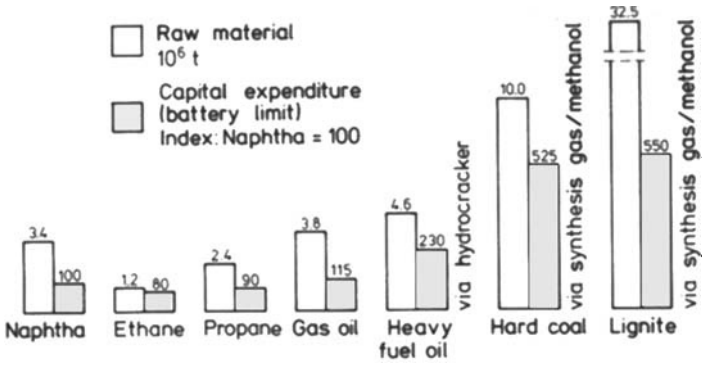

Fig. 3. Capital expenditure and gross requirement on raw materials for production of 1 million t of ethylene per annum from various starting material [1a].

is it possible to produce the hydrogen required for ethylene production (*e.g.* on the basis of lignite). This shows clearly that the slogan "Get away from oil" is inappropriate, at least for this form of upgrading. Gigantic misinvestments would result if we were to ignore suitability for upgrading in our deliberations over the future.

### 2.2. Biomass as a Source of Raw Materials

Among other possibilities, biomass could be used as an alternative source of raw materials. But in industrialized countries, in particular, even this regenerative source is subject to severe limitations. In tropical regions with large arable areas and rapid regeneration of the raw materials, bioalcohol based on carbohydrates is growing increasingly in importance as a source of energy and as a raw material for syntheses. One example of this is provided by Brazil. Yet even there an area the size of Belgium is required for sugarcane planting to replace only 20% of the gasoline requirement.

In heavily populated industrialized countries the use of valuable agricultural land to plant sugar beet would be totally uneconomic. Even to replace a mere 4.5% of the current gasoline demand (equivalent to 1 million t *per annum* in the Federal Republic of Germany), 4000 $km^2$ of land would have to be planted to yield the bioalcohol equivalent.

Furthermore, if nearly 40 mass-% were lost, for example, in dehydration to obtain ethylene from bioalcohol, it is clear that even regenerative biomass can hardly be a substitute for petroleum and can, therefore, provide no argument for continuing to use petroleum in a carefree manner in the major consumer sectors.

## 3. More Economic Methods for the Manufacture and Processing of Polymers

In the preceding section the problems associated with an economic breakthrough in alternative sources of monomers in the foreseeable future were highlighted. We now want to investigate the contributions being made by polymer research and development towards solving these problems by making economies in raw materials and energy.

### 3.1. New or Improved Polymerization Methods

The deteriorating situation with respect to raw materials and energy has undoubtedly done much to accelerate the development of improved or of new manufacturing methods. Mention should first be made of the so-called mass process, *i.e.* processes carried out without solvents or diluents. To the extent that the basic chemical and technological conditions exist, and the desired product properties are attainable, in many instances they afford advantages over the solution or dispersion processes.

As representative of these efforts, a number of examples dealing with olefin polymerization with Ziegler catalysts will be mentioned.

Polymerizations initiated by organometallic substances represent a classic example illustrating that progress in process technology is impossible without progress being made in the catalysts.

#### *3.1.1. Progress in the Development of Ziegler Catalysts*

The original Ziegler catalysts[2] consist of organometallic complexes produced by reaction of a transition-metal compound with an alkylaluminum compound. Their activity, *i.e.* the amount of polymer formed per gram of catalyst, is relatively low. Consequently, the crude polymers formed in such processes contain high amounts of residual catalyst which impairs the properties of the polymer; the crude polymer subsequently has to be upgraded using a process which is very expensive in terms of energy. Moreover, in the polymerization of propene an extraction stage is needed to remove atactic polypropylene formed because of the insufficient stereoselectivity of the catalyst. The last few years have witnessed the development of a new generation of Ziegler catalysts[3] which are notable for the following features:

- High activity ($\geq$ 1000 kg/g catalyst), which obviates the need for removal of residual catalyst from the polymer.
- High stereoselectivity ($\geq$95%), which obviates removal of atactic polypropylene.
- High selectivity with respect to the relative molecular weights of the product, *i.e.*, the molecular weight distribution can be varied within wide limits only by chemically modifing the catalyst.

Catalysts for the polymerization of ethylene[4] which meet these requirements are the so-called supported catalysts, obtained, for example, by reaction of titanium tetrachloride with a suitable solid (support) and subsequent activation with an alkylaluminum compound. These supported catalysts can be broadly divided into two groups: In the first group, the structure of the support is (largely) retained in the reaction with $TiCl_4$ (*e.g.* magnesium hydroxide supported catalysts), whereas in the second, the crystal lattice and, hence, the morphology are altered (*e.g.* magnesium alcoholate-supported catalysts).

The new supported catalysts differ from the original Ziegler catalysts in having, *inter alia*, a large specific surface area of *ca.* 60 $m^2/g$ and a very large pore volume

which does not change markedly during the polymerization process. Monomer is thus readily accessible to the polymerization-active centers over an extended period of time and, therefore, gives rise to a high conversion (Fig. 4). Associated with this is the high level of exploitation of titanium: 60 to 80% of the bound titanium is polymerization active (compared with *ca.* 10% in the classical Ziegler catalysts).

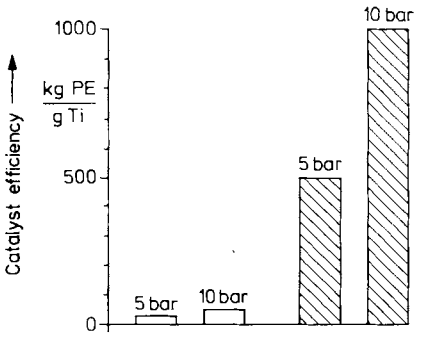

Fig. 4. Efficiency of Ziegler catalyst in the suspension polymerization of ethylene (PE = polyethylene): □ conventional catalysts, ▨ second generation catalysts.

Although long considered improbable, catalysts that possess both high activity and high stereoselectivity have also recently been discovered for the polymerization of propylene[5]. These are obtained by allowing, for example, titanium tetrachloride to react with specially pretreated magnesium chloride followed by activation with trialkylaluminum in the presence of so-called stereoregulators.

These new catalysts have not only made it possible to improve the existing dissolution or suspension processes but have also been the key to the development of totally new olefin polymerization processes[6], such as the liquid phase process for polypropylene and the gas phase process for polyethylene and polypropylene.

### *3.1.2. Progress in the Development of Processes for Polymerization with Ziegler Catalysts*

Progress in the production of polyolefins using a combination of new catalysts with new technologies is exemplified by polypropylene. Nowadays, polypropylene is produced industrially by three main methods (Fig. 5):

- Suspension process (in aliphatic hydrocarbons)
- Liquid-phase process (suspension process in liquid monomers)
- Gas-phase process

From the flow chart in Figure 5 it is clear that the use of new catalysts also enables the suspension process to be simplified because the catalyst no longer has to be removed. The mass polymerization processes (liquid-phase process and gas-phase process) have even fewer processing stages because the removal and return of the suspension agent are eliminated. Of course, these simplifications in processing contribute substantially to reducing energy consumption, although this is reflected only to a small extent in production costs, since 70% of the latter are now accounted for by the cost of the raw materials.

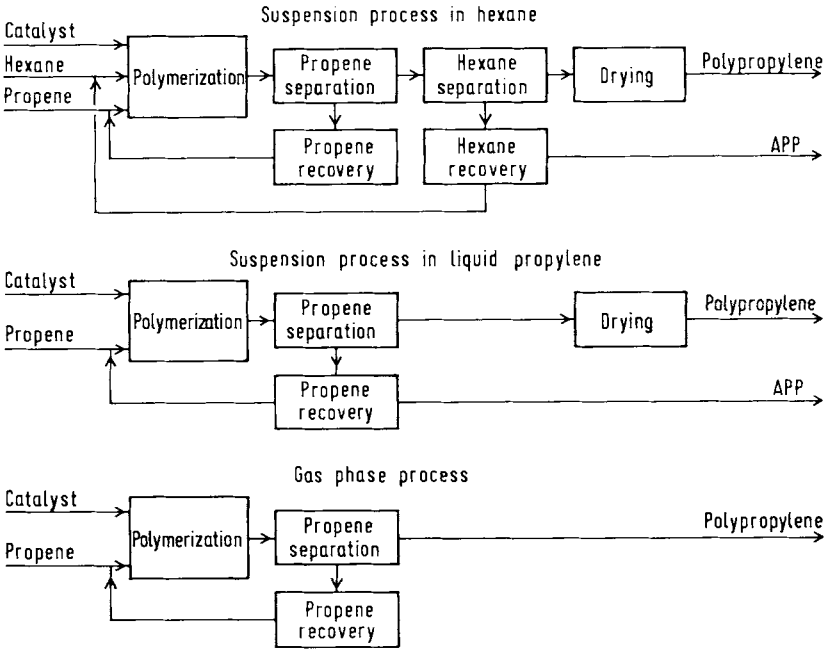

Fig. 5. Flow chart showing the various processes for production of polypropylene with Ziegler catalysts. APP = amorphous polypropylene.

## 3.2. New or Improved Processing Methods

In the sequence monomer-polymer-finished article, the processing methods, *i.e.* the conversion of the polymer powder or granules into a functional end product, are very important from the point of view of energy consumption. Thus, all processes that exploit the thermoplasticity of polymers require substantial amounts of energy, both to melt the polymer and to extrude the high-viscosity melts through nozzles or to shape them in molds. However, processing methods involving use of solutions also con-

sume large amounts of energy at the dissolution and solvent recovery stages.

As a result, considerable efforts have been, and continue to be, made to optimize existing processing methods or to develop completely new ones[7]. Examples of this include:

- Direct spinning processes for fibers,
- Improved or new nonwoven processes,
- Co-extrusion of films,
- Transfer molding processes for expanded polystyrene,
- SMC (sheet molding compounding) method for fiber-reinforced, unsaturated polyesters,
- RIM (reaction injection molding) and RRIM (reinforced reaction injection molding), *e.g.* for polyurethanes,
- New coating methods.

A number of new coating methods will be described to typify these developments.

The most important and universally applicable industrial coating methods involve use of solutions or of dispersions of a polymer. From the point of view of energy, evaporation and recovery of the organic solvent are important factors in the process. Consequently, major efforts have been made to develop alternative coating methods[8,9].

One group of methods operates without solvents (*e.g.* coating with polymer powders or radiation curing of liquid monomers), whereas the second group uses water as solvent or dispersing liquid. This includes the electrophoretic coating methods.

Today, electrophoretic coating (also known as electrodeposition coating) is used, for example, on a large scale for priming vehicle bodywork. For this purpose the coating resin, present in aqueous solution as a polyelectrolyte, is deposited on an immersed metal part by applying a direct current (anaphoretic or cataphoretic coating).

### 3.2.1. *Anaphoretic Coating*

For the coating resin, anodic deposition requires a water-soluble polyanion which can be coagulated by protons on the workpiece connected as the anode in the circuit (Fig. 6). The protons are formed by electrolysis of the water.

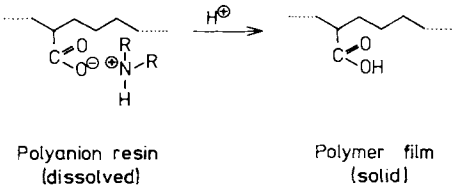

Fig. 6. Film formation in anaphoretic coating (schematic).

Suitable polyanions include, for example, low-molecular weight resins with carboxyl groups rendered water-soluble by neutralization with bases. After deposition on the workpiece, the solid film (thickness $\leq 20\ \mu m$) is crosslinked at elevated temperature in the presence of reactive compounds.

### 3.2.2. *Cataphoretic Coating*

Cathodic deposition requires a water-soluble polycation which can be coagulated by hydroxyl ions on the workpiece connected as the cathode in the circuit. The hydroxyl ions are formed by electrolysis of the water (Fig. 7).

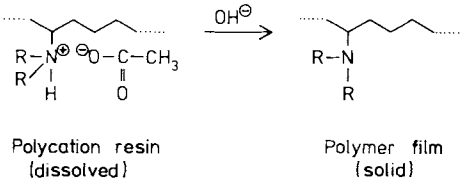

Fig. 7. Film formation in cataphoretic coating (schematic).

The solid film deposited on the workpiece (thickness $\leq 20\ \mu m$) is crosslinked by heating to 180—190 °C in the presence of catalysts.

The main advantages of the electrophoretic coating methods are the following:

- Only very small quantities of organic solvents are required;
- Optimum utilization of the polyelectrolytes in the coating baths;
- Possibility of automating the entire coating process;
- Uniform coating, even of complicated workpieces and cavities;
- Greatly improved protection against corrosion.

In addition to anaphoresis and cataphoresis, two other aqueous coating processes are being developed; namely, autophoresis and electrolytic powder coating, in which water also functions as solvent or dispersing liquid.

## 4. Recycling of Polymers

The main problems in devising a method for recycling plastics, films, fibers, and elastomers, and which is suitable for both industrial waste and communal refuse, lie in the collection and separation of the various polymers. It is thus understandable that the polymer-processing industry was the first to concern itself with re-utilization, since collection and classification within the industry can be organized relatively simply. For example, for many years in the processing of thermoplastics the scrap produced from the trimming of edges in film production or from sprue in injection molding has been ground and returned to the processing operation. Recently, as a result of the changed situation with respect to raw materials, increased attention has also been given to the recycling of polymers from communal refuse. In the Federal Republic of Germany this highly complex subject was studied under the auspices of the Association of the Plastics Manufacturing Industry (VKE) and with support of the Federal Ministry for Research and Technology (BMFT), and involved cooperation between various groups in universities and from industry. The results of this project, which covered not only the separation of polymers from other forms of refuse and their classification, but also re-utilization, have been published[10]. The following processes appear to be suitable for

the recycling of polymers—after their separation and classification:

- Direct re-utilization of polymers,
- Hydrolysis,
- Pyrolysis.

### 4.1. Direct Re-Utilization of Polymers

The direct re-utilization of polymers is dependent to a large extent on how completely it is possible to separate polymers from other materials and classify them according to type. This is particularly true if it is intended to manufacture further high-grade articles from polymer scrap by thermoplastic processing. This requirement becomes comprehensible if it is borne in mind that the great majority of polymers are not miscible, with the result that, for example, small amounts of polystyrene in polyethylene markedly affect the latter's solid-state properties[*].

An interesting example in which technical solutions have been found for the re-use of a polymer from communal refuse is provided by the recycling of polyethylene-terephthalate (PET) bottles. The process comprises the following steps[11]: The collected bottles are ground and then subjected to a number of separating processes in which paper (from the labels), aluminum (from the screw caps), and polyethylene (from the bottle bases) are removed. The PET granules after being segregated in this way are then dried carefully and can subsequently be processed to medium-quality fibers by melt-spinning, provided the polymer melt is cleaned by filtration.

To produce high-grade fibers or films, the PET granules are subjected to partial glycolysis to give low viscosity PET, which is simpler to purify; the molecular weight can subsequently be adjusted to the desired value by polycondensation. Finally, there is the third possibility: The total methanolysis or total hydrolysis of the PET to give ethylene glycol and either dimethyl terephthalate or terephthalic acid, which can be purified and polycondensed by the usual methods.

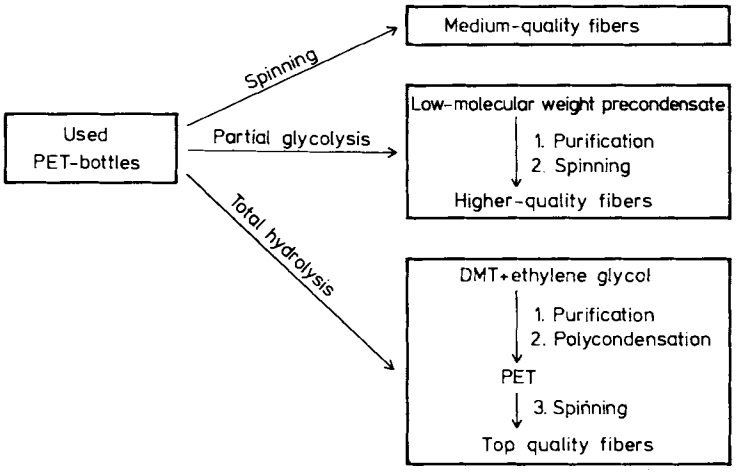

Fig. 8. Schematic representation of the possibilities for recycling polyethylene terephthalate (PET). DMT = dimethyl terephthalate.

[*] The materials known as polymer blends or polymer alloys are certainly multi-phase systems, but their favorable properties are achieved only by a defined phase morphology which requires special measures to be taken in the production of both the individual components and of the corresponding polymer blends.

### 4.2. Hydrolysis of Polymers

The re-isolation of the starting monomers by hydrolysis is possible, in principle, with many classes of polymers, *e.g.*, polyesters, polyamides, polycarbonates, and polyurethanes. For polyurethane foams[10,12], a method has been developed on a pilot plant scale in which foam-plastic scrap is hydrolyzed to polyethers and diamines in a twin-screw extruder. The reaction proceeds at 200—300 °C and 15—30 bar in the presence of water in 10 to 20 min in 90% yield. The only by-product formed is carbon dioxide. The diamine can be converted by reaction with phosgene into the corresponding diisocyanate, which then reacts with the polyether to yield a polyurethane foam.

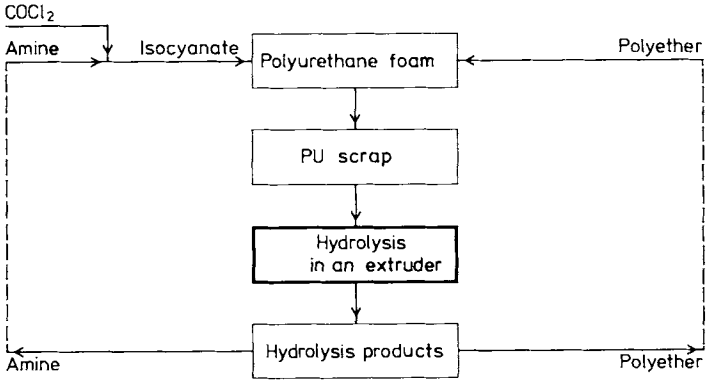

Fig. 9. Schematic representation of the recycling of scrap polyurethane foam by hydrolysis.

### 4.3. Pyrolysis of Polymers

Because it is not limited to particular structures, pyrolysis is a very widespread method of recycling polymer scrap in the form of pyrolysis products. Pyrolysis in a fluidized bed layer has proved to be a particularly elegant and versatile method[13,14].

The centerpiece of this method is a fluidized bed reactor which uses quartz sand as the fluidized medium. Fluidization is achieved by blowing in hot pyrolysis gases at 400 °C. The pyrolysis temperature of 600—900 °C is attained by means of heating coils which project into the fluidized bed and are also heated by pyrolysis gas. The polymers to be pyrolyzed are introduced into the fluidized bed in pulverized form[*]. The hot pyrolysis gases are freed from dust and soot in a cyclone, and after cooling to 30—50 °C are passed through an oil washer in which the liquid components separate out.

The composition of the pyrolysis products can be controlled by the choice of well-defined decomposition conditions (temperature, particle size, residence time, throughput rate). Examples of the material balance are shown in Table 1.

[*] Experiments with non-pulverized vehicle tires were also successful.

Table 1. Composition of the pyrolysis product of polyethylene (PE), polypropylene (PP), and a mixture (3:1:1) of PE, PP and polystyrene (PS) from a fluidized bed reactor; pyrolysis temperature: 740 °C.

| Pyrolysis products [% by weight] | Starting product PE | PP | PE/PP/PS |
|---|---|---|---|
| Hydrogen | 0.75 | 0.63 | 0.62 |
| Aliphatics | 59.52 | 52.04 | 52.01 |
| comprising methane | 23.58 | 20.60 | 20.46 |
| ethylene | 19.84 | 13.32 | 17.49 |
| propylene | 5.52 | 7.09 | 4.57 |
| Aromatics | 35.35 | 44.60 | 47.43 |
| comprising benzene | 19.07 | 18.12 | 14.80 |
| toluene | 3.86 | 6.67 | 6.41 |
| Tar | 2.76 | 5.87 | 5.91 |
| Total gases ($H_2$, $C_1$–$C_4$) | 58.56 | 49.62 | 50.69 |
| Total oils ($>C_4$) | 38.88 | 46.94 | 46.59 |
| Soot | 1.75 | 1.61 | 1.40 |

Up to 50% of the pyrolysis products are liquid and correspond to a mixture of light gasoline and tar, with a very high proportion of aromatics. The gaseous products (50–60%) are chiefly methane, ethane, ethene, and propene, and have a calorific value of $50 \times 10^6$ J/Nm$^3$. Less than half of this gaseous mixture is sufficient to heat the plant. The pilot plant experiments at the University of Hamburg are proving to be highly successful. Consequently, at the present time a plant capable of pyrolyzing 8000 t of old vehicle tires per annum is being constructed. This, too, is self-sufficient with respect to energy, *i.e.* the pyrolysis gases formed suffice to heat the reactor.

## 5. Raw Material- and Energy-Saving Technologies Using Polymers

The enormous growth in synthetic polymers in the last thirty years can be attributed to the following reasons:

- Synthetic polymers frequently have properties or combinations of properties that are attainable with known natural polymers only with difficulty, if at all;
- The properties of synthetic polymers can be "tailored" by specific measures during synthesis;
- Many of the synthetic polymers are thermoplastic and consequently can be processed considerably more easily with lower energy input.

As a result, synthetic polymers are a welcome addition to natural polymers and expand substantially the range of organic materials.

Undoubtedly, synthetic polymers are likely to make major contributions to inovations, especially the newer materials: highly heat-resistant polymers[15], high-modulus/high-tenacity polymers[15], high-grade polymer alloys[16], and polymer composites[16]. These allow, for example, lightweight construction in motor vehicles and aircraft[17], thereby contributing much to reduction of fuel consumption.

Besides "traditional" applications, such as in automobile and equipment construction and in the building, packaging and clothing industries, in the future polymers will find increasing applications in new technologies aimed at conserving raw materials and energy. Among these are:

- Tertiary recovery of petroleum
- Information and communication systems
- Biotechnology.

Although the amount of polymers used as a constituent in these applications is relatively small, it nevertheless represents an essential component of such systems, which would not function without them.

### 5.1. Polymers for the Tertiary Recovery of Petroleum

Synthetic polymers have long been used in petroleum recovery as drilling auxiliaries and as thickeners in so-called primary and secondary recovery. Despite all the improvements made in these two recovery techniques, *ca.* 70% of the petroleum still remains in the bore hole. As a result, considerable efforts have been made to reduce the quantity of oil retained in the rock capillaries (an improvement of a mere 1% in oil extraction at the present rate of world production would be equivalent to *ca.* 3 billion t of additional oil!). Among the various techniques grouped under the generic term tertiary recovery, surfactant- and polymer-flooding[18] have excellent potential. These processes require water-soluble polymers with extremely high molecular weight (several $10^6$ g/mol) which, nevertheless, are not decomposed by shearing or hydrolysis even at high temperatures, and whose solution viscosities are only slightly dependent on the salt content and p*H* value.

### 5.2. Polymers for Communication and Information Systems

The vital contributions made by photoreactive polymers to the development of new printing and copying processes are well known[19]. Furthermore, the surge in the development of electronics and microelectronics would have been impossible without the indispensable contribution made by polymers[20]. Here the trend towards increasingly short switching times ($<0.05$ µs) and increasingly high storage densities presents a new challenge to photolithography, and thus also to polymer chemistry.

The application potential of liquid crystalline polymers is difficult to estimate[21,22]. For low-molecular liquid crystals this extends from familiar uses (*e.g.* displays) to information storage.

Also at the initial stages of their development are polymers with special optical or electronic properties[23], whose potential applications include those as light conductors, electric conductors, or as building blocks for novel storage media.

### 5.3. Polymers for Biotechnical Applications

The wide-ranging field of biotechnology is also increasingly drawing upon the methods of polymer chemistry to optimize biocatalysts. In particular, mention should be

made here of the immobilization[24,25] of enzymes, of cofactors, and of entire cells. Two techniques of immobilization are used at present:

- The adsorptive or covalent bonding of enzymes to the surface of polymeric carriers;
- The inclusion of enzymes, cells or microorganisms into polymer networks or microcapsules.

The most important advantages of the immobilized biocatalysts are the following:

- Ease of separation of the solid catalyst from the liquid reaction medium;
- Multiple reuse;
- No contamination of the reaction products with the biocatalyst;
- Possibility of tailoring the polymer carrier/biocatalyst system and thus for methodical optimization of the entire process.

Immobilized biocatalysts have already been put to numerous uses in industrial processes. These include, for example, the isomerization of glucose to fructose, the production of L-amino acids by the selective cleavage of *N*-acyl-DL-amino acids with immobilized L-aminoacylase, or the production of 6-aminopenicillanic acid from penicillin G using immobilized penicillin amidase.

As knowledge concerning the highly complex requirements imposed on immobilized biocatalysts and the chemical reactions they initiate increases, this field will undoubtedly receive considerable additional stimuli.

## 3. Prospects

The innovative power of polymer research *on its own* is certainly not sufficient to change the present unsatisfactory economic situation in the polymer industry, but it is a crucial requirement in this respect.

Industrial polymer research, however—as can be understood against this economic background—is presently concentrating on solving short-term and medium-term problems such as optimization of production processes and processing methods, as well as modification of known polymers. This means that research into totally new fields, which requires substantial investment of time and money and is associated with a high degree of risk, is of necessity being forced into the background. To recreate the necessary leeway to reverse this trend, joint efforts from various quarters are essential: besides the reorientation of industrial research and development which is already taking place, the basic polymer research being conducted at the universities must be promoted and intensified in specific areas. In addition, an even closer symbiosis between basic university research and applied research in industrial laboratories should be strived for.

By harnessing all available resources in pure and applied research in a spirit of interdisciplinary cooperation, it ought to be possible to meet the new challenge presented to polymer research successfully, even on the long term.

## Derivatization-Free Enantiomer Resolution of Chiral Alcohols and Ketones by High-Resolution Complexation Gas Chromatography**

By *Volker Schurig** and *Roland Weber*

Complexation gas chromatography offers a method of precisely determining the enantiomeric purity of volatile chiral natural products as well as of products of enantioselective reactions *without derivatization*[1g].

Previously used separation systems for underivatized alcohols and ketones[1g] have the disadvantage of extremely long retention times (several hours) and markedly asymmetric peaks arising either from insufficient pretreatment of the capillary inner wall (coating efficiency $<20\%$, high surface activity) and/or from unfavorable properties of the stationary phase (poor chiral recognition, insufficient temperature stability).

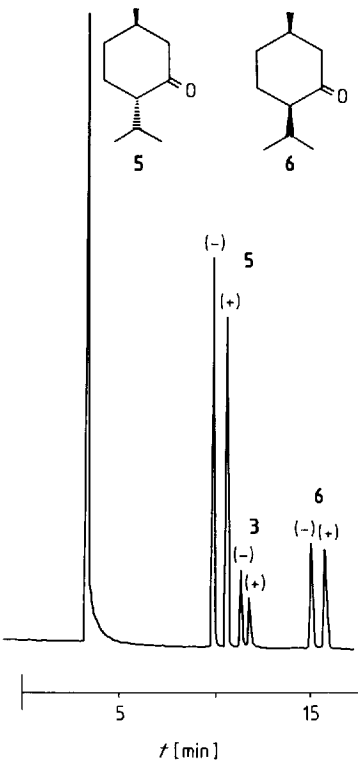

Fig. 2. Enantiomer resolution of menthone **5**, menthol **3**, and isomenthone **6** on nickel(II) bis[3-heptafluorobutyryl-(1*R*)-camphorate] (0.08 M in the methyl silicone fluid OV 101) at 133 °C; carrier gas: 1.0 bar $N_2$; Duran glass capillary (37 m × 0.75 mm).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. Haarmann & Reimer and Dragoco, Holzminden, are thanked for samples of terpenes.

Here, we report a highly promising further development of complexation gas chromatography using high resolution glass and quartz capillary techniques. By deactivating the glass or quartz surface (thermal cross-linking of Carbowax 20 M[3a] or OV 101[3b]) and using methylsilicone OV 101 as solvent for the optically active metal chelates, it has proved possible to make capillary columns having a coating efficiency of $>80\%$. Using these columns, we were able to resolve quantitatively alcohols and ketones such as *e.g.*, menthol, menthone, and isomethane into their enantiomers without derivatization within 20 minutes (Fig. 2).

In this way, particularly using the combination complexation gas chromatography/"selected-ion" mass spectrometry[4], the rapid, straightforward, and precise determination of the enantiomeric composition of natural products from complex mixtures can be performed directly[4]. The enantiomer resolution of volatile chiral alcohols and ketones by complexation gas chromatography is superior to the recently described resolution as urethane-, acyl-, or oxime-derivatives[5], since the disadvantages of derivatization (sample preparation, incomplete reaction, occurrence of by-products, and products of isomerization and racemization) can be avoided.

## Quantitative Separation of Deuterated Tetrahydrofurans $C_4H_{4(\beta)}H_{4-n(\alpha)}D_{n(\alpha)}O$ by Complexation Gas Chromatography on a Cobalt(II) Complex**

By *Volker Schurig** and *Dorothee Wistuba*

Complexation gas chromatography[1] uses the rapid and reversible coordinative interaction between a mobile substrate and a stationary metal complex to solve particularly difficult analytical separation problems. Whereas, previously, the enantiomer resolution of chiral donor molecules with heteroatoms having donor capabilities (O,S,N) was of prime interest[1b], we are now investigating the efficiency of the method for the quantitative separation of protio/deuterio isomers of Lewis bases with mass difference 1.

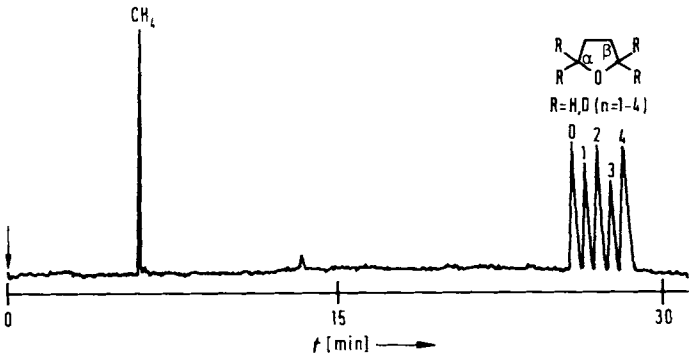
Selective separations of isotopomers by complexation gas chromatography were previously only known for deuterated alkenes (*e.g.* $C_2H_{4-n}D_n$) on $AgNO_3$/ethylene glycol[2a] and on $(CO)_2Rh$(3-trifluoroacetylcamphorate)/squalane[2b]. In addition, a slight difference in the retention times of 2-butanol and (2-D)-2-butanol was reported for gas chromatography on $Eu(fod)_3$/squalane[2c]. A decisive prerequisite for the *complete* and *rapid* separation of isotopomers which only differ by one mass unit is the further development of complexation gas chromatography using high resolution glass or quartz capillary techniques with a coating efficiency of *ca.* 95%[3].



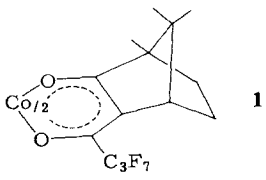


Fig. 1. Complexation gas chromatogram of α-deuterated tetrahydrofurans (0.1 M **1** in methylsilicone OV 101, deactivated [3] glass capillary (60 m × 0.25 mm), 70 °C, carrier gas: 1.9 bar $N_2$; split 1:50). Order of elution; $(D_0)$-THF, $(\alpha\text{-}D_1)$-THF, $(D_2)$-THF (all isomers), $(\alpha,\alpha,\alpha'\text{-}D_3)$-THF, $(\alpha,\alpha,\alpha',\alpha'\text{-}D_4)$-THF (peak classification corresponds to the number of deuterium atoms at the α-position). Peak assignment by GC-MS (Varian MAT 112S).

As shown in Figure 1, we succeeded for the first time in separating the isotopomers of deuterated cyclic ethers with full base line separation for all five isomers of tetrahydrofuran (THF) $C_4H_{4(\beta)}H_{4-n(\alpha)}D_{n(\alpha)}O$[4] using complexation glass capillary chromatography on cobalt(II) bis(3-heptafluorobutyrylcamphorate) **1** in less than 30 min at 70 °C. The separation factors $\alpha$ are logarithmically additive [$\alpha(70\,°C) = (1.03)^n$, n = number of deuterium atoms, $\alpha = t'_D/t'_H$, $t'$ = net retention time]. The separation depends on a marked "inverse" ($K_D > K_H$) secondary isotope effect, whose thermodynamic parameters for $(D_0)$-THF and $(\alpha,\alpha,\alpha',\alpha'\text{-}D_4)$-THF on **1** (0.1 M in squalane) were determined to be $\Delta_{D,H}\Delta H^0 = -0.2$ kcal mol$^{-1}$ and $\Delta_{D,H}\Delta S^0 = -0.4$ cal K$^{-1}$ mol$^{-1}$ between 50 and 80 °C[1a], and which rapidly decreases with the distance to the coordinating oxygen atom (no separation of $(D_8)$-THF and $(\alpha,\alpha,\alpha',\alpha'\text{-}D_4)$-THF).

**1**

The choice of cobalt as the central atom in **1** proved to be optimal, since with the corresponding nickel complex the coordinative interaction $K$ with cyclic ethers is too strong and with the manganese complex, too weak[5]. There are three configuration isomers of $(2,5\text{-}D_2)$-THF. Neither separation of the *meso/rac*-diastereomeric pair nor enantiomeric resolution of the *rac*-form on the enantiomerically pure cobalt complex (1*R*)-**1** was observed (cf. Fig. 1, peak 2).

We have also found similar "inverse" secondary isotope effects in the complexation of α-deuterated tetrahydropyrans and deuterated dioxanes on **1**. The separation factors are expected to double for the tritiated substrates. From the present findings it can be concluded that the introduction of chemical selectivity into the chromatographic separation process is a useful parameter for achieving higher separation efficiencies.

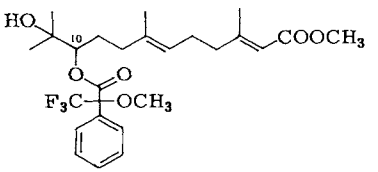
## Reversal of the Enantioselectivity in the Enzymatic Hydrolysis of Juvenile Hormone as a Consequence of a Protein Fractionation**



By *Martin G. Peter**, *Hans-Peter Stupp*, and *Klaus-Ulrich Lentes*

*Dedicated to Professor Peter Karlson on the occasion of his 65th birthday*

The juvenile hormones **1a**—**c** are hydrolyzed enzymatically in the blood of insects to afford biologically inactive acids. A conversion of 40—60% is observed after the hydrolysis of racemic **1c** in the blood of *Locusta migratoria*[1]. The unconverted educt contains an excess of naturally configurated (10*R*)-**1c** (*e.e.* 47.2%). We have shown previously that the hormone-binding protein present in the

**1a**: $R^1 = R^2 = CH_3$; $R^3 = H$
**1b**: $R^1 = CH_3$; $R^2 = R^3 = H$
**1c**: $R^1 = R^2 = R^3 = H$

**2a**: C-10 : *R*
**2b**: C-10 : *S*

[*] Priv.-Doz. Dr. M. G. Peter, H.-P. Stupp, K.-U. Lentes
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

hemolymph preferentially associates with (10*R*)-**1c**. The configuration was determined with established methods[2] using racemic [10-$^3$H] **1c** and involving the diastereomeric derivatives **2**, which can be separated by HPLC on a silica gel column.

After incubation of the hemolymph of *Locusta migratoria* with 2-mercaptoethanol we have now separated an esterase from the hormone-binding protein (HPLC, 0.7 × 60 cm, TSK-G-3000-SW gel permeation column, elution with 0.1 M potassium phosphate buffer pH 6.8; 0.2 mL/min); this esterase catalyzes the hydrolysis of **1c**. Surprisingly, the purified esterase reacts preferentially with (10*R*)-**1c**: the hormone recovered after partial hydrolysis of racemic **1c** contains an excess of (10*S*)-**1c** (*e.e.* 34.4%). Accordingly, the esterase has a chiral binding site which recognizes the configuration of the oxirane quite remote from the active site. The preferential degradation of the natural enantiomer, therefore, arises from the higher affinity of the enzyme for this molecular species. In the presence of the hormone-binding protein, which is also enantioselective, the rate of hydrolysis of the natural enantiomer is markedly reduced, and the enzyme preferentially hydrolyzes the unbound hormone containing an excess of (10*S*)-**1c**. With racemic **1c** the sense of chirality (*R* or *S*) of the enzymatic reaction is, therefore, reversed in the presence of the hormone-binding protein. The result indicates that the enantioselectivity observed with a purified enzyme does not necessarily have to be identical with that of the reaction *in vivo*.

The higher homologue (10*R*,11*S*)-**1a** has not yet been detected in *Locusta migratoria*. The hormone-binding protein does not discriminate between the enantiomers of **1a**[1]. In the enzymatic partial hydrolysis of racemic **1a** either in the presence of the hormone-binding protein or with the purified esterase, (10*S*,11*R*)-**1a** predominates in the recovered educt (*e.e.* ≤ 70%). Hence, the hormone-binding protein does not change the sense of chirality in the enantioselective enzymatic hydrolysis of racemic **1a**.

The esterase found in the blood of *Locusta migratoria* is the first example of an enantioselective enzyme involved in the deactivation of juvenile hormone. Previously, in the Colorado potato beetle, *Leptinotarsa decemlineata*[2b], and in the tobacco horn worm, *Manduca sexta*[3], we found only non-enantioselective esterases. All previously studied insect species have enantioselective hormone-binding proteins whose substrate specificity correlates with the naturally occurring homologues[1,2b,3,4]. Studies of the substrate specificity of esterases and hormone-binding proteins may possibly assist in understanding the considerable species-specificity observed in testing analogues of juvenile hormones as potential insecticides[5].

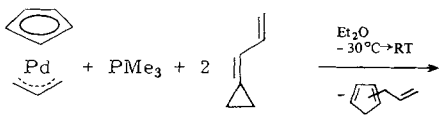
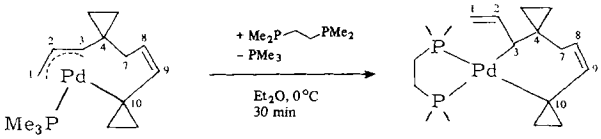
## Phosphane-Induced, Stepwise Rearrangement of an Octadienediyl Palladium Complex to Seven- and Nine-Membered Metallacycles**

By *Holger Michael Büch, Paul Binger*, Reinhard Benn, Carl Krüger,* and *Anna Rufińska*

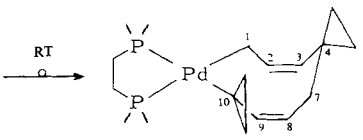


The octadienediyl metal complexes (**1**, **2**) of nickel and palladium[1], obtained by stoichiometric reactions with 1,3-dienes, are of importance in understanding the catalytic dimerization of these dienes. The bis-σ-allyl complexes **3**–**5** could be the last stages before the respective reductive eliminations to the various cyclodimers. Previously, only one platinacyclopentane derivative, analogous to **3**, having *trans*-arrangement of the vinyl groups has been isolated and characterized[2].



**1** **2** **3** **4** **5**

In the course of studies[3] of catalytic and stoichiometric reactions of the allylidenecyclopropane **6**, we have, for the first time, isolated metallacycles of type **4** and **5**; we have also been able to show that the *cis,cis*-metallacyclononadiene **5** can be formed *via* the α-vinyl metallacycloheptene **4** by interaction of a further ligand with the *syn*-π-allyl-σ-allyl form **2**.



Reaction of dark-red ($\eta^3$-allyl)($\eta^5$-cyclopentadienyl)palladium with trimethylphosphane and allylidenecyclopropane at −30 °C to room temperature leads, upon cleavage of allylcyclopentadiene[4], to the octadienediyl complex **7** (yellow crystals, m.p. = 94.5 °C) in 81% yield.

7 was identified from its spectroscopic data[5]. In particular, the typical shifts and splitting pattern of a *syn*-substituted $\pi$-allyl ligand and a *cis*-double bond can be detected in the $^1$H-NMR spectrum (400 MHz); the exact conformation of the $C_8$-chain was determined by X-ray structure analysis (Fig. 1). It should be noted that the double bond lies out of the Pd-coordination plane relative to the *syn*-position of the allyl group.

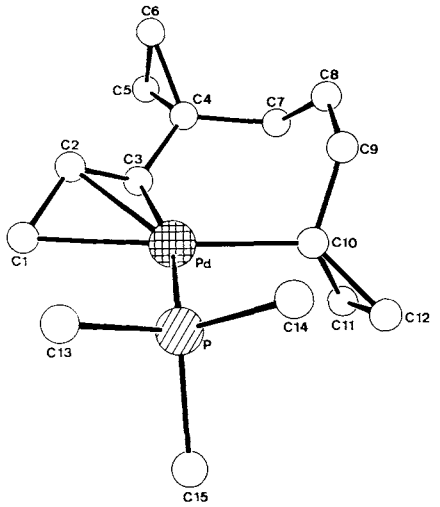

Fig. 1. Crystal structure of 7. Monoclinic, $P2_1/n$, $a = 8.7279(7)$, $b = 17.236(2)$, $c = 11.3139(6)$ Å, $\beta = 110.409(6)°$, $\rho_{calc} = 1.425$ g/cm$^{-3}$, $Z = 4$, $Mo_{K\alpha}$ radiation, $R = 0.034$ (3977 observed reflections, 154 refined parameters). Selected distances [Å] and angles [°]: Pd–P 2.265(1), Pd–C1 2.215(4), Pd–C2 2.179(3), Pd–C3 2.250(3), Pd–C10 2.094(3), C1–C2 1.414(5), C2–C3 1.399(4), C3–C4 1.488(4), C4–C7 1.539(5), C7–C8 1.491(5), C8–C9 1.333(5), C9–C10 1.470(4), P–Pd–C1 101.1(1), P–Pd–C10 96.7(1), C1–Pd–C3 66.9(1), C3–Pd–C10 95.1(1). Further details of the crystal structure investigations can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50538, the names of the authors, and the journal citation.

Reaction of a solution of 7 in diethyl ether with one equivalent of ethylenebis(dimethylphosphane) at 0°C leads to quantitative precipitation of almost colorless microcrystals of **8**, which can be isolated by filtration. Within a few hours at room temperature, **8** rearranges quantitatively and irreversibly to afford **9** (pale yellow needles, m.p. = 128°C).

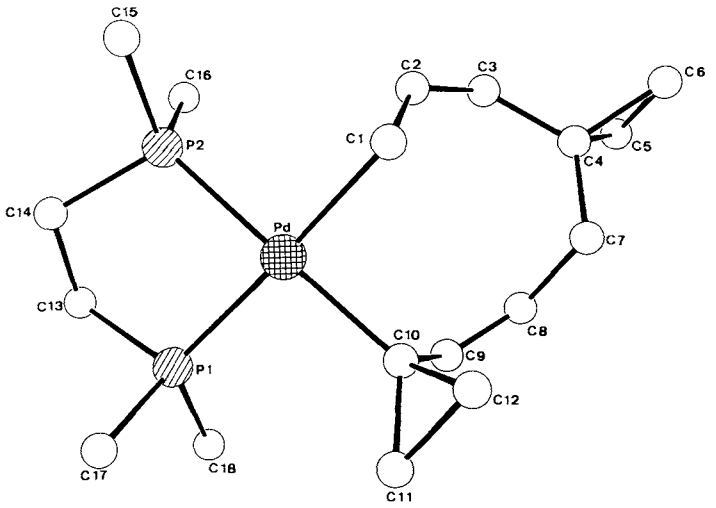

Fig. 2. Crystal structure of **9**. Monoclinic, $P2_1/c$, $a = 9.162(2)$, $b = 20.452(5)$, $c = 11.511(1)$ Å, $\beta = 111.65(1)°$, $\rho_{calc} = 1.379$ g cm$^{-3}$, $Z = 4$, $Mo_{K\alpha}$ radiation, $R = 0.028$ (3734 observed reflections, 190 refined parameters). Selected distances [Å] and angles [°]: Pd–P1 2.305(1), Pd–P2 2.303(1), P1–Pd–P2 84.6(1), Pd–C1 2.130(3), Pd–C10 2.101(3), C1–Pd–C10 87.3(1), C1–C2 1.477(4), C2–C3 1.335(5), C3–C4 1.491(5), C4–C7 1.518(5), C7–C8 1.506(5), C8–C9 1.335(5), C9–C10 1.486(4).

**8** and **9** were characterized from their $^1$H- and $^{13}$C-NMR spectra[5]. Based on the magnitude of the coupling constants $^2J(PC_\alpha)$, the Pd atom in both complexes has an almost square-planar environment. In **8** an uncomplexed vinyl group and a *cis*-double bond can be detected. The structure of the nine-membered ring in **9** can be deduced from the low temperature NMR spectra and was confirmed by X-ray crystallography (Fig. 2). Conformational changes occur at higher temperatures: the protons at $C_1$ and $C_7$ become equivalent as a consequence of inversion of the nine-membered metallacycle; simultaneously, exchange of each of the two geminal $CH_3$ groups as well as of the $CH_2$ groups of the two three-membered rings occur, whereas the C atoms of the chelate bridge remain inequivalent ($C_1$ and $C_{10}$ retain their P couplings).

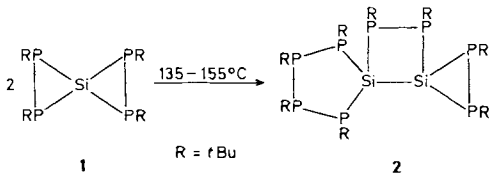
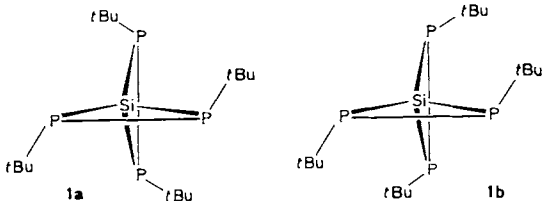
## ($t$BuP)$_8$Si$_2$— A Novel Dispirocyclic Silaphosphane**



By *Marianne Baudler**, *Thomas Pontzen*, *Ulrike Schings*, *Karl-Friedrich Tebbe*, and *Magda Fehér*

Cyclocondensation of 1,2-dipotassium 1,2-di-*tert*-butyldiphosphide with silicon tetrachloride leads to formation of the tetraphosphasilaspiro[2.2]pentane **1** as a mixture of



[*] Prof. Dr. M. Baudler, Dr. T. Pontzen, U. Schings, Prof. Dr. K.-F. Tebbe, Dr. M. Fehér

Greinstrasse 6, D-5000 Köln 41 (Germany)

[**] Contributions to the Chemistry of Phosphorus, Part 133. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 132: M. Baudler, T. Pontzen, *Z. Naturforsch. B*, in press.

**1a** and **1b**, which can be isolated separately[1]. At room temperature **1b** slowly rearranges into the sterically more favorable isomer **1a**.

We have now found that in the melt **1a** or also **1a**, **b** dimerizes almost quantitatively to afford the novel silaphosphane **2**; in the mixture, the rearrangement **1b** → **1a** occurs initially. As by-products tetra-*tert*-butylcyclotetraphosphane[2a], 1,2-di-*tert*-butyldiphosphane[2b], and other nonidentified compounds are formed. Instead of the expected dispiro compound consisting of a three-, six-, and three-membered ring, 1,2,5,6,7,8,9,10-octa-*tert*-butyl-1,2,5,6,7,8,9,10-octaphospha-3,4-disiladispiro[2.0.4.2]decane **2** immediately forms. The carbocyclic analogue is not yet known.

The lemon yellow, prismatic crystals of **2**[3] (decomposition at 265 °C with concomitant red-brown coloration and agglomeration) are only slightly air- and moisture-sensitive, but in solution (toluene, tetrahydrofuran) are rapidly hydrolyzed. Their composition is established from the correct elemental analysis and mass spectrum (field ionization, 200 °C) in which only $M^+$ ($m/z$ 760–762) occurs. The constitution is based on the NMR data, principally, the $^{31}$P-NMR parameters[4]. From these, the molecule has $C_1$ symmetry, and the phosphorus atoms form two two-membered bridges and a four-membered bridge, which are parts of three-, four-, and five-membered structural elements. The high-field position of the $^{29}$Si-NMR signal of the silicon atom of the three-membered ring is comparable with that in **1**[1a].

The X-ray structure analysis[5] confirms the constitution of **2** with the configuration shown in Figure 1. The strongly distorted four-membered ring is, as expected, folded ($|\bar{\tau}| = 13.1°$); the five-membered ring has flat twisted envelope conformation (sequence of the torsion angles from Si: 4.6, −13.9, 18.4, −14.8, 6.2°). Remarkable are the unequal Si–P bond lengths in the four-membered ring, which may principally be attributable to the different size of the substituents at the two silicon atoms.

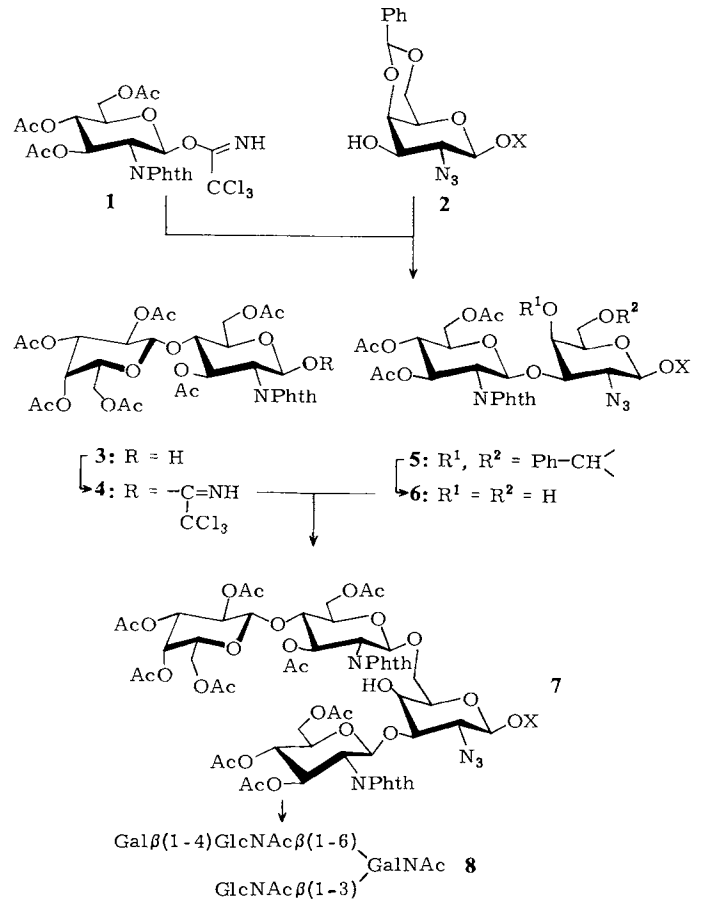
## Synthesis of a Tetrasaccharide of the Core Region of *O*-Glycoproteins**

By *Richard R. Schmidt** and *Gerhard Grundler*

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*



Oligosaccharides which are *O*-glycosidically linked to the serine- or threonine-side chains of proteins *via* *N*-acetylgalactosamine occur, *e.g.*, in the glycoproteins from epithelial mucous secretions, but also in classic blood-group substances[1]. These glycoproteins are designated mucine-type; here the tetrasaccharide **8** functions, *inter alia*, as the core region; α-glycosidically bound to serine, it is a component of the glycoproteins of the bronchial mucous of pa-

[**] Glycosyl Imidates, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. *G. G.* is grateful for the award of a Chemiefonds-Stipendium.—Part 8: R. R. Schmidt, M. Stumpp, *Liebigs Ann. Chem. 1983*, 1249.

tients suffering from cystic fibrosis[1]. Using the trichloroacetimidate method developed previously by us[2], we have now synthesized **8** from the disaccharide building blocks **4** and **6** using a method which dispenses with halogenoses and heavy metal salts[3].

Upon treatment with trichloroacetonitrile and sodium hydride, *N*-phthaloyl-3,4,6-tri-*O*-acetylglucosamine[4] afforded the *O*-(β-glycosyl) trichloroacetimidate **1** (76%, m.p. = 146 °C); the galactose derivative **2** with unprotected 3-OH group ($[\alpha]_{578}^{25}$ −10, $c$ = 1.0 in $CHCl_3$) was obtained by azidonitration of 3,4,6-tri-*O*-acetylgalactal and silylation of the free (anomeric) 1-OH group with *tert*-butyldimethylsilyl chloride (X—Cl)/imidazole (69%), deacetylation with sodium methoxide (88%), and benzylidenation with benzaldehyde dimethyl acetal/*p*-toluenesulfonic acid (78%). Under boron trifluoride-ether catalysis **1** and **2** react in dichloromethane at −20 °C to afford the β(1—3)-linked disaccharide **5**[5] (69%, m.p. = 238 °C (decomp.), $[\alpha]_{578}^{25}$ −22, $c$ = 1.0 in $CHCl_3$), which upon treatment with trifluoroacetic acid can be converted into the 4,6-unprotected disaccharide **6** (88%, m.p. = 203 °).

X = $(CH_3)_2SiC(CH_3)_3$

The lactosamine building block **3** was obtained from the peracetylated lactal by azidonitration, silylation of the anomeric 1-OH group with X—Cl/imidazole (63%), hydrogenation of the azido group with hydrogen, phthaloylation of the amino group with phthalic anhydride, treatment of the resultant compound with acetic anhydride/pyridine (73%), and cleavage of the silyl group with tetrabutylammonium fluoride (88%, $[\alpha]_{578}^{25}$ +39, $c$ = 1.0 in $CHCl_3$ after 2 h). **3** reacts with trichloroacetonitrile and sodium hydride to give the *O*-(2-amino-2-deoxylactosyl) trichloroacetimidate **4** (72%, $[\alpha]_{578}^{25}$ +43, $c$ = 0.5 in $CHCl_3$).

Under boron trifluoride-ether catalysis in dichloromethane at −20 °C the disaccharides **4** and **6** led exclusively to β(1—6)-coupling[5] and, hence, to the tetrasaccharide **7** (71%, m.p. = 168—170 °C, $[\alpha]_{578}^{25}$ +10, $c$ = 0.5 in $CHCl_3$). The phthaloyl group was removed first from **7** with hydrazine. Acetylation using acetic anhydride/pyridine (64%) and desilylation with tetrabutylammonium fluoride (74%) yielded an intermediate which could be used to glycosylate serine and threonine. 1-*O*-Acetylation with acetic anhydride/pyridine, reduction of the azido group with $NiCl_2/NaBH_4$, and *N*-acetylation with acetic anhydride afforded the completely acetylated tetrasaccharide as a 1:1 anomeric mixture [33%; $^1$H-NMR (250 MHz, $CDCl_3$, TMS): $\delta$ = 6.14 (d, α-1-H, $J_{1,2}$ = 3.7 Hz); 5.69 (d, β-1-H, $J_{1,2}$ = 8.9 Hz)]. The unprotected tetrasaccharide **8** ($[\alpha]_{578}^{25}$ = −5, $c$ = 0.2 in $H_2O$ after 2 h) was obtained by cleaving the *O*-acetyl groups with potassium carbonate in methanol (70%).

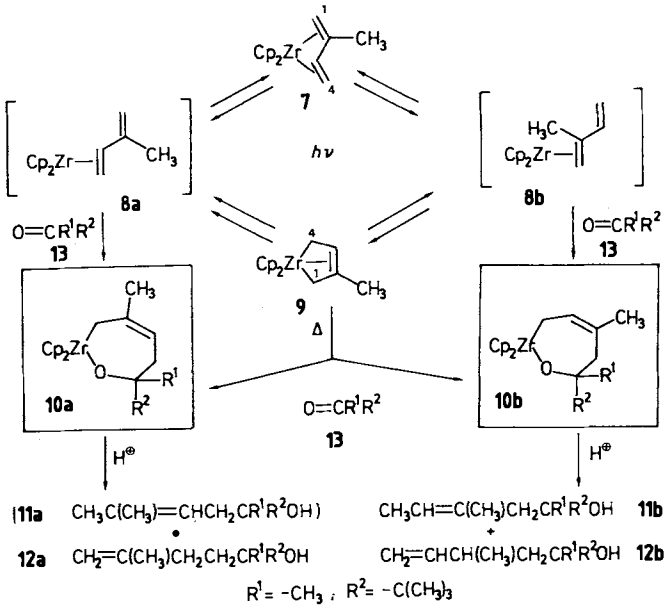
## Reversal of the Regioselectivity in the Zirconocene-Induced Coupling of a Ketone with Isoprene**

By *Gerhard Erker** and *Ulrich Dorf*



The reaction of (*s-cis*-isoprene)zirconocene **9** with organic carbonyl compounds often leads to regioselective CC coupling at the diene terminus C1 adjacent to the methyl group[3]. Recently, we showed that (*s-trans*-η$^4$-butadiene)zirconocene reacts much faster with aldehydes and ketones than the *s-cis*-isomer, with which it exists in equilibrium[6]. It was, therefore, expected that starting from (isoprene)zirconocene the course of the reaction and, hence, the regioselectivity of the CC coupling would also

[*] Priv.-Doz. Dr. G. Erker, U. Dorf
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

change if it were allowed to react with ketones under conditions allowing participation of the *s-trans*-isomer[5].

We have now treated (isoprene)zirconocene **9** with 3,3-dimethyl-2-butanone **13**. The major product (≈80%) of the thermally induced reaction (benzene, 60°C, 2 h) is the oxazirconacycloheptene **10b**, which can be hydrolyzed to give alcohols **11b** and **12b**. Photolysis of **9** and **13** in toluene solution leads to competitive formation of both **10b** and its isomer **10a**. The amount of **10a** increases as the temperature of the photolysis is lowered (Table 1). **10a** is also formed as the major product (≈75%) in the thermally induced reaction of (*s-trans*-η⁴-isoprene)zirconocene **7** and **13** at −70°C. Upon hydrolysis, only **12a** is obtained. (See Scheme II.)

Scheme II

Table 1. Reaction of (isoprene)zirconocene **9** with the ketone **13**: product ratio **10b**/**10a** as a function of the reaction conditions.

| | Δ | | | *hν* | |
|---|---|---|---|---|---|
| | +60°C | +37°C | 0°C | −40°C | −78°C |
| **10b** | 86 | 81 | 56 | 37 | 22 |
| **10a** | 14 | 19 | 44 | 63 | 78 |

The regioselectivity achieved [product ratio (**11b** + **12b**)/**12a**] was determined by gas chromatography (Table 1). In the thermally induced reaction of **9** and **13**, CC coupling at C1 of the diene is favored by >80/<20 relative to coupling at C4. When the irradiation is carried out at lower temperatures, the pathway *via* the very reactive intermediate (η²-isoprene)zirconocene complexes **8** becomes increasingly important[2b,6,7]. Here, the ketone couples preferentially with the less substituted olefin moiety. Irradiation of the reaction mixture at sufficiently low temperatures or reaction of the pure (*s-trans*-η⁴-isoprene)zirconocene isomer **7** eventually results in reversal of the observed regioselectivity: with 22/78 the product **10a** arising from coupling at C4 of the isoprene unit, *i.e.* away from the methyl group, is formed predominantly.

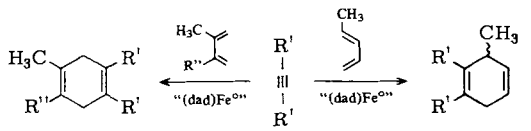
## Diels-Alder Reactions of Dienes with Alkynes Catalyzed by Diazadieneiron

By *Heindirk tom Dieck** and *Reiner Diercks*

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

Diels-Alder reactions between simple dienes and alkynes proceed thermally only under somewhat drastic conditions. We have now found that iron compounds modified by 1,4-diaza-1,3-dienes (dad) **4** as directive ligands catalyze the [4+2]cycloaddition of simple dienes with nonterminal alkynes at room temperature (R in dad, see Table 1). The same substrates yield 2:1 adducts or 2:2- and 1:2-cooligomers with ligand-nickel catalysts[3]. With bis(cyclooctatetraene)iron as catalyst, 1:1-adducts have been described[4].



The readily accessible complexes (dad)$FeCl_2$ **5** are activated in the presence of diene and alkyne using reducing agents such as triethylaluminum, alkylmagnesium halides, or magnesium-isoprene·2THF. Bis(diazadiene)iron, $(dad)_2Fe$ **6c**, also gives rise to an active catalyst with $AlEt_3$ at 90°C, just as do the multicomponent systems $Fe(acac)_3$/2dad/4$AlEt_3$ **7a** or $Fe(acac)_3$/2dad/6EtMgBr **8a**.

Table 1 indicates that the results depend on the substituents R on the ligand **4**. Under the conditions investigated to date, only *N,N'*-dialkyldiazadienes are active; in contrast, *N,N'*-diaryldiazadienes, which are highly active in diene cyclodimerizations, are not[1]. Since in the reaction of *trans*-1,3-pentadiene with 3-hexyne to afford **2** a center of chirality is formed, complexes with chiral dad (**4g**—**i**) were also used. Although **2** is also formed in good yield with **5g**—**i**, optical induction—in contrast to diene cyclodimerization using the same precatalyst[1]—could not be detected.

[a] Selectivity: mol-% **1**, **2** or **3** relative to volatile products; yield relative to diene, not optimized. [b] Not determined. [c] R in dad is (*R*)-$CH(CH_3)C_6H_5$. [d] R in dad is (1*S*, 2*S*, 3*S*, 5*R*)-3-pinanylmethyl. [e] R in dad is (1*R*, 3*R*, 4*S*)-3-menthyl.

In the presence of the catalyst, non-terminal unstrained alkynes do not react at room temperature. Diene dimers, which in the absence of alkynes are rapidly formed by the catalyst, also do not arise[1]; the only by-products found were alkyne trimers in low yields and, presumably as a secondary product of the work-up, the aromatic oxidation products of cyclohexadienes.

With the non-optimized reaction conditions given in Table 1, the conversion is 13—80%; however, in most cases the selectivity of formation of cyclohexadiene exceeds 90%. Up to 90 °C, neither cyclic dienes such as 1,3-cyclohexadiene or 1,3-cyclooctadiene nor the sterically demanding 2,5-dimethyl-2,4-hexadiene react with 3-hexyne. Experiments directed at the cycloaddition of isoprene to the strained 4,4,7,7-tetramethylcyclooctyne led only to isolation of good yields of the benzene derivative **9** as sole product[9].

**9**

Whereas with phosphanenickel catalysts the alkyne cooligomerization substrate of the diene is incorporated into the product after formation of the $C_8$ chain[3], with the (dad)iron system a normal, *i.e.*, unstrained, alkyne apparently prevents attack by a second diene molecule. In the absence of the alkyne, the dimerization of the diene is usually faster than the [4+2]cycloaddition investigated here. A (dad)iron($\eta^4$-diene)($\eta^2$-alkyne) could be a relatively stable intermediate, whose secondary reaction to afford the cyclohexadiene complex would be the rate determining step in the catalytic reaction.

## $^{27}$Al-NMR Spectroscopy: A Probe for Three-, Four-, Five-, and Sixfold Coordinated Al Atoms in Organoaluminum Compounds

By *Reinhard Benn**, *Anna Rufińska*, *Herbert Lehmkuhl*, *Edo Janssen*, and *Carl Krüger*

$^{27}$Al, like $^{10}$B and $^{11}$B, is suitable for NMR investigations of organometallic compounds of the 3rd main group elements because of its sensitivity and relatively favorable ratio of line width to spectral range. On the basis of the different chemical shifts $\delta(^{27}Al)$ of octahedrally and tetrahedrally coordinated aluminum salts, it has been assumed[1] that a connection exists between $\delta(^{27}Al)$ and the ligand symmetry at the metal. We show here that, in general, a simple correlation exists between coordination number and $\delta(^{27}Al)$ in organoaluminum compounds and that this can be used as an analytical aid to detect tri- and the much discussed pentacoordination[2] of Al atoms.

The NMR parameters of typical compounds together with their respective coordination number (C. N.) are given in Table 1. In contrast to earlier postulates[1], the high $\delta$-values of compounds **1**—**3** can be attributed to the tricoordination of the Al atom and not to substituent effects. In the dimeric compounds **4**—**6** the chemical shifts of the tetrahedrally coordinated Al atoms are found at approximately 153 ppm. With larger alkyl ligands (**6**) or higher degrees of association (**7**, **10a**), the linewidth increases markedly. Replacement of the terminal alkyl ligands by groups having α-heteroatoms can substantially alter $\delta(^{27}Al)$, *e.g.*, 140 for $(EtAlCl_2)_2$ and 95 for $(Cl_3Al)_2$. In contrast, $\delta(^{27}Al)$ for compounds (**4**—**11**) with tetracoordination is apparently insensitive to the type of ligand involved in the multicentered bonding. Ligands which have two do-

nor atoms (*e.g.* acetylacetonate or molecules containing $O(CH_2)_2XR_n$ groups (X = O, N)) can occupy an additional coordination site at the Al atom. In the dimeric, associated complexes **12**–**15**[4] $\delta(^{27}Al)$ lies at around 120 and we attribute this as arising from pentacoordination. In **12**, $\delta(^{27}Al)$ does not change up to 100 °C, and, hence, marked dissociation to tetracoordinated species[5] is precluded. Pentacoordination of the Al atoms has been confirmed by X-ray structural analysis of **12** (Fig. 1). The coordination geometry in **12** can be described as a distorted trigonal bipyramid in which two methyl groups and an oxygen atom (O1) are located in the equatorial plane. O1 is sited over a center of inversion and occupies an apical site of the second Al* atom with a longer Al*–O1 distance (+0.065 Å). Since the bond distance Al–O2 is 0.442 Å longer than the Al–O1 distance, O2 is apparently even more weakly bonded to aluminum.

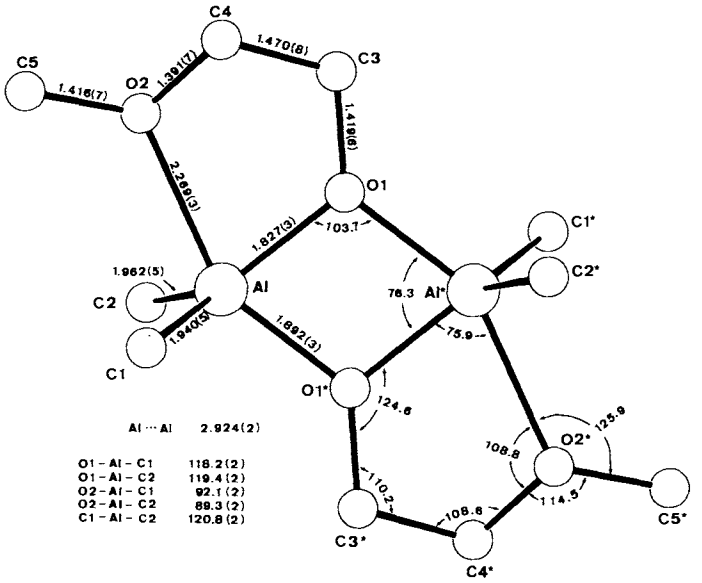

Fig. 1. Crystal structure of **12** with selected distances [Å] and angles [°]. Crystal data: Space group $P2_1/n$ (No. 14) $a = 7.4857(6)$, $b = 14.318(1)$, $c = 7.8940(4)$ Å, $\beta = 102.223(5)°$, $\rho_{calc} = 1.061$ g cm$^{-3}$, $Z = 2$, $\mu = 15.795$ ($Cu_{K\alpha}$), $\lambda = 1.5418$ Å, $R = 0.0614$, $R_w = 0.0776$ (998 observed reflections $I > 2\sigma(I)$, 1396 measured reflections, 73 refined parameters). Further details on the crystal structure determination can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50545, the names of the authors, and the journal citation.

Moieties containing three or more $CH_2$-units between the two O atoms function as monodentate ligands and lead to tetracoordinated Al atoms, as in **11** ($\delta(^{27}Al) = 150$).

Aluminum tris(acetylacetonate) **16** has an octahedral structure. In accord with the hexacoordination, $\delta(^{27}Al)$ is located at lower frequency and has a relatively small width at half-height ($\omega_{1/2}$). Accociates which formally correspond to the dialkoxy(alkyl)aluminum compounds $(R(RO)_2Al)_n$, and which until now have not been studied in detail, exhibit signals in the region of tetra- and hexacoordinated Al atoms. We therefore characterize these compounds as mixtures of the tetramers $R_nAl_4(OR)_{12-n}$ (R = Et, n = 1,...6), each of which has a central, hexacoordinated Al atom; this is also consistent with the results of mass spectroscopic studies.

Depending on the coordination number (3, 4, 5, or 6), organoaluminum compounds having similar terminal ligands thus exhibit characteristic chemical shifts, $\delta(^{27}Al)$. This property should be of importance for solving structural and analytical problems and together with the linewidths provide information upon degrees of association and equilibria.

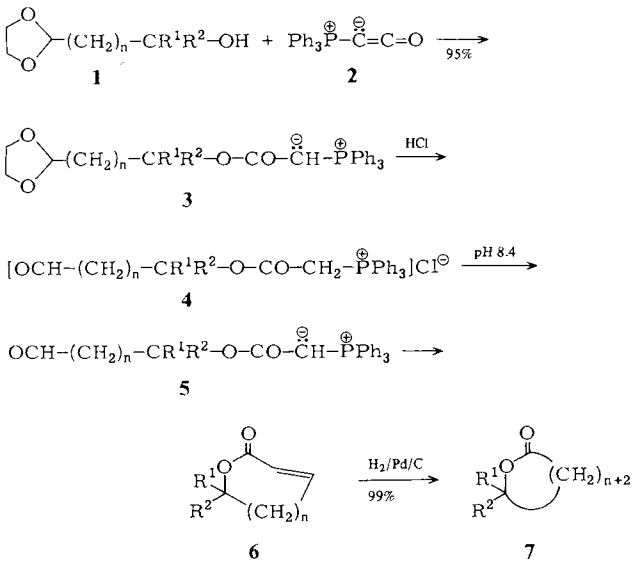
## A Novel Synthesis of Macrocyclic Lactones

By *Hans Jürgen Bestmann** and *Rainer Schobert*



*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

The readily accessible ketenylidenetriphenylphosphorane **2**[1] reacts with acetals of long-chain hydroxyaldehydes **1** to give ylides **3**. Dissolution of these in an equivalent amount of 0.1 N aqueous HCl leads to cleavage of the acetal moieties and formation of the phosphonium salts **4**. Slow dropwise addition of a solution of **4** into a buffer (pH 8.4) affords the ylides **5**, which are converted by intramolecular Wittig reaction[2] into α,β-unsaturated macrocyclic lactones **6** (Table 1). Consistent with our concepts of the mechanism of the Wittig reaction, the cycliza-

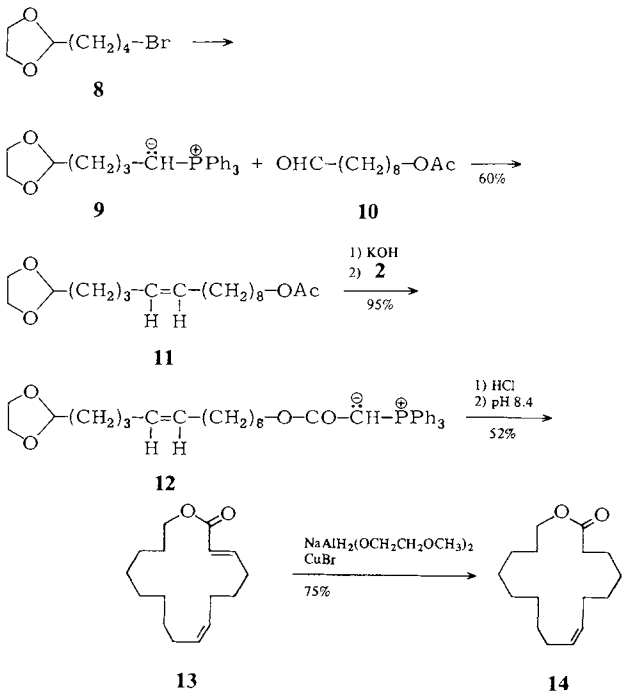
Henkestr. 42, D-8520 Erlangen (Germany)

tion proceeds *E*-selectively[3] (gas chromatographically determined amount of *Z*-isomer 5–8%).

Compounds **6** are reduced to the saturated lactones **7**; **7f** is the well-known exaltolide, **7g** a further natural product obtainable from galbanum oil (Scheme 1).

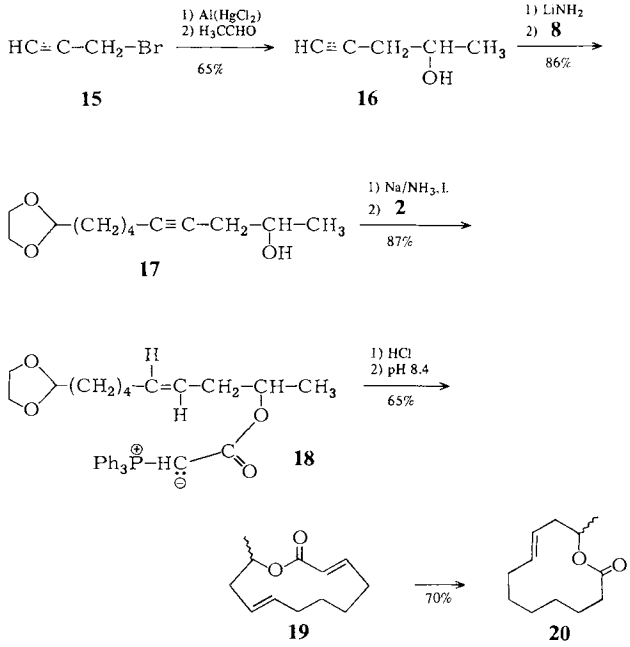
Scheme 1.

Table 1. Macrocyclic lactones **6** [a].



| 6 | n | $R^1$ | $R^2$ | Yield [%] [b] | B.p. [°C/torr] [c] |
|---|---|---|---|---|---|
| **a** | 7 | H | H | 65 | 58/0.01 |
| **b** | 7 | H | $CH_3$ | 60 | 50/0.05 (K) |
| **c** | 7 | H | *n*-$C_3H_7$ | 60 | 81/0.01 |
| **d** | 7 | $CH_3$ | $C_2H_5$ | 55 | 74–76/0.01 (K) |
| **e** | 9 | H | H | 65 | 78.5/0.02 |
| **f** | 11 | H | H | 60 | 76–78/0.05 (K) |
| **g** | 11 | H | $CH_3$ | 60 | 100/0.05 |

[a] A solution of **2** (3.02 g, 10 mmol) and **1** (10 mmol) in anhydrous toluene (100 mL) is heated under reflux (prim., sec. or tert. alcohol 2, 3 or 10d, respectively). After removal of solvent by evaporation, the oily residue (**3**) is dissolved in 101 mL 0.1 N aqueous HCl saturated with nitrogen (in the case of longer chains with 5% tetrahydrofuran), the solution allowed to stand for 1 h at RT, and then added dropwise (20 mL per h) to a well stirred two-phase mixture of 2 L aqueous buffer (3.68 g LiOH, 5.68 g 85% $H_3PO_4$, 2.96 g glacial acetic acid, 3.04 g $B(OH)_3$) and 1 L toluene. The phases are then separated; the aqueous phase is washed with toluene and the organic phase is dried over $Na_2SO_4$. After removal of the solvent by distillation, the residue is chromatographed on 20 g silica gel 60 with 200 mL hexane/ether (1:1); the eluate is evaporated down and distilled *in vacuo*. [b] Yield referred to **3**. [c] (K) signifies purification by Kugelrohr distillation; the temperature of the air-bath is quoted.



The 'musk ambrette' ambrettolide **14** was obtained as shown in Scheme 2.

5-Bromo-1-pentanol was oxidized to the aldehyde; reaction of its acetal **8** with triphenylphosphane furnishes the phosphonium salt. The corresponding ylide **9** reacts *Z*-selectively with 8-formyloctyl acetate **10** (readily accessible by ozone cleavage from oleyl acetate)[3] to give **11**; subsequent hydrolysis and reaction with **2** affords **12**, which is cyclized analogously to **3**→**6**. The resulting doubly unsaturated lactone **13** can be reduced selectively with Red-Al/CuBr[4] to **14**.

Recifeiolide **20**[5], which has been isolated from cultures of *Cephalosporium recifei*, could be synthesized in the *RS*-form *via* the route shown in Scheme 3.

Scheme 2. **11**, b.p. 104°C/0.03 torr; **13**, b.p. 99°C/0.02 torr; **14**, b.p. 154°C/1 torr.

Scheme 3. **16**, b.p. 127.3°C; **17**, b.p. 115°C/0.3 torr; **19**, b.p. 84°C/0.2 torr; **20**, b.p. 52.5°C/0.02 torr. Yield of **19** based on **17**.

The product formed from propargyl bromide **15** and aluminum in the presence of $HgCl_2$ reacts with acetaldehyde to give the yne-ol **16**, whose Li-salt can be converted with **8** into **17**. *E*-Specific reduction with sodium in liquid ammonia and subsequent reaction with **2** affords the ylide **18**, which is cyclized analogously to **3**→**6**. The macrocyclic *E,E*-diene **19** is isolated and selectively reduced analogously to **13**→**14** to give (*RS*)-**20**.

## A Method for the Synthesis of Ketones from Phosphorus Ylides and Olefins *via* "Mixed" Diorganoborinates

By *Hans Jürgen Bestmann** and *Thomas Röder*

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

We recently reported that the phosphonioborates **3** obtainable from phosphorus ylides **1** and the borane-tetrahydrofuran adduct **2** rearrange on heating to give the monoalkylborane-triphenylphosphane adducts **4**[1]. Reaction of **4** with olefins **5** in the presence of methyl or benzyl iodide **6** affords, aside from the phosphonium salts **7**, "mixed" trialkylboranes **8**, which can be converted by the DCME (dichloromethyl methyl ether) method[2] into the tertiary alcohols **11**.

**6**: $R^5$ = $CH_3$, $C_6H_5$–$CH_2$

**10, 12, 13**: **a**, X = Cl; **b**, X = $OCH_3$, **c**, X = $OC_6H_5$, **d**, X = o-

We have now carried out the reaction of **4** with X–H acidic compounds **10a—d**; even on prolonged reaction, only one mol of $H_2$ is evolved per mol of **4**. The monoalkylborinate-triphenylphosphane adducts thus formed were expected to react with **5** and **6** to give the salts **7** and the dialkylborinates **14** and be finally converted by the DCME method into the unsymmetrical ketones **15**[2,3].

[a] Bath temperature during Kugelrohr distillation. [b] Yields referred to **3**, not optimized. [c] Purification by preparative medium pressure liquid chromatography (MPLC) on a silica gel column (Merck, Lobar size B), elution with $n$-hexane/acetone 6:1. [d] As for [c] but elution with $n$-hexane/ethyl acetate 88:12. [e] Procedure for 3-tetradecanone **15f**: A solution of **3** (20 mmol), $R^1$=$CH_3$, in chlorobenzene (50 mL) is heated for 30 min at 131°C. The solvent is removed *in vacuo* and replaced by 50 mL of THF. A solution of **10d** (22 mmol), 1-undecene (20 mmol) and methyl iodide (20 mmol) in THF (10 mL) is then rapidly added dropwise at room temperature. After 48 hours' stirring at RT, the mixture is filtered to remove salt **7**; the filtrate is allowed to react with DCME and then oxidized [2]. The organic phase is freed of solvent, taken up in a little pentane, and extracted several times with 3 N NaOH to remove **10d**. After drying and removal of solvent, the residue is distilled in a Kugelrohr (analogously as in the case of **15a—c**, **17**). In the case of the lower boiling ketones **15d** and **15e** the residue is worked-up by preparative MPLC and Kugelrohr distillation.

We found that **12a—c** undergo considerable disproportionation to **13a—c** and **4**, especially on prolonged heating[4]. Reaction with **5** and **6** and subsequent DCME reaction led to a mixture of ketone **15** and tertiary alcohol **11**. If, however, the adduct **4** is treated in tetrahydrofuran with a solution of the bulky 2,4,6-trimethylphenol **10d**, an olefin **5** and methyl or benzyl iodide **6**, the disproportionation of **12** is completely suppressed. The borinate **12d** reacts immediately with **5** and **6** to give **14**. When $R^2$ = H, this hydroboration proceeds regioselectively at the terminal position. The conversion of **14** into the ketones **15** by reaction with **9** proceeds without difficulties (Table 1)[5].

Starting from benzylidenetriphenylphosphane **1** ($R^1$ = $C_6H_5$) we obtained from camphene **16**, *via* the intermediates **3** to **14**, the ketone **17**, which according to the $^1$H- and $^{13}$C-NMR data consists of 80% of the *endo* and 20% of the *exo* form, *i.e.* the hydroboration proceeds largely stereoselectively (yield 44%, b.p. 105°C/0.05 torr).

16   17

Since ylides are prepared from alkyl halides (or tosylates) and the olefins are accessible by Wittig reaction from carbonyl compounds, this method of synthesis for ketones can be regarded as based on two alkyl halides **18** and **19**, a carbonyl compound **20** and DCME **9** as fundamental building blocks.

The method which is also suitable for monoalkylboranes not accessible by hydroboration (*e. g.* $CH_3BH_2$, $C_6H_5CH_2BH_2$)[1], can also be regarded as a "reductive acylation" of olefins.

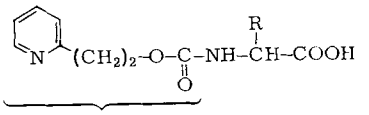
## The 2-(2-Pyridyl)ethoxycarbonyl-(Pyoc) Residue—An Acid- and Base-Stable, Hydrophilic Protecting Group for the Amino Function in Peptide Synthesis**



By *Horst Kunz** and *Regina Barthels*

*Dedicated to Professor Theodor Wieland on the occasion of his 70th birthday*

In the search for polarophilic, safe-to-handle, but nevertheless, readily removable amino protecting groups for the synthesis of peptides and glycopeptides[1], we developed the 2-(2-pyridyl)ethoxycarbonyl(Pyoc) group. It can be introduced most favorably by allowing the hydrochloride of the 2-(2-pyridyl)ethyl-*p*-nitrophenyl carbonate **1**, obtained straightforwardly from 2-(2-pyridyl)ethanol and *p*-nitrophenyl chloroformate, to react with amino acids in acetonitrile/water (1 : 1) at pH 9.5. The Pyoc-amino acids **2**[2] are isolated in good yields; the nitrophenol is extracted into ether at pH 6, and the aqueous solutions are concentrated. The more hydrophobic compounds Pyoc-leucine, Pyoc-phenylalanine, and even Pyoc-alanine are separated from sodium chloride by recrystallization from acetone, and the more hydrophilic compounds such as Pyoc-serine by recrystallization of the hydrochloride from isopropyl alcohol.

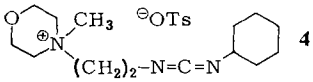
**1**

Pyoc

**2**, 85-100%

Peptide syntheses are performed with Pyoc-amino acids **2** using the mixed anhydride method[3] in dichloromethane. Thus, *e.g.*, **2a** and triethylamine are treated at −15 °C with an equivalent amount of ethyl chloroformate, and after 2 h at 0 °C the mixture is cooled to −15 °C and the amino acid-*tert*-butyl ester added dropwise. The Pyoc-dipeptide esters such as **3a** are purified by chromatography on silica gel (chloroform/methanol 12 : 1).

Pyoc-Phe-OH + H-Leu-O*t*Bu $\xrightarrow[NEt_3/CH_2Cl_2]{Cl-CO-OEt}$ Pyoc-Phe-Leu-O*t*Bu



**2a** **3a**, 76%

Also suitable for the preparation of the Pyoc-dipeptide ester **3** is the modified carbodiimide method[4] using *N*-hydroxysuccinimide (HO–SU). After removal of most of the dicyclohexylurea by filtration, any residues of this together with unreacted amino acid esters are separated chromatographically on silica gel.

Pyoc-Ser-OH + H-Ile-O*t*Bu $\xrightarrow[CH_2Cl_2/0°C]{DCC/HO-SU}$ Pyoc-Ser-Ile-O*t*Bu

**2b** **3b**, 83%

Pyoc-amino acids **2**, which are highly soluble in water, enable an effective peptide synthesis to be performed in water; the soluble carbodiimide **4** in the presence of 1-hydroxybenzotriazole (HOBT)[5] serves as the reagent[5].

**4**

Chromatography on silica gel affords the dipeptide esters **3** in good yield.

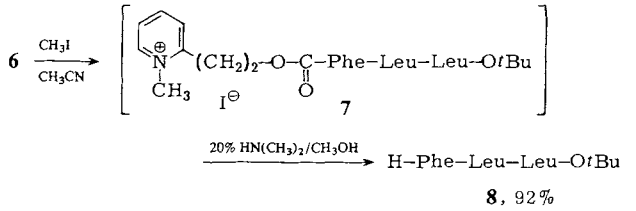
Pyoc-Ile-OH + H-PHe-O*t*Bu $\xrightarrow[HOBT/H_2O]{4}$ Pyoc-Ile-Phe-O*t*Bu

**2c** **3c**, 82%

The Pyoc group combines the advantages of solubility in water with those of stability to acids and bases. Cleave of the *tert*-butyl ester, *e.g.* from **3a**, with excess trifluoroacetic acid in dichloromethane leads (after neutralization) smoothly to zwitterionic Pyoc-dipeptides such as **5**. With an additional amino acid-*tert*-butyl ester, compounds of this type can be transformed (*e.g.* according to [4]) into tripeptides such as **6**.

**3a** $\xrightarrow[CH_2Cl_2/0°C]{CF_3COOH}$ Pyoc-Phe-Leu-OH

**5**, 88%



$\xrightarrow[DCC/CH_2Cl_2/HO-SU]{H\text{-}Leu\text{-}O\textit{t}Bu}$ Pyoc-Phe-Leu-Leu-O*t*Bu

**6**, 95%

For removal, the "safety form" of the protecting group is converted at room temperature with methyl iodide in acetonitrile into the pyridinium form **7**, which can be decomposed *via* an E1cB reaction in the presence of mild base to release the protected amino function (example: **6** → **7** → **8**).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

Using this modification the initially insensitive, readily manipulable, polarophilic protecting group can, therefore, be removed from the blocked peptide using mild conditions.—The method is not suitable for amino acids such as cysteine or methionine which are readily attacked by methyl iodide.

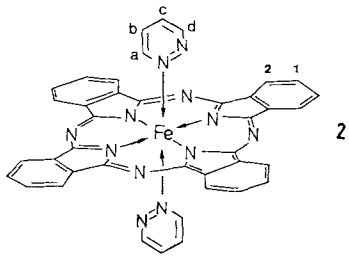
## Polymeric Electrically Conductive Phthalocyaninato(μ-s-tetrazine)iron**



By *Otto Schneider** and *Michael Hanack*

We have already reported on several occasions about the synthesis and properties of phthalocyaninato(Pc)-metal compounds $[PcML]_n$ which are one-dimensionally polymerized *via* bridging ligands L containing π-electrons[1]. In some cases the polymers $[PcML]_n$ exhibit a much higher electrical conductivity than the corresponding monomers PcML or $PcML_2$. Attempts have been made by a process of systematic variation to determine the influences of the three components of the polymer (macrocycle, central metal atom, bridging ligand) on its specific electrical conductivity σ.

Reaction analogously to the synthesis of the pyrazine(pyz) polymer $[PcFe(pyz)]_n$[1a,b], but with 1,2,4,5-tetrazine (tz)[2] as bridging ligand, affords the polymer $[PcFe(tz)]_n$ **1** as a blue, insoluble powder. The product **1** was characterized by elemental analysis, as well as simultaneous TG/DTA and IR measurements[3].

In contrast, with pyridazine (pdz) as ligand, formation of a polymer is not possible for steric reasons. The monomeric complex $PcFe(pdz)_2$ **2** is so soluble in $CDCl_3$ that its structure can be determined $^1$H-NMR spectroscopically. Due to the ring current of the aromatic Pc macrocycle, the signals of the pdz protons of **2** are shifted markedly upfield compared to those of the free ligand (cf. [1b]); a concomitant coordination of both nitrogen atoms of the ligand to the iron atom in PcFe can, on the basis of the NMR data[3], be ruled out. Our proposed structure for **1** is supported by this finding.

The electrical conductivity was measured on pressed-powder tablets (13 mm diameter, *ca.* 1 mm thick) by the 4-point technique at a pressure of $1 \times 10^8$ Pa (1 kbar). The tetrazine derivative **1** (without additional doping) has an electrical conductivity of $\sigma_{RT} = 1 \times 10^{-1}$ S/cm, the highest value so far recorded (cf. [1]) for a coordination polymer; activation energies $E_a$ of 95 meV (in the range 155—330 K) and 120 meV (in the range 80—155 K) are calculated from its temperature dependence using the expression $\sigma_T = \sigma_0(\exp -E_a/kT)$. Compound **1** thus exhibits semiconductor behavior.

We have also found high conductivities in undoped coordination polymers with cyanide as bridging ligand, for example in $[HPcFe(CN)]_n$ or $[PcFe(CN)]_n$ and $[PcCo(CN)]_n$[1c,d], whereas in a number of other one-dimensionally polymerized phthalocyaninatometal systems conductivities of $\sigma_{RT} > 10^{-3}$ S/cm are only achieved after doping (*e.g.* with iodine)[4].

Both **1** as well as the above mentioned cyanide derivatives are stable towards air and moisture and are thermally more stable than the iodine-doped polymers $[(PcMO)I_y]_n$ (M = Si, Ge) and $[(PcMF)I_y]_n$ (M = Al, Ga, Cr)[5a]. An accidental doping of **1** with oxygen cannot, of course, be ruled out; however, it is known that "doping" of PcFe with $O_2$ leads to a reduction in conductivity[5b].

## Cyanoformyl Chloride

By *Rolf Appel** and *Mustafa Siray*

The carbonyl cyanide $CO(CN)_2$[1] and the mixed fluoride cyanide CO(CN)F **8**[2] are the only cyano-substituted carboxylic acids to have been previously reported in the literature. Herein we report the chloride cyanide (cyanoformyl chloride) CO(CN)Cl **2**. It is formed in high yield together with sulfur dichloride on heating 2-chloro-2-(chlorothioimino)acetyl chloride **1**[3] in vacuo (Hg diffusion pump) at 800 °C. The pyrolyzate is collected in a cold trap; sulfur dichloride is converted with ethylene into bis(2-chloroethyl) sulfide and separated from **2** by recondensation[4].

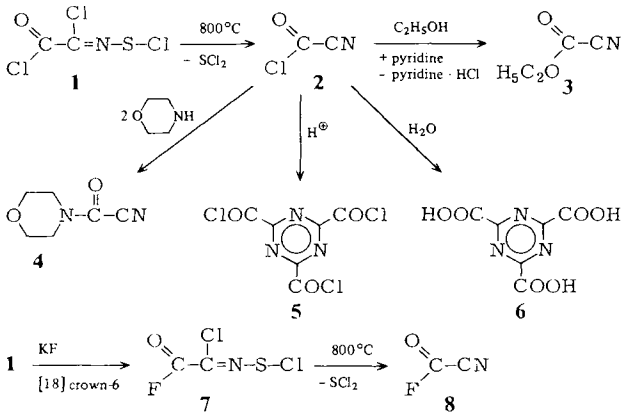

Table 1. Characteristic data of **2** and **8**.

**2**: Yield 3.6 g (88%); b.p. 20.3 °C; m.p. −89 °C; $^{13}C\{^1H\}$-NMR ([D$_8$]toluene, −20 °C): $\delta = 142.7$ (CO), 109.4 (CN); MS (20 eV): $m/z = 89$ (3%, $M^+$), 63 (54%, $M^+ - CN$), 61 (100%, ClCN), 54 (67%, $M^+ - Cl$); molecular weight: 82 (Victor Meyer)

**8**: Yield 2.7 g (74%); b.p. −49 °C; $^{19}F$-NMR (toluene/$CFCl_3$): $\delta = 23.0$; MS (70 eV): $m/z = 73$ (100%, $M^+$), 54 (34%, $M^+ - F$), 47 (59%, $M^+ - CN$), 45 (24%, FCN)

The structure of **2** is confirmed by correct elemental analysis, molecular weight determinations, by characteristic $^{13}C$-NMR and MS data (see also Table 1), and by its reaction with ethanol/pyridine and morpholine—in which the cyanoformyl derivatives **3** and **4**[5a] are formed. **2** can be stored without decomposition at −78 °C; at room temperature, however, slow and irreversible disproportion to the symmetric products phosgene and carbonyl cyanide takes place. In presence of acids, **2** is irreversibly converted within four days into the triazinetricarboxylic acid chloride **5**, while its violent reaction with $H_2O$ leads to the triazinetricarboxylic acid **6**[5b].

Cyanoformyl fluoride **8** could likewise be prepared from **1** by halogen exchange at the chlorocarbonyl function with KF/[18]crown-6[3] to give **7**, followed by pyrolysis. In contrast to **2**, **8** remains monomeric and shows no tendency to "symmetrize" into $COF_2$ and $CO(CN)_2$[4].

## The First Stable Phosphaketene**

By *Rolf Appel** and *Wilfried Paulen*

pπ–pπ-Multiple bonds between elements of the first and second short periods are a central theme in current main group chemistry. Iminophosphanes, phosphaalkenes, phosphaalkynes, even compounds with Si=Si and P=P double bonds are stable and have been prepared in large numbers during recent years[1]. The classical double bond rule could thus be abolished. On the other hand, only a few systems with cumulative double bonds and containing P=C sequences are known; these compounds, moreover, have a tendency to undergo self-addition. Thus, *tert*-butylphosphaketene, the first phosphaketene to be unequivocally detected, is stable as monomer only below −60 °C[2]. At higher temperatures it dimerizes to the diphosphetanedione.

We have now found that the first phosphaketene stable at room temperature, namely **3**, can be prepared by introduction of the unusually bulky tri-*tert*-butylphenyl moiety. It is formed on reaction of the disilylated phosphane **1** with phosgene, and can be isolated from the solution as orange crystals.

According to NMR investigations[3], molecular weight determination, elemental analysis, and IR and mass spectra, **3** clearly exists in monomeric form. Characteristic is the $^{31}P$-NMR signal, which, as in the case of *t*BuPCO[2] and *t*BuP=C=N*t*Bu[4], appears in the high field region at $\delta = -207.4$. Likewise, the IR band for the unsymmetric stretching vibration of the PCO group at 1953 $cm^{-1}$ is comparable with that of other cumulative double bond systems.

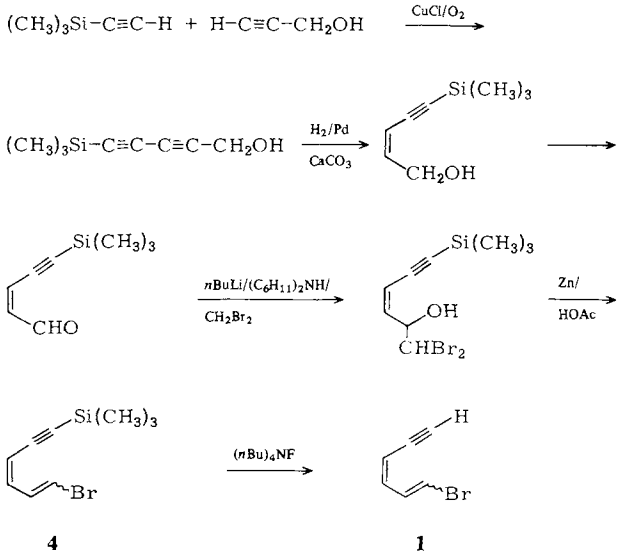
[4] O. J. Kolodiazhnyi, *Tetrahedron Lett. 23* (1982) 4933.



[5] *Procedure:* All operations were carried out under inert gas and with rigorous exclusion of light. A solution of **1** (3.2 g, 7.5 mmol) in toluene (8 mL) at 15 °C (water cooling) is treated dropwise, but relatively rapidly, with an 18% solution of phosgene (3% excess) in toluene. The cooling bath is then removed. After 5 minutes' heating to 40–45 °C, the reaction solution is immediately concentrated under vacuum (oil pump) and the residue quickly recrystallized from toluene at about 60 °C. Complete crystallization is achieved in the refrigerator (−2 °C). The orange crystals are filtered off, washed with a little *n*-pentane and dried in a vacuum (oil pump). Yield 0.8 g (35%), m.p. 115–117 °C.

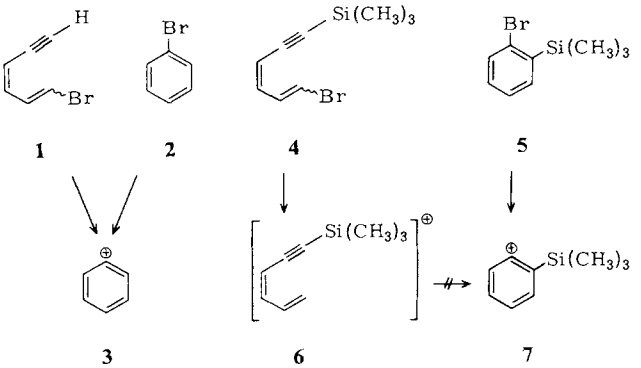
## Generation of the Phenyl Cation by Dissociative Ionization of a Dienynyl Bromide in the Gas Phase**

By *Gisbert Depke, Michael Hanack, Wolfgang Hümmer,* and *Helmut Schwarz**

*Dedicated to Professor Fred W. McLafferty on the occasion of his 60th birthday*

We recently reported[1] a novel route for the generation of substituted phenyl cations by anchimeric participation of a triple bond in the solvolysis of acyclic dienynyl trifluoromethanesulfonates. We now describe an experiment in which for the first time unsubstituted phenyl cation **3** has also been generated from a dienynyl derivative by dissociative ionization in the gas phase with participation of a triple bond[2]. The dienynyl bromides **1** and **4** employed in this experiment were prepared *via* the route given in Scheme 1.

Scheme 1.



Electron impact ionization (70 eV) of **1** with loss of $Br^{\odot}$ furnished a $C_6H_5^{\oplus}$ ion whose collisional activation mass spectrum (CAMS)[3] is identical in all respects with the CA mass spectrum of a $C_6H_5^{\oplus}$ ion which is accessible either by loss of $Br^{\odot}$ from the molecular ion of **2** or by elimination of HBr from protonated **2**. Since dehalogenation of **2** under the conditions of chemical ionization (CI)[4] leads directly to the phenyl cation **3**[5], it must be concluded from the identity of the CA mass spectra that **1** likewise yields **3** during the cleavage of $Br^{\odot}$—in a previously unobserved reaction. That **1** does not cyclize concomitantly with the formation of the molecular ions, but only after rupture of the C–Br bond, is evidenced by the following findings:

1) The CA mass spectra of the molecular ions of **1** and **2** are different[6];
2) The kinetic energy, $T_k$, released on decomposition of $\mathbf{1}^{\oplus\odot}$ and $\mathbf{2}^{\oplus\odot}$ to $C_6H_5^{\oplus}$ is different in each case.

The $T_k$ values for **1** and **2** are 0.37 kcal/mol and 0.55 kcal/mol, respectively, and were determined from the half-widths of the transient signals for

$$\underset{\mathbf{2}^{\oplus\odot}}{C_6H_5Br^{\oplus\odot}} \longrightarrow \underset{\mathbf{3}}{C_6H_5^{\oplus}} + Br^{\odot}$$

Furthermore, **1** gives a signal that no Gauss function satifies, whereas the signal for **2** corresponds to a Gauss function with $n = 1.8$.

The silylated compounds **4** and **5** likewise decompose under EI and CI conditions with rupture of the C–Br bond; however, the respective ions **6** and **7** thus formed furnish CA mass spectra which are so different that ionization to a common structure, *e.g.* **7**, can be completely ruled out.

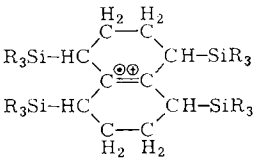
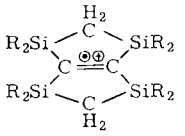
# $^{29}$Si-E(lectron)N(uclear)DO(uble)R(esonance)**



By *Hans Bock**, *Bernhard Hierholzer*, *Harry Kurreck**, and *Wolfgang Lubitz*



*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*

NMR double resonance methods have revealed—in the truest sense of the word—a multidimensional range of valuable information about diamagnetic molecules[2]. ESR spectroscopy, an established technique for the investigation of paramagnetic molecules $M^{\odot\oplus}$, $M^{\odot}$, and $M^{\odot\ominus}$ can likewise be extended to multiple resonance methods if the electron-nucleus hyperfine interaction is probed at the individual nuclei and not at the "unpaired" electron: The NMR transitions are measured *via* changes in absorption of a concomitantly irradiated radical specific ESR transition[3]. In further analogy to NMR spectroscopy numerous nuclei with nuclear spins $I \neq 0$ are suitable for ENDOR and TRIPLE resonance measurements; the influence of the nuclear properties on the ENDOR effect is predictable[4]. However, as a result of "critical" temperature- and solvent-dependence there is often only a "narrow window" open for observation of the frequently short-lived molecular radicals.

Herein we report on the first $^{29}$Si-ENDOR and TRIPLE resonance measurements on alkylsilyl-substituted radical ions[5] with natural isotopic abundance (4.70% $^{29}$Si) and, at the same time, demonstrate that the selective, oxygen-free oxidation system $AlCl_3/H_2CCl_2$[5] has the added advantage of being "ENDOR capable". Of the radical cations and radical anions investigated[5] (cf. Supplement, R = $CH_3$), the

example selected here is the radical cation of 1,4,5,8-tetrakis(trimethylsilyl)-1,2,3,4,5,6,7,8-octahydronaphthalene, whose ESR spectrum contains for $^1$H and $^{29}$Si nuclei a total of $5\times5\times5\times37+2(5\times5\times5\times5\times37)=13875$ (!) signals. The sterically shielded radical cation is persistent even at room temperature, and exhibits a dynamic behavior caused by $(-H_2C-CH_2-)$-wagging vibrations[6]. The ESR spectrum (Fig. 1: A) is dominated by the quintet signal of the four H($CSiR_3$)-protons; the satellites flanking both sides of this quintet arise from the corresponding quintet of a radical with a single $^{29}$Si nucleus present in $4.70\times4=18.8\%$ natural abundance. On irradiation into the $^1$H main signal, the $^1$H-ENDOR spectrum results (Fig. 1: B), on saturation of the satellite signal the $^{29}$Si($+^1$H)-ENDOR spectrum (Fig. 1: C).

A comparison of the spectra (Fig. 1) immediately reveals the advantages of $^1$H and $^{29}$Si ENDOR experiments over conventional ESR measurements:

1) In the ENDOR experiment each set of equivalent nuclei furnish only one signal pair: the "37 tet" becomes one pair of lines and the total of 13875 ESR signals of the $C_{22}H_{48}Si_4$ radical cation are reduced to 5 ENDOR line pairs (Fig. 1: Ⓑ and Ⓒ), corresponding to the four different protons and $^{29}$Si. The gain in resolution ESR⇒ENDOR amounts to several orders of magnitude.

2) The ENDOR technique enables the hyperfine coupling constants to be determined even when the ESR spectrum is either only incompletely resolved (Fig. 1: Ⓐ) or unresolved. Even the spin distribution for large organosilicon radicals of lower symmetry can be derived from the "hyperfine information"—including that from $^{29}$Si-ENDOR measurements (Fig. 1: Ⓒ).

3) In the case of small $^{29}$Si couplings or poorly resolved ESR satellite spectra, these should be detectable in the ENDOR experiment by systematic changes in position of the external magnetic field in the ESR spectrum (Fig. 1: Ⓐ and Ⓒ). As important additional information the relative signs of the $^1$H and $^{29}$Si couplings can be determined by TRIPLE resonance measurements (see caption of Fig. 1 and Supplement). Since the $^{29}$Si nucleus has a negative magnetic moment, the positive s-spin density at the Si center demonstrated here corresponds to a negative $^{29}$Si coupling.

4) The hyperfine couplings, which are easily and unambiguously measurable by means of the ENDOR technique, can be monitored as a function of experimental parameters such as solvent or temperature: thus, in the tetrakis(trimethylsilyl)octahydronaphthalene radical cation $a_{^{29}Si}$ decreases and $a_H^{CH}$ increases with increasing temperature, from which it follows for the molecular dynamics that, on the ENDOR time scale and contrary to steric demands, the H($CSiR_3$) protons have a higher probability of being located in the axial position favoring hyperconjugation.

[**] Radical Ions, Part 58.—Part 57: W. Kaim, U. Lechner-Knoblauch, P. Hänel, H. Bock, *J. Org. Chem.*, in press; cf. also W. Lubitz, W. Brosser, B. Kirste, H. Kurreck, K. Schubert, *Z. Naturforsch. A 33* (1978) 1072.

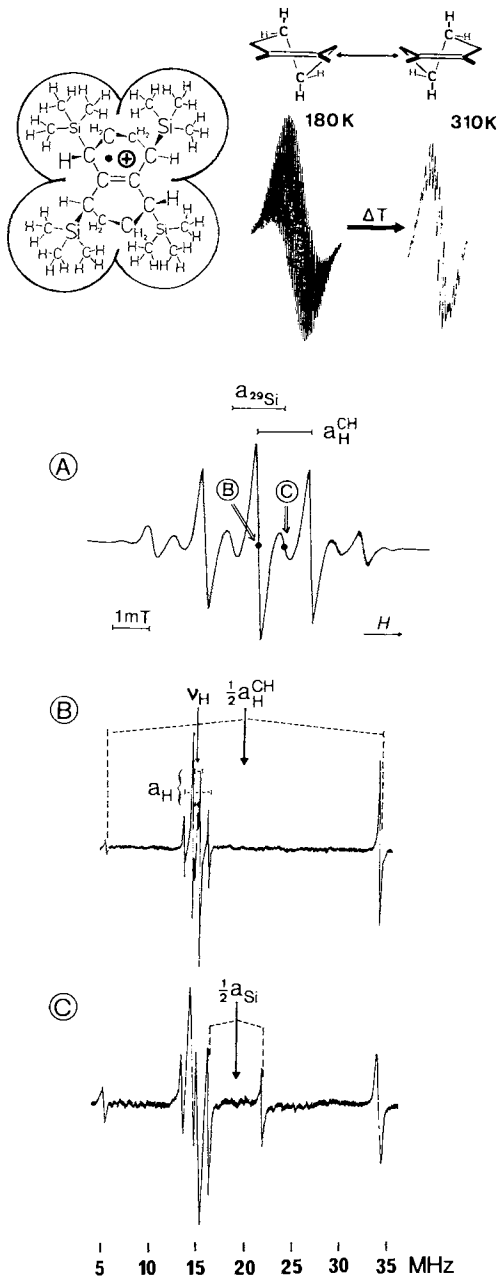

Fig. 1. ESR and ENDOR spectra of the radical cation of 1,4,5,8-tetrakis(trimethylsilyl)-1,2,3,4,5,6,7,8-octahydronaphthalene generated with $AlCl_3/H_2CCl_2$ (for details of the recording conditions cf. Supplement). Ⓐ ESR spectra at 200 K together with a section showing the *T*-dependence at 180 K (vibration frozen-in) and 310 K (vibration activated). Ⓑ $^1$H-ENDOR spectrum at 235 K: All couplings are resolved (signs from TRIPLE resonance measurements: $a_H^{CH} = +39$ MHz≙1.35 mT (!), $a_H^{NH} = +0.094$, $a_H^{SiR_3} = +0.026$, $a_H^{CH_3} - 0.011$ mT). Ⓒ $^{29}$Si-ENDOR spectrum ($a_{^{29}Si} = -37.8$ MHz≙1.33 mT).

5) ENDOR line amplitudes and widths and their dependence on experimental parameters provide additional information on the structure and molecular dynamics of the radicals investigated in solution (cf. Supplement): Thus, for an optimum $^{29}$Si-ENDOR effect the rotation correlation time is $\tau_R = 0.3$ ns at a hyperfine anisotropy of $TrA_{Si}^2 = 3$ MHz$^2$.

Summarizing, the ENDOR effect of the $^{29}$Si nuclei in the radical cation studied here is comparable with that of the protons. Measurement problems could be encountered if the radical contains only one Si nucleus, or if the π spin density at the Si center is rather large. In other cases ENDOR and TRIPLE resonance experiments on $^{29}$Si nuclei in natural abundance should decisively extend the measuring technique and generally contribute to a better understanding of the structure and dynamics of radical cations which are especially accessible in large numbers from π systems containing $R_3SiCH_2$ donor substituents[5].

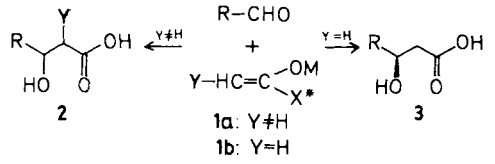
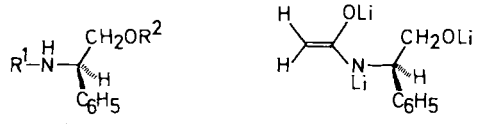
## Stereoselective Aldol Reaction with (*R*)-*N*-Acetyl-α-phenylglycinol**

By *Manfred Braun** and *Ralf Devant*



Chiral enolates **1a** facilitate aldol reactions with very high selectivity with formation of almost diastereomerically and enantiomerically pure products **2**. The prerequisite for such reactions, apart from an effective chiral auxiliary group X* and a suitable metal M, is a substituent Y in the α-position of **1a**[1]. The problem of stereoselective addition of an (α-unsubstituted) acetate enolate **1b** to prochiral carbonyl compounds to give enantiomerically pure β-hydroxycarboxylic acids **3** cannot be satisfactorily resolved with the chiral auxiliary groups X* previously employed in **1b**[2].

We have now investigated whether (*R*)-*N*-acetyl-α-phenylglycinol **4a** offers a solution to the problem. The trilithium compound **5**, obtainable from **4a** by threefold deprotonation with *n*-butyllithium, reacts with aldehydes RCHO at −70 °C to give mixed adducts **6**/**7**, the composition of which, however, cannot be determined by $^1$H-NMR spectroscopy. To determine the diastereoselectivity in the addition step we cleaved the crude adducts **6**/**7** into the β-hydroxycarboxylic acids **3a**–**d** and (*R*)-α-phenylglycinol by heating with methanolic potassium hydroxide[3]. The enantiomeric excess (*e.e.*) of the acids **3** has been determined by a comparison of the specific rotations and by $^1$H-NMR spectroscopic investigations of the methyl esters obtained with diazomethane in the presence of chiral shift reagents. From the results can be deduced the diastereomeric ratio **6**:**7** in the addition of **5** (Table 1).



It emerges that **5** shows a distinctly higher diastereoselectivity in the reaction with prochiral carbonyl compounds[4] than the previously investigated acetate enolates **1b**[1]. Moreover, this method enables the isolation of enantiomerically pure β-hydroxy carboxylic acids **3a**–**d**: In each case the diastereomer in excess can be obtained in isomerically pure form from the spontaneously crystalliz-

[a] Mixture of crude adducts. [b] Yield after recrystallization, referred to **4a**, not optimized. [c] Procedure for (*R*)-**3a**: A stirred solution of **4a** (1.8 g, 10.0 mmol) in 1,2-dimethoxyethane is treated under $N_2$ at 0°C with 30 mL of a 1.6 M solution of *n*-butyllithium in *n*-hexane and stirred for 15 h at 0°C. After cooling to −78°C and addition of 1.0 mL (10.0 mmol) benzaldehyde, the reaction mixture is stirred for a further 30 min at −78°C and poured into a saturated $NH_4Cl$ solution. Several extractions with $CHCl_3$, drying over $Na_2SO_4$ and removal of the solvent affords 2.74 g of a colorless crude mixture of **6a/7a**, which on recrystallization from $CH_2Cl_2$ yields 1.22 g of **6a**.—A mixture of **6a** (1.22 g, 4.30 mmol), methanol (60 mL), water (30 mL) and KOH (2.4 g, 43 mmol) is heated under reflux for 15 h. The methanol is distilled off, the residue washed with $CHCl_3$, rendered acid (pH 2) with dilute hydrochloric acid, and extracted with ether. After removal of the solvent there remains 0.60 g of **3a**, colorless crystals, m.p. 116–118°C, $[\alpha]_D^{25}$ = +17.9 (*c* = 2.33, ethanol) (116–118°C and +18.2°, resp. (*c* = 4.95, ethanol) after D. S. Noyce, C. A. Lane, *J. Am. Chem. Soc. 84* (1962) 1635). The enantiomeric purity of the methyl ester of **3a** (obtained with diazomethane) is greater than 97% ($^1$H-NMR in presence of Eu(tfc)$_3$). [d] Change of sign of configuration, since *n*-propyl—other than the groups R in **3a–c**—has a lower order than $CH_2COOH$.

ing crude adducts **6/7** by a single recrystallization; alkaline hydrolysis leads to the carboxylic acid **3** with optical purities of more than 97%. Concomitantly, the chiral auxiliary agent **4b** is liberated, from which **4a** can be regenerated by conversion of **4b** into the diacetyl compound **4c** and subsequent ester hydrolysis[5]. As a rule, **4b** is readily accessible by reduction of α-phenylglycine. Since both optical antipodes of this amino acid are commercially available, enantiomerically pure β-hydroxy carboxylic acids can be synthesized in any desired configuration. We have proven the absolute configuration of **3b** by conversion into (*R*)-2,2-dimethyl-3-hydroxypentane.

## A New Route to Tellurium-Nitrogen Compounds**

By *Joseph S. Thrasher* and *Konrad Seppelt**

Whereas there is a vast chemistry of sulfur-nitrogen compounds, very little is known about the corresponding tellurium-nitrogen systems. A few Te–N compounds have been prepared by replacement of an F atom in $TeF_6$ by nitrogen-containing groups, resulting, *e.g.*, in $H_2N-TeF_5$[1]. However, the possibilities offered by this method seem to have been exhausted.

We have now found that $TeF_5-Cl$ can add photolytically to nitriles with retention of the $TeF_5$ group.

$$TeF_5Cl + RC{\equiv}N \xrightarrow{h\nu;\ 20°C} F_5Te-N{=}CRCl + ClRC{=}N-N{=}CRCl + \cdots$$

R = Cl, $CF_3$

$F_5Te-N{=}CCl_2$, pentafluorotellurium isocyanidedichloride is obtained as a colorless liquid in 32% yield; $Cl_2C{=}N-N{=}CCl_2$[2] is formed as a by-product (9%), probably as a result of the decomposition of $F_5Te-N{=}CCl_2$. No evidence could be found for the formation of the unknown $Te_2F_{10}$, although $S_2F_{10}$ is observed in the reaction of $SF_5Cl$ with nitriles[3]; instead, both $TeF_4$ and $TeF_6$ are formed.

The reaction of $F_5Te-N{=}CCl_2$ with excess HF gives the amine $F_5Te-NH-CF_3$ as a clear liquid in 90% yield. The anion $[F_5Te-N-CF_3]^-$ can be generated directly from $F_5Te-N{=}CCl_2$ by reaction with caesium fluoride. The caesium salt is a crystalline solid which is readily soluble in acetonitrile.

$$F_5Te-N{=}CCl_2 \xrightarrow[-HCl]{HF;\ 40–50°C} F_5Te-NH-CF_3$$

$$F_5Te-N{=}CCl_2 \xrightarrow{CsF;\ 70°C} Cs^+[F_5Te-N-CF_3]^-$$

$F_5Te-N{=}CF_2$ is produced by pyrolysis of the salt formed between $F_5Te-NH-CF_3$ and KF in 35% yield. Unlike the corresponding sulfur compound, it does not isomerize to $F_4Te{=}N-CF_3$[3]. This is explained by the inability of tellurium(VI) to form five-coordinated species[4].

A mercury derivative, $Hg[N(CF_3)TeF_5]_2$, has also been obtained by reaction of $HgF_2$ with $F_5Te-NH-CF_3$. This

[*] Prof. Dr. K. Seppelt, Dr. J. Thrasher

Fabeckstrasse 34–36, D-1000 Berlin 33 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

colorless, crystalline, sublimable mercury derivative serves for the preparation of other Te–N compounds:

$$F_5Te-NH-CF_3 \xrightarrow{HgF_2,\ 70-80\,^\circ C} Hg[N(CF_3)TeF_5]_2$$

$$Hg[N(CF_3)TeF_5]_2 \xrightarrow{2XF} HgF_2 + 2X-N(CF_3)TeF_5$$

$X = Cl, Br$

Both chlor- and bromamine compounds are surprisingly stable; however, they decompose under UV-irradiation to yield the first compound with two tellurium atoms bonded to the same nitrogen atom.

$$2Cl-N(CF_3)TeF_5 \xrightarrow{hv;\ 20\,^\circ C} Cl_2 + CF_3N(TeF_5)_2 + \cdots$$

All new compounds have been identified by spectroscopic methods and by elemental analysis where possible. In all cases the $^{19}F$-NMR spectra exhibit an $AB_4$ pattern with $^{125}Te$ satellites, which is characteristic of $TeF_5$ groups.

The analogous reactions with $SeF_5Cl$ gave no evidence for formation of $F_5Se-N$ compounds and, hence, once again no light is thrown on selenium-nitrogen chemistry of this type.

## Unprecedented Oxidative Addition of the $P_4S_3$ Cage Molecule with Phosphorus-Phosphorus Bond Cleavage; Synthesis and Molecular Structure of $[Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)]_2$

By *Carlo A. Ghilardi, Stefano Midollini,* and *Annabella Orlandini**

As part of a study[1] on the synthesis and characterization of transition-metal complexes containing the $P_4$ molecule or its derivatives as ligands, we studied the reaction of the $P_4S_3$ cage molecule with the $d^8$-square planar $IrCl(CO)(PPh_3)_2$ (*Vaska*'s complex), whose ability to undergo oxidative additions with a variety of molecules is well-known. In $Mo(CO)_5P_4S_3$ the $P_4S_3$ cage was found to coordinate the metal *via* the apical P atom[2]. A metal-promoted fragmentation of this cage has been reported recently, leading to the triangular $P_2S$ unit[3].

When a solution of $P_4S_3$ in benzene is allowed to react with an equimolar solution of $IrCl(CO)(PPh_3)_2$ in the same solvent at *ca.* 60 °C, the solution rapidly turns red-brown and green crystals slowly precipitate. The complex formed, $\{Ir(P_4S_3)(PPh_3)Cl(CO)\}$, is air stable and practically insoluble in common organic solvents; its IR spectrum (Nujol) exhibits $\nu$(CO) at 2055 $cm^{-1}$. The increase of the $\nu$(CO) relative to *Vaska*'s complex (1965 $cm^{-1}$) is consistent with oxidation of the metal on adduct formation.

As indicated by the X-ray structure analysis (Fig. 1), the title compound is a dimeric iridium(III) derivative, the $P_3$ ring of the $P_4S_3$ molecule has opened, and one $PPh_3$ group *per* metal center has been displaced. To our knowledge no oxidative addition involving the rupture of a PP bond has previously been reported.

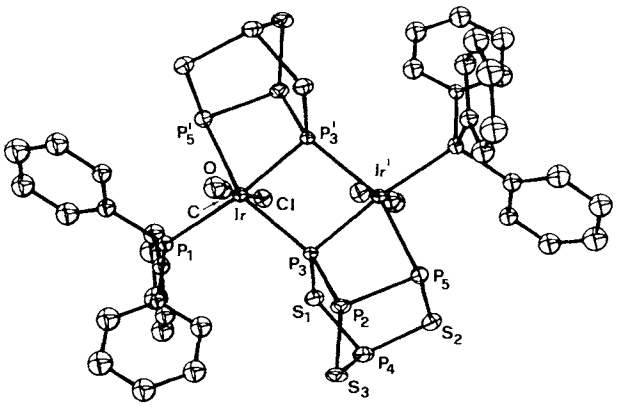

Fig. 1. Crystal structure of $[Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)]_2$. ORTEP representation with 30% probability ellipsoids. Monoclinic, space group $P2_1/n$, $a = 16.252(8)$, $b = 11.421(5)$, $c = 14.443(7)$ Å, $\beta = 97.53(4)°$, $Z = 2$. The structure was solved by the heavy atom method and refined to $R = 0.048$ and $R_w = 0.046$ for 2933 reflections having $I \geq 3\sigma(I)$. Selected bond distances: Ir–Cl 2.396(4), Ir–P1 2.421(4), Ir–P3 2.433(4), Ir–P3′ 2.356(4), Ir–P5′ 2.422(4), Ir–C 1.88(2), C–O 1.11(2), Ir...Ir 3.691(1) Å.

In the centrosymmetric, dimeric complex the two Ir atoms are held together by two $P_4S_3$ groups; each $P_4S_3$ cage functions as a bidentate ligand and bridges the two Ir atoms through one P atom, while another P atom is linked to only one Ir atom. The distorted octahedral geometry of each Ir atom is completed by a $PPh_3$ ligand, a Cl atom, and a CO group; Cl and CO are *trans* to each other (Cl–Ir–CO 177.1(6)°). The distortions from the idealized octahedral geometry are mainly due to the steric requirements of the $P_4S_3$ group, which although strongly distorted upon coordination, nevertheless, retains its rigidity. Due to the presence of the inversion center between the two Ir atoms, the $Ir_2P_2$ unit is strictly planar with an Ir...Ir separation of 3.691(1) Å and an Ir–P3–Ir′ angle of 100.8(1)°.

The $P_4S_3$ group, in contrast to compounds in which it behaves as a monodentate ligand, is significantly distorted compared to the uncoordinated molecule[5]. In fact, due to the bidentate coordination the $P_4S_3$ unit no longer has $C_{3v}$ symmetry: the P5–P2–P3 angle opens from 60.0° to 84.8(2)° and the P5–P3 bond is cleaved. It follows that the P3···P5 separation is 3.055(5) Å, whereas the P2–P3 and P2–P5 distances (2.249(5) and 2.281(6) Å, respectively) are only a little longer than the average value of 2.235 Å reported for the free ligand.—It is noteworthy that a

## Fourier Transform Far-Infrared (FT-Far-IR) Spectroscopy of Silver Atoms and Silver Clusters Entrapped in Zeolite NaY**

By *Geoffrey A. Ozin**, *Mark D. Baker*, and *J. Mark Parnis*

Metal clusters entrapped within zeolite cages are of catalytic importance[7]. Crystallographic data on silver atoms and silver clusters in zeolites have made them an attractive system for detailed spectroscopic study, since they are in a well defined setting as found for metal clusters entrapped in rare gas matrices[18–20].

Here, we wish to report the FT-far-IR spectra (400 to 30 $cm^{-1}$) of Ag atoms and clusters entrapped within the cages of zeolite NaY (Fig. 2). The spectrum of the zeolite recorded before cation exchange but after dehydration at 600°C is very similar to that reported by *Peuker et al.*[19]. All the bands below 200 $cm^{-1}$ are assigned to vibrations of sodium ions at different sites in the zeolite lattice. The strong doublet at 190 and 150 $cm^{-1}$ has been assigned to cationic occupancy of site II and site I, respectively, and the band at 100 $cm^{-1}$ to a site I′ sodium ion.

As shown in Figure 2 new features appear below 170 $cm^{-1}$ for the ion-exchanged zeolites; this is striking, and we can immediately assign these to vibrational modes involving silver species. Investigations by *Brodskii et al.*[18] of zeolites exchanged with Na, K, Rb, and Cs have shown that the vibrational frequencies of cationic modes (at the same sites) are proportional to $m^{-1/2}R^{-3/2}$, where $m$ = cation mass and $R$ = cationic radius. Application of this empirical formula to $Ag^+$ located at sites I and II indicates that $Na^+/Ag^+$ exchange should give rise to bands shifted by *ca.* 120 $cm^{-1}$ to lower frequency. We therefore tentatively assign the bands at 60 and 30 $cm^{-1}$ in the $Ag_{55}Y$ spectrum (Fig. 2c) to vibrational modes of $Ag^+$ in sites I and II, respectively. This then allows us to assign the bands above 60 $cm^{-1}$ to either Ag atom vibrations or to $Ag_n$ cluster modes.

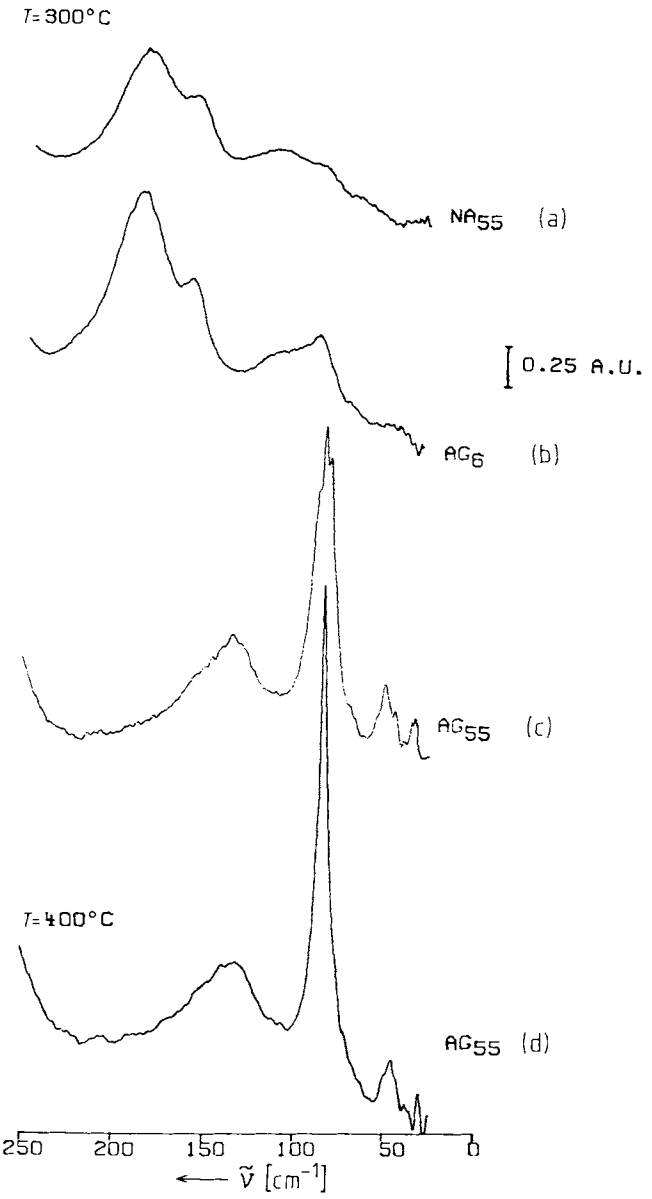

Fig. 2. FT-far-IR spectra of the zeolites $Na_{55}Y$ (a), $Ag_6Na_{49}Y$ (b), and $Ag_{55}Y$ (c: at 300°C, d: at 400°C).

It has been conclusively shown[23] that the thermal treatment of $Na^+/Ag^+$ exchanged Y zeolites *in vacuo* induces autoreduction and clustering processes which give rise to the charged silver clusters $Ag_2^+$ (sites I and I′) and $Ag_n^{q+}$ (n = 5–13; α-cage), as well as $Ag^0$ (site I). For $Ag_6Na_{49}Y$, the majority of species are $Ag^0$ and $Ag_n^{q+}$, whereas with the fully exchanged $Ag_{55}Y$, $Ag_2^+$ is also present. For $Ag_2^+$ the vibrational spectrum of the parent $Ag^0$ at site I will be perturbed by the approach of a $Ag^+$ at site I′. We assign the sharp multicomponent band at 80 $cm^{-1}$ to $Ag^0$ and $Ag_2^+$, and the band at 130 $cm^{-1}$ to the larger cluster in the α-cage. Annealing the $Ag_{55}Y$ (300→400°C) has the effect of removing the splitting of the 80 $cm^{-1}$ band and of sharpening this peak. This result indicates that the band splittings are probably not due to site effects associated with the Si/Al distribution around sites I and I′, and do not arise

M. P.* expresses his gratitude for an NSERC graduate scholarship. The assistance of *K. Molnar* and *T. Higson* in designing the *in situ* FT-far-IR zeolite cell was invaluable.

from $^{107}Ag/^{109}Ag$ isotopes. A more plausible explanation is to ascribe the multiplet structure to a perturbation of the $Ag^0$ or $Ag_2^+$ cage vibration modes by residual intrazeolitic $H_2O$ in the α- or β-cage ($H_2O$ is present at 300°C but absent at 400°C).

This study demonstrates that it is viable to investigate the infrared vibrational spectra of metal atoms and clusters immobilized in zeolite supports. This will provide new insights into the nature of their interaction with the surroundings (metal-support effects). An extension of this study in combination with other spectroscopic studies should certainly increase the amount of information.

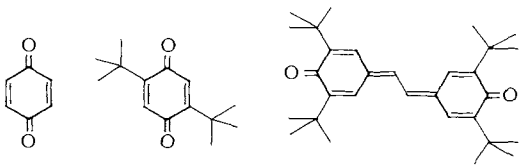
## Efficiency of the Physical Quenching of Singlet Oxygen with Benzoquinone Derivatives**

By *Ernst Gassmann, Titus A. Jenny,* and *André M. Braun** 

*Dedicated to Professor Günther O. Schenk on the occasion of his 70th birthday*

*p*-Benzoquinone and some of its derivatives are readily reduced by hyperoxide (superoxide) to the corresponding semiquinone radical anions (a). Since the product of reduction absorbs in the visible spectral region this reaction provides a very suitable means of analyzing the hyperoxide[1].



(a)

We have also used this reaction as a basis for working out an analytical method for the differentiation and parallel determination of singlet oxygen and hyperoxide[1]. It can be shown by hydrophobization of the benzoquinone to be reduced that solvated electrons can only penetrate the hydrophilic/hydrophobic interface of microemulsions formed with ionic surfactants under certain experimental conditions. An analogous transfer reaction of $O_2^{\odot\ominus}$ can be practically ruled out[1].

1 2 3

The parallel analysis of singlet oxygen and hyperoxide requires that the reagents to be used are physically and chemically specific. This means for the benzoquinones **1** and **2** that their chemical reactivity and their efficiency as physical quenchers can be neglected as far as singlet oxygen is concerned. We have already described the experimental conditions under which the former mentioned requirement is fulfilled[1]; we now report on the efficiency of the physical quenching of singlet oxygen caused by *p*-benzoquinone **1** or 2,5-di-*tert*-butyl-*p*-benzoquinone **2** (b).

(b)

When an aerobic solution of tetraphenylporphyrin ($5 \times 10^{-5}$ M) in tetrachloromethane is excited with monochromatic light of wavelength $\lambda = 546$ nm (HgXe 1000 W, monochromator), the phosphorescence of the $^1\Delta_g$-$O_2$ at 1270 nm can be measured[2a]. Measurements of signal intensity as a function of the concentration of a given quencher enable the product of the constants $k_q\tau$ to be calculated according to the Stern-Volmer equation (c).

$$I_0/I = 1 + k_q\tau[Q] \qquad (c)$$

$I_0$ is the signal intensity of solutions in the absence of quencher, $I$ that of solutions in the presence of quencher, $k_q$ is the rate constant of the physical quenching (b), and $\tau$ is the lifetime of the singlet oxygen in $CCl_4$ ($3 \times 10^{-2}$ s[2b]). For relatively large quencher concentrations [Q], deviations from the linearity required by equation (c) are observed (Fig. 1). Assuming that a steady state quenching must also be taken into consideration at these concentrations, equation (d) holds for $I_0/I = f([Q])$[3], in which we interpret $V$ as the equilibrium constant for complexation of oxygen and quencher.

$$(I_0/I)e^{-V[Q]} = 1 + k_q\tau[Q] \qquad (d)$$

This constant is so chosen that (d) yields a linear function in the range of [Q] ($V = 2\,M^{-1}$; Fig. 1). The constant $k_q = 2900\ M^{-1}\ s^{-1}$ for **1** calculated from $k_q\tau$ is about a factor of $10^4$ smaller than the value ($3.4 \times 10^7\ M^{-1}\ s^{-1}$) published by *Koka* and *Song*[4a].

To check our method of measurement we have determined the constant $k_q$ of a physical quencher of analogous chemical constitution whose value lies in the range $10^7$–$10^8\ M^{-1}\ s^{-1}$. *Taimr* and *Prospisil* found an almost diffusion-controlled quenching for the bisquinomethane **3** in dichloromethane[4b]; according to our measurements the rate constant for $^1O_2$-quenching in $CCl_4$ is $2 \times 10^8\ M^{-1}\ s^{-1}$ (cf. Fig. 2). The $k_q$ of $400\ M^{-1}\ s^{-1}$ found for the hydrophobicized benzoquinone **2** used by us as specific reagent for hyperoxide in the oil phase is, once again, to be classed in the range of very small quenching constants (Fig. 1)[1].

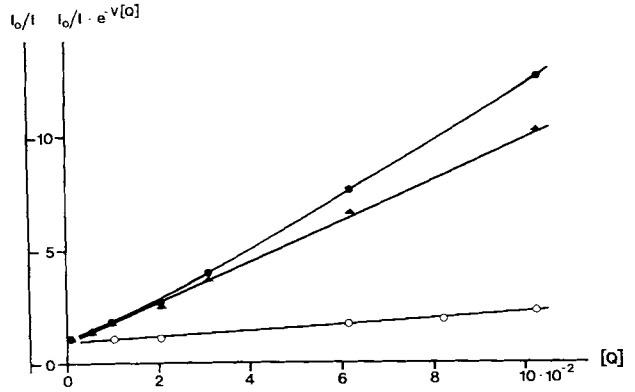

Fig. 1. Stern-Volmer function for the physical quenching of singlet oxygen with **1** (● (c), ▲ (d): $k_q\tau = 87\ M^{-1}$) and with **2** (○ (c): $k_q\tau = 12\ M^{-1}$).

The quenching constant quoted by *Koka* and *Song* has already been interpreted in the appendix to the publication[4a] as a rate constant of an electron transfer reaction *(C. S. Foote, I. Kraljic)*. With a value of $3.4 \times 10^7\ M^{-1}\ s^{-1}$ it lies in the range of the rate constants found by us for the electron transfer (a) from $O_2^{\odot\ominus}$ to **1**[1]. Since the generation of hyperoxide as main reaction during a sensitization with

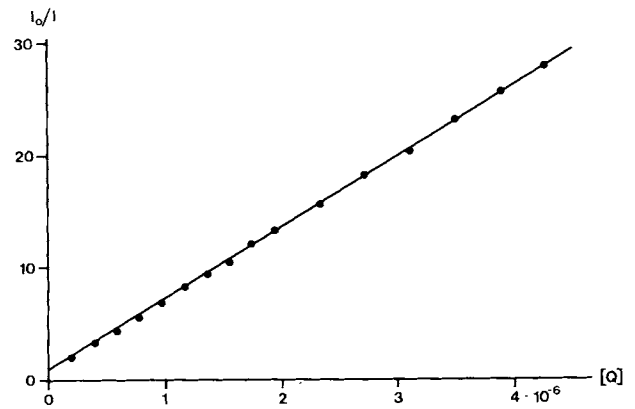

Fig. 2. Stern-Volmer function for the physical quenching of singlet oxygen with **3** ((c): $k_q\tau = 6.0 \times 10^6\ M^{-1}$).

rose bengal (RB) can be ruled out[5], an electron transfer from sensitizer to **1** is likely. This reaction (e) would, as observed by *Koka* and *Song*, compete with the generation of singlet oxygen and, thus, also with the photooxidation of chlorophyll a. A direct triplet quenching (f) can, on the other hand, be ruled out on grounds of the triplet energy of **1** ($E = 50$ kcal/mol).

$$\mathbf{1} + {}^3RB \longrightarrow \mathbf{1}^{\odot\ominus} + RB^{\odot\oplus} \quad (e)$$

$$\mathbf{1} + {}^3RB \longrightarrow {}^3\mathbf{1} + RB \quad (f)$$

Our data confirm the tentative suggestion made by *Foote* (cf. [4a]) that *p*-benzoquinone **1** is a very inefficient physical quencher for singlet oxygen; the quenching constant has the same order of magnitude as that of the commonly used solvent. The same holds for the hydrophobicized derivative **2**. Thus, the specificity of these reagents for hyperoxide[1] has been confirmed experimentally.

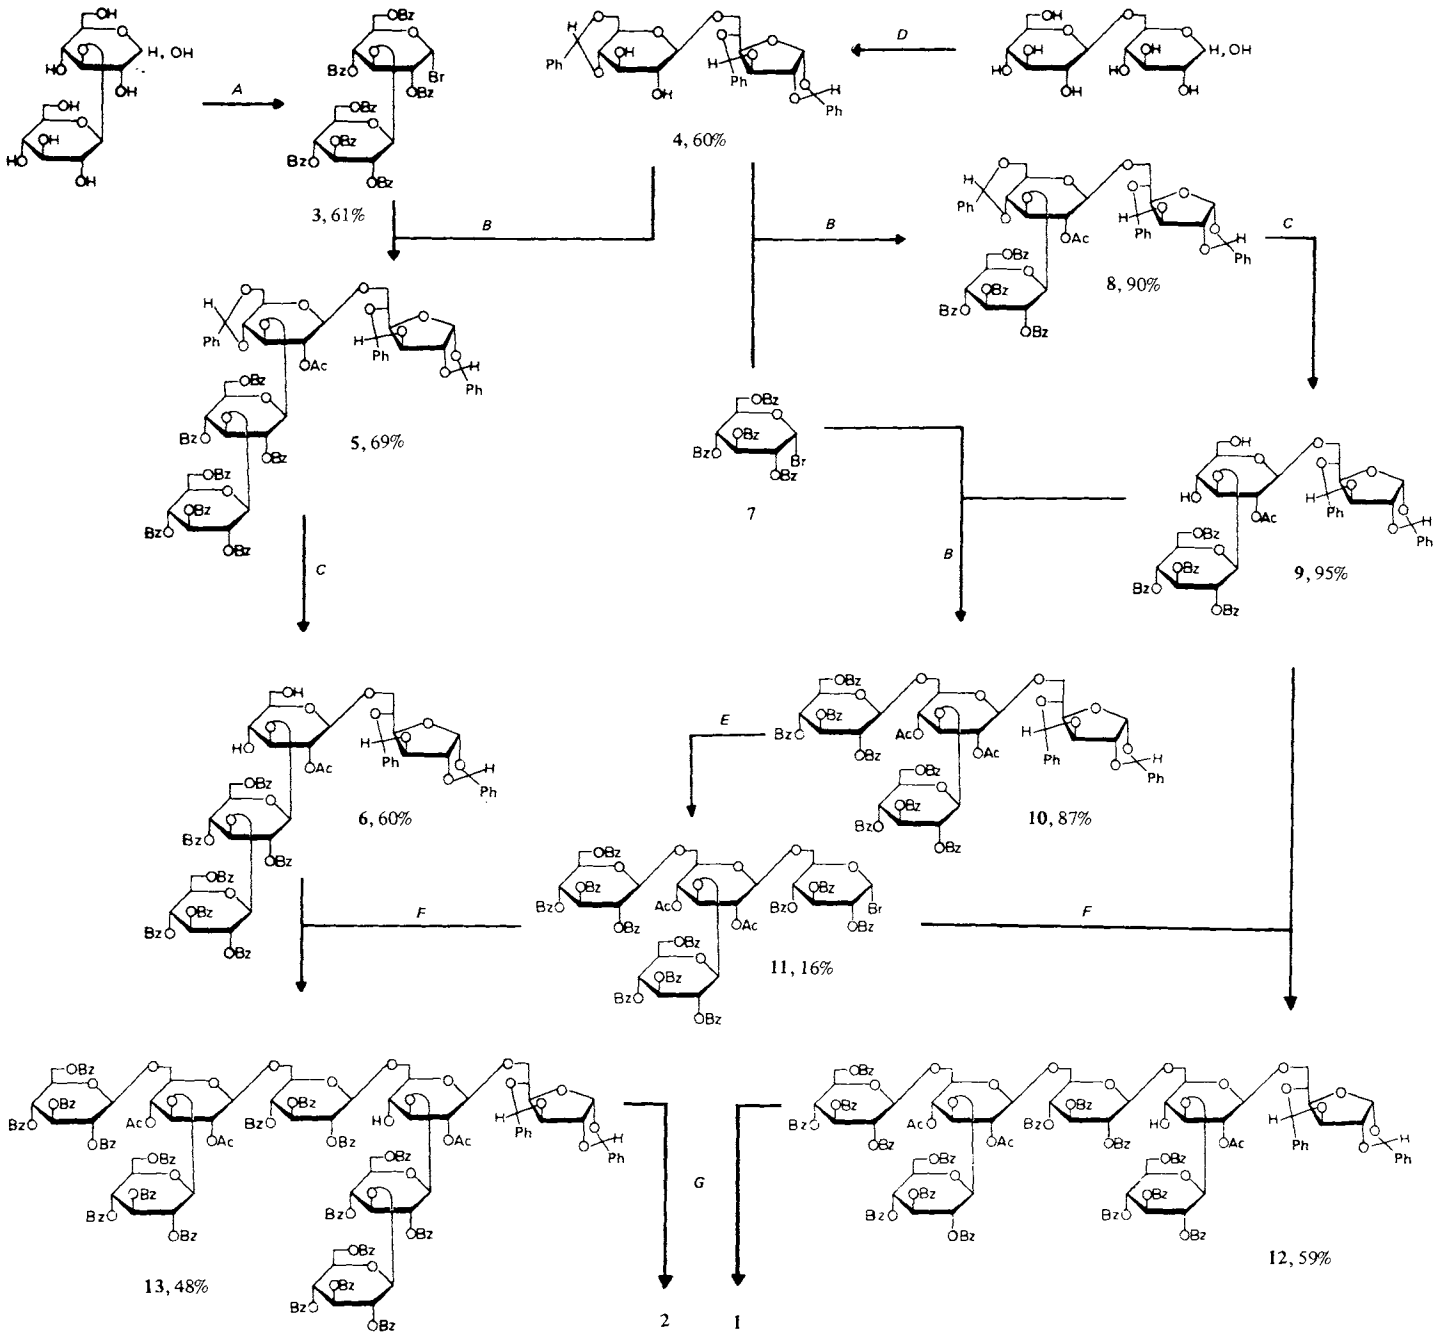
## Syntheses of a Branched Hepta- and an Octasaccharide with Phytoalexin-Elicitor Activity

By *Petra Ossowski, Åke Pilotti, Per J. Garegg*, and Bengt Lindberg*

When soybean tissue is infected with certain fungi, *e.g. Phytophthora megasperma* var. *sojae*, the formation of phytoalexins, *e.g.* glyceollin, is initiated by the action of an elicitor, a fungal glucan present in the mycelium[1]. *Albersheim et al.*[1,2] have isolated elicitor-active oligosaccharides by degradation of this glucan by consecutive enzymic and acidic hydrolysis, followed by extensive fractionation. The smallest of these oligosaccharides are a heptasaccharide and an octasaccharide for which the structures **1** and **2**, respectively, have been suggested. Due to difficulties in obtaining pure oligosaccharides in sufficient quantities, these structures were regarded as tentative only.



**1**, R = H; **2**, R = β-D-Glcp

We now report the syntheses of **1** and **2** by unambiguous methods. Silver triflate promoted condensations of benzoylated glycosyl bromides[3] with the appropriate hydroxy compounds were used throughout. Regioselective glycosidation of dihydroxy compounds ("open" syntheses) were used to obtain efficient routes. Good yields were obtained in all steps, except for that of the preparation of the tetrasaccharide bromide **11**, which due to degradation during the treatment of its precursor **10** with hydrogen bromide in acetic acid had to be purified by chromatography. The structures of the various intermediates and the final products were confirmed by appropriate analyses and by 400 MHz $^1$H-NMR spectroscopy. The final products **1** and **2** gave the expected results on methylation analysis of the sodium borohydride-reduced products[4].

As shown in Scheme 1 the benzoylated laminaribiosyl bromide **3** was condensed with the gentiobiose derivative **4**; the product was acetylated to give **5**, which was regio-

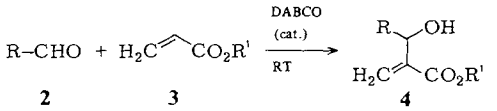
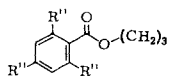
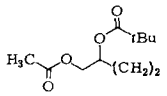
# Preparation of 2-(1-Hydroxyalkyl)acrylic Esters; Simple Three-Step Synthesis of Mikanecic Acid**



By *H. M. R. Hoffmann** and *Jürgen Rabe*

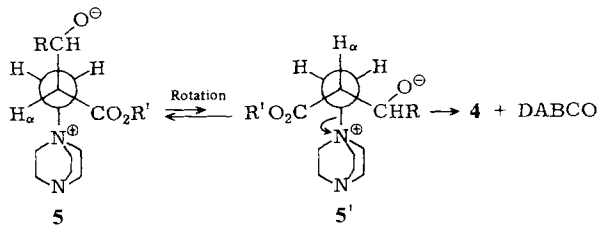
In recent years a variety of reagents and methods have been developed for generating α-acrylate synthons **1**. Reagents published during the last two years include the lithium salts **1a**[1a] and **1b**[1b] and the heterocyclic anion **1c**[1c]. Numerous older synthons have been listed by *Helquist et al.*[1a]. Many of these, however, proved to be unsatisfactory for the synthesis of specially functionalized





**1** **1a** **1b** **1c**

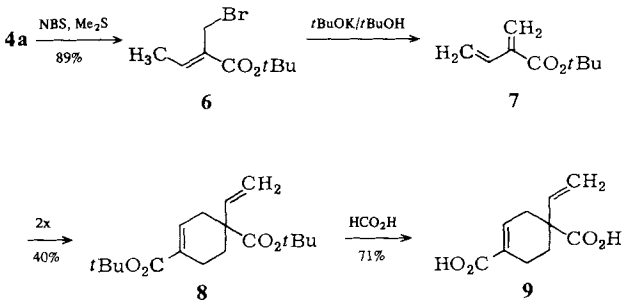
acrylic esters. We now report that acrylate esters **3** can be coupled readily at the α-position with a wide variety of aldehydes, also sensitive and functionalized representatives, in the presence of catalytic amounts of DABCO (1,4-diazabicyclo[2.2.2]octane)[2] at room temperature[3] (Table 1).



**2** **3** **4**

Table 1. DABCO-catalyzed coupling of functionalized aldehydes **2a**—**k** and acrylic esters **3** to form 2-(1-hydroxyalkyl)acrylic esters **4a**—**k** [a].

| | R | R' | *t* [b] | Yield [%] |
|---|---|---|---|---|
| **a** | $CH_3$ | *t*Bu | 7 d | 89 |
| **b** |  | Me | 7 d | 87 |
| **c** |  R''=H | Me | 7 d | 95 |
| **d** | R''=$CH_3$ | Me | 7 d | 87 |
| **e** |  | Me | 7 d | 89 |
| **f** | $Cl(CH_2)_3$ | Me | 7 d | ≈60 [c] |
| **g** | $CCl_3$ | Me | 20 h | >55 |
| **h** | $C_6H_5$ | Me | 6 d | 39 |
| **i** | 2-Furyl | Me | 18 h | 63 |
| **j** | 3-Pyridyl | Me | 4 h | >82 |
| **k** | $H_2C=C(CH_3)$ | Me | 20 d | 33 |



[a] All products were identified spectroscopically. Characteristically, in the $^1$H-NMR spectrum of **4** the two olefinic protons appear between $\delta=5.8$ and 6.2 as approximately two singlets which are well separated (the olefinic protons of the parent acrylic ester appear as a complex ABX system); see also ref. [5]. Yields are not optimized except for adduct **4c**; **4g**, **h**, **j**, **k** were purified by evaporating the remaining starting materials together with the solvent (oil pump) (**4h**, **j** are crystalline); **4i** was purified by chromatography. [b] Reaction mixture allowed to stand at room temperature until the aldehyde had disappeared. [c] Yield reduced by partial quaternization of DABCO.

Less reactive aldehydes such as benzaldehyde **2h** and methacrolein **2k** can also be coupled with acrylic ester. Remarkably, furfural **2i** and especially nicotinaldehyde (**2j**) react much more rapidly than the other aldehydes. We assume that reaction of **2** and **3** initially leads to formation of the intermediate zwitterion **5**, which is in equilibrium with the less favorable conformer **5'** (two gauche interactions). Only conformation **5'** allows an antiperiplanar departure of the crucial $H_\alpha$ proton and DABCO. The various proton migrations that are necessary to complete coupling, are aided by basic heteroatoms on the aldehyde as in **2j** and, less so, **2i**.

**5** **5'**

The new adducts **4** are highly versatile intermediates in organic synthesis and may be used, *inter alia*, for preparing 2-methylene-3-butenoic esters such as **7**[4]. Thus, a short and efficient route to mikanecic acid **9**[5] starts from acetaldehyde **2a** and *tert*-butyl acrylate **3**, R'=*t*Bu. The resulting ester **4a** undergoes allylic rearrangement on reaction with *N*-bromosuccinimide(NBS)/dimethyl sulfide to cleanly give the *Z*-isomer **6**. Following the lead given by *Dreiding et al.*[5] HBr was eliminated to generate *tert*-butyl 2-methylene-3-butenoate **7**, which dimerized *in situ* to the di-*tert*-butyl ester **8** of mikanecic acid. Previously, the diethyl ester of mikanecic has been saponified with base, giving mikanecic acid accompanied by monoester and diester,

**6** **7** **8** **9**

which cannot easily be separated[5a]. Thanks to the possibility of introducing two *tert*-butyl ester groups by our procedure, acid catalyzed ester cleavage in **8** is facile and clean, giving *free* mikanecic acid **9**, which is readily isolated.

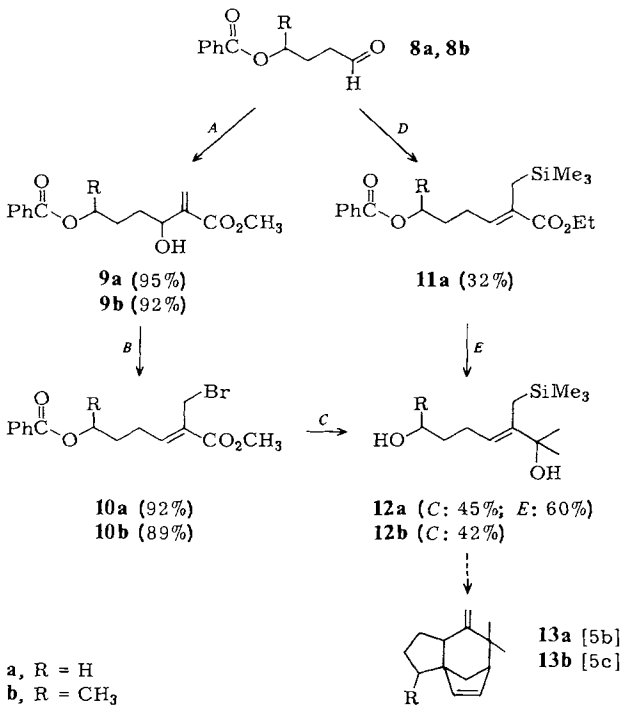
## A New, Efficient and Stereocontrolled Synthesis of Trisubstituted Alkenes *via* Functionalized Acrylic Esters**

By *Jürgen Rabe* and *H. M. R. Hoffmann**

The acrylic acid moiety is an integral feature of a large number of natural products, some of which—like the sesquiterpenoid α-methylene-γ-butyrolactones and related compounds—possess useful biological activity[2]. In reduced form, acrylates are equally important and occur as allylic alcohols and related isoprene units. Described herein is a reaction sequence which starts from inexpensive aldehydes and acrylic ester, and stereoselectively affords trisubstituted olefins.

As the first of several synthetic targets for our procedure we chose novel terpenoid $C_{14}$ ketone **1**, a constituent of costus root oil and presumably a metabolite of the irones, olfactory components of the violet[3a]. A general difficulty in the synthesis of **1** and related terpenes is the stereoselective construction of the central *E*-configurated C(5)–C(6) double bond. In previous preparations of **1** this critical step proceeded with an $E:Z$ ratio of $2:1$[3a], $1.5:1$[3b] and $1.7:1$[3c]. DABCO(1,4-diazabicyclo[2.2.2]octane)-catalyzed coupling of butyraldehyde **2a** or the protected levulinic aldehyde **2b** with methyl acrylate gave adducts **3a** and **3b**, respectively, in good to excellent yield. Interestingly, the sensitive aldehyde **2b** does not—as *e.g.* in chlorinated solvents—rearrange to the isomeric acetal-ketone[4a] under these conditions. After a standard acetylation of **3a**, **b** the resulting acetates **4a**, **b** were reduced with lithium triethylhydridoborate ("Super Hydride")[4b], resulting in clean allylic transposition to give **5a**, **b**. The methoxycarbonyl group of **4a**, **b** was not attacked. Thus, this reduction is not only chemoselective, but also regio- and *trans*-selective, no *Z*-isomer being discernible by $^1$H-NMR. Sterically hindered leaving groups, such as pivaloate[4c,d] and bulky benzoates, which have been used frequently in the past to induce $S_N2'$ displacements on allylic substrates[4d], were not necessary in our case. Note also that the reaction proceeds at −50 °C, although acetate is a comparatively poor leaving group in nucleophilic substitutions. In view of the conversion of **5b** into **1** by *Morizur* and *Tortajada*[3c] the preparation of ketal-acrylic ester **5b** completes a simple *trans*-selective synthesis of **1**[5a].

In a second reaction sequence **3a** was transformed cleanly into **6a**, another useful building block which here was reduced with $LiBEt_3H$ to give **7a**. Such α-alkylacrylic esters cannot be obtained directly from acrylic esters and alkyl halides in the presence of DABCO, because the catalyst is inactivated by quaternization.



As further examples we prepared the crystalline $C_9$- and $C_{10}$-diols **12a** and **12b**, respectively; they are key precursors in the synthesis of the strained tricyclic dehydronorzizaene **13a**[5b] and dehydrozizaene **13b**[5c], respectively. In our reaction sequence **8**→**9**→**10**→**12** the allylic OH group of **9a**, **b** ist not "wasted", as in the above examples, by simple replacement with hydride ion. Step *B* proceeds *trans*-stereoselectively and in high yield; Step *C* consists in the $S_N2$-like introduction of the $Cl_3Si$ anion[5d] followed by quenching with methyllithium.

Hitherto, functionalized α,β-unsaturated acrylic esters such as **11a** have been prepared mainly by the Horner-Wittig reaction (cf. Step *D*[5b]). Starting from **8a** the Horner-Wittig route furnishes **12a** in 19% yield, a figure which could not be improved upon despite many experiments, also with other aldehydes[5b,c]. Typically, the $Z:E$ selectivity is *ca.* 4:1, and the undesired *E*-isomer, with the ester group *cis* to the alkyl chain, must be separated by column

# BOOK REVIEWS

**Comprehensive Organometallic Chemistry.** *The Synthesis, Reactions and Structures of Organometallic Compounds.* Nine Volumes. Editors *G. Wilkinson, F. G. A. Stone, E. W. Abel,* Pergamon Press, Oxford 1982. Total *ca.* 8500 pp., bound, £ 1075.00.

*Volume 1*

The first volume (754 pp) of this exceptional work deals with the organoelement compounds of the 1st to the 3rd main groups of the periodic table. Even though the most spectacular developments since 1950 have been more in the area of the transition metals, the chemistry of the main group elements has also developed very rapidly and has stood in need of an adequate modern treatment for some time. Although the aim of the authors to provide a comprehensive coverage of a given field is of its nature unattainable, they have, nevertheless, performed an excellent service within the framework of this series.

Fourteen authors have contributed to this first volume, most of whom are especially active workers in their respective fields. Astonishingly the result is a work with a rather homogeneous style, evidently attributable to the editors. The volume begins with an informative chapter by *M. E. O'Neill* and *K. Wade* (University of Durham): Structural and Bonding Relationships among Main Group Organometallic Compounds (42 pages, 207 references). The most important structural and bonding types for organometallic compounds of the main group elements are presented using examples. Emphasis is placed on the bridge structures of the oligomeric organolithium and organoaluminum compounds, and on the polyhedral structures characteristic of the carbaboranes and metallacarbaboranes. The subsequent chapters deal with the chemistry of the individual elements: *J. L. Wardell* (University of Aberdeen): Alkali Metals (78 pages, 321 references); *N. A. Bell* (Sheffield City Polytechnic): Beryllium (34 pages, 260 references); *W. E. Lindsell* (Heriot-Watt University): Magnesium, Calcium, Strontium and Barium (98 pages, 635 references); *J. D. Odom* (University of South Carolina): Non-cyclic Three and Four Coordinated Boron Compounds (58 pages, 591 references); *J. H. Morris* (University of Strathclyde): Boron in Ring Systems (70 pages, 484 references); *G. E. Herberich* (Technische Hochschule Aachen): Boron Ring Systems as Ligands to Metals (30 pages, 90 refer-

ences); *T. Onak* (California State University): Polyhedral Organoboranes (48 pages, 247 references); *R. N. Grimes* (University of Virginia): Metallacarboranes and Metallaboranes (84 pages, 260 references); *L. J. Todd* (Indiana University): Heterocarboranes (12 pages, 71 references); *J. J. Eisch* (State University of New York): Aluminum (128 pages, 742 references); *D. G. Tuck* (University of Windsor): Gallium and Indium (52 pages, 282 references); *H. Kurosawa* (Osaka University): Thallium (29 pages, 143 references). Each chapter ends with a reference list covering the literature up to about 1980. The whole is a somewhat capricious, but nevertheless very useful compilation of very variable profundity. The compounds of Li, Mg, B, and Al are emphasized as becomes their importance. It should also be taken into account that their application in organic synthesis is the subject of most of Volume 7.

The contributions do not follow any regular pattern, but, nonetheless, regularly contain sections on the formation, structure and reactions of the compounds concerned. More detailed information concerning synthesis is still to be found in the relevant volume of "Houben-Weyl"; here, as also with "Gmelin", there is a not yet complete but updated new edition covering organoboron chemistry. A particularly valuable feature of Volume 1 of "Comprehensive Organometallic Chemistry"—and this applies to the other volumes too—is the information concerning questions of structure and bonding. Taken with the extraordinarily useful index volume the book is a regular treasure-trove and stimulates to repeated delving and reading. The stated intention of the editors to initiate new ideas and further discoveries is likely to meet with real success. The whole work is aimed at the worker engaged in basic research. Over and above this it will be a first-class source of information for all chemists and that for a long time to come. The desirable dissemination of the work is, however, impossible at a total price of more than DM 5000.—. The opportunity to buy individual volumes is, therefore, urgently necessary.

*Erwin Weiss*
Institut für Anorganische und Angewandte Chemie
der Universität Hamburg

*Volume 2*

The second volume of this nine-volume work comprises thirteen chapters dealing with very different areas of organoelement chemistry, so that the volume seems, at first sight, to be very heterogeneous. This is because of its character as a reference work which does not offer a systematic treatment of the material. However, this first impression is soon forgotten as a consequence of the quality and the independence of the individual sections.

The first four chapters are devoted to organosilicon chemistry: *D. A. Armitage* (University of London): Organosilanes (203 pages, 752 references); *T. J. Barton* (Iowa State University): Carbacyclic Silanes (99 pages, 415 references) *R. West* (University of Wisconsin): Organopolysilanes (33 pages, 136 references); *F. O. Stark et al.* (Dow Corning Corporation): Silicones (59 pages, 193 references). This arrangement seems somewhat arbitrary and naturally leads to overlapping. However, since almost every author has been successfully active in his respective field, the contributions are so stamped with a genuine understanding that their study is, nevertheless, of great value in each case. This is also particularly true for the article on the present state of silicone chemistry in industry, which emphasizes the practical importance of organosilicon compounds and summarizes the newest technical developments, briefly but informatively.

The chapters on the organometallic compounds of germanium (120 pages, 716 references) by *J. Satgé et al.* (Université Paul Sabatier, Toulouse), tin (109 pages, 722 references) by *A. G. Davies* and *P. J. Smith* (University College, London, and ITRI, Greenford) and lead (52 pages, 419 references) by *P. G. Harrison* (University of Nottingham) come likewise from laboratories which have made significant contributions to the developments discussed. Naturally only the highlights of the literature could be included: After all organotin chemistry now fills fifteen volumes of Gmelin!

The organoelement compounds of arsenic, antimony and bismuth are described (by *J. L. Wardell,* University of Aberdeen) on only 27 pages (179 references), which necessarily leads to a loss of quality. The expectations of the reader are greatly disappointed in this section; the relative importance of this area is not properly represented, a fact which affects the value of the whole work. Perhaps arsenic (and antimony) should rather have been omitted altogether.

The coinage metals copper, silver and gold are treated in a manner which takes account of the rapidly increasing importance of these elements; the first two by *J. G. Noltes* and *G. van Koten* (TNO Utrecht and University of Amsterdam and the third by *R. J. Puddephatt* (University of Western Ontario), in 55 pages (187 references) and 57 pages (227 references) respectively; here again the competence of the authors is happily apparent. The workers mentioned had already produced the previous leading monographs on the same topics. Finally, there are chapters on the organometallic compounds of zinc and cadmium (*J. Boersma,* Universität Utrecht; 40 pages, 163 references) and mercury (*J. L. Wardell,* University of Aberdeen; 116 pages, 545 references) which are certainly correctly placed alongside the coinage metals.

A concluding contribution from *P. J. Craig* (Leicester Polytechnic): Environmental Aspects of Oranometallic Chemistry (42 pages, 319 references) attempts to set out the more important aspects of the occurrence and effects of toxic (natural and anthropogenic) organometallic derivatives in the environment. Unfortunately the well-known "black sheep", mercury, lead, tin and arsenic, steal so much of the limelight that the desire for information concerning the environmental problems caused by the other elements is scarcely considered. Nevertheless, this chapter is worthy of note and is quite useful as a basis for teaching courses.

The external appearance of the volume, together with the quality of the print, are impeccable, and study is simplified by the attractive distribution of text, formulas, figures and tables. The literature is cited up to the most recent times in most of the contributions, so that this collected work will retain its topicality for some years. The inevitable transcription and typesetting errors (*e.g.* wrongly spelled names in the author index) have been kept to a minimum. Even the surname of the reviewer, which is particularly at risk, was rarely incorrectly spelled.

*Hubert Schmidbaur*
Anorganisch-chemisches Institut der
Technischen Universität München

*Volume 3*

The third volume (1384 pages) comprises ten chapters, of which the first two are devoted to general problems and the others to the organometallic compounds of the elements of the 3rd to 6th subgroups of the periodic table as well as of the lanthanoids and actinoids. This mass of ma-

terial is successfully crammed in, thanks largely to the expertise of most of the authors.

Volume 3 begins with a contribution from *D. M. P. Mingos* (Oxford University): Bonding of Unsaturated Organic Molecules to Transition Metals (88 pages, 551 references), which is mainly classified according to the type of ligands. Metal carbonyls, sandwich compounds, olefin- and alkyne-complexes, alkyl-, carbene- and carbyne-metal compounds are dealt with in separate sections. In addition, important types of reaction such as oxidative addition and reductive elimination, CO and alkene insertion, Ziegler-Natta polymerization and olefin metathesis are discussed. The author presents modern concepts in an instructive manner starting from simple bonding concepts (*e.g.* those of Dewar, Chatt and Duncanson for metal-olefin complexes) and compares the results of calculations (both ab initio and semi-empirical) with experimental data, from UPS measurements for example. Correlations, like those which emerge through the isolobal principle, are also mentioned.

*B. E. Mann* (University of Sheffield): Non-rigidity in Organometallic Compounds (83 pages, 185 references) in the second chapter deals first of all with the methods of studying fluxional structures. The extensive information that follows concerning the results obtained up to now (mostly in tabulated form) covers not only the rotation of $C_1$ (alkyl, carbene) but also of $C_n$ ligands (alkene, alkyne, di- and triene, allyl, cyclopentadienyl, arene) about the axis of the metal-ligand bond, together with intramolecular ligand exchange, the dynamics of σ-allyl and σ-cyclopentadienyl compounds, the rearrangement of $\eta^2$- to $\eta^6$-cyclic ligands (*e.g.* $C_7H_7$, $C_8H_8$, $C_8H_{10}$) at metals and, above all, the fluxional behavior of organic groups on metal clusters. Mechanistic considerations are mentioned, but their understanding requires a careful study of the cited literature.

The other eight "systematic" chapters are arranged according to the placing of the metal in the periodic table. It is pleasant to see that the elements scandium, yttrium, lanthanum as well as the lanthanoids and actinoids are not treated as exotica and pushed into a corner, but that they are given the place they now deserve. The organometallic compounds of the 4f and 5f elements have come into the sphere of general interest more than almost any other area in the last decade, and that largely because of the work of one of the authors, *T. J. Marks*. Of the remaining *ca.* 1100 pages about 280 are devoted to titanium and about 600 pages to the elements of the 6th subgroup (Cr, Mo, W); thus, the extent of this presentation alone reflects the technological importance of the organometallic compounds concerned. The flood of information (*e.g.* just on compounds derived from $(C_5H_5)_2TiCl_2$ or $Cr(CO)_6$) is also presented in part in tabular form, thus facilitating a general overview. The section on "Ziegler-Natta Catalysis" is particularly worthy of mention (pp. 475—547) and deals not only with industrially important aspects but also with the results of model studies and mechanistic considerations. It is also pleasing that even the, as yet, not so well developed fields, such as the compounds of zirconium, hafnium or of niobium and tantalum, have attracted prominent authors (such as *M. F. Lappert* and *J. A. Labinger*) who have played a leading part in the development.

The general impression given by this herculean publication: First-rate! Competent, comprehensive, well-illustrated (with, however, some superfluous ORTEP diagrams) with few printing errors (mainly in the literature references). It is to be hoped by all those who are interested—in industry and in university—that, in spite of the present miserable financial climate, this work will soon be available in all libraries.

*Helmut Werner*
Institut für Anorganische Chemie
der Universität Würzburg

*Volume 4*

The fourth volume fits perfectly into this monumental work and comprises seventeen chapters (1064 pages). *P. M. Treichel* (University of Wisconsin-Madison) describes the organometallic chemistry of manganese in a well laid out manner and with a sure nose for quality and balance (147 pages, 649 references). The treatment of the homologous elements technetium and rhenium (80 pages, 532 references) by *N. M. Boag* and *H. D. Kaesz* (University of California at Los Angeles) is of its very nature more modest but, nevertheless, competent and informative. Apart from the little studied technetium, there are numerous excellent examples of the vast differences in chemical behavior between the corresponding manganese and rhenium compounds. In view of the tidal wave of data which has poured out concerning iron since the renaissance in organometallic chemistry, the editors were well advised in their decision to divide it into five chapters. *D. F. Shriver* (Northwestern University, Evanston), *K. H. Whitmire, A. D. Johnson* (University College London), *A. J. Deeming* (University College London), *W. P. Fehlhammer, H. Stolzenberg* (University of Erlangen-Nürnberg) and *J. L. Davidson* (Heriot-Watt-University) put across the substantial essence over 400 pages (1477 references), whereby the individual treatments of iron complexes with various hydrocarbon ligands complement each other well and seldom overlap unnecessarily. The chemistry of organoruthenium compounds is divided between *M. I. Bruce* (University of Adelaide) and *M. A. Bennett* (Australian National University), who present their chosen classes of compound with experienced pens. Each of these nine contributions (Chap. 32.1—32.9) is rich in content but, thanks to the strict classification, easy to read. The chapter dealing with the chemistry of dodecacarbonyltriruthenium could be taken as a model for disciplined selection of material. The contribution by *M. A. Bennett* and *T. W. Matheson* (Chap. 32.9) gives an almost textbook review of the manifold, catalytic aspects of organometallic ruthenium complexes. Volume 4 finishes with the element osmium: *R. D. Adams* (Yale University) and *J. E. Selegue* (University of Kentucky) expertly describe, in particular, the modern aspects of this chemistry, using the same sensible classification system (carbonyl complexes, mononuclear complexes, cluster complexes) used in the previous chapters as a framework, whereby the treatment of trinuclear carbonyl derivatives is worth particular attention and is a regular treasure-trove of current results. The description of the fascinating osmium clusters of higher nuclearity (Section 33.3.6) could have been more detailed.

Not only the good scientific quality of this volume is impressive but also its presentation, with the exception of the occasional overlarge formulas (*e.g.* pp. 644, 647). The multinuclear complexes with complicated ligands, in particular, should have been drawn in perspective, which would often make understanding easier for the reader (*e.g.* pp. 899, 901, 905). The preparatively oriented chemist will sometimes miss an explicit recommendation of the best synthetic route; in this connection the key compound $(\eta^5\text{-}C_5H_5)Mn(CO)_3$ is incorrectly reported (p. 124; cf. G.

Bauer: *Handbuch der Präparativen Anorganischen Chemie*, 3rd edition, Vol. 3, p. 1866ff, Enke, Stuttgart 1982). In general, however, the fourth volume lives up to the proud record of this modern encyclopedia—indispensable for the specialist, helpful to those in related fields, a masterpiece!

*Wolfgang A. Herrmann*
Institut für Anorganische Chemie
der Universität Frankfurt am Main

*Volume 5*

The fifth volume (628 pages) of the series reviews the organometallic chemistry of cobalt (276 pages, 809 references), rhodium (264 pages, 1311 references) and iridium (88 pages, 512 references); the authors are *R. D. W. Kemmitt* and *D. R. Russel* (University of Leicester), *R. P. Hughes* (Dartmouth College) and *G. J. Leigh* and *R. L. Richards* (University of Sussex) respectively.

The chapters dealing with cobalt and rhodium compounds begin with a suitable historical retrospect. All three chapters are essentially based on the following scheme: carbonyl, carbonyl hydride, thiocarbonyl, carbon disulfide, isocyanide, nitrosyl complexes, divided each time into mono- and multi-nuclear compounds, then follow the complexes with σ-bonded hydrocarbons (alkyl and aryl compounds), carbene, alkylidene as well as carbyne and alkylidyne complexes and then, finally, the compounds with π-bonded hydrocarbons, classified according to the number of carbon atoms which are bonded to the metal (alkene, alkyne, allyl, diene and cyclobutadiene, cyclopentadienyl, arene ligands). The individual sections are, in the main, subdivided according to preparation, structure, properties and the reactivities of the compounds. The literature is covered for the 25 years up to the end of 1979 together with some references from 1980. Organocobalt(III) systems (cobaloximes) are discussed in detail as models for vitamin $B_{12}$. The many tables (more than 100) in which analogous compounds are summarized together with their methods of preparation, spectroscopic data (IR, NMR) are particularly valuable, as are the large numbers (1816) of clear illustrations of formulas and schemes concerning the structure, synthesis and reactivities of the compounds. Catalytic aspects are treated only briefly; these are dealt with in Volume 8.

This series illustrates once more the stormy development of organometallic chemistry since the discovery of ferrocene. The authors and editors have performed excellent work in their critical sifting of the immense body of results, it could scarcely have been done better. Volume 5 is at the moment probably the best source of information in its field for both newcomer and initiate. A treasure-trove of stimulation and, without question, a standard work for every library.

*Wolfgang Beck*
Institut für Anorganische Chemie
der Universität München

*Volume 6*

Two thirds of the sixth volume (1114 pages) are filled with complexes of the Ni, Pd, Pt triad. The rest is devoted to compounds containing heteronuclear bonds between different metals.

All three chapters concerning the organometallic chemistry of nickel, palladium and platinum are written by well-known authors, who had already made names for themselves in the early seventies with monographs devoted to their favorite metal. This explains, on the one hand, the retention with only slight modifications of the well-established classification of the material and, on the other hand, the concentration on the latest results and tendencies. Thus in the first chapter (231 pages, 50 tables), *P. W. Jolly* (Max-Planck-Institut für Kohlenforschung, Mülheim a. d. Ruhr) has deliberately built upon the foundations of Volume 1 of *"The Organic Chemistry of Nickel"* (*P. W. Jolly* and *G. Wilke*, Academic Press, New York 1974); in many of the tables it is noted that earlier work is reviewed in this book. Also the second chapter (237 pages, 13 tables) written by *P. M. Maitlis*, (University of Sheffield), *P. Espinet* (University of Saragossa) and *M. J. H. Russell* (Johnson Matthey Research Centre) is obviously built on the foundations of Volume One of *"The Organic Chemistry of Palladium"* (*P. M. Maitlis*, Academic Press, New York 1971). Similarly in the third chapter (289 pages, 47 tables) *F. R. Hartley* (Royal Military College of Science, Shrivenham) can refer to his monograph *"The Chemistry of Platinum and Palladium"* (Applied Science, London 1973). These contributions are excellently written and well illustrated by formulas; the density of information is very high. Although members of a large team the authors have been able to retain their own personal styles and their individual methods of presentation. Thus, the fifty tables of the first chapter give a quick picture of the known organonickel complexes (with appropriate references). In contrast the tables in both the following contributions serve more to present spectroscopic and other data pertaining to selected palladium and platinum complexes. The chapters on nickel and palladium offer the literature references portionwise at the end of each of the nine sections, while for the chapter on platinum they are collected together into one comprehensive list (1702 references). The fact that the editors did obviously not try to exert a levelling influence on their authors makes a favorable impression; the three individual chapters can certainly be considered as small, independent monographs. (Incidentally the use of nickel and palladium in organic synthesis is described separately in Chapter 8.)

In the last part of Volume 6 the dilemma becomes evident which is necessarily faced on considering the systematics of complexes with two or more different metals, as long as the chemistry of organometallic compounds is classified according to the metal. The problem of heteronuclear compounds has, however, been elegantly solved—without arbitrary definitions of priority. Compounds with heteronuclear bonds between transition metals are dealt with in a detailed chapter (115 pages, 13 tables) by *D. A. Roberts* and *G. L. Geoffroy* (Pennsylvania State University); the emphasis is not on individual complexes but on general synthetic procedures, spectroscopic methods and the (at the moment rather sparse) investigations of reactivity. The main body of information is collected in three long tables at the end of the chapter, which—divided into binuclear complexes, oligomeric compounds and clusters—contain data on all heteronuclear complexes with at least one bond between two different transition metals known before August 1980. These tables and the pertinent references take up 49 pages (42% of the total chapter); they seem likely to become a much cited literature source, since heterometal complexes are of topical importance as potential catalysts. However, it is by no means easy to confirm unequivocally the presence of a metal-metal bond in all cases. The last three chapters offer reviews, taking up 235 pages, of multinuclear complexes, where the bonding of a transition metal occurs to a representative element, such as boron (*K. B. Gilbert, S. K. Boocock*, and *S. G. Shore*, Ohio

State University), aluminum, gallium, indium, and thallium (*S. K. Boocock* and *S. G. Shore*), mercury, cadmium, zinc and magnesium (*J. M. Burlitch*, Cornell University) or silicon, germanium, tin and lead (*K. M. Mackay* and *B. K. Nicholson*, University of Waikato). The order of the sections is not particularly evident. The separation of boron (Chap. 41.1; 67 pages, 22 tables, 289 references) is justified by the structural variety of the boron-containing ligands; structures with up to 18 boron atoms are described. In comparison with boron the organometallic chemistry of its heavier homologues is significantly restricted, although many interesting bond types occur.

*Max Herberhold*
Laboratorium für Anorganische Chemie
der Universität Bayreuth

*Volume 7*

Volume 7 (729 pages) of the series is devoted to the use of organometallic reagents in organic synthesis. Lithium-, alkali- and alkaline earth-containing reagents are dealt with by *B. J. Wakefield* (University of Salford), and the application of organoboron compounds by authors from *H. C. Brown*'s school, namely *E. I. Negishi* (Purdue University) and *M. Zaidlewicz* (N. Copernicus University, Thorn). Organoaluminum compounds are reviewed by *J. R. Zietz, G. C. Robinson* and *K. L. Lindsay* (Ethyl Corporation), while the use of thallium compounds is dealt with by the protagonists of the field, *R. McKillop* (University of East Anglia) and *E. C. Taylor* (Princeton University). A further chapter is devoted to a comprehensive treatment of organosilicon compounds by *P. D. Magnus, T. Sarkar* and *S. Djuric* (Ohio State University). The work concludes with an overview of the applications of zinc, cadmium, mercury, copper, silver and gold compounds in organic synthesis by *W. Carruthers* (University of Exeter). Of the monohapto organometallic derivatives which have acquired wider preparative importance, those of tin and titanium are notably absent.

The volume is divided according to the key metals and to the reagents derived from them. This classification principle assumes that the reader already has a basic knowledge of the typical reactivities of these reagents. For, if he does not know, *e.g.*, that alkyl cuprates add particularly well to alkynes, when searching for such a reaction he is unlikely to stumble across it in Chapter 49, whether he uses the index or not. On the hand, if already armed with this knowledge before consulting the present volume, he will find a concise and precise exposition of the possibilities and limits for the use of the well-known homo- and hetero-cuprates and analogous copper(I) derivatives, which is precisely the information that is of help to him as a potential user. Such assistance is necessary in view of the enormous progress made in the last 25 years with organometallic reagents in organic synthesis: A look at the detailed documentation of "Houben-Weyl" or "Gmelin" in the case of organoboron chemistry illustrates how extensive the results already are. This is just where the utility of the present volume becomes apparent; it enables one to quickly familiarize oneself with the areas it deals with. Commendable are the chapters on organolithium, organoboron and organosilicon compounds; despite the flood of original publications cited they are still comprehensible and readable. Individually the text and the formulas make up a well balanced whole, and the numbers of mistakes in the formulas are minimal. Most of the chapters are written in such a manner as to stimulate voluntary reading which is rewarded with information and ideas that had previously been overlooked. The editors have, therefore, fulfilled their intention of creating a compendium which is very stimulating to study. Since this volume provides an ideal method of quick orientation in the application of organometallic reagents to organic synthesis, most organic chemists would be pleased to have at hand, if not the whole series, at least Volumes 7 and 8. However, only a few of them are likely to have a patron in the background and so most of them will have to use the well-thumbed library copy.

*Reinhard W. Hoffmann*
Fachbereich Chemie der Universität Marburg

*Volume 8*

The eighth volume (1106 pages) contains the following contributions: *R. P. A. Sneeden* (C.N.R.S., Villeurbanne): Preparation and Purification of Carbon Dioxide and Carbon Monoxide (17 pages, 44 references); *R. P. A. Sneeden:* Organic Syntheses where Carbon Monoxide is the Unique Source of Carbon (82 pages, 343 references); *I. Tkatchenko* (C.N.R.S., Villeurbanne): Synthesis with Carbon Monoxide and a Petroleum Product (123 pages, 185 references); *R. P. A. Sneeden:* Reactions of Carbon Dioxide (58 pages, 202 references); *B. R. James* (University of British Columbia): Addition of Hydrogen and Hydrogen Cyanide to Carbon-Carbon Double and Triple Bonds (85 pages, 525 references); *W. Keim, A. Behr, M. Roeper* (Technische Hochschule Aachen): Alkene and Alkyne Oligomerization Cooligomerization and Telomerization Reactions (91 pages, 491 references); *H. B. Kagan* (Université Paris-Sud): Asymmetric Synthesis using Organometallic Catalysts (36 pages, 125 references); *R. H. Grubbs* (California Institute of Technology): Alkene and Alkyne Metathesis Reactions (53 pages, 146 references); *C. U. Pittman Jr.* (University of Alabama): Polymer Supported Catalysts (58 pages, 346 references); *P. W. Jolly* (Max-Planck-Institut für Kohlenforschung, Mülheim a. d. Ruhr): Organonickel Compounds in Organic Synthesis (182 pages, 1210 references); *B. M. Trost, T. R. Verhoeven* (University of Wisconsin and Merck, Sharp and Dohme Research Laboratories, Rahway): Organopalladium Compounds in Organic Synthesis and in Catalysis (140 pages, 805 references); *A. J. Pearson* (University of Cambridge): Organoiron Compounds in Stoichiometric Organic Synthesis (73 pages, 231 references); *W. E. Watts* (New University of Ulster): The Organic Chemistry of Metal-coordinated Cyclopentadienyl and Arene Ligands (59 pages, 355 references); *J. R. Dilworth, R. L. Richards* (A.R.C. Unit of Nitrogen Fixation, University of Sussex): Reactions of Dinitrogen Promoted by Transition Metal Compounds (34 pages, 119 references).

As can be seen from the list of contents, Volume 8 is mainly concerned with very topical applications of transition metal compounds, both as stoichiometric reagents and as catalysts in organic synthesis. In spite of the size of the volume and the fact that two related chapters (Ziegler-Natta catalysis and the catalytic applications of ruthenium complexes) are dealt with in other volumes (3 and 4) of the work the perspective is incomplete. Some topics, *e.g.* oxidation, isomerization, rearrangement reactions and other synthetic steps with organometallic compounds of the first row transition metals, are only dealt with (if at all) in a cursory manner. The division of the contents into chapters that describe either reaction types or the use of particular metals results in some repetition and overlapping; this,

however, is not serious. The individual contributions are from competent authors. The already enormous numbers of references at the ends of the chapters are further augmented by references in the many tables. The patent literature is also included.

The three most important aspects of the product-orientated application of transition metal compounds are expounded upon: catalytic reactions, the modes of action of metal catalysts and reactions at coordinated organic (and inorganic) ligands; stereochemical aspects are discussed.

It is not possible to say that this volume is indispensable, because there are many excellent monographs which cover some of the topics discussed. However, because of the choice of the contributions, their quality, and the growing interdisciplinary importance of the material, this work will be an enrichment for every chemical library and an invaluable aid for many chemists.

*Giambattista Consiglio*
Technisch-chemisches Laboratorium der ETH Zürich

*Volume 9*

The ninth, last and thickest volume (1570 pages) of the series is intended to make the information in the other eight volumes easily available on the basis of several search criteria. The user has the choice of five indexes for this purpose: Subject Index (440 pages), Formula Index (382 pages), Author Index (386 pages), Index of Structures Determined by Diffraction Methods (312 pages), Index of Review Articles and Specialist Texts on Organometallic Chemistry (50 pages).

The Subject Index encompasses 30000 key-words, the Formula Index more than 32000 typical compounds with at least one metal-carbon bond ($\sigma$ or $\pi$; classified according to a modified Hill system). The Author Index contains more than 30000 names from about 40000 literature references. The two following indexes can be used independently of the main work and constitute a useful addition. Thus, the Structure Index compiled by *M. I. Bruce* (University of Adelaide) is a guide to thousands of organometallic structures elucidated during the period from 1927 to 1981 by X-ray, neutron or electron diffraction. Finally, interdisciplinary interest is excited by the presentation of a multifaceted collection of secondary and tertiary literature (*G. B. Young,* Imperial College of Science and Technology, University of London) covering all aspects of the chemistry of organometallic compounds.

All in all the chemist who works in university or in industry, or who sits at an editor's desk has had placed in his hands an extremely useful (yet very expensive and "unelectronic") tool.

*Otto Smrekar*
Angewandte Chemie, Weinheim

**Experimental Methods in Photochemistry and Photophysics.** By *J. F. Rabek.* John Wiley, Chichester 1982, 2 Volumes together 1098 pp., bound, £ 89.95

This book made a good impression on me at first glance. The many illustrations awoke the expectation that here a really versatile and experienced experimentalist had written something useful for experimental work in photochemistry and photophysics. Closer inspection quickly revealed, however, that the author is by no means an experienced experimentalist, but that, following a doubtful plan, he has made a book out of a heterogeneous literature collection.

The aims of this book and the way in which it has been made are set out by the author in the preface: "...This book is an up-to-date survey of the majority of available methods and commercially available equipment applied in the study of photochemical and photophysical reactions. Each major topic is introduced separately and is self-contained.... The material collected in this book has been prepared from hundreds of books, papers, catalogues and private information from laboratories round the world and from my own twenty years experience in experimental work in the photochemistry of polymers. My task was limited to the selection and arrangement of respective information to assist scientists, people from industry and students working in the field of experimental photochemistry and photophysics ...".

The sources of the material in the book can actually be identified as (1) catalogues, (2) books and (3) journals, because the source of each figure or table is usually (but not always) cited. The book also contains material that (4) cannot be traced to a single source or (5) does not refer to experimental methods.

(1) *Catalogs:* Here the author is, de facto, advertising for particular manufacturers. He does not shrink from using their texts as well as their illustrations and tables. Examples: Chapter 4, "Optical Systems", is largely identical with the catalog "Optics Guide" issued by the Melles Griot company, and Chapter 12.2.2, "Photomultiplier Tubes", is, to a large extent, identical with the catalog of the same name issued by the Hamamatsu company. The fact that there are also competing companies, here, for instance, Oriel, RCA and EMI, goes unmentioned.

(2) *Books:* Here the author seems to have inhibitions about reproducing texts without alterations. If he has nothing to add himself then he alters about every other sentence slightly, whereby the text is sometimes weakened or even falsified. Example: Chapter 27.2.2.1, "Potassium Ferrioxalate Actinometer", is, essentially, identical with chapter 7-4B-2 of the book "Photochemistry" by *Calvert* and *Pitts.* The names *Parker* and *Hatchard* are not mentioned in this book (names are not mentioned in the text, on principle) and of the two investigations cited in the original, the author cites only the first. The original sentence "The solid can be stored in the dark for long periods of time without change" has been altered in "the reagent can be stored in a dark bottle for long periods of time." The original sentence "Parker and Hatchard recommended that ... a standard calibration graph ... be prepared" has been altered in "for the preparation of a calibration graph ... it is necessary to prepare a standard calibration graph".

(3) *Journals:* Here the author usually limits himself to reproducing figures and tables with a few lines of text as commentary. Example: Chapter 19.3.3, "Frequency Mixing Technique (Part II)", reports on two publications, [1] "Generation of Vacuum Ultraviolet Radiation in Phase-Matched Cd Vapor", A. H. Kung et al., *Phys. Rev. Lett. 29* (1972) 985, and [2] "Tunable Coherent Vacuum-Ultraviolet Generation in Atomic Vapors", R. T. Hodgson et al., ibid. *32* (1973) 343. What has *Rabek* made out of these publications? The commentary is only 12 lines long. The physical basis of the method is not explained. Fig. 1 is taken from both [1] and [2] and *altered* without specific mention. The reader is left to assume that these are the original figures. The alteration in Fig. 1 of [1] has resulted in the loss of the important words "heat pipe oven" and the vacuum UV detection part. In Fig. 1 from [2] part of the block diagram of

the experiment has been altered and thereby made unintelligible; further, a "Glan Prism" has been turned into a "Glen Thompson Prism" (does *Rabek* think that *Thompson*'s christian name was Glen?), "Sr Oven" has become "heat pipe oven", and the nitrogen laser wavelength, the mention of the opposite circular polarizations of the dye laser beams and the detection part have been lost. Apart from this the mutilated figures take up more than twice as much space in the book as the original figures. *Rabek* took Table 1 out of [2], but left out a line, thus making the following line of the table unintelligible.—For comparison it should be mentioned that a competent author like *Demtröder* describes the same two publications also on two pages, but in such a manner that the reader receives a reasonable idea of the principle and the realization of the method (W. Demtröder: Laser Spectroscopy—Basic Concepts and Instrumentation, Springer 1981, pp. 366 and 367).

(4) *Multiple Sources:* Chapter 10.1 "Spectrometers" and Chapter 10.2 "Monochromators" may be taken as examples. *Rabek* has used the catalog "Das PI-Optische System" issued by Physik Instrumente GmbH to illustrate the construction of various types of spectrometers. On p. 193 of this catalog there are diagrams of five spectrometers. For three of them photographs show how they can be realized by using PI components. For typographical reasons the diagrams and the photographs are not printed side by side. *Rabek* did not notice this and proceeded to make two mistakes: Fig. 10.8 shows the catalog figure E instead of G, and Fig. 10.12 shows G; the photograph that ought to be shown in Fig. 10.12, does not at all exist in the catalog. The section 10.1.5, "Diffraction Gratings" is scanty. It is not even properly explained what is meant by the blaze angle of a diffraction grating. The probably most important manufacturer of optical diffraction gratings, the Jobin Yvon company, is not even mentioned and naturally neither is the instructive handbook on ruled and holographic diffraction gratings, published by this company. *Rabek*'s incompetence reveals itself in Chapter 10.2 "Monochromators". In Fig. 10.16 two setups are shown that are purported to illustrate a prism and a grating monochromator. What one sees, however, is something that looks like a prism spectrograph, and a transmission grating set up, with just the zeroth order going through the exit slit (both setups with lens optics). Nothing is said about the two normal types of grating drive (sine drive for linear wavelength change and cosecant drive for linear wavenumber change), nothing about problems with stray light, multiple diffraction, higher order diffraction, *etc.* Ten monochromator types are listed, four of them with incorrect spelling. This enumeration is useless anyway because nothing is said about the peculiarities of each monochromator type. The twelve literature references are, for the most part, useless: eight refer to special constructions for the vacuum ultra-violet and for space applications; the remaining four refer to an application of the smallest Jobin Yvon concave-grating double-monochromator, a publication from 1965 and two commercial leaflets. The Jobin Yvon company is not even mentioned here, although it produces the largest range of grating monochromators, and although its "high luminosity" concave grating monochromator should be suitable for many photochemical investigations.

(5) Even the two nonexperimental chapters 1 and 20 contain errors and many inaccuracies. In 1 "Nature and Properties of Light", the wave number $\bar{\nu}$ is defined as $(\text{wavelength})^{-1}$ instead of $(\text{wavelength in vacuo})^{-1}$. In Chapter 20, "Electronically Excited States" p. 732, final paragraph, it says: "In an isolated molecule in a very dilute *solution* ($\sim 10^{-6}$ M) or in low-pressure vapor, the fluorescence occurs from the vibronic state ($S_1^\dagger$) initially excited or ..." Thus the exact opposite of *Kasha's rule* is maintained.

An annotated list of all the mistakes and deficiencies would add another volume to the two that have been published. The author has failed to achieve a single one of his aims. Because of the arbitrary choice of manufacturers and the uncritical representation, the book offers no assistance in the purchase of a piece of equipment. It is not up-to-date, because often the very limited capability of a particular commercial instrument is identified with the state of the art. It is useless as a laboratory handbook, because one must be always prepared for a distorting account of the original literature. The book is only of limited use as a collection of literature references, as was illustrated by the example in (4). In conclusion my advice is not to buy this book, not to read it and not to quote it (always read and quote the original publications) and to warn students explicitly about it.

*Bernhard Nickel* [NB 596 IE]
Max-Planck-Institut für
Biophysikalische Chemie, Göttingen

**Advanced Sugar Chemistry. Principles of Sugar Stereochemistry.** By *R. S. Shallenberger.* Ellis Horwood Ltd., Chichester 1982. xx, 323 pp., bound, £ 31.50

The title of this book is somewhat misleading because it suggests to the reader a general treatment of advanced sugar chemistry; the subtitle "Principles of Sugar Stereochemistry" describes the book's content much better. It does not constitute a rival to the well-established textbooks; *Shallenberger* describes rather more the structure of carbohydrates, steric questions and connections such as conformational relationships. With the exception of the phenomenon of mutarotation none of the reactions of saccharides are mentioned, so that the book is in competition with the well-known work "Stereochemistry of Carbohydrates" by *Stoddart* that appeared in 1971 and, at the time, filled an important gap. If the books are compared with each other then that by Stoddart is seen to have the greater depth in places. *Shallenberger*'s book is, in that the material has gelled in the last ten years, better constructed didactically. It is easier to read and patiently introduces the beginner to the complicated stereochemical questions of carbohydrate chemistry.

Chapters 1 to 3 deal with nomenclature, structure and development of the monosaccharides, with stereochemical questions particularly the question of chirality well to the fore. Acyclic systems and their properties are discussed in Chapter 4. Chapters 5 and 6 explain the semiacetal construction of sugars and describe the attendant conformational complications in detail. The optical activity and structure of sugars are brought together in an excellent and detailed manner in Chapter 7. Chapter 8 deals extensively with mutarotation and anhydride formation. Chapter 9 contains many oligosaccharide formulas. It is a fault, however, that there is no discussion of oligosaccharide conformations, a topic which has particularly developed in the last few years. It is debatable whether Chapter 10 on the sweetness of sugars is necessary, since this topic is very speculative at the moment.

All in all the book is very suitable for chemists who are not directly involved with carbohydrate chemistry or for

biochemists and biologists who want an introduction to stereochemistry and the effects it causes. The often difficult or obscure relationships and connections are set down with almost moving patience, which greatly eases the process of understanding them.

# From Studies of Biochemical Mechanism to Novel Biological Mediators: Prostaglandin Endoperoxides, Thromboxanes, and Leukotrienes (Nobel Lecture)**

By Bengt Samuelsson*

## 1. Introduction

Following the completion of the structural work on the prostaglandins with *Sune Bergström et al.* (for review articles see [1–3]), I was very fortunate to be able to spend a year in the Chemistry Department at Harvard University, Cambridge, MA. During this stay I had the opportunity of studying both theoretical and synthetic organic chemistry. The year in Cambridge had a profound effect on my future research. At this time *Konrad Bloch, E. J. Corey, Frank Westheimer, Robert B. Woodward,* and several other prominent scientists were among the faculty members of the department, and it was indeed a stimulating place for a young doctor of medicine interested in chemistry. I worked in *E. J. Corey*'s laboratory, and we have continued to collaborate in several areas ever since.

In 1964 it was established that there was a biogenetic relationship between polyunsaturated fatty acids and prostaglandins[4,5]. This finding was of considerable biological interest, and, since the mechanisms of the reactions involved were unknown, I decided to study this problem in my newly established laboratory.

## 2. Mechanism of Biosynthesis of Prostaglandins

The conversion of 8,11,14-eicosatrienoic acid into prostaglandin $E_1$ ($PGE_1$) involves introduction of two hydroxyl groups and one keto group. Incubation of 8,11,14-eicosatrienoic acid in an atmosphere of $^{18}O_2$ showed that the oxygen atoms of the hydroxyl groups were derived from oxygen gas, whereas the keto oxygen did not contain any $^{18}O$[6,7]. That this was due to oxygen exchange between the keto group and water was shown later[8]. In these studies the keto group was reduced immediately with $BH_4^-$, and the resulting trihydroxy acid derivative was shown to contain three $^{18}O$ atoms. These experiments were extended by carrying out the reaction in a $^{18}O_2/^{16}O_2$ mixture[8]. The reduced product was converted into the trimethoxy derivative, and the side chain carrying a hydroxyl group was cleaved off by oxidation with permanganate/periodate. The resulting dicarboxylic acid ester contained the two oxygen atoms that were introduced into the five-membered ring during the biosynthesis. Analysis of this molecule by mass spectrometry showed that the ring contained either two atoms of $^{18}O$ or two atoms of $^{16}O$, and that molecules with one atom of $^{18}O$ and one atom of $^{16}O$ in the ring were virtually absent. The experiment demonstrated that the oxygen atom of the C-11 hydroxyl group and of the C-9 keto group originated from the same molecule of oxygen (Fig. 1).

It was also shown that the hydrogen atoms at C-8, C-11, and C-12 remain fixed during the conversion of 8,11,14-eicosatrienoic acid into $PGE_1$, which is in agreement with the proposed mechanism. Experiments with the hypothetical intermediates, 15-hydroperoxy-8,11,13-eicosatrienoic acid and 15-hydroxy-8,11,13-eicosatrienoic acid, indicated that the initial reaction consisted of the introduction of the oxygen atoms into the ring[9,10]. However, two mechanisms seemed possible[9–11]: either the oxygen is added across C-9 and C-11 with concomitant formation of the new carbon-carbon bond between C-8 and C-12, or a lipoxygenase-like reaction is involved with formation of 11-hydroperoxy-8,12,14-eicosatrienoic acid in the initial step. In both pathways leading to the cyclic intermediate one hydrogen atom at C-13 is removed. In the second pathway the initial step

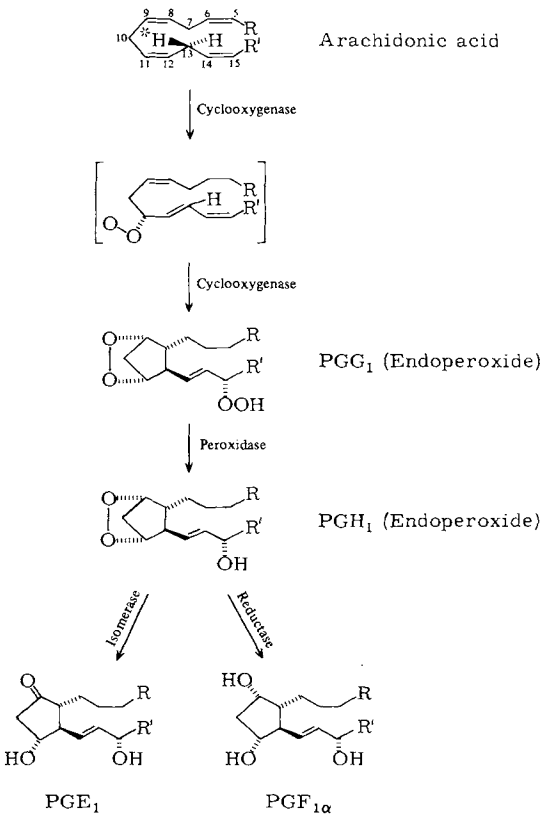

Fig. 1. Mechanism of prostaglandin biosynthesis based on the conversion of 8,11,14-eicosatrienoic acid. R = $(CH_2)_3COOH$, R' = $(CH_2)_4CH_3$.

probably involves removal of the hydrogen atom at C-13, whereas removal of this hydrogen atom occurs later in the first pathway. It was thus conceivable that removal of the hydrogen was the rate-determining step, and that substitution of tritium for hydrogen in the precursor should produce a kinetic isotope effect. In the second pathway the resulting enrichment should occur in the precursor acid, whereas in the first pathway the tritium enrichment should occur in an oxygenated intermediate. Precursor acids stereospecifically labeled with tritium at C-13 and labeled with $^{14}C$ at C-3 were therefore synthesized[10].

The conversion of the doubly labeled acids into $PGE_1$ was catalyzed by a vesicular gland preparation, and the $^3H/^{14}C$ ratio determined in the precursor, product, and in the precursor re-isolated after the reaction. It was found that 13 D-13-$^3$H-3-$^{14}$C-8,11,14-eicosatrienoic acid retained the tritium label throughout the conversion into $PGE_1$. The 13 L-13-$^3$H-3-$^{14}$C-8,11,14-eicosatrienoic acid, however, was transformed into $PGE_1$ with essentially complete loss of tritium. The precursor isolated after 75% conversion was significantly enriched (284% retention) with respect to tritium. Thus, the initial step in the transformation of 8,11,14-eicosatrienoic acid into prostaglandin is the stereospecific elimination of the 13 L-hydrogen atom. This is followed by introduction of oxygen at C-11 *via* a lipoxygenase-like reaction to give 11-hydroperoxy-8,12,13-eicosatrienoic acid[10,12]. It is of interest in this context that soybean lipoxygenase removes the same hydrogen both regio- and stereospecifically[9]. However, the plant lipoxygenase introduces the oxygen molecule at the ω6 position, whereas the lipoxygenase, which is a component of the prostaglandin synthetase, introduces the oxygen at the ω10 position[9]. The 11-peroxy-8,12,13-eicosatrienoic acid, conceived to be formed in the initial oxygenation, is subsequently transformed into an endoperoxide[8] by a concerted reaction involving addition of oxygen at C-15, isomerization of the $\Delta^{13}$-double bond, formation of the new CC bond between C-8 and C-12, and attack of the oxygen radical at C-9. Indirect evidence indicates a free radical mechanism[13,14]. The endoperoxide is transformed into $PGE_1$ by removal of a hydrogen atom at C-9 or into $PGF_{1\alpha}$ by reductive cleavage.

When washed microsomes are used as the enzyme source, eicosatrienoic acid gives rise to other products[15-17]. These cannot act as precursors in the biosynthesis of prostaglandins; however, their structures and the fate of $^3H$ in labeled precursors provided additional evidence for the proposed reaction mechanism. The monohydroxy acid fraction obtained from an incubation with eicosatrienoic acid was shown to consist of 11-hydroxy-8,12,14-eicosatrienoic acid, 15-hydroxy-8,11,13-eicosatrienoic acid, and (8*E*,10*E*)-12-hydroxy-8,10-heptadecadienoic acid. The mechanism of formation of the $C_{17}$ acid was studied using 3-$^{14}$C-eicosatrienoic acid which also contained a tritium label at C-9, C-10, or C-11[16]. These experiments showed that the conversion resulted in loss of the tritium labels in these three positions. Furthermore, malonaldehyde could be identified by condensation with L-arginine to give δ-N-2-(pyrimidinyl)-L-ornithine or with urea to give 2-hydroxypyrimidine. The derivatives of malonaldehyde contained the $^3H$ label from the 9-$^3$H and 11-$^3$H labeled precursors, whereas $^3H$ originally in position C-10 was lost by enolization of the malonaldehyde.

Additionally, it was found that a compound having chromatographic properties similar to those of $PGE_1$ and which was transformed into $PGF_{1\alpha}$ by $BH_4^-$ reduction was formed from eicosatrienoic acid[17]. The structure of the new product was found to be 9α,15-dihydroxy-11-keto-prosta-13-enoic acid (11-dehydro-$PGF_{1\alpha}$)[18]. In the conversion of 9-$^3$H,3-$^{14}$C- and 11-$^3$H,2-$^{14}$C-8,11,14-eicosatrienoic acids into 11-dehydro-$PGF_{1\alpha}$, only the second precursor lost the $^3H$ label. These experiments on the structures of the various products from eicosatrienoic acid and the fate of the $^3H$ labels in their formation provided strong evidence for the existence of the endoperoxide intermediate.

## 3. Isolation and Characterization of Prostaglandin Endoperoxides

Subsequently, it was possible to detect and isolate an endoperoxide obtained from rapid incubation of arachidonic acid with the microsomal fraction of homogenates of sheep vesicular glands[19]. The incubation mixtures were treated with $Sn^{II}Cl_2$ in ethanol to reduce endoperoxide to $PGF_{2\alpha}$. This was followed by $BD_4^-$ reduction and determination of the resulting $PGF_2$ species by mass spectroscopic analysis. Using this method it was possible to assay $PGE_2$ as well as 11-dehydro-$PGF_{2\alpha}$ and $PGF_{2\alpha}$. It was of particular interest that $PGF_{2\alpha}$ appeared in the initial stages of the incubation period. No metabolic transformation of

PGF compounds in preparations of sheep vesicular gland had previously been observed, and it was thus unlikely that $PGF_{2\alpha}$ could be formed enzymatically, followed by rapid metabolic degradation. Furthermore, when the $Sn^{II}Cl_2$ and $BD\bar{4}$ reduction was omitted no $PGF_{2\alpha}$ was detected, indicating that this species was formed by chemical reduction of an oxygenated derivative present in the initial phase of incubation. That an oxygenated intermediate was formed and temporarily accumulated was also suggested by the finding that the rate of $PGE_2$ formation was slower than the rate of oxygenation of the precursor acid.

Additional support for the existence of an oxygenated intermediate that was convertible into $PGF_{2\alpha}$ by $Sn^{II}Cl_2$ reduction came from experiments in which reduced glutathione or *p*-mercuribenzoate was added to the microsomal suspension: reduced glutathione increased the rate of formation of $PGE_2$ and suppressed formation of $PGF_{2\alpha}$, whereas reduced *p*-mercuribenzoate decreased the rate of formation of $PGE_2$ and resulted in a simultaneous increase in the amount of $PGF_{2\alpha}$. The oxygenated intermediate detected in these experiments was also isolated. On thin-layer radiochromatographic analysis of the product (methyl esters) isolated after short incubation (30 sec) of labeled arachidonic acid with microsomes in the presence of *p*-mercuribenzoate, a new radioactive derivative appeared. This was identified as the methyl ester of the previously postulated endoperoxide. In an extension of these studies the endoperoxide was obtained as the free acid; in addition, an endoperoxide with a hydroperoxy group at C-15 was isolated[20,21]. We suggested the trivial names $PGG_2$ for the less polar endoperoxide (15-hydroperoxy-9α,11α-epidioxyprosta-5,13-dienoic acid) and $PGH_2$ for the more polar endoperoxide (15-hydroxy-9α,11α-epidioxyprosta-5,13-dienoic acid). The structure of $PGG_2$ was established in three separate ways. Treatment of $PGG_2$ with mild reducing agents, such as $SnCl_2$ and triphenylphosphane, gave $PGF_{2\alpha}$ as the major product. This showed the presence of the epidioxy bridge between C-9 and C-11, but did not discriminate between a hydroxy and a hydroperoxy group at C-15 since the reagents used reduce the latter group into the former. In a second experiment, $PGG_2$ was treated with lead tetraacetate in benzene and subsequently with triphenylphosphane: in this case, 15-keto-$PGF_{2\alpha}$ was the major product. Lead tetraacetate dehydrates hydroperoxides to ketones and, hence, formation of a 15-ketoprostaglandin from $PGG_2$ in this way strongly indicates the presence of a hydroperoxy group at C-15; isomerization of $PGG_2$ to 15-hydroperoxy-$PGE_2$ in aqueous media provided independent evidence.

Two reactions are involved in the conversion of $PGG_2$ into $PGE_2$ (see also Fig. 1): reduction of the hydroperoxy group at C-15 to a hydroxy group (peroxidase) and isomerization of the endoperoxide structure to a β-hydroxyketone (endoperoxide isomerase). The endoperoxide isomerase was found to be almost entirely associated with the microsomal fraction. The enzymic activity was stimulated by reduced glutathione.

The endoperoxides were quite unstable ($t_{1/2} = 5$ min); however, when stored under anhydrous conditions in acetone they could be kept for several weeks. When their biological activity was tested on *in vitro* preparations it was found that the effects of the endoperoxides on gastrointestinal smooth muscle were comparable to those of $PGE_2$ and $PGF_{2\alpha}$. On the other hand, the effects on vascular (rabbit aorta) and airway (guinea pig trachea) smooth muscle were considerably greater than those of $PGE_2$ and $PGF_{2\alpha}$, respectively[22]. Both endoperoxides were potent contractors of the isolated human umbilical artery[23]. Administration of $PGG_2$ and $PGH_2$ intravenously to guinea pigs[22] produced an increase in insufflation pressure, which was more marked than that caused by comparable doses of $PGF_{2\alpha}$. The cardiovascular effects of the endoperoxides showed a complex pattern. The blood pressure response was triphasic, *i.e.*, a transient fall, consistently followed by a short-term rise, and then by a sustained reduction. These studies on vascular and airway smooth muscle demonstrated that the endoperoxides produced effects that could not be attributed to conversion into the stable prostaglandins.

Additional studies in our laboratory showed that both endoperoxides, $PGG_2$ and $PGH_2$, induced rapid and irreversible aggregation of human blood platelets[19,20,24].

## 4. Discovery of the Unstable Aggregating Factor and Thromboxanes

The biological effects of the pure endoperoxides were of particular interest in relation to other studies which demonstrated that arachidonic acid caused aggregation when added to human platelets[25,26], and that labile aggregating material (LASS) was formed from this acid when it was incubated with preparations of sheep vesicular glands[27-29]. Furthermore, the potency of the endoperoxides in causing contractions of the isolated rabbit aorta was of particular interest in relation to the so-called rabbit-aorta contracting substance (RCS)[30]. RCS was reported to be formed in guinea-pig lung during anaphylaxis and was later suggested to be due to the endoperoxide intermediate in prostaglandin biosynthesis[31]. We found that material with similar biological properties was formed after addition of arachidonic acid to human platelets. However, the rabbit-aorta contracting substance isolated from guinea-pig lung and platelets was found to consist of one major component with a $t_{1/2}$ of *ca.* 30 secs and a minor component ($PGG_2$ and/or $PGF_2$) with a $t_{1/2}$ of 4—5 min[32]. The short-lived major component of RCS could be generated by addition of arachidonic acid to platelets.

To obtain structural information about RCS we, therefore, incubated 1-$^{14}$C-arachidonic acid with suspensions of washed human platelets. Three major metabolites were isolated[33]: one of them was found to be (12*S*)-12-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE) (Fig. 2). The corresponding hydroperoxide (HPETE) could be isolated after incubation of arachidonic acid with sonicated plates. Formation of 12-HETE from arachidonic acid was also reported to occur in bovine platelets[34]. A more polar metabolite was identified as (12*S*)-12-hydroxy-5,8,10-heptadecatrienoic acid (HHT), whereas a third component was found to be the hemiacetal derivative of (12*S*)-8-(1-hydroxy-3-oxopropyl)-9-12-dihydroxy-5,10-heptadecadienoic acid (thromboxane $B_2$, PHD). 1-$^{14}$C-$PGG_2$ added to sus-

pensions of human platelets was rapidly converted into HHT and thromboxane $B_2$.

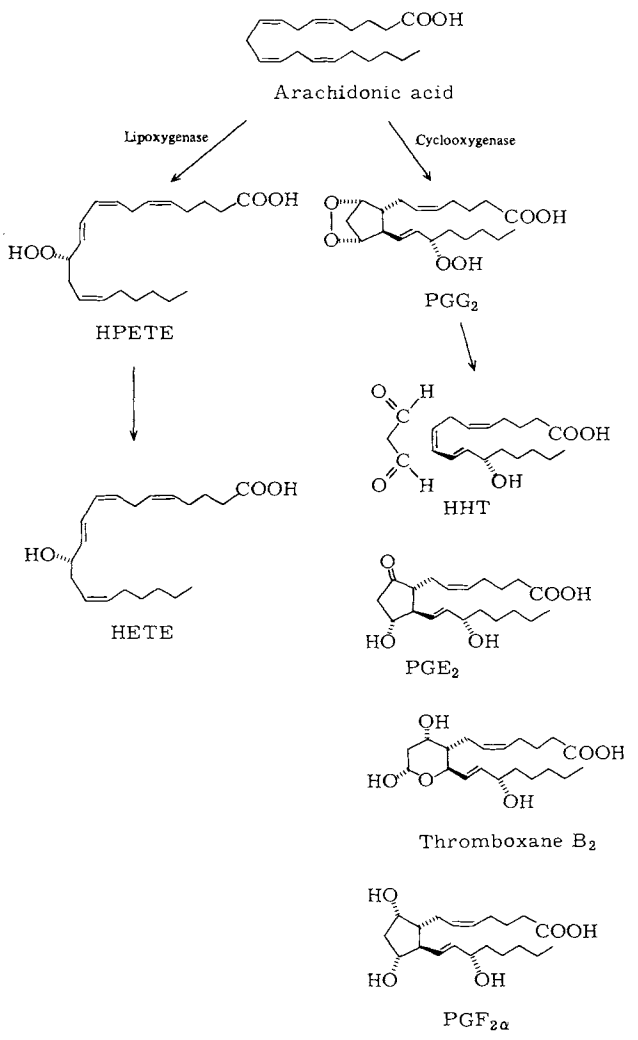

Fig. 2. Transformation of arachidonic acid in human platelets.

All the identified metabolites of arachidonic acid were stable compounds and could therefore not be identical to the very unstable RCS ($t_{1/2}=30$ sec). Additional biological work with the platelets involving characterization of the material formed from arachidonic acid was therefore carried out. When arachidonic acid was incubated with washed platelets and an aliquot of the incubate transferred to a suspension of platelets preincubated with indomethacin, aggregation took place. This was not due to $PGG_2$ or $PGH_2$, since the amounts found were only *ca.* 1% of those required to account for the response. A more detailed analysis of the appearance of the aggregating factor and the endoperoxides showed that the amount of endoperoxides was highest during the very early phase of the incubation period, whereas the aggregating factor reached a maximum later[35] (Fig. 3). Experiments using filtrates of incubates showed that the aggregating factor was very unstable. When the logarithm of the dose (arbitrary units) was plotted against the incubation time at 37 °C, a linear relationship was obtained. The half-life of the aggregating factor was 33–46 seconds. A factor with similar properties was also generated from the endoperoxide $PGG_2$. In addition to inducing irreversible aggregation, the unstable factor also caused release of serotonin from platelets.

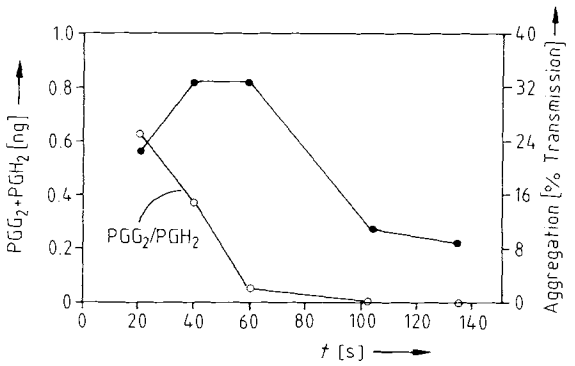

Fig. 3. Maximum aggregation induced by 0.1 mL of suspensions of washed platelets incubated for different times with 120 ng of arachidonic acid (●—●). The content of $PGG_2+PGH_2$ in these samples is also given (○—○). The platelet suspension in the aggregometer tube was preincubated for 2 min with $1.4\times10^{5}$ M indomethacin.

Further work involving experiments with $^{18}O_2$ suggested that thromboxane $B_2$ was formed from $PGG_2$ by rearrangement and subsequent incorporation of one molecule of $H_2O$[33]. It was, therefore, conceivable that if the rearranged intermediate had an appreciable lifetime it should be trapped by nucleophiles[36]: this was found to be the case. Addition of 25 volumes of methanol to washed platelets incubated with arachidonic acid for 20 seconds gave two derivatives that were less polar than thromboxane $B_2$. The mass spectral data indicated that these two compounds were epimers of thromboxane $B_2$ methylated at the hemiacetal hydroxyl group (Fig. 4). The two epimers were also formed when methanol was added to platelets incubated with $PGG_2$ for 30 seconds. Addition of ethanol to platelets incubated with arachidonic acid for 30 seconds analogously gave rise to epimers of thromboxane $B_2$ ethylated at the hemiacetal hydroxyl group. Finally, addition of 5 volumes of 5 M sodium azide to platelets incubated with arachidonic acid gave the corresponding azide (Fig.

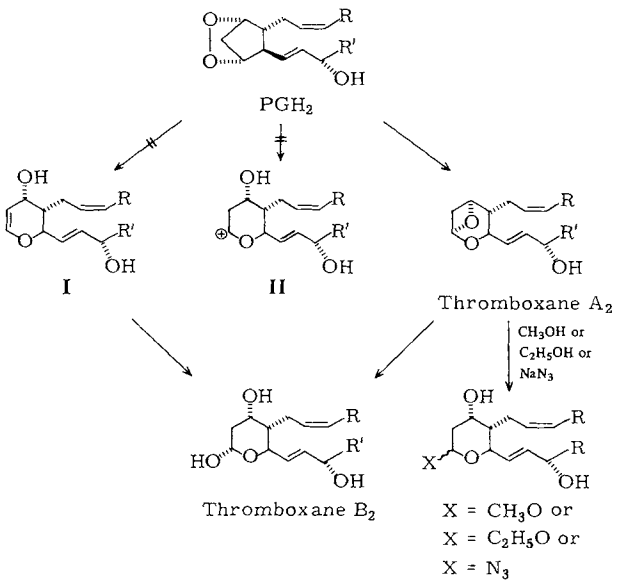

Fig. 4. Transformation of $PGH_2$ into thromboxane derivatives. $R=(CH_2)_3COOH$, $R'=(CH_2)_4CH_3$.

4). The trapping experiments showed the existence of a very unstable intermediate in the conversion of $PGG_2$ into thromboxane $B_2$.

In order to determine the half-life of the intermediate, the platelet suspension was incubated with 1-$^{14}$C-arachidonic acid for 45 seconds and the reaction was stopped by filtration. The clear, essentially platelet-free filtrate was kept at 37 °C, and aliquots were removed after different times and immediately added to 25 mL of methanol containing tritium-labeled monomethylthromboxane $B_2$. A straight line relationship between the logarithms of the $^{14}C/^{3}H$ ratios of the purified methyl ester of monomethylthromboxane $B_2$ and the incubation times was found; the half-life thus obtained was $32 \pm 2$ seconds.

Figure 4 shows the structure proposed for the unstable intermediate (thromboxane $A_2$). The acetal carbon atom should be susceptible to nucleophilic attack, *e.g.*, by $H_2O$ (giving thromboxane $B_2$) as well as by $CH_3OH$, $C_2H_5OH$, and $N_3^-$ (giving the derivatives of thromboxane $B_2$ described above). Addition of $CH_3O^2H$ to platelets incubated with arachidonic acid led to formation of monomethylated thromboxane $B_2$ with no carbon-bound $^2H$. This finding precluded an alternative structure for the unstable intermediate, *i.e.*, a 3,4-dihydro-2*H*-pyran derivative (**I** in Fig. 4). Furthermore, the $t_{1/2}$ of thromboxane $A_2$ seemed to preclude involvement of a carbonium ion structure (**II** in Fig. 4), which in aqueous media should be considerably less stable.

The available evidence indicated that the aggregating factor and RCS were one and the same compound. Thus, they were both derived from arachidonic acid or $PGG_2$, their formation from arachidonic acid was blocked by indomethacin, and their half-lives were similar. It was proposed that this material is identical to the unstable intermediate detected chemically in platelets (Fig. 4).

Because of their structure and origin, the new "oxane" derivatives were named thromboxanes. Thromboxane $A_2$ is a highly unstable bicyclic compound, and thromboxane $B_2$ is a stable derivative, provisionally named PHD. The subscript indicates the number of double bonds, as in the prostaglandin nomenclature. The structure of thromboxane $B_2$ has been confirmed by synthesis[37-40].

Thromboxane $A_2$ has been shown to be highly biologically active: Some of the better known of these effects are induction of platelet aggregation and the release reaction[36,40], as well as the strong constricting effects on vascular smooth muscle. The first blood vessel to be studied in this respect was the rabbit aorta[30,32]; later, similar contractile responses were observed in other blood vessels, such as coronary arteries[42-46], the mesenteric and celiac arteries[47,48], and the umbilical artery[23], *etc.*

These dual effects of $TXA_2$, induction of vasoconstriction and platelet aggregation, both come into operation after a blood vessel has been injured. They indicate that $TXA_2$ probably plays a role in normal hemostasis *in vivo* as well as in pathological conditions with an increased tendency to vasospasm and/or thrombosis. Several reviews have appeared on the biological effects and possible roles of thromboxanes *in vivo*[41,50]. Thromboxane $A_2$ also has potent contractile effects on airways, demonstrable both *in vitro* and *in vivo*[51].

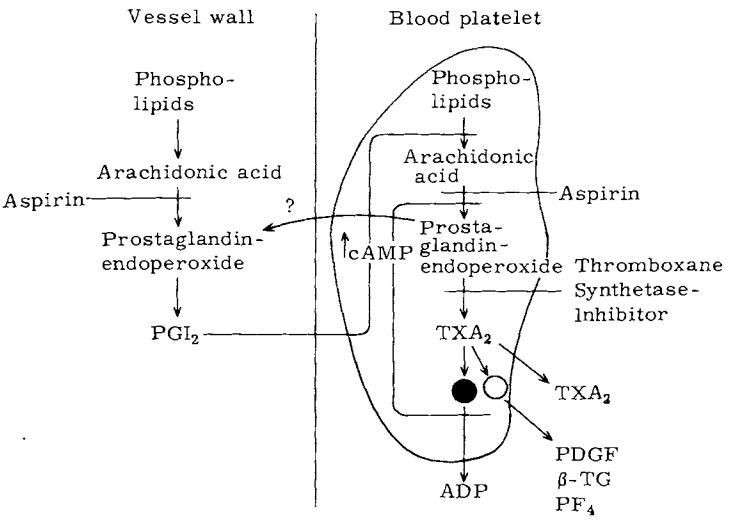

Fig. 5. Interaction between platelets and the blood vessel wall. PDGF = Platelet Derived Growth Factor; β-TG = β-Thromboglobin; $PF_4$ = Platelet Factor 4.

Following the isolation of the endoperoxides and the discovery of thromboxane $A_2$ it was found that arterial tissue converts the endoperoxide into a product with the opposite effects[52]. Structural work demonstrated that it was an enol ether derivative[53]. This vasodilator and antiaggregating compound was named $PGI_2$, or prostacyclin. Thromboxane $A_2$ and prostacyclin together probably form a hemostatic mechanism for controlling the tonus of blood vessels and the aggregation of platelets *in vivo*. These platelet and vessel wall reactions, which are of considerable interest in antithrombotic therapy, are summarized in Figure 5. The main focus is now on the development of specific thromboxane synthetase inhibitors. For a recent review see[54].

## 5. Discovery of the Leukotrienes

The role played by prostaglandins in inflammation was brought into focus by the discovery by *Vane et al.* that nonsteroidal anti-inflammatory drugs such as aspirin inhibit the enzyme (cyclooxygenase) responsible for conversion of arachidonic acid into prostaglandins and thromboxanes[55]. Anti-inflammatory steroids also inhibit the formation of prostaglandins; however, the mechanism of action is different. The steroids inhibit the formation of prostaglandins by blocking the release of arachidonic acid from the phospholipids. Since aspirin-like drugs and steroids have different anti-inflammatory effects it seemed conceivable to us that some of these differences might be due to formation of additional pro-inflammatory derivatives of arachidonic acid. Studies of the transformation of arachidonic acid in leukocytes which were carried out to test this hypothesis have recently resulted in the recognition of a novel group of compounds: the leukotrienes. These compounds seem to be of importance in both immediate hypersensitivity reactions and in inflammation.

When arachidonic acid was incubated with polymorphonuclear leukocytes it was found that the major meta-

bolite was a new lipoxygenase, (5*S*)-5-hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE)[56]. Additional studies also demonstrated the formation of (5*S*,12*R*)-5,12-dihydroxy-6,8,10,14-eicosatetraenoic acid (major product) (leukotriene $B_4$, see below), two additional (5*S*)-5,12-dihydroxy-6,8,10,14-eicosatetraenoic acids [(*E*,*E*,*E*,*Z*)-C-12 epimeric] and two isomeric 5,6-dihydroxy-7,9,11,14-eicosatetraenoic acids (Fig. 6)[57,58].

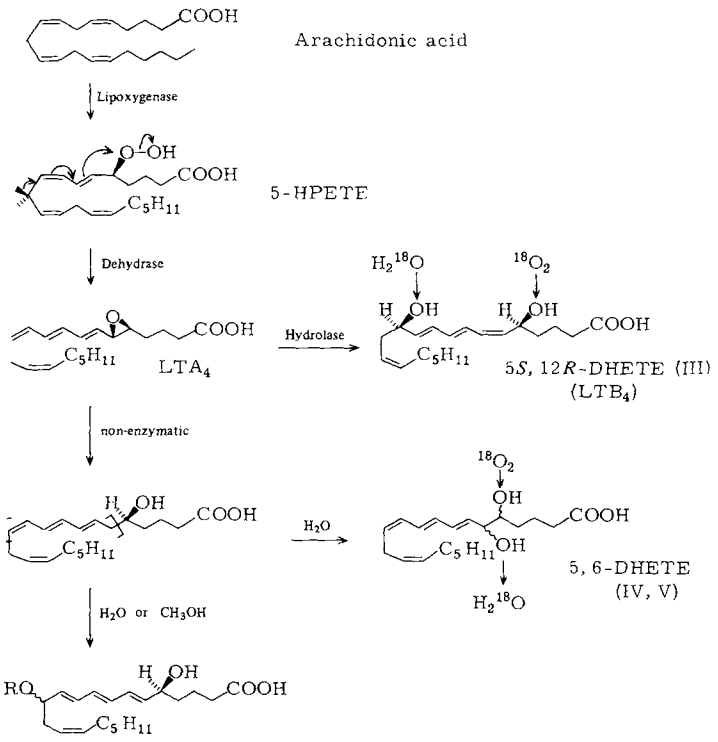

Fig. 6. Formation of dihydroxy derivatives *via* unstable intermediates. Origin of oxygen and trapping experiments.

Stereochemical studies, demonstrating formation of two acids with all-*trans* conjugated trienes which are epimeric at C-12 and of one major isomer (12*R*) with a different configuration of the triene, raised the question of the mechanism of formation[58]. Using $^{18}O_2$ and $H_2{}^{18}O$, it was demonstrated that the oxygen of the hydroxy group at C-5 originated from molecular oxygen, whereas the oxygen of the hydroxy group at C-12 was derived from water (Fig. 6)[59]. These observations led us to propose that leukocytes generated an unstable intermediate which could undergo attack by nucleophiles such as water, alcohols, *etc.* Leukocytes were therefore incubated for 30 seconds with arachidonic acid followed by addition of 10 volumes of methanol, 10 volumes of ethanol, or 0.2 volumes of N hydrochloric acid. Trapping with methanol (or ethanol) yielded two new less polar compounds, present in equal amounts and having ultraviolet spectra identical to those of compounds I and II (Fig. 6). IR spectroscopy indicated that the conjugated trienes had the all-*trans* geometry. Mass spectrometric analyses of the two compounds showed that they were isomeric and had hydroxy groups at C-5 and methoxy groups at C-12. Since C-5 in both cases had the (*S*)-configuration, it was clear that the compounds were the C-12 epimers of (5*S*)-5-hydroxy-12-methoxy-(6*E*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid (Fig. 6).

These experiments demonstrated that leukocytes generate a metabolite of arachidonic acid which can undergo a facile nucleophilic reaction with alcohols. Analysis of samples obtained from trapping experiments performed under different conditions always showed inverse relationships between the amount of compounds I and II and their 12-*O*-alkyl derivatives. This result suggested that compounds I and II and the 12-*O*-alkyl derivatives were formed nonenzymatically from the same intermediate.

The stability of the intermediate was determined by incubating leukocytes with arachidonic acid for 45 seconds; the enzyme was then inactivated by addition of 1 volume of acetone. After different time intervals aliquots of the mixture were transferred to flasks containing 15 volumes of methanol. Chromatographic analysis showed that the $t_{1/2}$ of the intermediate, determined as the 12-*O*-methyl derivative, was 3–4 min. Concomitant with the decrease in the concentration of the intermediate, the concentrations of compounds I, II, IV, and V increased; in contrast, the concentrations of compound III and of 5-hydroxy-6,8,11,14-eicosatetraenoic acid remained constant. These data suggested that the epimeric 5,12- and 5,6-dihydroxy acids (compounds I, II, and IV, and V) are formed by nonenzymatic hydrolysis of a common unstable intermediate, whereas compound III is generated by enzymatic hydrolysis of the same intermediate (Fig. 6). Similar experiments performed at acidic and alkaline pH showed that the intermediate was acid labile, but considerably more stable under alkaline conditions. It was also found that the two 5,6-dihydroxy derivatives (IV and V) were formed nonenzymatically from the same intermediate as the enzymatic product, (5*S*,12*R*)-5,12-dihydroxyeicosatetraenoic acid, and that $^{18}O$ from molecular oxygen was exclusively retained at C-5 of these derivatives; in contrast, $^{18}O$ from water was introduced at C-6 or C-12. On the basis of these experimental data, the structure (5*S*)-5,6-epoxy-7,9,11,14-eicosatetraenoic acid (leukotriene $A_4$, $LTA_4$) (Fig. 6) was proposed for the intermediate[59].

The formation of compounds I–V from the epoxide intermediate is shown in Figure 6. With the exception of compound III, these are formed by chemical hydrolysis of the epoxide *via* a mechanism involving a carbonium ion intermediate, which adds hydroxyl anion preferentially at C-6 and C-12 to yield four isomeric products containing the stable conjugated triene structural moiety. The formation of compound III is enzymatic since it is not racemic at C-12 and is only formed by nondenatured cell preparations.

The structure proposed for leukotriene $A_4$[59] has subsequently been confirmed by chemical synthesis[60]. The (5*S*, 12*R*)-5,12-dihydroxy acid formed enzymatically was earlier shown to contain one *cis* and two *trans* double bonds in the conjugated triene. The location of the *cis*-double bond ($\Delta^6$-position) was recently established by synthesis[61]. The intermediate allylic epoxide $LTA_4$ can exist in free form, since it has been isolated from human polymorphonuclear leukocytes[62]. The suggested mechanism for the biosynthesis of the epoxide from arachidonic acid (Fig. 6) involves initial formation of 5-hydroperoxy-6,8,11,14-ei-

cosatetraenoic acid (5-HPETE); epoxide formation follows by subsequent abstraction of the pro-*R* hydrogen atom at C-10 and elimination of hydroxide ion from the hydroperoxy group[63]. The dehydration reaction is catalyzed by a soluble enzyme, which was recently isolated from leukocytes[64].

## 6. Slow Reacting Substance of Anaphylaxis (SRS-A)

The occurrence of a smooth muscle stimulating factor (SRS) in the perfusate of guinea pig lung treated with cobra venom was described in 1938[65]. The factor was also shown to be released by immunological challenge[66]. Biological studies of SRS suggested that it might be an important mediator of anaphylactic and other immediate hypersensitivity reactions[67,68]. Characterization of SRS indicated that it was a polar lipid which absorbed in the UV and that it might contain sulfur[69–71]. Studies with labeled arachidonic acid suggested that this acid might be incorporated into SRS[72,73].

Studies in our laboratory showed that treatment of human neutrophils with the ionophore A23 187 resulted in stimulation of the synthesis of the 5,12-dihydroxy acid ($LTB_4$) described in the previous section[58]. On the basis of the stimulatory effect of the ionophore on both SRS production[74] and $LTB_4$ formation, the UV absorbance data, and other considerations we developed the hypothesis that there was a biogenetic relationship between the unstable allylic epoxide intermediate in neutrophils and SRS generated in a variety of systems.

For formation of relatively large amounts of SRS we found that murine mastocytoma cells (CXBGABMCT-1) stimulated with the calcium ionophore A23 187 were more suitable than previously described systems[75]. The SRS was purified by high performance liquid chromatography. The purified material showed an absorbance maximum at 280 nm and gave a typical contraction of guinea pig ileum which was reversed by FPL-55712[75]. The UV characteristics resembled those of the dihydroxy acids; however, the maximum was shifted 10 nm to higher wavelength. This was in accord with the presence of a sulfur substituent in the α-position to a conjugated triene. Labeled arachidonic acid and cysteine were incorporated into the product.

Degradation of SRS by Raney nickel desulfurization gave 5-hydroxyeicosanoic acid, indicating that the arachidonic acid derivative and cysteine were linked by a thioether bond (Fig. 7). This finding also supported the hypothesis that there was a biogenetic relationship between the 5-lipoxygenase pathway in leukocytes and SRS. The positions of the double bonds in SRS were determined by reductive ozonolysis. Isolation of 1-hexanol among the products indicated that the $\Delta^{14}$-double bond of arachidonic acid had been retained. The approach used for locating the conjugated triene was based on previous studies in our laboratory which had shown that arachidonic acid and related fatty acids containing two *cis* double bonds at the ω6 and ω9 positions separated by a methylene group are oxygenated to give derivatives in which the ω6 double bond has isomerized to ω7. Incubation of the isolated SRS with lipoxygenase resulted in isomerization of the $\Delta^{14}$-double bond to form a conjugated tetraene, since a bathochromic shift of 30 nm was observed. This finding indicated that SRS contained a $\Delta^{11}$-*cis* double bond and additional double bonds at Δ7 and Δ9. The structural work at this stage showed that SRS was a derivative of 5-hydroxy-7,9,11,14-eicosatetraenoic acid with a cysteine-containing substituent thioether-linked at C-6. That the cysteine is derivatized was suggested by the failure to isolate alanine after desulfurization. The cysteine-containing substituent was, therefore, referred to as RSH[75–77]. Further studies involving amino acid analyses of acid hydrolyzed SRS demonstrated that, in addition to cysteine, one mol of glycine and one mol of glutamic acid were present per mol of SRS. End group (dansyl method and hydrazinolysis) and sequence analyses (dansyl-Edman procedure) of the peptide showed that it was γ-glutamylcysteinylglycine (glutathione). The structure of the SRS from murine mastocytoma cells was therefore 6-*S*-glutathionyl-5-hydroxy-7,9,11,14-eicosatetraenoic acid, leukotriene $C_4$ ($LTC_4$) (Fig. 7)[78]. The structure was confirmed by comparison with synthetic material. This represented the first structure de-

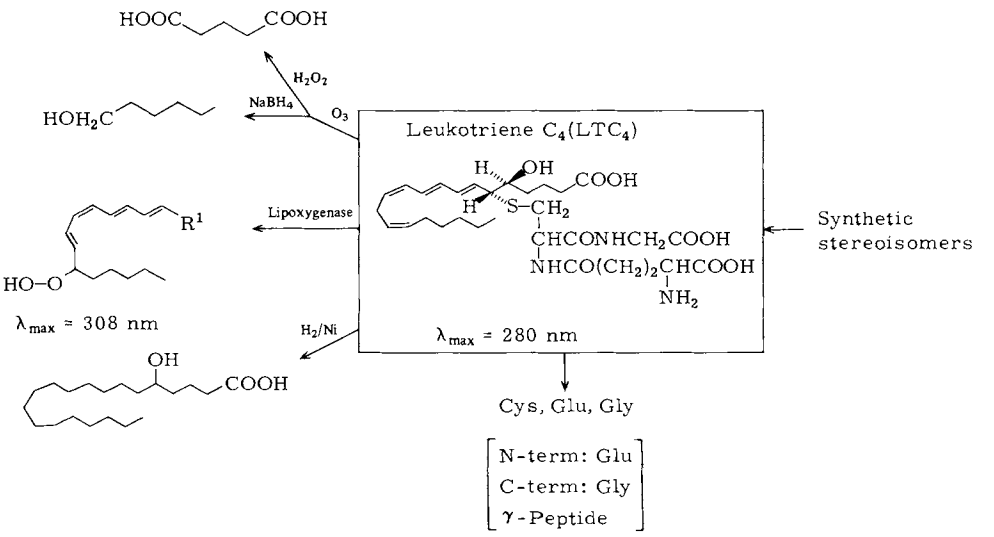

Fig. 7. Some transformations in structural studies on SRS.

termination of an SRS-A[78]. The preparation and some properties of the cysteinylglycine ($LTD_4$) and cysteinyl derivatives ($LTE_4$) were also reported at the same time[78]. These compounds were later isolated from natural sources (see below). The stereochemistry proposed for $LTC_4$ was confirmed and unambiguously assigned by total synthesis, including preparation of stereoisomers of $LTC_4$[79], by *E. J. Corey et al.*: $LTC_4$ is thus (5*S*,6*R*)-6-*S*-glutathionyl-5-hydroxy-(7*E*,9*E*,11*E*,14*Z*)-eicosatetraenoic acid.

Later studies using a different cell type, RBL-1 cells, showed that the major slow reacting substance was $LTD_4$ [(5*S*,6*R*)-6*S*-cysteinylglycine-5-hydroxy-(7*E*,9*E*,11*Z*,14*Z*)-eicosatetraenoic acid][80].

Following the structure determination of SRS from mastocytoma cells[75,78] and the synthesis of $LTC_4$, $LTD_4$, and $LTE_4$[78], all of these cysteine-containing leukotrienes (Fig. 8) were identified in a variety of biological systems using comparison with synthetic material or partial characterization by chemical or physical methods (Table 1). SRS-A is thus a mixture of leukotrienes containing cysteine, *e.g.*, the parent compound $LTC_4$ and the metabolites $LTD_4$ and $LTE_4$.

Transformation of $LTA_4$ into $LTC_4$ by enzymatic addition of glutathione has been demonstrated in both mastocytoma cells and human leukocytes pretreated with the inhibitor of arachidonic acid metabolism, BW755[81]. These studies confirm the originally proposed biosynthetic pathway for SRS, *i.e.*, formation of $LTA_4$ from arachidonic acid *via* 5-HPETE, followed by addition of glutathione to $LTA_4$ and cleavage of the epoxide ring at the allylic position C-6 to give $LTC_4$[75].

The biological significance of the biosynthetic pathways described and the cumbersome systematic names of the compounds involved suggested the introduction of a trivial name for these entities[76]. The term "leukotriene" was chosen because the compounds were discovered in leukocytes and the common structural feature is a conjugated triene. Various members of the group have been designated alphabetically: leukotriene A is a 5,6-epoxy-(7*E*,9*E*,11*Z*)-, leukotriene B a (5*S*,12*R*)-5,12-dihydroxy-(6*Z*,8*E*,10*E*)-, leukotriene C, a (5*S*,6*R*)-5-*S*-glutathionyl-5-hydroxy-(7*E*,9*E*,11*Z*)-, and leukotriene E a (5*S*,6*R*)-6-*S*-cysteinyl-5-hydroxy-(7*E*,9*E*,11*Z*)-eicosapolyenoic acid. Since precursor acids containing the $\Delta^5$-double bond system (*e.g.* 5,8,11-eicosatrienoic acid, arachidonic acid, and 5,8,11,14,17-eicosapentaenoic acid) can be converted into leukotrienes containing 3—5 double bonds, a subscript denoting this number is used[82]. Leukotriene $A_4$ is thus the epoxy derivative of arachidonic acid and can be further transformed into leukotrienes $LTB_4$, $LTC_4$, and $LTE_4$.

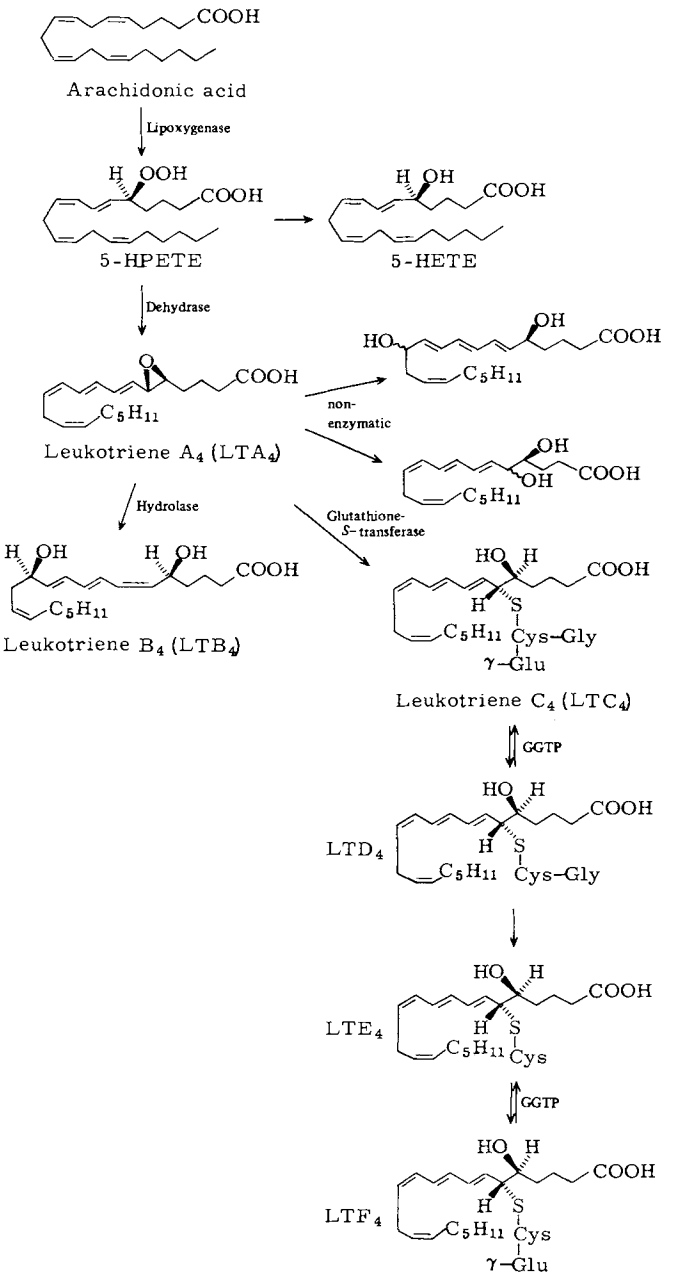

Fig. 8. Formation of leukotrienes from arachidonic acid *via* the 5-lipoxygenase pathway.

Leukotriene $C_4$ is metabolized to leukotriene $D_4$ by enzymatic elimination of glutamic acid by γ-glutamyl transpeptidase (GGTP)[80]. The remaining peptide bond in leukotriene $D_4$ is hydrolyzed by a renal dipeptidase to give leukotriene $E_4$[83]. It has recently been found that $LTE_4$ can also function as an acceptor for γ-glutamic acid, forming a γ-glutamylcysteinyl derivative, $LTF_4$[84,85] (Fig. 8).

In addition to the 5-lipoxygenase, leukocyte preparations contain enzymes catalyzing introduction of oxygen at C-12 and C-15[86]. Recently, evidence has been obtained for leukotriene formation after initial oxygenation at either of these positions[87–91].

## 7. Biological Effects of the Leukotrienes

Studies with pure leukotrienes have provided detailed information about the effects of this group of compounds in different biological systems. The leukotrienes containing cystein ($LTC_4$, $LTD_4$, and $LTE_4$) are potent bronchoconstrictors in several species, including humans, and seem to have specific effects on the peripheral airways[92–99]. They also show potent vasoconstrictor activity and have negative ionotropic effects on cardiac contractions[100].

In recent studies using bronchi from atopic patients sensitive to birch pollen[101], the relative importance of the leukotrienes as mediators of anaphylaxis has been demonstrated. Treatment of the preparation with a histamine antagonist (mepyramine) and a cyclooxygenase inhibitor (indomethacin) did not reduce the response to the specific allergen; however, benoxaprofen and a prostacyclin derivative (U-60257), both of which block leukotriene formation[102,103], inhibited the anaphylactic contraction in bronchi from asthmatics induced by birch pollen. Incubation of the atopic lung tissue with antigen resulted in release of $LTC_4$, $LTD_4$, and $LTE_4$, which could be inhibited by the prostacyclin derivative U-60257[101]. These studies indicate that the leukotrienes containing cysteine ($LTC_4$, $LTD_4$, and $LTE_4$) are major mediators of airway anaphylaxis; the finding that inhibition of leukotriene formation blocks ascaris-induced asthma in monkeys also indicates that leukotriene antagonists or inhibitors of their formation could be of therapeutic value in the treatment of bronchial asthma[102].

When injected intradermally into guinea pigs, $LTC_4$ and $LTD_4$ cause extravasation of Evan's blue[92,96,98]. More recent studies involving intravital microscopy of the cheek pouch of the hamster *(Mesocricetus sauratus)* have demonstrated that these leukotrienes have specific effects on the permeability of the post-capillary venules[104]. According to dose-response curves, $LTC_4$ and $LTD_4$ both induce a significant increase of vascular permeability at much lower concentrations than histamine. Leukotriene $C_4$ is approximately 5000 times more potent than histamine in this respect. The cysteinyl-containing leukotrienes seem to increase the vascular permeability by direct action on the blood vessel wall, since it occurs rapidly and does not require release of histamine or prostaglandins or the participation of polymorphonuclear leukocytes. Leukotriene $B_4$ also causes extravasation of plasma, although at higher concentrations. The reaction occurs with some latency and requires adhering leukocytes. Administration of a vasodilator together with leukotrienes potentiates the increase in plasma leakage caused by a submaximal dose of leukotrienes, as has been reported for $PGE_2$ and $LTD_4$ in guinea pigs[105] and for $PGE_2$ and $LTB_4$ in guinea pigs, rabbits, and rats[106,107].

When $LTB_4$ was administered to the hamster cheek pouch in the same dose-range as $LTC_4$ it caused a dramatic increase in the adhesion of leukocytes to the endothelium in small venules[104]. Increased adherence of human leukocytes caused by $LTB_4$ has also been demonstrated *in vitro* using a column of nylon fibers[108].

During superfusion with $LTB_4$ (6—10 min) the number of interstitial white cells increased. This finding is consistent with the chemotactic stimulant property of $LTB_4$, and has been shown *in vitro* using either the Boyden chamber technique or migration under agarose[109–112]. *In vivo* this effect has been monitored by determining white cell accumulation in the peritoneal cavity of guinea pigs following intraperitoneal injection of $LTB_4$[113]. The studies described above indicate that $LTB_4$ might be a mediator in the migration of leukocytes from the blood to areas of inflammation. Recent work has also demonstrated that $LTB_4$ activates neutrophils. Addition of nanomolar concentrations of $LTB_4$ to the cells results in rapid aggregation, degranulation, superoxide generation, and mobilization of membrane-associated calcium[114–116].

Studies of the mechanism of action of anti-inflammatory steroids indicate that they inhibit the release of the precursor, arachidonic acid, whereas cyclooxygenase inhibitors, such as aspirin, block the transformation of this acid into prostaglandins and thromboxanes (Fig. 9). The steroid induced inhibition of arachidonic acid release, proposed to be due to formation of peptide inhibitors of phospholipase $A_2$, prevent formation not only of prostaglandins and thromboxanes but also of leukotrienes and other oxygenated derivatives[117,118]. Some of the therapeutic effects of steroids which are not shared by aspirin-type drugs might, therefore, be due to inhibition of leukotriene formation.

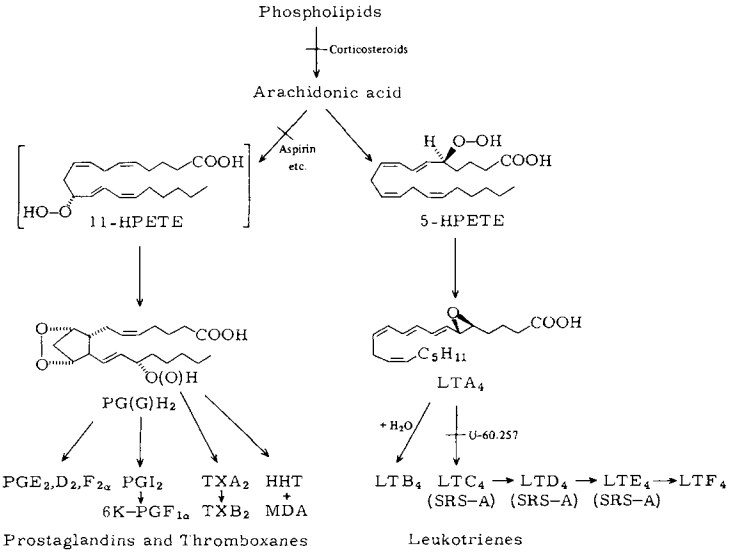

Fig. 9. Formation of prostaglandins, thromboxanes and leukotrienes from phospholipids.

The recent increase in knowledge about the transformation of arachidonic acid and the biological effects of the metabolites appear to provide new possibilities of developing novel and more specific therapeutic agents.

*It is a pleasure to acknowledge the important contributions of my associates who participated in the research described in this article. The work from the author's laboratory was supported by the Swedish Medical Research Council (project 03X-217) and the Knut and Alice Wallenberg Foundation.*

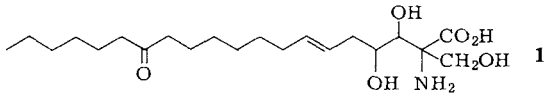
# New Naturally Occurring Amino Acids**

**By Ingrid Wagner and Hans Musso***

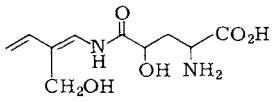
*Dedicated to Professor Hans Brockman on the occasion of his 80th birthday*

The majority of the 500 or so naturally occurring amino acids known today were discovered during the last 30 years, for example during the search for new antibiotics in the culture media of microorganisms, or as components of the antibiotics in fungi, seeds, in numerous plants and fruits, and in the body fluids of animals. Some 240 of these amino acids occur free in nature, some only as intermediates in metabolism. This article provides an overview of the developments that have taken place in this area since 1956 when the last review appeared. Summary accounts are presented, dealing with new unsaturated amino acids, cyclopropane- and cyclobutane-amino acids, heterocyclic amino acids, halogen-containing amino acids, sulfur-, selenium- and phosphorus-containing amino acids as well as aliphatic amino acids. In a few cases, *e.g.* betalamic acid and muscaflavin, the biosynthesis is described in detail.



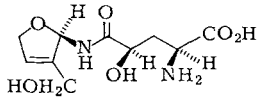
## 1. Historical Introduction

In 1820 glycine was isolated from gelatin hydrolyzates. In the following 100 years the remaining twenty amino acids, which are normally found in proteins, were identified. Only four more were found between 1920 and 1940. With the development of chromatographic methods the number of known naturally occurring amino acids increased rapidly. In 1956 alone over 60 new ones were reported[1]. At the moment 500 are known, of which *ca.* 240 occur free in nature. Still further naturally occurring amino acids are being found each year[2,3].



The methods of detection and determination of structure have improved so much in recent years that traces of a new fluorescent spot can be discerned in the two dimensional chromatogram of the dansyl derivatives (dansyl = 5-dimethylamino-1-naphthylsulfonyl)[4–6]. Combined GC-MS of the *N*-trifluoroacetyl-methyl ester derivatives[7] confirms that the sample is homogeneous and provides an empirical formula and often a hint as to the structure, which can be corroborated by $^1$H- and $^{13}$C-NMR on a few mg of the amino acid. In particularly difficult cases, such as for example streptolidin[8a], an X-ray structure analysis is also necessary[8b]. Nowadays one can determine the enantiomeric purity, usually to better than 0.1%, by gas chromatography of volatile amino acid derivatives on a peptide-ester stationary phase. Equally good results are obtained by chromatography of the free amino acids as diastereoisomeric copper complexes with L-proline on octadecylated silica-gel with aqueous eluents[9]. The absolute configuration can be easily determined from CD spectra if a characteristic longwave transition can be produced by making a complex[10a] or a dinitrophenyl derivative[10b]. If there are a number of chiral centers the unambiguous assignment of all the isomers is possible through stereospecific synthesis, as for example in the case of 3-hydroxyprolines[11] (cf. **39** in Section 4.1) or (−)-*S*-(2-carboxypropyl)-L-cysteine[12] (cf. **151** in Section 6).

## 2. Unsaturated Amino Acids



Thermocymocidin **1** from a thermophilic Eumyces species[2b,3l,13] and myriocin from the thermophilic fungus *Myriococcum albomyces*[14] are identical, both in their constitution, with a *trans* double-bond, and in their activity towards molds.

**1**

**2**

**3**

From the seeds of the bush *Staphylea pinnata* are obtained pinnatanine **2** and oxypinnatanine **3**; the absolute configuration of the dihydrofuran moiety of the latter has been established by X-ray analysis[3i].

α-Methylene-β-alanine is toxic and is found as its *N*-acetyl derivative in Hawaian sponges[15]; β-methylene-L-norvaline is found in the fungus *Lactarius helvus*[3b], β-methylene-L-norleucine in *Amanita vaginata*[2a] and (2*S*,3*S*)-3-hydroxy-4-methyleneglutamic acid in *Gleditsia caspica*[3g]. γ-Propylidene-L-glutamic acid was isolated from *Mycena pura* together with γ-methylene- and γ-ethylideneglutamic acid[3i]. Amino acids with methylenecyclopropyl units like **13–15** will be mentioned in Section 3. Further unsaturated naturally occurring amino acids, mostly not bound to proteins, are presented in Table 1.

Together with the amino acids containing one or more double bonds there are also some with triple bonds. The

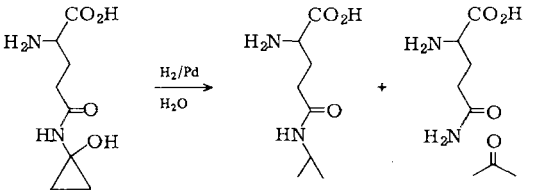
Table 1. New unsaturated amino acids.

| Unsaturated Amino Acid | Isolated from | Ref. |
|---|---|---|
| L-2-Amino-4-(2-aminoethoxy)-*trans*-3-butenoic acid | Unidentified streptomyces | [3g] |
| 2-Amino-4-(2-amino-3-hydroxypropoxy)-*trans*-3-butenoic acid | *Rhizobium japonicum* | [3e] |
| 4-Acetamido-2-butenoic acid | *Fusarium graminearum* | [3j] |
| L-2-Amino-3-formyl-3-pentenoic acid | *Bankera fulgineoalba* | [3a] |
| L-2-Amino-3-hydroxymethyl-3-pentenoic acid | *Bankera fulgineoalba* | [3a] |
| L-2-Amino-4-chlor-4-pentenoic acid | *Amanita pseudoporphyria* | [3g] |
| *trans*-2-Amino-5-chlor-4-hexenoic acid | *Amanita solitaria* | [3e] |
| 2-Amino-4-methyl-5-hexenoic acid | *Tricholomopsis rutilans* | [16] |
| 2-Amino-5-methyl-4-hexenoic acid | *Leucocortinarius bulbiger* | [3a] |
| 2-Amino-4-methyl-4-hexenoic acid | *Aesculus californicus* | |
| 2-Amino-6-hydroxy-4-methyl-4-hexenoic acid | *Aesculus californicus* | [3a] |
| L-2-Amino-6-hydroxy-5-methyl-4-hexenoic acid | *Blighia unijugata* | [2b] |
| 2-Amino-4,5-hexadienoic acid [a] | *Amanita solitaria* | [3e] |
| 2-Amino-4-methyl-5-hexynoic acid | | [3b] |
| 2-Amino-4-hydroxy-6-heptynoic acid | *Euphoria longan* | [3b] |
| 2-Amino-4-hydroxymethyl-5-hexynoic acid | | [3b] |
| 2-Amino-3-hydroxy-4-hexynoic acid | *Tricholomopsis rutilans* | [3f,g] |
| 2-Amino-4-hexynoic acid | a New-Guinea fungus | [3e] |

[a] This hexadienoic acid can be regarded as a precursor in the biosynthesis of hypoglycine A **14**.

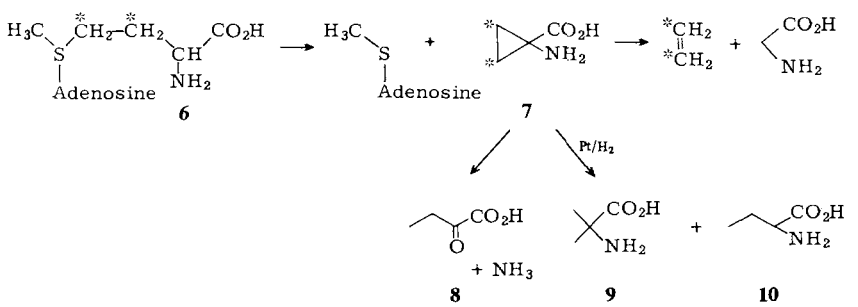


poly-yne amino acids **4** and **5**, which are produced by the fungus *Fayodia bisphaerigera* in its advanced stage of growth[17], and which are isolated as the methyl esters, are rather special. It is assumed that they are formed in nature by acylation of the amino acids with the hydroxyenetriynoic acid since this acid is found together with **4** and **5** in the same fungi. The synthesis was accomplished by coupling of the propiolylated amino acid with the hydroxyenediyne bromide.

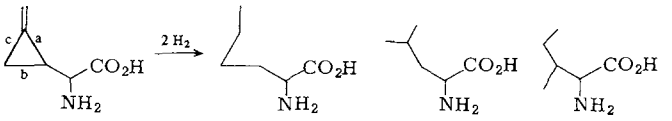
**4**, R = H
**5**, R = $CH_3$

## 3. Cyclopropane and Cyclobutane Derivatives

1-Aminocyclopropanecarboxylic acid **7** was first discovered in the late 1950s, bound to cranberry protein, and later in apples and pears[18]. This amino acid is an intermediate in the biosynthesis of ethylene[19,20], which acts as a plant growth regulator. In this process methionine is converted enzymatically *via* an adenosine complex **6** into **7** and methylthioadenosine; **7** is not, however, released but is immediately split into ethylene and glycine—most probably while complexed with an enzyme. In addition, **7** serves as sole source of nitrogen for the bacterium *Pseudomonas sp. ACP* and for the yeast *Hansenula saturnus*, which deaminate it enzymatically to α-oxobutyric acid **8**[20]. On hydrogenation with Pt in glacial acetic acid, α-aminoisobutyric acid **9** is formed predominantly owing to the substituent effect[21], whereas in alcoholic ammonia, α-aminobutyric acid **10** is the main product[22]. Similarly, in the hydrogenation of coprin **11** the $CH_2$–$CH_2$ bond in the cyclopropane is opened to give **12**. This amino acid was isolated from *Coprinus atramentarius*[23] and is responsible for the antabuse effect of this fungus[*].

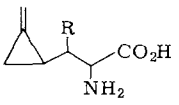


**11** **12**



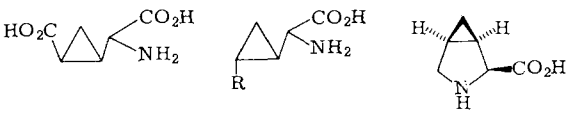
1-Amino-2-ethyl-1-cyclopropanecarboxylic acid, also known as coronamic acid, is a component of the toxin coronatin found in *Pseudomonas coronafacience var. atropurpurea*[24].

α-(Methylenecyclopropyl)glycine **13**, the corresponding alanine derivative hypoglycine A **14**, and hypoglycine B

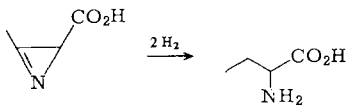


[*] The antabuse effect is the sensitization and intolerance of an organism towards alcohol caused by a drug.

(the dipeptide from **14** and Glu[25]) have been isolated from the unripe fruit of *Blighia sapida* and from litchi seeds[2b]. Compounds **13** and **14** reduce the blood-sugar concentration so drastically that eating the unripe fruit can lead to lethal hypoglycemia. Catalytic hydrogenation of **13** gave norleucine, leucine, and isoleucine (a, b, and c).

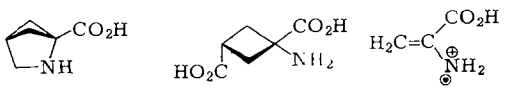


**13** a b c

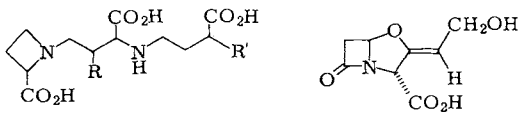


**14**, R = H
**15**, R = $CH_3$

β-(Methylenecyclopropyl)-β-methylalanine **15** has been found in the seeds of *Aesculus californica*[3a], while *cis*- and *trans*-α-(carboxycyclopropyl)glycine, **16** and **17**, can be isolated from the seeds of *Aesculus parviflora* and *Blighia sapida* respectively[3a]. *Blighia unijugata* contains the homologous carboxymethyl derivative **18** as well as L-*exo(cis)*-3,4-methanoproline **19**. The broad-spectrum antibiotic azirinomycin **20**[3d] from *Streptomyces aureus* is, as expected, unstable in concentrated solutions; catalytic hydrogenation of **20** gives L-α-aminobutyric acid.



**16** **17**, R = $CO_2H$ **19**
**18**, R = $CH_2$–$CO_2H$

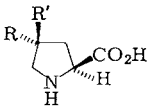


**20**

2,4-Methanoproline **21** and 2,4-methanoglutamic acid **22** from the seeds of the legume *Ateleia Herbert Smithii*[26,27] both have the base peak corresponding to **23** together with other common fragment peaks in their mass spectra.

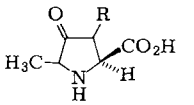
**21** **22** **23**

**24**, R = H, R' = $NH_2$
**25**, R = R' = OH



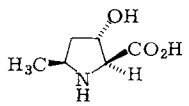
**26**

Other new azetidine derivatives have been reported such as nicotianamine **24** from the leaves of *Nicotiana tabacum*, mugineic acid **25** from oat roots[29], and clavulanic acid **26** from *Streptomyces clavuligerus*[30]. Nicotianamine has also been shown to be the normalization-factor in tomato mutants[28], while **26** acts as a β-lactamase inhibitor[30].



## 4. Heterocyclic Amino Acids

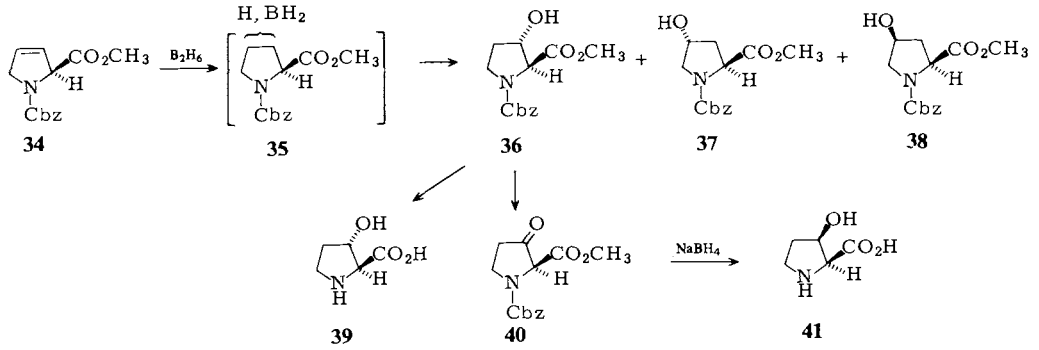
### 4.1. Proline Derivatives



Besides 4-hydroxy-L-proline **27** and the 4-allohydroxy-L-proline **28** with *cis*-L-configuration, already discovered by *H. Wieland* and *B. Witkop* in 1940[31], the D-form *ent*-**28** has also been noted as a structural unit in the antibiotic etamycin[32]. 4-Hydroxymethylproline **29** has been isolated

| | R | R' |
|---|---|---|
| **27** | OH | H |
| **28** | H | OH |
| **29** | H | $CH_2OH$ |
| **30** | = $CH_2$ | |

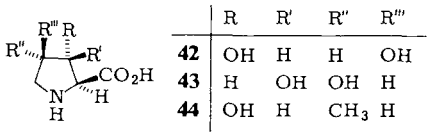
**31**, R = H
**32**, R = OH



**33**

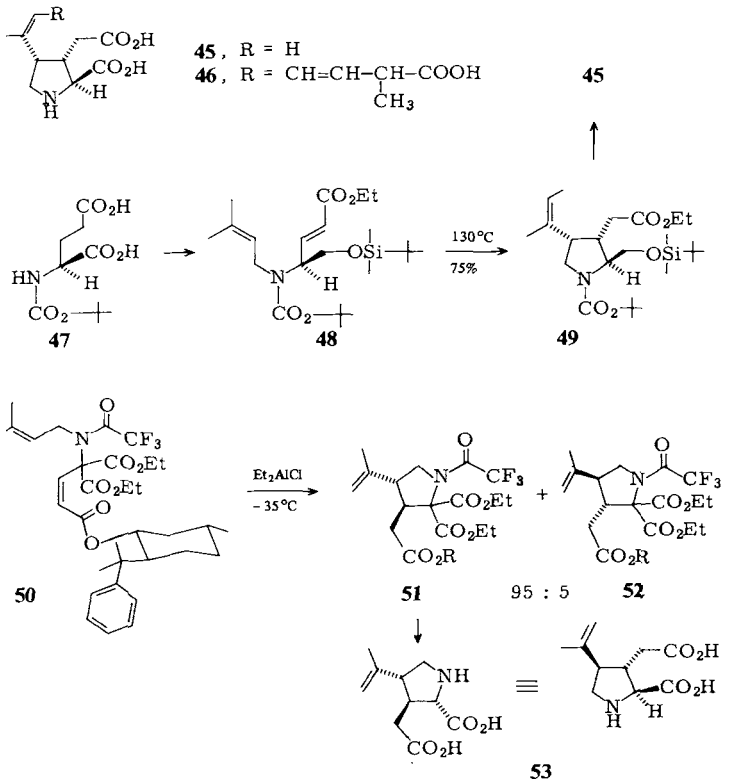
from apples[33] and from *Eriobotrya japonica*[2b], as has also 4-methylene-D,L-proline **30**/*ent*-**30**. Both 5-methyl-4-oxoprolines **31** and **32** and 3-hydroxy-5-methylproline **33** were found in the peptide lactone ring of the antibiotic actinomycin $Z_1$[11,2f], while 5-methylproline has been found in actinomycin $Z_5$[3f]. *N*-Methyl-4-hydroxyproline **27**, with $NCH_3$ replacing NH and also known as betonicin, occurs in many plants, one of which is yarrow[34,35].

To illustrate how configuration can be established by stereoselective synthesis we shall outline the case of *trans*-3-hydroxyproline **39**, isolated by ion-exchange chromatography from collagen hydrolyzate. **39** was later also found in Mediterranean sponges as well as in the antibiotic telomycin; the *cis*-isomer **41** is found only in the antibiotic[36,37].



In the hydroboration of *N*-benzoyloxycarbonyl-3,4-dehydro-D,L-proline methyl ester **34**/*ent*-**34** the molecule is attacked preferentially from the back side; oxidation with alkaline hydrogen peroxide gives a mixture of 68% *trans*-3-hydroxyproline **36**/*ent*-**36**, 10% *trans*-4-hydroxyproline **37**/*ent*-**37** and a trace of *cis*-4-hydroxyproline **38**/*ent*-**38**, in each case as the *N*-protected derivative. Oxidation of **36** with chromic acid gives the keto ester **40** which is also attacked from the rear by $NaBH_4$. Alkaline ester hydrolysis and catalytic hydrogenolysis of the protecting group on the nitrogen gives the pure amino acids **39** and **41** (from **36** and **40** respectively).

The *N*-methyl derivatives of *trans*- and *cis*-3-hydroxyprolines **39** and **41**, with $NCH_3$ replacing NH, have been isolated from the ripe fruits of *Courbonia virgata*[38]; the *trans-trans*-3,4-dihydroxyproline **42** is one of the seven amino acids in virotoxin from the Destroying Angel toadstool[39] and the *cis-trans*-isomer is a component of a protein obtained from diatoms[39].



34 35 36 37 38 39 40 41

(2*S*,3*S*,4*S*)-3-Hydroxy-4-methylproline **44** is found in the antibiotic enchinocandin B[3i]. The kainic acid **45**[40], its C-4 epimer allokainic acid **53**[41] and the domoic acid **46**[42] have been isolated from the alga *Digenea simplex*. Because of interest in the neuron-stimulating activity of these compounds enantioselective syntheses have been developed.

| **43** | H | OH | OH | H |
| **44** | OH | H | $CH_3$ | H |

(−)-α-Kainic acid **45** with the natural configuration was obtained from a glutamic acid derivative **47** by a thermal ene-reaction **48** → **49** with the induction of the (*S*,*S*)-configuration on the new chiral centers in **49** followed by removal of the silyl protecting group, oxidation, and ester hydrolysis[40]. The epimeric (+)-α-allokainic acid **53** is obtained by an analogous ene-reaction of the malonic ester **50**, in which the carboxy group attached to the *cis* double bond has been esterified with an optically active menthol derivative. Initiated by diethylaluminum chloride, **50** gives mainly the compound with the desired configuration **51** (95%) together with 5% of the unwanted stereoisomer **52**. When the starting material **50** contains a *trans* double bond the product ratio changes to 15 : 85[41].

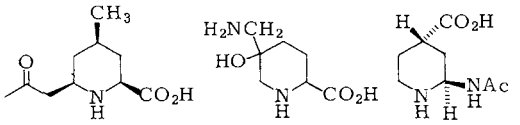
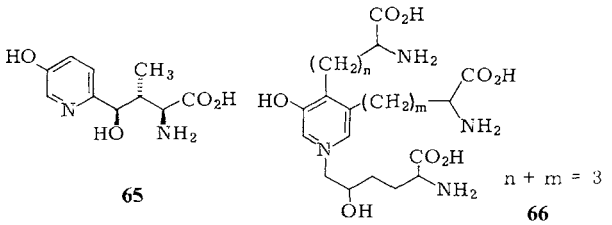
Other proline derivatives are a new amino acid **54** from *Pentaclethra macrophylla*[3h] and acromelic acids A **55** and B **56** which were isolated from the poisonous toadstool *Clitocybe acromelalga*[43]. *cis*-3-Amino-L-proline from *Morchella esculenta*[3b] and 4-carboxy-L-proline from *Chondria coerulesceus*[3j] should also be mentioned here. Cucurbitin **57**[44] obtained from the cucurbitaceae is no more a proline derivative than the pyrrolidineglycolic acid **58**, which was found to be a component of the depsipeptide detoxin-D[3e].



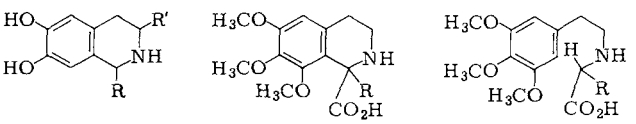
### 4.2. Piperidine, Pyridine, Quinoline, and Azepine Derivatives

Many new amino acids are derived from the long known pipecolic acid. The *N*-γ-L-glutamyl derivative **59** occurs in the seeds of *Gleditsia caspica*[2b]. The 3-hydroxy acid was found in halophytes[2a], the L-4-hydroxy acid in *Peganum harmala* and the 4,5-dihydroxypipecolic acid **60** in *Gymnocladus dioicus*[3j]. (2*S*,5*S*,6*S*)-5-Hydroxy-6-methylpipecolic acid **61** and its 5*R*-epimer are found free in *Fagus silvatica*[3i]. Trichoponamic acid **62** was isolated from *Trichoderma polysporum*[45].

5-Aminomethyl-5-hydroxypipecolic acid **63** could be identified in the hydrolyzate of *Pseudomanas* toxins[3l]; (2*R*,4*S*)-2-acetylamino-4-piperidinecarboxylic acid **64** is found in the leaves of *Calliandra haematocephala*[3e].



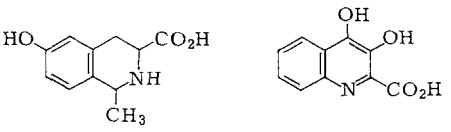
59 60 61



62 63 64

The pyridine derivative **65** is present as the *N*-terminal amino acid in the antibiotic nikkomycin[46,47], while the triamino acid **66** occurs in the bone collagen of cattle[3k].

65 66 (n + m = 3)



The tetrahydroisoquinolines **67** and **68** were isolated from the seeds of *Mucuna mutisiana* and *M. deeringiana*[2b]. Tris-*O*-methylpeyoxylic acid **69** and its methyl derivative **70** were found in extracts of the peyote cactus[2b], in which the possible precursor dihydro compounds mescaloxylic acid **71** and mescaloruvic acid **72** are also detected[2b]. The 6-hydroxy-1-methylcarboxylic acid **73** was isolated from *Euphorbia myrsinites*[3a] and 3,4-dihydroxy-2-quinolinecarboxylic acid **74** from the sponge *Aplysina aerophoba*[2a].

**67**, R = H, R' = $CO_2H$

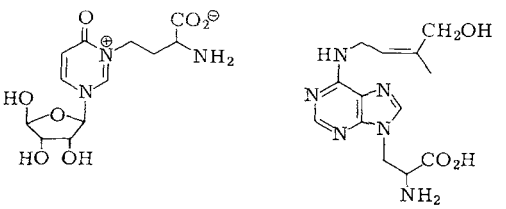
**70**, R = $CH_3$

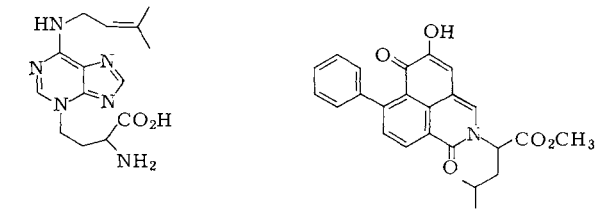
**71**, R = H
**72**, R = $CH_3$

73 74

5-Hydroxy-L-tryptophan appears in several plants[2a], $N^{\alpha}$-methyl-4-(3-methyl-2-butenyl)-L-tryptophan **75** in *Lotus subglauca*[2a]; the cyclic clavipitic acid **76** from *Clavi-*



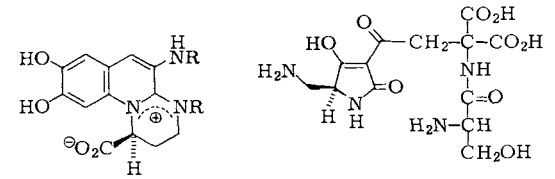
75 76



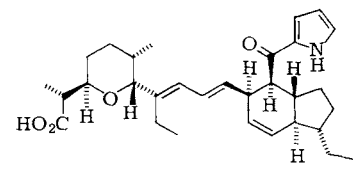
**77**, R = OH, L-
**78**, R = H, D-
**79**, R = Cl, D-

*ceps sp.* is possibly an intermediate in the biosynthesis of lysergic acid[3b].

The L-configuration of piperidazinecarboxylic acid **77** from monamycin has been correlated with that of L-ornithine; the configuration of the two D-amino-acids **78** and **79** from the same antibiotic was similarly established[3b].



80 81



82 83

Transfer-RNA from *E. coli* contains the modified uridine **80**[3g]. Lupinic acid **81** from the seeds of *Lupinus angustifolius*[3h], and discadenin **82** from *Dictyostelium discoideum* as well as sinefungin from streptomyces griseolus[105] are purine derivatives with amino acid residues.

**84**, R, R = H, H
**85**, R, R = >C=O

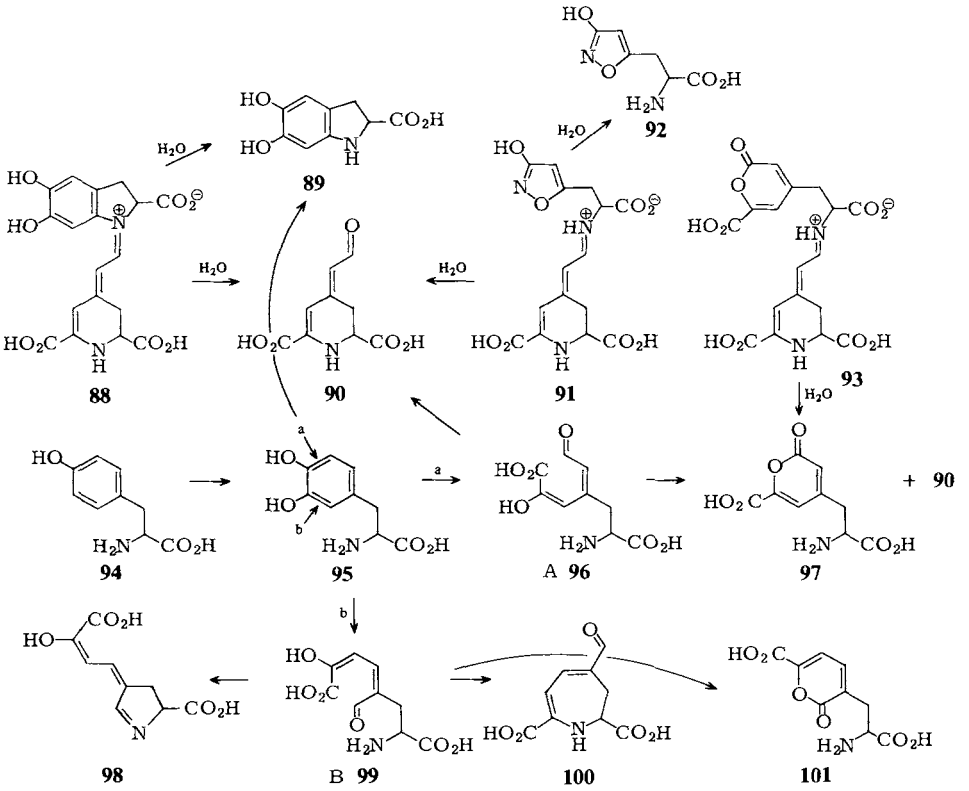
86

87

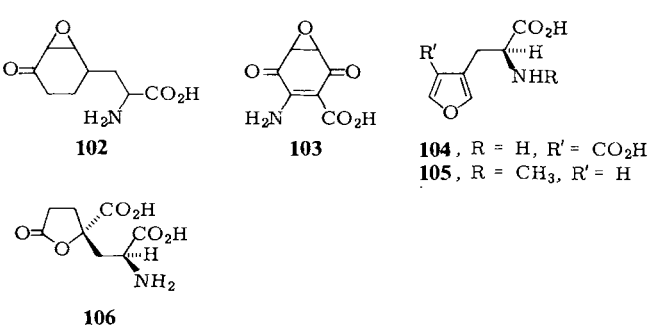
Compounds such as the pigment of **83** from the blossom of *Lachanthus tinctoria*[3i], the alkaloids like **84**[48] from pseudobactin as well as compound **85**[3c] from the hydrolyzate of a fluorescent peptide produced by *Azotobacter vinelandii*, and antibiotics such as malonomycin **86**[49] or the ionophoric antibiotic X-14547A **87**[50] are formally amino acids or related compounds but have little in common with the amino acids dealt with here. The tetrahydropyridine and dihydroazepine derivatives which follow, however, are produced in ordinary amino acid metabolism.

The elucidation of the structures of the betalaine pigments[51,52] from higher plants, such as the betanins and vulgaxanthins from red beetroot *(Beta vulgaris)* or muscaaurins I and II from fly agaric *(Amanita muscaria)*, has revealed a number of new amino acids. Mild hydrolysis of

betanidin **88** gives cyclodopa **89** and betalamic acid **90**; similar treatment of muscaaurin I **91** gives ibotenic acid **92** and **90**, while muscaaurin II **93** gives, together with **90**, stizolobic acid **97**, which had been isolated shortly before from *Stizolobium hassio*. The origin of cyclodopa **89** from tyrosine **94** and dopa **95** is quite clear. For the formation of betalamic acid one must imagine an oxidative opening of the benzene ring adjacent to the hydroxy group in **95** at point 'a' and a recyclization of the intermediate A **96** by condensation between the amino group and the enolized α-keto acid. This biosynthetic route has been confirmed *in vivo* with $^{14}C$- and $^{3}H$-labeled tyrosine[53,54]. If the intermediate A **96** undergoes hemiacetal formation followed by oxidation to a lactone, stizolobic acid **97** is obtained. This pathway has also been confirmed with labeled precursors in the legume *Stizolobium hassio*.



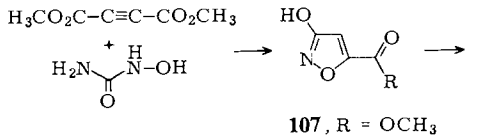
*ley*[56] has recently established the biosynthesis of the more or less unsaturated pyrrolidine moieties of the antibiotics anthramycin, tomaymycin, sibiromycin and lincomycin from tyrosine. To explain these results a cyclization of the same intermediate B **99** to compounds like **98** is required.



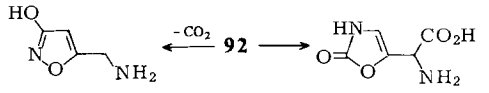
### 4.3. Oxygen Heterocycles

Related to the α-pyrones **97** and **101** are three epoxides and three furan derivatives. Anticapsin **102** is produced by *Streptomyces griseoplanus*[3d], the chloramphenicol antagonist **103** by *Streptococcus fulvoviolaceous*[3k], and (2*S*,9*S*)-2-amino-9,10-epoxy-8-oxodecanoic acid from chlamomycin a cyclic peptide with extreme cytostatic activity[106]. L-β-(4-Carboxy-3-furyl)alanine **104** occurs free in *Phyllotopsis nidulans* and the fruiting bodies of *Tricholomopsis rutilans*[3h]. *N*-Methyl-β-(3-furyl)alanine **105** is found in the cyclopeptide rhizonin A, a mycotoxin from *Rhizopus microsporus*[57]. Lycoperdic acid **106** was isolated from the fungus *Lycoperdon perlatum*[31].

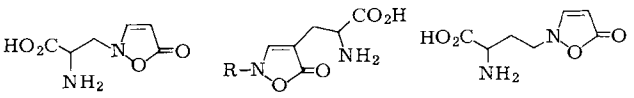
A further yellow amino acid, muscaflavin, was isolated from fly agaric and identified as the dihydroazepine derivative **100**. This biosynthesis could be explained in terms of a cleavage of the benzene ring in dopa **95** at point 'b', followed by a cyclization of the intermediate B **99** analogous to that of A **96**. Oxidation of the hemiacetal of **99** yields stizolobinic acid **101** isomeric with **97**, which, together with **97**, occurs free in small amounts in beans and fungi. The unstable betalamic acid **90** has already been detected as the free amino acid.



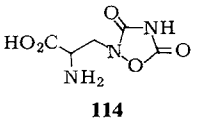
In the synthesis of muscaflavin **100** the formation of the intermediate B **99** by opening of a protected pyridine derivative was proposed. In fact the seven-membered ring in **100** is formed in this way, but first the preferred cyclization to a five-membered ring, a derivative of **98**, takes place[55]. This observation is of great interest, since *Hur-*



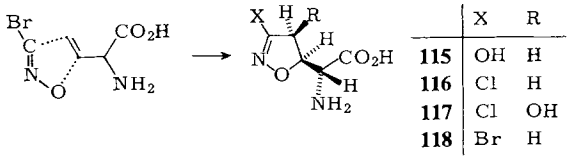
### 4.4. Isoxazoline Derivatives



Ibotenic acid **92** from *Amanita muscaria* has already been mentioned; it occurs in this toadstool in quite large amounts and decarboxylates readily to muscimol **109** and rearranges photochemically to muscazone **110**[58]. Because of its alleged psychotropic activity improved syntheses of muscimol are repeatedly being developed[59]. In the most recent method[59c] *N*-hydroxyurea was added to dimethyl acetylenedicarboxylate to give **107**. The corresponding amide **108** was then reduced with borane-dimethyl sulfide, thus providing **109** in three steps in *ca.* 30% yield.



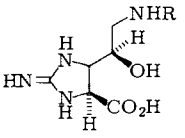
**107**, R = $OCH_3$
**108**, R = $NH_2$



**109** **110**

**111** **112**, R = Glucosyl **113**

**114**



| | X | R |

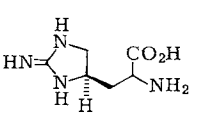
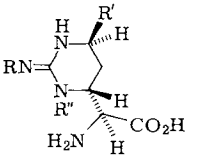
| **115** | OH | H |
| **116** | Cl | H |
| **117** | Cl | OH |
| **118** | Br | H |



The two oxazolidines **111** and **112** were isolated from young pea seedlings and identified by spectroscopy and degradation. Treatment with weak base and subsequent acid hydrolysis gave α,β-diaminopropionic acid from **111** and D-glucose and glutamic acid from **112**. It was suggested that these highly UV-sensitive compounds take part in a photobiological process[3c]. They were also detected in other leguminosae, *e.g. Lathyrus odoratus*, in which 2-amino-4-(5-oxo-2-isoxazolyl)butyric acid **113** also occurs[3g]. The constitution of quisqualic acid **114** with the L-configuration from *Quisqualis fructus* could be proven by synthesis[3h]. Tricholomic acid **115** has been isolated from *Tricholoma*[60] and the chloroisoxazolidine derivatives **116** and **117**[3h], with antibacterial and antitumor activity, from cultures of *Streptomyces sviceus*. Here again synthetic routes were investigated[61], of which the 1,3-dipolar addition of bromonitrile oxide to vinylglycine to give **118** proved to be successful[61b].

### 4.5. Cyclic Guanidine Derivatives



These compounds all occur as building units in the peptide antibiotics from microorganisms and are structurally and stereochemically related to arginine[3c]. The structure of the strongly basic amino acid streptolidin **119**, obtained from antibiotics such as streptolin, streptothricin and geo-

**126**

mycin by hydrolysis, which has been a subject of controversy was established by X-ray analysis and by synthesis from chiral sugar units[8b,62]. In the case of the *N*-methyl derivative **120**, similarly obtained from a streptothricin-type antibiotic, the configuration of the OH group is still obscure[3c]. The two α-epimers enduracididine and alloenduracididine **121** have been isolated from enduracidin[3b]. The two six-membered ring guanidine derivatives tuberactidine **122** and viomycidine **125**[3c] were obtained from the hydrolyzate of the highly antitubercular tuberactinomycin, and the capreomycidine **123** from the equally active capreomycin[63]. The relative and absolute configurations of stendomycidine **124** from the peptide antibiotic stendomycin have been established as L-*erythro*, mainly by ORD[3c]. Tetrahydrolathyrine **126** has been isolated from *Lanchocarpus costaricencis*[31].

## 5. Halogen-Containing and Other Aromatic Amino Acids

The chloro- and bromo-derivatives **127–131** of tyrosine were isolated from the hydrolyzates of the scleroproteins of molluscs. Halogenated tryptophane also occur in nature; the betaine 6-bromo-L-hypaphorine **132** in legumes

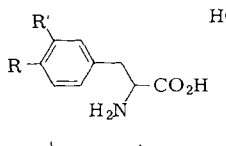
and sponges[64] and 5-chloro-D-tryptophan **133** as a component of the antibiotic longicatenamycin[65]. The positive Cotton effect indicates, as in the case of D-tryptophan, a D-configuration, which was confirmed by the ozonolysis of **133** to D-aspartic acid. The 4-chlorotryptophan derivatives **134** and **135** isolated from *Pisum sativum* also belong to the D-series[2a].



Antibiotics from the vancomycin group contain as a structural unit the unusual vancomycinic acid **136**, which itself contains 3-chloro-β-hydroxytyrosine units; the monochlorotricarboxylic acid **137** occurs in the glycopeptide antibiotic actinoidin and 3-chloro-4-hydroxyphenylglycine **138** is a component of the antibiotic LL-AV290[3g]. Two other chlorine-containing amino acids have already been mentioned with the unsaturated amino acids in Table 1[3g,3e] and the chloroisoxazolines **116** and **117** in Section 4.4.

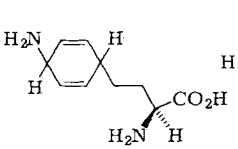
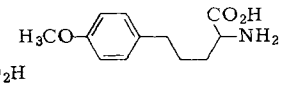
**142**

**143**

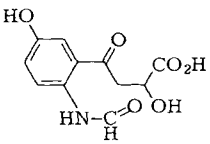


**144**



**145**

Before turning to sulfur-containing heterocycles, a few more phenylalanine derivatives from higher plants should be cited: the hydroxymethyl compounds **139** and **140** from *Caesalpinaia tinctoria* and the *p*-aminophenylalanine **141** from *Vigna vexillata*[2b].



The dimeric tyrosine **142** was identified as a component of alkali-soluble connective tissue protein[2b] and may have been formed by phenol oxidation[66]. Whether the antibiotic ristocetin, which is reminiscent of **136** and **137**, or ristomycin A **143**[31] is formed analogously is an open question. Pretyrosine **144**, derived from prephenic acid in the blue-green alga *Pseudomonas aeruginosa*, is of biosynthetic interest, being enzymatically converted into phenylalanine or tyrosine **94**[67]. Acid degradation of **144** gave phenylalanine. Further dihydroarenes are: L-β-(1,4-cyclohexadienyl)alanine **145** from rats, *Leuconostoc destranicum* and streptomycetes[2a]; the amino acid antibiotic L-2-amino-4-(4-amino-2,5-cyclohexadienyl)butyric acid **146**[3g];

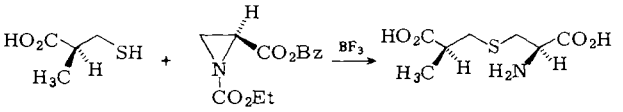
**146**

**147**

**148**

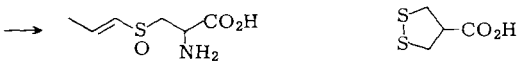
(+)-*trans*-2,3-dihydro-3-hydroxyanthranilic acid from *Str. aureofaciens S-652*[68]. L-β-(2,5-Dihydroxyphenyl)alanine from streptomycetes[2a] and *N*-carbamoyl-2-(4-hydroxyphenyl)glycine from the leaves of *Vicia faba*[2a], 3-carboxy-L-tyrosine from the seeds of *Reseda odorata*[69], 3-formylaminosalicylic acid from antimycin A3[70], alternamic acid **147**[71] from the toxin alternariolide in *Alternaria mali*, blespharismone **148** from *Blespharisma japonicum* and finally the oxime of the *p*-hydroxyphenylpyruvic acid[3h] from the sponge *Hymeniacidon sanguinea* are all new derivatives of aromatic amino acids.

## 6. Sulfur-, Selenium- and Phosphorus-Containing Amino Acids



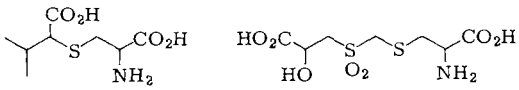
Many new sulfur-containing amino acids from the plant and animal kingdoms are derivatives or homologues of cysteine and methionine (Table 2).

Table 2. New sufur-containing amino acids.



| Sulfur-containing amino acid | isolated from | Ref. |
|---|---|---|
| *N*-Formylmethionine | *Clostridium pasteurianum*, rubredoxin, the thorax of the honey bee | [2a] |
| *N*-Acetylmethionine | thorax of bees | [2a] |
| L-Homomethionine | cabbage | [2a] |
| *N*-Methylmethionine sulfoxide | red algae | [3h] |
| *S*-(2-Carboxy-2-hydroxyethyl)cysteine | human urine | [2a] |
| *S*-(Carboxymethyl)homocysteine | urine of cystathionuric and homocystinuric patients | [2a] |
| *S*-(3-Carboxy-3-hydroxypropyl)cysteine | | [2a] |
| *S*-(3-Carboxy-3-hydroxypropylthio)homocysteine | | [2a] |
| *S*-(2-Carboxy-2-hydroxyethylthio)homocysteine | | [2a] |
| *S*-(3-Carboxy-3-hydroxypropyl)homocysteine | | [2b] |
| *S*-(Carboxymethylthio)homocysteine | | [2b] |
| *S*-(2-Carboxy-2-hydroxyethylthiomethyl)-L-cysteine | *Acacia georginae* | [2b] |
| Cystathionine sulfoxide | urine of cystathionuric patients | [3h] |
| Perhydro-1,4-thiazepin-3,5-dicarboxylic acid | | [3h] |
| α-*S*-Cysteinylthymine | collagen from cattle bones | [3k] |

(−)-*S*-(2-Carboxypropyl)-L-cysteine **151**[12] is found in the glutathione-like tripeptide from onions and garlic and is converted into *trans*-*S*-1-propenyl-L-cysteine *S*-oxide **152**, the precursor of the lachrymatory principle of the onion[1]. Asparagusic acid **153**[73] found in asparagus, is also formed from **151**. The absolute configuration of **151** was established by the synthesis of both stereoisomers. Both enantiomers of 3-mercapto-2-methylpropionic acid ester **149** were reacted with the aziridinecarboxylic acid ester **150**, which is readily available from L-serine, in the presence of $BF_3$ to give **151**. After removal of the protecting group only **151** derived from (*S*)-**149** showed a negative optical rotation corresponding to the natural acid[12].



Further examples are the cysteine derivative isovalthine **154**[74], which was first isolated some time ago from the urine of people with an excessive cholesterol level, dichrostachinic acid **155**[75] from the seeds of *Dichrostachys glomerata*, L-1,4-thiazinane-3-carboxylic acid **156**[3k] from the alga *Heterochordaria abietina* and dopa with two cysteine residues **157**[3h] from the eyes of the alligator gar *Lepisosteus spatula*.

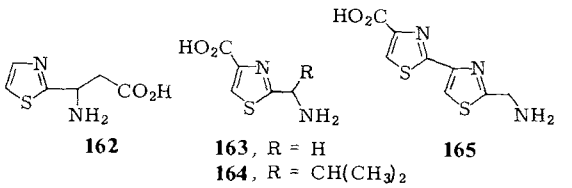
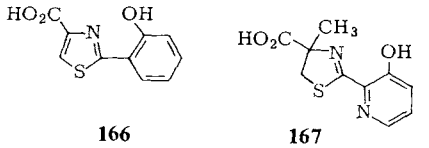
**154** **155**

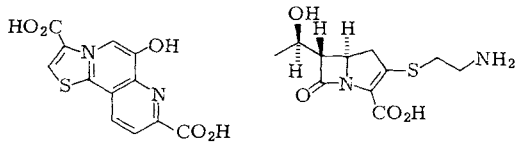


**156** **157** **158**, R = H
**159**, R = S–dimer



**160** **161**

5-Mercapto-1-methyl-L-histidine **158** can be separated from the hydrolyzate of the $Fe^{III}$-binding adenochrome of *Octopus vulgaris*. Recently **158** has been found in the eggs of sea urchins which also contain the corresponding disulfide **159**[76]. The mercaptohistidine derivatives clithioneine **160**[77] and *S*-(2-amino-2-carboxyethyl)ergothionine **161**[78] were isolated from the toadstool *Clitocybe acromelalga* and *Neurospora crassa*, respectively.



β-(2-Thiazolyl)-β-alanine[79] **162** from bottromycin and the other thiazole derivatives such as **163** which are com-

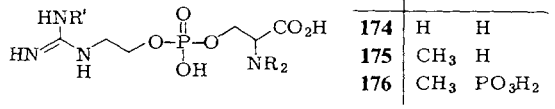
ponents of a cyclic peptide from the sea hare *Dolabella auricularia*[80], **164**[81a] from ascidiacyclamide, the *sec*-butyl isomer of **164** from bacitracin[81b] and related compounds, the absolute configuration of which can be derived from degradation products obtained with singlet $O_2$[81c], the bithiazolylcarboxylic acid **165** as the *N*-terminal amino acid of the anticancer antibiotic bleomycin $A_2$[82], aeruginic acid **166**[83] from *Pseudomonas aeruginosa*, **167**[84] from *Streptomyces antibioticus*, berninamycinic acid **168** from the antibiotic berninamycin A[85] and the penicillin-like antibiotic thienamycin **169**[86] conclude the list of new sulfur-containing amino acids.



Several examples of selenium- and phosphorus-containing amino acids have been confirmed. Selenocysteine was identified as amino acid No. 35 in the peptide chain of the enzyme glutathione peroxidase from cattle erythrocytes[87], *Se*-methylselenocysteine[3b] was found in *Astragalus bisculatus*, selenomethionine[3f] in lima beans and selenocystathionine **170**[2a] in *Morinda reticulata*. The *N*-Phosphonosulfonimidoxyl derivative **171**[3f] was isolated from an unclassified *Streptomyces* as a metabolite.

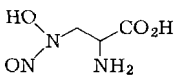
D-2-Amino-5-phospho-3-pentenoic acid **172**[3i] occurs in a tripeptide from *Streptomyces plumbeus*. The phosphate ester of 4-hydroxypipecolic acid[3k] was isolated from *Pel-*

*tophorum*. Phosphinothricin **173**[3g] is the *N*-terminal amino acid in a tripeptide, with two alanine residues, which is a component of an antibiotic. L-Lombricine **174** from *Lumbricus terrestris* is also found in smaller quantities in the marine worm *Thalassema neptuni*, from whose muscles the $N^{\alpha}$,$N^{\alpha}$-dimethyl derivative, L-thalassamin **175**, and *N*-phosphothalassamin **176** were isolated[3e,88].

## 7. Aliphatic Amino Acids

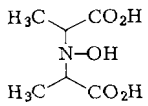
New amino acids whose constitutions differ only slightly from the regular protein amino acids have also been found in large numbers. Because of the rarity of the nitrile group in nature[89], β-cyanalanine from the embryos of *Vicia sativa* and *Acacia georginae*[2b] and L-2-amino-4-cyanobutyric acid from *Chromobacterium violaceum* cultures, which contain cyanide ion in the nutrient solution[3c], are mentioned first.

### 7.1. Neutral α-Amino Acids



α-Amino acids with the "unnatural" D-configuration have been repeatedly found: D-alanine[2b] in the cell walls of bacteria and also in higher plants, D-valine in valinomycin, and D-isoleucine[3b] in monamycin as well as D-Ala, D-Phe, D-Asp and D-Glu in a toxic peptide lophyrotonin from larvae of a fly (*Laphyrotoma interrupta*), which in Australia can be fatal for cattle[107]. With the cyclic peptide or peptidolactono-antibiotics the interesting question arises as to whether the D-amino acids are incorporated as such or whether they are first built in as the L-amino acids and then epimerized. In the latter case D-isoleucine must be derived from L-alloisoleucine, which has not yet been found in nature, although *N*-methyl-γ-methyl-L-alloisoleucine is found in etamycin and triostin C[2a]. Furthermore, *N*-methylalloisoleucine[3c] was found in cycloheptamycin, 2-amino-4-oxopentanoic acid[2a] in *Clostridium stricklandii*, and isoleucine, acylated on the nitrogen by jasmonic and dihydrojasmonic acids, in the fungus *Giberella fujikuroi*[2a]. Glutathione derivatives of leucotrienes play an important role in the human body[90].

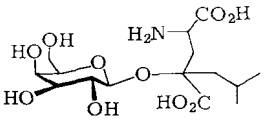
### 7.2. α-Branched Amino Acids



These compounds are of interest as antimetabolites and enzyme inhibitors, as for example α-methyldopa. They also occur naturally; like α-aminoisobutyric acid (α-methylalanine) and (−)-isovaline (2-aminovaleric acid, "β-ethylalanine") in peptide antibiotics. According to the X-ray crystallographic analysis of the *N*-chloroacetyl derivative, (−)-isovaline has the D-configuration[91], and is readily available through Schöllkopf's lactim-ether synthesis[92] with 93% enantioselectivity.

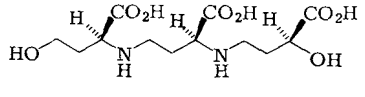
### 7.3. Hydroxy-α-Amino Acids

New hydroxy-α-amino acids are: *N*-(2-hydroxyethyl)-glycine and -alanine[2a] from the seaweed *Petalonia jascia* and from Rumen protozoa, *O*-ethyl-, *O*-*n*-propyl- and *O*-*n*-butyl-L-homoserine[3a] from *Corynebacterium ethanolaminophilum*, D-allothreonine from pseudobactin[48], *threo*-L-2-amino-3,4-dihydroxybutyric acid[2a] and L-β-hydroxynorvaline[2a] from microorganisms, (2*S*,4*S*)-(+)-γ-hydroxynorvaline and the (4*R*)-(−)-epimer[2b] from *Boletus satanus*, β-hydroxyvaline[2b] from an antibiotic, (2*S*,3*R*,4*R*)-γ-hydroxyisoleucine[2b] from the seeds of *Trigonella foenum-graecum*, γ,δ-dihydroxyisoleucine[2a] from *Amanita phalloides*, as well as alanosine **177**[93] from *Streptomyces alanosinicus*. Finally, we have the following four *N*-hydroxyamino acids: L-2-amino-5-(1-hydroxyguanidino)valeric acid ($N^5$-hydroxyarginine)[3f] from *Nanniizzia gypsea*, the D-enantiomer from the Fe(III) complex pseudobactin[48], $N^{\epsilon}$-hydroxylysine from aerobactin[94] and compound **178** from the fly agaric[95] which forms, *in situ*, the pale blue complex amavadin with vanadium.



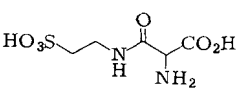
**177**

**178**

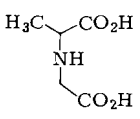


### 7.4. Acidic Amino Acids and Diaminodicarboxylic Acids

New amino acids in this group are: *threo*-β-hydroxy-L-aspartic acid[3h] from streptomyces and the compound with a D-configuration from the Fe(III) complex pseudobactin[48], *erythro*-β-hydroxy-L-aspartic acid[2a] from *Astralagus sinicus*, β-carboxyaspartic acid from the ribosomal protein of *E. coli*[96], *threo*-β-methyl-L-aspartic acid[2a] from the antibiotic amphomycin, *threo*-β-hydroxy-L-glutamic acid[2a] from streptomyces, (2*S*,4*R*)-4-methylglutamic acid[2b] from *Gleditsia caspica*, (2*S*,3*S*,4*R*)-3-hydroxy-4-methylglutamic acid[2b] from *Gleditsia caspica* and from *Gymnocladus dioicus*, as well as β-hydroxy-γ-methylglutamic acid[3i] from the seeds of the Kentucky coffee tree.



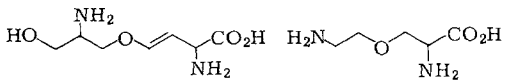
**179**



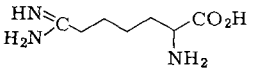
(2*S*,4*R*)-4-(β-D-Galactopyranosyloxy)-4-isobutylglutamic acid[3f] **179** from *Reseda odorata* is the first example, in the higher plants, of a glycoside in which the sugar is attached to the hydroxyl group of an aliphatic aminohydroxy acid. Further acidic amino acids are: 2-amino-4,5-hydroxyadipic acid from human urine[3k], 2-amino-4-methylpimelic acid[3h] from the fruiting body of *Lactarius quietus*, 2,6-

**180**

**181**



**182**

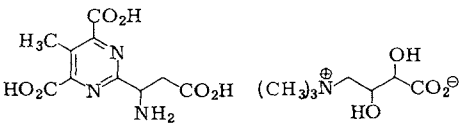


diamino-3-hydroxypimelic acid[2a] from the cell walls of microorganisms, 2,6-diamino-7-hydroxyazelaic acid[3c] from edeine A and B, avenic acid **180**[97] from oat roots (chelates with iron), arcamin **181**[98] from *Acra zebra* and strombin **182**[98] from *Strombus gigas*.

### 7.5. Basic Amino Acids

New basic amino acids to be mentioned are: β-acetamido-L-alanine[3a] from *Acacia armata*, β-(3-hydroxyureido)-L-alanine[3f] from streptomyces, L-2-amino-3-(oxalamino)propionic acid[2a] from *Lathyrus sativus*, 2-amino-3-(1-hydroxyureido)propionic acid[3f] from *Quisqualis fructus*, 4-guanidinobutyric acid together with 2,3-diaminopropionic acid from the seeds of *Trichosanthes cucumeroides*[99], 2,3-diaminobutyric acid from asparatocin (the L-*threo*- and D-*erythro* forms occur in amphomycin)[2a], 4-amino-2-(6-methyloctanoylamino)butyric acid[2a] from *Bacillus colistinus* as well as L-2-amino-4-(lactoylamino)butyric acid[2b] from *Beta vulgaris*. *O*-(2-amino-3-hydroxypropyl)homoserine, dihydrorhizobitoxin and the corresponding β,γ-unsaturated 2-amino-4-(2-amino-3-hydroxypropoxy)-*trans*-3-butenoic acid **183**[2b], known as rhizobitoxin, were isolated from *Rhizobium japonicum*. **183** deactivates β-cystathionase in bacteria and plants and prevents the formation of ethylene from methionine (see **6** and **7** in Section 3). δ-Amidinooxy-L-norvaline was isolated from a bacterial culture[3f]. Other new basic amino acids are: 2,4-diaminovaleric acid[2a] from *Clostridium stricklandii*, (2*S*,4*R*,5*R*)-4,5-dihydroxyornithine[3i] from the antibiotic

**183** **184**



**185**

echinocandin B, $N^{\delta}$-(1-iminoethyl)-L-ornithine[2b] from streptomyces (acts like an arginine metabolite), 2-amino-5-(1-methylguanidino)valeric acid[2a] from rat-liver proteins, 2-amino-5-(3,3-dimethylguanidino)valeric acid and 2-amino-5-(2,3-dimethylguanidino)valeric acid[3c] from human urine, γ-hydroxyarginine[100] from sea cucumbers, γ-hydroxycitrullin[2a] from *Vicia fulgens* and related species, $N^{\varepsilon}$,$N^{\varepsilon}$-dimethyllysine[2a] from amoebae, $N^{\varepsilon}$,$N^{\varepsilon}$,$N^{\varepsilon}$-trimethyl- and $N^{\varepsilon}$-methyllysine[2a] from myosine, β-hydroxy-$N^{\varepsilon}$,$N^{\varepsilon}$,$N^{\varepsilon}$-trimethyllysine[3i] from *Neurospora crassa*, δ-hydroxy-$N^{\varepsilon}$,$N^{\varepsilon}$,$N^{\varepsilon}$-trimethyl-L-lysine[3c] and the corresponding *O*-phosphoric acid ester from the cell walls of diatoms, *threo*-γ-hydroxy-L-lysine[3h] from the antibiotics cerexin A and B, $N^{\varepsilon}$-acetyl-*allo* δ-hydroxy-L-lysine[3l] from *Beta vulgaris*, $N^{\alpha}$,$N^{\varepsilon}$-(2,3-dihydroxybenzoyl)-L-lysine[3c] from *Azotobacter vinelandii*, γ-oxa-L-lysine[2a] **184** from *E. coli* and streptomycetes, indospicine[2a] **185** from plants (should have heptatoxic and teratogenic activity), $N^{\varepsilon}$-(4-amino-2-hydroxybutyl)lysine[2a] from cattle brain, and $N^{\varepsilon}$-acetyl-$N^{\varepsilon}$-hydroxylysine as the α-amide of citric acid in the Fe(III) complex from *Aerobacter aerogenes*[94,101].

### 7.6. Non-α-Amino Acids

Most amino acids in which the amino group does not occur in the α-position were formerly isolated from peptide antibiotics and are themselves antibiotics such as **86** and **87** or have complex structures such as the pigment **83** or the alkaloids **84** and **85**. In addition the following β- and γ-amino acids belong to this group: isoserine and β-tyrosine[2a] from edeine A and B, 4-amino-2,3-dihydroxy-3-methylbutyric acid[2a] from carcinophilin, 5-amino-4-hydroxyvaleric acid[2a] from *Rhodospirillum rubrum*, puretanin (3-(4-aminobutylamino)propionic acid)[2a] from, *inter alia*, human brain and urine, 3-amino-3-phenylpropionic acid[3c] from *Rocella canariensis*, 4-amino-2-hydroxy-3-oxo-butyric acid[3k] from human urine, $N^{\beta}$-methyl-L-β-arginine[3k] from the antibiotic LL-BM 547 B, γ-hydroxy- and δ-hydroxy-β-lysine[2a,b] from tuberactinomycin A as well as 4-amino-3,6-dihydroxymethylhexanoic acid[2b] from pepstatin A and 4-amino-3-hydroxy-2-methylhexanoic acid[2b], also from pepstatin A. β-2-(Thiazolyl)-β-alanine **162**[79] has already been mentioned in Section 6.

**186** **187**

The heterocyclic-substituted alanine **186**[2b] was found in bleomycin. Anthopleurine **187**[102], the alarm substance in sea anemones, has the trimethylammonium group in the γ-position.

## 8. Outlook

It is to be expected that the number of new amino acids will continue to increase, although not at the same rate as in the last 30 years. Already the number is overwhelming and one can ask whether it is still justifiable to group them roughly according to their structural features. However, so long as so little is known about their biosynthetic relationships and their function in metabolism, the form of classification chosen here may be accepted on the grounds that it at least helps to identify new naturally occurring amino acids.

Many modern developments in the chemistry of natural amino acids deserve more attention, for example the recognition of new metabolic pathways for tyrosine as a precursor of pigments and antibiotics which can be used as supporting evidence for the evolutionary tree, or the psychotropic activity of isooxazole derivatives such as ibotenic acid. Nature makes use of the *N*-hydroxyamino acids as the building units of chelating agents for the accumulation of heavy metals from the environment[95], or for the transportation of iron[94,101]. Last, but not least, the determination of the age of bones from classical antiquity[103], or the checking of the age of the Dead Sea Scrolls by means of measurements of the racemization of amino acids such as aspartic acid from the collagen which the

samples contain[104] may be of general interest and useful for non-chemists[108].

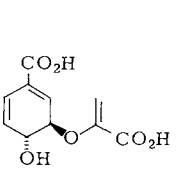
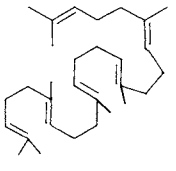
# Secologanin, a Biogenetic Key Compound— Synthesis and Biogenesis of the Iridoid and Secoiridoid Glycosides

**By Lutz-F. Tietze***

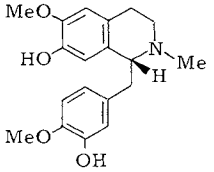


*Dedicated to Professor Hans Brockmann on the occasion of his 80th birthday*

The monoterpene glycoside secologanin is a key intermediate in the biosynthesis of most indole, cinchona, ipecacuanha, and pyrroloquinoline alkaloids, as well as of simple monoterpene alkaloids. More than a thousand alkaloids are formed from secologanin *in vivo*; this represents almost a quarter of this large group of natural products. It is also the parent compound of the secoiridoids. Many of the compounds derived from secologanin display a high degree of biological activity and are employed as pharmaceuticals, *e.g.*, the dimeric indole alkaloid leurocristine (vincristine) which is used very successfully in the treatment of acute leukemia. A knowledge of the biosynthesis and biological reactions of secologanin provides a sound basis for the biosynthesis-orientated classification of numerous natural products and the taxonomy of many plants. Secologanin and structurally related substances can be synthesized in a few steps by stereocontrolled photochemical and thermal cycloadditions. Its biomimetic reaction with amines and amino acids yields other natural products and compounds of pharmacological interest.



## 1. Introduction



The biosynthesis of natural products proceeds according to simple general principles and only involves a few building blocks. The so-called biogenetic key compounds are especially important; they are generally polyfunctional molecules which occupy a central position in biosynthetic pathways and act as starting compounds for a multitude of other natural products.

An example of one such biogenetic key compound is chorismic acid **1**, which reacts *in vivo* to produce *o*- and *p*-hydroxybenzoic acids and *o*- and *p*-aminobenzoic acids. *p*-Hydroxybenzoic acid as well as *o*- *and p*-aminobenzoic acids undergo further biosynthetic reactions, *p*-hydroxybenzoic acid yielding the ubiquinones, *o*-aminobenzoic acid the amino acid tryptophan, and *p*-aminobenzoic acid, folic acid. Chorismic acid is also the precursor of prephenic acid, which can be converted into the amino acids tyrosine and phenylalanine. Other key compounds worthy of mention are squalene **2**, from which the triterpenes and

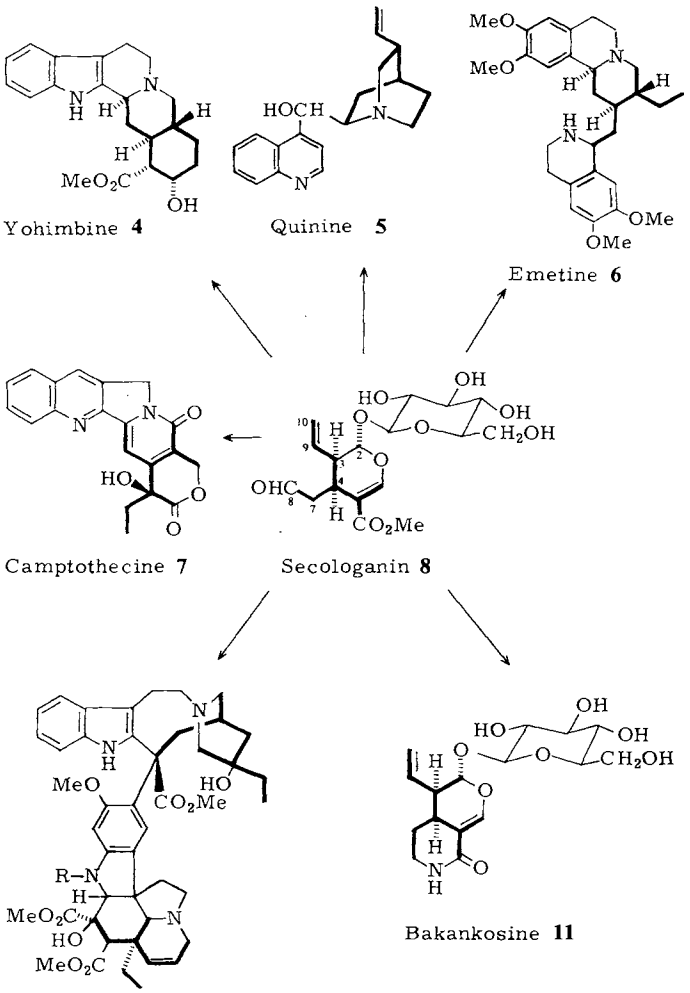
steroids are derived, and the benzyltetrahydroisoquinoline reticulin **3**, formed from the amino acid tyrosine[1], which functions as a precursor in the biosynthesis of the aporphine, morphine, and erythrina alkaloids. A knowledge of the key intermediates which act as common precursors in the biosynthesis of various natural products provides a basis for the biologically sound classification of these compounds and for a meaningful, chemically orientated plant taxonomy[2]. Furthermore, comparison of biogenetic key compounds with novel natural products can help to elucidate their structures; key compounds of this type can also serve as educts for the biomimetic synthesis of natural products[3].

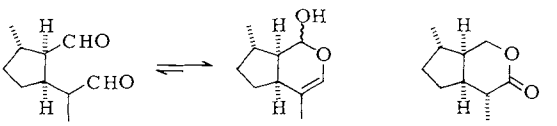
The most important key compound for alkaloid biosynthesis which is not derived from an amino acid is the monoterpene glycoside secologanin **8**. The majority of the indole alkaloids[4,5], the ipecacuanha[6], cinchona[7] and pyrroloquinoline[8] alkaloids, and simple monoterpene alkaloids[9] are formed from secologanin.



Examples are the indole alkaloid yohimbine **4**, which was isolated from various *Rauwolfia* and *Vinca* species and is used as an aphrodisiac in veterinary medicine[10], and the cinchona alkaloid quinine **5**, which is the oldest known antimalarial agent and has now regained importance for dealing with pathogenic agents which have become resistant to synthetic pharmaceuticals[12a]. Other alkaloids derived from secologanin **8** include the ipecacuanha alkaloid emetine **6**, which is effective in the treatment of amoebic dysentry[12], the pyrroloquinoline alkaloid camptothecin **7**[13], which once seemed to be a promising cytostatic agent[14], and the monoterpene alkaloid bakankosine **11**[15]. The dimeric indole alkaloids leurocristine (vincristine) **10** and vincaleukoblastine **9** are also formed from secologanin **8** *in vivo*, and these substances are used with great success to treat acute leukemia and Hodgkin's disease[16] (Scheme 1).

Furthermore, secologanin **8** is the parent compound of the secoiridoids[17]: sarracenin **13**[18] is an example of such a compound. It was isolated from *Sarracenia flava*, and the extract of these plants displays a strong cytostatic action[19].

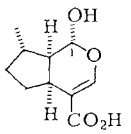
This brief review article illustrates the importance of secologanin **8** as a biogenetic key compound: It is the precursor of more than a thousand alkaloids and other natural products. Biologically, secologanin **8** is closely related to the iridoid glycoside logonin **12**, from which it is derived by cleavage of the cyclopentane ring.



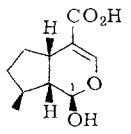
**12** **13**

Scheme 1. Secologanin **8** as a biogenetic key intermediate in the biosynthesis of alkaloids and secoiridoids. The secologanin moiety is shown in bold type.

## 2. Structure and Origin of the Iridoids and Secoiridoids



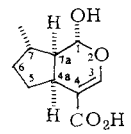
The iridoids and secoiridoids represent two widely distributed classes of natural products which are almost exclusively of plant origin[20]. However, the parent compound iridodial **14** and related substances such as the iridolactone **15** are found in the defensive secretions of some species of ants[21].



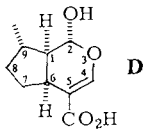
**14a** **14b** **15**

The iridoids are characterized by the presence of a *cis*-linked partially hydrogenated cyclopenta[c]pyran skeleton (iridene).

The formulas, nomenclature, and numbering of the iridoid skeleton used in the literature are inconsistent. Of the two formulas **A** and **B** usually employed, formula **A** is to be preferred as it is consistent with the usual way of representing both the methyl group in the biosynthetic precursors (*e.g.* geraniol) and the centers of chirality in the subsequent biosynthetic products (monoterpenoid indole alkaloids).

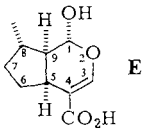


A



B

The iridoid skeleton can be named and numbered according to the nomenclature used for heterocycle **C** or bicycle **D**. Considerable simplification can be achieved by introducing the name "iridene" (saturated system: iridane = *cis*-2-oxabicyclo[4.3.0]nonane) for the basic iridoid skeleton (see **E**). This is, however, a nonsystematic name[28]. Here, we will adopt the numbering used in **E**.



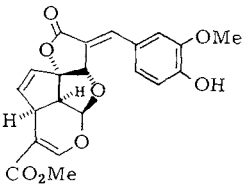
It should be noted that the designation of the absolute configuration at C-1 (formula **A**) may differ if the substituents at C-1 are changed. In the glycosides, C-1 has an (*S*)-configuration, whereas in the aglycones (formulas **C**—**E**) it has an (*R*)-configuration.—The traditional designation is used for secologanin **8** (see Scheme 1).

C

D

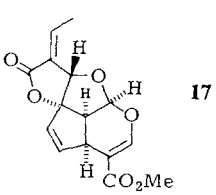
E

**C**: (1*R*,4a*S*,7*S*,7a*R*)-1-Hydroxy-7-methyl-1,4a,5,6,7,7a-hexahydrocyclopenta[*c*]pyran-4-carboxylic acid.



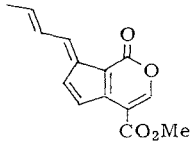
**D**: (1*R*,2*R*,6*S*,9*S*)-2-Hydroxy-9-methyl-3-oxobicyclo[4.3.0]non-4-ene-5-carboxylic acid.

**E**: (1*R*,5*S*,8*S*,9*R*)-1-Hydroxy-8-methyl-3-iridene-4-carboxylic acid.

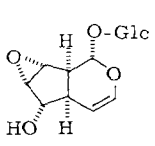


The majority of the iridoids are linked to D-glucose at C-1. There are also iridoids which are either bonded to glucose *via* glycosidic bonds at other positions[22], have other sugar residues[23], or only exist as aglycones[20a].

The carbon skeleton of the iridoids is generally composed of nine or ten C atoms. However, compounds belonging to this class of natural products are known which possess nineteen (*e.g.* oruwacin **16**[24]), fourteen (*e.g.* plumericin **17**[27]), thirteen (fulvoplumierin **18**[26]), or eight carbon atoms (*e.g.* unedoside **19**[27,28]). The constitution and absolute configuration of several iridoid glycosides have been determined by X-ray structure analysis[29].

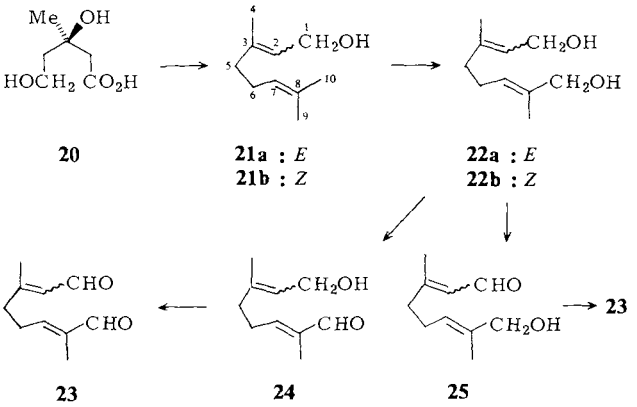


**16**



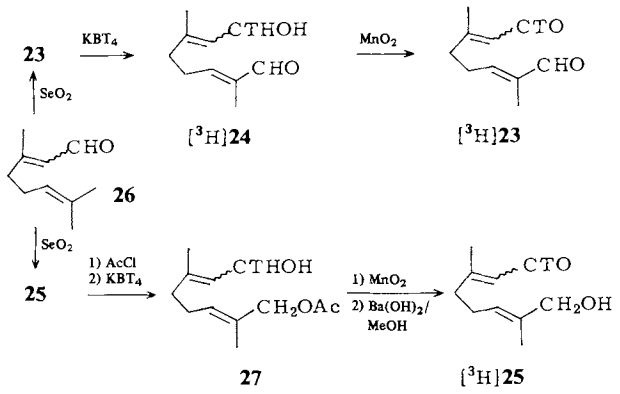
**17**

**18**



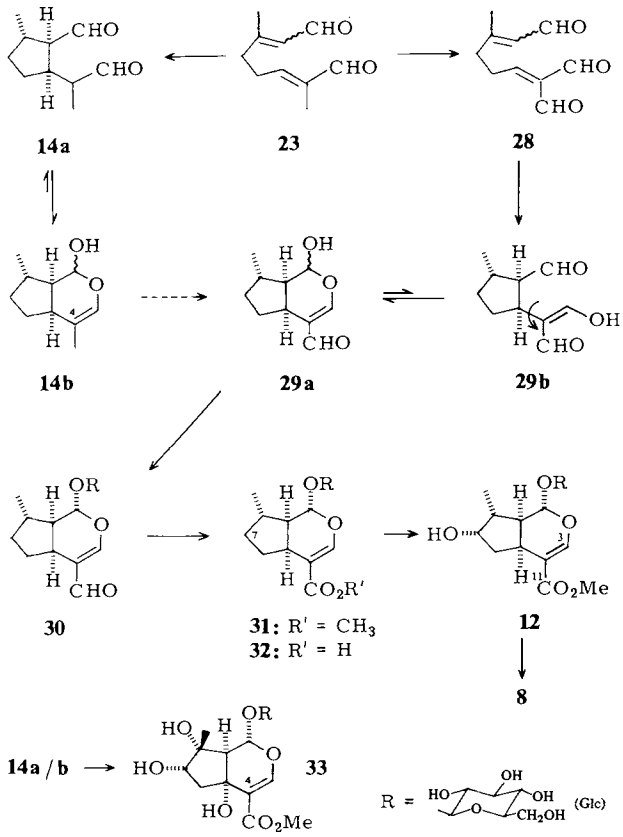
**19**

The secoiridoids are all derived from secologanin **8** and, apart from a few exceptions[30], all of these compounds contain ten C atoms; they may or may not be glycosidically bonded.



## 3. Biosynthesis of Loganin and Secologanin

The origin of the $C_9/C_{10}$ framework of the alkaloids shown in Scheme 1—which as we now know is derived from secologanin **8**—remained unclear for a long time and gave rise to much speculation. Dihydroxyphenylalanine[31] and shikimic acid[32] as well as acetyl CoA[33] were discussed as possible bioeducts. *Wenkert*[34] and *Thomas*[35] were the first to suggest that a cyclopentanoid monoterpene could be a precursor. *Battersby et al.*[36] and *Arigoni et al.*[37] were able to demonstrate that the iridoid glycoside loganin **12** is an intermediate in indole alkaloid biosynthesis; subsequently *Battersby et al.*[38] identified the secoiridoid secologanin **8** as the ultimate nitrogen-free precursor. In plants, loganin **12** and secologanin **8** are produced from geraniol **21a** or nerol **21b**, which are themselves synthesized from two molecules of mevalonic acid **20**[39]. To form the cyclopentane ring, C-6 in **21a** or **21b** must be transformed into an electrophilic center. This is achieved by specific oxidation with an oxygen-, NADPH-, and cytochrome $P_{450}$-dependent monooxygenase to give 10-hydroxygeraniol **22a** or 10-hydroxynerol **22b**[40,41], followed by the hydroxy aldehyde **24** and finally the dialdehyde **23**[42]. Alternatively, oxidation at C-1 could yield the aldehyde **25** and then the dialdehyde **23**. Experiments in which *Catharanthus roseus* G Don was fed with the labeled compounds [1-$^3H_1$]**24** and [1-$^3H_1$]**25** show, however, similar incorporation rates into loganin **12**, so that it is not possible in this experiment to decide between these two pathways[42].

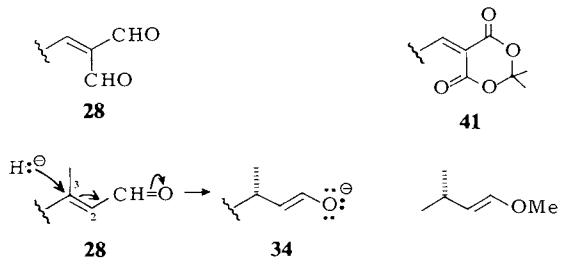


**20** **21a** : *E* **21b** : *Z* **22a** : *E* **22b** : *Z* **23** **24** **25**

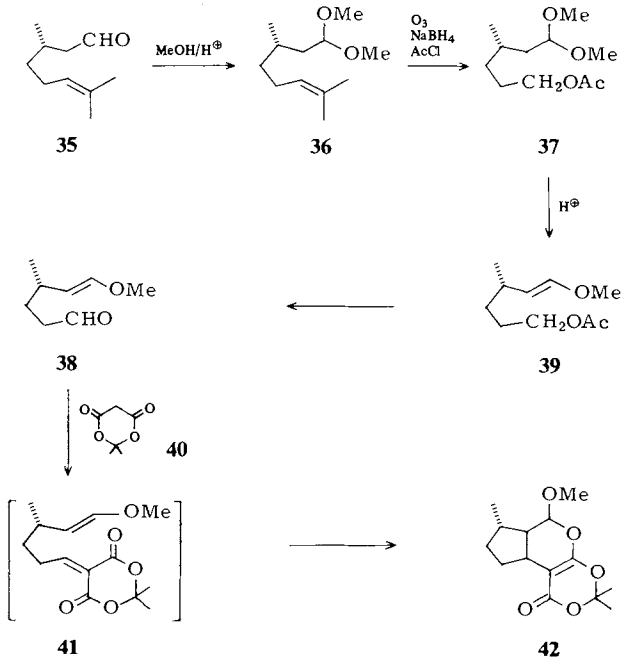
The appropriately labeled compounds can be synthesized[42] by oxidizing citral **26** (a mixture of 64% geranial and 36% neral) with excess selenium dioxide to give the dialdehydes **23** or with less than the stoichiometric amount of selenium dioxide to give the hydroxy aldehydes **25**. Selective reduction of **23** with [$^3$H]potassium tetrahydridoborate produces the hydroxy aldehydes [$^3$H]**24** labeled at the C-1 position; these can be converted into the dialdehydes [$^3$H]**23** specifically labeled at C-1 by oxidation with manganese dioxide. The hydroxy aldehydes [$^3$H]**25** labeled at C-1 are synthesized by acetylation of the hydroxy aldehydes **25** and reduction with [$^3$H]potassium tetrahydridoborate to give **27**. Oxidation with manganese dioxide and subsequent solvolysis with barium hydroxide in methanol afford [$^3$H]**25**.

**26**, [$^3$H]**23**, [$^3$H]**25**: 64%*E* + 36%*Z*

The dialdehydes **23** can cyclize to give iridodial **14a/b** (Scheme 2). The careful studies of *Inouye*[39c] have shown that this compound is the precursor of numerous iridoids having a methyl group at C-4. The biosynthesis of loganin **12** and secologanin **8** in *Catharanthus roseus* G Don, however, does not proceed *via* iridodial[43] **14a/b** but presumably *via* the acyclic trialdehyde **28**[40a], iridotrial **29a/b**, its glycoside **30**, and deoxyloganin **31**[44]. Deoxyloganic acid **32** may be the actual precursor which is first hydroxylated at C-7 and is then converted into loganin **12** by formation of the methyl ester[44b]. Ester formation at the stage of loganin **12** and secologanin **8** seems to be reversible (this does not apply to **32**) since the corresponding acids of **8** and **12** have also been detected in plants. Unlike the synthesis of loganin **12** and secologanin **8**, other compounds with a methoxycarbonyl group at C-4, such as lamiide **33**,



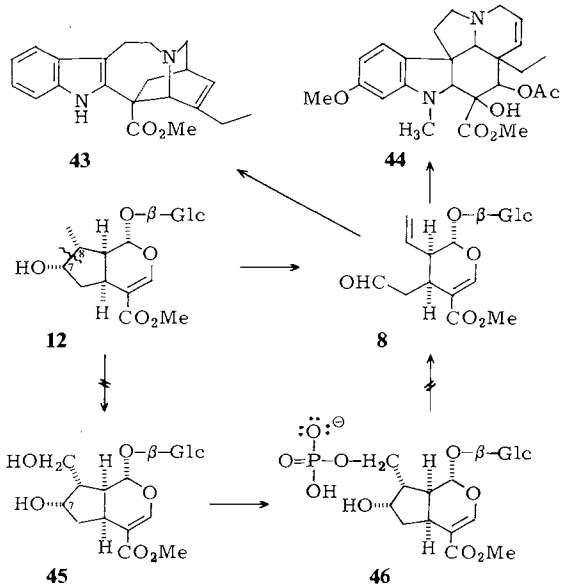
Scheme 2. Formation of the cyclopenta[c]pyran system (iridene skeleton) in the biosynthesis of the iridoids.



can be produced in certain plants (*e.g.* the deadnettle) from iridodial **14a/b** by an oxidative process[39a].

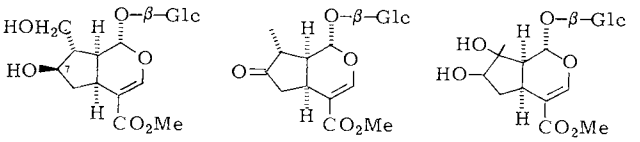
Since the C-3 and C-11 atoms of loganin **12** are equivalent at one stage in the *in vivo* reaction, it can be concluded that iridotrial **29a/b** is an intermediate in the biosynthesis of loganin **12** and secologanin **8**. Thus, after feeding geraniol **21a** specifically labeled at C-9, half of the radioactivity is located at position C-3 of loganin **12** and half at position C-11[39,44b].

A reductive Michael addition has been postulated for the cyclization of the trialdehyde **29**, which has not so far been used in feeding experiments. We have tried to achieve such a cyclization *in vitro* with the compound **41**[45]. An alkylidene derivative of Meldrum's acid was employed instead of the highly unstable alkylidenemalondialdehyde part structure in **29**. An enol ether functional group was used as an equivalent for the enolate **34** which is to be expected after hydride addition to the α,β-unsaturated aldehyde in **29**.



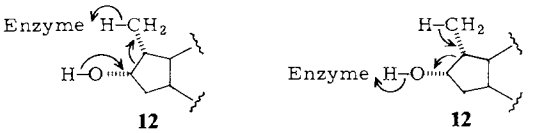
The aldehyde **38** required for the synthesis of **41**[45b] can be prepared in a few steps from enantiomerically pure (*S*)-citronellal **35**. Acetalization of **35** to **36** and subsequent ozonolysis, reductive work-up, and acetylation yield **37**. The acid-catalyzed elimination of **37** to give the enol ether **39** (an approximately 1:1 mixture of the *E/Z* isomers is obtained, which can be separated by distillation) with subsequent solvolysis of the ester functional group and oxidation of the primary hydroxy group affords the aldehyde

**38**. Condensation of **38** with Meldrum's acid **40** produces the alkylidene-1,3-dicarbonyl compound **41** within a few minutes; this cannot, however, be isolated since it cyclizes immediately in an intramolecular Diels-Alder reaction with inverse electron demand[46] to produce the iridoid derivative **42**.

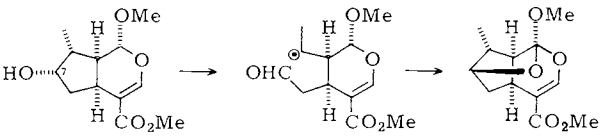


The reaction sequence described represents a novel approach to the synthesis of the iridoids and also verifies that it is possible to induce the *in vitro* cyclization of a tricarbonyl compound to afford a cyclopenta[*c*]pyran skeleton, as postulated by *Arigoni et al.*[40a].

When secologanin **8** is formed from loganin **12**, the methylcyclopentane ring is cleaved to give a δ,ε-unsaturated aldehyde. Neither the exact mechanism of this reaction nor the enzymes involved are yet known. *Battersby et al.*[47] suggested that hydroxyloganin **45** is an intermediate. As the monophosphate **46** this compound could be cleaved by heterolytic fragmentation to yield secologanin **8**. We were the first to accomplish the total synthesis of hydroxyloganin **45** and 7-epihydroxyloganin **47**[48]. However, administration of [$CO_2{}^{14}CH_3$,7-$^3$H]hydroxyloganin **45** and [$CO_2{}^{14}CH_3$]7-epihydroxyloganin **47** to *Catharanthus roseus* G Don results in very low absolute incorporation into the indole alkaloids catharanthine **43** (<0.02%) and vindoline **44** (<0.01%), which are synthesized *in vivo* from secologanin **8**; under the same conditions the incorporation of [$CO_2{}^{14}CH_3$]loganin **12** is more than 10 times greater[49]. It can thus be assumed that hydroxyloganin **44** and epihydroxyloganin **47** do not act as intermediates in the conversion of loganin **12** into secologanin **8**. The objection that hydroxyloganin **45** is not transported to the site of secologanin biosynthesis seems to be improbable since loganin **12**, which is chemically similar, can be metabolized by the plant. It is also highly unlikely that hydroxyloganin **45** is formed and cleaved in a multienzyme complex and, hence, plants cannot convert free **45** into secologanin **8**. In addition, hydroxyloganin **45** is presumably not a natural iridoid. Isolation experiments with *Menyanthes trifoliata*—a plant which contains numerous iridoids and secoridoids—show that **45** is present at less than the 0.0001% level (limit of detection)[49].

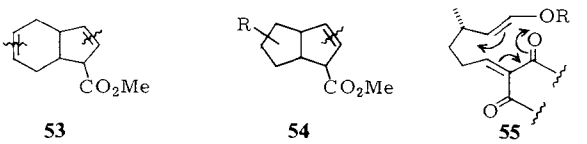


Similar results have been obtained by *Inouye et al.*[50], who has recently prepared hydroxyloganin **45** and epihydroxyloganin **47** from the iridoid geniposide and after labeling these compounds administered them to *Lonicera morrowii* and *Adina pululifera*.



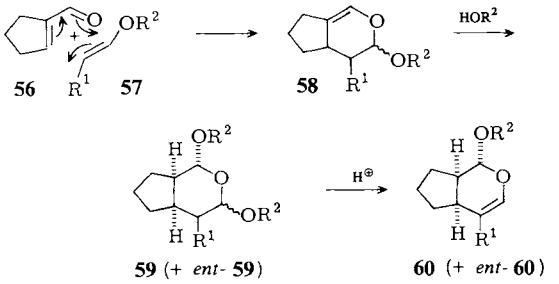
The results of feeding experiments performed with [$^3$H]loganin labeled at C-7 and C-8—the labeling pattern is retained during its conversion into secologanin **8**—preclude intermediates such as dehydrologanin **48**, the diol derivative **49**, and other loganin derivatives which are $sp^2$-hybridized or disubstituted at C-7 and/or C-8[39c].

It must, therefore, be concluded that cleavage of the cyclopentane ring in loganin **12** proceeds directly *via* an oxidative radical or ionic process.



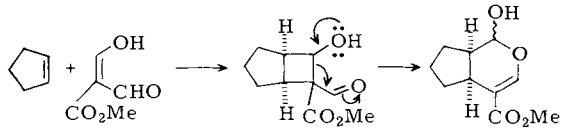
The reaction of loganinaglucone-*O*-methyl ether **50** with lead tetraacetate to form the tricyclic compound **52** may be regarded as a possible model reaction. Here, the open-chain radical **51** has been proposed as an intermediate since the configuration at C-7 is inverted during the oxidation[51].

## 4. Synthesis of Iridoids; Preparation of Hydroxyloganin and 7-Epihydroxyloganin



The cyclopenta[c]pyran ring (iridane skeleton) of the iridoids can be synthesized by several methods[52]. The most important of these are:

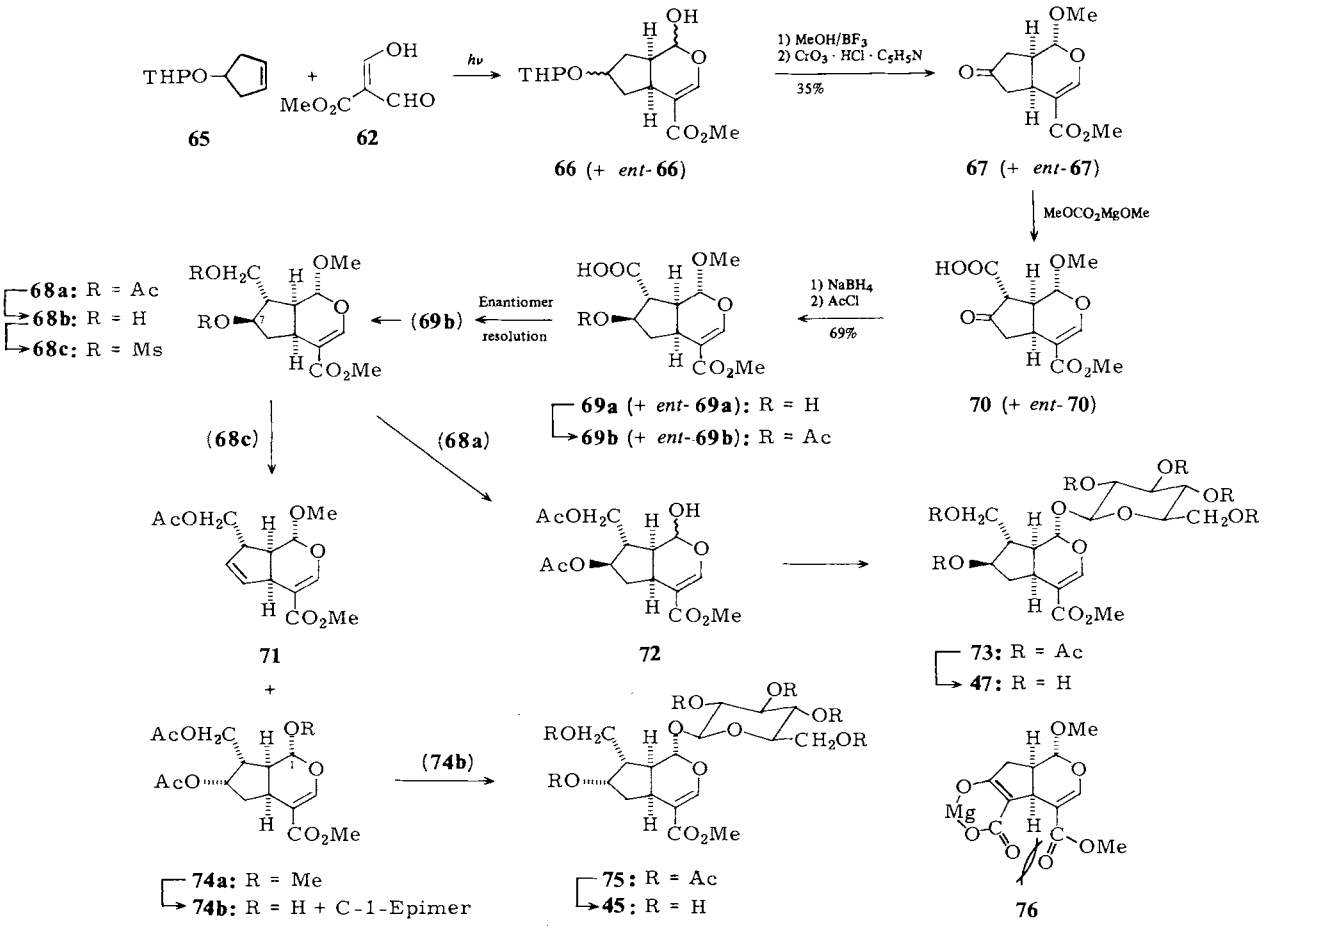
1) the double cleavage and cyclization of bicyclononadiene derivatives **53** first used by *Büchi et al.* for the synthesis of genipin[53],
2) the cleavage and cyclization of bicyclooctene derivatives **54**[54],



3) the intramolecular Diels-Alder reaction of compounds of type **55**[45],

4) the intermolecular Diels-Alder reaction of cyclopentenecarbaldehydes **56** and enol ethers **57** to **58**, and subsequent isomerization of the double bond by an addition-elimination sequence (**59** → **60**)[55],

**56** **57** **58** **59** (+ *ent*-**59**) **60** (+ *ent*-**60**)



**61** **62** **63** (+ *ent*-**63**) **64** (+ *ent*-**64**)

5) the photochemical cycloaddition[56] of cyclopentene and a tricarbonyl compound **62**. A cyclobutane derivative **63** may act as an intermediate which is cleaved in a retroaldol reaction and then recyclized to the dihydropyran system **64**[57,48].

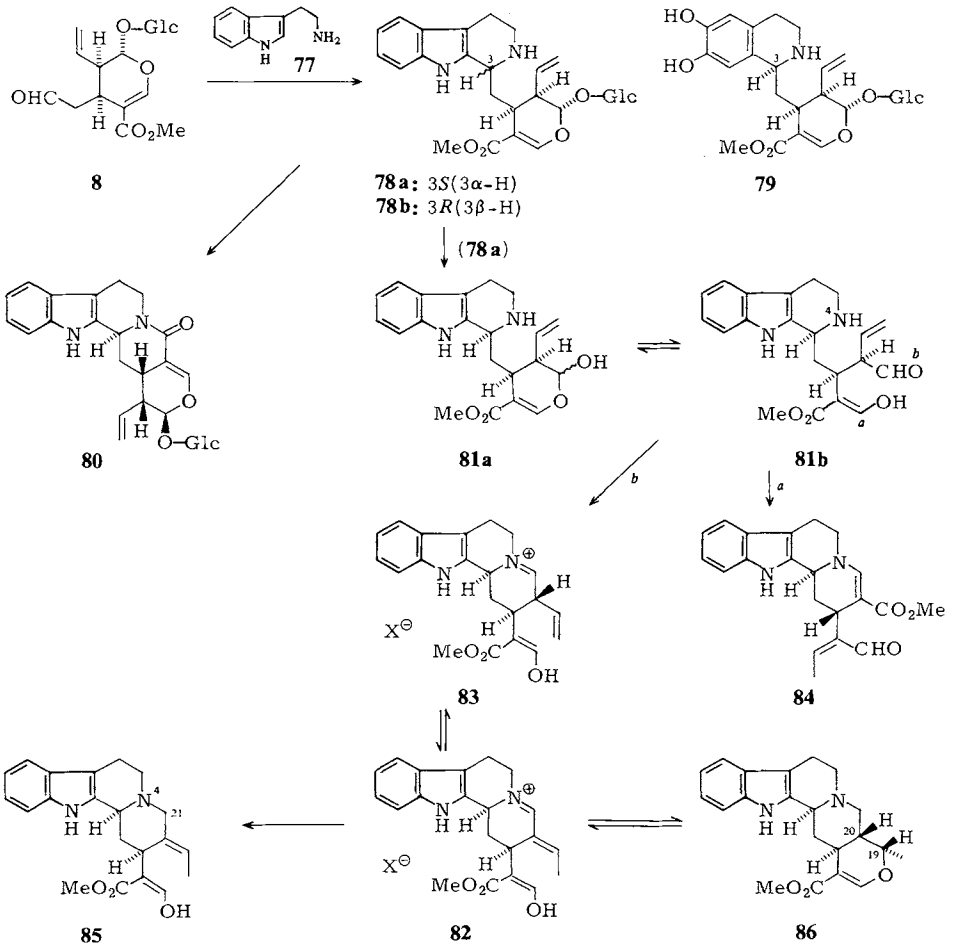
Hydroxyloganin **44**[48] and 7-epihydroxyloganin **47**[49] have been synthesized using photochemical cyclizations (Scheme 3). Irradiation of the tetrahydropyranyl ether **65** and methyl diformylacetate **62** affords the iridoid skeleton **66**. Reaction with methanol in the presence of boron trifluoride gives the acetal at C-1 and liberates the secondary hydroxy functionality. Subsequent oxidation yields the ketone **67**, which has also been utilized as an intermediate in the synthesis of loganin **12**[57a]. The missing $C_1$-unit is introduced as a carboxyl rather than as a hydroxymethyl group using methylmagnesium carbonate[58]. Thereby, resolution can be performed at a later stage in the synthesis to avoid formation of diastereomers in the subsequent glycosidation. The reaction proceeds regioselectively to yield exclusively the very sensitive keto acid **70**, which, without isolation, is reduced stereoselectively to the hydroxy acid **69a** with sodium tetrahydridoborate. Acetylation affords the acetoxycarboxylic acid **69b** as the sole product (69%, based on **67**); this compound can be resolved into its enantiomers simply and almost quantitatively using enantiomerically pure 1-phenylethylamines.

The high selectivity of the carboxylation **67** → **70**, which is presumably thermodynamically controlled, probably arises because the regioisomeric magnesium salt **76** is destabilized by steric interactions[59]. The possibility that "nonclassical" electronic interactions destabilize **76** or the $\Delta^6$-enolate primarily formed from **67** cannot, however, be excluded. The selectivity of the reduction step is a result of

Scheme 3. Synthesis of hydroxyloganin **45** and 7-epihydroxyloganin **47**. THP = tetrahydropyranyl. If in addition to the compound shown its enantiomer is also formed, the latter is designated by the prefix "*ent*-" before the formula number.

the folded shape of the molecule, which only allows the reducing agent to approach from the convex side. Neighboring group participation of the carboxy group would have the same effect.

Reduction of the carboxy group in (enantiomerically pure) **69b** with diborane and subsequent acetylation gives the diacetate **68a**, which can be converted into the hemiacetal **72** by acid-catalyzed reaction with acetic acid/perchloric acid/water. Glycosidation of **72** with 2,3,4,6-tetra-*O*-acetyl-β-D-glucose in the presence of boron trifluoride-ether affords a low yield of 7-epihydroxyloganin hexaacetate **73**, which undergoes solvolysis with barium hydroxide in methanol to give epihydroxyloganin **47**. For the problem of the glycosidation of the iridoid aglycones, see Section 9.



To synthesize hydroxyloganin **45** from **68a**, the C-7 center must be epimerized. This is accomplished by nucleophilic substitution with tetraethylammonium acetate *via* an $S_N2$ reaction of the bismethanesulfonate **68c** obtained from of the diol **68b.** The configuration at every center of chirality in the diacetate **74a** corresponds to that in loganin **12**. The olefin **71** is obtained as a by-product of the reaction. Cleavage of the acetal **74a** to afford **74b**, glycosidation of the latter to **75**, and solvolysis to give **45** can be performed in a manner analogous to that used in the synthesis of epihydroxyloganin **47**.

The introduction of the isotopic labels tritium and carbon-14 into **45** and **47**, respectively, follows by reduction of the keto acid **70** with [$^3$H]sodium tetrahydridoborate and esterification of the carboxylic acids obtained after hydrolysis of **45** and **47** with [$^{14}$C]diazomethane.

## 5. Biosynthesis of Monoterpenoid Indole Alkaloids

In the biosynthesis of the monoterpenoid indole alkaloids[4, 60], secologanin **8** condenses with tryptamine **77** to produce strictosidine **78a**, the first nitrogen-containing precursor of this class of compounds. Strictosidine **78a** also acts as an intermediate in the biosynthesis of the cinchona (*e.g.* quinine **5**) and pyrroloquinoline alkaloids (*e.g.* camptothecine **7**). The ipecacuanha alkaloids (*e.g.* emetine **6**) are, however, synthesized *via* desacetylisoipecoside **79**, which is formed from secologanin **8** and dopamine [4-(2-aminoethyl)pyrocatechol][61] (Scheme 4).

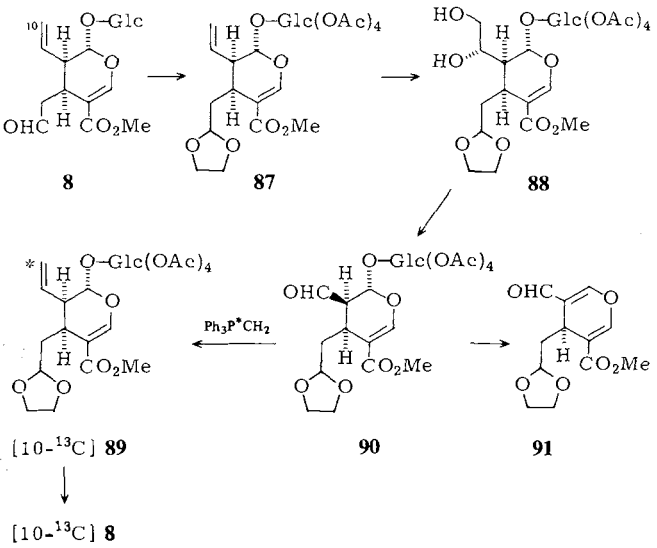
Strictosidine synthase has been isolated from cell cultures of *Catharanthus roseus* G Don and is the enzyme specific for the reaction of secologanin **8** with tryptamine **77** to give **78a** (this enzyme is unable to metabolize tryptophan)[62]. If **8** and **77** are allowed to react non-enzymatically, an almost 1:1 mixture of strictosidine **78a** and the epimeric compound vincoside **78b** is obtained; the latter is not a precursor of the monoterpenoid indole alkaloids.

Scheme 4. Biosynthesis of monoterpenoid indole alkaloids from secologanin **8**.

In the further course of the biosynthesis, enzymatic cleavage[63] of the glycosidic bond of **78a** may occur to form the aglycone **81a** which exists in equilibrium with the dialdehyde **81b**. It has not yet been possible to detect either of these compounds as intermediates since they immediately react further[64]. Condensation of either the enolized formyl group *a* with *N*-4 and subsequent isomerization of the double bond affords vallesiachotamine **84**, or the ammonium salt **83** is formed by reaction of the formyl group *b* with *N*-4 *via* an α-amino alcohol. Isomerization of the CC double bond leads to 4,21-dehydrogeissoschizine **82**, which undergoes hydrogenation of the iminium double bond to yield geissoschizine **85**. **82** can also be converted into ajmalicine **86** or its C-19, C-20 configurational isomers by intramolecular nucleophilic 1,4-addition of the enol functionality to the α,β-unsaturated heterodiene system and subsequent hydrogenation.

Strictosidine **78a** can, however, react in other ways: Thus, strictosidinelactam **80** can be formed prior to cleavage of the glycosidic bond; this compound is a precursor of the pyrroloquinoline alkaloids, *e.g.*, camptothecine **7**[8].

The multiplicity of possible reactions which can be undergone, therefore, accounts for the many different monoterpenoid indole alkaloids.



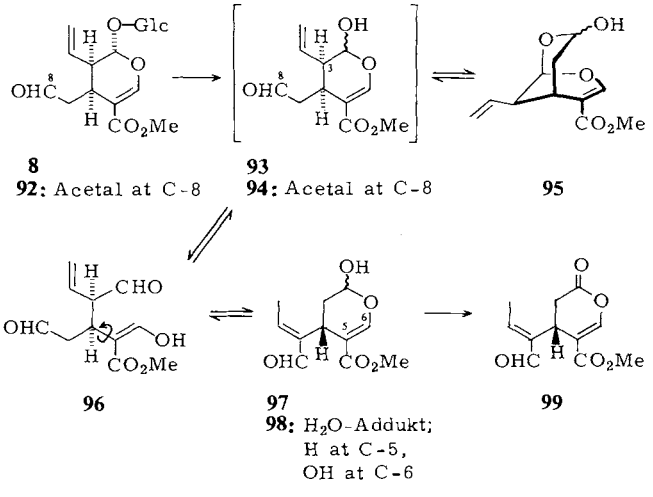
The key reaction steps in the biogenesis have been elucidated using cell cultures, cell-free enzyme systems, and isolated enzymes[65,60]. There is, however, no direct evidence for the existence of intermediates whose high reactivity precludes their isolation. It is also still uncertain whether some of the isolated substances involved in the enzymatic reactions function directly as intermediates or whether they are formed in secondary equilibria.

## 6. Synthesis of [10-$^{13}$C]Secologanin from Natural Secologanin

So far, studies on the biosynthesis have been performed almost solely using radioactively labeled precursors. This method has the chief disadvantage that it is impossible to follow the individual reaction steps directly. However, if $^{13}$C-labeled precursors are employed the successive sequence of reaction steps can be followed and evaluated kinetically with the aid of NMR spectroscopy. We have, therefore, synthesized a $^{13}$C-labeled secologanin **8**[66a] which can be utilized in biogenesis studies either directly or after conversion into $^{13}$C-labeled strictosidine **78a**. C-10 was selected as the labeling site since the hybridization and chemical environment of this C atom change during the enzymatic reaction, thus allowing identification of the intermediate products.

The label is introduced at C-10 by cleavage of the terminal double bond and a subsequent Wittig reaction (Scheme 5).

Secologanin **8**, isolated from *Symphoricarpus rivularis*[66b], was converted into the peracetylated acetal **87** by acetalization and subsequent acetylation. Oxidation of **87** with an equimolar amount of osmium tetraoxide proceeds stereoselectively to give the diol **88**. Tetraacetyl glucose (30%) can also be isolated. This indicates that oxidative degradation of the dihydropyran ring also occurs during this reaction[67].



Scheme 5. Synthesis of [10-$^{13}$C]secologanin [10-$^{13}$C]**8**.

Oxidative cleavage of **88** with lead tetraacetate affords a very high yield of the aldehyde **90**, which readily forms the pyran **91** upon cleavage of tetraacetyl glucose. This elimination is also the reason why the $^{13}$C-labeled secologanin derivative [10-$^{13}$C]**89** can only be obtained in a yield of 25% in the Wittig reaction with a [$^{13}$C]methanide. Labeled secologanin [10-$^{13}$C]**8** is produced from **89** by solvolysis and cleavage of the acetal. At present, we are using NMR spectroscopy to investigate the enzymatic glycoside cleavage of [$^{13}$C]secologanin and [$^{13}$C]strictosidine.

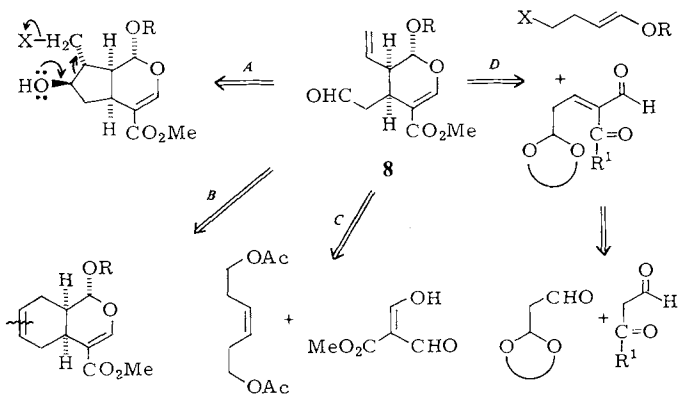
## 7. Enzymatic Glycoside Cleavage of Secologanin and Biomimetic Synthesis of Elenolide

The products of the enzymatic glycolysis of secologanin **8** have previously been identified[68]. At pH 5.2, **8** reacts with β-glucosidase (from almonds, 1 weight equivalent) to give the bicyclic compound **95** within a few minutes. The expected aglycone **93** could not be detected. If, however, the secologanin derivative **92** undergoes glycosidic cleav-

age good yields of the aglycone **94** are obtained[69a]. Compounds of this type isomerize at C-3 very readily[69]; this has not been taken into sufficient consideration in many biomimetic reactions of secologanin and loganin.

Under the conditions required for glycoside cleavage, the bicyclic compound **95** formed from **8** is slowly converted into the epimeric hemiacetals **97**, and it can be assumed that the aglycone **93** and the open-chain aldehyde **96** function as intermediates in this reaction.

**95** reacts with silver perchlorate to afford **97** in good yield. The bishemiacetal **98** is also obtained and can be almost quantitatively dehydrated to give **97**[69a].



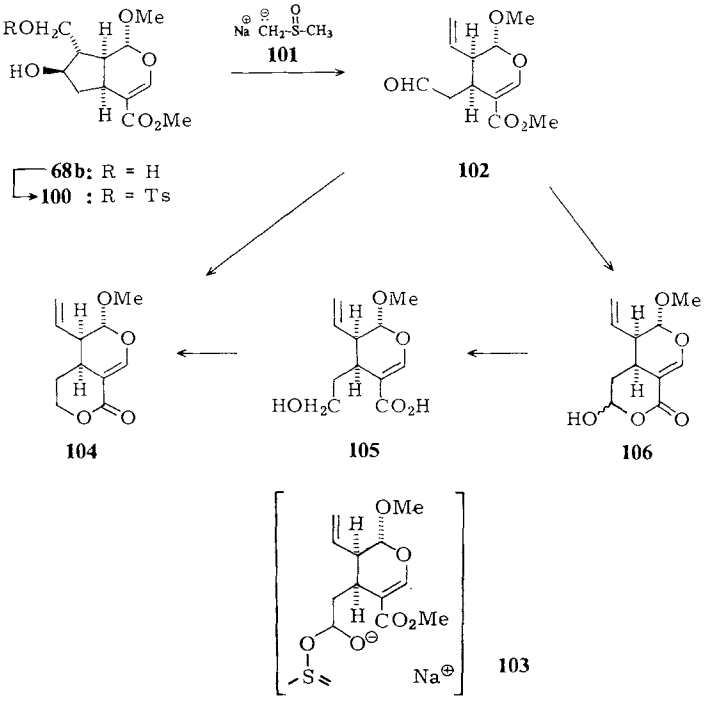
It seems likely that such reactions also occur in biological systems. Thus elenolide **99**, which has been isolated from *Olea europa* L, has a comparable structure[70].

This finding provided a simple, stereoselective, biomimetic synthesis for elenolide **99** in which both the relative and absolute configurations of this compound could be determined. Oxidation of **97** with pyridinium chlorochromate in the presence of sodium acetate gives **99** in 80% yield[71].

## 8. Total Synthesis of Secoiridoids: Secologanin and Sarracenin; Biomimetic Synthesis of Bakankosine

Secologanin **8** is of value not only because of its importance in biosynthesis but also as an educt for the synthesis of compounds of pharmacological interest. It can be isolated from the leaves and young shoots of *Lonicera tatarica* and *Lonicera morrowii* in *ca.* 1.5% yield (relative to the fresh weight). The berries of *Symphoricarpus rivularis* have also proved to be a good source of this compound since the extraction is easier and gives a purer product[66b]. However, due to the high water content of the berries the concentration of secologanin **8** in them is only 0.3% (relative to the fresh weight).

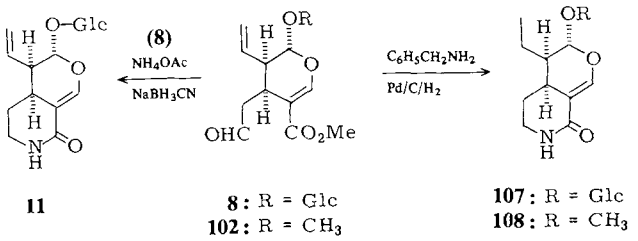
The isolation of **8** from plant material is, however, generally tedious, complicated to perform, and is not suitable for preparing large quantities. A total synthesis of secologanin **8** and especially of its derivatives is, therefore, desirable. These substances can then be allowed to react with amines and amino acids in biomimetic syntheses to yield compounds of pharmacological interest[72]. Possible retrosyntheses of secologanin **8** are given in Scheme 6.



Scheme 6. Retrosynthetic analysis of secologanin **8**. *A-D* see text.

Secologanin **8** is a highly functionalized molecule with one free aldehyde group and two others which are blocked in the form of a glycosidic acetal and an enol ether. It also contains an ester functionality and a vinyl group. Synthesis of this molecule is made problematic by its polyfunctionality and especially by the thermodynamically less stable *cis*-arrangement of the alkyl side chains on the dihydropyran ring.

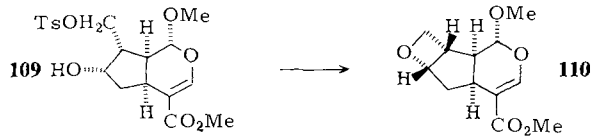
The first synthesis of the secologanin system[73] started, therefore, with a *cis*-linked cyclopenta[c]pyran ring system in analogy to the biosynthetic pathway (Scheme 9: A). The sensitive δ,ε-unsaturated aldehyde group of **8** was formed in the last step of the synthesis by heterolytic fragmentation[74].



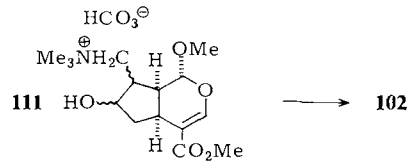
The diol **68b** (see Section 4) was converted into the monotosylate **100**, which can be cleaved within a few seconds by allowing it to react with the strong base sodium methylsulfinylmethanide **101** to give the secologanin derivative **102** in 67% yield. At longer reaction times and in the presence of excess **101**, the lactol **106** is also obtained; this

compound arises either by cleavage of the methyl ester by nucleophilic substitution or by formation of an intermediate of type **103**.

Reaction of **102** with sodium tetrahydridoborate affords sweroside aglycone-*O*-methyl ether **104**. Reduction of the lactol **106** yields primarily the corresponding hydroxycarboxylic acid **105**, which dehydrates to **104** on heating.



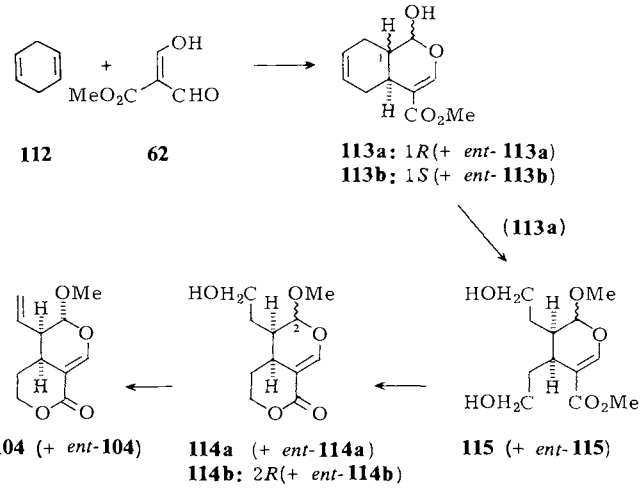
If **102** is reductively aminated with benzylamine (palladium/carbon, hydrogen), the bakankosine derivative **108** is obtained in a single step. In the same manner secologanin **8** can be transformed almost quantitatively into dihydrobakankosine **107**. The alkaloid bakankosine **11** can be synthesized with retention of the vinyl double bond by allowing **8** to react with sodium cyanotrihydridoborate in the presence of ammonium acetate; however, the yield is poor[74]. This permitted the relative and absolute configurations of **11** to be determined.



**11** **8**: R = Glc; **102**: R = $CH_3$ **107**: R = Glc; **108**: R = $CH_3$

The secologanin, sweroside, and bakankosine derivatives can be synthesized in both enantiomeric forms since the dihydroxy compound **68b** used as educt is also accessible as its enantiomer *ent*-**68b**.

Unlike **100**, the monotosylate **109**, which possesses the same relative configurations as loganin **12** at all its centers of chirality, does not react with strong bases to form a fragmentation product, but is converted quantitatively into the oxetane **110** by an intramolecular nucleophilic substitution[73]. The reaction of **109** can be interpreted as additional evidence against formation of hydroxyloganin **44** as an intermediate in the synthesis of secologanin **8** from loganin **12**. An explanation for the different reactivities of **100** and **109** is provided by the studies of *Hoffmann, Gleiter,* and *Stohrer*[76].

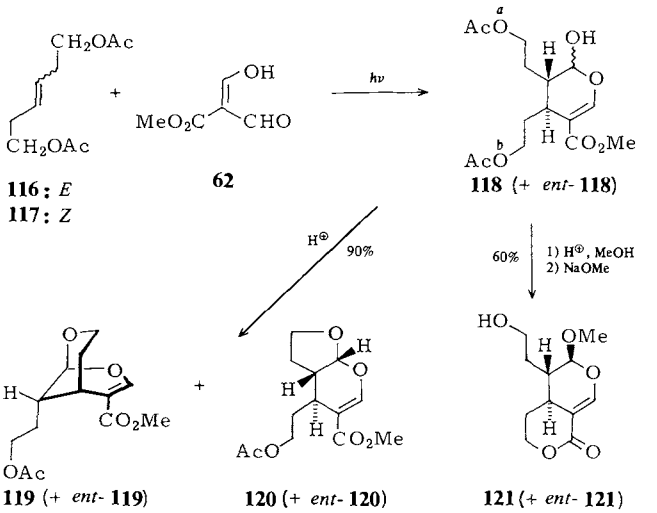


**109** **110**

**111** **102**

A novel fragmentation of the cyclopenta[c]pyran ring skeleton to give **102** can also be accomplished by flash pyrolysis of the γ-hydroxyammonium compound **111** at 350°C[77]. **111** can be synthesized from the ketone **67** *via* a Mannich reaction[78].

Preparation of **102** from the oxabicyclodecadiene system **113a** is based on a concept comparable to that used for the synthesis of **102** from **68b**, and has the advantage that the alkene **112** can be obtained more easily[79] (Scheme 6: B). **113a** can be prepared straightforwardly by photochemical cycloaddition of 1,3-cyclohexadiene **112** and methyl diformylacetate **62**. Whereas, however, formation of the cyclopenta[c]pyran skeleton in **68b** from cyclopentane derivatives and **62** results solely in *cis*-fused products, this reaction leads also to formation of the *trans*-isomer **113b** which can be separated. After acetalization of **113a** at C-1, the cyclohexene double bond is cleaved selectively by ozonolysis at −70°C to give the unstable dialdehyde (72%), which can be reduced to the diol **115** with sodium tetrahydridoborate The high selectivity of this reaction is remarkable, since selective ozonolysis of the vinyl group in secologanin **8** without destroying the dihydropyran ring can either not be achieved or only affords low yields. The cyclohexene system in **113a** can also be cleaved to afford **115**—albeit with poorer yields—by *cis*-hydroxylation with osmium tetraoxide and subsequent cleavage with periodate. Hydrolysis to the corresponding hydroxy acid and cyclization with loss of water yields the hydroxylactone **114a**. The racemic (2*R*)-lactone **114b**,



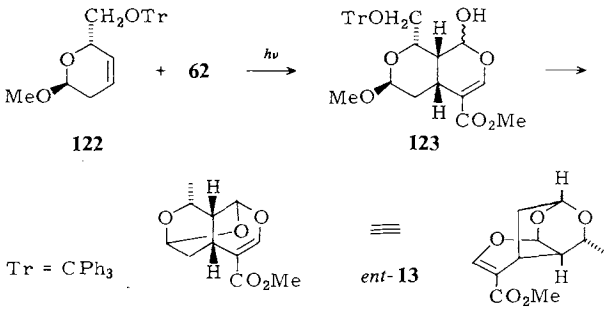
**112** **62** **113a**: 1*R*(+ *ent*-**113a**); **113b**: 1*S*(+ *ent*-**113b**)

**104** (+ *ent*-**104**) **114a** (+ *ent*-**114a**); **114b**: 2*R*(+ *ent*-**114b**) **115** (+ *ent*-**115**)

which is purified by chromatography, can be converted into the racemic sweroside aglycone-*O*-methyl ether **104** by transformation into an alkyl selenide and subsequent oxidative elimination. The secologanin derivative **102** can be obtained from **104** in a few steps.

Compounds of the secologanin type can also be readily synthesized on a larger scale by a further method: The photochemical cycloaddition of the readily accessible (*E*)- or (*Z*)-alkenes **116** or **117** with **62**, which proceeds in 70% yield (Scheme 6: *C*).

**116**: *E* **117**: *Z* **62** **118** (+ *ent*-**118**)

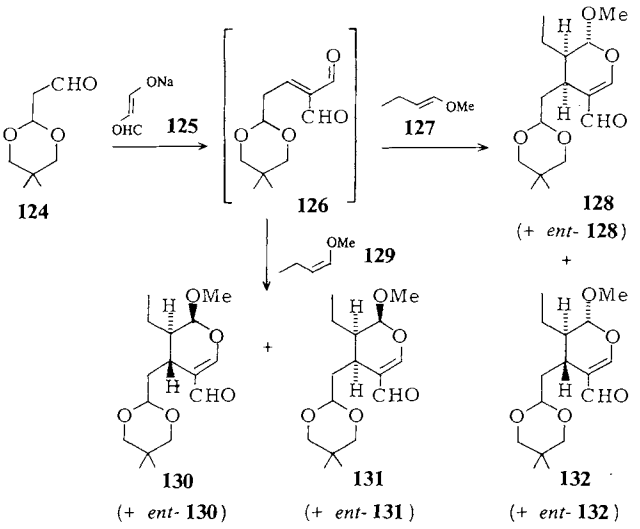


**119** (+ *ent*-**119**) **120** (+ *ent*-**120**) **121** (+ *ent*-**121**)

This method, however, only leads to the *trans*-substituted dihydropyran derivative **118**. Loss of stereochemical integrity in **117** indicates that biradical intermediates are formed, consistent with postulates made about photochemical cycloadditions of this type[56]. However, isomerization of a *cis*-substituted cycloadduct which may be formed primarily from **117** would also furnish the thermodynamically more stable *trans*-substituted dihydropyran **118**[69].

The two acetoxy groups in **118** can be differentiated in two ways: acid catalyzed reaction of **118** results in quantitative conversion into a 3:1 mixture of the bridged system **119** and the annelated compound **120**, which are in equilibrium with one another under the reaction conditions. Under conditions of acid catalysis, pure **119** and **120** form a 3:1 mixture of the constitutional isomers. In **119** the acetylated primary hydroxy group *b* of the cycloadduct **118** is protected by acetylation, and in **120** the group *a* is protected in the form of an acetal, whereas the second acetylated hydroxy groups in each of these two compounds can be selectively further reacted. Both compounds are valuable educts for the biomimetic synthesis of pharmacologically important compounds of the monoterpenoid indole alkaloid type.

The acetoxy groups in the cycloadduct **118** can also be differentiated by acid-catalyzed reaction with methanol and subsequent Zemplén saponification to afford the *trans*-sweroside derivative **121**; this compound can also be subjected to further reactions.



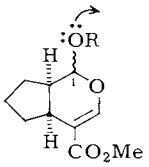
Photochemical cyclization is also a suitable method of preparing enantiomerically pure secoiridoids. Thus, it is possible to synthesize enantiomerically pure sarracenin **13** (which can be isolated from the carnivorous plant *Sarracenia flava*)[118]) and its unnatural isomer *ent*-**13** in a few steps from the galactose derivatives[81] *ent*-**122** and **122**, respectively, and methyl diformylacetate **62**. The main product of the photochemical cyclization of **122** and **62** is the bicyclic compound **123**[82,83].

Recently, we have developed a novel, surprisingly simple, flexible concept for synthesizing compounds of the secologanin type[84]. Here the $C_{10}$ skeleton of **8** is constructed from one $C_4$ and two $C_3$ units in a "one-pot" reaction (Scheme 6: *D*). The key step is a Diels-Alder reaction with inverse electron demand between the $C_4$ enol ether **127** and an alkylidene-1,3-dicarbonyl compound **126** which can be obtained *in situ* by condensation of the sodium salt of malondialdehyde **125** with the monoacetal of malondialdehyde **124**.

The cycloaddition gives the secologanin derivative **128** (48%); the relative configuration at each of its centers of chirality corresponds to that of secologanin **8**. The stereoisomer **132** is also obtained in 16% yield; however, this can be separated by chromatography. If the (*Z*)-enol ether **129** is used, an approximately 1:1 mixture of the two stereoisomers **130** and **131** is produced in 64% yield.

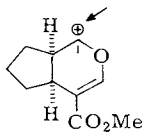
The Diels-Alder reaction of the alkylidene-1,3-dicarbonyl compound **126** (which cannot be isolated) is complete within a few minutes at 20°C. The markedly higher reactivity of the heterodiene unit in **126** compared to simple

α,β-unsaturated aldehydes can be explained through a decrease of the LUMO energy of the heterodiene by the electron acceptor functionality in the α-position[46].



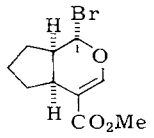
## 9. Synthesis of Iridoid Glycosides

Whereas considerable progress has been made in the last years regarding the isolation[20], structure determination[85], and the biogenesis of the iridoid and secoiridoid glycosides, as well as in the synthesis of the non-glycosidic compounds of this class of natural products, very few studies on the total synthesis of glycosidically bonded iridoids have been carried out. This is mainly because glycosidation of the corresponding iridoid aglycones is exceedingly difficult. Thus, in the glycosidation step in the synthesis of loganin **12**, which represents the first, and so far the only, total synthesis of a natural iridoid glycoside, the yield amounts only to 1.4%[57a]. Previously, *Schmid et al.*[85b] showed that the Koenigs-Knorr method was not suitable for the synthesis of iridoid glycosides.

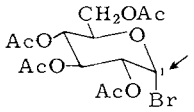


In principle, glycosidation of iridoid aglycones of type **133** can be achieved in two ways:

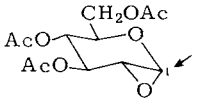
1) Nucleophilic attack of the hemiacetal hydroxy group of **133** at C-1 of a reactive glucose derivative such as acetobromoglucose **139**, 3,4,6-tri-*O*-acetyl-1,2-anhydroglucose triacetate **140**, or an orthoester[86].
2) Nucleophilic attack of the hemiacetal hydroxy group of tetraacetyl-β-D-glucose **141** or the trimethylsiloxy group of **142** at C-1 of the aglycone **133**. Here, it must be assumed that the carbenium ion **137** acts as an intermediate, since for steric reasons a $S_N2$-like transition state seems less probable and would lead to the "wrong" stereoisomer.



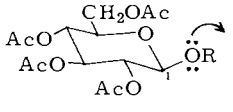
Reaction of **133** with acetobromoglucose **139** in the presence of silver carbonate, mercury cyanide/bromide, and mercury succinate using Koenigs-Knorr and related procedures[86] which give good yields of β-glucosides with alcohols and monosaccharides, fails completely. This is probably due to the low nucleophilicity of the hemiacetal



**133**: R = H
**134**: R = Me
**135**: R = Ac
**136**: NHAc instead of OR



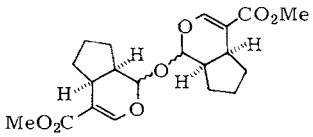
**137**



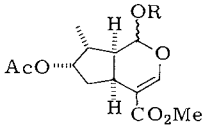
**138**

**139**

**140**

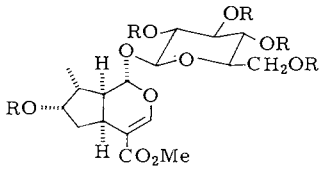


**141**: R = H
**142**: R = $SiMe_3$

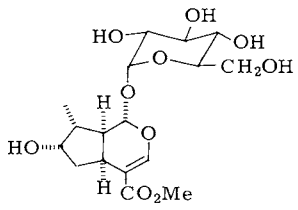


hydroxy group in **133**. If, however, silver perchlorate or silver trifluoromethanesulfonate is used as a heavy metal salt, a mixture of isomeric glycosides can be obtained from **133** in 28% yield; this mixture can be separated after solvolysis of the acetyl groups[87]. The dimeric aglycones **143** are also formed.

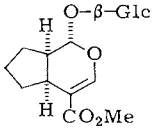
Loganin **12**, with a β-glycosidic bond, and the α-glycoside **147** can be obtained in 13% and 5% yield, respectively, from the 7-*O*-acetyl-loganin aglycone **144** after performing a complicated separation. Reaction of **133** with **140** in the presence of catalytic quantities of boron trifluoride-ether gives solely the α-glycoside; yields are moderate[88]. Small quantities of another glycoside were also detected in which the glucosyloxy group adopts the unfavorable *cis*-position with respect to the cyclopentane ring.



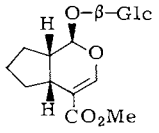
In the second glycosidation method the aglycone **133** or **144** must be transformed into a carbenium ion which can



**143**



**144**: R = H
**145**: R = Ac



**12**: R = H
**146**: R = Ac

**147**

**148**

**149**

then react with **141** or **142** with retention of the configuration of the glucose derivative at C-1. The cation **137** can be synthesized from **133** either directly with boron trifluoride-ether or after conversion into the bromide **138** with silver perchlorate. However, glycosidation does not proceed stereoselectively since the sugar component isomerizes under the reaction conditions. Furthermore, the dimeric aglycones **143** are formed preferentially and, hence, the yield of the desired β-glycoside **148** only amounts to 10%.

The procedures described are totally unsatisfactory with regard to yield and selectivity. They have, however, provided new information about the mechanism of glycosidation and supplied a wealth of NMR spectroscopic[89] and chiroptic data[90] which facilitate determination of the relative and absolute configurations of isomeric iridoid glycosides.

A new method has been described recently which at last promises to solve the problem, and thus open up an approach to the synthesis of the iridoid glycosides[91].

The dimethyl acetals of aldehydes can be converted selectively into the previously almost inaccessible glycosides with a 1,1′-diacetal structure by allowing them to react with β-trimethylsilyl glycoside **147** in the presence of catalytic amounts of trimethylsilyl trifluoromethanesulfonate (TMS-triflate). At −70°C only the β-glycosides are produced with retention of configuration at C-1 of **142**[92]; at 20°C exclusively the α-glycosides are formed[93] since anomerization of the trimethylsilyl glycoside **142** happens before the reaction with the acetal[94].

The methyl acetal **134** reacts very slowly at −70°C; at −20°C partial anomerization of **142** occurs to give a mixture of the α- and β-glycosides. Nevertheless, reaction with the acetylated hemiacetal *rac*-**135** in acetonitrile as a solvent affords after saponification the β-glycosides **148** and **149** in 70% yield within 10 h at −30°C. α-Glycosides and C-1 epimers of the aglycone component were not detected (< 5%). A slight blemish in this reaction is the formation of the amide *rac*-**136** (9%) by addition of the cation *rac*-**137** to the solvent. If liquid sulfur dioxide is employed—this is not used very commonly as a solvent in organic chemistry but is very easy and clean to work with—the two β-glycosides **148** and **149** are obtained in 91% yield at −50°C. Solvolysis of the enantiomerically pure acetylated aglycone **135**, which can be prepared from **148** by glycosidic cleavage with emulsin and subsequent acetylation, provides the desired β-glycoside **148** in 87% yield (!); the iridoid glycoside has the correct absolute configuration at all its centers of chirality.

Similarly, penta-*O*-acetyl-loganin **146** can be synthesized in 75% yield from di-*O*-acetyl-loganol **145** and **142** in the presence of catalytic amounts of TMS triflate in liquid sulfur dioxide at −40°C. The amount of α-glycoside obtained (**147**, peracetylated) is less than 10%. Other products are not formed. **146** can easily be converted into the natural product loganin **12** by solvolysis.

## 10. Outlook

So far, the designed synthesis of pharmaceuticals according to the "Rational Drug Design" model has only

found restricted application[95] because information about the structure of the receptors in the control systems of the human and animal organisms is still very limited. For the development of new pharmaceuticals it is, at present, best to start with model structures whose biological activity and biological sites of attack are known. In this respect, compounds derived from secologanin are of great interest. The elegant, simple syntheses of secologanin derivatives which have been developed recently have provided potent educts for biomimetic reactions. Reaction of these substances with amines and amino acids should give a multitude of biologically active compounds.

It has not yet been possible to synthesize glycosidically bonded iridoids and secoiridoids. Development of a high-yield, stereoselective glycosidation method has finally opened up a route for total syntheses of this widely distributed class of natural products. It also allows specifically [$^{13}$C]-labeled compounds of this type to be prepared. The reaction of substances thus labeled in cell cultures, cell-free enzyme systems, or with isolated enzymes should prove highly useful in solving the problems remaining in the biosynthesis of this class of natural compounds and of the ipecacuanha and monoterpenoid indole alkaloids. One of the main centers of interest in the future will be the characterization of the enzymes involved in the individual biosynthetic reactions. Use of suitable derivatives as substrates should provide information about the selectivity and perhaps even the structure of the active centers of the enzymes concerned. Cooperation between chemists and biologists should produce the best results.

*I wish to thank my coworkers for their enthusiasm, dedication and skill in completing the research projects described here. I am particularly grateful to Prof. G. Büchi, Cambridge, USA, Prof. A. R. Battersby, Cambridge, England, Prof. G. Sheldrick, Göttingen, and Prof. C. R. Hutchinson, Madison, for fruitful discussions and excellent collaboration.*

*Support by the Deutsche Forschungsgemeinschaft, the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie is greatfully acknowledged.*

# Synthesis of Peptide Hormones using Recombinant DNA Techniques**

By Friedrich Wengenmayer*

Recombination of genetic material enables the creation of new bacterial strains which can synthesize specific proteins in large amounts. Such bacteria permit the production of previously inaccessible proteins. They can therefore be used as starting materials for the production of drugs which will open up new paths for therapy. Several proteins produced by bacteria after DNA recombination are presently undergoing clinical trials while others are already being produced on a large scale. Thus, in the area of recombinant DNA techniques the transition from the research laboratory to industrial exploitation has occurred much faster than was anticipated several years ago. The methods, possibilities and problems encountered in the synthesis of peptide hormones by bacteria after DNA recombination are outlined, using insulin, somatostatin, and growth hormone as examples. Great emphasis is placed on the molecular biological aspects of this approach.

## 1. Introduction

After the first successful attempts to transfer antibiotic resistance genes to bacteria[1], the field of molecular biology developed rapidly, not least because of the wide variety of practical applications offered by recombinant DNA techniques and DNA transfer.

It was expected that the stable integration of a particular human gene into bacteria would lead to strains which could be used to isolate clinically relevant proteins. The advantages are obvious: the simple culture media and the short generation time of bacteria make it possible to produce proteins which are otherwise difficult to obtain.

From the beginning, interest focused on the production of peptide hormones. There are several reasons for this:

- Most peptide hormones are species specific. Thus, peptides isolated from animal tissue cannot be used in humans since they are inactive due to differences in sequence and structure. This problem can be overcome by recombinant DNA techniques, which allow the production of human hormones in bacteria after the appropriate gene transfer.
- The isolation of some peptide hormones required enormous efforts. In order to obtain less than one milligram of thyrotropin releasing hormone the groups of *Schally* and *Guillemin* had to start their purification from the hypothalami of 80000 sheep[2] or 200000 pigs[3]. And it is anticipated that the future isolation of other therapeutically important peptides and proteins will meet with similar difficulties unless it becomes possible to use genetically engineered bacteria for their production.
- Furthermore, the long years of experience in the successful treatment of diabetes with insulin led to the expectation that other metabolic disorders could also be treated in a similar way once the appropriate hormones were available.

As a result of efforts by several groups, the first peptide hormones produced *via* recombinant DNA techniques are now in hand. Human insulin, synthesized in bacteria, is commercially available, human growth hormone, somatostatin and thymosin α-1 are undergoing clinical trials, and other peptide hormones like relaxin, glucagon and GRF (growth hormone releasing factor) are imminent.

## 2. Isolation of Peptide Hormones

Before discussing recombinant DNA techniques, I will briefly mention the conventional methods used in the production of peptide hormones.

The classical isolation from animal organs is the method of choice for longer polypeptides. The organs are usually obtained from slaughtered animals; for example, the insulin used in the treatment of diabetes is isolated from the pancreas of pig or cow, since these animal hormones are very similar to human insulin (cf. Section 6.3).

In Germany the requirement for insulin is approximately 250 kg per year, which means that pancreatic glands of 2.5 million animals have to be extracted. Worldwide, approximately 2000 kg insulin from about 20 million animal pancreatic glands is prepared. Considerable effort and time goes into the collection and transport of these organs, since they have to be frozen quickly in order to avoid degradation and changes in the structure.

Not only is animal tissue used to obtain clinically important peptides and proteins, but also, in special cases, human organs are the source of the desired material. For example, in the case of the treatment of children deficient in growth hormone, it is not possible to employ equivalent animal hormones since there are too many structural differences. Thus, for the treatment of *ca.* 800 children in England several thousand human pituitary glands are col-

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/1111-0842 $ 02.50/0 

lected for the isolation of the required human growth hormone[4].

In general, the isolation of peptide hormones from tissue becomes impossible if the concentration of the desired hormone is extremely low or if the animal hormone is inactive in humans.

Chemicals synthesis of peptide hormones is a viable alternative to tissue isolation, especially in the case of smaller molecules. Examples of such peptides are the nonapeptide oxytocin and the decapeptide luteinizing hormone releasing hormone (LHRH), both of which are in clinical use.

In special cases where the quantities required lie in the order of one kg per year, industrial synthesis can be carried out up to a chain length of about 30 amino acids. This is the case of the gastrointestinal hormone secretin which contains 27 amino acids. In theory even larger proteins can be synthesized, as was demonstrated for insulin[5]. However, the costs for the synthesis and purification on an industrial scale are immense and therefore the synthetic approach cannot compete with the isolation from animal organs.

The amount of peptide produced by genetically engineered bacteria under ideal conditions is limited only by the size of the fermenter; furthermore, the length of the polypeptide chains should in principle create no problems. Recombinant DNA therefore opens up for the first time a route for the preparation of a variety of clinically important human proteins in sufficient quantities. Examples are polypeptide hormones, interferons and lymphokines.

As a first step in the production of a human protein in a bacterium, one has to develop a bacterial strain containing the corresponding gene stably integrated. In most cases further manipulations of the genetic material are necessary to insure a high yield of the protein.

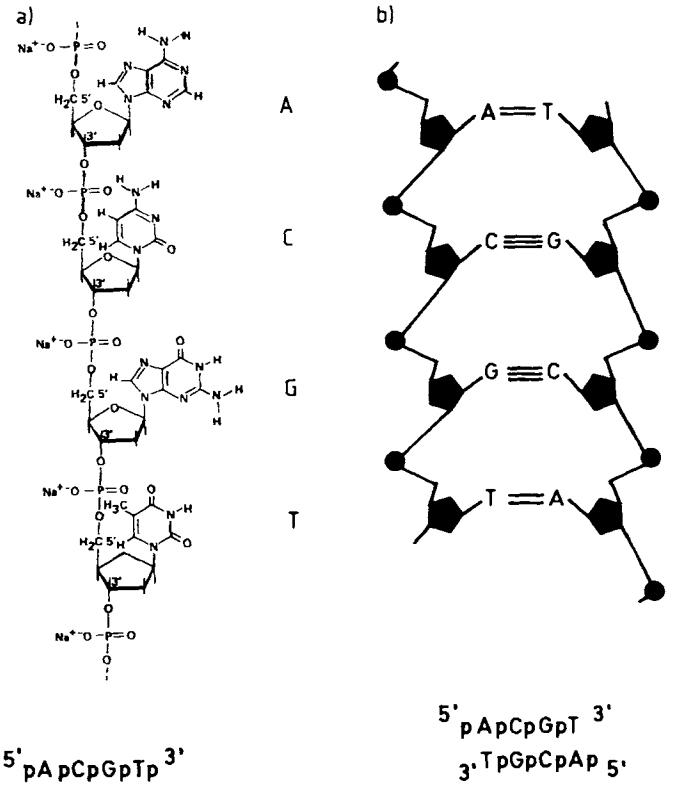

Fig. 1. Schematic representation of deoxyribonucleic acid (DNA). a) single stranded DNA; b) double stranded DNA. The two complementary strands of opposite directionality are held together by the interaction between the bases on each strand as indicated.

## 3. DNA Preparation

In human and animal cells the genetic material, deoxyribonucleic acid (DNA) is located in the nucleus. All the information concerning the amino acid sequence of every single protein synthesized by the organism is encoded in it. Furthermore, DNA also contains a variety of regions responsible for complex regulatory and control processes within the cell.

DNA consists of two anti-parallel 2-deoxyribose phosphate chains which carry at the 1′ position of each ribose one of the four bases adenine (A), thymine (T), cytosine (C) or guanine (G) (Fig. 1). Both chains are held together by hydrogen bonds between A and T and G and C respectively. Since A is always located opposite a T and G always opposite a C, the two chains are complementary but of opposite sense. Further details of the DNA structure are not the subject of discussion in this article.

The information for a particular amino acid sequence of a protein is encoded on a stretch of DNA in such a way that three consecutive bases determine the respective amino acid. Using the four available bases such a triplet code leads to 64 possible combinations (Table 1). Of these, three triplets are stop codons (TAA, TAG and TGA), one is a start codon (ATG) and the others encode amino acids with up to six different triplets coding for the same amino acid (*e.g.* leucine, serine, arginine).

Table 1. Coding of the amino acids by base triplets of mRNA. The first letter of the first base of the triplet is shown in the left-hand column, the first letter of the second base in the top row, and that of the last base in the extreme right-hand column. Usually the genetic code is represented as the RNA code. Since the mRNA strand is complementary to one of the two DNA strands, the sequence of the DNA strands can be deduced from the base-pairing rule. The examples mentioned in the text always refer to the DNA strand with the same base sequence as in mRNA.

| | U | C | A | G | |
|---|---|---|---|---|---|
| U | Phe | Ser | Tyr | Cys | U |
| | Phe | Ser | Tyr | Cys | C |
| | Leu | Ser | stop | stop | A |
| | Leu | Ser | stop | Trp | G |
| C | Leu | Pro | His | Arg | U |
| | Leu | Pro | His | Arg | C |
| | Leu | Pro | Glu | Arg | A |
| | Leu | Pro | Glu | Arg | G |
| A | Ile | Thr | Asn | Ser | U |
| | Ile | Thr | Asn | Ser | C |
| | Ile | Thr | Lys | Arg | A |
| | Met,start | Thr | Lys | Arg | G |
| G | Val | Ala | Asp | Gly | U |
| | Val | Ala | Asp | Gly | C |
| | Val | Ala | Glu | Gly | A |
| | Val | Ala | Glu | Gly | G |

Of crucial importance for the rapid development and propagation of recombinant DNA techniques was the discovery of restriction enzymes[6] and the possibility to covalently join DNA fragments with the enzyme DNA ligase[7].

Restriction enzymes recognize characteristic base sequences of the DNA, cutting the double strand either within the recognition sequence or in its neighborhood (Table 2). Up to date approximately 80 different recognition sequences for restriction enzymes from a wide variety of bacterial strains have been described[8]. To prevent restriction enzymes cutting the organism's own DNA, the recognition sequences of the DNA in the respective organisms are modified by specific methylases. Restriction enzymes therefore offer protection from foreign DNA which has invaded the organism and which is cut before a possible modification. Whether this is the only function of restriction enzymes in bacteria cannot yet be answered fully.

Table 2. Recognition sequences of some restriction enzymes. Cleavage sites on each strand are indicated by the arrows. The enzymes Hae III and Xmn I create blunt ends, Hha I cleavage results in 3′ protruding ends, and Eco RI as well as EcoR II produce 5′ protruding ends. N symbolizes T, C, G or A while N′ is the respective complementary base.

| Recognition sequence | Restriction enzyme |
|---|---|
| —5′G G C C 3′— <br> —3′C C G G 5′— | Hae III (from Haemophilus aegyptius) |
| —G A A T T C— <br> —C T T A A G— | Eco RI (from E.coli) |
| —N C C(A)G G N— <br> —N′G G(T)C C N′— | Eco RII (from E.coli) |
| —G C G C— <br> —C G C G— | Hha I (from Haemophilus haemolyticus) |
| —G A A N N N T T C— <br> —C T T N′N N′N′ N′A A G— | Xmn I (from Xanthomonas manihotis) |

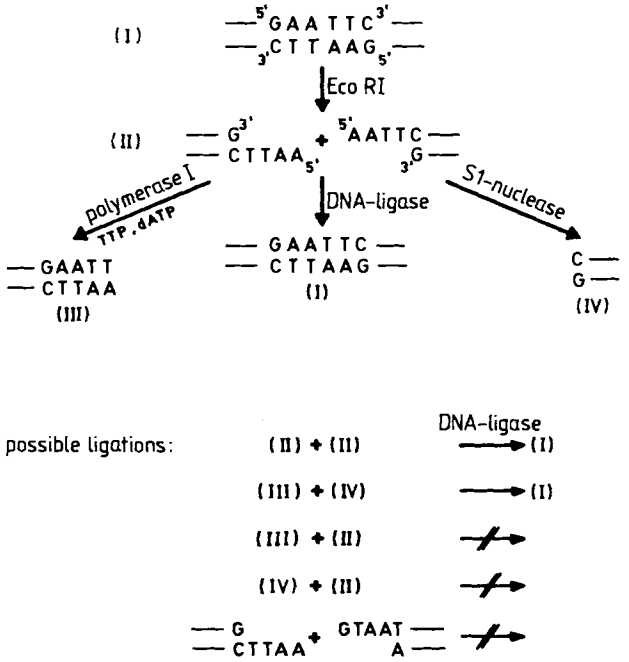

Fig. 2. Some enzymatic reactions of DNA *in vitro*. EcoR I cleavage results in fragments with 5′ overlapping ends which can be converted into blunt ends using S1 nuclease or polymerase I. Blunt ends are ligated by DNA ligase, staggered ends can only be joined if they have complementary sequences.

DNA fragments with blunt or staggered ends are obtained by the action of restriction enzymes. Staggered ends can be enzymatically converted into blunt ends (Fig. 2). This is achieved either with polymerase I which fills in the recessed end or with single strand specific nucleases (S1 nuclease, mung bean nuclease) which degrade the single stranded protruding end.

The enzyme DNA-ligase joins either DNA fragments with blunt ends or with staggered ends, provided that base pairing between the strands can occur. The term used for covalently joining DNA fragments is called "*in vitro* recombination of nucleic acids" and this area of research has recently been reviewed[9].

In order to obtain DNA coding for a human protein, several routes can be taken: a) chemical synthesis of DNA; b) isolation of a DNA fragment containing the gene; c) enzymatic synthesis using mRNA as a template.

### 3.1. Chemical Synthesis of DNA

The amino acid sequence of a human protein can be used to deduce the DNA sequence. Since in most cases one has a choice of several triplets (codons) for one amino acid, the synthesis can be varied according to different requirements. In most cases codons would be chosen in such a way as to yield appropriate restriction sites.

Looking for example at the peptide sequence -Glu-Phe- one has to combine one of the triplets coding for glutamic acid (GAA, GAG) with a codon for phenylalanine (TTT, TTC). Choosing -GAA-TTC- results in a restriction site for the enzyme Eco RI. Such a site consisting of six base pairs occurs statistically once in $4^6$, namely 4096 base pairs. Careful planning of such restriction sites in a chemical DNA synthesis will aid in joining or exchanging whole blocks of DNA.

Different organisms have different codon usage with respect to particular amino acids[14]. Table 3 clearly shows that in *Escherichia coli* the triplet CTG is commonly used for leucine whereas it finds no use at all in the yeast proteins studied so far. In yeast the predominant codon for leucine is clearly TTG. Similar differences are found for the other amino acids.

Table 3. Codon usage of the triplets coding for leucine, proline and glutamic acid in yeast and *E. coli*. Other amino acids show similar trends. Triplets of the mRNA are represented; base U instead of base T. The table is reproduced from *Ikemura et al.* [10].

| | | Yeast [%] | E.coli [%] |
|---|---|---|---|
| Leu | UUA | 6 | 5 |
| | UUG | 89 | 8 |
| | CUU | 2 | 8 |
| | CUC | 0 | 8 |
| | CUA | 3 | 2 |
| | CUG | 0 | 69 |
| Pro | CCU | 13 | 10 |
| | CCC | 0 | 6 |
| | CCA | 87 | 15 |
| | CCG | 0 | 69 |
| Glu | CAA | 98 | 22 |
| | CAG | 2 | 78 |

It is likely that DNA with codons not commonly used in *E. coli* will not yield large amounts of protein in this bacterium since the whole apparatus for protein synthesis is geared towards the normal *E. coli* conditions. Thus, it is advantageous to choose codons in such a way that they are closely matched to the organism in which the protein synthesis is going to take place.

Methods for DNA synthesis have undergone rapid development in recent years and a summary of the state of the art is described in [11]. In a well equipped and trained laboratory it is possible today to synthesize and purify several oligonucleotides of 20–30 base pairs in length within a few weeks. Several automated synthesizing machines are on the market which can be used continuously to synthesize any desired sequence. Genes for human interferons of over 500 base pairs in length[12] as well as DNA coding for both chains of insulin[13] have been successfully synthesized.

One cannot stress strongly enough the importance of chemical DNA synthesis for the production of biologically active substances in microorganisms. The synthesis of small 'linker' and 'adaptor' molecules carrying specific restriction sites is of special importance, since after joining them to DNA fragments they allow the insertion of such fragments into particular restriction sites.

### 3.2. Isolation of a Gene Fragment

In principle it is possible to isolate the desired DNA fragment from the respective genomic DNA. Human cells contain about 150000 different genes and approximately $5 \times 10^9$ base pairs[15]. The fact that it is nevertheless a realistic task to attempt the isolation of a gene[16] demonstrates the enormous power of modern molecular biological methods.

Genes for a variety of proteins have already been isolated and their nucleotide sequence completely determined[17]. The coding region for a protein in genes of higher organisms (*e.g.* cells which possess a nucleus, eukaryotic cells) is frequently interrupted by non-coding sequences. The function of these sequences (introns) is still unclear and they are removed from the precursors mRNA during the expression of the gene (Fig. 3). This event is called splicing[18]. Bacterial genes are organized in a simpler fashion and so far only one case of bacterial introns has been reported in an archaebacterium[123]. Therefore genes of higher organisms are not correctly processed in bacteria[19]. Introns are not recognized and cannot be removed from the precursor mRNA. Depending on the nucleotide sequence of the intron, this either leads to premature chain termination or to longer 'nonsense' proteins. Since the genes coding for most of the human hormones contain introns it is not possible to insert them directly into bacteria in order to produce the protein and alternative methods to obtain the appropriate DNA have to be employed. This does not, however, imply that it is impossible to use intron free parts of these genes which can then be complemented by synthetic DNA.

An exception worth mentioning are the genes for interferons from human leucocytes and fibroblasts. Interferons

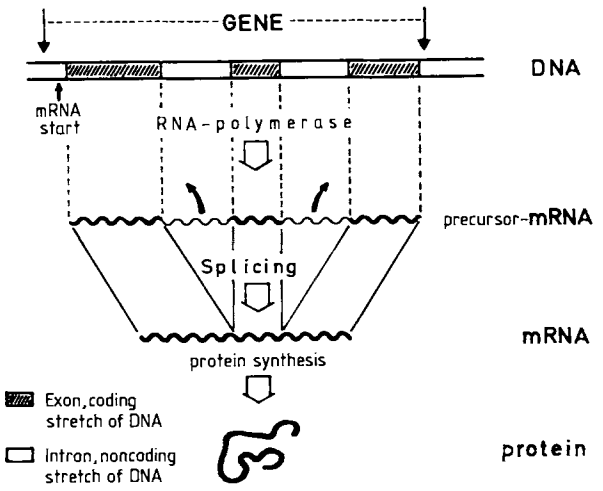

Fig. 3. Expression of a gene containing two introns. In the genes of higher organisms the coding sequences are frequently interrupted by non-coding DNA stretches. Expression of a gene is initiated by the synthesis of a precursor mRNA which is subsequently converted into mRNA *via* splicing. Mature mRNA is the template for protein synthesis.

are synthesized in eukaryotic cells in reaction to a virus infection. Furthermore, it is thought that interferons stimulate the immune system and therefore could play a role in the treatment of some types of cancer[20]. Since for a long time it was only possible to obtain interferons in minute amounts from human cell cultures, and because of the potential applications of these proteins, intensive research has been carried out in an effort to produce them in bacteria *via* recombinant DNA techniques.

Recently, several groups have succeeded in elucidating the sequences for different interferon genes[21]. It has been found that leucocyte interferon genes have no introns and thus can be used for production of the corresponding protein in bacteria. This opened the way for the rapid production of several interferons, some of which are already undergoing clinical trials[20]. Furthermore, hybrid interferons with a variety of interesting characteristics were created by joining parts from different genes *via* common restriction sites[22].

### 3.3. Enzymatic Synthesis of DNA from mRNA

As shown in Figure 3, protein synthesis in the cell starts with the synthesis of mRNA (or precursor mRNA). Using one DNA strand as a template, the enzyme RNA polymerase synthesizes a complementary strand of mRNA. This mRNA exhibits the same base sequence at the ribose phosphate chain as the non-transcribed DNA strand with the exception that thymine is substituted by uracil.

The mRNA contains through its base sequence signals for the binding to the ribosome as well as for start and stop of the protein synthesis.

Transcription of deoxyribonucleic acid (DNA) into messenger ribonucleic acid (mRNA) is not a unique event. In a cell specialized in the production of a particular hormone the respective DNA fragment is transcribed many times into mRNA, which results in mRNA concentrations up to several thousandfold the concentration of the gene.

It is possible to synthesize DNA enzymatically *in vitro* from isolated mRNA (Fig. 4)[23–26]. Therefore the isolation of mRNA is usually the first step in the production of a genetically engineered bacterial strain. In the purification of eukaryotic mRNA one exploits the fact that its 3′ end contains a poly A sequence which allows its separation by affinity chromatography on oligo-dT-cellulose[27].

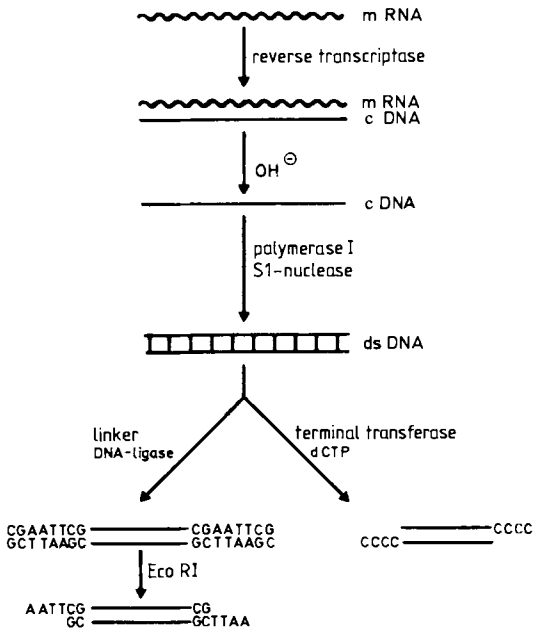

Fig. 4. *In vitro* synthesis of DNA from mRNA. The enzyme reverse transcriptase copies mRNA into single stranded DNA, termed cDNA (copy or complementary DNA). The mRNA is subsequently destroyed by hydrolysis with alkali. The DNA is converted into the double stranded form with polymerase I and blunt ends are created by S1 nuclease. In order to insert the DNA into a plasmid, synthetic oligonucleotides comprising appropriate restriction sites are jointed to the ends. Another method involves the ligation of homopolymers to the DNA ends.

The mRNA is transcribed into cDNA (copy or complimentary DNA) by the enzyme reverse transcriptase which requires a small oligonucleotide complementary to the 3′ end of the mRNA to start the synthesis. This oligonucleotide, called primer, is the 5′ end of the growing cDNA chain. Since the 3′ end of eukaryotic mRNA contains a poly A sequence, oligo $dT_{12-18}$ can be used as a non specific primer. This will lead to transcription of all mRNA molecules present in the preparation into cDNA (Fig. 5). It is however possible to employ selective conditions which will permit the transcription of only a single mRNA into cDNA. This involves the use of a synthetic primer of at least 12 nucleotides in length which is complementary to the 3′-end of the selected mRNA (Fig. 5)[28].

The sequence information necessary for the synthesis of the primer can be deduced from the amino acid sequence of the *C*-terminal region of the protein. In the most favorable case this end should contain amino acids which are encoded by a single triplet (tryptophan and methionine) in order to predict the nucleotide sequence unambiguously. In practice one chooses a sequence of five amino acids which show a very low multiplicity of the genetic code.

In order to assess which of the discussed methods is the most suitable to obtain DNA it is important to consider the length of the desired DNA fragment. To date cDNA preparation is preferred for DNA pieces of 150 nucleotides and longer; however, bearing in mind the rapid development of DNA synthesis this could well change in the near future.

## 4. Plasmids

DNA prepared by either of the above three routes (Section 3) is introduced into bacteria with the aid of plasmids. Plasmids are circular DNA molecules which are considerably smaller than the bacterial chromosome and can occur in bacterial cells (Fig. 6). Frequently plasmids carry resistance genes for antibiotics and are often responsible for the rapid spread of antibiotic resistance. Commonly used plasmids replicate independently of the bacterial chromosome; under favorable conditions, for example in the presence of chloramphenicol, there can be up to 500 plasmid copies per bacterial cell. Plasmid DNA can easily be separated from the chromosomal DNA of the bacterium[29]; purifica-

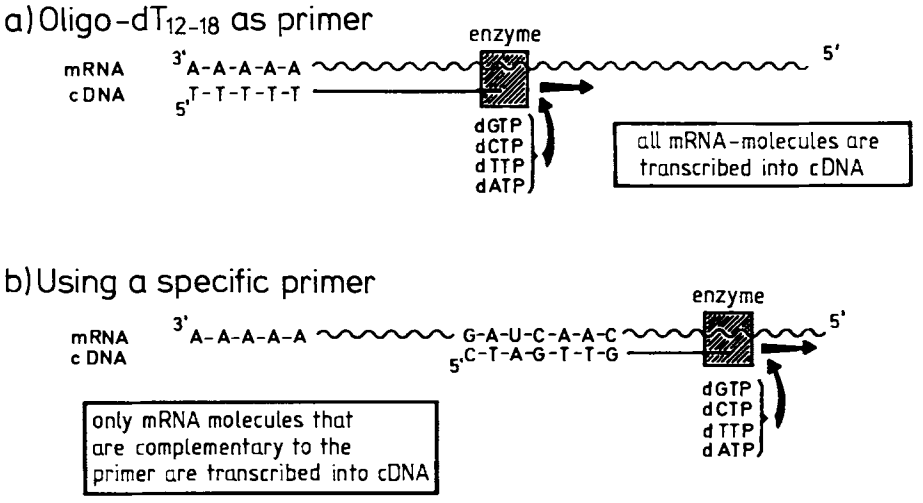

Fig. 5. Synthesis of cDNA from mRNA with reverse transcriptase: a) oligo $dT_{12-18}$ as primer; b) synthetic oligonucleotide as primer. (The length of the primer has been shortened for the sake of space; it should be at least 12 nucleotides long.)

tion is achieved by centrifugation in a CsCl gradient in the presence of the intercalating dye ethydium bromide. Due to their different structures chromosomal and plasmid DNA bind different amounts of this dye and hence exhibit different densities[26,39].

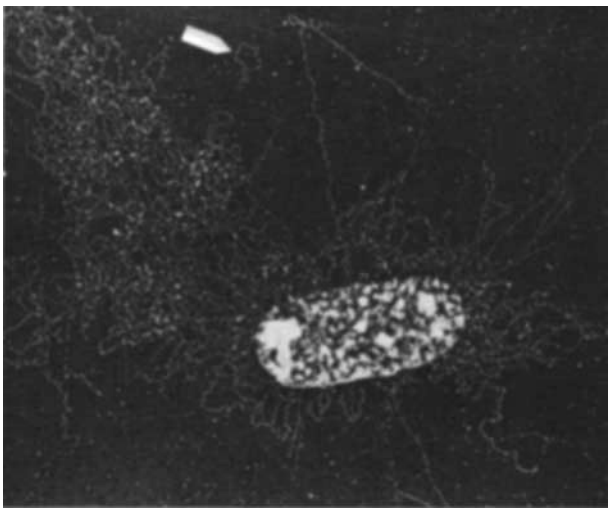

Fig. 6. Electronmicrograph [30] of an *E. coli* bacterium, whose cell wall has been made permeable. At the top of the picture a plasmid which was originally inside the cell is indicated by an arrow. The conglomerate of fibers represents the much larger bacterial chromosome.

In order to use plasmids as vectors transporting foreign DNA into bacteria, it is important that isolated and modified plasmids can easily be reintroduced under simple experimental conditions. This process is called transformation. In the presence of calcium chloride (*ca.* 50 mM) the cell wall and cell membrane of a variety of bacteria are changed in such a way that foreign DNA can penetrate into the cell.

From 1 μg of plasmid DNA about $10^6$ transformants are obtained. The transformants can easily be detected and selected *via* plasmid borne antibiotic resistances.

The multiplication of DNA *via* insertion in a plasmid and introduction into bacteria is frequently referred to as "molecular cloning" (Fig. 7). The underlying concept results in several practical consequences.

1. Any desired DNA fragment can be replicated with the help of plasmids and can subsequently be studied. This enables the investigation of processes which alter the genetic material. In the field of medicine this includes for example malignant transformations, viral infections and possibly conditions connected with aging. Needless to say, hereditary diseases can be studied as well. Preliminary important results concerning the initiation of tumors have already been reported[31]. The question, however, of whether the results of these investigations on DNA can soon be used for new possibilities in therapy, cannot be answered as yet.

2. Insertion of a DNA fragment coding for a protein into bacteria can yield an excellent source for the production of the protein.

Starting from naturally occurring plasmids a variety of specialized plasmids have been constructed (*e.g.* pUC 8[32] and pUR 250[33]). Figure 8 shows the most commonly used

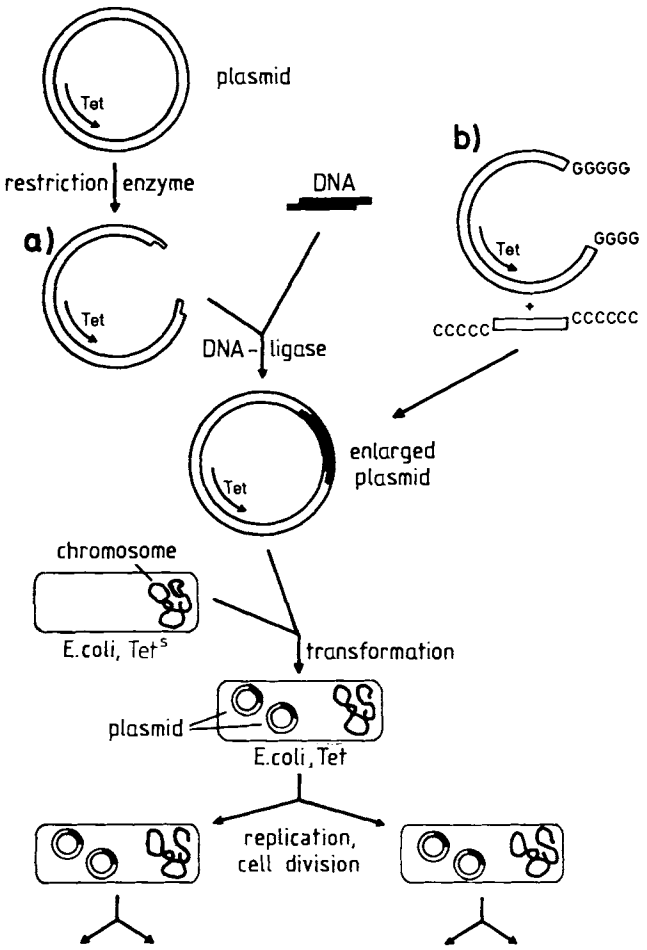

Fig. 7. DNA cloning *via* insertion into a plasmid and subsequent transformation. The circular plasmid is linearized by digestion with a restriction enzyme which has a single recognition site on the plasmid DNA.—a) Foreign DNA with suitable ends is introduced and the enlarged plasmid is used for transformation; b) insertion of DNA into the plasmid using complementary homopolymers [40]. The plasmid shown as an example carries the tetracycline (Tet) resistance gene, so that the plasmid-containing bacteria which were previously tetracycline-sensitive (Tet$^s$), can therefore easily be selected by adding the antibiotic to the medium.

plasmid at the present time, pBR 322[34]. Plasmids contain a region called origin (Or), where replication of the plasmid is initiated. Most of the plasmids used contain in addition several unique restriction sites as well as at least one antibiotic resistance gene in order to facilitate the selection.

After *in vitro* recombination and subsequent DNA replication it is necessary to use analytical methods to characterize the cloned DNA fragments. This is achieved by digesting the DNA with a variety of restriction enzymes and subsequent electrophoretic separation of the resulting fragments[41]. Such restriction analysis is useful for the sequencing procedure employed afterwards, which yields the final information about the DNA composition. Both sequencing methods, either that of *Maxam* and *Gilbert*[35] or of *Sanger et al.*[36], can be carried out quickly and give reliable results. Nowadays, in order to obtain a protein sequence, it is in many cases quicker to isolate the respective structural gene, sequence the DNA, and deduce the amino acid sequence from the nucleotide sequence. Indeed, in cases of certain large proteins the final amino acid se-

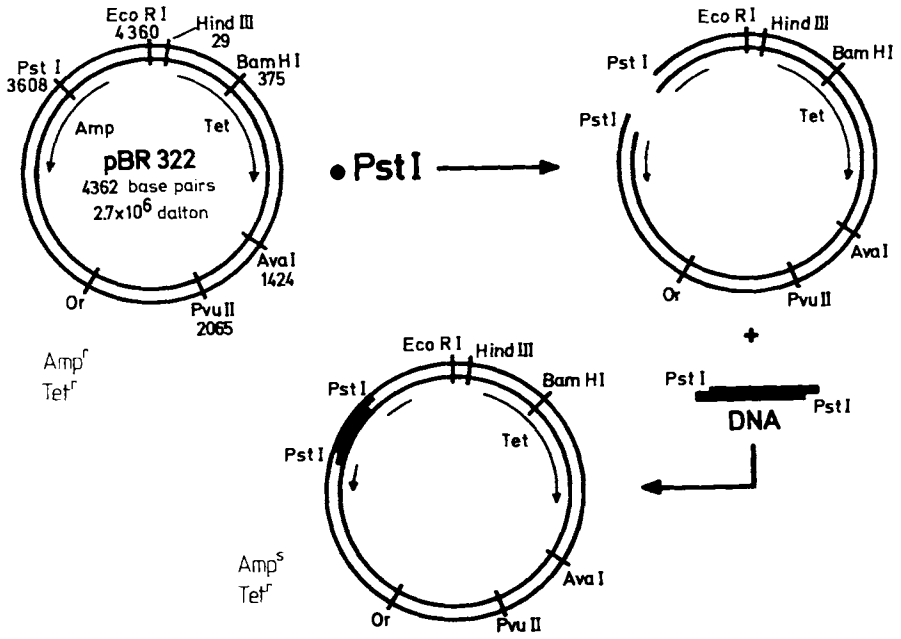

Fig. 8. Insertion of DNA into the Pst I restriction site of the plasmid pBR 322. The positions of several singular restriction sites are indicated. The plasmid contains resistant genes for ampicillin (Amp) and tetracycline (Tet), Or is the origin of replication. Insertion of DNA into the Pst I site abolishes ampicillin resistance. $Amp^s$ and $Tet^r$ bacteria can be recognized using replica plates containing ampicillin and tetracycline.

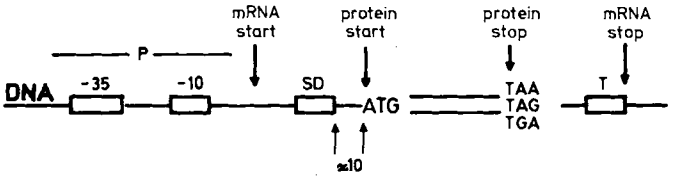

quence could only be completed using the DNA sequencing data in addition to partial amino acid sequence data of these proteins[37,38].

## 5. Gene Expression in *Escherichia coli*

Expression of a structural gene consists in the synthesis of the mRNA (transcription) and the synthesis of the protein (translation). In order to express a particular gene in *E. coli* it is not sufficient to stably integrate the DNA *via* a plasmid into the bacterium. In addition, the DNA has to contain important signal sequences[42,43] (Fig. 9).

From mRNA synthesis the enzyme RNA polymerase has to bind to a particular sequence on the DNA, the promotor. Depending on the amount of mRNA synthesized, promotors are termed weak or strong promotors. Comparison of a large number of promotor sequences led to the discovery of homologous sequences in the regions $-10$ and $-35$ in front of the mRNA start[44,45]. These are obviously sequences that are signals for the start of transcription. Figure 9 shows the consensus sequences derived from such comparisons which comprise the most frequent nucleotides for each position[45–47]. Nucleotide changes within the promotor lead to changes in transcription frequency, especially alterations in the 'constant' parts. Apart from the above mentioned promotor structure, more complex structures exist which regulate gene expression through several promotors[48].

In order to achieve high protein yields one needs in addition to a strong promotor an efficient protein synthesis machinery. Protein synthesis is carried out on the ribosomes with mRNA as a template[49]. It is therefore necessary to have a sequence on the mRNA which codes for the association and binding of the ribosome. Such sequences have been postulated after sequence analysis of the ribosome by *Shine* and *Dalgarno*[50] and later confirmed[51,52].

consensus sequences:

-35 : −TGTTGACA−TT−
-10 : −TGTTATAATG−

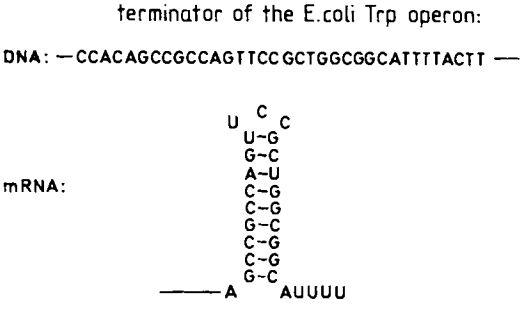

Fig. 9. Signal sequences for gene expression in prokaryotes. Regions approximately 35 and 10 nucleotides in front of the transcription start are labeled $-35$ and $-10$, respectively, P, promotor; SD, Shine-Dalgarno sequence; T, terminator. The indicated sequences [45] are located on the non-transcribed DNA strand (sequence equivalent to mRNA). The sequence of the terminator given [43] is representative of other terminator sequences which also contain complementary sequences.

The Shine-Dalgarno sequence (SD-sequence) is approximately 3—9 nucleotides long and is located 3—11 nucleotides in front of the start codon (AUG) for the protein synthesis. It is complementary to the 3′ end of the 16S RNA of the ribosome:

3′HO-AUUCCUCCACUA__

Further signal sequences are start and stop codons for protein synthesis. The start codon is AUG which also codes for the amino acid methionine. In most proteins the *N*-terminal methionine is removed by specific enzymes. One or several of the triplets UAA, UAG and UGA stop protein synthesis.

The SD sequence and signals for protein synthesis exert their function only on the mRNA. Since, however, mRNA is the copy of one of the DNA strands, these signals are also encoded in the DNA where the base uracil is substituted by thymine.

mRNA synthesis is terminated by special DNA structures, terminators, which are located in front of the last nucleotide of the mRNA[53]. Comparison of several such sequences have yielded no consensus sequence[45]. It was however noticed that they contain complementary sequences which can form hairpin loops (Fig. 9), from which it was concluded that termination is most probably caused by the structure of the mRNA itself rather than by the structure of the DNA[45].

For gene expression of a eukaryotic protein in bacteria it is desirable to have a fast rate of synthesis, which in addition should be subject to regulation. It is therefore useful to employ control sequences which are used in *E. coli* and which cause high concentrations of specific bacterial proteins.

Regulatory sequences combined with the appropriate structural genes are called operons. The following operons are frequently used to aid expression of eukaryotic DNA in *E. coli:* the lactose operon, the tryptophan operon, and promotors of the bacteriophage λ.

### 5.1. The Lactose Operon

In *E. coli* the enzymes β-galactosidase, permease and transacetylase are involved in the degradation of lactose. The structural genes for these enzymes as well as their regulatory sequences on the DNA are known as the *lac* operon.

Enzymes of the *lac* operon are only synthesized by the bacterium if lactose (or another inducer) is present in the medium. Investigations of this regulatory system are all based on the work of *Jacob* and *Monod*[54]. Figure 10 illustrates the structure and the regulatory mechanism of the *lac* operon.

With optimal induction it is possible to obtain β-galactosidase, a protein of molecular weight 500000 and composed of four subunits, in concentrations up to 30% of the total *E. coli* proteins. The possibility of switching on the synthesis of β-galactosidase at any given moment upon addition of appropriate substances into the medium (induci-

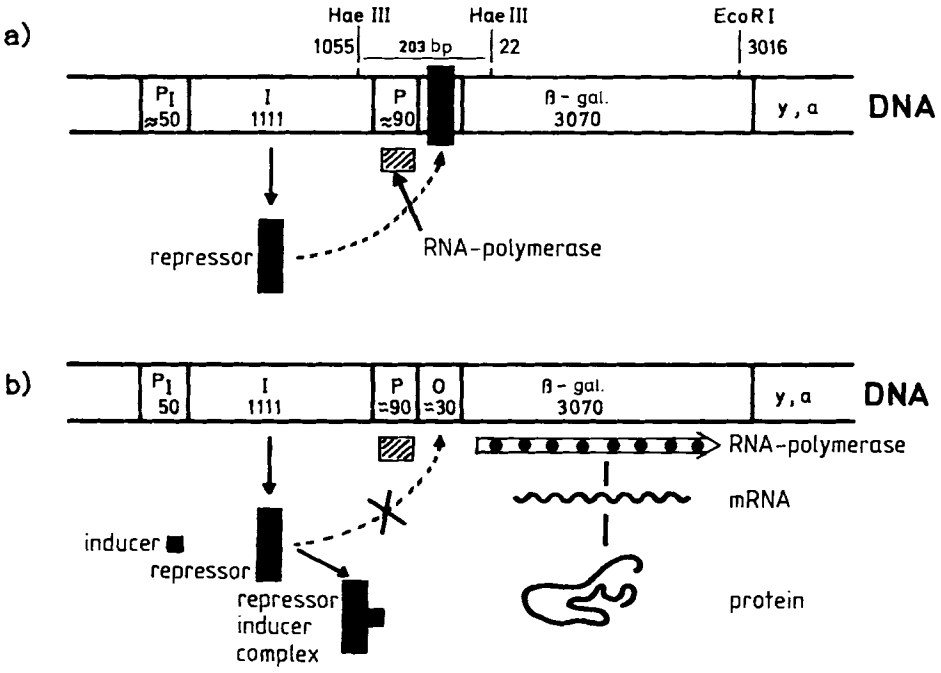

Fig. 10. Structure and regulation of the *lac* operon in *E. coli.*—a) The structural gene I with its promotor $P_I$ codes for a repressor protein, which binds to a site between the promotor P and the structural gene for β-galactosidase. This site on the DNA of the *lac* operon is called the operator (O). The repressor-operator complex blocks RNA polymerase; thus no mRNA is formed and no protein of the *lac* operon synthesized. y and a are the two other structural genes of the *lac* operon.—b) In the presence of the inducer lactose, an inducer-repressor complex is formed which no longer can bind to the operator. Therefore RNA polymerase is able to transcribe the DNA into mRNA and biosynthesis of β-galactosidase as well as the other proteins encoded by the *lac* operon proceeds. Numbers indicate fragment sizes in base pairs.

Insertion sites are indicated by arrows. - p β-gal 13C [60]: Insertion of DNA into the EcoR I restriction site results in synthesis of a chimeric protein containing 1005 amino acids of the β-galactosidase under control of the *lac* operon. - p tac 12 [65]: Expression of DNA inserted into the Pvu II site is achieved under control of a fusion promotor containing the −35 region of the *trp* promotor and the −10 region of the *lac* promotor. - p trp ED 5-1 [66]: Under control of the *trp* promotor the E protein of the tryptophan pathway is synthesized as well as a chimeric protein consisting of 92 amino acids of the D protein and the protein encoded by the inserted DNA. pCQV 2 [67]: DNA inserted into the Bam HI site is transcribed under the control of the $P_R$ promotor. $P_R$ is regulated *via* the thermolabile repressor CI.

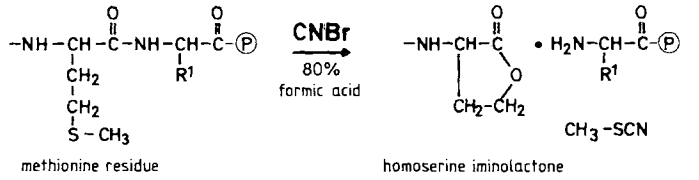

Fig. 12. BrCN cleavage of a peptide from a chimeric protein.

bility) as well as the high concentration of the enzyme in *E. coli* itself, renders the use of the regulatory units of the *lac* operon a tempting thought for the production of other proteins. Furthermore, one can use mutants which contain base changes in the promotor and show improved characteristics for high expression[55]. It is possible to isolate the regulatory region of the *lac* operon (promotor, operator and the coding sequence for the first seven amino acids of β-galactosidase) on a 203 base pair Hae III fragment[56]. Using synthetic linkers one can add suitable restriction sites to the ends of the fragment, and, after insertion into a plasmid, this fragment ensures expression of the attached structural gene[56–59].

One can also use the Eco RI site at position 3016 in the structural gene of β-galactosidase[37] for the insertion of foreign DNA. This leads to a chimeric protein comprising the first 1005 amino acids of β-galactosidase followed by the desired protein[58,60–63] (Fig. 11). In both cases the remainder of the β-galactosidase has to be cleaved off from the desired protein; this can be achieved either enzymatically or by chemical methods. The method of choice is determined by the amino acid composition of the desired protein and the cleavage site. For example, trypsin cleaves at the *C*-terminus of the amino acids lysine and arginine, and chymotrypsin cleaves at the aromatic residues and leucine. Of the chemical methods, cleavage with BrCN[65] (Fig. 12) at methionine is the most commonly used method at the present time.

The reading frame of the DNA should not be altered by the inserted DNA, as frame shifts lead to nonsense proteins or premature termination of the polypeptide chain.

### 5.2. The Tryptophan Operon

The biosynthetic pathway for tryptophan in bacteria branches at the chorismate stage from that of the aromatic amino acids (Fig. 13). The subsequent steps in the formation of tryptophan are catalyzed by enzymes, whose struc-

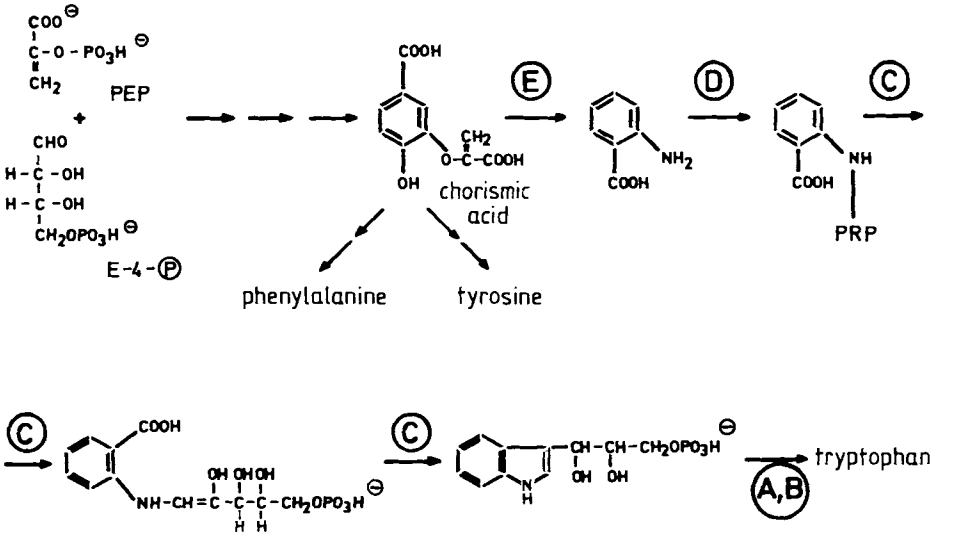

Fig. 13. Biosynthetic pathway of tryptophan. Abbreviations of enzymes are: Ⓔ anthranilate synthetase; Ⓓ anthranilate phosphoribosyltransferase; Ⓒ phosphoribosyl anthranilate isomerase and indole-3′-glycerol p-synthetase; Ⓑ and Ⓐ tryptophan synthetase, subunits α and β. PEP = phosphoenolpyruvate; E-4-Ⓟ = erythrose-4-phosphate; PRP = phosphoribosyl phosphate.

tural genes are sequentially encoded on the DNA and regulated simultaneously[68] (Fig. 14).

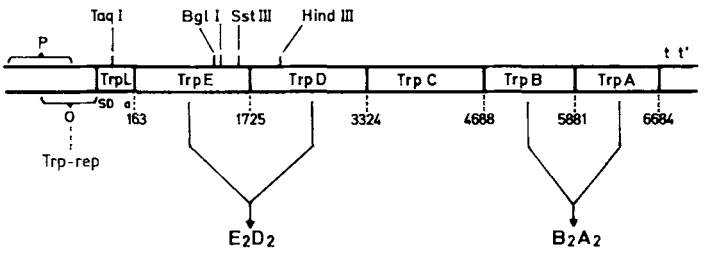

Fig. 14. Structure of the *trp* operon in *E. coli*. The structural genes E to A are regulated simultaneously; the mechanism of regulation is described in the text. Numbers indicate distances in base pairs beginning from the transcription start. Within L, E and D some restriction sites are indicated. Abbreviations used are: P = promotor; O = operator; L = leader peptide; a = attenuator; SD = Shine-Dalgarno sequence; t,t' = terminator sequences.

The *trp* repressor, which is encoded on another part of the DNA, can only bind to the operator after association with L-tryptophan (Trp)[69]. In the absence of tryptophan in the medium, RNA polymerase can interact with the promotor and transcription of the five structural genes takes place. This regulation is further modified by the so called attenuation. RNA polymerase starts transcription at sequences which encode a 14 amino acid long leader peptide. This peptide contains two tryptophan residues. Depending on the speed of translation, which is also dependent upon the concentration of tryptophan in the medium, the secondary structure of the mRNA is varied. If the movement of the ribosomes along the mRNA is fast (tryptophan in the medium), the mRNA forms structures for termination in the region of the attenuator and thus transcription is stopped. If the concentration of tryptophan in the medium is low, the slow movement of the ribosomes leads to alternative mRNA structures, so that RNA polymerase continues transcription of the subsequent five structural genes[70,71]. At the end of the *trp* operon transcription is stopped *via* two terminators.

The *trp* operon is therefore inducible by absence of tryptophan, resulting in high concentrations of the proteins E and D.

Restriction sites within the *trp* operon which can be used to insert foreign DNA are shown in Figure 14. A Taq I site is located between the SD sequence and the start codon for the leader peptide. Using this site it is possible to separate the regulatory units from the attenuation mechanism, since the latter is only exerted after synthesis of the leader peptide. Furthermore, one can avoid the formation of a chimeric protein by using the start codon of the gene coding for the protein to be expressed[72].

Chimeric proteins can be synthesized using proteins E and D since they are the first ones in the synthesis chain. The whole *trp* operon, up to the Hind III site in the D protein, has been inserted into a plasmid[66] (Fig. 11), and the conserved Hind III site used to insert the gene for human growth hormone which is subsequently expressed under control of the *trp* operon[73]. The E protein has also been used in the construction of proteins[74]. The regulatory region of the *trp* operon containing a DNA stretch coding for the first seven amino acids of the E protein has been inserted into the Hind III site of pBR 322. Thus, a set of plasmids has been constructed which allows the insertion of foreign DNA in all three reading frames[75]. Using these plasmids the expression of influenza antigens under control of the *trp* promotor has been achieved[76].

In addition, the construction of promotors containing parts of the *lac* and *trp* promotor has been successfully carried out[65,77] (Fig. 11). Using this *tac* promotor, in some cases higher expression rates were obtained than with the *lac* or *trp* promotors alone.

### 5.3. Bacteriophage λ Promotors

Infection of *E. coli* by the bacteriophage λ results either in phage multiplication and lysis of the bacterium or in integration of the phage DNA into the bacterial chromosome (Fig. 15).

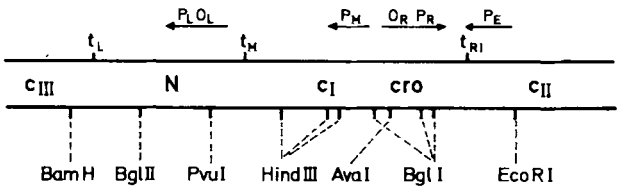

Fig. 15. Simplified genetic map of the bacteriophage λ in the region of 35000—40000 base pairs [78]. In the lytic cycle transcription starts at $P_R$ and $P_L$; the proteins N and cro are synthesized. Transcription stops at $t_L$ and partially at $t_{RI}$. The action of N allows transcription to proceed past $t_{RI}$ and $t_L$, cro takes part in the regulation of $P_R$ and $P_L$. In the lysogenic cycle only $c_I$ is expressed under control of $P_M$. $c_I$ is a repressor for multiple binding sites in the operators $O_R$ and $O_L$, thus the lytic cycle is blocked.

The early promotors of bacteriophages are designed to use the bacterial RNA polymerase to express their own genes, and thus weaken bacterial protein synthesis. They are probably highly suitable for stimulating synthesis of particular gene products in large amounts.

The $O_L$,$P_L$ regulatory unit has been introduced into plasmids in order to produce large amounts of certain proteins[79]. Induction is achieved using strains that contain a thermolabile $c_I$ repressor encoded on their DNA[80]. At temperatures around 30°C the repressor is active and the bacteria grow without the gene product regulated by the $P_L$ promotor. Raising the temperature to 43°C inactivates the $c_I$ repressor, and thus activates the $P_L$ promotor and synthesis of the subsequent structural gene products starts.

The $P_R$ promotor has also been used in the construction of an expression plasmid[67]; the structural gene for the thermolabile repressor has been introduced into the same plasmid (Fig. 11).

## 6. Examples of Peptide Hormones obtained by DNA Recombination

### 6.1. Somatostatin

The first peptide hormone which was shown to be present in bacterial extracts after DNA recombination was somatostatin[58]. It is a polypeptide, containing 14 amino acids (Fig. 16), which is found in several organs such as the pancreas, the hypothalamus and the stomach.

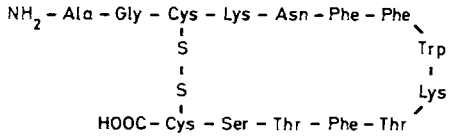

Fig. 16. Amino acid sequence of the human peptide hormone somatostatin.

Somatostatin inhibits the secretion of several other hormones; for example, growth hormone, insulin, glucagon and gastrin. It was chosen as a model to study peptide production *via* recombinant DNA techniques as its amino acid sequence was known, sensitive radioimmunoassays were available, and its size was compatible with methods for DNA synthesis. Using the known amino acid sequence, *Itakura et al.*[58] synthesized the appropriate DNA. Codons were selected according to the *E. coli* codon usage.

Two expression vectors were constructed in order to obtain somatostatin (Fig. 17 A and B). The first plasmid contains the promotor, the operator and the first 27 nucleotides (9 amino acids) of the *lac* operon followed by an ATG triplet and the DNA sequence coding for somatostatin. The presence of the promotor and operator ensure that protein synthesis of somatostatin can be regulated and is only carried out in the presence of an inducer (*e.g.* lactose). Two stop codons were attached to the end of the somatostatin DNA (symbolized by STP). After induction one expects the synthesis of a peptide with the following structure:

Met-(9 aa of β-galactosidase)-Met-somatostatin

The methionine in front of the somatostatin was introduced in order to obtain the free somatostatin after BrCN cleavage.

The second expression vector was constructed in a similar way; in this case, however, 3015 base pairs (corresponding to 1005 amino acids) of β-galactosidase were positioned in front of the somatostatin DNA. In this case too, an ATG triplet was introduced in order to have a methionine at the beginning of the somatostatin, thus enabling cleavage of the hybrid protein into the desired peptide hormone. Using the first plasmid no somatostatin was found in the bacterial extract; however, employing the second vector led to detectable amounts of somatostatin after cleavage of the hybrid protein with BrCN. In both cases the same regulatory system was used, and it is thus likely that transcription and translation occurred with the same frequencies. The explanation for the different results may lie in the rapid proteolytic degradation of the short peptide.

Proteins from other organisms are often recognized by bacteria as "foreign" and therefore rapidly degraded, although they have been synthesized by the bacterium itself after gene transfer. To avoid such degradation of peptide hormones synthesized in bacteria is still a major unsolved problem. In the case of the second expression vector, the synthesized somatostatin is protected from proteolytic attack by the large β-galactosidase residue. It should be mentioned that the procedure described above, involving the introduction of a methionine into the amino acid sequence in order to enable cleavage with BrCN, is only valid for peptide hormones which do not contain any further methionine residues in their sequence, since otherwise additional undesired cleavage would occur.

In the meantime the first clinical trials on somatostatin from *E. coli* have been carried out. It was hoped to use this hormone—now available in larger amounts—to treat particular cases of diabetes; however, as judged by the published data, such hopes have not been fulfilled as yet.

Recent molecular biological studies on the biosynthesis of somatostatin have revealed that the peptide is synthesized initially as a larger, inactive precursor-protein containing 116 amino acids[97,98]. The sequence of the active somatostatin is located at the *C*-terminal end of the pre-

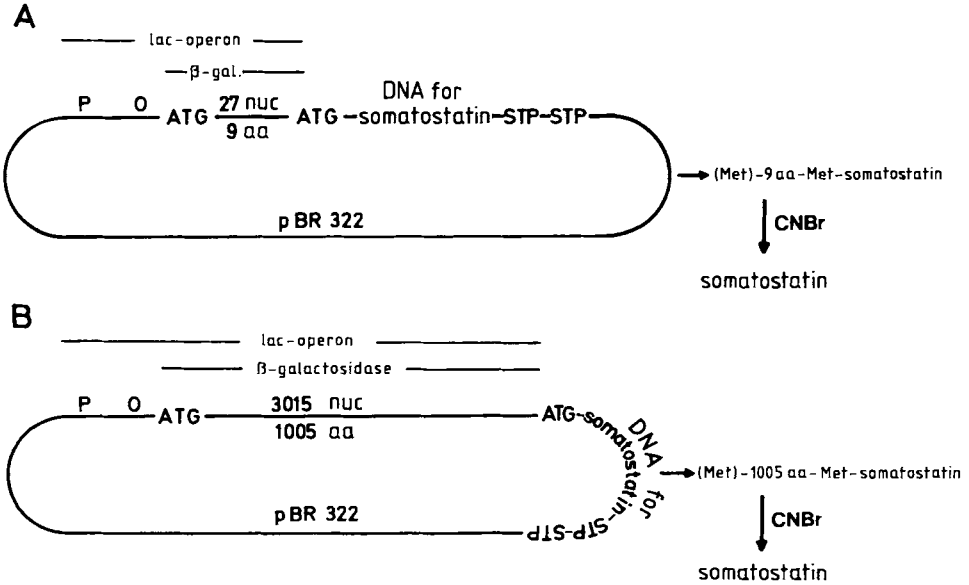

Fig. 17. Expression vectors used for synthesis of somatostatin in bacteria [58]. Both plasmids use the *lac* operon for expression and differ only in the location of the insertion site. Further particulars are given in the text.

somatostatin[*]; the mechanism of cleavage of the active portion has not yet been elucidated.

### 6.2. Human Growth Hormone

Human growth hormone (GH) is synthesized in the pituitary and consists of 191 amino acids. Pituitary hormones are crucially involved in growth and child development. Lack of one or several of these hormones can be overcome by using an appropriate substitution therapy. Children deficient in growth hormone are usually treated over a period of ten years with growth hormone extracted from human pituitary glands[81, 82]. *Tanner*[83] estimates the fraction of children who require to be treated with growth hormone to be approximately 1 : 7000. About 40% of dwarf children show normal concentrations of growth hormone (immunological assays); however, this hormone does not contain full biological activity[84, 85], probably due to variations in the amino acid required.

Apart from the treatment of dwarfism the use of growth hormone is being discussed for the following medical conditions: burns, stomach ulcers and ulcers of the colon, bone fractures and osteoporosis (deficiency of bone tissue)[84].

Growth hormones extracted from animals possess a different amino acid sequence compared to the human ones, and therefore human pituitary glands (from corpses) were the only source for these hormones.

The use of molecular biological methods led to the discovery of a whole gene family of human growth hormones and provided insight into the structure, expression and evolution of these genes[86].

The functional gene contains four introns with the boundaries of intron B occupying two alternative positions[87]. Different processing of the precursor mRNA leads to two distinct proteins containing 191 and 176 amino acids, respectively. 15% of the biological activity of growth hormone is attributed to the protein with the alternative amino acid sequence (176 aa)[88].

The mRNA for growth hormone encodes a pre-hormone which contains 26 additional amino acids at the *N*-terminal end. Such signal sequences are characteristic for proteins which are secreted from the cell and are probably cleaved off during transport through the cell membrane[89]. Combination of synthetic DNA coding for the 24 *N*-terminal amino acids and DNA transcribed from mRNA (550 bp) yielded a structural gene for human growth hormone. Expression in *E. coli* was achieved using a plasmid containing two *lac* promotors in tandem[90]. The reported yield was 2.4 mg/L; in the meantime however, this value may have been considerably increased. In the construction of the expression vector the structural gene for growth hormone was coupled directly behind the SD-sequence of the *lac* operon. The start signal for protein synthesis was introduced as the triplet ATG in the synthetic DNA fragment. Thus the growth hormone produced in bacteria contains an additional *N*-terminal methionine compared to the 191 amino acids of the naturally occurring protein. BrCN treatment to remove the methionine is not possible in this case, since growth hormone contains two further methionine residues and therefore would lead to cleavage of the protein. A practical way has not yet been found to remove this *N*-terminal methionine. Preliminary comparisons of the *in vivo* activity in rats of natural and bacterial growth hormone did not manifest any differences[91]. The first batch produced for human experiments, however, showed unpleasant side effects which were probably due to bacterial toxins[4]. Additional purification steps should easily overcome this problem.

The results of further clinical trials will have to be awaited in order to finally assess the possible uses of human growth hormone produced in bacteria.

### 6.3. Insulin

Insulin is produced in the β-cells of the pancreas and is critically involved in the regulation of glucose levels in the blood.

A large proportion of diabetics, comprising 1.5% of the total population, is dependent upon daily injections of insulin. For obvious reasons it is not possible to use human organs for extraction of the hormone, and therefore animal pancreatic glands are used which contain insulin with amino acid sequences closely related to the human one. Bovine insulin differs from human insulin in two amino acids in the A-chain and only one amino acid in the B-chain. In porcine insulin only the last amino acid of the B-chain is substituted (Thr for Ala).

Using trypsin under appropriate conditions the *C*-terminal alanine of the B-chain can be substituted for threonine, thus pig insulin can be converted into human insulin[92]. This procedure is now carried out on a commercial scale by several producers and the peptide hormone obtained in this manner is known as "semi-synthetic human insulin".

Like most other hormones, insulin is synthesized in the cell as a longer prehormone (Fig. 18)[93]. The preproinsulin contains an additional 24 amino acid long *N*-terminal peptide which is cleaved off during transport into the endoplasmic reticulum. It is probable that this peptide contains a signal sequence for the transport mechanism[89]. The conversion of proinsulin into insulin starts at the Golgi apparatus and continues during formation of the insulin granula in the β-cells.

The prospects of an increasing demand for insulin (the number of confirmed diabetics worldwide is increasing by approximately 3% per annum) and the possibility of producing human insulin have led almost automatically to attempts to prepare insulin from genetically engineered bacteria.

Enticed not least by the economic prospects of insulin production, a large number of groups began work on the isolation of the insulin gene and the determination of its structure[94] (Fig. 19).

Starting from mRNA the first cDNA to be cloned was that of rat insulin[95], and not much later a cDNA clone of human insulin was obtained[93, 96].

[*] Here a prehormone signifies an inactive precursor molecule which can be converted into the active hormone by cleavage of an *N*-terminal polypeptide. In contrast, by analogy to proinsulin, a prohormone should be a precursor molecule which is transformed into the active hormone by cleavage of a non-terminal polypeptide. Of course, in the latter case at least two cleavages are necessary.

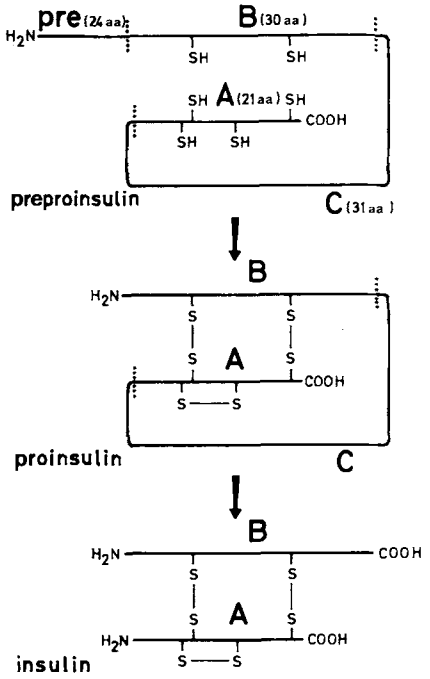

Fig. 18. Biosynthesis of insulin from preproinsulin. The chain segments Pre, B, C and A are marked with the numbers of amino acids they contain. The C-peptide is composed of 31 amino acids. Cleavage of proinsulin results in the release of the C-peptide and two additional dipeptides; thus, the A- and B-chain of human insulin are connected by a 35 amino acid long peptide. It is possible that the disulfide bridges are already formed at the stage of preproinsulin.

Active insulin consists of two separate polypeptide chains (A and B) which are connected *via* disulfide bridges. During biosynthesis, the three-dimensional structure of the proinsulin facilitates the formation of the correct disulfide bridges. Enzymes involved in the conversion of proinsulin into insulin have not yet been isolated[99]. Since it is not possible to encode the formation of disulfide bridges between different polypeptides on the DNA, one has to resort to other measures in order to produce insulin in genetically engineered bacteria.

Two alternative pathways can be followed to synthesize insulin in bacteria (Fig. 20 and Fig. 21). Using the procedure outlined in Figure 20 one initially obtains proinsulin, which subsequently has to be converted into insulin. The second possibility for insulin production is based on the separate synthesis of the A and B polypeptide chains which afterwards have to be oxidized to yield active insulin. Since oxidation results not only in the formation of the correct disulfide bridges, but leads also to a variety of inter- and intramolecular combinations, high losses are expected to occur at this stage.

The synthesis of proinsulin in bacteria has been described several times[101], and successful oxidation of the chains has also been reported[102].

With highly purified preparations of insulin rare cases of immunologically adverse reactions against these drugs occur. So far only minute differences in the immunogenic-

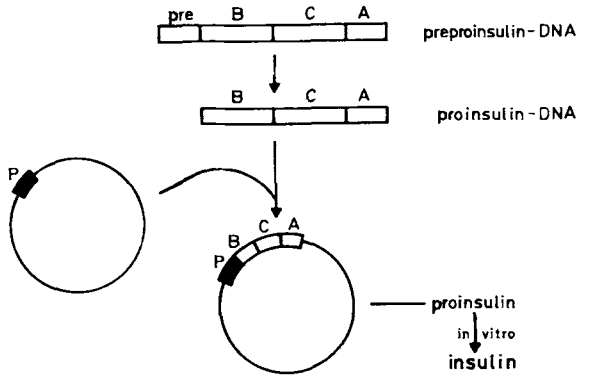

Fig. 20. Synthesis of human insulin by conversion of bacterial proinsulin. Reverse transcription of mRNA yields the DNA of preproinsulin. After removal of the pre-fragment, the DNA is integrated into an expression vector. The so produced proinsulin is enzymatically converted into active insulin [100].

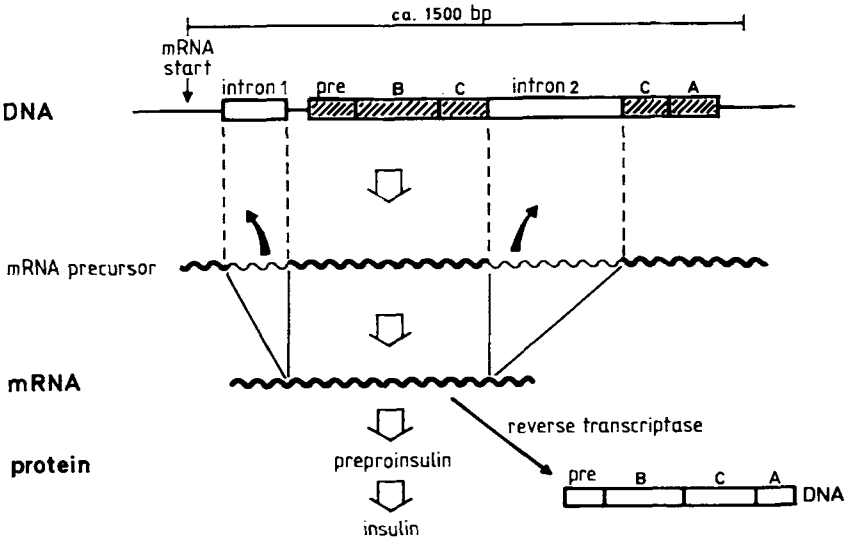

Fig. 19. Structure of the human insulin gene [18]. Two introns are excised from the precursor mRNA (the first one is located in front of the coding sequence for the pre-chain, the second is inside the coding sequence for the C-chain). Using reverse transcriptase and other enzymes (cf. Section 3.3) it is possible to transcribe the mRNA *in vitro* into DNA. This results in a structural gene without introns, since they were already removed by splicing.

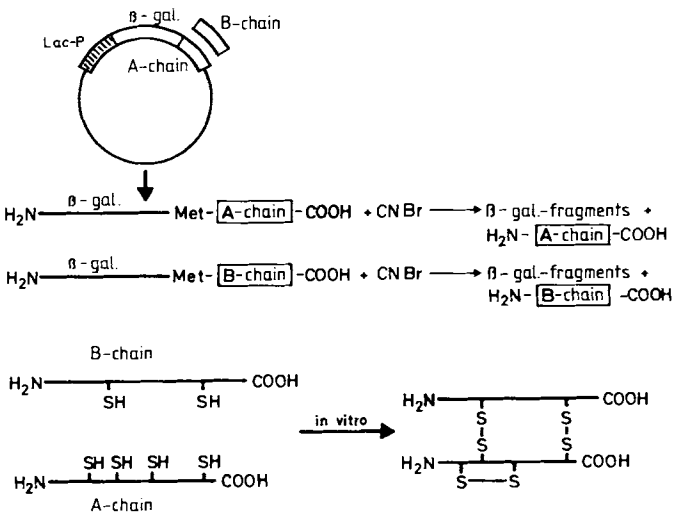

Fig. 21. Synthesis of human insulin in bacteria *via* oxidation of the separate chains. DNA coding for the A- and B-chains of insulin is chemically synthesized [13] and separately inserted into expression vectors. After isolation of the polypeptides [60] the disulfide bridges are formed in an additional step.

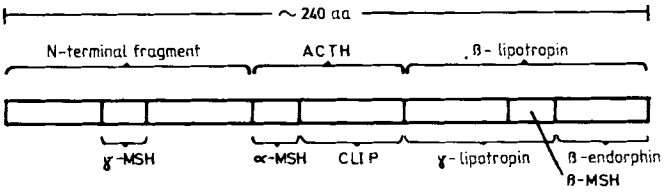
ity of highly purified pig and human insulin preparations have been observed[103].

### 6.4. Other Peptide Hormones

Relaxin has a similar structure to insulin; it also consists of two polypeptide chains linked by disulfide bridges. During biosynthesis preprorelaxin is initially formed, which, after cleavage of the pre-portion and removal of a C chain, is converted into active relaxin. There are surprising similarities in the length of the chains as well as in the arrangement of the disulfide bridges between insulin and relaxin.



Relaxin is synthesized in the placenta and uterus during pregnancy and is released into the blood stream immediately before birth. It aids the birth process by loosening the connective tissue. The nucleotide sequence of the gene has been determined and later confirmed by the biological activity of a synthetic protein[104].

As described for insulin (Section 6.3), the DNA fragments coding for the A and B chains of relaxin have been synthesized and expressed in *E. coli* as chimeric proteins[105].

Apart from the examples discussed above, DNA coding for a variety of other peptide hormones from different organisms has been cloned and its nucleotide sequence determined. In many cases the structure of the genes has been characterized as well. The following represents some examples of the numerous publications which have appeared recently: thyrotropin[106], HPL—human placental lactogen[107], epidermal growth factor[108], the common α-subunit of the hormones HCG, LH, FSH and TSH (human chorionic gonadotropin, luteinizing hormone, follicle stimulating hormone and thyroid stimulating hormone)[109], parathormone[110], glucagon[111], and gastrin[112].

Expression of thymosin α-1 (in its deacetyl form) has been achieved as a hybrid protein after chemical synthesis of the gene[113].

The use of the cloning methods illustrated above has not only permitted determination of the structure and sequence of particular genes, but has also led to the discovery and investigation of new regulatory principles. Pro-opiomelanocortin (POMC) is a protein (molecular weight 29000 dalton) which yields a variety of peptide hormones after cleavage (Fig. 22). It is synthesized in different tissues: pituitary, hypothalamus, placenta and lung. It is interesting to note that POMC is cleaved differently in different tissues. In the anterior pituitary it is predominantly converted into ACTH and β-lipotropin, and in the median pituitary (in mice) it is rapidly converted into MSC, CLIP, β-endorphine and γ-lipotropin. The sequence analysis of the gene has been carried out and the molecular basis for the cleavage is being investigated at present[114].

ACTH = adrenocorticotrophic hormone
MSH = melanocyte stimulating hormone
CLIP = corticotropin-like intermediate lobe peptide

Fig. 22. Structure of the pro-opiomelanocortin precursor protein.

Another example for the synthesis of different gene products from the same gene, depending on the cell type, is the calcitonin gene. This hormone plays an important role in the regulation of calcium levels. It contains several introns and the coding sequences are combined in different ways in the thyroid and the hypothalamus, since the mRNA is processed differently. Calcitonin is synthesized in the thyroid, while the peptide predicted from the mRNA sequence in the hypothalamus has not yet been characterized in its function[115].

## 7. Outlook

The advantages of hormone production in genetically engineered bacteria in comparison with classical methods of extraction from organs have been repeatedly pointed out:

- the possibility of synthesizing a peptide with the human amino acid sequence;
- independence of animal or human organs;
- almost no limits with respect to quantity;
- the possibility of introducing variations in the amino acid sequence *via* deliberate changes in the DNA sequence, thus opening the way to detect new properties of peptide hormones.

How do the yields of a hormone produced in genetically engineered bacteria compare to the yields achieved by isolation from organs?

The proportion of the desired protein in a genetically manipulated bacterial strain can be estimated to be *ca.* 10%

of the total protein, the upper limit being approximately 500 mg peptide hormone per liter of bacterial culture. To my knowledge, however, this could not be maintained and values of *ca.* 100 mg/L are today regarded as good yields. In the pancreas, for example, one finds about 100 mg insulin per kg of tissue. In addition to this straight comparison of yield one has to take into account that proinsulin synthesized in bacteria has to undergo further processing in order to be converted into biologically active insulin. This superficial comparison does not take into account the different efforts involved in purifying the hormone either from pancreas or from a bacterial extract. For most other peptide hormones the comparison is easily decided in favor of DNA recombination since these hormones usually occur in considerably smaller quantities in the respective organs.

Apart from factors illustrated in Figure 23, the yield of a peptide hormone produced in bacteria is influenced to a large extent by the intracellular location of the hormone. Signal sequences[89] are used to transport the synthesized proteins into the periplasmatic space, where they have a much greater stability than in the cytoplasm of a bacterium[116]. Aggregation of these proteins in the bacterium is a possible way of protection from proteolytic degradation[117].

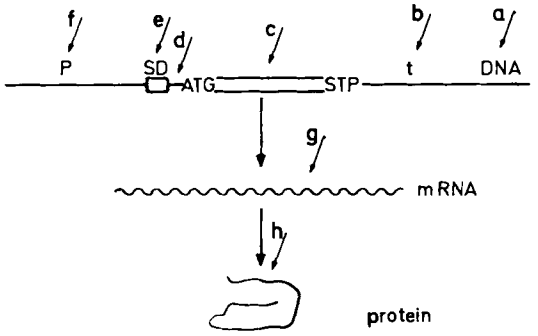


Fig. 23. Schematic representation of some factors which may influence the yield of a protein synthesized in bacteria after DNA-recombination. a) Stability of the plasmid, copy number of the plasmid in the bacterial cell; b) strength and structure of the terminator; c) codon usage for the different amino acids; d) distance between the Shine-Dalgarno sequence and the start signal for protein synthesis; e) nature of the Shine-Dalgarno sequence; f) strength and structure of the promotor and adjoining sequences, inducibility; g) mRNA stability; h) stability of the pre-hormone or hormone in bacteria.

The enzymes involved in proteolytic degradation of eukaryotic proteins synthesized in bacteria are still largely unknown. Recently, eight soluble proteolytic enzyme activities in *E. coli* have been reported[118]; it is, however, unclear if all or only a few of these initiate the proteolytic degradation. These factors do not therefore permit a clear prediction with respect to yield for any particular peptide hormone produced in bacteria after DNA recombination.

Molecular biology opens up the way to produce scarcely available peptide hormones in large quantities. Using somatostatin, growth hormone, and insulin as examples, some of the inherent problems have been illustrated. Most difficulties will probably be overcome in the near future. One can envisage several possible solutions: the use of protease-free bacterial strains in the production of peptide hormones; isolation of an enzyme which selectively removes *N*-terminal methionine; or the construction of hybrid peptides which ensure high yields. At the end of this decade the proportion of hormones produced *via* gene technology should well exceed 50% of the total.

Apart from *E. coli* other organisms will be used in the production of proteins in the near future; worth mentioning here are *Bacillus subtilis* and yeast.

*B. subtilis* allows the secretion of proteins into the medium. Up to now most of the plasmids used in *B. subtilis* were not stable and recombination with chromosomal DNA occurred, followed by deletion of the plasmid. Recently, however, major breakthroughs have been reported: proteins like α-amylase[119], hepatitis B antigen[120], and even proinsulin[121] have been obtained from *B. subtilis*.

Due to the eukaryotic nature of yeast it is envisaged that post-translational modifications occur in a similar fashion as in higher organisms. This is important for the production of proteins which have to be modified after synthesis (*e.g.* glycosylation, cleavage of a signal peptide) for biological activity.

Based on their DNA sequence, the existence of a variety of peptides and proteins has been predicted, although their physiological role is still unclear[114, 115, 122]. This aspect of recombinant DNA work, namely the discovery of new proteins and the elucidation of their biological function, may soon become of equal importance for medicine as the production of known substances.

# The Prostaglandins: From the Laboratory to the Clinic (Nobel Lecture)**

**By Sune Bergström***

The chemistry and biochemistry of the prostaglandins are now described in textbooks, and I have reviewed the early work in this area several times[1–4]. Here, I will instead discuss some of the early prostaglandin work carried out in Sweden and its background, together with some recent developments in the clinical fields that I have been associated with.

Now let me digress for a moment. My scientific work started in 1934 when I participated with Dr. *Erik Jorpes* in his early work on heparin. More than anyone, he is responsible for purifying heparin and introducing it as a drug into the clinic. At that time, Professor *Einar Hammarsten* was Director of the Chemistry Department of the Karolinska Institute, then one of the leading laboratories in the world in the field of nucleic acids and peptide hormones (*e.g.* secretin and cholecystokinin).

Dr. *Jorpes* always maintained that it was unfortunate that no work was being undertaken on lipids or steroids in Sweden. He financed my trip to England in 1938, where I spent a few months working on bile acids with Dr. *G. A. D. Haslewood* at Hammersmith Postgraduate Medical School. The following year I was awarded a fellowship from the British Council to work for a year at Dr. *Marrian*'s laboratory in Edinburgh. It was cancelled when the War broke out, but I was then lucky enough to get a Swedish American Fellowship, and worked for a year and a half at Columbia University and at the Squibb Institute with Dr. *Oskar Wintersteiner* on cholesterol autoxidation (1940–1942). After returning home, I started working on the autoxidation of linoleic acid and identified the structure of the main reaction products. It was established that conjugation of the double bonds took place and that oxygen was introduced as a hydroperoxy group at C-9 or C-13. I also found that the lipoxygenase enzyme of soybeans, which had just been described by Dr. *Sumner*, yielded the same products as the heavy metal-catalyzed autoxidation. At that time I was working in Dr. *Hugo Theorell*'s laboratory, and we started to cooperate on the purification of the soybean lipoxygenase enzyme.

My involvement with the prostaglandins started at the Meeting of the Physiological Society of the Karolinska Institute, October 19th, 1945, where I reported my work on the oxidation of linoleic acid. Dr. *Hugo Theorell* was chairman, Dr. *Yngve Zotterman* secretary, and Dr. *Ulf von Euler* signed the protocol.

After this meeting, *von Euler* asked me if I might be interested in studying his lipid extracts of sheep vesicular glands that he had stored since before the war. I agreed, and we began a most stimulating and pleasant cooperation.

The first observation that there were some biologically active compounds in human semen had been made in the Department of Obstetrics and Gynecology of Columbia University in New York. In 1930 *Kurzrok* and *Lieb*, with the technical cooperation of Dr. *Sara Ratner*[5], reported that when they were doing artificial inseminations in women they sometimes got violent contractions, sometimes relaxation of the uterus.

It is interesting to note that I met Dr. *Kurzrok* and worked in the same laboratory at Columbia University as Dr. *Sara Ratner* for a year, but never heard anything about prostaglandins.

In 1933, the British pharmacologist *Goldblatt*[6, 7] reported that human semen contained a factor that reduced blood pressure and stimulated smooth muscle.

At about the same time, Dr. *von Euler* was making a thorough study of the occurrence of compound P, a peptide he had discovered a few years earlier, in various organs. In semen and in extracts of "prostate" or vesicular glands of monkeys, sheep, and goats there is a strong blood-pressure decreasing factor that also stimulates smooth muscles. He showed that the factor involved was different from compound P, that it was lipid soluble, and he gave it the name prostaglandin. Dr. *Theorell* had shown that the substance behaved as an acid in his electrophoresis apparatus[8–10].

In the early work, we used the rabbit intestinal strip test to follow the activity. We mainly used counter-current extractions to purify *von Euler*'s crude extract.

I had just brought home one of Dr. *Lyman Craig*'s stainless steel counter-current extraction machines that proved ideal for working with these small amounts. We managed to purify the crude extract about 500 times. The most active fractions consisted of unsaturated hydroxy acids that were free of nitrogen[11].

The work was interrupted for a few years due to my appointment to the Chair of Physiological Chemistry at the University of Lund in 1948.

A practically empty institution had to be rebuilt, re-equipped, and staffed, but it was a very fortunate time (1948) for biomedical sciences in Sweden. The large build-up of resources for basic biomedical research in Swedish universities, initiated by the former Prime Minister *Tage Erlander*, had just started. The Swedish Medical Research Council had also just been founded. An additional advantage during the following decade was that the National Institutes of Health (NIH) in the USA started their unique international programme of supporting biomedical research.

We were fortunate to receive quite sizeable grants for our work in the field of steroid and bile acid metabolism from NIH over a number of years.

A group of able graduate students could then be trained in these fields—*Bengt Borgström, Jan Sjövall, Sven Lindstedt, Henry Danielsson, Bengt Samuelsson,* and *Rolf Blomstrand*. They all more or less directly contributed to the early development of prostaglandins that started up again in the fifties.

Collection of sheep glands was organized in Sweden and Norway. Using counter-current fractionations and partition chromatography, we were able to isolate small amounts of two crystalline compounds, prostaglandin $E_1$ and prostaglandin $F_{1\alpha}$[12–14] in 1957.

The correct empirical formulas were determined in cooperation with *Wolfgang Kirsten*, who had developed an ultramicro carbon-hydrogen determination in Dr. *Einar Stenhagen*'s laboratory in Uppsala. Together with the molecular weight, determined by Dr. *Ragnar Ryhage* in his mass spectrometer the formulas were found to be $C_{20}H_{34}O_5$ and $C_{20}H_{36}O_5$, respectively.

Collection of sheep glands was then extended to Sweden, Norway, Iceland, Greenland, and also to the USA through the Hormel Institute. These activities were generously supported by the Upjohn Co., USA.

In 1958–1959 the whole research group moved from Lund to the Department of Chemistry at the Karolinska Institute in Stockholm. What really played a decisive role in the prostaglandin work was the mass spectrometer development that Dr. *Ragnar Ryhage* was carrying out there. He had built the first functioning combined gas chromatograph-mass spectrometer. The structures of $PGE_1$ and $PGF_{1\alpha}$ were deduced largely from mass spectrometric identification of the products formed by oxidative degradation of these prostaglandins and the compounds formed from $PGE_1$ by treatment with weak acid or base (Fig. 1). The structure was then confirmed and the stereochemistry determined by Dr. *Sixten Abrahamsson* in Gothenburg on a derivative of $PGF_{1\alpha}$. It took him about a year with the technology available in those days. Today it would take less than three weeks. The absolute configuration was finally settled[25, 26].

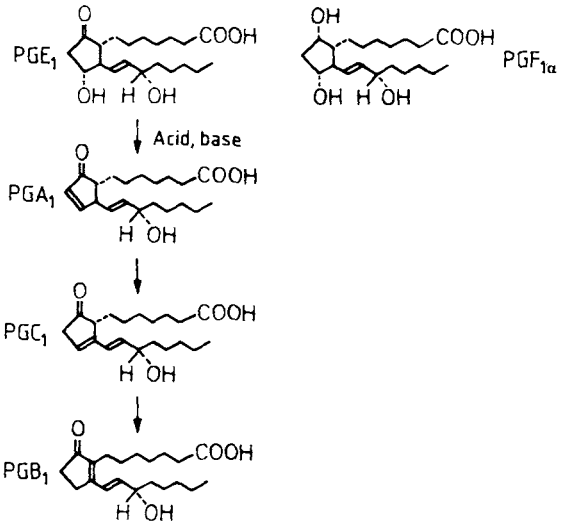

Fig. 1. The influence of weak acids and bases on the prostaglandins $PGE_1$ and $PGF_{1\alpha}$.

By 1962 the six prostaglandins listed in Figure 2 had been isolated and their structures determined[15–24]. It had also been found that these prostaglandins occur in many tissues other than the male reproductive organs.

These structures with 20 carbon atoms have *cis*-double bonds located in the same positions as in certain essential fatty acids, which made us suspect that these acids might be precursors.

I then telephoned Dr. *David van Dorp* at Unilever Research Laboratories in Holland, where these acids had previously been synthesized and isotopically labeled. When I asked him if he could supply isotopically labeled $C_{20}$ acids, it turned out that he was also planning to start investigating whether they were precursors, and that he had just prepared isotopically labeled dihomo-γ-linoleic acid for

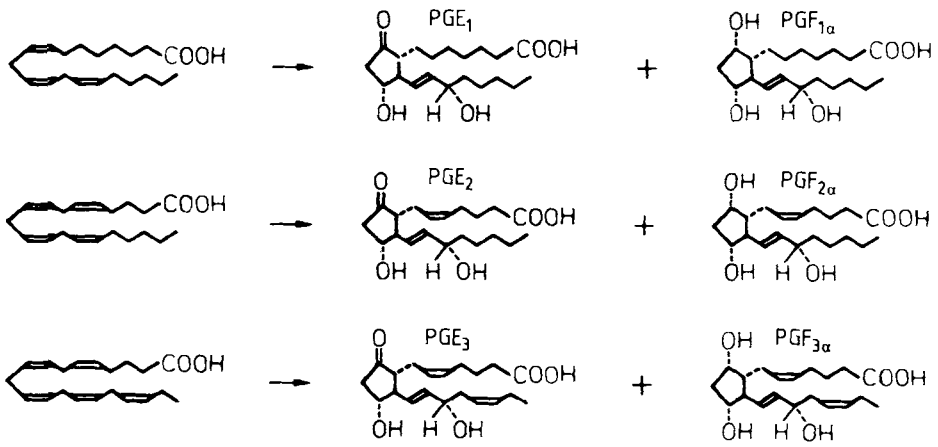

Fig. 2. Biosynthesis of prostaglandins from $C_{20}$ carboxylic acids with homogenates of sheep vesicular glands.

this purpose. He was most generous and sent us samples of the labeled acid. Simultaneously, we both started incubating the labeled acids with homogenates of sheep glands and could inform each other after two days that labeled prostaglandin $E_1$ and prostaglandin $F_{1\alpha}$ were indeed produced in good yields. We published our findings at the same time in 1964. This work was then followed up by studies using labeled tetraenoic arachidonic acid and the pentaenoic acid shown in Figure 2, which yielded prostaglandins of the 2 and 3 series, respectively[27-30].

As the yields could be up to 70%, these enzymatic methods were of great practical importance for obtaining material for further biochemical, physiological, and pharmacological work.

We prepared several grams of various prostaglandins, Unilever made considerably more, and the Upjohn Co. must have prepared hundreds of grams.

In spite of the efficiency of the enzymatic synthesis, supply became critical around 1970 when prostaglandins were needed for clinical investigations before large-scale total syntheses had been developed. An unexpected discovery was then made by *Weinheimer* and *Spraggins*[31], who had been studying the biochemistry of marine organisms in the Gulf of Mexico. They found that up to 1.5% of the dry weight of *Gorgonia* corals consisted of 15-epiprostaglandin $PGA_2$, which can easily be transformed into the common prostaglandins. For several years prostaglandins obtained from corals were used in clinical trials, but from about 1973 onwards the demand has been met by total syntheses.

After the structure of the prostaglandins was published, many projects were undertaken to prepare them by total synthesis.

Dr. *E. J. Corey,* who had collaborated with us in studies of the biosynthesis of bile acids using stereospecifically labeled cholesterol, was the first to succeed. In a series of classical papers in 1968—69[32-37], he described several elegant methods that still form the basis for most synthetic work in the prostaglandin field.

By that time many pharmaceutical companies had become interested in the field, and large synthetic programmes to synthesize prostaglandin analogues were started. These synthetic efforts were in part guided by the knowledge of metabolism of prostaglandins accumulated in Stockholm. More than 5000 prostaglandin analogues have now been prepared and tested in one way or another.

When the biosynthesis from the precursor acids was performed using lung homogenates, it was found that the prostaglandins formed were extensively further metabolized to inactive compounds[38-41] as indicated in Figure 3, *i.e.,* by reduction of the double bond between C-13 and C-14 and dehydrogenation at C-15. These reactions are so effective *in vivo* that prostaglandins are usually almost completely inactivated by one passage through the lungs. In later work it was found that these inactive compounds are further oxidized *in vivo* at the β- and γ-positions before excretion. A possible way to block the first reactions is to replace the C-15 hydrogen with a methyl group. The 15-methyl-prostaglandins prepared by *Bundy et al.* at the Upjohn Co.[42] turned out to be very useful for clinical work, and 15-methyl-$PGF_{2\alpha}$ is now a registered drug. Some of the different analogues that have been studied in clinical trials are listed in Figure 4. Efforts to obtain compounds with longer acting or more specific effects are continuing.

In the early sixties we had some difficulty convincing our colleagues to study the properties of prostaglandins in various pharmacological and physiological systems. This changed, especially after studies performed by Drs. *Dan Steinberg, Martha Vaughan,* and *Jack Orloff* at the NIH were published[43-47]. They were working with rat adipose tissue that releases glycerol and fatty acids due to increased lipolysis upon being stimulated with adrenaline, noradrenaline, glucagon or adenocorticotropin-releasing hormone (ACTH). It was found that $PGE_1$ and $PGE_2$ strongly inhibit the effects of all these compounds. $PGE_1$ and $PGE_2$ were also found to counteract both the lipolysis and the blood pressure effect of adrenaline *in vivo*. Later, it was found that these effects were mediated by a decrease in the level of cAMP in fat cells. In most other cell types, E-prostaglandins raise the level of cAMP. In some cases, the F-prostaglandins have been shown to influence the level of cGMP. I do not intend to discuss this field further here, but these findings explain why various prostaglan-

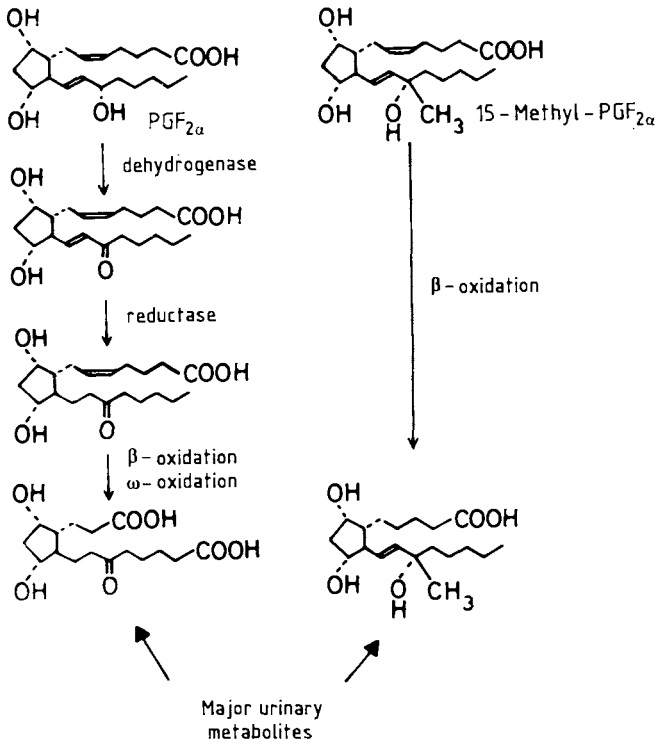

Fig. 3. Main metabolic pathway of $PGF_{2\alpha}$ and its inhibition by the methyl group at C-15.

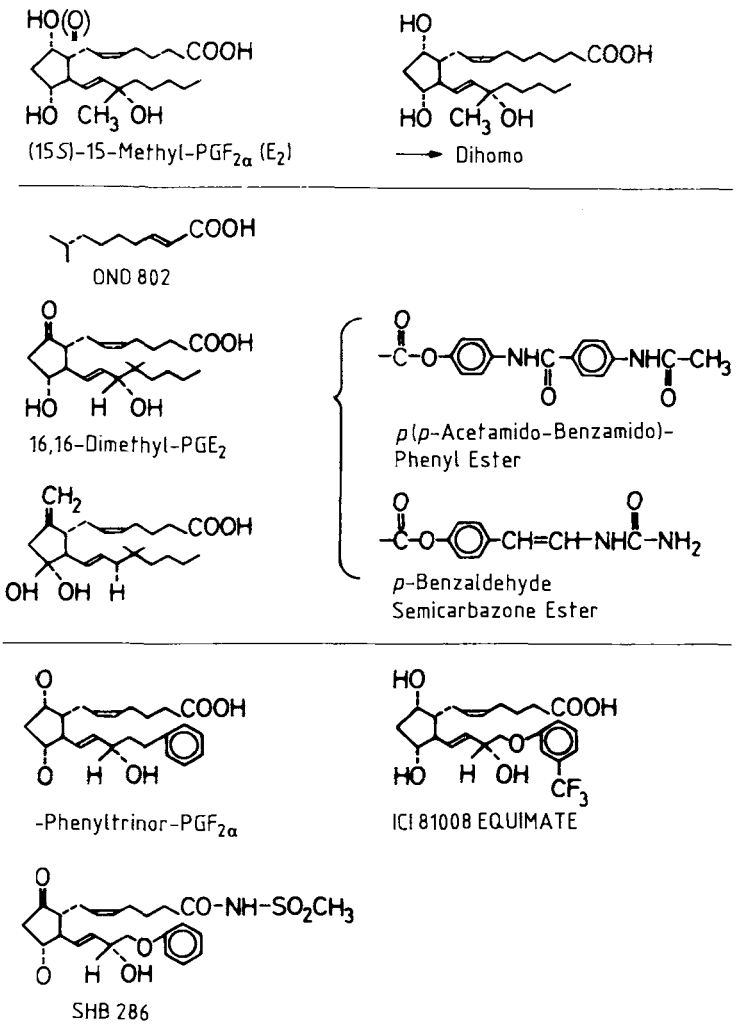

Fig. 4. Some prostaglandin analogues that have been studied in clinical trials.

dins can influence the metabolism of so many different cell types. A comprehensive summary of the early studies of the biological effects of prostaglandins was published in 1968[48].

It turned out that not only were there very large differences between the effects of different prostaglandins and their analogues, but also in their effects in different animal species. Clearly, one had to turn to clinical studies to explore the physiological role and therapeutic potential of these compounds.

The first study on the cardiovascular effects of pure prostaglandins in humans was carried out at the Karolinska Institute[49, 50]. In humans, $PGE_1$ lowers blood pressure and increases heart rate. My colleagues Drs. *Lars A. Carlson, Bengt Pernow,* and *Lennart Kaijser* and their respective coworkers performed much of the early, fundamental work on the effects of various analogues on the human cardiovascular system[51–54].

Dr. *Carlson* and his coworkers demonstrated that if it is administered intraarterially, 0.01 mg of $PGE_1$ can cause a tenfold increase in the flow of blood through an arm (Fig. 5). No change was observed in the flow of blood in the other arm since the compound is inactivated during passage through the lungs[55]. Together with Dr. *Anders Olsson,* he has developed this observation into a therapy for peripheral vascular diseases that in some cases has a dramatic effect.

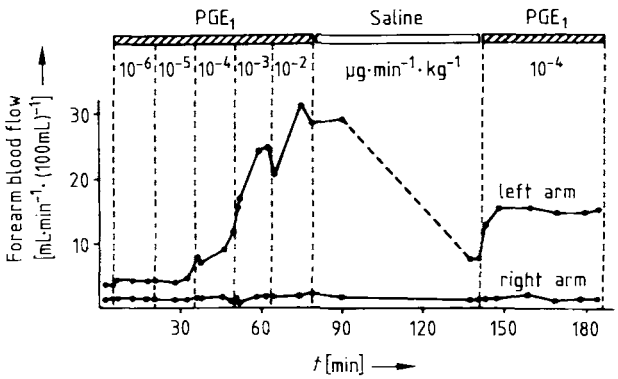

Fig. 5. The effect on forearm blood flow of continuous intra-arterial infusion of $PGE_1$ into the left brachial artery.

Another therapeutic application relates to the ductus arteriosus. It normally closes soon after birth. In certain congenital malformations, however, the E-prostaglandins have found clinical application to keep the ductus open for a few days to enable corrective surgery to be performed with less danger for the newborn baby. Furthermore, the open ductus can be closed by administration of cyclooxygenase inhibitors such as aspirin or indomethacin, *etc.* which inhibit the local synthesis of prostaglandins.

I will now turn to the effects of prostaglandins on the gastrointestinal tract, a field where Dr. *Robert* of the Upjohn Co. has been very active. In experiments on animals he found that gastric secretion could be inhibited by oral administration or by injecting prostaglandins of the E-type. The methyl analogues (15*S*)-15-methyl-$PGE_2$ and 16,16-dimethyl-$PGE_2$ were many times more active than $PGE_2$ itself[58]. Early clinical studies were performed in Stockholm by Dr. *Sven Andersson* and Dr. *B. Nylander*[57],

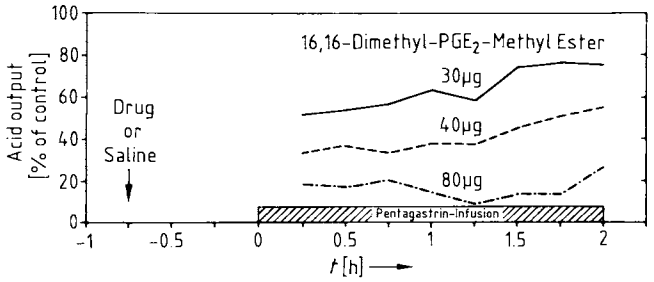

Fig. 6. The effect of the methyl ester of 16,16-dimethyl-$PGE_2$ on gastric secretion.

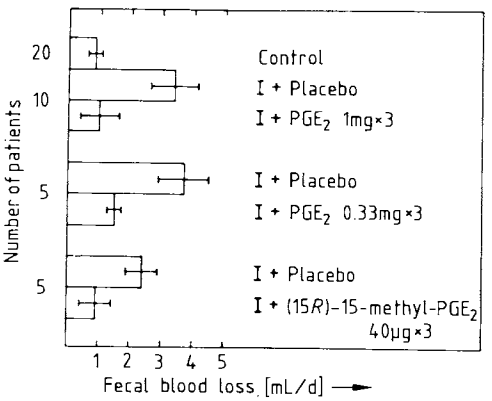

Fig. 7. The effect of prostaglandins on fecal blood loss upon administration of indomethacin. I = 3 × 50 mg indomethacin; duration of each experiment one week; in each case the data refer to the last three days of an experiment.

who found that an oral dose of only 80 µg of the methyl ester of 16,16-dimethyl-$PGE_2$ practically blocked the pentagastrin-stimulated gastric secretion in humans for several hours (Fig. 6). This work has been continued and expanded by Dr. *Catja Johansson* and her coworkers. Extensive clinical trials in many countries have been performed, and these indicate that several analogues have a healing effect on ulcers (for a recent summary see [58]).

Another important observation made by Dr. *Robert* was a phenomenon that he called "cytoprotection". If large doses of indomethacin or aspirin are administered to rats or if boiling water, strong acid, or base are given orally to anesthesized rats, extensive erosions and/or bleeding of the gastric mucosa occur, and the animals usually die within a few days. However, if less than 1 µg of 16,16-dimethyl-$PGE_2$ is administered orally 30 minutes beforehand, the mucusa is protected. An interesting observation made by *Robert et al.*[59] is that mild irritants like dilute ethanol can effect a certain protection, presumably by stimulating the mucosal cells to increase the biosynthesis of prostaglandins. Cytoprotection can be observed with prostaglandins at doses that do not inhibit acid secretion, and some prostaglandins stimulate secretion of mucus and bicarbonate. The mechanism of cytoprotection is not clear[58]. The effect is not limited to the gastrointestinal mucosa. Liver and kidney cells can also be protected to some extent from necrosis caused by carbon tetrachloride, *etc.* by administration of 16,16-dimethyl-$PGE_2$[60].

At this point we examined the effects of cytoprotective prostaglandins on some clinical side effects of indomethacin and aspirin. Normally, *ca.* 1 mL of blood is lost from the gut per day. The usual therapeutic dose of indomethacin increases this to 3 to 5 mL and in a few cases causes serious bleedings. It was shown at the Karolinska Institute for the first time that only 0.33 mg of $PGE_2$ or 40 µg of 15-methyl-$PGE_2$[61,62] three times a day completely protects the patient from this bleeding caused by indomethacin (Fig. 7). It is, however, still too early to evaluate the therapeutic value of administering prostaglandins to reduce the side effects of these drugs.

The last aspects that I shall discuss are related to fertility and the use of prostaglandins in obstetrics and gynecology. This is where the prostaglandins were discovered, and that is where they have found their greatest application so far.

Dr. *Marc Bygdeman* had just started his doctorate with Dr. *von Euler* when pure prostaglandins became available. He studied the effects of the different prostaglandins first *in vitro* and then *in vivo* in Dr. *Ulf Borell*'s department at the Karolinska Institute together with Dr. *Nils Wiquist*. They first demonstrated clinically that $PGE_1$ causes uterine contractions when injected in small amounts. This of course led to the expectation that it might be possible to induce labor or interrupt pregnancies by administering prostaglandins[63–65].

Dr. *Sultan Karim* was the first to report on the clinical use of prostaglandins to induce labor.

The first therapeutic abortion with $PGF_{2\alpha}$ was performed in May 1969 at the Karolinska Institute. During that summer Dr. *Karim* was in Stockholm and was informed about it. Back in Uganda, he confirmed and expanded this finding and showed that $PGE_2$ also could be used to induce pregnancy interruption. The results of both groups were published in the same issue of Lancet in January 1970[66,67].

An intense activity then started all over the world exploring these findings with normal prostaglandins, and later with some of the analogues shown in Figure 4. The early clinical data obtained in Stockholm are summarized in Figure 8[66–73].

First, the two natural prostaglandins $PGE_2$ and $PGF_{2\alpha}$ were studied extensively. When administered intravenously they caused very pronounced side effects. When administered intra- or extra-amniotically, the side effects were tolerable.

The (15*S*)-15-methyl-$PGF_{2\alpha}$ supplied by the Upjohn Co. was then studied and found to be much more active, but had considerably less side effects. It could also be injected intramuscularly, and we developed vaginal suppositories containing the methyl ester; it is now a registered drug in many countries.

16,16-Dimethyl-$PGE_2$ was even more active—sometimes being highly effective after oral administration of less than 1 mg. However, the side effects were more pronounced, and it was less stable. Recently, an analogue of 16,16-dimethyl-$PGE_2$ in which the carbonyl group at C-9 has been replaced by a methylene group has been extensively studied since it combines high activity with high stability and has only slight side effects[74].

| | $PGE_{2\alpha}$ | $PGE_2$ | (15S)-15-Methyl-$PGF_{2\alpha}$ | 16,16-Dimethyl-$PGE_2$ |
|---|---|---|---|---|

Fig. 8. Summary of early clinical trials indicating approximate doses of prostaglandins for interruption of pregnancy.

At that time an important development was initiated by SIDA (Swedish International Development Authority). In the sixties they had become heavily involved in supporting family planning in many developing countries; however, they found that the methods available left much to be desired and, therefore, were considering how best to stimulate and support research and development in this field.

The Director, *Ernst Michanek,* and *Carl Wahren* had developed advanced plans to start an international research foundation at the Karolinska Institute for this purpose. However, for various reasons, it was decided to make a feasibility study of alternative possibilities in conjunction with the Ford Foundation and the World Health Organization (WHO); a study in which I had the honor to participate. This resulted in 1971–72 in the creation of the WHO's "Special Programme" for research on human reproduction. Attention was focused on the needs of developing countries. Voluntary contributions to the programme soon exceeded 10 million US dollars annually, of which more than half was provided by Swedish sources.

One of the "task forces" of the programme was devoted to exploring the potential of the prostaglandins to interrupt pregnancy. During the first five years I had the stimulating assignment of serving as chairman of this group of distinguished experts. The exploratory work carried out at the Karolinska Institute and by Dr. *Karim*'s group formed the basis for extensive internationally coordinated clinical trials with drugs supplied by the Upjohn Co. Figure 9 shows the locations of the clinics involved, and Figure 10 the number of cases completed. The task force has continued its activities under the chairmanship of Dr. *Bygdeman*.

The most important new development has been the interruption of pregnancy during the "postconceptional" pe-

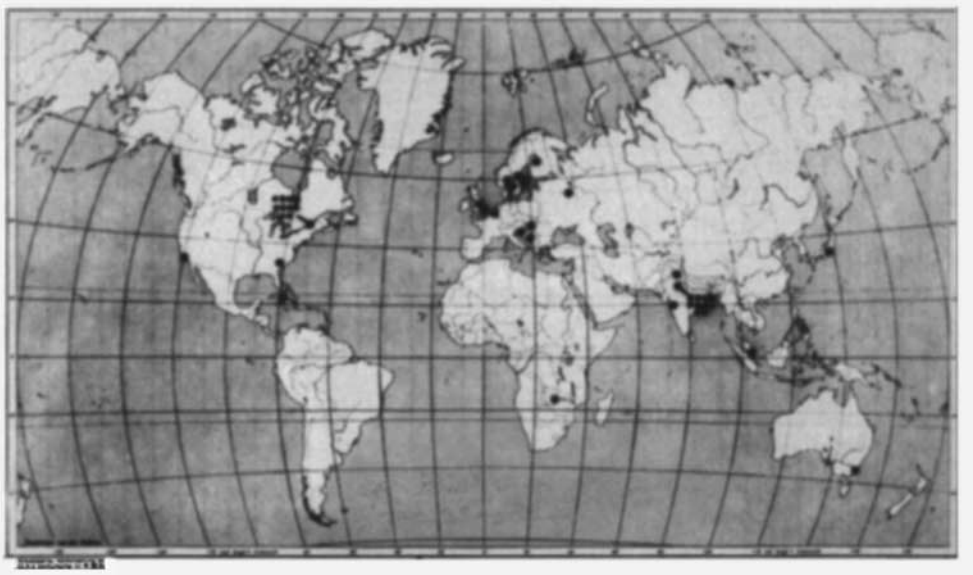

Fig. 9. Participating clinics in coordinated trials of the WHO Prostaglandin Task Force (1972–1977).

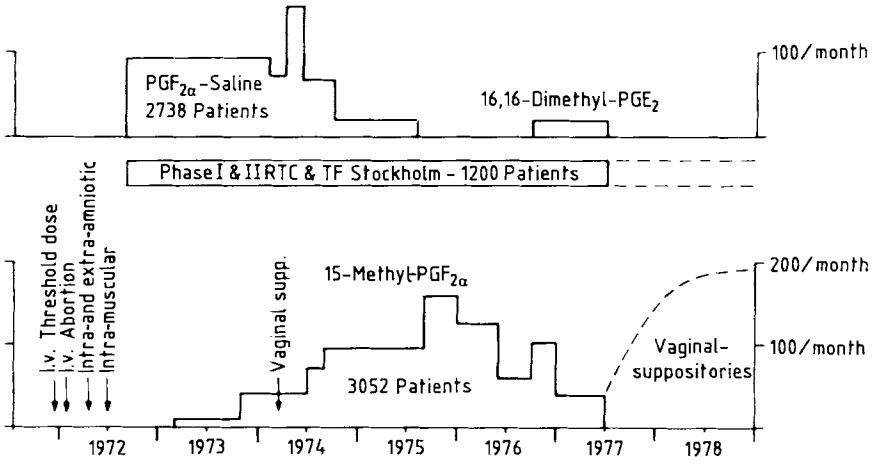

Fig. 10. Number of patients participating in coordinated trials of the WHO Prostaglandin Task Force.

riod, *i.e.* in the first three weeks after a missed menstrual period.

I have a very vivid memory of a late evening in Bombay when Dr. *Borell*, Dr. *Bygdeman*, and I were compiling results of abortions carried out at different stages of pregnancy in which we found a success rate of practically 100% complete abortions (see Fig. 11). This observation has been studied extensively, and Dr. *Bygdeman et al.* have just completed a successful trial with a 100 cases in Stockholm in which the patients self-administered the drug at home. This method obviously has a very great potential, especially in developing countries.

The therapeutic use of prostaglandins is, however, not limited to interruption of pregnancy. It is also used for induction of labor, treatment of serious bleeding after delivery, and for dilatation during diagnostic curettage.

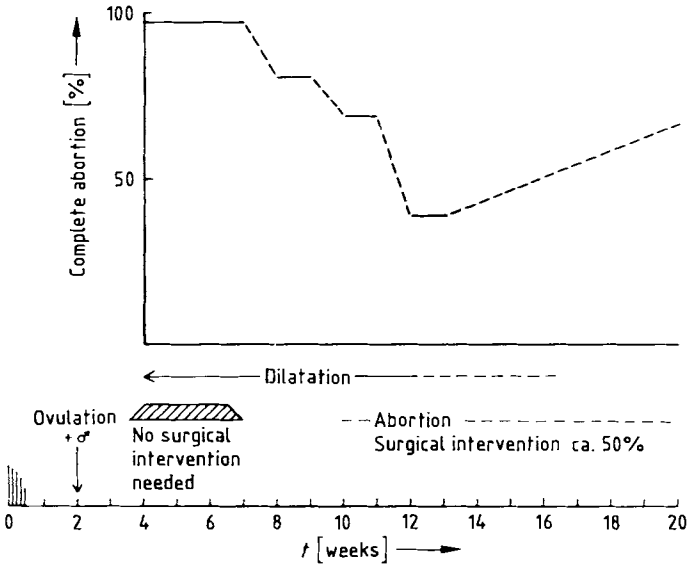

Fig. 11. Percentage of "complete" abortions after interruption of pregnancy with prostaglandins at various times.

Promising results have been reported of treating eclampsia with $PGA_1$.

A summary of the applications of prostaglandins in this area is given in Figure 12.

Prostaglandins have also found extensive use in animal husbandry, especially for "syncronization" of herds of cattle, *i.e.* injection of cows with 25 mg of $PGF_{2\alpha}$ at an appropriate time interrupts their cycles, and the whole herd can be inseminated three days later.

Prostaglandin precursors and the enzymatic systems appear to be present in practically every cell and can biosynthesize characteristic mixtures depending on cell type and conditions. Since the highest concentration is found in the lowest animal species, one can speculate that the ease of autoxidation of the percursor acids—a reaction that even has been reported to produce prostaglandins in minute amounts[75]—led to their utilization in metabolism at an early stage of evolution for many different functions.

Apparently, prostaglandins mainly play a role as local regulators—even if $PGF_{2\alpha}$ functions as a classical hormone in sheep, where it is produced in the uterus at the end of the cycle and transported in the blood to the ovary, causing luteolysis.

The complex pattern of arachidonic acid metabolism makes studies of the functions of prostaglandins in complex regulatory mechanisms in organs like the kidney, lung, *etc.* a difficult and challenging task.

Figure 13 illustrates how the field has developed from the early publications on the isolation, structure and biosynthesis to the present level of more than 5000 papers annually!

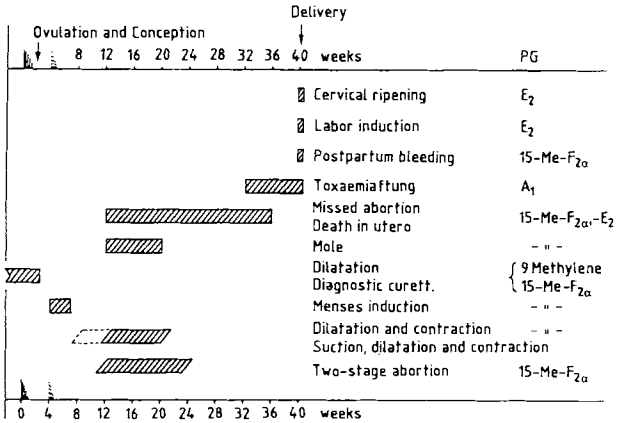

Fig. 12. Summary of therapeutic utility of prostaglandins in gynecology obstetrics.

Where did all these scientists get their prostaglandins? This is also answered in Figure 13. The Upjohn Company supplied something like 75000 samples during this period, and it can be seen that most of the samples gave rise to a publication, at least up to *ca.* 1970. At that point the prostaglandin-containing coral was found in the Gulf of Mexico. A number of pharmaceutical companies then collected corals, started synthetic programmes, and then also supplied samples to scientists.

Here it is appropriate to point out that the whole prostaglandin field would have been very much slower in developing without the outstanding research and development work initiated and organized at Upjohn by Dr. *David Weisblat.*

The prostaglandin story illustrates, once again, the importance of interaction between the pharmaceutical indus-

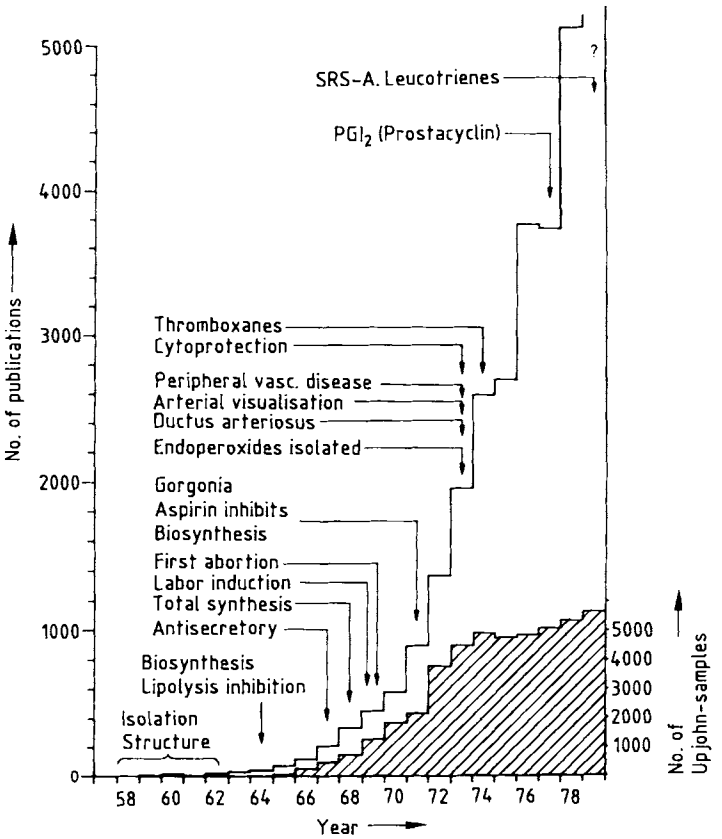

Fig. 13. Number of annual publications related to prostaglandins (left ordinate) and the number of free samples of prostaglandins distributed by Upjohn (right ordinate).

try and academic biomedical scientists. In this case, the World Health Organization's special programme for human reproduction has also greatly contributed to the speed of development and to the build up of research and development capabilities in this field in developing countries.

## Valence Isomerization of Phane-Bridged *cis*-Trioxatris-*o*-homobenzenes**

By *Michael Stöbbe, Ulrich Behrens, Gunadi Adiwidjaja, Peter Gölitz,* and *Armin de Meijere**

*Dedicated to Professor Hans Brockmann on the occasion of his 80th birthday*

*cis*-Benzene trioxide, with its almost planar cyclohexane ring, undergoes the $3\sigma \rightarrow 3\pi$ rearrangement characteristic of *cis*-tris-σ-homobenzenes to 1,4,7-trioxonin only above 200°C[1]. In view of the geometry-dependence of the [2+2+2]-cycloreversion observed in the carbocyclic tris-homobenzene system[2], it is of interest to know how much the deformation forced upon the trioxide six-membered ring in **1**[3] by phane-bridging influences its kinetic stability.

According to a crystal structure analysis, the epoxide rings in **1**, with a mean interplanar angle of 106.5° to the saturated six-membered ring, are oriented in almost the same fashion as those in the unbridged *cis*-benzene trioxide[1b], but the two substituted corners of the skeletal six-membered ring are bent at an angle of about 9.2° out of the plane of the other four C-atoms. Surprisingly, this saturated ring is thus less bent than the benzene ring in **1**, where the corresponding angle is 12.9°.

**1** **2** **3** **4**

I: $H_2/PtO_2$, EtOH, R.T., 10 h; II: 550°C, $10^{-3}$ torr.

[*] Prof. Dr. A. de Meijere, Dr. G. Adiwidjaja, Dr. U. Behrens, Dr. P. Gölitz, M. Stöbbe
Fachbereich Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

[**] This work was supported by the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie.

In the [2.2]paracyclophane trioxide **2**, where the bridging bonds are longer, the bending of the trioxide six-membered ring might be correspondingly smaller. **2** cannot be obtained directly from [2.2]paracyclophane analogously to **1**[3] but only by catalytic hydrogenation of **1**. **2** is much more soluble than **1** in organic solvents, is stable at room temperature, and like **1** decomposes below its melting point (>260°C). In the $^1$H-NMR spectrum of **2** a remarkably large shift difference of 0.98 ppm is observed in each case for the signals of the two protons on C-2 and on C-9, which must be due to the diamagnetic anisotropy of the oxirane ring[5].

Both **1** and **2** could be sublimed at 170—180°C/$10^{-3}$ torr through a quartz tube heated to 550°C. The condensates obtained at −196°C contained, aside from the educts, the phane-bridged 1,4,7-trioxonins **3** and **4**, respectively, in almost the same relative amounts (21%). **3** and **4** were purified by chromatography ($SiO_2$, $CH_2Cl_2$/pentane 2:1 and $CHCl_3/Et_2O$ 1:1, respectively) and subsequent sublimation (70°C/$10^{-2}$ torr) and characterized by NMR spectroscopy. Both differ considerably from their precursors in their properties; for example, they even dissolve in pentane, are considerably more volatile, and have lower melting points (117—118 and 123—124°C, respectively).

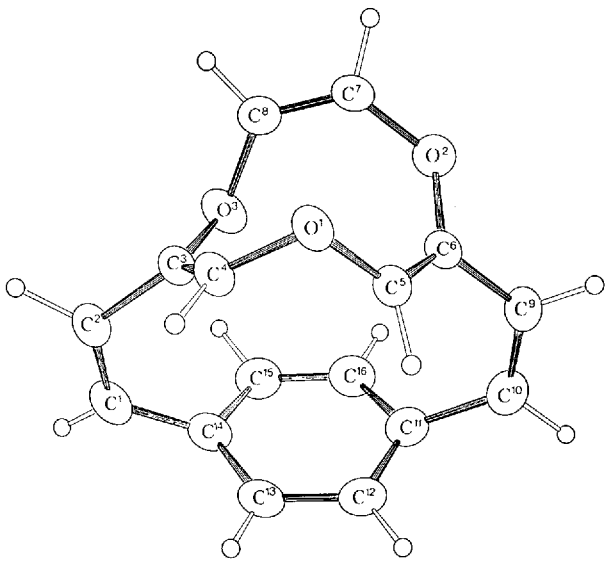

Fig. 2. ORTEP diagram and crystal structure parameters of the phane-bridged 1,4,7-trioxonin **3** (monoclinic crystals, $P2_1/c$, $Z=4$, $a=716.2(1)$, $b=2505.8(2)$, $c=758.8(1)$ pm, $\beta=114.18(1)°$, $\rho_{X\text{-ray}}=1.35$ g/cm$^3$; 2168 evaluated reflections, $\theta \leq 70°$, $Cu_{K\alpha}$; $R=5.0$, $R_w=5.0\%$). $C^1C^2$: 133.3; $C^2C^3$: 149.3; $C^3C^4$: 132.6; $C^5C^6$: 132.7; $C^7C^8$: 130.7; $C^6C^9$: 147.2; $C^9C^{10}$: 133.7; $C^{10}C^{11}$: 149.1; $C^{11}C^{12}$: 138.4; $C^{11}C^{16}$: 139.1; $C^{12}C^{13}$: 138.5; $C^{13}C^{14}$: 138.0; $C^{14}C^{15}$: 139.0; $C^{15}C^{16}$: 137.5; $C^4O^1$: 139.6; $C^5O^1$: 139.1; $C^6O^2$: 136.8; $C^7O^2$: 137.0; $C^3O^3$: 138.0; $C^8O^3$: 139.0 pm.

**3** is storable for prolonged periods at 0°C in the refrigerator, whereas **4** polymerizes within a few days, both in solution and in the solid state.

These findings for the rearrangement of **1** and **2** show, at least qualitatively, that the kinetic stability of the *cis*-benzene trioxide[1] is not significantly affected by phane-bridging such as in **1** and **2**. Contrary to expectation, even the conformation of the trioxonin ring in **3** is not notably

influenced by the bridging; the conformation preferred in the crystal (see Fig. 2) is not crown- but saddle-shaped, as in 1,4,7-troxonin[1b]. Since the change in conformation in all these cases[6] is not likely to require much extra energy, **3** and **4** may, like the parent system, be regarded as potential novel crown ether-like ligands for metal complexes.

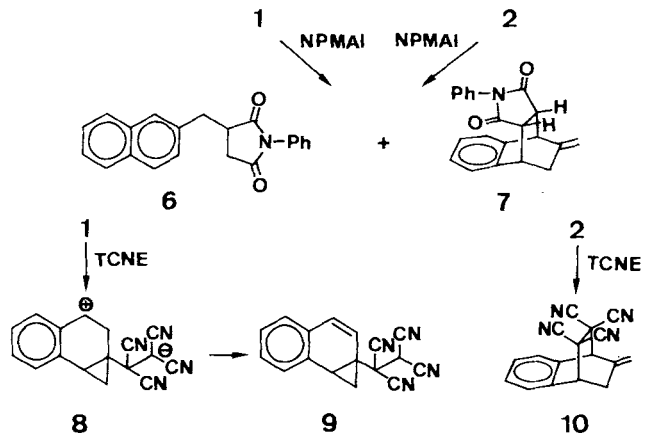
## Thermolysis and Reactions of 4,5-Benzotricyclo[4.1.0.0$^{1,3}$]hept-4-ene and *o*-(Propadienyl)styrene**

By *Udo H. Brinker**, *Gabriele Wilk*, and *Klaus Gomann*



Investigations of the reaction behavior of strained[1a,b] and highly unsaturated hydrocarbons[1c] are especially suitable for revealing relationships between structure and reactivity[1d]. 4,5-Benzotricyclo[4.1.0.0$^{1,3}$]hept-4-ene **1**[2] and *o*-(propadienyl)styrene **2**[2] are thermolabile $C_{11}H_{10}$ compounds. **1** and **2** rearrange quantitatively at a measurable rate even at 30°C. In each case the product mixture consists of more than 90% of six dimers together with small amounts of 2-methylnaphthalene **4**. The position of the two halves of the molecule in both major dimers **5a** and **5b** was determined by NOE difference $^1$H-NMR experiments. Both **4** as well as **5a**, **b** are formed *via* the intermediate **3**, which contains an *o*-quinodimethane moiety. **4** can be formed from **3** by a catalytically induced 1,3-H shift. The formation of the dimers **5a** and **5b** can be regarded as $[4\pi+6\pi]$- and $[4\pi+10\pi]$-cycloadditions, respectively, of two molecules of **3**. Consistent with the Woodward-Hoffmann rules[4a], **5a** and **5b** are present as *exo*-adducts. They are each formed in about the same ratio irrespective of whether **3** results from the rearrangement of **1** (41 and 42%) or **2** (39 and 44%).

The thermolyses of **1** and **2** were monitored by measurement of the decrease in intensity of characteristic $^1$H-NMR signals compared to an internal standard[5a]. The decrease

| | **1**→**3** (46°C) | **3**←**2** (46°C) |
|---|---|---|
| log*A* | 13.97 ± 0.22[5b] $s^{-1}$ | 9.55 ± 0.36[5b] $s^{-1}$ |
| $E_a$ | 26.46 ± 0.31 kcal $mol^{-1}$ | 19.70 ± 0.56 kcal $mol^{-1}$ |
| $\Delta H^+$ | 25.82 ± 0.31 kcal $mol^{-1}$ | 19.06 ± 0.56 kcal $mol^{-1}$ |
| $\Delta S^+$ | 3.3 ± 1.0 cal $mol^{-1}$ $K^{-1}$ | −17.0 ± 1.80 cal $mol^{-1}$ $K^{-1}$ |

in concentration of **1** and **2** obeys the rate law for irreversible first-order reactions. The temperature-dependence of the reaction rates measured for **1** and **2**, respectively, between 30.25 and 60.95°C, and 30.25 and 61.4°C, at seven and six temperatures, respectively, can be described in terms of Arrhenius parameters. That the formation of the intermediate **3** in the reactions of **1** and **2** is the rate-determining step is shown by the reactions with different concentrations (1.2 and 4 M) of *N*-phenylmaleic acid imide (NPMAI) at 52.2°C. In each case the reaction rates are consistent with those of the reactions without NPMAI. The Diels-Alder adduct **7**, formed by addition of NPMAI to C-1 and C-4 of **3**, has the *endo*-conformation[4]. The ene reaction to give **6** competes with the formation of **7** (**7**:**6** = *ca.* 2:1 from **1** or **2**).

The allene **2** undergoes the diene synthesis with the more reactive dienophile tetracyanoethylene (TCNE) in THF at 60°C to give **10**. An ene adduct[6] corresponding to **10** could not be detected by $^1$H-NMR spectroscopy.

The reaction of the tricycle **1** with TCNE in THF proceeds completely differently. Spontaneous reaction ($t_{1/2}$ < 15 min) with formation of **9** takes place even at room temperature. Apparently, even before rearrangement to **3** can take place (**1**: $t_{1/2}$(25°C) ≈ 51 h), TCNE attacks the central C-atom in the strained spiropentane moiety. The zwitterion **8** is stabilized by transfer of a H-atom to give **9**.

The values of the activation parameters of the rearrangement of **2** would suggest a concerted electrocyclization to

Hasselmann* for valuable discussions.

3. On the other hand, the rearrangement of the tricycle **1** could take place *via* retro-Diels-Alder reaction or *via* diradicals as intermediates. The conversion into **3** might be initiated by rupture of the C2–C3 and/or C1–C6 bonds.

Hydrogenation (Pt/C, pentane) of **1** affords 4- and 5-methyl-2,3-benzobicyclo[3.1.0]hex-2-ene in 55 and 25% yield, respectively, whereby the C1–C2 and C2–C3 bonds of one three-membered ring of the spiropentane moiety are broken.

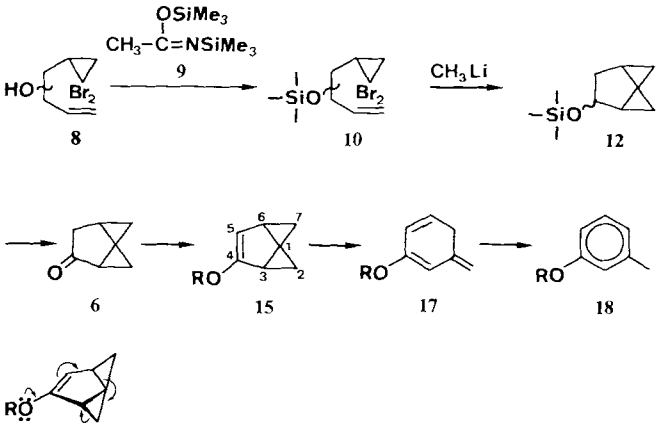
## Tricyclo[4.1.0.0$^{1,3}$]hept-4-enes as Intermediates**

By *Udo H. Brinker**, *Klaus Gomann*, and *Ruth Zorn*



Of the isomers of toluene, tricyclo[4.1.0.0$^{1,3}$]hept-4-ene **1** claims special interest. The possible interaction between the spiropentane moiety and the double bond should be reflected, *inter alia*, in the thermal behavior of **1**. The reputedly more stable benzo-annelated analogue **2** rearranges irreversibly, even at 30°C[1].

1 2 3 4

**1** has been discussed as intermediate in the reaction of *cis*-(1,3-butadienyl)cyclopropylidene **3** to 5-methylene-1,3-cyclohexadiene **4**[2]. **1** could be formed by intramolecular addition to the terminal double bond in **3** and then be converted in a retro-Diels-Alder reaction or *via* diradicals as intermediates into **4**[2b]. Labeling experiments are not only consistent with this possibility, however, but also with a reaction *via* intermediary *cis*-1,2,4,6-heptatetraene[2b]. **4** aromatizes in a base-catalyzed reaction to toluene.

An alternative entry to **1** could be provided by the ketone **6** as educt, which already has the [4.1.0.0$^{1,3}$]-moiety

a: R = H; b: R = Li; c: R = SiMe$_3$

available. **6** can be prepared in a four-step reaction from 1,5-hexadien-3-ol. The mixture of the isomeric alcohols **8** has been obtained (yield 30%) by addition of dibromocarbene and has then been converted with *N*-(trimethylsilyl)acetamide acid trimethylsilyl ester **9** into the silyl ethers **10** (yield 86%). Reaction of **10** with methyllithium (−80 to −100°C) afforded a mixture of silyl ethers in 63% yield, 13% being the tricyclic silyl ether **12**. Also at the temperatures employed the cyclopropylidene(carbenoid)-allene rearrangement [8] to the allenyl silyl ethers dominated over the competing intramolecular addition to give **12**[8]. Cleavage of ether and oxidation to **6** were accomplished in one step with pyridinium chlorochromate (yield 64%). The low thermal stability of **6** [$t_{1/2}$(40°C in $CCl_4$) *ca.* 11 h] necessitates the conversion **6** → **1** being carried out below 25°C. Following the method of *Ireland et al.*[14a], **6** was allowed to react at −78°C with lithium diisopropylamide and then converted with chlorodiethyl phosphate into the phosphate; this (and/or an already rearranged product) was then reduced with lithium in ammonia. Apart from toluene, 1-methyl-1,4-cyclohexadiene, the product of a Birch reduction, was isolated. In which sequence substitution, rearrangement, reduction and aromatization take place remains open. Addition of water at −20°C to the enolate **15b**, or to the already rearranged **17b**, furnished *m*-cresol **18a**. By reaction of **6** with triethylamine at 0°C and addition of trifluoromethanesulfonic acid trimethylsilyl ether it was possible to detect the already rearranged silyl ether **17c** by $^1$H-NMR spectroscopy; concomitantly, the decrease in the amount of **17c** with time at the expense of the formation of **18c** by aromatization could be monitored. The formation of **18a** and **18c** is consistent with a retro-Diels-Alder reaction[19] of **15a** and **15c**, respectively, or with their decomposition *via* diradicals as intermediates with rupture of the C2–C3 and/or C1–C6 bonds. *p*-Cresol or *p*-cresol-trimethylsilyl ethers could not be detected. These compounds should be formed by rupture of the C1–C3 and/or C6–C7 bonds in **15a** or **15c** and subsequent aromatization.

The sole formation of **18a** and **18c**, respectively, can be due to interaction between the C2–C3 bond and the OR function. Likewise, **15** could rearrange in a retro-Diels-Alder reaction exclusively to the thermodynamically more stable **17**, from which **18** is formed.

## Resolution, Circular Dichroism, and Absolute Configuration of 1,1'-Biazulenes**

By *Akio Tajiri**, *Masahiko Fukuda*, *Masahiro Hatano*, *Tadayoshi Morita*, and *Kahei Takase*

*rac*-2,2'-Dimethyl-1,1-biazulene *rac*-**1a**[4] has been resolved directly with the aid of HPLC using a commercially available (+)-polytriphenyl-methyl methacrylate column[5] (RT, hexane/2-propanol 80:20). The fraction of **1a** that

**1** : X = H
**1a**: X = $CH_3$
**1b**: X = $OCH_3$

elutes first is levorotatory and exhibits a distinct negative CD couplet in the region 30000–40000 $cm^{-1}$ (Fig. 2), whereas the second fraction, which is dextrorotatory, gives a mirror image of the CD spectrum. Accordingly, *rac*-**1a** is considered to be completely resolved.

A given excited electronic state of azulene (Fig. 3a) gives rise in *rac*-1,1'-biazulene **1** to two electronic states A and B of point group symmetry $C_2$, of which the B state is energetically more stable (Fig. 3b). Both the A←A and B←A transitions of *rac*-**1** originate from an excitation of azulene in which the long axis polarization has a particular value of the dipole strength[6] and a non-zero rotational strength for all values of the dihedral angle $\alpha$ between the planes of the azulene groups except 0 and 180°. Provided the absolute configuration is *R* (see Fig. 3c), a chirality consideration[9] leads to the negative CD band associated with the B←A transition and to the positive band associated with the A←A transition (Fig. 3d). A similar consideration reverses the sign of CD bands for *S*-configuration; however, the B state is lower in energy than the A state.

Chemical Research Institute of Non-aqueous Solutions
Tohoku University, Sendai 980 (Japan)
Dr. T. Morita, Prof. K. Takase
Department of Chemistry, Faculty of Science
Tohoku University, Sendai 980 (Japan)

[**] This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan, and by a grant from the Nissan Science Foundation (*M. H.*).

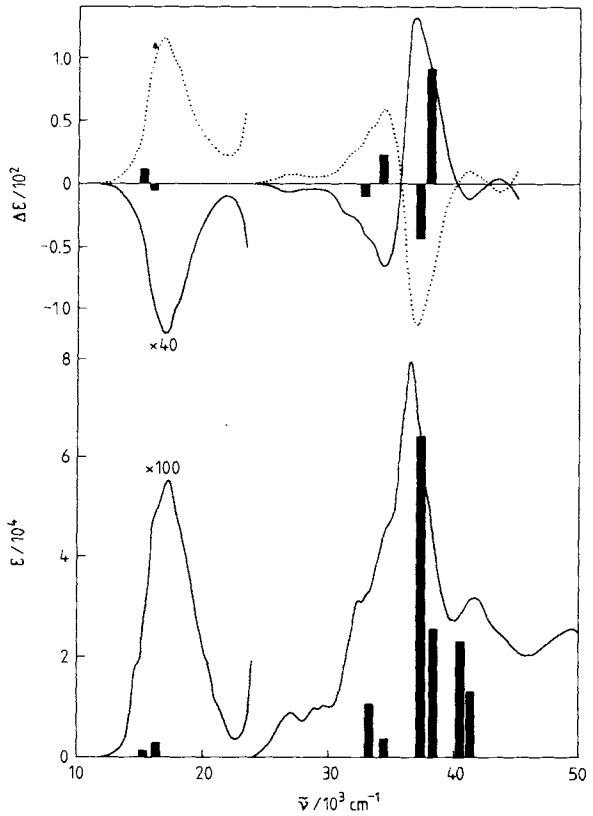

Fig. 2. Experimental (curves) and calculated (columns) absorption spectra (bottom) and CD spectra (top) of **1a** at room temperature (—— first fraction, ····· second fraction).

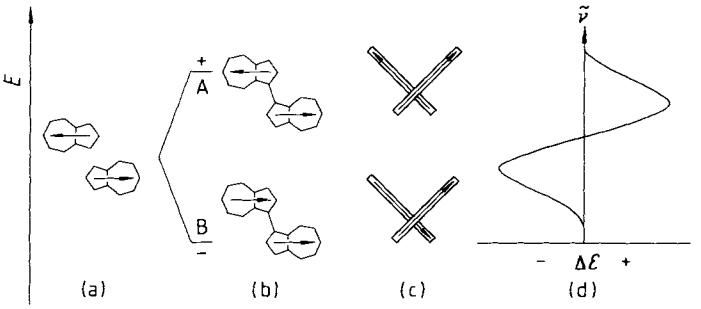

Fig. 3. The exciton chirality rule for (*R*)-1,1'-biazulene, (*R*)-**1**.

This was further confirmed by CNDO/S calculations assuming *R*-configuration and a dihedral angle of 130°, determined from the minimum of the potential energy curve calculated for **1** by the CNDO/2 method. The B←A transition predicted at 37300 $cm^{-1}$ is calculated to exhibit negative circular dichroism and is assigned to the observed negative CD band at 34400 $cm^{-1}$; the A←A transition at 37900 $cm^{-1}$ is predicted to show positive CD and is assigned to the observed positive CD band at 37200 $cm^{-1}$. We therefore conclude that the first fraction of *rac*-**1a** corresponds to 1,1'-biazulene with absolute configuration *R*(−) and that the second fraction is *S*(+).

In contrast to the remarkable stability of (*R*)- and (*S*)-**1a** in solution, the CD spectra of (*R*)- and (*S*)-2,2'-dimethoxy-1,1'-biazulene **1b** indicate that they are configurationally unstable and racemize rapidly at room temperature. From an Arrhenius plot, the energy of activation ($E_a$) and rate of

racemization ($k$) are determined to be *ca.* 71 kJ/mol and *ca.* $3.8 \times 10^{-3}$ $s^{-1}$ (39°C), respectively. The energy of racemization for (*R*)- and (*S*)-**1b** is comparable to those found for 1,1'-binaphthyl derivatives[12]. The steric hindrance caused by two substituents should be smaller in **1b** than in **1a**, since in **1b** the two methyl groups are further apart due to the presence of the oxygen atoms between the azulene skeleton and the two methyl groups.

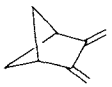
## 3,4-Bismethylenetricyclo[3.1.0.0$^{2,6}$]hexane—Synthesis and Diels-Alder Addition to Tetracyanoethylene**

By *Franz Lanzendörfer* and *Manfred Christl**

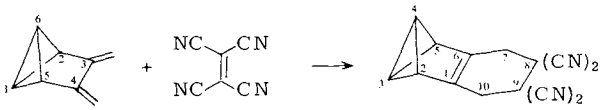


Addition of tetracyanoethylene (TCNE) to diene **1** proceeds $30.5 \times 10^6$ times as fast as that of TCNE to **2**[1]. *Hogeveen et al.*[1] suggested that this dramatic difference arises from orbital interactions between the strained σ-systems and the unsaturated bridges in **1** and **2** as well as in their TCNE adducts.

**1**

**2**

**3**



**4**

Recently, *Schwager* and *Vogel*[2] proposed an alternative explanation; they suggested that the *syn*-oriented methyl groups at C-5 and C-6 in **2** sterically hinder addition of TCNE since the rate of reaction of the methyl-group free hydrocarbon **3** is 850-fold that of **2** (Table 1). Even in **3** the cyclobutane ring retards the reaction for steric reasons, since the quasi-planar **4**, which has nearly the same HOMO energy, adds TCNE 1400 times as fast as **3**[3] (Table 1).

[*] Prof. Dr. M. Christl, F. Lanzendörfer
Institut für Organische Chemie der Universität Würzburg
Am Hubland, D-8700 Würzburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

**5** **6**

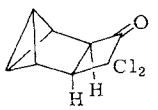


Table 1. HOMO energies (1st ionization potentials) of dienes **1**—**5** and relative rate constants for addition of **1**—**5** to TCNE.

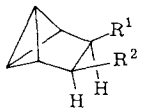
| Diene | HOMO [eV] | Ref. | $k_2$ (rel., 20°C) | Ref. |
|---|---|---|---|---|
| **1** | 7.82 | [1] | 30500000 | [1] |
| **4** | 8.54 | [3] | 1190000 | [3] |
| **5** | 8.27 | [4] | 250000 | — |
| **3** | 8.50 | [4] | 850 | [2] |
| **2** | 8.22 | [1] | 1 | [1] |



We have now synthesized the title compound **5** and studied its reaction with TCNE in benzene to afford **6** (70% isolated yield, m.p. = 164—166°C). Based on the second-order rate constants ($k_2 = 0.57$ and 0.25 $L \cdot mol^{-1} \cdot s^{-1}$ at 22 and 9°C, respectively), the relative reactivity of **5** is only 1/120th of that of the tetramethyl derivative **1** (Table 1). The four methyl groups of **1**, therefore, accelerate the addition of TCNE—probably by raising the energy of the HOMO (Table 1). A similar orbital effect may also operate on proceeding from **3** to **2**; however, the corresponding increase in reaction rate is more than compensated for by the steric hindrance of the *syn*-orientated methyl groups at C-5 and C-6 of **2**.

The factor of *ca.* 300 between the addition constants of **3** and **5** should also apply to **1** and **2** as an intrinsic effect of the systems; the five orders of magnitude difference between their addition constants are attributable to the influence of the methyl groups. However, the differences between the HOMO energies (0.23 eV) and steric demands of **3** and **5** are sufficient to account for this intrinsic effect of the systems, which makes a discussion of orbital effects in the products[1] unnecessary.

We synthesized **5** from the dichloroketene adduct **7**[5] of benzvalene, which was allowed to react with sodium methoxide to afford the ester **8** (70% yield). This was subsequently allowed to react with triphenyltin hydride to give the monochloro compound **9** (92%), which was reduced by $LiAlH_4$ to yield the (chloromethyl)(hydroxymethyl) derivative **10** (93%). After conversion into the mesylate **11** (94%), double elimination with potassium *tert*-butoxide in dimethyl sulfoxide led to **5** (28% after preparative GC).

**7**

**8**, $R^1 = CO_2CH_3$, $R^2 = CHCl_2$
**9**, $R^1 = CO_2CH_3$, $R^2 = CH_2Cl$
**10**, $R^1 = CH_2OH$, $R^2 = CH_2Cl$
**11**, $R^1 = CH_2O{-}SO_2{-}CH_3$, $R^2 = CH_2Cl$

Both analytical and spectroscopic data are consistent with the structures proposed for the novel compounds. Of note are the NMR spectra of **5** and **6**[6]: Whereas the chemical shifts of **5** deviate only slightly from the values expected for a normal bicyclo[1.1.0]butane system, **6** displays the anomalies exhibited by benzvalene[7] with the central bicyclo[1.1.0]butane CH groups (C-3,4; 3,4-H) absorbing at very low field, although in **5** *and* **6** the respec-

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/1111-0871 $ 02.50/0* 

tive σ-systems are each bridged by two $sp^2$-hybridized C atoms. The reason for this is possibly the different symmetries of the π* orbitals[7a] in the diene and monoene bridge-moieties of **5** and **6**, respectively.

## $SbF^{2+}$ as a Lewis Acid in $Na(SbF)PO_4 \cdot nH_2O$ (n = 2–4) and $NH_4(SbF)PO_4 \cdot H_2O$

By *Rainer Mattes** and *Klaus Holz*

$SbF_3$ forms adducts with numerous oxygen-containing compounds, and in this respect behaves as a Lewis acid; for example, the adducts with alkali metals or ammonium sulfates and ammonium nitrates have been studied. Recently, compounds with $SbF_2^+$ groups have been described; namely, $M^I(SbF_2)SO_4$ with $M^I$ = Rb, Cs[3], $K(SbF_2)HPO_4$[4], and $(SbF_3 \cdot SbF_5)_2$[5]. The novel compounds $Na(SbF)PO_4 \cdot nH_2O$ (n = 2–4) **1** and $NH_4(SbF)PO_4 \cdot H_2O$ **2** crystallize from 0.1–0.3 M solutions of $SbF_3$ and $NH_4H_2PO_4$ and $NaH_2PO_4$, respectively, after filtration from the immediately formed precipitate. They contain the previously unknown $SbF^{2+}$ group, which is coordinatively unsaturated and is, therefore, a strong Lewis acid.

X-ray structure analysis of **1** and **2** indicated that both compounds crystallize in highly symmetrical, almost identical layer structures. The four oxygen atoms of the $PO_4^{3-}$ anions are each bonded to different $SbF^{2+}$ groups. The antimony atoms are octahedrally coordinated if the stereochemically active 5s lone-pair is viewed as a sixth ligand. The Sb–F distance in **1** is 193.4(4) and in **2** 192.3(4) pm; the Sb–O distances vary from 216 to 220 pm. Because of the large spatial requirements of the lone-pair of electrons, all F–Sb–O angles are smaller than 79°. $PO_4$ tetrahedra and :$SbFO_4$ octahedra form layers with tetragonal symmetry, cross-linked *via* the oxygen atoms. In these layers, the fluorine atoms are orientated alternatingly upwards and downwards. $VOPO_4 \cdot 2H_2O$ and $NbOPO_4 \cdot 3H_2O$ are the first two further examples of the simple structure principle realized here (Fig. 1): the alternating linkage of tetrahedra and octahedra *via* four edges to planar layers. These compounds are interesting because of their intercalation behavior[6].

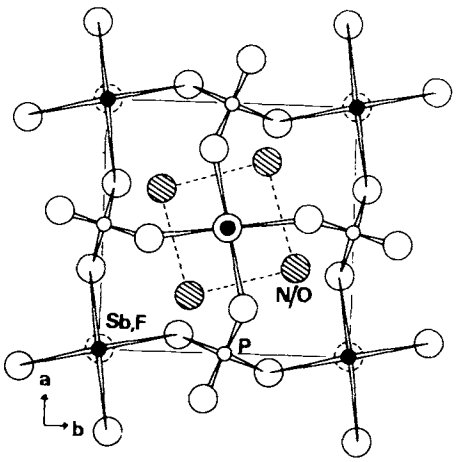

Fig. 1. Crystal structure of a layer of **2** (solid circles: Sb; F lies above or below Sb). Space group $I\bar{4}$, $a = 656.5(2)$, $c = 1439.8(5)$ pm, $Z = 4$; 646 reflections with $F > 3.92\sigma(F)$, 46 parameters, $R = 0.025$, $R_w = 0.035$. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CSD 50609, the names of the authors, and the journal citation.

The layers in **1** and **2** are stacked differently. In **2**, the fluorine atoms and lone-pair of electrons of neighboring layers face each other in the body-centered unit cell. The distance between the layers (1/2 of the *c*-axis) is 714.9(3) pm. The $NH_4^+$ ions and the $H_2O$ molcules are located between the layers, statistically distributed over just one point position. These form circular groups $(NH_4{-}OH_2)_2^{2+}$ *via* N–H···O hydrogen bonds of 290.0(8) pm length; these groups are bonded *via* further hydrogen bonds to the oxygen atoms of the immediately over- and underlaying layers. The hydrogen-bond systems are of importance for stabilizing the overall structures: under the same reaction conditions but using $KH_2PO_4$ instead of $NH_4H_2PO_4$, the compound $K(SbF_2)HPO_4$ of different composition is formed[4].

With respect to the sequence of the layers, the structure of **1** is disordered. Reflection of an A layer in the plane perpendicular to the *b*-axis through the P-, Sb-, and F-atoms gives rise to the "enantiomeric" B layer. Layers A and B are stacked along the *c*-direction in statistical sequence with a distance of 867.9(17) pm. X-Ray structure studies indicate the space group $P2_1/m$ in which all four-fold point positions are half-occupied. The diffuse images of all the reflections in the [001] direction is also indicative of the disrupted periodicity.

The high symmetry of the compounds is also apparent in their relatively band-deficient vibrational spectra. The Raman spectrum exhibits two intense bands in the PO stretching frequency region: $\nu_s(PO_4)$ at 958 and 955 $cm^{-1}$, respectively, and $\nu_{as}(PO_4)$ at 1004 and 1008 $cm^{-1}$, respectively (for **1** and **2**, respectively); $\nu$(SbF), which is also intense, appears at 540 for **1**, but for **2** at 605 $cm^{-1}$ (here, the difference in the layer sequence is probably decisive). The $^{125}$Sb Mössbauer spectra (measured at 4 K with Ba $^{121m}SnO_3$ as source) of **1** and **2** display a broad absorption band having a shoulder at the lower velocity side of the source. The values of the isomeric shifts ($\delta = -5.76(1)$ and $-4.98(1)$ mm/s in **1** and **2**, respectively), which are smaller than in $SbF_3$[8], indicate a lower s-electron density at the antimony nucleus, *i.e.*, the s lone-pair of electrons is

more involved in bonding to the ligands than in $SbF_3$; the quadrupole coupling constants $\Delta E_Q$ of 14.4(1) and 18.0(1) mm/s, respectively, are smaller than in $SbF_3$ since the coordination polyhedron is less distorted.

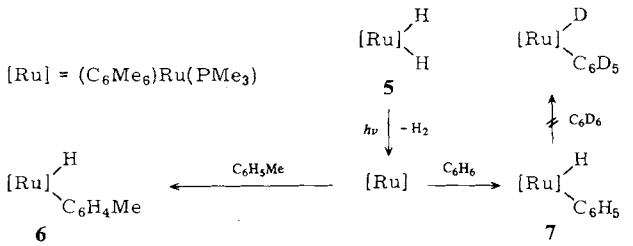
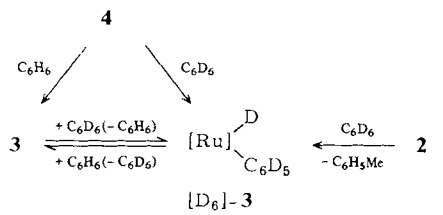
## Aryl(hydrido)ruthenium Complexes by C–H Addition: Isolation of a Four-Membered Metallacycle as Intermediate**

By *Heidrun Kletzin* and *Helmut Werner**



The problems surrounding the activation of C–H bonds by transition metals are currently attracting a great deal of interest[1a]. *Chatt* and *Davidson* first showed in 1965 that a coordinatively unsaturated metal complex of the type $RuL_4$ ($L_2 = C_2H_4(PMe_2)_2$) reacts with an aromatic hydrocarbon ($C_{10}H_8$) to give an aryl(hydrido)metal compound[1b]. Later, *Green et al.* found that the complex $W(C_5H_5)_2$ formed on thermolysis or photolysis of $(C_5H_5)_2WH_2$ behaves similarly, and in the presence of arenes forms compounds of the type $(C_5H_5)_2WH(R)$[1c]. It has recently been demonstrated that saturated, unsubstituted hydrocarbons (cyclohexane, neopentane) are also able to add oxidatively to 16-electron fragments such as $(C_5Me_5)Ir(PMe_3)$[2a] or $(C_5Me_5)Ir(CO)$[2b], which are formed on photolysis of $(C_5Me_5)IrH_2(PMe_3)$ and $(C_5Me_5)Ir(CO)_2$, respectively.

We have now found that the complexes $(C_6H_6)RuH_2(PiPr_3)$ **1**[3a] and $(C_6Me_6)RuH_2(PMe_3)$ **5**[3b], structurally related with $(C_5Me_5)IrH_2(PMe_3)$, also form aryl(hydrido)metal compounds on photolysis in arenes[4]. In cyclohexane, with **1** as educt, however, no reaction with the solvent is observed, but an intramolecular oxidative addition of a methyl C–H bond of the triisopropylphosphane ligand to the metal (Schemes 1 and 2). The irradiation time (Philips HPK 125 W) for formation of **2** or **3** is 2 h, of **4** 3 h, and of **6** or **7** 5 h at room temperature. Presumably in the photolysis of **1** or **5** the corresponding coordinatively unsaturated fragment $(C_6R_6)Ru(PR'_3)$([Ru]) is formed initially and then reacts with the arene or (in $C_6H_{12}$) with a C–H bond of the phosphane. The solvent



Scheme 1.

does not participate in the formation of **4** since the complex (with Ru–H bonding) is also formed in $C_6D_{12}$.

Scheme 2.

The metallaheterocycle **4** reacts with benzene at room temperature in *ca.* 5 min to give the hydrido(phenyl)-complex **3** and with $C_6D_6$, analogously, to give [$D_6$]-**3**. The 16-electron fragment $(C_6H_6)Ru(PiPr_3)$ ([Ru]) is presumably once again formed as intermediate. **3** and [$D_6$]-**3** are interconvertible at room temperature. These reactions are essentially slower than those of **4** with $C_6H_6$ or $C_6D_6$; completion of reaction is reached only after *ca.* 24 h. A Ru($\eta^2$-$C_6H_6$)- or Ru($\eta^2$-$C_6D_6$)-intermediate could be formed during conversion of **3** into [$D_6$]-**3** and *vice versa*, as has recently been assumed for similar rhodium compounds[5a]. The hydrido(tolyl)-complex **2** reacts with $C_6D_6$ at 40 °C in 6 h to give [$D_6$]-**3**; the identity of **2** is confirmed by independent synthesis from $(C_6H_6)Ru(C_6H_4Me)(PiPr_3)Br$ and $NaBH_4$ in ethanol.

That the postulated intermediate [Ru] in the reactions of **1** and **5** (Schemes 1 and 2), in contrast to $(C_5Me_5)Ir(PMe_3)$[2a] and $(C_5Me_5)Ir(CO)$[2b], does not react with cyclohexane to give a cyclohexyl(hydrido)-complex under the chosen conditions is presumably due to a greater lability of the RuH(R) group with respect to reductive

[**] Delivered in a lecture at the XIIth Sheffield-Leeds International Symposium on Organometallic, Inorganic and Catalytic Chemistry in Sheffield (England) on March 28, 1983. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by gifts of chemicals from BASF AG, Ludwigshafen and DEGUSSA AG, Hanau. We thank Dr. *G. Lange* and Dr. *D. Scheutzow* for recording the mass spectra and 400 MHz NMR spectra.

elimination rather than to a lower reactivity of [Ru] towards an $sp^3$-C–H bond. 5d-Metals (such as, *e.g.*, iridium) form more stable M–H and M–C bonds than 4d-metals (such as, *e.g.*, ruthenium), another finding consistent with the results published recently by *Jones* and *Feher*[5b]. We assume that a higher charge density at the central atom caused by the ligand in addition to the greater number of electrons of the metal effects stabilization of the M–H and M–C bonds. This hypothesis is supported by the fact that the complex **7** (with the better donor $C_6Me_6$ compared to $C_6H_6$), unlike **3**, does not react with $C_6D_6$ to give $(C_6Me_6)RuD(C_6D_5)(PMe_3)$ even on prolonged heating at 50 °C.

## Intramolecular Carbene-Carbon Monoxide Coupling in Chromium and Tungsten Complexes**

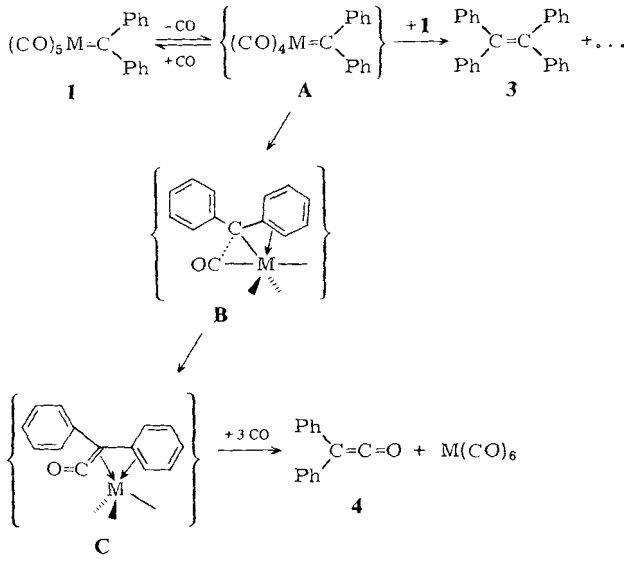
By *Helmut Fischer**

Transition-metal induced CC bond-forming reactions between CO and $CR_2$ as well as between two $CR_2$ moieties have recently been proposed as possible steps in the Fischer-Tropsch synthesis. Bond formation between two $CR_2$ ligands giving the dimer is a reaction characteristic of the decomposition of carbene complexes: thermolysis of pentacarbonyl(diphenylcarbene)tungsten **1** in refluxing heptane gives diphenylmethane **2** (10%) and tetraphenylethylene **3** (35%)[1]. Among the organic products formed in the mild thermolysis (20 to 50 °C) of dilute solutions of **1** $5\times10^{-2}$ to $10^{-3}$ mol/L) in polar or nonpolar solvents (methylcyclohexane, toluene, dibutyl ether, 1,1,2-trichloroethane), in addition to **2** and **3** the product of CO-carbene coupling, diphenylketene **4** was detected in 20 to 70% yield.

**1** **2** **3** **4**

Diphenylketene was identified by comparison of its spectra and its gas chromatogram with those of an authentic sample. At 50 °C the half-life of **1** upon thermolysis in 1,1,2-trichloroethane is *ca.* 1400 s ($[\mathbf{1}]_0=0.008$ mol/L). With increasing concentration of the complex the reaction rate increases slightly, whereas the yield of **4** decreases. The thermolysis proceeds significantly slower in nonpolar solvents than in polar. The reaction rate is reduced by the presence of free CO in the solvent, particularly with nonpolar solvents. The chromium compound analogous to **1** reacts at least 50 times faster or under even milder conditions (half-life at 32 °C, *ca.* 150 s). **4** is also formed from the chromium complex by warming the solid substance *in vacuo* (32 °C, *ca.* 15 min). If the thermolysis of **1** under $^{13}$CO is interrupted after *ca.* 25% conversion and the resultant **4** subsequently converted by treatment with methanol into methyl diphenylacetate, mass spectroscopic analysis of this ester indicates that $^{13}$CO is *not* incorporated into **4**. The CO group in the diphenylketene therefore originates from the coordination sphere of the metal. Hexacarbonyltungsten, which is formed simultaneously, consists of a mixture of $(^{12}CO)_{6-n}(^{13}CO)_nW$ (n = 0 to 4).

These results together with the results of kinetic studies and the determination of the yield of **4** as a function of the concentration of complex indicate that bond formation between a CO and the $CPh_2$ ligand to give diphenylketene proceeds *intramolecularly* in a $(CO)_4W(CPh_2)$ complex fragment produced by elimination of CO. In contrast, the dimerization of the carbene ligand to tetraphenylethylene presumably proceeds *via* a dinuclear intermediate. Whether this intermediate dissociates directly, eliminating olefin **3**, or whether carbene transfer occurs to form a biscarbene complex from which **3** cleaves off cannot yet be clarified. A corresponding bimolecular mechanism involving formation of a biscarbene complex has been proposed for the thermolysis of pentacarbonyl(2-oxacyclopentylidene)chromium on the basis of kinetic studies[2]. Scheme 1 may, therefore, be the best description of the course of the thermolysis of **1**.



Tricarbonyl(vinylcarbene)iron complexes related to intermediate **B** are known. In the presence of CO at room temperature, they insert CO into the metal-carbene carbon bond[3].

Carbonylation of a diphenylcarbene- to afford a diphenylketene-ligand has previously been reported using manganese complexes; however, the reaction is slower and requires high pressure[4]. In contrast to these reactions, the coupling of coordinated CO and $CPh_2$ in **1** and the analogous chromium complex occurs spontaneously under very

Scheme 1.

mild conditions without having to be induced by external CO or other nucleophiles. These results corroborate the mechanism proposed by *Rüchardt* and *Schrauzer* for the formation of ketenes in the reaction of diazoalkanes with tetracarbonylnickel[5a]. The ready interconversion (carbene)carbonyl complex/ketene complex (corresponding to **A** ⇌ **C**) could be proved in an iron system by labeling experiments[5b], and corresponds to the predictions of MO calculations[5c].

For chromium and tungsten compounds, both types of C-C coupling reactions—carbene-carbene and CO-carbene—have now been shown to occur simultaneously and at the same complex.

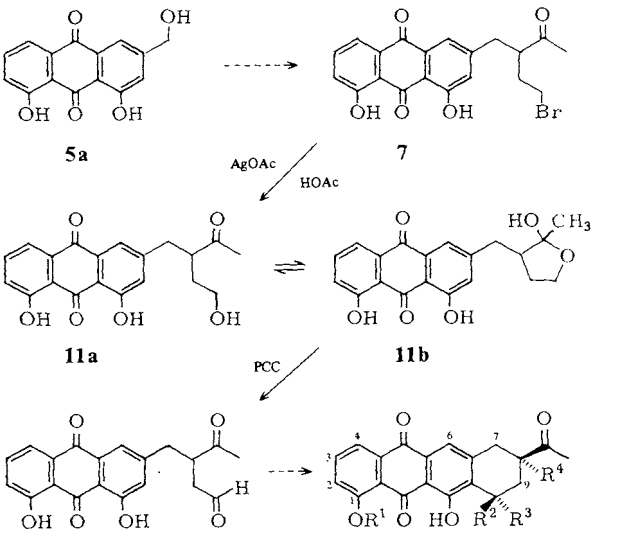
## Facile Synthesis of the (±)-6-Deoxycarminomycinone from Aloe-Emodin**



By *Karsten Krohn** and *Burkhard Sarstedt*

*Dedicated to Professor Hans Brockmann on the occasion of his 80th birthday*

The daunorubicin group of antitumour antibiotics[5] has recently been extended by the discovery of the possibly less toxic analogous 6-deoxy compounds (*e.g.* **2b**)[2]. We report here a seven-step synthesis of the racemic 6-deoxycarminomycinone **2a**[***] from the readily accessible aloe-emodin **5a**.

The acetal of the keto bromide **7**, which can be prepared in three stages from **5a** (70% yield)[18], surprisingly does not cyclize to the linearly condensed naphthacenequinone **3a** after reduction to the leuco form, but to a benzo[*a*]anthracene[18]. Since aldehydes always add to phenols at the *ortho*-position to the OH group, we synthesized the aldehyde **9** in order to study its cyclization.

Bromide **7** reacts with silver acetate in glacial acetic acid to afford a product (87%) which, according to the $^1$H-NMR spectrum ($CDCl_3$), is a mixture of the keto alcohol **11a** and the cyclic hemiacetal **11b**. The keto aldehyde **9** (55%) is formed by oxidation of **11a/11b**. Reduction of aldehyde **9** with alkaline dithionite to give leuco-anthraquinone is followed within a few minutes by the spontaneous cyclization to the 3 : 1 mixture of alcohols **12** and **13** (80%). The *cis*- and *trans*-compounds **12** and **13**, respectively, can be readily separated by chromatography. Because of the *trans*-diaxial interaction between 9(a)-H and 10-H the structure of **12** can be assigned straightforwardly from the $^1$H-NMR spectrum. The synthesis of **2a** is completed by hydroxylating C-8; for this purpose, the stereoisomers **12** and **13** need not be separated.

**2a**, $R^1 = R^2 = H$, $R^3 = R^4 = OH$
**2b**, $R^1 = CH_3$, $R^2 = H$, $R^3 = R^4 = OH$
**3a**, $R^1$–$R^4 = H$
**12**, $R^1 = R^3 = R^4 = H$, $R^2 = OH$
**13**, $R^1 = R^2 = R^4 = H$, $R^3 = OH$
**14**, $R^1 = R^3 = H$, $R^2 = R^4 = OH$

Oxygenation of the enolate obtained from **12/13** (dimethyl formamide, potassium *tert*-butoxide, −20°C) in the presence of triethyl phosphite leads to a mixture of (±)-6-deoxycarminomycinone **2a** (11%) and the epimer **14** (32%), which equilibrates upon addition of trifluoracetic acid (**2a** : **14** = 8 : 1)[3]. The spectroscopic data of racemic **2a** (m.p. = 215–216°C) are consistent with the literature values[8]. Chromatographically, (±)-**2a** behaves like optically active 6-deoxycarmonomycinone (m.p. = 176–177°C), which was obtained from naturally occurring 6-deoxydaunomycinone **2b**[2] by cleavage of the methyl ether ($AlCl_3$)[28].

## First Proof of di-, tri-, and all-*cis*-Conformations in Sterically Hindered Trimethinecyanines (Carbocyanines) of the Indoline and Benzothiazole Series**

By *Rudolf Allmann, Hans-Joachim Anis, Reinhard Benn, Walter Grahn*, Stanislaw Olejnek,* and *Alicja Waśkowska*

We have undertaken a systematic investigation of the effects of structural variations on the charge distribution and stereochemistry in cyanines and other cationic polymethines. These properties are of importance for the chemical and physical properties of the dyes and for their applications in photography[3] and laser technology. In addition, cyanines are model compounds for the chromophore of (bacterio)rhodopsin[5].

To study the steric effects, we selected the readily accessible trimethinecyanines (carbocyanines) **1** and **2** for the following reasons:

1) Molecular models of **1** and **2** indicate that if their methine chains (C2–C10–C11–C10′–C2′) adopt the normal planar all-*trans*-conformation, marked steric interactions occur between the terminal groups E,E′ and bulky substituents X.
2) According to previously reported UV/VIS[6], $^1$H-NMR spectroscopic[7], and X-ray crystallographic[8] findings, these interactions are relieved by torsions about the nonrigidized methine chains and by changing from the all-*trans*- to the mono-*cis*-(*EZEE* and *EEZE*) conformations. Opposing substituent-induced shifts and changes in intensity of the absorption bands of **1a** and **2a** (see Table 2+4) suggest that the steric effects of X lead, in particular, to conversion of the all-*trans*-form into unknown conformations.

**1,2** all-*trans* *EEEE*

To determine these and to clarify the effects of substituents X on the light absorption of **1a** and **2a**, we have studied **1** and **2d** by $^1$H-NMR spectroscopy between *ca.* −100 and 35 °C. We interpret the temperature-dependent spectra of the methyl, ethyl, and phenyl derivatives **1b**, **1c**, and **1e** as arising from isomerization between the degenerate conformers tri-*cis*(*ZEZZ*) **3** and tri-*cis*′(*ZZEZ*) **3′**, which in **1b** is frozen at −98 °C ($\Delta G_c^{\ddagger} = 38.5$ kJ/mol). In contrast, in the *tert*-butyl compound **1d** the process, which is interpreted as isomerization between the degenerate conformers all-*cis* **4** and all-*cis*′ **4′**, is frozen at *ca.* 0 °C ($E_A = 48.43 \pm 1.09$ kJ/mol, $\Delta S^{\ddagger} = -11.5 \pm 1$ J K$^{-1}$ mol$^{-1}$). The previously unobserved[7] temperature dependence of the $^1$H-NMR spectrum of the *tert*-butyl compound **2d** with benzothiazole groups can be explained by isomerization

[**] Conformational Analysis of Polymethines, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We thank Dr. *T. Debaerdemaeker*, Universität Ulm, for the MULTAN calculations on the structures of **1b** and **1d**.

between the degenerate conformers di-*cis*(*EZZE*) **5** and di-*cis*'-(*EZZE*) **5'**, which is frozen at −96 °C.

The $^1$H-NMR spectroscopic findings were corroborated by X-ray structure analyses of **1b**, **1d**, and **2d**. In the crystal, the cations of the cyanines adopt the same conformations as in solution. The pronounced twisting of the methine chain in **1d**, for example, forces the N atoms separated by 298 pm to lie almost on top of each other (cf. **4** and **4'**).

In principle, the cations in **1** and **2** can assume ten conformations which form five classes: all-*trans*, mono-, di-, tri-, and all-*cis* (cf. **3**–**5**). Now, one example of each of these is known. A sixth conformation, the unsymmetrical di-*cis*(*ZZEE* and *EEZZ*)-form, was observed in the crystalline 10,10'-dimethyltrimethinecyanine of the indoline series[17].

The steric demands of the substituents X and the groups E,E' determine the respective conformation and the position of equilibrium between the conformers (Table 2+4). In accord with inspection of molecular models, the steric interactions between X and E,E' in the all-*trans*-form adopted by **1a** and **2a** thus cause the changes in conformation. The different effects of the alkyl and phenyl groups X on the light absorption of **1a** and **2a** (Table 2+4) arise from these conformational changes which, because of the different steric demands of the groups E and E', produce different effects in the two dye series. This becomes particularly noticeable with the *tert*-butyl group: in the indoline series **1** this leads to the hypsochromic shift of the longest wavelength absorption band and to a change in conformation from all-*trans* to all-*cis*; in contrast, in the benzothiazole series **2** it leads to a bathochromic shift of the longest wavelength absorption band and transformation of the all-*trans*- into the all-*cis*-form and not—as previously suggested[7]—into the mono-*cis*-form.

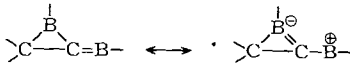
## A Boron-Carbon Double Bond**

By *Hartmut Klusik* and *Armin Berndt**

2,4-Diboramethylenecyclopropane [borirane-2-ylideneborane(2)] **3** is the first compound containing a B=C double bond. It is formed on reaction of 1,1-bis(*tert*-butylchloroboryl)-2,2-bis(trimethylsilyl)ethene **1**[1] with K/Na alloy in boiling pentane (yield 60%).



The structure of **3** follows from $^1$H-, $^{13}$C- and $^{11}$B-NMR spectra[2]. Signals for the two C-atoms of the $C_2B_2$ skeleton appear below −40 °C at $\delta = 115.2$ and 25.0 in the region for $sp^2$ and $sp^3$ C-atoms; both signals show line-broadening characteristic of a C-atom bound to boron. Hence the structure of a 2,3-diboramethylenecyclopropane[3] for **2** can be ruled out. Below −11 °C the B atoms give rise to

[*] Prof. Dr. A. Berndt, H. Klusik

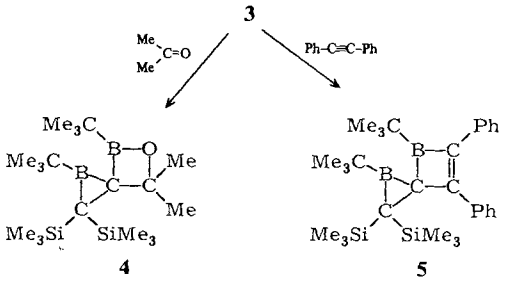
[**] This work was supported by the Fonds der Chemischen Industrie. We thank Dr. *P. H. M. Budzelaar* and Dr. *S. M. van der Kerk*, Utrecht, for the first hints on the structure of the compound **3**, and Prof. *K. Dehnicke*, Marburg, and Prof. *P. v. R. Schleyer*, Erlangen, for valuable discussions.

two signals at $\delta = 52$ and 18, which are shifted noticeably upfield compared to those of trialkylboranes ($\delta^{11}B \approx 80$). Upfield shifts are characteristic of sp-hybridized boron atoms: for iminoboranes, signals were found at $\delta = 2$–13[4]. We therefore assign the signal at $\delta = 18$ to the B-atom of the B=C bond; the upfield shift for the B-atom in the three-membered ring is presumably due to conjugation with the double bond.



The *tert*-butyl groups also give rise to two signals in the intensity ratio 1:1 in the $^1$H-NMR spectrum below $-47$°C, and in the $^{13}$C-NMR spectrum below $-30$°C. Increasing the temperature leads *via* line-broadening to coalescence and line-narrowing, both in the case of these signals as well as the signals of the boron atoms. In contrast, only one sharp signal is observed for the two trimethylsilyl groups between $-100$ and $+25$°C in the $^1$H-, $^{13}$C- and $^{29}$Si-NMR spectra.

From the coalescence temperatures ($-47$, $-30$ and $-11$°C) for $^1$H, $^{13}$C and $^{11}$B and the accompanying shift differences there results an energy barrier of 11.4 kcal/mol, which we assign to the topomerization of **3** by diboramethylenecyclopropane rearrangement.

**3** shows two bands in the Raman spectrum at 1675 and 1715 cm$^{-1}$ in the intensity ratio 4:1, which we ascribe to the $^{11}$B=C and $^{10}$B=C stretching vibrations, respectively.

**3** is storable for months in the absence of oxygen and water and no change is observed on heating at 100°C for 1 h. The stability of the compound is probably due to steric shielding by the four bulky substituents. Even the derivative of **3** in which one trimethylsilyl is replaced by a methyl group undergoes dimerization. **3** reacts with acetone at $-60$°C to give the 1,2-oxaboretane **4**, and with tolane at $-30$°C to give the 2-boretene **5**.

The structures of **4** and **5** are consistent with the $^1$H- and $^{13}$C-NMR spectra[2]. The spatial proximity of a $Me_3Si$ group to a methyl- and phenyl group, respectively, in **4** and **5** manifests itself in **4** in restricted rotation of this trimethylsilyl group, in **5** in significant shielding of its protons ($\delta^1H = -0.23$ compared to $+0.2$ in the case of **4**). At room temperature, products are formed from **4** and **5** whose structures are under investigation.

## Tetra-*tert*-butyltetrahedrane: $^{13}$C-$^{13}$C Coupling Constants and Hybridization

By *Thomas Loerzer, Reinhard Machinek, Wolfgang Lüttke*, Lothar Hermann Franz, Klaus-Dieter Malsch,* and *Günther Maier**

*Dedicated to Professor Hans Brockmann on the occasion of his 80th birthday*

NMR coupling constants $^1J$(C–C) represent a spectroscopic quantity with which the electron distribution in CC bonds can be characterized[1]. We therefore determined $^1J$(C–C) for the most highly strained hydrocarbon, tetra-*tert*-butyltetrahedrane **1**[2].

In the NMR investigation the problems associated with the limited sensitivity of measurement and the magnetic equivalence of the tetrahedrally arranged C atoms had to be overcome. According to model calculations the complete set of data should be obtainable from the tetrahedrane **1a** in which a *tert*-butyl group is labeled to 90 atom-% with $^{13}$C at one of the quaternary centers. Together with the $^{13}$C-atoms occurring in natural abundance at the corners of the tetrahedron one obtains, *inter alia*, the isotopomer **1b**; its ABM spin system enables determination of the coupling constant $^1J(C_r-C_r)$ between the ring carbon atoms. **1b** has a natural abundance of $2.7 \times 10^{-4}$ and is therefore just measurable with modern spectrometers.

•: $^{13}$C-Atom

**1a** was synthesized using [1-$^{13}$C]-1,1-dimethylethyllithium and 2-bromo-3,4,5-tri-*tert*-butylcyclopentadienone as starting materials[3]. Evaluation of the {$^1$H}-$^{13}$C-NMR spectrum of **1a** (330 mg **1a**, solvent [$D_{10}$]$Et_2O$, 50.4 MHz) gave the data listed in Table 1.

Table 1. $^{13}C$-$^{13}C$ coupling constants [Hz] of tetra-*tert*-butyltetrahedrane [a].

| $^1J(C_r-C_r)$ | $^1J(C_r-C_q)$ | $^2J(C_r-C_q)$ | $^1J(C_q-C_m)$ |
|---|---|---|---|
| 9.2 | 64.0 | −0.7 | 35.8 |

[a] $C_r$ = ring C-atom, $C_q$ = quaternary C-atom of a *tert*-butyl group, $C_m$ = methyl C-atom. Mean error: ±0.05 Hz.

The value of 9.2 Hz for $^1J(C_r-C_r)$ is almost as large as $^1J(C-C)$ for cyclopropane (12.4 Hz)[4a], thus indicating a similar s-character of the hybrid orbitals participating in the ring C–C bonds; for cyclopropane this can be determined very accurately from $^1J(CH)$ as 0.179[4a]. If it is assumed that the contribution of the non-contact terms to the overall coupling in these compounds is the same, then a somewhat smaller s-character of 0.161, corresponding to an $sp^{5.20}$-hybridization, is obtained with the previously reported relationship $^1J_{CC}=658\ s_1s_2-7.9$ for the hybrid orbitals of the tetrahedral C-atoms of **1** which participate in the ring CC bonding. Our SCPT-INDO calculations[4b], however, suggest that the contribution of the (here negative) non-contact terms in **1** is about 20% greater than in cyclopropane. If this is taken into consideration, then only a slightly greater s-character of *ca.* 0.170 results for **1** ($sp^{4.88}$; INDO[5a]: $sp^{4.99}$).

A further indicator for the hybridization of the C-atoms of the tetrahedrane skeleton can be obtained from the $^1J(C_r-C_q)$ coupling constant. Using the sum rule for hybrid orbitals[1a], it can be concluded that the hybrid orbital pointing from the $C_r$ to the $C_q$ atom is $sp^{1.04}$-hybridized (INDO[5a]: $sp^{1.21}$) and causes a correspondingly greater coupling constant. A comparison with the analogous couplings of various *tert*-butyl substituted hydrocarbons (Table 2) shows that the value for **1** (64.0 Hz) agrees well with that for *tert*-butylacetylene (66.1 Hz), whose acetylenic C-atoms unequivocally exhibit sp hybridization.

Table 2. $^{13}C$-$^{13}C$ coupling constants [Hz] [a] of *tert*-butyl compounds [4b].

| | $H_3C^x-C^q(CH_3)_3$ | $H_2C=C^xH-C^q(CH_3)_3$ | $HC\equiv C^x-C^q(CH_3)_3$ |
|---|---|---|---|
| $^1J(C_x-C_q)$ | 35.5 | 42.3 | 66.1 |
| $^1J(C_q-CH_3)$ | 35.5 | 35.5 | 35.4 |

[a] Mean error: ±0.1 Hz.

It follows from the hybridization of the C-atoms of the tetrahedrane skeleton that the axes of the "endocyclic" hybrid orbitals are in each case bent outwards from the edge of the ideal tetrahedron by about 28.4°. Thus, the "bent-bond" character is much more pronounced here than in the case of cyclopropane (21.3°)[4a].

The theoretical predictions[5] on the bonding properties of the tetrahedrane system are in agreement with these results.

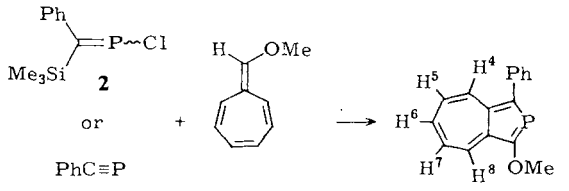
## 1-Methoxy-3-phenyl-2-phosphaazulene—the First Synthesis of 2-Phosphaazulenes

By *Gottfried Märkl**, *Ernst Seidl*, and *Irene Trötsch*

We recently described the synthesis of **1**, the first 1-phosphaazulene, in which the initial step is a McCormack cycloaddition of benzyldichlorophosphane to vinylcycloheptatriene[1b].

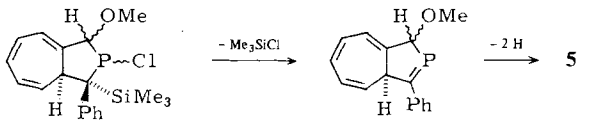


**1**

The synthesis of the first 2-phosphaazulene starts from the 1-chloro-2-phenyl-2-trimethylsilylphosphaethane **2**[1a] or the 2-phenyl-1-phosphaethyne **3** formed on elimination of chlorotrimethylsilane from **2**—whose dienophilic reactivity we recently demonstrated by [4+2]-cycloaddition with α-pyrones and cyclopentadienones to give $\lambda^3$-phosphorins[2].

According to *Daub et al.*[3], the electron-rich 8-methoxyheptafulvene **4** reacts regioselectively with reactive alkenes and alkynes, *e.g.* 1,1-dicyanoethenes, nitroethenes or diethyl acetylenecarboxylate, to give 3,8a-dihydroazulenes, which on suitable substitution can be converted into azulenes with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) *via* dehydrogenation or with acid catalysts by elimination of methanol.

We have now found that **2** (or **3**, see ref.[2]) reacts with **4** in boiling xylene in the presence of KF/[18]crown-6 in 2 h in a regioselective [8+2]-cycloaddition to give the 1-methoxy-3-phenyl-2-phosphaazulene **5**. After chromatographic isolation and purification, **5** is obtained in the form of red platelets (yield 6%, m.p. 85—87 °C) which dissolve in $CHCl_3$ to give a green solution[4].



The $^1H$-NMR spectrum of **5**[5a] clearly demonstrates the regioselectivity of the cycloaddition; presence of the isomeric 1-phosphaazulene can be ruled out. As in the case of **1**, the downfield shift of the signals of the ring protons 4-H and 8-H, and to a lesser extent of 6-H, is consistent with the dipolar structure of the azulenes. The $^{31}P$-NMR chemical shift ($CDCl_3/CHCl_3$, $\delta=+177.9$) is characteristic for trivalent phosphorus with coordination number 2 in a resonance-stabilized system ($\delta$(**1**) = +168.3; $\delta$(2,4,6-triphe-

[*] Prof. Dr. G. Märkl, E. Seidl, I. Trötsch
Institut für Organische Chemie der Universität
Universitätsstraße 31, D-8400 Regensburg (Germany)

nyl-$\lambda^3$-phosphorin) = +178). The UV spectrum of **5** is likewise consistent with the azulene structure[5b], as is shown by a comparison with the longwave absorption maxima of 1-methoxyazulene[6] and 1-phenylazulene[7].

In the [8+2]-cycloaddition of **2** to **4**, the tetrahydroazulene **6**, or by primary formation of **3**, the dihydroazulene **7** must be formed initially. The aromatization of **6** or **7** to **5**

**6** **7**

must then proceed *via* a chlorotrimethylsilane elimination and a dehydrogenation (spontaneous dehydrogenations to azulenes are known[8]). The 1-phenyl-2-phosphaazulene to be expected in a primary acid-catalyzed elimination of methanol could not be observed.

## Novel Catalytic Application of a Transition-Metal Cluster: Spirocyclization of Alkyl Isocyanates

By *Georg Süss-Fink*, Gerhard Hermann,* and *Ulf Thewalt*

Ever since transition-metal clusters were discussed as catalysts[1], a great variety of such compounds have been prepared and characterized[2]. However, novel catalytic applications of these complexes still remain to be discovered[3]. Herein we report a novel homogeneously catalyzed spirocyclization of alkyl isocyanates providing a surprisingly simple access to [4.5]-spiroheterocycles. The reaction proceeds in the presence of triethylsilane and the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^-$, discovered recently in catalytic silylation reactions[4], as the catalyst (precursor).

Reaction of MeNCO with $Et_3SiH$ and $[N(PPh_3)_2][HRu_3(CO)_{10}(SiEt_3)_2]$ (5000 : 1000 : 1) in tetrahydrofuran solution at 150 °C yields the spirocyclic compound **1**, which upon cooling crystallizes from the reaction solution. Triethylsilanol and its condensation product hexaethyldisilanol are formed as by-products. The oxygen atom of one of the five isocyanate molecules incorporated in **1** is apparently removed by triethylsilane. Other aliphatic isocyanates react analogously, but the spirocyclization products, because of their better solubility, are only isolable by chromatographic methods. Phenyl isocyanate does not react under these conditions. The cluster anion employed as the catalyst is actually altered under the reaction conditions, but the organometallic residue obtained from the solution remains catalytically active on further use.

| | **1** | **2** | **3** |

The composition of the compounds **1**–**3** is confirmed by elemental analysis and (high resolution) mass spectrometry. The spectroscopic data (IR, $^1$H-NMR, $^{13}$C-NMR) are consistent with a spirocyclic system of NR- and CO-structural units. The structure of the methyl derivative **1** was determined by X-ray crystallography (Fig. 1).

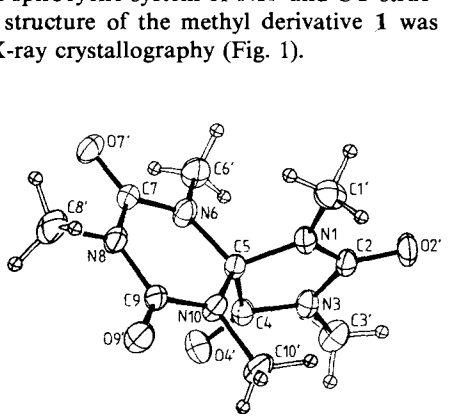

Fig. 1. Structure of the spiroheterocycle **1** in the crystal. Bond lengths [Å] in the rings: N1–C2 1.353(3), C2–N3 1.404(4), N3–C4 1.352(3), C4–C5 1.556(4), C5–N1 1.454(3), C5–N6 1.442(3), N6–C7 1.355(3), C7–N8 1.377(3), N8–C9 1.378(4), C9–N10 1.359(3), N10–C5 1.446(3). ## 1,2,4-Thiadiazole-3,5-dicarbonitrile by Reaction of Cyanogen with Sulfur**

By *Herbert W. Roesky**, *Klaus Keller*, and *Jan. W. Bats*

Cyanogen **1** reacts with sulfur trioxide in a criss-cross cycloaddition (molar ratio 1:2) to give a bicycle in which the CC bond of the cyanogen remains intact[1]. Reactions of **1** with elemental sulfur have so far never been described in the literature. As product of such a reaction in dimethylformamide at 120°C according to

$$1/8\,S_8 + 2(CN)_2 \longrightarrow (CN)_4S$$
$$\mathbf{1} \qquad\qquad \mathbf{2}$$

we have now isolated colorless crystals of the compound **2** (m.p. 67°C, yield 29%). It follows from the $^{13}$C-NMR spectrum that **2** contains four non-equivalent carbon atoms ($\delta = 161.5, 147.6, 111.7, 110.1$). No bands appear in the C≡N stretching vibration range in the IR spectrum, whereas the Raman spectrum shows three bands at 2248, 2256, and 2267 cm$^{-1}$. In the FI-mass spectrum of **2** the molecule appears at $m/z = 136$ and the fragment $(CN)_2S^+$ at $m/z = 84$.

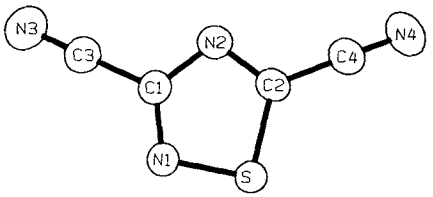

Fig. 1. Structure of 1,2,4-thiadiazole-3,5-dicarbonitrile **2** in the crystal. Bond lengths [Å] and angles [°]: N1–S 1.621(2), C2–S 1.697(2), C2–N2 1.301(3), C1–N2 1.357(3), C1–N1 1.300(3), C2–C4 1.428(3), C4–N4 1.139(3), C1–C3 1.438(3), C3–N3 1.129(3); N1–S–C2 92.1(1), C1–N1–S 107.9(2), N1–C1–N2 120.3(2), C1–N2–C2 106.7(2), N2–C2–S 113.1(2). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50279, the names of the authors, and full citation of the journal.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and Hoechst AG.

According to a single crystal structure analysis the molecule is almost planar (Fig. 1). Only one carbonitrile group C3N3 slightly deviates from the plane of the thiadiazole ring[2]. The packing leads to a contact distance of 305.0(2) pm between S and N4′ of an adjacent molecule; this distance is substantially shorter than the sum of the van der Waals' radii (335 pm). All other intermolecular distances are too long for participation of bonding between molecules.

## Reaction Control by Catalysts with Variable Specificity: Stable Palladium-Phthalocyanine as Hydrogenation Catalyst with Three Catalytic Patterns**

By *Heiner Eckert**, *Gudrun Fabry*, *Yvonne Kiesel*, *Gabriele Raudaschl*, and *Christoph Seidel*

The directed control of the course of a reaction might be realized by means of a catalyst having variable specificity[1]. The specificity of a metal-complex catalyst is dependent upon internal and external parameters (respectively, the metal and its valence *z*, type of ligand field *etc.*[3], and carrier material, reaction medium, reaction conditions, res-

Scheme 1. Reaction control by directed variation of the specificity of the catalyst Pd$^z$Pc with the catalytic patterns $P_1$–$P_3$. F = functional group, A = alkyl or aryl residue (see also Table 1).

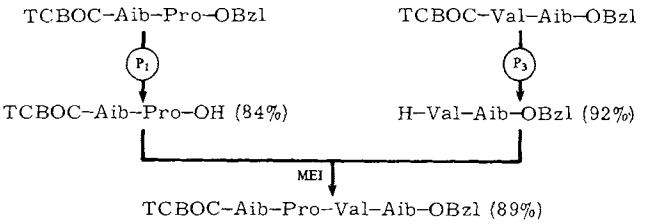
idence time, *etc.*) of the catalyst as well as the specific catalytic pattern $P_i$. The usual methods for achieving a certain specificity are either irreversible (*e.g.* modification of the catalyst by partial poisoning or special carrier materials) or lead to no significant catalytic pattern (*e.g.* kinetic control *via* the residence time)[2]; in both cases only a particular type of reaction can be catalyzed.

If, on the other hand, variation of the internal and external parameters is reversible *and* this variation causes specific catalytic patterns ($P_1$, $P_2$, $P_3 \ldots P_n$), then various reactions can be catalyzed with one catalyst, possibly even several successive steps of a multistep reaction.

In the case of thermally, chemically and photochemically stable palladium-phthalocyanine $Pd^zPc$, three patterns of catalysis can be regulated (Scheme 1 and Table 1).



According to catalytic pattern $P_1$, CC and CN double bonds as well as aromatic aldehydes and nitro compounds can be hydrogenated with $H_2$ on blue $Pd^{II}Pc$ ($z=2$) at pH < 9; benzyl esters can also be cleaved by hydrogenation; at pH ≥ 11, hydrogenation can be carried out according to $P_2$; the same reactions are catalyzed as in the case of $P_1$, but in addition the selective dehalogenation of aryl halides can be carried out. Changing the valency to $z=1$ by addition of $NaBH_4$ effects catalysis on black $[Pd^IPc]^\ominus$ according to $P_3$[3a]. CC and CN double bonds (olefins, enamines, and azomethines), aliphatic and aromatic aldehydes, ketones, acyl chlorides, nitriles and nitro compounds as well as aliphatic halides can be reduced in good yields and *O*-β-haloalkyl groups reductively fragmented. Aryl halides remain intact and benzyl groups are not attacked reductively. The changes in the catalytic pattern are reversible: by oxidative acidolysis of the hydride and appropriate adjustment of the pH the catalytic pattern $P_1$ or $P_2$ is again possible.

If the variability of the specificity of the catalyst is expressed in terms of the specific catalytic patterns $P_i$, then the sum of the catalytic patterns $P_i$ can be defined as the *effective specificity S*.

$$S = \sum_{i=1}^{n} P_i ; \qquad i = 1, 2, 3 \ldots n$$

Consequently, in the case of $Pd^zPc$, $S=3$.

Catalyses on uncharged $Pd^{II}Pc$ necessitate a π-electron-rich system in the substrate. In contrast, the nucleophilic $[Pd^IPc]^\ominus$ anion catalyzes reactions at the electrophilic center of a substrate. As a consequence, the catalytic patterns $P_1-P_3$ are also inversely selective with respect to certain reactions. The possibilities for controlling reactions in multistep syntheses can be illustrated by the synthesis of the subsequence 13–16 TCBOC-Aib-Pro-Val-Aib-OBzl[7a] of the peptide antibiotic alamethicin[9] (see Scheme 2).

Scheme 2. Reaction control by the catalyst $Pd^zPc$ in the synthesis of the subsequence of alamethicin[7,9].

Reaction according to $P_1$ leads to selective cleavage of the benzyl residue with retainment of the TCBOC residue, whereas reaction according to $P_3$ leads to removal of TCBOC residue (inverse selectivity), with the benzyl residue remaining intact.

A self-initiation of the system $Pd^{II}Pc/H_2$/solvent in air could not be observed in any of the experiments. The catalyst $Pd^{II}Pc$ can be recovered quantitatively and used again without further treatment.

# Flip-Flop Hydrogen Bonds in β-Cyclodextrin—A Generally Valid Principle in Polysaccharides?**

By *Wolfram Saenger**, *Christian Betzel*, *Brian Hingerty*, and *George M. Brown*

*Dedicated to Professor Friedrich Cramer on the occasion of his 60th birthday*

In crystal structure analyses on cyclodextrins (CD)[1] the positions of all H atoms could be determined only in a few structures of α-CD but not in any of the larger β- and γ-forms, because of the large size of the unit cells and of the disorders frequently found in host molecules or molecules of water of hydration. But a knowledge of such positions is required in order to define the many H-bridges of type O–H···O. All H-atom positions in α-CD·6$H_2O$[4], and now even in β-CD·11$H_2O$, have been determined by neutron diffraction, revealing in the latter case an interesting scheme of hydrogen bonds.

In β-CD·11$H_2O$ the 11 water molecules in the β-CD cavity and between the cyclodextrin molecules are randomly distributed over 18 positions. The neutron diffraction investigation shows that this disorder is accompanied by a disorder of the H-bonds, leading to interactions of the type O–H···H–O, where the two H-atoms are only about 1 Å apart form each other, *i.e.* too near for both to be present at the same time. This is confirmed by the occupation parameters of the H atoms, which are on average 0.5 and, to a good approximation, add to give 1.0 for a hydrogen bond of this type. From this, it was concluded that an equilibrium O–H···O ⇌ O···H–O of normal H-bonds is established and that we "see" only the averaged state. Since in some cases these systems form longer chains,

$$\text{O–H···O–H···O–H···} \rightleftharpoons \text{H–O···H–O···H–O···}$$

and a flipping of the OH groups from one direction to the other must proceed cooperatively, we have called the O–H···H–O bridges flip-flop bonds[7].

Calorimetric measurements on β-CD·11$H_2O$ indicated an exothermic reaction at −46 °C[8], which we interpret as a flip-flop ordering process in one of the two possible directions. Recent neutron diffraction studies at −100 °C confirm this, and show that flip-flop bridges indeed behave dynamically and not only exist in static disorder.

Similar H-bridges of the type O–H···H–O have already been found in ice and ice-clathrates and effect the zero-point entropy in ice of 0.87 cal $mol^{-1}$ $K^{-1}$[10]. The disorder of the H-atoms in these systems is enforced by the high crystallographic symmetry, which fixes the positions of all the atoms. Since all O–H···H–O bridges in β-CD·11$H_2O$ are formed symmetry-independently, a *fundamentally* new situation is present here which probably has general validity for the hydration of complex molecular structures.

Several flip-flop arrangements are present in the crystal of β-CD·11$H_2O$, but only two characteristic ones will be discussed here. The first flip-flop chain winds itself around the $2_1$ screw axis and runs as an "infinite" spiral through the whole crystal structure. The chain is made up of water molecules W1 and hydroxy groups O(26), O(37), which belong to the same β-CD molecule.

···H–OW1–H···H–O(26)–H···H–O(37)–H···
H–OW1–H···H–O(26)–H···

Chains running through the entire lattice have already been observed in other structures, as also in α-CD·6$H_2O$; these chains, however, represent the normal type O–H···O–H···O–H, and all O–H···O bridges point in the same direction, indicating the influence of the cooperative effect[13].

The second characteristic flip-flop arrangement is limited to the β-CD molecule, in which *intra*molecular flip-flop bridges are formed between all O(2),O(3) hydroxy groups of adjacent glucose moieties (Fig. 2); the hydroxy H-atoms not participating in the flip-flop bonds do, however, participate in hydrogen bonding to "external" hydroxy groups (see also Fig. 1 in Supplement).

The formation of the flip-flop bridges between O(2) and O(3) is favored by an almost ideal O(2)···O(3) distance (mean value 2.85 Å), which is slightly greater than the

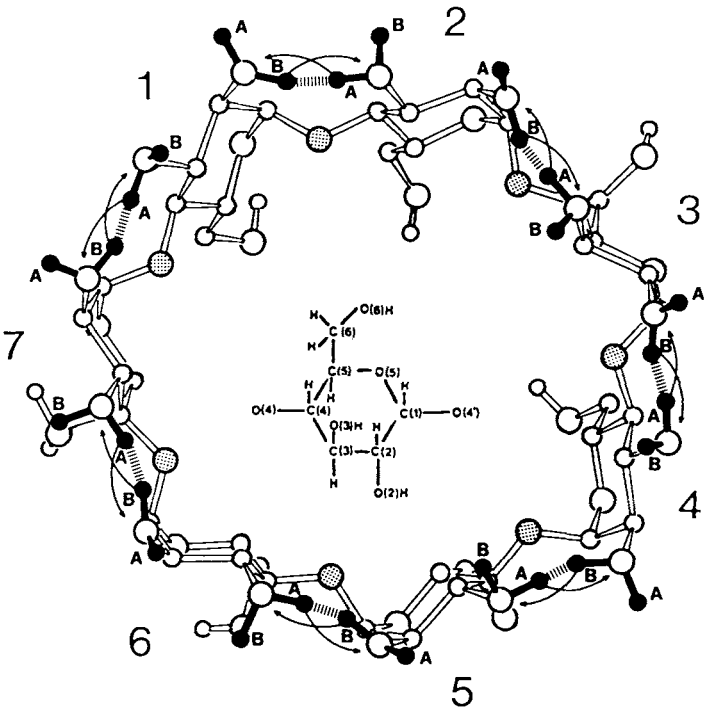

Fig. 2. Molecular structure of β-cyclodextrin in the crystal of β-CD·11$H_2O$. H-atoms on O(6) are shown as small open circles, on O(2),O(3) as small black circles, all other H-atoms have been omitted; O- and C-atoms are symbolized by large and medium sized circles, glucosidic O-atoms by dotted circles. The formula in the center illustrates the atomic designation. The ring-shaped structure of β-CD is stabilized by flip-flop hydrogen bridges of the type O–H···H–O between hydroxy groups O(2) and O(3) of neighboring glucose moieties. The corresponding H-atoms (A and B) cannot be present at the same time since the distances indicated by |||||||||| (≈1 Å) are too short. The H-atoms in each H-bridge are either only in position A or in position B (flip-flop). O–H···O Bridges between H-atoms (A, B) and O-atoms are indicated by bent arrows; they are in dynamic equilibrium. Between the positions A and B, which are adjacent to the glucosidic oxygen, and these oxygen atoms there are short distances of 2.23(5) to 2.58(2) Å, which are smaller than the sum of the van der Waals' radii (2.6 Å) and indicate weak attraction. Other distances in the H-bridges are: O(2)···O(3) 2.80(1) to 2.97(1) Å, O–H 0.87(2) to 0.98(2) Å, H···H 0.93(2) to 1.21(3) Å, O···H 1.83(2) to 2.12(3) Å.

standard distance of 2.75—2.80 Å. In addition, closer contacts (2.23(5)—2.58(2) Å) exist between H-atoms in O(2),O(3) flip-flop bridges and the adjacent glucosidic O(4) atoms than correspond to the ideal van der Waals' H···O distance of 2.6 Å; this points to an attraction, which, however, is weaker than in normal O—H···O hydrogen bridges with significantly shorter H···O distances of *ca.* 1.8 Å.

The flip-flop bridges should be of general significance in systems in which, similarly as in β-CD, special steric conditions provide favorable prerequisites. To such systems belong, in particular, polysaccharides such as starch, which has a helical structure—irrespective of whether one considers the A-, B- or V-form—and always contains neighboring O(2),O(3), hydroxy groups. Flip-flop bridges are entropically favored over normal O—H···O bonds, because of two energetically almost equivalent states. The H/D exchange, which is markedly smaller for β-CD than for α-CD and starch, also suggests particularly strong intramolecular interactions for the bonding of the hydrogen atoms to O(2),O(3).

## $[Mo_2(NO)_2(S_2)_3(S_5)OH]^{3-}$, a Complex Containing a Bidentate $S_5^{2-}$-Bridging Ligand in a $\{S_5Mo_2(S_2)\}$-Heterocycle with Cyclooctasulfur Geometry

By *Achim Müller**, *Werner Eltzner*, *Hartmut Bögge*, and *Erich Krickemeyer*

The structural chemistry of sulfur-containing complexes with a central $\{MoNO\}^{3+}$ moiety is very interesting. Thus, in $[Mo_4(NO)_4(S_2)_6O]^{2-}$ **1**[1a] and $[Mo_4(NO)_4(S_2)_5(S)_3]^{4-}$ **2**[1b], which have almost the same stoichiometry, one finds four different types of coordinated $S_2^{2-}$ ligands. Salts of **1** and **2** can be obtained, under slightly different conditions, by reaction of $\{MoNO\}^{3+}$-complexes[2] with $S_x^{2-}$ or $H_2S$. We have now succeeded in isolating the novel diamagnetic complex $[Mo_2(NO)_2(S_2)_3(S_5)OH]^{3-}$ **3** (Fig. 1a) in crystals of the salts $K_{1.5}(NH_4)_{1.5}[Mo_2(NO)_2(S_2)_3(S_5)OH]\cdot 2H_2O$ **3a** and $(NH_4)_3[Mo_2(NO)_2(S_2)_3(S_5)OH]\cdot 2H_2O$ **3b** and in characterizing it by elemental analysis, ESCA, UV/VIS, IR[3] and Raman spectroscopy, magnetic measurements and by a complete X-ray structure analysis of **3b**[4].

In the binuclear complex **3**, the anions $OH^-$, $S_2^{2-}$ ("roof-shaped" coordinated) and $S_5^{2-}$ act as bridging ligands. A complex with a bridging $S_5^{2-}$ ligand has hitherto not been reported. The pentagonal bipyramidal coordination of the molybdenum atoms, which also occurs in **1** and **2**, is completed by a side-on bonded $S_2^{2-}$-ligand and an NO-ligand. The equatorial plane of the bipyramids is made up of sulfur atoms only.

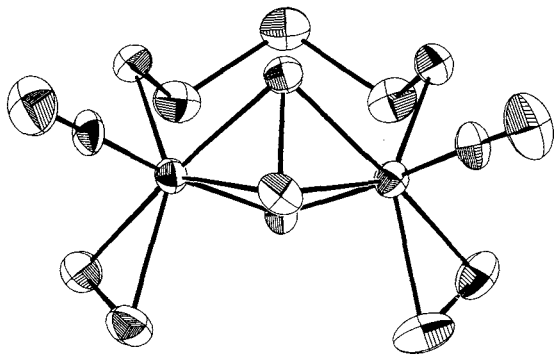

Fig. 1. Structure of the anionic complex **3** in crystals of **3b** in two different projections. Selected bond angles: S—S—S 108.2, S—S—Mo 108.1, S—Mo—S′ 111.6 (cf. text), Mo—S′—Mo 97.3, N—Mo—O3 173.4 (mean values), Mo—O—Mo 104.9(3)°. Further details of the crystal structure determination are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen on quoting the depository number CSD 50 504, the names of the authors, and full citation of the journal.

One structural aspect is particularly interesting since the eight-membered heterocyclic moiety $\{S_5Mo_2(S_2)\}$ has practically the same geometry as that of cyclooctasulfur (cf. Fig. 1b); the eighth ring atom (S′) is hereby assumed to be at the center of the $S_2^{2-}$ group. (A systematic structural chemistry of $S_2^{2-}$-complexes could perhaps be developed on the basis of this concept!).

The formation of **3** appears to be favored primarily by the fact that the pentagonal-bipyramidal environment of the central atoms, which is frequently observed in the case of $\{MoNO\}^{3+}$ complexes, is retained, but probably also because a crown form of the $\{S_5Mo_2(S_2)\}$-heterocycle is achieved, as in $S_8$. We suspect that it will be possible to prepare further metal complexes with "units" which formally correspond to derivatives of cyclooctasulfur.

Remarkably, **3** (in contrast to **1** and **2**) is formed only after prolonged reaction, the oxidation of $S_2^{2-}$ to $S_5^{2-}$ by atmospheric oxygen possibly playing an essential role (cf. Procedure[5]).

## $[Ph_4P]_2[V_2(SC_2H_4S)_4]\cdot 4MeOH$: The First Polynuclear Vanadium-Sulfur Complex with Pure Sulfur Coordination**

By *Detlef Szeymies, Bernt Krebs,* and *Gerald Henkel**

Polynuclear vanadium complexes with complete sulfur coordination were hitherto unknown. We have now been able to prepare the binuclear complex $[V_2(SC_2H_4S)_4]^{2-}$ **1** (Fig. 1) as the first representative of this class of compounds by reaction of $VCl_3$ with 1,2-ethanedithiolate and to isolate the dianion in red-brown crystals of $[Ph_4P]_2[V_2(SC_2H_4S)_4]\cdot 4MeOH$ **2**.

The complex **1** is also the first vanadium-sulfur compound in which the ligands have "pure thiolate character", since special electronic conditions are associated with the ligands of the known dithiolene complexes[3].

**1** could serve as an entry to the chemistry of polynuclear thiolate or sulfide-thiolate complexes of vanadium, which is well developed in the case of iron or molybdenum as demonstrated by numerous examples.

The metal atoms in the dinuclear anion **1** are symmetrically bridged by the S atoms of two 1,2-ethanedithiolate ligands in such a way that an almost square arrangement of the sulfur atoms results (S···S 281.9(1) to 301.8(1) pm, S···S···S 89.15(4) to 90.37(4)°, mean deviation from the best plane *ca.* 10 pm). The coordination number for each $V^{III}$ atom is increased to 6 by a terminally bound 1,2-ethanedithiolate ligand. The resulting coordination polyhedron can be derived from an ideal trigonal prism by rotating the S(5)–S(6) edge twofold the around axis on which the vanadium atoms are sited. This is demonstrated in Figure 2, which shows a schematic projection along the V–V axis to the plane of the four bridging sulfur atoms. The S(5)–S(6) edge of the prism is twisted through an angle μ from ideal symmetry; for the distorted prisms of the two metal atoms this angle is *ca.* 30° ($\mu_{V(1)}$) and 36° ($\mu_{V(2)}$), respectively.

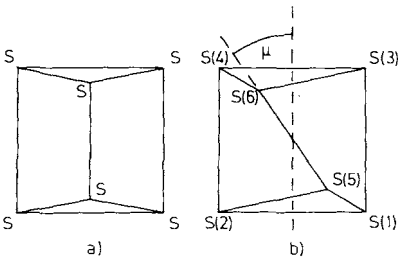

Fig. 2. Sulfur coordination about the metal atom V(1) (b), derived from an ideal trigonal prism (a).

The S···S distance within the terminal ligands, with an average value of 318.8 pm, is about 18 pm longer than the mean S···S distance within the bridging ligands (300.8 pm). This difference can be attributed to the *gauche* conformation of the terminal ligands, while the bridge ligands are in the eclipsed conformation. A particularly remarkable feature of the structure of **1** is the short distance between adjacent bridging S atoms which do not belong to the same dithiolate moiety. With an average value of 284.0 pm this distance is *ca.* 17 pm shorter than the S···S distance within the bridge ligands, and is thus indicative of a weakly bonding S···S interaction, as has also been discussed for the short S···S distance of *ca.* 307 pm in the mononuclear dithiolene complexes of vanadium, rhenium and molybdenum[3].

It has already been suggested that the structurally uncharacterized compounds $Cp_2V_2(SMe)_4$[18] and $Cp_2V_2(S_2C_2(CF_3)_2)_2$[19] contain a central $V_2S_4$ unit; the exis-

Corrensstrasse 36, D-4400 Münster (Germany)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

tence of a $V_2S_4$ core has now been demonstrated by a structural analysis in the case of **1**.

The distance between the vanadium atoms in the binuclear anion **1** is 257.5(1) pm. It thus lies between the values observed in $Cp_5V_5O_6$ (V···V 273.7(3) to 276.3(2) pm)[20] or $Cp_2V_2(CO)_5$ (V···V 246.2(2) pm), respectively, and $Cp_2V_2(CO)_4PPh_3$ (V···V 246.6(1) pm)[21], for which VV single and double bonds were discussed.

The UV/VIS spectrum of **1** shows two weak absorption bands at 615 and 540 nm and a shoulder at 470 nm. An intense band appears at 367 nm accompanied by a shoulder with about the same intensity at *ca.* 309 nm.

The IR spectrum exhibits a double absorption band below 400 $cm^{-1}$ at 365/354 $cm^{-1}$ (solid, CsI pellet); this could be caused by V–S stretching vibrations.

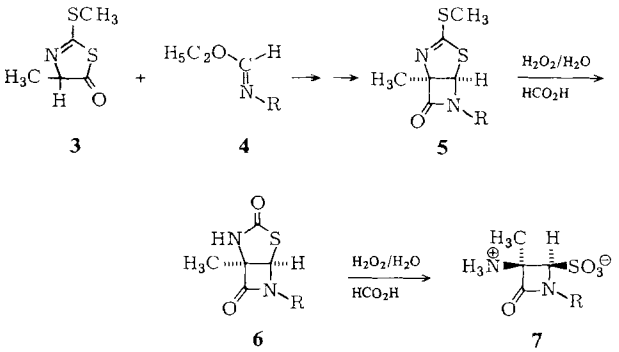
## Synthesis and Structure of (*Z*)-3-Amino-4-oxo-2-azetidinesulfonic Acids**



By *Dieter Hoppe**, *George M. Sheldrick**, *Ernst Egert*, and *Petra Kaars*

*Dedicated to Professor Hans Brockmann on the occasion of his 80th birthday*

Monobactams—*N*-acylated derivatives of the (*S*)-3-amino-2-oxo-1-azetidinesulfonic acid **1**—are naturally occurring β-lactam antibiotics[1]. Derivatives of the isomer **2** have so far never been described in the literature[2].

Herein we report a simple total synthesis of diastereomerically pure (racemic) (*Z*)-aminosulfonic acid **7** by oxidative-hydrolytic opening of the five-membered ring in the heterocycles **5**[3]; these dihydrothiazole-annelated azetidinones are obtained in only two steps from the thiazolone **3** and the formimidic acid esters **4**[3]. The conversion **5**→**7** was accomplished with aqueous $H_2O_2$ in formic acid—conditions under which we had previously obtained amines from open-chain imidothiocarbonates[4]. Reaction of with $H_2O_2$ in the molar ratio 1:6.5 in presence of *p*-toluene-**5**-sulfonic acid as catalyst afforded the crystalline, high-melting (m.p. > 260 °C) betaine **7** (Table 1); with a **5** : $H_2O_2$ ratio of 1 : 3, the 4-thia-2,6-diazabicyclo[3.2.0]heptane-3,7-diones **6** can be isolated. Thus, reaction is initiated by oxidation of the exocyclic sulfur atom in **5**; this is followed by hydrolysis and further oxidation steps.

the plane of its three neighbors. In the crystal there are two hydrogen bonds between the ammonium group and the sulfonate moieties of their neighboring molecules; the third hydrogen atom of the $NH_3^{\oplus}$ group takes part in inter- as well as intramolecular bridging. The planes of the four-membered ring and the unsaturated side chain are twisted through an angle of about 62.9° with respect to each other; presumably the loss of an enamide resonance is a consequence of the dense crystal packing.

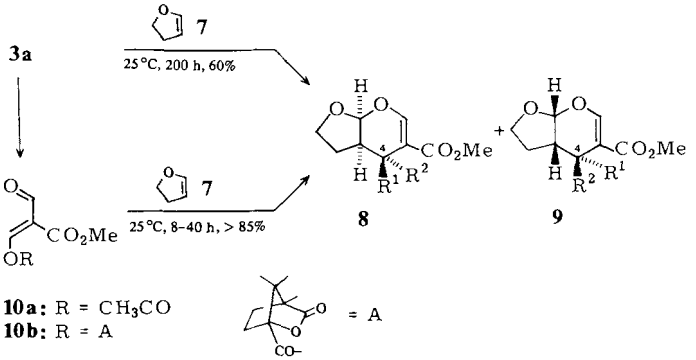
## Acceleration and Asymmetric Induction of Intermolecular Diels-Alder-Reactions of Triacyl Compounds**

By *Lutz-F. Tietze** and *Karl-Heinz Glüsenkamp*

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

Triacyl compounds are readily accessible educts which have been used with considerable success in the synthesis of complex natural products by photochemical cycloaddition[1]. Thus, photochemical reaction of methyl diformylacetate **3a** with cyclopentene **2** affords, in a single step, the molecular framework of the iridoids **1a**, a widely distributed class of natural products[1a]. We have shown that triacyl compounds such as **3b** also undergo thermal cycloadditions with enol ethers such as **4** and with thioenol ethers[2]: the diastereomeric dihydropyran derivatives *rac*-**5b** and *rac*-**6b** are formed in the ratio 3 : 1 from **4** within a few hours at 20 °C.



In contrast, less reactive triacyl compounds such as **3a** only form cycloadducts with exceedingly reactive enol ethers. After 200 h, reaction of **3a** with 1-methoxycyclopentene **4** (molar ratio: 1 : 3) at 20 °C leads to the diastereomers *rac*-**5a** and *rac*-**6a** (82%) in the ratio 3 : 1. With dihydrofuran **7** the cycloadducts **8a/9a** and **8b/9b** in the ratio 3 : 1 are obtained in 60% yield after 200 h, the reaction being incomplete; with dihydropyran practically no reaction occurs[4a]. However, if the sodium salt of **3a** is acylated to **10a** with acetyl chloride before the Diels-Alder reaction, the cycloaddition with **7** proceeds quantitatively in 8 h. The diastereomeric enantiomer-pairs **8c/9c** and **8d/9d** are formed in 85% yield. It is notable here that the diastereomeric ratio of 1 : 2 is almost inverted relative to the reaction with **3a**[4b].

**1** **3** **5** **6**

**a**: R = $CO_2Me$; **b**: R = CHO

Presumably the higher reactivity of the *O*-acyl compound **10a** in this Diels-Alder reaction with inverse electron demand[3] arises from a lowering of the energy of the LUMO of the diene component.

**10a**: R = $CH_3CO$
**10b**: R = A

| | $R^1$ | $R^2$ | |
|---|---|---|---|
| **8a** | OH | H | **9a** |
| **8b** | H | OH | **9b** |
| **8c** | OAc | H | **9c** |
| **8d** | H | OAc | **9d** |
| **8e** | O–A | H | **9e** |
| **8f** | H | O–A | **9f** |

**8a/9a, 8b/9b, 8c/9c,** and **8d/9d** are enantiomeric pairs.

Use of chiral acid chlorides for the *O*-acylation allows an asymmetric induction. Reaction of the sodium salt of **3a** with camphanoyl chloride in the presence of dihydrofuran **7** at 20 °C gives a mixture of diastereomers **8e** and **9e** as well as **8f** and **9f** (in **8e** and **9e** as well as **8f** and **9f** the dihydropyran systems exhibit enantiomeric properties) *via* **10b** after 40 h. The diastereomeric pairs **8e/9e** and **8f/9f**, which are formed in the ratio 1 : 2, can be separated by chromatography. The ratio of **8f** to **9f** is 1 : 3.2, corresponding to 52% *d.e.* Pure **9f** can be obtained in 41% yield by crystallization. The absolute configuration of **9f** was determined by X-ray structure analysis[5].

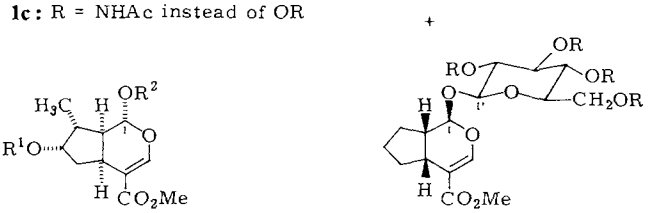
## Stereoselective Synthesis of Iridoid Glycosides**



By *Lutz-F. Tietze** and *Roland Fischer*

The iridoid glycosides are a widely distributed class of natural products. As characteristic structure element they contain a partially hydrogenated cyclopenta[c]pyran which is linked β-glycosidically at C-1 to D-glucose[1]. Glycosidation of iridoid aglycones is associated with considerable difficulties[2]. Thus in the preparation of loganin **6c**, the first and, to date, only total synthesis of a naturally occurring iridoid glycoside, low yields were obtained in the formation of the glycosidic bond[3].

[**] Iridoids, Part 19. This work was supported by the Fonds der Chemischen Industrie.—Part 18: L.-F. Tietze, K. H. Glüsenkamp, W. Holla, *Angew. Chem. 94* (1982) 793; *Angew. Chem. Int. Ed. Engl. 21* (1982) 787.

We now describe an efficient and stereoselective synthesis of iridoid glycosides using trimethylsilyl trifluoromethanesulfonate **3** as catalyst. In the course of investigations on the synthesis of glycosides with 1,1′-diacetal part structures, we were able to show that acetals reacted with the trimethylsilyl-β-glucoside **2** in the presence of catalytic amounts of **3** to form selectively the α- and β-glycosides[4a]. However, the reaction of the racemic model compound iridoid aglycone-*O*-methyl ether *rac*-**1a** with **2** and catalytic amounts of **3** in acetonitrile at −30°C proceeds exceedingly slowly, leading to anomerization[4c] of **2** as a side reaction. In contrast, the reaction with *rac*-**1b** leads in 10 h at −30°C to a 1 : 1-mixture of the two diastereomeric β-glycosides **4a** and **5a**, which can be separated by column chromatography (silica gel, petroleum ether/ethyl acetate 3 : 1) and solvolyzed (NaOMe, MeOH, 20°C, 95% yield) to the free glycosides **4b** and **5b**. α-Glycosides and C-1 epimers were not detected (< 3%). Since the mixture of acetates *rac*-**1b**, which are epimeric at C-1[4b], is used in the reaction, it must be presumed that a carbocation occurs as intermediate at C-1. The exclusive formation of the stereoisomer with *trans*-orientation of the glucose moiety to the cyclopentane ring probably arises from steric effects. However, a disadvantage is the formation of the amide **1c**, which is obtained in 8% yield from **1b** and acetonitrile. This side reaction does not occur when dichloromethane, chloroform, or toluene is used as solvent; however, the glycosidation becomes slower, leading to partial anomerization of **2** and formation of α-glycosides. If, in contrast, the reaction of *rac*-**1b** with **2** and 30 mol-% **3** is conducted in liquid $SO_2$ at −50°C, the β-glycosides **4a** and **5a**[5] are obtained in 91% yield (α-glycosides < 5%). Reaction of enantiomerically pure **1b**, obtained from **4b** by glycosidic cleavage using emulsin and subsequent acetylation, leads to glycoside **4a** in 92% yield.

By analogy, reaction of loganol diacetate **6a** (30 mol-% **3**, −40°C, 60 h) results in its conversion into loganin pentaacetate **6b** in 75% yield (α-glucoside < 10%), which can be solvolyzed (NaOMe, MeOH, 20°C, 4 h, 93% yield) to the natural product loganin **6c**.

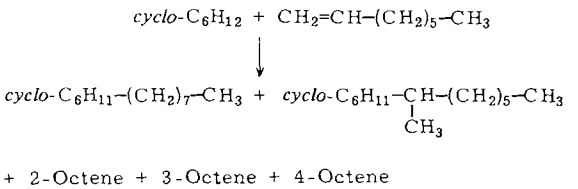
## Formation of Alkyl Radicals by Thermal Bimolecular Reaction of Alkanes and Alkenes

By *Jürgen O. Metzger**



The symproportionation (a) of an alkane and an alkene to give two alkyl radicals is a thermodynamically feasible elementary reaction that has long been sought[1]. It is the reverse of the disproportionation of alkyl radicals. In contrast to the intensively investigated homolysis of single bonds (b)—the reversal of the recombination of alkyl radicals—the symproportionation has so far never been unequivocally demonstrated[2].

$$R^1H + CH_2{=}CH{-}R^2 \rightleftharpoons {}^{\circ}R^1 + CH_3{-}\overset{\oplus}{C}H{-}R^2 \quad (a)$$

$$R^1{-}R^2 \rightleftharpoons {}^{\circ}R^1 + {}^{\circ}R^2 \quad (b)$$

The activation enthalpy of the bimolecular reaction (a) is substantially lower than that of the monomolecular homolysis (b); it is equal to the negative reaction enthalpy of the radical disproportionation and is thus easy to evaluate by thermochemical methods[3]. In some special cases a knowledge of the symproportionation was considered essential for interpreting the course of a reaction: A classical example is the initiation reaction of the spontaneous polymerization of styrene. However, recent findings by *Pryor* would appear to contradict such an initiation reaction[1b].

We have already shown in earlier experiments that alkanes can be added to alkenes in a thermally initiated reaction[10]. Kinetic studies on the addition of cyclohexane to 1-octene clearly revealed that a radical chain reaction is involved.

Cyclohexane was allowed to react with 1-octene (molar ratio 100:1) at 360—450°C and 200 bar with total exclusion of oxygen until *ca.* 90% conversion. 1-Octene reacts in two parallel reactions with formation of the adducts 1-cyclohexyloctane and 2-cyclohexyloctane (total yield of adducts *ca.* 50% referred to 1-octene; ratio of the two regioisomers 94.9:5.1) as well as isomeric octenes. In addition, *n*-octane and cyclohexylcyclohexane are also detected in the product mixture. The kinetics of the initiation reaction can be described in terms of equation (c).

$$v_{start} = k_i[\text{1-octene}][\text{cyclohexane}] \quad (c)$$

$$cyclo\text{-}C_6H_{12} + CH_2{=}CH{-}(CH_2)_5{-}CH_3 \underset{k_t}{\overset{k_i}{\rightleftharpoons}} cyclo\text{-}C_6H_{11}^{\circ} + CH_3{-}\overset{\oplus}{C}H{-}(CH_2)_5{-}CH_3 \quad (d)$$

The experimentally determined value of $\lg(k_i/k_t)^{1/2} = -6.89$ yields the quasi steady-state radical concentration $[\text{cyclohexyl}]_{exp} = 5.82 \times 10^{-8}$ mol/L at 450°C and 200 bar. This value is in good agreement with the radical concentration of $[\text{cyclohexyl}]_{calc} = 5.83 \times 10^{-8}$ mol/L obtained on calculation of the equilibrium (d) from the thermochemical data.

The results of the kinetic investigation can only be satisfactorily explained in terms of the initiation reaction (d). Other initiation reactions such as homolysis of CC bonds of the alkane and of the alkene, bimolecular disproportionation of alkene, or intermediary formation of a 1,2-diradical combined with an H-abstraction from the alkane, lead to other rate equations, other activation energies, or completely different A factors.

A two-step reaction path *via* a 1,2-diradical can be confidently ruled out; it would be orders of magnitude slower than the observed reaction. This means that the thermal formation of radicals from alkane and alkene must proceed in one step as bimolecular metathesis, *i.e.* indeed as a reversal of the disproportionation of alkyl radicals with the same transition state[1a]. Thus, the kinetics and thermodynamics are consistent with an initiation reaction as depicted in equation (a). This can be used for the investigation of radical reactions over a wide range of temperatures and without the addition of special radical initiators. This type of reaction obviously plays an important role in cracking processes[26]; it must also proceed intramolecularly and is possibly of significance in thermal intramolecular reactions such as the retro-ene reaction.

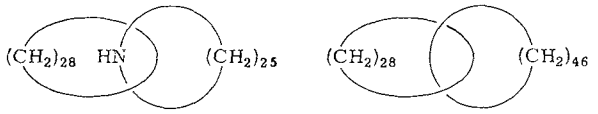
## [2]-[Cyclohexatetraoctane][cyclooctacosane]catenane, the First Hydrocarbon Catenane**

By *Gottfried Schill**, *Norbert Schweickert*, *Hans Fritz*, and *Walter Vetter*



*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

We previously obtained catenanes from precatenanes by specific cleavage of particular bonds[1]. The [2]-catenanes thus obtained contain a quinoid nucleus in one macrocycle and a nitrogen atom in the other. The simplest previously isolated catenane **1a** was synthesized by chemically degrading this system[2]. We have now prepared and isolated

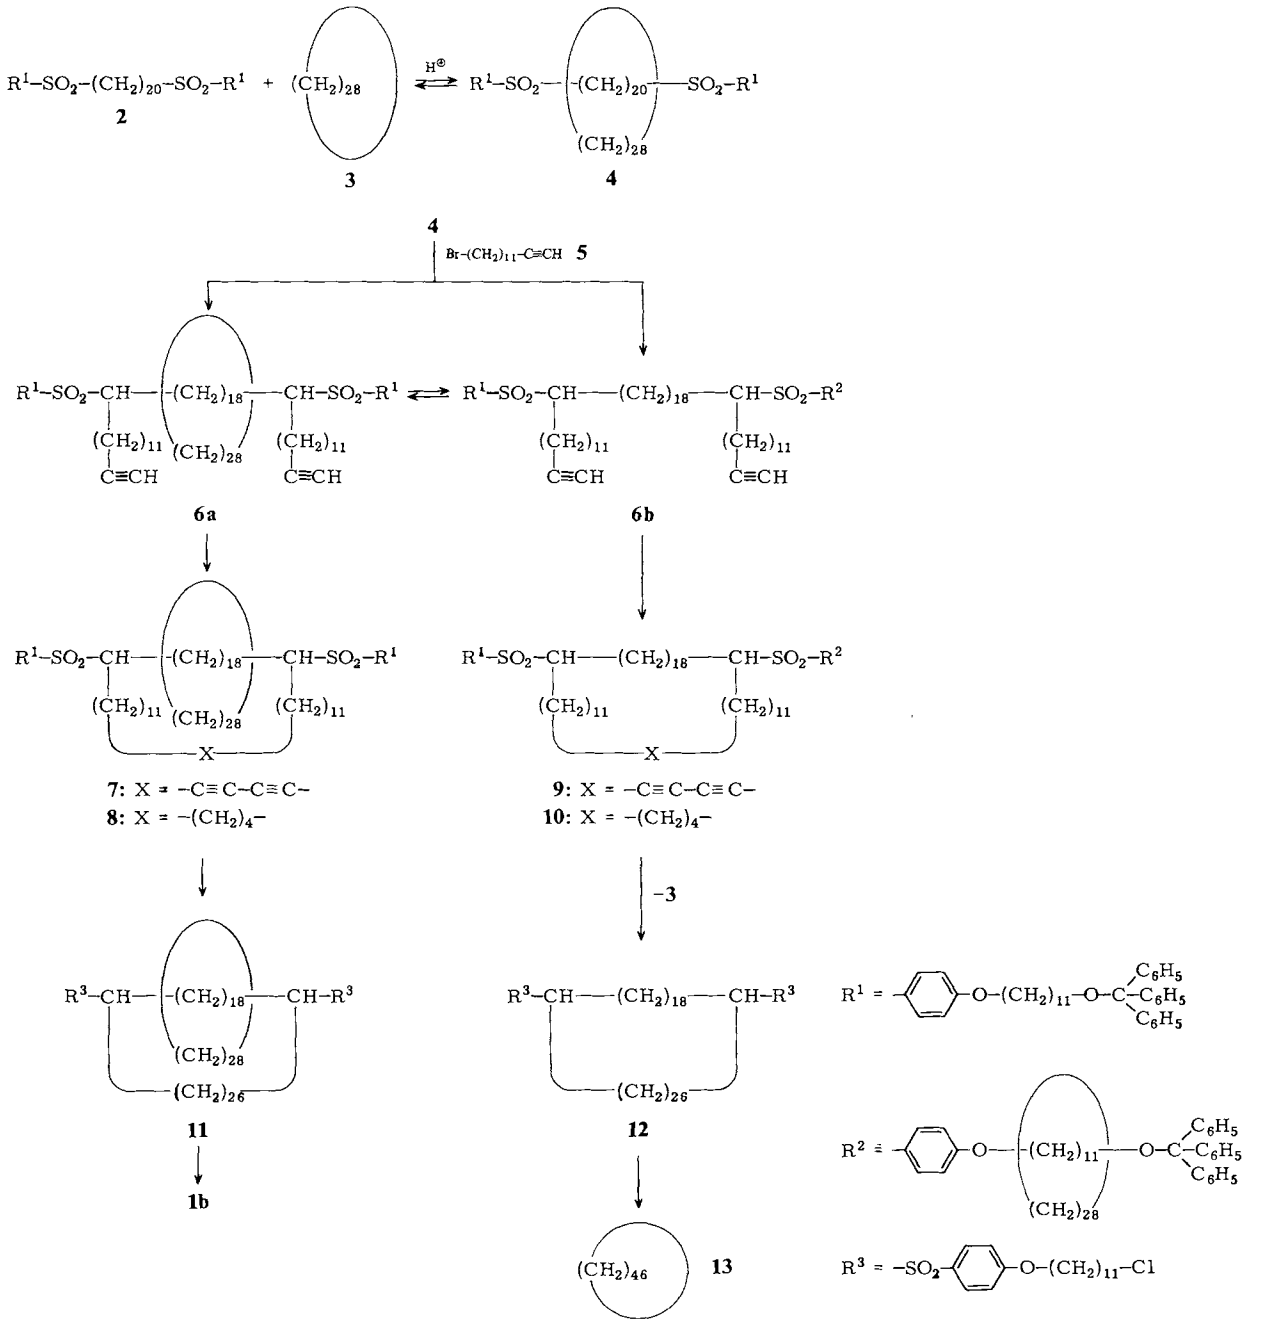
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.



the catenane **1b** in pure form, the first hydrocarbon representative of this class of compounds[3,4].

**1a** **1b**

By analogy to *Harrison*'s synthesis of rotaxanes[5], the dumbbell shaped compound **2** was heated with cyclooctacosane **3** for 1 h at 100 °C in the presence of *p*-toluenesulfonic acid as catalyst. The rotaxane **4** is formed in an equilibrium reaction as a consequence of reversible cleavage of the trityl ether groups (10% yield, colorless oil). **4** was metalated twice with lithium diisopropylamide in tetrahydrofuran (THF)/hexamethylphosphoric triamide at −55 °C and alkylated with 13-bromo-1-tridecyne **5** to afford **6** (50%, colorless oil). Thin layer chromatography ($Al_2O_3$, petroleum ether/THF = 4 : 1) indicates that **6** consists of two compounds with similar $R_f$ values. The same spot pattern is again observed after storing the chromatogram for several hours and re-development in the second dimension. To explain this result, we propose that a mixture of translationally isomeric[6] rotaxanes **6a** and **6b** is present, the barrier to whose interconversion is just large enough at room temperature to permit their separation.

Glaser oxidation of the mixture of isomers **6a**, **b** in ether/pyridine in the presence of copper(II) acetate and subsequent catalytic hydrogenation of the products of cyclization **7** and **9** led to a mixture of the catenane **8** and the rotaxane **10**. To separate the two compounds, the triphenylmethyl groups were cleaved under acid-catalyzed conditions and the two dichlorides **11** and **12** prepared using triphenylphosphane/tetrachloromethane. Reductive cleavage of catenane **11** (colorless, viscous oil) with sodium amalgam in THF/ethanol and catalytic hydrogenation led to the catenane **1b** (90%, colorless crystals, from ethanol

m.p. = 58–59.5 °C) (cyclooctacosane **3**: m.p. = 47–48 °C, cyclohexatetracontane **13**: m.p. = 81–83 °C).

In the $^{13}$C-NMR spectrum of **1b** (100.6 MHz, $CDCl_3$, 30 °C) the signals at $\delta = 29.65$ and 29.61 appear for the 28- and 46-membered ring, respectively. Compared to the two isolated macrocycles, the signals for the 28-membered ring and 46-membered ring are shifted to lower field by 0.52 ppm and 0.11 ppm, respectively. A similar shift has previously been observed for the 28-membered ring of another catenane[7]. These shifts to low field are most probably caused by van der Waals' interactions. This explanation is consistent with the smaller shift of the 46-membered ring, since in this case the interactions are distributed over more carbon atoms.

The electron impact (EI) mass spectrum (70 eV, 240 °C, direct inlet) displays the molecular ion of catenane **1b** as a low intensity peak (*m/z* 1036, 0.7% of the base peak at *m/z* 57). The two macrocyclic components of **1b** are represented by peaks of relatively high intensity at *m/z* 644 (13%) and *m/z* 392 (18%), respectively. H-Transfers between the two macrocycles, as frequently observed in catenanes[8], are indicated by the occurrence of $(M^{\oplus} - H)$ and $(M^{\oplus} - H_2)$ peaks for both macrocycles. By analogy to ion-molecule reactions of small alkanes[9, 10], it must be assumed that these ions are formed by loss of $H_2$ from intermediate, unstable, protonated macrocycles.

The CI mass spectrum with methane as reactant corroborates the results of the EI spectrum.

## A Facile, Efficient Synthesis of Acylated Glyculosyl Bromides from Hydroxyglycal Esters**

By *Frieder W. Lichtenthaler**, *Eckehard Cuny*, and *Sabine Weprek*

*Dedicated to Professor Friedrich Cramer on the occasion of his 60th birthday*

The reaction of glycal esters with *N*-bromo- or *N*-iodosuccinimide (NBS and NIS, respectively) in the presence of an alcohol leads stereoselectively to alkoxy halides (**I**→**III**, R′ = H) which have proved to be useful intermediates for the synthesis of 2-deoxy-α-glycosides[1]. With hydroxyglycal esters (**I**, R′ = OAcyl) this reaction (*e.g.* NBS/methanol in dichloromethane, 30 min) takes a different course: not 2-acyloxy-2-bromoglycosides (**III**, R′ = OAcyl) are formed as expected by analogy to the bromination **I**→**IIa**→**IV**[2], but the glyculosyl bromides **V** are elaborated smoothly and stereospecifically since the initially formed bromo adduct **IIa** is not attacked by the *O*-nucleophile (R″OH) at the anomeric carbon but at the 2-acyloxy group, leading to **V** via intermediate **IIb**.

X = Br, I; R = H, $CH_3$, $CH_2OAc$; Acyl = Acetyl(Ac), Benzoyl(Bz)

Contrasted with the previous three-step method of converting hydroxyglycal esters into α-glyculosyl bromides—involving hydroxylaminolysis[3a], deoximation[3b], and photobromination[3c]—the extended one-step process **I**→**IIa**→**IIb**→**V** proves to be an improved, general method (Table 1): not only monosaccharide derivatives (**1a**—**1d**) but also compounds derived from cellobiose and lactose afford the corresponding ulosyl bromides **2a**—**2f** in 80–90% yield. In this way, monosaccharide building blocks are made readily accessible that are as suitably functionalized for oligosaccharide synthesis as for the construction of non-carbohydrate natural products.

Among the versatile reactions undergone by ulosyl bromides of note is their ready reconversion back to the glycal stage by the Perkow reaction[4], whereby pyranoid enolphosphates such as **3b** and **3c** become accessible, as well as their β-selective alcoholysis. A silver carbonate-induced reaction leads smoothly to β-glycosiduloses, *e.g.*, **4a**, which is reduced uniformly by $BH_4^{\ominus}$ to isopropyl-β-D-mannopyranoside (79%)—a two step sequence that amply demonstrates the synthetic potential of the ulosyl bromides **2a**—**2f** for the construction of β-D-mannose-containing oligosaccharides. If the alcoholysis is followed by β-elimination, *e.g.* by stirring with bicarbonate in acetone, the β-D-enolone glycosides (**5a**—**5c**) are cleanly obtained, being of importance as versatile chiral building blocks. In the β-selective acidolysis of ulosyl bromides with sodium acetate or benzoate, elimination occurs under the reaction conditions; peracylated β-D-enolones such as **5d**—**5f** thus become satisfactorily accessible for the first time.

**5c** is a glycoside and **5f** is the dibenzoate of β-D-actinospectose, a 2,3-diketohexose which occurs in the antibiotic spectinomycin[6a] and in the arrow poison glycosides of the uscharin type[6b]. This emphasizes the synthetic potential of ulosyl bromides, and opens the possibility of synthesizing for the first time *Calotropa* cardenolides in which sugar and steroidal aglycones are linked as in structure **7**[6b],

## Radical Products in Single Electron Transfer Reactions of Lithium Triethylhydridoborate Detected by ESR and Multinuclear ($^1$H, $^{10}$B, $^{11}$B, $^{14}$N)-ENDOR Spectroscopy

By *Wolfgang Kaim** and *Wolfgang Lubitz**

Lithium triethylhydridoborate, $LiBEt_3H$ ("Super-hydride"), is one of the most powerful known hydride reductants, exceeding even the reducing capabilities of lithium tetrahydridoaluminate, $LiAlH_4$[1]. Reactions of alkyl derivatives and hydrides of Li, Mg, Zn, and Al with electron-deficient substrates have recently been shown to involve radicals generated *via* single electron transfer (SET) processes[4]; however, the identity of these stable paramagnetic products as radical anion complexes of non-radical metal fragments has not always been properly defined[4a,c]. Since aromatic N-heterocycles such as pyrazine **1**[6], 4,4′-bipyridine **2**, and 2,2′-bipyridine **3** have proven to be highly suitable SET substrates[4], we studied the reactions of these compounds with $LiBEt_3H$ in tetrahydrofuran (THF).

Persistent radicals were formed, and their identity was established by comparison of their ESR spectra with those of species generated by conventional routes[8].

In addition, we have obtained ENDOR (electron nuclear double resonance) and TRIPLE (electron nuclear-nuclear triple resonance) spectra of solutions of the paramagnetic complexes $[\mathbf{1}(BEt_3)_2]^{\odot\ominus}$ and $[\mathbf{2}(BEt_3)_2]^{\odot\ominus}$. These show signals not only from $^1$H, $^{14}$N, but also from the boron isotopes $^{10}$B and $^{11}$B, which could be detected by these techniques for the first time (Fig. 2).

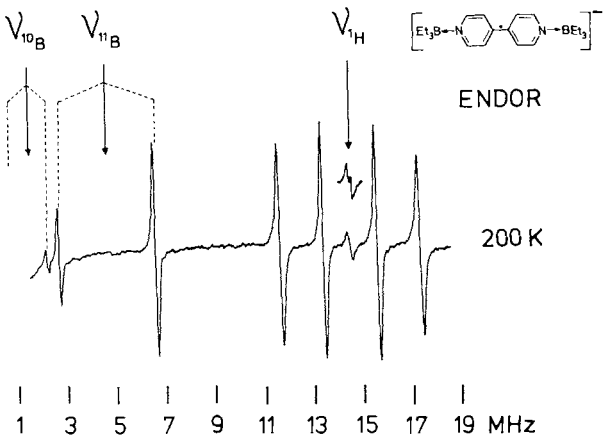

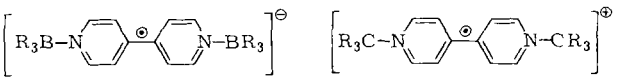

Fig. 2. Electron nuclear double resonance (ENDOR) spectrum of the radical complex $[2(BEt_3)_2]^{\odot\ominus}$ obtained from 4,4'-bipyridine **2** and $LiBEt_3H$ in THF. According to the ENDOR resonance condition $\nu_{ENDOR}=|\nu_n \pm a_n/2|$, line-pairs for three $^1H$ hyperfine couplings and one $^{11}B$ hyperfine coupling are detected centered around the respective free nuclear frequencies $\nu_n$ ($^1H$: $\nu_H=14.40$ MHz, nuclear spin $I=1/2$; $^{11}B$: 81.17% natural abundance, $\nu_{^{11}B}=4.62$ MHz, $I=3/2$). For $^{10}B$ (18.83%, $\nu_{^{10}B}=1.55$ MHz, $I=3$), the low-frequency line lies below 1 MHz and could not be detected. Signals from $^{14}N$ are only detectable at higher temperatures (cf. Supplement). Experimental conditions: 100 W rf power, 40 mW microwave power (X-band), frequency modulation 10 kHz, frequency modulation depth ±60 kHz, 1 scan (time constant 1.25 s).

The arrangement of the radical complex with the spin residing almost exclusively in the π-system of the heterocycle is very favorable for the ENDOR detection of heteronuclei such as boron coordinated to the heterocyclic nitrogen[12]. Complete analysis of the spectra yields the hyperfine coupling constants with their signs, as well as information on the relaxation behavior of the various nuclei.

The selectivity of formation of the radical products deserves special comment: In contrast to $LiAlH_4$, $LiBEt_3H$ reacts with **1** to form an anionic complex rather than the triple ion $[1(Li)_2]^{\odot\oplus}$[4b,6]. The formation of $[1(BEt_3)_2]^{\odot\ominus}$ may be due to the high Lewis acidity of triethylborane. The corresponding radical complex with 4,4'-bipyridine **2** is isoelectronic with the well-known viologen radical cations:

Conversely, 2,2'-bipyridine **3** yields the $Li^{\oplus}$ ion pair and not the diorganoboronium complex. Clearly, chelation of the small species $^{\oplus}BR_2$ by the 2,2'-bipyridine radical anion is not a highly favorable process[8c]. It thus seems that coordinative effects in hydride reductions not only determine the nature of the diamagnetic reduction products but also the radical species resulting from escape paths[6] in SET reactions. For identification of these radical species, the combination ENDOR/TRIPLE has proven to be the spectroscopic method of choice, in particular because heteronuclear studies are possible.

# BOOK REVIEWS

**Biotechnology, A Comprehensive Treatise in 8 Volumes.** Edited by *H.-J. Rehm* and *G. Reed*. Verlag Chemie, Weinheim. Vol. 1: **Microbial Fundamentals.** 1981, xii, 520 pp., bound, DM 425.00; Vol. 3: **Biomass, Microorganisms for Special Applications, Microbial Products I, Energy form Renewable Resources.** Edited by *H. Dellweg*. 1983, xix, 642 pp., bound, DM 425.00

At a time when over 200 companies worldwide have endeavors in biotechnology, a comprehensive treatment of the field in a series such as the one from Verlag Chemie is welcome indeed. It would be difficult for a series such as this to satisfy everyone, and this reviewer has his own points of contention. Still, if these two volumes are representative of the others to follow, the series should be an excellent reference source for anyone who seeks a starting point on a technical topic in biotechnology. Thus, students, instructors, and practitioners alike should find the series valuable. However, I do think the price could significantly limit the appeal.

The first two volumes of the series are intended for a discussion of the principles of biotechnology; the remaining six volumes are to deal with specific applications. Volumes 2 (Fundamentals of Biochemical Engineering) and 4 to 8 (Vol. 4: Microbial Products II; 5: Food and Feed Production with Microorganisms; 6a: Microbial Transformations; 6b: Special Microbial Processes; 7: Enzymes in Biotechnology; 8: Microbial Degradations) have not yet been released.

The cover titles on the applications volumes would appear somewhat redundant. It might have been better to or-

ganize the applications volumes according to industry, *e.g.* energy, food, pharmaceutical, waste utilization, *etc.* But perhaps such an approach was considered and found not to be practical.

Volume 1 starts with a review by *A. Kocková-Kratochvilová* of the taxonomy of animal, plant and microbial viruses as well as the prokaryotes and the eukaryotes. *C. L. Cooney* provides an overview of the methods of measurement of microbial growth and of how the nutritional and environmental factors might affect such growth. *H. W. Doelle* devotes nearly 100 pages to a presentation of the basic pathways through which the microorganisms derive energy for growth and maintenance. *J. F. Martin* and *P. Liras* extend this topic to the formation of secondary metabolites.

Volume 1 also contains well-presented contributions on the principles of genetics *(R. P. Elander, A. L. Demain)* and the techniques used in its practice: Mutation *(G. K. Jacobson)*, Hybridization *(K. Esser, U. Stahl)*, Genetic Engineering *(A. Pühler, W. Heumann)*. *K. Nakayama* and *A. Dietz* present complementary chapters on the sources and the maintenance of cultures in industry. *V. Vossius* introduces the topic of patent protection in this special sector. *A. Fiechter* reviews the batch and continuous culture of cells, appropriately including plant and animal cells. I agree with this author that plant and animal cell biotechnology will continue to gain in importance and I hope that one of the future volumes will devote more attention to this topic.

Volume 3 is the first of two volumes devoted to microbial products. The microbial cell mass as the product in itself is discussed in four chapters on "Biomass" and five chapters on "Special Applications."

*E. Oura* begins the subject by considering carbohydrates as the substrate (glucose, molasses, spent sulfite liquor, whey, starch). *A. Einsele* extends the discussion to higher alkanes as substrates. *U. Faust* and *P. Präve* deal with methane and methanol as substrates. The production of phototrophic microalgae is thoroughly analyzed by *A. Richmond*. There then follows an illustrated account of the cultivation of Edible mushrooms (fungi) by *F. Zaražil* and *K. Grabbe*.

The "special applications" considered in this volume are: Starter cultures for milk and meat processing *(R. K. Robinson)*, Microbes for the improvement of plant and soil health *(H.-J. Rehm, B. Novák)*, Nitrogen fixation and the production of legume inoculants *(H. Marečková)*, and The *in-vitro* and *in-vivo* production of microbial insecticides *(R. J. Quinlan, S. G. Lisansky)*. These chapters should be considered brief introductions to the topics. The remainder of volume 3 deals with products other than cell mass. Perhaps the most comprehensive chapter of these two volumes is the one on ethanol fermentations *(N. Kosaric, A. Wieczorek, G. P. Cosentino, R. J. Magee, J. E. Prenosil)*. An overview of acetic acid and citric acid as microbial products is presented by *H. Ebner* and *H. Follman* and by *M. Röhr, C. P. Kubicek*, and *J. Kominek*. The latter group of authors also briefly introduces the production of gluconic acid. Another brief presentation is on the production of lactic acid *(K. Buchta)*. This author introduces several other organic acids that could become of interest depending upon the trend in world oil prices, *e.g.* itaconic acid, malic acid, and oxogluconic acid.

The production of amino acids by microbes and by enzymatic synthesis is reviewed by *K. Soda, H. Tanaka*, and *N. Esaki. I. W. Sutherland* discusses strain development, production, product recovery, and the uses of extracellular polysaccharides. Microbial emulsifiers and de-emulsifiers are dealt with by *N. Kosaric, N. C. C. Gray*, and *W. L. Cairns*. *G. W. Barnard* and *D. O. Hall* conclude volume 3 with a discussion of the production of ethanol and methane from biomass.

In some of the chapters, the authors seem to have been forced to sacrifice depth of coverage in order to mention more of the microbes and the products reported in the literature. There is some redundance. For example, aspects of ethanol production, as well as a few points on microorganism growth, are covered in more than one chapter. It is incumbent upon the reader to integrate these. However, I do not see this as a major problem. In a diverse field such as biotechnology, a comprehensive but fully unified treatment would be an extremely difficult endeavor.

Since the series is intended to be a comprehensive treatise, the authors of future volumes may wish to include information on product uses, costs and production volumes. Not all the authors of volume 3 have done this. Comments on competing production schemes both inside and outside biotechnology would also help the reader gain a better perspective of the field.

The only other concern is that the very nature of a series such as this dictates that several years would pass before the entire series is published. This creates a time lag in the information presented and makes an integration of the topic more difficult. And, the detailed listing of the contents would not be known until much later. Despite all this, the editors and the publisher are to be sincerely commended for undertaking this formidable task.

Where might this series find a place among its possible surrogates such as Kirk and Othmer's *Encyclopedia of Chemical Technology* (Wiley Interscience), *Advances in Biochemical Engineering* (Springer), *Microbial Technology* and *Annual Reports on Fermentation Processes* (Academic Press), and *Topics in Enzyme and Fermentation Technology* (Wiley) *etc.* should become clearer after further volumes of this work are released. These two volumes suggest the place would be an honorable one.

**Advances in Chemical Physics, Vol. 50. Dynamics of the Excited State.** By *K. P. Lawley*. John Wiley & Sons, Chichester 1982. vii, 667 pp., bound, £ 35.90.

The purpose of the series "Advances in Chemical Physics" is to provide the reader with access to those areas of chemical physics in which he himself does not specialize but which are of interest to him. The rapid development taking place in many areas and the abundance of original publications create a great need for review articles from the pens of experts. The present volume fulfills this need in an exemplary manner, as does the series as a whole.

In the last few years laser spectroscopy has opened up new vistas in the experimental investigation of excited molecular states. Parallel to this, new theoretical models have been developed. The present volume contains nine reports concerning important areas which impressively cover the experimental and theoretical progress, in particular in the study of the excited states of small molecules and of the interaction of such molecules with each other and with the field of radiation.

*M. A. A. Clyne* and *I. S. McDermid* report on laser-induced fluorescence as a method of investigating the electronically excited states of small molecules. Much has been learned about the dynamic and spectroscopic properties of small molecules and radicals, which have been excited under precise, defined conditions, by means of tunable, narrow band dye lasers. The experimental technique is also comprehensively described. As much progress has also occurred in the area of multiphonon excitation with infrared quanta. *D. S. King* reports on chemical reactions influenced by such excitation, molecular dynamics, energy transport and distribution of excitation energy among the products following multiquantum infrared excitation.

The subject of the contribution by *A. M. F. Lau* is laser predissociation and autoionization by photons. *S. R. Leone* discusses the results of single photon ionization and dissociation of molecules. The distribution of the end-products, the dissociation time, the fluorescence polarization and the angular distribution of the products allow a detailed insight into the primary photochemical processes. Excited metal atoms can pass on their energy in collision with molecular gases. *W. H. Breckenridge* and *H. Umemoto* report on this area which is of such great importance for laser technology. *I. V. Hertel*'s contribution is concerned with the energy exchange between electronic and vibrational excitation. The measurement of effective cross sections, angular distributions and polarization are discussed.

Exclusively or mainly theoretical methods and results are discussed by *M. Quack* (The Reaction Dynamics and Statistical Mechanics of the Production of Highly Excited States by High Intensity Infrared Radiation), by *D. M. Hirst* (Calculation of the Potential Surfaces of Excited States) and *T. A. Brunner* and *D. Pritchard* (Fitting Laws for the Treatment of Rotation Inelastic Collisions).

Taken as a whole this book allows an insight into the basic concepts and into the latest results in some areas of molecular physics where—because of the advent of the laser—there have been especial advances in recent years. The individual contributions are well written, fit quickly and understandably into the general scheme, and include a tremendous number of literature references. Such books are of inestimable value to the molecular physicist and the physical chemist. The production is excellent, the price acceptable.

**Electrical Properties of Polymers.** Edited by *D. A. Seanor.* Academic Press, New York 1982, xi, 379 pp., bound, $ 52.00.

The tendency of publishers to assemble a range of individual reports of varying quality and with only a slight connection with each other and to market them is unfortunately increasing. This book is an example of the abuse.

In the first chapter *D. A. Seanor* gives a cursory review of electrical phenomena, measuring techniques and the electrical properties of various material classes and states of aggregation of polymers, under the title "Electrical Conduction in Polymers". The polymers with metal-like conduction (*e.g.* the polyacetylenes), which are decisive in recent work, are only mentioned here, as in the rest of the book, in passing. The section on ionic conduction in polymers is interesting, although, here too, there is no mention of the PEO salt complexes which are relevant for electrochemical applications.

It is characteristic of the quality of the article and of the book in general that the problem of the connection between the electrical properties and morphology of partially crystalline polymers are discussed in terms of an outdated model proposed by *Flory* (not *Florey* as given in the legend to Fig. 10!) dating from the year 1953!

Under the ambitious title "Structure and Charge Generation in Organic Molecular Self Assemblies", *J. H. Perlstein* deals in Chapter 2 (30 pp.) solely with thiapyrylium salts dispersed in polycarbonate. It becomes clear that not even the structure of the interstitial complex has been unequivocally established.

The topic "Photophysical Processes, Energy Transfer and Photoconduction in Polymers" is treated by *R. F. Cozzens* in *ca.* 30 pages in Chapter 3. Without going into details there is a very elementary introduction, attended by a plethora of historical citations concerning the photoconductivity of polymers and its technical application.

Chapter 4 (80 pp.) by *V. Y. Merrit,* entitled "Photovoltaic Phenomena in Organic Solids", devotes all of 11 lines to the subject of polymers. The author's remark that polymers behave in a very complex manner is diverting in the context of this book.

The subject matter of the 5th chapter by *H. Carr* (20 pp.) has been treated several times recently in other monographs and progress reports. The same applies to the remaining chapters of the book; in some cases similar reviews have recently been published elsewhere by the same authors. An example is *G. M. Sessler*'s contribution "Polymeric Electrets" in Chapter 6 (40 pp.). The two remaining chapters deal with "Contact Electrification of Polymers" (*D. K. Davies,* 40 pp.) and with "Dielectric Breakdown Phenomena in Polymers" (*P. Fisher,* 45 pp.).

Whoever buys this book will at least enjoy its solid getup and the careful work of the bookbinder.

**Anthracycline Antibiotics.** Edited by *H. S. El Khadem.* Academic Press, New York 1982. xii, 285 pp., bound, $ 25.00.

This volume is a compilation of the presentations at the Anthracycline Symposium held in New York in August 1981. The choice of topics takes account of the interdisciplinary character of anthracycline chemistry—ranging from pharmacology through microbiology to total synthesis.

In the first report *Narayanan et al.* present the National Cancer Institute's (NCI) screening programme for anthracycline derivatives. Besides an introduction to the evaluation of screening results a good summary is given of the range of substances (*ca.* 400) prepared to date by derivatization of daunorubicin. Scientists not working in the field will note that the NCI's screening results occasionally differ from those of other groups. Next *Arcamone et al.* report on the results of investigating doxorubicin (adriamycin). The group from Farmitalia has made important contributions, both in the area of structure effectivity relations and in the isolation and synthesis of new glycosides. It is sufficient here to mention the syntheses first reported of a furanoglycoside and of *enantio*-4-demethoxydaunorubicin which, as expected, is biologically inactive. *T. Oki* summarizes the work of the Sanraku Ocean group in his contribution. This Japanese company is to be thanked for the

isolation and structural characterization of dozens of new anthracyclines derived from aclavinone. The microbiological investigations of *Umezawa et al.* are included, which concern the microbiological glycosidation by particular Streptomyces mutants. A further report on industrial research (Upjohn) is given by *Wiley* in his review of nogalamycin chemistry. Even though nogalamycin derivatives originally did not belong to the favorites of the pharmacologists, the Upjohn workers have succeeded in synthesizing a derivative (7-*con*-*O*-methylnogarol) which has a comparatively low cardiac toxicity. Interestingly enough this derivative only interacts slightly with double-stranded DNA, which throws new light on the mode of action of anthracycline antibiotics. The systematic variation of the natural products, daunorubicin and doxorubicin, is the main theme of a report by *Acton et al.* The discussion of the chemical derivatization is closely linked with the biological action and with pharmacological considerations. Probably the most important result is that the *N*-alkylated derivatives of the natural products do not exhibit mutagenicity.

Mainly synthetic themes are treated in the second portion of the volume. Firstly, *Kende et al.* and *Swenton et al.* describe the results obtained by their groups in the area of aglycone synthesis. *Kende* concentrates on 11-deoxy-anthracyclines of the aclavinone type, while *Swenton* presents the daumomycinone synthesis *via* quinone acetals developed by his group. Although the work of other groups is naturally only mentioned in passing, both reports provide a deeper insight into the basic synthetic concepts. The great enthusiasm of both authors comes through to the reader. Finally, there are three presentations from *Horton, Monneret* and *El Khadem* concerned with glycoside syntheses. Although the problem of monoglycosidation seems to be basically solved (even for nitrogen-free sugars), the synthesis of the di- and the trisaccharides is only just beginning. The reviewer applauds the fact that the difficult chapter on oligosaccharide synthesis, partly with very rare sugars, is presented as a summary, even though some problems concerning yield and selectivity have not been completely solved.

The volume is very carefully edited and arranged; the reviewer could find only a few mistakes. The anthracycline chemist is stimulated by the results of well-known workers presented from their own personal viewpoints. In particular the summary of the work from the industrial laboratories facilitates literature studies. However, the book can be recommended not just to specialists. The clearly arranged presentation provides a rapid introduction to a fascinating chapter of interdisciplinary research.

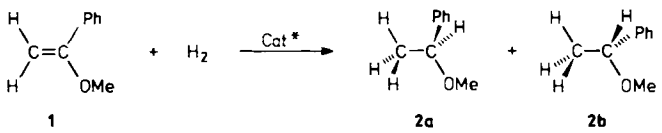
# Rhodium Catalysts for Enantioselective Hydrosilylation— A New Concept in the Development of Asymmetric Catalysts

**By Henri Brunner***

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Following a survey of the asymmetric hydrogenation of prochiral olefins with transition metal/phosphane catalysts, the problem of chirality transfer from the optically active ligands of the catalyst to the substrate is discussed. A new concept for this chirality transfer is introduced; the conformational analysis of model compounds as well as the development of catalysts for enantioselective hydrosilylation demonstrate the usefulness of this concept.



*For every reaction in which a new asymmetric center is created there exists a transition metal catalyst which—when added in small amounts—leads stereospecifically to one enantiomer. One only has to find it.*

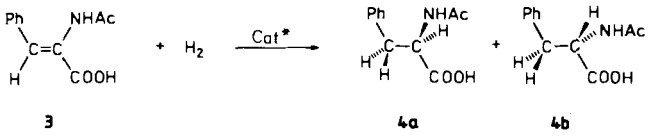
## 1. Introductory Remarks

Enzymes catalyze the synthesis of optically active compounds from prochiral precursors. The reactions are usually stereospecific. Since an enzyme molecule converts its substrate 10000 to 1000000 times per minute[1], the optical activity contained in it is multiplied by this factor each minute. Enzyme reactions are thus prime examples for "asymmetric catalysis" in which large amounts of optically active products are formed from a small amount of "optically active information". However, enzyme reactions are often restricted to natural substrates, and reactivity as well as stereoselectivity rapidly decrease when the substrate is varied. This poses the following questions: How good are synthetic catalysts in asymmetric catalysis? Can they make a contribution to the increasing demand for enantiomerically pure optically active pharmaceuticals, foods, animal feeds, pesticides, organic chemicals, etc.?

## 2. Enantioselective Catalysis with Transition Metal/Phosphane Complexes

In 1968 *Horner et al.*[2] and *Knowles et al.*[3] independently discovered that prochiral olefins can be hydrogenated enantioselectively using rhodium complexes similar to Wilkinson's catalyst[4] but having optically active phosphane ligands. Scheme 1 shows this for one of the first asymmetric hydrogenations—the conversion of α-methoxystyrene **1** into α-methoxyethylbenzene **2a**, **b**.

**1** **2a** **2b**



Scheme 1.

Using the catalyst [Rh(1,5-hexadiene)Cl]$_2$/(*S*)-(+)-PMePrPh[2] an optical yield of 4% *ee* for the (*R*)-product **2b** was achieved. The extraordinarily mild reaction conditions (room temperature, hydrogen at atmospheric pres-

[*] Prof. Dr. H. Brunner

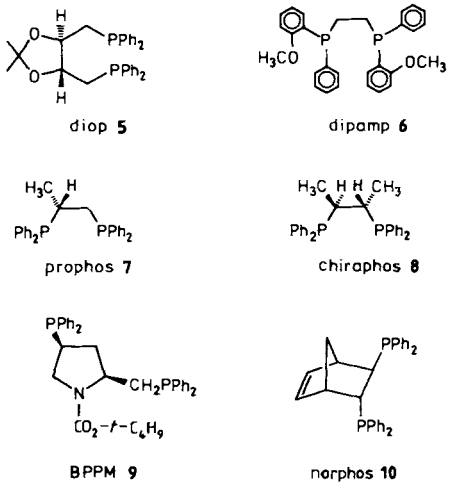
Universitätsstrasse 31, D-8400 Regensburg (Germany)

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/1212-0897 $ 02.50/0 

sure) and the possibility of converting dehydroamino acids into amino acids[5] soon resulted in world-wide attention for this area of research. Although the use of monodentate optically active phosphanes led to high optical inductions for some special substrates, it was only the switch to chelating phosphanes that brought decidedly better optical yields.



3 4a 4b

Scheme 2.

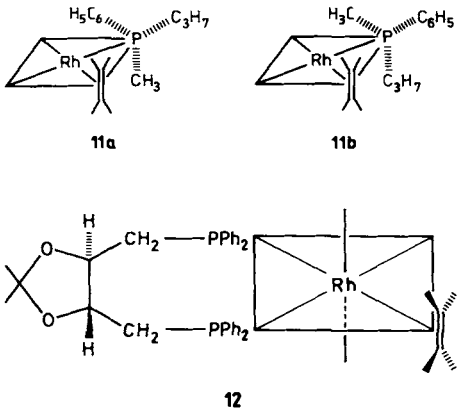
The synthesis of *N*-acetylphenylalanine **4a**, **b** from (*Z*)-α-(*N*-acetamido)cinnamic acid **3** according to Scheme 2 may be quoted as an example. The catalyst is formed *in situ* from the precatalyst $[Rh(cod)Cl]_2$ (cod = 1,5-cyclooctadiene) and the cocatalyst diop **5** (Scheme 3), and gives an optical induction of 81% *ee*. Thus (−)-diop, which is derived from naturally occurring tartaric acid, leads to *N*-acetylphenylalanine with an (*R*) : (*S*) ratio of 90.5 : 9.5[9]. These studies culminated several years ago in the development of an industrial process for the synthesis of L-Dopa, a drug used to treat Parkinson's disease[10–16]. Subsequently, hundreds of optically active phosphanes and prochiral substrates have been tested, not only for use in enantioselective hydrogenations, but also for transition-metal catalyzed enantioselective hydrosilylations, hydroformylations, and similar reactions[17–38].

Of the large number of optically active chelating phosphanes used in asymmetric catalysis, Scheme 3 depicts the six compounds **5**—**10** which have proved themselves in a multitude of catalytic reactions.

Scheme 3.

The tartaric acid derivative diop **5**[5] is the best known and most frequently used chelating phosphane. The ligand dipamp **6** is used in the Monsanto amino acid process for the synthesis of the L-Dopa. The asymmetric centers of prophos **7**[39] and chiraphos **8**[40,41] originate from lactic acid and tartaric acid, respectively. BPPM **9**[42] is a derivative of the amino acid proline, and norphos **10**[43,44] contains a norbornene skeleton. Both diop **5** and BPPM **9** form seven-membered chelate rings with metal atoms, whereas the other four ligands form five-membered rings. The acronyms in Scheme 3 have been accepted generally because the IUPAC names of ligands **5**—**10** occupy several lines.

The ligand dipamp is an exception in two respects, both in relation to the other five compounds in Scheme 3 as well as in relation to the majority of the other compounds tested so far. On the one hand, the chiral centers of dipamp are the phosphorus atoms themselves, whereas most other compounds contain the chiral center in the chelating bridge between the two P atoms; on the other hand, only one of the two rings on the doubly aryl-substituted P atoms is a phenyl ring, the other being an *o*-methoxyphenyl ring. In contrast, most of the commonly used chelating phosphanes are doubly phenyl-substituted at the P atoms. Despite these structural singularities of dipamp, the optical inductions achievable with this ligand do not differ significantly from those obtained with other chiral bisdiphenylphosphane ligands[17–22].

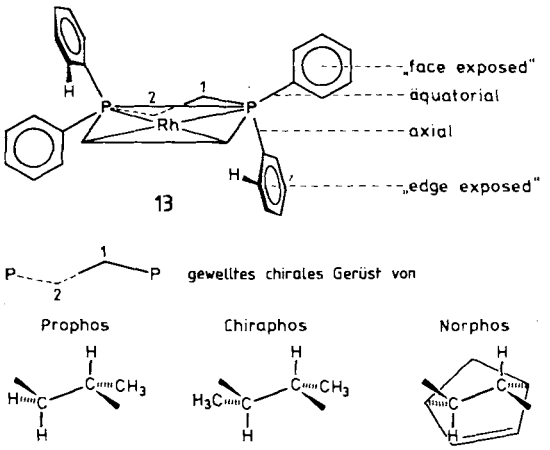


## 3. Increase in Stereoselectivity by Restriction of Conformational Variety

The development of models could not keep up with the rapid experimental progress, so that today asymmetric catalysis appears largely empirical. Progress was made more often by serendipitous discovery than by systematic planning. In the recent past, however, some guidelines have been developed which optically active phosphanes must fulfill to be suitable for use as ligands in catalysts. Some of the factors which favor high optical yields follow:

a) Use of monodentate rather than of bidentate ligands;
b) Formation of five-membered chelates;
c) Introduction of additional rigidity;
d) Aryl substitution of the P atoms of the chelating ligand.

A common feature of factors a)—c) is the restriction of the conformational variety available to the Rh/ligand system. This is especially evident in factor a). In complexes with monodentate ligands each rotamer with respect to the M—P bond, for example, **11a** and **11b** in Scheme 4 or other conformations, has to be viewed as a distinct catalyst with a certain *R* : *S* selectivity. The extreme dependence of stereoselectivity on small structural variations[9,24,45] usually results in low overall selectivity when this arises from different partial selectivities. With chelating ligands, however, free rotation around the M—P bond is removed, *e.g.* in **12** (Scheme 4). This difference finds its expression in the observation that a catalyst with the chelating ligand diop **5** leads to a significantly higher optical yield of 24.5% *ee*[46,47] in the hydrogenation of α-ethylstyrene to 2-phenylbutane than a catalyst with the monodentate ligand PMePrPh (7% *ee*)[2].



Point b) may be verified by a comparison of the complexes of diop **5** with those of propos 7, chiraphos **8**, and

Scheme 4.

norphos **10**. X-ray crystallographic studies of seven-membered chelate complexes of diop **5**, such as **12** (Scheme 4)[48–52], indicate that they adopt various ring geometries which can rapidly interconvert in solution. In contrast, the ligands prophos **7**, chiraphos **8**, and norphos **10** chelate metals to form puckered five-membered rings of a single type (**13**, Scheme 5). The preferred equatorial position of the methyl groups in prophos **7** and chiraphos **8**[40] or the rigid norbornene skeleton in norphos **10**[53] force the puckered five-membered ring into a δ- or λ-conformation. As shown in the lower part of Scheme 5, the (*S*)-configuration of the asymmetric centers in (2*S*)-prophos, (2*S*,3*S*)-chiraphos, and (2*S*,3*S*)-norphos leads to the δ-conformation of the five-membered chelate ring.

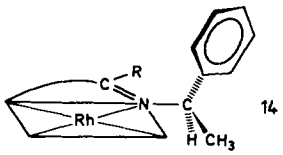
The δ/λ-conformation of the RhPC1C2P five-membered ring is defined here as in the corresponding structural element MNCCN in the numerous complexes of ethylenediamine[54]. The P–P connector (or the N–N connector in the en-complexes) and the C1–C2 bond form a pair of skew lines. Two such skew lines define a helix if one line is taken as the axis of the helix and the other as a tangent to it. For example, if the P–P connector in **13** (Scheme 5) is considered to be the axis and the C1–C2 bond a tangent to a helix, then a clockwise motion away from the observer is described by this helix. The chirality of the puckered RhPC1C2P-ring in **13** (Scheme 5) is, therefore, assigned the conformational symbol δ. Correspondingly its mirror image has the λ-conformation. This λ-conformation would be the result of an inversion of the five-membered ring in which C1 of **13** (Scheme 5) had moved down and C2 up. The asymmetric centers of (2*S*)-prophos and (2*S*,3*S*)-chiraphos would then have the H atoms in equatorial positions and the methyl groups axial. In ethylenediamine complexes[54–58] it is known that axial methyl groups suffer large steric interactions from other ligands. The λ-conformation of (2*S*)-prophos in the complex should thus be disfavored relative to the δ-conformation by *ca.* 2 kcal/mol, corresponding to only a few percent in the conformational equilibrium. For complexes of (2*S*,3*S*)-chiraphos, which contains two (*S*)-configurated carbon atoms, this tendency should be even more pronounced so that the fraction of λ-conformation may be vanishingly small. For (2*S*,3*S*)-norphos, participation of the λ-conformation is completely excluded because the bonds to the bridgehead atoms of the norbornene cannot reach the axial positions. The uniform ring conformation with five-membered rings as compared to seven-membered rings results in the high optical inductions of 90, 99, and 98% *ee* for prophos **7**, chiraphos **8**, and norphos **10**, respectively, compared to 81% *ee* for diop **5** in the model reaction in Scheme 2[9,39,40,44].

Scheme 5. Equatorial and axial positions of the face-exposed and edge-exposed phenyl moieties in the puckered chelate rings of the Rh complexes with ligands (2*S*)-prophos **7**, (2*S*,3*S*)-chiraphos **8**, and (2*S*,3*S*)-norphos **10**.

In a similar way, increasing the rigidity of the seven-membered ring in diop **5** (Scheme 3) by ketalization has a favorable effect on the optical induction[9]. The more flexible chelate ring with two OH-groups instead of the ketal ring in **5** results in significantly less selective catalysts than diop itself. Reduction of the conformational variety according to a)–c) and increase in optical yield can therefore be correlated.

## 4. Conformation of the Rhodium/Bisphosphane Chelate Rings

The increase in selectivity on aryl substitution at the P atoms—factor d) in Section 3—has different origins which are connected with the distance between the centers inducing chirality and the prochiral substrate. In **12** (Scheme 4) it can be seen that the chirality at the C atoms of the diop ligand, originally derived from tartaric acid, is separated by four bonds from the $sp^2$ centers of the substrate which become the new asymmetric centers, *i.e.* by *ca.* 6 Å. In those chelating phosphanes which form five-membered rings, the distance between the centers inducing chirality and the site where it is needed is one bond shorter. However, the distance is still so large that the question must be asked how the prochiral $sp^2$ centers in the coordinated substrate "feel" the chiral influence upon being converted to chiral $sp^3$ centers.



Certainly, the chiral information in the catalyst complex is also transmitted *via* the surrounding solvent cage. It appears, however, that the real transmitters are the phenyl rings at the P atoms. According to a proposal by *Knowles et al.*[50], and this has since been verified by numerous X-ray structure analyses[17,26,59,60], one has to envision this as depicted for the chelating phosphanes prophos **7**, chiraphos **8**, and norphos **10** in **13** (Scheme 5). C1 is located somewhat above the Rh-square and C2 somewhat below this plane. If the five membered-ring RhPC1C2P were planar,

the angles between all four P–C(phenyl) bonds and the Rh-plane would be equal and there would be no differentiation into axial and equatorial phenyl rings. However, since the bond from the right-hand P atom to C1 of the chelate ring points upward, the upper phenyl ring bound to this P atom occupies an equatorial position and the lower phenyl group is axial (see **13**). Correspondingly, the two phenyl groups at the left-hand P atom are equatorial and axial. These equatorial/axial positions of the phenyl rings in the $P(C_6H_5)_2$-groups arise because the chelate ring is puckered. Added to this is a second effect also shown in **13**. Frequently the two phenyl rings are nearly perpendicular to each other. While one of the phenyl rings is approximately parallel to the plane of the paper, the other is almost perpendicular to it. The two positions are distinguished as "face exposed" and "edge exposed". Thus each P atom of a diphenylphosphino group contains an equatorial phenyl ring in a "face exposed" position and an axial phenyl ring in a "edge exposed" position.

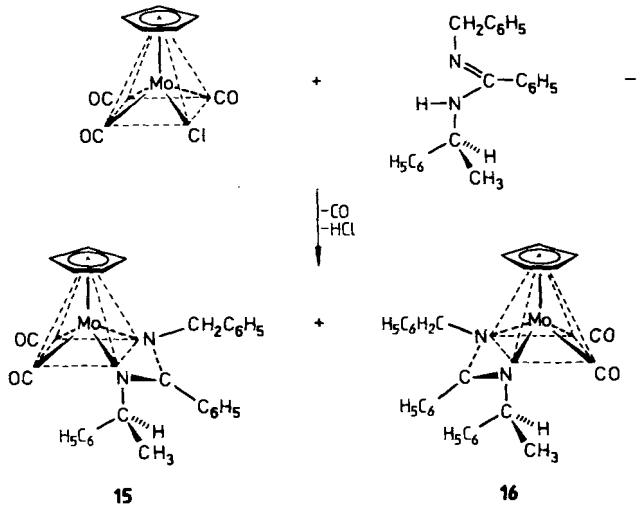
## 5. Chirality Transfer in the Catalyst from Optically Active Ligand to Substrate

Positioning the two phenyl rings at the P atom (axial/equatorial and face/edge exposed) causes chirality, which is determined by the puckering of the chelate ring and thus by the configuration of the asymmetric centers in the chelate skeleton. The chiral information is transmitted from the asymmetric center in the chelate framework through the $P(C_6H_5)_2$-groups to the catalytically active coordination sites at the metal atom. A substrate at the front right coordination site of the Rh-square encounters hardly any steric hindrance by the "face exposed" phenyl ring above the plane; however, below this plane strong steric interactions, especially with the *ortho*-hydrogen atom of the "edge exposed" phenyl ring, are to be expected. Even in those few chelating ligands in which the asymmetric P atoms bear the inducing chirality, the transfer of chirality to the substrate should proceed in a similar fashion. This is exemplified by dipamp **6** (Scheme 3), in whose complexes the *o*-methoxyphenyl group in the "face exposed" position is always equatorial[26, 50].

Although the chirality transfer through the two phenyl "ears" of the phosphorus is extraordinarily effective in numerous catalyses, for the following reasons it is not the optimal solution for asymmetric catalysis: The chelating phosphanes in Scheme 3 and the vast majority of optically active ligands used to date have different centers of chirality, *e.g.* the tartaric acid chirality in diop **5** and the proline chirality in BPPM **9**, *etc.* The transfer mechanism for all these specific chiralities, however, is the same. The $P(C_6H_5)_2$-transmitter can only react to the specific chiral information by positioning its phenyl rings more or less axial/equatorial and face/edge exposed. The prochiral substrate thus does not "see" the original chirality of the tartaric acid or proline *etc.*, but rather the phenyl "ears" of the transmitter only, whose positions do not differ substantially for the various specific inducing chiralities. Consequently, this transfer of chirality leads to a loss of information. One might therefore expect better results in asymmetric catalysis if the inducing center of chirality in the catalyst were located where the $P(C_6H_5)_2$-transmitter is situated. A loss of information due to transfer would then be avoided; the inducing chirality would interact directly with the substrate in the neighboring coordination site. This concept could be verified with the aid of a chelating ligand which is bound to rhodium *via* an N atom as shown in **14** (Scheme 6).

**14**

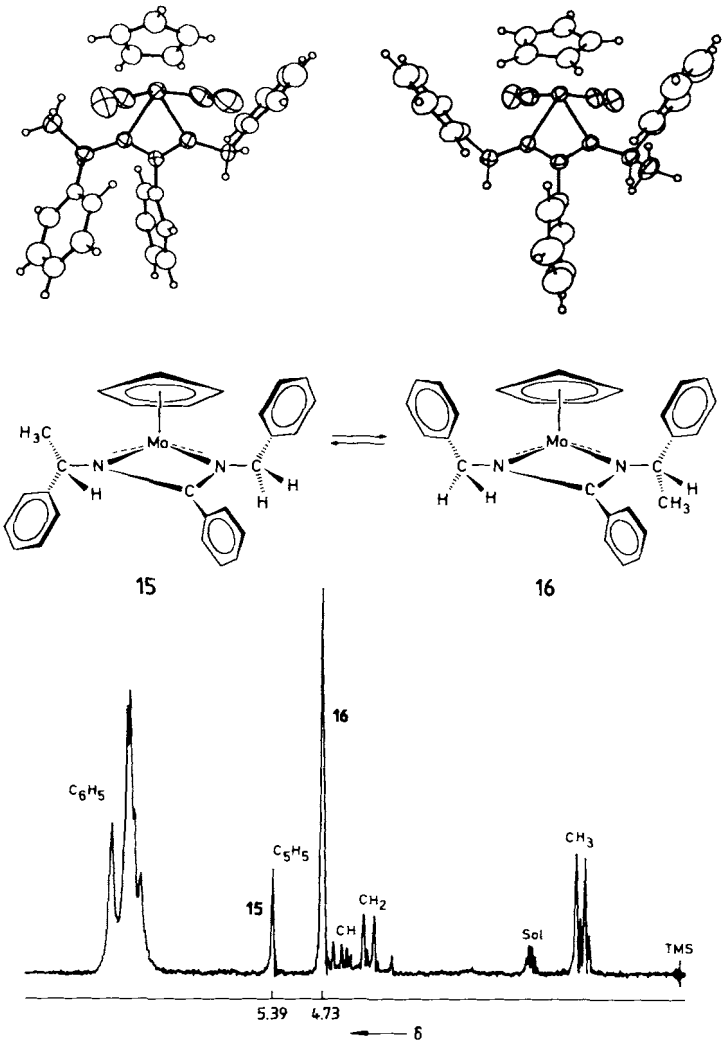
Scheme 6.



A chiral substituent at this N atom, *e.g.* the (R)–CHMePh-group, is then situated precisely where (Scheme 5) the phenyl groups transmitting the chirality were in the chelating phosphane complexes. If the chelating ring in **14** is planar and the nitrogen atom is $sp^2$-hybridized, the optically active group lies in the plane of the Rh atom. Schiff base condensation of carbonyl compounds with optically active primary amines should lead to imino ligands as in **14**, whose N atoms are also $\pi$-acceptors. With these Schiff base ligands the great potential of the known optically active primary amines[61] could be tapped. As discussed for mono-/bidentate phosphanes, the structural element =N–R* should form part of a chelating ring to eliminate rotation around the Rh–N bond and fix the optically active group R* in the desired position. Since the asymmetric center can rotate freely around the N–C* bond, one conformational problem remains: Can the optically active group assume several stable conformations or are some conformations clearly preferred? The latter would be the favorable case for asymmetric catalysis.

In the following, it will be shown using a model compound that the optically active group CHMePh can assume certain preferred conformations, depending on neighboring substituents R at the chelate ring and on other ligands at the metal atom. The application of this concept to asymmetric catalysis will then be described.

## 6. Diastereomeric $CpMo(CO)_2$amidinato Complexes with Labile Configuration at Mo



The synthesis of the model compounds starts from the square pyramidal $CpMo(CO)_3Cl$, in which the Cp-group occupies the apex of the pyramid, and an amidine derived from benzoic acid, in which one of the *N*-substituents is benzyl and the other (*S*)-1-phenylethyl, is shown in Scheme 7.

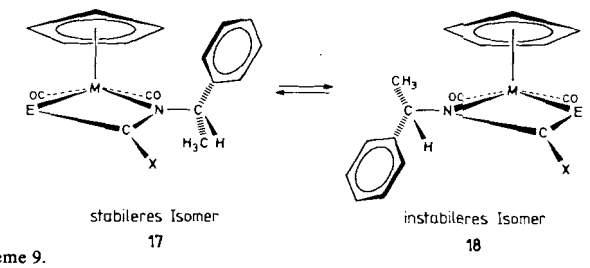
By elimination of CO and HCl two diastereomeric complexes, ($S_{Mo}S_C$)-**15** and ($R_{Mo}S_C$)-**16**, are formed in which the amidinate anion occupies the two vacant coordination sites of the basal square of the pyramid in two ways which only differ in the configuration about the Mo atom. The two isomers may be separated by fractional crystallization or by preparative liquid chromatography[62]. The separation can be monitored by $^1$H-NMR spectroscopy, since the chemical shifts of almost all resonances differ significantly

Scheme 7.

in both diastereomers (Scheme 8, bottom). This is especially true for the Cp-singlets, which are particularly suited for the determination of the diastereomeric purity.

Scheme 8. The diastereomers **15** and **16**: ORTEP representation of the structures (top) and $^1$H-NMR spectrum ([D$_6$]acetone) of the 20:80 equilibrium mixture (bottom).

Upon heating the separated diastereomers, *e.g.* in toluene, a change of configuration about Mo is observed[63-66]. The half-lives are approximately 30 min at 70°C. The course of this intramolecular isomerization can most simply be thought of as a rotation of the amidinate ligand by 180°[67], which transforms the ($S_{Mo}S_C$)-isomer **15** into the ($R_{Mo}S_C$)-isomer **16** and *vice versa*. After ten half-lives, an equilibrium mixture of diastereomers is produced, regardless of whether one started with **15** or **16**, or from a mixture of both. The lower part of Scheme 8 shows the spectrum of the equilibrium mixture **15** ⇄ **16**: integration indicates that this consists of 20% of **15** and 80% of **16**. The following formulas, which demonstrate the intramolecular interactions, are intended to indicate why isomer **16** is thermodynamically more stable.



In these formulas the Cp-ring is oriented upward. The two carbonyl groups of the $CpMo(CO)_2$ fragment are located at the rear and are sketched lightly in Scheme 9 but omitted for clarity in the other formulas. X-ray structural analyses show that the chelate ring, which is tilted forward, is completely planar and that $C_{ipso}$ of the ring-bound phenyl group and the two extra-annular C atoms of the *N*-substituents also lie in this plane.

Despite their complicated structure, the model compounds **15** and **16** have only limited possibilities of changing the structure of the molecule by intramolecular rotations. Rotation around the metal-Cp axis or the metal-CO bonds have no stereochemical consequences. According to X-ray structure analyses, the phenyl ring connected to the chelate ring is almost always perpendicular to the ligand plane. Derivatives with a methyl group or hydrogen atom in place of this phenyl ring (see Section 8) do not pose any problem with respect to rotamers. The only intramolecular motions which change the geometry of molecules **15** and **16** are rotations of the *N*-substituents around the N–C bonds in connection with adjustment of their phenyl rings, the conformational problem to be discussed in the following section.

## 7. Conformational Analysis of the Diastereomers

The rules which emerged in the conformational analysis of these compounds with respect to the position of the *N*-substituents are listed in decreasing order of importance[62,68-71] (cf. Scheme 9):

1) C–H bond in the ligand plane
2) Ph/Cp attraction
3) Me/Cp repulsion

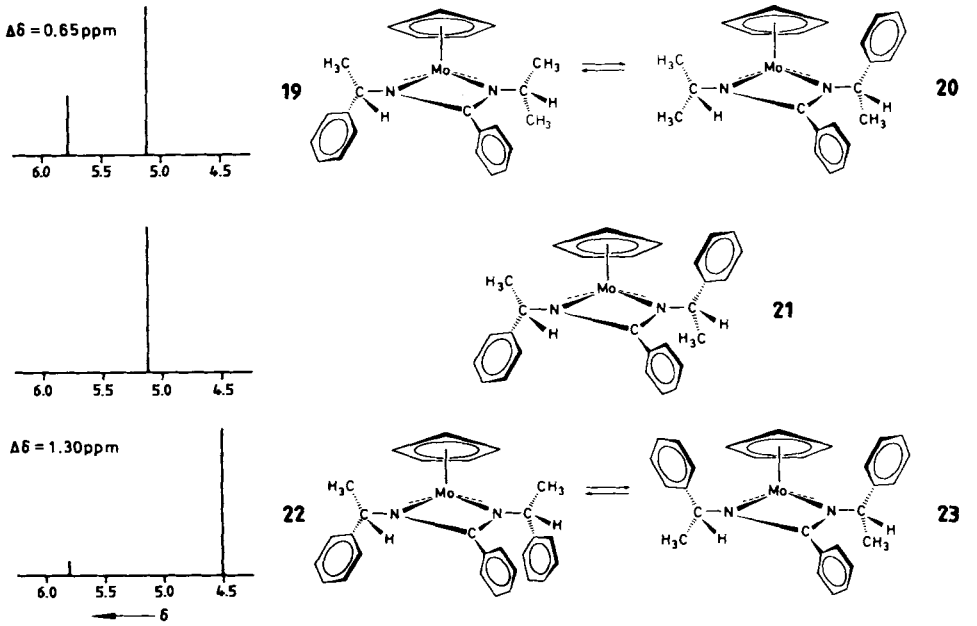
Scheme 9.

Decisive for the conformation is that the C–H bond of the asymmetric center always lies in the ligand plane pointing away from the molybdenum. This conformation

determining effect is a consequence of the steric hindrance of the substituents X (methyl or phenyl) with the substituents of the asymmetric C*-atom. Putting the methyl or phenyl substituents of C* close to the ligand plane would result in extremely short distances to X. The steric interaction with the neighboring methyl or phenyl substituent on the chelate ring is least for the small H-substituent.

Given the priority order[*] of the ligands Cp > NR* > E, the chiral center at the metal atom of **17** in Scheme 9 assumes the *R*-configuration[66,72-75]. With an (*S*)-configurated asymmetric C atom the phenyl ring in the ($R_{Mo}S_C$)-diastereomer **17** is directed upwards and approaches the Cp ring so closely that the distance between the midpoints of the Cp and phenyl rings is only *ca.* 5 Å, as in solid benzene. Similar to solid[76,77] and liquid[78] benzene, as well as to benzene dimers in the gas phase[79], the Cp and phenyl rings are mutually perpendicular and form a T-shaped arrangement. This interaction is energetically favored, and is designated the "β-phenyl effect" because of the β-position of the phenyl group relative to the metal atom[80-82].

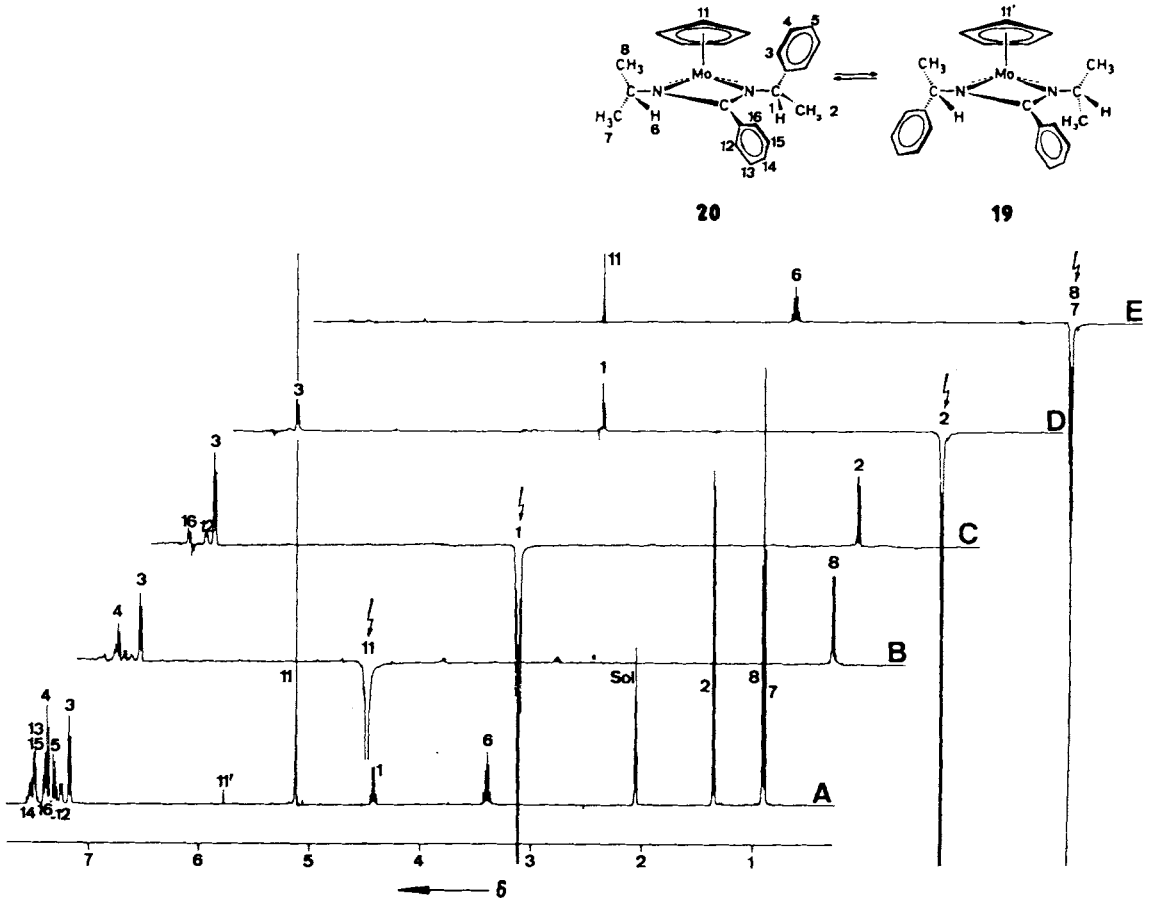
Rotation of the E,N-chelating ligand in **17** by 180° with respect to the $CpMo(CO)_2$-fragment results in **18** (Scheme 9), the ($S_{Mo}S_C$)-isomer. Since according to rule 1 the C–H bond of the asymmetric center in the ligand plane is directed away from the metal, an (*S*)-configuration at the asymmetric carbon atom directs the methyl group upwards and the phenyl group downwards. The very weak interaction Me/Cp is energetically unfavorable, *i.e.* it has a repulsive effect. In the equilibrium the ($R_{Mo}S_C$)-isomer **17** dominates.



With $E = N-CH_2C_6H_5$ we return to example **15**/**16** in Scheme 8[62,68-71]. For this system it was possible to obtain single crystals for both the thermodynamically more stable ($R_{Mo}S_C$)-isomer **16** and the less stable ($S_{Mo}S_C$)-isomer **15** and to carry out X-ray structure analyses[68,69]. The ORTEP drawings shown above the formulas of **15** and **16** confirm that the orientations of both *N*-substituents, 1-phenylethyl and benzyl, adhere to the above-mentioned rules. In both diastereomers the C–H bonds of the *N*-substituents on both sides lie in the ligand plane. In the thermodynamically more stable isomer **16** the two phenyl rings are directed upwards. This "winner"-type exhibits two stabilizing Ph/Cp interactions. In the thermodynamically less stable isomer **15** the phenyl ring of the benzyl group points upwards, but the phenyl ring of the 1-phenylethyl group hangs downwards. This "mixed"-type thus experiences a stabilizing Ph/Cp interaction and a destabilizing Me/Cp interaction. That the Ph/Cp interaction in **15** and **16** is actually stabilizing results from the following consideration: The 1-phenylethyl group orients its only C*–H bond in the ligand plane in both **15** and **16**, but, in contrast, the benzyl group does so with two different C–H bonds. If the amidinato ligand were to remain rigid throughout the 180° rotation which converts the "winner"-type **16** into the "mixed"-type **15**, the same C–H bonds would lie in the ligand plane in **15** as in **16**. However, both phenyl rings in **15** would hang downwards. To exploit the Ph/Cp attraction, the benzyl group in "mixed"-type **15** therefore rotates by 120°, and hence in **15** and **16** different C–H bonds of the benzyl group lie in the ligand plane.

X-ray structures of a dozen similar compounds indicate that the C–H bond of the 1-phenylethyl group lies practically in the ligand plane[68,69,83,84]. Small deviations are confined to the thermodynamically less stable diastereomers and consistently show the C–H bond pointed slightly above the ligand plane[70]. The reason for this minor deviation from the conformational rules 1–3 appears to be the Me/Cp repulsion, which is attenuated by this torsion.

The results of the X-ray structure determinations imply that the intramolecular interactions are more important than packing effects in the crystal lattice. $^1$H-NMR evidence confirms that the conformations found in the solid state are also the preferred conformations in solution. In the equilibrium **15** ⇌ **16** the "winner"-type **16** outweighs the "mixed"-type **15** (80 : 20)[62]. The chemical shifts of the Cp signals exhibited by diastereomers **15** and **16** (Scheme 8, bottom) differ by *ca.* 0.5 ppm. This can be attributed to the fact that the Cp ring of the "winner"-type **16** is located in the inner anisotropic region of the two phenyl rings, whereas the Cp ring of the "mixed"-type **15** experiences only one such anisotropic region. The Cp signal of **16** is therefore shifted to higher field relative to that of **15**[62]. Correspondingly, in all the diastereomers examined to date the Cp signals of the thermodynamically more stable isomers lie at higher field[62-71].

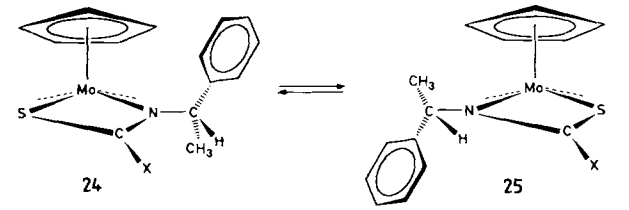


The three isomers **21**, **22**, and **23** (Scheme 10) demonstrate impressively the stabilization by Ph/Cp attraction and destabilization by Me/Cp repulsion. If the (*S*)-phenylethyl group is introduced at one N atom and the (*R*)-form at the other N atom of the amidinate complexes, two isomers are possible (Scheme 10, bottom). One is a "winner"-type **23**, with two Ph/Cp attractions, and the other a "loser"-type **22**, with two hanging phenyl groups and two Me/Cp repulsions. At equilibrium the diastereomers **22** and **23** are in the ratio 6 : 94: the Cp-signal of the "winner"-type is shifted by 1.3 ppm to higher field (two Ph/Cp interactions) with respect to the position of the "loser"-type[70]. If the same optically active (*S*)-1-phenylethyl group at both N atoms is used to synthesize the $CpMo(CO)_2$amidinate complex, isomer **21** is obtained (Scheme 10, center). Whereas "winner"-type **23** and "loser"-type **22** interconvert upon change of configuration at the Mo-atom, the "mixed"-type **21** transforms, so to speak, into itself in this metal-centered rearrangement. With the prerequisite that both C*–H bonds in **21** lie in the ligand plane, one Ph/Cp attraction and one Me/Cp repulsion result. Thus the anisotropic effect of only one phenyl ring is experienced by the Cp group so that the chemical shift of **21** lies exactly halfway between those of the isomeric compounds **22** and **23** (Scheme 10). The diastereomers **19** and **20**, substituted at the N atoms with (*S*)-1-phenylethyl and isopropyl groups, fit neatly into this picture with their diastereomeric ratio of 30 : 70 and their chemical shifts (Scheme 10, top)[62].

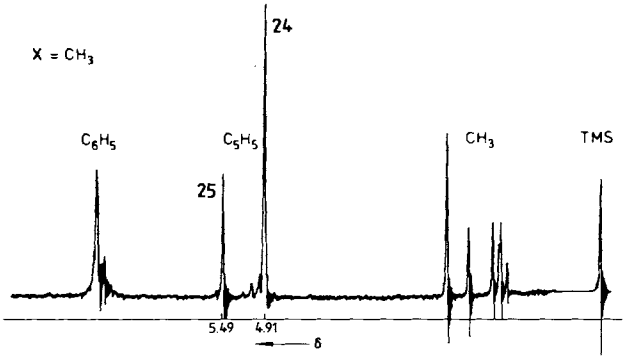
[*] The *R,S* system proposed by *Cahn, Ingold,* and *Prelog* [74] makes no provision for inclusion of π-bonded ligands in the sequence rule. *Tirouflet* [72] and *Baird* [73] have suggested that polyhapto ligands be considered as pseudoatoms with atomic number equal to the sum of the atomic numbers of the π-bonded atoms. Thus, for example, $\eta^6$-$C_6H_6$, $\eta^5$-$C_5H_5$, and $\eta^2$-$C_2H_4$ are classified as pseudoatoms having the atomic numbers 36, 30, and 12, respectively.

Scheme 10. $^1$H-NMR line spectra of the compounds **19**—**23**. The ring-current effect of the phenyl substituents influences the position of the Cp signals.

As shown for **20** in Scheme 11, nuclear Overhauser effect (NOE) difference spectroscopy provides direct proof that the conformations depicted in Schemes 8—12 are also those preferred in solution[71,85,86]. Spectrum A shows the 400 MHz $^1$H-NMR spectrum of **20** contaminated with 3% of diastereomer **19**. Upon saturation of the Cp-signal 11 of **20** (spectrum B) the signals of protons 3 and 4 of the 1-phenylethyl substituent and those of the methyl group 8 of the isopropyl substituent are enhanced, corresponding to their close proximity in space. In contrast, no enhance-



Scheme 11. A = 400 MHz $^1$H-NMR spectrum of **20/19** in [D$_6$]acetone. B to E = $^1$H-NMR-NOE difference spectra after saturating the signals indicated by the arrows (cf. also text).



ment is found in the signals of protons 1 and 6 nor in those of methyl groups 2 and 7, which lie far removed from the Cp-ring. In spectra C and D the signals 1 and 2, respectively, are saturated. Enhancements are observed for the *ortho*-phenyl protons 3 as well as for the methyl group 2 and the proton 1, *i.e.* those substituents bonded to the same C atom.

Close proximity in space of the Cp-protons 11 with the protons 1 and 6 and with the methyl group 2, respectively, is precluded by spectra C and D. However, upon saturation of the methyl group 8 of the isopropyl substituent the resonances for both 6 and the neighboring Cp-ring 11 are enhanced (spectrum E)[71]. These NOE difference spectra thus confirm the preferred conformations deduced from the diastereomeric ratios and chemical shifts.

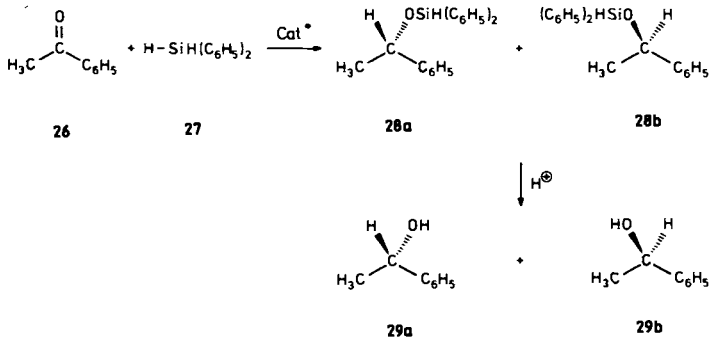
## 8. Equilibria of Diastereomeric CpMo(CO)$_2$thioamidato Complexes

The thioamidato complexes **24** and **25** in Scheme 12, which are similar to the amidinato complexes **15**—**23**, also contain a planar four-membered chelate ring[83,84].

| X | H | $CH_3$ | $C_6H_5$ | $C_{10}H_7$ |
|---|---|---|---|---|
| **24**:**25** | 50:50 | 69:31 | 77:23 | 87:13 |

Scheme 12. Equilibrium of diastereomers **24** ⇌ **25**. 60 MHz-$^1$H-NMR spectrum ([D$_8$]toluene, 40 °C) and dependence of the position of equilibrium on substituents X.

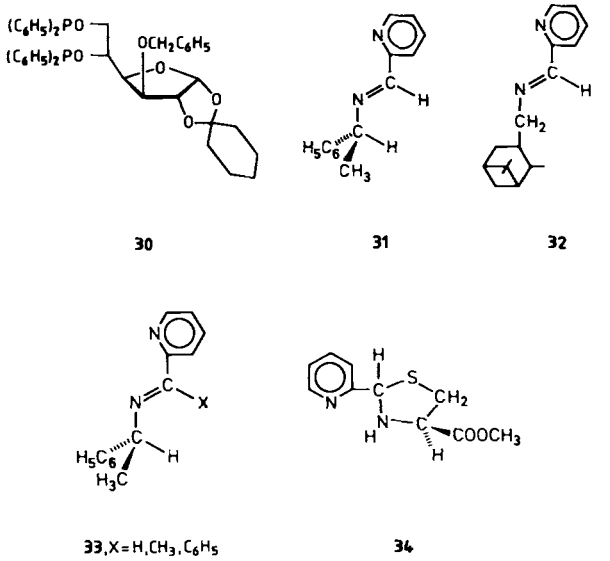
With these compounds, too, the two diastereomers interconvert *via* an intramolecular metal-centered rearrangement. The stability of diastereomers **24** and **25** is also determined by the interaction of the substituents at the asymmetric C atom with the other substituents. Under the assumption that the C*—H bond lies in the ligand plane, complexes with "large" substituents X = $C_{10}H_7$ (1-naphthyl), $C_6H_5$, and $CH_3$ are thermodynamically more stable in the form of diastereomer **24** due to the Ph/Cp attractive interaction than as diastereomer **25** with a Me/Cp repulsive interaction. For the system derived from acetic acid with X = $CH_3$, this results in a diastereomeric ratio of 69:31 (Scheme 12, bottom) and in a shift of the Cp-signal to high field in the favored isomer **24** (Scheme 12, middle). Similar high field shifts are exhibited by the complexes derived from benzoic acid and 1-naphthoic acid (X = $C_6H_5$ and 1-$C_{10}H_7$, resp.), whose diastereomer ratios are 77:23 and 87:13, respectively.



More than 50 different CpMo(CO)$_2$amidinato and -thioamidato complexes—more than a dozen of which have been studied by X-ray structure analysis—confirm this conformational concept without exception. It holds even for complexes with methyl substituted Cp-rings in which the rotation of the five-membered ring around the metal-ring axis and the associated repulsion of the methyl group and the neighboring phenyl group do not cancel out the Ph/Cp attraction[91]. However, difficulties are encountered with rules 1—3 (Section 7) if it is attempted to extend the conformational analysis to five-membered chelate rings. Apparently, additional interactions of the substituents of the expanded chelate ring with other groups in the molecule, *e.g.* the metal carbonyls, are introduced which are absent in CpMo(CO)$_2$-complexes with four-membered chelate rings[92–95].

Difficulties of an entirely different kind are encountered in the transition to CpMo(CO)$_2$thioamidato complexes derived from formic acid with X = H. Here, both diastereomers ($S_{Mo}S_C$)-**24** and ($R_{Mo}S_C$)-**25** are present in equal amounts in the equilibrium mixture (Scheme 12, below) and both exhibit approximately the same chemical shifts for the Cp-ring. This basic change when X = H results from the absence of steric hindrance between the chelate ring and the Me- and Ph-substituents of the asymmetric C atom. Thus rule 1 (Section 7), the basis of the conformational analysis, no longer holds.

The result of the conformational analyses of CpMo(CO)$_2$amidinato and -thioamidato complexes is, thus, that the substituents of an asymmetric center at the N-atom of a chelate ring assume certain preferred conformations, despite free rotation about the N—C* bond. These conformations are determined by Ph/Cp attractions, Me/Cp repulsions, and especially by the neighboring substituent X at the chelate ring.



## 9. Asymmetric Hydrosilylation with Catalysts Containing Nitrogen Ligands

Asymmetric hydrosilylation of prochiral ketones with compounds containing SiH bonds is only moderately successful when those Rh/phosphane catalyst systems are used which are highly efficient for hydrogenations. For example, in the model reaction of acetophenone **26** with diphenylsilane **27**, which leads to the diphenylsilyl ethers **28a** and **28b** and to 1-phenylethanols **29a** and **29b** after hydrolysis[46,96,97] (Scheme 13), the precatalyst [Rh(cod)Cl]$_2$ with diop **5** as cocatalyst only results in 32% and with norphos **10** only in 16% optical induction[46,98,99]. Until recently, the best result achieved for the model reaction was 55% optical induction employing the system [Rh(cod)Cl]$_2$/glucophinite, where glucophinite **30** is a P-containing chelate ligand which is derived from D-glucose (Scheme 14)[100].

Scheme 13.

In comparison, chelating ligands with a lateral center of asymmetry based on model compound **14** were a distinct improvement. In the model reaction of Scheme 13 the precatalyst $[Rh(cod)Cl]_2$ with the pyridineimine **31**—a derivative of (−)-1-phenylethylamine—gives 57.3% *ee*[101] and with the pyridineimine **32**—a derivative of (−)-3-aminomethylpinane—even 78% *ee*[102] (Scheme 14). Similar stereoselectivities are observed in the asymmetric hydrosilylation of other prochiral ketones such as benzyl methyl ketone and *tert*-butyl methyl ketone[99]. Chelate complexes of the type **14** are thus not only catalytically active but their enantioselectivity also surpasses those catalyst which transfer chiral information as outlined in Scheme 5.

Scheme 14.

Catalysts with the ligands **31** and **32** demonstrate the superiority of the concept of direct interaction between the inducing chirality center and the coordination site at the metal where the prochiral substrates are converted into the optically active compounds, compared with the principle of using two phenyl rings to transfer the chiral information.

A connection between the conformation of $CpMo(CO)_2$-derivatives and the results of asymmetric hydrosilylation is also indicated. The conformational analysis of thioamidato complexes (Scheme 12) shows that the position of the substituents at the asymmetric C atom is principally determined by the substituents X. A corresponding variation of this substituent X from H to $CH_3$ and $C_6H_5$ (**33**, Scheme 14) also results in large variations in the optical induction of the asymmetric hydrosilylation from 57% *ee* (*S*) to 18% *ee* (*R*) and 9% *ee* (*S*)[101] in the catalyst system $[Rh(cod)Cl]_2$/**33**. A direct parallel between the model complex **24**/**25** and the system $[Rh(cod)Cl]_2$/**33** should not be expected, since the model exhibits interactions such as Ph/Cp attraction or Me/Cp repulsion, which are absent in the catalyst. However, the influence of the conformation of the chiral substituent at the chelate ring by the neighboring moiety X is apparent.

The restriction of rotational freedom around the metal-ligand bond, the use of five-membered chelate rings, and the introduction of additional rigidity are known to enhance induction with optically active chelating phosphanes. For ligands **31**—**34**, with their laterally bound centers of asymmetry, the first two points are taken into consideration by the structures favoring five-membered chelate rings. According to the results of the conformational analysis, the lateral asymmetric centers in complexes **31**, **32**, and **33** should assume certain preferred conformations, but a further restriction of conformational variety, *e.g.* by incorporation of the asymmetric center in a ring skeleton, should have a further positive effect on the optical induction. This concept is realized in **34**, in which the asymmetric center of cysteine is part of a thiazolidine ring. The added rigidity allows the optical induction achieved with the $[Rh(cod)Cl]_2$/**34** catalyst to be increased to 87.6% *ee*[102], the highest value obtained so far for the model reaction in Scheme 13.

## 10. Summary and Prospects

Complexes with the ligands **31**–**33** correspond to type **14** (Scheme 6). One end of the chelating ligand is an imino group with a chiral substituent and the other a pyridine nitrogen. If the Rh atom of the catalyst is assumed to be octahedrally coordinated, four additional coordination sites beyond the two for the chelate ligand have to be filled. Of these, three are *cis* to =N−R*; one in, one above, and one below the plane of the chelate ring. A further position is *trans* to =N−R* in the plane of the chelate ring (Scheme 6). These four positions are stereochemically different. The *cis*-positions are directly influenced by the chiral substituent; in contrast, the *trans*-position is far removed from the inducing chirality center. One might therefore attempt to introduce the same optically active R*-group at both N atoms of the chelating ligand. A ligand of that kind would have a $C_2$-axis. In an octahedral chelate complex all positions of the Rh-octahedron would be under the direct influence of the chiral groups. Furthermore, the four remaining coordination sites in such a chelate complex would become pairwise equivalent. This reduction of the number of possible binding sites for the substrate from four to two should facilitate a further increase in stereoselectivity.

The catalysts $[Rh(cod)Cl]_2$/**31**—**34** with their laterally bound centers of asymmetry are not catalytically active in the asymmetric hydrogenations described in Section 2. The success achieved in hydrosilylation suggests, however, that

systems of the type **14** should be used in asymmetric catalyses such as Grignard cross-coupling, hydroformylation, olefin oligomerization, olefin/diazoalkane cyclopropanation, Michael addition, *etc.* One could thus exploit the advantage of the new concept, *i.e.* of bringing a multitude of chiralities derived from optically active amines into direct contact with those positions at the central metal at which the conversion of the prochiral substrate into the optically active product takes place. It is to be hoped that these developments in the area of enantioselective catalysis constitute a step toward the goal stated in the thesis which precedes this review.

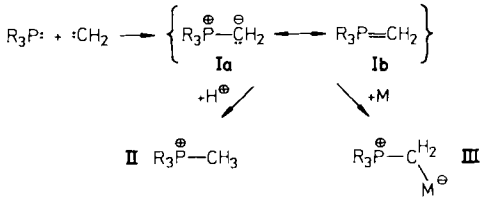
# Phosphorus Ylides in the Coordination Sphere of Transition Metals: An Inventory

**By Hubert Schmidbaur***



*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

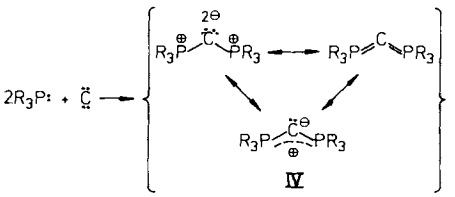
Phosphorus ylides are not only classical reagents in organic chemistry, but also play an increasingly important role as novel components in organometallic compounds. These metallic "ylide complexes" are either synthesized from "preformed ylides" and coordination compounds by addition or substitution, on the building block principle, or they are formed, in sometimes complicated reactions, from phosphanes, metal complexes, and $C_1$ substrates in the coordination sphere of the metals. The resulting metal-carbon bonds are greatly modified in their properties by the immediate presence of the phosphonium center and often belong to the most stable of M-C structural units. The metal can come from any group of the periodic table, including the lanthanoids and actinoids. Numerous preparative and structural studies are gradually enabling us to gain an overall picture of the scope of this area of research.

## 1. Introduction

Phosphorus ylides are remarkable compounds from many points of view. Too little emphasized, however, is the fact that they can be classified as phosphane-stabilized carbenes, and may thus constitute the oldest and best studied class of carbene complexes[1]. In contrast to such complexes with all the other elements these phosphorus-carbene complexes are very stable even in the absence of stabilizing substituents or salt components. This exceptional position vividly manifests itself on comparison with the carbene complexes of the homologous amines, arsanes or stibanes (nitrogen, arsenic and antimony ylides) or of sulfanes (sulfur ylides), which decompose very easily and act as carbene carriers. Therefore, phosphorus ylides are not only described as dipolar carbene complexes with the formula **Ia**, but also in the sense of a formal charge compensation as neutral molecules **Ib**[2,3]. Their reactions and most of their physical properties, however, give a clear indication that their actual bonding pattern is much closer to the 1,2-zwitterionic structure **Ia**. The functional effect of the two reactive centers—carbanion and phosphonium group—is, however, differently exhibited and the phosphonium unit remains very much in the background during the primary step of almost all the reactions.

The absolute dominance of the carbanion formed by polarization of the carbene function becomes obvious in ylides and particularly in "salt-free" ylides from an extraordinarily high *Brønsted basicity*, which is of importance in the secondary process known as "transylidation" in reactions with free ylides[4].

The exceptional donor character with respect to practically all metals M (formula **III**), which in many cases suffices to drive almost all other ligands out of the metal's coordination sphere, is even more striking[5]. There are alternatives, however, if an ylide attack is also possible at one of the ligands already present, whereupon the strong nucleophilicity of the ylide comes into play, which also constitutes the most important characteristic of ylide reactivity in organic chemistry[1].



The three important characteristic features of the phosphorus ylides—basicity, donor activity, and nucleophilicity—are expressions of the excess charge on the ylide C atom, which is not adequately compensated by the $P^{\oplus}$ center and which expresses itself differently depending on the

[*] Prof. Dr. H. Schmidbaur
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

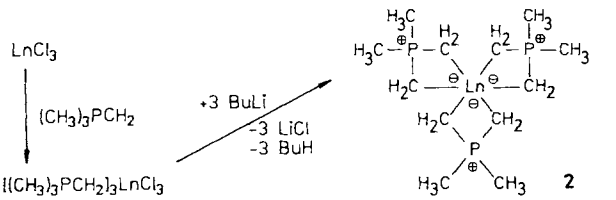
nature of the reaction partner. From this it will be clear that the enormous variety of oxidation levels, coordination numbers, and complex geometries that characterize metals, offers a plethora of interaction possibilities for ylides that are only now beginning to be understood.

It must be emphasized here that—as can be seen from formula **III**—ylide complexes of metals principally constitute organometallic compounds, whose novel metal-carbon bonds lie under the electronic and steric influence of the onium center. In contrast to syntheses with organometallic reagents (RLi, MNgX, *etc.*) the cation accompanying the anion (**Ia**!) stays in the product (**III**) which is formed after attachment to the metal, whereas otherwise the organic residue is separated from the $Li^{\oplus}$ or $Mg^{2\oplus}$ cations.

This rapidly expanding research area has received further impetus from new developments ranging from multifunctional ylides, on the one hand, to multinuclear metal compounds on the other. The symmetrical ylides of type **IV** bearing the trivial name "carbodiphosphoranes" play an important role among the multifunctional ylides and may be formulated as bisphosphane complexes of naked carbon.

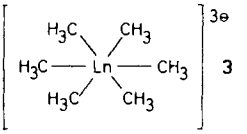
**IV**

It should be noted that other similar element-carbon-element bridges $E{=}C{=}E$ or $\overset{\oplus}{E}{-}\overset{2\ominus}{\underset{\cdot\cdot}{C}}{-}\overset{\oplus}{E}$ are, as yet, almost completely unknown, which once again emphasizes the special position of the phosphorus double ylides.



The stimulus for working with ylide complexes results from the real possibility of utilizing the compounds for metal-catalyzed reactions and for other purposes. The ever increasing use of tertiary phosphanes as additional ligands in stoichiometric or catalytic reactions at transition metal complexes makes it more likely that ylide complexes play a part as intermediates or products in such processes. In fact it has been known for a long time that phosphorus ylides can be formed in the coordination spheres of metals, and hence the directed introduction of preformed ylides is no longer the only preparative route to these complexes.

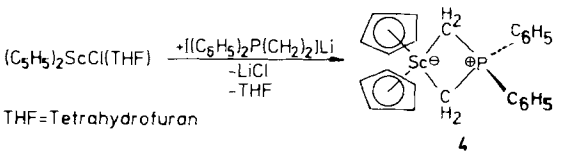
The literature concerning the formation and reactions of ylides at metal centers, which is rapidly becoming more difficult to survey, has been reviewed several times from various points of view[1, 5–7]. These valuable reviews will now be supplemented here, in that developments of recent years will be put into perspective with the basic discoveries of the past. The subject can best be systematized according to the *periodic table*, since the interested reader is usually seeking element-specific information, which is most easily made available to him *via* this approach. Newer results are treated in more detail than earlier ones, which have already received greater attention[1, 5–7]. The subject will deliberately be restricted in this article to *transition metal compounds*. The corresponding compounds of phosphorus ylides with main group metals will be described in a further paper. A review article on the complex chemistry of the *sulfur* ylides has been published recently[8].



## 2. Complexes of Phosphorus Ylides with Scandium, Lanthanum, the Lanthanoids, and Actinoids

It is characteristic of the special position of ylide complexes amongst organometallic compounds that, even with the elements of Group 3A where the development of the chemistry of σ-bonded organometallic compounds had a late start, derivatives of methylenephosphoranes $R_3P{=}CH_2$ already play a significant role.

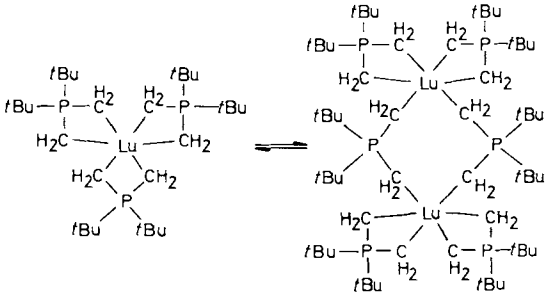
It was first shown in 1976[9] that the elements La, Pr, Nd, Sm, Gd, Ho, Er and Lu could form stable "homoleptic" ligand sheaths (**2**) with "difunctionalized $(CH_3)_3PCH_2$"[10, 11] that is with the corresponding anion $[(CH_3)_2P(CH_2)_2]^{\ominus}$. The "mixed" halide complexes **1** are reaction intermediates. Complexes of type **1** and **2** are exceedingly sensitive to oxidation and hydrolysis, but some are stable to 200°C under an inert gas. Compounds of type **2** were precursors for the hexamethylmetalate anions **3**, first described some five years later[12]:



**1** **2** Ln=La,Pr,Nd,Sm,Gd,Ho,Er,Lu

**3**

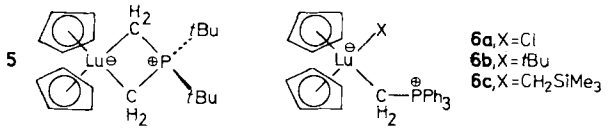
It was also discovered in 1976[13] that the bis($\eta^5$-cyclopentadienyl)scandium residue could be combined with diphenylphosphoniobismethanide to form a stable organometallic compound: The pale yellow, crystalline complex **4** is formed from $(C_6H_5)_2P(CH_3)CH_2$[14] *via* the lithiated intermediate; like the diamagnetic members of the series **2**[12] it could be characterized NMR spectroscopically.



THF=Tetrahydrofuran

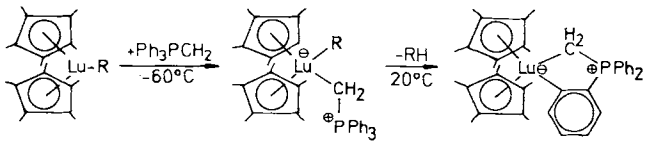
**4**

The sixfold *tert*-butyl-substituted homologue of **2**, Ln = Lu, that has recently been synthesized[15], has proven even more suitable for spectroscopic investigation, and it has been shown by means of temperature-dependent $^1H$-, $^{13}C$- and $^{31}P$-NMR spectra that there is an oligomer equilibrium **2a** ⇌ **2b** ⇌ ... in solution.



Consequently, these compounds behave like the homoleptic ylide complexes of nickel[16] or zirconium[17], in

2a 2b

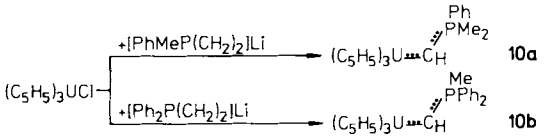


which the bidentate $[R_2P(CH_2)_2]^{\ominus}$ ligands can function both as bridge-builders as well as chelaters.

A lutetium analogue of **4** is, in contrast, strictly monomeric in benzene solution (**5**, decomp. 156°C)[15].

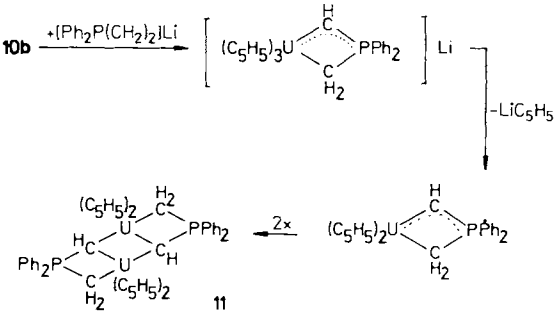
**6a**, X = Cl
**6b**, X = tBu
**6c**, X = $CH_2SiMe_3$

The mixed ylide/halide or ylide/alkyl complexes **6** formed from $(C_5H_5)_2LuCl$ or $(C_5H_5)_2LuR(THF)$ and $(C_6H_5)_3PCH_2$ in toluene are important examples of lanthanoid compounds with terminal monodentate-coordinated methylenephosphorane. Hydrolysis of **6a** leads to cleavage of Lu–C and formation of methyl(triphenyl)phosphonium chloride[18,19]. The alkyl compounds **6b** and **6c** can also be obtained from **6a** with alkylmetal reagents. $Me_3P{=}CHSiMe_3$ was used instead of $Ph_3P{=}CH_2$[19]. The hydride- and methyl-compounds **7a** and **7b**, until now only accessible with *pentamethyl*cyclopentadienyl ligands, can also yield 1:1 adducts (**8a** and **8b**, respectively) with $(C_6H_5)_3PCH_2$, but they undergo intramolecular metalation with expulsion of $H_2$ or $CH_4$ and formation of the cyclic ylide complex **9**, even at 20°C[20].



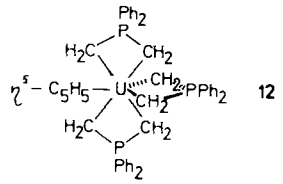
**7** **8** **9**

**a**, R = H, **b**, R = $CH_3$



The reaction **8a**, **b** → **9** is not without precedent, since similar *ortho*-metalations also occur with platinum(0), which—in accord with the oxidation state of the metal—are classified as oxidative additions[21].

To date, the sole coordination partner for phosphorus ylides amongst the actinoids is uranium. Depending upon the stoichiometry of reaction, $(\eta^5\text{-}C_5H_5)_3UCl$ reacts with the lithiated ylides $C_6H_6(CH_3)_2P{=}CH_2$ and $CH_3(C_6H_5)_2P{=}CH_2$ to give a range of new organouranium compounds, some of which exhibit remarkable types of bonding. Thus, with a 1:1 ratio of reactants[22] the dark green complexes **10a** and **10b** are formed, of which the structure of **10a** has been established by X-ray diffraction[23]. According to the X-ray structure analysis this compound possesses the shortest U–C bond known to date (2.29(4) Å), suggesting the presence of multiple-bonding; the U=C=P angle is 142(1)°.



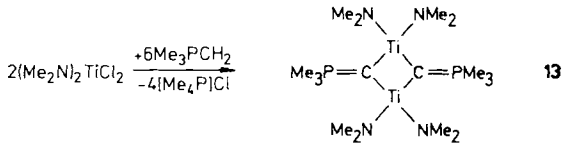
**10a**
**10b**

With molar ratios of 1:2, on the other hand, a red binuclear complex **11** is formed, presumably according to the mechanism outlined below; a monoclinic modification (containing 1/2 mol diethyl ether) and an orthorhombic modification (containing 1 mol *n*-pentane) have been elucidated by X-ray diffraction. The latter has been identified as (*M*)-[{(μ-*S*-CH)$P(C_6H_5)_2CH_2$}$U(C_5H_5)_2]_2$, taking into account the configuration at the chiral centers[24,25]. Both ylide ligands in the dimers are effective as bridging and as chelating agencies, whereby in each case one of the C atoms carries out both functions.

**11**

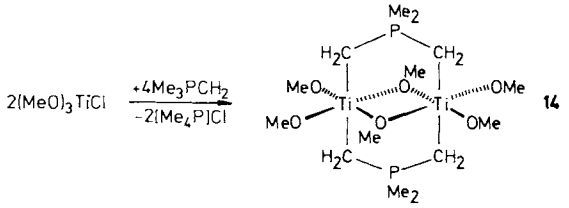
Finally, with a molar ratio of 1:3 a gold-colored, mononuclear organouranium compound **12** is obtained[22].

**12**



Aside from the remaining $\eta^5$-cyclopentadienyl ligand, **12** contains three diphenylphosphoniobismethanide ions as chelate forming ligands. The uranium atom is thus surrounded by eleven carbon atoms, of which six represent ylidic centers[22].

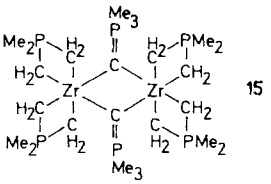
## 3. Complexes of Phosphorus Ylides with Titanium, Zirconium, and Hafnium



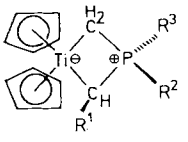
The first attempts at synthesizing organo-titanium and -zirconium compounds with ylidic ligands met with little success, since the simplest reactions, *e.g.* of $TiCl_4$ with $(CH_3)_3PCH_2$, only yield insoluble and hardly characterizable products[26]. Analytical data gave only rough indications of the stoichiometry.

However, novel prototypes of polynuclear ylide complexes were discovered on using dimethylamino- or methoxy-titanium halides as starting materials. Thus, reaction

of $[(CH_3)_2N]_2TiCl_2$ with $(CH_3)_3PCH_2$ affords the 1,3-dititanacyclobutane **13**[26], whereas reaction with $(CH_3O)_3TiCl$ yields the double octahedral species **14**[27]. In **14** the Ti atoms appear as substituents at the ylidic C atom—a situation which was previously only known in Si analogues[28]. The ylide braces of the coordination octahedron in **14** are unique. In both reactions the ylides are deprotonating in the sense of a transylidation, giving rise to the formation of $[(CH_3)_4P]Cl$ as a byproduct.

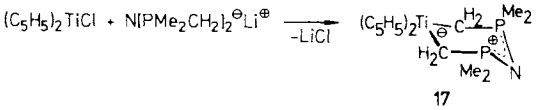


**13**



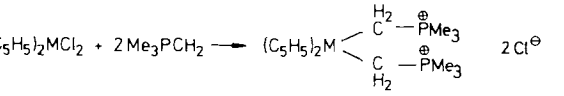
**14**

A stimulating analogy to the bonding observed in the titanium compound **13** has recently been discovered in the zirconium compound **15**, which is formed from $[(CH_3)_3CCH_2]_4Zr$ and $(CH_3)_3PCH_2$ as yellow, monoclinic crystals. The Zr–C bonds of the 1,3-dizirconiacyclobutane are extremely short, whereas the $PC_2Zr$ chelate rings correspond to the known models with other transition metals. The Zr–C bonds *trans* to the ylide bridges (equatorial) are, however, significantly longer than the apical Zr–C bonds.



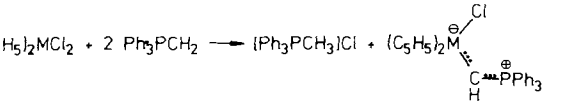
**15**

Derivatives which have a close relationship with their metal(III) analogues have been prepared by the reaction of bis($\eta^5$-cyclopentadienyl)metal halides of Group 4a with phosphorus ylides. According to magnetic and ESR studies the simplest type **16** is to be regarded as a genuine $Ti^{III}(d^1)$ complex[13].



**16a**, $R^1$ = H, $R^2$ = $R^3$ = Ph; m.p. = 152–153 °C; purple
**16b**, $R^1$ = H, $R^2$ = Ph, $R^3$ = Me; m.p. = 147–150 °C; purple
**16c**, $R^1$ = H, $R^2$ = $R^3$ = Me; m.p. = 122–123 °C; black-green
**16d**, $R^1$ = Me, $R^2$ = $R^3$ = Et; m.p. = 61–63 °C; dark green

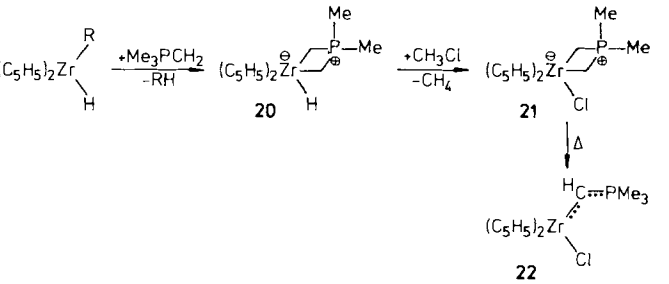
A related double ylide complex **17** exhibits similar properties[26].



**17**

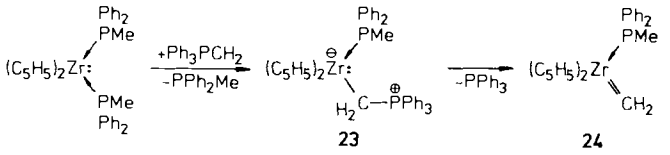
Without prelithiation of the ylides[26], the double onium salts **18** are formed,

**18a**, M = Ti
**18b**, M = Zr



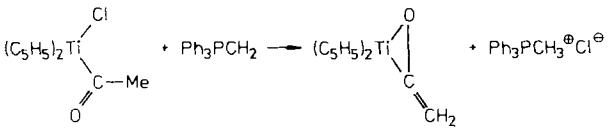
or, in the case of triphenylphosphoniomethanide when M = Zr or Hf, the transylidation product[27], **19**.

**19a**, M = Zr; m.p. = 199–210 °C; yellow
**19b**, M = Hf; m.p. = 120 °C (decomp.), yellow



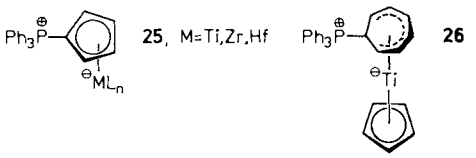
X-ray structure analysis of **19a** reveals that both of the bonds in the Zr–CH–P bridge possess substantial multiple bond character: Zr–C 2.152(8), P–C 1.708(6) Å, Zr–C–P 135.9(3)°. Thus, the bonding is similar to that in the uranium compound **10a**. Correspondingly, compounds **10a** and **19a** also behave similarly in their reactions, of which the important CO insertion has been studied in detail[23,28].

Yet another type of product is formed on reaction of alkylbis($\eta^5$-cyclopentadienyl)zirconium hydride with $(CH_3)_3PCH_2$: elimination of alkane takes place, resulting in formation of the green-colored ylide chelate **20**, which undergoes a hydride/chloride exchange with chloromethane to give the colorless derivative **21**[29].



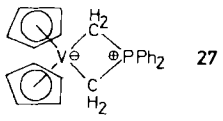
Thermal rearrangement of **21** at 65–70 °C leads to the yellow isomer **22**, which corresponds to the triphenylphosphonio compound **19a**. In the case of **19a**, isomerization to the ylide-chelate of type **21** is precluded, since no second alkyl group with an acid H atom is available at the P-atom[29].

An electron-rich bis($\eta^5$-cyclopentadienyl)zirconium(II) complex ($d^2$!) reacts with $(C_6H_5)_3PCH_2$ with transfer of methylene to the metal atom. The likely intermediate **23**, containing a $Zr–CH_2–P(C_6H_5)_3$ moiety, is converted by elimination of $P(C_6H_5)_3$ into the—albeit nonisolable—complex **24**[30,31].



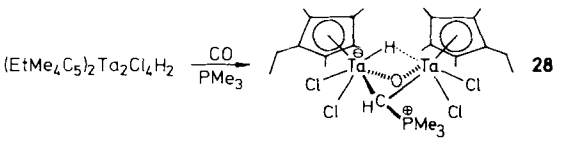
23 24

Reaction of an acetyl(chloro)titanium(IV) complex with $(C_6H_5)_3PCH_2$ does not lead to the formation of an ylide complex or to the product of a simple Wittig olefination, but to the formation of a metal ketene complex[32].



Phosphonio-cyclopentadienide and -cycloheptatrienide complexes of titanium, zirconium and hafnium (**25**, **26**) involve a special relationship between metal and ligand and will, therefore, not be considered here. None of the structures is as yet sufficiently well known[33,34].

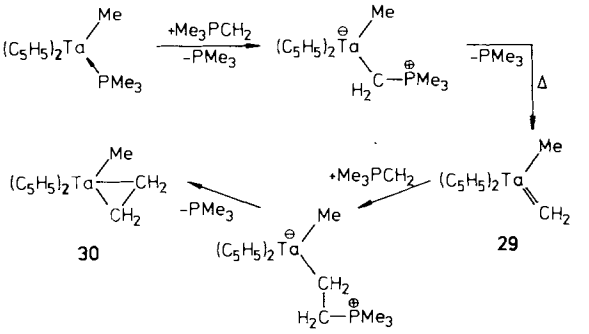
25, M=Ti,Zr,Hf 26



## 4. Complexes of Phosphorus Ylides with Vanadium and Tantalum

Vanadium and its homologues have as yet rarely been used as coordination centers for phosphorus ylides. True, the cation formulated as $[(C_6H_5)_3PCH_2]_4V^{2\oplus}$ constitutes one of the oldest examples of a transition metal-ylide complex[35], yet no other such vanadium compound has since been described, apart from the chelate **27**. The complex **27** can be synthesized according to the method given for **4** or **16a** and has been unequivocally identified as a $V^{III}(d^2)$ complex by ESR spectroscopy[13].

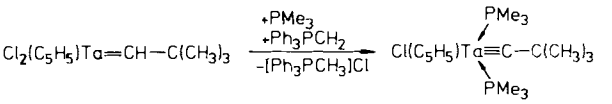
27



Surprisingly, a binuclear tantalum complex **28** was obtained on reaction of a dihydride precursor with CO followed by $P(CH_3)_3$[36].

28

The $[(CH_3)_3P^{\oplus}-CH]$ unit, which functions as a bridge ligand in **28**, is evidently formed in the course of this reaction from complexed CO, whereby oxygen is separated from the C atom and transformed into an oxo bridge. The overall process is one of the most remarkable findings yet in the field of ylide complexes. The molecular structure of **28** in the yellow, monoclinic crystal has been determined X-ray crystallographically. The P–C separation is 1.751(19) Å and, thus, can scarcely be classified as ylidic. The unequal Ta–C distances, on the other hand, are relatively short (2.187(17) and 2.354(17) Å)[37].

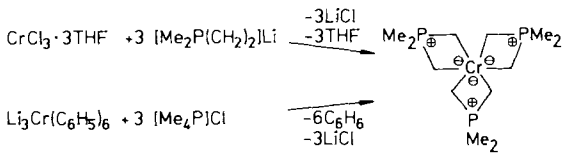


The nonisolable intermediate formed in the reaction of the electron-rich $Ta^{III}$ complex $(C_5H_5)_2TaCH_3[P(CH_3)_3]$ with $(CH_3)_3PCH_2$ should be formulated as an ylide adduct; elimination of phosphane, even under mild conditions, then furnishes the complex **29**, which reacts with further $(CH_3)_3PCH_2$ in a similar manner to yield the ethylene complex **30**[38].

30 29

Noteworthy here, is the ease of transfer of the carbene from the ylide to the metal, *i.e.* the ylide multiple bond (!) can be ruptured without difficulty. Closely related tungsten compounds exhibit similar behavior (cf. Section 5.3).

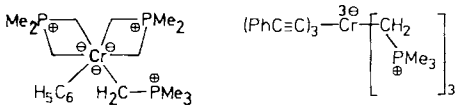
The reaction steps formulated above for $(CH_3)_3PCH_2$ can also be accomplished with $(CH_3)_3P{=}CHC_6H_5$, $(C_6H_5)_3P{=}CHC_6H_5$ and $(C_2H_5)_3P{=}CHCH_3$, but not with $(C_6H_5)_3P{=}CH{-}C(CH_3)_3$ and $(C_2H_5)_3P{=}CH{-}C(O)CH_3$, where limits are set by steric hindrance or reduction in nucleophilicity[38]. In contrast, in the reaction



the ylide functions only as dehydrohalogenating base[39].

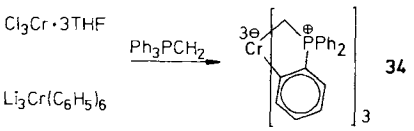
## 5. Complexes of Phosphorus Ylides with Chromium, Molybdenum, and Tungsten

### 5.1. Homoleptic Chromium- and Molybdenum-Ylide Complexes



The homoleptic tris-chelate complex **31** was first isolated almost exactly ten years ago as a red, sublimable, crystalline substance. It represents the first phosphorus ylide derivative of trivalent chromium. The preparative methods used became models for the later synthesis of further analogous trivalent complexes of the earlier transition metals, which have already been mentioned.

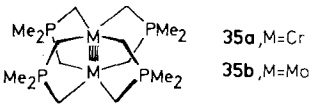
Compound **31** is strongly paramagnetic ($\mu_{eff}=3.6\mu_B$), which is in good agreement with the $d^3$ state of the central atom, chromium(III)[40].



31

A red intermediate product **32**, in which the metal carries a further phenyl group, can also be isolated in the synthesis of **31** from $Li_3Cr(C_6H_5)_6$. The reaction of **31** with three equivalents of tolan[41] leads, with opening of the chelate rings, to formation of the yellow trisalkynyl complex **33**.

32 33



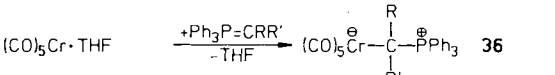
When the educts of the synthesis of **31** are allowed to react with ylides of the type $(C_6H_5)_3PCH_2$ rather than with metalated or metalatable alkyl-substituted ylides of the type $(CH_3)_3PCH_2$, then *ortho*-metalation of the phenyl rings occurs to give the ylide complex **34**[40]. Later, analogies for this mode of reaction were found, *inter alia*, for platinum and lutetium[20,21].

34

Chromium(II) and molybdenum(III) halides react with $(CH_3)_2P(CH_2)_2Li$ to yield binuclear complexes **35a** and **35b**, respectively, which have attracted continual attention[42,43]. X-ray diffraction studies[44,45] have revealed extremely short metal-metal distances (M≡M) in these diamagnetic compounds.

The particularly simple ylide ligands, whose coordinating $CH_2$ groups do not lead one to expect either back-bonding phenomena or other electronic or steric side effects, are almost ideal for further experimental investigation of the M≡M unit[46] and for its theoretical description[47].

**35a**, M=Cr
**35b**, M=Mo



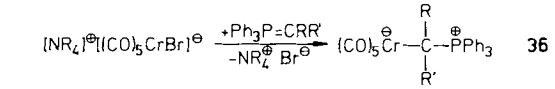
**35a, b** can be crudely described as having paddle-wheel structures, with a metal axis of 1.895(3) (Cr≡Cr) or 2.082(2) Å (Mo≡Mo). The metal carbon distances are 2.21—2.23 (Cr—C) and 2.30—2.32 Å (Mo—C). It is possible to distinguish long P–C methyl distances (1.81—1.90 Å) and short P–$CH_2$ distances (1.77—1.79 Å) at the quasi-tetrahedral P atom, thus indicating residual ylide character for the latter[44,45].

## 5.2. Carbonylmetal Complexes of Phosphorus Ylides

Carbonylmetal(0) complexes of phosphorus ylides count among the most investigated of the metallic ylide compounds. They are accessible *via* various, widely differing routes and have been the subject of intensive research for more than 20 years, not least because of their close relationship to the corresponding carbene complexes. The extensive findings are classified in this review article according to the methods of preparation.

### 5.2.1. Direct Coordination of Ylide Ligands at the Metal

Whereas hexacarbonylchromium does not react with "salt-free" phosphorus ylides only by CO substitution, but rather by attack at the CO ligand, its tetrahydrofuran derivative $(CO)_5Cr\cdot THF$ is a suitably modified, selectively reacting starting compound for the introduction of ylides at the metal atom[48].

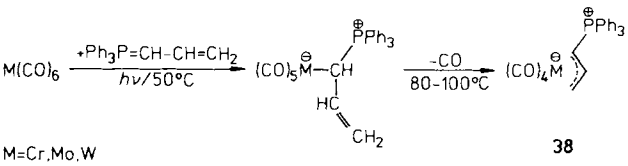


36

R=H,Me
R'=H,Ph,$PPh_2$,Me

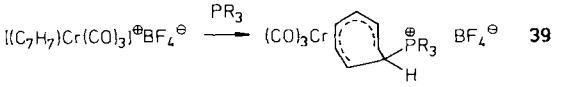
37

Benzene(dicarbonyl)chromium-tetrahydrofuran reacts analogously and yields complexes **37**, which have been described in seven different R,R'-combinations[50]. The halogen atoms of the complex salts $[(C_2H_5)_4N]^{\oplus}[(CO)_5CrBr]^{\ominus}$ are also good leaving groups, which facilitate the preparation of ylide complexes. Amongst the known examples (> 15), there are also some with phosphane ligands at the metal[51].

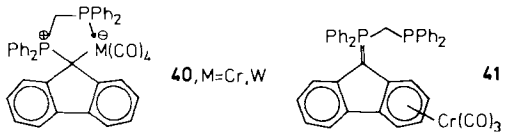


36

Ligand exchange also takes place in the triphenylphosphane derivative:



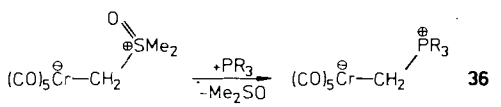
Reports that $Mo(CO)_6$ reacts with $(C_6H_5)_3P{=}CHCH_3$ to form a complex $(CO)_3Mo[(C_6H_5)_3P{=}CHCH_3]_3$ have not been confirmed[52]. The reaction of ylides with conjugated olefinic double bonds can lead to multiple CO exchange, whereupon π-allyl type complexes **38** can be formed[53–55]:



M=Cr,Mo,W 38

With phosphoniocyclopentadienide, $\eta^5$-$C_5H_4{=}PR_3$ coordination is achieved[56–59], which, because of the special constitution of the product (cf. also **25**) will not be dealt with here. $\lambda^5$-Phosphabenzene complexes are also not discussed[60]. A $(CO)_5W$ complex of $Ph_3P{=}C(SMe)_2$ was

found to be *S*-bonded[61]. On reaction of phosphanes with the tropylium(tricarbonyl)metal cation of chromium[62] (but not of molybdenum[63]), related $\eta^5$-organometallic compounds **39** with a phosphonium center in the side chain are formed.

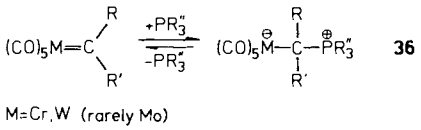


Fluorene ylides with additional phosphane function yield spirocyclic complexes **40**, but also, *e.g.*, the $\eta^6$-fluorene complex **41**[64].

### 5.2.2. Sulphane/Phosphane Exchange at Sulfur Ylide Complexes

In the synthetic methods already discussed, an intact phosphorus ylide was coordinated to the metal atom. Important alternatives to this are the formation of the ylide within the coordination sphere of the metal, either from another ylide complex by onium-center exchange or (cf. Section 5.2.4) from a carbene complex by addition of a phosphane. The first method has been used to advantage on $(CO)_5Cr$ complexes of the dimethyl(oxo)sulfoniomethanide $(CH_3)_2S(O)CH_2$, whereby dimethyl sulfoxide proved to be an excellent leaving group. A particular advantage of this method is that unstable ylides can be fixed to the metal and stabilized[65].

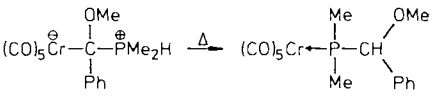
Arsanes undergo similar reactions[66].



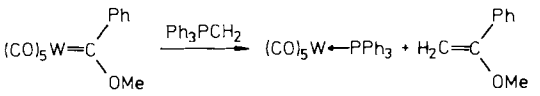
### 5.2.3. Ylide Complexes from Haloalkyltungsten Complexes

$(C_5H_5)(CO)_3WCH_2Cl$, a (chloromethyl)tungsten complex which is now readily accessible, can easily be converted into the corresponding ylide derivative by reaction with $P(C_6H_5)_3$ in boiling methanol[67]. Analogous substitution reactions have been demonstrated with Fe, Rh, Ru, *etc.* (cf. Sections 7 and 8).

### 5.2.4. Ylide Complexes from Stable Carbene Complexes and Phosphanes



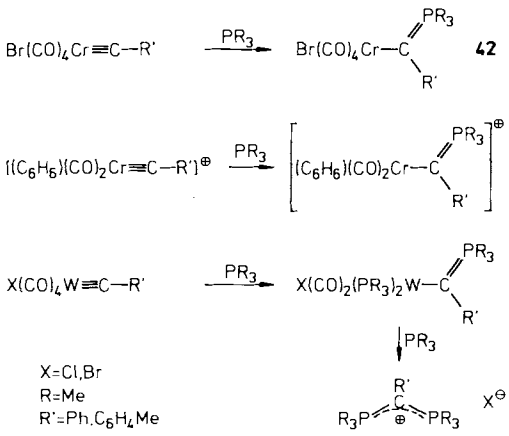
Although the first investigations had shown that the thermal reactions of $(CO)_5Cr$ carbene complexes with phosphanes and other nucleophiles finally lead to irreversible CO exchange[68,69], later studies showed that, under mild conditions, the reversible addition at the carbene carbon atom predominates[70-79]. This important reaction enables access to a series of ylide complexes, in as far as their substituent combinations at the carbene C atom are realizable. This applies in particular to phosphorus ylides with electron-rich substituents.



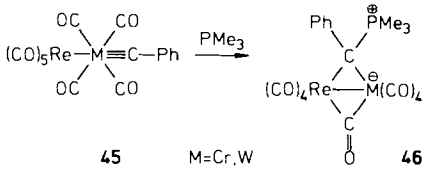
The reversibility of this equilibrium has been demonstrated kinetically[78]. Typical enthalpies of reaction lie in the range $-15$ to $-20$ kcal mol$^{-1}$. The rates of reaction are in the order Mo > W > Cr[79].

The reactions do not, however, always proceed according to the desired scheme. Apart from the CO exchange already mentioned, a strong substituent effect is also observed. Thus, $(CO)_5W{=}C(C_6H_5)_2$ reacts with $P(CH_3)_3$ in the expected manner[74], whereas reaction with $P(C_6H_5)_3$ leads to an unexpected cleavage of the ylide $(C_6H_5)_3P{=}C(C_6H_5)_2$ from the metal[76]. The last mentioned reaction is one of the few examples known where the intact ylide can be removed from the metal.

Ylides with P–H bonds can undergo rearrangement to phosphane complexes[71]:



With ylides (instead of phosphanes), carbene complexes usually undergo Wittig olefination, whereby the $(CO)_5W$ fragment formally plays the role of the oxygen atom of the aldehyde or ketone (!)[80]:

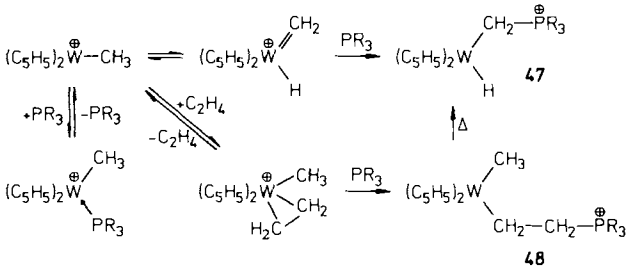


### 5.2.5. Reaction of Carbyne Complexes with Phosphanes

Phosphanes can add to metal carbynes analogously to their reaction with metal carbenes. Metal-substituted phosphorus ylides **42** are formed whose substituents depend on the reactants[81-86]. If the central atom is tungsten, an addi-

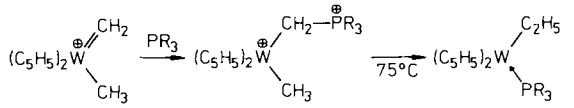
tional partial CO exchange takes place and, in certain circumstances, a cleavage of the metal carbon bond[87]; in this case semi-ylide salts **44** can be isolated.

The binuclear carbyne complexes **45** add $P(CH_3)_3$ to form an ylide-bridged product **46** whose constitution has been determined by X-ray diffraction analysis[85,86]. This reaction, which until now is without parallel, demonstrates that in suitable cases the bridging double coordination of an ylide to a metal is preferred over the terminal coordination (as in **42** or **43**).



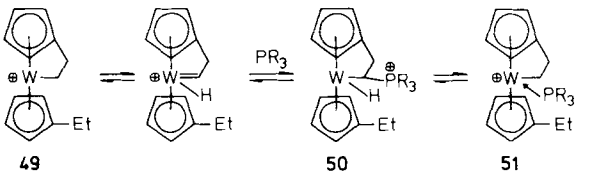
**45** M=Cr,W **46**

### 5.3. Ylide Complexes from Activated Alkyltungsten Compounds



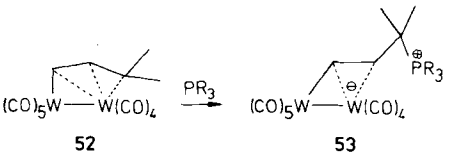
In the presence of donor molecules, alkyl compounds of bis(cyclopentadienyl)tungsten exhibit a complicated reaction behavior, the unraveling of which is of considerable interest for an understanding of the metal catalyzed reactions of olefins. Trapping the reactive intermediates with phosphanes to give ylide complexes has allowed great progress to be made in the study of this problem[88-90].

The ylide complexes **47** and **48** can be isolated with $P(CH_3)_3$ from the equilibria between metal hydride, alkylmetal compound, and metal-olefin complex, if suitable stoichiometric conditions are chosen:



**47** **48**

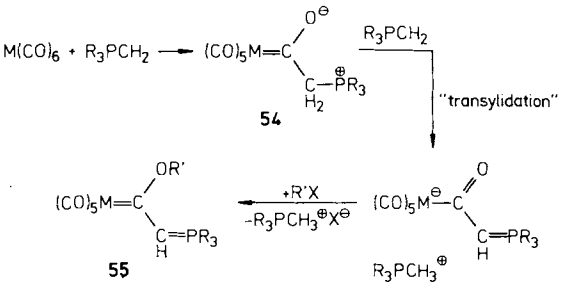
Similar products are formed when carbene precursors are produced photochemically[91] or *via* radical sources and proton acceptors[92,93] from $(C_5H_5)_2W(CH_3)_2$ and $(C_5H_5)_2W(CH_3)C_2H_5$. The $PR_3$ components employed were $P(CH_3)_3$, $P(CH_3)_2C_6H_5$ and $P(C_6H_5)_2CH_3$. Both the kinetics and equilibrium of the reaction depend on the nature of the phosphane[94].



A similar equilibrium between the phosphanes $P(CH_3)_3$ and $P(CH_3)_2C_6H_5$ with the complex cation **49**, in which one of the cyclopentadienyl rings is additionally attached to the tungsten atom by a $C_2$ bridge, affords an ylide complex **50** which only slowly reacts to form the stable end product **51**[95].

**49** **50** **51**

The binuclear tungsten complex **52** with $\eta^1,\eta^2$-bonded 3,3-dimethylated allyl groups adds phosphanes at C-3 to give a product **53** with a $\sigma,\pi$-bonded bridge ligand[96].

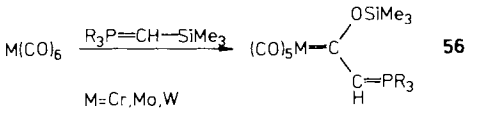


**52** **53**

The structure of one representative of the range of compounds formed from five different phosphanes was determined by X-ray diffraction. Because of its constitution, the bridge ligand in **53** can no longer be regarded as a phosphorus ylide[96].

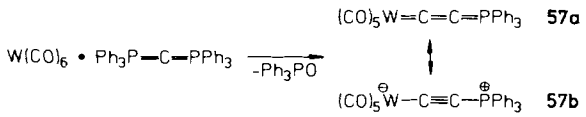
Surprisingly, it has been found that a terminal ylide complex $[(Me_3P)_3(CO)ClWCH_2PMe_3]^{\oplus}$ is formed on reaction of the cationic carbene complex $[(Me_3P)_4ClW{=}CH_2]^{\oplus}$ with CO. The reaction has been interpreted as a W→C phosphane shift[97].

### 5.4. Ylide Reactions at the Ligands of Carbonyl Complexes



The finding that strongly nucleophilic phosphorus ylides attack the metal complexes $M(CO)_6$ at the CO ligand[98,99] could be explained step for step as a transylidation reaction[100]. The following scheme illustrates the reaction which has been confirmed for several cases (including also metals other than Cr, Mo, W):

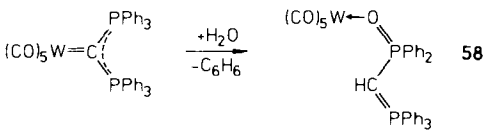
**54** **55**



The zwitterionic carbene complex **54** is transformed with a second equivalent of ylide in a transylidation step into the corresponding anion, which can then be derivatized by *O*-alkylation to the neutral carbene complex **55** bearing ylide substituents[100]. Such a derivatization can also be accomplished with a powerful silylating agent ($RX = Me_3SiOSO_2CF_3$). An X-ray structure analysis has been performed on the product[101].

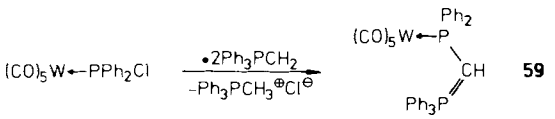
Related complexes can also be synthesized directly from the hexacarbonylmetal with silylated ylides[102]. An arsenic ylide corresponding to **56** is also known.

56



UV irradiation of $W(CO)_6$ and the double ylide $Ph_3P{=}C{=}PPh_3$ yields the acetylide **57**, which crystallizes as yellow needles (m.p. 140–142 °C)[99].

**57a** **57b**

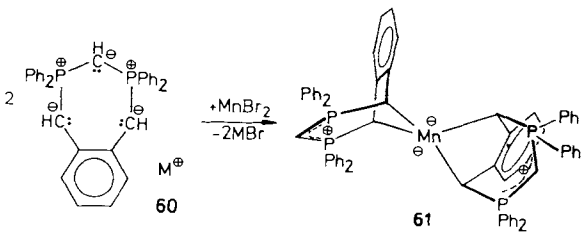


The reaction can be classified, on the basis of the mesomeric form **57a**, as a Wittig olefination of CO in the coordination sphere of the metal[99,100].

The simple $(CO)_5W$-adduct of hexaphenyl carbodiphosphorane obtainable from $(CO)_5W{\cdot}THF$ is easily hydrolyzed and, on reaction with water, yields adduct **58** with oxo-coordination; the structure of **58** has been confirmed by X-ray diffraction[103].

**58**

The reaction of a chloro(diphenyl)phosphane complex with ylides yields a related *P*-coordinated ylide complex **59**[104].

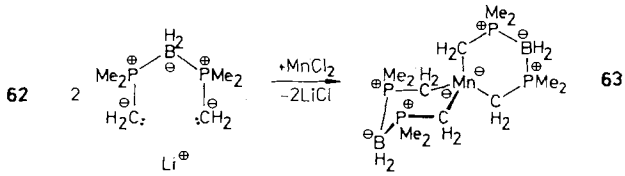


**59**

Metal complexes with arsane ligands, on the other hand, are cleaved by ylides at the M–As bond[105].

Reaction of $(C_6H_5)_3PCH_2$ with the binuclear complex $(C_5H_5)_2Mo_2(CO)_5$ yields a whole range of products, whose formation is still not completely clarified[106].

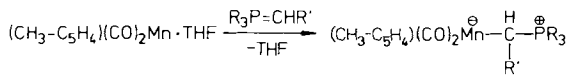
## 6. Complexes of Phosphorus Ylides with Manganese and Rhenium



No simple coordination compounds of ylides with manganese have as yet been described. Only specific multiple ylides form homoleptic manganese complexes with phosphonium centers β to the metal atom. The best characterized of these are the bisbenzodiphosphepinyl complex **61** and the boron-containing bis-chelate **63**. The former is obtainable in good yields by the reaction of alkali-metal salts of the diphosphonio triple ylide **60** with the tetrahydrofuran adduct of $MnBr_2$[107].

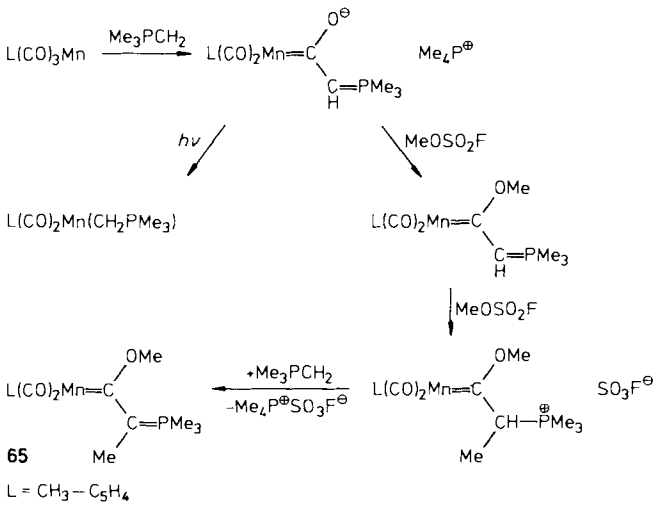
**60** **61**

The metal atom of the paramagnetic, brilliant yellow product ($\mu_{eff.} = 5.9\,\mu_B$, $d^5$) is pseudotetrahedrally surrounded by four ylidic carbon atoms. Both the remaining carbanion centers (P–CH⊕–P) point away from the metal atom. The X-ray structure analysis was carried out on a bistetrahydrofuran adduct, whose solvate molecules are likewise not coordinated to the metal[107].



The manganese(II) complex **63** formed on reaction of the lithiated boranato-bisylide **62** with $MnCl_2{\cdot}THF$ also contains pseudotetrahedrally oriented ylidic C atoms. The yellow compound, which may be regarded as a simple tetraalkylmanganese, is paramagnetic ($\mu_{eff.} = 5.84\,\mu_B$, $d^5$). Crystal structure analysis revealed Mn–C distances of 2.214(4)–2.239(13) Å, which correspond to a carbon-manganese σ-bond. The P–$CH_2$ and P–$CH_3$ distances are *ca.* 1.75 and 1.82 Å, respectively, as are typical for other ylide complexes.

**62** **63**

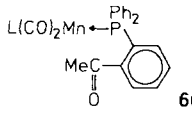


Both six-membered rings in **63** are in a chair conformation, the boron and phosphorus atoms have tetrahedral environments[108].

A wide variety of dicarbonyl(methylcyclopentadienyl)manganese complexes **64** are accessible from the THF precursor and free ylides (cf. also Section 5.2.1).

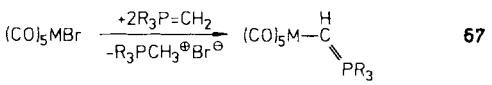
**64**: R′=H, $R_3$=$Ph_3$, $Ph_2Me$, $PhMe_2$, $Me_3$;
R′=Ph, $R_3$=$Ph_2Me$, $PhMe_2$, $Me_3$

The analogous tricarbonyl compounds, on the other hand, react with ylides at the CO ligands according to the scheme described for $Cr(CO)_6$ (cf. Section 5.4). The following scheme shows the reaction paths and products discovered up to now[109].



**65**

L = $CH_3-C_5H_4$



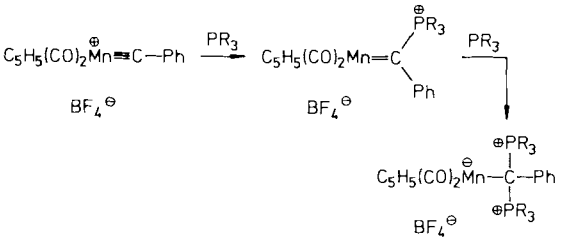
The structure of the end product **65** has been confirmed by X-ray diffraction[110].

Surprisingly, the course of the reaction with the ylide $(C_6H_5)_3P{=}CH_2$ is much more complicated. The complex **66** is one of the numerous compounds isolated from the product mixture[111].

**66**

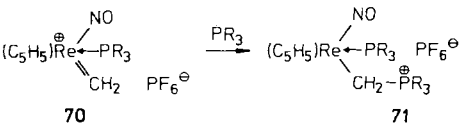
Bromo(pentacarbonyl)manganese and the analogous rhenium compound react with $(C_6H_5)_3P{=}CH_2$ (with transylidation, cf. Sections 2 and 3) to give the metal substituted ylide **67**[100]:

**67**



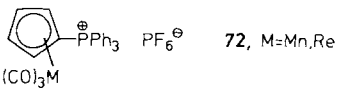
**68**

M=Mn, Re



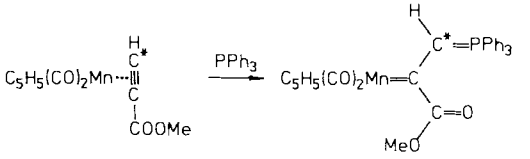
Pseudo-Wittig olefination and phosphane oxide cleavage occur once again with the double ylide and the same starting complexes[100] (cf. Section 5.4). The structure of the manganese compound **68**, which can also be formulated as an acetylide, has been confirmed by X-ray diffraction[111,112].

A carbyne complex of manganese also allows single and double addition of tertiary phosphane, according to the scheme described for the 6a-elements Cr, Mo, and W (Section 5.2.5). The product **69** then undergoes a cleavage of the Mn–C bond to yield $(R_3P)_2CR^{\oplus}X^{\ominus}$ salts[87].



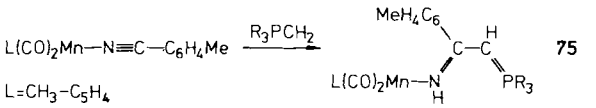
**69**

An ylide complex of rhenium **71** is obtainable by addition of phosphane to a cationic methylene complex **70**; the nitrosyl ligand is not attacked[113].



**70** **71**

Triphenylphosphoniocyclopentadienide can be readily incorporated as a ligand in the complex **72**[114].



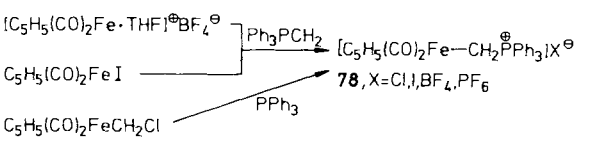
**72**, M=Mn,Re

Addition of $P(C_6H_5)_3$ to the alkyne complex **73** occurs at the *C atom, which in the product is no longer attached to the metal atom[115], so that the compound **74** contains an ylide function in the β-position. X-ray structure analysis confirms the P=C-bonding:

**73** **74**

The attachment of $C_6H_5(CH_3)_2P{=}CH_2$ to a nitrile complex leads to formation of the adduct **75**, whose structure was deduced from spectroscopic data alone[116].

**75**

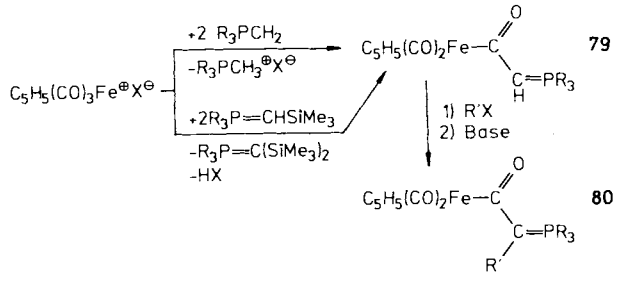


The ylide complexes **46** with Cr–Re and W–Re bonding have already been mentioned in Section 5.2.5[85,86].

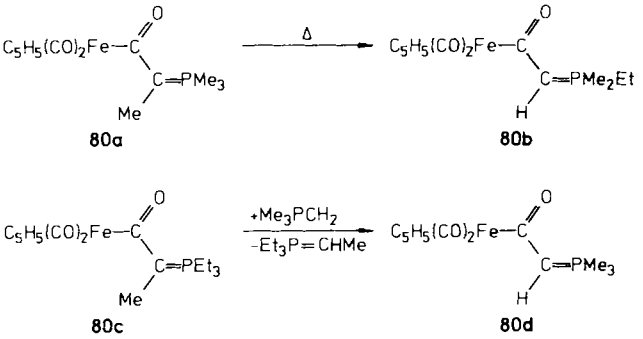
## 7. Complexes of Phosphorus Ylides with Iron, Ruthenium, and Osmium

The elements of the eighth subgroup of the periodic system often reflect the synthetic principles and compound types already found with manganese and rhenium.

Homoleptic ylide complexes of iron only exist in the presence of complex ligands, such as have been described for the manganese complexes **61** and **63** (cf. Section 6). The $Fe^{II}$ analogues **76** and **77** are tetrahedral, high-spin complexes whose metal atoms coordinate exclusively aliphatic carbon atoms[107,108].

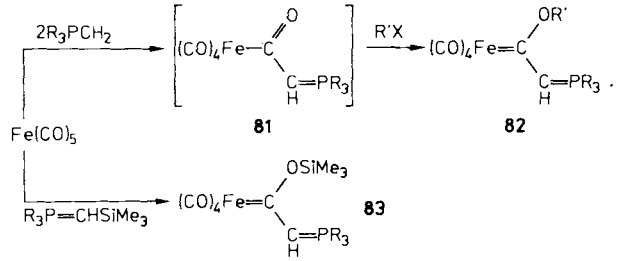


Ylide complexes which contain other ligands aside from the ylide are formed from reactive $C_5H_5(CO)_2FeL^{\oplus}$ precursors (L=tetrahydrofuran)[117] or the corresponding halides[118] by reaction with free ylides, or from the chloromethyl compounds with phosphane[67]. A range of structurally ill-defined adducts is formed on reaction of $(C_6H_5)_3P{=}C_5H_4$ with $FeCl_2$[119].

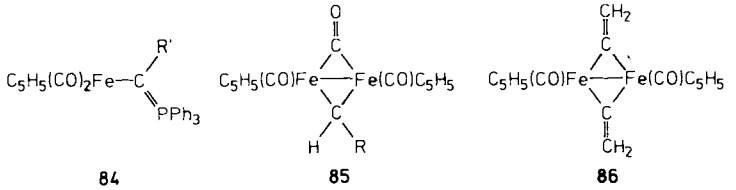


**78**, X=Cl,I,$BF_4$,$PF_6$

Unactivated $C_5H_5(CO)_3Fe^{\oplus}$, on the other hand, reacts (like $Fe(CO)_5$[98]), with ylides with attack at the CO ligands; transylidation yields the compounds **79** and **80**[120,121].

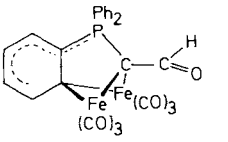


The complex **79** (R=$CH_3$) has been subjected to an X-ray structure analysis[121]. Of great interest are the novel

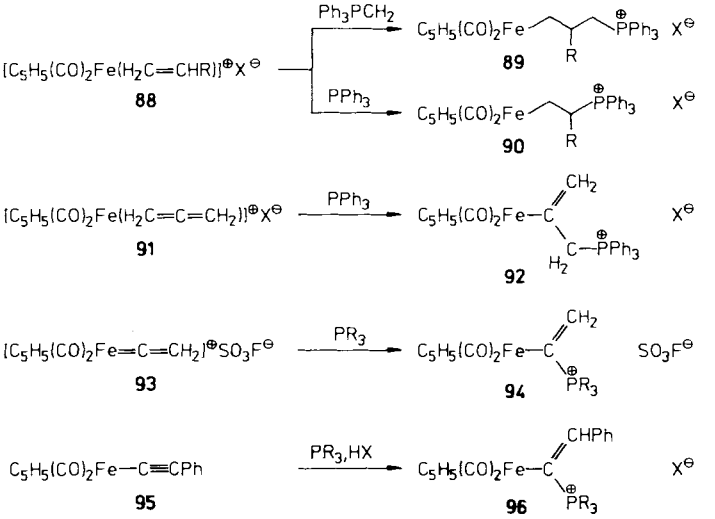


rearrangements **80a**→**80b** and the exchange of complete ylide units **80c**→**80d**. Plausible mechanisms have been suggested for both processes[122].

Ylides and $Fe(CO)_5$ yield a range of analogous products **81**—**83**[100, 102, 103].



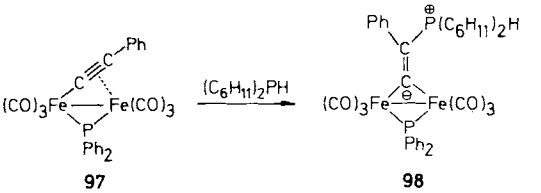
The binuclear complex $[C_5H_5Fe(CO)_2]_2$ reacts with $(C_6H_5)_3P{=}CHR'$ to give a mixture of products from which, *inter alia*, **84**—**86** have been isolated[111].



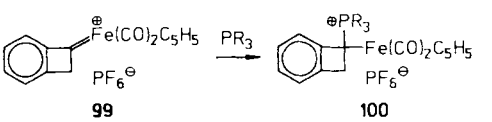
Reaction of $Fe_2(CO)_9$ with $Ph_3P{=}C{=}PPh_3$ is reported to lead to formation of $(CO)_3Fe(\mu\text{-}CO)[\mu\text{-}C(PPh_3)_2]Fe(CO)_3$, but its structure has not been confirmed[124].

The product **87**, which unexpectedly carries a formyl residue at a formally ylidic C-atom (confirmed by X-ray diffraction), is formed in the reaction of $Fe_3(CO)_{12}$ with $(C_6H_5)_3P{=}C(SnMe_3)_2$, a reaction which is extremely puzzling[125, 126].

The cationic ethylene complex **88** adds $Ph_3P{=}CH_2$ at one of the two olefinic C-atoms to form a γ-phosphonioalkylmetal compound **89**[117]. A series of alkyl derivatives **90**

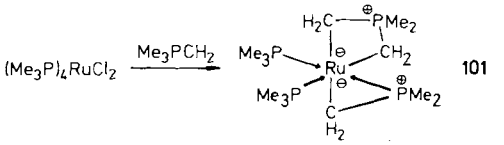


can also be obtained from olefin complexes **88** by nucleophilic attack of tertiary phosphanes at one of the two C atoms, which then carry the phosphonium center at the β-C atom[127]; they are stable when R = H, but very unstable when $R = C_6H_5$[128]. Derivatives of type **92** are obtainable from the related allene complexes **91**[128], while carbene complexes such as **93** yield "genuine" ylide (alkylidene) compounds **94**[129]. The latter are also accessible *via* the acetylides and phosphanes[130].



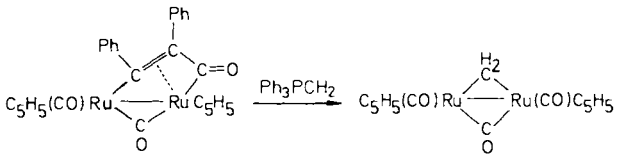
The structures of the compounds **94** and **96** have been determined by X-ray crystallography; the P—C distances are found to be 1.811 and 1.800 Å, respectively, and are thus not ylidic in nature[129, 130].

A comparable binuclear acetylide **97** yields a related complex **98** on reaction with dicyclohexylphosphane[131–133].



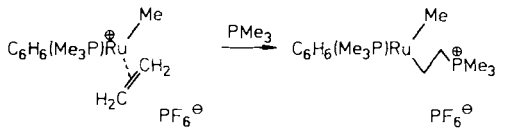
*Polyhapto*olefin-iron complexes react with phosphanes to give a range of phosphonium salts with π-bonded metal atoms which, on account of their difficultly defineable composition, are only mentioned in passing[134–137].

In the organoiron compound **100** the benzocyclobutyl residue is only $\eta^1$-bound; the precursor is the cationic carbene complex **99**[138].



Reaction and transylidation of $(CO)_4Fe(PPh_2Cl)$ with $Ph_3P{=}CH_2$ yields the complex $(CO)_4Fe(PPh_2{-}CH{=}PPh_3)$ with *P*-coordinated ylide[104].

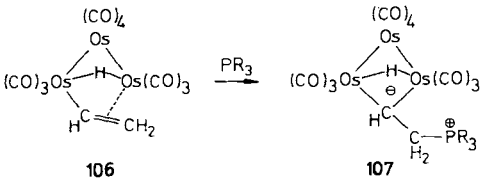
Ruthenium complexes of phosphorus ylides are so far limited to only a few examples. The complex **101**[139] contains the chelate-forming ligand $(CH_3)_2P(CH_2)_2^{\ominus}$.



101

This octahedral complex additionally contains the $CH_2$-depleted fragment $(CH_3)_2PCH_2^{\ominus}$, which is formed by deprotonating a $P(CH_3)_3$ ligand. The reaction of $Ph_3P{=}CH_2$ with the binuclear ruthenium complex **102** surprisingly leads to a compound with a $CH_2$-bridge **103** and is thus reminiscent of the behavior of $[(C_5H_5)_2Fe(CO)_4]_2$[111]; the details of the reaction are still unclear[140].

102 103



Cationic ethylene complexes such as **104** add tertiary alkylphosphanes to give γ-phosphonioalkylruthenium compounds **105**, which are related to the iron complexes **90** or **92**[141].

104 105

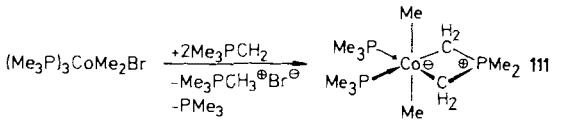
A $RuCl_3$ complex of $(C_6H_5)_3P{=}C(CH)_4$ of unknown structure requires further investigation[119].

Osmium complexes of phosphorus ylides in the strictest sense of the phrase are unknown. The products formed on reaction of tertiary phosphanes with trinuclear osmium clusters such as **106**, which contain phosphonium centers in the γ-position to the metal (**107**), are of peripheral interest[142, 143].

106 107

## 8. Complexes of Phosphorus Ylides with Cobalt, Rhodium, and Iridium

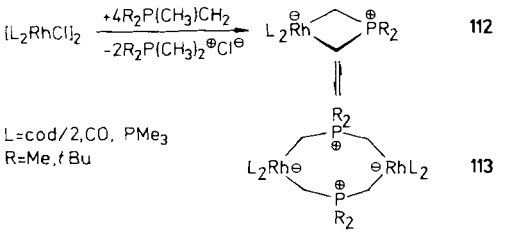
Homoleptic ylide complexes of cobalt (as in the case of Mn and Fe) are only obtainable with the triple ylide anions of **60** and **62**. These compounds, **108**[107] and **109**[108], correspond to the $Mn^{II}$ analogues **61** and **63**. The crystals of the paramagnetic $d^7$-compound **109** ($\mu_{eff.} = 4.2\mu_B$) are isomorphous with those of the manganese complex **63**. The molecules thus have $Co^{II}$-centers surrounded tetrahedrally by C atoms.



Terminal monodentate $(CH_3)_3P{=}CH_2$ is a component of the ligand sphere of a deep blue compound with the formula $[(CH_3)_3P{=}CH_2]_2CoCl_2$, **110**, whose exact structure, however, is not known. The substance, which is insoluble in all the usual solvents, is strongly paramagnetic and is formed in the course of the oxidative addition of $CH_2Cl_2$ to $(Me_3P)_4Co$, where intermediates with $Co{-}CH_2Cl$ units are probably formed[144–146]. An alternative synthetic possibility is the reaction of $(Me_3P)_3CoCl$ with $(CH_3)_3P{=}CH_2$[146].

$$3\,(Me_3P)_4Co + 2\,CH_2Cl_2 \longrightarrow (Me_3PCH_2)_2CoCl_2 + 2\,(Me_3P)_3CoCl + 4\,PMe_3$$

$$2\,(Me_3P)_3CoCl + 2\,Me_3P{=}CH_2 \longrightarrow (Me_3PCH_2)_2CoCl_2 + (Me_3P)_4Co + 2\,PMe_3$$



**110**

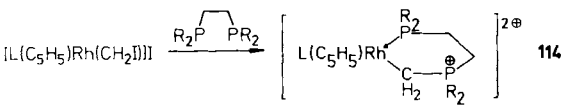
Chelate forming $(CH_3)_2P(CH_2)_2^{\ominus}$ units are realized in the diamagnetic $Co^{III}$-complex **111**, which is formed in a transylidation reaction[146]; its structure has been determined by X-ray diffraction[147].

111

Square planar rhodium(I) complexes contain the same chelate formers in various ligand combinations. Starting from 1,5-cyclooctadiene- or dicarbonyl-rhodium chloride the mononuclear complexes **112** are easily obtained *via* transylidation with free ylides and can dimerize to eight-membered metallocycles if the spatial requirements of the substituents allow it: **113**[148–150].

112

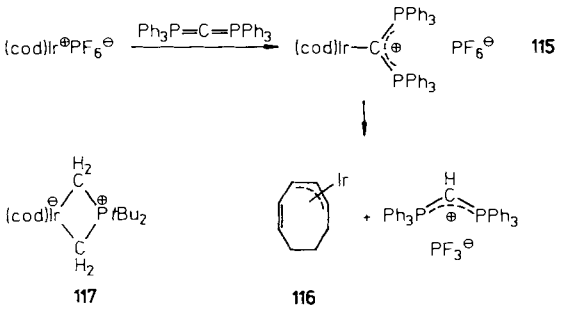
L=cod/2,CO, $PMe_3$
R=Me, *t*Bu



113

When L=CO and R=$CH_3$ the equilibrium (in toluene at 25 °C) lies on the side of the dimer with $\Delta H = -10.5$ kcal/mol[150]. Analogous complexes have been obtained with the cyclic ylides $(CH_2)_nP(CH_3){=}CH_2$ (n=4, 5) and the double ylide $(CH_3)_3P{=}N{-}P(CH_3)_2{=}CH_2$[149]. Some of the compounds are good hydrogenation catalysts[148]. The corresponding iridium compounds are known but unfavorable solubility behavior and difficulties in crystallizing them have, until now, hindered their satisfactory characterization[151].

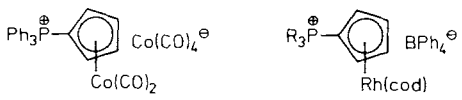
Some mononuclear cationic rhodium(III) complexes with monodentate ylides are accessible *via* reaction of tertiary phosphanes with halomethyl precursors[152], *e.g.*



$$[C_5H_5(Me_3P)_2RhCH_2I]^{\oplus}I^{\ominus} \xrightarrow{PMe_3} [C_5H_5(Me_3P)_2RhCH_2PMe_3]^{2\oplus}2I^{\ominus}$$

The corresponding cyclic variants **114** are formed with bifunctional phosphanes[153–154].

**114**



Hexaphenylcarbodiphosphorane reacts with $Co_2(CO)_8$ to give an ionic product $[(CO)_4Co{-}C(PPh_3)_2]^{\oplus}[Co(CO)_4]^{\ominus}$, but no details of the reaction have been quoted[100,124]. A similar coordination unit is found in the iridium complex **115**, which, however, decomposes in THF by intramolecular proton transfer and elimination to give the 1,8-cyclooctadienyl complex **116**[155].

**115** **117** **116**

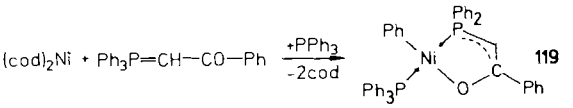
Reaction of $[(cod)IrCl]_2$ with $(tert\text{-}Bu)_2MeP{=}CH_2$ leads *via* transylidation to formation of the mononuclear ylide complex **117**[156].

$Co_2(CO)_8$ likewise reacts with $Ph_3P{=}C(CH)_4$ with partial CO-exchange to give an ionic product **118a**, whose crystal structure has been determined[157].

**118a** **118b**

Triphenylphosphoniocyclopentadienide complexes of rhodium, such as **118b**, have a related structure[158]; instead of 1,5-cyclooctadiene (cod), they can also contain $C_7H_8$, $CO/PR_3$, $C_5Me_5$, *etc.*[159]. An ylide-adduct of $RhNO_3$ is also known[119].

## 9. Complexes of Phosphorus Ylides with Nickel, Palladium, and Platinum

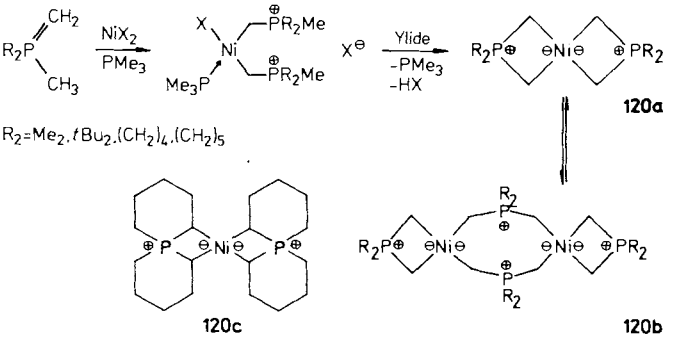


### 9.1. Homoleptic Ylide Complexes without Auxiliary Ligands

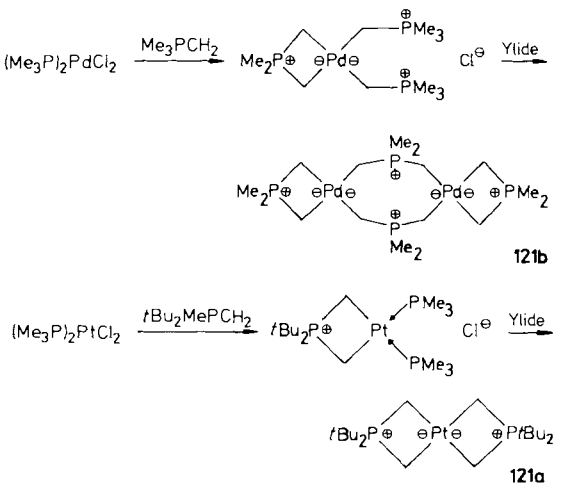
It was already found in 1972[160] that the coordination of monofunctional phosphorus ylides at nickel(0), for example by substitution of 1,5-cyclooctadiene, is accompanied by a rearrangement of the ylide in the sense of a Stevens rearrangement to give $Ni^0$ complexes of the isomeric tertiary phosphanes.

$$(cod)_2Ni + 4\,Ph_3P{=}CH_2 \xrightarrow[-2\,cod]{70^{\circ}C} (Ph_2PCH_2Ph)_4Ni$$

It was possible to develop this process into a catalytic ylide isomerization[160]. However, it has so far proven impossible to isolate a tetrakis(ylide)nickel(0) complex. Only in the presence of accessory ligands is it possible to fix monodentate ylides on $Ni^0$.

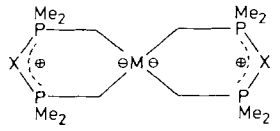


Reaction of $(cod)_2Ni^0$ with a *C*-benzoyl stabilized ylide in the presence of $PPh_3$ leads to oxidative addition of a phenyl group to the metal atom with formation of an arylnickel(II) complex **119**[161].



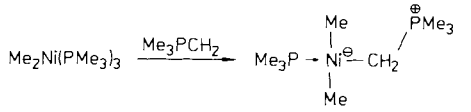
**119**

It has been postulated that **119** is one of the catalytically active species in the oligomerization of ethylene[162].

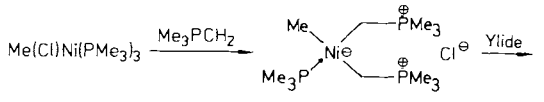


In contrast, it is possible to realize a homoleptic ligand sheath at the $Ni^{II}$ center with phosphonium bis-ylide anions. Reaction of nickel(II) halides with $Me_3P{=}CH_2$ or its homologues leads *via* intermediates with mixed ligands to transylidation and formation of the mono or binuclear ylide complexes **120a**, **b**[16,147,163].

Formation of **120a** is favored by bulky substituents R. A polycyclic variant **119c** is accessible after previous metalation of a spirophosphonium salt[164]. X-ray structure analyses have been carried out on **119b** and **119c**[147,164]. The corresponding $Pd^{II}$ and $Pt^{II}$ compounds were obtained by analogous reactions[163,165], *e.g.* according to

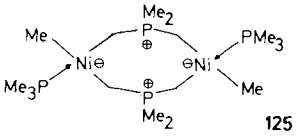


Both with $Ni^{II}$ as well as with $Pd^{II}$ and $Pt^{II}$, the nitrido-, methanido- and boronato-bis(phosphoniomethanide) anions $X(PMe_2CH_2)_2^{\ominus}$ yield isoelectronic, square planar complexes **127**, the structures of which have been determined by X-ray diffraction[108, 165–169].



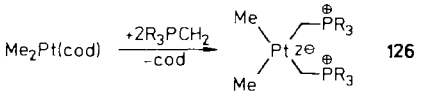
**122** M=Ni, Pd, Pt; X=N,CH,$BH_2$,$BMe_2$

## 9.2. Ylide Complexes of Alkylmetal Compounds and Metal-Phosphinomethanides

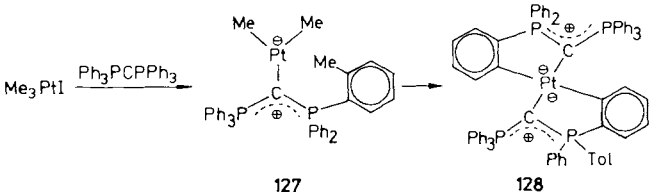


The $PMe_3$ complex of $(CH_3)_2Ni$ reacts with $Me_3P{=}CH_2$ with partial displacement of the tertiary phosphane to yield only the *trans*-configurated ylide complex **123**. Already in the case of $CH_3NiCl$, however, the reaction proceeds *via* the isolable intermediate **124** with transylidation to the binuclear ylide-bridged complex **125**, which resembles compounds of type **120b**[170].

**123**

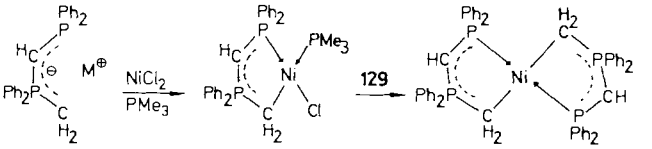


**124**



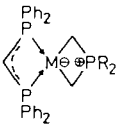
**125**

Reaction of the cod-complex of $(CH_3)_2Pt$ with ylides leads quantitatively to the *cis*-configurated complexes **126**[156].



**126**

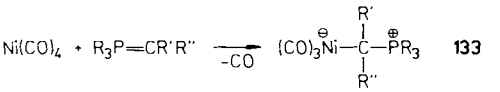
$(CH_3)_3PtI$ reacts with $Ph_3P{=}C{=}PPh_3$ in a complicated reaction to form the $Pt^{II}$ complex **128**, in which all the $CH_3$ groups have been cleaved from the metal[121]; **127** is postulated as an intermediate.



**127** **128**

The highly stable *trans* ylide complex **131** can be synthesized *via* the precursor **130** formed on reaction of the metalated ylide **129** with $PMe_3$-complexed $NiCl_2$; the structure of **131** has been determined X-ray crystallographically[171].

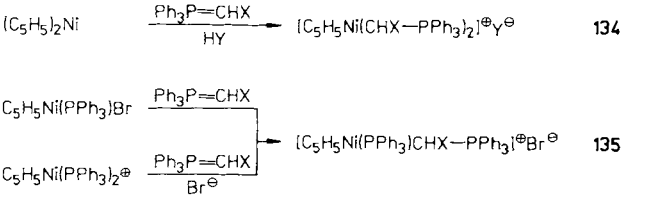
**129** **130** **131**



Bis(diphenylphosphano)methanide ligands and simple ylides form the similarly stable complexes **132**[172, 173]. X-ray data again reveal the environment of the metal to be square planar[172].

**132** M=Ni,Pd,Pt; R=Me,Et

## 9.3. Ylide Complexes of Carbonyl- and Cyclopentadienylnickel



It was first demonstrated 15 years ago[174] that phosphorus ylides can displace at least one CO ligand from $Ni(CO)_4$. The tetrahedral $Ni^0$ complexes that result have since been synthesized in large numbers[102, 160] and one of them has been studied crystallographically[175].

**133**

The CO ligands are not attacked by silylated ylides (in spite of the higher affinity of silicon for oxygen)[102] and even the carbodiphosphorane $Ph_3P{=}C{=}PPh_3$ reacts with exclusive displacement of CO to give **133** ($R'R'' = PPh_3$)[100]; however just as little is known about the structure of the product as about that of the complex obtained on reaction of $(Ph_3P)_2Pt(C_2H_5)$ and $PH_3P{=}C{=}PPh_3$[98]).

Bis($\eta^5$-cyclopentadienyl)nickel reacts with $Ph_3P{=}CH_2$ with exchange of one of the two $C_5H_5$ rings to give the complex **134**, which is accessible in an analogous manner from $C_5H_5Ni(PR_3)_2^{\oplus}$. Appropriate stoichiometric reactions of the $C_5H_5Ni(PR_3)X$ precursors lead to the mixed cations **135**[176, 177].

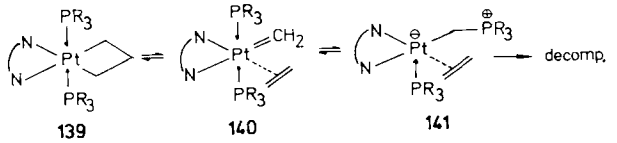
**134**

**135**

X=Me,Et,*n*Pr,*n*Bu,Cl,OMe; "HX"=$Me_2$; Y=Br,$PF_6$

### 9.4. Formation of Ylide Complexes *via* Haloalkylmetal Precursors, from Olefin Complexes or by $CH_2$-Insertion

It was first reported in 1970[178] that $(R_3P)_4Pt^0$ complexes undergo oxidative addition with dihalomethanes, leading, *via* haloalkylmetal intermediates, to ylide complexes[179,180]. Under suitable reaction conditions it is possible to isolate the $ClCH_2Pt$ intermediate; hence, the second reaction step can be monitored separately[181,182].

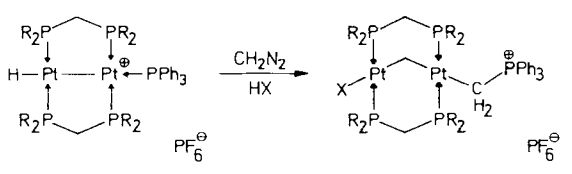


$$Pt(PPh_3)_4 \xrightarrow{CH_2ClI} cis\text{-}[(Ph_3P)_2Pt(Cl)CH_2PPh_3]^{\oplus}I^{\ominus} \quad \mathbf{136}$$

$$Pt(PEt_3)_4 \xrightarrow{CH_2I_2} trans\text{-}[(Et_3P)_2Pt(I)CH_2PEt_3]^{\oplus}I^{\ominus} \quad \mathbf{137}$$

$$(Ph_3P)_2Pt(CH_2Cl)Cl \xrightarrow{PPh_3} [(Ph_3P)_2Pt(Cl)CH_2PPh_3]^{\oplus}Cl^{\ominus} \quad \mathbf{138}$$

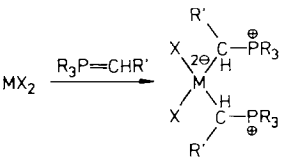
On changing the phosphane and in the presence of Lewis acid catalysts the compounds are inclined to isomerize (*cis/trans* or ligand isomerization). A typical structure has been elucidated X-ray crystallographically[179,180].



The six-fold coordinated platinacyclobutane compound **139** decomposes in the presence of tertiary phosphanes with formation of a series of hydrocarbons (such as cyclopropane, propylene, ethylene, and methane), whose formation is best interpreted in terms of an equilibrium, the position of which is influenced by the $PR_3$ components. It has not yet been possible to demonstrate directly the presence of the postulated ylide complex **141**[183].

**139** **140** **141**

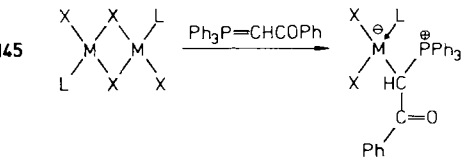
Reaction of a 1,5-cyclooctadiene-$Pt^{II}$ complex $(R_2N_4)Pt(cod)$, R = 4-$C_6H_4NO_2$, with $PEt_3$ furnishes a σ,π-alkylmetal compound bearing a newly introduced onium center in position 2 of the ring. The structure has been elucidated by X-ray diffraction analysis[184].



On treatment with diazomethane, the hydridodiplatinum complex **142** yields a μ-methylene-ylide complex **143** bearing a terminal $Ph_3PCH_2$ function. The mechanism of formation is unknown, but the structure has been confirmed by X-ray diffraction[185].

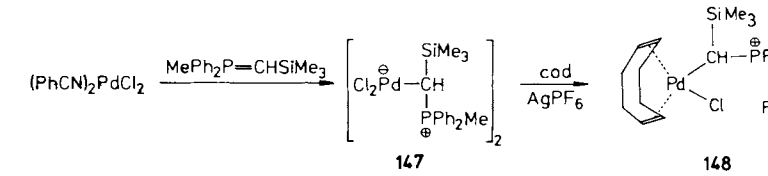
**142** **143** R=Ph

### 9.5. Ylide Complexes of Palladium(II) and Platinum(II) Halides



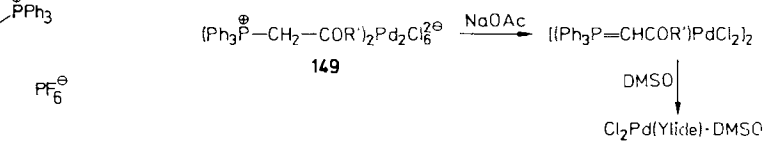
Complexes of $Pd^{II}$ and $Pt^{II}$ halides with phosphorus ylides, in which the ligand is bound to the central atom by a metal carbon bond, have been synthesized on a large scale and subjected to detailed studies. This is particularly true for the group of compounds with ylides which bear an additional donor function and can, thus, function as bidentate ligands. $PdX_2$ and $PtX_2$ react with phosphorus ylides in a molecular ratio of 1:2 to give products of the type **144**. The oldest examples are the adducts of $PdCl_2$ or $PtCl_2$ with $Ph_3P{=}CH{-}CO{-}Ph$[186].

**144**



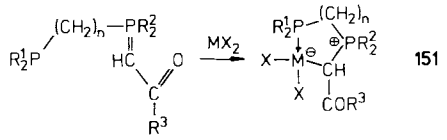
M = Pd, Pt; X = Cl; R = Ph; R' = COPh[186]
M = Pd; X = Cl; R = Ph; R' = COPh, COMe, COOMe[187]
M = Pd, Pt; X = Cl, SCN; R = Ph; R' = COPh, COMe, COOMe, COOEt, COCN[188]

The binuclear $M^{II}$ complexes **145** form the corresponding 1:1 compounds with an auxiliary ligand L[189]:



M = Pd; X = Cl; L = $PMe_3$, $PMe_2Ph$
M = Pt; X = Cl, Br, I; L = $PMe_3$, $PMe_2Ph$

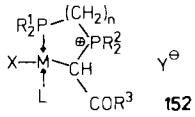
Reaction of bisbenzonitrilepalladium(II) chloride with $MePh_2P{=}CHSiMe_3$ yields first the binuclear ylide complex **147**, which reacts further with diolefins and $AgPF_6$ to give a mononuclear cation complex **148**. The product has been identified by X-ray structure analysis[190,191].



**147** **148**

With $Ph_3P{=}CHCOR'$ (R' = Me, Ph), the 1:2 complex $Cl_2Pd(ylide)_2$ is formed[192]. Complexes of the same ylide type can be obtained on starting with a salt precursor **149**, which yields the binuclear complex **150** even on treatment with the weak base sodium acetate. The binuclear complex **150** is cleaved to mononuclear species in donor solvents such as dimethyl sulfoxide (DMSO)[193]:

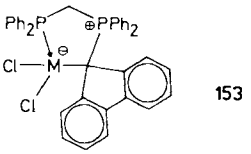
**149** **150**



Ylides with a terminal phosphane function in the side chain are excellent chelaters of metal dihalides. The formation and structure of the products **151** have been studied in great detail.

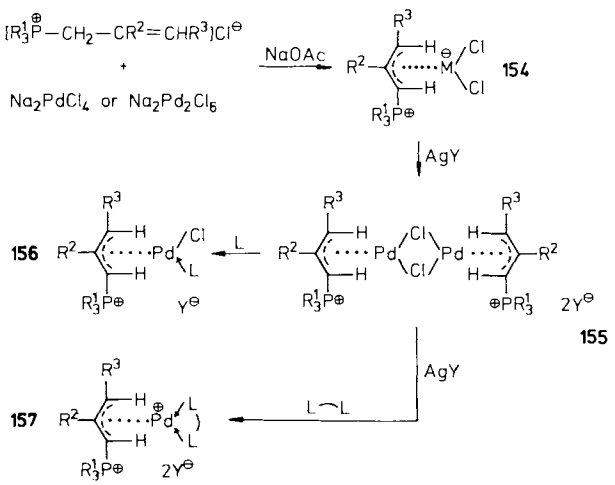
**151**

n = 1; M = Pd, Pt; X = Cl; $R^1 = R^2 = R^3 = Ph$[194-197]; $R^1 = R^2 = Ph$, $R^3 = Me$, OMe[195]
n = 1; M = Pd, Pt; X = Cl, Br, I, SCN; $R^1 = R^2 = Ph$, $R^3 = Ph$, Me, OMe, OEt[198]
n = 0; M = Pd, Pt; X = Cl; $R^1 = R^2 = Ph$, $R^3 = Ph$, Me, OMe[198]
n = 1; M = Pd, Pt; X = Cl; $R^1 = R^2 = CH_2Ph$, $R^3 = Ph$[199]



Ionic complexes **152** are formed with the same ylides from precursors of type **145**; again L has been varied within wide limits[200].

**152**

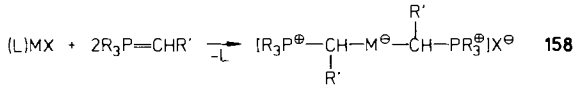


n = 0, 1; M = Pd, Pt; $R^1 = R^2 = R^3 = Ph$[201]; L = $PPh_3$, $P(C_6H_{11})_3$, $AsPh_3$, $PPh_2Me$, $P(OMe)_3$, SbPh, py, pyMe, pyrazole

The 1 : 1 complexes **153** of $PdCl_2$ and $PtCl_2$ with a fluorene ylide probably also have a similar five-membered ring structure as in **151**[64].

**153**

Allylphosphonium salts react with $Na_2Pd_2Cl_6$ or $Na_2PdCl_4$ in methanol in the presence of even weak bases (acetate) to give phosphonioalkylide complexes **154**. The stepwise removal of halogens with silver salts of poorly coordinating anions leads to binuclear dications **155** or, in the presence of donor molecules, to mononuclear complexes **156**[202-204].

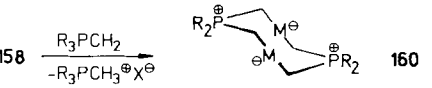


$R^1$ = Ph, Et; $R^2$ = H, Me; $R^3$ = H, Me; Y = $BF_4$, $PF_6$, $SO_3CF_3$; LL = cod, $Ph_3P{=}C(CH)_4$

Triphenylphosphoniocyclopentadienide, which has already been used in **156** as a donor, is also represented in a whole range of other $Pd^{II}$ and $Pt^{II}$ complexes[205, 206].

## 10. Complexes of Phosphorus Ylides with Copper, Silver, and Gold

The coinage metals form particularly simple complexes with ylides, which are distinguished by their stability towards oxidation and hydrolysis. They also belong to the most thermally stable organometallic compounds of these elements[207, 208].

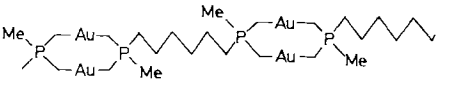


Homoleptic ylide complexes exist both with terminal monodentate ligands and with bridging bidentate ligands. The former are represented by the ionic compounds **158**, which are particularly common for M = Au with various residues R[209-217].

**158**

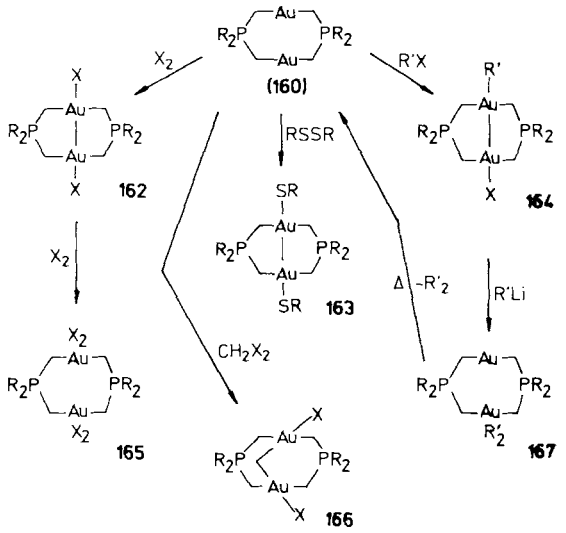
X = Cl (Br); M = Cu, Au; R = Me; R′ = H, $SiMe_3$
M = Cu, Ag, Au; R = Ph; R′ = H, Me, *i*Pr
M = Au; R = Et, *n*Bu; R′ = H;
M = Au; R = $NMe_2$; R′ = H
$[(Ph_3P{-}CHCOPh)_2Au]^{\oplus}AuCl_4^{\ominus}$[186]
$[\{Ph_3P{-}C(CH_2)_2\}_2Au]^{\oplus}Cl^{\ominus}$ **159**

Many of these complexes dissolve in water without decomposition and are easily characterized analytically and spectroscopically. The triphenylphosphoniocyclopropanide complex **159**[218] is a special case, which exhibits quite exceptional properties. In spite of the ring strain at the ylide C atom, the species nevertheless exhibits high stability. The most important reaction of these complexes, with their linear configuration and a coordination number of two for the central atom, is transylidation with excess ylides (as catalyst) to binuclear complexes **160**[219-228]:



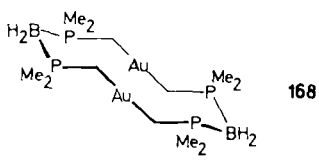
**160**

M = Cu, Ag, Au; R = Me, Et
M = Cu, Ag; R = Me, Ph
M = Au; $R^2 = (CH_2)_4$, $(CH_2)_5$, (*c*-$C_3H_5$)Me, (*c*-$C_5H_9$)Me



According to crystal structure data, these heterocycles, which without exception are stable and colorless, contain two almost parallel C–M–C axes of doubly coordinated metal atoms which are 2.843 (Cu)[224] or 3.023 Å (Au)[225, 226] apart. UV investigations[227] and theoretical calculations[228] indicate that the metal-metal interaction is very weak. The eight-membered ring of type **160** can also be incorporated in polymers[229], if α,ω-difunctional ylides are used (**161**):

Several complexes of types **158** and **160** have been tested for their pharmacological activity in polyarthritis. The effect is comparable with that observed with conventional preparations[215, 230].

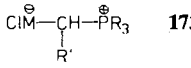


**161**

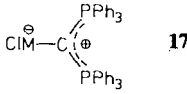
The auracycles **160** easily undergo oxidative addition on reaction with halogens[220,221], disulfides[231] and alkyl halides[232], whereby bicyclic gold(II) compounds **162** to **164** are first formed in which a transannular Au–Au bond has been confirmed by X-ray diffraction[221], by magnetic measurements and by Mössbauer[222,231] and Au-ESCA studies[222].

Further oxidation of **162** leads, with cleavage of the Au–Au bond, to the binuclear $Au^{III}$ complex **165**[220,222]. The $CH_3I$ adduct **164**, whose structure was originally deduced solely from NMR data[220], has recently been unequivocally confirmed by X-ray structural analysis[232]. On further alkylation it yields the unstable, unsymmetrical dialkyl derivative **167**, which easily undergoes thermal decomposition with elimination of ethane to give **160**.

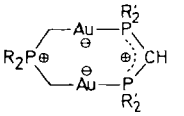
Addition of dihalomethanes to **160** results in formation of a $CH_2$ bridge between the metal atoms, raising their coordination number from 2 (in **160**) to 4 (in **166**). Crystal structure analysis reveals a square planar ligand arrangement as is to be expected for $Au^{III}(d^8)$[233]. A gold(I) complex of the double anion **62** probably has the twelve-membered ring structure **168**[234].



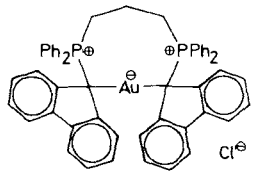
A large variety of ylide complexes of the coinage metals with additional ligands are also known and exist as cations or neutral molecules. Formulas **169** to **176** summarize the individual examples with monovalent central atoms:



$Me_3SiCH_2CuCH_2PMe_2$ **169**[211]



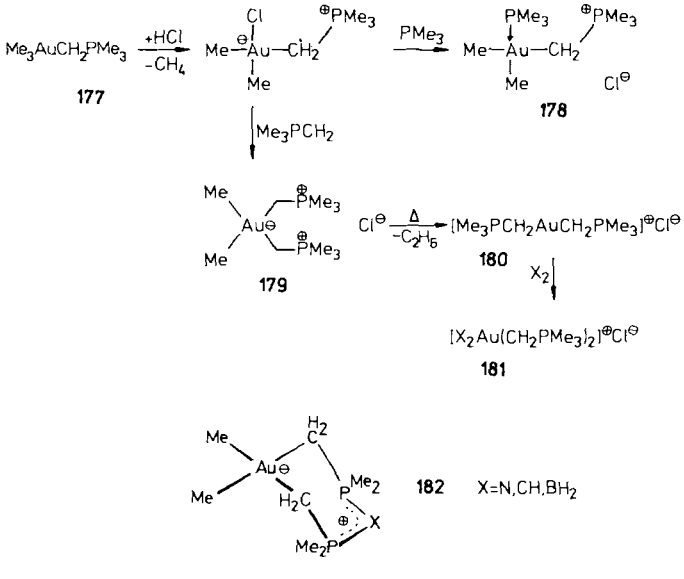
$[Me_3PCHCuCHPMe_3]^{\oplus}Cl^{\ominus}$ **170**, R′ = H, $SiMe_3$[211]



$RAuCHPMe_3$ **171**, R = Me, $CH_2SiMe_3$; R′ = H, $SiMe_3$

$[LAu{-}CR'_2{-}PR'_3]^{\oplus}X^{\ominus}$ **172**, X = Cl (Br);
L = $Me_3P$; R′ = H, H/$SiMe_3$, $SiMe_3$; R″ = Me[209,213]
L = $Ph_3P$; R′ = $SiMe_3$; R″ = Me[213]
L = $Ph_3P$; R′ = H, H/Me, W/*i*Pr; R″ = Ph[216]
X = $NO_3$;
L = $Ph_3P$; R′ = H/COPh; R″ = Ph[186]

**173**, M = Cu, Ag; R = Ph; R′ = H, Me, *i*Pr[236]

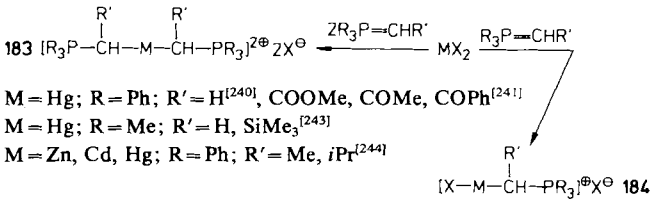


**174**, M = Cu, Ag, Au[237]

**175**, R = Me, Et, *t*Bu; R′ = Ph[173,235]

**176**[64]

In addition, some square planar complexes of trivalent gold with various alkyl-, halogen-, and ylide-ligand combinations have been described[213,214,236–238]. One example, **177**, has also been investigated by X-ray diffraction and by ESCA spectroscopy. The results show that the ylides are powerful donor ligands that have practically no back-bonding acceptor effect[238].



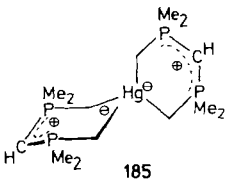
Three isoelectronic auracycles **182** are derived from $(CH_3)_2Au^{\oplus}$ and have been studied in detail, particularly by X-ray diffraction. The folding of the six-membered ring into the chair conformation depends on the nature of the bridge element X; the environment of the gold atom, however, remains practically constant[239,235].

## 11. Complexes of Phosphorus Ylides with the $d^{10}$-Metals Zinc, Cadmium, and Mercury

The guiding principle in the chemistry of the ylide complexes of the elements of the second subgroup is—similarly to that for the whole organometallic chemistry of these elements—strongly directional σ-bonding with small coordination numbers.

Homoleptic coordination compounds with monodentate ylide ligands are the cationic complexes **183**, which have been synthesized in large numbers and with a wide range of substituents[240–244].

**183** $[R_3P-\underset{\displaystyle R'}{\underset{|}{CH}}-M-\underset{\displaystyle R'}{\underset{|}{CH}}-PR_3]^{2\oplus}\,2X^{\ominus}$



$M = Hg$; $R = Ph$; $R' = H$[240], COOMe, COMe, COPh[241]
$M = Hg$; $R = Me$; $R' = H$, $SiMe_3$[243]
$M = Zn$, Cd, Hg; $R = Ph$; $R' = Me$, $i$Pr[244]

**184** $[X-M-\underset{\displaystyle R'}{\underset{|}{CH}}-PR_3]^{\oplus}X^{\ominus}$

$M = Hg$; $X = Cl$; $R = Me$; $R' = H$[243]
$M = Hg$; $X = Cl$; $R = Ph$; $R' = COPh$[242]
$M = Hg$; $X = I$; $R = Me$; $R' = SiMe_3$[245]

If only small amounts of ylide are available the 1:1 complexes **184** are formed, alkyl metal analogues of which are also known $[R''-Hg-CHR'-PR_3]X$ ($R'' = Me$[243]).

The high donating power of the double ylides is demonstrated in the unusual chelate complex **185**, which is one of the few tetracoordinated organomercury compounds known[246].

**185**

Open chain and cyclic double ylides also yield complexes with the two lighter metals of the second subgroup, *i.e.* zinc and cadmium[247–249]. As is to be expected such complexes can be ascribed formulas of the type **63**, **76** and **109**[248]. In passing, the cadmium complexes of fluorinated phosphinatomethylide anions are worth mentioning. Their relationship to real ylide compounds is only of a formal nature[250].

Finally, however, the mercury complexes of triphenylphosphoniocyclopentadienide[251,119] are of greater interest. In the organometal compounds formed on reaction of this ylide with mercury(II) salts, the metal atom is $\eta^1$-coordinated to the C-3 atom of the $C_5H_4$ ring, as has been confirmed by an X-ray structural analysis of the adduct $[Ph_3P-C_5H_4 \cdot HgI_2]_2$. This unusual type of structure has otherwise never been observed amongst ylide complexes.

## 12. Outlook

The present review represents a snapshot glimpse at a field of chemistry that is in the process of rapid development. The trend in interest is unmistakably towards the intentional or accidental formation of ylides *in situ* at the metal atom, rather than the planned introduction of "preconstructed" ylides into a complex. The latter development seems temporarily complete now that the most important modes of formation and interactive mechanisms are known. However, these constitute but the preliminary studies necessary for an understanding of some of the complicated reactions in the system metal/phosphane/$C_1$ building block.

*Work in the author's laboratories was performed by a large number of co-workers, whose skill and enthusiasm are gratefully acknowledged. Thanks are also due to the Fonds der Chemischen Industrie, Deutsche Forschungsgemeinschaft, Hoechst AG, Degussa AG, and Proctor & Gamble Ltd. for generous and continued support.*

# Electron-Rich Half-Sandwich Complexes—Metal Bases *par excellence*

**By Helmut Werner***

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Electron-rich, half-sandwich complexes of the type $C_nR_nML_2$ or $C_nR_nMLL'$ are built up of an aromatic five- or six-membered ring, a $d^8$-metal, and either a pair of two-electron donors or an equivalent chelating ligand. Such complexes behave like Lewis bases and react with a wide variety of electrophiles, El or ElX, to form products with a new metal-element bond. According to their reactivity they are comparable to the Vaska-type compounds. Certain of the products obtained after addition of the electrophile undergo interesting subsequent reactions in which, for example, metal complexes containing molecules that are unstable in the free state, such as CS, CSe, $CH_2S$, $CH_2Se$, $CH_2Te$, $CH_3CHS$, $CH_3CHSe$, $CH_2{=}C{=}S$, $CH_2{=}C{=}Se$, and $CH_2{=}C{=}Te$ are formed. Moreover, cycloadditions as well as reactions with coordinatively unsaturated transition-metal compounds which result in formation of heterometal binuclear complexes demonstrate that the metal bases $C_nR_nML_2$ and $C_nR_nMLL'$ are valuable synthetic building blocks. Furthermore, very recent investigations have indicated links between metal basicity and the problem of C—H activation.

## 1. Introduction

Half-sandwich complexes are almost as old as ferrocene—the progenitor of all sandwich compounds. Shortly after the structure of dicyclopentadienyliron had been accurately determined and analogous metallocenes had been synthesized, *Fischer* und *Hafner*[1] reported the synthesis of tetracarbonyl(cyclopentadienyl)vanadium, $C_5H_5V(CO)_4$. Later work—involving highly competitive research efforts in Munich and Harvard—produced the homologous manganese and cobalt complexes $C_5H_5Mn(CO)_3$ and $C_5H_5Co(CO)_2$[2,3]. Because the metal atom in these compounds is enclosed on only *one* side by a $C_nH_n$-disk (as in the metallocenes) but is bonded to conventional ligands on the other side, the structure resembles a "half-sandwich". This term was later applied to similar compounds: instead of CO, ligands such as NO, halogenides, isocyanides, phosphanes, and olefins were now coordinated to the metal, and instead of $C_5H_5$ other ring systems such as $C_4H_4$, $C_6H_6$, $C_7H_7$ or $C_8H_8$ were employed[4].

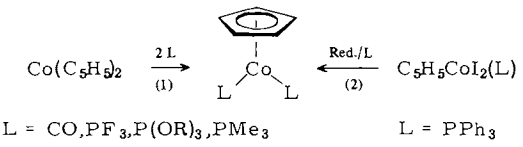
There was no indication in early publications[2,3] that half-sandwich complexes can behave as *metal bases, i.e.* that they react with electrophiles, El or ElX, to form new metal-element bonds[5]. Such behavior was hardly to be expected since both the carbonyl(cyclopentadienyl)metals mentioned above and most of the analogous compounds with the general formula $C_mH_mML_n$ are 18-electron complexes. At least in a formal sense these possess no lone pair of electrons capable of forming a covalent bond with a Lewis acid. Vaska-type compounds *trans*-$[MX(CO)L_2]$ (M = Rh, Ir; X = Cl, Br, I, $N_3$; L = $PR_3$, $P(OR)_3$, $AsR_3$ *etc.*) do possess such a lone pair of electrons and react not only with known electrophiles, *e.g.* HCl, $CH_3I$, $CH_3COCl$, $BX_3$, $SO_2$, *etc.* but also with $H_2$ or $R_3SiH$ by oxidative addition[6]. The Vaska-type compounds are thus typical metal bases, and it is not only thanks to their chemistry that the concept of *metal basicity* has become increasingly known since the beginning of the seventies[5].

The central atom in the *trans*-$[MX(CO)L_2]$ complexes is a *$d^8$-system*, as is the case in the dicarbonyl(cyclopentadienyl)metal compounds $C_5H_5M(CO)_2$ (M = Co, Rh, Ir). In an article which indicated the great significance of the nucleophilicity of transition-metal atoms in complexes having full valence shells, *Wilkinson et al.*[7] mentioned that

[*] Prof. Dr. H. Werner
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

$C_5H_5Co(CO)_2$ is rapidly decomposed in strong acids, such as $H_2SO_4$ or $BF_3 \cdot H_2O$, whereas in weakly acid media, such as $CF_3CO_2H$, it is stable for at least 10 minutes. It did not prove possible using NMR spectroscopy to confirm the proposal that a cation $[C_5H_5CoH(CO)_2]^+$ was formed in the process.

The first evidence for such an interaction between the central atom in $C_5H_5Co(CO)_2$ and an electrophile was provided by *Kemmitt et al.*[8]. They isolated 1:1 adducts from the reaction of the half-sandwich complex with $HgX_2$ (X = Cl, Br, I), which they then compared with known compounds such as $C_4H_8S \cdot HgCl_2$, and whose formation they interpreted as a Lewis acid/Lewis base reaction. This suggestion was confirmed shortly thereafter[9] by X-ray crystallographic studies on $[C_5H_5Co(CO)_2HgCl_2]$. Similarly, with $HgCl_2$ and $HgBr_2$, $C_5H_5Rh(CO)_2$ forms 1:1 adducts whose IR data indicate the presence of a direct metal-metal bond[10].

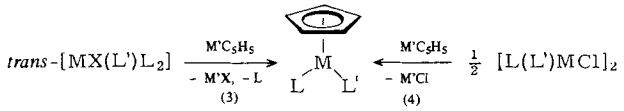


Further development of this field was stimulated by the work of *Graham et al.* which appeared in 1970/71[11]. They were the first to show that the compound $C_5H_5Rh(CO)(PMe_2Ph)$, *i.e.* a derivative of $C_5H_5Rh(CO)_2$, reacts with $Cl_2$, $Br_2$, $CH_3COBr$, and $CF_3COCl$ at low temperatures to form ionic compounds $[C_5H_5RhR(CO)PMe_2Ph]X$ (R = Cl, Br, $COCH_3$, $COCF_3$; X = halogen) which can be isolated as stable salts after exchanging $X^\ominus$ for $BPh_4^\ominus$[11a]. The iridium complex $C_5H_5Ir(CO)PPh_3$ not only behaves similarly but is also capable of forming a hydridometal cation with HBr in $CH_2Cl_2$ at −70 °C. This cation, $[C_5H_5IrH(CO)PPh_3]^+$, can again be isolated as the $BPh_4$ salt[11b]. Kinetic data for the compounds $C_5H_5M(CO)PPh_3$ indicate that the metal basicity increases along the sequence Co ≲ Rh < Ir (*i.e.* within the group from top to bottom) and that there is also an increase in basicity along the sequence $C_5H_5Co(CO)PPh_3$ < $C_5H_5Co(CO)PMePh_2$ < $C_5H_5Co(CO)PMe_2Ph$[11c]. It thus became evident that a better donor ligand would increase not only the electron density but also the nucleophilicity of the metal—an observation which has since been confirmed in many different ways in our own investigations.

## 2. Metal Bases having Five-Membered Ring Ligands

### 2.1. Synthetic Methods

Both ligand exchange reactions and redox reactions have been used for the preparation of metal bases having five-membered ring ligands. Thus, the dicarbonyl complex $C_5H_5Co(CO)_2$ mentioned in the introduction was synthesized from cobaltocene and CO by displacing one of the cyclopentadienyl ligands by two CO groups[2,3]. In this case, the ligand exchange is associated with reduction of cobalt(II) to cobalt(I). In the same way, the compounds $C_5H_5Co(PF_3)_2$[12] and $C_5H_5Co[P(OR)_3]_2$ (R = Me, Et, Ph)[13] are also accessible. Analogously, $C_5H_5Co(PMe_3)_2$ may be prepared according to reaction (1)[14], although this method is hardly recommended because of the amount of trimethylphosphane required.



A reductive method starting from a cobalt(III) compound is given in reaction (2)[15]. The reducing agent is

*i*PrMgBr. The bis(triphenylphosphane)cobalt(I) complex $C_5H_5Co(PPh_3)_2$ is formed without having to add $PPh_3$ to the reaction mixture, although in low yield. The rhodium compound $C_5H_5Rh(PPh_3)_2$ is obtainable analogously[15]. In addition, starting from $[C_5Me_5RhCl_2]_2$ and L (molar ratio 1:4; L = $PMe_3$, $PMe_2H$, $PMe_2Ph$, $P(OMe)_3$) and using Na/Hg as the reducing agent, some of the half-sandwiches can be prepared almost quantitatively[16]. The reduction of $[C_5H_5Rh(C_2F_4Br)(PPh_3)Br]$ with Zn is highly unusual in that it yields the tetrafluoroethylene complex $C_5H_5Rh(C_2F_4)PPh_3$[11d]—an analogue of the compounds $C_5H_5Rh(C_2H_3R')PR_3$ obtained in reactions (4) and (7).

The most direct route to metal bases having five-membered ring ligands is offered by the exchange of coordinated halides for $C_5H_5$, $C_5H_4R$, $C_5Me_5$, or $C_9H_7$. Thus, for example, the cobalt complexes $C_5H_5CoL_2$ (L = $PMe_2Ph$, $PMePh_2$[17], $PPh_3$[18], $PEt_3$[19], and $PMe_3$[20]) may be prepared by allowing the appropriate paramagnetic cobalt(I) compound $ClCo(PR_3)_3$ to react with $M'C_5H_5$ (M' = Na, Tl) or $LiC_5Me_5$. $C_5H_5Co(PPh_3)_2$ can also be obtained from $CoH(N_2)(PPh_3)_3$ and $C_5H_6$[21].

Both Vaska-type compounds and binuclear complexes $[L_2MCl]_2$ and $[L(L')MCl]_2$ (M = Rh, Ir) are suitable educts for the preparation of the complexes $C_5H_5ML_2$ and $C_5H_5MLL'$ (M = Rh, Ir), respectivley, by substitution of a halide- by a cyclopentadienyl-ligand. Several examples of such syntheses are collected together in reactions (3) and (4).

M = Rh; L = L' = $PPh_3$[22]
M = Rh; L = $PPh_3$, L' = $C_2H_4$[11b]
M = Rh, Ir; L = $PPh_3$, L' = CO[11b]
M = Rh, Ir; L = $PPh_3$, L' = CS[23]
M = Rh, Ir; L = P(*i*Pr)$_3$, L' = $C_2R_2$[24,25]
M = Rh; L = L' = $P(OR)_3$[26]
M = Rh; L = $PR_3$, L' = $P(OR')_3$[27]
M = Rh; L = $PMe_3$, L' = $C_2H_3R'$[28]
M = Rh; L = P(*i*Pr)$_3$, L' = $C_2H_4$[28]
M = Ir; L = P(*i*Pr)$_3$, L' = $C_8H_{14}$[25]

According to reaction (3), the preparation of $C_5H_5Rh(PPh_3)_2$ involves a reaction type related to that used for the synthesis of $C_5H_5Rh(PMe_3)_2$[29,30] and $C_9H_7Rh(PMe_3)_2$[31] from $[Rh(PMe_3)_4]Cl$; in the cation of this salt the rhodium atom is square-planar coordinated[32]. Similarly, the compounds $(C_5H_4R)Rh(PMe_3)_2$ (R = *i*Pr, *t*Bu)[33] and $C_5Me_5Rh(PMe_3)_2$[16], which are analogous to $C_5H_5Rh(PMe_3)_2$, are obtained by allowing $[(PMe_3)_2RhCl]_2$ to react with $TlC_5H_4R$ or $NaC_5Me_5$.

Half-sandwich complexes of the type $C_5R_5M(CO)L$ and $C_5R_5M(C_2H_4)L$ (M = Co, Rh; R = H, Me) are also frequently prepared by ligand displacements, as in reactions (5) and (7). Replacement of CO by a phosphane or phosphite generally takes place under milder conditions than the displacement of ethylene. Kinetic studies by *Schuster-*

*Woldan* and *Basolo*[34] confirmed an A- or $S_N2$-type mechanism for the formation of $C_5H_5Rh(CO)L$ from $C_5H_5Rh(CO)_2$ and L [see reaction (5)]. Disubstitution as shown in reactions (6) and (8) has been observed only in a few instances up till now. Since the π-acceptor ligand CO or $C_2H_4$ is bonded much more firmly in the compounds $C_5H_5M(CO)L$ and $C_5H_5M(C_2H_4)L$ than in the educts, it is evident that reactions (6) and (8) involve a very high activation energy.

$$C_5R_5M(CO)_2 \xrightarrow[-CO]{+L} C_5R_5M(CO)L \xrightarrow[-CO]{+L} C_5R_5ML_2 \quad (5)\ (6)$$

$$C_5R_5M(C_2H_4)_2 \xrightarrow[-C_2H_4]{+L} C_5R_5M(C_2H_4)L \xrightarrow[-C_2H_4]{+L} C_5R_5ML_2 \quad (7)\ (8)$$

*Reaction (5):*

* not isolated, characterized by NMR spectroscopy.

The displacement of a phosphane ligand in $C_5H_5Co(PMe_3)_2$ by CO[41] or CNR (R=Me, *t*Bu, Ph)[42] is also possible. Interestingly, the corresponding reaction of $C_5Me_5Co(PMe_3)_2$ with CO yields the monocarbonyl compound, while with CNMe the bis(isocyanide) complex $C_5Me_5Co(CNMe)_2$ is formed[20].

## 2.2. Complexes of the Type $C_5R_5ML_2$

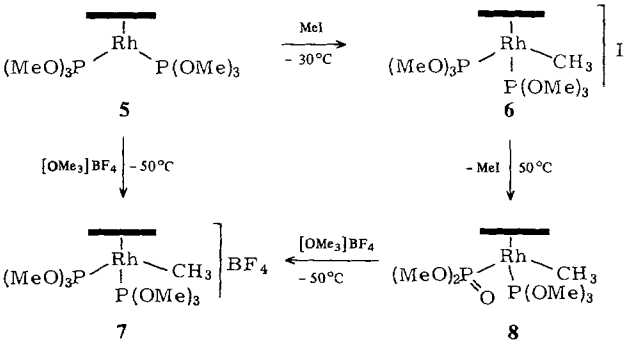
### 2.2.1. Dicarbonyl- and Bis(olefin)metal Complexes

$C_5H_5Co(CO)_2$ is not stable in acids[7], and nothing is known about the reactions of $C_5H_5Rh(CO)_2$ with HX to form $[C_5H_5RhH(CO)_2]X$. Dicarbonyl(cyclopentadienyl)metal compounds are thought to be inert toward methyl iodide[43], which is also to be expected in view of the good acceptor properties of CO and the resulting relatively low electron density at the metal. However, if $C_5H_5$ is replaced by $C_5Me_5$ and the central atom thus becomes more *electron-rich*, both $C_5Me_5Rh(CO)_2$ and $C_5Me_5Ir(CO)_2$ react with MeI [reaction (9)][44]. Whereas for M=Ir the reaction does not go beyond the stage of the salt-like complex **3**, the corresponding rhodium compound cannot be isolated and very rapidly yields the product **4** with CO insertion (or $CH_3$ migration[45a]). More recently, evidence has been presented that protonation of $C_5Me_5Ir(CO)_2$ gives the corresponding hydridometal cation[45b].

(9)

**1**,**2** **3** **4**

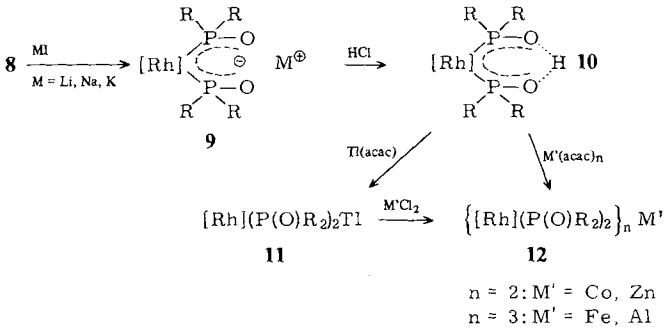
**1**,**4**: M = Rh; **2**,**3**: M = Ir



With HCl the compound $C_5H_5Rh(C_2H_4)_2$ forms the ethylrhodium(III) compound $C_5H_5RhC_2H_5(C_2H_4)Cl$[46]. A conjectured intermediate hydrido(olefin)metal cation could not be detected either here or in the reactions of mixed bis(olefin) complexes of the type $C_5H_5Rh(C_2H_4)(C_2H_3X)$ (X=F, CN, $CO_2Me$) with HCl[47]. That the rate of the reaction of $C_5H_5Rh(C_2H_3X)_2$ with HCl increases along the sequence $X=CN<CO_2Me<CH_3$[47], supports the postulated protonation at the metal. Since the donor character of the olefin increases along the same sequence, the resulting increase in electron density at the metal should favor electrophilic addition.

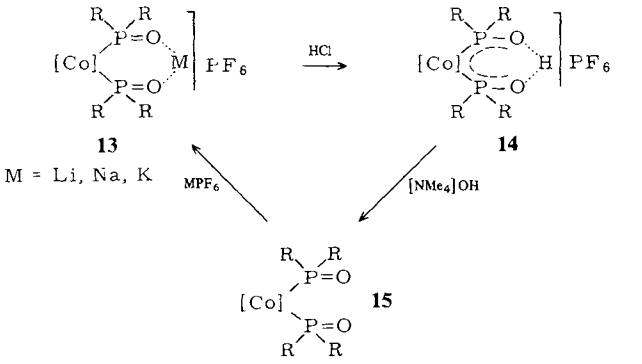
### 2.2.2. Bis(phosphite)metal Complexes

In addition to the carbonyl(phosphane) derivatives, the bis(phosphite) compounds have also played a major role in establishing the metal basicity of cyclopentadienylmetal complexes of the type $C_5R_5ML_2$ or $C_5R_5MLL'$. Although the first representative of this group, the complex $C_5H_5Rh[P(OMe)_3]_2$ had already been described in 1966[34], its reactivity was not investigated in detail at that time.



We were closely associated with compounds of this type in our endeavors to find new synthetic routes to trinuclear complexes of the "super-sandwich" type[48], $[C_5H_5Co(\mu\text{-}P(OR)_2O)_3Co(\mu\text{-}P(OR)_2O)_3CoC_5H_5]$. These compounds were initially prepared by pyrolysis of $C_5H_5Co[P(OR)_3]_2$ (R=Me, Et)[49], although—as *Kläui* and *Dehnicke*[50], and more recently *Brill et al.*[51] have demonstrated—they are more readily produced starting from cobalt(III)-trialkylphosphite or cobalt(III)-dialkylphosphonate complexes.

Attempts to obtain analogous trinuclear rhodium complexes starting from $C_5H_5Rh[P(OR)_3]_2$ proved to be unsuccessful[52,53]. We discovered from these studies, however, that the bis(phosphite) compounds $C_5H_5Rh[P(OR)_3]_2$ are good nucleophiles and that they react (at least for R=Me) even under very mild conditions with Brønsted acids, methyl iodide, or *Meerwein*'s reagent, $[OMe_3]BF_4$, to form the corresponding rhodium(III) complexes[54,55]. For the methylation reaction the sequence given in Scheme 1 has been confirmed[54].

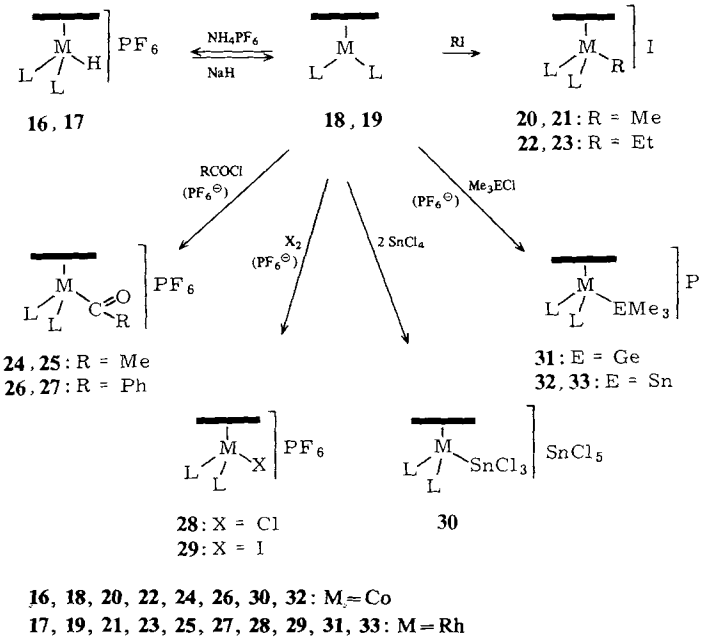


Scheme 1. The bar symbolizes a cyclopentadienyl ligand.

The iodide salt **6** obtained by electrophilic addition at −30°C in acetone eliminates methyl iodide when heated to form the phosphonate compound **8**, which is an isomer of the starting complex **5**. Evidently, the rupture of an O–$CH_3$ bond is highly favored kinetically compared to that of a Rh–$CH_3$ bond, an observation in accord with the high metal basicity of **5**. The conversion of **5** into **8** illustrates that trialkylphosphite complexes frequently behave like the intermediate moiety $[R'P(OR)_3]^+$ (R = alkyl) in the Michaelis-Arbuzov reaction and thereby offer a convenient route to metal phosphonate compounds.

Scheme 2. [Rh] = $C_5H_5RhCH_3$; R = OMe.

Proof of this is also to be seen in the subsequent reactions undergone by some of the products obtained from the metal bases $C_5H_5M[P(OMe)_3]_2$. Thus, **8** reacts with alkali metal iodides, for example, to yield rhodium(phosphonate) complexes **9**, which react with HCl to give **10**; the latter presumably contains a six-membered ring having a symmetric OHO bridge[56]. Starting from **10** or **11**, it is possible to prepare polynuclear complexes **12** (see Scheme 2) which are similar to the "super-sandwich" compounds[56,57]. The marked ability of metallabis(phosphonates) to complex alkali metal ions is also illustrated by the fact that the compounds **15** prepared from $(C_5H_4R)Co(CH_3)_2PR'_3$ (see Section 3.2) act as strong complexing agents toward $Li^+$, $Na^+$, and $K^+$. The complexes formed release the alkali metal ion $M^+$ from the coordination sphere only when HCl is added, but not on addition of water (see Scheme 3)[58].



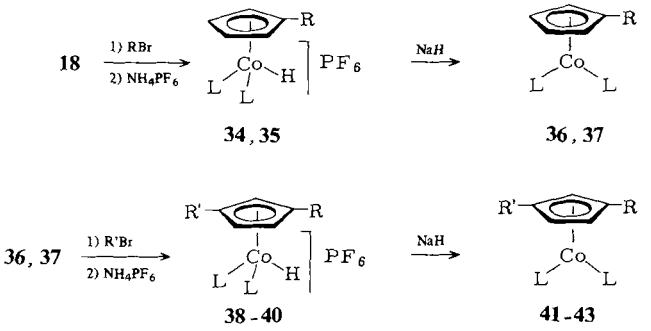
Scheme 3. [Co] = $(C_5H_4R')CoPMe_3$; R' = H, *i*Pr, *t*Bu; R = OMe.

The type of coordination of the $M^+$ cations by the oxygen atoms of the phosphonate groups was established by X-ray analysis of the complex $C_6H_6OsI[P(O)(OMe)_2]_2Na$, which is related to **9** and to the cation of **13**, and which crystallizes with one equivalent of NaI[59]. In this salt there exist intermolecular interactions between the sodium ions and a *pair* of $C_6H_6OsI[P(O)(OMe)_2]_2^-$ anions, with the result that the O=P–Os–P=O unit is no longer planar and the O···O distance relative to that in $C_6H_6OsI[P(O)(OMe)_2]_2H$ (a compound readily comparable with **10**) is substantially increased.

### 2.2.3. *Bis(phosphane)metal Complexes*

Since phosphanes are better donor ligands than phosphites, the $C_5H_5M(PR_3)_2$ complexes should also be stronger metal bases than their phosphite analogues $C_5H_5M[P(OR)_3]_2$. This prediction proved to be true, in particular when $PMe_3$ was used as a phosphane ligand. Whereas the compounds $C_5H_5M[P(OMe)_3]_2$ (M = Co, Rh), for example, can be protonated only with strong acids such as $CF_3CO_2H$ or $HBF_4$[55], the conversion of the phosphane complexes **18** and **19** into **16** and **17**, respectively, can be carried out using $NH_4PF_6$[17,29]. The high basicity of **18** is evidenced very clearly by the fact that the compound reacts slowly even with methanol to form the hydridometal cation $[C_5H_5CoH(PMe_3)_2]^+$[41].

Some typical examples illustrating the reactivity of the complexes **18** and **19** with electrophiles are summarized in Scheme 4[17,29,60]. In addition to the Lewis acids $SnCl_4$, $Me_3SnCl$, and $Me_3GeCl$ also $ZnCl_2$, $HgCl_2$, and CuCl (as a $PMe_3$ adduct) were allowed to react with **18** and compounds having Co–Zn, Co–Hg and Co–Cu bonds isolated[60]. Adducts of boron halides $BX_3$ (X = F, Cl, Br) with **14** are similarly accessible[61].



**16**, **18**, **20**, **22**, **24**, **26**, **30**, **32**: M = Co
**17**, **19**, **21**, **23**, **25**, **27**, **28**, **29**, **31**, **33**: M = Rh

Scheme 4. L = $PMe_3$.

The differing behavior of methyl and ethyl iodides, on the one hand, and isopropyl and *tert*-butyl halides, on the other, toward bis(trimethylphosphane) compounds of the type $C_5H_5M(PMe_3)_2$ is quite remarkable. Under the same conditions that **18** reacts with MeI and EtI to form **20** and

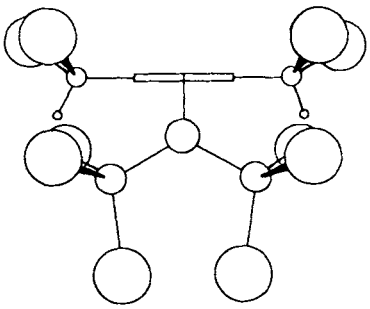
**22**, respectively (see Scheme 4), it forms the alkylcyclopentadienyl(hydrido)metal complexes $[(C_5H_4R)CoH(PMe_3)_2]Br$ with *i*PrBr and *t*BuBr[19,62]. The corresponding hexafluorophosphates **34** and **35** (Scheme 5) can readily be converted by NaH into the neutral compounds **36** and **37** which, after further reaction with *i*PrBr or *t*BuBr, afford the *doubly* ring-substituted products **38**, **39**, or **40**. Subsequent deprotonation with NaH yields the complexes **41**—**43**. These also react very rapidly with methyl iodide, *i.e.* an electrophilic addition involving the formation of a $Co-CH_3$ bond is possible even when two bulky substituents are present on the ring. The introduction of a third alkyl group to the cyclopentadienyl ligand, however, is not possible; **41**—**43** are inert toward *i*PrBr and *t*BuBr[19].

**34**, **36**: R = *i*Pr **38**, **41**: R = R' = *i*Pr
**35**, **37**: R = *t*Bu **39**, **42**: R = *i*Pr, R' = *t*Bu
**40**, **43**: R = R' = *t*Bu

Scheme 5. L = $PMe_3$.

It is surprising that in **40** and **43** (R = R' = *t*Bu) rotation about the metal-ring bond is so strongly hindered that *rigid conformers* are present in solution up to a temperature of *ca.* 100°C. It is likely here that the size of the phosphane ligands is an important factor. Even for **42** a frozen conformation can be detected below −10°C. The fact that the rotational barrier is lower than in **43**, and that for **41** there is absolutely no spectroscopic evidence of any hindrance to free rotation can be explained by means of a model based on a "gear wheel mechanism"[19,62]. For a 1,3-$(t\text{Bu})_2C_5H_3$ ring it is clearly not possible for the *tert*-butyl groups to pass the $PMe_3$ ligand as they rotate about the ring-metal axis (despite free rotation about the C-*t*Bu bond). However, if in the *t*Bu groups a $CH_3$ group replaces an H atom, *i.e.* *t*Bu is substituted for *i*Pr, the two ring substituents can probably arrange themselves in such a way that at the moment of passing a phosphane the H atom of the isopropyl group is directed "inwards" and—like the teeth on a gear wheel—fits in-between the methyl groups on the phosphorus (Fig. 1).

MO calculations[63] indicate that the barrier to rotation about the ring-metal bond in half-sandwich complexes of the type $C_5H_5ML_2$ and $C_5H_5ML_3$ is extremely low. Thus, for purely electronic reasons the formation of preferred conformers is not to be expected. Steric effects should thus play the determining role. Recently, using NMR spectroscopy *Pomeroy* and *Harrison*[64] succeeded in demonstrating rotational hindrance in a similar compound $[C_6H_4(t\text{Bu})_2]Ru(CO)(SiCl_3)_2$.



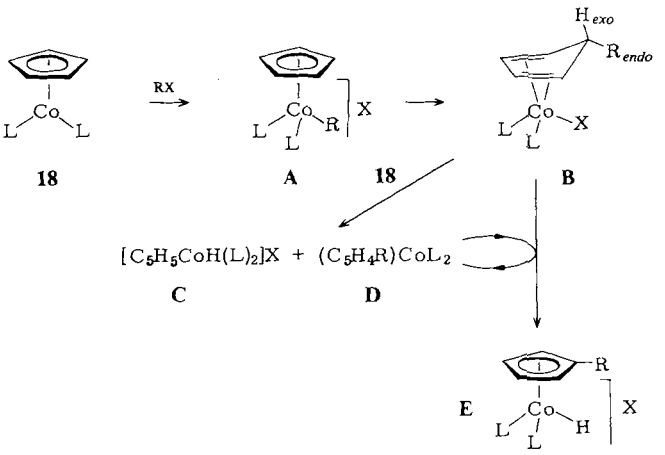


Fig. 1. Proposal based on a model of the space-filling capacity of 1,3-$(i\text{Pr})_2C_5H_3Co(PMe_3)_2$ **41** [62].

A proposal for the mechanism of the highly unusual ring substitution of **18** is shown in Scheme 6[19]. It draws on concepts which help to understand the aromatic nature of cyclopentadienylmetal complexes such as $Fe(C_5H_5)_2$ or $C_5H_5Mn(CO)_3$[4]. We assume that in the initial step—completely analogously to that for the reactions of **18** with methyl and ethyl iodides—an electrophilic addition takes place and the ionic compound **A** is formed; intermediate **B** is produced from **A** by intramolecular rearrangement. Reaction of **B** with the metal base **D**, which acts autocatalytically as indicated in Scheme 6, leads to **E** (**34** and **35** in Scheme 5), which after completing the exchange can be isolated (along with small amounts of $[C_5H_5CoH(L)_2]X$) in more than 90% yield.

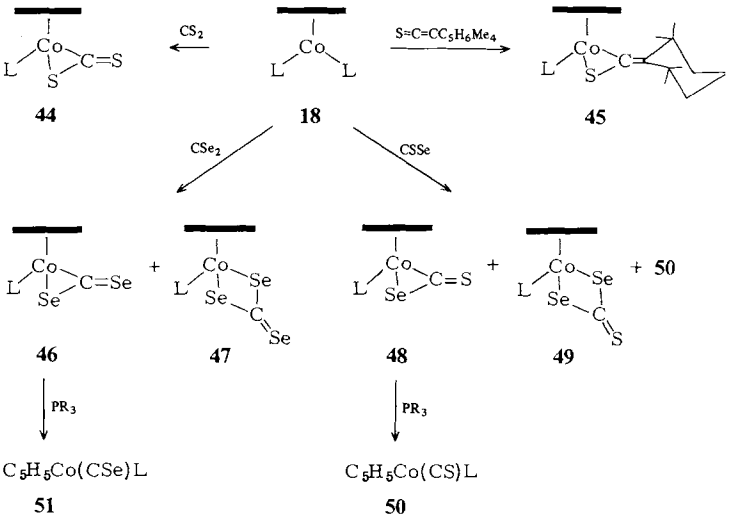
Evidence that the hydride hydrogen atom in **E** originates from the cyclopentadienyl ring in **18** (and not from the alkyl halide) is provided by the reaction of $C_5D_5Co(PMe_3)_2$ with *t*BuBr which leads to $[(C_5D_4R)CoD(PMe_3)_2]Br$[19]. Low-temperature NMR data[19] also support the formation of the postulated intermediate **B** as do our recently published results on a rapid H/D exchange between the cations $[C_5Me_5Co(PMe_3)(CNR)_2]^{2+}$ and $CD_3NO_2$ in the presence of traces of $NEt_3$. In this case it is assumed[20] that the intermediate formation of a cobalt(I) complex with an ($\eta^4$-$C_5Me_5$-*exo*-$CD_2NO_2$) ligand occurs.

Scheme 6. L = $PMe_3$; R = *i*Pr, *t*Bu.

The alternative to the proposal outlined in Scheme 6 would be a radical reaction. A one-electron transfer from **18** to the electrophile RX would then initially occur to

form a "contact radical pair", similar to that postulated for the intermediate in the reaction of carbonylmetalate ions $[M(CO)_5]^-$ (M = Mn, Re) with the corresponding halo complexes[65]. Co–R or $C_5H_5$–R bond formation could then occur from the radical pair $\{C_5H_5CoL_2^{\oplus\odot}, RX^{\ominus\odot}\}$.

One reason we believe this alternative is possible, although for RX = MeI, EtI unlikely, is the result of the reaction of **19** with *i*PrBr or *t*BuBr which produces a mixture of $[C_5H_5RhBr(PMe_3)_2]Br$, $[(C_5H_4R)RhBr(PMe_3)_2]Br$ and other compounds which have not yet been identified[33]. We assume that the cations involved are formed *via* free radicals, whose appearance as intermediates seems probable on the basis of CIDNP measurements[33]. A radical cation, $[C_5H_5Rh(PPh_3)_2]^{\oplus\odot}$, is also allegedly produced as an intermediate in the formation of $[(\eta^{10}\text{-}C_{10}H_8)Rh_2(PPh_3)_4](BF_4)_2$ from $C_5H_5Rh(PPh_3)_2$ and $AgBF_4$[66a]. *McKinney*[66b] was also able to synthesize the $BF_4$ salts of the corresponding cobalt complexes, $[C_5H_5CoL_2]^+$ (L = $PPh_3$, $PEt_3$, $PEtPh_2$, $P(OiPr)_3$), both by oxidizing $C_5H_5CoL_2$ and by reaction of $C_5H_5CoXL$ with $TlBF_4$ in the presence of L. Finally, the observation that $C_5Me_5Co(PMe_3)_2$ reacts with methyl iodide to form $[C_5Me_5CoI(PMe_3)_2]I$ and not $[C_5Me_5CoCH_3(PMe_3)_2]I$ fits well into the overall picture of conceivable radical reactions involving electron-rich half-sandwich compounds[20].



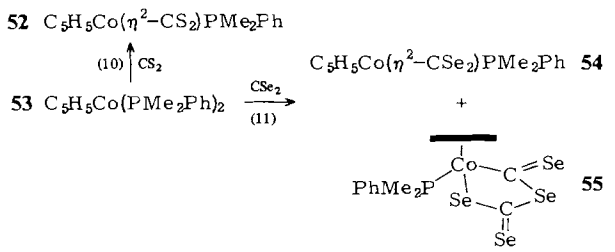
### 2.2.4. $CO_2$ Homologues as Electrophiles

Carbon dioxide, a well-known electrophile, has recently been allowed to react with electron-rich metal compounds, especially in connection with attempts to "activate" $CO_2$ by transition metals. However, there are very few notable results of such attempts[67]; $CO_2$ is evidently too inert toward "soft" bases, among which are the half-sandwich compounds discussed here.

Rather more reactive than $CO_2$ itself are its homologues (often designated as heteroallenes), some of which react very readily with metal bases. The pioneering work in this field was carried out by *Baird* and *Wilkinson*[68], who, as far back as 1966, studied the reactivity of the compounds $RhCl(PPh_3)_3$, $Pd(PPh_3)_4$, and $Pt(PPh_3)_3$ toward $CS_2$. Among others, they isolated the first thiocarbonylmetal complex, *trans*-$[RhCl(CS)(PPh_3)_2]$[69].

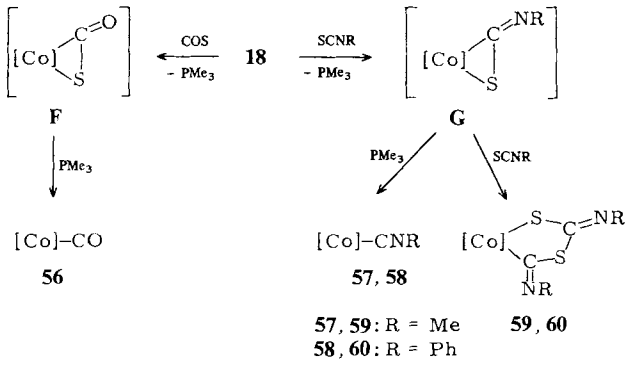
That *half-sandwich* compounds behave in a similar way was primarily established by *Yamazaki et al.*[15,22]. By allowing $C_5H_5M(PPh_3)_2$ (M = Co, Rh) to react with $CS_2$ they obtained—albeit in modest yields—the complexes $C_5H_5M(\eta^2\text{-}CS_2)PPh_3$ in which, as in **44**, the carbon disulfide is probably bonded to the metal *via* the C atom and one S atom[70].

Because $C_5H_5Co(PMe_3)_2$ **18** and $C_5H_5Rh(PMe_3)_2$ **19** are stronger metal bases than the analogous triphenylphosphane derivatives, they react significantly faster with $CS_2$ and other $CO_2$ homologues and yield—as shown in Scheme 7 using **18** as example[71–73]—a whole series of novel metal(I) and metal(III) complexes. The initial step in these reactions involves attack of the nucleophilic metal center at the electrophilic C atom of the heteroallene. The subsequent elimination of a phosphane ligand will probably be favored because $PMe_3$ forms—at least with $CS_2$ and $CSe_2$—zwitterionic 1:1 adducts which are rather insoluble in organic solvents and thus precipitate. The heteroallene complexes **46** and **48** react with free trimethyl- or triphenylphosphane to give the corresponding thio- or selenocarbonylcobalt compounds **50** or **51**[71–73]. Brief mention will also be made of the reactivity of **50** and **51** toward electrophilic substrates in Section 2.3.1.



**44** **18** **45** **46** **47** **48** **49** **51** **50**

Scheme 7. L = $PMe_3$.



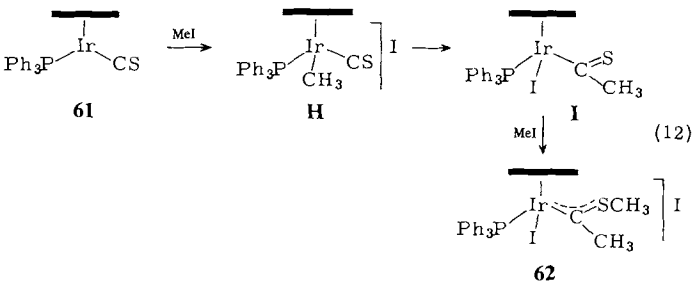
X-ray structural analyses have been carried out on **44** and **45**[70,72]. These have revealed very similar distances for the three-membered CoCS ring and also an almost identical SCX bond angle (X = S or C) for the no longer linear $CS_2$ or thioketene molecules in the complex. It thus appears that both heteroallenes possess rather comparable ligand characteristics. An X-ray analysis of **48** is now underway, and we are very optimistic that the result will confirm the structural proposal presented in Scheme 7. Recently, we were able to confirm for the palladium compound $[1,2\text{-}C_6H_4(CH_2PPh_2)_2]Pd(\eta^2\text{-}CSSe)$ that the thiocarbonyl selenide is indeed coordinated to the metal *via* C and Se and not *via* C and S[74].

$C_5H_5Co(PMe_2Ph)_2$ **53** behaves quite similarly to **18** towards $CO_2$ homologues[73]. Using $CS_2$, compound **52**, *i.e.* the analogue of **44**, is formed practically quantitatively, while with $CSe_2$ the five-membered ring complex **55** is obtained in addition to **54** (and small amounts of $C_5H_5Co(PMe_2Ph)CSe_3$). The formation of **55** can be interpreted according to a 1,3-dipolar cycloaddition of **54** to a second $CSe_2$ molecule. A compound having the composition $C_5H_5Rh(PMe_3)C_2S_4$, which is structurally very closely related to **55**[75], is formed in the reaction of $C_5H_5Rh(PMe_3)C_2H_4$ with $CS_2$. As confirmed in this particular instance by X-ray analysis, the atoms of the metallaheterocycle are roughly coplanar. Moreover, the C–S distances in the ring and to the exocyclic sulfur atoms are almost identical, which suggests the presence of a highly delocalized $\pi$-electron system[75]. The reaction of **53** with CSSe yields compounds analogous to **49** and **50**[73]. It is possible here also that an $\eta^2$-CSSe complex is initially formed which immediately reacts with $PMe_2Ph$ or CSSe to give the products indicated.

The results summarized in Scheme 7 and in equations (9) and (10) generally support that—in contrast to the reactions of the half-sandwich complexes **18** and **53** with $CS_2$—use of the more reactive heteroallenes CSSe and $CSe_2$ yields *via* the initially formed $C_5H_5Co(\eta^2\text{-}CSSe)PR_3$ or $C_5H_5Co(\eta^2\text{-}CSe_2)PR_3$ compounds further, secondary products, some of which are structurally novel. Presumably both the lower dissociation energy of the C–Se bond (as compared to the C–S bond) and the greater reactivity of the CoCSe three-membered ring in the *dihapto*-bonded CSSe and $CSe_2$ complexes are responsible for their formation.

The CoCS three-membered ring in the compounds **F** and **G** postulated as the primary intermediate in the reactions of **18** with COS and SCNR is probably even more labile. These intermediates react very rapidly with the $PMe_3$ released in the primary step by $SPMe_3$ elimination to form the carbonyl or isocyanide complexes **56** or **57**, and **58** which—as shown below—are themselves metal bases (see Section 2.3.2). The course of the reaction of **18** with SCNR outlined in Scheme 8 is supported by the fact that under certain conditions (especially with excess isothiocyanate) the metallaheterocycles **59** and **60** are isolated in addition to **57** and **58**. These heterocycles structurally resemble the compounds **55** and $C_5H_5Rh(PMe_3)C_2S_4$[42].

Scheme 8. [Co] = $C_5H_5CoPMe_3$.



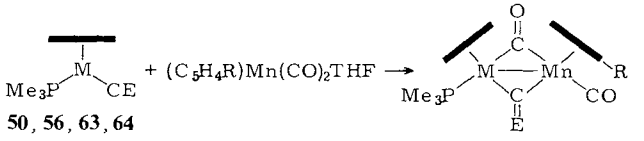
## 2.3. Complexes of the Type $C_5R_5MLL'$

### 2.3.1. *Carbonyl(phosphane)- and Thiocarbonyl(phosphane)metal Complexes*

In terms of their nucleophilicity, the $C_5R_5M(CO)PR'_3$ (R = H, Me; M = Co, Rh, Ir; R' = alkyl, aryl) half-sandwich complexes—numerous examples of which are known—occupy an intermediate position between the bis(phosphane)- and dicarbonylmetal compounds. As *Graham et al.* have shown for $C_5H_5Co(CO)PR'_3$ ($PR'_3 = PPh_3$, $PMePh_2$, $PMe_2Ph$), $C_5H_5Rh(CO)PPh_3$, $C_5H_5Ir(CO)PPh_3$, *etc.*[11], they react with alkyl halides (especially with methyl iodide) to form the acyl complexes.

Protonation to afford the hydridometal cations $[C_5R_5MH(CO)PR'_3]^+$ has proved to be successful in only a few cases so far. Starting from the carbonyl(tri*phenyl*phosphane) compounds $C_5H_5M(CO)PPh_3$ only the iridium derivative forms a stable cation of this type[11b], which merely confirms the tendency to increasing basicity according to the scheme 3d- < 4d- < 5d-element (in the same triad) put forward by *Shriver*[5]. When we turn to the carbonyl(tri*methyl*phosphane) complexes $C_5H_5M(CO)PMe_3$ a stable salt, $[C_5H_5RhH(CO)PMe_3]X$ (X = $BF_4$, $CF_3SO_3$), can be isolated for M = Rh[37]. The corresponding $C_5Me_5Rh$ compound can be prepared similarly[38].

Only very little is known about the reactivity of phosphane(thiocarbonyl) complexes, $C_5H_5M(CS)PR'_3$, towards electrophiles. *Faraone et al.*[23] have studied the reaction of $C_5H_5Ir(CS)PPh_3$ **61** with excess methyl iodide and isolated the thiocarbene compound **62**. The reaction pathway postulated in reaction (12) is based on the plausible assumption that **61** behaves similarly to $C_5H_5Ir(CO)PPh_3$[11b], and that the intermediate **H** is produced primarily by oxidative addition of a methylcarbenium ion to the metal. It is quite possible that there is a further intermediate between **H** and **I** involving a *dihapto*-bonded thioacyl group, as indicated by *Roper et al.* for the corresponding osmium complexes[76].



(12)

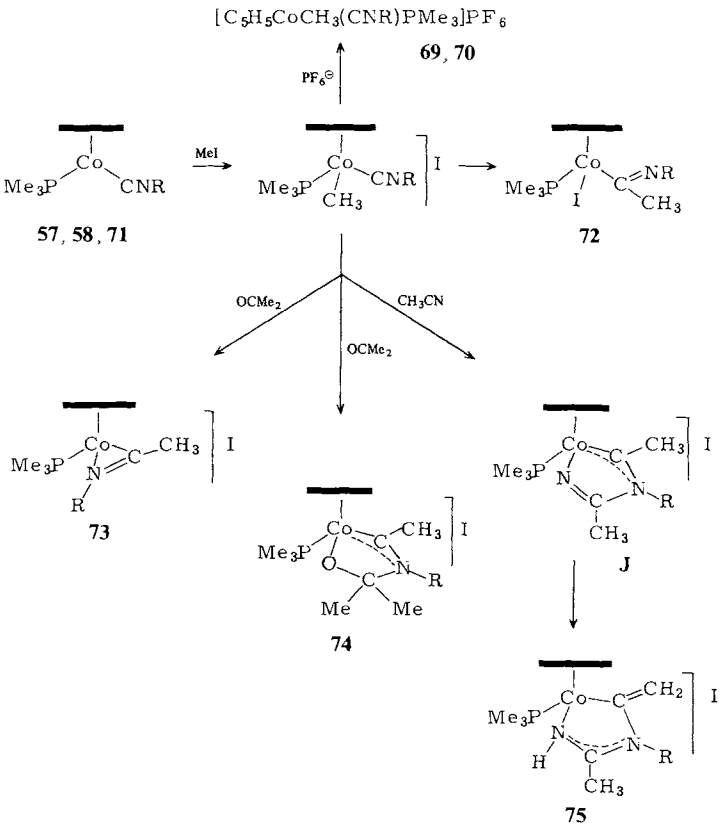
In reacting with methyl iodide, the trimethylphosphane compounds **50** and **64** yield—in contrast to **61**—no products analogous to **H**, **I**, or **62**. Even electrophilic addition at the sulfur atom with formation of a methylthiocarbyne complex (which occurs in the reaction of [W(CS)(CO)(diphos)$_2$] with $CF_3SO_3Me$[77]), cannot be proven[73]. **50** reacts with $CH_2I_2$ to give a mixed product containing both $[C_5H_5CoI(PMe_3)_2]I$ and, rather surprisingly, the binuclear compound $C_5H_5Co(\mu\text{-}CS)_2Co(PMe_3)C_5H_5$, whose structure, with unsymmetric CS bridges as a characteristic feature, has been established by X-ray analysis[78].

The carbonyl- and thiocarbonyl(trimethylphosphane) complexes **56** and **63**, and **50** and **64** behave very similarly toward the 16-electron species $[(C_5H_4R)Mn(CO)_2]$ (R = H, Me). The latter are typical electrophiles[79], and accordingly react with the half-sandwich metal bases to give the binuclear compounds **65**–**68** [reaction (13)] in high yield[14,73,80,81]. We assume that an interaction initially takes place between the nucleophilic metal center in **50**, **56**, **63**, or **64** and the electronically and coordinatively unsaturated manganese atom, followed by stabilization re-

sulting from the formation of the CO or CS bridges. X-ray crystallographic studies of **65**[82] and **66**[83] indicate that a *cis*-arrangement of the cyclopentadienyl ligands is preferred in each case. The CS group in **66** and **68** is exclusively bridging (and is not in a terminal site), a fact which emerges particularly from the IR data[73]. In the synthesis of **66** and **68** a second product is also formed containing a $C_5H_5Mn(CO)_2$ group as the ligand on the sulfur atom[81]. The yields obtained vary according to the amount of $C_5H_5Mn(CO)_2THF$ used.

**50**, **56**, **63**, **64**

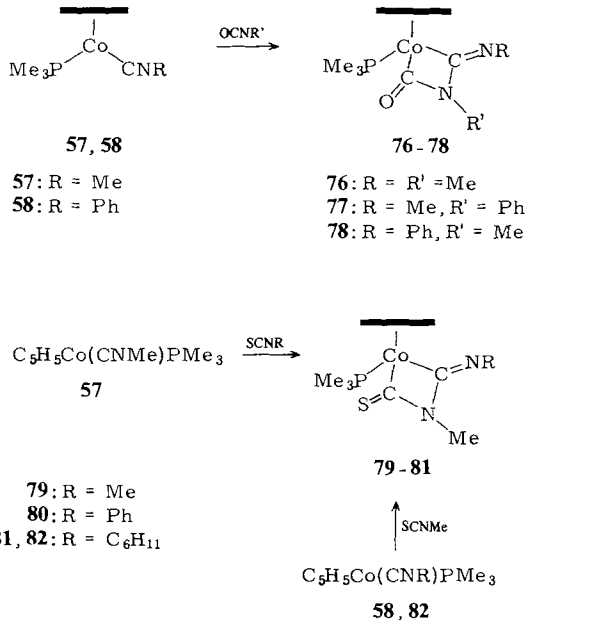
**56**, **65**: M = Co; E = O
**50**, **66**: M = Co; E = S
**63**, **67**: M = Rh; E = O
**64**, **68**: M = Rh; E = S



**65**, **67**: R = Me
**66**, **68**: R = H (13)

### 2.3.2. *Isocyanide(phosphane)metal Complexes*

The isocyanide complexes $C_5H_5M(CNR)PMe_3$ (M = Co, Rh) behave as nucleophiles toward both methyl iodide and heteroallenes. Interestingly, the course of the reactions of the cobalt compounds **57**, **58** and **71** (Scheme 9) with MeI is utterly dependent upon the group R of the isocyanide ligand. With R = Me and *t*Bu, in pentane as solvent the $[C_5H_5CoCH_3(CNR)PMe_3]^+$ cations are obtained which can be characterized readily as the $PF_6$ salts **69**, **70**. With R = Ph, the corresponding cationic complex is rather unstable and rapidly rearranges to form the neutral imidoylcobalt(III) compound **72** when the attempt is made to dissolve and recrystallize it from acetone/ether[42]. This subsequent reaction is to be expected in view of the similar ligand characteristics of CO and CNR and the comparable metal basicity of $C_5H_5Co(CO)PMe_3$ **56** and $C_5H_5Co(CNR)PMe_3$ (**57**, **58**, **71**).



However, if the methyl isocyanide and *tert*-butyl isocyanide complexes $[C_5H_5CoCH_3(CNR)PMe_3]I$ are dissolved in acetone, no product analogous to **72** is formed. When R = *t*Bu another cation (**73** with iodide as the anion) having a *dihapto*-bonded imidoyl group is obtained after migration of the $CH_3$ group from the metal to the isocyanide carbon[42]. It is conceivable that an intermediate analogous to **72** or **73** is also formed when $[C_5H_5CoCH_3(CNMe)PMe_3]I$ is dissolved in acetone; however, this is extremely labile and thus reacts with the solvent *via* a [3+2]-cycloaddition to form the metallaheterocycle **74** (Scheme 9)[84]. This product has been characterized by X-ray structure analysis[85]. The reaction of $[C_5H_5CoCH_3(CNMe)PMe_3]I$ with acetonitrile gives **75**, a five-membered ring compound containing Co; this is probably formed *via* intermediate **J**. The structure of **75** has also been established by X-ray analysis[84].

The reaction of **57** with methyl and phenyl isocyanates and of **58** with methyl isocyanate probably proceeds *via* attack of the nucleophilic cobalt atom at the electrophilic center of the heteroallene to yield the four-membered ring compounds **76**—**78** (Scheme 10)[86]. Methyl isothiocyanate reacts analogously with **57**, **58**, and **82**. Surprisingly, the

Scheme 9. **57**, **69**, **74**, **75**: R = Me; **70**, **71**, **73**: R = *t*Bu; **58**, **72**: R = Ph.

metallaheterocycles **79**—**81** prepared in this way are also formed from $C_5H_5Co(CNMe)PMe_3$ and SCNR, which suggests the intermediate formation of a four-membered ring containing a sulfur atom. Cleavage of a C—S bond and renewed ring closure leads to the thermodynamically stable product bearing a methyl group on the ring nitrogen atom. As indicated by X-ray crystallographic studies of the complexes **79** and **80**, planar CoCNC four-membered

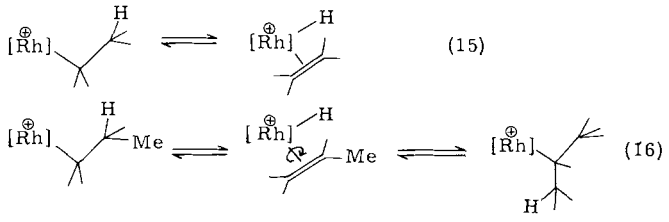
rings are present whose C and N atoms are, as expected, coordinated in a strictly trigonal-planar manner[86]. Protonation and methylation of the heterocycles **76—81** lead to formation of cyclic aminocarbenecobalt compounds, which also opens up a route to metallaindole derivatives[87].

In connection with the preparation of **80** from **57** it should also be mentioned that the isocyanide compound $C_5H_5Co(CO)CNMe$ is formed when the complex $C_5H_5Co(CO)PMe_3$ **56**—which is comparable with **57**—reacts with SCNPh[80]. In contrast, the reaction of $C_5H_5Co(CO)PPh_3$ with SCNPh leads to $C_5H_5Co(\eta^2$-SCNPh)$PPh_3$, among others, and not to a four-membered ring species related to **80**[88].

### 2.3.3. *Olefin(phosphane)metal Complexes*



The lack of evidence of attack by a proton at the metal in the reaction of bis(olefin)rhodium complexes with HCl is certainly not mirrored by the mixed olefin(phosphane) compounds **83—85**. Using $HBF_4$ in ether, one obtains the $BF_4$ salts **86—88**, which are also relatively stable in solution (*e.g.* $CH_3NO_2$)[28]. The temperature dependence of the NMR spectra and deuteration experiments indicate that in solution a rapid proton exchange takes place involving the olefinic protons and the hydridic proton. The positions of the equilibria in reactions (15) and (16) are certainly shifted to the side of the hydrido(olefin) complexes, since it has proved impossible either by $^1H$- or $^{13}C$-NMR spectroscopy to establish the presence of an alkylrhodium cation[28].

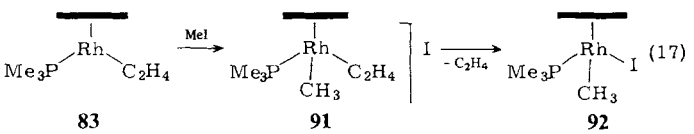
(16)

[Rh] = $C_5H_5RhPMe_3$

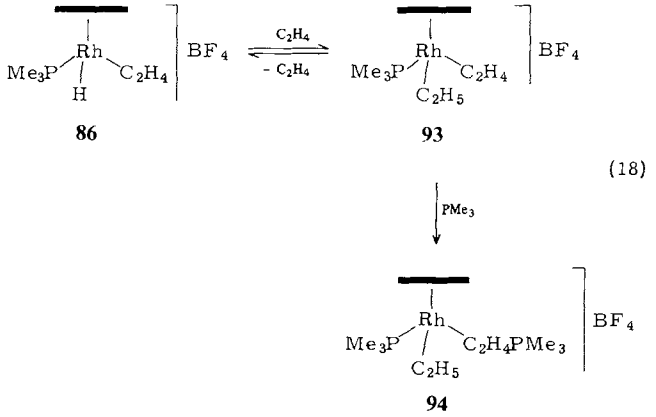


It is interesting to note that protonation of the propene-rhodium compound **84** yields the two diastereomeric pairs of **87**, not in equal amounts but roughly in the ratio 70:30, *i.e.* an *asymmetric induction* occurs[89]. Since the configuration at the two chiral centers (the metal and the methyl-substituted carbon atom of propene) is constantly changing as a result of equilibrium (16), one diastereomer is rapidly transformed into another. This is evidenced in the NMR spectra by the line broadening of the signals from the ring and phosphane protons or carbons atoms[28].

The reaction of the styrene complex **89** with $HBF_4$ or $CF_3CO_2H/NH_4PF_6$ leads to a product corresponding analytically to a hydrido(olefin) compound analogous to **86—88**. The IR and NMR spectra of this product, however, show no evidence of an Rh—H bond. As proved by X-ray structure analysis (X = $PF_6$), in the crystal exclusively **90** is present, *i.e.* the methylbenzyl group formed from the proton and the styrene is linked to the metal *via* a $\pi$-allyl type bond[28]. The formation of **90** probably takes place *via* the intermediates **K** and **L** which—as demonstrated by labeling experiments—are in equilibrium with **M** and **90** (Scheme 11). The fact that the complex **90**—in contrast to other $\eta^3$-methylbenzyl metal compounds—possesses a rigid rather than a fluctuating structure in solution may arise because the rhodium(III) has the preferred octahedral coordination[28].

Scheme 11. [Rh] = $C_5H_5RhPMe_3$; X = $BF_4$, $PF_6$.

The methylation of the rhodium atom in **83** takes place similarly [reaction (17)]. The ethylene(methyl) complex formed, **91**, is stable at room temperature and reacts only upon warming in tetrahydrofuran (THF) to eliminate $C_2H_4$ and yield **92**. The analogous compound obtained by allowing **89** to react with MeI ($PhCHCH_2$ instead of $C_2H_4$) is much more labile than **91** and rearranges to **92** when dissolved in $CH_3NO_2$[28]. It would appear that in cations of composition $[C_5R_5RhCH_3(C_2H_3R')PR_3]^+$ the positive charge is stabilized by increasing donor character in the ligands. It is thus easy to understand why the compound $[C_5H_5RhCH_3(C_2H_4)PPh_3]I$ described by *Graham et al.*[11d] rapidly eliminates ethylene even at room temperature, whereas **91** does not. However, what does not fit into this picture is the fact that the cations $[C_5Me_5RhCH_3(C_2H_4)L]^+$ (L = $PMe_3$, $P_2Me_4$) formed by methylating $C_5Me_5Rh(C_2H_4)L$ are very labile, and in solution in the presence of iodide they are spontaneously converted into the neutral complexes $C_5Me_5RhCH_3(L)I$[16].

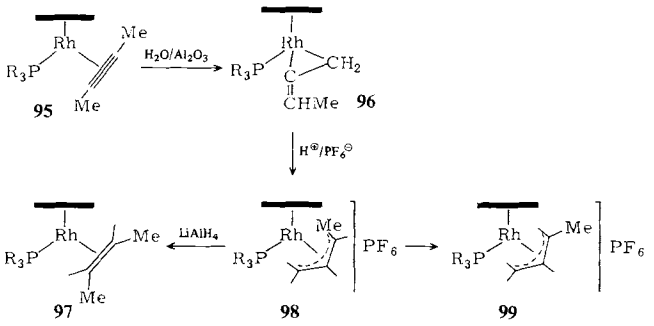


(17)

**83** **91** **92**

A number of subsequent reactions involving the ethylene(hydrido) cation **86** should also be mentioned. With $Cl^-$, $Br^-$ and $I^-$ as reagents, even at room temperature in-

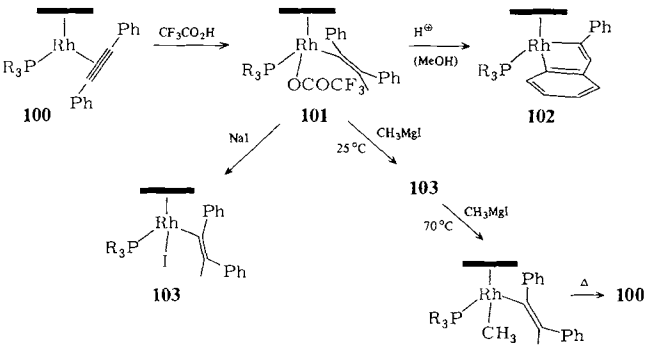
sertion of the olefin into the Rh–H bond occurs to form the ethyl(halo) complexes $C_5H_5RhC_2H_5(PMe_3)X$ (X = Cl, Br, I)[37]. In the reaction of **86** with ethylene an insertion also occurs, although the product formed, **93**, is stable only under a $C_2H_4$ atmosphere and transforms into **86** when any attempt at isolation is made. However, $PMe_3$ undergoes nucleophilic addition to the ethylene to yield the β-phosphonioethyl compound **94**[37]. Insertion of $C_2H_4$ into the Rh–$C_2H_5$ bond in **93** could not be detected, even with ethylene under pressure.



Displacement of olefin occurs when **86** reacts with $P(iPr)_3$ and the $BF_4$ salt of the cation $[C_5H_5RhH(PMe_3)P(iPr)_3]^+$ is obtained. This can readily be deprotonated, providing access to the mixed bis(phosphane) complex $C_5H_5Rh(PMe_3)P(iPr)_3$[37].

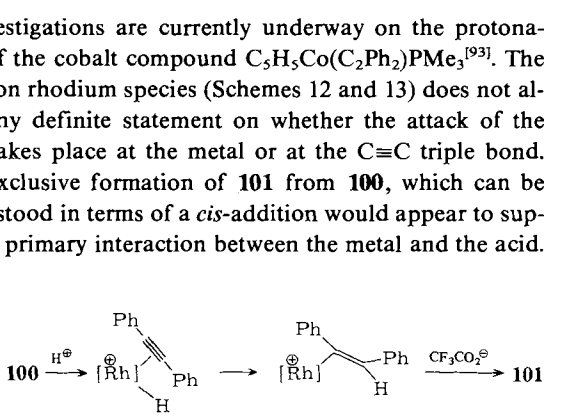
### 2.3.4. *Alkyne(phosphane)- and Vinylidene(phosphane)metal Complexes*

The reversibility of olefin insertion into the metal-hydride bond in hydrido(olefin)metal complexes is well documented[90], as is evident, for example, in reactions (15) and (16) and in Scheme 11. On the other hand, there is no proof of a corresponding equilibrium between alkyne(hydrido)- and vinylmetal compounds. All presently known syntheses of vinyl complexes from alkynes have been carried out by allowing a metal hydride to react with $C_2R_2$ or $RC_2H$, *i.e.* the M–CR=CHR– (or M–CH=CHR– and M–CR=$CH_2$–) linkages have not been produced by reactions between alkynemetal compounds and acids HX[91].



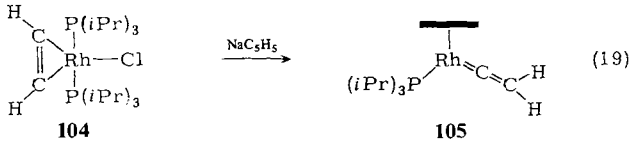
The compounds **95** and **100** recently prepared by us, which are analogues of the olefin complexes **83**—**85**, react with $CF_3CO_2H$ or $HBF_4$ even at room temperature[24]. After addition of $PF_6^-$, **95** forms the *syn*-1-methylallyl complex **98**, which is slowly converted into the thermodynamically more stable *anti*-isomer **99**[91]. Investigation of the reaction pathway indicates that in the presence of a weak acid such as $H_2O$ (on $Al_2O_3$) an initial rearrangement of **95** to the isomeric methylallene compound **96** is followed by protonation to yield the allyl complex. The *syn*-configuration of the 1-$MeC_3H_4$ group in **98** has been confirmed by NMR data and by the formation of the *cis*-2-butene compound **97** upon addition of a hydride ion.

The reaction of **100** with $CF_3CO_2H$ yields the complex **101**, which is known from X-ray analysis to contain a vinyl



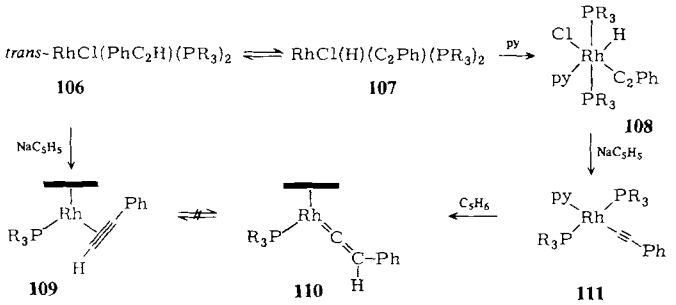
Scheme 12. R = *i*Pr.

ligand with phenyl substituents in *cis*-positions[92]. Among the subsequent reactions of this compound, special mention must be made of the rearrangement to the metallaheterocycle **102**, which is isomeric with **100**. This rearrangement takes place in methanol upon addition of $NH_4PF_6$ or traces of $CF_3CO_2H$. We assume that the trifluoroacetate group of **101** is initially displaced by the solvent, and that the cationic intermediate formed reacts by *ortho*-metallation. The lability of the Rh–$OCOCF_3$ bond in **101** is evident from the smooth reaction with NaI or $CH_3MgI$ to form **103**[24]. The five-membered metallacycle in **102** possesses an approximate chair-like conformation which, together with the varying C–C bond distances, suggests that there is no delocalized π-electron system present[24].



Scheme 13. R = *i*Pr.

Investigations are currently underway on the protonation of the cobalt compound $C_5H_5Co(C_2Ph_2)PMe_3$[93]. The work on rhodium species (Schemes 12 and 13) does not allow any definite statement on whether the attack of the acid takes place at the metal or at the C≡C triple bond. The exclusive formation of **101** from **100**, which can be understood in terms of a *cis*-addition would appear to support a primary interaction between the metal and the acid.

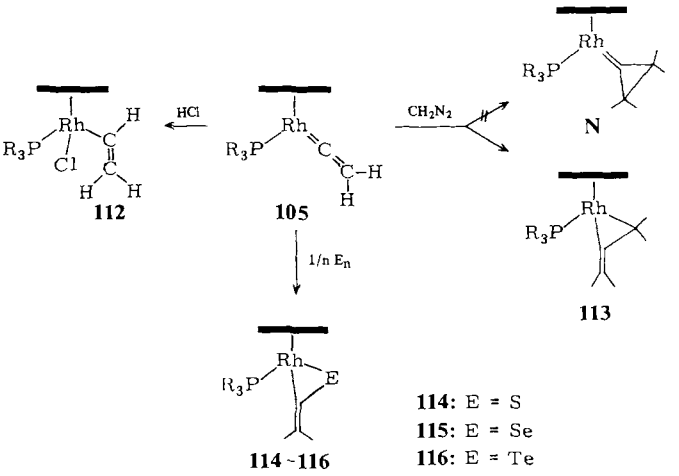


However, in view of results on the stereochemical course of reactions of metal hydride complexes with alkynes[91], caution seems to be indicated here.

An attempt to obtain the acetylenerhodium compound $C_5H_5Rh(C_2H_2)PiPr_3$ analogous to **95** or **100** by allowing **104** to react with $NaC_5H_5$ led rather surprisingly to almost quantitative formation of the vinylidene complex **105**[94].

**104** **105** (19)

Depending on the reaction conditions, the phenylacetylene compound **106** reacts with $NaC_5H_5$ to form either the alkyne complex **109** or the vinylidene complex **110**[95]. A conversion of this type of a 1-alkyne to a vinylidene ligand in the coordination sphere of a transition metal has already been observed in related cyclopentadienylmanganese, cyclopentadienyliron, and cyclopentadienylruthenium compounds. In general, it has been explained by assuming the formation of an alkynyl(hydrido) intermediate[96]. Such an intermediate was first isolated during the reaction of **106** to form **110**[95]. The equilibrium between **106** and **107** in ether or toluene can be shifted completely to the right by addition of pyridine to yield the chiral octahedral complex **108**. The latter reacts with $NaC_5H_5$ in THF at room temperature to give the phenylvinylidene compound **110**. If, however, a solution of **108** in THF is very rapidly treated at 0°C with an equimolar amount of $NaC_5H_5$ and worked-up in the cold, the square-planar complex **111** is isolated[95]. This complex reacts with cyclopentadiene virtually quantitatively to give **110**; when $C_5D_6$ is used, $C_5D_5Rh(=C=CDPh)PiPr_3$ is formed[97].

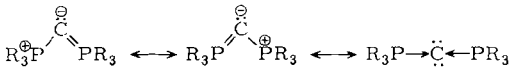


Scheme 14. R = *i*Pr.

The reaction sequence shown in Scheme 14 illustrates that although the conversion of a 1-alkyne into a vinylidene ligand actually involves an alkynyl(hydrido) intermediate there is no intramolecular hydride shift from the metal to the carbon as originally supposed[96]. In fact, a two-step elimination/addition is responsible for the final isomerization which occurs. Rearrangement of **109** into **110** (or *vice versa*) is not observed either on irradiation or on after leaving the compound to stand for a considerable time in solution[95].

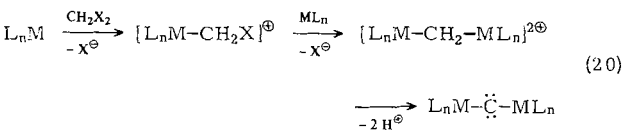
As established by X-ray structure analysis, there is a fairly short bond in complex **110** between the metal and the α-C atom of the phenylvinylidene which is some 15–20 pm shorter than in carbenerhodium compounds[95]. This distance points to considerable overlap of the orbitals involved in the Rh–C-π bond, which indicates that there should be a high electron density at the metal center. Accordingly, the vinylidenerhodium complexes should also behave as metal bases.

The first tentative steps in this direction seem to support this suggestion. Thus, **105** reacts with HCl (1:1) in benzene to yield the chloro(vinyl)rhodium compound **112**, whose formation may take place *via* a hydrido(vinylidene)rhodium cation[97]. Using $CH_2N_2$ in the presence of $Cu^{2+}$ leads to the allene complex **113** but not to the isomeric carbene compound **N** which should result from $CH_2$ addition to the vinylidene C=C double bond. The electrophile $CH_2$ thus clearly prefers the more electron-rich Rh=C instead of the C=C bond in adding to the "metallaallene" moiety $C_5H_5(L)Rh=C=CH_2$. It thereby provides a new synthetic route to allenemetal complexes[97].



Scheme 15. R = *i*Pr.

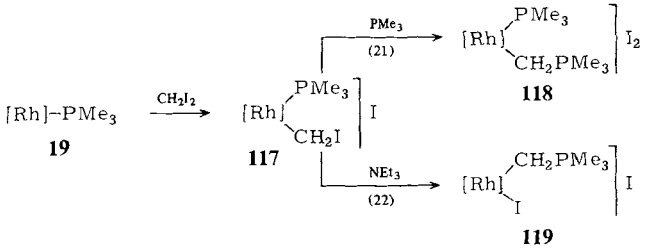
Recently, by making use of the electrophilic addition of a sulfur, selenium, or tellurium atom to the Rh=C bond in **105**, it became possible for the first time to prepare transition-metal compounds with thio-, seleno- and telluroketenes, $CH_2=C=E$, *i.e.* with molecules which are very short-lived (E = S, Se) or unknown (E = Te) in the free state (Scheme 15)[94]. The complexes **114** and **115** are remarkably stable both in the solid state and in solution, whereas the telluroketene compound **116** reacts slowly in solution to form **105** and metallic tellurium. X-ray analysis of **114** has shown that in the crystal *both* enantiomers are present[94]. Overall, there is a close analogy between the structural data of **114** and those of complex **45** obtained from the half-sandwich complex **18** (see Scheme 7). This complex, **45**, contains the thioketene 1,1,3,3-tetramethyl-2-thiocarbonylcyclohexane as ligand, which in contrast to $CH_2=C=S$ is stable in the free form. *Behrens et al.*[98] have isolated from this compound and, more recently, from di-*t*-butylthioketene, mono- and binuclear thioketene complexes by reaction with various carbonylmetal compounds. In these thioketene complexes the appropriate thioketene is coordinated either *via* the sulfur (*i.e. monohapto*) or as a bridge between two metal atoms. Some iridium(I) and platinum(0) complexes with $\eta^2$-bonded bis(trifluoromethyl)thioketene described in 1970 by *Stone et al.*[99] are structurally related to **114** (and **45**); they were synthesized, however, not from $(CF_3)_2C=C=S$ but rather from heterocyclic, $CF_3$-substituted sulfur compounds.



### 2.4. Reactions of $C_5R_5ML_2$ and $C_5R_5MLL'$ with Dihalogeno- and Trihalogenomethanes

In a brief review on the chemistry of carbodiphosphoranes which appeared in 1979, *Schmidbaur*[100] advanced the provocative suggestion that the bonding patterns in $C(PR_3)_2$ molecules could be described not only in terms of the resonance structures **a** and **b** but also as an extreme case in terms of **c**.

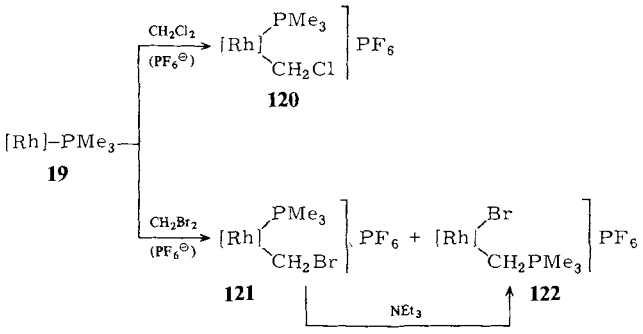
**a** **b** **c**



We took this as a challenge and attempted to prepare binuclear metal complexes according to reaction (20). In such complexes both of the metal atoms would be linked only by a carbido bridge. The metal base, $ML_n$, would then act as a donor toward the "naked" C atom, just as the phosphane group in the above-mentioned formula **c** for carbodiphosphoranes.

(20)

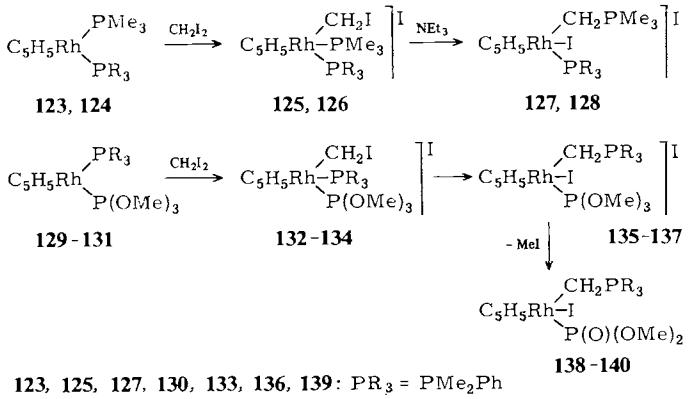
As a test molecule we first selected the bis(trimethylphosphane)rhodium complex **19**, which reacts with $CH_2I_2$ under exactly the same conditions as it does with methyl iodide to form the iodomethylrhodium(III) compound **117** in 62% yield[101]. The latter is stable for several days in nitromethane, although in dimethyl sulfoxide it rapidly loses "$CH_2$" to form $[C_5H_5RhI(PMe_3)_2]I$.



The presence of a reactive C–I bond in the cation of **117** is evidenced by its reaction with $PMe_3$, which leads quantitatively to **118**. With $NEt_3$, no nitrogen-ylide complex analogous to **118** is formed from **117**, which rather surprisingly isomerizes to **119**[101]. The anion clearly is not involved in this rearrangement since the $BF_4$ salt also reacts analogously to **117**.

[Rh] = $C_5H_5RhPMe_3$

The conversion of **117** to **119** is catalyzed not only by $NEt_3$ but also by NaOMe and—disappointingly in view of our stated objective—by the complex **19**. Even after changing the reaction conditions and replacing **19** by the more reactive half-sandwich compounds $C_5H_5Rh(CNMe)_2$, $C_5H_5Fe(CO)_2^-$, and $C_5H_5Mo(CO)_3^-$[39,109] it is not possible to isolate a binuclear complex having a $CH_2$ bridge *without* a metal-metal bond.



To determine what factors influence the conversion of a halogenmethyl(phosphane) complex into a halogen(methylenephosphorane) complex, we changed both the dihalomethane and the metal base. **19** also reacts smoothly with $CH_2Cl_2$ (though somewhat less rapidly than with $CH_2I_2$) to form the cation $[C_5H_5RhCH_2Cl(PMe_3)_2]^+$, whose $PF_6$ salt **120** is exceptionally stable[109]. When **19** reacts with $CH_2Br_2$ a mixed product is formed from which after dissolving and reprecipitating with $NH_4PF_6$ the bromomethyl complex **121** and the isomeric methylenephosphorane **122** can be isolated; the latter is obtained quantitatively after addition of $NEt_3$. Isomerization of **120** could not be observed even after it was allowed to stand for some considerable time in the presence of triethylamine[39].

Scheme 16. [Rh] = $C_5H_5RhPMe_3$.

The products obtained by starting from the mixed bis(phosphane) complexes **123**, **124** and the phosphane(phosphite) compounds **129**–**131** are summarized in Scheme 17[27,102]. Two striking points are that in the rearrangement it is always the better donor ligand which migrates and that in the case of **132**–**134** the isomerization takes place even *without* adding $NEt_3$ or another base. Kinetic measurements[39] reveal that the rate of the reaction of **132** to **135** is—after an induction period—practically independent of the concentration of the educt and increases with increasing polarity of the solvent. Since addition of iodide ions has no effect on the rate, the mechanism might be compared to that of some anionotropic rearrangements of organic compounds in which a concerted pathway is very probable on the basis of labeling experiments[103]. The observation that the rate of isomerization of **132** to **135** is significantly increased by addition of $NEt_3$ and the fact that the complex $[C_5H_5RhCH_2Br(PMe_3)P(OMe)_3]PF_6$ does not rearrange are consistent with a non-stepwise 1,2-shift of the iodide and phosphane. Such a mechanism could also apply to the reactions of other phosphanemetal compounds, *e.g.* $Co(PMe_3)_4$, $Pt(PPh_3)_4$, or $Pt(PEt_3)_3$ with dihalomethanes, which lead to methylenephosphorane complexes[104–106].

Similarly to **19** (Scheme 16), **123** and **124**, the chelate complexes **141** and **142** also react with $CH_2I_2$ by oxidative addition to yield the iodomethyl compounds **143** and **144**[27]. Although **144** is inert and does not isomerize even in the presence of NaOH, the reaction of **143** with $NEt_3$, involving insertion of $CH_2$ into one of the Rh–P bonds, leads to the quantitative formation of the metallaheterocycle **145** (Scheme 18). The Rh–I bond in the latter is fairly labile and thus at room temperature in the presence of

123, 124 125, 126 127, 128

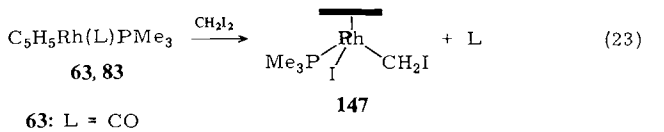
Scheme 17.

$PMe_3$ (and subsequent addition of $NH_4PF_6$) the complex **146** is formed. The relatively broad $^1$H-NMR signals indicate that in solution a rapid interconversion of the two possible chair conformations probably takes place[27]. An alternative method of preparing **146** from **147** and $C_2H_4(PMe_2)_2$ proved not to be successful.

141, 142 143, 144



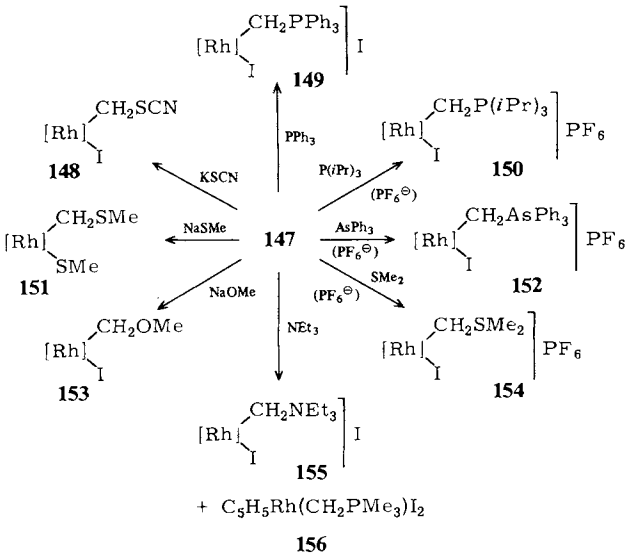
141, 143: R = Me
142, 144: R = Ph

145 146

Scheme 18.

The reactions of the cobalt compounds analogous to **19**, **129**, and **141** with $CH_2Cl_2$, $CH_2ClI$, and $CH_2I_2$ proceed very rapidly even at $-78$ °C, although they give no products containing a Co–$CH_2Cl$ or Co–$CH_2I$ bond. In addition to paramagnetic species, all that can be isolated from the reaction mixture are the halometal complexes $[C_5H_5CoXL_2]X$ (X = Cl, I)[102]. Investigations of the reactivity of $C_5H_5Co(CO)PMe_3$ with dihalomethanes have proven that this result is not due to the instability of methylenephosphoranecobalt(III) compounds.

The metal bases $C_5H_5Rh(CO)PMe_3$ **63** and $C_5H_5Rh(C_2H_4)PMe_3$ **83**, which are weaker nucleophiles than the bis(phosphane) compounds $C_5H_5Rh(PMe_3)PR_3$ **19**, **123**, and **124**, also react under very mild conditions with $CH_2I_2$[107]. In this case the neutral complex **147** is formed. The unique course of the reaction of the carbonyl compound **63** is remarkable insofar as an acyl complex, $C_5H_5RhCOCH_2I(PMe_3)I$, analogous to



(23)

63, 83 147

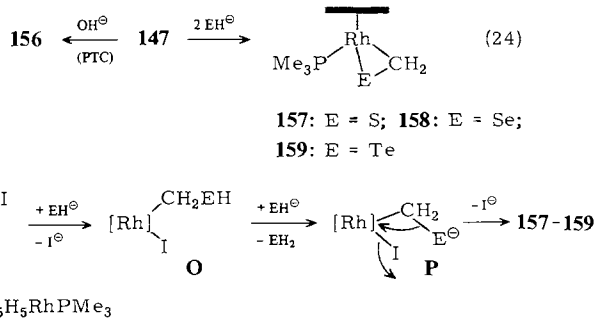
63: L = CO
83: L = $C_2H_4$

$C_5H_5RhCOCH_3(PMe_3)I$, cannot be observed[108]. The course of the reaction of **83** with $CH_2I_2$ depends on the solvent used. Whereas in ether only **147** is formed, in methanol mainly the compound $C_5H_5RhI_2(PMe_3)$ is produced *via* elimination of $CH_2$[107].

The reactivity of the C–I bond towards nucleophiles renders the complex **147** (rather like **117**) a very suitable starting material for the synthesis of numerous novel organorhodium compounds (see Scheme 19). In particular, formation of the complexes **152**, **154**, and **155** should be mentioned in which the ylides $Ph_3AsCH_2$, $Me_2SCH_2$ and $Et_3NCH_2$, which are unstable in the free state, are fixed at the metal[107].

149 148 150 151 147 152 153 154 155

+ $C_5H_5Rh(CH_2PMe_3)I_2$



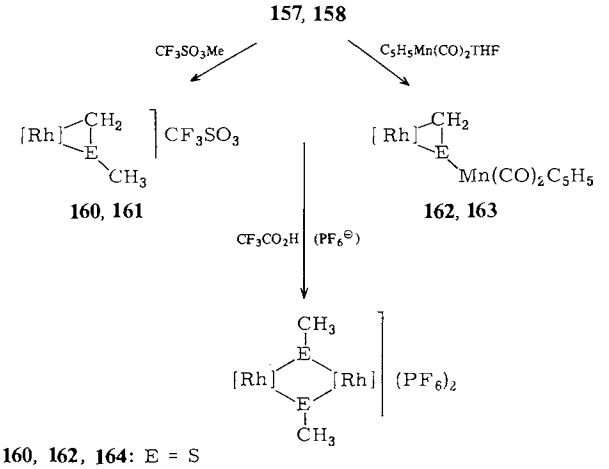
156

Scheme 19. [Rh] = $C_5H_5RhPMe_3$.

The isomer **156**, obtained together with **155** in the reaction of **147** with $NEt_3$, is formed quantitatively when **147** reacts with NaOH in a two-phase benzene/water system in the presence of triethylbenzylammonium chloride acting as phase transfer catalyst (PTC)[109]. The expected formation of the hydroxymethyl compound $C_5H_5RhCH_2OH(PMe_3)I$ — by analogy to the synthesis of **153** from **147** and NaOMe — does not occur, although the former could be a suitable starting material for the preparation of Rh=$CH_2$ complexes.

In contrast to $OH^-$, the weaker bases $SH^-$, $SeH^-$ and $TeH^-$ effect a substitution of the C–I bond in **147** and thereby open up a simple route to thio-, seleno- and telluroformaldehyderhodium compounds[110]. The structure of **158** has been confirmed by X-ray structure analysis[111]. The synthetic pathway adopted may involve proton abstraction from the initially formed intermediate **O** by $EH^\ominus$ (which is present in excess) and a subsequent substitution of iodide by the more nucleophilic chalcogen atom in **P** to form the three-membered ring of the product.

Independently, but at the same time as us, *Roper et al.*[112] obtained the chalcogenoformaldehydeosmium complexes $Os(\eta^2\text{-}CH_2E)(CO)_2(PPh_3)_2$ (E = S, Te) from osmiumhalomethyl or osmiumformaldehyde precursors. Moreover, *Herberhold et al.*[113] and *Herrmann et al.*[114] recently succeeded in preparing binuclear manganese compounds



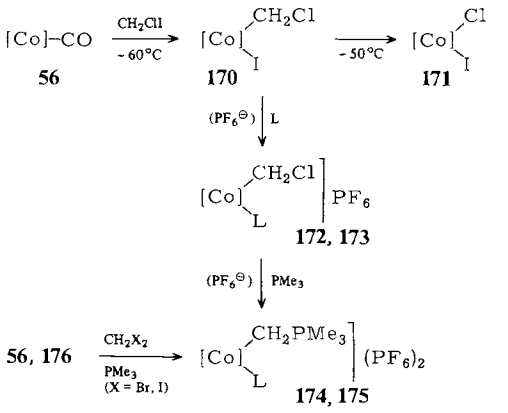
157: E = S; 158: E = Se;
159: E = Te

[Rh] = $C_5H_5RhPMe_3$

Scheme 21. [Rh] = $C_5H_5RhPMe_3$.

with $CH_2S$, $CH_2Se$, or $CH_2Te$ as the bridging ligand by allowing $[C_5R_5Mn(CO)_2]_2E_n$ (E = S, Se; R = H, Me; n = 1 or 2) or $[C_5H_5Mn(CO)_2]_3Te$ to react with $CH_2N_2$.

Several results pertaining to the reactivity of complexes **157** and **158** toward Lewis acid substrates are summarized in Scheme 20. Accordingly, it is clear that electrophilic addition occurs directly at the chalcogen atom in the reactions with $CF_3SO_3Me$ and $C_5H_5Mn(CO)_2THF$. However, in the reaction with $CF_3CO_2H/NH_4PF_6$ it is possible that the metal is initially protonated and that this is followed by a hydrogen shift to the $CH_2E$ carbon atom. **162** and **163** are the first examples of binuclear compounds in which a thioformaldehyde or selenoformaldehyde ligand links two *different* metal centers[115].

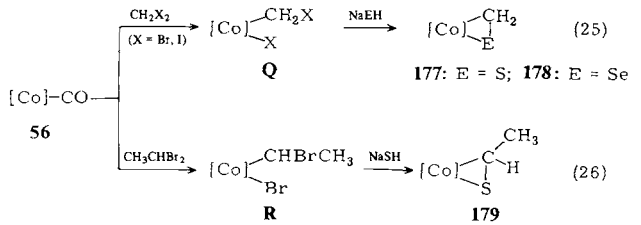


160, 162, 164: E = S
161, 163, 165: E = Se

Scheme 20. [Rh] = $C_5H_5RhPMe_3$.

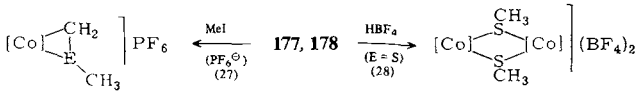
The ethylene(phosphane) complex **83** reacts not only with $CH_2I_2$ [see reaction (23)] but also with other di- and trihalomethanes[116]. The reaction with $CH_2ClI$ proceeds at almost the same rate as with $CH_2I_2$, which is plausible since in both cases the cleavage of a C–I bond occurs. In the case of $CH_2Br_2$ only a very slow reaction takes place, which (in ether/pentane) affords **167** after two days at room temperature or after 15 h at 45 °C (Scheme 21). $CH_2Cl_2$ does not react at all under similar conditions. The observed difference in the reaction rate reflects very clearly the C–X bonding energy differences; in going from C–I to C–Cl there is an increase of *ca.* 105 kJ/mol.

The compounds **168** and **169** obtained using $CHBr_3$ and $CHI_3$, respectively, can readily be handled in the solid state, although they are labile in solution. In nitromethane, for example, they form, among other products, $C_5H_5RhBr_2(PMe_3)$ or $C_5H_5RhI_2(PMe_3)$. The complexes $C_5Me_5RhCHX_2(CO)X$, which correspond to **168** and **169** insofar as their properties are concerned, are formed from $C_5Me_5Rh(CO)_2$ and $CHX_3$ (X = Br, I)[116]. **169** and its $C_5Me_5$ analogue represent the first isolated diiodomethyl transition-metal compounds whose reactivity is of interest on the basis of the results presented in Scheme 19 and reaction (24).



The carbonyl(phosphane)cobalt complex **56** is considerably more reactive toward dihalomethanes than its rhodium analogue **63**. At −60 °C with $CH_2ClI$ the compound **170**, which has been characterized by NMR spectroscopy, is obtained; even at −50 °C in acetone, this eliminates $CH_2$ to form **171**. Addition of an equimolar amount of $PMe_3$ or $P(OMe)_3$ to **170** results in formation of the cationic chloromethylcobalt complexes **172** and **173**, which react at room temperature with trimethylphosphane to give **174** and **175**, respectively. These compounds can also be prepared from **56** or **176** and $CH_2X_2/PMe_3$ simply by mixing the reactands (molar ratio 1 : 1); $C_5H_5Co(CO)_2$ is also formed. In this case it can be assumed that an intermediate analogous to **170** is formed in which the cobalt-halogen bonds are evidently so labile that a very rapid subsequent reaction with the phosphane takes place. Astonishingly, the formation of **174** and **175** is independent of the polarity of the solvent; in toluene, ether, or acetone no difference is observed either in the reaction rate or in the composition of the products (Scheme 22)[117].

172, 174: L = $PMe_3$
173, 175: L = $P(OMe)_3$
176: $C_5H_5Co(CO)P(OMe)_3$



Scheme 22. [Co] = $C_5H_5CoPMe_3$.

Preparation of the thioformaldehyde- and selenoformaldehyde cobalt complexes **177** and **178**, respectively, is possible *via* the conjectured intermediate **Q** formed from **56** and $CH_2X_2$. At least as important as this result is the isolation of the first *dihapto*-bonded thioacetaldehydemetal compound, which is formed—in addition to small amounts of $C_5H_5CoBr_2(PMe_3)$—according to reaction (26)[117]. Like the chalcogenoformaldehydes, $CH_2E$, thioacetaldehyde is also unstable in the monomeric form and has previously not been fixed in a complex, despite ligand characteristics which are comparable to those of $CH_2S$. In this context it should be mentioned that *Herrmann et al.*[114] were able to generate not only $CH_2Se$ and $CH_2Te$ but also the dimethylseleno ketone $Me_2CSe$—which is also unstable in the free state—as bridging ligand between two Mn atoms.

[Co] = $C_5H_5CoPMe_3$

The reactivity of the complexes **177** and **178** corresponds to that of the rhodium compounds **157** and **158**. Methylation can be achieved even with methyl iodide, a fact which confirms the great nucleophilicity of the sulfur and selenium atoms in CoCE three-membered rings[117].

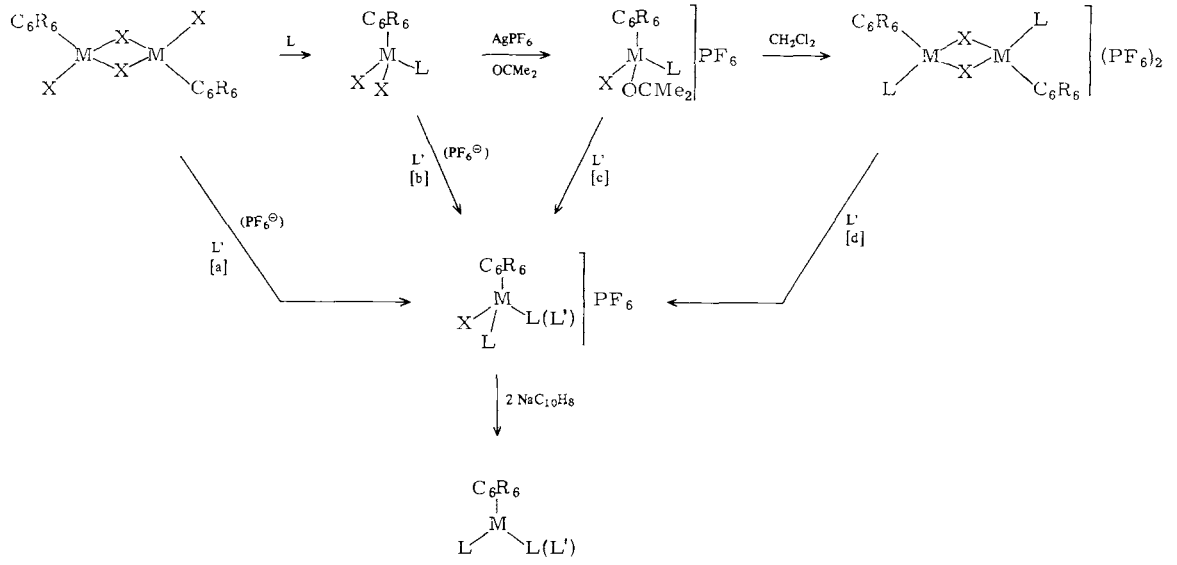
## 3. Metal Bases with Six-Membered Ring Ligands

### 3.1. $d^8$-Systems

From the structural and bonding point of view, the aromatic metal compounds $C_6R_6ML_2$ and $C_6R_6MLL'$ (M = Fe, Ru, Os) are comparable to the cyclopentadienylmetal complexes, $C_5R_5ML_2$ and $C_5R_5MLL'$ (M = Co, Rh, Ir). The metal atom now is in the oxidation state zero and, like $Co^I$, $Rh^I$ and $Ir^I$, thus represents a $d^8$ system. In contrast to the cyclopentadienyl complexes $C_5R_5ML_2$, until recently principally only compounds of the type $C_6R_6ML_2$ were known with $L_2$ = diolefin (*e.g.* $C_4H_6$, 1,3-$C_6H_8$, 1,3-$C_7H_{10}$, and 1,5-$C_8H_{12}$). Most of these were prepared by the "Grignard method"[118]. Before 1978 (*i.e.* when we began our studies[119]), only a few iron complexes with *monodentate* ligands L existed, namely with $L = PF_3$[120] and CO[121]. Because of the pronounced π-acceptor properties of trifluorophosphane or carbon monoxide, these complexes are probably only weak metal bases.



#### *3.1.1. Synthetic Methods*

The synthesis of the bis(trifluorophosphane) complexes $(C_6H_5Me)Fe(PF_3)_2$ and $C_6H_6Fe(PF_3)_2$ has been carried out using metal atom vaporization techniques[120]. By this means, the corresponding phosphite compounds $C_6R_6Fe[P(OMe)_3]_2$ ($C_6R_6 = C_6H_6$, $C_6H_5Me$, 1,4-$C_6H_4Me_2$, 1,3,5-$C_6H_3Me_3$), and $(C_6H_5Me)Fe[P(OEt)_3]_2$, as well as the phosphane complex $(C_6H_5Me)Fe(PMe_3)_2$ are also accessible[122]. In the cocondensation of iron atoms with arenes it seems likely that molecules such as $Fe(C_6R_6)$ or $Fe(C_6R_6)_2$ are formed initially and that these then react with the phosphite or phosphane. The preparation of $C_6Me_6Fe(CO)_2$ proceeds *via* the complex $Fe(C_6Me_6)_2$, which can be isolated as a solid. In the reaction, an $\eta^4$-bonded six-membered ring is probably substituted by the CO groups[121].

For the synthesis of the ruthenium and osmium compounds $C_6R_6ML_2$ ($L = PR_3$, $P(OR)_3$) and $C_6R_6MLL'$ ($L = PR_3$; $L' = P(OR)_3$, CO, CNR, $C_2H_3R$), a reductive procedure employing $NaC_{10}H_8$ as the reducing agent has proved to be useful[123]. The starting materials for the procedure are the salts of the cations $[C_6R_6MXL_2]^+$ or $[C_6R_6MXLL']^+$, which can be obtained from the halide-bridged compounds $[C_6R_6MX_2]_2$ by one of the routes indicated in Scheme 23[124, 131, 134]. It depends primarily upon the ligands L and L' which is the best preliminary step for the preparation of the salts. The acetone complexes can be isolated only for M = Ru (R = H[124], Me[125]; X = Cl; $L = PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$); for M = Os only the binuclear dications $[(C_6H_6OsL)_2(\mu\text{-}X)_2]^{2+}$ are stable. The synthesis of the ruthenium compounds $[C_6H_6RuCl(PR_3)_2]PF_6$ ($PR_3 = PMe_2Ph$, $PMePh_2$, $PPh_3$) has also been carried out by allowing $[(C_6H_6Ru)_2(\mu\text{-}Cl)_3]PF_6$ to react with the appropriate phosphane[126].

Apart from $NaC_{10}H_8$, experiments were also performed using Na, Na/Hg, NaH, $NaNH_2$, $Li_2CH_2$, $Li_2C_8H_8$, Mg, $Co(C_5H_5)_2$, and diphenylketyl Na as reducing agents although no satisfactory result could be achieved. The successful synthesis of the metal(0) complexes $C_6R_6ML_2$ and $C_6R_6MLL'$ using $NaC_{10}H_8$ has the disadvantage that it is not at all easy to completely separate the naphthalene formed during the reduction from the highly volatile and very soluble products. In the case of thermally relatively stable compounds (*e.g.* M = Os, $L = PMe_3$, $L' = C_2H_4$, $C_3H_6$), this is possible *via* the hydridometal cations and their deprotonation with NaH[127].

Unexpectedly, the complex $C_6H_6Os(PMe_3)_2$ could not be obtained by reducing $[C_6H_6OsI(PMe_3)_2]PF_6$ with $NaC_{10}H_8$. Even the attempt to exchange the olefinic ligand in **183** and **184** by trimethylphosphane did not succeed. Rather the hydrido(phenyl)osmium(II) compound **186** forms by oxidative addition of an $(sp^2)C-H$ bond to the electron-rich metal center. When R = H it is possible to isolate the intermediate **185**. The conversion of the $C_6H_6Os$ into the $OsH(C_6H_5)$ moiety occurs strictly *intra*molecularly, as may be seen from the quantitative formation of **186** in $C_6D_6$ as solvent[128]. It may be that in the initial step after attack of the trimethylphosphane at the metal a reorientation of the benzene from an $\eta^6$- to an $\eta^4$-mode of coordination occurs. This has been postulated by *Muetter-*

Scheme 23. Possible routes to the salts $[C_6R_6MXLL']PF_6$.

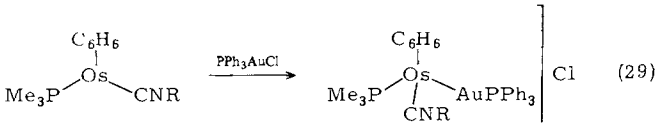
**184**: R = Me

Scheme 24.

### 3.1.2. Reactions with Electrophiles



As might be expected, the complexes $C_6R_6ML_2$ and $C_6R_6MLL'$ react with Brønsted acids and with methyl iodide or $[OMe_3]BF_4$ to form salts of the cations $[C_6R_6ML_2]^+$ and $[C_6R_6MLL']^+$, respectively. These are considerably more stable (thermally and towards oxidizing agents) than the metal(0) compounds. Here, too, the metal basicity depends quite significantly on the donor strengths of the ligands L and L'. Whereas, for example, the bis(trimethylphosphane) complexes $C_6R_6Ru(PMe_3)_2$ ($C_6R_6 = C_6H_6$, 1,4-$C_6H_4(Me)iPr$, $C_6Me_6$) react even at −78 °C with $NH_4PF_6$ in methanol to form the compounds $[C_6R_6RuH(PMe_3)_2]PF_6$, the formation of $PMePh_2$ and $PPh_3$ analogues occurs only at room temperature[123]. Moreover, for the synthesis of $[C_6Me_6RuH(PMe_3)CO]PF_6$, $[C_6H_6RuH(PMe_3)C_2H_4]BF_4$, and $[(C_6H_5Me)FeH(P(OMe)_3)_2]BF_4$ it is necessary to use acids stronger than $NH_4^+$, such as $CF_3CO_2H$ or $HBF_4$[122a, 123, 127].

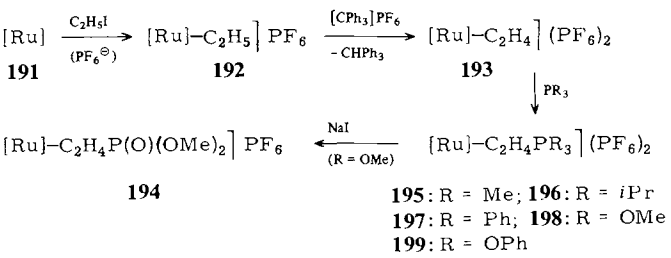
It is generally found that 1) the presence of a good π-acceptor ligand such as CO or $C_2H_4$ weakens the metal basicity and 2) the osmium(0) compounds are more reactive than the homologous iron and ruthenium complexes.

Methylation proceeds just as smoothly as protonation. Here, the reaction rate here also depends characteristically on the metal and on the nature of the ligands. Thus, for example, $C_6H_6Os[P(OMe)_3]_2$ reacts with methyl iodide to form $[C_6H_6OsCH_3(P(OMe)_3)_2]I$[123], whereas $[OMe_3]BF_4$ is necessary for the formation of the corresponding cationic iron complex[122a]. In the case of bis(phosphane)ruthenium compounds of the type $C_6R_6Ru(PR_3)_2$, there is a decrease in the rate of methylation along the sequence $PMe_3$ > $PMe_2Ph$ > $PMePh_2$ > $PPh_3$ (for $C_6R_6 = C_6H_6$) and $C_6H_6$ > 1,4-$C_6H_4(Me)iPr$ > $C_6Me_6$ (for $PR_3 = PMe_3$)[123]. This indicates that, in addition to electronic effects, steric effects also play a role in determining the ease of attack of the electrophile at the metal atom in $C_6R_6ML_2$ complexes.

Only $C_6H_6Ru(PMe_3)_2$ **191** reacts smoothly with ethyl iodide to give the corresponding ethyl compound $[C_6H_6RuC_2H_5(PMe_3)_2]^+$ (which is isolated as the $PF_6$ salt **192**[123]). When **191** is allowed to react with *n*-propyl and *n*-butyl bromides or iodides, in addition to the expected products $[C_6H_6RuR(PMe_3)_2]X$, the corresponding metal halide complexes $[C_6H_6RuX(PMe_3)_2]X$ are also formed. As for the analogous reactions of the cyclopentadienyl compounds, $C_5R_5M(PMe_3)_2$ (see Section 2.2.3), this result suggests the formation of radical intermediates. Of the Lewis acidic trimethylelement halides $Me_3ECl$ (E = Si, Ge, Sn), only the tin compound affords a product having the composition $[C_6H_6RuEMe_3(PMe_3)_2]X$ upon reaction with $C_6H_6Ru(PMe_3)_2$[123]. Under the same conditions, $Me_3SiCl$ and $Me_3GeCl$ form mixtures of products in which only the hydridoruthenium cation $[C_6H_6RuH(PMe_3)_2]^+$ can be unequivocally detected.

Recently, two complexes containing an osmium-gold bond have been prepared by oxidative addition of $PPh_3AuCl$ to $C_6H_6Os(PMe_3)CNR$ (**187**, **188**)[131]. According to the IR data of **189** and **190**, the possibility of the isocyanide forming a bridge between the two metal atoms can be excluded. The $PPh_3Au^+$ cation thus behaves completely analogously to a proton towards the compounds **187** and **188**, which is certainly to be expected from their isolobal relationship[132].

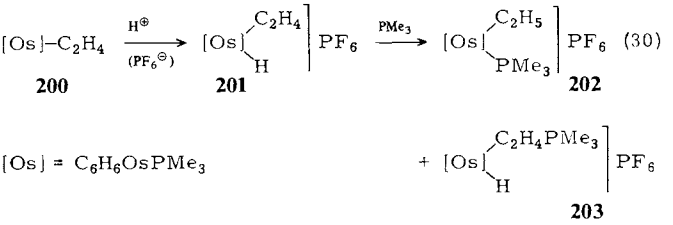
(29)



**187**, **188** **189**, **190**

**187**, **189**: R = Me
**188**, **190**: R = *p*-Tolyl

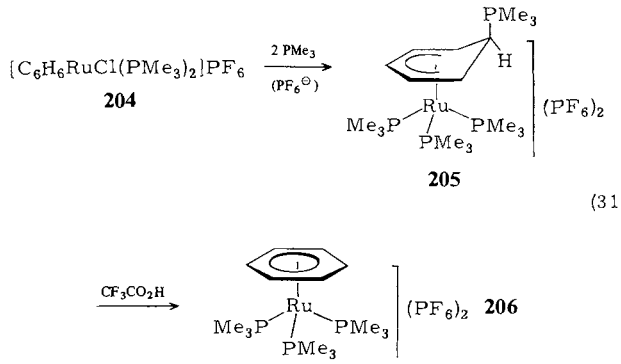
Overall, the metal basicity of the arenemetal complexes $C_6R_6ML_2$ would even appear to exceed that of the cyclopentadienylmetal compounds $C_5R_5ML_2$. While the $PF_6$ salts of the cations $[C_5H_5MH(PMe_3)_2]^+$ **16** and **17** readily react with NaH to form the neutral complexes $C_5H_5M(PMe_3)_2$ **18** and **19**, respectively, deprotonation of the analogous benzeneruthenium and benzeneosmium compounds $[C_6H_6RuH(PMe_3)_2]^+$ and $[C_6H_6OsH(PPh_3)_2]^+$ does not occur under the same conditions[123]. These cations react very slowly even with MeLi or *t*BuLi to form **191** and $C_6H_6Os(PPh_3)_2$, respectively. Measurements (MS and PES) currently being made to determine the ionization potentials should provide information on how these values differ for typical derivatives of the two complex series $C_5R_5ML_2$ and $C_6R_6ML_2$, and how this may be correlated with the difference in metal basicity.



### *3.1.3. Subsequent Reactions of the Primary Products*

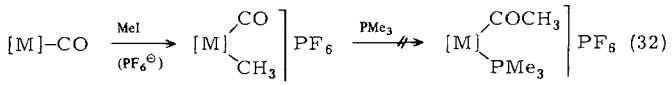
The ethyl compound $[C_6H_6RuC_2H_5(PMe_3)_2]^+$ formed from **191** reacts with $[CPh_3]PF_6$ to give the dication $[C_6H_6Ru(PMe_3)_2C_2H_4]^{2+}$, which behaves as an electrophile and reacts with phosphanes or phosphites even at room temperature. The process, which involves the conversion of the Ru–$C_2H_4$ π-bond into an Ru–$C_2H_4PR_3$ σ-bond, yields the complexes **195**–**199** (Scheme 25)[133]. It has not been possible to eliminate a hydride ion from the methyl compound $[C_6H_6RuCH_3(PMe_3)_2]^+$. Reaction of the hydrido complex $[C_6H_6RuH(PMe_3)_2]PF_6$ with $[CPh_3]PF_6$ in acetone leads to the $PF_6$ salt of the dication $[C_6H_6Ru(PMe_3)_2(OCMe_2)]^{2+}$. This salt contains an unusually inert Ru–$OCMe_2$ bond, and is therefore not a suitable starting material for the preparation of octahedral ruthenium(II) complexes of general type $[C_6H_6Ru(PMe_3)_2L]^{2+}$ (L = $PR_3$, $P(OR)_3$, CO, *etc.*)[134].

Scheme 25. [Rh] = $C_6H_6Ru(PMe_3)_2$.



Nucleophilic addition of a phosphane to coordinated ethylene has also been observed in the reactions of $[C_6H_6MCH_3(PMe_3)C_2H_4]PF_6$ (M = Ru, Os) and **201** with $PMe_3$[127]. In the latter case, according to reaction (30) a mixture of **202** and **203** is obtained which contains the two isomers in a ratio of 3:2. The ruthenium complex analogous to **201** yields exclusively the ethyl compound **192** with trimethylphosphane. The variable mobility of the ligands in the $[C_6H_6RuH(PMe_3)C_2H_4]^+$ and $[C_6H_6OsH(PMe_3)C_2H_4]^+$ cations is, in general, reflected in the NMR spectra, of which only that for the ruthenium complex shows a temperature dependence consistent with an equilibrium between the ethylene(hydrido) and ethyl tautomers[127].

(30)

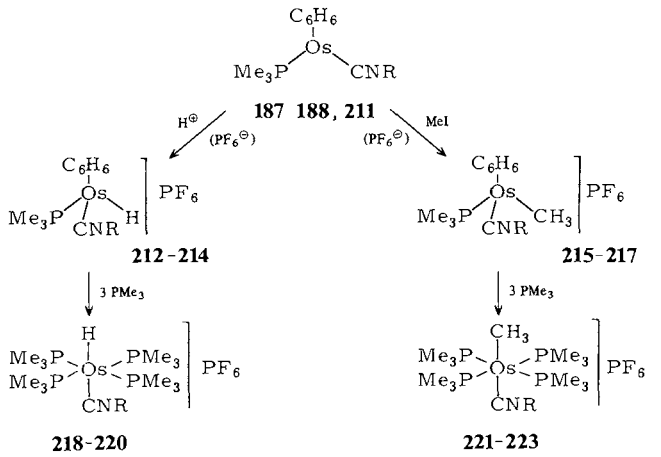


In addition to the $[C_6H_6MR(PMe_3)C_2H_4]^+$ cations obtained from $C_6H_6Ru(PMe_3)C_2H_4$ and **200**, the structurally related $[C_6H_6RuCl(PR_3)PR'_3]^+$ complexes are also capable of adding a phosphane. According to reaction (31), in the reaction of **204** and $PMe_3$, for example, the ($\eta^5$-6-phosphoniocyclohexadienyl)ruthenium(II) compound **205** is obtained. In this process, addition of phosphane to the ring occurs initially and is followed by substitution of the chloride[135]. At low temperatures, rotation about the metal-ring bond in the cations $[(6\text{-}C_6H_6PMe_3)Ru(PMe_3)_2PR_3]^{2+}$ with R = Ph or $NMe_2$ is so strongly hindered that rigid rotamers can be observed. The C–$PMe_3$ bond in **205** can easily be cleaved by trifluoroacetic acid and thus opens up a route to half-sandwich complexes of the type $[C_6H_6Ru(PR_3)(PR'_3)L]^{2+}$ (*e.g.* **206**) which are not accessible by any other method[135].

Surprisingly, the carbonyl(methyl) complexes **209** and **210**, prepared according to reaction (32), are highly inert

(31)

and react neither with $PMe_3$ nor with iodide ions by CO insertion (or by methyl group migration) to form the acetyl compounds $[C_6R_6MCOCH_3(PMe_3)_2]PF_6$ and $C_6R_6MCOCH_3(PMe_3)I$, respectively[123,136]. For adjacent CO and $CH_3$ groups such immobility is very unusual and is paralleled only in the behavior of $OsCH_3(CO)_2(PPh_3)_2I$[137]. The acetylruthenium cation of composition $[C_6H_6RuCOCH_3(PMe_3)_2]^+$ also cannot be obtained by reacting **191** with $CH_3COCl$; in this instance only decomposition (even at −78 °C) is observed[123].



(32)

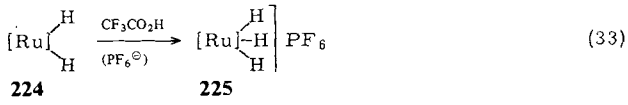
**207, 208** **209, 210**

**207, 209**: [M] = $C_6Me_6RuPMe_3$; **208, 210**: M = $C_6H_6OsPMe_3$

The related isocyanide(methyl) compounds **215—217** are similarly as inert as **209** and **210**. In contrast to the cobalt complexes $[C_5H_5CoCH_3(PMe_3)CNR]X$ (see Scheme 9), the cations of **215—217** do not rearrange either in acetone or in acetonitrile—not even in the presence of a large excess of iodide ions—to form acetimidoyl compounds; nor do they react to form metallaheterocycles[131a]. With trimethylphosphane in acetone, the complexes **221—223** having the $CH_3$ and CNR ligands in the *trans* position are formed by displacing the six-membered ring (Scheme 26);

**187, 212, 215, 218, 221**: R = Me
**188, 213, 216, 219, 222**: R = *p*-Tolyl
**211, 214, 217, 220, 223**: R = *t*Bu

Scheme 26.

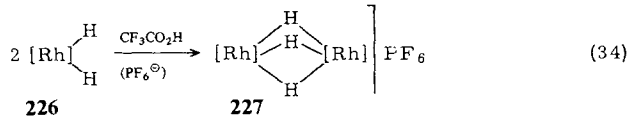


the hydrido(isocyanide) compounds **212—214** react analogously[131b]. The stability of the Os—$CH_3$ bond in **221—223** and of the Os—H bond in **218—220** evidently prevents migration of a methyl or hydride ligand to the isocyanide group. Accordingly, even in the presence of an excess of $PMe_3$ (or CNR), the formation of corresponding cationic imidoylosmium complexes cannot be observed.

### 3.2. $d^6$-Systems

In contrast to the cyclopentadienylmetal compounds $C_5H_5Co(CO)_2$ and $C_5H_5Rh(CO)_2$ which—as mentioned in the introduction—are rapidly decomposed in $H_2SO_4$ or $BF_3 \cdot H_2O$, the arenechromium tricarbonyls $C_6R_6Cr(CO)_3$ are transiently stable in strongly acidic media (*e.g.* $HSO_3F$ in $SO_2$[138] or $CF_3CO_2H/BF_3 \cdot H_2O = 1/1$[139]) and form hydridometal cations $[C_6R_6CrH(CO)_3]^+$ which can be detected by IR and NMR spectroscopy. Substitution of a CO group in $C_6R_6Cr(CO)_3$ by a phosphane such as $PPh_3$ increases the electron density at the metal, and thus protonation, even with $CF_3CO_2H$ in toluene (ratio 1 : 10), becomes possible[140]. If the compounds $C_6R_6M(CO)_2PMe_2Ph$ (M = Cr, Mo, W) are used as starting materials, the formation of two isomers of $[C_6R_6MH(CO)_2PMe_2Ph]^+$ (with H and $PMe_2Ph$ in the *cis* and *trans* positions respectively) as well as their rearrangement have been detected by NMR spectroscopy[141]. To isolate stable salts of the type $[C_6R_6MHL_3]X$, it is necessary to start out from the appropriate tris(phosphane) complexes, such as $C_6H_6Mo(PMePh_2)_3$ or $C_6H_6Mo(PMe_2Ph)_3$, which react with $CF_3CO_2H$ or HCl in ethanol to yield the corresponding hydridomolybdenum cations[142]. The manganese compounds $C_5H_5Mn(PR_3)_3$ (R = Me, OMe, OEt)[143], which are structurally related to $C_6H_6Mo(PR_3)_3$, rapidly decompose when dissolved in acidic media. Accordingly, it is not yet possible to make any statement about the existence of the hydrido complexes $[C_5H_5MnH(PR_3)_3]^+$.

Of the presently known areneruthenium and areneosmium compounds having a $d^6$-electron configuration, the dihydrido complexes $C_6H_6RuH_2[PiPr_3]$, $C_6Me_6RuH_2(PR_3)$ (R = Me, Ph), and $C_6H_6OsH_2[PiPr_3]$ are metal bases[144]. They react even at −78 °C with $CF_3CO_2H/NH_4PF_6$ or $HBF_4$ in ether to form $[C_6R_6MH_3(PR_3)]^+$ cations which possess a fluxional structure in solution at room temperature. This behavior corresponds to that of the $[MH_3(PMe_3)_4]^+$ cations in which the metal is similarly in the oxidation state +4 and which are formed from the compounds $MH_2(PMe_3)_4$ (M = Ru, Os) and $NH_4PF_6$[145]. It is especially noteworthy that the complex **226**, which is closely related to **224**, yields a binuclear cation upon protonation[146]. The low tendency of rhodium to form compounds having the oxidation state +5 (as would be the case in a cation of the type $[C_5H_5RhH_3(PR_3)]^+$) obviously prevents formation of a mononuclear product.

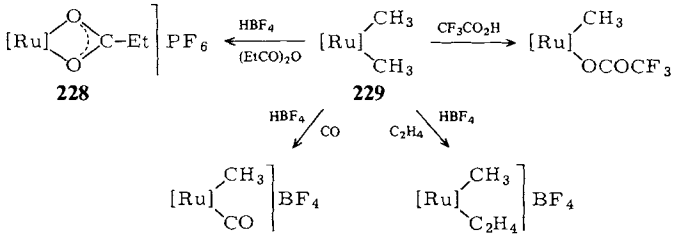


As well as the dihydrido complexes, the analogous dimethylruthenium(II) complexes also react with Brønsted acids. The reactions carried out using **229** are summarized in Scheme 27[144b,147]. Since the ligands $H^-$ and $CH_3^-$ are comparable in their ability to act as σ-donors, it may also

(33)

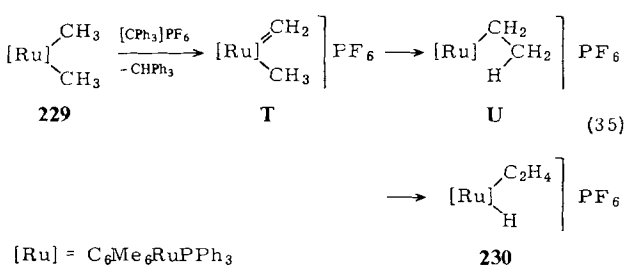
224 225

[Ru] = $C_6H_6RuP(iPr)_3$



(34)

226 227

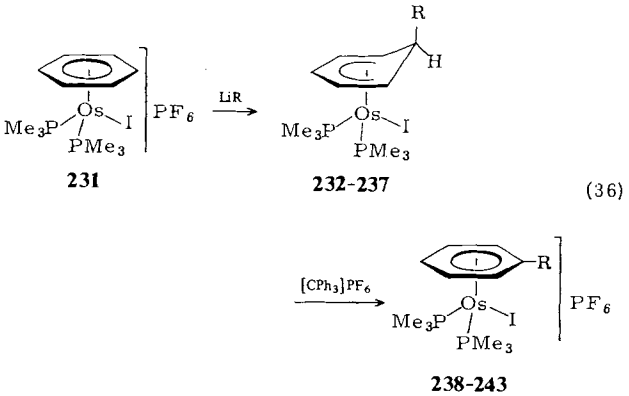


[Rh] = $C_5H_5RhP(iPr)_3$

be assumed that in the reactions of **229** an initial protonation at the metal takes place followed by a reductive elimination of methane. The dimethylcobalt compounds $(C_5H_4R')Co(CH_3)_2PMe_3$ (R′=H, *i*Pr, *t*Bu) behave analogously[148]. The bis(trifluoroacetato) complexes $(C_5H_4R')Co(OCOCF_3)_2PMe_3$, formed from the dimethylcobalt complexes in the presence of excess trifluoroacetic acid, yield with $P(OMe)_3$ in a sequence of reaction steps the phosphonate compounds mentioned in Scheme 3 (see Section 2.2.2). The circle is thereby completed to the starting point of our own studies on electron-rich half sandwich complexes.

Scheme 27. [Ru] = $C_6Me_6RuPPh_3$.

The compound **229** reacts very readily not only with $HBF_4$ or $CF_3CO_2H$ but also with Lewis acids such as $[CPh_3]^+$. Thereby, the ethylene(hydrido) complex **230**, whose structure has been determined by X-ray analysis, is obtained in high yield[149]. As established by labeling experiments the solvent does not participate in this reaction. The mechanism of the CC bond formation presumably involves primary attack of the trityl cation on a C–H bond of one of the Ru–$CH_3$ groups to eliminate a hydride ion, and subsequent formation of the coordinatively unsaturated ethyl compound **U** from the intermediate **T** by intramolecular rearrangement. The compound **U** stabilizes itself by a β-H migration to form the ethylene(hydrido) complex.



(35)

229 T U 230

[Ru] = $C_6Me_6RuPPh_3$

*Cooper et al.* have discovered a completely analogous conversion of an $M(CH_3)_2$ moiety into an $MH(C_2H_4)^+$ group for $M=(C_5H_5)_2W$[150]. In this case it was possible to show that in the primary step an electron transfer takes place from the dimethyl compound to the trityl cation and that the trityl radical reacts with the paramagnetic moiety $[(C_5H_5)_2W(CH_3)_2]^+$. There are no indications of similar radical processes in the formation of **230** (nor in the formation of the homologous osmium complex[144b]). The CC bond formed during the conversion of **T** into **U** [see reaction (35)] represents, in addition, a model reaction for an elementary step in the heterogeneous Fischer-Tropsch synthetic process. The most generally accepted mechanism for this is that $CH_2$ and $CH_3$ groups are formed on the surface of the catalyst and that the chain is built up by successive insertion of methylene units into metal-alkyl bonds[151]. After β-H elimination (analogous to that in the conversion of **U** into **230** according to reaction (35)), α-olefins are formed which are, of course, known to be primary products of the Fischer-Tropsch synthesis.

Finally, a $d^6$-metal system should be mentioned which can be protonated and was discovered during our attempts to synthesize the metal base $C_6H_6Os(PMe_3)_2$. The compound $[C_6H_6OsI(PMe_3)_2]PF_6$ **231**, which—as indicated in Scheme 24—cannot be reduced by $NaC_{10}H_8$ to form $C_6H_6Os(PMe_3)_2$, reacts with lithiumorganyls, LiR, by *exo*-addition of the carbanion to the arene ring to produce the cyclohexadienyl complexes **232—237**[152]. The latter react with $[CPh_3]PF_6$ to yield the corresponding ring-substituted areneosmium(II) compounds **238—243** together with $CHPh_3$. This result is surprising insofar as there are only a few examples currently known where cyclohexadienylmetal complexes $(\eta^5\text{-}C_6H_6R)ML_n$ in which the group R is in the *exo*-position react with trityl salts by hydride elimination[153].

**232**, **238**: R = Me **235**, **241**: R = *n*Bu
**233**, **239**: R = Et **236**, **242**: R = *t*Bu
**234**, **240**: R = *n*Pr **237**, **243**: R = Ph

Mechanistic investigations on the conversion of **232—237** into **238—243** indicate that the hydride abstraction does not take place directly but occurs only in the presence of protons (formed, for example, from $[CPh_3]^+$ in acetone)[154]. In the primary step a hydridoosmium(IV) cation is formed which for R = *t*Bu can be isolated as the $PF_6$ salt. However, with the other R groups it rearranges intramolecularly to afford an isomer in which R is found in the olefinic part of the ring. In the intermediate **V** either a cyclo-

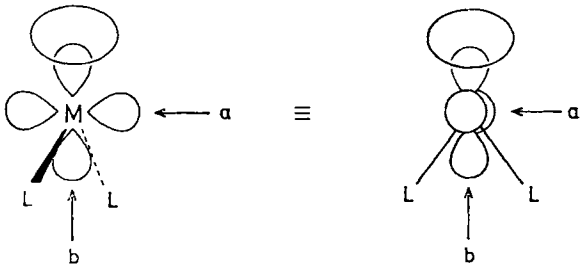
hexadiene ligand (formed by hydride migration from the metal to the $C^1$ carbon atom) or an OsCH three-center bond could be present—as in similar manganese complexes[155]. Deprotonation of the hydrido cation formed from **V** (which for R = Me and *n*Bu was isolated as the $PF_6$ salt) yields a cyclohexadienyl compound with a $CH_2$ group in the ring which then reacts with $[CPh_3]^+$ by hydride elimination.

Scheme 28.

The reaction sequence shown in Scheme 28 demonstrates that even the complexes **232—237** function as metal bases. Because of the coordination of two trimethylphosphane ligands, the metal clearly has a relatively high electron density and accordingly is able to react by proton addition. The cyclopentadienylruthenium and cyclopentadienylosmium(II) compounds, $C_5H_5MX(PMe_3)_2$ (M = Ru, X = Cl; M = Os, X = Br) recently synthesized by *Bruce et al.*, also form stable hydridometal cations with $HPF_6$ and behave completely analogously to **232—237**[156]. This, together with results obtained using $[C_6H_6OsI(PMe_3)_2]$, increases the number of examples known which show that not only half-sandwich complexes having a $d^8$ configuration at the metal but also those with a $d^6$ metal center are capable of oxidative additions.

## 4. Conclusions

Following in the footsteps of the square-planar Vaska-type compounds (including Wilkinson's catalyst), the half-sandwich complexes $C_5R_5ML_2$ and $C_6R_6ML_2$ have established themselves in coordination chemistry over the past decade—primarily due to the contributions discussed in this review—as an additional group of *metal bases* having a $d^8$-metal system. Their nucleophilicity is determined primarily—as has been documented in many instances—by the donor properties of the ligands $C_nR_n$ and L. As the donor strength increases electron density increases at the metal and hence facilitates the attack of any electrophile. As far as is known there are only minor differences between the cyclopentadienyl- and arenemetal complexes. This can be understood qualitatively from MO calculations carried out by *Hoffmann* and *Albright*[157] which show that half-sandwich complexes $C_nR_nML_2$ (n = 5 or 6) possess an energetically relatively high-lying occupied molecular orbital which has non-bonding character with respect to the metal-ligand bonds present. Its electron density distribution can be described as shown in Figure 2.



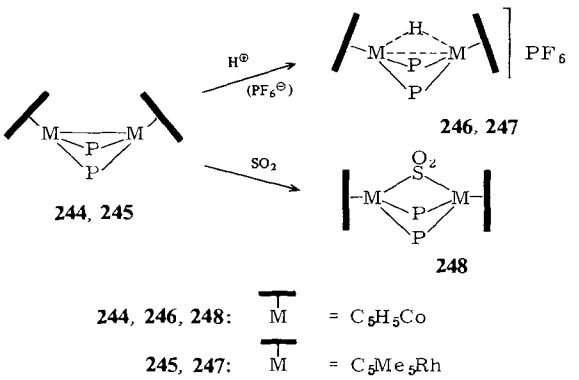


Fig. 2. Electron density distribution in an occupied MO of $C_5R_5ML_2$ or $C_6R_6ML_2$ [157].

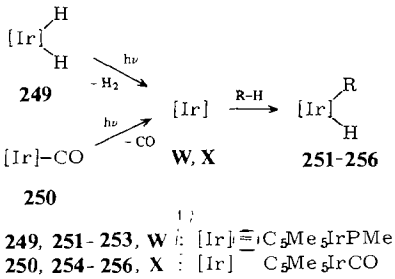
Such an MO (whose "shape" very closely resembles the $d_{z^2}$ orbital of the metal in a planar $d^8$ system) represents, according to *Roald Hoffmann*[158], "the spearhead of nucleophilic activity of the compounds $C_nR_nML_2$". This "spearhead" clearly exceeds even the nucleophilicity of the phosphorus atom in a phosphane, as is evidenced by the reaction of $C_5Me_5Rh(CO)PMe_2PMe_2$ with methyl iodide (which leads *via* the cation $[C_5Me_5RhCH_3(CO)PMe_2PMe_2]^+$ to the compound $C_5Me_5RhCOCH_3(PMe_2PMe_2)I$)[38]. Kinetic measurements by *Pearson* and *Figdore*[159] support the conclusion that the rate of methylation of the $C_5H_5M(CO)PPh_3$ (M = Co, Rh, Ir) complexes at room temperature is 10—100 times that for uncoordinated $PPh_3$.

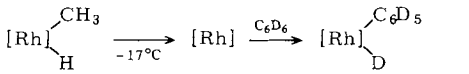
In addition to the electronic factors determining the metal-base character of the half-sandwich compounds $C_5R_5ML_2$ and $C_6R_6ML_2$, steric factors cannot be entirely neglected when considering the reactivity. Results obtained to date suggest that a substantial number of electrophiles are capable of addition to a metal to form a metal-element bond. Such results also indicate that when bulky (space-filling) Lewis acids are used radical reactions frequently occur which are in most cases associated with decomposition. This behavior can be understood by recalling that the metal in the five- and six-membered ring $ML_2$ complexes is relatively well shielded by the ligands, as should be apparent from Figure 2. A fairly large electrophile thus has difficulty in interacting with the nucleophilic center. In several cases the reactivity is directly paralleled by the space-filling capacity of L (*e.g.* expressed in terms of the Tolman cone angle[160]). Thus, for instance, the rate of the reaction of $C_5H_5CoL_2$ with methyl iodide decreases with increasing bulkiness of the ligand L (according to the sequence: $PMe_3 < PMe_2Ph < PEt_3 < PMePh_2 < PPh_3$)[161].



Interestingly enough, the metal basicity of cyclopentadienylcobalt and rhodium compounds is not confined to species having only *one* metal center. The binuclear complexes **244**[162] and **245**[163], in which the two metal atoms are coordinated in a *formally* similar way to those in the compounds $C_5R_5M(PMe_3)_2$, react for example with Brønsted acids and $SO_2$ by electrophilic addition to the metal-metal bond[162-164]. The hydrido bridge formed upon protonation can be opened by Lewis bases thus allowing formation of binuclear cobalt(III) and rhodium(III) hydrido complexes. These may be viewed as potential reducing agents and are capable, for example, of intramolecularly converting an isocyanide- into a formimidoyl-ligand and an alkyne- into a vinyl-group[165]. From these observa-

tions it seems that bridge building could be a means of increasing the reactivity of metal clusters (and perhaps also of metal surfaces).

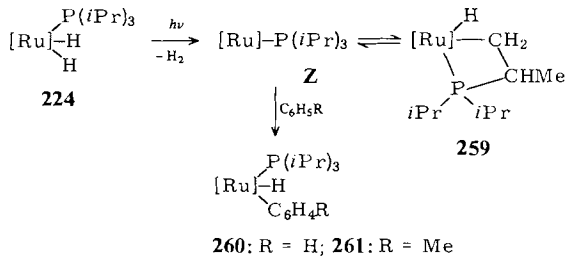
Scheme 29. P = $PMe_2$.



What are the trends for the future? An extremely relevant topic—which is connected at least indirectly with the chemistry of metal bases $C_nR_nML_2$—is the "activation" (or, more precisely, the facile cleavage) of C–H bonds by transition metals[166]. Although there is still no concrete evidence that compounds of the type $C_5R_5ML_2$ or $C_6R_6ML_2$ react *directly* with aliphatics or arenes, the corresponding moieties $[C_5R_5ML]$ and $[C_6R_6ML]$ are definitely able to do so. Thus, *Janowicz* and *Bergman*[167] and, independently, *Hoyano* and *Graham*[168] have recently found (see Scheme 30) that UV irradiation of solutions of both **249** and **250** in benzene, cyclohexane or neopentane leads to oxidative addition with formation of the corresponding aryl(hydrido) or alkyl(hydrido) iridium complexes $C_5Me_5IrH(R)L$ (R = Ph, $C_6H_{11}$, $CH_2CMe_3$). The authors assume that in these reactions a 16-electron moiety $[C_5Me_5IrL]$ (**W**, **X**) is initially formed which then reacts with a C–H bond in the hydrocarbon.

249, 251-253, W: [Ir] = $C_5Me_5IrPMe_3$
250, 254-256, X: [Ir] = $C_5Me_5IrCO$

Scheme 30.



Results obtained over the last few months provide evidence that not only iridium but also analogous rhodium and ruthenium compounds can effect such a C–H bond cleavage. Low temperature photolysis of $C_5Me_5RhH_2(PMe_3)$ in pure propane yields the spectroscopically characterized complex $C_5Me_5RhH(nPr)PMe_3$. This complex reacts at −15 °C by reductive elimination of $C_3H_8$, but upon addition of $CHBr_3$ it can be converted into the stable product $C_5Me_5Rh(nPr)(PMe_3)Br$[169]. The hydrido(methyl) compound **257** prepared from $C_5Me_5RhCH_3(PMe_3)Cl$ is also extremely labile and very rapidly forms the complex **258** in $C_6D_6$[169].

[Rh] = $C_5Me_5RhPMe_3$

(37)

With other phosphane ligands it is possible to stabilize an intermediate such as **W** or **Y** [see Scheme 30 and reaction (37)] even by means of *intramolecular* C–H addition. Thus for example, photolysis of $C_6H_6RuH_2[P(iPr)_3]$ **224** at room temperature in $C_6H_{12}$ or $C_6D_{12}$ and leads to isolation of **259**, which can be characterized by elemental analysis and NMR spectroscopy. By dissolving **259** in benzene or toluene and allowing the reaction to take place in the *dark*, the corresponding aryl(hydrido) complex **260** or **261** is obtained. It seems probable that the moiety actually reacting is the intermediate **Z**. This C–H bond cleavage *without any simultaneous irradiation* may offer a possibility to make other, more sensitive hydrocarbons react with transition metals and thereby bring a new stimulus to the problem of "C–H activation".

Scheme 31. [Ru] = $C_6H_6Ru$.

In an article which appeared in 1970 and made the concept of *metal basicity* popular, *Shriver*[5] wrote that "It can be anticipated that metal basicity will become an increasingly important concept because current vigorous activity in the synthesis of new low oxidation-state complexes will lead to new metal bases and because available spectroscopic tools allow convenient recognition of metal-base interaction with Lewis acids". This expectation has been more than fulfilled, not least in investigations of the behavior of electron-rich half sandwich complexes. It may well be conceivable that $d^8$ systems of the type $C_nR_nML_2$ or $C_nR_nMLL'$, where M is $Fe^0$, $Ru^0$ and $Os^0$, as well as $Co^I$, $Rh^I$ and $Ir^I$, will soon find counterparts in other systems having $Ni^{II}$, $Pd^{II}$, and $Pt^{II}$ as the central atom. This again would represent an extension of the palette of nucleophilic transition-metal compounds, which nowadays are relatively common and are no longer curiosities.

*I should like first and foremost to thank my co-workers in this field whose names appear in the literature citations. Without their involvement and enthusiasm it would not have been possible to reach our goals. Thanks are also due to colleagues who by carrying out numerous X-ray analyses have contributed to the success of these investigations: Dr. C. Burschka, Dr. G. Evrard, Prof. C. Krüger, Prof. U. Schubert, Prof. M. L. Ziegler and their co-workers. Finally, our*

*success is due in large measure to support by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the companies BASF, Bayer and Degussa, all of which I heartily thank. Last but not least, I extend cordial thanks to Professor Sir Jack Lewis, Cambridge (U. K.), whose kind invitation made it possible for me to prepare this article in the stimulating atmosphere of the Chemical Laboratory in Lensfield Road and in Robinson College.*

# The Electrochemistry of Black Carbons

**By Jürgen O. Besenhard* and Heinz P. Fritz**

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

"Modifications" of carbon—as long as they predominantly have the layered graphite structure—exhibit the following properties: 1) electrical conductance, 2) the ability to accomodate ions or molecules between the layers of the lattice, and 3) the ability to react *via* functional groups at their surfaces (largely at the layer edges). The first of these properties has led to carbon being used as an "inert" electrode material; this aspect will not be considered in this article. The combination of the first and second properties leads to the possibility of electrochemical intercalation. This aspect of black carbon's properties will be described, using both literature data and our own results, in terms of both the basic information and the methodology associated with its uses. In addition to the formation of graphite salts the origin of graphite oxide and the various methods which have been used to analyze these materials will be reviewed. The functional groups [(cf. 3) above] can also be reacted electrochemically. Here, particular emphasis will be placed on detailed results obtained from chemically modified carbon electrodes and also from surface oxides and fluorides. Reference will be made to the technological uses of surface oxidized carbon fibers in composite materials and also generally to possible future uses of graphite based compounds.

## 1. Introduction

The term "black carbons" may sound rather alchemistic for those chemists more used to reading about compounds with well defined names. However, this trivial, phenomenological description is the smallest common denominator for the many, and indeed varied, forms of elementary carbon which at least have a predominantly graphite-like *layered structure* and therefore also exhibit electrical conductance. Carbon is alone among the elements in that it exists, in its elementary form, in almost every possible structural order and morphology, from well defined three-dimensionally ordered graphite to X-ray amorphous glassy carbon[1–4].

The aim of this article is to describe the chemistry *of* carbon electrodes; not the chemistry *at* such electrodes. Thus, reactions which take place at the surface of "inert" carbon electrodes will not be discussed.

The chemistry and the electrochemistry of black carbon can be described in terms of one of two types of reaction: Intercalation (or insertion) reactions and surface reactions. In the *intercalation reactions* cations or anions, and often also solvating neutral molecules, come between the graphite-like ordered carbon layers and, thus, the distance between these layers is increased. Since the intercalated ions are generally held between two carbon layers directly facing each other (AαA stacking) and, preferentially, tend to locate themselves at the midpoint between the carbon-carbon hexagons one is led to make the analogy with the metallocenes or the arene-metal complexes. However, this analogy should be made only with reservation because, despite considerable efforts[5–10], some with the aid of electrochemical methods[11,12], it has proven impossible to produce conclusively intercalation compounds of graphite with the transition elements which are typical of metallocene chemistry.

There are several, in part very up to date and specialized, review articles on the subject of graphite intercalation (cf. Table 1). However, the electrochemistry associated with this topic, an area which has grown particularly rapidly in the last few years, has generally been either ignored or, at best, only superficially treated. The aim of this article

is to fill this gap. Other areas, such as the applications of graphite compounds as "molecularly wrapped reagents"[13-17] and also as heterogeneous catalysts[18-22] (especially for the stereospecific anionic polymerization by alkali metal-graphite[23,24]) have already been reviewed in detail.

The *surface reactions* of black carbon are generally reactions of C atoms at the edges of the layers or at other lattice defects, or reactions of other functional groups which are bound to such C atoms. Large effects from surface reactions are thus only to be expected from microcrystalline carbon materials. At the basal planes, on the other hand, essentially only physical adsorption is observed[52]. This physical adsorption is of interest in its own right because of its regularity (cf. *e.g.* [53-57]).

The classical chemistry of the functional groups attached to the carbon lattice has already been reviewed under a variety of headings[58-61]. Some of the more recent articles describe the functionalization of carbon fibers for composite materials[62-69]. Naturally, there are also numerous articles which discuss the properties, production and applications of charcoals and carbon blacks.

Electrochemical studies on the surface reactivity have also been reviewed up to about 1975[70,71] and some developments in the area of "chemically modified" carbon electrodes have been described[72-74].

Therefore, only the newest results from the areas "chemically modified electrodes" and "electrochemical surface oxidation of carbon fibers" will be discussed in this article.

## 2. Historical

Carbon as an electrode material has interested electrochemists for a very long time. Of course, the object of this interest has not always been the development of intercalation and surface compounds. In the first instance, carbon has long been of interest—in view of its thermodynamic characteristics—as a surprisingly "inert" electrode material which has proven especially useful as an anode in corrosive environments (*e.g.* in the production of $Cl_2$, $ClO_3^-$ and in electrolyses of molten alkali and alkaline earth halides). It is, therefore, also not surprising to note that the authors of the initial, preliminary reports about the reactions of carbon anodes to yield inclusion compounds (*e.g.* in $HClO_4$[75] or $HNO_2$[76]), or to form surface compounds (*e.g.* in $HF \cdot KF$[77]), complained about these unwanted side reactions.

Moreover, electrochemists have felt themselves under pressure, for more than 100 years, to develop an electrochemical cell in which, in conjunction with an $O_2$-cathode, carbon or simply coal could be used as a fuel. The efforts to build such fuel cells, based on the initial investigations by *A. C. Becquerel* (1855)[78], *Ostwald* (1894)[79] and others (cf. [80]), in particular on alkaline electrolytes at high temperature, have repeatedly failed. More recently, therefore, the efforts have been directed towards developing a process in which $H_2$ and CO, obtained by gasification of coal, are oxidized in conventional fuel cells[80,81].

Electroorganic syntheses in which the carbon electrodes function as a reactant also have a very long history. Examples of such processes are the production of urea (C-anodes in aqueous $NH_3$ and $(NH_4)_2CO_3$[82,83]) or that of mellitic acid (C-anodes in alkaline solution[84]). $O_2$, CO and $CO_2$, were recognized at a very early date as the major by-products formed during electrolyses at carbon anodes in acid, alkaline and aqueous solution[85,86], whereas larger molecules (*e.g.* $H_2CO$ or $CH_2(OCH_3)_2$[87]) were found to occur at most in only trace amounts. On electrolyzing aqueous suspensions of brown coal, the coal is reductively converted into soluble compounds, but the yields are variable and depend on the precise conditions used[88]; a variety of aromatic compounds are produced such as, *e.g.*, benzoic acid and pyrocatechol, as well as low molecular weight organic acids such as succinic, malonic and oxalic acids. The glow-discharge electrolysis of aqueous graphite suspensions (20—25 g graphite/100 mL) in 1 M LiOH yielded mainly $H_2$, together with CO, $CO_2$ and $CH_3$ as by-products[89].

## 3. Electrochemical Intercalation

### 3.1. Background

Electrochemical intercalation reactions are confined to electron/ion transfer reactions[90-96]. *Guest ions (cations* $M^+$ or anions $X^-$) penetrate (during the cathodic reduction of the anodic oxidation of carbon electrodes) into the van der Waals gaps between the carbon layers and enlarge the inter-layer distance. The corresponding (negative or positive) charges are accepted into the carbon host lattice.

$$C_n + M^{\oplus} + e^{\ominus} \underset{\text{cathodic reduction}}{\rightleftharpoons} M^{\oplus}C_n^{\ominus} \quad (1a)$$

$$C_n + X^{\ominus} - e^{\ominus} \underset{\text{anodic oxidation}}{\rightleftharpoons} C_n^{\oplus}X^{\ominus} \quad (1b)$$

For such a reaction mechanism it is necessary that electrons can be conducted by $C_n$ and that "mixed conduction" (*i.e.* electron and $M^+$ or $X^-$ conduction) occurs in $M^+C_n^-$ or in $C_n^+X^-$.

Furthermore, the host lattice must be capable of accepting, not only sterically but also electronically, the guest ions; *i.e.* a suitable energy band structure must be available. The band structure of graphite compounds has been discussed in a large number of both theoretical and experimental papers (*e.g.*[32,40,97-105]). Qualitatively, the available levels which accept or give up electrons are very high or low and the corresponding $M^+C_n^-$ or $C_n^+X^-$ phases are thus strong reducing or oxidizing agents, respectively. As a consequence, such structures are only possible for cations $M^+$ which are stable to reduction (*e.g.* alkali and alkaline earth metal ions) or with anions which are stable to oxidation (*e.g.* $ClO_4^-$, tetrafluoro anions, and hexafluoro anions).

Intercalation reactions of the types (1a) and (1b) are, ideally, reversible and "topotactic"; *i.e.* the reaction leads to a different inter-layer distance but the carbon atom arrangement within the layers remains, essentially, unchanged. Only in exceptional cases does electrochemical intercalation give rise to binary phases $M^+C_n^-$ or $C_n^+X^-$.

Examples of such cases are the electrochemical intercalation of cations from solid[106], polymeric[107], or molten[108,109] electrolytes. More generally, ternary phases $M^+(solv)_yC_n^-$ or $C_n^+(solv)_yX^-$ are produced because the solvent from the electrolyte is also accepted into the carbon lattice.

$$C_n + M^{\oplus} + e^{\ominus} + y\,solv \underset{\text{anodic oxidation}}{\overset{\text{cathodic reduction}}{\rightleftharpoons}} M^{\oplus}(solv)_yC_n^{\ominus} \quad (2a)$$

$$C_n + X^{\ominus} - e^{\ominus} + y\,solv \underset{\text{anodic oxidation}}{\overset{\text{cathodic reduction}}{\rightleftharpoons}} C_n^{\oplus}(solv)_yX^{\ominus} \quad (2b)$$

From the degree of solvation it is possible to distinguish between two-dimensional and three-dimensional solvated phases (cf. Fig. 1).

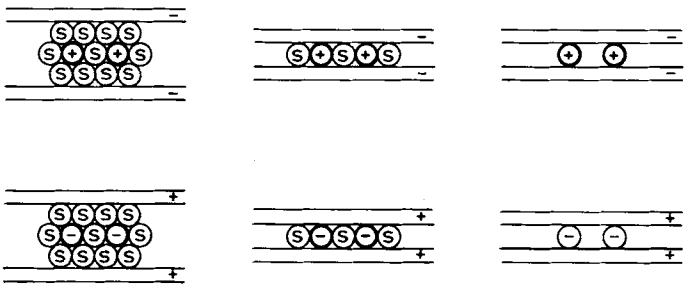

Fig. 1. Schematic diagram showing the three-dimensional and two-dimensional solvated and unsolvated cationic and anionic intercalation compounds; S = Solvent.

In the two-dimensional solvates the distance between the carbon layers is determined either by the size of the solvent molecule (*e.g.* in $K(THF)_1C_{24}$ (THF = tetrahydrofuran)[110] or in $Na(DME)_yC_{32}$ and $K(DME)_yC_{32}$ (DME = 1,2-dimethoxyethane)[111]) or by the size of the ions. The latter is true, for example, for $C_n(NM)_2PF_6$ or $C_n(NM)_2AsF_6$ (NM = nitromethane)[112,113], where the distances between the carbon atom layers for the solvated and the unsolvated phases $C_nPF_6$ and $C_nAsF_6$ are practically identical (cf. Section 3.5). Occasionally, other forms of solvation have also been discussed (*e.g.* "one-sided" solvation, as in the benzene solvated phases $K(Bz)_yC_n$) in which the included ions are separated only from one of the two carbon layers by a solvent molecule[114–117]. However, the mobility of the ions and the solvent molecules in ternary phases is normally so great, even at room temperature, that the model of a "melted intercalation layer" generally applies.

Of course, all the various types of graphite compounds described above can be synthesized not only by cathodic reduction or anodic oxidation but also with the aid of chemical reducing or oxidizing agents. However, the electrochemical method has important advantages[118]:

- —the products are free from impurities arising from the reducing or oxidizing agent,
- —the degree of oxidation or reduction can be controlled,
- —the rate of reaction can be controlled[*],
- —the thermodynamics of the intercalation processes can be followed by the electrochemical potential,
- —from the relationships between current, potential, and time it is possible, at least qualitatively, to study the kinetics of the process.

In contrast to the above advantages, the electrochemical intercalation reaction is difficult to "scale up" due to the necessity for electrical contact between the large number of small particles. Nevertheless, making contact between a large number of small particles is possible using, for example, high pressures[119], fluid-bed reactors[120], or "stirred electrodes" (a suspension of the particles to be reacted is stirred onto net-like electrodes).

A special feature of the intercalation of graphite is the formation of a *regular* array of unoccupied layer gaps (= stage formation) when only a low concentration of the guest species is present. In compounds of stage s the guest containing layers are separated by s carbon layers; non-integer values of s (*e.g.* 1.5) are used to describe alternating layer sequences (*e.g.* guest-C-guest-C-C-...). Stages from s = I to *ca.* s = VII can be confidently determined *via* X-ray techniques, but even considerably higher s values have also been postulated. More recently it has been suggested ([122], see Fig. 2) that where s > I all the layers contain some guest species but that the guest species form "islands", stagewise, within the otherwise empty interlayer gaps.

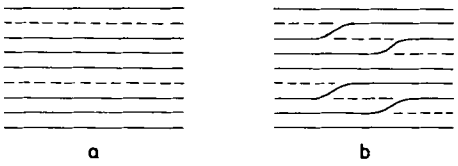

Fig. 2. Classical (a) and more recent (b) model of a stage III; ——— carbon layer, ------- guest layer (according to Ref. [122]).

Carbon which has only a slight degree of structural order cannot be used to produce intercalation compounds with higher stages s.

The distribution of the guest species among the interlayer spaces can be described as either "commensurable" or "incommensurable". In commensurable structures the guests are ordered according to the "raster" of the carbon layers, *i.e.* they form superstructures. Commensurable structures are frequently found in binary compounds $M^+C_n^-$ in which the metal atoms take up an ordered structure and are positioned above the mid-point of particular carbon-carbon hexagons.

As the temperature of such compounds is raised, order/disorder transitions leading to incommensurable structures can be observed.

Finally, it should be noted that the notation $M^+C_n^-$, $M^+(solv)_yC_n^-$, $C_n^+X^-$ and $C_n^+(solv)_yX^-$ need not necessarily reflect a full charge transfer, that is an ionicity $f = 1$. In particular, there is some doubt about the degree of ionicity in unsolvated and two-dimensionally solvated phases. Unfortunately, despite the fact that $f$ can be measured by a variety of physical methods[123–125] its determination remains a problem. Thus, the literature contains very erratic data not only for $C_n^+$ (= acceptor) com-

[*] The crystallinity of the intercalation compound (not only for carbon lattices) can be decisively influenced by the rate of reaction. This has been demonstrated in a transition temperature study of superconducting phases of $K_x(H_2O)_yTaS_2$ prepared by different methods [121].

pounds (compare for example: [126] with [127] and also [128,129]) but also for the $C_{\overline{n}}$ (=donor) compounds (compare for example the lower values in [130–132] with the higher values in [133,134]). Generally, it is found that the ionicity increases with increasing dilution.

### 3.2. Standard Electrochemical Methods and Their Application to Intercalation Reactions

Electrochemistry—where the emphasis is on the chemistry—has expanded rapidly in the last few years, mainly because of the availability of relatively cheap commercial equipment for the easy control of both current and potential.

For studying the processes involved in intercalation reactions two methods have proved particularly useful, namely cathodic or anodic intercalation

- —with constant current and continuous plotting of the electrochemical potential of the product in comparison with a reference electrode and
- —with continuously changing potential controlled by a potentiostat and, under this forced potential, plotting the resulting current.

These methods can also be used for the controlled preparation of intercalation compounds.

#### *3.2.1. Controlled Current (= Galvanostatic) Reactions*

In the simplest case a constant current $I$ is allowed to flow between the desired substance (working electrode W) and a counter electrode C in a divided cell (Fig. 3). The potential difference between the working electrode and a reference electrode R is then measured *via* a chart recorder with a high input resistance (Fig. 4).

The experimental parameter $E'$, measured by such experiments, is not the equilibrium potential since it also contains a term due to the overpotential. Of the various types of overpotential (cf. textbooks on electrochemical kinetics, *e.g.* [135,136] and [137–140]), those due to diffusion controlled concentration gradients in solids and, in particular for porous electrodes, those due to the concentration gradients in the electrolyte phase ($\eta_{d(solid)}$, $\eta_{d(liquid)}$) are the most relevant for intercalation reactions. In comparison,

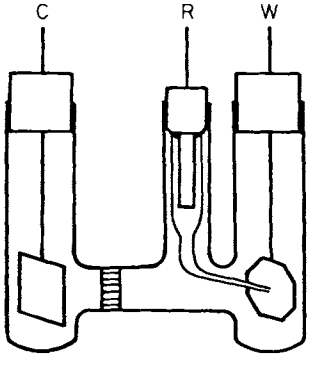

Fig. 3. Partitioned electrolysis cell with working electrode W, reference electrode R and counter electrode C.

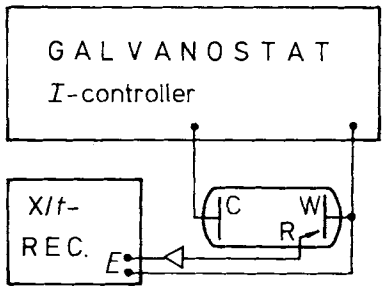

Fig. 4. Principle of a galvanostatic reaction technique with an electrolysis cell, galvanostat and an X/$t$ chart recorder equipped with an impedance transformer.

the charge-transfer overpotential $\eta_{CT}$ is, generally, negligible.

Using Ohm's relationship for the potential drop $I \cdot R$ ($R$ is given by the electrical resistance between the working and the reference electrodes) one can write:

$$E' = E + \eta_{d(solid)} + \eta_{d(liquid)} + \eta_{CT} + \cdots + I \cdot R \qquad (3)$$

A complete separation of the various overpotential terms is only partly realizable and in any case requires very complicated experimental techniques (cf. Section 3.7). When the current density is small enough[*] equation (3) can be simplified to $E' \approx E$. Qualitatively, this assumption is easily verified; *e.g.* using a pulsed current (when $E'_{\text{under load}}$ should be negligibly different from $E'_{\text{open cell}}$).

Figure 5 (left-hand side) shows a constructed potential-charge curve for the anodic intercalation of graphite (with the condition that the packing density of the anions in the interlayer spaces remains constant).

The plateaus on the potential curve indicate 2-phase regions (mixtures of two neighboring stages)—pure stages form infinitesimal limits due to the imposed, strict stoichiometry. The higher the stage s the smaller the difference between the potentials $E_{(s+1)/s}$ and $E_{s/(s-1)}$ for the coexisting stages s and s+1.

Thus, from the characteristic potential *vs* charge curves a phase analysis can be made and—assuming that the current yield is 100%—one can determine the stoichiometric factor n for the individual stages $C_nX$. The current yield and/or the reversibility of the intercalation reaction can be checked by current reversal, *i.e.* by removal or "deintercalation". Ideally, current reversal should yield a mirror image of the characteristic intercalation curve. Obtaining a plot for $E$ or $E'$ is almost a prerequisite for the preparation of a particular stage or stoichiometry of intercalation product.

#### *3.2.2. Controlled Potential (= Potentiostatic) Reactions*

Potentiostatic experiments are normally begun at the equilibrium potential of the working electrode, *i.e.*, at $I=0$; the potential is then varied at a constant rate $\Delta E/\Delta t$

[*] Because of the relatively rapid diffusion within highly oriented graphite, the crystallites with a basal plane area of several mm² can easily "cope with" prism current densities, that is with current densities referred to the areas of the sides of the prism, in the order of 1 mA·cm$^{-2}$.

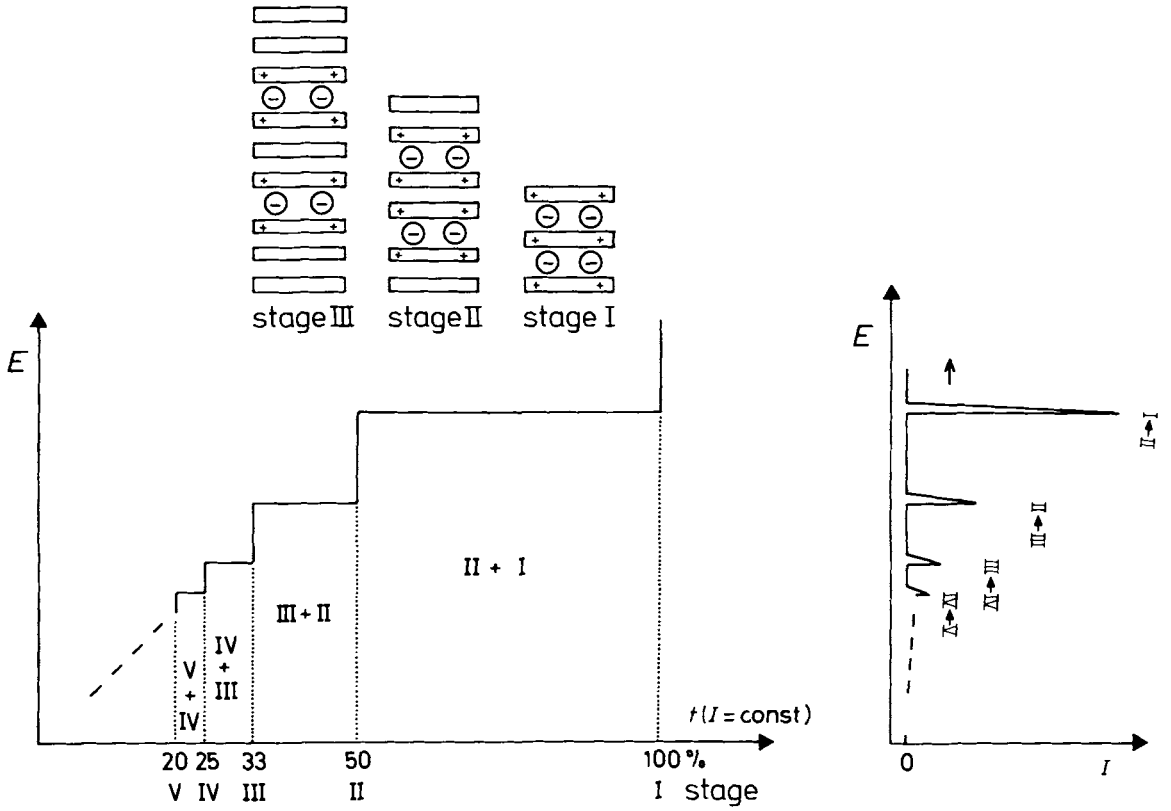

Fig. 5. Electrochemical intercalation with stage formation; bottom left: constructed $E$/charge curve, bottom right: constructed $I/E$ curve for $\Delta E/\Delta T$ = constant.

and the resulting current is plotted. An electronic potentiostat is used to bring the potential of the working electrode (measured against a reference electrode, the latter being connected to a high impedance input of the potentiostat) to a particular value by adjusting $I$. This method, which is called linear sweep voltammetry, is similar to the method used in polarography (Fig. 6).

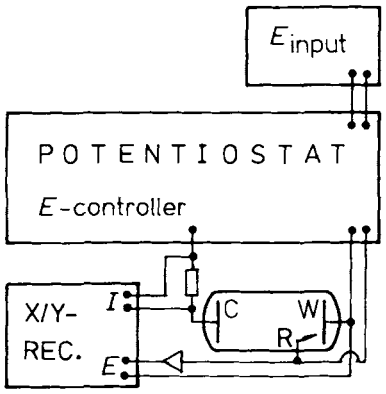

Fig. 6. Principle of the potentiostatic reaction technique with electrolysis cell, potentiostat, desired voltage source (generally a triangular voltage generator) and an X/Y chart recorder.

Figure 5 (right-hand side) shows the current curve to be expected during the formation of an intercalation compound of various stages: the potential plateaus of the galvanostatic technique are transformed into current peaks. No current flows during the sweeps of the potential areas between these plateaus.

Subsequent reversal of the direction of potential change (= cyclic voltammetry) leads to a mirror image plot about the axis $I=0$ for reversible reactions and for reactions where conditions are close to equilibrium, *i.e.* when the rate of change of the potential $v$ is slow enough[*].

The various types of overpotential which have been described above each lead to a characteristic peak broadening during cyclic voltammetry. For simple reactions, and in particular for reactions in solution, the kinetic parameters can be derived from such peak broadening effects[141–144]. A similar, in depth analysis has also been attempted for intercalation reactions and for reactions involving mixed conductors[145–147]. However, the large number of experimental variables and the difficulties associated with the control of these variables make such analyses difficult. This is particularly true for reactions involving polycrystalline electrodes where parameters such as the orientation and size of the crystallites and pores and the ionic and electronic intercrystalline orientation are difficult to estimate.

### 3.3. Galvanostatic and Potentiostatic Anodic Intercalation of Graphite in $H_2SO_4$—a Model Reaction

The anodic oxidation of graphite to $C_n(H_2SO_4)_y(HSO_4)$ and the corresponding back reaction were originally described by *Rüdorff* and *Hofmann*[148], who also observed the stepwise changes in $E$. X-ray and other analytical data

[*] Good peak resolution from crystallites of highly oriented graphite with a basal plane area of several mm$^2$ is only achieved when $v < ca.$ 0.1 Vh$^{-1}$.

were used to corroborate the stoichiometry of the stage I as $C_{24}(H_2SO_4)_2(HSO_4)$[148,149] and the corresponding commensurable $C_8X$ structure. The oxidation of graphite in $H_2SO_4$ has since been followed potentiometrically by many other authors[150–154]. A sharp potential break has generally been observed corresponding to a stoichiometry $C_{48}^+$; this has led to the suggestion that there is a correlation between the stoichiometry and the stage s of $C_{24\times s}^+$.

However, more recent potentiometric results[120,155–159] using a very low current density—*i.e.* "close to equilibrium" conditions—on highly oriented pyrolytic graphite (HOPG) indicate a rather more complicated relationship between stoichiometry and stage. These experiments on the graphite/$H_2SO_4$ system have a model character in as much as the results obtained can be usefully generalized not only with respect to other graphite compounds but also for the intercalation of other layered host lattices.

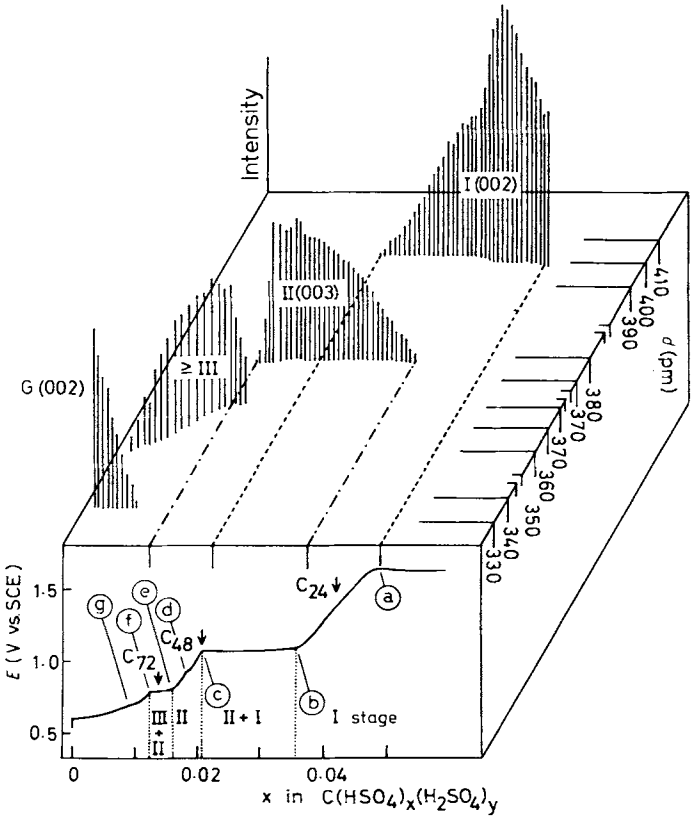

Fig. 7. Galvanostatic oxidation of HOPG (highly oriented pyrographite) close to equilibrium in 96% $H_2SO_4$ (Sample *ca.* 4×4×0.03 mm; $I=15$ μA); top: inter-layer distances and the corresponding intensities of the strongest 00l-reflections from each stage; bottom: *E*/charge curve (for details of the points a–g see text), SCE = saturated calomel electrode.

The potential change during the slow, galvanostatic oxidation of HOPG in $H_2SO_4$ is shown in Figure 7[*]. There are significant differences between the trace in Figure 7 and the constructed plot in Figure 5 (bottom left); in particular in the "inclined" potential areas which are characteristic of 1-phase preparations. In 1-phase graphite compounds the packing density of the intercalated ions is variable although the stage remains constant, thus leading to nonstoichiometric and incommensurable structures. The dependence of the variable electrochemical potential on the ion density is qualitatively analogous to the EMF of amalgam chains, which is determined by the concentration term $\ln c1/c2$. A quantitative appraisal taking into account the receptivity of the host lattice for the ions and the electrons necessary for compensating the charge of the ions or defect electrons can be found in [145,160].

The characterization of compounds as 1- or 2-phase according to the potential curves obtained can be corroborated by X-ray analysis. In Figure 7 the strongest 001-reflections[*], their positions, and their intensities are given for each stage. The diffraction pattern was taken *in situ* with an electrolysis cell mounted on a two-circle diffractometer (Fig. 8). Similar assignments have also been used by other workers (*e.g.* [161–163]).

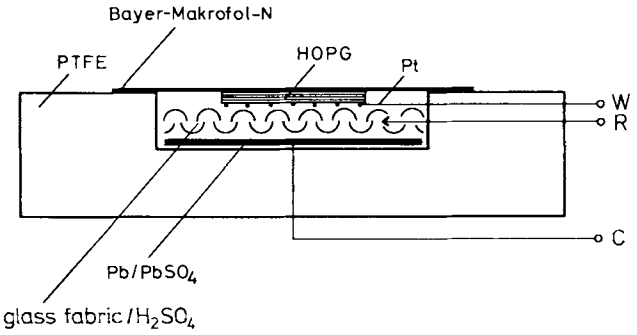

Fig. 8. Electrolysis cell for the 2-circle diffractometer. PTFE = polytetrafluoroethylene.

It is easily seen in Figure 7 that in the 1-phase region of stage I (b–a) no parts of stage II are present and that in the 2-phase region of stages II + I (c–b) both stages are always present *etc.* The expected sequence of the n-values (24, 48, 72...) according to the model $n=24\times s$ is, however, certainly not observed; only the potential break at $C_{48}$ fits with this sequence. The observed potential breaks (marks a–g) correspond to the following n-values (determined from several measurements): a) 21—20/b) 29—27/c) 48/d) 56—54/e) *ca.* 60/f) 84—81/g) *ca.* 110.

Two points particularly worthy of note from Figure 7 are the "additional" potential break in the apparent 1-phase region of stage II (d) and the increasing anion density with decreasing distance between the layers in the 1-phase region of stage I.

For confirming results, and as an aid to explaining such small but important effects for the understanding of the intercalation process, *in situ* dilatometry has proved very useful. With this method the macroscopic swelling of the graphite crystal[**] can be measured.

The bottom half of Figure 9 shows a cyclic voltammogram of HOPG in $H_2SO_4$ in its, perhaps unusual, "unfolded" form. The relationship between the graphs in the lower parts of Figures 7 and 9 can easily be followed by comparing the points a–f.

[*] In order to linearize the abscissa the $C_n(H_2SO_4)_y(HSO_4)$ phases are represented as $C(HSO_4)_x(H_2SO_4)_y$.

[*] The lattice plane spacings along the crystallographic c-axis, *i.e.*, perpendicular to the layers.

[**] Such studies do not necessarily require single crystals; HOPG, which is a polycrystalline material [39], albeit with a very regular crystallite order, is quite adequate.

Carrying out the reaction potentiostatically with a linear change in potential is particularly advantageous for an *in situ* structural analysis since the 2-phase "information branches" with their greater current density are quickly recorded and, thus, the resolution in the 1-phase region is better.

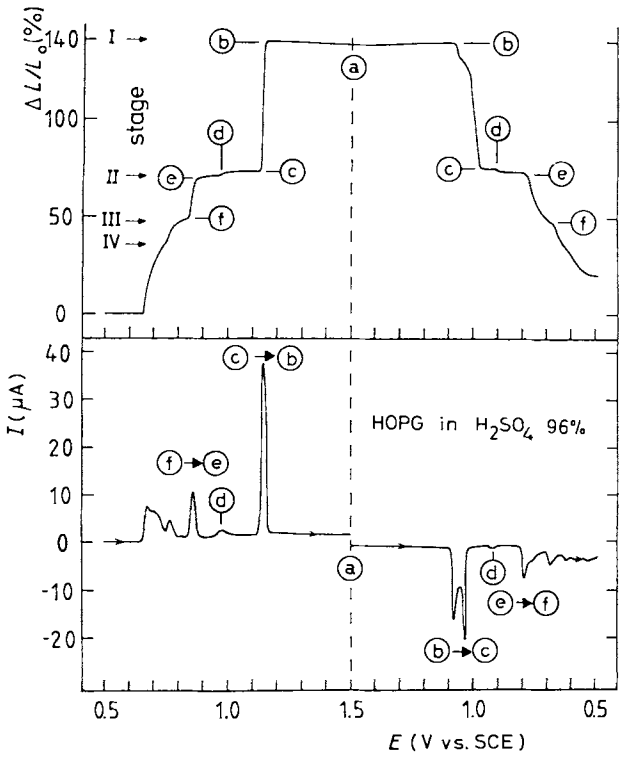

Fig. 9. Oxidation/reduction of HOPG in 96% $H_2SO_4$ (slow cyclic voltammetry, $v = 1.4$ mV min$^{-1}$); top: relative expansion of the crystal along the c-axis, bottom: current/potential curve (for details of the points a—f see text).

In the plot of the relative expansion in the c-direction $\Delta L/L_0$ (shown in the top half of Fig. 9) the 1-phase regions appear as plateaus, whereas the 2-phase regions appear as almost vertical jumps. In the 1-phase region of stage I it is again clear that as the anion density increases the interlayer separation decreases due to Coulombic attraction; during the back reaction this process is reversed and the inter-layer distance expands.

From the expanded plot the "additional" potential break d can be unambiguously ascribed to a slight change in the interlayer gaps in a "pseudo-1-phase" region of stage II. There are clearly two second stages, IIa and IIb, which can be differentiated on the basis of their anion packing densities[*]. From the back reaction it can be seen that the transition IIa/IIb is reversible.

In contrast, the "split" peak b→c during the back reaction suggests that this part of the reaction is irreversible. Since this splitting has not been observed in 99% $H_2SO_4$[**] it can be ascribed to a hydration or hydrolysis of the primary, electrochemically formed product (EC-mechanism, *i.e.* a secondary chemical reaction following a primary electrochemical reaction).

Even after complete back reaction the original value in the dilatometer is only sometimes reached[155]; due to particular experimental difficulties (*e.g.* the ingress of electrolyte into the capillary space) the original value is not always achievable. X-ray measurements have shown that, without doubt, the end product of the reverse reaction is graphite.

Figure 10 shows the design of the high resolution dilatometer. The sample displaces the ferrite core of a coil which is part of an oscillatory circuit whose resonance frequency can be calibrated in units of length[155].

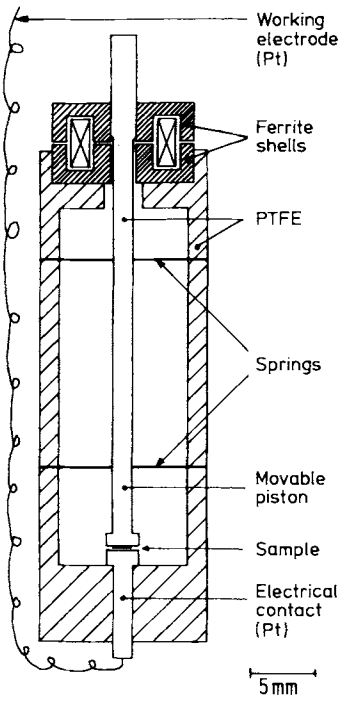

Fig. 10. Dilatometer for electrochemical experiments.

Potential/stoichiometry or current/potential curves with clear profiles (such as those shown in Fig. 7 and Fig. 9) can only be obtained using good crystalline graphite samples. Poor crystal material (where the C-atom sites and, as a consequence, those of the guest ions and molecules are non-equivalent and additionally where the diffusion of the guests into the layer gaps is significantly hindered) can be identified by the "smeared" curves which they produce. This is exemplified in Figure 11, which shows the change

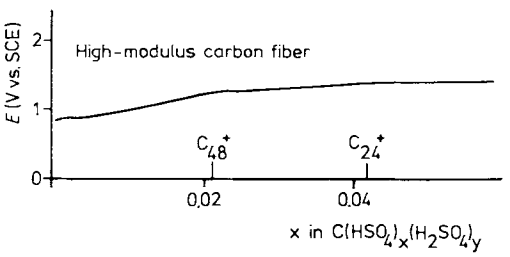

Fig. 11. Galvanostatic oxidation of highly oriented carbon fibers (Celion GY 70, Celanese USA) close to equilibrium in 96% $H_2SO_4$; the potentials were measured pointwise 2 min after each current break.

[*] Very recent X-ray experiments have shown that the stacking sequence of the carbon layers also changes at the transition from stage IIa to IIb [159].

[**] At even greater concentrations an exclusively electrochemical reaction is no longer possible due to partial self-oxidation.

in potential during a "near to equilibrium" oxidation of carbon fibers[*] (checked by a pulsed reaction).

Further possibilities for characterizing carbon materials by electrochemical measurements are described in Section 3.8.

### 3.4. Anodic Intercalation of Graphite in Other Acid Electrolytes

The $H_2SO_4$ system, described in detail in Section 3.3, can be seen as a model for many other Brønsted acid systems containing little or no water. However, as the water concentration in the system increases, side reactions, such as the production of $O_2$ or $CO_2$ and CO, become dominant and, in addition, a partial hydrolysis of the "acid graphite salt" $C_n(HX)_yX$ to "graphite oxide" takes place (cf. Section 3.7). The acid HX, of course, must be sufficiently stable towards oxidation; the redox potentials of acid graphite salts of stage I are approximately +1 V relative to the $H_2$ electrode.

#### *3.4.1. Concentrated Acids Containing Little Water*

The stoichiometries of most of the acid graphite salts of stage I which have been described in the literature closely approach the "ideal" of $C_{24}(HX)_2X$. However, it must be emphasized that the sequence of 1- and 2-phase regions shown by the $H_2SO_4$ example, and the appearance of incommensurable structures which are a result of this sequence, is only *qualitatively* applicable to the complete class of compounds.

Thus, it is not surprising that analytical results often yield "uneven" stoichiometries, and, in particular, that the number of neutral molecules HX often deviates significantly from 2, with a dependence on the size of X.

Typical results for y in $C_n(HX)_yX$ of stage I are: $H_2SO_4$ ($y=2$[148], $y=2.5$[166], $y=2.42$[167]); $H_2F_2$ ($y=2$[168]); $HClO_4$ ($y=2$[166,169]); $HSO_3F$ ($y=2.5$[170,171]); $HNO_3$ ($y=3$[172]); $HSO_3CF_3$ ($y=1.63$[167]).

Well characterized phases $C_n(HX)_yX$ of stage I have been obtained, for example, by the anodic oxidation of graphite in the following acid media: $H_2SO_4$[148,150–159], $HClO_4$[150,151], $HNO_3$[151], $H_2F_2$[168], $HSO_3F$[173], $HSO_3Cl$[151,174] and $HSO_3CF_3$[167,175]. Graphite has also been anodically intercalated in $H_2SeO_4$, $HIO_4$, $H_3AsO_4$[151], $CF_3COOH$[176] and also in fluoride-containing acids such as $HBF_4$ and $HPF_6$. However, the products of these latter reactions remain almost uncharacterized; indeed, complications may be expected due to loss of HF during the reactions. Surprisingly, no intercalation takes place in $H_3PO_4$. The compounds formed when $HX=HSO_3Cl$ remain controversial: it has been assumed that predominantly $SO_3$ and $H_2SO_4$ or $H_2S_2O_7$ are accepted into the lattice[177].

The anodic oxidation of graphite in $CF_3COOK/CF_3COONa$ melts leads essentially to fluorocarbons and $CO_2$[178]. There are also indications that where $HX=H_2SO_4$ iso-polyacids occur in the interlayer gaps[179,180]. Furthermore, simple acid anhydrides (*e.g.* $SO_3$[181] and $Cl_2O_7$[182] have been intercalated in graphite. In the latter case the compounds are not "molecular" intercalation compounds but rather partially ionic compounds such as $C_n^{2+}(SO_3)_ySO_4^{2-}$, "two-dimensionally solvated" by acid anhydrides[181]. That there is a stoichiometric "upper limit" of $C_{12}^+$ for salt-like compounds in the system graphite/$H_2SO_4$ has also been occasionally discussed[154,183].

Very similar relationships exist for the metal halide-graphite compounds (*e.g.* "$AlCl_3$-graphite", "$AsF_5$-graphite"); these compounds are also partially ionic (*e.g.* $C_n^+(AlCl_3)_yAlCl_4^-$). As is to be expected on the basis of such structures "$AlCl_3$-graphite" can only be prepared from $AlCl_3$ and graphite in the presence of oxidizing reagents such as $Cl_2$. Such reactions have been thoroughly discussed in several reviews on graphite compounds (cf. [30,38,45]). "$AlCl_3$-graphite" can be prepared electrochemically *via* the anodic oxidation of graphite in molten $LiCl/AlCl_3$; in this process the partial pressure of $Cl_2$ which is required for the chemical intercalation process can be correlated with the electrochemical potential[184]. In a similar way, $BiCl_3$[185] and $BF_3\cdot O(C_2H_5)_2$[179,186] have also been intercalated by partial anodic oxidation.

#### *3.4.2. Dilute Acids*

With increasing water content of the acid medium, only the higher stages of the acid graphite salts become accessible. For example: in 10 M $H_2SO_4$ stage II can be prepared, whereas in 6 M $H_2SO_4$ the lowest stage that can be prepared is stage IV, and in 1 M $H_2SO_4$ stage XX[187,188]. The variation in potential during the galvanostatic anodic oxidation of HOPG in 70–100% $H_2SO_4$ is qualitatively the same as that shown in Figure 7, *i.e.*, $H_2O$ has almost no influence on the phase sequence until the maximum anion packing density is reached. Beyond this limit, further oxidation leads to the release of $O_2$, $CO_2$ and CO and the formation of "graphite oxide" (GO), a compound made up of C, H and O with covalent C–O bonds. These products result from the hydrolysis of acid salts which are no longer stable in the presence of water. This is particularly true for the salts of stage I:

$$C_n^{\oplus}(HX)_yX^{\ominus} + H_2O \longrightarrow \text{"}C_nOH\text{"} + (y+1)\,HX \qquad (4)$$

In very dilute acids the development of gases predominates[189] whereas, for example, in 70% $HClO_4$ or 80% $H_2SO_4$, GO is formed with a current yield of practically 100%[190].

Obviously, during intercalation in dilute acids $H_2O$ also diffuses into the interlayer spaces. For any one stage the distance between the layers shows a clear dependence on $H_2O$ content and, indeed, it has been shown that the interlayer distance decreases with increasing $H_2O$ content[187].

Very soon after such compounds were first prepared, the idea of using graphite salts $C_n(HX)_yX$ as positive, active electrode materials in rechargeable batteries was put forward[148]. However, since the time-honored, negative electrodes (especially Pb, Zn and Cd) could not be used in concentrated acids it is only reasonable that attempts have been made using dilute acids as electrolytes. *Fujii* has studied, for example, such a rechargeable cell with $H_2$(Pd) as

[*] The interlayer distance in these fibers is *ca.* 340 pm and is thus typical of a turbostratic ordering of the C-planes. The "layer packets" are relatively thin (< 10 nm [164, 165]) and corrugated.

the negative electrode in 12 M $H_2SO_4$[191] and with Cu as the negative electrode in 15 M $H_2SO_4$; he has reported high cycle numbers (up to 6500 charge/discharge cycles)[192].

In more recent studies, *Beck et al.* have used $HBF_4$, $H_2F_2$, and $HClO_4$ instead of $H_2SO_4$[193–201]. In these studies the acid concentration was generally between 20—80% by weight. Under these conditions Cu, Pb, Zn, and Fe are all suitable anode materials, and as cathode a mechanically stable, hot-pressed composite from 80% natural graphite and 20% polypropylene was preferentially used. However, because of the high water content of the acids, the graphite salts of stage II determine the upper charge limit for the graphite cathode, and consequently the energy density of such accumulators is very low. For the cell $C_{48}(H_2F_2)_2HF_2$/50% $H_2F_2$/Zn with a discharge voltage of 2.2 V[198] a theoretical energy density of 70 Wh $kg^{-1}$ can be calculated. For the "heavy" acids and more noble metal anodes the values are considerably less favorable; for comparison, the theoretical energy density of a lead acid accumulator is 161 Wh $kg^{-1}$ (cf., *e.g.*, [202,203]).

### 3.5. The Anodic Intercalation of Graphite in Neutral Electrolytes

In neutral, aqueous solutions it is either not possible to prepare ionic graphite compounds or they are not stable[*].

Only the development of $O_2$ at the graphite anode or the oxidation of the graphite to covalent carbon compounds has been observed in such solutions (see Section 3.4). In contrast, in many nonaqueous solutions compounds of the general formula $C_n^{+}(solv)_yX^{-}$ are easily prepared by the anodic oxidation of graphite. However, these compounds generally decompose within a few days because, in order to prepare the electrolyte solutions, very polar solvents have to be used and these are not stable to oxidation[**]. Nevertheless, there are a large number of solvents which are *kinetically* stable enough (*i.e.* that oxidize slowly enough), so the compounds $C_n(solv)_yX$ can at least be prepared.

The possibility of anodically oxidizing graphite in nonaqueous solution has proved interesting, in particular, in connection with efforts to develop a rechargeable lithium battery along the lines of equation (5)[175,204–217] (cf. also Section 5.1):

$$Li + C_n^{\oplus}(solv)_yX^{\ominus} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} LiX + C_n + y\,solv \qquad (5)$$

Despite the high voltage of such cells (up to *ca.* 5.2 V), the energy density, taking solvation into account, is only moderate ($E_{theor.}$ is of the order of 200 Wh·$kg^{-1}$). Furthermore, up to now no suitably stable solvent has been found. The cyclic voltammogram in Figure 12 demonstrates that such graphite electrodes are reversible.

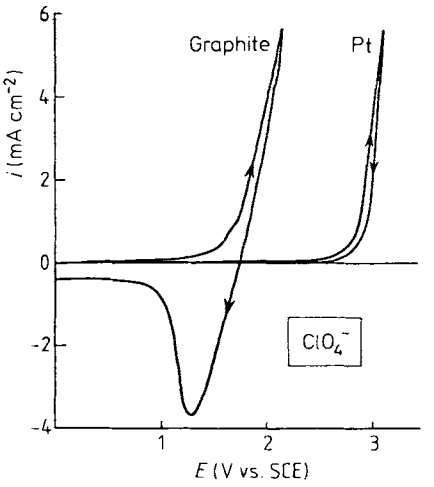

Fig. 12. Oxidation/reduction curve of graphite foil (a fine crystalline and well textured material with *ca.* 50% pore volume [1]) in 1 M $LiClO_4$/propylene carbonate, $v = 5$ mV $s^{-1}$; for comparison: an inert electrode under identical conditions.

The stoichiometry of the $C_n(solv)_yX$ phases has been determined from potential measurements made during galvanostatic oxidations. For stage I n is generally *ca.* 24 (1-phase region ± about 15%, as for $C_n(H_2SO_4)_y(HSO_4)$) and for stage II n is *ca.* 48[175,209,211,218–221]. The progress of the *E*/charge curve is usually very similar to that for the anodic oxidation of graphite in $H_2SO_4$; even such details as the "break" in the "pseudo-1-phase" region of stage II (corresponding to d in Fig. 1) are frequently observed during the anodic oxidation of graphite in nonaqueous electrolyte solutions. The degree of solvation y depends on the nature of the solvent: In two-dimensionally solvated phases (*e.g.* where solv = nitromethane) y is *ca.* 2[221] and in three-dimensionally solvated phases it is usually greater. For the $PF_6^-$ compounds solvated with propylene carbonate (PC) a value of y = 4 has been reported[218,219]. In the latter compounds the inter-layer distance (stage I: 1410 pm[219]) and, in particular the calculated structure factors[220] fit with the assumed tetrahedral coordination of $PF_6^-$ by PC. On the basis of polarity considerations, the carbonyl groups must be directed towards the carbon planes[219].

Table 2 is an up to date list of the anions ($X^-$) and the solvents (solv) which are known to form $C_n(solv)_yX$ phases. The "blank spaces" in Table 2 are completely accidental and do not have any fundamental significance. For solv = NM (nitromethane) the self-decomposition is the slowest. The anodic intercalation of doubly charged anions generally fails because of the insolubility of the corresponding salts in the commonly used solvents; normally, only 1:1 salts with large anions are suitably soluble.

In addition, there are also a number of products from the self-decomposition or "over-oxidation" of $C_n(solv)_yX$ which have, as yet, not been fully explained. Since these products often still show "redox activity" they have frequently been suggested as possible candidates for the active material in battery electrodes[224,232]. With the exception of NM-solvated phases, which can also be prepared *via* the reaction of $NO^+X^-$[225,226,228,230] and $NO_2^+X^-$[225–227,229,231] with graphite in nitromethane, the electrochemical method provides the sole route to this

[*] Thus, the trend already seen in aqueous acid solutions is seen to be continued: As the solution becomes more dilute the electrochemical potential of the graphite salts increases and the potential at which $O_2$ starts to be released decreases.

[**] The standard potential of the phases $C_n(solv)_yX$ of stage I is *ca.* +2 V.

class of materials[233,234]. If an acid, as well as the organic solvent, is present in the electrolyte solution, it is possible to produce $C_n^+(HX)_x(solv)_yX^-$ phases, *e.g.* $C_{48}^+(HBF_4)_{1.4}(ET_2O)_{0.9}BF_4^-$[235].

Unsolvated $C_n^+X^-$ phases can be prepared from ternary, solvated phases, especially those containing very volatile solvents, simply by pumping off the solvent *in vacuo*[175,211]. It is also possible that the anodic oxidation of graphite in $SO_2ClF$ solution (*e.g.* of $Bu_4N^+$ salts) leads directly to unsolvated phases[118]. It is at least clear that $SO_2ClF$ is a very weak solvating agent, since in such solutions, for example of $PF_6^-$ or $AsF_6^-$ graphite salts, the stoichiometry approaches $C_{12\times s}^+$, *i.e.* the anion packing density is doubled. The salts of stage I are not very stable and thus, as for other graphite compounds containing fluoro-anions[236–238], partial covalent fluorination of the carbon planes is the major side reaction.

The products obtained *via* electrolysis in $SO_2ClF$ have a composition $C_nX$ at room temperature and under normal pressure. Nevertheless, because of the highly volatile nature of $SO_2ClF$ (b.p. +7.1 °C) it cannot be excluded that a desolvation has already occurred under these conditions. Figure 13 shows the potential changes observed during a galvanostatic oxidation of graphite foil in saturated $Bu_4NAsF_6/SO_2ClF$.

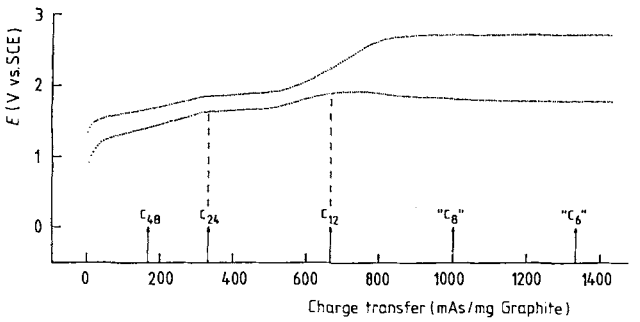

Fig. 13. Pulsed galvanostatic oxidation of a graphite foil in saturated $Bu_4NAsF_6/SO_2ClF$ (Sample *ca.* 7 × 7 × 0.2 mm; $I = 200\ \mu A$); top: current circuit open (in each case for 66 s); bottom: current circuit closed (in each case for 78 s).

The potential breaks close to $C_{24}^+$ (stage II, d = 1137 pm) and $C_{12}^+$ (stage I, d = 800 pm) corresponding to a stage sequence $C_{12\times s}$[240] can be seen; the irreversible oxidation beyond the point corresponding to $C_{12}^+$ leads to the formation of covalent C–F bonds. In this case, when no current is flowing, the potential decreases slightly as the degree of fluorination increases. This behavior is typical of covalent graphite fluorides $C_nF$[145,241].

*Bartlett et al.* have described the preparation of a "graphite salt" $C_8^+AsF_6^-$ *via* an oxidation of graphite with $O_2^+AsF_6^-$ in $SO_2ClF$[126,242,243]; however, the stoichiometry of $C_8^+$ does not agree with the potential curve shown in Figure 13. Hence, we believe that the products which have an analytical composition $C_8AsF_6$ also contain some non-ionic groups $C_nF \cdot AsF_5$ (cf. also [244]) and thus can be represented by the formula $C_{24}^{2+}F(AsF_5)(AsF_6^-)_2$.

Other $C_8^+$ compounds have also been postulated (*e.g.* in[126,245]) but the completely ionized state of these compounds has been questioned since the carbon atom can avoid a high "charge-transfer" (electrochemically it has a standard potential higher than +2 V) by forming covalent bonds. In contrast, the reaction of $AsF_5 + F_2$ with graphite has been shown to yield a stage sequence $C_{12\times s}$ similar to that produced during anodic oxidation[246]. $C_{12}^+$ salts have also been formulated with $CF_3SO_3^-$[247] and with a range of other anions[245,248,249].

The electrochemically prepared $C_nPF_6$ and $C_nAsF_6$ phases generally have relatively good degrees of crystallinity and thus well defined and reproducible inter-layer distances. On the other hand, the inter-layer distances reported for the compounds prepared from $O_2^+AsF_6^-$ or $AsF_5 + F_2$ are very variable (for stage I compounds: 810 pm for "$C_8AsF_6$"[242]; 786 pm for "$C_{8.1}AsF_6$"[245]; 804 pm for $C_{13.1}AsF_6$[245]).

### 3.6. Cathodic Intercalation of Graphite in Aprotic Electrolyte Solutions

The cathodic reduction of graphite in electrolyte solutions which are suitably stable against reduction[*] (*e.g.* alkali metal, $NR_4^+$- and $SR_3^+$-salts in ethers, esters, amides, sulfoxides *etc.*) always leads to solvated $M^+(solv)_yC_n^-$

[*] The standard potential of $A^+(solv)_yC_n^-$ phases of stage I is *ca.* −2 V and is thus about 1 V more positive than that of the alkali metals A.

phases. The unsolvated phases can, when desired, be obtained by removing the solvent *in vacuo*[250]. Analogous products containing doubly charged cations also exist (*e.g.* $Mg(HMPT)_{2.1}C_{130}$[251]; where HMPT = hexamethylphosphoric triamide). However, due to the limited solubility of most $M^{2+}$ salts in organic solvents it is only possible in a restricted number of cases to prepare these salts *via* cathodic intercalation.

The early work on the cathodic reduction of graphite in solutions of $NR_4^+$ and $K^+$ salts in liq. $NH_3$ demonstrated the formation only of the very unstable $NR_4^+(NH_3)_yC_n^-$[252,253] and $K^+(NH_3)_yC_n^-$[254] phases. In contrast, the DMSO-solvated phases $A^+(DMSO)_yC_n^-$ (where $A = Li^+$, $Na^+$, $K^+$, $Rb^+$ or $Cs^+$) and $NMe_4^+(DMSO)_yC_n^-$ (DMSO = dimethyl sulfoxide)[255-257] are considerably more stable. The relationship stoichiometry/stage for these phases has been determined from their *E*/charge curves. When $A^+ = K^+$, $Rb^+$ and $Cs^+$ and also for $NMe_4^+$ the limiting stoichiometry for stage I is around $C_{24}^-$ (1-phase region ± *ca.* 15%) and that for stage II at *ca.* $C_{48}^-$. When $A^+ = Li^+$ or $Na^+$ it is possible that the anion packing density is even greater[256]. In solvents which are poorer solvating agents than DMSO higher packing densities have been achieved (*e.g.* $Li^+(DME)_yC_{18}^-$ from the reduction of a graphite foil in $LiClO_4$/DME (DME = 1,2-dimethoxyethane[256]).

The reversibility of the electrochemical reduction of graphite in an $NMe_4^+$-electrolyte is corroborated by the evidence presented in Figure 14; on an inert electrode such as Pt the $NMe^+$ cation will be irreversibly reduced.

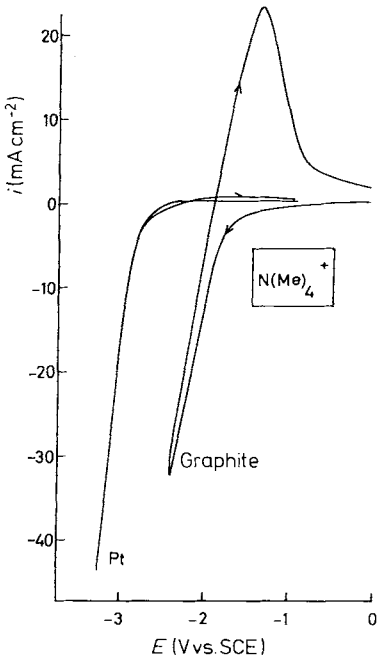

Fig. 14. Reduction/oxidation of graphite foil in saturated $NMe_4Cl$/DMSO, $v = 50$ mV $s^{-1}$; for comparison: an inert electrode under identical conditions.

Naturally, by varying the nature of $A^+$, $NR_4^+$ and/or the solvent a great variety of $M^+(solv)_yC_n^-$ phases can be electrochemically produced. The stability of these phases is in most cases questionable since, as is also the case for the $C_n^+(solv)_yX_n^-$ phases, the necessarily, strongly polar organic solvents are only *kinetically* stable relative to their reduction by the graphite compounds. The apparent stability of the "free" alkali metals in many of these solvents is simply due to a "passivating" surface layer (see *e.g.* [258-262]).

The stability of $M^+(solv)_yC_n^-$ phases can easily be checked by an electrochemical "back titration". Figure 15 shows the principle of this technique using the back oxidation of $K^+(DMSO)_yC_{24}^-$ and $Li^+(DME)_yC_{18}^-$ as examples. Here it can be seen that $K^+(DMSO)_yC_{24}^-$ can be back-oxidized with a charge yield of some 90% at *ca.* −2 V *vs.* SCE (*i.e.* reversible, close to the potential of formation), whereas the charge yield for $Li^+(DME)_yC_{18}^-$ is only about 60%, and at a potential of *ca.* +1 V *vs.* SCE the oxidation of decomposition products from the starting materials begins to take place. The phases $A^+(PC)_yC_n^-$ are extremely unstable[175,255,263].

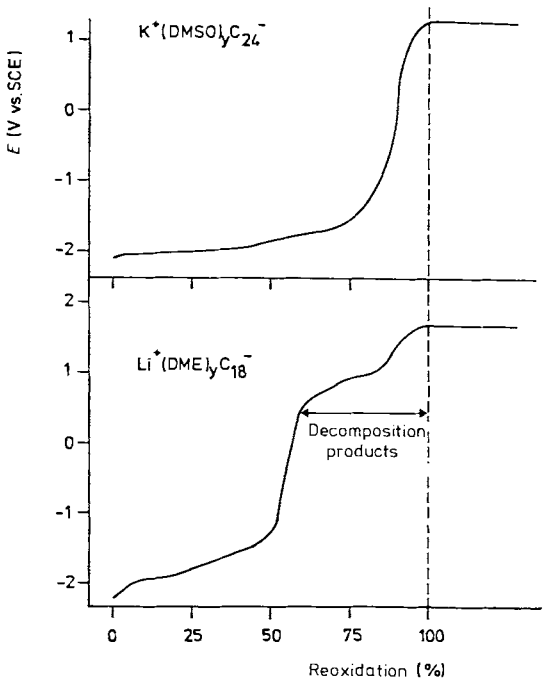

Fig. 15. Galvanostatic back oxidation of $K^+(DMSO)_yC_{24}^-$ and $Li^+(DME)_yC_{18}^-$, $I = 250$ μA·cm$^{-2}$; time scale: 100% back oxidation corresponds to 300 min, time required for sample preparation is also 300 min.

An alternative method for the preparation of solvated alkali metal-graphite compounds is by secondary solvation[264,265] of binary compounds prepared from the elements at higher temperature (*e.g.* [25,26,38,266,267]) or by A-transfer in unpolar media[268-270]. An additional alternative is the reduction of graphite in ethers in the presence of alkali metal salts of organic radical anions such as sodium dihydronaphthylide (*e.g.* [271,272], cf. also [256] and references therein) or in solutions of alkali metals in "electron solvating" solvents such as HMPT[273,274] or liq. $NH_3$ (*e.g.* [25-27, 266]). The chemical reduction of graphite in solution leads (depending on the solvent used) to formation of the corresponding ether-, HMPT-, or $NH_3$-solvated alkali metal-graphite.

Until now DMSO-solvated phases and $NR_4^+(solv)_yC_n^-$ phases have only been prepared electrochemically.

The DMSO-containing phases are three-dimensionally solvated and have especially large inter-layer distances; *e.g.* 1582 pm for stage I of $NMe_4^+(DMSO)_yC_n^-$ or 1493 pm for stage I of $K^+(DMSO)_yC_n^-$[257]. These inter-layer distances and an estimated volume (*i.e.*, the volume of the inter-layer gaps less the volume of the unsolvated cations ($NMe_4^+$ or $K^+$), where the remaining volume was assumed to be filled with DMSO whose density was taken to be equal to $DMSO_{liq}$) indicated, in each case, an approximately sixfold, octahedral coordination of the cations by DMSO[219]. However, this result is not in accordance with the findings of *Okuyama et al.*[275], who, on the basis of gravimetric experiments, report a degree of solvation of $y=3$ for $K^+(DMSO)_yC_n^-$. It is possible that various degrees of solvation exist for such phases, as also is the case for $K^+(THF)_yC_{24}^-$[264,276,277].

The electrochemical potential of $A^+(solv)_yC_n^-$ in terms of the alkali metal A are very dependent on the nature of the solvent; as the donicity[257] of the solvent decreases the electrochemical potential of $A^+(solv)_yC_n^-$ approaches that of the free alkali metal. The ionic character of solvated alkali metal-graphites is considerably better developed than that of the binary phases $AC_n$, as can be seen from their surprisingly high electrical conductivity. Furthermore, little $H_2$ is produced when such compounds react with water. The latter reaction has been used by *Bergbreiter* and *Killough*[278,279] as an ionicity indicator in accordance with equation (6a) or (6b).

$$A^{\oplus}C_n^{\ominus} + H_2O \longrightarrow AOH + H^{\oplus}C_n^{\ominus} \quad (6a)$$

$$AC_n + H_2O \longrightarrow AOH + C + 1/2\,H_2 \quad (6b)$$

### 3.7. Electrochemical Preparation and Analysis of Graphite Oxide

Graphite oxide (GO) is a rather nebulous term for C,H and O-containing compounds with a layer structure derived from their graphite precursor and *covalent* C–O bonds, which are formed by "overoxidation" of acidic graphite salts in the presence of water.

Overoxidation is taken to mean exceeding the maximum possible (ionic) charge transfer to the conjugated π-system; thus, overoxidation can then only lead to covalent oxidation products. The electrochemical potential at which overoxidation begins depends on the nature of the partner (nucleophile) available for the covalent bond. Thus, for example, the maximum possible (ionic) charge transfer to the carbon planes decreases with increasing water content for overoxidation in aqueous Brønsted acids[280]. The classical method for synthesizing GO is by the oxidation of graphite with strong oxidizing agents in Brønsted acids containing water; for example, in fuming $HNO_3 + KClO_3$[281,282], in $H_2SO_4 + HNO_3 + KClO_3$[282–284], or in $H_2SO_4 + NaNO_3 + KMnO_4$[282,285]. The mechanism of the reaction involves acid graphite salts as intermediates[286].

All the above methods yield a graphite oxide as end product which is no longer electrically conducting and has a high degree of oxidation. In the following discussion the degree of oxidation will be quoted in terms of oxidation equivalents per C atom.

Thus, graphite oxide with the idealized stoichiometry $C_8O_2(OH)$[287] has a degree of oxidation of 0.75. The dominating functional groups in GO are $>C=O$ and $\geqslant C-OH$[288]. Furthermore, it can be assumed that the C–C layers in GO are partially puckered ($sp^3$ hybridized carbon[289,290]) despite the fact that if keto-enol tautomerism is considered then it is possible to envisage a considerable degree of (covalent) oxidation without the formation of puckered structures[287,291].

To date very little is known about *electrochemically* produced GO (EGO) obtained from the anodic overoxidation of graphite in aqueous acids. The maximum degree of oxidation x of EGO is considerably lower than that obtainable for conventional GO ($x = \max.$ *ca.* 0.5)[41,190]. Further electrochemical oxidation is not possible due to the drastically reduced electrical conductivity. The formation of EGO from aqueous salt solutions[292] has also been reported. In many respects, the properties of EGO are very similar to those of GO; *e.g.* the interlayer distance *d* of washed and vacuum-dried preparations is *ca.* 650 pm (empirical formula: "$C_{4.6}O \cdot 0.75\,H_2O$", x *ca.* 0.43[293], starting material: graphite foil, oxidized in 70% $HClO_4$) as compared with $d = 590$–$670$ pm for conventional, chemically prepared samples[287]. In addition, both GO and EGO swell in similar ways in polar media. During intercrystalline swelling the inter-layer distances of EGO often expand more than 100%[41,294–296] (*e.g.* from 650 pm to 1000 pm in $H_2O$, to *ca.* 1150 pm in nitrobenzene, to *ca.* 1430 pm in PC and to *ca.* 1640 pm in pyridine).

On the basis of these similarities it seems reasonable to assume that EGO and GO differ essentially only in their degrees of oxidation. However, it is worth noting that in the region where EGO formation begins (the plateau marked by a in the lower part of Fig. 7 and by A in Fig. 16a), formation of acid salts $C_n(HX)_yX$ containing peroxysulfates has also been discussed[154,248,249].

A remarkable property of EGO is its ability to undergo back reduction to graphite with current and material yields of practically 100%. However, it should be noted that after such an oxidation/reduction cycle the graphite structure is considerably altered, whereas a similar cycle going only as far as the acid salt leads to little change in the original lattice. Nevertheless, the reversibility of the formation of EGO is interesting for energy storage. The formation of EGO is not, however, reversible in a thermodynamic sense, because the reduction of EGO occurs at a much more negative potential than the back oxidation (in 70% $HClO_4$ *ca.* +0.8 and +1.6 V *vs.* SCE, respectively), owing to considerable reaction overpotential. The gap between the "discharging" and "charging" processes widens with increasing dilution of the acid medium. In alkali media the reduction is irreversible[297]. The oxidation and reduction of a graphite foil is shown in Figures 16a and b. The oxidation up to the mark A in Figure 16a corresponds to an oxidation to the acid salt $C_n(HClO_4)_y(ClO_4)$ of stage I. The further oxidation, from A to B, corresponds to the formation of EGO[*]. Beyond B, $O_2$ development dominates.

[*] The properties of EGO still emersed in the acid medium in which it has been produced are, of course, not identical with those of washed and vacuum-dried material. Thus, for example, the inter-layer distance of EGO in acid media is almost the same as that in the acid salts of stage I.

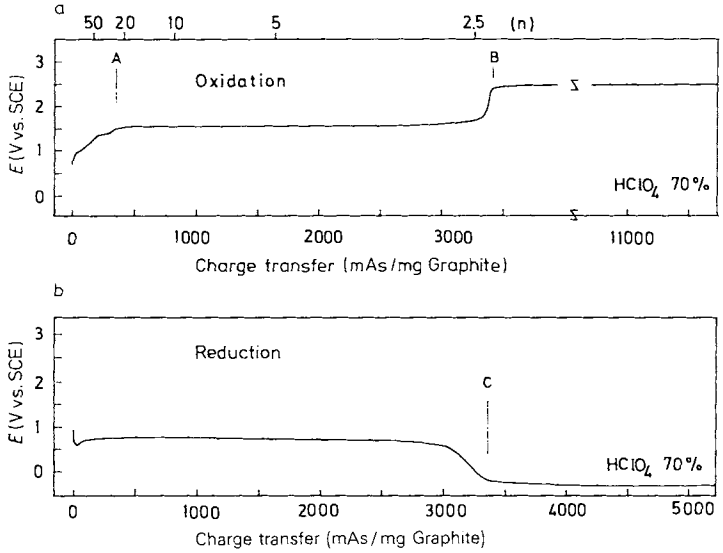

Fig. 16. Galvanostatic oxidation (a) and reduction (b) of graphite foil in 70% $HClO_4$, $I = 1$ mA cm$^{-2}$.

During the back reaction almost 100% of the charge equivalents used can be measured up to the point when $H_2$ starts to develop (mark C). This type of oxidation/reduction cycle is repeatable but the number of lattice defects accumulates and the conductance of the material continually decreases. In comparison to the intercalation of ions in graphite the formation of EGO is a relatively slow, *i.e.* kinetically unfavorable, electrode reaction. This can be qualitatively demonstrated in that the length of the plateau regions in Figures 16a and b decreases rapidly as the current density $i$ increases, whereas the "intercalation region" (start: A) is much less influenced by $i$[158].

Quantitative information on the kinetics of electrochemical reactions requires, in the first instance, a separation of the total polarization into its various components (cf. Section 3.2). The most effective method for this task is "impedance spectroscopy", in which the real and imaginary parts of the complex alternating current resistance of the working electrode is measured over as wide a range of frequencies as possible (*e.g.* [298–304]). Provided the situation is not too complicated, analysis of the data obtained permits an equivalent circuit diagram to be constructed in which the major components are: the electrolyte resistance $R_{EL}$, the "charge transfer resistance" $R_{CT}$, the double-layer capacity $C_{DL}$ and the "Warburg-impedance" $W$[*]. The essential parts of an equivalent circuit diagram which has often been used for describing electrode processes is given in Figure 17.

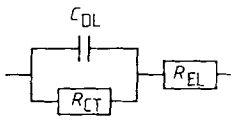

Fig. 17. A simplified equivalent circuit for the phase boundary electrode/electrolyte without diffusion effects being taken into account; $C_{DL}$ = capacity of the double layer, $R_{CT}$ = charge-transfer resistance, $R_{EL}$ = resistance of the electrolyte.

[*] $W$ is a difficult component to handle in terms of electronic calculations since it describes a complex resistance related to diffusion controlled reactions. In the following examples the experimental parameters have been so chosen as to make $W$ negligible.

The alternating current can flow across the working electrode/electrolyte phase boundary *via* a Faradayic reaction and/or *via* the double layer capacity $C_{DL}$. This arrangement corresponds to $C_{DL}$ and $R_{CT}$ being connected in the circuit in parallel. Furthermore, since the resistance of the electrolyte $R_{EL}$ (between the working and reference electrodes) cannot be eliminated experimentally it has to be included as a resistance in series. Since the double layer becomes "blocked" on measuring the resistance with an alternating current or voltage of the frequency $f \rightarrow 0$, the sum of the resistances $R_{EL} + R_{CT}$ can be obtained. For $f \rightarrow \infty$ the capacitive resistance $R_C = 1/\omega C \rightarrow 0$ and thus only $R_{EL}$ is measured. By varying the frequency $0 < f < \infty$ and plotting $R_{real}$ against $R_{imaginary}$ (= frequency response locus of the electrode impedance) a semicircle is obtained in Figure 17 for the equivalent circuit diagram, the diameter of which is equal to $R_{CT}$ (cf. Fig. 18).

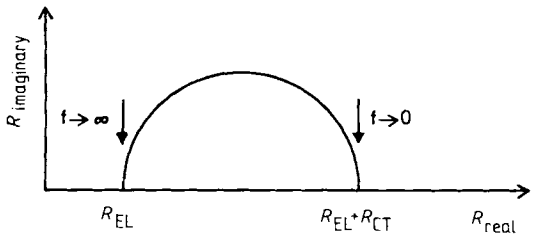

Fig. 18. Frequency response locus for the electrical impedance of the equivalent circuit in Figure 17.

Using impedance spectroscopy to monitor the anodic oxidation of graphite in aqueous acids the occasionally drastic changes in the resistance of the charge transfer reaction which coincide with the transition from simple intercalation to the formation of EGO and finally to the development of $O_2$ can be followed. For example, during the oxidation of HOPG in 96% $H_2SO_4$ (shown in Figure 19) it can be seen that towards the end of the period in which EGO is formed the value of $R_{CT}$ rapidly increases and finally achieves a very high value during the period when $O_2$ is produced.

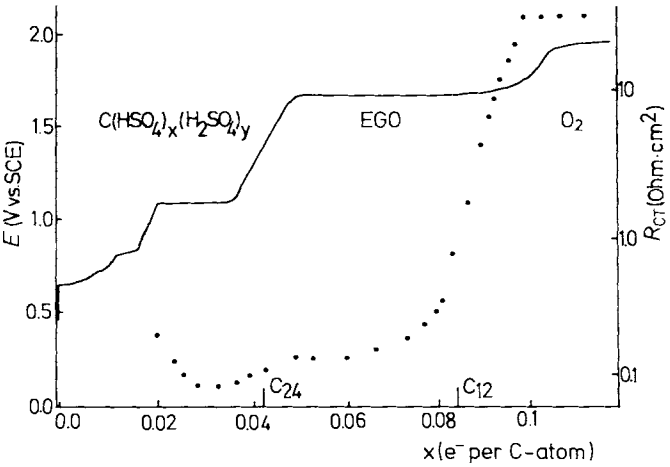

Fig. 19. Galvanostatic oxidation of HOPG in 96% $H_2SO_4$ (sample *ca.* 5 × 5 × 0.07 mm; $I = 100$ μA) with simultaneous measurement of the charge-transfer resistance $R_{CT}$ (frequency range 2.5 Hz–50 kHz; superimposed alternating current in the range 5–50 μA); the values of $R_{CT}$ are given solely on the basis of the prismatic areas.

In contrast the value of $R_{CT}$ is surprisingly low for the intercalation region. The values of about 0.1 Ohm·cm$^2$ calculated from $R_{CT}$ and the prismatic area of the HOPG electrode suggest that the electrochemical step of the intercalation reaction proceeds essentially uninhibited. The exchange current densities $i_0$ are, according to $i_0 = R \cdot T/n \cdot F \cdot R_{CT}$[139,305], in the region of 100 mA·cm$^{-2}$ (for comparison: $H_2$ on Pt in 1 N acid yields a value of $i_0 = 1$ mA·cm$^{-2}$ and Ag in $10^{-3}$ M $Ag^+$ yields a value of $i_0 = 150$ mA·cm$^{-2}$[139]).

The lack of any considerable barrier to the progress of the intercalation reaction is particularly remarkable in view of the considerable *deformation* of the carbon atom planes associated with the process. The transition zone from original to a more than 100% expanded inter-layer distance apparently travels as a "wave" through the lattice without requiring any significant activation energy. The limit to the intercalation reaction rate controlled by the diffusion of the guest species into the host lattice was not measured in these experiments. This limit is particularly noticeable in low frequency measurements and also when high current densities and long diffusion paths are involved. The diffusion coefficients $D$ of guest ions and molecules in laminar graphite compounds have been measured by a variety of different techniques. Although the absolute values recorded have a considerable spread, a value at room temperature of between $10^{-6}$ and $10^{-8}$ cm$^2$·s$^{-1}$ may be taken as standard (*e.g.* "$HNO_3$" in HOPG: $3.38 \times 10^{-6}$ cm$^2$ s$^{-1}$[306]; "$Br_2$" in HOPG: $2.45 \times 10^{-8}$ cm$^2$ s$^{-1}$[306]; $H_2SO_4^-$ in pyrolytic graphite: $9.75-13.6 \times 10^{-6}$ cm$^2$ s$^{-1}$[192]; anions in acid graphite salts: $10^{-7}-10^{-8}$ cm$^2$ s$^{-1}$[195,196,198,199]. The almost perfect semicircle produced from the measurements (Fig. 20) confirm that in this case the relatively simple equivalent circuit diagram without a diffusion related component is perfectly adequate.

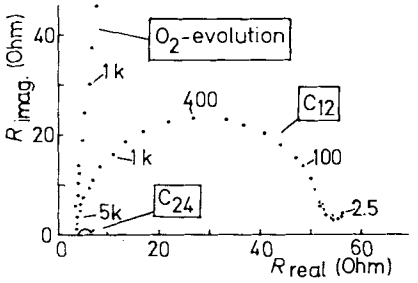

Fig. 20. Characteristic frequency response locus of the electrical impedance during the oxidation of HOPG in 96% $H_2SO_4$; the curves correspond to the three points in Figure 19 (at a stoichiometry of "$C_{24}$", "$C_{12}$" and during the development of $O_2$).

The experimental arrangement derived from the galvanostatic circuit (Fig. 4) used for such experiments is shown in Figure 21. In this arrangement the constant direct current is modulated with an alternating current of variable frequency. The resulting modulation of $E$ can then be analyzed in terms of both phase and amplitude (for a "frequency response analyzer" cf. [307,308]).

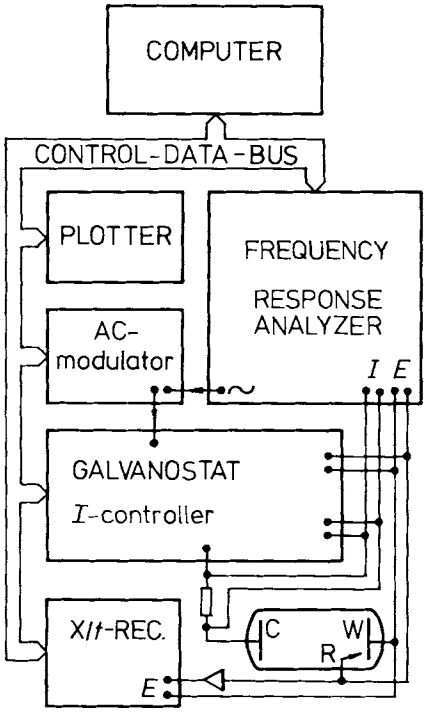

Fig. 21. Schematic diagram showing the experimental arrangement for impedance spectroscopy under galvanostatic conditions.

### 3.8. Electrochemical Intercalation as an Aid for the Characterization of Carbon Materials

The kinetics of intercalation reactions are partly dependent on the degree of order in the host lattice. At high concentrations of defects in the host lattice an influence on the thermodynamics of the process becomes noticeable. Thus, electrochemical measurements can be used as a method of *characterizing* the host lattice materials[153,309-311]. In the following discussion of the characterization of carbon fibers with varying degrees of crystallinity the example of "oxidation/reduction in $H_2SO_4$" will be used. Such fibers are, for example, produced from the graphitization of polyacrylonitrile or cellulose fibers and have proved particularly useful as reinforcing elements in composite materials[68,312]. It has already been shown (see Fig. 11) that the $E$/charge curves for carbon fibers have virtually no profile in comparison to those for HOPG. Naturally, this lack of profile also affects the cyclic voltammogram (cf. Fig. 22). Furthermore, the difference between the first and the second sweep is particularly remarkable.

When carbon with a low degree of order is intercalated for the *first time* a relatively high "additional" voltage is necessary[34,68,311,313-317]. This additional voltage is required, for example, in order to break up cross-links between the carbon planes. Thus, this "overvoltage" is thermodynamically and not kinetically controlled. Intercalation of graphite from the gas phase for the first time requires a corresponding "threshold" vapor pressure[318,319]. The second intercalation process for such materials takes place at essentially the same potential as for highly ordered materials (the arrows in Figure 23 mark the positions of the peaks corresponding to stages IV—I of an HOPG electrode under the same experimental conditions). It is in-

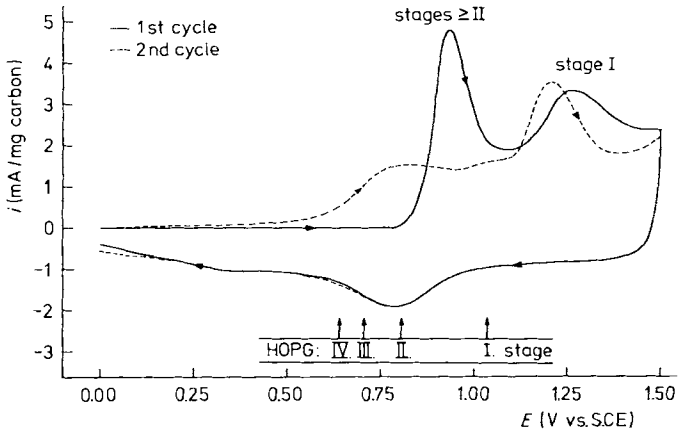

Fig. 22. Cyclic voltammogram (1st and 2nd cycles) of a highly orientated carbon fiber (Thornel 100, Union Carbide) in 96% $H_2SO_4$, $v = 5$ mV·s$^{-1}$.

teresting to note that the formation of higher stage $C_n(H_2SO_4)_yHSO_4$ phases is not observed during the first intercalation process: for example, with the carbon fiber Celion GY 70 only stages I and II were obtained. In contrast, after one complete intercalation/deintercalation cycle the higher stages can be synthesized. For the preparation of fiber-based intercalation compounds with either oxidation sensitive anions or reduction sensitive cations a "precycle" using more stable ions is often very useful[118]. The additional voltage necessary for the "first time" intercalation of carbon fibers can be used as a "crystallinity indicator". With decreasing crystallinity the additional voltage increases (cf. Fig. 23) until finally no intercalation takes place at all.

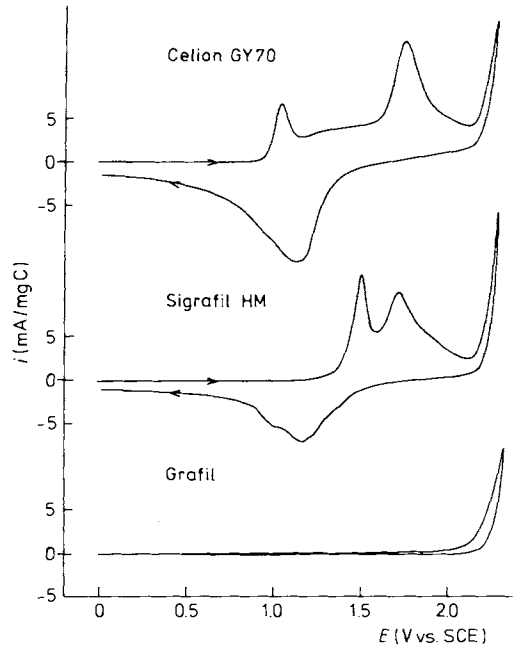

Fig. 23. Cyclic voltammograms (in each case the 1st cycle) of carbon fibers having different degrees of crystallinity (characterized for example by *Franklin*'s *p*-value [320], *Young*'s modulus $E$ [N m$^{-2}$] and 001-linewidth $b$ [degree $2\theta$]); in 96% $H_2SO_4$, $v = 5$ mV·s$^{-1}$:
Celion GY 70: $p = 0.731$, $b = 0.70$, $E = 5.2 \times 10^{11}$;
Sigrafil HM: $p = 0.940$, $b = 1.55$, $E = 3.5 \times 10^{11}$;
Grafil: $p = (1.886)$, $b = (3.50)$, $E = 2.4 \times 10^{11}$.

In contrast, the potential required for the preparation of EGO is practically independent of the nature of the graphite starting material since the breaking of any cross-links present has already occurred during the formation of the acid salts. Other electrochemical parameters can also be used for the characterization of carbon materials; *e.g.* the completeness of the galvanostatic deintercalation (HOPG, in contrast to less ordered materials, can be almost quantitatively deintercalated). Of course, these "electrochemical parameters", which in some cases are very easy to measure, can be correlated with structural parameters such as the mean inter-layer distance, the 001 line width, *Franklin*'s p-values *etc.*[320], as well as the modulus of elasticity and the electrical conductance[311].

## 4. Surface Electrochemistry of Black Carbons

### 4.1. Basic Information

The anisotropic character of carbon having a layered structure makes itself particularly noticeable in terms of the electrochemical properties of the material. Thus, the double layer capacities $C_{DL}$ of the basal planes are around 3 μF·cm$^{-2}$, although those of the prismatic planes are generally >50 μF·cm$^{-2}$[70]. However, it must be remembered that the plane edges do not end at the prismatic planes with "dangling bonds" but rather that they are saturated with heteroatoms—in aqueous solutions generally with oxygen containing species. These "surface oxides" have already been thoroughly reviewed[58-61,70]. In aqueous electrolyte solutions only the "acid surface oxides" are important; essentially these are composed of carboxyl groups, alcoholic and phenolic hydroxyl groups, and quinones. Additionally, keto-enol tautomerism and the formation of lactones must also be considered[59,60,321-323].

Electrochemical methods such as the polarography of carbon suspensions (*e.g.* [71,324-327]) and, in particular, the cyclic voltammetry of carbon electrodes can also be used for studying the surface oxides. However, electrochemical analysis has proved useful almost solely for the identification of quinonoid groups in various environments. In contrast, monitoring the reduction of the other (difficultly reducible) groups is a difficult task—at least in aqueous solution. This difficulty is due partly to the production of $H_2$ which occurs as a side reaction and partly to the slow kinetics associated with these reactions. The latter lead, for example, to the peak potential of the cyclic voltammograms being very dependent on the scan rate $v$.

Finally, it should be noted that there is a difference between the surface oxides and GO or EGO: GO and EGO have their O functionalities between the carbon planes, whereas in the surface oxides they are only found at plane edges or in lattice defects on the basal planes. Electrochemically, GO and EGO have very different reduction behavior to that of the surface oxides: whereas the reduction of EGO in strongly acid media is close to its formation potential (*e.g.* according to the upper and middle curves in Fig. 23, in 96% $H_2SO_4$ *ca.* +1.25 V *vs* SCE or +1.5 V *vs* $H_2$ and thus corresponding to a very strong oxidizing agent) and is thus *quasireversible*, the surface oxides, except for a relatively small number of quinonoid groups,

are reduced *irreversibily*, close to the potential at which $H_2$ starts to be produced. Thus, the reduction of the surface oxides is similar to that of other organic molecules with the same functional groups.

The surface oxides are of decisive importance in many technical applications of carbon, and particularly of active charcoal[333] or carbon black[334], for example in absorbents, fillers for rubber and other polymeric materials[334–336], and printing inks *etc.* More recently, surface oxides have received considerable attention from electrochemists who have employed them as "anchor groups" for the irreversible coating of electrode surfaces with specific reactive compounds. In contrast, basal planes can only be coated *via* adsorption and thus by reversible processes. Since electrode reactions are heterogeneous processes their rates and also the product ratios produced can be dramatically changed by using such "chemically modified" electrodes.

### 4.2. Chemically Modified Carbon Electrodes

The term modification of electrode surfaces means the intentional coating of such surfaces with foreign molecules[337]. *Miller et al.*[338] were the first to attach optically active amino acids to the surface of a graphite electrode. Somewhat later it became obvious that the basal plane and the layer edge surfaces of pyrolytically prepared graphite have very different reactivities with respect to modification.

The formation of covalent linkages occurs preferentially at the layer edges[339,340] whereas physical adsorption occurs on both basal and prismatic planes, although smaller background currents have been observed for the basal planes[341].

Since this general topic has already been covered by several comprehensive articles[71–73,342] only a discussion of the more recent literature and a brief description of the experimental techniques will be given here. The production of modified electrodes or the immobilizing of foreign molecules on the surface of electrodes takes place in several stages. Particularly important is the preparation of the carbon surface. If the modification is to occur *via* an adsorption then the oxygen-containing species must generally be removed as completely as possible. Where the modification involves the formation of covalent bonds the first stage is generally an oxidation or reduction process and a bridging group is then attached to the surface before the desired substrate is finally attached to the bridging groups.

Cleaning of the graphite surface is commonly carried out by polishing the surface or in an argon plasma[343]; a suitable apparatus has recently been described[344]. The reduction of the carbon surface is either achieved chemically with, for example, $LiAlH_4$ (the carboxyl groups are converted into hydroxyl groups by such a process) or electrochemically[345] (whereby subsequent reaction with nucleophiles is made possible). Oxidation of the carbon surface can be achieved chemically (*e.g.* with $KMnO_4$[346], NaOCl[58] or $O_2$ at high temperature[338]), electrochemically (*e.g.* by anodic oxidation in $H_2SO_4$ or $HNO_3$[347]), or physically (*i.e.* in an RF-oxygen plasma[348,349]). The plasma process allows the production of a larger number of functional groups on the surface and thus of more "anchoring sites" than can be achieved by conventional electrochemical processes[349]. The oxidized or reduced electrode surfaces are generally coated with an "anchoring group" before the actual effective material is applied. Typical anchoring groups are provided for example by the reaction of thionyl chloride[338,347] and acetyl chloride[350] with the HOOC-groups on the electrode surface. Other examples are the often used reaction of cyanuric chloride with the surface HO-groups[349,351–355], the reaction of phenolic groups with iminodiacetic acid[346], or the silanization technique, which is commonly used for metal electrodes and has been applied to carbon electrodes by *Murray et al.*[356]. Where necessary, a pre-reduction can be carried out to convert the HOOC- surface-groups into $HO-CH_2$-groups, which can then be coupled with the desired reagent. Where no achoring group is used, the transition between covalent bonding and chemical or physical adsorption becomes more difficult to define. An early paper which deserves explicit mention is one which describes the coupling of olefins to an "oxide-free" carbon surface[357]. In the reviews already published[71–73,342] there are many references to the utility of this principle.

Closely related to this technique is the adsorption of polymeric material onto electrode surfaces. Vinyl compounds such as 4-vinylpyridine[71] or vinylferrocene (*e.g.* [358]) have often been used to produce such polymeric materials. Further examples of polymers which have been utilized for electrode coating are polyacrylic acid[359], quinonoid polymers[360] and poly(xyleneviologen)[361]. More and more commonly, papers are published in which the polymers are used simply as an embedding medium for redox systems. In addition to the information given in [71–73,342], the coordination of Ru(III)(edta) in or on layers of poly(4-vinylpyridine) on transparent graphite electrodes (prepared by depositing carbon onto a quartz support from the gas phase[362]) and the compounds formed from cyano complexes of Mo, W and Fe[363,364] or of $(Ru(bipy)_3)^{2+}$[365] on polymers are worth mentioning. In the latter example the graphite electrode so coated is described as part of a photogalvanic cell.

A possible application for graphite electrodes coated with redox polymers is for the deionization of water[366,367]. In water softening processes multiply charged cations are cathodically preferentially deposited.

To regenerate these preparations the polarity of the "cationic and anionic absorbants" are simply reversed. A glass-carbon-electrode coated with Berlin Blue has been used spectroelectrochemically[368]. Iron-porphyrin, also coated onto a glass-carbon electrode, has been used for the reduction of $O_2$; it is interesting to note that effective reduction is only observed when the Fe-porphyrin units are orientated flat on the electrode surfaces and not when they are perpendicular to the surface[369]. Electrocatalytic effects have been observed with graphite electrodes coated with metal phthalocyanines of Fe, Co, Ni and Cu[370,371]; in the case of the iron compound such electrodes have also been used for studying adsorbed species *via* Mössbauer spectroscopy[372]. An example of a biochemical application of these electrodes is that of the immobilization of flavoen-

zymes on the surface of a cyanuric chloride modified graphite electrode[334]; the reduction of FAD demonstrated that a direct electron transfer between the enzyme and the electrode had taken place.

Although modified carbon electrodes have been shown to have many uses with respect to both electroanalytical and kinetic studies, this is not the case regarding electrosynthetic applications.

In the first report of a modified graphite electrode *Miller*[338] used a "chiral" electrode for synthesizing an optically active alcohol *via* a cathodic reduction of a ketone. The results are, however, in disagreement with the analogous experiments of *Horner* and *Brich*[347]. More recently, an assymmetric reduction of prochiral active olefins at a poly-l-valine coated electrode has been described for the first time. Yields of optically active materials of 23 and 43% were obtained[373]. It is possible that the lack of examples regarding the use of coated electrodes for electrosynthesis is due to the unsatisfactory stability of such coatings. In the case of the polymer coated electrodes in particular, swelling in the electrolyte solution is observed and, in the adsorbed species, even a leaching of some of the redox reagents is found to take place. Thus, it is important that developments on modified carbon electrodes concentrate not only on surface modifications but also on modifications within the electrode material itself.

### 4.3. Surface Oxides and Three-Dimensionally Distributed "Defect Oxides"

The classical techniques already described in Section 4.2 for the surface oxidation of carbon and the anodic oxidation in dilute, aqueous electrolyte solutions cannot be employed for attack at intact basal planes of graphitic carbon[374]. Extending the length of the oxidation reaction time or making the conditions more drastic (*e.g.* $H_3PO_4$ at 135 °C[375] or hydrogen sulfate in the molten state at 180–320 °C[376]) only lead to a complete disintegration of the starting material (mainly to $CO_2$), which begins at the layer edges. In an attempt to hinder the disintegration of the electrode material industrial carbon anodes have been impregnated for example with oil or pitch (*e.g.* [377] and extensive patent literature); this seals off the pores, which, because of their poor accessibility have little effect on the desired electrode reaction, but present a large surface area for corrosive attack.

Since it is generally the basal planes which are most exposed on a carbon electrode it is important, for example, that the basal planes are also functionalized for efficient surface modification. Such basal plane modification is possible to a limited extent by a two stage process in which EGO is synthesized (cf. Section 3.7) and then reduced back to "graphite".

The "graphite" obtained from the reduction of EGO is characterized by a high concentration of lattice defects. C–C bonds which are broken during the formation of EGO are only partially re-formed during the reduction process. The number of these "irreversible" defects can be greatly increased by successive formation and reduction of EGO[378].

The electrochemical introduction of lattice defects is relatively easy, and because of the characteristic reaction potentials of the defects the process can even be followed almost quantitatively. This is exemplified in Figure 24, which shows the fifth cycle (−0.7 to +2.1 V *vs* SCE) of the oxidation/reduction of a highly orientated carbon fiber (Celion GY 70) in 96% $H_2SO_4$; a first cycle under essentially the same experimental conditions is shown in the top part of Figure 23.

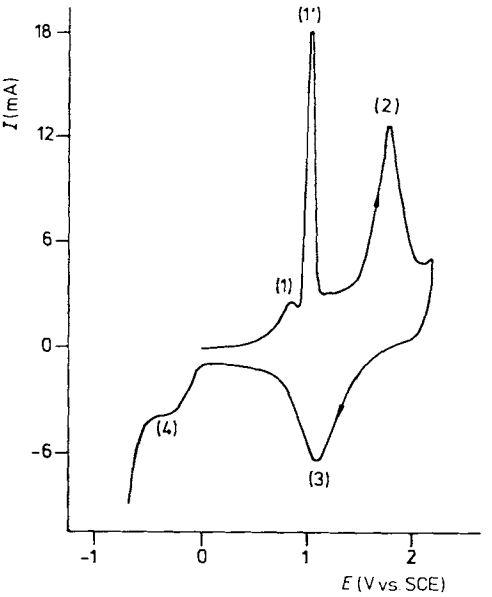

Fig. 24. Cyclic voltammogram (5th cycle) of carbon fibers (Celion GY 70) in 96% $H_2SO_4$, $v = 2.5$ mV·s$^{-1}$, $F$(geom) = *ca.* 0.7 cm$^2$ (for an explanation of the points 1–4 see text).

The peaks (1), (2) and (3) correspond, similarly[*] to the peaks in the first cycle, to the formation of acid salts $C_n(H_2SO_4)_yHSO_4$, EGO and the back reduction of this product to "graphite", respectively. The 3rd peak is only poorly resolved in this fifth cycle. The (1′) peak which was not yet visible in the first oxidation half-cycle corresponds to the oxidation at defect sites left over from the reduction of EGO. "Peak" (4) correlates with peak (1′) and represents the kinetically very slow reduction of the oxidation products arising during the progress of peak (1′). The areas of peaks (1′) and (4) grow rapidly as the number of completed cycles increases, whereas those of peaks (2) and (3) grow only slowly. However, after five completed cycles the electrical conductivity and the mechanical stability of the fiber electrode are rapidly lost. If this "cyclic treatment" is constrained within the potentials −0.7 and +1.2 V, thus avoiding any renewed formation and back reduction of EGO, then the areas and shapes of peaks (1′) and (4) remain constant.

Assuming that one-electron processes are involved, it can be calculated from the areas of peaks (1′) and (4) that *ca.* 15% of the C atoms are in the form of reactive defects and are thus functionalized or functionalizable. Such a high percentage of active sites excludes the possibility of their interpretation as "surface oxides at the layer edges".

[*] Compared with the first cycle, the formation of $C_n(H_2SO_4)_yHSO_4$ begins in the fifth cycle at less positive potentials (cf. Fig. 23).

Nevertheless, the potential range of the reduction "peaks" (4) lies in exactly the same place at which surface oxides are typically, at least in part, reduced (cf. Section 4.4). Thus, it can be assumed that at least the functional groups involved are very similar to those of the surface oxides[*]. Certainly, in these very disturbed carbon lattices it is not only the layer edges which are oxidizable but rather the lattice defects generally, so that analogous to the "surface oxides" it is better to call these products "defect oxides". A variety of technical applications for the defect oxides of black carbon can be envisaged (cf. Section 5). They are relatively good electrical conductors[**], and at the same time they are highly functionalized on the basal planes, on the plane edges, and within the material itself. Similar reactions can be carried out on defect oxides as on surface oxides; they can be "chemically modified" in the same way as for −C−OH groups with, for example, Cl−$SiMe_3$[379]. In this way a higher grade of modification can be obtained than can be produced from conventional surface oxide starting materials. This has been demonstrated using the example of the reduction of *o*-nitrophenol adsorbed onto a trimethylsilylated carbon fiber electrode. For the conventional fibers (*i.e.* having only the surface oxides at the layer edges) the silylable proportion of the total surface area and thus the amount of adsorbed *o*-nitrophenol was low, whereas the electrodes based on defect oxide fibers adsorbed so much *o*-nitrophenol that it must be assumed that not only the basal plane but also defects within the electrode had undergone silylation[379].

### 4.4. Surface Fluorides

The electrochemical surface oxidation of carbon is not restricted to the synthesis of surface oxides. Carbon anodes in fluoride melts have been, for example, considerably fluorinated; in this process "graphite fluorides" develop[30,38,45,241,380,381] which form poorly conducting surface layers. This phenomenon ("anode effect"[382–385], which is a considerable technical problem (for example in the production of Al), as well as the general behavior of carbon anodes in fluoride melts have been widely studied (cf. the review[386] and also, *e.g.* [387–391]). The fluorination of electrodes has also been used as a means of protecting the electrodes against corrosion[392]. An electrochemical synthesis of graphite fluorides $(CF_x)_n$ analogous to the formation of graphite salts (Eq. 1b) is not possible; because of its covalent character, $(CF_x)_n$ is not a mixed conductor. The only report of such a process is that of an indirect electrochemical production of $(CF_x)_n$ *via* the attack of $F^-$ on $C_n^+(solv)_yX^-$ in accordance with the following equation[145]:

$$C_n^{\oplus}(solv)_yX^{\ominus} + F^{\ominus} \longrightarrow C_nF + y\,solv + X^{\ominus} \quad (7)$$

[*] ESCA measurements (C 1s and O 1s) of *R. Schlögl* (Universität München) on carbon fibers which were removed from the electrolyte solution and washed with water after a single oxidation/reduction cycle at 0 V *vs* SCE (*i.e.* before the reduction (4)) showed the presence of many ≥C−O− groups and only a few >C=O groups.

[**] Due to considerable perturbation of the structure of the carbon planes a drastic drop in the electrical conductivity is to be expected. This effect is compensated, and sometimes overcompensated, by an increase in the electrical conductance following an increase in the concentration of the defect electrons in the valence band as a consequence of the oxidation. The resulting conductivity of defect oxides is generally some 100% more than that of the starting material [41, 118].

### 4.5. Electrochemical Surface Oxidation of Carbon Fibers

Because of their excellent mechanical properties in relation to weight, carbon fibers[1–3,393–395] are finding increasing application in high grade fiber/polymer composites. The quality of composite materials is often limited by the unsatisfactory anchorage of the fibers to the polymerizate, *i.e.* the strength of the fibers cannot be fully utilized. The anchoring of the fibers within the polymer matrix is to some extent purely mechanical (determined by surface roughness[396–398]), but by and large it is of a chemical nature: surface groups (generally surface oxides) *react* during the polymerization for example with an epoxide phenol or an amine component[62–64,66,399–401]. Thus, an improvement in the anchorage of fibers to the polymer matrix has the prerequisite that the surface functionality of the fiber is optimal. The surface oxidation of carbon fibers can also be carried out both in the gas phase (*e.g.* $O_2$[62–66,68], $O_3$[396,402]) and in solution (*e.g.* with $Ce^{4+}$, $HNO_3$[62–66,68]) as well as anodically[403–406].

The type of surface oxide produced generally depends on the method of oxidation[407]. Thus, for example, the oxidation with $HNO_3$ yields more carbonyl groups than does the oxidation with air[408–410]. Furthermore, the −COOH group is well suited as an anchorage site, whereas the surface oxides obtained from the oxidation with $O_3$ are, for example, not so good[396]. Following the electrochemical surface oxidation of carbon fibers ESCA measurements have demonstrated the presence of −COOH, >C=O, and ≥COH groups[406]. Electrochemical surface oxidation is a process which can be carried out quite easily (similarly to the surface oxidation of glassy carbon[322,411]) on fibers with low degrees of crystallinity and consequently a high concentration of lattice defects which are *not possible* to intercalate (cf. Fig. 23, lower part). In principle, the yield of surface oxides can be determined electrochemically (cf. Fig. 25); however, the carboxyl groups, in particular, would probably be very difficult to reduce since $HNO_3$-oxidized and, consequently, carboxyl-rich fibers exhibit only a small amount of cathodically reducible surface oxides, despite the fact that thermogravimetric analysis indicates a considerable degree of surface oxidation[412–414].

The "roughening" of the surface by oxidation can be measured not only by the BET method but also by measuring the capacity of the double layer[415–417]. In the case of "Grafil" fibers (for data see Fig. 23) an increase by a factor of 15 or 250 (measured at the potential at which $H_2$ develops) has been observed[414] after electrochemical preoxidation (corresponding to Fig. 25, 1 or 10 min, respectively, with 10 mA/mg fiber in 0.5 M $H_2SO_4$) and subsequent reduction (10 min at the $H_2$ potential)[*]. Comparable values can only be obtained in refluxing 65% $HNO_3$ after very long reaction times (a factor 30 after 34 h or a factor 150 after 72 h). Furthermore, the fibers lose much of their mechanical strength after 72 h of $HNO_3$-treatment, whereas

[*] The considerable increase in the capacity of the double layer cannot simply be attributed to an increase in the surface area, since it is probable that the capacity of the double layers at basal and prismatic planes are very different and, thus, lattice defects in the basal planes greatly increase their double layer capacities. SEM photographs (magnification × 10000) show a surprisingly low degree of "roughening" of the fiber surface after oxidation.

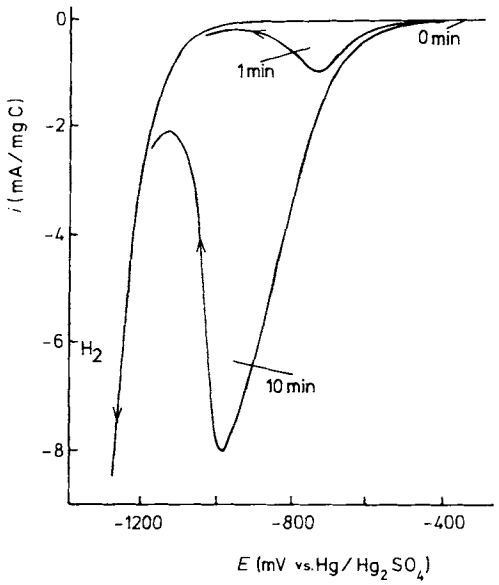

Fig. 25. $I \cdot R$-corrected voltammogram of the reduction of surface oxides on Grafil fibers (for data see Fig. 23) in 0.5 M $H_2SO_4$ ($O_2$ free), $v \approx 5$ mV·s$^{-1}$; the minutes given refer to the duration of the previous oxidation in 0.5 M $H_2SO_4$ at 10 mA/mg fiber.—$I \cdot R$ correction: The resistance $R$ between the reference and working electrodes leads, when current flows, to a voltage drop $I \cdot R$, which in turn leads to a corresponding error in the potential curve. With small currents and when $R$ is constant such errors could be accepted but due to disintegration of the covering layer $R$ is expected to vary so that a correction for $R$ is necessary. This is possible by simultaneously measuring the impedance at high frequencies (in this case 20 Hz) which essentially measures only the electrolytic resistance and that of the covering layer (cf. Fig. 17 and 18). The resulting value of $R$ is multiplied by $I$ and the voltage drop $I \cdot R$ automatically added to the desired voltage signal.

on anodic oxidation the mechanical strength of the material remains essentially intact[414].

In contrast to fibers of low crystallinity, those of *highly oriented,* graphitic carbon are very difficult to surface oxidize, both by chemical and electrochemical techniques. This is because the number of C-atoms along the layer edges and the number of lattice defects are much lower in the latter; this can be demonstrated, for example, by BET surface area measurements or by titration or electrochemical reduction of the surface oxides. In addition, the highly orientated fibers, and particularly those derived from PAN (PAN = polyacrylonitrile), have an "onion skin" morphology at their surfaces, *i.e.* mainly basal planes are exposed[66,418]. Because of the problems associated with intercalation, such as loss of mechanical strength, the more drastic oxidation techniques (roughly speaking those which lead to graphite oxide formation) cannot be used. Thus, the technique described in Section 4.3 for the functionalization of basal planes cannot be used since it involves a considerable degree of intercalation into the fibers with a corresponding deterioration in their physical properties.

An alternative technique commonly employed, at least on a laboratory scale, is an electrochemical surface treatment analogous to that described in Section 4.3 for the preparation of 3-dimensionally distributed defect oxides by cycling, for example in 96% $H_2SO_4$, between $-0.7$ and $+2.1$ V *vs* SCE (cf. Fig. 24). However, since highly orientated carbon fibers with a typical diameter of 5—10 μm are almost quantitatively intercalated within a few seconds[118] it is obvious that potentials close to $+2.1$ V can only be applied for a very short time. The best results are obtained using a "cycling frequency" of about 50 Hz, since with much higher frequencies the major effect of an alternating current is a continuous reversal of the charge at the double layer, and with lower frequencies the risk of intercalation within the fibers increases. "Cyclization" of Celion GY 70 fibers in 96% $H_2SO_4$ (20 s of cycling treatment, 50 Hz, $-1.4$ to $+2.1$ V *vs* SCE) produced *ca.* 2.5 mAs/mg of electrochemically reducible oxides without any noticeable intercalation as measured by X-ray analysis and electrical conductance[414].

Nevertheless, the high oxide coverage of fibers with a low degree of crystallinity (the "10 min" curve in Figure 25 corresponds to *ca.* 400 mAs/mg) cannot be achieved for the highly orientated material.

Particularly worthy of note is that very little surface oxidation takes place when graphite fibers are cyclically treated at 50 Hz in electrolyte solutions in which no intercalation is possible (for example in dilute acids or $H_3PO_4$), suggesting a mechanism which involves primary intercalation (cf. also [419]).

## 5. Possible Applications

Electrochemical reactions involving black carbon materials often produce electron conducting materials with very unusual properties. Thus, considerable attention has been paid to the possible industrial applications of such materials. Indeed, there are a great number of ideas for applications but, apart from a few exceptions, these ideas have not been realized.

The subject of general applications[41] and of specific applications with special reference to electrochemical energy sources[420] have been reviewed recently, so this Section will be limited to a brief discussion of the major points.

### 5.1. Electrochemical Energy Sources

"Graphite fluoride" $(CF_x)_n$ with a degree of fluorination $x < 1$ has been used as the positive electrode in lithium batteries with organic electrolytes (*e.g.* [41,241,420–427]). The working voltage of these batteries is close to 2.8 V and the theoretical energy content is about 2190 Wh·kg$^{-1}$[427]; the practical energy content of commercial cells (Matsushita National-Panasonic) is about 300 Wh·kg$^{-1}$. The discharging reaction does not yield simply $LiF + C_n$, but rather a ternary compound $Li^+[(CF_x)_n]^-$[241,426,428–430]. Teflon[431], chlorinated C-polymers[432], chlorinated graphite[433], and chlorinated amorphous carbon[434] have all been suggested as positive electrode materials for Li-batteries.

Graphite oxide (GO) attracted attention at a very early date as potential substitute for $MnO_2$ in Leclanché cells; for this application *Brown* and *Storey* used a material prepared by electrochemical oxidation in dilute $HNO_3$[435,436]. Like $(CF_x)_n$, GO and EGO can also be reduced in organic Li-containing electrolytes[41,420,437–439] but, as in the case of polar electrolyte solutions, the swelling of the electrodes creates some problems[41].

Many other graphite compounds such as the metal halide-graphites, *e.g.* "$FeCl_3$-graphite", have also been discussed as positive electrode materials for Li-batteries[433,440-445] without any clear advantages becoming obvious. Because of the sensitivity of the electrolyte solutions to oxidation, rechargeable batteries on the basis of Eq. (5) in Section 3.5 are almost unrealizable. $LiC_n$ in combination with a polymeric electrolyte has been suggested as a material for negative electrodes[107]. An interesting thermogalvanic cell has been put forward by *Lalancette*[446], and improved versions were later reported by *Endo et al.*[447] and other workers[448,449]. This cell is composed of two electrodes of unequal concentrations, made, for example, from "$Br_2$-graphite" or "$HNO_3$-graphite". Such cells can be continually or discontinually regenerated by applying a temperature gradient.

*Flandrois* has suggested nickel-cadmium accumulators with modified Ni-electrodes; these yield very finely distributed $Ni(OH)_2$ or NiOOH and graphite as products from the "$NiCl_2$-graphite" starting material[420,450,451].

### 5.2. Electron Conducting Ion Exchangers

Graphite oxide[41,287,290,452] and also "defect oxides" (cf. Section 4.3) have a notable cation-exchange capacity which remains after the reduction of the quasireversibly reducible portion[41]. This exchange property, on an *electrically conducting* support, allows them to be used for example, for the production of highly dispersed noble metal coatings on carbon materials (an exchange of the noble metals is achieved by subsequent chemical or electrochemical reduction[41,453,454]). Accumulators[455] with electrodes composed of ion-exchanging carbon felt have also been suggested.

### 5.3. Roughening of Carbon Electrodes

Carbon electrodes can be roughened by electrochemical oxidation. This effect has already been discussed for the surface oxidation of carbon fibers and is of particular importance for electrochemical analysis *at* carbon electrodes[456], mainly because polarization effects are thus reduced (the electrodes in this context are mostly composed of glassy carbon[1-4]). There are many examples in the literature for such roughening procedures and for the uses of the electrodes produced (*e.g.* [457-459]). Recently, a material with comparable surface roughness ("reticulated vitreous carbon") has become commercially available[460].

### 5.4. Graphite Compounds as Intermediates in Electrochemical Syntheses

Lamellar graphite compounds formed in accordance with equations (1a, b) or (2a, b) are strong reducing or oxidizing agents, respectively, which can undergo a secondary reaction with a component of the electrolyte solution to yield "graphite" (EC-mechanism; an *e*lectrochemical reaction proceeds a *c*hemical reaction). Since electrochemical intercalation reactions are generally "fast" and, for example, the conversion of many organic compounds at the electrode surface are kinetically slow, the electrochemical reductions or oxidations occur considerably faster *via* a graphite intermediate than by the direct process at inert electrodes.

Although not very useful, an example of such a process is the reduction of propylene carbonate (PC) to propene with, for example, $LiClO_4$ as supporting electrolyte: at the inert electrode, Li metal is essentially the sole product, whereas at the graphite electrode, propene is formed with a current yield of almost 100%[263,461]. The primary electrochemical product in the process is $Li^+(PC)_yC_n^-$[255,263]. The instability of solvated graphite compounds with respect to self decomposition suggest that this reaction pathway is of general importance.

The secondary reactions of the phases $NR_4^+(solv)_yC_n^-$, $PR_4^+(solv)C_n^-$, $SR_3^+(solv)_yC_n^-$ have been studied on numerous occasions[345,462-465]. In these reactions it is possible to obtain surface modified carbon electrodes (*e.g.* polycarboxylated or polybutylated[345]) *via* a complex reaction with electrophiles.

### 5.5. Other Applications

In addition to the more general areas of application which have been described above several more specific areas of application for electrochemical reactions of black carbon have been proposed. Thus, for example, electrochromic displays have been described[466,467] using the reversible color change associated with the formation of $A^+(DMSO)_yC_n^-$.

A new modification of carbon, which presumably involves an sp-hybridized C-chain, can be produced by the electrochemical reduction of polytetrafluoroethylene (PTFE) in, for example, $NBu_4BF_4$/dimethyl formamide[468]. The chemical reduction of PTFE (for example, with Na in $NH_{3(liq)}$ or with Li-amalgam[469-473]) yields identical products and, indeed, an electrochemical mechanism has been demonstrated for the reduction using $Li_xHg$[469,474,475]. At the "dry" contact, $Li_xHg$/PTFE, a local element is formed, and the necessary charge transport is achieved by $Li^+$ ions in the solid phase.

PTFE has been widely used as the hydrophobic component in gas diffusion electrodes (for fuel cells) (*e.g.* [81,476]); more recent experiments suggest that graphite fluoride is particularly suitable for this purpose[477].

For studying the electrical conductivity of ionic graphite compounds[*] an electrochemical preparation has proved especially suitable[148, 150, 154, 215, 248, 257, 479-481] because the "chemical charge-transfer" (*not* the ionicity) can be easily varied. The measurement of the conductivity of intercalated carbon fibers can even be carried out *in situ, i.e.* in the electrolyte solution, since the "electrolytic short circuit" can be negligible in comparison to the high electrical conductivity. The bottom half of Figure 26 shows such a conductivity trace that was measured concomitantly with a cyclic voltammogram[118,439].

[*] Graphite is an intrinsic semiconductor whose valence and conduction bands approximately overlap (*e.g.* [27, 71]. The reduction or oxidation of graphite leads to a considerable increase in the number of electrons in the conduction band or the number of defect electrons in the valence band, respectively, and thus to the formation of "synthetic metals" [478].

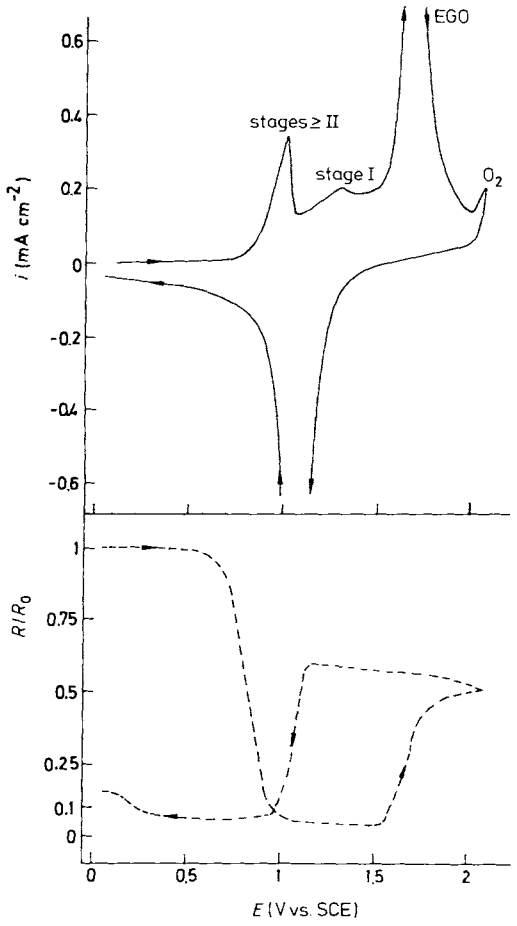

Fig. 26. Cyclic voltammetry on a Celion GY 70 single fiber in 96% $H_2SO_4$ (cf. Fig. 23), $v = 10$ mV·s$^{-1}$; top: current/potential curve, bottom: simultaneous resistance measurement (actual resistance $R$/starting value $R_0$).

Particularly worth noting are: the sharp decrease in $R/R_0$ at the start of the intercalation process, the increase in $R/R_0$ during the formation of EGO and its subsequent decrease during the back reduction of EGO, and, lastly, the relatively small resistance of the "residual compound" between the end of the reduction and 0 V *vs* SCE. After the deintercalation of graphite compounds, "residual compounds" generally remain in which the guest molecules and ions are bound within lattice defects[26, 30, 31, 34, 38, 318, 482]. Thus, the residual compound which remains, even at 0 V *vs* SCE, retains an ionic character ($C_n^+$) and a consequently higher conductivity. Such "residual compounds", and especially those derived from relatively defect-rich graphite materials (such as carbon fibers), are stable for a surprisingly long time[483].

Finally, there are two other properties of surface oxides and graphite oxides which are important electrochemically. The electrochemical potential of surface oxides is notably pH dependent[456, 484–487]: the electrode potential varies by approximately 20 mV/pH. Thus, glassy carbon can be utilized as indicator electrode for potentiometric acid/base titrations[485, 486]. It has been known for a long time that graphite oxide catalyzes the decomposition of $H_2O_2$ (*e.g.* [488, 489]). In this context the exceptional activity of GO as a catalyst for the electrochemical reduction of $O_2$[471, 487, 490] is worth noting since this reduction is known to occur *via* $H_2O_2$ as an intermediate (*e.g.* [492–494]).

A completely new area of interest should develop for fabrics made from *activated* carbon fibers whose properties are very similar to those of activated charcoal; for example the specific surface area ($N_2$ BET) is between 900 and 1400 m$^2$/g[495]. The electrochemical potential of such cloths can, in contrast to active charcoal, be easily adjusted. In this way the adsorption/desorption processes of neutral molecules can be controlled since these processes are extremely dependent on the electrochemical potential[496].

## 6. Outlook

The electrochemistry of black carbons can, to a large extent, be generalized as the "electrochemistry of polymers with conjugated π-systems". In the last few years many of the "old" reactions of graphite have been "extended", in particular, to polyacetylenes and poly(*p*-phenylenes) and also to polymers containing heteroatoms such as polyphenylene sulfides and polythiazenes. This is true for the non-electrochemical processes such as, for example, reduction (="n-doping") with alkali metals (in particular with sodium/naphthalene in ether), oxidation (="p-doping") with halogens, and also the reactions with Lewis acids and metal halide oxidizing agents such as $AsF_5$, $FeCl_3$, *etc.* The flood of pertinent publications exceeds those concerned with carbon generally by an order of magnitude so that only a few reviews, books, and conference proceedings can be referred to here[497–500]. The great interest in this class of compounds is due to the fact that the n- and p-doped polyenes, like the $C_n^-$ and $C_n^+$ graphite compounds, respectively, have a very much larger electrical conductivity than the starting materials.

The electrochemistry of such "polyenes" is also very similar to that of their corresponding graphite compound analogues. In particular the electrochemical reduction and oxidation in organic electrolyte solutions and the associated possibility of constructing rechargeable batteries (Eq. 5, where for polyacetylene "C" is replaced by "CH") has fascinated many research groups[501, 502].

The problems associated with Li batteries using $(CH)_n$ cathodes are similar to those which have hindered the de-

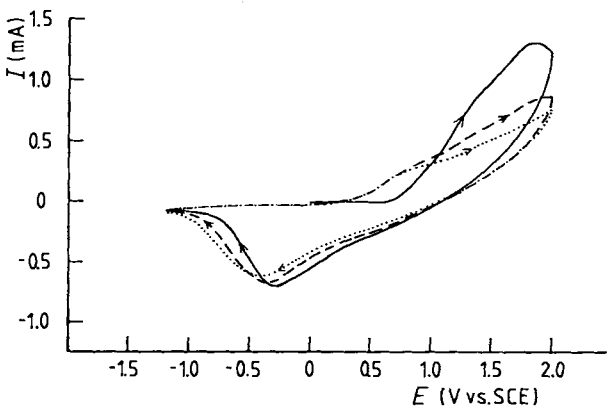

Fig. 27. Cyclic voltammogram of *cis*-polyacetylene (*ca.* 5 × 5 mm film, weight 0.54 mg) in 0.25 M $LiClO_4$/PC, $v = 10$ mV·s$^{-1}$, oxidation in the 1st cycle to "$(CH)^{+}_{25}ClO_4^-$"; —— 1st cycle, –– 2nd cycle, ..... 3rd cycle.—The authors wish to thank Dr. *K. Menke*, Max-Planck-Institut für Festkörperforschung, Stuttgart, for donating the polyacetylene film.

velopment of their graphite analogues: insufficient long term stability of the electrolyte solutions, a tendency to solvate, and, lastly, a low energy density. The theoretical energy density for a $Li/(CH)_n^+ClO_4^-$ cell, n = 14.3, is 255 Wh $kg^{-1}$ without taking solvation into account[502], whereas that for some more conventional rechargeable Li batteries is approximately 1000 Wh $kg^{-1}$[503–506]. In addition, the incomparable stability of the graphite matrix has not been achieved using "polyenes"; irreversible deterioration have in some cases been observed after only a few oxidation/reduction cycles[507] (cf. Fig. 27).

The electrochemistry of "polyenes" in concentrated or aqueous acids is also very similar to that of graphite (*e.g.* [507–509]).

The well established electrochemistry of "black carbon" can thus furnish a fund of information which can be relatively easily applied to many other polymer systems with conjugated π-systems.

*The authors are indebted to many coworkers and in particular to H. Möhwald and also Dr. E. Theodoridou, R. Sauter and E. Wudy for their work in conjunction with our own research which is quoted here. The authors also wish to thank the many collegues and especially W. Biberacher, Dr. W. Foag and Dr. A. Lerf for their intensive cooperation which enabled the solving of some of the problems discussed here which are of a particularly interdisciplinary nature. The authors also wish to acknowledge the liberal support of SIGRI Elektrographit GmbH, Meitingen who supplied a wide range of carbon samples and the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie without whose financial help many of the problems could not have been investigated.*

## Naked Phosphorus Atoms as Trigonally Planar Coordinated Bridge Ligands**

By *Heinrich Lang, Laszlo Zsolnai,* and *Gottfried Huttner** 

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Compounds in which a phosphorus atom is $\mu_3$-bonded to three transition-metal centers in a trigonal planar coordination have so far never been described. Since it was found that complexes with planar threefold bridging arsenic atoms are accessible by reaction of haloarsanediyl complexes with organometallic nucleophiles[1], we attempted the synthesis of trigonally planar coordinated $\mu_3$-phosphorus in a similar way.

Indeed, the complex **2** could be obtained as the first compound containing this structural element by reductive dehalogenation of $(\eta^5\text{-}C_5H_5)Mn(CO)_2PBr_3$ **1** with $Fe_2(CO)_9$.

**1** **2** (34%)

**2** dissolves in *n*-pentane or toluene, yielding wine-red solutions. Crystals of **2** exhibit the metallic luster characteristic of the chromophoric system of metal complexes containing trigonally planar coordinated elements of the fifth main group[2]. The composition of **2** is confirmed by elemental analysis and by the mass spectrum. IR and $^1$H-NMR spectra are consistent with a hindered rotation about the P–Mn axes. The $^{31}$P-NMR spectrum indicates an unconventional structure; it shows a singlet at $\delta = 977$, *i.e.* with the largest downfield shift known so far. Only "phosphinidene" complexes exhibit similarly extreme signal positions $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]_2P\text{–}C_6H_5$: $\delta = 884$)[9]. A bonding system in which the P atom is involved in phosphorus-p$\pi$/metal-d$\pi$ interactions—with its low-lying LUMOs[7, 10], due to the "weak" $\pi$-bonding—apparently increases the paramagnetic contribution to the chemical shift to a considerable extent. The trigonal-planar environment of the phosphorus atoms in **2**, indicated by the $\delta(^{31}P)$ value, was proven by an X-ray structure analysis (Fig. 1).

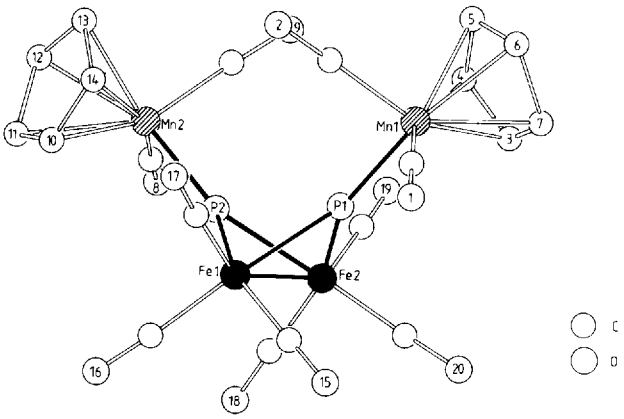

Fig. 1. Molecular structure of the complex **2**, a compound with trigonally planar coordinated phosphorus atoms. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50601, the names of the authors, and full citation of the journal.

The tetranuclear complex **2** has almost $C_2$-symmetry. The two P atoms each lie in a plane with their three nearest neighbor atoms (maximum deviation 5.0 pm); the interplanar angle for Fe1–P1–Fe2 and Fe1–P2–Fe2 is 94.1°. The vacant p-orbital of the phosphorus is predominantly filled by back-bonding from manganese donor orbitals: the manganese-phosphorus bond, with a length of 210 pm, is even shorter than the corresponding bonds in phosphinidene complexes, which are similarly shortened by manganese-d$\pi$–phosphorus-p$\pi$ interactions[4].

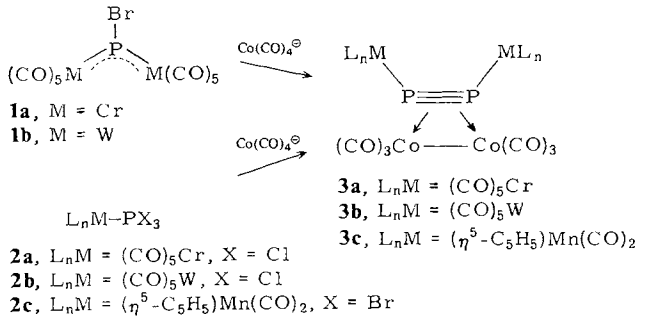
## Diphosphorus, :P≡P:, as Eight-Electron Ligand**

By *Heinrich Lang, Laszlo Zsolnai,* and *Gottfried Huttner** 



*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

It was already demonstrated some time ago that the $P_2$ and $As_2$ molecular homologues of dinitrogen can be stabilized as side-on bonded 4$\pi$-donor ligands in carbonylcobalt complexes $Co_2(CO)_6E_2$ (E = P, As). We have now found

[*] Prof. Dr. G. Huttner, H. Lang, L. Zsolnai
Lehrstuhl für Synthetische Anorganische Chemie der Universität
Postfach 5560, D-7750 Konstanz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

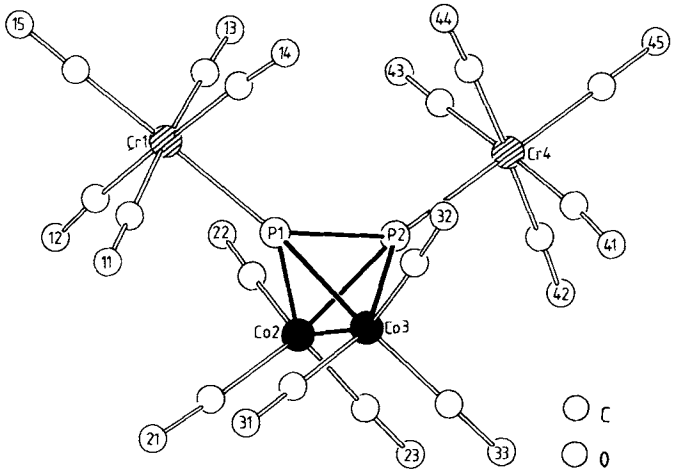
that the phosphorus lone pairs of the diphosphorus coordinated in $Co_2(CO)_6P_2$ allow additional coordination of a 16-electron complex fragment at each of the two phosphorus atoms with formation of the compounds **3**. Synthesis of **3** was accomplished by reaction of halophosphanediyl- ("phosphinidene") complexes **1** or halophosphane complexes **2** with tetracarbonylcobaltate.

**1a**, M = Cr
**1b**, M = W

**3a**, $L_nM = (CO)_5Cr$
**3b**, $L_nM = (CO)_5W$
**3c**, $L_nM = (\eta^5\text{-}C_5H_5)Mn(CO)_2$

**2a**, $L_nM = (CO)_5Cr$, X = Cl
**2b**, $L_nM = (CO)_5W$, X = Cl
**2c**, $L_nM = (\eta^5\text{-}C_5H_5)Mn(CO)_2$, X = Br

The $P_2$-unit in the new complexes **3** functions as an 8-electron ligand, whose side-on bonding in the cluster corresponds to that known for other E≡E ligands, particularly that in $Co_2(CO)_6P_2$[3]. The X-ray structure analysis of **3a** (Fig. 1) shows that the PP bond (206 pm) is only slightly lengthened compared to that in the parent compound $Co_2(CO)_5P(C_6H_5)_3P_2$[3b] (201.9 pm) by the additional coordination *via* the lone pairs of electrons. The Co–P distances in **3a** (mean value 224.7 pm) are likewise scarcely different from those in the $\mu_2$-parent compound (mean value 226.4 pm).



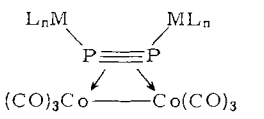


Fig. 1. Molecular structure of the tetranuclear complex **3a** in the crystal. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50603, the names of the authors, and full citation of the journal.

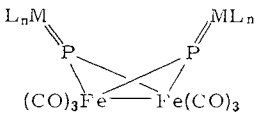

Compounds **3** form deep red (**3b**) and green-blue (**3c**) crystals, which are readily soluble in apolar solvents. The EI mass spectra give clear patterns which reveal the successive cleavage of all carbonyl groups. The $^{31}$P-NMR spectra show $\delta$-values between 44 (**3b**) and 197 (**3c**) for the $P_2$ ligands.

Compound **3c** has formally the same composition as $[\eta^5\text{-}(C_5H_5)Mn(CO)_2]_2(\mu_3\text{-}P)_2Fe_2(CO)_6$, **4**[13]. In order to obtain closed shell electron configurations, the phosphorus atoms of **4** have to donate two additional electrons in comparison with **3c**.

**3c**

$L_nM = (\eta^5\text{-}C_5H_5)Mn(CO)_2$

**4**

This difference in electron demand leads in the case of **4** to complete cleavage of the PP bond and to formation of $\mu_3$-phosphorus bridges in which all five valence electrons of the trigonally planar coordinated phosphorus atoms participate in the metal-phosphorus bonding. It remains to be shown whether the transition $\mu_4\text{-}P_2 \rightleftharpoons 2\,\mu_3\text{-}P$ may be realized as a redox reaction in one and the same system.

## $(C_6H_5)_2P_2[Cr(CO)_5]_2$, a Diphosphene Complex with Free Phosphorus–Phosphorus Double Bond**

By *Jutta Borm, Laszlo Zsolnai,* and *Gottfried Huttner**

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

As homologues of the azo compounds {R–Ë=Ë–R} (E = P, As, Sb), some diphosphenes (R = 2,4,6-$t$Bu$_3$C$_6$H$_2$, $(Me_3Si)_3C$, $(Me_3Si)_2CH$[1a], $(Me_3Si)_2N$[1b]) which are stable in the free state have only recently been reported in the literature. The existence of such species as side-on coordinated ligands with E = P, As[2, 3], and Sb[3] had already been demonstrated earlier. In all previously characterized complexes the reactive E=E double bond is stabilized by interaction with a metal center[2, 15]; in addition, the two lone pairs can be coordinatively active[3]. The binuclear complex **2** is the first stable derivative of an unstable diphosphene, in which only the n-electron pairs are complexed, while the P=P double bond remains free.

The novel complex **2** is formed on heating the trinuclear compound **1**, which—as analogue of other $R_2E_2[M(CO)_5]_3$ complexes[3]—is readily accessible from $Na_2Cr_2(CO)_{10}$ and $(CO)_5Cr(PPhCl_2)$.

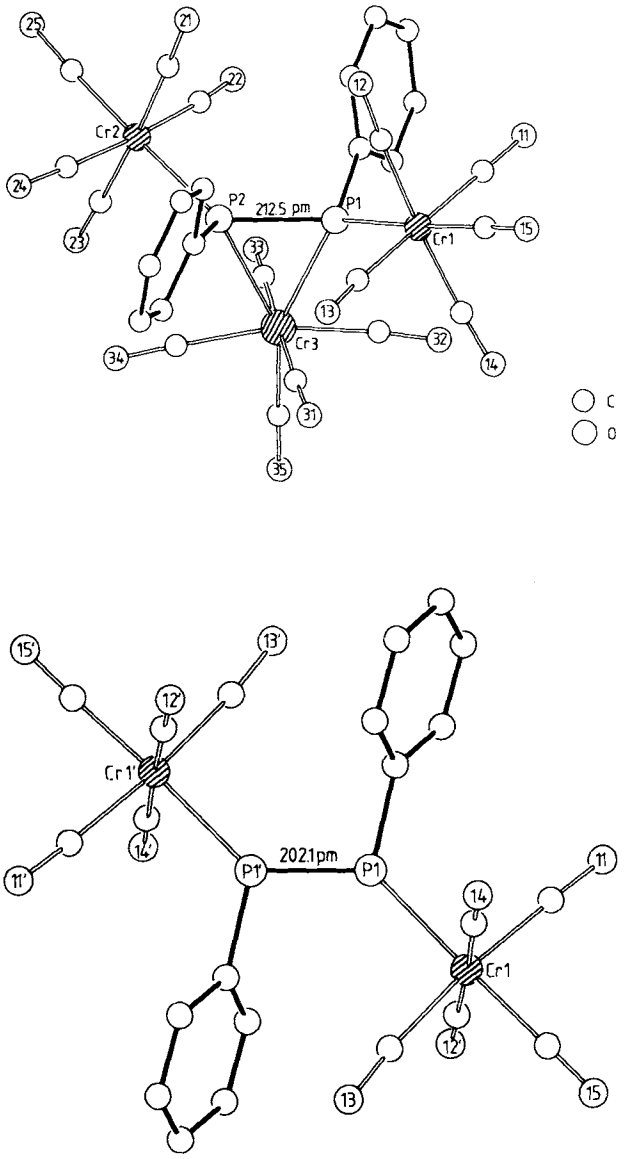

Fig. 1. The molecular structure of the $Ph_2P_2$-complexes **1** (top) and **2** (bottom) in the crystal. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50604, the names of the authors, and the full citation of the journal.

In **1**, diphenyldiphosphene is bound both *via* the lone electron pairs as well as *via* the central double bond (cf. Fig. 1).

As a result of the side-on coordination, the P=P bond in **1** is lengthened from 203 to 212.5 pm compared to that in free diphosphenes[1]. Thermal cleavage of the side-on bonded $Cr(CO)_5$-group leads to the centrosymmetric complex **2**, whose P=P bond length in a planar framework geometry (maximum deviation 3 pm) corresponds to a diphosphene P=P double bond. This means that the end-on bonded $Cr(CO)_5$-groups in **2** have no influence on the PP bond order, even though they shield the reactive double bond to such an extent that the system is stable even without protection by bulky organic substituents[1, 15].

The stabilization of a reactive multiple bond by blocking of the lone pairs, as found in **2**, has its analogy in the stability of diazene complexes homologous to **2**[8].

The electronic influence of the pentacarbonylchromium groups is obvious from the $^{31}$P-NMR spectrum: whereas free diphosphenes show signals in the range $\delta = 470-600$[1], the signal of **2** appears at $\delta = 927$.

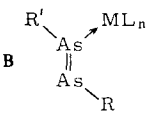
[15] *Note added in proof:* See, however: K. M. Flynn, M. M. Olmstead, Ph. P. Power, *J. Am. Chem. Soc. 105* (1983) 2085. The $^{31}$P-NMR shift of 384.55 ppm for a diphosphene complex given in this paper is, however, improbable.



## Synthesis and Structure of a Diarsenechromium Complex with an Unsupported Arsenic-Arsenic Double Bond**

By *Alan H. Cowley**, *Jon G. Lasch*, *Nicholas C. Norman*, and *Marek Pakulski*

Previously described diarsene (RAs=AsR) complexes are of the $\eta^2$-type **A** and involve arsenic-arsenic bond orders of *ca.* 1.5[1–3]. We now report the synthesis and X-ray crystal structure of a new type of diarsene complex **B** which features an unsupported AsAs double bond.

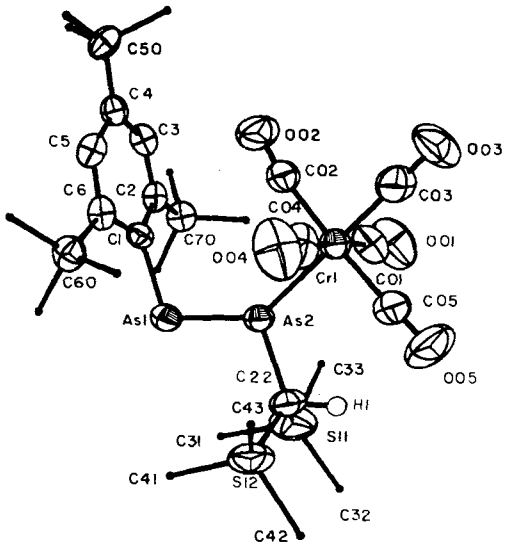
**A** R = $C_6H_5$, X = $Cr(CO)_5$; $ML_n$ = $Cr(CO)_5$[1]
R = $C_6F_5$, X = :; $ML_n$ = $Fe(CO)_4$[2], $Pt(PPh_3)_2$[3]

**B** **1**, R = 2,4,6-($t$Bu)$_3C_6H_2$; $ML_n$ = $Cr(CO)_5$; R′ = $CH(SiMe_3)_2$

The diarsene complex **1** was prepared by the reaction of the uncoordinated diarsene[4] with $Cr(CO)_5THF$ in tetrahydrofuran (THF) solution and purified by chromatography (silica gel/*n*-hexane). Orange crystals of **1** (m.p. = 138–139 °C) formed from *n*-hexane solutions held at −20 °C.

[*] Prof. Dr. A. H. Cowley, J. G. Lasch, Dr. N. C. Norman, Dr. M. Pakulski
Department of Chemistry, University of Texas at Austin
Austin, TX 78712 (USA)

[**] This work was supported by the U. S. National Science Foundation and the Robert A. Welch Foundation.



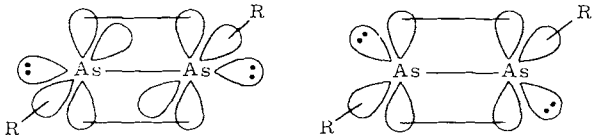


Fig. 1. Structure of **1** in the crystal. Selected bond lengths [Å] and angles [°]: As1–As2 2.246(1), As1–C1 1.964(5), As2–C22 1.989(5), As2–Cr1 2.454(1); As2–As1–C1 104.0(1), As1–As2–C22 105.2(2), As1–As2–Cr1 138.48(3), Cr1–As2–C22 116.3(2).

The X-ray structure analysis of **1** (Fig. 1) reveals that the $Cr(CO)_5$ group is attached to only one As atom. The AsAs bond length of 2.246(1) Å in **1** is considerably shorter than the range of 2.43–2.46 Å observed for AsAs single bonds[5], and the values of 2.388(7)[2] and 2.371[1] Å reported for $\eta^2$-diarsene complexes of type **A**. Moreover, within experimental error, the $C_2As_2Cr$ framework is planar. These facts suggest the presence of a double bond between the As atoms. This is supported by the UV/VIS spectrum of **1** which exhibits peaks expected for the As=As chromophore [$\lambda_{max}$ = 240 ($\varepsilon$ = 36700), 293 (16750), 345 (3800), and 470 nm (7800)].

All the skeletal bond lengths in **1** are longer than those of the uncoordinated diarsene due to the steric demands of the $Cr(CO)_5$ group. However, the largest increase occurs at the AsAs double bond (*ca.* 0.02 Å). Interestingly, *both* CAsAs angles increase upon coordination. The bond angle increase at As2 is not ascribable to steric effects and is presumably due to rehybridization of arsenic from approximately sp (**I**) to $sp^2$ (**II**).

## Addition of Methylene to Multiple Bonds between Ligand-Free, Main-Group Elements and Transition Metals—A General Reaction[1]

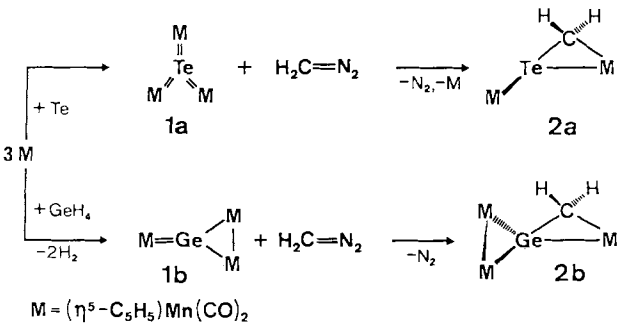
By *Wolfgang A. Herrmann**, *Josef Weichmann*, *Ulrich Küsthardt*, *Adolf Schäfer*, *Rolf Hörlein*, *Christian Hecht*, *Erdmuthe Voss*, and *Ricardo Serrano*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Multiple bonds between transition metals are centers of high reactivity unless bulky ligands prevent approach of the reactands. Sterically exposed metal-metal multiple bonds are thus not inferior to active metal surfaces with regard to metal-centered addition, fragmentation, and coupling reactions of saturated or unsaturated hydrocarbons—examples of potential applications in catalysis[2]. Only recently have some complexes **1** been prepared containing multiple bonds between "naked" main-group elements and transition metals[6–8]. According to *Kostić* and *Fenske*[9], multiple bond character is required for theoretical reasons in the germanium compound **1d**.

The particular advantages of type **1** complexes are that they not only are preparatively readily accessible and, nevertheless, very reactive, but also that they contain distinctly different types of reaction centers (cf. Mn and Ge); they are, therefore, ideal candidates for model studies in catalysis. After conversion of the $\mu_3$-tellurium complex **1a** into a $\mu_2,\eta^2$-telluroformaldehyde derivative[10] (**2a** in Scheme 1), we recognized the generality of the method used and, as an example, now report the synthesis and unusual properties of a novel type of metallaspiro compound **2b**.

The germanium-manganese complex **1b** can be prepared more straightforwardly and in higher yield (40–60%) using our synthetic method, *i.e.* reaction of the solvent-stabilized complex fragment $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ with gaseous germane in the presence of acid (cf. Scheme 1 and Supplement). By way of contrast, the two-step germylpotassium route[7] gives only small yields (1%) of **1c**[7].

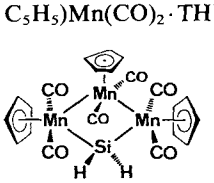


$GeH_4$ reacts with $(\eta^5\text{-}C_5Me_5)Mn(CO)_2$ in the presence of traces of sulfuric acid to afford exclusively the orange complex $(\mu_2\text{-}Ge)[(\eta^5\text{-}C_5Me_5)Mn(CO)_2]_2$ having a strictly linear Mn–Ge–Mn skeleton known for compound **1d**)[**]; here, the bulky $C_5Me_5$ ligands prevent formation of the trinuclear compound analogous to **1b**, **c**. We observed the same effect in the synthesis of the tellurium complex $(\mu_2\text{-}Te)[(\eta^5\text{-}C_5Me_5)Mn(CO)_2]_2$ (**1f**, cf. Supplement).

Solutions of **1b** in tetrahydrofuran (THF) react with diazomethane over the temperature range −20 to 0°C with evolution of dinitrogen. According to elemental analysis and spectroscopic data (FD-MS, IR, NMR), the product

[*] Prof. Dr. W. A. Herrmann, Dr. J. Weichmann, U. Küsthardt, A. Schäfer, R. Hörlein, C. Hecht, E. Voss, Dr. R. Serrano
Institut für Anorganische Chemie der Universität
Niederurseler Hang, D-6000 Frankfurt am Main 50 (Germany)

[**] Note added in proof: The linear geometry of this compound has been confirmed by X-ray structure analysis, according to which the Mn–Ge distances are *ca.* 218 pm, and are thus a little shorter than in the methylcyclopentadienyl derivative **1d** [7] (*I. Bernal, J. D. Korp*, unpublished results).



**2b** (air-stable, brown crystals; m.p. 112°C), isolated in 85–95% yield, has the structure of a previously unknown $\mu_3,\eta^2$-methylenegermanediyl complex and results from addition of $CH_2$ to the Mn=Ge multiple bond of **1b**; the seemingly much less reactive Mn–Ge single bonds are not affected by diazomethane.

Scheme 1.

Although in the two typical cases addition of methylene to **1a**[10] and **1b** proceeds quite uniformly (Scheme 1), the products **2a** and **2b** exhibit completely different properties: The $CH_2Te$ complex has a rigid structure with a pyramidally configurated Te atom; in contrast, the $CH_2Ge$ complex has a fluxional structure ($^1$H-NMR, $CD_2Cl_2$): Below −50°C, three well resolved $C_5H_5$ signals appear, two of which broaden upon increasing the temperature and collapse into a single line at *ca.* 20°C; simultaneously, a very broad $CH_2$-signal appears. This observation can be assigned either to an opposing rotation of the two three-membered rings at the spiro-Ge atom in **2b** or to a *cis/trans*-isomerization within the binuclear fragment $(\eta^5\text{-}C_5H_5)_2Mn_2(CO)_4$. Of greater chemical significance is the different thermolysis behavior of compounds **2a** and **2b**. Although the $CH_2Te$ complex decomposes rapidly at 180°C, the tellurium-carbon bond remains intact. In contrast, the $CH_2Ge$ complex **2b** decomposes *slowly* above *ca.* 50°C and *immediately* upon melting (112°C) to form both ethylene *quantitatively* (GC) and the *intact* precursor **1b** (MS, IR, NMR); the latter species can add again to methylene. In the presence of hydrogen (1 atm) this thermolysis affords significant amounts of methane. In accord with NMR data ($\delta(CH_2) \approx 1.9$), the reversible elimination of methylene classifies **2b**, in contrast to **2a**, as a thermolabile metallaspiro compound in which, for the first time, a methylene group bridges a substituent-free main group element and a transition metal. **2b** reacts with $[D_2]$diazomethane (THF/$Et_2O$, 25°C) with $CH_2/CD_2$ exchange.

Because of the greater strength of the Si–H bond compared to a Ge–H bond, the route developed for the synthesis of **1b** was expected to be less successful for the synthesis of the homologous silicon compound. The major product (≈70%) of the reaction of $(\eta^5\text{-}C_5H_5)Mn(CO)_2\cdot THF$ with $SiH_4$ was the novel silanediyl

**3**

complex **3** (elemental analysis, MS, IR, NMR); the colorless derivative $(\mu\text{-}SiH_2)_2[(\eta^5\text{-}C_5H_5)Mn(CO)_2]_2$ as well as the red silicon compound $(\eta^5\text{-}C_5H_5)_3Mn_3(CO)_6Si$ are formed as by-products (in each case *ca.* 5%). With $(\eta^5\text{-}C_5Me_5)Mn(CO)_2\cdot THF$, pure monosilane gives the hydrido(silylene) complex of composition $(\mu\text{-}SiH_2)[(\eta^5\text{-}C_5Me_5)Mn(CO)_2H]_2$ (Me=$CH_3$).

## $\mu_2$-E[V(CO)$_3$diphos]$_2$ (E = S, Se, Te): Complexes with Linear VEV Multiple-Bond Systems

By *Jan Schiemann, Peter Hübener,* and *Erwin Weiss**

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Novel transition metal-main group element compounds containing multiple bonds have attracted a great deal of interest in recent years. Typical examples are the cyclopentadienyl or methylcyclopentadienyl complexes $[(\eta^5\text{-}C_5H_5)Cr(CO)_2]_2S$[1a], $[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_2Ge$[1b], $[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_3Ge$[1c], and $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]_3Te$[1c]. The synthesis of vanadium-chalcogen compounds with multiple bonds in linear VEV groups (E = S, Se, Te) has now also been accomplished.

We obtained the binuclear sulfur compound **1** *via* routes (a) and (b)[2] (diphos = ethylenebis(diphenylphosphane)).

$$Na[V(CO)_4diphos] \xrightarrow[20°C,\ H_2O]{Na_2SO_3/H^+} [V(CO)_3diphos]_2S\ \mathbf{1}\ (ca.\ 25\%) \quad (a)$$

$$Na[V(CO)_4diphos] \xrightarrow[20°C,\ H_2O]{Na_2S/H^+} \mathbf{1}\ (ca.\ 50\%) \quad (b)$$

For the preparation of the selenium and tellurium compounds **2** and **3** we have so far only used route (a), with appropriate modification.

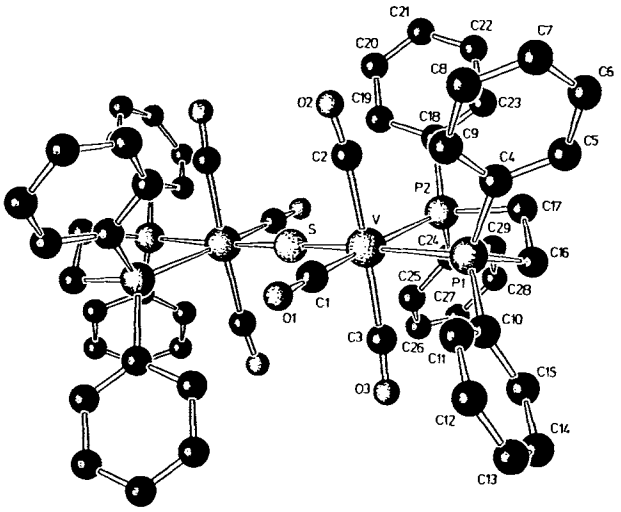
$$Na[V(CO)_4diphos] \xrightarrow{Na_2SeO_3/H^+} [V(CO)_3diphos]_2Se\ \mathbf{2}\ (ca.\ 25\%)$$
$$\xrightarrow{Na_2TeO_3/H^+} [V(CO)_3diphos]_2Te\ \mathbf{3}\ (ca.\ 25\%)$$

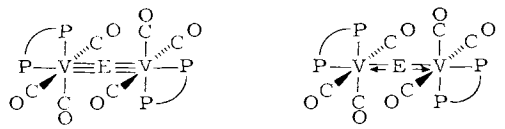
In all cases, the mechanism of the reaction is still unclear.

An X-ray structure analysis of the red, diamagnetic complex **1** reveals a centrosymmetric molecule (Fig. 1) with very short V–S distances (217.2 pm). Values for comparison are not available, since **1** is the first carbonylvanadium compound containing sulfido ligands. In other S-contain-

[*] Prof. Dr. E. Weiss, Dr. J. Schiemann, Dr. P. Hübener
Institut für Anorganische und Angewandte Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)

ing compounds the V–S distances are always greater than 230 pm.





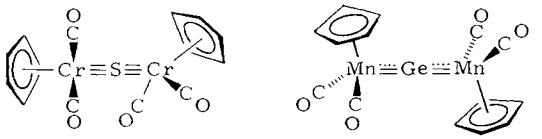


Fig. 1. Molecular structure of **1** in the crystal([V(CO)$_3$diphos]$_2$S·3C$_6$H$_5$CH$_3$). Triclinic, P$\bar{1}$, $a=1214.9(4)$, $b=1259.1(7)$, $c=1388.8(7)$ pm, $\alpha=77.60(4)$, $\beta=73.02(3)$, $\gamma=63.77(3)°$, $Z=1$; $Mo_{K\alpha}$ radiation, Patterson and direct methods (SHEL-X), $R=6\%$ for 2789 reflections (H positions calculated). Bond lengths [pm]: V–S 217.2(1), V–P1 248.9(2), V–P2 248.7(4), V–C1 194.1(3), V–C2 199.9(9), V–C3 198.7(9); angles [°]: V–S–V 180.0, P1–V–P2 79.9. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldhsafen on quoting the depository number CSD 50456, the names of the authors, and the full citation of the journal.

According to their composition and spectroscopic data the complexes **2** and **3** undoubtly have a structure analogous to that of **1**. In principle, three $\nu$(CO) absorption bands are to be expected for the fragment V(CO)$_3$, the same as for the whole molecules **1**–**3** when they have a center of symmetry. The four bands observed for **1** and **2**[4] indicates loss of the symmetry center in the dissolved state. Probably there is extensive rotation about the VEV axis in solution, resulting in formation of a mixture of various rotamers.

On the basis of the electron balance rule the complexes **1**–**3** are formulated with double and triple bonds (**B** and **A**, respectively).

**A** E = S, Se, Te **B**

**4** **5**

The actual bond order could lie between double and triple, as in the case of the cyclopentadienyl complexes **4**[1a] and **5**[1b]. The partial triple bonding reported by *Kostić* and *Fenske*[5] to be present in **5** and thus the easier internal rotation are consistent both with the centrosymmetric molecular structure in the crystal as well as with the occurrence of rotamers without a center of symmetry in solution.

Neugebauer, *Angew. Chem. 95* (1983) 46; *Angew. Chem. Int. Ed. Engl. 22* (1983) 59; *Angew. Chem. Suppl. 1983*, 10–22.

[2] Compound **1** is also formed in the reaction of Na[V(CO)$_4$diphos] with $S_3N_3Cl_3$ in tetrahydrofuran at −78 °C (yield *ca.* 1%).

[3] Procedure: For the synthesis of **1** (route (b)) an aqueous suspension (200 mL) of Na[V(CO)$_4$diphos] (1.17 g, 2.0 mmol) and $Na_2S\cdot 9H_2O$ (0.7 g, 3.0 mmol) is acidified dropwise with 2 N $H_2SO_4$ and then stirred for 12 h. The resulting precipitate is filtered off (G3 frit), washed twice with water, and dried. The product, which is still hydrous, is dissolved in ether (20 mL) on the frit. After separation of the aqueous phase the etheral solution is filtered, the solvent removed, and the residue recrystallized from toluene/hexane (1:1) (cooling to *ca.* −30 °C). Yield 0.54 g (49%).—For the synthesis of **1**, **2**, or **3** (according to route (a)) an aqueous solution (200 mL) of Na[V(CO)$_4$diphos] (2.0 mmol) and $Na_2EO_3$ (2.0 mmol) is acidified dropwise with 1 M $H_3PO_4$ and then stirred for *ca.* 12 h. In each case the resulting precipitate is worked-up as described above. Yields *ca.* 25%.

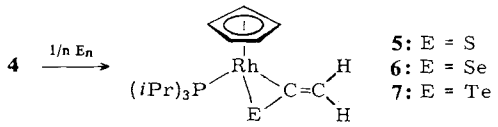
## Synthesis and Structure of [($\eta^5$-C$_5$H$_5$)RhP(*i*Pr)$_3$($\eta^2$-EC=CH$_2$)] with E = S, Se, Te: Generation and Stabilization of Thioketene, Selenoketene, and Telluroketene at a Transition Metal**

By *Helmut Werner**, *Justin Wolf*, *Ralf Zolk*, and *Ulrich Schubert*

Whereas thioketene CH$_2$=C=S and selenoketene CH$_2$=C=Se are extremely reactive molecules and are only detectable in the gas phase, telluroketene is unknown[1]. We have now succeeded in generating these species, CH$_2$=C=E (E = S, Se, Te), in a straightforward way as ligands in the coordination sphere of a transition metal.

Recently, we showed that the reaction of RhCl[P(*i*Pr)$_3$]$_2$ **1** with PhC$_2$H and NaC$_5$H$_5$ leads to the phenylvinylidene complex C$_5$H$_5$Rh(=C=CHPh)P(*i*Pr)$_3$ **2** *via* alkyne-, alkynyl(hydrido)-, and alkynylrhodium intermediates[2]. Using similar conditions, **1** also reacts with acetylene. In pentane as solvent the yellow, air-sensitive complex **3** is obtained, which according to its IR spectrum probably has a metallacyclopropene structure[3]. The *trans*-orientation of the triisopropylphosphane ligands can be deduced from the $^1$H-NMR data. A similar structure has been proposed for RhCl(C$_2$H$_2$)[P(C$_6$H$_{11}$)$_3$]$_2$[4].

**1** **3** **4**



Reaction of **3** with NaC$_5$H$_5$ (tetrahydrofuran, 25 °C, 1 h) yields the vinylidene complex **4** (yield 35%)[3]. In addition

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by gifts of chemicals from BASF AG, Ludwigshafen, and DEGUSSA AG, Hanau. We are grateful to Drs. *G. Lange*, *W. Buchner*, and *D. Scheutzow* for the MS and NMR spectra.

to the IR data structural proof is provided principally by the $^{13}$C-NMR spectrum (in $C_6D_6$) which, apart from signals of the phosphane- and cyclopentadienyl-carbon atoms, contains two doublets of doublets at $\delta = 311.41$ and 94.14; these are assigned, respectively, to $C^1$ and $C^2$ of the vinylidene ligand. In the case of the phenylvinylidene compound **2**[3] the corresponding signals are observed at $\delta = 316.99$ and 116.31, respectively.

Complex **4** reacts with sulfur (in hexane), selenium, and tellurium (in benzene) to afford the intensely colored chalcogenoketenerhodium compounds **5**—**7** in good yield (E = S: 45%, E = Se and E = Te: 70%)[3]. The reactivity of the chalcogenes decreases markedly from sulfur *via* selenium to tellurium; red selenium is considerably more reactive than the gray allotrope. Whereas **5** (red) and **6** (red-brown) are air-stable, **7** (green) is readily oxidized. Solutions of **7** (*e.g.* in $C_6H_6$) slowly decompose to yield **4** and tellurium; additional products cannot be detected.

**5**: E = S
**6**: E = Se
**7**: E = Te

The NMR spectra of **5**—**7**[3] support the proposed structure. Since the compounds are chiral, two signals for the diastereotopic methyl groups of the $P(iPr)_3$ ligand are observed in the $^1$H-NMR spectra of **5** and **6**; in **7** the diastereotopic shift is too small to be resolved. For E = S, the $CH_2$ protons of the chalcogenoketenes give rise to an AX-, for E = Se an $A_2$-, and for E = Te an AB-pattern; for E = S and Se additional PH coupling arises.

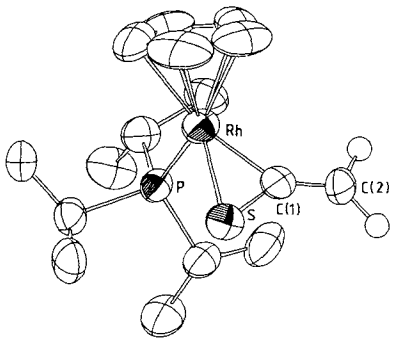

Fig. 1. Crystal structure of **5**. The disorder of the thioketene ligand is not indicated. Selected bond lengths [pm] and angles [°]: Rh—P 228.6(2), Rh—S 238.0(3), Rh—C(1) 196(2), S—C(1) 169(3), C(1)—C(2) 131(3); S—Rh—P 92.7(1), S—Rh—C(1) 44.7(6), P—Rh—C(1) 95.1(6), Rh—S—C(1) 54.3(7), Rh—C(1)—C(2) 140.5(18), S—C(1)—C(2) 138.1(18).

Figure 1 shows the result of the crystal structure analysis of **5**[5]. In the crystal **5** is disordered in such a way that each site is occupied by both enantiomers in the ratio of *ca.* 87:13. The plane through Rh, P, and the centroid of the five-membered ring exactly bisects the C(1)-S bond; the planes $C_5$(middle)-Rh-P and Rh-S-C(1) enclose an angle of 86.7°. C(2) lies only 8(2) pm outside the Rh-S-C(1) plane. The angle S-C(1)-C(2) is almost the same as the angle S-C-S in $C_5H_5(PMe_3)Co(\eta^2\text{-}CS_2)$ **8**[6a] and the angle S-C-C in $C_5H_5(PMe_3)Co(\eta^2\text{-}SC{=}CCMe_2(CH_2)_3CMe_2)$ **9**[6b].

To our knowledge **5**—**7** are the first metal complexes of unsubstituted thio-, seleno-, and telluroketene. Both we[6b] and *Behrens et al.*[7a] have already synthesized mono- and binuclear metal compounds with *substituted* thioketenes; of these, **9** is similar in structure to **5**. *Stone et al.*[7b] obtained iridium(I) and platinum (0) complexes with $\eta^2$-bonded bis(trifluoromethyl)thioketene, however, not starting from (the still unknown) $(CF_3)_2C{=}C{=}S$ but from $CF_3$-substituted heterocyclic sulfur compounds.

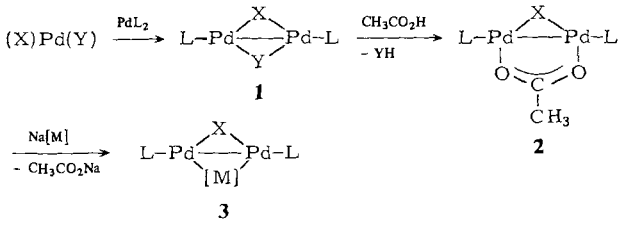
## Synthesis and Structure of $[CuMo(CH_3CO_2)_2(L)(CO)_2(\eta^5\text{-}C_5H_5)]$: Monomeric Copper(II) Diacetate as Building Block of a Heterometallic Binuclear Complex**

By *Helmut Werner**, *Joachim Roll*, *Klaus Linse*, and *Manfred L. Ziegler*

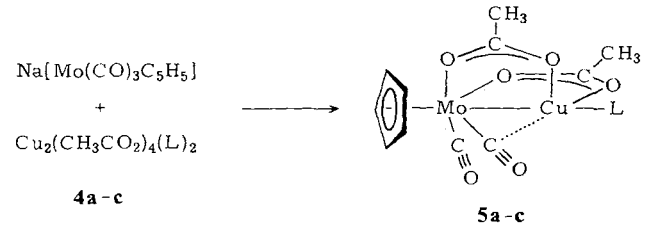


Metal complexes with heteronuclear metal-metal bonds are currently enjoying considerable interest in connection

[*] Prof. Dr. H. Werner, J. Roll
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)
Prof. Dr. M. L. Ziegler, K. Linse
Anorganisch-chemisches Institut der Universität Heidelberg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *D. Scheutzow* for the 400 MHz NMR spectra and Prof. Dr. *U. Schubert* for valuable discussions.

with the preparation of selective, heterogeneous catalysts[1]. Above all, the most promising goal is the synthesis of compounds containing an electron-deficient and an electron-rich transition metal, which exert a synergistic interaction on each other.



We have already shown that heterometallic trinuclear metal clusters, *e.g.* **3**, can be synthesized stepwise from mononuclear metal starting materials[2].

X = 2-$MeC_3H_4$; Y = $C_5H_5$; L = $P(iPr)_3$; [M] = $Mo(CO)_3C_5H_5$[2b]

In the compounds **1–3**, palladium is present in the oxidation state +1. Since both $Cu^{II}$ and $Pd^{I}$ are $d^9$-systems, and numerous binuclear complexes of $Cu^{II}$ with carboxylate bridges are known, we also attempted to achieve a ligand exchange between $CH_3CO_2$ and [M] (as in the reaction **2**→**3**) in the pyridine adducts of dimeric copper(II) acetate.

The reaction of $Na[Mo(CO)_3C_5H_5]$ (≡Na [M]) with **4a–c** ($C_6H_6$, 25 °C, **2d**) affords the pale red, air-sensitive solids **5a–c**, which can be separated by column chromatography from $[C_5H_5Mo(CO)_3]_2$[7] formed as a by-product. **5a–c** are diamagnetic and contain Cu and Mo in the ratio 1:1. From the intensities of the $^1$H-NMR signals it follows that there are one pyridine and two acetate ligands present per cyclopentadienyl ring[3].

**4a-c** **5a-c**

**a**: L = $C_5H_5N$; **b**: L = 4-$CH_3C_5H_4N$; **c**: L = 4-$tC_4H_9C_5H_4N$

In addition to the signals for the $C_5H_5$, $RC_5H_4N$, and $CH_3CO_2$ carbon atoms, the $^{13}$C-NMR spectra of **5a–c** each exhibit a signal at *ca.* 252 ppm[3] which corresponds to the CO groups. According to the chemical shift, these should be in a bridging position[4]. However, as proved by the crystal structural analysis[5] of **5b** only weakly bridging CO groups are found in the crystal. Whereas the carbonyl group C(2)–O(2) has largely terminal character, C(1)–O(1) is to be considered as "semibridging"[6]. Of note is the distance Cu–Mo, which is significantly shorter than that in the Cu–Mo compounds with μ–S bridges thoroughly studied by *Müller et al.*[8]. The five-membered rings MoOCOCu are planar and form an angle of 84.29° with each other.

As indicated by ongoing studies, heterometallic binuclear complexes are also probably formed in the reactions of **4a–c** with $Na[W(CO)_3C_5H_5]$. In addition to those and $[C_5H_5W(CO)_3]_2$[7], the compound $C_5H_5W(CO)_3(OCOCH_3)$ is also obtained, which is not accessible from $C_5H_5W(CO)_3CH_3$ and $CH_3CO_2H$ and which has been characterized by a crystal structure analysis[9].

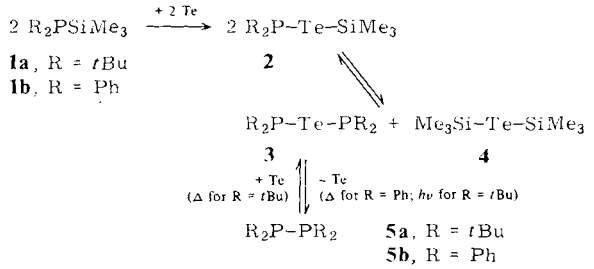
## Small Heterocycles containing Phosphorus and Tellurium**



By *Wolf-Walther du Mont*, Tevfik Severengiz,* and *Bernd Meyer*

Tellurium differs markedly from the other chalcogens in its reactivity towards phosphanes; most characteristic is

[*] Prof. Dr. W.-W. du Mont, T. Severengiz, Dr. B. Meyer

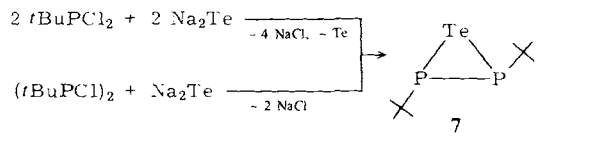
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

the lability of $P^V-Te^{II}$ compounds (tellurium atom transfer between phosphanes)[1]. Thus, we have recently shown that tellurium can be inserted into the P–Si bond of di-*tert*-butyl(trimethylsilyl)phosphane **1a**, but is incapable of inducing a further oxidation of the tellurophosphinite **2a**[2a]. The insertion product merely equilibrates with the symmetrically substituted tellurium compounds **3** and **4**. We have now found that when a less bulky silylphosphane is used as starting material, a novel P–P coupling by detelluration (**3**→**5**) follows the reaction steps **1**→**2** and **2**→**3**+**4**: diphenyl(trimethylsilyl)phosphane **1b** reacts smoothly with tellurium to give tetraphenyldiphosphane **5b** and bis(trimethylsilyl) telluride **4**.



A tellurophosphinous anhydride **3b** is apparently unstable and decomposes with formation of the diphosphane **5b**, though conversely the bulkier diphosphane **5a** reacts thermally with elemental tellurium to give **3a**[2b].

All three types of reaction: Te-insertion, dismutation, and P–P coupling detelluration can be drawn on to explain the unexpected formation of a telluratriphosphetane **6** from *tert*-butylbis(trimethylsilyl)phosphane and tellurium.

The four-membered heterocycle **6** is formed in almost quantitative crude yield ($^{31}$P-NMR) when the silylphosphane is stirred with tellurium powder in excess at room temperature for about 14 d. After removal of **4** under reduced pressure, **6** remains as a red liquid[3]. If the reaction temperature is increased, cyclophosphanes $(tBuP)_n$ (n = 3, 4) and the telluradiphosphirane **7** are formed as well as **6**. The three-membered heterocycle **7** is formed as main product when sodium telluride is allowed to react with *tert*-butyldichlorophosphane or with 1,2-di-*tert*-butyl-1,2-dichlorodiphosphane.

The structures proposed by us for **6** and **7** have been confirmed by EI and FI-MS data as well as by $^{31}$P- and $^{125}$Te-NMR coupling patterns[3]. The highly resolved $^{125}$Te-NMR signal of **6** appears as a doublet split into a triplet (Fig. 1). The contribution of the coupling between tellurium and the adjacent phosphorus nuclei characteristically differs from $P^V=Te^{II}$ couplings (1600–2300 Hz) and is even smaller than $^2J$(TeP). The telluradiphosphirane **7**—the first molecule with tellurium in a three-membered ring[2a,3]—can be regarded as an epitelluride of di-*tert*-butyldiphosphene. The NMR data of **7** allow its unequivocal placement in the series of thia- and selenadiphosphiranes described by *Baudler et al.*[4]. The tendency of **7** to release tellurium has hitherto precluded its isolation in the pure state; however, we are attempting to preparatively exploit the detelluration of **7**.

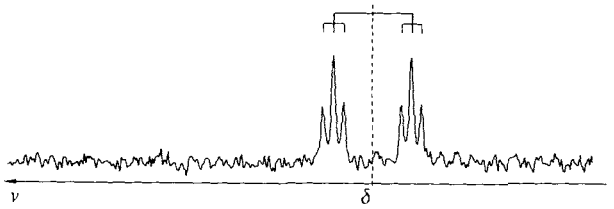


Fig. 1. $^{125}$Te-NMR spectrum of the telluratriphosphetane **6**. Bruker WP 80 FT-NMR spectrometer, 25.271 MHz for $^{125}$Te, $\delta$ = 2994.568 Hz (–118 ppm rel. ditolyl ditelluride as standard), $J$ = 84 Hz (d), 10.7 Hz (t).

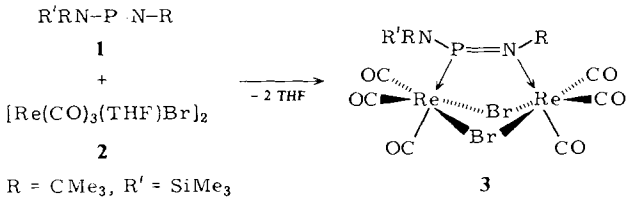
## N,P-Coordination of an Amino(imino)phosphane**

By *Otto J. Scherer*, Jürgen Kerth, Ralf Anselmann,* and *William S. Sheldrick*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Of the conceivable possibilities of coordination of the amino(imino)phosphanes >N–P=N– only those of type **A**[1a,b] and type **B**[1c] have hitherto been verified.



**A** **B** **C**

[**] This work was supported by the Fonds der Chemischen Industrie through a grant to *J. K.*

Using **1** and **2** as starting compounds, we have now been able to prepare **3**, a compound of type **C** in which the amino(imino)phosphane **1** is coordinatively bridged as four-electron donor to two rhenium atoms *via* the imino-N atom and the P atom.

**3**[4] forms yellow-orange crystals which are sensitive to hydrolysis, readily soluble in benzene, moderately soluble in ether, and sparingly soluble in pentane.

The crystal structure analysis[5] shows (Fig. 1) that *trans*-**1** isomerizes to *cis*-**1** through the $\mu$-$\eta^1$,$\eta^1$-coordination of the P=N moiety of the molecule. In the process the NPN angle widens from 104.9°[2] to 122.6°, while the PN bond lengths remain almost unchanged.

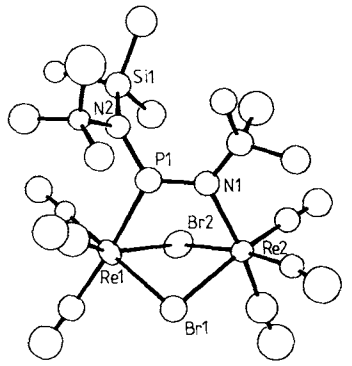

Fig. 1. Structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: P1–N1 1.56(2), P1–N2 1.66(2), P1–Re1 2.481(6), Re1–Br1 2.626(2), Re1–Br2 2.578(3), Re2–Br1 2.625(2), Re2–Br2 2.631(2), N1–Re2 2.21(2), Re1...Re2 3.603(1), N1–P1–Re1 111.9(7), N1–P1–N2 122.6(9), P1–N1–Re2 119.7(9), P1–N1–C11 121(1), Br1–Re1–Br2 83.74(9), Br1–Re2–Br2 82.75(9), Re1–Br1–Re2 86.67(5), Re1–Br2–Re2 87.53(7). Dihedral angle between the faces Re1Br1Br2 and Re2Br1Br2 134.4; sum of angles at P1: 356.0, N1: 359.7, N2: 359.1.

**3** is the first representative of the class of substances $Re_2(\mu\text{-}Br)_2(CO)_6(\mu\text{-}Ph_nE\text{–}EPh_n)$, E = P, n = 2[3a]; E = S, Se or Te, n = 1[3b], in which the ligand with E–E bridge is replaced by one with a four-electron donor double-bond system (–P=N–). The shortening of the bond length (2.308(6) → 1.56(2) Å) on going from the P–P[3a] to the P–N bridge is so drastic that the molecule compensates for this by the $Re(\mu\text{-}Br)_2Re$ fragment folding itself stronger about the Br–Br axis (angle between the normals to the $ReBr_2$ planes = 45.6° in the case of **3** and 23.4° in the P–P derivative[3a]; the Re...Re distance becomes shorter (**3**: 3.603(1), P–P derivative: 3.890(1) Å[3a]) and the two edge-sharing coupled distorted octahedra are oriented markedly more towards face-sharing coupling (Re...Re distance in the case of the Br face-sharing $[(OC)_3Re(\mu\text{-}Br)_3Re(CO)_3]^-$: 3.46 Å[3c]).

The $^{31}P\{^1H\}$-NMR signal[4b] (200 MHz, $CD_2Cl_2$, $H_3PO_4$ ext.) of **3** (with the *cis*-**1** ligand), with $\delta = 303.4$ is shifted only slightly upfield compared to that of the free ligand *trans*-**1** (327.4[4a]).

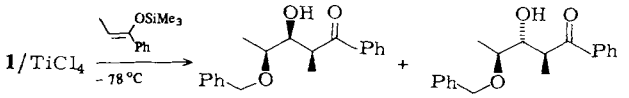
## Chelation or Non-Chelation Control in Stereoselective Reactions of Titanium Reagents with Chiral Alkoxycarbonyl Compounds**

By *Manfred T. Reetz**, *Kurt Kesseler*, *Susi Schmidtberger*, *Bernd Wenderoth*, and *Rainer Steinbach*

Following the pioneering work of *Cram* on chelation control in Grignard additions involving alkoxycarbonyl compounds[1], a number of publications on this topic have appeared[2]. We wish to report that chelation-controlled 1,2- and 1,4-asymmetric inductions are possible using Lewis acidic titanium reagents, and that diastereoselectivity can be *reversed* by changing the ligands at titanium[3] (non-chelation control). This extends our previous work on 1,3-asymmetric induction involving β-alkoxy aldehydes[10].

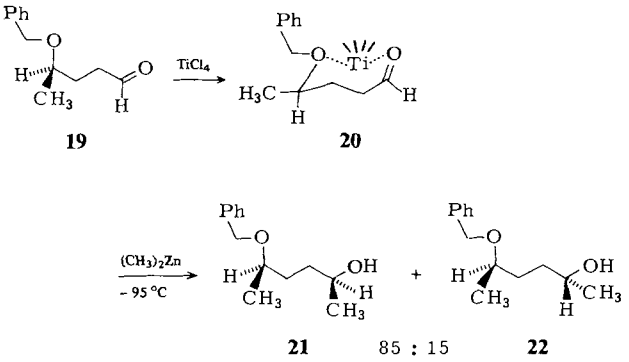


The reaction of the Lewis acidic $H_3CTiCl_3$[3] with aldehyde **1** leads *via* chelate **2** to the adducts **3** and **4** (92 : 8). Chelation mediated 1,2-asymmetric inductions of 90–96% are also observed if **1** is first chelated with $TiCl_4$ and subsequently treated with dialkylzinc, allylsilanes, or silyl enol ethers.

[*] Prof. Dr. M. T. Reetz, K. Kesseler, S. Schmidtberger, Dr. B. Wenderoth, Dr. R. Steinbach
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

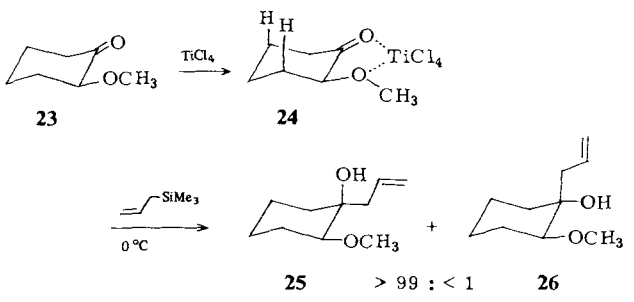
Reaction of the *Z*-configurated trimethylsilyl enol ether of propiophenone with **1**/$TiCl_4$ leads to formation of practically only one (**9**) of the four possible diastereomers; this product, formed *via* chelation control, has *syn*-stereochemistry at the two new chiral centers. Since the *Mukaiyama* aldol addition normally affords mixtures of *syn*/*anti*-adducts[7], an unusual phenomenon is operating. $SnCl_4$ gives the same result.



**9** 97 : 3 **10**

With titanium reagents which contain alkoxy- instead of chloro-ligands, *the 1,2-asymmetric induction can be reversed: e.g.*, the weak Lewis acid $H_3CTi(O\text{-}iPr)_3$ **13**[3] reacts with **1** to give **3** and **4** in the ratio 8 : 92. The observed stereoselectivity, which can be accounted for by *Anh*'s model[14], has not been observed previously using any other methylmetal reagents.

**13** allows for this type of control even in complicated cases, *e.g.*, in the reaction with a protected furanose. Reversal of diastereoselectivity is also observed in the addition of the tris(isopropoxy)titanium enolate derived from propiophenone (**9** : **10** = 13 : 87).



Unusually high 1,4-asymmetric induction is achieved by chelating the γ-benzyloxy aldehyde **19** with $TiCl_4$.

**19** **20**

**21** 85 : 15 **22**

Finally, chelation control is also feasible with the chiral ketone **23**. Presumably, **24** is the intermediate, since allyltrimethylsilane adds to **23** in the presence of $TiCl_4$ to afford practically only **25**. Weakly Lewis acidic reagents such as allylmagnesium chloride or allyltitanium tris(diethylamide) afford only 3 : 1 mixtures of **25** and **26**. Previously, the role played by chelation has only been deduced indirectly from stereochemical information[1,2]. $^1H$- and $^{13}C$-NMR spectroscopic studies of **23** in the presence of $TiCl_4$ suggest formation of the chelate **24** before stereoselective introduction of the allyl moiety.

## Tricyclo[2.1.0.$0^{2,5}$]pentan-3-one**

By *Günther Maier**, *Manfred Hoppe*, and *Hans Peter Reisenauer*

*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

The long-sought[1a] title compound **3** is interesting for a number of reasons: Is there, by analogy to the tetra-*tert*-butyl derivative[2], a route from **3** to the unsubstituted tetrahedrane **4**, or does the photoelimination of CO in an argon matrix lead directly to cyclobutadiene **5**? If the latter occurs, can free cyclobutadiene or a CO complex of **5** be detected?

Preparation of **3**: Hydrolysis of methyl 2,3-bis(trimethylsilyl)-2-cyclopropene-1-carboxylate[3a] with chlorotrimethylsilane/sodium iodide yields the carboxylic acid **1a**. Treatment of **1a** with oxalyl bromide leads to formation of the acid bromide **1b**, which—without further purification—can be converted into the diazoketone **1c**. Heating

**1** **2** **3**

**1a**, R = $CO_2H$; **1b**, R = COBr; **1c**, R = $COCHN_2$

**1c** with CuBr gives 1,5-bis(trimethylsilyl)tricyclo[2.1.0.$0^{2,5}$]pentan-3-one **2**. Desilylation of **2** occurs using KF/dibenzo[18]crown-6. Subsequent gas chromatographic separation (OV 101, 100 °C), which is associated with considerable losses, leads to a colorless oil. The spectroscopic data of this product (Table 1), which is stable at room temperature, are consistent with assignment to structure **3**. Here, the $^{13}C$-H coupling constant of C-1/C-5 of

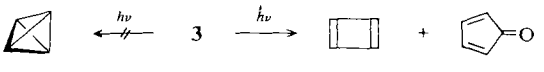
Table 1. **1a—c**, **2**, and **3**: Reaction conditions, yields, and physical and spectroscopic properties: IR [$cm^{-1}$], NMR ($CDCl_3$; $\delta$-values rel. TMS).

**1a**: $CH_3CN$, 20 h, 80°C; 67%; colorless crystals, m.p. = 86—88°C.—IR ($CCl_4$): 1770 (C=C), 1685 (C=O).—$^1$H-NMR: 0.29 (s, 18H), 1.87 (s, 1H); $^{13}$C-NMR: −1.8, 18.1, 124.4, 176.2

**1b**: 30 min, 60°C; colorless oil.—IR (film): 1790, 1750 (C=O).—$^1$H-NMR: 0.30 (s, 18H), 2.34 (s, 1H); $^{13}$C-NMR: −1.7, 33.2, 126.7, 178.0



**1c**: Ether, 15 h, −20°C; 32% (rel. to **1a**); yellow oil.—IR (film): 2100 ($CN_2$), 1745 (C=C), 1620 (C=O).—$^1$H-NMR: 0.22 (s, 18H), 2.04 (s, 1H), 4.76 (s, 1H); $^{13}$C-NMR: −1.6, 28.7, 50.6, 127.2, 201.1

**2**: $CHCl_3$, 2 h, 60°C; colorless oil.—IR (film): 1780 (C=O).—$^1$H-NMR: 0.21 (s, 18H), 1.92 (s, 2H); $^{13}$C-NMR: −0.8 ($CH_3$), 0.6 (C-1, C-5), 42.1 (C-2, C-4), 182.7 (C=O).—MS ($C_9H_{17}Si_2$, M−CO−$CH_3$): 181.0868 (calc.), 181.0867 (found)

**3**: $CH_3CN$, 2 h, 25°C; ≈10%; colorless oil.—IR ($CD_3CN$): 1775 (C=O).—$^1$H-NMR: 2.08 (t, 2H, $J$ = 1 Hz), 4.01 (t, 2H, $J$ = 1 Hz); $^{13}$C-NMR: −1.0 (C-1, C-5, $J(^{13}C\text{-}H)$ = 247.4 Hz), 36.6 (C-2, C-4, $J(^{13}C\text{-}H)$ = 189.3 Hz), 184.0 (C=O).—MS($C_4H_4$, M−CO): 52.0317 (calc.), 52.0315 (found)

247.4 Hz, the highest value reported to date, provides particularly significant evidence; this high value arises from the considerable ring strain in **3**[4] and the associated acetylenic character of the C—H bonds involved.

Matrix irradiation of **3**: Photolysis (monochromatic, 240 nm) of **3** in argon at 10 K proceeds slowly. After 16 h, the carbonyl bands typical of **3** [1878 (m), 1853 (w), 1829 (m), 1810 (vs), 1792 (m), 1729 (m), 1779 (s) $cm^{-1}$] disappear to 70%. Instead, absorptions for CO [2138 (s) $cm^{-1}$], cyclobutadiene **5** [1241 (m), 721 (vw), 571 (s) $cm^{-1}$], cyclopentadienone[3b] **6** [1727, 1724, 1332, 1136, 822 $cm^{-1}$], and acetylene [secondary product from **5**: 3270, 730—750 $cm^{-1}$] are observed.

**4** **5** **6**

Conclusion: Irradiation of tricyclopentanone **3** gives no evidence[5] to suggest formation of tetrahedrane **4**: cyclobutadiene **5** is formed as the major product. Since the CO band occurs at the frequency expected, the presence of a complex[3c] of cyclobutadiene with CO—which would be consistent with theoretical considerations[1b]—is precluded.

Soc. 99* (1977) 4851] the $^{13}$C-H coupling constant of C-1/C-3 of 210 Hz certainly corresponds to the expectation value but not the chemical shift of this C-atom ($\delta$ = 20.8), which in comparison to **3** and the numerous bicyclobutane derivatives investigated by *Christl* appears at extremely low field.

[5] A weak band at 927 $cm^{-1}$ cannot be assigned to any of the products mentioned. It is curious that tetrahedrane **4** should exhibit its only intense IR absorption in this region (940 $cm^{-1}$): J. M. Schulman, J. Venanzi, *J. Am. Chem. Soc. 96* (1974) 4739.

## Synthesis and Structure of $[Na(tmeda)_2]^{\oplus}[HNi_2(C_2H)_4]^{\ominus}$**

By *Klaus Richard Pörschke*, Wolfgang Kleimann, Günther Wilke, Karl Heinz Claus,* and *Carl Krüger*

Tris(ethene)nickel(0) **1**[2] reacts below −70°C with alkali metal trialkyl(hydrido)aluminates and -gallates in diethyl ether/tetrahydrofuran (THF) or ether/amine mixtures as solvent to afford the yellow, crystalline, thermally labile compounds $[M_A(n\text{-donor})_n]^{\oplus}[R_3M'\text{—}H\text{—}Ni(C_2H_4)_2]^{\ominus}$ **2** ($M_A$ = Li, Na; M' = Al, Ga; R = Me, Et, *i*Bu)[1]. Above −70°C in ether/*N,N,N',N'*-tetramethylethylenediamine (tmeda), the alkali metal-μ-hydridotetrakis(ethene)diniccolate(0) complexes **3** and **4** are formed by release of the $R_3M'$-solvate complexes.

$$2\ Ni(C_2H_4)_3 + M_AHAlR_3 \xrightarrow[-40\,°C]{\text{Ether/tmeda}} [M_A(tmeda)_2]^{\oplus}[HNi_2(C_2H_4)_4]^{\ominus} + 2\ C_2H_4 + AlR_3\cdot Solv$$

**1**

**3**, $M_A$ = Li
**4**, $M_A$ = Na

R = Me, Et, *i*Bu

The lithium compound **3** was obtained as a sparingly soluble, yellow precipitate from ether, and the sodium compound **4** could be isolated as yellow-brown crystals. Both salts were characterized by elemental analysis, NMR spectra, and by their reactions, and the structure of **4** was determined by X-ray structure analysis. The compounds are particularly interesting since the nickel atoms are only coordinated by ethene and a hydride ion[3].

Both in solution and in the solid state the ion pairs **3** and **4** are stable only below −20°C. NMR spectra indicate that tmeda is released from the complex cations upon its dissolution in THF. Reaction with alcohols leads to hydrogenation of the ethene to afford ethane, without formation of free hydrogen. The presence of the hydride hydrogen is confirmed by the formation of methane from methylating agents such as methyl iodide or dimethyl sulfate.

In **3** and **4** the ethene is relatively strongly bonded. It cannot be displaced by norbornene, and no exchange with free ethene is observed by $^1$H-NMR spectroscopy. However, with cyclooctatetraene the ethene is liberated quantitatively. **3** reacts with CO in ether at −70°C to give yellow $[Li(tmeda)_2]^{\oplus}[HNi_2(CO)_6]^{\ominus}$ **5**. Compounds with the same complex anion are known[1,4], and its existence has previously been proved by X-ray crystallography[4]. In contrast to the binuclear niccolates **3** and **4**, the fragment $[(C_2H_4)_2NiH]^{\ominus}$—in accord with theoretical considerations[8]—readily adds ethene.

The low temperature 400 MHz $^1$H-NMR and 100.6 MHz $^{13}$C-NMR spectra are consistent with a trigonal-planar coordination of the nickel atoms by two ethene ligands

[**] The Lewis Acidity of Nickel(0), Part 5.—Part 4: [1].

and a hydride ligand, with the ethene C atoms in the coordination plane. The strong shielding of the ethene C and H atoms of **4**, the chemical shifts of which are similar to the values found for $[Li(tmeda)_2]^{\oplus}[CH_3Ni(C_2H_4)_2]^{\ominus}$ **9**[6,9] in $[D_8]$THF, indicates that the extent of charge transfer from the hydride H atom to the bis(ethene)nickel(0) groups is greater than that from the hydridoaluminate group in **2**.

The crystal structure analysis of **4** indicates that the individual ions of the ion pair are present as separate entities. In the anion, two precisely trigonal-planar bis(ethene)nickel(0) moieties are linked *via* a hydride bridge. The angle between the coordination planes is 95.1°. The average values of the lengths of the Ni–C bonds (1.986(9) Å) and the complexed C=C bonds (1.412(8) Å) correspond to the values expected. The hydride H atom can be localized unequivocally and its parameters refined. The Ni–H–Ni unit is not linear, and a Ni–Ni distance of 2.596(1) Å is found; the electron deformation density indicates the presence of a metal-metal interaction.

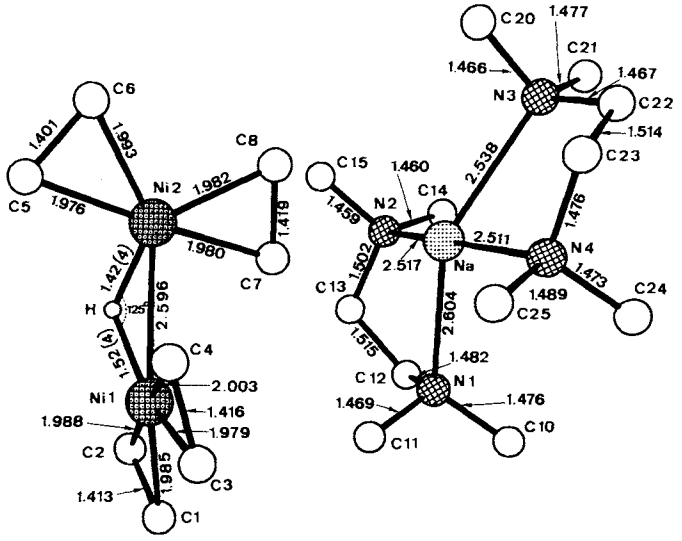

Fig. 1. Crystal structure of the ion pair **4**. Space group $P2_1/c$, $a=9.021(2)$, $b=16.949(6)$, $c=17.559(2)$ Å, $\beta=103.43(2)°$, $Z=4$. 11332 of the diffractometer data (4103 unobserved, $2\sigma$) collected at 100 K were used to solve the structure ($R=0.050$, $R_w=0.054$). This data set is the basis for a detailed investigation of the electron density distribution in **4** in combination with theoretical considerations. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50622, the names of the authors, and the journal citation.

The geometry of the Ni–H–Ni three-centered bond system corresponds both to that of the carbonyl complex $[(Ph_3P)_2N]^{\oplus}[HNi_2(CO)_6]^{\ominus}$ (Ni–Ni 2.864(3) Å)[4] and to that of the isoelectronic, doubly H-bridged phosphane complex $[\{(C_6H_{11})_2P(CH_2)_3P(C_6H_{11})_2\}NiH]_2$ (Ni–Ni 2.441(1) Å).

## Activity of Coordinated 1,4-Diaza-1,3-dienes (dad) in C-C Bond Forming Reactions: 1,5-Dihydropyrrol-2-ones from (dad)$Fe(CO)_3$ and Dimethyl Acetylenedicarboxylate**

By *Hans-Werner Frühauf*, Frank Seils, Maria J. Romao,* and *Richard J. Goddard*

Reactions of 1,4-diaza-1,3-dienes (dad) coordinated to transition metals in which C-C bonds are formed have hitherto only been observed for binuclear complexes $(dad)M_2(CO)_6$ of, *e.g.*, molybdenum and particularly of ruthenium[4]. In the latter, the authors[4] claim that the unsymmetrical 6e-coordination mode of the dad system in these complexes, which we first described for the corresponding iron complexes[2], is crucial for the activation of dad for C-C bond formation.

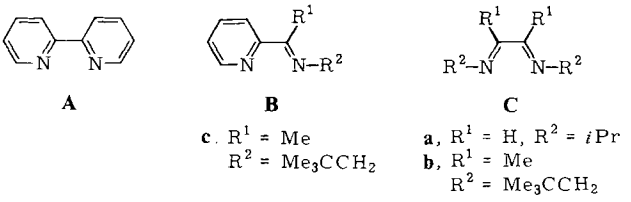

Fig. 1. 1,4-Diaza-1,3-diene (dad) ligand types and examples of substituents.

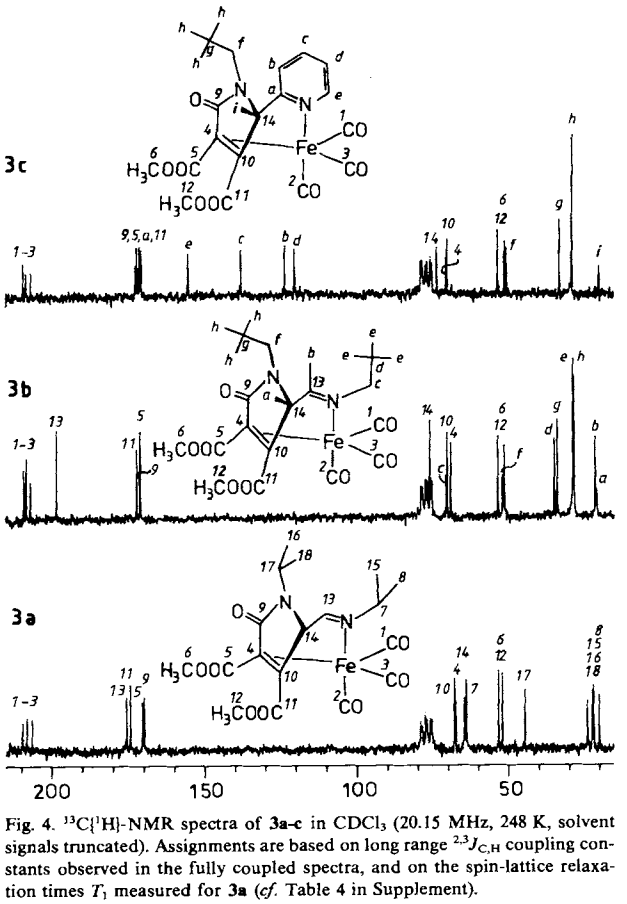

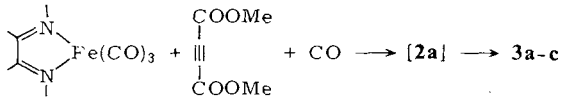

Fig. 4. $^{13}C\{^1H\}$-NMR spectra of **3a-c** in $CDCl_3$ (20.15 MHz, 248 K, solvent signals truncated). Assignments are based on long range $^{2,3}J_{C,H}$ coupling constants observed in the fully coupled spectra, and on the spin-lattice relaxation times $T_1$ measured for **3a** (*cf.* Table 4 in Supplement).

[+] X-Ray structure analysis

[**] This work was supported by the Fonds der Chemischen Industrie.

Treatment of compounds **1a-c** of dad-type B or C (cf. Fig. 1) with dimethyl acetylenedicarboxylate under CO gives 1,5-dihydropyrrol-2-ones as their $Fe(CO)_3$-complexes **3a-c**. At elevated temperatures the synthetically interesting heterocycles can, *e.g.* from **3a**, be displaced by adding dad and regenerating the starting tricarbonyl **1a** (see Fig. 4 for formulas **3a-c**).

**1a-c**

(dad)$Fe(CO)_3$

The reaction clearly demonstrates that C-C bond formation is also feasible for dad coordinated to a transition metal solely through the nitrogen lone pairs; the above mentioned 6e-coordination mode, which involves the π-electrons of one C=N moiety, is not a necessary prerequisite.

The structure of **3a** was solved by single crystal X-ray analysis. According to their spectroscopic (cf. Fig. 4 and Table 5) and other properties, the structures of **3b** and **3c** resemble that of **3a**. Despite this, there are marked differences in the product forming reactions. Whereas **3b** and **3c**

Table 5. IR bands $\nu$ (C≡O) stretches for **3a-c**: in $CHCl_3$.

| Compd. | $\nu$ (C≡O) [$cm^{-1}$] [a] |
|---|---|
| **3a** | 2064, 2003, 1981 |
| **3b** | 2060, 1998, 1980 |
| **3c** | 2063, 2002, 1983 |

[a] Wavenumber calibration by DCl gas; precision better ±0.5 $cm^{-1}$.

are formed without observable intermediates, **3a** results from rearrangement of an isomeric precursor **2a**, which could be isolated in pure crystalline form below 0°C and characterized spectroscopically and by elemental analysis.

## Conversion of Imidazole into μ-2,3-Dihydro-1*H*-imidazole-1,2,2-triyl Ligands**

By *Jörn Müller** and *Rainer Stock*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Binuclear bis($\eta^4$-cyclodiene-μ-chlororhodium) complexes can be cleaved by suitable P and N donor ligands L into mononuclear species ($\eta^4$-cyclodiene)Rh(L)Cl. Thus, reaction of $[(cod)RhCl]_2$[1] (cod = 1,5-cyclooctadiene) with $P(CH_3)_3$ affords the compound $(cod)Rh[P(CH_3)_3]Cl$, which can readily be converted into $(cod)Rh[P(CH_3)_3]CH_3$ with methyllithium[2].

By analogy, the reactions of $[(cod)RhCl]_2$ with 1-methyl- or 1-vinylimidazole (molar ratio 1:2) in tetrahydrofuran (THF) give the complexes **1** and **2** (**1** has already been described[3] but incompletely characterized). Surprisingly, the action of $CH_3Li$ on **1** and **2** in *n*-hexane does not lead to isolation of the expected $(cod)Rh(L)CH_3$ species; rather, they eliminate methane to form the binuclear complexes **3** and **4**, in which, for the first time, μ-2,3-dihydro-1*H*-imidazole-1,2,2-triyl ligands occur *via* orthometalation of the 2-position of the imidazole rings.

**1**: R = $CH_3$
**2**: R = $CH=CH_2$

**3**: R = $CH_3$ (79%)
**4**: R = $CH=CH_2$ (49%)

The orange-red compounds **3** and **4** decompose without melting only at temperatures above 200°C. Whereas **1** and **2** decompose in the reverse way to their mode of formation when it is attempted to volatilize them in the mass spectrometer, high intensity peaks of the molecular ions of **3** and **4** appear under EI conditions (70 eV) (**3**: *m/z* 584; **4**: *m/z* 608).

The $^1H$- and $^{13}C$-NMR spectra of **3** and **4** are consistent with a $C_i$ symmetry for the complexes, *i.e.* the ligand spheres of the two Rh atoms are not coplanar ($C_{2h}$ symmetry). If the ligand configuration expected for four-coordinated rhodium(I) is assumed, the observed $C_i$ symmetry suggests a pyramidal geometry, at least for the $N^1$ atoms of the bridging ligands; a planar RhCNRhCN six-membered ring with slightly tilted cod ligands would be a conceivable structural alternative.

The signals for $H^2$ ($\delta$ *ca.* 8.3) in **1** and **2** are absent in **3** and **4**. The carbene character of $C^2$ in **3** and **4** expresses itself in a large shift of the $^{13}C$-NMR signal by *ca.* 40 ppm to low field relative to the signal of $C^2$ in **1** and **2** ($\delta$ values in [$D_8$]THF): **3** 180.8; **4** 184.0 ppm); at the same time, in **3** and **4** a large $^{103}Rh$-$C^2$ coupling of *ca.* 51 Hz is found. In contrast to **3** and **4**, in solution **1** and **2** exhibit dynamic behavior, which results in a marked broadening and coalescence, respectively, of the olefinic cod-NMR signals.

In **3** and **4** the valence shells of the Rh atoms have only 16 electrons. The mode of formation of the compounds *via* an orthometalation is related to the thermolysis of 1,3-dimethylimidazolium pentacarbonylhydridochromate(1−), which *via* elimination of $H_2$ led to the first metal complex of 1,3-dimethyl-2,3-dihydro-1*H*-imidazole-2-ylidene[4].

## Lithium Complexes with *pentahapto*-Bonded Cyclopentadienyl Ligands

By *Peter Jutzi**, *Ewald Schlüter*, *Carl Krüger*, and *Siegfried Pohl*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

According to MO calculations, cyclopentadienyllithium $C_5H_5Li$ has a pentagonal-pyramidal structure[1], and is thus the simplest metallocene[1a]. Experimentally there is spectroscopic evidence for a structural element of this type for solutions of $C_5H_5Li$ in donor solvents[2], but the isolation and unequivocal characterization of such species have not yet been described[3]. Addition of the mono-, di-, and tridentate nitrogeneous bases quinuclidine, tetramethylethylenediamine (tmeda), and pentamethyldiethylenetriamine (pmdeta), respectively, to a solution of tris(trimethylsilyl)cyclopentadienyllithium **1**[4] in hexane leads to isolation of the air-sensitive, crystalline 1:1 adducts **2a—c**. These compounds are also readily soluble in hexane and, according to molecular weight determinations using cryoscopic methods, exist as monomers in benzene[5a].

| | | Base | M.p. [°C] |
|---|---|---|---|
| $(Me_3Si)_3C_5H_2Li \cdot$base | **2a** | quinuclidine | 86 |
| | **2b** | tmeda | 124 |
| | **2c** | pmdeta | 79 |

The X-ray crystal structure analyses of **2b** and **2c**[5b] indicate that in each case the cyclopentadienyl ring is $\eta^5$-coordinated to the alkali metal atom[6]. The structures of the complexes **2b** and **2c** are very similar since in the latter only two nitrogen atoms of the potentially tridentate base pmdeta are coordinated to the lithium atom (Fig. 1).

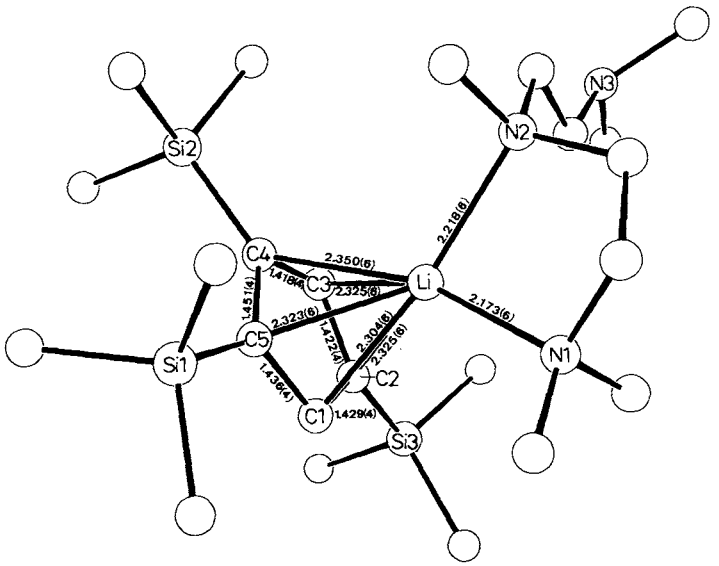

Fig. 1. Crystal structure of the lithium compound **2c**.

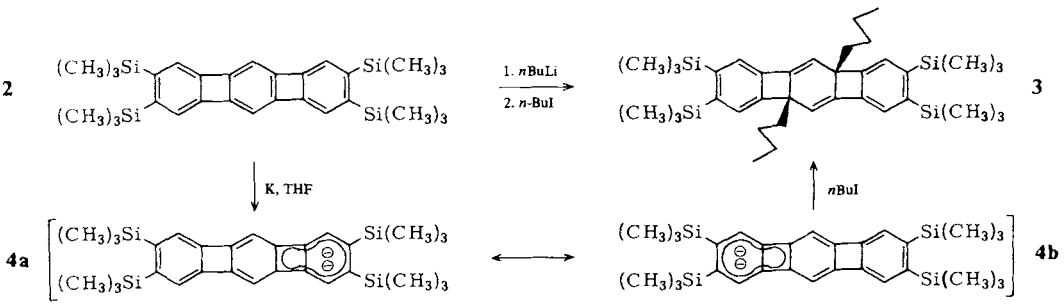
## The Structure and Reactivity of 2,3,7,8-Tetrakis(trimethylsilyl)terphenylene***, a Novel Linear Multiphenylene**

By *George H. Hovakeemian* and *K. Peter C. Vollhardt**

We recently reported[1] an iterative approach to the synthesis of the theoretically interesting linear multiphenylenes **1** and **2**[2] using a synthetic sequence involving both palladium and cobalt as catalysts.

**1**, R = H, n = 3
**2**, R = $(CH_3)_3Si$, n = 3

The central benzene ring in **1** and **2** is extraordinarily reactive, undergoing complete and all-*cis* hydrogenation, in the case of R = H faster than cycloheptene[1]. We now report further unusual transformations of **2** together with its X-ray structure.



In order to pinpoint the acidity[3] of the H atoms of the central benzene ring, **2** was treated with *n*-butyllithium in tetrahydrofuran (THF) at −78 °C. A blue solution ensued

[**] This work was supported by the National Institutes of Health (CA 20713). *K. P. C. V.* is a Camille and Henry Dreyfus Teacher-Scholar (1978—1983). *G. H. H.* is on sabbatical leave from the University of Kuwait. The X-ray structural analyses were carried out by Dr. *F. J. Hollander*, staff crystallographer.

[***] According to IUPAC rules the title compound would be 2,3,7,8-tetrakis(trimethylsilyl)cyclobutabenzo[1,2-*b*]biphenylene.

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/1212-0994 $ 02.50/0* 

which when quenched with *n*-butyl iodide gave the very strained *cis*-dibutyl adduct **3** in 81% yield (m.p. 165.5–166°C), whose structure was ascertained by X-ray crystallography. Other combinations of alkyllithium and alkylating reagents effected similar double additions.

Remarkable also was the reduction of **2** to the dianion **4**, a transformation which converts a neutral $[4n+2]\pi$-system into a [4n] polycyclic dianion. Exposure of the orange-red starting material to a potassium mirror in $[D_8]$THF instantly produced an emerald green solution of the presumed radical anion, which turned red-brown on further reduction to **4**. Despite the $[4n]\pi$-system and the addition of two negative charges, the chemical shift of the central benzene protons increased (from $\delta=6.34$ to $\delta=6.52$), whereas that on the outside ring decreased only slightly (from $\delta=6.75$ to $\delta=6.23$). An explanation for this astonishing behavior might be found within the framework of other results concerned with the problem of aromaticity in polycyclic ions[4], which indicate that such systems tend to maximize the development of aromatic circuits at the expense of those involving only the periphery. Thus, resonance structures such as **4a** and **4b** might be strong contributors to the ground state of the molecule, diamagnetic ring currents offsetting the charge effect. Protonation of **4** ($CH_3OH$, $H_2O$) gave a white solid, which on exposure to air instantly reformed **2**, indicating a considerable driving force for re-aromatization. On the other hand, butylation gave **3**.

Because of its unusual reactivity, an X-ray structural analysis of **2** was undertaken (Fig. 1)[5]. The molecule contains a crystallographic inversion center in the middle of the central ring. Although basically flat, it deviates significantly from planarity. The $Me_3Si$ group at C2 is bent by 0.27 Å out of the plane defined by C3C2C1C6. Relevant bond lengths and angles are compiled in Table 1.

In comparison with the structures of 1,2-dihydro-4,5-bis(trimethylsilyl)cyclobutabenzene[6a] and biphenylene[6b], several features are unusual. First, the unreactive outer benzene rings exhibit considerably more pronounced bond fixation than the model compounds, and are in the order of that found in the antiaromatic 1,2-di-*tert*-butyl-3,4,5,6-tetramethylcyclobutabenzene[6a]. Second, the bonds of the fused four-membered ring are remarkably short, particularly compared to those in biphenylene, and are very similar in length to those found in benzene itself. Third, the reactive central six-membered ring shows very little bond alternation, being best described as two strongly interacting allyl units.

The structure-activity relationships described here suggest that multiphenylenes are not simply extended biphenylenes, but indeed novel $\pi$-systems with unusual properties.

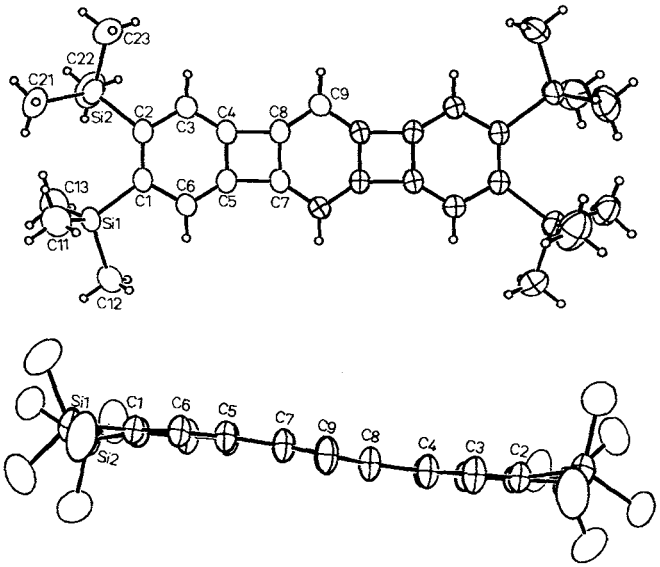

Fig. 1. Crystal structure of **2**. Top: frontal view; bottom: side-view. The numbering does not follow IUPAC rules but the requirements of the X-ray structure analysis.

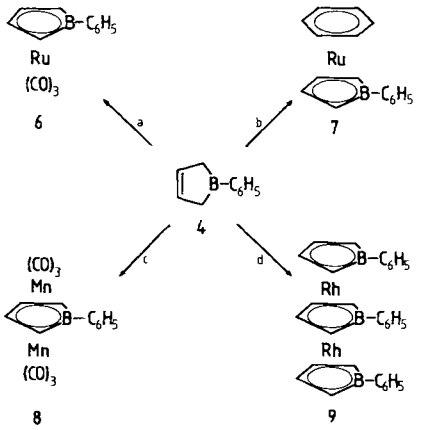
## A Novel and General Route to ($\eta^5$-Borole)metal Complexes: Compounds of Manganese, Ruthenium, and Rhodium**

By *Gerhard E. Herberich*, Bernd Hessner, Wilfried Boveleth, Herbert Lüthe, Roland Saive,* and *Ljerka Zelenka*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

As four-electron ligands, boroles **1** are able to form transition metal complexes with *closo*- and *nido*-structures[3]. Such complexes are sparsely documented and have hitherto only been accessible *via* specific synthetic routes.



Herein we wish to report a general synthetic approach, which, for the first time, enables a systematic and versatile access to (borole)metal complexes. Reaction of 1-phenyl-2,5-dihydroborole **4**[7] with a wide variety of transition-metal complexes leads to catalytic isomerization to 1-phenyl-2,3-dihydroborole **5**[8] and dehydrogenating complexation with formation of ($\eta^5$-borole)metal complexes.

1 4 5

Thus, **4** reacts with $Ru_3(CO)_{12}$ on heating to give the (borole)tricarbonylruthenium complex **6** in 35% yield. Reaction with $Ru(C_6H_6)(C_6H_8)$ in liquid benzene at 160°C leads to formation of the complex **7** (22%) as main product. Reaction with $Mn_2(CO)_{10}$ in boiling mesitylene affords the triple-decked complex **8** (15%). Dehydrogenating complexation with the catalytically highly active $[(C_2H_4)_2RhCl]_2$ proceeds exceptionally smoothly, slowly furnishing the triple-decked complex **9** (80–95%), even at room temperature.

Each of the new complexes **6–9** contains *pentahapto*-bonded borole rings. This has already been demonstrated by an X-ray structural analysis in the case of the 2-ethyl derivative of **8**[4], and, in all cases, has been established from $^{11}$B-NMR data[1,3]. In the case of the triple-decked

a: $Ru_3(CO)_{12}$, toluene, 90°C, 6 d; b: $Ru(C_6H_6)(C_6H_8)$, benzene, 160°C, 3 d; c: $Mn_2(CO)_{10}$, mesitylene, 155–160°C, 3 d; d: $[(C_2H_4)_2RhCl]_2$, tetrahydrofuran, 20°C, 16 h (thereafter 65°C, 4 h).

complex **9** the $^{11}$B signal of the central ligand appears, consistent with a general rule, at higher field than the signal of the outer ligands and is less broadened by nuclear quadruple relaxation because of the higher coordination number at the B atom.

Our synthetic approach permits other groups at the B atom, *e.g.* alkyl, amino, and, in certain cases, halogen groups. Introduction of organic substituents at the ring C atoms is also possible. Depending on the system, the hydrogen eliminated from the dihydroborole during the dehydrogenating complexation is liberated as $H_2$ or HCl, or is consumed by olefin hydrogenation ($C_2H_4 \rightarrow C_2H_6$).

[**] Preparation and Properties of and Reactions with Metal-Containing Heterocycles, Part 34. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 33: E. Lindner, G. A. Weiss, W. Hiller, R. Fawzi, *J. Organomet. Chem.*, **255** (1983) 245.

diates and final products[1]. In the course of investigations of suitable model reactions, we succeeded in performing such a C-C coupling by means of the reaction between $[Mn(CO)_5]^-$ and thioaroyl chloride **1** in tetrahydrofuran at −78 °C. The first step possibly involves nucleophilic attack of the Lewis base $[Mn(CO)_5]^-$ at the thioaroyl carbon atom. The thioaroyl derivatives **2**, which presumably form as intermediates, rearrange to the carbenoids **3** which dimerize to give **4** and **6**. The *cis*-compounds **4** are stabilized by the favorable arrangement of the metal atoms leading to complex **5** *via* coordination of the lone-pairs of electrons of the sulfur atoms and displacement of CO.

**a**, $R^1 = C_6H_5$
**b**, $R^1 = C_6H_4F$-(4)

The *trans*-species **6**, which are unstable in solution, can be trapped by electrophilic alkynes in a [2+2]-cycloaddition to afford the compounds **7**, which are thermally stable and also stable towards atmospheric oxidation. The complexes **5a**, **b**, **6a**, **b**, and **7a**, **b**, which can be isolated in crystalline form, were characterized by complete elemental analysis and by mass-, IR-, Raman- and $^{13}C\{^1H\}$-NMR spectroscopy; moreover, **5a**[10], **6b**, and **7b** were also characterized by X-ray structure analysis[11] (Fig. 1).

Notable structural features of **6b** and **7b** are the sterically bulky $(OC)_5MnS$ and thiamanganacyclobutene moieties, respectively, which are linked *via* a 1,2-ethenediyl group. In **6b** the Mn–C(5) distance of 180 pm for the CO ligand lying opposite the S atom is considerably shorter than the average value of the other Mn–CO bonds (187 pm). The Mn–S distances in **6b** and **7b** (240.5 and 243.4 pm, respectively) lie in the upper expectation range. As a result of the strain in the four-membered ring caused by the C(5)=C(7) bond (131.1 pm), the Mn–S bond length in **7b** is increased. Nevertheless, the fact that **7b** is more stable than **6b** can be attributed to the coordinative saturation of the sulfur. In **6b**, apart from S–Mn–C(2), the S–Mn–C angles of the S atom *cis* to the CO ligands are up to 5° smaller than those of octahedrally coordinated Mn; the CO ligands are therefore displaced towards the Mn–S bond. The opposing deviation of C(2)–O(2) results from the steric repulsion between this CO ligand and the 4-fluorophenyl group bonded to C(6'). In contrast, the coordination octahedra of the metal in **7b** is markedly distorted.

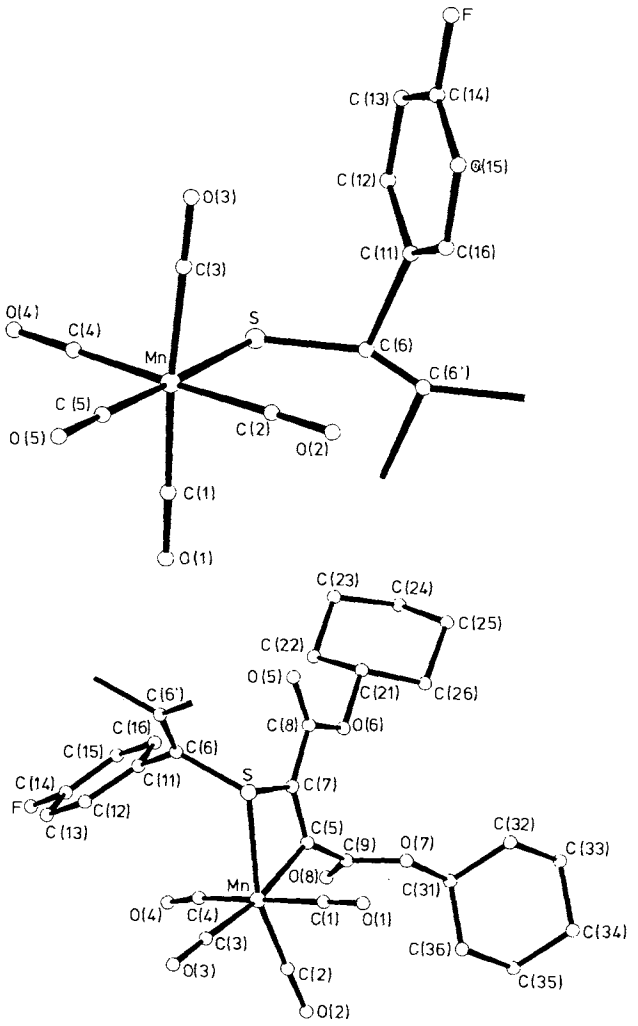

Fig. 1. Structures of **6b** (above) and **7b** (below). Since both compounds have centers of inversion, only one half of the respective molecules is shown.

## $Rb_7NaGe_8$ and $K_7NaGe_8$, Zintl Compounds with $Na(Ge_4)_2$ Units

By *Jaime Llanos, Reinhard Nesper,* and *Hans Georg von Schnering*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

The binary Zintl compounds ME (M, M′ = Na, K, Rb, Cs; E, E′ = Si, Ge) are characterized by the tetrahedral anions $E_4^{4-}$[1]. In an attempt to define the stability ranges of the various structures, we have synthesized the ternary compounds $ME_xE'_{1-x}$ and $M_xM'_{1-x}E$, respectively. Crystals of these ternary compounds are prepared from the elements and are black with a metallic luster. Like the binary germanides, these materials are extremely reactive, spontaneously igniting in the presence of moisture.

The $ME_xE'_{1-x}$ compound $Na_4Ge_2Si_2$ has the NaSi structure, containing tetrahedra which are composed of mixed anions $(E_xE'_{4-x})^{4-}$[2]. The $M_xM'_{1-x}E$ compounds $Rb_7NaGe_8$ and $K_7NaGe_8$ on the other hand, possess a novel cubic structure. To date, only the Rb compound has been studied in detail[3].

The novel cubic structure also contains the tetrahedral anions $Ge_4^{4-}$, which are surrounded by the cations in a similar way as in the binary phases NaGe, KGe and RbGe. The metal atoms act as $\mu_3$-ligands, coordinating the faces of the tetrahedra. In this way, distorted cubane-like species $M_4Ge_4$ are formed as primary structural units; their variable packing leads to the above-mentioned structure types[4]. The different sizes of the cations in $Rb_7NaGe_8$ modify this structural principle in a surprising way, which also explains the remarkable composition of this compound. Each Na atom links two $Ge_4$ tetrahedra *via* $2\times3$ equivalent Na–Ge bonds to form the quasi-linear $[Na(Ge_4)_2]$ unit (Fig. 1). The average distances $\bar{d}$(Ge–Ge) = 257.2 pm in the $Ge_4$ tetrahedron are as large as in the binary phases, but the individual distances are considerably different (253–262 pm). In particular, the face of the tetrahedron coordinated by the Na atom is enlarged. Six of the large cations are located above the vacant triangular faces of the tetrahedra and are also in contact with neighboring anions. The bond lengths (Na–Ge 298.1, Rb–Ge 361.8) are in the usual range. The structure of the unit consisting of Na, 6 M, and 8 Ge corresponds to two condensed cubanes with a shared apex (Na atom). According to the reaction $2\,Me_4Ge_4 = M_7Ge_8 + M$, one eighth of the M atoms is eliminated and can no longer participate in coordination to $Ge_4^{4-}$. Double cubanes of this type pack optimally and simply in the space group Pa3, forming one cavity per double cubane group[4]. The seventh large cation of $Rb_7NaGe_8$ is located in this large cavity, surrounded at relatively large distances by six Ge atoms (Rb–Ge = 406.6 pm) and, in addition, by six cations at a distance of 438.9 pm. The structure type is thus characterized by the formula $Rb\{Rb_6[Na(Ge_4)_2]\}$, which indicates that the aristotype is represented by a quarternary compound (*e.g.* "$CsK_6NaGe_8$"). Consequently, this compound was recently obtained. The expected distribution of cations for that structure is exactly fulfilled[6].

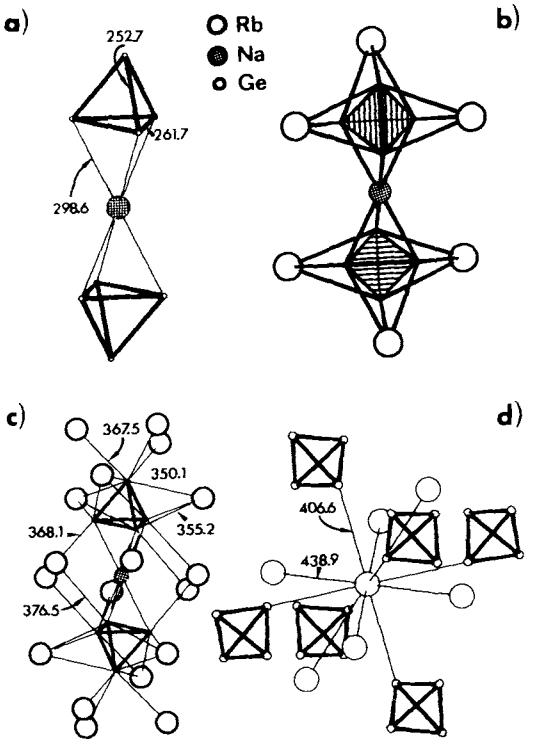

Fig. 1. Structural elements of $Rb_7NaGe_8$: a) Quasi-linear unit $[Na(Ge_4)_2]$ with markedly increased tetrahedral faces in the direction of coordination to the Na atom. b) Condensed double cubane $Rb_7NaGe_8$ with highly distorted tetrahedral star [5]. c) Enlarged coordination of the double cubane. d) Environment around Rb2: octahedral coordination by six tetrahedron apices Ge2 without direct contact to a cubane moiety. The neighboring atoms of type Rb1 give an impression of the size of the cavity in which Rb2 lies. All distances in pm.

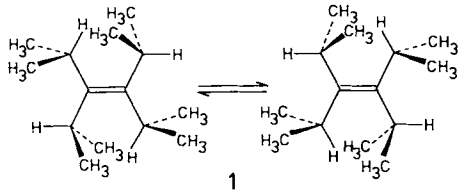
## Conformational Inversion of Tetraisopropylethylene: No Cog-Wheel Mechanism!



By *Otto Ermer**

*Dedicated to Professor Shneior Lifson on the occasion of his 70th birthday*

The most favorable minimum energy conformation $M_1$ of tetraisopropylethylene **1** has $C_{2h}$ symmetry and a planar double bond, as predicted computationally[1a] in 1974 and

[*] Priv.-Doz. Dr. O. Ermer
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

confirmed crystallographically[1b] in 1980. The authors who described the first synthesis of **1**[2] in 1975 considered a "cog-wheel" ("gearing") mechanism for the conformational inversion of **1**, implying a single-step interconversion with synchronous rotation (by 180°) of the isopropyl groups about the $C(sp^2)-C(sp^3)$ bonds.

**1**

An inversion barrier of 17 kcal $mol^{-1}$ ($\Delta G^{+}$) was derived from NMR data[2b]. We report here empirical calculations with the aid of our consistent force field[3a,b], which show that the inversion of **1** does not follow a cog-wheel pathway, but proceeds stepwise such that the four isopropyl groups rotate consecutively *via* three intermediate minima.

For the inversion of **1** seven minima ($M_1-M_7$) are relevant, which may be characterized by the orientation of the methine C–H bonds with respect to the double bond (*syn-* or *antiperiplanar*). Some calculated energetical and structural data as well as the symmetries are collected in Figure 1 (Newton-Raphson optimizations). The seven minima may be linked by eight non-equivalent interconversion paths, since the number of different paths emanating from a minimum must be equal to the number of its non-equivalent isopropyl groups (Fig. 2).

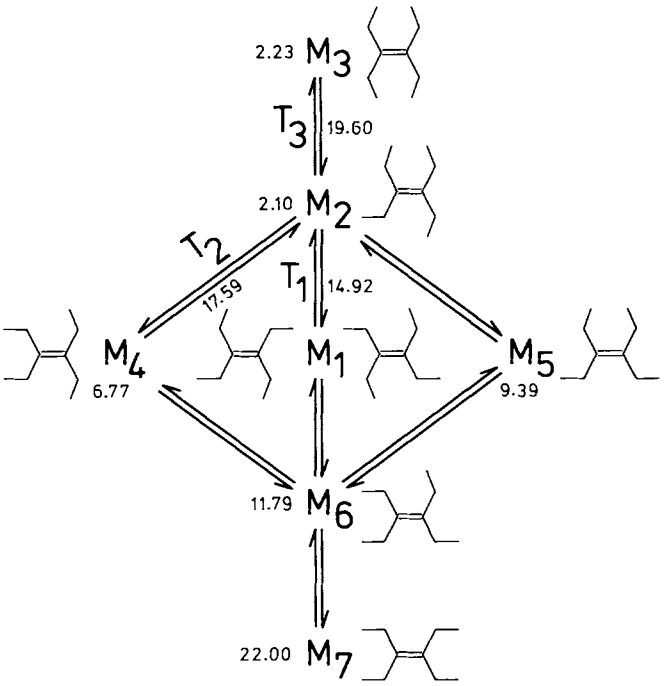


Fig. 2. Chart of the non-equivalent partial inversion paths of **1** (with relative potential energies in kcal $mol^{-1}$). Only the methine C–H bonds are drawn to indicate the orientation of the isopropyl groups in the minima.

As a consequence of the numerous, rather weakly restricted torsional degrees of freedom in **1**, the localization of the transition states for the partial inversions of the chart of Fig. 2 was difficult and time-consuming. To sim-

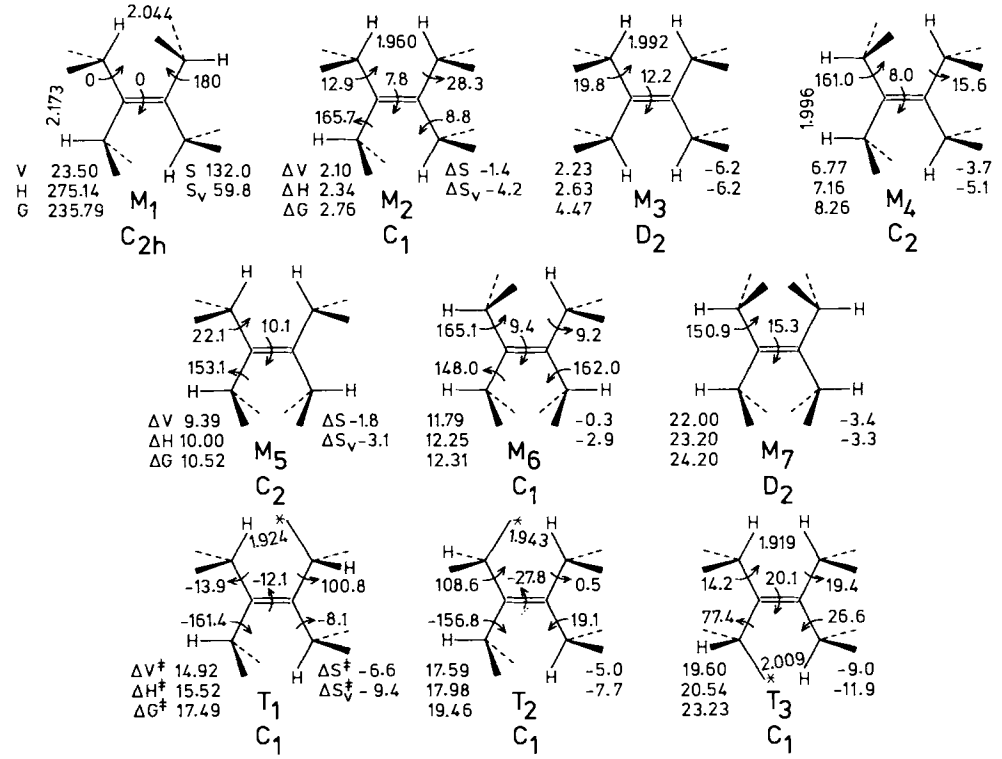

Fig. 1. Calculated minima (M) and transition states (T) of **1** relevant for the inversion process. Structural data: H–C–C=C torsion angles, double bond twist angles [°], short H···H contacts [Å]. Except for $M_1$, the energies [kcal $mol^{-1}$] and entropies [cal $mol^{-1}$ $K^{-1}$] given are relative quantities referring to $M_1$ (standard symbols; *V* optimum potential energies, $S_v$ harmonic vibrational entropies). The congested methyl groups of the rotating isopropyl groups in the transition states are indicated by an asterisk.

plify the calculation, interconversions involving $M_5$, $M_6$, and $M_7$ were not considered. These minima have 1,2-*cis*-configurated isopropyl groups with four methyl groups in close proximity which, according to model considerations, is particularly unfavorable. With this assumption, only the three interconversions involving $M_1$—$M_4$ had to be considered in the detailed analysis. The associated transition states could be located with appropriate eigenvector methods[3b,c]. Some important energetical and structural properties of the most favorable transition states for these three partial inversions are also included in Figure 1. As expected, they are characterized by particularly short nonbonded H···H distances which are the origin of the present conformational barriers. The energetically cheapest inversion process calculated for **1** proceeds in four steps (partial inversions involving the hindered rotation of a single isopropyl group) from $M_1$ *via* $M_2$ to $M_4$, and from there along equivalent paths *via* $M_2'$ to the inverted $C_{2h}$ minimum $M_1'$. The second (third) step of the inversion is rate-determining (transition state $T_2$) with a calculated free energy of activation $\Delta G^{\neq}$ of 19.46 kcal mol$^{-1}$. The moderate computational overestimation of the inversion barrier (experimental value 17 kcal mol$^{-1}$[2b]) is probably due to the excessive hardness of our nonbonded H···H potential at short distances[4]. The activation entropies of all three calculated partial inversions are markedly negative. This appears to arise from a vibrational effect since the stronger H···H repulsions in the transition states as compared to the minima lead to frequency increases and thus to entropy decreases for the saddle points (Fig. 1).

Our calculations thus support a distinctly stepwise inversion mechanism of **1**. The consecutive rotations of the four isopropyl groups proceed *via* deep intermediate minima, which shows that a synchronous cog-wheel mechanism is energetically considerably less favorable than the stepwise partial inversions. This is due to the fact that more short H···H contacts occur simultaneously if the isopropyl groups rotate synchronously than with consecutive single rotations.

The example presented here leads to the more general conclusion that despite the conceptually appealing mechanical model, cog-wheel mechanisms are by no means the rule for conformational interconversions in overcrowded molecules. In fact, rather the opposite seems true: Unequivocally proven cog-wheel processes are scarce; probably the most convincing evidence in favor of such a process has been put forward for bis(9-triptycyl)methane and related compounds[5].

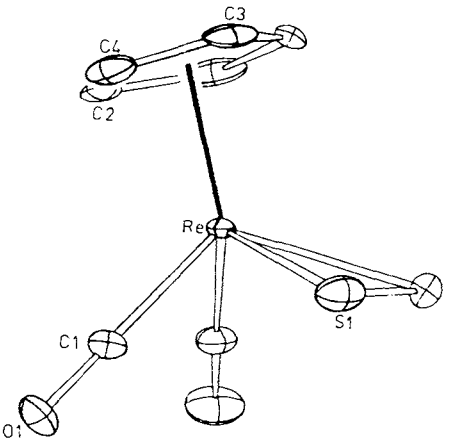
## Disulfur and Diselenium as Strong Acceptor Ligands in $(\eta^5\text{-}C_5H_5)Re(CO)_2S_2$ and $[\eta^5\text{-}C_5(CH_3)_5]Mn(CO)_2Se_2$**

By *Max Herberhold*, Dietmar Reiner,* and *Ulf Thewalt*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Disulfur complexes of transition metals are distinguished by the exceptionally wide variation in their structures and types of bonding[1]. Nevertheless, it would seem that the pronounced acceptor properties of the $S_2$ ligand have so far never been documented. These have now been established from the IR and NMR spectra of the novel disulfur complex $CpRe(CO)_2S_2$ **2** (Cp = $\eta^5$-cyclopentadienyl). According to an X-ray structure analysis (Fig. 1), **2** contains an $\eta^2$-coordinated $S_2$ ligand which occupies the place of a CO group in the half-sandwich complex $CpRe(CO)_3$ **1**.



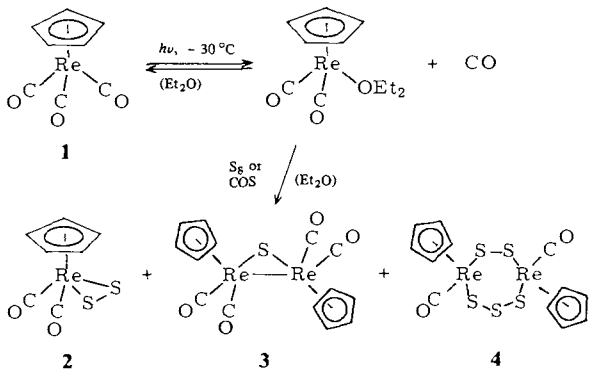


Fig. 1. Molecular structure of the disulfur-rhenium complex **2** in the crystal. Important bond lengths [Å] and angles [°]: Re-S1 2.410, S1-S1' 1.996; S1-Re-S1' 48.9, C1-Re-C1' 77.9, Re-C1-O1 179.4. The molecule has crystallographic mirror image symmetry. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik on quoting the depository number CSD 50557, the names of the authors, and full citation of the journal.

Photolysis of **1** in diethyl ether leads primarily to cleavage of CO with formation of the solvent-stabilized complex $CpRe(CO)_2(OEt_2)$. Further reaction with either sulfur

or carbon oxide sulfide yields a complex mixture of products containing, *inter alia*, the diamagnetic complexes **2**—**4**. The structures of **2**—**4** were determined by X-ray crystallography[4].

In the IR spectrum of the red-brown mononuclear disulfur complex **2**, the pattern of the CO stretching absorptions (baricenter 1979.5 $cm^{-1}$) appears at higher wavelengths than in the spectrum of the parent compound **1** (baricenter 1965.3 $cm^{-1}$). A corresponding increase is also observed in the (approximate) force constants $k$(CO), which were calculated from the $\nu$(CO) frequencies. The $k$(CO) values are better suited for a comparison of complexes of differing symmetry than the experimentally observed CO valence absorptions. Both in the $^1$H- and in the $^{13}$C-NMR spectrum, the singlet of the Cp ring in **2** is shifted downfield compared to that in **1**. All these data (Table 1) are consistent with the novel $S_2$ ligand removing more charge from the [$CpRe(CO)_2$] fragment than the original CO group. Accordingly, $S_2$ is a better acceptor ligand than CO—as are other sulfur-containing two-electron ligands (*e.g.* $CS_2$ and CS[6]).

A corresponding comparison of $Cp^*Mn(CO)_3$ **5** ($Cp^* = \eta^5$-pentamethylcyclopentadienyl) with the diselenium complex $Cp^*Mn(CO)_2Se_2$ **6** formed therefrom infers that $Se_2$ also surpasses the CO ligand in acceptor ability (Table 1).

The molecular structures of the dichalcogen complexes **2** and **6** are consistent with the spectroscopically derived transfer of charge from the metal to a side-on bonded $E_2$ ligand (E = S and Se, resp.). The S—S' distance (1.996(5)Å) in **2** lies between the values for single bonding and double bonding (cf. S=S 1.89 Å, $S_8$ 2.06 Å[7]); it is short compared to the lengths observed in other complexes with $\eta^2$-coordinated $S_2$ ligands (1.99—2.09 Å[1]). The Re—S distance (2.410(2) Å) is shorter than the sum of the covalent (single bond) radii, which can be taken to be 2.55 Å using $Re_2(CO)_{10}$ (1.52 Å)[8] and $S_8$ (1.03 Å)[7] as reference compounds. According to a preliminary X-ray structure analysis of **6**, the Se—Se (2.263(8) Å) and Mn—Se (2.463(4) Å) distances are likewise unusually short when compared with those in suitable reference compounds (Se=Se 2.19 Å and $Se_8$ 2.34 Å[7]; $Mn_2(CO)_{10}$, Mn—Mn 2.90 Å[8]).

In view of the short $E_2$ bond lengths, the ligands $S_2$ and $Se_2$ in **2** and **6**, respectively, can be regarded as the coordination-stabilized form of the (unstable) heteroolefins S=S and Se=Se, whose double bonds are lengthened by $\pi$-complex formation. In contrast to the formulation of anionic $S_2^{\ominus}$ or $S_2^{2\ominus}$ ligands, frequently proposed in recent studies (cf.[1]) and even more strongly emphasizing the acceptor character of the dichalcogen ligands, the model used here with $S_2$ and $Se_2$ as uncharged two-electron ligands also reveals the analogy to the complexes $CpM(CO)_2L$ (M = Mn, Re) containing other neutral acceptor ligands (L = CO, CS, $CS_2$[6]).

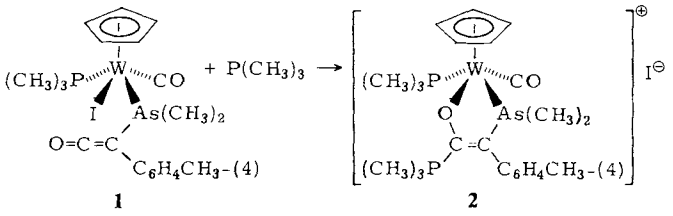
## An Arsanylketene by Elimination from an Oxaarsatungstacyclopentene Complex**

By *Fritz Roland Kreissl*, Mathias Wolfgruber*, and *Werner Sieber*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*



Arsenic- and phosphorus-substituted ketenes could hitherto not be obtained by organochemical methods[2], even though their preparation in the coordination sphere of tungsten has already been achieved on numerous occasions[3]. The dissolution and isolation of the intact ketene ligands thus presented a stimulating challenge.

The arsanylketene ligand could be cleaved from **1** with carbon monoxide (100 °C/60 bar) with formation of $\eta^5$-$C_5H_5(CO)_2[P(CH_3)_3]WHal$, but could not be detected without sign of decomposition. In contrast, all attempts to displace phosphanyl- and arsanylketene ligands with trimethylphosphane initially led *via* attack of the phosphane at the central ketene carbon to cationic phospha- and arsatungstaheterocycles[4] of type **2**; mass spectroscopic findings (FD), however, pointed to the possibility of thermal liberation of the original ketene ligands. In the case of the

[**] Transition-Metal-Ketene Compounds, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Instustrie.—Part 15: [1].

arsenic compound **2** this reaction could be reproduced for the first time on a preparative scale. When carried out in boiling toluene the novel arsanylketene **3** was formed in almost quantitative yield together with nearly quantitative amounts of tungsten complex **4**[5].

**1** **2**

**3** **4**

The surprisingly stable ketene **3** is a yellow, "cacodyl-like" smelling oil, which was characterized IR, $^1$H-NMR, $^{13}$C-NMR, and mass spectroscopically. The spectroscopic data for the free ketene and the complexed ketene moiety differ only slightly (Table 1). The expected high-field shift of all NMR signals of **3** compared to those of **1** is naturally greatest in the case of the $As(CH_3)_2$ group.

Table 1. IR-, $^1$H-NMR, and $^{13}$C-NMR spectroscopic data for **1** and **3**.

| | | **1** | **3** |
|---|---|---|---|
| IR (in $CH_2Cl_2$) [$cm^{-1}$] | $\nu$(C=C=O) | 2095 vs | 2074 vs |
| $^1$H-NMR (in $CD_2Cl_2$, $\delta$-value rel. $CDHCl_2 = 5.4$) | $C_6H_4$ | 7.30 s, 4H | 7.17 s, 4H |
| | $AsCH_3$ | 1.89 d, 6H $J = 3.0$ OHz | 1.26 s, 6H |
| | $CH_3$ | 2.47 s, 3H | 2.38 s, 3H |
| $^{13}$C{$^1$H}-NMR (in $CD_2Cl_2$, $\delta$-value rel. $CD_2Cl_2 = 54.2$) | CO-ketene | 182.90 | 183.77 |
| | C-ketene | 31.26 | 28.80 |
| | $C_6H_4$ | 137.91–125.56 | 134.88–127.41 |
| | $CH_3$ | 21.44 | 21.45 |
| | $AsCH_3$ | 15.51 | 11.08 |

The mass spectrum of **3** (EI, 70 eV), whose signals were already contained in spectra of **1** and **2**, shows the molecular ion as base peak, the fragmentation of which triggered off with the successive cleavage of a methyl radical and a carbon monoxide molecule.

## $P_{12}iPr_4$ and $P_{13}iPr_5$, Two Novel Polycyclic Organophosphanes**

By *Marianne Baudler*, Yusuf Aktalay, Volker Arndt, Karl-Friedrich Tebbe,* and *Magda Fehér*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

We recently found that dehalogenation of dichloro(organo)phosphanes with magnesium in the presence of white phosphorus, as well as thermolysis of bi- and tricyclic organophosphanes, in particular $P_7R_5$ and $P_9R_5$, open up a preparative route to polycyclic organophosphanes $P_nR_m$ ($m < n$) with $n \geq 8$[1]. In each case, mixtures of several compounds are formed, which with small alkyl groups R are largely insoluble and, therefore, cannot be separated. However, the solubility increases with the number of C atoms in the substituents and, hence, isolation of individual species becomes possible[1a].

Using the "thermolysis route", we have now prepared the tetraisopropyldodecaphosphane(4) **1** and the pentaisopropyltridecaphosphane(5) **2**[5] and have clarified the structures of the pentacyclic $P_{12}$(4)- and $P_{13}$(5)-frameworks.

R = *i*Pr **2**

**1** and **2** form light yellow platelets and needle-shaped crystals, respectively, which do not change up to 250 °C and which are stable under an inert gas atmosphere. They are readily soluble in arenes and tetrahydrofuran (THF), moderately soluble in cyclohexane, but, in contrast, sparingly soluble in aliphatic hydrocarbons. The compounds, which in the solid state are only slightly sensitive to atmospheric oxygen, are rapidly oxidized in solution. The compositions of **1** and **2** are corroborated by correct elemental analysis and molecular weight determinations (MS: **1**: *m/z* 544; **2**: *m/z* 618).

The $^{31}$P{$^1$H}-NMR spectra of **1** and **2** exhibit a series of substructured signal groups in the region $\delta = +85$ to $-30$, which is characteristic for condensed phosphorus five- and six-membered rings[1c]. The quasi-triplet structure of the respective high-field groups at $\delta \simeq -30$ indicates the presence of a two-atom bridge as component of a norbornane-analogous part structure[1c]. Consistent with this, the X-ray structure analysis of **1**[2] yielded the molecular geometry shown in Figure 1; **1** is accordingly a 3,4,9,10-tetraisopropylpentacyclo[6.4.0.0$^{2,6}$0.$^{5,12}$.O$^{7,11}$]dodecaphosphane. The bond lengths and angles of the $P_{12}$(4)-framework (approximate $C_{2v}$ symmetry) exhibit considerable differences; above all, the zero-bridges of the central $P_8$(4)-moiety are markedly lengthened. The needles of **2** were too thin for

[*] Prof. Dr. M. Baudler, Dr. Y. Aktalay, Dr. V. Arndt, Prof. Dr. K.-F. Tebbe, Dr. M. Fehér

Greinstrasse 6, D-5000 Köln 41 (Germany)

[**] Contributions to the Chemistry of Phosphorus, Part 137. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.—Part 136: M. Baudler, J. Hellmann, *Z. Anorg. Allg. Chem.*, in press.

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/1212-1002 $ 02.50/0* 

an X-ray structure analysis. Because of the common mode of formation with **1** and $P_{11}iPr_5$[1c] as well as of the analogy of the $^{31}P\{^1H\}$-NMR spectrum with that of **1** and $P_{11}Et_5$[1c], it is highly probable that **2** is a 3,4,7,10,11-pentaisopropylpentacyclo[7.4.0.0$^{2,6}$.0$^{5,13}$.0$^{8,12}$]tridecaphosphane.

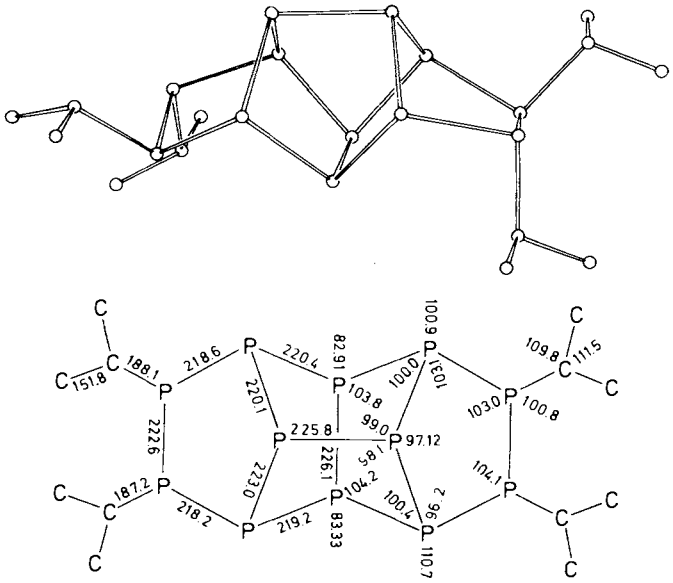

Fig. 1. Molecular structure of **1** in the crystal [2]; top: ORTEP representation; bottom: projection of the molecule parallel to the $C_2$ axis with average bond lengths in pm ($\sigma \leq 0.7$ pm) and selected average angles in degrees ($\sigma \leq 0.6°$; exceptions: $110.7 \pm 1.2°$ and $96.2 \pm 1.4°$).

Some time ago we were able[3] to detect mass spectroscopically the phosphorus hydrides $P_{12}H_4$ and $P_{13}H_5$, respectively, among the products of hydrolysis of calcium phosphide and in the products of thermolysis of diphosphane; however, their structures were not yet amenable to experimental investigations. Since in **1** and **2** significant steric influences of the substituents on the constitution of the phosphorus frameworks can be ruled out[1b], the hydrides can be considered to be the parent compounds of **1** and **2**, respectively.

The polycycloalkane $C_{12}H_{16}$ corresponding to **1** is known[3c], but not the **2**-analogue $C_{13}H_{18}$.

The $P_{12}$(4)- and $P_{13}$(5)-frameworks are essential structural units of Hittorf's phosphorus, in which they are linked alternatingly *via* the two-atom bridges as common zero-bridges to form five-cornered cylinders[4]. In **1** and **2** unaltered, P-rich part structures of the element occur for the first time as discrete molecules.

[5] Procedure: A mixture (45 g) consisting of approximately 60% $P_9iPr_5$, 20% $P_7iPr_5$, 5% $P_7iPr_3$, as well as further isopropylphosphanes (obtained by reaction of $iPrPCl_2$ and $PCl_3$ (5:4) with magnesium in boiling THF) is thermolyzed for 7 h at 230 °C. The yellow-brown, highly viscous product is taken up in 30 mL cyclohexane and chromatographed portionwise on $Al_2O_3$ (dried by heating *in vacuo*) using *n*-hexane and cyclohexane; the chromatographic process is monitored using $^{31}P$-NMR and mass spectroscopy. The fractions having the highest amount of **2** are combined, the solvent is evaporated off, and the more soluble portions are removed from the residue by extraction with *n*-pentane ($3 \times 5$ mL). Several recrystallizations from THF/pentane (3:1) yields 0.18 g pure **2** (not optimized); pure **1** is obtained from the mothor liquor.

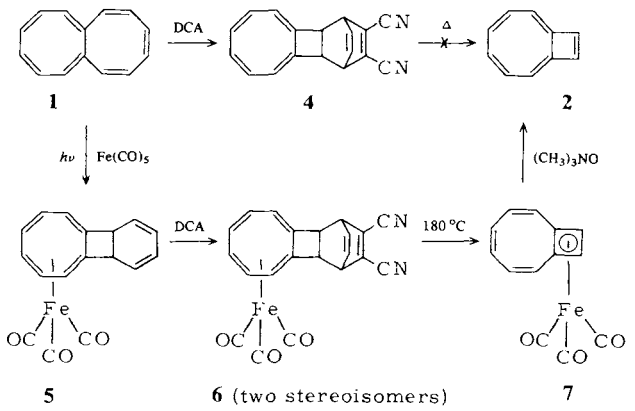
## Octalene—Bicyclo[6.2.0]decapentaene Conversion Mediated by Transition-Metal Complexes

By *Dieter Kawka, Peter Mues,* and *Emanuel Vogel**

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

The naphthalene- and azulene-isomer bicyclo[6.2.0]decapentaene is a molecule of current interest, both from the synthetic[1] and theoretical[2] point of view, due to the question of whether the *fusion* of two antiaromatic [4n]annulenes leads to an aromatic bicycle with a peripheral $(4n+2)\pi$-electron system. After *Schröder et al.*[1b,d,g] had succeeded in opening an entry to substituted bicyclo[6.2.0]decapentaenes, *Oda et al.*[1i] were able in 1980 to prepare the parent compound **2** for the first time starting from bicyclo[4.2.0]octa-3,7-diene-2,5-dione.

**1** **2** **3**



Parallel to *Oda*'s studies we attempted the synthesis of **2** from the olefinic octalene **1**[3] by the classical sequence of Diels-Alder reaction with an acetylenic dienophile and Alder-Rickert cleavage. In combination with transition-metal complex chemistry this concept now enabled an alternative access to **2**.

Reaction of octalene with dienophiles such as maleic anhydride[3c] or dicyanoacetylene (DCA) afforded sterically uniform 1:1 adducts, which—as suggested by the structure of the corresponding Diels-Alder adducts of cyclooctatetraene—derive from the tricyclic octalene valence isomer with a central four-membered ring, whereas reaction with 4-phenyl-1,2,4-triazole-3,5-dione yields an adduct with the carbon skeleton unchanged [(8+2)-cycloaddition][3a]. The octalene-dicyanoacetylene adduct **4** of interest here is obtained on heating a mixture of **1** and dicyanoacetylene (50% excess) in acetone (40–50 °C; 18 h); m.p. 163–164 °C (yield 34%). Contrary to our expectation the Alder-Rickert cleavage of **4** presented problems. Under analytical conditions [injection of a solution of **4** in dichloromethane into the injector of a gas chromatograph at 240 °C] the adduct **4** did in fact thermolyze in the expected way to give **2** and phthalic dinitrile, but on attempted translation of the reaction to the preparative scale a complex mixture of products was always formed, from which **2** could be isolated only with difficulty.

A way out of this impasse was opened by the observation that irradiation of a mixture of **1** and pentacarbonyl-

iron in pentane furnished the 1:1 complex **5** (together with 1:2 complexes), which, like the adduct **4**, derives from the octalene valence isomer with a central four-membered ring; red crystals, m.p. 112–113 °C (yield 22%). According to an X-ray structure analysis, the tricarbonyliron group and the six-membered ring in **5** are located on opposite sides of the eight-membered/four-membered ring system. As anticipated, **5** readily undergoes Diels-Alder reactions at the diene system of the six-membered ring, which is easily accessible from both sides. The addition of dicyanoacetylene leads to the chromatographically readily separable stereoisomeric adducts **6a** and **6b**, whose configurations still await assignment; **6a**: m.p. 143–144 °C (yield 56%), **6b**: m.p. 159–161 °C (yield 28%). In view of the tendency of tricarbonyl(1–4-η-9,10-dimethylbicyclo[6.2.0]decapentaene)iron to isomerize to thermodynamically stable tricarbonyl(1,8–10-η-9,10-dimethylbicyclo[6.2.0]decapentaene)iron at 90 °C[1g], it would appear that the thermal conversion of **6a/6b** into the cyclobutadiene complex **7** (and phthalic dinitrile) is predestined. When a mixture of solid **6a/6b** is heated to 180 °C the complex **7** is in fact formed in a smooth reaction [violet crystals, m.p. 74–75 °C (yield 62%)], without any trace of the assumed intermediate 1–4-η-bicyclo[6.2.0]decapentaene(tricarbonyl)iron being detectable[5]. The oxidative liberation of **2** from **7** with trimethylamine *N*-oxide dihydrate in acetone (20 h, room temperature) presented no difficulties; with diammonium hexanitratocerate(IV), however, only indefinable products were obtained. The bicyclo[6.2.0]decapentaene **2**, purified by chromatography on silica gel, precipitates from concentrated pentane solution at −78 °C as orange-red crystals (needles); these were dried *in vacuo* at the same temperature; m.p. < −30 °C (yield 70%).

The spectra of **2**[1i,2e], which have now been supplemented by the $^{13}$C-NMR spectrum [(75.4 MHz, $CD_2Cl_2$): $\delta = 143.90$ (C-9,10), 140.80 (C-1,8), 122.86, 122.60 (C-3,4,5,6), 109.90 (C-2,7)], do not as yet allow conclusions to be drawn about the π-electronic structure. In the case of the $^1$H-NMR spectrum [(90 MHz; $C_6D_6$): $\delta = 6.35$ (s, H-2,3,4,5,6,7), 7.47 (s, H-9,10)] it is still unclear why the chemical shifts of the four-membered and eight-membered ring protons differ by no less than 1.1 ppm. Consistent with the theoretical arguments put forward by *Aihara*[2d], it is obvious that application of the ring-current criterium for aromaticity to annelated ring systems such as **2** is inadmissible. On the basis of the structure analysis of 9,10-diphenylbicyclo[6.2.0]decapentaene[1h], it can be safely assumed that **2** is virtually planar and that the non-cyclobutadienoid resonance structure (as in Formula **2**) is most plausible. Interestingly, force field calculations predict an almost planar carbon skeleton even for an olefinic **2** parameterized to 1,3-butadiene. It thus appears attractive to determine by measurement of the heat of hydrogenation whether **2** profits energetically through delocalization of the peripheral 10π-electron system.

The possibility that **2** can—in analogy to its formation from **1**—be converted by the agency of transition-metal complexes into the butalene **3** hitherto not isolated in substance[9] [complex intermediates: **7**, dicyanoacetylene adduct of **7**, and butalene(tricarbonyl)iron] is presently under investigation.

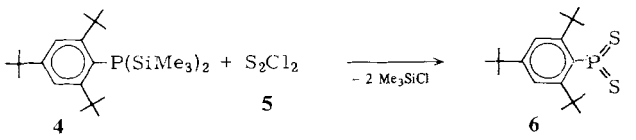
## The First Organodithioxophosphorane**

By *Rolf Appel**, *Falk Knoch*, and *Holger Kunze*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

Until now, the last member of the triply coordinated planar phosphoranes **1**[1], **2**[2], and **3** was missing; its existence had previously only been speculated about[3].



**1** **2** **3**

We have now been able to synthesize the first compound of this type. Dithioxo(tri-*tert*-butylphenyl)phosphorane **6** was obtained by reaction of bis(trimethylsilyl)(tri-*tert*-butylphenyl)phosphane **4**[4] with disulfur dichloride **5**.

This result is surprising in that phenylbis(trimethylsilyl)phosphane reacts with $S_2Cl_2$ and phenyldichlorophos-

4 5 6

phane with disulfane to afford the dimeric compound **7**[5].

**7**

**6** forms as a yellow, amorphous powder; when recrystallized from toluene/acetontrile it is orange. Its composition is consistent with the results of elemental analysis, cryoscopic molecular weight determination and mass spectroscopy; its structure is established by $^{31}P\{^1H\}$-NMR spectroscopy and X-ray diffraction analysis (Fig. 1)[6].

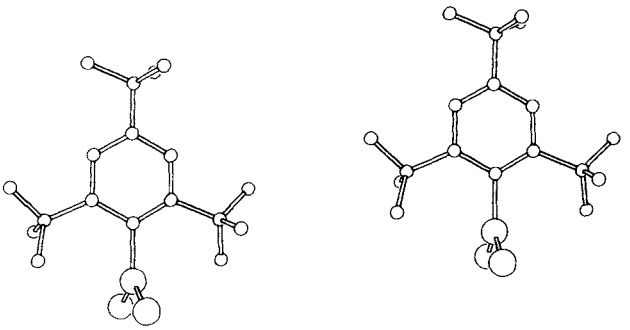

Fig. 1. Stereoscopic projection of the molecular structure of **6** (without H atoms) in the crystal (monoclinic, $P2_1/n$, $a=1021.7(4)$, $b=1032.4(3)$, $c=1910.2(8)$ pm, $\beta=98.4(3)°$, $V=1993.3\cdot10^6$ pm$^3$, $\varrho_{calc}=1.13$ g/cm$^3$, $Z=4$). The structure was solved by direct methods (SHELXTL) from 3129 single-crystal diffractometer data and refined to $R=6.5\%$ ($R_w=5.6\%$). Geometry: $CPS_2$ moiety planar, torsion angle of the aryl group to the $PS_2$ plane *ca.* 80°; angles (*CPS*) *ca.* 117° (*SPS*) 126°; distances (PS) 190 pm, (SS) 338 pm.—Further details on the crystal structure determination can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50568, the names of the authors, and the journal citation.

Both the monomeric compound **6** and the dimer **7** react with alcohols ROH to form the dithiophosphonic acid *O*-monoester aryl-P(S)(SH)(OR).

*Procedure:* A solution of **5** (1.35 g, 10 mmol) in 25 mL *n*-pentane is slowly added dropwise into a solution of **4** (4.23 g, 10 mmol) in 50 mL *n*-pentane cooled with methanol/dry-ice. When the addition is complete, the reaction mixture is allowed to warm up, the amorphous precipitate filtered off, and the solvent removed *in vacuo*. The residue is taken up in a little toluene and the resultant solution treated with acetonitrile until it becomes turbid. At the onset of crystallization the solution is stored in the refrigerator at *ca.* −3 °C until this is complete. Yield of **6**: 2.45 g (72%), m.p. = 148 °C.

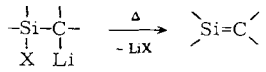
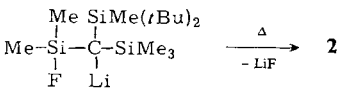
## A Novel Stable Silaethene**

By *Nils Wiberg** and *Gerhard Wagner*



*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

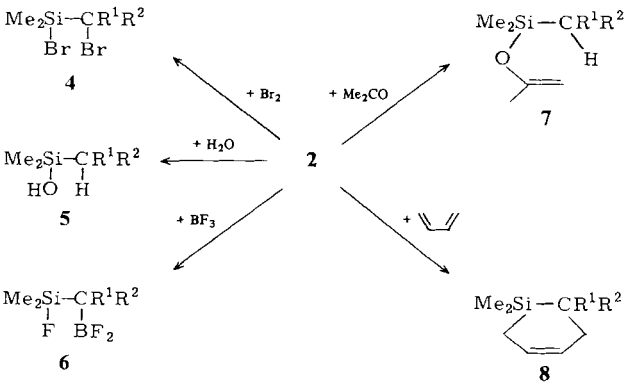
Recently, *Brook et al.* were able to isolate the "silaenol ether" **1** (R = 1-adamantyl), the first silaethene stable at room temperature, and characterize it spectroscopically and by X-ray structure analysis[1]. As a second example, we now wish to describe "silaene" **2**.



**1** **2**

As described for other silaethenes[2], **2** can be obtained by "thermal salt elimination" (X = electronegative moiety):

In this respect, a tetrahydrofuran adduct of compound **3**, which loses LiF above *ca.* 100 °C, serves as a silaethene precursor[3].



**3**

At room temperature in the presence of chloro(trimethyl)silane, **3** is rapidly transformed into **2**, which can be obtained in crystalline form by slow crystallization from diethyl ether at −78 °C[4].

The silaethene **2** exhibits the expected mass spectrum (molecular ion at *m/z* 300) and $^1$H-NMR spectrum (90 MHz, THF, 30 °C: $\delta=0.446$ ($Me_2$Si), 0.082 (Si*Me*($t$Bu)$_2$), 0.049 (Si*Me*$_3$), 0.969 (SiMe($t$Bu)$_2$).

Compound **2** decomposes within a few days at room temperature (at 100 °C, very rapidly) to afford secondary products which, from mass spectroscopic studies, contain dimers of **2**. **2** reacts vigorously with oxidizing reagents such as atmospheric oxygen or bromine, in the latter case

$R^1$ = $SiMe_3$; $R^2$ = $SiMe(tBu)_2$

Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (Germany)

[**] Compounds of Silicon, Part 55. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 54: See [2].

to form the dibromoadduct **4**. With water, **2** affords the silanol **5**, and with boron trifluoride, the compound **6**. Reaction with acetone leads, as expected, to **7**, the product of an ene reaction; with 1,3-butadiene, the Diels-Alder adduct **8** is formed.

The relatively high thermal stability of **2** with respect to dimerization can be attributed to the bulky *tert*-butyl groups (even at −78 °C, $Me_2Si{=}C(SiMe_3)_2$ dimerizes very rapidly[2]). In contrast to **1**, **2** lies at the limits of isolability under normal conditions and exhibits the high reactivity observed for non-isolable silaethenes.

Received: July 28, 1983; revised: September 8, 1983 [Z 493 IE]
German version: *Angew. Chem. 95* (1983) 1027

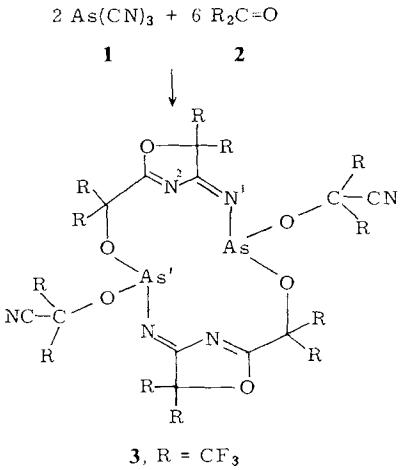
[3] Preparation of **3**: Reaction of $tBu_2SiHF$ with $LiCH(SiMe_3)_2$ at 130 °C leads to $tBu_2SiH{-}CH(SiMe_3)_2$, which, *via* $tBu_2SiBr{-}CH(SiMe_3)_2$ (reaction with $Br_2$ in $CCl_4$ at room temperature) and $tBu_2SiF{-}CH(SiMe_3)_2$ (reaction with KF in $C_6H_6$ in the presence of [18]crown-6 for 1 week) is converted into $tBu_2SiF{-}CLi(SiMe_3)_2$ (reaction with LiMe in tetrahydrofuran for 1 week at room temperature). A solution of $tBu_2SiF{-}CLi(SiMe_3)_2$ in diethyl ether rearranges over a period of a few weeks to afford **3**. The necessary $tBu_2SiHF$ is obtainable by fluoridation of $tBu_2SiHCl$ (from $HSiCl_3 + 2\,LitBu$ in pentane at room temperature) with $ZnF_2$ at 90 °C, and the necessary $LiCH(SiMe_3)_2$ by analogy to $LiCBr(SiMe_3)_2$ (cf. [2]) by the action of LiBu and $Me_3SiCl$ on $HCBr_3$.

[4] The crystals contain tetrahydrofuran, which according to X-ray structure analysis, is loosely bound to the unsaturated Si atom of **2**. Thermolysis of the diethyl ether adduct of **3** leads to solvent-free **2**, which to date could not be obtained in crystalline form suitable for X-ray structure analysis.

## Synthesis and Structure of a Macrocycle with a Skeletal Framework of Arsenic, Carbon, Oxygen, and Nitrogen Atoms**

By *Herbert W. Roesky*, Habibollah Djarrah, Joachim Lucas, Mathias Noltemeyer,* and *George M. Sheldrick*



*Dedicated to Professor Karl Winnacker on the occasion of his 80th birthday*

Macrocyclic compounds containing members capable of coordination have been the subject of intensive studies in recent years, because they can be used as complexing agents and for the fixation of smaller guest molecules[1,2].

We have now found that the reaction of arsenic(III) cyanide **1** with hexafluoroacetone **2** in the molar ratio 1 : 3 unexpectedly leads[3] to formation of a fourteen-membered heterocycle **3**.

Depending on the solvent, **3** crystallizes as a colorless adduct containing two molecules of dichloromethane or acetonitrile, which can easily be removed by heating to 80 °C and 100–110 °C, respectively, in an oil pump vacuum. An X-ray structure analysis of a single crystal showed that two arsenic atoms in **3** are coupled *via* two identical bridges of the sequence $N^1{-}C{-}N^2{-}C{-}C{-}O$; each bridge also contains a dihydrooxazole ring (with $N^2$).

The planes of the two halves of the molecule are folded at an angle of 90° to each other by coordinative As–$N^2$ interaction (mean atomic distance 265 pm). Thus, one side of the molecule is completely shielded by $CF_3$ groups, whereas on the other side a solvent molecule (acetonitrile) is taken up in each of the coordination spheres of the arsenic atoms (As–$NCCH_3$ 301 pm). A penetration of these ligands into the macrocycle is however impossible because of the short As···As distance (437 pm).

The structure of **3** (cf. Supplement) clearly demonstrates that during its formation all the As–C bonds in **1** are ruptured. Two CN groups are needed for the construction of the fourteen-membered ring, the third migrates to the carbonyl-C atom of an exocyclically bonded hexafluoroacetone molecule.

[1] D. J. Cram, *Science 219* (1983) 1177.

[2] J.-M. Lehn, *Struct. Bonding (Berlin) 16* (1973) 1.

[3] *Procedure:* 4.0 g (24.09 mmol) of **2** is passed into a solution of **1** (2.3 g, 15.03 mmol) in $CH_3CN$ (60 mL) at 0 °C. Unreacted **2** is immediately refluxed back into the reaction mixture by means of a condenser (dry ice). The mixture is stirred for 3 h and then allowed to warm to room temperature. After filtration and cooling of the filtrate to 60 °C a colorless crystalline solid precipitates out. Yield 1.5 g (14%); m.p. 171 °C. The solvent molecules in the adduct $3 \cdot 2\,NCCH_3$ are detectable by $^1$H-NMR spectroscopy: $\delta(CH_3CN) = 2.0$. $^{19}$F-NMR ($CH_3CN$): $\delta = 84.2, 48.6, 85.9$.

## $[Ni(S_4)_2]^{2\ominus}$, a Homoleptic Tetrasulfido-Nickel(II) Complex

By *Achim Müller*, Erich Krickemeyer, Hartmut Bögge, William Clegg,* and *George M. Sheldrick*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

The existence of numerous binary and tertiary metal sulfide minerals with three-dimensional network structures would suggest that it ought to be possible, under selective conditions, to obtain pure, discrete sulfido-complexes and -clusters, too (cf. in this respect, *e.g.*, the preparation of

$[Mo_2(S_2)_6]^{2\ominus}$[1], or $[Cu_3(S_6)_3]^{3\ominus}$[2]). Potential ligands for this purpose are, aside from $S^{2\ominus}$, the polysulfide ions $S_n^{2\ominus}$.

We have now been able to isolate $[Ni(S_4)_2]^{2\ominus}$ **1**—the first "binary nickel-sulfur" complex and the first complex containing only $S_4^{2-}$ ligands—as the reddish-black, diamagnetic $[(C_2H_5)_4N]^+$-salt **1a**[3], and to characterize it by elemental analysis, IR, Raman, UV/VIS/NIR spectroscopy, magnetic measurements, and a complete X-ray structure analysis (Fig. 1).

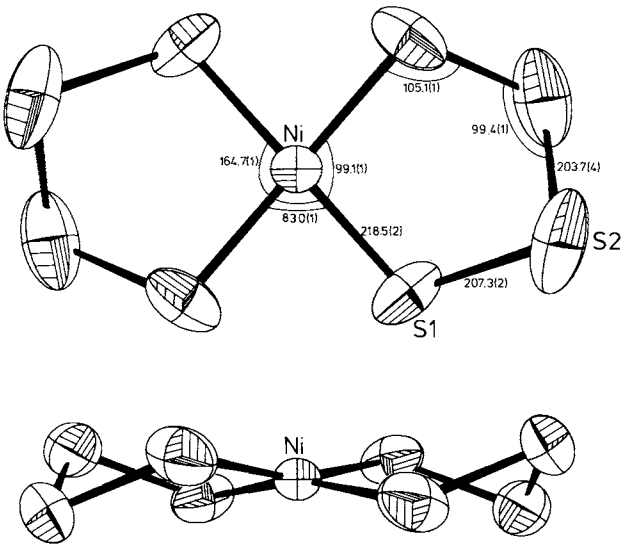

Fig. 1. Structure of the anionic complex **1** (two projections) in the tetraethylammonium salt **1a** (tetragonal crystals, space group $P\bar{4}n2$, $a = 1044.8(2)$, $c = 1276.2(3)$ pm, $Z = 2$; $R = 0.038$ for 1238 independent reflections ($F_0 > 4.0\sigma(F_0)$), $Mo_{K\alpha}$ radiation). Atomic distances in [pm], bond angles in [°]. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, on quoting the depository number CSD 50553, the names of the authors, and full citation of the journal.

The anion **1** with point symmetry $D_2$ exists as a spirobicycle in which the central Ni is surrounded by an approximately square-planar array of four S-atoms.

In the vibrational spectra of **1a** characteristic bands [IR(solid/CsI pellet) and Raman (solid, $\lambda_e = 647.1$ nm)] are found at 480, 430, 375 ($\nu(S_4)$), 280($\nu_{as}(NiS_4)$) and 480 ($\nu_s(S_4)$), 293 ($\nu_s(NiS_4)$), 153 $cm^{-1}$, respectively. The solid state electronic spectrum [reflection; substance distributed on cellulose] shows the characteristic d→d transitions of a $NiS_4$ chromophore ($d^8$Ni): 14.9 ($^1A_{1g} \rightarrow {}^1A_{2g}$), 21.3 ($^1A_{1g} \rightarrow {}^1B_{1g}$)[4]; further bands are observed at 27.4 and 33.3 $10^3$ $cm^{-1}$.

The new complex **1** extends the series of the transition-metal complexes containing only polysulfido ligands, namely $S_2^{2\ominus}$-($[Mo_2(S_2)_6]^{2\ominus}$[1]), $S_4^{2\ominus}$- (**1**), $S_5^{2\ominus}$ ($[Pt(S_5)_3]^{2\ominus}$[1b]) and $S_6^{2\ominus}$ ligands ($[Cu_3(S_6)_3]^{3\ominus}$[2]). It is our aim to find conditions[5] under which pure discrete metal-sulfur aggregates, but also the corresponding mononuclear complexes, can be prepared (the first such species have only recently been described); of particular interest are structures which represent sections from crystal lattices of sulfide minerals.

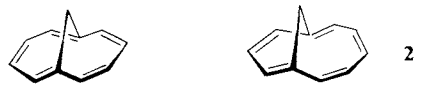
[2] A. Müller, U. Schimanski, *Inorg. Chim. Acta Lett., 77* (1983) 187.

[3] *Procedure:* 4 g of $[(C_2H_5)_4N]Br$ is dissolved with stirring in 50 mL of methanolic ammonium polysulfide (100-mL Erlenmeyer flask). After stepwise addition of 2 g $Ni(CH_3COO)_2 \cdot 4H_2O$, the mixture is heated to 45 °C, quickly filtered, and the dark brown filtrate stored in a closed flask at room temperature. After 1 h the precipitated shiny black crystals of **1a** are filtered off and washed with isopropanol (analytically pure) and $CS_2$; yield 0.9 g.—For the preparation of the methanolic ammonium polysulfide solution a stream of $NH_3$ is passed into 1L of absolute methanol for 1 h. After addition of 100 g sulfur ($S_8$), $H_2S$ is passed through the solution for 1 h. The sulfur is almost completely dissolved during the reaction. Any undissolved material is removed by filtration.

[4] For the assignment cf. A. B. P. Lever: *Inorganic Electronic Spectroscopy*, Elsevier, Amsterdam 1968.



[5] Slight differences in the preparative cconditions (*e.g.* different polysulfide concentrations) can lead to different products. Thus, *e.g.*, from the same solution, $[Mo_3S(S_2)_6]^{2\ominus}$ is obtained on heating and $[Mo_2(S_2)_6]^{2\ominus}$ at room temperature[1b]. *Note added in proof:* The corresponding Pd complex ($[(C_2H_5)_4N]_2[Pd(S_4)_2]$, shiny black crystals) could also be obtained and characterized by an X-ray structure analysis.

## Resonance Energy of Bridged [10]Annulenes**

By *Wolfgang R. Roth*, Manfred Böhm, Hans-Werner Lennartz,* and *Emanuel Vogel*

*Dedicated to Professor W. von E. Doering on the occasion of his 65th birthday*

The numerous experiments carried out to test the Hückel rule, which culminated in the discovery (or rediscovery) of the tropylium ion by *Doering* some 30 years ago, have enriched organic chemistry with a plethora of aromatic and nonaromatic cyclically-conjugated ring systems (annulenes and ionic species derived therefrom). Although many of these ring systems have been the subject of detailed investigation from the chemical, spectroscopic, and structural point of view, their thermodynamical behavior has so far been studied only in isolated cases. We have now analyzed the effect of conjugation on the bridged [10]annulenes **1**[1] and **2**[2] by measurement of the heats of hydrogenation.

We have used the resonance energy as a measure of the stabilization. This is not an observable quantity, but the difference between the experimentally determined enthalpy of formation and that of a hypothetical model built up additively from localized two-center bonds. To calculate this value we have adopted the method proposed by *Dewar*, who defined 1,3-butadiene as a "normal" polyene and designated deviations compared to the bonding of this reference compound as resonance[6a].

As a rule the enthalpy of formation of the model is either estimated from bond increments or determined by quantum mechanical calculations. Both methods are unsatisfactory. The inadequacies can be avoided if the heat of formation of the model is derived from force field calcula-

[**] Heats of Hydrogenation, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 4: [7].

tions. If the force field is adjusted to 1,3-butadiene then a comparison of the experimentally determined enthalpy of formation with the calculated value directly affords the resonance energy normalized to 1,3-butadiene. We found by such a comparison for a large number of polyenes that there is good agreement (0.5 kcal/mol) between experimental and calculated enthalpies of formation in acyclic systems, *i.e.* there is no greater resonance stabilization than in 1,3-butadiene[7]. On the other hand, for "cyclohexatriene" an additional stabilization of 26.1 kcal/mol is obtained, which is in good agreement with the resonance energy (23.3 kcal/mol[6b]) derived from quantum mechanical calculations.

The calculated resonance energies of the bridged [10]annulenes **1** and **2** are listed together with the values of naphthalene **4** and azulene **5** for comparison in Table 1. In the case of **1**, **2**, and **5** the experimental enthalpies of formation were ascertained by measurements of heats of hydrogenation. Since the enthalpies of formation of the products of reduction of **1** and **2** are not known, these values were taken from force field calculations, so that the enthalpies of formation have a "pseudo-experimental" character. However, in view of the high reliability of the method in the case of saturated hydrocarbons, the errors might very well be small.

Table 1. Enthalpies of formation and resonance energies of some cyclic polyenes.

| Cpd. | | $H_f^0$(g) exp. [kcal/mol] | $H_f^0$(g) calc. [a] [kcal/mol] | Resonance energy [kcal/mol] |
|---|---|---|---|---|
| 3 |  | 19.81 | 45.88 | 26.1 |
| 4 |  | 36.05 | 76.70 | 40.7 |
| 1 |  | 77.1 [7]<br>75.2 | 94.33 | 17.2 |
| 5 |  | 73.5 | 89.60 | 16.1 |
| 2 |  | 95.5 | 102.03 | 6.5 |
| 6 |  | 62.3 [7] | 68.36 | 6.1 |
| 7 |  | 35.0 [7] | 39.69 | 4.7 |
| 8 |  | 44.6 | 48.54 | 3.9 |

[a] Modified MM2 force field [7].

The resonance energies determined for the bridged [10]annulenes **1** and **2** and for **4** and **5** revealingly reflect the different chemical reactivity of these compounds: **1** and **5** are markedly more reactive than naphthalene **4**, yet share with it the ability to form substitution products on reaction with electrophilic agents[1]. The annulene **2**—in striking contrast to **1**—even polymerizes in air and no longer shows any tendency to form substitution products with electrophiles[2].

The noticeably different resonance energies of **1** and **2**, together with the different degree of deviation of the $C_{10}$ perimeter from planarity, may be caused mainly by the transannular interaction (homoconjugation *via* C1—C6), which is only possible in **1**. This interpretation is supported, not only by the observed increase in resonance energy (bracket effect) in the transition from **8** to **7** and **6**, but is also indicated by the short C1—C6 distance in **1** (2.235 Å), by the absorption and emission spectra[14], and by the circular dichroism[15] of **1**. In the light of the C1—C6 interaction in **1** derived from the resonance energy and the spectra it appears justified to regard 1,6-methano[10]annulene as 9,10-homonaphthalene.

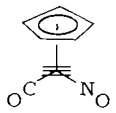
## The Transformation of Acetylene from a Four- to a Two-Electron Ligand: Acetylene(carbonyl)nitrosyl Complexes of Tungsten**

By *Helmut G. Alt** and *Heidi I. Hayen*

*Dedicated to Professor Ernst Otto Fischer on the occasion of his 65th birthday*

[CpW(CO)($C_2H_2$)COMe] **1** is a highly reactive, easily accessible alkyne complex in which $C_2H_2$ behaves formally as a four-electron ligand. We have now found that solutions of **1** in toluene at −78 °C react instantaneously with gaseous nitric oxide to form the two monomeric nitrosyl(alkyne) complexes **2** (51%) and **3** (9%) which can be separated by column chromatography.

[**2**, IR (THF): $\nu$(CO) = 1985, $\nu$(NO) = 1605,



**1** **2** **3**

Universitätsstrasse 30, D-8580 Bayreuth (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

$\nu$(C≡C) = 1723 cm$^{-1}$; $^1$H-NMR, $^{13}$C-NMR; MS: *m/z* 333 ($M^+$) relative to $^{184}$W; m.p. = 142–146 °C.—**3**, IR (THF): $\nu$(CO) = 2008, $\nu$(NO) = 1602, $\nu$(C≡C) = 1700, $\nu$(C=O) = 1650 cm$^{-1}$; $^1$H-NMR, $^{13}$C-NMR; MS: *m/z* 375 ($M^+$) relative to $^{184}$W; at room temperature greasy.] Compared to those of **1**, the $^1$H- and $^{13}$C-NMR signals of the acetylene ligands in **2** and **3** are shifted to high field ($\Delta\delta \approx 4$ and 80 ppm, respectively), which can be expected as the result of a transformation from a four- to a two-electron ligand. This assumption is also corroborated by the increase in the coupling constants $^1J$(C,H) ($\approx$220 Hz) and $^2J$(C,H) ($\approx$22 Hz) in **2** and **3** relative to **1** or [CpW(CO)($C_2H_2$)Me][2]. In accord with this, the $\nu$(C≡C) band is shifted markedly to higher wavenumbers, whereas the $\nu$(NO) band is located in the region typical for terminal three-electron nitrosyl ligands. In **2** and **3**, astonishingly high barriers for rotation of the $C_2H_2$ ligand around the tungsten-alkyne bond axis are found: in contrast to the analogous chromium complex [CpCr(CO)($C_2H_2$)NO] ($\Delta G^+ = 55.9$ kJ/mol in [D$_8$]toluene[4]), temperature-dependent $^1$H-NMR measurements of **2** and **3** indicate $\Delta G^+ > 90$ kJ/mol. We therefore assume the involvement of metallacyclopropene mesomeric structures in **2** and **3**, as postulated for [Cp$_2$Ta(alkyne)H] (alkyne = substituted acetylene) for the same reasons[5]. The formation of metallacyclopropene derivatives is also corroborated by the observation of $^2J$(W,H) couplings (7.3, 9.2, and 6.1 Hz, resp.) in the $^1$H-NMR as well as $^1J$(W,C) couplings (51, 32 and 48 and 15 Hz, resp.) and $^1J$(C,H) couplings ($\approx$228 Hz) in the $^{13}$C-NMR spectrum, which indicate a significant contribution from a metal-carbon σ bond. Consequently, $\Delta G^+$ is not the only criterion for classifying an alkyne formally as a two- or four-electron ligand. Our spectroscopic findings were confirmed by the results of calculations using the EHMO method[9]: for the acetylene ligand in [CpMo(CO)($C_2H_2$)NO] the rotation barrier around the metal-alkyne bond axis was determined to be 146 kJ/mol. For the lowest energy conformation an orientation of the alkyne ligand is predicted in which the –C≡C– axis and the

metal-CO axis are no longer coplanar but are twisted by 20°[10]. This probably arises from the better π-acceptor behavior of the NO ligand compared to CO. The synthesis of **2** and **3** described here is also remarkable from a preparative point of view. Previously, it had not proved possible to convert the parent compound [CpW(CO)$_2$NO] into derivatives of the type [CpW(CO)(L)NO] (L = alkene, alkyne) by photo-induced exchange of a CO ligand.

[10] In contrast, the X-ray structure analysis of [(C$_5$Me$_5$)W(CO)($C_2H_2$)Me] indicates that the C≡C axis of the alkyne ligand and the W–CO axis are almost parallel and coplanar H. G. Alt, U. Thewalt, unpublished results.

## Structural Relationship of [($C_6H_5$)$_4$As]NdCl$_4$·8 H$_2$O and NdCl$_3$·6 H$_2$O: Transition from a Three-Dimensional to a Layer Structure

By *Werner Urland** and *Ulrich Schwanitz-Schüller*

The hydrates of the lanthanoid chlorides MCl$_3$·6 H$_2$O (M = Nd–Lu) contain the complex cation [M(H$_2$O)$_6$Cl$_2$]$^{\oplus}$[1]. Reaction of NdCl$_3$·6 H$_2$O with aqueous ($C_6H_5$)$_4$AsCl in CH$_3$CN/C$_2$H$_5$OH leads to formation of the novel compound [($C_6H_5$)$_4$As]NdCl$_4$·8 H$_2$O[6]. The structure of this compound (Fig. 1) is likewise determined by the cation [Nd(H$_2$O)$_6$Cl$_2$]$^{\oplus}$. The arrangement of the complex cations corresponds to a two-dimensional section of the NdCl$_3$·6 H$_2$O structure, but now with H$_2$O molecules as well as Cl$^{\ominus}$ ions bridging the cations. These layers are separated by intercalated ($C_6H_5$)$_4$As$^{\oplus}$ ions; the original structure of NdCl$_3$·6 H$_2$O is formally dissected. The bridging Cl$^{\ominus}$ ion (Cl(2) in Fig. 1) can be regarded as the site of incision, which now exhibits a remarkably unilateral instead of distorted octahedral coordination. The Cl(2)-anion lies outside of a distorted tetrahedron of water molecules, its "free side" faces the ($C_6H_5$)$_4$As$^{\oplus}$ layer. The transition from a spatial network to a layer structure necessitates a change in composition. The number of bridging Cl$^{\ominus}$ ions per [Nd(H$_2$O)$_6$Cl$_2$]$^{\oplus}$ moiety is doubled. At the same time cavities are created in the layer, and these are occupied by water molecules. The water molecules apparently stabilize the unilaterally coordinated bridging Cl(2). The orientation of the H$_2$O molecules points to strong hydrogen bonding and to interactions with the Cl$^{\ominus}$ ions. Such a cross-linking to layers is structure-determining and concomitantly enforces the layer-like arrangement of the ($C_6H_5$)$_4$As$^{\oplus}$ counterions. This is unusual, since columnar

## Alkyne Complexes of Tungsten(IV)**

By *Klaus H. Theopold, Steven J. Holmes,* and *Richard R. Schrock**

Alkyne ligands can be regarded as dianions[1]. Our interest in the chemistry of alkyl, alkylidene, and alkylidyne complexes of tungsten(*VI*)[3] therefore urged us to attempt the preparation of simple alkyne complexes of tungsten(IV), for we hoped that these compounds would behave like tungsten(VI) complexes in their reactions with alkylating agents. This in fact turned out to be the case, and we now report on the first mild protonation of an alkyne ligand with formation of a vinyl-$W^{VI}$ derivative. The synthesis of $W(C_2R_2)Br_4$ and $Mo(C_2R_2)Cl_4$ (R = Me, Ph) was actually described[4] some ten years ago, while $[Mo(C_2Ph_2)Cl_4]_x$ has recently been the subject of further study, together with the new compounds $[W(C_2Ph_2)Cl_4]_x$, $[Nb(C_2Ph_2)Cl_3]_4$, and $Re(C_2Ph_2)Cl_5$[5].

Tungsten tetrachloride reacts with alkynes in diethyl ether at room temperature to give $W(C_2R_2)Cl_4 \cdot Et_2O$ (R = Me, Et, Ph). Ether-free $W(C_2Ph_2)Cl_4$ is formed on reaction of $WCl_6$ with diphenylacetylene in $CH_2Cl_2$; in the presence of ether it is readily converted into $W(C_2Ph_2)Cl_4 \cdot Et_2O$. The IR spectra of these complexes show a band at 1700–1750 $cm^{-1}$ characteristic of a strongly bound alkyne ("metallacyclopropene"). The chemical shifts of the alkyne C-atoms in the NMR spectra (cf. Supplement) with $(^{13}C) \approx 270$ are, to the best of our knowledge, greater than all previously reported values.

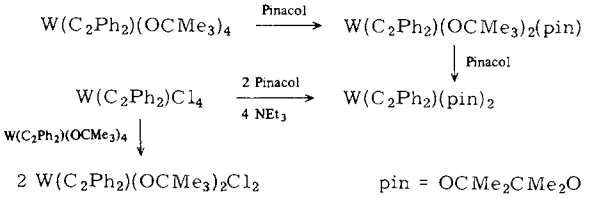
In view of the formation of the ether adduct it is not surprising that $W(C_2R_2)Cl_4$ also adds chloride ions.

$$W(C_2R_2)Cl_4 + [NEt_4]Cl \xrightarrow{CH_2Cl_2} [NEt_4]^{\oplus}[W(C_2R_2)Cl_5]^{\ominus}$$

The anionic alkyne complexes thus formed are especially suitable for alkylations with dialkylzinc, whereby compounds of the type $W(C_2R_2)R'_3Cl$ are obtained in good yields (60–80%).

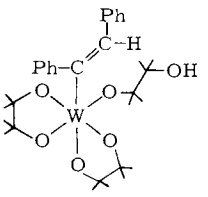
$$[NEt_4]^{\oplus}[W(C_2R_2)Cl_5]^{\ominus} \xrightarrow[0.5\ NEt_4Cl]{1.5\ ZnR'_2} W(C_2R_2)R'_3Cl$$

$CH_2Cl_2$ R = Et, R' = Me; R = Me, R' = $CH_2SiMe_3$

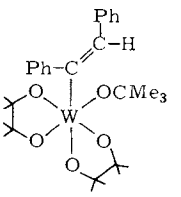


Attempts to prepare $W(C_2Et_2)(CH_2CMe_3)_3Cl$ resulted in the formation of a mixture of products, from which $W(C_2Et_2)(CHCMe_3)(CH_2CMe_3)_2$ could be isolated as a distillable yellow oil in poor yield.

All of the chemistry concerning the formation of alkyl (and alkylidene) complexes is remarkably similar to that recently reported for phenylimido complexes[3b]. We therefore propose to extend the concept of alkyne-metal interaction: alkyne ligands are not only doubly charged anions, but also *good π-donors*, analogous to the imido and oxo ligands.



$d^2$-Metal-C(alkyne) bond distances are usually quite short (*ca.* 205 ppm) so that especially for third row metals the overlap of metal d orbitals with the ligand π-system is likely to be substantial. In certain situations, therefore, the alkyne functions as a strongly π-bonded dianionic auxiliary ligand which stabilizes the $d^0$ oxidation state of the metal center.



$W(C_2Ph_2)Cl_4$ reacts smoothly with $LiOCMe_3$ to give yellow crystalline $W(C_2Ph_2)(OCMe_3)_4$ in high yield. Several related complexes can be prepared in a similar fashion.

Consistent with our description of the alkyne ligand, $W(C_2Ph_2)(pin)_2$ reacts with pinacol to produce $W(pin)_3$ and *cis*-stilbene in high yield. As expected, the $^1$H-NMR spectrum of $W(pin)_3$ shows two singlets. In the presence of (+)-1-(9-anthryl)-2,2,2-trifluoroethanol one of these signals splits into a doublet, demonstrating the presence of a racemic mixture of both enantiomers of the chiral complex. On monitoring the course of the reaction $^1$H-NMR spectroscopically we found evidence for the existence of an intermediary vinyl complex **A**.

**A**

**B**

The reaction of $W(C_2Ph_2)(pin)_2$ with *tert*-butyl alcohol leads to the analogous vinyl complex **B**, which could be isolated and characterized.

# Structure Analysis of a $CaF_2$ Single Crystal with an Edge Length of only 6 μm: An Experiment using Synchrotron Radiation

By *Rolf Bachmann, Heinz Kohler, Heinz Schulz*, Hans-Peter Weber, Vladimir Kupčik, Michael Wendschuh-Josties, Andreas Wolf,* and *Reinhard Wulf*

Until now the high intensity and low divergence of the X-ray radiation from an electron synchrotron has been used in structural analysis 1) to reduce the measuring time (*e.g.* to minimize radiation damage of protein crystals); 2) to enable selection of the optimal wavelength for the experiment (*e.g.* for determination of the phases using anomalous dispersion); and 3) to increase the spatial resolution (*e.g.* in powder spectra to achieve separation of previously unresolved peaks)[1].

Furthermore, the high brightness of the radiation and its natural collimation lead to a considerable increase in the signal/noise ratio of the Bragg reflections. We have used this property to answer the question to what extent accurate reflection intensities can also be measured on extremely small crystals. The work was carried out at the synchrotron radiation laboratory "Hasylab" at DESY (Hamburg). For this purpose, a five-circle diffractometer was used[2] which is equipped with a germanium (111) double monochromator. Its angular resolution of 1/1000° permits the measurements of reflections having a width at half-height $< 1/100°$ (Fig. 1). Single crystals of $CaF_2$ of various sizes were investigated with synchrotron radiation (storage ring DORIS II, 3.5 GeV, 60—25 mA). The results were compared with those from a conventional molybdenum X-ray source (2 kW). $CaF_2$ was chosen as standard substance since it consists only of light elements with small atom scattering factors. The smallest crystal which could be measured using a conventional X-ray tube had a volume of 2000 $\mu m^3$. Using synchrotron radiation, a data set ($(\sin\vartheta/\lambda)_{max} = 0.73$ Å$^{-1}$) was recorded on a crystal with a volume of only 200 $\mu m^3$ (Fig. 2). Previously, measurements were only made on similarly small crystals, but which exhibited a 30-fold larger crystal scattering power[3].

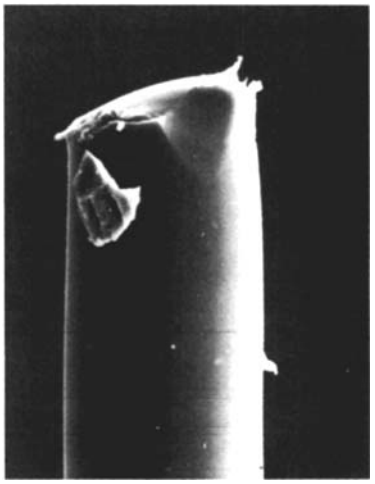

Fig. 2. 1000-fold magnification of the calcium fluoride crystal mounted on a glass pin. The width of the photograph corresponds to the diameter of a human hair; the bar at the bottom edge corresponds to 10 μm.

Table 1. Crystal scattering power [a]: comparison of the measured $CaF_2$ crystal with a crystal of similar size.

| | $\rho = \frac{\Sigma e}{v}$ [$10^{24}$ cm$^{-3}$] | $V_{cryst.}$ [$10^{-12}$ cm$^3$] | $\lambda$ [$10^{-8}$ cm] | $S$ [$10^{12}$] |
|---|---|---|---|---|
| $CaF_2$ | 0.929 | 200 | 0.9101 | 130.1 |
| $Re_2P$ [3] | 7.317 | 200 | 0.7107 | 3840 |

[a] The crystal scattering power $S$ is defined as $I^2 \cdot V_{cryst.} \cdot \lambda^3$, where $\Sigma e$ is the number of electrons per unit cell of volume $v$, $V_{cryst.}$ is the volume of the crystal, and $\lambda$ is the wavelength.

Our experiment showed that single crystal diffraction measurements can also be performed on crystallites having a crystal scattering power of *ca.* $10^{14}$ (Table 1). Until now, many substances from which larger crystals could not be grown could only be studied with powder techniques, which provide less information. In the future it is expected that the structures of numerous interesting groups of substances from different areas of solid-state chemistry (*e.g.*, ion-conducting crystals such as NASICON, and catalysts such as zeolites), mineralogy (*e.g.* lamella of zone-structured crystals) and biochemistry (*e.g.* protein crystals) will be solved. Moreover, the use of small crystals leads to a considerable reduction of systematic error such as absorption and extinction, which are both dependent on the crystal size. In the present case, the influence of the absorption can be neglected. A preliminary crystal structure refinement makes it very probable that the 24 measured reflections are not influenced by extinction. For this purpose, the known temperature factors of $CaF_2$ were used[4]. In contrast, in the standard crystal project of a $CaF_2$ sphere of 440 μm radius of the American Crystallographic Association, 85% of the reflections are extinction attenuated by more than 10%[4b]. Preliminary refinement of our data gave an unweighted $R$-value of 4%. It follows that a signal/noise ratio is achieved which corresponds to that obtained using conventional diffractometer measurements, despite the extremely small size of the crystal.

By preparing the crystals using a micromanipulator and by increasing the radiation intensity with a "wiggler"[5], it should even be possible in the near future to make measurements on single crystals whose crystal scattering power is at least one order of magnitude less.

## Preparation of Ethyl (*R*)-(−)-3-Hydroxy-2-methylpropanoate by Yeast Reduction of Ethyl α-Formylpropanoate

By *Max F. Züger, Fabio Giovannini,* and *Dieter Seebach**

Derivatives of 3-hydroxy-2-methylpropanoic acid **1a** are useful chiral building blocks. This is mainly due to the fact that "interconversion" of the functionalized C atoms of **1** provides both enantiomeric building blocks **2** and *ent*-**2**[1a]. The (*S*)-(+)-acid **1a** is formed by hydroxylation of the (*Re*)-methyl group of isobutyric acid with *Pseudomonas putida*[1b], a microorganism which is not easy to grow in the routine organic chemistry laboratory. Furthermore, the free acid is labile, its isolation from the fermentation broth is not easy, and the interconversion of the "enantiotopic branches" requires several steps[1].

**3a**, R = $C_2H_5$ ($[\alpha]_D^{20}$ +1.2, 50% *ee*)
**3b**, R = $CH(CH_3)_2$ ($[\alpha]_D^{20}$ −2.5, 60% *ee*)
**3c**, R = $CH_2C_6H_5$ ($[\alpha]_D^{20}$ +17.3, 46% *ee*)
**3d**, R = $C_6H_5$ ($[\alpha]_D^{20}$ +38.9, 83% *ee*)

[*] Prof. Dr. D. Seebach, F. Giovannini, M. F. Züger
Laboratorium für Organische Chemie

Universitätstrasse 16, CH-8092 Zürich (Switzerland)

We have now found that simple yeast reduction[2] of ethyl α-formylpropanoate[3] (*ca.* 12 g/L water) produces the (*R*)-(−)-ester *ent*-**1b** in 60—65% *ee* (70—80% yield). Enantiomerically pure ester *ent*-**1b** ($[\alpha]_D^{20}$ −21.6° (*c* = 4, $CH_3OH$; ref. [1b] 19.9°) is prepared *via* the crystalline 3,5-dinitrobenzoate in an overall yield of 25% (calculated from the formyl ester)[4]. Optimization of the reaction with other microorganisms has already led to appreciable increases of the *ee*-values.

Asymmetric reductions of other formyl esters with fermenting yeast are also possible. Thus we obtained the optically active hydroxy esters **3a,b,c** of unknown absolute configuration in 50–70% yield as well as ethyl (*R*)-tropate **3d**[5].

# SUBJECT INDEX

(R) = Review Article (C) = Short Communication (B) = Book Review

ACARNIDINE, Synthesis of acylpolyamines: acetylspermidines and $C_{12:0}$-acarnidine (C) 618

Acceptor ligands, Disulfur and diselenium as strong acceptor ligands in $(\eta^5\text{-}C_5H_5)Re(CO)_2S_2$ and $[\eta^5\text{-}C_5(CH_3)_5]Mn(CO)_2Se_2$ (C) 1000

Aceheptylenide ion, Direct synthesis of a [13]annulenide ion (C) 241

Acetylene(carbonyl)nitrosyl complexes, The transformation of acetylene from a four- to a two-electron ligand: acetylene(carbonyl)nitrosyl complexes of tungsten (C) 1008

Acetylenes, Novel synthesis of acetylenes (C) 167

Acrylic esters, Preparation of 2-(1-hydroxyalkyl)acrylic esters; simple three-step synthesis of mikanecic acid (C) 795
A new, efficient and stereocontrolled synthesis of trisubstituted alkenes *via* functionalized acrylic esters (C) 796

Addition, Bond-forming initiation in spontaneous addition and polymerization reactions of alkenes (R) 440
Formation of CC bonds by addition of free radicals to alkenes (R) 753
Kinetic and thermodynamic control in the reaction of $(Ph_3P)_2PtO_2$ with (*E*)-2-butenal (C) 47
The zirconocene-induced coupling of butadiene with carbonyl compounds (C) 494
of alkanethiols to diketene—a correction (C) 498
Base-induced isomerization of cycloalkenynes in competition with addition reactions (C) 627
Aryl(hydrido)ruthenium complexes by C—H addition: isolation of a four-membered metallacycle as intermediate (C) 873

Adducts, $[Me_3Si(py)]^{\oplus}X^{\ominus}$ (X = Br, I): X-ray structural analysis of the 1:1-adducts of bromo- or iodotrimethylsilane and pyridine (C) 725

Aldol reaction, Stereoselective aldol reaction with (*R*)-*N*-acetyl-α-phenylglycinol (C) 788

Aldosterone-antagonist, A novel synthetic route to the aldosterone-antagonist spirorenone (C) 406

Alkadienylcarbamates, Regio- and diastereoselective synthesis of (4-hydroxy-3-methyl-1,2-alkadienyl)carbamates from α-titanated 2-butynylcarbamates and aldehydes (C) 54

Alkanethiols, Addition of alkanethiols to diketene—a correction (C) 498

Alkenes, A new, efficient and stereocontrolled synthesis of trisubstituted alkenes *via* functionalized acrylic esters (C) 796

Alkylbenzenes, $\eta^6$-Bonded alkylbenzenes as novel bridging ligands in dinuclear complexes of iron and cobalt (C) 620

Alkyl radicals, Formation of alkyl radicals by thermal bimolecular reaction of alkanes and alkenes (C) 889

Alkyne complexes, The transformation of acetylene from a four- to a two-electron ligand: acetylene(carbonyl)nitrosyl complexes of tungsten (C) 1008
of tungsten(IV) (C) 1010

Alkyne ligand, Synthesis of $[C_5H_5Rh(PhC{\equiv}CH)P(iPr)_3]$ and $[C_5H_5Rh(={=}C{=}CHPh)P(iPr)_3]$: mechanism of the conversion of an alkyne ligand into a vinylidene ligand (C) 414

Alkynes, Novel synthesis of acetylenes (C) 167

Alkynylamines, 1-Alkynylamines by electrophilic amination (C) 53

Allyl cations, [2+2]-Cycloadditions of allyl cations (C) 49

Aloe-Emodin, Facile synthesis of the (±)-6-deoxycarminomycinone from aloe-emodin (C) 875

Aluminum atoms, Probing the environment of Al atoms in noncrystalline solids: $Al_2O_3$—$SiO_2$ gels, soda glass, and mullite precursors (C) 614

Amino acids, New naturally occurring amino acids (R) 816

Amino acid synthesis, Trifluoromethanesulfonates of α-hydroxycarboxylates—educts for the racemization-free synthesis of *N*-substituted α-amino acids (C) 65

Amino(imino)phosphane, N,P-coordination of an amino(imino)phosphane (C) 984

Aminopenicillanic acid, Synthesis of the chiral synthetic building block (1*R*,5*S*)-3-phenyl-4-oxa-2,6-diazabicyclo[3.2.0]hept-2-en-7-one from 6-aminopenicillanic acid (C) 711

Amino protecting group, The 2-(2-pyridyl)ethoxycarbonyl-(Pyoc) residue—an acid- and base-stable, hydrophilic protecting group for the amino function in peptide synthesis (C) 783

Analytical chemistry, Organic trace analysis by liquid chromatography (B) 66
Analytiker-Taschenbuch (B) 67

Analytical methods, Holographic methods for the investigation of photochemical and photophysical properties of molecules (R) 582

Annulene, A novel planar antiaromatic dibenzo[8]annulene (C) 332
2D-NMR spectroscopy in annulene chemistry: complete assignment of the $^{13}C$-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene by $^1H,^{13}C$ shift correlation (C) 499
Resonance energy of bridged [10]annulenes (C) 1007

Annulene dioxide, Synthesis of an [18]annulene dioxide: an oxygen-bridged [18]annulene possessing equivalent Kekulé structures (C) 417
Synthesis of hetero[17]annulene dioxides and a [16]annulene dioxide using furan building blocks (C) 417

Annulenide ion, Direct synthesis of a [13]annulenide ion (C) 241

Annulenone, Straightforward preparation and stabilization of 2-*trans*-4,7:10,13-diepoxy[15]annulenone (C) 253

Anthracycline antibiotics (B) 895

Antiaromaticity, Unusual NMR phenomena of anthracene and phenanthrene dianions—thermal stimulation of triplet states in antiaromatic systems (C) 45
A novel planar antiaromatic dibenzo[8]annulene (C) 332

Antibiotics, Anthracycline antibiotics (B) 895

Antimony compounds, Synthesis and structure of metallocene cations of the Vb elements arsenic and antimony (C) 250
Synthesis and structure of a bicyclic SbNP compound with intramolecular donor-acceptor bonding (C) 404
$SbF^{2+}$ as a Lewis acid in $Na(SbF)PO_4 \cdot nH_2O$ (n = 2–4) and $NH_4(SbF)PO_4 \cdot H_2O$ (C) 872

Aromaticity, Quenching of the aromaticity of the 5-dibenzo[*a,d*]cycloheptenylium ion by complexing with $(CO)_3Cr$ (C) 559

Arsanylketenes, Generation and stabilization of phosphanyl- and arsanylketenes within the coordination sphere of tungsten (C) 149
An arsanylketene by elimination from an oxaarsatungstacyclopentene complex (C) 1001

Arsenic-arsenic double bond, Synthesis and structure of a diarsenechromium complex with an unsupported arsenic-arsenic double bond (C) 978

Arsenic compounds, Synthesis and structure of metallocene cations of the Vb elements arsenic and antimony (C) 250
Dicarbonyl($\eta^5$-cyclopentadienyl)(di-*tert*-butyl-$\lambda^4$-arsanediyl)molybdenum and -tungsten—the first complexes with a metal-arsenic double bond (C) 416

Arsenic phosphorus sulfide, Equilibria in the formation of $A_4B_3$ molecules (C) 317

Arylindenes, Can radicals participate in pericyclic reactions? Model reactions for electron-transfer induced valence isomerization of 1-arylindenes (C) 254

Asarone, Olefins from β-hydroxycarboxylic acids—synthesis of isomerically pure α- and β-asarone (C) 628

Asymmetrically sensitized photoreaction, Asymmetry of emission quenching and product formation in an asymmetrically sensitized photoreaction (C) 550

Asymmetric catalysts, Rhodium catalysts for enantioselective hydrosilylation—a new concept in the development of asymmetric catalysts (R) 897

Asymmetric induction, Acceleration and asymmetric induction of intermolecular Diels-Alder reactions of triacyl compounds (C) 887

Asymmetric reduction, Preparation of ethyl (*R*)-(−)-3-hydroxy-2-methylpropanoate by yeast reduction of ethyl α-formylpropanoate (C) 1012

*"Atmungsferment"*, Structure and evolution of the *"Atmungsferment"* cytochrome c oxidase (R) 275

Atomic radii, Intermetallic compounds and the use of atomic radii in their description (R) 95

Azaallenium salts, Reactions of *N*-methylenecarboxamides with electrophiles: 1-alkoxy-2-azaallenium salts and *N*-acyl(methylene)ammonium salts (C) 252

Azatriphosphetidines as cyclotrimers of an iminophosphane—synthesis and crystal structure (C) 552

Azetidinesulfonic acids, Synthesis and structure of (*Z*)-3-amino-4-oxo-2-azetidinesulfonic acids (C) 886

Azetones, Thietones, oxetones, and azetones (C) 543

Azirines, Kinetics of the reaction of electron deficient olefins with nitrile ylides generated by laser flash photolysis of substituted azirines (C) 625

BASICITIES, The relative basicities of imidazole and benzimidazole (C) 323

Benzene, Aerial oxidation of benzene in the presence of electrochemically generated $Cu^+$ ions (C) 502
*p*-(*o,p*)-*o*-Tribenzene and *p*-(*o,p*)-(*o,o*)-*p*-tetrabenzene, Diels-Alder oligomers of benzene (C) 617

Benzene dioxide, *syn*-Benzene dioxide/1,4-dioxocin systems *via* a Diels-Alder route (C) 410
Benzimidazole, The relative basicities of imidazole and benzimidazole (C) 323
Benzocyclobutenes, Unexpected ring-opening of benzocyclobutenes upon reaction with lithium in tetrahydrofuran (C) 246
Benzodioxepin, 2*H*-1,5-Benzodioxepin and 3-halo derivatives (C) 64
Benzyl(triethyl)ammonium permanganate, Detonation of benzyl(triethyl)ammonium permanganate (C) 625
Benzynes, 1,2-Benzynes from 6-halopentafulvenes (C) 490
Biazulenes, Resolution, circular dichroism, and absolute configuration of 1,1'-biazulenes (C) 870
Bicyclo[6.2.0]decapentaene, Octalene-bicyclo[6.2.0]decapentaene conversion mediated by transition-metal complexes (C) 1003
Bile pigments, Solution conformations, photophysics, and photochemistry of bile pigments; bilirubin and biliverdin dimethyl esters and related linear tetrapyrroles (R) 656
Bimetallic complex, $[Cl_2FeS_2MoO(S_2)]^{2-}$, a novel bimetallic complex with unusual electronic structure and a substituted tetrachalcogenometalate as "ligand" (C) 561
Bioassay, Adventures and excursions in bioassay: the stepping stones to prostacyclin (Nobel lecture) (R) 741
Biomimetic synthesis of primary enamides by decarboxylation of α,β-dehydroamino acids (C) 550
Bioorganic chemistry, Four-membered ring peroxides as excited state equivalents: a new dimension in bioorganic chemistry (R) 529
Biotechnology, a comprehensive treatise in 8 volumes (B) 893
Bipyridinium compounds, Phanes with two 4,4'-bipyridinium moieties—a new class of compounds (C) 489
Bisdehydrobenzo[18]annulene, 2D-NMR spectroscopy in annulene chemistry: complete assignment of the $^{13}C$-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene by $^1H,^{13}C$ shift correlation (C) 499
Bis(dimethylamino)fluorene, 4,5-Bis(dimethylamino)fluorene, a new "proton sponge" (C) 731
Bisdioxetane, Crystal structure of 2,4,5,7,9,10-hexaoxa-1,3,6,8-tetraphenyltricyclo[6.2.0.0$^{3,6}$]decane: an authentic bisdioxetane (C) 546
Bisnorcobester, 5,15-Bisnorcobester: an unexpected mode of formation (C) 736
A simple route to 5-nor-, 15-nor-, and 5,15-bisnorcobesters (C) 737
Bis(tetramethylethylenedioxy)silane, Strong distortion of the tetrahedral geometry in a spirosilicate: molecular structure of bis(tetramethylethylenedioxy)silane (C) 65
Bond formation, Bond forming initiation in spontaneous addition and polymerization reactions of alkenes (R) 440
Formation of CC bonds by addition of free radicals to alkenes (R) 753
Reversal of the regioselectivity in the zirconocene-induced coupling of a ketone with isoprene (C) 777
Activity of coordinated 1,4-diaza-1,3-dienes (dad) in C-C bond forming reactions: 1,5-dihydropyrrol-2-ones from (dad)Fe(CO)$_3$ and dimethyl acetylenedicarboxylate (C) 992
Metal-induced C-C coupling by reductive dimerization of thioaroyl groups (C) 996
Bonding electron density distribution in tetra-*tert*-butylcyclobutadiene—a molecule with an obviously non-square four-membered ring (C) 403
Borirenes, Synthesis of borirenes and diboretenes—a novel class of 2π-aromatic compounds (C) 48
Borolemetal complexes, A novel and general route to ($\eta^5$-borole)metal complexes: compounds of manganese, ruthenium, and rhodium (C) 996
Boron-carbon double bond, A boron-carbon double bond (C) 877
$\mu_3$-Bridging, Capping of metal atom triangles in clusters by $R_3PAu$ moieties (C) 326
Bridging ligands, Seleno- and telluroformaldehyde as bridging ligands in organometallic complexes (C) 314
$\eta^6$-Bonded alkylbenzenes as novel bridging ligands in dinuclear complexes of iron and cobalt (C) 620
Naked phosphorus atoms as trigonally planar coordinated bridge ligands (C) 976
Butadiene, The zirconocene-induced coupling of butadiene with carbonyl compounds (C) 494
Butadienyltriazoles, 1-(1,3-Butadienyl)triazoles from 1-vinyltriazoles and electron-rich alkynes—cleavage to "push-pull" 1,3-butadienes (C) 553
Butenal, Kinetic and thermodynamic control in the reaction of $(Ph_3P)_2PtO_2$ with (*E*)-2-butenal (C) 47
Butyl cation, C-Scrambling in the *tert*-butyl cation (C) 50
Butynylcarbamates, Regio- and diastereoselective synthesis of (4-hydroxy-3-methyl-1,2-alkadienyl)carbamates from α-titanated 2-butynylcarbamates and aldehydes (C) 54

CAGE MOLECULE, Unprecedented oxidative addition of the $P_4S_3$ cage molecule with phosphorus-phosphorus bond cleavage; synthesis and molecular structure of $[Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)]_2$ (C) 790
Carbanions, Successive electron transfers in molecules with two electrophoric groups: novel singlet, doublet, and triplet states (C) 242
The structure of tris(diphenylthiophosphinoyl)methanide, a mesomerically stabilized carbanion (C) 254
Carbene-carbon monoxide coupling, Intramolecular carbene-carbon monoxide coupling in chromium and tungsten complexes (C) 874
Carbene complex, Synthesis and structure of $(CO)_4\overline{W[C(NEt_2)PMePh]}$, a novel cyclic carbene complex (C) 411
A carbene-complex route to vitamin E (C) 732
Carbenes, Expansion of three-membered heterocycles to five-membered cyclic carbenes—novel reactions of aziridine, oxirane, and thiirane with CO and CS ligands in iron, ruthenium, and manganese complexes (C) 163
Carbocyanines, First proof of di-, tri-, and all-*cis*-conformations in sterically hindered trimethinecyanines (carbocyanines) of the indoline and benzothiazole series (C) 876
Carbodications, Stable carbodications (R) 390
The *endo*-3,10-dimethyltricyclo[5.2.1.0$^{2,6}$]deca-4,8-dien-3,10-diyl dication, a novel bishomoaromatic/allylic dication and its rearrangement to the symmetrical *cis-anti-cis*-3,10-dimethyltricyclo[5.3.0.0$^{2,6}$]deca-4,8-dien-3,10-diyl dication (C) 712
Carbodiphosphorane, Coinage metal complexes of hexaphenylcarbodiphosphorane—organometallic compounds with coordination number 2 (C) 729
Carbon, The electrochemistry of black carbons (R) 950
Carbonylation, Metal-induced carbonylation of a phosphane-stabilized "carbyne ligand": conversion of a phosphorus ylide-carbonylmetal adduct into an $\eta^1$-ketenyl complex (C) 151
Carbonyl olefinations with organomolybdenum compounds (C) 244
Carborane, Synthesis and structure determination of $[(PEt_3)RhC_2B_9H_{10}]_2$—a binuclear rhodacarborane containing four bonds between two icosahedra (C) 722
Carbyne ligand, Metal-induced carbonylation of a phosphane-stabilized "carbyne ligand": conversion of a phosphorus ylide-carbonylmetal adduct into an $\eta^1$-ketenyl complex (C) 151
Carminomycinone, Facile synthesis of the (±)-6-deoxycarminomycinone from aloeemodin (C) 875
Caronaldehyde acid methyl ester, Diastereo- and enantioselective synthesis of (1*R*,3*R*)-caronaldehyde acid methyl ester and (1*R*,3*R*)-chrysanthemic acid methyl ester from (*R*)-glycerinaldehyde acetonide (C) 63
Catalysis by molecular metal clusters (R) 135
Allyl(hydrido)platinum(II)-catalyzed partial hydrogenation of dienes (C) 246
Catalysts, Novel nickel-oligomerization catalysts with arsenic-oxygen chelate ligands (C) 503
Solution-phase metal atom preparation of catalytically active zeolite-encapsulated metal clusters; characterization and application to the selective reduction of CO to butene (C) 624
"Organically solvated" magnesium for the synthesis of transition-metal complexes and catalysts (C) 728
Reaction control by catalysts with variable specificity: stable palladium-phthalocyanine as hydrogenation catalyst with three catalytic patterns (C) 881
Catenane, [2]-[Cyclohexatetraoctane][cyclooctacosane]catenane, the first hydrocarbon catenane (C) 889
Cercosporin, a singlet oxygen generator (C) 720
Chain-forming step, A model reaction of an elementary step in the Fischer-Tropsch synthesis: $[C_6Me_6RuH(C_2H_4)PR_3]^+$ from $C_6Me_6Ru(CH_3)_2PR_3$ (C) 46
Charge-transfer absorption, Cation-induced charge-transfer absorption of intramolecular quinhydrones with oligooxaparacyclophane structure (C) 334
Chelating ligands, The structure of tris(diphenylthiophosphinoyl)methanide, a mesomerically stabilized carbanion (C) 254
Novel nickel-oligomerization catalysts with arsenic-oxygen chelate ligands (C) 503
Chelation control, Chelation or non-chelation control in stereoselective reactions of titanium reagents with chiral alkoxycarbonyl compounds (C) 989
Chemical technology, Ullmanns Encyklopädie der technischen Chemie (B) 564
Chemical transport, Preparation of solid-state compounds by chemical transport—interpretation and control using the cooperative transport model (R) 82
Chiral synthetic building block, Synthesis of the chiral synthetic building block (1*R*,5*S*)-3-phenyl-4-oxa-2,6-diazabicyclo-[3.2.0]hept-2-en-7-one from 6-aminopenicillanic acid (C) 711
Chromatography, A quarter century of thin-layer chromatography—an interim report (R) 507
Chromatographic resolution of cyclic organic compounds on a Λ-Tris(1,10-phenanthroline)ruthenium(II) montmorillonite column (C) 162
Isotope effects in the low-pressure, high-pressure, and thin-layer chromatography of the lanthanoids (C) 325
Chromium compounds, $\mu_2$-($\eta^5$:$\eta^5$-Cyclooctatetraene)-bis($\eta^5$-cyclopentadienylchromium): a "siamese twin" of two half-open sandwich moieties (C) 330

Chrysanthemic acid methyl ester, Diastereo- and enantioselective synthesis of (1*R*,3*R*)-caronaldehyde acid methyl ester and (1*R*,3*R*)-chrysanthemic acid methyl ester from (*R*)-glycerinaldehyde acetonide (C) 63
Circular dichroism, Resolution, circular dichroism, and absolute configuration of 1,1'-biazulenes (C) 870
Clathrands, A novel type of ionic clathrands for numerous inclusion compounds (C) 409
Clusters, Catalysis by molecular metal clusters (R) 135
Exchange of the apical tin atom in the *nido*-cluster $(CH_3)_5C_5Sn^+$ (C) 56
Reversible opening of a thioketene-iron cluster containing a $\mu_2$-$C_2$,$\mu_2$-*S*-thiocarbonyl group (C) 153
FT-FIR spectroscopy of ligand-free metal clusters; matrix effects on the molecular geometry of trichromium, $Cr_3$ (C) 166
Synthesis and structure of $[AsPh_4][Ru_6H(\mu\text{-}O{=}CNMe_2)_2(\mu\text{-}CO)_4(CO)_{14}]\cdot Me_2C{=}O$; a cyclic hydrido-hexametallic anion (C) 249
$[Co_3\{\mu_3\text{-}S\}\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: the first trinuclear cobalt cluster with tetrahedral $CoS_4$-coordination (C) 318
Capping of metal atom triangles in clusters by $R_3PAu$ moieties (C) 326
Synthesis of a tetranuclear manganese(IV) cluster with adamantane skeleton: $[(C_6H_{15}N_3)_4Mn_4O_6]^{4+}$ (C) 328
$(C_5H_5)_6Ni_2Zn_4$—the first zinc-containing mixed-metal cluster (C) 329
Synthesis and structure of $[\{[CH_3C(CH_2PPh_2)_3]IrP_3\}_3Cu_5Br_4]CuBr_2$—a 21 atom Ir/Cu/P/Br cluster (C) 554
Cobalt cluster, $[Co_3\{\mu_3\text{-}S\}\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: the first trinuclear cobalt cluster with tetrahedral $CoS_4$-coordination (C) 318
Cobester, 5,15-Bisnorcobester: an unexpected mode of formation (C) 736
A simple route to 5-nor-, 15-nor-, and 5,15-bisnorcobesters (C) 737
Cog-wheel mechanism, Conformational inversion of tetraisopropylethylene: no cog-wheel mechanism (C) 998
Color photography, Dye diffusion systems in color photography (R) 191
Columnar structure, Construction of an alternating (Rh, Rh, Ir, Ir)$_\infty$-columnar structure *via* a quasiracemate (C) 327
Complexation gas chromatography, Derivatization-free enantiomer resolution of chiral alcohols and ketones by high-resolution complexation gas chromatography (C) 772
Quantitative separation of deuterated tetrahydrofurans $C_4H_{4(\beta)}H_{4-n(\alpha)}D_{n(\alpha)}O$ by complexation gas chromatography on a cobalt(II) complex (C) 772
Complexing, Quenching of the aromaticity of the 5-dibenzo[*a*,*d*]cycloheptenylium ion by complexing with $(CO)_3Cr$ (C) 559
Complexing agents, Synthesis and structure of a macrocycle with a skeletal framework of arsenic, carbon, oxygen, and nitrogen atoms (C) 1006
Complex ion pair, Synthesis and structure of $[Na(tmeda)_2]^{\oplus}[HNi_2(C_2H_4)_4]^{\ominus}$ (C) 991
Conformations, Solution conformations, photophysics, and photochemistry of bile pigments; bilirubin and biliverdin dimethyl esters and related linear tetrapyrroles (R) 656
First proof of di-, tri-, and all-*cis*-conformations in sterically hindered trimethinecyanines (carbocyanines) of the indoline and benzothiazole series (C) 876
Conformational inversion of tetraisopropylethylene: no cog-wheel mechanism (C) 998
Coordination, Phosphorus ylides in the coordination sphere of transition metals. An inventory (R) 907
Tellurium as six-electron donor—synthesis and structure of $\mu_3$-Te[$Mn(CO)_2(\eta^5\text{-}C_5H_5)]_3$ (C) 59
$[Co_3\{\mu_3\text{-}S\}\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: the first trinuclear cobalt cluster with tetrahedral $CoS_4$-coordination (C) 318
$[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_2\{SC_6H_5\}_2]^{2-}$ and $[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: binuclear thiolatoiron(II) anions with tetrahedral $FeS_4$-coordination (C) 319
Coinage metal complexes of hexaphenylcarbodiphosphorane—organometallic compounds with coordination number 2 (C) 729
$^{27}$Al-NMR spectroscopy: a probe for three-, four-, five-, and sixfold coordinated Al atoms in organoaluminum compounds (C) 779
$SbF^{2+}$ as a Lewis acid in $Na(SbF)PO_4\cdot nH_2O$ (n = 2–4) and $NH_4(SbF)PO_4\cdot H_2O$ (C) 872
N,P-coordination of an amino(imino)phosphane (C) 984
Lithium complexes with *pentahapto*-bonded cyclopentadienyl ligands (C) 994
Cope-rearrangement, Ring-opening by [3,3]-diphospha Cope-rearrangement (C) 61
Copper compounds, Are the previously described $[ClF_6][CuF_4]$ and $[Cu(H_2O)_4][SiF_6]$ identical? (C) 408
Copper(II) diacetate, Synthesis and structure of $[CuMo(CH_3CO_2)_2(L)(CO)_2(\eta^5\text{-}C_5H_5)]$: monomeric copper(II) diacetate as building block of a heterometallic binuclear complex (C) 982
Coriolin, Synthesis and structure of a linearly *anti*-annelated tetracycloundecane. A potential precursor for a coriolin synthesis (C) 721
Corrins, Novel methods for demetalating tetrapyrrolic metallo-macrocycles (C) 734
Acid-catalyzed demetalation of nickel-hydrocorphin and cobalt-corrin complexes with 1,3-propanedithiol (C) 735
Coupling constants, Tetra-*tert*-butyltetrahedrane: $^{13}C$-$^{13}C$ coupling constants and hybridization (C) 878
Crown ethers, Cation-induced charge-transfer absorption of intramolecular quinhydrones with oligooxaparacyclophane structure (C) 334
Surfactants with novel structural characteristics (C) 616
Macrocyclic polyether syntheses (B) 257
Crystallographic disorder, Cautionary example of incorrect structural assignment due to crystallographic disorder (C) 251
Crystal structure, Structural relationship of $[(C_6H_5)_4As]NdCl_4\cdot 8H_2O$ and $NdCl_3\cdot 6H_2O$: transition from a three-dimensional to a layer structure (C) 1009
Crystal structure investigation, Are the previously described $[ClF_6][CuF_4]$ and $[Cu(H_2O)_4][SiF_6]$ identical? (C) 408
Cubane type, A general method for the synthesis of heterometal clusters of the $M_2Fe_2S_4$-cubane type (M = Cr, Mo) (C) 549
Cyanoformyl chloride (C) 785
Cyanouracil, Photocycloaddition of 6-cyanouracil to ketene diethyl acetal: synthesis of a uracil derivative possessing a cyclobutenone framework (C) 629
Cyclic reaction, Straightforward preparation and stabilization of 2-*trans*-4,7:10,13-diepoxy[15]annulenone (C) 253
Cyclizations, Homolytic cyclizations of *N*-chloroalkenylamines (R) 337
Cycloadditions, [2+2]-Cycloadditions of allyl cations (C) 49
Photocycloaddition of 6-oxopurines and thymine to products with cyclobutane part structures (C) 623
Photocycloaddition of 6-cyanouracil to ketene diethyl acetal: synthesis of a uracil derivative possessing a cyclobutenone framework (C) 629
[4+2]-Cycloaddition of singlet oxygen to 2,5-dimethylfuran: isolation and reactions of the monomeric and dimeric endoperoxides (C) 726
Cycloalkenynes, Base-induced isomerization of cycloalkenynes in competition with addition reactions (C) 627
Cyclobutabenzene, Unexpected ring-opening of benzocyclobutenes upon reaction with lithium in tetrahydrofuran (C) 246
Cyclobutadiene, Three arguments supporting a rectangular structure for tetra-*tert*-butylcyclobutadiene (C) 402
Bonding electron density distribution in tetra-*tert*-butylcyclobutadiene—a molecule with an obviously non-square four-membered ring (C) 403
Tricyclo[2.1.0.$0^{2,5}$]pentan-3-one (C) 990
Cyclodextrin, Flip-flop hydrogen bonds in β-cyclodextrin—a generally valid principle in polysaccharides? (C) 883
Cyclohexadiene, 1,2-Cyclohexadiene (C) 542
Cyclopentadienylbis(ethene)cobalt, Synthesis and reactions of $\eta^5$-cyclopentadienylbis(ethene)cobalt (C) 716
Cyclopentadienyl ligands, Lithium complexes with *pentahapto*-bonded cyclopentadienyl ligands (C) 994
Cyclopentanecarboxylates, Novel one-step synthesis of oxocyclopentanecarboxylates by electrochemical reduction of cinnamic acid esters (C) 52
Cyclophanes, Cation-induced charge-transfer absorption of intramolecular quinhydrones with oligooxaparacyclophane structure (C) 334
New link between cyclophane and ferrocene chemistry (C) 633
Cyclopropane derivatives, 1-Lithio-1-phenylcyclopropanes—structure and dynamics (C) 243
Cytochrome c oxidase, Structure and evolution of the *"Atmungsferment"* cytochrome c oxidase (R) 275
Cytochrome P450 enzyme, Prostacyclin synthase, a cytochrome P450 enzyme (C) 487

DAILY RHYTHMS, Turgorins, hormones of the endogeneous daily rhythms of higher organized plants—detection, isolation, structure, synthesis, and activity (R) 695
Defect tetrahedral structure, GaGeTe, a novel defect tetrahedral structure (C) 407
Dehalogenation, Selective reductive dehalogenation of tertiary and benzylic halides with $Zn(BH_4)_2$ in diethyl ether (C) 562
Dehydrobenzene, 1,2-Benzynes from 6-halopentafulvenes (C) 490
Demetalation, Novel methods for demetalating tetrapyrrolic metallo-macrocycles (C) 734
Acid-catalyzed demetalation of nickel-hydrocorphin and cobalt-corrin complexes with 1,3-propanedithiol (C) 735
Deoxycarminomycinone, Facile synthesis of the (±)-6-deoxycarminomycinone from aloe-emodin (C) 875
Description of structure, On the description of complex inorganic crystal structures (R) 69
Intermetallic compounds and the use of atomic radii in their description (R) 95
Detonation of benzyl(triethyl)ammonium permanganate (C) 625
Deuteriofurans, Quantitative separation of deuterated tetrahydrofurans $C_4H_{4(\beta)}H_{4-n(\alpha)}D_{n(\alpha)}O$ by complexation gas chromatography on a cobalt(II) complex (C) 772
Deuteroporphyrin-IX dimethyl ester: assignment of the $^1$H-NMR spectrum by NOE measurements in presence of a diamagnetic shift reagent (C) 551
Dialkoxytrimethylene, 1,1-Dialkoxytrimethylene radical cations (C) 500
Diaminodiphosphene, Tetrakis(trimethylsilyl)diaminodiphosphene (C) 155

Diaminodiphosphenes—synthesis, crystal structure and bonding properties (C) 486
Dianions, Unusual NMR phenomena of anthracene and phenanthrene dianions—thermal stimulation of triplet states in antiaromatic systems (C) 45
Di(9-anthryl)ethylene, *cis*-1,2-Di(9-anthryl)ethylene: photochemical isomerization by intramolecular Diels-Alder reaction (C) 495
Diarsenechromium complex, Synthesis and structure of a diarsenechromium complex with an unsupported arsenic-arsenic double bond (C) 978
Diastereoselective syntheses of *C*-glycopyranosides (C) 622
Diazadienes, Diels-Alder reactions of dienes with alkynes catalyzed by diazadieneiron (C) 778
Activity of coordinated 1,4-diaza-1,3-dienes (dad) in C-C bond forming reactions: 1,5-dihydropyrrol-2-ones from (dad)$Fe(CO)_3$ and dimethyl acetylenedicarboxylate (C) 992
Diazaquinodimethanes, donor-substituted pyrazines, and dihydropyrazines (C) 717
Diazasilacyclopentenes, The one-electron oxidation of diazasilacyclopentenes (C) 621
Diazenidomolybdenum complex, $[Mo\{N_2C(S)SC_2H_5\}\{NH_2NC(S)SC_2H_5\}\{(CH_3)_2NCS_2\}_2]$—a sulfur-rich heptacoordinated diazenidohydrazido(1−)molybdenum complex (C) 245
Diazines, The versatile chemistry of 1,4-diazines: organic, inorganic and biochemical aspects (R) 171
Dibenzo[8]annulene, A novel planar antiaromatic dibenzo[8]annulene (C) 332
Dibenzo[*a*,*d*]cycloheptenylium ion, Quenching of the aromaticity of the 5-dibenzo[*a*,*d*]cycloheptenylium ion by complexing with $(CO)_3Cr$ (C) 559
Diboretenes, Synthesis of borirenes and diboretenes—a novel class of 2π-aromatic compounds (C) 48
Dicyanoketene: flash vacuum thermolysis of alkyl dicyanoacetates (C) 165
Diels-Alder oligomers, *p*-(*o*,*p*)-*o*-Tribenzene and *p*-(*o*,*p*)-(*o*,*o*)-*p*-tetrabenzene, Diels-Alder oligomers of benzene (C) 617
Diels-Alder reaction, *syn*-Benzene dioxide/1,4-dioxocin systems *via* a Diels-Alder route (C) 410
*cis*-1,2-Di(9-anthryl)ethylene: photochemical isomerization by intramolecular Diels-Alder reaction (C) 495
of dienes with alkynes catalyzed by diazadieneiron (C) 778
3,4-Bismethylenetricyclo[3.1.0.0$^{2,6}$]hexane—synthesis and Diels-Alder addition to tetracyanoethylene (C) 871
Acceleration and asymmetric induction of intermolecular Diels-Alder reactions of triacyl compounds (C) 887
Diepoxy[15]annulenone, Straightforward preparation and stabilization of 2-*trans*-4,7:10,13-diepoxy[15]annulenone (C) 253
Difluoroantimony cation, $SbF^{2+}$ as a Lewis acid in $Na(SbF)PO_4 \cdot nH_2O$ (n = 2–4) and **$NH_4(SbF)PO_4 \cdot H_2O$ (C) 872**
Difluoromethylene group, $(FMe_2Si)_2CF_2$: synthesis and reactions (C) 730
Diketene, Addition of alkanethiols to diketene—a correction (C) 498
Dilithioethane, 1,1-Dilithioethane (C) 733
Dimerization, Phosphane-induced, stepwise rearrangement of an octadienediyl palladium complex to seven- and nine-membered metallacycles (C) 774
Metal-induced C-C coupling by reductive dimerization of thioaroyl groups (C) 996
Dinuclear complexes, $\eta^6$-Bonded alkylbenzenes as novel bridging ligands in dinuclear complexes of iron and cobalt (C) 620
Dioxocin, *syn*-Benzene dioxide/1,4-dioxocin systems *via* a Diels-Alder route (C) 410
Diphospha Cope-rearrangement, Ring-opening by [3,3]-diphospha Cope-rearrangement (C) 61
Diphosphene, A diphosphene as tetrahedrane building block: synthesis of $[Fe_2(CO)_6(P_2tBu_2)]$ (C) 154
Tetrakis(trimethylsilyl)diaminodiphosphene (C) 155
Diaminodiphosphenes—synthesis, crystal structure and bonding properties (C) 486
Diphosphene complex, $(C_6H_5)_2P_2[Cr(CO)_5]_2$, a diphosphene complex with free phosphorus-phosphorus double bond (C) 977
Diphosphorus, :P≡P:, as eight-electron ligand (C) 976
Disaccharide synthesis, Synthesis and structure of the disaccharide fragment B-A of mithramycin (C) 58
Diselenium, Disulfur and diselenium as strong acceptor ligands in $(\eta^5\text{-}C_5H_5)Re(CO)_2S_2$ and $[\eta^5\text{-}C_5(CH_3)_5]Mn(CO)_2Se_2$ (C) 1000
Disorder, Cautionary example of incorrect structural assignment due to crystallographic disorder (C) 251
Disulfur and diselenium as strong acceptor ligands in $(\eta^5\text{-}C_5H_5)Re(CO)_2S_2$ and $[\eta^5\text{-}C_5(CH_3)_5]Mn(CO)_2Se_2$ (C) 1000
Dithian-2-yl methyl ester, 1,3-Dithian-2-yl methyl ester as two-step protecting group for the carboxy function in peptide synthesis (C) 62
Dithioxophosphorane, The first organodithioxophosphorane (C) 1004
DNA, Synthesis of peptide hormones using recombinant DNA techniques (R) 842
DNA synthesis, Chemical and enzymatic synthesis of gene fragments. A laboratory manual (B) 504
Dodecapentaenebis(tricarbonyliron), Organometallic variants of the Wittig reaction: synthesis and structure of *trans*-μ-(2-5; 8-11-η-dodecapentaene)bis(tricarbonyliron) (C) 713
Donor-acceptor bonding, Synthesis and structure of a bicyclic SbNP compound with intramolecular donor-acceptor bonding (C) 404
Dye diffusion systems in color photography (R) 191

ECOTOXICOLOGY, From environmental analytical chemistry to ecotoxicology—a plea for more concepts and less monitoring and testing (R) 380
Eight-Electron ligand, Diphosphorus, :P≡P:, as eight-electron ligand (C) 976
Electrical conductivity, Preparation and properties of tetrabenzoporphyrinatoiron(II) and its isocyanide complexes (C) 724
Polymeric electrically conductive phthalocyaninato(μ-s-tetrazine)iron (C) 784
Electrical properties of polymers (B) 895
Electrochemical reduction, Novel one-step synthesis of oxocyclopentanecarboxylates by electrochemical reduction of cinnamic acid esters (C) 52
Reactions at the counter electrode in electroreductions under aprotic conditions in one-compartment cells (C) 492
Electrochemistry, The electrochemistry of black carbons (R) 950
Aerial oxidation of benzene in the presence of electrochemically generated $Cu^+$ ions (C) 502
Industrial electrochemistry (B) 421
Electromicrobial reduction using yeasts (C) 322
Electron diffraction with the transmission electron microscope as a phase-determining diffractometer—from spatial frequency filtering to the three-dimensional structure analysis of ribosomes (R) 456
Electronic theory of chemical reactions, Electrons in chemical reactions; first principles (B) 635
Electron microscopy, From macromolecules to biological assemblies (Nobel lecture) (R) 565
E(lectron)N(uclear)DO(uble)R(esonance), $^{29}$Si-E(lectron)N(uclear)DO(uble)R(esonance) (C) 787
Electron transfer, Successive electron transfers in molecules with two electrophoric groups: novel singlet, doublet, and triplet states (C) 242
Electrophilic alkylation, Reactions of *N*-methylenecarboxamides with electrophiles: 1-alkoxy-2-azaallenium salts and *N*-acyl(methylene)ammonium salts (C) 252
Elimination, An arsanylketene by elimination from on oxaarsatungstacyclopentene complex (C) 1001
Enamides, Biomimetic synthesis of primary enamides by decarboxylation of α,β-dehydroamino acids (C) 550
Enantiomer resolution, Derivatization-free enantiomer resolution of chiral alcohols and ketones by high-resolution complexation gas chromatography (C) 772
Enantioselective hydrosilylation, Rhodium catalysts for enantioselective hydrosilylation—a new concept in the development of asymmetric catalysts (R) 897
of acetophenone with rhodium/thiazolidine catalysts (C) 331
Enantioselectivity, Reversal of the enantioselectivity in the enzymatic hydrolysis of juvenile hormone as a consequence of a protein fractionation (C) 773
Endoperoxides, [4+2]-Cycloaddition of singlet oxygen to 2,5-dimethylfuran: isolation and reactions of the monomeric and dimeric endoperoxides (C) 726
ENDOR-Spectroscopy, The first $^{13}$C-ENDOR investigation of an organic triradical in the quartet state; synthesis of a triply $^{13}$C-labeled trisgalvinol (C) 150
$^{29}$Si-E(lectron)N(uclear)DO(uble)R(esonance) (C) 787
Radical products in single electron transfer reactions of lithium triethylhydridoborate detected by ESR and multinuclear ($^1$H, $^{10}$B, $^{11}$B, $^{14}$N)-ENDOR spectroscopy (C) 892
Energy, Raw materials and energy: a challenge for polymer research (R) 764
Enol, (*Z*)-2-Methoxy-1,2-diphenylvinyl alcohol, a remarkably stable enol (C) 405
Environmental analytical chemistry, From environmental analytical chemistry to ecotoxicology—a plea for more concepts and less monitoring and testing (R) 380
Enzyme reaction, Reversal of the enantioselectivity in the enzymatic hydrolysis of juvenile hormone as a consequence of a protein fractionation (C) 773
Estrogens, The photooxygenation of estrogens: a new synthesis of 19-norsteroids (C) 711
Estrone, Stereoselective synthesis of enantiomerically pure natural products—estrone as example (R) 637
Ethanedithiol, Novel methods for demetalating tetrapyrrolic metallo-macrocycles (C) 734
Ethyl α-formylpropanoate, Preparation of ethyl (*R*)-(−)-3-hydroxy-2-methylpropanoate by yeast reduction of ethyl α-formylpropanoate (C) 1012
Excited state, Four-membered ring peroxides as excited state equivalents: a new dimension in bioorganic chemistry (R) 529
Advances in chemical physics, Vol. 50. Dynamics of the excited state (B) 894
Explosion, Detonation of benzyl(triethyl)ammonium permanganate (C) 625
Extraction, Highly selective extraction of uranyl ions by acyclic ligands containing L-phenylalanine moieties (C) 563

FERRIOSTIBANE-TRIMETHYLPHOSPHANE COMPLEXES, Transition-metal substituted stibanes as acceptors: $Cp(CO)(L)Fe—SbBr_2 \cdot PMe_3$ (L = CO,

$Me_3P$, MeNC) —1:1-ferriostibane-trimethylphosphane complexes (C) 60
Ferrocene, New link between cyclophane and ferrocene chemistry (C) 633
Fischer-Tropsch synthesis, A model reaction of an elementary step in the Fischer-Tropsch synthesis: $[C_6Me_6RuH(C_2H_4)PR_3]^+$ from $C_6Me_6Ru(CH_3)_2PR_3$ (C) 46
Solution-phase metal atom preparation of catalytically active zeolite-encapsulated metal clusters; characterization and application to the selective reduction of CO to butene (C) 624
Intramolecular carbene-carbon monoxide coupling in chromium and tungsten complexes (C) 874
Flash photolysis, Kinetics of the reaction of electron deficient olefins with nitrile ylides generated by laser flash photolysis of substituted azirines (C) 625
Flash vacuum thermolysis, Dicyanoketene: flash vacuum thermolysis of alkyl dicyanoacetates (C) 165
Flip-flop hydrogen bonds in β-cyclodextrin—a generally valid principle in polysaccharides? (C) 883
Force field calculations, Molecular mechanics calculations in organic chemistry: examples of the usefulness of a simple nonquantum mechanical model (R) 1
Formylpropanoate, Preparation of ethyl (*R*)-(−)-3-hydroxy-2-methylpropanoate by yeast reduction of ethyl α-formylpropanoate (C) 1012
Four-electron ligands, A novel and general route to ($\eta^5$-borole)metal complexes: compounds of manganese, ruthenium, and rhodium (C) 996
Four-electron redox reaction, Photochemical four-electron redox reaction of hexaazidoplatinate(IV) (C) 154
Fourier transform far-infrared spectroscopy, FT-FIR spectroscopy of ligand-free metal clusters; matrix effects on the molecular geometry of trichromium, $Cr_3$ (C) 166
of silver atoms and silver clusters entrapped in zeolite NaY (C) 791
Fourier transform methods, Modern pulse methods in high-resolution NMR spectroscopy (R) 350
Free radical reactions, Formation of CC bonds by addition of free radicals to alkenes (R) 753
Friedel-Crafts alkylation, Regiocontrolled prenylations and alkylations of furans: preparation of rosefuran and novel analogues (C) 719

GAS CHROMATOGRAPHY, Derivatization-free enantiomer resolution of chiral alcohols and ketones by high-resolution complexation gas chromatography (C) 772
Quantitative separation of deuterated tetrahydrofurans $C_4H_{4(\beta)}H_{4-n(\alpha)}D_{n(\alpha)}O$ by complexation gas chromatography on a cobalt(II) complex (C) 772
Genetic engineering, Synthetic gene fragments in genetic engineering—the renaissance of chemistry in molecular biology (R) 13
Germanium compounds, $Rb_7NaGe_8$ and $K_7NaGe_8$, Zintl compounds with $Na(Ge_4)_2$ units (C) 998
Glucopyranosyl derivatives, Synthesis of C-α- and C-β-D-glucopyranosyl derivatives from *O*-(α-D-glucopyranosyl) trichloroacetimidate (C) 406
Glycopeptide synthesis, *O*-Glycopeptide synthesis using 9-fluorenylmethoxycarbonyl (Fmoc)-protected synthetic units (C) 62
Glycoproteins, Synthesis of a tetrasaccharide of the core region of *O*-glycoproteins (C) 776
Glycopyranosides, Diastereoselective syntheses of *C*-glycopyranosides (C) 622
Glyculosyl bromides, A facile, efficient synthesis of acylated glyculosyl bromides from hydroxyglycal esters (C) 891
Gold compounds, Capping of metal atom triangles in clusters by $R_3PAu$ moieties (C) 326
Graphite, Incorporation of mercury into graphite *via* K/Hg intercalation compounds (C) 53

HAFNIUM COMPOUNDS, Zircona- and hafnacyclobutenes—a new route to metallacyclobutanes (C) 248
Half-sandwich complexes, Electron-rich half-sandwich complexes—metal bases par excellence (R) 927
Heavy atom effect in the photoelectron spectra of transition metal complexes (C) 329
Hetero[17]annulene dioxides, Synthesis of hetero[17]annulene dioxides and a [16]annulene dioxide using furan building blocks (C) 417
Heterocycles, Homolytic cyclizations of *N*-chloroalkenylamines (R) 337
Expansion of three-membered heterocycles to five-membered cyclic carbenes—novel reactions of aziridine, oxirane, and thiirane with CO and CS ligands in iron, ruthenium, and manganese complexes (C) 163
Heterocyclic chemistry, Contemporary heterocyclic chemistry: syntheses, reactions and applications (B) 739
Heteromacrocycle, Synthesis and structure of a macrocycle with a skeletal framework of arsenic, carbon, oxygen, and nitrogen atoms (C) 1006
Heterometal clusters, A general method for the synthesis of heterometal clusters of the $M_2Fe_2S_4$-cubane type (M = Cr, Mo) (C) 549
Synthesis and structure of $[\{[CH_3C(CH_2PPh_2)_3]IrP_3\}_3Cu_5Br_4]CuBr_2$—a 21 atom Ir/Cu/P/Br cluster (C) 554
$[Cl_2FeS_2MoO(S_2)]^{2-}$, a novel bimetallic complex with unusual electronic structure and a substituted tetrachalcogenometalate as "ligand" (C) 561
Heterometallic binuclear complex, Synthesis and structure of $[CuMo(CH_3CO_2)_2(L)(CO)_2(\eta^5\text{-}C_5H_5)]$: monomeric copper(II) diacetate as building block of a heterometallic binuclear complex (C) 982
Hexaphenylcarbodiphosphorane, Coinage metal complexes of hexaphenylcarbodiphosphorane—organometallic compounds with coordination number 2 (C) 729
Hexopyranoside acetophenone acetals, Formation, structure, and synthetic use of gluco- and galactopyranoside acetophenone acetals with 1,3-dioxane rings (C) 255
Holographic methods for the investigation of photochemical and photophysical properties of molecules (R) 582
Hydrazidinyl radicals, 1,5-Dimethylverdazyls, hydrazidinyl radicals with pyramidal 1,5-nitrogen atoms (C) 320
Hydrazido(1−)molybdenum complex, $[Mo\{N_2C(S)SC_2H_5\}\{NH_2NC(S)SC_2H_5\}\{(CH_3)_2NCS_2\}_2]$—a sulfur-rich heptacoordinated diazenidohydrazido(1−)molybdenum complex (C) 245
Hydride addition, Novel $\eta^3,\sigma$-sulfur double ylide chromium complexes by *endo*-hydride addition to cationic ($\lambda^6$-thiabenzene 1-oxide)chromium complexes (C) 498
Hydrido complexes, Photolysis of the cyclopentadienyl(hydrido) complexes $C_5H_5M(CO)_3H$ (M = Cr, Mo, W) in matrices and in solution: characterization of $[C_5H_5W(CO)_2H]_2$ and $[C_5Me_5W(CO)_2H]_2$ (C) 544
Hydrido-hexametallic anion, Synthesis and structure of $[AsPh_4][Ru_6H(\mu\text{-}O{=}CNMe_2)_2(\mu\text{-}CO)_4(CO)_{14}]\cdot Me_2C{=}O$; a cyclic hydrido-hexametallic anion (C) 249
Hydrogenation, Allyl(hydrido)platinum(II)-catalyzed partial hydrogenation of dienes (C) 246
Hydrogenation catalysts, Reaction control by catalysts with variable specificity: stable palladium-phthalocyanine as hydrogenation catalyst with three catalytic patterns (C) 881
Hydrogen bonds, Flip-flop hydrogen bonds in β-cyclodextrin—a generally valid principle in polysaccharides? (C) 883
Hydrosilylation, Rhodium catalysts for enantioselective hydrosilylation—a new concept in the development of asymmetric catalysts (R) 897
Enantioselective hydrosilylation of acetophenone with rhodium/thiazolidine catalysts (C) 331
Hydroxyglycal esters, A facile, efficient synthesis of acylated glyculosyl bromides from hydroxyglycal esters (C) 891
Hydroxy-2-methylpropanoate, Preparation of ethyl (*R*)-(−)-3-hydroxy-2-methylpropanoate by yeast reduction of ethyl α-formylpropanoate (C) 1012

IMIDAZOLE, The relative basicities of imidazole and benzimidazole (C) 323
Conversion of imidazole into μ-2,3-dihydro-1*H*-imidazole-1,2,2-triyl ligands (C) 993
INADEQUATE Pulse sequence, Structure determination by $^{13}C$-NMR spectroscopy using an INADEQUATE pulse sequence: differentiation of heteroatom-substituted organic constitutional isomers by means of $^{13}C$-$^{13}C$ coupling constants (C) 548
Inclusion complexes between a macrocyclic host molecule and aromatic hydrocarbons in aqueous solution (C) 715
Inclusion compounds, A novel type of ionic clathrands for numerous inclusion compounds (C) 409
Initiation, Bond-forming initiation in spontaneous addition and polymerization reactions of alkenes (R) 440
Inorganic oligomers, Thio- and seleno-compounds of main group elements—novel inorganic oligomers and polymers (R) 113
Interactions, Proximity effects in organic chemistry—The photoelectron spectroscopic investigation of non-bonding and transannular interactions (R) 283
Intercalation compounds, Incorporation of mercury into graphite *via* K/Hg intercalation compounds (C) 53
Intercalation reactions, Redox intercalation reactions of $VOPO_4\cdot 2H_2O$ (C) 412
Intermediates, Reactive intermediates (B) 420
Intermetallic compounds and the use of atomic radii in their description (R) 95
Intramolecular donor-acceptor bonding, Synthesis and structure of a bicyclic SbNP compound with intramolecular donor-acceptor bonding (C) 404
Inversion, Conformational inversion of tetraisopropylethylene: no cog-wheel mechanism (C) 998
Iridium-rhodium compounds, Construction of an alternating (Rh, Rh, Ir, Ir)$_\infty$-columnar structure *via* a quasiracemate (C) 327
Iridoid glycosides, Secologanin, a biogenetic key compound—synthesis and biogenesis of the iridoid and secoiridoid glycosides (R) 828
Stereoselective synthesis of iridoid glycosides (C) 888
Iron compounds, Optically active iron complexes with tetrahedral structure (C) 164
Iron sulfur anions, $[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_2\{SC_6H_5\}_2]^{2-}$ and $[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: binuclear thiolatoiron(II) anions with tetrahedral $FeS_4$-coordination (C) 319
Isomerization, The cation di-μ-oxo-*trans*-dioxobis[(1,4,7-triazacyclononane)molyb-

denum(V)] (*Mo—Mo*) and its acid-catalyzed *cis*-isomerization (C) 491
Base-induced isomerization of cycloalkenynes in competition with addition reactions (C) 627
Octalene-bicyclo[6.2.0]decapentaene conversion mediated by transition-metal complexes (C) 1003
Isotope effects, Extremely long-range $^2H$ isotope effects on the chemical shifts in the $^{13}C$-NMR spectra of compounds with conjugated double bonds (C) 321
in the low-pressure, high-pressure, and thin-layer chromatography of the lanthanoids (C) 325

JUVENILE HORMONE, Reversal of the enantioselectivity in the enzymatic hydrolysis of juvenile hormone as a consequence of a protein fractionation (C) 773

KETENE, An arsanylketene by elimination from an oxaarsatungstacyclopentene complex (C) 1001
Ketene-alkyne conversion using Lewis acids (C) 493
Ketones, A method for the synthesis of ketones from phosphorus ylides and olefins *via* "mixed" diorganoborinates (C) 782
Kinetics, Linear control of temperature with time—a new approach to reaction kinetics (R) 225
Equilibria in the formation of $A_4B_3$ molecules (C) 317
Non-formal kinetics (B) 739

LACTAM ANTIBIOTICS, Synthesis and structure of (*Z*)-3-amino-4-oxo-2-azetidinesulfonic acids (C) 886
Lactones, A novel synthesis of macrocyclic lactones (C) 780
Lanthanoids, Isotope effects in the low-pressure, high-pressure, and thin-layer chromatography of the lanthanoids (C) 325
Lasers, Techniques of chemistry. Applications of lasers to chemical problems (B) 421
Lead-oxygen structural group, A novel lead-oxygen structural group: $Pb_8O_4^{8+}$ (C) 324
Leukotrienes, From studies of biochemical mechanism to novel biological mediators: prostaglandin endoperoxides, thromboxanes, and leukotrienes (Nobel lecture) (R) 805
Lewis acid, $SbF^{2+}$ as a Lewis acid in $Na(SbF)PO_4 \cdot nH_2O$ (n=2–4) and $NH_4(SbF)PO_4 \cdot H_2O$ (C) 872
Ligand-free metal clusters (R) 674
Solution-phase metal atom preparation of catalytically active zeolite-encapsulated metal clusters; characterization and application to the selective reduction of CO to butene (C) 624
Ligands, $[Mo\{N_2C(S)SC_2H_5\}\{NH_2NC(S)SC_2H_5\}\{(CH_3)_2NCS_2\}_2]$—a sulfur-rich heptacoordinated diazenidohydrazido(1−)-molybdenum complex (C) 245
$[Cl_2FeS_2MoO(S_2)]^{2-}$, a novel bimetallic complex with unusual electronic structure and a substituted tetrachalcogenometalate as "ligand" (C) 561
Pentacarbonylrhenium complexes with thiazylamide ligands (C) 723
Unprecedented oxidative addition of the $P_4S_3$ cage molecule with phosphorus-phosphorus bond cleavage; synthesis and molecular structure of $[Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)]_2$ (C) 790
$[Mo_2(NO)_2(S_2)_3(S_5)OH]^{3-}$, a complex containing a bidentate $S_5^{2-}$-bridging ligand in a $\{S_5Mo_2(S_2)\}$-heterocycle with cyclooctasulfur geometry (C) 884
Conversion of imidazole into μ-2,3-dihydro-1*H*-imidazole-1,2,2-triyl ligands (C) 993
Liquids, Properties of liquids and solutions (B) 256
Lithio-1-phenylcyclopropanes, 1-Lithio-1-phenylcyclopropanes—structure and dynamics (C) 243
Lithiumcarbamoyl-bis(ethene)nickel(0) (C) 547
Lithium-carbon structural units, $(PhC{\equiv}CLi)_4(tmhda)_2$, a polymeric organolithium compound with cubic $Li_4C_4$ structural units (C) 496
Lithium complexes with *pentahapto*-bonded cyclopentadienyl ligands (C) 994

MACROCYCLES, Inclusion complexes between a macrocyclic host molecule and aromatic hydrocarbons in aqueous solution (C) 715
A novel synthesis of macrocyclic lactones (C) 780
Magic-angle-spinning NMR (MAS-NMR) spectroscopy and the structure of zeolites (R) 259
Magnesium, "Organically solvated" magnesium for the synthesis of transition-metal complexes and catalysts (C) 728
Main group element-chalcogen compounds, Thio- and seleno-compounds of main group elements—novel inorganic oligomers and polymers (R) 113
Malonic ester dianion, Tetraethoxyallene: equivalent of the fictive malonic ester dianion—a versatile synthetic building block (C) 321
Manganese(IV) cluster, Synthesis of a tetranuclear manganese(IV) cluster with adamantane skeleton: $[(C_6H_{15}N_3)_4Mn_4O_6]^{4+}$ (C) 328
Mass spectroscopy, Generation of the phenyl cation by dissociative ionization of a dienynyl bromide in the gas phase (C) 786
Mercury, Incorporation of mercury into graphite *via* K/Hg intercalation compounds (C) 53
Mesomerism, The structure of tris(diphenylthiophosphinoyl)methanide, a mesomerically stabilized carbanion (C) 254
Metal-arsenic double bond, Dicarbonyl($\eta^5$-cyclopentadienyl)(di-*tert*-butyl-$\lambda^4$-arsanediyl)molybdenum and -tungsten—the first complexes with a metal-arsenic double bond (C) 416
Metal bases, Electron-rich half-sandwich complexes—metal bases par excellence (R) 927
Metal clusters, Catalysis by molecular metal clusters (R) 135
Ligand-free metal clusters (R) 674
Solution-phase metal atom preparation of catalytically active zeolite-encapsulated metal clusters; characterization and application to the selective reduction of CO to butene (C) 624
Metal-induced C-C bond formation, Activity of coordinated 1,4-diaza-1,3-dienes (dad) in C-C bond forming reactions: 1,5-dihydropyrrol-2-ones from (dad)$Fe(CO)_3$ and dimethyl acetylenedicarboxylate (C) 992
Metal-induced C-C coupling by reductive dimerization of thioaroyl groups (C) 996
Metallacycle, Aryl(hydrido)ruthenium complexes by C—H addition: isolation of a four-membered metallacycle as intermediate (C) 873
Metallacyclobutanes, Zircona- and hafnacyclobutenes—a new route to metallacyclobutanes (C) 248
Metallocene cations, Synthesis and structure of metallocene cations of the Vb elements arsenic and antimony (C) 250
Metal-metal bonds, Synthesis and structure of $[CuMo(CH_3CO_2)_2(L)(CO)_2(\eta^5\text{-}C_5H_5)]$: monomeric copper(II) diacetate as building block of a heterometallic binuclear complex (C) 982
Metal-metal multiple bonds, Addition of a phosphaalkyne to metal-metal multiple bonds (C) 413
Addition of methylene to multiple bonds between ligand-free main-group elements and transition metals—a general reaction (C) 979
Multiple bonds between metal atoms (B) 563
Metaphosphate derivatives, $P(NSiMe_3)_3^{\ominus}$—a derivative of the monomeric metaphosphate ion as building block for a tricyclic rhenium complex (C) 503
Metazidohemerythrin, $[\{(C_6H_{15}N_3)Fe\}_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2+}$, a dinuclear iron(III) complex with a metazidohemerythrin-type structure (C) 727
Methylation, The chemistry of pyrrocorphins: *C*-methylation of pyrrocorphinates at the ligand periphery (C) 631
Methylene addition, Addition of methylene to multiple bonds between ligand-free main-group elements and transition metals—a general reaction (C) 979
(Methylene)ammonium salts, Reactions of *N*-methylenecarboxamides with electrophiles: 1-alkoxy-2-azaallenium salts and *N*-acyl(methylene)ammonium salts (C) 252
Mikanecic acid, Preparation of 2-(1-hydroxyalkyl)acrylic esters; simple three-step synthesis of mikanecic acid (C) 795
Mimosa, A new phytohormone from *Mimosa pudica L.* (C) 617
Mithramycin, Synthesis and structure of the disaccharide fragment B-A of mithramycin (C) 58
Mixed crystals, Equilibria in the formation of $A_4B_3$ molecules (C) 317
Molecular biology, Synthetic gene fragments in genetic engineering—the renaissance of chemistry in molecular biology (R) 13
From macromolecules to biological assemblies (Nobel lecture) (R) 565
Molecular mechanics calculations in organic chemistry: examples of the usefulness of a simple non-quantum mechanical model (R) 1
Molybdenum compounds, Carbonyl olefinations with organomolybdenum compounds (C) 244
Synthesis and structure of $\mu_2$-oxobis[chloro(tetra-*p*-tolylporphyrinato)molybdenum(IV)]: a complex with central $Mo^{IV}$—O—$Mo^{IV}$ unit (C) 247
The cation di-μ-oxo-*trans*-dioxobis[(1,4,7-triazacyclononane)molybdenum(V)]-(*Mo—Mo*) and its acid-catalyzed *cis*-isomerization (C) 491
Molybdenum-sulfur compounds, $[Mo_2(NO)_2(S_2)_3(S_5)OH]^{3-}$, a complex containing a bidentate $S_5^{2-}$-bridging ligand in a $\{S_5Mo_2(S_2)\}$-heterocycle with cyclooctasulfur geometry (C) 884
Mucronin B, Total synthesis of mucronin B (C) 152
Multiphenylene, The structure and reactivity of 2,3,7,8-tetrakis(trimethylsilyl)terphenylene, a novel linear multiphenylene (C) 994
Multiple bonds, Addition of a phosphaalkyne to metal-metal multiple bonds (C) 413
Addition of methylene to multiple bonds between ligand-free main-group elements and transition metals—a general reaction (C) 979
$\mu_2$-E[V(CO)$_3$diphos]$_2$ (E=S, Se, Te): complexes with linear VEV multiple-bond systems (C) 980
between metal atoms (B) 563

NADH, Selective generation of NADH by visible light (C) 497
Natural products, Homolytic cyclizations of *N*-chloroalkenylamines (R) 337
Stereoselective synthesis of enantiomerically pure natural products—estrone as example (R) 637

Turgorins, hormones of the endogeneous daily rhythms of higher organized plants—detection, isolation, structure, synthesis, and activity (R) 695
Neodymium compounds, Structural relationship of $[(C_6H_5)_4As]NdCl_4 \cdot 8H_2O$ and $NdCl_3 \cdot 6H_2O$: transition from a three-dimensional to a layer structure (C) 1009
Nickel complexes, Synthesis and structure of $[Na(tmeda)_2]^{\oplus}[HNi_2(C_2H_4)_4]^{\ominus}$ (C) 991
Nickel(0) complexes, Lithiumcarbamoylbis(ethene)nickel(0) (C) 547
Nickel(II) complexes, $[Ni(S_4)_2]^{2\ominus}$, a homoleptic tetrasulfido-nickel(II) complex (C) 1006
Nickel-oligomerization catalysts, Novel nickel-oligomerization catalysts with arsenic-oxygen chelate ligands (C) 503
Nitrile ylides, Kinetics of the reaction of electron deficient olefins with nitrile ylides generated by laser flash photolysis of substituted azirines (C) 625
NMR Spectroscopy, Modern pulse methods in high-resolution NMR spectroscopy (R) 350
Unusual NMR phenomena of anthracene and phenanthrene dianions—thermal stimulation of triplet states in antiaromatic systems (C) 45
Extremely long-range $^2H$ isotope effects on the chemical shifts in the $^{13}C$-NMR spectra of compounds with conjugated double bonds (C) 321
2D-NMR spectroscopy in annulene chemistry: complete assignment of the $^{13}C$-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene by $^1H,^{13}C$ shift correlation (C) 499
Structure determination by $^{13}C$-NMR spectroscopy using an INADEQUATE pulse sequence: differentiation of heteroatom-substituted organic constitutional isomers by means of $^{13}C$-$^{13}C$ coupling constants (C) 548
Deuteroporphyrin-IX dimethyl ester: assignment of the $^1H$-NMR spectrum by NOE measurements in presence of a diamagnetic shift reagent (C) 551
Probing the environment of Al atoms in noncrystalline solids: $Al_2O_3$—$SiO_2$ gels, soda glass, and mullite precursors (C) 614
$^{27}Al$-NMR spectroscopy: a probe for three-, four-, five-, and sixfold coordinated Al atoms in organoaluminum compounds (C) 779
NMR Studies of yeasts grown on substrates at "zero" level radioactivity (C) 49
Nobel lecture, From macromolecules to biological assemblies (Nobel lecture) (R) 565
Adventures and excursions in bioassay: the stepping stones to prostacyclin (Nobel lecture) (R) 741
From studies of biochemical mechanism to novel biological mediators: prostaglandin endoperoxides, thromboxanes, and leukotrienes (Nobel lecture) (R) 805
The prostaglandins: from the laboratory to the clinic (Nobel lecture) (R) 858
Non-Born-Oppenheimer effects, Symmetry breaking and non-Born-Oppenheimer effects in radical cations (R) 210
Noncrystalline solids, Probing the environment of Al atoms in noncrystalline solids: $Al_2O_3$—$SiO_2$ gels, soda glass, and mullite precursors (C) 614
Norcobester, A simple route to 5-nor-, 15-nor-, and 5,15-bisnorcobesters (C) 737
Norsteroids, The photooxygenation of estrogens: a new synthesis of 19-norsteroids (C) 711
Nucleophilic reagents, Organometallic compounds of titanium and zirconium as selective nucleophilic reagents in organic synthesis (R) 31
Nucleophilic substitution, On the stereochemistry of the $S_N2'$ reaction (C) 613
Nucleotide analogues, Phosphorothioate analogues of nucleotides—tools for the investigation of biochemical processes (R) 423

OCTADIENEDIYL PALLADIUM COMPLEX, Phosphane-induced, stepwise rearrangement of an octadienediyl palladium complex to seven- and nine-membered metallacycles (C) 774
Octalene-bicyclo[6.2.0]decapentaene conversion mediated by transition-metal complexes (C) 1003
Olefins, Kinetics of the reaction of electron deficient olefins with nitrile ylides generated by laser flash photolysis of substituted azirines (C) 625
Olefin synthesis, Olefins from β-hydroxycarboxylic acids—synthesis of isomerically pure α- and β-asarone (C) 628
Oligosaccharides, Syntheses of a branched hepta- and an octasaccharide with phytoalexin-elicitor activity (C) 793
One-electron oxidation, The one-electron oxidation of diazasilacyclopentenes (C) 621
Optical activity, Optically active iron complexes with tetrahedral structure (C) 164
Organoborinates, A method for the synthesis of ketones from phosphorus ylides and olefins *via* "mixed" diorganoborinates (C) 782
Organodithioxophosphorane, The first organodithioxophosphorane (C) 1004
Organometallic chemistry, Comprehensive organometallic chemistry (B) 797
Organomolybdenum compounds, Carbonyl olefinations with organomolybdenum compounds (C) 244
Organosilicon compounds, $(FMe_2Si)_2CF_2$: synthesis and reactions (C) 730
Orthosilicic acid ester, Strong distortion of the tetrahedral geometry in a spirosilicate: molecular structure of bis(tetramethylethylenedioxy)silane (C) 65
The crystal and molecular structure of bis(1,8-naphthalenedioxy)silane—a contribution to the controversy over planar, four-coordinated silicon in orthosilicic acid esters (C) 501
Oxetones, Thietones, oxetones, and azetones (C) 543
Oxidation, Aerial oxidation of benzene in the presence of electrochemically generated $Cu^+$ ions (C) 502
Oxidative coupling of the selenolate functions in $(C_6H_5)_3PC(Se)P(C_6H_5)_3$: crystal structure of $\{[(C_6H_5)_3P]_2CSe\}_2^{2\oplus} \cdot Fe_2OCl_6^{2\ominus} \cdot 4CH_2Cl_2$ containing a linear Fe—O—Fe axis (C) 156
Oxidoylide reactions, Some cautions in the interpretation of oxidoylide reactions based on $^{31}P$-NMR data (C) 56
Oxo-hexachlorodiferrate(III), Oxidative coupling of the selenolate functions in $(C_6H_5)_3PC(Se)P(C_6H_5)_3$: crystal structure of $\{[(C_6H_5)_3P]_2CSe\}_2^{2\oplus}Fe_2OCl_6^{2\ominus} \cdot 4CH_2Cl_2$ containing a linear Fe—O—Fe axis (C) 156

PALLADIUM-PHTHALOCYANINE, Reaction control by catalysts with variable specificity: stable palladium-phthalocyanine as hydrogenation catalyst with three catalytic patterns (C) 881
Peptide alkaloids, Total synthesis of mucronin B (C) 152
Peptide hormones, Synthesis of peptide hormones using recombinant DNA techniques (R) 842
Peptide synthesis, 1,3-Dithian-2-yl methyl ester as two-step protecting group for the carboxy function in peptide synthesis (C) 62
Permanganate, Detonation of benzyl(triethyl)ammonium permanganate (C) 625
Peroxides, Four-membered ring peroxides as excited state equivalents: a new dimension in bioorganic chemistry (R) 529
PE spectroscopy, Proximity effects in organic chemistry—the photoelectron spectroscopic investigation of non-bonding and transannular interactions (R) 283
Heavy atom effect in the photoelectron spectra of transition metal complexes (C) 329
Phanes with two 4,4'-bipyridinium moieties—a new class of compounds (C) 489
Valence isomerization of phane-bridged *cis*-trioxatris-*o*-homobenzenes (C) 867
Phenol, Aerial oxidation of benzene in the presence of electrochemically generated $Cu^+$ ions (C) 502
Phenyl cation, Generation of the phenyl cation by dissociative ionization of a dienynyl bromide in the gas phase (C) 786
Phosphaalkyne, Addition of a phosphaalkyne to metal-metal multiple bonds (C) 413
Phosphaallyl cations, 2-Phosphaallyl cations by formal insertion of $P^{\oplus}$ into the C=C double bond (C) 545
Phosphaazulene, 2-Benzyl-1-phosphaazulene (C) 57
1-Methoxy-3-phenyl-2-phosphaazulene—the first synthesis of 2-phosphaazulenes (C) 879
Phosphaketene, The first stable phosphaketene (C) 785
Phosphanes, N,P-coordination of an amino(imino)phosphane (C) 984
$P_{12}iPr_4$ and $P_{13}iPr_5$, two novel polycyclic organophosphanes (C) 1002
Phosphanylketenes, Generation and stabilization of phosphanyl- and arsanylketenes within the coordination sphere of tungsten (C) 149
Phosphiranes, The first X-ray structure analysis of a thiadiphosphirane (C) 418
Phosphoranes, Dephosphorylating "ylide diketone"-rearrangement of the arylcarbonyloxyalkylidenephosphoranes (C) 619
The first organodithioxophosphorane (C) 1004
Phosphorothioates, Phosphorothioate analogues of nucleotides—tools for the investigation of biochemical processes (R) 423
Phosphorus atoms, Naked phosphorus atoms as trigonally planar coordinated bridge ligands (C) 976
Phosphorus heterocycles, $(tBuP)_2C(tBuP)_2$—the first tetraphosphaspiro[2.2]pentane (C) 632
Small heterocycles containing phosphorus and tellurium atoms (C) 983
Phosphorus-nitrogen compounds, $P(NSiMe_3)_3^{\ominus}$—a derivative of the monomeric metaphosphate ion as building block for a tricyclic rhenium complex (C) 503
Phosphorus-phosphorus double bond, $(C_6H_5)_2P_2[Cr(CO)_5]_2$, a diphosphene complex with free phosphorus-phosphorus double bond (C) 977
Phosphorus polycycles, $P_{12}iPr_4$ and $P_{13}iPr_5$, two novel polycyclic organophosphanes (C) 1002
Phosphorus selenide sulfide, Equilibria in the formation of $A_4B_3$ molecules (C) 317
Phosphorus-silicon compounds, $(tBuP)_8Si_2$—a novel dispirocyclic silaphosphane (C) 775
Phosphorus-sulfur compounds, Unprecedented oxidative addition of the $P_4S_3$ cage molecule with phosphorus-phosphorus bond cleavage; synthesis and molecular structure of $[Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)]_2$ (C) 790
Phosphorus ylides in the coordination sphere of transition metals. An inventory (R) 907
Some cautions in the interpretation of oxidoylide reactions based on $^{31}P$-NMR data (C) 56
Metal-induced carbonylation of a phosphane-stabilized "carbyne ligand": conversion of a phosphorus ylide-carbonylmetal adduct into an $\eta^1$-ketenyl complex (C) 151

A method for the synthesis of ketones from phosphorus ylides and olefins *via* "mixed" diorganoborinates (C) 782
Photochemistry, Holographic methods for the investigation of photochemical and photophysical properties of molecules (R) 582
Photochemical four-electron redox reaction of hexaazidoplatinate(IV) (C) 154
Selective generation of NADH by visible light (C) 497
of previtamin $D_3$ at 92 K: formation of an unstable tachysterol$_3$ rotamer (C) 718
Topics in current chemistry 103: preparative organic photochemistry (B) 505
Experimental methods in photochemistry and photophysics (B) 802
Photocycloaddition, Some substituent effects in the photocycloaddition of dihalomaleiimides to uracils (C) 161
of 6-oxopurines and thymine to products with cyclobutane part structures (C) 623
of 6-cyanouracil to ketene diethyl acetal: synthesis of a uracil derivative possessing a cyclobutenone framework (C) 629
Photography, Dye diffusion systems in color photography (R) 191
Photoisomerization, *cis*-1,2-Di(9-anthryl)-ethylene: photochemical isomerization by intramolecular Diels-Alder reaction (C) 495
Photolysis of the cyclopentadienyl(hydrido) complexes $C_5H_5M(CO)_3H$ (M = Cr, Mo, W) in matrices and in solution: characterization of $[C_5H_5W(CO)_2H]_2$ and $[C_5Me_5W(CO)_2H]_2$ (C) 544
Photooxygenation, The photooxygenation of estrogens: a new synthesis of 19-norsteroids (C) 711
Photophysics, Experimental methods in photochemistry and photophysics (B) 802
Photoreaction, Asymmetry of emission quenching and product formation in an asymmetrically sensitized photoreaction (C) 550
Phthalocyaninato(μ-s-tetrazine)iron, Polymeric electrically conductive phthalocyaninato(μ-s-tetrazine)iron (C) 784
Phytoalexin-elicitor activity, Syntheses of a branched hepta- and an octasaccharide with phytoalexin-elicitor activity (C) 793
Phytohormones, Turgorins, hormones of the endogeneous daily rhythms of higher organized plants—detection, isolation, structure, synthesis, and activity (R) 695
A new phytohormone from *Mimosa pudica L.* (C) 617
Platinum compounds, Kinetic and thermodynamic control in the reaction of $(Ph_3P)_2PtO_2$ with (*E*)-2-butenal (C) 47
Polymerization, Bond-forming initiation in spontaneous addition and polymerization reactions of alkenes (R) 440
Carbocationic polymerization (B) 505
Polymer research, Raw materials and energy: a challenge for polymer research (R) 764
Polymers, Electrical properties of polymers (B) 895
Porphyrinatomolybdenum complexes, Synthesis and structure of $\mu_2$-oxobis-[chloro(tetra-*p*-tolylporphyrinato)molybdenum(IV)]: a complex with central $Mo^{IV}$—O—$Mo^{IV}$ unit (C) 247
Porphyrinogen, The chemistry of pyrrocorphins: stereoselectivity in the porphyrinogen→pyrrocorphin tautomerization (C) 630
Porphyrins, Novel methods for demetalating tetrapyrrolic metallo-macrocycles (C) 734
Previtamin $D_3$, Photochemistry of previtamin $D_3$ at 92 K: formation of an unstable tachysterol$_3$ rotamer (C) 718
Propanedithiol, Acid-catalyzed demetalation of nickel-hydrocorphin and cobaltcorrin complexes with 1,3-propanedithiol (C) 735
Prostacyclin, Adventures and excursions in bioassay: the stepping stones to prostacyclin (Nobel lecture) (R) 741
Prostacyclin synthase, a cytochrome P450 enzyme (C) 487
Prostaglandin endoperoxides, From studies of biochemical mechanism to novel biological mediators: prostaglandin endoperoxides, thromboxanes, and leukotrienes (Nobel lecture) (R) 805
Prostaglandins, The prostaglandins: from the laboratory to the clinic (Nobel lecture) (R) 858
Protecting group, 1,3-Dithian-2-yl methyl ester as two-step protecting group for the carboxy function in peptide synthesis (C) 62
*O*-Glycopeptide synthesis using 9-fluorenylmethoxycarbonyl (Fmoc)-protected synthetic units (C) 62
The 2-(2-pyridyl)ethoxycarbonyl-(Pyoc) residue—an acid- and base-stable, hydrophilic protecting group for the amino function in peptide synthesis (C) 783
Protein-protein-interactions (B) 168
Proton sponge, 4,5-Bis(dimethylamino)-fluorene, a new "proton sponge" (C) 731
Proximity effects in organic chemistry—The photoelectron spectroscopic investigation of non-bonding and transannular interactions (R) 283
Pulse methods, Modern pulse methods in high-resolution NMR spectroscopy (R) 350
Purines, Photocycloaddition of 6-oxopurines and thymine to products with cyclobutane part structures (C) 623
Push-pull 1,3-butadienes, 1-(1,3-Butadienyl)triazoles from 1-vinyltriazoles and electron-rich alkynes—cleavage to "push-pull" 1,3-butadienes (C) 553
Pyrazine, The versatile chemistry of 1,4-diazines: organic, inorganic and biochemical aspects (R) 171
Diazaquinodimethanes, donor-substituted pyrazines, and dihydropyrazines (C) 717
Pyridine, $[Me_3Si(py)]^{\oplus}X^{\ominus}$ (X = Br, I): X-ray structural analysis of the 1:1-adducts of bromo- or iodotrimethylsilane and pyridine (C) 725
Pyrrocorphin, The chemistry of pyrrocorphins: stereoselectivity in the porphyrinogen→pyrrocorphin tautomerization (C) 630
The chemistry of pyrrocorphins: *C*-methylation of pyrrocorphinates at the ligand periphery (C) 631

QUANTUM CHEMISTRY, Elektronenstruktur organischer Moleküle. Grundbegriffe quantenchemischer Betrachtungsweisen (B) 335
Quartet state, The first $^{13}$C-ENDOR investigation of an organic triradical in the quartet state; synthesis of a triply $^{13}$C-labeled trisgalvinol (C) 150
Quasi (III—V)-phases, GaGeTe, a novel defect tetrahedral structure (C) 407
Quasiracemate, Construction of an alternating (Rh, Rh, Ir, Ir)$_\infty$-columnar structure *via* a quasiracemate (C) 327
Quenching, Efficiency of the physical quenching of singlet oxygen with benzoquinone derivatives (C) 792
Quinhydrones, Cation-induced charge-transfer absorption of intramolecular quinhydrones with oligooxaparacyclophane structure (C) 334

RADICAL ANIONS, Successive electron transfers in molecules with two electrophoric groups: novel singlet, doublet, and triplet states (C) 242
Efficient method for generation of radical anions from benzene derivatives of low electron affinity (C) 556
Radical cations, Symmetry breaking and non-Born-Oppenheimer effects in radical cations (R) 210
Generation of the tetraphenylcyclobutadiene radical cation by ionizing gas-phase decarbonylation (C) 51
1,1-Dialkoxytrimethylene radical cations (C) 500
Radical products in single electron transfer reactions of lithium triethylhydridoborate detected by ESR and multinuclear ($^1$H, $^{10}$B, $^{11}$B, $^{14}$N)-ENDOR spectroscopy (C) 892
Radicals, The first $^{13}$C-ENDOR investigation of an organic triradical in the quartet state; synthesis of a triply $^{13}$C-labeled trisgalvinol (C) 150
Radioactivity, NMR Studies of yeasts grown on substrates at "zero" level radioactivity (C) 49
Raw materials and energy: a challenge for polymer research (R) 764
Reaction kinetics, Linear control of temperature with time—a new approach to reaction kinetics (R) 225
Reaction mechanism, Can radicals participate in pericyclic reactions? Model reactions for electron-transfer induced valence isomerization of 1-arylindenes (C) 254
Chelation or non-chelation control in stereoselective reactions of titanium reagents with chiral alkoxycarbonyl compounds (C) 989
Rearrangement, Dephosphorylating "ylide diketone"-rearrangement of the arylcarbonyloxyalkylidenephosphoranes (C) 619
Phosphane-induced, stepwise rearrangement of an octadienediyl palladium complex to seven- and nine-membered metallacycles (C) 774
Recombinant DNA techniques, Synthesis of peptide hormones using recombinant DNA techniques (R) 842
Redox intercalation reactions of $VOPO_4 \cdot 2H_2O$ (C) 412
Redox reaction, Photochemical four-electron redox reaction of hexaazidoplatinate(IV) (C) 154
Reducing agents, Complex reducing agents (CRA's)—versatile, novel ways of using sodium hydride in organic synthesis (R) 599
Regioselectivity, Reversal of the regioselectivity in the zirconocene-induced coupling of a ketone with isoprene (C) 777
Resolution, Chromatographic resolution of cyclic organic compounds on a Λ-Tris(1,10-phenanthroline)ruthenium(II) montmorillonite column (C) 162
circular dichroism, and absolute configuration of 1,1'-biazulenes (C) 870
Resonance energy of bridged [10]annulenes (C) 1007
Rhenium compounds, $P(NSiMe_3)_3^{\ominus}$—a derivative of the monomeric metaphosphate ion as building block for a tricyclic rhenium complex (C) 503
Rhodacarborane, Synthesis and structure determination of $[(PEt_3)RhC_2B_9H_{10}]_2$—a binuclear rhodacarborane containing four bonds between two icosahedra (C) 722
Rhodium catalysts for enantioselective hydrosilylation—a new concept in the development of asymmetric catalysts (R) 897
Ribosomes, Electron diffraction with the transmission electron microscope as a phase-determining diffractometer—from spatial frequency filtering to the three-dimensional structure analysis of ribosomes (R) 456
Ring expansion, Expansion of three-membered heterocycles to five-membered cyclic carbenes—novel reactions of aziridine, oxirane, and thiirane with CO and CS ligands in iron, ruthenium, and manganese complexes (C) 163
Ring-opening by [3,3]-diphospha Cope-rearrangement (C) 61
Unexpected ring-opening of benzocyclobutenes upon reaction with lithium in tetrahydrofuran (C) 246

Ring strain, Through-bond interaction *via* strained σ-bonds—the synthesis and PE spectrum of 1,5-dimethyltetracyclo-[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione (C) 488
Thermolysis and reaction of 4,5-Benzotricyclo[4.1.0.0$^{1,3}$]hept-4-ene and *o*-(Propadienyl)styrene (C) 868
Tricyclo[4.1.0.0$^{1,3}$]hept-4-enes as intermediates (C) 869
Rosefuran, Regiocontrolled prenylations and alkylations of furans: preparation of rosefuran and novel analogues (C) 719
Ruthenium compounds, Synthesis and structure of [$AsPh_4$][$Ru_6H(\mu$-O=CNMe$_2$)$_2$($\mu$-CO)$_4$(CO)$_{14}$]·Me$_2$C=O; a cyclic hydrido-hexametallic anion (C) 249
Stereospecific reactions of chiral chlororuthenium(II) complexes with Grignard reagents (C) 333
Aryl(hydrido)ruthenium complexes by C—H addition: isolation of a four-membered metallacycle as intermediate (C) 873
Ruthenium(III) halides, Topotactic redox and exchange reactions of ruthenium(III) halides (C) 555

SANDWICH COMPLEXES, $\mu_2$-($\eta^5$:$\eta^5$-Cyclooctatetraene)-bis($\eta^5$-cyclopentadienylchromium): a "siamese twin" of two half-open sandwich moieties (C) 330
Scrambling, C-Scrambling in the *tert*-butyl cation (C) 50
Secododecahedrene, Cautionary example of incorrect structural assignment due to crystallographic disorder (C) 251
Secoiridoid glycosides, Secologanin, a biogenetic key compound—synthesis and biogenesis of the iridoid and secoiridoid glycosides (R) 828
Secologanin, a biogenetic key compound—synthesis and biogenesis of the iridoid and secoiridoid glycosides (R) 828
Selectivity, Organometallic compounds of titanium and zirconium as selective nucleophilic reagents in organic synthesis (R) 31
Selenoformaldehyde bridge, Seleno- and telluroformaldehyde as bridging ligands in organometallic complexes (C) 314
Selenoformaldehyde ligand, Synthesis of [($\eta^5$-$C_5H_5$)Rh($PMe_3$)($\eta^2$-$CH_2$E)] with E=S, Se, Te: thio-, seleno-, and telluroformaldehyde as ligands in mononuclear rhodium complexes (C) 316
Selenoketene, Synthesis and structure of [($\eta^5$-$C_5H_5$)Rh$P(i$Pr$)_3$($\eta^2$-EC=$CH_2$)] with E=S, Se, Te: generation and stabilization of thioketene, selenoketene, and telluroketene at a transition metal (C) 981
Selenolate/diselenide pair, Oxidative coupling of the selenolate functions in ($C_6H_5$)$_3$PC(Se)P($C_6H_5$)$_3$: crystal structure of {[($C_6H_5$)$_3$P]$_2$CSe}$_2^{2\oplus}$$Fe_2OCl_6^{2\ominus}$·4$CH_2Cl_2$ containing a linear Fe—O—Fe axis (C) 156
$^1$H,$^{13}$C Shift correlation, 2D-NMR spectroscopy in annulene chemistry: complete assignment of the $^{13}$C-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene by $^1$H,$^{13}$C shift correlation (C) 499
Silaethene, A new stable silaethene (C) 1005
Silaphosphane, ($t$BuP)$_8$$Si_2$—a novel dispirocyclic silaphosphane (C) 775
Silicon-lead bonding, Tetrakis(trimethylsilyl)plumbane, the first organosilicon-lead compound (C) 557
Silver clusters, Fourier transform far-infrared spectroscopy of silver atoms and silver clusters entrapped in zeolite NaY (C) 791
Single electron transfer, Radical products in single electron transfer reactions of lithium triethylhydridoborate detected by ESR and multinuclear ($^1$H, $^{10}$B, $^{11}$B, $^{14}$N)-ENDOR spectroscopy (C) 892
Singlet oxygen, Cercosporin, a singlet oxygen generator (C) 720
[4+2]-Cycloaddition of singlet oxygen to 2,5-dimethylfuran: isolation and reactions of the monomeric and dimeric endoperoxides (C) 726
Efficiency of the physical quenching of singlet oxygen with benzoquinone derivatives (C) 792
$S_N2'$ Reaction, On the stereochemistry of the $S_N2'$ reaction (C) 613
Sodium hydride, Complex reducing agents (CRA's)—versatile, novel ways of using sodium hydride in organic synthesis (R) 599
Solids, Probing the environment of Al atoms in noncrystalline solids: $Al_2O_3$—$SiO_2$ gels, soda glass, and mullite precursors (C) 614
Solid-state chemistry, Preparation of solid-state compounds by chemical transport—interpretation and control using the cooperative transport model (R) 82
Thio- and seleno-compounds of main group elements—novel inorganic oligomers and polymers (R) 113
Topotactic redox and exchange reactions of ruthenium(III) halides (C) 555
Novel surface-modified solids by topochemical oxidation of Zintl anions (C) 558
Solid-state NMR spectroscopy, Magic-angle-spinning NMR (MAS-NMR) spectroscopy and the structure of zeolites (R) 259
Solutions, Properties of liquids and solutions (B) 256
Spermidines, Synthesis of acylpolyamines: acetylspermidines and $C_{12:0}$-acarnidine (C) 618
Spirocyclization, Novel catalytic application of a transition-metal cluster: spirocyclization of alkyl isocyanates (C) 880
Spirorenone, A novel synthetic route to the aldosterone-antagonist spirorenone (C) 406
Spirosilicate, Strong distortion of the tetrahedral geometry in a spirosilicate: molecular structure of bis(tetramethylethylenedioxy)silane (C) 65
The crystal and molecular structure of bis(1,8-naphthalenedioxy)silane—a contribution to the controversy over planar, four-coordinated silicon in orthosilicic acid esters (C) 501
Stereochemistry, On the stereochemistry of the $S_N2'$ reaction (C) 613
Stereocontrolled synthesis, A new, efficient and stereocontrolled synthesis of trisubstituted alkenes *via* functionalized acrylic esters (C) 796
Stereoselective aldol reaction with (*R*)-*N*-acetyl-α-phenylglycinol (C) 788
Stereoselective reactions, Chelation or nonchelation control in stereoselective reactions of titanium reagents with chiral alkoxycarbonyl compounds (C) 989
Stereoselective synthesis of enantiomerically pure natural products—estrone as example (R) 637
Stereoselective synthesis of iridoid glycosides (C) 888
Stereospecific alkylation, Stereospecific reactions of chiral chlororuthenium(II) complexes with Grignard reagents (C) 333
Stibanes, Transition-metal substituted stibanes as acceptors: Cp(CO)(L)-Fe—$SbBr_2$·$PMe_3$ (L=CO, $Me_3P$, MeNC)—1:1-ferriostibane-trimethylphosphane complexes (C) 60
Structure analysis, Electron diffraction with the transmission electron microscope as a phase-determining diffractometer—from spatial frequency filtering to the three-dimensional structure analysis of ribosomes (R) 456
Cautionary example of incorrect structural assignment due to crystallographic disorder (C) 251
of a $CaF_2$ single crystal with an edge length of only 6 μm: an experiment using synchrotron radiation (C) 1011
Substituent effects, Some substituent effects in the photocycloaddition of dihalomaleiimides to uracils (C) 161
Sugar chemistry, Advanced sugar chemistry. Principles of sugar stereochemistry (B) 803
Sulfur bridges, [$Mo_2(NO)_2(S_2)_3(S_5)OH]^{3-}$, a complex containing a bidentate $S_5^{2-}$-bridging ligand in a {$S_5Mo_2(S_2)$}-heterocycle with cyclooctasulfur geometry (C) 884
Sulfur coordination, [$Ph_4P]_2$[$V_2(SC_2H_4S)_4$]·4MeOH: the first polynuclear vanadium-sulfur complex with pure sulfur coordination (C) 885
Sulfur double-ylide chromium complexes, Novel $\eta^3$,σ-sulfur double-ylide chromium complexes by *endo*-hydride addition to cationic ($\lambda^6$-thiabenzene 1-oxide)chromium complexes (C) 498
Sulfur ylides, Metal complexes of sulfur ylides: coordination chemistry, preparative organic chemistry, and biochemistry (R) 516
Surface modification, Novel surface-modified solids by topochemical oxidation of Zintl anions (C) 558
Surfactants with novel structural characteristics (C) 616
Symmetry breaking and non-Born-Oppenheimer effects in radical cations (R) 210
Symmetry operations, On the description of complex inorganic crystal structures (R) 69
Symproportionation, Formation of alkyl radicals by thermal bimolecular reaction of alkanes and alkenes (C) 889
Synchrotron radiation, Structure analysis of a $CaF_2$ single crystal with an edge length of only 6 μm: an experiment using synchrotron radiation (C) 1011
Synthetic methods, Organometallic compounds of titanium and zirconium as selective nucleophilic reagents in organic synthesis (R) 31
Homolytic cyclizations of *N*-chloroalkenylamines (R) 337
Complex reducing agents (CRA's)—versatile, novel ways of using sodium hydride in organic synthesis (R) 599

TACHYSTEROL$_3$ ROTAMER, Photochemistry of previtamin $D_3$ at 92 K: formation of an unstable tachysterol$_3$ rotamer (C) 718
Taxane, The tricyclo[9.3.1.0$^{3,8}$]pentadecane system—a short synthesis of a C-aromatic taxane skeleton (C) 419
Tellurium compounds, Tellurium as six-electron donor—synthesis and structure of $\mu_3$-Te[Mn(CO)$_2$($\eta^5$-$C_5H_5$)]$_3$ (C) 59
Tellurium heterocycles, Small heterocycles containing phosphorus and tellurium atoms (C) 983
Tellurium-nitrogen compounds, A new route to tellurium-nitrogen compounds (C) 789
Telluroformaldehyde bridge, Seleno- and telluroformaldehyde as bridging ligands in organometallic complexes (C) 314
Telluroformaldehyde ligand, Synthesis of [($\eta^5$-$C_5H_5$)Rh($PMe_3$)($\eta^2$-$CH_2$E)] with E=S, Se, Te: thio-, seleno-, and telluroformaldehyde as ligands in mononuclear rhodium complexes (C) 316
Telluroketene, Synthesis and structure of [($\eta^5$-$C_5H_5$)Rh$P(i$Pr$)_3$($\eta^2$-EC=$CH_2$)] with E=S, Se, Te: generation and stabilization of thioketene, selenoketene, and telluroketene at a transition metal (C) 981
Terphenylene, The structure and reactivity of 2,3,7,8-tetrakis(trimethylsilyl)terpheny-

lene, a novel linear multiphenylene (C) 994
Tetrabenzene, *p*-(*o*,*p*)-*o*-Tribenzene and *p*-(*o*,*p*)-(*o*,*o*)-*p*-tetrabenzene, Diels-Alder oligomers of benzene (C) 617
Tetrabenzoporphyrinatoiron(II), Preparation and properties of tetrabenzoporphyrinatoiron(II) and its isocyanide complexes (C) 724
Tetra-*tert*-butylcyclobutadiene, Three arguments supporting a rectangular structure for tetra-*tert*-butylcyclobutadiene (C) 402
Bonding electron density distribution in tetra-*tert*-butylcyclobutadiene—a molecule with an obviously non-square four-membered ring (C) 403
Tetra-*tert*-butyltetrahedrane: $^{13}C$-$^{13}C$ coupling constants and hybridization (C) 878
Tetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione, Through-bond interaction *via* strained σ-bonds—the synthesis and PE spectrum of 1,5-dimethyltetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione (C) 488
Tetracycloundecane, Synthesis and structure of a linearly *anti*-annelated tetracycloundecane. A potential precursor for a coriolin synthesis (C) 721
Tetraethoxyallene: Equivalent of the fictive malonic ester dianion—a versatile synthetic building block (C) 321
Tetrahedral geometry, Strong distortion of the tetrahedral geometry in a spirosilicate: molecular structure of bis(tetramethylethylenedioxy)silane (C) 65
The crystal and molecular structure of bis(1,8-naphthalenedioxy)silane—a contribution to the controversy over planar, four-coordinated silicon in orthosilicic acid esters (C) 501
Tetrahedral structure, Optically active iron complexes with tetrahedral structure (C) 164
GaGeTe, a novel defect tetrahedral structure (C) 407
Tetrahedrane, A diphosphene as tetrahedrane building block: synthesis of [Fe$_2$(CO)$_6$(P$_2$*t*Bu$_2$)] (C) 154
Tetra-*tert*-butyltetrahedrane: $^{13}C$-$^{13}C$ coupling constants and hybridization (C) 878
Tricyclo[2.1.0.0$^{2,5}$]pentan-3-one (C) 990
Tetrahydrofuran, Twist conformation of tetrahydrofuran in the crystal (C) 410
Tetraphenylcyclobutadiene radical cation, Generation of the tetraphenylcyclobutadiene radical cation by ionizing gas-phase decarbonylation (C) 51
Tetraphosphaspiro[2.2]pentane, (*t*BuP)$_2$C(*t*BuP)$_2$—the first tetraphosphaspiro[2.2]pentane (C) 632
Tetrasaccharide, Synthesis of a tetrasaccharide of the core region of *O*-glycoproteins (C) 776
Tetrasulfido-nickel(II) complex, [Ni(S$_4$)$_2$]$^{2\ominus}$, a homoleptic tetrasulfido-nickel(II) complex (C) 1006
Tetrazocines, 1,3,5,7-Tetrazocines (C) 543
Theoretical methods, Molecular mechanics calculations in organic chemistry: examples of the usefulness of a simple nonquantum mechanical model (R) 1
Thiabenzene 1-oxide, Novel η$^3$,σ-sulfur double-ylide chromium complexes by *endo*-hydride addition to cationic (λ$^6$-thiabenzene 1-oxide)chromium complexes (C) 498
Thiadiazole-3,5-dicarbonitrile, 1,2,4-Thiadiazole-3,5-dicarbonitrile by reaction of cyanogen with sulfur (C) 881
Thiadiphosphirane, The first X-ray structure analysis of a thiadiphosphirane (C) 418
Thiazylamide, Pentacarbonylrhenium complexes with thiazylamide ligands (C) 723
Thiazylfluoride complexes, Synthesis of the thionitrosylrhenium dication [Re(CO)$_5$(NS)]$^{2+}$; reactions and structure of the thiazylfluoride complex [Re(CO)$_5$(NSF)]$^+$ (C) 162
Thietones, oxetones, and azetones (C) 543
Thin-layer chromatography, A quarter century of thin-layer chromatography—an interim report (R) 507
Thiocarbonyl compounds, A novel route to thiocarbonyl compounds (C) 55
Thioformaldehyde bridge, A binuclear complex with a thioformaldehyde bridge (C) 315
Thioformaldehyde ligand, Synthesis of [(η$^5$-C$_5$H$_5$)Rh(PMe$_3$)(η$^2$-CH$_2$E)] with E = S, Se, Te: thio-, seleno-, and telluroformaldehyde as ligands in mononuclear rhodium complexes (C) 316
Thioketene, Synthesis and structure of [(η$^5$-C$_5$H$_5$)RhP(*i*Pr)$_3$(η$^2$-EC=CH$_2$)] with E = S, Se, Te: generation and stabilization of thioketene, selenoketene, and telluroketene at a transition metal (C) 981
Thioketene-iron cluster, Reversible opening of a thioketene-iron cluster containing a μ$_2$-*C*$_2$,μ$_2$-*S*-thiocarbonyl group (C) 153
Thionitrosylrhenium dication, Synthesis of the thionitrosylrhenium dication [Re(CO)$_5$(NS)]$^{2+}$; reactions and structure of the thiazylfluoride complex [Re(CO)$_5$(NSF)]$^+$ (C) 162
Three-dimensional structure analysis, Electron diffraction with the transmission electron microscope as a phase-determining diffractometer—from spatial frequency filtering to the three-dimensional structure analysis of ribosomes (R) 456
Thromboxanes, From studies of biochemical mechanism to novel biological mediators: prostaglandin endoperoxides, thromboxanes, and leukotrienes (Nobel lecture) (R) 805
Through-bond interaction *via* strained σ-bonds—the synthesis and PE spectrum of 1,5-dimethyltetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione (C) 488
Thymine, Photocycloaddition of 6-oxopurines and thymine to products with cyclobutane part structures (C) 623
Tin-boron exchange, Exchange of the apical tin atom in the *nido*-cluster (CH$_3$)$_5$C$_5$Sn$^+$ (C) 56
Titanium compounds, Organometallic compounds of titanium and zirconium as selective nucleophilic reagents in organic synthesis (R) 31
Regio- and diastereoselective synthesis of (4-hydroxy-3-methyl-1,2-alkadienyl)carbamates from α-titanated 2-butynylcarbamates and aldehydes (C) 54
Titanium reagents, Chelation or non-chelation control in stereoselective reactions of titanium reagents with chiral alkoxycarbonyl compounds (C) 989
Tobacco mosaic virus, From macromolecules to biological assemblies (Nobel lecture) (R) 565
Topochemical oxidation, Novel surface-modified solids by topochemical oxidation of Zintl anions (C) 558
Topotactic reactions, Topotactic redox and exchange reactions of ruthenium(III) halides (C) 555
Trace analysis, Organic trace analysis by liquid chromatography (B) 66
Transition-metal cluster, Novel catalytic application of a transition-metal cluster: Spirocyclization of alkyl isocyanates (C) 880
Transition metals, Phosphorus ylides in the coordination sphere of transition metals. An inventory (R) 907
Transmission electron microscope, Electron diffraction with the transmission electron microscope as a phase-determining diffractometer—from spatial frequency filtering to the three-dimensional structure analysis of ribosomes (R) 456
Transport model, Preparation of solid-state compounds by chemical transport—interpretation and control using the cooperative transport model (R) 82
Tribenzene, *p*-(*o*,*p*)-*o*-Tribenzene and *p*-(*o*,*p*)-(*o*,*o*)-*p*-tetrabenzene, Diels-Alder oligomers of benzene (C) 617
Trichromium, FT-FIR spectroscopy of ligand-free metal clusters; matrix effects on the molecular geometry of trichromium, Cr$_3$ (C) 166
Tricyclo[5.2.1.0$^{2,6}$]deca-4,8-dien-3,10-diyl, The *endo*-3,10-dimethyltricyclo[5.2.1.0$^{2,6}$]-deca-4,8-dien-3,10-diyl dication, a novel bishomoaromatic/allylic dication and its rearrangement to the symmetrical *cis-anti-cis*-3,10-dimethyltricyclo[5.3.0.0$^{2,6}$]deca-4,8-dien-3,10-diyl dication (C) 712
Tricyclo[6.2.0.0$^{3,6}$]decane, Crystal structure of 2,4,5,7,9,10-hexaoxa-1,3,6,8-tetraphenyltricyclo[6.2.0.0$^{3,6}$]decane: an authentic bisdioxetane (C) 546
Tricyclo[4.1.0.0$^{1,3}$]hept-4-enes, Thermolysis and reaction of 4,5-Benzotricyclo-[4.1.0.0$^{1,3}$]hept-4-ene and *o*-(Propadienyl)-styrene (C) 868
as intermediates (C) 869
Tricyclo[3.1.0.0$^{2,6}$]hexanes, 3,4-Bismethylenetricyclo[3.1.0.0$^{2,6}$]hexane—synthesis and Diels-Alder addition to tetracyanoethylene (C) 871
Tricyclo[9.3.1.0$^{3,8}$]pentadecane, The tricyclo[9.3.1.0$^{3,8}$]pentadecane system—a short synthesis of a C-aromatic taxane skeleton (C) 419
Tricyclo[2.1.0.0$^{2,5}$]pentan-3-one (C) 990
Trimethinecyanines, First proof of di-, tri-, and all-*cis*-conformations in sterically hindered trimethinecyanines (carbocyanines) of the indoline and benzothiazole series (C) 876
Trioxatris-*o*-homobenzenes, Valence isomerization of phane-bridged *cis*-trioxatris-*o*-homobenzenes (C) 867
Triphosphetidines, Azatriphosphetidines as cyclotrimers of an iminophosphane—synthesis and crystal structure (C) 552
Tris(diphenylthiophosphinoyl)methanide, The structure of tris(diphenylthiophosphinoyl)methanide, a mesomerically stabilized carbanion (C) 254
Tungsten complexes, The transformation of acetylene from a four- to a two-electron ligand: acetylene(carbonyl)nitrosyl complexes of tungsten (C) 1008
Alkyne complexes of tungsten(IV) (C) 1010
Turgorins, hormones of the endogeneous daily rhythms of higher organized plants—detection, isolation, structure, synthesis, and activity (R) 695
Twist conformation of tetrahydrofuran in the crystal (C) 410

ULLMANNS Encyklopädie der technischen Chemie (B) 564
Uracil, Some substituent effects in the photocycloaddition of dihalomaleiimides to uracils (C) 161
Photocycloaddition of 6-cyanouracil to ketene diethyl acetal: synthesis of a uracil derivative possessing a cyclobutenone framework (C) 629
Uranyl ions, Highly selective extraction of uranyl ions by acyclic ligands containing L-phenylalanine moieties (C) 563

VALENCE ISOMERIZATION, Can radicals participate in pericyclic reactions? Model reactions for electron-transfer induced valence isomerization of 1-arylindenes (C) 254
Vanadium compounds, Redox intercalation reactions of VOPO$_4$·2H$_2$O (C) 412
μ$_2$-E[V(CO)$_3$diphos]$_2$ (E = S, Se, Te): complexes with linear VEV multiple-bond systems (C) 980
Vanadium-sulfur complex, [Ph$_4$P]$_2$[V$_2$(SC$_2$H$_4$S)$_4$]·4MeOH: the first polynuclear vanadium-sulfur complex with pure sulfur coordination (C) 885

Verdazyl, 1,5-Dimethylverdazyls, hydrazidinyl radicals with pyramidal 1,5-nitrogen atoms (C) 320
Vinyl alcohol, (*Z*)-2-Methoxy-1,2-diphenylvinyl alcohol, a remarkably stable enol (C) 405
Vinylidene ligand, Synthesis of $[C_5H_5Rh(PhC{=}CH)P(iPr)_3]$ and $[C_5H_5Rh(=C{=}CHPh)P(iPr)_3]$: mechanism of the conversion of an alkyne ligand into a vinylidene ligand (C) 414
Vinylimidazoles, A simple route to 2-vinylimidazoles (C) 560
Vitamin $B_{12}$, 5,15-Bisnorcobester: an unexpected mode of formation (C) 736
A simple route to 5-nor-, 15-nor-, and 5,15-bisnorcobesters (C) 737
Vitamin E, A carbene-complex route to vitamin E (C) 732

WITTIG REACTION, Some cautions in the interpretation of oxidoylide reactions based on $^{31}$P-NMR data (C) 56
Organometallic variants of the Wittig reaction: synthesis and structure of *trans*-μ-(2-5; 8-11-η-dodecapentaene)bis(tricarbonyliron) (C) 713
World energy supply: resources, technologies, perspectives (B) 634

YEASTS, NMR Studies of yeasts grown on substrates at "zero" level radioactivity (C) 49
Electromicrobial reduction using yeasts (C) 322
Preparation of ethyl (*R*)-(−)-3-hydroxy-2-methylpropanoate by yeast reduction of ethyl α-formylpropanoate (C) 1012
Ylide complexes, Novel $\eta^3,\sigma$-sulfur double-ylide chromium complexes by *endo*-hydride addition to cationic ($\lambda^6$-thiabenzene 1-oxide)chromium complexes (C) 498
Ylide diketone-rearrangement, Dephosphorylating "ylide diketone"-rearrangement of the arylcarbonyloxyalkylidenephosphoranes (C) 619
Ylides, Metal complexes of sulfur ylides: coordination chemistry, preparative organic chemistry, and biochemistry (R) 516
Phosphorus ylides in the coordination sphere of transition metals. An inventory (R) 907

ZEOLITES, Magic-angle-spinning NMR (MAS-NMR) spectroscopy and the structure of zeolites (R) 259
Solution-phase metal atom preparation of catalytically active zeolite-encapsulated metal clusters; characterization and application to the selective reduction of CO to butene (C) 624
Fourier transform far-infrared spectroscopy of silver atoms and silver clusters entrapped in zeolite NaY (C) 791
Zinc cluster, $(C_5H_5)_6Ni_2Zn_4$—the first zinc-containing mixed-metal cluster (C) 329
Zintl anions, Novel surface-modified solids by topochemical oxidation of Zintl anions (C) 558
Zintl compounds, $Rb_7NaGe_8$ and $K_7NaGe_8$, Zintl compounds with $Na(Ge_4)_2$ units (C) 998
Zirconium compounds, Organometallic compounds of titanium and zirconium as selective nucleophilic reagents in organic synthesis (R) 31
Zircona- and hafnacyclobutenes—a new route to metallacyclobutanes (C) 248
Zirconocene, The zirconocene-induced coupling of butadiene with carbonyl compounds (C) 494
Reversal of the regioselectivity in the zirconocene-induced coupling of a ketone with isoprene (C) 777
