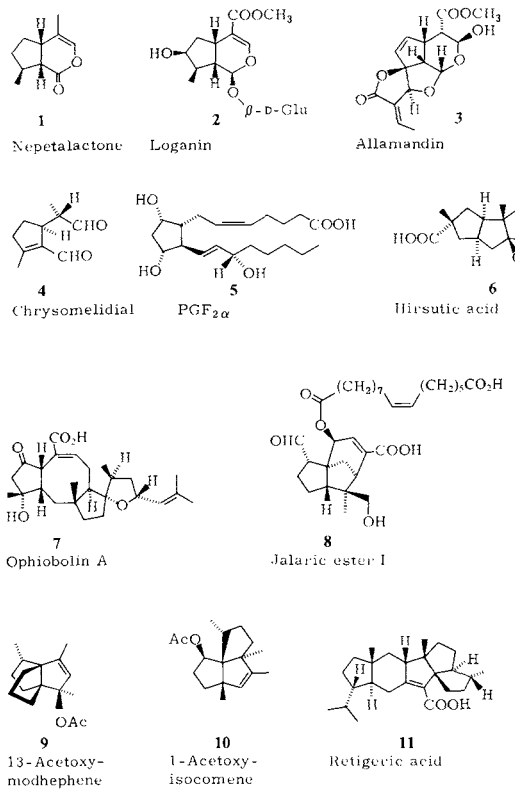
[3+2] Cycloaddition Approaches to Five-Membered Rings via Trimethylenemethane and Its Equivalents

New Synthetic Methods (55)

By Barry M. Trost*

The power of cycloadditions for ring formation derives from the potential for chemo-, regio-, diastereo-, and enantioselectivity. Trimethylenemethane (TMM) and its equivalents offer the possibility of extending such benefits to the synthesis of five-membered rings. Three types of conjunctive reagents appear to be promising candidates: 1) selected 4-alkylidene-4,5-dihydro-3*H*-pyrazoles, 2) 2-[(trimethylsilyl)methyl]allyl esters and halides, and 3) alkylidenecyclopropanes. Thermal reactions, especially intramolecular ones, effect the cycloaddition of the pyrazoles to olefins—especially electron-poor olefins. The latter two precursors require a catalyst, notably a palladium complex, to unlock the synthetic potential. With the 2-[(trimethylsilyl)methyl]allyl esters, a general chemo-, regio-, and diastereoselective cycloaddition with typical Diels-Alder dienophiles forms methylenecyclopentanes in both inter- and intramolecular fashion. A tin analogue allows extension of this cycloaddition to aldehydes, and, in a related sequence, to ketones and imines to form 3-methylenetetrahydrofurans and 3-methylenepyrrolidines with excellent diastereoselectivity. The 2-[(trimethylsilyl)methyl]allyl esters also serve to effect net methylenecyclopentane annulation to cyclic enols. Such adducts can further undergo three-carbon intercalation or combined ring contraction-spiroannulation simply by the use of either a nucleophilic or electrophilic trigger. Alkylidenecyclopropanes undergo cycloadditions to both electron-rich and electron-poor olefins when stimulated by metal catalysts, especially palladium. A complementary regiochemistry to the approach based upon silicon conjunctive reagents is observed. The availability of these cycloadditions provides new strategies for the synthesis of natural products.

1. Introduction



Cyclopentanoids, also termed quinanes, constitute an exploding area of natural and non-natural products.[1] While the presence of a five-membered ring in the steroid nucleus generated some interest in methods for its synthesis, problems associated with stereocontrolled formation of such rings frequently turned the formation of the steroid D ring into a synthesis of a six-membered ring followed by ring contraction. The iridoids[2] represent an early recognized, important class of cyclopentanoid monoterpenes. They are exemplified in Table 1 by nepetalactone **1**,[3] the active principle of catnip, loganin **2**,[4] a key biosynthetic intermediate of alkaloids, and allamandin **3**,[5] an antibiotic and antitumor agent, as well as close relatives like chrysomelidial **4**,[6] a constituent of the defense secretion of the beetles *Gastrophysa cyanea* and *Plagiodera versicolora*. The emergence of such a ring system as a major structural feature in natural products came with the structure elucidation of the prostanoids, represented by $PGF_{2\alpha}$ **5**,[7]

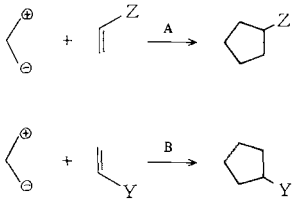
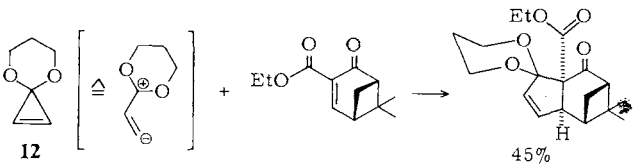
and of hirsutic acid C **6**,[8] a triquinane antibiotic whose unusual structure eluded assignment, owing in part to the occurrence of a rather unusual structural rearrangement in the X-ray diffractometer. A plethora of natural products, some bearing one or more five-membered rings as appendages as in ophiobolin A **7**,[9] some being derivatives of well-known substances such as jalaric ester I **8**,[10] a derivative of the cedrenes, and some being rather unusual structures such as 13-acetoxymodhephene **9**,[11] 1-acetoxyisocomene **10**,[12] and retigeranic acid **11**,[13] have recently been isolated and identified (Table 1).

Table 1. Representative cyclopentanoid (quinane) natural products.



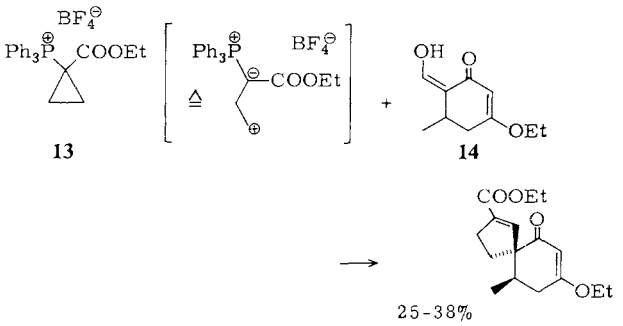
In addition to the natural products, some theoretically intriguing systems also are based upon five-membered rings. For example, the pentalenes are potentially antiaromatic molecules with interesting electronic properties. Dodecahedrane exemplifies a class of molecules whose unusual geometries are often reflected in interesting properties.

The ability to explore the cyclopentanoids ultimately depends upon their accessibility. In considering synthetic strategies, the concept of cycloaddition becomes very attractive. The chemo-, regio-, and diastereoselectivity associated with the Diels-Alder reaction has profoundly influenced the strategy for the synthesis of six-membered rings. The virtues of the Diels-Alder reaction encourage the manipulation of the adducts for formation of other rings.



To reap the benefits of cycloadditions, however, direct formation of five-membered rings would be more practical. Indeed, 1,3-dipolar cycloaddition is an established methodology for the formation of heterocycles, which, by further reactions, may be transformed into many other structural units.[14] Until recently, however, the use of cycloadditions to make five-membered carbocyclic rings was a missing link.

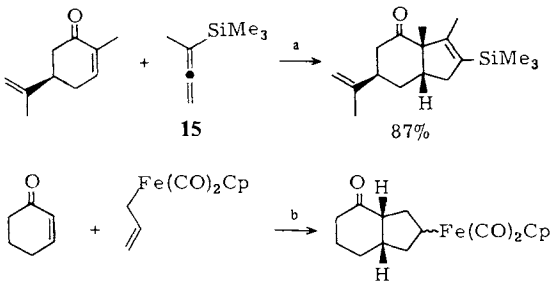
In close analogy to the Diels-Alder reactions, a [3+2] strategy (as depicted in Scheme 1) for formation of five-membered rings is conceivable.



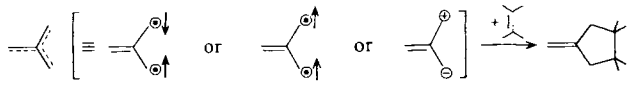
Scheme 1. Formation of cyclopentanes by 1,3-dipolar cycloaddition. Z = electron acceptor, Y = electron donor.

The use of polarized cyclopropanes as synthons for the 1,3-dipoles has brought some progress.[15] For example, cyclopropenone ketal **12** thermally adds to strongly electron-deficient double bonds (Scheme 2), an addition of type A according to Scheme 1.

Scheme 2. Reaction conditions: 75 °C, 13 h, C_6H_6, N_2.



On the other hand, the cyclopropylphosphonium salt **13** adds to enols such as the hydroxymethylene derivative **14** (Scheme 3). This reaction formally represents an addition of type B (Scheme 1) to an electron-rich double bond.[16]



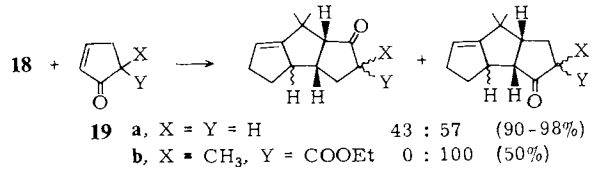
Scheme 3. Reaction conditions: RT, 1-2 d, NaH/hexamethylphosphoric triamide (HMPA).

Metals may play an important role in such reactions. In main-group chemistry, the addition of allenylsilanes (e.g., **15**) to enones, catalyzed by Lewis acids, represents a most unusual cyclopentene annulation (Scheme 4).[17] A transition-metal version using the iron compound **16** proceeds in moderate to low yields.[18] Both reactions exemplify reactions of type A (Scheme 1), where the acceptor is an electron-deficient olefin. All of these cases most likely involve stepwise processes.

An alternative approach makes use of the theoretically interesting trimethylenemethane **17** (Scheme 5).

Scheme 4. Reaction conditions: a) $TiCl_4$, −78°C, 1 h, CH_2Cl_2; b) $AlBr_3$, −78°C, 10 min, CH_2Cl_2, 0°C, 1 h. Cp = η^5-cyclopentadienyl.

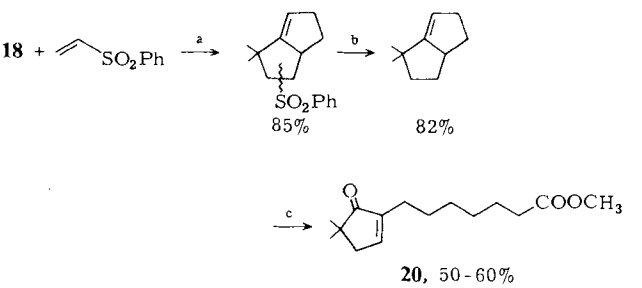
Scheme 5. The trimethylenemethane synthon (TMM) **17** and its [3+2] cycloaddition to olefins.



The products from such a cycloaddition also possess a quite useful functionality for further structural elaboration. Attempts to exploit such a route synthetically in the parent system have been frustrated by the lack of suitable methods to generate this reactive intermediate and/or its uncontrolled reactivity.[19] Taming the behavior of trimethylenemethane by forming its iron tricarbonyl complex went overboard in the opposite direction.[20,21] This species is almost devoid of reactivity. The attractiveness of this route continues, however, to lead to studies aimed at defining synthetically viable approaches to the use of trimethylenemethane or its equivalents. This review summarizes these synthetic ventures.

2. Trimethylenemethanes (2-Methylene-1,3-propanediyls)

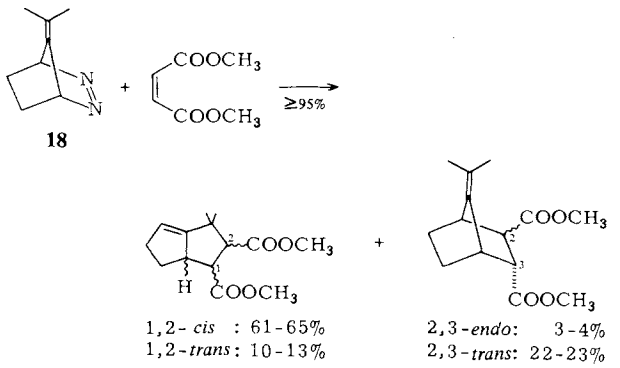
Whereas capture of trimethylenemethane itself by olefins proceeds in poor yields, the constrained analogue **18** leads to cycloaddition products in good yields (Scheme 6).[22]



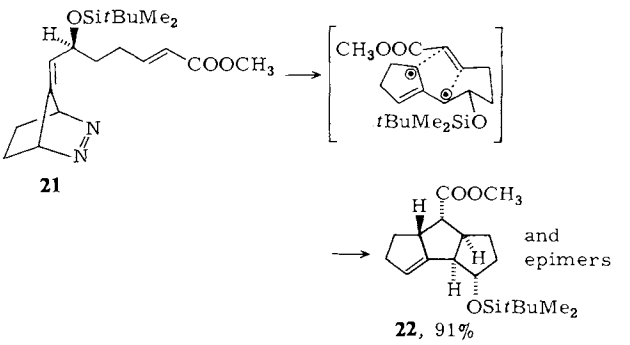
Reaction of **18** with dimethyl acetylenedicarboxylate produces the corresponding cycloadduct in 76% yield. These fused-ring products arise mainly from trapping of the singlet trimethylenemethane since a quite different spectrum of products arises from the triplet.

The diylophilicity of a series of olefins toward the singlet diradical derived from **18** roughly parallels their dienophilicity.[23] It is noteworthy that cyclopentenones **19a** and **19b** react well,[24] even though such acceptors are normally poor dienophiles. Whereas **19a** reacts with poor regioselectivity, the substituted acceptor **19b** reacts with excellent regioselectivity although the yield is lower. Steric factors may account for this selectivity (Scheme 7).

Scheme 7. Reaction conditions: 65–70°C, 1 h.



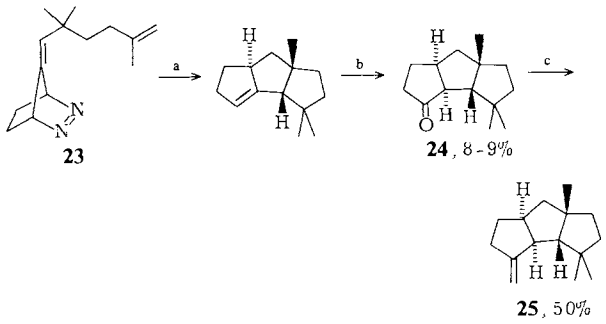
The first step in a synthesis of the dimethylprostaglandin precursor **20** is the intermolecular trapping of **18** with phenyl vinyl sulfone (Scheme 8).[25] Regio- and diastereoselectivity problems, however, limit the usefulness of this intermolecular reaction.



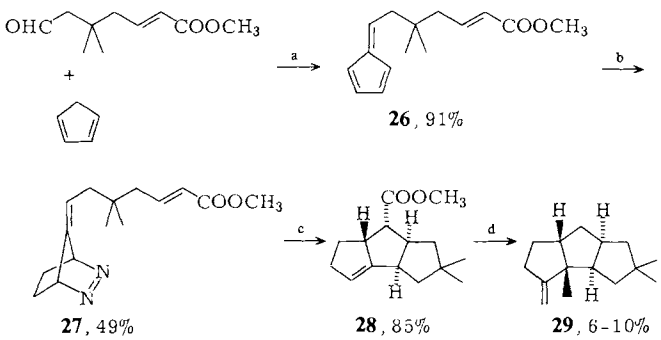
Scheme 8. Reaction conditions: a) Δ, CH_3CN; b) 6% sodium amalgam, Na_2HPO_4, RT, 2.5 h, CH_3OH; c) roughly ten steps.

Intramolecular trapping of such species, on the other hand, proves very useful. For example, thermal (CH_3CN, reflux) or photochemical decomposition of the azo compound **21** leads preferentially (11 : 1 to 26 : 1) to the triquinane **22**,[26] presumably invoking the bias of the siloxy substituent for an equatorial-like orientation in the intermediate diyl (Scheme 9).

Acceptors without an electron-withdrawing group normally afford much lower yields. In a synthesis of (±)-

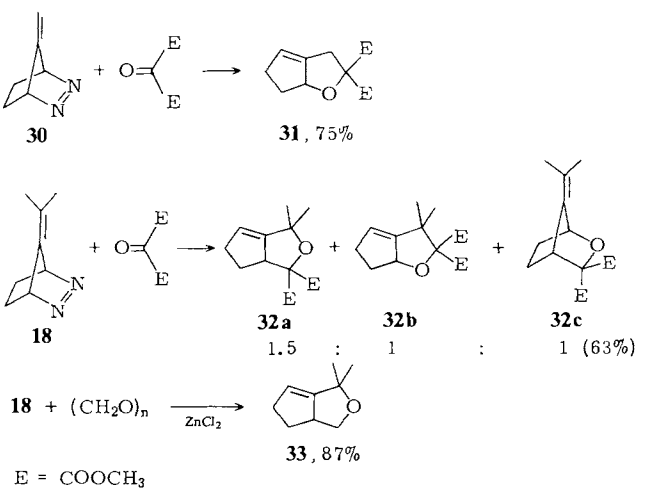


Scheme 6. Reaction conditions: 60°C, 2–8 h, CH_3CN.



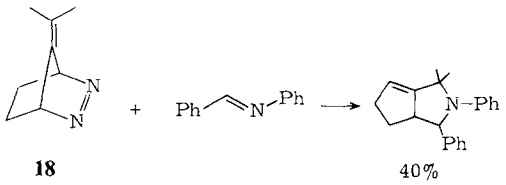
Scheme 9. Reaction conditions: Δ, 2.5 h, CH_3CN.

$\Delta^{9(12)}$-capnellene **25**, the ketone **24** is obtained in only 8–9% overall yield from the diyl precursor **23** (Scheme 10).[24b,27]



Scheme 10. Synthesis of (±)-$\Delta^{9(12)}$-capnellene **25**. Reaction conditions: a) Δ, 66 h, tetrahydrofuran (THF); b) 1. BH_3·THF, 2. $H_2O_2/OH^{\ominus}$, 3. pyridinium chlorochromate (PCC), diatomaceous earth, c) $Ph_3P{=}CH_2$.

A synthesis of (±)-hirsutene **29** is based upon this synthetic strategy.[28] The requisite diyl precursor **27** arises from the fulvene **26** by a straightforward series of three reactions (Scheme 11). The diyl is trapped by the acrylate group in excellent yield to give the triquinane skeleton **28**, which requires only minor structural adjustments to complete the synthesis.

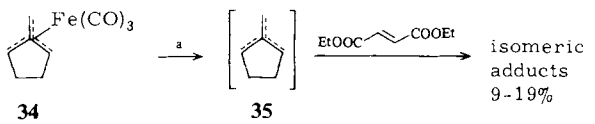


Scheme 11. Synthesis of (±)-hirsutene **29**. Reaction conditions: a) 5–10°C→RT, Et_2NH; b) 1. bis(2,2,2-trichloroethyl) diazodicarboxylate, 0°C; 2. potassium diazodicarboxylate/AcOH; 3. electrolytic deprotection, 4. $K_3Fe(CN)_6$, 0°C; c) Δ, 6 h, CH_3CN; d) eleven steps.

Scheme 12. Addition of 2-alkylidene-1,3-cyclopentanediyls to carbonyl groups.

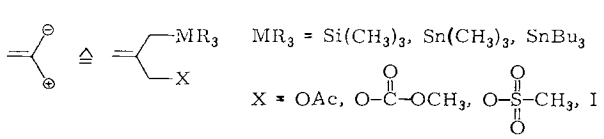
Multiple bonds involving heteroatoms can also be suitable diylophiles.[29] Reactive carbonyl groups such as that in dimethyl mesoxalate trap the diyl from either **18** or its unsubstituted analogue **30**. The formation of **31** from **30** is in agreement with frontier orbital considerations; however, steric effects apparently outweigh this electronic bias such that **32a** is predominantly formed from the precursor **18**. With a less reactive carbonyl partner, addition of a Lewis acid promotes cycloaddition; for example, in the presence of zinc dichloride, formaldehyde gives an excellent yield of **33**(Scheme 12).

Even an unsubstituted imine may serve as a diylophile, although the yield is only modest (Scheme 13).



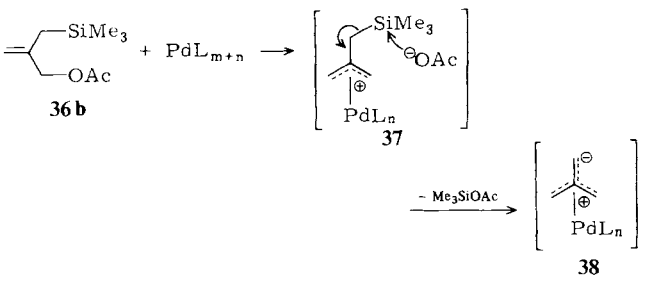
Scheme 13. Addition of a 2-alkylidene-1,3-cyclopentanediyl to benzylideneaniline.

The possible expansion of the use of selective trimethylenemethane (TMM) systems appears promising. The seed for adaptations of strategies based upon such species is planted in the form of intramolecular variants. The structural requirements for good yields of trapping products with high regio- and stereocontrol and the synthetic routes to appropriate precursors appear to be current limitations.[30]



3. Transition-Metal-Substituted Intermediates: Use of 1,3-Bifunctional Conjunctive Reagents

The excitement of isolating stable TMM–metal complexes subsequently vanished as a result of their poor reactivity in cycloadditions. For example, whereas generation of the diyl **35** from the azo precursor **30** led to excellent trapping yields, the liberation of **35** from **34** led to cycloaddition yields of only 9–19% (Scheme 14).[20]

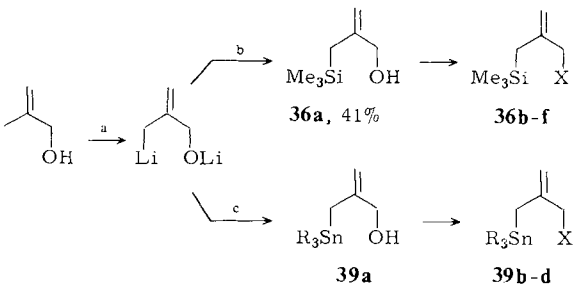


Scheme 14. Reaction conditions: a) $Me_3N^{\ominus}$–O°, 60°C, C_6H_6.

In considering a zwitterion equivalent of TMM, synthons for a carbanion and carbocation that do not self-annihilate are required. Silyl and stannyl groups serve as carbanion equivalents; carboxylate as well as more reactive leaving groups such as methanesulfonate and halide may serve as carbocation equivalents (Scheme 15).

Scheme 15. TMM equivalents.

The mutual compatibility of such synthons translates into a lack of reactivity and establishes the need for an activator. Palladium(0) complexes serve as such activators because they can readily effect the ionization of even poor leaving groups.[31] In the resulting π-allylpalladium intermediate **37**, the C-Si bond is weakened by the proximal positive charge, resulting in formation of the palladium complex of TMM **38** as a fleeting reactive intermediate.

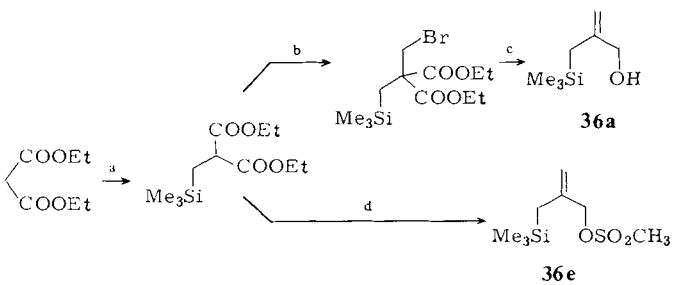


36b **37** **38**

Scheme 16. Activation of the TMM equivalent **36b** by complex formation with palladium(0).

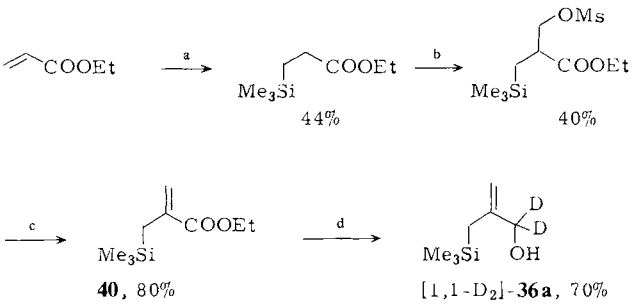
3.1. Preparation of Conjunctive Reagents

The synthesis of species such as those shown in Scheme 15 proceeds most directly by lithiation and subsequent silylation or stannylation of methallyl alcohol according to Scheme 17.[32]



36: **b**, X = OAc; **c**, X = $OCOOCH_3$; **d**, X = OCOPh; **e**, X = OSO_2CH_3; **f**, X = I

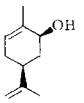
39: **b**, R = Me, X = OAc; **c**, R = Bu, X = OAc; **d**, R = Bu, X = OSO_2CH_3

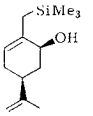


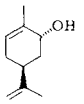
Scheme 17. Reaction conditions: a) 2 BuLi/tetramethylethylenediamine (TMEDA), 0°C, 4 h; RT, 40 h, hexane/Et_2O/THF; b) Me_3SiCl, $H_3O^{\oplus}$; c) R_3SnCl, $H_3O^{\oplus}$.

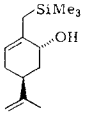
Alternatively, two routes from diethyl malonate using the expensive (chloromethyl)- or (iodomethyl)trimethylsilane also provide reagents of type **36** (Scheme 18).[33,34]

Scheme 18. Reaction conditions: a) 1. NaOEt/EtOH, Δ; 2. Me_3SiCH_2I or Me_3SiCH_2Cl, Δ; b) 1. NaH, C_6H_6; 2. CH_2Br_2, Δ; c) 1. KOH/H_2O, Δ, EtOH; 2. $LiAlH_4$; d) 1. NaH/$LiAlH_4$, Δ, THF; 2. CH_3SO_2Cl/collidine, 0°C, dimethylformamide (DMF).



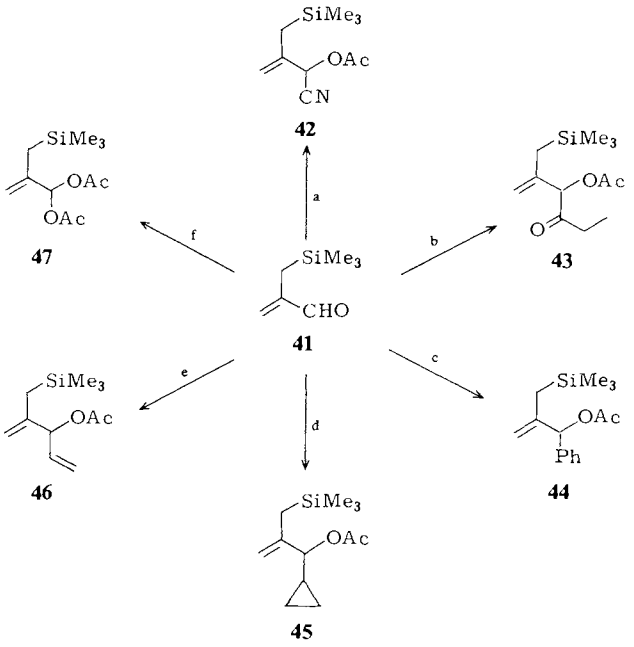






Ethyl acrylate also serves as a readily available starting material in a route where the silicon source is again the inexpensive chlorotrimethylsilane. Scheme 19 outlines this route to a 1,1-dideutero analogue of **36a**, although it can also be used to prepare **36a** itself.[35]

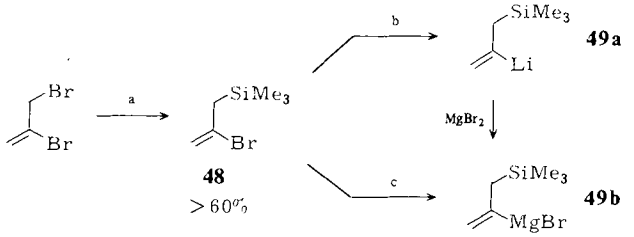
Scheme 19. Reaction conditions: a) Me_3SiCl/Li; b) 1. $LiN(iPr)_2$, THF; 2. $(CH_2O)_n$, 3. CH_3SO_2Cl/Et_3N; c) 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), RT, Et_2O; d) $LiAlD_4$, −25°C, Et_2O.



The direct metalation approach (cf. Scheme 17) serves as a general route from readily available alcohols. As shown in Table 2, a number of alcohols can be silylated at the methyl group under these conditions. Although this direct approach is very effective, the presence of functionality is limited by the use of *n*-butyllithium.

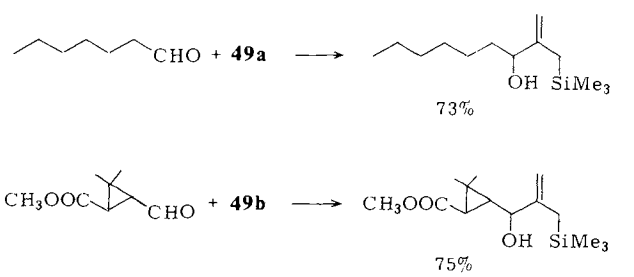
Table 2. *C*-Silylation of dilithiated methallyl alcohols.

No.	Alcohol	Silylated product	Yield [%]	Ref.
1			67	[36]
2			75	[37]
3			37	[38]
4			>51	[39]
5			98	[39]



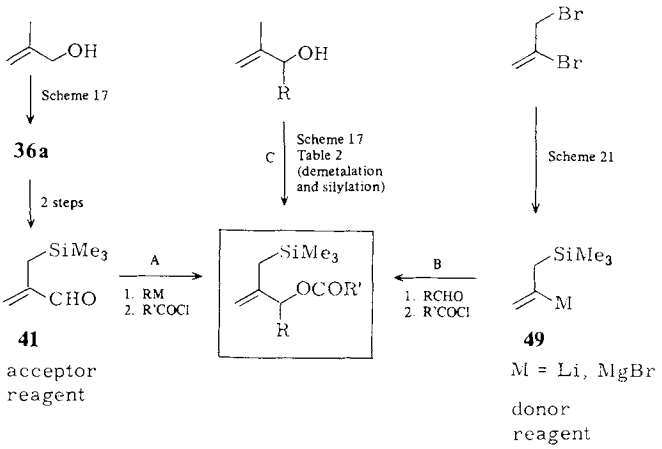
The ready availability of the aldehyde **41** by Swern oxidation (dimethylsulfoxide (DMSO)/oxalyl chloride) of the alcohol **36a** opens a very general approach to substituted TMM precursors (**42**–**47**) as illustrated in Scheme 20.[38,40] The acceptor conjunctive reagent **41** opens the entire arena of organometallics as possible reaction partners.

A donor conjunctive reagent permits the expansion of the reaction partners to carbonyl compounds. The isopropenyl bromide **48**,[41] easily derived from commercially available 2,3-dibromopropene, undergoes smooth halogen-



Scheme 20. Preparation of substituted 1,3-bifunctional conjunctive reagents from the aldehyde **41**. a) 1. Me_3SiCN, ZnI_2, neat, 83%; 2. Ac_2O, 9 mol-% $FeCl_3$, neat, 0°C, 81%. b) 1. $EtCH(SCH_3)_2/nBuLi$, THF, −78→0°C, 65%; 2. Ac_2O/pyridine, 4-dimethylaminopyridine (DMAP), RT, 95%; 3. $AgNO_3$, 95% $EtOH/H_2O$, 50°C, 83%. c) 1. PhLi, Et_2O, −78→20°C, 82%; 2. AcCl/pyridine, DMAP, CH_2Cl_2, 90%. d) 1. (*cyclo*-C_3H_5)MgBr, THF, 89%; 2. AcCl/pyridine, DMAP, CH_2Cl_2, 72%. e) 1. $LiCHCH_2$, Et_2O, −60→20°C; 2. AcCl, DMAP, CH_2Cl_2, 73% overall. f) Ac_2O, 5 mol-% $FeCl_3$, neat, 0°C, 71%.

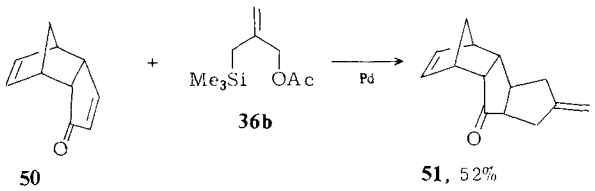
metal exchange with *tert*-butyllithium to give **49a**. Addition of anhydrous magnesium bromide produces the Grignard reagent **49b** (Scheme 21).



Scheme 21. Reaction conditions: a) (2 Me_3SiLi + 3 CuCN), 0°C, THF/HMPA or 1. $HSiCl_3/Et_3N$, CuCl, 2. 3 CH_3MgBr, Et_2O; b) *t*BuLi, −78°C, Et_2O; c) Mg turnings.

The vinyllithium reagent **49a** adds easily to aldehydes or ketones, e.g. to heptanal (Scheme 22).[38] The Grignard reagent **49b** shows good chemoselectivity in its additions to aldehydes and ketones (Scheme 22).[42]

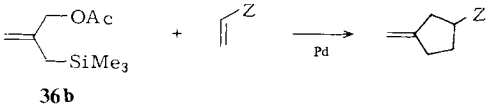
Scheme 22. Examples of the use of **49a** and **49b**.



A number of approaches exist to create the 1,3-bifunctional units required for cycloaddition. These are summarized in Scheme 23. Besides the direct metalation (pathway C), the most useful general approaches involve the employment of 2-[(trimethylsilyl)methyl]propenal **41** (pathway A) or of 1-[(trimethylsilyl)methyl]ethenyllithium **49a** or 1-[(trimethylsilyl)methyl]ethenylmagnesium bromide **49b** (pathway B).

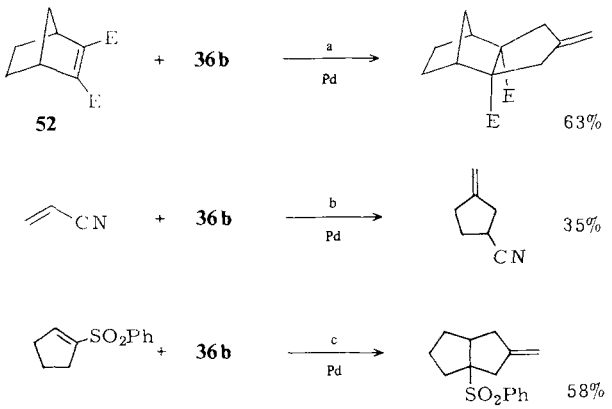
Scheme 23. Main synthetic pathways (A, B, and C) to 1,3-bifunctional conjunctive reagents of type **42**–**47**.

3.2. Cycloadditions with the Unsubstituted TMM System



The lack of any information regarding the feasibility or type of reaction to be expected from a palladium complex of TMM led to the use of the bifunctional trapping agent **50**, which possesses both an electron-rich and an electron-poor olefinic bond. Heating a mixture of this dienone and the silyl-acetate **36b** in the presence of a catalytic amount of a palladium(0) complex leads to clean cycloaddition to the electron-deficient double bond to give adduct **51** (Scheme 24).[43] Products derived from attack at the electron-rich double bond are not observed.

Scheme 24. Reaction conditions: ≈5 mol-% $[(Ph_3P)_4Pd]$, ≈2.5 mol-% $Ph_2PCH_2CH_2PPh_2$ (DPPE), Δ, THF.

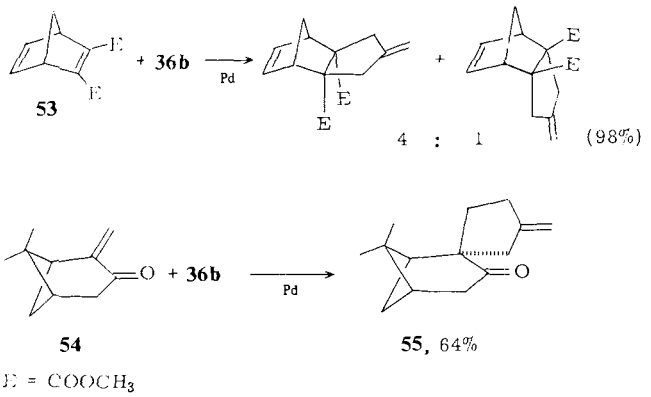


The reaction is generalized in Scheme 25. The acceptor requires an electron-withdrawing group—similarly to a dienophile in a Diels-Alder reaction.

Suitable activators on the olefinic bond that have been tested to date include an ester,[43] a cyano,[43,44] and a sul-

Scheme 25. Z = electron-withdrawing group.

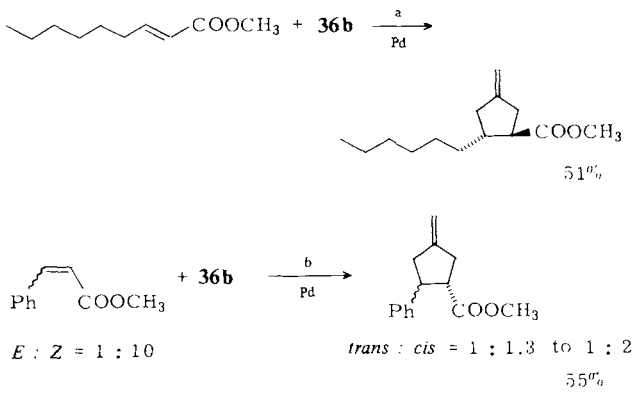
fone group (Scheme 26)[43,44] in addition to a ketone carbonyl group (Scheme 24). Any electron-withdrawing group that activates an olefin in terms of a Michael reaction should function similarly here. As in the case of the Diels-Alder reaction, the use of 2-cycloalkenones leads to poor yields. However, 2-cyclopentenones (e.g., **50** in Scheme 24) are an exception.



E = $COOCH_3$

Scheme 26. Reaction conditions: a) $(iPrO)_3P/Pd(OAc)_2$ (6 : 1), Δ, 3.5 h, THF; b) 6 mol-% $[(Ph_3P)_4Pd]$, 60 °C, 6 d, toluene; c) ≈5 mol-% $[(Ph_3P)_4Pd]$, ≈1.5 mol-% DPPE, Δ, 40 h, THF.

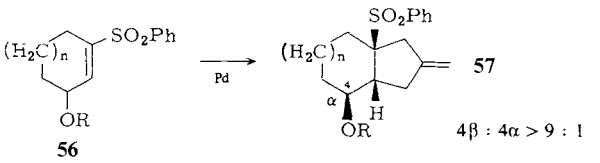
The choice of catalyst can substantially affect the yield of this process. An excellent catalyst arises by simply mixing palladium acetate with 6–8 molar equivalents of triisopropyl phosphite, the latter serving to both reduce the palladium(II) and ligate the formed palladium(0); the catalyst may be formulated as $[\{(iPrO)_3P\}_nPd]$ where n is probably 3 or 4.[39,45] This catalyst increases the yield of the cycloaddition of **36b** to the diester **53** from 78 to 98%[46] and promotes formation of the cycloadduct **55** in 64% yield from enone **54**[47] (Scheme 27). While the turnover numbers have not been determined, they are probably high. For a typical laboratory-scale reaction, 0.1–10 mol-% of catalyst, depending on the scale of the reaction (the larger the scale, the smaller the amount of catalyst), has been employed. For larger-scale reactions, even smaller amounts of catalyst will probably be satisfactory.



The tin analogues of **36b**, the esters **39b** and **39c**, also participate in these cycloadditions.[48,49] In contrast to the normal observation that the tin derivative improves the reaction, the higher reactivity of the C–Sn bond leads to lower yields due to decomposition of the conjunctive reagent **39** competing with the cycloaddition.

The stereoselectivity of the cycloaddition normally is very good. The geometry of (*E*)-olefins is retained in the product; however, that of (*Z*)-olefins is partly lost (Scheme 28).[43,44]

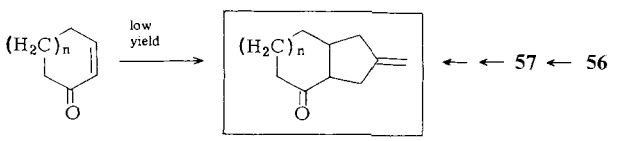
E = $COOCH_3$



Scheme 27. Catalyst: $[\{(iPrO)_3P\}_nPd]$.

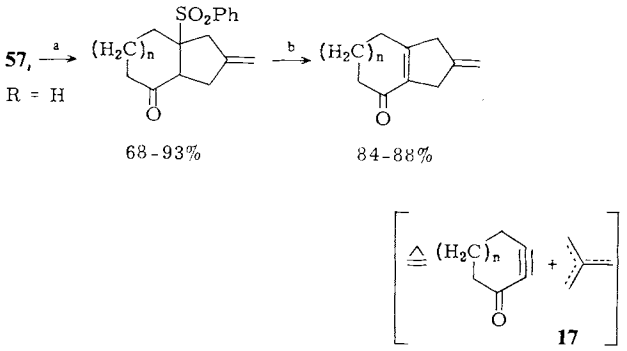
Scheme 28. Reaction conditions: a) $[(Ph_3P)_4Pd]$/DPPE, Δ, 12 h, THF; b) as in a), but only 3 h.

Diastereoselectivity also tends to be high. For example, acceptors **50** (Scheme 24), **52** (Scheme 26), and **54** (Scheme 27) form only one diastereomer, the TMM unit adding to the less-hindered face. Some loss of selectivity occurs in the case at the norbornadiene **53** (Scheme 27), which may arise from coordination of palladium to the second double bond, although simple steric arguments cannot be ruled out.[43,50]



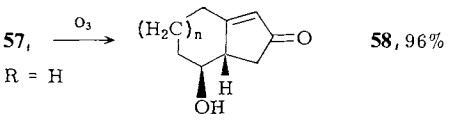
Diastereoselectivity with sulfone acceptors has particular importance because of the versatility offered by the adducts. Simple substituents bonded through oxygen effect good selectivity in both six- and seven-membered rings (Scheme 29).[51]

n = 1, R = $SitBuMe_2$: 87%
n = 2, R = CH_2OCH_3 : 93%



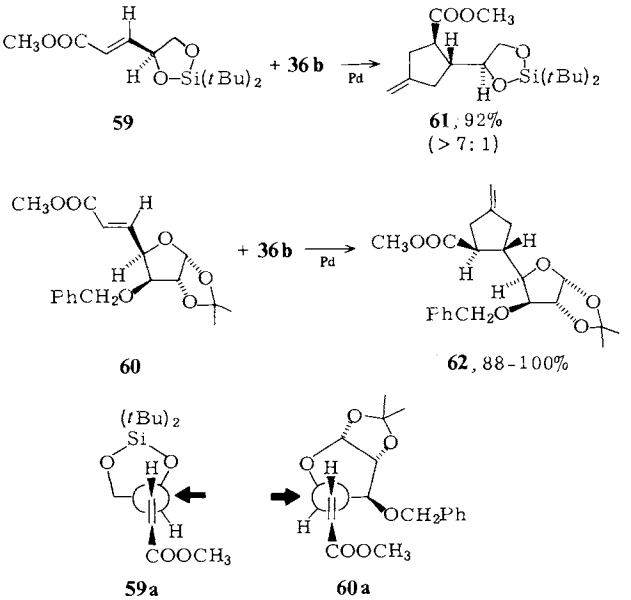
Scheme 29. Reaction conditions: $[\{(iPrO)_3P\}_nPd]$, toluene.

These adducts serve as the equivalents of stereocontrolled addition to 2-cyclohexenone and 2-cycloheptenone (two acceptors that react poorly or not at all) because of the ease of desulfonylation (Scheme 30).



Scheme 30. n = 1, 2.

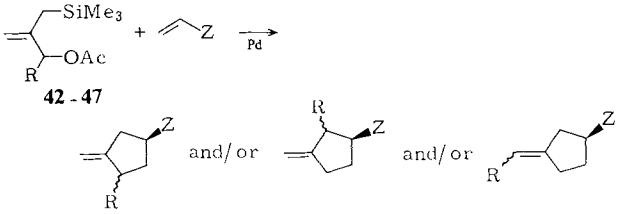
Alternatively, the leaving group ability of the sulfone transforms this reaction into an equivalent of addition to the hypothetical 2-cycloalkynones (Scheme 31).



Scheme 31. Reaction conditions: a) DMSO/$(COCl)_2$; b) Al_2O_3.

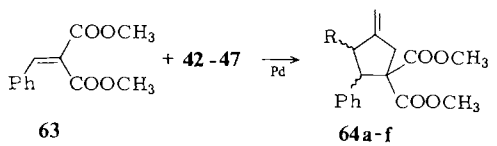
A most useful variant of this sequence arises by ozonolysis of these adducts to form the cyclopentenones **58** (Scheme 32), which corresponds to a useful cyclopentenone annulation.

Scheme 32. Cyclopentenone annulation.



Acyclic systems also show excellent diastereoselectivity. Reaction of the acrylate **59** occurs with >7:1 diastereoselectivity, and the more elaborate acrylate **60** gave only one detectable diastereomer (Scheme 33).[47] Minimization of dipole-dipole and steric interactions suggests conformers **59a** and **60a** should be favored. Independent verification of the stereochemistry in the case of **61** supports this contention.

Scheme 33. Catalyst: $[\{(iPrO)_3P\}_nPd]$.

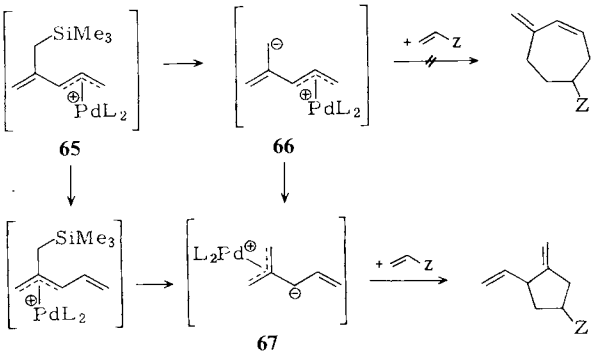


3.3. Cycloadditions with Substituted TMM Systems

The generality of this cycloaddition approach depends upon the range of donors (i.e., substituted TMM precursors) as well as acceptors. Questions of regiochemistry immediately arise since the symmetry of the parent system is destroyed. Combining the three possible regioisomers with the two diastereomers that are possible in each case leads to a total of six possible products (Scheme 34).

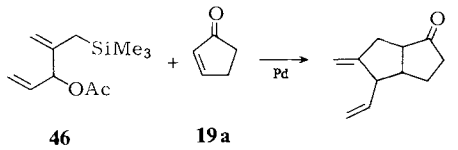
Scheme 34. Z = electron-withdrawing group.

Dimethyl benzylidenemalonate **63** serves as a standard acceptor to test the compatibility of various substituents as well as the regioselectivity of the reaction. Conjunctive reagents **42–47** all condense with this acceptor if $[(Ph_3P)_4Pd]$ or, more commonly, $[\{(iPrO)_3P\}_{3-4}Pd]$ is used as catalyst, preferably in hot dioxane (Scheme 35).[40] The compatibility of reactive functional groups, such as cyano, keto, and ester groups, and the lack of isomerization of the double bond into the thermodynamically more stable endocyclic conjugated position confirms the mildness of the reaction conditions. The case of the *gem*-diacetate precursor **47** is particularly striking since the product **64f**, an allylic acetate, is potentially very labile toward Pd^0 catalysts.



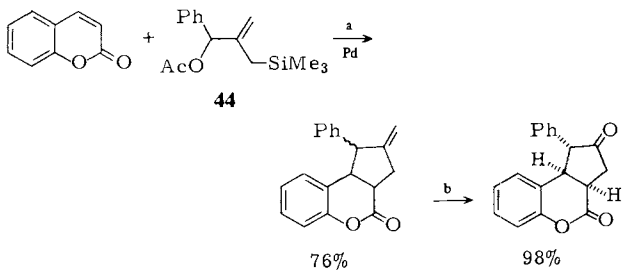
Scheme 35. Synthesis of **64a–f**.

Reagent	Product	R	Yield [%]	
42	**64a**	CN	54	*trans*
43	**64b**	COEt	59	*trans*
44	**64c**	Ph		*cis + trans*
45	**64d**	cyclopropyl	61	*cis + trans*
46	**64e**	$CH{=}CH_2$	89	*cis + trans*
47	**64f**	OAc	86	*cis + trans*



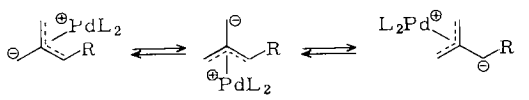
The surprising formation of only five-membered-ring products with the vinyl derivative **46** suggests that the kinetically favored π-allylpalladium cation **65**, which should produce seven-membered-ring products via the zwitterion **66**, is not a product-determining intermediate (Scheme 36).[38,40] Eventually, all intermediates funnel through **67**, which is presumably the product-determining intermediate.

As in the parent cases, the choice of catalyst can improve the reactions. The yield from the cycloaddition of **46** with 2-cyclopentenone **19a** increases from 50% to 60%



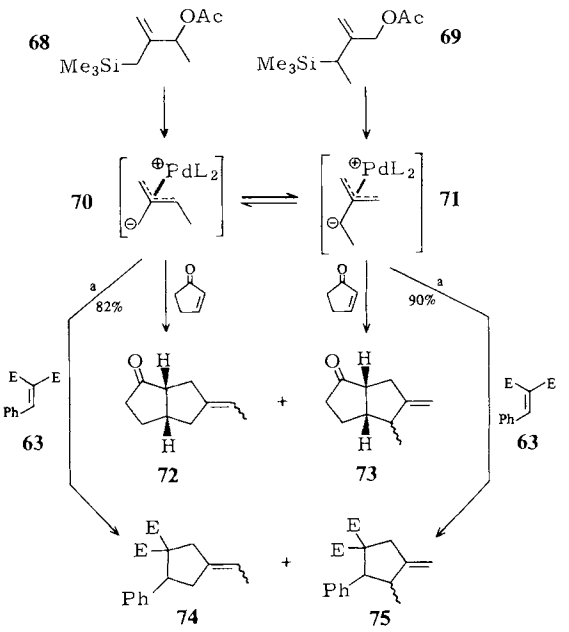
Scheme 36. Z = electron-withdrawing group.

upon switching from $[(Ph_3P)_4Pd]$ to $[\{(iPrO)_3P\}_{3-4}Pd]$ as catalyst (Scheme 37).[38,40]



Scheme 37. For catalysts and yields see text.

In all cases (Schemes 35 and 37), a single regioisomer results. The TMM precursors bearing an electron-withdrawing group (**42** and **43**) also give only single stereoisomers (**64a** and **64b**, respectively), which are assigned the *trans* geometry. All the remaining cases produce mixtures. Since, synthetically, the exocyclic methylene group will frequently be oxidatively cleaved to give the ketone, which can be readily epimerized, the stereoselectivity problem is not severe. For example, the adduct of **44** and coumarin, which is a 70 : 30 stereoisomeric mixture, undergoes ozonolysis to afford a single cyclopentanone (Scheme 38).[39,40]

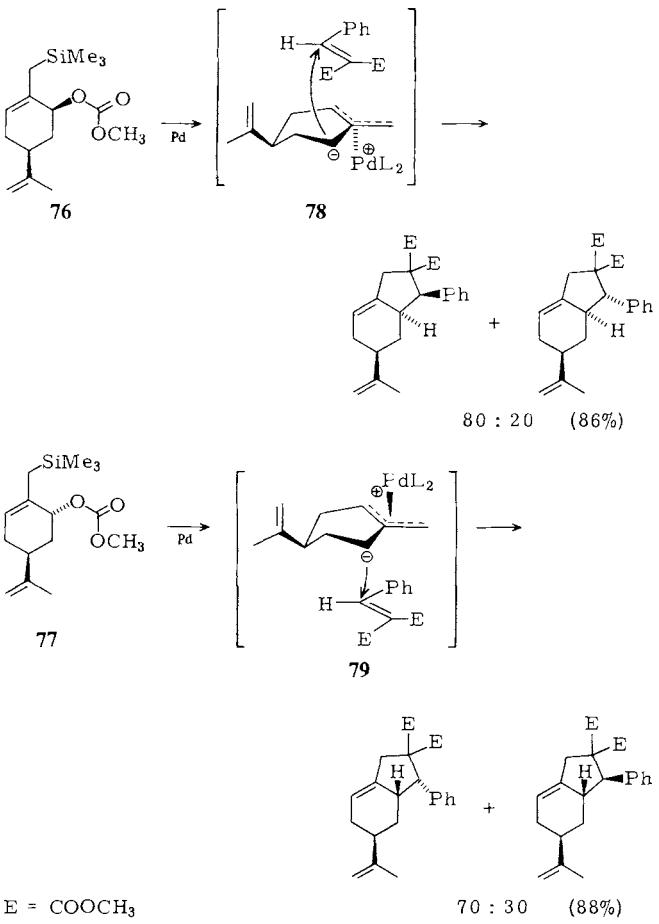


Scheme 38. Reaction conditions: a) $[(Ph_3P)_4Pd]$, Δ, toluene; b) 1. ozone, 2. thin layer chromatography.

Does the regioselectivity derive from the regioselective reaction of the TMM precursor? Assuming an η^3 structure for the TMM-palladium complex (Scheme 39), the question may be restated as follows. Do the unsymmetrical TMM complexes equilibrate faster than they undergo cycloaddition?

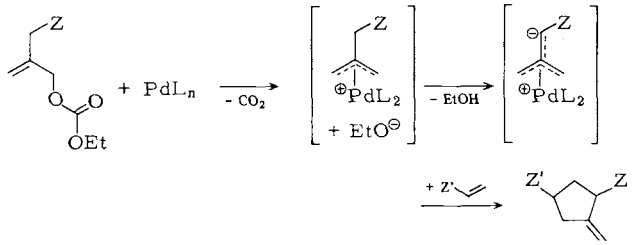
Scheme 39. η^3-Structure of the TMM-palladium complex.

The isomeric methyl-TMM precursors **68** and **69** allow such a concept to be tested since **68** should kinetically generate the complex **70** and **69** the complex **71** (Scheme 40).[52] With a less reactive trap, such as 2-cyclopentenone, both precursors give identical product mixtures, in which adduct **73** greatly predominates over adduct **72** (> 20 : 1).[36] On the other hand, a much more reactive trap, such as dimethyl benzylidenemalonate **63**, leads to some trapping before complete equilibration. Thus, a slightly larger amount of adduct **74** is formed from **68** (**74** : **75** = 1 : 3.3) than from **69** (**74** : **75** = 1 : 6.7),[52] although in both cases, adducts derived from **71** are favored (cf. Section 5). Thus, the methyl analogue **68** follows the same trend as all the other derivatives in terms of regioselectivity. The results indicate that the regioselectivity of the cycloaddition is largely independent of the regiochemistry of the precursors. In choosing the TMM precursor, therefore, the selection need only be determined by synthetic availability.



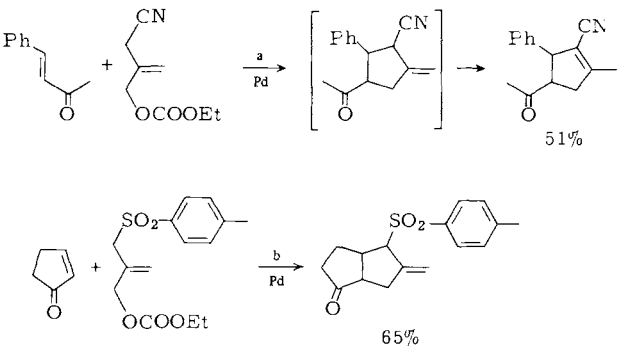
Scheme 40. Test of the regioselectivity of Pd^0-catalyzed cycloadditions using **68** and **69**. In **73**, the ratio α : β is 1 : 1, in **75**, 1 : 1.4. Reaction conditions: a) $[(Ph_3P)_4Pd]$, Δ, THF.

Reactants	Products	Yield [%]	Product ratios
68 + cyclopentenone	**72** + **73**		< 5 : > 95
69 + cyclopentenone	**72** + **73**		< 5 : > 95
68 + **63**	**74** + **75**	82	23 : 77
69 + **63**	**74** + **75**	90	13 : 87



The substituted TMM systems allow examination of the stereochemistry with respect to the TMM unit. As shown in Scheme 41, the reactions are regioselective and *cis/trans* stereoselective, but, as expected, complete racemization occurs.[53] Surprisingly, the reaction proceeds with overall net retention of the *cis* and *trans* configurations of **76** and **77**, respectively—an observation that suggests that the olefin approaches distal to the metal as depicted in **78** and **79**, in contrast to almost all metal-catalyzed olefin oligomerizations. Furthermore, the reaction shows an "endo-type" selectivity—a further analogy to the Diels-Alder

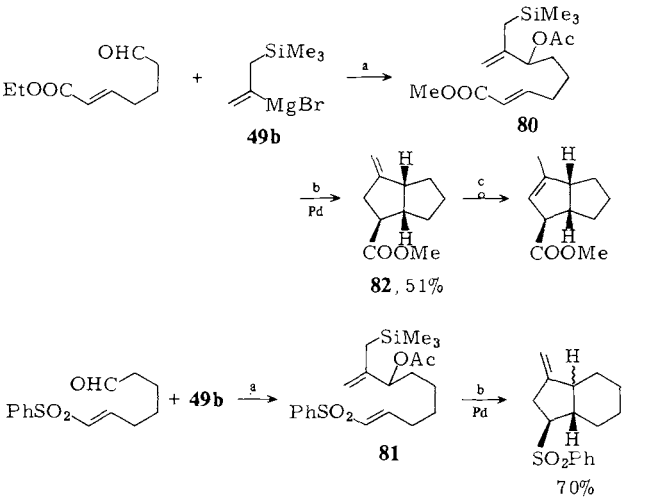
reaction. Unlike the Diels-Alder reaction, minimization of steric interactions in an end-on approach (as depicted in **78** and **79**) accounts for this observation. The excellent regioselectivity combined with the diastereocontrol makes this annulation approach very useful.



Scheme 41. Reaction conditions: [$(Ph_3P)_4Pd$], Δ, THF. Racemates are formed.

In the special case of substituents Z that are good anion-stabilizing groups, a non-silyl TMM derivative also serves as a suitable substrate (Scheme 42).

Scheme 42. Z, Z' = electron-withdrawing groups.

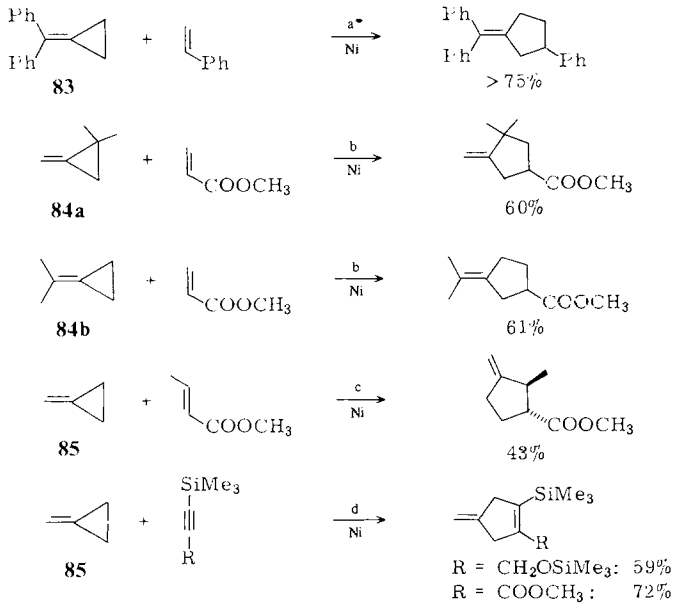


A leaving group that can generate a sufficiently strong base effects proton abstraction to create the TMM analogue in the special case when the anion-stabilizing group is on the carbon from which the proton must be removed. Two groups have met this requirement so far, cyano and sulfonyl (Scheme 43).[54]

Scheme 43. Reaction conditions: a) [$Pd_2(dba)_3(CHCl_3)$], DPPE, Δ, 1 h, THF; b) as in a) but 10 h. dba = dibenzylideneacetone [31c].

3.4. Intramolecular Cycloadditions

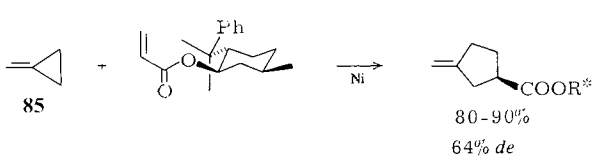
The extraordinary usefulness of the intramolecular Diels-Alder reaction encourages exploration of its [3+2] counterpart. The donor conjunctive reagent **49** (cf. Scheme 21) provides ready access to the requisite substrates as shown in Scheme 44.[41] For the intramolecular cycloaddition, a sterically less-encumbered catalyst, $(dppe)_2Pd$, is preferred. Heating **80** and **81** in the presence of this catalyst in refluxing THF or 1,2-dimethoxyethane (DME) results in elimination of trimethylsilyl acetate to give the bicyclo[3.3.0]octane and bicyclo[4.3.0]nonane skeletons, respectively. The acid-catalyzed isomerization of the diastereomerically pure bicyclic compound **82** illustrates one possible reaction of the exocyclic methylene group.



Scheme 44. Reaction conditions: a) 1. Grignard reaction, 2. AcCl/pyridine, DMAP; b) [$(Ph_3P)_4Pd$], DPPE, Δ, THF or DME; c) TosOH, 55°C, $CHCl_3$.

4. The Methylenecyclopropane Strategy

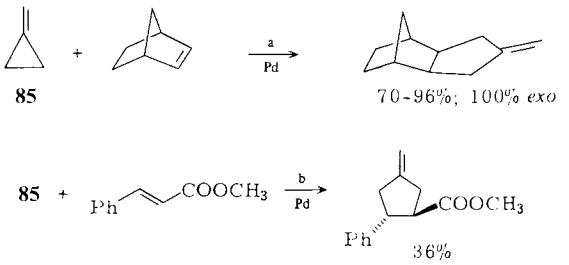
In spite of the thermal isomerizations of methylene cyclopropanes, which proceed through trimethylenemethane,[19,55] this reactive intermediate has seldom been trapped from such precursors. In the special case of 5-alkylidenebicyclo[2.1.0]pentane, trapping does occur at low temperatures; nevertheless, such methods appear unpromising for synthetic purposes. The possibility that tran-



sition metals may facilitate cycloadditions of methylenecyclopropane arises from the observation that disrotatory opening of these reactive strained rings occurs smoothly under the influence of diiron nonacarbonyl to give isolable trimethylenemethane iron tricarbonyl complexes.[56–58] A molybdenum complex forms in like fashion.[59] As in the earlier work on such complexes, further reactions of such TMM derivatives have not been reported.

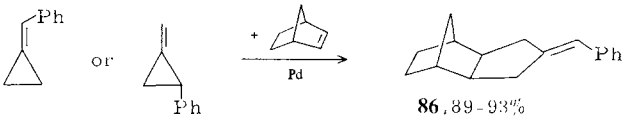
On the other hand, low-valent nickel catalyzes the codimerization of methylenecyclopropanes with both electron-rich[60] and electron-poor olefins (Scheme 45).[60–64] In addition, electron-rich and electron-poor alkynes codimerize in the presence of such catalysts to form 4-methylenecyclopentenes.[64b] For the parent system, the yields are acceptable only for electron-poor acceptors. Methylenecyclopropanes with two substituents on the methylene group give satisfactory yields with both types of olefins. High regioselectivity accompanies these reactions and indicates that TMM species are not likely intermediates.

Scheme 45. Reaction conditions: a) $Ni(cod)_2$, 40–60 °C, toluene; b) $Ni(acrylonitrile)_2$, 60 °C, 48 h, reaction bomb tube; c) $Ni(cod)_2$, 35 °C, 20 h; d) $Ni(cod)_2$/TOPP 1:1, 80 °C, 5–8 h, autoclave. cod = 1,5-cyclooctadiene; TOPP = tris(*o*-biphenylyl)phosphite.



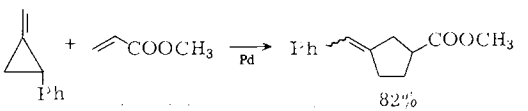
The possibility for asymmetric induction in such a codimerization where both acceptor and donor are simultaneously bonded to the metal appears high as reflected in a 64% diastereomeric excess in the simple reaction of 8-phenylmenthyl acrylate (Scheme 46).[65a] The absolute configuration has not been established but is assigned by analogy to the Diels-Alder reaction with the same acrylate as well as to organocuprate additions.[65b] Unfortunately, only very

Scheme 46. R* = (1*R*,3*R*,4*S*)-8-phenylmenthyl. Reaction conditions: $Ni(cod)_2$, RT, 4 h, toluene.



simple acceptors have been used to date. The difficulty in preparing and handling the catalysts constitutes a drawback to this approach.

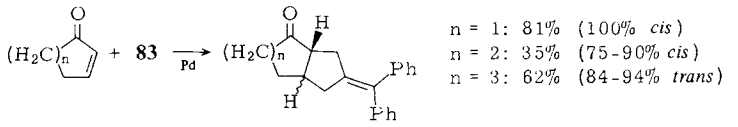
Palladium catalyzes similar reactions, as is shown in Scheme 47 by the codimerization of **85** with both norbornene[66,67] and methyl cinnamate.[67,68] The best catalysts are trialkylphosphane-palladium(0) complexes such as $[(iPr_3P)_nPd]$ generated from palladium bis(acetylacetonate), bis(dibenzylideneacetone)palladium, or (η^3-allyl)(η^5-cyclopentadienyl)palladium.



Scheme 47. Reaction conditions: a) $Pd(acac)_2/iPr_3P/Et_2AlOEt$ (1:1:2), 100 °C, 1 h, C_6H_6, reaction bomb tube; b) [(allyl)CpPd]/iPr_3P (1:1), 100–140 °C, toluene, reaction bomb tube. acac = acetylacetonato.

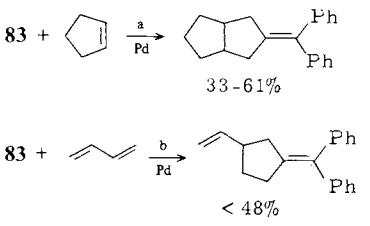
Unlike the nickel-catalyzed reactions, the regioselectivity appears to be independent of the structure of the starting methylenecyclopropane.[69] In the codimerization of norbornene with either of the phenyl-substituted compounds in Scheme 48, the same product mixture, with **86** as the predominant product, resulted.

Scheme 48. Reaction conditions: $(dba)_2Pd/iPr_3P$ (1:1), 70–90 °C.



1-Methylene-2-phenylcyclopropane reacts with methyl acrylate to give a single regioisomer bearing the phenyl group only on the exocyclic methylene carbon (Scheme 49).[70] It should be noted at this point that the regiochemistry of Pd-catalyzed additions of the 1,3-bifunctional silylacetate conjunctive reagents is totally different from that of the methylenecyclopropanes.

Scheme 49. Reaction conditions: $(dba)_2Pd/iPr_3P$ (1:1).

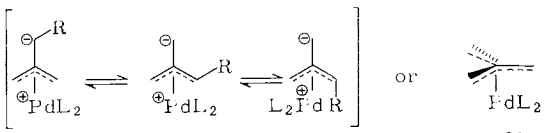


The efficiency of these cycloadditions appears highly dependent upon the nature of the substituents in the methylenecyclopropane with the order being approximately vinyl > alkyl > H > aryl. Methylenecyclopropane adds to simple acrylates but very few other acceptors have been reported. Thus, 2-cycloalkenones are particularly poor acceptors. For example, the use of 2-cyclohexenone leads to alkylation rather than cycloaddition.[71] On the other hand, diphenylmethylenecyclopropane **83** reacts with 2-cycloal-

kenones to give regioisomerically pure products (Scheme 50).[72]

Scheme 50. Reaction conditions: [(allyl)CpPd]/iPr$_3$P (1:1), 80–130°C, toluene.

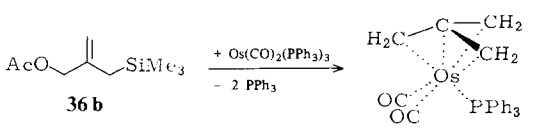
The diphenyl derivative **83** also reacts with a variety of simple electron-rich olefins including 1-butene and cyclopentene, as well as with conjugated olefins like styrene and 1,3-butadiene. Examples are shown in Scheme 51.



Scheme 51. Reaction conditions: a) [(allyl)CpPd]/iPr$_3$P (1:1), 130°C, 6 h, toluene; b) as in a) but 120°C, 8 h.

The location of the substituents also appears to be important. Of the *gem*-dimethyl analogues **84a** and **84b** (Scheme 45), the isopropylidene derivative **84b** undergoes codimerization with norbornene, whereas the methylene derivative **84a** merely isomerizes. In general, 2-alkyl- and 2,3-dialkyl-1-methylenecyclopropanes undergo codimerization either poorly or not at all, whereas the alkylidenecyclopropanes react smoothly. The exception is the series of phenyl-substituted derivatives, which undergo cycloaddition regardless of where the substituent is located.

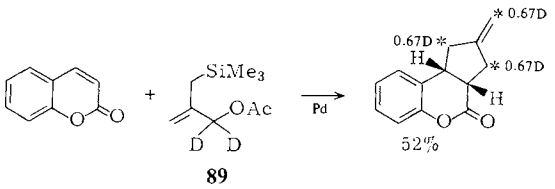
5. Mechanisms



The cycloadditions of 2-[(trimethylsilyl)methyl]allyl esters catalyzed by palladium(0) appear to be in accord with polar (η^3-TMM)PdL_2 species such as **87a–c** as intermediates (Scheme 52).[35,73] The alternative η^4-coordinated form **88** must also be considered (cf. Scheme 39).

87a **87b** **87c** **88**

Scheme 52. Possible structures of TMM-Pd complexes.

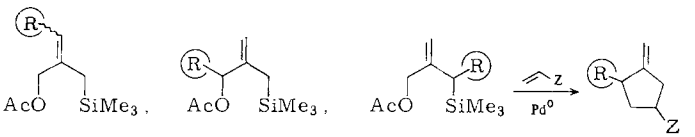


Support for the formation of an η^3- or η^4-TMM complex, is provided by the isolation of a TMM–metal complex from the silyl-acetate 1,3-bifunctional reagents in the case of osmium (Scheme 53) and iridium.[74]

36b

Scheme 53. An (η^4-TMM)-Os complex.

Deuterium labeling studies using **89** reveal complete scrambling of the label in the cycloaddition with coumarin (Scheme 54).[35,50]

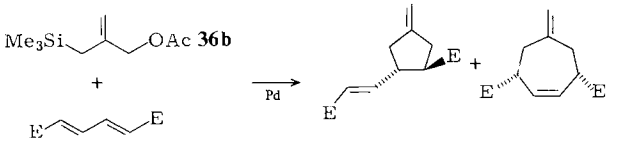


89

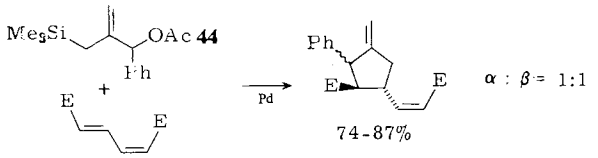
Scheme 54. Reaction conditions: 5 mol-% [(Ph$_3$P)$_4$Pd], 2 mol-% DPPE, Δ, THF.

The symmetry of the intermediate demanded by this result would be in accord with either rapid equilibration among **87a–c** or the η^4 structure **88**. A decision in favor of the η^3 structure **87** derives from the lack of any deuterium scrambling in reactions of **89** with carbon acids in the presence of palladium catalysts—clearly indicating the kinetic generation of an η^3 species. Furthermore, the degree of isomerization of substituted TMM-Pd conjunctive reagents in the cycloaddition reaction depends upon the nature of the acceptor. Whereas the two methyl-substituted TMM precursors **68** and **69** give the same product mixture with 2-cyclopentenone (see Section 3.3),[36,52] the more reactive trapping agent dimethyl benzylidenemalonate **63** leads to only partial isomerization (Scheme 40). That a larger amount of **74** is formed from **68** than from **69** is consistent with trapping of **70** being competitive with its isomerization.

The regioselectivity of the reactions is remarkable. All substituents tested to date, be they electron donating or electron withdrawing, end up preferentially at the carbon in the product that becomes bonded to the β carbon of the acceptor (Scheme 55). **87a** (cf. Scheme 52) thus represents the reactive form regardless of the electronic character of the R group.



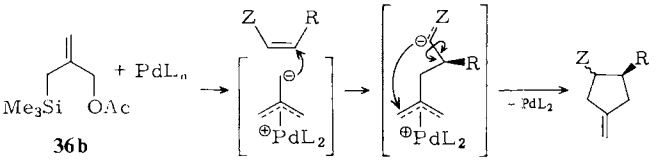
Scheme 55. Regioselectivity of [3+2] cycloadditions.



Calculations support these conclusions.[75,76] The η^3 structures **87a–c** are calculated to be more stable than the η^4 structure **88**. Surprisingly, **87a** is calculated to be more stable than **87b** or **87c** regardless of the substituent. It is obvious that electron-withdrawing groups such as cyano and carbonyl prefer to be on the most electron-rich carbon of the TMM unit; it is understandable that conjugating groups like vinyl and phenyl prefer this carbon; it is heresy, however, that an electron-donating group like methyl or acetoxy (+M, −I) prefers this carbon. The metal is responsible for this violation of the normal rules of stability. The electron repulsion experienced by the electron-donating substituent in **87a** is apparently offset, energetically, by the increased bonding energy to the metal.

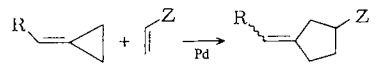
Is the reaction concerted or stepwise? The partial loss of olefin geometry (cf. Scheme 28)[43] and the observation of

seven-membered-ring formation in the reaction of dimethyl *trans,trans*-muconate **90** with **36b** support the notion of a stepwise process.[77] On the other hand, dimethyl *cis,trans*-muconate **91** undergoes addition of **44** preferentially to the *trans* double bond (Scheme 56).



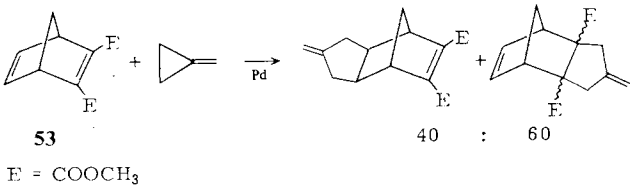
90 $[(Ph_3P)_4Pd]$, DPPE, THF, Δ: 62 : 38 (47%)
$[(Ph_3P)_4Pd]$, DPPE, dioxane, Δ: 79 : 21 (98%)
$[\{(iPrO)_3P\}_nPd]$, THF, Δ: 52 : 48 (89%)

91 E = $COOCH_3$



Scheme 56. Cycloaddition to *cis/trans* isomers.

Huisgen has stated that "the ratio of the *trans/cis* rates offers an elegant and theoretically clear criterion for concerted additions leading to five- and six-membered rings."[14c] This criterion suggests a concerted reaction. At present, the best interpretation appears to be a stepwise reaction initiated by nucleophilic attack, in which the ring closure occurs competitively with bond rotations (Scheme 57).

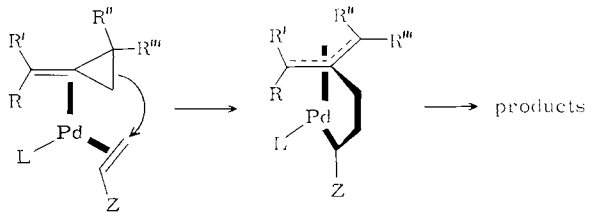


Scheme 57. Stepwise mechanism of [3 + 2] cycloaddition.

These results are strikingly different from those observed in the Pd-catalyzed codimerization of methylenecyclopropanes. In these cases, Scheme 58 best summarizes the regioselectivity.

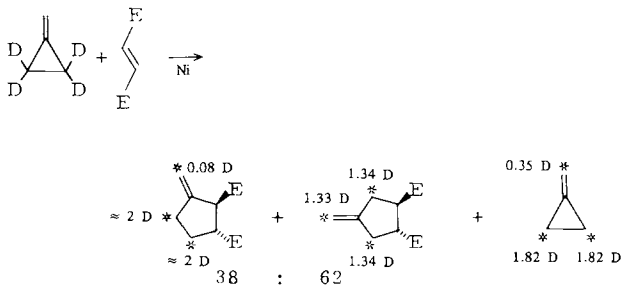
Scheme 58. Regioselectivity in the codimerization of alkylidenecyclopropanes.

The observed regioselectivity differs from that theoretically predicted for $(\eta^3$-TMM)PdL_2. The fact that the experimental observations of the silyl-acetate reactions agree fully with theory lends credence to the theoretical description of $(\eta^3$-TMM)PdL_2. Furthermore, the lack of chemoselectivity in catalyzed additions of methylenecyclopropane **85** to norbornadiene **53**, which results in cycloaddition to both double bonds (Scheme 59), differs dramatically from the reactions of the silyl-acetate species, which result exclusively in addition to the electron-deficient double bond (Scheme 27).



E = $COOCH_3$

Scheme 59. Reaction conditions: [(allyl)CpPd], iPr_3P.

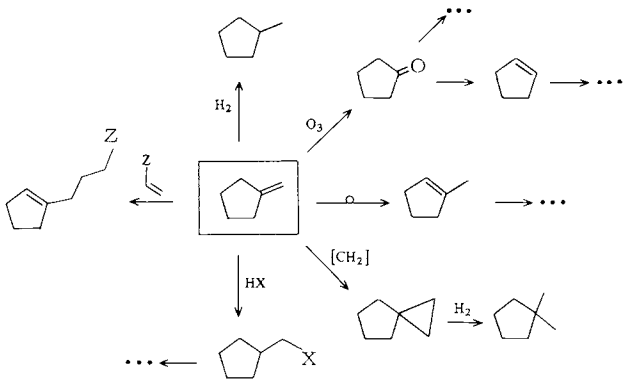


What, then, is the explanation for the reactions of alkylidenecyclopropanes? The picture becomes even murkier in that their reactions with carbon acids such as dimethyl malonate[69] parallel the reactions of the silyl-acetate species.[35]

A clue may reside in the ligand effects on the reaction. In the codimerization of the methylenecyclopropanes, a P : Pd ratio of 1 : 1 and the use of trialkylphosphanes such as triisopropylphosphane are optimal. In the silyl-acetate reactions, P : Pd ratios of ≥ 2 : 1 are preferred and triisopropylphosphane fails to serve as a ligand. It is possible that with alkylidenecyclopropanes direct dimerization on the metal occurs (Scheme 60) rather than prior opening to the TMM-Pd complex.

Scheme 60. Direct codimerization of alkylidenecyclopropanes.

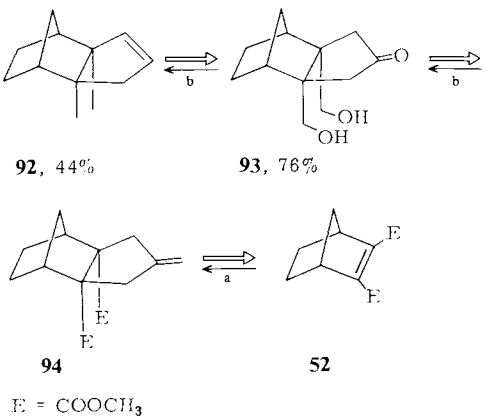
Such an interpretation is in accord with the nickel-catalyzed codimerizations of methylenecyclopropane. In these cases, opening of the 1,2 as well as the 2,3 bond of **85** is observed.[62,79,80] Furthermore, Ni(0) complexes of methylenecyclopropane can be isolated.[62,81] Nevertheless, a TMM-Ni intermediate appears to be involved, in part, in the codimerization of methylenecyclopropane with dimethyl fumarate based upon deuterium labeling results (Scheme 61).[80]



E = $COOCH_3$

Scheme 61. Reaction conditions: Ni(acrylonitrile)$_2$, 60 °C, 2.5 h, C_6H_6, ≈ 1% conversion.

6. Applications of Metal-Catalyzed TMM Additions



The direct cycloaddition approach to five-membered rings creates synthetic strategies not heretofore available. The exocyclic methylene group that arises in syntheses with TMM serves as a very versatile functionality for further elaboration (Scheme 62). Its easy oxidative cleavage to a ketone carbonyl group establishes its most important structural equivalent. The formation of a methyl or *gem*-dimethyl grouping is self-evident. Ene reactions, furthermore, allow chain elongations.

Scheme 62. Elaboration of the exocyclic double bond.

6.1. (±)-Albene

Albene **92** illustrates the types of problems that can be resolved using such cycloadditions, since a five-membered ring is fused *exo* to a norbornene system. Attack from the less-hindered face of the norbornene **52** directly creates the requisite stereochemistry (Scheme 63). Indeed, either the silyl-acetate species **36b** or methylenecyclopropane **85** add to give the requisite adduct, which was converted into albene. The simple five-step sequence starts from the readily available dimethyl 2,3-norbornenedicarboxylate (**52**).[45]

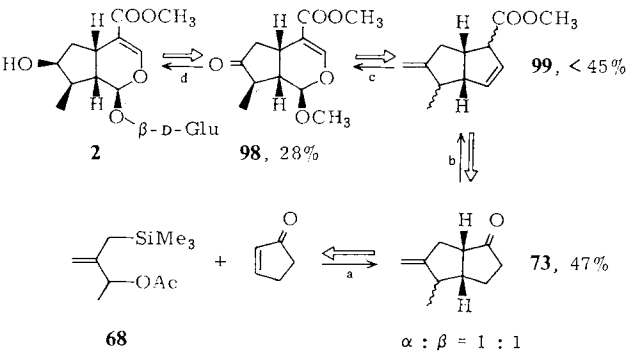
6.2. (±)-Hirsutene

The easy creation of a *gem*-dimethyl group provides an entry into hirsutene **29**.[82] A key step involves the use of alkylative cyclopentanone annulation with diphenylsulfoniocyclopropanide,[83] which simplifies **95** to **96** in the retrosynthetic analysis (Scheme 64). The easy cyclopropanation of **97** to form **96** reveals the presence of a trimethylenemethane unit and the obvious formation of **97** by cycloaddition to 2-cyclopentenone. Indeed, both the silyl-acetate species **36b**[43] and methylenecyclopropane **85**[82] undergo cycloaddition with 2-cyclopentenone, a reaction that allows transformation of this strategy into a synthesis of hirsutene, as outlined in Scheme 64.[82]

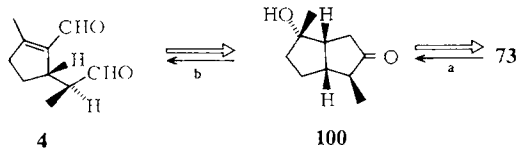


29 **95** **96** **97**

Scheme 64. (±)-Hirsutene **29**. a) Cycloaddition with **36b** or **85**; b) Et_2Zn, CH_2I_2; c) four steps; d) two steps.

6.3. (±)-Loganin

The iridoids constitute a more complex family of cyclopentanoids. Loganin **2**, a key intermediate in the biosynthesis of alkaloids, is derived from the ketone **98** in four steps. The presence of a hidden 1,5-dialdehyde in **98**, the ready accessibility of such a functionality by oxidative cleavage of a cyclopentene ring, and the synthon relationship between an exocyclic methylene group and a ketone simplify the problem to the diene **99**, which should be convertible in a single oxidation step into **98** (Scheme 65). Furthermore, by proceeding through the ketone, the stereochemistry of the methyl group in the early stages of synthesis becomes irrelevant since it can be easily epimerized to the thermodynamically favored, required configuration in **98**. The accessibility of the β,γ-unsaturated ester **99** from the cyclopentanone system **73** by standard methods reveals the presence of a methyl-substituted TMM unit. The cycloaddition of the requisite methyl-substituted silyl-acetate species **68** with 2-cyclopentenone to give **73** (see Scheme 40) allows this analysis to be transformed into a loganin synthesis as outlined in Scheme 65.[36]

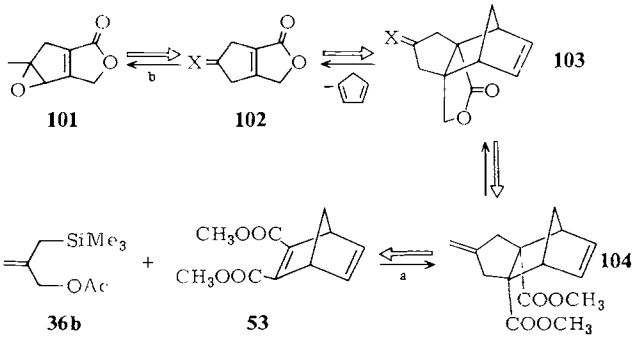


2 **98**, 28% **99**, < 45%

68 **73**, 47% α : β = 1 : 1

Scheme 65. (±)-Loganin **2**. Reaction conditions: a) $Pd(OAc)_2/(iPrO)_3P$; b) three steps; c) 1. ozonolysis; 2. $CH_3OH/H^{\oplus}$; 3. $NaOCH_3$; d) four steps.

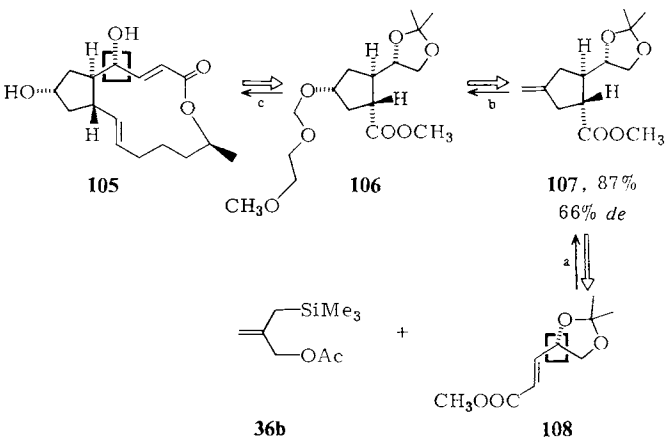
6.4. (±)-Chrysomelidial



A structure related to loganin is the *seco*-iridoid chrysomelidial **4**, a constituent of the larval defense secretion of a chrysomelide beetle. The problem of side-chain stereochemistry is resolved by converting it into a problem of ring stereochemistry as in **100**. Since thermodynamic epimerization at the methyl-bearing carbon can be relied upon to produce the correct stereochemistry, this aspect need not concern us in the earlier stages. Once again, the recognition of the synthon relationship between a ketone and an exocyclic methylene group combined with the obvious ability to create the tertiary alcohol by methyllithium addition simplifies the task to the synthesis of **73** (see Schemes 40 and 65). The cycloaddition approach provides the key bicycle **100** in only four steps in contrast with a fourteen-step synthesis using conventional approaches.[84] In this case, the annulated five-membered ring is ultimately cleaved to create the side chains of **4** (Scheme 66).

Scheme 66. (±)-Chrysomelidial **4**. a) Three steps, b) seven steps.

6.5. (±)-2β-Hydroxyjatrophone Precursor



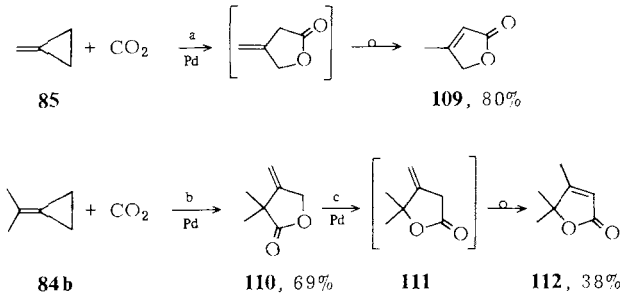
A projected synthesis of 2β-hydroxyjatrophone envisions the use of the highly functionalized cyclopentene **101** as a key intermediate. The accessibility of such an epoxide by simple methods from **102** immediately discloses the elements of TMM. The inability to use acetylenes as substrates for cycloaddition led to the use of the cyclopentadiene adduct **103** as a synthetic equivalent of the double bond in **102**. By so doing, the simple transformation of a diester to a lactone suggests **104** as the logical precursor (see Scheme 27). The efficiency of this route (Scheme 67) is highlighted by the approximately 60% overall yield of **101** from the norbornadiene diester **53**.[46]

Scheme 67. X = methylene or (protected) keto group. a) cf. Scheme 27; b) two steps.

6.6. (+)-Brefeldin A

Brefeldin A **105** represents a significant challenge in terms of the functionality, the macrocyclic ring, and absolute stereochemistry. Four of the five chiral centers are retained in the cyclopentane **106** (Scheme 68). The readily recognized relationship between a ketone and an exocyclic methylene group converts **106** into **107** in the retrosynthetic direction. The features of trimethylenemethane embodied in **107** once again demonstrate the widespread utility of the TMM approach. In this case, the critical question of the diastereoselectivity of addition to **108** arises. The availability of **108** from D-mannose translates this approach into an enantioselective one in which the one epimeric center of **108** increases to four epimeric centers in **106**. The final center in **105** arises from an independent synthesis of the lower side chain. Using our standard cycloaddition conditions, a good diastereoselective (4 : 1) cycloaddition occurs to give the methylenecyclopentane **107**. Sixteen subsequent steps complete the synthesis of optically pure (+)-brefeldin A **105** (Scheme 68).[85]

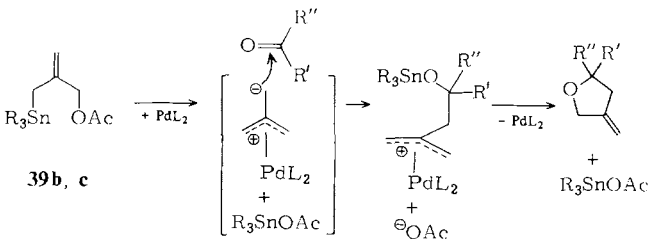
Scheme 68. (+)-Brefeldin A **105**. Reaction conditions: a) $Pd(OAc)_2$/$(iPrO)_3P$; b) three steps: c) thirteen steps. C-4 in the starting material **108** and the corresponding C atom in the product **105** are enclosed in boxes.



Although the [3+2] cycloaddition strategy to form five-membered rings is still in its infancy, the syntheses accomplished to date begin to show the effective solutions to problems of selectivity that such an approach offers. The exocyclic methylene group is an exceedingly important part of this strategy since it provides a handle for structural elaboration. Clearly, the opportunities have barely been probed yet.

7. Additions to C=O and C=N Bonds

The possibilities for stereocontrolled heterocyclic synthesis arising from Diels-Alder type additions to carbonyl groups raises the question whether five-membered heterocycles may also be approached using this chemistry. The presence of tetrahydrofuran and γ-butyrolactone structures in so many biologically important natural products highlights the relevance of such a question.

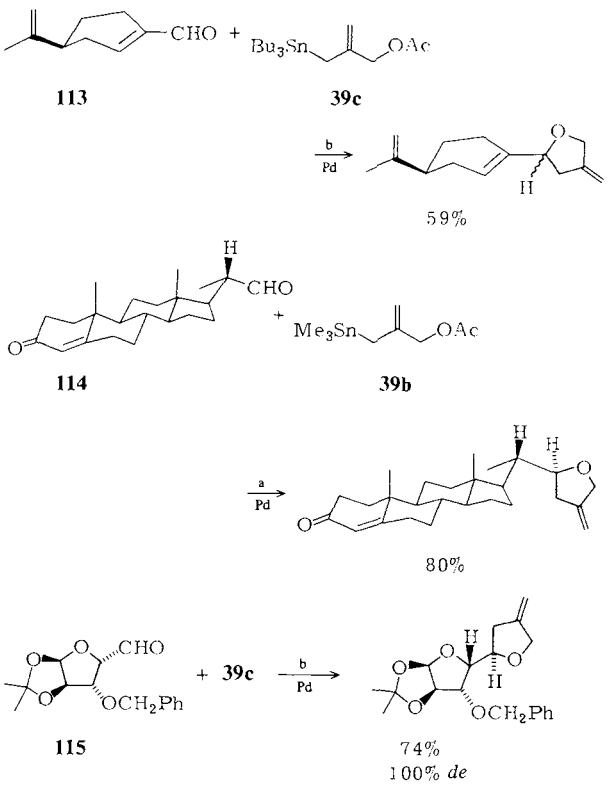


The codimerization of methylenecyclopropanes with carbon dioxide leads to γ-lactones (Scheme 69).[86,87] If an easily enolizable hydrogen exists in the initial adduct, isomerization to the γ-butenolide occurs under the reaction conditions. This addition appears to be reversible with the proper catalyst. The γ-butyrolactone **110** undergoes a

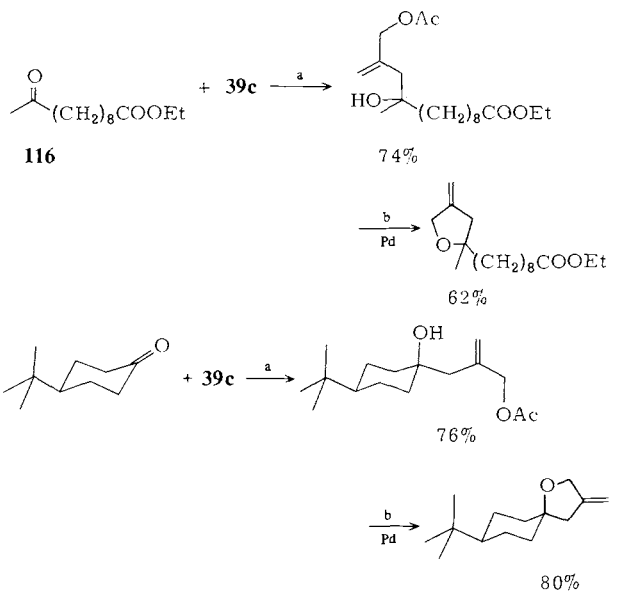
reversal of the elements of CO_2 using a catalyst bearing DPPE ligands (but not Ph_3P) to give initially **111**, which, as expected, isomerizes to the γ-butenolide **112**.[88]

Scheme 69. Reaction conditions: a) 40 bar CO_2 at RT, [(allyl)CpPd]/Ph_3P (1:4), DMF, 165–170°C, 2 h; b) 40 bar CO_2 at RT, $(dba)_2Pd/Ph_3P$ (1:4), C_6H_6, 130°C, 20 h; c) 60 bar CO_2, $(dppe)_2Pd$, C_6H_6, 110°C, 1.5 h.

Considering the nucleophilic characteristics of the $(TMM)PdL_2$ species, addition to carbonyl groups of aldehydes and ketones would appear feasible as outlined in Scheme 70. Because of the generally poor nucleophilic properties of oxygen toward π-allylpalladium intermediates and because the tin ethers have been reported[89] to react more smoothly, the tin analogues **39b,c** of the 1,3-bifunctional conjunctive reagents would appear to be more promising.



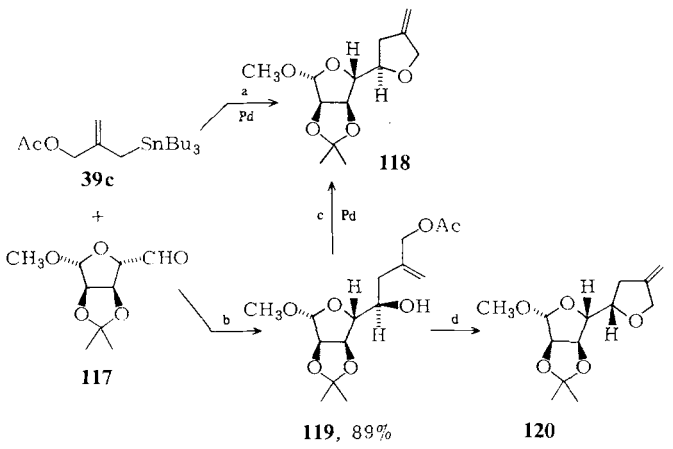
Scheme 70. Addition of $(TMM)PdL_2$ to carbonyl groups (cf. Scheme 57).



Initial studies with the silyl reagent **36b** did not lead to cycloaddition.[43] On the other hand, an excellent chemoselective addition occurs upon mixing the trimethyltin reagent **39b** with aldehydes even at room temperature (Scheme 71).[49] Remarkably, even α,β-unsaturated aldehydes such as **113** undergo cycloaddition to the carbonyl group in preference to cycloaddition to the double bond! Excellent diastereoselectivity accompanies this reaction.

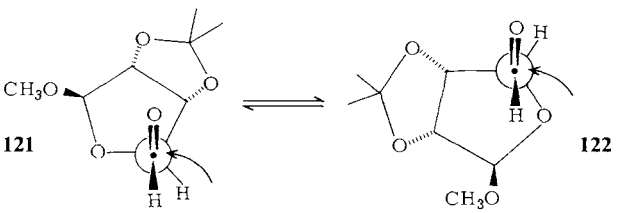
Not only 3-oxo-23,24-bisnor-4-cholen-22-al **114** but also the *xylo* aldehyde **115**, a model for an ionophore synthesis, forms only a single diastereomer.

Ketones do not undergo this cycloaddition in satisfactory yields. On the other hand, Lewis-acid-initiated additions of allylstannanes to ketones suggested that a two-stage sequence might enhance the scope of this cycloaddition. Indeed, chemoselective addition of **39c** to the ketoester **116** occurs smoothly in the presence of boron trifluoride at −78°C (Scheme 72).[48] The initial adduct smoothly cyclizes using a palladium catalyst prepared in situ. With 4-*tert*-butylcyclohexanone, equatorial attack is strongly preferred.



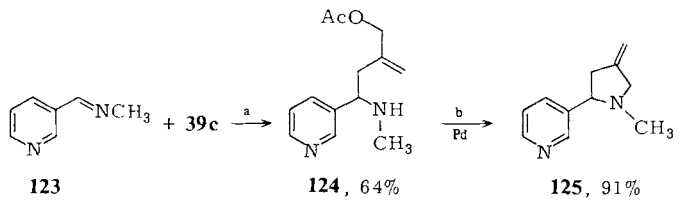
Scheme 71. Reaction conditions: a) 3 mol-% $Pd(OAc)_2/Ph_3P$, 40°C, dioxane; b) as in a), but Δ.

Scheme 72. Reaction conditions: a) $BF_3 \cdot Et_2O$, −78°C, 1 h, CH_2Cl_2; b) $Pd(OAc)_2/Ph_3P/BuLi$ (1:6:2), in situ; DBU, Δ, 16–36 h, dioxane.



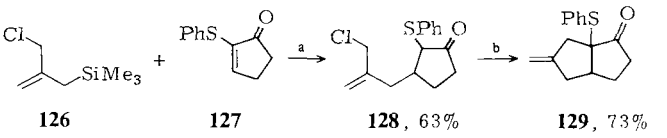
Performing this sequence in such a two-stage fashion has an advantage in the ability to manipulate the overall stereochemistry. Thus, *ribo* aldehyde **117** produces only the annulation product **118** in the one-step cycloaddition. The same compound also arises from the palladium-catalyzed cyclization of the initial adduct **119** in the two-step sequence.[48] Alternatively, mesylation converts the OH group at the α-C atom in the initial adduct **119** into a leaving group, so that cyclization upon treatment with base re-

Scheme 73. Reaction conditions: a) 3 mol-% $Pd(OAc)_2/Ph_3P$, dioxane; b) $BF_3 \cdot Et_2O$, $-78°C$, CH_2Cl_2; c) $[(Ph_3P)_4Pd]$, DBU, Δ, dioxane; d) 1. CH_3SO_2Cl, Et_3N; 2. KOH, H_2O, CH_3OH. Yields of **118** via a: 81%; via c: 60%.



sults in inversion of this stereocenter in the final product **120**.[49] Thus, from aldehyde **117**, either diastereomeric annulated product, **118** or **120**, is available.

The stereochemistry observed follows the normal Felkin-Anh rules invoking reaction via rotamer **121**, although the rotamer **122**, which better minimizes nonbonded interactions, also rationalizes these results (Scheme 74).

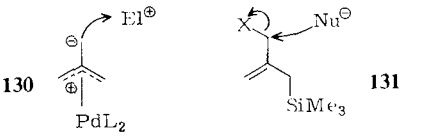


Scheme 74. Two rotamers of the reactant **117**.

The Lewis-acid-catalyzed reaction extends this strategy for heterocycle synthesis to pyrrolidines. Thus, the nicotine aldehyde imine **123** reacts with allylstannanes in the presence of a Lewis acid. Amines are excellent nucleophiles in palladium-catalyzed alkylations and thus these adducts smoothly cyclize to form 3-methylenepyrrolidines as exemplified in the synthesis of the nicotine analogue **125** (Scheme 75).[48]

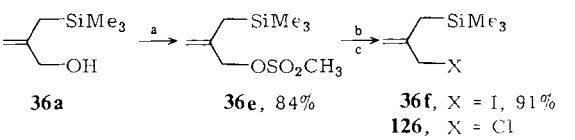
Scheme 75. Reaction conditions: a) $BF_3 \cdot Et_2O$, $-78°C$, CH_2Cl_2; b) $[(Ph_3P)_4Pd]$, DBU, Δ, dioxane.

Such a strategy has also been used with enones as acceptors, preferably with those that are particularly good Michael acceptors. [2-(Chloromethyl)allyl]trimethylsilane **126** does not undergo addition to 2-cyclopentenone in the presence of Lewis acids in satisfactory yield (8%) but does add to 2-(phenylthio)-2-cyclopentenone **127** in good yields (Scheme 76).[34]



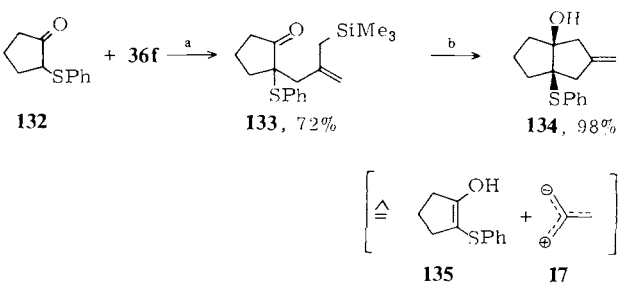
Scheme 76. Reaction conditions: a) $EtAlCl_2$, $-78 \rightarrow 0°C$, CH_2Cl_2; b) KO*t*Bu, *t*BuOH, RT, 3 h.

This approach may complement the direct metal-catalyzed cycloaddition in cases such as 2-cycloalkenones, which fail to satisfactorily cyclize in the transition-metal-catalyzed reaction.



8. Ancillary Strategies for Incorporating a TMM Structural Unit

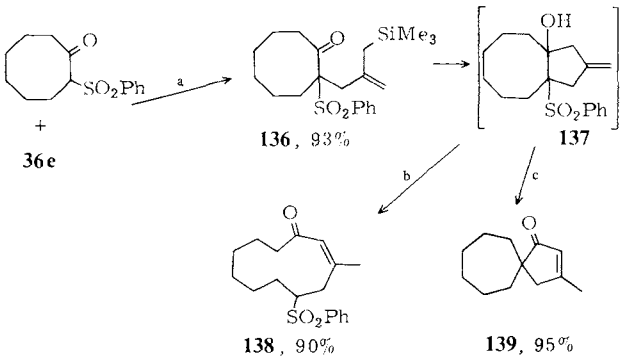
The use of $(TMM)PdL_2$ as a reactive intermediate for incorporating a TMM unit depends upon reactions initiated by its nucleophilicity, as shown by **130**. An approach that inverts the electronic sense of this TMM unit such that it reacts with nucleophiles, as shown by **131**, would greatly enhance the utility of these 1,3-bifunctional reagents (Scheme 77).



Scheme 77. Nucleophilic (**130**) and electrophilic (**131**) TMM species.

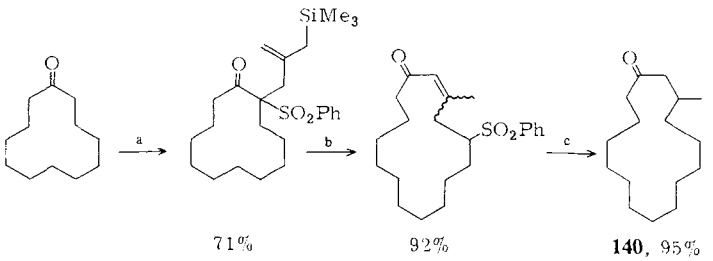
The halides **36f** and **126** and the mesylate **36e**, which are derived from the alcohol **36a**, serve as such electrophilic synthons (Scheme 78).[90,91]

Scheme 78. Reaction conditions: a) CH_3SO_2Cl/Et_3N, 0°C, CH_2Cl_2; b) NaI, Δ, acetone (→ **36f**); c) LiCl, 0°C, DMF (→ **126**).



The trimethylsilyl group, even though it is remote from the carbon undergoing substitution, retards alkylation.[91] Nevertheless, stabilized anions react smoothly to give the products of simple alkylation (Scheme 79). Fluoride ion promotes efficient cyclization of the resulting allylsilane,

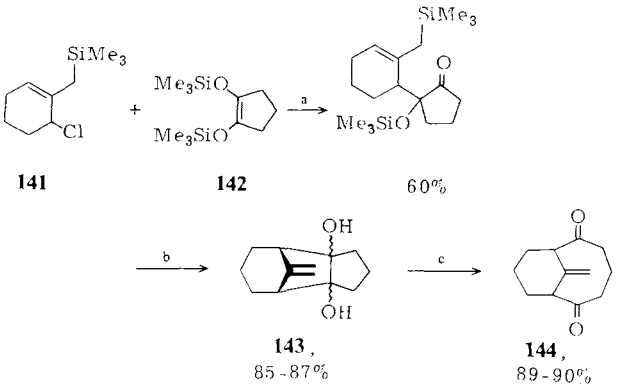
Scheme 79. Reaction conditions: a) KH, DME; b) Bu_4NF, Δ, 1 h, THF.



e.g., **133**, to effect a formal methylenecyclopentane annulation onto an electron-rich double bond (enol **135**).

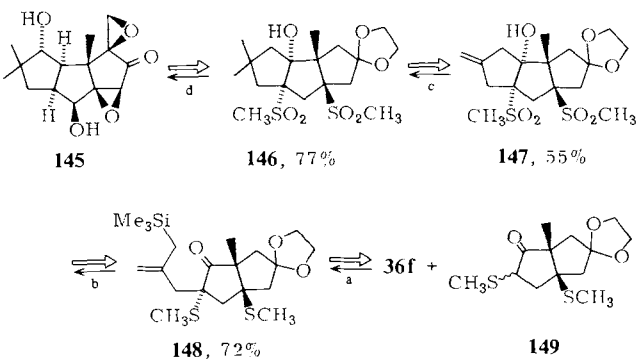
If 2-(phenylsulfonyl)cyclooctanone is used, the alkylated intermediate product **136** cyclizes to the reactive methylenecyclopentane **137**. In the presence of fluoride ion, the β-hydroxysulfone fragments to the ring-enlarged product, which isomerizes to the more stable conjugated enone **138**.[90,92] On the other hand, if Lewis acids are employed to promote the cyclization, intermediate **137** undergoes a pinacol-type rearrangement with expulsion of the phenylsulfonyl group to give, after isomerization of the double bond into a conjugated position, the spiro cyclopentenone **139**.[93] The intermediate methylenecyclopentane **137** can be isolated in 70% yield using ethylaluminum dichloride at −78 °C. Thus, from intermediate **136**, a nucleophilic trigger effects a net three-carbon intercalation (**136** → **138**) and an electrophilic trigger effects a combined ring contraction-spiroannulation (**139** → **139**) (Scheme 80).

Scheme 80. Reaction conditions: a) KOH/KI/$(Bu_4N)_2SO_4$, CH_2Cl_2/H_2O; b) Bu_4NF, 55 °C, 0.5 h, THF; c) $EtAlCl_2$, CH_2Cl_2, RT → Δ, 3 h.



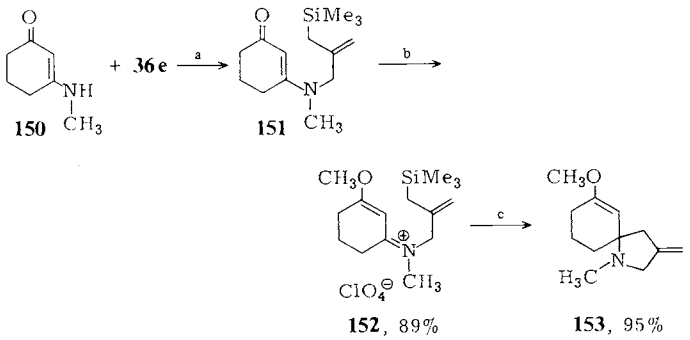
The three-carbon intercalation provides a very efficient strategy for the synthesis of muscone **140** from cyclododecanone (62% overall yield; Scheme 81).[90]

Scheme 81. (±)-Muscone **140**. Reaction conditions: a) 1. $Br_2/CHCl_3$; 2. $PhSO_2Na$; 3. NaH/**36e**; b) Bu_4NF, 55 °C, 0.5 h, THF; c) 1. H_2/Pd; 2. Na/Hg.



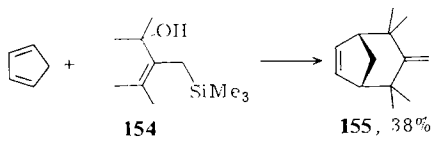
A slight variant of this sequence serves as an approach to the bicyclo[5.3.1]undecane system of the taxanes, which are antitumor agents (Scheme 82).[37] Careful treatment with a Lewis acid effects alkylation of the enediol bis(silyl) ether **142** by the cyclic TMM system **141**.[94] Cyclization as in Schemes 79–81 creates the "methylenecyclopentane" **143**, which is oxidatively cleaved to give **144**.

The synthetic equivalent of the cycloaddition to an enol (see **135**) forms the basis for a synthesis of coriolin **145**, an

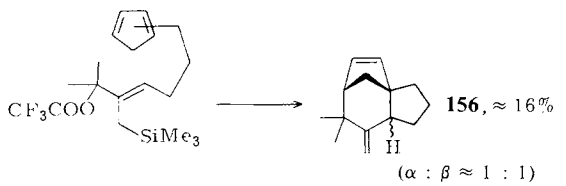


Scheme 82. Reaction conditions: a) $ZnCl_2$, 0 °C, 2 h, CH_2Cl_2; b) 1. $EtAlCl_2$, −78 °C, toluene; 2. $H_3O^{\oplus}$; c) $NaIO_4$, RT, 1–3 d, CH_3OH/H_2O.

antitumor agent and antibiotic that is the most complicated member of the hirsutene family (Scheme 83).[95] Manipulating functionality conceptually suggests **146** as a viable intermediate. The possibility of creating a *gem*-dimethyl group from an exocyclic methylene group simplifies the target further to **147**. At this point, the presence of the elements of methylenecyclopentane is quite obvious and can arise by annulation of an enol with the electrophilic versions of the 1,3-bifunctional conjunctive reagents. The sluggishness of alkylation of a β-ketosulfone led to the use of the β-ketosulfide **149** as the nucleophile that reacts with the iodide **36f**. Although cyclization to complete the annulation proceeds quantitatively upon exposing the β-ketosulfide **148** to fluoride ion, the ultimate need for the sulfone led to oxidation of **148** followed by cyclization to **147**. Cyclopropanation and catalytic hydrogenolysis simply converts the exocyclic methylene group into the *gem*-dimethyl unit of **146**. With this effective annulation protocol for the enol of the β-ketosulfide **149**, the stage was set for the completion of the synthesis, which mainly required adjustment of the oxidation pattern. The inverse polarity conjunctive reagents also are used for construction of heterocycles. In a novel sequence, the vinylogous amide **150** is alkylated with **36e** (Scheme 84).[96] *O*-Alkylation of **151** creates the iminium salt **152** for final ring closure. Photostimulation effectively achieves the nucleophilic addition of the allylsilane and consequently completes the annulation.



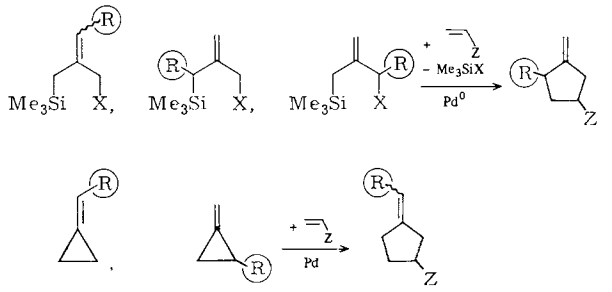
Scheme 83. (±)-Coriolin **145**. Reaction conditions: a) KH, DME, RT; b) 1. *m*-chloroperbenzoic acid (63% yield); 2. Bu_4NF, THF (87% yield); c) 1. CH_2I_2/Et_2Zn; 2. H_2/PtO_2; d) twelve steps.



Scheme 84. Reaction conditions: a) NaH/THF; b) CH_3I, $AgClO_4$; c) $h\nu$, $\lambda > 280$ nm, CH_3CN.

These electrophilic versions of TMM participate in a [4+3] type of cycloaddition that can be envisioned as a cycloaddition of an allyl cation to the diene, which is symmetry allowed in a suprafacial sense.[97] For example, the highly substituted 1,3-bifunctional silyl alcohol **154** requires only exposure to a Lewis acid to generate a reactive electrophile and participate in a cycloaddition (Scheme 85).[98] Although the yields are modest, alternative approaches failed.

Scheme 85. Reaction conditions: $TiCl_4$, $PhNHCH_3$, $-20°C$, 3 h, CH_2Cl_2.



An intramolecular version of this reaction creates the basic ring system of the zizaenes (Scheme 86), albeit only in 16% yield.[99]

Scheme 86. Reaction conditions: $ZnCl_2/SiO_2$, $-30°C$, CH_2Cl_2/pentane.

9. Conclusion

Transforming trimethylenemethanes from intellectual curiosities into synthetic tools continues to be an exciting challenge. One key appears to be the discovery of a transition metal, palladium, that achieves a proper balance between stability and reactivity and that unlocks the synthetic potential of this type of reactive intermediate. The applicability of this principle of using transition-metal templates as carriers for reactive intermediates, which had previously only been applied in the realm of physical studies in the case of TMM, has proven to be extremely powerful. The bonus of complementary regioselectivity depending upon the choice of precursors, as outlined in Scheme 87, is synthetically very useful even though it is not yet satisfactorily explicable.

Scheme 87. The dependence of regioselectivity on the choice of precursor.

The functionality available and the selectivity of this cycloaddition provide unusual opportunities for efficiency in the synthesis of cyclopentanoids.

I wish to thank my collaborators who are all identified in the references and who have played such a critical role in developing the chemistry coming from our laboratories. Support of our work from the National Science Foundation and the National Institutes of Health is gratefully acknowledged. I also thank Professors Daniel Little and Paul Binger for making available unpublished work from their laboratories.

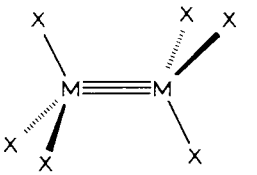
The $\sigma^2\pi^4$ Triple Bond between Molybdenum and Tungsten Atoms: Developing the Chemistry of an Inorganic Functional Group

By Malcolm H. Chisholm*

Numerous analogies between organic and inorganic chemistry have emerged in recent years. The most prominent example is the isolobal relationship. Many reactions have shown that metal-metal double and triple bonds exhibit a pattern of reactivity similar to that of alkenes and alkynes. In compounds containing a $\sigma^2\pi^4$ triple bond between molybdenum and tungsten atoms, the M-M bond order can be increased from three to four by reductive elimination or decreased from three to two or one by oxidative addition. Complexes with M≡M bonds can be used to prepare clusters or can serve as catalysts. In this review relationships between structure (electronic and stereochemical) and reactivity that are characteristic for modern inorganic chemistry are discussed.

1. Introduction

It is interesting, at least from a historical perspective, that unsaturation between carbon atoms in simple hydrocarbons was recognized on the basis of chemical reactivity long before the concept of σ and π bonds was understood or even advanced. By contrast, the "discovery" of multiple bonds between the transition elements was laid carefully on a physical and theoretical groundwork based on an understanding of the molecular and electronic structure of such compounds.[1] Once the extent of the field of multiple bonds had been surveyed, interest naturally turned toward chemical reactivity. Are there simple chemical tests available to distinguish between M-M quadruple, triple, and double bonds based on reactivity? Some 20 years after the discovery of the M-M quadruple bond,[2] the answer is still no! In part this should not be surprising since it is not unreasonable that a triple bond between say rhenium atoms should react in any way like a triple bond between osmium or tungsten atoms, just as the triple bonds in ethyne, dinitrogen, and carbon monoxide are quite different in their chemical reactivity. However, this is only a part of the problem. Two other factors enter in and are certainly equally important.



First, the simple molecular orbital (MO) description of the double or triple bonds between carbon atoms is, respectively, $\sigma^2\pi^2$ and $\sigma^2\pi^4$, whereas triple bonds between tungsten atoms, for example, may have a variety of MO configurations: $\sigma^2\pi^4$, $\sigma^2\pi^2\delta^2$, $\pi^4\delta^2$, and even $\sigma^2\pi^4\delta^2\delta^{*2}$. In the latter case, even though the population of both δ and δ* orbitals leads to a cancellation of the δ contribution, the reactivity of this type of triple bond is, as might be expected, quite different from that of triple bonds having the $\sigma^2\pi^4$ configuration. There is an obvious analogy here to the double bonds in say ethylene and dioxygen, which show vastly different chemistry.

The second factor is that the M-M bonding configuration $\sigma^2\pi^4$ for a triple bond, or any of the others listed above, is an oversimplification. In reality a mixing of metal-ligand and metal-metal bonding may occur, and always does occur in the presence of bridging ligands. The highest-energy orbitals (HOMO/LUMO) may be ligand centered, thereby greatly modifying or even obscuring completely the reactivity of the M-M multiple bond. To some extent the latter phenomenon has a parallel in the substituent effects in simple organic alkenes and alkynes, although the effects in transition-metal chemistry are even greater than in organic chemistry.

With this background in mind, my group has been trying over the past 10 years to develop systematically the chemistry of triple bonds between molybdenum and tungsten atoms, keeping the M-M configuration constant, namely, $\sigma^2\pi^4$. This review deals with our present understanding of the bonding and reactivity of this class of compounds. Wherever possible, analogies with the chemistry of the C≡C bond will be presented, since all chemists are familiar with the chemistry of alkynes.

2. The $\sigma^2\pi^4$ M≡M Bond

The simplest complexes having a $\sigma^2\pi^4$ M≡M bond are the unbridged d^3-d^3 dinuclear compounds of molybdenum and tungsten.[3] These include the ethane-like dimers M_2X_6, **1**, X = R (e.g., CH_2SiMe_3), NMe_2, OR, and SAryl,[4]

1

together with a wide variety of mixed-ligand-containing compounds of formula $M_2X_{6-n}Y_n$, where X and Y can be any combination of the above groups and Y may be a halide for n = 2 and X = NMe_2. The structure of $Mo_2(NMe_2)_6$ is shown in Figure 1.

For **1**, X = OR, there is a clear separation in energy between the $\sigma^2\pi^4$ M≡M bonding orbitals and the orbitals of the metal-oxygen σ bonds and oxygen lone pairs. This shows up very nicely in the He(I) and He(II) photoelectron

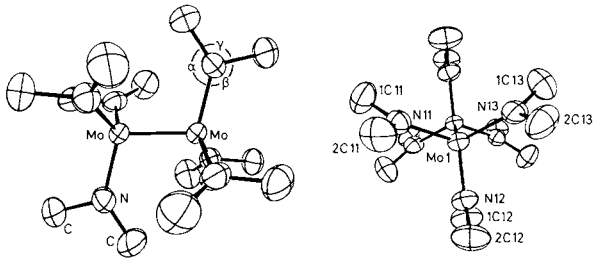

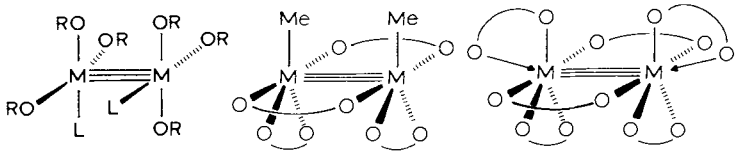

Fig. 1. Two views of the $Mo_2(NC_2)_6$ skeleton of $Mo_2(NMe_2)_6$ showing the unbridged Mo≡Mo bond (Mo-Mo distance: 2.214(3) Å) and the staggered ethane-like Mo_2N_6 moiety (Mo-N: 1.98 Å, Mo-Mo-N: 104°). Left: View perpendicular to Mo-Mo axis. Right: View along Mo-Mo axis. The NC_2 planes are aligned along the Mo-Mo axis, creating six proximal and six distal methyl groups.

spectra, where the ionization energies of the M-M π orbitals and σ orbital are ca. 6-7 and 7-7.5 eV, respectively, whereas those of the M-O σ bonds and the oxygen lone pairs are in the range 8-10 eV. There are some interesting differences in the ionization energies as a function of the metal and the alkoxide ligands, the ease of electron removal being in the order tBuO > iPrO > tBuCH$_2$O and W > Mo.[5,6] These differences are important in determining subtle differences in the chemistry of the $M_2(OR)_6$ compounds (see Section 3). In the compounds $M_2(NMe_2)_6$, there are Me_2N-M π bonds and Me_2N non-bonding electron pairs, the latter being close in energy to the M-M π bonds. In the M_2R_6 compounds, there is extensive mixing of the M-C and M-M bonding orbitals, which all transform as either a or e in a symmetry group with a threefold axis.

In general there is a problem with σ bonds even in the simple diatomics like CO, which, in fact, has several σ components, namely, bonding, non-bonding, and antibonding.[7] In ethyne there is extensive mixing of C-C and C-H σ bonding orbitals such that the C≡C configuration $\sigma^2\pi^4$ is also only an approximation. So too in compounds of type **1** is the M-M configuration $\sigma^2\pi^4$ only a good approximation. Similar arguments can be extended to the d^3-d^3 dimers **2**-**4** with four-, five-, and even six-coordinate metal atoms.

2 **3** **4**

Examples of compounds of type **2** include $[Mo_2(OR)_6L_2]$ compounds, where L is a neutral donor ligand such as an amine, pyridine, or a tertiary phosphane.[8] Other examples arise from the presence of four monodentate and two bidentate ligands at the dinuclear center, e.g., $[M_2(NMe_2)_4(ArylN_3Aryl)_2]$[9] and $[M_2(OR)_4(acac)_2]$.[10] Examples of type **3** and **4** are less common but again the employment of bidentate ligands is helpful, particularly those with small "bite" angles. For instance, in the two compounds of type **3** $[W_2Me_2(O_2CNEt_2)_4]$[11] and $[W_2(CH_2tBu)_2(O_2CMe)_2(S_2CNEt_2)_2]$[12], there are two O_2CX ligands spanning the W≡W bond; two bidentate ligands (O_2CNEt_2 or S_2CNEt_2) and two monodentate ligands (Me or CH_2tBu) complete the coordination such that each tungsten atom forms five bonds to ligand atoms that lie roughly in the same plane. The only structurally characterized compounds of type **4** are $W_2(O_2CNMe_2)_6$[11] and $W_2(O_2Ct$Bu$)_6$.[13] The six bidentate ligands at the $(W{\equiv}W)^{6+}$ center allow the formation of five W-O bonds in a plane perpendicular to the W-W axis supplemented by weak W→O bonds along the W-W axis. The latter vary in length from 2.4 to 2.7 Å and thus the formation of the sixth W-O bond has little perturbation on the structure of compounds of type **3**.

In compounds of types **1**-**4**, the M≡M bond may be considered to be formed from interactions of metal d_{z^2} atomic orbitals to give the σ bond and d_{xz} and d_{yz} atomic orbitals to give π_x and π_y components, respectively. This simple picture is supported by calculations.[14-16] Whenever the molecules contain a threefold axis of symmetry, the π_x and π_y orbitals will be degenerate. For symmetries lower than those found for compounds of type **1**, the degeneracy of the π_x and π_y orbitals will be formally removed, but the two π components will be of similar energy. As a result, facile rotation about the $\sigma^2\pi^4$ M≡M bond is commonly observed and, at least to a first-order approximation, restricted rotations correspond to steric constraints of the ligands spanning the M≡M bond.[17]

The other metal atomic orbitals, s, p_x, p_y, $d_{x^2-y^2}$, and d_{xy}, are used to form M-L bonds in the xy plane: three M-L σ and two M-L π bonds in **1**, four M-L σ and one M-L π bond in **2**, and five M-L σ bonds in **3**. The M-M distances span the range 2.2 to 2.4 Å with W-W distances being ca. 0.08 Å longer than Mo-Mo distances in otherwise identical compounds.

3. Chemical Reactions

3.1. Interconversion of M-M Multiple Bonds

It seemed that redox reactions should, by elimination and addition, allow the interconversion of bond orders between metal atoms in a manner akin to that well established for the interconversion of carbon-carbon bonds of order 3, 2, and 1. Moreover, many of the principles already established for oxidative additions and reductive eliminations in mononuclear chemistry[18-22] should be transferable to dinuclear chemistry. *Cotton* and *Walton* were the first to show that simple electrochemical oxidations and reductions could interconvert M-M bonds of order 4, 3.5, and 3 by feeding electrons into and removing them from δ and δ* orbitals.[1] Our work has focused attention on chemical reactions wherein the ligands are intimately involved in the redox reaction.

3.1.1. Formation of $\sigma^2\pi^4\delta^2$ Quadruple Bonds by Reductive Eliminations from Compounds Containing $\sigma^2\pi^4$ Triple Bonds

Our initial strategy was to devise routes to thermodynamically stable quadruply bonded compounds via elimi-

nation of kinetically labile organic molecules or fragments. Suitable precursor compounds were the 1,2-diorgano dimetal tetraamides, which can readily be prepared from $M_2(NMe_2)_6$ according to the reaction sequence outlined in Reactions (a) and (b).

$$M_2(NMe_2)_6 \xrightarrow[-2\,Me_3SiNMe_2]{+2\,Me_3SiCl} 1,2\text{-}[M_2Cl_2(NMe_2)_4] \quad (a)$$

$$1,2\text{-}[M_2Cl_2(NMe_2)_4] \xrightarrow[-2\,LiCl]{+2\,LiR} 1,2\text{-}[M_2R_2(NMe_2)_4] \quad (b)$$

A wide variety of R groups have been attached to the dinuclear metal center, including R = Me, Et, Pr (*n* and *i*), Bu (*n*, *i*, *s*, and *t*), Ph, *o*- and *p*-tolyl, CH_2Ph, CH_2CMe_3, and CH_2SiMe_3.[23,24] The dimetallacycles ($R=(CH_2)_4$) have also been prepared.[25]

These compounds contain a central ethane-like $M_2N_4C_2$ core with M≡M distances in the range of 2.2 Å (M = Mo) to 2.3 Å (M = W). In the solid state either *anti* or *gauche* rotamers may be found; in solution there is generally a mixture of the two with the equilibrium favoring the *gauche* form. These compounds are thermally stable at room temperature and may be sublimed in vacuo (10^{-4} torr) at ca. 80–120 °C with little decomposition. The reluctance of these compounds to undergo facile β-hydrogen elimination can be understood in terms of the existence of (1) the M≡M bond and (2) the strong Me_2N–M π bond. Metal d orbitals are not available for M–H–C interactions.[23] Also, on thermodynamic grounds, we would not expect the formation of a M–M quadruply bonded compound to be favored by either C–C or C–N coupling reactions since the inorganic residue formed by such an elimination, $Mo_2(NMe_2)_4$ or $Mo_2R(NMe_2)_3$, has no known analogue and is expected to be a relatively high-energy species.

Since CO_2 is known[26] to react with M–NMe_2 bonds to generate, by a formal insertion process, carbamate ligands, O_2CNMe_2, a reaction between $[M_2R_2(NMe_2)_4]$ compounds and CO_2 was expected to open up a route to $M_2(O_2CNMe_2)_4$ compounds, analogues of the well-known carboxylates of formula $Mo_2(O_2CR)_4$ (*Mo*≡*Mo*),[11] providing that the organo ligands R could be eliminated by a kinetically labile pathway.

This expectation was realized in the chemistry of 1,2-$[Mo_2R_2(NMe_2)_4]$ compounds, where R is an alkyl group containing a β-hydrogen atom. These react with CO_2 to give the desired tetracarbamate [Reaction (c)].[27]

$$[Mo_2R_2(NMe_2)_4] + 4\,CO_2 \longrightarrow Mo_2(O_2CNMe_2)_4 + \text{alkene} + \text{alkane} \quad (c)$$

Similarly, reactions involving 1,3-diaryltriazines led to elimination from the dimolybdenum center and formation of quadruply bonded compounds of formula $Mo_2(ArylN_3Aryl)_4$ (*Mo*≡*Mo*) [Reaction (d)].[27]

$$1,2\text{-}[Mo_2R_2(NMe_2)_4] + 4\,ArylNNNHAryl \longrightarrow Mo_2(ArylN_3Aryl)_4 + 4\,HNMe_2 + \text{alkene} + \text{alkane} \quad (d)$$

Rather interestingly, the tungsten analogues $[W_2R_2(NMe_2)_4]$ (R = an alkyl ligand containing β-hydrogen atoms) do not react according to (c) and (d).[28] However, a general procedure for the formation of W–W quadruple bonds has been devised, involving the addition of carboxylic anhydrides to $[M_2R_2(NMe_2)_4]$ [Reaction (e)] (R′ = Me, Et, *t*Bu, Ph).[29]

$$1,2\text{-}[M_2R_2(NMe_2)_4] + 4\,R'COOCR' \longrightarrow M_2(O_2CR')_4 + 4\,R'CONMe_2 + \text{alkene} + \text{alkane} \quad (e)$$

By labeling the alkyl ligands of $[M_2R_2(NMe_2)_4]$, we have found that the β-hydrogen atom of one alkyl ligand is transferred to the α-carbon atom of the other in the elimination step, as shown in Reaction (f).[27]

$$CD_3CH_2\text{–}M{\equiv}M\text{–}CH_2CD_3 \longrightarrow M{\equiv}M + CD_3CH_2D + CD_2{=}CH_2 \quad (f)$$

In reactions involving the metallacyclic compound $[Mo_2(CH_2)_4(NMe_2)_4]$, the formation of the Mo–Mo quadruple bond is accompanied by the liberation of two equivalents of ethylene.[28]

Reactions employing $[M_2R_2(NMe_2)_4]$ compounds where R is an alkyl ligand lacking β-hydrogen atoms, e.g., Me, $PhCH_2$, or $tBuCH_2$, cannot undergo this type of reductive elimination (alkyl group disproportionation). Upon reaction of these compounds with CO_2, compounds of the type $[M_2R_2(O_2CX)_4]$, where $X = NMe_2$[11] or R′,[30] have been isolated. Reductive elimination is still possible, however, and may occur by a radical pathway, which may be promoted either thermally or photochemically. The ease of reductive elimination follows the order Mo > W and $R = PhCH_2 > tBuCH_2$.[31,32] An extension of this type of reductive elimination involves reactions of $[(L_nM')(Me_2N)_2M{\equiv}M(NMe_2)_2(M'L_n)]$, where $L_nM' = CpFe(CO)_2$ or $(Me_3Sn)_3Sn$ [Reaction (g)].[28,33,34]

$$[(L_nM')(Me_2N)_2Mo{\equiv}Mo(NMe_2)_2(M'L_n)] + 4\,CO_2 \longrightarrow Mo_2(O_2CNMe_2)_4 + 2\,L_nM'^{\odot} \quad (g)$$

The fate of $L_nM'^{\odot}$, like that of $R^{\odot}$, depends on its relative reactivity. $[CpFe(CO)_2]^{\odot}$ and $PhCH_2^{\odot}$ undergo dimerization in aromatic solvents. $[(Me_3Sn)_3Sn]^{\odot}$ undergoes decomposition to Me_4Sn and Sn(metal), while $tBuCH_2^{\odot}$ abstracts hydrogen or deuterium from the solvent.

In some instances, reductive elimination was found to occur in what might have been considered the least likely of conditions. For example, during the reaction of $[Mo_2(iBu)_2(NMe_2)_4]$ with *i*PrOH [Reaction (h)], $[Mo_2(OiPr)_4(HOiPr)_4]$, which contains a Mo–Mo quadruple bond, is formed as purple crystals.[35]

$$[Mo_2(iBu)_2(NMe_2)_4] + i\text{PrOH(excess)} \xrightarrow{\text{hexane}} [Mo_2(OiPr)_4(HOiPr)_4] + 4\,HNMe_2 + i\text{BuH} + Me_2C{=}CH_2 \quad (h)$$

3.1.2. Oxidative Additions to Compounds Containing $\sigma^2\pi^4$ Triple Bonds with Formation of $(M{=}M)^{8+}$ and $(M\text{–}M)^{10+}$ Compounds

Following a similar strategy, we attempted to convert a $(M{\equiv}M)^{6+}$ compound into known $(M{=}M)^{8+}$ or $(M\text{–}M)^{10+}$

compounds. The dinuclear alkoxide $Mo_2(OiPr)_6$ was converted into $Mo_2(OiPr)_8$ by reaction with diisopropyl peroxide [Reaction (i)].[36] Steric considerations are apparently important since reactions employing analogous complexes containing *t*BuO ligands and/or *t*BuOO*t*Bu failed to yield oxidative-addition products.[36]

$$Mo_2(OiPr)_6 + iPrOOiPr \longrightarrow Mo_2(OiPr)_8 \quad (i)$$

Halogens, X_2, add to $Mo_2(OiPr)_6$ in solution to give directly $[Mo_2X_4(OiPr)_6]$ (X = Cl, Br, I); only in the case of I_2 is there any evidence for the formation of an intermediate.[26] Similarly, reactions of a variety of substituted (H, alkyl, and Cl) *ortho*-quinones with $M_2(OR)_6$ yield 2:1 adducts,[8,37] as do α-diketones [Reaction (j)].[38] In these reactions, each ligand is reduced by two electrons upon complexation to the M_2 center.

$$M_2(OR)_6 + 2 \;\text{O=C–C=O} \longrightarrow [M_2(OR)_6(O\text{–}C\text{=}C\text{–}O)_2] \quad (j)$$

In the reaction between $Mo_2(OiPr)_6$ and 1,4-diisopropyl-1,4-diaza-1,3-butadiene, the 1:1 adduct $[Mo_2(OiPr)_6(iPrNCH{=}CHNiPr)]$ ($M{=}M$) is formed. Formally, this reaction may be viewed as a Diels-Alder type of addition to the Mo≡Mo bond, although the X-ray structure analysis reveals that the bisamide ligand is chelated to only one metal atom.[39]

The $M_2(OR)_6$ compounds also react with π-acceptor ligands such as CO and acetylenes to form 1:1 adducts, which may be viewed as a redox reaction between the π-acceptor ligand and the M≡M bond as donor.[40] From studies of these reactions it is clear that the reducing power of the W≡W bond is greater than that of the Mo≡Mo bond. In this context, the remarkable metathesis reactions involving $W_2(OtBu)_6$ and alkynes or nitriles [Reactions (k) and (l)] may be viewed as oxidative cleavages, which are favored for W but not Mo.[41,42]

$$W_2(OtBu)_6 + RC{\equiv}CR \longrightarrow 2(tBuO)_3W{\equiv}CR \quad (k)$$
$$W_2(OtBu)_6 + RC{\equiv}N \longrightarrow (tBuO)_3W{\equiv}CR + (tBuO)_3W{\equiv}N \quad (l)$$

The reactions between the M≡M bonds in $M_2(OR)_6$ compounds and the triple bonds in alkynes, nitriles, and carbon monoxide, which are quite fascinating, have been the subject of a recent review[40] and consequently are not discussed further in this article.

3.1.3. Mechanistic Considerations Concerning Oxidative Additions and Reductive Eliminations from Dinuclear Centers

Although in the first few years our efforts were aimed at establishing these types of reactions, the intimate pathway by which they proceed provides a fascinating area for continued research. In the reductive elimination of alkane and alkene from the dinuclear metal center, does β-hydrogen activation occur across the M≡M bond or does alkyl migration occur first, so that the essential features of the elimination parallel reductive elimination from mononuclear metal complexes? The answers to questions like these are currently uncertain but a case can be made for redox chemistry occurring at *one* metal center followed by rapid ligand redistribution reactions. For example, it has been shown that addition of PMe_3 to 1,2-$[Mo_2(CH_2Ph)_2(OiPr)_4]$ produces a facile 1,2 benzyl migration with formation of $[(iPrO)_3Mo{\equiv}Mo(CH_2Ph)_2(OiPr)(PMe_3)]$.[43] The oxidative addition of *i*PrOH to $W_2(OiPr)_6$ to give $[W_2(\mu\text{-}H)(OiPr)_7]_2$, on the other hand, does not proceed in the absence of added base ($HNMe_2$, NMe_3, etc.).[44] Here, a case can be made for initial base promoted formation of a bridged d^3-d^3 dimer followed by oxidative addition of *i*PrOH to one tungsten center. Clearly, detailed mechanistic studies represent an important area for future research.

3.2. Cluster Syntheses

Metal-carbon and metal-metal multiple bonds have been found to be good reagents for metal-cluster building reactions. *Stone*[45] has emphasized the synthetic strategy that has at its root isolobal relationships[46] involving the coordination of C-C double and triple bonds to coordinatively unsaturated metal centers. Many of the ideas advanced by *Stone* and co-workers can be carried over to the chemistry of the M-M triple bonds of configuration $\sigma^2\pi^4$. In addition, many cluster-building reactions of d^0 metal complexes with M≡M compounds can be viewed in terms of redox reactions wherein the electrons of the M-M triple bond are used to form new metal-metal bonds. Alternatively, the M≡M bond may act as a reducing agent toward other metal-ligand bonds, again leading to new M-M and M-L bonding in cluster assembly reactions. Finally, since the M≡M bonds are generally shielded by bulky ligands around the metal center, oligomerization reactions are not favored. Controlled substitution of bulky groups by less bulky groups will thus favor oligomerization. These principles are exemplified in the following cluster building reactions.

3.2.1. $M{\equiv}M(\sigma^2\pi^4) + M'{\equiv}X(d^0)$

The comproportionation of d^0 oxomolybdenum alkoxides with $Mo_2(OR)_6$ compounds provided the first example of this type of reaction [Reaction (m)].[47,49]

$$Mo_2(OR)_6 + MoO(OR)_4 \longrightarrow [Mo_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu_2\text{-}OR)_3(OR)_6] \quad (m)$$

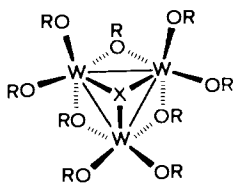
Such reactions are limited by the steric properties of the R group. The oxo-capped triangular Mo_3 compounds are formed when R = *i*Pr and CH_2tBu. When R = *t*Bu, stable (isolable) $M_3O(OR)_{10}$ compounds are not formed. Reaction (m) is directly extendable to the syntheses of $W_3O(OR)_{10}$ compounds by related reactions involving $WO(OR)_4$ and $W_2(OR)_6$ compounds. It is also possible to make the mixed-metal compounds $[Mo_2WO(OR)_{10}]$ (R = *i*Pr, CH_2tBu) [Reaction (n)].[50]

$$Mo_2(OR)_6 + WO(OR)_4 \longrightarrow [Mo_2WO(OR)_{10}] \quad (n)$$

Attempts to prepare the related compounds $[W_2MoO(OR)_{10}]$ failed, probably because the oxo group transfer from d^0-Mo to d^0-W is thermodynamically favorable and the triangular complex breaks apart to give $WO(OR)_4$ compounds. In the case of the bulky *t*BuO ligands, this provides a route to the mixed-metal d^3-d^3 dimers [Reaction (o)], although their isolation free from the homonuclear compounds $M_2(OtBu)_6$ has not been possible.

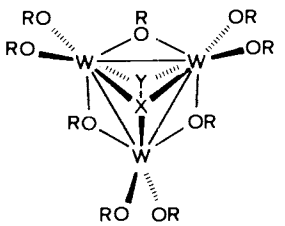
$$W_2(OtBu)_6 + MoO(OtBu)_4 \longrightarrow WO(OtBu)_4 + MoW(OtBu)_6 \quad (o)$$

Similar reactions employing the carbyne complex $(tBuO)_3W{\equiv}CR'$ and $M_2(OR)_6$ compounds have led to the isolation of W_3 and Mo_2W alkylidyne-capped clusters [Reactions (p) and (q)].[51,53] Steric factors are again important (R = *i*Pr, CH_2tBu, R' = Me, Et, Ph).[53]



$$(tBuO)_3W{\equiv}CR' + W_2(OR)_6 \xrightarrow[\text{hexane/ROH}]{25\,^\circ C} [W_3(\mu_3\text{-}CR')(\mu_2OR)_3(OR)_6] \quad (p)$$

$$(tBuO)_3W{\equiv}CR' + Mo_2(OR)_6 \xrightarrow[\text{hexane/ROH}]{25\,^\circ C} [Mo_2W(\mu_3\text{-}CR')(\mu_2\text{-}OR)_3(OR)_6] \quad (q)$$



Attempts to prepare the analogous nitrido complexes $[M_2M'(\mu_3\text{-}N)(\mu_2\text{-}OR)_3(OR)_6]$ failed, but, in the presence of alcohols, ROH, imido-capped compounds have been isolated for both molybdenum and tungsten [Reaction (r)].[54,55]

$$(tBuO)_3M{\equiv}N + M_2(OR)_6 \xrightarrow[\text{hexane/ROH}]{25\,^\circ C} [M_3(\mu_3\text{-}NH)(\mu_3\text{-}OR)(\mu_2\text{-}OR)_3(OR)_6] \quad (r)$$

The structure of the alkylidyne-capped M_3 clusters is depicted by **5**, while that common to the oxo- and imido-capped complexes is depicted by **6**. In each case the six electrons of the M≡M bond are used to form three localized M–M single bonds (a^2e^4) in the symmetry group C_3.

5, R = *i*Pr, CH_2tBu; X = Me, Et, Ph

6, R = *i*Pr, CH_2tBu; X = NH, O; Y = OR

By changing the stoichiometry of these reactions, other products may sometimes be obtained. For example, we have prepared a fascinating tetranuclear nitrido molybdenum complex as shown in Reaction (s). We have reason to believe that related alkylidyne complexes may be similarily accessible.[55,56] The molecular structure of the complex $[Mo_4(\mu_3\text{-}N)_2(OiPr)_{12}]$ is shown in Figure 2.

$$Mo_2(OiPr)_6 + 2(iPrO)_3Mo{\equiv}N \xrightarrow[\text{hexane}]{25\,^\circ C} [Mo_4(\mu_3\text{-}N)_2(OiPr)_{12}] \quad (s)$$

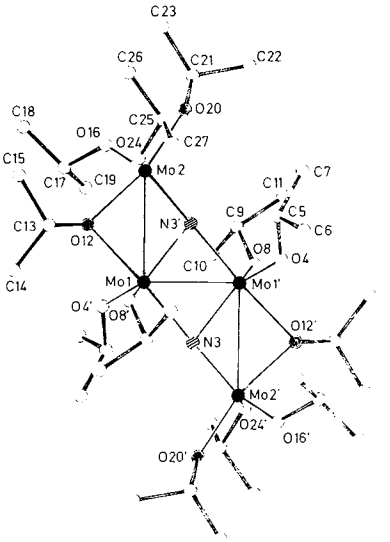


Fig. 2. The centrosymmetric structure of $[Mo_4(\mu_3\text{-}N)_2(OiPr)_{12}]$ in the crystal (ball-and-stick drawing) showing the T-shaped coordination about the nitrogen atoms and the trigonal bipyramidal coordination at each molybdenum atom. The atoms O20, O12, N3, Mo2, and Mo1, together with their symmetry-related atoms, lie in a plane. Important distances [Å]: Mo1-Mo1' 2.552(1), Mo1-Mo2 2.918(1), Mo2-N3' 1.841(2), Mo1-N3 2.034(2), Mo1-N3 1.996(2).

It seems quite likely that similar reactions of $M_2(OR)_6$ compounds with d^0-Nb^V, d^0-Ta^V, or d^1-Re^{VI} oxo, nitrido, or alkylidyne complexes could lead to similar clusters.

3.2.2. 2 M≡M → M_4

The only homonuclear triple bond that is stable with respect to oligomerization is found in N_2. For phosphorus, the dimerization of P_2 to P_4 is rapid, and subsequent oligomerization to polymeric P_x (red or black) is kinetically slow but thermodynamically favorable. In an attempt to oligomerize the M≡M bonds in $M_2(OR)_6$ compounds, we have studied the replacement of the OR group by halides. We believed that substitution of a more electronegative and smaller halide would increase the Lewis acidity of the metal and also make association sterically possible.

Several synthetic routes have been devised for this task, which so far has only been undertaken for molybdenum. We have thereby obtained a fascinating group of $[M_4X_4(OR)_8]$ compounds whose structures are dependent on both the nature of X and R.

The reaction between PF_3 and $Mo_2(OtBu)_6$ (molar ratio 2:1) proceeds smoothly in hexane at temperatures between −78 and 0 °C to give $[Mo_4F_4(OtBu)_8]$ [Reaction (t)].[57,58]

$$2\,Mo_2(OtBu)_6 + 4\,PF_3 \xrightarrow{\text{hexane}} Mo_4F_4(OtBu)_8 + 4\,tBuOPF_2 \quad (t)$$

The molecular structure of $[Mo_4F_4(OtBu)_8]$ is shown in Figure 3. Each molybdenum atom is coordinated by four ligands that lie roughly in a plane and joined to one other molybdenum atom by a Mo≡Mo bond (2.26 Å). The molecule can be viewed as a dimer, $[Mo_2(\mu\text{-}F)_2(OtBu)_4]_2$, which is consistent with the electronic absorption spectrum.[58]

Moreover, the mere addition of PMe_3 leads to cleavage and formation of $[Mo_2F_2(O\mathit{t}Bu)_4(PMe_3)_2]$,[58] which is a compound of type **2**.

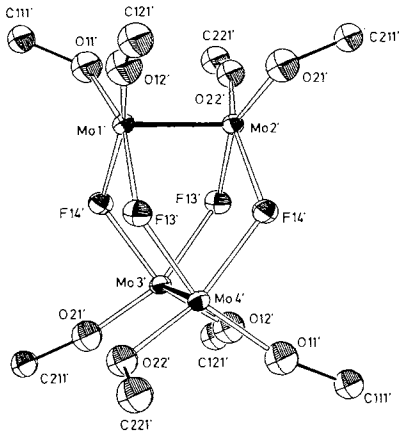

Fig. 3. An ORTEP view of the central skeleton of $[Mo_4(\mu\text{-}F)_4(O\mathit{t}Bu)_8]$. Important distances [Å] and angles [°]: Mo1'-Mo2' 2.262(2), Mo3'-Mo4' 2.263(2), Mo1'-Mo3' 3.743(2), Mo1'-Mo4' 3.730(2), Mo2'-Mo3' 3.713(2), Mo2'-Mo4' 3.700(2), Mo-(μ-F) 2.10(2) (averaged), Mo-O 1.94(2) (averaged), Mo-F-Mo 125° (averaged).

$[Mo_4Cl_4(O\mathit{i}Pr)_8]$ can be prepared from the reaction between $Mo_2(O\mathit{i}Pr)_6$ and MeCOCl (molar ratio 1:2) in toluene, and related reactions employing Me_3SiBr and Me_3SiI allow syntheses of bromo and iodo analogues [Reaction (u)].[59,60]

$$2\,Mo_2(O\mathit{i}Pr)_6 + 4\,Y{-}X \xrightarrow[\text{toluene}]{25\,^\circ C} [Mo_4X_4(O\mathit{i}Pr)_8] + 4\,YO\mathit{i}Pr \qquad (u)$$

$Y = MeCO, Me_3Si;\ X = Cl, Br, I$

The molecular structure of the chloro compound in the solid state (Fig. 4) consists of a square of molybdenum atoms with Mo-Mo distances of 2.37(1) Å, eight μ_2-O*i*Pr ligands, four lying above the Mo_4 plane and four below, and Mo-Cl bonds radiating from the center of the Mo_4-square.[59]

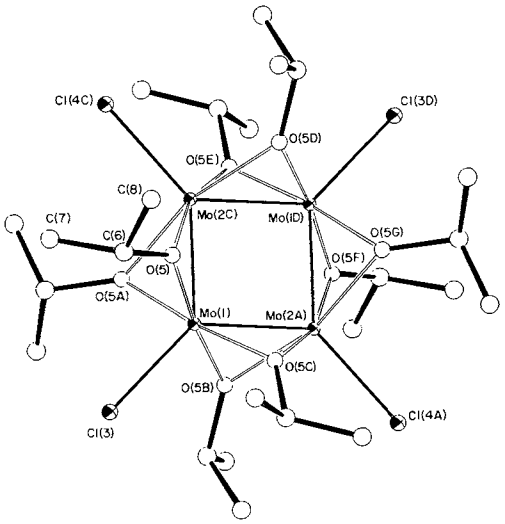

Fig. 4. An ORTEP view of the skeleton of $[Mo_4Cl_4(O\mathit{i}Pr)_8]$. The $Mo_4Cl_4O_8$ unit has virtual, but not crystallographically imposed D_{4h} symmetry. Each molybdenum atom is in a square-pyramidal environment ($ClMoO_4$) with the Cl atom occupying the axial position. Important distances [Å]: Mo-Mo 2.37, Mo-O 1.98, Mo-Cl 2.44.

The molecular structure of the bromo compound in the solid state (Fig. 5) consists of an Mo_4-butterfly with five short Mo-Mo distances, (average: 2.51(2) Å) and one long (non-bonding) Mo-Mo distance (3.1 Å). Two O*i*Pr ligands cap the two Mo_3 triangles, four symmetry-related μ_2-O*i*Pr ligands bridge the edges, and two O*i*Pr ligands, as well as the four bromo ligands, are terminal.[59]

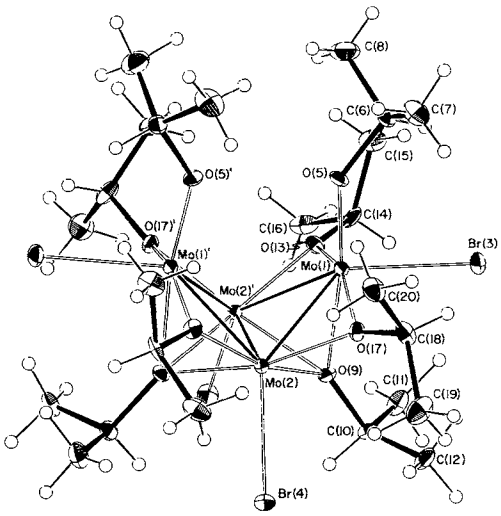

Fig. 5. An ORTEP view of the structure of $[Mo_4Br_4(O\mathit{i}Pr)_8]$. The molecule has C_{2v} symmetry with two equivalent μ_3-O*i*Pr ligands (Mo-(μ_3-O) 2.19 Å), four equivalent μ_2-O*i*Pr ligands (Mo-(μ_2-O) 2.02 Å), two terminal O*i*Pr ligands (Mo-O 1.84 Å), and four terminal bromo ligands (Mo-Br 2.59 Å). Each molybdenum atom is in a square-pyramidal environment ($BrMoO_4$) with the Br atom in the axial position. The Mo_4 butterfly has five Mo-Mo distances of 2.51 Å (averaged) and one long, formally non-bonding, Mo-Mo distance of 3.1 Å between the wing-tip Mo atoms Mo(1) and Mo(1)'.

The molecular structure of the iodo compound has not been determined by a single-crystal X-ray study, but from infrared and ^{1}H-NMR data it can be seen to be directly analogous to the bromo compound.[60]

Rather interestingly, all three $[Mo_4X_4(O\mathit{i}Pr)_8]$ compounds (X = Cl, Br, I) adopt a butterfly Mo_4 geometry with C_{2v} symmetry in toluene solutions at low temperatures but are fluxional at room temperature, showing O*i*Pr ligand exchange on the NMR time scale.[60] Furthermore, it is possible to isolate an intermediate compound in the synthesis of $[Mo_4X_4(O\mathit{i}Pr)_8]$ (X = Cl, Br), namely, $[Mo_4X_3(O\mathit{i}Pr)_9]$. On the basis of an X-ray study, the bromo compound is found to have a butterfly Mo_4 unit (Fig. 6).[60] The ^{1}H-NMR spectrum (Fig. 7) of the chloro compound supports an analogous structure.

Why does $[Mo_4Cl_4(O\mathit{i}Pr)_8]$ adopt a square Mo_4 structure whereas the related bromo and iodo compounds, and even the immediate precursor, have butterfly Mo_4 structures? The only logical answer to this question is that packing forces are sufficient to cause a geometry change in the solid-state structure of $[Mo_4Cl_4(O\mathit{i}Pr)_8]$ and that the total energies of the square and butterfly molecules are very similar. At first this might seem surprising, but both can be considered as fragments of the well-known $[Mo_6(\mu_3\text{-}X)_8]^{4+}$ structure (see Fig. 8).[61-63] The fluxional process interconverting the O*i*Pr ligands in solution is intramolecular and

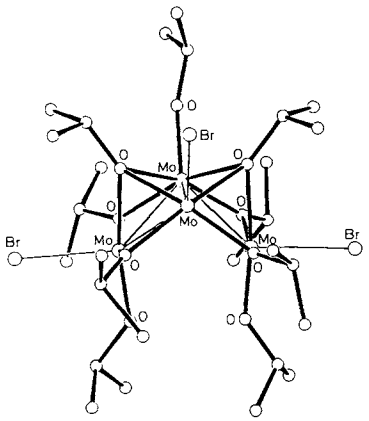

Fig. 6. The structure of $[Mo_4Br_3(OiPr)_9]$ (ball-and-stick drawing). The Cl and I analogues have the same type of structure, which differs from that of the $[Mo_4Br_4(OiPr)_8]$ molecule (Fig. 5) by the replacement of one Br atom by O*i*Pr on one of the central molybdenum atoms. The Mo–Mo, Mo–O, and Mo–Br distances are essentially identical to those in $[Mo_4Br_4(OiPr)_8]$ (see caption to Fig. 5) except that the Mo–O bond of the additional O*i*Pr ligand is longer (1.94 Å).

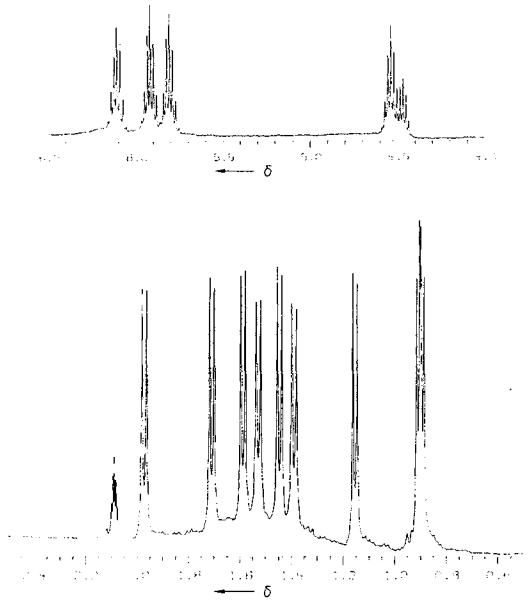

Fig. 7. ^{1}H-NMR spectrum of $[Mo_4Cl_3(OiPr)_9]$ ([D_8]toluene, 22°C, 360 MHz). Top: five methine septets in the integral ratio 2:2:2:2:1; bottom: the nine partially overlapping sets of methyl doublets. The molecule has only a mirror plane of symmetry containing the backbone Mo atoms, the Br atom, and the unique Mo–O bond between the O*i*Pr ligand and one of the backbone Mo atoms (see Fig. 6).

could well involve the interchange Mo_4-butterfly ⇌ Mo_4-square.

Thus far we have not been able to prepare and characterize the fluoro compound $[Mo_4F_4(OiPr)_8]$, which may have yet another geometry or be unstable with respect to further oligomerization. However, by reaction of $Mo_2(OiPr)_6$ with MeCOF (molar ratio 1:1) or PF_3 [Reaction (v)], we have been able to isolate a crystalline sub-

$$2\,Mo_2(OiPr)_6 + 2\,MeCOF/PF_3 \xrightarrow[\text{toluene}]{-80^\circ C} [Mo_4(\mu\text{-}F)_2(\mu\text{-}OiPr)_2(OiPr)_8] + 2\,MeCOOiPr/iPrOPF_2 \quad (v)$$

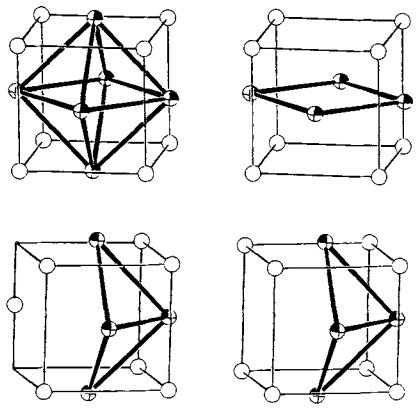

Fig. 8. Cube-octahedral structure of $[Mo_6(\mu_3\text{-}X)_8]^{4+}$ compounds (top left); Mo_4O_8 moiety in $[Mo_4Cl_4(OiPr)_8]$ (top right); Mo_4O_8 moiety in $[Mo_4Br_4(OiPr)_8]$ (bottom right); $Mo_4I_7^{2+}$ moiety in $Mo_4I_{11}^{2-}$ (bottom left): S. Stensrad, B. J. Helland, M. W. Babich, R. A. Jacabson, R. E. McCarley, *J. Am. Chem. Soc. 100* (1978) 6257.

stance of formula $[Mo_4F_2(OiPr)_{10}]$, which has a rectangular Mo_4 unit in the solid state with two Mo≡Mo bonds (2.23 Å) and two Mo–Mo non-bonding distances of 3.7 Å (Fig. 9).[60]

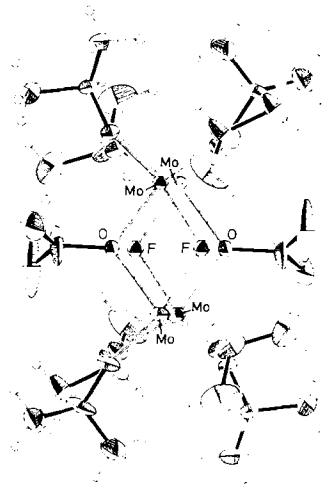

Fig. 9. An ORTEP view of the centrosymmetric structure of $[Mo_4F_2(OiPr)_{10}]$ (Mo-Mo distance: 2.23 Å). The dimer $[Mo_2(\mu\text{-}F)(\mu\text{-}OiPr)(OiPr)_4]_2$ is formed by fluoride and alkoxide bridges. The non-bonding Mo–Mo distances are 3.41 Å and the Mo–F–Mo and Mo–O–Mo angles 109° and 108°, respectively.

It should be noted that the rectangular Mo_4 unit found for $[Mo_4F_2(OiPr)_{10}]$ provides a way of preserving the Mo≡Mo bonds—namely, by the formation of bridging fluoride groups—that is an alternative to the bisphenoid Mo_4 unit in $[Mo_4F_4(OtBu)_8]$ (Fig. 3).

It is tempting to suggest that all reactions involving replacement of halide by OR proceed in a similar manner for $Mo_2(OR)_6$ compounds, differing only in the dimerization of the two dinuclear centers. This is controlled by both the steric properties of R and the nature of the halide. The initial dimerization occurs via Mo–X–Mo bridges as seen for X = F in the characterized products. However, for X = Cl, Br, or I, the halide is capable of forming relatively acute Mo–X–Mo angles, which allow, with OR bridge forma-

tion, the assembly of Mo_4 cluster units. Of course, more work still needs to be done to characterize compounds of empirical formula $MoF(OiPr)_2$, which could turn out to be higher oligomers than the $[Mo_4X_4(OR)_8]$ compounds thus far characterized.

Although the thrust of this article is placed on syntheses involving compounds with M≡M bonds, it is worth noting, at least in passing, that these 12e Mo_4 clusters are fascinating with respect to geometry and electronic structure. The structure of $[Mo_4Cl_4(OiPr_8]$ provides the first example of a 12e square M_4 unit and is well suited for modern calculational techniques.

Fenske-Hall calculations reveal that the Mo_4^{12+} unit is indeed an inorganic analogue of square cyclobutadiene, although the introduction of the ligands removes the strict analogy with the C_4H_4 molecule.[64] The twelve electrons are accommodated in M-M bonding molecular orbitals; ten electrons occupy M-M σ orbitals and two electrons an M-M π orbital. An orbital energy-level diagram that follows the mainly Mo-Mo bonding MOs of the Mo_4^{12+} core through the various stages of ligand addition for the model compound $[Mo_4Cl_4(OH)_8]$ is shown in Figure 10.

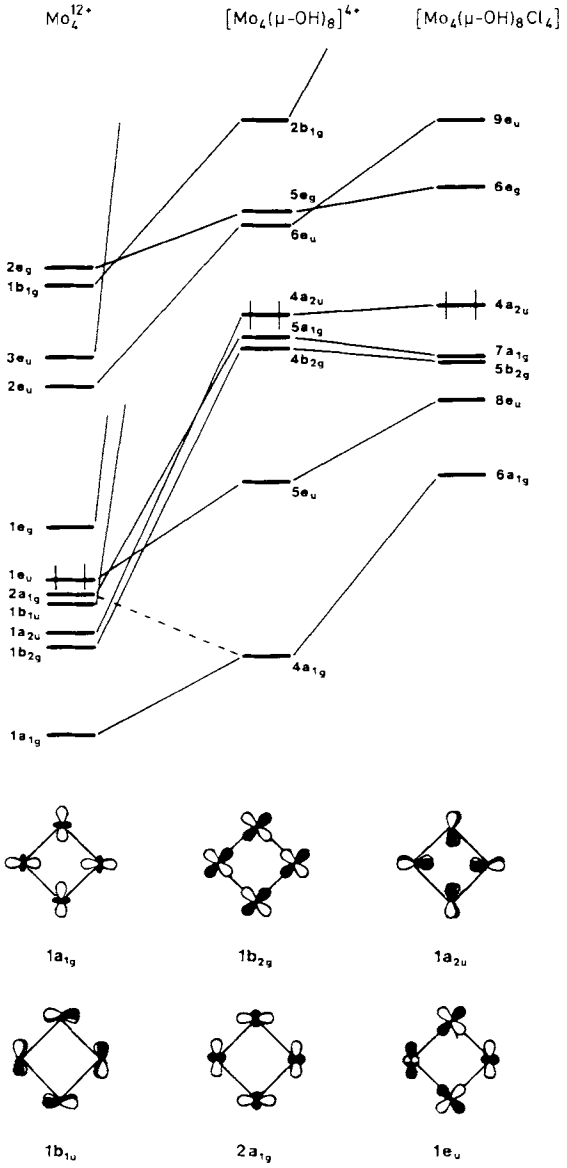

Fig. 10. MO correlation diagram for a square Mo_4^{12+} unit (left), following the mainly M-M bonding orbitals as ligation occurs through (1) introduction of the eight μ-OH ligands (center) and (2) introduction of the four terminal Cl ligands (right). The twelve electrons of the Mo_4^{12+} cluster occupy MOs belonging to the irreducible representations a_{1g} (two), b_{2g}, a_{2u}, b_{1u}, and e_u, which arise from the interactions of Mo d atomic orbitals (bottom). Note: only one of the e_u set is shown pictorially, and in Mo_4^{12+} the HOMO, $1e_u^2$, represents a diradical. There are eight electrons in M-M σ MOs and four in M-M π MOs (a_{2u} and b_{1u}); Mo_4^{12+} is thus the formal inorganic analogue of C_4H_4. Introduction of the eight μ-OH ligands increases the energy of the $1b_{1u}$ orbital. The introduction of the four Cl ligands principally affects the energies of the a_{1g} and e_u orbitals. In the resulting hypothetical $[Mo_4(\mu\text{-}OH)_8Cl_4]$, ten electrons occupy M-M σ MOs (a_{1g}, e_u, b_{2g}, and a_{1g}) and two electrons a π MO, a_{2u}, which is the HOMO.

3.2.3. $M{\equiv}M + M'L \rightarrow M_2(L')M'$

The reducing power of the M≡M bond can be used in reactions with metal complexes that contain redox-active ligands. In the heteronuclear metal complexes formed, the ligand L, originally bonded to one metal center, is now bonded to the M_2 center (M = Mo, W) and changed in character (L→L'); both the formal oxidation state and, of course, the mode of bonding are different since the newly created ligand, L', is now shared between M' and the M_2 group. The general applicability of this concept should be far reaching and is well illustrated in the following two reactions.

1. Alkynes react with $M_2(OR)_6$ compounds to give a wide variety of compounds: alkylidyne η^1 and μ complexes via C≡C scission, alkyne adducts, and a variety of products derived from C-C coupling reactions.[40] The reactions between alkynylmetal complexes (M'L) and $M_2(OR)_6$ might be expected to lead to heteronuclear C_1 or C_2 carbido-containing compounds. The reaction between $W_2(OtBu)_6$ and *trans*-$[Pt(C{\equiv}CH)_2(PMe_2Ph)_2]$ (molar ratio 2:1) leads by successive elimination of *t*BuOH to *trans*-$[Pt\{C_2W_2(OtBu)_5\}_2(PMe_2Ph)_2]$ [Reaction (w)].[65]

$$\textit{trans}\text{-}[Pt(C{\equiv}CH)_2(PMe_2Ph)_2] + W_2(OtBu)_6 \xrightarrow[-t\text{BuOH}]{25\,^\circ C,\ \text{hexane}}$$

$$\textit{trans}\text{-}[Pt(C{\equiv}CH)\{C_2W_2(OtBu)_5\}(PMe_2Ph)_2] \xrightarrow[-t\text{BuOH}]{+W_2(OtBu)_6} \quad \text{(w)}$$

$$\textit{trans}\text{-}[Pt\{C_2W_2(OtBu)_5\}_2(PMe_2Ph)_2]$$

trans-$[Pt\{C_2W_2(OtBu)_5\}_2(PMe_2Ph)_2]$ adopts a centrosymmetric structure in the solid state (Fig. 11). The square-planar geometry about the platinum atom together with the observed Pt-P and Pt-C distances and coupling constants ($^1J_{^{195}Pt-^{31}P} = 2776$ Hz and $^1J_{^{195}Pt-^{13}C} = 801$ Hz) are consistent with the view that this compound may be considered a derivative of Pt^{II}. However, the $C_2W_2(OtBu)_5$ moiety shows that redox chemistry has occurred between the $(W{\equiv}W)^{6+}$ center and the C≡C moiety. Indeed, based on C-C, W-C, and W-W distances, the C_2 ligand is best viewed as a dicarbido ligand, C_2^{4-}, with charge being partitioned as −1 to Pt, −1 to W3 and −2 to W2.

2. In that no new metal-metal bonds are formed, the above reaction does not truly conform to the description of a cluster-building reaction. An example of a reaction in which both ligand reduction and M-M' bond formation

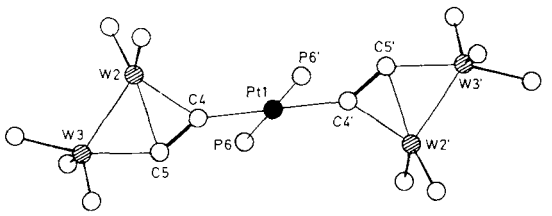

Fig. 11. The structure of the central skeleton of *trans*-$[Pt\{C_2W_2(O/Bu)_5\}_2(PMe_2Ph)_2]$ (ball-and-stick drawing). The PtC_2W_2 unit is planar. Selected distances [Å] and angles [°]: Pt-C4 2.06(1), Pt-P 2.29(1), W-W 2.44(1), W2-C4 2.05(1), W2-C5 2.12(1), W3-C5 2.06(1), W-O 1.91(2) (averaged), C4-C5 1.33(1), Pt1-C4-C5 144.0(1), Pt-C4-W2 140.5(1), W2-C4-C5 74.4(1), W3-C5-C4 140.2(1), W2-C5-C4 68.6(1), W2-C5-W3 71.7(1).

occur is the reaction between $[W_2(OiPr)_6(py)_2]$ ($M{\equiv}M$) and $[Fe_2(CO)_6(\mu\text{-}S_2)]$ ($M{-}M$) [Reaction (x)].[66]

$$[W_2(OiPr)_6(py)_2] + [Fe_2(CO)_6(\mu\text{-}S_2)] \xrightarrow[\text{hexane}]{25\,^\circ C} [W_2Fe_2(\mu_3\text{-}S)_2(OiPr)_6(CO)_5(py)] + py + CO \quad (x)$$

Given the formula $[W_2Fe_2S_2(OiPr)_6(CO)_5(py)]$ one would be hard pressed to predict the molecular structure, which is shown in Figure 12. The ^{1}H-NMR and infrared data of the compound *in solution* are consistent with expectations based on this structure. Furthermore, the molecule is not fluxional on the NMR time scale.

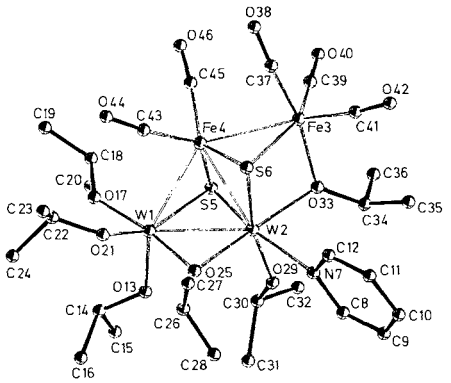

Fig. 12. Structure of $[W_2Fe_2S_2(OiPr)_6(CO)_5(py)]$ in the crystal (ball-and-stick drawing), showing the μ_3-S ligands capping triangular W_2Fe and Fe_2W units below and above the W_2Fe_2 plane. Important M-M distances [Å]: W1-W2 2.714(1), W1-Fe4 2.699(3), W2-Fe3 3.148(3), W2-Fe4 2.632(3).

There are several points worthy of note. 1) The S_2^{2-} ligand in $[Fe_2(CO)_6(S_2)]$ has been reduced to two S^{2-} ligands, which cap the two M_2M' triangles above and below the planar W_2Fe_2 unit. 2) The loss of one CO ligand, formally from Fe4, leaves one Fe atom electron-deficient with respect to the 18-electron rule. The carbene-like Fe center, Fe4, thus adds across the $(W{=}W)^{8+}$ moiety resulting from the S_2^{2-} reduction noted above. 3) The W_2 center has thus been formally oxidized to $(W\text{-}W)^{10+}$, consistent with its W-W distance of 2.714(1) Å and the pseudo-octahedral coordination about each W atom.[8] 4) The electron count at Fe3 satisfies the 18-electron rule in the absence of a W-Fe bond (W2-Fe3 3.148(3) Å) but with a dative bond formed by the μ-O*i*Pr ligand.

4. Concluding Remarks

1. There is an extensive coordination chemistry involving $\sigma^2\pi^4$ triple bonds between molybdenum and tungsten atoms. Not all tungsten and molybdenum d^3-d^3 dimers have this type of M-M bond and the systematic interconversion of various types of d^3-d^3 dimers having the M-M bonding configurations $\sigma^2\pi^4$, $\pi^4\delta^2$, $\sigma^2\pi^2\delta^2$, or $\sigma^2\pi^2\delta^2\delta^{*2}$ remains to be achieved.

2. It is possible to increase M-M bond orders from three to four and to decrease them from three to two or one in a manner somewhat akin to that well documented in organic chemistry. The reactions described here involve oxidative addition or reductive elimination from the dinuclear metal center. The detailed reaction pathway of such reactions remains a topic for active research. The coupling of oxidative addition and reductive elimination opens up the possibility of using these dinuclear centers in catalytic reactions. At least two such processes have already been observed: a) the oligomerization of alkynes in their reactions with $Mo_2(OR)_6$ compounds[67] and b) the isomerization of terminal alkenes to *cis*-2-alkenes by $[W_2(H)(OiPr)_7]_2$.[68]

3. The M≡M moiety provides a building block for the synthesis of heteronuclear compounds. This may be by direct attachment to the M≡M moiety as in the synthesis of compounds of the type $[M_2\{Sn(SnMe_3)_3\}_2(NMe_2)_4]$, which retain the central ethane-like $Sn(N)_2M{\equiv}M(N)_2Sn$ skeleton (M = Mo or W) or by the use of redox reactions involving either ligands or electron-deficient metal centers. The latter often, but not necessarily, afford cluster-building reactions. It is also possible to devise oligomerization reactions involving the M≡M bonds. Thus far, a fascinating array of 12e Mo_4-containing compounds have been characterized. We do not envisage that the reactions should stop here but rather expect that further oligomerization reactions should be possible giving M_6- or M_8-containing compounds.

4. The M_2 center can serve both as a reducing agent and a template for C-C bond coupling reactions involving RC≡CR, RC≡N, and C≡O ligands. These have not been described in this article since a recent review dealt specifically with this aspect of the chemistry of M≡M bonds.[40] It should be noted, however, that the reducing power of the dimetal center, particularly the W≡W bond in $W_2(OtBu)_6$, far exceeds that displayed by mononuclear metal centers. The reactions between alkynes and nitriles, which lead to cleavage of the W≡W bond with formation of W≡CR and W≡N groups, respectively, represent a formal 6e reduction of the RC≡CR or RC≡N ligands. In some instances it takes more than one dinuclear center to effect cleavage of a C-X multiple bond, as is the case in the reaction between acetone and $[W_2(OiPr)_6(py)_2]$ [Reaction (y)], which provides a molecular model for the McMurray reaction.[69,70]

$$2[W_2(OiPr)_6(py)_2] + 2\,Me_2C{=}O \xrightarrow[\text{hexane}]{25\,^\circ C} [W_4O_2(OiPr)_{12}] + Me_2C{=}CMe_2 \quad (y)$$

Clearly, the opportunities for organic and inorganic syntheses using metal-metal multiple bonds are just beginning to be realized.

I thank my co-workers for their various and talented contributions and the National Science Foundation for financial support over the past several years for work in this area.

The Chemistry of the Noncrystalline State

By Stephen R. Elliott, C. N. R. Rao, and John M. Thomas*

This article sets out to describe and account for the chemical and physical consequences of the presence of gross disorder in solids. Knowledge of the structure of such disordered materials is an obvious prerequisite to a further understanding of other properties and behavior, and our current knowledge of the structure of various noncrystalline systems is discussed together with the experimental techniques which need to be employed in order to obtain such information. The so-called glass transition, which takes place as a liquid is supercooled below the crystallization temperature, is discussed in terms of the various models which have been proposed to account for this phenomenon. The effect of noncrystallinity on electronic properties is also discussed, and we highlight new developments in the understanding of electron localization and transport processes. Finally, two applications of amorphous solids are considered in some detail: optical fibers for use in communication networks and "superionic" glasses for possible use in solid-state batteries.

1. Introduction

Many catalysts and catalyst supports, most optical fibers and numerous other optical components, several xerographic photoreceptors and thin-film transistors, large-area solar cells, a substantial proportion of biominerals—these and some other materials of considerable technological and biological importance have one feature in common: they are noncrystalline. Chemists are so innured to the pictures portrayed in textbooks of elemental structural chemistry that they are apt to assume that all solids are devoid of structural irregularity. There is a subconscious tendency to believe that solid materials are composed of unit cells which are regularly stacked or properly packed in a three-dimensionally repeated fashion. But even crystalline solids contain defects ranging in character from those of a point nature (where there are vacancies or interstitial species), to line defects (dislocations) through to sub-grain boundaries (i.e. intersecting or aligned dislocations) which separate microcrystallites of one orientation from adjacent ones of another. Chemists have known for a long time, however, how to produce solids which are noncrystalline even though they may have been ignorant of the structural niceties of such solids—silica glass is an obvious example, but even liquids such as isopentane when cooled to 65 K and ethanol cooled to 90 K form a glass (as anyone who has looked into ways of establishing the validity of the third law of thermodynamics knows), and so do very many other materials. Even metals and alloys, if quenched sufficiently rapidly to low temperatures, can form noncrystalline, isotropic solids.

Noncrystalline solids possess no long-range order (i.e. no translational periodicity—see Fig. 1). Their structure can be viewed as being similar to that of a frozen liquid, but with the thermal fluctuations present in a liquid frozen out leaving only "static" structural disorder. As a result, X-ray diffraction patterns consisting of sharp Bragg spots or rings, characteristic of the periodicity (long-range order) in single crystals or polycrystalline aggregates, respectively, become broadened into diffuse haloes. The same effect is observed of course also for very small microcrystallites (having diameters less than $\simeq 50$ Å), and as such sometimes it is difficult, by diffraction means alone, to determine whether an "X-ray amorphous" material is truly amorphous or just grossly disordered. In certain cases, however, e.g. in the case of Si or Ge, a Bragg peak characteristic of a particular interatomic spacing in the crystal is completely absent in the amorphous phase,[1] and so in such cases there is little or no ambiguity. The atoms in a glass, however, are seldom distributed completely at random, as the simple picture might imply, but rather there is often present a considerable degree of *local* structural or chemical order. The extent of the structural "order" within an amorphous or noncrystalline solid (we use the terms

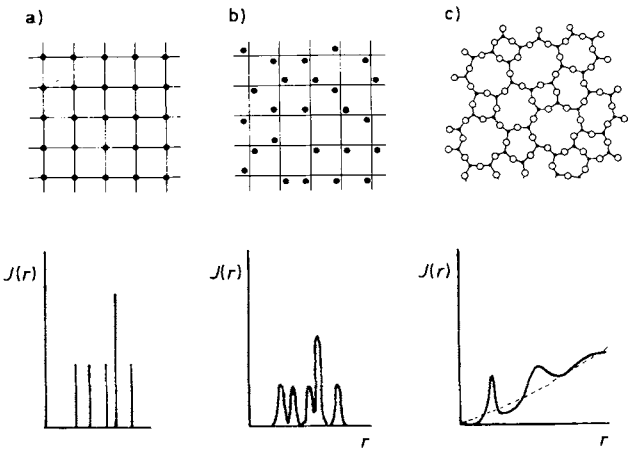

Fig. 1. Types of disorder. (a) Ordered lattice; (b) vibrational disorder; (c) topological disorder. The radial distribution functions (RDFs), $J(r)$, describing such two-dimensional structures are shown below each figure. Note that the widths of all peaks are equal in the RDF of a lattice with just vibrational disorder, whereas the peaks become progressively wider with increasing distance for a topologically disordered structure as a result of static disorder (bond angle fluctuations etc.).

synonymously) is the subject of much current debate and we return to it later in Sections 4 and 5.

A recent exciting development has been the discovery[2] of long-range *orientational* order accompanied by fivefold point-group symmetry in small regions of rapidly quenched specimens of the alloy $Al_{86}Mn_{14}$; tenfold symmetry axes were observed in the patterns of sharp Bragg spots produced by electron diffraction for certain orientations of the specimens. The importance of such observations lies in the fact that classical crystallography precludes the presence of fivefold or tenfold symmetry axes for truly periodic crystals, i.e. those having long-range translational order. Spurious tenfold symmetry in diffraction patterns can be produced by twinning of ordinary crystals, but lattice-imaging micrographs of the Al-Mn alloys clearly reveal the existence of five coexisting sets of atomic planes with normals pointing to the vertices of a regular decagon. Thus, the fivefold symmetry appears to be an intrinsic property, and the structures containing such symmetry elements have been termed "quasi-crystals".[3] Although several theories have been proposed to account for quasi-crystals (see ref. [4] for a review), none at present are entirely satisfactory. Two different approaches have been used: one which focuses on the geometric arrangement of atoms in space, and the other which describes the structure in terms of a density function $\rho(r)$ (or more conveniently in terms of the Fourier transform of the density in reciprocal space, ρ_q) using the Landau theory for crystallization. The former approach was first used by *Levine* and *Steinhardt*,[3] who considered the structure to be constructed from a "Penrose tiling" in three dimensions, a 3D analogue of the 2D aggregates of two types of rhombuses, found to have fivefold symmetry,[5] and which produced optical Fourier transform patterns having tenfold symmetry.[6] The quasi-crystal is distinguished by the existence of two characteristic length scales in the structure, whose ratio is an irrational number; for the case of the Penrose tiling, this ratio is the golden mean, $\tau=(\sqrt{5}+1)/2$. Calculations of the diffraction patterns for such quasi-crystals yield a series of sharp diffraction spots having icosahedral symmetry, in agreement with experiment, even though there is no long-range translational periodicity in the structure. The discovery of fivefold symmetry in diffraction patterns of otherwise apparently perfectly crystalline materials has not just revolutionized the science of crystallography; the theoretical advances required to understand the nature of such quasi-crystalline structures should in turn shed much light on the structure of amorphous materials themselves.

The layman's conception of a "glass" is simply that of an optically transparent, silica-based material; and whilst many amorphous materials produced are indeed of this variety and used in a range of applications, both traditional (window materials, utensils) and advanced technological (glass fibers for optical communications), very many other materials can also be rendered amorphous (see Table 1).[1,7] Some of these non-siliceous amorphous materials have important technical applications. Amorphous selenium films, for instance, form the photoreceptors at the heart of the Xerox process; certain organic glasses are used in an analogous fashion. Some halide glasses have promise as optical fiber materials for use at long wavelengths; amorphous metallic films and ribbons have a variety of prospective applications, including transformer cores and magnetic shielding, superconducting magnetic windings, and high-strength ribbons in fiber-reinforced composites; amorphous films containing a high proportion of chalcogens offer a wide variety of opto-electronic applications, including optical storage media and resists for photo- or electron-beam lithography. Semiconducting amorphous silicon films (containing about 5 percent hydrogen) are currently used as large-area solar cells, for xerography, and as thin-film transistors. In addition many supported catalysts[8] (e.g. 'V_2O_5' on titania[9] used extensively for selective oxidation of hydrocarbons—cf. Section 8) are unquestionably amorphous in the sense conveyed in this article.

Table 1. Some representative non crystalline solids, their principal bonding type and the temperature T_c at which they form when cooled from the vapor, or the glass-transition temperature T_g if cooled from the melt, at an appropriate rate for each material.

Material	Type of bond	T_c [K]	T_g [K]
Tetracene ($C_{18}H_{12}$)	van der Waals	—	< 180
Isopentane	van der Waals	—	65
H_2O	Hydrogen bridges	—	140
Se	covalent	—	320
SiO_2	covalent/ionic	—	1450
BeF_2	ionic	—	600
Bi	metallic	< 4	—
$Au_{0.8}Si_{0.1}Ge_{0.1}$	metallic	—	300

An amorphous solid may be regarded as differing from its crystalline counterpart in containing excess free energy and entropy. These are incorporated during the process of preparation, and this must be sufficiently rapid to preclude the formation of crystalline material by not allowing time for the atoms to reach the lowest energy state, viz. the crystal. Thus, vapor can be rapidly quenched[10,11] to form amorphous thin films using the techniques of evaporation or sputtering, or the glow-discharge or thermal decomposition of unstable molecular species.[1] Crystalline solids can also be rendered amorphous directly by radiation damage by using high-energy neutrons, or electrons or other radiations as in "metamict" minerals such as uranium-containing zircon ($ZrSiO_4$). They may be amorphized even by the simple expedient[11] of allowing solvent molecules of crystallization to evaporate at modest temperatures (see below). Solid-state reactions may also produce amorphous solids from starting crystalline materials. An interesting recent development in this area has been the demonstration[12] that the absorption of hydrogen by a *crystalline* Zr_3Rh alloy produces a hydrided *amorphous* material. The reason for this rather remarkable behavior appears to be that the diffusion coefficients of the metal atoms are less than that of the hydrogen. The most energetically stable *crystalline* products of the hydriding reaction are the hydride ZrH_2 and Rh metal: in order to form these products, there must be an appreciable degree of metal diffusion, which cannot take place at low temperatures, and so an (X-ray) amorphous product is formed instead. But, perhaps the most common technique for preparing noncrystalline materials is by the rapid quenching of a liquid to form a glass—a method discovered accidentally by the

Phoenicians to generate glass from a melt of lime, sand, and soda.

2. The Glass Transition

Glasses are distinct from other amorphous materials by virtue of a characteristic transition, the so-called glass transition, that they exhibit.[13] At the glass transition temperature, T_g, the super-cooled liquid departs from the equilibrium behavior (Fig. 2), the actual value of T_g itself depending on the cooling rate. T_g is generally around $0.67\,T_f$, where T_f is the fusion temperature. The glass transition also has features apparently similar to those found in second-order phase transitions. For example, C_p and other second derivatives of Gibbs' free energy increase sharply at T_g. As seen in Figure 2, the entropy of a liquid would become equal to that of a crystal well above 0K, provided that there is no intervening transition. This problem is circumvented by postulating the existence of a transition at a temperature T_0, (thermodynamic transition temperature) which limits the decrease in entropy. In order to avoid the paradoxical situation as to what happens when $T < T_0$, in the absence of a transition, one assumes that the glass crystallizes at $T > T_0$. What is interesting is that T_0 values estimated from calorimetry (C_p vs lg T plots) are close to those obtained from Equation (1), which describes the temperature variation of viscosity and other dynamic properties:

$$\psi = \psi_0 \exp[A/(T - T_0)] \tag{1}$$

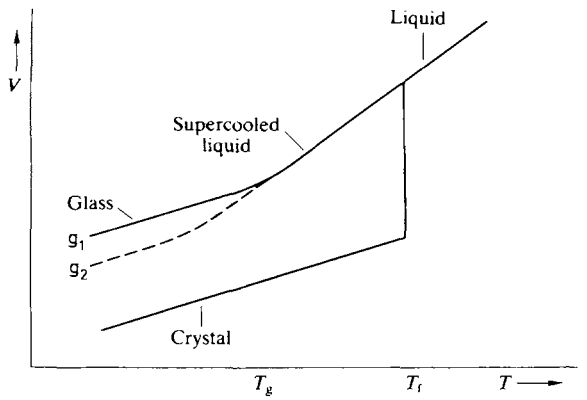

Fig. 2. Schematic illustration of the changes in volume which can occur on cooling a liquid. Crystallization may occur (at T_f), or if the liquid is supercooled below this temperature, glass formation can occur. The temperature marking the break in the slopes of V vs T is termed the glass-transition temperature, T_g. Note that the actual value of T_g varies with cooling rate q ($q_1 > q_2$; the T_g value in the figure holds for q_1).

An "ideal" glass has been defined as one in which T_g approaches T_0. Nonideality of a glass would then be a measure of the entropy frozen in at T_g (this becoming zero when $T_g = T_0$). The existence of a thermodynamic transition at T_0 has not been observed so far, since relaxation times are too long below T_g. The experimental T_g itself occurs when the relaxation time attains a constant value on the time scale of the experiment.

A variety of relaxation, spectroscopic and other techniques have been employed to investigate the behavior of various properties of glass around T_g, but the nature of the glass transition is still not completely understood.[13, 14] Noteworthy among the various models proposed for the transition are the free volume model[15] and the configurational entropy model,[16] and these have been reviewed in the literature.[13]

The entropy frozen-in below the glass transition has a fairly large non-configurational component. The role of communal entropy has been considered and it is suggested that the communal entropy vanishes at T_g, when the liquid-like properties cease to exist.[17] This would require the glass transition to be insensitive to cooling history, but this is contrary to experience. Recent computer experiments[18] as well as electron microscopic studies[19] have indicated the existence of ordered regions or clusters (with noncrystalline motifs) distributed in a tissue material of lower density. When clusters grow in number and size, a congelation to a glass occurs resulting in the elimination of configurational entropy; the tissue material in the intercluster regions could continue to undergo configurational changes, thereby accounting for significant values of the configurational entropy. A cluster model of the glass transition has been developed with the relative size of the cluster as the order parameter.[20]

The term glass transition is generally used in connection with positionally disordered materials, but the transition is also found in solids that are characterized by other degrees of freedom. For example, orientational disorder in plastic crystals may be quenched to yield "glassy crystals" which exhibit glass-like transitions.[21] Disorder in dipole interactions may be frozen-in to yield dipole glasses (similar to spin glasses), typical examples[22] being KBr doped with CN^- ions or $KTaO_3$ doped with Li^+. Frozen liquid crystals are also found to exhibit glass-like transitions.[23] Thus, the glassy state includes long-range disorder of many types while the glass transition manifests itself when relaxational and experimental time scales intersect.

Simulation of the local structures of liquids has its origins in the classic work of *Bernal* who used mechanical assemblies for this purpose. The importance of non space-filling symmetries (such as the icosahedral and the pentagonal) to "ordered" aggregates in the amorphous state has been indicated by some of the studies. The role of such aggregates or clusters in understanding the glass transition was pointed out earlier. Computer simulation studies[24] have yielded useful information on the prototype glass transition in simple liquids, although the use of high quenching rates limits the applicability of the results. The high fictive temperatures of the simulated glasses suggest high diffusion rates. Both hard and soft spheres can be compacted into amorphous assemblies, but the characteristic C_p discontinuity is absent in these cases. The hard sphere ensemble shows that the diffusivity D does not vary linearly with free volume at low temperatures and V_0^D in Equation (2),

$$D = A \exp[-B/(V - V_0^D)] \tag{2}$$

seems to represent the *Bernal*'s limiting dense random packing of hard spheres. Computer simulation studies have yet to demonstrate clearly the existence of the C_p

overshoot, which is the hallmark of the experimental glass transition. Molecular dynamics simulation studies do, however, provide valuable insights into ion movements in glasses.[25]

3. Vitreous Water or Amorphous Solid Water

Water is by far the most common substance that one can think of and yet its extraordinary properties and behavior continue to confound us. While the various models and predictions have helped in understanding the nature of liquid water, they have always met with failure of one kind or another. Amorphous solid water can be produced by vapor deposition of dilute gas molecules on a cold substrate.[26] The resulting material appears glassy and is amorphous to X-rays. A glass transition has been noticed in such deposits[27] and the T_g predicted by the extrapolation of data for binary salt solutions (139 K) was until recently considered to be consistent with the T_g obtained by thermal measurements.[28] The heat capacity of amorphous solid water measured by adiabatic calorimetry does indeed show an increase, as expected of a glass transition.[29] The extrapolated T_g was however not considered to be compatible with the heat capacity of liquid water.[28]

The structure of amorphous solid water prepared by vapor deposition is not different from what is expected for the low-temperature ground state for liquid water. Ultrafast quenching of samples of liquid water has been found to produce amorphous material similar to that prepared by vapor deposition; furthermore, crystallization does not occur during such cooling.[30,31] Crystallization of amorphous solid water occurs around 162 K. What is rather puzzling about amorphous solid water is the very recent observation[32] that no thermal manifestation of the glass transition occurs anywhere in the temperature region predicted by the extrapolation of the data on binary salt solutions.[32] It appears that water in the amorphous state is not any easier to understand than in the liquid state.

4. The Structure of Amorphous Materials

The determination of the structure of amorphous materials has remained a challenge ever since X-ray diffraction was first used as a structural tool for such solids in the 1930's. The problem lies in the fact that in the absence of periodicity (i.e. regularly spaced planes of atoms), the scattering of X-rays (or neutrons or electrons) produces diffuse haloes of scattered intensity, rather than the sharp Bragg spots or lines characteristic of single crystals (see Fig. 3 and 4). Expressed in terms of the scattering vector, $k = 4\pi \sin\theta/\lambda$, in reciprocal space, the intensity is a damped series of broad oscillations superimposed on the square of the atomic form factor, $f_x^2(k)$. Real-space information can be obtained from the scattered intensity data by Fourier transformation after suitable normalizations have been carried out. The resulting curve, the radial distribution function (RDF), $J(r)$, exhibits peaks (Fig. 3b) at distances corresponding to the *average* interatomic separation for the first shell, second shell, etc., superimposed on a background curve, the average density parabola, $4\pi r^2\rho^0$. Although there is a severe problem for higher-lying peaks in that *different* shells can contribute to the *same* peak in the RDF, nevertheless, for the first (and second) peak, the *area* under the peak in the RDF gives the coordination number directly.

The difficulty with a structural interpretation of the RDF of an amorphous material lies in the fact that the RDF is an average quantity; it describes the spatially averaged structural arrangement about a given origin atom, and is a chemical average over all types of atom in the sample. Just as in endeavoring to describe the structure of a liquid via RDF's, we proceed likewise with amorphous solids. The very same obstacles encountered in specifying the structure of liquids are also encountered here: the RDF itself is not sufficiently sensitive to variations in the model, partly because it is a spatially-averaged property.

Since very many amorphous materials contain several

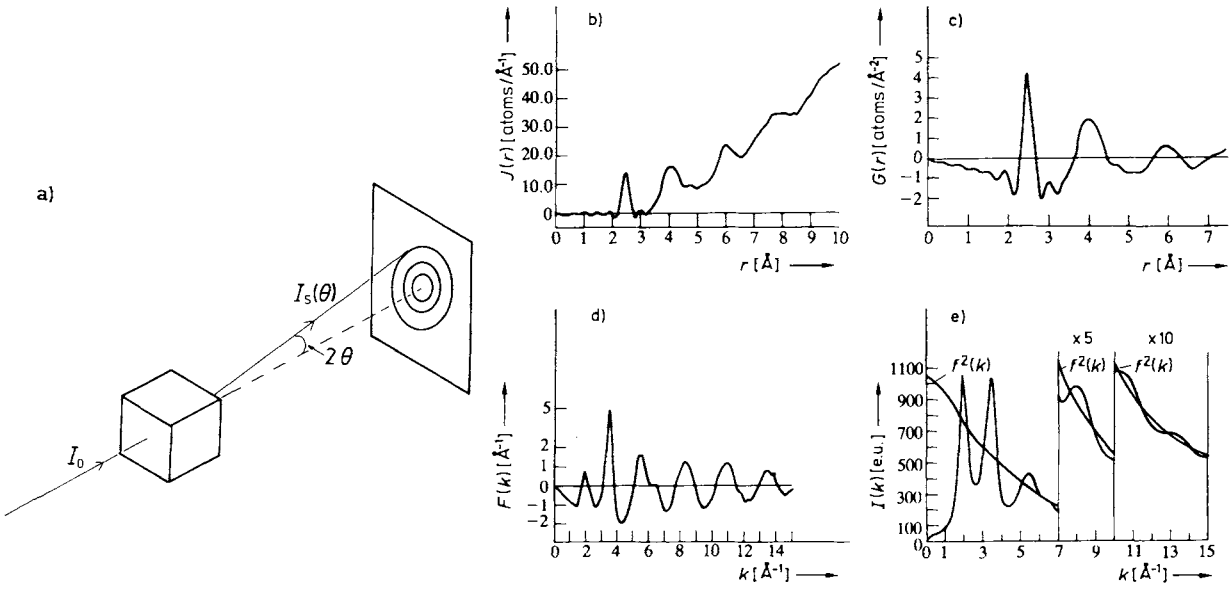

Fig. 3. (a) Schematic illustration of the experimental arrangement used in a diffraction measurement; (b)-(e) X-ray scattering data for a-Ge (after *Temkin* et al. [33]). (b) the RDF (cf. Fig. 1c); (c) the reduced RDF; (d) the reduced scattering intensity; (e) the total (corrected) measured scattering intensity.

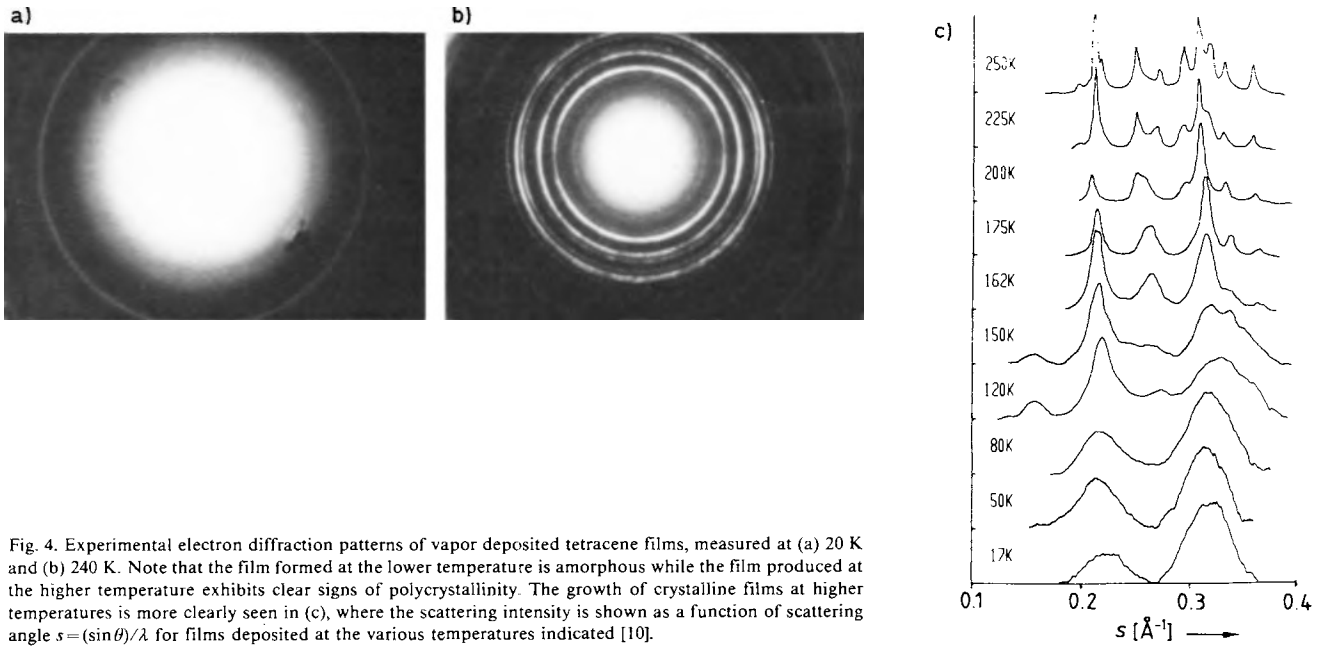

Fig. 4. Experimental electron diffraction patterns of vapor deposited tetracene films, measured at (a) 20 K and (b) 240 K. Note that the film formed at the lower temperature is amorphous while the film produced at the higher temperature exhibits clear signs of polycrystallinity. The growth of crystalline films at higher temperatures is more clearly seen in (c), where the scattering intensity is shown as a function of scattering angle $s=(\sin\theta)/\lambda$ for films deposited at the various temperatures indicated [10].

components, this lack of chemical specificity of conventional diffraction techniques is a severe handicap. One technique which is chemically specific and of considerable promise is the method of extended X-ray absorption fine structure (EXAFS).[34–36] In this, X-rays from a broad-band source (e.g. synchrotron radiation or Bremsstrahlung from a conventional X-ray generator) eject photoelectrons from an atom if the X-ray photon energy is greater than the binding energy of a core electron (say from the K-shell). The photoelectron will be backscattered from any surrounding atoms and interference can occur between outgoing and backscattered states, depending on the energy of the initial X-ray (and hence the kinetic energy of the photoelectron); in this way the X-ray absorption coefficient is modulated, leading to "fine structure" on the high energy side of the (K) edge (see Fig. 5). The method is chemically specific because the X-ray absorption edges of different atoms fall at different energies, and hence the EXAFS for different elements can be well separated in energy (Fig. 5b). Real-space structural information can be obtained from the experimental EXAFS data by Fourier transformation after suitable background subtractions and normalizations. The method is particularly sensitive to the nearest-neighbor environment, but does not probe interatomic correlations beyond about the third nearest neighbor. It is a technique particularly suited for the structural study of disordered materials since it does not depend for success upon the presence of long-range order.

Another technique which is capable of elucidating the structural characteristics of simple (elemental or binary) amorphous materials is electron Compton scattering.[38,39] Compton scattering generally, whether it involves scattering of γ (or X-ray) photons or high energy electrons, can yield[39] the ground state wave-functions of the material under investigation. Even when there is no long-range order, the local electronic environment surrounding a central atom can be probed via the so-called reciprocal form factor. As the form factors for the corresponding crystalline materials are well known by separate determinations, the experimentally derived Compton profile yields the reciprocal form factor, $B(z)$, as defined in Equation (3).

$$B(z)=\int_{-\infty}^{+\infty}\exp(ip_z\cdot z)J(p_z)\,\mathrm{d}p_z=\iiint_{-\infty}^{+\infty}\psi(r-z)\psi(r)\,\mathrm{d}r \qquad (3)$$

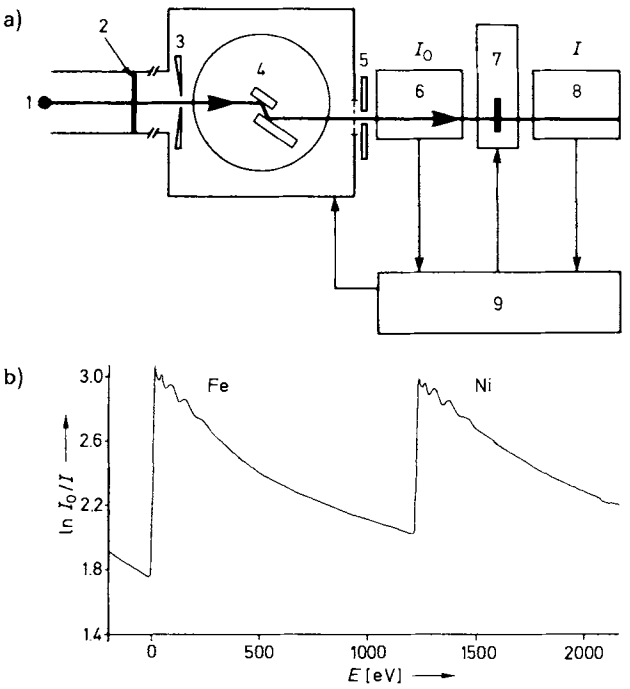

Fig. 5. (a) Schematic illustration of the experimental arrangement employed for transmission EXAFS measurements. 1: Source point of synchroton radiation; 2: Be window; 3: slit; 4: monochromator channel-cut crystal; 5: mask; 6, 8: ionization chambers 1 and 2 in which intensities of the incident and transmitted X-rays, respectively, are measured; 7: sample; 9: computer. (b) K-edge EXAFS spectra of Fe and Ni in $Fe_{40}Ni_{40}B_{20}$ glass at 77 K (after [37]). E signifies energy above Fe K edge.

In other words, the Compton profile $J(p_z)$ [Equation (4)], defined as the projection of the momentum density $\rho(p)$ onto the scattering vector p_z, where

$$J(p_z) = \int_{-\infty}^{+\infty} \rho(p)\,dp_x \cdot dp_y \qquad (4)$$

can be determined directly from experimental Compton profiles. The reciprocal form factor is[38] the overlap of the ground-state wave-function with itself as a function of the distance r. For the amorphous material, this gives us a means of ascertaining the local bonding. In this way it was recently established[40] that noncrystalline elemental carbon involved predominantly sp^2 not sp^3 bonding (i.e. was essentially graphitic).

Another chemically specific structural probe which has great potential for the study of amorphous solids is nuclear magnetic resonance (NMR),[41] which is capable of giving high-resolution (liquid-like) spectra if special ancillary techniques such as magic-angle spinning or multiple-pulse sequencing are employed with modern pulse (Fourier transform) spectrometers;[42] the method is again sensitive mainly to the nearest-neighbor environment. Earlier broad-line NMR studies[43] yielded important, but somewhat limited, structural information, particularly concerning borate glasses. ^{29}Si magic-angle-spinning NMR (MAS-NMR) is proving to be particularly useful in both crystalline and noncrystalline siliceous solids.[44] There is a well-established correlation[45] between the anisotropic ^{29}Si chemical shift (δ values; standard: tetramethylsilane) and the T-O-T angle (T≡Si or Al) given by

$$\delta = -25.44 - 0.5793\ (\theta/\text{deg})$$

so that quantitative deductions about local structure can be made from the observed ^{29}Si chemical shifts. When zeolite A, an aluminosilicate (having the empirical formula $Na_{12}Al_{12}O_{48} \cdot 27\,H_2O$) crystallizes out from an amorphous gel precursor the change in T-O-T bond angles in going from $Si(O\text{-}Al)_4$ (gel) to $Si(O\text{-}Al)_4$ (zeolite A) results in a readily detectable change (from -85.1 to -90.8 ppm with respect to tetramethylsilane TMS) in the ^{29}Si isotropic shift characteristic of the $Si(OAl)_4$ environment. Conversely, when zeolite-A is rendered amorphous by high-temperature (hydrothermal) treatment typical of that employed in procedures for burying radioactive waste, the chemical shifts (and line widths) change as shown in Figure 6.

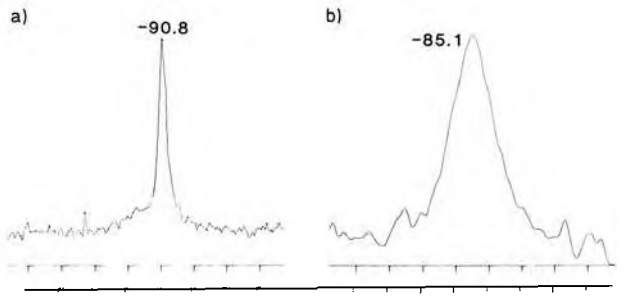

Fig. 6. Section of the ^{29}Si MAS-NMR spectrum of zeolite A (a) before and (b) after amorphization (e.g., as in the sealing of radioactive waste for disposal) [8]. δ values, standard TMS.

Dupree and *Pettifer*[46] have recently shown how line shapes in ^{29}Si-MAS-NMR spectra can be used to set limits to the T–O–T angles present within a glass.

MAS-NMR is ideally suited to probe local site environments and to determine changes in site occupancies during solid-state transformations. So far, most work has been done on systems containing ^{27}Al, which, being a quadrupolar nucleus, relaxes rapidly, thereby yielding good-quality spectra in relatively short-duration experiments.[44] But there is clearly abundant scope for the exploration of organic glasses (via the ^{13}C, ^{1}H, ^{2}H and ^{3}H nuclei) and for a variety of inorganic systems with the *sixty* or so nuclei that exhibit magnetic resonance of acceptable intensity.

5. Models of the Amorphous State

One of the first models to describe the amorphous state was proposed by *Zachariasen* in 1932 for the case of *covalently bonded solids*.[47] The structure was supposed to be formed from polyhedra (e.g. SiO_4 tetrahedra in the case of SiO_2), connected together to form a "*continuous random network*" (CRN), in which long-range order is destroyed by allowing freedom of rotation of neighboring polyhedra about the connecting atom, i.e. the T-O-T angle is allowed to take up a variety of values. Note that the term "random network" is somewhat of a misnomer here, for the structure is not truly random in the statistical sense; well-defined local order exists in the glass by virtue of the existence of the polyhedra, and if the polyhedra connect together to form say rings, then the distribution of torsion ("dihedral") angles for neighboring units is not uniform (i.e. random), but instead certain dihedral angles are preferred.

In 1971, *Polk*[48] demonstrated that it was possible to build an extended continuous random network (consisting of 440 atoms), based on an invariant coordination number of four, for tetrahedrally bonded amorphous semiconductors such as silicon and germanium. The key point about *Polk*'s work was that even when all bond lengths were kept close to their equilibrium value (for the crystalline state) no intolerable bond-length strain was produced, provided a modest spread in angles was permitted. Significantly, five-, six-, and seven-membered rings were present in such a continuous network—there are only six-membered rings in the crystalline semiconductors but, even more important, the density of the resulting noncrystalline structure differed from that of the corresponding (diamond-like) structure by about one percent. The message here is that, for covalently bonded, relatively simple amorphous solids (Si, Ge, SiO_2, GeO_2, etc.) the short-range order is very similar to that which prevails in the corresponding crystals. (Even in the ionic noncrystalline solid formed by BeF_2, 4:2 coordination is still retained in view of the magnitude of the respective ionic radii, $r_{Be^{2+}} = 0.27$ Å, $r_{F^-} = 1.31$ Å, thereby favoring 'tetrahedral' coordination of fluoride ions around the central cations.)

The question of "intermediate-range" order, beyond the short-range local structure characterized by the polyhedral units in covalent glasses, is also of much current interest. In particular, there is a growing body of evidence for the

existence of rather well-defined clusters of atoms, containing 10 or more atoms, in the structure of certain covalent glasses (e.g. Ge–Se alloys); vibrational spectroscopy as well as diffraction experiments indicate their presence, and, as we have seen, certain aspects of glass-transition behavior can be understood in terms of the existence of clusters (see Section 2).

Polymeric solids, typified by polystyrene, poly(vinyl chloride) and poly(vinylidene chloride) more often than not are noncrystalline—some chemical ingenuity is required to produce crystalline polymers—and here the "*random coil model*" is the most appropriate description (see Fig. 7). Like the continuous random network model, the random coil model implies a homogeneous, single-phase solid. It is superior to an earlier, contending theory proposed to account for the behavior of polymeric organic glasses, namely the microcrystalline model, in which microcrystallites of crystalline polymer are embedded in a surrounding noncrystalline matrix. This is incompatible with all the experimental facts for organic glasses, as it is also for most other kinds of glasses. There are, however, partially crystalline polymers (e.g. poly(4-methyl-1-pentene) and poly(ethylene glycol)) in which well-defined coiled regions *are* embedded within the randomly coiled analogue. Likewise, in polyethylene it is well-known that there are amorphous regions connecting the ordered, folded-chain elements in the so-called crystalline material.

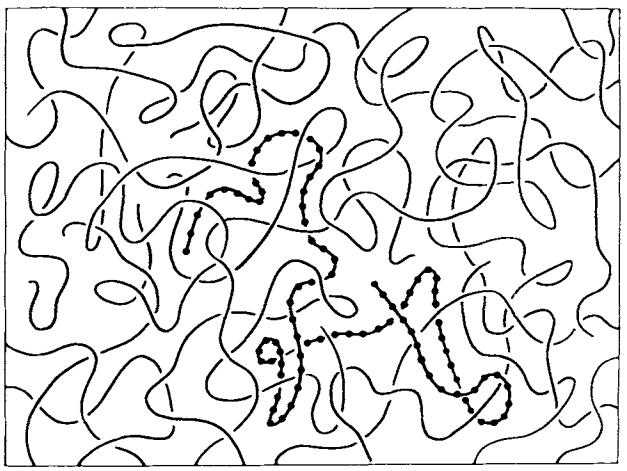

Fig. 7. Schematic diagram of the random-coil model for the structure of polymeric glasses. One chain is clearly marked for ease of visualization (after [7]).

Ionic-covalent, noncrystalline solids are typified by amorphous zeolites (general formula $M_{x/n}(AlO_2)_x(SiO_2)_y \cdot m\,H_2O$). Here, there are several levels of structural order in the parent crystalline form: local order, such as tetrahedrally coordinated Si^{4+} and Al^{3+} ions forming TO_4 tetrahedra, and variously connected tetrahedra which produce a range of possible polyhedral units (Fig. 8a) that can, in turn, be joined to form a three-dimensional solid (Fig. 8b). In partially amorphized zeolitic structures the scale of residual local ordering is such as to be quite amenable to high-resolution electron microscopy (Fig. 9a). Islands of crystalline structure, as well as more or less isolated patches consisting of a few (or a single) polyhedral units, can be directly identified[49–51] in such micrographs. Moreover, if strongly scattering ions (e.g. UO_2^{2+}) are introduced, by ion exchange, into the microcrystalline region of a zeolitic glass, the locally ordered parts of the solid are readily seen[51] (Fig. 9b). For comparison Figure 9c shows an HREM image of dehydrated silica gel which is thought to be a *bona fide* example of the continuous random network model.[49]

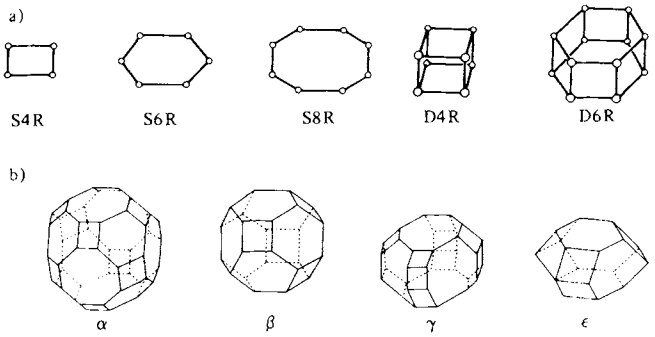

Fig. 8. (a) Simple building blocks and (b) various kinds of polyhedra formed when TO_4 tetrahedra are corner-linked. S, D and R denote single, double and ring respectively. Thus a hexagonal prism, being a double six ring, is designated D6R. The β cage is made up of eight S6R and six S4R.

Glassy metals and metallic *alloys* are best thought of, structurally, as being made up of a *dense random packing of hard spheres*. The notion of dense random packing (DRP) figured eminently in the classic work of *Bernal*[52] on the structure of monoatomic liquids. *Bernal*'s work on liquids involved ball bearings packed into rubber bladders, kneaded, set in black paint with the positions analyzed by hand and eye. Later variants of this approach entailed computer simulations. All these approaches showed that it is possible to generate a randomly-packed model which is sufficiently dense (64 per cent occupancy of available space compared with 74 per cent in cubic or hexagonal close packing of spheres) to reproduce experiment. Such a DRP model involves no crystalline regions provided the spheres are not bounded by a regular surface. (Spheres poured into a cylinder can be densely, randomly packed: this is not the case if poured into a cubic or rectangular box!)

Whereas it is well known that, in the closest packing of spheres (as in crystalline metals such as Ag, Au and Pt), there are 'holes' which are tetrahedral and octahedral in shape (as indeed there are in close-packed anions, e.g., in the structures of Fe_2O_3 and Fe_3O_4), *Bernal* observed that, in the DRP model, holes were of five distinct types. In addition to the tetrahedral and octahedral holes (see Fig. 10) there are three others. All these are polyhedra with equal triangular facets (i.e. deltahedral objects) which are small enough not to admit another sphere of the same size. These are known as Bernal's 'canonical holes'. It transpires that an almost indefinite number of structures, each with almost identical nearest-neighbor distances, can be formed by packing the five deltahedra together. *Finney* constructed a dense randomly packed structure, composed of 7994 'atoms' with a packing efficiency of 44 percent. The (total) radial distribution function (see Fig. 11a) for this structure compares well with that determined experimentally for amorphous $Ni_{76}P_{24}$, although the agreement

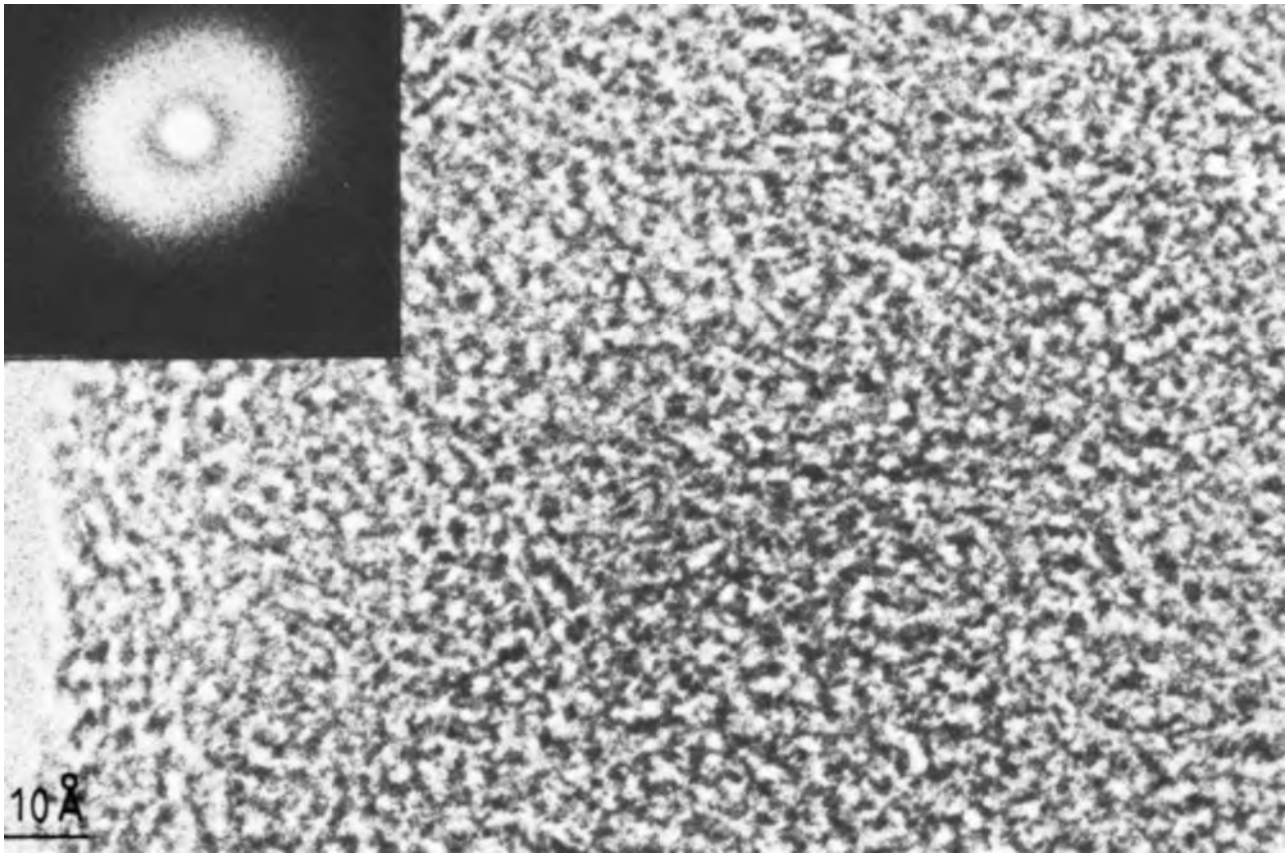

Fig. 9c. High resolution electron micrograph of random network amorphous region of dehydrated silica gel.

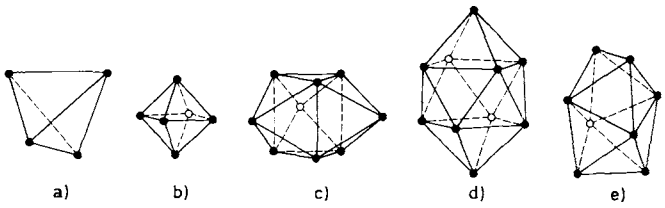

Fig. 10. The five "canonical" holes described by *Bernal*. They are a) tetrahedron; b) octahedron; c) trigonal prism (capped with three half-octahedra); d) Archimedian anti-prism (capped with two half-octahedra); e) tetragonal dodecahedron.

for the individual partial pair correlation functions is less good (Fig. 11b and c).

The DRP model does, however, certainly seem to account well for the structure of amorphous metal-metal alloys, say Zr-Cu. However, there is an important class of amorphous metallic alloys which do not appear to be described by this model—these are the so-called "metglas" alloys formed from approximately 80% transition metal and 20% semimetal (e.g. B, Si, P), this being approximately the eutectic composition. In these materials, chemical or-

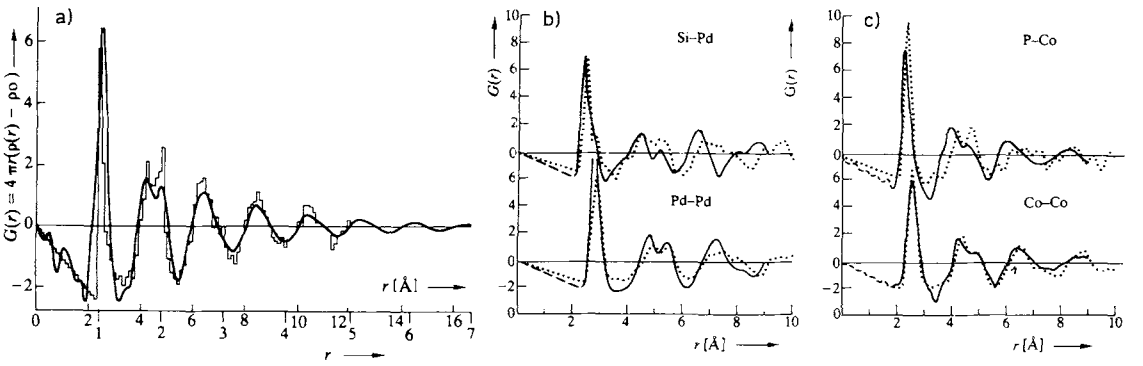

Fig. 11. Reduced radial distribution curves $G(r)$ (cf. Fig. 3c). (a) Calculated for the Finney DRP model compared with the experimental curve for a Ni-P glass; (r is given in units of the diameter of the sphere); (b) and (c) reduced RDFs calculated for the Gaskell trigonal prismatic model compared with experimental curves for Pd-Si and Co-P glasses.

dering beyond that expected for the DRP model appears to exist, and a detailed understanding of the structure is lacking, although it has been suggested that crystalline motifs such as trigonal prismatic units might exist in the glass. It is well known[53] that the structure of *crystalline* transition metal-semimetal alloys, such as cementite (Fe_3C) or Fe_3P (not quite the same composition, note, as that of the glasses, which is approximately Fe_4P, for example) comprise trigonal prismatic structural units consisting of MT_6 arrangements, in which M is the semimetal and T the transition metal (see Fig. 10c). It has been suggested by *Gaskell*[53] that the structure of the glassy alloys also consists primarily of such well-ordered local units (see Fig. 11b). In this way, semimetal-semimetal nearest-neighbor avoidance is achieved (consistent with diffraction evidence), which is not the case for the DRP model, in which it is supposed that the small semimetal atoms, such as P, reside in the canonical polyhedral holes in the structure, and as such, there is nothing to stop them being nearest neighbors. It is of interest to note in passing that the trigonal prismatic model for the structure of metallic glasses can be thought of as a bridge between the CRN and DRP approaches; it can be regarded as a random network of trigonal prismatic structural polyhedra (somewhat distorted to allow complete connectivity), or alternatively, since the trigonal prism is one of the Bernal canonical holes, it can be regarded as a special case of a DRP, in which only one type of polyhedron is allowed to exist. The precise structure of metal glasses is, however, still the subject of some dispute.

The general question of the extent of chemical ordering in amorphous materials is of considerable interest. In crystalline solids, nonstoichiometry can be achieved by several distinct means.[54] Certain crystalline solids can be progressively denuded of one of their constituents leaving the structure more open but in broad architectural terms quite intact. Some perovskites (ABO_3), e.g. $CaMnO_3$, behave[55,56] in this fashion when reduced by H_2 or hydrocarbons to yield ABO_{3-x} ($0 < x < 0.5$), the residual oxygen vacancy sites adopting ordered structures. Another way in which gross nonstoichiometry can be accommodated is for local, but well-defined collapsed regions, such as crystallographic shear planes, to be introduced at intervals through the bulk solid whilst, at the same time, preserving the local coordination, e.g. $MO_3 \rightarrow MO_{3n-1}$, MO_{3n-2}, MO_{3n-3}, etc. ($n = 3 \ldots 20$). In amorphous materials however, gross nonstoichiometry, which can be more or less continuously varied, can be achieved in a different manner, there being no translationally repeated sharply-defined architectural unit in the structure to begin with. This continuous variation can be realized, for the case of a covalent solid, by the local environment changing, so that, say, more like-atom bonds of the elements in excess of that corresponding to stoichiometry are produced.

6. Structural and Chemical Changes in Noncrystalline Solids

It should not be thought that the structure of an amorphous solid is immutable. For instance, a glass quenched rapidly from the melt is in a metastable state, in several senses. If it is held at a temperature near T_g for a sufficient length of time, the structure "stabilizes", and the glass evolves to a state characteristic of a material produced using a slower quench rate. Apart from being able to explore such local, shallow potential minima, the glass is of course energetically metastable with respect to the crystalline state, and will tend to crystallize if held at or above T_g for a sufficiently long period of time. An as-deposited amorphous thin film can also have its structure altered in this manner by thermal means.

There are indications[57] that considerable motion, including transport and agglomeration of ions may occur rather freely within noncrystalline structures. Some polyethylene oxide and organic polycarbonate glasses, for example, permit facile migration of ions such as Li^+ at low temperatures (ca. 60–80 °C) and this fact is harnessed[58] in certain types of solid-state batteries (e.g. those utilizing metallic lithium and TiS_2 into which Li^+ species are readily incorporated).

Another phenomenon, worthy of further investigation, is the precipitation from glassy materials at relatively very low temperatures, of phases which are normally prepared at much higher temperatures. Thus, FeS crystallizes[59] out of a Fe-containing As_2S_3 noncrystalline solvent. Certain glasses, based on alloys containing S or Se, suffer[60] structural changes when irradiated by light. The nature of such photostructural changes, which can be removed by annealing at T_g is, at present, uncertain, although the photoinduced changes are not confined to the structure alone since changes in the optical properties and even in chemical properties (e.g. photo-enhanced dissolution of metals) are also observed. These effects have many potential technological applications, including optical storage media and resists for photo- or electron-beam lithography.

7. Electronic Properties

The effect of structural disorder on the electronic properties of solids may at first sight be thought to be small: glasses can be variously metals, semiconductors or insulators, like crystals, and indeed even the overall shape of the bands of electron states in an amorphous solid (e.g. Si) can be broadly similar to that observed in the corresponding crystal (see Fig. 12). However, the presence of disorder does have[61–63] at least two very important ramifications: electrons can be spatially *localized* by the existence of spatial (topological) disorder, and the absence of periodicity means that the reciprocal lattice vector, k, is no longer a good quantum number. (It should be noted in passing that disorder can produce exactly the same effects for vibrational excitations, i.e. phonons.)

There obviously cannot exist a *reciprocal* lattice if a periodic *spatial* lattice is absent, as is the case for a disordered material, and thus the reciprocal lattice vector k becomes redundant as a description of the solid and of the excitations (electronic or vibrational) which occur within it. The unimportance of k for disordered solids leads to an immediate paradox, namely, why theoretically should a forbidden energy gap appear between bands of states for an

amorphous material? It is common experience that this is the case: for instance, common silicate glass is transparent to photons in the visible spectrum (and indeed has a band gap of almost 10 eV). The paradox arises because electrons in *crystalline* solids are conventionally described within the Bloch formalism, i.e. the electron wave function has the form of a plane wave, modulated according to Equation (5) by the function $\mu_k(r)$, which has the periodicity of the underlying lattice:

$$\psi_k(r)=\mu_k(r)\exp(ik\cdot r) \tag{5}$$

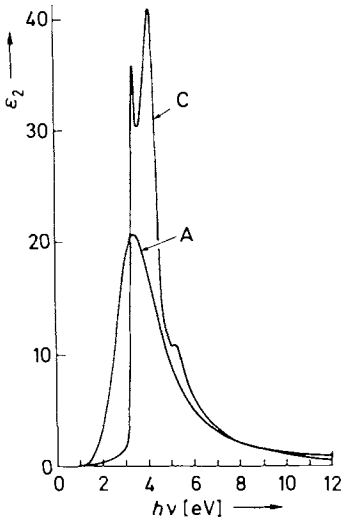

Fig. 12. Optical absorption spectra for crystalline (C) and amorphous (A) silicon. The shape of the absorption bands is related to the joint density of states. Note the sharp features in the spectrum of the crystal (a result of the constraint of k-conservation and the existence of singularities in the joint density of states) are absent in the spectrum of the amorphous material as a result of the loss of k-conservation (ε_2 is the imaginary part of the dielectric constant).

Interference between Bloch waves results in standing waves being set up and an energy difference (band gap) arises for the cases where the electron density is concentrated near the ion cores and where it is concentrated between the cores. Such an explanation is manifestly inapplicable for noncrystalline materials, and instead of invoking long-range order and its effect on the electrons, the answer must be sought in the *local* order in a glass. We have already seen that indeed the local order of (covalent) materials is very similar for both the amorphous and crystalline forms; for example Ge and Si in both forms consist of atoms in tetrahedral coordination. If just two (short-range) interactions are considered between the sp^3-hybrid orbitals emanating from each atom, one an intersite interaction (V_2) responsible for the separation of bonding and antibonding orbitals and the other (V_1) an intrasite interaction responsible for the width of the bands (see Fig. 13), then according to *Weaire* and *Thorpe* a gap between valence and conduction band is predicted as long as the following condition is satisfied:[63]

$$V_2 > 2V_1 \tag{6}$$

Thus, the existence of a band gap for a noncrystalline solid can be understood in terms of *chemical* concepts.

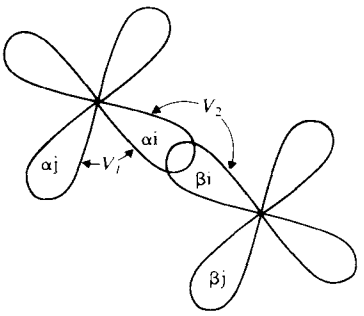

Fig. 13. Weaire-Thorpe model: Intersite (V_2) and intrasite (V_1) interactions.

There are two further consequences of the unimportance of k in disordered materials which are worth mentioning here. The first is that electron (or phonon) states cannot be described in terms of a "band structure", i.e. E vs k (or equivalently a dispersion curve, ω vs q), but instead the "density of states" is the only parameter which equally well applies to an amorphous material as to a crystalline solid. (See Figure 14 for a schematic representation of the form of the density of electron states for an amorphous semiconductor.) The second ramification of the fact that k is no longer a good quantum number is that optical spectra are affected. In crystals, periodicity dictates that the wave vector of the initial and final states involved in the transition is conserved; no such restriction applies for the amorphous case and as a result the spectra of amorphous materials do not exhibit the sharp features characteristic of crystals and which are due to critical points in the joint density of states (i.e. when $\nabla_k E=0$) dominating the matrix element for the transition (see Fig. 12).

The other important effect of disorder on electron states is the possibility of *localization*. Whilst this behavior is not unusual as viewed by a chemist, for whom the concept of localization of electrons in molecular orbitals is commonplace, it is most unusual for those versed in conventional *crystalline* solid-state theory, such as physicists, for whom the electron states in solids are viewed in terms of essentially free electrons only weakly scattered by the ion cores. One approach proposed by *Mott* et al.[61] is that in an amorphous material there exists a critical energy below which (for electrons in the conduction band) the electrons are spatially localized in the region of a single atomic site, and above which they are spatially extended throughout the material, as in a crystal, although the phases of the wave function may be random from site to site. This picture is indicated in Figure 14, and the critical energies E_c in the conduction band and E_v in the valence band are often termed "mobility edges". This is because electrons in extended states, say just above E_c, do not require thermal energy for transport in the bands (their motion being diffusive) and consequently they have relatively high mobilities ($\mu \simeq 10\ cm^2\ V^{-1}\ s^{-1}$), whereas localized electrons can only move from site to site via interactions with phonons and consequently their mobility is activated and much smaller ($\mu \simeq 10^{-2}\ cm^2\ V^{-1}\ s^{-1}$); the thousandfold change in mobility (and hence conductivity) at E_c and E_v means that ($E_c - E_v$) marks a "mobility gap" even though the density of (localized) electron states may well extend considerably

into this region and be continuous through E_c and E_v (see Fig. 14).

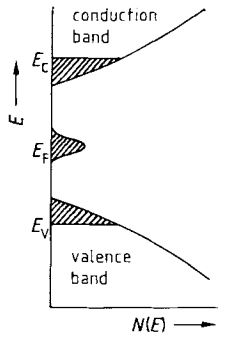

Fig. 14. Schematic density of states, $N(E)$, for an amorphous semiconductor. The mobility edges at E_c and E_v are shown, and all states lying in energy between these levels are localized (and shown shaded). A band of states near the Fermi level, E_F, due to defects, is also shown.

It should be mentioned in passing that structural effects such as dangling bonds have electron states which lie approximately in the middle of the gap, near the Fermi energy, E_F. Electrical conduction by means of transport amongst these levels can only proceed by a process of phonon-assisted tunneling, in which the probability of transfer between two sites separated in distance by R and in energy by W (see Fig. 15) is given by

$$p = \nu_{ph} \exp(-2\alpha R) \exp(-W/kT) \tag{7}$$

where ν_{ph} is a typical phonon frequency. The first exponential factor represents the tunneling probability between the two sites having localized electron wave functions associated with them of the form $\psi \propto \exp(-\alpha r)$, and the second factor represents the probability of a phonon existing having an energy W. At very low temperatures, the proba-

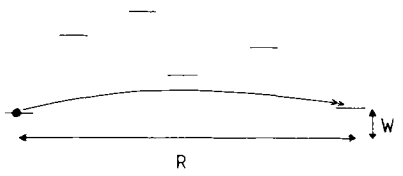

Fig. 15. Schematic diagram of the variable-range hopping process for electron transport among defect electron energy levels near the Fermi level at low temperatures.

bility of electron transfer can be optimized by tunneling, *not* to the nearest site but to a more distant site which has a smaller energy difference, W. Optimization of this sort led *Mott* to derive his famous law for "variable-range hopping" [Eq. (8)] where the factor A is defined by Equation (9)

$$\sigma = \sigma_0 \exp(-AT^{-1/4}) \tag{8}$$

$$A = 2.1[\alpha^3/kN(E_F)]^{1/4} \tag{9}$$

and where $N(E_F)$ is the density of states at the Fermi level. Such behavior has been observed many times in various amorphous semiconductors, and an example[64] for the case of a-silicon is shown in Figure 16. An interesting effect is observed when the conductivity is measured in gap geometry and the thickness of a film is progressively reduced: when the thickness of the film, d, becomes comparable to the hopping distance, the transport process be-

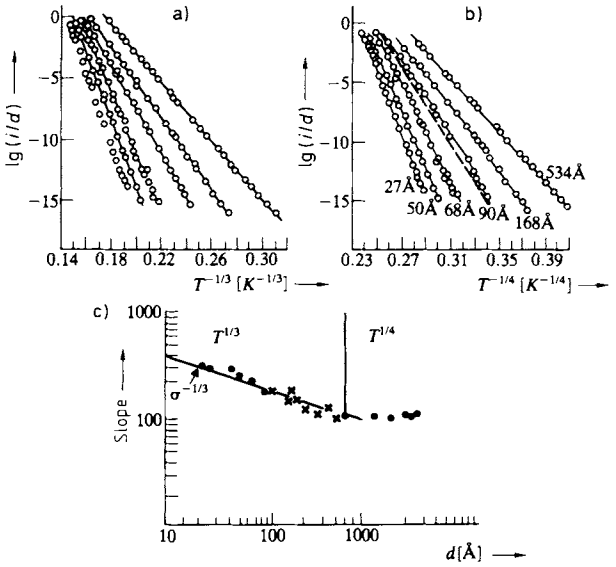

Fig. 16. Variable-range hopping conduction in a-Si; a) two-dimensional transport exhibiting $T^{-1/3}$ behavior; b) three-dimensional transport exhibiting $T^{-1/4}$ behavior; i/d is the quotient of the current strength and thickness of the conducting layer (in Å); c) dependence of the exponents on the thickness d.

comes essentially *two*-dimensional and a different temperature dependence of the conductivity is predicted in accordance with Equation (10), where the constant B becomes thickness dependent [Eq. (11)]:

$$\sigma_{2D} = \sigma_0' \exp(-BT^{-1/3}) \tag{10}$$

$$B = [3\alpha^2/dkN(E_F)]^{1/3} \tag{11}$$

This picture of a well-defined mobility edge, with electrical conduction at high temperatures taking place by means of electron transport in the bands of extended states beyond the mobility edges, has not gone unchallenged however. A rival theory for electrical conduction has been proposed[62], particularly for the case of chalcogenide glasses (alloys of Ge, As etc. containing S and Se), in terms of "polaron" transport. A polaron is a charge carrier which causes a considerable amount of lattice distortion when it occupies a site. As a result the charge carrier digs itself a potential well; it must carry the lattice distortion along with it when it moves, and hence the mobility is thermally activated. Polarons can be of several types (see Fig. 17): "electrostatic" polarons can exist in ionic solids, where the lattice distortion occurs because of the electrostatic interaction between the ions of the lattice and the charge carrier; "molecular" polarons exist when the interaction is of a covalent type involving some change in the bonding between atoms when a charge carrier is inserted between them, and such polarons are found in solid rare gases and perhaps in chalcogenide glasses, where a hole formed in a chalcogen p-π orbital (forming the top of the valence band) can result in a local distortion. The essential differences between the polaron model and the band model for electronic conduction in amorphous semiconductors can be illustrated by reference to the defining equation for the conductivity, σ [Eq. (12)]

$$\sigma = ne\mu \tag{12}$$

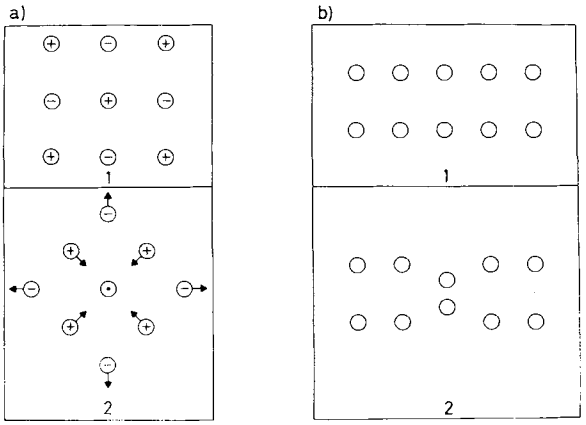

Fig. 17. Schematic representation: (a) electrostatic and (b) molecular polarons. 1: Undisturbed lattice; 2: effects of the polarons.

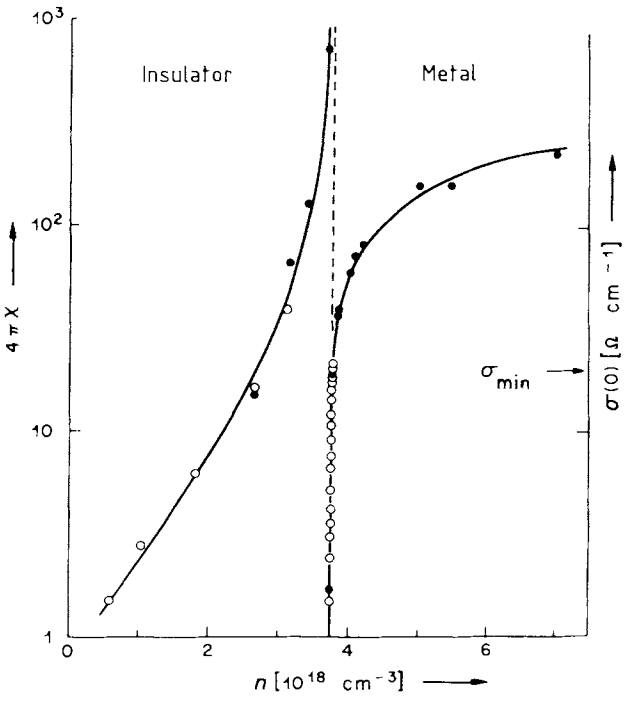
where n is the charge-carrier density, e the electronic charge, and μ the mobility. The band model assumes that μ is high and temperature independent (transport in extended states) and that n is small and thermally activated (carriers must be thermally excited across the band gap), whereas the polaron model assumes that μ is small and thermally activated (because transport involves interaction with phonons) and that n is large and temperature independent (because every atomic site can form a polaron center). It is still not clear which model is the more appropriate.

The other challenge to *Mott*'s picture of the electronic structure of noncrystalline solids has been to the concept of the mobility edge. Recent studies[65] of localization using so-called scaling methods (similar to those employed in studies of phase-transition phenomena) have indicated that the mobility and conductivity change in a continuous, rather than a discontinuous, manner through the localization transition. Experimental support[66] for this picture has come from studies of *crystalline* phosphorus-doped silicon (Si : P), where the randomly distributed P atoms act as donors, and the electrons experience a disorder potential due to the random positions of the P^+ ions; Figure 18 shows the behavior observed. It is interesting to note from this figure that values of the conductivity are measured *below* the value of the "minimum metallic conductivity", $\sigma_{min} \approx 500\,\Omega^{-1}\,cm^{-1}$, proposed by *Mott* as the limiting conductivity of a disordered material on approaching the localization transition (i.e. $E = E_c$; cf. Fig. 14) from the metallic side.



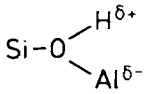


Fig. 18. Crystalline phosphorus-doped silicon; behavior of the conductivity, σ, and the susceptibility, χ, as a function of the charge carrier density n near the localization edge for electrons.

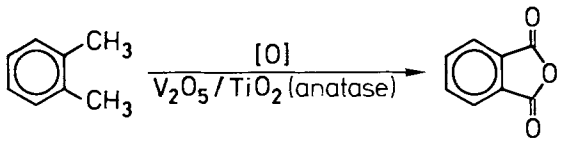
8. Heterogeneous Catalysis and the Noncrystalline State

It has long been recognized that periodicity in a crystallographic sense, though often a vital and generally desirable attribute of most heterogeneous catalysts, is by no means essential. Indeed there are well-known molten salt catalysts which, by definition, lack long-range order. One of these, molten $ZnCl_2$, was used over a century ago by *La Bel* et al.[67] to synthesize hexamethylbenzene in a 'one-step' conversion of methanol.



$$CH_3OH \longrightarrow C_6(CH_3)_6 + H_2O.$$

Perhaps the most widely known and arguably the most widely used catalysts until the advent of zeolitic catalysts in the petrochemicals industry in the mid sixties, are the silica-alumina 'gels', consisting usually of about 10 to 25 per cent Al_2O_3 in solid-solution in 'X-ray amorphous' silica (SiO_2). This composition range has advantageous Brønsted acidity attributable to the presence of accessible groups of the type,

from which the proton is rather readily detached by a conjugate base, such as an olefin. Such Brønsted acidity, coupled with the very large surface areas (typically 200–800 $m^2\,g^{-1}$) is the root cause of the catalytic activity of amorphous SiO_2–Al_2O_3 materials and gives rise to their widespread use in isomerization, hydration, and cracking of hydrocarbons.

There has been much speculation as to whether supported catalysts are amorphous or whether they possess crystallographic order, and indeed persuasive arguments have recently been formulated suggesting that a close epitactic match between a crystalline support (the substratum) and an oriented monolayer (supported) active catalyst phase is a prerequisite for the performance of oxide catalysts for the selective oxidation of hydrocarbons. To be specific, supported V_2O_5 catalysts on the anatase polymorph of TiO_2 are of considerable commercial importance,[9] since they exhibit high activity and selectivity in the oxidative conversions of *o*-xylene to phthalic anhydride, a valuable precursor in the production of anthraquinone and polyesters.

(V_2O_5—alone or when supported on other substrates—is a rather indifferent catalyst for this reaction.)

EXAFS and XANES (X-ray absorption near edge structure) investigations on typical V_2O_5/TiO_2 catalysts and a range of related compounds leave us in little doubt that the catalytically active (monolayer) phase of V_2O_5 supported on anatase is *not* in epitactic registry with the substratum but is in a state of structural disorder. The experimental facts and their interpretation are briefly as follows. In Figure 19 we show the EXAFS spectra, beyond the K-edge of

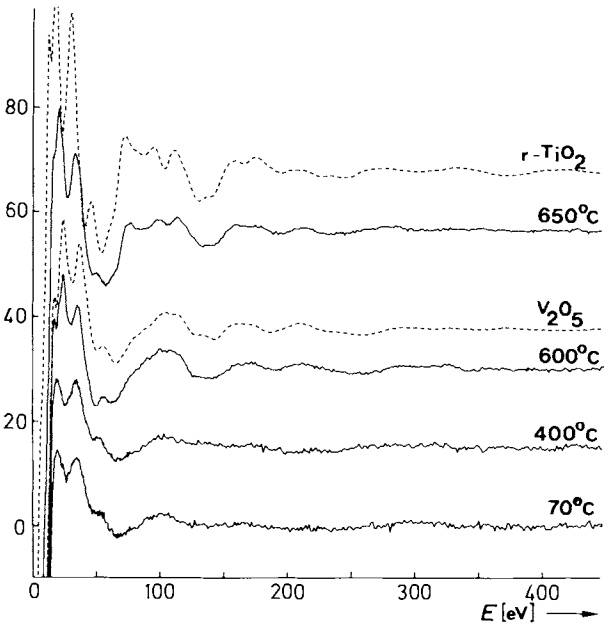


Fig. 19. EXAFS spectra for the vanadium edge of the V_2O_5 monolayer on TiO_2 (anatase) after 5 h heat treatments at various temperatures: EXAFS spectra of crystalline V_2O_5 and TiO_2 (rutile) shown as dashed curve. E denotes the energy above the absorption edge of vanadium. The numbers on the ordinates denote the EXAFS amplitude.

vanadium ($Z=23$), for a typical V_2O_5/TiO_2 (anatase) catalyst after heat treatment at various temperatures; also shown are the EXAFS spectra of crystalline V_2O_5 and of TiO_2 rutile (beyond the K-edge of titanium ($Z=22$)). It is clear that the bottom two EXAFS curves in Figure 19 are essentially the same and possess poor structure, characteristic of a poorly crystalline or amorphous phase. Few or no structural changes occur upon heating the system to 350 °C, which is not far removed from the optimal temperature for catalytic conversion. On heating beyond 600 °C, we know, from X-ray diffraction and microcalorimetry, that the finely dispersed anatase sinters and the vanadium oxide is liberated. Clearly the jettisoned oxide is, from its EXAFS spectrum, indistinguishable from *crystalline* V_2O_5. Upon yet further heating (to 650 °C) some oxygen is expelled and a solid-solution, $Ti_{1-x}V_xO_4$, forms, possessing a rutile structure (as indicated by the top two curves in Figure 19). XANES studies fully confirm this picture. Moreover, a quantitative treatment of the EXAFS data yields further insight into the basic structural unit of the catalytically active, disordered phase: it has two terminal V-O bonds of length 1.65 Å and two bridging V-O-Ti bonds in which the V-O distance is 1.90 Å.

It would be premature to draw too many conclusions from the V_2O_5/TiO_2 (anatase) system. Until such time as EXAFS data for a range of temperatures (under *in situ* conditions) become available it is difficult to decide whether the intrinsic disorder in the active catalyst is of a static or dynamic kind. Moreover, we do not yet know how generally valid is the picture of noncrystallinity for supported monolayers of catalytically active materials anchored to crystalline substrate.

9. Materials Applications and Design

A variety of materials of vital technological importance are amorphous or quasi-crystalline. For instance, a promising photovoltaic material for conversion of solar energy into electricity is amorphous hydrogenated silicon. Magnetic, electric, and other properties of materials rendered amorphous promise several applications as well. The ease of fabrication of glassy or amorphous materials makes them attractive for use in a variety of situations. Thus, there are available glasses which are transparent in most regions of the electromagnetic spectrum, glasses which are semiconducting, glasses which behave like ferroelectrics, and glasses with controlled magnetic behavior. Ferroelectric glasses (such as $LiNbO_3$) and glasses with controlled anisotropy of properties are materials worthy of further exploration. We shall deal here, however, with fast-ion conducting glasses and fibers for optical communication in some detail.

One of the most exciting current applications of a glass is the replacement of copper telephone cables by optical fiber light-guides. Light, in either a single mode or a multimode, propagates down the fiber by a process of total internal reflection, a process which occurs whenever light from a high refractive index medium strikes the interface between it and a low index medium with greater than a critical angle of incidence.

Obviously for long-distance applications, the glass fiber must be extremely transparent, i.e. have a very low light loss. There are two possible sources of light loss, scattering and absorption. Scattering (from density fluctuations) follows the Rayleigh law, i.e. the scattered intensity is proportional to λ^{-4}, where λ is the wavelength of the propagating light. There are two possible absorption mechanisms, depending on the wavelength of the light. At short wavelengths, the light can cause electronic excitation across the forbidden energy gap of the insulating glass: the spectral dependence of this absorption process follows the so-called Urbach law, viz. $\alpha = A\exp(B/\lambda)$, i.e. the absorption band has an exponential edge tailing into the gap, and for silica glass, this edge lies in the hard UV region. At the other end of the wavelength scale, i.e. in the IR region, the absorption of light arises from excitation of phonon (vibrational) modes in the glass, and this too has an exponential spectral dependence, viz. $\alpha = C\exp(-D/\lambda)$. The resulting

wavelength dependence of the overall optical loss in a glass thus has a characteristic V-shaped profile, as shown in Figure 20. Light losses due to Rayleigh scattering are obviously minimized for light of long wavelengths. The low-loss "window" is then given by the intersection of the Rayleigh curve with the multiphonon absorption edge, which for SiO_2 occurs at about 1.6 μm, with a theoretical loss of only ~0.2 dB/km, although actual fibers are found to have losses near 10 dB/km, resulting principally from absorption by OH groups, a ubiquitous impurity.

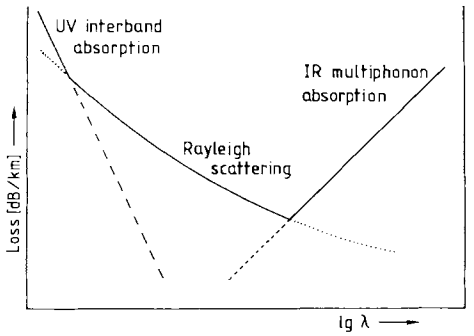

Fig. 20. Mechanisms of light loss in optical fibers as a function of the wavelength λ.

Since Rayleigh scattering decreases with increasing wavelength, losses can be further reduced by making fibers out of materials for which the multiphonon edge lies at a longer wavelength than for SiO_2, and hence intersects the Rayleigh curve at a longer wavelength and a lower value of loss (see Fig. 20). The frequency of phonon modes in a glass can be "tailored" either by choosing a material with a weaker force constant or containing heavier atoms than SiO_2. An example of the former strategy is to use *fluoride* glasses based on ZrF_4 (containing other fluorides such as LaF_3 and BaF_2 as well), where the fluorine atoms are for the most part twofold coordinated in the structure (like the oxygen atoms in SiO_2), but the bonding between cation and anion is weaker. Whilst these glass materials have extremely low theoretical losses ($\simeq 10^{-3}$ db/km), they are difficult to make and to form fibers from without crystallization taking place. The other alternative, namely substituting light (Si) atoms by heavier ones (e.g. Ge or Sb) has also been tried and losses of about 5 db/km have been achieved for GeO_2–Sb_2O_3 alloy glasses.

There is a large and growing number of solids in which certain ions exhibit unusually rapid transport. Such materials associated with high ionic conductivity and small activation energies for ion migration are called fast ion conductors.[68] Typical materials exhibiting fast ion conduction (FIC) are iodides related to AgI and oxides of the type $Zr_{1-x}Ca_xO_{2-x}$ and $Na_{1-x}Al_{11}O_{17+x/2}$ (β-alumina). Much of the early work on fast ion conduction was related to crystalline materials, but many fast ion conducting glasses have been discovered in recent years. Both Li^+ and Ag^+ conducting glasses are known. AgI is almost always a component of the Ag^+-containing FIC's; Li^+ FIC's are generally formed in systems with network structures. The ionic conductivity of these fast ion conducting glasses[69] is comparable to those of crystalline FIC's (Fig. 21). The glass

Vertical lines: T_g and T_f, respectively (see Fig. 2); vertical dotted lines: T_g, estimated. 1: α-AgI; 2: $RbAg_4I_5$; 3: $29.8\,Ag_2O$-$40.4\,(AgI)_2$-$29.8\,P_2O_5$; 4: $28.6\,Ag_2O$-$42.8\,(AgI)_2$-$28.6\,MoO_3$; 5: Li_3N; 6: β-PbF_2-2% KF; 7: $60\,Ag_2S$-$5\,GeS$-$45\,GeS_2$; 8: $35\,Li_2O$-$30\,Li_2SO_4$-$10\,(LiCl)_2$-$12.5\,SiO_2$-$12.5\,B_2O_3$; 9: $Li_4B_7O_{12}Cl$; 10: Li_2O-$Nb_2O_5(LiNbO_3)$; 11: $26.9\,Li_2O$-$9.0\,(LiCl)_2$-$64.1\,B_2O_3(Li_4B_7O_{12}Cl)$; 12: $LiAlSiO_4$; 13: $25\,Li_2O$-$25\,Al_2O_3$-$50\,SiO_2(LiAlSiO_4)$; 14: $Zr_{0.6}Ba_{0.33}Y_{0.07}F_{3.27}$; 15: $25\,Li_2O$-$75\,B_2O_3$; 16: $LiNbO_3$; 17: ZrO_2-9% Y_2O_3; 18: $NaAl_{11}O_{17}$ (β-alumina).

FIC's offer several advantages for their use in power devices and related systems, besides the ease of fabrication. Properties of glassy materials can be manipulated through composition control. The isotropic behavior of glasses can also be of considerable advantage.

Molecular Biological Background of the Species and Organ Specificity of Influenza A Viruses

By Christoph Scholtissek*

Influenza is one of the great plagues which is not yet under control. The reason for this is the immense variability of the infecting agent, the influenza A viruses. These viruses behave like a chameleon: they adapt very rapidly to varying environments. New strains are "synthesized," which can escape the immune response of the host, cross species barriers, and become highly pathogenic. We are beginning to understand the molecular background of this extraordinarily high variability. The genome of influenza A viruses consists of eight single-stranded RNA segments, each of which constitutes a gene. The total base sequence of the eight RNA segments of several strains is known. If a suitable organism becomes doubly infected with two different influenza A strains, each of the RNA segments behaves like a chromosome. This means that by reassortment of the 16 RNA segments, $2^8 - 2 = 254$ new combinations (= reassortants) are theoretically possible, each having different properties. Furthermore, mutations in the various RNA segments are relatively easily tolerated. Another great problem resides in the enormous reservoir of different influenza A viruses in the animal kingdom, especially in feral waterbirds. In these birds the avian influenza A viruses normally cause at most mild symptoms, and therefore these viruses are distributed over and between continents. Bearing this in mind it appears to be necessary to develop new ideas as to how to overcome this great plague.

1. Introduction

Influenza A viruses are the causative agents of the great pandemics, e.g., the Spanish influenza in 1918/19 and the Hong Kong pandemic in 1968. Furthermore, under natural conditions, influenza A viruses—in contrast to type B and C viruses—infect other species in addition to humans, including birds, horses, pigs, seals, mink, and whales, in which they cause various symptoms. Therefore, only influenza A viruses will be treated in this article.

1.1. Structure

Influenza A viruses have a relatively complex structure (Fig. 1, right).[1] They have a lipid bilayer, which is derived from the host cell during maturation and contains two different glycoproteins on the exterior surface. One is the hemagglutinin (HA), which, as a trimer, binds to the neuraminic acid-containing receptors of the host cell. The HA is the most important immunogenic component, since the infected organism produces neutralizing antibodies against this glycoprotein. The second surface component is the receptor-destroying enzyme, the neuraminidase (NA), which is less important with respect to the immune defense of the organism. Although this enzyme has been studied extensively,[2,3] many questions remain concerning its role during natural infection.

The lipid bilayer is covered on the inside by the matrix or membrane (M) protein. The nucleocapsid exhibits a thread-like helical structure as revealed by the electron microscope. Its main component is the basic nucleoprotein (NP). Only ten molecules of each of the three so-called P proteins (PB1, PB2, and PA) are present in the nucleocapsid. Embedded in this structure is the genetic material of the influenza A virus, which consists of single-stranded RNA (vRNA). In contrast to most other viruses, the RNA of the influenza A virus does not exist as a single molecule per viral particle, but as eight segments. Each segment constitutes one gene (Fig. 1, left).[4,5] The nucleocapsid has RNA-polymerase activity—i.e., the complementary RNA (cRNA) is synthesized on the internal vRNA templates.

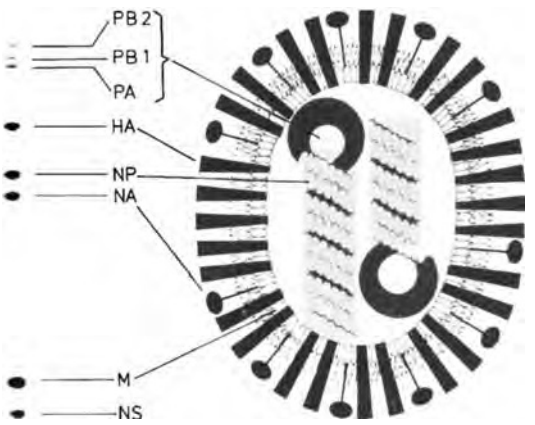

Fig. 1. Structure and structural elements of an influenza A virus (right) and assignment of the gene products (middle) to the viral RNA segments (genes) separated by polyacrylamide gel electrophoresis (left). The polymerase complex is located in the interior of the particle. It consists of the three P proteins PB2, PB1, and PA and the nucleoprotein NP. The lipid bilayer is covered on the inside by the membrane or M protein. The two glycoproteins hemagglutinin (HA) and neuraminidase (NA) are located on the exterior surface. The smallest RNA segment contains the information for two nonstructural proteins (NS).

1.2. Nomenclature

The proteins inside the virus, such as the NP or M proteins, are group-specific antigens, according to which the influenza viruses are categorized as types A, B, or C. Since these viral components cannot be reached in the intact particle by monospecific antibodies, they are not under the selection pressure of the immune system of the host and are therefore genetically conserved in contrast to the surface components HA and NA.

The influenza A viruses are divided into subtypes according to significant serological differences in their HAs and NAs. At present thirteen HA and nine NA subtypes are known. They have been found in nature in almost all possible combinations,[6] but only three different HA and two different NA subtypes have been found among virus isolates obtained from humans. In naming influenza viruses, one adds to the name the type (A, B or C) and the species from which the virus was isolated, except for human viruses. The site of isolation, the isolate number, and the year of isolation are also noted. In most cases, a simplified version of the serotypes for the HA (H) and NA (N) is added to the end of the name. The following isolate, which was obtained in 1976 from a duck in Alberta (Canada), will be used as an example: A/duck/Alberta/35/76 (H1N1).

1.3. The Multiplication Cycle

The influenza viruses belong to the negative-strand viruses. This means that the RNA isolated from virus particles (vRNA) is not infectious, since it has no messenger RNA (mRNA) function. Since a noninfected cell does not contain an RNA-dependent RNA polymerase, all negative-strand viruses must provide their own enzyme. After adsorption onto the host cell and fusion of the viral membrane with cellular membranes, the nucleocapsid is set free and migrates into the cell nucleus. There, the very complicated synthesis of the viral messenger RNA begins. In the first step, the viral polymerase complex binds to the fully

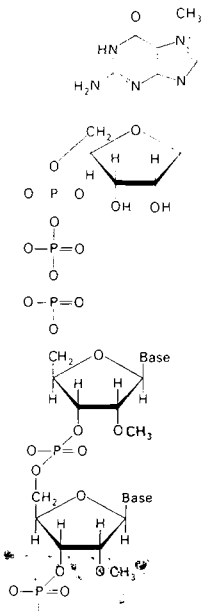

Fig. 2. Fully methylated cap structure at the 5′ end of an eukaryotic messenger RNA.

methylated cap structure (see Fig. 2) at the 5′ end of a newly synthesized precursor mRNA (high-molecular-weight, heterogeneous nuclear RNA: hnRNA) of the host cell and cleaves this hnRNA at a point 10–13 nucleotides from the 5′ end, following a purine (Fig. 3). This 5′ end of

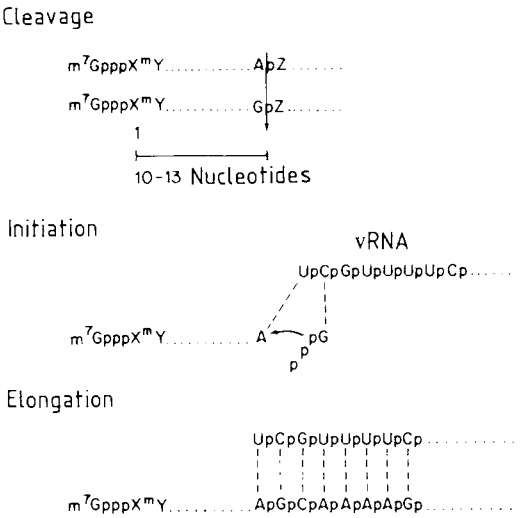

Fig. 3. Three steps that are necessary for the start of influenza-virus-specific messenger RNA synthesis. 1. Binding of the viral polymerase complex to the fully methylated cap structure of the newly synthesized cellular hnRNA and cleavage 10 to 13 nucleotides from the 5′ end, following a purine nucleotide. 2. Initiation of viral messenger RNA by base-pairing of the last uridine monophosphate at the 3′ end of the vRNA with the purine at the 3′ end of the cellular starter molecule, and incorporation of the first guanosine triphosphate (base-pairing with the penultimate cytidine monophosphate of the vRNA). 3. Elongation of the viral messenger RNA according to the Watson-Crick rules (according to *Krug* [7]).

the cellular hnRNA functions as a primer molecule for the viral mRNA synthesis (base-pairing according to the Watson-Crick rules), so that after this last purine nucleotide the RNA sequence is complementary to the 3′ end of the vRNA.[7] Close to the 5′ end of the vRNA is a signal for the unspecific addition of a polyadenylic acid tail of 50–200 AMPs. Thus, the residual 16 nucleotides at the 5′ end of the vRNA are not transcribed. This means that the eight influenza-virus-specific mRNA segments synthesized in vivo are heterogeneous at the 5′ end, because almost any cellular hnRNA can function as a primer molecule. Moreover, since some information is missing at the 3′ end, this cRNA cannot function as a template for the synthesis of vRNA segments that are later incorporated into mature viral particles. Therefore, a second type of viral cRNA is synthesized in virus-infected cells, which contains neither the cap structure and cellular RNA sequences at the 5′ end nor the polyadenylic acid tail at the 3′ end, but consists of the total, unmodified complementary sequence.[8] Both types of viral cRNA—for all eight segments—are found in the infected cell. The mechanisms by which their synthesis is regulated are completely unknown. For each of the six largest vRNA segments, only one mRNA is transcribed, while for each of the two smallest vRNA segments two different mRNAs are synthesized. One of these mRNAs is created by splicing so that for RNA segment 7, besides the unspliced mRNA coding for the M protein, a second spliced mRNA coding for the nonstructural M2 protein is

transcribed. Correspondingly, the RNA segment 8 contains the information for the two nonstructural proteins NS1 and NS2.[9] The mechanism by which the correct eight vRNA segments are selected and assembled during virus maturation is not yet known.

The nonglycosylated viral proteins (presumably with the exception of the M2 protein) are synthesized on free polysomes in the cytoplasm of the infected cell, while the glycoproteins (and presumably also the M2 protein) are produced on membrane-bound polysomes. During migration via the Golgi apparatus to the cytoplasmic membrane of the host cell, certain modifications of the viral glycoproteins occur such as the trimming and maturation of the carbohydrate side chains, the incorporation of fatty acids, and the cleavage of the HA into the cleavage products HA_1 and HA_2, which are held together by disulfide bridges.[10] By assembly of the various structural elements and budding, new infectious virus particles are formed.

1.4. Assignment of the RNA Segments to the Gene Products

In order to assign the RNA segments to the corresponding gene products, we isolated a large number of temperature-sensitive (ts) mutants of fowl plague virus (A/FPV/Rostock/34; H7N1) after mutagenesis with fluorouracil and selection using the plaque enlargement technique.[11] Primary chick embryo cells (CEC) in culture were doubly infected pairwise with all ts mutants. A plaque test was performed with the culture fluid at the so-called nonpermissive temperature (40°C). If the ts defects of the two isolates used for double infection are in different RNA segments (i.e., genes) reassortment to wild-type virus should be possible (see Fig. 4) by complementation of the genes without a defect. If, however, the two defects are located in exactly the same RNA segments, reassortment to wild-type virus is not possible. In this way it is possible to place all ts mutants into eight recombination groups in accordance with the number of RNA segments. Correspondingly, a rough assignment of the various groups of ts mutants to specific biological defects can be made.[12] If CEC at 40°C are doubly infected with a ts mutant of FPV and another influenza A subtype that cannot form plaques on these host cells (see Section 4), all plaque-formers obtained at 40°C are necessarily reassortants in which at least the defective gene of FPV is replaced by the allelic gene of the superinfecting influenza A strain. The derivation of the various RNA segments in the reassortants, whether they are supplied by the one or the other parent strain, has been determined by the hybridization technique.[13] Another possibility to determine the derivation of the various genes in reassortants is to compare the migration rates of both the RNA segments and the viral proteins of the parent viruses. The tryptic fingerprints of the parents and reassortants can also be compared.[14] The results obtained with FPV are shown in Figure 1.

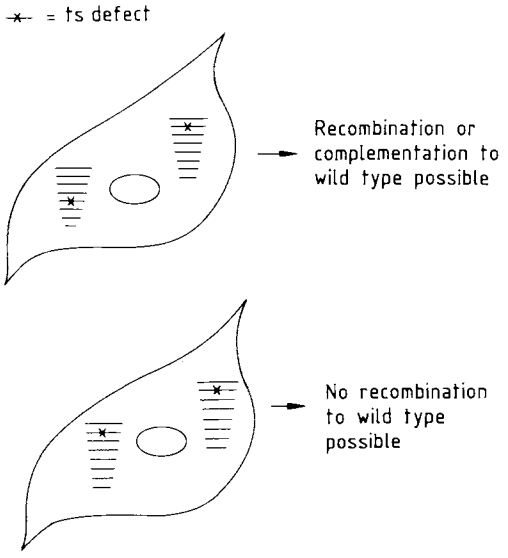

Fig. 4. Scheme to explain reassortment (recombination) to wild type after double infection of a cell by two different temperature-sensitive (ts) mutants of an influenza A virus. The ts defects are located either in two different or in the same segments. Selection for the wild-type virus is carried out at the nonpermissive temperature of 40°C.

2. Molecular Background of the Influenza Pandemics and Epidemics

2.1. Antigenic Shift

Every 10 to 20 years a human influenza A virus suddenly appears with new surface glycoproteins, against which no neutralizing antibodies are present in the human population. Such a new strain can start a pandemic (antigenic shift). When the A/Hong Kong/1/68 (H3N2) virus was analyzed by the hybridization technique, it was found that all genes except the HA gene were almost identical with those of the earlier H2N2 virus (A/Singapore/1/57). The HA gene of the Hong Kong strain, however, was highly related to the allelic gene of an influenza A virus isolated earlier in 1963 from a duck in the Ukraine.[15] Therefore, we envisage the creation of the Hong Kong virus according to Figure 5. All genes involved in species specificity, i.e., necessary for multiplication and causing symptoms in humans, were derived from the foregoing H2N2 strain during reassortment in a doubly infected host—possibly in pigs (see Section 6.2.). Only the HA gene is contributed by the animal virus. That means that in nature "a wolf in sheep's clothing" was produced in order to overcome the immune defense of the organism. With regard to the Singapore strain, which caused the pandemic in 1957, it was found that only the RNA segments 1, 5, 7, and 8 were de-

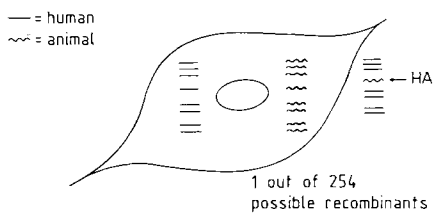

Fig. 5. Scheme to explain the creation of a new pandemic influenza A strain (antigenic shift). A cell becomes doubly infected by an animal virus and by the prevailing human influenza A strain. One of the 254 possible new reassortants has the gene constellation shown on the right. Only the HA gene is derived from the animal strain, while all the other genes are derived from the human virus.

rived from a foregoing human H1N1 strain. Segments 2, 3, 4, and 6, i.e., both genes coding for surface glycoproteins, were replaced.[15]

There is another possible explanation for the appearance of an influenza pandemic: a virus strain disappears for many years from the human population, but when a new generation has grown up it suddenly reappears. This happened in 1977 when an H1N1 virus caused a pandemic. This strain was almost indistinguishable from an H1N1 virus already isolated in 1950.[16,17] Mainly young people born after 1950 were infected by this virus since the older population still had protecting antibodies against it. Possibly, in 1950, this virus had changed its species specificity by replacing genes (see Section 3), had survived in the new host for 27 years and, by replacement of the same genes, went back to the original host. In a corresponding model experiment in the laboratory, we have been able to change the host range of fowl plague virus twice by replacing the necessary genes.[18]

2.2. Antigenic drift

The sudden appearance of new influenza A strains caused by replacements of genes coding for the surface glycoproteins is rendered possible by the segmented genome. Besides this antigenic shift there exists also the relatively slow process of mutation of the surface glycoproteins and selection of corresponding variants by the immune system. This is called antigenic drift. A quite strong antigenic drift is found with influenza A viruses because within the HA and NA molecules there are domains in which mutations are seldom lethal—i.e., these domains are not really necessary for the function of HA or NA. However, the antigenic determinants are located in these areas. In contrast to the other genes, which are highly conserved, the HA and NA genes contain regions of high genetic variability[19] and exactly these domains are identical with the antigenic sites[20,21] (see Fig. 6). In spite of the antigenic drift there are still serological cross reactions to a certain extent between the original virus and its variant—i.e., the variants are partly recognized by the antibodies already present. Therefore, such drift viruses usually start epidemics, which are not so severe and are often confined to certain areas.

3. The Influence of Reassortment on Pathogenicity, Host Specificity, and Organ Tropism

3.1. Construction of Nonpathogenic Reassortants

In nature, "wolves in sheep's clothing" are produced by the antigenic shift. Therefore, we[22] and others[23,24] have tried to obtain live vaccine strains by constructing "a sheep in wolf's clothing." The genes coding for the surface glycoproteins are kept, while the genes responsible for the pathogenicity are replaced. By the method described in Section 1.4, using our ts mutants, we obtained a large number of reassortants of fowl plague virus. When these reassortants were tested for their pathogenicity in chicken, it became apparent that replacement of RNA segment 1 (PB2 gene) by the allelic gene of the human A/PR/8/34 (H1N1) strain led to a virus completely nonpathogenic for chicken

Fig. 6. Schematic tertiary structure of the hemagglutinin monomer of the A/Aichi/2/68 (H3N2) strain. The four symbols ▲, ●, ■, and ◆ indicate mutations in the four antigenic sites, which lead to immunological changes. The broad lines represent α-helix, the flat arrows β-sheet (taken from the cover of *Nature (London) 289* (1981) No. 5796 with permission of Macmillan Journals Ltd.) [21].

but containing the surface antigens of the pathogenic strain. Chickens inoculated with this reassortant withstood a superinfection with the wild-type FPV. When the swine influenza virus A/sw/1976/31 was used for the same purpose, the corresponding reassortant was as pathogenic as the wild type. In this case a ts mutant with a defect in the PB1 gene (RNA segment 2) had to be used. The reassortant of FPV that contains the RNA segment 2 of the swine virus was also completely nonpathogenic for chicken and can therefore be regarded as a potential live vaccine strain.[22] During these studies we were not able to predict which gene of the dangerous virus had to be replaced by the gene of the other prototype virus in order to lose pathogenic properties. However, we recognized that the gene constellation coding for the polymerase complex, or better the correct cooperation of its gene products, is important in this context (see Section 1.1).[25] In further studies it was found that the nonpathogenic reassortants of FPV multiplied only slowly at the body temperature of the chicken (41 °C) so that in the infected organism the immune defense is fast enough to prevent the disease. This observation enabled us to rapidly isolate potential vaccine strains by double infection (even starting with two highly pathogenic parent strains) and selection using the plaque enlargement technique of reassortants that grow only slowly at 41 °C. All these reassortants were nonpathogenic for chickens and had replaced genes belonging to the polymerase complex.[26]

3.2. Neurotropic Reassortants

If it is possible to lose, by reassortment, pathogenic properties of influenza A viruses, it should also be possible

to start with two harmless parent strains and create reassortants highly pathogenic for a certain host. Mice are especially suitable to study an increase in pathogenicity, since these animals are free of influenza under natural conditions. As long as influenza strains are not adapted by passaging (i.e., by several cycles of infection and isolation) to grow in these animals, mice artificially infected with these viruses normally do not become sick. When reassortants between fowl plague virus and other human or avian influenza strains were tested in young mice, it turned out that certain reassortants were able to kill the animals. In contrast to the parent strains, these highly pathogenic reassortants grew in mouse brains to high titers. The same reassortants also multiplied in mouse brain cells cultured in vitro, in contrast to the parent viruses. Here again, the replacement of certain polymerase genes was important.[27,28] A correlation between the gene constellation and neurotropism for reassortants between the avian parents FPV and virus N is shown in Table 1.[29] This is an especially clear

Table 1. Multiplication of reassortants obtained from fowl plague virus (F) and A/chicken/Germany "N"/49 (N) in lungs and brains after intranasal inoculation of two-day-old mice. With exception of the first virus (virus N), the genes PB2, HA, NA, and M of the reassortants are derived from fowl plague virus. If the PB1 and/or PA genes are derived from virus N, the reassortants are neurotropic for mice. If, in addition, the NS gene is derived from virus N, the virus titer found in the brain increases even further. On the other hand, replacement of the NP gene causes loss or decrease of neurotropic properties. All animals with detectable virus in their brains die. However, the mean time required for death correlates inversely with the virus titer in the brains [29].

Origin of the genes				Virus titer four days after infection [plaque-forming units/mL suspension]	
PB1	PA	NP	NS	Lung	Brain
N	N	N	N	10^4	$<10^1$
F	F	F	F	10^1	$<10^1$
N	F	F	F	10^6	10^3
N	F	F	N	10^6	10^5
F	N	F	F	10^6	10^4
N	N	F	F	10^7	10^5
N	N	F	N	10^7	10^6
F	F	N	F	$<10^1$	$<10^1$
F	N	N	F	$<10^1$	$<10^1$
N	N	N	F	10^6	10^4

example of a change of organ tropism by reassortment paralleled by an increase in pathogenicity. Most importantly, immunized mice are not protected against an intranasal infection—which is the natural route of infection—by these neurotropic reassortants, since the virus is taken up by the nerve endings in the nasal mucosa and spreads via the olfactory bulb over the entire brain. Immunization only prevents viremia and a generalized infection[30] but has no influence on virus multiplication in the brain, and the animals die.[31]

In nature this kind of increase of pathogenicity seems indeed to happen. In 1979 many dead seals were found on the New England coast of the USA. From the lungs and brains of these dead animals an influenza A virus could be isolated.[32] When this virus was analyzed genetically, it appeared to be a reassortant between avian influenza A viruses.[33]

4. The Influence of Mutation on Pathogenicity and Host Range

In general, loss of pathogenic properties by mutation and selection of nonpathogenic variants can be achieved by passaging a highly pathogenic virus in another host. Several years ago the possible use of temperature-sensitive (ts) mutants of influenza viruses as potential candidates for a live vaccine was proposed. The idea is that such viruses can multiply at the relatively low temperature in the respiratory tract and induce there the production of antibodies of mainly the IgA class. The body temperature in the lower respiratory tract, however, would prevent further multiplication of the ts mutants.[34,35] Viruses that are adapted to growth at low temperature by many passages at 25 °C and thus have a large number of mutations seem to be especially suitable for this purpose, since the probability of reversion to the wild-type virus is very low.[36,37] However, the following facts have to be taken into consideration: Due to the segmented genome, suppressor mutations[38,39] and suppressor recombinations[40] (i.e. the suppression of the ts property by mutation in a different gene or replacement of a different gene by one from a prototype strain, without loss of the ts mutation) with influenza viruses are quite frequent, so that reversion to the ts^+ phenotype (i.e., the ability to multiply at the nonpermissive temperature) is measurable even with viruses with multiple ts defects. An exact analysis of such ts mutants has revealed that the reversion rate to the ts^+ phenotype depends on the RNA segment in which the ts defect is located. The reversion rate is highest in those genes whose gene products cooperate with other viral proteins. Thus reversion, in this case, is mainly due to suppressor mutation. When double mutants are passaged in tissue cultures at intermediate temperatures, ts^+ revertants are found after a few passages. At high temperature the mutant is lost (no replication). At low temperature there is no selection pressure and therefore revertants have no chance to develop. Correspondingly, chickens infected intratracheally by such double mutants of FPV (relatively low temperature in the upper respiratory tract) died or became sick. When they were infected intramuscularly (immediately 41 °C), no symptoms were recognized.[41] Therefore, the respiratory tract does not appear to be promising as a route of application for ts mutants.

Furthermore, it was found that during passage of the nonpathogenic reassortants described in Section 3.1 at the elevated temperature highly pathogenic variants rapidly appeared.[42] This demonstrates that even the replacement of a whole RNA segment does not lead to a safe live vaccine.

In infected cells the cleavability of the hemagglutinin (HA) into the cleavage products HA_1 and HA_2 by trypsin-like enzymes is a presupposition for numerous cycles of multiplication of influenza A viruses.[43,44] Therefore, the cleavability of the HA is an important factor for pathogenicity.[45] Unless small amounts of trypsin are added to the culture medium, noninfectious virus particles are released from cells in which a corresponding protease is not present or is unable to cleave the HA of a given influenza virus.[43,44,46] The cleavability of the HA depends, on the one hand, on the virus strains under investigation and, on the

other hand, on the host cell. For example, all influenza viruses so far tested multiply in the chorioallantoic membrane of embryonated chicken eggs. The released virus particles contain a cleaved HA and can therefore be used to infect primary chick embryo cells (CEC) in culture. However, only a few strains of the H5 and H7 subtypes are released from these cells with a cleaved HA and are able to form plaques on CEC. The other virus strains undergo only a single cycle of multiplication in CEC and do not form plaques on these cells.[43,44,45] Therefore, one would expect that the HA gene of a virus whose HA cannot be cleaved in a certain cell can be changed by mutation in such a way that the gene product can be cleaved. Exactly this has been achieved during adaptation of an influenza virus by passaging it in a normally (almost) nonpermissive cell line. The variants obtained in this way produced virus particles with cleaved HA and multiplied in this host cell to high titers. A comparison of the sequence of the HA of the original virus with that of the variant revealed that the cleavability in this host correlated with the replacement of a single amino acid.[47] This example demonstrates that after a single point mutation a virus can be released from a previously nonpermissive cell in an infectious form.

Nature takes advantage of this possibility in order to increase the pathogenicity of an influenza virus for its natural host. In the spring of 1983 in a chicken farm in Pennsylvania, an influenza virus was isolated that caused only mild symptoms in chickens such as decreased egg production. However, in October of the same year many chickens died in the surrounding farms. From these chickens an influenza virus was isolated, which, except for a few point mutations, was identical to the earlier isolate. The virus with low pathogenicity was released from primary chick embryo fibroblasts with an almost uncleaved HA, and the virus titer in these cells in culture was very low. In contrast, the highly pathogenic variant was released from the same tissue culture cells with a cleaved HA, and the titer was very high. Here also the sequencing of the HA genes revealed that this change in pathogenicity was due to the replacement of a single amino acid, which led to the loss of a carbohydrate side chain.[48]

5. Possible Organ Tropism by Stability of the Virus in an Acidic Environment

The cleaved hemagglutinin of influenza A viruses undergoes an irreversible conformational change at a pH between 5 and 6. This conformational change is correlated with the fusion of the viral membrane with the membrane of endosomes (intracellular vesicles) and, in this way, with the entrance of the nucleocapsid into the infected cell.[49] In viruses with a noncleaved HA this conformational change does not occur. Such viruses cannot start an infection, since they do not undergo the conformational change of the HA and, therefore, are not taken up into endosomes.[50] If viruses with a cleaved HA in free solution are exposed to low pH, a conformational change occurs which leads to an irreversible loss of infectivity. Many viruses with noncleaved HA, however, withstand a long treatment at a pH far below 5. These viruses need, for their further replication, a short treatment with an enzyme with a trypsin-like cleavage specificity (see Section 4). The highly pathogenic avian influenza viruses are, in contrast to nonpathogenic strains, released from most cells with a cleaved HA[45] and are therefore extremely sensitive to low pH.[51] Water birds are the greatest reservoir for the various influenza A viruses, which are more or less nonpathogenic for their natural host and are transported and distributed by these birds over great distances.[52] They multiply in these animals in a well-defined part of the gut.[53] The natural route by which water birds are infected is not yet known. In the laboratory, however, they can be infected easily via the cloaca. If this is also the natural route of infection, then the viruses surviving in lake water[54] with uncleaved HA might penetrate to a region within the intestine where enough trypsin is still present for their activation, and multiplication could begin. In lower regions of the intestine, where trypsin is absent, the virus would be produced with a noncleaved HA and would be released via the feces into the lake water. This behavior of avian influenza A viruses would explain, on the one hand, why they have such a defined organ tropism and are nonpathogenic in water birds, and on the other hand, why they spread in nature so easily. Furthermore, this would also explain why the highly pathogenic avian viruses, owing to their high sensitivity toward low pH (uric acid, which predominates in avian feces, has a pK value of 5.5), do not spread very well and, therefore, do not eradicate their natural host.[51] The above-mentioned property of the HA of viruses of water birds is surely not the only factor determining the organ tropism, since in the laboratory reassortants between duck and human viruses can have a different organ tropism.[55]

6. The Role of the Nucleoprotein in Organ and Species Specificity

6.1. The Nucleoprotein as Phosphoprotein

Viruses can only infect a cell if it carries corresponding receptors for the virus. Receptors for influenza A viruses are neuraminic acid-containing glycoproteins or glycolipids, such as gangliosides. Although there are clear receptor specificities for influenza viruses, depending on the linkage of the neuraminic acid,[56] all vertebrate cells have almost all kinds of neuraminic acid-containing receptors. Therefore, all warm-blooded vertebrate cells so far tested can be, at least abortively, infected by influenza A viruses. This means that there must exist other factors that forbid or allow these viruses to multiply in such cells. Important is the presence within the cell, or in its immediate neighborhood, of an enzyme with a trypsin-like cleavage specificity (cleavage after Arg and Lys) to cleave the hemagglutinin into the cleavage products HA_1 and HA_2. Since reassortants exist, however, in which the HA is cleavable in certain cells but which nevertheless do not multiply in these cells,[18] there must be further restrictions.

The question is whether or not the host cell modifies one or several viral components in such a way that the virus can multiply. In nature a commonly used method to modify proteins is phosphorylation.[57] There are at least three

virus-specific proteins in influenza viruses which could be phosphorylated. These are the NP,[58-62] the M protein,[63] and the NS1 protein.[64] Since in all influenza A virus strains studied so far the NP is phosphorylated, but not in all virus-infected cells the NS_1 or M protein, we have concentrated our studies first on the phosphorylation of the NPs.[65]

If, indeed, cellular protein phosphokinases with different specificities determine whether the phosphorylated NP can exert its function during virus replication, the following predictions can be made: 1) If the same host cells are infected with different influenza A viruses, the phosphopeptide fingerprints of the NPs after labeling with [^{32}P]-orthophosphate in vivo and digestion of the isolated NPs with trypsin should be different. 2) The phosphopeptide fingerprints of the NP of a given influenza A virus should be different if different cells were used for propagation of that virus. 3) If the function, i.e., the phenotype, of the NP is changed by mutation, the phosphopeptide fingerprints of the NP should also be influenced. As shown in Figure 7, the phosphopeptide fingerprints of the NPs are indeed specific for the virus used for infection of one and the same cell type. Furthermore, the pattern depends on the host cell used for virus propagation and it has been shown that the fingerprints co-vary with the ts mutation in the NP gene and with reversion to the wild type. These observations do not strictly prove but are nonetheless compatible with the idea that the infected organism controls the replication of viral proteins via phosphorylation. At present we are attempting to influence virus replication by compounds that specifically interfere with cellular protein phosphokinases. Hormones, which may influence the disease at this level, are of special interest. The first results of investigations along this line have shown that insulin, at close to physiological concentrations, can retard virus replication. This effect is potentiated by compounds that interfere with the phosphorylation of the insulin receptor.[66]

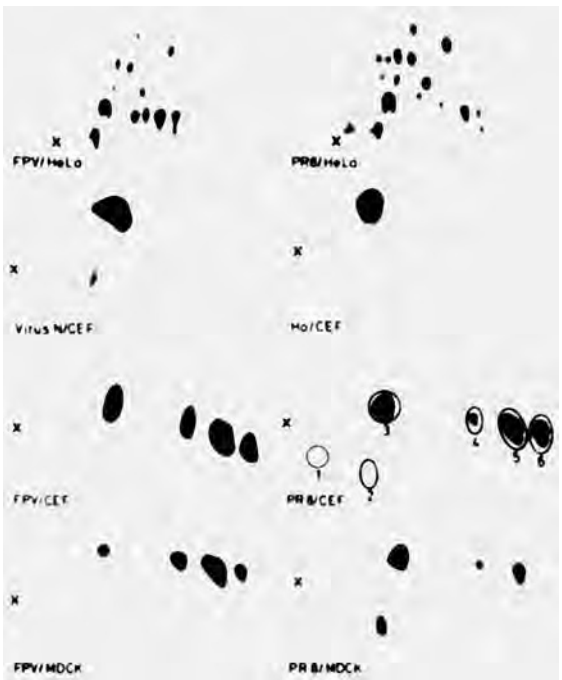

Fig. 7. Phosphopeptide fingerprints of the nucleoproteins of different influenza A strains, which were labeled with [^{32}P]-orthophosphate in different cells. The following viruses were investigated: fowl plague virus (A/FPV/Rostock/34), virus N (A/chicken/Germany "N"/49), HO (A/Hong Kong/1/68), and PR8 (A/PR/8/34). The following host cells where investigated: CEF = primary chick embryo fibroblasts; MDCK = immortal canine kidney cells; HeLa = immortal human carcinoma cells. The virus yield in MDCK cells is on average about 10% of that in CEF; the yield in HeLa cells is about 0.1% of that in CEF. During growth in HeLa cells, the nucleoprotein (NP) is overphosphorylated. During growth in MDCK cells, the PR8 NP is missing phosphopeptide 6. In FPV-infected MDCK cells, the major phosphopeptide 3 is only weakly labeled [65].

6.2. The Nucleoprotein as a Possible Determinant of Species Specificity

According to our experience, avian influenza viruses under natural conditions do not infect humans, and human viruses do not infect birds. The same holds true for horses and the equine influenza viruses. However, pigs are apparently an exception. Human influenza A strains have been isolated from pigs,[67] and farmers have been infected with porcine influenza viruses present in their pig herds.[68,69] Furthermore, there is circumstantial evidence that porcine influenza viruses have infected turkeys under natural conditions.[70] These observations raise the question which viral components are responsible for the species barrier.

The first hint for the role of the nucleoprotein in determining the species specificity came from experiments in which the defective genes of ts mutants of fowl plague virus were to be replaced by the allelic genes of the A/Hong Kong/1/68 (H3N2) virus after double infection of primary chick embryo cells at the nonpermissive temperature (see Section 1.4). This replacement was possible with all ts mutants except those carrying a defect in the HA or NP genes. The replacement was not possible in the case of the HA gene because the HA of the Hong Kong strain is not cleavable in chick embryo cells.[13] The failure to replace the defective NP gene of FPV was not understandable at first, since replacement was possible after double infection with equine, porcine, or avian influenza viruses. When for the double infection another host cell was used, namely, an immortal canine kidney cell line (MDCK), the replacement of the defective NP gene of FPV by the gene of the Hong Kong virus was possible. These reassortants carrying the HA of FPV, which grew excellently on MDCK cells, were unable to multiply on chick embryo cells and were nonpathogenic for chicken.[18] Thus, the fowl plague virus was forced by replacement of its NP gene to change its host.

Within the last decade *Shortridge* et al. have isolated a large number of H3N2 viruses from humans, birds, and pigs in the area of South China. As a consequence of the age-old agricultural techniques practiced in that region, humans, ducks, and pigs always live in close contact.[71] Therefore, these isolates are especially suitable to study the question how far influenza viruses are able to cross the species barrier. We have investigated eight human, ten porcine, and fifteen avian H3N2 isolates using the above-mentioned double-infection or so-called rescue test with mutants having a ts defect in the NP gene of FPV in order to determine whether we could isolate reassortants capable of multiplying in chick embryo cells. As shown in Table 2, we

were unable to replace the NP of the ts mutants of FPV with that of any of the human isolates (i.e., to rescue the ts mutants), whereas all avian strains were able to rescue these mutants. For the porcine strains, rescue was possible with two isolates (Sw126 and Sw127), but not with the other eight strains. According to the hybridization data, the NP gene of the Sw126 and Sw127 isolates exhibited the same low genetic relatedness to the NP gene of the human A/WSN/33 (H1N1) strain as did the avian H3N2 strains. The other porcine isolates, which behaved in the rescue test like the human viruses, were genetically more closely related to the NP gene of the WSN virus (Table 2). The NPs were also tested serologically using five different monoclonal antibodies directed against the NP of the WSN strain. In this test the isolates Sw126 and Sw127 showed intermediate behavior (Table 2). Our results are compatible with the idea that the human H3N2 viruses cannot be transmitted directly to birds and presumably also not the other way around without prior reassortment in pigs. The pigs seem to be more tolerant toward the multiplication of human and avian influenza viruses. In the example studied here, the species specificity apparently is determined by the NP gene or its gene product. The genes coding for the surface glycoproteins H3 and N2 can presumably cross the species barrier quite easily, since they were found on all isolates studied, independent of the species. The experiments on double infection with mutants with ts defects in other genes of FPV demonstrate that these genes also do not play an important role in determining the species specificity.[72]

Table 2. Summary of properties of H3N2 influenza A viruses isolated from humans, pigs, or birds. WSN is a test strain originally isolated from man; 3/1, 5/1 etc. are individual monoclones that produce the monoclonal antibodies used in these studies.

Property under study	Virus isolated from: Human all isolates	Pigs all, except Sw126 and Sw127	Poultry all isolates	Pigs only Sw126 and Sw127
Ability to replace the NP gene of FPV (rescue)	–	–	+	+
Hyhridization with RNA segment 5 of WSN, RNase resistance [%]	28–31	28	17	17–18
Binding of monoclonal antibodies against the NP of WSN; monoclones bound	3/1, 5/1, 7/3	3/1, 5/1, 7/3	3/1, 5/1, 7/3, 150/4, 469/4	3/1, 5/1, 150/4

The isolates Sw126 and Sw127 are intermediate in behavior with respect to the NP genes compared with human and avian H3N2 strains (Table 2). This could mean that these NPs are of avian origin and are now on the way to becoming adapted to the new host. The phosphopeptide fingerprints of the NPs of these two viruses are identical with those of the other porcine H3N2 strains but different from the avian and human H3N2 isolates.[72]

The particular position of the pigs as hosts for influenza A viruses of different origin is of special interest for understanding the sudden appearance of new pandemic strains by reassortment. The special living conditions in China would specifically explain why most of the pandemics start from the area of South China.[71] Changing these conditions might help to avoid or at least to lower the probability of the antigenic shift.

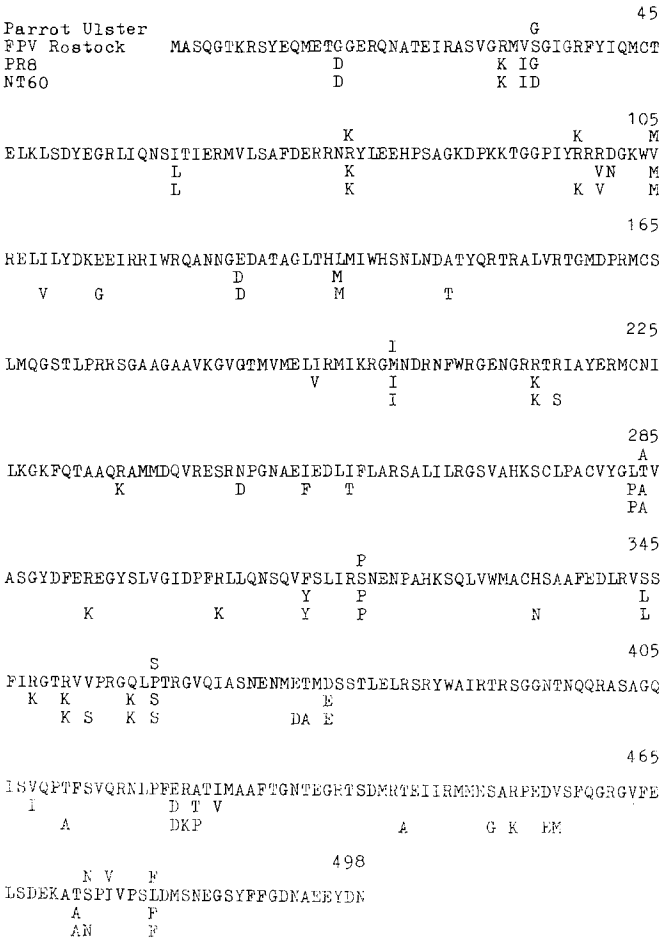

Fig. 8. Comparison of the amino acid sequences of the nucleoprotein of the four influenza A viruses A/parrot/Ulster/73 (H7N1), A/FPV/Rostock/34 (H7N1), A/PR/8/34 (H1N1), and A/NT/60/68 (H3N2). The sequence of the nucleoprotein of the FPV is presented in the one-letter code. For the other three viruses only the amino acid replacements are shown. The four NPs each contain 498 amino acids [73].

A comparison of the amino acid sequences of the NPs of human and avian isolates are also in agreement with the idea that NPs can adapt to the new host. As shown in Figure 8, the amino acid sequence of the NP of an influnza A virus isolated from a parrot in 1973 (A/parrot/Ulster/73) is highly related to the sequence of fowl plague virus. However, of the eleven amino acid replacements in the NP of the parrot virus, eight are identical with those of the human A/PR/8/34 virus and nine are identical with those of the human A/NT/60/68 virus. This clearly demonstrates that the NP of the parrot strain is located genetically between that of FPV and the human viruses.[73] However, further comparisons of sequences are necessary to strengthen the point that NPs can adapt to the new host. In the case of the Parrot/Ulster strain, the question arises again whether an intermediary host was also necessary for the adaptation.

7. Outlook

Because of the specific structure of the segmented genome, influenza A viruses are extremely variable. This variability is due, on the one hand, to the possibility of constructing new viruses by reassortment, which is not possible with viruses whose genome is not segmented. On the other hand, mutations in one gene do not have direct polar effects (e.g., changes of the secondary structure of the RNA or of the polyprotein) on another gene, which is normally the case for viruses with a nonsegmented genome. Therefore, influenza A viruses can adapt very rapidly to new conditions; and variants appear which can easily escape certain selection pressures such as the immune defense system of the infected organism. For this reason it is extremely difficult to develop a safe live vaccine. Even the application of a killed or split vaccine, as it is used today, is not without problems, since it is unpredictable which variant will show up next. And we are always somehow behind schedule.

Another problem is caused by the large reservoir of influenza A viruses in the animal kingdom, especially in water birds. Feral ducks and other water birds travel thousands of kilometers each year—also from continent to continent—and distribute the various influenza viruses all over the world. This is possible because these strains do not cause clinical symptoms in their hosts. Surely, it is not a selection advantage for a virus to be especially pathogenic for its host, since such a virus would be eradicated by eradication of its host. However, influenza viruses can afford to produce such highly pathogenic strains, since from the large reservoir new reassortants with different properties can always be "synthesized." An example is the sudden appearance of the H7N7 strain that was responsible for killing so many seals on the New England coast of the USA during the winter of 1979/80. This virus never reappeared in this population, although another influenza A virus belonging to a different subtype was isolated later. It is not unlikely that the highly pathogenic fowl plague viruses, which sporadically appear and have been isolated in different parts of the world, are indeed unique creations, since in most instances the subtype combinations are different.

Taking into consideration the properties of influenza A viruses described here, it is unlikely that in the near future we will be able to eradicate the causative agent of human influenza—in contrast to smallpox or polio, where we either have succeeded already or will succeed soon.

The experiments performed in the author's laboratory were supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 47) and by the Fonds der Chemischen Industrie. I thank these institutions for their generous help. Furthermore, I thank Dr. R. Rott for helpful discussions, Dr. B. Simpson for help with the manuscript, and Mrs. M. Seitz for typing.

Multiple Bonds between Transition Metals and "Bare" Main Group Elements: Links between Inorganic Solid State Chemistry and Organometallic Chemistry

By Wolfgang A. Herrmann*

In memoriam Professor Wilhelm Klemm

The last two decades have seen a dramatic development in the study of metal-metal multiple bonds, particular successes being recorded in the field of organometallic chemistry. Syntheses designed to produce novel transition metal complexes with single, double, triple and quadruple metal-metal bonds occupy a most important place in such research, as also do reactivity studies. A striving to establish general principles has provided much of the motivation for such work, but one less obvious goal—the commercial application of the catalytic properties of metal-metal multiple bonding systems, in the medium and long term—should not be overlooked. All aspects of the investigations of metal-metal multiple bonds also apply to a particular class of compound that has, however, enjoyed little limelight and thus deserves the present review: complexes with multiple bonds between transition metals and substituent-free ("bare") main group elements. Although based mostly on accidental discoveries, the few noteworthy examples are now beginning to unfold general concepts of synthesis that are capable of being extended and thus are deserving of exploitation in preparative chemistry. The availability of further structural patterns exhibiting multiple bonds between transition metals and ligand-free main group elements might enable preparative organometallic chemistry to expand in a completely new direction (for instance by the stabilizing or activation of small molecules at the metal complex). This essay discusses the chemistry of complexes of bare carbon, nitrogen, and oxygen ligands (carbido-, nitrido-, and oxo-complexes) and their relationships to higher homologues from both a synthetic and a structural point of view.

1. Introduction

The topic "organometallic chemistry", after 40 years of research, is a monumental one. The basic structures have often become so embellished as to be scarcely recognizable.[1,2] The rich variety of structures is far from being exhausted, since new structural principles, provided by consideration of novel materials, in turn allow the recognition of relationships to other areas of chemistry and of new concepts capable of extension.[3,4] Although the great diversity of carbon-containing ligands underlines the smooth transition to organic chemistry, the core structures of polynuclear complexes are clearly closely related to the structures of inorganic materials and, like those, more or less determined by conditions of synthesis, atomic radius ratios and electron configurations of the combining atoms. Similarly to inorganic solid state chemistry, organometallic chemistry comprises materials ranging from small ensembles of metals via medium-sized clusters to giant multiatomic frameworks such as are seen in gold and palladium chemistry (e.g. the cubic close-packed "giant sphere" $Au_{55}[P(C_6H_5)_3]_{12}Cl_6$—precursor of a new gold modifica-

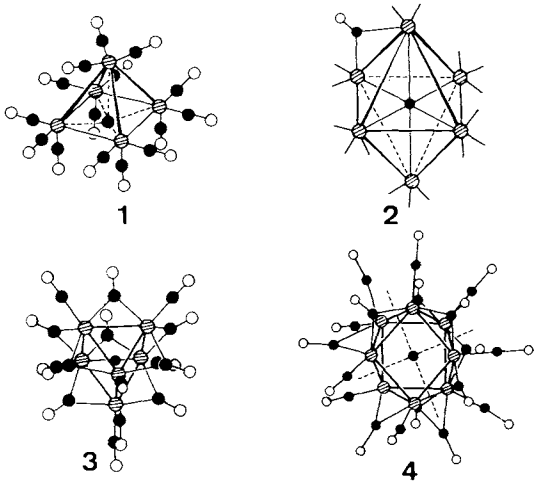
tion based on Au_{13} cuboctahedra—and the water-soluble $Pd_{570\pm30}$-giant with 240 ± 13 ligands[5-8]).

The structures of polyatomic clusters should not be forgotten, even if the current article stresses the topic of multiple bonds between transition metals and "bare" main group elements. The author has not striven to provide a catalog, but rather to demonstrate the connection between preparation and structure of such complexes and also that between "bare" main group atoms with low or high coordination numbers. The restriction of the scope of this article to the carbon, nitrogen, and oxygen groups was necessary to prevent its becoming too unwieldy. Although it may be too early to generalize, it is hoped that typical reactivity patterns of multiple bonds between transition metals and substituent-free main group elements will gradually emerge.

2. Bare Carbon Group Elements as Bridging Ligands

2.1. Cage Structures

Several years ago, complexes containing bare carbon ligands were regarded as laboratory curiosities. These days, however, clusters of this type can be routinely prepared, even if the reactivity of the carbon atom in its metal "cage" is difficult to characterize or to classify.[9-15] Aliphatic hydrocarbons and a wide range of carbon-containing ligand precursors are appropriate for the synthesis of interstitial carbide cluster compounds. The famous textbook examples **1–4** deserve special mention here (Fig. 1), not least for their aesthetic attractiveness.



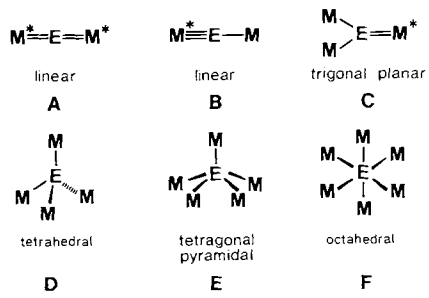


Fig. 1. Atomic carbon in isolable, discrete transition metal cage structures with five, six, and eight metal vertices (atom key: C black, metal atoms hatched, O as circles). Except for the Fe_5C cluster **1**, which displays a sterically exposed carbon atom, these complexes all involve interstitial (encapsulated) carbon ligands.—$Fe_5C(CO)_{15}$ **1**: the five-coordinated carbon atom lies 15 pm out of the basal plane of the Fe_5 pyramid, with FeC bond lengths 189 pm (basal) and 196 pm (axial).—$Ru_6C(CO)_{17}$ **2**, an octahedral 86e complex, isoelectronic with the structurally analogous $[Fe_6C(CO)_{16}]^{2-}$ anion.—$[Rh_6C(CO)_{15}]^{2-}$ **3**: the carbon atom is at the center of an Rh_6 trigonal prism (six terminal, nine edge-bridging CO ligands; 90e cluster).—$[Co_8C(CO)_{18}]^{2-}$ **4**, an interstitial carbide complex with a square antiprismatic metal framework (Co–C 195–220 pm).

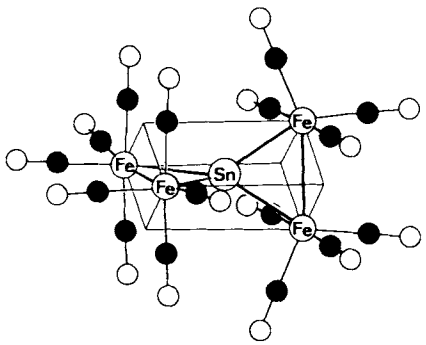
The Fe_5C- and Ru_6C-cage structures **1** and **2** are representatives of the basic structural types **E** (square pyramidal) and **F** (octahedral), respectively (see Scheme 1). Multiple bonding between the central atom E (here carbon) and the transition metals M cannot be seriously considered here. Despite the differing frameworks, the C_1 ligands in both these and all other known cases contribute four electrons to the cluster cores.

Scheme 1. Possible types of coordination for bare carbon group elements.

It is striking that the structural types **A** and **B** (linear) and **C** (trigonal planar) do not occur for carbon,[*] although these geometries in particular have shown themselves to be stable for the higher homologues (see Sections 2.2–2.4). The organomercury compounds of general composition $C(HgR)_4$ [R = alkyl, aryl] may be considered as examples of the tetrahedral class **D**.[16]



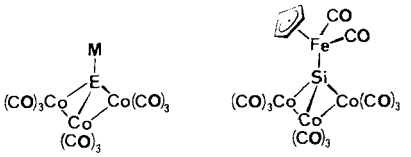


Fig. 2. Scale drawing of the approximately D_{2d}-symmetrical $SnFe_4$ cluster compound **5**, the first cluster example of unsubstituted tin. **5** is isolobal with spiropentane. The tin–iron bond lengths are ca. 254 pm, with FeSnFe angles of 69° and 133°. Weak interactions between the $5d_{z^2}$ and $5d_{xy}$ orbitals of tin and the $3d_{x^2-y^2}$ orbitals of the iron atoms are assumed to occur in this unique molecule.

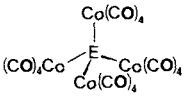
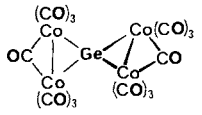
F. G. A. Stone et al. discovered the first coordination compound of a substituent-free tin atom in 1966; the Fe_4Sn cluster compound

$[(\mu_4\text{-Sn})\{Fe_2(CO)_8\}_2]$ **5**[17]



which according to *R. Hoffmann* is an "inorganic spiropentane" fitting well into the nowadays powerful concept of the isolobal analogy,[3] shows a tin atom with distorted tetrahedral environment (Fig. 2; Scheme 1, type **D**). The structurally characterized complexes **6a** and **9** (Fig. 3, Scheme 1, type **D**) contain carbonylcobalt fragments

[*] A possible exception is represented by the structurally not yet unambiguously characterized porphyrin complex of composition $[(\mu\text{-C})\{Fe(TPP)\}_2]$ (TPP = tetraphenylporphyrin), cf. D. Mansuy, J.-P. Lecomte, J.-C. Chottard, J. F. Bartoli, *Inorg. Chem. 20* (1981) 3119.



6a. E = Si, M = $Co(CO)_4$

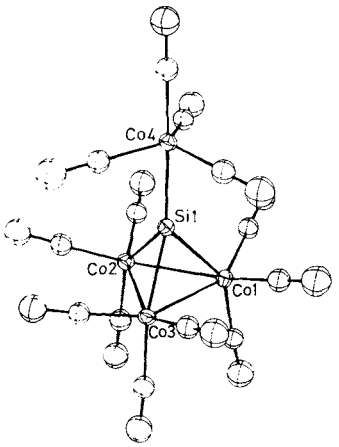
6c. E = Ge, M = $Mn(CO)_5$

7

8a. E = Sn
8b. E = Pb

9

grouped around four-coordinate silicon and germanium.[18–22] Similar structures may be assumed for the interesting $FeCo_3Si$ compound **7**, prepared by *Malisch* et al. by metalation of the silyl ligand of $[(\eta^5\text{-}C_5H_5)Fe(CO)_2(SiH_3)]$ with octacarbonyldicobalt,[20] and for the complexes **8a** and **8b**, obtained by *Schmid* et al. by treatment of elemental tin and lead, respectively, with octacarbonyldicobalt.[18, 19]



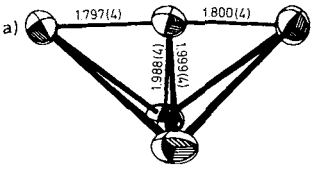


Fig. 3. The C_{3v}-symmetrical structure of the silicon complex **6a**, obtained in 5% yield from $Na[Co(CO)_4]$ and SiI_4 (*n*-hexane, 50°C, UV irradiation, 14 d). The pseudotetrahedrally coordinated silicon atom caps symmetrically to a Co_3 triangular face (Co-Si 221.8 pm, Co-Si-Co 71.9°) and also bears a $Co(CO)_4$ group (Co-Si 228.8 pm, Co-Si-Co 137.3° (av.)).

To these isolated examples can be added the long list of carbido clusters, which demonstrate the substituent-free carbon atom in a wide variety of coordination modes. Although the pentanuclear iron complex **1** (Fig. 1) was for a long time the only representative of this class, nowadays the chemistry of complexes of the bare carbon atom ranks among the most favored themes of organometallic laboratories. The elementary steps in the coordination of carbon monoxide to transition metals have become an important area of research in the quest to elucidate the mechanism of the Fischer-Tropsch synthesis and other industrially important syn-gas reactions.[23]

Notwithstanding the current variety of carbido clusters, there is as yet no structurally reliably characterized example of substituent-free carbon multiply bonded to two metal centers in structures of type **A** and thus available for further reactions on the simple grounds of steric accessibility. The closest approach to M*=C=M* structures is provided by *Bradley*'s Fe_4C butterfly **10**, the fascinating framework of which species is shown in Figure 4a.[12] One of the two FeCFe units is almost linear (175°) with very short Fe-C bonds (ca. 180 pm) to which double bonding character may be attributed. Substitution at the exposed carbon atom, as in **11**,

$[Fe_4C(CO)_{13}]$ **10**

$[Fe_4(CCO_2CH_3)(CO)_{12}]^-$ **11**

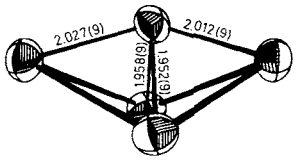

Fig. 4. Butterfly structures of the cores of a) the carbido cluster **10** and b) of the anion **11** present in $[NEt_4][Fe_4(CCO_2CH_3)(CO)_{12}]$. In both cases the Fe_4 polyhedra are folded into a "roof" form (dihedral angles 101 and 130°, respectively) with a μ_4-C_1 ligand.

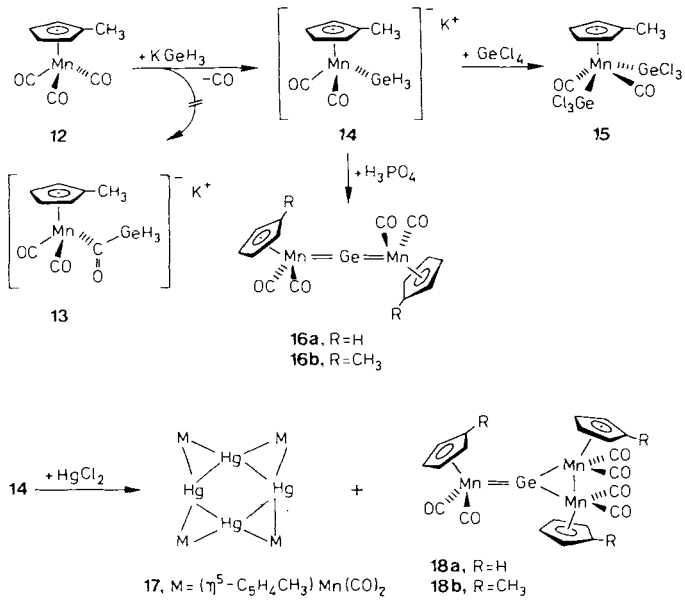


lowers the FeCFe angle by 28° while increasing the bond lengths by approximately 22 pm (Fig. 4b). The structure of **10** offers a plausible model for the chemical environment of carbidic carbon at catalytically active transition metal surfaces.[24]

2.2. Substituent-Free Germanium as Bridging Ligand

2.2.1. Syntheses

A serendipitous discovery of particular significance happened in 1981 when *E. Weiss* et al. obtained type **A** and type **C** compounds containing unsubstituted germanium (e.g. E = Ge; Scheme 1) attached to organometallic fragments through formal double bonds.[25] Reaction of $KGeH_3$ with the carbonylmanganese complex **12** did not lead to the germylcarbonyl derivative **13**, the expected product of a so-called Hieber base reaction, but, with CO elimination, to the pseudotetrahedral, pyrophoric complex anion **14**, the GeH_3 ligand of which proved to be a useful precursor for other germanium-containing materials.[26] Upon reaction of **14** with germanium(IV) chloride the neutral complex **15** is formed in 45% yield; X-ray structure analysis shows the presence of two *trans*-oriented trichlorogermyl groups. With non-oxidizing mineral acids, however, the Mn_2Ge complex **16b** is formed in 40% yield. **16b** is an orange-red, diamagnetic, crystalline, air-stable compound that demonstrates for the first time the structural type **A** (Scheme 1), characterized by a cumulated multiple bonding system between transition metals and a two-coordinate, substituent-free element of the fourth main group. In contrast, reaction of mercury(II) chloride with the complex anion **14** yields the planar (!) star-shaped Mn_4Hg_4 complex **17** in 55% yield and, albeit only in a yield of 1%, the Mn_3Ge complex **18a** (type **C**, Scheme 1), which may be considered as a distant oxidation product of

the germyl precursor **14**. The mechanism of formation of the spectacular germanium complexes **16b** and **18b** is still unclear. It is however accepted that the germanium-hydrogen bond in the precursor **14** is extremely labile to sub-

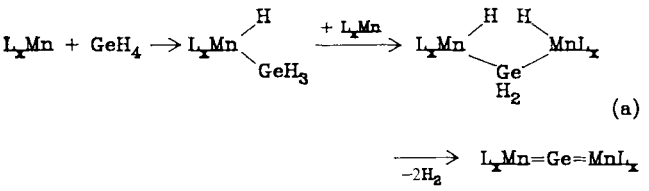
stitution. This suggested the use of monogermane, GeH_4, as a productive source of bare germanium ligands, particularly since oxidative addition reactions of organogermanium compounds R_nGeH_{4-n} (n = 0-3) are well-documented in transition metal chemistry.[28] Along this line we succeeded in preparing the Mn_3Ge compound **18a** by treatment of the solvent-stabilized organometallic fragment

$[(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)]$ **19**

with monogermane in tetrahydrofuran (THF) at room temperature.[29] This method gives appreciably better yields (40-60%, cf. 1% above) and, furthermore, avoids the need to prepare $KGeH_3$ (from the binary hydride GeH_4 and potassium metal). It should be noted at this point that the use of the binary hydrides EH_x has convincingly proved to be a general method of introducing a bare main group element E into transition metal complexes.

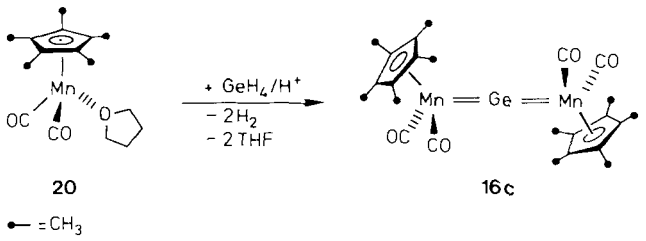
The French group of *Corriu* has shown in numerous publications that organosilanes add smoothly and readily to coordinatively unsaturated organometallic fragments to give hydrido(silyl) complexes.[30] The parent compound monosilane, SiH_4, behaves in an essentially similar manner upon reaction with the 16e-fragment of the compound

$[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(thf)]$ **20**



to give the Mn_2-complex

$[(\mu\text{-}SiH_2)\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2H\}_2]$ **21**,



the X-ray structure of which shows the expected bent MnSiMn skeleton with two terminal hydrido ligands at manganese.[31] Attempts to split off H_2 thermolytically, with the intention of preparing the still unknown silicon complex

$[(\mu\text{-}Si)\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$ **22**

have been unsuccessful; these failures may be attributed to the comparatively high stability of the SiH bonds in the complex **21**. As long as there are no indications to the contrary, the sequence (a) may be assumed, at least as a tentative working hypothesis, to represent the formation of unsubstituted germanium atoms at transition metal centers.

X-ray structure analyses have shown that the Mn_3Ge compounds **18a** and **18b** (type **C**), in contrast to the more simply constituted Mn_2Ge derivatives **16a** and **16b** (type **A**), are sterically rather crowded (see Fig. 7 and 8).[25,32] It was therefore to be expected that bulky ligands in the precursor species **19** would tend selectively to form complexes with *linear* MnGeMn backbones. Proof of this is seen in the straightforward synthesis of the compound **16c** by reaction of the solvent complex $[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(thf)]$ **20** with monogermane in the presence of sulfuric acid.[29,33] While the coordination of a further 16e-fragment (e.g. $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]$) to one of the two MnGe multiple bonds of the cyclopentadienyl compound **16a** is possible, and indeed leads smoothly to the Mn_3Ge system **18a**,[32] this addition reaction fails to occur in the case of the pentamethylcyclopentadienyl derivative **16c**.

Simply because of their size, germanium atoms call for an increase of their coordination sphere and preferentially give up their multiple bonds in favor of incorporation in cluster structures. The New Zealand group of *Mackay* and *Nicholson* was recently able, by the action of monogermane or digermane on octacarbonyldicobalt,[21,22] to prepare the structurally fascinating cobalt-germanium clusters **23** (Fig. 5) and **24** (Fig. 6), both striking and excellent examples of tetrahedral M_4Ge and square-pyramidal M_5Ge systems, respectively (types **D** and **E**, Scheme 1).

23 $[(\mu_4\text{-}Ge)\{Co_2(CO)_7\}_2]$ $[(\mu_5\text{-}Ge)_2\{[Co(CO)_4]_2[Co(CO)_3]_4\}]$ **24**

Schmid et al. had in 1977 reported the Co_4Ge complex **6b**, accessible by thermolytic CO abstraction from **23**.[18a] In-

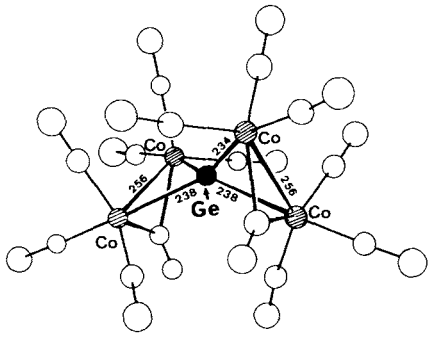


Fig. 5. A germanium atom as spirocenter: crystal structure of **23**, which compound is isovalent with $[(\mu_4\text{-Sn})\{Fe_2(CO)_8\}_2]$ **5** (Fig. 2). The two closed Co_2Ge moieties lie almost at right angles to each other (dihedral angle 96°). The angles at the spirocenter are 66° and 135°; the molecule possesses C_2 symmetry. The same core geometry is seen in the complex cation $[(\mu_4\text{-As})\{(\eta^5\text{-}C_5H_5)_2Co_2(CO)_2\}_2]^+$ **53** (Fig. 24).

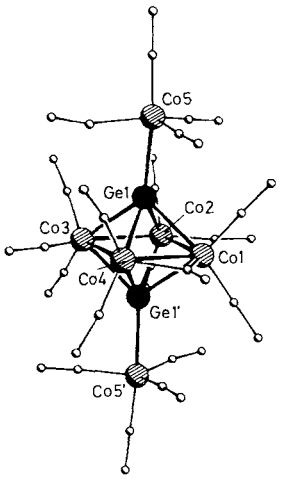

Fig. 6. Structure of the Co_6Ge_2 cluster **24** in the crystal. The octahedral, *closo* Co_4Ge_2 framework bears eleven CO ligands at the four cobalt atoms. All CoGe bond lengths lie in the range 239–243 pm. This complex is formed by the effect of heat on the isolable precursor compound $[Ge_2Co_6(CO)_{20}]$ of unknown structure (possibly a Ge-spirocycle).

terestingly, even alkylgermanes such as CH_3GeH_3 can transfer germanium atoms onto suitable carbonylmetal complexes. If polygermane mixtures are used, the reaction with organometallic fragments never preserves the GeGe bonds.[21,22] Germanium has not yet been incorporated into the center of an octahedral M_6 group, presumably because of its size (cf. carbon, Section 2.1).

2.2.2. *Structural Chemistry*

It is no surprise that the germanium ligands in the polynuclear Co_xGe_y complexes **23** and **24** are not associated with multiple bonding; in general, cluster compounds arise from the aggregation of smaller, reactive fragments. The only realistic hope of obtaining an authentic multiply bonded system, such as the manganese complexes **16a–c** and **18a,b** (Fig. 7 and 8), is that the atom ensemble will be kinetically stable. The extremely short MnGe bonds in **16c** (Fig. 7) are proof enough of multiple bonding in a cumulated (type **A**) system; the Mn=Ge bond lengths of ca. 218 pm (Table 1) are comparable with those of the bridged MnMn triple bond (217.0(1) pm) in the related complex

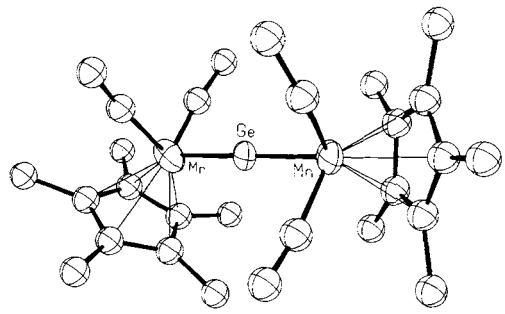

Fig. 7. Molecular structure of the Mn_2Ge compound **16c** (type **A**, Scheme 1), with its linear Mn=Ge=Mn system (Mn-Ge 218(2) pm, Mn-Ge-Mn 179(1)°) and anticlinal conformation (cf. Fig. 10).

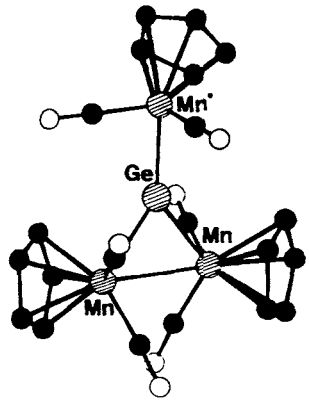

Fig. 8. Molecular structure of the Mn_3Ge compound **18b** with its trigonal-planar core geometry (type **C**, Scheme 1). The exocyclic Mn*-Ge bond (225.0(1) pm) is a formal double bond, whereas the endocyclic Mn-Ge bonds (236.0(1), 236.4(1) pm) should be considered as single bonds according to the EAN rule and the principle of isolobal analogy. CH_3 groups are omitted.

$[(\eta^5\text{-}C_5Me_5)_2Mn_2(\mu\text{-}CO)_3]$.[34,35] This similarity may be attributed to the almost exactly equal covalent radii of germanium and manganese,[35] which statement is at least true for $[(\eta^5\text{-}C_5H_5)Mn(CO)_2]$ derivatives. Genuine single bonds between germanium and low oxidation state manganese are at least 25 pm longer: $[(CO)_5Mn(GeH_3)]$ (249 pm, gas phase electron diffraction), $[(CO)_5Mn(GePh_3)]$ (260 pm), and $[(\mu\text{-}GeMe_2)\{Mn_2(CO)_9\}]$ (248–252 pm)[36–38] may be cited as reference compounds. The formal double bonds in the trigonal-planar Mn_3Ge complexes **18** (type **C**) (structure of **18b**, see Fig. 8) occur in the intermediate range around 225 pm; the reactivity of these systems will be discussed in Section 2.2.4.

2.2.3. *Bonding in Cumulated M*-E-M* Complexes*

The bonding scheme in the linear Mn_2Ge complex **16b** was, in the original publication, described on the basis of simple electron bookkeeping (noble gas rule, EAN rule) as an "organometallic allene system" with sp-hybridized germanium.[25] This view has since been extensively revised on the basis of Fenske-Hall calculations as well as evidence from vibrational spectroscopy and structural chemistry; triple bonding contributions are now being discussed.[39] An allene-type system would be associated with a rotational barrier of ca. 70 kcal/mol, whereas the infrared spectrum indicates the presence of a mixture of rotamers.

Table 1. Structure types and bond lengths in complexes with bonds between transition metals and "bare" main group elements [a].

Bonding	Compound	Structure-type	Bond lengths [pm] Single bonding	Double bonding	Triple bonding

[a] All complex compounds have been referenced in the text. The designated structural types refer to the Schemes 1, 3, and 4. The (formal) bond orders are classified according to the noble gas rule. - Abbreviations: dppe = bis(diphenylphosphino)ethane, np_3 = tris(2-diphenylphosphinoethyl)amine, p_3 = 1,1,1-tris(diphenylphosphinomethyl)ethane, $HB(pz)_3$ = hydridotris(3,5-dimethylpyrazolyl)borate.

A detailed molecular orbital discussion of this problem is thoroughly treated in the original literature,[39] but as a summary (see orbital scheme of Fig. 9) it should be stated

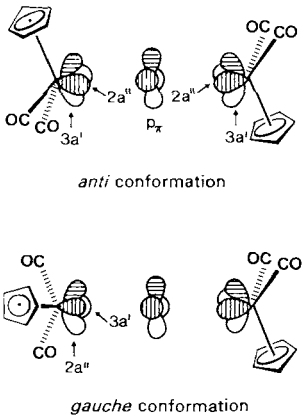

Fig. 9. Schematic representation of the most important π orbital interactions in linear type **A** complexes (Scheme 1) of composition $[(\mu\text{-E})\{(\eta^5\text{-}C_5R_5)M(CO)_2\}_2]$ (here: E = Ge, M = Mn) in the conformations *anti* (above) and *gauche* (below). The p_π orbitals of the monatomic bridging ligand are shown. The same scheme can be applied to the isovalent complexes of type **R** (Scheme 4), e.g. compounds **57a**, **b** (Section 4.1).

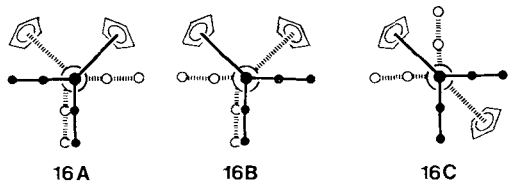
here that the metal-centered orbitals 2a″ and 3a′ are of very similar energy and that the π-electron system of the three atoms possesses an approximate cylindrical symmetry. Similar bonding systems can be seen in the isovalent sulfur and selenium complexes of general formula $[(\mu\text{-E})\{(\eta^5\text{-}C_5R_5)Cr(CO)_2\}_2]$ (E = S, Se; R = H, Me) (Section 4). The Mn_2Ge complex **16c** displays both anticlinal conformers **16A** and **16B** in the crystal, the feasible antiperiplanar form **16C** not being observed; for **16b**, however, the antiperiplanar conformation is the only rotameric form observed (Fig. 10).



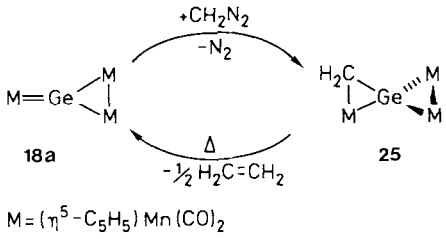


Fig. 10. Anticlinal (**16A** and **16B**) and antiperiplanar (**16C**) conformations of the M=E=M complexes of type **A** (Scheme 1), seen as Newman projections.

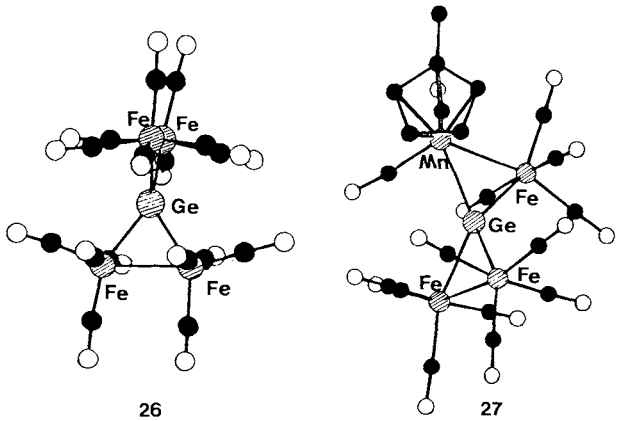
2.2.4. *Reactivity*

Multiple bonding systems can only display reasonable reactivity when they are sterically exposed and thus accessible to substrate molecules. In organometallic complexes with their numerous, often quite bulky ligands this is not always the case, but the Mn_xGe compounds discussed here do indeed show the hoped-for reactivity. Diazomethane transfers its methylene group to the obviously very reactive Mn=Ge double bond of **18a**, with evolution of N_2, at temperatures from −20 to 0°C. The metallaspirane **25** is formed in 85-95% yield. The MnGe single bonds, as expected, do not react.[29] ^{1}H-NMR spectroscopy shows **25** to have a fluctional geometry: below −50°C three well-resolved C_5H_5 signals can be seen, two of which become broader as the temperature is raised and finally merge to a single line at 20°C, with the simultaneous appearance of a broad CH_2 signal. These results can be interpreted in terms of a mutual rotation of both three-membered rings at the spirocenter (Ge) or, alternatively, of a *cis/trans* isomerization within the binuclear fragment $[(\eta^5\text{-}C_5H_5)_2Mn_2(CO)_4]$.

It is interesting that **25** decomposes slowly in solution above 50°C and immediately upon melting (112°C) with quantitative evolution of ethylene, whereupon the precursor **18a** is regenerated intact. In the presence of hydrogen this simple thermolysis also evolves methane. The reversible elimination of methylene allows **25** to be classified, in agreement with the NMR data and in contrast to the related tellurium compound $[(\mu\text{-}TeCH_2)\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$ (see Section 4.3.1), as a thermolabile metallaspirane, in which the methylene bridging of a substituent-free main group element and a transition metal is realized for the first time. The $Fe(CO)_4$ group is isolobal with the methylene fragment,[3] and does indeed add to the double bond of **16b**; in this case, consecutive metathesis reactions lead to the spirocyclic products **26** (8%) and **27** (21%). Single-crystal X-ray structure analysis shows that the germanium atom (formerly in the cumulated multiple bonding system of **16b**) is now at a spiro center (Fig. 11), forming single bonds to iron and manganese (Table 1). We have already referred to the addition of the $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ system (isolobal with both methylene and $Fe(CO)_4$) to the linear Mn_2Ge complex **16a**, leading to formation of the trigonal planar Mn_3Ge derivative **18a**.[32]



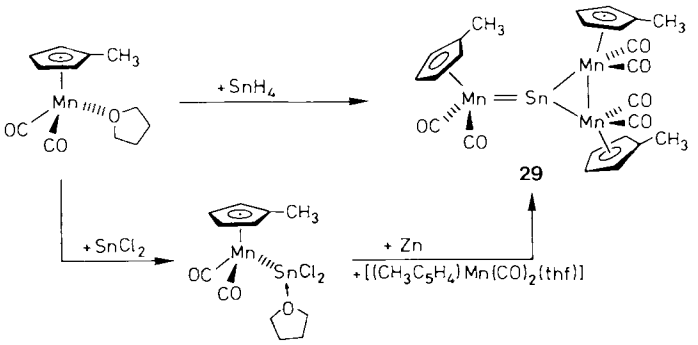


Fig. 11. Structure of the addition metathesis products of the reaction of $Fe_2(CO)_9$ with the Mn_2Ge complex **16b**: left, $[(\mu_4\text{-}Ge)\{Fe_2(CO)_8\}_2]$ **26**; right, $[(\mu_4\text{-}Ge)\{Fe_2(CO)_8\}\{Fe(CO)_4\}\{(\eta^5\text{-}C_5H_4Me)Mn(CO)_2\}]$ **27**. For bond lengths, see Table 1.

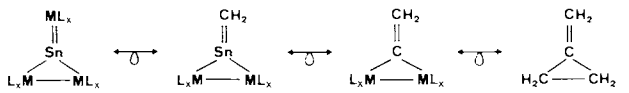
2.3. Substituent-Free Tin as Bridging Ligand



Tin forms not only the prototypal M_4Sn spirocycle **5** with distorted tetrahedral geometry of the M_4 framework and tin–metal single bonds (see Section 2.1). Substituent-free tin has recently proved to be not inferior to its germanium homologue (see above) in forming trigonal planar systems (type **C**, Scheme 1). The two isovalent M_3Sn complexes **28** and **29** (M = W or Mn) are synthesized according to different strategies.[40,41] The tungsten compound **28** is formed in 8–37% yield upon reaction of the ionic com-

28 $[(\mu_3\text{-Sn})\{W(CO)_5\}_3]$ $[(\mu_3\text{-Sn})\{(\eta^5\text{-}C_5H_4CH_3)Mn(CO)_2\}_3]$ **29**

plex $Na_2[W_2(CO)_{10}]$ with tin(IV) chloride while the isolobal manganese derivative **29** $[W(CO)_5 \leftrightarrow (\eta^5\text{-}C_5R_5)Mn(CO)_2]$ is obtained from the neutral precursor $[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2(thf)]$, either in one step with stannane, SnH_4, (55% yield) or in two steps from tin(II) chloride, leading first to the isolable dichlorostannanediyl complex $[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2(SnCl_2)(thf)]$, which is then dehalogenated with zinc dust in the presence of the solvent complex $[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2(thf)]$. The final product **29** is air-stable (yield 60%).

The structures of **28** and **29** are very similar (cf. Figure 12). The M_3Sn groups are planar and are reminiscent of the structures of μ-vinylidene complexes[42,43] and their (as yet unknown) stanna derivatives, with which they are (like with methylenecyclopropane) connected via the isolobal chain of Scheme 2. The M_2Sn moieties form isosceles

Scheme 2.

triangles with relatively long metal–metal and metal–tin distances, which, considering the metallic covalent radii, are best interpreted as single bonds.[40,41] Like the MCM units in μ-methylene and μ-vinylidene complexes, the MSnM units in **28** and **29** enclose acute angles (74.1°, 75.5° respectively). The exocyclic organometallic fragments $W(CO)_5$ and $(\eta^5\text{-}C_5R_5)Mn(CO)_2$, isolobal with methylene,[3] are bound to the tin atom via markedly shortened bonds; the extent of this shortening is, as in the analogous germanium compounds **18**, 7–11 pm with respect to the normal MSn single bond length.

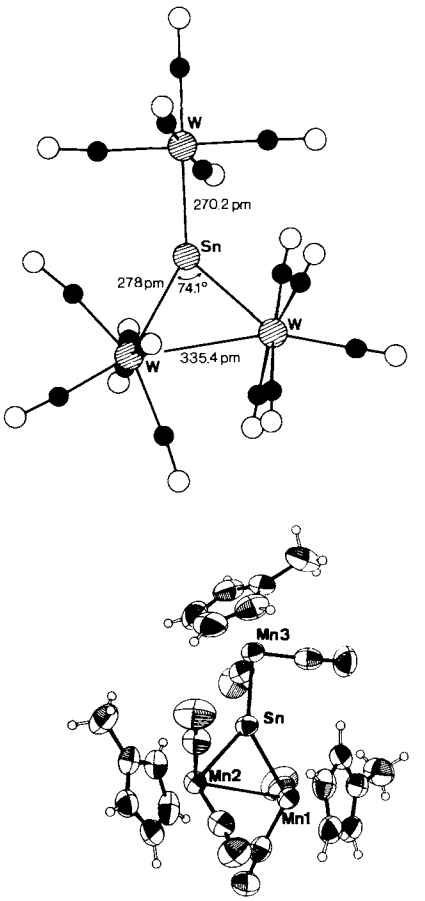


Fig. 12. Crystal structures of the complexes **28** (top) and **29** (bottom). In both complexes the substituent-free tin atom is trigonal planar coordinated (type **C**, Scheme 1).

We have just recently been able to synthesize the complex $[(\mu\text{-Sn})\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$, the first organometallic compound with two-coordinate tin, by reaction of $[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(thf)]$ **20** with either SnH_4 (one step) or $SnCl_2$ (two steps).[44]

2.4. Substituent-Free Lead as Bridging Ligand—The First Example

Although the coupling of a substituent-free germanium or tin atom to an organometallic fragment is often achieved via the hydride route, this method fails with lead, the heaviest member of the group, because of the instability of monoplumbane. Notwithstanding the danger that the potentially more promising low-valent halides might not be completely converted into substituent-free main group ligands on reaction with organometallic complexes, we allowed the substitution-labile solvent complex **19** to react with lead(II) chloride. In this manner we obtained the Mn_2Pb complex **30**, a deep red-brown compound that is relatively sensitive to light and oxygen in solution but is air-stable for a short time up to 130°C in the crystalline state.[45] It is too early to make reliable statements as to

$$2\,[(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)] + PbCl_2 \longrightarrow \underset{\mathbf{19}}{} \qquad (b)$$

$$[(\mu\text{-Pb})\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2] + \ldots$$
$$\mathbf{30}$$

the mechanism of the formation of **30**, particularly because considerable quantities of finely-divided lead are precipitated during the reaction; however, it is relevant that **30** is not formed from the precursor **20** with elemental lead, even when the latter is converted into a reactive form by high-power sonication. It is possible that the first step involves formation of a dichloroplumbanediyl complex; upon reaction of germanium(II) chloride with **19**, the mono- and binuclear dichlorogermanediyl complexes $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(GeCl_2)]$ (as solvent adduct) and $[(\mu\text{-}GeCl_2)\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2]$ (solvent-free), respectively, are present in solution.[46,47] **30** is likely to be formed from a labile intermediate of this type by consecutive halogen abstraction.

A single crystal X-ray study proved that **30** is the first example of a substituent-free lead atom bonded to transition metals by multiple bonds. The triatomic MnPbMn-backbone is linear (177.2(1)°), and there are thus no direct Mn···Mn contacts (Fig. 13).

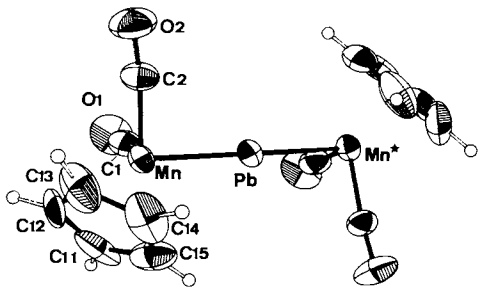

Fig. 13. ORTEP picture of the crystal structure of **30**. Selected bond lengths [pm] and angles [°]: Mn-Pb 245.9(1), Mn-C1 185(2), Mn-C2 181(1), C1-O1 111(2), C2-O2 113(2) pm; Mn-Pb-Mn* 177.2(1), Mn-C1-O1 174(1), Mn-C2-O2 174(1)°; torsion angle C2-Mn-Mn*-C1 −115.2(5)°.

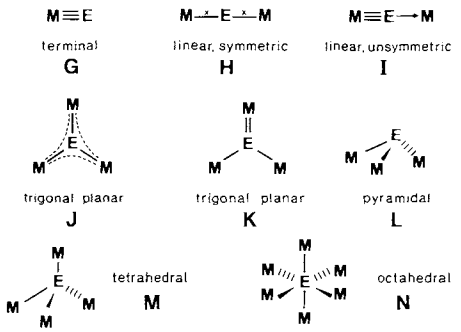
According to the bonding models evolved for the analogous germanium complexes **16a** and **16c** (Mn-Ge 218–220 pm), the bridging lead atom should also be involved in cumulated double bonds with triple bonding components. The Mn-Pb bond lengths (245.9(1) pm) justify this view; Mn-Pb single bond lengths can be more or less reliably estimated as 265–270 pm by extrapolation from known structural data;[48] Mn=Pb double bonds should be at least 20 pm shorter, and at the same time ca. 20 pm longer than the analogous Mn=Ge double bonds. The trends that we and *Huttner* et al. have discovered for germanium and tin complexes is thus continued to the heavier elements (see Table 1).

2.5. Do Carbyne Complexes M*≡C–M and Their "Big Brothers" M*≡E–M Exist?

Since we have discussed triple bonding components for the extended structural type **A**, the question arises as to whether the asymmetric bridging mode between (different) transition metals, also giving a linear structural type (**B**), can be demonstrated. Although this is a mere paper speculation, experiences with the carbyne chemistry of *Fischer*[49] justify a certain degree of optimism. If M* is a 15e- and M is a 17e-organometallic fragment, the following isolobal relationships may be drawn up:



$$HC{\equiv}C{-}H \xrightarrow{-e^-} M^*{\equiv}C{-}H \xrightarrow{-e^-} M^*{\equiv}C{-}M \xrightarrow{-e^-} \underset{\mathbf{B}}{M^*{\equiv}E{-}M} \quad (c)$$

It is not clear whether the "Big brothers" of carbon—silicon, germanium, tin, and lead—are compatible with the carbyne-analogous complexes of structure type **B** with colinear single and triple bonds, but we see a genuine chance of realizing the carbon complexes M*≡C–M; should it not be possible to combine Fischer carbynes $L_xM^*{\equiv}C{-}X$ with metal-containing 1e-ligands, either by "salt metathesis" (e.g. with $Na[Mn(CO)_5]$; X = halogen, SiR_3, etc.) or by oxidative addition (X = H; e.g. to $[(\eta^5\text{-}C_5R_5)Ir(CO)]$ fragments; CH activation)? Imagination and skill of the organometallic chemist are called upon to close this remaining gap in the already wide range of structural types.

3. Bare Nitrogen Group Elements as Bridging Ligands

3.1. Nitrido Ligands

Scheme 3 shows the most prominent of the many structural varieties in which the members of the nitrogen group function as unsubstituted ligands to transition metals. In

Scheme 3. Possible types of coordination of substituent-free elements of the fifth main group.

contrast to the bare carbon ligand, which is most often encountered encapsulated in metal polyhedra, nitrogen frequently forms mono-, bi- and trinuclear structures characterized by multiple bonds between the nitrido ligand and the adjacent transition metal atoms.[50,51] As *Strähle* and *Dehnicke* have shown in their highly informative essay,[52] inorganic azides (e.g. chloro- and iodoazide, XN_3) and nitrogen trichloride, NCl_3, are excellent reagents for the introduction of bare nitrogen into transition metal complexes; hydrazine, ammonia, and potassium amide can also be used.

Archetypal examples of mono- and binuclear nitride complexes with terminal (type **G**), symmetric bridging (**H**) or asymmetric bridging (**I**) nitrogen are shown in Figure 14. A typical, extremely short metal-nitrogen triple bond (161.4(13) pm) is seen in the pseudo-octahedral complex anion $[OsNCl_5]^{2-}$ **31**,[53] which at the same time represents an excellent example of the *trans* influence of terminal nitrido ligands (Fig. 14a); the bond between the metal atom and the ligand *trans* to the M≡N bond can be up to 30 pm longer than that between the metal atom and the identical *cis* ligand! This *trans* influence is quite often so strong that

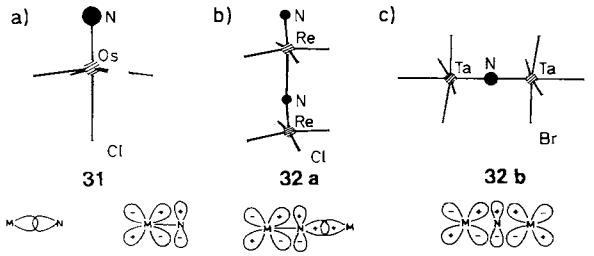


Fig. 14. Bare N_1 ligands in mono- and binuclear complexes (top), with simplified MO bonding schemes (bottom).—a) Structure of $[OsNCl_5]^{2-}$ **31** (Os-N 161.4(13) pm, Os-Cl_{ax} 260.5(4) pm (av.), Os-Cl_{eq} 236.4(4) pm (av.)); b) Part of the column structure of $[ReNCl_4]_\infty$ **32a** (Re-N 158(4) and 248(4) pm, Re-Cl 227 pm (av.)); c) structure of $[Ta_2NBr_{10}]^{3-}$ **32b** (Ta-N 185.9, Ta-Br_{ax} 273.8(6), Ta Br_{eq} 251.4(3) (av.) pm).

the effected *trans* ligand site even remains unoccupied; a similar effect is the dissociation equilibrium (d) of $[MoNCl_5]^{2-}$, which can be demonstrated in dichloromethane solution.[54]

$$[MoNCl_5]^{2-} \rightleftharpoons [MoNCl_4]^- + Cl^- \qquad (d)$$

Other well-documented examples of structures containing metal-nitrogen triple bonds are the tetragonal pyramidal complex anions $[MNCl_4]^-$ (M = Mo, W, Re, Ru, Os); the metal-nitrogen bond lengths range between 166 pm (Mo) and 157 pm (Ru);[52] triply bonded nitrido ligands and the isoelectronic carbyne groups (CR) are the strongest known π-donors in coordination chemistry. As can be seen from the schematic representation in Figure 14a (bottom), the M≡N bond is interpreted in terms of a combination of a σ-bond and two degenerate π-bonds, the lone pair conferring only weak basic properties on the nitrido ligand.

Under certain conditions the lone pair of the nitrido ligand can coordinate a further metal complex fragment; a linear N-bridged arrangement (such as in the columnar structure of tetrachloro(nitrido)rhenium **32a**) is thereby formed (Fig. 14b).[55] The bridge is markedly asymmetric, with quite different bond lengths of 158 and 248 pm; the short bond can be interpreted as a triple bond (cf. terminal M≡N), whereas the long bond corresponds to a σ-type single bond in which the occupied sp orbital of the nitrogen atom overlaps with a vacant d^2sp^3 hybrid metal orbital (Fig. 14b, bottom). If the requirements for the formation of two degenerate d_π-p_π-d_π three-center molecular orbitals are met, each being occupied by an electron pair (Fig. 14c, bottom), then symmetric nitrido bridges are formed, with colinear double bonds to both metal atoms. A good example is the complex anion $[Ta_2NBr_{10}]^{3-}$ **32b**, with the Ta-N distances amounting to 186 pm.[56]

The trigonal planar type **J**, more often encountered for the heavier group V homologues, is represented in nitrogen chemistry by one single example only, the iridium complex **33** investigated by *Griffith* et al.; the Ir_3N moiety displays three identical Ir-N bond lengths of 192 pm[57] and is presumably held together by the bonding situation schematically drawn in Figure 15, with (for each metal atom) a σ-bond and a p_π-d_π overlap between the occupied N(p_z) orbital and a metal d_{xz} orbital.

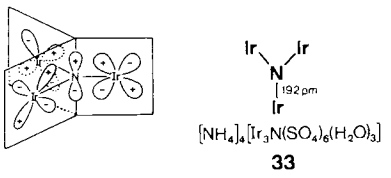

Fig. 15. Bonding behavior of the Ir_3N complex **33** as the only known example of a trigonal-planar nitrogen bridge (**J** in Scheme 3).—A T-shaped M_3N moiety has been found in the complex $[Mo_3N(O)(CO)_4(\eta^5\text{-}C_5H_5)_3]$: N. D. Feasey, S. A. R. Knox, A. G. Orpen, *J. Chem. Soc. Chem. Commun. 1982*, 75.

3.2. Clusters with Interstitial Atoms of the Nitrogen Group

To demonstrate the relationship to the structurally fascinating class of carbido clusters (Section 2.1), we must remind one here of the cluster compounds with interstitial nitrogen atoms, the first example of which was prepared by the Milan group of *Martinengo* by the reaction of $K_2[Co_6(CO)_{15}]$ with nitrosyl tetrafluoroborate.[58] Figure 17a shows that the complex anion $[Co_6N(CO)_{15}]^-$ **34** (and also the Rh analogue) has a trigonal prismatic metal atom architecture with approximate D_{3h} symmetry. The bare nitrogen ligand resides in the cavity of the Co_6 polyhedron, and hence the structural analogy to the isoelectronic carbido clusters $[M_6C(CO)_{15}]^{2-}$ (M = Co, Rh; see **3** in Fig. 1) is obvious. The nearly equal cobalt-nitrogen bond lengths of ca. 194 pm imply a covalent radius of 67 pm for the interstitial nitrogen atom. The Fe_4N-cluster

$[N(PPh_3)_2][Fe_4N(CO)_{12}]$ **35**

was prepared by *Gladfelter* et al. by a similar deoxygenation of the nitrosyl group, using as starting materials $[N(PPh_3)_2][Fe(CO)_3NO]$ and $Fe_3(CO)_{12}$.[59]

35 shows a tetranuclear Fe_4-butterfly geometry (approximate C_{2v} symmetry) with a sterically exposed low-valent nitrogen ligand that, because of the observed ready protonation reaction, is clearly electron-rich (Fig. 16). As in the isosteric Fe_4C cluster **10**, one almost linear atom sequence (Fe3-N-Fe4 179.0°) with strikingly short bonds

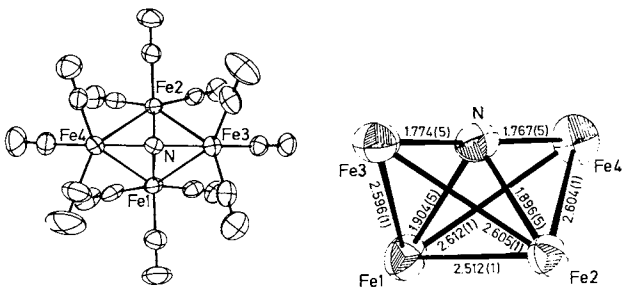

Fig. 16. Left: Structure of the anion of $[N(PPh_3)_2][Fe_4N(CO)_{12}]$ **35** in the crystal. Right: Core structure with bond lengths. The N_1 ligand is sterically exposed and thus reactive; the anion can, e.g., be protonated with H_3PO_4, giving the neutral complexes $[HFe_4N(CO)_{12}]$ and $[Fe_3(\mu_3\text{-}NH)(CO)_{10}]$.

(ca. 177 pm) is supported by a bent Fe1-N-Fe2 moiety with considerably longer FeN bonds (ca. 190 pm).

Let us now proceed to the organometallic chemistry of bare phosphorus and, in particular, to the spectacular Rh_9P ion **36**.

$[Rh_9P(CO)_{21}]^{2-}$ **36**

Surprisingly, triphenylphosphane served as the source of the phosphorus atom, which is finally encapsulated in a capped square antiprism of nine rhodium atoms (Fig. 17b). To construct the cluster ion **36**, triphenylphosphane was heated in an autoclave with $[Rh(CO)_2(acac)]$ under carbon monoxide (300 bar CO; acac = acetylacetonate).[60] It is instructive to consider the spatial requirements of a bare atom of the nitrogen group. Figure 17 compares the smallest possible *closo* clusters with interstitial N, P, As or Sb atoms. The nitrogen atom is accommodated in a closed M_6 framework (here a trigonal prism, Fig. 17a), while phosphorus requires an M_9 cage (Fig. 17b), or at least an opening up of the M_6 structure to a basket-type framework as can be seen in the case of the cluster compound

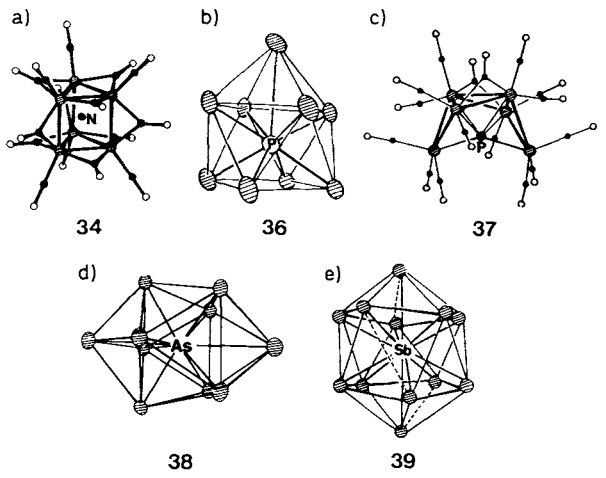

Fig. 17. Clusters with interstitial elements of the nitrogen group. – a) The ion $[Co_6N(CO)_{15}]^-$ **34** possesses a trigonal prismatic framework; in the structurally analogous rhodium complex, six chemically and magnetically equivalent metal atoms are detectable by ^{15}N-NMR spectroscopy. The N atom has the coordination number (CN) 6. – b) The P_1 ligand of the *closo* complex anion $[Rh_9P(CO)_{21}]^{2-}$ **36** is encapsulated in a monocapped cubic antiprism (CN 9 for phosphorus). – c) A smaller M_x cage has to be open on at least one side because of the size of the P atom, as in the ion $[Co_6P(CO)_{16}]^-$ **37** (CN 6 for phosphorus). – d) and e) Increasing spatial demands of the heavier homologues arsenic and antimony lead to the even larger cavities in the M_{10} and M_{12} cages of the ions $[Rh_{10}As(CO)_{22}]^{3-}$ **38** (CN 10 for arsenic) and $[Rh_{12}Sb(CO)_{27}]^{3-}$ **39** (CN 12 for antimony).

$[Co_6P(CO)_{16}]^-$ **37**

in Figure 17c.[61] Impressive evidence for the increasing spatial requirements of the higher homologues is provided by the doubly capped square antiprismatic μ_{10}-arsenic cluster **38** and the icosahedral μ_{12}-antimony cage **39**, both from the fine series of rhodium complexes[62,63] (Fig. 17d and 17e, respectively).

38 $[Rh_{16}As(CO)_{22}]^{3-}$ $[Rh_{12}Sb(CO)_{27}]^{3-}$ **39**

The covalent radius of antimony is twice as large as that of nitrogen (N 70, P 110, As 120, Sb 140, Bi 150 pm). Encapsulated bismuth is not yet known, but the element is quite capable of homonuclear cluster formation in ions such as Bi_5^{3+} (trigonal bipyramid, D_{3h}), Bi_8^{2+} (square antiprism, D_{4d}) and Bi_9^{5+} (triply capped trigonal prism, $C_{3h} \approx D_{3h}$). For the related elements antimony, arsenic, phosphorus, lead, tin, and germanium, mainly the groups of *von Schnering* and *Corbett* have prepared and structurally characterized a fascinating array of homopolyions in Zintl phases (e.g. P_{11}^{3-}, Ge_9^{2-}/Ge_9^{4-}, Sn_9^{4-}, Pb_5^{2-} and As_{11}^{3-}).[64-69] Such main group clusters can in turn encapsulate smaller atoms; good examples of this are basic lead(II) perchlorate $[Pb_6O(OH)_6(ClO_4)_4 \cdot H_2O]$[70] which shows an encapsulated oxygen atom in a Pb_4-tetrahedron and the long-known basic beryllium(II) acetate $[Be_4O(O_2CCH_3)_6]$.[71]

3.3. Substituent-Free Mono- and Biatomic Bridging Ligands Containing Phosphorus, Arsenic, and Antimony

The trigonal planar coordination type **K** (Scheme 3) with triply metalated phosphorus as central component was first verified by *Huttner* et al. in the unprecedented complexes **40** and **41**.[72,73]

$[\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2P_2\{Fe(CO)_3\}_2]$ **40**

$[(\mu_3\text{-}P)\{[Cr(CO)_5]_2[(\eta^5\text{-}C_5H_5)W(CO)_2]\}]$ **41**

The general strategy of synthesis is based on the dehalogenation of halogenophosphanediyl ligands (=PX) or phosphorus trihalide ligands (PX_3). The heteronuclear Mn_2Fe_2-compound **40** is obtained on reaction of $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(PBr_3)]$ with the well-known halogen trapper $Fe_2(CO)_9$.[72] Each of the two phosphorus atoms and its three nearest neighbor atoms lie in a plane (maximum deviation 5 pm), the interplanar angle being almost orthogonal (94.1°) (Fig. 18, top). The empty p orbital of the bare phosphorus ligand is filled by back bonding from manganese donor orbitals; the manganese-phosphorus bond length (210 pm) is even shorter than in conventional phosphanediyl (phosphinidene) complexes, where the bonds are also shortened by manganese-d_π-phosphorus-p_π interactions.

The Cr_2-complex $[(\mu\text{-}PBr)\{Cr(CO)_5\}_2]$ reacts with the complex anion $[(\eta^5\text{-}C_5H_5)W(CO)_3]^-$ with salt metathesis to give the μ_3-phosphorus complex **41**, a fine example of the structure type **K** in Scheme 3. The structural details of this complex are consistent with a bonding interpretation according to which the exocyclic phosphorus-chromium bonds incorporate more π-bonding than the endocyclic bonds (Fig. 18, bottom).

A much marveled-at curiosity in the organometallic chemistry of phosphorus is the P_2 complex

$[\{Cr(CO)_5\}_2P_2\{Co(CO)_3\}_2]$ **42**

(see Fig. 19); its preparation is not essentially different from that of the P_1 complexes **40** and **41** described above, but leads to coupling of two phosphorus atoms—a conse-

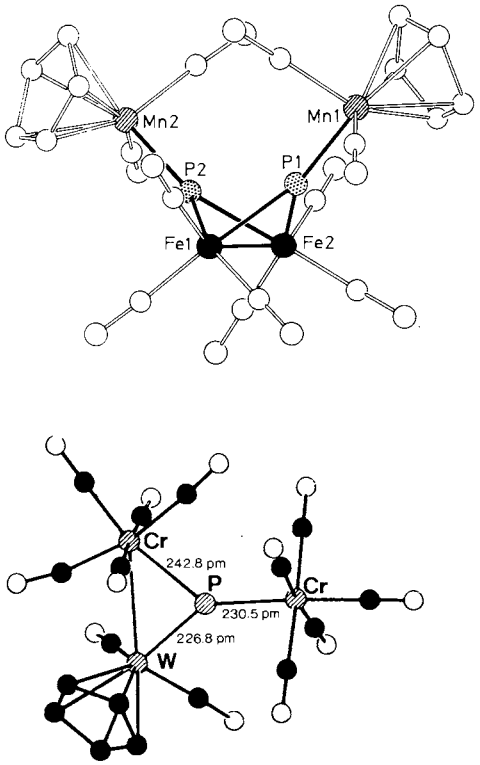

Fig. 18. Bare phosphorus ligands with trigonal planar coordination (type **K**, Scheme 3). Top: Structure of the $Mn_2Fe_2P_2$ complex **40** in the crystal (approximate C_2 symmetry). Structural data of **40**: Fe-P 218.1 (av.), Mn-P 210.0 (av.), Fe-Fe 267.5(3) pm.—Bottom: Structure of the Cr_2WP complex **41**.

quence of the differing electron balance in the organometallic fragments concerned.[74]

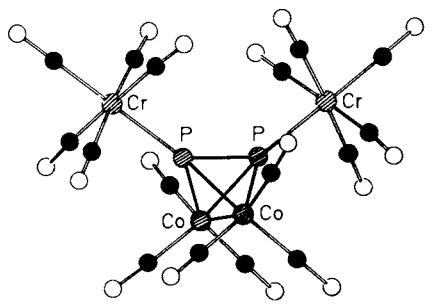

Fig. 19. P_2 fragments as 8e ligands. Crystal structure of the $Cr_2Co_2P_2$ complex **42**. The Co_2P_2-tetrahedron bears two $Cr(CO)_5$ groups at phosphorus. The compound is isolobal with dimethyltetrahedrane $C_4H_2(CH_3)_2$ (because of $Cr(CO)_5 \leftarrow\sigma\rightarrow CH_3^+$; $P \leftarrow\sigma\rightarrow C^-$; $Co(CO)_3 \leftarrow\sigma\rightarrow CH$). Structural data: P-P 206.0(5), Co-P 224.7 (av.), Cr-P 227.7 (av.) pm.

Such coupling reactions are the rule in the organometallic chemistry of arsenic, but the structural type **J**/**K** can also be attained; the method used for the isovalent P_1 complexes can, with minor variations, be used for arsenic. The complexes **43** and **44** can be cited as examples; their structures (Fig. 20) have been confirmed by X-ray structure analyses.[40]

$[(\mu_3\text{-As})\{[Cr(CO)_5]_2[Mn(CO)_5]\}]$ **43**

$[(\mu_3\text{-As})\{[Cr_2(CO)_9][Mn(CO)_5]\}]$ **44**

Starting from the complex $[(\mu\text{-AsCl})\{Cr(CO)_5\}_2]$, the expected primary substitution product **43** can be obtained by reaction with the nucleophilic $[Mn(CO)_5]^-$ anion; a comparison of the UV spectrum of **43** with that of $[(\mu\text{-}AsCH_3)\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2]$ underlines the isolobal relationship $CH_3 \leftarrow\sigma\rightarrow [Mn(CO)_5]^-$.[3] The spectrum is also consistent with the X-ray crystallographically determined structure (Fig. 20, left);[74] there are two short arsenic-chromium bonds (242–244 pm) and an appreciably longer arsenic-manganese bond (251 pm), although chromium and manganese, because of their immediate neighborhood in the periodic table, are not otherwise distinguishable here with X-ray methods. The complex decarbonylates rapidly in solution at 80 °C, forming the Cr_2AsMn structure **44** (Fig. 20, right), in which the arsenic-manganese bond is shortened to 235 pm and thereby is indistinguishable from the arsenic-chromium bonds.

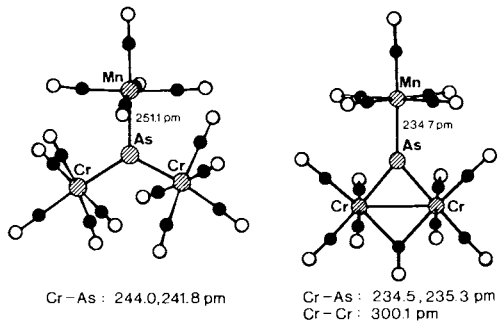

Fig. 20. Structure of the complexes **43** (left) and **44** (right) in the crystal. In both complexes the substituent-free arsenic is trigonal planar coordinated (**J** in Scheme 3).

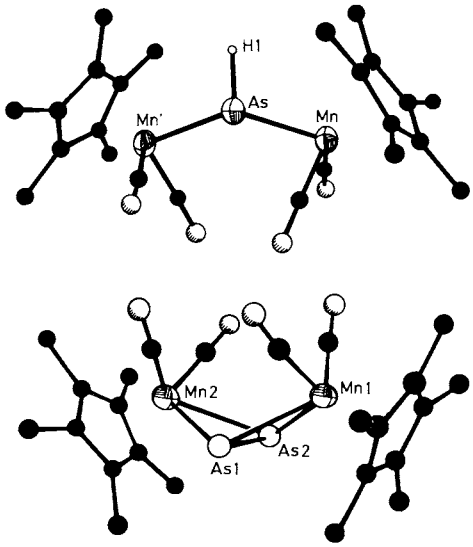
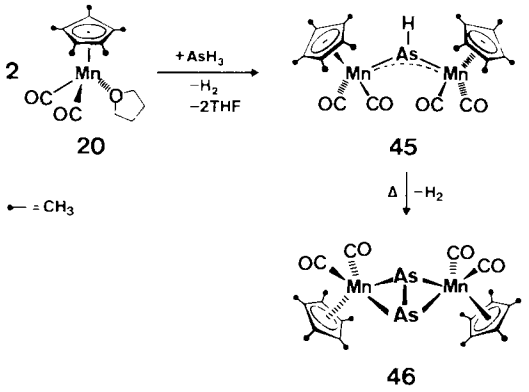
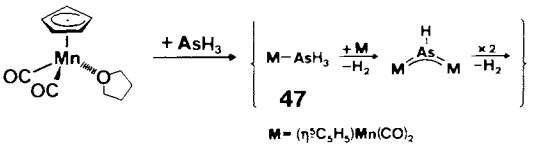
The coupling of bare arsenic atoms can be achieved by a modified synthetic strategy, which involves the use of arsenic-containing precursors with easily removable substituents. The synthesis of the μ_2-AsH- and μ_2-As_2-complexes **45** and **46**, respectively, is an excellent example.[76,77] The AsH complex **45** (Fig. 21, top) is formed on reaction of







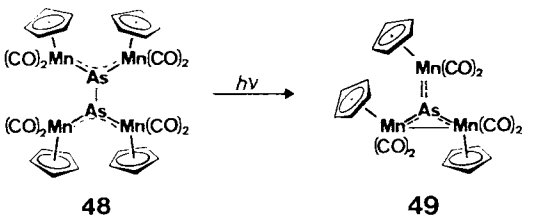


Fig. 21. Top: Structure of the AsH complex **45** in the crystal (Mn-As 224.7(1) pm, Mn-As-Mn' 139.3(1)°).—Bottom: Structure of the As_2 complex **46** in the crystal (As1-As2 222.5(2), Mn-As 255.6 pm (av.)).

$[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(thf)]$ **20** with arsane; it is converted in >85% yield into the As_2 complex **46** (Fig. 21, bottom) upon solid state thermolysis (high vacuum, 120–140 °C); **46** displays a butterfly framework rather than the expected tetrahedrane.

Attempts to prepare the arsane complex $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(AsH_3)]$ **47** led instead in >80% yield to the Mn_4As_2 complex **48**, for which spectroscopic data allowed an unambiguous structural assignment; the structure can be understood as a combination of two AsH precursors of the type **45**, via elimination of H_2, and provides further evidence for the weakness of the AsH bond.[76] A similar coupling reaction is no longer feasible if the much more bulky pentamethylcyclopentadienyl ligands are used (cf. Fig. 21, top). The As_2 complex **48**, also obtainable by reductive dehalogenation of $[(\mu\text{-AsCl})\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2]$ with zinc dust, is in turn a suitable precursor of the trigonal planar As_1-complex **49**,[77] which is formed on irradiation.

Unsubstituted As_2-ligands—As_2 itself is the main component of arsenic vapors at high temperature—are formed under mild reaction conditions also from arsenic(III) chloride, or thermolytically from cycloarsanes (e.g. *cyclo*-As_5R_5; $R=CH_3$, C_6H_5). The As_2 moieties function, depending upon the type and number of the coordinated organometallic fragments, as 4e-, 6e-, or 8e-ligand. The D_{3h}-symmetrical tungsten complex

$[(\mu_3,\eta^2\text{-}As_2)\{W(CO)_5\}_3]$ **50**

should be mentioned as an outstanding example of a series of interesting compounds; it possesses a considerable aesthetic appeal. **50** is obtained by the reaction of $AsCl_3$ with either $[W(CO)_5(thf)]$ or $Na_2[W_2(CO)_{10}]$, and has been structurally characterized (Fig. 22).[79a] The AsAs bond length is

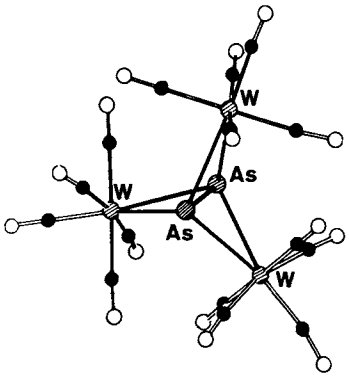

Fig. 22. Structure of the W_3As_2 complex **50** in the crystal, with As_2 being present as a μ_3,η^2-ligand. **50** is isolobal with bicyclo[1.1.1]pentane, C_5H_8, according to the connectivity modes As $-\sigma-$ CH and $W(CO)_5$ $-\sigma-$ CH_2.

227.9(4) pm, markedly shorter than expected for an AsAs single bond. The triple bond of the free As_2 molecule is lengthened by interaction with the organometallic fragment in a similar manner to that for CC or NN bonds in acetylene or dinitrogen complexes, respectively. A theoretical study of such systems shows that the strong π-acceptor capability of the As_2 molecule makes an important contribution to the stability of the organometallic fragment. A weak π bond between the arsenic atoms is associated with low-lying π* energy levels, which can combine favorably with the d orbitals of the transition metal. When As_2 fragments are bonded to two metal centers in the manner of acetylenes, as in $[(\mu_2,\eta^2\text{-}As_2)\{(\eta^5\text{-}C_5H_5)W(CO)_2\}_2]$,[80] they behave as bases and thus readily add 16e fragments such as, e.g., $Cr(CO)_5$. The antimony compound

$[(\mu_3,\eta^2\text{-}Sb_2)\{W(CO)_5\}_3]$ **51**

analogous to **50**, is obtainable by the analogous reaction and it also possesses a star-shaped structure.[79b] Arsenic attains a higher degree of aggregation in the triple-decker sandwich complex

$[\{(\eta^5\text{-}C_5H_5)Mo\}_2(\mu,\eta^4\text{-}As_5)]$ **52**

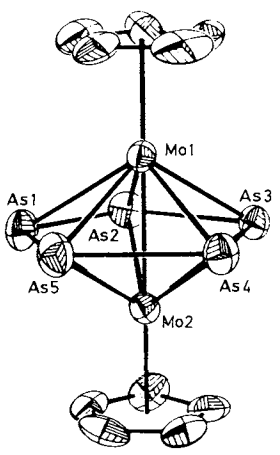

Fig. 23. Structure of the triple-decker sandwich complex **52** containing a planar As_5 ring. The As-As bond lengths lie in the range 238.9–276.2 pm.

with its planar As_5 ring enclosed by two molybdenum atoms (Fig. 23).[81] Just recently, *Scherer* et al. have been able to synthesize an analogous complex with *cyclo*-P_5.[81b]

An example of the structural type **M** of Scheme 3 (organometallic arsonium ion) is furnished by the half-open tetrahedron of the Co_4As complex cation **53** (Fig. 24).[82]

$[(\mu_4\text{-As})\{(\eta^5\text{-}C_5H_5)Co(CO)\}_3]^+$ **53**

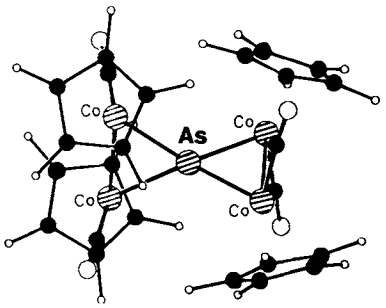

Fig. 24. Structure of the Co_4As complex ion **53** in the crystal (Co-As 227 (av.), Co-Co 260, Co···Co 414 pm).

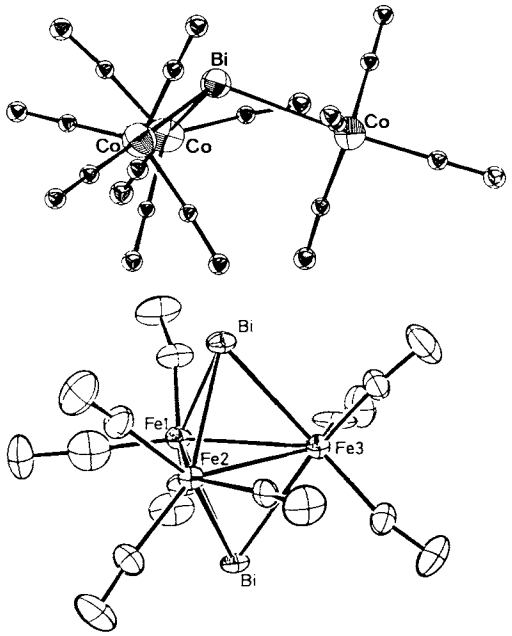
3.4. Bare Bismuth Ligands

Bismuth, the largest and heaviest element of the fifth main group, can also occur as a substituent-free ligand bound to transition metals. There is no authentic example of a metal-bismuth multiple bond (i.e. the structural types **G**–**K** in Scheme 3 are unknown for bismuth), but M_3Bi moieties (type **L**) have demonstrated their stability in several representatives. The cobalt and iron complexes **54** and **55** respectively, obtainable from metallic bismuth, bismuth(III) chloride or sodium bismuthate(V), contain pyramidal bismuth bridges (Fig. 25).[18a,75]



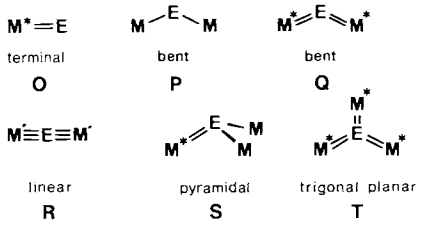


Fig. 25. Molecular structures of the pyramidal μ_3-Bi complexes **54** (top) and **55** (bottom). **54** has no Co-Co bond; **55** has three Fe-Fe bonds. The M_3Bi geometry of **55** tends more towards the pyramidal than that of **54** (Fe-Bi-Fe 62.6° av., Co-Bi-Co 107° av.) because of the shorter MM bonds. The iridium complex $[(\mu_3\text{-Bi})\{Ir_3(CO)_9\}]$ similar to **55** has been described by *Schmid* et al. [19b].

$[(\mu_3\text{-Bi})\{Co(CO)_4\}_3]$ **54** $[(\mu_3\text{-Bi})_2\{Fe_3(CO)_9\}]$ **55** $[(\mu_3,\eta^2\text{-}Bi_2)\{W(CO)_5\}_3]$ **56**

The only known Bi_2 complex **56** contains, like its arsenic and antimony analogues **50** and **51** respectively,[79a,b] no metal–main group element multiple bonds, but displays considerable multiple bonding character in the BiBi interaction (bond length 281.8(3) pm).[79c] Soluble bismuth cluster molecules could be important for the explanation of the mechanism of the industrially important ammonoxidation of propene ("SOHIO process"), which relies on highly active bismuth/tungsten oxide catalysts.

4. Bare Oxygen Group Elements as Bridging Ligands

The complex chemistry of oxygen and its homologues is extensive. Bonding to transition metal centers leads to structural types **O**–**T** (Scheme 4), if higher nuclearity clusters are not considered. Substituent-free oxygen shows preference for forming terminal bonds (type **O**) or symmetric, bent bridges (**P**). The availability of d orbitals at the metal centers leads preferentially with the higher homologues to incorporation in multiple bonding systems (d_π-p_π interactions) with frameworks **Q**–**T**, but oxygen too is known in linear and trigonal planar structures as in the ions $[Ru_2OCl_{10}]^{4-}$,[83] $[Si_2O_7]^{6-}$ (and coesite),[50] $[O(HgCl)_3]^+$, and in metal dioxides of the rutile type. The highest coordination number (CN 10) of a chalcogen atom is seen in the doubly capped square antiprism of the cluster ion $[Rh_{10}S(CO)_{22}]^{2-}$.[84]

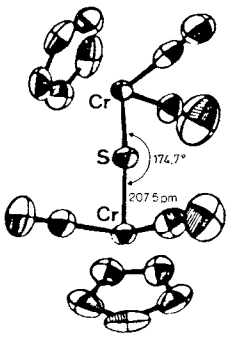
Scheme 4. Possible types of coordination for substituent-free elements of the 6th main group.

4.1. Bent and Linear Coordination

We shall begin with the surprises which have arisen in the chemistry of bare sulfur, selenium, and tellurium in the last few years. Although bent S_1 bridges (type **P**) are so common that their mention here would depart from the scope of this review, the discovery and correct interpretation of the Cr_2S compound **57a** (type **R**; Fig. 26) by *Legzdins* et al. in 1979 proved to be another landmark in organometallic chemistry.[85] They obtained **57a** by reaction of trithiazyl trichloride, $N_3S_3Cl_3$, with the complex ion $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]^-$.

$[(\mu\text{-S})\{(\eta^5\text{-}C_5H_5)Cr(CO)_2\}_2]$ **57a**

Cumulated triple bond systems of this type have since been obtained from the most varied strategies of synthesis



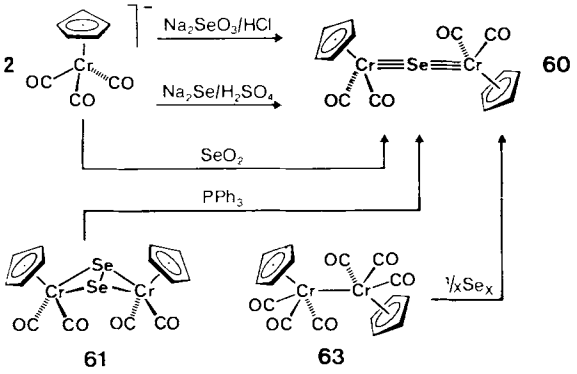


Fig. 26. Structure of the Cr_2S complex **57a** in the crystal. **57a** is a prototypal example of cumulated M'≡E≡M' complexes (E = chalcogen; type **R**, Scheme 4). The metal-sulfur bond is the shortest known (CrS 207.4 pm (av.)).

as summarized in Scheme 5. A necessary condition for the existence of linear M'≡E≡M' complexes is that the organometallic fragments M' must be 15e systems, capable of taking up all the valence electrons of the bare bridging ligand.

Scheme 5.

Other established precursors of unsubstituted sulfur ligands are elemental sulfur, hydrogen sulfide and sodium sulfite/hydrochloric acid; for the construction of analogous selenium systems, favored reagents are red or black selenium, sodium selenite/hydrochloric acid, and selenium(I) chloride.[86-90,94-98,106] Possibly the first examples of extended M_2S molecules, although their full significance was not realized at the time, were the d^8 configurated cobalt and nickel compounds **58a** and **58b**, respectively,

58a $[(np_3)Co{=}S{=}Co(np_3)]$ $[(p_3)Ni{=}S{=}Ni(p_3)][BPh_4]_2$ **58b**
$np_3 = N(CH_2CH_2PPh_2)_3$ $p_3 = H_3CC(CH_2PPh_2)_3$

isolated by *Sacconi* et al. back in 1978. The M_2S backbones are strictly linear and display strikingly short bonds (Fig. 27). To quote the authors from their original publication:[90] "Noteworthy is the Ni-S bond distance (2.034(2) Å), which is the shortest ever found for such a linkage in transition metal complexes ... Since the two individual d^8 entities would be paramagnetic, it seems probable that a superexchange mechanism through the sulfur atom, utilizing p_π orbitals of the sulfur and orbitals of higher energy of the metal (symmetry D_{3d} or D_{3h}) is involved. This interaction (which must be introduced to account for the diamagnetism of the complexes) will be favored by the linearity of the sulfur bridge and by the relatively low electronegativity of the sulfur atom".

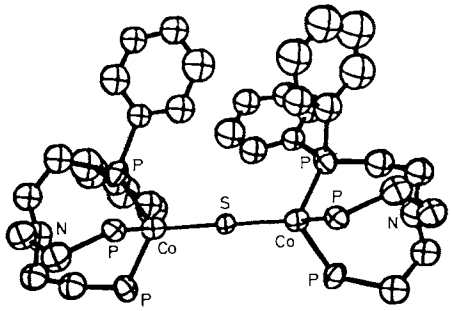

Fig. 27. Molecular structure of the Co_2S complex **58a** in the crystal.

Related complexes with linear $[MoSMo]^{2+}$, $[MoSMo]^{6+}$ and $[MoSeMo]^{2+}$ units (Mo-S 218.1(1) and 217.1(1) pm; Mo-Se 232.3(1) pm, see Table 1) are now known,[91-93] as are the low-valent vanadium compounds **59**.[94,95]

$[(\mu\text{-E})\{(dppe)V(CO)_3\}_2]$ dppe = $Ph_2PCH_2CH_2PPh_2$
59a, E = S; **59b**, E = Se; **59c**, E = Te

If one accepts packing effects as the origin of the crystallographically significant deviation from linearity, the μ-tellurium complex **59c**, with V-Te-V 165.9°, may be considered the first example of "linear", two-coordinate tellurium (type **R**) in organometallic chemistry, particularly since the V-Te bond lengths are quite short (251.4 and 252.2 pm); the fully analogous μ-S and μ-Se complexes **59a,b** display strictly linear bridges (as does the sulfur derivative **57a**) with short VSe bond lengths at 229.8(2) pm. The structure of the V_2S complex **59a** is shown in Figure 28.

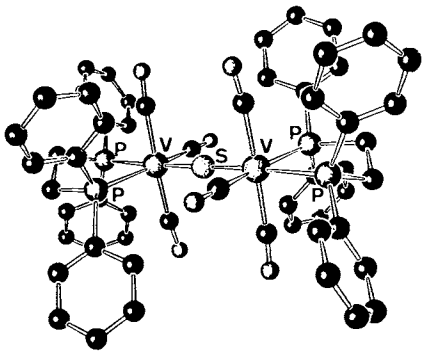

Fig. 28. Structure of the V_2S complex **59a** in the crystal. The V≡S triple bonds in the complex can be postulated on the basis of the V-S bond length (217.2(1) pm).

4.2. Chromium-Selenium, Chromium-Tellurium, and Manganese-Tellurium Bonds

Despite their cumulated multiple bonding systems (type **R**), the Cr_2S complexes **57a**, **b**

$[(\mu\text{-S})\{(\eta^5\text{-}C_5R_5)Cr(CO)_2\}_2]$
57a, R = H; **57b**, R = CH_3

are chemically remarkably inert. In order to induce some reactivity (by exploiting longer bonds with essentially the same bonding systems), *Rohrmann* (in our Munich laboratories) and, later, *Goh* and *Weiss* et al. opened up the chemistry of complex **60** (Scheme 5).[94–98] The partial extrusion of selenium from the diselenido complex **61** (Fig. 29, top) by means of triphenylphosphane is a particularly fascinating route to **60**, which, like its sulfur analogue (Fig. 26), contains a linear backbone (Fig. 29, bottom). The very short Cr-Se bonds (220–221 pm) support the presence of cumulated triple bonds (see Section 2.2.3).[39]

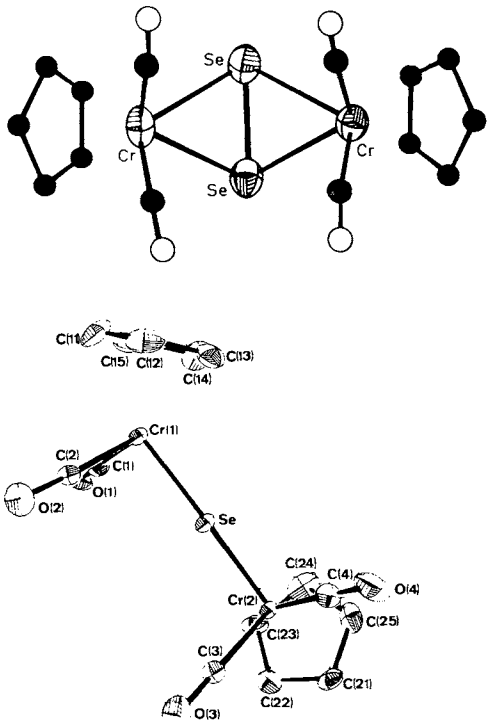

Fig. 29. Molecular structures of the folded Cr_2Se_2 complex **61** (top) and of the linear Cr_2Se complex **60** (bottom) in the crystal. The CrSe bonds in **61** are, as expected, appreciably longer (253–254 pm) than in **60** (220–221 pm). The total length of ca. 440 pm renders the CrSeCr backbone of **60** sterically accessible and therefore reactive.

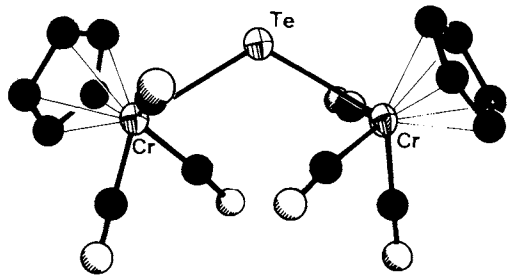
On fractional crystallization, **60** is obtained in two crystal modifications with different solid-state infrared spectra; this phenomenon is probably to be ascribed to the existence of rotational isomers. The immediate equilibration of the isomers in solution and the occurrence of only one proton NMR signal for both C_5H_5 groups (down to the lowest attainable temperatures) point to a free rotation of the halves of the molecule about the Cr-Se-Cr axis. Such a rotation of the L_xM moieties about M≡E≡M bonds for compounds of this type is also consistent with MO calculations;[39] rotational isomers have been shown by X-ray structure analysis to coexist in analogous complexes but have hitherto eluded separation.[85]

Attempts to prepare tellurium compounds analogous to the sulfur and selenium complexes **57** and **60** have so far failed, despite the use of a wide range of synthetic methods. The reaction sequences end at the stage of the bent μ-Te complex **62** (structural type **P**) which has very long



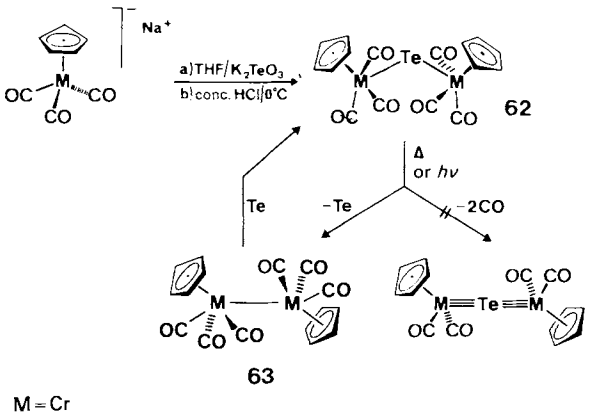


Fig. 30. In contrast to the Cr_2Se complex **60** (Fig. 29, bottom), the Cr_2Te complex **62** (type **P**, Scheme 4), with two more CO groups, displays a bent core geometry and is isolobal with $(CH_3)_2Te$. The CrTe bonds are very long (280–281 pm) and correspond to simple single bond character; the compound is basic and can be protonated at the μ-Te atom.

CrTe single bonds (280–281 pm; Cr-Te-Cr 117.2°) (Fig. 30). Contrary to expectation, **62** cannot be decarbonylated to the target compound $[(\mu\text{-Te})\{(\eta^5\text{-}C_5H_5)Cr(CO)_2\}_2]$; when it is heated or exposed to light, extrusion of the tellurium bridge takes place, with formation of the CrCr compound **63**, which in turn is a suitable starting material for the preparation of **62** (reaction with elemental tellurium, 97% yield).[99] If the 17e-fragments M of the structural type **P**

(Scheme 4) are replaced by 16e-fragments M*, compounds of type **Q** are obtained; these are again bent at E, but display M*=E double bonds. They are isolobal with sulfur dioxide. The only confirmed example, **64**, originates from manganese chemistry and was prepared by *Hecht* in our group when he treated the solvent complex **20** with Al_2Te_3/HCl, a reaction that was surprisingly successful.[100] The angle at tellurium in the Mn_2Te unit, 123.8(1)°, is as expected for an sp^2-hybridized chalcogen group element. The MnTe bond lengths, 245.9(2) pm, clearly prove the presence of multiple bonds, since MnTe single bonds would be expected to be 270 pm on the basis of the covalent radii (Mn ca. 133, Te 137 pm) (Fig. 31, top).

$[(\mu\text{-Te})\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$ **64**

$[(\mu_3\text{-Te})\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_3]$ **65**

Correspondingly short bonds are observed in the trigonal planar μ_3-tellurium complex **65** (type **T**, av. MnTe 248.5 pm; see Fig. 31, bottom), prepared by *Herberhold* et al. using the same method but also obtainable from elemental tellurium.[101,102] A comparison of both compounds (Fig. 31) emphasizes the structural analogy between the

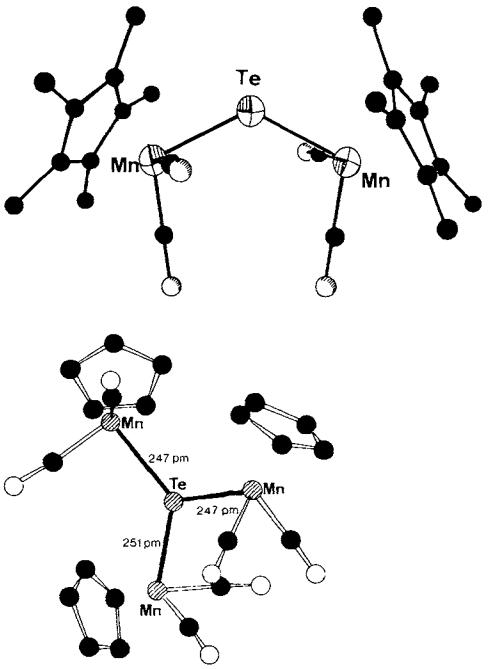

Fig. 31. Organometallic analogues of TeO_2 and TeO_3 with bent and trigonal planar skeletal geometries, respectively. Top: Structure of the μ-Te complex **64** in the crystal; bottom: structure of the μ_3-Te complex **65** in the crystal. The short MnTe bonds are best interpreted as double bonds.

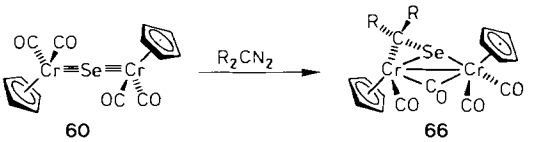
above complexes **64** and **65** and the chalcogen oxides XO_2 (bent) and XO_3 (planar), respectively, because of the isolobal relationship[3,4]

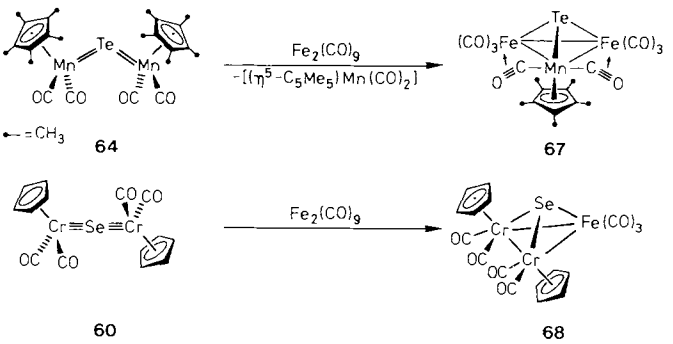


$$O \leftarrow\!\!\circ\!\!\rightarrow S \leftarrow\!\!\circ\!\!\rightarrow Se \leftarrow\!\!\circ\!\!\rightarrow Te \leftarrow\!\!\circ\!\!\rightarrow [(\eta^5\text{-}C_5R_5)Mn(CO)_2] \quad (e)$$

4.3. Multiple Bond Reactivity of π-Bonded Selenium and Tellurium Bridges

Although the μ-S complexes $[(\mu\text{-}S)\{(\eta^5\text{-}C_5R_5)Cr(CO)_2\}_2]$ (**57a**, **b**) are chemically remarkably inert despite their cumulated triple bonds at the bridge atom, complexes with multiple bonded selenium and tellurium bridges do undergo reactions.

4.3.1. Alkylidene Additions



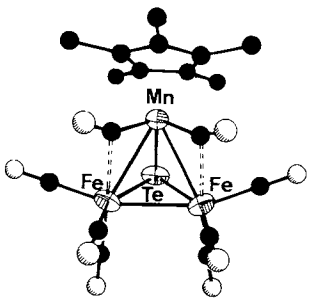
The μ-Se complex **60** smoothly adds methylene and small alkylidene groups to one of the Cr≡Se bonds to give **66**.[96,97] The tellurium complex **64**, an example of structural type **Q**, reacts analogously—a reaction that should be generalizable for M′≡E and M*=E structural elements. The reader is reminded here of the successful diazoalkane route to μ-alkylidene complexes of transition metals.[103] Complex **65**, with its planar Mn_3Te central unit, is accessible to methylene groups too, as is the related Mn_3Ge complex **18a** (Section 2.2.4), but loses one of the M* groups on reaction with diazomethane.[29]

60 R = H, CH_3 66

4.3.2. Formation of Cluster Structures

Organometallic fragments are also capable of adding to Mn=Te and Cr≡Se groups. In this way, the $MnFe_2Te$-

tetrahedrane cluster compound **67** (Fig. 32) is obtained from **64** and $Fe_2(CO)_9$.[104] Reaction of the μ-Se complex



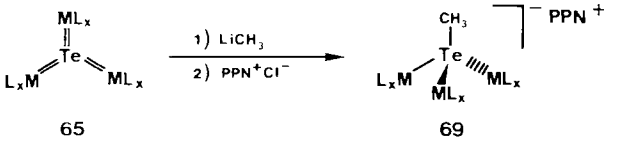


Fig. 32. Structure of the $MnFe_2Te$ tetrahedrane cluster **67** in the crystal; the M-Te bond lengths (247-251 pm) indicate single bonding.

60 with $Fe_2(CO)_9$ furnishes a product (**68**) which is structurally closely related to the $MnFe_2Te$ compound **67**.[105]

4.3.3. Nucleophilic and Electrophilic Reactions with Extension of Bridge Coordination

We were able to show in comparative studies that bridging tellurium atoms in structural type **P** display pronounced nucleophilicity, but are electrophilic in type **T**. Two typical examples can be noted here: The complex **62** (type **P**) undergoes reversible protonation with Brønsted acids and electrophilic methylation with $CF_3SO_3CH_3$,[106] but is resistant to nucleophilic methylating agents (e.g. MeLi). The opposite is the case for complex **65** (type **T**), in which, because of its extensive participation in π-bonding, the bridge atom is particularly electron-deficient and is thus attacked by alkyllithium reagents, but not by elec-

trophilic protonating and methylating agents. Methylation of **65** with methyllithium gives a salt **69** whose anion is ex-

65 69

$L_xM = (\eta^5\text{-}C_5H_5)Mn(CO)_2$

$PPN^+ = (C_6H_5)_3P{=}N{=}P(C_6H_5)_3$

tremely air-sensitive. The Mn_3TeCH_3 anion of **69** adopts a slightly pyramidalized structure and is hence far away from the expected tetrahedral geometry (Fig. 33).[106, 107]

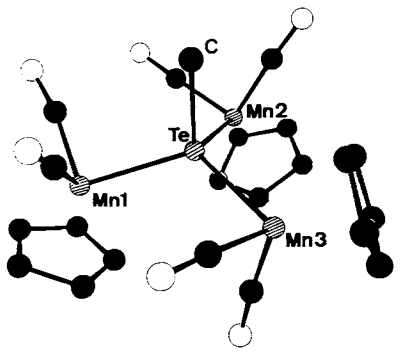

Fig. 33. Structure of the anion of **69** in the crystal. Selected dimensions: Mn-Te 257.4 (av.), Te-C 215(1) pm; Mn-Te-Mn 115.4 (av.), Mn-Te-C 102.5 (av.)°, sum of angles at Te 346°.

According to the isolobal relationship $[(\eta^5\text{-}C_5H_5)Mn(CO)_2] \leftarrow\!\!\!\!\!\!\bigcirc\!\!\!\!\!\!\rightarrow CH_2 \leftarrow\!\!\!\!\!\!\bigcirc\!\!\!\!\!\!\rightarrow CH_3^+$,[3,4] electron-rich bridging atoms of structural type **P** should be prone to coordinate to unsaturated organometallic fragments. Thus, the μ-Se compound **70**,[106] isovalent with the tellurium complex **62**, reacts with the solvent complex $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)]$ (**19**), with smooth formation of the adducts **71** and **72** (Fig. 34).[108]

$$[(\mu\text{-Se})\{(\eta^5\text{-}C_5H_5)Fe(CO)_2\}_2] + [(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)] \longrightarrow$$

70 **19**

(f)

$$[(\eta^5\text{-}C_5H_5)_3MnFe_2Se(CO)_6] + [(\eta^5\text{-}C_5H_5)_3MnFe_2Se(CO)_5]$$

71 **72**

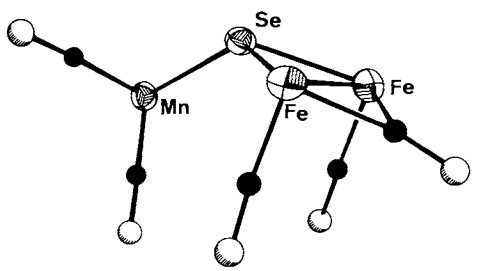

Fig. 34. Structure of the Fe_2MnSe complex **72** in the crystal. **72** is a representative of structural type **S** (Scheme 4). The π-bonded C_5H_5 ligands of iron and manganese are omitted for clarity. The sum of angles at Se is 314.9°.

4.3.4. Redox Chemistry

The delocalized π-electron systems of the Cr_2S, Cr_2Se, Mn_3Te and Mn_2Te complexes manifest themselves also in the electrochemical behavior of the complexes: Cyclovoltammograms of all the complexes display two reversible (or at least quasi-reversible) one-electron reduction steps (Table 2).[109] Figure 35 shows the voltammogram of the Cr_2Se

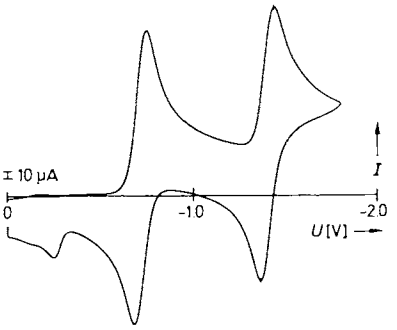

Fig. 35. Cyclovoltammogram of the Cr_2Se complex **60**, recorded in *N,N*-dimethylformamide/0.1 M TBAP vs SCE (100 mV/s; 28°C). The two reduction steps $\mathbf{60} \rightarrow [\mathbf{60}]^- \rightarrow [\mathbf{60}]^{2-}$ are reversible ($E^1_{1/2} = -0.72$ V, $E^2_{1/2} = -1.40$ V).

Table 2. First and second reduction steps ($E^1_{1/2}$ and $E^2_{1/2}$) of some μ-S-, μ-Se- and μ-Te-complexes [a].

Complex	$E^1_{1/2}$ [V]	ΔE [mV] [b]	$E^2_{1/2}$ [V]	ΔE [mV] [b]
$[(\mu\text{-S})\{(\eta^5\text{-}C_5H_5)Cr(CO)_2\}_2]$ **57a**	−0.92 (qr)	70	−1.48 (qr)	90
$[(\mu\text{-S})\{(\eta^5\text{-}C_5Me_5)Cr(CO)_2\}_2]$ **57b**	−1.15 (qr)	70	−1.80 (qr)	110
$[(\mu\text{-Se})\{(\eta^5\text{-}C_5H_5)Cr(CO)_2\}_2]$ **60**	−0.72 (r)	65	−1.40 (qr)	70
$[(\mu_3\text{-Te})\{(\eta^5\text{-}C_5H_4CH_3)Mn(CO)_2\}_3]$	−0.55 (r)	70	−1.18 (r)	70
$[(\mu\text{-Te})\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$ **64**	−0.82 (r)	60	−1.72 (qr)	80

[a] r = reversible, qr = quasi-reversible. [b] ΔE is the difference between the half-wave potentials of the forward and backward reactions.

compound **60** as one example. According to the electrochemical series of Figure 36, the complexes illustrated

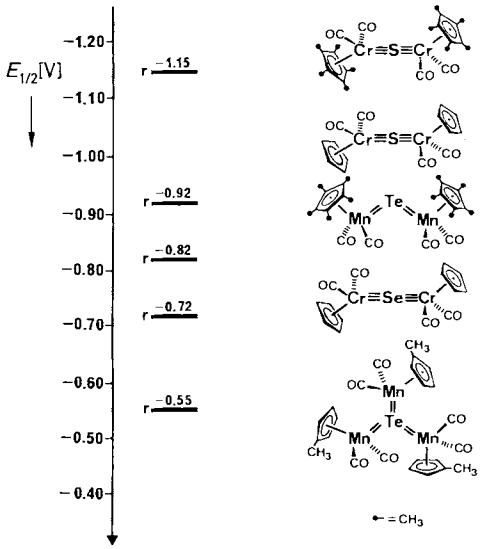

Fig. 36. Electrochemical series for selected complexes that contain multiple bonds between transition metals and bare main group elements. The first reduction potentials are given (measured in *N,N*-dimethylformamide/0.1 M TBAP solution); r = reversible. For further data see Table 2.

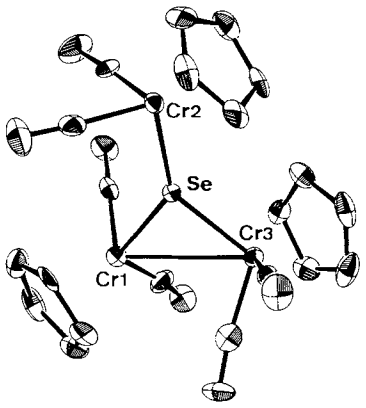
should also undergo reduction reactions on a preparative scale, provided suitable reducing agents can be found. (The observable oxidation steps in the region +0.46 to −0.87 V are irreversible). The selenium complex **60** will again serve as an example here. The potentials −0.72 V (radical anion)/−1.40 V (dianion) would suggest that reducing agents with potentials between these values might make the radical anion accessible. The reaction with cobaltocene ($E_{1/2}[Cp_2Co^+/Cp_2Co] = -0.77$ V, *N,N*-dimethylformamide[110]) in tetrahydrofuran/diethyl ether at −30 °C slowly gives the black, crystalline, ionic complex

$[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_5)_3Cr_3(CO)_6Se]^-$ **73**[111]

The complex anion of this compound has a planar (!) Cr_3Se backbone containing a Cr_2Se three-membered ring (Fig. 37). The exo- and endocyclic CrSe bonds (227.9(2) and 233.2(2)/234.3(2) pm, respectively) have different bond multiplicities; the CrCr bond, with a length of 308.3(2) pm, compares with a single bond. The linear Cr_2Se complex **60** is isoelectronic with the Mn_2Ge compound **16a** and both systems are considered as having



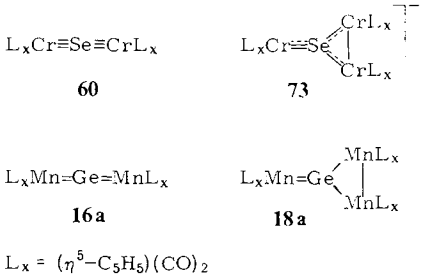


Fig. 37. Structure of the complex anion of **73** in the crystal (−60 °C). The planar (!) Cr_3Se backbone represents a novel type of coordination, which is not shown in Scheme 4. The salt-like compound crystallizes from tetrahydrofuran/diethyl ether (−30 °C) with one equivalent of THF.

identical bonding systems (cf. Section 2.2.3), whereas the Cr_3Se complex anion of **73** is isoelectronic with the neutral Mn_3Ge compound **18a** (Scheme 6). The central bare selenium atom contributes all valence electrons for bonding to the three $[(\eta^5\text{-}C_5H_5)Cr(CO)_2]$ fragments, which are isolobal with CH and CH_2^+ fragments. Hence, for the singly charged complex anion of **73**, as for **18**, there is an isolobal relationship to methylenecyclopropane because of $Se \leftarrow\!\!\!\!\!\!\rightarrow C^{2-} \leftarrow\!\!\!\!\!\!\rightarrow CH^-$, $Ge \leftarrow\!\!\!\!\!\!\rightarrow C$, and $(\eta^5\text{-}C_6H_5)Mn(CO)_2 \leftarrow\!\!\!\!\!\!\rightarrow CH_2$.[3,4]

As can be seen from the ^{1}H-NMR spectra ([D$_6$]acetone) **73** has a fluctional structure: At −80 °C, three well resolved C_5H_5 signals are observed, two of which become broader on increasing the temperature, and at ca. −50 °C finally merge to a single line. This finding can be explained in terms of a *cis/trans* isomerization in the dinuclear fragment $[(\eta^2\text{-}C_5H_5)Cr(CO)_2]_2$. The appearance of a sharp signal for the exocyclic $[(\eta^5\text{-}C_5H_5)Cr(CO)_2]$ unit between −80 and 25 °C is indicative of a free rotation of this

Scheme 6.

structural unit about the CrSe bond. **73** is extremely oxygen-sensitive and on contact with air immediately reverts to the starting material **60**, although not quantitatively. It is stable in solution only at low temperature and decomposes quickly at room temperature, giving the selenium-free salt $[(\eta^5\text{-}C_5H_5)_2Co]^+[(\eta^5\text{-}C_5H_5)Cr(CO)_3]^-$ (X-ray structure analysis[112]) and a carbonyl-free $[(\eta^5\text{-}C_5H_5)CrSe]_x$-cluster molecule of unknown structure. The composition of the diamagnetic (!) complex **73** shows that the one-electron reduction of **60** can lead to secondary reactions, which in the present case form polynuclear molecules. The CrSe complex **60** also reacts, immediately, with potassium superoxide, KO_2, as a reducing agent in the presence of [2.2.2]-cryptand, under fragmentation, forming the structurally characterized novel complex anion $[(\eta^5\text{-}C_5H_5)Cr(CO)_2(\eta^2\text{-}Se_2)]^-$ **74**.[113]

5. Prospects

In this essay we have encountered unsubstituted ("bare") elements of the carbon, nitrogen and oxygen groups as distinctive structural subunits, both in multiple bonding systems of limited extent and also encapsulated in transition metal clusters. Although there is still not the rich variety of compounds that we might have expected on the basis of our two decades' experience of metal-metal multiple bonds, it is to be hoped that preparative methods will prove capable of development. For the heavier, more metallic main group elements, the high reactivity of the elemental modifications themselves and of the binary hydrides on reaction with organometallic complexes is striking. The relationship to the chemistry of the transition metals is very close, since the atomic radii and the electronic structures are broadly comparable. Structural similarities with classical inorganic solid state chemistry have become quite obvious by now, and it is to be expected that iso- and heteropolyanions such as Se_4^{2+}, Te_4^{2+}, Te_5^{2-}, Te_6^{4+}, $[Au_2Te_4]^{2-}$, and $[As_{10}Te_4]^{2-}$[50,64c,115] will soon form part of the organometallic chemist's arsenal. The chemistry of multiple bond systems consisting of transition metals and bare main group elements promises, on the basis of current knowledge, to be a rich one; probably, it will basically not differ too much from the reactivity of metal-metal multiple bonds, and is likely to find applications in catalysis.

This essay arose from a lecture that I gave at the Technical University of Munich. My thanks are due to my students for their intelligent questions and comments, which caused me to think more deeply about several topics. I am also

thankful for the skill and resourcefulness of my coworkers, who have carried out their contributions to the work described here with diligence and perseverance: Basile Koumbouris (chemistry of arsenic), Heinz-Josef Kneuper (germanium, tin, and lead), Jürgen Rohrmann (sulfur, selenium, and tellurium), Christian Hecht (selenium and tellurium), Erdmuthe Voss (silicon), Rolf Hörlein and Dr. Josef Weichmann (germanium) deserve special mention. The structure determinations were performed by Dr. Eberhardt Herdtweck of our Munich laboratory and the groups of my colleagues Manfred L. Ziegler (Heidelberg University), Ivan Bernal (University of Houston) and Heinrich Nöth (Munich University), who are all to be thanked for their contributions. My colleague Hans Bock (Frankfurt University) provided intellectual stimulation and also contributed practically to the useful electrochemical studies mentioned at the end of this review. The whole research area described here owes much to the impulse it received from the work of the following groups of Herberhold (Bayreuth University), Huttner (Konstanz University), and Weiss (Hamburg University), to whom I am indebted for frank discussions. Finally, I would like to express my gratitude to Freya and our children for their continuous patience.

Ag_3O_4, the First Silver(II,III) Oxide**

By *Burkhard Standke* and *Martin Jansen**

In memory of Wilhelm Klemm

Divalent silver in a square-planar oxygen environment was unknown up to now. In accordance with the formulation $Ag^+Ag^{3+}O_2$, AgO is described as mixed valent,[1] a contention that has been disputed. During the decomposition of Ag_2O_3, which we had prepared earlier and characterized by an X-ray structure analysis,[2] we obtained evidence for the existence of a new phase between Ag_2O_3 and AgO. In both thermal investigations (differential thermogravimetry) and electrochemical methods (discharge curve), the stage at which silver(III) oxide decomposes into "silver(II) oxide" and oxygen exhibited an apparent critical point. A binary oxide with a composition between Ag_2O_3 and AgO contains (insofar as a peroxidic or hyperoxidic nature can be excluded) silver in different oxidation states. Its detection and the characterization of its structure could contribute to the clarification of the vague and often contradictory statements made concerning higher silver oxides ($AgO_{\geq 1}$).[3]

We obtained the expected mixed-valent oxide, Ag_3O_4, by anodic oxidation of solutions of silver salts (e.g., AgF or $AgClO_4$) at potentials that were lower than those used in the preparation of Ag_2O_3.[4]

Ag_3O_4 separates out as plate-like, metallic, black crystals. According to thermal investigations (simultaneous differential thermal analysis and thermogravimetric analysis, Netzsch STA 429, extrapolation to a heating rate of 0°C/s), the decomposition to AgO begins at 63°C in a strongly exothermic reaction. Accordingly, Ag_3O_4 is more stable than Ag_2O_3. Ag_3O_4 decomposed already at room temperature upon irradiation with X-rays. Therefore, the X-ray studies[6] were carried out at −50°C. Under these conditions, the reference reflections exhibit no decrease in intensity during the course of measurement.

According to the X-ray structure analysis, silver in Ag_3O_4 is exclusively present in a square-planar oxygen environment (Fig. 1). This coordination is preferred for d^9- and d^8-configurated transition-metal ions and characterizes the new compound as silver(II,III) oxide. A formulation with mono- and divalent silver—roughly in analogy with the suggestion for AgO[1]—is thus ruled out. The composition of the unit cell, corresponding to $Ag_2^{2+}Ag_4^{3+}O_8$, and the occupation of two point sites in $P2_1/c$ of appropriate multiplicity (Ag1 on 2a, and Ag2 on 4e) suggest the assignment of Ag1 and Ag2 to oxidation states +2 and +3, respectively. This conflicts, however, with the Ag–O bond lengths, which are slightly, but significantly, shorter for Ag1 (average value: 203 pm) compared with Ag2 (average value: 207 pm). Thus, it is necessary to assume extensive charge equalization over the silver positions with a slightly higher effective positive charge on Ag1. The larger Ag–O distances compared with those of Ag_2O_3 are in agreement with this assumption. The deviations of the AgO_4 polyhedrons from the ideal geometry are of the same order as the experimental error for Ag1 (point symmetry $\bar{1}$); for Ag2, they are larger, especially with regard to the angles (cf. Fig. 1). Ag2 lies about 13 pm from the "best plane" through the four neighboring O atoms. The AgO_4 structural units are linked together via common corners and edges to form a three-dimensional spatial network in which oxygen always joins three silver ions to one another, corresponding to the simplest possible formal representation $AgO_{4/3}$. Two polyhedrons around each Ag2 share a common edge; this structural unit with point symmetry $\bar{1}$ is shown in Figure 1, bottom. We hope to obtain further details of the bonding situation, in particular, the possible lo-

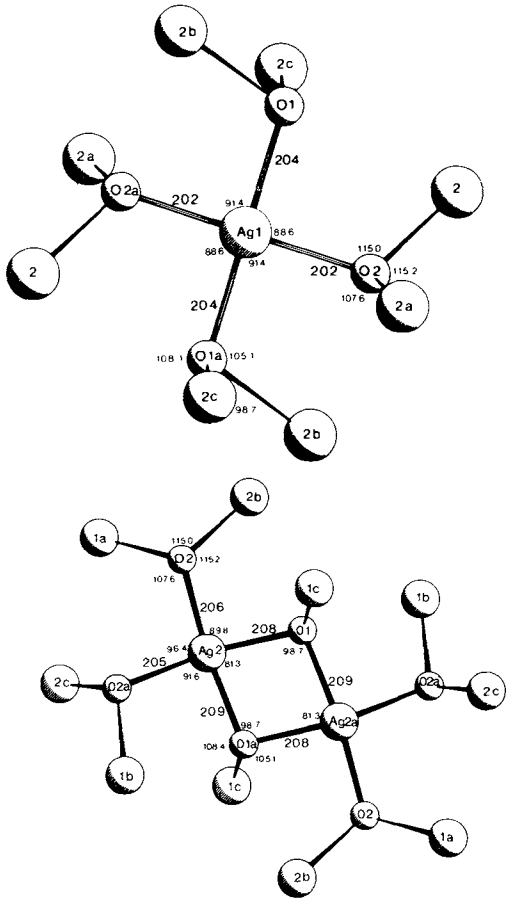

Fig. 1. Perspective view of the coordination polyhedron around Ag1 (above) and Ag2 (below) and the second nearest neighbors in each case. The smaller spheres represent Ag, distances [pm], angles [°]. The maximum standard deviations for the bond lengths and angles are 0.8 pm and 0.4°.

[4] The electrolysis was carried out in a platinum dish (as cathode) with a ca. 12-cm long, 0.4-mm thick spirally wound platinum wire as anode. AgF was preferentially used as electrolyte. In the electrolytes used, the kind of oxidation product formed is clearly dependent on the concentration of silver: in a concentration range of 0.45–1.2 mol/L, the clathrate $Ag_7O_8HF_2$ [5] is formed along with Ag_3O_4. Pure $Ag_7O_8HF_2$ is formed above a concentration of 1.3 mol/L, whereas pure Ag_3O_4 is formed only when the concentration is below 0.35 mol/L. In order to increase the conductivity, the aqueous solution of silver salt was saturated, in each case, with sodium fluoride. The optimal conditions for the synthesis of pure Ag_3O_4 are as follows: $c_{Ag^+}=0.2$ mol/L, $c_{F^-}=2$ mol/L, $U=0.8$ V, $I=12$ mA, $T=0°C$, anodes as described in text. The crystals that grew on the anode were washed with distilled water (0°C) and methanol (0°C) and dried for a short period of time in vacuum.

[4+2] Cycloadditions with Transition-Metal-Coordinated Selenoaldehydes and Selenoketones as Heterodienophiles**

By *Helmut Fischer,* Ulrike Gerbing, Jürgen Riede,* and *Reinhard Benn*

Monomeric selenobenzaldehydes and diarylselenoketones are not stable as free species. In the coordination sphere of transition metals, however, they can be formed from molecular fragments and stabilized by bonding to the metal.[1,2] The extremely high reactivity of the free selenoaldehydes and -ketones is thereby only reduced, so that the complexes should be useful as easily handled synthetic building blocks for those selenacycles that are only accessible with difficulty via other routes. This is demonstrated by their reactions with 1,3-dienes.

Deep blue pentacarbonyl(selenobenzaldehyde)tungsten **1a**[1] reacts with dimethylbutadiene and cyclopentadiene at $-30°C$ in a small amount of pentane or dichloromethane within a few seconds, undergoing [4+2] cycloaddition to give the yellow selenacyclohexene and selenanorbornene complexes **2a** and **3a**, respectively.[3] The corresponding reactions of the selenoketone complexes **1b** and **1c** proceed analogously, albeit more slowly.[3] The rate of reaction decreases with increasing electron density in the Se=C bond of the metal-coordinated dienophile—i.e., in the series **1a**, **1c**, **1b**.

The structures of the yellow complexes **2** and **3**, which are stable at room temperature, were confirmed by elemental analyses and IR, NMR, and mass spectra.[4] In addition, an X-ray structure analysis was carried out for **2b** (Fig. 1).[5] The coordination geometry around the selenium atom is a distorted pyramid. The C_5Se ring is nonplanar:

3a–c **1a–c** **2a,b**

a, R = H; **b**, R = Ph; **c**, R = p-$C_6H_4CF_3$

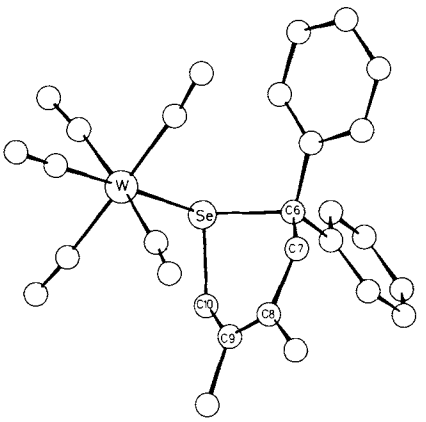

Fig. 1. Crystal structure of **2b**. Selected distances [pm] and angles [°]: W-Se 267.4(1), Se-C6 201.2(10), C6-C7 152.4(13), C7-C8 153.5(14), C8-C9 134.3(17), C9-C10 147.0(14), Se-C10 194.8(9); W-Se-C6 113.6(3), W-Se-C10 107.3(3), C6-Se-C10 91.9(4); angle between the planes C7-C8-C9-C10 and Se-C6-C7: 134.6°.

the C7-C8-C9-C10 plane is bent toward the $(CO)_5W$ fragment and is nearly coplanar with the plane of the CO groups in *cis* positions to Se. The W-Se distance in **2b** (267.4(1) pm) is longer than that in **1a** (263.5(2) and 263.7(2) pm in the two crystallographically independent molecules[1]). On the basis of the $^3J(H,H)$ coupling in the ^{1}H-NMR spectrum of **2a** at $-80°C$, the conformer with the phenyl group in quasi-equatorial position is presumably favored. At higher temperatures, an exchange of the geminal protons takes place for **2b**, probably owing to the pyramidal inversion of selenium. At room temperature, the signals of **3** are strongly broadened; upon cooling to $-80°C$, however, neither further broadening nor splitting of the resonances is observed for **3c**. Since the barrier for the pyramidal inversion of selenium is 58.5 kJ mol^{-1} for $[(CO)_5W\{Se(CH_2SiMe_3)_2\}]$,[6] **3c** is probably present as only one conformer in solution.

The reactions of the chromium complex $[(CO)_5Cr\{Se=C(H)Ph\}]$ and the corresponding thiobenzaldehyde complexes of chromium and tungsten, $[(CO)_5M\{S=C(H)Ph\}]$ (M = Cr, W),[7] with dimethylbutadiene and cyclopentadiene are analogous to the reaction of **1a**. In principle, the heterocycles may be released from the metal by oxidation of the central atom with $(NH_4)_2Ce(NO_3)_6$ as shown, for example, by the Diels-Alder adduct from $[(CO)_5Cr\{S=C(H)Ph\}]$ and dimethylbutadiene.[8] Other molecules of the type X=Y that are not stable as free species should also be employable in an indirect fashion, via their metal complexes, for the formation of heterocycles.

[3] Experimental procedure: Solutions of **1** (0.2 mmol) and 2 mL of dimethylbutadiene or cyclopentadiene in dichloromethane or pentane were stirred at −30°C (**1a**) or room temperature (**1b**, **1c**) for a few seconds (**1a**), 5 min (**1c**), or 10 h (**1b**). The solutions turned from dark blue to reddish orange. After removal of the solvent in vacuum, the residue was chromatographed at −25°C with pentane/CH_2Cl_2 (10:1) on silica gel and the yellow band was eluted. The solvent was removed in vacuum and the residue was recrystallized from pentane. Yield: 53–85%. m.p. = 72°C (**2a**), 145°C (decomp.) (**2b**), 73°C (**3a**), 107°C (**3b**), 86°C (decomp.) (**3c**).

Hexa-*tert*-butyldisilane—the Molecule with the Longest Si–Si Bond**

By *Nils Wiberg,** *Harald Schuster, Arndt Simon,** and *Karl Peters*

Recently, a silicon compound with an unusually long Si–Si bond, hexa-*tert*-butylcyclotrisilane (251.1 pm; normal Si–Si single bond: 234 pm), was described.[1] We now report hexa-*tert*-butyldisilane **1**, a compound with a considerably longer Si–Si bond.

1 is not accessible from tri-*tert*-butylsilylsodium or -potassium **2** (M = Na, K) and tri-*tert*-butylhalosilane **3** (X = Cl, Br).

$$t\mathrm{Bu_3SiM} + \mathrm{XSi}t\mathrm{Bu_3} \not\longrightarrow t\mathrm{Bu_3Si{-}Si}t\mathrm{Bu_3} + \mathrm{MX}$$
2 **3** **1**

1 is formed, however, by reaction of nitrosyl cations (in the form of nitrosyl tetrafluoroborate) with **2**.[2] Apparently, NO^+ acts as an oxidizing agent, which transforms $t\mathrm{Bu_3Si^-}$ into—dimerizing—tri-*tert*-butylsilyl radicals.

$$\mathbf{2}\ \mathbf{2} \xrightarrow[-2\mathrm{NO},\ -2\mathrm{M^+}]{+2\mathrm{NO^+}} 2\ \{t\mathrm{Bu_3Si^{\odot}}\} \longrightarrow \mathbf{1}$$

The colorless, crystalline compound **1**, which is readily soluble in organic media and melts at 162°C, is stable toward air and moisture. In mesitylene, it decomposes at 100°C—possibly via the free radicals $t\mathrm{Bu_3Si^{\odot}}$—with formation of tri-*tert*-butylsilane (half-life of decomposition at 100°C: 6.8 h).

$$\mathbf{1} \xrightarrow[\text{Mesitylene}]{100^{\circ}\mathrm{C},\ (+2\mathrm{H})} 2\,t\mathrm{Bu_3SiH}$$

The NMR spectra of **1** are very simple, in accordance with its symmetrical structure.[3] In the mass spectrum of **1**, no molecular ion peak is observed, as is the case for many other tri-*tert*-butylsilyl compounds.[3] The Si–Si stretching vibration in the Raman spectrum lies at comparatively small wave number ($\nu_{Si-Si} = 271\ cm^{-1}$).[3] In the UV spectrum of **3**, no absorption band appears above 200 nm.[3]

The X-ray structure determination[5] of **1** shows an unusually long Si–Si bond (269.7 pm). This distance apparently results (despite a staggered conformation) from mutual repulsion of the *tert*-butyl groups (Fig. 1). This inter-

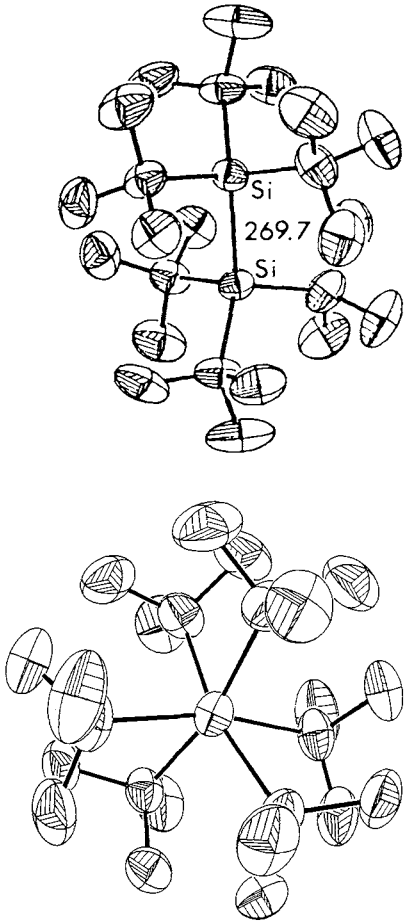

Fig. 1. Above: Stereoprojection of the crystal structure of **1**. Si–Si bond lengths [pm]. Below: Newman projection of the crystal structure of **1** along the Si–Si axis.

[**] Compounds of Silicon, Part 62.—Part 61: N. Wiberg, K. Schurz, G. Fischer, *Angew. Chem. 97* (1985) 1058; *Angew. Chem. Int. Ed. Engl. 24* (1985) 1053.

pretation is supported by the significantly lengthened Si-C bonds (199 pm compared with 187 pm for the single bond) and the expanded angle at the tertiary C atoms (C-C-C between 104.2 and 106.5°, Si-C-C between 110.9 and 114.8°). The Si-Si distance in **1** corresponds to a Pauling bond order of 0.45 and, as in the case of hexa-*tert*-butylcyclotrisilane,[1] the sum of the bond orders for the Si atom in **1** (2.55) is considerably less than the expected value of four.

The variability in the distance between Si atoms is remarkable. The distance for a bonding interaction found in **1** is larger than that in fibrous SiO_2 (258 pm[6]), although the interaction in the latter case is repulsive. The extreme case of the approach of Si atoms toward one another as a consequence of their surrounding was recently found in cyclosiloxanes $(-R_2Si-O-)_2$.[7] In that case, the Si-Si distance is shorter (231 pm) than that of a Si-Si single bond.

[2] *Experimental procedure:* Potassium (0.782 g, 20.0 mmol) and tri-*tert*-butyliodosilane (3.263 g, 10.0 mmol) [4] were allowed to react in refluxing heptane for 6 h. Nitrosyl tetrafluoroborate (0.771 g, 6.60 mmol) in 20 mL of heptane was added to the tBu_3SiK-containing reaction solution so formed after it had been cooled to −100°C. The reaction mixture was warmed to room temperature and filtered to separate the colorless precipitate (KBF_4). All volatiles were removed from the solvent at room temperature in high vacuum and the residue was dissolved in 30 mL of pentane. Colorless, crystalline **1** (0.58 g, 1.46 mmol, 44%) was obtained at −30°C.

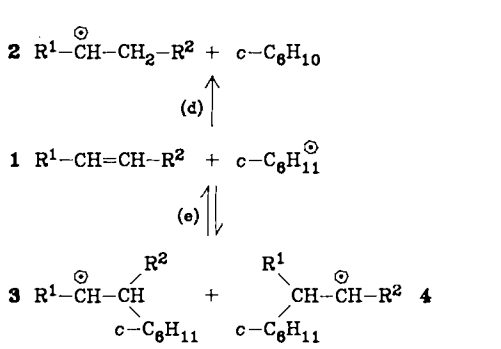
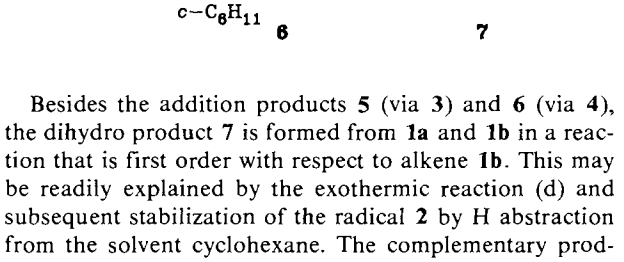
Metathesis of Alkyl Radicals and Alkenes—a Novel Elementary Reaction of Alkyl Radicals

By *Jürgen O. Metzger**



A notable gap exists in the series of known elementary reactions (a)-(c) of alkyl radicals in which a hydrogen atom is transferred: the thermochemically possible transfer (d) of a β-hydrogen atom of an alkyl radical to an alkene with the formation of a new alkyl radical and a new alkene.

The search for an example of the frequently postulated[1] reaction (d) appeared promising since corresponding reactions in analogous oxygen-containing systems are



known.[2] The first experimental example of reaction (d) is reported here.

Reaction (d) should be possible to observe as a reaction competing with the addition (e) of an alkyl radical to the CC double bond of an alkene.

a, $R^1 = R^2 =$ COOMe; **b**, $R^1 =$ Ph; $R^2 =$ COOMe

As an example, the addition of cyclohexane to dimethyl fumarate **1a** and to methyl cinnamate **1b** was studied. This radical chain reaction (f) can be carried out above 250°C under mainly thermodynamic control with respect to the addition (e).[3]

(f)

Besides the addition products **5** (via **3**) and **6** (via **4**), the dihydro product **7** is formed from **1a** and **1b** in a reaction that is first order with respect to alkene **1b**. This may be readily explained by the exothermic reaction (d) and subsequent stabilization of the radical **2** by H abstraction from the solvent cyclohexane. The complementary product, cyclohexene, was identified in the reaction mixture (**7a** : cyclohexene, ca. 1.2 : 1) as the dibromo adduct.

The experimental results (Table 1) are easily understandable. The metathesis (d), as a "closed-shell" reaction, has a higher activation energy than the "open-shell" reaction (b). Accordingly, the amount of the dihydro product **7** increases relative to the amounts of addition products **5** and **6** with increasing temperature (experiments 1-5). The reaction rate of (d) is independent of the concentration of H donor in contrast to that of (b). Therefore, the relative amount of **7** increases with lower concentrations of cyclohexane; **7** can even become the main product (experiments 5-9). The addition of radical formers such as 2,3-diphenylbutane[4] increases the rate of formation of both competitive products equally (experiment 4). Activated

9	400	0.40	49	14.1	7.7	1.8	4	0.4	0.2	0.9	0.7

[a] With the exception of No. 1, the reactions were carried out in a high-pressure, high-temperature flow reactor [3,7] in a stainless steel capillary; reaction time 2–3 min; molar ratio cyclohexane : **1** = 1000 : 1. The concentration of cyclohexane was adjusted by variation of the pressure. The addition products are stable under the reaction conditions. Under the same conditions at 400°C, less than 1% of **5b** decomposes to **7b**. [b] mol/L. [c] Yields and conversion in mol-% based on unreacted **1**. [d] Reaction in duran glass ampules; reaction time 10 min. Upon addition of activated charcoal (1 mg/mL reaction solution) as radical trap, only traces of the products were formed. [e] Reaction time 1 min. [f] Addition of 10 mol-% 2,3-diphenylbutane based on **1b**.

charcoal as a radical trap inhibits the formation of both products (experiment 1). The kinetic chain length is estimated to be 100 from the amount of chain-terminating product cyclohexylcyclohexane (ca. 1 mol-% based on reacted starting material **1a**).

Alternative explanations for the formation of the dihydro product **7**, such as the frequently postulated pericyclic H transfer[5] or the symproportionation of alkene and alkane to give two alkyl radicals (a),[3,6] are clearly ruled out on the basis of the experimentally confirmed radical chain reaction. A conceivable β-cleavage of the cyclohexyl radical (c) and addition of the H atom to the alkene **1** would be a reaction of zero order with respect to **1** and thus is also ruled out.

The unequivocal experimental proof of the metathesis of alkyl radicals and alkenes (d) and the reaction conditions required for it to occur show that chain transfer during polymerization[1a] via this reaction, which has been frequently postulated, is unlikely. A thermal pericyclic hydrogenation of alkenes with alkanes[5] is also kinetically unlikely.

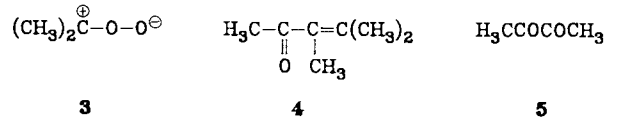
A Stable Diozonide of a Conjugated Diene by Ozonolysis of 2,3,4,5-Tetramethyl-2,4-hexadiene on Polyethylene

By *Karl Griesbaum** and *Willi Volpp*

Stable diozonides of conjugated dienes were hitherto unknown. Admittedly, the diozonides of 2,3-dimethyl-1,3-butadiene and of isoprene could be obtained by ozonolysis of the respective dienes in pentane, but they exploded violently upon attempted isolation.[1] Since ozonides are known to be stabilized by methyl substituents, ozonolysis of **1** in pentane was also attempted, but no ozonide was obtained.[2] This is concordant with the experience that tetrasubstituted olefins do not furnish the corresponding ozonides.[3] We have recently found, however, that ozonolysis of olefins adsorbed on polyethylene may provide ozonides from olefins for which other methods of ozonation fail.[4]

1



2

Ozonolysis of **1** on powdered polyethylene at −75°C and subsequent chromatographic separation of the crude product (water-cooled column 3 × 62 cm, 200 g of silica gel; *n*-pentane/diethyl ether 20 : 1, ca. 14 mL/min) afforded a mixture of two ozonides of structure **2**, probably the *meso*- and *rac*-isomers, in ca. 43% yield. They could be isolated by HPLC separation (column 3.2 × 12 cm, Lichrosorb Si 60, particle size 5 μm; *n*-pentane/diethyl ether 20 : 1, ca. 7.5 mL/min), albeit not yet assigned stereochemically. Each of the isomers gave a positive peroxide test, correct values for the elemental analysis, a $(M+1)^{\oplus}$ ion at *m/z* 235 in the CI/MS analysis, two quartets ($\delta = 1.30$, 1.43, $J = 0.64$ Hz, and $\delta = 1.30$, 1.40, $J = 0.61$ Hz, respectively) and a singlet ($\delta = 1.52$, each) with relative intensities of 1 : 1 : 1 in the ^{1}H-NMR spectrum (C_6D_6, TMS), three quartets ($\delta = 20.16$, 23.12, 24.94 and $\delta = 20.13$, 23.41, 24.93, respectively) and two singlets ($\delta = 108.98$, 109.60 and $\delta = 108.88$, 109.76, respectively) in the ^{13}C-NMR spectrum ($CDCl_3$, TMS), and no carbonyl absorption in the IR spectrum. The two isomers show significant differences in their melting points (51°C and < −60°C, respectively). At −20°C each ozonide was stable for months, whereas at room temperature decomposition was observed to take place after a few hours. Reduction of a mixture of the isomers of structure **2** with $LiAlH_4$ gave a mixture of *meso*- and *rac*-2,3-butanediol as well as 2-propanol; **2** reacts with triphenylphosphane to give a mixture of acetone, biacetyl **5**, and acetic anhydride.

It is known that **1** is cleaved by ozone to give **3**, **4**, and **5**.[2,5] Consistent with the finding that carbonyl oxides do not undergo cycloadditions with non-activated ketones,[3]

3 **4** **5**

carbonyl oxide **3** reacted with itself in pentane to give dimers, trimers, and oligomers.[2] By contrast, in the ozonolysis of **1** on polyethylene, the primary fragments **3**, **4**, and **5** apparently remained fixed at their places of origin, so that **3** could not react with itself and thus was indirectly forced to undergo cycloadditions with the keto groups in **4** and/or **5**.

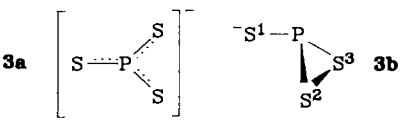
Trithiometaphosphate PS_3^-—an Anion with Phosphorus of Coordination Number 3**

By *Herbert W. Roesky,* Reinhart Ahlrichs,** and *Stefan Brode*



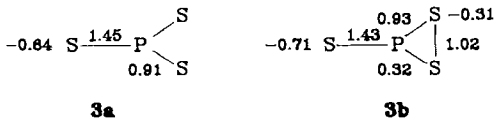
Dedicated to Professor Fritz Seel on the occasion of his 70th birthday

A number of sulfur-containing phosphoranes **1** in which phosphorus has coordination number 3 have been reported in recent years.[1-3] X can be O, S, NR, or CR_2 and Y either NR_2 or aryl. We report here the reaction of P_4S_{10} with KCN and H_2S, which affords the trithiometaphosphate anion PS_3^- **3** in addition to the known $[(CNPS_2)_2S]^{2-}$ **2**.[4] **3** was isolated as the tetraphenylarsonium salt.[5] The reaction, the mechanistic details of which are not yet known, is very surprising since alkali metals react with sulfur and phosphorus at 750 °C to give only the dimeric anion **4**.[6] We assume that the large cation kinetically inhibits the formation of the dimer. Monomeric metaphosphate PO_3^- has only been identified in the gas phase or in solution.[7] Recently, a tris(methylene)phosphate ion of type $[P(=C<)_3]^-$ was reported.[8]

The tetraphenylarsonium salt of **3** was obtained from methanol as yellow crystals (m.p. = 183 °C) and its composition confirmed by elemental analysis and field-desorption mass spectroscopy. Thus, the peak for the Ph_4S^+ ion is observed at *m/z* 383 (+FD) and that for the PS_3^- ion at *m/z* 127 (−FD). Ions with larger or smaller mass numbers were not detected. This result rules out the presence of a dimeric or polymeric anion. In the ^{31}P-NMR spectrum (acetone/C_6D_6) a signal is observed at $\delta = 52.3$ (85% H_3PO_4 ext.), in the region where signals for diiminophosphoranes (phosphorus with coordination number 3) are normally found ($\delta = 45$–55).[9]

As shown by X-ray structure analysis, $[Ph_4As][PS_3]$ forms monoclinic crystals in the space group C2 with the cell parameters $a = 18.944(4)$, $b = 7.101(1)$, $c = 13.393(2)$, and $\beta = 134.67(1)$. The thermal motion of the anion prevented a refinement of the structure. Nevertheless, these results indicate a pyramidal structure and, therefore, the dimeric $[P_2S_6]^{2-}$ as well as the linear structure $[SPSS]^-$ can be ruled out.[9, 10] Thus, only structures **3a** and **3b** need be considered.

3a **3b**



Since $[AsPh_4]^+$ is a relatively large cation and, therefore, electrostatic interactions should not have a large effect on PS_3^-, it appeared reasonable to carry out ab initio calculations for the free PS_3^- ion in order to determine the structures and relative energies of **3a** and **3b**. Molecular orbital (MO) calculations using the self-consistent field (SCF) method[11] gave the following structural parameters: **3a**: symmetry D_{3h}, P-S 196 pm; **3b**: symmetry C_s, $P\text{-}S^1$ 199 pm, $P\text{-}S^2$ 221 pm, $S^2\text{-}S^3$ 212 pm, $S^1\text{-}P\text{-}S^2 = 112°$. Experience has shown[12] that the interatomic distances are generally underestimated by only a few pm at this level of calculation. Furthermore, the $[SPSS]^-$ chain and the planar ring with C_{2v} symmetry were included in the calculations. Upon optimization of geometry, the chain gives the structure **3b**, and the ring has a very high energy for reasonable distances (dissociation into $[SPS]^-$ and S).

In order to determine the relative energies of **3a** and **3b**, configuration interaction calculations (CI) were carried out using the CPF method,[13] a more flexible basis set[14] being used. **3a** was found to be more stable than **3b**: SCF: $\Delta E = E(\mathbf{3a}) - E(\mathbf{3b}) = 141$ kJ/mol; CPF: $\Delta E = 122$ kJ/mol. The CPF result is probably more accurate and should have an error of 20–30 kJ/mol.

In order to visualize the electronic structure, a population analysis of the SCF wave functions was carried out. The method used[15, 16] characterizes the bonding relationships by net atomic charges for the atoms (Q_A) and by "shared electron numbers" (SEN) assigned to the bonds. The SEN gives the number of electrons that can be equally assigned to the two atoms involved in bonding; it is a reliable indication of the strength of a covalent bond.[15] The results are shown in Scheme 1. In order to better understand the SEN, it should be noted that for strongly covalent single bonds (C-H, C-C, H-H) SEN is about 1.4 and for polar single bonds 1.0 (for HF).

Scheme 1.

In Figure 1 the SCF orbital energies ε of the high-energy MOs of **3a** are given (the relationships for **3b** are simple and are discussed in the text) and the corresponding MOs are characterized.

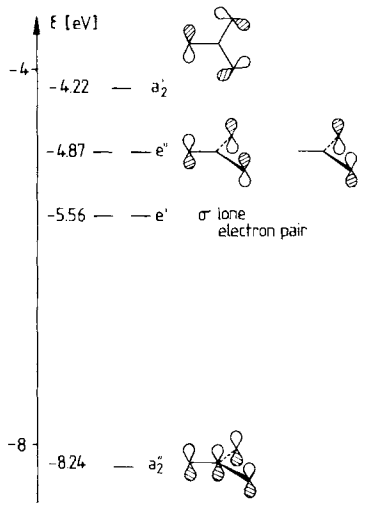

Fig. 1. Schematic representation of the energetically high-lying MOs for PS_3^- (structure **3a** with D_{3h} symmetry).

In addition to the three PS σ bonds present in both **3a** and **3b**, a 6-electron 4-center π system (MOs a_2'' and e'') is present in **3a** and an SS bond in **3b**. The sums of the covalent bond strengths are similar for the two structures. The sum of the SEN is 4.35 for **3a** and 4.31 for **3b**. The π system in **3a** is most stable for the planar structure. The energy required to achieve planarity is difficult to estimate but should not be large. In PCl_3, the ClPCl angle is already 100.3°; the larger coulombic repulsion of the ligands in PS_3^- should lead to an even larger angle.

Decisive for the relative stability of **3a** and **3b** are the charge distributions, which, in each case, are a consequence of the electronic structure. In **3b**, the negative charge, as expected, is localized primarily on S^1. A weak charge delocalization is achieved by $3p_\pi(S^1)$-$3d_\pi(P)$ back-bonding, which strengthens the PS^1 bond. This is reflected in the SEN of 1.43 (compared with $SEN(PS^2)=0.93$) and in the relatively short PS^1 distance of 199 pm. The SS bond in **3b** is relatively weak (SEN = 1.02) owing to the charge on the S atoms ($Q_S=-0.31$). The localization of the charge on S^1, which is not stabilized by the proximity of a highly positively charged P atom, as in **3a**, is reflected above all in the orbital energies of the highest MOs in **3b**, which correspond to the lone electron pairs on S^1: $\varepsilon(a')=-3.6$ eV, $\varepsilon(a'')=-3.7$ eV. These orbitals are considerably higher in energy than the MOs in **3a** (Fig. 1), which is crucial for the instability of **3b**.

The charge distribution in **3a** is determined by the π system. Only the bonding a_2'' MO has $3p_\pi(P)$ contributions; in contrast, the e'' MOs do not have such contributions (Fig. 1). Consequently, the net result is a transfer of ca. one π-electron from P to the ligands S—in agreement with the population analysis ($Q(P)=+0.91$). The positive charge on the P atom favors stabilizing $3d_\pi(P)$ contributions to e'' so that those MOs are weakly bonding. A simple Hückel MO calculation gives the bonding a_2'' π MO a π bond order of $3^{-1/2}=0.58$. The partial double bond character of the PS bond in **3a** is clearly reflected in the $SEN(PS)=1.45$ (compared with $SEN(PS^2)=0.93$ in **3b**) and in the short PS distance (196 pm).

The calculations show that PS_3^- has a planar structure with D_{3h} symmetry in the gas phase. However, the molecule is not very rigid; shifting the P atom 16 pm out of the plane increases the energy only 10 kJ/mol. Therefore, a pyramidal structure cannot be ruled out in the solid state.

[5] *Experimental procedure:* P_4S_{10} (22.2 g, 0.05 mol) and KCN (32.5 g, 0.5 mol) were stirred in 250 mL of CH_3CN at room temperature. The solution warmed up to ca. 50°C. As soon as it had cooled down to room temperature, H_2S (excess) was admitted over 3 h. The reaction mixture was then filtered and the volatile products were removed from the filtrate in vacuum. The solid residue was dissolved in 100 mL of H_2O, which did not result in warming of the solution. A solution containing 30 g of nPr_4NBr in 150 mL of H_2O was added to this solution. A yellow precipitate forms (30 g), 15 g of which redissolves in 150 mL of CH_3OH upon suspension. The remaining solid, which can be recrystallized from CH_3CN/CH_3OH (5:1) is $[nPr_4N]_2[(NCPS_2)_2S]$. The methanol solution was concentrated in a hood, affording a viscous oil. This was dissolved in 50 mL of CH_3OH by warming and then treated with a solution of Ph_4AsCl (excess) in CH_3OH. Careful concentration at room temperature afforded yellow crystals of $[Ph_4As][PS_3]$ (yield: 3 g).

The Polymeric Silver Complexes $[Ag\{S_n(CN)_2\}_2][AsF_6]$ (n = 3, 4): Stable Coordination Compounds of Dicyanotri- and Dicyanotetrasulfanes

By *Herbert W. Roesky,* Thomas Gries, Jürgen Schimkowiak,* and *Peter G. Jones*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

The behavior of cyanosulfanes toward metals and metal ions is unknown. However, reactions such as the synthesis of a 1,2,4-thiadiazole from cyanogen and sulfur, which takes place only in the presence of copper metal, demonstrate the influence of metal centers.[1] Dicyanotrisulfane **1**, first prepared in 1885 by *Schneider*,[2] and dicyanotetrasulfane **2**[3] are unstable compounds, which tend to undergo polymerization in air; **2**, in particular, decomposes at room temperature within a few minutes, forming orange triazines.[4] We recently found that in the reaction of **1** with hexafluoroacetone the S–S bonds remain intact.[5] Although metal complexes of the cyanosulfanes were unknown up to now, both cyanogen and organic disulfanes form stable compounds with silver hexafluoroarsenate **3**.[6, 7]

The reactions of **1** and **2** with $AgAsF_6$ in liquid sulfur dioxide lead, without decomposition, to the silver complexes **4**[8] and **5**,[9] which we have been able to isolate as light yellow and orange-yellow crystals, respectively.

$$2\,S_n(CN)_2 + Ag[AsF_6] \xrightarrow{SO_2} [Ag\{S_n(CN)_2\}_2][AsF_6]$$

1, n = 3 **3** **4**, n = 3
2, n = 4 **5**, n = 4

According to single-crystal X-ray analyses and vibrational spectra,[10] **4** and **5** contain intact polysulfane chains. The dicyanosulfanes **1** and **2** serve in these complexes as bridging ligands and undergo coordination through their terminal nitrogen atoms. **4** is a chain polymer (Fig. 1), **5** a layer polymer (Fig. 2).

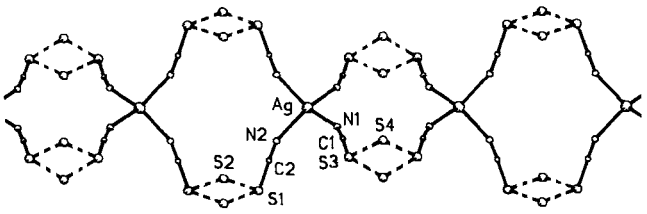

Fig. 1. Crystal structure of the polymeric cation (chain polymer) of **4**. Space group $P4_2/mnm$, $a = b = 1051.0(5)$, $c = 1527.0(2)$ pm, $Z = 4$. $R = 0.049$ for 691 absorption-corrected reflections with $F > 4\sigma(F)$ and $2\theta_{max} = 50°$ ($Mo_{K\alpha}$). Ag lies on the special position x, $1-x$, 0 (symmetry mm 2, As on 1/2, 0, 3/4 ($\bar{4}$), S1, S4, N2, and C2 on x, x, z (m), S2 on x, $1-x$, z (m), N1 and C1 on x, y, 1/2 (m). The S2 and S4 positions are half-occupied, indicating twofold disorder of these atoms (broken bonds indicate the alternative positions). S3 also is disordered (alternative half-occupied positions on both sides of the mirror plane x, y, 0). For clarity, only the idealized position of S3 is shown. The ligands **1** each bridge two silver atoms, the coordination geometry of which is a slightly compressed tetrahedron; the silver atom are "end-on" coordinated to nitrogen atoms of four ligands **1**. Bond lengths [pm] and angles [°]: Ag-N1 227.4(11), Ag-N2 230.1(10), S1-S2 199.7(6), S3-S4 207.4(5), C1-N1 113.6(14), C1-S3 170.8(11), C2-S1 169.6(11), C2-N2 112.4(14); N1-Ag-N1′ 105.1(5), N1-Ag-N2 112.4(3), N2-Ag-N2′ 102.5(5), C1-N1-Ag 156.7(9), C2-N2-Ag 159.2(9), S3-S4-S3′ 101.0(4), S1-S2-S1′ 109.7(2), S4-S3-C1 96.4, C2-S1-S2 104.3(4), N1-C1-S3 168.9(5), S1-C2-N2 178.5(10) [14].

Institut für Anorganische Chemie der Universität
Tammannstrasse 4, D-3400 Göttingen (FRG)

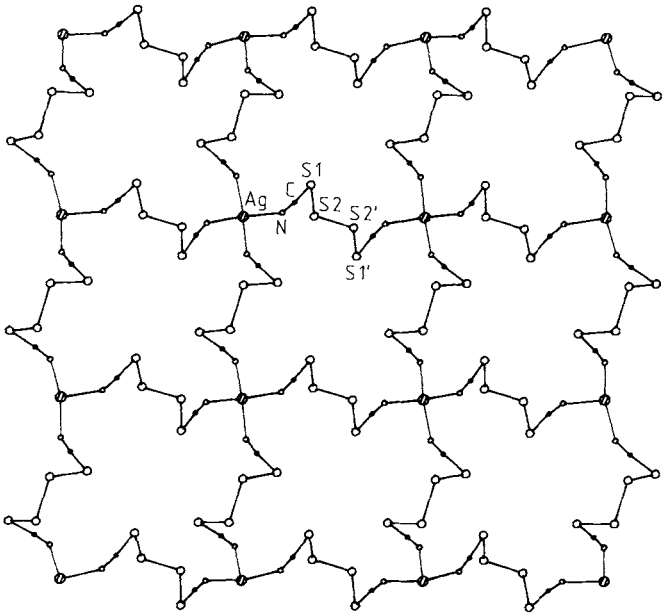

Fig. 2. Crystal structure of the polymeric cation (layer polymer) of **5** (projection along z; Ag atoms hatched). Space group $P\bar{4}$, $a = b = 838.1(2)$, $c = 666.1(2)$ pm, $Z = 1$. $R = 0.037$ for 822 absorption-corrected reflections with $2\theta_{max} = 55°$ ($Mo_{K\alpha}$). Absolute structure [12] by η refinement [13]; $\eta = +1.06(6)$. The silver atoms lie on the special positions 0, 0, 0, the arsenic atoms on 1/2, 1/2, 0 (symmetry $\bar{4}$). The silver atoms are coordinated to one terminal nitrogen atom of each of four molecules of **2**, resulting in a slightly compressed tetrahedral geometry. By linking of the second ligand nitrogen atom with a further silver atom, an undulating, two-dimensional layer polymer is formed. Bond lengths [pm] and angles [°]: Ag-N 228.8(7), S1-S2 206.1(4), S2-S2′ 200.3(4), C-S1 169.5(8), C-N 113.2(10), C-S1-S2 98.5(3), S1-S2-S2′ 105.6(2), S1-C-N 175.2(7), Ag-N-C 152.5(6). Torsion angles of the ligands: C-S1-S2-S2′ 104°, S1-S2-S2′-S1′ −85° [14].

Since the S_3 structural units are disordered in **4**, their structure can be discussed only with some reservations. In complex **4**, dicyanotrisulfane is in the *cis* conformation, as in the free species.[11] The C–N distances are strikingly short in **4** and **5**: 113.0 pm in **4** and 113.2 pm in **5**, compared with 121 pm in **1** (average values). The same is true for the S–S distances (206.1 and 200.3 pm in **5**, compared with 212 pm in **1**). The similar Ag–N distances in **4** and **5** (average value: 228 pm) are 10 pm shorter than in the dicyano complex.[6]

Complexes **4** and **5** are stable up to 25 °C, but decompose upon exposure to moisture or light. Upon melting, they afford clear liquids, which polymerize at 125 (**4**) and 110 °C (**5**) with evolution of gas.

[8] SO_2 (20 mL) was condensed at −190°C into a pressure flask containing 1.0 g (6.8 mmol) of **1** and 1.0 g (3.4 mmol) of **3**. The colorless solution was allowed to warm up in the dark to room temperature and stirred for 18 h. The moderately soluble precipitate that formed was filtered off and the solvent was removed from the filtrate in vacuum. The residue was recrystallized from SO_2, affording 1.6 g (79%) of **4** as pale yellow crystals, m.p. = 115°C (decomposition at 125°C).—IR (nujol): ν = 2175, 700, 575, 498, 464, and 395 cm^{-1}.—Raman: ν = 2175, 683, 658, 498, 460, 430, and 206 cm^{-1}.

[9] Freshly prepared **2** (1.56 g, 8.7 mmol), which had been dried in a vacuum at −30°C, was heated rapidly to the melting point (−3°C) and then added under a stream of nitrogen to **3** (1.29 g, 4.3 mmol) in a pressure flask at −190°C. In the evacuated flask, 20 mL of SO_2 was condensed and the stirred solution was then slowly warmed in a cold bath (−50°C) in the dark over 4 h to room temperature. After two hours of stirring, the sparingly soluble solid was filtered off and the solvent removed from the filtrate. Orange crystals of **5** were obtained by recrystallizing the residue from SO_2. Yield: 1.9 g (67%), m.p. = 92°C (decomposition at 110°C).—IR (nujol): ν = 2165, 705, 692, 685, 465, and 395 cm^{-1}.—Raman: ν = 2165, 678, 506, 438, 420, 401, 223, 189, 180, 127, 93, and 78 cm^{-1}.

[10] The Raman- and IR-active ν(C≡N) vibrations are shifted by 19 (**4**) and 13 (**5**) cm^{-1}, respectively, to shorter wavelengths by complexation. ν(C-S), ν(S-S), δ(C-S-S), and δ(S-S-S) frequencies are also shifted; the number of bands, however, remains the same, thereby confirming that no sulfur-sulfur bonds are broken.

[11] The crystal structure of **1** could only be imprecisely determined by X-ray diffraction at −20°C (R = 0.25), while that of **2** is unknown. Cf. F. Fehér, K. H. Linke, *Z. Anorg. Allg. Chem. 327* (1964) 151; O. Foss, *Acta Chem. Scand. 10* (1956) 136.

Nitrile Ylides and Azirines: Gas-Phase Generation from 2,3-Dihydro-1,4,2λ⁵-oxazaphospholes and Matrix Isolation**

By *Curt Wentrup,* Stephan Fischer, Hans-Michael Berstermann, Martin Kuzaj, Holger Lüerssen,* and *Klaus Burger*

Nitrile ylides are among the most important nitrilium betaines.[1,2] Although nitrile ylides have been directly observed, mostly by UV spectroscopy following photochemical generation from 2*H*-azirines,[2] and a single example of a stable nitrile ylide has been reported,[3] there has been no direct observation of thermally generated nitrile ylides. We now wish to report the first such example.

Flash vacuum pyrolysis of 5-*tert*-butyl-3,3-bis(trifluoromethyl)-2,3-dihydro-1,4,2λ⁵-oxazaphosphole **1a**[4] at 400°C/10^{-3} torr with isolation of the products on a KBr window at −196°C for IR spectroscopy resulted in the quantitative formation of trimethyl phosphate **2** and a new species characterized by a triplet at ν = 1740 (m), 1715 (s), and 1695 (m) cm^{-1}. On warming the window to −70°C, this species reacted with the phosphate **2** to regenerate the starting material, as seen by the simultaneous disappearance of the triplet and the appearance of a new band at 1620 cm^{-1} (characteristic of **1a**). After warming to room temperature and opening the apparatus, the sample remaining on the window was identified as pure **1a**.

In similar experiments, in which the pyrolysis products were isolated in a cold trap at −196°C, it was possible to distill the new compound into a second cold trap in high vacuum, thus freeing it from **2** and preventing the regeneration of **1a**. The sample thus obtained showed a ^{19}F-NMR signal at δ = 73.07 as expected for a bis(trifluoromethyl)azirine;[5] it was extremely sensitive to moisture and hydrolyzed to the amide **5a** simply on exposing the apparatus to the atmosphere. On the basis of the spectroscopic and chemical properties, the new compound is identified as the azirine **3a**. Hydrolysis with cleavage of the C-C bond (**3a** → **5a**) is normal for bis(trifluoromethyl)azirines.[5a]

a, R = $C(CH_3)_3$; **b**, R = C_6H_5

When the pyrolysis of **1a** was carried out at 700-860°C and the products examined by IR spectroscopy at −196°C, the azirine **3a** was no longer observed; instead, a species absorbing strongly at ν = 2250 cm^{-1} had appeared. This species, too, was sensitive to moisture and hydrolyzed on warming up (−90 to −50°C) to give the same product (**5a**), as seen by the disappearance of the band at ν = 2250 cm^{-1} simultaneous with the appearance of a band at ν = 1680 cm^{-1} (characteristic of **5a**). The ^{1}H-NMR spectrum of the isolated product established its identity as **5a**, formed in virtually quantitative yield.[6]

On the basis of the IR spectrum and the reactivity we identify the high temperature species as the nitrile ylide **4a**. The asymmetric stretching vibration at ν = 2250 cm^{-1} is similar to that reported for the only nitrile ylide isolated so far.[3] Further bands belonging to **4a** appear at ν = 1460 (m), 1365 (m), 1345 (m), 1280 (s), 1250 (m), 1225 (m), 1215 (m), 1180 (vs), 1095 (s), 995 (vs), 890 (m), 770 (m) cm^{-1}. Trapping reactions of thermally generated **4a** in solution have been described previously.[4]

Further proof for the identity of the nitrile ylide **4a** is given by its photochemical formation from the matrix-isolated azirine **3a**. The azirine was generated at 400°C and isolated in argon on a BaF_2 window at 11 K. Subsequent irradiation with a low-pressure Hg lamp (λ = 254 nm) resulted in the slow disappearance of the azirine triplet concomitant with the appearance of the bands due to the nitrile ylide **4a**.[6]

The corresponding 5-phenyloxazaphosphole **1b** reacted similarly to give the azirine **3b** (IR: ν = 1730, 1690 cm^{-1}; ^{19}F-NMR: δ = 72.88), which reverted quantitatively to **1b** on warming up and reacted with water to give **5b**. In this

$[Et_4N][M(SCH_2CH_2S)_3]$ (M = Nb, Ta), Homoleptic 1,2-Ethanedithiolate Complexes of Niobium and Tantalum**

By *Kazuyuki Tatsumi, Yoitsu Sekiguchi, Akira Nakamura,* Roger E. Cramer,** and *John J. Rupp*

Very few niobium and tantalum complexes with thiolate ligands have so far been reported.[1-3] During investigations of dithiolates of metals of the vanadium group we were able to synthesize **1**–**3**, the first homoleptic 1,2-ethanedithiolate complexes of niobium and tantalum, by reaction of $NbCl_5$ (or $TaCl_5$) with $LiSCH_2CH_2SLi$.[4a]

$[Li(thf)_3][Nb(SCH_2CH_2S)_3]$ **1** $[Et_4N][M(SCH_2CH_2S)_3]$ **2**, M = Nb; **3**, M = Ta

When $NbCl_5$ was allowed to react with $Li_2S_2C_2H_4$ in benzene and then in THF, the air-sensitive compound **1** was obtained.[4b] Cation exchange of **1** with Et_4NCl in acetonitrile yielded the tetraethylammonium salt **2**,[4c] which is relatively air-stable (several hours). With the stoichiometry established, it was found that **2** could be synthesized more readily from a 1:3:1 mixture of $NbCl_5$, $Li_2S_2C_2H_4$, and Et_4NCl in acetonitrile. A similar procedure with $TaCl_5$ instead of $NbCl_5$ afforded the Ta complex **3**.[4d]

$$NbCl_5 + LiSCH_2CH_2SLi \xrightarrow{C_6H_6} \text{brown powder} \xrightarrow{THF} \mathbf{1}$$

$$MCl_5 + LiSCH_2CH_2SLi \xrightarrow[CH_3CN]{Et_4NCl} [Et_4N][M(SCH_2CH_2S)_3]$$

(Et_4NCl ↓ CH_3CN)

2, M = Nb; **3**, M = Ta

Tatsumi* and *A. Nakamura* in Osaka and *J. W. Gilje* and *R. E. Cramer* in Honolulu). *R. E. C.* acknowledges partial support from an NSF grant (CHE 8210244).

The anion of the complex has—according to an X-ray structure analysis of **2**—an approximate C_3 symmetry (Fig. 1). This is evident from the well-ordered propeller-type arrangement of the three SCH_2CH_2S ligands: S-Nb-S, 81.58(4)-82.14(4)°; S-Nb-S (*trans*), 156.29(4)-157.55(4)°. The torsional angles (ϕ) of the three chelate ligands are 31.4, 30.6, and 29.41° indicating that the coordination sphere defined by the six sulfur atoms is midway between trigonal-prismatic ($\phi = 0°$) and octahedral ($\phi = 60°$). For the very recently described Ti complex **4**,[5] the torsional angles are similar, ranging from $\phi = 35°$ to 42°. However, this stereochemistry contrasts with the trigonal-prismatic geometry found for the niobium complex **5**,[3b] $\phi = 0.7°$ (av.).

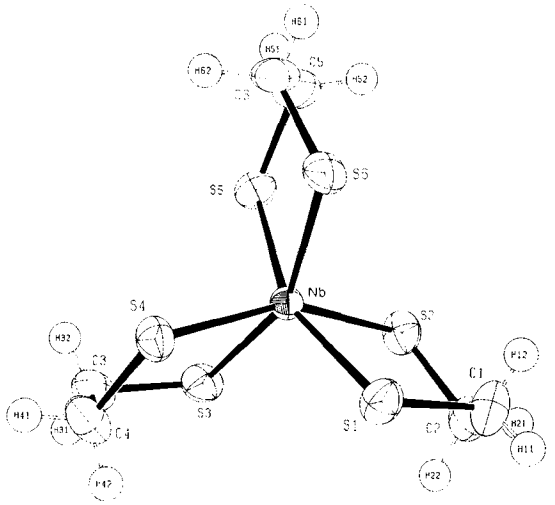

Fig. 1. An ORTEP representation of the structure of the complex anion in **2** with 50% probability ellipsoids. Monoclinic, space group $C2$, $a = 19.920(3)$, $b = 8.0424(9)$, $c = 14.070(2)$ Å, $\beta = 101.55(5)°$, $\rho_{calc.} = 1.503$ g cm^{-3}, $Z = 4$, $\mu(Mo_{K\alpha}) = 10.06$ cm^{-1}. The structure was solved by MULTAN 80 and refined to $R_w = 0.0292$ and $R_G = 0.0294$ using the SHELX program system with all atoms anisotropically refined except for hydrogen atoms. In this figure, the thermal parameters of the H atoms are arbitrarily fixed at 0.05 (3702 observed reflections $I > 3\sigma(I)$, 4228 measured reflections, 328 refined parameters). Selected bond lengths [Å]: Nb-S 2.425(1)-2.4422(9); C-S, 1.811(5)-1.823(5); C-C, 1.493(8)-1.499(7); C-H, 0.87(5)-1.04(5). The locations of hydrogen atoms are normal. The absolute configuration of the complex anion was determined to be Λ by refinement of both configurations using the complete data set which spanned Friedel pairs. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, Lensfield Road, Cambridge CB21EW (England) on quoting the full citation of this journal.

$[Et_4N]_2[Ti(SCH_2CH_2S)_3]$ **4** $[Ph_4As][Nb(1,2\text{-}S_2C_6H_4)_3]$ **5**

Apart from the complexes $[Ta(1,2\text{-}S_2C_5H_4)_3]^-$[3a] and $[Zr(1,2\text{-}S_2C_6H_4)_3]^{2-}$,[10] dithiolate chelates having π-conjugated bridges prefer to form trigonal-prismatic complexes,[6] while those without π-systems, e.g. **1**–**3**, distort from trigonal-prismatic. The C–S bond distances in **2** (av. 1.816(5) Å) are substantially longer than those in **5** (av. 1.745(9) Å), since the S atoms in SCH_2CH_2S have a different π donor ability than the S atoms in $1,2\text{-}S_2C_6H_4$. However, the observed Nb–S distances in **2** (av. 2.434(7)) are surprisingly close to those of **5** (av. 2.44(1) Å). Nevertheless, because of the decreased steric bulk of SCH_2CH_2S compared to that of $1,2\text{-}S_2C_6H_4$, and the longer C–S distance in the former compound, we anticipate that the anions of **2** (and **3**) are more reactive than $[Nb(S_2C_6H_4)_3]^-$, the anion of **5**.[11]

It follows from the ^{1}H-NMR spectrum that **1** contains three THF molecules, presumably surrounding the Li cation. The SCH_2CH_2S ligands of **1** ($(CD_3)_2SO$ solution) give a sharp singlet at $\delta = 3.69$ in the ^{1}H-NMR spectrum at room temperature, which is slightly shifted to $\delta = 3.67$ for **2** and to $\delta = 3.87$ for **3**. The FIR spectrum of **2** shows bonds arising from Nb–S stretching vibrations in $D_3(O_h)$ symmetry: 354 (s) [$E(T_{1u})$], 388 (s) [$A_2(T_{1u})$], 240 cm^{-1} (w) [$E(E_g)$].[7] The corresponding bands of the Ta complex **3** appear at 335 (s), 318 (s), and 225 cm^{-1} (w). These shifts agree quite well with what one would expect from the difference in the relative atomic masses of Nb and Ta;[8] thus, the Nb–S and the Ta–S bonds are essentially equal in strength. The similarity of the IR absorption patterns, especially those of the $E(T_{1u})$–$A_2(T_{1u})$ splitting, indicates that the structures of **2** and **3** are isotypic. The cyclovoltammograms exhibit a quasi-reversible one-electron reduction ($[M(SCH_2CH_2S)_3]^-/[M(SCH_2CH_2S)_3]^{2-}$): $E_{1/2}(Nb) = 1.20$ V; $E_{1/2}(Ta) = -1.56$ V (vs. SCE). The additional electron is transferred to the lowest nonbonding metal d level of a_1 symmetry (LUMO);[9] thus, the observed first reduction potentials verify that the d-level of **2** lies energetically lower than that of **3**. The higher positioning of Ta d levels also manifests itself in the systematic blue shift of all the four UV-visible absorption bands on going from **2** to **3**. The role of the d energy levels has occasionally been noted in the conformational choice (trigonal-prismatic or octahedral) for $[M(1,2\text{-}S_2C_6H_4)_3]$ complexes.[3, 10] No such effect, however, is visible in the case of $S_2C_2H_4$ complexes, for **2**, **3**, and the Ti complex are similar in structure.

[6] All dithiolene complexes except $[Mo(S_2C_2(CN)_2)_3]^{2-}$ are trigonal-prismatic: see for example; M. Draganjac, D. Coucouvanis, *J. Am. Chem. Soc. 105* (1983) 139, and references cited therein.

[7] The notation $E(T_{1u})$ means that the vibration is of E symmetry in the D_3 point group, which arises from the T_{1u} vibration of the parent O_h point group. Note that the $A_1[A_{1g}]$ vibrational mode is IR silent.

[8] The square root of the reduced-mass ratio, $[\mu(Ta\text{-}S)/\mu(Nb\text{-}S)]^{1/2}$, is 1.07.

[9] a) Extended Hückel calculations on $[Nb(SCH_2CH_2S)_3]^-$ were carried out for various torsional angles ϕ. For $\phi = 30°$, the a_1 (LUMO) level was calculated to be ca. 0.5 eV lower than the next lowest e level. b) R. Hoffmann, J. M. Howell, A. R. Rossi, *J. Am. Chem. Soc. 98* (1976) 2484.

[10] M. J. Bennett, M. Cowie, J. L. Martin, J. Takats, *J. Am. Chem. Soc. 95* (1973) 7504.

[11] *Note added in proof* (December 16, 1985): The complex anions $[M(SCH_2CH_2S)_3]^-$ (M = Nb, Ta) were found to undergo an unusual rearrangement via cleavage of a C–S bond in the presence of water, resulting in formation of $[MS(SCH_2CH_2S)(SCH_2CH_2SCH_2CH_2S)]^-$.

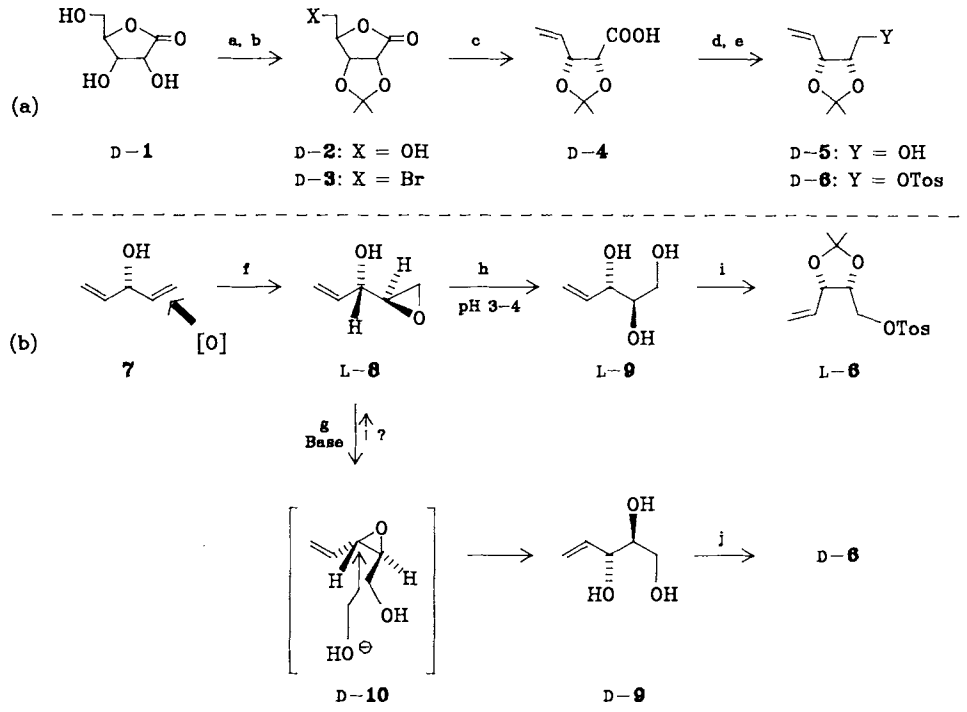
Synthesis of *erythro*-D- and -L-4-Pentenetriols. Selective Epoxy Allyl Alcohol Hydrolysis with Retention or Twofold Inversion (Enantiomerization)**

By *Brigitte Häfele, Detlef Schröter,* and *Volker Jäger**

For studies on stereoselection in cycloadditions,[1] we required 5-substituted 4-vinyldioxolanes with *erythro (cis)* configuration (cf. **4**–**6**). We report here two approaches, starting from either D-ribonolactone D-**1** (a) or 1,4-pentadien-3-ol (divinylcarbinol) **7**, which make accessible D- and L-**6** with high diastereomer and enantiomer ratios (Scheme 1).

The D-*erythro* compounds **4**–**6** were prepared from D-ribonolactone D-**1** in a straightforward manner.[2] The tosylate D-**6**—which was known to be crystalline from parallel studies[3]—was obtained as a single diastereomer; $[\alpha]_D^{20} = -44.5$ ($c = 1.87$, $CHCl_3$).

In order to synthesize the L-*erythro* compounds, a route based on the asymmetric epoxidation of *Sharpless* et al.[4] was devised. Results with chiral, secondary allylic alcohols[4b-d, 5] suggested **7** as a promising starting material. **7**, an achiral compound with four stereoheterotopic faces, should undergo addition from the *Re,Re* face with high stereoselectivity when the (+)-diethyl tartrate (DET) version of the above reaction is used.[6]



Indeed, epoxidation of **7** gave, after distillative workup,[5] the epoxy allyl alcohol **8** (55–65%), along with *tert*-butyl hydroperoxide/*tert*-butyl alcohol. Since attempts to isolate pure **8**, which is present as a single diastereomer (^{13}C-NMR), failed,[7] the mixture was treated with potassium hydroxide in aqueous dioxane at 100°C to afford the crude triol **9** (viscous oil with positive optical rotation[7b]). Tosylation and acetonation of **9** afforded the crystalline tosylate **6**, again as a single diastereomer; $[\alpha]_D^{20} = -27.6$ ($c = 0.54$, $CHCl_3$).

Comparison of this optical rotation with the value for D-**6** (obtained from D-**1**) indicates a ca. 80:20 ratio of D-**6**/L-**6**, which is at variance with the established steric course of this reaction. First, the sequence had proceeded with very high diastereo- but rather low enantioselectivity. Second, the *wrong major enantiomer* had been formed!

The analysis of these results made clear that this D-**6**/L-**6** mixture could *not* reflect the actual stereofacial differentiation of the (+)-DET epoxidation, since D-**8** (and

Michel* for experimental assistance.

Scheme 1. Routes to protected D- and L-4-pentenetriols from (a) ribonolactone D-**1** and (b) 1,4-pentadien-3-ol **7**. The diastereomer ratios are given in brackets. a) Ref. [2a]. b) *N*-Bromosuccinimide, PPh_3 [2b]; D-**3**: 80%, m.p. = 88.5–89.5 °C, $[\alpha]_D^{25}$ −44.7 (c = 1.01, $CHCl_3$); cf. ref. [2c]. c) Zn-Cu, acetone, reflux [2d]; D-**4**: 85%, [> 97 : 3 by ^{1}H- and ^{13}C-NMR] [2e, f]. d) $LiAlH_4$; D-**5**: 93%, $[\alpha]_D^{20}$ −44.0 (c = 4.89, $CHCl_3$ [> 99 : 1 by ^{13}C-NMR]. e) TosCl, pyridine, CH_2Cl_2, 50 °C, 7 d; D-**6**: 57%, m.p. = 56–57 °C (from petroleum ether/Et_2O), $[\alpha]_D^{20}$ −44.5 (c = 1.87, $CHCl_3$); [> 98 : 2 by HPLC and NMR]. f) *t*BuOOH, Ti(O*i*Pr)$_4$, *R,R*-(+)-diethyl tartrate (2 : 1 : 1), CH_2Cl_2, −24 °C, 26 h (cf. [4a, e]); boiling range 70–100 °C/15 torr (Kugelrohr); composition: L-**8** 40–60%, rest *t*BuOH/*t*BuOOH; overall yield 55–65% (estimated by ^{1}H-NMR), [> 95 : 5 by ^{13}C-NMR]. g) KOH (6 equiv.), H_2O-dioxane (1 : 1.2), 100 °C, 16 h; boiling range 150–170 °C/0.1 torr (Kugelrohr); D-**9**: 68%; [> 95 : 5 by ^{13}C-NMR], $[\alpha]_D^{18}$ = +21.7 (c = 0.567, CH_3OH) [7b]. h) H_2O, pH 3–4, 60 °C, 18 h; boiling range 150–170 °C/0.1 torr (Kugelrohr); L-**9**: 61%, $[\alpha]_D^{18}$ = −25.5 (c = 1.336, CH_3OH). In other runs, rotations of 24.2 to 28.4 were obtained. D-**9**, obtained from D-**5** (starting from D-**1**), showed $[\alpha]_D^{18}$ = +27.6 (c = 0.89, CH_3OH). i) TosCl (1.1 equiv.), pyridine (3 equiv.), 0 °C → room temperature, 16 h; L-**9** monotosylate: 60–70% after flash chromatography on silica (Et_2O/ethyl acetate/NEt_3 8 : 2 : 0.1); $Me_2C(OMe)_2$ (1.5 equiv.)/$SnCl_2$ (cat.)/1,2-dimethoxyethane, 60 °C, 75 min; L-**6**: 59%, m.p. = 55–56 °C (from petroleum ether/ether), $[\alpha]_D^{20}$ = +42.0 (c = 1.005, $CHCl_3$). j) Analogous to i).

hence D-**6**) would have been produced by attack mainly at the *Si,Si* face of **8**, i.e., the *least* reactive one.[4b,c]

Indeed, epoxide hydrolysis by the strong base employed turned out to be the stereo-diverting step: hydrolysis at pH 3–4 gave the triol **9** in ca. 60% yield with higher and opposite rotation[7b] (see Scheme 1). As described above, this triol was converted into the tosylate **6**, which, after crystallization, showed a specific rotation of $[\alpha]_D^{20}$ +42.0 (c = 1.005, $CHCl_3$). This corresponds to a D-**6**/L-**6** ratio of ca. 3 : 97, in accordance with expectation.

The reaction of L-**8** with strong base to yield D-**9** as the major enantiomer is thus rationalized as a net *enantiomerization by a two-step double inversion* (see Scheme 1). This unusual course of an epoxy alcohol Payne rearrangement/opening[4d,8] is attributed to the fact that the allylic position in D-**10** is more strongly activated than the (usually favored) terminal position in L-**8**.

The optically active C_5 building blocks described here have many potential uses.[9] In addition, the reaction sequence in Scheme 1 (b) may allow for stereocontrol at two levels: L- and D-**8** are both accessible from **7** by employing either (+)- or (−)-DET, respectively, in the epoxidation step; both enantiomers of **9** may be obtained from the single epoxy allyl alcohol L-**8** if conditions for complete double inversion can be elaborated.

Synthesis of Deoxyhexoses from Divinylglycols—The Synthesis of D- and L-Chalcose

By *Ulrike Küfner* and *Richard R. Schmidt**

Deoxyhexoses and especially 2,6- and 4,6-dideoxyhexoses are components of numerous natural products.[1] We have developed a variable concept for the synthesis of enantiomerically pure dideoxy sugars starting from racemic or *meso*-divinylglycols,[2,3] which requires only a few steps and is exemplified by the synthesis of D- and L-chalcose (D-**6** and L-**6**) (Scheme 1).[4,5]

Scheme 1. Synthesis of D- and L-chalcose, D-**6** and L-**6**. a) $PhCH_2Br$, dimethylformamide (DMF), $BaO/Ba(OH)_2$ (46%), b) $Ti(OiPr)_4$, *t*BuOOH, CH_2Cl_2, (+)-diethyl tartrate (35%), c) $Ti(OiPr)_4$, *t*BuOOH, CH_2Cl_2, (−)-diethyl tartrate (35%), d) Red-Al, tetrahydrofuran (86%), e) 1. O_3, $MeOH/CH_2Cl_2$; 2. Me_2S (81%), f) $PhCH_2OH$, HCl (70%), g) MeI, NaH, DMF (83%), h) Pd/C, H_2, ethyl acetate (89%).

[**] De Novo Synthesis of Carbohydrates and Related Natural Products, Part 20. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 19: [3].

The *threo*-dipropenylglycol DL-**1**, which is obtained by reductive dimerization of crotonaldehyde[6] and simple separation of the diastereomers,[2] reacts with benzyl bromide to give the monobenzyl derivative DL-**2**. Sharpless oxidation[7] leads to kinetic resolution of the racemate with formation of the enantiomerically pure epoxides D-**3** and L-**3**, respectively. In order to obtain the other isomer in each case, the unreacted starting materials, enriched in L-**2** and D-**2**, respectively, are allowed to react further, thereby affording correspondingly higher yields (ca. 70%) of L-**3** and D-**3**. The epoxide ring in L-**3** is opened regioselectively with Red-Al (sodium hydridobis(2-methoxyethoxy)aluminate) to give the triol derivative L-**4**; analogous opening of hydroxyalkyl-substituted epoxides has already been observed.[8] Ozonolysis of L-**4** affords the 2-*O*-benzyl-protected 4,6-dideoxy-L-*xylo*-hexose L-**5** in only four steps. Conversion into the benzyl glycoside, 3-*O*-methylation, and hydrogenolytic debenzylation give L-chalcose L-**6**[9] in good yield. Similarly, the 4,6-dideoxyhexose D-**5** and D-chalcose D-**6**[9] are obtained from D-**3**.

Direct Determination of Rate Constants for the Addition of Carbenium Ions to Alkenes**

By *Reinhard Schneider, Ute Grabis,* and *Herbert Mayr**

The rates of the addition of carbenium ions to alkenes are important for the understanding of carbocationic polymerizations and with regard to reactivity-selectivity relationships. Probably because such reactions are difficult to control, kinetic investigations have only been carried out under special conditions, e.g., with radiolytically generated carbenium ions.[1] Based on our previous work on the selective formation of 1:1 products from carbenium ions

[*] Prof. Dr. H. Mayr, Dipl.-Chem. R. Schneider, U. Grabis

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *O. Nuyken*, Mainz, and *R. Bederke*, Lübeck, for their help in constructing the apparatus.

and alkenes, we have now developed a method for the determination of the corresponding reaction rates.

The diarylcarbenium tetrachloroborates **1a–1e** can quantitatively be generated from the corresponding diarylmethyl chlorides and boron trichloride in dichloromethane at -20 to -90°C. When 2-methyl-1-pentene **2** is added to these solutions, the addition products **3a–3e**, which are practically un-ionized under these conditions, are formed (>90% yield). The course of these reactions can easily be followed conductometrically and photometrically (fiber optics) since the electrical conductivity and the absorption of visible light decrease to less than 3% of the initial values.

The reactions were found to be first order with respect to both alkene and carbenium ion over the entire concentration range examined (**2**: 1.1×10^{-2} to 8.6×10^{-5} mol/L; **1d**: 4.1×10^{-3} to 4.1×10^{-5} mol/L). One to two equivalents of BCl_3 are sufficient to achieve complete ionization of **1a–1d**, whereas complete ionization of the di-*p*-tolyl compound **1e** requires approximately 500 equivalents of BCl_3 in the concentration range studied. The reaction rate of **1d** (2.1×10^{-4} mol/L) is not influenced by variation of the BCl_3 concentration from 10^{-1} to 3.6×10^{-3} mol/L.

The addition of **1** to **2** initially yields the carbenium ion **4**, and it is conceivable that **4** either reacts with $BCl_4^{\ominus}$ to give **3** and BCl_3 or undergoes retroaddition to give **1** and **2**. The latter possibility, i.e., the reversible formation of **4**, was excluded since the addition of 10^{-2} mol/L of benzyltriethylammonium tetrachloroborate to a 10^{-4} M solution of **1d**-$BCl_4^{\ominus}$ did not affect the reaction rate. The same conclusion can be derived from the observation that the systems **1a**-$BCl_4^{\ominus}$ ($k_2=2.9\times10^{-2}$ L mol^{-1} s^{-1}), **1a**-$BBr_3Cl^{\ominus}$ (2.7×10^{-2} L mol^{-1} s^{-1}), and **1a**-$SnCl_5^{\ominus}$ (2.5×10^{-2} L mol^{-1} s^{-1}) show similar reactivity toward **2**, although the rate of the reaction **4** → **3** is altered when the anion is varied.[3] The observation that the reaction rate of **1d** is not affected when the $BCl_4^{\ominus}$ concentration is increased 100 fold indicates that either specific ion pairs do not exist or that ion pairs and free ions do not differ in their reactivity toward **2**.

The decreasing electron-releasing ability of R^1 and R^2 in going from **1a** to **1e** is accompanied by an increase in reactivity of 5 orders of magnitude (Table 1). In accordance with the solvolysis rates of methoxy-substituted diphenylmethyl derivatives,[4] we do not find a linear correlation between $\lg k_2$ and σ^+. A uniform reaction mechanism and the absence of ion-pair effects is also indicated by the linear correlation between $\ln k_2/T$ and $1/T$ in the temperature ranges investigated (mostly -30 to -70°C). These plots allow the determination of the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$. Especially in the additions of the less-stabilized carbenium ions, the entropy term $T\Delta S^{\neq}$ is the main contribution to the free energy of activation. Whereas the activation entropy is almost unaffected by the variation of R^1 and R^2, $\Delta H^{\neq}$ decreases considerably with decreasing stabilization of the carbenium ions **1a–1e**. If $\Delta S^{\neq}$ of the corresponding addition of the diphenylmethyl cation **1** (R^1, $R^2=H$) is assumed to be of the same order of magnitude, $\Delta H^{\neq}$ is estimated to be zero or negative.

Table 1. Rate constants (CH_2Cl_2, -70°C) and activation parameters for the addition of diarylcarbenium tetrachloroborates **1** to 2-methyl-1-pentene **2**.

	R^1	R^2	k_2 [a] [L mol^{-1} s^{-1}]	k_{rel}	$\Delta H^{\neq}$ [kJ/mol]	$\Delta S^{\neq}$ [J mol^{-1} K^{-1}]	$\Delta G^{\neq}$ (-70°C) [kJ/mol]
1a	OCH_3	OCH_3	2.9×10^{-2}	1	29.8	−125	55.1
1b	OCH_3	OPh	1.7×10^{-1}	5.9			51.9
1c	OCH_3	CH_3	3.4	117	22.7	−120	47.1
1d	OCH_3	H	2.4×10^{1}	828	18.8	−122	43.6
1e	CH_3	CH_3	3.6×10^{3}	124000	11.6	−117	35.4

[a] Reproducibility for **1a–1d** better than ±5%; for **1e**, better than ±10%.

In accord with these conclusions, a negative activation enthalpy (-25 kJ/mol) was reported for the carbocationic polymerization of *p*-methoxystyrene,[5] in which attacking and resulting carbenium ion correspond to the same structural type. The small (positive or negative) activation enthalpies and large negative activation entropies for the additions of reactive carbenium ions to alkenes are in accordance with previously reported data for the corresponding reactions of carbenes and radicals.[6]

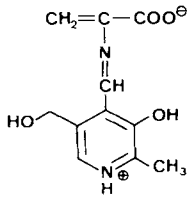
Amino Acid Derivatives from *N*-(Arylmethylene)dehydroalanine Methyl Esters**



By *Günter Wulff** and *Helmut Böhnke*

N-Pyridoxylidenedehydroalanine **1** has been postulated to be a reactive intermediate in the pyridoxal-phosphate-catalyzed biosynthesis of some amino acids;[2] for example,

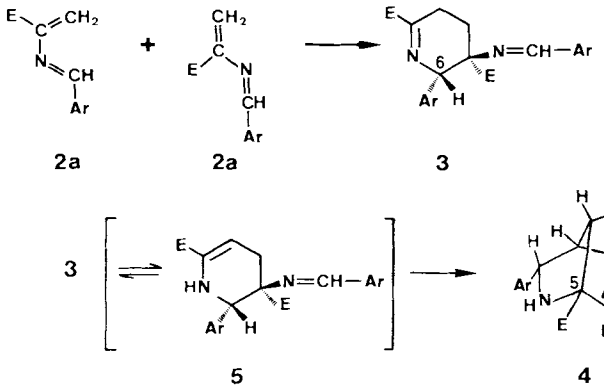
Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

[**] Activated Dehydroamino Acids, Part 2. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.—Part 1: [1].

tryptophan is formed in vivo by Michael addition of the enamine indole to **1**. It had not been possible to isolate or synthesize pure **1** up to now owing to its extreme lability.[3]

1



2

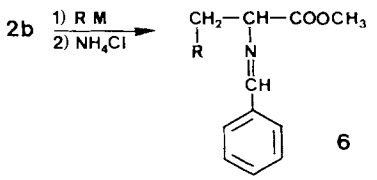
2a, Ar = 4-(C_6H_5)C_6H_4 ; R = CH_3
2b, Ar = C_6H_5 ; R = CH_3

We recently synthesized and characterized the esters **2a** and **2b**, the first compounds having the general structure **2**, from which **1** is also derived.[1] We report here their interesting properties.

2a can be obtained at −90 °C in pure, crystalline form in high yields.[1] However, when it is left in solution for a short time at room temperature, a dimer crystallizes out in yields of up to 56%, which was shown to be the tetrahydropyridine derivative **3**.[4] **3** is obtained as a pure racemic diastereomer. It is formed by [4+2] cycloaddition. The 2-azabutadiene structure of **2a** functions as the 4π component, while the doubly activated CC double bond of **2a** acts as the dienophile.

2a **2a** **3**

5 **4**



E = $COOCH_3$; Ar = 4-(C_6H_5)C_6H_4

Since **3** is also very reactive, its subsequent reactions can only be prevented by the appropriate choice of solvent so as to promote rapid crystallization. In solution at room temperature, **3** reacts within a few hours to give, with high selectivity in 92% yield, the diastereomerically pure 3,6-diazabicyclo[3.2.1]oct-2-ene derivative **4**.[4] Its formation from **3** probably proceeds via the enamine **5**.[5] In this reaction, the nucleophilic β-C atom of the endocyclic enamine moiety attacks intramolecularly the electrophilic carbon atom of the exocyclic azomethine group.

The relative configuration of C1 with respect to C5 of **4** results from the *cis* geometry of this cyclization. The *endo* position of the *p*-biphenylyl group on C7 is established unequivocally by the $^3J(^1H(C1)\text{-}^1H(C7))$ coupling constant of 4.2 Hz.

4 is the final product of a sequence of reactions beginning with the unstable **2** and proceeding via **3**. Compounds **3** and **4** are readily accessible, novel, cyclic amino acid derivatives.

In order to investigate the suitability of **2b** as a Michael acceptor in the synthesis of amino acids,[6] it was allowed to react with organometallic compounds directly after its preparation (see Table 1).

6

a, R = Me ; **b**, R = Bu ; **c**, R = *s*Bu ; **d**, R = *t*Bu ; **e**, R = Ph

$Me_2CuMgBr\cdot(LiI)$	1.5	−15	**6a**	30	n.d.
$Me_2CuMgBr\cdot(LiI)$	1.5	−15	**6a**	78 [c]	n.d.

[a] Determined by ^{1}H-NMR spectroscopy. [b] Isolated (see [7]). [c] In tetrahydrofuran (THF) as solvent.

As expected,[8] MeMgBr and BuLi hardly underwent reaction with **2b** to give **6a** and **6b**, respectively. When diorganocopper(I) reagents R_2CuLi[9] were used, the desired Michael addition was strongly preferred (see Table 1). The amount of side reaction (addition to the C=O and/or C=N bond) was significantly smaller.[10]

The cuprates of the type $R_2(CN)CuLi_2$ studied by *Lipshutz* et al.[11] have proved useful for the addition of the groups R = *s*Bu and *t*Bu. The addition of $sBu_2(CN)CuLi_2$ gave, after distillation, the two racemic diastereomers of **6c** in a ratio of 7:3 as estimated by ^{13}C-NMR spectroscopy. In the reaction of **2b** with $Me_2CuMgBr\cdot(LiI)$, a change of the solvent (THF instead of ether) resulted in a significant increase in yield.

Overall, the cross-conjugated system **2b** shows the expected behavior of a Michael acceptor and can, despite its low stability, be used advantageously for the synthesis of complicated amino acid derivatives. **2b** thus corresponds to a reactive a^3 synthon in the synthesis of amino acids.

[4] The structures of **3** and **4** were established by spectroscopic means (IR, MS, ^{1}H- and ^{13}C-NMR) and by elemental analysis. Determination of the relative configuration at C4 of **4** was not possible on the basis of the spectroscopic data. Examination of models indicates that the *p*-biphenylyl group is *exo*. The resulting configuration for C4 relative to C5 was thus taken as a basis for the corresponding atom in the formula of **3**, namely, C6. The unequivocal determination of this configuration remains to be established by X-ray crystallography.
[5] The amount of **5** in the reaction mixture was too small for direct spectroscopic detection.
[6] Michael additions for C-C bond formation had already been carried out on the less reactive *N*-acyl derivatives of open-chain dehydroalanines, merely by addition of carbon acids. In the recently described addition of

cuprates, a mixture of **7–9** was obtained in which the Michael addition product was present in only minor amounts: J. A. Bajgrowicz, A. El Hallaoui, R. Jacquier, C. Pigiere, P. Viallefont, *Tetrahedron 41* (1985) 1833.
R–CH_2–CH(NHBz)–COR **7**, R–CH_2–CH(NHBz)–$COOCH_3$ **8**, R–CH_2–C($COCH_3$)–(NHBz)–CH_2–CH(NHBz)–$COOCH_3$ **9**

[7] The products **6a–6e** were identified on the basis of their mass, ^{1}H-, and ^{13}C-NMR spectra. All new compounds afforded correct elemental analyses. Yields are based on the amount of *N*-benzylidene serine methyl esters employed.

[8] T. L. Ho, *Tetrahedron 41* (1985) 1.

[9] General experimental procedure: An imidazole-free solution of **2b** (4 mmol) [1] was added to an ether solution containing 20 mmol of R_2CuLi [C. R. Johnson, C. A. Dutra, *J. Am. Chem. Soc. 95* (1973) 7777] over 10 min at −15°C. After 1–5 h of reaction time (see Table 1), followed by hydrolysis (saturated NH_4Cl solution), and subsequent work-up, the products were distilled with a Kugelrohr apparatus in an oil-pump vacuum.

[10] An attack on the β-carbon atom of **2b** leads to a stabilized dihetero pentadienyl anion, an attack on the C=N bond to an energetically less favorable 1-azaallyl anion.

Synthesis, Structure, and Addition Reactions of $[Cp(CO)_2W{=}PR_2]$, R = *i*Pr, *t*Bu**

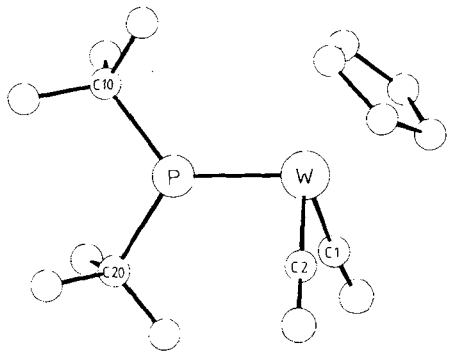
By *Klaus Jörg, Wolfgang Malisch,* Wolfgang Reich, Angelika Meyer,* and *Ulrich Schubert*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

We recently reported a novel method for introducing phosphorus–metal double bonds into complexes of the type $[Cp(CO)_2M{=}PR_2]$ by 1,2-elimination of hydrogen chloride or dimethylamine from the complexes $[Cp(CO)_2M(H)PR_2X]$ (M = Mo, W; X = Cl, Me_2N).[1] Following the synthesis of *P*-alkoxy- and *P*-dimethylamino-substituted species we have now succeeded in preparing the previously unknown *P*-alkyl derivatives. Such derivatives are of special interest for studying double bond reactivity, which in this case is unaffected by hetero substituents.[1–3]

Since the corresponding chlorophosphane-metal hydride is not available,[4] complexes **3a, b** with phosphorus-hydrogen and metal-chlorine groups must be used as starting substances. The complexes **3a, b** are obtainable from the chloro complex **1** and the secondary phosphanes **2a, b** in boiling benzene,[5] and, according to the IR and NMR data, separate as pure *cis* isomers (diastereotopism of the alkyl groups, intensity ratio $\nu(CO)_s : \nu(CO)_{as} > 1$).[6] Their dehydrohalogenation to the double-bond complexes **4a, b** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in methylcyclohexane at room temperature proceeds smoothly and cleanly. Upon cooling, **4a, b** precipitate from pentane as violet microcrystalline powders that are readily soluble in benzene and very sensitive to air. They melt with decomposition to give $(tBu_2P)_2$ and the dinuclear complex $[Cp(CO)_2W]_2$ via cleavage of the W=P bond.

The composition of **4a, b**, which, on account of a kinetic stabilization, are highly stable towards aggregation,[7] is confirmed by elemental analysis and by mass spectrometric data. The large *J*(PW) coupling constants of 591 and 552 Hz, respectively, for **4a** and **4b** (which are characteristic for phosphorus-metal double-bond complexes) and the respective $\delta(^{31}P)$ values of 401 and 373,[5] may be regarded as proof of the structure. The non-equivalence of the *tert*-butyl groups observed in the ^{1}H-NMR spectrum below −50°C reveals that the conformation with the doubly bonded P_2P ligand oriented "perpendicular" to the cyclopentadienyl unit is the energetically most favorable in solution.[8] The $\Delta G^{\neq}$ value for rotation about the metal-phosphorus double bond is, according to the temperature-dependent ^{1}H-NMR spectra, 10.3 kcal/mol. The X-ray structure analysis of **4b** is consistent with the molecular structure with "vertical" conformation and an exactly planar phosphorus atom (Fig. 1).[9] The W–P bond length (2.28 Å) lies in the range typical for a phosphorus-tungsten double bond (2.26 Å).[10]



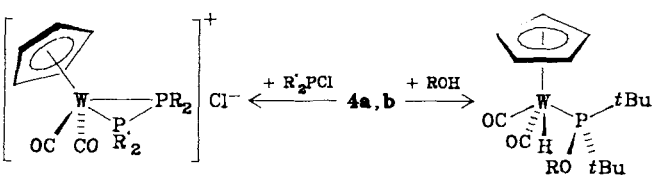


Fig. 1. Crystal structure of **4b**. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W-P 2.284(4), P-C10 1.90(2), P-C20 1.91(2), W-C1 1.87(1), W-C2 1.94(2); M-W-P 134.4, W-P-C10 126.1(6), W-P-C20 124.4(6), C10-P-C20 109.4(8), P exactly planar, C1-W-C2 79.8(8), C1-W-P 93.6(6), C2-W-P 92.4(5). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51700, the names of the authors, and the full citation of the journal.

Despite the shielding by bulky alkyl groups, the W=P bonds of **4a, b** are very reactive. Water, methanol or ethanol add spontaneously with formation of the *cis*-configurated complexes **5a–c**. Upon reaction with the chlorophos-

Lange* and Dr. *W. Buchner* for recording the mass spectra and NMR spectra, respectively.—Part 6: W. Malisch, K. Jörg, E. Gross, M. Schmeusser, A. Meyer, *Phosphorus Sulfur*, in press.

phanes R_2PCl (R = *i*Pr, *t*Bu), heterocyclic cleavage of the P-Cl bond takes place, followed by addition of R_2P^+ to the W=P double bond. This results in formation of the acetonitrile-soluble complexes **6a,b**, in which the diphosphane is coordinated side-on to the metal.

This type of coordination, shown for the first time for diphosphanes, follows from the appearance of only one *J*(PP) coupling in the case of **6b** and from the simple ^{183}W satellite pattern in the case of **6a** [*J*(WP) = 143 Hz] and **6b** [*J*(WP) = 112 Hz (Me_2P), 160 Hz (tBu_2P)].[11] The rapid olefin-like rotation of the $(R_2P)_2$ ligand attached to the metal of **6a**, **b** [$\Delta G^{\neq} = 13.5$ kcal/mol (**6a**)] and its unusually large *J*(PP) coupling of 400 Hz[12] in **6b** suggest a composition of the diphosphenium cation $[R_2P{=}PR_2]^{2+}$, hitherto unknown in the free state, and the metal fragment $Cp(CO)_2W^{\circ}$ for **6a**, **b**.

Experimental

3b: A solution of **1** (615 mg, 1.67 mmol) and **2c** (244 mg, 1.67 mmol) in benzene (60 mL) yielded, after boiling for 28 h under reflux, filtration, evaporation to dryness in vacuo, dissolution in methylcyclohexane (12 mL) and freezing (−78 °C), 642 mg (80%) of orange-red crystalline powder **3b**.—M.p. 128 °C (decomp.).

4b: A solution of **3b** (620 mg, 1.27 mmol) in methylcyclohexane (60 mL) was combined within 30 min at −78 °C with a suspension of DBU (192 mg, 1.16 mmol) in methylcyclohexane (10 mL) and the mixture stirred for 2 h. Subsequent filtration, evaporation to dryness in vacuo, and low-temperature crystallization from 15 mL of pentane/methylcyclohexane (3 : 2) gave 456 mg (80%) of **4b**, m.p. 109 °C (decomp.). **4a** was obtained analogously. Yield 398 mg (88%).—Violet crystalline powder, m.p. 69 °C (decomp.).

5a/b/c: Degassed H_2O/anhydrous MeOH/EtOH 3003 mg (166.7 mmol)/1030 mg (32.1 mmol)/2368 mg (51.4 mmol), respectively, were treated dropwise with solutions of **4b** in 10/5/10 mL of benzene. After removal of the solvent in vacuo the residue was washed with pentane and dried in vacuo. Yields 78/72/74%, respectively, of ocher colored/brown/light-brown solids.—M.p. 121/124/130 °C.

6a/6b: A solution of **4a** (386 mg, 0.89 mmol)/**4b** (172 mg, 0.38 mmol) in 50/20 mL of benzene was treated dropwise with iPr_2PCl/Me_2PCl (196 mg, 0.89 mmol) (84 mg, 0.38 mmol). **6a/6b** precipitated immediately. In each case the separated solid was washed with pentane and dried in vacuo.—Yield 76/84%.—Bright yellow solids.—M.p. 190—193/202 °C.

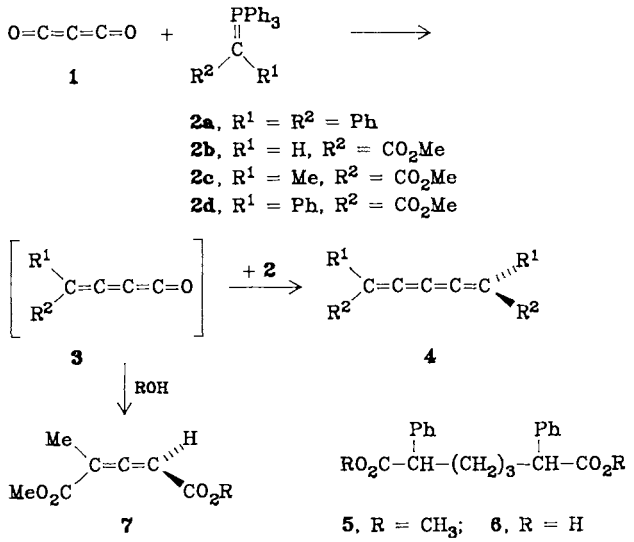
Wittig Reaction with Carbon Suboxide: Synthesis of Dimethyl 1,5-Diphenyl-1,2,3,4-pentatetraenedicarboxylate**

By *Franz W. Nader** and *Angelika Brecht*

Despite their interesting stereochemical properties very few derivatives of 1,2,3,4-pentatetraene are known,[1] and none of those so far reported contain functional groups. The only instance of a stereoisomeric resolution of a chiral pentatetraene derivative was described in 1979 by *Jochims* et al.[2]

The Wittig reaction should in principle provide a synthetic entry to this class of compounds, since it allows, inter alia, the conversion of heterocumulenes into C-cumulenes by carbonyl olefination. Thus, reactions of ketenes with ylides lead to allenes,[3] while reactions of propadiene ylides with ketones[4] and of propadienone derivatives with simple ylides[5] lead to butatrienes. Following this concept, symmetrically substituted pentatetraenes **4** ought to be accessible by double Wittig reaction of the heterocumulene carbon suboxide **1** and simple ylides **2**, with the butatrienone derivative **3** being formed as intermediate.



Although the reactivity of carbon suboxide has been studied in detail,[6a] Wittig reactions of this compound have hitherto been overlooked.[6b]

Of the various methods available for the synthesis of C_3O_2[7] we initially employed the procedure described by *Hopff* et al.[9] and based on the method due to *Staudinger* et al.,[8] which furnishes C_3O_2 in ethereal solution. It emerged, however, that the course of the reaction is strongly dependent upon the nature of the solvent. We therefore resorted to the thermolysis of bis(trimethylsilyl) malonate, the method of *Birkofer* and *Sommer*,[10] in which C_3O_2 is distilled into petroleum ether.

The Wittig reactions with carbon suboxide are best carried out in benzene at high dilution ($c < 0.01$ M). Reaction with **2a** does indeed lead to formation of the respective tetraene **4a** (detection by IR and ^1H-NMR spectroscopy) but nevertheless always accompanied by substantial amounts of benzophenone and diphenylmethane, the latter preventing a chromatographic purification. In the reaction of the ylide **2b**, the C_3O_2 was rapidly consumed, but

[**] Chemistry of the Cumulenes, Part 5.—Part 4: F. W. Nader, C.-D. Wacker, *Angew. Chem. 97* (1985) 877; *Angew. Chem. Int. Ed. Engl. 24* (1985) 852.

neither desired product nor triphenylphosphane oxide could be detected. The ylide **2c** reacts rapidly at room temperature with formation of $Ph_3P{=}O$ and large amounts of polymeric material; by thin-lay chromatography a substance was detected, which, upon column chromatographic separation of the dark brown reaction solution, could be isolated as a colorless oil. This, however, rapidly decomposed to a red tar—even at low temperatures. The IR spectrum showed a medium strong band at 2050 cm^{-1}, which was interpreted as an indicator of the substance being the tetraene **4c**.

The best results were afforded by the ylide **2d**: It reacts with C_3O_2 to give the lemon-yellow, crystalline pentatetraene dicarboxylate **4d** in yields of up to 46%.[11] The structure of **4d** was unequivocally characterized by the IR cumulene band at 2040 cm^{-1}, by the ^{1}H-NMR spectrum, and by its hydrogenation (4 equivalents of H_2) to the α,α'-diphenylpimelic acid dimethyl ester **5**, which was hydrolyzed to the crystalline dicarboxylic acid **6**.[12]

In the absence of air, the crystalline tetraene **4d** is storable over long periods at room temperature, and almost indefinitely at −20°C. In dilute solution, **4d** is storable for short periods; in higher concentrations ($c > 0.01$ M), and especially in the oily form, rapid decomposition occurs, ultimately leading to polymers and presumably initiated by dimerization reactions. It was therefore impossible to obtain a definite ^{13}C-NMR spectrum of **4d**. The instability in concentrated solutions is also the reason for not having been able to isolate the oily di-(−)-menthyl ester analogous to **4d**, thus preventing a study of the asymmetric induction in this reaction.

As expected, the tetraene diester **4d** readily reacts with nucleophiles such as, e.g., alcohol/alkoxide (catalytically), amines, and triphenylphosphane, whereupon well-defined but unusual Michael adducts are formed.[13] For this reason, all attempts to prepare the dicarboxylic acid by basic ester cleavage failed—even under the mild conditions of the two-phase system [18]crown-6/tetrahydrofuran/KOH/H_2O), which proved successful in the case of the analogous butatrienecarboxylates.[14]

The butatrienone intermediate **3** could be detected in the 1:1 reactions of C_2O_3 with **2c** by trapping with alcohols such as, e.g., methanol and benzyl alcohol. In each case the allenedicarboxylate **7** was formed in 10–15% yield as the only well-defined product; the colorless oils gave characteristic ^{1}H-NMR spectra (coupling between allene-H and CH_3-group).

In order to synthesize unsymmetrically substituted pentatetraenes, butatrienones such as **3** must be used. Possible starting materials for their preparation are alkyl esters of 4-chloroformyl-2,3-butadienoic acids unsubstituted in the 4-position.[15] In our first investigations, pentatetraene diesters were obtained in yields of up to 75%.

[11] The ylide **2d** (23 g, 56 mmol) was dissolved in anhydrous benzene (800 mL) under N_2 in a 1 L single-necked flask. The stirred solution was treated with 28 mmol of C_3O_2 (petroleum ether solution, $c = 0.2$–0.6 M) and three drops of triethylamine. After 6 d, the dark red-brown solution was transferred portionwise onto three columns (2.5 cm (ID) × 35 cm) packed with silica-gel and eluted with benzene. The combined deep-yellow eluates (1.1 L) proved to be pure (TLC). The benzene was now removed by evaporation under oil-pump vacuum (maximum bath-temperature 30°C) and simultaneously replaced by petroleum ether (b.p. 110–120°C) via a dropping funnel. Yellow crystals of the tetraene ester finally began to separate out. The mixture was then concentrated to about 50 mL and the resulting crystalline mass recovered by filtration. Lemon-yellow crystals (recrystallization: 1 mL of ice-cold CH_2Cl_2 and 10 mL of petroleum ether per 100 mg of **4d**; −20°C) m.p. 120°C (decomp.). Yield: 4.3 g (46%).—IR (KBr): $\nu = 2040$ cm^{-1} (ms, cumulene band); ^{1}H-NMR (90 MHz, $CDCl_3$): $\delta = 3.87$ (s, 6H, $2OCH_3$), 7.30 (m, 6H, *m-/p*-arene-H), 7.70 (m, 4H, *o*-arene-H); correct elemental analysis.

[12] 300 mg of **4d** was added to a prehydrogenated suspension of Raney nickel in ethyl acetate (50 mL) and the mixture hydrogenated. Uptake of H_2 was complete within 30 min (90 mL $H_2 = 4$ equiv. H_2). After filtration and removal of solvent there remained 250 mg of **5** as a colorless oil [^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 1.27$ (m, 2H, $-CH_2-$), 1.95 (quint. 4H, $-CH_2-CH$), 3.53 (t, 2H, α/α'-CH-Ph), 3.59 (s, 6H, $2OCH_3$), 7.33 (m, 10H, arene-H)]. Since the ester **5** did not crystallize, it was hydrolyzed with 10% NaOH in methanol/water at room temperature. After the usual work-up, **6** was obtained as a colorless oil which crystallized on standing. Colorless crystals (benzene/petroleum ether), m.p. 100–103°C (not diastereomerically pure).—^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 0.73$–2.37 (two m, 6H, $(CH_2)_3$), 3.30–3.67 (m, 2H, α/α'-CH-Ph), 7.22 (s, 10H, arene-H), 9.77 (broad s, 2H, CO_2H); correct elemental analysis. M.p. (Lit.) 147–149°C (diastereomerically pure, presumably *meso*): C. G. Screttas, M. Micha-Screttas, *J. Org. Chem. 44* (1979) 713.

Synthesis and Structure of 1,3-Diphenyltriazenidogold(I), a Tetrameric Molecule with Short Gold-Gold Distances**

By *Johannes Beck* and *Joachim Strähle**

Polynuclear complexes whose metal atoms have d^{10} configuration are currently attracting a great deal of attention, primarily because of the much debated subject of metal-metal bonding between d^{10} centers. Hückel MO calculations[1-3] show that a bonding interaction results by incorporation of vacant s- and p-orbitals. Cu^I forms a series of such polynuclear complexes with Cu-Cu distances of not more than 235 pm.[1,4] In the case of complexes with monovalent gold, Au-Au distances of down to as short as 260 pm are not uncommon.[3,5,6] In clusters containing Au^I along with another metal, still shorter distances have been observed.[7]

In most cases the short metal-metal distances are favored by bridging ligands. A remarkable exception is the cluster **1**,[8] in which a Pt^0-Pt^0 bond of 276 pm without bridging ligand has been found.

$[Pt(t\mathrm{Bu})_2P(CH_2)_3P(t\mathrm{Bu})_2]_2$ **1**

Bridging ligands can also stabilize d^{10}-d^{10} interactions by accomodating antibonding charge density from the metals via their π-system.[9] As also shown by trimeric 1,5-ditolyl-1,4-pentaazadien-3-idocopper(I), with its extremely short Cu-Cu distances,[4] polyazenido ligands are especially capable of effecting such a stabilization. We have therefore prepared the complex 1,3-diphenyltriazenidogold(I) **2**. In metal complexes the 1,3-diphenyltriazenide functions either as a bidentate chelate ligand to a metal atom or as a bridging ligand for two metal atoms. The short distance between the two outer nitrogen atoms (223 pm) gives rise thereby to short metal-metal distances.

The structures of several complexes with divalent metals are already known.[10] The Cu^I complex **3** is dimeric with a Cu-Cu distance of 245 pm,[11] the corresponding complex of dimethyltriazenide **4** is tetrameric. The four Cu atoms form a rhombus with a mean Cu-Cu distance of 266 pm.[12]

$[Au(PhNNNPh)]_4$ **2** $[Cu(PhNNNPh)]_2$ **3**

$[Cu(H_3CNNNCH_3)]_4$ **4** $[Au(CH_3CSS)]_4$ **5**

Au^I can form both types of complex with single negatively charged bidentate ligands. For example, dipropyldithiocarbamatogold(I) is dimeric with a Au-Au distance of 276 pm,[13] whereas the tetramer **5** containing a rhombic Au_4 ring is formed with the dithioacetato ligand.[9] The mean Au-Au distance of 301 pm in this complex is, however, markedly longer than in the metal (288.4 pm[14]).

We obtained tetrameric **2** from AuI and $Na(PhN_3Ph)$ in liquid ammonia.[15] The yellow, air-stable compound crystallizes from tetrahydrofuran (THF)/hexane as rectangular crystals of the composition **2**·THF which decompose without melting above 180°C. A molecular weight determination revealed that **2** is also tetrameric in $CHCl_3$ solution. In the IR spectrum, the asymmetric N-N stretching vibration appears at 1380 cm^{-1}.

The structure determination[16] (Fig. 1) shows that four atoms are located at the corners of a rhombus and the four ligands form bridges alternately above and below the plane of the Au_4 ring.

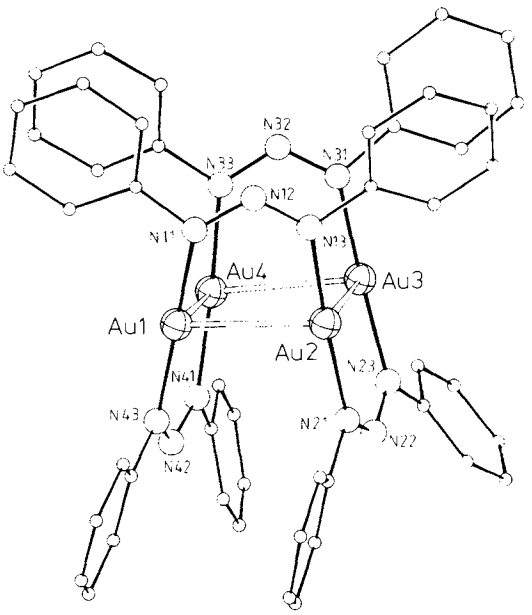

Fig. 1. Structure of **2** in the crystal of **2**·THF. Important bond lengths [pm] and angles [°]: Au1-Au2 284.8(1), Au2-Au3 285.6(1), Au3-Au4 285.5(1), Au4-Au1 284.2(1), Au2-Au4 331.9(1), Au-N 201.8(5) to 206.6(5), N-N 127.7(7) to 130.6(6); Au2-Au1-Au4 71.38(1), Au1-Au2-Au3 108.51(1), Au2-Au3-Au4 71.07(1), Au1-Au4-Au3 108.72(1), N-Au-N 175.2(2) to 178.0(2), N-N-N 118.3(6) to 118.9(5).

The mean gold-gold distance of 285 pm is somewhat shorter than in the metal; so a bonding interaction may therefore be assumed. The Au_4 ring is folded at an angle of 7° along the Au1-Au3 axis, with Au2, for example, protruding about 21 pm from the plane of the other three gold atoms. The gold-nitrogen distances (204 pm) lie in the range typical for gold-nitrogen single bonds. The gold atoms are linearly coordinated, and the N-Au-N angles are on average 176°. The bridging N_3-unit and the two associated gold atoms always lie in a plane (N23 shows the largest deviation (9 pm) from the Au2/Au3/N21/N22/N23 plane). Opposite planes each form a dihedral angle of about 22°. The N-N distances are almost equivalent. They lie between 127.7 and 130.6 pm and thus correspond to slightly stretched double bonds, as are also found in other triazenido complexes[10-12] and in the essentially ionic 1,5-ditolyl-1,4-pentaazadien-3-idothallium(I) complex.[17]

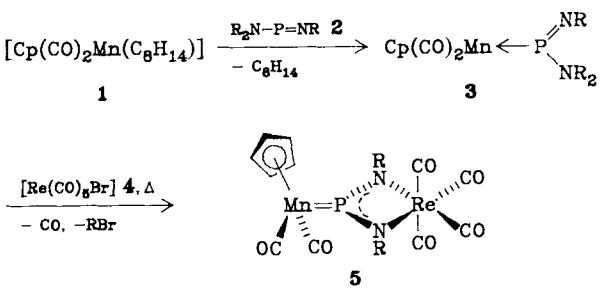
$Me_3SiNPNSiMe_3^{\ominus}$, the Monophosphorus Analogue of a Triazenido Ligand**



By *Otto J. Scherer,* Ekkehard Franke,* and *Jürgen Kaub*

If the central N atom in the triazenido ligand **A** is replaced by a P atom, the monophosphorus analogue **B** is obtained (cf. the complex-stabilized RPCHPR, R = 2,4,6-$(t\text{Bu})_3C_6H_2$[1]). Whereas only the two terminal N atoms of **A** are used in coordination (monodentate, chelating, or μ-bridging),[2] the η^1 type of P coordination, in addition to the chelate type, is observed for **B** (**B** as a tridentate 6e donor ligand).

A   **B**

The *cis*-cyclooctene complex **1** undergoes ligand exchange reaction with the amino(imino)phosphane **2** to give the complex **3**, which reacts in turn with the rhenium complex **4** to give the species **5** in which **B** is present as a 6e donor.

5[3] forms yellow, extremely air-sensitive (brown coloration) crystals, which are sparingly soluble in hexane but readily soluble in benzene, toluene, and dichloromethane. Its $^{31}P\{^1H\}$-NMR signal ($\delta = 394.6$) is significantly shifted to lower field in comparison with the precursor **3** ($\delta = 312.5$).[4]

Cp = η^5–C_5H_5; R = $SiMe_3$; C_8H_{14} = *cis*–cyclooctene

The X-ray structure analysis[5] confirms the tridentate coordination of the $RNPNR^{\ominus}$ ligand (Fig. 1). **5** exhibits approximate C_S symmetry. The geometry around the P (360°) and the N atoms (359, 360°) is trigonal planar. The atoms Mn, P, N1, Si1, N2, Si2, Re, C15, and C17 lie in a plane. The dihedral angle between the planes $C_5H_{5(centr.)}$, Mn, P and N1, P, N2 is 91°.

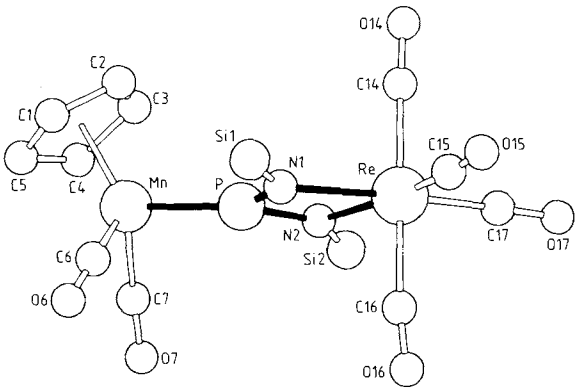


Fig. 1. Crystal structure of **5** (methyl groups and hydrogen atoms have been omitted for clarity). Selected bond lengths [Å] and angles [°] (see also text): Mn-P 2.122(8), P-N1 1.60(3), P-N2 1.62(2), N1-Si1 1.78(3), N2-Si2 1.78(2), Re-N1 2.19(2), Re-N2 2.19(2), Re-C15 1.94(3), Re-C17 1.89(3); N1-P-N2 97(1), P-N1-Re 98(1), P-N2-Re 98(1), N1-Re-N2 66.7(8), P-Mn-C6 93.4(8), P-Mn-C7 95.0(8), P-Mn-$C_5H_{5(centr.)}$ 123.

In the cluster **6a**,[6a] which is also planar at the P atoms and which has a P_2Fe_2 butterfly skeleton, the corresponding planes nearly coincide. This orientation (conformation), which is preferred on the basis of theoretical calculations,[7] is energetically unfavorable for **5**, possibly as a result of steric and electronic effects. The stepwise-formed exocyclic Mn-P bond is remarkably short (2.122(8) Å); it is only slightly longer than that of **6a**[6a] (mean value: 2.10 Å) but shorter than that in the phosphanediyl complex **6b**[6b] (mean value: 2.184 Å). As discussed already in the case of **6**,[6] this bond has multiple bond character.

$[\{Cp(CO)_2Mn{=}P\}_2Fe_2(CO)_6]$ **6a** $[\{Cp(CO)_2Mn\}_2PC_6H_5]$ **6b**

$[(OC)_5Cr\{P(=NR')(NR_2)\}]$ $[Pt\{P(=NR')(NRR')\}_3]$
7 R = $SiMe_3$, R' = *t*Bu **8**

trans-$[(Ph_3P)_2(OC)_2\overline{ReN(R)NNR}]$
9, R = *p*-MeC_6H_4

As a result of its charge and its bonding to the $Re(CO)_4$ fragment, the $Me_3SiNPNSiMe_3^{\ominus}$ ligand apparently exhibits more pronounced π-acceptor behavior than the amino(imino)phosphane ligand in complexes of type **7**[8a] and **8**[8b]. The lengths of the Re-N bonds (2.19(2) Å) and the Re-C bonds (C15, C17) *trans* to them are nearly identical to those of the comparable triazenido complex **9**[9] (mean values: Re-N 2.19, Re-C 1.92 Å). The mean value of the P-N distances (1.61 Å) in **5** is that expected based on the values of the free ligand **2** (P=N 1.545(2), P–N 1.674(1) Å).[10]

[3] Experimental procedure: **3**: **1** (1.197 g, 4.18 mmol) [11] and **2** (1.165 g, 4.18 mmol) [12] in 20 mL of toluene were stirred at 90°C for ca. 3.5 h. After removal of all volatiles, the product was dried for several hours in an oil-pump vacuum. **3** separated out quantitatively as a pure (NMR) red oil, which could not be induced to crystallize (NMR and IR data [4]). **5**: **3** (1.901 g, 4.18 mmol) and **4** (1.698 g, 4.18 mmol) were refluxed in 30 mL of xylene for ca. 15 h (end of reaction determined by ^{1}H-NMR). After removal of all volatiles, the product was dried for several hours in an oil-pump vacuum. The yellow, partially viscous residue was dissolved in ca. 30 mL of toluene, filtered through filter flocks and cooled for 1 d at 0°C and again at −35°C. After the toluene had been decanted, the yellow crystals were washed with ca. 3 mL of cold toluene and dried in vacuum (10 torr). Yield: 1.28 g (46%).
[4] ^{31}P{^{1}H}-NMR (81.0 MHz, 20°C, C_6D_6, 85% H_3PO_4 ext.). Facile Synthesis of Pentaphenylnickelocene and Other Pentaphenylcyclopentadienylnickel and -cobalt Complexes**

By *Wolfgang Kläui** and *Ludwig Ramacher*

Pentamethylcyclopentadienyl complexes have been extensively studied in recent years.[1] They can be obtained from halogeno-transition-metal complexes $[ML_mX_n]$ and alkali-metal-, Grignard- or thallium-cyclopentadienides. Several reports show that the synthesis of transition-metal-pentaphenylcyclopentadienyl complexes via this route is possible.[2-4] The preparation of alkali-metal-pentaphenylcyclopentadienides is, however, not unproblematical. When pentaphenylcyclopentadiene is allowed to react with alkali metals, formation of the remarkably stable pentaphenylcyclopentadienyl radical is frequently observed as a side reaction. Furthermore, the secondary products of this radical are often difficult to separate. We have therefore searched for an alternative entry to perphenylated cyclopentadienyl-metal complexes.

Using the reaction of pentacarbonyliron with bromopentaphenylcyclopentadiene to give bromodicarbonyl(pentaphenylcyclopentadienyl)iron[5] as starting point, we found that the oxidative addition of bromopentaphenylcyclopentadiene is an elegant method for the preparation of pentaphenylcyclopentadienyl-nickel and -cobalt complexes. C_5Ph_5Br is easier to obtain than C_5Ph_5H and is smoothly accessible in large amounts in analytically pure form.[6] Reaction of stoichiometric amounts of C_5Ph_5Br and tetracarbonylnickel in tetrahydrofuran (THF) leads to the formation of di-μ-bromobis(pentaphenylcyclopentadienylnickel) **1** in almost quantitative yield.

$$C_5Ph_5Br + Ni(CO)_4 \longrightarrow [(C_5Ph_5)Ni(\mu\text{-}Br)_2Ni(C_5Ph_5)]\ \mathbf{1}$$

The chloro compound can be prepared in the same way. **1** is remarkably stable towards heat (no decomposition below 200°C), but is sensitive to air in solution. It is the second halogeno-bridged cyclopentadienylnickel compound of this type so far reported. The corresponding pentamethylcyclopentadienyl compound, first synthesized by *Kölle* et al., is storable only below −10°C.[7] The analogous unsubstituted cyclopentadienyl complex is not known. Depending upon the temperature, varying amounts of the carbonyl complex **2** are also found to be formed in addition to the dimeric compound **1**. The complex **2**, which is probably the primary product of the reaction, can be synthesized by reaction of **1** with CO at room temperature and normal pressure in THF.[8] The method used for the synthesis of **2** can also be used for the synthesis of **3**[8] starting from C_5Ph_5Cl.[6] It is surprising that **2** and **3** are the first stable compounds of type **A** that have become accessible. We have been able to prepare the iodo complex **4** for the first time by halide-exchange from **2** in acetone.[8] The carbonyl complexes **2**, **3**, and **4** are, like **1**, deep-red crystalline compounds that are storable in presence of air for weeks at room temperature but air-sensitive in solution. They are of interest as starting substances for the synthesis of sandwich complexes of the type **B** and **C**.[9] **1** reacts with thallium cyclopentadienide in THF to give the previously unknown pentaphenylnickelocene **5**.[10]

The air-sensitive, olive-green compound is, as expected, paramagnetic in solution and in the solid state. The magnetic moment (dichloromethane, Evans method) is $\mu_{eff} = 2.9$ B.M. The magnetic moment of the solid was found to be $\mu_{eff} = 3.2$ B.M. at 25°C.

$[(C_5Ph_5)Ni(CO)Br]$ **2** $\quad$ $[(C_5Ph_5)Ni(CO)Cl]$ **3**

$[(C_5Ph_5)Ni(CO)I]$ **4** $\quad$ $[(C_5Ph_5)Ni(C_5H_5)]$ **5** $\quad$ $[(C_5Ph_5)Co(CO)_2]$ **6**

Pentaphenylnickelocene **5** can be reversibly oxidized at +0.085 V and +0.98 V (SCE) in dichloromethane to the mono- and dication, respectively (Fig. 1). The oxidation potentials are shifted slightly compared to those of the unsubstituted nickelocene (−0.02 V, + ~0.9 V under identical conditions). The markedly greater stability of the pen-

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *H. Lueken* for measuring the magnetic susceptibilities and Mrs. *S. Paul* and Priv.-Doz. Dr. *U. Kölle* for recording the cyclovoltammograms.

taphenylnickelocinium dication compared to that of $[Ni(C_5H_5)_2]^{2+}$ is probably due to the sterically very bulky pentaphenylcyclopentadienyl ring. By way of contrast electronic effects are responsible for the stability of the corresponding permethylated dication.[11]

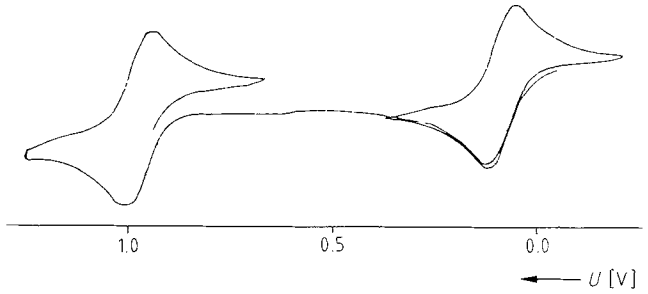

Fig. 1. Cyclovoltammogram of **5** in $CH_2Cl_2/[Bu_4N]PF_6$; Pt electrodes, 100 m V s^{-1}.

Reaction of C_5Ph_5Br with octacarbonyldicobalt in THF led to a product mixture from which we were unable to isolate any pentaphenylcyclopentadienyl complexes. However, we were able to synthesize dicarbonylpentaphenylcyclopentadienyl cobalt **6** in good yields by reaction of C_5Ph_5Br with $K[Co(CO)_4]$.[12] This compound too is distinguished by its exceptional thermal stability compared to that of the corresponding C_5H_5- and C_5Me_5-compounds. It is, e.g., sublimable in vacuo at 180°C. However, in the solid state it is rather sensitive to oxidation. Preliminary investigations have shown that **6** is suitable as starting compound for the photochemical synthesis of cyclooctadiene(pentaphenylcyclopentadienyl)cobalt and probably also for a series of analogous bis(olefin) complexes.

Five phenyl groups appear to stabilize cyclopentadienyl complexes even more strongly than do five methyl groups. We have now found that the oxidative addition of halogenopentaphenylcyclopentadienes also constitutes a simple strategy for the synthesis of C_5Ph_5 complexes of 4d and 5d metals.

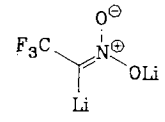
[6] We have prepared C_5Ph_5Br and C_5Ph_5Cl from tetracyclone on a 50 g scale (see, e.g., A. K. Youssef, M. A. Ogliaruso, *J. Org. Chem. 37* (1972) 2601; W. Broser, P. Siegle, H. Kurreck, *Chem. Ber. 101* (1968) 69; K. Ziegler, B. Schnell, *Justus Liebigs Ann. Chem. 445* (1925) 266).
[7] U. Kölle, B. Fuss, F. Khouzami, J. Gersdorf, *J. Organomet. Chem. 290* (1985) 77.
[8] *Procedure.* **1**: A solution of C_5Ph_5Br (5.0 g, 9.5 mmol) in anhydrous THF (30 mL) was treated with 1.25 mL (9.6 mmol) of $Ni(CO)_4$, and the mixture stirred for 24 h. The resulting reddish brown precipitate was filtered off, washed with a small amount of THF, and then dried in a high vacuum. Yield 5.2 g (90%). The product contained a small amount of **2** and was suitable in this form for further reactions.—**2**: Upon passage of CO through a suspension of **1** in THF at 25°C a dark-red, clear solution was obtained. The solvent was removed by bubbling with CO, and the reddish brown product that separated was briefly dried in vacuo. IR (KBr): 2047 cm^{-1} (ν(CO)).—**1**, Cl instead of Br: C_5Ph_5Cl (1.0 g, 2.1 mmol) and $Ni(CO)_4$ (0.27 mL, 2.1 mmol) in THF (10 mL), 50°C, analogously to the preparation of **1**. Yield 0.99 g (88%), correct C,H analysis.—**3**: By gassing a suspension of **1**, Cl instead of Br, with CO as described for **2**. IR (KBr): 2052 cm^{-1} (ν(CO)).—**4**: A suspension of **2** (200 mg, 0.33 mmol) in acetone was treated with excess NaI. After 5 h the solvent was removed by distillation and the residue was taken up in dichloromethane; undissolved NaI and NaBr were removed by filtration, and the filtrate evaporated to dryness. Yield: 180 mg (83%). IR (KBr): 2039 cm^{-1} (ν(CO)). The mass spectrometrically controlled bromide/iodide exchange went to completion.
[9] Complexes of type **B** are formed upon reaction of **1** with stoichiometric amounts of L, e.g. tertiary phosphites, at room temperature in dichloromethane. Purification by column chromatography on silica gel; yield ca. 70%. Cationic complexes C are formed upon reaction of **1** with an excess of L in the presence of $TlBF_4$ in dichloromethane. Purification on a silica gel column with acetone. Yield ca. 80%.
[10] *Procedure.* **5**: A suspension of **1** (300 mg, 0.26 mmol) in freshly distilled THF (10 mL) was treated with 140 mg (0.52 mmol) of thallium cyclopentadienide. After 2 h the green solution was filtered and evaporated to dryness. Subsequent purification by chromatography on silica gel with THF (2 ×) under nitrogen followed by removal of the eluent by distillation afforded 260 mg (88%) of **5** as an olive-green microcrystalline powder. Correct C,H analysis. MS (EI, 70 eV, 160°C) *m/z* 568 ($M^{\oplus}$, ^{58}Ni).
[11] U. Kölle, F. Khouzami, *Angew. Chem. 92* (1980) 658; *Angew. Chem. Int. Ed. Engl. 19* (1980) 640.
[12] *Procedure.* **60**: A solution of $K[Co(CO)_4]$ (0.69 g, 3.3 mmol) in THF (50 mL) was treated with 1.72 g (3.3 mmol) of C_5Ph_5Br and the mixture stirred for 3 d at room temperature. The solvent was then removed by distillation and the reddish-brown residue chromatographed at +10°C on a silica gel column (eluent: first hexane, then ether/dichloromethane 1 : 1). The dicarbonyl complex **6** was eluted as a purple solution, which, after evaporation to dryness, furnished 1.50 g (81%) of **6** as a reddish brown, microcrystalline powder. The product is air-sensitive and can be purified by sublimation at 180°C in vacuo. Correct C,H analysis. IR (CH_2Cl_2): 2010, 1952 cm^{-1} (ν(CO)). MS (EI, 70 eV, 25°C) *m/z* 560 ($M^{\oplus}$).

Di- and Trifluoro-Substituted Dilithium Compounds for Organic Syntheses**

By *Dieter Seebach,* Albert K. Beck,* and *Philippe Renaud*

Fluoroorganic compounds are of increasing interest, mainly for the synthesis of biologically active products.[1] Fluoro substitution can cause problems in synthetic transformations, since fluoride can act as a leaving group.[2] Thus, the β-fluoro-substituted nitroalkanes **1**[3] do not undergo base-catalyzed nitroaldol additions to carbonyl compounds:[4] β-elimination is so strongly favored that reaction of **1** with *N,N*-dimethyl(trimethylsilyl)carbamate affords fluorine-free nitroenamines **2**. To our great surprise, the dilithio derivatives **3** and **4** of the fluoronitroalkanes **1a**,

1a: R = H, X = F
1b: R = X = H
1c: R = Me, X = F



2a: R = H, X = NMe_2 (75%)
2b: R = X = H (62%)
2c: R = Me, X = NMe_2 (67%)

1b could be generated with butyllithium, were of comparable stability (up to −70°C) to the nonfluorinated analogues,[5] and reacted with aldehydes and ketones to give the adducts **6–9** (Table 1; for experimental procedure see ref. [5]). The adducts were formed in 50–60% yield but

[a] Determination of the ratio of diastereomers not possible by ^{13}C-NMR.

A double deprotonation is also possible with the (*R*)-trifluorohydroxybutanoate **10a**. This compound is readily available in >90% enantiomeric excess (*ee*) through yeast reduction of the corresponding β-ketoester.[7] At low temperatures (≤ -25 °C), the enolate-alkoxide **5** does not undergo γ-elimination (to an epoxide or a cyclopropane), and, like the nonfluorinated analogue,[8] can be alkylated (→ **10b**–**10d**) or cyclized (→ **11**) diastereoselectively (Table 2; for experimental procedure see ref. [8]).

Table 2. Products **10** and **11** from the dilithio derivative **5** of ethyl (*R*)-4,4,4-trifluoro-3-hydroxybutanoate **10a** (92% *ee*) [7] and CH_3I, CH_2=CH–CH_2Br, $C_6H_5CH_2Br$, I_2 (yields of >95% configurationally pure samples from flash chromatography; % *ds* = [(A/A + B) × 100] from ^{13}C-NMR spectra of crude products; NMR signal of C(3) of major isomer; $[\alpha]_D$ at c = 1.2 in $CHCl_3$).

Selenium-rich Chalcogen Rings Se_5S, Se_5S_2, and Se_7 from Titanocene Pentaselenide**

By *Ralf Steudel,* Maria Papavassiliou, Eva-Maria Strauss,* and *Risto Laitinen*

While the synthesis of sulfur-containing homocycles and heterocycles by reaction of titanocene pentasulfide with non-metal chlorides has been studied in detail, nothing has hitherto been reported about analogous reactions of titanocene pentaselenide.[1] We report here on the synthesis and properties of the six- and seven-membered ring molecules Se_5S and Se_5S_2 and Se_7, respectively, which can be prepared according to Equations (a) to (c).

$$[(C_5H_5)_2TiSe_5] + SCl_2 \longrightarrow Se_5S + [(C_5H_5)_2TiCl_2] \quad (a)$$
$$[(C_5H_5)_2TiSe_5] + S_2Cl_2 \longrightarrow Se_5S_2 + [(C_5H_5)_2TiCl_2] \quad (b)$$
$$[(C_5H_5)_2TiSe_5] + Se_2Cl_2 \longrightarrow Se_7 + [(C_5H_5)_2TiCl_2] \quad (c)$$

Se_5S was obtained from CS_2 in the form of deep-red, shiny, hexagonal needles,[2] whose composition,[3] Raman spectrum,[4a] and crystal structure[5] proved the presence of thiapentaselenacyclohexane. The HPLC retention time[6] lies, as expected, between that of Se_4S_2 and Se_6 (Se_4S_2 2.94, Se_5S 3.07, Se_6 3.40 min; dead time 1.40 min; eluent: methanol).

[**] Sulfur compounds, Part 95. This work was supported by the Deutsche Forschungsgemeinschaft, the Alexander-von-Humboldt Stiftung, the Fonds der Chemischen Industrie, and the TU Berlin (MIT-Sondermittel). – Part 94: [10a].

Crystalline Se_5S is stable for days at 20°C; upon heating, however, a change of the crystal shape is observed at 100°C, indicated in the DSC diagram[7] by a (endothermic) peak at 105°C and a (exothermic) peak at 110°C. Further peaks at 160°C (endothermic) and 165°C (exothermic) indicate melting and polymerization. In CS_2 solution, Se_5S decomposes at 20°C within 5 h, mainly to the heterocycles Se_7S, Se_6S, and Se_5S_3, which were identified by their HPLC retention times.[6] Upon prolonged stirring of the solution, Se_8 and Se_6S_2 are also formed.

The crystal and molecular structures of Se_5S correspond entirely to those of S_6[8] and Se_6[9] both of which form chair-like rings. The atomic positions are occupied statistically by S and Se. The reduction in symmetry from D_{3d} for S_6 and Se_6 to C_s for Se_5S manifests itself in the Raman spectrum by removal of all degenerations and of the rule of mutual exclusion. The observed[4a] and calculated[10a] vibrational spectra are in good agreement.

Seven-membered chalcogen rings claim special interest because of their unusual structures[11] and because of their resulting high reactivity.[12] We have therefore synthesized Se_5S_2 and Se_7 [Equations (b) and (c), respectively].

Se_5S_2 crystallizes from CS_2 at −50°C in the form of dark-red, rod-like crystals, which, in contrast to S_7[12] and Se_2S_5,[13] are stable for months at 20°C.[14] Se_5S_2 apparently decomposes with polymerization at 90–100°C (color change from red to silver), and the substance melts only at 146°C. A DSC investigation showed an endothermic transformation at 70–85°C, followed by an exothermic reaction (polymerization) at 85–95°C and a melting peak at 135–150°C (heating rate 5°C/min).[7]

The chromatogram (HPLC)[6] of a freshly prepared CS_2 solution of pure Se_5S_2 shows a large Se_5S_2 peak and two small peaks, which, on the basis of their retention times (2.94 and 4.94 min; Se_5S_2: 3.49 min; dead time: 1.4 min), can be assigned to the compounds 1,2-Se_4S_2 and 1,2-Se_6S_2 by comparison with reference substances.[6, 13] Se_5S_2 decomposes in CS_2 at 20°C within 60 min, essentially according to Equation (d); this can be interpreted in terms of a mechanism previously proposed by us and involving a hypervalent intermediate.[13] On prolonged reaction, further eight-membered selenium-sulfur rings are formed.

$$2\,Se_5S_2 \longrightarrow Se_4S_2 + Se_6S_2 \qquad (d)$$

Se_6S_2 has been isolated together with residual Se_5S_2 by cooling the CS_2 solution to −78°C; it crystallizes in the form of orange-colored bar-shaped crystals and must be manually separated from the accompanying Se_5S_2 by sorting according to crystal shape and color under the microscope. The Raman spectrum of Se_6S_2[4b] agrees well with the spectrum calculated[10b] for a crown-shaped cyclic molecule 1,2-Se_6S_2 with the Se atoms in neighboring positions.

The Raman spectrum of Se_5S_2 (Fig. 1) cannot be interpreted in terms of a single conformation. This follows from a comparison of the spectra of numerous crystallizations. Rather, it can be shown by argument along the same lines as for the assignment of the Raman spectrum of Se_2S_5[13] and by comparison with calculated wave numbers,[10a] that the isomers **A** and **C** (Fig. 2) are formed alongside each other in the form of mixed crystals. The isomers **B** and/or **D**, which probably give rise to the very weak lines at 425 and 380 cm^{-1},[10a] can only be present in traces. The concentration ratio **[A]:[C]** is all the smaller the lower the temperature of crystallization, and at −78°C is roughly estimated (from the peak areas of the SeS stretching vibrations) to be 1:1. At higher temperatures (up to −20°C) more **A** than **C** is formed; above −10°C, **C** is partially transformed in the crystalline state into **A**, such that an estimated ratio of 4:1 is reached at 20°C.

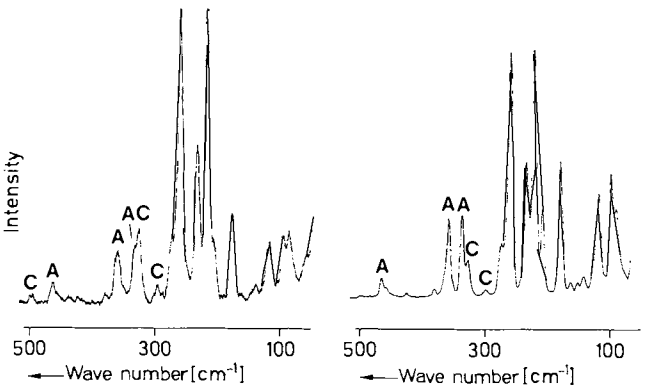

Fig. 1. Left: Raman spectrum of Se_5S_2, which was recrystallized at −50°C from CS_2. Right: Spectrum of the same sample after warming to −10°C; warming to higher temperatures (up to 45°C) did not lead to any change in the spectrum. Measuring temperature −100°C; for wave numbers see [4c].

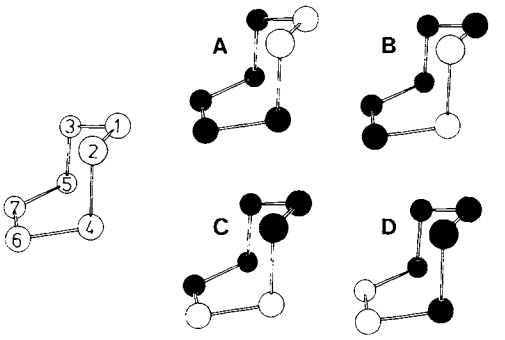

Fig. 2. Numbering of the atoms in Se_5S_2 (left) and molecular structure of four isomers of Se_5S_2.

An X-ray crystal structure analysis carried out on such a crystal at 20°C[15] confirmed this analysis: Accordingly, the atomic sites 1 and 2 (see Fig. 2) are occupied with sulfur to ca. 75% (±5%), the sites 3 and 4 to ca. 15%, the site 6 to ca. 10%, and the sites 5 and 7 to 0%. Due to this disorder, the bond lengths and angles cannot be determined, but there is no doubt about the molecular conformation: Comparison of the torsional angles (Table 1) shows that the conformation of Se_5S_2 corresponds very closely to that of the S_7 molecule[11], so that a chair conformation can be assumed also for Se_7 and other seven-membered chalcogen rings.

Table 1. Equivalent torsional angles of Se_5S_2 and γ-S_7. The atomic numbers given correspond to those in Figure 2. Standard deviations in parenthesis.

	Se_5S_2	γ-S_7
3-1-2-4	80.1(4)	78
2-1-3-5	78.0(4)	76
1-2-4-6	109.4(3)	109
1-3-5-7	109.0(3)	107
2-4-6-7	81.3(2)	82
3-5-7-6	85.3	84
4-6-7-5	1.5(2)	0.4

cyclo-Se_7 was obtained according to Equation (c) as a dark-red powder[16] consisting of microscopically small

needles, and was identified by HPLC.[17] The Raman spectrum[4d] agrees exactly with that of "orthorhombic selenium",[18a] which is formed on recrystallization of glassy selenium from CS_2 and for which the molecular size Se_7 has been derived from the unit cell, which contains 28 atoms.[18b] An X-ray structure analysis of Se_7 has not been reported yet. In contrast to S_7, solid Se_7 is also stable for days at 20°C; at 96°C the crystals turn shiny silver, due to transformation into gray selenium, and melt at 221°C.

Selenium-sulfur rings containing all Se atoms in neighboring positions are, as we have found, the main components of selenium-rich Se–S melts (HPLC analysis after quenching to 0°C and extraction with CS_2 at 20°). These include the compounds Se_5S, Se_5S_2 and Se_6S_2, which have now been obtained in pure form for the first time. Their investigation can contribute to an understanding of the complex composition of liquid selenium and the amorphous (glassy) selenium prepared therefrom on quenching.

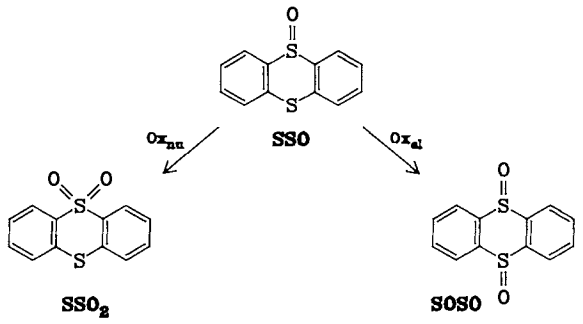
Thianthrene 5-Oxide as Mechanistic Probe in Oxygen Transfer Reactions: The Nucleophilic Character of Carbonyl Oxides**

By *Waldemar Adam,* Heinz Dürr, Wolfgang Haas,* and *Bhushan Lohray*

The mechanistic aspects of short-lived intermediates such as the carbonyl oxides (Criegee Zwitterions) are currently the subject of intensive study.[1] Particularly interesting is the question on which of the hypothetical resonance structures **1a–e** best reflects the chemical behavior of the



1a **1b** **1c** **1d** **1e** **2**

carbonyl oxides or whether even the cyclic valence structure of the dioxirane **2** applies. For example, in oxygen transfer to π-bonds (alkenes, arenes) and heteroatoms (amines, sulfides, sulfoxides, phosphanes) the negatively charged terminal oxygen in **1a**, **b** should be more nucleophilic than the radical type oxygen in **1c** or the positively charged or uncharged oxygen in **1d** or **1e**, respectively. Recently,[2] it could be demonstrated by intramolecular competition with thianthrene 5-oxide (**SSO**), that carbonyl oxides **1** transfer oxygen more nucleophilically than dioxiranes **2**. Thus, nucleophilic oxidants (Ox_{nu}) preferably oxidize at the sulfoxide sulfur to give mainly thianthrene 5,5-dioxide (**SSO_2**), while electrophilic oxidants (Ox_{el}) react predominantly at the sulfide sulfur to afford thianthrene 5,10-dioxide (**SOSO**).

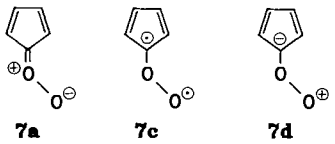
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



This mechanistic probe further revealed (Table 1) that the R substituent of the carbonyl oxide **1** influences the nucleophilic character of the terminal oxygen: alkyl-substituted derivatives such as **4** and **5** lead expectedly to the most nucleophilic transfer of oxygen, whereas phenyl-substitution (**8**) and benzoyl-substitution (**10**) give rise to less nucleophilic oxygen transfer. This tendency can hardly be explained in terms of steric effects. The question arises as to whether one of the resonance structures **1a–e** of the carbonyl oxides could be intentionally favored by appropriate substitution, that is can the electronic character of the terminal oxygen be changed at will? Should this be possible, then differentiation between carbonyl oxides **1** and dioxiranes **2** ought to be possible using thianthrene 5-oxide as mechanistic probe. Our experimental results are presented in Table 1.

The X_{SO} scale (X_{SO} = molar fraction of nucleophilic attack at the sulfoxide group of thianthrene 5-oxide) extends from $X_{SO} = 1.00$ for dibenzotropone oxide **3** to $X_{SO} = 0.61$ for 1,4-naphthoquinone oxide **12**. Consequently, it follows that appropriate substitution can increase the X_{SO} value of the carbonyl oxides (typically 0.80–0.96[2]) even up to the maximum value $X_{SO} = 1.00$ or can decrease X_{SO} to the value for dioxiranes (typically 0.57–0.67[2]). Control experiments rule out photooxidation of thianthrene 5-oxide by electron transfer, since the latter could explain the lower value $X_{SO} = 0.61$. On the basis of these facts we presume that the resonance structure **12f** of 1,4-naphthoquinone oxide is favored through aromatization. In contrast, the

complete nucleophilic oxygen transfer of dibenzotropone oxide **3**, in which aromatization stabilizes the positive charge, can be explained in terms of the resonance structure **3b**. If this aromatization is suppressed as in dibenzodihydrotropone oxide **9**, then less nucleophilic oxygen transfer is observed.

In the cases discussed so far, the electron density of the terminal oxygen in the carbonyl oxide correlates very well with the nucleophilic character of the oxygen transfer to thianthrene 5-oxide. Quite contrary to expectation, however, was the behavior of fluorene oxide **6** and cyclopentadienone oxide **7**, for which on the basis of the resonance structure **7d** we would have expected that oxygen transfer should have proceeded at least as electrophilically as in the case of **12**. The observed pronounced nucleophilic oxygen transfer is best explained in terms of **7a**. The same applies also for **6**.

Unfortunately, IR spectroscopic investigations on matrix-isolated cyclopentadienone oxide **7** led to controversial data for its electronic structure.[3] *Chapman* et al.[3a] prefer, on the basis of $\nu_{CO} \approx 1390\ cm^{-1}$, the resonance structure **7a**, whereas *Dunkin* et al.[3b,c] argue in favor of the resonance structures **7c**, **d**. However, the resonance structure **7d** is in no way compatible with the observed pronounced nucleophilic oxygen transfer. Less nucleophilic oxygen transfer was also expected for the diradical-type resonance structure **7c**, since the *tert*-butylperoxy radical transfers oxygen strongly electrophilically to the thianthrene 5-oxide ($X_{SO} = 0.03$).[4]

Until further spectroscopic investigations clarify this dispute on the electronic character of carbonyl oxide **7**, we favor **7a** as the most plausible resonance structure. The recent direct IR spectroscopic demonstration that cyclopentadienone corresponds to a "normal" α,β-unsaturated ketone,[5] suggests that its carbonyl oxide should transfer oxygen, predominantly nucleophilically.

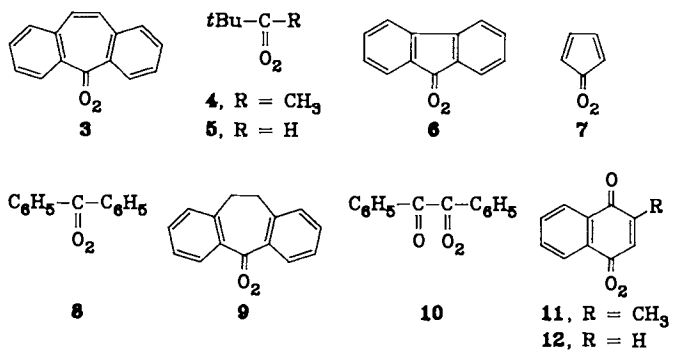


Table 1. Oxygen transfer to thianthrene 5-oxide with carbonyl oxides **3–12**, generated by photooxygenation of diazoalkenes [a].

Carbonyl oxide	Yield [mmol/L] [b] SSO_2 (n_{SO})	SOSO (n_S)	X_{SO} [c]

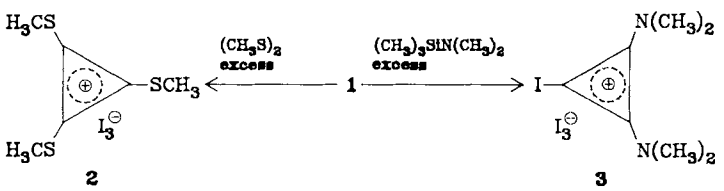
cyclo-C_3I_4—The First Saltlike Halocarbon**

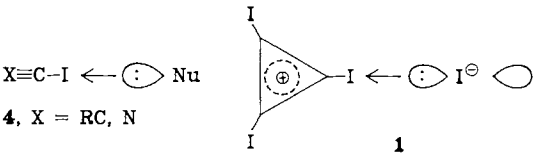


By *Robert Weiss,* Georg-E. Miess, Alfons Haller,* and *Werner Reinhardt*

The energy-rich perhalogenocyclopropenes *cyclo*-C_3X_4 (X = F, Cl, Br), which are widely used synthetic building blocks, are volatile, thermally relatively stable, covalent compounds.[1] During our investigations of iodocarbenium ions[2,3] we have now been able to synthesize the last missing member of this class of substances, namely *cyclo*-C_3I_4 **1**; compound **1** differs dramatically in its structure and reactivity from its lighter homologues.

Scheme 1.

1 can be conveniently obtained from *cyclo*-C_3Cl_4 in two different ways (Scheme 1); in these halogen-exchange reactions it separates from CH_2Cl_2 as an analytically pure, yellow-brown crystalline powder (m.p. 80°C, *violent decomposition;* vide infra). The insolubility of **1** is indicative of an ionic structure, proof for which is provided by the IR spectrum. The dearth of bands in the spectrum, which is dominated by an intense absorption at 1200 cm^{-1}, points to a high degree of symmetry of **1**. A comparison of the IR spectrum with the IR spectra of known *cyclo*-$C_3X_3^{\oplus}$ systems (X is a ligand which is bound via an element of main group 6 or 7) shows that this band arises from the characteristic E′-ring deformation vibration of the cyclopropenium ion (SCH_3 1241,[5] $SeCH_3$ 1220,[5] $TeCH_3$ 1169,[5] Cl 1313,[4] Br 1276[4]). The position of this band reflects the expected red shift in going from the lighter to the heavier halogen substituents, as is also observed in the series of organochalcogeno-substituted cyclopropenium systems. No band appears in the range 1600–2000 cm^{-1}, which rules out a covalent cyclopropene or isomeric allene structure.[6]



Derivatizations of **1** using previously established strategies led in high yields to the known cyclopropenium systems **2** and **3**,[7] thus lending further support to the presence of an intact three-membered ring in **1**. All our findings indicate that **1** is best formulated as triiodocyclopropenium iodide, $C_3I_3^{\oplus}I^{\ominus}$, *thus making this compound the first saltlike halocarbon.*

When **1** is synthesized in the presence of one equivalent of I_2, a blackish violet salt of the composition C_3I_6 is formed whose IR spectrum is identical in the region down to 600 cm^{-1} with that of **1**. The compound must therefore be *cyclo*-$C_3I_3^{\oplus}I_3^{\ominus}$. This is all the more remarkable, as all previously known *cyclo*-C_3X_6 systems (X = F, Cl, Br) have a *cyclopropane structure.*[1]

Iodine obviously claims a special position as ligand within the series of homologous tetrahalogeno-*cyclo*-C_3 compounds.

The following structural and electronic aspects are of importance for an understanding of this phenomenon: According to recent calculations[8] the electronegativity (2.46) of the iodine bound via a 5 p orbital corresponds to that of sp^3-hybridized carbon. This implies considerable +I donor properties of the iodine ligand for **1**, since it is bound to an sp-hybridized C-atom.[9] Since the ring C-atoms in **1** also carry positive partial charges, the electropositivity of the iodine ligands in *cyclo*-$C_3I_3^{\oplus}$ should be more pronounced than in electronically comparable neutral systems such as I–C≡C–I and I–C≡N.[10] It is known that these two systems tend to form linear n→σ* complexes of the type **4** with 3c/4e configuration.[11] For *cyclo*-$C_3I_3^{\oplus}$, the iodide counterion is, in principle, an ideal partner for the realization of such a hypervalent contact.[2,3] Since cation and anion are, in principle, trifunctional, there is the additional possibility that the structure of **1** in the solid state is characterized by three-dimensional n→σ* association similarly to that of $CI_5^{\oplus}$.[12] This possibility of stabilization provides a further argument in favor of an ionic structure for **1** and is consistent with the observed insolubility of this compound.

The iodine-iodine contacts should have a tendency to promote facile α-elimination of I_2 from **1**; this does in fact take place, but *explosively,* upon rapidly heating the salt. Besides I_2, exclusively a homogeneous, satiny black powder of composition $C_{13}I$ is formed. This confirms that **1**—rather like NI_3—tends to decompose to the elements. It still remains to be clarified whether **1** can be converted at low temperatures into other C_3-derivatives—either thermally, photochemically, or in the presence of iodine acceptors.

Danger! On several occasions **1** *exploded violently,* not only when handled in the dry state at room temperature, but also upon dissolution in polar solvents (e.g. CH_3OH, CH_3CN). *As a cautionary measure it is therefore strictly advised that not more than 1 mmol of the salt be prepared in a*

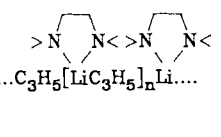
Crystal Structure of the η^3-Allyllithium Compound [1,3-Diphenylallyllithium · Diethyl Ether]$_n$**

By *Gernot Boche,* Heinz Etzrodt, Michael Marsch, Werner Massa, Gerhard Baum, Hans Dietrich,* and *Waruno Mahdi*



Allyl-transition metal complexes count among the most studied species in organometallic chemistry.[1] In the case of allyllithium, however, no evidence has hitherto been put forward of an η^3-structure in the solid state, as found in the transition metal complexes. According to calculations, monomeric allyllithium has such an η^3-structure in which the H atoms, as in some transition metal complexes,[11] are bent out from the plane of the C atoms (cf. **1**).[2-4]

According to a crystal structure determination of allyllithium · tetramethylenediamine (TMEDA), polymer chains are present in which the Li atoms coordinated to TMEDA each couple two terminal allylic-C atoms (Cf. **2**).[5] In tetrahydrofuran, allyllithium is present as a monomeric[6b] η^3-compound.[6]

In 1,3-diphenylallyllithium · diethyl ether **3** we found for the first time η^3-allyllithium moieties also in the solid state. They aggregate to form polymeric chains[7] (Fig. 1). The lithium atoms lie almost symmetrically above and below the allyl group. The Li-C2 distance being shorter than the Li-C1 and Li-C3 distances, corresponds to the situation found in most allyl-transition metal complexes.[1d,g] The angle C1-C2-C3 (131(1)°) is quite large. This is consistent with the comparably small $^1J(^{13}CH^2)$ coupling constants of allyl-alkali metal compounds in solution and with quantum mechanical calculations.[1h,4] The expected bending of the substituents in monomeric allyllithium compounds (see **1**) does not occur in **3**, apparently because of stacking. The 1,3-diphenylallyl moieties are approximately planar (maximum deviation from the best plane: 8 pm) and are inclined at 120° to each other in the direction of the chain. Compound **3** crystallizes from a diethyl ether/hexane/benzene mixture.[8] In diethyl ether, allyllithium has a degree of aggregation of at least 10.[9] Since this should be greater in diethyl ether/hexane/benzene and should similarly hold for 1,3-diphenylallyllithium, the crystal structure of **3** probably largely corresponds to its structure in solution.

1[2]

2[5]

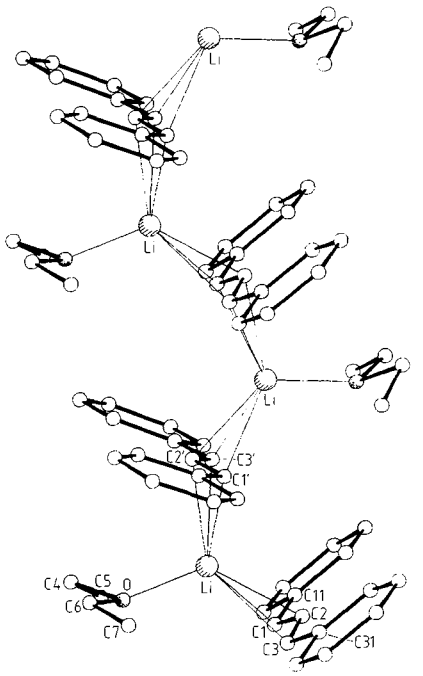


Fig. 1. Section of the polymeric chain structure of **3**. The atoms are represented by spheres with arbitrary radii. Selected bond lengths [pm] and bond angles [°]: Li-C1 248(3), Li-C2 230(3), Li-C3 250(3), Li-O 192(3), Li-C1' 240(3), Li-C2' 232(3), Li-C3' 252(3), C1-C11 147(1), C1-C2 139(1), C2-C3 138(2), C3-C31 145(1); C11-C1-C2 127(1), C1-C2-C3 131(1), C2-C3-C31 127(1).

Structures of the "η^3-allyl type" have been known since *Stucky* et al. elucidated the crystal structure of benzyllithium · triethylenediamine.[10a] Interestingly, the frequently occurring benzyllithium type structure, likewise possible in **3**,[2,10b] is not found. The energy difference between such structures should, however, be small, as has been shown by

Polymeric (η^5,μ-2,3-Dihydro-1,3-diborolyl)nickel—the First Polydecker Sandwich Compound**

By *Thomas Kuhlmann, Siegmar Roth, Jacques Rozière,* and *Walter Siebert**

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Polydecker sandwich compounds are one-dimensional transition-metal complex systems which should exhibit electrical conductivity. INDO-MO calculations[1] on eleven model compounds have yielded different band structures, which are a function of the metals (Mn-Zn) and the bridge ligands coupling them: Polymeric $[(Mn(C_5H_5)]_n$ is an insulator, $[Zn(B_5H_5)]_n$ an electrical conductor. The syntheses of oligodecker sandwich compounds with carbacycles have hitherto only led to triple-decker compounds,[2] whereas with the electron-deficient 2,3-dihydro-1,3-diborolyl ligand it has been possible to synthesize tetra-, penta-, and hexadecker-complexes of type **1** (n = 1–3).[3] These results and the unusual conversion of bis(2,3-dihydro-1,3-diborole)nickel sandwich complexes into the oligodeckers[4] **2** (n = 1–8) at room temperature demonstrate that the 13e fragment $[Ni(R_5C_3B_2)]$ is an electronically favorable stacking unit. We report here on the synthesis and properties of the first polydecker sandwich compound **3**.

Reaction of 1,3,4,5-tetramethyl-2,3-dihydro-1,3-diborole[5] with an excess of bis(allyl)nickel leads at low temperature to the dinuclear complex **4**.[6] In solution it reacts slowly to give the tetradecker $[\{(C_3H_5)Ni(Me_4HC_3B_2)\}_2Ni]$, whereupon nickel, hexadiene, and small amounts of polymeric products separate out. When thin layers of **4** are heated in vacuo, the condensation product $[(\eta^3\text{-}C_3H_5)_2Ni]$ and hexadiene are removed from the reaction mixture. A black film forms on the wall of the flask, which upon cooling splinters into shiny metallic platelets. The almost quantitative formation of polymeric **3** presumably proceeds via the complex **5** initially formed from **4**.

3 is remarkably stable towards heat and is insoluble in organic solvents. Upon measurement of the capacity[7] in propylene carbonate/$LiClO_4$ a partial dissolution of the polydecker electrode took place. Analysis of the very oxygen-sensitive polymer[8] yielded the empirical formula $C_7H_{13}B_2Ni$ calculated for the stacking unit. Compound **3** ignites in a stream of O_2, while suspensions in mesitylene take up two molecules of oxygen per stacking unit.[9]

The allyl group (m/z 41) is the only fragment that can be observed in low intensity in the mass spectrum up to 620 K. Solid-state NMR investigations show broad ^{11}B- and ^{13}C-signals in the diamagnetic range;[10] a recording of ^1H-decoupled spectra is not possible on account of discharging in the sample. In the X-band ESR spectrum the polymer shows a very broad signal (864 G, $g=2.25$) at 280 K; below 50 K a new signal appears at $g=2.10$ whose intensity increases on further cooling, while the original signal disappears. At 2 K a relatively sharp signal (165 G) is present which is assigned to Ni^{2+}.[11]

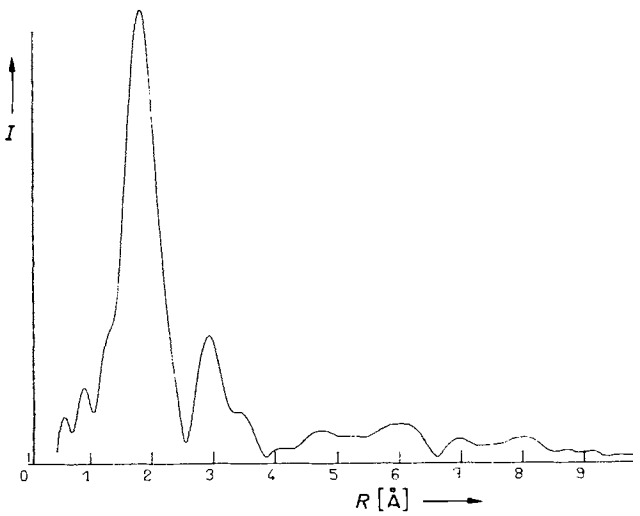

Fig. 1. Fourier transformed EXAFS spectrum (77 K) of the nickel polymer **3**; phase shift not corrected.

EXAFS investigations on **3** (Fig. 1) confirm the polydecker structure with the expected nickel : ligand ratio of 1 : 1. The EXAFS data yield two nickel-ring atom distances (Ni-C or Ni-B) of 2.17(2) and 2.56(2) Å in the ratio 1 : 1 and one Ni-Ni distance of 3.35(2) Å. Each Ni atom has, however, only *one* nickel atom as a neighbor at a distance of 3.35(2) Å. This and the short Ni-C(B) distance of 2.17 Å are consistent with a $Ni(C_3B_2)Ni$ group, which has also been found in a pentadecker[3b,12]. A coupling of this seven-atom cluster with other C_3B_2 rings over the longer distances Ni-C(B) (2.56 Å) leads to polymeric **3**. For such an arrangement, there must be a longer Ni-Ni distance, which can scarcely be observed in the EXAFS measurement; we have evidence of a further Ni-Ni distance in the 3.8-3.9 Å range.

The two-contact powder conductivity[13] of **3** at 2500 bar is 0.25 S cm^{-1}. Four-contact measurements give 10^{-2} S cm^{-1}. The temperature dependence of the conductivity was measured in the range from 380 to 30 K. The conductivity decreases upon cooling over the entire range. At 300 K a jump by a factor of about 2 occurs, thus indicating a structural phase transition. Near room temperature the temperature coefficient of the conductivity corresponds to an activation energy of 0.08 eV. The conductivity data are better described in terms of the equation

$$\sigma=\sigma_0\exp[-(T/T_0)^{1/4}]$$

which is characteristic for variable range hopping in strongly perturbed semiconductors and in conducting polymers.[14]

A numerical fit furnishes the parameters $\sigma_0=1.2\times10^{-3}$ S cm^{-1} and $T_0=5\times10^5$ K. These values lie in the range that is also found for strongly "doped" polyacetylenes. The resistance of **3** increases rapidly in the presence of oxygen or iodine.

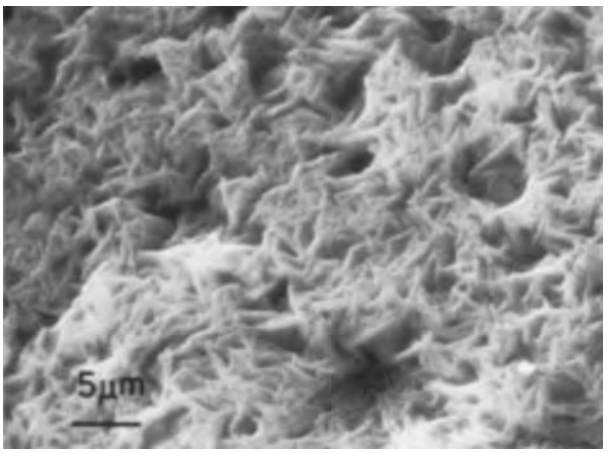

Fig. 2. Electron photomicrograph (magnification 2000×) of **3**.

Figure 2 shows an electronmicrograph of the polymer, present in isotropic distribution. A definite statement cannot be made about the average chain length of the stacking molecule. As MS investigations up to 620 K have shown, allyl groups are eliminated in low intensity from the polymer.

[6] Procedure for **4**: 0.55 g (4.6 mmol) of 1,3,4,5-tetramethyl-2,3-dihydro-1,3-diborole [5] was added to a solution of 2 g (14.3 mmol) of bis(allyl)nickel in 50 mL of petroleum ether (40/60) at −180 °C under nitrogen and the resulting mixture was stirred for 2 h at −15 °C. Petroleum ether and excess $[Ni(C_3H_5)_2]$ were then removed from the mixture at −15 °C and the product chromatographed on a low-temperature column (−20 °C, Al_2O_3, deactivated with 5% H_2O). **4** was isolated as a deep orange-yellow, thermolabile and oxygen-sensitive oil (1.16 g, 70%) [4b]; ^1H NMR (300 MHz; [D$_8$]toluene, −10 °C): $\delta = 4.84$ (sept, 1H), 4.32 (m, 2H), 3.52 (d, 2H, $J(HH) = 8.1$ Hz), 2.86 (s, 1H), 2.82 (d, 2H, $J(HH) = 14.7$ Hz), 2.66 (d, 2H, $J(HH) = 6.6$ Hz), 1.76 (m, 2H), 1.47 (s, 6H), 1.43 (d, 2H, $J(HH) = 13.2$ Hz), 1.32 (m, 2H), 0.45 (s, 6H); ^{11}B NMR (C_6D_6): $\delta = 21.6$; EI-MS: m/z 358 (M^+, 71%). Procedure for **3**: A horizontally fixed cylindrical flask containing a solution of **4** (0.5 g, 1.45 mmol) in petroleum ether (5 mL) was rotated during evacuation so that a uniform film was formed on the wall of the flask (approx. 40 cm^2 surface area). The cylinder was slowly heated in an oil bath to 160 °C, whereupon $[Ni(C_3H_5)_2]$ and hexadiene were released and trapped in a cool trap. Small amounts of the reddish orange tetradecker $[\{(\eta^3\text{-}C_3H_5)Ni(Me_4HC_3B_2)\}_2Ni]$ also distilled over. Upon cooling, the black film splintered into irregular platelets (0.1 to 1.0 cm in length), which were washed three times with petroleum ether and dried in a vacuum. Yield 330 mg (89%) of **3**, which is stable up to 500 °C.

The Structure of Chlorosilyl-*N,N*-dimethylamine in the Gaseous and Solid Phases

By *David G. Anderson, Alexander J. Blake, Stephen Cradock,* E. A. V. Ebsworth, David W. H. Rankin,* and *Alan J. Welch*

Silylamines exhibit some striking structural features that are related to the ability of four-covalent silicon to accept additional electrons, using its vacant 3d orbitals. Thus, trisilylamine[1] and disilylamines[2] have planar coordination at nitrogen, while *N,N*-dimethyl(silyl)amine (which appears to have a non-planar nitrogen in the gas phase[3]) forms a cyclic pentamer in the crystal[4] with five-coordinate silicon linked by four-coordinate nitrogen, all the Si-N bonds being equivalent.

As part of systematic a study of silylamines and their structures we have prepared chlorosilyl-*N,N*-dimethylamine **1**. This compound has been briefly reported by *Emsley*.[5] We have synthesized it by reaction of dichlorosilane with two molar equivalents of dimethylamine in the gas phase, and characterized it by its IR and Raman spectra in the gas, liquid, and solid phase, and by its NMR spectra in solution.

$ClH_2Si-N(CH_3)_2$ **1**

The vibrational spectra of **1** are strikingly different in the gas and the annealed solid phases, particularly in the region associated with Si-N stretching modes (600–900 cm^{-1}). A prominent band at 688 cm^{-1} (IR, gas)/694 cm^{-1} (Raman, liquid) is absent in the annealed solid, being apparently replaced by two bands in each spectrum, with frequencies of 796 and 619 cm^{-1} in the IR spectrum, and of 802 and 610 cm^{-1} in the Raman spectrum. These observations suggested that the species present in the annealed solid was not monomeric, as in the gas and the liquid; they would be consistent with a centrosymmetric dimer unit with a Si_2N_2 ring, but do not suffice as proof that such a ring is present. Accordingly, we used electron diffraction in the gas phase and X-ray diffraction in the annealed solid phase in order to determine the molecular structures unequivocally in each case. The results confirmed our initial conjectures from the vibrational spectra, revealing that **1** forms a novel centrosymmetric dimer in the crystal.

According to the electron diffraction pattern gaseous **1** is monomeric, with the expected four-coordinate silicon (Fig. 1a). The Si-N and Si-Cl bond lengths are similar to those found in related compounds, 168.9(4) pm and

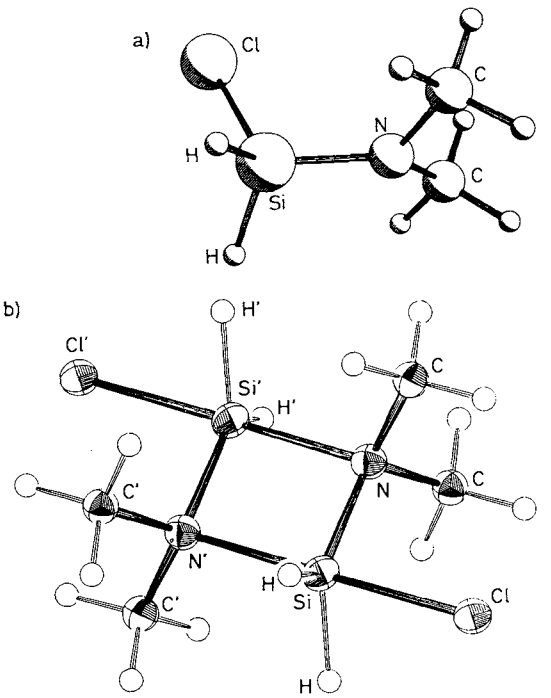

Fig. 1. a) Structure of gaseous monomeric chlorosilyl-*N,N*-dimethylamine **1** at 298 K. Bond lengths [pm] and angles [°]: Si-Cl 207.0(2), Si-N 168.9(4), Si-H 147(2), N-C 146.4(4), C-H 110.2(5); Cl-Si-N 113.0(6), Si-N-C 121(1), C-N-C 115(1). b) Structure of **1** in the crystal at 116 K. The Si_2N_2Cl group is almost planar; the dimer contains a center of inversion. Bond lengths [pm] and angles [°]: Si-Cl 223.1(6), Si-N 181.4(13), Si-H 149(1), N-C 149.8(18), Si'-N 205.4(13); Cl-Si-N 96.1(5), Si-N-C 112.8(9), C-N-C 108.8(14), N-Si-N' 83.0(5), Si-N-Si' 97.0(6).

207.0(2) pm respectively. The Si–N bond is slightly shorter than those in other *N,N*-dimethyl(silyl)amines (171–172 pm), which are themselves shorter than those in other silylamines,[6] whereas the Si–Cl bond is somewhat longer than that found in SiH_3Cl (205 pm). The nitrogen appears very slightly non-planar, though this may well be a shrinkage effect, and the ClSiN and CNC planes are almost perpendicular to each other.

The crystal structure[7] consists of well-separated dimers (Fig. 1b), packed in sheets parallel to *ac*, about 500 pm apart, with dimers in one plane above interstices in the plane below. The dimer has crystallographically-required C_{2h} symmetry. The central Si_2N_2 unit is not equilateral; two opposite Si–N distances are 181.4(13) pm, whilst the other two are much longer, 205.4(13) pm. The dimers can therefore be described in terms of two strongly-interacting monomers. The strength of the interaction is shown by the extent to which the normal tetrahedral coordination at Si is distorted in the dimer; the N–Si–Cl angle 96.1(5)° is much smaller than in the gas-phase monomer (113.0(6)°), allowing the additional bond to N′ to develop. The N′···Si–Cl angle is 179.0(4)°, very close to linear, so that Si is adopting trigonal bipyramidal coordination, though the "axis" ClSiN is not strictly perpendicular to the "equatorial plane" containing N′ and the two H atoms attached to Si. The fact that the Cl atom adopts the axial position rather than an equatorial position is in accord with its position in the "apicophilicity series", which has been proposed[12] to account for some observed structures of pentacoordinate phosphorus compounds.

The effect of the additional Si···N′ interaction on the Si–Cl and Si–N bond lengths is striking; these are, respectively, 16 and 12 pm longer in the crystal than in the gas-phase monomer, even though the Si–Cl bond is *trans* to the additional Si···N′ bond and the Si–N bond is almost orthogonal to it. The lengthened Si–Cl bond may be compared with other Si–Cl bonds *trans* to nitrogen at five- or six-coordinated silicon, with lengths such as 227.4 pm and 239.3 pm.[13] The Si–N···Si′ angle (97.0(6)°) probably represents a compromise between 90° (as would be needed for a square Si_2N_2 unit, and as is appropriate to trigonal bipyramidal coordination at Si) and the tetrahedral angle of 109.47°. We may regard the dimer as a "frozen" intermediate in an S_N2 reaction involving attack at Si by N′; the leaving group is Cl, and the putative "product" would be an ionic form of the dimer, with all Si–N bonds equal in length.

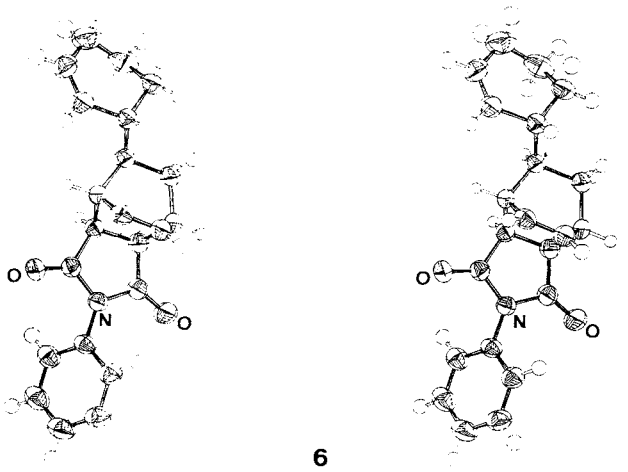
Mechanism of the Thermal 1,3-Cyclohexadiene Dimerization: A Non-Concerted Diels-Alder Reaction Leading to the *exo*-[4 + 2] Adduct and a Novel [6 + 4]-Ene Reaction**

By *Frank-Gerrit Klärner,* Barbara M. J. Dogan, Otto Ermer, William von E. Doering,* and *Martin P. Cohen*

In the thermal dimerization of 1,3-cyclohexadiene **1** a novel stereospecific [6 + 4]-ene reaction was observed which competed with [2 + 2]- and the already known [4 + 2]-cycloadditions.[1] A study of the pressure dependence (up to 7 kbar) gave relatively large differences in the activation volumes, which are explainable, inter alia, in terms of a non-concerted Diels-Alder dimerization to the *exo*-adduct.



Scheme 1.

[**] This work was sponsored by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie (FRG) and by the National Science Foundation (USA).

At temperatures above 150°C, **1** dimerizes to the [4+2] Diels-Alder adducts *endo*-**2** and *exo*-**2**.[1] Below 150°C, not only *endo*-**2** and *exo*-**2** but also the [2+2]-cycloadducts *syn*-**3** and *anti*-**3** and a further unknown dimer are formed (at 110°C in the ratio 74.3 : 11.4 : 4.1 : 2.5 : 7.7). The product mixture can be separated gas chromatographically and *endo*-**2** and *exo*-**2** as well as *syn*-**3** and *anti*-**3** can be individually identified by comparison with authentic samples[2] prepared via an alternative route. The previously unknown dimer is—according to its spectra and its degradation to 3-vinylcyclohexene (via Diels-Alder addition with methyl acetylenedicarboxylate and subsequent Alder-Rickert cleavage)—an isomer of 5-(2-cyclohexenyl)-1,3-cyclohexadiene **4**.[3] An elucidation of the stereochemistry at C-5 and C-1′ is provided by the crystal structure analysis of the Diels-Alder adduct **6** (Fig. 1), which was prepared from the liquid dimer **4** by reaction with *N*-phenylmaleimide.[4] According to the X-ray diffraction pattern, **4** has the *threo* configuration and is formally the result of a [6+4]-ene reaction vinylogous to the conventional [4+2]-ene reaction.

6

Fig. 1. Stereoview of the structure of **6** in the crystal (with vibration ellipsoids (50%) for the heavy atoms); isotropic temperature factors of the H atoms reduced by a common factor.

We have investigated the pressure- and temperature-dependence of the 1,3-cyclohexadiene dimerization at 70.5°C in the range from 1 to 7000 bar and at 70–150°C under normal pressure. A strategy analogous to that described by *Stewart*[5] for the dimerization of chloroprene was used in an attempt to obtain an insight into complex processes with several reaction paths. Our results are listed in Table 1. All the dimers are stable at 70°C up to 3000 bar as well as at 110°C and normal pressure. This stability is also reflected in the product ratios being independent of the reaction times. At 70°C and 7000 bar *threo*-**4** reacts slowly to give gas-chromatographically undetectable, high molecular weight compounds (conversion: 33% after 74 h). Under normal pressure *threo*-**4** first starts to disproportionate at higher temperatures in benzene and cyclohexene (5% after 22 h at 161°C)—presumably as a result of a retro-[4+2]-ene reaction. At 118.8 and 151.5°C the known[2] rearrangements of *syn*- and *anti*-**3** into *exo*- and *endo*-**2**, respectively, slowly take place. In each case product ratios are extrapolated to zero reaction time.

The five products of the cyclohexadiene dimerization can be divided into two stereochemical classes (Scheme 1): The *endo*-**2**, *anti*-**3**, and *threo*-**4** dimers are formally derived from the diradical *rac*-**5**, whereas *exo*-**2**, and *syn*-**3** are derived from *meso*-**5** (formation of *erythro*-**4** is not observed).

The [2+2]-cycloadducts *anti*-**3** and *syn*-**3** are doubtlessly formed in two steps via the diradicals *rac*-**5** and *meso*-**5**. Besides the two-step routes indicated in Scheme 1, also concerted [4+2]-cycloadditions and [6+4]-ene processes must be considered for the formation of the remaining dimers. Differentiation between the various mechanisms is possible by comparison of the activation volumes of formation of those dimers which can be formed from one and the same diradical. The activation volumes of the reaction leading to *exo*-**2** and *syn*-**3** are, within the limits of error, equal. This finding suggests a similar mechanism of formation for both products. Assuming that formation of *syn*-**3** involves a two-step process, *exo*-**2** is accordingly the product of a non-concerted Diels-Alder reaction.[6] The activation volumes of the reactions leading to *endo*-**2** and *threo*-**4** are, respectively, 10 and 14 cm^3/mol more negative than the activation volume of the reaction leading to *anti*-**3**.

Table 1. Pressure- and temperature-dependence of the dimerization of **1** and [5,5,6,6-D_4]-**1**.

T [°C]	p [bar]		Rate constants $k_{1,i} \times 10^9$ [L mol^{-1} s^{-1}] [a]			
		i: *endo*-**2**	*exo*-**2**	*syn*-**3**	*anti*-**3**	*threo*-**4**
70.5 [b]	1	1.19	0.141	0.0472	0.0261	0.151
	3000	15.0	1.02	0.327	0.134	2.71
	7000	129.	5.35	1.34	0.502	31.5
118.8	1	71.8 [c]	11.2	4.06	2.32	7.25
		75.1 [d]	10.9	3.92	2.30	3.54
151.5 [b]	1	658.	120.	40.1	31.9	62.0
70.5	ΔV_0^* [cm^3/mol] [e]	−28	−22	−22	−18	−32
	$\Delta\Delta V_0^*$ [cm^3/mol]	−10	−4	−4	(0)	−14
118.8	k_H/k_D [d]	0.95	1.03	1.04	1.01	2.42
	E_A [kcal/mol] [f]	22.6	24.2	24.3	25.3	21.5
	lg$A$	5.46	5.51	5.10	5.52	3.87

[a] The specific rate constants were calculated from the time dependence (at least four times) of the gas-chromatographically determined product concentrations (70-cm glass capillary column (silicone oil OV101), 120°C, dodecane as internal standard) by the least squares method. Standard deviations < 2.5%. [b] $[1]_0 = 1.73$ mol/L. [c] $[1]_0 = 1.33$ mol/L. [d] $[[5,5,6,6\text{-}D_4]\text{-}1]_0 = 1.33$ mol/L; the kinetic isotope effects k_H/k_D are corrected for the deuterium distribution determined from the MS and ^{2}H-NMR spectra [3] of 5,5,6,6-D_4-**1**: $k_H = k_{H(exp)}/4$; $k_D = k_{D(exp)} - 0.513\,k_H)/3.487$. [e] ΔV_0^* and $\Delta\Delta V_0^*$ were calculated from the pressure dependence of the rate constants ($k_{p,i} \equiv k_{1,i}$) or the product ratios (referred to *anti*-3: $k_{p,i} \equiv p_i/p_{anti\text{-}3}$) directly obtainable from the GC analyses, using $k_{p,i} = a_i + b_{i,p} + c_i p^2$; $\Delta V_{0,i}^*$ and $\Delta\Delta V_{0,i}^* = -b_i RT$ at 70.5°C; error of $\Delta\Delta V_{0,i}^* < 1$ cm^3/mol. [f] The Arrhenius parameters were calculated from the temperature dependence of $k_{1,i}$ at 1 bar by the least squares method (standard deviations of $E_A < 0.5$ kcal/mol).

This indicates that their transition states are significantly more compact. Consequently, these three adducts have no common intermediate, so that *endo*-**2** (always the main product of the Diels-Alder reaction) and *threo*-**4** are most likely formed by concerted mechanisms.

To our knowledge there is no precedent for the [6+4]-ene reaction.[7] To confirm the proposed mechanism we have therefore measured the kinetic isotope effect of the dimerization of 5,5,6,6-tetradeuterio-1,3-cyclohexadiene, which was prepared according to a procedure given in the literature for the synthesis of **1**[8] from tetradeuterioethylene and 1,2,3,4-tetrachloro-5,5-dimethoxy-1,3-cyclopentadiene. The primary isotope effect k_H/k_D, with a value of 2.42 (Table 1), is of the same order of magnitude as in the normal [4+2]-ene reaction.[9]

The conclusions drawn from the pressure-dependence for the cyclohexadiene dimerizations are consistent with the activation energies obtained from the temperature-dependence. For the formation of *exo*-**2** and *syn*-**3** these are practically of equal magnitude, whereas those for the formation of *endo*-**2** and *threo*-**4** are smaller than for the formation of *anti*-**3** (Table 1). The smaller activation barriers can be regarded as an indicator of a certain degree of resonance stabilization ($\leq$2.7 and 3.8 kcal/mol, respectively) of the transition state of the concerted processes. The small differences in the activation energies clearly show, however, that these transition states are only slightly more favorable than that of the diradical process. The steric and secondary electronic effects occurring in a concerted approach to *exo*- and *endo*-**2**, indicated in Scheme 1 only for the diradical intermediates, could give rise to the change in mechanism from the *endo*- to the *exo*-Diels-Alder reaction.

The structures of the transition states of the [6+4]-ene reactions leading to the *threo*- and *erythro*-products are comparable with those of the chair- and boat-Cope rearrangements, respectively, of 1,5-hexadiene.[10] Similar factors as in the boat Cope rearrangement could therefore be responsible for *erythro*-**4** not being formed.

Periodic Potential Surfaces in Crystal Structures

By *Reinhard Nesper* and *Hans-Georg von Schnering**

Wilhelm Klemm In Memorium

We first started calculating periodic equipotential surfaces (PEPS) at the beginning of 1984;[1] in the meantime we have developed a computer program which now allows, for the first time, a combined representation of crystal structures or structural features and calculated PEPS.[2] Over the past two years, *Andersson* et al. have reported on several occasions on the relationships between periodic minimal surfaces (PMS) and crystal structures.[3–5] Such minimal surfaces, which are most simply defined as surfaces of zero mean curvature, are figures of exceptional harmony, familiar to all who have played with soap bubbles. They can be disjunct or periodically continuous, that is exhibit translational symmetry; they can be free or not free of intersections. The periodic minimal surfaces so far reported in the literature,[6] however, do not allow simple and complete assignment to the symmetry of the 230 space groups characterizing 3D translational space, and, moreover they are difficult to derive via the relationships described by *Weierstrass*[7] or other numerical approximations.[8] Furthermore, it can be shown that no PMSs exist for certain space groups.[2] Despite all the fascination in the idea of spatial division by PMSs and in their curvilinear properties, an immediate reference to physical properties has so far been lacking. In our opinion PEPS should close this gap.

We have investigated PEPS of Coulomb fields of simple point charges in the various space group symmetries and thereby established that the zero potential surfaces (POPS), in particular, are topologically very similar to the respective PMS of the same symmetry (Fig. 1a, top left: POPS for "CsCl" (symmetry $Im\bar{3}m$; corresponds to the P-surface of *Schwarz*)). When the two partial structures are commutative, the POPS divide the space into two equal halves and are invariant to interchange of the partial structures. They are then also topologically closely related with interpenetrating sphere packings of the corresponding symmetry.[9, 10] But contrary to what was previously presumed,[11] not the PEPS are in general similar to the well-known PMS but the POPS, since only they are subject to any comparable topological invariants. It also does not

[*] Prof. Dr. H. G. von Schnering, Dr. R. Nesper

Heisenbergstrasse 1, D-7000 Stuttgart 80 (FRG)

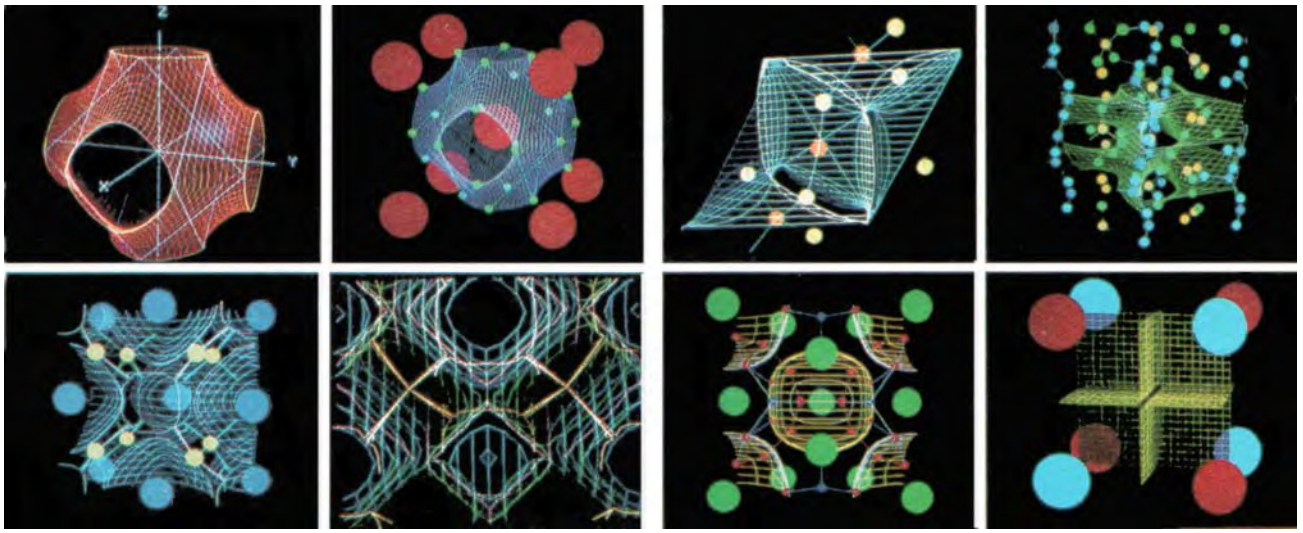

Fig. 1. Top left: POPS of the $Im\bar{3}m$ symmetry, generated in the space group $Pm\bar{3}m$ with (+) in 1a and (−) in 1b. Top right: The same POPS with the experimentally determined distribution of Ag^+ (green) and I^- (red) in the superionic conductor AgI.—Bottom left: POPS for "CaF_2" ($Fm\bar{3}m$), and the atomic distribution of Pb^{2+} (blue) and F^- (yellow); the experimentally determined paths of the F^- ions (green and white lines) follow the topology of the POPS.—Bottom right: Section with POPS (blue), a neighboring PEPS of negative potential (green) and the F^- paths (yellow and white).

Fig. 2. Top left: Q* surface with the structure of β-quartz (Si = orange).—Top right: Q* surfaces with the structure of $CaSO_4(H_2O)_{0.8}$ with Ca (dark yellow), S (light yellow) and O (green and blue). Bottom left: POPS of the A15 structure ($Pm\bar{3}m$) with the clathrate structure of $Xe_8(H_2O)_{46}$: Xe (green), O (red and blue).—Bottom right: POPS of the $Pm\bar{3}m$ symmetry, typical for the NaCl structure.

hold in the case of POPS that the mean curvature necessarily disappears ($H=0$); it follows, however, from the interchange ability of (+) and (−) for commutative partial structures that the *overall* mean curvature disappears ($\overline{H}=0$).

The astonishing consequence with which nature quite obviously exploits the topology of POPS and PMS will be demonstrated with a few examples:

1) In the superionic conductor AgI the experimentally determined preferred positions and paths of Ag^+[12] lie exactly on the corresponding POPS with $Im\bar{3}m$ symmetry (Fig. 1, top left). The positions with low field gradients perpendicular to the POPS are preferred. In contrast, the free spaces in the center of the cubes surfaces are not used (Fig. 1, top right). Migration of the Ag^+ ions through this space would have to be along higher field gradients.

2) The experimentally determined, curved paths of the F^- ions in the ionic conductor PbF_2[13] follow the course of the corresponding POPS ($Fm\bar{3}m$ symmetry; Fig. 1, bottom left). The PEPS of negative potential adjacent to the POPS (Fig. 1, bottom right) clearly shows the anharmonicity of the potential in the direction of the fluorine paths. The free space in the region of the unoccupied position $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}$ is apparently not used.[13] A movement in this direction would have to follow higher field gradients, i.e. less parallel to PEPS.

3) The POPS Q* was calculated for $P6_222$ symmetry, without using the structure of quartz. It divides the space into two topologically equal four-branched tunnel systems, almost tailor made for a tetravalent framework. This POPS has helical fragments along $\frac{1}{3}\,\frac{2}{3}z$ and $\frac{2}{3}\,\frac{1}{3}z$, but also intersections of 120° along $00z$ (Fig. 2, top left). The structures of α-quartz (low-quartz) ($P3_121$) and β-quartz (high quartz) ($P6_422$) follow exactly this topology, whereby one tunnel system is occupied and the other remains vacant. The hydrate $CaSO_4(H_2O)_{0.8}$ crystallizes in the subgroup $P3_121$ of Q*.[14] Here, all the Ca atoms are located in the center of the one labyrinth, the S atoms in the center of the other, while the O atoms of the sulfate groups lie very close to the POPS Q* (Fig. 2, top right). The symmetry of the POPS Q* is distinguished by two 3_1 screw axes, and by one 6_2 screw axis which produces the intersections. No significant changes occur for moderate distortional variants of Q*. If, however, the point charges generating the Coulomb field[1] are shifted from $x=\frac{1}{2}$ to $x=\frac{1}{3}$, then the POPS continually changes to an intersection-free surface of the cubic-P type (CsCl). Topological relationships between space groups and various crystal systems are clearly in evidence in this instance. Furthermore, such correlations could be of importance for phase transformations.

4) Figure 2 (bottom left) shows the POPS for the A15-type structure and the reported structures of Cr_3Si (large circles) as well as of clathrate-I = $Xe_8(H_2O)_{46}$ (large and small circles). These POPS, like those of PbF_2, do not form any interconnecting surface but bubbles of $m\bar{3}$ symmetry about the Si positions. In the clathrate the Xe atoms occupy the positions of the Cr and Si atoms in the A15 structure, while the O atoms of the H_2O molecules are practically all on the POPS. Only one O position is lying in space, and this is exclusively the partly occupied site in defect chlathrate structures (e.g. $K_8Ge_{44}\square_2$[15]).

5) The NaCl structure contains an equally simple and unusual POPS: Three sets of orthogonal planes form closed cubes around the charge centers! This is the only case known so far in which the two generating charged centers are completely shielded. In this instance the POPS obviously shows the ideal conditions for an ionic compound AB (Fig. 2, bottom right).

Periodic potential surfaces are especially important for the elucidation of problems regarding diffusion, electron density, and phase transformations as well as topological problems in general.

Procedure

The potential spaces are determined after occupation of selected point configurations [16] in the appropriate space groups with (+)- and (−)-charges using the Ewald procedure applied to prescribed 3D meshes. The PEPS for CsCl is obtained for the charge distribution (+) on the Wyckoff positions 1a and (−) on 1b in $Pm\bar{3}m$, respectively. Both positions fix primitive point configurations P. That is the pertinent POPS is characterized by $P^{\{+\}}_{(1a)} \wedge P^{\{-\}}_{(1b)}$ and is given the symbol P* ($Im\bar{3}m$). In the same way the Schwarz D surface is obtained from the combination $D^{\{+\}}_{(8a)} \wedge D^{\{-\}}_{(8b)}$ in $Fd\bar{3}m$. Other than hitherto reported,[6] it belongs to the Cheshire group $Pn\bar{3}m$, since the generating point configurations already have $Fd\bar{3}m$ symmetry. Color pictures: Using DI-3000 graphic software, own programs, and an AED-767 colorgraphic screen.

BOOK REVIEWS

Kristallstruktur und chemische Bindung. By *A. Weiss* and *H. Witte*. Verlag Chemie, Weinheim 1983, xi, 396 pp., bound, DM 98.00.—ISBN 3-527-25612-1

In the typical classical German tradition of dividing chemistry into basic fields, this monograph treats that part of the "physical chemistry of solids" (i.e. with a minimum of compounds) which is concerned with the relationships between physical properties, structures, and chemical bonding. This vitally necessary and until now missing contribution is intended for students in the second half of their courses, but is also quite suitable for experienced colleagues in university and industry who require basic information concerning this area of chemistry. It would be desirable for this book, which is written by leading experts in the field, to become a part of the miniaturized "library" of young chemists, since basic knowledge of this particular field is going to be necessary in the future. The treatment is deliberately kept simple and the most important areas are discussed in about 200 pages divided into seven sections, namely: lattice energy and its importance for the stability of solids; the band model for metals and semiconductors; the importance of the typical cooperative properties for solids and their connection with structure and bonding; the importance of anisotropy in solids; lattice dynamics; defects in solids; high polymers and amorphous materials. These are preceded by two chapters on the fundamentals of crystallography and chemical bonding. An important section amounting to 90 pages then follows describing experimental methods such as diffraction, angular momentum methods, Mössbauer spectroscopy, optical methods, X-ray and photoelectron spectroscopy, and Compton scattering. Essential data and relationships are included in an appendix, as well as a structural discussion using the mineral olivine as an example.

As terse an introduction as that in this monograph is unlikely to escape the wishes of colleagues of the main field for supplementation and change. A few of these are: (1) the difference between lattice and structure must be defined and employed without compromise; (2) the fundamental importance of symmetry, not just for crystalline materials, is not nearly enough emphasized; (3) specific heats, magnetism, magnetic fields, conductivity, low temperatures, high pressures do not find a place under the important experimental methods; (4) with respect to the topic of this book, the selection of substances is very limited and the choice of structures conveys a dangerous impression to the reader that only a dozen examples are required for an understanding of the relevant relationships. This book has been well produced by the publisher, but was it really necessary that each fraction, each root sign etc. should inevitably lead to a doubling of the line spacing?

Hans-Georg von Schnering [NB 681 IE]
Max-Planck-Institut für Festkörperforschung Stuttgart (FRG)

1,3-Dipolar Cycloaddition Chemistry. Edited by *A. Padwa*. Wiley Interscience, New York 1984. Volume I: xiii, 817 pp.; Volume II: xiii, 704 pp., hardback, together $ 392, ($ 292 in USA).—ISBN 0-471-00354-X

1,3-Dipolar cycloadditions were first carried out by *Buchner* in 1888 with esters of diazoacetic acid. Many other examples followed; however, the fundamental principle of this reaction was not recognized until the pioneering formulation of the general concept by *Huisgen*, also at Munich. 1,3-dipolar additions play an important rôle in the synthesis of heterocycles and also, increasingly, in the regio- and stereoselective construction of carbo- and acyclic compounds. The great advances with regard to the theory and mechanism of these reactions are due to the work of the Munich school, the formulation of the Woodward-Hoffmann rules, and the application of *Fukui*'s frontier orbital concept, in particular by *Sustmann*, *Bastide*, and *Houk*. The reactivity and the regioselectivity of the concerted-asynchronous 1,3-dipolar cycloadditions can thus be satisfactorily interpreted or predicted in many cases. Yet, until now a comprehensive account of this area was not available, in spite of many monographs or chapters dealing with separate aspects (this is equally true for the even more famous sister reaction, the Diels-Alder addition).

A. Padwa, together with a further 18 authors from six countries, has now succeeded in producing a collective

volume of ca. 1500 pages that will fill this gap for many years, albeit in a not entirely satisfying way.

R. Huisgen's introductory chapter (*Introduction, Survey, Mechanism*, 176 pp. with 522 references) consists of a highly readable excursion through the history of this chemistry. It covers all aspects of 1,3-dipole reactions, presented concisely, clearly and with exemplary formula schemes. Although stress is laid on the essential Munich contributions, the (self)critical commentaries on the entire arsenal of methods available for mechanistic studies are a delight, with terse general introductions in each case, pointing out the relationships to other reaction types, with practical directions and topical observations. This is informative reading for anyone interested in reaction mechanisms in particular, or in the formulation, development, and consolidation of one of the great general concepts of organic chemistry!

The subsequent chapters are concerned with the most important classes of 1,3-dipoles, above all those involving C, N and O [chapters 2–11; oxyallyl is dealt with, carbonyl ylides are not (?)] as well as with the unifying principles (chapters 12–15). In detail: nitrile ylides (2; *Hansen, Heimgartner*, 114 pages/231 references); nitrile oxides and imines (3; *Caramella, Grünanger*, 102/552), diazoalkanes (4; *Regitz, Heydt*, 166/714); azides and N_2O (5; *Lwowski*, 94/253), azomethine ylides (6; *Lown*, 80/182); azomethine imines (7; *Grashey*, 84/394), mesoionic ring systems (8; *Potts*, 82/203); nitrones (9; *Tufariello*, 86/384); azimines, azoxy and nitro compounds (10, *Storr*, 32/65); ozone and carbonyl oxides (11; *Kuczkowski*, 80/194); intramolecular 1,3-dipolar cycloadditions (12; *Padwa*, 130/388); theory of 1,3-dipolar cycloadditions (13; *Houk, Yamaguchi*, 44/89); 1,3-dipolar cycloreversions (14; *Bianchi, Gandolfi*, 92/419); higher order dipolar cycloadditions (15; *Crabb, Storr*, 52/98). Both volumes are carefully edited; printing mistakes and errors of fact are rare in the text and in the numerous formula diagrams, as well as in the author and subject indices (65 and 40 pages, respectively).

Each author is known for his research in the area he deals with, and together they present competent and, for the greater part, systematic surveys organized according to their own interests. I should like to single out chapters 1, 2, 4, 7, 9, 12 and 14 as being "reader friendly" (systematic arrangement; up-dated literature coverage; experimental details/yields; interesting cross-references and suggestions). It should be noted that the entire project has, in my opinion, been concluded rather carelessly. Points at issue: "coordination of the chapters", "formula diagrams", "cut-off date/up-dating of literature references", "current developments and outlook", "price". As is often the case with multi-author projects (cf. the Patai series), the individual chapters are not coordinated. Thus, for example, about half of the contents of chapters 12 and 15 can be found elsewhere. Chapter 11 presents an extensive discussion of the individual steps of alkene ozonolysis and *only* this (80 pages, with one reference from 1982); later a more precise and up to date synopsis appears (chapter 14, 8 pp., 20 references from 1982/3). Discussions on mechanisms, reactivity, and regioselectivity occur in many sections on the individual dipoles, although these subjects comprise the general theme of chapters 1 and 13!

Two of the 15 chapters contain clearly laid out formula schemes, probably executed by the authors. The rest seems to have been produced by the press: sprawling, badly set out, with bond angles and spatial formulas that are out of question (by contrast, those of the ApSimon series of the same press are excellent).

The cut-off date of the literature references, very important to the user, is dealt with pitifully. The foreword dates from March 1984; no indications appear in the individual chapters, which were obviously concluded in 1980/1 (a praiseworthy exception is chapter 7). Gratefully, a few authors (chapters 2, 4, 7, 9, 12, 14) make use of addenda to bring their contributions up to date, i.e. to the end of 1982/1983, as can be learnt by examining the lists of references. Thus, recent developments in this field are sometimes not covered (cf. *Nachr. Chem. Tech. Lab. 32* (1984) Vol. 10 and 11): a) the Vedejs method (1979) for the generation of synthetically useful 1,3-dipoles *without* aryl substituents; b) stereoelectronic effects in the use of chiral dipoles or dipolarophiles.

The present volumes appear at the end of a long era in which, thanks to *Huisgen*, these reactions have developed from being mechanistically puzzling curiosities to being theoretically attractive and rationalizable ones, and further, have advanced to the point of being useful, because of being "predictable" tools in organic synthesis. Adding 3 + 2 the right way is going to become routine (it is in part already) and will have fruitful repercussions on the recognition and solution of new theoretical problems. These surveys will play their part in that.

Summary: A few deficiencies notwithstanding, the Padwa books are a rich mine of information for any chemist involved in reaction mechanisms, cycloadditions, heterocycles or stereoselective synthesis. For the newcomer they offer a stimulating starting point. Without doubt, this enterprise will be a commercially successful one; however, the horrific cost of these volumes will probably make them library-shelf copies only, against the intention and to the alarm of many of the authors involved.

Volker Jäger [NB 686]
Institut für Organische Chemie
der Universität Würzburg (FRG)

Total Synthesis of Natural Products: The "Chiron" Approach. By *S. Hanessian*. Pergamon Press, Oxford 1983. xvii, 291 pp., Paperback, £ 11.25.—ISBN 0-08-030715-9

The utilization of carbohydrates as chiral building blocks for the synthesis of enantiomerically pure target molecules has, in recent times, become one of the most powerful and versatile synthetic strategies. Due to some unique advantages, such as low cost, flexibility and efficiency, this approach has been used extensively for the synthesis of complex natural products. The vast amount of synthetic work done in this area, in conjunction with the high potential for widespread applications, dictated the need for an authoritative monograph on the subject. Stephen Hanessian, who has been a long time leader in the conceptual development and exploitation of this technology, was able to produce an excellent "how-to" monograph, filled with a plethora of well-analyzed examples.

The book is divided into sixteen chapters, arranged in seven parts (Basic concepts, Design, Discovery and Execution). Chapters 1–4 give a general introduction to the subject and illustrate the basis of this methodology, by giving some guidelines on how to analyze a target molecule in terms of carbohydrate-derived precursors. The author suggests here the use of the term "*chiron*" to describe these enantiomerically pure synthons. Chapters 5–10 deal with the synthesis of natural products with "apparent carbohydrate-type symmetry", such as those having a tetrahydrofuran or a tetrahydropyran ring. Justifiably, this section of

the book is the largest one, covering more than 1/3 of the total pages. Chapters 11 and 12 describe the application of this methodology to molecules with "partially-hidden carbohydrate-type symmetry", such as the leukotrienes and various other acyclic and cyclic natural products. Chapters 13–15 demonstrate the power of this approach to the synthesis of natural products with "hidden carbohydrate-type symmetry", such as the prostaglandins, the macrolides and other complex antibiotics. Finally, Chapter 16 gives a brief outline of a computer program, designed to assist the chemist in identifying optically active chiral precursors.

Numerous natural products of all types are represented in the examples given in the book. Each synthesis is illustrated with two flow charts, one for the retrosynthetic analysis and one for the actual synthesis. Although these charts are quite clearly presented, they would have been more readable if the various reagents and conditions were placed on the arrows, rather than the bottom of the chart.

In general, this is a well-written authoritative monograph on a very important topic in organic synthesis, and should find a broad spectrum of readers in academia and industry. It will definitely be a useful addition to any library, private or communal.

Physicochemical and Cytochemical Investigations on the Binding of Ethidium and Acridine Dyes to DNA and to Organelles in Living Cells

By Herbert W. Zimmermann

Ethidium and acridine dyes are classical model substances for studying the binding of small, pharmacologically active molecules to DNA. Intercalation between the DNA base pairs is nearly always proposed as the most important type of binding. According to our investigations, however, there is a second type of binding, which also occurs when the concentration of the bound molecules is low and will be referred to here as external or preintercalative binding. The experimental binding isotherms show that the binding constant for intercalation K_{S1} is considerably smaller than that for external binding K_{S2} ($K_{S1} \ll K_{S2}$). This surprising result is not due to the binding enthalpy ($\Delta H^0_{S1} \approx \Delta H^0_{S2}$) but to the binding entropy ($\Delta S^0_{S1} \ll \Delta S^0_{S2}$). Electrostatic interactions between the dye and the DNA represent the most important contribution to both types of binding; they are supplemented by hydrogen bonds and hydrophobic interactions. The behavior of a substance in living cells, however, cannot be reliably predicted from its in vitro binding to DNA. Very few substances are bound to the DNA of the nuclear chromatin in cell culture; for example, dyes often accumulate instead in the lysosomes. In some cases the dye binds specifically and very efficiently to the mitochondria of the living cell, especially to the mitochondrial membranes, the sites of oxidative phosphorylation.

1. Introduction

In 1961 *Lerman*[1] published his fundamental studies on the binding of proflavine to DNA in which he first proposed the intercalation model. However, intercalation is by no means limited to proflavine—it is observed in many more or less planar cationic molecules with conjugated π-electron systems, the classical examples being ethidium and the aminoacridines. These substances can be classified as pharmacologically active dyes in the sense defined by *Paul Ehrlich*, which include not only trypanocides as well as antimalarial and antibacterial drugs but also mutagens and carcinogens. Many antibiotics are assumed to bind similarly. The pharmacological activity of all these substances is most likely related to their intercalation, which is currently under much discussion as a model for interpreting biological and pharmacological phenomena. The extraordinary interest shown in this type of binding has resulted in a flood of publications that is almost impossible to survey. Accordingly, a review of this highly branched and wide-ranging subject will not be given in this article—the reader is instead referred to the literature, e.g., the competent articles by *Peacocke*[2] and *Waring*,[3] which provide the newcomer to this field with access to both earlier and more recent studies.

Intercalation is an unusual type of binding between the DNA polyanion and dye cations, in which the cation undergoes insertion between the DNA base pairs. The double helix must therefore unwind to create sufficient space for the intercalated molecule. An objective observer would scarcely dare to predict this unusual binding geometry, since simpler possibilities can be conceived to account for the binding of a molecular cation to the DNA polyanion. Why do they not occur? Or if they do, why are they not of biological importance?

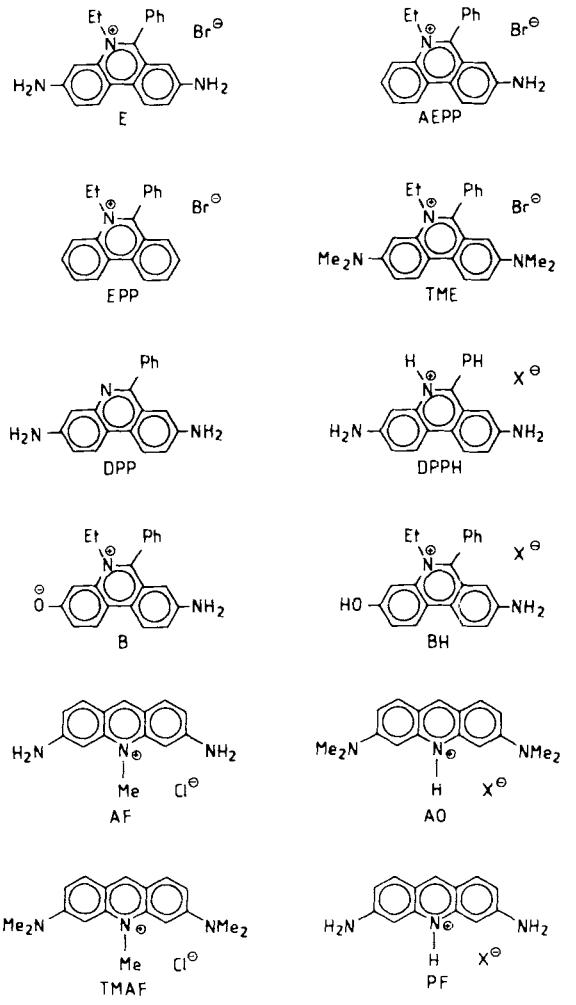
A great deal of effort was required to establish the intercalation model, which is supported by several indirect and direct lines of evidence.[3] The model is now generally accepted, even though some problems still remain to be solved in detail. The X-ray structure studies of *Sobell* et al.[4-6] on low-molecular-weight, crystalline ethidium-DNA complexes are generally regarded as being the most convincing proof of intercalation. Other authors extended these investigations to complexes between low-molecular-weight DNA and aminoacridines;[3] intercalation was found in all cases, the binding geometry being adapted to the different molecular conditions. Despite the magnificent achievements of these authors, it must be pointed out that the DNA used in these studies was only two base pairs long. It is therefore justifiable to ask whether the results obtained in these studies can be applied without any reservations to high-molecular-weight DNA, particularly in view of the fact that the binding geometry in the crystal is determined by the condition of electroneutrality and minimization of the lattice energy.

A few earlier X-ray structure studies were also performed on high-molecular-weight dye-DNA fibers.[1,7] The fiber diagrams of these complexes only provide a limited amount of information, however, and do not allow any detailed conclusions to be drawn about the binding geometry. In another X-ray structure study, carried out on a high-molecular-weight, crystalline ethidium-tRNA complex, *Liebman* et al.[8] found that the ethidium cations are bound externally to the biopolymer although intercalation in the double-helical regions of the tRNA employed was, in principle, possible and indeed expected. This finding is of importance because it was made on a complex between a dye and natural tRNA. Unfortunately, however, this study has not been followed up.

The conclusion to be drawn from these X-ray studies is that both intercalation and external binding are possible. The type of binding and the geometry that are adopted in each particular case, however, cannot be easily predicted. This complicates our problem because we are now confronted with not only one but at least two types of binding.

Chemical binding can be characterized by thermodynamic parameters, e.g., the equilibrium constant (binding constant) between the bound and free species, the binding enthalpy, and the binding entropy. These parameters do not depend on the binding mechanism. The thermodynamics of intercalation has been dealt with in a number of investigations[2,3] but in most cases only a few selected molecules were studied. Very few authors have gone to the trouble of performing comparative binding studies to determine which structural features a molecule must possess in order to bind to DNA.[2,3,9,10] Supplementary studies of a series of simple, systematically modified molecules under identical experimental conditions are required.

The interest shown in binding enthalpies and entropies has also been surprisingly small so far.[2,3,11-13] These parameters are the thermodynamic key for understanding chemical binding and should provide valuable information for the discussion of intercalation. This lack of information is due to the considerable amount of experimental work that is needed to obtain these data with sufficient reliability. Furthermore, thermodynamic studies are regarded as being dull and unattractive. However, intercalation is such an unusual type of binding that it should be better understood if only because of its importance in biology and pharmacology. We have therefore carried out further studies on this subject, which will be discussed and summarized below.[14-19] We endeavored not only to fill in the gaps mentioned above but also tried to study another problem: it has long been known and many authors have confirmed[2,3] that the binding constants of dye cations to DNA depend strongly on the concentration of salts in the dye-DNA solution and decrease with increasing salt concentrations. This finding has always been interpreted as an indication of the involvement of electrostatic interactions in dye binding. According to the theory of the condensation of counterions onto polyelectrolytes,[20,21] which is now generally accepted, DNA is almost saturated with counterions even at low salt concentrations.[21] Strong dependence of the binding constant on the salt concentration is therefore not easy to understand and requires further studies.



Binding constants can be determined experimentally from binding isotherms, the simplest type being that of *Scatchard*.[22] The Scatchard isotherm is a linear representation of the Langmuir adsorption isotherm and is based on the law of mass action. It applies—and surprisingly well—when relatively few molecules are bound to the biopolymer and when the interactions between these molecules can be neglected. Deviations from linearity are found when the dye occupies more of the DNA. Several explanations have been proposed to account for this phenomenon: different types of bound molecules, which vary in their affinities for the substrate; interactions between the bound molecules, which result in cooperative effects; the binding of molecules that simultaneously occupy several binding sites. A variety of models have been developed which take into consideration these aspects.[2,3,23-33] The large number of models demonstrates in itself that it is difficult to interpret curved Scatchard isotherms unambiguously. Furthermore, experimental errors can result in the simulation of slightly curved binding isotherms. We have therefore restricted the following studies to the linear portion of the Scatchard isotherm and thus to low concentrations of bound molecules. This was done for two main reasons:

1. In vivo the binding of a pharmacon to DNA is limited because the quantity administered is necessarily restricted. The linear portion of the Scatchard isotherm is consequently of primary interest for the discussion of the biological and pharmacological significance of binding. It will be shown below or at least made highly plausible that the linear region of the Scatchard isotherm is accounted for by two different types of binding—namely, intercala-

tion and external or pre-intercalative binding. Although external binding is thermodynamically more favorable than intercalation, the latter may dominate under the conditions found in the cell. The question still has to be answered as to whether the pharmacon really does bind to the DNA in living cells.

2. The linear region of the Scatchard isotherm approximately obeys the law of mass action. Binding can therefore be discussed in terms the chemist is familiar with—i.e., binding constants (equilibrium constants), binding enthalpies, and entropies.

We have measured the binding isotherms of several, selected ethidium and acridine dyes with calf thymus DNA in aqueous medium under identical experimental conditions. The measured binding constants, enthalpies, and entropies can therefore be compared directly with one another. The substances are summarized in Scheme 1. Comparison of the binding properties of the molecules reveals the importance of electrostatic interactions, hydrogen bonds, and hydrophobic interactions in binding.

Scheme 1. E, ethidium bromide; AEPP, 8-amino-5-ethyl-6-phenylphenanthridinium bromide; EPP, 5-ethyl-6-phenylphenanthridinium bromide; TME, tetramethylethidium bromide; DPP, 3,8-diamino-6-phenylphenanthridine; DPPH, protonated DPP; B, 8-amino-5-ethyl-6-phenylphenanthridinium-3-olate; BH, protonated *B*; AF, acriflavine; AO, protonated acridine orange; TMAF, tetramethylacriflavine; PF, protonated proflavine.

2. Experimental Remarks

The binding isotherms between a dye molecule D and a nucleic acid N can be determined experimentally in many ways.[2,3] The aim of all of these methods is to measure the concentrations C of the bound (b) and free (f) dye (C_{Db} and C_{Df}, respectively) for different concentrations of the dye, $C_D = C_{Df} + C_{Db}$, and nucleic acid, C_N. This problem seems to be simple and almost trivial, but in practice there are, unfortunately, many traps which falsify the results or even render them unusable. Experimental methodology must therefore be discussed.

We have determined our binding isotherms by means of absorption spectrophotometry. The longest wavelength absorption band of D is usually shifted to a longer wavelength when a dye molecule is bound to DNA; moreover, the intensity of the band decreases. At long wavelengths the absorption spectra for different C_D and C_N values generally intersect at one or more isosbestic points: the free and bound dye are in equilibrium with each other. We have limited our studies to those systems and experimental conditions in which the thermodynamic equilibrium is substantiated by isosbestic points. Isosbestic points are not observed at short wavelengths because not only the free and bound dye but also the nucleic acid absorb in this region.

The concentrations C_{Df} and C_{Db} can be obtained from the measured extinction coefficient ε.

$$\varepsilon C_D = \varepsilon_f C_{Df} + \varepsilon_b C_{Db}$$

In addition to C_D and C_N, the molar extinction coefficients of the free and bound dye (ε_f and ε_b, respectively) must also be known exactly. Even small errors in these parameters can produce systematic differences which simulate curved Scatchard binding isotherms. Some critical problems must therefore be pointed out.

ε_f can be obtained from the absorption spectra of dye solutions that obey the Beer-Lambert law. In the case of associating substances (e.g., aminoacridines) complications arise, which necessitate extrapolation to $C_D = 0$.[18]

ε_b is the limiting value of the absorption spectrum at a high excess of nucleic acid, $C_N \rightarrow \infty$. This limit can only be reached approximately under the usual experimental conditions. It is therefore advisable to use an extrapolation method originally proposed by *Benesi* and *Hildebrand*,[34] which we have adapted for this problem.[14]

Determination of C_D is trivial provided that an analytically pure sample of the dye is available. Unfortunately, this criterion is often disregarded; many researchers who employ their dyes without testing them would be amazed at the magnificent ranges of colors which appear on a simple thin layer chromatogram. Even chromatographically pure substances can obstinately retain solvent residues (water, alcohol, etc.), which resist drying under a high vacuum and result in incorrect sample weights.

The concentration of mononucleotide units present, C_N, is best determined by phosphate analysis. Several reliable methods are available.[35,36]

Small statistical errors are unavoidable despite careful work and observance of all the usual precautionary meas-

ures; under unfavorable conditions they can lead to considerable problems. This applies especially to the Scatchard plots of binding isotherms that involve differences between large numbers; small errors are then greatly amplified. The points obtained are not in a line as expected but scattered. This can be overcome to some extent by averaging a large number of independent, individual measurements, which naturally involves a great deal of effort.

Another possibility is to smooth the experimentally measured values. If, for example, the extinction ε is determined at different nucleic acid concentrations C_N for a given C_D and then plotted against C_N, a group of points is generally obtained that only deviates slightly from an ideal curve. Nevertheless, these small differences can cause larger deviations in the Scatchard plot. In order to minimize errors, an empirically smoothed curve can be drawn through the points in the plot of ε versus C_N and new, improved values can then be determined. Statistical errors are thereby suppressed while systematic differences are retained. We empirically smooth the measured values with a computer program originally developed by *Weidner*[37] for analogous problems in the X-ray structure study of liquids. This automated procedure is preferable to smoothing "by hand."

The expectations placed on the accuracy of the determined binding constants, binding enthalpies, and especially the binding entropies should not be too high, owing to the experimental difficulties already described. The data provide, however, a useful basis for the following discussion.

3. Langmuir and Scatchard Binding Isotherms

In the simplest case the binding of a dye molecule D to the biopolymer DNA [Reaction (a)] can be characterized by two parameters: the binding constant K and the fraction n of the mononucleotide that is capable of binding. Both parameters can be determined with the aid of the Scatchard binding isotherm.

$$D + DNA \overset{K}{\rightleftharpoons} D\text{-}DNA \qquad (a)$$

If the concentration of the bound molecules, C_{Db}, is sufficiently small, cooperative binding phenomena can be neglected. The law of mass action (LMA) applies to the equilibrium concentrations of the free and bound dye molecules (C_{Df} and C_{Db}, respectively) and the available free binding sites of the nucleic acid (C_{Nf}) [Eq. (1)].

$$K = C_{Db}/C_{Nf}\,C_{Df} \qquad (1)$$

The concentration of the mononucleotide present is C_N and that of the available binding sites $n\,C_N$. The factor n ($0 < n < 1$) takes into consideration that on average only a fraction of the binding sites are capable of binding D. If C_{Db} molecules are bound at equilibrium, the concentration of free binding sites still available is given by

$$C_{Nf} = n\,C_N - C_{Db}$$

Combination of this equation with Equation (1) yields Equation (2).

$$K_S = C_{Db}/[(n\,C_N - C_{Db})\,C_{Df}] \qquad (2)$$

As discussed in Section 4, the equilibrium constant $K = K_S$ is adapted to the method of counting the binding sites according to *Scatchard*. Substituting $r = C_{Db}/C_N$, the number of bound molecules per mononucleotide unit, gives the Langmuir adsorption isotherm [Eq. (3)].

$$r = n\,K_S\,C_{Df}/(1 + K_S\,C_{Df}) \qquad (3)$$

Simple rearrangement yields the Scatchard form of the binding isotherm [Eq. (4)]:[22]

$$r/C_{Df} = K_S(n - r) \qquad (4)$$

If r/C_{Df} is plotted against r and Equation (4) applies, a straight line with a negative slope is obtained which intersects the abscissa at $r = n$. The slope of the line provides K_S. Thus, n and K_S can be determined. In this simplest plot the extrapolated value $r = n$ characterizes the maximum number of bound dye molecules per mononucleotide. However, this interpretation can lead to contradictions (see Section 4). It is better to regard $r = n$ as the upper limit of the range in which the LMA is at least approximately obeyed and in which the dye molecules are bound to the nucleic acid independently of one another.

Scatchard binding isotherms for the ethidium bromide–DNA system (E/DNA) at low dye concentrations are given in Figure 1.[14] In addition to E and DNA, the aqueous solutions also contain NaCl as a neutral salt. The isotherms shown in Figure 1 correspond to different salt concentrations C_S. When r is small, all the isotherms can be approximated as straight lines; the LMA is thus formally obeyed. When r is larger, positive deviations from linearity are found. This region of curved Scatchard isotherms will not be discussed here for the reasons given above.

The slopes of the straight lines for different C_S values differ (Fig. 1). All the extrapolated lines intersect the ab-

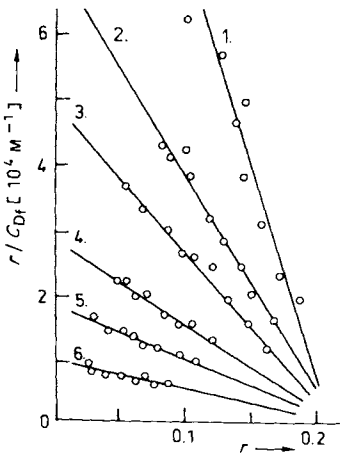


Fig. 1. Scatchard binding isotherms for the E/DNA system at various concentrations C_S of the competitor salt S = NaCl. 1. $C_S = 2 \times 10^{-3}$ M, 2. 0.05 M, 3. 0.1 M, 4. 0.25 M, 5. 0.5 M, 6. 1.0 M. pH = 7.7, T = 298 K [14].

scissa, however, at $n = 0.21$ within the limits of error. Thus, n is virtually independent of the salt concentration C_S (Fig. 2). The same behavior is also observed with the salts KCl and $MgCl_2$.[14] Therefore, n is also independent of the type of salt (Fig. 2). In the low r region, linear Scatchard isotherms are also obtained at different temperatures; these isotherms once again intersect the abscissa at $n = 0.21$ and are independent of S and C_S.[14] Thus, n is a parameter that characterizes the binding of the dye to the biopolymer.

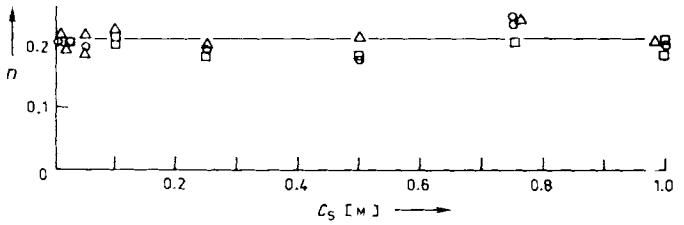

Fig. 2. Binding parameter n for the E/DNA system at various concentrations C_S of the competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7, T = 298 K [14].

Determination of n from the point of intersection of the extrapolated Scatchard plot with the abscissa is—like all extrapolations—subject to error. It should therefore be pointed out that, in the case of the E/DNA/NaCl system, n can also be obtained by a second, independent method, which consists of directly titrating the dye present with a DNA solution of known concentration, the end point being determined spectroscopically.[14] The titration is not subject to any special conditions such as the validity of the LMA or the extinction coefficients of the free and bound species. The value determined by titration, $n = 0.21$, is independent of C_S over a wide range of concentrations and is identical to the extrapolated value.

The slopes of the binding isotherms and thus the binding constant K_S depend not only on the temperature T but also on the type of salt S and its concentration C_S.[14] Consequently, $K_S = K_S(T, C_S)$ has the character of an apparent equilibrium constant. Figure 3 shows K_S as a function of the concentration C_S of the salts NaCl, KCl, and $MgCl_2$ at the standard temperature $T = 298$ K. K_S decreases as C_S increases—very rapidly in the case of $MgCl_2$ and more slowly for NaCl and KCl. When C_S is sufficiently large, K_S apparently approaches a limiting value, K_{S1}, which is small but differs from zero. The curves in Figure 3 can be approximated as hyperbolas that intersect the ordinate when $C_S = 0$ and reach an asymptotic value K_{S1} as $C_S \to \infty$ (Fig. 3).

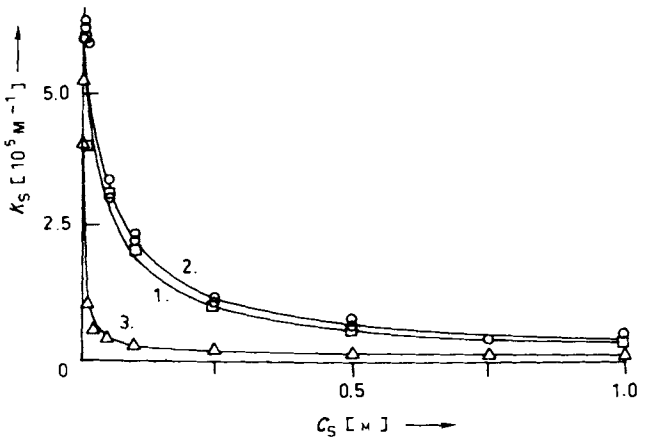

Fig. 3. Dependence of the apparent Scatchard binding constant K_S of the E/DNA system on the concentration C_S of the competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7, T = 298 K. 1.–3. calculated curves [Eq. (21), data taken from Table 1] [14].

In the same way as the binding constant K_S, the number of dye molecules bound per mononucleotide unit, r, also falls as the salt concentration increases (Fig. 4).[14] The bound dye is apparently displaced from the polymer. The decrease in r is once again much more pronounced for $MgCl_2$ than for NaCl. The bound dye E cannot, however, be completely displaced from the DNA even at high salt concentrations ($C_S = 2$ M). The curves shown in Figure 4 indicate that r, like K_S, approaches a limiting value at high salt concentrations C_S, which is attained more quickly in the presence of $MgCl_2$ than NaCl. Studies at very high C_S values can only be interpreted to a limited extent because the competitive salt effect is masked by phenomena that are difficult to assess, such as salting out effects and denaturation of the polymer. We have therefore generally restricted our measurements on competitive effects to concentrations $C_S \leq 1$ M.

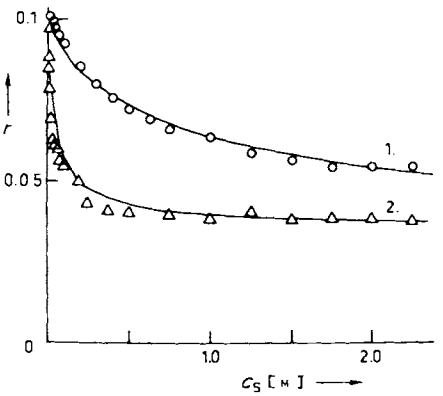

Fig. 4. Number $r = C_{Db}/C_N$ of bound dye molecules per DNA mononucleotide unit of the E/DNA system as a function of the concentration C_S of the competitor salt S = NaCl (○), $MgCl_2$ (△). Dye concentration $C_D = 2.5 \times 10^{-5}$ M, DNA concentration $C_N = 2.5 \times 10^{-4}$ M. pH = 7.7, T = 298 K. 1. and 2. calculated curves [Eq. (18), data taken from Table 1] [14].

The standard binding enthalpy ΔH_S^0 and entropy ΔS_S^0 can be determined from the temperature dependence of the Scatchard binding constants K_S with the aid of the van't Hoff equation [Eq. (5)].

$$\ln K_S = -\Delta H_S^0/RT + \Delta S_S^0/R \qquad (5)$$

The temperature range available for determining ΔH_S^0 and ΔS_S^0 is only very small because the DNA denatures at high temperatures and the solution solidifies at low temperatures. A large number of single measurements are therefore required to minimize experimental errors. Figure 5 shows the temperature dependence of K_S for the E/DNA system by means of van't Hoff plots at various concentrations, C_S, of the competitive salts NaCl, KCl, and $MgCl_2$.[14] The plots are groups of approximately parallel straight lines. The apparent binding enthalpy ΔH_S^0 is thus

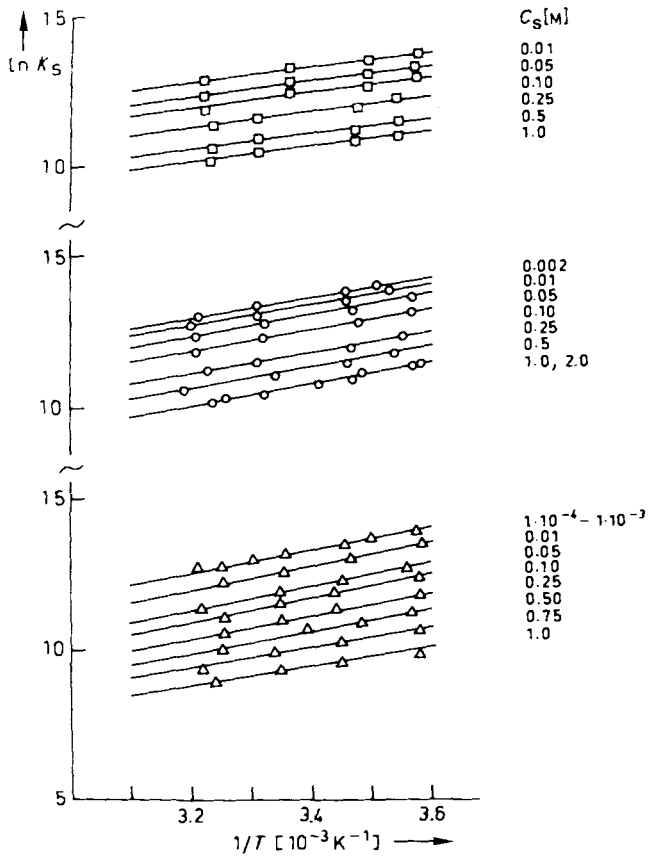

Fig. 5. Temperature dependence of the apparent Scatchard binding constant K_S of the E/DNA system at various concentrations C_S of the competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7 [14].

largely independent of S and C_S (Fig. 6), whereas the dependence of the binding constant K_S on S and C_S is reflected in the behavior of the apparent binding entropy ΔS_S^0 (Fig. 7).

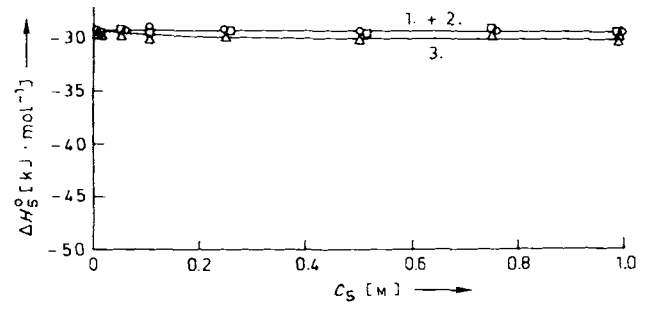

Fig. 6. Dependence of the apparent Scatchard binding enthalpy ΔH_S^0 of the E/DNA system on the concentration C_S of the competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7. 1.-3. calculated curves [Eq. (21) and (5), data taken from Tables 1 and 2] [14].

Finally, I would like to refer to the pioneering work of *Waring*[38] and of *LePecq* and *Paoletti*,[12] who, in 1965 and 1967, respectively, investigated the binding of ethidium bromide to DNA in wide-ranging studies. They described linear Scatchard isotherms with $n = 0.2$ that were independent of the DNA base composition. Accordingly, binding of E to DNA does not display pronounced base specificity. These authors also found that the binding constant K_S de-

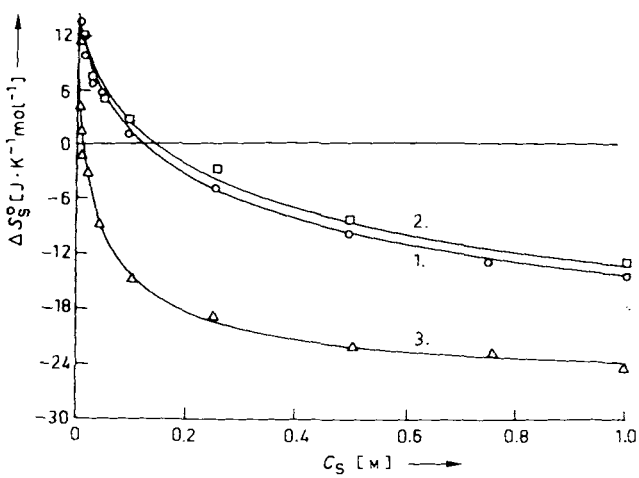

Fig. 7. Dependence of the apparent Scatchard binding entropy ΔS_S^0 of the E/DNA system on the concentration C_S of the competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7. 1.-3. calculated curves [Eq. (21) and (5), data taken from Tables 1 and 2] [14].

creases as the salt concentration increases and approaches a plateau at high C_S values. The quantity of dye bound then remained constant and was virtually independent of the salt concentration C_S. *LePecq* and *Paoletti* were the first to describe the temperature dependence of K_S and attempted to determine ΔH_S^0 and ΔS_S^0 from measurements made at two temperatures (23 and 37 °C) for different NaCl concentrations. There are many qualitative parallels between the findings of these authors and our measurements. In quantitative terms, however, they differ considerably, especially as regards the dependence of the thermodynamic parameters K_S, ΔH_S^0, and ΔS_S^0 on the salt concentration C_S. We believe that these differences are due to experimental difficulties, which we have endeavored to overcome in our investigations.

4. Crothers Binding Isotherm, the Law of Mass Action, and the Counting of Binding Sites

In deriving the Scatchard binding isotherm it is formally assumed that only nC_N of the C_N mononucleotides employed are capable of binding a dye molecule D. A free molecule in the solution "sees" $C_{Nf} = nC_N - C_{Db}$ free binding sites and chooses one to which it then binds. The number of free DNA sites is then reduced by one. The equilibrium constant K_S is adapted to this method of counting the binding sites.

According to the studies of *Waring*[30] and *LePecq* and *Paoletti*,[12] binding of E to DNA does not exhibit base-specific preferences. Intercalation between all neighboring DNA base pairs should therefore be equally possible. The experimental value for the binding parameter $n \cong 0.2$ is too small, however, and is not consistent with this expectation. In order to take the equivalence of the binding sites into account, *Armstrong* et al.[39] and *Crothers* et al.[27,40] proposed another method for counting the binding sites, which is referred to in the literature as the nearest neighbor exclusion principle. According to this method, intercalation is, in principle, possible between all neighboring DNA

base pairs and all the binding sites are equivalent. If one of the sites is occupied, however, binding to the neighboring sites is hindered. *Crothers* et al.[40] used this exclusion principle as the basis for deriving the following binding isotherm using the matrix method [Eq. (6)]:

$$r'/C_{Df} = K_C \cdot (1-2r')^2/(1-r') \tag{6}$$

r' refers to the concentration of base pairs $C'_N = C_N/2$, and $r' = C_{Db}/C'_N = 2r$. The binding constant describes the binding of D to the unperturbed DNA binding sites; i.e., when r' is small, Equation (7) applies.

$$\lim_{r' \to 0} K_C = C_{Db}/C'_N C_{Df} \tag{7}$$

Equation (6) no longer contains the binding parameter n since it is fixed by the formalism. The limiting behavior of Equation (6) when $r' < 1$ is of sole interest in the following discussion. Substitution of the infinite geometrical series

$$1/(1-r') = 1 + r' + r'^2 + \cdots$$

into Equation (6) yields Equation (8).

$$r'/C_{Df} = K_C(1 - 3r' + r'^2 + \text{higher terms}) \tag{8}$$

If r' is sufficiently small, the progression in Equation (8) can be approximated by ignoring the terms following the linear r' term. If the concentration of the mononucleotides C_N is reintroduced, Equation (8) gives Equation (9).[14]

$$r/C_{Df} = 3K_C[(1/6) - r] = K_S(n - r) \tag{9}$$

When r is small, the Crothers binding isotherm is therefore also of the Scatchard type. Comparison of the coefficients gives $K_S = 3K_C$ and $n = 1/6 = 0.17$. A binding parameter of $n = 0.17$, which is in agreement with the theory, was indeed found for the aminoacridines we studied; in the case of ethidium bromide and its derivatives the experimental value of $n = 0.21$ is somewhat higher. If only the linear portion of the binding isotherm is considered, the law of mass action also formally applies to the nearest neighbor exclusion model. The Crothers isotherm differs from the Scatchard isotherm in the way the binding sites are counted.

The exclusion principle of binding sites proposed by *Armstrong* et al. and *Crothers* et al. makes physical sense. The law of mass action can be applied to this method of counting binding sites. The mononucleotide concentration used is again C_N, and the possible binding sites are given by a fraction pC_N. When a molecule of D is bound, an average of q neighboring DNA sites are assumed to be blocked. The concentration of free binding sites is then $C_{Nf} = pC_N - qC_{Db}$ and, from Equation (1), Equations (10) and (11) are obtained.

$$K_Z = C_{Db}/[(pC_N - qC_{Db})C_{Df}] \tag{10}$$

$$r/C_{Df} = qK_Z[(p/q) - r] = K_S(n - r) \tag{11}$$

Comparison of the coefficients with the Scatchard isotherm yields $K_S = qK_Z$ and $n = p/q$. In the case of the nearest neighbor exclusion model, for example, $C'_N = pC_N = C_N/2$, $p = 1/2$. Comparison of Equations (11) and (9) reveals that binding of one molecule of D to a DNA binding site blocks $q = 3$ base pairs in the linear region of the Crothers binding isotherm when r is small. This means that—in contradiction to the name of the model—not only the neighboring sites but also the next nearest sites are excluded from binding. At this point it should be recalled that in favorable cases this value, $q = 3$, can be determined directly by titration and not only by extrapolation of the linear region of the binding isotherm. On titration the properties of the system change "discontinuously" in the vicinity of the end point. Therefore, n is a physically relevant parameter and characterizes the range that obeys the LMA.

The Crothers isotherm approaches the limiting value $(1-2r') = 0$ when $C_{Df} \to \infty$ and then reaches the maximum value of bound molecules $r' = C_{Db}/C'_N = 1/2$ or $C_{Db} = C'_N/2$. In agreement with the nearest neighbor exclusion principle, an average of one dye molecule is bound to every second base pair when the DNA is saturated with D ($q = 2$).

In practice, Equation (11) is more versatile then Equation (9) because p/q is not fixed by a model and q—as a mean value—is not only an integer but can also be a fraction. Only the two constants $K_S = qK_Z$ and $n = p/q$ can be determined directly by experiment. The three unknowns K_Z, p, and q cannot be obtained from these equations without making further assumptions about p or q. This leads to fundamental difficulties in the discussion of the binding constants. The equilibrium constants K_S and K_Z are based on different methods of counting the binding sites. This difference is reflected in the binding entropy but not in the binding enthalpy. If $K_S = qK_Z$ is substituted into Equation (5), Equations (12) and (13) are obtained.

$$\Delta H^0_S = \Delta H^0_Z \tag{12}$$

$$\Delta S^0_S = \Delta S^0_Z + R \ln q \tag{13}$$

It is not our intention to develop a theory to account for the binding between the dye and DNA but rather to describe and interpret our experimental findings. It is initially advisable to rely solely on experimentally accessible data. We therefore have to make do with the Scatchard isotherm, bearing in mind the fact that it is based on an incorrect way of counting the binding sites. Since ΔS^0_S and ΔS^0_Z only differ by an additive constant, a comparative qualitative discussion is possible even at this level. The isotherms described above can easily be interconverted by means of calculation. The Scatchard isotherm can then always be changed into another binding isotherm with the aid of special assumptions about p and q.

5. A Simple Equilibrium Model for Describing the Competitive Effect, $K_S = K_S(T, C_S)$

According to Figures 3 and 4, K_S and r at first fall rapidly as C_S increases but then approach a limit at high C_S values. A competitive salt effect occurs. The metal cations M of the salt S displace the dye cations D bound to the

DNA. A residue of bound dye cations is, however, generally observed even at very high competitor concentrations.[3, 14] In contrast, the binding parameter n is practically independent of S and C_S (Fig. 2).[3, 14] Two models will be compared to describe these findings.

1. D undergoes two types of binding to DNA, 1 and 2, which can be distinguished by means of the competitive effect. Type 1 binding is resistant to competitive salts and still occurs at high salt concentrations (noncompetitive binding). In type 2 binding, on the other hand, D may be displaced by competitors M (competitive binding). Using the theory of counterion condensation, *Record* et al.[21] have demonstrated that approximately 88% of the negative charge of the DNA polyanion in aqueous solution is compensated by the "binding" of metal cations M such as $Na^{\oplus}$ or $K^{\oplus}$. The charge compensation is independent of the concentration of the cations M in the solution within a wide range of concentrations. According to the theoretical studies of *Manning*,[20] this charge compensation is essential for stabilization of the polyanion. Presumably, the dye cations also contribute to compensating the charge of the DNA and are thus bound. The competitive effect exerted by metal cations M on dye cations D can thus be interpreted as an exchange of these ions at the DNA.

2. There is only one type of binding but two contributions to the binding energy—an electrostatic component resulting from the interactions between the dye cation D and the DNA polyanion and a second contribution that is composed of the interactions of the π-electrons with the DNA base pairs, hydrogen bonds, etc. According to this model, advocated by *Fromherz*,[41] the competitive salt effect is a result of the compensation of the electrostatic component by the binding of the competitor cations M; the second component remains unaffected. This model undoubtedly displays some interesting features but it is difficult to reconcile with the theory of counterion condensation. Since the quantity of counterions M bound to the DNA polyanion is not only very high but also independent of the concentration of M in solution, the electrostatic binding component should always be largely compensated and, moreover, should not be affected by varying C_S. In the following discussion, preference will be given to the first model on account of this inconsistency.

When r is sufficiently small, the Scatchard isotherms are virtually straight lines for all competitor concentrations C_S (Fig. 1). The LMA then applies—at least approximately. The noncompetitive type 1 binding

$$D + DNA_1 \overset{K_{S1}}{\rightleftharpoons} D\text{-}DNA_1$$

is described by the binding constant K_{S1} and the binding parameter n_1 [Eq. (14)].

$$K_{S1} = C_{Db1}/[(n_1 C_N - C_{Db1}) C_{Df}] \tag{14}$$

In the case of competitive type 2 binding, it must be taken into account that about 88% of the negative charge of the DNA is compensated by the counterions M but that at most only 20% of the mononucleotide can bind the dye. The competitive effect can then be described by a simplified reaction originally proposed by *Record* et al. [Reaction (b)].[21]

$$M + D\text{-}DNA_2 \overset{1/K_{S4}}{\rightleftharpoons} D + M\text{-}DNA_2 \tag{b}$$

Reaction (b) can be divided into two steps [Reactions (c) and (d)].

$$D\text{-}DNA_2 \overset{1/K_{S2}}{\rightleftharpoons} D + DNA_2 \tag{c}$$

$$M + DNA_2 \overset{K_{S3}}{\rightleftharpoons} M\text{-}DNA_2 \tag{d}$$

These are formally assigned the binding constants K_{S2} and K_{S3} for the binding of D and M, respectively, to the DNA; the binding parameter is n_2. Equations (15) and (16) are thereby obtained.

$$K_{S2} = C_{Db2}/[(n_2 C_N - C_{Db2} - C_{Mb}) C_{Df}] \tag{15}$$

$$K_{S3} = C_{Mb}/[(n_2 C_N - C_{Db2} - C_{Mb}) C_{Mf}] \tag{16}$$

It must be emphasized that the separation of Reaction (b) into steps (c) and (d) only involves the exchange of the cations D and M at the DNA. This exchange process may approximately obey the LMA, but the condensation of the counterions M to the DNA polyanion does not. Equation (17) is then obtained for the ion exchange according to Reaction (b).

$$K_{S4} = K_{S2}/K_{S3} = C_{Db2} C_{Mf}/(C_{Df} C_{Mb}) \tag{17}$$

K_{S4} is the binding constant of D to DNA in the presence of M.

Elementary calculations using the terms

$$C_D = C_{Db} + C_{Df}$$

$$C_{Db} = C_{Db1} + C_{Db2}$$

$$C_M = C_{Mf} + C_{Mb}$$

$$r = r_1 + r_2 = (C_{Db1} + C_{Db2})/C_N$$

yield Equation (18).[14]

$$r = n_1 K_{S1} C_{Df}/(1 + K_{S1} C_{Df}) + n_2 K_{S2} C_{Df}/(1 + K_{S2} C_{Df} + K_{S3} C_{Mf}) \tag{18}$$

This is an extension of the Langmuir isotherm to two types of binding, as has already been proposed, in principle, by *Peacocke* et al.,[23] and has been extended here to apply to the competitive effect. Conversion of Equation (18) into the Scatchard form gives Equation (19).[14]

$$r/C_{Df} = K_{S1}(n_1 - r) + K_{S2}(n_2 - r)/(1 + K_{S3} C_{Mf}) + K_{S1} K_{S2}(n_1 + n_2 - r) C_{Df}/(1 + K_{S3} C_{Mf}) \tag{19}$$

In the limiting case where $C_D \ll C_N$, the following apply: $C_D/C_N \to 0$, $C_{Df} \to 0$, and $r \to 0$. The third term on the right-hand side of Equation (19) can then be neglected. The Scatchard isotherm then consists of two additive, independent, linear components, which describe noncompetitive and competitive binding. Linear Scatchard isotherms can still be expected even at somewhat higher C_D/C_N concen-

tration ratios. According to our experiments, the binding parameter n is independent of S, C_S, and C_M within the limits of error when r is small. Apparently, $n=n_1=n_2$. In order to produce the competitive salt effect, relatively high competitor concentrations must also be used; in this case, $C_N \ll C_M$ and $C_{Mb} \ll C_{Mf} \approx C_M$. Under these conditions, Equation (19) can be rearranged to give Equation (20).[14]

$$r/C_{Df} = \{K_{S1} + K^*_{S2}/(1+K_{S3}C_M)\}(n-r) \quad (20)$$

Under our experimental conditions, the experimentally accessible effective binding constant $K^*_{S2}=K_{S2}(1+G)$ differs only slightly from K_{S2}. If C_{Df} and r are sufficiently small, the function

$$G = K_{S1}C_{Df}[1+1/(1-u)] = K_{S1}C_{Df}[2+u+u^2+\cdots]$$
$$u = r/n < 1$$

can either be neglected when compared with 1 or replaced by its mean value $\overline{G}$. Equation (20) then approximately describes Scatchard isotherms which—in agreement with the experimental findings—intersect the abscissa at $r=n$ independently of S, C_S, and T. Comparison of Equation (20) with Equation (4) gives the apparent Scatchard equilibrium constant $K_S=K_S(T, C_S)$ in the form of Equation (21).[14]

$$K_S = K_{S1} + K^*_{S2}/(1+K_{S3}C_M) \quad (21)$$

In the case of molecules that are only bound competitively ($K_{S1}=0$), Equation (22) applies.

$$K_S = K_{S2}/(1+K_{S3}C_M) \quad (22)$$

In the case of the competitor salts NaCl, KCl, and $MgCl_2$, $C_M=C_S$. Equations analogous to Equation (22) are known.[12,42,43]

Equations (21) and (22) are hyperbolic equations. They describe the dependence of the Scatchard binding constant K_S on the competitor concentration $C_M=C_S$. In the E/DNA system the curves shown in Figure 3 were calculated using Equation (21) and the binding constants K_{S1}, K^*_{S2} or K_{S2}, and K_{S3} were determined by means of linear regression (Table 1). The binding isotherms in Figure 4 were then finally determined with the aid of these constants and Equation (18).[14] The agreement between the calculated curves and the experimental values is surprisingly good. It must be borne in mind that some radical simplifications have been made in the course of the derivation.

The binding constants K_{S1} and K^*_{S2} or K_{S2} are, as is to be expected, independent of the type of competitor within the range of error. The competitor specificity is reflected in the binding constant K_{S3}. Accordingly, $Mg^{2\oplus}$ is a much stronger competitor than $Na^{\oplus}$ or $K^{\oplus}$.

Unlike K_S, the independent constants K_{Si}, i = 1-3, depend solely on T. The standard binding enthalpies ΔH^0_{Si} and entropies ΔS^0_{Si} can be determined from the temperature dependence of K_{Si} in the customary way by using the van't Hoff equation. As an example, the temperature dependence of K_{Si} for the E/DNA system is given in the form of a van't Hoff plot in Figure 8. The ΔH^0_{Si} and ΔS^0_{Si} values thus obtained are listed in Table 2. The binding enthalpies and entropies of the noncompetitive and competitive types of binding (types 1 and 2, respectively) are once again independent of the type of competitor within the relatively large range of error. The individual properties of the competitor are described by the thermodynamic parameters of binding of M.[14]

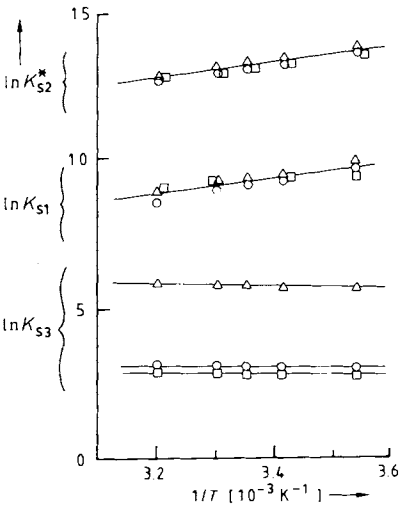

Fig. 8. Temperature dependence of the actual binding constants K_{S1}, K^*_{S2}, and K_{S3} of the E/DNA system, competitor salt S = NaCl (○), KCl (□), $MgCl_2$ (△). pH = 7.7 [14].

Table 2. Binding enthalpies ΔH^0_{Si} [kJ mol^{-1}] and binding entropies ΔS^0_{Si} [J K^{-1} mol^{-1}] of noncompetitive and competitive binding i = 1-3. E/DNA system, competitor salts NaCl, KCl, and $MgCl_2$ [14].

Competitor		K_{S1}	K^*_{S2}	K_{S2}	K_{S3}
NaCl	ΔH^0_{Si}	−28	−29	—	+ 1.7
	ΔS^0_{Si}	−21	+13	—	+28
KCl	ΔH^0_{Si}	−27	−29	—	+ 0.4
	ΔS^0_{Si}	−17	+17	—	+21
$MgCl_2$	ΔH^0_{Si}	−29	−30	—	+ 2.1
	ΔS^0_{Si}	−21	+17	—	+42
mean	ΔH^0_{Si}	−28	−29	−27	—
	ΔS^0_{Si}	−20	+16	+18	—

The data given in Table 2 were employed in conjunction with Equation (21) and the van't Hoff equation [Eq. (5)] to calculate the dependence of the apparent binding enthalpies ΔH^0_S and entropies ΔS^0_S on the competitor concentration C_S.[14] The calculated curves for the E/DNA system are shown in Figures 6 and 7. There is good agreement between the experimental values and the theoretical curves over the whole range of concentrations; this once again confirms the usefulness of the described equilibrium model.

Table 1. Binding constants K_{S1}, K^*_{S2}, K_{S2} and K_{S3} [M^{-1}] for the E/DNA system and the competitor salts NaCl, KCl, $MgCl_2$; $T=298$ K [14].

Competitor	K_{S1}	K^*_{S2}	K_{S2}	K_{S3}
NaCl	1.0×10^4	6.2×10^5	—	22
KCl	1.1×10^4	6.5×10^5	—	19
$MgCl_2$	1.2×10^4	7.0×10^5	—	350
mean	1.1×10^4	6.6×10^5	5.6×10^5	—

6. The Noncompetitively Bound Dye Cations Intercalate

The binding constants K_{S1} and K_{S2} for the noncompetitive and competitive binding of ethidium cations to DNA differ by more than one order of magnitude (Table 1, $K_{S1} \ll K_{S2}$). This is also found to be the case for other dyes (Table 3). The intercalated molecules are largely screened off from their surroundings by the neighboring DNA base pairs and the anionic phosphodiester residues together with their bound counterions. Accordingly, changes in the competitor concentration should only have a slight effect on their binding. It therefore seems reasonable to assign the noncompetitive binding with its smaller binding constant K_{S1} to the intercalated dye cations. However, the intercalated molecules would then be much more weakly bound than is customarily assumed to be the case. In order to clarify this discrepancy we used optical polarization to study the geometry of the noncompetitive binding of ethidium cations to DNA.

Many authors have described experiments in which they determined the orientation of intercalated dye molecules in mechanically aligned dye-DNA preparations by using the absorption of linearly polarized light (see ref. [17]). Different methods are available for mechanically aligning high-molecular-weight dye-DNA preparations, such as drawing and spinning fibers and films, drawing polyvinyl alcohol foils containing nucleic acid, and flow orientation of solutions. In all of these methods it is presumed that the longitudinal axis of the double helix is orientated in the mechanically preferred direction $\vec{k}$.

The dichroic ratio of light absorption serves as a measure of the quality of orientation [Eq. (23)].

$$R = A_{\parallel}/A_{\perp} \tag{23}$$

$A_{\parallel}$ and $A_{\perp}$ are the absorbances of the dye band of the preparation when the polarizer $\vec{e}_p$ is set parallel and perpendicular to $\vec{k}$, respectively. If the dye molecules are statistically equally distributed, then $A_{\parallel} = A_{\perp}$ and $R = 1$. If alignment is complete, the dichroic ratio of a band that is polarized in or perpendicularly to the preferred direction $\vec{k}$ ($A_{\perp}$ or $A_{\parallel} = 0$, respectively) assumes a limiting value of $R = \infty$ or $R = 0$, respectively. Dyes with a planar chromophore are usually used for intercalation experiments. The transition moment $\vec{m}$ of the long-wavelength dye band then lies in the molecular plane. According to *Lerman*, however, the molecular plane of intercalated dyes is perpendicular to the longitudinal DNA axis. This means that for ideally orientated dye-DNA preparations $\vec{m} \perp \vec{k}$, $A_{\parallel} = 0$, and $R = 0$. Dichroic ratios ranging from 0.25 to 0.50 have been measured for various mechanically orientated dye-DNA preparations (see ref. [17]). These ratios are significantly less than 1, the value for statistical distribution; the dichroic ratio $0 < R < 1$ also indicates intercalation. These figures are not, however, convincing. The experimental dichroic ratio should differ very little from $R = 0$ if the dye molecules are intercalated; the value $0 < R < 1$, on the other hand, is compatible with other molecular arrangements.

In order to obtain unequivocal results we improved the experimental methodology in three respects.[17]

1. In the dye-DNA preparations investigated in earlier studies, the dye was bound both noncompetitively and competitively. Since only the geometry of the noncompetitively bound dye is of interest here, we ensured that the preparations were free of competitively bound molecules by adding a competitor salt. If a suitable preparative procedure is adopted, highly viscous dye-DNA gels can be synthesized from which very fine, excellently orientated fibers can be drawn. These fibers are birefringent—the more so, the better the mechanical orientation. The sites of best orientation for optical polarization measurements can then be selected under the polarization microscope.

2. So far, macroscopically orientated samples have always been employed for investigating linear dichroism. Since it is almost impossible to prevent the microscopic arrangement of these preparations from being nonuniform, all the microscopic states are averaged during measurement. The results obtained are thus poor and R is shifted in the direction of an equal statistical distribution. We therefore performed our measurements on microscopic samples using a microspectrophotometer equipped with a polarizer and an analyzer. The sites of best orientation in the preparation were located with the aid of the birefringence of the dye-DNA fibers and then measured by means of optical polarization.

3. The dye-DNA fibers are dichroic and birefringent. We have developed a formalism that takes the dichroism and birefringence of the sample into consideration and permits the determination of the dichroic ratio R_0, corrected for the birefringence, from the experimental material.

We studied a highly orientated E-DNA fiber as an example.[17] R_0 varies considerably within the preparation, ranging from 0.03 to 0.5. In order to prove intercalation the smallest value, $R_0 = 0.03$, is usually preferred but this is problematic. It is better to characterize the quality of the orientation at the site under investigation using an independent criterion. We used an indirect criterion for selection. It can be assumed that the mechanical orientation of the fiber will be better the finer the preparation. The layer thickness d is directly proportional to an experimentally accessible factor $K = K(d)$.[17] If R_0 is plotted versus $K(d)$, a correlation should be obtained which can be used to determine the limiting value of R_0 in an ideally orientated sample for $K(d) \rightarrow 0$ and thus $d \rightarrow 0$. The demands made on the correlation should naturally not be too high; it depends on the relationship between the layer thickness and the quality of the orientation (i.e., the experimental skill of the preparer), and this is difficult to assess. The correlation for the E-DNA fiber studied is shown in Figure 9 and is better than originally expected. If a straight line is drawn through the points by means of linear regression, extrapolation to $K(d) = 0$ gives the dichroic ratio of an ideal sample as being $R_0 = 0.00$. This is precisely the value that is expected from *Lerman*'s intercalation model. Consequently, we presume that the noncompetitively bound ethidium cations—which are the only ones present according to the preparative method used—do indeed intercalate. The smaller binding constant K_{S1} can then be assigned to the intercalated molecules. It can be assumed that the same applies to other intercalated dyes.

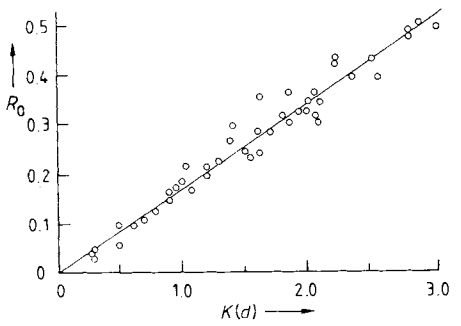

Fig. 9. Correlation between the corrected dichroic ratio R_0 and the layer thickness parameter $K(d)$ for the E/DNA/$MgCl_2$ system [17].

The extrapolation $K(d)\rightarrow 0$ only covers a very small range, namely from the smallest measured value $R_0=0.03$ to $R_0=0.00$. In earlier studies extrapolations were made from $R=0.25$–0.5 to $R=0.0$; the improvement made to the method is obvious.

7. Structural Features of Intercalated and Externally Bound Dye Cations

Intercalated dye cations inside the double helix are largely protected against the action of competitors. The competitively bound molecules can, in contrast, be displaced by competitor cations. These molecules are apparently bound further outward on the DNA. This external binding should not, however, be regarded as consisting of electrostatic 1 : 1 complexes between the dye cations and the anionic DNA phosphodiester groups. Such complexes are indeed known and have already been described by *Feulgen*[44] but they are found at high concentration ratios C_D/C_N and are usually poorly soluble, $n=1$ and $r\approx 1$. Our experiments, however, were performed at $C_D/C_N \ll 1$ ($r \ll 1$). According to our investigations, the binding parameters for noncompetitive and competitive binding are approximately the same ($n_1=n_2=n$). For the ethidium derivatives studied $n=0.21$, and for the acridine derivatives $n=0.17$. External binding in which $n\approx 0.2$ is thus a separate type of binding which can be experimentally distinguished from the 1 : 1 complex where $n=1$.

External binding in which $n_1=n_2$ also displays one of the features of intercalation. Competitive binding is perhaps a precursor of intercalation in which, for example, the bound molecules are only partially inserted between the DNA base pairs. It is noteworthy in this context that *Gursky*[45] and *Peacocke* et al.[24,46] have already proposed other binding geometries for DNA-bound dye cations that differ from the classical intercalation model.[3] The hypothesis that several types of binding with different geometries may occur when r is small is therefore by no means unreasonable. Studies still have to be performed on the geometries of external or pre-intercalative binding.

Intercalation and external binding take place independently of one another and only interfere slightly with one another in the region of sufficiently small r values, which we have limited ourselves to. The Scatchard isotherm [Eq. (20)] can thus be formally divided into two additive components when $n_1=n_2=n$, namely, $K_{S1}(n-r)$ and $K^*_{S2}(n-r)/(1+K_{S3}C_M)$, which are related to intercalation and external binding, respectively. The binding parameter n will not be discussed in more detail on account of the difficulties described in Section 4. The relationship $n_1=n_2=n$ should be regarded here as an experimental finding.

Comparative study of the binding constants K_{S1}, K_{S2}, and K_{S3} of a series of systematically modified dyes provides further insight into intercalation and external binding (cf. Scheme 1). The molecules were investigated under comparable experimental conditions and the binding constants were determined with the aid of the model already described (cf. Table 3).[14–16, 18, 19]

Table 3. Binding constants K_{S1}, K_{S2}, and K_{S3} [M^{-1}] and equilibrium constants K_{S4} for systems consisting of a dye D, DNA, and a competitor salt S; $T=298$ K.

D	K_{S1}	K_{S2}	S	K_{S3}	K_{S4}
E [14]	1.1×10^4	5.6×10^5	NaCl	22	2.5×10^4
			$MgCl_2$	350	1.6×10^3
DPPH [15]	0.9×10^4	7.5×10^5	NaCl	25	3.0×10^4
			$MgCl_2$	380	2.0×10^3
AEPP [15]	0.8×10^4	3×10^5	NaCl	30	1×10^4
BH [19]	0.9×10^4	1.0×10^6	NaCl	33	3.0×10^4
AF [18]	4.2×10^4	1.0×10^6	NaCl	30	3.3×10^4
AO [18]	3.0×10^4	7.0×10^5	NaCl	24	2.9×10^4
EPP [15]	≈ 0	5×10^4	NaCl	30	2×10^3
TME [16]	≈ 0	1.6×10^5	NaCl	30	5.3×10^3
TMAF [18]	≈ 0	3.0×10^5	NaCl	25	1.2×10^4
DPP [15]	≈ 0	≈ 0			
B [19]	≈ 0	≈ 0			

The significance of electrostatic interactions, hydrogen bonds, and hydrophobic interactions in the binding of dye molecules to DNA was noted very early.[2, 3, 10, 12] On the basis of our studies, dye molecules can be divided into three groups (see Scheme 1 on p. 117).

1. Dyes that both intercalate and are bound externally (E, AEPP, DPPH, BH, AF, AO). These dyes are cations and contain NH_2, NH, and OH groups that can act as proton donors for hydrogen bonds formed between the dye and the DNA. The electron donor for the hydrogen bond is very likely the DNA phosphodiester residue. $K_{S1} \ll K_{S2}$ is valid for all molecules. The intercalation binding constant is much smaller than the external binding constant. The binding constants K_{S1} and K_{S2} of the various molecules only differ slightly from one another: $K_{S1}=1\times10^4$–4×10^4 M^{-1}, $K_{S2}=4\times10^5$–1×10^6 M^{-1}.

2. Dyes that are bound externally but do not intercalate (EPP, TME, TMAF). These dyes are cations and do not contain any functional groups that can act as proton donors for hydrogen bonds formed between the dye and the DNA. The bound molecules are displaced from the DNA by competitor salts. Intercalated molecules cannot be detected within the experimental range of error ($K_{S1}\approx 0$). The binding constant for external binding varies between the limits $K_{S2}=5\times10^4$ and 3×10^5 M^{-1}, and is less than the values found for the parent compounds E and AF. The dyes belonging to group 2 show that external binding is a separate type of binding from intercalation.

3. Dyes that neither intercalate nor undergo external binding (DPP, B). These molecules are electrically neutral

and contain functional groups that can form hydrogen bonds with DNA. Binding to DNA has not, however, so far been demonstrated experimentally ($K_{S1} \approx 0$, $K_{S2} \approx 0$). This cannot be due to steric hindrance because protonation produces the dye cations DPPH and BH, which are capable of intercalation and external binding.

The binding constant K_{S3} for the binding of competitor cations to DNA only varies within a narrow range for the various dyes, which is determined by the experimental accuracy and the approximations made in the formalism. $K_{S3} = 2 \times 10^1$–$3 \times 10^1\ M^{-1}$ is found for the competitor salt NaCl and $4 \times 10^2\ M^{-1}$ for $MgCl_2$. As expected, divalent magnesium is a stronger competitor than monovalent sodium.

The equilibrium constants K_{S4} [Eq. (17)] for the exchange between the dye and competitor (cations D and M, respectively) at the DNA are also listed in Table 3. K_{S4} for the commonly used competitor salt NaCl is of the same order of magnitude as the binding constant K_{S1} of intercalation. This could be one of the reasons why it has not so far been possible to clearly distinguish between intercalation and external binding in the region of small r values.

Comparison of the binding constants K_{S1} and K_{S2} given in Table 3 shows that the most important binding component for intercalation and external binding is electrostatic interaction that is supplemented by hydrogen bonds (group 1). If hydrogen bonds cannot be formed, only weak external binding is observed (group 2). If electrostatic interaction is impossible, binding does not take place even if the molecule is capable of forming hydrogen bonds (group 3). When compared with electrostatic interactions, both hydrophobic interactions and hydrogen bond formation appear to be of minor significance. If hydrophobic interactions were predominant, they would force DPP and B to bind to DNA. Both molecules should be more strongly hydrophobic than the DPPH or BH cations, which are formed on protonation of DPP and B and readily bind to DNA. Nevertheless, hydrophobic interactions and hydrogen bonds are involved in the binding process (Section 8).

Discussion of the binding constant gives an overall, uniform impression of the interaction contributions that result in intercalation and external binding. It must not be forgotten, however, that we have studied simple molecules whose binding can be approximately described by a simple model. In the case of more complicated molecules, resort must be made to more complicated theories. Complications can be expected even for proflavine (PF), a classical, intercalating acridine dye. PF exhibits structural features that are similar to those of acriflavine (AF) and acridine orange (AO), namely, two NH_2 groups in positions 3 and 6 and a NH group in position 10 (Scheme 1). The latter is formed by protonation of the strongly basic molecule at the aza nitrogen atom. In AF and AO, hydrogen bonds are involved in intercalation and external binding. The related molecule tetramethylacriflavine (TMAF) can be derived from AF or AO by replacing the NH_2 or NH groups by $N(CH_3)_2$ or NCH_3 groups, respectively, and is incapable of forming hydrogen bonds; it does not intercalate and only undergoes weak external binding. On account of the different positions of the NH_2 and NH groups in AF and AO, it can be assumed that the binding geometries of these molecules to DNA differ. PF combines the structural features of AF and AO. It is therefore conceivable that different intercalated and externally bound molecular species are formed when PF is bound to long-chain DNA; these differ with respect to their geometries and thermodynamic parameters. Further investigations are still required.[47]

8. The Thermodynamic Disadvantage of Intercalation compared with External Binding

The binding constants given in Table 3 show that in the region of small r values intercalation is less favorable than external binding ($K_{S1} \ll K_{S2}$). This finding is surprising and contradicts normal expectations. In order to obtain a more accurate picture of the binding conditions we determined the binding enthalpies ΔH^0_{Si} and entropies ΔS^0_{Si} ($i = 1$–3) of E, AF, AO, and TMAF (Table 4).[14, 18] The experimental difficulties encountered in these measurements and the consequent errors, especially in the case of the binding entropies, have already been referred to in Section 2. The values are, however, sufficiently accurate for the purposes of the following qualitative discussion.

Table 4. Binding enthalpies ΔH^0_{Si} [kJ mol^{-1}] and binding entropies ΔS^0_{Si} [J K^{-1} mol^{-1}] of binding types $i = 1$–3 for systems consisting of a dye D, DNA, and a competitor salt S.

D	ΔH^0_{S1}	ΔH^0_{S2}	ΔS^0_{S1}	ΔS^0_{S2}	S	ΔH^0_{S3}	ΔS^0_{S3}
E [14]	−28	−27	−20	+18	KCl	+0.4	+21
					NaCl	+1.7	+28
					$MgCl_2$	+2.1	+42
AF [18]	−26	−26	− 2	+28	NaCl	≈0	+29
AO [18]	−30	−28	−15	+20	NaCl	≈0	+23
TMAF [18]	—	−15	—	+54	—	[a]	[a]

[a] Not determined experimentally [18].

The binding enthalpies ΔH^0_{S1} and ΔH^0_{S2} for the intercalation and external binding of E, AF, and AO to DNA are negative and are the same within the limits of error ($\Delta H^0_{S1} = \Delta H^0_{S2} < 1$). They scarcely differ for the different dyes. The differences between the binding constants K_{S1} and K_{S2} can thus be attributed to the binding entropy. There is an increase in entropy when external binding occurs ($\Delta S^0_{S2} > 0$), but in the case of intercalation the entropy change is either negative (E, AO) or almost zero (AF). In all cases, $\Delta S^0_{S1} \ll \Delta S^0_{S2}$. Since a gain in entropy is thermodynamically favorable, external binding dominates over intercalation ($K_{S2} \gg K_{S1}$).

A negative binding enthalpy ΔH^0_{S2} and a positive binding entropy ΔS^0_{S2} are also observed in the external binding of TMAF to DNA; both of these conditions are thermodynamically favorable. The enthalpy change is, however, considerably smaller and the entropy change considerably larger than the corresponding values found for the external binding of E, AF, or AO to DNA.

The binding enthalpies of all competitor cations are virtually zero ($\Delta H^0_{S3} \approx 0$). Binding is possible as a result of the thermodynamically favorable increase in entropy ($\Delta S^0_{S3} > 0$); it is thus an entropic effect. The binding entropy depends within the limits of error on the competitor cation but not on the dye.

The values for the binding enthalpies and entropies of the competitor cations, ΔH^0_{S3} and ΔS^0_{S3}, respectively, are typical of hydrophobic interactions. Magnesium, sodium, and potassium ions are so-called structure-forming ions; $Mg^{2\oplus}$ is stronger than $Na^{\oplus}$, which in turn is stronger than $K^{\oplus}$.[48,49] The water molecules in the hydration shells of structure-forming ions are more tightly and rigidly bound than those in the surrounding bulk water. This structure formation produces a thermodynamically unfavorable fall in entropy. When competitor cations are bound to DNA, water molecules must be transferred from the hydration shell to the bulk water for steric reasons. The necessary energy can be supplied from the electrostatic interaction energy. The binding enthalpy of the competitor cations is therefore not negative but virtually zero ($\Delta H^0_{S3} \approx 0$). The transferred water molecules, on the other hand, gain degrees of freedom of motion; the gain is the larger, the more rigidly and tightly the molecules were originally bound. The water molecules remaining in the hydration shell also gain degrees of freedom of motion as partial charge compensation occurs during formation of ion pairs between the competitor cation and the anionic binding site of the DNA. The net gain in degrees of freedom of motion is responsible for a thermodynamically more favorable increase in entropy, which more than compensates for the entropy decrease due to the immobilization of the bound ions. This gain in entropy ($\Delta S^0_{S3} > 0$) is the driving force for binding cations as a result of hydrophobic interactions and, as is to be expected, increases in the direction of increasing structure formation ($K^{\oplus} < Na^{\oplus} < Mg^{2\oplus}$, Table 4).

Dye cations are also structure-forming ions.[14] Unlike the small metal cations, water molecules are more loosely bound to the large organic molecules. In the case of TMAF, less energy is therefore required to transfer a water molecule from the hydration shell of the dye cation to the bulk water; the overall energy balance remains negative ($\Delta H^0_{S2} < 0$). The gain in entropy ($\Delta S^0_{S2} > 0$) is once again characteristic of a hydrophobic interaction. It is especially large for the external binding of TMAF on account of the five methyl groups of the molecule.

The energy balance for the external binding of E, AF, and AO is more negative than for TMAF because additional hydrogen bonds are formed between the dye and the DNA ($\Delta H^0_{S2} < 0$). Hydrophobic interactions again result in an increase of entropy ($\Delta S^0_{S2} > 0$).

The binding enthalpies for intercalation and external binding are practically the same ($\Delta H^0_{S1} \approx \Delta H^0_{S2}$). In both types of binding the molecules apparently endeavor to saturate the valences at their disposal in the same way. It is thus understandable that the absorption spectra of the intercalated and externally bound dye cations scarcely differ. The spectral changes are virtually identical for both types of binding.

The finding that $\Delta S^0_{S1} \ll \Delta S^0_{S2}$ is surprising. It must, however, be appreciated that the double helix stiffens on intercalation[3] and that the loss of degrees of freedom of motion of both the DNA and the intercalated dye is responsible for a decrease in entropy when compared with external binding. In intercalation this thermodynamically unfavorable loss of entropy must be offset by a correspondingly large enthalpy decrease.

The binding entropy plays a critical role in the binding of dye and competitor cations (D and M, respectively) to DNA. According to Equation (13), the method used to count the binding sites affects the binding entropy but not the binding enthalpy [Eq. (12)]. The magnitude of this effect can be estimated as follows. Application of Equation (13) with $n_1 = n_2 = n = p_i/q_i$ (i = 1-3) gives Equation (24).

$$\Delta S^0_{Zi} = \Delta S^0_{Si} - R \ln q_i \tag{24}$$

In the case of intercalation it can be assumed that on an average each base pair provides one potential binding site; therefore, $p_1 = 1/2$ and $q_1 = 1/2n$. If we presume that each DNA phosphodiester group represents a potential binding site for the external binding of D or M, then $p_{2,3} = 1$ and $q_{2,3} = 1/n$. In the case of the ethidium and acridine dyes studied, $n = 0.21$ (0.17), $R \ln q_1 = 7$ (9), and $R \ln q_{2,3} = 13$ (15) $JK^{-1}\,mol^{-1}$ (the values for the acridine dyes are given in parentheses). The ΔS^0_{Zi} values are on the whole less than the ΔS^0_{Si} values. Although the binding entropies change, our comparative qualitative discussion is still valid. The binding constants, enthalpies, and entropies can thus be understandably interpreted within a uniform framework.

9. Biological and Pharmacological Aspects of Dye Binding

According to our studies, the binding constant for intercalation is much smaller than that for external binding ($K_{S1} \ll K_{S2}$). Intercalation is therefore less thermodynamically favorable in vitro than external binding. This difference between the binding constants is a result of the binding entropies ($\Delta S^0_{S1} \ll \Delta S^0_{S2}$) since the enthalpies of the two types of binding are almost equal ($\Delta H^0_{S1} \approx \Delta H^0_{S2}$). The living cell contains a complex mixture of inorganic salts. Physiological saline is a simple equivalent for these salts; its NaCl concentration is $C_S \approx 0.15$ M. According to Equation (21) (Fig. 3), the apparent binding constant K_S drops markedly in the region of small C_S values as the salt concentration increases. The competitively bound molecules (type 2) are already largely displaced at $C_S = 0.15$ M, whereas the noncompetitively bound, intercalated molecules (type 1) are not affected by the action of the competitor. It can therefore be estimated that, in vivo, either intercalation dominates over external binding ($r_1 > r_2$) or the contributions of the two types of binding are comparable ($r_1 \approx r_2$).

Acridine and ethidium derivatives are mutagenic;[2,3,50] they must therefore enter the cell and interact with DNA. The uptake and transport of substances in living cells are, however, very complex, selective processes. The question therefore arises as to whether the biological and pharmacological actions of these substances can solely be attributed to their binding to DNA or whether binding to DNA is a side reaction, the bulk of the dye molecule perhaps acting in a different way. Some experiments will therefore finally be described in which the sites of preferred dye accumulation in the living cell are visualized directly.

The acridine and ethidium derivatives discussed in this article are highly fluorescent dyes (fluorochromes) and can

be detected very sensitively inside the cell with the fluorescence microscope. The low dye concentrations that can be detected by fluorescence microscopy are generally not toxic or are only of limited toxicity for the cell. This provides a way of following the route taken by the fluorochrome in the living cell and of identifying the site of dye accumulation.

The cell materials used in our model experiments are tissue cultures of HeLa cells and LM cells (mouse fibroblasts) which are relatively easy to obtain experimentally and are of a consistent quality. Tissue cultures have the advantage that the cells grow in a monolayer on a support (coverslips) where they can easily be observed with a microscope. The cells are incubated together with the support in a dye solution of concentration C_D at 37 °C; after incubating for a period τ_I, the cells are rinsed in Hank's solution to remove excess dye and then examined under the fluorescence microscope.

Fixed cells behave totally differently from living cells after treatment with fluorochromes. We will first consider a tissue culture of ethanol-fixed HeLa cells that were stained with the fluorochrome AO under appropriate conditions. The cell nucleus fluoresces intense green-yellow, while the cytoplasm and nucleoli are an intense orange. It is known from spectroscopic studies that AO undergoes association in aqueous solution as its concentration increases;[51,52] this is accompanied by changes in the absorption and fluorescence spectra. The monomers likewise fluoresce green-yellow, whereas the dimers fluoresce orange. Accordingly, AO is present in the nucleus in its monomeric form but occurs as a dimer in the cytoplasm and nucleoli. The substrates to which the dye binds in the cell are also known from enzymatic digestion experiments—they are the nucleic acids DNA and RNA. If the nuclear DNA or the RNA in the cytoplasm and nucleoli is degraded, the associated staining disappears. The dye can thus be employed as an analytical reagent for detecting DNA and RNA. *Von Bertalanffy* et al.[53] have developed the fluorochrome staining of cytological material with AO for the diagnosis of malignant tumors. The same fluorescence microscopy pictures, however, are also shown by other cells that divide rapidly.

Green fluorescent nuclei are also observed after vital staining of HeLa cells with the fluorochrome AO. The fluorescence is, however, relatively weak. The chromosomes of cells undergoing mitosis are stained by the fluorochrome. It therefore seems reasonable to assume that the dye is bound to the DNA localized in the nucleus and the chromosomes. It can be demonstrated that the cell functions are not significantly affected by vital staining.[54] The vital staining of chromosomes with the basic acridine dye 3-amino-6-methoxy-9(2-hydroxyethylamino)acridine, which we have recently investigated, is especially impressive (Fig. 10).[55] The cells can tolerate high fluorochrome concentrations and long incubation periods without a detectable fall in their respiratory activity.

Vital fluorochrome staining of the nuclear chromatin, however, is a rare exception. The nuclei of living cells usually exhibit virtually no fluorescence, a property that is regarded as a criterion for assessing tissue cultures as being healthy. Under suitable conditions, however, numerous

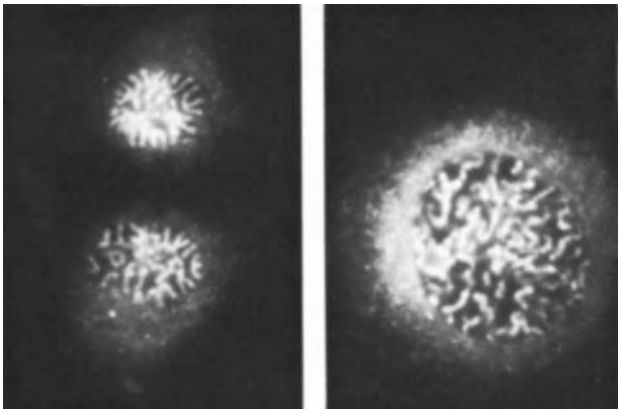

Fig. 10. Fluorescent chromosomes in mitotic LM cells after vital staining with 3-amino-6-methoxy-9(2-hydroxyethylamino)acridine. Dye concentration $C_D = 1 \times 10^{-3}$ M, incubation period $\tau_I = 45$ min, magnification $\times 1000$ [55]. Left: Telophase. Right: Prophase.

small, intensely fluorescent organelles can be observed in the cytoplasm which may accumulate near the nucleus. The organelles that accumulate the dye are the lysosomes.[56,57] When AO is used for vital staining, the cytoplasm is studded with orange-fluorescing lysosomes. Many other dyes are also accumulated in the lysosomes of living cells, such as the basic fluorochrome 3-dimethylamino-6-methoxyacridine, which is closely related to AO (Fig. 11). In fixed cells the same dye produces Bertalanffy-like fluorochrome staining of DNA in the nucleus and of RNA in the nucleolus and cytoplasm.[58]

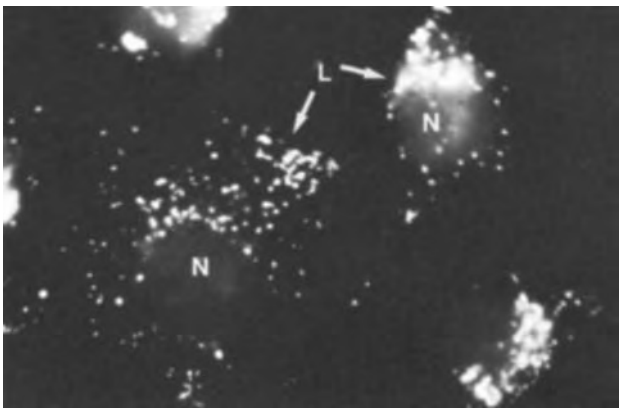

Fig. 11. Fluorescent lysosomes L in the cytoplasm of LM cells after vital staining with 3-dimethylamino-6-methoxyacridine. Dye concentration $C_D = 1 \times 10^{-5}$ M, incubation period $\tau_I = 4.5$ h, magnification $\times 1000$. The intensely fluorescing lysosomes are either distributed in the cytoplasm or accumulated near the nucleus. The cell nucleus N fluoresces very weakly and the cytoplasm scarcely fluoresces at all. The cytoplasm is therefore not observed in fluorescence microscopy [55].

Lysosomes do not contain nucleic acids; they are the digestive organelles of the cell. Their task is to enzymatically cleave substances inside the cell and then direct the cleaved products so that they can be metabolized. Dyes are difficult to digest; indeed, they can be enriched in the lysosomes by an unknown mechanism in such high concentrations that they associate. If the lysosomes cannot store any more dye, the fluorochrome reaches the nucleus, resulting generally in cell death. Cell death can be recognized by

intense fluorescence of the cell nucleus. The dye is very probably bound to the DNA of the nuclear chromatin. Dye accumulation in the lysosomes apparently has a protective function, namely to prevent the dye from interacting with the vitally important nucleic acids.

Small modifications of the molecular structure suffice to produce a completely different response of the cell to the action of a fluorochrome. AO, for example, is a strong base whose nitrogen atom in position 10 is almost completely protonated at pH = 7; the dye is accumulated in the lysosomes as a cation. Alkylation of AO results in the formation of the related 10-alkylacridinium orange cations. Alkyl-AOs—like the parent compound—fluoresce intensely and associate at higher concentrations in an aqueous medium.[59] We studied n-C_mH_{2m+1}-AOs ($m = 1$–9). When $m > 9$, the substances dissolve poorly in water. Methyl-AO behaves similarly to AO when it is used for the vital staining of HeLa or LM cells; dye accumulation in the lysosomes is observed along with a weak fluorescence of the mitochondria. In the case of ethyl-AO, however, the microscopic picture changes drastically; the dye is now preferentially bound to the cell mitochondria.[60] The vital staining of the mitochondria becomes more pronounced as the chain length of the alkyl residue increases (Fig. 12).[61] In the case of nonyl-AO, for example, only fluorescent mitochondria can be recognized under the fluorescence microscope; neither the lysosomes, the nuclear chromatin, nor the cytoplasm are stained by the fluorochrome. Bertalanffy-like staining can be produced with the same dye in fixed cells; the fluorochrome is then bound to the DNA and RNA in the nucleus and cytoplasm.

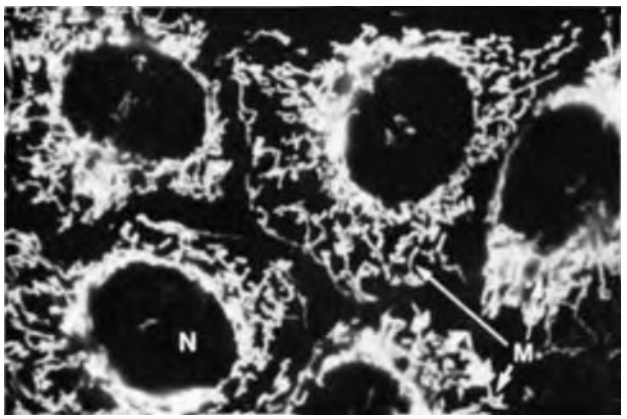

Fig. 12. Fluorescent filamentous mitochondria M in the cytoplasm of HeLa cells after vital staining with 10-n-nonylacridinium orange chloride. Dye concentration $C_D = 5 \times 10^{-7}$ M, incubation period $\tau_I = 10$ min, magnification $\times 1000$. Neither the cell nucleus nor the cytoplasm is observed in fluorescence microscopy [61, 63].

Vital staining of the mitochondria with nonyl-AO is very specific and efficient;[61] it even occurs when the dye concentration of the incubation medium is $C_D = 1 \times 10^{-8}$ M. This concentration is one order of magnitude smaller than the hydrogen ion concentration of pure water. At 5×10^{-7} M the fluorescent mitochondria can already be observed after an incubation period of $\tau_I < 1$ min. When $C_D \geq 1 \times 10^{-7}$ M and $\tau_I = 10$ min, the dye is bound to the mitochondria in such high concentrations that it dimerizes. The mitochondria of cells that are cultured in a dye-free medium after vital staining retain the dye for more than one week.

The entire energy metabolism of the cell takes place in the mitochondria: respiration, the electron transport processes, and the vitally important synthesis of ATP. The majority of the enzymes responsible for oxidative phosphorylation are localized on the internal mitochondrial membranes and the membranes of the cristae. Our investigations indicate that nonyl-AO is bound to these membranes by hydrophobic interactions.[61] The respiratory activity is a measure of the functional capability of the mitochondria. In HeLa cells neither the oxygen consumption nor the mitochondrial ultrastructure is affected up to $C_D \leq 5 \times 10^{-7}$ M and $\tau_I = 10$ min. With higher dye concentrations and longer incubation periods, inhibition of respiration is observed, which is accompanied by ultrastructural changes, especially in the internal mitochondrial membranes and the membranes of the cristae.[61,62] In the terminal stage (5×10^{-6} M and 30–60 min) the hydrophobic dye cations transform the mitochondria into multilamellar liposomes and bizarre myelin bodies. It is remarkable that these dramatic ultrastructural changes can only be seen in the mitochondria under the electron microscope. The other cell membranes (e.g., the nuclear membrane) appear to be resistant to the action of the dye. Binding of the dye to the nuclear membrane has not yet been demonstrated by fluorescence microscopy. Hydrophobic interactions between the dye and the mitochondrial membranes represent one contribution to binding,[61,63] which is, however, apparently supplemented by another mitochondrial-specific component.[61]

Not only alkyl-AOs but also other dyes that are bound to DNA in vitro, such as E, TME, and BH, produce drastic changes in the ultrastructure of the mitochondria.[64–66] TME has the strongest effect and is the most strongly hydrophobic of the ethidium derivatives mentioned. We therefore presume that the ultrastructural changes may be due to the hydrophobic interactions between the dye and the mitochondrial membranes.

These few examples should suffice to demonstrate that the in vitro binding of acridine and ethidium derivatives to DNA does not allow unequivocal conclusions to be made about the binding and sites of accumulation of the same substance in living cells. The accumulation of dyes in the lysosomes evidently provides the living cell with a mechanism for protecting the nuclear chromatin and prevents the toxic substances from being bound to the DNA. It is still not exactly known under which conditions this mechanism is modified so that the dye is instead bound to the mitochondria. The specific binding of substances to the mitochondrial membranes, where oxidative phosphorylation takes place, is of general interest as it provides a way of directly or indirectly interfering with energy metabolism. Exploitation of this principle for pharmacological purposes should prove to be rewarding.

I am indebted to the Bundesministerium für Forschung und Technologie and the Deutsche Forschungsgemeinschaft for supporting these studies. I am especially grateful to my

co-workers—who are all cited in the list of references—for their enthusiastic efforts and productive discussions.

Resonance Raman Spectroscopy, and Its Application to Inorganic Chemistry

New Analytical Methods (27)

By Robin J. H. Clark* and Trevor J. Dines

Resonance Raman spectra are obtained when the wave number of the exciting radiation is close to, or coincident with, that of an electronic transition of the scattering species. Such spectra are usually characterized by a very large enhancement of the intensities of particular Raman bands, sometimes with the appearance of intense overtone and combination tone progressions. The technique provides detailed information about excited electronic states because it is only the vibrational modes associated with the chromophore that are resonance-Raman active. Additionally, the high sensitivity is such that compounds at concentrations as low as 10^{-6} mol/L may be detected, enabling resonance Raman spectroscopy to be used as an analytical tool and for the study of chromophores in molecules of biological interest.

1. Introduction

The theory and practice of resonance Raman (RR) spectroscopy have both been developed substantially over the past decade to the extent that it is now possible to present a coherent picture of the subject within the confines of a single article. The object of the present review is to do this in a readily comprehendable manner and also to review the applications of the subject within the broad bounds of inorganic chemistry. To this end, Section 2 relates to the theoretical development of the subject, as it now stands. In particular, the relation between normal and RR scattering is developed, as is the nature of A-, B-, C- and D-term scattering, and scattering by both totally symmetric and non-totally symmetric modes. The significance of the depolarization ratio of a Raman band is also outlined, both with respect to vibrational as well as electronic band assignments.

Following a discussion of experimental techniques in Section 3, the results of many studies of inorganic compounds are then reviewed beginning with diatomic species and progressing through increasingly complicated species to metalloporphyrins and related species. In order to achieve conciseness this section has been restricted to RR studies reported since 1977, a comprehensive compilation of the earlier work being available already.[1] The investigations of small molecules (Section 4) have been considered in detail because these have contributed most to the understanding of the RR effect. The discussion of larger molecules (Section 5) has been restricted to a few illustrative examples and the reader is referred to reviews dealing specifically with metal-metal bonded species,[2] mixed-valence molecules,[3,4] and metalloporphyrins.[5] The attention of the reader is also directed elsewhere for reviews of RR studies on semiconductors,[6] electronic Raman scattering,[7] and time-resolved resonance Raman (TR^3) experiments.[8]

Many people have contributed to the development of experimental and theoretical aspects of the subject, notably *Albrecht*,[9-12], *Shorygin*,[13,14] *Behringer*,[15,16] *Peticolas*,[17,18] *Koningstein*,[19-21] *Rousseau* et al.,[22], *Clark*,[1,23,24] *Stewart*,[1,24] *Spiro*,[25-27] *Kiefer*,[28] *Tsuboi*,[29,30] *Mortensen*,[31] *Siebrand* and *Zgierski*,[32] *Barron*,[33,34] *Hong*,[35] and *Heller*.[36,37] Although a variety of different systems of nomenclature have been used to present the subject, that adopted in this review is essentially due to *Clark* and *Dines*.[7,38]

The central feature of interest in RR spectroscopy is the fact that, when the wave number of the exciting line is made to coincide with that of an allowed electronic transition in a molecule, the intensities of certain Raman bands of the scattering molecule are greatly enhanced relative to their off-resonance values. Thus the technique is a much more sensitive one than is normal Raman spectroscopy. Moreover, it proves to be a much more specific technique in the sense that it is solely modes to do with the chromophore in the scattering molecule which can be enhanced at resonance. Thus, information relating to the chemically significant parts of molecules is obtainable by this form of Raman spectroscopy. RR spectroscopy can also be applied to the determination of the displacements of the potential surfaces of excited states relative to that of the ground state, a matter of considerable importance in spectroscopy, photophysics, and photochemistry. The manner in which this may be done is outlined in the following pages.

2. Theory of Resonance Raman Scattering

In this section the theoretical approach that is most commonly used in the interpretation of RR data is outlined, based on the earlier developments of *Albrecht* et al.[9,10] and *Shorygin* et al.[13,14] RR scattering is described, in the energy-frame, in terms of the Kramers-Heisenberg dispersion formula,[39] obtained by second-order perturbation theory. Other approaches that have been described recently include the time correlator theory[36,37] and the optical transform theory.[11,12] These are claimed to be able to

deal more easily with polyatomic molecules in which several modes are RR-active, but this view is not yet generally accepted.

For a Raman transition between two states $|i\rangle$ and $|f\rangle$ of a scattering system, the intensity of light scattered at 90° to the direction of irradiation is given by Equation (1).

$$I_{fi}(\pi/2) = \frac{\pi^2}{\varepsilon_0^2}(\tilde{\nu}_0 \pm \tilde{\nu}_{fi})^4 \mathscr{I}_0 \sum_{\rho,\sigma} [\alpha_{\rho\sigma}]_{fi}[\alpha_{\rho\sigma}]^*_{fi} \quad (1)$$

$\mathscr{I}_0$ is the irradiance of the incident radiation, $\tilde{\nu}_0$ and $\tilde{\nu}_{fi}$ are the wave numbers of the exciting line and of the Raman transition $|f\rangle \leftarrow |i\rangle$, respectively, ε_0 is the permittivity of free space, and $[\alpha_{\rho\sigma}]_{fi}$ is the $\rho\sigma$th element of the transition polarizability tensor [Eqn. (2)].

$$[\alpha_{\rho\sigma}]_{fi} = \frac{1}{hc}\sum_r \left[\frac{[\mu_\rho]_{fr}[\mu_\sigma]_{ri}}{\tilde{\nu}_{ri} - \tilde{\nu}_0 + i\Gamma_r} + \frac{[\mu_\sigma]_{fr}[\mu_\rho]_{ri}}{\tilde{\nu}_{rf} + \tilde{\nu}_0 + i\Gamma_r}\right] \quad (2)$$

In this equation $[\mu_\rho]_{fr}$ is the ρth component of the transition dipole moment associated with the transition $|f\rangle \leftarrow |r\rangle$ and $i\Gamma_r$ is a damping factor, which is related to the lifetime of the state $|r\rangle$. Strictly, the summation is over all states $|r\rangle$ of the system, including $|i\rangle$ and $|f\rangle$, but it has been shown that, for Raman scattering, $|i\rangle$ and $|f\rangle$ may be excluded from the sum.[40] (In the SI system, I is in W, $\mathscr{I}_0$ in W m^{-2}, ε_0 in F m^{-1}, $[\alpha_{\rho\sigma}]_{fi}$ in C V^{-1} m^2 and $[\mu_\rho]_{fr}$ in C m. The use of the unit cm^{-1} for wave number requires that the right-hand side of Equation (2) be multiplied by 10^8.) For vibrational Raman scattering excited far from resonance, the tensor is symmetric, i.e. $\alpha_{\rho\sigma} = \alpha_{\sigma\rho}$, but it may become asymmetric for electronic Raman (ER) and RR scattering.

The nature of the Raman effect is determined by the initial and final eigenstates $|i\rangle$ and $|f\rangle$, and by the proximity of the wave number of the exciting radiation to that of any electronic transition of the system. Clearly, the RR effect occurs when $\tilde{\nu}_0 \approx \tilde{\nu}_{ri}$, resulting in an increase of $[\alpha_{\rho\sigma}]_{fi}$ and consequently an enhancement of the Raman intensity. In order to answer such questions as which Raman bands may undergo enhancement and why overtone progressions are observed in RR spectra it is necessary to probe the dependence of $[\alpha_{\rho\sigma}]_{fi}$ on the properties of excited states by looking closely at Equation (2). As a prelude to such an analysis it is instructive to consider first the case of normal, i.e. non-RR scattering.

2.1. Normal Raman Scattering

The adiabatic Born-Oppenheimer approximation is invoked, in which the vibronic states $|i\rangle$, $|f\rangle$, and $|r\rangle$ are formed by products of the pure vibrational and the pure electronic states. The latter are referred to some fixed positions of the nuclei and are parametrically dependent on the normal coordinates, Q_k, of the molecule.

Assuming that the system is initially and finally in the ground electronic state $|g\rangle$ (i.e. a vibrational Raman transition, for instance, is under consideration), we may write:

$$\begin{aligned} |i\rangle &= |gm\rangle = |g\rangle|m\rangle \\ |f\rangle &= |gn\rangle = |g\rangle|n\rangle \\ |r\rangle &= |ev\rangle = |e\rangle|v\rangle \end{aligned} \quad (3)$$

where $|e\rangle$ represents an excited electronic state and $|m\rangle$, $|n\rangle$, and $|v\rangle$ represent vibrational states of the scattering species. This enables the transition polarizability to be rewritten in the form

$$[\alpha_{\rho\sigma}]_{gn,gm} = \frac{1}{hc}\sum_{ev}\left(\frac{\langle n|[\mu_\rho]_{ge}|v\rangle\langle v|[\mu_\sigma]_{eg}|m\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} + \frac{\langle n|[\mu_\sigma]_{ge}|v\rangle\langle v|[\mu_\rho]_{eg}|m\rangle}{\tilde{\nu}_{ev,gn} + \tilde{\nu}_0 + i\Gamma_{ev}}\right) \quad (4)$$

where $[\mu_\rho]_{ge}$ is the pure electronic transition moment associated with the transition $|g\rangle \leftarrow |e\rangle$. Under the conditions for which the Born-Oppenheimer condition is valid, the dependence of such an electronic transition moment on the k normal coordinates of the system, Q_k, is small. Thus, $[\mu_\rho]_{ge}$ may be expressed as a rapidly converging Taylor series expanded around the equilibrium position:

$$[\mu_\rho]_{ge} = [\mu_\rho]^0_{ge} + \sum_k [\mu_\rho]'_{ge} Q_k + \cdots \quad (5)$$

where $[\mu_\rho]'_{ge} = \partial[\mu_\rho]_{ge}/\partial Q_k$. Higher order terms in this series are, in most cases, negligibly small. A second simplification arises from the Born-Oppenheimer approximation in that the electronic and vibrational parts of the integrals in Equation (4) may be separated, such that, for example

$$\langle n|[\mu_\rho]_{ge}|v\rangle = [\mu_\rho]^0_{ge}\langle n|v\rangle + \sum_k [\mu_\rho]'_{ge}\langle n|Q_k|v\rangle \quad (6)$$

The following approximations may also be made in the ideal limit of excitation far from any region of electronic absorption:

(1) The denominators in the transition polarizability are large and insensitive to the vibrational quantum numbers m, n, and v, such that differences between the various $\tilde{\nu}_{ev,gm}$ and $\tilde{\nu}_{ev,gn}$ may be neglected;
(2) The states $|v\rangle$ represent a complete orthonormal set and the sums over them may be evaluated by invoking the closure theorem, which states that $\sum_v |v\rangle\langle v| = 1$, and arises from the matrix product rule $\sum_j A_{ij} B_{jk} = (AB)_{ik}$;
(3) Since $(\tilde{\nu}_{ev,gm} - \tilde{\nu}_0)$ and $(\tilde{\nu}_{eg,gn} + \tilde{\nu}_0)$ are much larger than the damping factors, $i\Gamma_{ev}$, the latter may be neglected.

With these approximations, and noting that

$$(\tilde{\nu}_e - \tilde{\nu}_0)^{-1} + (\tilde{\nu}_e + \tilde{\nu}_0)^{-1} = 2\tilde{\nu}_e(\tilde{\nu}_e^2 - \tilde{\nu}_0^2)^{-1}$$

the transition polarizability may be recast in the following form:

$$\begin{aligned} [\alpha_{\rho\sigma}]_{gn,gm} = {} & \frac{1}{hc}\sum_e \frac{2\tilde{\nu}_e}{(\tilde{\nu}_e^2 - \tilde{\nu}_0^2)}[\mu_\rho]^0_{ge}[\mu_\sigma]^0_{eg}\langle n|m\rangle \\ & + \frac{1}{hc}\sum_e\sum_k \frac{2\tilde{\nu}_e}{(\tilde{\nu}_e^2 - \tilde{\nu}_0^2)}\{[\mu_\rho]'_{ge}[\mu_\sigma]^0_{eg} + [\mu_\rho]^0_{ge}[\mu_\sigma]'_{eg}\}\langle n|Q_k|m\rangle \\ & + \frac{1}{hc}\sum_e\sum_{k,k'} \frac{2\tilde{\nu}_e}{(\tilde{\nu}_e^2 - \tilde{\nu}_0^2)}[\mu_\rho]'_{ge}[\mu_\sigma]'_{eg}\langle n|Q_k Q_{k'}|m\rangle \end{aligned} \quad (7)$$

Because n and m are both vibrational quantum numbers of the ground electronic state, the overlap integral

$\langle n|m\rangle = \delta_{nm}$. Thus, the first term in Equation (7) contributes only to Rayleigh scattering. The integral $\langle n|Q_k|m\rangle$ is non-zero if $n = m \pm 1$ and has the value $[h(m+1)/8\pi^2 c\tilde{\nu}_k]^{1/2}$ for $n = m+1$ and $[hm/8\pi^2 c\tilde{\nu}_k]^{1/2}$ for $n = m-1$. It follows that the second term in Equation (7) is responsible for both the Stokes and the anti-Stokes Raman scattering for vibrational fundamentals. The third term gives rise to first overtones ($k = k'$) and binary combination tones ($k \neq k'$), but is usually so small that bands so attributed are very weak in normal Raman scattering. It is obvious that the magnitude of $[\alpha_{\rho\sigma}]_{gn,gm}$ is unaffected by transposition of the coordinate suffixes ρ and σ. Hence the transition polarizability tensor is symmetric about the leading diagonal and has only six independent components. It may be regarded essentially as a ground state property of the system.

2.2. Resonance Raman Scattering

In the usual treatment of RR scattering the adiabatic Born-Oppenheimer approximation is assumed to be valid, but the other assumptions associated with normal Raman scattering are assumed no longer to apply. That is to say:

(1) The v-dependence of the denominators in Equation (4) cannot be neglected, so that the closure theorem may not be invoked;
(2) the wave-number difference $(\tilde{\nu}_{ev,gm} - \tilde{\nu}_0)$ is comparable with the damping factor, $i\Gamma_{ev}$, so that the latter may not be neglected;
(3) the first-order term $\partial[\mu_\rho]_{ge}/\partial Q_k = [\mu_\rho]'_{ge}$ in the Taylor expansion of Equation (5) needs to be defined explicitly.

In the Herzberg-Teller[41] perturbation description of vibronic coupling the derivative of the transition moment arises because the variation in the Hamiltonian with respect to the normal coordinate Q_k can mix the state $|e\rangle$ with other states $|s\rangle$ of the appropriate symmetry, viz.

$$[\mu_\rho]_{ge} = [\mu_\rho]^0_{ge} + \sum_s \sum_k [\mu_\rho]^0_{gs} \frac{h^k_{es}}{\Delta\tilde{\nu}_{es}} Q_k + \cdots \tag{8}$$

$$h^k_{es} = \langle e|\partial H/\partial Q_k|s\rangle_{Q_k=0}$$

where $|s\rangle$ represents another excited state. As before, higher order terms are generally negligible.

The term $h^k_{es}/\Delta\tilde{\nu}_{es}$ is a measure of the strength of vibronic coupling of the states $|e\rangle$ and $|s\rangle$ via the normal coordinate Q_k. The Herzberg-Teller expansion is only valid for weak vibronic coupling, i.e. within the framework of the adiabatic Born-Oppenheimer approximation. It is not applicable to cases in which there is strong vibronic coupling, i.e. when $\Delta\tilde{\nu}_{es}$ is of the order of vibrational wave numbers (in which case non-adiabatic coupling is important) or zero (such as for a degenerate state, in which Jahn-Teller (JT) coupling occurs).

Some considerable simplification of the transition polarizability is made possible for excitation under resonance conditions. This is because, as $\tilde{\nu}_0$ approaches some particular transition wave number $\tilde{\nu}_{ev,gm}$, the relevant excited state will dominate the sum over states. It is therefore generally sufficient to consider only one, or at most, two electronic manifolds. Also, the non-resonant part of the transition polarizability may be neglected at resonance. Applying these considerations to Equation (4) it is evident that there are now four contributions (the so-called A, B, C, and D-terms) to the transition polarizability, viz.

$$[\alpha_{\rho\sigma}]_{gn,gm} = A + B + C + D \tag{9}$$

where

$$A = \frac{1}{hc}[\mu_\rho]^0_{ge}[\mu_\sigma]^0_{eg} \sum_v \frac{\langle n_g|v_e\rangle\langle v_e|m_g\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} \tag{10}$$

$$B = \frac{1}{h^2c^2} \sum_{s\neq e} [\mu_\rho]^0_{gs}[\mu_\sigma]^0_{eg} \frac{h^k_{se}}{\Delta\tilde{\nu}_{se}} \sum_v \frac{\langle n_g|Q_k|v_e\rangle\langle v_e|m_g\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} + \frac{1}{h^2c^2} \sum_{s\neq e} [\mu_\rho]^0_{ge}[\mu_\sigma]^0_{sg} \frac{h^k_{es}}{\Delta\tilde{\nu}_{es}} \sum_v \frac{\langle n_g|v_e\rangle\langle v_e|Q_k|m_g\rangle}{\tilde{\nu}_{eg,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} \tag{11}$$

$$C = \frac{1}{h^2c^2} \sum_{s\neq g} [\mu_\rho]^0_{se}[\mu_\sigma]^0_{eg} \frac{h^k_{gs}}{\Delta\tilde{\nu}_{gs}} \sum_v \frac{\langle n_g|Q_k|v_e\rangle\langle v_e|m_g\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} + \frac{1}{h^2c^2} \sum_{s\neq g} [\mu_\rho]^0_{ge}[\mu_\sigma]^0_{es} \frac{h^k_{sg}}{\Delta\tilde{\nu}_{sg}} \sum_v \frac{\langle n_g|v_e\rangle\langle v_e|Q_k|m_g\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} \tag{12}$$

$$D = \frac{1}{h^3c^3} \sum_{s,s'\neq e} [\mu_\rho]^0_{gs}[\mu_\sigma]^0_{s'g} \frac{h^k_{es}h^{k'}_{es'}}{\Delta\tilde{\nu}_{es}\Delta\tilde{\nu}_{es'}} \sum_v \frac{\langle n_g|Q_k|v_e\rangle\langle v_e|Q_{k'}|m_g\rangle}{\tilde{\nu}_{ev,gm} - \tilde{\nu}_0 + i\Gamma_{ev}} \tag{13}$$

In these equations the vibrational quantum numbers n, v and m have been subscripted to indicate the electronic state to which they refer, all other terms having been defined previously. We now look closely at each of these four contributions.

2.2.1. *A-term Resonance Raman Scattering*

For the A-term contribution to the transition polarizability to be non-zero it is necessary that the following two conditions are fulfilled:

(1) The transition dipole moments $[\mu_\rho]^0_{ge}$ and $[\mu_\sigma]^0_{eg}$ must be non-zero;
(2) The products of vibrational overlap integrals (Franck-Condon factors), $\langle n_g|v_e\rangle\langle v_e|m_g\rangle$, must be non-zero for at least some values of v.

The first of these two conditions dictates that the resonant electronic transition should be electric-dipole-allowed. Thus the technique requires excitation within the contour of an intense absorption band, such as one of charge transfer (CT) or π-π^* type. Excitation within the contour of a weak band, e.g. one resulting from a ligand-field or spin-forbidden transition, would not be expected to produce a significant A-term. The restrictions imposed by the second condition are less obvious and therefore warrant a more detailed discussion.

Vibrational overlap integrals of the type $\langle n_g|v_e\rangle$ are zero (except for the case $n = v$) unless the vibrational wave functions χ_n and χ_v are non-orthogonal. For any one vibrational mode ν_k of a molecule non-orthogonality of these wave functions will subsist if, between the ground state and excited states, there is either (a) a difference of vibrational wave number ($\tilde{\nu}^e_k \neq \tilde{\nu}^g_k$), i.e. a change in shape of the

potential energy surface, or (b) a displacement of the potential energy minimum along the normal coordinate, ΔQ_k. Symmetry arguments dictate that such a displacement may only occur for totally symmetric modes unless the molecular symmetry is altered in the excited state. If the molecular symmetry is the same in the ground and excited states, then geometric changes are confined to combinations of alterations in bond lengths and bond angles that, overall, do not change the molecular symmetry. Thus, the geometric changes are confined to those along totally symmetric symmetry coordinates which, of course, relate only to displacements along totally symmetric normal coordinates. However, if a change of molecular symmetry accompanies the electronic transition, this restriction no longer applies. The term totally symmetric then applies not to the ground state point group but to the subgroup formed by the operations that are common to both the ground- and excited-state point groups (the common group).

As shown in Figure 1, four cases (a)—(d) may be distinguished: It is obvious that in case (a) the orthogonality of the wave functions would not be removed and in such a situation there would be no A-term for any vibrational mode. Case (b) produces non-zero overlap integrals for both totally and non-totally symmetric modes, whereas cases (c) and (d) only apply to totally symmetric modes. In practice it is found that a significant change of vibrational wave number usually occurs only where there is a displacement of the potential energy minimum, hence case (d) is the most important. Dependent on the magnitude of ΔQ, the Franck-Condon factors, $\langle n_g|v_e\rangle\langle v_e|m_g\rangle$, may have appreciable size for up to several quanta of n. Thus the A-term can give rise to overtones of intensity comparable to that of the fundamental.

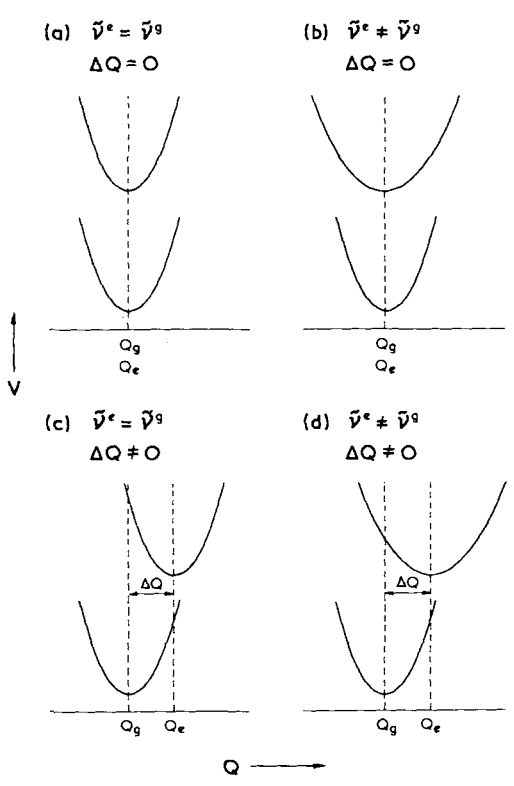

Fig. 1. Potential energy diagrams for the ground and resonant excited states, showing the four cases (a)—(d) (see text).

2.2.2. B-Term Resonance Raman Scattering

The B-term contribution to the transition polarizability arises from the vibronic coupling of the resonant state to other excited states. Its magnitude is dependent on the vibronic coupling integral h^k_{es}, on the products of vibrational transition integrals and overlap integrals, e.g. $\langle n_g|Q_k|v_e\rangle\langle v_e|m_g\rangle$, on the transition dipole moments $[\mu_\rho]^0_{ge}$ and $[\mu_\sigma]^0_{sg}$, and on the energy difference between the coupled states, $hc(\tilde{\nu}_s - \tilde{\nu}_e)$. For the B-term to be non-zero it is a requirement that both the resonant transition and the transition $|s\rangle \leftarrow |g\rangle$ should be electric-dipole-allowed. Because of the additional factor $h^k_{es}(\nu_s - \nu_e)^{-1}$ in the equation, the B-term is usually very much smaller than the A-term. However, if the resonant transition gives rise to zero or very small displacements ΔQ_k, then only the diagonal overlap integrals (i.e. $n = v$, $v = m$) are non-vanishing and the A-term becomes zero. In the harmonic oscillator approximation $\langle n_g|Q_k|v_e\rangle$ and $\langle v_e|Q_k|m_g\rangle$ are non-zero for $n = v \pm 1$ and $v = m \pm 1$. Thus, under the conditions for which the B-term is of importance (diagonal overlap integrals) the products $\langle n_g|Q_k|v_e\rangle\langle v_e|m_g\rangle$ and $\langle n_g|v_e\rangle\langle v_e|Q_k|m_g\rangle$ are restricted to the cases where $n = m \pm 1$ and, in the low temperature limit ($m = 0$), only two such products would contribute, viz. $\langle 1_g|Q_k|0_e\rangle\langle 0_e|0_g\rangle$ and $\langle 1_g|1_e\rangle\langle 1_e|Q_k|0_g\rangle$. It is usually the case that coupling to only one other state $|s\rangle$ needs to be considered and the summation may be dropped, giving the following expression for the B-term:

$$B = \frac{1}{h^2c^2}[\mu_\rho]^0_{gs}[\mu_\sigma]^0_{eg}\frac{h^k_{se}}{\Delta\tilde{\nu}_{se}}\left(\frac{\langle 1_g|Q_k|0_e\rangle\langle 0_e|0_g\rangle}{\tilde{\nu}_{e0,g0} - \tilde{\nu}_0 + i\Gamma_{e0}}\right) + \frac{1}{h^2c^2}[\mu_\rho]^0_{ge}[\mu_\sigma]^0_{sg}\frac{h^k_{es}}{\Delta\tilde{\nu}_{es}}\left(\frac{\langle 1_g|1_e\rangle\langle 1_e|Q_k|0_g\rangle}{\tilde{\nu}_{e1,g0} - \tilde{\nu}_0 + i\Gamma_{e1}}\right) \quad (14)$$

Clearly, B-term scattering occurs only for fundamentals ($n = 1$) and the symmetry selection rules are constrained by the symmetries of the states $|e\rangle$ and $|s\rangle$. The vibronic coupling integral h^k_{es} is non-zero if the irreducible representation of Q_k (i.e. Γ_k) is contained in the direct product $\Gamma_e \otimes \Gamma_s$. It follows that B-term activity may be expected for both totally symmetric and non-totally symmetric vibrations, but for the former to be realized it is necessary that $|e\rangle$ and $|s\rangle$ have the same symmetry.

2.2.3. C- and D-Term Resonance Raman Scattering

The C-term differs from the B-term in that the ground state, rather than the resonant excited state, is vibronically coupled to other excited states. It is normally assumed that the C-term is negligibly small, due to the large energy separation between the ground state and excited states. To our knowledge no experimental evidence for C-term scattering has yet been presented.

The D-term is also very much smaller than the B-term. It may give rise to first overtones ($k = k'$) and binary combination tones ($k \neq k'$) of both totally symmetric and non-totally symmetric modes. The observation of weak overtones and binary combination tones in the RR spectra of some metalloporphyrin species has been ascribed to D-term scattering (see Sections 2.4 and 5.4).

2.3. Resonance Raman Scattering Involving Totally Symmetric Modes

Raman bands attributed to totally symmetric fundamentals may acquire intensity under resonance conditions from either the A- or B-terms of the transition polarizability. It is generally the case, however, that only the A-term contribution is important, for the reasons mentioned in Section 2.2. In this section we discuss in detail the properties of A- and B-term RR scattering for totally symmetric fundamentals and their overtones. To begin with we consider the simplest case of a species possessing only one totally symmetric mode (such as diatomic, tetrahedral or square planar (MX_4), or octahedral (MX_6) molecules), in which case only diagonal components of the transition polarizability, $[\alpha_{\rho\rho}]_{gn,gm}$, are non-zero. If it is further assumed that (a) only a single resonant excited state $|e\rangle$ makes a significant contribution, and (b) all molecules are initially in the $m=0$ vibrational level of the ground electronic state (low temperature limit) then

$$[\alpha_{\rho\rho}]_{gn,g0} = \frac{1}{hc}\,|[\mu_\rho]^0_{ge}|^2 \sum_v \frac{\langle n_g|v_e\rangle\langle v_e|0_g\rangle}{\tilde{\nu}_{ev,g0}-\tilde{\nu}_0+i\Gamma_{ev}} \tag{15}$$

For a system with only one totally symmetric normal coordinate, Q_1, the vibrational overlap integrals are one-dimensional. Assuming harmonic potentials for the states $|g\rangle$ and $|e\rangle$, the overlap integrals may be calculated using the recurrence formulas derived by *Manneback*:[42]

$$\langle 0_e|0_g\rangle = \left(\frac{2(\tilde{\nu}^e_1\tilde{\nu}^g_1)^{1/2}}{\tilde{\nu}^e_1+\tilde{\nu}^g_1}\right)^{1/2} \exp\left(\frac{-\Delta^2}{2}\right) \tag{16a}$$

$$\begin{aligned}\langle n_g|v_e+1\rangle = &-\left(\frac{v}{v+1}\right)^{1/2}\left(\frac{\tilde{\nu}^g_1-\tilde{\nu}^e_1}{\tilde{\nu}^g_1+\tilde{\nu}^e_1}\right)\langle n_g|v_e-1\rangle\\ &+\left(\frac{n}{v+1}\right)^{1/2}\frac{2(\tilde{\nu}^e_1\tilde{\nu}^g_1)^{1/2}}{\tilde{\nu}^e_1+\tilde{\nu}^g_1}\langle n_g-1|v_e\rangle\\ &-\left(\frac{1}{v+1}\right)^{1/2}\Delta\left(\frac{2\nu^g_1}{\tilde{\nu}^g_1+\tilde{\nu}^e_1}\right)^{1/2}\langle n_g|v_e\rangle\end{aligned} \tag{16b}$$

$$\begin{aligned}\langle n_g+1|v_e\rangle = &\left(\frac{n}{n+1}\right)^{1/2}\left(\frac{\tilde{\nu}^g_1-\tilde{\nu}^e_1}{\tilde{\nu}^g_1+\tilde{\nu}^e_1}\right)\langle n_g-1|v_e\rangle\\ &+\left(\frac{v}{n+1}\right)^{1/2}\frac{2(\tilde{\nu}^e_1\tilde{\nu}^g_1)^{1/2}}{\tilde{\nu}^e_1+\tilde{\nu}^g_1}\langle n_g|v_e-1\rangle\\ &+\left(\frac{1}{n+1}\right)^{1/2}\Delta\left(\frac{2\tilde{\nu}^g_1}{\tilde{\nu}^g_1+\tilde{\nu}^e_1}\right)^{1/2}\langle n_g|v_e\rangle\end{aligned} \tag{16c}$$

where the dimensionless shift parameter Δ is given by

$$\Delta = \left(\frac{4\pi^2 c}{h}\right)^{1/2}\Delta Q_1\left(\frac{\tilde{\nu}^e_1\tilde{\nu}^g_1}{\tilde{\nu}^e_1+\tilde{\nu}^g_1}\right)^{1/2} \tag{16d}$$

The displacement, ΔQ_1, of the excited-state potential minimum is related to the displacement along the symmetry coordinate ΔS_1 by the equation

$$\Delta Q_1 = \mu^{1/2}\Delta S_1 \tag{17}$$

where μ is the reduced mass associated with the vibration. Expressions for ΔQ_1 in terms of Δr for a number of common molecular geometries are summarized in Table 1.

Table 1. Relationship between ΔQ_1 and Δr for various molecular geometries.

$\Delta Q_1 = \mu^{1/2}\Delta S_1$

Molecular type	Point group	μ	ΔS_1	ΔQ_1
XY	$C_{\infty v}$	$\frac{m_x m_y}{m_x+m_y}$	Δr	$\left[\frac{m_x m_y}{m_x+m_y}\right]^{1/2}\Delta r$
X_2	$D_{\infty h}$	$m_x/2$	Δr	$(m_x/2)^{1/2}\Delta r$
MX_2, X_3	$D_{\infty h}$	m_x	$\frac{1}{\sqrt{2}}(\Delta r_1+\Delta r_2)$	$(2m_x)^{1/2}\Delta r$
MX_3, X_3, X_4	D_{3h}	m_x	$\frac{1}{\sqrt{3}}(\Delta r_1+\Delta r_2+\Delta r_3)$	$(3m_x)^{1/2}\Delta r$
MX_4, X_4	D_{4h}, T_d	m_x	$\frac{1}{2}(\Delta r_1+\Delta r_2+\Delta r_3+\Delta r_4)$	$2(m_x)^{1/2}\Delta r$
MX_6, X_6	O_h	m_x	$\frac{1}{\sqrt{6}}(\Delta r_1+\Delta r_2+\Delta r_3+\Delta r_4+\Delta r_5+\Delta r_6)$	$(6m_x)^{1/2}\Delta r$

The Franck-Condon overlap integrals may possess appreciable magnitudes for up to several quanta of n if ΔQ_1 is sufficiently large, in which case several overtones of ν_1 may appear in the RR spectrum. The intensity distribution within such an overtone progression depends on the magnitude of ΔQ (and hence on the bond length change Δr) and, in general, the larger the displacement the greater is the extent of the progression. Thus, excitation resonant with charge-transfer or π-π^* transitions of small molecules typically produces RR spectra that are characterized by an intense overtone progression $v_1 \nu_1$.

Substitution of Equation (15) into Equation (1) and expansion of the square modulus of $[\alpha_{\rho\rho}]_{gn,g0}$ gives the following expression for Stokes A-term RR intensities:

$$\begin{aligned}I_{gn,g0}(\pi/2) = &K(\tilde{\nu}_0-\tilde{\nu}_{gn,g0})^4\,|[\mu_\rho]^0_{ge}|^4\\ &\times\sum_v\sum_{v'}\frac{\langle n_g|v_e\rangle\langle v_e|0_g\rangle\langle n_g|v'_e\rangle\langle v'_e|0_g\rangle[\varepsilon_v\varepsilon_{v'}+\Gamma_v\Gamma_{v'}]}{(\varepsilon_v^2+\Gamma_v^2)(\varepsilon_{v'}^2+\Gamma_{v'}^2)}\end{aligned} \tag{18}$$

where $\varepsilon_v = \tilde{\nu}_{ev,g0}-\tilde{\nu}_0$ and K incorporates all of the constants appearing in Equations (1) and (15). From this expression it is possible to calculate the variation of the intensities of the fundamental and overtone bands throughout the region of the resonant absorption band. Such a plot, which is called an excitation profile (EP), differs markedly from the absorption spectrum if the vibrational fine structure of the latter is resolved (small Γ). Whereas absorption profiles are simply given by the superposition (i.e. sum) of the individual vibronic bands, the double summation in Equation (18) involves cross-terms ($v \neq v'$) which produce interference between the contributions from different vibronic states. These interference effects may result in an increase or decrease in scattered intensity compared with that arising solely from the sum of the individual resonances ($v=v'$). However, when Γ is large these interferences are not apparent and both the excitation profiles and the absorption spectrum are smooth and devoid of fine structure. The maxima of the excitation profiles are then blue-shifted for successive overtones, the differ-

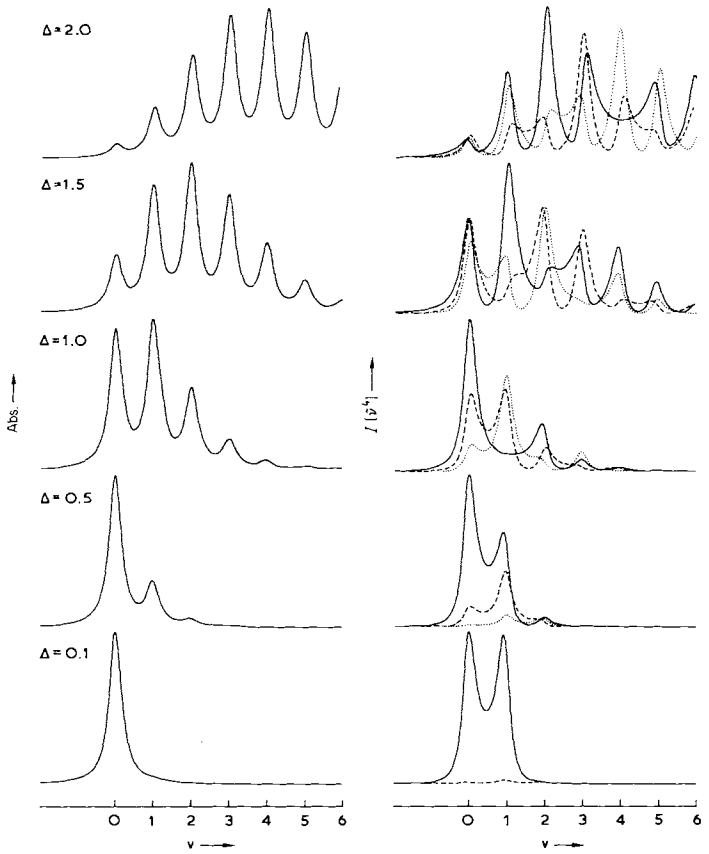

Fig. 2. Left, Absorption spectra, and right, resonance Raman excitation profiles (ν_1 (——), $2\nu_1$ (---) and $3\nu_1$ (····) bands) for different values of the shift parameter Δ; $\tilde{\nu}^e = \tilde{\nu}^g$ and $\Gamma = 0.2\,\tilde{\nu}^e$ (abscissa is expressed in terms of excited-state vibrational quanta v). Abs = Absorption, I = Raman intensity.

ence in peak position being approximately equal to the vibrational wave number of the excited state.

In Figure 2 is shown the effect of the displacement parameter Δ on Raman intensities. For simplicity a model system has been chosen in which $\tilde{\nu}^e = \tilde{\nu}^g$ and $\Gamma = 0.2\,\tilde{\nu}^e$ and the EPs are displayed for ν_1, $2\nu_1$ and $3\nu_1$ for several values of Δ. These profiles clearly demonstrate the above-mentioned interference effects and it is evident that EPs are more sensitive to variation in Δ than are absorption bands. It is readily seen that, as Δ increases, the EP maximum is shifted to higher wave number and that the intensities of overtones increase with respect to that of the fundamental, becoming the more intense in some regions.

By fitting calculated excitation profiles to experimental data the parameters Δ and Γ may be extracted. Thus, the technique provides a sensitive method for the determination of excited state geometries and lifetimes and several results of such calculations are discussed in later sections. It is, however, important to appreciate that lifetime, i.e. homogeneous, broadening is not the only contribution to bandwidths and that the influence of inhomogeneous broadening must also be taken into account. Inhomogeneous broadening is due to the variation of molecular environment (i.e. molecules occupying different sites) and the "spread" of electronic energies resulting from it is described by a Gaussian or Lorentzian distribution about the mean value. Although a Gaussian distribution would normally be the correct description of inhomogeneous broadening, the influence of the band shape is not very great and a Lorentzian function is usually chosen for simplicity.[43,44] The inhomogeneous band shape is then given by

$$\mathscr{S}(\tilde{\nu}) = \frac{\gamma}{[\langle\tilde{\nu}_{e0}\rangle - \tilde{\nu}_{e0}]^2 + \gamma^2} \tag{19}$$

where γ is the inhomogeneous bandwidth (half width at half maximum) and $\langle\tilde{\nu}_{e0}\rangle$ is the average value of the electronic transition wave number. The effect of inhomogeneous broadening on the transition polarizability is taken into account by convolution with the above band-shape function, integrating over all possible values of $\tilde{\nu}_{e0}$:

$$[\alpha_{\rho\rho}]_{gn,g0} = \frac{1}{hc}\,|[\mu_\rho]^0_{ge}|^2 \int_{-\infty}^{\infty} \left(\sum_v \frac{\langle n_g|v_e\rangle\langle v_e|0_g\rangle}{\tilde{\nu}_{ev,g0} - \tilde{\nu}_0 + i\Gamma_{ev}}\right) \mathscr{S}(\tilde{\nu})\cdot d\tilde{\nu}_{e0} \tag{20}$$

Such integrals have been evaluated by *Siebrand* et al.,[43,44] and the following expression is obtained for the Raman intensity:

$$I_{gn,g0}(\pi/2) = K(\tilde{\nu}_0 - \tilde{\nu}_{gn,g0})^4 |[\mu_\rho]^0_{ge}|^4 \sum_v \sum_{v'} \langle n_g|v_e\rangle\langle v_e|0_g\rangle\langle n_g|v'_e\rangle\langle v'_e|0_g\rangle \times \left(\frac{[(\varepsilon_v - \varepsilon_{v'})^2 + 4\Gamma\Sigma][\varepsilon_v\varepsilon_{v'} + \Sigma^2] - 2(\varepsilon_v - \varepsilon_{v'})\gamma\Sigma}{[\varepsilon_v^2 + \Sigma^2][\varepsilon_{v'}^2 + \Sigma^2][(\varepsilon_v - \varepsilon_{v'})^2 + 4\Gamma^2]}\right) \tag{21}$$

where $\Sigma = \Gamma + \gamma$.

In most cases Γ is small, rarely exceeding about $0.5\,\tilde{\nu}^e_1$, but γ may range from zero (putting $\gamma = 0$ in Equation (21) yields Equation (18)) to a few thousand cm^{-1}. Where excitation profiles are broad and unresolved, γ is the dominant bandwidth contribution. Homogeneous broadening and inhomogeneous broadening have markedly different effects on the excitation profiles, as illustrated in Figure 3.

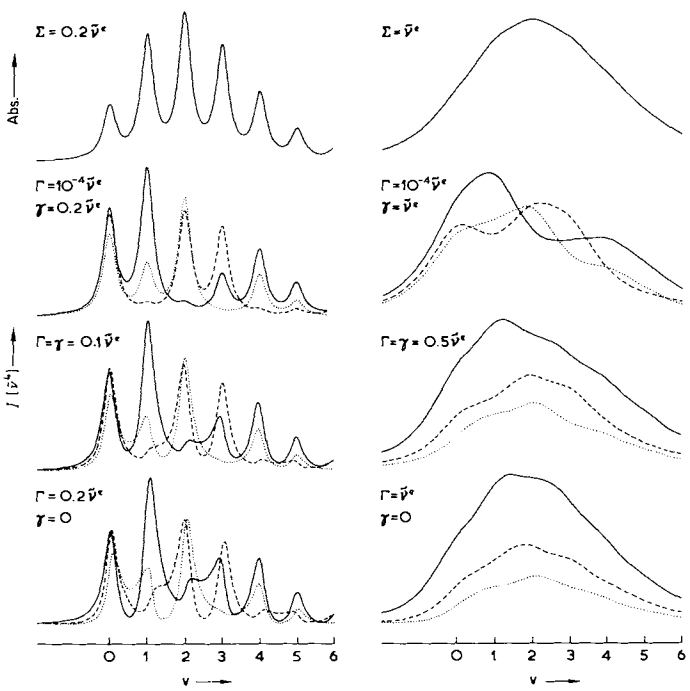

Fig. 3. Top, Absorption spectra, and bottom, resonance Raman excitation profiles (ν_1 (——), $2\nu_1$ (---) and $3\nu_1$ (····) bands) for $\tilde{\nu}^e = \tilde{\nu}^g$, $\Delta = 1.5$ and $\Sigma = 0.2\,\tilde{\nu}^e$ or $\tilde{\nu}^e$ (abscissa expressed in terms of excited-state vibrational quanta, v). The excitation profiles are given for $\Gamma/\gamma = \infty$, 1 and ca. 0 (Γ may not be equated to zero because the excitation profile is then indeterminate). Abs = Absorption, I = Raman intensity.

The principal differences are that (a) γ plays no part in the aforementioned interference phenomena, and (b) increasing the Γ contribution (maintaining constant Σ) decreases the intensity of overtones relative to that of the fundamental. By measuring EPs of molecules in different environments (i.e. different solvents or host lattices) it is possible to determine Γ, and hence the excited-state lifetime, since this is largely independent of molecular environment. This information cannot be obtained from absorption spectra because these are insensitive to variation in the relative contributions of Γ and γ, the bandwidths being given by the sum Σ.

So far the treatment has been restricted to molecules with only one totally symmetric mode and for which only one excited state contributes to the transition polarizability. This latter assumption is not justified when two or more (N) excited states are in close proximity to one another, and the transition polarizability must then include the sum of contributions from each state, viz.

$$[\alpha_{\rho\rho}]_{gn,g0} = \frac{1}{hc}\sum_{i=1}^{N}|[\mu_\rho]^0_{ge_i}|^2\sum_{v_i}\frac{\langle n_g|v_{e_i}\rangle\langle v_{e_i}|0_g\rangle}{\tilde{\nu}_{e_iv}-\tilde{\nu}_0+i\Gamma_{e_iv}} \tag{22}$$

The Raman intensity is given by

$$I_{gn,g0}(\pi/2) = K(\tilde{\nu}_0-\tilde{\nu}_{gn,g0})^4\sum_{i=1}^{N}\sum_{i'=1}^{N}|[\mu_\rho]^0_{ge_i}|^2|[\mu_\rho]^0_{ge_{i'}}|^2 \times \sum_{v}\sum_{v'}\langle n_g|v_{e_i}\rangle\langle v_{e_i}|0_g\rangle\langle n_g|v'_{e_{i'}}\rangle\langle v'_{e_{i'}}|0_g\rangle$$
$$\times\left(\frac{[(\varepsilon^i_v-\varepsilon^{i'}_{v'})^2+(\Gamma_i+\Gamma_{i'})(\Sigma_i+\Sigma_{i'})][\varepsilon^i_v\varepsilon^{i'}_{v'}+\Sigma_i\Sigma_{i'}]-\frac{1}{2}(\varepsilon^i_v-\varepsilon^{i'}_{v'})(\gamma_i+\gamma_{i'})(\Sigma_i+\Sigma_{i'})}{[(\varepsilon^i_v)^2+\Sigma_i^2][(\varepsilon^{i'}_{v'})^2+\Sigma_{i'}^2][(\varepsilon^i_v-\varepsilon^{i'}_{v'})^2+(\Gamma_i+\Gamma_{i'})^2]}\right) \tag{23}$$

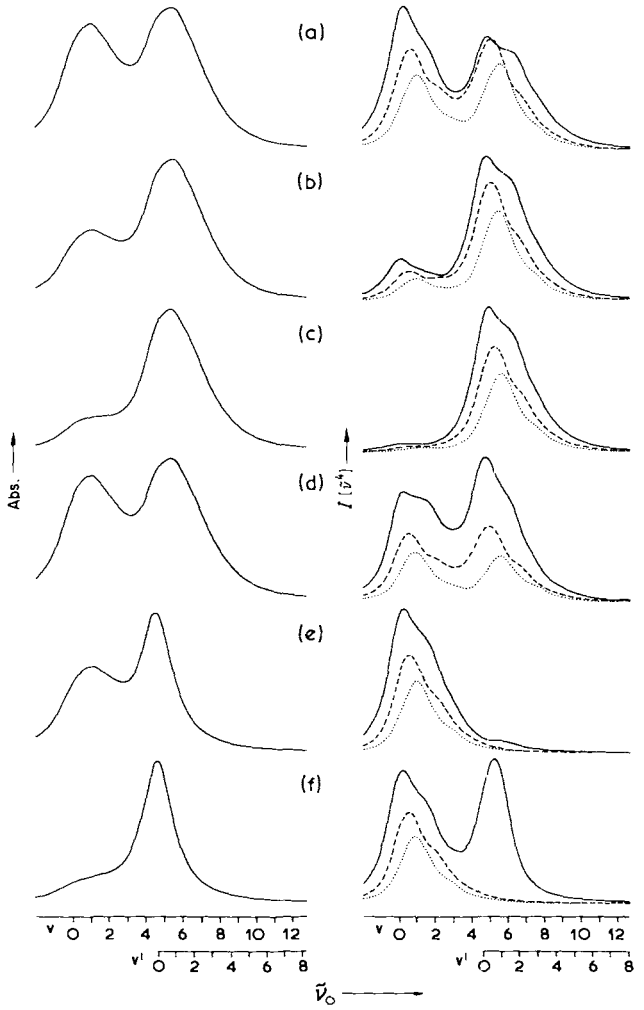

Fig. 4. Absorption spectra and resonance Raman excitation profiles (ν_1 (——), $2\nu_1$ (– – –), and $3\nu_1$ (· · · ·) bands) for a selection of different examples in which two electronic transitions, $|e_1\rangle\leftarrow|g\rangle$ and $|e_2\rangle\leftarrow|g\rangle$, contribute. (a) $R_{12}=1$, $\Delta_1=\Delta_2=1.5$; (b) $R_{12}=2$, $\Delta_1=\Delta_2=1.5$; (c) $R_{12}=5$, $\Delta_1=\Delta_2=1.5$; (d) $R_{12}=1$, $\Delta_1=1.5$, $\Delta_2=-1.5$; (e) $R_{12}=1$, $\Delta_1=1.5$, $\Delta_2=0.1$; (f) $R_{12}=5$, $\Delta_1=1.5$, $\Delta_2=0.1$. $R_{12}=|[\mu_\rho]^0_{ge_2}/[\mu_\rho]^0_{ge_1}|^2$; Δ_1 and Δ_2 are the displacement parameters for the two transitions. The abscissa is expressed in terms of vibrational quanta of the excited states $|e_1\rangle$ (v) and $|e_2\rangle$ (v'), where $\tilde{\nu}^{e_1}=\tilde{\nu}^{e_2}$. Other parameters used in the calculation are $\Delta\nu_{e_2e_1}=4.3\,\tilde{\nu}^{e_1}$ and $\Gamma=\gamma=0.5\,\tilde{\nu}^{e_1}$. The observed interference effects are diminished when Γ and γ are made smaller.

In addition to the interferences between vibronic contributions of the same state there are also interferences between the contributions from different states; these arise from the sign differences of ε^i_v values at certain positions and will also occur if Δ is positive for one state but negative for a second. Some examples of interference effects are shown in Figure 4.

The extension of the theory to molecules with several totally symmetric modes is straightforward if it may be assumed that the normal coordinates of the excited state are identical to those of the ground state. The multi-dimensional overlap integrals $\langle\bar{n}_g|\bar{v}_e\rangle$ may then be expressed as products of one-dimensional ones:

$$\langle\bar{n}_g|\bar{v}_e\rangle = \langle(n_1\,n_2\,n_3\ldots n_N)_g|(v_1\,v_2\,v_3\ldots v_N)_e\rangle = \prod_{i=1}^{N}\langle n_{ig}|v_{ie}\rangle \tag{24}$$

Substitution of these products into either Equation (18) (one-state) or Equation (23) (multi-state) enables excitation profiles to be calculated. By fitting these to experimental data, values for ΔQ_1, ΔQ_2, etc., can be deduced, i.e. the displacement of the excited-state potential minimum along each of the totally symmetric normal coordinates. The relationship between these displacements and the geometric changes attendant upon electronic excitation (bond-length and bond-angle changes) is less straightforward than in the single-mode case. Internal coordinates are related to normal coordinates by the matrix equation

$$\mathbf{R} = \mathbf{L}\mathbf{Q} \tag{25}$$

where $\mathbf{R}$ is a column matrix comprising the $3N-6$ internal coordinates, $\mathbf{Q}$ is a column matrix of the $3N-6$ normal coordinates, and $\mathbf{L}$ is a square matrix effecting the transformation from normal to internal coordinates; it is obtained by solution of the vibrational secular equation. For the states $|g\rangle$ and $|e\rangle$ we may write

$$\mathbf{R}_g = \mathbf{L}_g\mathbf{Q}_g \qquad \mathbf{R}_e = \mathbf{L}_e\mathbf{Q}_e \tag{26}$$

$$\mathbf{R}_e - \mathbf{R}_g = \mathbf{L}_e\mathbf{Q}_e - \mathbf{L}_g\mathbf{Q}_g \tag{27}$$

By making the assumption that the **L** matrix is unchanged in the excited state (which is necessary in the absence of a detailed knowledge of the excited-state vibrations), it follows that

$$\mathbf{R}_e - \mathbf{R}_g = \mathbf{L}(\mathbf{Q}_e - \mathbf{Q}_g)$$
$$\text{or } \Delta\mathbf{R} = \mathbf{L}\Delta\mathbf{Q} \tag{28}$$

where $\Delta\mathbf{R}$ is a column matrix of the internal coordinate changes and $\Delta\mathbf{Q}$ is a column matrix of the normal coordinate displacements. We may take advantage of molecular symmetry by recasting this equation in the form

$$\Delta\mathbf{R} = \tilde{\mathbf{U}}\,\mathscr{L}\,\Delta\mathbf{Q} \tag{29}$$

where $\tilde{\mathbf{U}}$ is the transpose of the matrix relating internal coordinates to symmetry coordinates and $\mathscr{L}$ is the symmetrized version of the **L** matrix. The $\mathscr{L}$ matrix factorizes into a block diagonal form and only the block involving totally symmetric coordinates needs to be considered.

RR spectra of molecules possessing more than one totally symmetric mode may display overtone progressions for each of the active vibrations, i.e. those for which there are normal coordinate displacements. Additionally there may also be combination band progressions involving quanta of more than one mode. In general it is true that the most displaced coordinate will give rise to the greatest intensity enhancement and the longest overtone progression. On this basis it is still possible to make a qualitative assessment of the excited-state geometry from RR data when detailed calculations cannot be performed.

A special case of the A-term scattering regime exists when each of the displacements, ΔQ, is very small but non-zero.[38] In this situation it can be seen from Equations (16) that, assuming $\tilde{\nu}_i^e = \tilde{\nu}_i^g$, the overlap integrals have the values

$$\langle 1_g|1_e\rangle = \langle 0_g|0_e\rangle = 1$$
$$\langle 1_g|0_e\rangle = -\langle 0_g|1_e\rangle = -\Delta$$

Integrals in which either n or v has a value of 2 or more and $n \neq v$ may be approximated to zero because they involve higher powers of Δ ($\Delta \ll 1$ and so $\Delta^2 \ll \Delta$). The summation over the levels v is therefore restricted to the $v=0$ and $v=1$ contributions, and Franck-Condon factors will be non-zero only for $n=0$ (Rayleigh scattering) and $n=1$ (fundamental Raman scattering). Thus, in the small displacement approximation, overtones are forbidden.

The multi-dimensional Franck-Condon factors may be expressed in the following form:

$$\langle \bar{n}_g|\bar{v}_e\rangle\langle \bar{v}_e|\bar{0}_g\rangle = \langle 1_{ag}|0_{ae}\rangle\langle 0_{ae}|0_{ag}\rangle \prod_{i=1}^{m-1} \langle 0_{ig}|v_{ie}\rangle^2$$
$$\text{or } \langle 1_{ag}|1_{ae}\rangle\langle 1_{ae}|0_{ag}\rangle \prod_{i=1}^{m-1} \langle 0_{ig}|v_{ie}\rangle^2 \tag{30}$$

Within the framework of the small-displacement approximation the product has the value unity, allowing each vibrational mode to be treated as an independent oscillator.

The excitation profile for the ath fundamental is then given by

$$I_{g1_a,g0} = K(\tilde{\nu}_0 - \tilde{\nu}_{g1_a,g0})^4 |[\mu_\rho]^0_{ge}|^4 \times \Delta_a^2 \frac{\left\{\frac{\Sigma}{\Gamma}[\varepsilon_0^2+\varepsilon_1^2+2\Sigma^2][(\varepsilon_1-\varepsilon_0)^2+4\Gamma^2]-2[\varepsilon_0\varepsilon_1+\Sigma^2][(\varepsilon_0-\varepsilon_1)^2+4\Gamma\Sigma]\right\}}{(\varepsilon_0^2+\Sigma^2)(\varepsilon_1^2+\Sigma^2)[(\varepsilon_0-\varepsilon_1)^2+4\Gamma^2]} \tag{31}$$

where Δ_a is the displacement parameter for the ath totally symmetric mode, the wave number of which is $\tilde{\nu}_a$. Although it is not possible to determine absolute values for the displacement parameters in this approximation, the relative magnitudes (but not signs) may be deduced from the relative intensities of the RR bands. Taking account of molecules initially in $m>0$ vibrational levels, the relative displacements can be calculated from

$$\frac{|\Delta_a|}{|\Delta_b|} = \left\{\frac{I_{g1_a,g0}}{I_{g1_b,g0}}\left(\frac{\tilde{\nu}_0-\tilde{\nu}_b}{\tilde{\nu}_0-\tilde{\nu}_a}\right)^4\left(\frac{1-\exp(-hc\tilde{\nu}_a/kT)}{1-\exp(-hc\tilde{\nu}_b/kT)}\right)\frac{\tilde{\nu}_b^2}{\tilde{\nu}_a^2}\right\}^{1/2} \tag{32}$$

As pointed out earlier, B-term scattering may occur for totally symmetric modes if the excited states $|e\rangle$ and $|s\rangle$ are of the same symmetry. B-term excitation profiles for totally symmetric modes are given by

$$I_{g1_a,g0} = K|[\mu_\rho]^0_{ge}|^2 |[\mu_\rho]^0_{gs}|^2 \left(\frac{h^a_{es}}{\Delta\tilde{\nu}_{es}}\right)^2 (\tilde{\nu}_0-\tilde{\nu}_{g1_a,g0})^4 \times \frac{\left\{\frac{\Sigma}{\Gamma}[\varepsilon_0^2+\varepsilon_1^2+2\Sigma^2][(\varepsilon_1-\varepsilon_0)^2+4\Gamma^2]+2[\varepsilon_0\varepsilon_1+\Sigma^2][(\varepsilon_0-\varepsilon_1)^2+4\Gamma\Sigma]\right\}}{(\varepsilon_0^2+\Sigma^2)(\varepsilon_1^2+\Sigma^2)[(\varepsilon_0-\varepsilon_1)^2+4\Gamma^2]} \tag{33}$$

The wave-number-dependent part of this expression differs from that of Equation (31) in that the second term in the numerator is positive rather than negative. This may result in destructive interference between the 0-0 and 0-1 maxima and constructive interference elsewhere, the opposite being true for the A-term. Figure 5 shows examples of B-term and small-displacement A-term excitation profiles, while Figure 6 shows the effect of A-term/B-term interference; this occurs when the two terms have similar magnitudes.[45] The interference is constructive for the 0-0 resonance and destructive for the 0-1 resonance, but this behavior is reversed if the transition moments $[\mu_\rho]^0_{ge}$ and $[\mu_\rho]^0_{gs}$ have opposite signs. Similar excitation profiles may result if there is non-adiabatic coupling of the states $|e\rangle$ and $|s\rangle$ (vide infra).

2.4. Resonance Raman Scattering Involving Non-Totally Symmetric Modes

RR bands attributed to non-totally symmetric fundamental vibrations may acquire intensity via one of three scattering mechanisms:

(1) A-term activity due to a change of molecular symmetry in the resonant excited-state;
(2) A-term activity due to excited-state JT coupling;
(3) B-term scattering, involving the vibronic coupling of the resonant state to a second electronic excited state.

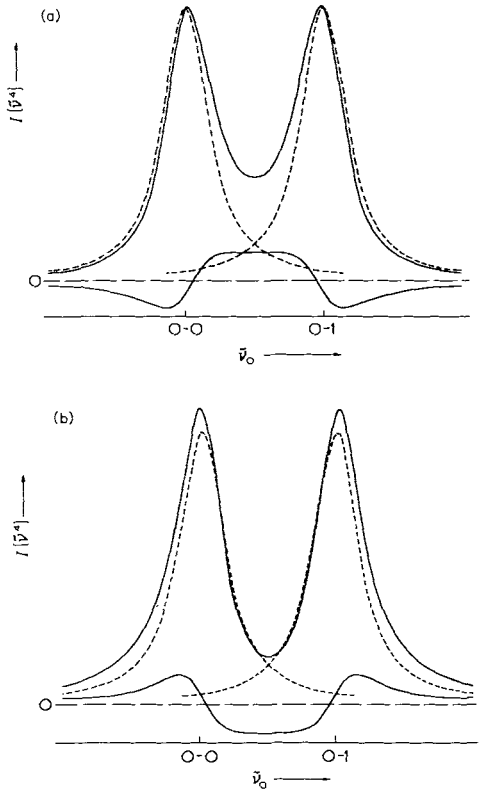

Fig. 5. Excitation profiles for (a) small displacement A-term scattering, and (b) B-term scattering, showing the 0-0 and 0-1 contributions (---) and the interference contribution (——) to the Raman intensity I, calculated with $\Gamma=\gamma=0.1\,\tilde{\nu}^e$.

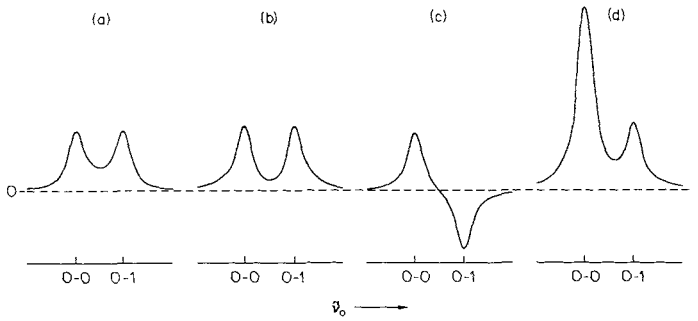

Fig. 6. Excitation profile (d) for A-term/B-term interference showing (a) the A-term, (b) B-term, and (c) interference contributions to the Raman intensity for the case where the A-term and B-term are equal. The calculations were obtained with $\Gamma=\gamma=0.1\,\tilde{\nu}^e$, and only small changes occur when Γ/γ is varied.

If a molecule undergoes a change of symmetry upon excitation then the A-term active modes are those that are totally symmetric in the subgroup formed by the symmetry operations common to the ground- and excited-state point groups (common group). A good example is provided by the molecule ethylene which has a planar D_{2h} geometry in the ground state and a twisted D_{2d} geometry in the first $^1B_{1u}$ excited state. The common group is D_2 and, by correlation of D_2 to D_{2h}, it is seen that the A-term active modes are those of a_g and a_u symmetry. Of course the a_u fundamental (ν_7, the twist about the C=C bond) is Raman inactive but even quanta thereof, i.e. $2\nu_7$, $4\nu_7$, etc., have A_g symmetry and are accordingly Raman active. Excitation within the contour of the π-π^* transition of ethylene using 193.4 nm irradiation[46] yields RR spectra displaying progressions in the ν(C=C) mode and even harmonics of $\nu_7(a_u)$. This recent study thus provided the first unambiguous evidence for a twisted excited state for ethylene. It is a general empirical rule that the vibrational coordinates responsible for converting a molecule from its ground- to excited-state geometry will give rise to resonance-enhanced Raman bands (*Tsuboi*'s rule[47]).

In cases where the resonant excited state is degenerate, A-term activity may arise for some non-totally symmetric modes. The non-totally symmetric vibrations belonging to the irreducible representations contained in the symmetric direct product $\{\Gamma_e \otimes \Gamma_e\}$ may be responsible for JT coupling in the excited state. Some common examples of excited states so influenced are $T_2(T_d)$, $T_{1u}(O_h)$ and $E_u(D_{4h})$, for which the direct products are as follows:

$$T_2 \otimes T_2 = \{A_1 + E + T_2\} + [T_1]$$
$$T_{1u} \otimes T_{1u} = \{A_{1g} + E_g + T_{2g}\} + [T_{1g}]$$
$$E_u \otimes E_u = \{A_{1g} + B_{1g} + B_{2g}\} + [A_{2g}]$$

Vibrations transforming as the antisymmetric part of the direct product (given in square brackets) are not JT active because they do not lift the degeneracy of the excited state. This point is best illustrated by reference to an ion belonging to the D_{4h} point group, e.g. in Figure 7 is shown the effect of vibrations of b_{1g}, b_{2g} and a_{2g} symmetry for the square planar $[Pt(CN)_4]^{2-}$ ion. It is evident that, whereas b_{1g} and b_{2g} vibrations remove the C_4-axis (which is responsible for the double degeneracy), an a_{2g} vibration does not; thus the b_{1g} and b_{2g} modes, but not the a_{2g} mode, are JT active.

The effect of excited-state JT effects on RR spectra may be summarized as follows:

(1) The appearance of combination band progressions involving quanta of totally symmetric modes plus one quantum of a JT-active vibration (small JT effect);

(2) the appearance of combination band progressions involving quanta of totally symmetric modes plus multiple quanta of JT-active vibrations, as well as overtone progressions of the latter (strong JT effect).

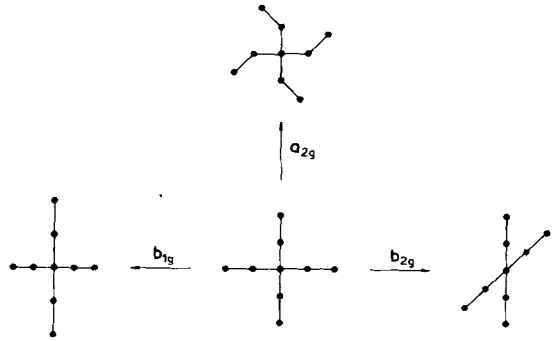

Fig. 7. Diagram showing the effect of a_{2g}, b_{1g} and b_{2g} distortions on a D_{4h} species, e.g. $[Pt(CN)_4]^{2-}$.

It is to be expected that the excited-state JT effect is a dynamic one and that no permanent distortion of the molecule occurs. Thus the major geometric changes accompanying excitation to a degenerate excited state are those involving totally symmetric modes and case (2) is something of a rarity.

For many polyatomic molecules B-term scattering is the major source of RR activity for non-totally symmetric modes. As pointed out earlier, its magnitude is dependent on the vibronic coupling integral h^k_{es}. It is therefore necessary that, for a non-totally symmetric coordinate Q_k to be B-term active, it must be effective in coupling the resonant state $|e\rangle$ to a second excited state $|s\rangle$. Expressed group theoretically, Γ_k must be contained in the product $\Gamma_e \otimes \Gamma_s$. From Equation (14) the transition polarizability is given by

$$[\alpha_{\rho\sigma}]_{g1,g0} = \frac{1}{h^2c^2}[\mu_\rho]^0_{gs}[\mu_\sigma]^0_{eg}\frac{h^k_{se}}{\Delta\tilde{\nu}_{es}}\langle 1|Q_k|0\rangle(\varepsilon_0 + i\Gamma)^{-1} + \frac{1}{h^2c^2}[\mu_\rho]^0_{ge}[\mu_\sigma]^0_{sg}\frac{h^k_{es}}{\Delta\tilde{\nu}_{es}}\langle 1|Q_k|0\rangle(\varepsilon_1 + i\Gamma)^{-1} \quad (34)$$

where $\langle 1|Q_k|0\rangle = \langle 1_e|Q_k|0_g\rangle = \langle 1_g|Q_k|0_e\rangle$

Close examination of this expression reveals that $\alpha_{\rho\sigma} \neq \alpha_{\sigma\rho}$, i.e. that the polarizability tensor is asymmetric. The latter may be expressed as the sum of symmetric and antisymmetric tensors, viz.

$$\alpha_{\rho\sigma} = \left(\frac{\alpha_{\rho\sigma} + \alpha_{\sigma\rho}}{2}\right) + \left(\frac{\alpha_{\rho\sigma} - \alpha_{\sigma\rho}}{2}\right) \quad (35)$$

where the matrix elements are given by

$$[\alpha_{\rho\sigma}]_{g1,g0} \pm [\alpha_{\sigma\rho}]_{g1,g0} = \frac{1}{h^2c^2}\frac{h^k_{es}}{\Delta\tilde{\nu}_{es}}\langle 1|Q_k|0\rangle \times \{[\mu_\rho]^0_{gs}[\mu_\sigma]^0_{eg} + [\mu_\rho]^0_{ge}[\mu_\sigma]^0_{sg}\}\left(\frac{1}{\varepsilon_0 + i\Gamma} \pm \frac{1}{\varepsilon_1 + i\Gamma}\right) \quad (36)$$

Excitation profiles for Raman bands involving symmetric (+) and antisymmetric (−) tensor contributions are given by

$$I^{(\pm)}_{g1,g0} = K\frac{\left\{\frac{\Sigma}{\Gamma}[\varepsilon_0^2 + \varepsilon_1^2 + 2\Sigma^2][(\varepsilon_1 - \varepsilon_0)^2 + 4\Gamma^2] \pm 2[\varepsilon_0\varepsilon_1 + \Sigma^2][(\varepsilon_0 - \varepsilon_1)^2 + 4\Gamma\Sigma]\right\}}{(\varepsilon_0^2 + \Sigma^2)(\varepsilon_1^2 + \Sigma^2)[(\varepsilon_0 - \varepsilon_1)^2 + 4\Gamma^2]} \quad (37)$$

The antisymmetric tensor EP resembles that arising from the small displacement A-term, i.e. there is constructive interference between the 0-0 and 0-1 resonances and destructive interference elsewhere. Thus, the antisymmetric tensor contribution becomes zero outside of the resonance region and normal, i.e. off-resonance, vibrational Raman scattering is controlled exclusively by a symmetric polarizability tensor. By contrast, electronic Raman transitions can involve antisymmetric scattering even in the off-resonance case. The most notable observations of antisymmetric scattering by non-totally symmetric modes have been for metalloporphyrin systems. Resonance Raman spectra obtained by excitation within the Q-band (E_u symmetry) are dominated by B-term scattering by vibrations which couple the Q-state to the higher energy Soret state (also of E_u symmetry). The B-term active vibrations are given by

$$E_u \otimes E_u = A_{1g} + A_{2g} + B_{1g} + B_{2g}$$

and the antisymmetric part of the product, A_{2g}, gives rise to antisymmetric scattering. Weak overtones of a_{1g}, a_{2g}, b_{1g}, and b_{2g} modes are sometimes observed in metalloporphyrin RR spectra and represent the only known examples of D-term scattering.

In concluding this section it should be pointed out that two complications may arise:

(1) Interference between contributions to the transition polarizability from JT-activity (intramanifold coupling) and B-term activity (intermanifold coupling);
(2) Non-adiabatic coupling, which may arise when the states $|e\rangle$ and $|s\rangle$ are close together, i.e. when $\Delta\tilde{\nu}_{es}$ is comparable with vibrational band wave numbers.[48]

The effect of either of these two processes is that the 0-0 and 0-1 peaks in the excitation profiles display unequal intensities. Modes of a_{2g} symmetry are JT inactive and show only the non-adiabatic effect, which favors the 0-1 resonance. This contrasts with the behavior of the other modes which tend to produce stronger 0-0 scattering, arising from interference between the inter- and intramanifold contributions.

2.5. Depolarization Ratios

The depolarization ratio for 90° Raman scattering excited by linearly polarized incident radiation (see Fig. 8) is given by

$$\rho(\pi/2) = \frac{{}^{\perp}I_{\parallel}(\pi/2)}{{}^{\perp}I_{\perp}(\pi/2)} \quad (38)$$

where $\perp$ and $\parallel$ are defined by reference to the scatter plane (the plane containing the directions of propagation of the incident and scattered radiation) and the superscripts and subscripts refer to incident and scattered polarizations, respectively. For an assembly of randomly orien-

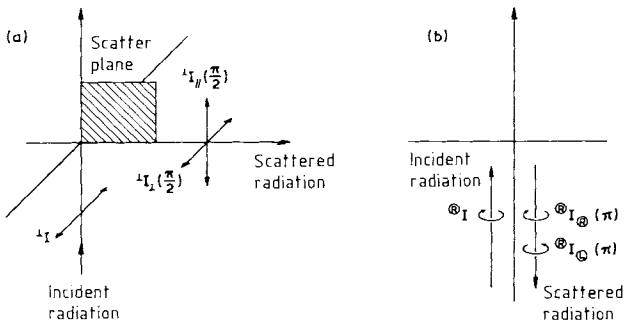

Fig. 8. The geometry for scattering at (a) 90° using linearly polarized incident radiation, and (b) 180° using circularly polarized incident radiation.

tated molecules $\rho(\pi/2)$ may be expressed in terms of the tensor invariants $\bar{\alpha}$, γ_s, and γ_{as} thus:

$$\rho(\pi/2) = \frac{3\gamma_s^2 + 5\gamma_{as}^2}{45\bar{\alpha}^2 + 4\gamma_s^2} \tag{39}$$

where

$$\gamma_s^2 = \tfrac{1}{2}[(\alpha_{xx}-\alpha_{yy})^2 + (\alpha_{yy}-\alpha_{zz})^2 + (\alpha_{zz}-\alpha_{xx})^2 + \tfrac{3}{2}[(\alpha_{xy}+\alpha_{yx})^2 + (\alpha_{yz}+\alpha_{zy})^2 + (\alpha_{zx}+\alpha_{xz})^2]]$$

$$\gamma_{as}^2 = \tfrac{3}{4}[(\alpha_{xy}-\alpha_{yx})^2 + (\alpha_{yz}-\alpha_{zy})^2 + (\alpha_{zx}-\alpha_{xz})^2]$$

For vibrational non-RR scattering γ_{as}^2 is zero, because, as stated previously, the antisymmetric polarizability tensor vanishes under these conditions. The following behavior is then observed:[49]

(1) For non-totally symmetric modes only off-diagonal polarizability tensor elements, $\alpha_{\rho\sigma}$, and the combination $(\alpha_{xx}-\alpha_{yy})$ are non-zero. Therefore $\bar{\alpha}=0$ for all non-totally symmetric modes and $\rho(\pi/2)=3/4$;
(2) for cubic molecules $\alpha_{xx}=\alpha_{yy}=\alpha_{zz}$, hence $\gamma_s^2=0$ for totally symmetric modes and $\rho(\pi/2)=0$. Both $\bar{\alpha}$ and γ_s^2 may be non-zero for the totally symmetric modes of non-cubic molecules and $0 \leqslant \rho(\pi/2) \leqslant 3/4$.

Depolarization ratios for RR scattering are determined by the symmetry of the resonant transition and can provide a valuable tool for the determination of electronic band assignments. For totally symmetric modes of molecules not belonging to the point groups C_1, C_i, C_s, C_2 or C_{2h}, only the diagonal polarizability components, $\alpha_{\rho\rho}$, are non-zero. If the resonant transition is non-degenerate then only one of these will be non-zero (say α_{xx} if the transition is x-polarized) and, from Equations (39), $\rho(\pi/2)=1/3$. Similarly, it can be shown that a doubly-degenerate resonant transition (x,y-polarization) gives rise to $\rho(\pi/2)=1/8$, and that a cubic molecule for which only triply-degenerate transitions are electric-dipole-allowed (x,y,z-polarization), $\rho(\pi/2)=0$. Two further cases may arise when either two non-degenerate transitions lie close together or when a non-degenerate transition is in close proximity to a doubly-degenerate one. In the former case the $\rho(\pi/2)$ value will depend on the relative magnitudes of, say α_{xx} and α_{yy}, illustrated in Figure 9, and will vary as functions of the excitation wave number $\tilde{\nu}_0$ (polarization dispersion). Likewise, in the second case the $\rho(\pi/2)$ value will depend on the relative magnitudes of say $\alpha_{xx}=\alpha_{yy}$ and α_{zz}; this situation is shown in Figure 10.

If the molecular point group is either C_1, C_i, C_s, C_2 or C_{2h} then off-diagonal components, $\alpha_{\rho\sigma}$, may also be non-zero if B-term scattering occurs. Thus, the $\rho(\pi/2)$ is most likely to be within the range 0 to 3/4.

Departure from the above-mentioned behavior is expected if the electronic ground state is degenerate, for then the Raman transition is not a purely vibrational one. The Raman transition is $|g\rangle|n\rangle \leftarrow |g\rangle|0\rangle$, in the low temperature limit, and the irreducible representation for this process is given by $\Gamma_g \otimes \Gamma_n \otimes \Gamma_g \otimes \Gamma_1$ (the v=0 level is necessarily totally symmetric). It is clear that, for a non-degenerate ground state, the product is simply Γ_n because $\Gamma_g \otimes \Gamma_g = \Gamma_1$. However, it is equally clear that if the ground state is degenerate then this will affect the symmetry of the transition. As an example, consider a doubly degenerate E_g'' ground state of an octahedral molecule (O_h point group). The product $E_g'' \otimes E_g'' = A_{1g} + T_{1g}$, and thus the Raman bands attributed to $\nu_1(a_{1g})$ and its overtones will transform as $A_{1g}+T_{1g}$. Both $\bar{\alpha}$ and γ_{as}^2 will be non-zero and $\rho(\pi/2)$ may take any value between zero and infinity, depending on the relative magnitudes of $\bar{\alpha}$ and γ_{as}^2, and will show dispersion throughout the resonance region. Such behavior has been observed for $[IrBr_6]^{2-}$ and $[IrCl_6]^{2-}$,[50] where the ground state is the E_g'' spin-orbit component of the $^2T_{2g}$ term.

If the ground state is orbitally non-degenerate but possesses spin degeneracy then strong spin-orbit coupling may cause mixing of the ground state with degenerate excited states of the same spin degeneracy. Thus, the ground state acquires some degenerate character and the depolarization ratios of totally symmetric modes may become anomalously large. The only reported observation of this is for $[FeBr_4]^-$ where spin-orbit coupling causes the $^6A_1$ ground state to be mixed with sextet excited states, and $\rho(\pi/2)=0.15$ is observed for the ν_1 band in the RR spectrum.[51,52]

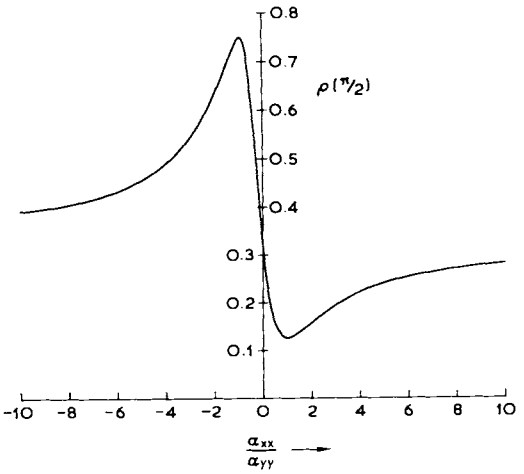

Fig. 9. Plot of $\rho(\pi/2)$ versus α_{xx}/α_{yy} for the case in which two non-degenerate transitions contribute to the transition polarizability.

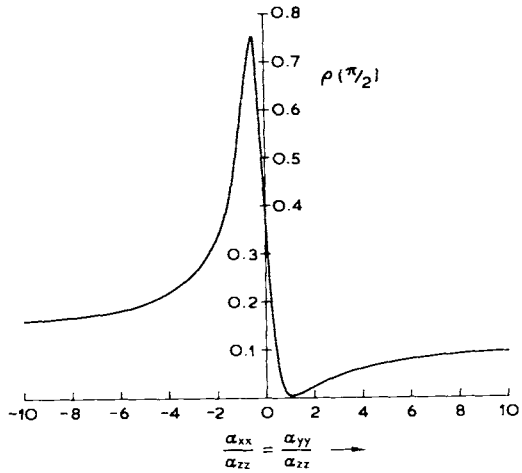

Fig. 10. Plot of $\rho(\pi/2)$ versus $\alpha_{xx}/\alpha_{zz}=\alpha_{yy}/\alpha_{zz}$ for the case in which one degenerate and one non-degenerate transition contribute to the transition polarizability.

$$\rho(\pi/2)=\frac{3}{4}+\frac{5}{4}\frac{\gamma_{as}^2}{\gamma_s^2}=\frac{3}{4}+\frac{5}{4}\left|\frac{[\alpha_{p\sigma}]_{gn,g0}-[\alpha_{\sigma p}]_{gn,g0}}{[\alpha_{p\sigma}]_{gn,g0}+[\alpha_{\sigma p}]_{gn,g0}}\right|^2=\frac{3}{4}+\frac{5}{4}\frac{\left\{\frac{\Sigma}{\Gamma}[\varepsilon_0^2+\varepsilon_1^2+2\Sigma^2][(\varepsilon_1-\varepsilon_0)^2+4\Gamma^2]-2[(\varepsilon_1-\varepsilon_0)^2+4\Gamma\Sigma][\varepsilon_1\varepsilon_0+\Sigma^2]\right\}}{\left\{\frac{\Sigma}{\Gamma}[\varepsilon_0^2+\varepsilon_1^2+2\Sigma^2][(\varepsilon_1-\varepsilon_0)^2+4\Gamma^2]+2[(\varepsilon_1-\varepsilon_0)^2+4\Gamma\Sigma][\varepsilon_1\varepsilon_0+\Sigma^2]\right\}} \tag{40}$$

For non-totally symmetric modes $\bar{\alpha}$ is zero and the $\rho(\pi/2)$ value is dependent on the relative sizes of γ_s^2 and γ_{as}^2. If, for a given symmetry class, there are only symmetric or antisymmetric tensor components, then $\rho(\pi/2)=3/4$ or ∞, respectively, and does not display dispersion. Examples of such vibrational modes are the b_{1g} and b_{2g} modes (symmetric tensor) and a_{2g} modes (antisymmetric tensor) of metalloporphyrins. By contrast, for cases in which both symmetric and antisymmetric tensor components transform as the same irreducible representation (e.g. B_{1g}, B_{2g} or B_{3g} in the D_{2h} point group), $\rho(\pi/2)$ lies between 3/4 and ∞ and displays dispersion throughout the resonance region. The variation of $\rho(\pi/2)$ with excitation wave number [Equation (40)] is readily obtained from Equations (37) and (39).
The depolarization ratio $\rho(\pi/2)$ maximizes at the midpoint between the 0-0 and 0-1 resonances and decreases asymptotically towards 3/4 on either side. Its maximum value is a function of Γ and γ, as shown in Figure 11.

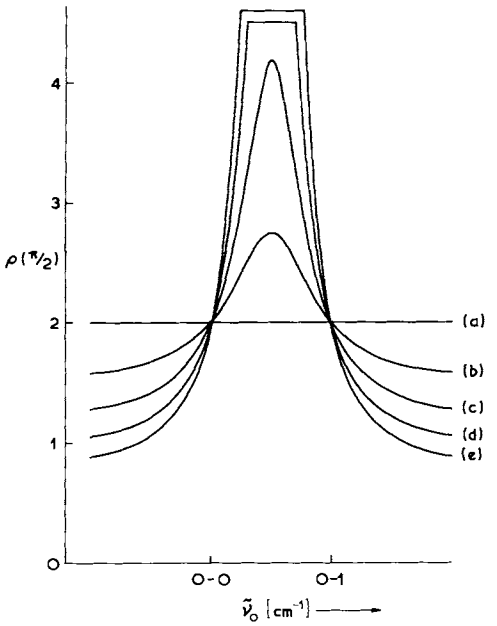

Fig. 11. Polarization dispersion for mixed symmetric/antisymmetric B-term scattering. (a) $\Gamma=10^{-4}\bar{\nu}^e$, $\gamma=0.1\bar{\nu}^e$; (b) $\Gamma=0.025\bar{\nu}^e$, $\gamma=0.075\bar{\nu}^e$; (c) $\Gamma=\gamma=0.05\bar{\nu}^e$; (d) $\Gamma=0.075\bar{\nu}^e$, $\gamma=0.025\bar{\nu}^e$; (e) $\Gamma=0.1\bar{\nu}^e$, $\gamma=0$.

The overtones of non-degenerate non-totally symmetric modes all transform as the totally symmetric representation and their $\rho(\pi/2)$ values will be the same as for totally symmetric fundamentals. Overtones of degenerate fundamentals transform as the symmetric part of the direct product (e.g. in the O_h point group $\{E_g\otimes E_g\}=A_{1g}+E_g$ and $\{T_{2g}\otimes T_{2g}\}=A_{1g}+E_g+T_{2g}$). $\rho(\pi/2)$ values for the overtones of degenerate vibrations have been determined by *Pawlikowski* and *Zgierski*.[53]

An alternative method of investigating the polarization properties of RR scattering involves the use of circularly polarized incident radiation and a 180° scattering geometry, as shown in Figure 8. The quantities that are determined are the reversal ratio, $\mathscr{P}(\pi)$, which is the ratio of the intensity of contra-rotating to that of co-rotating scattered light, and the degree of circularity, $\mathscr{C}(\pi)$, of the scattered light:

$$\mathscr{P}(\pi)=\frac{{}^{\circledR}I_{\textcircled{L}}(\pi)}{{}^{\circledR}I_{\circledR}(\pi)}=\frac{{}^{\textcircled{L}}I_{\circledR}(\pi)}{{}^{\textcircled{L}}I_{\textcircled{L}}(\pi)}=\frac{45\bar{\alpha}^2+\gamma_s^2+5\gamma_{as}^2}{6\gamma_s^2} \tag{41}$$

$$\mathscr{C}(\pi)=\frac{{}^{\circledR}I_{\circledR}(\pi)-{}^{\circledR}I_{\textcircled{L}}(\pi)}{{}^{\circledR}I_{\circledR}(\pi)+{}^{\circledR}I_{\textcircled{L}}(\pi)}=-{}^{\textcircled{L}}\mathscr{C}(\pi)=\frac{45\bar{\alpha}^2-5\gamma_s^2+5\gamma_{as}^2}{45\bar{\alpha}^2+7\gamma_s^2+5\gamma_{as}^2} \tag{42}$$

The measurement of Raman spectra excited with both circularly and linearly polarized radiation permits the determination of all three tensor invariants, and so-called "complete" polarization measurements have been carried out for a number of molecules.[54–58] Furthermore, it has recently been shown that meaningful circular polarization measurements can be obtained from samples dispersed in alkali halide disks.[59]

Using the information presented in this section in conjunction with point group tables it is possible for the reader to determine the depolarization ratio, under resonance conditions, for a vibration of any type in any point group. A tabulation of $\rho(\pi/2)$ values for the symmetry classes of all the common point groups is given in Ref. [1].

3. Experimental Techniques

The apparatus required for the excitation, dispersion and detection of RR scattering is precisely the same as that used for normal Raman spectroscopy, although sample illumination procedures are more critical. In order that RR spectroscopy may be applied to a wide range of molecules it is necessary that laser excitation throughout the visible and near UV spectral regions be available. Most RR studies to date have involved excitation provided by CW argon-ion and krypton-ion lasers and CW dye lasers, the latter providing continuously tunable radiation from 395 to 800 nm with seven different dyes (stilbene 1, stilbene 3, coumarin 30, sodium fluorescein, rhodamine 6G, rhodamine 101, and LD 700). Unfortunately, ion lasers provide only a small number of lines in the near-UV (330–370 nm), so it has been necessary to use different laser sources in order to obtain tunable radiation down to 250 nm. At the time of writing, three systems are in current use:

(1) Frequency-doubled output of a mode-locked ion or dye laser. With a repetition rate of ca. 40 MHz the radiation is quasi-CW, but only modest average power can be obtained (ca. 10–20 mW);

(2) Frequency-narrowed excimer lasers and excimer-pumped dye lasers. These have a repetition rate of ca. 10 Hz and average power of the order of 1–10 W; they are, however, very expensive;
(3) Frequency-tripled and -quadrupled pulsed Nd:YAG lasers which may be used to pump a dye laser. Such systems have found considerable application in time-resolved resonance Raman (TR^3) studies.

For most RR studies the scattered light is detected by photomultiplier tubes using photon-counting methods, in many cases employing dedicated computers which also control the spectrometer. In recent years many experiments have been performed using multichannel detection involving either a TV camera (intensifier-vidicon) or diode array. Multichannel detection reduces the time required to obtain a spectrum by several orders of magnitude, thus permitting RR studies of photochemically labile species. In combination with picosecond pulsed lasers, multichannel detection facilitates TR^3 experiments in which transient species and molecules in optically (or radiolytically) pumped excited states may be investigated.[8]

Sample illumination procedures present certain problems associated with strong absorption of the laser beam. These are:

(1) The need for optimization of the concentration of the scattering species in order to achieve a compromise between absorption and scattering processes. Experience has shown that the optimum concentration is best determined experimentally by trial-and-error, but several attempts have been made to calculate optimum sample concentrations for a wide variety of different scattering geometries;

(2) the avoidance of overheating the sample at the laser focus. Various rotating cells for solids, liquids, and gases have been employed and some workers have used devices which enable the focused laser beam to be swept over the sample in a linear or circular fashion. Recently, the use of flowing samples for TR^3 studies has been described;[8]

(3) The elimination of photolysis and luminescence. These can now be discriminated against by the TR^3 techniques mentioned above. Luminescence rejection can be achieved by using single-channel spectrometers in conjunction with pulsed lasers by time-adjusted gating of the photon-counting electronics.

Profound advantages accrue from measuring RR spectra of samples maintained at low temperature, viz. that of minimizing hot-band contribution to intensities and of alleviating thermolysis. This procedure results in a sharpening of the spectral features, thereby improving resolution and signal-to-noise ratios. Several cryostats are available for Raman studies, the most popular being those in which liquid nitrogen (77 K) or liquid helium (4 K) are used as coolants, and also closed-cycle helium gas cryostats (10–12 K). The latter are widely used for matrix-isolation studies.

4. Resonance Raman Studies of Small Molecules

4.1. Diatomic Molecules

Diatomic species (both neutral and ionic) have been subjected to some of the most detailed RR investigations during the last two decades. While many of the earlier studies were concerned with stable species, such as halogen and interhalogen molecules and ions, more recent work has centered on studies of matrix-isolated diatomic metal species. Data on the latter are summarized in Table 2, that on the former being included in earlier tabulations.[1,23]

Recent investigations of the halogens have been concerned with the theoretical interpretation of the spectra of Br_2[77–79] and Cl_2.[80–82] Whereas RR scattering from I_2 can be accounted for by assuming that the transition polarizability is dominated by a single electronic state, $^3\Pi_{0u}^+$ (see Ref. [1] and references therein), scattering from Br_2 contains a contribution from the repulsive $^1\Pi_{1u}$ state. A theoretical study of the EPs[79] has clearly demonstrated the involvement of both states in the scattering process. The theoretical model took account of interference between these contributions but assumed negligible coupling between the two states; this might be an unjustified assumption because the agreement between theory and experiment is poor in the 19500–21000 cm^{-1} region. The RR behavior of Cl_2 is quite different in that there seems to be no contribution from the $^3\Pi_{0u}$ state. A RR spectrum displaying an eight-membered progression is observed for 363.8-nm excitation within the contour of the $^1\Pi_{1u} \leftarrow {}^1\Sigma_g^+$ absorption band. However, the intensity enhancement factor of the fundamental for UV excitation with respect to visible, i.e. non-resonant, excitation is only 1.3, and the intensity of the first overtone is only 1/3 of that of the fundamental. These observations have been explained in terms of non-resonant contributions to the polarizability from higher energy states, especially a $^1\Sigma_u^+$ state at 78500 cm^{-1}. The reason for the absence of a $^3\Pi_{0u}^+$ contribution for Cl_2 is that the transition to this state is spin-forbidden. Its contribution to the RR scattering of Br_2 and, to a greater extent, to that of I_2, obtains from the induction of allowed character into the $^3\Pi_{0u}^+ \leftarrow {}^1\Sigma_g^+$ transition via spin-orbit coupling (this increases in the order Cl < Br < I).

Recent developments in the RR spectroscopy of matrix-isolated metal dimers are of special interest because they provide valuable experimental data upon which to test quantum-chemical calculations. An example of RR scattering by a metal dimer is shown in Figure 12 and Table 1 lists the results obtained so far on diatomic species, although many other metal dimers have been characterized by luminescence spectroscopy.[65] The occurrence of luminescence for some regions of excitation has precluded the more extensive application of RR spectroscopy and renders difficult the measurement of excitation profiles. It is to be hoped that these problems may be overcome in the near future in order that the theoretical interpretation of the spectra may proceed. In particular, it is noted that no unambiguous electronic band assignments have yet been proposed for metal dimers.

Table 2. Resonance Raman data on diatomic species. λ_{max} = wavelength of the electronic band, λ_0 = wavelength of the excitation radiation, ω_e = harmonic wave number, x_e = anharmonicity constant.

Species	State	Electronic band assignment	λ_{max} [nm]	λ_0 [nm]	ω_e [cm^{-1}]	$\omega_e x_e$ [cm^{-1}]	Comments	Ref.
Bi_2	Kr matrix, 8 K	$A \leftarrow X$	560	568.2	172.7	0.35		[60, 61]

[a] DMF = dimethylformamide. [b] Obtained from calculations of excitation profiles.

One aspect of these studies that deserves mention concerns the observation of anti-Stokes overtone progressions in Ca_2, Fe_2, Ti_2, and V_2. These cannot arise from thermal population of vibrational levels of the ground state because, at ca. 10 K, all molecules must be in the $v = 0$ level. The effect has been attributed to population of the $v > 0$ levels by the RR process, implying that these levels have long, but as yet undetermined, lifetimes. Such a phenomenon could form the basis of an infrared laser.

Finally, in this section, attention is drawn to recent work on the radical anions S_2^- and Se_2^- in ultramarines.[72] The ultramarine host lattice has a structure in which the radicals are trapped and stabilized in octahedral holes in the aluminosilicate lattice. Detailed measurements of the exci-

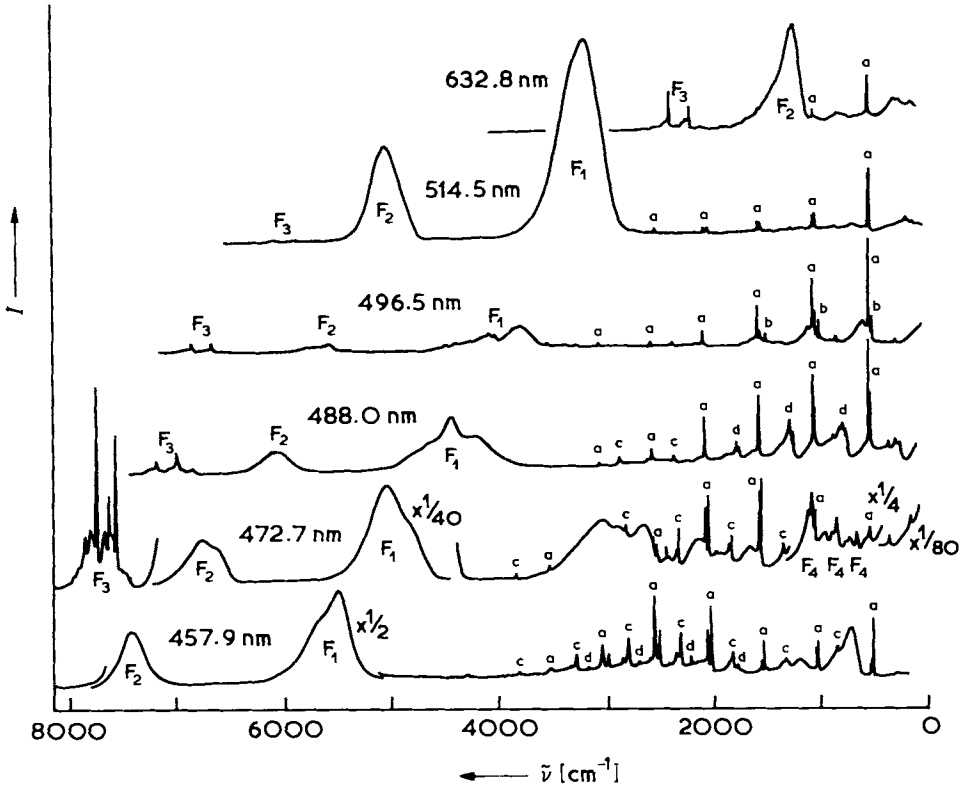

Fig. 12. Resonance Raman spectra of vanadium isolated in a solid argon matrix at 15 K, obtained using various excitation lines. The progressions consist of (a) ground state Raman bands, (b) excited state Raman bands, and (c) and (d) electronic Raman bands. The bands designated F1, F2, F3, and F4 are assigned to fluorescence (after Ref. [75]).

tation profiles of the ν, 2ν, and 3ν RR bands of the radicals were fitted to Equation (21), thus enabling the determination of the bond length changes attendant upon excitation. These are substantial (0.30 and 0.32 Å for S_2^- and Se_2^- respectively), reflecting the decrease in bond order from 1.5 in the $^2\Pi_u$ ground state to 0.5 in the $^2\Pi_g$ excited state. The potential use of ultramarine host lattices for trapping other small species (both stable and unstable) offers an attractive possibility for their detailed investigation by RR spectroscopy.

4.2. Triatomic and Tetratomic Molecules

A summary of the recent investigation on the RR spectra of triatomic molecules is given in Table 3. Several of these have been concerned with the characterization of metal trimers in noble gas matrices. The properties of metal trimers are less well established than for dimers but structural information on the former is of importance since it is only with these that a proper comparison between cluster and bulk metal properties can be made. However, at this early stage there is still considerable controversy over electronic band assignments. Most of the spectra obtained can be interpreted in terms of a C_{2v} or distorted D_{3h} ground state for the scattering species but, in the case of Cu_3, evidence has been obtained to show that it is a Jahn-Teller fluxional molecule, pseudorotating even at 15 K.

RR data pertaining to tetratomic molecules are summarized in Table 4. Although there have been fewer studies of tetratomic molecules than of diatomic and triatomic species, a number of important features of these studies are worthy of comment. The recently reported investigation of gaseous NH_3 heralds a new era of RR studies involving the use of far-UV excitation. By using the fifth harmonic of a pulsed Nd:YAG laser (212.8 nm), *Ziegler* and *Hudson*[96] were able to excite the singlet electronic transition of lowest energy (ca. 190 nm) assigned to the transfer of an electron from the nitrogen lone pair to a 3s Rydberg-type orbital. This excitation results in a change of molecular geometry from C_{3v} to D_{3h}, as evidenced by a long overtone progression in the deformation mode ν_2 in the absorption spectrum. The RR spectrum displays a progression $\nu_2\nu_2$ extending to $\nu_2=4$ and also a combination band progression $\nu_1+\nu_2\nu_2$ extending to $\nu_2=4$. This latter observation constitutes the first direct evidence from which it may be concluded that the N–H bond length changes upon excitation to the 190-nm state. Measurements of excitation profiles should enable the N–H bond-length change to be calculated.

The square planar molecules S_4^{2+}, Se_4^{2+}, and Te_4^{2+} are 6π-electron systems and they are thus examples of inorganic aromatic molecules. In each case the allowed electronic transition of lowest energy is $\pi^*\leftarrow\pi$ ($^1E_u\leftarrow{}^1A_{1g}$), corresponding to the transfer of a electron from the nonbonding e_g orbital to the antibonding b_{2u} orbital. Excitation within the contour of the relevant absorption bands gives rise to RR spectra that are characterized by an intense progression $\nu_1\nu_1$ and weaker subsidiary progressions

Table 3. Resonance Raman data on triatomic species.

[a] Irregular overtone progressions precluded the calculation of molecular constants.

$\nu_1\nu_1+\nu_2$ and $\nu_1\nu_1+\nu_3$, the latter being evidence for excited-state JT effects involving $Q_2(b_{1g})$ and $Q_3(b_{2g})$. However, for Se_4^{2+} and Te_4^{2+}, ν_3 is overlapped by ν_1, as evidenced by $\rho(\pi/2)=0.33$. For excitation resonant with an E_u state (x,y-polarization) the theoretical requirement is that $\rho(\pi/2)=1/8$ for ν_1 and 3/4 for ν_3; thus the measured ρ value for the overlapping bands results from an intensity ratio $I(\nu_1)/I(\nu_3)$of 1.3. An analysis of the vibrational data showed that the coalescence of ν_1 and ν_3 arises because the interaction force constant associated with two adjacent bonds (f_{rr}) is near zero.

4.3. Tetrahedral Molecules

RR investigations of tetrahedral species (Table 5) have been centered on (a) transition metal oxo- and thio-anions, and (b) main group and transition metal tetrahalides. In each case excitation was into the contour of the charge-transfer absorption band of lowest energy in the visible/near UV region. The resonant electronic transition involves the promotion of an electron from the t_1 orbital localized on the ligands to the e metal-ligand antibonding orbital (Fig. 13). Such an electronic transition results in a significant lengthening of the bonds; thus the RR spectra are characterized by intense overtone progressions in the $\nu_1(a_1)$ mode. Additionally, subsidiary progressions are observed which involve single quanta of one or more of the non-totally symmetric modes $\nu_2(e)$, $\nu_3(t_2)$ and $\nu_4(t_2)$, i.e. progressions of the type $\nu_1\nu_1+\nu_2$, etc. These are attributed to JT coupling in the triply degenerate excited state, all three non-totally symmetric modes being potentially JT active.

In cases where the absorption spectra and excitation profiles display vibrational fine structure, serious attempts have been made to calculate the bond-length changes attendant upon excitation by fitting the experimental data to Equation (21). These bond-length changes, which range from 0.029 Å for $[WS_4]^{2-}$ to 0.046 Å for $[MnO_4]^-$, are given in Table 4, together with the other parameters involved in the calculations. However, all of the bond-length changes determined for tetrahedral molecules have been miscalculated due to use of an erroneous relation between Δr and ΔQ. The values in the literature[24, 99, 102, 112, 115] are a factor of two greater than the correct ones, which are given in this review. The absorption spectrum and experimental and calculated EPs for $[MnO_4]^-:K[ClO_4]$ are shown in Figure 14. By comparison with the bond-length changes determined for the diatomic species (e.g. 0.30 Å for S_2^-), these values are small. This is because the change of bond order upon excitation is also much smaller, from 2.25 to 2.125, as compared to 1.5 to 0.5 for S_2^-.

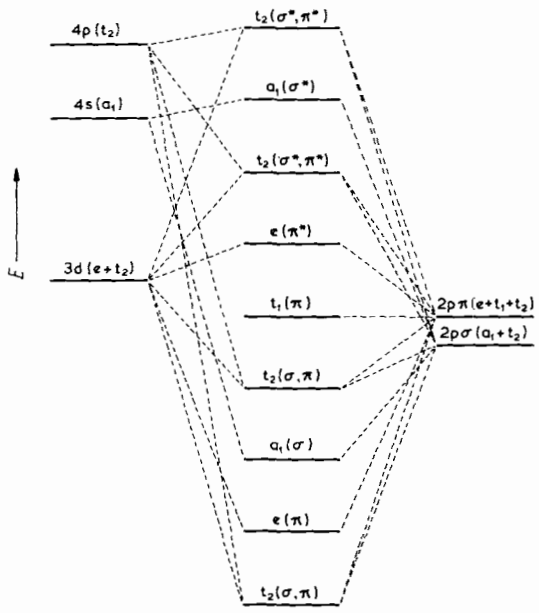

Fig. 13. Schematic molecular orbital diagram for tetrahedral transition-metal complexes.

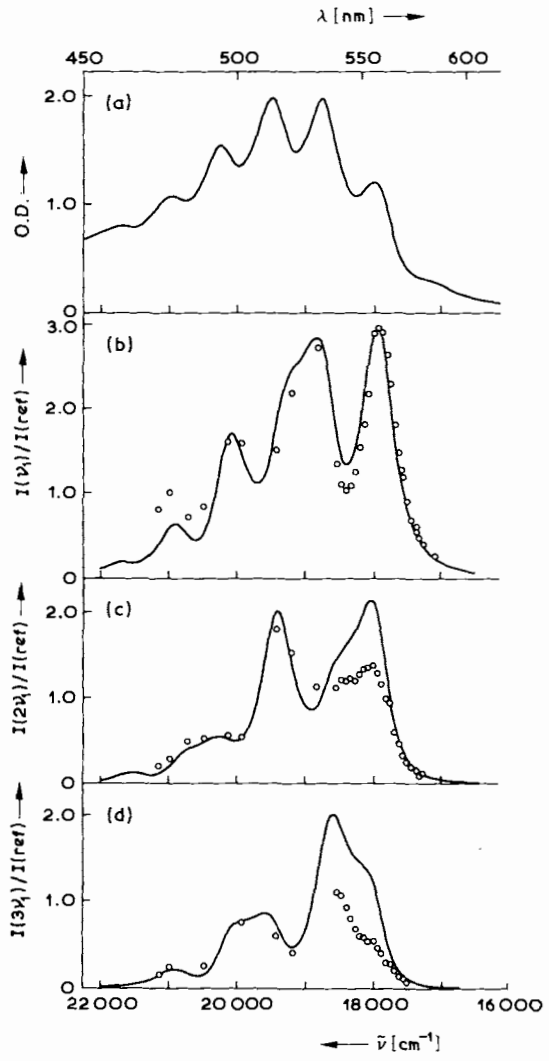

Fig. 14. (a) Absorption spectrum of $[MnO_4]^-:K[ClO_4]$ in a $K[ClO_4]$-disk at room temperature. O.D. = optical density. (b)–(d) Experimental (○) excitation profiles for the ν_1, $2\nu_1$, and $3\nu_1$ bands of $[MnO_4]^-$, respectively. The full lines represent the (best fit) calculated profiles for $\Gamma=300\ cm^{-1}$, $\gamma=0$, and $\Delta r=0.46$ Å (after [24]).

The electronic spectrum of $[WS_4]^{2-}$ in the 400–450 nm region consists of a strong band at ca. 400 nm and a weak shoulder at ca. 430 nm. The strong band has been assigned to the fully-allowed $^1T_2\leftarrow{}^1A_1$ transition arising from the $e\leftarrow t_1$ electronic transition. However, the excited $(t_1)^5(e)^1$ configuration gives rise to three other terms, $^1T_1$, $^3T_1$ and

$^3T_2$, and the 430-nm shoulder has been assigned to the $^1T_1 \leftarrow {}^1A_1$ transition. The two other possible assignments are ruled out on the grounds that (a) the $^3T_2 \leftarrow {}^1A_1$ transition would be expected to be of much lower energy than $^1T_2 \leftarrow {}^1A_1$,[159] and (b) $^3T_1 \leftarrow {}^1A_1$ is both spin- and orbitally-forbidden. Excitation profiles measured throughout the $^1T_2 \leftarrow {}^1A_1$ and $^1T_1 \leftarrow {}^1A_1$ bands display minima in the region of the latter (Fig. 15). This behavior can be accounted for by interference between the $^1T_2$ and $^1T_1$ contributions to the transition polarizability. Calculations were performed on the assumption that Δr is the same for both states (Fig. 16). This seems reasonable as these two terms arise from

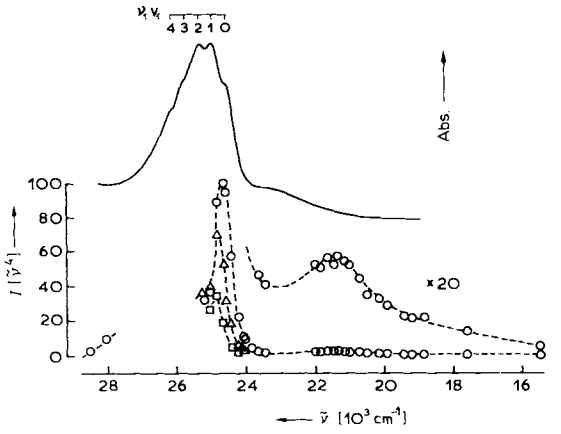

Fig. 15. Electronic absorption spectrum of $[Bu_4N]_2[WS_4]$ at 14 K (solid line) and the excitation profiles for ν_1 (o), $2\nu_1$ (△) and $3\nu_1$ (□) at 80 K (after Ref. [115]).

the same excited configuration. Corroborative evidence for the $^1T_1 \leftarrow {}^1A_1$ assignment is provided by the observation of, and analogous assignment for, similar bands in the absorption spectra of $[CrO_4]^{2-}$ [116] and $[MnO_4]^-$.[117] Unfortunately, these occur in less accessible regions (385 and 850 nm, respectively) and thus have not yet been subjected to RR investigation.

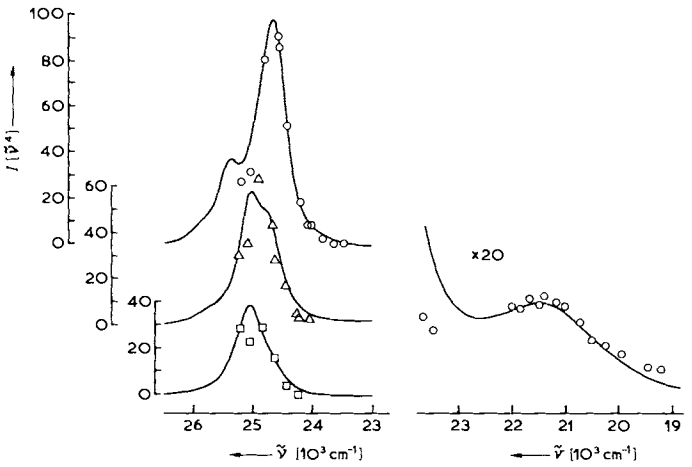

Fig. 16. Calculated (solid lines) and experimental excitation profiles for the ν_1 (o), $2\nu_1$ (△), and $3\nu_1$ (□) bands of $[Bu_4N]_2[WS_4]$ at 80 K (after Ref. [115]).

Attention is drawn to the observation of $\rho(\pi/2)=0.15$ for the ν_1 band of $[FeBr_4]^-$, where a value of zero might, at first sight, be expected. The non-zero value has been shown to be due to an antisymmetric contribution to the transition polarizability tensor,[56, 100] resulting from spin-orbit coupling of the $^6A_1$ ground state with various excited states of the same spin multiplicity. The magnitude of the antisymmetric tensor contribution is likely to be governed by the spin-orbit coupling constant for both the metal and ligand atoms, and the reciprocal of the energy separation between the ground state and those excited states to which it is coupled. On this basis it would be expected that ν_1 $\rho(\pi/2)$ values for the series of molecules $[FeX_4]^-$ would increase in the order X = Cl < Br < I. Partial support for this hypothesis is provided by the observation that $\rho(\pi/2)=0$ for the ν_1 band of $[FeCl_4]^-$. Studies on the $[FeI_4]^-$ molecule were precluded by its rapid decomposition in solution.

4.4. Planar Four-Coordinate Molecules

There have been no new reported RR studies on square planar MX_4-type molecules during the last few years, and the reader is referred to earlier reviews[1, 23] for examples of these. However, there have been a number of RR investigations of bis(dithio) complexes of nickel(II)[118–123] and copper(II),[120, 121] which have assisted in the electronic band assignments for these molecules. The copper complexes are of particular interest as they are model compounds for the study of copper(II)-sulfur interactions in blue copper proteins. In all of the systems studied, absorption bands in the visible region were assigned to metal-ligand charge transfer (MLCT) transitions on the basis that excitation within the contours of these bands yields intense RR spectra dominated by several totally symmetric modes. Due to the lack of bands attributable to either overtones or non-totally symmetric modes in most of these spectra, it may be concluded that any changes of geometry in the MLCT excited states are confined to minor alterations of some bond lengths and angles. One notable exception is the "red" form of bis(dithiooxalato)nickel(II)[123] for which the following progressions were observed: $\nu_1\nu_1$ extending to $\nu_1=6$, and $\nu_1\nu_1+\nu_2$ extending to $\nu_1=4$, where ν_1 is a combination of CC and CS stretching coordinates and ν_2 is a combination of CO and CC stretching coordinates. Clearly, there is a significant change in the size of the C_2S_2Ni ring upon electronic excitation.

4.5. Five-Coordinate Molecules

The only five-coordinate molecules to have been studied recently are the tetrahalooxotechnetate(V) ions, $[TcOX_4]^-$, where X = Br[124] or I.[125] For the bromide a progression reaching to $4\nu_4$ was observed, where ν_4 is the b_1 class $\nu(TeBr_4)$ mode. This is clear evidence for a strong excited-state JT effect involving Q_4. Additionally, weak bands assigned to $2\nu_1$ and $2\nu_1 \pm \nu_4$ were observed, where ν_1 is the $\nu(TcO)$ mode. The RR spectrum of the iodide displays a progression in $\nu_1\nu_1$ extending to $5\nu_1$ ($\omega_1 = 1005.3 \pm 0.2$, $x_{11} = -4.7 \pm 0.1$ cm^{-1}) and several weaker progressions of the sort $\nu_1\nu_1+\nu_i$, where ν_i is ν_2, ν_3, ν_4, ν_6 or an unidentified lattice mode. Weak first overtones of $\nu_2(a_1)$, $\nu_3(a_1)$, $\nu_4(b_1)$, and $\nu_8(e)$ are also observed and it may be concluded that excited-state JT effects are weaker for the iodide than for the bromide.

4.6. Octahedral Molecules

The results of RR studies of hexahalometalate ions are summarized in Table 6. The ions concerned are derivatives of d^3, d^4, and d^5 transition metals and the $d^{10}s^2$ complexes $[TeX_6]^{2-}$, X = Br or Cl. The low spin d^4 and d^5 species are of special interest in that the $^3T_{1g}$ and $^2T_{2g}$ ground terms are split by spin-orbit interaction to give, respectively, four

and two states (Fig. 17). These states all lie within ca. 5000 cm^{-1} of each other and in each case Raman bands have been observed which may be assigned to transitions from the ground to these states. The most recently reported study is of the vibrational and electronic RR spectra of the $[RuCl_6]^{2-}$ and $[RuBr_6]^{2-}$ ions. The RR spectra and EPs for $[RuCl_6]^{2-}$ are shown in Figure 18. The electronic and vibrational Raman bands display maximum intensity for resonance with different excited states, although it is not understood why this should be so.

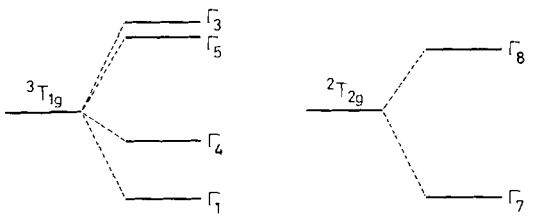

Fig. 17. Qualitative energy level diagrams for the spin-orbit splitting of the $^3T_{1g}$ and $^2T_{2g}$ ground terms.

The $5d^5$ species $[IrCl_6]^{2-}$ and $[IrBr_6]^{2-}$ possess Kramers degenerate $\Gamma_6(^2T_{2g})$ ground states. As a consequence of the ground-state degeneracy, the three Raman-active fundamentals (ν_1, ν_2 and ν_5) all give rise to anomalously polarized bands.[50] Some of the hexahalometalates have been investigated by the relatively new technique of magnetic Raman optical activity, which enables the sign of the

ground-state g-factor to be determined from circular intensity differential measurements.[131]

4.7. Species with No Discrete Vibrating Unit

In this section we discuss some recent RR studies on the two-dimensional layer compounds ZrS_3[138] and HfS_3.[139] Although these are strictly semiconductor species we have chosen to include them because their RR behavior is in many ways similar to that of small molecular species. ZrS_3 has a band gap energy of about 2.5 eV (20000 cm^{-1}) and excitation in this region produces RR spectra that are dominated by progressions involving three fundamentals, at 152, 285, and 326 cm^{-1}. These are assigned to the vibrational R_y' motion, the totally symmetric stretching mode of Zr-S_I interchain bonds, and the $\nu_s(ZrS_2^{2-})$ vibration, respectively. Off-resonance polarized Raman spectra indicate that the intensities of all three of these bands are dominated by α_{yy} components. Since the excitation profiles of these bands were found to maximize close to the absorption maximum at 492 nm, it was concluded that the transition must be y-polarized ($A_u \leftarrow A_g$ in the C_{2h} factor group). Neglecting any changes of vibrational wave number in the excited state, the best fit to the excitation profiles was calculated with the parameters $\tilde{\nu}_{00} = 20325$ cm^{-1}, $\Gamma = 450$ cm^{-1}, and $A = 0.894$ (285 and 326 cm^{-1} bands) or 1.0 (152 cm^{-1} band).

For HfS_3 the first absorption maximum is at ca. 22700 cm^{-1} and excitation in this region produces RR spectra and excitation profiles that are similar to those of ZrS_3. The most enhanced bands are the four totally symmetric modes at 128, 261, 275, and 322 cm^{-1}, which were shown by off-resonance Raman orientation measurements to be dominated by their α_{yy} components. It was postulated that at least two allowed y-polarized transitions contribute to the RR scattering process for both HfS_3 and ZrS_3.

5. Resonance Raman Studies of Larger Polyatomic Molecules

5.1. Six-Coordinate Transition Metal Complexes

There have been a number of RR studies of tris(α-diimine) and related complexes of iron(II),[140-145] ruthenium(II),[146-152] and, to a lesser extent, osmium(II).[141,148] A great deal of interest has been focused on $[Ru(bpy)_3]^{2+}$, bpy = 2,2'-bipyridyl, because of its importance as a photocatalyst for the photodecomposition of water. RR investigations of $[Ru(bpy)_3]^{2+}$ have involved (a) excitation resonant with the first singlet MLCT excited state at 22000 cm^{-1}, and (b) optical pumping of the first triplet MLCT state (via the singlet), designated $[^*Ru(bpy)_3]^{2+}$, followed by resonant excitation from the populated triplet state to a higher triplet state. The latter enables the measurement of the RR spectrum of the ion in the first triplet excited state. This is characterized by a number of new vibrational bands which are ca. 60 cm^{-1} lower than for the ion in its ground state. The similarity between these bands and those of the bipyridyl radical anion have led to the conclusion that the electron transfer from the metal is to one bpy ligand only (rather than to a molecular orbital encompassing all three), such that the excited state may be formulated as $[Ru^{III}(bpy)_2(bpy^{\bullet -})]^{2+}$. Additional evidence for the localized model is provided by (a) the observation of additional bands which are unshifted with respect to the ground state, indicating the presence of neutral bipyridyl ligands in the excited state, (b) similar behavior for $[Os(bpy)_3]^{2+}$, substituted bis(bipyridyl)ruthenium(II) complexes, and *fac*-$[XRe(CO)_3(bpy)]$, X = Br or Cl.[148,152]

Tris(α-diimine)iron(II) complexes exhibit a strong absorption band in the visible region ($\lambda_{max} = 524$ nm for $[Fe(bpy)_3]^{2+}$) which has been assigned to a MLCT $^1E \leftarrow {}^1A_1$ transition on the basis of single-crystal polarized absorp-

tion studies. In each case there is an unresolved shoulder ca. 1500 cm^{-1} above the absorption maximum, which could be assigned to a vibronic side-band or to a second electronic transition. RR spectra and excitation profiles of these complexes have been measured using excitation throughout the absorption region and the results interpreted in terms of a single transition giving rise to a 0-0 and a conglomerate of 0-1 bands.[140] This conclusion was reached on the bases that (a) the most enhanced Raman bands are those in the 1400–1600 cm^{-1} region (ligand ring vibrations involving C–C and C–N bonds) and (b) these modes are responsible for the vibronic sideband in the absorption spectra. However, the RR band depolarization ratios vary between 0.10 and 0.71,[140] an observation which is inconsistent with RR scattering involving only a $^1E \leftarrow {}^1A_1$ resonant transition ($\rho(\pi/2) = 1/8$ for totally symmetric modes), but which could be accounted for by contributions from both ^1E and $^1A_2$ resonant excited states. New absorption and CD spectroscopic data obtained for $[Fe(bpy)_3]^{2+}$ indicate that there may be a number of transitions within this spectral region.[153] A reassessment of the RR spectrum of the ion is in progress in our laboratory.

A number of carbonyl-imine and -diimine complexes of Cr, Mo, W, Re and Fe have been investigated by *Stufkens* et al.[154–157] The RR spectra of these complexes were obtained by excitation within the MLCT band of lowest energy, i.e. in the 400–600 nm region. In common with the diimine complexes discussed previously, the spectra display only polarized Raman bands. Thus the scattering mechanism is undoubtedly of A-term origin and the small displacement approximation is probably valid because any bands attributable to overtones are very weak. The MLCT bands have been shown to consist of the overlap of three or four bands on the basis of RR EPs and magnetic circular dichroism spectra. These bands are assigned to charge transfer resulting from the promotion of an electron from one of the metal d-orbitals to a π^* orbital localized on the diimine ligand. The RR data are consistent with this assignment in that the most enhanced Raman bands are those associated with the diimine ligand, i.e. bands in the 1400–1600 cm^{-1} region which are attributed to ν(CC) and ν(CN) stretching modes. Surprisingly, it is found that the ν_s(*cis*-CO) bands are also enhanced, which implies that the CO bond lengths are affected by transitions to an MLCT state. That the ν_s(*trans*-CO) bands do not display RR activity suggests that the effect is not due either to the oxidation of the metal atom or to a change of π-backbonding accompanying the transition. Instead, it is believed that the RR activity of ν_s(*cis*-CO) is due to an excited state interaction between the diimine and the *cis*-carbonyl ligands. Such an interaction is expected to increase as the central atom becomes smaller, this inference being supported by the observation that, for the series [M(CO)$_4$(diazabutadiene)], where M = Cr, Mo, or W, the intensity of ν_s(*cis*-CO) increases with respect to ν_s(CN) in the order W < Mo < Cr. It was also found that these compounds are photoreactive when irradiated in the presence of a phosphane ligand within the MLCT band. This process results in the substitution of a *cis*-carbonyl group by the phosphane with a quantum yield varying from 10^{-2} to 10^{-4}. The quantum yield is found experimentally to be directly related to the Raman intensity of the ν(*cis*-CO) band, and complexes which do not display a RR effect for this vibration are photochemically stable. These results clearly show that RR spectroscopy is a powerful tool for the interpretation of the photochemistry of inorganic molecules.

RR studies of $K_3[Cr(CN)_5NO]$[158] at resonance with the $^2B_2 \leftarrow {}^2B_1$ chromium-to-NO transition have shown that the most enhanced Raman band, and the one which forms the longest (to three members) progression, is ν(CrN). Intensity ratio calculations have led to the conclusion that the CrN bond length increases by ca. 0.10 Å on excitation to this MLCT state, but that the CrC bond length also increases, though by a lesser amount (ca. 0.07 Å).

5.2. Metal–Metal Bonded and Bridged Species

Of the very large number of metal-metal bonded species known,[160] those for which RR studies have proved to be particularly valuable are the quadruply bonded ones $[Mo_2Cl_8]^{4-}$, $[Mo_2Br_8]^{4-}$, and $[Re_2X_8]^{2-}$, X = F, Cl, Br, or I.[161–166] In each case the eight halogen atoms are situated virtually at the corners of a cube, thereby encapsulating the M_2 unit, the MMX angle being ca. 105° in each case. The molybdenum and rhenium species are effectively isoelectronic, the molybdenum species possessing a single moderately intense and highly structured band in the visible region. The principal progression-forming mode giving rise to this structure has, in each case, been identified as the MM stretch. For the rhenium species there are a number of bands throughout the visible/near UV region (Fig. 19). The lowest energy band in each case, as for the molybdenum

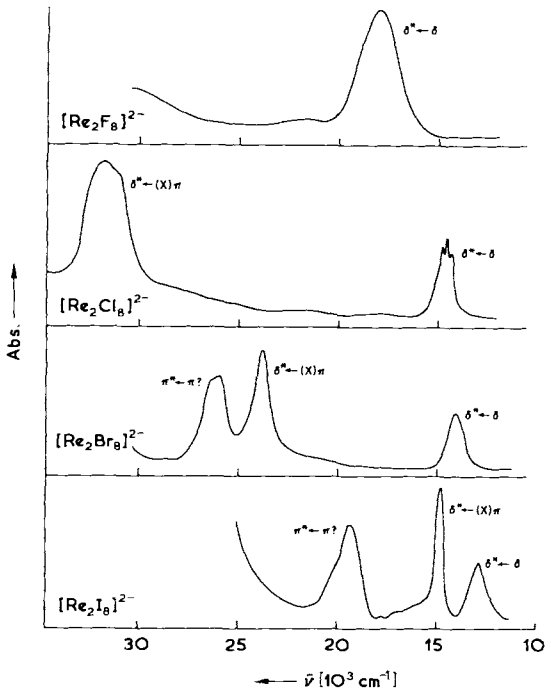

Fig. 19. Electronic absorption spectra of the complexes $[Bu_4N]_2[Re_2X_8]$ at ca. 14 K in the region of their $\delta^* \leftarrow \delta$, $\delta^* \leftarrow \pi(X)$ and $\pi^* \leftarrow \pi$ (?) transitions. ($Cs[BF_4]$, KCl, KBr, and CsI disks for X = F, Cl, Br, or I, respectively) (after Ref. [167]).

species, has been assigned to the $^1A_{2u} \leftarrow {}^1A_{1g}$ ($\delta^*(b_{1u}) \leftarrow \delta(b_{2g})$) transition. Excitation of such an ion from the ground to the $^1A_{2u}$ state in effect changes the MM bond order from four to three, with consequential increase in bond length (hence the observed progression in ν(MM)).

Irradiation within the contour of the $\delta^* \leftarrow \delta$ band leads, in each case, to the generation of an RR spectrum characterized by (a) substantial enhancement to the intensity of ν(MM) and (b) the development of a long (at most to eleven members) progression in ν(MM). These results confirm the conclusion drawn from the electronic spectra, namely that the equilibrium MM bond length in the δ^* state is significantly longer than that in the ground state. The set of four dirhenium anions are particularly interesting (Fig. 20). Raman spectra of these ions, in each case obtained at resonance with the $\delta^* \leftarrow \delta$ transition, give rise to long progressions in ν(ReRe) (318, 275, 276, and 257 cm^{-1} for X = F, Cl, Br, or I, respectively); these observations clearly indicate the similar nature of the lowest electronic transition in each case. This conclusion is substantiated by measurements of the depolarization ratio of the ν(ReRe) Raman band at resonance with the $\delta^* \leftarrow \delta$ transition. This has been found to take the value 1/3 for $[Re_2F_8]^{2-}$, $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$, a result which is only possible if the resonant electronic transition is z-polarized (Section 2.5). This is precisely the polarization of the $\delta^* \leftarrow \delta$ transition (transition moment A_{2u} in the D_{4h} symmetry point group to which the ions belong).[167, 168]

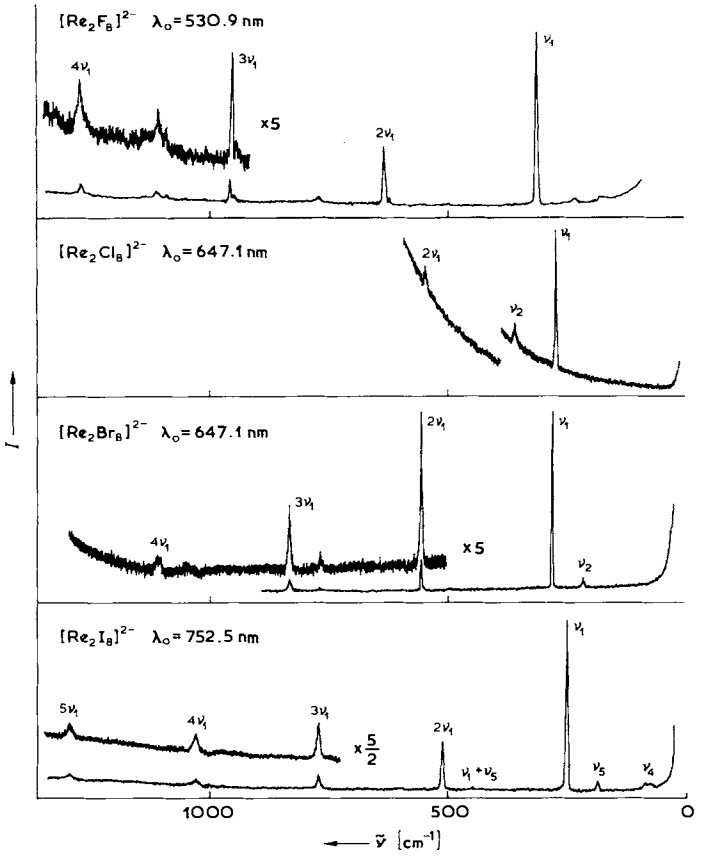

Fig. 20. Resonance Raman spectra of the complexes $[Bu_4N]_2[Re_2X_8]$ at ca. 80 K in the region of their $\delta^* \leftarrow \delta$ transitions (after Refs. [167], [168]).

Irradiation within the contour of the second electronic transition of each ion produces substantially different spectra in each case (Fig. 21). Such RR spectra are characterized by resonance enhancement to the bands attributed to ν(ReX) and its overtones. (ν(ReX) occurs at 624, 362,

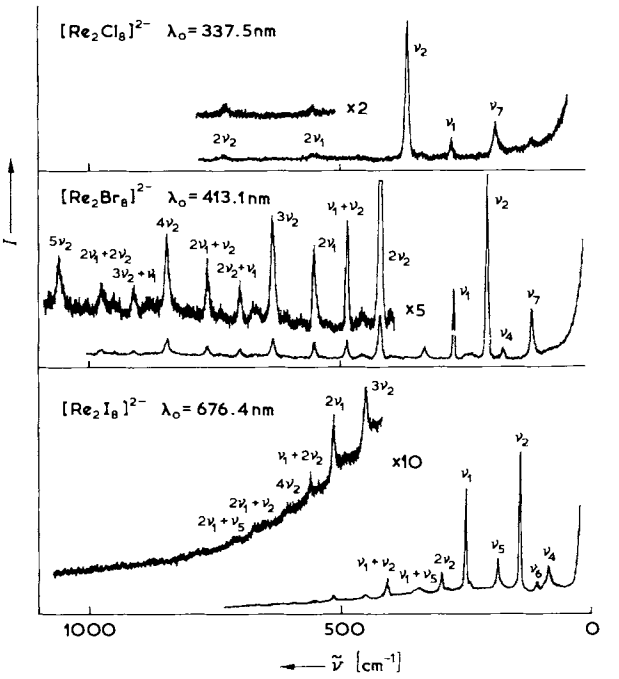

Fig. 21. Resonance Raman spectra of the complexes $[Bu_4N]_2[Re_2X_8]$ at ca. 80 K in the region of their $\delta^* \leftarrow \pi(X)$ transitions (after Refs. [167], [168]).

211 and 152 cm^{-1} for X = F, Cl, Br or I, respectively). Thus, the principal structural change undergone by each ion on excitation to its second excited state is along the ReX coordinate. This result clearly implies that the second electronic transition is in each case of the halogen-to-metal charge-transfer type. The assignment of the second strong band in the electronic spectra of the $[Re_2X_8]^{2-}$ ions is thus clearly $b_{1u}(\delta^*) \leftarrow X, e_g(\pi)$, $^1E_u \leftarrow {}^1A_{1g}$. This result is confirmed by the fact that the measured depolarization ratio of the ν(ReX) band of $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$ at resonance with the second electronic band is 0.15, i.e. close to the value of 1/8, as required for a $^1E_u \leftarrow {}^1A_{1g}$ transition.

Many other metal-metal multiply bonded species yield richly detailed RR spectra at resonance with their lowest electronic transition. The most notable of the recent studies along these lines have been those on $[Ru_2(O_2CR)_4Cl]$, R = H, CH_3, C_2H_5, or C_3H_7,[169] and related studies on diosmium and dirhodium carboxylates.[170, 171] In addition to the bond between them the metal atoms are bridged by the carboxylate ligands.

Another type of bridged species is that in which the metal atoms are separated by one or more atoms. Of these, $[Ru_2OCl_{10}]^{4-}$ (Fig. 22) and related ions have been subjected to the most intensive RR investigations.[172, 173] The spectra of these ions are characterized by intense progressions involving the M–O–M stretching coordinate (ν_1), the axial and equatorial metal–halogen stretches (ν_2 and ν_3), the $\delta(OMX_{eq})$ coordinate (ν_4), and even quanta of the infrared-active modes $\nu_5(\nu_{as}(MOM))$ and $\nu_9(\delta(MOM))$. It is

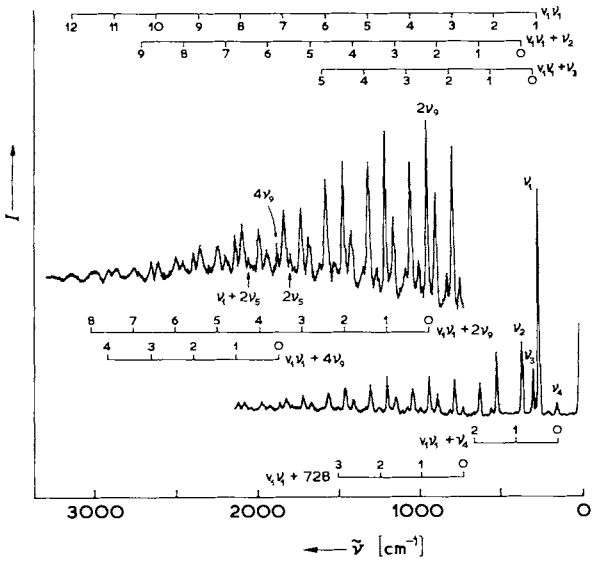

Fig. 22. Resonance Raman spectrum of $K_4[Ru_2OCl_{10}]$ at ca. 80 K, obtained with 488.0 nm excitation (after Ref. [173]).

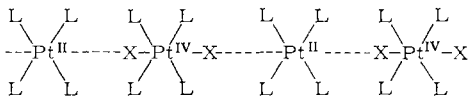
clear, then, that there must be a substantial alteration of molecular geometry accompanying the resonant, $^1A_{2u} \leftarrow {}^1A_{1g}$, electronic transition. The observation of progressions involving even quanta of $\nu_5(a_{2u})$ and $\nu_9(e_u)$ is strong evidence for a reduction in symmetry in the excited state, although it is not obvious what that symmetry might be.



Other bridged species that have been studied recently include ones in which the bridging moiety is N,[174] N_2,[175], or O_2 (both peroxo and superoxo).[176] In all cases the RR spectra are characterized by a number of bands attributable to totally symmetric fundamentals. Together with the absence of any overtones for most of these species this observation indicates that the geometric changes attendant upon excitation are small and spread over many atoms.[38] There have been several studies of μ_2- and μ_3-sulfur-bridged species in which there are $[MS_4]^{2-}$ sub-units, where M = Mo or W.[177-179] Considerable interest has developed in the molybdenum complexes, some of which are model compounds for the MoFe cofactor of nitrogenase.

5.3. Mixed-Valence Complexes

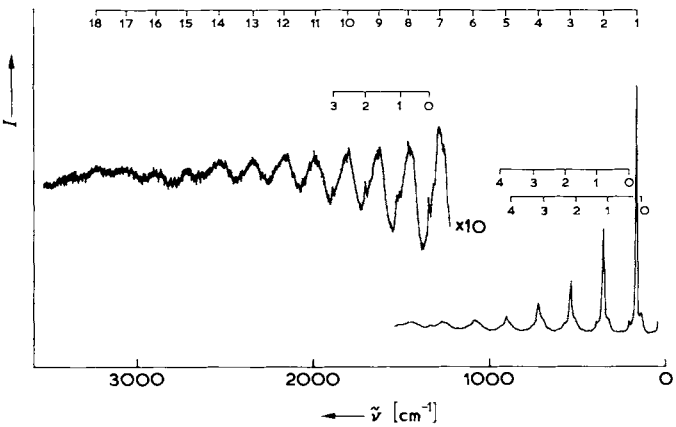
Complexes in which the metal atom is present in more than one oxidation state are of considerable importance, not only in inorganic chemistry, but also in bioinorganic chemistry and geology. Thus, at least 40 elements in the periodic table form mixed-valence complexes, many of which have very striking properties. Mixed-valency is central to the role of Fe_4S_4 clusters for promoting redox processes in enzymes such as ferredoxin and rubredoxin, and many minerals (particularly iron minerals) contain the metal in at least two oxidation states.

The two most significant properties of mixed-valence complexes are their colors and their electrical conductivities. Each of these properties differs substantially, in many cases, from those of the constituent single-valence species. In the first place, the colors of certain mixed-valence species are so intense that they have been used as dyestuffs (e.g. Prussian blue, ruthenium red), while in the second place, certain mixed-valence complexes are best described as one-dimensional conductors (e.g. $[K_2Pt(CN)_4 \cdot Br_{0.30} \cdot 3H_2O]$ (KCP)). The reader is referred elsewhere to recent reviews of the classification and properties of mixed-valence complexes.[3,4]

The colors of mixed-valence complexes are dominated by intervalence transitions which, being electric-dipole allowed, are in general intense. Raman studies of such complexes at resonance with the intervalence bands prove to be very sensitive probes of the geometric changes undergone on excitation from the ground to the intervalence state. Particularly detailed studies of certain types of linear-chain complexes have now been made, viz. that of Wolffram's red and its analogues, which are examples of Pt^{II}/Pt^{IV} mixed-valence complexes of the type **1**, where

1

L = amine, X = Cl, Br, or I. Irradiation within the contour of the intervalence band of such complexes leads to enormous intensification of the band attributed to the symmetric chain-stretching mode, $\nu_1(X\text{-}Pt^{IV}\text{-}X)$, together with the development of a long, intense, overtone progression $\nu_1 \nu_1$ (reaching to, at most, 18 members) (Fig. 23). These results



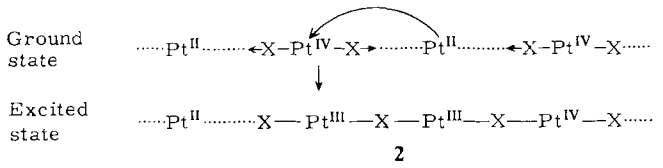


Fig. 23. Resonance Raman spectrum of $[Pt(tn)_2][Pt(tn)_2Br_2][ClO_4]_4$ in a KBr disk at ca. 80 K, obtained with 488.0 nm excitation (after Ref. [180]), tn = 1,3-diaminopropane.

indicate that the Pt^{IV}-X bond lengths increase substantially (probably by at least 0.1 Å)[180] on excitation of the complex from the ground to the intervalence state. This structural change is precisely that expected (on conductance grounds) on excitation to the Pt^{III}/Pt^{III} intervalence state since, in its relaxed geometry in this state (as in **2**), the axial halogen atoms would be expected to be midway between the Pt^{III} ions.

The assignment of the progression-forming mode to the symmetric chain-stretching vibration has been confirmed

2

by single crystal orientation measurements, an example of which is shown in Figure 24.

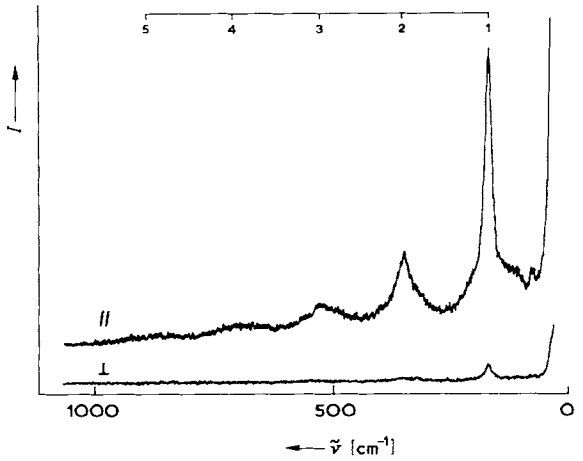

Fig. 24. Resonance Raman spectra of a single crystal of $[Pt(tn)_2][Pt(tn)_2Br_2][ClO_4]_4$ at ca. 298 K with the incident radiation polarized along the crystal Z axis and the scattered radiation ($\lambda_0 = 568.2$ nm) measured for polarization parallel and perpendicular to the Z axis (after Ref. [180]).

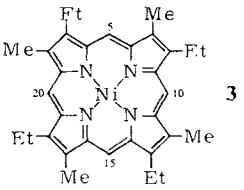
Related studies have been carried out on analogous mixed-valence Pd^{II}/Pd^{IV} chain complexes, and also on certain mixed-metal, mixed-valence complexes (e.g. Ni^{II}/Pt^{IV} and Pd^{II}/Pt^{IV} chain complexes), with similar results.[181-183] In all cases, harmonic wave numbers and anharmonicity constants have been calculated from the observed band wave numbers, and tabulated.[3] It has recently been discovered that, for certain linear-chain mixed-valence platinum complexes, the wave number, ν_1, of the symmetric chain-stretching mode increases as the excitation wave number (ν_0) increases.[184] For any set of complexes the wave-number change



$\nu_1(\nu_0 = \text{high wave number}) - \nu_1(\nu_0 = \text{low wave number})$

increases in the order Cl < Br < I and is largest for those complexes in which the $Pt^{II} \cdots Pt^{IV}$ separation is least and for which the bond length ratio $r(Pt^{IV}\text{-}X)/r(Pt^{II}\text{-}X)$ is nearest to unity. This behavior, which is not observed for any of the equatorial modes, is believed to be due to solid state effects rather than an intrinsically mixed-valence property.

One other type of mixed-valence complex that is worthy of note is the so-called Creutz-Taube ion, $[(NH_3)_5Ru(pyrazine)Ru(NH_3)_5]^{5+}$, in which the ruthenium oxidation states are formally +2 and +3 or both +2.5. Various spectroscopic techniques have led to conflicting conclusions concerning the electronic structure of this ion, especially on the extent of valence-delocalization.[185] RR spectra display several broad bands assigned to totally symmetric modes which are probably associated with the pyrazine ring. However, the spectroscopic evidence obtained to date has not unequivocally established whether the odd electron is delocalized or trapped on one Ru atom, and further investigations are in progress. Another mixed-valence Ru^{II},Ru^{III} complex that has been investigated recently is $[(NH_3)_3Ru(\mu_3\text{-}X_3)Ru(NH_3)_3]^{2+}$ (X = Cl, Br, or I). Whereas the A_1' ground state of this complex is localized (non-equivalent Ru centers), RR spectroscopy has indicated that, in the A_2'' excited state (14000-17000 cm^{-1}), the odd electron is delocalized.[186]

5.4. Metalloporphyrins

The study of metalloporphyrins and heme proteins by RR spectroscopy has developed into a major field of research since the pioneering work, over a decade ago, of *Spiro*.[25] Several comprehensive reviews of this subject have been written[5, 11, 26, 27] and it is our intention here to present only the essential features of metalloporphyrin RR spectra.

3

Absorption spectra of metalloporphyrins consist of an intense near UV band ($\varepsilon \approx 10^5$ M^{-1} cm^{-1}), called the Soret band, and a weaker ($\varepsilon \approx 10^4$ M^{-1} cm^{-1}) Q band in the visible region which displays a 0-0 and conglomerate 0-1 maxima. The positions of these bands vary considerably according to the central metal atom, its spin- and oxidation-state, and substituents on the metalloporphyrin ring (shown in Fig. 25) but typically the Soret band is at around 400-450 nm and the Q-band around 550-600 nm. Both bands are assigned to $\pi\text{-}\pi^*$ $^1E_u \leftarrow {}^1A_{1g}$ transitions (in the idealized D_{4h} geometry) associated with the porphyrin ring. The electronic structures of metalloporphyrins have been investigated in some considerable detail by *Gouterman*,[187] and it has been shown that these two transitions arise from the promotion of electrons from filled, nearly degenerate, $1a_{1u}$ and $3a_{2u}$ orbitals to unfilled $4e_g$ orbitals. As a consequence of configuration interaction the transition to the higher energy Soret state is dipole-allowed while that to the Q state is nearly forbidden. Thus the latter transition acquires intensity by (Herzberg-Teller) vibronic coupling of the Soret and Q states, via a_{1g}, a_{2g}, b_{1g}, and b_{2g} vibrations, which give rise to the 0-1 conglomerate band.

RR spectra excited within the contour of the Q-band consist of the vibronically (B-term) active fundamentals of the porphyrin ring, which are distinguishable by their depolarization ratios: $\rho = 1/8$ (a_{1g}), $\rho = \infty$ (a_{2g}) and $\rho = 3/4$ (b_{1g} and b_{2g}). Deviations from these values bear witness to the lowering of the symmetry, especially to the loss of the fourfold axis, due to substituents on the porphyrin ring or to interaction with the environment within which the molecule is accommodated. Then, mixed symmetric/antisymmetric scattering may occur (see Section 2.5) giving

$3/4 < \rho < \infty$ for non-totally symmetric modes, and deviation from $\rho = 1/8$ might be observed for the totally symmetric modes. However, the latter are usually quite weak for Q-band excitation, and it may be impossible to obtain sufficiently accurate polarization data. Weak overtones of some of the non-totally symmetric fundamentals are sometimes observed, and have been ascribed to D-term scattering.

By contrast, RR spectra obtained by excitation within the contour of the Soret band are dominated by bands attributed to totally symmetric fundamentals. These owe their activity to an A-term scattering regime in which the displacement parameters are quite small. There have been far fewer studies of Soret-excited RR spectra, mainly because excitation in this region is not so widely available in most laboratories; however, it is expected that this situation will change, and that a wealth of experimental data will soon build up. In particular, Soret excitation offers the opportunity of monitoring the lowering of the symmetry (from D_{4h}) by measuring deviations of ρ from 1/8.

There have been several measurements of excitation profiles (mostly confined to the Q-band region). These have been analyzed in terms of contemporary RR theory. Typically, EPs display two maxima within the Q-band (0-0 and 0-1) which are of unequal intensity. For B-term scattering it is predicted that the 0-0 and 0-1 resonances are of equal intensity. As pointed out in Section 2.4, deviations from equal scattering intensity arise from (a) non-adiabatic coupling between the Q and Soret states, and (b) JT distortion in the Q state. The a_{2g} modes (those for which $\rho = \infty$) are not JT-active and therefore show only the non-adiabatic effect which favors the 0-1 resonance. Polarized ($\rho = 1/8$) and depolarized ($\rho = 3/4$) bands tend to show stronger 0-0 scattering, believed to arise from additional A-term contributions. Enhanced scattering in the 0-1 region can also arise from A-term/B-term interference.[45] Examples of all of these effects can be seen in the Q-band EPs of nickel aetioporphyrin I (see **3**) (Fig. 25),[188] which represent the most complete Q-band profiles obtained for a symmetric metalloporphyrin.

The most detailed excitation profiles in the Soret region have been obtained for ferrocytochrome c (1362 cm^{-1} band) and ferricytochrome c (1374 cm^{-1} band) by *Champion* and *Albrecht*.[189] The EP of the former is asymmetric and has higher intensity in the 0-1 region, whereas the latter shows a broad structureless peak slightly blue-shifted from the 0-0 position. These observations were accounted for by a theoretical model encompassing both homogeneous and inhomogeneous broadening and a multidimensional subspace of vibrational and librational modes in the excited state. The latter was calculated analytically by approximating the product of Franck-Condon factors with the density of states to a truncated Lorentzian distribution. However, *Shelnutt*[190] has convincingly demonstrated that the enhanced scattering in the 0-1 region can be accounted for by a single-mode calculation including interference between inter- and intramanifold coupling (i.e. A-term/B-term interference).

In this short section we have attempted to present the essential features of metalloporphyrin RR scattering. As already pointed out a vast literature on this subject exists,

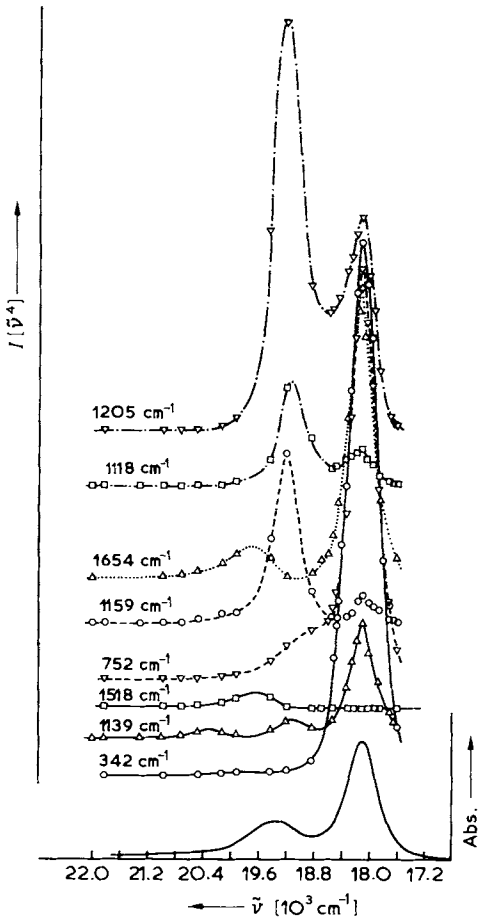


Fig. 25. Q-band resonance Raman excitation profiles of nickel(II) aetioporphyrin I in $CDCl_3$. Bands at 1118 and 1205 cm^{-1} are inversely polarized, those at 752, 1159 and 1654 cm^{-1} are depolarized, and those at 342, 1139 and 1518 cm^{-1} are polarized. The uppermost excitation profile relates to the [5,10,15,20-D_4]-derivative (after Ref. [188]).

the major interest being concerned with biological aspects, such as electron transfer, respiratory function, catalysis, and metal transport or storage. Furthermore, the intricacies of the theoretical analysis of the spectra have become rather complicated due to the large number of phenomena involved. A recent paper by *Shelnutt*[19] is commended, in which is developed a simple model of vibronic states that brings out the essential features of metalloporphyrin RR spectra, excitation profiles, and polarization dispersion.

6. Conclusion and Future Outlook

The sensitivity of RR spectroscopy has transformed the technique of Raman spectroscopy from being one of greatly restricted use in inorganic and analytical chemistry to one of great value. Not only can species frequently be detected at very low concentrations by RR spectroscopy, but information is obtained specifically about the chromophoric center in the species. Since this part of a molecule is usually the one of greatest chemical interest—particularly in molecules of biochemical importance—increasing attention is being paid to RR studies of such species. Increasing attention is also being paid to the spectroscopy of molecules in excited electronic states, to the nature and spectroscopy of species generated at electrode surfaces, to ther-

mally sensitive species isolable only in matrices, and to the spectroscopy of transients in chemical reactions.

It is to be expected that, during the next few years, new developments of RR theory will considerably increase the amount of information obtainable from experimental data. In particular it is envisaged that more attention will be paid to the theoretical analysis of excitation profiles and to the polarization dispersion of Raman bands of molecules for which the absorption spectra are devoid of vibrational structure. In conjunction with the availability of a wider range of excitation lines, this will enable the RR technique for the determination of excited-state molecular geometries to be applied to a considerably larger number of inorganic molecules.

The Ferrocenylmethyl(Fem) Group as a Highly Lipophilic and Chromophoric Group for the Masking of Peptide Bonds**

By *Heiner Eckert** and *Christoph Seidel*

In the course of exploring a new strategy for the chemical synthesis of peptides,[1] which is characterized by the use of strongly lipophilic and chromophoric groups, we have developed a method for the masking of peptide bonds. The treatment of the chemically reactive functional groups is largely covered by the conventional protecting group methodology.[2] Peptide bonds, on the other hand, are particularly "physically reactive"—i.e., they exert a great effect on the secondary structure and solubility of a peptide. Such conformational effects often make the synthesis of peptides difficult. *Weygand* et al. have attempted to prevent[3] these effects by using the 2,4-dimethoxybenzyl group.[3a] *Ugi* et al. recognized the preparative value of the lipophilic and chromophoric ferrocenylalkyl group in stereospecific reagents.[3b] The *tert*-butoxycarbonylation of the peptide bond in a prolyl-glycine derivative was recently described by *Ragnarsson* et al.[3c]

The chromophoric (yellow) ferrocenylmethyl(Fem) group[4] makes possible an economically practical, regenerative masking of peptide bonds in order to suppress or manipulate the secondary structures of peptide derivatives and in order to solubilize them lipophilically. The Fem group can be introduced by facile catalytic reductive alkylation of amino acids or amino acid esters with commercially available ferrocenecarbaldehyde **1** and hydrogen. The highly selective palladium(II) phthalocyanine[5] may be used as hydrogenation catalyst. Whereas **1** is only reduced extremely slowly, the azomethine **2** obtained from **1** and the amino acid or the amino acid ester undergoes hydrogenation within a few hours. The Fem-amino acids, or their esters, are thereby formed in high yields without racemization (Table 1) and without undergoing further reduction. The racemization-free course of the reaction is exemplified by reaction of the amino acid phenylalanine, which is highly susceptible to racemization. After isolation and subsequent hydrogenation of ferrocenylmethylene-Phe-O*t*Bu, the ester Fem-Phe-O*t*Bu is deblocked using trifluoroacetic acid and the specific optical rotation of the free phenylalanine is measured to be $[\alpha]_D^{25}$ −32.7. This value is identical with that of the starting phenylalanine. Fem-amino acids are very stable; for example, Fem-Gly-OMe can be distilled (b.p. = 235 °C/0.1 torr) quantitatively

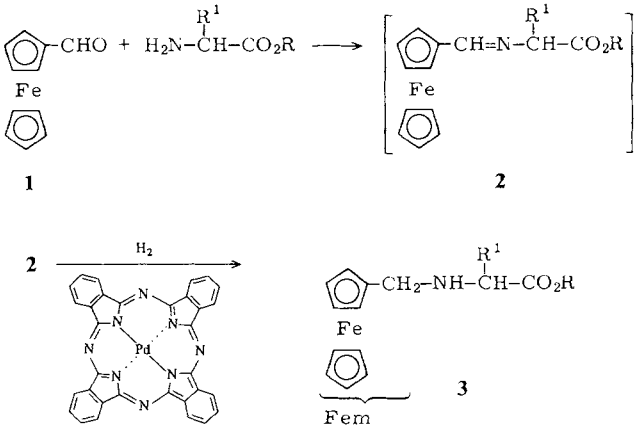

Table 1. Synthesis of Fem-amino acids and derivatives (**3**, R = H, Me, *t*Bu or Na).

	Fem–NH–CHR¹–CO₂R **3**	Yield [%]	M.p. [°C]	$[\alpha]^{25}$ (λ [nm])
3a	Fem–Gly–OH	73	198	—
3b	Fem–Gly–OMe	60	oil	—
3c	Fem–Ala–ONa	83	232	−38.3 (546)
3d	Fem–Ala–OMe	71	oil	−73.3(546); −53.4 (589)
3e	Fem–Phe–ONa	82	305	− 9.5(546)
3f	Fem–Phe–O*t*Bu	81	oil	−13.8 (589)
3g	Fem–Leu–O*t*Bu	85	oil	−26.7 (546)
3h	Fem–Val–O*t*Bu	89	oil	−34.0 (546); −23.5 (589)

without undergoing decomposition. In contrast, the corresponding "free" H-Gly-OMe ester undergoes quantitative decomposition within a few hours at room temperature to give 2,5-diketopiperazine.

The coupling of *N*-protected amino acids with Fem-amino acid derivatives **3** to give peptides **4**, which have Fem-masked peptide bonds, can be carried out conveniently according to the DCCI method[2a,6] within a few hours (Table 2). The yields are generally high. Even the coupling of Tcboc-Val-OH[6] with Fem-Val-O*t*Bu **3h**, which is a sterically highly hindered reaction, affords **4f** in 50% yield. The investigation of the racemization[2a] during the coupling of Boc-Gly-Fem-Ala-OH with H-Leu-O*t*Bu using DCCI showed that the Izumiya test peptide derivative Boc-Gly-Fem-Ala-Leu-O*t*Bu (92% yield) contained 27% D-alanine and 73% L-alanine. The comparable reaction without the Fem group under the same conditions afforded the test peptide derivative (84% yield) with 12% D-alanine and 88% L-alanine. This observation must be taken into consideration in fragment condensations, which are subject to racemization. In contrast, the coupling of Tcboc-Fem-Ala-OH with H-Leu-O*t*Bu (85% yield) gives a product with < 0.02% D-alanine. This means that no racemization occurs in the coupling of *N*-urethaneprotected Fem-amino acids, which makes a stepwise peptide synthesis relatively easy.

Intermediates that contain the Fem group can be purified by column chromatography on inexpensive silica gel with hexane-containing solvent systems (high resolution). This is due to their extremely high lipophilicity[7] and their strong yellow color. The Fem group may be cleaved with trifluoroacetic acid/β-thionaphthalene in dichloromethane

Table 2. Coupling reactions with Fem-amino acid derivatives **3** to give peptides **4** containing Fem-protected peptide bonds [6].

Starting materials	Products	Yield [%]
Z–Ala–OH + Fem–Phe–O*t*Bu **3f**	Z–Ala–Phe–O*t*Bu (Fem) **4a**	83
Boc–Gly–OH + Fem–Ala–OMe **3d**	Boc–Gly–Ala–OMe (Fem) **4b**	91
Boc–Gly–OH + Fem–Ala–Leu–O*t*Bu	Boc–Gly–Ala–Leu–O*t*Bu (Fem) **4c**	75
Tcboc–Phe–OH + Fem–Leu–O*t*Bu **3g**	Tcboc–Phe–Leu–O*t*Bu (Fem) **4d**	93
Tcboc–Fem–Gly–OH + Fem–Gly–OMe **3b**	Tcboc–Fem–Gly–Gly–OMe (Fem) **4e**	80
Tcboc–Val–OH + Fem–Val–O*t*Bu **3h**	Tcboc–Val–Val–O*t*Bu (Fem) **4f**	50

within 2–4 h at the same rate as that observed for cleavage of the Boc or O*t*Bu groups.

Experimental Procedure

Fem-amino acid esters 3 (R = alkyl): A mixture consisting to the amino acid amino acid (10 mmol), **1** (2.14 g, 10 mmol), anhydrous Na_2CO_3 (2.12 g, 20 mmol), and palladium(II) phthalocyanine (0.06 g, 0.1 mmol)/[5] in 40 mL of methanol was saturated with H_2 and then vigorously stirred under H_2 (from a gas burette) for several hours, until gas absorption stopped. The suspension was filtered through a 4-cm thick layer of Na_2SO_4, which is then washed with methanol, and the filtrate is concentrated to 10–20 mL. Addition of ether results in precipitation of the sodium salt of the Fem-amino acid. This is recrystallized from water or methanol/water, affording yellow crystals.

Fem-amino acid esters 3, (R = alkyl): A mixture consisting of the amino acid ester or its hydrochloride (10 mmol), **1** (2.14 g, 10 mmol), and palladium(II) phthalocyanine (0.06 g, 0.1 mmol) [5] in 10 mL of methanol and 20 mL of ethyl acetate (triethylamine (0.8 mL, 11 mmol) added in the case of the amino acid ester hydrochlorides) was saturated with H_2 and vigorously stirred under H_2 (from a gas burette) for several hours, until gas absorption stopped. The reaction mixture was then filtered through a 4-cm thick layer of Na_2SO_4, which was washed with ethyl acetate, and the filtrate was concentrated. The residue was chromatographed on silica gel with hexane/ethyl acetate (ca. 3 : 1). A deep orange oil was obtained.

Coupling reaction to give 4: The *N*-urethane-protected amino acid (10 mmol) and the Fem-amino acid ester **3** (10 mmol), R = alkyl, were cooled to −20 °C in 40 mL of dichloromethane. A solution of DCCI (2.27 g, 11 mmol) in 10 mL of dichloromethane was added over 5 min and the cold bath was then removed. After 12 h, the dicyclohexylurea was filtered off and the filtrate was concentrated. The residue was chromatographed on silica gel with hexane/ethyl acetate (ca. 3 : 1) [7]. A yellow solid was obtained.

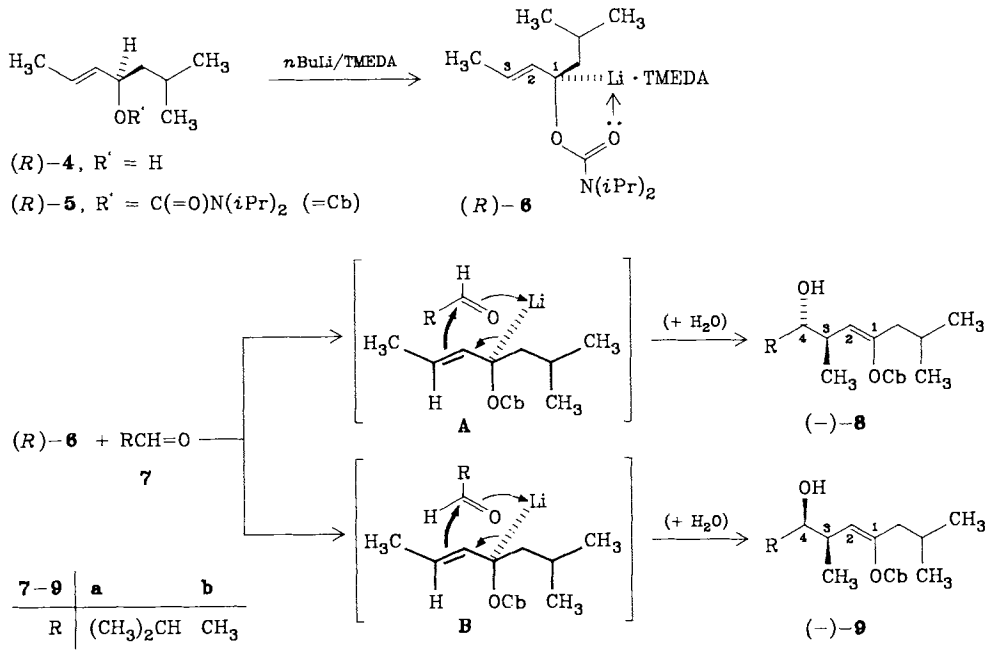
α-Deprotonation of an α-Chiral 2-Alkenylcarbamate with Retention and Lithium-Titanium Exchange with Inversion—the Homoaldol Reaction with 1,3-Chirality Transfer**

By *Dieter Hoppe** and *Thomas Krämer*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Chiral 1-oxy alkyllithium compounds **2** (R^1, R^2 = alkyl, H) are configurationally stable,[1] and their substitution reactions with electrophiles to give **3** proceed with retention. The tin-lithium exchange[1] of stannanes **1a** has proved useful for the synthesis of **2**. In contrast, the reductive cleavage of monothioketals or monothioacetals[2] **1b** to give **2** is accompanied by racemization or epimerization, since radicals having low barriers to inversion are formed as intermediates. The simplest conceivable route—the stereospecific deprotonation of **1c** (R^1, R^2 = alkyl)—is not promising owing to the insufficient kinetic acidity of **1c**. Although resonance-stabilizing groups (e.g., R^1 = phenyl or vinyl) increase the carbon acidity of **1c**, they also increase the danger of racemization of **2** since they favor planarity and dissociation into ion pairs. We have now investigated the α-deprotonation of the optically active, α-chiral 2-alkenylcarbamate **5**[3] as well as the subsequent lithium-titanium exchange and the carbonyl addition, and report here our surprising results.



The *N*,*N*-diisopropylcarbamate (−)-(*R*)-**5**,[5] prepared from the allyl alcohol (+)-(*R*)-**4**,[4a] was deprotonated with

1a, X = $SnBu_3$
1b, X = SPh
1c, X = H

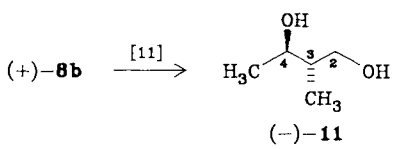
[**] Metalated Nitrogen Derivatives of Carbon Dioxide in Organic Synthesis, Part 31. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 30: D. Hoppe, C. Gonschorrek, E. Egert, D. Schmidt, *Angew. Chem. 97* (1985) 706; *Angew. Chem. Int. Ed. Engl. 24* (1985) 700.



n-butyllithium (ether/hexane, 0.95 equiv. *N,N,N',N'*-tetramethylethylenediamine (TMEDA), 7 h at −78 °C),[3b] and the intermediary lithium compound **6** was trapped with 2-methylpropanal **7a**. Along with 25% of the starting material (68% *ee*[7]), the optically active (*Z*)-*anti* adduct[3a] (−)-**8a** (yield 24%, 52% *ee*[7,8]) and the (*Z*)-*syn* isomer (−)-**9a** (yield 29%, ≥25% *ee*[7,8]) were obtained.[6]

In a further experiment—under otherwise identical conditions—the "cation" Li was exchanged for Ti, before the addition of the aldehyde, by treatment with 1.1 equivalents of chlorotris(diethylamino)titanium[9,10] (2 h at −78 to −70 °C). Addition of **7a** to the titanium compound **10** afforded only one adduct, the (*Z*)-*anti* diastereomer (+)-**8a** (yield 36%, 35% *ee*[7,8]). Similarly, after metalation and metal exchange, (*R*)-**5** afforded the adduct (+)-**8b** (yield 58%, 41% *ee*[7,8]) upon addition of aldehyde **7b**. The absolute configuration of (+)-**8b** was determined to be (3*S*,4*R*) by degradation[11] to the known diol[12] (−)-(2*S*,3*R*)-**11**.

7/8: **a**, R = $(CH_3)_2CH$; **b**, R = CH_3

Since, for the carbonyl addition reactions of α-chiral allylmetal compounds[1c,13] (corresponding to the transition states **A**–**C**), the asymmetric induction at C-3 (1,3-chirality transfer) is determined by the configuration at C-1—and not by the aldehyde **7**—the (3*S*,4*R*) configuration for (+)-**8a** and the (3*R*,4*S*) configuration for (−)-**8a** are also established. (−)-**9a** can be converted into (−)-**8a** by oxidation/reduction[14] with inversion at C-4 and, therefore, has the (3*R*,4*R*) configuration. The lithium and titanium compounds (*R*)-**6** and (*R*)-**10** that afford the excess enantiomer in each case thus have opposite configurations at C-1.[15]

The following important conclusions can be drawn from these results: (1) The deprotonation of (*R*)-**5** to give (*R*)-**6** occurs with *retention*. Lithium compounds of type **6** racemize only slowly ($t_{rac\,1/2} \geq 7$ h) under the reaction conditions at temperatures below −70 °C. Accordingly, the lithium in **6** must—despite the possibility of resonance in the anion[16,17]—be tightly bonded (covalently?) to the nonplanar-coordinated C-1. (2) Titanium compounds[10] of type **10** are also largely configurationally stable at temperatures below −70 °C. The lithium-titanium exchange of (*R*)-**6** to give (*R*)-**10** takes place with *inversion*.[18] Since inversion has never been observed for intermolecular electrophilic substitution at an sp^3-hybridized C atom,[19] it remains to be shown whether our exceptional results are due to the transition-metal "cation," to the allyl system, or to the interplay of both. (3) If it is possible to further suppress the racemization, these findings would provide a very flexible procedure for the enantioselective homoaldol reaction,[1c,20] which is very attractive with respect to both the constitution and configuration of the target molecule.

Novel Octahedral Si and Ge Complexes with a Hexadentate Diphenol Ligand

By *Bernardo Wolff* and *Armin Weiss**

Catechol forms the very stable complex anions **1** with silicon[1,2] in which silicon has sixfold coordination, which is unusual for an oxygen environment at normal pressure. The structure of **1** has been elucidated by X-ray structure analysis.[3] Even quartz can be transformed into such complexes in aqueous suspension at pH values between 8 and 10.[4] The question arises whether further stabilization of the complex can be achieved by intramolecular bridging of the catechol ligands. Therefore, we have synthesized the new hexadentate ligands **2**.

1

2a, n=2 ; **2b**, n=3

When tris[3-(2,3-dihydroxyphenoxy)propyl]ammonium chloride **2b** is allowed to react with tetraethoxysilane in refluxing methanol in the presence of triethylamine, the colorless salt **3** separates out within a few hours.

$[HNEt_3][MC_{27}H_{28}NO_9]$ **3**, M = Si; **4**, M = Ge

The ^{29}Si-NMR spectrum of **3** exhibits a singlet at δ = −138.55. This value agrees well with known ^{29}Si-NMR data for other hexacoordinated complex anions of Si with catechol.[5] The protons of the propanediyl chain give broad multiplets with unresolved fine structure in the ^{1}H-NMR spectrum. The propanediyl chains in the complex are probably present in a fixed conformation, the protons of the three methylene groups giving rise to a multiline ABMNCD spin system.

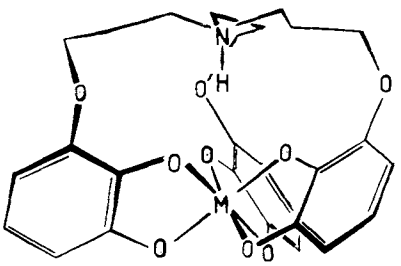

Fig. 1. Structural model of the complex anions of **3** and **4**.

Several bands are observed in the IR spectrum of **3** between 600 and 700 cm^{-1} (Fig. 2); these have been assigned

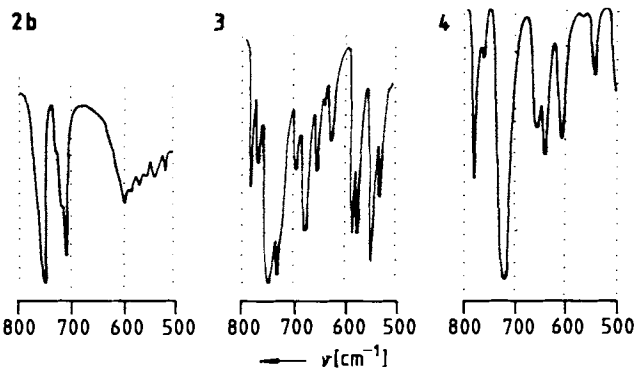

Fig. 2. Section of the IR spectra of the free ligand **2b** as well as the complex compounds **3** and **4**.

Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (FRG)

to the Si-O stretching vibrations in the SiO_6 octahedron. With ligand **2b**, no absorptions are observed in this region (Fig. 2). A value of $\nu = 692\ cm^{-1}$ has been reported for the Si-O stretching vibration in $(NH_4)_2[Si(o\text{-}O_2C_6H_4)_3]$.[6]

When a saturated solution of **3** is evaporated, **3** slowly crystallizes as small cubes. It is moderately soluble in dimethylsulfoxide (DMSO), sparingly soluble in CH_3CN, and insoluble in water. The striking stability of the complex anion of **3** is demonstrated by two observations. If a suspension of fine-grained **3** in aqueous 2 N acetic acid is stirred at room temperature, no major changes are observed in the IR spectrum and in the X-ray powder diagram after 24 h; however, after about 3 weeks, the compound has undergone quantitative decomposition under these conditions. The simple catechol complexes **1** undergo immediate cleavage to catechol and silicic acid in dilute acetic acid. On the other hand, a suspension of finely divided amorphous SiO_2 ("Aerosil 380") in a refluxing methanolic solution of **2b** (ca. 0.04 M) and excess sodium acetate is completely transformed in one week into the sodium salt analogous to **3**. NaF is required as a catalyst in this reaction. The product was characterized by both spectroscopy and X-ray diffraction.

2b reacts with $GeCl_4$ to form the salt **4**, which, like **3**, is moderately soluble in DMSO and sparingly soluble in acetonitrile. Upon slow evaporation of acetonitrile solutions, **4** forms small, birefringent cubes. The IR spectra of **3** and **4** are virtually identical, apart from small shifts of the bands. Between 600 and 670 cm^{-1}, **4** exhibits absorptions that are assigned to Ge-O vibrations. They are characteristically shifted to smaller wave numbers compared with the analogous bands of **3** (Fig. 2).

Weissenberg photographs confirm that the germanium and silicon compounds are isotypic.[7] The lattice constant of **4** is only 6.0 pm larger ($a = 1841.5(22)$ pm) than that of **3**. This is in accord with the replacement of the Si by the somewhat larger Ge atom. In addition, the structure of **4** (Fig. 3) corresponds to the model of Figure 1, as established by a crystal structure analysis.[7] The Ge-O bond lengths are 187.2(6) and 188.0(6) pm. The bond angles in the central GeO_6 octahedron deviate somewhat from the values for a regular octahedron. The isotypism of the structures of **3** and **4** shows that the anions have the same structure.[8]

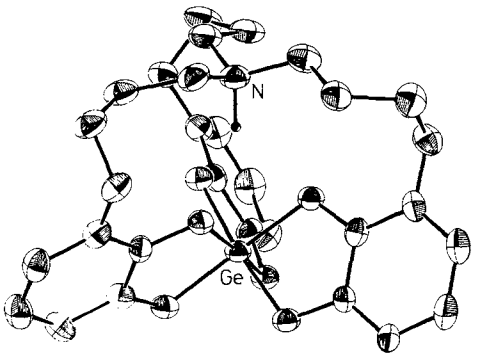

Fig. 3. ORTEP plot of the structure of the anion of **4**.

For larger central atoms (e.g., Sn) the ligand **2b** tends to form amorphous (X-ray diffraction) oligomers or polymers. Such compounds are also formed with Si or Ge as the central atom when **2a** is used in place of **2b** as ligand. Owing to the short bridges, the intramolecular complex formation apparently results in unfavorable conformations and, therefore, ring strains.

Experimental Procedure

Preparation of **3**: **2b** (2 g, 3.6 mmol), tetraethoxysilane (0.81 mL, 3.6 mmol), and triethylamine (1.5 mL, 10.9 mmol) were dissolved under nitrogen in 50 mL of refluxing methanol. After the solution had been refluxed for 12 h, the precipitate was filtered off, washed with methanol, and dried in high vacuum. Yield: 2.17 g (93%) colorless powder. The product was recrystallized by dissolving it in ca. 200 mL of refluxing acetonitrile (1 h), filtering off the insoluble matter, and allowing the clear solution to evaporate slowly in the air. Small cubic crystals formed. The undissolved residue may be treated similarly. Correct elemental analysis. The crystals turn dark above ca. 230°C and decompose at 300°C. IR (KBr): ν [cm^{-1}]: 3055 (m-s), 2940 (m), 1592 (vs), 1481 (vs), 1465 (vs), 1272 (vs), 1257 (vs), 1230 (s), 1219 (s), 1060 (vs), 847 (s), 740 (s), 670 (m), 573 (m), 562 (m), 533 (m-s). ^{1}H-NMR ([D$_6$]DMSO): $\delta = 1.17$ (t, $^3J = 7.20$ Hz, 9H, NCH_2CH_3), 1.78 (m, br., unresolved, 6H, $OCH_2CH_2CH_2N$), 3.08 (q, $^3J = 7.20$ Hz, 6H, NCH_2CH_3), 2.97 (m, br., unresolved, covered by the preceding signal, 6H, $OCH_2CH_2CH_2N$), 3.74 (m, br., unresolved, 6H, $OCH_2CH_2CH_2N$), 6.01-6.34 (m, ArylH, 9H), 8.14 (s, br., 1H, NH), 8.90 (s, br., 1H, NH). ^{13}C-NMR ([D$_6$]DMSO): $\delta = 8.48$ (NCH_2CH_3), 22.53 ($NCH_2CH_2CH_2O$), 45.76 (NCH_2CH_3), 49.38 ($NCH_2CH_2CH_2O$), 70.57 ($NCH_2CH_2CH_2O$), 105.99, 110.24, 115.46, 141.00, 144.82, 152.88 (C_{Aryl}). The ^{29}Si-NMR spectrum was recorded in [D$_6$]DMSO.—Preparation of **4**: **2b** (1 g, 1.8 mmol) was dissolved in 25 mL of anhydrous methanol. A solution containing 0.19 mL (1.6 mmol) of $GeCl_4$ and 3 mL (21.7 mmol) of dry triethylamine in 25 mL of anhydrous methanol was added to the refluxing solution of **2b** under nitrogen. A colorless precipitate forms immediately. The solution was refluxed for ca. 30 min following the addition and then filtered. The product was washed with warm methanol and dried in high vacuum. Yield: 0.94 g (94%) colorless powder. Crystals were obtained as described for **3**. Correct elemental analysis. The crystals slowly turn dark above ca. 230°C and decompose at 325°C. IR (KBr): ν [cm^{-1}]: 3085 (s), 2935 (m), 1583 (s), 1460 (vs), 1272 (vs), 1256 (vs), 1230 (s), 1218 (s), 1055 (vs), 839 (s), 719 (vs), 653 (m), 639 (m), 606 (m), 412 (m), 344 (s). ^{1}H-NMR ([D$_6$]DMSO): $\delta = 1.14$ (t, $^3J = 7.25$ Hz, 9H, NCH_2CH_3), 1.79 (m, br., unresolved, 6H, $NCH_2CH_2CH_2O$), 3.08 (q, $^3J = 7.26$ Hz, 6H, NCH_2CH_3), ca. 3.0 (m, br., unresolved, covered by the preceding signal, 6H, $NCH_2CH_2CH_2O$), 3.72 (t, br., unresolved, 6H, $NCH_2CH_2CH_2O$), 6.07-6.37 (m, 9H, ArylH), 7.68 (s, br., 1H, NH), 8.86 (s, br., 1H, NH). ^{13}C-NMR [D$_6$]DMSO): $\delta = 8.58$ (NCH_2CH_3), 22.85 ($NCH_2CH_2CH_2O$), 45.74 (NCH_2CH_3), 49.61 (NCH_2CH_2O), 70.88 ($NCH_2CH_2CH_2O$), 107.13, 110.38, 115.16, 142.38, 144.69, 152.33 (C_{Aryl}).

Decamethylsilicocene—Synthesis and Structure**

By *Peter Jutzi,* Dieter Kanne,* and *Carl Krüger*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

We recently reported the syntheses of the decamethylmetallocenes of germanium and tin starting from the bis(pentamethylcyclopentadienyl) dihalides of these elements.[1] We have now been able to synthesize the analogous silicon compound using this procedure. Reaction of dichloro[bis(pentamethylcyclopentadienyl)]silane **1**[2] with naphthalenelithium, naphthalenesodium, or naphthalenepotassium in tetrahydrofuran (THF) affords bis(pentamethylcyclopentadienyl)silanediyl (decamethylsilicocene) **2**.[3]

$$(Me_5C_5)_2SiCl_2 \xrightarrow[THF]{MC_{10}H_8} (Me_5C_5)_2Si \quad (M = Li, Na, K)$$

1 **2**

The colorless,[4] crystalline compound **2** undergoes ready sublimation in an oil-pump vacuum and is thermally stable (m.p. = 171 °C), but it is extremely air-sensitive (presumably undergoing oxidation). The silicocene **2** is readily soluble in aprotic solvents such as hexane, benzene, and chlorinated hydrocarbons. According to cryoscopic molecular weight determinations, it is a monomer in benzene.

In the $^{13}C\{^1H\}$-NMR spectrum the ring and the methyl carbon atoms each exhibit only one sharp signal, and in the ^1H-NMR spectrum the protons of the methyl groups also exhibit only one sharp signal. On the basis of the chemical shifts,[5] this is more indicative of the presence of a π-complex than of a rapidly fluctuating σ-structure in solution. One resonance at very high field strength is observed in the ^{29}Si-NMR spectrum ($\delta = -577$).[6] If the ^{29}Si and ^{119}Sn chemical shifts are correlated, the value for **2** is in the expected range. Chemical and electron-impact ionization mass spectroscopy yield almost exclusively the ion fragment m/z 163 ($C_5Me_5Si^+$).

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

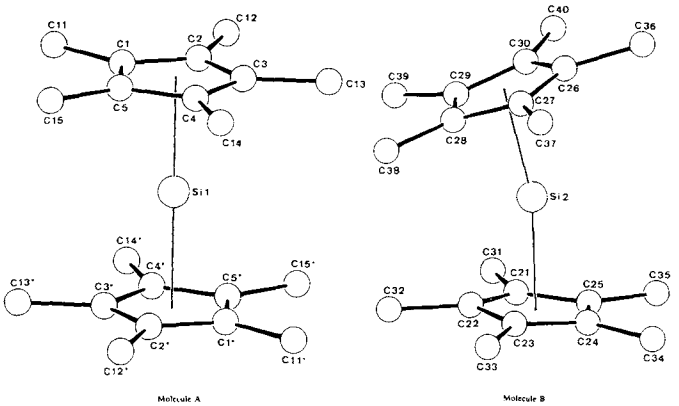

Fig. 2. Crystal structure of decamethylsilicocene **2**.

The single-crystal structure analysis[7] affords a surprising result. Two conformers are present in the unit cell in the ratio 1 : 2 (Fig. 1). Whereas in the molecule A, in which Si1 occupies a center of inversion, the two pentamethylcyclopentadienyl rings are staggered and their planes strictly parallel (Fig. 2, left), they are staggered and form an interplanar angle of 25.3° in molecule B (Fig. 2, right). Whereas the Si-C separations are equidistant in molecule A (mean value 2.42(1) Å), they lie between 2.324(8) Å (Si2-C22, Si2-C28) and 2.526(7) Å (Si2-C25) or 2.541(7) Å (Si2-C26) in B. The distance between the Si atoms and the center of gravity of the Cp rings is 2.11 Å in A and 2.12 Å in B. All methyl groups lie in the planes of the Cp rings within the given error limits (±0.006 Å). The C-C distance, averaged over 15 bonds, is 1.394(15) Å, the likewise averaged C-CH_3 distance 1.501(9) Å. The arrangement of the molecules in the crystal (Fig. 1) suggests that the interplanar angle of molecule B is caused by intermolecular interactions and packing effects.

Decamethylsilicocene **2** is the first silanediyl that is stable under normal conditions and the first π-complex with silicon as the central atom.

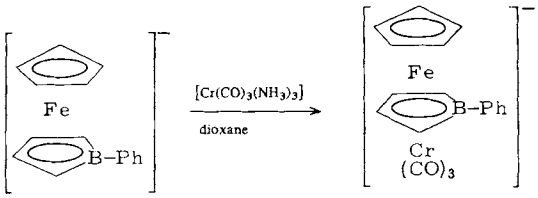
[3] *Experimental procedure:* A solution containing 33 mmol of naphthalenesodium in 100 mL of THF was added at −70 °C to 3.1 g (8.4 mmol) of **1** in 70 mL of THF over 5 h. The reaction mixture was allowed to warm up to room temperature and the solvent was then removed in vacuum. After fractional sublimation, the product was recrystallized from *n*-pentane. Yield: 376 mg (15%), colorless crystals (m.p. = 171 °C). — ^1H-NMR (300 MHz, $CDCl_3$): $\delta = 1.89$ (s, C_5Me_5). ^{13}C-NMR (75.5 MHz, $CDCl_3$): $\delta = 119.1$ (s, C_5), 10.0 (s, Me_5). ^{29}Si-NMR (59.6 MHz, C_6D_6): $\delta = -577$. Correct elemental analysis.

[4] Of interest are the colors of the decamethylmetallocenes of the 4th main group: colorless (Si), light yellow (Ge), dark yellow (Sn), orange red (Pb).

[5] $(C_5Me_5)_2M$: $\delta(^{13}C)$ (75.5 MHz, $CDCl_3$): M = Si: 119.1, 10.0; M = Ge: 118.1, 9.8; M = Sn (in C_6D_6): 117.0, 10.1; M = Pb: 117.6, 9.7. — $\delta(^1H)$ (60 MHz, C_6H_6): M = Si: 1.99; M = Ge: 2.04; M = Sn: 2.07; M = Pb: 2.24.

[6] This is the highest value for a silicon compound.



[7] Cell parameters: $a = 31.969(5)$, $b = 8.525(1)$, $c = 23.212(3)$ Å, $\beta = 108.75(1)°$, $V = 5990.8$ Å^3, $\rho_{calcd} = 0.99$, space group $C2/c$, $Z = 12$, 6746 reflections; 2611 reflections with $I \geq 2\sigma(I)$; 286 refined parameters; hydrogen atoms on calculated sites were not considered in the refinement; $R = 0.088$, $R_w = 0.096$, Refinement in the space group Cc leads to the same results. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51619, the names of the authors, and the journal citation.

Synthesis of Anionic Triple-Decker Complexes Having Closed 30e Valence Shells by Stacking of Sandwich Anions with $Cr(CO)_3$ Fragments**

By *Gerhard E. Herberich,** *Bernd Hessner, Judith A. K. Howard, Dieter P. J. Köffer,* and *Roland Saive*

The 30 valence electron rule[2] plays the same role for triple-decker complexes as the 18-electron rule for mononuclear organometallic complexes. Indeed, of the numerous triple-decker complexes with boron-containing heterocycles as central ligands, those having closed 30e valence shells are particularly common and especially stable.[3] It is surprising, therefore, that no anionic 30e triple-decker complexes have been reported so far. This is primarily due to the fact that no reactions are known that would allow introduction of 12e fragments into a sandwich complex.

We now have found that (borole)metal sandwich anions, like the isolobal systems benzene, cyclopentadienide, 1-methylboratabenzene ion,[4a] and 7,8-carbollide ion $[7,8\text{-}C_2B_9H_{11}]^{2-}$,[4b] react with the 12e building block $Cr(CO)_3$.

1 2

Thus, **1**[5] reacts regiospecifically with $[Cr(CO)_3(NH_3)_3]$ to give the triple-decker anion **2**;[6] the phenyl group is not attacked. In contrast to **1**, complex **2** is stable in aqueous solution and was isolated in the form of a purple-red, light-sensitive $[NMe_3Ph]^+$ salt.[6]

The anion **2** has a typical triple-decker structure (Fig. 1).[7] The ring ligands are nearly planar (deviation <0.5 pm) and lie in nearly parallel planes (deviation 1.9°).[7] One CO group almost eclipses the B atom (deviation 11.1°); the same conformation was also found for $[(\mu\text{-}2\text{-}EtC_4H_3BPh)\{Mn(CO)_3\}_2]$.[1]

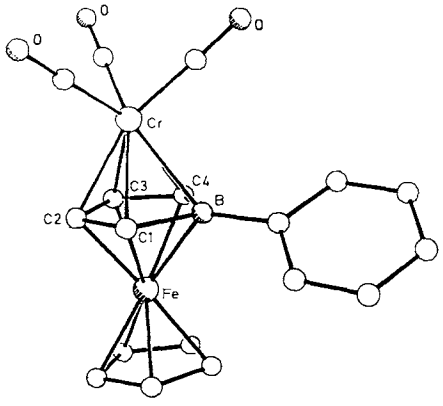


Fig. 1. Structure of the anion **2** in the crystal of the $[NMe_3Ph]^+$ salt. Selected distances [pm]: Cp-Fe 165.4, C_4B-Fe 163.9, C_4B-Cr 186.5; Fe-B 215.3(3), Fe-C(C_4B) 205.6 (average), Cr-B 232.0(3), Cr-C(C_4B) 224.3 (average), B-C1 156.5(4), B-C4 156.5(4), C1-C2 144.7(4), C3-C4 144.3(4), C2-C3 146.2 (4).

The Cr–CO distances (average 180.8 pm) are not significantly longer than in $[NMe_4][CpCr(CO)_3]$ (average 180 pm[8]); the charge distribution in the $Cr(CO)_3$ group of **2** is accordingly very similar to that of $[CpCr(CO)_3]^-$. In accordance with this, the $\tilde{\nu}$(CO) data of the $[NMe_3Ph]^+$ salt of **2** [(CH_2Cl_2) 1895 (s), 1779 (s), 1764 (s) cm^{-1}] and of $[NMe_3Ph][CpCr(CO)_3]$ [(CH_2Cl_2) 1888 (s), 1773 (s), 1756 (s, sh) cm^{-1}] show that the donor ability of **1** is only slightly weaker than that of Cp^-.

Other 18e anions with borole ligands, e.g., $[CoL_2]^-$, $[RhL_2]^-$, and $[LMn(CO)_3]^-$ (L = C_4H_4BMe and C_4H_4BPh), also react with $[Cr(CO)_3(NH_3)_3]$ to afford the corresponding anionic 30e triple-decker complexes.[9]

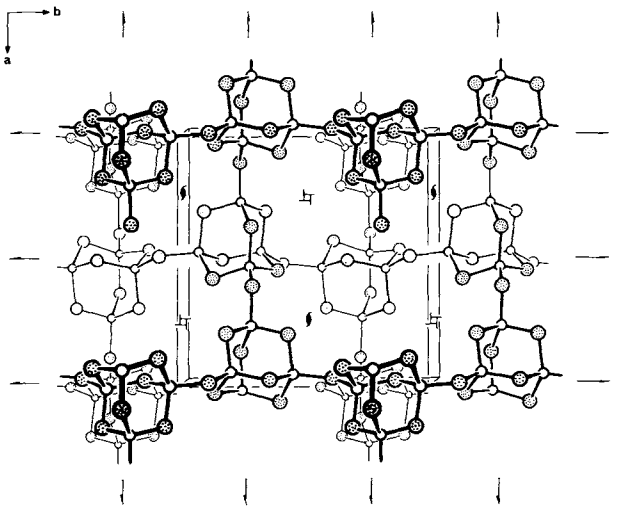
The Three-Dimensionally Non-Molecular Polyadamantanoid Structure of $Cd(SPh)_2$**

By *Don Craig, Ian G. Dance,** and *Robert Garbutt*

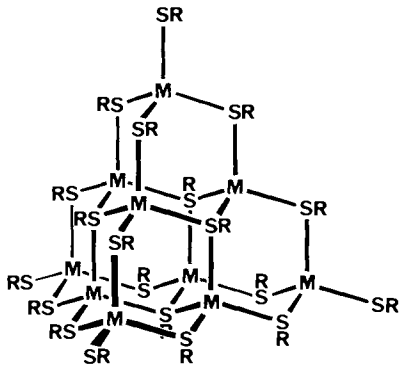
A characteristic property of the long-known compounds $M(SPh)_2$ is their sparing solubility in inert solvents, presumed but not proven to be a consequence of non-molecu-



[*] Prof. Dr. I. G. Dance, D. Craig, R. Garbutt
School of Chemistry, University of New South Wales
PO Box 1, Kensington, NSW 2033 (Australia)

[**] This research was supported by the Australian Research Grants Scheme.

lar crystal structures. When M is tetrahedrally coordinated, possible non-molecular structures include tetrahedra edge-linked in one dimension $^{1}_{\infty}\{M(\mu\text{-}SPh)_{4/2}\}$, or vertex-linked in two dimensions $^{2}_{\infty}\{M(\mu\text{-}SPh)_{4/2}\}$. The confirmed structure of $Zn_4(SPh)_8(MeOH)$[1] prompted the suggestion[2] of a two-dimensionally non-molecular structure for $M(SPh)_2$ comprised of linked adamantanoid cages $^{2}_{\infty}\{(\mu\text{-}SPh)_6M_4(\mu\text{-}SPh)_{4/2}\}$. Until now no *three*-dimensionally non-molecular crystal structure of any type has been reported or proposed for a homoleptic metal thiolate.



Bis(benzenethiolato)cadmium(II), **1**, prepared by standard methods from benzenethiol, triethylamine, and cadmium nitrate in ethanol, and crystallized from dimethylformamide (DMF) by addition of alcohols, acetone, or acetonitrile, has the three-dimensionally non-molecular polyadamantanoid structure $^{3}_{\infty}\{(\mu\text{-}SPh)_6Cd_4(\mu\text{-}SPh)_{4/2}\}$ (Fig. 1).[3] Each adamantanoid cage is linked through its four outer (terminal) PhS^- ligands to four surrounding cages. Linked cages occur in zig-zag chains (along 2_1 axes) parallel to *a* and *b*, but in the third orthogonal direction the cage linkages occur in fourfold helical sequences about pseudo 4_1 (exact 2_1) axes (marked on Fig. 1).[4] These helical connections, and the consequent interweaving of the chains parallel to *a* and *b* are the source of the three-dimensional non-molecularity. An alternative presentation of the structure of **1** derives from the conception of the Cd_4S_{10} adamantanoid cage as a large tetrahedron (edge-centered and comprised of four vertex-sharing coordination tetrahedra). The vertex linkage pattern of these large tetrahedra is very similar to that in α-cristobalite and many related compounds.[5] However the structure of **1** is unprecedented for complexes with organic substituents: the phenyl groups that are accommodated between the adamantanoid cages of **1** are responsible for the openness of the structure and the 20 Å translation along *c*. Two-dimensionally non-molecular polyadamantanoid structures also occur in the metal chalcogenides $KInSe_2$, $TlGaSe_2$ and $Ag_3B_5S_9$.[6]

Even though **1** is high melting (340 °C) it is very soluble in DMF (ca. 1.3 g/mL at ambient temperature). The ^{113}Cd-NMR spectrum (66.6 MHz, natural isotopic abundance, standard 0.1 M $Cd(NO_3)_2$) of **1** in DMF shows one temperature dependent signal; at $T = 220$, 240, 260 K, $\delta(^{113}Cd) = 593$, 588, 578 and $\nu_{1/2} = 150$, 275, 1350 Hz. The signal broadens with increasing temperature up to 300 K. The chemical shift of this species, which predominates in a slowly exchanging equilibrium at low temperature, is very close to that of the adamantanoid cage $[Cd_4(SPh)_{10}]^{2-}$ ($\delta = 586$ at 260 K),[7,8] and is consistent with the Cd^{2+} in **1** being coordinated only by PhS^-.[9] We propose that the principal species generated when **1** dissolves in DMF is molecular $Cd_{10}(SPh)_{20}$, with the tetra-adamantanoid cage structure (Fig. 2).

$^{3}_{\infty}\{(\mu\text{-}SPh)_6Cd_4(\mu\text{-}SPh)_{4/2}\}$ **1**

Fig. 1. The polyadamantanoid framework in crystalline $Cd(SPh)_2$ **1** (drawn with all phenyl groups omitted). The larger dotted circles are the sulfur atoms. The view direction is tilted 3° from the *c* axis. Average bond distances [Å] and angles [°] are (intra-cage bridges are S^b, inter-cage bridges are S^v): Cd-S^b 2.543, Cd-S^v 2.530 Å; S^b-Cd-S^b 109.2, S^b-Cd-S^v 109.6, Cd-S^b-Cd 108.8, Cd-S^v-Cd 136.0.

tetrahedro-$(\mu_3\text{-}SPh)_4$-*octahedro*-Cd_6-*truncated-tetrahedro*-$(\mu\text{-}SPh)_{12}$-*tetrahedro*-$(CdSPh)_4$ **2**

Fig. 2. Proposed structure for $Cd_{10}(SPh)_{20}$ **2**, which is formed upon dissolution of **1** in DMF.

The structure of **2** has already been postulated by extension from $[S_4Cd_{10}(SPh)_{16}]^{4-}$,[10] and should not incur intramolecular interference of ligand substituents. The ^{113}Cd-NMR line widths at 220 K are too large to permit resolution of the two Cd sites in **2**, with $(\mu_3\text{-}SPh)_2(\mu\text{-}SPh)_2Cd$ and $(\mu\text{-}SPh)_3CdSPh$ coordination, or resolution of any Cd-Cd scalar coupling.[7,8] Straightforward aggregation of the adamantanoid cages of **1** to form **2** cannot be sufficient for general dissolution of **1** in inert solvents, and other species in equilibrium with that giving the observed line presumably contain some coordinated DMF and give ^{113}Cd-NMR signals at much higher field.

Vicinal Dilithioalkenes by Addition of Lithium to Simple Cyclic and Acyclic Alkynes**

By *Adalbert Maercker,* Thomas Graule,* and *Ulrich Girreser*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 60th birthday

Addition of lithium to diphenylacetylene affords, depending on the conditions, either the unstable *cis*-dilithiostilbene[2] or the dimeric 1,4-dilithio-1,2,3,4-tetraphenyl-1,3-butadiene.[3] Only the latter has found applications as a difunctional organolithium compound in synthetic chemistry.[4] We have now attempted to extend this reaction to dialkylacetylenes in order to develop, ultimately, an approach to the synthesis of aliphatic, vicinal dilithioalkenes, which have not yet been prepared.[5]

In order to exclude the possibility of lithium hydride elimination, the most important competing reaction in the synthesis of polylithium organic compounds,[6] we initially selected di-*tert*-butylacetylene as a starting material—however, without success. No reaction was observed, even after heating the compound with lithium powder for eight hours in diethyl ether, tetrahydrofuran (THF), or cyclopentane.

a: $R^1 = R^2 = H$; **b**: $R^1 = R^2 = D$
c: $R^1 = H$; $R^2 = CH_3$; **d**: $R^1 = R^2 = CH_3$

The reaction with cyclooctyne **1**,[7] however, proceeded successfully. This strained cycloalkyne reacts with excess lithium powder in diethyl ether at −35°C under argon over the course of 2 h to give a yellow solution of *cis*-1,2-dilithiocyclooctene **3**, which is stable for several hours at −40°C but undergoes decomposition with a half-life of 1 h at room temperature. After the excess lithium had been filtered off, the reaction mixture was treated with CH_3OD. GC/MS analysis (internal standard: decalin) established the presence of 64% *cis*-1,2-dideuteriocyclooctene **5b** (96% D_2, 4% D_1)[8] and 19% 2,2'-dideuterio-1,1'-bicyclooctenyl **6b** (85% D_2, 10% D_1),[9] which is formed by deuterolysis of the dilithio compound **4**, the product of dimerization. In addition, traces of unidentified compounds (total < 1%) were detected by gas chromatography; the remainder (16%) consisted of nonvolatile reaction products.

In a second experiment, the reaction mixture was treated with dimethyl sulfate. The corresponding *cis*-1,2-dimethylcyclooctene **5d** (65%)[10] and 2,2'-dimethyl-1,1'-bicyclooctenyl **6d**[11] (9%) were obtained along with the monomethylated compounds **5c**[12] and **6c**[13] and the hydrolysis products **5a**[14] and **6a**[15] (Table 1).

Table 1. Solvent-dependent yields of monomeric and dimeric products in the addition of lithium to cyclooctyne followed by subsequent reaction with dimethyl sulfate. See also [7].

	Et_2O (−35°C) [%]	THF (−30°C) [%]	cyclopentane (−10°C) [%]
1	–	–	5
5a	2	12	2
5c	3	10	–
5d	65	15	13
6a	4	15	4
6c	4	6	7
6d	9	30	50
? [a]	13	12	19

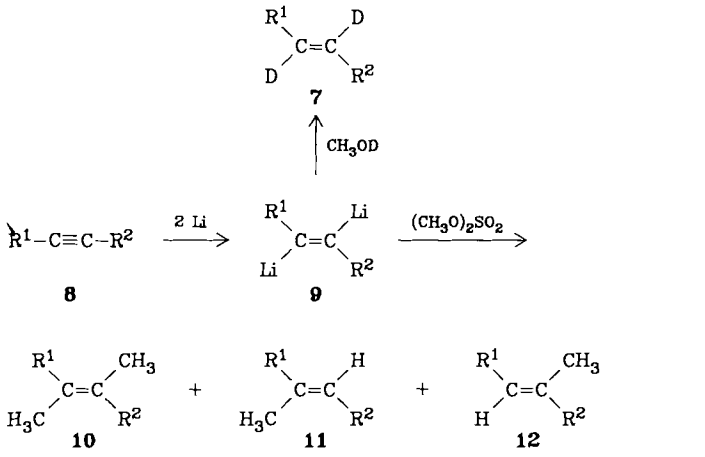
[a] Higher-molecular-weight products not detectable by gas chromatography.

The yield of **3** is poorer in THF at the same reaction temperature. However, not only is more of the dimer **4** formed, but also the dilithio compounds partly undergo decomposition by reaction with the solvent. Thus, even at −30°C, considerable amounts of the monomethyl compounds **5c** and **6c** as well as the hydrolysis products **5a** and **6a** are formed (Table 1). No reaction takes place at lower temperatures.

In cyclopentane the reaction of cyclooctyne **1** with lithium only begins to take place at −10°C. The large proportion of dimeric and higher-molecular-weight products is possibly due to the higher reaction temperature (Table 1).

The structures of the dilithio compounds **3** and **4** are still unknown. Experimental results for *cis*-dilithiostilbene[2] and ab initio calculations on *cis*-1,2-dilithioethylene[16] and 1,4-dilithio-1,3-butadiene[17] suggest doubly bridged structures such as **3A** and **4A**, respectively. ^{13}C- and ^6Li-NMR spectroscopic studies of the ^6Li-labeled compounds did not afford definitive results.[18]

3A **4A**



Since, contrary to our fears, no elimination of lithium hydride from 1,2-dilithiocyclooctene **3** occurred at low temperatures, we have also studied the reaction of sterically less-hindered, open-chain alkynes with lithium.

Indeed, treatment of 3-octyne **8a** with freshly prepared lithium powder (2% sodium) results in addition—which, however, proceeds slowly—to the triple bond. Interestingly, solely *trans* addition is observed, giving **9a**. The reaction is complete after 48 h in diethyl ether at room temperature. The insoluble product, a silvery, pale green sediment, still contains excess lithium. The deuterolysis was

[**] Polylithium Organic Compounds, Part 5. This work was supported by the Fonds der Chemischen Industrie.—Part 4: [1].

carried out by very slow addition of a 10% solution of CH_3OD in diethyl ether at $-30°C$ (**danger of explosion**) and afforded pure *trans*-3-octene **7a** (77% D_2, 18% D_1, 5% D_0) in 96% yield according to GC/MS analysis. In addition, traces of unidentified compounds (total < 1%) were detected by gas chromatography; the remaining products (3%) were nonvolatile substances. Dimeric products were only formed, this time, in trace amounts (< 1%).

a: $R^1 = C_2H_5$, $R^2 = C_4H_9$; **b**: $R^1 = R^2 = C_3H_7$; **c**: $R^1 = R^2 = C_4H_9$

Derivatization was also carried out with a 10% solution of dimethyl sulfate in diethyl ether at 0°C (very slowly, **danger of explosion**); (*E*)-3,4-dimethyl-3-octene **10a** (62%) was obtained along with the monomethylated compounds (*E*)-3-methyl-3-octene **11a** and (*E*)-4-methyl-3-octene **12a** (together 6%) as well as 15% of the hydrolysis product **7a** (D_0). Furthermore, several unidentified products (total ca. 9%) were detected by gas chromatography; the remaining substances (8%) were nonvolatile.

Table 2. Addition of lithium to open-chain alkynes in diethyl ether at room temperature and trapping of the organolithium intermediates.

Starting material	*t* [h]	Trapping reagent	Yield [%] [a] 7 (degree of deuteration)	10	11 (+ 12)
8a	48	CH_3OD	96 (77% D_2; 18% D_1; 5% D_0)	—	—
	48	$(CH_3O)_2SO_2$	15 (D_0)	62	6
8b	24	CH_3OD	90 (67% D_2; 20% D_2; 13% D_0)	—	—
	16	$(CH_3O)_2SO_2$	2 (D_0)	73	11
8c	48	CH_3OD	85 (64% D_2; 30% D_1; 6% D_0)	—	—

[a] Not optimized.

As expected, the symmetrically substituted acetylenes 4-octyne **8b** and 5-decyne **8c** also underwent reaction with lithium. Derivatization with dimethyl sulfate resulted, this time, in the formation of only one side product, since for $R^1 = R^2$ the monomethyl compounds **11** and **12** are identical (Table 2). Only *trans* addition is observed; the *cis* addition of lithium to cyclooctyne **1** and diphenylacetylene,[2] however, suggests a subsequent *cis-trans* isomerization, as we have found to be the case for unsubstituted 1,2-dilithioethylene.[19]

[7] *Experimental procedure:* Approximately 2% of a solution of **1** (1.08 g, 10 mmol) in 30 mL of diethyl ether was added to 0.3 g (43 mmol) of lithium powder (2% sodium) suspended in 5 mL of anhydrous diethyl ether under argon at −5°C. After start of the reaction (yellow coloration of the reaction mixture), the suspension was cooled to −35°C and the remainder of the solution of **1** was added over 2 h. The excess lithium was then filtered off under inert gas. In order to carry out the derivatization, the filtrate was cooled to −70°C and a 10% solution of CH_3OD or dimethyl sulfate in diethyl ether was added with stirring.

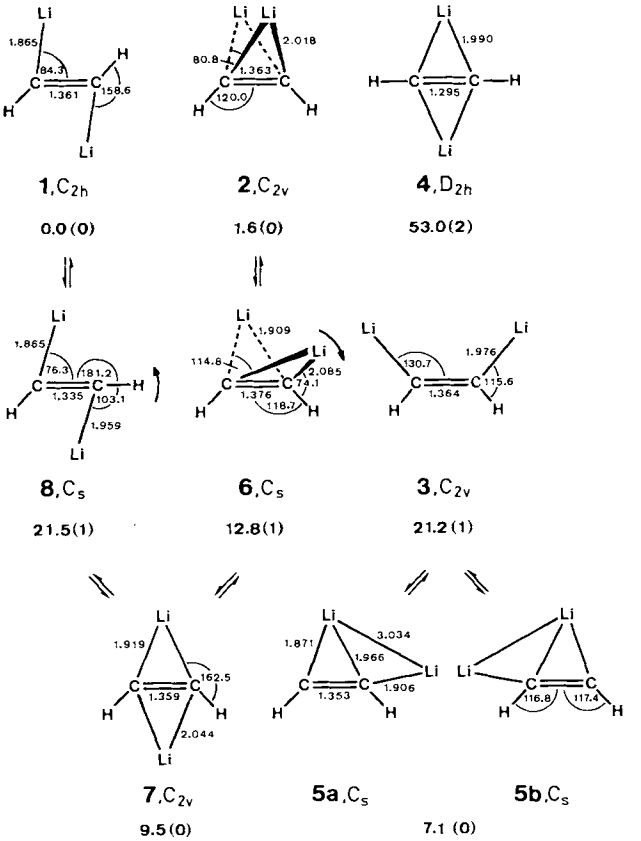
1,2-Dilithioethylene Isomers and Their Mechanisms of Interconversion: an Ab Initio Study**



By *Paul von Ragué Schleyer,* Elmar Kaufmann, Alexander J. Kos, Timothy Clark,* and *John A. Pople*

Polylithium compounds favor unusual geometries, quite unlike those of typical organic compounds.[1] Our earlier theoretical study of 1,2-dilithioethylene structures[2] is illustrative. The *trans* isomer **1** was found to prefer a distorted planar, partially bridged geometry. At the levels of theory employed in 1979, the nonplanar doubly bridged *cis* isomer **2** was found to be slightly more stable than **1**, and substantially lower in energy than the "classical" *cis* structure **3**. The more symmetrical (D_{2h} point group) bridged structure **4** was much higher in energy. At that time, experimental attempts to prepare 1,2-dilithioethylene had been unsuccessful.[3] The recent achievement of this goal by *Maercker* et al.[4] prompts us to report our further studies in this area. *Maercker*'s results indicate that *cis*-1,2-dilithioethylene rearranges readily into the more stable *trans* isomer. We now propose a mechanism for this isomerization.

Recent developments in theoretical methods[5,6] facilitate the characterization of stationary points on potential energy surfaces. Thus, both **1** and **2** are now confirmed to be minima (no imaginary frequencies[7]), but **3** is a transition-state structure (one imaginary frequency[7]) and **4**, with two imaginary frequencies,[7] has little chemical significance. All $C_2H_2Li_2$ structures have now been reoptimized with the polarized split valence 6-31G* basis set and the relative energies have been calculated at the correlated MP2/6-31G*//6-31G* level with zero-point energy corrections at 3-21G//3-21G (Scheme 1, Table 1). While these new relative energies for **1**–**4** differ only modestly from our earlier values,[2] the *trans* isomer **1** is now found to be somewhat more stable than any *cis* isomer, in agreement with the experimental findings.[4]

Four new stationary points, **5**–**8**, have been located on the potential energy surface. The unsymmetrical planar *cis* isomer **5** was found to be 14 kcal/mol more stable than **3**, which is the transition-state structure for the degenerate interconversion of the equivalent minima **5a** and **5b**. However, doubly bridged **2** is still the most stable *cis* isomer.

The most favorable pathway we have found for the transformation of **2** (*cis*) into **1** (*trans*) does not involve rotation around the carbon-carbon double bond, but rather in-plane inversion of one of the CH groups. The first step of this process is the rearrangement of **2** into another doubly bridged *cis* isomer, **7**, in which both lithiums are in the molecular plane. The rearrangement **2**→**7** involves movement of the lithiums apart, as indicated by the arrow in the transition state **6**. The much greater stability of **7** over **4** is noteworthy, and is due to the strong preference for bent vinyl anion centers.[8] Indeed, **8**, the transition-state structure for the overall *cis-trans* interconversion

Scheme 1. Stationary points on the potential energy surface of 1,2-dilithioethylene. Relative energies, given below each structure in kcal/mol, were calculated at the MP2/6-31G*//6-31G* level and include zero-point energy corrections. The number of imaginary frequencies [7] (at the 3-21G level) is enclosed in parentheses: 0 = minima, 1 = transition-state structures, 2 = higher order saddle points. Some geometrical parameters are given (in Å and degrees).

(i.e., the highest energy point through which the process occurs), has only one nearly linear H–C=C geometrical arrangement. The energy required for the linear distortion in **8** is roughly half that required for linearization of both H–C=C moieties simultaneously, as in **4**.

Table 1. Total energies (−a.u.) of 1,2-dilithioethylene isomers.

Structure	Point group	3-21G//3-21G	6-31G*//6-31G*	MP2/6-31G*//6-31G*	ZPE [a]	IFs [b]

[a] Zero-point energies in kcal/mol; these are multiplied by 0.9 to give the final relative energies in Scheme 1. [b] Imaginary frequencies in cm^{-1} [7].

We thus predict the barrier for the isomerization of **2** into **1** to be about 20 kcal/mol for a hypothetical gas-phase process. This relatively low value is consistent with *Maercker*'s findings in solution,[4] where, however, solvation and aggregation effects will further influence the rela-

tive energies. Nevertheless, it seems likely that vinyl inversion will be the preferred *cis-trans* isomerization mechanism in solution as well. In an increasing number of cases, our predicted structures of organolithium compounds, although calculated for isolated monomers, have proven to be remarkably accurate when compared with subsequently determined X-ray structures, especially with regard to the carbanion moieties.[1,9]

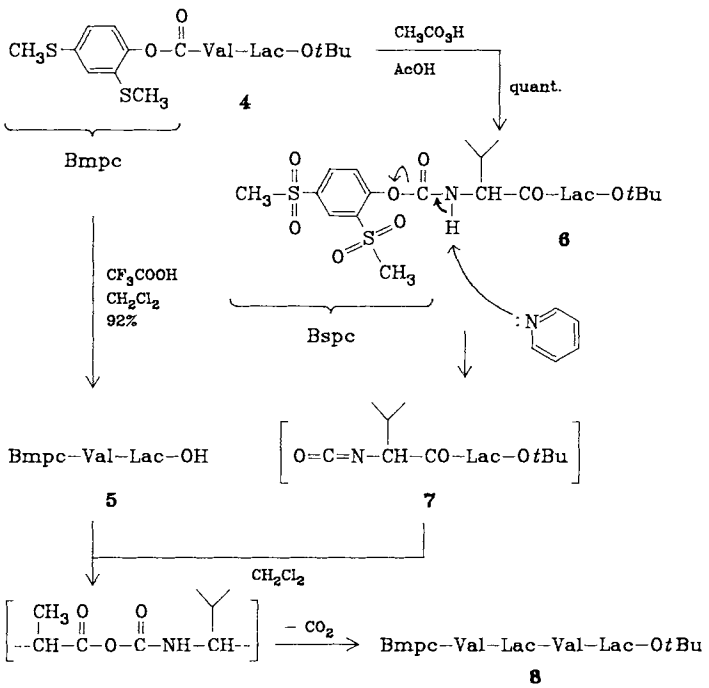
Synthesis of the all-L-Configurated Cyclotetradepsipeptide *cyclo*[-L-Val-L-Lac-]$_2$ by the Combined Protection/Activation Method with the 2,4-Bis(methylthio)phenoxycarbonyl Group

By *Horst Kunz** and *Hans-Jürgen Lasowski*

Dedicated to Professor Rolf C. Schulz on the occasion of his 65th birthday

The natural cyclic depsipeptides are characterized by selective complexing ability and antibiotic activity.[1] Since their biosynthesis[2] differs from that of other peptides, they are not accessible by means of gene technology. The most difficult step of chemical depsipeptide synthesis is the cyclization. Especially in the case of ring closure to give the smaller cyclodepsipeptides, the success of the synthesis depends strongly on the configuration of the building blocks, as *Shemyakin* et al.[3] have shown for several tetradepsipeptides, **1**, prepared from *N*-methylvaline and α-hydroxyisovaleric acid. The yields were 40–75% as long as at least one of the four building blocks had a different configuration from the others. In contrast, the all-D-configurated diastereomer of **1** could be cyclized in only 8% yield.

H-MeVal-Hyiv-MeVal-Hyiv-OH **1**



When the amino acid building blocks in **1** have no *N*-methyl groups, the tendency to cyclize is even smaller despite the opposite configurations of the building blocks. The corresponding cyclodepsipeptide was formed in only 6% yield.[3] Nonetheless, cyclotetradepsipeptides without *N*-methyl groups are formed in nature, e.g., *cyclo*[-L-Hyiv-L-Ile-Hyiv-D-*allo*-Ile-], whose precursors, moreover, are all-L-configurated.[4]

In investigations concerning new methods of depsipeptide synthesis,[5] we have now developed a concept for the chemical cyclization of peptides, even such tetradepsipeptides as **2**, whose building blocks all have the same configuration and no *N*-methyl groups.

H[-L-Val-L-Lac-]$_2$OH ⟶ *cyclo*[-L-Val-L-Lac-]$_2$
2 **3**

This ring closure, which is difficult on account of both of the factors discussed above, we carried out using the 2,4-bis(methylthio)phenoxycarbonyl(Bmpc) amino protecting group, which is capable of undergoing activation. It is added to the amino acids by means of 2,4-bis(methylthio)phenyl chloroformate, as has already been described for the 4-methylthiophenoxycarbonyl(Mtpc) group.[6] The coupling of the Bmpc-amino acids with L-lactic acid is also carried out analogously to the procedure already described[6] with benzenesulfonyl chloride.[7]

The Bmpc group of the protected depsipeptide **4** is stable toward trifluoroacetic acid in dichloromethane, so that the *tert*-butyl ester groups can be selectively cleaved with formation of **5**. The Bmpc group in **4** can be activated to

Scheme 1. Reaction conditions: **5** (20 mmol) and **6** (20 mmol) in 160 mL of dry dichloromethane and 32 mL of dry pyridine, 4 Å molecular sieves, room temperature, preparative HPLC in petroleum ether/ethyl acetate (4:1). **8** is formed in 57% yield (based on **5**).

[*] Prof. Dr. H. Kunz, Dr. H.-J. Lasowski

the 2,4-bis(methylsulfonyl)phenoxycarbonyl (Bspc) group in **6** with anhydrous peracetic acid (10%)[8] (Scheme 1).

Even pyridine causes the elimination of 2,4-bis(methylsulfonyl)phenol from the Bspc group, resulting in the formation of the isocyanate **7** from **6**. If **7** is released in the presence of the carboxyl component **5** that is to be coupled, direct reaction occurs, via the mixed carboxylic acid–carbamic acid anhydride, leading to the desired protected tetradepsipeptide **8**.

In this case, the Mtpc group used earlier by us[6] has the disadvantage that for the elimination from the sulfonyl (Mspc) form triethylamine is required, which partly attacks the nonactivated Mtpc group. The depsipeptides obtained in this way contain lower homologues (detectable by analytical HPLC) that cannot be separated. Therefore, no cyclization was achieved with this group.

In order to carry out the cyclization, **8** is deblocked at the *C*-terminal end with trifluoroacetic acid to give **9**, which then reacts with anhydrous peracetic acid at the *N*-terminal protecting group to afford activated **10** (Scheme 2).

Scheme 2. Reaction conditions: **10** (0.25 mmol) in 200 mL of dry CH_2Cl_2 and 50 mL of dry NEt_3, 4 Å molecular sieves, 20 d, room temperature, chromatography in petroleum ether/ethyl acetate (2 : 1). **3** is formed in 33% crude and 11% pure yield.

In dilute dichloromethane solution in the presence of triethylamine, **10** undergoes elimination of disulfonylphenol. The isocyanate formed undergoes intramolecular reaction to give the cyclic mixed anhydride **11** (not isolated). Compound **11** eliminates CO_2 to form the desired cyclotetradepsipeptide **3**, the first synthetically obtained cyclotetradepsipeptide that consists only of identically configurated building blocks having no *N*-methyl groups. That compound **3** (which according to the results of *Shemyakin* et al.[3] should hardly be accessible) could be prepared according to Scheme 2 is due in part to the fact that **11**, with a less strained fourteen-membered ring, is formed initially. In **11** the two ends that are to be coupled are arranged favorably, so that spontaneous elimination of CO_2 leads to formation of the twelve-membered ring. **3** is obtained from chloroform/petroleum ether as a colorless compound which is pure according to HPLC (heptane/ethyl acetate 85 : 15) ($[\alpha]_D^{22}$ −32.4 (c = 0.08, CH_2Cl_2); FD-MS: m/z 342 (M^+)). In the 400-MHz ^{1}H-NMR spectrum[9] each kind of proton gives only one signal (with the exception of the diastereotopic valine methyl protons). Accordingly, epimerization of the activated L-lactic acid building block in the cyclic mixed anhydride **11** is unlikely, since this would otherwise be observed in the NMR spectrum of **3**.

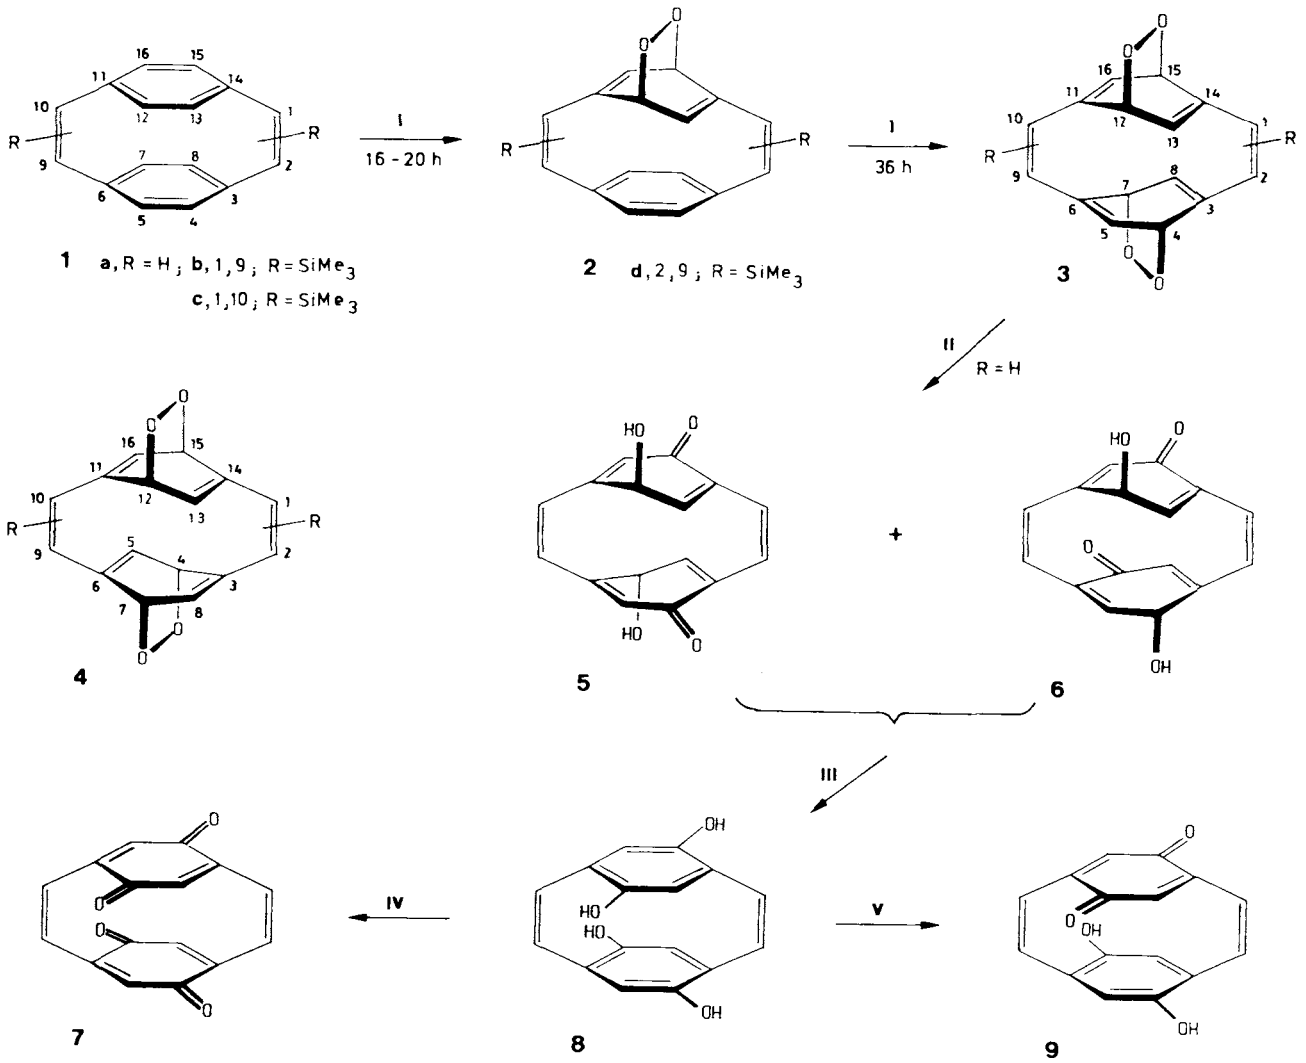
A Simple Route to the Intramolecular Quinhydrone of [2.2]Paracyclophanediene**

By *Michael Stöbbe, Stephan Kirchmeyer, Gunadi Adiwidjaja,* and *Armin de Meijere**



Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Molecules exhibiting intramolecular charge transfer are useful, among other things, as rigid models to test experimentally charge transfer as a function of distance.[1,2] All previously reported systems of this kind containing the [2.2]- or [3.3]paracyclophane skeleton have been constructed in multistep sequences by the combination of suitably substituted molecular halves. The twofold addition of singlet oxygen ($^1O_2$) to [2.2]paracyclophane-1,9-diene **1a** provides a short route to a further system of this kind.

The photooxidation of **1a** yields the endoperoxide **2a**[3] and a by-product (2–3%), which is formed in a slow secondary reaction and has an appreciably higher R_F value. This product was purified by column chromatography using polar eluents and identified by NMR spectroscopy as a *single* bisendoperoxide, either **3a** or **4a**. Reaction of pure **2a** with $^1O_2$ gave **3a** or **4a**[4] in better yield (28%). **3a** or **4a** could be recrystallized (colorless, monoclinic, explosive dec. > 115 °C). X-ray analysis, however, did not result in a definitive structural assignment: the data indicate that the O-atoms lie at a position intermediate between those expected for diastereomers **3a** and **4a**. This evidently results from a statistical distribution of the enantiomers of **3a** in

Scheme 1. I: $^3O_2$, *hv*, tetraphenylporphyrin, $CHCl_3$, 20°C; II: NEt_3, CH_2Cl_2, 0-20°C, 14-18 h; III: MeOH/AcOH/CF_3CO_2H (1:1:0.16), 6 h reflux; IV: $Ce(NH_4)_2(NO_3)_6$, CH_2Cl_2/THF/H_2O, 20°C, 2 min; V: O_2/SiO_2, 24 h.

the crystal array. The clarification of the stereochemical question and the unambiguous assignment of the structure to diastereomer **3a** was finally achieved by the reaction sequence leading to the single quinhydrone **9** (Scheme 1).

Treatment of **3a** with triethylamine gave a mixture of the diastereomeric bisquinols **5** and **6**[4] (60%), which could be separated by column chromatography and purified by fractional recrystallization. The rearrangement of **5** and **6** to the bishydroquinone **8**[4] (40%) required treatment with trifluoroacetic acid. **8** was readily oxidized to the bisquinone **7**[4] (yellow crystals, dec. >200°C) with cerium(IV) ammonium nitrate.

A single quinhydrone, **9**, was obtained by air oxidation of **8**, which was adsorbed on silica gel. Subsequent column chromatography (SiO_2) yielded **9**[4] as brown-black crystals (73%, dec. > 180°C). The configuration of **9** was unambiguously established by its UV/VIS spectrum, which shows absorption bands at $\lambda_{max}(\lg\varepsilon)=330$ (3.43) and 517 nm (2.14) (ethanol), since the charge-transfer band corresponds in both position and extinction coefficient to that of pseudo-*ortho*-[2.2]paracyclophanequinhydrone,[1] [$\lambda_{max}(\lg\varepsilon)=317$ (3.46) and 515 (2.23) (methanol)]. The pseudo-*gem* quinhydrone of [2.2]paracyclophane, has a charge-transfer band that is distinctly more intense and at shorter wavelength [$\lambda_{max}(\lg\varepsilon)=495$ nm (3.20) (methanol)].[1]

The observed diastereoselectivity in the addition of $^1O_2$ to the monoadduct **2** is probably based on both steric and electronic factors. The transition state leading to the unobserved **4a** would be less favorable sterically because of the very close contact between H atoms on C8/C13 and on C5/C16. **3a** would be electronically favored since, according to MNDO calculations,[5] the coefficients in the HOMO of **2a** are larger on C4/C7 than on C5/C8, resulting in a better transition-state interaction with the LUMO of $^1O_2$.

The addition of $^1O_2$ to 1,9-bis(trimethylsilyl)[2.2]paracyclophanediene **1b**,[4,6] which is much more soluble in hydrocarbon solvents than **1a**, led by way of **2b** to the 1,9-bis(trimethylsilyl) derivative **3b**[4] (8%), which is readily soluble in dichloromethane. Analogously, a ca. 1:1 mixture of 1,9-**1b** and 1,10-bissilyldiene **1c**[4,6] gave a mixture of the three endoperoxides **2b**, **2c**, and **2d** (22, 32, and 8%) and the bisendoperoxide **3c**[4] (9.4%), formed by the preferential further reaction of 1,10-**2c** and/or the 2,9-bissilyl derivative **2d**. Products **3b** and **3c** open the way to the cor-

responding silyl derivatives of **7**, **8**, and **9**, which, because of their expected better solubility, will facilitate further physical and chemical investigations of this class of compounds.

The Tetrasilabicyclo[1.1.0]butane System: Structure of 1,3-Di-*tert*-butyl-2,2,4,4-tetrakis-(2,6-diethylphenyl)tetrasilabicyclo[1.1.0]butane**

By *Ray Jones, David J. Williams, Yoshio Kabe,* and *Satoru Masamune**

Our efforts directed toward the construction of strained cyclic silicon systems[1] have recently culminated in the synthesis of the title compound **1**,[2] the first uncharged[3] tetrasilabicyclo[1.1.0]butane derivative.[4] The weakness and high reactivity of the critical Si1–Si3 bond of **1** were anticipated and, indeed, are shown by the chemical reactivity of this compound. The puckered ring system undergoes rapid inversion (**1** ⇄ **1'**) and the central bond is readily cleaved by oxygen and chlorine as well as water.[2] We report here the crystal structure of compound **1**.[5]

R = 2,6-$Et_2C_6H_3$

The molecule (Fig. 1) has approximate, noncrystallographic, twofold symmetry about an axis perpendicular to the Si1–Si3 bond.[6] The Si1–Si3 distance (2.373(3) Å) is typical for a cyclic Si–Si bond.[7] However, the peripheral Si–Si bonds are all significantly shorter than in other cyclotetrasilane systems.[7] There is also, interestingly, a small alternation in the bond lengths around the ring. The dihedral angle between the two three-membered rings is 121° and the nonbonding Si2–Si4 distance is 3.475 Å. The Si–C bond lengths are normal and range between 1.921(7) and 1.959(7) Å.

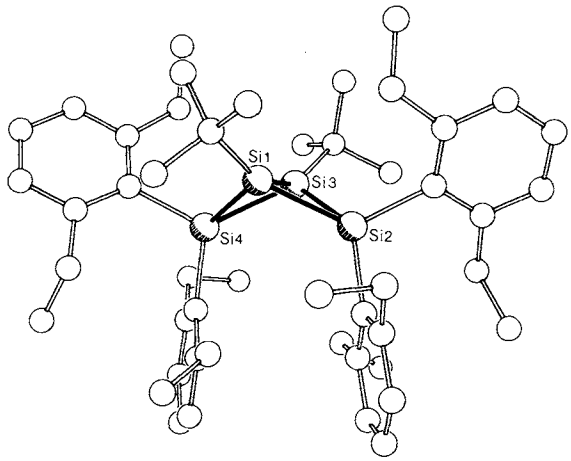

Fig. 1. Crystal structure of **1** [5]. Bond lengths [Å] and bond angles [°]: Si1–Si2 2.311(3), Si1–Si4 2.336(3), Si2–Si3 2.334(4), Si3–Si4 2.308(3), Si1–Si3 2.373(3); Si1–Si2–Si3 61.4(1), Si1–Si3–Si2 58.8(1), Si1–Si3–Si4 59.8(1), Si1–Si4–Si3 61.4(1), Si2–Si1–Si3 59.8(1), Si3–Si1–Si4 58.7(1), Si2–Si1–Si4 96.8(1), Si2–Si3–Si4 96.9(1).

In view of the extremely facile ring inversion, the relatively short Si1–Si3 distance is somewhat unexpected. It is shorter than the Si–Si bonds in hexa-*tert*-butylcyclotrisilane (ca. 251 pm)[1h] and hexa-*tert*-butyldisilane (ca. 270 pm),[8] the latter of which exhibits the longest Si–Si bond observed so far. While, due to the bulky substituents, the observed geometry of the silicon framework may be slightly distorted from that of the unknown parent tetrasilabicyclo[1.1.0]butane, the Si1–Si3 bond is undoubtedly bent and rich in p-character. The (carbon) bicyclobutane system has been extensively investigated;[9] comparative studies of sila-analogues should therefore be interesting and important from both theoretical and experimental viewpoints.[10]

[5] Orthorhombic, $a=11.244(3)$, $b=18.521(5)$, $c=21.985(6)$ Å, $V=4578$ Å^3, space group $P2_12_12_1$, $Z=4$, $\rho_{calcd}=1.11$ gcm^{-3}, $\mu(Cu_{K\alpha})=14$ cm^{-1}. The crystals are extremely air and moisture sensitive and subject to serious twinning. Data for a small slightly twinned crystal [6] sealed under argon in a Lindemann glass capillary tube were measured on a Nicolet R3m diffractometer with graphite monochromated $Cu_{K\alpha}$ radiation using the ω-scan routine. The structure was solved by direct methods and refined anisotropically, with the aromatic rings being treated as idealized rigid bodies. $R=0.0734$, $R_w=0.071$, for 2546 independent observed reflections [$\theta \leq 58°$, $|F_0| > 3\sigma(xF_0)$]. The slightly high final value of R is probably a consequence of the high thermal vibration of the ethyl groups and the small amount of twinning in the only suitable crystal available [6]. Further details of the crystal structure investigation are available on request from the director of the Cambridge Crystallographic Centre University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England) by quoting the full literature citation.

[6] The conformation adopted by the molecule is chiral and the space group, which is non-centrosymmetric, contains molecules of one chirality only.

[7] For instance, in *trans,trans,trans*-(*t*BuMeSi)$_4$ the Si-Si bond is 2.377 Å long: C. J. Hurt, J. C. Calabrese, R. West, *J. Organomet. Chem. 91* (1975) 273. For other examples, see footnote [14] in [1a].

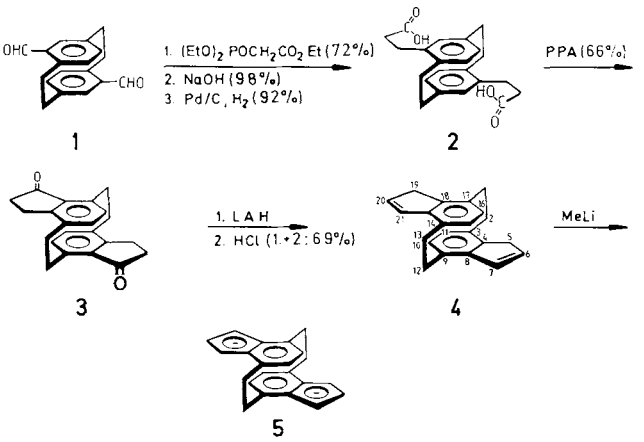
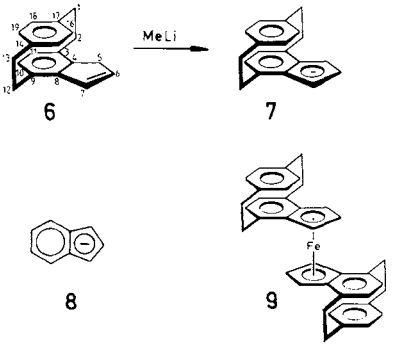
[2.2]Indenophane Dianion: A Novel Double-Layered Dianion



By *Ron Frim, Friedrich-Wilhelm Raulfs, Henning Hopf,** and *Mordecai Rabinovitz**

[2.2]Paracyclophanes are aromatic hydrocarbons with unique steric and electronic properties. The two π-systems interpenetrate, so that they behave as one π-system.[1-3] Paracyclophane anions are of interest in view of the proximity of the two anionic moieties and their mutual interaction. Anionic paracyclophanes have been previously studied.[4] *Haenel*[5] has described the preparation and ^{1}H-NMR spectra of anions derived from *syn*- and *anti*-[2.2](2,7)fluorenophanes, but no ^{13}C-NMR spectra of these species have been reported.[6] We report here the preparation and the ^{1}H- and ^{13}C-NMR spectroscopic data of the dianion of [2.2]indenophane **5** and the monoanion of [2.2]benzoindenophane **7**. This is the first comprehensive study of the properties and through-space interactions of double-layered mono- and dianions.



The starting material in the preparation of [2.2]indenophane **4** is the dialdehyde **1**,[7c] which underwent a chain elongation by the Wittig-Horner reaction followed by reduction of the double bond and cyclization of the diacid **2** to give the "[2.2]indanonophane" **3**. The diketone **3** was reduced to the corresponding diol, which was then dehydrated to the [2.2]indenophane **4**.[7] A similar route starting from 4-formyl[2.2]paracyclophane afforded the benzoindenophane **6**.[7]

Reaction of **4** and **6** with methyllithium in [D$_8$]tetrahydrofuran ([D$_8$]THF) at -78°C led to the corresponding anions **5** and **7**. When **4** was allowed to react with a colorless solution of MeLi in [D$_8$]THF (prepared from a commercial solution of MeLi in ether) in the NMR tube, the solution turned orange. After several minutes, clean ^{1}H- and ^{13}C-NMR spectra, entirely different from those of **4**, were recorded (Table 1). The ^{1}H-NMR spectrum is very simple and shows a triplet and a doublet for the five-membered-ring protons at $\delta=6.35$ (H-6, H-20) and 5.80 (H-5, H-7, H-19, H-21), respectively, a singlet at $\delta=5.23$ for the aromatic protons, and an AA'BB' multiplet for the ethano bridge protons at $\delta=3.27$–2.87.

When a double-layered dianion such as **5** is formed from a neutral precursor, the following NMR spectral phenomena may be expected: (a) shielding due to the negative charges, (b) deshielding resulting from the formation of conjugated 10π-electron systems, and (c) a through-space interaction between the two halves of the double-layered structure. The center of gravity of the ^{1}H-NMR spectrum of **5** is at $\delta=4.53$, while that of the hydrocarbon **4** is at $\delta=4.65$. This shows that the shielding effect due to the charge is overcome by the diatropicity of the two indenylide aromatic components (even when the change of hybridization of C-5 and C-19 is taken into account). According to well-known correlations,[8] the net effect of the charge alone would have shifted the center of gravity of the spectrum of this three-dimensional dianion to $\delta=3.45$. The comparison with the ^{1}H-NMR spectrum of the indenylide monoanion **8**[9] is revealing. The six-membered-ring protons of **5** show a very significant high-field shift compared to those of **8** (ca. 2 ppm), while the five-membered-ring protons of **5** and **8** show similar chemical shifts. This phenomenon cannot be attributed to a charge delocaliza-

tion effect since such a charge delocalization should also prevail in **8**. It should therefore be attributed to the through-space interaction of the two fully aromatic halves of the dianion.

The chemical shifts of the five-membered-ring protons of the monoanion **7** are similar to those of corresponding protons of **5** and **8** (see Table 1). The six-membered-ring protons are again shifted to higher field but to a lesser degree than in **5**. This phenomenon can be rationalized in terms of a lesser degree of through-space interaction, since only one indenyl moiety interacts with only one benzene moiety. In the ferrocenophane **9**[7b] derived from **6**, the five-membered-ring protons are shifted strongly to high field, but the six-membered-ring protons show only a slight high-field shift of ca. 0.3 ppm (Table 1).

Only six lines appear in the ^{1}H-decoupled, ^{13}C-NMR spectrum of the dianion **5** due to its high degree of symmetry. The ^{13}C chemical shifts (Table 1) also point to a higher degree of charge density residing at the five-membered ring as compared to the six-membered ring. Nonetheless, the formation of a dianion can be deduced from the shift of all signals to high field (relative to those of **4**). As expected, monoanion **7** shows ten lines in the ^{1}H-decoupled ^{13}C-NMR spectrum (Table 1), all of which are shifted to high field.

Table 1. ^{1}H- and ^{13}C-NMR spectroscopic data for **4**–**9** [a].

[a] Chemical shifts (δ values) relative to TMS, coupling constants in Hz. The ^{13}C-NMR spectra are ^{1}H-decoupled. [b] In [D$_8$]THF at room temperature. The solution of the anions contains residual diethyl ether. [c] In $CDCl_3$ at room temperature. [d] See [9].

As *Edlund* et al. have demonstrated for indenyllithium and related systems, the NMR spectra are influenced by solvation of both the cation *and* the anion.[10] The same is probably true for **5** and **7**.

Anions **5** and **7** react with D_2O to give mixtures of products. Dianion **5** gives dideuterated derivatives, as shown by mass spectroscopy (*m/z* 286). Monoanion **7** affords a monodeuterated derivative (*m/z* 247).

The surprisingly stable anions **5** and **7** represent a new class of stacked anionic structures. The interaction of the two components of which this system is composed seems to be very significant, especially in **5**. The high-field shift of 0.97 ppm for the signals of the six-membered-ring protons of **5** (compared with those of **4**) indicates an even stronger interaction than the one prevailing in the [2.2]paracyclophanes. Furthermore, the comparison between the two ionic structures **5** and **7** shows the greater importance of the interaction between two negatively charged moieties in **5** relative to that in **7**.

$[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]$, a Product of the Reaction of $[CoCl_2(PPh_3)_2]$ with $PhAs(SiMe_3)_2$**

By *Dieter Fenske** and *Johannes Hachgenei*

Recently, we described the reaction of $[MCl_2(PPh_3)_2]$ (M = Co, Ni) with $PhP(SiMe_3)_2$, which results in the formation of the complexes $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ and $[Ni_8(\mu_4\text{-}PPh)_6(PPh_3)_4]$,[1] respectively, along with Me_3SiCl. More-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank the staff of the Institut für Kristallographie der Universität Karlsruhe for their help in obtaining the crystal data.

over, the reaction of $[MCl_2(PPh_3)_2]$ with $E(SiMe_3)_2$ (E = S, Se) affords in high yields clusters such as $[Co_7S_6Cl_2(PPh_3)_5]$, $[Co_6E_8(PPh_3)_6]^n$ (E = S, n = +1, E = Se, n = 0), $[Ni_8S_6Cl_2(PPh_3)_6]$, $[Ni_8S_5(PPh_3)_7]$, $[Co_9Se_{11}(PPh_3)_6]$, and $[Ni_{34}Se_{22}(PPh_3)_{10}]$.[2,3] We have now studied the application of this principle to the synthesis of complexes containing AsPh ligands.

When $[FeCl_2(PPh_3)_2]$ is allowed to react with $PhAs(SiMe_3)_2$ a redox reaction is observed, which gives Fe, $(AsPh)_n$, and Me_3SiCl. In contrast, reaction of $[CoCl_2(PPh_3)_2]$ **1** with $PhAs(SiMe_3)_2$ results in the formation of an intense green solution (with the formation of a small amount of Co). Dark green crystals of **2** are obtained from the filtrate in a yield of 95% (based on As).[4]

$$\underset{\mathbf{1}}{[CoCl_2(PPh_3)_2]} \xrightarrow{PhAs(SiMe_3)_2} \underset{\mathbf{2}}{[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]}$$

In the ^{1}H-NMR spectrum of the paramagnetic Co_4As_6 cluster, the signals of the phenyl protons appear at $\delta = 6.80$–8.40. No ^{31}P-NMR signal can be observed. According to the X-ray structure analysis, the structure of **2** consists of a Co_4 tetrahedron, three Co_3 faces of which are each capped by a μ_3-As ligand (As2, As2a, As2b) and one face of which (Co1, Co1a, Co1b) is linked to an As_3 ring (As1, As1a, As1b) (Fig. 1).[5] Cluster **2** may be regarded as a heterocubane cluster having the formula $[Co_4(\mu_3\text{-}As)_4(PPh_3)_4]$ in which one μ_3-As is replaced by an η^3-As_3 ligand. In addition, each Co atom is coordinated by PPh_3 (P1, P2). Cluster **2** can alternatively be regarded as having been derived from a Co_3As_3 octahedron (As1, As1a, As1b, Co1, Co1a, Co1b) that is connected by a Co_3 face to a $Co_4(\mu_3\text{-}As)_3$ unit. The η^3-E_3 complexes (E = P, As) reported so far, on the other hand, are regarded as derivatives of the tetrahedral $As_4(P_4)$ in which As or P is replaced by an isolobal transition-metal fragment.[6,8]

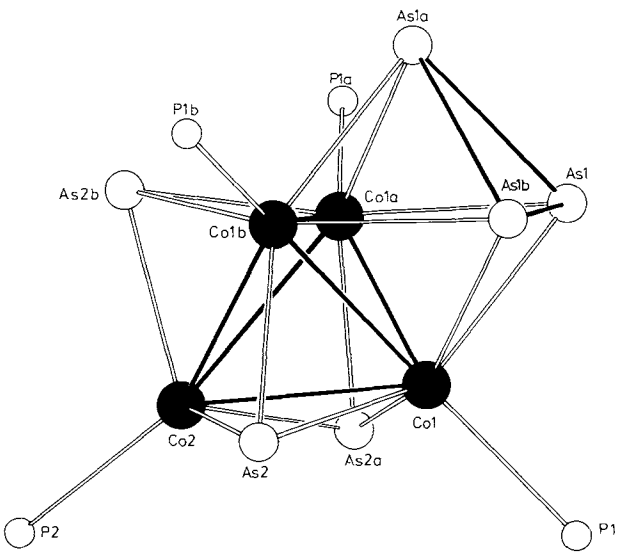

Fig. 1. Crystal structure of the cluster **2** (without phenyl groups). P1, P1a, P1b, and P2 represent the P atoms of the PPh_3 ligands. Most important bond lengths [pm] (±0.1 pm) and bond angles [°] (±0.1°): Co1-Co1a(Co1b) 243.8, Co1-As1 248.8, Co1-As1b 243.3, Co1-Co2 261.6, Co1-P1 220.1, Co1-As2 229.4, Co2-As2 227.4, Co2-P2 217.5, As-As (in η^3-As_3) 246.3; As-As-As (in η^3-As_3) 60.0, Co-Co-Co 55.4–62.2, Co2-(μ_3-As)-Co 64.2–69.8, P1-Co1-As1 99.8, P1-Co1-As2 101.7–105.1, P2-Co-As2 112.2, (μ_3-As)-Co1-As2 91.5–93.0, Co1b-Co1-As1b 61.4, As1b-Co1-As1 60.1, Co1b-Co1a-As1 90.4, Co1a-As1-As1b 90.3, Co1a-As1-As1a 61.1, As1a-As1-Co1 89.0.

Cluster **2** has a threefold axis. Co2 and P2 occupy the 6c sites and Co1, As1, As2, and P1 the 18f sites (in the space group $R\bar{3}$). The As1–As1a distance of 246.3(2) pm is in accord with the As–As distances in As_4, $(AsPh)_6$,[7] and the Co_2As_3 cluster **3**; however, it is 10 pm longer than the As–As distance in the As_3 complexes **4** and **5**.[8] Co1 is bonded to four As ligands and one PPh_3 ligand (P1) in a square-pyramidal fashion. In contrast, Co2 is coordinated by three μ_3-As ligands and one PPh_3 ligand (P2) in a distorted tetrahedral fashion.

$$\underset{\mathbf{3}}{[(triphos)Co\text{-}\mu(\eta^3\text{-}As_3)Co(triphos)]^{2+}} \qquad \underset{\mathbf{4}}{[As_3Co(CO)_3]}$$

$$\underset{\mathbf{5}}{[(C_5H_5)Mo(CO)_2As_3]}$$

The shortening of the As–As bonds in **4** and **5** (compared with those in As_4) is explained by an increase in bonding and a decrease in antibonding interactions within the As_3 ring. The bonding situation in **2** is obviously different since each As atom of the η^3-As_3 ligand is bonded to two Co atoms. The Co1–As1 a distance (243.3–248.8(2) pm) is about as large as that in **4** (244 pm) and longer than that in **3** (241 pm). The bonds between the Co atoms and the μ_3-As (Co1-As2: 229.3(2), Co2-As2: 227.4(2) pm) are significantly shorter.

If η^3-As_3 and μ_3-As are considered to be 3e donors and PPh_3 a 2e donor, **2** contains 56 valence electrons (eight electrons for six Co–Co bonds) and thus four electrons fewer than expected for an M_4 cluster having a tetrahedral structure. In agreement with this observation, the Co–Co bonds have differing lengths (Co1-Co2: 261.6(2), Co1-Co1a: 243.8(1) pm).[1,9]

The formation of **2** is surprising since it occurs at room temperature with cleavage of the As–C(Ph) bond. Evidence for the instability of As–C bonds has already been reported.[8,10] Cluster **2** reacts with $Co_2(CO)_8$, $Ni(CO)_4$, $[M(CO)_5(thf)]$ (M = Cr, Mo), and $[CpMo(CO)_3]_2$ to give cluster compounds that have not yet been identified.

The First Evidence of Endogenous Pyridoxyl Isoquinoline Alkaloids in Mammalian Organisms**

By *Gerhard Bringmann** and *Stephan Schneider*

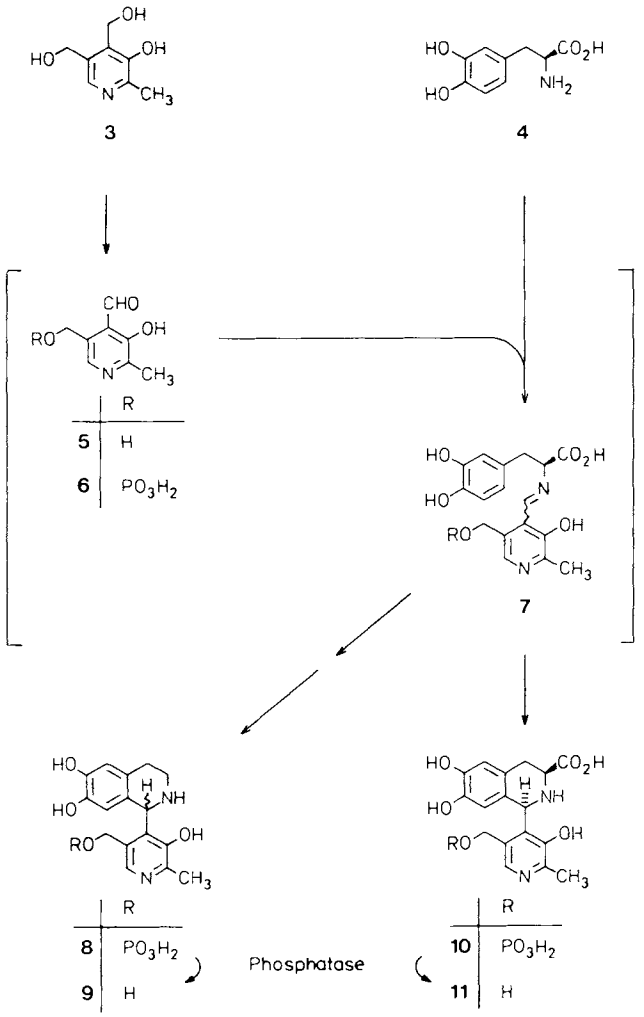
The ease with which the biosynthesis of isoquinoline alkaloids from arylethylamines and aldehydes or α-keto acids can be imitated in vitro[1] led very early to the assumption[2] that such condensation reactions could also take place in mammalian organisms, e.g., after alcohol consumption.[3] In particular, the aldehyde pyridoxal **5**, the key coenzyme in amino acid metabolism, might react with endogenous dinucleophilic amines to give the alkaloid-like metabolites **2** via the biochemically familiar Schiff base intermediates **1** (Scheme 1). We now report the first evidence for the in vivo formation of novel alkaloids

Scheme 1.

in mammalian organisms from vitamin B_6 **3** and L-Dopa **4**, which are administered in unphysiologically high doses, often gram amounts, in the treatment of certain metabolic disorders, such as Parkinson's disease[4] and homocystinuria.[5] Such alkaloids are also unknown in plants.

Using in vitro model reactions, we first synthesized the isoquinoline alkaloids **8**–**11** (which are derived from vitamin B_6) from pyridoxal **5** or pyridoxal phosphate **6** and L-Dopa **4** or dopamine under physiological conditions[6] (water, pH 6–8, 35 °C), compound **7** probably being an intermediate (Scheme 2). After their constitution and configuration[7] had been established (^{1}H-NMR data in Table 1), an analytical method was elaborated for these extremely polar, in part multi-zwitterionic substances. Using ion-pair-assisted reverse phase HPLC (RP 18; 0.01 M H_3PO_4 in H_2O + 0.3% sodium dodecyl sulfate / 0.01 M H_3PO_4 in CH_3OH), we found conditions that permitted the efficient chromatographic separation and detection of these substances in nanogram quantities, even in complex biological systems.

After intravenous administration of therapeutically common doses (20 mg/kg) of pyridoxine **3** and L-Dopa **4** to Wistar rats, however, the expected isoquinoline **11** could not be detected in the blood, even if, instead of **3**, the aldehyde pyridoxal **5**, which is able to undergo condensation, was injected. Instead, we found even more polar metabolites in both cases, which are chromatographically (HPLC, see above) identical with the *O*-phosphorylated heterocycles **8** and **10**.



In order to confirm the identification of **8** and **10** and to quantify their formation, we carried out animal experiments with [4,5-^{14}C]pyridoxine **3***. For a reverse isotope dilution analysis, blood plasma, obtained from venous blood after incubation (2–6 h), was treated with unlabeled **8** or **10** and with the unlabeled educt **3**. After addition of 5% trifluoroacetic acid, the proteins were centrifuged off, and the supernatant was freeze dried. Preparative HPLC (for conditions see above) and subsequent separation of the ion-pair reagent afforded **8*** and **10***, which were purified to constant radioactivity by crystallization. In order to obtain preliminary information regarding the distribution of these novel metabolites in the body and their possible biotransformation, we also analyzed the liver. The results of the animal experiments are summarized in Table

Table 1. ^{1}H-NMR data for the condensation products **8**, **9**, **10**, and **11** (300 MHz, tetramethylsilane or sodium[2,3-D_4]-3-trimethylsilylpropionate int., δ values).

Scheme 2. In vitro and in vivo formation of pyridoxyl isoquinoline alkaloids.

2.[8] For a further structural proof, the alkaloids **8*** and **10*** could be dephosphorylated in vitro to the radioactive alcohols **9*** and **11*** using an acid phosphatase (E.C. 3.1.3.2).

Table 2. Results of the reverse isotope dilution analysis after administration of pyridoxine **3*** (10 μCi, 20 mg/kg) and L-Dopa **4** (20 mg/kg) to rats.

Isolated alkaloid (sample)	Incubation time [h]	Total radio-activity [nCi]	Absolute rate of incorporation [%] × 10^2	Alkaloid content [ng/mL or ng/g]
8 (blood)	4	1.9	1.9	133
8 (blood)	6	3.0	3.0	206
8 (liver)	6	0.2	0.2	28
10 (blood)	2	0.7	0.7	53
10 (blood)	4	0.8	0.8	57
10 (liver)	6	<0.007	<0.007	<1

The identification of pyridoxyl isoquinoline alkaloids in living mammalian organisms expands the range of specific, enzymatically catalyzed reactions of vitamin B_6 to include the probably nonenzymatic Pictet-Spengler condensation to heterocyclic metabolites.

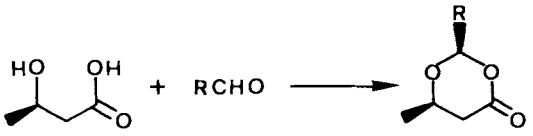
[7] The configuration of the pyridoxyl substituents on C-1 in **10** and **11** was determined from the ^{1}H-NMR ^5J coupling between 1-H_a and 4-H_a to be equatorial, and therefore *cis* with respect to the equatorial carboxyl group and (1*R*). In order to carry out the mass spectrometric analysis, **8** and **10** were enzymatically dephosphorylated to **9** and **11** (acid phosphatase, H_2O, pH 5), since they could not be detected as phosphoric esters, even when mild ionization techniques (field desorption or fast atom bombardment) were used.—The synthesis of these condensation products has already been described. However, their spectroscopic characterization was incomplete since, in particular, the configuration of possible epimeric products was not taken into consideration: E. A. Rudd, W. C. Cunningham, J. W. Thanassi, *J. Med. Chem. 22* (1979) 233; C. Borri Voltattorni, A. Orlacchio, A. Giartosio, F. Conti, C. Turano, *Eur. J. Biochem. 53* (1975) 151; T. Kametani, M. Koizumi, K. Okui, Y. Nishii, M. Ono, *J. Med. Chem. 15* (1972) 203; J. H. Fellman, E. S. Roth, *Biochemistry 10* (1971) 408; H. F. Schott, W. G. Clark, *J. Biol. Chem. 196* (1952) 449.
[8] In interpreting the absolute rates of incorporation of radioactivity (total radioactivity of the isolated alkaloids divided by that of the labeled precursor **3** × 100), it is necessary to take into consideration the fact that the precursors, which are familiar to the body, also undergo competing metabolic reactions after their distribution in the living organism and that, moreover, the alkaloids seem to undergo rapid further transformations.

Preparation of Optically Active Alcohols from 1,3-Dioxan-4-ones. A Practical Version of the Asymmetric Synthesis with Nucleophilic Substitution at Acetal Centers**

By *Dieter Seebach,** *René Imwinkelried*, and *Gerhard Stucky*

Several groups have recently investigated the preparation of optically active secondary alcohols via chiral, nonracemic acetals, as shown in Scheme 1.[1–8] Since the chiral "auxiliary" is sacrificed, the usefulness of this method crucially depends upon the price of the auxiliary. The compounds employed thus far, 2,3-butanediol (A)[1,2,8] 2,4-pentanediol (B),[2,3,5,8] *N,N,N',N'*-tetramethyltartaramide (C),[4] mandelic acid (D),[6] and 1-phenylethanol (E),[7] have



Scheme 1. For (a) to (d) see text.

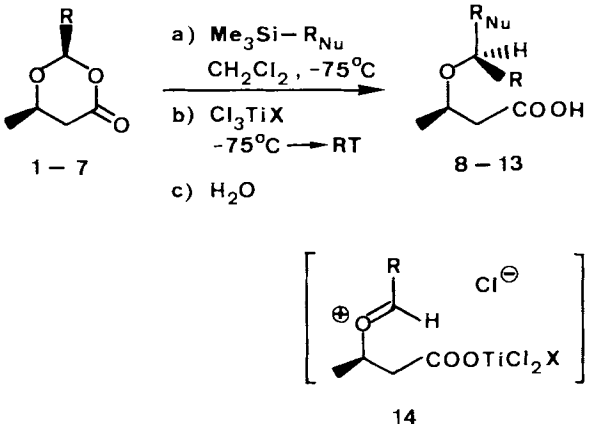
[**] Part of the projected Dissertation of *R. I.* and of the Master's Thesis (1985) of *G. St.*, ETH Zürich.

the following disadvantages: expensive auxiliary (A, B, E); poor yields of the acetals in step (a) (D); insufficient stereoselectivity in step (b) (A, D, E); removal of auxiliary in step (c) requires oxidation (all but E); constitutionally identical, diastereotopic leaving groups in the asymmetric substitution (b) (all but D); very delicate reaction conditions must be followed (see, for instance, ref. [3]).

Owing to our experiences,[7,9] it occurred to us that the 1,3-dioxan-4-ones **1**–**7** should be ideal intermediates for the realization of the conversion (d): (1) the two acetal oxygens in **1**–**7** are constitutionally heterotopic and of vastly different nucleofugicity; (2) (*R*)-3-hydroxybutanoic acid is available from inexpensive[10] poly(hydroxybutanoate), the (*S*) enantiomer by yeast reduction of acetoacetate;[11] (3) the dioxanones **1**–**7** may be prepared in good yields from *aliphatic* aldehydes[12] and 3-hydroxybutanoic acid in benzene[13] (5–10 mol-% pyridinium 4-toluenesulfonate) with azeotropic removal of water. A 70–90% yield of a *cis/trans* mixture (9 : 1) is formed, from which the pure *cis* isomer may be obtained by recrystallization from ether/pentane[14] (Table 1); (4) removal of the chiral "auxiliary" after nucleophilic ring opening of the acetal requires simple β-elimination from a 3-alkoxy acid.



1 – 7

Table 1. *cis*-1,3-Dioxan-4-ones **1**–**7** from (*R*)-3-hydroxybutanoic acid and aliphatic aldehydes; yields of recrystallized, pure *cis* isomers (except **1** and **5**).

Product	R	Yield [%]	M.p. [°C]
1	CH_3	60	—
2	$CH(CH_3)_2$	61	ca. −25
3	$C(CH_3)_3$	40	82.2–82.8
4	n-C_7H_{15}	71	ca. −20
5	n-C_8H_{17}	66	ca. −25
6	$CH_2CH_2C_6H_5$	66	49.7–50.9
7	CCl_3	50	113.6–114.4

Indeed, when the dioxanones **1**–**7** are treated at −75 °C with a silyl nucleophile, Me_3SiR_{Nu}, and titanium tetrachloride or isopropoxytitanium trichloride, the β-alkoxy acids **8**–**13** are produced in high yields and with high diastereoselectivities[15] (Table 2). The reactions are performed with normal concentrations (ca. 0.3–0.4 M in CH_2Cl_2) and mixing periods of the reactants—even at higher temperatures (see Experimental Procedure and No. 2 in Table 2). The products are purified through base extraction and are isolated without chromatography. Moreover, even the *cis/trans* mixtures (9 : 1) of the dioxanones furnish products of the same configurational purity as those obtained from the pure *cis* isomers (see No. 4, 6, 9 in Table 2; we do not know whether this is due to *cis–trans* equilibration under the reaction conditions, or else due to a common intermediate oxonium ion **14**[6]).

The "chiral auxiliary" is removed from the alkoxy acids by treatment with excess lithium diisopropyl amide (LDA) in tetrahydrofuran (THF) to give the alcohols **15**–**18** with >90% *ee*[16] (Table 3). The byproduct, crotonic acid, is removed by extraction with aqueous alkali. The optically active alcohols are purified and isolated by distillation. To avoid epimerization by base, the nitrile **12** was hydrolyzed to the amide (H_2O_2, K_2CO_3, MeOH, 1-hexene)[17] prior to treatment with 3.0 molar equivalents of LDA (−78 °C → RT) to give **18**. No racemization was observed.

8 – 13 **15 – 18**

Table 3. Cleavage of the β-alkoxy carboxylic acids **8**–**12** with formation of the alcohols **15**–**18** [16].

Starting material	LDA [equiv.]	Prod. (config.)	Yield [%]	*ee* [%]	$[\alpha]_D$
8	2.2	**15** (*R*)	80	94	+22.5 [a]
ent-**8** [b]	2.2	*ent*-**15** (*S*)	75	84	−20.5 [a]
9	2.2	**16** (*R*)	78	92	+10.2 [c]
10	3.2	**17**	67	97	−19.2 [b]
12 [d]	3.0	**18** (*R*)	68	96	+33.8 [e]

[a] In $CHCl_3$, $c = 2$. [b] 92% *ee*. [c] In CCl_4, $c = 3.5$. [d] **12**, $R_{Nu} = CONH_2$. [e] In EtOH, $c = 1.8$.

Conversions with nucleophiles other than those described here are possible. We are convinced that the procedure proposed here will eventually become a method of choice for asymmetric syntheses with substitution at acetal centers.

Experimental Procedure

A solution of $TiCl_4$ (11 mmol) in CH_2Cl_2 (5 mL, 2 M) [for $R_{Nu} = CH_3CH{=}CH_2$, $Cl_3Ti(OCHMe_2)$ [18] (1 M in CH_2Cl_2) was used] was added within 7–10 min to a solution of the 1,3-dioxan-4-one **1**–**7** (10 mmol) and Me_3SiR_{Nu} (13 mmol) in 20 mL of the same solvent with stirring at −75 °C. The reaction mixture was warmed to room temperature over ca. 12 h followed by addition of 15 mL H_2O and extraction with ether. The β-alkoxy acids **8**–**13** were extracted into 2 N aqueous NaOH, freed with conc. HCl, extracted with ether, and isolated, after drying over $MgSO_4$, by evaporative removal of the solvent.

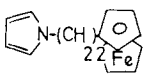
Ferrocene-Modified Polypyrrole Films by Electrochemical Copolymerization**



By *Alfred Haimerl* and *Andreas Merz**

Polypyrrole can be readily prepared in the form of films on suitable electrodes by anodic oxidation.[1] Its properties—it can be reversibly charged with ca. one elementary charge per 3–4 monomeric units and it is electrically conducting in the potential range of ca. −0.2 to +1.0 V[2]—make it a technologically interesting material, like polyacetylene.[3] We are presently investigating its potential use in the modification of electrodes for organic electrochemistry.

The structure of the polymer has not yet been satisfactorily elucidated. However, since pyrroles substituted at nitrogen[4] or in the 3,4-positions[5] can be polymerized as well, it must be assumed that the pyrrole moieties are linked via the 2,2′-positions and that the polymer contains at least partial structures as shown in formula **1a**.[6]

1a, R = H; **1b**, R = H/(CH$_2$)$_2$Fc

2

The structure **1a** suggests that the properties of the polypyrrole film should be influenced by substitution at the N-atom. In order to modify the electrochemical characteristics of polypyrrole films it is best to incorporate redox active substituents with redox potentials within the conductivity region of the polymer. We have prepared *N*-(2-ferrocenylethyl)pyrrole **2**[7] and investigated its electrochemical behavior. The cyclovoltammogram of **2** (Fig. 1a) shows a reversible oxidation of the ferrocene redox system at +0.38 V[8] and an irreversible oxidation of the pyrrole moiety at +1.40 V; this peak is shifted about +250 mV compared to unsubstituted pyrrole. On repeated scanning of the potential range no changes in the voltammogram occur like those observed for pyrrole on film formation (Fig. 1b). Likewise, electrochemical polymerization of **2** is not achieved by controlled current or potential electrolysis.

Ferrocene-containing polypyrrole layers **1b** can, however, be prepared by *copolymerization* of **2** with pyrrole.[9] Figure 1c shows the development of the electrode coating during the continuous cyclovoltammetry of a 1 : 1 solution of **2** and pyrrole. The successive curves demonstrate the growth of the polypyrrole film, recognizable as in Figure 1b by the broadening of the voltammogram similar to a

Fig. 1. capacitive current, and the increase of the ferrocene content. The curve of the first run shows the irreversible oxidation peak of pyrrole. The pyrrole radical cation that is formed here apparently serves as polymerization initiator; the polymerization is promoted by its addition to pyrrole or **2**.[5, 10] Apparently the radical cation of **2** *cannot* function as initiator.[11] The final curve in Figure 1c is approximately reproduced in pure solvent after withdrawal of the electrode from the polymerization solution. Better layers are obtained by copolymerization with controlled current density with $[Bu_3NH][PhSO_3]$ as supporting electrolyte.[12] The cyclovoltammogram in Figure 2 also demonstrates the reversible complete discharge of the polypyrrole film.[13]

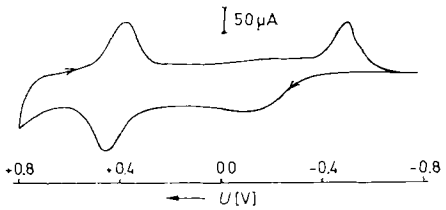

Fig. 2. Steady-state cyclovoltammogram of a layer of **1b** on a Pt-disk electrode; for conditions see caption to Figure 1. Coating solution: each 0.05 M pyrrole and **2** in 0.1 M $[Bu_3NH][PhSO_3]/CH_3CN$ + 1% H_2O; galvanostatic (40 mA cm^{-2} for 5 s).

The ferrocene-containing polypyrrole layers **1b** can serve as model substance for modified polypyrroles on the basis of *N*-substituted pyrrole monomers. An application as a reference electrode for non-aqueous solvents free of salt-bridges[14] already emerges: by application of a potential of +0.38 V the polymer layer of a **1b**-coated platinum wire is brought to a 1 : 1 ratio of ferrocene and ferrocinium ion. As a "zero-current" reference electrode in a three electrode device the wire maintains this potential for several hours in acetonitrile. During storage in air, however, a considerable negative potential drift takes place, corresponding to a decrease in the content of ferrocenium ions.[15] By improvement of the coating technique and elucidation of optimum storage conditions the development of a practical reference electrode seems possible.

A Facile Synthesis of a New Class of Eight-Membered Heterocycles from 1-Azabutadienes**

By *José Barluenga,* Miguel Tomás, Alfredo Ballesteros, Vicente Gotor, Carl Krüger,** and *Yi-Hung Tsay*

1-Azabutadienes are useful building blocks in organic synthesis.[1] The more stable, easily available 4-amino-1-azabutadienes **1**[2] have proved to be valuable starting materials for the preparation of five- and six-membered nitrogen-containing heterocycles, some of them with other heteroatoms (O, S, P) incorporated in the ring.[3] Furthermore, organosilicon compounds have found wide application in synthetic chemistry[4] and the use of species with silicon–nitrogen bonds in the synthesis of nitrogen-containing functional groups[5] and heterocycles[6] has been reported.

We report here an easy, regioselective preparation of a new class of eight-membered nitrogen-containing heterocycles. Reaction of **1** with dichlorodiphenylsilane at room temperature gave high yields of substituted 1,2-dihydro-1,3,2-diazasilines **2**.[7] Interestingly, when esters of acetylenedicarboxylic acid were added to a solution of **2** in benzene and the mixture heated at 60 °C, 1,5-diazocine-2(1*H*)-ones **3** were formed in good yields;[7, 8] examples are given in Table 1.

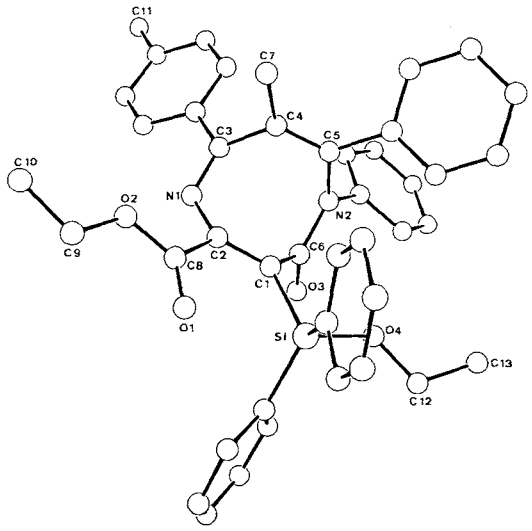
[a] Recrystallized from hexane/chloroform; melting points are uncorrected. [b] Decomposition. [c] Based on **1**.

The formation of compounds **3** can be explained by addition of the imine nitrogen–silicon bond to the activated carbon–carbon triple bond of the ester[9] followed by silicon-assisted intramolecular rearrangement.

Compounds **3** were characterized on the basis of their elemental analyses and spectroscopic (IR, ^{1}H-, and ^{13}C-NMR) and mass spectrometric data;[10] an X-ray structure of **3c** confirmed the assignments[11] (Fig. 1).



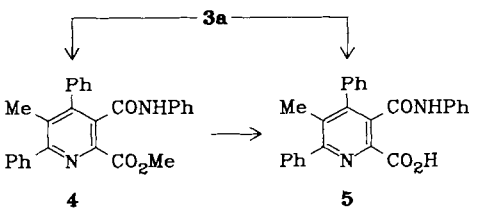


Fig. 1. Crystal structure of **3c** [11].

Heterocycles **3** rearrange in acidic or basic solution, undergoing desilylation to give the corresponding pyridines. Thus, treatment of **3a** with two molar equivalents of either trifluoroacetic acid in chloroform (48 h) or constant boiling hydriodic acid in benzene (6 h), reagents known to induce protodesilylation in vinyl silanes,[12] afforded quantitatively the heterocycle **4** (m.p. = 196–198 °C). Ring contraction of **3a** also took place under normal ester hydrolysis conditions (KOH, refluxing EtOH, 5 h) giving the acid **5** (m.p. = 180–182 °C); compound **5** was alternatively formed by hydrolysis of **4**.

The strategy described here provides a facile entry to 1,5-diazocine-2(1*H*)-ones **3**, which, to the best of our knowledge, have not been described previously.[13] Analogous perhydro derivatives are encountered in the homaline alkaloid skeletons;[14] substituted 3,4-dihydro-1,5-benzodiazocine-2(1*H*)-ones have been reported to exhibit biological activity.[15]

[7] *Experimental procedure:* To a solution of **1** (5 mmol) and Et_3N (12 mmol) in benzene (40 ml) was slowly added under argon a solution of Cl_2SiPh_2 (6 mmol) in benzene (20 mL). The mixture was stirred overnight at room temperature and then filtered (Et_3NHCl). The filtrate was heated with the acetylenedicarboxylic acid ester (6 mmol) at 60 °C for 24 h and the resulting mixture hydrolyzed (2 N H_2SO_4, 80 mL), extracted with ether, and concentrated; column chromatography (silica gel, hexane/ether 2:1) and recrystallization (hexane/chloroform) gave the pure diazozines **3**. The diazasilines **2** could be isolated and purified from their benzene solutions, before addition of the esters, by solvent evaporation in vacuum and recrystallization (hexane/chloroform).

[8] Azabutadienes **1** react with esters of acetylenedicarboxylic acid, J. Barluenga, S. Fustero, V. Gotor, *Synthesis 1975*, 191.

[9] For addition of simple silylamines to esters of acetylenedicarboxylic acid, see T. A. George, M. F. Lappert, *J. Organometallic Chem. 14* (1968) 327.

[10] Spectral data of compounds **2** are in agreement with the proposed structure, but their mass spectra do not show the corresponding molecular peak. Structure **2** is supported by the fact that its reaction with 3 N KOH or thionyl chloride led to the azabutadienes **1** and to the known 1,2,6-thiadiazine-*S*-oxides [3c], respectively.

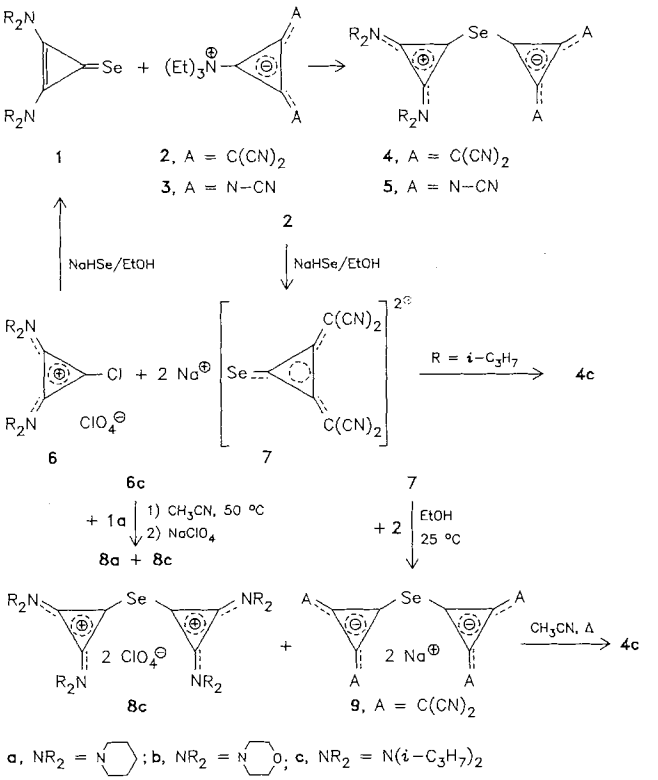
Stable Selenocarbonyl Ylides**

By *Rudolf Allmann, Franz-Josef Kaiser, Magda Krestel,* and *Gunther Seitz**

Suitably "push-pull"-substituted carbonyl ylides[1,2] or thiocarbonyl ylides[3] have sufficient stability for isolation and have been the subject of several detailed investigations during the last ten years. Isolable selenocarbonyl ylides, on the other hand, were hitherto unknown.[4] We report here on the synthesis and characteristic properties of the first stable compounds of this type with cyclopropenylium and bis(methylene) or bis(imino)cyclopropanide functions as stabilizing termini.

As we have found, the selone function in the diaminocyclopropeneselones **1**, which are readily accessible from the cyclopropenylium salts **6** and sodium hydrogen selenide,[5] is sufficiently nucleophilic to displace triethylamine from the zwitterions **2**[6] or **3**.[7] For the synthesis of **4a** [yield 84%, m.p. 178°C (dec.)], one hours' heating in anhydrous dichloromethane until complete removal of triethylamine suffices; the synthesis of **5c** (yield 85%, m.p. 230°C (dec.) was achieved by one hours' reaction in boiling ethanol. On cooling the reaction solution the desired selenocarbonyl ylides **4** and **5** precipitate as colorless to pale-beige, air-stable crystals and can be recrystallized from nitromethane. **4c** [m.p. 207°C (dec.)] could be obtained in 52% yield via another route. **2** was converted with freshly prepared sodium hydrogen selenide into the salt **7**,[8] which reacts smoothly with the salt **6c**[9] to yield the selenocarbonyl ylide **4c**.



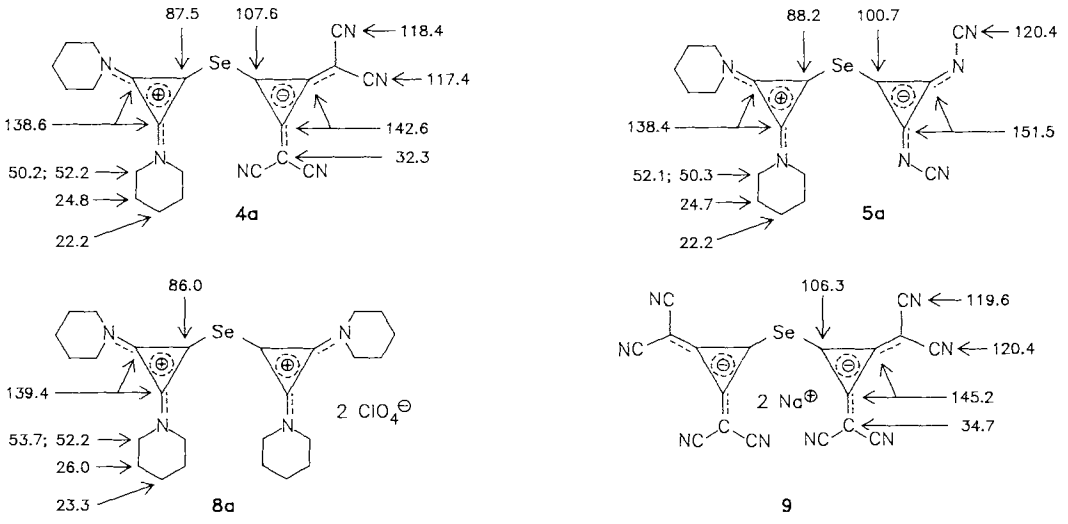


Table 1. Selected spectroscopic data of **4a**, **5a**, **8a**, and **9**. IR (KBr): $\tilde{\nu}$ [cm^{-1}] (C_3 = three-membered rings); UV: λ_{max} [nm] (lgε); ^{13}C-NMR (25 MHz, **4a** and **5a** in [D$_6$]DMSO, **8a** in CD_3CN, standard: ^{13}C-signals of the solvent, **9** in D_2O, dioxane external): δ values.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The constitutions of **4** and **5** were verified by elemental analyses and spectra (Table 1). The assignment of the signals in the particularly informative ^{13}C-NMR spectra was accomplished by comparison with the data of the likewise novel selenium-bridged three-membered ring compounds **8** and **9**. The dication perchlorate **8a** can be obtained

(along with **8c**) from **6c** and **1a** as the product of a symmetrization reaction[10] [yield 22%, m.p. 233 °C (dec.), from CH_3CN/ether]. The sparingly soluble sodium dianion **9** is formed upon reaction of **7** with **2** [yield 50%, m.p. >300 °C, from $CH_3CN/CHCl_3$]. **8c** and **9** are thermodynamically unstable compared to **4c**, the zwitterionic combination of both three-membered ring derivatives: Upon heating the salts **8c** and **9** in acetonitrile, **4c** was obtained (yield 42%) together with an hitherto unidentified yellow substance. Remarkably, the (^{13}C)-δ values for the cationic terminus and the anionic terminus of **4a** are almost identical to those in the dication of **8a** and in the dianion of **9**, respectively (Table 1). The occurrence of two signals each for the nitrile C atoms and the C atoms in the α-position to the piperidine-N in **4a** points to hindrance to rotation and thus to a high bond order for the corresponding bonds to *both* three-membered rings.

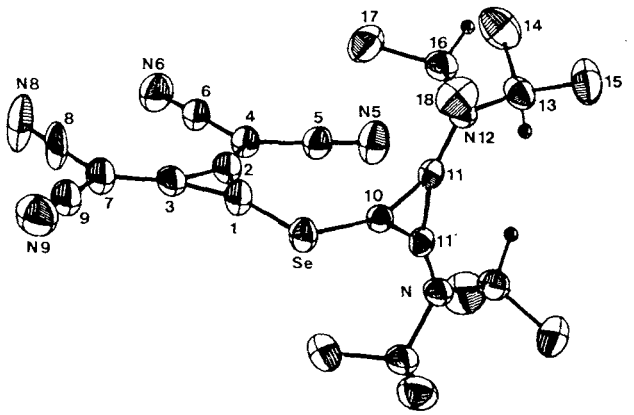

Fig. 1. Molecular structure of **4c** in the crystal. Pnma, $a = 15.919(3)$, $b = 13.050(3)$, $c = 11.927(3)$ Å, $Z = 4$, $\rho_{calc} = 1.334$ g cm^{-3} (with $4H_2O$ in the unit cell), 2014 reflections, $R = 0.067$, $R_w = 0.075$. The methyl hydrogen atoms (all in staggered form) are not shown. The mirror plane passes through the Se, C1–10 and N5,6,8,9 atoms and between C11–C11′ etc. The vibration ellipsoids (except for H) are drawn at the 50% probability level. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51666, the names of the authors, and the full citation of the journal.

The structure of **4c** was determined X-ray crystallographically (Fig. 1). The planar anionic terminus lies in a mirror plane. The almost planar cationic terminus is perpendicular thereto and is bisected by the mirror plane. Both three-membered rings contain one long bond and two short bonds;[11] the bonds to the ring substituents show a high proportion of double bond character ($n \approx 1.5$). The CSeC bond angle is 92.8°, while the two C–Se bond lengths differ only slightly, being 1.88 and 1.90 Å. This corresponds to a C_{sp}–Se bond order of $n \approx 1.0$.

Synthesis of Bis(trifluoromethyl)-Analogues of the Pyrethroids**

By *Helmut Mack* and *Michael Hanack**

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 60th birthday

By systematic variation of the structure of the active substances of natural pyrethrums,[1] it has been possible over the past 15 years to develop highly active and, in particular, photostable pyrethroids, e.g. decamethrin **1**.[2] The structural modifications were primarily carried out in the ester components and in the side chain of the cyclopropanecarboxylate.[3] Almost all synthetic pyrethroids contain two geminal methyl groups on the cyclopropane ring, since these have a decisive influence on the insecticidal activity.[4]

We have now synthesized for the first time the pyrethroids **2–6** containing two trifluoromethyl groups, the corresponding caronaldehyde **7**, and the fenvalerate analogue **8d**.[5,6]

	R^1	R^2	2-8	X
2	Cl	Cl	**a**	OH
3	CH_3	CH_3	**b**	OC_2H_5
4	Br	Br	**c**	Cl
5	CF_3	CF_3	**d**	O–CH(CN)-3-C_6H_4–O–C_6H_5
6	Cl, CF_3			

Using our new method[5] for the synthesis of the Wittig reagent **9**,[7] the geminal 1,1-bis(trifluoromethyl)olefins **11a–c** employed as intermediates can be synthesized in a simple way in 61–83% yield. Reaction of the readily accessible 2,2-dichlorohexafluoropropane[8] with triphenylphosphane directly affords the thermally unstable phosphorus ylide **9**. This is generated in situ and immediately allowed to react with the aldehydes **10a**,[9] **10b**,[10] and **10c**[11] to give the new olefins **11a–c**.[5] In analogy to the Michael reaction, the sulfur ylide **12**[12] is added to **11a–c** in the β-position.

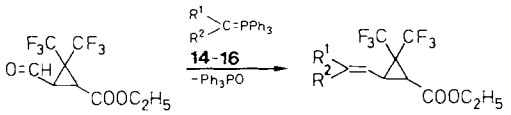
[**] *H. M.* thanks the Studienstiftung des Deutschen Volkes for a postgraduate scholarship.

Finally, γ-elimination of dimethyl sulfide leads to the compounds **13a–c** in 42–84% yield.[5] In all cases the *trans*-configuration predominates, to the extent of ca. 90–95%.



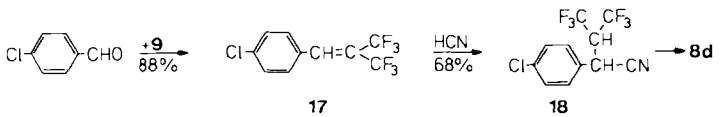
9

11 **13**

10, 11, 13	R	
a	$Cl_2C{=}CH$	**13a** ≡ **2b** → **2a**
b	$(CH_3)_2CH{-}CHCl$	**13b** → **3a**
c	$(C_2H_5O)_2CH$	**13c** → **7b**

Alkaline hydrolysis of the ester **13a** (≡ **2b**) leads to formation of **2a** (yield 94%); in the same way, the ester **13b** furnishes the carboxylic acid **3a** (yield 91%) in a one pot reaction under alkaline conditions. Cleavage of acetal from **13c** with acid furnishes the hexafluorocaronaldehyde **7b** in 93% yield.

7b is the central intermediate in the synthesis of substituted ethyl 3-(1-alkenyl)-2,2-bis(trifluoromethyl)cyclopropanecarboxylates. Reaction of **7b** with the phosphoranes **14**,[13] **15**,[5] and **16**[14] affords the pyrethroid esters **4b**, **5b**, and **6b**, respectively, in 43–95% yield;[5] these can be converted by acid hydrolysis into the pyrethroid acids **4a**, **5a**, and **6a**, respectively.



7b **4b,5b,6b**

	R^1	R^2
4, 14	Br	Br
5, 15	CF_3	CF_3
6, 16	{Cl, CF_3}	

The acid chlorides **2a** and **3c**, generated by reaction of sulfinyl chloride with **2a** and **3a**, respectively, are allowed to react with 2-hydroxy-2-(3-phenoxyphenyl)acetonitrile[15] to give the pyrethroids **2d** and **3d**.

A simple route was also found for the synthesis of the hexafluorofenvalerate **8d**. 4-Chlorobenzaldehyde reacts with the phosphorane **9**[5] to give the bis(trifluoromethyl)olefin **17**. Addition of hydrocyanic acid under basic conditions then leads to formation of the nitrile **18** (68% yield referred to overall conversion). 2-Hydroxyisobutyronitrile is a suitable reagent for supplying the HCN. Subsequent acid hydrolysis of **18** leads, via the carboxylic acid **8a** (94%) and in analogy to **2d**, to the fenvalerate analogue **8d**. All the new compounds were unequivocally characterized by ^{1}H-, ^{13}C-NMR, IR, and MS spectroscopy.[16]

CF_2-Bridged Metal Complexes**

By *Wolfgang Schulze, Hans Hartl,* and *Konrad Seppelt**

CH_2-bridged metal complexes have been investigated extensively; they are of interest with regard to the mechanism of catalytic processes such as the Fischer-Tropsch synthesis.[1] In spite of the well-known analogy between CH- and CF-compounds very little is known about CF_2-bridged metal complexes, since the methods currently in use for the preparation of their CH_2-bridged counterparts are not suitable for CF_2-bridged complexes. *Seel* et al. have already described the complexes $[Co_2(CF_2)(CO)_7]$, $[Co_2(CF_2)_2(CO)_6]$, and $[Fe_2(CF_2)_2(CO)_7]$,[2,3] but without giving structural data. We report here, with two examples, a synthetic route which affords direct access to CF_2-bridged complexes, and the structural properties of such complexes.

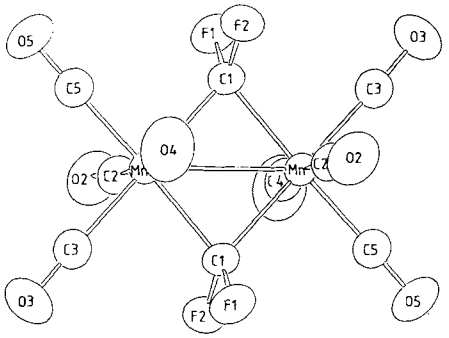
Sodium pentacarbonylmanganate **1** reacts with difluoromalonyl dichloride **2** to give the malonyl compound **3**, which decomposes almost completely upon heating, undergoing extrusion of one molecule of CO to give the difluoroacetyl complex **4**. Further heating leads only to the known complex $[(CO)_5MnCF_3]$. UV irradiation, however, gives $Mn_2(CO)_{10}$ and the doubly CF_2-bridged complex **5**. According to an X-ray structure analysis, **5** is highly symmetric (Fig. 1). The CO ligands *trans* to the CF_2 bridges are more tightly bound than the *cis* ligands.



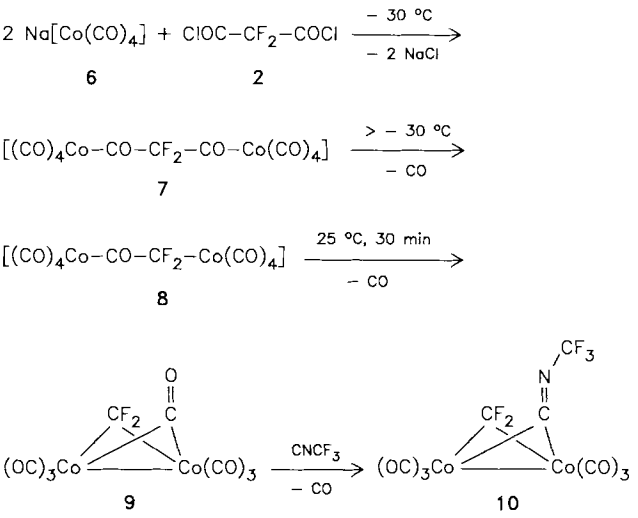


Fig. 1. Structure of $[(CO)_4Mn(\mu\text{-}CF_2)_2Mn(CO)_4]$ **5** in the crystal. Crystallographic data: $P2_1/n$, $a=8.367(2)$, $b=10.613(3)$, $c=7.996(2)$ Å, $\beta=90.01(2)$, $V=710.04$ Å^3, $Z=2$, $\rho_{calc}=2.03$ g·cm^{-3}, $\mu=8.9$ cm^{-3}, $R=0.020$, $R_t=0.033$; 3024 measured reflections, 1248 crystallographically independent observations with $I>2.0\sigma(I)$, 110 refined parameters. The manganese atoms essentially remain in an octahedral environment. Selected distances [Å] and angles [°]: Mn-Mn 2.664(3), Mn-C1 2.026(4), Mn-C2 1.880(6), Mn-C3 1.846(4), C1-Mn-C1 98.2(1), F1-C1-F2 102.7(2). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51697, the names of the authors, and the full citation of the journal.

If sodium tetracarbonylcobaltate **6** is allowed to react with difluoromalonyl dichloride **2**, multiple elimination of CO already takes place at room temperature. The complexes **7** and **8** were only detected as intermediates by ^{19}F-NMR spectroscopy (**7**: $\delta(F)=-92.3$, **8**: $\delta(F)=-32.2$). The Co_2-complex **9** is formed as end product in high yields; the orange-yellow liquid is probably identical to the compound $[Co_2(CF_2)(CO)_7]$ described by *Seel* et al.[2] The ^{13}C-NMR spectrum of **9** (up to -40 °C) shows a singlet for the time-averaged equivalent CO groups as well as a triplet for the CF_2 group. In the ^{19}F-NMR spectrum the singlet line of the CF_2 group ($\delta=44.7$) does not change on lowering the temperature to -100 °C. The intramolecular CO exchange of all CO ligands must therefore be still rapid even at -100 °C.

The CO bridge, which obviously participates in the intramolecular exchange, can be replaced by the $CNCF_3$ ligand, which strongly prefers the bridge positions[4] (**9** → **10**). The two fluorine atoms of the CF_2 group of **10** are not equivalent; the coupling constant of the geminal fluorine atoms is quite small (12.2 Hz).

The method described here should, in principle, be of general utility for the introduction of CF_2 bridges.

Experimental

3: **2** (2.2 mmol) was added to a stirred solution of **1** [5] (4 mmol) in anhydrous oxygen-free tetrahydrofuran (THF) at -78 °C. After 2 hours' stirring, slow warming to room temperature, and removal of the solvent in a high vacuum, there remained a yellowish-orange greasy solid. The fraction soluble in CH_2Cl_2 was chromatographed on silica gel (4 × 60 cm column) with CH_2Cl_2/petroleum ether 40-60 (1 : 3) at 0 °C. **3** was eluted as an almost colorless zone. After crystallization from CH_2Cl_2/pentane at -40 °C, **3** was obtained as air-stable, pale yellow needles. Yield 445 mg (55%). M.p. 97 °C (dec.).—MS: *m/z* 496 ($M^{\oplus}$) and fragments. IR (pentane) ν(CO) = 2122 (m), 2067 (w), 2039 (vs), 2013 (s), 1641 (m, br) cm^{-1}. ^{19}F-NMR (CH_2Cl_2, $CFCl_3$ ext.): $\delta=-96.5$.

4: 1 mmol of **3** was melted in an argon atmosphere for 15 min at 97 °C, and evolution of gas was observed. After cooling down, the yellow-brown melt was dissolved in $CHCl_2$ and chromatographed at 0 °C on silica gel (4 × 60 cm column) with CH_2Cl_2/petroleum ether 40-60 (1 : 3). **4** was eluted as a yellow zone; air-stable, yellow crystals were obtained upon crystallization from CH_2Cl_2/pentane. Yield 398 mg (85%). M.p. 99 °C (dec.).—MS: *m/z* 468 ($M^{\oplus}$) and fragments. IR (pentane) ν(CO) = 2113 (s), 2038 (vs, sh), 2022 (s), 2007 (vs), 1967 (w), 1641 (m, sh) cm^{-1}. ^{19}F-NMR (CH_2Cl_2, $CFCl_3$ ext.): $\delta=-41.7$.

5: A solution of **4** (0.1 mmol) in pentane (250 mL) was irradiated with a Phillips immersion lamp (HPK 125 W) for 30 mins at 0 °C under inert gas in a circulated photolyzer. After removal of the solvent in a high vacuum, the yellowish orange residue was taken up in a few mL of CH_2Cl_2. The solution was chromatographed on silica gel in a medium-pressure column with pentane (column: 2.5 × 60 cm, Merck silica gel 0.015-0.040 mm). The second orange zone contained **5**. The pentane solution was evaporated down to ca. 10 mL; upon slow cooling of the solution to -50 °C, **5** was obtained as air-stable yellow crystals. Yield 5 mg (12%). M.p. 118 °C.—MS: *m/z* 434 ($M^{\oplus}$) and fragments. IR (pentane): ν(CO) = 2084 (s), 2035 (vs), 2028 (vs), 1985 (w) cm^{-1}. Raman (solid) ν(CO): 2121 (s), 2038 (vs), 2020 (vs), 2004 (m) cm^{-1}. ^{19}F-NMR (pentane, $CFCl_3$ ext.): $\delta=71.6$.

9: **2** (1.1 mmol) was added to a stirred solution of **6** [5] (2 mmol) in anhydrous oxygen-free diethyl ether (60 mL) at -30 °C. The solution turned yellowish-orange in color. After warming and 30 minutes' stirring, the solution was fractionally distilled under high vacuum. **9** was collected at -30 °C as a yellow, air-stable solid, m.p. -2 °C. **9** is thermally stable (up to 80 °C) and photochemically stable. Yield 325 mg (90%). The spectroscopic data (^{19}F-NMR, IR, and MS) were identical with the values given in the literature [2]. ^{13}C-NMR (CD_2Cl_2, TMS ext.): $\delta=200.5$ (CO), 194.1 (CF_2, $J(CF)=390$ Hz). ^{19}F-NMR (CD_2Cl_2, $CFCl_3$ ext.): $\delta=44.7$.

10: $CNCF_3$ (2 mmol) was condensed under high vacuum into a solution of **9** (2 mmol) in pentane (10 mL). The stirred solution was warmed to room temperature. Fractional distillation under high vacuum afforded **10** in the collector cooled at -60 °C; air-stable yellow crystals, m.p. -18 °C. Yield quantitative.—MS: *m/z* 431 ($M^{\oplus}$) and fragments. IR (pentane) ν(CO) = 2140 (s), 2110 (vs), 1990 (vs), 2038 (m), ν(CN) = 1720 (s, br) cm^{-1}. ^{19}F-NMR (pentane, $CFCl_3$ ext.): $\delta=43.3$, 26.1 (CF_2, $J=12.2$ Hz), -58.8 (CF_3). ^{13}C-NMR

(CD_2Cl_2, TMS ext., −25°C): δ = 196.0 (CO), 192.3 (CF_2, $^1J(CF)$ = 395 Hz), 236 (CN), 116.5 (CF_3, $^1J(CF)$ = 263 Hz.

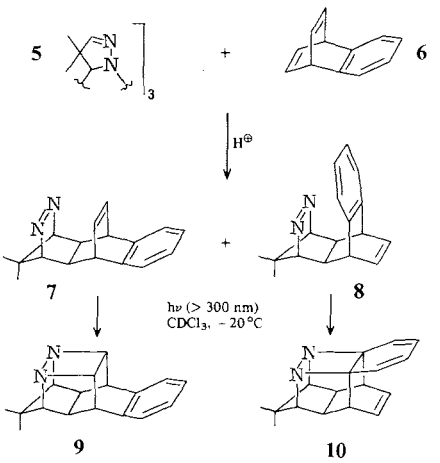
Laticyclic 1,5-Conjugation between Parallel, Neighboring Azo-Groups and Phenyl Groups**

By *Karin Beck* and *Siegfried Hünig**

Since the discovery of the first system **1**, with parallel oriented C=C/N=N bonds[1] with analyzed[2] laticyclic 1,5-conjugation,[3] general methods have been developed for the synthesis of related systems by [4+2]-Cycloadditions with cyclic azines as electron-deficient dienes.[4] It emerged thereby that the size of the ring (five-membered ring (5), six-membered ring (6)), which the π-bridges span, has no influence on the smooth [2+2]-photocyclization to diazetidines with a cage structure.[1a,5] This is valid in the case of C=C(5)/N=N(6) (e.g. **1**), C=C(6)/N=N(6), C=C(5)/N=N(5), and, as shown by **7**, also in the case of C=C(6)/N=N(5) (for further examples see ref. [6]). We have now checked whether a hitherto unknown [6+2]-photocyclization takes place upon replacement of the etheno-bridge by an *o*-phenylene bridge in these systems.

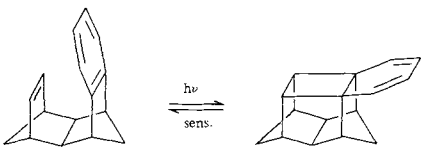


1 **3**

4

We report here on the first positive result.[7] The desired *o*-phenylene bridge can be incorporated with one of the cycloaddends (here benzobarrelene **6**) or by subsequent conversion of the double bond in a benzene ring.

The trimeric 4,4-dimethyl-4*H*-pyrazole **5** reacts under proton catalysis conditions[4] with **6** to give a 4:1 mixture of the adducts **7** and **8** (phenylene (6)/N=N(5)), which can be separated chromatographically.[8] The expected cycloadducts **9** and **10** are formed almost quantitatively (no by-products recognizable in the ^{1}H-NMR spectrum of the reaction solution) upon unsensitized irradiation ($\lambda > 300$ nm, $CDCl_3$, −20°C). As expected, **9** and **10** do



not show any absorptions UV for the azo group. In the ^{1}H-NMR spectrum ($CDCl_3$, δ values) the signals of the etheno bridge (5.93 (dd)) migrate into the region typical for diazetidines (4.08 (mc)) during the transition **7**→**9**, whilst those of the arene remain virtually stationary (7.06→7.25). Conversely, in the reaction **8**→**10** the signals of the olefinic protons of **10** (5.64, 5.88) appear in place of those of the arene (7.08), whereas those of the additional double bond remain virtually stationary (6.65 (dd)→6.23 (dd)). In addition, the signals of the protons on the bridgeheads of the azo bridges experience a typical upfield shift of ≈1.2 pm upon closure of the diazetidine ring: **7** (4.64 (bs))→**9** (3.42 (bs)); **8** (4.45 (bs))→**10** (3.19 (bs)). That is, both the interaction with the etheno bridge (cf. [2]) as well as that with the phenylene residue is so strong upon n-π*- and/or π-π*-excitation of the azo group that the extraordinarily efficient photoextrusion from the 2,3-diazabicyclo[2.2.1]heptene (Φ_{N_2} = 1.00[9]) present in **7** and **8** is completely overshadowed.[10] Interestingly, compound **4**, in which the bridges are, as it were, interchanged (phenylene(5)/N=N(6)), is not cyclized under the same irradiation conditions.[10] It remains unchanged, since it contains the photostable 2,3-diazabicyclo[2.2.2]octene skeleton.[2,9] The different interaction between the parallel π systems observable in the UV spectrum (in each case in hexane) corresponds to the difference in photochemical behavior. The bathochromic shift in **1** (λ_{max} = 396 nm (ε = 155))[1] of 15 nm compared to that in the same system with an ethano bridge **1** [2H] (λ_{max} = 381 nm (ε = 155))[4b] is only 6 nm in the case of the benzo derivative **4** (λ_{max} = 387 nm (ε = 185)). In contrast, the bathochromic shift of 9 nm in the transition from **7** [2H] (hydrogenated etheno bridge (λ_{max} = 354 (ε = 366)) to **7** (λ_{max} = 363 nm (ε = 370)) stays the same in the case of the benzo derivative **8** (λ_{max} = 364 nm (ε = 641)), while the intensity almost doubles.—**4**[11] is formed by addition of tetrachlorothiophene dioxide **2**[12] to **1** via the readily interceptable intermediate **3**, which, after smooth dehydrogenation,[13] is dehalogenated[15] in the conventional way[14] to **4**.

Of the systems with laticyclic 1,5-conjugation still to be examined, namely *o*-phenylene(6)/N=N(6) (which in the meantime has also attracted interest from another point of view[16]) and *o*-phenylene(5)/N=N(5), at least the latter is expected to photocyclize upon direct excitation. A photo-

equilibrium of the *o*-phenylene(5)/C=C(5) analogue **11** with the [6+2]cycloadduct **12** has already been observed, but only upon sensitized excitation.[17]

[7] The structures of all the new compounds are consistent with their elemental analyses and UV, IR, ^{1}H-NMR, and ^{13}C-NMR spectra. The latter compare very well with those of the related systems already discussed in detail in the literature [1b, 4, 5].

[8] A mixture of **5** (500 mg, 1.74 mmol), trifluoroacetic acid (1.20 mL, 15.5 mmol) and **6** (802 mg, 5.20 mmol) was stirred for 1 d at RT. The crude product isolated with water/$CHCl_3$/K_2CO_3 was, after Kugelrohr distillation (25 °C/0.01 torr), separated several times (with heavy losses) by medium-pressure chromatography (petroleum ether/ethyl acetate (9 : 1); the products were sublimed at 60 °C/0.01 torr. Yield: 63 mg (5%) **7**, m.p. 147–148 °C, and 16 mg (1%) **8**, m.p. 158–159 °C.

[9] Cf. also P. S. Engel, D. W. Horsey, D. E. Keys, C. J. Nalepa, L. R. Soltero, *J. Am. Chem. Soc. 105* (1983) 7108, and references cited therein.

[10] An NMR tube containing **4**, **7** or **8** in $CDCl_3$ was secured to an immersion cylinder cooled to −20 °C and irradiated with a 150-W Hg-high-pressure lamp (Pyrex filter). On completion of reaction (^{1}H-NMR monitoring), the solvent was removed. The crude product, after purification on a silica gel column, was sublimed in vacuo. 30 mg of **7** (0.12 mmol) furnished 20 mg (67%) of **9**, m.p. 177–178 °C. 15 mg (0.06 mmol) of **8** yielded 8.6 mg (57%) of **10**, m.p. 130 °C (dec.).

[11] **4** was discussed in a lecture delivered at a conference convened by the Arbeitsgemeinschaft Organische Chemie at Bad Nauheim (FRG), October 4–6, 1984.

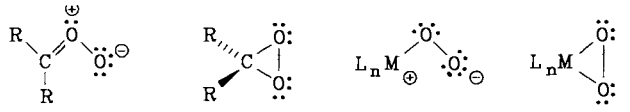
[13] Since the dehydrogenation even takes place with atmospheric oxygen in boiling benzene, a dyotropic terminal-group transfer of hydrogen to the azo group could be at issue. This transfer has already been demonstrated in the case of a related system at 200 °C with an ethano group as neighbor (D. Ginsburg, M. Koral, *Tetrahedron 29* (1973) 2373.

[14] N. J. Hales, H. Heaney, J. H. Hollinshead, *Synthesis 1975*, 707.

[15] A mixture of **1** (1.01 g, 3.96 mmol) and **2** (841 mg, 3.96 mmol) in chloroform (10 mL), which was allowed to stand for 7 d at room temperature, afforded 1.61 g (101%) of **3** (^{1}H-NMR spectroscopically pure). Extraction of the solid yielded 1.40 g (88%) of **3**, m.p. 166–168 °C. A weak stream of air was passed through a solution of **3** (1.40 g, 3.48 mmol) in boiling benzene (50 mL) for 2 d. The product obtained upon evaporating the solution to dryness was purified by extraction with acetic acid; there remained 1.10 g (79%) of **4**[CI_4], m.p. 274–276 °C. The crude product obtained from **4**[CI_4] (0.250 mmol), Na (100 mg), and *t*BuOH (0.30 mL) in THF (4.00 mL) afforded, by the procedure given in ref. [14], 43 mg (66%) of **4** (m.p. 197–199 °C) after chromatography on silica gel and subsequent sublimation.



[16] The ^{13}C,^{13}C-coupling constants of the C atoms on the nitrogen bridges of the homologues of **4** and its azoxy derivative, which are accessible by means of our method, have recently been reported: H. Fritz, G. Fischer, W. Marterer, H. Prinzbach, *Tetrahedron Lett. 26* (1985) 4427.

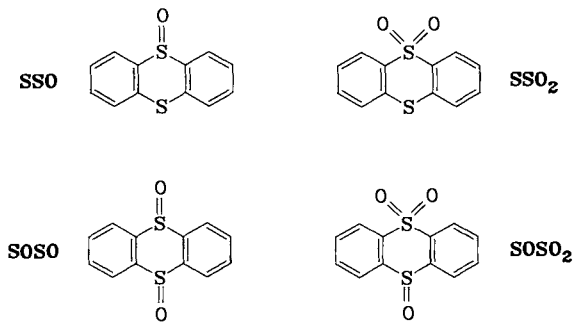
Thianthrene 5-Oxide as Mechanistic Probe in Oxygen Transfer Reactions: Substrate Complexation in Oxidations with Transition Metal Peroxides**

By *Waldemar Adam** and *B. Bhushan Lohray*



Recently, we succeeded in determining quantitatively the electronic character of oxidizing agents by employing oxygen transfer to thianthrene 5-oxide (**SSO**).[1] Thus, we showed that carbonyl oxides **1** and dioxiranes **2** are chemically different species.[2] Peroxo complexes of transition

1 **2** **3** **4**

metals can be represented, analogously to **1** and **2**, in terms of their dipolar structure **3** and the cyclic valence structure **4**, respectively.[3] Expectedly the terminal oxygen of **3** should be transferred more nucleophilically to thianthrene 5-oxide than by **4**. Prior complexation of the substrate at the metal center would, however, mask the electronic character of the oxygen transfer. A necessary condition for the use of thianthrene 5-oxide as mechanistic probe for the electronic character of a species is that the oxygen transfer takes place directly at the peripheral oxygen without prior complexation of the oxidizing agent. However, the question whether complexation of the substrate takes place in oxidations with transition-metal peroxides is presently being actively debated.[4] Consequently, the determination of the product pattern in the oxygen transfer by these peroxo complexes to thianthrene 5-oxide offers the unique opportunity of either gaining insight into the electronic character of these oxidizing agents or demonstrating prior complexation of the substrate at the transition metal center. Our present results (see a–d) suggest that thianthrene 5-oxide is first complexed by the metal at the sulfide sulfur and that the oxygen is transferred subsequently.

a) The diperoxo complexes (HMPT)CrO_5, (HMPT)MoO_5, (HMPT)$_2$$MoO_5$, (HMPT)($H_2O$)$MoO_5$, (HMPT)$WO_5$, and (HMPT)($H_2O$)$WO_5$ (HMPT = hexamethylphosphoric triamide) were allowed to react with thianthrene 5-oxide (**SSO**) in CH_2Cl_2 in the ratio 1 : 10, respectively. Independent of the transition metal and ligands, the amount of oxygen transfer to the sulfoxide sulfur to

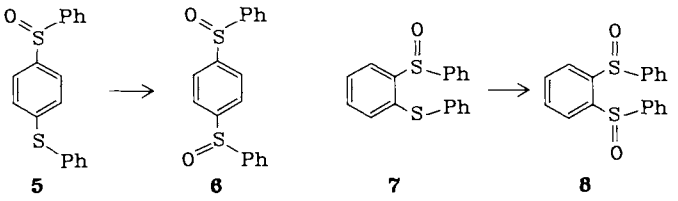
give the thianthrene 5,5-dioxide (**SSO_2**) and to the sulfide sulfur to give the thianthrene 5,10-dioxide (**SOSO**) was about equal (0.50 ± 0.05).

b) A competition experiment with an equimolar mixture of **SSO_2** and **SOSO** showed that **SOSO** was oxidized about three times more rapidly than **SSO_2** by (HMPT)MoO_5.

c) A ^{31}P-NMR spectrum, recorded immediately after mixing **SSO** and (HMPT)$_2MoO_5$ in $CDCl_3$, showed the presence of bound HMPT ($(\delta^{31}P) = 37.8$) and free HMPT ($(\delta^{31}P) = 28.2$) at ca. 37 °C. Precipitation of the metal peroxide by dilution with ether and immediate filtration afforded ca. 4% of oxidized thianthrene 5-oxide as a 1 : 1 mixture of **SSO_2** and **SOSO** in the filtrate.



d) Only the *cis*-isomer of thianthrene 5,10-dioxide (*cis*-**SOSO**) was formed when **SSO** was oxidized with (HMPT)MoO_5 in CH_2Cl_2. As shown by control experiments, authentic *trans*-**SOSO** was stable under the conditions of the oxygen transfer and the HPLC analysis.

A plausible mechanism for these observations is outlined in Scheme 1. The metal center is first complexed at the nucleophilic sulfide sulfur of **SSO** by ligand exchange. Subsequently, the oxygen is transferred transannularly to the sulfoxide sulfur with formation of **SSO_2**. Oxidation at the complexed sulfide sulfur leads to *cis*-**SOSO**.

Scheme 1. Mechanism of complexation for oxygen transfer to thianthrene 5-oxide **SSO**.

Unexpected is the finding that the products **SSO_2** and *cis*-**SOSO** are formed in equal amounts. According to molecular models, in the well-known folded conformation of **SSO** the transannular oxygen transfer can take place comfortably. The steric shielding of the equatorial lone pair favors the required axial complexation at the sulfide sulfur by the *peri*-hydrogen atoms. This very special arrangement of the oxygen donor and oxygen acceptor also promotes formation of *cis*-**SOSO**. Peripheral attack without complexation would lead to *cis*- and *trans*-**SOSO**. A further prerequisite is presumably the necessary distance between the sulfoxide sulfur and the complexed molybdenum oxidizing agent. The following reactions support this concept: oxygen transfer with (HMPT)MoO_5 in CH_2Cl_2 to 1-(phenylsulfinyl)-4-(phenylthio)benzene **5** and to the *ortho* isomer **7** gave, besides traces of the trioxides (double oxygen transfer), exclusively the disulfoxides **6** and **8**, respectively. "Transannular" oxygen transfer in the case of the derivative **7** would lead to the sulfone. Hence, for transannular oxygen transfer to take place, the conformational arrangement of the sulfide lone pair to be complexed and its steric accessibility are also important, as well as the proper distance between the sulfur centers.

These conditions are apparently optimally fulfilled in the case of the rigid and folded thianthrene 5-oxide. This concept is further supported by the fact that a 1 : 1 mixture of *cis*- and *trans*-disulfoxide **8** was obtained in the oxidation of **7** with (HMPT)MoO_5,[5] whereas only *cis*-**SOSO** was formed from **SSO**, alongside **SSO_2**. We presume that both sulfide lone pairs can be complexed in the case of **7**, but only the axial lone pair in the case of **SSO** (Scheme 1). Furthermore, the almost exclusive oxidation of the substrates **5** and **7** at the sulfide sulfur reflects the electrophilic character[6] of the transition metal peroxides.

We postulate that for the transannular oxygen transfer (only *cis*-**SOSO**; 1 : 1 ratio of **SOSO** : **SSO_2**) to occur between thianthrene 5-oxide **SSO** and (HMPT)MoO_5 one can presume that the sulfide sulfur of the oxygen acceptor **SSO** must be complexed at the metal center of the oxygen donor (HMPT)MoO_5 during the oxygen transfer. Whether this complexation also takes place with other substrates (olefins, amines, phosphanes etc.) cannot be generalized.[4] The concept does, however, provide interesting possibilities for stereoselectively controlled oxygen transfer in synthesis.

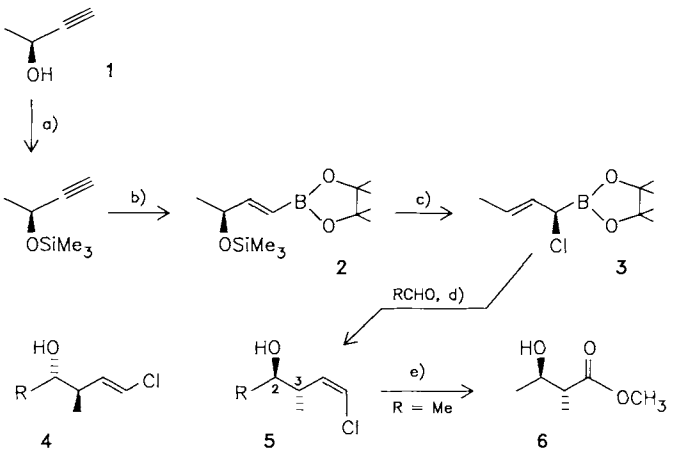
Optically Active α-Chloro-(*E*)-crotylboronate Esters by Allyl Rearrangement



By *Reinhard W. Hoffmann** and *Stefan Dresely*

Esters of α-chloroallylboronic acid[1] belong to the α-chiral allylmetal compounds, whose addition to aldehydes proceeds with high or complete transfer of chirality.[2] Un-

[*] Prof. Dr. R. W. Hoffmann, Dipl.-Chem. S. Dresely

Mans-Meerwein-Str., D-3550 Marburg (FRG)

fortunately, we were unable to synthesize the homologous α-chlorocrotylboronate **3** according to the method of *Matteson* et al.[3] We therefore developed an alternative route to **3** using an allyl rearrangement (Scheme 1). Racemic or optically active 3-butyn-2-ol **1** was silylated and hydroborated with dicyclohexylborane. The resulting alkenyldicyclohexylborane could be selectively oxidized[4] at the two alkyl-boron bonds with trimethylamine oxide to give the vinylboronate, which was transesterified with pinacol to give **2**. Subsequent reaction with sulfinyl chloride and attendant allyl rearrangement afforded the α-chloro-(*E*)-crotylboronate **3**, which was allowed to react without purification with a series of representative aldehydes.

Cleavage of the initially formed borates with nitrilotriethanol followed by chromatography on silica gel with petroleum ether/ethyl acetate furnished the homoallyl alcohols **5** (Table 1).

Scheme 1. a) Hexamethyldisilazane, quantitative; b) dicyclohexylborane/dimethoxyethane 0–25 °C, then 2 equiv. Me_3NO 25 °C, then 1 equiv. pinacol 25 °C, 80–85% yield; c) $SOCl_2$, petroleum ether 25 °C, ca. 75% yield; d) 12 h 20 °C, petroleum ether, work-up with nitrilotriethanol; e) O_3, CH_3OH.

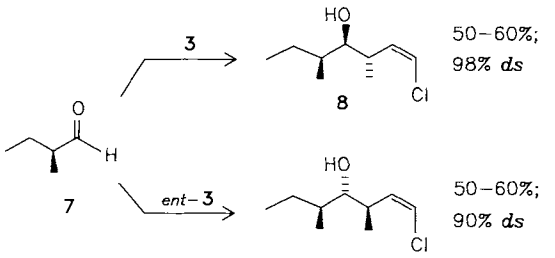

Table 1. Synthesis of homoallyl alcohols **5** according to Scheme 1. Yields based on **2**.

	R	Yield [%]	*ee* [%]
5a	C_6H_5	53–68	96 [a]
5b	CH_3	53–60	92 [b]
5c	C_2H_5	47–65	96 [b]
5d	$(CH_3)_2CH$	55–84	95 [b]
5e	n-C_5H_{11}	60–67	92 [c]

[a] Determined gas-chromatographically after conversion into the isopropylurethane [6]. [b] Determined gas-chromatographically as urethane after derivatization with (*S*)-(−)-1-phenylethyl isocyanate. [c] Determined as in [a] after hydrogenation of the double bond and hydrogenolytic cleavage of the C–Cl bond [1].

The double bond in **5** is *Z*-configurated, $^3J = 7$ Hz. The anti-configuration of the hydroxyl and methyl groups follows from the conversion of **5b** into the known[7] ester (−)-**6**. The absolute configuration of **5b** can thereby also be confirmed as being (2*R*,3*S*), which presumably arises from (*S*)-**1** via (*R*)-**3**.[1] The diastereomeric purity of the isolated products was, according to the ^{13}C-NMR spectra, 95%. However, the crude product was found to contain up to 5% of **4**, which was apparently removed during chromatography.

Thus, on starting from **1**, with 97% *ee*, the homoallyl alcohols **5a** or **5c** are formed with practically the same enantiomeric purity. Hence all steps proceed with a high level of chirality transfer. The slight racemization in the other cases could occur at the stage of **3**. Since both enantiomers of the butynol **1** can readily be obtained by simple resolution,[5] both enantiomers of the reagents **3** and the homoallyl alcohols **5** are accessible as well.

The quality of a chiral reagent is assessed on its ability to override a 1,2-asymmetric induction originating from a chiral aldehyde.[8] The extent of asymmetric induction originating from aldehyde **7**[9] revealed itself in the addition of the achiral (unsubstituted) (*E*)-crotylboronate ester, whereby the product with the same configuration as **8** is formed with a selectivity of 83%.[7] Here, the reaction of **7** with the chiral reagent **3** resulted in an increased diastereoselectivity of 98%. With *ent*-**3**, a reversal of stereocontrol could in fact be achieved to a considerable extent. In this case the selectivity is presumably limited by partial racemization (of either **3** or **7**).

acceptor groups have been the subject of intensive study for many years. The great majority of such species have structures in which the metal cores are based on polyhedra with triangular faces.[1] Less common are cluster compounds comprising chains of metal atoms, although the isolobal model[2,3] has been successfully applied to the systematic synthesis of species containing chains of platinum and tungsten atoms bridged by carbyne ligands.[4] During the course of studies in this area, we have discovered a new type of metal cluster species possessing a ring of eight metal atoms and involving three different transition elements.

Treatment of the trinuclear complexes **1a** and **1b**[4,5] in tetrahydrofuran at room temperature with $[Ni(cod)_2]$ affords the $Ni_2Pt_2W_4$-clusters **2** and **3**, or **4**, respectively.[6]

tion study. A band at 1838 cm^{-1} (CH_2Cl_2) in the infrared spectrum is assigned to the semi-bridging CO ligands.

The black isomeric species **3a** and **3b** are formed in equal amounts, and have closely related structures. This is clearly shown by the NMR data.[6] Thus, the $^{13}C\{^1H\}$-NMR spectrum of the isomeric mixture reveals that **3a** and **3b** each contain one edge-bridging and three triply-bridging CPh ligands. Moreover, the NMR data for the black isomers **4a** and **4b**[6,9] show that these species are structurally similar to **3a** and **3b**. An X-ray structure analysis, which was carried out on a crystal obtained from a solution of the mixture of **4a** and **4b**, showed that both isomers were present in the crystal.[10] The core structures of these asymmetric isomers are shown in Figure 2, together with the core of **2** for comparison. It will be seen that the difference between the asymmetric isomers lies in the disposition of the μ_2-CR ligand: in one isomer it bridges a Ni–W bond and in the other a Pt–W bond.

$$[PtW_2(\mu_2\text{-}CR)_2(CO)_4(\eta\text{-}C_5H_5)_2] \xrightarrow{[Ni(cod)_2]} [Ni_2Pt_2W_4(\mu_3\text{-}CPh)_4(CO)_8(\eta\text{-}C_5H_5)_4] + [Ni_2Pt_2W_4(\mu_2\text{-}CR)(\mu_3\text{-}CR)_3(CO)_8(\eta\text{-}C_5H_5)_4]$$

1a, R = Ph; **1b**, R = *p*-$C_6H_4CH_3$ — **2** — **3a**, **b**, R = Ph; **4a**, **b**, R = *p*-$C_6H_4CH_3$

According to an X-ray structural analysis, the core of the green cluster **2**[7] consists of a ring of eight metal atoms (Fig. 1). The four tungsten atoms form the points of a 'star', with the two nickel atoms *trans* to each other and the two platinum atoms *trans* to each other. The Ni···Pt separations (mean 2.763(3) Å) suggest little or no direct bonding between these metal atoms. Such distances are probably the consequence of the stereochemical demands of the μ_3-CPh groups.[8] The four carbyne groups occupy triply bridging sites with respect to the metal atoms, two being above and two being below the slightly puckered $Ni_2Pt_2W_4$ ring. The $^{13}C\{^1H\}$- and $^{195}Pt\{^1H\}$-NMR spectra of **2**[6] show, respectively, one resonance for the ligated μ_3-C nuclei and one signal for the platinum atoms. This is in accord with the symmetrical structure established by the X-ray diffrac-

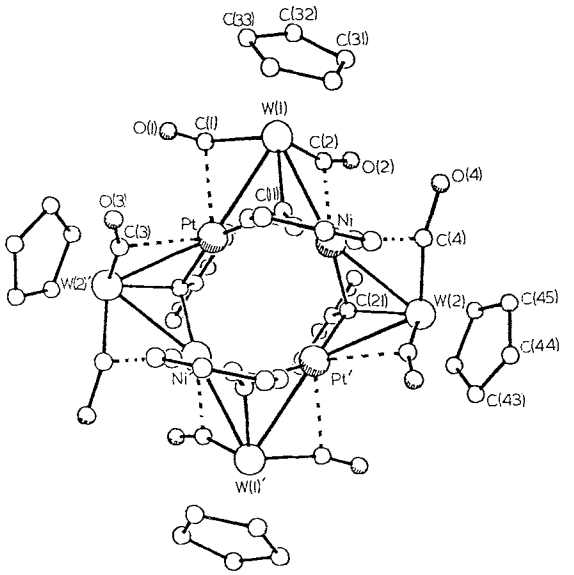

Fig. 1. Crystal structure of **2**. Selected bond lengths [Å] and angles [°] (mean values): Ni–W 2.646(3), Pt–W 2.741(2), Ni···Pt 2.763(3), μ_3-C–Ni 2.00(3), μ_3-C–Pt 2.09(3), μ_3-C–W 1.96(3); W–C–O 163.6.

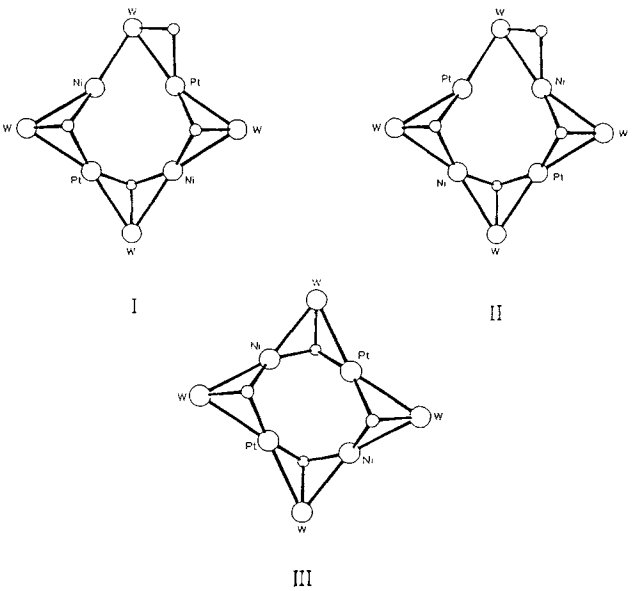

Fig. 2. The core structures of the cluster compounds **3** and **4** (I and II) and of **2** (III), showing the metal atoms and the ligated carbon atoms of the carbyne groups.

Several trimetal complexes have been described with two carbyne ligands occupying either edge or triply bridging sites,[11] and monotungstentriosmium compounds are known having two CR groups bicapping a WOs_3 tetrahedron.[12] Compounds **2**–**4** are the first reported examples of species having four bridging carbyne groups. Their preparation should lead to the discovery of new reactivity patterns for these ligands in a multinuclear metal environment. Moreover, the presence in these clusters of open rings of metal atoms and carbyne groups raises the interesting possibility of introduction of other molecules within

the cavities. In **2** the transannular Ni···Ni and Pt···Pt separations are 4.137 and 3.614 Å, respectively.

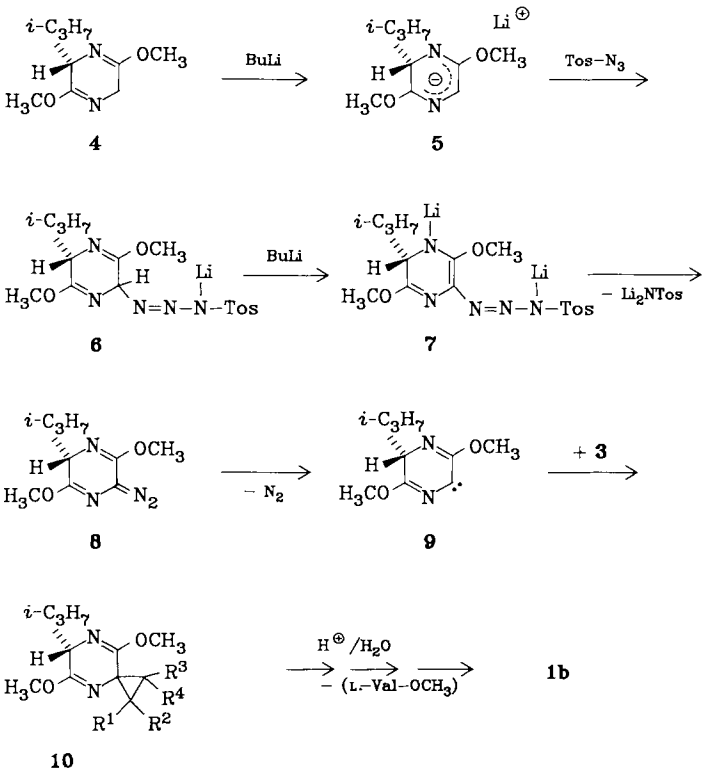
Synthetic Equivalent for Aminocarboxycarbene; Synthesis of 1-Amino-1-cyclopropanecarboxylic Acid Methyl Esters

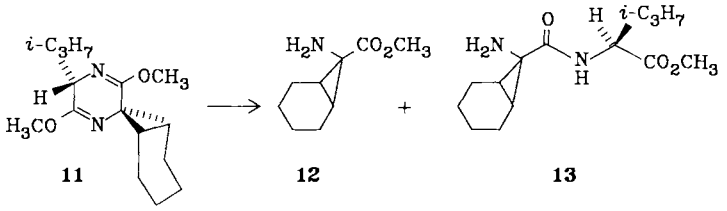
By *Ulrich Schöllkopf,* Manfred Hauptreif, Joachim Dippel, Martin Nieger,* and *Ernst Egert**



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

1-Amino-1-cyclopropanecarboxylic acids of type **1a** attract special interest because of their proven or potential biological activity.[1] Although conventional methods for the synthesis of this class of amino acids are already well known,[2–4] an entry to such compounds on a carbene basis in accordance with the reaction **2** + **3** → **1** is still lacking since there has so far been no synthetic equivalent available for aminocarboxycarbene **2**.

1a, X = H; **1b**, X = CH_3 **2** **3**



During studies on asymmetric amino acid syntheses with bislactim ethers of diketopiperazines[5] we have observed that a diazo-group transfer[6] can be carried out with tosyl azide in the case of lithiated bislactim ethers **5** of *cyclo*(L-Val-Gyl-), whereby the diazo compound **8**, the precursor of the carbene **9**, is formed. To achieve good yields of **8** it

4 **5** **6** **7** **8** **9** **10**

is essential to add a second equivalent of butyllithium after the addition of tosyl azide. Presumably, the dilithium compound **7**, which is stable at ca. −70°C, is formed as intermediate but loses dilithium tosylamide with formation of **8** upon warming to room temperature. If **8** is generated in the presence of an olefin, spiro compounds of type **10** are obtained, which can be hydrolyzed to methyl valinate and 1-amino-1-cyclopropanecarboxylic acid methyl esters of type **1b**. We postulate the carbene **9** as intermediate; this adds to the double bond of the olefin.[7] **9** contains a latent carboxy group and a latent amino group and is thus a synthetic equivalent for the synthon **2**.

11 **12** **13**

As typical example we describe the synthesis of the 7-aminobicyclo[4.1.0]heptane-7-carboxylic acid methyl ester **12** with *endo* amino group via the adduct **11** of the carbene **9** and cyclohexene.[8] The carbene addition takes place with high diastereoselectivity (ca. 49:1 in favor of **11**).[11] We were able to elucidate the configuration of **12** by X-ray structure analysis of the dipeptide ester **13** (cf. Fig. 1),[9] which precipitates as byproduct upon hydrolysis of **11**. If it is assumed that **9** is a singlet carbene with a

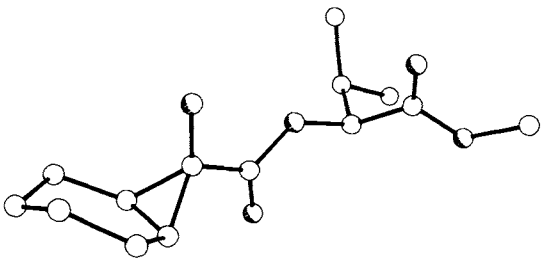

Fig. 1. Structure of the dipeptide ester **13** in the crystal [9]. Remarkably, the "envelope" conformation of the cyclohexane ring is apparently induced by the three-membered ring: One C atom is displaced 54 pm from the plane by the remaining ring atoms ($\sigma = 3$ pm). This is accompanied by a considerable widening of the bond angles in the cyclohexane ring ($113° < \alpha < 120°$).

vacant p-orbital perpendicular to the heterocycle plane, the olefins **3** should preferably enter from the *Re* side. In the case of olefins without a symmetry plane perpendicular to the double bond, optically active aminocyclopropanecarboxylic acids of type **1a** should be formed.

Experimental

11: *n*-Butyllithium (3.2 mmol; 2 mL of a 1.6 N solution in hexane) was added dropwise at −70°C to a solution of **4** (0.55 g, 3 mmol) [10] in tetrahydrofuran (5 mL). The mixture was stirred for 15 min and then transferred at −70°C via a Telefon tube into a solution of tosyl azide (0.59 g, 3 mmol) in THF (5 mL). After 2.5 hours' stirring at −70°C the reaction mixture was treated with *n*-butyllithium (3.2 mmol; 2 mL of a 1.6 N solution in hexane) such that the temperature did not rise above −70°C. After 30 minutes' stirring at −70°C the deep-red solution was transferred within 60 min through a Telefon tube (cooled with dry ice) into 30 mL of cyclohexene at room temperature. After 18 h the mixture was filtered, and the filter-cake washed twice with 50 mL of diethyl ether. The filtrate was washed twice with 30 mL of 5% aqueous sodium hydroxide and once with 30 mL of water. After drying over magnesium sulfate and removal of the solvent in a vacuum, 0.56 g (71%) of **11** was obtained; b.p. 80°C/0.005 torr (Kugelrohr distillation), diastereomeric ratio 49:1 [11]. IR (film): 1685 (C=N) cm^{-1}. ^{1}H-NMR ($CDCl_3$): $\delta = 0.75$ and 1.02 [2d, $J = 7.2$ Hz; 6H, $C(CH_3)_2$], 1.1-1.9 (m; 10H, CH_2 and CH), 1.95-2.40 [m; 1H, $CH(CH_3)_2$], 3.62 and 3.68 (2s; 6H, OCH_3), 4.14 (d, $J = 4$ Hz; 1H, 2-H). ^{13}C-NMR ($CDCl_3$): $\delta = 16.88$ and 18.79 (CH), 17.94, 18.53, 21.79 and 22.91 (CH_2), 22.25 and 23.31 (CH_3), 32.35 (CH), 43.03 (C_{quart}, C-2), 52.35 and 52.52 (CH_3), 61.46 (CH), 163.42 and 164.74 (C=N).

12: A mixture of **11** (0.264 g, 1 mmol), 0.25 N hydrochloric acid (8 mL), and THF (4 mL) was stirred for 7 d at room temperature. After washing with diethyl ether (2 × 10 mL), the aqueous phase was first treated with 20 mL of diethyl ether and then, with stirring, with concentrated ammonia solution until pH 9. The ether phase was separated off and the alkaline aqueous phase washed once again with ether (2 × 20 mL). After drying the combined ether phases over magnesium sulfate, the ether was removed in a vacuum. The residue was chromatographed on silica gel (low-pressure chromatography, silica gel 60, 500 × 15 mm column, eluted with ether/petroleum ether = 2:1); yield 72 mg (43%) of **12** as oil ($R_F = 0.5$) and 99 mg (38%) of the dipeptide ester **13** ($R_F = 0.4$) of m.p. 90-91°C. **12**, IR (film): 3375 and 3320 (N−H), 1720 cm^{-1} (C=O). ^{1}H-NMR ($CDCl_3$): $\delta = 1.0$-2.1 (m; 12H, NH_2, and alkyl-*H*), 3.63 (s; 3H, OCH_3). *N*-(3,5-dinitrobenzoyl) derivative: m.p. 177-178°C.

Kirk-Othmer Concise Encyclopedia of Chemical Technology. Edited by *M. Grayson* and *D. Eckroth*. John Wiley and Sons, New York 1985. xxxii, 1318 pp., bound, $ 172.85.—ISBN 0-471-86977-5.

The condensation of twenty-six volumes of information into a single reference volume is a formidable task, especially when not only text but also a large number of tables, figures, graphs, charts, formulas, and even pictures are involved. The editors of the renowned *Kirk-Othmer Encyclopedia of Chemical Technology* have achieved this goal in such a way that the abridgment, the *Concise Encyclopedia of Chemical Technology,* should find wide use, both by professionals as a single source of key information and as a guide to further literature and by students as a lucid introduction to the multifarious aspects of the chemical industry.

Each subject in the twenty-four main volumes and supplementary volume of the parent work has been condensed and, in some cases, updated. The entries include important chemical substances (acetaldehyde to zirconium), chemical processes (absorption to zone refining), and the many facets of chemical technology itself (from the manufacture of dyes and the processing of milk to the large-scale production of antibiotics and chemotherapeutic agents and the recent applications of genetic engineering). The curious reader will find discussions of the design of experiments, fine art examination and conservation, information retrieval, nomenclature, patents, recycling, regulatory agencies, trademarks and copyrights, and much more.

Only a small fraction of the original tables and figures remain, but those selected are the most important. Likewise, the number of references has been drastically reduced, but those given are fairly up-to-date and enable the reader to locate efficiently further sources of information. Moreover, the numerous formulas, subheadings, and cross-references, as well as the index, facilitate the search for specific facts. Lists of conversion factors, abbreviations, and unit symbols at the front and of nomenclature under some entries (for example, "Mass Transfer" and "Thermodynamics") further assist the reader.

The entry "Phosphorus Compounds" illustrates the amount of condensation involved. In the third edition of *Kirk-Othmer,* the subject is treated in fifty pages, which include eighteen tables and nine figures and conclude with sixty-seven references. The *Concise Encyclopedia* handles the subject in a little over two pages, three tables, and five general references (although the smaller print size and the larger pages roughly double the informational content per page). Nonetheless, the entry presents key information, including the physical properties of the phosphorus sulfides, halides, and oxides, the phosphorous acids, the phosphazenes and other phosphorus-nitrogen compounds, and phosphine and its derivatives as well as descriptions of their industrial preparation and main applications. Illustrated are the structures of the phosphorus oxo acids and the phosphorus sulfides along with a diagram of a plant for the production of phosphorus trichloride and phosphorus pentachloride.

Of course, any reference work that attempts to distill the essentials of so huge a body of information as that presented in *Kirk-Othmer*'s third edition is bound to disappoint at times. The individual reader will no doubt find the treatment of some topics too cursory and that of others too drawn out. Moreover, the explosive growth in the number of new chemical substances and the continual introduction of new technologies will outdate some entries. These limitations are inherent in any such work, however, and are more than outweighed by the sheer wealth of useful information that is presented here in a well-organized, clearly written manner. My only qualm is that the price may deter some, especially students, from purchasing the book, which, in order to be most useful, should be readily at hand.

David I. Loewus [NB 730 IE]
Angewandte Chemie, Weinheim

Chemistry of the Elements. By *N. N. Greenwood* and *A. Earnshaw*. Pergamon Press, Oxford 1984, 1542 pp., hardback, $ 95.00.—ISBN 0-08-022056-8

The appearance of a new textbook on a fundamental scientific discipline is an important literary occurrence. If the new work can establish itself, it will influence the knowledge and way of thinking of generations of students for years to come. The existing works have certainly done this, and the traces are generally easy to identify. The author's selection of material and his distribution of emphasis amongst the theoretical concepts can direct a mass of young talents towards certain areas while others remain apparently unattractive—at least they were to the author. Furthermore, it is the case that if standard works do not accomodate new material early enough, then the rising generation is educated in a certain language with inadequate teaching and learning aids while those learning in other languages are already getting to grips with new perspectives.

Such disadvantageous developments can only be avoided if genuine alternatives appear on the market and lead to fruitful competition. In this sense the appearance of the German translation of *Cotton* and *Wilkinson* was, in its day, the extraordinarily beneficial compensation for the failings of *Holleman-Wiberg* that was then unmistakably showing its age. This is not to imply that from then on everyone would be happy with the new style of textbook—it quickly becomes evident from edition to edition that many outmoded ideas may have been opposed too forcefully.

Greenwood and Earnshaw, which has been available from mid 1984 is a very remarkable book, quite aside from its natural rôle as a complement to the assortment of traditional texts. In a "test drive" over several months, this reviewer got so used to the new vehicle that he rarely wanted to bring the other models out of the garage. The book rarely disappointed, neither when complete chapters were used to refresh knowledge nor when "spot checks" were made to recall individual facts. Incidentally, it should be emphasized at the outset that, in spite of the title, this is a textbook of *inorganic chemistry*. This is true at any rate to the extent that no organic chemistry is included. Fortunately, fringe areas in all directions are considered so that practically no stone is left unturned in respect of the definition of inorganic chemistry, surprisingly dismissed in the foreword as an outmoded concept.

The greatest advantage of the book is that it has already taken into account the most up to date developments. The

extensive bibliography is spread through the text; its entries, both in the biographical/historical part and, not least, in the scientific/technical sections really do extend into 1983. Naturally, it would have been astounding if this success had been uniform and it must be said that, for example, more than 2 sentences (on p. 110) could have been wished on the natride ion, Na^-, and on the corresponding oxidation state of gold, Au^-, (on p. 1367); nor is the most recent technology in iron and steel production included. Yet such points are exceptions which require practically microscopic examination of the text.

Optically the text is well produced with pleasing formula depictions and clearly laid out tables and diagrams. Annoyingly, the latter are not free of mistakes: on p. 58 the caption is twiceover puzzling (H_2!). Blocks of text printed on a grey background emphasize special sections; for some people this will seem overdone since it breaks up the continuity of the text or at least renders it clumsy. The theoretical chapters and the selection of material show a distinct preference for the s and p block elements, to which 1000 of the total 1500 pages are given over. d and f block elements are banished to the last third of the book so that little space remains for their coordination and organometallic chemistry. However, this does not amount to being "anti Cotton and Wilkinson", since it is precisely in the chapters on the transition elements that the authors have striven to pick out the essential points from a superabundance of facts.

Ultimately the question must be posed whether the book leans toward molecular or solid state chemistry and whether it can be recommended to protagonists of either case. The answer must be that the former prevails. Here the book is best able to satisfy high expectations. However, in all the other passages too it makes fascinating reading material, especially for students in first or middle semesters, as well as for the practising chemist and the chemistry teacher.

The presentation of the book is pleasing and convenient; the English is pleasantly relaxed but still precise. The book could well be taken from the writing desk, if not straight into bed, at least as far as the sofa. For around DM 100 (in paperback) it is edifying entertainment, well worth the money.

Is a German translation desirable? For reasons already given in the introduction this would be an enrichment, assuming that the German version was immediately brought back up to date and that the language was kept as fluent as in the original so that nothing was lost in this respect. The book would then easily be in a position to compete with (the new) Holleman-Wiberg and Cotton and Wilkinson could only stay in contention so long as it too was modernized and reorganized.

In the introduction (by *R. J. Gillespie*) and in the authors' foreword referred to above, it transpires that "Chemistry of the Elements" breaks with the tradition of British and American textbooks insofar that it is concerned more with timeless facts and phenomena, which theoretical concepts can be measured against and directed towards. This is supposed to stimulate the curiosity without which future research cannot thrive. As is well known, this approach is not so novel in German textbooks and so this newcomer fits well into our landscape.

Professor *Greenwood* was distinguished in 1983 with one of the major awards of the German Chemical Society. He would have deserved it for this textbook alone, even if many of the modern results about boron compounds were not based on his scientific work. In the circumstances no one would begrudge the fact that the chapter on boron hydride compounds has turned out too long.

The Chemistry of the Catalyzed Hydrogenation of Carbon Monoxide. By *G. Henrici-Olivé* and *S. Olivé*. Springer Verlag, Berlin 1984. x, 231 pp., hardback, DM 146.00.— ISBN 3-540-13292-9

The oil crisis and a looming oil shortage have brought about strong growth in the interest in carbon monoxide derived from coal. In recent years various monographs concerned with the hydrogenation of carbon monoxide have already appeared. Thus, duplications in the description of CO hydrogenation reactions were inevitable. The book at hand, which deals with the literature up to the beginning of 1984, gives a good survey of the present state, and of the problems encountered in homogeneous and heterogeneous catalytic hydrogenation of CO. Mechanistic considerations assume a central position, and the chemistry of organometallic complexes stands, to a certain degree, at the center of attention. The attempt to build a bridge between molecular chemistry and possible surface species is successful. The authors have been able to choose the essential aspects of the relevant coordination chemistry from the extensive literature and have illustrated clearly the "metal-organic zoo" of possible surface compounds by model reactions. Here the book is of great value.

In 11 chapters the following areas are covered: *Transition metal-hydrogen/carbon monoxide interactions:* those reactions that are seen as significant in the hydrogenation of CO, e.g. hydride formation, CO coordination and CO bond cleavage are introduced in two opening chapters. *Non-catalytic interactions of CO with H_2:* apart from mechanistic aspects of the interaction of CO and H_2, the formation of formyl-, formaldehyde-, methoxy-, and carbide complexes is dealt with. *Key reactions in catalysis:* this chapter is devoted to certain key reactions, e.g. insertion of CO, formaldehyde and olefins, as well as elimination of hydrogen and the influence of ligands. *Catalysts and supports:* here the interactions of molecular complexes with carriers is presented. *Methanation:* after the first part of this book has mainly been concerned with model reactions, the consideration of catalytic processes begins with methanation. Again, mechanistic aspects such as carbide mechanism and CO insertion mechanism are the central themes. *Methanol from CO and H_2:* the homogeneous and heterogeneous catalysis of methanol formation is described in this very short chapter. *Fischer-Tropsch synthesis:* this is the longest chapter. Alongside model reactions stand such technical parameters as the influence of pressure and temperature. *Homogeneous CO hydrogenation:* in the first section hydroformylation is introduced, in the second, the formation of polyalcohols. *Methanol as raw material:* this chapter, which is concerned with the homologation and conversion of methanol on zeolites, does not entirely fit in the supposed context of CO-hydrogenation. *Attempt of unified view:* In this chapter an attempt is made to simplify the general problem of CO hydrogenation from a mechanistic standpoint.

For those interested in the chemistry of organometallic complexes, the book contains many well known reactions. Nevertheless, the purchase of this book can be recommended on account of its comprehensive approach. It of-

fers an abundance of information about model reactions of organometallic compounds to the chemist or physicist working in the field of heterogeneous hydrogenation of CO.

Cluster Beam Chemistry—from Atoms to Solids

By T. Patrick Martin*

How do the properties of a solid gradually evolve as atoms are brought together to form increasingly larger units? In order to answer this question one must study aggregates of atoms too large to be called molecules but still too small to have even the structure of a crystal. Recent advances in both theory and experiment have made possible some first explorations in this long neglected but fascinating field of study. This review will emphasize the generation, growth, and properties of homo- and heteronuclear clusters in the vapor phase, particular attention being paid to mass spectrometric investigations.

1. Introduction

Recently it has become possible to produce and detect aggregates of atoms varying continuously in size from two to several hundred atoms. Because these aggregates have attracted wide-ranging attention, a colorful but confusing array of terms has been used to describe them, including small particles, microclusters, grains, oligomers, specks, and microcrystals. Considering this state of affairs it is best to define several terms as they will be used in this article. A ring of eight sulfur atoms or a tetrahedron of phosphorus atoms cannot with good conscience be called a cluster. Such stable units exist in the vapor, liquid, and solid phases and have long been called *molecules*. Because molecules are readily available, their proerties are usually well investigated. The term *cluster* will be reserved for atom aggregates that are not found in appreciable numbers in an equilibrium vapor. Clusters therefore represent new objects for investigation (Fig. 1).[1–4]

Clearly this use of the word cluster differs from that employed for many years to describe several classes of new crystalline cluster compounds.[5–8] However, one of the objectives of cluster beam research is to determine whether these units, already identified in solids, can also exist as isolated clusters or even as clusters of clusters in the vapor phase.

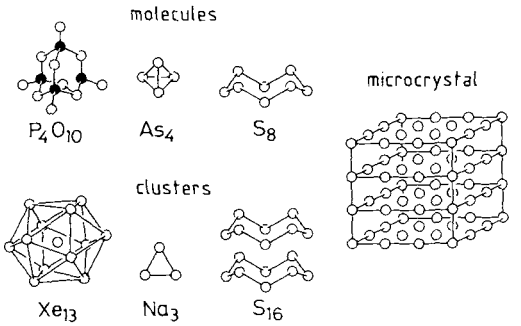

Fig. 1. Molecules, clusters, and a microcrystal. Clusters do not exist in equilibrium vapors. Microcrystals have the symmetry of the crystalline bulk substance.

After a cluster reaches a critical size, it is no longer free to rearrange its structure each time a new atom is added. A final lattice structure becomes frozen into the cluster. This crystallization may occur for aggregates containing less than 100 atoms. Still it is convenient and meaningful to give these aggregates a new name, *microcrystals*, because deviations from the bulk structure can be described as a surface relaxation.

Why are the properties of clusters of interest? We would like to understand the crystal growth process on a microscopic level. Everytime a new atom or molecule condenses

onto a cluster, the atoms in the cluster completely rearrange themselves; the cluster "reconstructs." We would like to know the sequence of structures a cluster assumes as it grows from a molecule into a crystal.

Another reason for studying clusters is to learn how the electronic band structure of a solid develops. This is represented in Figure 2 by a simple Hückel calculation of the electronic energy levels of silicon clusters with increasing size. It is of interest to observe how the discrete levels coalesce to form bands and at what stage a distinct gap appears between filled and unfilled states.

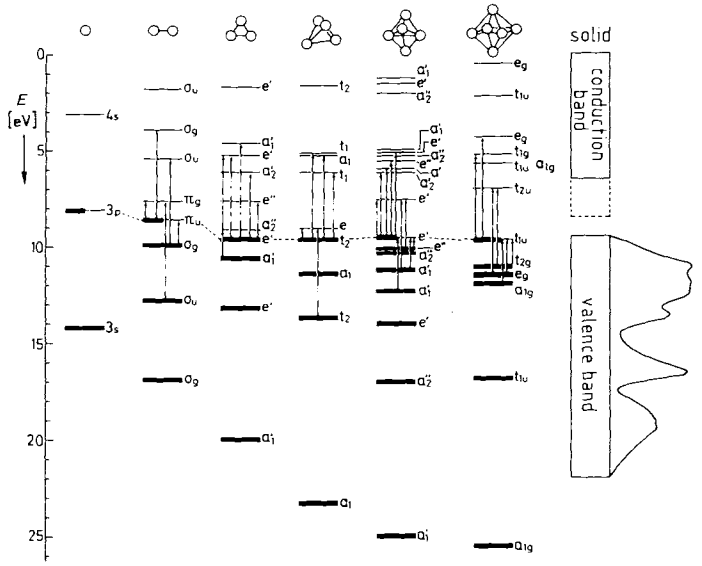

Fig. 2. Calculated electronic energy levels of Si atoms and clusters.

A question often asked is, how many metal atoms are required to form a cluster that has metallic properties? One characteristic property of a metal is its optical response, i.e., its interaction with light. A single Li atom has a very simple absorption spectrum, consisting of essentially one line in the visible (Fig. 3). This absorption can be well described as a one-electron transition from a 2s to a 2p state. A lithium crystal, on the other hand, has a completely different absorption spectrum. The absorption is strong in the far-infrared, goes through a minimum in the visible, and rises again in the ultraviolet (Fig. 3). The reason for the strong far-infrared absorption is that very low energy photons can excite electrons from the continuum of states just below the Fermi energy to states just above the Fermi energy. The strong UV absorption is caused by interband transitions. Suppose we chip off a small corner of the crystal, producing a microcrystal that contains only 50 atoms. The absorption spectrum changes completely. A relatively broad absorption maximum appears in the visible (Fig. 3). This absorption is due to a plasmon excitation, i.e., a collective excitation of outer electrons. The Li crystal also exhibits plasmon excitations, but these excitations have a longitudinal character and do not couple to transverse light waves. In the microcrystal one can consider a plasmon as a collective sloshing motion of the electrons from one side of the microcrystal to the other. Obviously, such a motion has a strong dipole moment, thus giving rise to the strong absorption band in the visible. The absorption of light by a Li atom is well described within the one-electron picture. However, this picture cannot describe even qualitatively the plasmon excitations that dominate the optical response of a 50-atom cluster. Between a few atoms and 50 atoms, we must completely change our way of looking at optical response. Clusters offer us the opportunity of studying this transition.

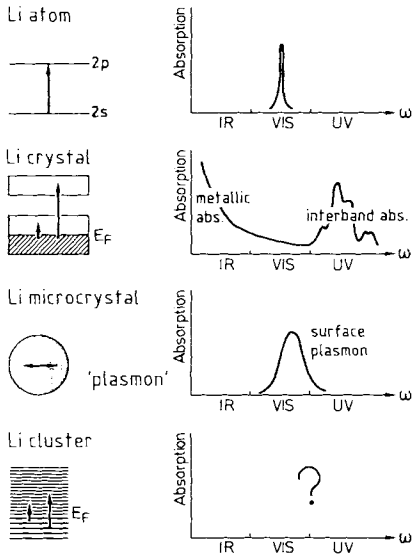

Fig. 3. Absorption of light by lithium in various stages of aggregation.

Another reason for studying clusters is that the technique of cluster-beam mass spectrometry offers a new and convenient method of allowing elements to react in a controlled manner and of determining the stability of the reaction products.[9] This topic will be the main theme of this article, which will begin with a very brief review of work in the field of cluster preparation.

2. Four Case Studies

Four case studies will first be presented, each representing a different method of cluster preparation, a different substance, and a different level of interpretation.

2.1. Water Clusters Produced by Gas Expansion

It has been known for several decades[10,11] that when a gas under relatively high pressure (1 bar) expands into a vacuum through a small (0.1-mm) nozzle, clusters condense out of the cooled gas. The size distribution of the clusters can be controlled by varying the expansion parameters. This technique has been used to study a large variety of gas-phase and vapor-phase clusters, including those of hydrogen,[12] water,[13-21] sodium,[22-27] inert gases,[28-33] and tetracene.[34,35] Figure 4 shows the mass spectrum of water clusters formed by expanding a mixture of H_2O (4.6 torr) in argon through a 0.22-mm nozzle. The average cluster size increases with increasing total pressure and the mass peak corresponding to the cluster $[H(H_2O)_{21}]^+$ stands out particularly strongly. This finding is usually interpreted to indicate an enhanced stability for the 21-molecule water cluster. What does this cluster look like? Ice has a wurtzite

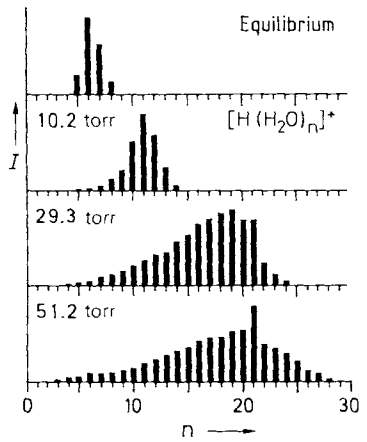

Fig. 4. Dependence of the size of water clusters on total pressure (determined by mass spectrometry). The water clusters were produced by expanding a mixture of H_2O vapor and argon at the indicated pressure through a 0.22-mm orifice into a vacuum [14]. n = number of water molecules per cluster; I = relative amount of cluster.

structure in which each oxygen atom is surrounded tetrahedrally by four other oxygen atoms. One hydrogen atom is found between each pair of oxygen atoms. It is not possible to find a highly symmetric arrangement of 21 H_2O molecules within the wurtzite structure. However, the tetrahedral bonding scheme may be used to construct a dodecahedral cage consisting of 20 H_2O molecules. In fact, such a cage has been identified in many clathrate compounds. The stability of the dodecahedron could explain the strength of the n = 21 peak in the mass spectrum (i.e., the 20 molecules comprising the dodecahedron surround a central, charged molecule).

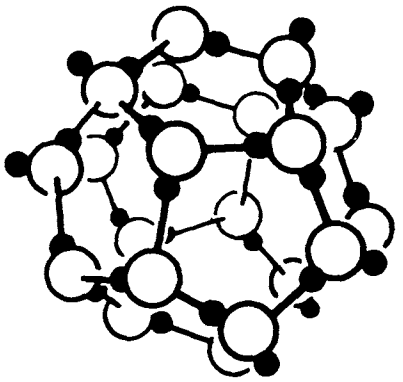

Fig. 5. Clathrate cage composed of twenty water molecules.

2.2. Alkali Halide Clusters Produced by Ion Bombardment

If an intense beam of high-energy (5-keV) xenon ions (Xe^+) is directed against a solid surface (e.g., CsI), secondary ions are ejected from the surface and can be detected in mass spectrometer. These secondary ions include not only simple, ionized molecules but also large clusters containing hundreds of atoms.[36-41] A mass spectrum of $[Cs(CsI)_n]^+$ clusters produced in this way is shown in Figure 6. The peak corresponding to the cluster $[Cs_{14}I_{13}]^+$ is particularly strong. Analogous clusters produced from NaCl[41-43] and CuBr[44] have also been shown to have an enhanced stability. Since this cluster is too small to be observed directly, theoretical considerations are required in order to determine its structure. Stable cluster configurations can be calculated at widely varying levels of sophistication. The simplest method uses a model involving the packing of hard spheres. At the other end of the scale, stable structures can be determined by elaborate configuration interaction calculations of the total energy. Such calculations are appropriate for all types of clusters but are limited in practice to very small clusters of light atoms. The total energy of clusters with either purely ionic[45,47] or purely van der Waals[48] bonding can be determined much more simply. It is possible to define a size-independent,

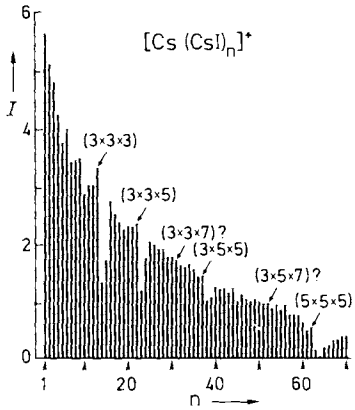

Fig. 6. Size distribution of $[Cs(CsI)_n]^+$ clusters determined by secondary mass spectrometry (SIMS). The numbers in parentheses indicate the sizes of perfect, rectangular clusters. I is a measure of the intensity of the mass peak (lg counts per second) [37].

two-body interatomic potential. By summing this potential over all atom pairs, a multidimensional total energy surface is obtained. Each minimum on this surface corresponds to a stable cluster configuration. The main computational difficulty is not to define the surface but to find all true minima without getting trapped at a saddle point with a low curvature.

Such total energy calculations indicate that $[Na_{14}Cl_{13}]^+$ has more than the usual binding energy. The reason for this is quickly seen by looking at the structure of this cluster (Fig. 7). $[Na_{14}Cl_{13}]^+$ is highly symmetric, resembling a

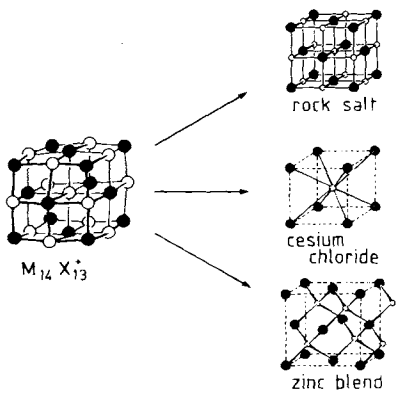

Fig. 7. The most stable form of the metal halide cluster $[M_{14}X_{13}]^+$ (left) and the crystal structures of NaCl, CsI, and CuBr (right, top to bottom).

portion of the rock salt structure. Calculations with parameters appropriate for the compounds CuBr and CsI indicate that the cubic cluster $[M_{14}X_{13}]^+$ is responsible for the strong peaks in the mass spectra of these substances also. This is quite surprising because CuBr and CsI condense to form crystals of the zinc blende (coordination number (CN) 4) and cesium chloride type (CN 8), respectively. Thus, the rock salt form (CN 6) appears to be energetically favored in the early stages of growth of not only NaCl but also CsI and CuBr.

2.3. Quenching of Ge and Sn Vapors in Helium Gas

Most substances when heated to a sufficiently high temperature in an inert-gas atmosphere produce a dense smoke composed of microcrystals.[49-52] The linear dimension of the microcrystals varies from 10 to 1000 Å depending on experimental conditions. Recently, a time-of-flight mass spectrometric study showed that the technique of inert-gas evaporation produces not only microcrystals but also clusters containing fewer than 100 atoms.[53,54]

Not all elemental vapors produce a detectable number of clusters when quenched in helium gas. Germanium and tin, however, form clusters readily and are particularly interesting because a transition from covalent to metallic bonding occurs in the solid forms. Perhaps this transition is reflected in the cluster mass spectra. Mass peaks of the Ge_x^+ clusters (Fig. 8) are strong for x = 6, 10, 14, 15, and 18

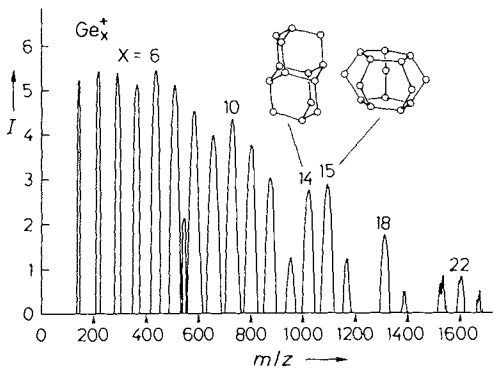

Fig. 8. Mass spectrum of clusters formed by quenching Ge vapor in He gas. Peaks corresponding to clusters with x = 6, 10, 14, 15, and 18 Ge atoms are particularly strong. Two structures having bond angles of nearly 109° are indicated.

and particularly weak for x = 13, 17, 20, and 24. A discussion of the structures of these stable clusters should be based on total energy calculations. However, such calculations have only been made for very small Ge clusters.[55] Therefore, we will limit the discussion to pointing out several atomic arrangements within a Ge crystal. The basic structure in such a crystal is a six-membered ring in the chair conformation; this structure can form the basis of an adamantane system, which can in turn be enlarged still further. In this way a sequence of closed polycyclic Ge_x structures is formed corresponding to x = 6 + 4a where a is an integer. A plausible structure may also be formulated for the Ge_{15}^+ cluster ion (Figure 8).

The dominant feature of the mass spectrum of the Sn_x^+ clusters is the weakness, or in this case the absence, of the peak for x = 14 (Fig. 9). In this respect tin resembles lead.[53] That tin should more resemble lead than germanium can be seen already in the solid state. Although tin does have a low-temperature semiconducting crystalline modification with the diamond structure (α-Sn), at room

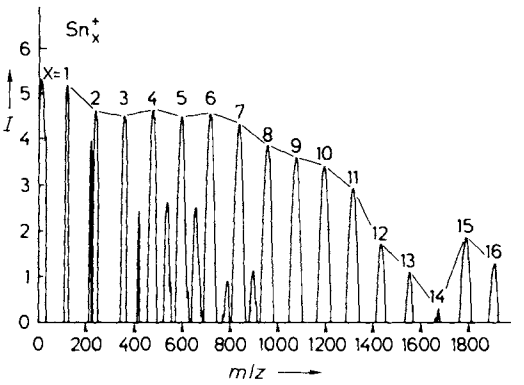

Fig. 9. Mass spectrum of clusters formed by quenching Sn vapor in He gas.

temperature it is a metal with the β-Sn structure (CN 6). Once again we can only speculate as to the cause of the instability of the cluster ion Sn_{14}^+. There are several close-packed structures corresponding to Sn_{13}^+ consisting of a central atom surrounded by a complete shell of twelve outer atoms.[4] An additional atom, which lies on the surface of such a highly symmetric, compact core, could be expected to be weakly bonded.

2.4. Carbon Clusters by Laser Evaporation

A pulsed cluster source has been developed which uses a focused laser beam for vaporization.[56-59] The vaporization is timed to occur at the peak of a high-pressure He pulse. Such a source is particularly appropriate for time-of-flight mass spectrometry. It has the advantage that essentially any material can be vaporized, even carbon.[56] The mass spectrum of C_x^+ clusters has a bimodal size distribution. For x < 30, clusters containing both even and odd numbers of atoms have been observed. The peaks corresponding to x = 3, 11, 15, and 19 are particularly strong. For x > 30, however, only clusters containing even numbers of atoms have been observed. Recently, a C_{60} cluster was generated and found to be particularly stable.[56b] This cluster, named "Buckminsterfullerene," is assumed to owe its stability to its highly symmetric, spherical structure.[56c]

3. Heteronuclear Clusters

Heteronuclear clusters, i.e., clusters composed of more than one element, can be produced by allowing the elements to react in the vapor phase.[9] The composition of the clusters can be determined by mass spectrometry. By varying the partial pressures of the two elements, the stability of clusters having all conceivable compositions can be tested in just one experiment. Various combinations of elemental vapors (Ge, Sn, Pb, Ga, In, Cs, Rb, Sr, Tm, Eu, Cl, O, S, and P) have been allowed to react in the vapor

phase and then thermally quenched in cold He gas. Heteronuclear clusters condensed out of the vapor and were identified using a quadrupole mass spectrometer. The average cluster composition could be changed by varying the partial pressure of the two elements. Of particular interest are mass peaks having unusually strong or weak intensities, because such peaks allow clusters of unusually high or low stability to be identified.[4] Also significant in such experiments is the observation of a sequence of strong mass peaks corresponding to clusters with the composition $(A_xB_y)_n$. This identifies the unit A_xB_y as a building block for cluster construction and for possible use in the synthesis of new solids.

3.1. Experimental Procedures

Elemental vapors are produced in ovens of various design and allowed to react in a chamber containing from 0.7- to 5-mbar He gas. The outer mantel of the reaction chamber is cooled with liquid nitrogen. The kind of oven used depends on the element to be evaporated. For S, Rb, Cs, and P, the oven consists of a resistively heated quartz crucible (1 cm in diameter and 8 cm long) with a pocket at the bottom to hold a thermocouple. The crucible fits snugly into an Al_2O_3 cylinder grooved and wrapped with a Ta coil. This unit is inserted into a closely fitting second cylinder (also made of Al_2O_3). This is followed by several layers of radiation shielding. The outermost cylinder is a stainless steel jacket having good thermal contact with a water-cooled electrode. The same unit can be used for evaporation of Pb, In, and Ga, except that in these cases a graphite rather than a quartz crucible is required. A stainless steel crucible is used for Tm and Eu. The high temperatures necessary for the evaporation of Sn require that the oven length be scaled down by a factor of almost 2. Ge is evaporated from a resistively heated graphite tube.

The reaction chamber contains two of these ovens. The vapors from the ovens are mixed and cooled. Heteronuclear clusters condense out of the supersaturated vapor and pass through a 3-mm diameter hole into an intermediate chamber where the excess He gas is pumped off with a turbopump (150 L/s). The cluster beam then passes through a 1-mm diameter hole into a high-vacuum chamber containing a quadrupole mass spectrometer (pumped with a 360-L/s turbopump). The cluster beam intersects the axis of the spectrometer, where the clusters are ionized with 80-eV electrons. The spectrometer can be operated in the range from 1 to 2000 amu. A quartz-film thickness monitor, located on the farside of this chamber, allows the total mass flux in the cluster beam to be measured. A schematic drawing of the apparatus is shown in Figure 10.

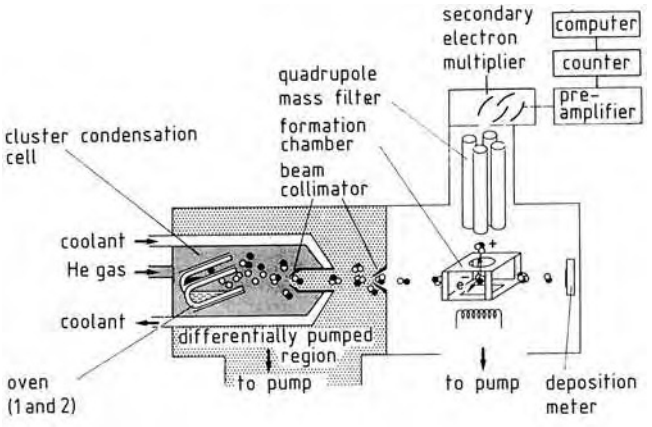

Fig. 10. Experimental apparatus (schematic) for the formation, reaction, and mass spectrometric analysis of clusters.

3.2. The Cesium–Sulfur System

3.2.1. Sulfur Clusters

The cesium–sulfur system is of particular interest since it permits the investigation of an entire range of cluster compositions from pure sulfur to pure cesium. The mass spectrum of a mixture of clusters formed by quenching pure sulfur vapor in He gas is shown in Figure 11, top. Clusters containing from 2 to 56 sulfur atoms are easily identified.

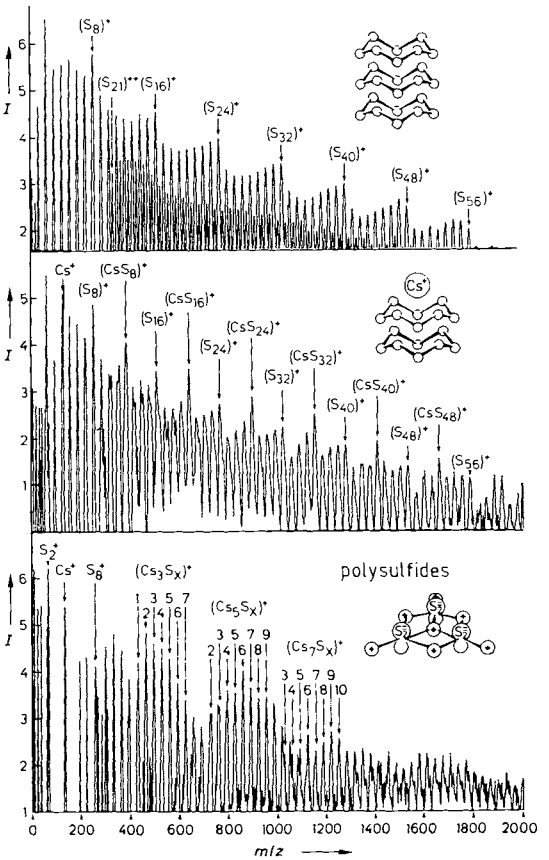

Fig. 11. Mass spectra of a mixture of clusters formed by quenching various mixtures of sulfur vapor and cesium vapor in He gas. Pure sulfur clusters are constructed out of S_8 rings (top). Clusters with composition $[CsS_{8n}]^+$ seem to be stable against fragmentation (middle). At increased partial pressure of Cs, polysulfide clusters composed of Cs^+ ions and S_2^{2-} and S_3^{2-} ions (bottom) appear.

The mass peaks corresponding to clusters containing 8, 16, 24, 32, and 40 sulfur atoms are particularly strong. Apparently sulfur clusters have a tendency to be constructed out of eight-atom building blocks, presumably ring molecules. In large clusters the molecules are bonded together by means of weak van der Waals forces. Orthorhombic sulfur is constructed in exactly the same way (i.e., S_8 rings are

stacked one on top of another). Thus, the cluster mass spectrum appears to reflect the initial growth of a sulfur crystal. This is somewhat surprising since the clusters are all positively charged. In fact, the removal of a lone pair electron from one of the sulfur rings does appear to affect the overall stability of the cluster. Although the clusters S_{8n}^+ are represented by strong peaks (Fig. 11, top), neighboring peaks corresponding to the loss of one to seven atoms are almost as strong. This gives the spectrum a step-like appearance.

Doubly positively charged sulfur clusters S_n^{2+} appear for $n=20$ or 21. The uncertainty in this value arises from the fact that S_{20}^{2+} is superimposed on S_{10}^+. The existence of a critical size for the appearance of doubly ionized clusters has been substantiated in a number of systems[60] and is thought to reflect the instability of small clusters in which two positive charges are forced to exist in close proximity.

3.2.2 *Cesium Polysulfide Clusters*

A mass spectrum of clusters produced by mixing a small amount of cesium vapor with sulfur vapor is shown in Figure 11, middle. The spectra of the Cs-S system must be analyzed carefully since four sulfur atoms (128 amu) are distinguishable from one Cs atom (133 amu) only in high resolution mass spectra. Fortunately, the required resolution lies just within the specifications of our quadrupole analyzer. The series of peaks in Figure 11, middle, due to pure sulfur clusters is very strong. The unusual strength of peaks corresponding to S_{8n}^+ is once again noteworthy. However, the strongest peaks in the spectrum belong to the series $[CsS_{8n}]^+$. Apparently, only one Cs atom is bonded to each sulfur cluster. Presumably, the positive charge on each cluster tends to be localized on the Cs atom. Removal of even a lone pair electron from a sulfur ring apparently leads to considerable fragmentation (see Section 3.2.1). A sulfur cluster containing one Cs atom, on the other hand, can be ionized with only a small amount of fragmentation. This is reflected in the mass spectra by the presence of a clear maximum in the series of peaks at $[CsS_{8n}]^+$ rather than a step. Presumably, Cs^+ is located on the central axis of a stack of S_8 rings and is bound to the rings through a point charge-induced dipole electrostatic interaction.

One might expect that by increasing the partial pressure of Cs vapor, additional metal atoms would be incorporated into the S_{8n} clusters. But this is not what happens (Fig. 11, bottom). An entirely new type of cluster appears, in which the S_8 rings are broken up into smaller chains (S_2^{2-} and S_3^{2-} ions). We can gain insight into the structure and bonding of polysulfide clusters by considering the results of investigations on BaS_2 and BaS_3 crystals, which contain the same polyatomic anions.[61,62] BaS_2 crystals are made up of Ba^{2+} and S_2^{2-} dianions. The exact structure of this crystal is rather complicated, the lattice being monoclinic with four BaS_2 formula units per unit cell. However, if one considers an idealized crystal constructed by replacing the S_2^{2-} ions by single anions located at the centers of the dianions, the picture simplifies considerably. The idealized crystal has a slightly distorted rock salt structure: each Ba^{2+} ion is surrounded by six S_2^{2-} units and vice versa. Apparently, the bonding between Ba^{2+} and S_2^{2-} is essentially ionic. The same conclusion can be drawn from the results of investigations on BaS_3.[61] This crystal is tetragonal, each unit cell containing two formula units. The sulfur is solely in the form of trisulfide units with an angle of 114.9° and an S-S bond length of 2.076 Å. However, the essentially ionic nature of the bonding between Ba^{2+} and S_3^{2-} is revealed by the observation that the two units are arranged in a slightly distorted CsCl type structure.

3.2.3. *Cesium Sulfide and Subsulfide Clusters*

Increasing the Cs partial pressure still further results in the formation of cesium sulfide clusters $[Cs(Cs_2S)_n]^+$ (see Fig. 12, top). These clusters are built out of Cs^+ and S^{2-} ions. No strong intensity anomalies were observed for clusters with $n=1$–6. The possible structure of these sulfides will be discussed below in connection with cesium oxide clusters for which explicit calculations have been made (see Section 3.4).

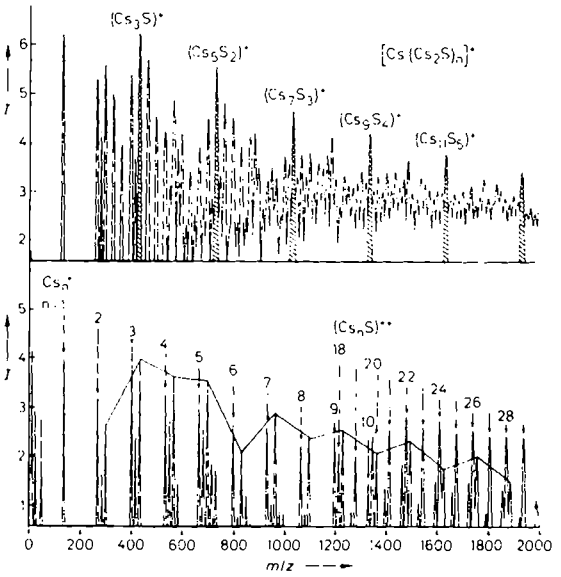

Fig. 12. Mass spectrum of cesium/cesium sulfide clusters (composed of Cs^+ and S^{2-} ions) (top) and of cesium/cesium subsulfide clusters (below). The mass peaks due to $[Cs_nS]^+$ clusters (connected) alternate in intensity (bottom).

If sulfur is evaporated at a very low oven temperature (53 °C), it is possible to produce cesium-rich subsulfide clusters (see Fig. 12, bottom). In the mass spectrum the peaks of the pure Cs clusters are each followed by an intense cesium sulfide peak (which are joined by lines for clarity). Exactly halfway between each Cs_n^+ and $[Cs_nS]^+$ peak, additional weaker peaks appear which are due partly to cesium oxide clusters and partly to doubly ionized cesium sulfide clusters. The intensities of the Cs peaks alternate and that of $[Cs_6S]^+$ is particularly weak.

3.3. The Cesium Chloride and Rubidium Chloride Systems

Alkali clusters have been intensively studied both experimentally and theoretically.[45] In the experiments car-

ried out until now a solid salt was used as the source for the production of clusters.[38-43,63] By using cesium metal and gaseous chlorine we are able to study Cs–Cl clusters deviating strongly from the normal stoichiometry.

3.3.1. Cesium Subchloride Clusters

The relative yields of clusters formed when only a small amount of chlorine gas is introduced into the system is shown in Figure 13. The top curve indicates that if only one Cl atom is incorporated into the cluster, mass peaks corresponding to $[Cs_2Cl]^+$, $[Cs_4Cl]^+$, $[Cs_6Cl]^+$, $[Cs_8Cl]^+$, etc., are particularly strong. However, if two Cl atoms are incorporated into the cluster, an odd number of Cs atoms are preferred, i.e., the peaks $[Cs_3Cl_2]^+$, $[Cs_5Cl_2]^+$, $[Cs_7Cl_2]^+$, etc., are strong. Inspection of the entire series of curves in Figure 13 reveals that, if the number of Cs atoms

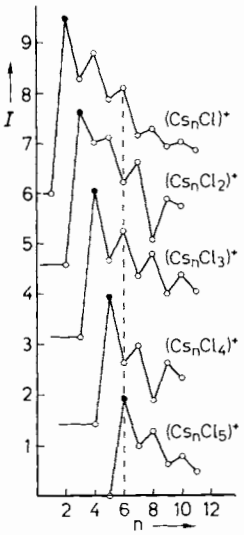

Fig. 13. The yield of cesium subchloride clusters formed by quenching Cs vapor in a mixture of He and Cl_2. Noteworthy is the vertical and horizontal alternation in the amount of cluster formed. The filled circles correspond to clusters containing ions with rare gas electronic configurations.

plus the number of Cl atoms is odd, the peak in the mass spectrum is strong. This result can be understood if all electrons are required to occur in pairs. Each Cs atom and each Cl atom has one unpaired electron. Therefore, the total number of atoms must be odd, since one electron is removed upon ionization. This effect has already been observed for pure alkali metal clusters.[22,64] The rule can be stated more generally; *a highly stable cluster, either charged or neutral, must contain only paired electrons.* The same rule will be seen to apply also to oxide, sulfide, and phosphide clusters.

3.3.2. Rubidium Chloride Clusters

As the partial pressure of chlorine is increased, the cluster mass spectrum simplifies considerably. A series of very strong peaks emerges corresponding to clusters with the composition $[M(MX)_n]^+$. Because of this simplification in the spectrum, a lighter alkali metal can be used without causing confusion due to overlapping peaks. Figure 14 shows the results for the Rb–Cl system for which mass

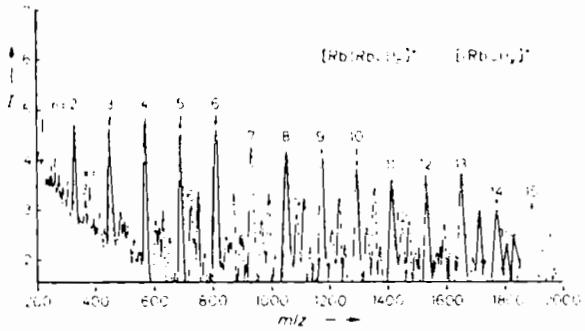

Fig. 14. Mass spectrum of rubidium chloride clusters formed by quenching Rb vapor in a mixture of He and Cl_2. Noteworthy is the intense peak $[Rb(RbCl)_{13}]^+$ and the relatively high intensities in the $[(RbCl)_x]^+$ series (x = 3, 6, 9, 12, and 15).

peaks can be observed for clusters containing up to 30 atoms.

The peaks for the clusters $[Rb(RbCl)_n]^+$ with n equal to 6, 9, and 13 are particularly strong. A second series of peaks, each peak occurring exactly halfway between peaks of the principal series, is due to doubly ionized clusters $[Rb_2(RbCl)_n]^{2+}$. A third series corresponds to clusters with composition $[(RbCl)_x]^+$. Peaks in this series stand out strongly for x = 3, 6, 9, 12, and 15.

Clusters in the principal series do not contain equal numbers of rubidium and chloride atoms. This fact reflects the strongly ionic character of the clusters and can be explained as follows: Mass selection is possible only if a cluster is charged. If all electrons in the cluster are localized and paired, the electrons most easily removed belong to the chloride ions. After ionization, the neutral chlorine atom is bonded to the remaining ions in the cluster only through a monopole-induced dipole interaction. This interaction is weak compared with the large amount of energy that is converted into vibrational motion during the ionization. Therefore, the neutral chlorine atom is lost, resulting in the formation of a cluster with composition $[Rb(RbCl)_n]^+$.

The intensity of a given line in a mass spectrum is influenced by many factors; the stability of the neutral clusters entering the ionization chamber, the cross section for ionization, the probability of fragmentation, and finally the stability of the ionized products. The relative stability of clusters can be determined by minimizing the total energy, which is given by the sum of all two-body interactions.[46,47]

$$V_{ij} = \frac{Z_i Z_j}{r_{ij}} + A \exp(-r_{ij}/\rho) \qquad \text{(a)}$$

The symmetries of the most stable configurations depend on the form of the two-body interaction.[63] Nonetheless, Figure 15 gives a fairly good representation of the stable forms of alkali halide clusters $[M_nX_{n-1}]^+$.

The calculated energy per MX unit for the most stable form of RbCl clusters with rock salt structure, ranging in size from 6 to 32 atoms, is shown in Figure 16. The binding energy for neutral clusters is particularly large for n = 6, 9, 12, and 15, because stacked six-membered rings and six-atom rectangles are the favored structures. The curve for

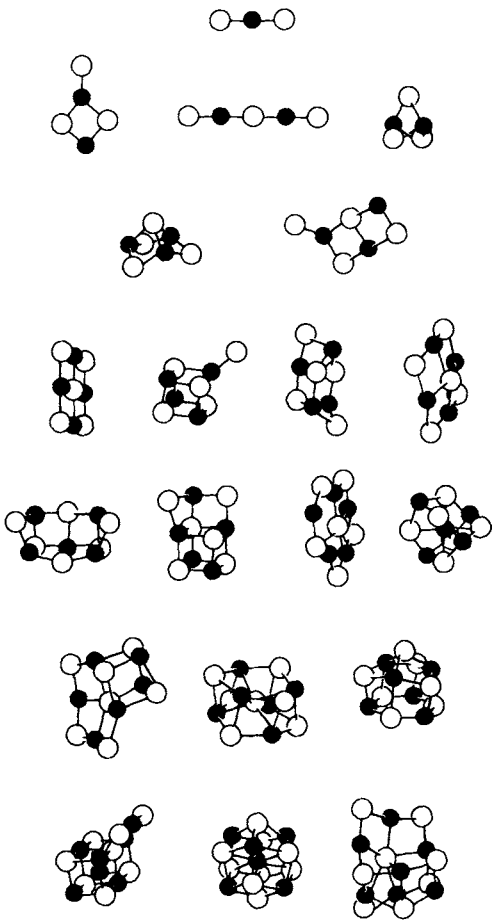

Fig. 15. Calculated stable configurations of alkali halide clusters.

charged clusters with composition $[Rb_nCl_{n-1}]^+$ is rather smooth except for $[Rb_{14}Cl_{13}]^+$, which appears to have more than the usual binding energy. The reason for this is quickly seen by looking at the structure of this cluster (Fig. 16). $[Rb_{14}Cl_{13}]^+$ is highly symmetric, resembling a portion of the rock salt structure.

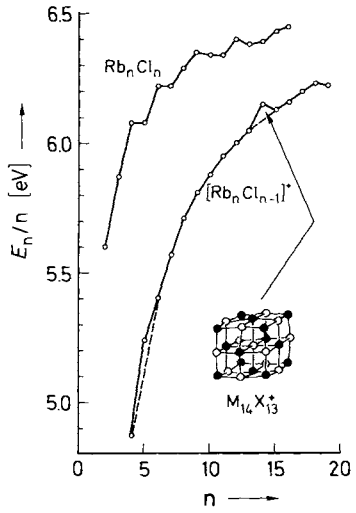

Fig. 16. Binding energy per MX unit for the most stable forms of positively charged and neutral clusters.

3.4. The Cesium–Oxygen System

The elements cesium and oxygen combine to form a bewildering array of crystalline compounds (Cs_7O, Cs_4O, $Cs_{11}O_3$, Cs_2O_2, Cs_2O_3, CsO_2, and CsO_3). The structures of the suboxides Cs_7O, Cs_4O, and $Cs_{11}O_3$ are particularly intersting and unusual.[29] Crystallographic investigations indicate that these compounds are composed of $Cs_{11}O_3$ clusters having strongly ionic character.[65–68] However, the bonding between the clusters is metallic. This bonding model is supported by comparison of the interatomic distances in the suboxides with the corresponding distances in normal oxides and pure metals. The metal–oxygen distances in the suboxide clusters are nearly the sum of the ionic radii, whereas the metal–metal distances between clusters are nearly those found in the pure alkali metal.

The superoxides owe their formation to the ability of oxygen to appear as O_2^{2-}, O_2^-, or O_3^- ions.[68] Cesium oxide clusters of all possible compositions were produced by evaporating cesium metal into a $He-O_2$ gas mixture containing an increasing amount of oxygen.

3.4.1. Cesium Clusters

Almost no clusters could be detected in the mass spectrometer if oxygen-free helium was used as the quenching gas. Upon addition of 0.01% oxygen (10^{-4} mbar), the cluster signal rose three orders of magnitude (Fig. 17). The intensity of the peaks of the pure Cs clusters also increased

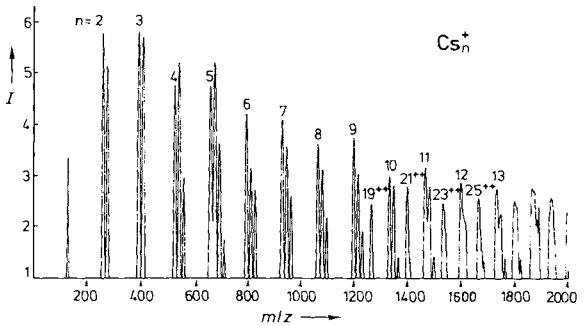

Fig. 17. Mass spectrum of a mixture of lightly oxidized Cs clusters. The mass peaks of the pure cesium clusters Cs_n^+ and Cs_n^{2+} have been labeled explicitly. Each subsequent peak indicates the addition of one or more oxygen atoms.

dramatically, indicating that these clusters may be fragments created during the ionization process. The first peak in every group corresponds to a pure Cs cluster containing the indicated number of atoms. The following, closely spaced peaks correspond to clusters containing one or two additional oxygen atoms. The intensities of the peaks of the pure metal clusters alternate. Peaks corresponding to clusters containing an odd number of Cs atoms are stronger. Since the clusters are positively charged, an odd number of atoms means an even number of valence electrons. Apparently, Cs clusters containing paired electrons have an enhanced stability.

After the group marked n = 9, new peaks appear exactly halfway between the pure Cs peaks. This new series corre-

sponds to doubly ionized cesium and cesium oxide clusters. For large clusters the individual peaks in each group have merged together. This is not due to a worsening of the mass resolution at high masses but to the newly emerging doubly ionized oxides, which are now separated by only 8 amu.

The intensity of the doubly ionized, pure metal clusters rises sharply at $n = 19$. Configuration interaction[70-72] and density functional[73-75] calculations have shown that small metal clusters do not necessarily have closed-packed structures. Still it is worth pointing out that there exist two highly symmetric arrangements of 19 spheres,[48] a large octahedral structure and a double icosahedron.

3.4.2. Cesium Suboxide Clusters

Increasing the amount of oxygen in the He buffer gas to 0.1% results in the formation of metal-rich suboxide clusters (Fig. 18). In order to observe irregularities in the intensities more easily, it is convenient to make comparisons between clusters containing the same number of oxygen atoms. The peak corresponding to the cluster $[Cs_6O]^+$ is particularly weak.

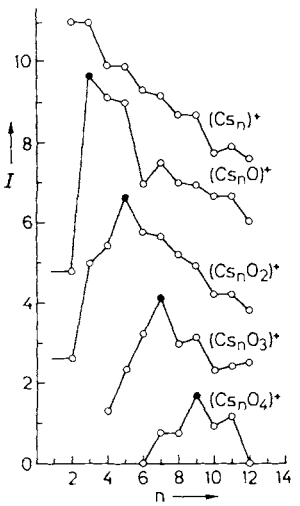

Fig. 18. Composition of a mixture of cesium-rich suboxide clusters (see text).

The strongest peak in each series corresponds to the normal oxide $[Cs(Cs_2O)_n]^+$ (solid circles in Fig. 18). As more cesium atoms are added to the normal oxide cluster, the peak intensities tend to alternate. However, the alternation is in the horizontal direction (Cs) only and not in the vertical direction (anions) as was the case for the halides (Fig. 13). The different behavior of the oxides and halides supports, nonetheless, the same rule (Section 3.3.1): stable clusters prefer to have paired electrons. Strong peaks are found not only for $[Cs_3O]^+$, $[Cs_5O]^+$, $[Cs_7O]^+$, etc., but also for $[Cs_3O_2]^+$, $[Cs_5O_2]^+$, $[Cs_7O_2]^+$, etc.

Electron correlation calculations for Li_4O offer some insight into the bonding of suboxide clusters.[76,77] The most stable form, even for the positive ion, seems to have tetrahedral geometry. Although the central oxygen atom acquires a negative charge of 0.87, Li–Li bonding makes a large contribution to the total energy.

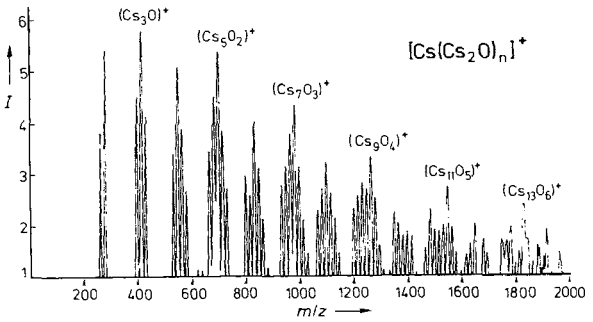

Fig. 19. Mass spectrum of a mixture of cesium oxide clusters formed by quenching Cs vapor in a mixture of He and O_2 gas.

3.4.3. Cesium Oxide Clusters

If the concentration of O_2 in helium is raised to 0.6%, a mixture of clusters is obtained, the mass spectrum of which is shown in Figure 19. Certain clusters containing an odd number of cesium atoms are represented particularly strongly. These clusters have the composition $[Cs(Cs_2O)_n]^+$, two Cs atoms for each oxygen and one extra Cs atom for the positive charge. Each of the ions in these clusters has a rare gas electronic configuration. In this respect they might be regarded as normal oxides. The distribution of charge between the ions is therefore unambiguous, namely, Cs^+ and O^{2-}. Therefore, Equation (a) may be used to calculate the structures of the stable configurations. The parameters, $A = 4000$ eV and $1/\rho = 3.03$ Å^{-1}, were chosen so that the Cs–O distance in $[Cs_5O_2]^+$ is that observed for crystalline Cs_2O.

$[Cs_3O]^+$ has only one stable configuration, a planar structure with a binding energy of 119.46 eV with respect to dissociation into ions. The dimer has two stable configurations. The symmetric dimer with a threefold symmetry axis (Fig. 20, top right) has 0.6 eV more binding energy than the unsymmetric dimer. Larger clusters with a threefold axis are also energetically favored over less symmetric structures. The cluster $[Cs_7O_3]^+$ consists of a Cs_3O_3 ring

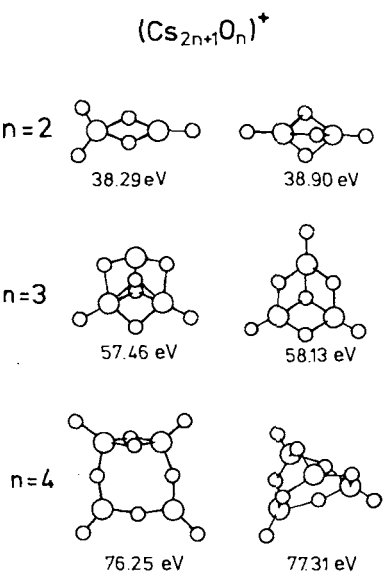

Fig. 20. The most stable configurations of $[Cs_{2n+1}O_n]^+$ clusters containing ions with rare gas electronic configurations. The total binding energy is given below each structure.

along with one central and three terminal Cs atoms. The most stable form of $[Cs_9O_4]^+$ has 77.31 eV of binding energy, 1 eV more than its closest competitor.

3.4.4. *Cesium Superoxide Clusters*

The character of the mass spectrum changes again as the oxygen concentration is increased to about 40% (Fig. 21).

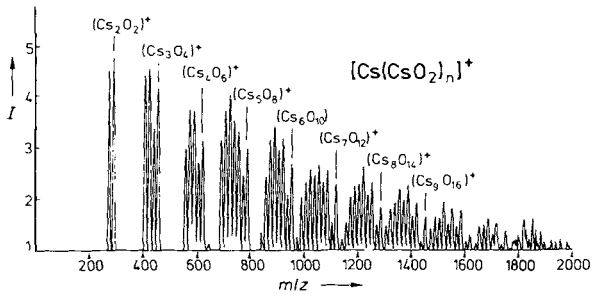

Fig. 21. Mass spectrum of a mixture of cesium oxide and cesium hyperoxide clusters. Each group of peaks begins with clusters containing O^{2-} ions, goes through a maximum for clusters containing O_2^{2-} ions, and ceases abruptly at clusters containing O_2^- ions.

In addition to clusters containing O^{2-} and O_2^{2-} ions, the oxygen-rich clusters $[Cs(CsO_2)_n]^+$, which contain O_2^- ions, are formed. Thus, as expected, clusters containing an even number of oxygen atoms show up more strongly in the mass spectrum. Although no calculations are available for the structure of large superoxide clusters, LCAO-MO SCF calculations indicate that Li_2O_2 is planar with D_{2h} symmetry.[78]

3.5. Lead-Indium Clusters

If the elements in a heteronuclear cluster are chemically equivalent and the vapors of the two elements are mixed together in a ratio of about 1:1, then clusters having all possible compositions should appear in the mass spectrum. The probability of finding a cluster with a given size and composition should follow a binomial distribution.

Lead and indium have nearly the same electronegativity and mix very well; the mass spectrum of a mixture of clusters is correspondingly complicated (Fig. 22). Rather than trying to label all peaks in this spectrum, we have connected the peaks corresponding to clusters containing eight atoms, starting with In_8 and ending with Pb_8. Clusters containing an odd number of In atoms, i.e., containing an even number of electrons (in the ion), appear to be particularly stable. $[Pb_2In_6]^+$ is an exception.

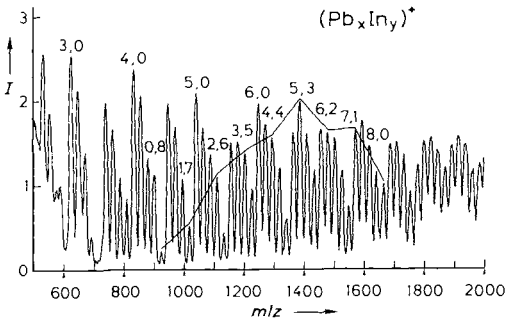

Fig. 22. Mass spectrum of a mixture of Pb-In clusters. The peaks of the pure Pb clusters have been labeled (3,0; 4,0; 5,0; etc.). Each immediately following peak corresponds to the removal of one Pb atom and the addition of two In atoms. The peaks corresponding to eight atom clusters (0,8; 1,7; 2,6; etc.) have been connected.

3.6. Cesium-Lead Clusters

When two metals are mixed together, the properties of the mixture usually do not change continuously with concentration.[5] In the solid state the discontinuities are due to the formation of well-defined intermetallic compounds.[6] Strong evidence exists that such compounds form even in the liquid state.[79,80] Here we present evidence for the existence of analogous heteronuclear clusters in the vapor phase.

Intermetallic compounds are particularly stable if the two metals are characterized by a large electronegativity difference. A classic example is CsAu.[80,81] When Cs and Au are mixed in the ratio 1:1, a compound is formed with an ionic character similar to that of CsCl. In fact, CsAu crystallizes in the CsCl structure. Even though Cs and Au, separately, are excellent electrical conductors, the 1:1 mixture is nonmetallic in both the liquid and solid phases.

The Cs-Pb system is particularly interesting because of the large electronegativity difference between its two components. In an early study of a solution of this alloy in liquid NH_3, *Zintl* and co-workers[5] came to the conclusion that there was polar bonding between the Pb_9^{4-} anions and the alkali metal ions. The obvious question is therefore whether evidence can be found in cluster mass spectra for the existence of Pb_9 groups and for charge transfer between Cs and Pb. A mass spectrum of a mixture of Cs-Pb clusters is shown in Figure 23. Pb_9 is just light enough to

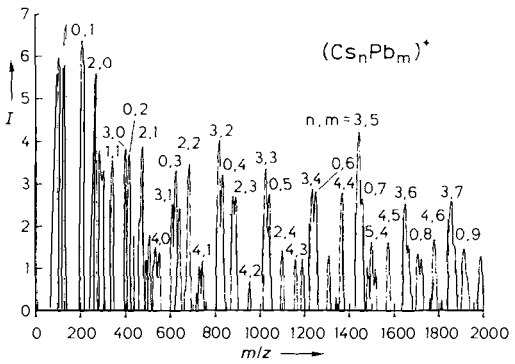

Fig. 23. Mass spectrum of a mixture of Cs-Pb clusters. Peaks corresponding to $[Cs_3Pb_2]^+$ and $[Cs_3Pb_5]^+$ are particularly strong.

fall within the mass region (1-2000 amu) accessible with our mass spectrometer. However, the cluster we are looking for is $[Cs(Cs_4Pb_9)]^+$, since, in addition to nine Pb atoms, four Cs^+ ions are needed to compensate the charge on Pb_9^{4-}, and one additional Cs^+ is required to provide the overall positive charge on the cluster. This cluster has a mass of 2529 amu, well above the mass limit. We solved this problem by investigating a system with lighter elements (see Section 3.7). First, however, there are several features of the Cs-Pb mass spectra that must be pointed

out. Two of the strongest peaks in the spectrum correspond to the clusters $[Cs_3Pb_2]^+$ and $[Cs_3Pb_5]^+$. As discussed below, evidence exists[82] that Pb_5 is a very stable polyanion and has the exact charge required to explain the mass peak, i.e., Pb_5^{2-}.

Although *Zintl* was able to identify many polyanions in solution, these ions did not prove to be sufficiently stable to act as building blocks for the construction of crystals when the solvent was evaporated. This problem was solved by *Corbett* and co-workers[83] who stabilized the sodium salts of the polyanions in crystals by complexation with 4,7,13,16,21,24-hexaoxa-1,10-diazatricyclo[8.8.8]hexacosane (2,2,2-crypt). In this way they were not only able to grow the salt $[2,2,2\text{-crypt } Na]_2^+[Pb_5]^{2-}$ but also to determine the structure of the P_5^{2-} polyanion (trigonal bipyramidal).

Thus, the strongest peak in the mass spectrum (for a cluster containing more than two atoms) corresponds to $[Cs_3Pb_5]^+$. The structure can probably be described as a cluster within a cluster; that is, a covalently bonded, trigonal bipyramid of five Pb atoms ionically bonded to three, symmetrically placed, outer Cs ions.

3.7. Cesium-Tin Clusters

The Cs-Pb system has the advantage that the small number of isotopes present results in sharp mass peaks. However, Pb is so heavy that the stability of two important clusters, the Zintl cluster $[Cs_5Pb_9]^+$ and the cluster $[Cs_5Pb_{10}]^+$, cannot be checked with our spectrometer. What is the significance of this second cluster? We stated in the introduction that two types of information concerning stability can be obtained from the mass spectra of clusters. A single, intense, isolated mass peak indicates a highly stable cluster; a periodicity in the mass spectrum means that this cluster can be used as a building block to construct larger clusters. Since $[Cs(Cs_2Pb_5)]^+$ is stable, the question arises whether the next cluster in the series $[Cs(Cs_2Pb_5)_2]^+$ is also stable. In order to determine the stability of such clusters we turn to the analogous system containing the lighter element Sn. This change has the disadvantage, however, that, because Sn has many more isotopes, the mass peaks are broader. A mass spectrum of a mixture of Cs-Sn clusters is shown in Figure 24. Although the mass peaks are broad, pure Sn clusters containing as many as ten atoms can be identified. Among the heteronuclear clusters, $[Cs_3Sn_5]^+$, $[Cs_3Sn_9]^+$, and $[Cs_5Sn_9]^+$ appear to be particularly stable (intense mass peaks). The first cluster type was already observed in the Cs-Pb system; the last cluster was expected from earlier work.[5,83]

The cluster $[Cs_3Sn_9]^+$ supports the existence of the polyanion Sn_9^{2-}. Although this polyanion has never been observed for Sn, a Ge analogue has been stabilized[83] as part of a complicated solid, [(2,2,2-crypt $K)_6$ $Ge_{18}\cdot 2.5$ en], which contains Ge_9^{4-} and Ge_9^{2-} anions. The structure of Ge_9^{2-} is probably similar to that of Sn_9^{2-} (Fig. 25).

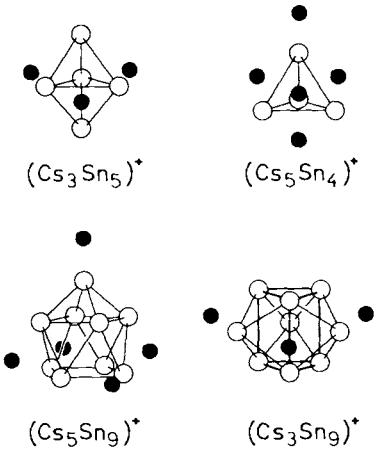

Fig. 25. The structure of several polyanions (empty circles) [24-28] and the probable distribution of alkali metal ions (filled circles) in the corresponding Cs-Sn clusters.

Not found in the mass spectrum of Cs-Sn clusters (Fig. 24) is a strong peak corresponding to $[Cs(Cs_2Sn_5)_2]^+$. That is, the Sn_5^{2-} polyanion does not act as a building block for larger clusters and is therefore less likely to be found as a unit in pure crystals.

Increasing the Cs partial pressure results in the cluster mass spectrum shown in Figure 26. All peaks due to pure Sn clusters are absent. Two series of peaks emerge—one for clusters containing three Cs atoms and the other for clusters containing five Cs atoms. This selectivity reflects the strong tendency to form clusters with paired electrons only. Sn atoms contain an even number of valence electrons, Cs atoms an odd number. However, one Cs electron is ejected on cluster ionization. Therefore, an odd number of Cs atoms leads to an even number of electrons in the cluster ion.

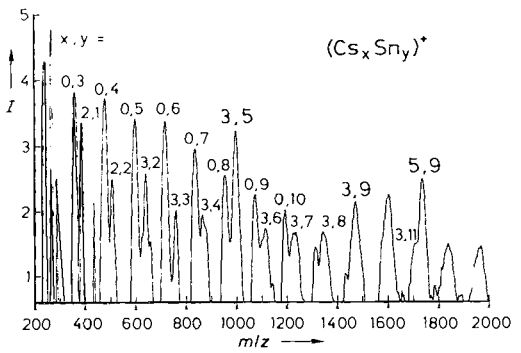

Fig. 24. Mass spectrum of a mixture of Cs-Sn clusters. The peaks are broad due to the large number of Sn isotopes. The clusters $[Cs_3Sn_5]^+$ and $[Cs_5Sn_9]^+$ are particularly stable.

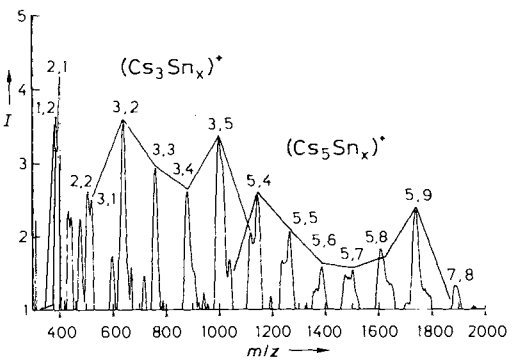

Fig. 26. Mass spectrum of a mixture of Cs-Sn clusters.

Among clusters having a higher Cs content, $[Cs_5Sn_4]^+$ is unusually stable. This may indicate the presence of the polyanion Sn_4^{4-}. Since this anion is isoelectronic with P_4, it would be expected to have a tetrahedral structure. In fact, tetrahedral Ge_4^{4-} units have been observed in lithium and sodium germanide crystals.[84-86] $[Cs_5Sn_4]^+$ could also be described as $[Cs(Cs_2Sn_2)_2]^+$. The mass peak corresponding to the first member of this sequence, $[Cs(Cs_2Sn_2)]^+$, is also strong.

3.8. Indium–Phosphorus Clusters

InP is a good semiconductor. However, the InP molecule is not found in the vapor phase. On evaporation, InP dissociates into In atoms and P_4 and P_2 molecules. Therefore, we would not have been surprised to find that In and P do not react in the vapor phase—but they do. A mass spectrum of the mixture of clusters is shown in Figure 27. The shaded peaks correspond to pure In clusters. The peaks immediately following each shaded peak correspond to clusters containing one or two P atoms. Clusters containing three P atoms are also present but they are one order of magnitude weaker. In Figure 27 we have joined with a short vertical bar the peaks of clusters containing one or two P atoms but the same number of In atoms. The peak corresponding to $[In_6P]^+$ is stronger than that of $[In_6P_2]^+$, whereas the peak identified as $[In_7P]^+$ is weaker than that of $[In_7P_2]^+$. In general, $[In_xP]^+$ clusters are more stable for even values of x and $[In_xP_2]^+$ clusters are more stable for odd values of x. This is another manifestation of the rule that stable clusters prefer to have an even number of electrons. $[In_5P]^+$ is an exception to this rule. Two other clusters that stand out from the rest are $[In_9P_2]^+$ and $[In_8P_3]^+$.

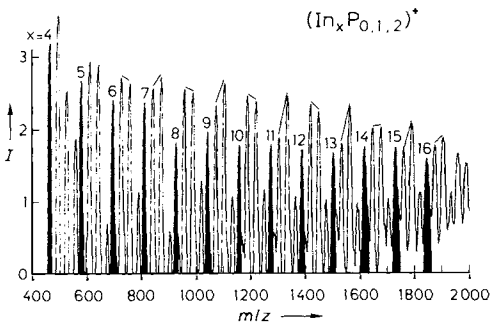

Fig. 27. Mass spectrum of a mixture of In–P clusters formed by combining red phosphorus vapor (390 °C) with indium vapor (970 °C). Black peaks correspond to pure In clusters. Each subsequent peak corresponds to the addition of one more P atom. Clusters containing an odd number of atoms tend to be more stable.

3.9. Potassium–Phosphorus Clusters

A mass spectrum of clusters formed by quenching the mixed vapors of red phosphorus and potassium is shown in Figure 28. Analysis of this spectrum reveals a double periodicity; that is, two highly stable building blocks exist. One series corresponds to the clusters $[K(K_3P_7)_n]^+$. P_7^{3-} is a well-known[8] polyanion of phosphorus occurring in several compounds, including K_3P_7. The other series indicates the existence of a new polyanion, P_4^{2-}. The clusters observed in this case are $[K(K_2P_4)_n]^+$. Also easily identified are the mixed clusters $[K(K_2P_4)_n(K_3P_7)_m]^+$. The polyanion P_4^{2-} may have the butterfly configuration (Fig. 28), already observed[87] in R_2P_4 ($R=(Me_3Si)_2N$, 2,4,6-tBu$_3$C$_6$H$_2$).

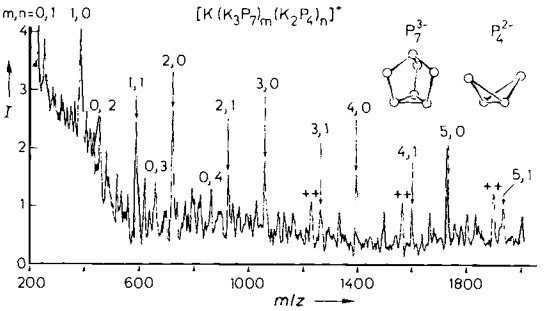

Fig. 28. Mass spectrum of a mixture of K–P clusters formed by combining potassium vapor (230 °C) with red phosphorus vapor (390 °C) in cold He gas. The clusters contain the phosphorus polyanions P_7^{3-} and P_4^{2-}.

3.10. Clusters Prepared from Elements of the 5th and 6th Main Groups

Arsenic and sulfur combine to form a rich variety of compounds. As_4S_4 (realgar) is composed of eight-atom molecules weakly bonded to one another by van der Waals forces. As_2S_3 has a polymeric layer structure (orpiment). Finally, molten As–S can be quenched to form a glass. One motivation for studying the relative stability of As–S clusters is the identification of other highly stable building blocks, which could lead to the synthesis of new compounds. Moreover, information concerning the stability of cluster ions in the vapor phase could shed light on the structure of glasses.

Before examining the results of experiment, it is useful to first consider qualitatively what types of clusters might be expected in quenched vapors containing various As:S ratios. Pure arsenic vapor is known to contain As_4 molecules. On quenching the vapor, these molecules would presumably condense into As_{4n} clusters composed of tetrahedral units weakly bonded to one another. The first sulfur atoms to be incorporated into the As_4 tetrahedral unit can be expected to bridge As atoms. This will be possible until all six edges of the tetrahedron are occupied by S atoms. High stability is expected for the symmetric molecules As_4S_3, As_4S_4, and As_4S_6 (Fig. 29). Pure sulfur has two crystalline forms, which consist of ordered arrays of S_8 rings. These rings can persist even into the melt. Therefore, clusters composed of S_8 rings weakly bonded together would not be unexpected. On the other hand, sulfur also forms polymer chains. Addition of a small amount of As to the vapor could result in the linking of rings and chains together. Two of the bonds to arsenic are required in order to incorporate the As atom into the ring. The remaining valence is available for branching (Fig. 29, top right), or it can form an As–As bond with a second arsenic atom in the same ring or in another sulfur ring.

Before analyzing the relatively complex mass spectra of As–S clusters, it is instructive to first consider the spectra of two seemingly closely related materials, phosphorus sul-

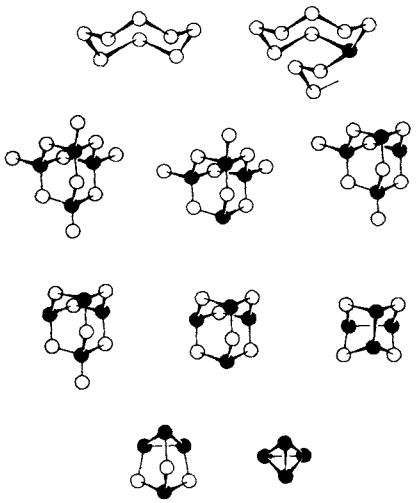

Fig. 29. Some probable structures of As_nS_m molecules and clusters. Filled circles are As atoms, empty circles are S atoms.

fides and arsenic oxides. The mass spectrum of a mixture of clusters formed by quenching the vapor of P_4S_3 in helium gas is shown in Figure 30. The analysis of this spectrum is made difficult by the similarity of the atomic masses of the two component atoms, ^{31}P and ^{32}S. In principle, we can determine from a low-resolution mass spectrum only the total number of atoms in a cluster. Each

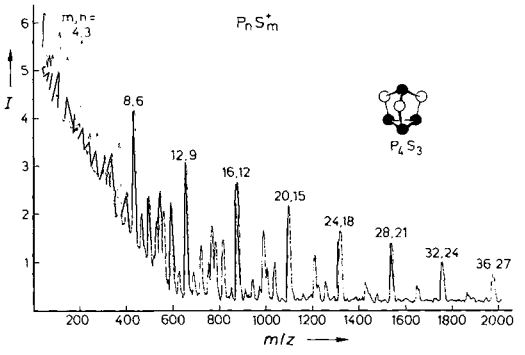

Fig. 30. Mass spectrum of clusters formed by quenching of P_4S_3 vapor.

strong line in the spectrum is separated from the other strong lines by a distance corresponding to seven atoms. Since P_4S_3 is a stable molecule,[88] the strong lines most likely correspond to the clusters $[P_4S_3]_n^+$ (n = 1–9). The next strongest lines occur exactly halfway between the strongest lines and are, therefore, probably due to the doubly ionized clusters $[P_4S_3]_n^{2+}$. Double ionization without fragmentation appears to be more probable in large clusters, where the excess positive charge can occupy a greater volume, thus reducing the energy of the species. The weaker lines correspond to fragments. The most important feature of the mass spectrum of the P–S clusters can be seen at first glance: it is extremely simple. Singly and doubly charged clusters of only one type are observed. These clusters are constructed from P_4S_3 building blocks. Presumably, these units are only weakly bonded to one another, as is the case in the molecular crystal. This simplicity is in sharp contrast to the mass spectrum of As–S clusters (see below).

The mass spectrum of clusters formed by quenching the vapor of As_2O_3 in helium is also easy to interpret (Fig. 31).[89] The mass peaks of the clusters $[As_4O_6]_n^+$ (n = 1, 2, 3, ...) are strongest. As_4O_6 is a building block in two mod-

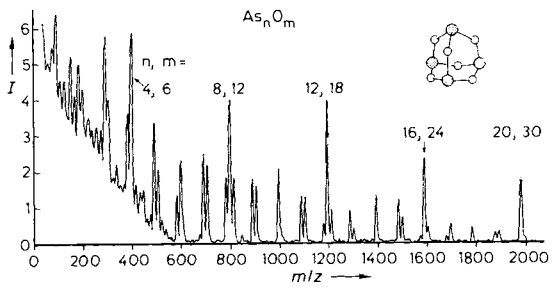

Fig. 31. Mass spectrum of clusters formed by quenching of As_2O_3 vapor.

ifications of arsenic oxide, arsenolite and claudetite. The As_4O_6 units are weakly bonded to one another to form cubic and monoclinic structures in the crystal. Since the most intense lines in the cluster mass spectrum belong to As_4O_6, As_8O_{12}, $As_{12}O_{18}$, $As_{16}O_{24}$, and $As_{20}O_{30}$, it is clear that stable As_4O_6 units are also building blocks in the formation of clusters. The next strongest peaks occur exactly halfway between the strongest peaks and are therefore probably due to either $[As_4O_6]_n^{2+}$ or $[As_2O_3]_n^+$. This ambiguity did not exist for the corresponding peaks of the P–S clusters. In that case they were identified as doubly ionized clusters.

Figure 32 shows the mass spectrum of clusters formed by the evaporation of As_2S_3 glass.[89] The spectrum contains many lines, but all can be assigned to $[As_nS_x]^+$ clusters. The peaks corresponding to n = 4, 6, 8, and 10 have been labeled explicitly. The remaining peaks are due to clusters with odd values of n. Particularly strong lines are observed, for example for $[As_4S_3]^+$, $[As_4S_4]^+$, $[As_4S_8]^+$, $[As_6S_9]^+$, $[As_8S_{13}]^+$, and $[As_{10}S_{17}]^+$. It would not be proper to conclude that these clusters necessarily occur in the beam of neutral clusters, because relatively high energy (70-eV) electrons have been used for ionization. This results in high sensitivity but also in a high degree of fragmentation. It is valid to assume, however, that a strong line in the mass spectrum indicates the existence of a highly stable cluster of the same mass, be it neutral cluster or ionized fragment. The fragmentation, far from being a hindrance, allows us to examine the stability of a larger variety of clusters than is found in the beam of neutral clusters.

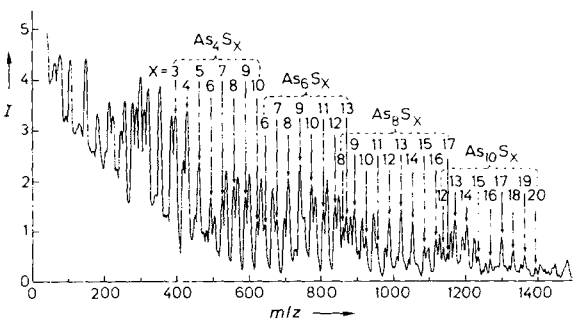

Fig. 32. Mass spectrum of clusters formed by quenching As_2S_3 vapor.

Although many As–S clusters can be identified as being highly stable, only As_4S_4 is observed to act as a building block in the formation of larger van der Waals clusters. Many of the other clusters, such as $[As_7S_{13}]^+$ are probably stable only in the ionic form and are therefore not suitable as building units in the absence of charge compensating anions. On the other hand, these stable ions could be of interest in the synthesis of ionic cluster compounds.

As_2S_3 condenses into a glassy state. As_2S_3 glass prepared from the melt is thought to contain almost exclusively As–S bonds.[90] As_2S_3 condensed from the vapor phase, on the other hand, seems to contain a large fraction of homonuclear bonds. Assuming that As_2S_3 glass has the same local composition as these clusters, we can draw the following conclusions: The molecule As_4S_6 plays no important role in the structure of As_2S_3 glass. Our mass spectra suggest that the first stable building block with composition $As_{2n}S_{3n}$ is the molecule As_6S_9. In addition, excess sulfur does not result in the formation of S–S bonds but rather in fourfold-coordination of As atoms by terminal sulfur atoms.

4. Concluding Remarks

Not all elements are equally suited for the type of investigation reported in this article. The ideal element has the following properties: a high vapor pressure at low temperature; only one isotope; high reactivity; not too large but not too small atomic mass. If an element is too heavy, large clusters cannot be observed in the mass range available to us (0–2000 amu). If the element is too light, the masses of the reaction products overlap one another, making it difficult to assign mass peaks.

It would appear from these findings that a strong peak in a mass spectrum usually reflects a high stability of the corresponding charged cluster. This is true not only for cluster ions, for example $[Rb_{14}Cl_{13}]^+$, but also for the more covalently bonded suboxides and subhalides for which the total electron spin seems to play a decisive role. The question arises to what extent the stability of the neutral parent cluster influences the mass spectra. The results for the pure sulfur clusters and for As–O, As–S, P–O, and P–S clusters indicate that very stable neutral clusters (S_8, As_4O_6, P_4S_3) can indeed be observed as positive ions by mass spectroscopy even though the removal of an electron decreases their stability. However, these "neutral clusters' are so strongly bonded that they appear in the solid, liquid, and vapor phases and are therefore more appropriately called molecules. In summary, neutral clusters composed of exceptionally highly stable units (molecules) can appear as strong peaks in mass spectra. However, in general, the character of a mass spectrum is determined by the stability of charged fragments.

Although the stable clusters M_9O_2 and $M_{11}O_3$ found in cesium and rubidium suboxide crystals can be thought of as being constructed from face-sharing M_6O octahedra, our mass spectrometric study shows that the clusters $[M_6O]^+$ and $[M_6S]^+$ are particularly unstable. Therefore, this cluster probably does not act as a building block for the growth of larger clusters.

An important finding of our investigations is the rule that stable clusters contain an even number of electrons. This rule is particularly valid for subhalide and suboxide clusters and indicates that a strong covalent contribution is made to the bonding of metal-rich clusters. The normal halides, for which each ion has a rare gas electronic configuration, can be well described by a purely ionic model of the bonding.

Mass spectrometry of clusters formed by the reaction and quenching of elementary vapors should prove to be of value in the search for new compounds. The composition of the clusters can be changed quickly and continuously by adusting the oven temperature of each of the elements. The relative stability of each cluster can be immediately determined from the mass spectrum. However, it is important to remember that it is usually the stability of a charged fragment that is being measured.

Mass spectra are capable of indicating two different degrees of cluster stability. An isolated, intense mass peak indicates a high stability for a particular cluster. A periodic appearance of intense peaks indicates that a cluster is stable not only as an isolated unit but can be used as a building block in the construction of larger clusters. It should be possible to synthesize solids from the same unit. The two kinds of stability are illustrated by clusters containing the two polyanions Sn_5^{2-} and P_4^{2-}. Although $[Cs(Cs_2Sn_5)]^+$ is stable as an isolated cluster, it does not appear to have a strong tendency to build larger units $[Cs(Cs_2Sn_5)_n]^+$. The tetraphosphorus dianion does occur in the sequence of mass peaks $[K(K_2P_4)_n]^+$ and is therefore a candidate for a new solid compound.

Many stimulating discussions with H. G. von Schnering and A. Simon are gratefully acknowledged.

New Methods for the Synthesis of Glycosides and Oligosaccharides—Are There Alternatives to the Koenigs-Knorr Method?

New Synthetic Methods (56)

By Richard R. Schmidt*

Dedicated to Professor Rudolf Gompper on the occasion of his 60th birthday

Glycoproteins, glycolipids, and glycophospholipids (glycoconjugates) are components of membranes. The oligosaccharide residue is responsible for intercellular recognition and interaction; it acts as a receptor for proteins, hormones, and viruses and governs immune reactions. These significant activities have stimulated interest in oligosaccharides and glycoconjugates. With their help it should be possible to clarify the molecular basis of these phenomena and to derive new principles of physiological activity. Major advances in the synthesis of oligosaccharides have been made by the use of the Koenigs-Knorr method, in which glycosyl halides in the presence of heavy-metal salts are employed to transfer the glycosyl group to nucleophiles. The disadvantages of this procedure have led to an intensive search for new methods. Such methods will be discussed in this article. Emphasis is placed on glycoside and saccharide formation by 1-*O*-alkylation, on the trichloroacetimidate method, and on activation through the formation of glycosylsulfonium salts and glycosyl fluorides.

1. Introduction

Carbohydrates and proteins were long viewed quite differently. Proteins were considered particularly important because of enzymatic activity (i.e., as carriers of specific biological information). Corresponding properties were not established for the carbohydrates; they were assumed to have only structural, protective, and energy-storing functions. The large number of biological polymers in which carbohydrates and proteins are chemically linked to each other by a covalent bond (glycoproteins) were not recognized until the beginning of the 1950s. Thus, much effort was often expended in attempts to remove "sugar impurities" from proteins or "protein impurities" from sugars. Only in the last twenty years has it been shown that covalently linked glycoconjugates of carbohydrates and proteins are ubiquitous and occur, for example, as components of cell membranes (Fig. 1).[1-3] In addition, glycoconjugates of carbohydrates and lipids (glycolipids) or phospholipids (glycophospholipids) are encountered in membranes.[4] The biological information in these substances is carried mainly by the carbohydrate part.[5,6]

The membranes of different cells differ from one another in their composition and in the arrangement and mobility of their components. A central role of the immune system of mammalian organisms is the recognition and discrimination of endogenous and exogenous structures.[7] The immune system monitors the constancy of the cellular surfaces in the organism. It responds when the tolerance limits of the endogenous surface structure are exceeded.

Membrane glycoproteins and lipids, specifically their oligosaccharide components, govern these tolerance limits;[2,5,8] they are therefore decisive for specific immune reactions. Moreover, they fulfill important functions in intercellular recognition and interaction, in the control of cell growth and thus tumor formation, and in the interaction with biologically active factors such as enzymes, hormones, bacteriotoxins, and viruses. As an example, glycosphingolipids undergo significant changes when malignant cell growth starts. In particular, the structure of the hydrophilic carbohydrate residue becomes simplified.[8]

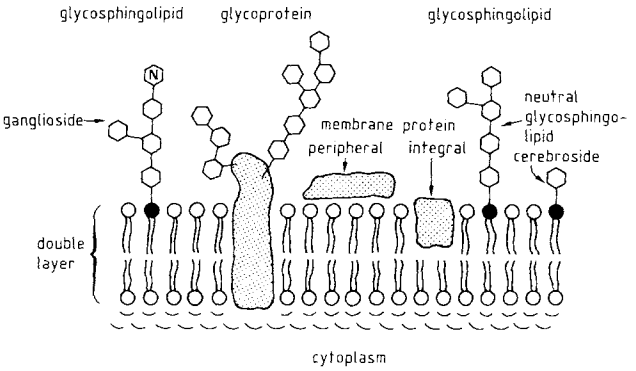

Fig. 1. Cell membranes of erythrocytes with carbohydrate and protein components, schematic. The hexagons represent hexopyranose units, the hexagon marked with N indicates an *N*-acetylneuraminic acid unit. ○= in the double layer represents a phosphoglycerolipid or phosphosphingolipid, ●= represents a ceramide.

The biological significance of glycoconjugates should be viewed by the synthetic chemist as a major challenge. The synthesis and modification of oligosaccharide units and their coupling with appropriate lipids, phospholipids, and proteins is essential to extend our knowledge on the molecular mode of action of glycoconjugates and, furthermore, to derive new principles of physiological activity, since homogeneous compounds are often only very difficultly accessible from biological material.

2. Synthesis of Complex Oligosaccharides—General Aspects

2.1. General Remarks

The synthesis of oligosaccharides is characterized by a much larger number of possibilities for coupling than that of other natural biopolymers, such as peptides or proteins and ribo- or deoxyribonucleotides. The comparison of the number of possible isomers of di-, tri-, tetra-, and pentasaccharides with those of the corresponding peptides and nucleotides given in Table 1 impressively illustrates this point.[9] The wide structural variety renders sugars and, in particular, oligosaccharides ideal as carriers of biological information. In contrast to peptides and nucleotides, in which the informational content is determined solely by the number and sequence of different monomer units, the informational content of oligosaccharides is fixed additionally by the site of the coupling, by the configuration of the glycosidic linkage (α or β), and by the occurrence of branching. Thus, polymers made up of carbohydrates can carry considerably more information per building block than proteins and nucleic acids.

The structural variety, however, complicates the specific biosynthesis of complex *oligo*saccharides. "Zipper" processes are not known. In general, the formation of each saccharide linkage requires a specific enzyme; thus, in comparison with the synthesis of proteins and nucleic acids, much more effort is required. Therefore it is not surprising that complex *poly*saccharides with corresponding functions are unknown.

The chemical synthesis of oligosaccharides is also more complicated than that of other biopolymers. Up to a few years ago, the unambiguous synthesis of a di- or trisaccharide was an outstanding achievement.[10–12] We have only learned how to synthesize more complex oligosaccharides in the last few years.[13,14] The construction of each individual oligosaccharide poses a new challenge, requiring a knowledge of methods, experience, and experimental dexterity. There are no universal methods either for chemical in vitro or for biological in vivo syntheses.

Table 1. Isomeric possibilities for biopolymers [9]. D- and L-forms not included.

Product	Composition	Number of isomers	
		Peptide, nucleic acid [a]	Saccharide [b]
monomer	Z	1	1
dimer	Z_2	1	11
trimer	Z_3	1	120
tetramer	Z_4	1	1424
pentamer	Z_5	1	17872
monomer	Z	1	1
dimer	YZ	2	20
trimer	XYZ	6	720
tetramer	WXYZ	24	34560
pentamer	VWXYZ	120	2144640

[a] 3′→5′ deoxyribo- or ribonucleic acid. [b] Referred to hexopyranoses (Glc, Gal, Man, ...).

In a disaccharide synthesis, two polyfunctional sugar components must be linked. Regioselectivity is generally achieved when the glycosylating component (glycosyl donor) possesses selectively protected hydroxyl groups and an activating group at the anomeric C atom and when the sugar component with the free hydroxyl group (glycosyl acceptor) possesses protecting groups at all other hydroxyl functions (Fig. 2). Thus, complicated protecting strategies and suitable procedures for activation at the anomeric C atom are required. In addition, the coupling step must oc-

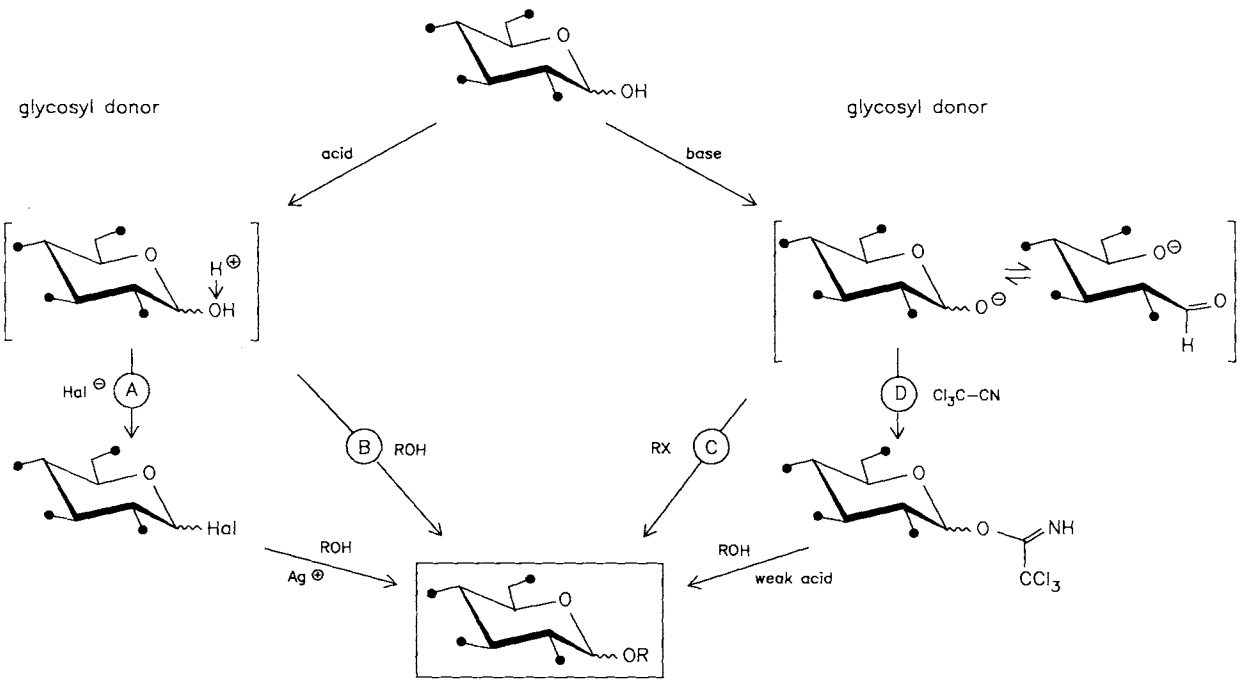

Fig. 2. Syntheses of glycosides and saccharides, schematic. R = alkyl, aryl, (mono)saccharide moiety. Ⓐ Koenigs-Knorr method (glycosyl halide activation). Ⓑ Fischer-Helferich method (acid activation). Ⓒ 1-*O*-Alkylation (base activation). Ⓓ Trichloroacetimidate method (base-acid activation); instead of trichloroacetonitrile, other reagents of the type A≡B or A=B=C can be employed (e.g., ketene imines $R_2C{=}C{=}NR$).

cur diastereoselectively with respect to formation of an α- or β-linkage.

2.2. Oligosaccharides by the Koenigs-Knorr Method

In the classical Koenigs-Knorr method, dating from 1901, and the subsequently developed, efficient variants, the activation is achieved through the formation of glycosyl halides (halogen = bromine, chlorine) and their reaction in the presence of heavy-metal salts (preferentially silver salts).[13-16] Recent reviews[13,14] give the following general picture.

(1) The reactivity of the glycosyl donor (i.e., the glycosyl halide) can be varied over relatively wide ranges by the choice of the halogen, the catalyst (promotor), and the protecting group pattern.
(2) Diastereoselectivity in the coupling is attained by
   (a) participation of neighboring groups for β-glycosides of D-glucose, D-glucosamine, D-galactose, and D-galactosamine and for α-glycosides of D-mannose, L-fucose, and L-rhamnose,
   (b) in situ anomerization of the α-glycosyl halide to the more reactive β-glycosyl halide,[17] which reacts preferentially to give the more stable α-glycosides of D-glucose, D-glucosamine, D-galactose, and D-galactosamine (exploitation of the anomeric effect), and
   (c) heterogeneous catalysis,[18] which gives good results in the difficult formation of the β-D-mannose linkage.
(3) The reactivity of the glycosyl acceptor, which, for D-glucopyranose, gives the approximate order water > methanol > ethanol > 6-OH ≫ 3-OH > 2-OH > 4-OH groups of D-glucose, is controlled by the choice of the protecting groups (steric and electronic effects) and by modification of the structure (e.g., formation of 1,6-anhydro structures).[13]

The application of these generalizations has led to excellent results.[13,14]

In spite of the development of efficient variants, however, severe, partly inherent disadvantages of the Koenigs-Knorr method for the synthesis of oligosaccharides could not be overcome. These disadvantages include the following:

(1) Relatively harsh conditions are needed for the generation of the glycosyl halide;
(2) The glycosyl halides exhibit low thermal stability and can often be generated only in situ and at lower temperatures, thus necessitating the use of compounds that are frequently sterically nonhomogeneous and sometimes even impure;
(3) the glycosyl halides are highly sensitive to hydrolysis;
(4) the heavy-metal salts are expensive;
(5) the use of heavy-metal salts, especially in large scale reactions, is often dangerous (toxicity of mercury salts, explosions with silver perchlorate; these risks can be reduced sometimes by using catalytic amounts).

Many attempts have been made to develop competitive methods, which do not require the use of heavy-metal salts, to synthesize glycosides or saccharides.[19] However, until recently, their general significance was described as being modest.[13]

2.3. Derivation of New Principles for Glycoside Synthesis

The Koenigs-Knorr method for glycoside synthesis consists of a two-step reaction (Fig. 2, Path Ⓐ): introduction of a leaving group at the anomeric center and catalytic nucleophilic substitution of this leaving group. In general, for a sterically uniform α- or β-coupling, both steps must proceed under steric control. This is achieved mainly by exploitation of stereoelectronic effects (anomeric and inverse anomeric effects) and neighboring group participation and by the choice of catalyst (see Section 2.2). The acid-catalyzed glycosylation according to the Fischer-Helferich method (Fig. 2, Path Ⓑ), which proceeds via normal acetal formation, does not involve an isolable intermediate and, partly as a result of its reversibility, has attained hardly any significance for the synthesis of complex saccharides. A new saccharide synthesis must meet the following requirements:[19]

(1) The first step must involve a sterically uniform activation of the anomeric center with formation of a stable glycosyl donor having either an α- or β-structure,
(2) the second step should involve a catalyzed, sterically uniform, irreversible glycosyl transfer to the acceptor, proceeding with either retention or inversion at the anomeric center and in high chemical yield; the configuration of other glycosidic bonds must not be affected in the process.

Apart from the acid activation (Fig. 2, Paths Ⓐ and Ⓑ), the simplest form of activation is base activation with formation of the 1-alkoxide of a pyranose or furanose (Fig. 2, Paths Ⓒ and Ⓓ). Direct 1-*O*-alkylation (Section 3; Fig. 2, Path Ⓒ) is unlikely to fulfill both of the requirements given above for a glycoside synthesis. Ring-chain tautomerism and anomerization, instability of aldehydic intermediates in basic media, and insufficient or undifferentiated reactivities of the α- and β-alkoxides lower the expectations for a stereocontrolled glycoside or oligosaccharide synthesis; or, are there other, unrecognized controlling factors?

The stereocontrolled trapping of the base-generated 1-alkoxide by addition to a triple bond system A≡B (or to a compound containing cumulative double bonds A=B=C) to give a stable intermediate (Fig. 2, Path Ⓓ), would seem to be more promising than the direct 1-*O*-alkylation. The formation of stable intermediates is promoted by independent catalysis of the activation and glycosylation steps. Thus, after basic activation and trapping (first step), mild acid treatment, which leads to irreversible acetal formation, remains as the simplest form of catalysis for the glycosylation (second step). The multiple bond system A≡B (or A=B=C) must be selected accordingly. The trichloroacetimidate method makes use of this apparently simple

concept (Section 4). In addition, other imidate methods and other base-catalyzed 1-*O*-activation methods will be discussed.

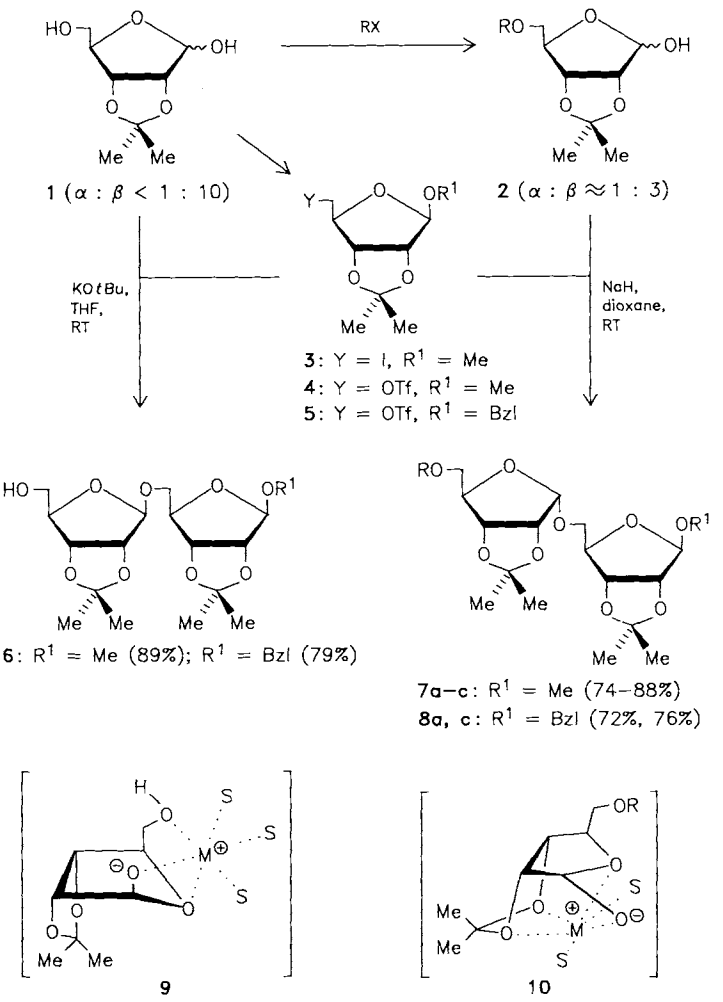
The exchange of the anomeric hydroxyl group of carbohydrates for chlorine or bromine according to the Koenigs-Knorr method has been extended in recent years to include, in particular, the electronegative elements nitrogen, sulfur, and fluorine. Therefore, recent results with other elements as leaving groups will also be mentioned (Section 5).

The examples given in this review have been chosen so as to illustrate typical reaction conditions and results in oligosaccharide synthesis.

3. Direct 1-*O*-Alkylation

3.1. General Considerations

The direct 1-*O*-alkylation of furanoses and pyranoses with simple alkylating agents, particularly methyl iodide and dimethyl sulfate, has long been known.[20-27] Depending on the reaction conditions, either α- or β-glycosides are formed. Furthermore, *Bredereck* and *Hambsch*[28] obtained trehalose mixtures in moderate yields from tetra-*O*-methylglucose and the corresponding glycosyl halide in a basic medium.



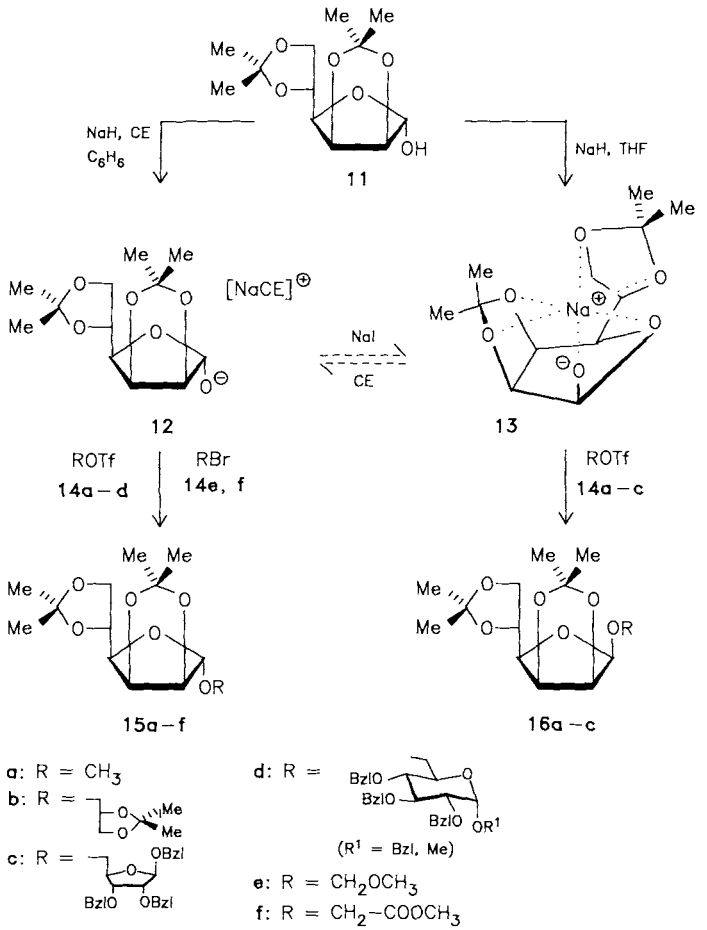
When all remaining hydroxyl groups are blocked by protecting groups, the ring-chain tautomerism between the two anomeric forms and the open-chain form (Fig. 2, Path ©) alone gives three possible sites of attack for the alkylating agent. Thus, the yield, regioselectivity, and stereoselectivity of the direct 1-*O*-alkylation are governed by at least the following factors:

(1) the stability of the generated, deprotonated species,
(2) the ring–chain tautomeric equilibrium and its dynamics,
(3) the relative reactivities of the three *O*-deprotonated species.

3.2. Direct 1-*O*-Alkylation of D-Ribofuranose and D-Mannofuranose

In our first experiments, we used the iodine derivative **3** (Y = I) as the alkylating agent, the 2,3,5-protected D-ribose **2a**, and various bases for the 1-*O*-deprotonation. However, this system was not sufficiently reactive.[29] The introduction of the trifluoromethanesulfonate (triflate) leaving group fundamentally changed the situation: Treatment of the 5-*O*-unprotected D-ribose **1** with one equivalent of base and the triflates **4** and **5** afforded exclusively (i.e., regio- and stereoselectively) the β-linked disaccharides **6** in excellent yield (Scheme 1).[30] This result was attributed initially to the preference of substrate **1** for adopting the β-furanose form and to the higher acidity of the anomeric hydroxyl group in comparison with the primary 5-hydroxyl group.

This interpretation was shown to be incorrect by the introduction of bulky protecting groups at the 5-*O* atom of **1** to give the derivatives **2a–c**: 1-*O*-alkylation with the triflates **4** and **5** led almost exclusively to the corresponding α-linked disaccharides **7a–c** and **8a**, **c**, respectively, even though the β-anomer predominates in the 1-*O*-protonated substrates. Therefore, in addition to steric effects of the 5-*O*-substituents, the formation of differing intramolecular complexes (**9** and **10**) of the metal ions with the 1-oxides was suggested.[30]

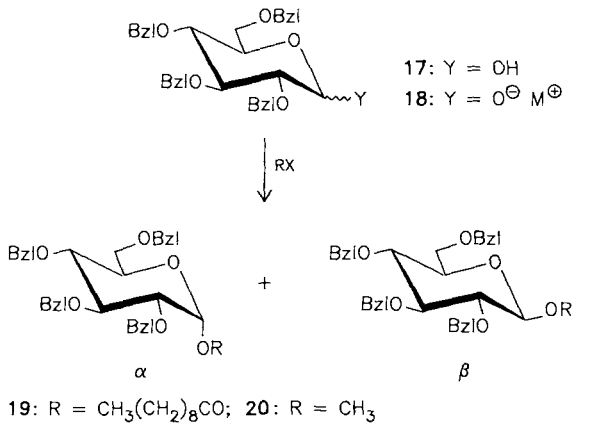


Scheme 1. **a**: R = trityl, **b**: R = methoxytrityl, **c**: R = *tert*-butyldimethylsilyl. — THF = tetrahydrofuran, Tf = trifluoromethanesulfonyl, Bzl = benzyl, S (in **9** and **10**) = solvent molecule.

The effect of the intramolecular metal-ion complexation was further substantiated by investigations on the D-mannofuranose **11**.[31,32] In contrast to the synthesis of the α-D-mannofuranosides **15**, the stereoselective synthesis of the β-D-mannofuranosides **16** by the usual glycosidation methods is difficult.[10,12] The 1,2-*cis* arrangement of the functional groups in **11** is opposed by an unfavorable steric and electronic interaction and the anomeric effect as stereoelectronic effect. Thus, as expected, the α-anomer **15** is obtained from the reaction of **11** with methyl iodide and silver oxide in dimethylformamide (DMF) (Kuhn methylation).[33] However, reaction of the sodium salt of **11** with methyl iodide in benzene gives the β-anomer **16** as the main product.[33] Formula **13** shows that the β-oxide has practically ideal crown ether geometry, which probably stabilizes the β-configuration in less solvating media but

decreases the reactivity.[31,32] Good β-selectivity with especially reactive electrophiles is thus to be expected under kinetic control.

Following this hypothesis, we alkylated **11** with the triflates **14a–c** and obtained almost exclusively the β-D-mannofuranosides **16a–c**. Furthermore, the expected influence of the reactivity of the electrophile on the anomeric ratio could be confirmed by reactions with the α-halo ether **14e** and the α-halo ester **14f** (Scheme 2).[32]



Scheme 2. CE = dibenzo[18]crown-6.

If the intramolecular complexation is responsible for the high β-selectivity, more strongly solvating conditions should promote the α-selectivity. This was confirmed by the addition of an equimolar amount of the crown ether dibenzo[18]crown-6.[31,32] The alkylating agents **14a–f** then gave exclusively the α-D-mannofuranosides **15a–f**. Addition of sodium iodide leads to competition of the sodium ions for the crown ether so that the anion **12** can revert partly to the anion **13**.

3.3. Direct 1-*O*-Alkylation of Glycopyranoses with Primary Triflates

Can the excellent results with respect to both yield and regio- and stereoselectivity obtained by the direct 1-*O*-alkylation of protected and partially unprotected D-ribofuranoses and D-mannofuranoses also be achieved with glycopyranoses? This question was initially examined for reactions with the 2,3,4,6-tetra-*O*-benzyl-D-glucose **17** (Scheme 3).[34,35]

Scheme 3. Reaction of **17** via **18**, Y = O⊖Li⊕, with RX = $CH_3(CH_2)_8COCl$ gives **19**; reaction of **17** via **18**, Y = O⊖Na⊕ with RX = CH_3OTf **14a** gives **20**.

According to *Pfeffer* et al.,[36] **17** exists at room temperature in benzene or THF in an anomeric ratio of α : β ≈ 3 : 2. More recent studies give a value of 4 : 1,[37] which is in better agreement with our results. This ratio is not changed significantly by 1-*O*-lithiation to give **18**, Y = O⊖Li⊕.[36] However, when the acylation of this lithiated species with decanoyl chloride is studied as a function of solvent and temperature, other relations are obtained (Fig. 3). Higher temperatures, especially in benzene, favor the β-product **19β**.[36]

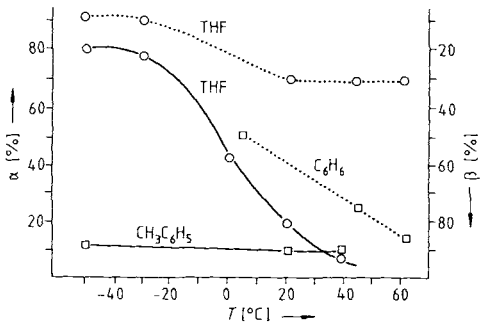


Fig. 3. Reaction of tetrabenzylglucose **17** via **18**, Y = O⊖Li⊕, with decanoyl chloride to give **19α, β** (···) and of **17** via **18**, Y = O⊖Na⊕, with methyl triflate **14a** to give **20α, β** [35] (—) as a function of temperature and solvent.

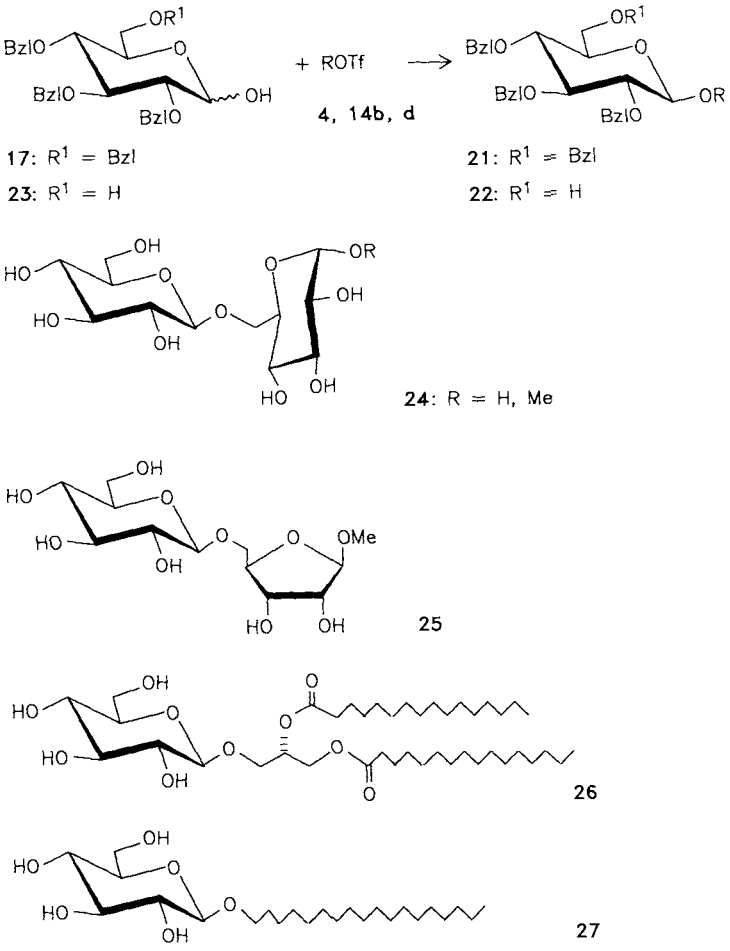
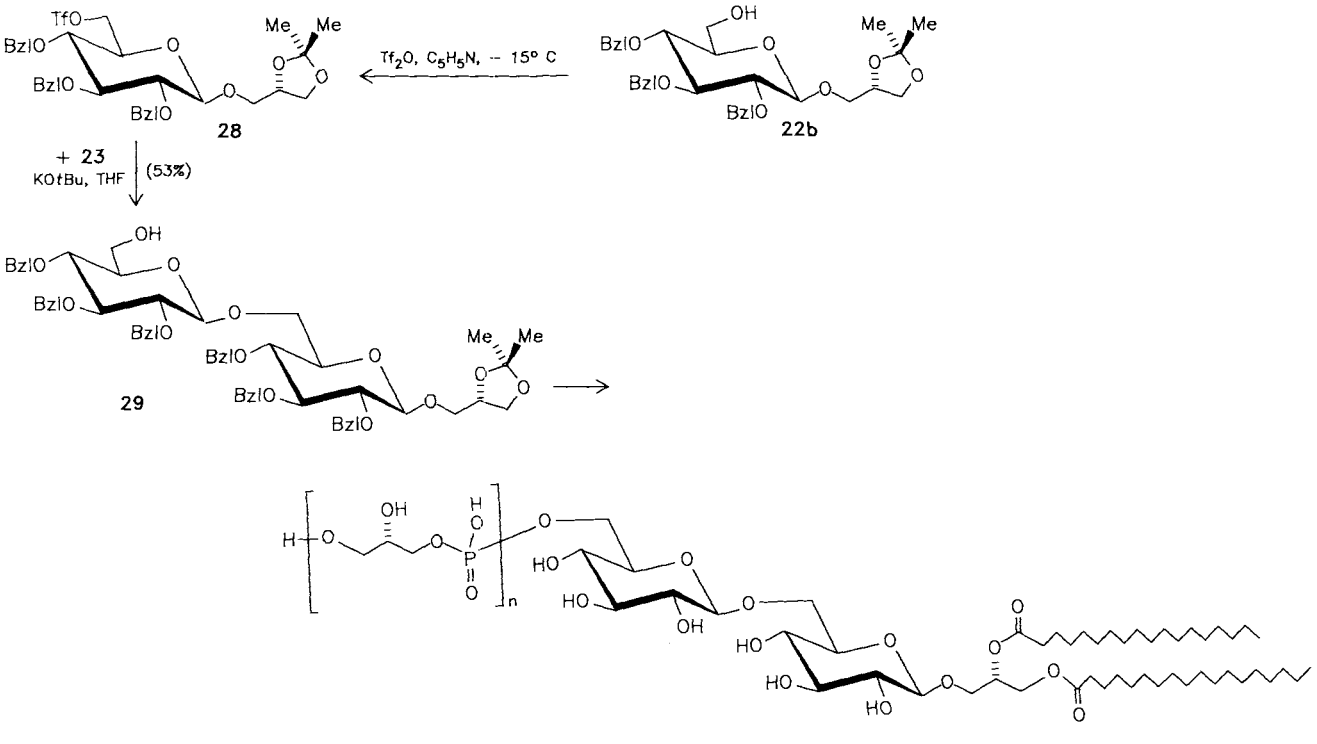


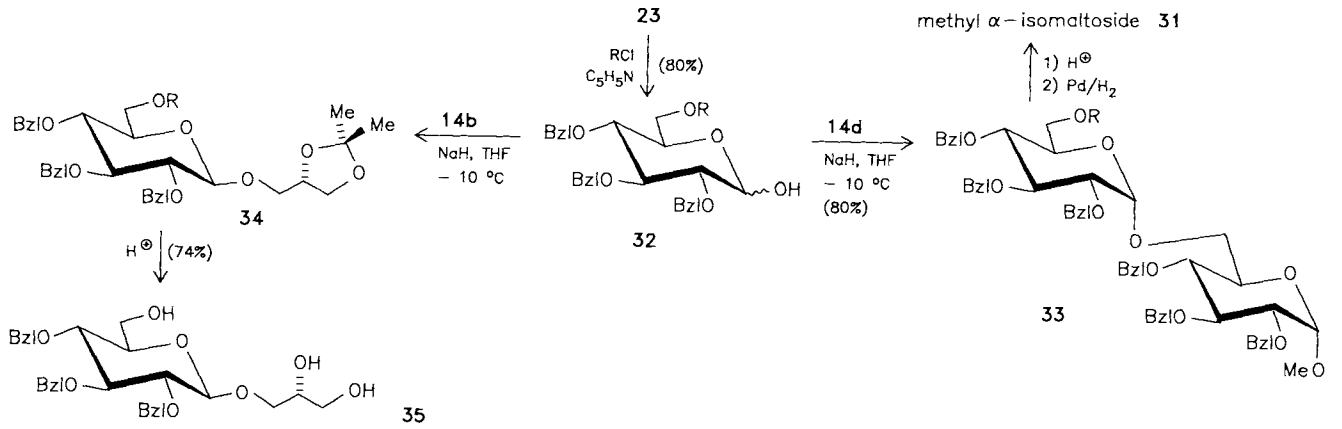
The same result, in principle, is obtained with the sodium salt **18**, Y = O⊖Na⊕, and methyl triflate **14a** (Fig. 3);[35] higher temperatures favor the β-product **20β** even more markedly. The rate of the α/β anomerization and the increased nucleophilicity of the β-oxide salt **18β** were assumed to explain this finding.[34,35] In contrast to the results obtained with the mannofuranose **11**, the addition of crown ether had no significant influence. Thus, intramolecular complexation probably does not play a major role.[29,35]

The 1-*O*-methylation of tetrabenzylglucose **17** demonstrates a method for stereocontrol of this reaction, which



was also successful for reactions with the triflates **4** and **14b,d**. When sodium hydride in dioxane at room temperature was used, the β-glycosides **21** were obtained practically exclusively. The partially protected glucose derivative **23** also underwent regioselective reaction when one equivalent of base was added. Only the β-anomer **22** was formed. Cleavage of the protecting groups afforded the disaccharides **24** and **25** and the glycolipid analogues **26** and **27** in a simple manner and in excellent yields (Scheme 4). Recently, the complex lipoteichoic acid carrier fragments **30** were prepared in this way (Scheme 5).[38,39] Compound **22b** was first converted into the triflate **28**, which underwent direct reaction with **23** to give the 6′-*O*-unprotected disaccharide-glycerol derivative **29**. Compound **29** was transformed in a few steps into product **30**. Similarly, 6-*O*-unprotected 2,3,4-tri-*O*-benzylgalactoses and 2,3,4-tri-*O*-benzylxyloses were combined to give β-pyranosides.[34,40]

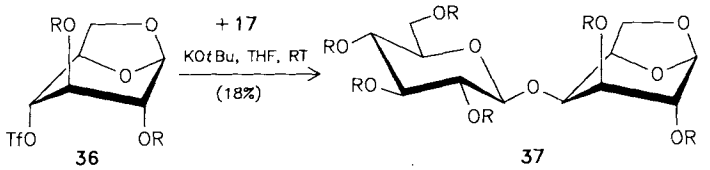
The effect of sterically demanding protecting groups on the stereochemistry of glycoside formation was studied with the help of the 6-*O*-methoxytrityl group in compound **32**.[34,35] At lower temperatures, i.e., when the rate of anomerization is slow, reaction with the triflate **14d** gave, indeed, the isomaltose derivative **33**, which was subsequently deprotected to give **31**. Reaction with the triflate **14b** under identical conditions, however, gave the β-glycoside **34** exclusively. Cleavage of the acid-labile protecting groups of **34** gave the β-glucopyranosylglycerol **35** (Scheme 6). According to the concepts developed above, steric and reactivity differences in the triflates should be responsible for these findings.



The syntheses of β-D-mannopyranosides, like those of β-D-mannofuranosides, are also accompanied by particular difficulties[13] (see Section 2.2). However, the observation

Scheme 4. Conversion of **17** into **21**: NaH, dioxane, RT; of **23** into **22**: KO*t*Bu, THF, RT. **24** is formed from **17** or **23** and **14d** via **21** or **22**, respectively, and **25** is formed from **17** or **23** and **4** via **21** or **22**, respectively.

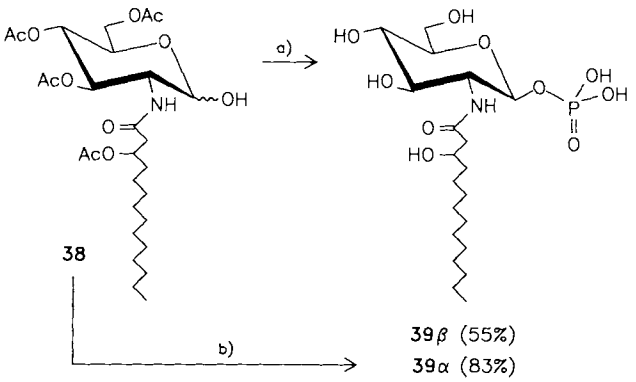
Scheme 5. **22b** is the product formed from **23** and **14b**.



Scheme 6. R = methoxytrityl.

that the thermodynamically less stable anomer is preferentially formed at higher temperatures (cf. Fig. 3) made their direct synthesis also possible.[32]

3.4. Direct 1-*O*-Alkylation with Secondary Triflates



The direct 1-*O*-alkylation of carbohydrates by primary triflates has become a simple method for the synthesis of glycosides and saccharides because of its facility and the yields and stereoselectivities obtained. The question was whether similar results could be obtained with secondary triflates, which are less stable and undergo nucleophilic substitution less readily. Earlier studies had shown that decomposition reactions of the triflates predominate.[40] A modest success, however, was achieved in the reaction of the 1,6-anhydroglucose triflate **36** with the tetrabenzylglucose **17** to give the disaccharide **37**.[40] This example also illustrates the unusual aspect of this method of disaccharide synthesis: as a result of the inversion of configuration of the triflate center, the starting material and the product no longer belong to the same series of sugars (Scheme 7).

Scheme 7. R = Bzl.

3.5. 1-*O*-Acylation and 1-*O*-Phosphorylation

The possibilities for regio- and stereocontrol of 1-*O*-alkylations should also be exploited to a greater extent for directing 1-*O*-acylations and 1-*O*-phosphorylations.[41] The selective 1-*O*-acylation of unprotected lactoses[42] and the 1-*O*-phosphorylation of glucosamine,[43] in particular, should be mentioned. Thus, in analogy to the work of *Granata* and *Perlin*,[44] the β-phosphate **39β** was obtained from the 3,4,6-tri-*O*-acetylglucosamine derivative **38** and dibenzyl phosphorochloridate in the presence of thallium(I) ethoxide as base in benzene/acetonitrile after cleavage of the protecting groups (Scheme 8).[43] The corresponding α-phosphate **39α** was prepared similarly in high yield by the use of butyllithium as base in THF at −60 °C.[43]

Scheme 8. a) 1) TlOEt, benzene/acetonitrile, 2) dibenzyl phosphorochloridate, 3) H_2/Pd, 4) NaOMe; b) 1) BuLi, THF, 2) to 4) as in a).

3.6. Steric Effects, Chelate Effects, and Stereoelectronic Effects on 1-*O*-Alkylation

Primary triflates are excellent reagents for regio- and stereoselective 1-*O*-alkylation, whereby protection of all the other hydroxyl groups of the nucleophile is not necessary. For the furanoses studied, the stereocontrol results primarily from steric and chelate effects, according to present knowledge, whereas for the pyranoses, the rate of anomerization and the different nucleophilicities of the α- and β-oxide atoms are the governing factors. In particular, the increased nucleophilicities of the β-oxide atoms of the gluco-, galacto-, and mannopyranoses studied are worthy of note, because they enable the thermodynamically less stable anomers to be obtained preferentially.

On the assumption that the pyranoses in question have predominantly or exclusively the $^4C_1$ conformation, the higher nucleophilicity of the β-oxide can be attributed to a steric effect in combination with a stereoelectronic effect, resulting from repulsions of the lone electron pairs or from dipole effects (Fig. 4).[19,35,45] This effect[46] should be more pronounced in pyranosyl β-oxides, with three lone electron pairs on the oxide atom, than in pyranosides. Recently, such an effect in pyranosides was discussed briefly in con-

nection with the differing reactivities of the α- and β-anomers.[47,48]

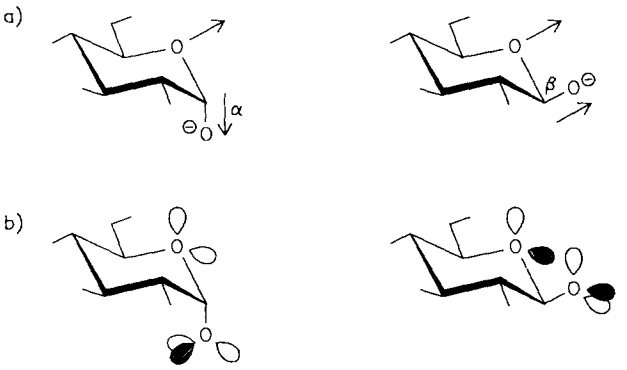


Fig. 4. Increased nucleophilicity of the β-oxide: explanation a) by unfavorable dipole-dipole interaction, b) by repulsion of lone electron pairs.

For the same reasons as with the thermodynamically efficient anomeric effect in the α-mannopyranoses, this kinetically efficient stereoelectronic effect[45] should be particularly pronounced in mannopyranosyl β-oxide. Thus, β-mannopyranosides can be obtained in spite of steric hindrance. The stereoelectronic effects in α- and β-furanosyl oxides should differ less for conformational reasons. The significance of this stereoelectronic effect for kinetically controlled, reversible reactions will become apparent from the results on the formation of *O*-glycosyl trichloroacetimidates (see Section 4.1).

4. Synthesis and Reactions of *O*-Glycosyl Trichloroacetimidates and Other 1-*O*-Activated Carbohydrates

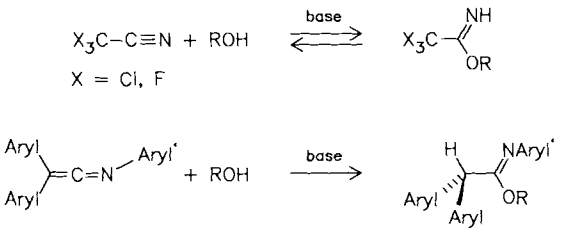
4.1. The Trichloroacetimidate Method—Synthesis of *O*-Glycosyl Trichloroacetimidates

The direct 1-*O*-alkylation of carbohydrates demonstrates that pyranoses and furanoses deprotonated at the 1-*O* atom react analogously to alkoxides. Although the higher acidity of the 1-OH group of the hemiacetal might be expected to result in a lower nucleophilicity of the 1-oxide, the stereoelectronic effect apparently partially compensates for this influence.

These results and the observed stereocontrol suggest that pyranoses and furanoses should undergo base-catalyzed addition directly and in a stereocontrolled manner to suitable triple bond systems A≡B or compounds containing cumulative double bonds A=B=C (see Fig. 2). The stable intermediates thus obtained should, by appropriate choice of the centers A and B or A, B, and C, respectively, have good glycosyl donor properties in the presence of acid. The water liberated in the glycoside formation is transferred, in two separate steps, to the activating agent, which, by taking up water, provides the driving force for the whole process. This simple concept should fulfill the requirements given above for a good glycoside or saccharide synthesis (see Section 2.3).

From these points of view, *O*-glycosyl imidates are suitable intermediates provided that they can be obtained as stable compounds directly from nitriles or ketene imines under base catalysis and that they exhibit a high glycosyl transfer potential upon treatment with acid (cf. Fig. 2). *O*-β-Glycosyl *N*-methylacetimidates, first prepared by *Sinaÿ* et al.,[49] do not fulfill this requirement. They must be synthesized laboriously from α-glycosyl halides in the presence of three molar equivalents of silver oxide. Furthermore, only the β-imidates are known and these have proved to be relatively unreactive in acid-catalyzed glycosidation[13] (see Section 4.3).

Electron-deficient nitriles such as trichloroacetonitrile are known to undergo direct and irreversible, base-catalyzed addition of alcohols to give *O*-alkyl trichloroacetimidates (Fig. 5, X = Cl).[50] This imidate synthesis has the advantages that the free imidates can be isolated as stable adducts, which are less sensitive than their salts to hydrolysis. The pioneering work on this reaction was carried out by *Nef*;[51] in the meantime the reaction has found interesting applications.[52]



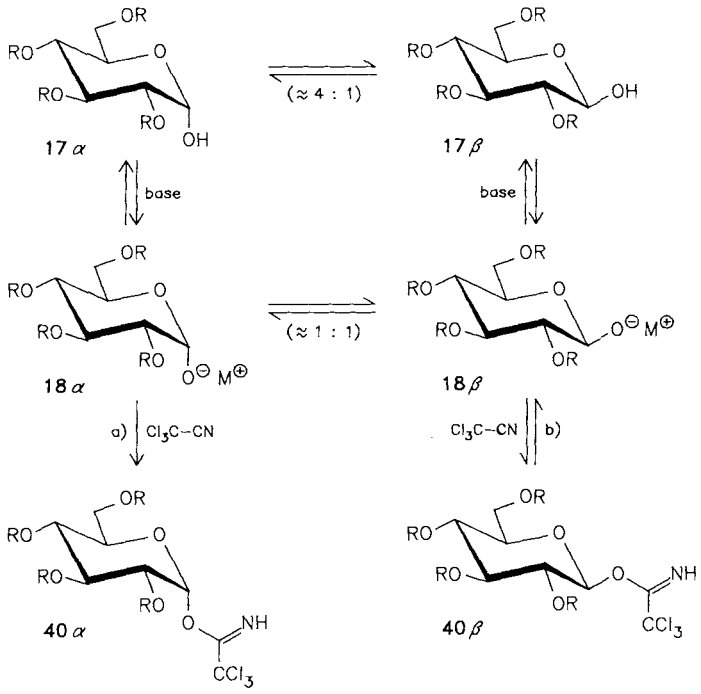


Fig. 5. Base-catalyzed addition of alcohols to activated nitriles and ketene imines.

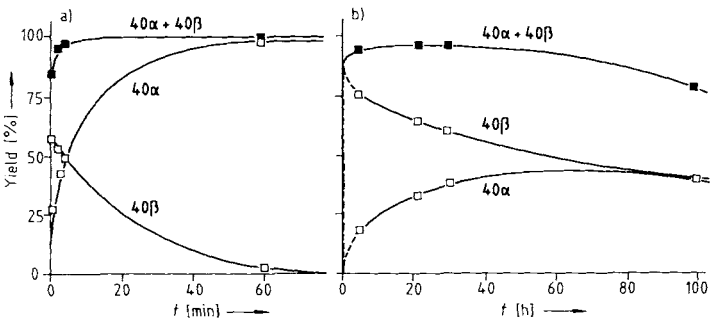
Can the mild, base-catalyzed formation of *O*-alkyl trichloroacetimidates be extended to the preparation of *O*-glycosyl trichloroacetimidates? The results of our initial experiments with tetrabenzylglucose **17** in which sodium hydride was used as base were at first surprising but, on consideration of the results obtained for direct 1-*O*-alkylation (Section 3), understandable. The *O*-α-glucopyranosyl trichloroacetimidate **40α** was isolated in almost quantitative yield (Scheme 9).[53] Simple filtration through silica gel was sufficient to purify **40α**.[54,55] Compound **40α** is crystalline and can be stored at +5 °C without any special precautions, whereas the corresponding α-glycosyl bromide, for instance, is stable at −80 °C for only a short time.[17] Product **40α** is also surprisingly stable at higher temperatures (e.g., in dry toluene at +110 °C).

A detailed study showed that, following the formation of the oxide, the β-trichloroacetimidate **40β** is formed preferentially or even exclusively in a very rapid and reversible addition reaction (Fig. 6a). However, this product anomerizes in a slow, base-catalyzed reaction (via retro-reaction, oxide anomerization, and renewed addition) practically completely to the α-trichloroacetimidate **40α** with the electron-attracting 1-substituent in an axial position.[19,45] The markedly higher reactivity of the 1-oxide atom in **18β** as compared with that in **18α** can be demonstrated by the use of potassium carbonate as base (Fig. 6b). Potassium car-

Scheme 9. a) Thermodynamically controlled product formation; b) kinetically controlled product formation. R = Bzl, M = Na, K.

bonate catalyzes the addition relatively rapidly and practically quantitatively, whereas it has only a small effect on the retro-reaction. Thus, the β-anomer **40β** also can be isolated as a pure product in 78% yield. The stabilities of the two anomers are comparable. The corresponding β-glycosyl halides were generated as intermediates.[13]



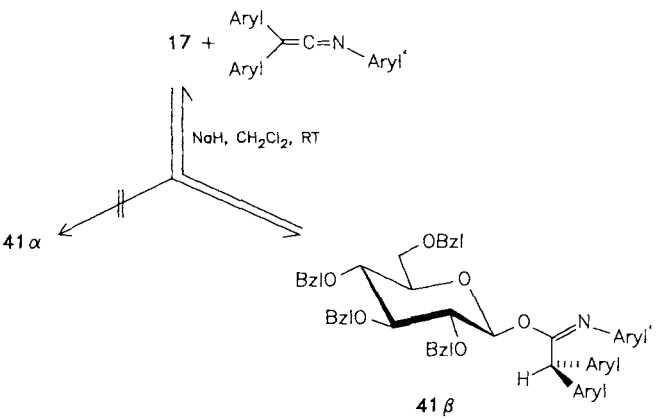


Fig. 6. Course of the base-catalyzed formation of *O*-(tetrabenzylglucopyranosyl)trichloroacetimidate **40α** and **40β** from tetrabenzylglucose **17** and trichloroacetonitrile a) with NaH, b) with K_2CO_3 as base.

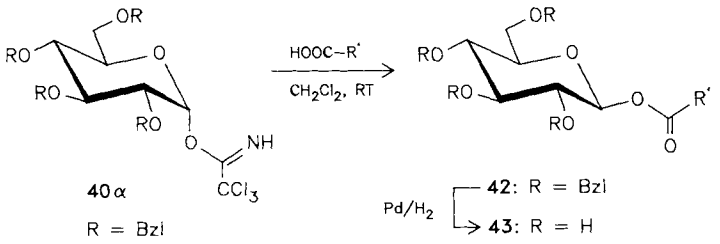
The kinetically controlled, rapid formation of the β-trichloroacetimidate **40β** and the slower, thermodynamically controlled formation of the α-trichloroacetimidate **40α** support the theory that the higher nucleophilicity of **18β** results mainly from a stereoelectronic effect.

Comparable results have since been obtained with other carbohydrates, with carbohydrates having other protecting groups, and with 2-azido-2-deoxy and 2-deoxy-2-phthalimido sugars.[19,45,53-74] The stereoselective anomeric activation of carbohydrates and their derivatives through the formation of *O*-glycosyl trichloroacetimidates is applicable to all important *O*-protected hexopyranoses (glucose, galactose, mannose, glucosamine, and galactosamine), hexofuranoses, pentopyranoses, and pentofuranoses, as well as to glucuronic acid and muramic acid. Thus, the first requirement for a new glycoside or saccharide synthesis (see Section 2.3) is fulfilled. Other nitriles (e.g., trifluoroacetonitrile) have not proved to be so successful as trichloroacetonitrile.[19]

The difference in the rates of formation of the α- and β-*O*-glycosyl trichloroacetimidates, the reversibility of the reaction, and the differing kinetic stabilities of the anomers have been used to govern the type of product formed. Restriction of the reversibility should lead exclusively to the product of the kinetically controlled reaction. This result is expected for reactions with *N*-substituted ketene imines because the proton in the addition product is bonded to a C atom (Fig. 5), which, under the conditions of direct imidate formation, is not easily deprotonated. Therefore, this product is protected from retro-cleavage.

As expected, the corresponding *O*-β-glucosyl imidate **41β** is obtained exclusively from the reaction between tetrabenzylglucose **17** and *N*,2,2-triarylketene imines with sodium hydride as base (Scheme 10).[19,53,54] The strong

Scheme 10. Aryl, Aryl' = phenyl, *p*-chlorphenyl, etc.



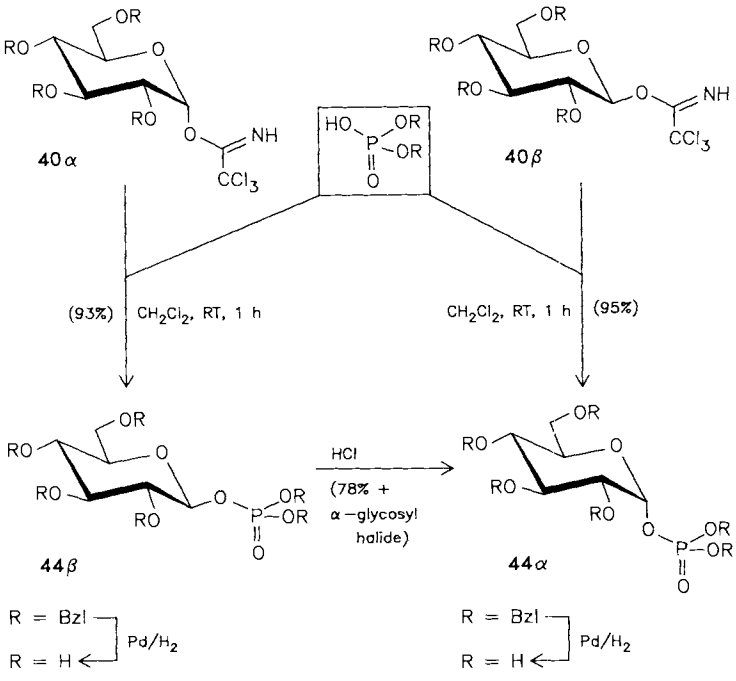
anomeric effect in the *O*-benzyl-protected mannopyranose is manifested both kinetically and thermodynamically in this reaction:[19] with trichloroacetonitrile and sodium hydride as base only the α-imidate is isolated; with *N*,2,2-triarylketene imines only the β-imidate is formed in spite of the steric hindrance on the β-side. This is a further indication of the significance of stereoelectronic effects.

4.2. Reactions of *O*-Glycosyl Trichloroacetimidates

Ultimately, the significance of the *O*-glycosyl trichloroacetimidates is derived solely from their glycosylation potential under acidic catalysis. This potential has indeed been confirmed in many investigations.

4.2.1. Carboxylic Acids and Phosphoric Acids as O-Nucleophiles

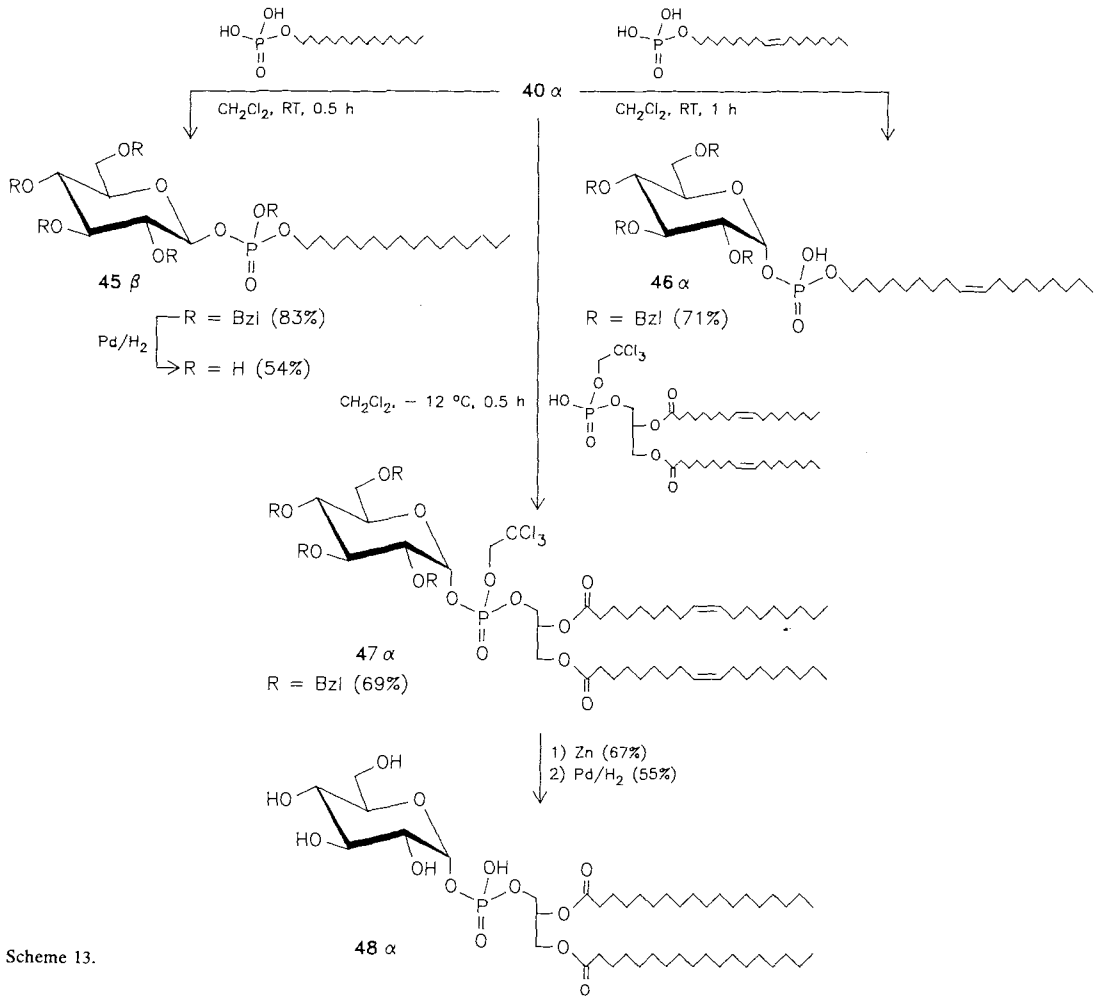
The direct glycosylation of Brønsted acids is a particularly advantageous property of these new glycosyl do-



Scheme 11. Examples for acids HOOC-R: formic acid (70% yield of **42**), acetic acid (84%), benzoic acid (82%), *o*-chlorobenzoic acid (80%), acetylsalicylic acid (87%), methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside uronic acid (66%), 3-indoleacetic acid (78%).

nors.[53,74] Carboxylic acids react with the *O*-α-glucosyl trichloroacetimidates **40α**, with inversion of configuration at the anomeric center to give the β-*O*-acyl compounds **42** (Scheme 11).[53,69] The reactions are performed at room temperature using equimolar amounts of acid and without the addition of a further catalyst. The examples given illustrate the versatility of this simple and mild method for 1-*O*-glycosylation of carboxylic acids, which also may be of interest for the modification of pharmaceuticals.[75] This method differs fundamentally from the conventional 1-*O*-acylation of pyranoses and furanoses (see Section 3.5) and from the esterification of trichloroacetonitrile-activated carboxylic acids.[76] In addition, it is less tedious than the corresponding reactions with the Sinaÿ imidates, which are derived from glycosyl halides (see Section 4.3).[77] Reactions of carboxylic acids can also be employed for racemate resolution.[69]

Glycosyl phosphates and glycophospholipids are intermediates in biological glycosyl transfer and are constituents of cell membranes (see Section 1). Syntheses of these compounds starting from 1-*O*-unprotected or 1-*O*-acylated carbohydrates mostly gave products with low α/β-selectivities. Improvements in this respect have been reported, especially in the last few years[64] (see also Section 3.5[43,44]).



The uncatalyzed glycosyl transfer from *O*-glycosyl trichloroacetimidates to phosphoric acid mono- and diesters opens up a simple route to the above compounds. Reaction of **40α** with highly pure dibenzyl phosphate gives, with inversion, the expected β-phosphate **44β**; the α-phosphate **44α** is obtained analogously from the β-trichloroacetimidate **40β** (Scheme 12).[54,58,64] Even in the presence of traces of strong acid, the β-phosphate **44β** undergoes anomerization to the thermodynamically more stable α-phosphate **44α**. Thus, the stereochemical result of this glycosyl phosphate synthesis depends on the purity and acidity of the phosphoric acid ester (autocatalysis of the anomerization). This is confirmed by further reactions of **40α**, especially with phosphoric acid monoesters to give glycophospholipids.[64] The β-glycosyl hexadecyl phosphate **45β** is obtained by the use of highly pure hexadecyl phosphate. This reaction is markedly accelerated by the addition of boron trifluoride etherate, which results in exclusive formation of the α-anomer **45α**. Analogous observations were made for the reactions of **40α** to give the compounds **46α** and **47α** and for the conversions of galactopyranosyl,[64] mannopyranosyl,[64] talopyranosyl,[78] and 2-azido-2-deoxyglucopyranosyl[79] trichloroacetimidates into the corresponding glycosyl phosphates. In general, the α-product, which is favored by the anomeric effect and which is usually encountered in nature, is obtained more easily or, under acidic catalysis, exclusively. The unprotected glucophosphoglycerolipid **48α** is prepared by reduction and hydrogenation of **47α** (Scheme 13).

Scheme 12.

4.2.2. Alcohol Components as O-Nucleophiles—Synthesis of Glycosides, Oligosaccharides, and Glycoconjugates

For reaction as *O*-nucleophiles with *O*-glycosyl trichloroacetimidates, alcohol components generally require the presence of an acid catalyst.[53,74] Boron trifluoride etherate at −40°C to room temperature in dichloromethane as solvent has proved to be eminently suitable.[54,69] This is exemplified by the reactions of α-trichloroacetimidate **40α** with cholesterol **49a** and with glucose derivatives **49b-e** to give the glycosides or disaccharides **50α** and **50β** (Table 2). Under these conditions with the non-neighboring-group-active 2-*O*-benzyl protecting group, preferred inversion to give the β-product (1,2-*trans*) is observed. This inversion is favored by lower temperatures. *p*-Toluenesulfonic acid and other Brønsted acids are not suitable as catalysts for the formation of the thermodynamically less stable β-product. Analogous observations were made in the syntheses of (1→6)-branched and linear cellotetraoses **52** and **53**, respectively, starting from disaccharide **50c-β** via the trisaccharide **51**, and in the syntheses of the glucuronate disaccharides and glycoside **55a-c** and **56**, respectively, starting from the α-glucuronate trichloroacetimidate **54α** (Scheme 14).[56] *O*-Benzyl-protected α-galactopyranosyl trichloroacetimidate behaves in principle in a similar manner.[54] Studies on the synthesis of digitoxin glucopyranosides

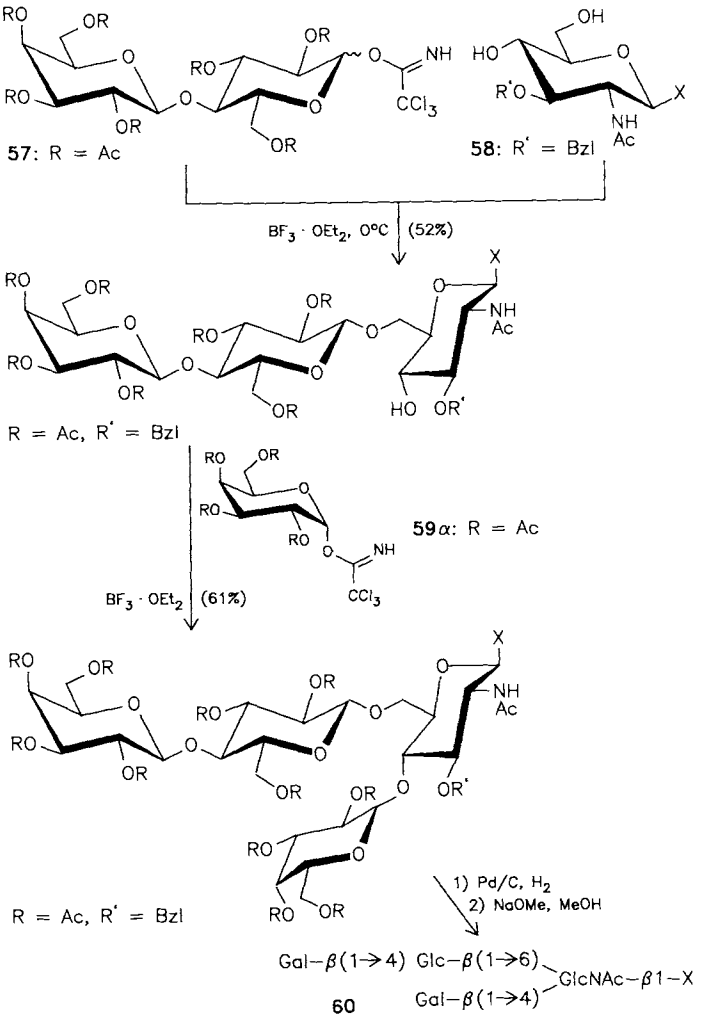
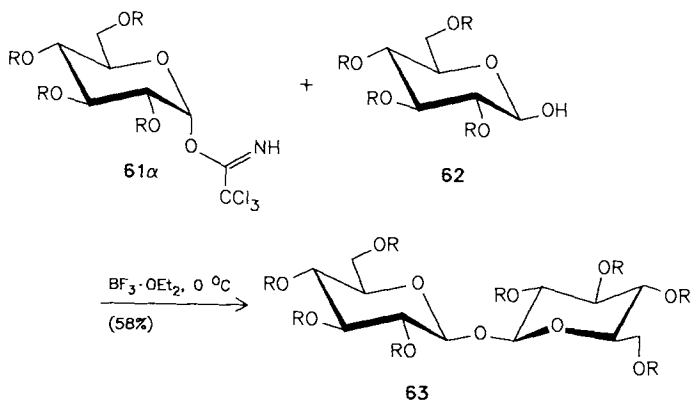
showed that markedly better results were obtained with the trichloroacetimidate method than with the Koenigs-Knorr method.[80] In addition, *O*-glycosylserine building blocks for the synthesis of glycopeptides were prepared in this way.[65,81]



Peracetylated α- and β-trichloroacetimidates of glucose and galactose react to give, as expected from the neighboring-group participation of the 2-*O*-acetyl group, exclusively the β-glycosides or β-saccharides (1,2-*trans*). This was confirmed, for example, by *Sinaÿ* and *Amvam-Zollo*[82] with the synthesis of the tetrasaccharide antigen **60** starting from the α-lactosyl and α-galactopyranosyl trichloroacetimidates **57** and **59α**, respectively, as donors and 4,6-*O*-unprotected *N*-acetylglucosamine **58** as acceptor, which additionally contains a spacer (Scheme 15). Corresponding studies in which the Koenigs-Knorr method was used were considerably less successful.[82] These authors also performed comparative studies on the synthesis of *N*-acetyllactosamine by the trichloroacetimidate method, different variants of the Koenigs-Knorr method, and the ortho ester method (see Section 5). For this example, the trichloroacetimidate method was shown to be at least competitive.[82] The per-*O*-acetylated α-glucosyl trichloroacetimidate **61α** is also suitable for glycosylating the anomeric hydroxyl group of tetraacetylglucose **62** (Scheme 16). The β,β-linked trehalose **63** was isolated in good yield, whereas it could only be obtained in low yield by the Koenigs-Knorr method.[83]

Reactions with per-*O*-benzylated α-mannopyranosyl trichloroacetimidate[54,84] and *O*-glycosylated derivatives[85] at lower temperatures in the presence of boron trifluoride etherate as catalyst gave preferentially or exclusively α-glycosides and α-saccharides; these results reflect the stronger anomeric effect.[54,84,85] Corresponding results were obtained also with the *O*-benzyl-protected α-rhamnopyranosyl trichloroacetamidate.[84] *O*-Acetyl-protected α-mannopyranosyl trichloroacetimidate also gave exclusively α-glycosides and α-saccharides (1,2-*trans*)[54] as a result of neighboring-group participation.



Because of the great importance of 2-amino sugars, especially *N*-acetylglucosamine and *N*-acetylgalactosamine, in complex oligosaccharides and glycoconjugates (see Section 1), their stereoselective coupling in glycoside and sac-

charide syntheses is of particular interest. A new glycosidation process must also prove itself in this field in order to satisfy the requirement of having wide scope. Therefore, we turned to the synthesis of oligosaccharides of the "core region" of *O*-glycoproteins of the mucin type.

Epithelial mucous secretions consist mainly of glycoproteins in which the oligosaccharide part is *O*-glycosidically linked to the amino acids L-serine or L-threonine through 2-acetylamino-2-deoxy-D-galactose.[2a,3] Galactose is frequently linked to the galactosamine to give a Gal-β(1→3)GalNAc disaccharide unit. However, a new structural type, which contains the GlcNAc-β(1→3)GalNAc disaccharide unit, has also been isolated from mucous secretions.[86] Compounds with this structure are of interest with respect to dysfunctions of the respiratory tract. For instance, the tetrasaccharide **69** was identified as the "core region" of glycoproteins isolated from bronchial mucous secretions of patients suffering from chronic bronchitis or cystic fibrosis.[86] This tetrasaccharide was obtained by a convergent synthesis based on the trichloroacetimidate method.[65,66] Lactose was first converted into the *N*-phthaloyllactosamine **64**, from which the stable trichloroacetimidate **67** was prepared as lactosaminyl donor. The disaccharide acceptor **68** was synthesized correspondingly from glucosamine (via its trichloroacetimidate **65**) and galactose (via the azide derivative **66**). The boron trifluoride etherate catalyzed coupling of **67** with **68** proceeded with β-specificity, as did the synthesis of **68**, owing to the *N*-phthaloyl group. Cleavage of the protecting groups led to the tetrasaccharide **69** (Scheme 17).

The occurrence of glucosamine in a variety of β-glycosidic linkages necessitates differing protecting group strategies. Accordingly, studies on the glycosidic coupling of 2-azido-2-deoxy-D-glucose containing *O*-benzyl and *O*-isopropylidene protecting groups were performed using the trichloroacetimidate method.[68] Here, the high diastereoselectivity of the reaction was expected to be achieved only as a result of the strict inversion of configuration in the trichloroacetimidate and not as a result of neighboring-group participation. The trisaccharide **75** of the capsule polysaccharide of *Neisseria meningitidis* (serum group L)[87] serves as an example. The *O*-benzyl-protected 2-azidoglucosyl trichloroacetimidate **72** (as donor) was synthesized from D-glucal **70** (R = Bzl). Compound **72** was coupled, under boron trifluoride etherate catalysis, with the 3-*O*-unprotected 2-azidoglucose derivative **71** (as acceptor), obtained from D-glucal **70** (R = Ac), to give exclusively the β(1→3)-linked disaccharide **73**. Conversion of **73** into the α-trichloroacetimidate **74**, as disaccharide donor, and reaction of **74** with the glycosyl acceptor **71** gave the tri-

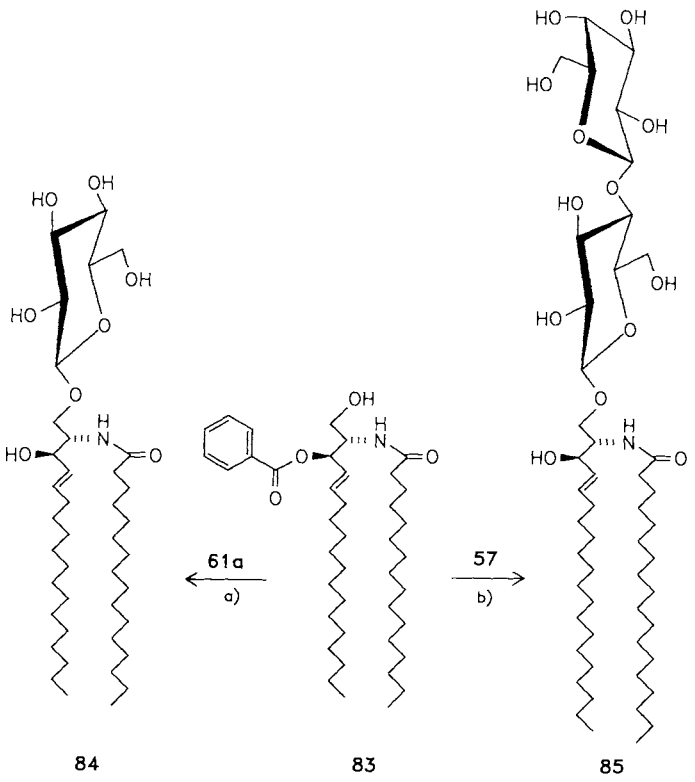
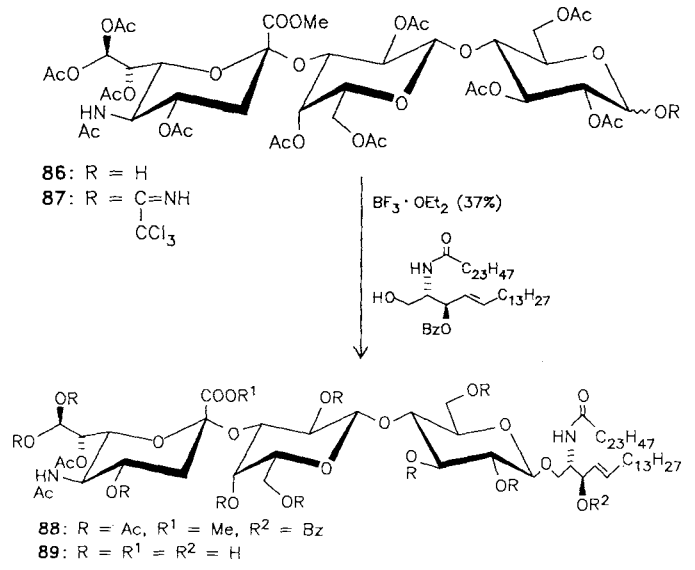
saccharide **75** with β-specificity. Cleavage of the protecting groups then gave the expected trisaccharide **76** (Scheme 18). In the same way, the disaccharide unit **78** of the cell-wall peptidoglycan of bacteria was built up from the imidate **72** and the muramic acid derivative **77**.[79]



The syntheses of α-glucopyranosides **80a,b** (1,2-*cis*) and, especially, of α-galactopyranosides **80c,d** (1,2-*cis*) were achieved starting from the *O*-benzyl-protected β-trichloroacetimidates **40β** and **79β**, respectively (Scheme 19).[88] In these reactions good results were obtained with diethyl ether as the solvent and trimethylsilyl triflate as the catalyst. The latter catalyst has also proved suitable for the synthesis of α-glycosides of glucosamine and galactosamine (both 1,2-*cis*).[65] For instance, the α-linked disaccharide **82** was prepared in a diastereoselective manner from the β-trichloroacetimidate of 2-azido-2-deoxygalactose **81β**.

Scheme 19. R^3 = *tert*-butyldimethylsilyl. a) Et_2O, HOR, RT, 1 h, $TfOSiMe_3$; b) CH_2Cl_2, $-20\,^{\circ}C$, $TfOSiMe_3$ (70%).



The significance of membrane constituents discussed in Section 1 demonstrates the necessity for developing glycosphingolipid syntheses. The required D-*erythro*-ceramide acceptor was prepared in the form of its 3-*O*-benzoylated derivative **83** by the use of a method developed by us.[89] The trichloroacetimidate method for glycosylating this compound[67] gave better results than the Koenigs-Knorr

or Helferich-Weis methods.[90] Thus, the glucosyl cerebroside **84** was obtained from the *O*-acylated α-glycosyl trichloroacetimidate **61α** and the lactosyl cerebroside **85** from the *O*-acylated α-lactosyl trichloroacetimidate **57** (Scheme 20).[91] Such compounds have proved to be active

in the healing of wounds.[71] Recently, *Ogawa* et al. synthesized the G_{M3} ganglioside **89**[92] and the asialo-G_{M1} and asialo-G_{M2} gangliosides[93] using the trichloroacetimidate method. The trisaccharide **86**, prepared by classical methods, was converted into the α-trichloroacetimidate **87** in

Scheme 21. Bz = benzoyl.

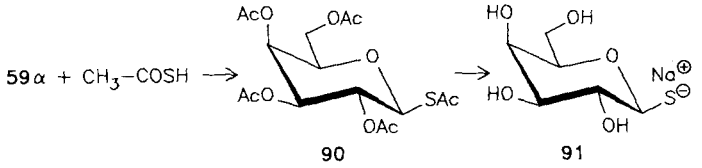
good yield and allowed to react with a ceramide in the presence of boron trifluoride etherate. The protected G_{M3} ganglioside **88** thus obtained was deprotected to give **89** (Scheme 21).[93]

The results obtained hitherto for *O*-glycoside formation with the trichloroacetimidate method give the following general picture. With acid catalysis, glycosides and saccharides generally are obtained under mild conditions in good yields and often in a sterically homogeneous form. Depending on the catalysts and protecting groups, reactivities are achieved that are comparable to those obtained for the glycosyl halide/silver triflate system. With very unreactive glycosyl acceptors, imidate rearrangements and/or glycosyl fluoride formation are sometimes observed.[70,72] According to our present experience, a sterically homogeneous reaction course with hexopyranoses is favored by the following factors:

(1) Neighboring-group participation gives rise to 1,2-*trans*-glycosides, i.e., β-glycosides with D-glucose, D-glucosamine, D-galactose, and D-galactosamine and α-glycosides with D-mannose and L-rhamnose.
(2) At low temperatures with boron trifluoride etherate catalysis, non-neighboring-group-active protecting groups lead preferentially to inversion products. In this way 1,2-*trans*-glycosides (i.e., β-glycosides) of D-glucose, D-glucosamine, D-muramic acid, D-glucuronic acid, D-galactose, and D-galactosamine can be prepared from the α-trichloroacetimidates.
(3) With the stronger catalyst trimethylsilyl triflate, non-neighboring-group-active protecting groups lead preferentially to the thermodynamically more stable product. In this way 1,2-*cis*-glycosides (i.e., α-glycosides) of D-glucose, D-glucosamine, D-galactose, and D-galactosamine have been prepared.

Only a few of the important types of linkage occurring in natural products (such as α-L-fucoside, β-D-mannoside, and β-L-rhamnoside) remain to be studied in detail. With the present state of methodological development, only β-D-mannose and β-L-rhamnose might present problems. Thus, the second requirement for a new saccharide synthesis (see Section 2.3) may be considered to be fulfilled "almost completely" after only a few years of research.

The successes with the *O*-glycosyl trichloroacetimidates up to now have forced studies on *O*-glycosyl *N*,2,2-triarylacetimidates **41** into the background.[53,54] Variations of the substituents on the imidate part could make "tailor-made glycosyl donors" available. However, the steric requirements of the triaryl-substituted imidate group may be disadvantageous for reactions at the anomeric center and for the required separation of the large triarylacetamide molecule from the reaction products.



4.2.3. N-, S-, and C-Nucleophiles

Up to now, only a few studies with *N*-nucleophiles have been performed. Hydrazoic acid, as a strong acid, reacts with **40α** to give the expected α-azide without any additional catalyst.[69] Nitrogen heterocycles, however, require an acid catalyst; thus, bis-trimethylsilylated uracil and thy-

mine gave exclusively the β-linked nucleosides at room temperature with boron trifluoride etherate as catalyst.[69,94,95] Reactions of **40α** in acetonitrile as solvent with a carboxylic acid as activator gave *N*-bisacylated *N*-glucosides via nitrilium salts.[69] Corresponding reactions with *O*-glycosyl *N*-methylacetimidates[49] demonstrated the markedly higher reactivity of the *O*-glycosyl trichloroacetimidates.

The strong interest in 1-thioaldoses and 1-thioglycosides,[41,55,96,97] including their recent use as protecting groups and for glycosyl transfer (see Sections 5.1 and 5.2), was a motivation for studying the high reactivity of *O*-glycosyl trichloroacetimidates in the glycosylation of *S*-nucleophiles.[55] Hitherto, 1-thioglycosides were prepared mainly by direct nucleophilic substitution of glycosyl halides with thiolates or by *S*-alkylation of metal salts of 1-thioaldoses (see Section 3).[41,96,98,99]

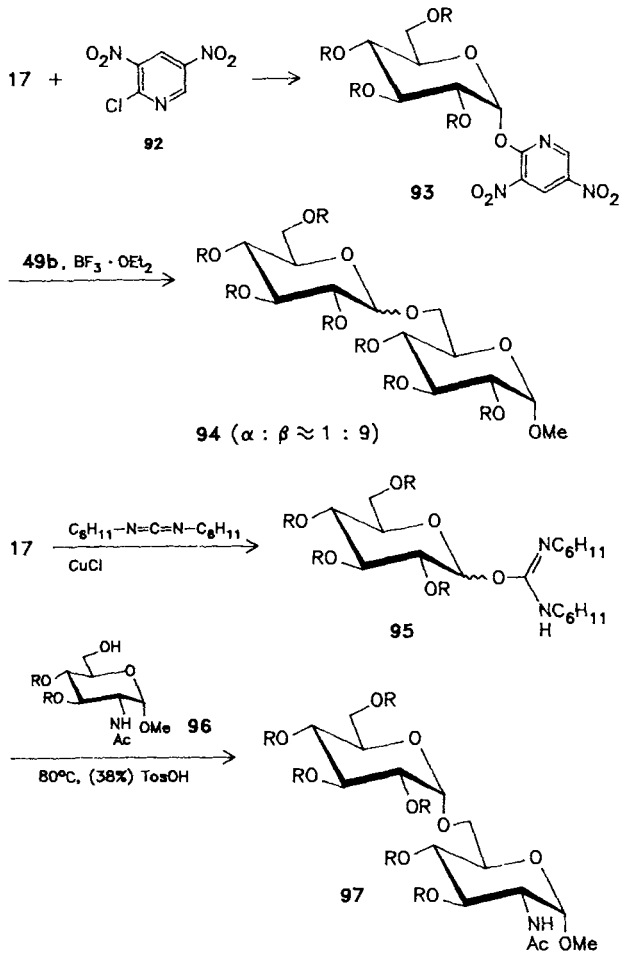
The acetyl-protected α-glucosyl and α-galactosyl trichloroacetimidates **61α** and **59α**, respectively, react with thiols in the presence of boron trifluoride etherate as catalyst to give β-configurated 1-thioglycosides in high yields. Surprisingly, with the benzyl-protected α-trichloroacetimidate **40α** under identical conditions, α-configurated 1-thioglycosides are obtained exclusively. Because the anomeric effect in alkyl 1-thioglycosides approximately corresponds to that in alkyl glycosides,[100] both anomers should be formed, even under thermodynamic control.[10] Obviously, the glycosyl transfer to the *S*-nucleophile in these cases occurs by a different mechanism. It was assumed that, as in S_Ni reactions, the configuration is retained by intramolecular reaction in a close ion pair.[55]

90 91

Scheme 22.

Like carboxylic acids, thioacetic acid reacts, for example, with the acetyl-protected α-galactosyl trichloroacetimidate **59α** without a further catalyst to give the 1-acetylthio compound **90** directly. By cleavage of the acetyl groups, the sodium salt **91** of the known 1-thio-β-D-galactopyranose can be obtained conveniently (Scheme 22).[101]

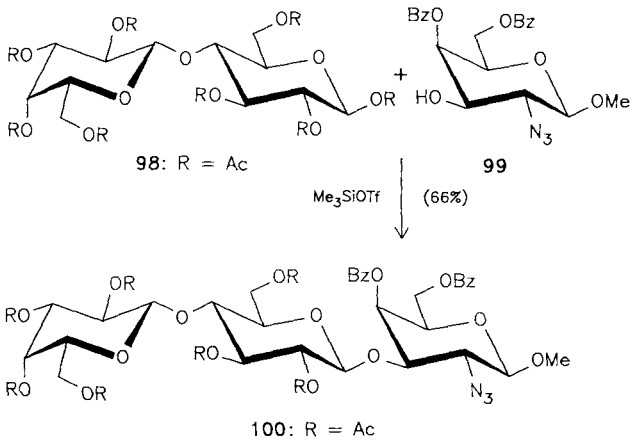
Structurally very different *C*-glycosides with interesting biological properties are found in nature.[102] In addition, *C*-glycosides have been recognized as partial structures of many natural products and, thus, they are of interest as chiral building blocks in natural products synthesis.[103] This large biological and preparative interest is reflected in the extensive research in this field.[104] Here, only successful studies with *O*-glycosyl trichloroacetimidates as glycosyl donors and phenol ethers,[59,105] silyl enol ethers,[72] trimethylsilyl cyanide,[72] or allyltrimethylsilane[72] as *C*-acceptors will be mentioned. These results are suitable to confirm the wide scope of application of *O*-glycosyl trichloroacetimidates as glycosyl donors. Comparable reactions of glycosyl halides are unknown.



4.3. Other Methods Involving Imidates or Imidate-Like Intermediates

The β-*O*-glycosyl imidates prepared by *Sinaÿ* et al.[49] from α-glycosyl halides and *N*-substituted amides (particularly *N*-methylacetamide) using three equivalents of silver oxide have been discussed above (see ref. [13] and Section 4.1). These compounds require acid catalysis (usually *p*-toluenesulfonic acid, see also ref. [69]) for the transfer of especially reactive hexopyranosyl groups (mainly tetrabenzylgalactose, tribenzylfucose, and tetrabenzylglucose); the reactions proceed with inversion to form α-glycosidic linkages.[49,77,82,106] Neighboring-group-active protecting groups such as 2-*O*-acetyl groups lead to ortho ester formation and not directly to the glycoside or saccharide.[77] As a result of their laborious syntheses and comparatively low reactivities, these imidates have only been employed in special cases to date.[106]

Some of the necessary glycosyl halides were prepared from the 1-*O*-unsubstituted sugars using the Vilsmeier-Haack reagent $Me_2\overset{\oplus}{N}=CHCl\ Cl^{\ominus}$.[106] *Gross* et al.[107] have shown spectroscopically that the *O*-glycosyl iminium esters are stable at low temperatures and can undergo reaction with glycosyl acceptors to give disaccharides. However, two equivalents of silver toluenesulfonate are required to remove the chloride and liberate the *p*-toluenesulfonic acid. The chemical yields are good but, as expected, low α/β-selectivities are observed. In principle, the same problem arises on activation of the anomeric center with 2-fluoro-1-methylpyridinium toluenesulfonate.[108,109]



Mukaiyama et al.[110] have also suggested the use of the 3,5-dinitro-2-pyridyl group for activating carbohydrates. This group can be introduced easily by reaction of the corresponding chloro compound **92** in the presence of base, potassium fluoride, and crown ether. Not unexpectedly, the α-product **93** is formed preferentially with tetrabenzylglucose **17**. In the presence of boron trifluoride etherate, primary and simple secondary alcohols can be converted into β-glucosides (e.g., **94**) in good chemical yields and with good stereoselectivities. This glycosyl transfer method is that most closely related to the trichloroacetimidate method. Routes for the specific preparation of the corresponding β-configurated intermediates have not been developed, and hydroxyl groups that are difficult to glycosidate have not been studied to date.

Other groups analogous to the imidates are the isourea groups introduced by *Ishido* et al.[111] These are generated in situ from carbodiimides in the presence of copper(I) chloride and react with nucleophiles at about 80°C. Phenols,[111,112] thiophenol,[111,112] carboxylic acids,[111,113,117] and carbohydrates[111,114] have been used as nucleophiles. The corresponding glycosides are obtained, but sometimes in only modest yields and with low diastereoselectivities. On reaction of **17** with *N,N'*-dicyclohexylcarbodiimide, the *O*-glycosylisourea derivative **95** is formed as an intermediate and reacts, under drastic conditions, with the glucosamine derivative **96** to give the α-disaccharide **97** (Scheme 23).

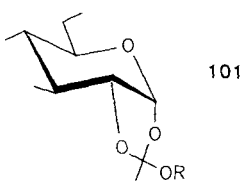
Scheme 23. R = Bzl.

hydrooxazoles are presumed to be intermediates in these reactions. Similarly, boron trifluoride etherate is used to prepare simple *O*-glycosides from 1-*O*-acetylated *N*-phthaloylglucosamine and -lactosamine derivatives.[121] In the last few years, especially the use of trimethylsilyl triflate as catalyst has afforded good results for *N*-[122] and *O*-glycoside[13,123] syntheses. For example, *Ogawa* et al.[123] reported the successful reaction of primary hydroxyl groups of sugars. *Paulsen* and *Paal*[13,124] achieved reaction of the corresponding secondary hydroxyl groups. For example, the peracetylated lactose **98** and the 3-*O*-unprotected azidogalactose **99** were coupled to give the β-linked trisaccharide **100** (Scheme 24). In all of the examples studied, the glycosyl donor had neighboring-group-active protecting groups so that stereoselectivity was ensured. Ortho esters have been suggested as intermediates. These simple procedures are valuable additions to oligosaccharide synthesis.

Scheme 24.

4.4. 1-*O*-Acyl Compounds and Ortho Ester Formation

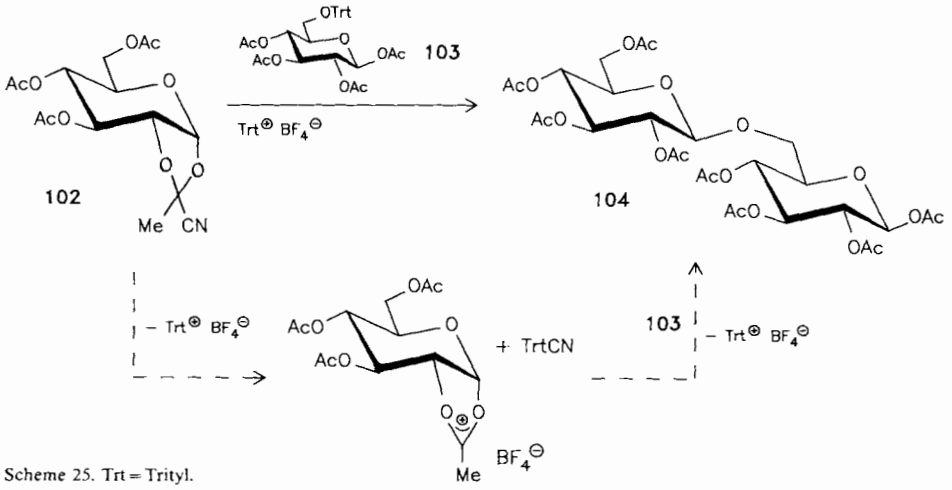
The disadvantage of a low activation of the glycosyl moiety for glycosyl transfer, which is obvious in the case of isourea formation, is even more pronounced in the case of carbonate activation.[115] Disaccharides can be prepared only by condensations of melts at about 160–180°C.



When the glycosyl donor properties of the 1-*O*-unsubstituted sugar are reduced, glycosylation can still be achieved by the use of correspondingly stronger acid catalysts; however, the process is not applicable to acid-labile sugars. Such reactions are especially successful with simple alcohols as acceptors. This approach, ultimately leads to the conditions of the Fischer-Helferich method (Fig. 2), which does without a 1-*O*-activated intermediate and builds up the glycosyl donor potential solely by the action of strong acids.

Helferich and *Schmitz-Hillebrecht*[116] were able to convert 1-*O*-acylated sugars into simple *O*-glycosides using Lewis acids (especially $ZnCl_2$).[10,117,118] *Hanessian* and *Banoub*[119] prepared disaccharides using tin tetrachloride. Using iron(III) chloride and tetramethylurea as acid scavenger, *Kiso* and *Anderson*[120] achieved disaccharide coupling between 1-*O*-acetylated *N*-acetylglucosamines and the primary and secondary hydroxyl groups of sugars. Di-

An interesting variant of the glycoside synthesis, reported by *Hanessian* and *Banoub*,[125] is the reaction of 1-*O*-acyl sugars, possessing neighboring-group-active protecting groups, with amide acetals as acceptors and tin tetrachloride as catalyst.

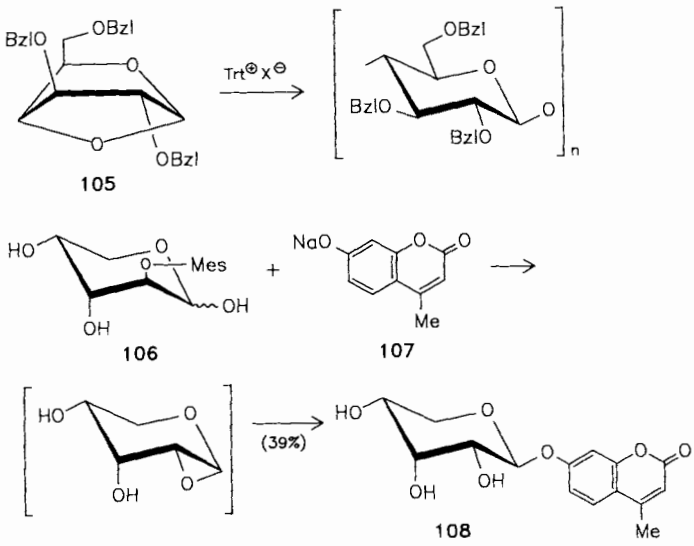


1-*O*-Acyl sugars with *O*-benzyl protecting groups were activated using trityl perchlorate by *Mukaiyama* et al.[126] For example, the bromoacetate of tetra-*O*-benzyl-β-D-glucose afforded preferentially α-glycosides. Our investigations[127] on the direct reduction of the carboxyl groups of 1-*O*-acyl sugars led to the successful synthesis of simple glycosides.

The synthesis of ortho esters from glycosyl halides and their mercury-salt-catalyzed rearrangement to glycosides and saccharides have been known for a long time.[10,13] Activation of the C–O glycoside bond for glycosyl transfer results from the alkylating character of ortho esters (see **101**); thus, as expected, treatment of the ortho esters with carboxylic acids results in the formation of 1-*O*-acyl com-

101

pounds.[128] *Kochetkov* et al.,[129] in particular, have developed the ortho ester method. One disadvantage of this method is the formation of the 2-*O*-unsubstituted sugar by a competing protonation at the 2-*O* atom.[130] This side reaction can be avoided by formation of the acyloxonium intermediate and trapping it with cyanide.[129] For example, the ketal **102**, derived from pentaacetylglucose, is converted into peracetylgentiobiose **104** in good yield by reaction with the 6-*O*-tritylglucose derivative **103** in the presence of trityl tetrafluoroborate according to the method of *Bredereck* et al.[131] Compound **102** reacts with trityl tetrafluoroborate to form initially triphenylacetonitrile and an acyloxonium intermediate, which, in turn, reacts irreversibly with the trityl ether **103** to give the disaccharide **104** (Scheme 25). In this way, the presence of strong acids (e.g., HBF_4) is avoided. This method has also been used for the synthesis of polysaccharides such as α(1→3)-L-rhamnan.[132] The same advantage is attained by the introduction of an alkylthio group.[133] *O*-Trityl sugars as acceptors with trityl perchlorate as coactivator result in good yields of 1,2-*trans*-linked disaccharides of glucose, galactose, mannose, and rhamnose.[133,134]

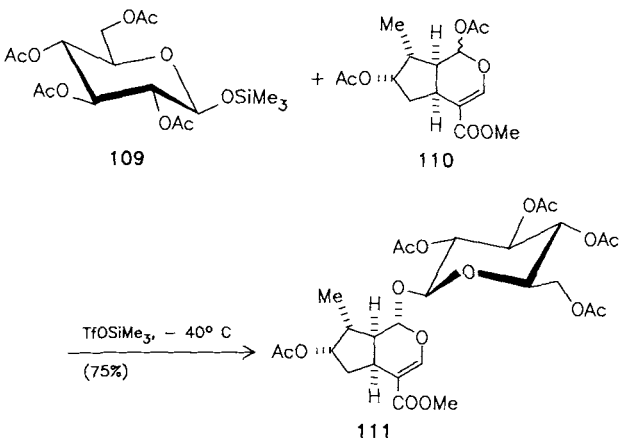


Scheme 25. Trt = Trityl.

4.5. Anhydro Sugars as Intermediates

Similar to the ortho ester method is the formation of anhydro compounds as activated intermediates. For example, *Micheel* et al.[135] employed the 1,4-anhydro-α-D-glucopyranose **105** in a synthesis of polymeric sugars (Scheme 26). The use of trityl hexafluorophosphate and hexafluoroantimonate resulted exclusively in β(1→4) coupling.

More obvious is the use of the strongly activated 1,2-anhydro sugars for glycoside synthesis. *Brigl*'s anhydride was thus used for the syntheses of the disaccharides maltose,[136] maniocose,[137] sucrose,[138] and trehalose.[139] However, only modest yields of the disaccharides were obtained by reactions of the 4-*O*-unprotected glucose derivatives in dry toluene at 130°C. Attempts to prepare iridoid glycosides gave similar results.[141] Since the thermodynamically more stable α-saccharides are formed preferentially in these reactions, the possibilities with reactive 1,2-anhydrides probably are not exhausted. This is illustrated by the synthesis of the ribopyranoside **108**, starting from the 2-*O*-mesyl compound **106** and the sodium salt of 7-hydroxy-4-methylcoumarin **107**, via the anhydro compound; controlled ring opening to give exclusively 1,2-*trans* coupling was observed (Scheme 26).[142] Acyclic enol ether epoxides were also suggested for glycoside synthesis.[143]



Scheme 26.

4.6. 1-*O*-Silylated Sugars as Intermediates

1-*O*-Trimethylsilylglycosides, obtainable in anomerically pure form from 1-*O*-unprotected sugars,[144] have been shown by *Tietze* et al.[144,145] to be useful in the synthesis of phenylglycosides. With *O*-silylated phenols as acceptors and trimethylsilyl triflate as catalyst, practically exclusively β-glucopyranosides are obtained from compounds with neighboring-group-active acyl protecting groups and practically exclusively the corresponding α-glucopyranosides from compounds with inactive benzyl protecting groups.

In this way, α- and β-glycosides with 1,1'-diacetal structures have been prepared at lower temperatures with retention of configuration.[146] Iridoid glycosides could also be synthesized in this manner.[147] For example, the loganin pentaacetate **111** was prepared from the 1-*O*-silylated glucose derivative **109** with loganol diacetate **110** as the acceptor (Scheme 27).

Scheme 27.

The glycosylation potential of the *O*-silylated glycosides probably does not exceed that of normal glycosides, so that the catalyst and the formation of hexamethyldisiloxane are responsible for the course of the reaction. The stereocontrol results from neighboring-group participation or from the anomeric effect. The retention of configuration of the 1-*O*-silylated intermediate in the 1,1'-diacetal formation probably results from intermediary 1-*O*-alkoxyalkylation. Corresponding results obtained for 1-*O*-alkylations can be interpreted similarly.[29,32] This interpretation is supported further by the trifluoromethanesulfonic anhydride activated formation of trehalose.[148] In all these reactions, the conditions of the transglycosidation[149] or the Fischer-Helferich method are employed, which are not suitable for the synthesis of more complex oligosaccharides.

4.7. 1-*O*-Sulfonylated Sugars as Intermediates

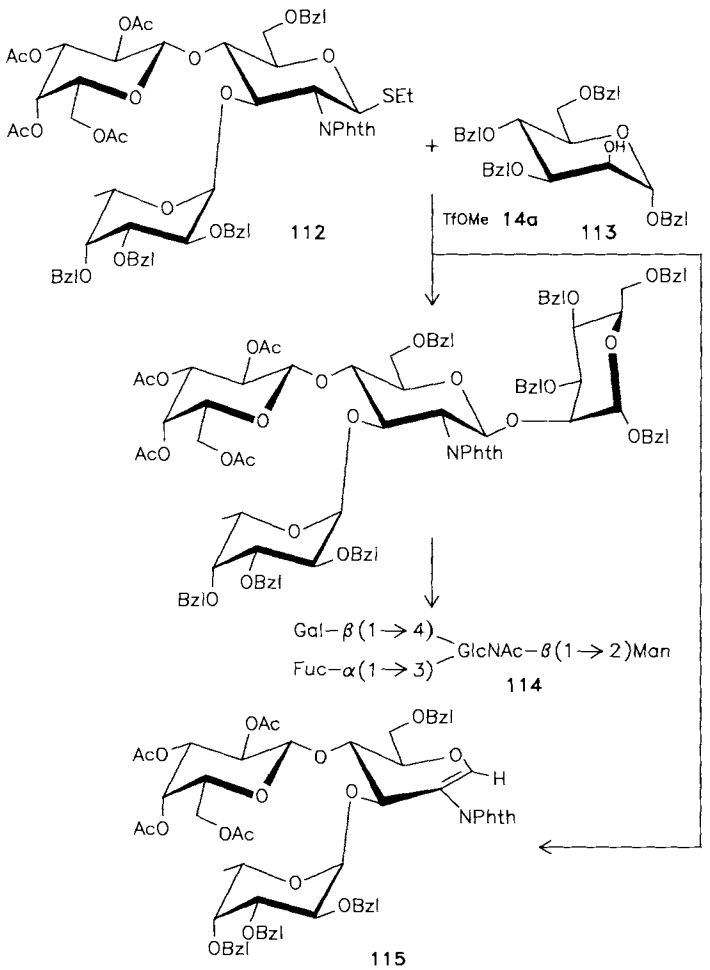
The generation of a better leaving group by 1-*O*-toluenesulfonyl formation has been known for a long time.[150,151] These compounds were prepared by reaction of the corresponding α-glycosyl halides with silver toluenesulfonate, predominantly α-toluenesulfonates being obtained. According to *Schuerch* et al.,[151] the introduction of an electron-attracting acyl or carbonyl group at the 6-*O* atom leads to stabilization of the 1-*O*-toluenesulfonate group. In this way, especially in ether as solvent, α-glycopyranosides could be obtained preferentially from glucose and galactose when 2-*O*-benzyl protecting groups were employed. The stereochemistry of this reaction is explainable by the intermediacy of an onium species with ether as a reaction partner.[16,152] The corresponding *p*-nitrobenzenesulfonyl derivative of 2,3,4,6-tetrabenzylglucose, generated as an intermediate from silver triflate, *p*-nitrobenzenesulfonyl chloride, and triethylamine, gives β-glucopyranosides in dichloroethane as solvent.[153] Under identical conditions but in the presence of dimethylacetamide, α-saccharides are formed,[154] presumably via an iminium ester intermediate (see Section 4.3). In this reaction, the glycosyl donor is used in a fourfold excess.

By introducing a strongly electron-attracting group at the 2-*O* atom (mesyl, *p*-nitrobenzoyl, or benzoyl group), it was possible to strengthen the S_N2 character of the substitution at the anomeric carbon atom to such a degree that β-glycopyranosides of glucose,[155] galactose,[156] and even mannose[157] and rhamnose[157] could be obtained. The amounts of reagent and the difficult stereocontrol of both intermediate and end product prevent a broader application of this straightforward method. Apparently, the route via glycosyl halides and their activation with silver triflate, as reported by *Hanessian* and *Banoub*,[158] which is, in effect, a variant of the Koenigs-Knorr method, is considerably more efficient.

Studies on 1-*O*-activation with the Mitsunobu reagent have not attained general significance.[159,160]

5. Leaving Groups with Elements other than Oxygen at the Anomeric Center: O/Element Exchange for 1-*O*-Activation

The exchange of the anomeric hydroxyl group for a better leaving group, e.g., chlorine or bromine, is realized in the Koenigs-Knorr method, which makes use of coactivation by halophilic metal salts.[13] Due to their relative instability, the more reactive iodine compounds[151a,161] have not gained importance. Silver and mercury salts, above all, have proved successful as metal salts. The introduction of silver triflate as a homogeneous catalyst by *Hanessian* and *Banoub*[158] and of silver silicate as a heterogeneous catalyst by *Paulsen* et al.[13,18] have considerably improved the efficiency and scope of this method. Other metal salts also have been examined.[162,163]



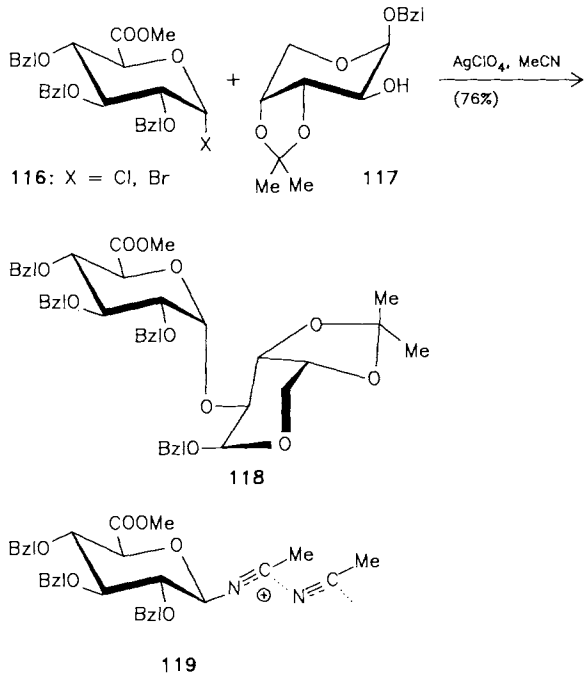
Because of the extensive literature on the Koenigs-Knorr method, the question whether other elements can be introduced as leaving groups at the anomeric center and be exchanged in a stereocontrolled manner by *O*-nucleophiles should be discussed. Of the electronegative elements that are particularly suitable for nucleophilic substitution, there remain, apart from oxygen (Section 4), chlorine, bromine, and iodine (see above), the elements nitrogen, sulfur, phosphorus, and fluorine. Of these, the first two can be envisaged in various bonding forms.

5.1. Ammonium, Sulfonium, Phosphonium, and Nitrilium Intermediates

Ammonium, sulfonium, and phosphonium groups are suitable as leaving groups for the formation of stabilized carbonium ions, although they have different leaving-group tendencies. *Schuerch* et al.[151b,164–166] have studied these groups at the anomeric centers of carbohydrates. Starting from α-bromo-2,3,4,6-tetrabenzylglucose and -galactose, the corresponding onium compounds were generated by reaction with amines, dialkyl sulfides, or tertiary

phosphanes. NMR data confirm the β-configuration, which would be expected from the inverse anomeric effect.[167] Methanolysis studies showed the expected order of reactivity: sulfonium > ammonium > phosphonium compounds.[165] In view of their low reactivity, further studies on phosphonium compounds were unnecessary. Predominantly α-glycosides were obtained as products. Studies on disaccharide synthesis with a reactive 6-*O*-unprotected glucopyranoside and various ammonium leaving groups gave modest results with regard to yield and stereoselectivity. The best results were obtained when diethyl ether or triethylamine/acetone was used as solvent.[166]

Recently, *Lönn* reported good glycosidation results for sulfonium leaving groups.[168-170] β-Alkylthio derivatives of *N*-phthaloylglucosamine were *S*-methylated with methyl triflate, and the β-glycosides were obtained in good yields owing to phthaloylamido group control. For example, the tetrasaccharide **114** was constructed from the trisaccharide **112** as donor and the mannose derivative **113** as acceptor.[170] This tetrasaccharide has been found as a structural element of glycoproteins in the urine of patients suffering from fucosidosis.[171] The 1,2-elimination, previously observed by *Kronzer* and *Schuerch*,[165] was observed as a competing reaction to give, in this case, the glycal derivative **115** (Scheme 28). A nonasaccharide was built up in the same way. Glycosidation with non-neighboring-group-active protecting groups at the 2-*O* atom gave α/β mixtures



Scheme 28.

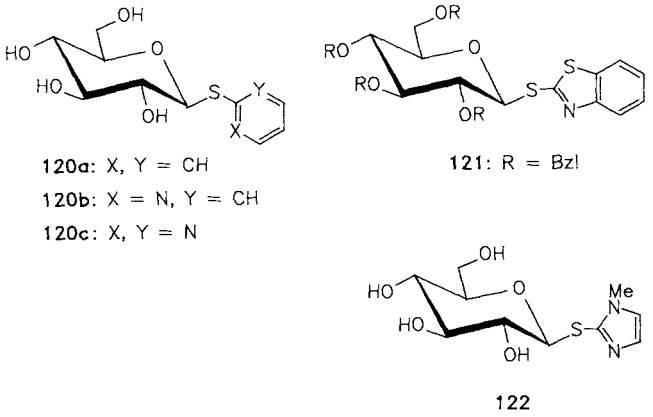
in high yields; with diethyl ether as solvent, the best α-selectivity was observed.[168] New methods for the preparation of thioglycosides have been described recently by *Hanessian* et al.[172] and *Nicolaou* et al.[173]

Glycosyl disulfides, sulfonates, and sulfones are not practical as glycosyl donors.[174]

The nitrile group in nitrilium compounds acts as a leaving group, especially when formally stable carbonium ions are formed. The leaving properties are favored when a nitrile is used as the solvent since the nucleophilic attack at the nitrilium *C* atom is then hindered by the formation of a nitrilium-nitrile conjugate.[16,175] Therefore, we have converted α-halo derivatives of glucuronic acid **116** into the *N*-glucosylnitrilium-acetonitrile conjugates **119** by treatment with silver perchlorate in acetonitrile as solvent; as a result of the inverse anomeric effect, the β-product is formed.[16,176] Disaccharides (e.g., **118**) were obtained in very good yields and with high α-selectivities with glycosyl donors such as the arabinose derivative **117** (Scheme 29).

Scheme 29.

Correspondingly, riburonic acids were coupled in a β-glycosidic manner.[176] An analogous process using cladinose was employed for the synthesis of erythromycin.[177]



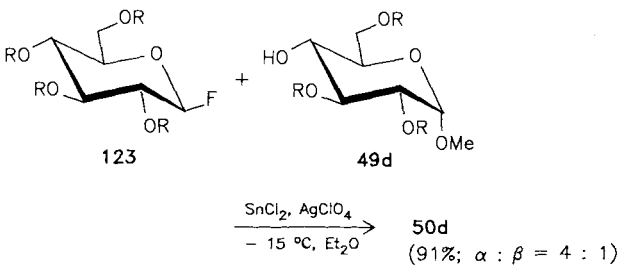
Nitrilium salts react to give *N*-acylglycosylamines and glycosylamines.[49,69,178] Their conversion into diazonium compounds also affords glycosyl donors.[179]

5.2. Activation of Thioglycosides by Thiophilic Metal Salts and *N*-Bromosuccinimide

The anomeric thioalkyl group in glycosides and saccharides opens up possibilities for selective activation owing to its good stability as a protecting function and as a result of sulfur-specific reactions (see Section 5.1). Particularly obvious is the selective activation of thioglycosides by thiophilic metal salts. *Ferrier* et al.[180,181] and *VanCleve*[182] car-

ried out the first systematic studies with mercury(II) salts. By using phenylmercury triflate, *Garegg* et al.[183] were able to convert phenyl-β-thioglycosides of tetrabenzylglucose and tetrabenzylgalactose to disaccharides in good yields and with high α-selectivities. Phenyl-β-thioglycosides of tetraacylglucose and tetraacylgalactose gave inconsistent results for as yet unknown reasons.

Comparative studies by *Hanessian* et al.[184] on the proton activation of phenylthio- and pyridin-2-ylthioglucopyranosides **120a** and **120b**, respectively, demonstrated the dramatic effect of the heteroatom (remote activation) as a basic anchor for the proton and as a better leaving group, resulting from the negative inductive effect. *Mukaiyama* et al.[185] previously exploited this effect for glycosylation with the benzothiazolylthioglucoside **121** in the presence of copper(II) triflate as catalyst. *Hanessian* et al.[184] studied the reaction of the *O*-unprotected glucosylthioheterocycles **120b,c** and **122** with reactive glycosyl acceptors using mercury(II) nitrate as catalyst and acetonitrile as solvent (Scheme 30). They obtained glycosides and the disaccharide Glc(1→6)Gal in good yields but with only modest α/β-selectivities. Benzothiazolylthio activation was also employed successfully in a synthesis of erythromycin.[177]



Scheme 30.

In addition to protons and metal salts, bromonium ions are also thiophilic. Thus, thioglycosides can serve as convenient substrates for the synthesis of glycosyl bromides through introduction of bromine.[186] If the counterion of the bromonium ion is a poor nucleophile, as is the case with *N*-bromosuccinimide (NBS), then the introduction of alcohols as nucleophiles, for example, should be possible in competition. This has been confirmed already by *Hanessian* et al.[184] Recently, *Nicolaou* et al.[173] reported on the wide scope of this method starting from phenylthioglycosides; however, low α/β-selectivities were frequently obtained. The described "intramolecular glycosidation," in which 1,6-anhydro derivatives were obtained, should be of particular value.

5.3. Activation by Fluoride

The use of fluoride at the anomeric center as leaving group has aroused interest in the last few years.[187] This brings us full circle back to the Koenigs-Knorr method. Being a poorer leaving group, fluoride leads to intermediates more stable than glycosyl chlorides and bromides. In addition, fluorophilic properties are found not only in heavy-metal salts. These facts show that reactive promoters are necessary for activation. In the first studies by *Mukaiyama* et al.,[187] tin(II) chloride/silver perchlorate was employed for activation. Syntheses of glycosides and disaccharides starting from the glycosyl fluoride **123** afforded good α-selectivities; with the 4-*O*-unprotected glucoside **49d**, the α-form of the maltoside **50d** was formed preferentially (Scheme 31). This method was used by *Nicolaou* et al.[188,189] for the synthesis of complex glycosides and oligosaccharides such as the rhynchosporides.[189] Glycosyl transfer was effected by activation with 1.8 equivalents each of tin(II) chloride and silver perchlorate in ether at −15°C. With neighboring-group-active acyl protecting groups, β-coupling was achieved. Analogously, *Mukaiyama* et al.[109] obtained α-ribofuranosides preferentially from β-ribofuranosyl fluoride with tin(II) chloride/silver perchlorate as promotor and β-arabinofuranosides from α-arabinofuranosyl fluoride with tin(II) chloride alone. *Noyori* et al.[190] were able to activate glycosyl fluorides with tetrafluorosilane and trimethylsilyl triflate when the acceptors were used in the form of their trimethylsilyl ethers. Good yields but frequently only modest α/β-selectivities were observed.

Scheme 31. R = Bzl.

Mukaiyama et al.[108,185,187] prepared isolable glycosyl fluorides by reaction of the 1-*O*-unprotected compounds with 2-fluoro-1-methylpyridinium toluenesulfonate in the presence of triethylamine. Generally, anomeric mixtures were obtained. Anomerization to the thermodynamically more stable fluoride could be effected.[109,191] The interest in glycosyl fluorides has led to further new syntheses,[192] whereby diethylaminosulfur trifluoride (DAST) in tetrahydrofuran has proved to be particularly valuable.[37,193] *Nicolaou* et al.[188] converted phenylthioglycosides into glycosyl fluorides by reaction with NBS/DAST and HF-pyridine/NBS.

Because of the methodological analogies, the results with glycosyl fluorides have to be compared with those obtained with the classical Koenigs-Knorr method (i.e., results with glycosyl chlorides and bromides). However, with the results presently available, a conclusive evaluation with regard to the requirements listed in Section 2.3 for a new glycoside synthesis is not possible. Glycosyl fluorides, like the trichloroacetimidates, have also proved useful in the syntheses of, for example, *C*-glycosides,[104a,194,195] so that a

broad application is guaranteed for these glycosyl donors.

6. Summary and Prospects

In spite of the complexity of oligosaccharide syntheses, enormous progress has been achieved by new methods and by modifications of the Koenigs-Knorr method. The controlled, efficient synthesis of an oligosaccharide or a glycoconjugate—a dream just a decade ago—can be planned and performed today.

Particularly worthy of note are two new methods: the stereocontrolled, direct 1-*O*-alkylation of sugars, which makes saccharides accessible by a particularly simple method; and the trichloroacetimidate method, which leads to stable *O*-glycosyl trichloroacetimidates with high glycosylation potentials in a stereocontrolled manner by utilization of kinetic and thermodynamic stereoelectronic effects. Neither method requires heavy-metal salts and both are suitable for large-scale preparations. The selective activation of alkyl- or arylthioglycosides with thiophilic reagents or of glycosyl fluorides with fluorophilic reagents present interesting perspectives.

In spite of these advances, chemical oligosaccharide syntheses are still not quantitative, diastereospecific reactions. Thus, further development of the available methods is desirable. In addition, the regioselective reactivity of partially protected glycosyl acceptors must be studied and exploited; initial investigations have already been performed.[66, 70, 82, 196]

As mentioned at the beginning of this article, each chemical oligosaccharide synthesis is a special problem requiring both knowledge of methods and experimental dexterity. The differing reactivities and stereoselectivities of donors and acceptors, which depend in part on the effect of protecting groups, neighboring groups, through-space steric interactions, and amphiphilic properties, make the development of generalizable reaction conditions for oligosaccharide synthesis difficult, in contrast to the presently available possibilities for peptide and oligonucleotide synthesis. The diversity of the combinations of sugars with themselves and with other sugars (see Table 1) has also forced nature to adopt special solutions. The imitation of these specific enzymatic processes in the laboratory would require an arsenal of enzymes that are not available today, although interesting initial successes have been reported.[197]

I thank my colleagues who developed the direct 1-O-alkylation and trichloroacetimidate methods during the course of master and doctoral theses at the University of Konstanz. These are G. Effenberger, A. Eßwein, M. C. Faas, G. Grundler, P. Hermentin, M. G. Hoffmann, K.-H. Jung, W. Kinzy, R. Kläger, A. Köhn, K. Laesecke, J. Lutz, J. Michel, U. Moering, M. Reichrath, M. Roos, E. Rücker, M. Stumpp, B. Wegmann, and P. Zimmermann.—Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support of this work.

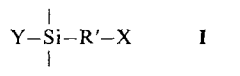
3-Chloropropyltrialkoxysilanes—Key Intermediates for the Commercial Production of Organofunctionalized Silanes and Polysiloxanes



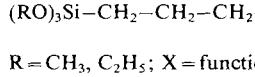
By Ulrich Deschler,* Peter Kleinschmit, and Peter Panster

Dedicated to Dr. Konrad Henkel on the occasion of his 70th birthday

Silicon and carbon may be looked upon as the two fundamental antipodes with respect to the naturally occurring forms of matter and life on earth: Silicon plays the key role in the "petrification" of inanimate matter, while carbon is the representative element for the "incarnation" of living organisms. If a scientist were to search for a highly efficient method of uniting inorganic and organic matter, he would, at a very early stage of attempting to solve this problem, combine these two natural principles of matter and think of "bireactive" molecules containing a silicon functionality for bonding to inorganic material on the one hand and a carbon functionality for anchoring to an organic counterpart on the other. The title compounds and their derivatives epitomize such molecules: they are wanderers between both (chemical) worlds. Owing to their bifunctionality they are capable of binding to inorganic (especially siliceous) systems as well as to organic polymers. Whether their commercial application concerns the strengthening of polyester resins with glass fibers for use in boatbuilding or the incorporation of silica as a filler in rubber mixtures for the manufacture of wear-resistant tires or even the immobilization of enzymes on glass spheres for carrying out reactions in enzyme reactors—in all cases organofunctionalized silanes guarantee a reliable and permanent union between two otherwise "incompatible" material systems.

1. Introduction

Hydrolyzable organofunctionalized silanes, as represented by the general formula **I**, have two reactive centers:



I

They are bifunctional in nature, bearing one reactive center X attached to a tetracoordinated silicon atom via a carbon-to-silicon bond and at least one group Y that is subject to hydrolysis under the influence of water (e.g. Y = Hal, OR, NR_2).

With regard to their industrial application, the bifunctional silanes of composition **II** and **III** are the most important:

II

III

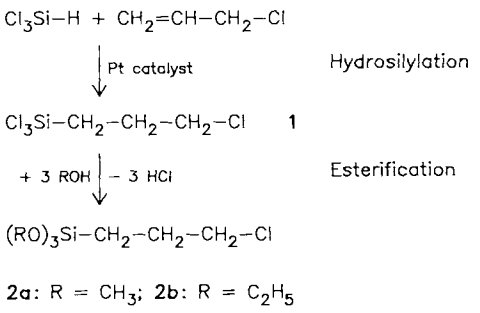
R = CH_3, C_2H_5; X = functional group

In this review we shall limit our discussion to silanes of type **III** containing a *functional group X* attached to silicon via a trimethylene spacer group on one side and a *hydrolyzable trimethoxy* or *triethoxy silyl group* on the other.

[*] Dr. U. Deschler, Dr. P. Kleinschmit, Dr. P. Panster
Degussa, Forschung Chemie Anorganisch
Postfach 1345, D-6450 Hanau 1 (FRG)

Organofunctionalized silanes are a relatively new class of compounds. They were first prepared in the early 1940s, after the discovery of the *Mueller-Rochow-process*[1] and the *hydrosilylation reaction*.[2]

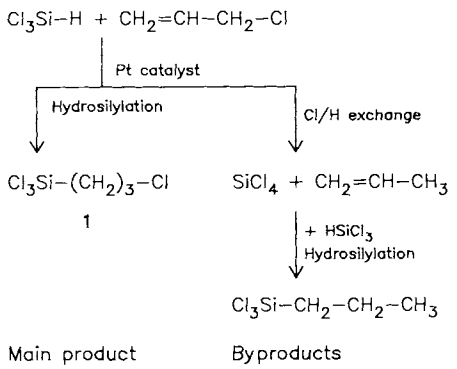
The potential of such compounds was soon realized, and, by 1949, the first industrial applications for these silanes had already evolved: *Silane-treated glass fibers* showed superior performance as reinforcement materials for organic resins.[3] In 1962, more than 100 organofunctionalized silanes—many of them derivatives of 3-chloropropyltrichlorosilane **1**—had been evaluated in glass-fiber reinforced polyester and epoxy laminates, and the term *coupling agent*, describing their function in these composites, was well established.[4] Later on, the use of silane couplers was extended to other *polymer systems reinforced by particulate inorganic fillers*, since silanes could almost be tailor-made to fit a certain polymer-filler combination.[5]



A major breakthrough in this field was achieved in the early 1970s when certain derivatives of the title compounds proved to be effective coupling agents in *silica-reinforced* rubber articles, especially *tires*.[6] Since then, other applications for silanes **III** in the fields of *surface modification*, *active substrate immobilization* and *silane polycondensation* have been published.

As a result of this development, organofunctionalized silanes are produced today on a commercial scale in the United States of America, in Japan, and in Europe. They have become the fourth important class of commercially used organosilicon compounds, the others being silicones,[7] organosilicates,[8] and silylating agents.[9]

2. Syntheses

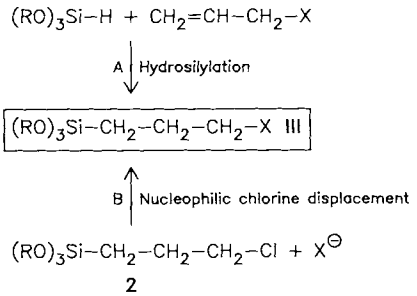


2.1. Synthesis of 3-Chloropropyltrialkoxysilanes

The industrial production of the title compounds **2** involves a two-step process as shown in Scheme 1.

Scheme 1. Industrial synthesis of the title compounds **2** via trichloro-3-chloropropylsilane **1**, b.p. 182°C/750 torr [10]. **2a**: b.p. 195°C/750 torr [10]; **2b**: b.p. 124°C/30 torr [10].

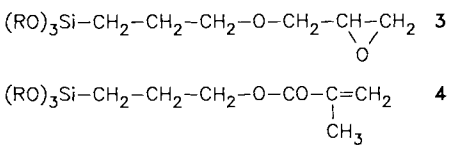
The catalytic addition of trichlorosilane to allyl chloride using various catalysts has already been reviewed.[2a] Most effective are homogeneous or heterogeneous platinum catalysts, which lead to almost quantitative conversion of allyl chloride, although a partial reduction of allyl chloride as side reaction cannot be avoided (Scheme 2).



Scheme 2. Products of the addition of trichlorosilane to allyl chloride.

As a result of this side reaction, propene, silicon tetrachloride, and trichloropropylsilane are formed. Under favorable reaction conditions, yields of 66% to 83% of **1** have been claimed.[10,11] **1** is a colorless liquid and can be purified by rectification.

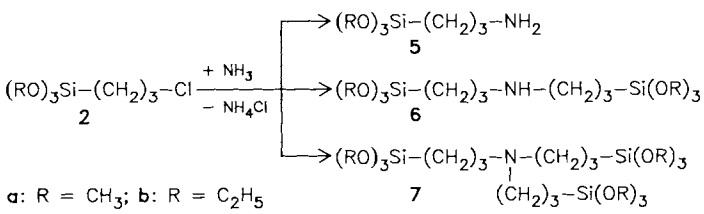
The trichlorosilyl group in **1** readily reacts with alcohols to give a trialkoxysilyl function. Only methanol and ethanol proved to be of industrial significance in reaction step 2 of Scheme 1 yielding the title compounds **2** as colorless liquids. Difficulties in conducting these esterification reactions arise from evolution of hydrogen chloride, which, under these reaction conditions, leads to formation of alkyl chlorides, water, and even ethers. The most undesired byproduct is water, since it causes oligomerization of **2**. Methods for fast HCl-removal have been published,[12] thus allowing high yields of **2**.



2.2. Synthesis of Organofunctionalized Derivatives of 3-Chloropropyltrialkoxysilanes

Silanes of type **III** are generally produced by the two synthetic routes depicted in Scheme 3.

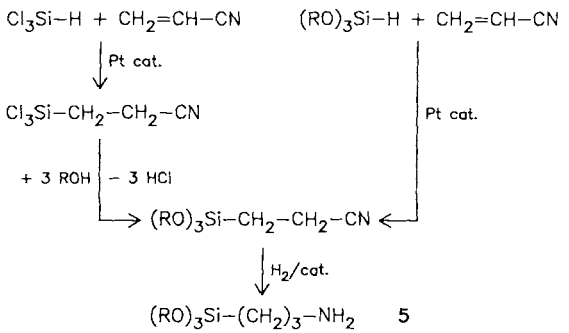
Scheme 3. Methods for the synthesis of organofunctionalized silanes of type **III**. A, B see text.



The *hydrosilylation of 3-functionalized 1-propenes* with trialkoxysilanes (Route A) necessitates the implementation of comparatively strict industrial safety measures because of the hazardous and toxic nature of trialkoxysilanes.[13] Technically important examples of this reaction involve the utilization of allyl glycidyl ether[14] and allyl methacrylate[15] for the production of epoxy- and methacryl-functionalized silanes **3** and **4**, respectively.

In this review we mainly deal with the production of silanes according to the second reaction path in Scheme 3 (Route B), namely the one involving *nucleophilic chlorine displacement* in **2**.

2.2.1. *Ammonia as Nucleophile*



Numerous publications[16,17] have been concerned with the reaction of anhydrous ammonia with **2** as shown in Scheme 4. For complete conversion of the starting materials **2**, which cannot be separated from the products **5** by distillation, the reaction of **2** with ammonia must be conducted at elevated temperatures and under pressure using

Scheme 4. Amino-functionalized silanes by reaction of **2** with ammonia. **5a**: b.p. 104°C/30 torr [16]; **5b**: b.p. 115°C/19 torr [16]; **6a**: b.p. 115°C/0.1 torr (distillation in a thin-film evaporator); **6b**: b.p. 145°C/1 torr [17a]; **7a**: b.p. 155°C/0.05 torr (distillation in a thin-film evaporator); **7b**: b.p. 200°C/1 torr [17a].

a large excess of ammonia. Under these conditions formation of the secondary amines **6** and tertiary amines **7** cannot be avoided. Since until now only the primary amines **5a**, **b** (in particular **5b**) have been of commercial interest, many efforts have been made to raise the yields above 50%, the value reported in the original publication.[17a] In one approach sodium methoxide was used as an HCl-acceptor, resulting in a 74% yield of the desired silane **5a**.[17b] A yield of 81% of **5b** was claimed under special reaction conditions.[17c]

In order to avoid formation of the undesired by-products **6** and **7**, another synthetic concept has been developed for the commercial production of **5** as shown in Scheme 5. The hydrosilylation of acrylonitrile with trichlorosilane[18] followed by the esterification of the trichlorosilyl function[19] yields 2-cyanoethyltrialkoxysilanes, which can also be obtained by addition of trialkoxysilanes to

Scheme 5. Industrial method for the production of byproduct-free **5**.

acrylonitrile.[20] Catalytic reduction of the nitrile function leads exclusively to the primary amines **5**.[21]

The direct hydrosilylation of allylamine with trialkoxysilanes has been described as a third preparative entry to **5**,[22] but it does not seem to be competitive, for economic reasons.

2.2.2. *Ethylenediamine as Nucleophile*

The ethylenediamine derivative of **2** has also claimed importance for numerous technical applications. In its preparation according to Equation (a) at least a 2.5-fold excess of amine has to be employed in order to remove the by-product hydrogen chloride effectively and to avoid the formation of doubly silylpropyl-substituted ethylenediamine.[16,23]

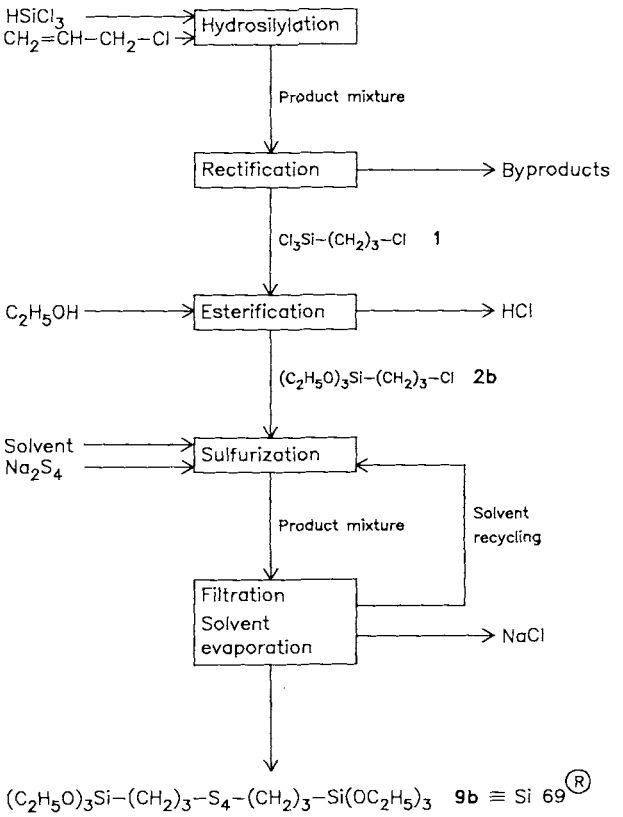
$$\underset{\mathbf{2}}{(RO)_3Si-(CH_2)_3-Cl} + H_2N-(CH_2)_2-NH_2 \longrightarrow \underset{\mathbf{8}}{(RO)_3Si-(CH_2)_3-NH-(CH_2)_2-NH_2} + HCl \qquad (a)$$

8a: R = CH_3, b.p. 146 °C/15 torr[16]
8b: R = C_2H_5, b.p. 156 °C/15 torr[16]

In the absence of a solvent the reaction mixture separates into two phases. Distillation of the upper layer furnishes the desired products **8** in yields of up to 88%.[23]

The hydrosilylation of allylethylenediamine with trialkoxysilanes[22b] as an alternative access to **8** does not seem to be competitive because of high costs for raw materials and comparatively low yields of desired silanes.

2.2.3. *Disodium Tetrasulfide as Nucleophile*



The chlorine displacement in **2** according to Equation (b) using disodium tetrasulfide as nucleophile, which can be prepared separately[24] or generated in situ,[25] is also of commercial importance.

$$2\underset{\mathbf{2}}{(RO)_3Si-(CH_2)_3-Cl} + Na_2S_4 \longrightarrow \underset{\mathbf{9}}{(RO)_3Si-(CH_2)_3-S_4-(CH_2)_3-Si(OR)_3} + 2\,NaCl \qquad (b)$$

a: R = CH_3; **b**: R = C_2H_5

When the reaction is carried out in boiling alcohol as solvent (methanol for the reaction of **2a**, ethanol for that of **2b**), the yellow tetrasulfanes **9** are obtained in almost quantitative yield.[25]

The ethyl derivative **9b** (trade name "Reinforcing agent Si 69®", Degussa) has become one of the most important organofunctionalized silanes known today and is used mainly as a coupling agent in silica-filled rubber systems. It has been produced on a technical scale at Degussa's plant in Antwerp since 1976, using a three-step process as shown in Scheme 6. The characteristic properties of the commercially available product are listed in Table 1.

Scheme 6. Simplified flow diagram for the industrial synthesis of **9b**.

Table 1. Typical properties of **9b**.

Color and appearance:	Yellowish liquid
Boiling point at 1013 mbar:	Decomposition above 250°C
Pour point:	ca. −80°C
Flash point (DIN 51758):	>100°C
Density at 20°C:	1.095 g/cm³
Viscosity at 20°C:	ca. 11.4 cP
Total sulfur:	>22.0%
Polysulfidic sulfur:	> 9.5%
Toxicology:	Nontoxic according to tests on acute toxicity, *local skin toleration, local mucous membrane* toleration and sensitization

As is known for other dialkyltetrasulfanes,[26] in an equilibrium reaction the tetrasulfanes **9** can disproportionate to a mixture of polysulfanes having different sulfur chain-lengths. The proportions of the individual polysulfanes in such mixtures is dependent, inter alia, upon the pH value and the temperature,[27] and can be determined quantitatively by HPLC[28] and ^{1}H-NMR spectroscopy.[29] The short-chain members of the series of bis(silylpropyl)polysulfanes can be individually prepared by special synthetic methods up to and including the tetrasulfane;[29a,30] this is outlined in Equation (c) for the case of **9a**.

$$\underset{\textbf{10a}}{2(CH_3O)_3Si-(CH_2)_3-SH} + S_2Cl_2 \longrightarrow (CH_3O)_3Si-(CH_2)_3-S_4-(CH_2)_3-Si(OCH_3)_3 + 2HCl \quad (c)$$

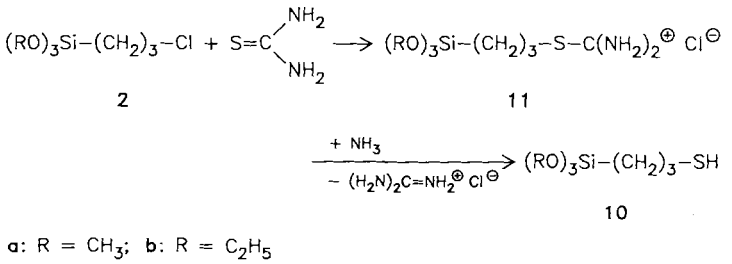
9a

In addition, further methods for the synthesis of the silanes **9** have been proposed.[31]

2.2.4. *Hydrogensulfide as Nucleophile*

Mercapto-functionalized silanes **10** can be obtained from **2** and anhydrous solutions of alkali-metal or ammonium salts of hydrogen sulfide according to Equation (d).[32]

$$\underset{\textbf{2}}{(RO)_3Si-(CH_2)_3-Cl} + MHS \longrightarrow (RO)_3Si-(CH_2)_3-SH + MCl \quad (d)$$



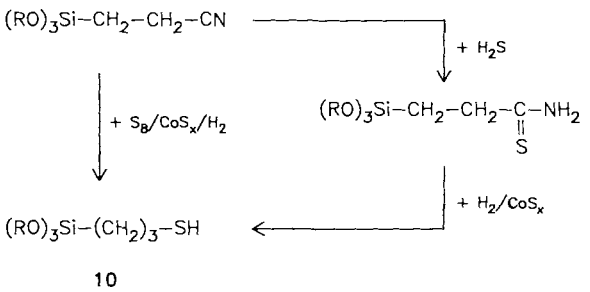
10

10a: R = CH_3, b.p. 53°C/0.8 torr[23a]
10b: R = C_2H_5, b.p. 112°C/14 torr[24a]

Alkali-metal hydrogensulfides (M = Na, K) seem to be less suitable (long reaction times, moderate yields[32a]) than the corresponding amine/H_2S combinations (M = NH_3,[32b] $N(CH_3)_3$,[32b] $H_2N-(CH_2)_2-NH_2$[32c]), where yields of up to 90% at reaction times of, at best, several hours and at temperatures of about 100°C are reported.

Another route to **10** is the reaction of halosilanes **2** with thiourea leading to the corresponding isothiuronium salts **11** and subsequent cleavage of the latter by means of ammonia (or other alkaline materials) as shown in Scheme 7.[33]

This synthesis can also be carried out as a "one-pot-process".[33] According to the patent literature substantial



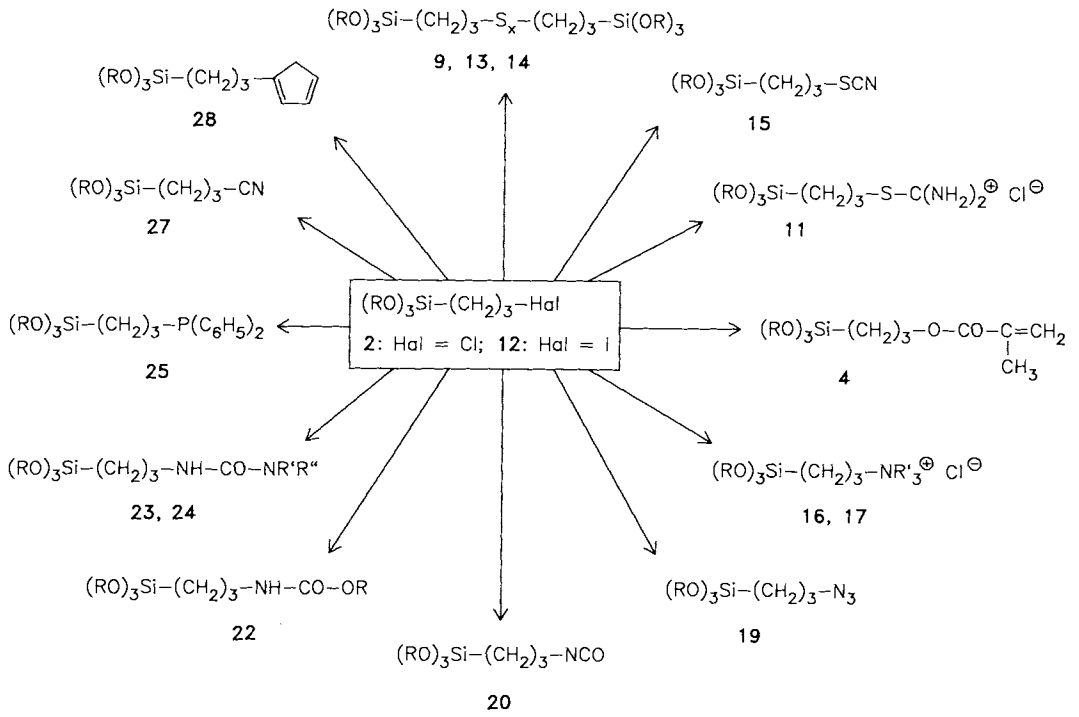
a: R = CH_3; b: R = C_2H_5

Scheme 7. Production of **10** via the isothiuronium salt **11**.

improvements with respect to yield, purity, and reaction conditions are achieved when dimethylformamide is used as solvent.[33c]

A third method for the preparation of the silanes **10** is based on the catalytic addition of H_2S to 2-cyanoethyltrialkoxysilanes as outlined in Scheme 8.[34]

Scheme 8. Production of **10** from cyanoethyltrialkoxysilanes.



2.2.5. *Other Nucleophiles*

Numerous other organofunctionalized silanes are known that are derived from **2** by nucleophilic chlorine displacement. With exception of the methacryl-functionalized silanes **4**, which, however, are not produced technically from **2** (cf. Scheme 3), these silanes still play a subordinate role, at least quantitatively, so that details of the production conditions will not be dealt with here. Rather, the multitude of silanes accessible via **2** and the iodide **12** will be outlined in general with Scheme 9 and Table 2.

3. Industrial Applications of Bifunctional Silanes

The applicability of a certain organofunctionalized silane is determined by the *reactivities* of its *functional groups*.

All the silanes under discussion have a *trialkoxysilyl group* in common; hence their chemical reactivity towards hydroxy-functional substrates are quite similar. As a result of this reactivity a bonding interaction between silane molecules and substrate surface is observed. The nature of this bonding, and the structure of the resulting silane film, depends upon the reaction conditions applied during silanization and has been investigated and reinterpreted several times. The monomolecular layer repeatedly given in the literature (Scheme 10) in which the silicon atoms are covalently bonded via oxygen bridges to one another and to the solid surface is only observed in certain individual cases[55] after silanization.

Scheme 9. Bifunctional silanes obtainable by nucleophilic displacement of halogen from **2** and **12**.

Depending upon the method of silanization chosen, much "thicker" silane layers are also formed at the phase interface,[56] the exact nature of which has been interpreted differently.[57] In any case a key role might be played by the catalytic amounts of water present at the phase interface, which enables a reversible opening and reformation of the oxygen bridges via intermediacy of hydrogen bonds:[58] It is by this reversible bond formation in the presence of water that stress along the filler-to-silane interface can be released.

Scheme 10. Monomolecular layer of silane as idealized concept of a bonding interaction between trialkoxysilanes and hydroxyfunctional surfaces. El = Si, Al, Ti, Zr, Fe, Zn, Cr, C, etc. [54].

The reactivity of the trialkoxysilyl group as discussed above is one of the two factors determining the usefulness of a certain silane. The other is the specific nature of the *functional group X*. Since X can be varied extensively (see Scheme 9 and Table 2) there is a wide scope of applications for these ccompounds today.[5,59]

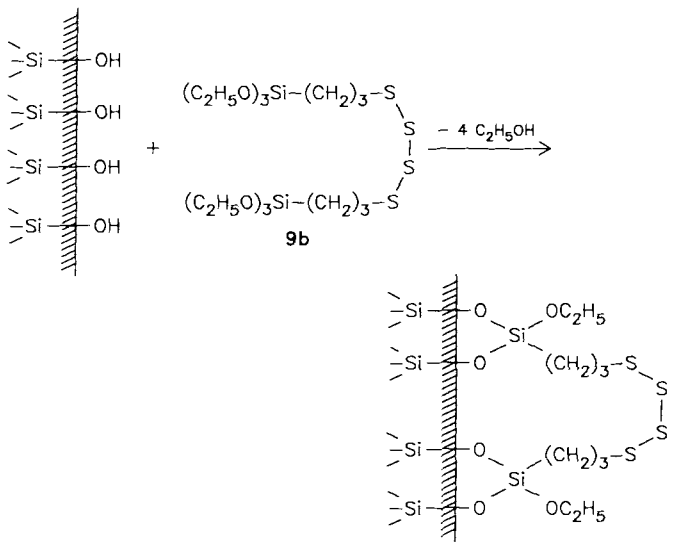
In this paper the term industrial applications is used for those applications where silane quantities ranging from about 100 tons to more than 1000 tons per year are involved worldwide. This does not imply, however, that other applications to be discussed in Section 4 are of no commercial importance.

3.1. Glass-Fiber Reinforced Thermosetting and Thermoplastic Resins

It is not only for historic reasons that this field of silane coupling application is discussed first[3]: The silane treatment of glass fibers before their incorporation into various polymer systems is one of the "big volume" silane applications today, even though the quantities of silane used generally only amount to 0.1–0.5% of the weight of glass.[60]

Depending on the polymer system to be reinforced, an appropriate choice of functional group X must be made: Amino-, epoxy-, methacryl- or chloro-functionalized silanes such as **5**, **3**, **4**, and **2**, respectively, play a major role in this respect.[60]

The most important polymer systems in use (e.g., for the production of glass fiber reinforced laminates for construction of boat and car bodies) are unsaturated polyester, epoxy, and phenolic resins.[5] Suitable silane/polymer combinations have already been reviewed several times.[4,60,61]

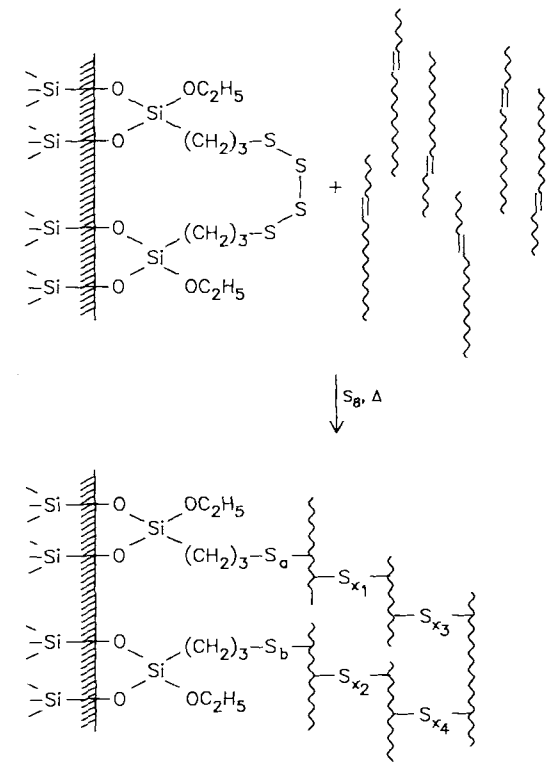


3.2. Mineral-Filled Rubbers (Elastomers)

Highly dispersed carbon blacks are the classical reinforcement fillers for almost all types of natural and synthetic rubbers.[62] Although precipitated silicas with similar particle sizes and surface areas were developed some forty years ago and have been produced since then on a technical scale,[63] their use in the rubber industry has, until recently, been restricted to special applications (e.g., shoe soles, certain mechanical rubber goods[63b]). The main disadvantages of silicas in this area, compared to the corresponding carbon blacks, are a considerably higher compound viscosity and a prolonged scorch time, both causing difficulties in the processing steps;[63b,64] furthermore, the attainable cross-linking density in sulfur-curing systems is reduced, resulting in a lower rubber reinforcement.[6,63b,64c]

It could be shown that these technical shortcomings in fact arise from the incompatibility of the two phases involved: The silica particles, with their hydrophilic surface,[65] very poorly interact with the hydrophobic rubber matrix. This problem can be overcome by installing chemical bonds between the two differing matrices with the aid of suitable bifunctional silanes.[66,67] This concept will be described in some detail choosing **9b** as an example, because this silane has developed into today's most successful and widely used *coupling agent for silica-filled rubbers* (especially natural rubber (NR) and styrene-butadiene rubber (SBR)).[6,63b,64c,67,68]

In the course of the manufacturing process for rubber goods **9b** *reacts* with silica or silica/carbon black reinforced rubber compounds *in a twofold manner*: In the first step, during the mixing process at temperatures below the curing temperature, the triethoxysilyl groups of **9b** become bonded to the filler surface. Formation of siloxane bonds takes place with elimination of ethanol (Scheme 11).



As a result of this *hydrophobation of the silica surface*, the high Mooney viscosity of silica-filled rubber com-

Scheme 11. Filler hydrophobation with **9b**.

pounds is reduced to values normally observed with carbon blacks. In order to achieve total hydrophobation of commercial rubber grade silicas (BET surface area $\sim 175\ m^2/g$; silanol group density $\sim 5\text{-}6/nm^2$) about 13 parts of **9b** per 100 parts of silica are required, taking into account that, because of steric reasons, only up to four of the six ethoxy groups of **9b** can react with silanol groups of the silica.[67a] However, in practice, far smaller amounts of silane already lead to a remarkable reduction in the compound viscosity.[67a]

In the second step (cf. Scheme 12), which starts at higher temperatures under curing conditions (e.g. 150–170 °C, in

Scheme 12. Coupling of the filler hydrophobated by **9b** with elastomers during vulcanization (in the presence of sulfur), idealized ($a+b=4$, $1 \leq x_i \leq 8$).

the presence of accelerators and in the presence or absence of sulfur), the sulfur chain of **9b** is split and the fragments are added to double bonds of the elastomer, thus forming *covalent sulfur-to-carbon bonds* which chemically link together the filler particles and the rubber network.[6, 63b, 67a–c]

The combined use of silica and **9b** in rubber materials, especially NR and SBR (for the use of **9b** in ethylene-propylene-diene rubber cf. [69]), leads to products with mechanical properties equal to or even superior to those of rubbers filled with carbon blacks.[67a, e] Hence, for the first time, substitution of semi-active and active carbon blacks in carcass and tread mixtures of car tires has become technically feasible without any loss of performance.[64c] From an economic viewpoint, however, the combination SiO_2/**9b** cannot, at least under present conditions, compete with carbon blacks as a reinforcement system for automobile tires.

The reason for today's increasing industrial use of various SiO_2/**9b** formulations in the rubber industry is to be seen in the technical superiority of durable rubber products that can be manufactured on this basis: Besides its role as coupling agent, the silane **9b** can—independently of the kind of filler— also act as *new type of reversion-free cross-linking agent*.

A "normal" sulfur vulcanization process proceeds in two phases with respect to the S–C cross-linking density (cf. Fig. 1). At the beginning ($t < t_e$), the number of S–C bonds formed per unit of time with increasing temperature is far greater than that of the thermally ruptured bonds, so that the overall number of S–C cross-linking sites increases. Reversion occurs at long curing times ($t > t_e$) and causes more S–C bonds to be split than newly formed, which results in unsatisfactory mechanical properties of the cured rubber article. Reversion is a problem, for example, in the manufacture of certain mechanical rubber goods and massive speciality tires such as the so-called off-the-road or heavy duty truck tires, where long curing times have to be applied in order to complete vulcanization through the thick rubber walls. Hitherto, attempts have been made to solve this problem by using the lowest possible curing temperature.[67d] A new concept by which reversion can be eliminated involves using a three-component cure system containing sulfur, accelerator and **9b** (*equili-*

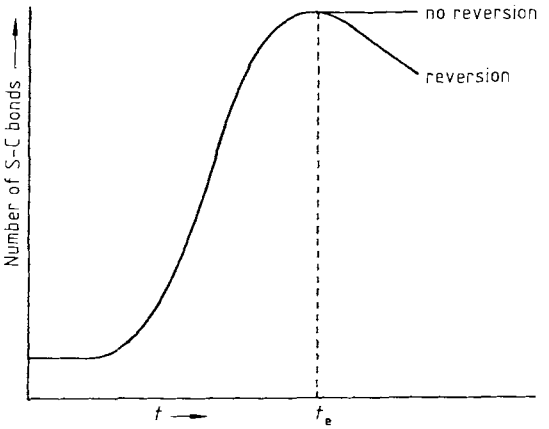


Fig. 1. Idealized vulcanization curves for normal and reversion-free sulfur cross-linking.

brium cure system), allowing higher vulcanization temperatures and shorter vulcanization periods for thick-walled rubber goods without loss of performance.[67d, 68e]

A few other silane derivatives of **2** are used to a limited extent in the rubber industry in combination with naturally occurring silicate fillers (silane applications in the automobile industry, e.g. in tires, bumpers, hoses, gaskets and windscreen sealants have been reviewed[70]). Table 3 lists some known examples of silane/rubber/filler combinations from the patent literature.

Table 3. Use of bifunctional silanes in filler-reinforced rubber.

Silane	Type of rubber [a]	Filler [b]	Ref.
2	halogenated	SiO_2	[71, 72]
	NR, SBR	SiO_2, clay	[66d]
5	NR, SBR	SiO_2, clay	[66]
	EPDM	clay	[73e]
8	EPDM	clay	[73b, c]
9b	NR, SBR	clay	[74]
10	NR, SBR	SiO_2, clay	[66, 75]
	EPDM	clay	[73, 75]
11	halogenated	SiO_2	[76]
	NR, SBR	SiO_2, clay	[66d]
15	NR, SBR	SiO_2	[38]
28	EPDM	SiO_2, clay	[53]

[a] NR = natural rubber, SBR = styrene-butadiene rubber, EPDM = ethylene-propylene-diene rubber. [b] Clay: collective term, for naturally occurring fillers, mainly consisting of aluminum silicates (kaolinites) containing additional cations (Fe, Mg, etc.).

3.3. Sealants

Sealants basically consist of highly viscous organic prepolymers and inorganic fillers besides plasticizers, solvents or curing agents. The sealants are cured after application to yield a semielastic material. In order to provide good adhesion to inorganic surfaces, sealants usually contain adhesion promoters. Organofunctional silanes if used as integral blend additives can serve this purpose.[77] Thus, silanes such as **3**, **5**, **8** and **10** are extensively used in polysulfide, polyurethane, polyvinyl chloride and silicone based sealants.[77, 78] Silanes may also be present in primer formulations to improve the adhesion of the sealant to an inorganic surface. However, the use of silane-containing primers[79] is losing importance because of the additional working step involved compared with sealants already containing silane.

3.4. Foundry Sand Molds

Several techniques for the preparation of foundry sand molds are available in the metal casting industry. Usually quartz sand is employed as principle refractory material for preparing molds, and normally small amounts of organic resins such as phenol or furan resins are used to function as binding material during mold production. However, since these organic components decompose with formation of volatiles at the temperatures used for casting, the quality of the castings deteriorates; therefore, any method permitting a reduction in the quantity of binder is most welcome. This can be achieved by incorporation of about 0.1% of aminosilane **5b** into the molding sand, which allows the amount of organic binder to be reduced from 3% to 1.5%.[80] Other useful silanes known from the patent literature include **3**, **4**, **8** and **10**[81] and urea derivatives of **5**.[82]

4. Other Applications of Bifunctional Silanes

Besides the "big volume" applications discussed above, numerous other areas are known where bifunctional silanes have proven useful. Literally thousands of patent publications deal with these various applications of silanes, thus making it impossible to mention all of them here. Therefore, in this review we shall only consider a selection of those uses which are already of some commercial importance (see, e.g., Sections 4.1.1, 4.1.2, 4.2.5, and 4.2.10) although the silane quantities involved may be small or which in our opinion bear a reasonable potential for further development.

For the purpose of an easy comprehensive survey these applications will roughly be classified into the fields of *coupling*, *substrate modification*, and *silane polycondensation*.

4.1. Coupling Applications

In principle, bifunctional silanes can provide a bonding interface between organic and inorganic matrices, as discussed in Section 3 for filler reinforced elastomers. It is essential for all coupling applications that the silane accumulates at the interface. Depending upon the nature of the organic and inorganic phases, this can either be achieved by addition of a silane (as an *integral blend additive*) to a prepolymer provided there is sufficient silane mobility in the organic polymeric material or, when mobility is poor, by *pretreatment of the inorganic surface* with pure (dry blending) or diluted silanes, either by immersion, painting or spraying.[59] Since the second mode of silane application involves an additional treatment step, the first method is used whenever possible. Pretreatment of the inorganic surface on the other hand allows a better control of the interface and is especially useful in coupling applications on massive structures (sealants, coatings, adhesives), where *primers* containing silanes[83] are used for surface pretreatment.

4.1.1. Particulate Mineral-Filled Thermosetting and Thermoplastic Resins

Numerous particulate mineral fillers have been found to improve the mechanial properties of filled polymer pieces after treatment with an appropriate silane coupler (silica, alumina, glass, aluminum and iron particles, clay, titanium oxide, and zinc oxide[59]).

Suitable methods for applying silanes to inorganic particulate fillers are filler treatment by organic or aqueous so-

lutions or by dry blending resulting in changes of physical properties (improved wettability by organic resins, reduced particle agglomeration) and of the processibility (improved dispersibility, reduced viscosity) of the silanized material.

Before curing, most thermosetting resins contain reactive centers suitable for chemical bonding to silanized fillers, as for instance unsaturated polyester, phenolic or epoxy resins. Certain thermoplasts (polydienes, polyvinyl chloride, polystyrene) also enable regular silane-to-polymer bonding by formation of covalent bonds.[5] In thermoplasts of relatively low molecular weight use can be made of end-group reactivity, as for instance in the case of polybutylene terephthalate.[5] Most thermoplasts, however, do not provide reactive centers for chemical bonding to silane couplers, so that the observed coupling interaction must be physical in nature: Aminosilanes **5**, for instance, play a major role in coupling inorganic fillers to polyesters, polyamides or polycarbonates via *hydrogen bonds*.[5] Silanes **4** containing a methacryl function may bind to unreactive thermoplasts (e.g. to polyethylene) by formation of *interpenetrating polymer networks* at the interface.[84] The *solution compatibility* of the organic part of a silane with a certain thermoplast may serve as a measure of the physical coupling interaction.[59] Several reviews have appeared concerning suitable filler/silane/resin combinations.[5,59,85]

A promising strategy for covalently coupling "unreactive" thermoplastic resins with silanized fillers involves the use of azide-functionalized silanes, e.g. **19**, which, at molding temperatures liberate reactive nitrene[86] and imine intermediates[87] that are expected to insert into C–H bonds of polyolefins.[5,88]

4.1.2. Dental Materials

Dental varnish and filling materials based on filler reinforced peroxide-curable acrylic polymers containing methacryl-functionalized silanes **4** have been described in numerous publications[89,90] and are used extensively. Thereby, the silane provides adhesion of the organic polymer to the natural tooth material.

4.1.3. Rock/Asphalt Mixtures

The rock/asphalt mixtures used in road building contain up to 95% of mineral aggregates, which may either be siliceous (e.g. granite) or calcareous (e.g. limestone) in nature. These mineral contents are held together by a bituminous binder. It was already established at a very early stage of organosilane chemistry that certain alkylsilanes may very well serve as adhesion promoters in rock/asphalt mixtures, though the technique proposed for silane processing (treatment of the mineral components with silane vapors) was prohibitive for realization on a large scale.[91] Many years later, the use of organofunctionalized silanes, such as **4**, **5**, **8**, **10**, and, in particular **9b**, for this purpose was published in connection with a very favorable method of silane addition:[92] The silane is first treated with carbon black or silica and can then be admixed in a quasi-powdered form with the solid mineral components.[92b]

4.1.4. Coatings for Siliceous and Metallic Surfaces

Adhesion of organic coatings (paints or inks) to inorganic surfaces (glass, steel, aluminum) is improved, if the uncured coating material contains a silane like **2**, **3**, **4**, **5**, **8**, or **10** as additive.[93] For optimum performance the silane must accumulate at the interface, which is quite easily achieved in the case of latex coatings.[83a] In other cases the same effect can be realized with an undercoat of silane-containing primer.[83,93]

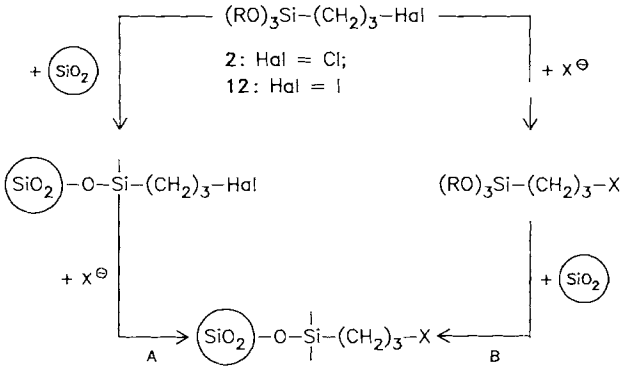
4.1.5. Coatings for Organic "Glasses"

Transparent organic polymers such as polycarbonates or polyacrylates are superior to silicate glass from the point of view of handling and processibility, but cannot compete with inorganic glasses as far as resistance to abrasion and scratching is concerned.[94] This disadvantage can be overcome by applying a thin layer of siliceous material onto the polymer surface. Here again bifunctional silanes such as **3** and **4** can decisively improve the coupling between inorganic coating and organic surface.[95]

4.1.6. Adhesives

Silanes find another application which is closely related to those discussed in Sections 3.3 and 4.1.4, namely as additives to or primers for adhesives that are used to improve the adhesion between inorganic materials (ceramics, glasses, metals).[96] The adhesive strength of thermosetting and thermoplastic polymers can be increased markedly by addition of small amounts (ca. 1%) of silane to the adhesive.[96a] The choice of silane coupler largely depends upon the curing mechanism of the adhesive: The silanes **3**, **4**, **5**, and **10** are claimed to be of particular value in the more important adhesive systems currently on the market.[96]

4.2. Fixation of Functional Groups and Active Compounds to Inorganic Substrates



The immobilization of functional groups or (macro-)molecules showing a certain reactivity in the homogeneous phase on solid supports has attracted increasing interest during the last two decades, especially in the fields of transition metal-[97] and enzyme-catalysis,[98] organic synthesis,[99] chromatography,[100] and ion exchange.[101]

The advantages of these immobilized systems are the ease of separation and inexpensive recycling on the one hand, and the high stability and long lifetime on the other.[97,98]

Organic polymers were the first carriers to be used commercially.[99d] Inorganic supports such as silica, silica gel, alumina and other mineral oxides proved to be superior with respect to structural stability, swelling behavior, thermal properties and aging, accessibility of reactive centers, and insolubility in organic media.[97]

One concept developed for the immobilization of functional groups or active molecules on inorganic substrates involves their attachment via bifunctional silanes (e.g., **2** and its derivatives).[97e,98e]

Two synthetic routes have proven useful for the preparation of functionalized surfaces with the title compounds, namely those shown in Scheme 13.[102]

Scheme 13. Preparation of silanized silica with the silanes **2** and **12**. SiO_2 in a circle denotes silica carrier (without surface groups). A, B see text.

According to route A, the silanes **2** or **12** are first attached to the carrier; the resulting silanized silica is then modified by nucleophilic substitution with the functional group X. Route B involves the reverse procedure, i.e., substitution of **2**/**12** with X followed by attachment of the resulting silane derivative to the carrier. Route A is preferred in those cases only, when the nucleophile also reacts with the trialkoxysilyl group. Alkoxypropylsilylated surfaces, for instance, can only be prepared via route A (X = OR).[103]

4.2.1. Textile Fiber Treatment

The silanization of textile fibers (including cotton as well as synthetic fibers) was one of the very early applications of hydrolyzable organosilanes; this enabled the manufacture of water-repellent textiles.[104] Today, silicones are the only organosilicon compounds of commercial importance in this field of application.[105]

In the early 1970s, it was found that ammonium-functionalized silanes, especially **18**, exhibit bactericidic and algaecidic activity after attachment to glass or other siliceous carriers[106] and textile fibers;[107] this immediately suggested the utilization of these silanes for the manufacture of surgical drapes.[107b]

4.2.2. Liquid Crystals

After fixation to glass, some bifunctional silanes, e.g. the long-chain ammoniopropylsilane **18**, impose a certain steric orientation upon an organic substrate, since all alkyl chains in **18** tend to orientate parallel to each other.[108] This effect can be utilized for the manufacture of liquid crystal displays.[108] Silanized liquid crystal phases have been prepared starting from the isocyanate **20**.[109]

4.2.3. Metal (Oxide) Electrodes

Elements such as Si[55a] or Ag[110] and metal oxides such as Al_2O_3,[110] SnO_2,[111] TiO_2,[112] or PbO[55b] have been covered with monolayers of the silanes **2**,[111a] **4**,[55b] **5**,[55a,111a,c] **8**,[111a,e] **10**,[110,111b] and **27**.[111d] Redox active molecules can be attached to these silanized surfaces by chemical reaction, thereby changing the electron-transfer properties of the underlying electrode.[111,112] Attachment of light absorbing redox dye molecules to silanized electrodes was proposed as a concept for construction of photoelectrochemical devices.[113]

4.2.4. Electrostatographic Developing Materials (Toners)

Numerous photocopying printers are based on electrostatographic processes: Under the influence of light, latent electrostatic images are formed as negative charge patterns on an electroreceptor surface. In the indirect process this latent image is developed by a toner powder of reversed polarity and transferred to plain paper. Basically, toners consist of an organic resin and a dye pigment. Their performance is highly improved by a uniform and stable distribution of positive charges within the powder. This uniform distribution can be achieved by addition of fumed silica particles pretreated with aminosilanes such as **5**, **6** or **8**.[114]

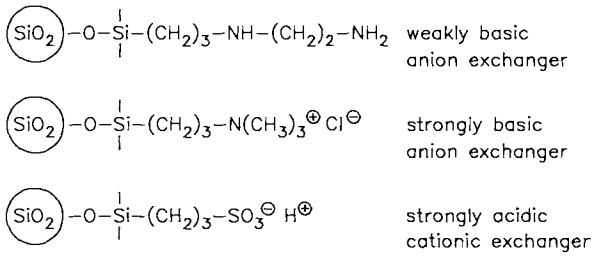
4.2.5. Chromatography

Hydrolyzable organosilanes have become an important tool for the preparation of modified silica gels[100a] that are used as stationary phases in *gas-*[115] and *liquid-chromatography*[115c,116] (especially *HPLC*[117]) as well as in *thin layer chromatography*.[118] Long-chain alkylsilanes play a major role in *reversed phase chromatography*,[119] but will not be discussed here further. Besides hydrophobicity, other physicochemical properties useful for chromatographic separations can be conferred on silica gel by modification with organofunctionalized silanes.

A selection of silanized phases that are useful for liquid chromatography is listed in Table 4.

4.2.6. Metal (Ion) Extraction

In principle, all silanes containing electron donating or chelating groups, for instance **5**, **8**, **10** and **13**, exhibit metal-ion complexing properties after attachment to an inorganic support.[128] Another access to such metal adsorbing materials is provided by the silanization of inorganic substrates with the silanes **2**, **5** or **12** and subsequent incorporation of the complexing group according to Route B in Scheme 13.[129] Practical utilizations published for these materials include the removal of metal-ions (especially uranyl ions[128a,129b]) from aqueous media and organic media (e.g. from kerosene[129b]) as well as the preconcentration of metal ions (e.g., for analytical detection[130]).



4.2.7. Ion Exchangers

The silanization of inorganic carriers with **8**,[124c] **16**[124d] or a sulfonate-functionalized silane derived from **10**[123a] or **11**[39a] yields materials showing ion exchange properties

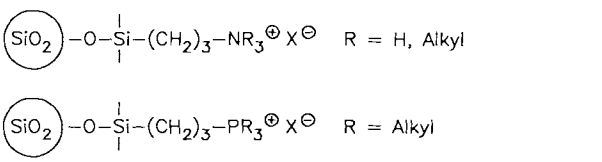
(Scheme 14). Alternatively, these ion exchangers can be prepared by silanization of inorganic substrates with halo-functionalized silanes **2** or **12** followed by nucleophilic substitution with tertiary amines[131] or sulfite ion.[123b]



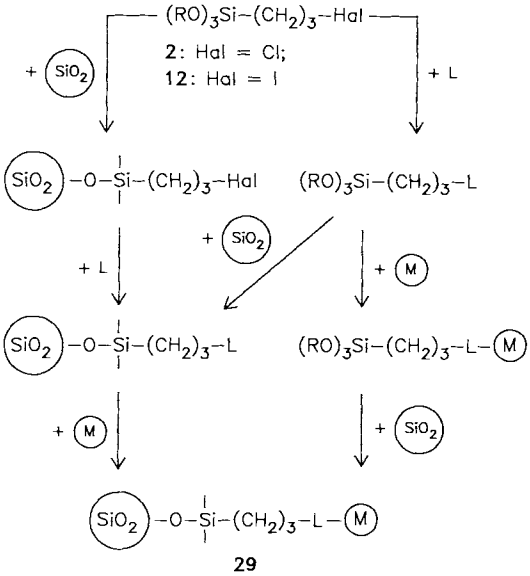
Scheme 14. Silanized siliceous materials as ion exchangers.

A principal disadvantage of these ion exchangers is their relatively low capacity as compared to that of conventional organic exchangers.[101a, 124d] New inorganic ion exchangers with hydrolytically stable bonding of the functional groups to the carrier, which can be obtained by polycondensation of bifunctional silanes, have higher capacities (cf. Section 4.3).

4.2.8. *Phase Transfer Catalysts*

Only ten years after first being described in the literature, phase transfer catalysts are already being used on an industrial scale for heterogeneous catalysis.[132] A group of such catalysts[133] (cf. Scheme 15) is accessible by modification of silica[133a,b] or alumina[133c] with ammonium[133a,c] and phosphonium[133b,c] active groups, once again via the two routes in Scheme 13.[133a]

Scheme 15. Examples of phase-transfer catalysts for heterogeneous catalysis.



The influence of various alkyl substituents attached to the onium center on activity and selectivity was studied[133a], as also was the influence of the bridge length (3–27 atoms) between the silyl group and the onium function.[133b,c]

4.2.9. *Transition-Metal Catalysts*

The immobilization of catalytically active transition-metal centers on oxidic carriers (SiO_2, Al_2O_3, TiO_2, SnO_2, ZnO_2, MgO)[134] is also possible with certain silanes;[97e] thereby, the advantages of homogeneous (well defined active sites, availability of all metal centers, flexible steric and electronic environment) and heterogeneous (easy recovery and recycling) catalysis[97b] should be combined.

The preparation of these transition-metal catalysts can be carried out by several routes, since silanization, introduction of the ligand-group, and attachment of the metal center can be achieved in various orders of succession, as indicated in Scheme 16.[102, 135]

Selected examples of siliceous carriers silanized with derivatives of **2** are listed in Table 5.

Scheme 16. Preparation of immobilized transition-metal complexes **29** from **2** or **12** (see also Tables 5).

Table 5. Transition-metal complexes of type **29** as heterogeneous catalysts, prepared with bifunctional silanes.

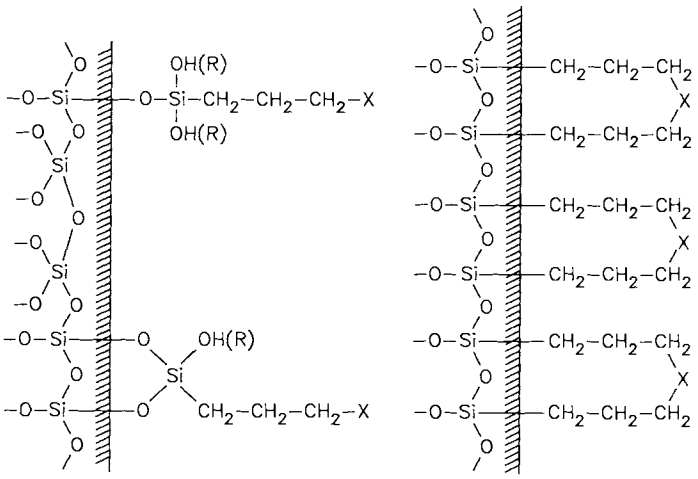
4.2.10. Enzymes and Polypeptides

After immobilization on solid carrier materials, enzymes can easily be utilized in industrial processes. Once again, inorganic supports, such as glass beads or silica gel, exhibit greater structural and operational stability as well as a higher resistance to microbial attack as compared to carriers based on organic polymers.[98]

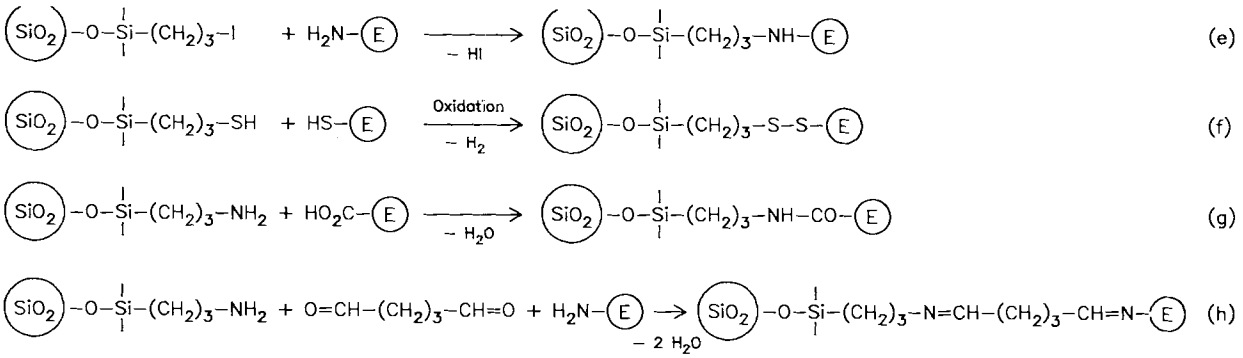
Numerous methods have been described for the coupling of enzymes to silanized supports.[5, 142, 143] A few of them, starting with silanes **5**,[142] **10**,[142a] and **12**,[143] are summarized in Scheme 17 to demonstrate exemplary bonding environments of fixed enzymes.

Porous glass beads treated with **5b** are commercially available for enzyme immobilization[144] and are used in packed-bed reactors for the degradation of yeast and for the isomerization of fructose.[98c, e]



Of the numerous *analytical applications* of immobilized enzymes,[145] only those are mentioned here, in which silanized supports are involved, namely *bioaffinity chromatography* (cf. Table 4) and *enzyme flow analysis*.[98c, 146] Silanized glass beads have also been proposed for substrate immobilization for the sequence analysis of peptides and proteins by *Edman degradation*.[147]

4.3. A New Class of Functionalized Organopolysiloxanes by Polycondensation of 6, 7, 13, 14, and 26

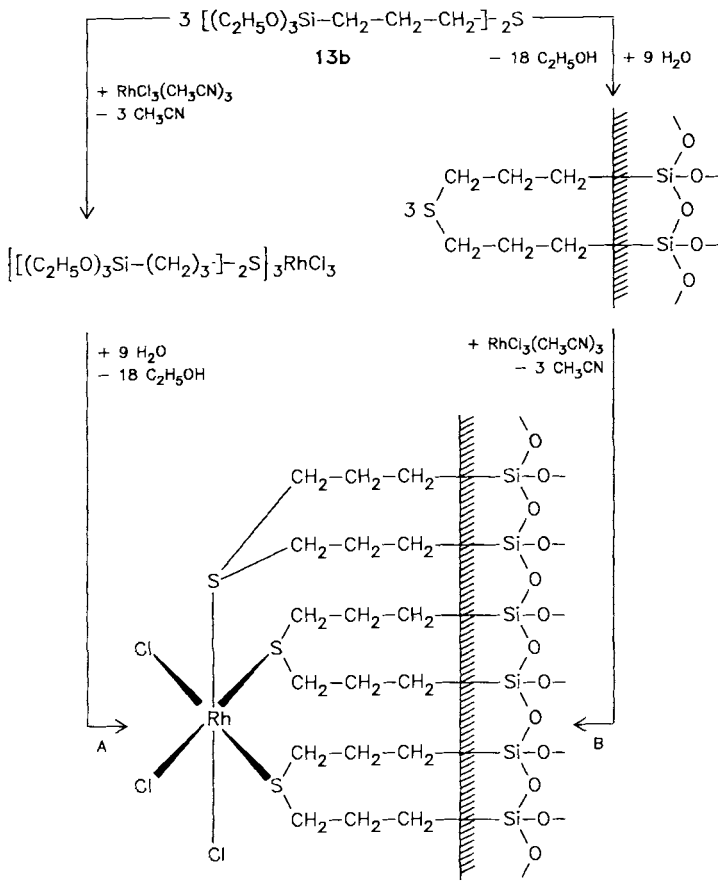


Silanized inorganic materials have a number of advantages compared to organic polymers; nevertheless, their properties as supports for immobilized functional groups and active compounds are not optimal. Because of the relatively low concentration of surface hydroxy groups, on average only 1-1.5 of three possible bonds are formed between the organofunctionalized silane and the support. As a consequence, the concentration of functional groups is quite low and the silane-to-surface bond is labile, especially in alkaline aqueous media.

In view of this, a newly developed concept may provide an interesting alternative: Polycondensation of suitable bifunctional silane monomers leads to solids with a *siliceous core* and a *high concentration of functional groups*, which, moreover, are bound to the matrix via carbon-silicon bonds that are stable towards hydrolysis.

Scheme 18 shows the qualitative difference between silicic acid that has been treated with bifunctional silanes and polycondensed silanes.

Scheme 18. Silanized siliceous surface (left) obtained from a monomer $(RO)_3Si-(CH_2)_3-X$, and polycondensed functionalized silanes (right), obtained from a monomer $(RO)_3Si-(CH_2)_3-X-(CH_2)_3-Si(OR)_3$.



Scheme 17. Selected reactions for the coupling of enzymes (E) to siliceous carriers silanized with **12**, **10**, and **5**. (f): cysteine coupling; (g): carbodiimide coupling; (h) Schiffs-base coupling.

The physical and chemical properties of the solid silane polycondensates can be tailor-made during or after the polycondensation for particular purposes; examples are, as *heterogeneous metal complex catalysts* and *ion exchangers*.

4.3.1. Immobilized Metal Complex Catalysts with Organopolysiloxane Structure

Following this concept we have prepared rhodium complexes as heterogeneous catalysts, starting from sulfide-functionalized silane precursors **13b**.[135] Two synthetic routes met with success (Scheme 19): Either **13b** is first allowed to react with a rhodium compound, e.g. tris(acetonitrile)trichlororhodium to give a monomeric complex,[135] which is subsequently polycondensed (Route A), or **13b** is first polycondensed and then converted into the rhodium complex (Route B).[148] In both cases the spontaneous polycondensation furnishes an insoluble solid. It was found that the polymeric rhodium complex does not necessarily need to be stoichiometrical, with a ligand/metal ratio of 3:1. If desired, more sulfide ligands can be present in the polymer complex. By means of so-called cross-linking agents or cocatalysts, which are incorporated into the matrix, control of the sulfide density is possible. For example, tetraalkyl silicates and tetraalkyl titanates can be used for this purpose. The carriers for these polymeric complexes can in this way be tailor-made for certain catalytic requirements.

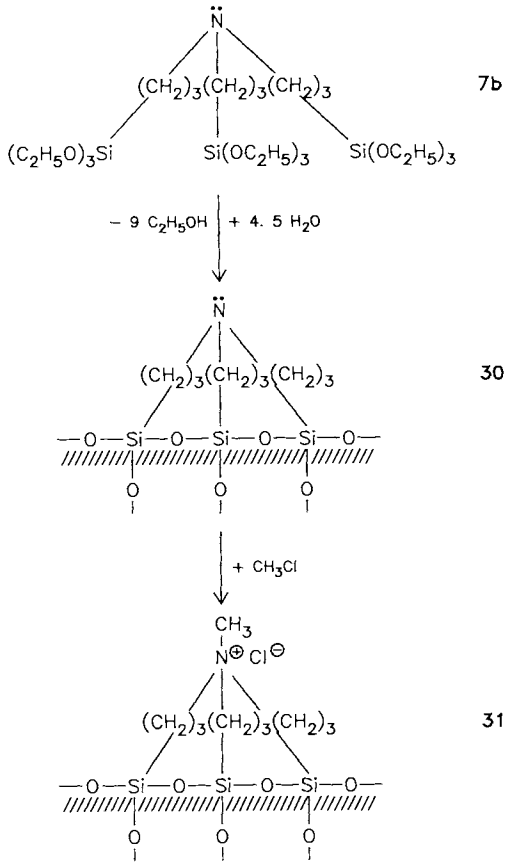
Scheme 19. Synthesis of organopolysiloxane-based thiorhodium complexes as heterogeneous catalysts. A, B see text.

Rhodium complexes prepared from other silane precursors appear to be even more promising as heterogeneous catalysts: Thus, polymeric phosphanerhodium complexes with siliceous frameworks are obtained from the phosphane-functionalized silane **26b** according to the procedure outlined in Scheme 19. Again the phosphane/metal ratio can be adjusted to meet certain catalytic requirements.[149] Finally, aminorhodium complexes of this type can also be prepared in the same manner, starting from the amino-functionalized silanes **6b** or **7b**.[150]

Rhodium is just one typical example as catalytic center: Naturally, analogous immobilized complexes with other transition metals can also be synthesized.[149a, 150b, 151]

Table 6. Typical fields of application for some organopolysiloxane-based transition-metal complexes as heterogeneous catalysts.

Catalyst composition [a]	Catalyzed reaction
"$RhH(CO)\{S[(CH_2)_3-SiO_{3/2}]_2\}_3$"	Hydrogenation
$RhCl_3\{N[(CH_2)_3-SiO_{3/2}]_3\}_3 \cdot 2PPh_3$	Hydrogenation
$RhCl_3\{S[(CH_2)_3-SiO_{3/2}]_2\}_3$	Hydroformylation
$RhCl_3\{N[(CH_2)_3-SiO_{3/2}]_3\}_3$	Hydroformylation
$RhCl_3\{C_6H_5-P[(CH_2)_3-SiO_{3/2}]_2\}_3$	Carbonylation
$IrCl_3\{C_6H_5-P[(CH_2)_3-SiO_{3/2}]_2\}_3$	Carbonylation
$\{H_3C-N[(CH_2)_3-SiO_{3/2}]_3\}_2^{2+}[PtCl_4]^{2-}$	Hydrosilylation
$PtCl_2\{N[(CH_2)_3-SiO_{3/2}]_3\}_2$	Hydrosilylation



[a] The notation $X[(CH_2)_3-SiO_{3/2}]_n$ signifies that the complex is a complete polycondensate of a trialkoxysilane precursor of the composition $X[(CH_2)_3-Si(OR)_3]_n$ with n = 2, 3.

The catalytic properties of a few selected examples listed in Table 6 are very promising; however, the systems will have to be optimized prior to their employment on an industrial scale.

4.3.2. New Ion Exchangers with Organopolysiloxane Structure

For the synthesis of anion exchangers on the basis of polycondensed amino-functionalized silane precursors[150a, 152] the reaction of the title compounds with ammonia had to be optimized in a new direction: under well-defined reaction conditions and stoichiometries, the reaction already presented in Scheme 4 leads almost quantitatively to the tertiary amine **7b**,[150a] which, upon addition of water readily undergoes condensation to give an amino-functionalized solid **30** containing a polysiloxane framework (Scheme 20). This substance, which itself is a weakly basic ion exchanger can be quaternized, e.g. with methyl chloride, to give **31**, which can function as a strongly basic anion exchanger.

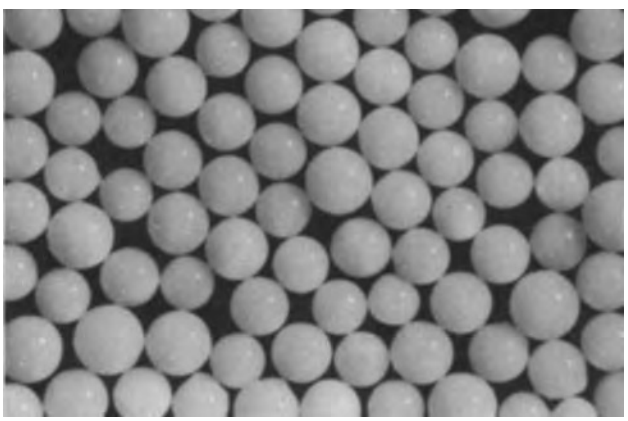
After the usual condensation process, both types of exchanger are obtained in the form of unsymmetrical particles, which can be milled and classified according to size. Their surface areas in this form are in a range of about 0 to 700 m^2/g, depending upon the conditions of preparation. Recently, a process was developed by us which also allows the preparation of *spherical particles* with grain sizes of about 0.1–1.5 mm and surface areas from only a few m^2/g up to about 700 m^2/g (Fig. 2). The exchange capacities, which can be controlled, inter alia, by insertion of different quantities of cross-linking agents (e.g. tetraalkyl silicates)

Scheme 20. Production of organopolysiloxane-based weakly basic and strongly basic anion exchangers **30** and **31**, respectively.

into the polysiloxane matrix, are, in the case of the strongly basic type exchanger **31**, partly in excess of 1.6 meq $Cl^{\ominus}$/mL, and thus reach the upper values of conventional organic exchanger systems.[101] The main advantage of the new exchangers lies in their high temperature stability, up to 200°C. This is primarily a consequence of the threefold matrix-bound ion-exchanging groups.

Strongly acidic cation exchangers can also be obtained on the basis of this concept[153] (Scheme 21).

Their synthesis starts from the silane **14b**, which is polycondensated in the usual manner.[153a] The cation-exchang-



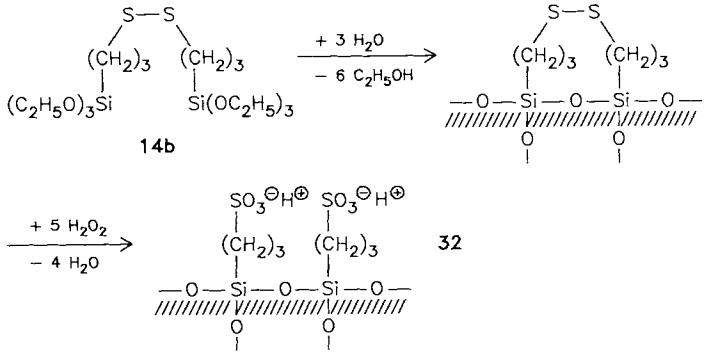


Fig. 2. Organopolysiloxane-based anion exchangers of type **31** in the form of spherical particles (magnified about eleven times).

Scheme 21. Production of organopolysiloxane-based strongly acidic cation exchanger **32**.

ing sulfonate groups are generated in the resulting solid material by subsequent oxidative cleavage of the disulfide bridges, e.g. with hydrogen peroxide; exchange capacities of 1–2 meq/g can be achieved.[153b]

Materials of type **32** show similarly good properties as the anion exchangers discussed above, especially a high temperature stability of up to 300°C. Therefore they can also be used as solid catalysts in acid-catalyzed reactions at elevated temperatures.

5. Conclusion

3-Chloropropyltrialkoxysilanes, and some derivatives obtainable therefrom by nucleophilic displacement of chlorine, have been produced on a commercial scale for about 20 years. They were originally used as *coupling agents*, mainly in *glass fiber-reinforced thermoplasts*, in organic *sealants* containing inorganic fillers, and in *casting molds* prepared from foundry sand and organic binders. Within the last decade the benefit of silanes for the rubber industry has been established, since sulfur derivatives of the title compounds have been found to be useful as coupling agents in *silica-reinforced rubber articles* (e.g., *special tires*) or as essential ingredients of *equilibrium cure systems* for sulfur-curable elastomers. Less important with respect to the silane quantities involved are coupling applications in the fields of particulate filler-reinforced thermoplasts, dental materials, rock/asphalt mixtures, coatings and adhesives, though foreseeable future developments are likely to result in higher silane consumptions in these areas, too.

A second group of applications for these compounds with a high potential in future developments exists in the *modification of hydroxy-functional surfaces* in a very general sense: Until now promising practical realizations have been achieved by silanization of glass (e.g. for the preparation of liquid crystal display systems), of silica (e.g. for the manufacture of toners), and of textile fibers or metal oxide electrodes. The *fixation of functional groups and active compounds* to inorganic carriers with the help of bifunctional silanes as a special type of surface modification has shown promise in the fields of chromatography, metal extraction, and catalysis, and is used commercially in certain *enzyme reactors*.

Finally, certain derivatives of 3-chloropropyltrialkoxysilanes, after *polycondensation*, yield *solid functional polysi-*

loxanes. Possible utilizations of these materials include the manufacture of ion exchangers and the preparation of transition-metal complexes as heterogeneous catalysts.

Future demands on silanes in all the areas listed above will most likely be met with the help of known silanes (e.g., by *optimization of the silane-to-substrate interface*) rather than by the development of new classes of silanes. Parallel to the discovery of yet unknown or to the expanded use of known composite materials new or extended markets for bifunctional silanes can be expected in the future.

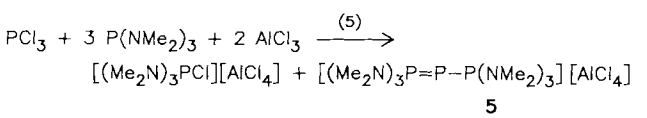
New Products from PCl_3, $P(NMe_2)_3$, and $AlCl_3$**

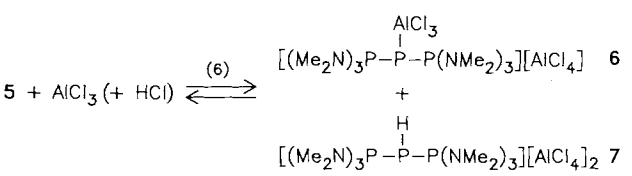
By *Alfred Schmidpeter** and *Siegfried Lochschmidt*

Dedicated to Professor Rolf Appel on the occasion of his 65th birthday



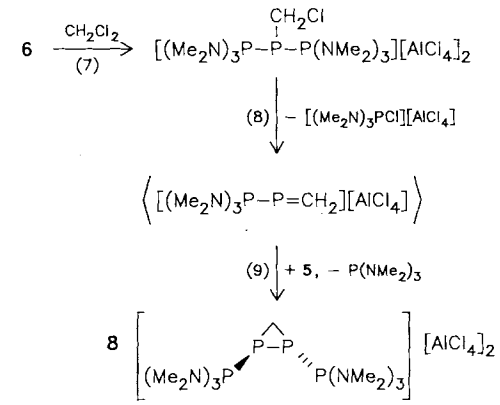
PCl_3 reacts with $P(NMe_2)_3$, resulting in substituent exchange [reaction (1)].[1] When $AlCl_3$ is present as a third component, the phosphenium tetrachloroaluminate **1** and phosphonium tetrachloroaluminates **2** and **3** are formed according to reactions (2) to (4).[2]

Because PCl_3, Ph_3P, and $AlCl_3$ undergo a redox reaction to give the triphosphenium salt **4**,[3]



$[Ph_3P{=}P{-}PPh_3][AlCl_4]$ **4**

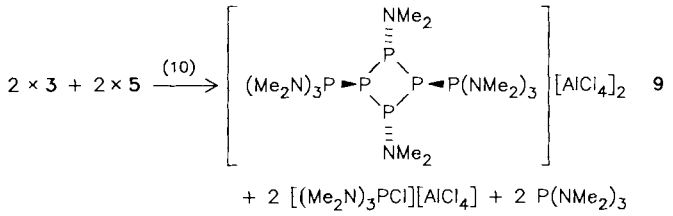
it was of interest to find out whether the system PCl_3/$P(NMe_2)_3$/$AlCl_3$ could undergo the corresponding reaction (5) to form **5**. The theoretically required molar ratio of the reactants $PCl_3 : P(NMe_2)_3 : AlCl_3$ (1 : 3 : 2) for the formation of **5** lies just between that for the formation of **3** (1 : 2 : 1.5) and that for the formation of **2** (1 : 5 : 3). Compound **5** had been synthesized earlier from **4** by means of $Ph_3P/P(NMe_2)_3$ exchange and proved to be stable,[3] so that we undertook a new investigation of the system PCl_3/$P(NMe_2)_3$/$AlCl_3$.



We found that the sequence in which the reactants are added determines the products of the reaction: If a 1 : 3 mixture of PCl_3 and $P(NMe_2)_3$ in CH_2Cl_2 is initially prepared, so that the substituent-exchange reaction (1) can occur, then the subsequently added $AlCl_3$ reacts according to reactions (2) to (4). The reactions are reversible and, as expected from the stoichiometry, reaction (2) becomes predominant with increasing amounts of $AlCl_3$; when $AlCl_3 : PCl_3$ is 4 : 1, it is virtually the only reaction. On the other hand, if $P(NMe_2)_3$ and $AlCl_3$ in a molar ratio of 3 : 2 are dissolved in CH_2Cl_2 at 0 °C (cf. ref. [2]) and subsequently treated with PCl_3, then reductive formation of **5** takes place according to reaction (5).

Products **1** and **5**, formed via these two pathways, cannot be interconverted. Although different ratios of the reactants (1 : 2 : 3 and 1 : 3 : 2, respectively) are involved in their formation, subsequent compensation (i.e., addition of $P(NMe_2)_3$ or $P(NMe_2)_3/PCl_3$ mixtures to **1** or of $AlCl_3$ to **5**/$[(Me_2N)_3PCl][AlCl_4]$ does not effect the desired change.

With an equimolar amount of $AlCl_3$, **5**, in a fast reaction, gives the adduct **6** [reaction (6)].[4] A small amount of the product **7**[5] is also formed by addition of HCl (presumably from the solvent) (cf. ref. [3, 6]). Over approximately a week at room temperature, compound **6** reacts completely with CH_2Cl_2 to give the diphosphoniodiphosphirane tetrachloroaluminate **8**.[7] Although no intermediates can be observed, comparable reactions suggest that initial chloromethylation occurs [reaction (7)][3,6] followed by cleavage of the resulting intermediate [reaction (8)] and formation of the three-membered-ring compound **8** by [2 + 1] addition of a phosphoniophosphanediyl (formed by dissociation of **5**; cf. ref. [8]) to the P=C system [reaction (9)]. Like di-*tert*-butyldiphosphirane,[9] **8** is formed as the *trans* isomer and is characterized by a ^{31}P-NMR spectrum[7] of the $[AB]_2$ type.



If PCl_3 is added, as described above, at 0 °C to a $P(NMe_2)_3/AlCl_3$ mixture, which, however, contains less $AlCl_3$ (molar ratio 1 : 3 : 1), then $AlCl_3$ is consumed only

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

according to reaction (5). The remaining half of the $P(NMe_2)_3$ and PCl_3 undergoes substituent exchange (1) and reacts with subsequently added $AlCl_3$ to give **3** according to reaction (4). If more $AlCl_3$ is added, reaction (10) occurs, resulting in an equal decrease in the amounts of **3** and **5** and in the formation of a new product. On the basis of the ^{31}P-NMR spectrum ($[AB]_2C_2$ spin system),[10] this product was identified as the 1,3-diphosphoniocyclotetraphosphane **9** (all-*trans* isomer, cf. ref. [9]).

Depending on the sequence of addition, therefore, the three-component system $PCl_3/P(NMe_2)_3/AlCl_3$ may be used to prepare either the salt **1**, **5**, or **9**, whereby the oxidation state n/3 of phosphorus steadily decreases: n = 9, 7, 5. Consequently, the amount of $[(Me_2N)_3PCl][AlCl_4]$ formed also steadily increases. The reaction to give the product with n = 3 (reduction of Me_2NPCl_2 to $(Me_2NP)_x$) has not yet been possible.[11]

Owing to the competing and subsequent reactions, reaction (5) is not well suited for the preparative formation of **5**. On the other hand, the tetraphenylborate[8] of the same cation

$[(Me_2N)_3P{=}P{-}P(NMe_2)_3][BPh_4]$ **10**

may be synthesized analogously and in a facile manner by addition of PCl_3 to $P(NMe_2)_3/NaBPh_4$.[12]

[3]).

Synthesis and Structure of the Co_3Ti_2 Complex $[\{\mu_3\text{-}[(C_5H_5)_2TiOC]\}_2\{(C_5H_5)_3Co_3\}]$: CO Reduction by Two Different Metal Centers

By *Sandro Gambarotta, Sergio Stella, Carlo Floriani,* Angiola Chiesi-Villa,* and *Carlo Guastini*

Metal-oxygen bond formation is the driving force for the reduction of carbon monoxide by early transition metals. For example, CO is reduced by ZrH complexes to methanol, formaldehyde, and C_2 compounds.[1] The reductive coupling of CO is achieved by reaction of $[(C_5H_5)_2Fe_2(\mu\text{-}CO)_2(CO)_2]$ with $[(C_5H_5)_2ZrN_2]_2N_2$.[2] Other metal carbonyls react with oxophilic metal complexes in low oxidation states, electron transfer occurring from the oxophilic metal center to the metal atom of the carbonyl complex; this provides a strong acidic site for the carbonyl's oxygen.[3] In this way, $[(C_5Me_5)_2Yb\text{-}OC\text{-}Co(CO)_3]$[4] and $[(C_5H_5)_2(thf)Ti\text{-}OC\text{-}Mo(CO)_2(C_5H_5)]$[5] were obtained. These reactions are not real reductions of CO, because the fragment $\geqslant C{-}O{-}M$ (M = early transition metal) is not formed. A few examples of such reductions are provided by the reactions of $[(C_5Me_5)_2V]$[6] and $[C_5H_5)Ti(CO)_2]$[7] with $Co_2(CO)_8$ to form the complex $[(CO)_9Co_3CO\text{-}M]$. Indeed, this type of complex is very well documented when M = Ti, Zr, and Hf in the form of cyclopentadienyl derivatives.[8] These compounds were synthesized, however, by the metathesis reaction between $[(CO)_9Co_3COLiS_n]$ and $[(C_5H_5)_2MCl_2]$ derivatives or by the reaction between $[(C_5H_5)_2MCl_2]$ and $Co_2(CO)_8$.[8]

We report here the reduction of CO to a $\geqslant C{-}O{-}$ ligand promoted by a Ti^{II} complex acting as a one-electron reducing agent. This result was achieved by reaction of the titanium complex **1** with an equimolar amount of the cobalt complex **2** in toluene.[9] The solution was gently heated to 50 °C for a few minutes, then allowed to stand at room temperature for one day. Crystals of the air-sensitive Co_3Ti_2 complex **3** formed (yield: ca. 55%).

The Ti atoms in **3** have an oxidation number of +3 [$\mu_{eff} = 1.85$ BM at 293 K per titanium]. The IR spectrum shows a broad, strong CO band centered at $\tilde{\nu} = 1300\ cm^{-1}$. The structure of **3** (Fig. 1)[10] consists of an equilateral triangle of Co atoms, each of which is bonded to an η^5-

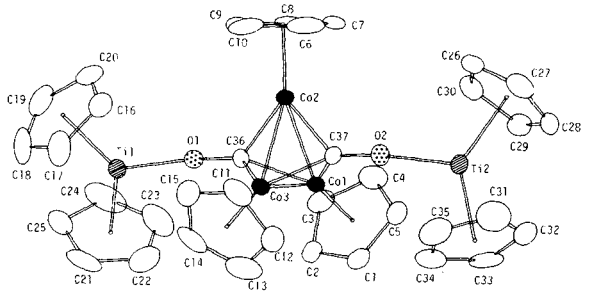

Fig. 1. Crystal structure of **3** [10]. Important bond lengths [Å] and bond angles [°]: Co1-Co2 2.404(2), Co1-Co3 2.385(2), Co2-Co3 2.401(2), Co1-C36 1.88(1), Co1-C37 1.87(1), Co2-C36 1.91(1), Co2-C37 1.89(1), Co3-C36 1.87(1), Co3-C37 1.88(1), Ti1-O1 1.89(1), Ti2-O2 1.91(1), O1-C36 1.30(2), O2-C37 1.29(2); Co2-Co1-Co3 60.2(1), Co1-Co2-Co3 59.5(1), Co1-Co3-Co2 60.3(1), Ti1-O1-C36 164.6(8), Ti2-O2-C37 160.2(8).

cyclopentadienyl ligand that is nearly perpendicular to the plane defined by the three Co atoms; the dihedral angles range from 87.9(3) to 89.5(4)°. A $(C_5H_5)_2TiOC$ group caps each of the two faces of the Co_3 triangle; the C–O bonds are nearly perpendicular to the Co_3 plane (89.1(1)°). Co–C and Ti–O bond distances are very close to those found in $[Co_3(CO)_9(\mu_3\text{-}C{-}O{-}MX(C_5H_5)_2)]$.[8] The C–O bond distances (ca. 1.30 Å) indicate, as expected, a reduced form of carbon monoxide. The large C–O–Ti angles (164.6(8) and 160.2(8)°) are probably due to a partial double bond between titanium and oxygen. A strong band centered at $\tilde{\nu} = 795\ cm^{-1}$ can be assigned to the Ti–O vibration. Bond distances within the $[(C_5H_5)_3Co_3]$ fragment are very close to those found in $[(C_5H_5)_3Co_3(CO)_3]$,[11] $[(C_5H_5)_3Co_3(\mu_3\text{-}CMe)(\mu_3\text{-}CCO_2Me)]$,[12] and $[(C_5H_5)_4Co_4(CO)_2]$[13] complexes. Complex **3** may be regarded as the two-electron reduction product of the $[(C_5H_5)_3Co_3(CO)_3]$ cluster.[11,14]

Benzophenone *O*-Oxide**

By *Wolfram Sander**

Carbonyl oxides are important intermediates in the ozonolysis of olefins, in the oxidation of carbenes with molecular oxygen,[1-5] and presumably also in enzymatic oxygenations.[6] Despite this importance, only the resonance-stabilized cyclopentadienone *O*-oxide[2,3a] and its benzannulated derivatives[3c] have been characterized spectroscopically following matrix isolation in argon or nitrogen. For benzophenone *O*-oxide **3**, which has been extensively studied by trapping experiments in solution, the only spectroscopic evidence available is a UV/VIS spectrum from a laser photolysis experiment.[1] The structure, whether open-chain or cyclic (dioxirane), could not be determined.[1a] Attempts to isolate **3** in a matrix failed on account of the instability of this compound.[2]

The IR and UV/VIS spectroscopic characterization of matrix-isolated benzophenone *O*-oxide **3** is reported here. This technique also made possible the elucidation of the photochemistry of **3** as well as of the mechanism of chemiluminescence in the oxidation of **2**.

Diphenylcarbene **2** was generated by photolysis ($\lambda > 515$ nm, 8 K) of matrix-isolated diphenyldiazomethane **1**[2] and characterized by comparison of the IR and UV spectra (cf. Fig. 1 and 2) with literature data.[2,4] By doping the argon matrix with 0.5–15% O_2, we found increasing amounts of oxidation products with increasing oxygen content. Because the diffusion of O_2 in solid argon at 8 K is very slow,[7,8] **2** is only oxidized, under these conditions, by O_2 molecules in the immediate proximity of the carbene

center. When the O_2 content was 1%, free carbene **2** was still present in addition to the oxidation products. Therefore, the experiments described here were carried out at this O_2 concentration.

The reaction between **2** and O_2 was controlled by varying the temperature of the matrix. If the matrix was warmed slowly (1 K/min) from 8 K to 45 K (softening of the matrix) and then cooled again to 8 K, **2** underwent almost complete conversion, and an intense yellow color indicated the formation of a new species. The UV/VIS maximum of this new compound at 422 nm (Fig. 2) agrees well with that of **3** found by *Scaiano* et al. in a laser photolysis experiment (acetonitrile, room temperature).[1a,b]

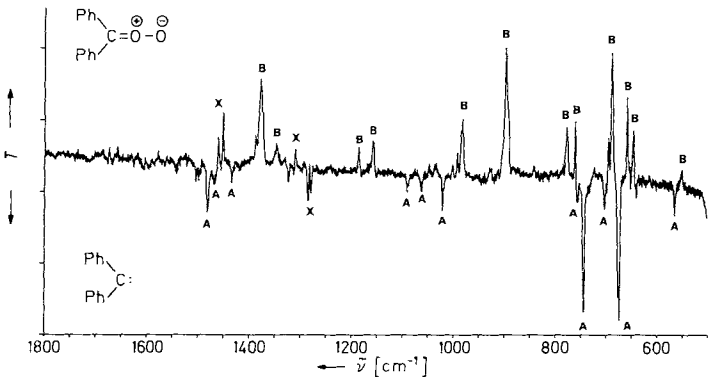

Fig. 1. Difference IR spectrum of the reaction $2 + O_2 \rightarrow 3$. The spectrum shows the changes that occur after warming the matrix from 8 K to 40 K over 20 min. Bottom part: before reaction; top part: after reaction. A, diphenylcarbene **2**; B, benzophenone *O*-oxide **3**; X, unknown side products and bands that were not completely subtracted.

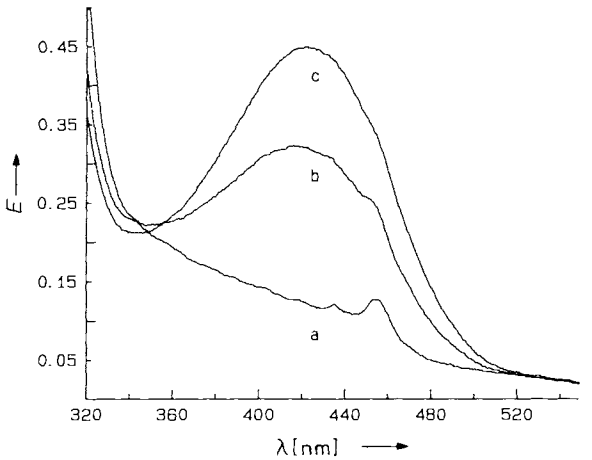

Fig. 2. UV spectra of the reaction $2 + O_2 \rightarrow 3$. a) Diphenylcarbene in Ar/O_2 at 8 K; b) after warming the matrix over 10 min to 35 K, **2** has undergone partial reaction; c) after warming the matrix over 10 min to 40 K, **2** has undergone complete conversion to **3** ($\lambda_{max} = 422$ nm).

The assignment of IR bands to **3** was achieved by observing the changes in the IR spectrum during an analogous annealing experiment (Fig. 1).[9] Noteworthy is the good agreement of the bands at 1377 (m), 1185 (w), 1158 (w), 983 (m), and 897 (s) cm^{-1} with corresponding bands of cyclopentadienone *O*-oxide.[10] This is presumably due to the large contribution of O-O and C-O vibrations to these bands. In order to allow more exact assignments, the experiments were repeated with $^{18}O_2$-containing matrices. The bands listed above exhibited the strongest isotopic shifts in the IR spectrum.[9] On the basis of the band position and the isotopic shift (35 cm^{-1}) and in agreement with studies on alkyl peroxides,[11] we assign the band at 897 cm^{-1} to the O-O vibration.[12] On account of its relatively large intensity, the band at 1377 cm^{-1} is presumably a fundamental vibration. The isotopic shift of 8 cm^{-1} suggests a large contribution of the C-O vibration to this band.

The carbonyl oxide **3** is more sensitive than diphenyldiazomethane **1** to irradiation with visible light. It was therefore found only after thermal reaction of **2** with O_2 and not after direct irradiation of **1**. When **3** was irradiated for a few minutes ($\lambda > 515$ nm), all the IR bands assigned to this compound disappeared. A new compound, **4**,[13] was formed along with small amounts of benzophenone **5** (Scheme 1). **5** was not formed upon thermal reaction of **2** with O_2.

The identification of **4** as diphenyldioxirane is based on the following evidence:

- Upon irradiation with short-wavelength light ($\lambda > 438 \pm 10$ nm), **4** undergoes rearrangement to give phenyl benzoate **6**. This demonstrates that **4** contains two oxygen atoms. Because both the precursor **3** and the final product **6** contain two phenyl groups, it is plausible that **4** also contains two intact phenyl groups.
- The IR spectrum of **4**[13] shows no bands in the carbonyl or carboxyl region.
- Labeling with ^{18}O results in a shift of the weak band at 590 cm^{-1} by 14 cm^{-1} to lower wave numbers. This strong shift can only be explained by assuming a large contribution of O-O vibrations to this absorption.

When the matrix was warmed from 10 to 50 K, a strong luminescence was observed, depending on the concentration of oxygen, at $T > 35$ K. A similar luminescence had been observed earlier upon oxidation of **2** in organic glasses[4] or in Freon[5] at 77 K and identified as the phosphorescence of benzophenone. In order to study the luminescence in more detail, the total emission from the matrix was measured as a function of temperature (glow curve) with a photomultiplier. At several points along the curve, spectra were recorded with an optical multichannel analyzer. Under all experimental conditions, the phosphorescence spectrum of benzophenone was found.

Comparison of the glow curve with the conversion curve (conversion of **2** as a function of temperature for a constant rate of warming) showed that the chemiluminescence is not directly related to the reaction $2 + O_2 \rightarrow 3$. The luminescence was almost completely suppressed by high O_2 concentrations (> 1%), although the formation of **3** was demonstrated unequivocally. The strongest luminescence was observed when the matrix contained no O_2 and the carbene **2** reacted with the unavoidable surface contaminants (air layer due to small leaks in the vacuum system) upon rapid evaporation of the matrix ($T > 45$ K). These findings indicate that, in order to generate the chemiluminescence, both free carbene **2** and carbonyl oxide **3** (as oxygen transfer agent) must be present.

The chemiluminescence mechanism found in the oxidation of phenylcarbene—reaction of the free carbene with oxygen atoms[8]—plays a minor role in the oxidation of **2**, because the formation of oxygen atoms and **5** proceeds in low yield compared with the formation of **3**, **4**, and **6**.

[10] Our data are in good agreement with those in [2] but in poorer agreement with those in [3a]. The discrepancy between the IR data for cyclopentadienone *O*-oxide in [2] and [3a] is due, according to *Dunkin* et al. [3b], to a photoisomerization in *Chapman*'s experiment [12]. Because **3** is formed almost exclusively by a thermal route, a photoisomer is ruled out.

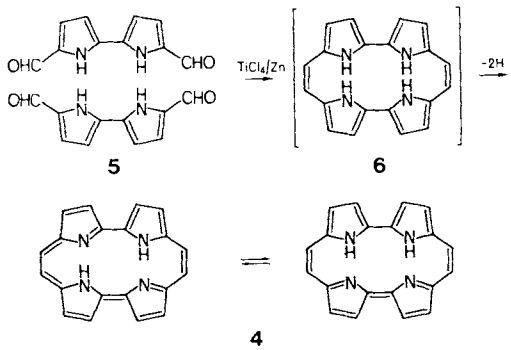
Porphycene—a Novel Porphin Isomer**



By *Emanuel Vogel,* Matthias Köcher, Hans Schmickler,* and *Johann Lex*

Porphin **2**, the parent compound of the porphyrins, contains a central 16-membered ring that corresponds to the dianion of [16]-85-annulene **1**[***] in configuration and conformation (planar).[1] In addition, **2** and $\mathbf{1}^{2\ominus}$ bear a distinct relationship in their π-electron structure, since **2** may be regarded alternatively as a diaza[18]annulene (outer pathway of conjugation) or as a tetraaza[16]annulene dianion (inner pathway of conjugation; drawn boldface in the formula).[2,3] The [16]annulene dianion model appears to be especially suited for the understanding of the spectroscopic properties of metalloporphyrins.[4]

These observations in conjunction with a study of 1,6:9,14-bismethano[16]annulene (CH_2-bridged **3**)[5] made us become aware of the analogy existing between the dianion of the hypothetical [16]-51-annulene **3**[***] and the porphin structural isomer **4**. Compared with $\mathbf{3}^{2\ominus}$, however, compound **4** has the geometrical advantage that it is nearly planar, because the nonbonding H,H interactions that force $\mathbf{3}^{2\ominus}$ to adopt a nonplanar conformation are absent. To our great surprise, there was no evidence in the literature for either **4** or derivatives of **4**, even though the synthesis of structural variants of **2** has long been pursued intensively in porphyrin research.[6]

We report here on the synthesis and properties of "porphycene" **4**, which, in accordance with our supposition, is porphyrin-like and aromatic.[7] Compound **4** is formed in 2–3% yield as the only nonpolymeric product by the reductive coupling of 5,5′-diformyl-2,2′-bipyrrole **5**[6c] with low-valent titanium.[8] The reaction, which presumably involves

6 as a readily oxidized intermediate, was carried out as follows: **5** (940 mg, 5 mmol) was added to a slurry of the titanium reagent, prepared from 9.49 g (50 mmol) of titanium tetrachloride and 6.55 g (100 mg-atom) of activated zinc in the presence of 2.5 mL of pyridine in 400 mL of tetrahydrofuran (THF), and the reaction mixture was then refluxed for 4 h. After conventional workup, a product was obtained from which **4** could easily be separated by chromatography on silica gel (column: 3 cm × 10 cm) with ether/pentane (1 : 1). Compound **4**, which is stable toward air, dissolves in organic solvents to give blue solutions showing beautiful red-violet fluorescence, and crystallizes from benzene in the form of violet needles (the compound undergoes sublimation above 250 °C with virtually no decomposition); yield: 20 mg.

Convincing evidence as to the structure and aromaticity of **4** is provided by the spectra of the compound. The ^{1}H-NMR spectrum (Fig. 1) exhibits only a singlet at $\delta = 9.83$ (H_C), an AB system at $\delta = 9.67$ (H_A) and 9.23 (H_B) ($J_{AB} = 4.36$ Hz, $J_{AN} = 0.85$ Hz, $J_{BN} = 0.72$ Hz) and a relatively broad signal at $\delta = 3.15$ (H_N)[9] (relative intensities 2 : 2 : 2 : 1); in the ^{13}C-NMR spectrum (75.5 MHz, $CDCl_3$), five signals appear, occurring at $\delta = 130.50$ (C_B), 125.85 (C_A), 114.98 (C_C), 144.84, and 135.87 (quaternary carbon atoms). The equivalence of the four pyrrole rings, as indicated by the simplicity of the ^{1}H- and ^{13}C-NMR spectra, is readily explained by assuming that **4**, like many porphyrins, is subject to an NH tautomerism that is rapid on the NMR time-scale. In view of the far-reaching analogies in the NMR spectra of porphycene **4** and porphin **2**, it is striking that the NH signal of **4** is significantly less shifted

[***] For nomenclature see [1].

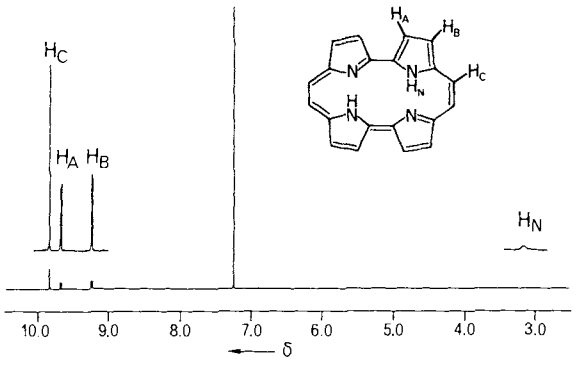

Fig. 1. ^{1}H-NMR spectrum of porphycene **4** (300 MHz, $CDCl_3$).

to high field, relative to that of pyrrole ($\delta = 7.70$), than that of **2** ($\Delta\delta = 4.55$ and 11.46 ppm, respectively[2]). This finding is suggestive of strong intramolecular N-H···N hydrogen bonding in **4**, which is expected if the molecule is planar. The UV/VIS spectrum (benzene) of **4** also reveals the porphyrin-like nature of the compound since it consists of a double band at $\lambda = 358/370$ nm ($\varepsilon = 139200$ and 106900), which may be interpreted as a Soret band, along with three longer wavelength bands at $\lambda = 558$ (34200), 596 (30400), and 630 nm (51900). In addition, the mass spectrum (electron-impact ionization, 75 eV) of **4** is reminiscent of that of porphyrins in that the molecular ion (m/z 310) gives rise to the base peak and the doubly charged molecular ion (m/z 155, intensity 10%) causes a further prominent peak.[10, 11] The IR spectrum of **4** is noteworthy insofar as it exhibits no typical N-H stretching vibration.[12]

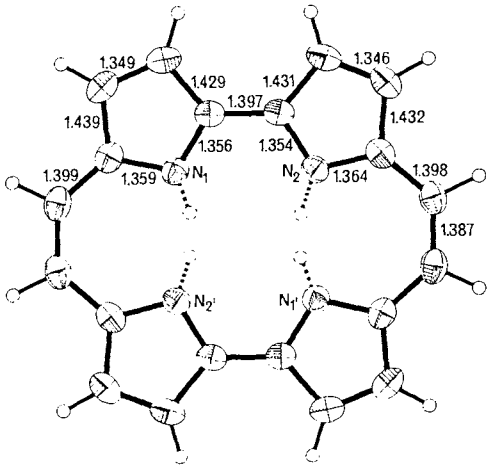

Fig. 2. Structure of porphycene **4** in the—partly disordered—crystal (bond lengths in Å) [13].

According to an X-ray structure analysis (Fig. 2),[13] **4** is partly disordered in the crystal. The molecules are (on the average) centrosymmetric and, like porphin **2**,[3] virtually planar (maximum distance of the C and N atoms from the mean plane: ±0.04 Å; for **2**: ±0.02 Å). **4** is slightly strained since, as a consequence of the planarity, the CCC angles in the 16-membered ring are expanded to 131 and 132°, respectively.[14] In contrast to **2**, it was not possible in the case of **4** (at least at room temperature) to assign the two imino hydrogen atoms unequivocally to specific nitrogen atoms. This difficulty is most likely due to a statistical distribution of NH tautomers in the crystal or to rapid interconversion of the tautomers during the time required for measurement. Therefore, the bond lengths given in Figure 2 apply to a spatially and/or time averaged structure. As already revealed by molecular models, the cavity between the four pyrrole rings, which is significant for the properties of **4**, is smaller than that in **2**: The four nitrogen atoms form a rectangle, the sides of which are 2.83 Å (N_1N_2) and 2.63 Å ($N_1N_{2'}$)[15] long (NN distance in **2**: 2.89 Å). In view of the very short $N_1N_{2'}$ and $N_2N_{1'}$ distances, **4** must be distinguished by strong hydrogen bonding (as already evidenced by the NMR spectrum); this conclusion becomes even more compelling if one takes into account that the N-H···N hydrogen bonds are in a nearly linear arrangement.[16]

Despite the smaller cavity, porphycene **4** is capable of forming stable metalloporphyrin-type complexes. It appears, however, that the tendencies of formation of these "metalloporphycenes" are, in general, somewhat lower than those of the corresponding metalloporphyrins (conditions for the synthesis of nickel porphycene: $NiCl_2$/dimethylformamide, 8 h, reflux).[17]

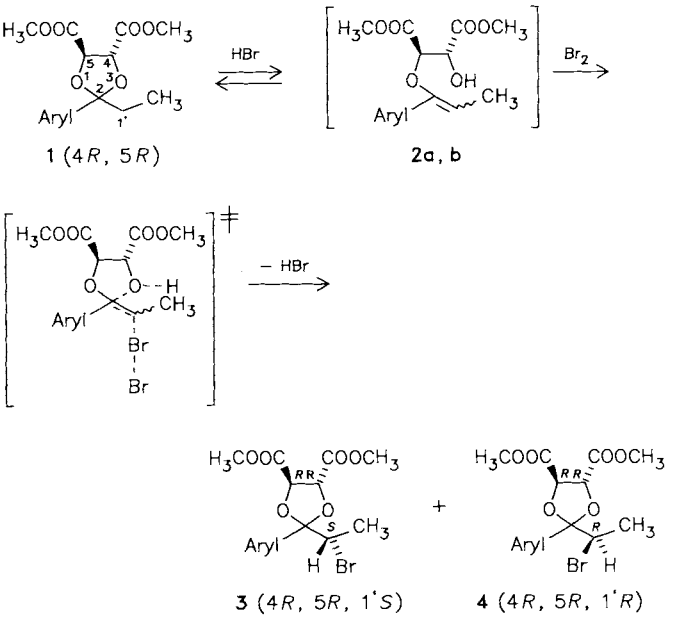
[9] The signal of the NH protons remain unchanged too −110°C (CD_2Cl_2/CF_2Br_2, 1:1), the lowest temperature achieved so far. **4** undergoes H/D exchange only very slowly in THF/D_2O. For this reason, the *N*-deuterated compound may be prepared most practically by successive treatment of **4** with butyllithium (in ether) and D_2O.

[10] H. Budzikiewicz in D. Dolphin: *The Porphyrins, Vol. III*, Academic Press, New York 1978, p. 395. A detailed mass spectrometric study of **4** and its derivatives is being carried out with Prof. *H. Budzikiewicz* (Universität Köln).

[11] High-resolution mass spectra and elemental analysis are correct.

[12] IR spectrum (KBr) of **4**. ν = 3099, 1562, 1469, 1410, 1224, 1167, 1054, 932, 813, 745, and 651 cm^{-1}. An evaluation of the IR spectrum by means of *N*-deuterated **4** is in progress.



[13] **4** forms monoclinic crystals, space group $P2_1/c$, $a = 10.088(3)$, $b = 4.987(1)$, $c = 15.464(4)$ Å, $\beta = 108.36(2)°$, $Z = 2$; 710 reflections, $R = 0.030$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51701, the names of the authors, and the journal citation.

[14] Remarkably, expansion of CCC angles on this order of magnitude is observed even for maleic acid. M. N. G. James, G. J. B. Williams, *Acta Crystallogr. B30* (1974) 1249.

[15] A similarly short NN distance (2.626 Å) has also been found for the hydroperchlorate salt of the "proton sponge" 4,5-bis(dimethylamino)fluorene. H. A. Staab, T. Saupe, C. Krieger, *Angew. Chem. 95* (1983) 748; *Angew. Chem. Int. Ed. Engl. 22* (1983) 731.

[16] We thank Prof. *O. Ermer* (Universität Köln) for helpful discussions in the interpretation of the X-ray structure data of **4**.

[17] According to investigations of Dr. *K. Pramod* (note added in proof, January 22, 1986): **4** has also been converted into the zinc, copper, and cobalt complexes.

Asymmetric Bromination of Enantiomerically Pure Acetals of Alkyl Aryl Ketones

By *Graziano Castaldi,* Silvia Cavicchioli, Claudio Giordano,** and *Fulvio Uggeri*

In the course of our studies on the synthesis of 2-arylalkanoic acids, we required acetals of optically active α-functionalized alkyl aryl ketones as intermediates.[1] To this end, we investigated the α-bromination of the enantiomerically pure alkyl aryl acetals **1** and *ent*-**1**, which are readily prepared from alkyl aryl ketones and the dimethyl ester of (2*R*,3*R*)- and (2*S*,3*S*)-tartaric acid in high yields.[2,3]

Thus, by adding bromine (10 mmol) to a solution of the (4*R*,5*R*) acetal **1** (10 mmol) in CCl_4 (20 mL) at 15 °C in the presence of a catalytic amount of HBr, a mixture of the diastereomeric α-bromo acetals **3** and **4** is obtained in high yield with **3** in high diastereomeric excess (^{1}H-NMR, HPLC, see Table 1). As expected, the absolute configuration at C-1 is reversed when *ent*-**1** is used as starting material.[4] The absolute configuration at C-1 of **3** and **4** was assigned by means of their rearrangement (1,2-aryl shift with 100% inversion of configuration) into the corresponding 2-arylalkanoic acids of *S* and *R* configuration, respectively.[2,5]

The reaction appears to be very general as it can be applied to acetals derived from many alkyl aryl ketones as well as from other tartaric acid derivatives.[5] The main feature of the reaction is the high diastereoselectivity observed even at room temperature; in contrast, most asymmetric syntheses require lower temperatures.[6] A catalytic amount of HBr is required to promote the reaction, the role of HBr being to set up the equilibrium between the acetal **1** and its enol forms **2a**, **b** (*E*/*Z* isomers).

The observed asymmetric induction is presumably the result of diastereofacial selection in the kinetically controlled attack of electrophilic bromine on the double bond of the enol ether intermediates **2a**, **b** with anchimeric assistance by the hydroxyl group.

The asymmetric α-bromination of acetals has been employed as the key step of a new synthesis of enantiomerically pure 2-arylalkanoic acids.[5] The method has also been successfully applied to the industrial manufacturing of optically pure (2*S*)-(+)-2-(6-methoxy-2-naphthyl)propanoic acid (Naproxen),[5] which is the most important of the optically active 2-arylalkanoic acids.[7]

Moreover, α-bromo acetals **3** and **4** have been hydrolyzed to the corresponding optically active α-bromo ketones,[8] thus extending the synthetic scope of the reaction. Thus, the mixture of **3a** and **4a** (Table 1) was hydrolyzed, without racemization, by treatment with methanesulfonic acid in methanol.[9]

Table 1. Yields and diastereomeric ratios for the bromination of **1a**–**1d** to **3a/4a**–**3d/4d**.

1–4	Aryl	Yield 3 + 4 [%]	Ratio 3 : 4
a	5-bromo-6-methoxy-2-naphthyl	98	90 : 10 [a]
b	*p*-methoxyphenyl	95	92 : 8
c	phenyl	94	93 : 7
d	*p*-chlorophenyl	93	94 : 6

[a] The bromination of **1a** requires two moles of bromine per mole of **1a**.

[9] *Experimental procedure:* A 90:10 mixture of **3a** and **4a** (10 mmol) was added to a solution of methanol (5 mL) in methanesulfonic acid (20 mL). The reaction mixture was stirred at 20°C for 18 h and then poured onto crushed ice and extracted with dichloromethane. The organic phase was washed with water and a 2% $NaHCO_3$ solution and dried over sodium sulfate. Evaporation of the solvent in vacuo gave 2.8 g (75%) of 2-(*S*)-(+)-2-bromo-1-(5-bromo-6-methoxy-2-naphthyl)propan-1-one. $[\alpha]_D^{20} = +130°$ ($c = 0.5$, $CHCl_3$). The enantiomeric excess was 80% as determined by ^{1}H-NMR analysis with the optically active shift reagent Eu(hfc)$_3$.

Metal Dependence of Cyclometalation and Arene C–H Activation in the Photolysis of *cis*-$H_2M[P(CH_2CH_2CH_2PMe_2)_3]$ (M = Fe, Ru) in Benzene**

By *Martin Antberg* and *Lutz Dahlenburg**

The cleavage of hydrocarbon C–H bonds at metal centers is currently the subject of much research in organometallic chemistry. Besides a few derivatives of "hard" metal ions,[1] the Ir^I and Rh^I complex fragments $(C_5R_5)(L)M$ (R = H, Me; L = CO, PMe_3)[2] have proved particularly potent as arene and alkane activators. Also promising are the Ru^0 and Os^0 species $(C_6R_6)(L)M$ (L = alkylphosphane)[3] and the tetrakis (P ligand) systems L_4M of iron, ruthenium, and osmium. The latter often undergo *intra*molecular isomerization, however, to give cyclometalated hydridometal(II) complexes,[4] so that only the 16e fragment $(Me_2PCH_2CH_2PMe_2)_2M$ (M = Fe, Ru, Os)[5a-c] and $[(MeO)_3P]_2(Me_3P)_2M$ (M = Ru, Os)[5d] have proved suitable so far for the *inter*molecular C–H cleavage.

We have now found that the photolytic dehydrogenation of the *cis*-dihydrides $(pp_3)FeH_2$ **1**[6b] and $(pp_3)RuH_2$ **2**[6d] (both of which are stabilized by our "pp_3" ligand $P(CH_2CH_2CH_2PMe_2)_3$[6a]) in C_6H_6 leads, depending on the central metal atom, to either *intra*- or *inter*molecular C–H activation. In the iron system, internal addition to $H-CH_2P$ results in formation of the three-membered-ring derivative **5**. In the ruthenium system, on the other hand, $H-C_6H_5$ cleavage results in formation of the phenyl hydride **6**.[7a]

The structures of **5** and **6** were established by elemental analysis and spectroscopy.[7b-f] The dt splitting of the ^{1}H-coupled Fe*C* resonance of **5** ($J(PC) = 13$, $J(CH_2) = 148$ Hz) rules out a CH_2 cleavage product formed by metalation of the trimethylene chains, as has been discussed, for example, for (dmpp)($\overline{C_7H_{17}P_2}$)FeH (dmpp = $Me_2P(CH_2)_3PMe_2$, $C_7H_{18}P_2$).[4c]

For both reactions, we postulate intermediate 16e d^8 fragments $(pp_3)M$, **3** and **4**, respectively, because these incorporate particularly advantageous structural features for the oxidative C–H addition owing to their bent, *cis*-unsaturated configuration.[8] The *metal*-dependent transition between intra- and intermolecular C–H addition, the first example of its kind, might be due to the different crowding of the groups and the different chelate ring strain in the required intermediates **3** and **4**: The M–Cl distances in the dichloro complexes $[FeCl_2(pp_3)]$, ca. 239 and 241 ppm,[6c] and $[RuCl_2(pp_3)]$, ca. 251 and 252 ppm,[6d] demonstrate that the covalent radius of the ruthenium atom stabilized by the pp_3 ligand is at least 10 pm larger than that of the iron atom in the same coodination environment. The 16e Ru^0 system should therefore be more strained and more open at the central metal atom, which, on the one hand, suppresses the cyclometalation and, on the other hand, facilitates the approach of a solvent molecule. Increased ring strain and reduced crowding of the groups are also responsible, according to *Karsch*,[4c] for the *ligand*-dependent change in reactivity from intramolecular addition in the case of $[Me_2P(CH_2)_3PMe_2]_2Fe$ to intermolecular reaction in the case of $[Me_2P(CH_2)_2PMe_2]_2Fe$. The transition from intramolecular C–H addition by the Ru and Os species $(Me_3P)_4M$ to intermolecular C–H cleavage by the phosphite-substituted 16e fragment $[(MeO)_3P]_2(Me_3P)_2M$, described by *Werner* and *Gotzig*,[4f,5d] likewise represents a favoring of the intermolecular reaction in the case of less-filled coordination spheres.

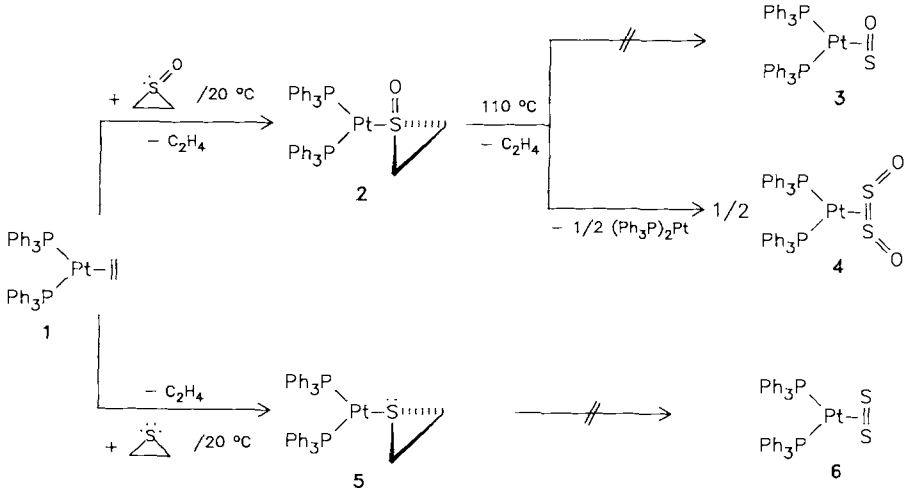
Complex Stabilization of Disulfur Dioxide in the Fragmentation of Thiirane *S*-Oxide on Bis(triphenylphosphane)platinum(0)**

By *Ingo-Peter Lorenz** and *Jürgen Kull*



Complex stabilization of sulfur monoxide has been achieved by several methods. Particularly favorable is the fragmentation of thiirane *S*-oxide in the presence of coordinatively unsaturated or substitutionally labile transition-metal complexes.[1–3] Two reaction mechanisms are conceivable: (1) initial fragmentation of C_2H_4SO with in situ complex stabilization of SO; (2) initial coordination of C_2H_4SO with subsequent elimination of ethylene (Scheme 1). It was suggested that the second mechanism of reaction is operative in the synthesis of $[\{(C_5H_5)(CO)_2Mn\}_2SO]$;[3] this is further supported by ^{31}P-NMR data.[2b] We have now succeeded in isolating the first thiirane *S*-oxide complex **2** as an intermediate in the synthesis of the disulfur dioxide complex **4** from the ethylene complex **1**. This is strong support for the second reaction mechanism discussed above.

Scheme 1.

Reaction of equimolar amounts of $[(Ph_3P)_2Pt(C_2H_4)]$ **1** and C_2H_4SO affords the yellow complex **2** in nearly quantitative yield; complex **2** is stable in air up to 70 °C. In toluene at 110 °C, **2** undergoes fragmentation to form not the η^2-SO complex **3** but rather the S_2O_2 complex **4** (Scheme 2).[4] S_2O_2 has been suggested as the unstable, initial product of SO decomposition in the gas phase[5] (cf. Scheme 3); S_2O_2 has only been prepared as a ligand via an oxidative pathway starting from the η^2-S_2 ligand.[6,7]

The compositions and structures of the new compounds **2** and **4** were determined by elemental analysis and by mass, IR, ^{1}H-NMR, and ^{31}P-NMR spectroscopy. For comparison, the spectroscopic data for the thiirane complex **5**, which is accessible by a reaction analogous to that used to prepare **2**, is also given in Table 1. However, **5** cannot be converted into the S_2 complex **6**.

Scheme 2.

The FD mass spectra of **2**, **4**, and **5** exhibit peaks for the respective molecular ions. In the IR spectra of **2** and **4**, the ν(SO) bands lie at surprisingly long wavelength compared with those of *S*-coordinated dimethylsulfoxide (DMSO)

complexes of platinum(II)[8] and the only known S_2O_2 complex.[6,7] This is presumably due to the better π-donor ability of the $[(Ph_3P)_2Pt^0]$ fragment. The PtS stretching vibrations of **2**, **4**, and **5** give bands between 300 and 400 cm^{-1}. ν(SS) of **4** is unequivocally assigned to the band at 657 cm^{-1}.

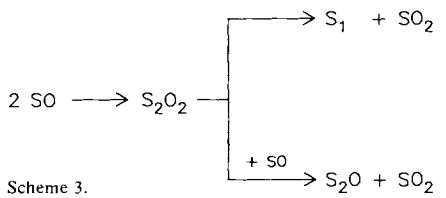

Table 1. Selected spectroscopic data for the complexes **2**, **4**, and **5**.

[a] Relative to ^{195}Pt. [b] KBr. [c] C_6D_6, 20°C. [d] Toluene, −40°C.

In the ^{1}H-NMR spectrum of the adduct **2**, the AA'BB' multiplet, which is unresolved owing to complicated coupling relationships, appears at $\delta = 4.4$–5.7. Such a multiplet is also found for the thiirane complex **5** at $\delta = 4.1$–5.2. Such a large low-field shift in comparison to those of the free ligands ($\delta = 2.02$ (m) and 2.29 (s) in $CDCl_3$) is not observed for the complexation of DMSO and dimethyl sulfide and rules out the formation of the thiaplatinacyclobutane $[(Ph_3P)_2\overline{PtS(O)_nCH_2CH_2}$ (n = 0, 1).

The unequivocal structural confirmation was provided by the ^{31}P{^{1}H}-NMR spectra, which exhibit only one signal for **4** and **5** but an AB quartet with the expected ^{195}Pt satellites and the usual Pt–P coupling constants[9] for **2**. For **5**, no evidence of a hindering of rotation around the Pt–S bond or of an inversion of the pyramidal sulfur is observed. In **2**, on account of the nonequivalence of the P atoms and the equivalence of the CH_2 units, the SO group must lie in the P_2PtS plane. The driving force for formation of this structure could be the favorable orbital overlap in the π-system Pt=S=O. The spectroscopic findings could also be interpreted, on the other hand, in terms of η^2-SO coordination. The ^{31}P-NMR data of the S_2O_2 complex **4** are comparable with those of the η^2-O_2 complex $[(Ph_3P)_2PtO_2]$ ($\delta = 16.4$, $J_{PtP} = 4059$ Hz[10]); S_2O_2 is presumably, therefore, η^2-coordinated in **4** as in the complex cation $[(diphos)_2IrS_2O_2]^+$[6,7] (diphos = $Ph_2P-CH_2CH_2-PPh_2$) and—for steric and electronic (π-donor) reasons—twisted. According to microwave spectroscopic investigations, free S_2O_2 is planar and *cis*-configurated.[11]

Scheme 3.

It has thus been possible to expand the role of thiirane *S*-oxide as a source of SO in organometallic chemistry. Starting from C_2H_4SO, we and *Rauchfuss* et al. have identified, in addition to the SO complexes,[1–3] C_2H_4SO (**2**), S_2O_2 (**4**), S_2O,[7] and $C_2H_4S_2$ complexes.[12] The course of SO decomposition shown in Scheme 3 has, therefore, an analogy in the complex chemistry in solution.

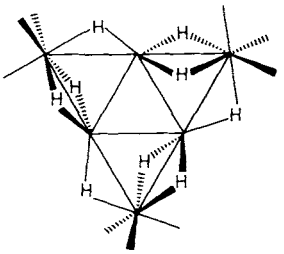
Synthesis of $[Cu_3Os_3H_9(PMe_2Ph)_9]$, a Bimetallic Raft, by Reductive Elimination of Alcohol or H_2**

By *Timothy H. Lemmen, John C. Huffman,* and *Kenneth G. Caulton**

Among heteronuclear clusters, polyhydrides are particularly important because they bear transferable hydrogen reducing equivalents and because they permit determination of hydrogen migrational preferences on model alloy phases. We report here the synthesis and structural characterization of a neutral complex with a Cu_3Os_3 framework; the raftlike geometry leaves the metals open on two sides. Equally important, the synthesis employs two unprecedented[1] methods for the formation of metal–metal bonds, alcohol elimination and H_2 elimination.

Reaction of $[CuO\mathit{t}Bu]_4$ with $[H_4Os(PMe_2Ph)_3]$ proceeds without hydrogen evolution to yield a product that bears a stoichiometric resemblance to the alkali metal analogue $[KOsH_3(PM_2Ph)_3]$ [(Eq. (a)].[2]



$$1/4[CuO\mathit{t}Bu]_4 + [H_4Os(PMe_2Ph)_3] \longrightarrow 1/x[CuOsH_3(PMe_2Ph)_3]_x + \mathit{t}BuOH \quad \text{(a)}$$

[**] This work was supported by U.S. National Science Foundation (CHE 83-05281), by award of a Lubrizol Fellowship to *T. H. L.*, and by gifts of chemicals from Johnson Matthey Co. We thank *Scott Horn* for skilled technical assistance.

The phosphane ligands in compound **1** are equivalent according to the ^{1}H- and ^{31}P-NMR data at +30° and −75°.[3] The hydride ligands show an AA'A''XX'X'' pattern, which is indicative of a *facial* $[H_3Os(PMe_2Ph)_3]$ unit. An X-ray diffraction study[4] of crystals of **1** grown from toluene/pentane shows it to be a trimer with the empirical formula $[Cu_3Os_3H_9(PMe_2Ph)_9]$. The molecular core is a planar raft of the six metal atoms (Fig. 1). The three copper atoms form an equilateral triangle with each Cu–Cu edge asymmetrically bridged by an $[H_3Os(PMe_2Ph)_3]$ unit. Each pyramidal $[Os(PMe_2Ph)_3]$ moiety is oriented such that one phosphorus lies in the Os_3Cu_3 plane, and the three $[Os(PMe_2Ph)_3]$ groups are oriented in phase such that the molecule has an idealized C_3 axis. The ^{1}H-NMR data permit the conclusion that one hydride is *trans* to every Os–P bond (see Scheme 1).

Scheme 1. Idealized structure of **1**.

The inequivalent Cu–Os distances support this placement of hydride ligands since all three singly hydride-bridged Cu–Os distances are longer (2.636(2) Å) than those that are doubly hydride-bridged (2.595(2) Å). Cryoscopic measurements prove that **1** dissolves without dissociation in benzene at 5 °C. With the structure established, it is possible to deduce from the NMR data that the molecule executes a facile local rearrangement in solution: rigid body rotation of the intact octahedral $[(PMe_2Ph)_3OsH_3]$ unit about its internal threefold axis. However, rapid migration of hydrogen between osmium centers is excluded by the ^{1}H-NMR data, implying a substantial activation energy for hydrogen migration via a hydride *terminally* bound to copper.

The same Cu_3Os_3 cluster **1** is formed by elimination of H_2 [Eq. (b)].

$$1/2[HCuPPh_3]_6 + 3[H_4Os(PMe_2Ph)_3] \longrightarrow \underset{\mathbf{1}}{[CuOsH_3(PMe_2Ph)_3]_3} + 3\,PPh_3 + 3\,H_2 \qquad (b)$$

The success of this reaction is noteworthy since no phosphane scrambling is observed and since coordinated PPh_3 is released. PPh_3 thus cannot disrupt the $[Cu_3Os_3(\mu\text{-}H)_9]$ bonding network. R_3PAu is frequently a structural "ersatz" hydrogen.[5] It is therefore remarkable that the product of Equation (b) is not the predicted complex $[(Ph_3PCu)H_3Os(PMe_2Ph)_3]$, an isolobal substitution product of pentagonal bipyramidal $[H_4Os(PMe_2Ph)_3]$. Presumably, the Cu_3 triangles in **1** are particularly stable on account of Cu–Cu bonding (2.626(3) Å) and/or because of the trigonal and quasi-planar CuH_3 unit.

The two synthetic routes to **1**, alcohol elimination and H_2 elimination, are of great conceptual simplicity and are unprecedented[1] and rare,[6] respectively, in heterobimetallic chemistry. The observed mild conditions, high yield, and product selectivity suggest that this will become a synthetic procedure of broad utility for coupling metals at

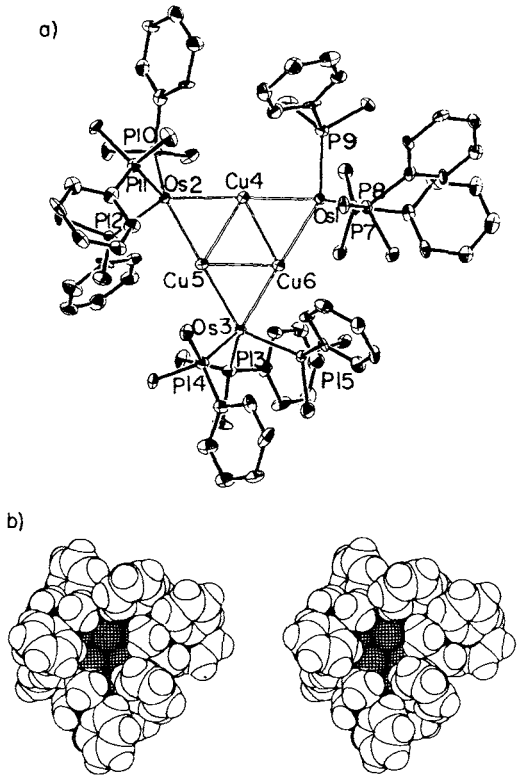

Fig. 1. a) ORTEP drawing of the crystal structure of **1** (without hydrogen atoms) viewed down the idealized C_3 axis. b) Stereoscopic space-filling drawing from the same perspective, with metal atoms hatched. The accessibility of the copper centers through the tunnel of phenyl and methyl groups is evident.

will. At the same time, this work, taken together with other recent results,[7–10] shows that, whereas gold leads to *closo* polyhedral bimetallic clusters, copper (often as a Cu_3 unit) frequently forms flat arrays more amenable to the approach and modification of substrate molecules.[11]

Equation (a) is significant in demonstrating that a transition metal hydride has the ability to liberate alcohol from a copper alkoxide.[12] Methanol synthesis from $CO + H_2$ over a copper/zinc oxide catalyst[13] may therefore occur by reductive elimination from ZnH and $CuOCH_3$ moieties.

2-(2,4,6-Tri-*tert*-butylphenyl)-1-arsaethyne—the First Compound Containing an Arsenic-Carbon Triple Bond

By *Gottfried Märkl** and *Hans Sejpka*

Since the synthesis of 2,2-dimethylpropylidinephosphane **1a**, the first phosphaethyne that was found to be stable at room temperature, by *G. Becker* et al.,[1] several stable phosphaethynes, **1b–1d**,[2–4] have been reported. In contrast, stable arsaethynes **2** were unknown until now.

R–C≡P **1**

a, R = *tert*-butyl[1]
b, R = 9-triptycyl[2]
c, R = adamantyl[3]
d, R = 2,4,6-tri-*tert*-butylphenyl[4]

R–C≡As **2**

a, R = 2,4,6-tri-*tert*-butylphenyl

This is not very surprising, because the arsinines[5] (arsabenzene) and the arsaalkenes,[6] which contain the –As=C bond are also less stable than the corresponding phosphorus compounds and can undergo decomposition with formation of brown, arsenic-containing products. Synthesis of **2** by KOH- or $[(n\mathrm{Bu})_4\mathrm{N}]$F-catalyzed elimination of hexamethyldisiloxane from the arsaalkenes $Me_3Si \sim As{=}C(OSiMe_3)R$, in analogy to the synthesis of **1**, has not, therefore, been possible so far.

Recently, we showed[4] that 2,4,6-tri-*tert*-butylbenzoyl chloride **5** undergoes reaction with tris(trimethylsilyl)phosphane only at elevated temperatures, e.g., in refluxing dimethoxyethane to give the phosphaethyne **1d** along with 1,4-bis(trimethylsiloxy)-1,4-bis(2,4,6-tri-*tert*-butylphenyl)-2,3-diphosphabutadiene and traces of the phosphaalkene precursor of **1d**. The corresponding reaction of **5** with tris(trimethylsilyl)arsane **3**[7] results primarily in the formation of the brown, arsenic-containing decomposition products.

We have now found that, upon addition of the acid chloride **5** to a solution of lithium bis(trimethylsilyl)phosphide·2THF in tetrahydrofuran (THF) [prepared from tris(trimethylsilyl)phosphane and *n*BuLi in THF[8]], exclusively the phosphaethyne **1d** (yield 12–20%) is formed after 48 h at room temperature, in contrast to the reaction with $P(SiMe_3)_3$.

Lithium bis(trimethylsilyl)arsenide·2THF **4** (see ref. [7a]), prepared from tris(trimethylsilyl)arsane **3** and methyllithium, also undergoes reaction at room temperature with the acid chloride **5** in anhydrous THF. After reaction for 20 h under nitrogen in the dark, chromatographic workup (oven-dried silica gel 60) of the portion of the reaction mixture that is soluble in *n*-pentane affords a pale yellow, crystalline compound, m.p. = 114–116 °C, which, according to spectroscopic and analytical data, is 2-(2,4,6-tri-*tert*-butylphenyl)-1-arsaethyne **2a**, the first stable compound containing an arsenic-carbon triple bond.

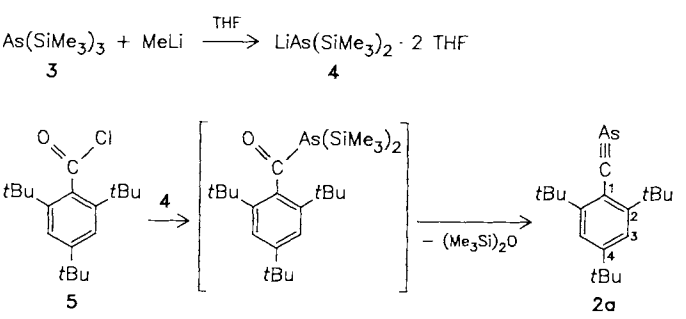

Table 1. Spectroscopic data for the arsaethyne **2a** and comparison with the ^{13}C-NMR data for phosphaethyne **1d**.

MS (70 eV, *m/z* (rel. int.)): $[M+H]^{\oplus}$, 333 (5%); $M^{\oplus\ominus}$, 332 (26%); $[M-{}^{\ominus}CH_3]^{\oplus}$, 317 (4%); $[M-{}^{\ominus}C_4H_9]^{\oplus}$, 256 (16%); $[M-{}^{\ominus}AsH_2]^{\oplus}$, 255 (28%); $[M-{}^{\ominus}AsH-{}^{\ominus}CH_3]^{\oplus\ominus}$, 241 (25%); $[256-C_4H_8]^{\oplus}$, 200 (30%); $[255-C_4H_8]^{\oplus}$, 144 (33%); $[199-C_4H_8]^{\oplus\ominus}$, 143 (22%); $[144-{}^{\ominus}CH_3]^{\oplus}$, 129 (14%); $C_4H_9^{\oplus}$, 57 (100%)

High resolution (MS): $M^{\oplus\ominus}$, found 332.14795, calcd. 332.14853, ΔmM 0.58, 1.70 ppm, $C_{19}H_{29}As$; $[M-{}^{\ominus}AsH-{}^{\ominus}CH_3]^{\oplus\ominus}$, found 241.19573, calcd. 241.19563, ΔmM 0.10, 0.40 ppm, $C_{18}H_{25}$; $[M-{}^{\ominus}AsH_2]^{\oplus}$, found 255.21156, calcd. 255.21128, ΔmM 0.28; 1.00 ppm, $C_{19}H_{27}$

^{1}H-NMR (250 MHz, $CDCl_3$, δ values): $C(CH_3)_3$: 1.29 (s, 9H); $C(CH_3)_3$: 1.70 (s, 18H); phenyl-H: 7.28 (s, 2H)

$^{13}C\{^1H\}$-NMR (62.89 MHz, $CDCl_3$):

	2a	**1d** [a]	*J*(PC) [Hz]
C1	131.70 (s)	124.78 (d)	22.0
C2	157.01 (s)	156.89 (d)	5.79
C3	121.10 (s)	121.07 (d)	1.48
C4	150.96 (s)	151.40 (d)	6.33
C5	37.10 (s)	37.03 (s)	1.77
C6	31.20 (s)	30.92 (s)	
C7	35.49 (s)	35.45 (s)	
C8	31.07 (s)	31.14 (s)	
C≡As	191.86 (s)		
C≡P [b]		168.87 (d)	53.22

[a] For direct comparison. [b] **1a**, δ = 184.8 (d, *J*(PC) = 38.5 Hz); **1b**, δ = 163.3–165.1 (d, *J*(PC) = 46.4–46.7 Hz); **1c**, δ = 184.7 (d, *J*(PC) = 39.0 Hz).

In the high-resolution *mass spectrum* of **2a** (Table 1), the peak for the molecular ion confirms the elemental composition; the pattern of fragmentation is largely in agreement with that of the phosphaethyne **1d**. The 250-MHz *^{1}H-NMR spectrum* (Table 1) is in accord with the structure. In the *$^{13}C\{^1H\}$-NMR spectrum*, the signal of the sp C atom appears at δ = 191.86. Table 1 permits a comparison with the spectral data of phosphaethynes **1**.

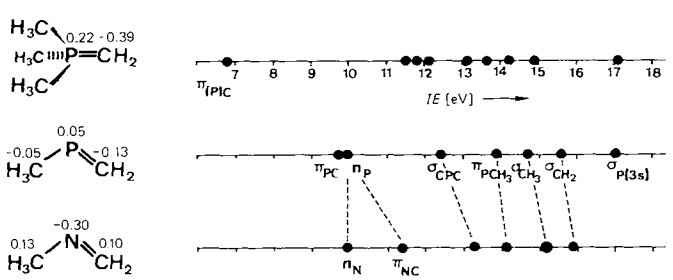
$H_3C-P=PCH_2$: An Ylide with Two-Coordinate Phosphorus?

By *Hans Bock** and *Martin Bankmann*



Dedicated to Professor Rolf Appel on the occasion of his 65th birthday

An large number of X–P=Y compounds containing 18 valence electrons and phosphorus of coordination number 2 have been synthesized: Examples are Cl–P=O,[1] Cl–P=S,[1] $H_3C-P=S$,[2] and $Cl-P=CH_2$.[3] All are bent, as predicted by the Walsh rules,[4] and may be regarded as propene analogues within the "united atom" approximation.[5] We report here on 2-phosphapropene **2**, which can be prepared from chlorodimethylphosphane **1** by gas-phase pyrolysis and identified by its photoelectron (PE) and mass spectra (Fig. 1).

According to the useful rule of thumb $(\Sigma np_{El}+\Sigma 1s_H)/2=n\,IE_n^v$,[7] six intense ionization bands are expected in the He(I) PES measurement region for molecules having the composition C_2H_5P and containing seven $np_{Element}$ and five $1s_H$ valence electrons. All of them are indeed observed for both 2-phosphapropene **2** (Fig. 1) and the isomeric phosphirane $(H_2C)_2PH$.[8] The first band in the PE spectrum of **2** is due to two ionizations, which, according to MNDO calculations, involve the removal of electrons from the $\pi_{P=C}$ bond with formation of the radical cation ground state $\tilde{X}(^2A'')$ and from the lone pair at the P atom with formation of the radical cation in its first excited state $\tilde{A}(^2A')$. Between 12 eV and 16 eV, four ionizations from the molecular skeleton follow, which can be characterized as $\sigma_{HCPCH}(a')$, $\pi_{CH_3}(a'')$, $\sigma_{CH_3}(a')$, and $\sigma_{CH_2}(a')$. According to the MNDO calculation, the weak-intensity band at 17.0 eV may be assigned to a radical cation state with a large phosphorus 3s contribution.[9]

Of particular interest is the electron distribution in $H_3C-P=CH_2$ **2** as calculated by MNDO, which is supported experimentally by comparison of the PE spectroscopic data of **2** with those of trimethyl(methylene)phosphorane $(H_3C)_3P=CH_2$,[10] the simplest known phosphorus ylide, and the isosteric methyl(methylene)amine $H_3C-N=CH_2$[11] (see Scheme 1).

Scheme 1. MNDO charge distribution (left) and PE spectroscopic ionization energies (right) of $(H_3C)_3P=CH_2$, $H_3CP=CH_2$, and $H_3CN=CH_2$.

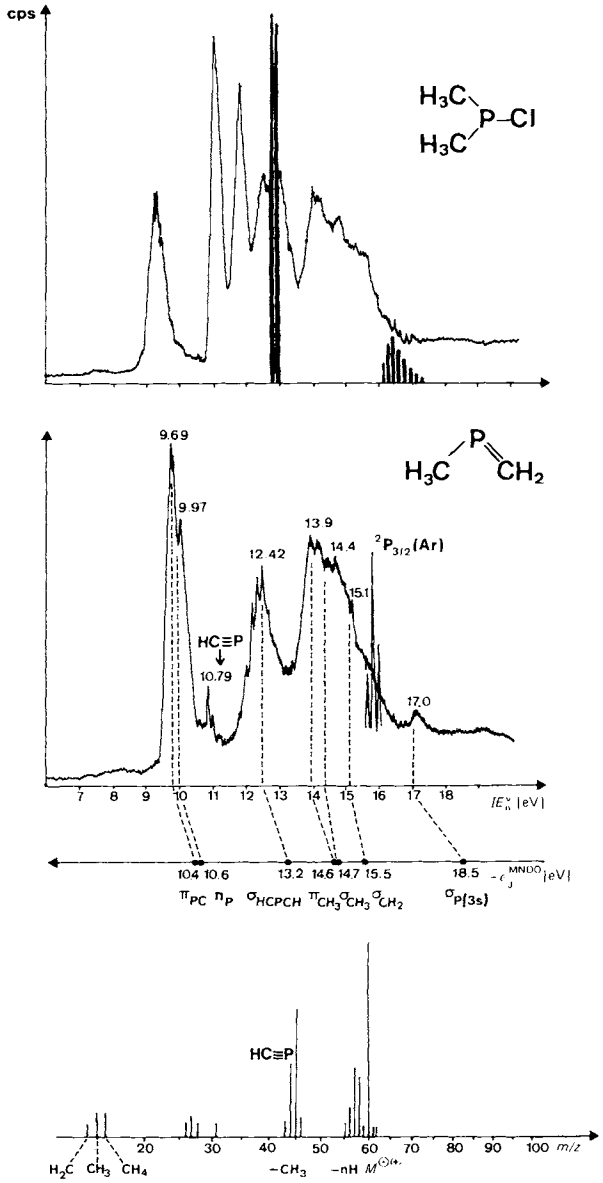


Fig. 1. He(I) PE spectra of the starting material $(H_3C)_2PCl$ **1** (above), which contains traces of HCl (black), and the pyrolysis product at 820 K, $H_3C-P=CH_2$ **2** (middle). Excess starting material and the cleavage product HCl are removed by condensation in a cold trap, which is introduced between the oven (quartz tube: 2 cm × 30 cm) and the spectrometer and which is cooled with ethanol/N_2 to 170 K. The PE spectrum of **2** can be assigned, e.g. (cf. text), by means of Koopman's correlation, $IE_n^v=-\varepsilon_j^{MNDO}$, on the basis of MNDO eigenvalues. Under the pyrolysis conditions that were optimized by PE spectroscopy, it is also possible to record the mass spectrum (below). Both the PE and the mass spectra confirm the formation of HC≡P, which is presumably formed at higher temperature according to $H_3C-P=CH_2\rightarrow CH_4+HC\equiv P$ [6].

The PE spectra of all P ylides exhibit a band at low ionization energies (5.95 to 6.85 eV[10]), which is assigned to electron removal from the polar $P^{\delta\oplus}=C^{\delta\ominus}$ bond exhibiting a high negative charge density at the C atom. In contrast, the first ionization of $H_3C-P=CH_2$ **2** is observed only at 9.69 eV and its PE spectrum is very similar to that of $H_3C-N=CH_2$,[11] the change of sequence $\pi_{PC}<n_P\Rightarrow n_N<\pi_{NC}$ being a consequence of the high effective charge at the nitrogen and the wider CNC angle (compared with CPC in **2**). The calculated charge densities

[**] Gas-Phase Reactions, Part 54. This work was supported by the Land Hessen, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Hoechst AG.—Part 53: H. Bock, R. Dammel, *Inorg. Chem. 24* (1985) 4427.

(Scheme 1) illustrate that the four-coordinate ylide phosphorus contributes much less to the π delocalization than the two-coordinate phosphorus in **2**.[12] The new molecule $H_3C-P=CH_2$ **2**, therefore, is best characterized as being a 2-phosphapropene and not an ylide.

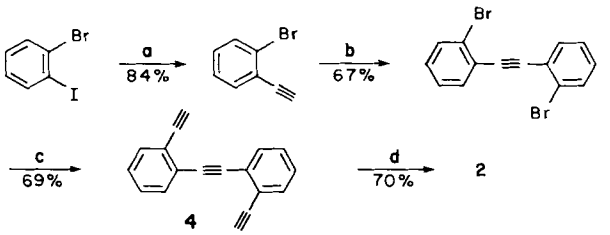
[12] The PE spectrum of $H_3C-P=CH_2$ can be satisfactorily assigned by MNDO calculations without including phosphorus d orbitals in the basis set (Fig. 1). Therefore, the answer to the "Hamlet" question for phosphorus bonds, "to d or not to d," is no, except when a highly correlated eigenfunction containing polarization components is desired.



Novel Synthesis of the Angular [3]Phenylene (Terphenylene) by Cobalt-Catalyzed Cyclization of Bis(2-ethynylphenyl)ethyne: a Molecule with an Internal Cyclohexatriene Ring**

By *Rainer Diercks* and *K. Peter C. Vollhardt**

We recently reported[1] an iterative approach by linear cyclobutabenzoannulation to the [n]phenylenes **1**, a novel class of theoretically interesting molecules in which (formally) aromatic benzene rings alternate with antiaromatic cyclobutadienes. There is a topologically alternative series in which the rings are fused in an angular manner as in **2**; this series culminates in the "anti-kelulene" **3**. In **3** both the inside and outside π circuits are 4n, unlike in kekulene.[2] In an effort to approach **3** by application of cobalt-catalyzed alkyne cyclizations,[3] we chose as a test system **2**, prepared earlier by a high-temperature pyrolysis route in low yield.[4] This molecule and its isomer **1** have been the target of several conflicting theoretical treatments.[1d, 5] By making available larger quantities of **2** and investigating its chemistry and structure, we hope to resolve some of the controversy surrounding these compounds.

A retrosynthetic analysis of **2** suggests bis(2-ethynylphenyl)ethyne **4** as the most straightforward precursor. However, considering the four-membered-ring strain in biphenylene, estimated to lie between 64.3 and 75.4 kcal mol^{-1},[6] and assuming that in **2** such strain is cumulative, there was the possibility that the conversion of **4** into **2** was contrathermodynamic, since the cyclotrimerization of ethyne to benzene releases only 143 kcal mol^{-1}[3] (or, for **4** → **2**, $4\,C_t(C_B)+2\,C_t(H)-4\,C_b(C_B)-2\,C_B(H)=-144.2$ kcal mol^{-1}).[7] Moreover, an intramolecular cyclization of the type required had never been reported[3] and in fact failed for the related 1,5,9-decatriyne.[8]

Scheme 1. **a**: 1) Trimethylsilylacetylene, $[PdCl_2(PPh_3)_2]$, CuI, Et_3N, 25°C; 2) CH_3OH, potassium hydroxide; **b**: *o*-bromoiodobenzene, $[PdCl_2(PPh_3)_2]$, CuI, Et_3N, 25°C; **c**: 1) trimethylsilylacetylene, $[PdCl_2(PPh_3)_2]$, CuI, Et_3N, 110°C; 2) CH_3OH, potassium hydroxide; **d**: 1) $[(C_5H_5)Co(CH_2=CH_2)_2]$, tetrahydrofuran, −30°C; 2) CO (8 atm), 100°C.

An efficient and convergent synthesis of **4** is depicted in Scheme 1. It begins with *o*-bromoiodobenzene,[9] which undergoes iterative sequences of palladium-catalyzed couplings with trimethylsilylacetylene and deprotections.[10] Gratifyingly, cyclization of **4** (m.p. = 74°C) with $[(C_5H_5)Co(CO)_2]$[3] as catalyst (30%) or, better, stepwise with $[(C_5H_5)Co(CH_2=CH_2)_2]$[11] gave **2** as yellow crystals in 70% yield (m.p. = 185°C, lit. [4] 175–177°C). The spectral data agree with those reported. The four quaternary carbons (not previously located) resonate (C_6D_6, 125 MHz, 25°C) at $\delta = 136.16$, 149.44, 149.49, and 150.88 (2C each), which, except for the relatively high-field position of the first peak, are similar to the values for related compounds.[1d, 12] The coupling constant between the two hydrogens on the central ring ($J = 6.42$ Hz, not previously determined) was obtained from ^{13}C satellite ^1H-NMR mea-

surements. It is less than J_{H1-H2} (6.6 Hz) in **1**, n = 3,[1d] suggesting strong bond localization. Consistent with this notion, catalytic hydrogenation of **2** (Pd-C, 10-atm H_2) proceeded cleanly (99%) to give a hexahydro derivative, assigned the all-*cis* configuration.[13] Its conformational mobility is restricted at −60 °C.[13] Interestingly, in a competitive hydrogenation experiment, **1** reacted 2–3 times faster than **2**.

Preliminary cyclic voltammetry on **2** (Pt electrode vs. $Ag/Ag^{\oplus}$, CH_3CN, 0.1 M $Bu_4N^{\oplus}PF_6^{\ominus}$) reveals a reversible one-electron ($E_{1/2} = -2.34$ V) and, in contrast to **1**, n = 3, an irreversible two-electron reduction wave ($E = -2.73$ V) in addition to an irreversible oxidation wave ($E = 0.96$ V). Exposure to a potassium mirror changed the color of a solution of **2** in [D_8]tetrahydrofuran instantly from yellow to green (presumably the color of its radical anion); however, unlike **1**, n = 3, no dianion $\mathbf{2}^{2\ominus}$ was observed upon prolonged reaction.

The ^{1}H-NMR spectrum of **2** exhibits an unusually strongly shielded singlet for the central aromatic hydrogens ($CDCl_3$, $\delta = 6.13$;[4] C_6D_6, $\delta = 5.96$), which initially[4] seemed to be indicative of the presence of two strongly paratropic cyclobutadienoid rings. Recently, an alternative explanation involving reduced diatropism of the central benzene ring was suggested.[1d, 14] In light of this uncertainty and in order to compare the structural features of **2** with those of a tetrasilyl derivative of **1**, n = 3,[1b,d] an X-ray structural study was carried out (Fig. 1).[15]

Finally, the structural data and the successful catalytic conversion of **4** into **2** allow us to estimate an upper limit for the combined ring strain in **2**: ΔH^0 of **4** → **2** (cyclohexatriene) = $4\,C_t(C_B) + 2\,C_t(H) - 4\,C_D(C_B,C) - 2\,C_D(C_D,H) = -122.54$ kcal mol^{-1}. This value also suggests that the second cyclobutadiene moiety in **2** adds considerably less strain than the first[6] to the system.

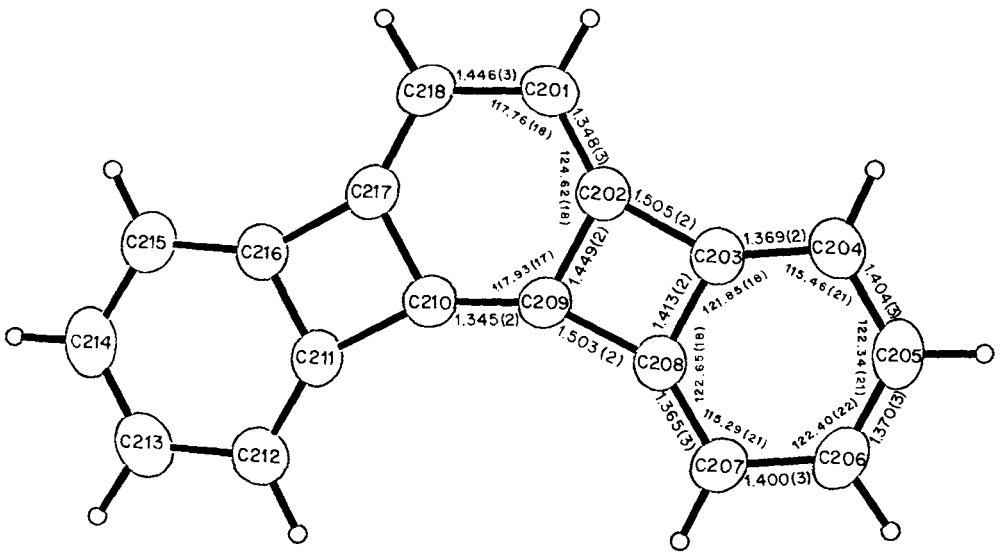

Fig. 1. ORTEP drawing of the crystal structure of **2** (IUPAC name: benzo[3,4]cyclobuta[1,2-*a*]biphenylene). Ellipsoids are scaled to represent the 50% probability surface. Selected bond lengths [Å] and angles [°] are taken from the center one of three closely similar and quite symmetrical molecules stacked in the unit cell. The bond angles in the four-membered rings deviate from 90° by less than 1°.

The molecule is completely flat. In contrast to the framework of **1**, n = 3, the outside benzene rings show very little bond alternation. This bond alternation is comparable to that in strained cycloalkabenzenes[16a] and consistent with the more recent ^{1}H-NMR analysis.[1d, 14] The bonds in the central ring, however, are *considerably more localized than in all related structures* synthesized in order to detect the elusive cyclohexatriene unit[1, 16] and are comparable to the bonds in 1,3-buta-,[17] 1,3-cyclohexa-,[18] and 1,3-cyclopentadiene[19]! We conclude that **2** contains the first such unit verified by X-ray analysis.

Hexaethynylbenzene**

By *Rainer Diercks, James C. Armstrong, Roland Boese,* and *K. Peter C. Vollhardt**

Hexaethynylbenzene **1** is exceedingly interesting for a variety of reasons: (1) It is aesthetically pleasing because of its symmetry. (2) It is the only other known $C_{18}H_6$ isomer,[1,2] the first being 1,7,13-cyclooctadecatriene-3,5,9,11,15,17-hexayne.[1] The two compounds are potentially interconvertible by a series of Cope-like rearrangements.[3] (3) Its π-framework may be stabilized by double aromaticity[4] involving the two orthogonal sets of ethynyl π-orbitals, which should exhibit strong through-bond and/or through-space interactions.[5] (4) It should function as a highly electron-rich species on which to anchor transition-metal clusters with potentially novel catalytic activity.[6] (5) It may be a unique starting material for cobalt-catalyzed cyclizations leading ultimately to triangular multiphenylenes.[7] (6) Finally, it should be an exceptional monomer in (co)polymerizations to furnish novel conducting materials.[8]

The most straightforward preparation of **1** can be envisaged to proceed through a palladium-catalyzed hexaethynylation of a hexahalobenzene with a protected alkyne, followed by deprotection.[9] Although such a strategy proved futile with hexaiodobenzene,[10] we have found that hexabromobenzene **2** undergoes this remarkable sixfold carbon-carbon bond formation not only to give **3a** but also **3b**, either employing 2-methyl-3-butyn-2-ol or trimethylsilylacetylene[11] (Scheme 1), and that **3** can be deprotected to give **1** (Table 1). Whereas deprotection of **3a** always resulted in the formation of **1** contaminated with partially protected material, deprotection of **3b** proved to be much more convenient and proceeded essentially quantitatively.[12]

Table 1. Physical data for **3a**, **b**, and **1**.

3a [10]: m.p. > 300°C (dec.); UV (CH_3OH): $\lambda = 273$ (sh, $\lg\varepsilon = 4.88$), 289 (5.13), 297 (sh, 4.83), 309 (4.85) nm; IR (KBr): $\tilde{\nu} = 3340$, 2991, 2939, 2233, 1420, 1378, 1366, 1220, 1156, 958 cm^{-1}; ^{1}H-NMR (CD_3COCD_3): $\delta = 4.56$ (s, 6H), 1.58 (s, 36H); ^{13}C-NMR (CD_3OD-CD_3COCD_3, 1:1): $\delta = 128.1$, 105.2, 65.9, 31.7; MS (70 eV): *m/z* 570 (53), 552 (10), 465 (100), 425 (19), 300 (18).

3b: m.p. = 320°C (dec.); UV (hexane): $\lambda = 286$ (sh, $\lg\varepsilon = 4.76$), 291 (4.86), 302 (5.18), 315 (sh, 4.87), 321 (4.95) nm; IR (KBr): $\tilde{\nu} = 2970$, 2910, 2160, 1400, 1250, 940, 850, 760, 705, 640 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 0.26$ (s); ^{13}C-NMR ($CDCl_3$): $\delta = 128.0$, 105.2, 101.0, 0.016; MS (70 eV): *m/z* 654.2828 (calculated: 654.2841).

1: UV (DME): $\lambda = 267$ (sh, $\lg\varepsilon$ (based on quantitative conversion of **3b**) = 4.77), 279 (5.02), 289 (sh, 4.69), 298 (4.76) nm; IR (DME): $\tilde{\nu} = 3240$, 2100 cm^{-1}. Further bands obscured by solvent; ^{1}H-NMR (C_6D_6): $\delta = 3.17$ (s); ^{13}C-NMR (CD_3SOCD_3): $\delta = 128.0$, 91.54, 79.38; MS (70 eV): *m/z* 222 (100), 221 (22), 220 (14), 152 (19).

Hexaethynylbenzene **1** can be precipitated as a white powder, which turns brown slowly in the absence of air but rapidly in its presence. **1** is only soluble in the more polar solvents, such as THF, dimethoxyethane (DME), or dimethylsulfoxide (DMSO), in which it can be stored in dilute form. Preliminary results show that **1** and **3b** form complexes with transition metals.

The spectral data for **1** and **3** are similar to those for other ethynylbenzenes.[9,13] Thus, there are no readily detectable spectral indications of peripheral conjugation. The UV spectra exhibit considerable bathochromic shifts and relatively larger extinction coefficients compared with those found for phenylacetylene and phenyl(trimethylsilyl)acetylene.[14] Curiously, whereas the mass spectrum of phenyl(trimethylsilyl)acetylene shows a base peak corresponding to $M^{\oplus} - CH_3$ (*m/z* 159) and no significant signal for $Me_3Si^{\oplus}$,[15] the latter signal forms the base peak and the only dominant fragmentation signal for **3b**. Because of the

[**] This work was supported by the U.S. Department of Energy (Materials Sciences Division, Office of Basic Energy Sciences, Office of Energy Research, Contract No. DE-AC03-67SF00098). *J. C. A.* was an IBM Polymer Fellow (1984–1985). *R. D.* was the recipient of a NATO Science Fellowship (1984–1985). *K. P. C. V.* is a Miller Research Professor in Residence (1985–1986).

novelty of the structures of these molecules, an X-ray structural analysis was carried out on **3b** (Fig. 1).[16]

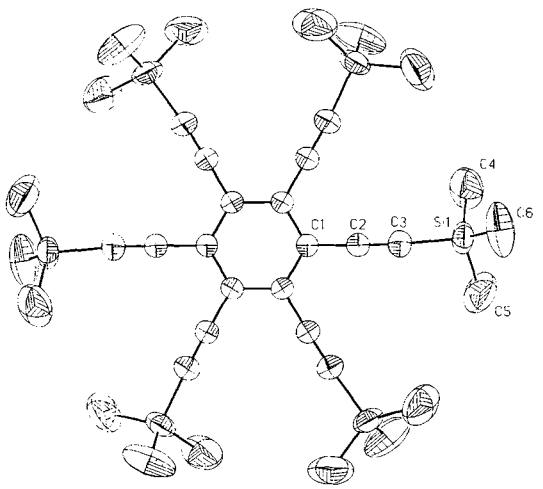

Fig. 1. Crystal structure of **3b** [16]. Important bond lengths [Å] and angles [°]: C1-C2 1.432(3), C1-C1a 1.406(3), C1-C1b 1.406(1), C2-C3 1.195(3), Si1-C3 1.836(2), C2-C1-C1a 120.3(2), C2-C1-C1b 119.7(2), C1-C2-C3 176.5(2), Si1-C3-C2 175.0, C1-C2-C3-Si1 17.5, C2-C1-C1a-C2a 4.4. C1a and C1b indicate the C atoms adjacent to C1 in the benzene ring.

Surprisingly, the molecule (at least in the crystalline state) distorts from perfect symmetry and the alkyne units are not completely linear. All trimethylsilyl groups are "twisted" from a symmetrical radialene structure in alternating directions above and below the molecular plane and in the same direction along the C1-C2-C3 axis (Fig. 2). The closest intramolecular "nonbonded" H-H distance from one trimethylsilyl group to another is 2.72 Å.

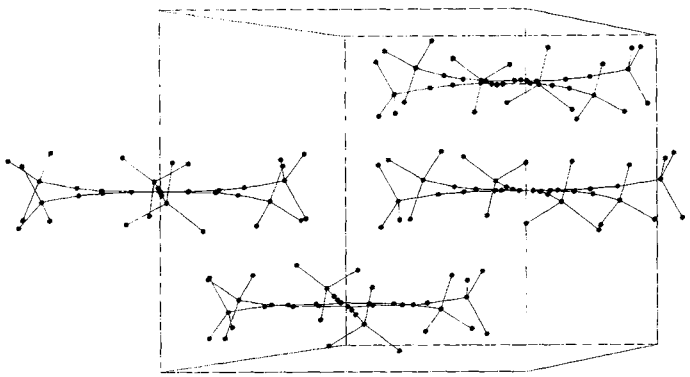

Fig. 2. Side view of the unit cell of the crystal structure of **3b** [16].

A calculated ideal symmetry (planar system, torsional angle C1-C2-C3-Si1 0°, same bond lengths) results in a "nonbonded" H-H separation of 2.30 Å, which is less than the sum of the van der Waals radii of two hydrogens. It must be assumed that the distortions in the molecule are (at least to a major part) due to intramolecular repulsions of the bulky silyl substituents. The aromatic double bonds are longer (by almost 0.02 Å) than those in phenylacetylene,[17] whereas the bond to the alkynyl group and the triple bond are slightly shorter.

A Simple Access to 2-Epoxy Alcohols: Titanium(IV)-Catalyzed Oxygen Transfer from Allylic Hydroperoxides**

By *Waldemar Adam,* Axel Griesbeck*, and *Eugen Staab*

Whereas the chemistry of saturated hydroperoxides in the presence of metals has been the subject of numerous studies,[1] little is as yet known about the behavior of the corresponding unsaturated hydroperoxides.[2] Reactions with titanium(IV) isopropoxide have, to our knowledge, so far not been described.

In the presence of stoichiometric or catalytic amounts (1-5 mol-%) of Ti(O*i*Pr)$_4$, the allylic hydroperoxides **1a-d**[3] are converted into the corresponding 2-epoxy alcohols **2a-d** under mild conditions.

Table 1. Synthesis of 2-epoxy alcohols **2** [a].

	R^1	R^2	R^3	Epoxy alcohol **2**	
				Yield [%] [b]	d. r. [c]
a	*t*Bu	H	H	87	
b	Me	*t*Bu	H	84	95:5
c	Me	Me	Me	91	
d	CO_2Et	Me	H	68 [d]	90:10

[a] Ca. 0.1 M hydroperoxide solution, 0 °C, 1–5% $Ti(OiPr)_4$ in the case of **1a–c**, equimolar amounts in the case of **1d**; addition of 1 mL of H_2O per mmole $Ti(OiPr)_4$ on completion of the reaction (monitored by TLC and NMR); filtration over celite. [b] Yields after Kugelrohr distillation. [c] Diastereomeric ratios (d. r.) determined by 400-MHz ^{1}H-NMR. [d] In addition, **3d** is formed in 25% yield. **2d** and **3d** were not separated; assignment by comparison of ^{1}H- and ^{13}C-NMR spectra with authenic samples.

Table 1 shows that, independent of the degree of substitution (primary, secondary or tertiary) of the hydroperoxide **1**, the corresponding epoxy alcohols **2** can be isolated in good yields. In the case of the epoxy alcohols **2b** and **2d** the two possible diastereomers are formed in 95:5 and 90:10 ratios, respectively. In the reaction of **1d**, the allylic alcohol **3d** is a by-product; moreover, larger quantities of $Ti(OiPr)_4$ than usual must be used. This finding prompted us to carry out a mechanistic study of this novel oxygen transfer reaction.

For the model study we chose the reaction of **1c** with $Ti(OiPr)_4$. The results are summarized as follows:

- the oxygen transfer does not take place (or only to a small extent) intramolecularly:[4] **1c** is stable for long periods in the presence of catalytic amounts of $Ti(OiPr)_4$ (5%).
- the chain carrier in the step **1c**→**2c** is the allylic alcohol **3c**; addition of small amounts of **3c** to a 20:1 mixture of **1c** and $Ti(OiPr)_4$ accelerates the reaction considerably.
- the epoxy hydroperoxide **4c** could not be detected at any time during the course of the reaction. Independently prepared **4c**[5] transfers oxygen considerably slower than the allylic hydroperoxide **1c** and should accumulate in the reaction **1c**→**2c**.

Scheme 1. A=R^1-C(=CH_2)-CR^2R^3-.

Therefore, we propose the mechanism outlined in Scheme 1. In the case of the allylic hydroperoxide **1c**, k_2 must be substantially greater than k_1; consequently, **3c** lies below the NMR detection limit. Furthermore, k_3 is negligibly small and **4c** does not participate. In the reaction of **1d** with $Ti(OiPr)_4$ the rate constants k_1 and k_2 are of about the same order of magnitude; hence, **3d** accumulates. This also explains why larger amounts (30–40 mol%) of $Ti(OiPr)_4$ are necessary for completion of the reaction **1d**→**2d**.

The reaction outlined here enables the conversion of allylic hydroperoxides, readily accessible by ene reaction with singlet oxygen,[6] into synthetically valuable 2-epoxy alcohols.

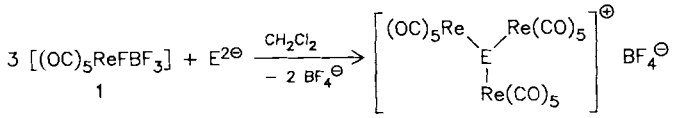
Tris(pentacarbonylrhenium)-sulfonium, -selenonium, and -telluronium Ions: Synthesis and Structure of $[\{(OC)_5Re\}_3E]^{\oplus}BF_4^{\ominus}$ (E = S, Se, Te)**

By *Wolfgang Beck,* Wolfgang Sacher,* and *Ulrich Nagel*



Dedicated to Professor Rudolf Gompper on the occasion of his 60th birthday

Pentacarbonyl(tetrafluoroborato)rhenium(I) **1** behaves like the coordinatively and electronically unsaturated cation $(OC)_5Re^{\oplus}$ and adds numerous nucleophiles.[1] $(OC)_5Re^{\ominus}$ (16e) is isolobal[2] with the carbenium ion $R_3C^{\oplus}$ (6e). We have now found a further analogy between inorganic and organic chemistry in the reaction of **1** with alkali metal chalcogenides, which leads to the tris-metalated sulfonium, selenonium, and telluronium salts **2–4**, respectively. This reaction corresponds to the alkylation of chalcogenides (e.g. with alkyl halides). **1** was allowed to react heterogeneously with Na_2S, Na_2Se, and Li_2Te at 20 °C in

On preparing a single crystal of **2** in nitromethane/ether, partial hydrolysis took place with formation of **5**. This compound crystallizes together with **2** in one crystal (cf. Figures 2 and 3) and could thus be analyzed at the same

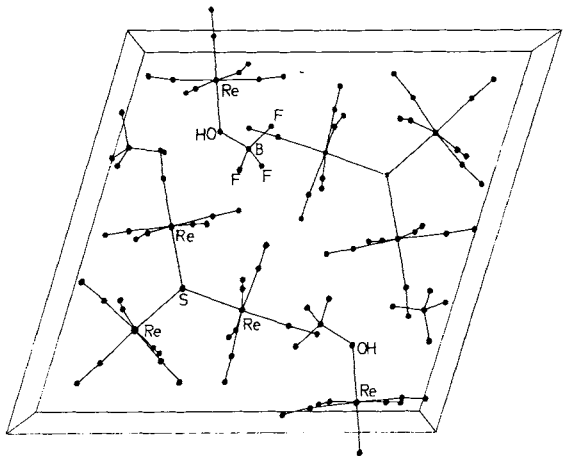

Fig. 2. Unit cell of the crystal of **2** and **5** (measurement at room temperature). Space group P$\bar{1}$, a = 734.7(3), b = 1584.4(5), c = 1608.7(6) pm, α = 106.96(3), β = 91.34(3), γ = 92.24(3)°, V = 1.789(1) nm^3, Z = 2. Crystal size 0.2 × 0.1 × 0.1 mm^3, μ(Mo$_{K\alpha}$) = 138.5 cm^{-1} (absorption corrected), 18288 collected, 6180 independent, 3981 observed ($I > 2\sigma(I)$) reflections. Number of refined parameters 247, heavy atoms Re and S anisotropic. R = 0.077, R_w = 0.072, $w = 1/(\sigma^2(F) + g \cdot F^2)$, g = 0.0008. Maximum residual electron density 2.16 e·pm^{-3} × 10^6 [13].

time. A remarkable feature of **2** is the almost planar arrangement of the $Re_3S^{\oplus}$ moiety (cf. Table 2). This is due more to the spatial requirement of the three Re(CO)$_5$ moie-

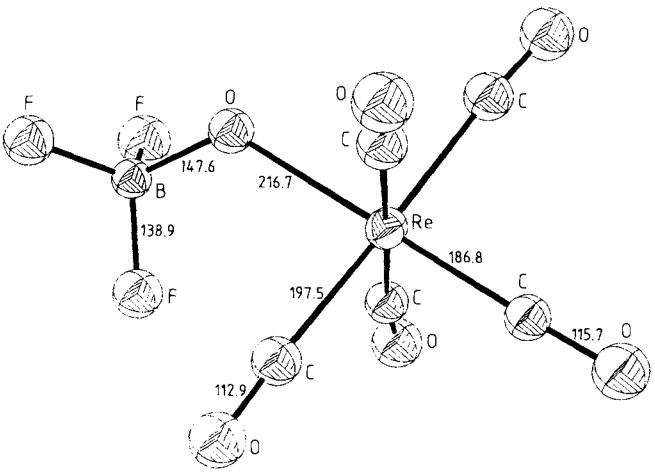

Fig. 3. Molecular structure (at room temperature) of **5** in the crystal. Bond lengths [pm] [13].

ties and less to a significant metal-chalcogen π-bonding in **2**. Because of the greater Re-chalcogen distance, a pyramidal structure is possible in **4**. The Re-S distance of 254 pm in **2** is identical with that in $[Re_3S_2(CO)_{13}SnMe_3]$ containing a μ_3-SRe_3 unit (254 pm).[6] In complexes with metal-sulfur multiple bonds, the metal-S distances are considerably shorter.[10] As proposed earlier,[11] the trifluorohydroxoborate ligand in the crystal of **2** and **5** is bound to the rhenium via the oxygen atom; $F_3B\text{-}F\cdots H\text{-}OBF_3$ hydrogen bridges (F-O 267 pm) are observed between the OH-group and the "free" $BF_4^{\ominus}$ ion.

Experimental

All reactions were carried out in anhydrous solvents under argon. **1** was prepared immediately before the reaction from $[Re(CO)_5CH_3]$ and HBF_4 (54% solution in diethyl ether) [12]. The alkali-metal chalcogenides were dried for several hours in a high vacuum at about 40–50°C.—**2**: A suspension of **1** (0.29 mmol, 120 mg) and Na_2S (0.15 mmol, 12 mg) in CH_2Cl_2 (3 mL) was stirred for 18 h at room temperature. The residue was centrifuged off, washed with 2 mL of CH_2Cl_2, and dried in a high vacuum. When the bands of the coordinated $BF_4^{\ominus}$ ion no longer appeared in the IR spectrum of the product mixture, the residue was extracted twice with 3 mL of nitromethane. **2** was precipitated by dropwise addition of the intensely red-violet solution into 20 mL of Et_2O; yield after drying for 4–5 h in a high vacuum at 30–40°C: 60 mg (55%).—**3** and **4** were prepared analogously. *Properties of* **2**–**4**: stable in air, decomposition above 120°C with brown coloration; **2** red-violet; **3** blue-violet; **4** red.

$[Re_4^{IV}S_{22}]^{4-}$, a Highly Symmetrical Metal-Sulfur Cluster with Six S_3^{2-} Ligands

By *Achim Müller,* Erich Krickemeyer,* and *Hartmut Bögge*

Dedicated to Professor Rolf Appel on the occasion of his 65th birthday

Homo- and heteronuclear metal-sulfur clusters of the early transition metals are of special interest in connection with heterogeneous catalysis.[1] Thus, e.g., $[Mo_3^{IV}S_{13}]^{2-}$ is a model for the catalyst MoS_2 and the products of the thermal decomposition of its NH_4^+ salt are excellent catalysts for various processes, such as, e.g., the desulfurization of crude oil.[1] The corresponding rhenium compounds should, in view of their modified electronic structure, be even better catalysts. We have now succeeded in isolating $[Re_4S_{22}]^{4-}$, the first discrete *rhenium*-sulfur cluster, in the form of the NH_4^+ salt **1**.[2] The cluster anion $[Re_4S_{22}]^{4-}$ contains hitherto unknown M_2S_3 rings.

$[NH_4]_4[Re_4S_{22}]\cdot 0.3\,NH_4Cl\cdot 0.7\,H_2O$ **1**

The reddish-brown, diamagnetic salt **1**, which crystallizes in the cubic system, is soluble in H_2O; it is formed upon heating a perrhenate solution with an aqueous polysulfide solution, using $NH_2OH\cdot HCl$ as reducing agent.[9] It was characterized by elemental analysis, magnetic measurements, UV/VIS, IR and Raman spectroscopy,[3] as well as by thermogravimetry, powder diffraction,[4] and a single-crystal X-ray structure analysis.[5] Four Re and four S atoms form a cube (Fig. 1, left). The coordination number 6 of the metal atom is achieved by six S_3^{2-} ligands bridging the faces of the cube; this type of cluster stabilization was hitherto unknown. With this type of coordination the cluster anion (despite its relatively large size) has almost T_d symmetry[6] (fulfilled exactly for the fragment without central S3 atoms). The six Re_2S_3 rings have envelope conformation (see Figure 1 on the right with torsional angles).

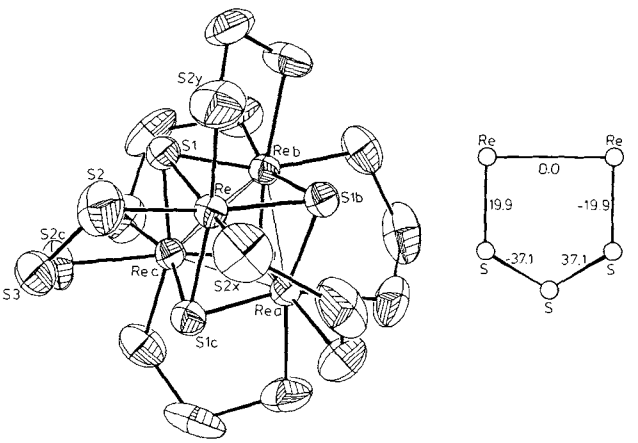

Fig. 1. Left: Structure (thermal ellipsoids at the 40% probability level) of the $[Re_4S_{22}]^{4-}$ anion in crystals of **1**. Important bond lengths [pm] and angles [°]: Re-Rec 276.4(3), Re-S1 231.9(7), Re-S2 246.3(12), S2-S3 214.0(30), S1-S1c 366.9(19); S1-Re-S1c 104.6(4), S1-Re-S2 87.7(4), S1-Re-S2x 159.5(6), S2-Re-S2x 76.3(7), Re-S1-Rec 73.2(2), Re-S2-S3 108.4(9), S2-S3-S2c 112.3(10)). Right: Re_2S_3 ring system with torsional angles [°].

The Re atoms are linked by metal-metal bonds, which is inferred from the diamagnetism of **1** and the short Re-Re distances (ca. 276 pm). The presence of the Re_4 tetrahedron is consistent with our counting rule for clusters.[7] According to Extended-Hückel SCCC-MO calculations the cluster anion of **1** has six bonding MOs (a_1, e, t_2, occupied in the cluster) and six antibonding MOs (t_1, t_2 unoccupied), which have predominant Re-5d character. The stabilization of the Re_4S_4 cluster, however, is essentially due to the Re-S bonding system (MOs: a_1, e, t_1, $2t_2$). Owing to the high symmetry of $[Re_4S_{22}]^{4-}$, there are only a few bands in the vibrational spectra of **1**.[3]

According to preliminary studies, **1** thermally decomposes in a vacuum in several steps to ReS_2, and, finally,

above 1000 °C to rhenium and sulfur.[8] The intermediates could be potentially useful hydrodesulfurization catalysts.

[9] Note added in proof (Februar 14, 1986): The chloride-free compound $(NH_4)_4[Re_4S_{22}] \cdot 2H_2O$ (**2**) has now been obtained by reaction of ammonium perrhenate with an aqueous polysulfide solution at ca. 60 °C. In this case, S_7^{2-} acts as a reducing agent. The bond lengths and angles determined for **2** by X-ray structure analysis resemble those of **1**.

$[Bi_2^{III}S_{34}]^{4-}$, the Hitherto Sulfur-Richest Complex

By *Achim Müller**, *Marion Zimmermann*, and *Hartmut Bögge*

The chemistry of polysulfido complexes is always full of surprises—especially for the structural chemist.[1,2] We have now been able to synthesize the sulfur-rich compound

$[AsPh_4]_4[Bi_2S_{34}]$ **1**,

the complex anion of which has a remarkable structure (Fig. 1). Small, brownish-red crystals of **1** are obtained in good yield upon reaction of a CH_3CN polysulfide solution with $BiCl_3$ in the presence of Ph_4AsCl.[3] The salt was characterized by elemental analysis, IR and Raman spectroscopy,[4] and a complete X-ray structure analysis.[5]

In the anion $[Bi_2S_{34}]^{4-}$ the two Bi atoms, which are linked via a S_6^{2-} chain, are each coordinated to two bidentate S_7^{2-} ligands (Fig. 1). The coordination polyhedron of each Bi atom is a strongly distorted square pyramid (influence of the lone pair!), whose apex is formed by the coordinating atom of the S_6^{2-} chain. As expected, the axial Bi-S bonds, with a mean length of 268.3 pm, are shorter than the equatorial ones (281.7 pm). The torsional angles

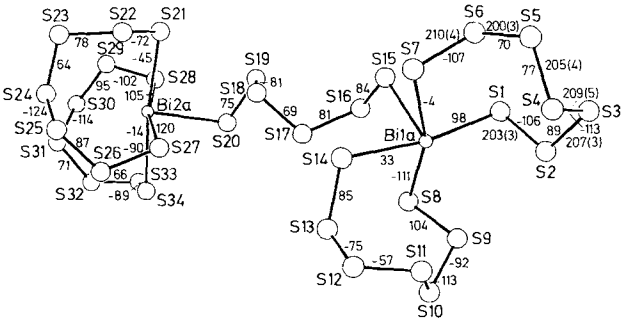

Fig. 1. Structure of the $[Bi_2S_{34}]^{4-}$ ion [5] in crystals of **1** with torsional angles [°], bond lengths [pm] for one S_7^{2-} ligand; other bond lengths [pm] (mean values): Bi-S_{eq} 281.7; Bi-S_{ax} 268.3; selected bond angles [°]: S-Bi-S 72.3(7)-103.8(7) and 161.3(7)-171.7(10); S-S-S (S1-S7-ring) 102.8(16)-110.3(14); S-S-S (S_6 chain) 105.7(14)-113.0(18).

(Fig. 1) show that the S_6^{2-} chain has an all-*trans* conformation and that the BiS_7 eight-membered ring roughly approximates a "boat-chair" conformation[6] (with the Bi atoms causing strong distortion). The four mirror planes to be expected for such a conformation run approximately through the S2 and S6, S9 and S13, S22 and S26, and S29 and S33 atoms.

Neither a complex with a bridging S_6^{2-} ligand nor one with a bidentate S_7^{2-} ligand has hitherto been reported in the literature. The latter fact is surprising, as this type of coordination is most frequently observed in the case of polysulfide ligands; so far, only one structural type with a tridentate S_7^{2-} ligand has been reported.[7] Since the successful isolation of **1** there are now examples for n = 3-7 and 9 that are known for the monocyclic MS_n systems.[1,2]

[3] Procedure: CH_3CN (100 mL, AR) was first treated with a stream of NH_3 for 10 min and then, after addition of Ph_4AsCl (1 g) and S_8 (1 g), with a stream of H_2S for 45 s (flow rate: 10 L/h). The mixture was stirred for a further 30 s and then treated with a solution of $BiCl_3$ (1 g) in dimethylformamide (30 mL); after ca. 1 min the dark precipitate was filtered off. On storing the dark reddish-brown filtrate in a sealed vessel at 20-25 °C, dark brown crystals (brownish-red streak) of **1** precipitated within 1-2 d; these were filtered off and washed several times with H_2O, isopropyl alcohol, toluene, and diethyl ether. (The PPh_4^+ salt can be prepared analogously.) Yield: 0.56 g (ca. 60%).

[4] IR (solid, CsI pellet; weak bands of the PPh_4^+ salt, since the bands of the $AsPh_4^+$ ion partly mask the relevant region for the anion of **1**): 500, 465, 456, 448 cm^{-1} (ν(S-S)); Raman (solid; $\lambda_e = 647.1$ nm; bands below 500 cm^{-1} with medium to strong intensity): 449, 450 (ν(S-S)), 277, 264, 234, 186 cm^{-1}.

[5] **1** crystallizes in the triclinic system; $P\bar{1}$, $a = 1423.1(7)$, $b = 1816.3(8)$, $c = 2393.5(11)$ pm, $\alpha = 72.45(3)$, $\beta = 80.71(4)$, $\gamma = 86.15(4)°$, $V = 5820.2 \times 10^6$ pm^3, $Z = 2$, $\rho_{calc} = 1.74$ g cm^{-3}. Empirical absorption correction. Solution of structure by heavy atom methods; $R_w = (\sum w(|F_0| - |F_c|)^2 / \sum w|F_0|^2)^{1/2} = 0.108$ ($w = \sigma^{-2}(F_0)$), $R = 0.149$ for 4300 independent reflections ($F_0 > 3.92\sigma(F_0)$); Syntex $P2_1$ diffractometer; $Mo_{K\alpha}$ radiation. The anion of **1** is statistically distributed over two sites in the ratio 0.9:0.1 (structure of the main component in Fig. 1). This disorder could be resolved quite well for the Bi atoms, but not for the S atoms (limited data set due to small size of crystal). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, 7514-Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51670, the names of the authors, and the full citation of the journal.

Asymmetric Double-Bond Isomerization of 4,7-Dihydro- to 4,5-Dihydro-1,3-dioxepins

By *Herbert Frauenrath** and *Thomas Philipps*

Allyl alcohols and allyl ethers can be converted by transition metal-catalyzed double-bond isomerization into aldehydes and enol ethers, respectively.[1] Recently, the isomerization of prochiral substrates with chiral catalysts has also been investigated in connection with studies on asymmetric syntheses,[2] but so far only the isomerization of allylamines to enamines has been successfully achieved.[3]

We report here on the hitherto uninvestigated asymmetric double-bond isomerizations of prochiral 4,7-dihydro-1,3-dioxepins **1**, which, in contrast to the above mentioned educts, do not contain a center of prochirality at the double bond, but have a prochiral acetal C-atom at the 2-position of the seven-membered heterocycle. Such isomerizations of **1** lead to optically active 4,5-dihydro-1,3-dioxepins **2**, which are suitable precursors, e. g., for the synthesis of 2,3-substituted tetrahydrofurans or 3,4-substituted 4-butanolides.[4]

For the asymmetric isomerization of **1**, we used $Ru_2Cl_4(diop)_3$[5] and $[Rh(cod)Cl]_2$/diop,[6] which we converted with $NaBH_4$ in CH_3OH/THF in situ into the catalytically active hydridic species (Table 1).

1 **2** **3**

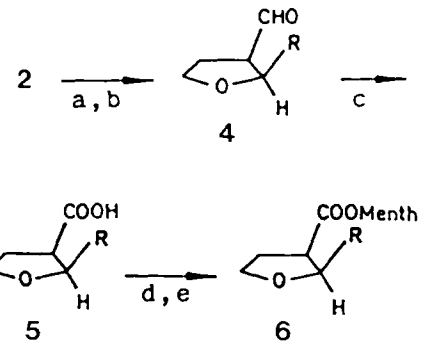

Table 1. Asymmetric isomerization of the dioxepins **1** [a]. **a**, R = *n*-C_4H_9; **b**, R = CH_2-CH_2-Cl; **c**, R = CH_2CH_2-CN. diop = *P,P'*-(2,2-dimethyl-1,3-dioxolanediyldimethylene)bis(diphenylphosphane); cod = 1,5-cyclooctadiene; THF = tetrahydrofuran.

Catalyst	1	2			3
		Conversion [%] [b]	Yield [%] [c]	*ee* [%] [d]	Yield [%] [c]
$Ru_2Cl_4(diop)_3$	**a**	97	91	13	4
	b	95	83	9	5
	c	93	84	25	5
$[Rh(cod)Cl]_2$/diop (1:2)	**a**	100	61	3	32
$[Rh(cod)Cl]_2$/diop (1:4)	**a**	95	91	12	2
	b	99	88	12	7
	c	92	80	23	6

[a] 0.5 mmol of catalyst in 40 mL THF/20 ml CH_3OH, then 0.5 g of $NaBH_4$, 0.1 mol of **1**, 24 h, room temperature, N_2. Catalyst deactivation by bubbling with air. Work-up by distillation. Catalysts were used with (+)- or (−)-diop. [b] Determined gas-chromatographically. [c] After distillation. [d] Reproducibility ±2%.

Almost complete conversions were achieved at room temperature with catalyst concentrations of 0.5 mol-%. Hydrogenation to the 1,3-dioxepanes **3** was generally only of a secondary nature. The highest enantiomeric excess (*ee* 25%) was observed with $Ru_2Cl_4(diop)_3$ as catalyst for **1c**.[7] The *ee* values depend on the substituents R (Table 1).

For the determination of the enantiomeric excess, the products **2** were first transformed into the 2-substituted *cis*-tetrahydrofuran-3-carbaldehydes **4**[8] and then converted via **5** into the menthyl esters **6**[9] (see Scheme 1), whose diastereomeric excesses were determined gas-chromatographically.[10]

Scheme 1. a) $BF_3 \cdot Et_2O$, −30 °C, in CH_2Cl_2, $HC(OCH_3)_3$. b) $H_2O/H^{\oplus}$ in THF. c) CrO_3/H_2SO_4 in acetone/water. d) $SOCl_2$. e) Menthol/pyridine in ether.

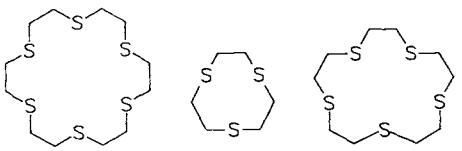
Palladium(II) and Platinum(II) Complexes of 1,4,7,10,13,16-Hexathiacyclooctadecane**

By *Alexander J. Blake, Robert O. Gould, Aidan J. Lavery,* and *Martin Schröder**



Although the coordination chemistry of first row transition metal ions with macrocyclic ligands has been an area

[*] Dr. A. J. Blake, Dr. R. O. Gould, Dr. A. J. Lavery, Dr. M. Schröder
Department of Chemistry, University of Edinburgh
West Mains Road, Edinburgh EH9 3JJ (Scotland)

[**] This work was supported by the Science and Engineering Research Council (UK) (to *A. J. L.*). Generous loans of platinum from Johnson-Matthey PLC are gratefully acknowledged.

of extensive research over the past twenty years,[1] by comparison the corresponding complexation of second and third row metals to non-porphyrinoid macrocycles remains an area to be fully developed. As part of a general study on the synthesis of platinum group metal complexes of macrocyclic ligands, we have investigated the complexation of d^8 metal ions with the polythia ligands **1** and **2**.

Whereas oxygen donor polyether crown ligands and related ionophores are known to bind, sometimes highly selectively, Group I and II metal ions, the corresponding polythia ligands appear to bind transition metal ions more effectively. Homoleptic octahedral complexes of the type $[M(\mathbf{1})]^{2\oplus}$ ($M=Co^{II}$, Ni^{II}),[2] $[M(\mathbf{2})_2]^{2\oplus}$ ($M=Co^{II}$, Ni^{II}, Cu^{II}),[3] and the tetrahedral and trigonal bipyramidal species $[Cu(\mathbf{3})]^{\oplus}$ and $[Cu(\mathbf{3})]^{2\oplus}$[4] have been described. More recently, we have synthesized the binuclear dicopper(I) adduct $[Cu_2(\mathbf{1})(NCCH_3)_2]^{2\oplus}$[5] in which **1** is coordinated fa-

1 2 3

cially via three sulfur donor atoms to each tetrahedral copper(I) unit. In connection with our studies aimed at further developing new coordination modes for the potentially hexadentate ligand **1**, we report here the synthesis and single crystal X-ray structures of the square planar complexes $[M(\mathbf{1})]^{2\oplus}$ ($M=Pd^{II}$, Pt^{II}), the first examples of platinum group metal complexation to **1**, and one of the few thiaether macrocyclic coordinations to Pd^{II} or Pt^{II}.[1,6,7]

1,4,7,10,13,16-Hexathiacyclooctadecane **1** (hexathia[18]-crown-6), isolated from the preparation of **2**,[3,8] was refluxed with one molar equivalent of $PdCl_2$ or $PtCl_2$ in $CH_2Cl_2:CH_3CN$ (1:3 v/v) for 4 h to give a yellow solution. The reaction mixture was filtered, and on addition of $NaBPh_4$ yellow-brown crystals of $[M(\mathbf{1})][BPh_4]_2$ were deposited in up to 70% yield. The single crystal X-ray structures of these complexes were undertaken[9] to confirm their connectivities and stereochemistries.

The conformation of the macrocycle in the isomorphous $[Pd(\mathbf{1})]^{2\oplus}$ and $[Pt(\mathbf{1})]^{2\oplus}$ cations (Fig. 1) is an S-shaped dou-

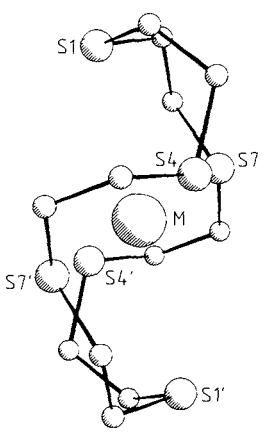


Fig. 1. Structure of the cation $[M(\mathbf{1})]^{2\oplus}$ in the $[M(\mathbf{1})][BPh_4]_2$ crystal, M = Pd or Pt. Most important angles [°]: M = Pd: S1-Pd-S4 75.06(5), S1-Pd-S7 103.88(5), S4-Pd-S7 86.24(5); M = Pt: S1-Pt-S4 74.16(8), S1-Pt-S7 104.78(8), S4-Pt-S7 86.76(9).

ble boat wherein the M^{II} ion at the molecular inversion center is coordinated to the four sulfur donor atoms S4, S7, S4′, and S7′ in a square planar arrangement with Pd-S = 2.3114(14), 2.3067(15) Å and Pt-S = 2.2980(25), 2.2948(24) Å reflecting the difference in ionic radii between Pd^{II} and Pt^{II}.[7,10] The two remaining sulfur donors, S1 and S1′, participate in weak interactions with the central M^{II} ion, characterized by particularly long Pd-S [3.2730(17) Å] and Pt-S [3.380(3) Å] distances. Interestingly, the S-M-S angles in these complexes deviate substantially from 90°; this contrasts with the values observed for the essentially octahedral Ni^{II} and Co^{II} complexes of **1**, which show angles of close to 90° around the metal center.[2]

These results confirm the possibility of square planar stereochemistry being adopted by the coordinatively ambivalent hexathia macrocycle **1** on binding to a large, stereochemically constrained d^8 metal ion and suggest that binding of **2** to such metal ions might yield complexes of the type $[M(\mathbf{2})_2]^{2\oplus}$ ($M=Pd^{II}$, Pt^{II}) and $[M(\mathbf{2})_2]^{\oplus}$ ($M=Rh^{I}$, Ir^{I}) with square planar stereochemistries and weak M-S axial interactions.[11]

[8] Syntheses of **2** [3] and **1**: A solution of *bis*-(2-mercaptoethyl) sulfide (17.5 g, 0.114 mol), benzyltrimethylammonium methoxide (40% solution in methanol, 200 mL) (from Aldrich Chemical Co.) in methanol (250 mL), and a solution of 1,2-dichloroethane (11.3 g, 0.114 mol) in methanol (450 mL) were added simultaneously from two dropping funnels over a period of 4 h to stirred refluxing methanol (300 mL) under N_2. After addition of the reactants, the reaction mixture was refluxed for a further 1 h, allowed to cool, and the precipitated benzyltrimethylammonium chloride was filtered off and washed with methanol. The methanol filtrate and methanol washings were combined and the solvent removed in a vacuum. The residue was extracted with diethyl ether (3 × 100 mL) and the ether solution of **2** reduced to dryness. The crude product was purified by column chromatography on silica gel (60-120 mesh) eluting with hexane:ethyl acetate (9:1 v/v) and **2** recrystallized from dichloromethane:ethanol (4:1 v/v). Typical yield: 1.0 g (2.4%); m.p. 84°C.—The 2 + 2 condensation product **1** was isolated by extracting the residue left after extraction with diethyl ether as described above with hot dichloromethane (3 × 200 mL). The dichloromethane was removed in a vacuum and the product recrystallized from dichloromethane:diethyl ether (4:1 v/v) to give **1**. Yield: 6.5 g (32%); MS: *m/z* 360 ($M^{\oplus}$), ^{1}H-NMR ($CDCl_3$, 80 MHz): $\delta = 2.81$ (s, CH_2); IR (KBr): $\tilde{\nu} = 2900$, 1415, 1298, 1192, 1145, 840, 712, 681, 659, 660 cm^{-1}.

[9] $[Pd(\mathbf{1})][BPh_4]_2$, monoclinic, $P2_1/c$: $a = 12.913(4)$, $b = 12.092(4)$, $c = 17.436(7)$ Å, $\beta = 108.496(22)°$; $V = 2582$ Å^3, $\rho_{calcd} = 1.422$ g·cm^{-3}, $Z = 2$; 4598 data measured to $\theta = 25°$, refinement based on 3602 data with $F \geq 3.0\sigma(F)$. At convergence R, $R_w = 0.0541$, 0.0567 respectively for 158 parameters; $[Pt(\mathbf{1})][BPh_4]_2$, monoclinic, $P2_1/c$, $a = 12.982(9)$, $b = 12.063(8)$, $c = 17.487(15)$, $\beta = 108.46(5)°$; $V = 2598$ Å^3, $\rho_{calcd} = 1.527$ g·cm^{-3}, $Z = 2$; 3306 data measured to $\theta = 22°$, refinement based on 2340 data with $F \geq 2.5\sigma(F)$. At convergence, R, $R_w = 0.0395$, 0.0429 respectively for 158 parameters.—In the case of $[Pt(\mathbf{1})][BPh_4]_2$, intensity statistics showed that reflections with $k + l = 2n$ were strong relative to those

with $k+l=2n+1$, giving the location of the metal atom on a special position. The structure solution was completed using the DIRDIF system [12]. By virtue of the isostructuralism of the two complexes it was possible to take the final coordinates from the converged Pt structure as starting values for the refinement of the Pd structure. For refinement [13] hydrogen atoms were included in fixed, calculated positions; at convergence, the difference electron density map showed no feature above 1.25 and 1.07 eÅ^{-3} for M = Pd[II], Pt[II] respectively. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW. Any request should be accompanied by the full literature citation for this communication.

Ethylene Oxide—X-Ray Structure Analysis (at 150 K) and ab initio Calculations**

By *Peter Luger,* Chakib Zaki, Jürgen Buschmann,* and *Rainer Rudert*

Dedicated to Professor George A. Jeffrey on the occasion of his 70th birthday

In a series of studies on the structure of small, unsubstituted cyclic ethers we have so far determined the crystal structures of tetrahydrofuran,[1] oxetane,[2] and dioxane.[3] We have now been able to prepare crystals of ethylene oxide (oxirane). Its crystal structure and accompanying ab initio calculations are reported herein. Apart from in a conference report on the structure of cyclopropane,[4] no results of an X-ray structure analysis of a nonsubstituted three-membered ring have so far been published. In the works of *Jeffrey* et al.[5,6] on ethylene oxide hydrate the three-membered ring was treated with rigid geometry.

The ethylene oxide, which is gaseous at room temperature (m.p. 161 K, b.p. 284 K), was crystallized in situ on a Stoe four-circle diffractometer by a method described in Refs. [1,2], and the intensity measurements were carried out at 150 K.[7] After convergence of the refinement, a difference Fourier synthesis showed a residual electron-density maximum in the ring plane outside of the ring and equidistant from the two C atoms (distance to the C-C bond 70 pm), pointing to the existence of bent bonds in the three-membered ring.

In the crystal, the ethylene oxide molecule is, within the estimated standard deviations, practically an equilateral triangle (Fig. 1, top). The C-O bond (mean value 143.1 pm) has about the same length as in the other cyclic ethers; only in oxetane is it longer (146.0 pm). The C-C bond length is shorter than that found for ethylene oxide by other methods. It is also shorter than that found for a number of derivatives by other methods[11] (Table 1).

Table 1. Bond lengths [pm] in ethylene oxide determined by various methods.

[a] "Rigid body" correction [14–16] with the temperature parameters of all atoms. The results of this correction should be regarded with some care, since only isotropic temperature factors are available for the hydrogen atoms. [b] Average values from twelve X-ray and neutron diffraction studies on ethylene oxide derivatives carried out after 1975 (source: Cambridge Data File [11]).

A complete optimization of the geometry by ab initio calculations[12] was carried out at the MP2/6-31G* level, and the results were compared with those of earlier calculations (Table 1). Compared to the results of the X-ray structure analysis, which indicated that all bonds in the ring are almost of the same length, the MP2/6-31G* calculations gave the same C-O bond lengths, but a longer C-C bond length.

In the crystal lattice of ethylene oxide (Fig. 1), two intermolecular C-H···O contacts fall within the van-der-Waals distance (van-der-Waals radii of 152 pm for O and

Synthesis of *N*-(1-Carboxy-5-aminopentyl)dipeptides as Inhibitors of Angiotensin Converting Enzyme**

By *Rüdiger Escher* and *Peter Bünning**

N-Carboxymethyldipeptides have gained great importance in recent years as inhibitors of angiotensin converting enzyme (ACE) in the treatment of hypertension and conjestive heart failure.[1] In the form of *N*-(1-carboxy-5-aminopentyl)dipeptides, these inhibitors are, moreover, valuable tools for biochemical studies on ACE; owing to their functional ε-amino group they are suitable, after coupling to a gel matrix, as ligands for an affinity chromatography of the enzyme. The following synthetic routes provide access to these *N*-substituted dipeptides: reductive amination of α-keto acids or reaction of primary amines with α-bromo-, α-methanesulfonyloxy-, or α-trifluoromethanesulfonyloxy-carboxylic esters **2**. However, only the reaction of esters **2** with amino acid derivatives furnish *N*-substituted α-aminocarboxylates **3** in high yield via Walden inversion.[2] In this way, a series of *N*-(1-carboxy-5-aminopentyl)glycyl- and *N*-(1-carboxy-5-aminopentyl)alanyl-amino acids, **6a** and **6b** respectively, were synthesized.

Scheme 1. Synthesis of *N*-(1-carboxy-5-aminopentyl)dipeptides **6**. Bzl = benzyl, Boc = butoxycarbonyl. **a**, $R^1=H$; **b**, $R^1=CH_3$.

The synthesis of the *N*-(1-carboxy-5-aminopentyl)dipeptides **6** is outlined in Scheme 1. For the synthesis of the glycyl derivatives **6a** and the L-alanyl derivatives **6b**, benzyl glycolate **1a** and benzyl D-lactate **1b** were allowed to react with trifluoromethanesulfonic acid anhydride/pyridine to give **2a** and **2b**, respectively. The low stability of the ester **2a** necessitated careful reaction with two equivalents of N^{ε}-Boc-L-lysine methyl ester, whereupon one equivalent served as base for buffering of the liberated trifluoromethanesulfonic acid. In contrast, for the reaction of the ester **2b**, equimolar amounts of N^{ε}-Boc-L-lysine methyl ester could be employed, with triethylamine as base. The benzyl group was removed from the products **3** by catalytic hydrogenation; subsequent condensation of **4** with amino acid esters by the propylphosphonic anhydride method[3] furnished the protected dipeptide derivatives **5**. Hydrolysis of the esters with sodium hydroxide and cleavage of the Boc group with trifluoroacetic acid then afforded the active ACE inhibitors **6** (Table 1).

Investigation of the inhibition of ACE by the compounds **6** showed that the IC_{50} values vary over a range from 5500 nmol/L for the weakest inhibitor, $\mathbf{6a_1}$, to 10 nmol/l for the strongest inhibitor, *N*-(1-carboxy-5-aminopentyl)-L-alanyl-L-alanine, $\mathbf{6b_2}$ (Table 1).

The inhibitors were coupled to a Sepharose 6B matrix (Pharmacia, Freiburg) according to the carbodiimide method[5] via a spacer, which was synthesized from 1,4-bis

CH_3	Bzl	C_2H_5	**6b**$_4$	57	12

[a] Yield of **5** referred to **1**: The step **5**→**6** proceeds with ca. 70% yield. [b] Concentration of **6** at which half maximal inhibition of ACE from rabbit lungs occurs under standard assay conditions [4] (enzyme concentration: 2 nmol/L).

(2,3-epoxypropoxy)butane and 6-(4-aminobenzamido)hexanoic acid.[6] The compounds **6a**$_2$, **6a**$_3$, **6a**$_4$, and **6b**$_1$ are suitable as ligands for affinity chromatography of ACE. The highest yields of enzyme are achieved with **6a**$_2$ and **6b**$_1$; in contrast **6a**$_1$ gives only a very slight binding of the enzyme to the affinity resin, whereas the enzyme is tightly but almost irreversibly bound by the ligands **6b**$_2$ to **6b**$_4$.

The synthesis described here affords *N*-(1-carboxy-5-aminopentyl)dipeptides **6** in high yields. They exhibit a broad spectrum of inhibition towards ACE, and are valuable tools for biochemical studies of this enzyme.

Experimental

1a: A mixture of glycolic acid (7.60 g, 100 mmol) and triethylamine (10.10 g, 100 mmol) in ethyl acetate (50 mL) was treated with 11.50 g (90 mmol) of benzyl chloride.[7] After 6 hours' boiling, the mixture was filtered and the filtrate worked up by distillation. Yield: 6.72 g (45%) **1a**, b.p. 136 °C/14 torr.

2a: A stirred mixture of **1a** (1.66 g, 10 mmol) and pyridine (0.89 mL, 11 mmol) in CH_2Cl_2 (40 mL) was treated dropwise for 20 min at −12 °C with 1.84 mL (11 mmol) of trifluoromethanesulfonic acid anhydride. Column chromatography on silica gel at 4 °C with CH_2Cl_2 and subsequent evaporation of the eluate to dryness afforded 2.24 g of **2a** (75%).

3a: A stirred solution of **2a** (2.24 g, 7.5 mmol) in CH_2Cl_2 (30 mL) was treated with 3.90 g (15 mmol) of H-Lys(Boc)-OMe at −15 °C. After one hours' stirring, the reaction solution was washed with water, dried over $MgSO_4$, evaporated down, and chromatographed on a silica gel column with ethyl actate/cyclohexane (1:1, v/v). Yield of **3a**: 2.75 g (90%).

4a: A solution of **3a** (2.45 g, 6 mmol) in 250 mL of methanol was hydrogenated with Pd/C (10%) for 4 h. After filtration and evaporation, **4a** crystallized at 4 °C. Yield: 1.62 g (85%).

5a$_2$: A mixture of **4a** (0.64 g, 2 mmol), Ala-OMe-HCl (0.84 g, 6 mmol), and triethylamine (2.51 mL, 18 mmol) in CH_2Cl_2 (60 mL) was treated dropwise at −12 °C with 1.4 mL of a dichloromethane solution containing 50 wt-% propylphosphonic anhydride. After 4 hours' stirring at room temperature, the mixture was washed with ice-water, then with saturated KH_2PO_4 solution (pH 4.5), and finally with saturated NaCl solution; after drying over $MgSO_4$, 0.7 g (86%) of oily **5a**$_2$ was obtained.

6a$_2$: A solution of **5a**$_2$ (0.40 g, 1 mmol) in acetone (3 mL) was treated with 2.0 mL of 0.5 M NaOH and the mixture shaken for 8 h; after addition of a further 2.0 mL of 0.5 M NaOH, the mixture was shaken for a further 24 h. After neutralization with trifluoroacetic acid, the organic phase was evaporated in vacuo and then chromatographed on a silica gel column with ethyl acetate. Subsequent elution with methanol and renewed evaporation afforded the Boc-protected compound. This was suspended in 80 µL of water, treated dropwise at 0 °C with 770 µL (10 mmol) of trifluoroacetic acid, and stirred for 3 h at 23 °C. Evaporation to dryness and subsequent exchange of the trifluoroacetate by acetate on Amberlite IRA 93 (Serva, Heidelberg) followed by lyophilization afforded **6a**$_2$ as the hydroacetate.

Thin Layer Chromatographic Separation of Stereoisomeric Dipeptides

By *Kurt Günther*,* *Jürgen Martens*, and *Maren Schickedanz*

We have recently developed a method for the *direct* enantiomeric resolution of D,L-amino acids by ligand exchange on thin-layer chromatographic plates.[1-4] Our strategy not only constitutes a simple and rapid analytical method[5] but also enables the determination of trace amounts of each of the enantiomers.[3,4] The requisite chromatographic plates are now commercially available.[6]

The thin-layer chromatographic separation of diastereomeric dipeptides has already been well documented,[7,8] but the separation of enantiomeric dipeptides by thin-layer chromatography has, to our knowledge, never been reported.

As long ago as 1979, *Lindner* et al.[9] reported the HPLC separation of enantiomeric dipeptides after dansylation. For the gas-chromatographic determination of amino-acid enantiomers in proteins and peptides these must be previously cleaved under acid conditions.[10] Stereoisomeric dipeptides can also be separated by gas-chromatography, but this requires previous esterification and perfluoroacylation of the sample.[11] A direct separation of the enantiomers by gas chromatography is of course impossible in the case of dipeptides. Experience has shown that there is always the danger of racemization taking place, both during the derivatization as well as upon hydrolysis. Consequently, a *direct* analytical method as described in this communication is much to be preferred over these methods.

It has now been possible for the first time to accomplish the *direct* separation of enantiomeric and diastereomeric dipeptides. In this new approach a derivatization is unnecessary. Figure 1 shows a typical example of a separation of enantiomeric dipeptides on Chiralplate®.[6]

In the enantiomeric separations (Table 1, top) it emerges that the antipodes with *C*-terminal L-configuration always

L-Ala-D-Ala	0.70	
L-Ala-L-Phe	0.59	B
L-Ala-D-Phe	0.65	
L-Met-L-Met	0.62	B
L-Met-D-Met	0.71	

[a] Length of run 13 cm. [b] A: methanol/water/acetonitrile = 5/5/20 (v/v/v); B: methanol/water/acetonitrile = 5/5/3 (v/v/v).

Diastereomeric dipeptides can of course also be separated by the method described here. A few selected examples from a host of such separations that have already been accomplished are listed in Table 1 (bottom).

Procedure

In each run a 1% solution of the mixture of stereoisomeric dipeptides (2 μL) to be separated was applied to a commercially available Chiralplate®[6] and then developed (30–90 min) with the eluents mentioned in Table 1. After drying, the spots were made visible by spraying with 0.1% ninhydrin reagent. As can be seen in Figure 1 it should also be possible to determine trace amounts of the antipodes.

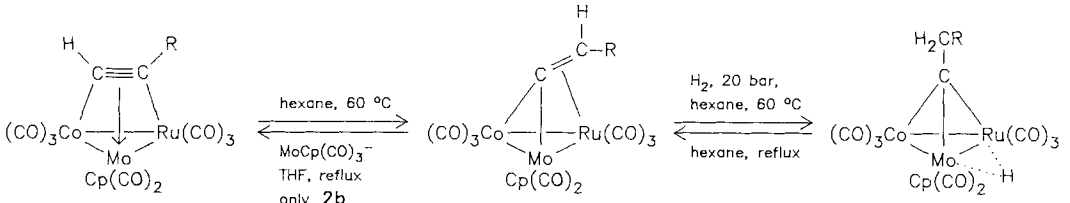
Reversible Interconversion of C–C and C–N Multiple Bond Systems on Clusters**

By *Wolfgang Bernhardt, Christine von Schnering,* and *Heinrich Vahrenkamp**



Redox transformations of unsaturated organic systems as well as C–C bond forming reactions in the coordination sphere of clusters are appropriate objectives in order to investigate the cluster-surface analogy.[1] Accordingly, hydrogenation and dehydrogenation reactions of cluster-bound C–C and C–N multiple bond systems have been well studied,[2] and examples are known for each step of the reaction sequence $C{\equiv}C \rightleftarrows C{=}C \rightleftarrows C{-}C$ or $C{\equiv}N \rightleftarrows C{=}N \rightleftarrows C{-}N$. In special cases, it has been possible to realize the entire sequence in one direction for a compound or to demonstrate the reversibility of specific steps.[2,3] However, compounds have not yet been found for which the entire sequence can be realized in both directions. We have now been able to carry out reversible transformations of cluster-bound multiple bond systems for both the C–C and the C–N systems.

The reversible acetylene–vinylidene–alkylidyne transformation was achieved on a RuCoMo framework. The acetylene-bridged clusters **1** are formed from the clusters $[RuCo_2(CO)_9(HC{=}CR)]$ (R = H, *t*Bu)[4] by metal exchange with $Na[MoCp(CO)_3]$ (Cp = cyclopentadienyl) in tetrahydrofuran (THF). When the clusters **1** are heated in hexane to 60 °C, they are transformed, as expected, into the vinylidene-bridged clusters **2**. Complex **2a** can then be con-

[**] This work was supported by the Fonds der Chemischen Industrie and by Heraeus.

verted into **3a** by treatment with hydrogen (20 bar) in hexane at 60 °C.[5] The reverse reaction, **3a** → **2a**, takes place in refluxing hexane in the absence of hydrogen; no example was known for such a spontaneous alkylidyne-vinylidene transformation. All these reactions proceed nearly quantitatively. Completion of the reverse sequence was achieved by metal exchange of $[RuCo_2(CO)_9(C{=}CHtBu)]$[4] with $Na[MoCp(CO)_3]$, which afforded in low yield the expected **2b** along with the isomerized product **1b**.

a, R = H; b, R = *t*Bu

The reversible imide-amide-nitrene transformation was achieved with the previously described compounds **4**, **5**, and **6**.[6] While the transformation **4** → **5** → **6** occurs upon heating under hydrogen at normal pressure,[6a] **6** is converted back into **5** in 77% yield upon refluxing in ligroin (135 °C) under CO at normal pressure. The thermal dehydrogenation of **5** to give **4** likewise occurs in boiling ligroin, albeit only as a side reaction, the main reaction being

the decarbonylation to give **6**; both decarbonylation and dehydrogenation are inhibited by CO. As in the analogous Fe_3 system,[3] the further dehydrogenation of **4** to the unknown $[Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}PhC{\equiv}N)]$ was not observed.

The reaction sequences **1** ⇄ **2** ⇄ **3** and **4** ⇄ **5** ⇄ **6** confirm that the interconversion of organic ligands on M_3 clusters may be controlled by the composition of the clusters (cf. the C-C system on the Os_3 or $RuCo_2$ unit[2,4] and the C-N system on the Fe_3 or Os_3 unit[3]). The present state of knowledge of preparative organometallic chemistry allows a wide range of directed cluster syntheses. The next challenge is to formulate and to systematize the relationship between M_3 unit and the direction of ligand transformation. A further goal is to find methods to release the transformed C-C or C-N substrate and to recover the starting cluster, which has so far been achieved only under special conditions.[7]

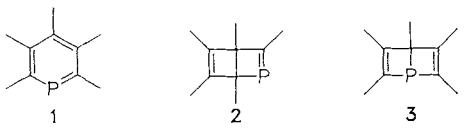
2-Dewar Phosphinines—a New Class of Compounds Containing Two-Coordinate Phosphorus**

By *Jürgen Fink, Wolfgang Rösch, Uwe-Josef Vogelbacher,* and *Manfred Regitz**



Dedicated to Professor Rolf Appel on the occasion of his 65th birthday

Phosphinines **1** have long been known and their reactivity has been studied in great detail.[1] However, their bicyclic isomers, the 2- and 1-phosphabicyclo[2.2.0]hexadienes (2- and 1-Dewar phosphinines) **2** and **3**, respectively, were, to the best of our knowledge, unknown.

We obtained **6** and **7**, the first compounds of type **2**, by reaction of the kinetically stabilized cyclobutadienes **4a**[2]

1 2 3

and **4b**[3] with the phosphaalkynes **5a–e**.[4] For steric reasons, the cycloaddition takes place at C-1 and C-4 and occurs in such a way that, in the product, the ester substituent and the substituent R^2 of the phosphaalkyne are preferentially or exclusively in neighboring positions (quantitative yields; **6** ≥ 85%, **7** ≤ 15%). It is understandable that the reactions with **4a** proceed more selectively than those with **4b**. Compounds **6a–d** are obtained from the mixture of Dewar phosphinines **6/7** by crystallization from pentane or petroleum ether (30–75°C) in isomerically pure form (Table 1). Surprising is the stability of the phosphabicycles toward atmospheric oxygen (a single crystal of **6d** is still intact after several weeks) as well as their thermal stability (the mixture **6g/7g** can be distilled at 220°C without decomposition). The aromatization observed in the case of the nitrogen analogues (**6**, N instead of P)[5] can therefore not be achieved by heating.

Decisive for the determination of the constitution of the Dewar phosphinines **6a–h** are the ^{31}P-NMR signals (δ = 312–317) and the ^{13}C-NMR signals of C-3 (δ = 223.6–242.1; $^1J_{P,C}$ = 31.7–36.5 Hz), the low-field position being typical for the phosphaalkene moiety.[6] The existence of regioisomers **7a–c** and **7e–h** is indicated by their phosphorus signals, which are shifted to high field relative to those

of **6** (δ = 285–300); these signals were used for quantitative analysis of the products. The small difference in the chemical shifts of C-5 and C-6 (Table 1) reveals—as mentioned above—the reaction centers of the cycloaddition.[7]

The X-ray structure analysis of **6d**[8] confirms the conclusions made on the basis of NMR spectroscopy (Fig. 1). The two four-membered-ring moieties are planar within threefold standard deviation and the dihedral angle is 113°.

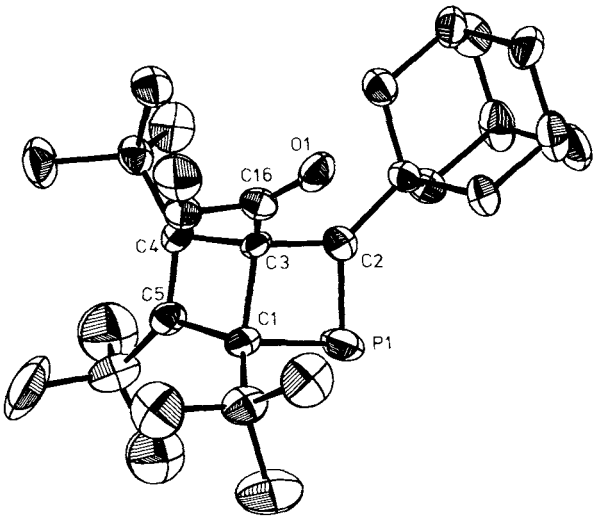

Fig. 1. ORTEP plot of one of the two independent molecules of **6d** [9]; the hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and bond angles [°]: P1-C1 1.89(1), P1-C2 1.68(1), C1-C3 1.59(1), C1-C5 1.53(1), C2-C3 1.54(1), C3-C4 1.54(1), C4-C5 1.35(1); C1-P1-C2 79.5(4), P1-C1-C3 88.2(5), C3-C1-C5 85.3(6), P1-C2-C3 98.3(6), C1-C3-C2 93.9(6), C1-C3-C4 85.8(6), C3-C4-C5 93.9(6), C1-C5-C4 95.0(7).

Experimental Procedure

6c: A solution of **5c** (400 mg, 4 mmol) [4] in 1 mL of pentane (dry) was added to a solution of **4a** (835 mg, 3 mmol) [2] in 10 mL of pentane (dry) under argon at −78°C. The mixture was allowed to thaw after 1 h (decolorization). Evaporation afforded 1.14 g (100%) of a pale yellow, oily mixture of the isomers **6c** and **7c** (96 : 4 by ^{31}P-NMR spectroscopy), which, after kugelrohr

Hydroxyacetylene: Generation and Characterization of the Neutral Molecule, Radical Cation and Dication in the Gas Phase**

By *Ben van Baar, Thomas Weiske, Johan K. Terlouw,* and *Helmut Schwarz**

Dedicated to Professor David Ginsburg on the occasion of his 65th birthday

Neutral C_2H_2O isomers[1a] as well as their singly[1b] and doubly charged[1c] analogues have recently been examined by "state of the art" ab initio MO calculations. Apart from the well known ketene, **1**, these calculations also predict the isomers hydroxyacetylene (ethynol) **2**, the carbene oxiranylidene **3**, and oxirene **4** to be potentially observable stable species in the gas phase. However, because of the very low barrier predicted for the isomerization **4** → **1** it is highly improbable that **4** will ever be generated as a stable species.[2] For the systems $C_2H_2O^{\oplus\odot}$ and $C_2H_2O^{2\oplus}$ it is predicted[1b,c] that, apart from **1a** and **1b**, **2a** and **2b** should also be stable. We report here the generation and characterization of **2**, **2a**, and **2b** as stable species in the gas phase.

The use of tandem mass spectrometers[3] enables not only monocations to be structurally characterized under solvent-free conditions,[4] but also dications to be prepared

from monocations by the technique of "charge stripping mass spectrometry"[5]

$$m^{\oplus} + N \longrightarrow m^{2\oplus} + N + e^{\ominus}$$

and monocations to be neutralized by reaction with metal vapors or inert gases such as xenon.[6]

$$m^{\ominus} + Xe \longrightarrow m + Xe^{\oplus\odot}$$

Re-ionization of these neutral species by collision with helium (Neutralization Re-ionization Mass Spectrometry, NRMS[6]) allows them to be characterized on the basis of their ionic dissociation products.[7]

The radical cation $[HC{\equiv}COH]^{\oplus\odot}$ **2a** of hydroxyacetylene can be generated by decarbonylation of $[HC{\equiv}C{-}COOH]^{\oplus\odot}$ (70 eV electron impact ionization). The collisional activation (CA) spectrum of **2a** (Fig. 1B) is completely different from that of **1a** (Fig. 1A); thus, **2a** and **1a** do not isomerize within the mass spectrometric time scale ($t < 10^{-5}$ s). Further, the two spectra also show several peaks of structurally diagnostic value. In the case of **2a**, loss of HC (*m/z* 29) is much more pronounced than the formation of *m/z* 28 (loss of H_2C or HC + H), whereas in the case of **1a** the reverse holds true. Analogously, the CA spectrum of **1a** displays a peak for the loss of oxygen (*m/z* 26) which is almost absent in **2a**. The weak but readily recognizable peak at *m/z* 17 ($OH^{\oplus}$) in the spectrum of **2a** has its counterpart at *m/z* 16 in **1a**. Examination of $[HC{\equiv}C{-}OD]^{\oplus\odot}$, obtained by decarbonylation of $[HC{\equiv}C{-}CO_2D]^{\oplus\odot}$, confirms our analysis (Fig. 1C). The corresponding mass shifts (*m/z* 29 → *m/z* 30; *m/z* 17 → *m/z* 18; *m/z* 25 → *m/z* 25) are in agreement with the analysis of the spectrum of **2a**.

The heat of formation of **2a**, $\Delta H_f^0 \leq 247$ kcal/mol, was derived from the appearance energy (AE) for the loss of CO from metastable $[HC{\equiv}C{-}CO_2H]^{\oplus\odot}$ (using AE = 11.4 ± 0.2 eV, determined by the Burgers/Holmes method,[8] $\Delta H_f^0(CO) = -26.4$ kcal/mol[9], and $\Delta H_f^0(HC{\equiv}CCO_2H) = -42$ kcal/mol).[10] The ion **2a** is less stable than its isomer **1a** by 36 kcal/mol; theoretical calculations[1b] predict an energy difference of 45 kcal/mol.[11]

Further insight into the gas phase chemistry of **1a** and **2a** is provided by their unimolecular dissociations. Excited **1a** dissociates unimolecularly into $CH_2^{\oplus\odot}$ and CO with a release of translation energy (T_k) of $T_{0.5} = 2.0$ meV.[12,13] Assuming that the loss of $H^{\odot}$ from **2a** by direct cleavage

$$[HC{\equiv}C{-}OH]^{\oplus\odot} \longrightarrow H{-}\overset{\oplus}{C}{=}C{=}O + H^{\odot}$$
2a

has no barrier for the reverse reaction, this process is estimated to have an activation energy of 68 kcal/mol (from ΔH_f^0(**2a**) = 247 kcal/mol and ΔH_f^0 products: $H\overset{\oplus}{C}{=}C{=}O$

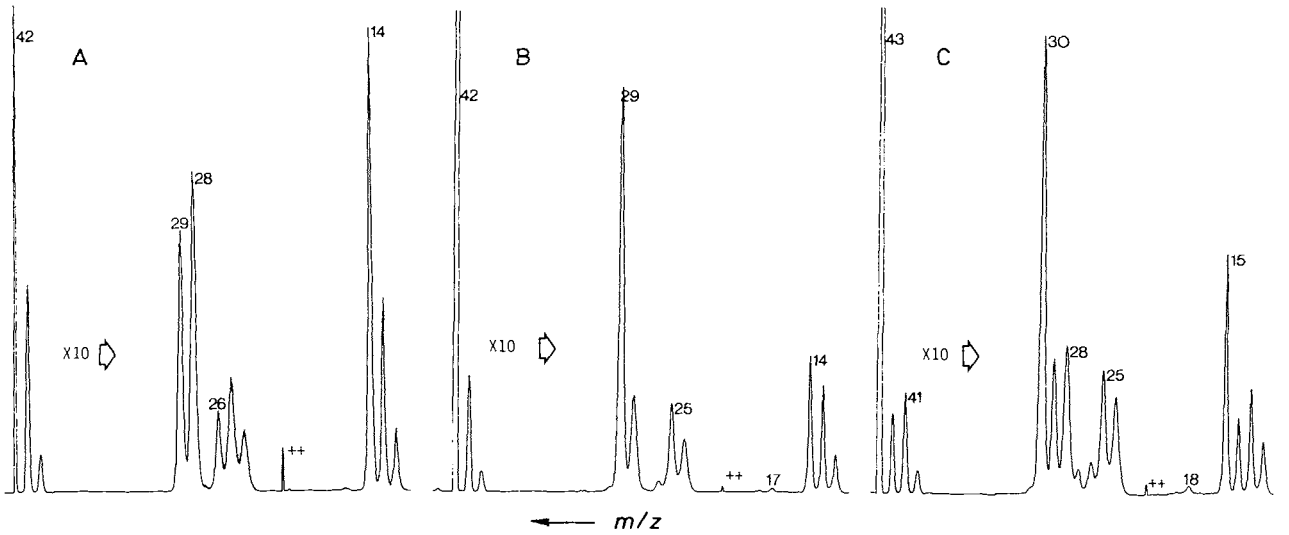

Fig. 1. Collision activation (CA) spectra of A) $[CH_2{=}C{=}O]^{\oplus\odot}$ **1a**, B) $[HC{\equiv}COH]^{\oplus\odot}$ **2a**, and C) $[HC{\equiv}COD]^{\oplus\odot}$.

$=263$ kcal/mol[6d] and $H^{\odot}=52$ kcal/mol[9]). Since theoretical calculations predict the isomerization **2a** → **1a** to require 79 kcal/mol, **2a** and its analogue $[HC{\equiv}C{-}OD]^{\oplus\odot}$ are expected to dissociate unimolecularly by loss of $H^{\odot}$ and $D^{\odot}$, respectively. The experimental finding that **2a** exclusively produces $CH_2^{\oplus\odot}$ by loss of CO, and the fact that the kinetic energy release in this reaction is much larger ($T_{0.5}=26$ meV) than that for the direct cleavage in **1a**, implies the following: 1) The dissociation **2a** → $CH_2^{\oplus\odot}$ only occurs from ions having internal energies in excess of that at the thermochemical threshold. 2) Prior to this reaction, **2a** isomerizes into energy-rich **1a**; this step seems to be rate-determining in the sequence **2a** → **1a** → $CH_2^{\oplus\odot}$, and from the thermochemical data for **2a**, $CH_2^{\oplus\odot}$, and CO a *minimum* value of 60 kcal/mol is readily derived for the isomerization barrier, E^0. 3) Isomerization of **2a**, via a barrier of $60<E^0<79$ kcal/mol, suppresses the direct loss of $H^{\odot}$ (or $D^{\odot}$ from $HC{\equiv}COD^{\oplus\odot}$) and thus this cleavage must involve a significant barrier.

Hydroxyacetylene H–C≡C–OH **2** is less stable than ketene **1** by 36 kcal/mol; the high barrier of 73 kcal/mol for the isomerization **2** → **1** indicates that once generated **2** should at least be stable in the gas phase. We have utilized a NRMS experiment to generate neutral **2** from the corresponding ion **2a** by neutralizing it with an electron donor. Thus, mass selected $HC{\equiv}COH^{\oplus\odot}$ ions were neutralized with xenon in a tandem collision cell[6d]; the ions not neutralized in the first cell were diverted by a deflector electrode and only the remaining beam of highly accelerated neutral molecules **2** was allowed to enter the second collision cell. Here, the neutral molecules were re-ionized by impact excitation with He to **2a** and the CA spectrum was recorded.

Figure 2 shows the NRMS spectra of **1a**, **2a**, and $[HC{\equiv}COD]^{\oplus\odot}$. Comparison of the structurally diagnostic features of the spectra leads to the conclusion that neutralization of $[HC{\equiv}COH]^{\oplus\odot}$ **2a** yields stable hydroxyacetylene **2**, which, under the conditions of the experiment, does not isomerize to the thermodynamically more stable ketene **1**.[14]

The dication [HC≡COH]$^{2\oplus}$ **2b** of hydroxyacetylene is, according to MP2/6-31G*//4-31G computations, ca. 59 kcal/mol less stable than **1b**.[1c] Dications **1b** are accessible by charge stripping from **1a**; the ionization energy (IE)

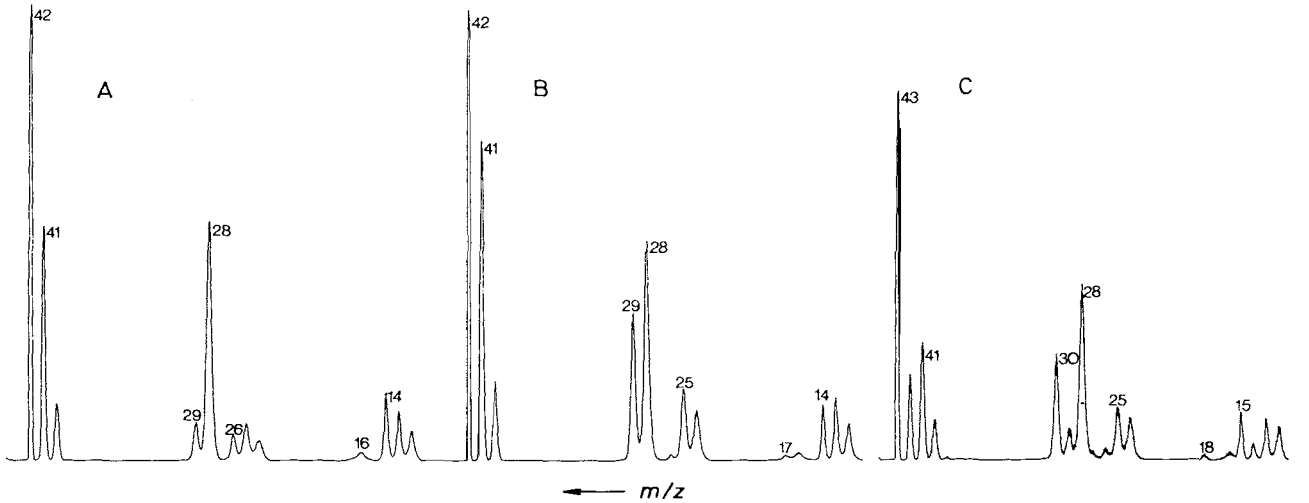

Fig. 2. NRMS of A) $[CH_2{=}C{=}O]^{\oplus\odot}$ **1a**. B) $[HC{\equiv}COH]^{\oplus\odot}$ **2a**, and C) $[HC{\equiv}COD]^{\oplus\odot}$.

for **1a** → **1b** + e$^{\ominus}$ is 18.6 eV.[1c] It already follows from the presence of the narrow signal at *m/z* 21 in Figure 1B that charge stripping of **2a** also yields a stable dication and preliminary measurements of the ionization energies for **2a** → **2b** + e$^{\ominus}$ give IE = 18–19 eV. Ab initio MO calculations (MP2/6-31G*//4-31G) yield a value of 18.6 eV for the adiabatic ionization of **2a**;[1c] the recently computed (MP3/6-31G*//6-31G*)[15] value for the vertical transition to the triplet ground state of **2b** is 18.5 eV.

Conclusion: The existence of keto/enol tautomeric pairs of neutral and singly or doubly charged species is now well established. The present work provides the first experimental evidence that the ynol of the most simple ketene/ynol tautomeric pair, hydroxyacetylene, exists as a stable neutral molecule **2**, radical cation **2a**, and dication **2b**, as predicted by theory.

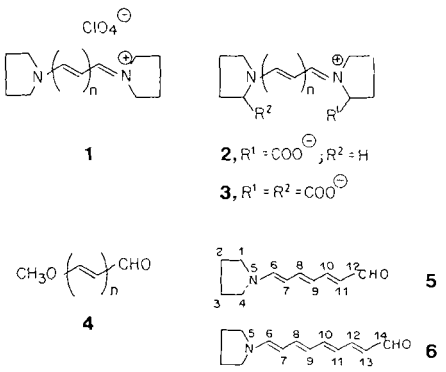
Influence of External Negative Charges on the Absorption Maxima of Symmetrical Cyanines. A Study with Model Compounds and Artificial Bacteriorhodopsin Pigments**



By *Mordechai Sheves** and *Noga Friedman*

Symmetrical cyanine dyes show narrow, red-shifted absorption maxima (relative to the corresponding protonated Schiff base) as a result of their highly delocalized π electrons. Perturbation that reduces the symmetry of a symmetrical cyanine should result in blue shifts and broadening of the electronic spectrum.

Bacteriorhodopsin (bR) is the protein pigment of the purple membrane of the halophilic microorganism *Halobacterium halobium*.[1] Its role is to convert light energy into a proton gradient across the membrane, which is subsequently used to synthesize ATP via a chemiosmotic mechanism. bR consists of all-*trans*-retinal linked to the ε-amino group of a lysine residue to form a protonated Schiff base.[2]

The absorption maximum of bR (λ_{max} = 570 nm) is red-shifted relative to that of the protonated retinal Schiff base in methanol solution (λ_{max} = 440 nm). At present, it is assumed that this red shift is a consequence of several factors: (1) weak hydrogen bonding to the positively charged Schiff base nitrogen;[3] (2) a planar *s-trans* ring–chain conformation of the retinal chromophore in the binding site;[4] (3) an interaction between an ion-pair in the protein near the cyclohexene moiety and the retinal chromophore.[3d,e,4] Recently, an artificial bR pigment containing a cyanine dye chromophore, which exhibited a narrow, red-shifted absorption maximum (relative to bacteriorhodopsin), was prepared.[5] Calculations[6] predicted that this characteristic absorption should originate from interaction of the polyene with negative charges symmetrically distributed along the chromophore.

In this study, we have examined the effect of a nonsymmetrical distribution of negative charges along the polyene on the absorption maximum of symmetrical cyanines, using compounds **1**–**3**, which bear symmetrically (**1** and **3**) or nonsymmetrically (**2**) distributed negative charges.

Cyanines **1** were prepared as described earlier.[7] Compounds **2** (mixtures of *syn–anti* isomers) were prepared by condensation of the corresponding merocyanines (obtained by basic hydrolysis of **1**, cf. **5** and **6**) with proline. Compounds **3** (likewise mixtures of *syn–anti* isomers) were synthesized by condensation of **4** with proline followed by addition of Et_3N. Compounds **1**, **2**, and **3** exhibited very similar absorption maxima in both ethanol and methylene chloride. The introduction of the second negative charge (see **3**) only slightly changed the absorption maxima and the bandwidth (as measured at the half-height) (Table 1). None of the recorded absorption maxima was shifted following dilution up to 10^{-5} M, which was necessary to minimize the possibility of aggregation. Thus, the absorption maxima of symmetrical cyanines are not affected significantly by the location of their counterion in organic solvents.

2b	424	1920	429	2100
3b	429	1880	431	2470
1c	521	1380	530	1240
2c	526	1460	530	1230
3c	528	1330	534	1400
1d	625	1040	635	1020
2d	631	1190	639	1160
3d	633	1200	642	1100

The symmetry of chromophores **1a–d** and high degree of charge delocalization in the ground state are reflected in their ^1H- and ^{13}C-NMR spectra (Table 2).

Table 2. ^1H- and ^{13}C-NMR data of **1a–d** and **1a**, **b**, **2a**, **b**. For numbering of the atoms see **5** and **6**. J in Hz.

^1H-NMR (CD_3OD): **1a**: $\delta = 5.52$ (t, 1, $J = 12$, 7-H), 7.92 (d, 2, $J = 12$, 6(8)-H); **1b**: $\delta = 5.67$ (t, 2, $J = 11.8$, 7(9)-H), 7.48 (t, 1, $J = 11.8$, 8-H), 7.72 (d, 2, $J = 11.7$, 6(10)-H); **1c**: $\delta = 5.74$ (t, 2, $J = 11.8$, 7(11)-H), 6.26 (t, 1, $J = 12.6$, 9-H), 7.30 (t, $J = 11.8$, 2, 8(10)-H), 7.70 (d, 2, $J = 11.8$, 6(12)-H); **1d**: $\delta = 5.95$ (t, 2, $J = 12$, 7(13)-H), 6.21 (t, 2, $J = 12$, 9(11)-H), 7.17 (t, 1, $J = 12$, 10-H), 7.25 (t, 2, $J = 12$, 8(12)-H), 7.45 (d, 2, $J = 12$, 6(14)-H)

^{13}C-NMR (CD_3OD): **1a**: $\delta = 92.90$ (C-7), 159.66 (C-6/8); **2a** [a]: $\delta = 93.49$, 93.12 (C-7), 159.65, 159.74, 159.83, 160.88 (C-6/8); **1b**: $\delta = 105.16$ (C-7/9), 158.76 (C-6/10), 163.57 (C-8); **2b** [a]: $\delta = 105.44$, 105.55, 105.59, 106.31 (C-7/9), 158.50, 159.09, 160.12 (C-6/10), 163.45, 163.72 (C-8)

[a] *syn-anti* mixture.

The ^{13}C-NMR spectra indicate that **2a**, **b** do not differ significantly from **1a**, **b** with respect to charge delocalization and the high degree of symmetry. The corresponding carbon atoms in **1a** and **2a** have virtually identical chemical shifts. This is also true for **1b** and **2b**. This insensitivity to location of the counterion (symmetrical in **1** and unsymmetrically fixed in **2**) is reflected in the absorption maxima of these cyanines (Table 1).

To gain further information on the influence of external charges on the electronic spectra of symmetrical cyanines, we incubated merocyanine **5** (obtained by basic hydrolysis of **1c**) with bacterioopsin[8] for 48 h (pH = 6.5, 20 mM HEPES buffer). This resulted in formation of the artificial pigment **V**, which has an absorption maximum at $\lambda = 530$ nm (Fig. 1) with a narrow bandwidth (1350 cm^{-1}). Competition experiments with all-*trans*-retinal showed that the chromophore occupied the binding site. Similarly, incubation of merocyanine **6** with bacterioopsin (1 h) afforded pigment **VI**, which absorbed at $\lambda = 640$ nm with a bandwidth of 1100 cm^{-1}. Both artificial pigments exhibit similar absorption maxima and bandwidths to those of the corresponding cyanines **1c** and **2c** or **1d** and **2d**, respectively, in EtOH and CH_2Cl_2 (Table 1).

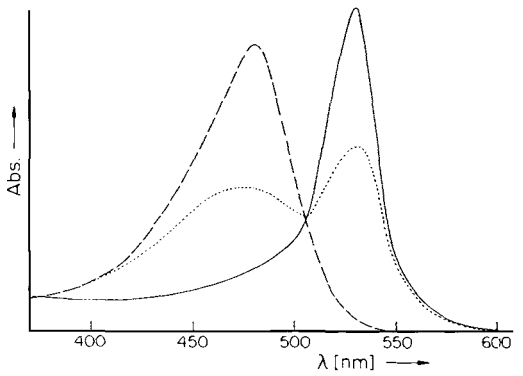

Fig. 1. Incubation of merocyanine **5** with bleached purple membrane at 25°C, pH = 6.5; formation of the artificial bacteriorhodopsin pigment **V** (---) Absorption after 1 min; (· · · ·) after 12 h; (——) after 48 h.

Artificial bR pigments based on dihydroretinals exhibit opsin shifts that vary, depending on the length of the chromophore. (The opsin shift is defined as the difference between the absorption of the pigment and that of a protonated Schiff base of the corresponding retinal chromophore in MeOH.)[9] For example, it was suggested that the pigments derived from 5,6- and 7,8-dihydroretinals differ quite significantly from each other on account of different charge distribution introduced by the protein around these two chromophores.[3d,9] Pigments **V** and **VI** are comparable to 7,8- and 5,6-dihydro pigments, respectively, in their chromophore length. However, the absence of significant opsin shifts points to the insensitivity of symmetrical aliphatic cyanines to charge distribution around their polyene skeleton. This result is consistent with our experimental observation in organic solvents that the absorption maxima of symmetrical cyanines are not affected significantly by interaction with external negative charges.

The red-shifted absorption maxima and the narrow bandwidth of symmetrical cyanines reflect the high degree of charge delocalization in both the ground and excited states; the charge in these cyanines is distributed similarly, in each case, along the polyene chain.[10] This phenomenon is not perturbed by interaction with nonsymmetrically distributed negative charges in the vicinity of the nitrogen atoms. Similar arguments hold for the insensitivity of the absorption maxima to solvent polarity. This behavior is completely different from that found in protonated retinal Schiff bases, which are markedly influenced by nonconjugated charges,[3e] because the positive charge is distributed differently in the ground and excited states.

Remarkable Ease of Ring Oxidation in Cerium(IV) Bisporphyrinates with Double-Decker Structure**

By *Johann W. Buchler,* Kyra Elsässer, Martina Kihn-Botulinski,* and *Bernd Scharbert*

Dedicated to Professor Hans Herloff Inhoffen on the occasion of his 80th birthday

The structure of the reaction center of bacterial photosynthesis in *Rhodopseudomonas viridis* was recently elucidated by *Huber* et al.[1] This extensive membrane protein complex proves to contain the long postulated "special pair", a bacteriochlorophyll b dimer $(BChl)_2$, in which the tetrapyrrole ligands cohere about 3 Å apart from each other via π-π interactions of the two pyrrole rings I. According to present knowledge,[1] this "special pair" donates an electron to a neighboring bacteriopheophytin monomer (BPhe) according to Eqn. (a) under the action of light quanta.

$$(BChl)_2 + BPhe + h\nu \longrightarrow (BChl)_2^{\oplus} + BPhe^{\ominus} \quad (a)$$

The ionized "special pair", $(BChl)_2^{\oplus}$, is recognized by a characteristic absorption band at about 1300 nm in the near infrared (NIR).[2]

We recently described sandwich-like lanthanoid bisporphyrinates, e.g., the cerium(IV) derivative of 5,10,15,20-tetra(*p*-tolyl)porphyrin, $Ce(TTP)_2$,[3] and the derivatives of 2,3,7,8,12,13,17,18-octaethylporphyrin, $Ce(OEP)_2$,[4,5] $Pr(OEP)_2$,[4] and $Eu(OEP)_2$,[4] which contain Ce^{IV}, Pr^{III}, and Eu^{III}, respectively, as central ions; in the case of the trivalent lanthanoid ions, the formula $Ln(OEP)_2$ can only be explained in terms of one porphyrin ligand being present in the complexes as dianion $(OEP)^{2\ominus}$ and the other as radical monoanion $OEP^{\odot\ominus}$. The combination of two porphyrin systems in different oxidation states is recognized in $Pr(OEP)_2$ and $Eu(OEP)_2$, inter alia, by characteristic absorption bands in the NIR at 1400 and 1280 nm, respectively, which can be tentatively assigned to an internal charge transfer (CTI).[6]

The finding that the cation $(BChl)_2^{\oplus}$ in Eqn. (a) likewise absorbs in the NIR at 1300 nm, suggests that these absorptions could be a common characteristic of such mixed valence tetrapyrrole dimers. In the meantime, the double-deckers $Ln(OEP)_2$ with all lanthanoids excepting Pm have been prepared. With exception of the Ce^{IV} derivative all complexes show a NIR band whose wave number monotonously decreases with increasing ionic radius of the rare-earth metal.[6] These observations finally prompted attempts to convert the neutral Ce^{IV} double-deckers likewise into mixed valence cations by oxidation according to Eqn. (b); formulated for octaethylporphyrin, Eqn. (b) then describes a redox system analogous to the "special pair".

$$Ce(OEP)_2 \rightleftharpoons Ce(OEP)_2^{\oplus} + e^{\ominus} \quad (b)$$

Indeed, the oxidation is realized on a preparative scale by reaction of the Ce^{IV} double-decker $Ce(TTP)_2$ with the hexachloroantimonate of the phenoxathiin radical cation[7] in 1,2-dichloroethane (DCE) according to Eqn. (c).

$$Ce(TTP)_2 + [phenoxathiin]^{\odot\oplus}SbCl_6^{\ominus} \longrightarrow Ce(TTP)_2SbCl_6 + phenoxathiin \quad (c)$$

1a

$Ce(TTP)_2PF_6$ **1b** $Ce(OEP)_2SbCl_6$ **2** $Ce(TPP)_2SbCl_6$ **3**

After evaporation to dryness and redissolution in DCE/toluene, blue-violet crystals of **1a** · 2 DCE separate. **2** and **3**, the derivative of 5,10,15,20-tetraphenylporphyrin, are obtained likewise. The salts are characterized by elemental analyses and conductivity measurements, and by their UV/VIS, IR, and NMR spectra.[8] As expected, NIR bands are observed at 1340 nm (**1a**), 1270 nm (**2**), and 1350 nm (**3**) showing halfwidths of about 300 nm.

The redox potentials for the reversible first ring oxidation to **1a** or **2** are taken from the cyclic voltammograms (Fig. 1). The waves appearing in the more positive potential region correspond to an oxidation to the dication; the quasi-reversible waves lying in the negative region presumably indicate the reduction to Ce^{III}. Electrolysis of $Ce(TTP)_2$ in CH_2Cl_2/NBu_4PF_6 at a controlled potential of about +0.7 V affords **1b**[8] after removal of the solvent and recrystallization from acetone.

Very informative is a comparison of the redox potentials (calomel electrode, CH_2Cl_2/NBu_4PF_6) for the first ring oxidation. On comparison with the documented monoporphyrins the following series emerges: TTP complexes: Zn(TTP): 0.81 V, $Ce(TTP)_2$: 0.62 V; TPP complexes: Zn(TPP): 0.71 V,[10] $Ce(TTP)_2$: 0.68 V, Mg(TPP): 0.54 V;[10] OEP complexes: Zn(OEP): 0.69 V, Mg(OEP): 0.53 V, $Ce(OEP)_2$: 0.17 V. In general, these potentials decrease in going from the zinc to the magnesium complexes;[10,11] Mg(OEP) belongs to the metal porphyrins that are particularly readily oxidized at the ring. In the case of the tetraarylporphyrins the value for the cerium double-decker lies between those of the magnesium complex and the zinc

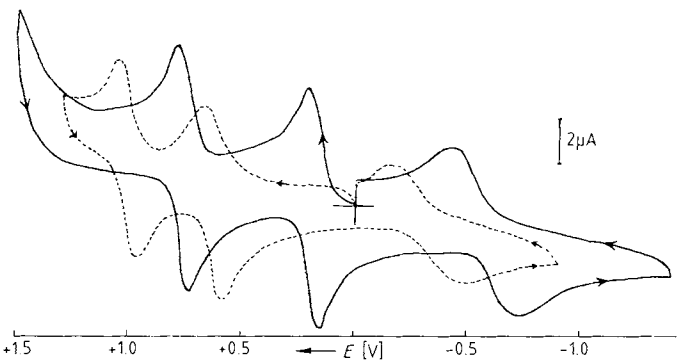

Fig. 1. Cyclic voltammograms of the cerium(IV) bisporphyrinates $Ce(TTP)_2$ (----), 1.0×10^{-4} mol/L, and $Ce(OEP)_2$ (—), 1.2×10^{-4} mol/L; scan rate 100 mV/s, solvent CH_2Cl_2, supporting electrolyte NBu_4PF_6, Pt-disk electrode, calomel reference electrode.

[**] Metal Complexes with Tetrapyrrole Ligands, Part 41. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Vereinigung von Freunden der Technischen Hochschule Darmstadt.—Part 40: [5].

complex; however, in going from the mono- to the bisporphyrin there is a further substantial drop in the value. If the electron-attracting aryl groups in the *meso* positions are replaced by the electron-donating, peripheral ethyl groups the ring oxidation to the radical cation is noticeably enhanced: the oxidation potential of the cerium double-decker is about 0.36 V lower than that of the magnesium complex.

$(BChl)_2$ exists likewise as a pair of highly alkylated yet hydrogenated tetrapyrrole systems. In the case of bacteriochlorophyll a, the association of the "special pair" effects a further enhancement in the ring oxidation in addition to that due to the presence of the magnesium: The oxidation potential of the dimer is about 0.2 V smaller than that of the monomer.[12] A corresponding, but clearly smaller effect by about 0.07 V was recently established in the case of the dimers of 5,10,15,20-tetrakis(benzo[15]crown-5)porphyrinatomagnesium, which are formed from this complex by reaction with potassium salts.[13]

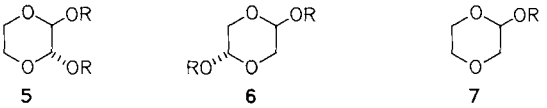
Solvent Polarity and the Anomeric Effect**

By *Benzion Fuchs,* Aviyakar Ellencweig, Evgeny Tartakovsky,* and *Pinchas Aped*

The anomeric effect is one of the most studied and reviewed phenomena in modern organic chemistry.[2,3] It was first discovered in carbohydrates[4] and interpreted in terms of electrostatic interactions between the C–X and C–O–C dipoles, for example, in **1** and **2**. The lesser stability of **2** was attributed to repulsive interactions between parallel dipoles or lone pairs. A subsequently postulated[3c] and then theoretically supported[5–7] interpretation invoked delocalization of a lone pair of electrons (n_p) on oxygen into the σ^* orbital (see **3**) of the adjacent C–X bond in **1** and hence its stabilization relative to **2**. While the second (MO) approach, with its valence bond counterpart (double bond–no bond resonance, **3**↔**4**) has been increasingly accepted, the extent to which each of the above phenomena may contribute to the origin of the anomeric effect has not yet been systematically investigated, let alone solved.



1 **2** **3** **4**

The strongest argument in favor of the initial, electrostatic rationalization of the anomeric effect was its apparent suppression by polar solvents since these were found to stabilize the equatorial forms of carbohydrates[3a,b,h,j] or other, simpler systems.[8] We now report data that are in apparent contradiction to this trend, suggesting that, in reality, polar solvents may *enhance* the anomeric effect.

We recently reported[10] that *trans*-2,3- and *trans*-2,5-dimethoxy-1,4-dioxanes **5a** and **6a**, respectively, as well as the analogous diphenoxy and diacetoxy derivatives (R = Ph, Ac) overwhelmingly prefer the diaxial conformation, mainly because of the anomeric effect but also because of *gauche* effects. This conformational preference is so strong that no significant changes could be experimentally detected by variation of temperature or solvent polarity. The corresponding bis(trimethylsiloxy) derivatives **5b** and **6b** and di(*tert*-butoxy) derivatives **5c** and **6c**[11] exist as conformational mixtures of diaxial and diequatorial forms. We have now carried out a detailed ^{1}H-NMR spectroscopic analysis of the CH_2–CH_2 (AA'BB') system in **5b** and **5c** and of the CH_2–CHOR system in **6b**, **6c**, and **7a** in various solvents and evaluated the conformational composition using the following relation:[10b]

$$J_{exp} = X J_{aa} + (1 - X) J_{ee}$$

Representative data for solutions in $CDCl_3$ are given in Table 1 and the evaluated conformational compositions in five solvents are listed in Table 2. (The literature values for 2-methoxy-1,4-dioxane **7a**[3f], in fact, promoted the present study.)

5 **6** **7**

a, R = Me; b, R = $SiMe_3$; c, R = *t*Bu

Tables 1 and 2 reveal a striking picture: increased solvent polarity stabilizes diequatorial conformations in the *trans*-2,3-disubstituted derivatives, whereas the opposite is true in the monosubstituted and 2,5-disubstituted analogues. This can be understood only in conjunction with the dipole moments that we have calculated for the 2-methoxy-1,4-dioxanes **7a** and the *trans*-2,3- and *trans*-2,5-

dimethoxy-1,4-dioxanes **5a** and **6a**, respectively, using simple vector addition techniques[13, 14] as well as molecular mechanics (e.g. MM2 as recently parametrized to include the anomeric effect) (Table 3).[11, 12]

Table 3. Dipole moments μ of the two lowest energy conformations ((di)axial and (di)equatorial) of **5a**, **6a**, and **7a**, as calculated by vector addition (VA) and molecular mechanics (MM2—parametrized for the anomeric effect). R = Me.

		μ [D]		$\Delta\mu$ [D]	
		VA	MM2	VA	MM2
5a		0.2	0.5	1.5	0.8
		1.7	1.3		
6a		0.0	0.0	0.0	0.0
		0.0	0.0		
7a		1.5	1.3	0.0	−0.2
		1.5	1.1		

The conclusion to be drawn from Tables 2 and 3 is compelling: The stabilization of diequatorial forms by polar solvents occurs only in the *trans*-2,3-dialkoxy- or *trans*-2,3-disiloxy-1,4-dioxanes for which μ(diequatorial) > μ(diaxial). This is found, e.g., for the 2-alkoxy- or 2-siloxytetrahydropyrans.[8, 15] When the μ values are similar, however, as in the 2,5-dialkoxy- and 2,5-disiloxy-1,4-dioxanes, the proportion of diaxial (or axial) conformer increases. Since this occurs in all cases with $\mu_{ax} = \mu_{eq}$, both when $\mu = 0$ and when $\mu \neq 0$, as well as with a number of different substituents (R = Me, *t*Bu, $SiMe_3$) and until solvation energy data become available,[16] we can think of only one explanation: the well-known stabilization of equatorial forms by polar media in compounds exhibiting anomeric effects is due to a fortuitous codirectionality of *molecular* dipole moments ($\mu_{eq} > \mu_{ax}$) with the *local* group moment (in R–X–C–Y–R'). However, when $\mu_{eq} \approx \mu_{ax}$ (in spite of the local group moments), the opposite is true: the (di)axial contribution increases, i.e., *polar solvents actually enhance the anomeric effect*, as one could expect from the resonance **3** ↔ **4**. This suggests that hyperconjugative[3k] electron delocalization ($n_p - \sigma^*$)[3c, 5] is the main origin of the so-called anomeric effect.

Novel Fulvalene Derivatives of Zirconium: A Facile Entry into Organozirconium(III) Chemistry**

By *Terence V. Ashworth, Tomas Cuenca Agreda, Eberhardt Herdtweck,* and *Wolfgang A. Herrmann**

Despite numerous investigations in recent years,[1,2] the chemistry of low-valent zirconium remains relatively undeveloped in comparison to that of titanium. Whereas the organometallic chemistry of trivalent titanium is fairly extensive,[3] including, in particular, a number of dimeric titanium derivatives containing the $\eta^5:\eta^5$-fulvalene ligand,[4] the corresponding chemistry of Zr(III) is rather scanty,[1,2,5] and in only one single instance has the presence of a fulvalene ligand been postulated.[6] During our investigations of synthetic routes to low-valent organozirconium derivatives we have discovered a simple, high-yield synthesis of the key compound **2**. This compound represents the first undisputed example of a dimeric compound of Zr(III) containing a fulvalene ligand, and it offers a unique opportunity to develop the chemistry of dinuclear complexes of low-valent zirconium.

Reduction of the cyclopentadienyl complex **1** in toluene with sodium amalgam (1% Na) containing exactly 1.5 molar equivalents of sodium afforded a dark red solid in high yield (75%) which could be characterized as the fulvalene complex **2**.[7] The mass spectrum of this complex confirmed its dinuclear structure, while the ^{1}H- and ^{13}C-NMR

1 2 3

spectra revealed the presence of a $\eta^5:\eta^5$-fulvalene ligand in a molecule possessing an averaged plane of symmetry through the central carbon–carbon bond of the fulvalene ligand and the metal atoms. This requires that the chloride ligands occupy coordination sites bridging the two zirconium centers.

So far, all attempts at obtaining crystals for an X-ray diffraction study of **2** have met without success. Compound **2** reacts quantitatively, however, with oxygen to give the pale-yellow derivative **3**, which has been characterized by

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, the Alexander-von-Humboldt Foundation (Fellowships to *T. V. A.* and *T. C. A.*), and Hoechst Aktiengesellschaft.

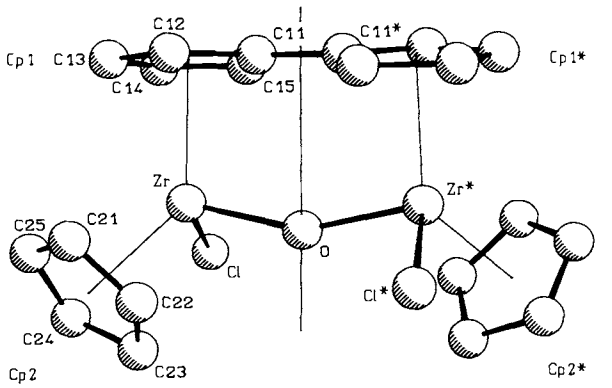

Fig. 1. PLUTO drawing [9] of the structure of **3** in the crystal. **3** crystallizes with 0.5 mol toluene disordered around a center of symmetry. Selected bond lengths [pm] and angles [°]: Zr-Cl 247.1(1), Zr-O 194.3(1), Zr-Cp1 223.0(4), Zr-Cp2 222.7(5), Cl-Zr-O 98.1(1), Zr-O-Zr* 156.0(2), Cp = centroids of the Cp-ligands.

X-ray structural analysis[8] (Fig. 1). The two zirconium atoms in **3** are linked by the fulvalene and an oxygen atom. The remaining coordination positions about each metal atom are taken up by a $C_5H_5^-$ and a Cl-ligand. The coordination geometry is similar to that of the related complexes **4**[10] and **5**,[11] but the presence of the fulvalene ligand leads to interesting conformational distinctions. Whereas the ligands attached to the ZrOZr unit of the latter compounds adopt a staggered conformation, in the novel complex **3** the ligands are eclipsed (Fig. 2). Furthermore the torsional angle a is confined to 13.5° and reduces the non-bonded distance (3.801(1) Å) between the zirconium atoms. This gives rise to a ZrOZr angle of 156.0(4)° in **3** (cf. 168.9° in **4**) which is the largest deviation from linearity yet observed in oxo-bridged cyclopentadienyl transition metal dimers.[11]

$[\{ZrCl(\eta^5\text{-}C_5H_5)_2\}_2(\mu\text{-}O)]$ **4** $[\{Zr(SC_6H_5)(\eta^5\text{-}C_5H_5)_2\}(\mu\text{-}O)]$ **5**

The spectroscopic data[7] for **3**, obtained in solution, are consistent with the above structure (Fig. 1). The mirror symmetry observed in the NMR spectra of **2** is lost in **3** (*ABCD*-spin system in the ^{1}H-NMR spectrum).

$[\{ZrCl(\eta^5\text{-}C_5H_5)_2\}_2O]$ **4** $[\{ZrCl(\eta^5\text{-}C_5H_5)\}_2(\eta^5:\eta^5\text{-}C_5H_4\text{-}C_5H_4)O]$ **3**

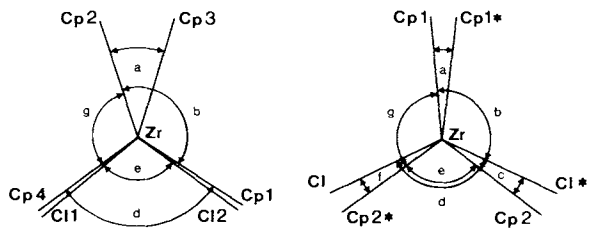

Fig. 2. Molecular conformation of μ-oxo complexes **4** (left) and **3** (right) along the Zr–Zr* vector.

	a	b	c	d	e	f	g
4	34.7	143.5	1.9	109.2	105.4	1.8	109.2
3	13.5	121.4	13.8	130.7	103.0	13.8	121.7

In **4** the angles c and f, respectively, are taken between Cp1 and Cl2, Cl1 and Cp4. The atoms Cl2, Cp3, Cp4 are coordinated to Zr*.

That the rigid fulvalene bridging ligand can bind two metal atoms in close proximity is well known.[12] As demonstrated by the synthesis of **2**, this has now also been accomplished with the rarely investigated Zr^{III} complexes. The potential of universally modifying such complexes by replacement of the chloro ligands by other functionalities is now receiving our active attention.

BOOK REVIEWS

Principles of Nucleic Acid Structure. By *W. Saenger*. Springer Verlag, Berlin 1984. xx, 556 pp., bound, DM 79.00.—ISBN 3-540-90761-0

Wolfram Saenger has done a considerable service for the community of scientists interested in nucleic acids with the publication of his monograph "Principles of Nucleic Acid Structure". The book is a rich compendium of information about the three dimensional properties of DNA, RNA, and related compounds, with particular emphasis on structure at the level of nucleosides and nucleotides. The magnitude of the task can be appreciated by examination of the size of the reference list, which includes over 1400 items.

Particularly commendable features include the careful definition of terms provided in Chapter 2, much needed in a field beleaguered for years by competing systems of nomenclature. The book states clearly the standard definitions recommended in 1983 by the IUPAC-IUB subcommission, and adheres to their use with high fidelity. The same chapter includes a detailed description of the nomenclature of pseudorotation, which provides a systematic scheme for describing the conformation of the ribose ring. This is followed in Chapter 4 with an authoritative account of the principles which underlie the preference for particular sugar ring puckers. The distinction between *syn* and *anti* conformations of the base relative to the sugar ring is also examined in detail, as are the principles which govern the rotational orientations about P-O bonds.

Chapters 5 and 6 consider physical properties of the nucleic bases, such as charge densities, protonation and tautomerization equilibria, spectroscopic properties, and the tendency to hydrogen-bond in solution. Stacking forces and the thermodynamics of double helix formation are also treated. These subjects are followed by a chapter detailing the properties of modified nucleotides, including those of general biochemical interest such as the cyclic nucleotides and pyrophosphate-containing compounds.

The book devotes considerable space to several nicely illustrated chapters describing the many possible helical structures of nucleic acids, including the extensive polymorphism of DNA. Both crystallographic results and models built from fiber diffraction studies are presented in some detail. Even some of the generally discredited models are dredged up from the past, presumably to give a flavor of the nature of debate in the field.

Later chapters in the book will be found widely useful for their structural account of subjects such as tRNA, drug-DNA complexes, and the rapidly developing field of protein-nucleic acid interactions. Included among the latter are some general principles of amino acid-nucleotide interactions and the structural features underlying the interaction of ordered protein segments with nucleic acid

helices. Specific structures examined in detail include tobacco mosaic virus, specific DNA-binding proteins such as CAP and *cro*, and nucleosomes.

The early chapters of the book are rather intensively technical, and unfortunately lacking in general signposts, so that the non-specialist reader will find the going rather tortuous; the later chapters are significantly better in this regard, and should be quite useful as reference material for students and professionals alike in the fields of molecular biology and biochemistry.

All research-level monographs contain errors, and this one is no exception, although I did not find many. The proofreading was generally very good, but a too-generous sprinkling of double bonds around the purine and pyrimidine ring systems was allowed to sneak through in Chapter 2, which may confuse beginning students. The only error of principle which I feel obliged to mention is the incorrect treatment of the dissection of linking number into twist and writhe. Both the text and the figures make it seem that one can determine the writhe of a superhelical structure simply by counting the number of superhelical turns. This error (the writhe of a superhelix depends on its pitch) sets back understanding of DNA topology substantially.

This is a valuable reference book, which should be on the shelves of all who are interested in the structure and function of nucleic acids.

Bio-inorganic Chemistry. By *R. W. Hay*. Ellis Horwood, Chichester 1984. 191 pp., stitched, $ 24.95.—ISBN 0-470-20066-9

Inorganic biochemistry is in a turbulent state of development. An up-to-date introduction to this field which is not only aimed at specialists is years overdue. Thus, *Hay*'s book will encounter an eagerly expectant public—and, to come straight to the point, it is therefore particularly disappointing.

The introductory chapter, short and informative, is concerned with biologically essential metal ions, with their ligands in physiological media and with some of their chemical characteristics that are relevant in this context. Subsequently, the important physical methods of inorganic biochemistry are described, necessarily by means of examples. Only the section on EXFAS, the most important of the new sources of information for the investigation of metal binding in proteins, is more extensive.

Apart from a short (and adequate) chapter on the biochemistry of the alkali metals and alkaline earths, the book is devoted to the rôle of the transition metals in biology. Here, the reader is confronted with a lamentably disorganized collection of partly out-of-date information with very arbitrary emphases and exclusions. To begin with the positive: the chapter on substrate-activating metalloenzymes (carboxypepsidase, carboanhydrase and alcohol dehydrogenase) amounts to an up-to-date, well thought out introduction. It is clear that the author's own research interests lie in this area. Unfortunately, in the case of carboanhydrase, of the many model systems examined, the most convincing one by *Groves* (1981) is missing. Equally well handled are oxygen fixation and iron-sulfur proteins—a considerable achievement in light of the abundance of proteins with Fe-S clusters known today.

Set against this, the presentation of the theme "oxygen transport" suffers from *Hay*'s after all very "inorganic" viewpoint. The willful impression is conveyed that iron-porphyrin can accomplish the transport perfectly well on its own and that the protein is only a sort of packing. Hemoglobin itself is pushed into the background by the depth and extent of the treatment of model systems and of the (biochemically irrelevant) cobalt-oxygen complexes.

It becomes really annoying in the section on the fascinating catalytic properties of cytochromes of type P450. These heme proteins "can" hydroxylate alkanes under physiological conditions. In 1982 (for which year the book claims to present the state of knowledge) much was already known about the mechanism responsible for this. We are offered a random selection from the state of discussion around 1980; the rôles of the axially coordinated sulfur and of the active Fe-O species are either quite wrongly represented or simply not referred to. Cytochrome P450, catalase and hemoglobin are three heme proteins whose remarkably different interactions with oxygen are decisively determined by axial ligands of the heme iron: the opportunity of a comparative discussion of these three is let slip. This is particularly regrettable because in this case "inorganic" and "biochemical" interests really have coalesced in ideal fashion to a genuine "bioinorganic" research area.

The biochemistry of iron in aerobic media offers the chance of a sheer "exciting" account of how the insolubility of iron(III) hydroxide has been come to terms with. On uptake, transport and storage, before and during its inclusion in functional proteins, the iron is kept in solution through a seamless sequence of strong complexing agents. Unfortunately, the few particulars on this are dotted right through the whole book so that the connection is lost in exotic detail and is not made very comprehensible. The biochemistry of copper is equally unsystematically handled: a direct comparison of the three types of copper binding centers in proteins is sought in vain; this certainly does not facilitate the understanding of the not-yet-expert (and the book is aimed at students!).

It only remains to be pointed out that one of the functionally most important and "bio-inorganically" interesting metallo-proteins—cytochrome-c-oxidase, currently the subject of much research, receives no more than a passing reference from the author. The purchase of this book can be recommended to no-one—least of all its intended readership of advanced students.

Michael Weller [NB 700 IE]
VCH Verlagsgesellschaft, Weinheim (FRG)

Methods of Enzymatic Analysis. Vol. 6. Metabolites 1: Carbohydrates. Edited by *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grassl*. 3rd Edition. Verlag Chemie, Weinheim 1984. xxix, 701 pp., bound, DM 295.00.—ISBN 3-527-26046-3

This volume describes analyses for carbohydrates and related compounds. The coverage is broad: from poly-, oligo-, and disaccharides through monosaccharides to three-, two-, and one-carbon compounds. The four chapters of this volume are subdivided into sections. Each section normally covers the analysis of a single metabolite, although, several metabolites which can be co-analyzed are occasionally grouped together. Certain important com-

pounds are covered by several sections, each employing a different analytical technique. These sections, which have been prepared by a number of different authors, have been brought together by the editors into a very even and high-quality volume.

The coverage of the third edition is essentially the same as that of the second edition. The chapter on poly-, oligo-, and disaccharides covers the important energy storage materials (starch, glycogen and inulin), plant structural materials (cellulose, pectin and polygalacturonic acid), other, clinically important polysaccharides (hyaluronate, chondroitin and sialic acid etc.) and several disaccharides of interest in food chemistry (raffinose, sucrose, lactose and maltose).

The monosaccharide chapter, the bulk of the book, mainly covers hexoses and pentoses. Glucose, its oxidized and amino derivatives and some of their phosphate derivatives account for 25% of the chapter. Also well covered are galactose, mannose, fructose and derivatives. Ascorbate, dehydroascorbate, sorbose and two derivatives, *myo*-inositol and its 1-phosphate round out the hexose coverage. The pentoses are represented by 6 ribo-sugars, arabinose and 3 xylo-sugars. Octulose 1,8-bisphosphate sedoheptulose 7-phosphate and 1,7-bisphosphate, and two erythrose derivatives are also covered.

The chapter on 3-carbon compounds, which contains assays for PEP, pyruvate, hydroxypyruvate, lactate and methylglyoxalate, concentrates on assays for glyceraldehyde, glycerol and glycerate and their derivatives.

The final chapter covers formate, formaldehyde, acetyl phosphate and 7 of the 9 common oxygenated C-2 compounds (only glycolic acid and oxaldialdehyde are omitted).

Most of the analytical procedures are the same as those in the second edition. Some obsolete procedures have been replaced or omitted and some of those that have been retained have been revised and modified to incorporate new developments.

Each section is highly detailed and contains more, valuable explanatory text and background than the second edition. Each section begins with the structure of the analyte, a new addition since the second edition. Some information about the substance (history, physical and biological properties, biogenesis, occurrence, properties relevant in analysis, references and standards, etc.) is provided, and is followed by a brief, critical review of other available analytical methods for the substance.

The core of each section—the assay—is extensive. The principle of the assay is first explained with text and equations. Sections listing optimum measurement conditions, necessary equipment, and reagents then follow. Specific information about reagent and solution purity, preparation, storage and stability and about specimen collection, processing and stability help the analyst consistently to obtain valid data. The assay procedure itself takes a "cookbook" approach which allows even unfamiliar workers to execute the analysis successfully the first time. The detailed, step-by-step procedure covers all aspects of data collection and processing including the calculations and formulae needed to work-up the raw data. Finally, a discussion of precision, accuracy, sensitivity, limit of detection, error and specificity aids in evaluating the method.

Each section is well-referenced. The references are up-to-date as a cursory inspection reveals many from 1982 and 1983. Several appendices listing commonly encountered constants, abbreviations and formulae are provided. Unfortunately, the index is little more than an alphabetization of the table of contents. Although the lack of cross-indexing may be inconvenient to some, the book's format makes finding information straightforward.

This volume is not, nor was intended to be, a comprehensive handbook. However, its more than one hundred individual assays cover all of the most commonly analyzed materials and many which are less common. This volume is a valuable work of reference and guide and is strongly recommended to those doing analyses of biological materials.

Strategies and Tactics in Organic Synthesis. Edited by *T. Lindberg*. Academic Press, New York 1984. xiv, 370 pp., hardback, $ 57.00.—ISBN 0-12-450280-6

In our peace-loving time everbody talks about "strategies" not only in the army but also in industrial concerns, on football grounds and, not least, in organic synthesis. In the title of the book under consideration "strategies" are even combined with "tactics". Is organic synthesis a war game? The analogy cannot be rejected out of hand. After all, anyone who has struggled through a multi-step synthesis knows the feeling of standing against an insidious foe who does not play by the rules and can only be overcome by heroic effort. Thus, this book sets out to report not only the successes but also the setbacks and dead ends which even brilliant synthetic chemists cannot avoid. It aims to show how the "strategy" of a plan conceived in broad terms must finally be helped along by manifold "tactical" variations. Precisely this fascinating struggle with matter is concealed by the conventional form of publication, which aims at a concise account of positive results.

Thirteen celebrated american synthetic chemists report in individual chapters on spectacular projects that were successfully concluded. The round is opened by *V. Boekelheide*'s "superphane" (19 pages); then *R. Danheiser* reports on *Corey*'s gibberellin acid synthesis (50 pages), *J. Fried* on the epoxide route to the prostaglandin system (12 pages), *P. Magnus* on his new indole-alkaloid synthesis (39 pages), *S. Masamune* on the macrolide aglycon tylonolide (30 pages) *K. C. Nicolaou* on the endiandric acid cascade (18 pages), *L. A. Paquette* on dodecahedrane (25 pages), *M. F. Semmelhack* on the methylenecyclobutenes fommanosin and illudol (21 pages), *A. B. Smith III* on iatrophone (51 pages), *R. V. Stevens* on tricyclic pyridine alkaloids (23 pages), *K. P. C. Vollhardt* on cobalt induced alkyne cyclization (25 pages), *S. M. Weinreb* on the hetero-Diels-Alder route to the alkaloid streptonigrin (20 pages), and, finally, *J. D. White* on the synthesis of methynolide via [3+4] additions to furan derivatives (19 pages).

This variegated programme conveys a gripping picture of the aims and ability of modern organic synthesis. Achievements are described here which, not all that long ago, would have been banished to the realm of fantasy. Just consider the intricate stereo- and protecting group problems in the macrolide synthesis or the exotic bond linkages in superphane or dodecahedrane. The difficulties were enormous yet again and again the strategies, mostly based on systematic retro-synthetic analysis, led to the target, thanks, not least to "tactical" dexterity, determination, and to the co-workers. To this extent the comparison with

chess, which has often been used and is here cited by *Magnus*, is wide of the mark. Chess is a purely intellectual pursuit, involving none of the physical labor of benchwork, which makes the experience of defeat that much more bitter and painful.

The reader obtains much more inside information about the development of the project as a whole from the personal style of the chapters. The initial motivation, which mostly lay in the magnitude of the synthetic challenge, the first model experiments up to the actual laborious realization, calling on all the cunning and ability of the chemist, and finally the relief at the successful conclusion, all this can be followed and reiterated without difficulty. The length of each chapter reflects the engagement of its author; thus *Danheiser*'s contribution is certainly the most fascinating, especially since it is written from the standpoint of a graduate student and not that of the group leader.

Each chapter is accompanied by a wealth of formula schemes and literature references which contribute information to the whole, as do the numerous practical directions; better still would have been experimental sections with descriptions of the key experiments.

Summary: The book in question shows the way to a stimulating new approach to the documentation of organic synthesis. It inspires both enthusiasm and the wish to match the author's achievements. However, there are two flies in the ointment: the material is not easy to follow, even for those in the field, and the price of around DM 180. practically rules out the private acquisition of the book.

Bacterial Endotoxin. Chemical, Biological, and Clinical Aspects. Edited by *J. Y. Homma, S. Kanegasaki, O. Lüderitz, T. Shiba,* and *O. Westphal.* Verlag Chemie, Weinheim 1984. ix, 420 pp., bound, DM 118.00.—ISBN 3-527-26164-8

The recent progress in endotoxin research is summarized in 33 contributions by leading groups from Japan, West Germany, and the United States of America. The book has been published at a time when the decisive breakthrough in the chemical analysis and synthesis of the toxic component of endotoxin, the lipid A moiety, had been achieved. Structure elucidation and chemical synthesis has now confirmed that the important biological actions of endotoxins from gram-negative bacteria reside in the lipid A moiety, as proposed 3 decades ago by *O. Westphal* and *O. Lüderitz.*

Several chapters deal with the endotoxic activities of synthetic lipid A analogs and modified lipopolysaccharides and contribute thereby to an improved understanding of the structural requirements for certain biological activities; some of these are desirable, such as induction of the tumor necrosis factor by endotoxin. Most of the toxic actions of bacterial endotoxins in humans and animals result from the production of endogenous mediators. This mediator theory of *V. Menkin* has now gained strong support and one contribution focuses on the role of arachidonic acid metabolites, particularly prostanoids and leukotrienes, generated by macrophages under the influence of endotoxin.

Remarkable progress in the analysis of endotoxins, including the ones detectable in blood under pathophysiological conditions, is reflected in the chapters on the Limulus test and the Limulus coagulation cascade. However, the specificity of this test for endotoxins is still unsatisfactory when applied for the clinical diagnosis of endotoxemia.

The book provides an excellent and highly competent survey of recent developments in endotoxin research. In selecting certain aspects, the reader should follow the Table of Contents since an Index with key words is lacking. But this is a minor obstacle in view of the wealth of information offered to those working and interested in the exciting area of endotoxin research.

Dietrich Keppler [NB 703 IE]
Biochemisches Institut der
Universität Freiburg (FRG)

Biotransformation von Arzneimitteln. Band 4. By *S. Pfeifer.* 717 pp., bound, DM 192.00.—ISBN 3-527-25926; *Band 5.* By *S. Pfeifer* and *H.-H. Borchert.* 468 pp., bound, DM 168.00.—ISBN 3-527-26075-7, Verlag Chemie, Weinheim 1981 and 1984.

This series concerning the biotransformation of drugs has been provisionally completed since 1984. Monographs are now available concerning approximately 1000 compounds representing all significant types of active agents.

The telegraphic style and the use of many abbreviations and symbols results in compressed and not always easily readable presentations. Each monograph is set up in the same manner. A formula scheme is presented and partial structures are given for most of the metabolites—whereby no differentiation is made between the major and minor pathways of biotransformation. Details of the excretion form in animals and in man and of analysis follow. Additional information is then provided concerning pharmacokinetics and metabolic data under key headings in the section labeled "Bemerkungen"; no claims are made here to comprehensiveness. From Volume 4 the "Remarks" section has been enlarged and divided into topics. At the end, the literature surveyed is listed alphabetically according to the authors' names.

The literature to 1981 is covered in Volume 5—Volume 1 covers the literature to 1972/1973—more recent literature was included in later volumes. Furthermore, a total of over 200 monographs was compiled in supplements. With this, the total series includes the literature to at least the beginning of 1978 for important compounds.

The author has performed a remarkable feat with this series of monographs, considering the amount of information and the number of publications, which have grown considerably in recent years because of increasing requirements and technical progress. This made selection and limitation necessary and reports are included on "only" 1063 substances. It is, however, not possible to discern the criteria for selection. On the one hand, substances are described which are not yet or no longer used as drugs, and on the other, many very common pharmaceuticals are absent (e.g. reserpine, allopurinol, erythromycin, vincristine, ajmaline, norfenefrine).

The use of the monographs is made more difficult by the widespread use of Latin names (e.g. Calcii benzamidosalicylas). These terms are familiar to the phamacist and are used, among others, in the German and European pharmacopoeias; however, the majority of the users of this work

are chemists, biologists or physicians. Reference is necessary to other works for unambiguous identification. The problem could have been avoided by enlarging the index and cross referencing. Once the reader has taken this hurdle successfully, he then has to deal with a large number of abbreviations that could cause difficulties to the occasional user. However, these allow a very compressed presentation in a small space.

The monographs should not be regarded as critical evaluations suitable as primary information for the non-specialist in presenting the metabolic fates of individual pharmaceuticals, because significant data are accompanied to some extent by non-confirmed data without differentiation. This work is, however, a very comprehensive collection from the literature concerning the chosen substances and provides easy access to the primary literature necessary for intensive study.

The collection of monographs is very useful as a reference work and is likely to be welcomed by all who are concerned with the biotransformation of pharmaceuticals, because even today a comprehensive literature search is often time-consuming, at least as far as the older literature is concerned.

The constantly increasing number of publications dealing with biotransformations and pharmacokinetics makes a new form of documentation necessary in order to guarantee greater topicality; the authors are now making efforts in this direction. These volumes retain their importance as basic information concerning the substances covered.

K.-O. Vollmer [NB 678 IE]
Gödecke AG, Abt. Biochemie,
Freiburg (FRG)

Cytochrome P-450. By *K. Ruckpaul* and *H. Rein*. Akademie Verlag, Berlin 1984. 405 pp., hardback, ca. DM 80.00.—Order No. 763-110-9 (6703)

"At last", you may wish to say, along with the many biochemists, pharmacologists, microbiologists or chemists who hope to find under a title like this everything they always wanted to know about cytochrome P450. There is, without doubt, a gap in the market, which no-one has been brave enough to fill yet, for a comprehensive and, above all, systematizing monograph on cytochrome P450. This may well be because of the constant development of ideas about this cytochrome which does not exist as "the" cytochrome P450, whose description as "P450" follows no rational nomenclature, and which, strictly speaking, is not even a cytochrome.

Admittedly, it is difficult to bring order into the mass of results that have been published about cytochrome P450. It is difficult to separate the wheat from the chaff so that the important findings will open the way, for specialist and interested layman alike, to the unusual enzymology, the mechanistic features—of significance to chemists also—and the physiological, pharmacological, and toxological aspects of this enzyme. This task is not made any easier when it is entrusted to 25 authors, who deal with the significant aspects in eight chapters. The first six chapters are almost exclusively concerned with the unspecific microsomal monooxygenase system of the liver. To this extent the title of the book is undeserved in that some introduction to common structural features and to mitochondrial, bacterial, and microsomal monooxygenases might have been expected, as well as a survey of the individual enzymes.

The camphor hydroxylating system, which is dealt with in only six pages in chapter 7, is surely under-represented and it would probably have been more easily understandable to the reader than the very complex drug monooxygenating system. The phenomenon of induction, which is so important for this P450 system, appears in chapter 6 but is already presupposed in chapter 2. Also, differing designations for "monooxygenases", such as MFO (mixed function oxidases) or "monooxygenatic systems" do not promote the comprehension of the student or non-specialist.

However, for the specialist the book contains a wealth of details with an almost complete literature compilation on the mechanistic aspects. Each chapter is competently written in itself, since the authors, nearly all from the central Institute for Molecular Biology at Buch in (Berlin-East), have all made appreciable contributions in their own fields. Thus, *K. Ruckpaul* and *R. Bernhardt* present a good survey of the endoplasmic reticulum, *G. R. Jänig* and *D. Pfeil* contribute an extensive treatment of the enzymology of the liver system, and *H. Rein, C. Jung, O. Ristau* and *J. Friedrich* collate all the structural data on P450.

The chapter on cytochrome P450 in microorganisms is very lucid but not comprehensive enough in its theoretical and practical significance. A contribution on steroid hydroxylases would also have been desirable. In this case it would not have been necessary to devote a special chapter to the not very meaningful NMR data and to the still less promising biotechnological aspects.

Regardless of these well meant criticisms, this book remains the first comprehensive monograph on cytochrome P450, if the 1978 publication of the same title by *Sato* and *Omura*, which is around half the length, is overlooked. The decision to buy the book is facilitated by the reasonable price. Since the paper quality is not of the best and the index still needs supplementing, it is to be hoped that a second, improved edition is planned soon.

Volker Ulrich [NB 698 IE]
Fakultät für Biologie
der Universität Konstanz (FRG)

Methoden der Analytischen Chemie. Eine Einführung. Band 2: Nachweis- und Bestimmungsmethoden, Teil 2. By *R. Bock*. Verlag Chemie, Weinheim 1984. xi, 379 pp., bound, DM 188.00.—ISBN 3-527-25865-5

The book in question is the fourth and penultimate volume of a comprehensive and systematic account of the methods and instrumentation of analytical chemistry. After "Decomposition Methods in Inorganic and Organic Chemistry" (1972), this general review of analytical methods, originally planned as a single volume by the author, turned out to be like the mythical hydra. Volume 1 was fully taken up with an account of "Separation Methods" (1975). "Methods of Detection and Determination" (Vol. 2) proved to be so comprehensive that it is now being published in three parts. The first part (1980) dealt with procedures that are based on a measurement of electromagnetic radiation. The second part, considered here, describes analytical methods involving the measurement of electrical values as well as those based on thermal effects and phase changes. The subjects of the third part, now in preparation, will include, inter alia, gravimetric, volumetric, and barometric analysis as well as analysis employing chemical reactions.

The arrangement of the work as a whole shows that the author has introduced order into the manifold results of

analytical inventiveness; he reduces methods, instruments, and variations with impressive names and confusing abbreviations to the fundamental physical phenomena on which they are based.

Basically, an electrical measurement is the common characteristic of potentiometry, coulometry, voltammetry, chronopotentiometry, and amperometric and galvanic analysis. Gas chromatographic detection that depends on electrical conductivity (flame ionization detector, thermionic detector, photoionization detector) and β absorption (electron capture detector and helium detector) are also mentioned in this context. Scintillation measurements are dealt with under this heading as are β-backscattering methods, electron diffraction, electron spectroscopy (electron spectroscopy for chemical analysis, ultraviolet photoelectron spectroscopy, Auger electron spectroscopy, electron impact spectroscopy), and the variants of mass spectrometry.

These methods are described in varying depth according to their significance. Under thermochemical methods, besides differential thermal analysis (DTA) and differential scanning calorimetry (DSC), calorimetry/enthalpimetry and the measurement of heats of adsorption and thermal conductivity are dealt with in adequate detail. The final chapter is devoted to methods involving phase changes: turbidity, micellar and solution titrations, the determination of salting-out curves and the precipitation curves of polymers as well as phase solubility analysis.

The reader repetitively experiences the feeling that "the penny has dropped" when he realizes that very different procedures are based on similar physical principles—and this is quite a desirable effect from the educational point of view. The arrangement of the book facilitates understanding and learning. The section on "electrical" methods is preceded by a chapter dealing with the fundamentals of electronics (from *a*mpère to *o*perational amplifier). The descriptions of methods are arranged clearly; a historical summary is often appended. Areas of application and the possibilities of error are critically indicated. Without losing sight of the significant, an abundance of information is introduced in tables, sketches and diagrams. The text remains readable thanks to the consciously frugal use of abbreviations. Numerous clear examples make plain the practical applications of analytical work. Each chapter is accompanied by a carefully selected and organized literature section, which enables quick access to original literature.

"Methods of Analytical Chemistry" will be much appreciated as a German language textbook by advanced students of analytical chemistry. For those working in the field, it may serve as a reference work designed to deepen their knowledge, and will be of particular use when a general index will be available with the final volume.

Jürgen Auffarth [NB 693 IE]
Bundesanstalt für Arbeitsschutz,
Dortmund (FRG)

Reactive Molecules. The Neutral Reactive Intermediates in Organic Chemistry. By *C. Wentrup*. Wiley, Chichester 1984. xi, 333 pp., bound, £ 33.20.—ISBN 0-471-87639-9

Professor *Wentrup*'s book provides a delightful and authoritative survey of the chemistry of neutral organic reaction intermediates. After a lucid presentation of basic notions concerning reaction kinetics, thermochemistry, and frontier MO theory in Chapter 1, the author discusses the various classes of highly reactive molecules in a very readable fashion: radicals in Chapter 2, biradicals in Chapter 3, carbenes and nitrenes in Chapter 4, strained ring compounds in Chapter 5, and cyclobutadienes in Chapter 6. The section on radicals, which includes an introduction to the use of ESR and CIDNP, and the section on the chemistry of carbenes and nitrenes, which is especially well done, are about three times the length of the others. Throughout, the emphasis is on chemical reactivity rather than the details of matrix-isolation or transient spectroscopy. Indeed, some of the reactive intermediates have only been characterized by trapping reactions so far. Each chapter concludes with a useful set of problems, including information permitting the reader to consult the original literature to check the answers.

The text contains a number of useful tables and up-to-date references. Those given in Chapter 1 are primarily to monographs and reviews, those given in Chapters 2–6 are mostly to original literature. They number from about fifty to well over two hundred per chapter. References to specialized monographs, at least one of which exists for every chapter, are also provided and will be useful to readers seeking in-depth information.

In spite of its general excellence, the book does contain a few errors. Some are trivial and barely worth mentioning, such as "ΔH^0(subl) for styrene" on p. 5, which should read "for stilbene", or the presence of charge on formula **161** on p. 113, which is not compatible with the rest of the equation, as well as the overabundance of hyphens, the only clue which gives away the author's continental background (as in "in the gas-phase").

A few other errors are more likely to mislead a novice. The equation for a_{N_i} on p. 38 does not make it clear that spin densities on the neighboring atoms as well as that on the atom i need to be considered; on p. 88 one might get the impression that a more exothermic reaction is always faster; on p. 110 the relation of LUMO energies to electron affinities as determined from electron transmission spectroscopy and electron photodetachment spectroscopy could have been included in addition to the mention of UV spectroscopy (whose use for the determination of LUMO energies is not straightforward); on p. 128 and 129 transition states are referred to as maxima rather than saddle points on surfaces; on p. 163 S_1 is a singly excited and S_2 a doubly excited configuration; the arguments offered to account for the inaccessibility of the cyclobutadiene dianion on p. 312 could be applied equally well to the easily accessible cyclooctatetratene dianion.

It should also be noted that the correlation energy of two electrons is not the energy required to bring them into the same orbital (p. 163, 176), that the "heavy atom effect" normally does not refer to the mass of the collision partner in collision-induced intersystem crossing (p. 183), that the internal bond of a propellane does not tend to have a zero electron density (p. 299), and that a triplet ground state is not expected for square cyclobutadiene (p. 310, 316; cf. dynamic spin polarization). Finally, although the occurrence of rapid tunneling between the two rectangular forms of cyclobutadiene may eventually indeed be excluded by photoorientation results as claimed on p. 319, our experiments are still underway and until the final verdict is in, a conclusion is premature (Ref. 34c does not exist).

All of the shortcomings I noted above are of a theoretical or physicochemical nature and somewhat peripheral to the main subject of the book, which is treated in a very nice manner. For those interested in the preparation and chemical properties of the uncharged reactive interme-

diates of organic chemistry, the book is to be recommended very highly indeed. I plan to use it in advanced undergraduate and graduate teaching of organic chemistry.

Josef Michl [NB 697 IE]

Mammalian Semiochemistry. The Investigation of Chemical Signals Between Mammals. By *E. S. Albone*. Wiley, Chichester 1984. xii, 360 pp., hardback, £ 29.50.—ISBN 0-471-10253-9

It has really been known for a very long time that there are signal agents (semiomones) that affect the behavior of mammals. Yet natural product chemists and biochemists were initially more interested in insect pheromones, which are perhaps of greater economic significance. *Albone*'s excellent study shows how the unknown and often still mysterious world of signal agents has only recently begun to be investigated with the modern instrumental analytical techniques of natural product chemistry. A distinction is made between substances used for communication by mammals with one another and those used by mammals to communicate with other species in their environment (allelochemicals).

The second chapter of the book shows comprehensively, e.g. in the description of vapor analysis, the advances that have been made and the progress that new techniques will enable in the scientific investigation of the chemical ecology of mammals. It quickly becomes clear how complex is the chemistry of an emotionally charged remark like "he's in bad odor with me" when a list of 135 substances in human perspiration is presented. Not only hydrocarbons—unsaturated and branched—alcohols, ketones, acids, esters, aromatics and heterocycles were identified, but also compounds containing sulfur and even chlorine, such as dichlorobutane. When *Albone* discusses the semiomones of apes, elephants and predators, we can see that man is "only" a mammal, since we find more or less the same chemistry every time. The organs for producing and storing allomones give the author the opportunity to extend the treatment to cover allelochemicals. The significance of the skin as a particularly environmentally sensitive organ is indicated and reference is made to all glands that produce odors and, above all, to the urine. It's "imprinting power", even that of the less volatile components, is admirably discussed.

In the final chapter *G. Shirley* deals, briefly but very informatively, with the mammalian olfactory system, so restricted compared with that of insects. The author includes a discussion of the manner of information transfer in the olfactory nerves.

In every regard, *Albone*'s book is a successful presentation of an area of natural product chemistry whose significance is steadily increasing. It is to be hoped that the book will find a wide readership amongst students, teachers, and those engaged in research.

Oligonucleotide Synthesis. A Practical Approach. Edited by *M. J. Gait*. IRL Press, Oxford 1984. 232 pp., stitched, £ 11.00.—ISBN 0-904147-74-6

This book provides a concentrated introduction to oligonucleotide synthesis. Modern methods of DNA synthesis and analysis are introduced by competent authors in individual chapters. The following topics are comprehensively described: the preparation of protected synthetic units, solid phase synthesis by the phosphate triester and the phosphite triester methods, the purification of synthetic oligonucleotides by HPLC and polyacrylamide gel electrophoresis and sequencing by the mobility shift and *Maxam-Gilbert* methods. These are supplemented by chapters on newer methods for the synthesis of shorter oligoribonucleotide sequences and the interesting enzymatic synthesis of oligoribonucleotides. Each chapter contains a comprehensive introduction followed by a detailed experimental section which also supplies suggestions on obtaining reagents and equipment. The book scarcely offers anything new to the experienced nucleotide chemist but is an excellent introduction for those who are looking for the quickest possible experimental access to this class of natural products. An appendix provides such practical directions as are necessary for oligonucleotide synthesis by those with little chemical experience, e.g. the packing of silica gel columns, TLC on silica gel, distillation at atmospheric pressure and in vacuo and the packing of HPLC columns. Here the book is clearly intended for those who have only studied chemistry as an ancillary subject. However, it is questionable whether the "fundamental chemical techniques" presented in this book would equip, say, a biochemist or a physician sufficiently to carry out manual oligonucleotide synthesis. For those using a DNA synthesizer, however, it could supply the necessary chemical background information. The book can be recommended to all those who need a modern, straightforward introduction to oligonucleotide synthesis.

Adolf von Baeyer's Scientific Achievements — a Legacy**

By Rolf Huisgen*

> „Ich halte Lehre und Studium der historischen Entwicklung der Wissenschaft für unentbehrlich ... Unsere Lehrbücher versagen darin."
>
> *Richard Willstätter*

The history of chemistry has not gained any additional prominence in our curriculum since the time *Richard Willstätter* made this statement in his memoirs some 45 years ago. Whether this is due to an inadequacy of presentation or to a lack of interest on the side of the students is a question unlikely to lead to a fruitful discussion. Textbooks tend to convey a false impression of chemistry to the student: namely that of a completed edifice, where sober facts are governed and ordered by fundamental principles. Only insiders are aware of the forging force personalities had on this well-established order. *Emil Fischer* commented as follows along this line:

> "The sciences are not abstract constructions, but rather the results of human endeavor; they are closely connected with the personalities and the fates of the dedicated researchers who developed them."

Fig. 1. *Adolf von Baeyer* monument in Munich (*H. Hahn*, 1915).

1. The Setting

The conceptual evolution of chemistry during the first half of the last century could be termed "genesis of land and sea from chaos." Most historians commit a serious error in singling out only a few eminent personalities as participants in this intellectual struggle. "Time blots out small merit while fattening big glory", as the French writer *Henri de Montherlant* phrased the injustice.

In 1873, *Hermann Kopp*, a student of *Liebig*, retraced "The Development of Chemistry in the Recent Past",[2]

i.e., from 1780–1860, in an 850-page book. I quote from his epilog:

> "What comes as completely natural to the young generation, acquired almost playfully, was assembled through most painstaking efforts of preceding generations to form a set of lasting truths. On the other hand, what was welcomed as an important and seemingly unshakable revelation in one epoch, was often discarded as fallacy by the next."

The development was complicated by the fact that chemists did not focus on simple compounds first and leave the more complex substances to be tackled later. Toxins, medicines, and dyes aroused human curiosity quite early. In 1805 *Friedrich Sertürner* isolated morphine from opium and described it as "one of the strangest substances, bearing some resemblance with ammonia."[3] Several decades were to pass before the simple alkylamines were discovered. Illustrating the road from the complicated to the simple once again, quinoline was first obtained by treating quinine or strychnine with molten alkali; later quinoline was found in coal tar by the ton.

Moreover, the reliability of experimental observation had to reach a higher level. For example, "ethyl hydrogen" and "dimethyl" were supposed to be different compounds until *Carl Schorlemmer*[4] proved them to be identical in 1864.

These were the scientific grounds on which one of the most successful architects of organic chemistry made his appearance, namely *Adolf von Baeyer*. His monument (Fig. 1), created by *Hermann Hahn*, will continue to remind oncoming generations of his achievements.

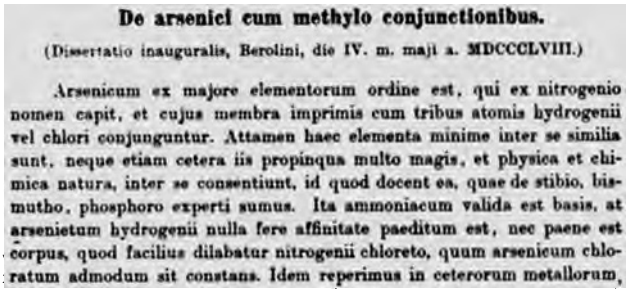
2. A Scientist's Life

One hundred and fifty years ago, in 1835, *Adolf Baeyer* was born in Berlin (Fig. 2), the son of a Prussian general staff officer and geodesist *Johann Jakob Baeyer*. His mother was a descendant of the respected Jewish family *Hitzig*. Among the frequent visitors to the *Hitzig* household were *E. T. A. Hoffmann*, *Emanuel Geibel* and *Theodor Fontane*. The poet *Adalbert von Chamisso* was *Adolf Baeyer*'s godfather.[5] However, at the age of 70, *Baeyer* confessed in his memoirs:[6]

> "I rejected all these literary influences completely, and, even as a small boy, was only interested in the phenomena of nature."

Adolf Baeyer was precocious. As a nine-year-old he began to experiment using *Stöckhardt*'s "Schule der Chemie." In a speech on the history of the indigo synthesis,[7] presented during a ceremony in 1900, he commented on this period as follows:

> "I shall never forget the feeling of delight when I held in my hands a chunk of indigo which I had purchased in the pharmacy for a 'Two-Thaler' on my 13th birthday. With awe I sniffed the perfume of the *o*-nitrophenol while following the instructions of *Wöhler's* 'Grundriss der organischen Chemie' to convert the dye into isatin."



For three semesters *Baeyer* took courses in mathematics and physics at Berlin. After his obligatory military service, he switched to chemistry, and moved to Heidelberg. Even as early as his second semester, he undertook a small kinetic investigation assigned to him by *Robert Bunsen*.

Baeyer's work on his Ph. D. Thesis was carried out in the laboratory of *August Kekulé* who was a lecturer at the University of Heidelberg. *Baeyer*'s research topic, concerning organic arsenicals, originated from *Bunsen*'s field of interest. In 1858, at the age of 22, *Baeyer* submitted his thesis in Latin (Fig. 3) and obtained his degree from the University of Berlin.

Much later, in 1897, *Baeyer* participated in establishing the "Chemische Verbandsexamen". According to this new set of rules, the votaries of chemistry were no longer al-

Fig. 2. A glance at *A. von Baeyer*'s curriculum vitae.

De arsenici cum methylo conjunctionibus.

(Dissertatio inauguralis, Berolini, die IV. m. maji a. MDCCCLVIII.)

Arsenicum ex majore elementorum ordine est, qui ex nitrogenio nomen capit, et cujus membra imprimis cum tribus atomis hydrogenii vel chlori conjunguntur. Attamen haec elementa minime inter se similia sunt, neque etiam cetera iis propinqua multo magis, et physica et chimica natura, inter se consentiunt, id quod docent ea, quae de stibio, bismutho, phosphoro experti sumus. Ita ammoniacum valida est basis, at arsenietum hydrogenii nulla fere affinitate paeditum est, nec paene est corpus, quod facilius dilabatur nitrogenii chloreto, quum arsenicum chloratum admodum sit constans. Idem reperimus in ceterorum metallorum,

Fig. 3. Excerpt from *A. Baeyer*'s dissertation, University of Berlin, 1858.

lowed to set their sails for research after only one semester of formal training.

When *Kekulé* received a professorship at Gent (Belgium), *Baeyer* followed him to explore the chemistry of uric acid. From there he returned to his hometown in 1860. In July he sent the following message to *Kekulé*:

> "On July 4 I presented a lecture in Latin for my 'habilitation', and since then I am a Privatdozent in full splendor."[*]

Since at that time the University of Berlin did not even have a chemical laboratory, *Baeyer* considered himself fortunate to be entrusted with a brand-new lecturer's post at the Gewerbeinstitut, i.e., an institute for vocational training which later evolved into the Technische Hochschule Charlottenburg.

The majority of research projects which we associate with *Baeyer* were launched during the twelve prolific years in Berlin. The first collaborators joined *Baeyer: Carl Graebe* and *Carl Liebermann* elucidated the structure of alizarin, the dye prepared from the madder root; its synthesis was of eminent importance for the young dye-producing industry. *Baeyer*'s contact with *Heinrich Caro*, who

[*] Part of the correspondence between *A. von Baeyer* and *A. Kekulé* can be found in the bequest of *A. Kekulé* at the Institute of Organic Chemistry, TH Darmstadt (FRG).

headed the research on dyes at the Badische Anilin- und Sodafabrik, developed into a friendship that lasted for decades.

In Berlin, *Adolf Baeyer* married *Lida Bendemann* (Fig. 4), and fathered a daughter and three sons.

August Wilhelm Hofmann and *Adolf Baeyer* played a prominent role in founding the Deutsche Chemische Gesellschaft.[8] *Baeyer* inaugurated the constituent assembly in 1867 and *Hofmann* was elected its first president. In 1868 the journal "Berichte" was established; an article by *Baeyer* on the reduction of indigo blue[9] was the first paper to be published in this journal.

Baeyer's appointment as professor at Strassburg in 1872 reflects political events: the victory of 1870/71 (Franco-German war) and the foundation of the Deutsche Reich.

Fig. 5. *A. Baeyer* in 1872.

Emil Fischer and his cousin *Otto Fischer* joined *Baeyer* as his students. In Strassburg, just as in Berlin, *Baeyer* was immediately confronted with the necessity of building a laboratory. But as soon as it was completed, *Baeyer* was asked to succeed *Justus von Liebig*, who had died in 1873, at the University of Munich.

Fig. 6. *Liebig's* auditorium and official residence in Munich around 1860 [10].

Setting up new buildings became a routine for *Baeyer*. During *Liebig*'s era, chemistry in Munich was endowed with an auditorium (Fig. 6) and research facilities, but lacked laboratories for the training of students. *Liebig*, during his years in Munich, had given priority to promot-

Fig. 7. *Baeyer's* laboratory in Munich, 1877–1906 [10].

ing chemistry and its applications to medicine and agriculture in word and print.

The only old part which was integrated into the large new building (Fig. 7) designed by *Baeyer* was *Liebig's* auditorium. Moreover, the professor's official residence was replaced by a new, almost palatial structure. When the house was taken over in 1915 by *Willstätter,* who had each of the three floors equipped with a bathroom, *Baeyer* commented with indignation:

> "Sir, you are converting my house into a public bath."

Baeyer was active in Munich from his 40th to his 80th year, finishing old projects and tackling new problems. Young chemists from all over the world crowded into *Baeyer*'s laboratory, which was one of the important centers of chemistry, then a still juvenile science. The master's scientific achievements were acknowledged with prestigious awards, some of which are recorded in Figure 2.

It appears that the art of photography in its early years singled out group-portraits as a favorite theme. From Figure 8, looking at the caps, we might deduce that heating was deficient in the winter of 1877/78. To the left of *Baeyer* we see *Jacob Volhard* who taught analytical chemistry; to the right the 25-year-old *Emil Fischer*, equipped with a prominent chapeau and striking self-confidence, having obtained his Ph.D. in Strassburg three years earlier.

3. A Brief Survey of Baeyer's Achievements

Baeyer's scientific opus covers an unprecedented range (Fig. 9). His contributions may be viewed as weighty blocks which later served as a foundation for the systematic development of numerous classes of compounds. The first two areas listed were early fields of activity to which *Baeyer* was drawn by chance. In terms of popularity and industrial importance, the leading position among his scientific ventures is clearly held by indigo, the king of the natural dyes.

Baeyer succeeded in synthesizing indigo in 1883, even before he was completely certain about its structure. A letter, dated May 1878, informs *H. Caro* that the synthesis of isatin had been accomplished (Fig. 10).

Distillation over zinc dust, a procedure introduced by *Baeyer* in 1866, was used for the conversion of oxindole, a degradation product of indigo, into its parent compound, indole;[11] the nature of this aromatic heterocycle was established in 1870.[12] Studies on related heteroaromatic compounds served as supplements. Take any of the familiar formulae of pyrrole, furan, furfural, quinoline, and cinnoline—they all originated from *Baeyer*.[12–15]

Fig. 8. Photograph of the group in the chemical laboratory of the Bavarian Academy of Sciences in the winter of 1877/78; laboratory of combustion analysis.

Fig. 9. *Baeyer*'s areas of research and publications.

On the occasion of *Baeyer*'s 70th birthday in 1905, his former co-workers arranged for a reprinting of all his publications; the master grouped them as indicated in Figure 9 and added "Erinnerungen aus meinem Leben".[6]

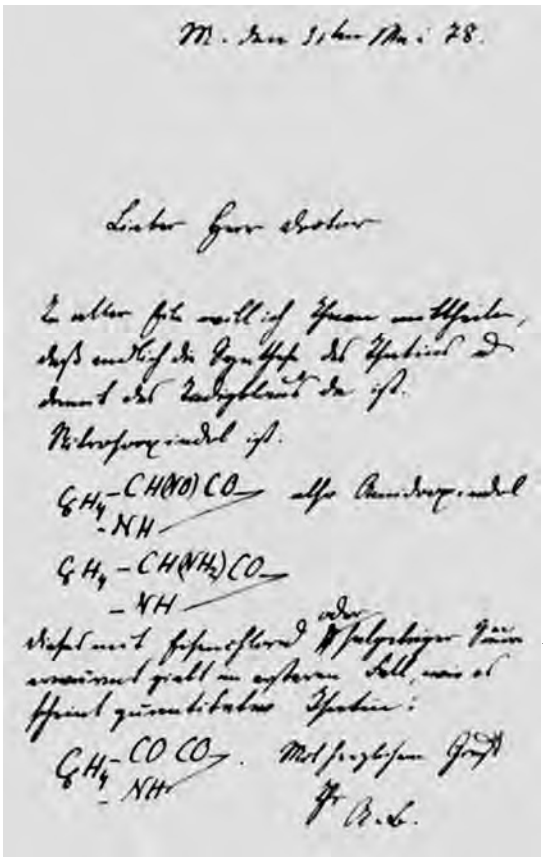

Fig. 10. *Baeyer*'s letter to *H. Caro*, 1878. [*]

The condensation of aldehydes and ketones with aromatic compounds—*Baeyer*'s serial title was "Über Wasserentziehung und Kondensation"—dealt with the linkage of two aromatic nuclei by a methylene function and was studied extensively. On allowing phenol to react with formaldehyde in 1872, *Baeyer* obtained a colorless resin[16] which he promptly discarded. This was the era of crystallizable and distillable substances; the epoch of macromolecular compounds was still to come. In 1909, the first patents on phenol-formaldehyde resins were issued to *L. H. Baekeland*. The reaction of chloral with chlorobenzene—one of a plethora of condensations—was explored by *Baeyer*'s student *O. Zeidler* in 1874.[17] The product with the acronym DDT was to trigger the development of highly active contact insecticides 70 years later.

That phthalic anhydride, like a ketone, was capable of condensing with aromatic compounds, led *Baeyer* to the discovery of the phthaleins, a prominent class of synthetic dyes.[18] Since all of *Baeyer*'s publications present information in a highly condensed form, the number of pages indicates the intensity of labor involved. From that point of view, indigo is surpassed by the phthaleins. Following this line, *Emil Fischer* centered his Ph.D. Thesis[19] on the chemistry of fluorescein.

If we measure intensity of research by the scale just mentioned, the "Chemie hydroaromatischer Verbindungen, Abbau der Mellithsäure und Konstitution des Benzols" would head the list. The field of aromatic nitroso compounds was developed by *Baeyer* from scratch, initially together with *H. Caro*.[20]

Under the heading of "Dibenzalaceton und Triphenylmethan" one finds a cache of fundamental insights into the basicity of carbon and the properties of 'carbonium salts'. *Baeyer* and *Villiger*[21] compared triphenylmethyl with the metal aluminum:

[*] *Baeyer*'s correspondence with *H. Caro* is kept in a collection at the Deutsches Museum, Munich. The author is indebted to Dr. *Otto Krätz* for his kind cooperation.

"Aluminum hydroxide does not show alkaline reaction, but yields an authentic salt when combined with sulfuric acid. Triphenylcarbinol is not a base; nevertheless it is converted to a salt by sulfuric acid."

At an age of well over 60, *Baeyer* embarked upon the investigation of terpenes, peroxides, and oxonium salts; the latter were described as derivatives of quadrivalent oxygen.

Two papers on nomenclature conclude the list of Figure 9. Who of us nowadays is aware that terms such as "carboxyl" or "carbonium salt" as well as the familiar bicyclo nomenclature originated from *Baeyer*?[22]

Let us focus on three of *Baeyer*'s sixteen fields of interest (Fig. 9), in order to illustrate a few sections of the conceptual background of our science. We will start with his contributions to the chemistry of uric acid. *Baeyer* himself regarded this work as the last phase of his apprenticeship.

4. On the Uric Acid Group

In 1838 *Friedrich Wöhler* und *Justus Liebig* published a paper entitled "Untersuchungen über die Harnsäure".[23]

"No other substance in organic chemistry attracts the attention of the physiologist and chemist to a higher degree than uric acid."

Uric acid was subjected to transformations and degradations. The resulting network of relationships between the products involved mere unknowns, until finally mesoxalic acid, oxalic acid, and urea established a bridge to simple compounds. The acids were mostly formulated as anhydrides (Fig. 11). The terms "equivalent", "atom", and "molecule" were not consistently differentiated. Moreover, all molecular formulae appeared in doubled proportions to those which later turned out to be correct. How did this come about? *Jöns Jacob Berzelius* believed that the biatomic nature of the molecules of oxygen, hydrogen, and nitrogen was preserved in their compounds; he postulated that carbon atoms occurred in pairs as well. For *Berzelius*, carbonic acid was C_2O_4.

Charles Gerhardt recognized this error in 1843, but nobody believed him. It was only at the legendary Congress

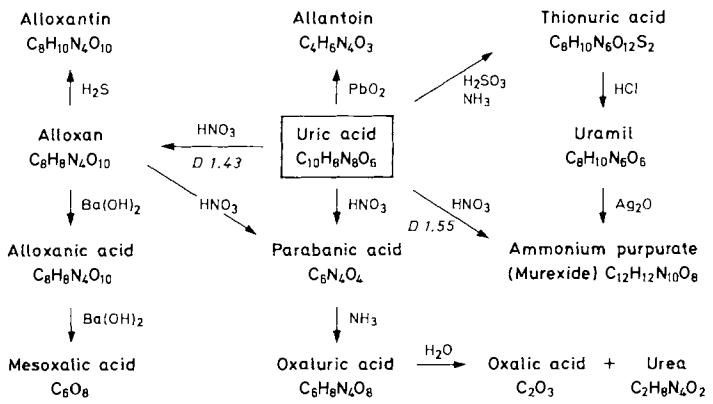

Fig. 11. Degradation scheme of uric acid according to *Wöhler* and *Liebig* [23].

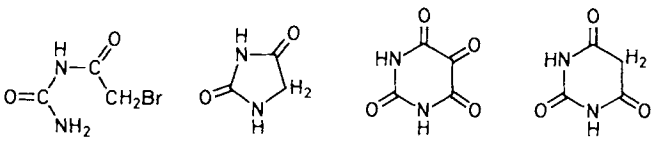
of 1860 in Karlsruhe that *Stanislao Cannizzaro* persuaded his contemporaries to cut the molecular formulae in half and to double the atomic weights.

In 1861, a short paper by *Adolf Baeyer* dealt with the conversion of allantoin and alloxanic acid to hydantoin by hydrogen iodide.[24] The endearing description of hydantoin (Fig. 12) indicates that fear of chemicals had not yet surged to the mass hysteria of today.

Das Hydantoïn scheint das Glied einer Reihe von Reductionsproducten der Parabansäure zu sein :



Parabansäure	$C_3H_2O_3N_2$
Leucotursäure	$C_3H_4O_3N_2 + C_3H_2O_3N_2$
Allanturs̈äure	$C_3H_4O_3N_2$
Hydantoïn	$C_3H_4O_2N_2$.

Diese Substanz krystallisirt in farblosen Krystallen, die leicht in Wasser löslich sind. Sie schmeckt schwach süfs und kracht etwas zwischen den Zähnen.

Fig. 12. From a publication by *Baeyer* on hydantoin [24].

What is the meaning of the "barred" symbols of elements in Figure 12? It is *Berzelius*' representation for double atoms, but only C and O are so designated, no longer H and N. In *Baeyer*'s next paper—one year later—the double atom spook had finally disappeared and a simple footnote declared: H=1, O=16, C=12.[25]

In 1864, *Baeyer* converted *N*-bromoacetylurea (**1**) by reaction with ammonia into hydantoin (**2**), which was regarded as glycolic acid ureide.[26] Does this mean that an underlying ring structure had been recognized? No, the idea of a cyclic arrangement of atoms in a molecule had not yet been conceived.

The first full paper on uric acid was published in the "Annalen der Chemie und Pharmazie" in 1863.[27] Its introduction disclosed an imaginative thought:

"It will become obvious that the material can be related in a simple way to the substance $N_2C_4O_3H_4$, which I will name barbituric acid, and that the problem of the constitution of uric acid can be reduced to an investigation of this substance."

Barbituric acid was still a phantom—but a phantom with a name. As in this case, *Baeyer* usually did not explain the motives for his nomenclature. Is there a "Barbara" involved somewhere along the line?

The preparation of barbituric acid from alloxan required the reduction of a carbonyl to a methylene group. Lacking a direct method, *Baeyer* elaborated a multi-step sequence with violuric acid as an intermediate;[26,27] this name was derived from the blue-violet alkali salt. In 1864, barbituric

Hiernach unterliegt es keinem Zweifel, dafs die Barbitursäure ein Amid der Kohlensäure und der Malonsäure, d. h. Malonylharnstoff ist, und es wird ihre Zersetzung durch folgende Gleichung erklärt:

$$N_2C_2H_4O_3 + 3H_2O = C_3H_4O_4 + CO_2 + 2NH_3$$

Barbitursäure — Malonsäure.

Dieses Resultat ist besonders deswegen von Interesse, weil, wie wir gesehen haben, die Barbitursäure den directen Ausgangspunkt für die Darstellung aller zur Alloxangruppe gehörigen Derivate bildet und die Constitution der letzteren somit auch nachgewiesen ist.

Fig. 13. An excerpt from *Baeyer*'s publication on the chemistry of barbituric acid [26].

acid (**4**) was born. *Baeyer* observed its alkaline hydrolysis to malonic acid, carbon dioxide, and ammonia.[26] Figure 13 shows his conclusion.

The formulae of barbituric acid and malonic acid differ from today's versions. *Baeyer* used the notation based on the "theory of types" which assembles a molecule from groups of atoms which remain unchanged or are replaced en bloc during chemical reactions.

In our time, chemical structures are first encountered in school; communicating by means of these formulae becomes as easy as using one's mother tongue. We find it hard to imagine how scientists of the past were able to exchange their insights by means of "type formulae".

Fig. 14. *August Kekulé* in 1857.

In 1864—when *Baeyer* published an article on barbituric acid—*Kekulé*'s structure theory[28] was six years old. *Kekulé* (Fig. 14) recognized that carbon is "four-atomic" and

> "that carbon atoms bind each other whereby part of the affinity of one is compensated by the same part of affinity of the other."

Why did *Baeyer* not write structural formulae? *Kekulé* himself avoided them, applying the notation of the "theory of types" instead; he justified this choice in his textbook:[29]

> "because the complete disintegration of radicals furnishes formulae of such a complexity that a clear overview is lost."

A thorny path led to current chemical notation (Fig. 15). *Kekulé* expressed the four valences of the carbon atom by a sequence of four spheres;[30] contemporaries disrespectfully termed these "sausage formulae". *Archibald Scott Couper* is usually regarded as being the father of the "valence line";[31] his fuzzy notation, however, makes me hesitate to accept this attribution. The much clearer formulae of the physicist *Josef Loschmidt* did not find the recognition they deserved, since they were not published officially. Notations similar to modern ones were adopted no earlier than the late 1860s.

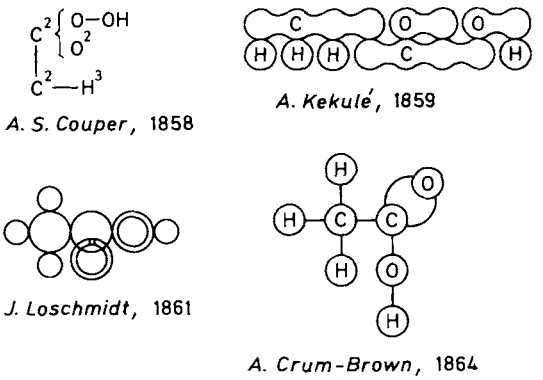


Fig. 15. Evolution of the structural formula of acetic acid.

At the age of 29, *Baeyer* turned to new hunting-grounds without having clarified the structure of uric acid. He considered the formula to be that of a cyanamido-barbituric acid;[27] *Baeyer*'s type-theoretical notation is translated into a structural formula in Figure 16. In 1868, i.e., three years after *Kekulé*'s benzene formula, *Adolf Strecker*[32] proposed a cyclic structure which borrowed the cyanamido group from *Baeyer*'s formula. By contrast, *Hermann Kolbe*'s proposal of a tartronic acid bis-cyanamide[33] was a step backward. Even in 1878, *Kolbe* dismissed the structure theory; instead, he complained about "the fantasy of the so-called chain theory and the heresy of the benzene ring".[34]

In 1875, *L. Medicus* brilliantly deduced the correct formula of uric acid[35] (Fig. 16) which was confirmed in an elegant synthesis by *Behrend* and *Roosen*[36] in 1889.

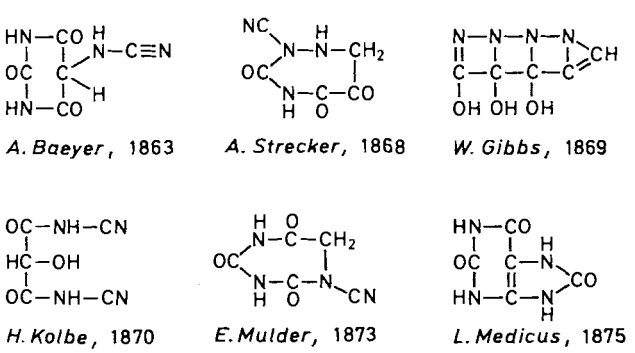

Fig. 16. Development of the formula of uric acid.

Let us branch off for a short interlude to discuss *Baeyer*'s experimental methods. Anecdotes reveal the simplicity of his lab equipment. Thus, *Baeyer* proudly told the visiting *Emil Fischer* of a marvelous new apparatus; it turned out to be a test-tube fixed on a support over a Bunsen burner.

Fig. 17. *A. Baeyer*, 1907 [10].

A photograph of the 72-year-old (Fig. 17), as well as reports of his associates in this later period of his career contributed to *Baeyer*'s reputation as a master of the test-tube experiment. While the test-tube may have dominated his late years in Munich, it does not pertain to his early activity in Berlin. Thus, the 27-year-old *Baeyer* informed *Kekulé* of the progress of his uric acid studies (Fig. 18):

> "The most painstaking part of the work was devising the preparative methods; however, I can now manufacture all these substances in large quantities, and I am all the more pleased to set to work on the second hundredweight of uric acid, since the first has passed to the fathers (guano ducks probably)."

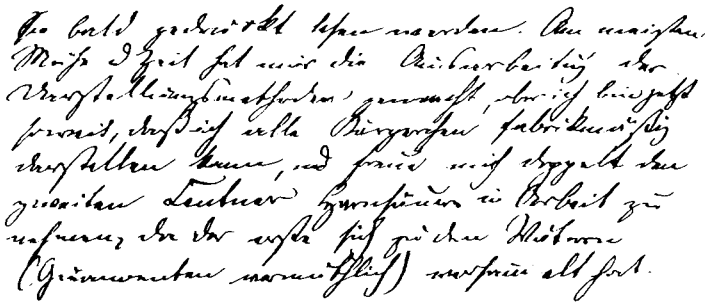

Fig. 18. From *Baeyer*'s letter to *Kekulé*, March 22, 1863.

In another letter to *Kekulé, Baeyer* discussed the constitution of the "pee compounds", as he facetiously labeled them; he then described an efficient method for converting dialuric acid to alloxantin by using sodium amalgam.[37]

> "For that purpose I need large amounts of sodium; I won't buy it here, however, because it is so expensive."

He wanted ten pounds of sodium and asked *Kekulé* to help him get it at a low price. The scale of such experiments clearly surpasses the limitations of the test-tube.

When a *Baeyer* procedure stated "was stirred for 3 hours," it really meant what it said: boring activity for the experimentalist. One morning, during his late years in Munich, the squeaking noise of two stirring devices, driven by a primitive water turbine, was heard in *Baeyer*'s laboratory. The master's anger was assuaged by his collaborator's assurance that regular stirring improves the yield. The next day, *Lida Baeyer* admired the technical progress and mused on how well this gimmick would serve in making mayonnaise.[5]

5. The Chemistry of Hydroaromatic Compounds and the Structure of Benzene

The "Benzolfest", celebrated in 1890 in honor of *August Kekulé* (Fig. 19), was one of the highlights in the history of the German Chemical Society.

> "It is imperative to express thanks and homage to the man who, 25 years ago, enriched the world of chemistry with his theory on the constitution of benzene and the aromatic compounds which proved to be so prolific. The stimulation and success which chemistry and technology owe to this single new concept remain unparalleled. As a consequence, the celebration was not limited to experts, but roused the interest of a far wider public."[38]

Fig. 19. Left: *Adolf von Baeyer*, 1890; right: *August Kekulé*, 1890.

The cyclic formula of benzene was a prerequisite to the systematic development of aromatic chemistry; the consequences for aliphatic chemistry were just as important. *Adolf von Baeyer*, the official speaker, addressed *Kekulé* emphatically:[39]

> "With your theory of benzene, you were the first to conceive the idea that carbon atoms not only can form chains, straight and branched, but also rings."

In 1865 *Kekulé* proposed "sausage formulae" for benzene and toluene (Fig. 20) which, however, only allowed

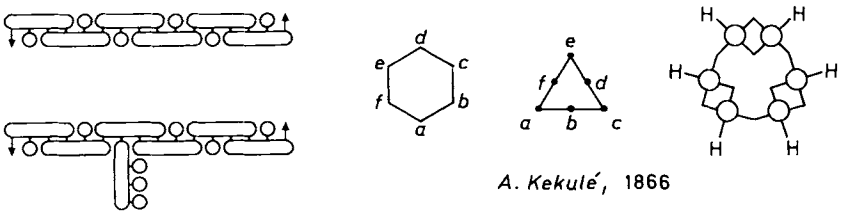

Fig. 20. Development of the formula of benzene.

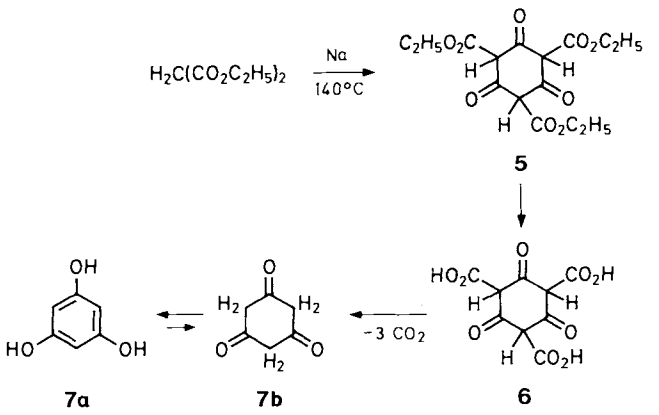
the expert to decipher the alternating sequence of single and double bonds as well as the cyclic structure signaled by the terminal arrows.[40] In the next year, hexagonal and triangular representations—differing in symmetry—were recommended by *Kekulé*.[41] Late in 1866, the symbol depicted on the upper right of Figure 20 appeared in *Kekulé*'s textbook.

This did not completely solve the benzene problem, however; according to *Baeyer*,[39]

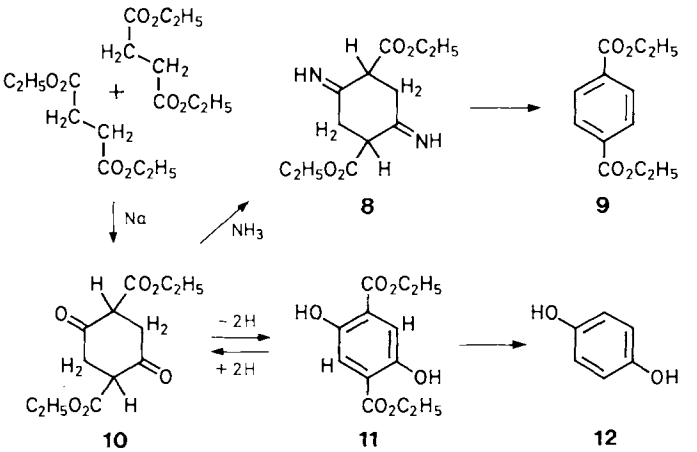
> "benzene behaves in a basically different manner than unsaturated compounds of the fatty acid series."

This difficulty was met by *Claus* with a "diagonal formula", and later by *Ladenburg* with an especially elegant prismatic image. Both notations eliminated a weak point: *Kekulé*'s benzene was expected to give isomeric *o*-disubstitution products. His own remedy was the somewhat adventurous oscillation hypothesis of 1872; the double bonds were not considered to be fixed, but rather to migrate rapidly[42] (Fig. 20).



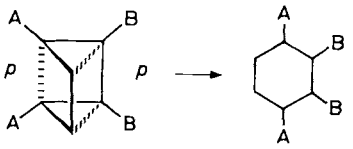
The products of the second and third substitution corresponded to those expected for a regular hexagonal structure of benzene. Many of *Kekulé*'s contemporaries indulged in the fascinating play on the "substitution piano" and in devising methods for locating the positions of the substituents.

Baeyer's concern was the bonding of benzene. He opened his *Kekulé* lecture[39] with the question:



> "... was this theory correct in the first place?"

In 1866 *Baeyer* saw an endorsement of *Kekulé*'s formula in the acid condensation of three molecules of acetone yielding mesitylene; as expected, the elimination of three molecules of water resulted in an alternating sequence of double and single bonds.[43]



Phloroglucinol (**7a**), being a triphenol, can be alkylated three times on the oxygens. On the other hand, *Baeyer* supposed the triketo tautomer **7b** to be responsible for trioxime formation. Ester condensation was reckoned to furnish the triketo form via the tricarboxylic ester **5**. If the triketone **7b** contains a six-membered ring, the same must be true for the aromatic phloroglucinol.[44,45]

The condensation of two moles of diethyl succinate afforded the structurally secured "succinylosuccinic ester" **10**.[46] Removing two H atoms by bromine yielded the dihydroxyterephthalic ester (**11**) which was reconverted to the aliphatic dihydro form **10** by means of zinc and hydrochloric acid.[47] In short, the benzene and the cyclohexane derivatives must share the same carbon skeleton.

Baeyer demonstrated the inconsistency of *Ladenburg*'s prism formula of benzene in an ingenious way.[48] The transformation of prismane **13** to the cyclohexane ring requires the rupture of the three bonds indicated by broken lines. The substituents A define the *p*-relation in prismane;

13 14

the same is true of the two substituents B. Only *one* *p*-relation of prismane can be converted into a 1,4-disubstituted cyclohexane **14**, whereas the other *p*- give rise to 1,2-relations in **14**.

The succinylosuccinic ester **10** contains 1,4-situated ester groups; the same is true for the two keto groups. *Baeyer* proved these relative locations to be retained, since dehydrogenation furnished the diethyl dihydroxyterephthalate (**11**);[47] **10** was converted into **9** in several steps via the bis-imine **8**. The *p*-positions of the substituents in hydroquinone (**12**) and terephthalic ester (**9**) had been secured previously.

Let us go back two decades to *Baeyer*'s first encounter with aromatic compounds. Occasionally, an odd mineral, honeystone, is found in coal deposits; it is the aluminum salt of mellitic acid. *Baeyer* recognized the latter to be benzenehexacarboxylic acid[49] and wrote to his friend *Kekulé* (Fig. 21):

> "Mellitic acid is: $C_6(CO.HO)_6$, a six-basic acid. I am sending you the academy reprint of November. With sodium amalgam it yields $C_6H_6(COHO)_6$; 6-fold carboxylated benzene and 6-fold carboxylated C_6H_{12}, isn't that nice? You might use it for your textbook, the series of aromatic acids is now complete ..."

Nearly 20 years later, *Baeyer* systematically studied the reduction of benzenecarboxylic acids by sodium amalgam in aqueous medium; he expected insight into the bonding. Aromatic hydrocarbons are not reduced by sodium amalgam. Catalytic hydrogenation had not yet been discovered; it was not until 1900 that *Paul Sabatier* converted benzene into cyclohexane by hydrogen on a nickel catalyst.

On reducing terephthalic acid under mild conditions, the $\Delta^{2,5}$-dihydro acid was isolated; hence, hydrogen added to the carboxyl-bearing carbon atoms[50] (Fig. 22). Isomerization to the $\Delta^{1,5}$ acid took place in boiling water, whereas base catalysis afforded the $\Delta^{1,4}$ acid. Only the latter two acids can be reduced further by sodium amalgam. Bromine, hydrogen bromide, potassium hydroxide, and potassium permanganate: this was the entire arsenal of reagents which were applied as probes. What an amazing achievement to firmly establish the structures of the four dihydro- and the two tetrahydroterephthalic acids with so limited a set of reagents! This was the supreme art of logical deduction from a network of experimental results.

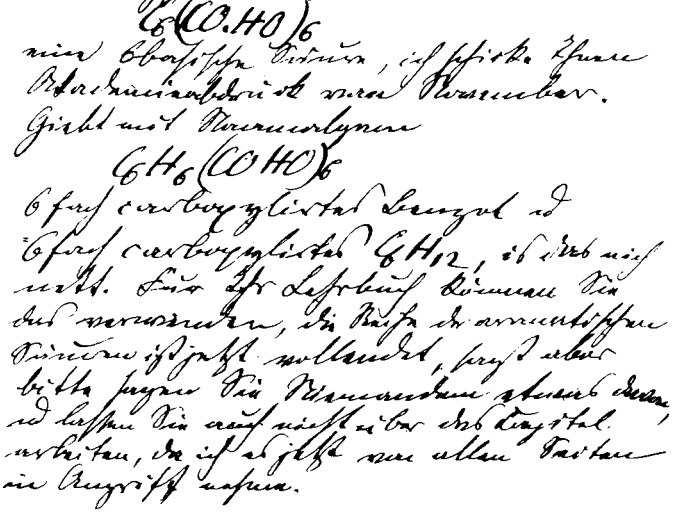


Fig. 21. From *Baeyer*'s letter to *Kekulé*, December 17, 1866.

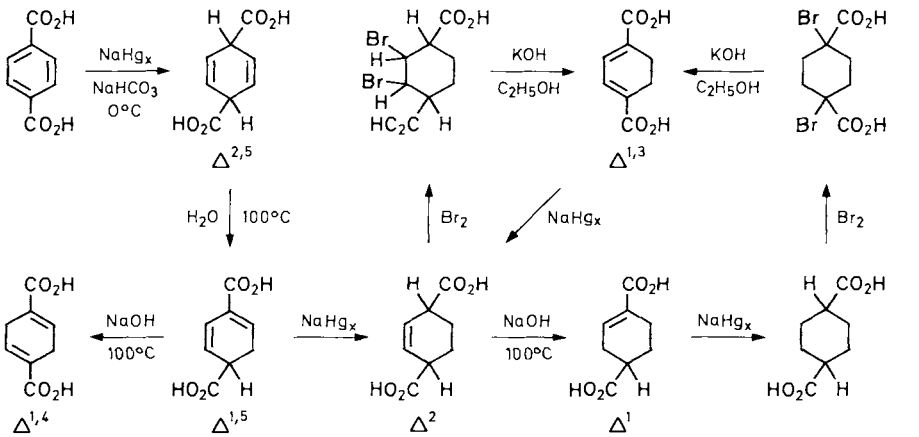
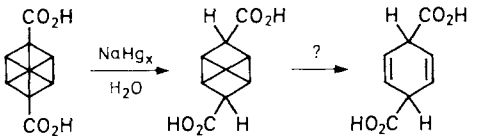
What are the conclusions with respect to the benzene problem? The initial 1,4-addition of hydrogen corresponds to the annihilation of one *p*-bond in the *Claus* formula **15** of terephthalic acid. However, the product, the $\Delta^{2,5}$-dihydro acid **16**, does not contain the two residual *p*-bonds, but rather possesses normal olefinic double bonds instead.[50]

A key observation: The olefinic $\Delta^{1,3}$-dihydro acid **17** added hydrogen at the termini of the conjugated system.[50] Muconic acid, i.e., the *open-chain* butadiene-1,4-dicarboxylic acid, also underwent 1,4-reduction by sodium amalgam in water.[51] Here *Baeyer* prepared the ground for the studies of *Johannes Thiele* who first correctly viewed conjugated double bonds as reactive units.[52] Since *Kekulé*'s





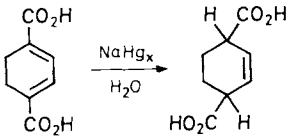


Fig. 22. Stepwise hydrogenation of terephthalic acid by sodium amalgam in water.

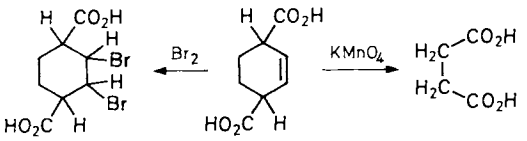
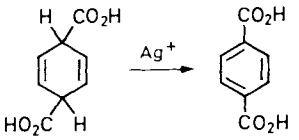


15 16

benzene contains conjugated double bonds as well, *Claus'* assumption of *p*-bonds in benzene was shown to be superfluous.



17

The olefinic reactivity of the partially hydrogenated acids towards bromine and permanganate is illustrated by the behavior of **18**. On the other hand, permanganate—

18

19

and even silver ion—converted the $\Delta^{2,5}$-dihydro acid **19** to terephthalic acid.[50] The aromatic system is energetically favored and tends to be formed easily. *Baeyer*'s comment:[39]

> "To provide an explanation for this discontinuity in the chemical properties upon introduction of the third double bond, is the task set for the theory of benzene."

The benzene anniversary of 1890 offered the opportunity for a resumé:[39]

> "The benzene ring approaches a limiting state which I propose to call the 'ideal benzene': the six CH groups are tied to each other with such extraordinary strength that the ring appears to be completely symmetric and the fourth valence of carbon vanishes from our perception."

Which of the formulae should we favor?

20 21

> "... I propose to describe the ideal benzene by the formula which I have dubbed centric; the arrows indicate the strong pressure directed inwards."

The arrows—*Henry Armstrong* and *Lothar Meyer* proposed the same symbol **20**—suggest the mutual equalization of the six residual valences, whereas the *Kekulé* formula implies a compensation in pairs.

Benzene derivatives are capable of certain addition reactions, e.g., the hydrogenation of benzenecarboxylic acids by sodium amalgam and water as discussed above. The chemistry of naphthalene, anthracene, and phenanthrene presents transitions from aromatic to olefinic reactivity. *Baeyer's* explanation strikes a downright modern note:[39]

> "The limiting states of benzene are represented by the *Kekulé* structure and the centric formula ... The nature of the benzene ring in any derivative may be intermediate between the extremes."

Even today an empirical description of aromatic bonding could hardly be more to the point.

The central valences served *Baeyer* to emphasize the special character of benzene, although their nature remained vague:[53]

> "The present state of knowledge gives us no clue to the passivity of the central valences. Whether this phenomenon ... is caused by an especially high density of the ether in the center of the ring, remains to be seen."

We are amused by the appeal to a vague, but fashionable rationalization, "ether", to account for the benzene mystery. But we need to adjust our view to the times. It was not until 1896 that *Henri Becquerel* discovered natural radioactivity. In 1890 the atom was still regarded as ἄτομος, as indivisible. Nuclei and electron clouds were unheard of. In particular, the nature of chemical bonding forces was still completely obscure. As late as 1900, *Ernst Mach* and *Wilhelm Ostwald*[54] regarded the atomic hypothesis as "univerified", and *Ostwald*'s book "Prinzipien der Chemie"[55] of 1907 got by without mention of atoms.

Adolf Baeyer, who employed molecular models of the ball and stick type, had adopted *van't Hoff*'s concepts of stereochemistry. He isolated the hydrogenated terephthalic acids in "malenoid" and "fumaroid" forms (Fig. 23); the

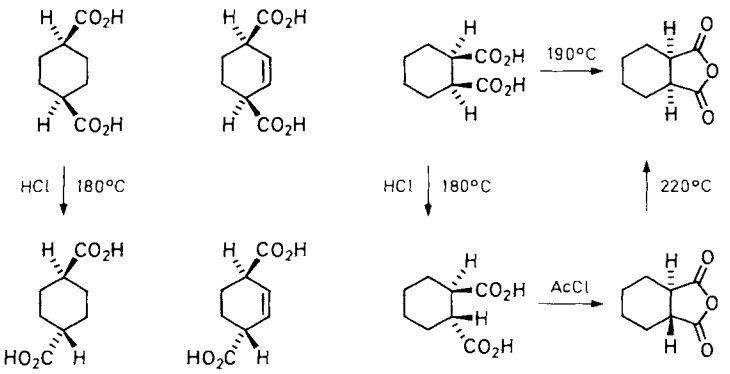


Fig. 23. Geometrical isomerism of hydrogenated benzenedicarboxylic acids; above malenoid forms, below fumaroid forms.

former were more soluble than the latter. Thus, the discovery of *cis,trans* isomerism in ring compounds was *Baeyer*'s accomplishment.[50,53,56-58]

The formation of hexahydrophthalic acid anhydrides turned out to be a valuable criterion.[58] Whereas the *cis* acid afforded the anhydride thermally, the *trans* acid required treatment with acetyl chloride[57] (Fig. 23). In contrast to fumaric acid, *trans*-hexahydrophthalic acid can form an anhydride. With unerring instinct, *Baeyer* attributed this to bond angle variations: 180° for fumaric acid, but less for hexahydrophthalic acid. The greater stability of the *cis* anhydride in comparison to that of the *trans* isomer was accounted for exactly as it is today. The concept of ring strain is *Baeyer*'s achievement.

According to *Baeyer*'s evidence, hydrogenation of phthalic acid likewise occurs at the carboxyl-bearing C-atoms[58] (Fig. 24). Let us focus on a detail. The $\Delta^{3,4}$-dihydrophthalic acid, on oxidation with copper(II) ions or

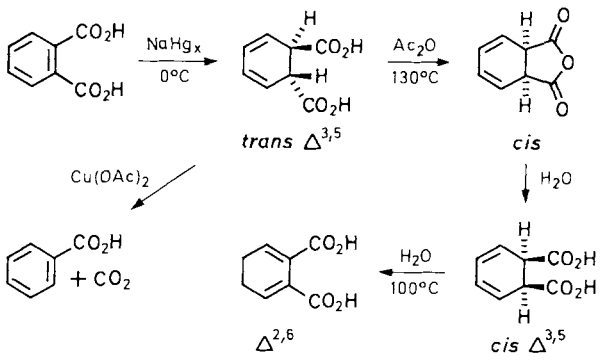

Fig. 24. The chemistry of dihydrophthalic acids.

silver ions, fragmented into benzoic acid and carbon dioxide.[58] *Baeyer*'s propensity to describe chemical behavior in terms of mechanical models turned a somersault here:

> "The elimination of carbon dioxide obviously arises from the jolt imparted to the α-carbon atom—the carrier of the carboxyl—through the abstraction of hydrogen."

The popularity of the mechanical model is easily understood. The mechanical theory of heat, associated with the names of *Clausius, Maxwell,* and *Boltzmann,* celebrated its greatest triumph in the period from 1860 to 1880. *Boltzmann* put the new trend into a nutshell:

> "Today everything is placed on the physico-mechanical loom."

That isophthalic acid does not form an anhydride, was taken by *Baeyer* to be evidence for the rigidity of the benzene nucleus (Fig. 25). In contrast, anhydride formation from *cis*-hexahydroisophthalic acid turned out to be feasible. *Baeyer* and *Villiger* concluded that a ring made up of saturated carbon atoms can be deformed as easily as an open chain.[59]

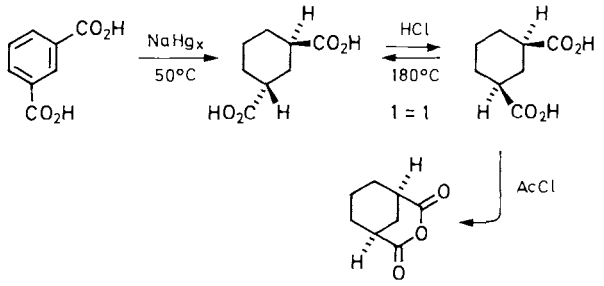

Fig. 25. Stereoisomeric hexahydroisophthalic acids.

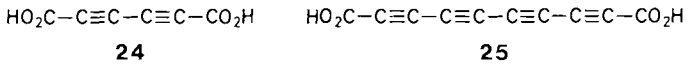
6. The Strain Theory of Carbon Ring Compounds



How did the strain theory of carbon rings evolve? From which sources did *Baeyer* draw his inspiration?

In 1876 *Victor Meyer* pointed out that certain reactions, expected to render 3- or 4-membered rings, took a different course. This "makes the non-existence of such rings at least highly probable."[60]

22 **23**

In 1882 *William Henry Perkin Jr.* came to Munich at the age of 22 in order to work on his thesis under *Baeyer*'s direction. *Perkin* was familiar with *Victor Meyer*'s paper, and personal debates with *V. Meyer, A. Baeyer,* and *E. Fischer* did not dissuade him from his intention to synthesize small carbon rings.[61] Applying the malonic ester synthesis, he actually succeeded in preparing diethyl tetramethylene-1,1-dicarboxylate (**23**) in 1883 and the trimethylene derivative **22** in 1884.[62] However, he observed the striking tendency of the cyclopropane rings to reopen.

24 **25**

26 **27**

Personal experience always tips the balance. *Baeyer* had prepared polyacetylenes, e.g., **24-27**, and complained about their explosive character:[63]

> "Diacetylene silver ... explodes when rubbed between the fingers —even in moist condition."

The decomposition of polyacetylenes produces "common coal". The concurrent evolution of heat indicates the unfavorable valence state of the carbon-carbon triple bond.

Baeyer's now famous "theory of ring closure" was an addendum to the polyacetylene publication.[63] Much later, in 1929, *Perkin* commented on *Baeyer*'s strain theory:[61]

> "This remarkable theory, published in August 1885, occupies only two pages of print and its description always seems to me to be a striking ex-

ample of how much can be said in a very small place."

This strain theory, now a hundred years old, was introduced by *Baeyer* as follows:

> "Whereas chains of 5 or 6 members can be closed easily, considerable difficulties are encountered in trying to do the same with shorter or longer chains. There must be steric reasons for this behavior."

Based on the tetrahedral angle of 109°28′ in methane, the inference was:

> "The direction of the attractive power can be deflected; the result is a strain that increases with growing deflection."

The planar five-membered ring involves hardly any bending at all; on the other hand, the deflection of the bond angles in smaller and larger rings—assumed to be planar as well—generates strain (Fig. 26). *Baeyer* courageously postulated that ethylene is a two-membered ring, the first member of the homologous series of cycloalkanes.

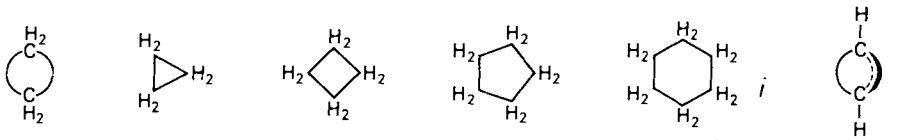


Fig. 26. Bending of the tetrahedral angle, 0.5 (109°28′−α), in carbon rings [63].

> "Dimethylene is indeed the weakest ring, opened by reactions with bromine, hydrogen bromide, or even iodine; trimethylene is forced open by hydrogen bromide, but not by bromine, whereas tetra- and hexamethylene can only be cleaved with difficulty or not at all."

The contributions of *Niels Bohr, G. N. Lewis, W. Heitler,* and *F. London* trace the development which was to lead to the quantum mechanical theory of covalence. In 1930 *Erich Hückel* viewed the CC double bond as a combination of two bonds which differ in the symmetry of their electron distributions and are denoted σ and π.[64] This interpretation proved fruitful. Is it correct? That is an all-too-simplistic question. There are various models allowing a consistent mathematical description. In 1931 *Linus Pauling*[65] declared his preference for the *Baeyer* model of ethylene with its two identical bent bonds, even though the MO treatment affords the same quantum mechanical expression for the two models. In 1958, he listed arguments in favor of the bent-bond concept, concluding:[66]

> "I contend that the σ,π description is less satisfactory than the bent-bond description, that this innovation is only ephemeral, and that the use of the σ,π description will die out before long."

In view of *Baeyer*'s passion for playing with molecular models, it is surprising that he assumed six-membered rings to be planar. In 1890 *H. Sachse* reported that two nonplanar models of cyclohexane—conformations as they were called later—do not require bending of the tetrahedral angle,[67] a discovery which was exploited and extended to larger rings by *E. Mohr*.[68] In 1905 *Baeyer* ruminated on this topic in his "Erinnerungen"[6] as follows:

> "Sachse disagreed ... with my opinion that larger rings are planar. He is certainly right from a mathematical point of view; yet in reality, strangely enough, my theory appears to be correct. The reason is not clear ..."

Let us follow *Baeyer*'s line of thought. If rings with more than six members were free of strain, why should their formation tendency be so low? Only decades later did chemists realize that more variables are involved. Not only angle bending (*Baeyer* strain), but also conformational strain and *van der Waals* repulsion contribute to the energy content of a ring.

According to *Baeyer*'s theory, the cage-like bond system of acetylene (Fig. 26) consists of three bonds, each of which deviates by 70° from the tetrahedral angle. The strain energy is set free in the explosive conversion of polyacetylenes into elementary carbon. *Baeyer* dubbed the latter "black coal" and believed it to be a stable molecular arrangement with numerous single bonds. Neither the graphitic nature of this "black coal" nor even the structure of graphite were known at that time.

7. Epilog

If we are willing to accept the number of *Baeyer*'s publications (Fig. 27) as a measure of his personal energy and productivity, we find a broad maximum from his 30th to his 50th year and a remarkably high level up to his 70th year.

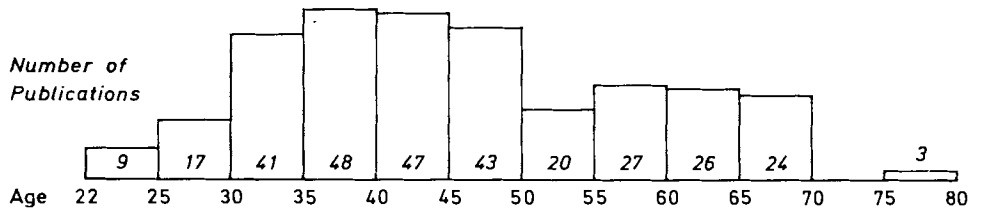

Fig. 27. Number of *Baeyer*'s papers for five-year periods plotted versus age.

Among the chemists to whom *Baeyer* introduced scientific thinking and the art of experimentation were: *G. von Brüning, W. Dieckmann, C. Duisberg, E. Fischer, O. Fischer, P. Friedländer, C. Graebe, E. Hepp, B. Homolka, W. Ipatieff, C. Liebermann, E. ter Meer, V. Meyer, W. A. Noyes, W. H. Perkin jr., H. Rupe, C. Schraube,* and *V. Villiger. Baeyer* supervised only a small group of co-workers; he carried out most of his experimental studies with his own hands.

Much larger is the illustrious group which *Willstätter* referred to as "associates in a wider sense";[69] the selection includes: *E. Bamberger, Th. Curtius, L. Claisen, O. Dimroth, A. Einhorn, M. Gomberg, K. A. Hofmann, A. F. Holleman, W. Koenigs, H. von Pechmann, W. Schlenk, J. Thiele, H. Wieland,* and *R. Willstätter.* These scientists worked in *Baeyer*'s environment, were influenced and inspired by him, and regarded themselves as members of the *Baeyer* School. Thus, *Heinrich Wieland* obtained his Ph.D. with *Johannes Thiele,* and *Alfred Einhorn* guided *Richard Willstätter*'s thesis work. Who can draw the borders of such a scientific school? Beyond doubt, the influence of *Baeyer*'s personality was amazing.

Fig. 28. Bronze bust of *A. von Baeyer* (by *A. von Hildebrand,* 1905).

Some light was shed on the secret of *Baeyer*'s success during the celebration of his 70th birthday. His students and friends presented him with a bronze bust, sculpted by *Adolf von Hildebrand,* who created, inter alia, the Wittelsbach Fountain in Munich. In his subsequent address *Baeyer* mused:[70]

> "The fact that I had such a sizable number of students and received recognition during my professional career is—so I believe—mainly due to my very timely appearance on the scientific stage."

Baeyer carried out the work for his thesis in *Kekulé*'s laboratory. Since it concerned a self-chosen topic, he sometimes claimed to be self-trained. This was not the case. In fact, *Baeyer* was *Kekulé*'s student in the most fundamental sense.

August Kekulé conceived his structural theory in Heidelberg and published it in 1858. It sparked an ignition comparable to that of *Kekulé*'s benzene theory of 1865.

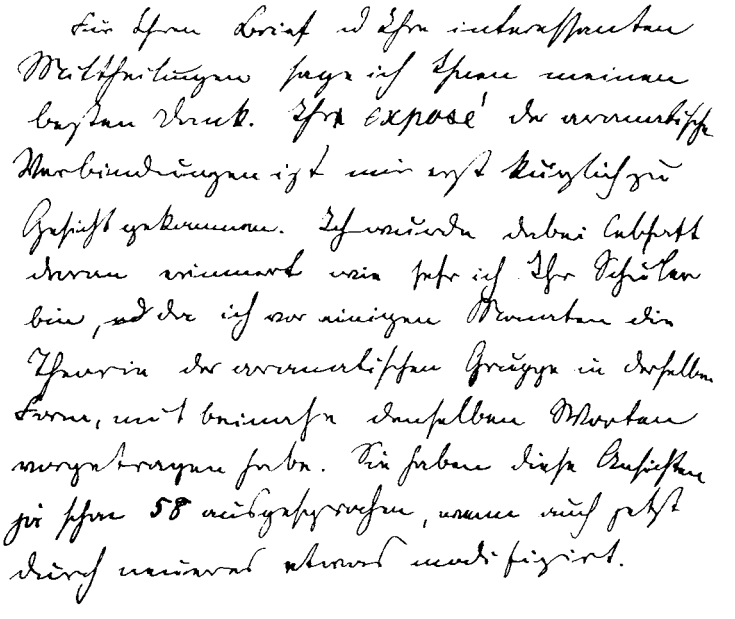

Fig. 29. From *Baeyer*'s letter to *Kekulé*, April 26, 1865.

The intellectual bond between the two scientists was unequivocally expressed in a letter dated April 26, 1865 from *Baeyer* to *Kekulé* (Fig. 29):

> "Your exposé on aromatic compounds has only recently come to my attention. It was a vivid reminder of the extent to which I am your student; my own lecture on the theory of the aromatic group a few months ago followed the same form with almost the same words."

Two more quotations from *Baeyer*'s address[70] characterize *Kekulé* in contrast to his own position.

> "*Kekulé* was not interested in the compounds themselves; his only concern was whether their behavior coincided with his concepts, and this was what he tested."
> "My own role, on the other hand, was that of a miner. I considered it my mission to reapproach nature and to look at the substances themselves, quite the way they are."

The passage of time corrects many a distortion of perspective. In my view the similarities between these two eminent personalities were more pronounced than their differences, and I hope that this opinion has been documented in my account.

Having had the first word, *Richard Willstätter* (Fig. 30) shall also have the last. A grateful student of *Baeyer*'s, he stated:[69]

> "By maintaining a close and personal interchange over many years, and by communicating his beliefs at their earliest stages of budding and maturing, *Kekulé* led his friend and junior of six years to a high level ... So provided with a new type of compass, *Baeyer* was able throughout his career to

orientate himself in the old and new domains of carbon compounds, to master the major roads, and to gain access to many a side trail as well."

Fig. 30. *R. Willstätter*, etching by *Peter Halm*.

The author wishes to express his gratitude to Professor Klaus Hafner, Darmstadt, for the kind permission to quote from the unpublished correspondence of Baeyer and Kekulé. Furthermore, the author thanks his daughters, Helga Huisgen and Professor Birge Zimmermann-Huisgen, for the preparation of the English version. Finally, he is highly indebted to Professor Paul v. R. Schleyer, Erlangen, for a careful revision.

The Concept of Strain in Organic Chemistry

By Kenneth B. Wiberg*

"Die Ringschließung ist offenbar diejenige Erscheinung, welche am meisten über die räumliche Anordnung der Atome Auskunft geben kann. Wenn eine Kette von 5 und 6 Gliedern sich leicht, eine von weniger oder mehr Gliedern sich schwierig oder auch gar nicht schließen läßt, so müssen dafür offenbar räumliche Gründe vorhanden sein. ... Die vier Valenzen des Kohlenstoffatoms wirken in den Richtungen, welche den Mittelpunkt der Kugel mit den Tetraederecken verbinden, und welche miteinander einen Winkel von 109°28′ machen. Die Richtung der Anziehung kann eine Ablenkung erfahren, die jedoch eine mit der Größe der Letzteren wachsende Spannung zur Folge hat." [**] This is the quintessence of the "ring-strain theory" formulated by *Adolf von Baeyer* over one hundred years ago. Although it is today only one facet of the many aspects of strain theory, it has repeatedly stimulated experimental and theoretical chemists. Among the most spectacular of the recent successes in synthetic chemistry are the syntheses of tetra-*tert*-butyltetrahedrane and [1.1.1]propellane. The reasons for the great stability of these two highly strained compounds are completely different. The experimental findings as well as the results of theoretical analysis by means of molecular mechanics and ab initio calculations have contributed decisively to our present state of knowledge of the structure, energy, and reactivity of organic compounds.

1. Introduction

The second half of the nineteenth century was a period of rapid development for the structural theory of organic chemistry. The Karlsruhe conference of 1860 finally established the atomic weights of hydrogen, oxygen, and nitrogen, and led to the general acceptance of the molecular formula of water as H_2O and not HO or H_2O_2. In 1858, *Kekulé* and *Couper* independently proposed that carbon is tetravalent, and shortly thereafter *Crum Brown* proposed a carbon–carbon double bond for ethylene and *Erlenmeyer* proposed a carbon–carbon triple bond for acetylene. In 1865 *Kekulé* suggested that carbon chains could form rings and in 1874 *van't Hoff* and *LeBel* independently proposed that a four-coordinate carbon has a tetrahedral geometry.

As a result of these developments, the structures of a large number of organic compounds were correctly determined, and it was observed that whereas many compounds had five-or six-membered rings, other ring sizes were rarely found. This led *Adolf von Baeyer* in 1885 to propose his strain theory.[1] He correctly deduced that compounds with three- and four-membered rings would be less stable because of the deviation in bond angles from the normal tetrahedral values. His application of this concept to larger rings proved to be incorrect because it was not recognized at that time that these rings would be nonplanar. Nevertheless, strain is present in the medium rings (C_7–C_{12}), although for a reason different from that originally proposed.

Perkin worked in *von Baeyer*'s laboratory at the time the strain theory was being developed, and in 1884 he reported the first directed syntheses of cyclopropane and cyclobutane derivatives.[2] Many years passed before the strain in these compounds could be experimentally determined, but in 1949 and 1950 the heats of combustion of cyclopropane and cyclobutane, respectively, were determined[3] and allowed the calculation of their heats of formation and strain energies. The strain energy is the difference between the observed heat of formation and that expected for a strain-free molecule with the same number of atoms.

The concept of strain has been expanded from *von Baeyer*'s original idea[4] and is now discussed in terms of bond length and bond angle distortions as well as torsional terms and nonbonded interactions. Strain energies have proven to be very valuable quantities with which to examine organic compounds having unusual geometries or intramolecular interactions. They also provide a convenient way in which to examine a major component of the driving force for some reactions. The heats of formation of compounds with different numbers of atoms are difficult to compare directly, but the strain energy factors out the contribution to the energy derived from the number of bonds and atoms present and gives a value which is more easily compared among compounds.

2. Origin of Strain

Steric strain, which results from nonbonded interactions, is present in most compounds. In methane, as with all

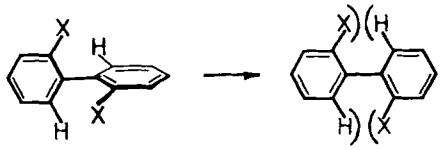
[**] Ring formation is evidently the reaction that can provide the most important information on the spatial arrangement of atoms. Steric reasons should explain the observation that a 5- or 6-membered chain undergoes ready closure, whereas a shorter or longer chain undergoes difficult or no closure.... The four valences of the carbon atom act in the directions that connect the center of a sphere with the corners of a tetrahedron and form angles of 109°28′ with one another. The direction of the attraction can deviate, but this results in increasing strain as the sizes of the latter increase.

compounds, the total energy is made up of contributions from the kinetic (T) and potential (V_1) energies of the electrons, the electron repulsion (V_{12}), and the nuclear repulsion (V_N) [Eq. (a)].

$$V_T = T + V_1 + V_{12} + V_N \qquad (a)$$

The first three of these terms may be considered to be electronic terms, and the equilibrium structure (i.e., that with the lowest value of V_T) will result from a balance between the electronic terms and nuclear repulsion term. For example, a distortion from tetrahedral geometry that maintains one of the C_3 axes leads to a decrease in the electronic energy. This is opposed, however, by a larger increase in V_N.[5] Thus, the tetrahedral geometry of methane results largely from the repulsive interaction between the hydrogen nuclei and is the one that maximizes the distance between hydrogens for a given C–H bond length.

When two of the hydrogens of methane are replaced by methyl groups, forming propane, the C–C–C bond angle is found to be larger than tetrahedral (112°).[6] Clearly, the repulsive interaction between the methyl groups is greater than that between the methylene hydrogens, leading to an increased angle. The repulsion between methyl groups also may be seen in the *syn* and *anti* conformations of *n*-butane:[7] the C–C–C bond angle in the *syn* conformer is considerably larger than that in the more stable *anti* conformer.



In one of the first quantitative studies of nonbonded interactions, *Brown* et al. examined the equilibrium constants for the reaction of tertiary amines with trimethylboron [Eq. (b)].[8]

$$R_3N: + B(CH_3)_3 \rightleftharpoons R_3\overset{\oplus}{N}-\overset{\ominus}{B}(CH_3)_3 \qquad (b)$$

As the size of the alkyl groups attached to nitrogen increased, the equilibrium constant decreased. This was attributed in part to the repulsive interaction between the alkyl groups, which increased as the pyramidal amine was converted into the ammonium salt with smaller C–N–C bond angles, and was termed B (back) strain. The same effect is seen in the increased rate of solvolysis of tertiary alkyl halides having bulky alkyl substituents[9] and in addition to carbonyl groups.[10] The latter reaction is probably the most widely studied example of this general effect, in which the conversion of a trigonal into a tetrahedral center is retarded (or the reverse reaction accelerated) by the increased repulsion of alkyl groups in the sterically more crowded tetrahedral species. The free energy changes for such processes are frequently well correlated by *Taft*'s E_s values, which were derived from the rates of acid-catalyzed hydrolysis of esters, a reaction that exhibits little sensitivity to polar effects.[11]

The problem of quantitatively accounting for steric strain led *Westheimer* and *Mayer*[12] to perform the first calculation of the type that is now referred to as molecular mechanics. They calculated the activation energies for the racemization of *ortho*-substituted, optically active biphenyls. The racemization requires that the molecules pass through a planar activated complex in which the *ortho*-substituents must come close to the *ortho*-hydrogen (or other substituents) on the other ring. By using reasonable

values for the nonbonded interactions, along with force constants derived from IR spectroscopy, they were able to reproduce the observed activation energy. Molecular mechanics has been developed considerably since that time, particularly as a result of the availability of fast computers, and has been applied to a variety of conformational problems and to the dynamics of conformational change.[13] The intramolecular potential functions used in this procedure will be discussed in Section 4.

If we return to propane and consider the hypothetical reaction in which the two methyl groups are brought together with the elimination of hydrogen to form cyclopropane, it can be seen that considerable energy must be expended in the constriction of the C–C–C bond angle, leading to angle strain. Although the cyclopropane bond angle is conventionally given as 60°, this is misleading. It is known that the bending of bond angles results in limited orbital following.[14] Thus, the nuclei move ahead of the overlap or bonding electron density in the bond. As a result, bent bonds are formed. This is easily seen in an electron density diagram for cyclopropane. The total electron densities (Fig. 1a) are not very revealing because they are

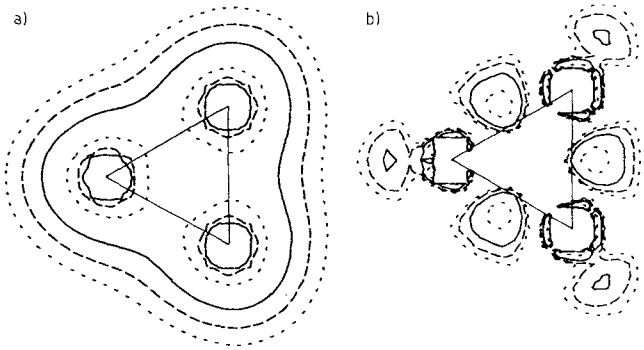


Fig. 1a) Total electron density in the three-carbon plane of cyclopropane. b) Regions of positive deformation density for cyclopropane (i.e., regions of greater electron density than would be expected for three carbon atoms in the same positions).

dominated by the density near the nuclei. However, if we subtract the electron density that would be expected for three carbon atoms at the same locations, we obtain the more interesting difference density map shown in Figure

1b. Here, it can be seen that the extra electron density in the bonding regions (deformation density) lies outside of lines drawn between the carbon nuclei. The bonds are indeed bent! It is possible to define a bond path between two carbon atoms that is the path of maximum electron density between the nuclei.[15] It is colinear with the nominal C-C bond for acyclic or unstrained compounds, but is markedly curved in the case of cyclopropane or cyclobutane. The angle between the C-C bond paths is 78° compared to the conventional 60° bond angle. Bonds of this type are weaker than normal C-C bonds; whereas the bond dissociation energy for ordinary C-C bonds is on the order of 84 kcal/mol,[16] the bond dissociation energy in cyclopropane appears to be 65 kcal/mol.[17]

As noted above, bond angle deformation is not the only source of strain. Torsional interactions also are of importance. In planar cyclobutane, the methylene groups would be eclipsed, which is a relatively high energy arrangement. Puckering will improve the torsional angles and lead to a decrease in torsional strain, but at the same time, the C-C-C bond angles are reduced leading to an increase in angle strain.[18] The two effects find a balance when the ring is puckered about 35° out of planarity, leading to torsional angles of 24° and bond angles of 88°.[19]

The two most important components of the total strain energy are usually bond angle distortion and nonbonded repulsion. The latter is commonly referred to as a steric effect. An examination of these components of the strain energy will be presented in Section 4.

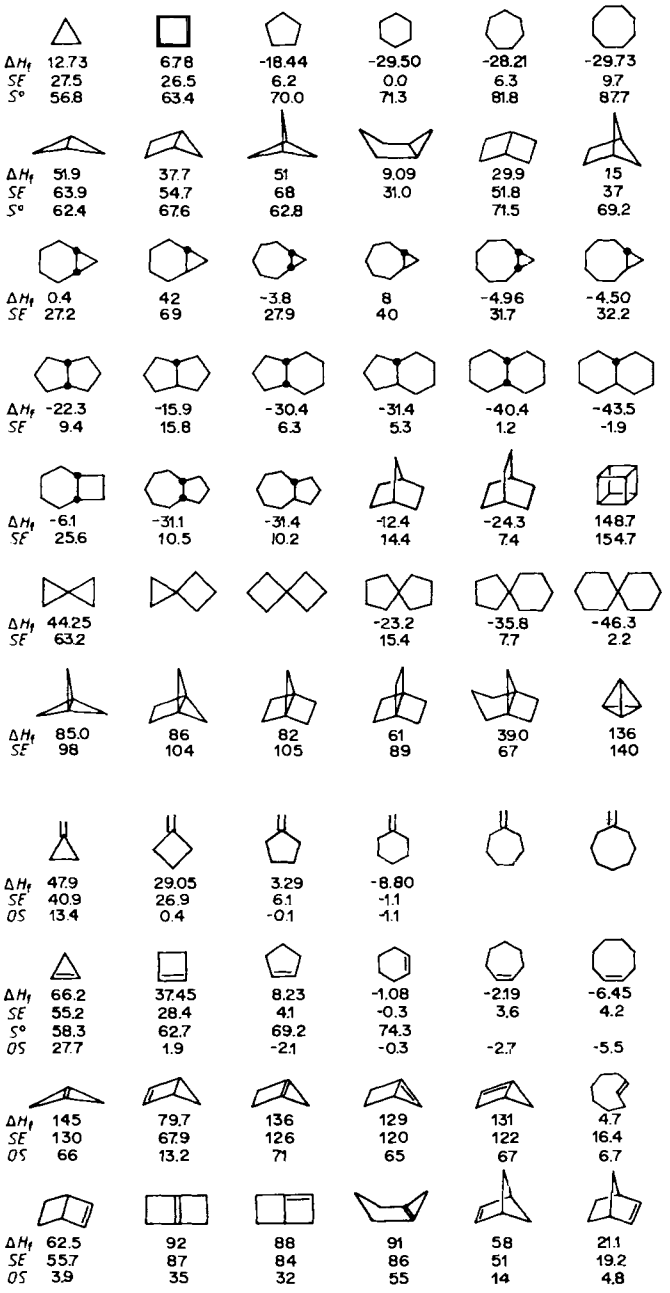
3. Strain Energies

The strain energy of a molecule is derived from its heat of formation from the elements (ΔH_f) by comparison with a hypothetical "strainless" model. Any model of this type will have some arbitrary features. For example, we might take cyclohexane to be a strain-free model. Its heat of formation is −29.5 kcal/mol,[3] which is equivalent to −4.92 kcal/mol per methylene group. Cyclopropane, with three methylene groups, would then be expected to have $\Delta H_f = -14.75$ kcal/mol. The observed ΔH_f is +12.73 kcal/mol.[3] The difference between these values, 27.5 kcal/mol, is the strain energy. Similarly, cyclobutane would be expected to have $\Delta H_f = 4 \times -4.92 = -19.7$ kcal/mol, which when compared with the observed value, +6.8 kcal/mol, gives a strain energy of 26.5 kcal/mol.

If one wished to be precise, one would recognize that cyclohexane is not entirely strain free. The C-C-C-C torsional angles are 59°, corresponding to the *gauche* conformation of *n*-butane, which is less stable than the *anti* conformer by about 0.9 kcal/mol.[10] The observation that the normal methylene increment for a straight-chain hydrocarbon, −4.926 kcal/mol,[21] is very close to the methylene value for cyclohexane simply reflects the fact that relatively few molecules of a linear hydrocarbon are in the *anti* conformation. The *gauche* conformations, although energetically disfavored, predominate because, whereas there is only one *anti* conformer, there are many possible *gauche* conformers. It can be seen that the methylene increment for an alkane which is completely in the *anti* conformation will be somewhat more negative than −4.926 kcal/mol.

This is, however, of little consequence. Strain energies are used in a comparative fashion, and thus any reasonable and consistent definition will be satisfactory. The simplest approach is to use *Franklin*'s group equivalents[21] (Table 1) in determining the energy of the strain-free model.

Table 1. *Franklin*'s group equivalents for the calculation of the energies of model compounds.



Group	Equivalent [kcal/mol]	Group	Equivalent [kcal/mol]
CH_3	−10.12	$\diagdown CH{=}CH_2$	+15.00
CH_2	− 4.926	$\diagdown CH{=}CH\diagup$	+18.88
CH	− 1.09	$\diagup CH{=}CH\diagup$	+20.19
C	+ 0.80	$\gtrdot C{=}CH\diagup$	+20.19
		$\gtrdot C{=}C\lessdot$	+24.57

Table 2 gives the heats of formation[3] and strain energies for a variety of cyclic hydrocarbons. In the cases in which the experimental error was ≤0.3 kcal/mol, ΔH_f is given to the nearest 0.01 kcal/mol, and where it was >0.3 kcal/mol it is given to the nearest 0.1 kcal/mol. The values are not available for many interesting cyclic hydrocarbons. It is unfortunate that only a few laboratories are presently determining the heats of combustion from which the heats of formation are derived. Moreover, even if such measurements were more frequently carried out, it would be of little use for compounds that can only be obtained in small amount or can only be observed under unusual conditions such as matrix isolation. In these cases, theoretical calculations frequently provide very useful information. It has been shown that the total energies obtained by ab initio molecular orbital calculations with the 6-31G* basis set may be converted into ΔH_f values with an average error of only ±1 kcal/mol using a set of group equivalents.[22] When these values are included in the table, they are given to the nearest 1 kcal/mol.

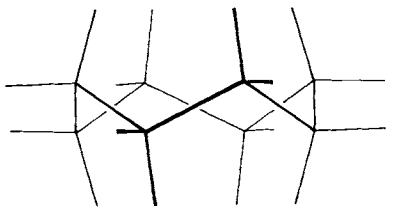
The interplay of the various components of the strain energy is nicely illustrated by the homologous series of cycloalkanes. Cyclohexane is generally taken as "strain free" (although it does have six *gauche* C-C-C-C torsional angles). In the case of cyclopentane, the planar conformation would have a low strain energy if angle strain were the only important component. However, the planar conformer has five eclipsed methylene groups. If each contributed a torsional strain of 3 kcal/mol (as in ethane), cyclopentane would have an additional 15 kcal/mol of strain. In order to minimize the torsional strain, cyclopentane assumes puckered conformations (C_s and C_2), which are rapidly interconverted by pseudorotation.[23]

Cyclobutane cannot avoid considerable angle strain since even the planar conformer has formal bond angles of 90°. Besides the angle strain, there is also the torsional strain arising from four eclipsed methylene groups. In order to minimize the total strain, cyclobutane adopts a puckered conformation. This results in a small increase in angle strain (88°), but a considerable reduction in torsional

Table 2. Experimentally determined heats of formation (ΔH_f), calculated strain energies (SE), and entropies ($S°$) of cycloalkanes, methylenecycloalkanes, and cycloalkenes [a]. For methylenecycloalkanes and cycloalkenes, an olefinic strain (OS) is also given.

[a] The data were taken from [3], [22], [55], and W. R. Roth, F.-G. Klärner, H.-W. Lennartz, *Chem. Ber. 113* (1980) 1818.

strain (C-C-C-C=24°). The puckered conformer is 1.5 kcal/mol lower in energy than the planar conformer.[19]



The angle strain in cyclopropane is considerably larger than that in cyclobutane. It may therefore appear strange that cyclopropane has essentially the same strain energy as cyclobutane, especially since the torsional strain cannot be relieved in any way. However, cyclopropane has two sources of stabilization. In all cycloalkanes larger then cyclobutane there are as many 1,3-repulsive interactions as there are bond angles; both terms are lumped together in the bond angle distortion energy. In cyclobutane, the number of 1,3-interactions is reduced to one-half the number of angles, and in cyclopropane, there are no 1,3-nonbonded interactions (Scheme 1). Thus, one source of destabilization is not present in cyclopropane.

Scheme 1.

Furthermore C-H bonds in cyclopropane have larger bond dissociation energies than those of other cycloalkanes.[24] The experimental value for cyclopropane is 106 kcal/mol. The normal value for a methylene C-H bond is 98 kcal/mol,[25] and it is unlikely that the value for cyclobutane is greater than 100 kcal/mol.The bond dissociation energy for a cyclopropane C-H bond is therefore 8 kcal/mol greater than that for open-chain methylene groups. A part of this difference is probably due to the difficulty of introducing a trigonal center into a three-membered ring,[36] but some is almost surely due to a stronger and shorter bond.[27] If the latter contribution were only 2 kcal/mol, it would lead to a total stabilization of 12 kcal/mol for the six bonds! The corrected strain would then be about 40 kcal/mol. This estimate should not be taken too seriously, especially since bond energies and bond dissociation energies are not directly related. However, it is clear that cyclopropane compensates for its weaker C-C bonds by increasing the strength of its C-H bonds, leading to a smaller strain energy than might otherwise be expected.

A contrary situation is found with the larger rings. With cyclooctane, for example, one can readily find a conformation that has good C-C-C bond angles and torsional angles, namely, the crown conformation. However, another problem arises—some hydrogens point in toward the center of the ring, resulting in very short nonbonded distances and a larger nonbonded strain term. Cyclooctane is thus forced to adopt a conformation (Scheme 2) that is a compromise between the angle, torsional, and nonbonded terms.[23]

Scheme 2.

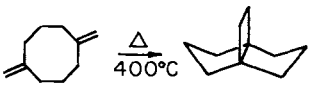
Many of the larger cycloalkanes could adopt an ideal diamond-lattice arrangement for the carbons, but again, such conformations would have strong H-H nonbonded interactions.[29]

The strain energy of many bicyclic compounds is close to the sum of the strain of the monocyclic components. Thus, bicyclo[2.1.0]pentane and bicyclo[2.2.0]hexane have essentially the same strain energy, which is twice the strain in cyclopropane or cyclobutane. This is presumably the re-

sult of compensating increases in angle strain and a decrease in torsional strain since one bond is common to both rings. The interesting cases are those in which the strain energy is greater than this estimate. For example, the strain energy of bicyclobutane is 9 kcal/mol greater than expected. A similar and generally larger strain increase is found with the small-ring propellanes. These are cases in which there is an unusual degree of angular deformation at the bridgehead positions. The [1.1.1]- through [2.2.1]propellanes are forced to have "inverted" tetrahedral geometries at the bridgehead positions.[30] It is interesting to note that bicyclobutane also assumes this geometry although it is not required by structural constraint,[31] and that the strain energy of bicyclobutane is the average of those of cyclopropane and [1.1.1]propellane.

The spiro compounds also have increased strain energies. Spiropentane has 8 kcal/mol of extra strain. The central carbon, having four identical C-C bonds, is required to be sp^3 hybridized and therefore introduces considerable extra destabilization. The other cases with considerable extra strain are those having relatively small *trans*-fused rings. *trans*-Bicyclo[4.1.0]heptane is calculated to have 41 kcal/mol of extra strain[32] and readily undergoes *trans-cis* isomerization.[33] The extra strain decreases to 6 kcal/mol with *trans*-bicyclo[5.1.0]octane, and with bicyclo[6.1.0]nonane, the strain energies of the *cis* and *trans* isomers are smaller and essentially the same.[32]

It is interesting that the strain energy of cubane is just 6 times that of cyclobutane. However, the strain energy of tetrahedrane is 30 kcal/mol greater than 4 times the strain of cyclopropane. This would be expected since the strain in bicyclobutane is more than 2 times the strain in cyclopropane. The heat of dissociation of tetrahedrane to two acetylenes is calculated to be −40 kcal/mol, which is in good accord with the experimental studies.[34]

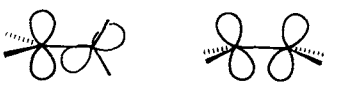


The carbon-carbon double bond is one of the more important of the functional groups in chemistry. The double bond in ethylene is commonly taken as strain free. Here, an examination of the thermochemistry of the dimerization of ethylene to cyclobutane is instructive.

$\Delta H_r = -18.2$ kcal/mol (25 °C)
$\Delta S_r = -41.5$ cal · K^{-1} · mol^{-1}
$\Delta G_r = -5.8$ kcal/mol
$K = 1.8 \times 10^4$

The reaction is quite exothermic at room temperature, despite the strain energy of cyclobutane; the results would require that ethylene be destabilized by about 22 kcal/mol. This is in good accord with the observation that whereas the dissociation energy of a carbon-carbon single bond is about 84 kcal/mol,[16] the energy of its π-bond (as determined from the barrier to rotation in *cis*-dideuterioethylene) is only 64 kcal/mol.[35]

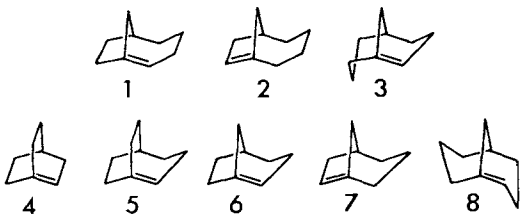
Why isn't the dimerization of ethylene a practical synthesis for cyclobutane? The thermal interconversion requires a relatively high temperature, and the strongly negative entropy change leads, therefore, to a positive ΔG_r and an unfavorable equilibrium constant. If the entropy factor can be minimized, as when the two double bonds are in the same molecule, the thermal dimerization is successful; an example is the synthesis of [3.3.2]propellane from 1,5-dimethylenecyclooctane.[36]



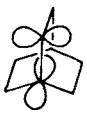
In the case of ethylene, a catalyst that would allow the equilibrium to be set up at a lower temperature is required. If it could be found, cyclobutane would become one of the most common organic compounds. Despite these considerations, for convenience in the following discussion we will adopt the conventional view that ethylene is strain free.

The introduction of a trigonal center may lead to either an increase or a decrease in strain. Here, it is useful to define the *olefinic strain* (*OS*) as the difference in strain energy between the alkene and its corresponding alkane (cf. Table 1).[37] In the case of cyclopropane, one trigonal center leads to a 13 kcal/mol increase in strain, and two trigonal centers increase the strain by 28 kcal/mol.[26] The normal bond angle at a trigonal center is ca. 120°, and a decrease to 60° would lead to a much larger increase in strain than found with cyclopropane. The larger C-C-C angle in cyclobutane should lead to a smaller increase in strain energy; indeed, it is 1 and 3 kcal/mol for one and two trigonal centers, respectively.

Cyclopentane provides a much different case. Here, the main problem is the torsional interaction. Removal of two hydrogens to form a double bond relieves part of the torsional interaction and results in a decrease in strain. Thus, whereas cyclopentane has a strain energy of 6.2 kcal/mol, in cyclopentene it is decreased to 4.1 kcal/mol.



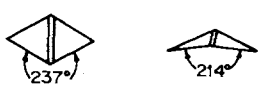
In the above examples, there is no important deformation of the π-electron system, and the strain is largely associated with the σ-bonds. There is, however, another large group of alkenes in which distortion of the π-system is responsible for much of the strain. The π-system may be deformed in two quite different fashions—twisting and bending (or pyramidalization) (Scheme 3).[38] The twisting distortion is found in small *trans*-fused alkenes such as *trans*-cyclooctene,[39] in the bridgehead alkenes that violate Bredt's rule,[40] and in alkenes with bulky substituents.



Scheme 3.

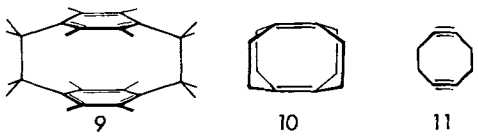
The *trans*-cycloalkenes have received considerable study.[41] For cyclopentene, cyclohexene, and cycloheptene, the *trans* isomers are too reactive to be isolated, but may be obtained and used as reactive intermediates.[42] The difference in energy between *cis*- and *trans*-cyclooctene has been determined from their heats of hydrogenation;[43] the *trans* compound is 11 kcal/mol less stable than the *cis*. With larger rings, the difference in energy decreases, and for cycloundecene, the *trans* isomer is more stable.[44] The twisting distortion is well seen in the structure of *trans*-cyclooctene as determined by electron diffraction.[39] The π-system is twisted out of planarity by 44°.

The bicyclic alkenes with bridgehead double bonds are a very interesting group, and many of these compounds have been prepared.[45] Examples include compounds **1**–**8**.

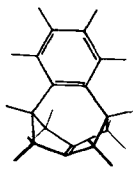


Compounds **1**–**3**, which have the *trans* double bond in an eight-membered ring, can be isolated,[46] but compounds **4**–**8**, with the *trans* double bond in a smaller ring, can only be utilized as reactive intermediates.[45,47] The problem with these compounds is easily seen by examining bicyclo[2.2.2]oct-1-ene **4**. The p-orbital at C-2 should be approximately orthogonal to the p-orbital at the bridgehead. In order to achieve any degree of π-bonding, the σ-system must be strongly twisted, and even then, the π-bond will be weak. It has been estimated that bridgehead alkenes with olefinic strain greater than about 21 kcal/mol will not be observable at room temperature.[37]

Steric interactions also may lead to twisted double bonds. Even in *cis*-2-butene, the repulsion between the alkyl groups can be seen in the C-C-C angle of 127°.[48] With *cis*-1,2-di-*tert*-butylethylene, the angle is increased to about 135° leading to a strain energy of 11 kcal/mol.[49] The introduction of a third *tert*-butyl group will oppose the increase in bond angle and would lead to greatly increased strain for a planar conformation. The strain could be partially relieved by twisting the double bond; the calculated torsional angle is 16°.[50] The synthesis of tetra-*tert*-butylethylene has not as yet been accomplished.[51]



There also are many examples of bent (pyramidalized) alkenes. One of the more remarkable cases is bicyclo[1.1.0]but-1(3)-ene.[52] Theoretical calculations led to the prediction that it should be bent. An orbital analysis has been presented to explain this result, but the bent structure also may be viewed as an attempt to minimize σ-strain. In the planar form, one of the C-C-C bond angles at the bridgehead would be 237°; this can be reduced to a more reasonable 214° by bending.



Bicyclo[2.1.0]pent-1(4)ene also is calculated to be nonplanar with a large barrier to inversion. Despite their high strain energies and unusual structures, derivatives of both of these alkenes have been formed as reaction intermediates.[53] It has not as yet proven possible to examine them via matrix isolation.

Bending of double bonds is found in less extreme cases. Norbornene is calculated to be bent out of plane by 5°,[54] and this has been explained as resulting from torsional interactions with the bridgehead position.[55] The bending distortion has been suggested as an explanation for the unusually high reactivity of norbornene in cycloaddition reactions.[56]

There are a number of compounds in which bending is forced by structural constraints. Some of the best known examples are found with the cyclophanes.[57] [2.2]Paracyclophane **9** would have an impossibly small distance between the benzene rings if they were planar. A bending distortion relieves part of the strain. Similar examples are tricyclo[4.2.2.2^{2,5}]dodeca-1,5-diene **10**[58,59] and 1,5-cyclooctadiyne **11**.[60] The distance between the double bonds in **10** could be increased to 2.4 Å by bending, and even this distance is a full 1 Å smaller than the normal shortest contact between π-systems. Another type of bending at a double bond is found with the bridged alkene **12**.[61] Unfortunately, relatively little is known about the energies of these bent alkenes.

The above examples represent only a small selection of the large number of compounds that show the effect of strain. Carbocyclic compounds have been selected because almost no information is presently available concerning the strain energies of heteroatom-containing systems.[62]

4. Quantitative Analysis of Strain

The contributions to the total strain in a molecule are summarized below:

(1) Bond length distortion
(2) Bond angle distortion
(3) Torsional strain
(4) Nonbonded interactions
(5) Energy changes due to rehybridization

The bond length distortions are usually relatively unimportant. The energy change for stretching or compressing a bond is given by Equation (c).

$$V = k_r(\Delta r)^2 \qquad \text{(c)}$$

k_r is the stretching force constant and Δr is the change in length from a "normal" value. The constant k_r for C–H and C–C bonds, as determined by IR spectroscopy, is on the order of 5 mdyn/Å or 360 kcal · mol^{-1} · Å^{-2}. Thus, a change in bond length causes a large change in energy, and changes in other geometrical parameters are generally to be preferred to bond stretching. There are, however, some notable exceptions.[63]

The distortion of bond angles leads to much smaller increases in energy. In this case, the energy change is given by Equation (d).

$$V = k_\theta(\Delta\theta)^2 \qquad \text{(d)}$$

k_θ is the force constant and $\Delta\theta$ the change from the "normal" bond angle. Analysis of IR data shows that the C–C–C force constant for cyclohexane and similar compounds is 0.8 mdyn/Å or 0.0175 kcal · mol^{-1} · degree^{-2}. Thus, an angle can be distorted by a few degrees without much increase in energy. The force constants are appropriate for small changes in angle and might reasonably be used for angles between 105 and 115° (i.e, tetrahedral ±5°). A change to 90° as in cyclobutane or 60° as in cyclopropane will result in a change in hybridization and a change in force constant. These compounds must be treated as special cases.[64]

The torsional strain for C–C–C–C angles is reasonably well understood. The potential function may be written as a sum of onefold, twofold, and threefold terms [Eq. (3)].

$$V = \frac{V_1^\circ}{2}(1+\cos\tau) + \frac{V_2^\circ}{2}(1+\cos 2\tau) + \frac{V_3^\circ}{2}(1+\cos 3\tau) \qquad \text{(e)}$$

τ is the torsional angle, and V_1°, V_2°, and V_3° are the potential terms for the onefold, twofold, and threefold barriers, respectively. The experimental data for *n*-butane may be used to obtain these terms for alkanes.[65]

Barriers to rotation for single bonds adjacent to double bonds are somewhat different. Here, alkyl groups are known to prefer to eclipse C=O groups.[66] A similar tendency is found for bonds adjacent to carbon–carbon double bonds,[67] but it is not as pronounced. Again, the total energy may be represented by one-, two-, and threefold terms.[68]

It is possible to obtain direct experimental data for each of the above intramolecular potentials, and they are therefore reasonably well understood. The other main term that dictates energies and conformations is the nonbonded interaction. However, it is much more difficult to establish the magnitude of this interaction. It is generally believed that the nonbonded interaction is well approximated by the Buckingham potential [Eq. (f)], which is shown in Figure 2.[69]

$$V = Ae^{-Br} - C/r^6 \qquad \text{(f)}$$

r is the distance between the nonbonded atoms, and A, B and C are constants that depend on the atoms involved in the interaction. In terms of the minimum in the energy curve (r_0) and the depth of the well (ε_0) and assuming a twelfth power repulsion curve, the constants may be written as follows:

$A = \varepsilon_0 e^{12}$
$B = 12/r_0$
$C = 2\varepsilon_0 r_0^6$

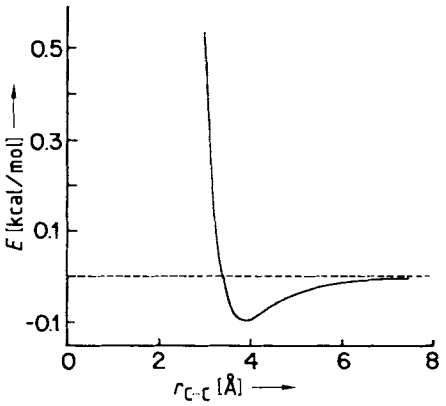


Fig. 2. Interaction energy as a function of distance for two nonbonded carbon atoms.

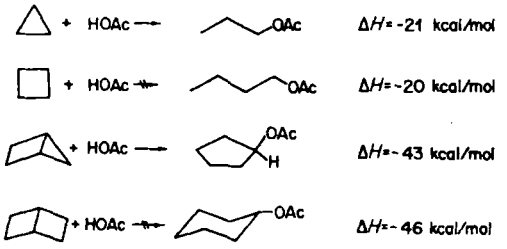
One way in which to obtain these constants is via an analysis of the intermolecular interactions in crystals, along with the heats of sublimation.[70] In the case of hydrocarbons, the nonbonded interactions are the only important terms. The sum of all the interactions between one molecule and all of its neighbors will be twice the heat of sublimation, and if the terms are chosen correctly, the observed intramolecular spacing between molecules will correspond to the calculated minimum energy arrangement. Constants that give good fits to the experimental data have been obtained.[70]

It is more difficult to obtain parameters for other atoms because here another term becomes significant. When an atom other than hydrogen is bonded to carbon, a bond dipole is created. These bond dipoles interact via a coulombic term, and must also be included in calculating the intermolecular interaction energy. In some cases, the bond dipoles may be estimated from the total dipole moment, and in other cases they may be estimated using the results of theoretical calculations.[71]

Once one has the necessary values for the potential functions, one may start with a guess as to the structure, and calculate the bond lengths, bond angles, torsional angles, and nonbonded distances. The application of the above functions will yield a total steric energy. The structure may then be adjusted in a systematic fashion until a minimum, corresponding to the most stable conformation, is reached. This procedure is commonly known as *molecular mechanics* and generally gives quite good results for compounds that are similar to those used in determining the parameters.[13]

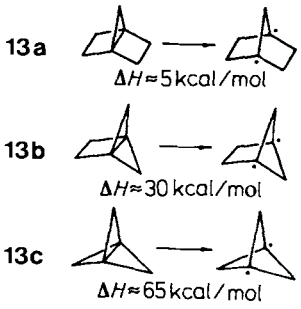


As a semi-empirical method, molecular mechanics is limited in the types of compounds for which it is applicable. Adequate experimental data are required in order to fix the parameters used, and such data are largely limited to hydrocarbons and their simple derivatives. Ab initio molecular orbital theory is much more general in its applicability and does not depend on any experimental data.[72]

Geometry optimization is now routinely carried out for many types of compounds, making use of the analytical procedure for calculating the rate of change in the energy with changes in coordinates.[73] The total energies that are calculated may be converted into heats of formation with reasonable accuracy,[22] and the structures that are calculated are, with few exceptions, in very good agreement with the experimental structures.[72] These calculations require large amounts of computer time and become impractical for molecules with more than about 10–12 atoms other than hydrogens. It seems likely that the results of ab initio calculations will prove useful in improving the parameters for molecular mechanics calculations, and a synergetic relationship will allow the study of a wider range of compounds with useful accuracy (±1 kcal/mol, ±0.01 Å, and ±1°).[74]

5. Chemical Consequences of Strain

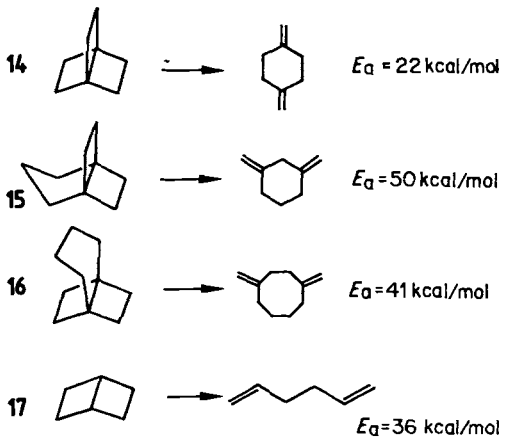
One might reasonably expect that increased strain would lead to increased reactivity. This is, however, not always the case. Factors that must be considered include the location of the activated complex along the reaction coordinate and the strain energies of the compounds that are formed as products or reaction intermediates. If the activated complex resembles the reactants, little of the strain energy would be released in the rate-determining step, and there would be little rate acceleration. Similarly, if the products or intermediates have large strain energies, there would be little driving force to help accelerate the reaction.



The first case is illustrated by the electrophilic reactions of cyclopropanes and cyclobutanes. Here, the strain energy relief is essentially the same, but whereas the cyclopropanes are quite reactive, the cyclobutanes are essentially inert (Scheme 4).[75]

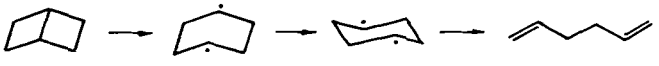
Scheme 4.

A study of the kinetics of the acetolysis of cyclopropanes found a kinetic solvent hydrogen isotope effect wherein the reaction with CH_3COOH was significantly faster than that with CH_3COOD. This shows that proton transfer is the rate-determining step, leading to the formation of a protonated cyclopropane. Since there is little change in geometry in the rate-determining step, there is essentially no driving force from strain relief. The difference in reactivity between cyclopropanes and cyclobutanes results from the difference in their basicities, which, in turn, is related to the different bonding in these two hydrocarbons.



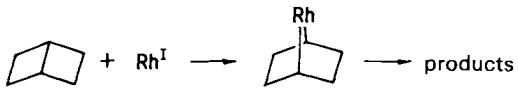
The second case is well illustrated by [1.1.1]propellane.[76] The strain energies of [1.1.1]-, [2.1.1]-, and [2.2.1]propellane are essentially the same and, therefore, these compounds might be expected to have similar reactivities. However, whereas [1.1.1]propellane is thermally stable to ca. 100 °C, the other propellanes polymerize at 50 °K![30] The reason for the difference in reactivity is easily seen by considering the energy required to "dissociate" the central bonds (Scheme 5).

Scheme 5.



The differences in energy are mainly a result of the differences in strain between the bicycloalkanes from which the diradicals are derived. Bicyclo[1.1.1]pentane has two small rings, which, along with extra distortion, lead to a large strain energy, whereas norbornane with no small rings has a relatively low strain energy.

There are, of course, many reactions in which the strain energy of the reactant is important. One particularly interesting example is the thermolysis of [2.2.2]propellane **14**.[77] Here, a formally orbital-symmetry-forbidden reaction occurs at room temperature and may be contrasted with related compounds (Scheme 6).[73] Starting with bicyclo[2.2.0]hexane **17**, 1,4-bridging first increases the activation energy for ring opening (**15**, **16**), and then, with [2.2.2]propellane **14**, decreases it markedly.

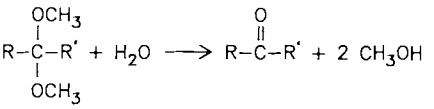


Scheme 6.

The increase in activation energy on going from **17** to **15** or **16** is easily understood. The cleavage of **17** involves the following series of steps:[79]

The final cleavage of the chair diyl is orbital symmetry allowed and occurs with the predicted stereochemistry.[80] When a 1,4-bridge is introduced, the conversion of the boat diyl to the chair form is no longer possible, and cleavage must occur via a symmetry-forbidden process which has a larger activation energy. There is no reason to think that **14** should react via a mechanism different from that for **16**. The decrease in activation energy may be accounted for by the difference in strain energy between **14** and **16** (estimated to be 34 kcal/mol). This large increase in strain in the reactant leads to a marked decrease in activation energy since there is little strain in either diyl.

Another case in which strain relief is important is in the transition-metal-induced cleavage of cyclopropanes and cyclobutanes. In contrast to the reaction with electrophiles, in which the former are reactive and the latter are almost inert, both types of compounds will react with reagents such as $[\{Rh(CO)_2Cl\}_2]$.[81] This shows that whereas the activated complex is found early along the reaction coordinate in electrophilic cleavage, it is found well along toward products in the reaction with the rhodium reagent. In the latter case, oxidative insertion occurs, leading to considerable relief of strain.



Substituents that cause steric strain may also cause low reactivity by hindering the attack by an external reagent. Thus, tri-*tert*-butylethylene reacts with bromine only slowly,[82] and tetraneopentylethylene is inert to bromine.[83] The most spectacular examples of stabilization of a compound by large alkyl groups are found with tetra-*tert*-butylcyclobutadiene[84] and tetra-*tert*-butyltetrahedrane.[84] Cyclobutadiene itself dimerizes quickly even at low temperatures,[85] and tetrahedrane, which has not been prepared, appears to cleave easily to acetylene.[34] Both of the tetra-*tert*-butyl compounds are quite stable. The large groups prevent bimolecular reactions and hinder the motions required to convert the tetrahedrane derivative into other more stable compounds.

The above examples are mainly concerned with small-ring compounds in which angle strain—the type first considered by *von Baeyer*—is of particular importance. It must, however, be recognized that strain is a controlling factor in many reactions involving quite ordinary compounds. Probably, the most common reaction of this type is addition to a carbonyl group. If bulky substituents are attached, an addition that converts the trigonal carbonyl carbon into a tetrahedral carbon will decrease the bond angle and bring the groups closer together. The effects on rates of reaction have received much attention and generally are well correlated by *Taft*'s E_s parameters.[11]

Relatively little quantitative information on energy changes has been available. One example is the hydrolysis of acetals, ketals, and ortho esters (Scheme 7).

The heats of these reactions may be measured calorimetrically,[86] and the changes in heats of hydrolysis give direct measures of the changes in steric interactions on going

Scheme 7. R' = H, CH_3, OCH_3

from the tetrahedral reactant to the trigonal product. Whereas rates of reaction (related to free energies of activation) or equilibrium constants (related to free energies of reaction) correlate well with the E_s parameters, the heats of reaction do not. This is specially noticeable in the series methyl, ethyl, *n*-propyl, where changes in rates or equilibrium constants are found, but there is essentially no change in heat of reaction. This indicates that the entropy is the major component of the steric effect for these small groups and may possibly be associated with steric inhibition of solvation.

These open-chain systems are difficult to analyze in detail because of the number of conformations with similar energies. The methyl-substituted norbornyl ketals provide a case in which the hydrocarbon residue is rigid, and the attached methyl groups should cause no conformational problems. An examination of a variety of these ketals showed large changes in heats of reaction, with the hydrolysis of the ketal of camphor being 4 kcal/mol more exothermic than that of norcamphor.[87] Examination of systems of this type should provide much of the information which is needed to gain a quantitative understanding of nonbonded interactions.

6. Conclusion

In the hundred years that have passed since the publication of *von Baeyer*'s theory, strain has been found to be a major factor in determining the structures, energies, and reactivities of organic compounds. A remarkable variety of compounds have been prepared which are significantly destabilized by one or more of the four types of strain. Studies of these compounds have led to improved understanding of chemical bonding, intramolecular interactions, and reaction mechanisms. Quantitative information is still lacking for many of these compounds, but as the capability of theoretical methods continues to improve, such information will become available via computation. The smaller compounds with large degrees of angle strain have proven to be specially useful targets for a synergistic interaction between experiment and theory. The next decade should see a marked improvement in our understanding of the role of strain in organic chemistry.

Ordering of Ionic Solutes in Dilute Solutions through Attraction of Similarly Charged Solutes— A Change of Paradigm in Colloid and Polymer Chemistry**

By Norio Ise*

Dedicated to Professor Georg Manecke on the occasion of his 70th birthday

EXAFS measurements indicate the presence of a quasi lattice-like ordering of simple ions in dilute solutions. Small-angle X-ray scattering (SAXS) measurements on dilute aqueous solutions of synthetic macroions, polynucleotides, and proteins show a single broad peak; a binary mixture of synthetic macroions of different molecular weight gives a new scattering curve that is entirely different from the composite curve of the constituents before mixing. This would indicate that the macroions are distributed in a fairly regular way in the solution. The intermacroion spacing ($2D_{exp}$) obtained by the Bragg equation is found to be smaller than the average spacing ($2D_0$) calculated from the polymer concentration. Furthermore, the $2D_{exp}$ value decreases with increasing number of charges per macroion. This finding is confirmed by studies on model systems, e.g. on monodisperse ionic latex particles, which are large enough (diameter: about 3000 Å) to be seen under the ultramicroscope. It follows, from the inequality relation $2D_{exp} < 2D_0$, that there is an attraction between ionic species of like-charge. This conclusion contradicts prevailing views in colloid chemistry; it has been pointed out that such a behavior can be explained in terms of a new theory, in which counterions between the macroions or ionic latex particles play a decisive role.

This picture, painted by *Mitsuyoshi Tosa* (1539–1613), illustrates a story in the Genji monogatari (Tale of Genji),*** written by the Japanese authoress *Murasaki Shikibu*, in the early eleventh century. The two gentlemen are simultaneously attracted by the lady playing a Koto, a Japanese board zither with 13 strings. The lady is so attractive that the two gentlemen, despite their mutual repulsion, are drawn into close proximity. A similar situation seems to exist for charged solutes in dilute solutions. (Reproduced by courtesy of the Kyoto National Museum and Gakushu kenkyusha.)

1. Introduction

Elements and chemical compounds can exist in three physical states, namely solid, liquid, and gaseous states. In solids, the molecules are highly ordered, whereas in the gaseous state they are completely disordered. The distribution in the liquid state may lie between these two extremes; but our knowledge thereof is still scanty. This is also the case with solutions. When the solute concentration is high, it might not at all be surprising that the solute particles are "packed" in a more or less regular manner in the solution, provided that they have the same size and geometry. On the other hand, at low concentrations, one might expect that the solute particles behave in an irregular manner like "gas molecules". If "solid-like" ordered arrangements of the solute particles are to be found under such conditions, then we have an unexpected and interesting phenomenon which warrants careful investigation. In order to facilitate

an understanding of this situation, let us consider balls of the same radius contained in a vessel of definite volume. When the number of balls (and hence the concentration) is sufficiently high, the space requirement forces the balls to be close-packed. In this case the distance between the centers of two balls ($2D_{exp}$) must be roughly the same as the average distance ($2D_0$) calculated from the number of the balls and the volume of the vessel. If the number of balls is relatively small, however, the average value of $2D_{exp}$, if it can be measured, is expected to be equal to $2D_0$, provided that the balls are distributed completely irregularly throughout the vessel. If a localized "solid-like" arrangement were to occur, the $2D_{exp}$ value in the ordered region would be smaller than $2D_0$. Over the past few years, it has emerged that ionic solutes (such as simple ions, synthetic macroions, proteins, polynucleotides, ionic detergent micelles, and polymer latex particles) form unexpectedly "ordered" arrays in relatively dilute solutions, irrespective of the molecular geometry and mass, and, under some conditions, $2D_{exp}$ is found to be smaller than $2D_0$. Although many related problems still remain unsolved, recent studies on dilute ionic solutions have revealed essential aspects of interionic interaction in solutions. The experimental data now available and the theoretical predictions deriving therefrom are so unexpected and contradictory to prevailing views in colloid and macromolecular science that a review of the present state-of-the-art in this sector was deemed necessary, irrespective of whether many controversies have not yet been settled.—For earlier work in this area, the reader is referred to a previous review.[1]

2. EXAFS Studies on Simple Ions

The dependence of the activity coefficient, the heat of dilution, and the viscosity on concentration suggests, though not conclusively, that simple ions form ordered structures in dilute regions.[1] A more direct argument in support of this hypothesis can now be presented on the basis of recent EXAFS (Extended X-ray Absorption Fine Structure) experiments. A French group[2,3] reported for solutions of $ZnBr_2$ that the interionic distance between Zn^{2+} and Br^- is 2.37 Å in 0.089 M aqueous solution and 2.30 Å in 0.05 M ethyl acetate. Both values are very close to that observed in the crystalline state (2.40 Å). This observation indicates that local ordering similar to that in the solid crystal persists even at these low concentrations, although the lifetime of the ordered structure would be quite short.

3. X-ray Scattering on Macroions, Proteins, and Polynucleotides in Solution

Under suitable conditions, aqueous solutions of synthetic macroions continue to show a single, broad peak in the small-angle X-ray scattering (SAXS) curves. The experimental data recently obtained for poly-L-lysine · HBr[4] and sodium polystyrenesulfonate[5] are completely consistent with those reported earlier for sodium polyacrylate:[6] When the polymer concentration and molecular weight are reasonably high and the concentration of coexisting salt is low, a scattering peak is observed which, with increasing polymer concentration and decreasing salt concentration, shifts towards larger scattering angles. This tendency is also observed with t-RNA.[7]

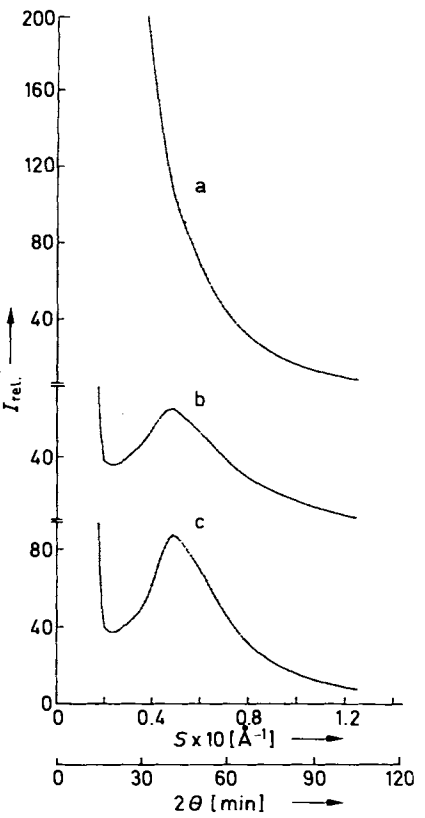

Fig. 1. Small-angle X-ray scattering of an aqueous solution of bovine serum albumin (0.075 g/mL) at 25 °C and (a) pH=5.06, (b) pH=3.44, and (c) pH=10.94. S is the scattering vector ($4\pi\sin\theta/\lambda$, where 2θ is the scattering angle and λ the wavelength of the X-rays). (Taken from Ref. [8] by courtesy of the American Institute of Physics.)

Figure 1 shows the SAXS curves for bovine serum albumin (BSA), an amphoteric polyelectrolyte.[8] A SAXS peak is observed at alkaline and at acidic pH, whereas it disappears at a pH near the isoelectric point. Unneutralized polyacrylic acid[6] and polyvinylpyrrolidone, a neutral polymer, show no scattering peak.[5,9] These findings imply that the appearance of the peak is due to electric charges on the solutes.

We shall now turn to synthetic macroions and homologues with various degrees of polymerization. The scattering vectors of the peak position of polystyrenesulfonate samples with narrow molecular weight distributions were 0.091 and 0.073 for M_W=4600 and 74000, respectively ($M_W/M_N = 1.07 - 1.17$) at the same concentration (0.04 g/ml).[5] Obviously the peak position shifts to smaller scattering vectors when the molecular weight increases, as was previously observed for sodium polyacrylate[6] and poly-L-lysine.[4] Interestingly, the scattering curves of binary mixtures of two samples of different molecular weight cannot be reproduced by a composite one drawn by the summation of two original curves.[5] This indicates that the observed peak is due to an intermolecular and not to an intramolecular ordering, otherwise the peak position would not change by mixing. In other words, the SAXS data indi-

cate the presence of an ordered array of the macroions in solution.[10]

It is now possible to estimate the approximate interparticle distance ($2D_{exp}$) with the help of the Bragg equation. Some data obtained for sodium polystyrenesulfonate are listed in Table 1.[5] The behavior of $2D_{exp}$ (e.g., dependence on polymer and salt concentrations) is essentially in agreement with previous findings.[4,6] A comparison of the results of experiments 9 and 10, or 11 and 12 (Table 1) reveals that $2D_{exp}$ decreases with increasing molecular weight when the number of macroions per unit volume remains constant. For such macroions, the ionic charge increases with increasing molecular weight. According to the usually accepted interpretation, $2D_{exp}$ might be expected to become larger with increasing charge on the macroion because of enhanced mutual repulsion of the particles. The observed tendency, however, is completely the opposite.

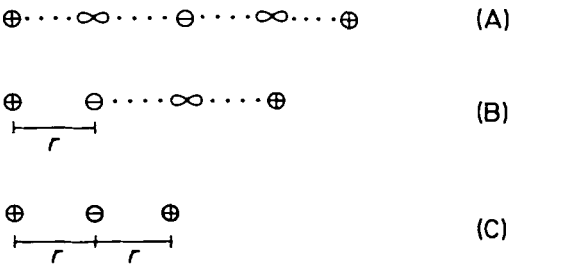

Table 1. Small-angle X-ray scattering data for aqueous solutions of sodium polystyrenesulfonate at 25°C [a]. S_m: scattering vector at the peak ($S=4\pi\sin\theta/\lambda$, 2θ: scattering angle, λ: wavelength). $2D_{exp}$: observed interparticle distance. The $2D_{exp}$ value for macroions is obtained by the Bragg equation. The uncertainty was estimated to be within ±5% from repeated runs. $2D_0$: theoretical interparticle distance calculated from the concentration by assuming uniform distribution.

No.	Polymer concn. [g/mL]	M_W	NaCl concn. [g/mL]	S_m [Å^{-1}]	$2D_{exp}$ [Å]	$2D_0$ [Å]
1	0.01	7.4×10^4	0	0.040	157	231
2	0.02	7.4×10^4	0	0.052	122	183
3	0.04	7.4×10^4	0	0.073	87	145
4	0.16	7.4×10^4	0	0.134	47	92
5	0.04	4.6×10^3	0	0.091	69	58
6	0.04	7.8×10^5	0	0.073	87	319
7	0.04	1.8×10^4	0.1	0.067	(94) [d]	91
8	0.04	1.8×10^4	0.5	0.051	(123) [d]	91
9 [b]	0.02	4.6×10^3	0	0.074	85	73
10 [b]	0.078	1.8×10^4	0	0.102	62	73
11 [c]	0.02	1.8×10^4	0	0.053	119	115
12 [c]	0.08	7.4×10^4	0	0.096	65	115

[a] M_W/M_N is 1.07, 1.14, and 1.17 for the samples with $M_W=4.6\times10^3$, 1.8×10^4, and 7.4×10^4, respectively. [b] Number of macroions per unit volume 2.6×10^{18} mL^{-1}. [c] Number of macroions per unit volume 6.6×10^{17} mL^{-1}. [d] These values are believed to be overestimated because the intramacroion scattering must have affected the S_m value at small angles.

This implies that either the scattering measurements and the data analysis have not been carried out correctly, or that the widely accepted interpretation is incorrect. The first possibility has been considered very carefully and could be ruled out. Our positive assessment of the experimental data relies on our more direct experiments (see Section 4) on solutions of ionized latex particles, which are so large that their distribution in the solution can be observed directly with the ultramicroscope. (The resolution of a simple microscope is as large as the wavelength of the light used, whereas that of an ultramicroscope is 40 – 100 Å, depending on the refractive index of the particle.) It should be noted that macroions (studied by X-ray scattering) and polymer latices give consistent results.

The second possibility invites detailed consideration. Naturally, like charges repel each other and unlike charges attract each other. We are not, of course, questioning this axiom. If only macroions or colloidal particles of the same charge were to exist in solution, they would repel each other. However, this is not physically possible. In ionic solutions, there must exist macroions of the same charge and, *in addition*, equivalent amounts of oppositely charged counterions (such as H^+ or Na^+). The presence of the counterions between two macroions generates a Coulombic attraction between the macroions, which overwhelms the Coulombic repulsion between them. This can be illustrated quite easily in the following way: Suppose two cations and one anion each bear a charge (e) of the same magnitude. We now compare the potential energy of three systems (A, B, and C), namely free ions (A), an ion pair and a free ion (B), and a triple ion (C). The potential energy of case A is, of course, zero; that of case B is given by $-e^2/r$, where r is the distance between the cation and anion in the ion pair. The potential energy of the triple ion is $-1.5e^2/r$, since we have attraction ($-2e^2/r$) between the cation and anion (at a distance r) and naturally repulsion ($+e^2/2r$) between the two cations (at a distance $2r$). It is

immediately clear that, as far as the potential energy is concerned, the triple ion is the most stable of the three possibilities and is more stable than the ion pair plus a free ion, in spite of the repulsion between the cations. This argument can be extended to much higher ionic aggregate systems. In real solutions we cannot ignore the contribution of kinetic energy of the various particles, and we must also take into account the asymmetric nature of the ionic species, particularly in the case of highly charged macroions with monovalent counterions. Essentially, however, the stabilization can be caused by the very presence of oppositely charged species between similarly charged species: In other words, similarly charged species attract each other through the intermediary of oppositely charged species. (For readers who might be interested in an analogy taken from human behavior, we suggest the illustration of the Tale of Genji as being instructive.) This situation is lucidly described by *Feynman*, et al. who state that attraction arises "because the repulsion of likes and attraction of unlikes will tend to bring unlikes closer together and push likes farther apart".[14] For the same reason, ionic crystals such as sodium chloride are essentially stable. Ionic solutions are stabilized in the same way, that is they can exist as condensed systems. As a matter of fact, the free energy of interaction for simple ionic solutions is always negative according to the Debye-Hückel theory, despite repulsion between ions of the same sign;[15] this demonstrates that the *net* interaction is attraction. This important aspect has been almost completely ignored in some widely accepted treatises. It will be discussed in the following.

Table 2. Shortening of the intermacroion spacing in various polyelectrolyte solutions with increasing number of charges at 25 °C.

Polyelectrolyte	Degree of neutralization or pH	Concn. [g/mL]	$2D_{exp}$ [Å]	Ref.
Sodium polyacrylate	0.1	0.02	(129) [c]	[6]
	0.2	0.02	111	
	0.3	0.02	98	
	0.4	0.02	93	
	0.5	0.0221	88	
	0.65	0.02	92	
Sodium polymethacrylate [a]	0.2	0.0331	106	[16]
	0.4	0.0331	73	
	0.8	0.0331	72	
Poly-L-lysine·HBr [b]	pH = 9.8	0.04	114	[4]
	pH = 8.2	0.04	74	
Bovine serum albumin	pH = 8.08	0.073	133	[8]
	pH = 10.9	0.072	127	
	pH = 12.2	0.069	105	
	pH = 4.07	0.073	157	
	pH = 3.44	0.072	129	
	pH = 2.65	0.069	128	

[a] P_w (weight average degree of polymerization) = 590. [b] P_w = 406. [c] This value was obtained from a vague scattering peak, so that the experimental error would largely exceed the value (±5%), which is expected for other data.

Not only the data on sodium polystyrenesulfonate, but also existing data for weak macroions indicate that the $2D_{exp}$ value *decreases* with increasing charge. The $2D_{exp}$ values measured by *Dušek* et al. for sodium polymethacrylate,[16] and those found for sodium polyacrylate,[6] poly-L-lysine · HBr,[4] and bovine serum albumin[8] are listed in Table 2.

4. Microscopic Studies on Model Systems (Latex Solutions)

Although X-ray scattering experiments provide comparatively direct information about ordering phenomena, and although we believe that the conclusions drawn therefrom are basically correct, we cannot be absolutely sure about such information. One could carry out theoretical calculations of the scattering intensity using various geometrical models and then compare the results with experimental findings. In the case of ordered structures *in liquids*, however, such a strategy would be uninformative. What we are doing instead is to accumulate experimental data for dilute solutions of ionized latex particles. With these data we hope to gain insights into the behavior of macroions in solution.[17] Monodisperse polymer latex particles are not difficult to synthesize, and methods for their purification and characterization are well-established.[18] Owing to the difference in the refractive indices of the solvent and particle, aqueous polystyrene latex solutions are milky. When ionic impurities are removed, the solution becomes iridescent for latices of relatively small diameters.[19] It has been demonstrated that the iridescence is due to Bragg diffraction of visible light by an ordered array of the latex particles in soluion.[20] The most direct evidence for the ordering was obtained by *Hachisu* et al. by using a metallurgical microsope as ultramicroscope.[21]

Figure 2a shows such an ordering of latex particles. From this picture, the interparticle distance ($2D_{exp}$) can be estimated directly.

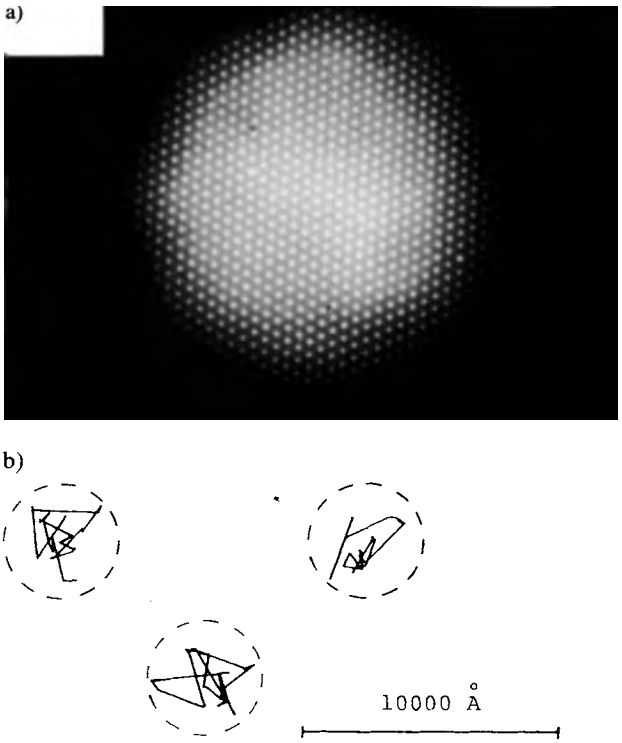

Fig. 2. Microscopic investigation of the ordering of polymer latex particles in dilute solutions. a) Static aspect of the ordering. The latex was prepared by emulsifier-free emulsion copolymerization of styrene and styrene sulfonate. Diameter: 3690 ± 100 Å, charges (SO_3H): 2.7×10^5 per particle. Latex concentration: 0.0066 g/ml. The figure, taken with a Carl-Zeiss Axiomat IAC at 25 °C, is *not* an electron micrograph. The interparticle distance ($2D_{exp}$) directly estimated from this picture is about 9000 Å, whereas that calculated from the concentration ($2D_0$) is 15000 Å. From this difference, it can be concluded that ordered regions and less dense disordered regions must coexist (cf. Fig. 3). The ordering of the latex particles in a horizontal plane is shown. b) Trajectory of the centers of the latex particles in the ordered structure [22]. Latex: SS-37, a styrene-styrenesulfonate copolymer, diameter: 4500 Å, latex concentration: 4%, charges: 1.76×10^5 per particle; film speed: 24 fps (frames per sec), exposure: 1/6s, *T*: 25 °C. The particle motion was followed using twelve consecutive film frames, i.e., for 0.5 s.

Figure 2a is indeed quite impressive, but it can lead to false conclusions. Under the microscope, the particles are not stationary but oscillate quite "rapidly" around their equilibrium positions. It is a grave mistake to presuppose something like a rigid lattice-like structure as found in solid crystals. In order to show how dynamic the ordered structure of the latex is, the particle motion was photographed with a movie camera and the trajectory of the particle center was recorded and reproduced as shown in Figure 2b.[22] By using such a technique, it is possible to estimate the *two-dimensional* standard deviation ($\Delta 2D_{exp}$) of the interparticle distance. Under the experimental conditions of Figure 2b, $\Delta 2D_{exp}$ was found to be 900–1000 Å, i.e. for an interparticle distance ($2D_{exp}$) of 10000–12000 Å. The ratio $\Delta 2D_{exp}/2D_{exp}$ amounts to about 0.1 at concentrations of 0.039 g/mL. Needless to say, these values vary with the experimental conditions. At lower latex concentrations, and naturally also for smaller particles, the ratio must be larger.

This information is of considerable significance in the case of macroion systems. As already mentioned, small-angle X-ray (and also neutron) scattering gives a single, broad peak for macroions. It is often insisted that the ob-

served scattering peak does not correspond to a Bragg diffraction, because higher peaks are lacking. In this respect, it should be remembered that the scattering intensity is strongly influenced by the size and number of the ordered structures, thermal motion, and paracrystalline disorder of the diffracting components. Thus, the observed single broad peak implies either (i) the absence of an ordered structure or (ii) substantial distortion of an ordered structure. According to a theory proposed by *Hosemann* and *Wilke*[23] for paracrystals, when the distortion factor multiplied by the order of the diffraction peak n is larger than 0.35, the n-th peak is not distinguishable. If $\Delta 2D_{exp}/2D_{exp}$ is equated to the distortion factor, though not rigorously correct, the number of observable peaks should be three for the 0.039 g/mL solution. At lower latex concentrations or for macroions, which are much lighter and smaller than latex particles, it is reasonable to anticipate much more pronounced disorder and hence one or two scattering peaks. This is a very rough estimate but might not be very far from the truth, judging from the recent work of *Kato* et al. on laser light scattering,[24] which shows only a single broad peak at a concentration of 0.00018 g/mL (much lower than that in Fig. 2b, 0.039 g/mL) for smaller latex particles (diameter: 1540 Å). A similar situation was reported for a latex solution by *Versmold* et al.[25] Although a more rigorous calculation is in progress,[8,26] it might be claimed that the lack of higher diffraction peaks does not necessarily imply the absence of an ordered structure. Due attention must be paid to paracrystalline distortion of the ordered structures.

5. Comparison of $2D_{exp}$ with $2D_0$ — Two-State Structure and Interparticle Attraction

In addition to the Bragg spacing ($2D_{exp}$), a theoretical interparticle distance ($2D_0$) calculated from the solute concentration by assuming a uniform simple cubic distribution is given in Table 1.[27] It is immediately clear that $2D_{exp}$ is smaller than $2D_0$, except for the samples with low molecular weight ($M_W = 4.6 \times 10^3$ and 1.8×10^4), if a $\pm 5\%$ error in $2D_{exp}$ is assumed. The relation $2D_{exp} < 2D_0$ was also confirmed for sodium polyacrylate[6] and poly-L-lysine · HBr.[4] In this respect, it is interesting to inquire into the case of polymer latex particles. The interparticle distance observed ($2D_{exp}$) for latex samples is compared with the theoretical values ($2D_0$) in Table 3.[28] For the sample of *Hachisu* et al.[21], which has a relatively small number of charges, the relation $2D_{exp} \approx 2D_0$ is seen to hold. On the other hand, for highly charged particles $2D_{exp} < 2D_0$ applies at low concentrations, and $2D_{exp} \approx 2D_0$ when the concentration is high. These facts, and the relation $2D_{exp} < 2D_0$ observed for the macroions, suggest that there must be an attraction between the solute particles and, furthermore, that the attraction is more intense for particles having a larger number of charges. The second aspect is consistent with the tendency for $2D_{exp}$ to become smaller with increasing molecular weight of the synthetic macroions, and hence number of charges (cf. Table 1, entries 9 and 10 or entries 11 and 12, and Table 2).

These results are unexpected, but can be rationalized if the concentration effect of charged particles and the action of counterions are properly considered. The inequality of $2D_{exp}$ and $2D_0$ suggests the coexistence of ordered and disordered regions of solute particles (namely a two-state structure) in dilute solutions. The existence of a two-state structure can be confirmed by the naked eye for latex solutions at relatively low concentrations.[17] Figure 3[30] shows the two-state structure. The difference between the coexisting ordered and disordered regions is more than obvious by comparing the trajectories of the particles in the two regions. Figure 3 provides visible evidence for the interparticle attraction, since the localized ordering seen on the left-hand side of the figure has a free boundary, and such a "condensed" or "non-space-filling" ordered structure is inconceivable unless an interparticle attraction really does exist.

Table 3. Comparison of the observed interparticle distance ($2D_{exp}$) and the theoretical average distance ($2D_0$) for charged polymer latex solutions [a]. A: *Hachisu*'s sample [21] (diameter 3410 Å, < 1000 charges per particle [b]. B: *Ise*'s sample [17] (diameter 4190 Å, 2×10^5 charges per particle) [b].

Sample	Concn. [Vol-%]	$2D_{exp} \times 10^{-3}$ [Å]	$2D_0 \times 10^{-3}$ [Å]
A	0.4	18	19.4
	0.55	15	17.5
	1.5	10	12.5
	4	8	9
B	0.75	12.6 ± 0.7	19.4
	1.40	10.7 ± 0.7	15.7
	3.72	8.9 ± 0.7	11.4
	5.59	8.2 ± 0.6	9.9
	11.2	7.1 ± 0.6	7.9

[a] The error in our measurements was estimated to be 15% at worst. The data for *Hachisu*'s sample were evaluated from a published micrograph. An error of 15% is also reasonable. [b] The diameter was determined by electron micrography and the number of charges per particle was estimated by conductometric titration. The number of charges in *Hachisu*'s sample could not be measured because of the small number. Thus, 1000 is the largest possible value estimated on the basis of the experimental precision of the conductometric measurements.

Kato et al.[24] also calculated $2D_{exp}$ for the above-mentioned small latex particles. For a 93%-sulfonated (i.e., highly charged) polystyrene latex of 1540 Å diameter, the $2D_{exp}$ values were found to be 8×10^3, 3.8×10^3, 2.9×10^3, and 2.8×10^3 Å at concentrations of 1.81×10^{-4}, 5.45×10^{-4}, 1.09×10^{-3} and 2.18×10^{-3} g/mL, respectively, while the $2D_0$ values were 1.5×10^4, 5.2×10^3, 4.1×10^3 and 3.3×10^3 Å. The relation $2D_{exp} < 2D_0$ is obviously fulfilled. This experiment is important in that it shows that the inequality holds also in the inner part of the solution, where the laser light was diffracted. When we claim the inequality relation purely on the basis of microscopic observation, it may be criticized that the relation is an artifact whose origin lies in the sedimentation of latex particles to the bottom of the solution cell. (With the microscopic method, we are forced to observe particles in the region not much further than 10^5 Å from the bottom of the cell, since an inverted microscope is used, and the solution is usually turbid (cf. Ref. 21). It must be remembered that the specific weight of our latex sphere (copolymer of styrene and styrenesulfonate) is 1.03 g/cm^3). The local concentration near the bottom can be higher than that in the upper part of the solution. If the concentration difference is very high, it may happen that $2D_{exp}$ is smaller than $2D_0$. However, the fact that $2D_{exp} < 2D_0$ was also observed by the

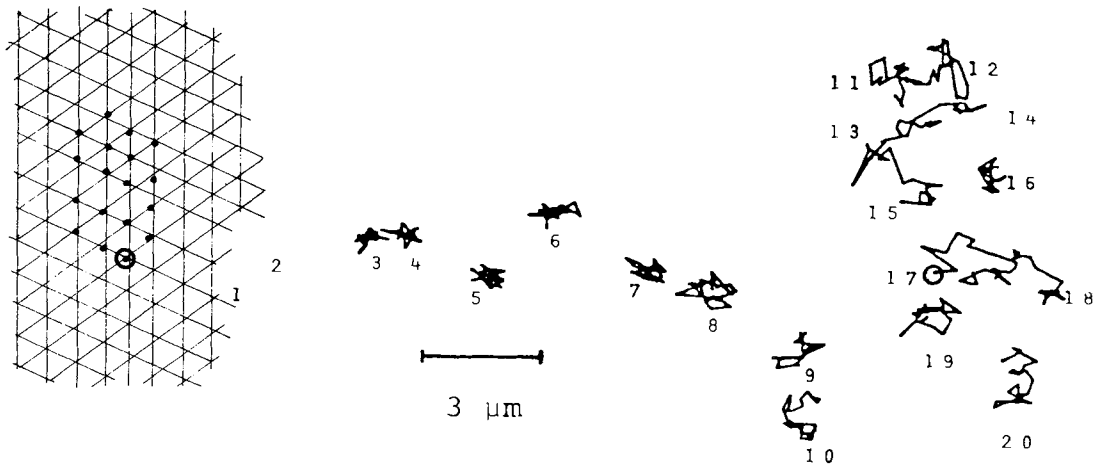

Fig. 3. Coexistence of ordered (left) and disordered regions (right) in a latex solution and trajectory of the particles in 1 s. Latex: SS-37 (the same as in Fig. 2b), concentration: 2%. On the left-hand side, a "solid"-like hexagonal array with a high density is seen, which coexists with a much less dense "gas"-like disordered region (right-hand side). $2D_{exp}$ in the ordered region is about 10^4 Å, whereas $2D_0$ is about 1.5×10^4 Å. Thus the total volume of the ordered regions in the solution amounts to $1/3.4=[(10^4/1.5 \times 10^4)^3]$ of the total solution volume, although the volume of a single ordered region has not yet been determined. The particles in the ordered region show oscillatory motion (as in Fig. 2b), but the amplitude is too small to see on the scale chosen here. The random motion of the particles in the disordered region is close to that predicted according to the Einstein theory for Brownian motion, though we would like to postpone drawing a definite conclusion until a much larger number of particles have been treated. (Taken from Ref. [30] by courtesy of the American Chemical Society.)

laser light diffraction clearly indicates that the sedimentation effect, if any, was not of considerable importance. The relatively minor role of this effect is also demonstrated in Figure 3, which shows the particle distribution in a horizontal, (not vertical) plane: if this effect were to be substantial in producing local ordered regions of latex particles (and hence in leading to $2D_{exp} < 2D_0$), we would have to admit larger acceleration of gravity on the left-hand side of Figure 3 than on the right-hand side. This is inconceivable.

A most convincing result substantiating the inequality $2D_{exp} < 2D_0$ for polymer latex solutions was recently reported by *Yoshiyama* et al.,[31] who obtained very clear Kossel images. At low latex concentrations below 2 vol-% a body-centered-cubic structure was found, whereas above 3% a face-centered-cubic lattice was identified. In both cases, lattice constants were found that were typically smaller than would be expected for a uniform particle distribution.

6. Activity of Ionic Solutes

The activity a is a measure of the non-ideality of the solution. In spite of the basic nature of this quantity, not much attention has been paid to it as far as ionic polymers and polymer latex particles are concerned. Needless to say, all concepts or conclusions drawn from experimental data must be consistent with the activity data. Thus, it would be of interest to analyze the concept of intermacroion interaction discussed in Sections 3–5 in terms of the activity. Figure 4 gives experimental data of the activities of polymer latex particles (a_{2p}) and of their counterions (protons) (a_{2g}) and the mean activity (a_z). These quantities were obtained from vapor pressure measurements, using the Gibbs-Duhem relation. Most noteworthy is the dramatically steep decrease of a_{2p} with increasing solute concentration.[33] In contrast, the counterion activity (a_{2g}) increases steadily with concentration, as is usually the case

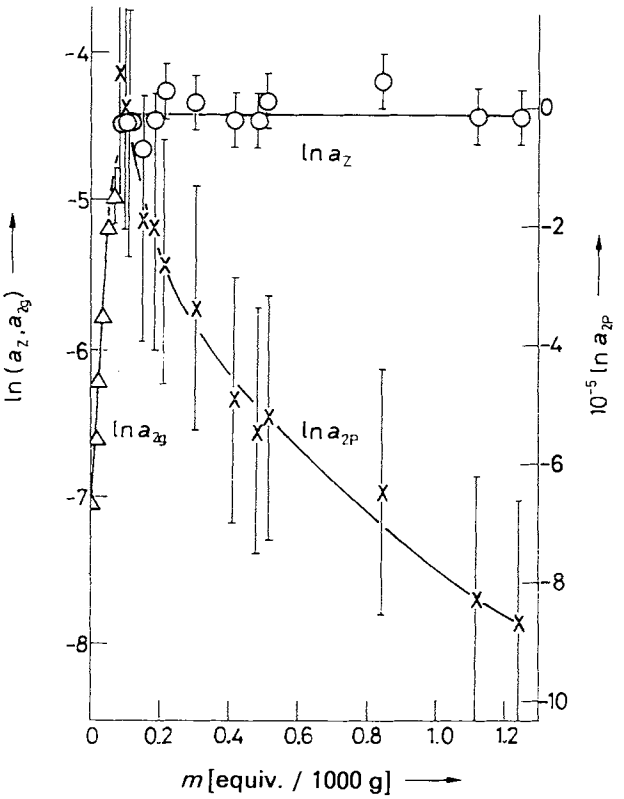

Fig. 4. Mean activity of latex particles (a_z) and ionic activities of the latex ions (a_{2p}) and of the counterions (protons) (a_{2g}) in water at 25 °C. Latex: polystyrene latex sulfonated with sulfur trioxide ("Latex No. 3"), diameter: 620 Å, charges (Z): 3.5×10^5 per particle (charge density=4.5×10^8 µC/cm^3). a_z was evaluated by the Gibbs-Duhem equation from the solvent (water) activity determined by vapor pressure measurements. a_{2g} was determined by conventional potentiometry. The a_z value at 0.1 equiv/1000 g water was set equal to the a_{2g} value so that a_{2p} was unity at this reference concentration. The vertical bar denotes the estimated error limit. (Taken from Ref. [32] by courtesy of the American Chemical Society).

with simple ions. The activity a is defined as the quotient of the vapor pressure (or more exactly fugacity) of the solute and that of a reference state. According to Roult's law, in an ideal solution, in other words in the complete absence of interaction, $a=N$, where N is the concentration. That is, in the ideal case a must increase with increasing concentration. This is readily accepted, because a signifies the volatility of a component, and the vapor pressure (and hence the number of component molecules or ions in the gas phase) may be expected to increase when the number (and hence concentration) of components in the solution increases. When taking this into consideration, the tendency of a_{2p} to decrease is at first sight perplexing. Nevertheless, it is understandable if we accept the existence of an intermacroion attraction, which prevents macroions from transferring from the solution phase to the gas phase. A similar trend is also found in the case of linear macroions.[34] The activity of the macroions decreases steeply with increasing concentration, and the rate of this decrease increases when the charge density of the macroion increases. The latter feature suggests that the attraction under discussion becomes stronger with increasing charge density. This is indeed consistent with the previous finding that $2D_{exp}$ (estimated by X-ray scattering or by microscopy) becomes smaller with increasing number of charges on the macroion (see Sections 3 and 5).[35]

7. Recent Theoretical Approach—Verification of Electrostatic Attraction between Similarly Charged Particles—Limit of the DLVO Theory of Colloidal Stability

As discussed in the preceding sections, there is indeed an attraction between macroions or ionic latex particles in solution in spite of charges of the same sign. As shown by the dependence of $2D_{exp}$ on the salt concentration,[5-7] the attraction is of an electrostatic nature. Furthermore, the attraction increases (or $2D_{exp}$ becomes smaller) with increasing charge. About 20 years ago, we realized the existence of such an intermacroion attractive interaction on the basis of the dependence of the mean activity coefficients of polyelectrolytes on concentration.[38] For colloidal systems, *Langmuir*[39] had already emphasized the importance of attraction between charged micelles and a surrounding atmosphere of ions of opposite charge; this attraction exceeds the repulsive force between the micelles. According to him, it is one of the three fallacies in the theories of colloidal systems to ignore or neglect this interaction.

Langmuir's claim was criticized by colloid scientists.[40] Similary, the electrostatic interparticle attraction, which we discuss on the basis of X-ray and microscopic studies on macroions and latex particles, appears to be judged as "unacceptable" in the light of the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory of colloidal stability. According to this theory, two colloidal spherical particles immersed in a continuous medium (dielectric constant ε) should simply repel each other. The repulsive potential (V_R) is given by

$$V_R = \frac{\varepsilon x \psi_0^2}{2} \ln\left[1+\exp\left(-\kappa x\left(\frac{R}{x}-2\right)\right)\right]$$

where x is the radius of the sperical particle, R the center-to-center interparticle distance, ψ_0 the surface potential, and $1/\kappa$ the Debye radius. However, since condensed systems such as colloidal solutions or solutions of macroions can exist only by virtue of some kind of attractive interaction, V_R does not represent the total potential. As a matter of fact, a van der Waals type attraction (V_A) is assumed in the DLVO theory, which is written

$$V_A = -\frac{A}{6}\left[\frac{2x^2}{R^2-4x^2} + \frac{2x^2}{R^2} + \ln\frac{R^2-4x^2}{R^2}\right]$$

where A is the Hamaker constant. This constant is said to lie between 0 and 6×10^{-12} erg.[40] Thus, the DLVO theory indicates that the electrostatic interaction between colloidal particles must be repulsive, and that the interparticle attraction must be non-electrostatic. This contradicts our observations.

Recently, *Sogami*, a theoretical elementary particle physicist, became interested in latex solutions as classical models for atomic and molecular assemblies and has formulated a new theory.[41,42] He successfully proved the presence of an electrostatic attraction between similarly charged particles and has clarified the origin of such an attraction. The reader is referred to the original articles[41,42] for detailed calculations; here, we shall comment only briefly on the essential aspects of the theory. In Figure 5, three negatively charged colloidal particles and their counterions are illustrated. When the particles are not highly charged (Fig. 5a), the interaction between the particles and the counterions is relatively weak, so that the solution volume (V) represents the space in which the counterions can move. In the case of highly charged particles (Fig. 5b), however, the particle-counterion interactions are so intense that the counterions are forced to reside in a small space (v'). Under such conditions, there arise two basic problems. First, an interaction is generated between the particles, e.g. P-1 and P-2, because the counterions such as A, which reside in the space in between the two particles, are attracted by the two particles at the same time. Here, the readers are reminded of the analogy with the triple ion formation or with the one lady-two gentlemen relationship depicted in the Tale of Genji. It would be no wonder if attraction were to be created with other neighboring particles in succession and in a three-dimensional way. Under suitable conditions, the attraction would lead to the formation of intermacroion "linkage" according to our earlier terminology[38] and eventually to some kind of clusters of particles.

There are several factors favoring or disfavoring the intermacroion attraction: (1) Obviously, the kinetic energy disfavors it. Elevation of the solution temperature would help the counterions to escape from the sphere of influence of the particles. In other words, the volume v' increases with increasing temperature. Under such conditions, the attraction would be weakened. (2) Similarly, a lowering of the concentration of the particles (and hence of the counterions) diminishes the chances for the counterions to stay in the region near the particles. (3) In contrast, the use of multivalent counterions (as opposed to monovalent ones such as H^+ or Na^+) would intensify the inter-

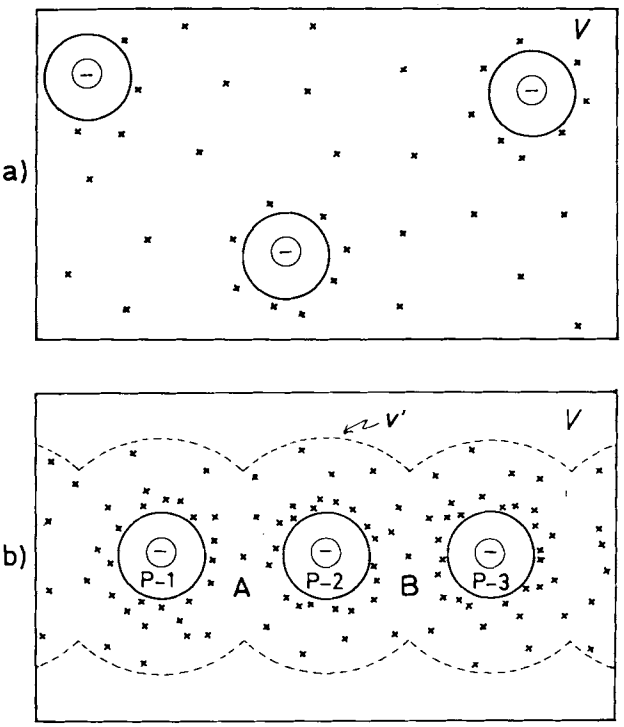

Fig. 5. Schematic representation of the distribution of counterions around charged particles. a) Distribution around low charge particles. The counterions can reside in the entire volume (V) of the solution, because the particle-counterion interaction is not strong; the number of the counterions per unit volume, however, decreases with increasing distance from the particles. b) Distribution around highly charged particles. The strong interaction between the particles and counterions restricts the freedom of motion of the latter: the counterions are confined to a small space v'. The difference $V-v'$ is expected to become larger with increasing charge of the particle. Thus, the solution volume loses its significance as the thermodynamic parameter for highly charged particles. Because of the weak particle-counterion interactions, no ordering of the particles is expected in the case (a), whereas we have ordering of the particles in the case (b).

macroion attraction, because the attraction between the particles and the counterions increases with increasing valency of the counterions. (4) Similarly, the intermacroion attraction would become stronger if the particle valency is raised, because the counterion-particle interaction would be enhanced. Although the particle-particle repulsive interaction is intensified at the same time, this interaction is operating at much larger distances than the counterion-particle interaction, so that the overall result is the intensification of the attraction. In this respect, the aforementioned statement by *Feyman*[14] is informative (cf. Section 3).

It should be pointed out that all these four changes in the attraction between macroions are predicted in *Sogami*'s theory. Also noteworthy is that these changes have, at least qualitatively, been demonstrated experimentally. For example, the ordering of polymer latex particles in solution can be destroyed by increasing the temperature.[43] Our own experiments on a soluble polyelectrolyte[5] showed that the intensity of the diffracted X-ray diminished with increasing temperature, indicating deterioration of ordering of the macroions (and hence weakening of the intermacroion attraction). It is widely recognized that the ordering of latex particles can be observed at relatively high latex concentrations. This seems to be the case with other charged species. Regarding the third factor mentioned above, namely the counterion valency, the intensified intermacroion attraction explains the autocomplex-coacervation reported by a Dutch group,[44] which was observed when the counterions of valency two or higher were involved. And with respect to the fourth factor, it was mentioned earlier (Section 5) that $2D_{exp} \approx 2D_0$ applies for low charge density latices, whereas $2D_{exp} < 2D_0$ holds for highly charged latices (Table 3). The intensification of the intermacroion attraction with increasing charge number of the macroion follows quite clearly from Table 2.

The second important feature associated with the confinement of the counterions within the small space v' is the inequality of the Gibbs and Helmholtz free energies of interaction. When ionic species have low charge numbers, as is the case for simple salts, this problem is not serious. At sufficiently low concentrations, interionic interaction is relatively weak so that the ions have the freedom to move around in the entire volume of the solution. Thus, the solution volume V has a definite thermodynamic significance. For such solutions, the free energy of interaction can be calculated with the assumption of a constant solution volume, if the compressibility of the solvent is negligibly small. Then, as *Debye* and *Hückel* carefully discussed in their original paper,[15] this is a permissible assumption as far as simple salt solutions are concerned. The Helmholtz free energy change (dF) is then equal to the Gibbs free energy change (dG). In other words, in the basic thermodynamic relation $dF = dG - p\,dV$, the second term on the right-hand side is neglected. It seems to us that the basic nature of this assumption is not given sufficient attention: a careful discussion of this problem is only to be found in a textbook by *Fowler* and *Guggenheim*.[45] The problem is not mentioned at all in most of the text-books on colloid chemistry and statistical thermodynamics. This is also true in the case of the DLVO theory on colloidal stability: dF is assumed to be equal to dG. But, in our opinion this assumption is invalid for colloidal particles, and even more so when such particles are highly charged. This is almost self-evident from Figure 5. As has already been pointed out, the solution volume V has no thermodynamic significance for highly charged particle systems, because the counterions have only volume v' at their disposal. In other words, the systems are "compressed" from V to v' by charging-up of the particles and counterions. This compression makes the term $p\,dV$ negative and sizeable, and even more so for highly charged particles[46] In other words, dF is larger than dG. It should be remembered that the difference between dF and dG has nothing to do with the compressibility of the solution, but has its origin in the high valency of the particles and hence in the intense interaction between the particles and the counterions.

Since the free energy of interaction is given as the product of the potential and the quantity of charge, the above mentioned difference in dF and dG may lead to different potential values (cf. Ref. [45] for problems relevant to the determination of the free energy of interaction in ionic solutions). Figure 6 shows a graphical representation of *Sogami*'s potentials. The potential curve derived from the Helmholtz energy (U^F) shows a monotonous decrease with increasing particle-particle distance R. This implies that

only electrostatic repulsion exists between the two particles. However, the potential from the Gibbs free energy (U^G) has a minimum point at a relatively large R value. This means that there is strong repulsion at small distances and weak attraction at large ones.

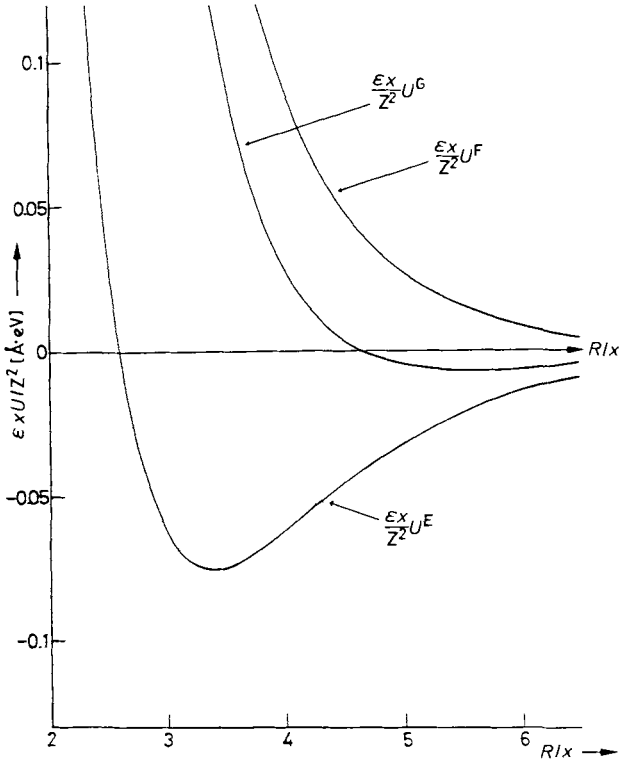

Fig. 6. Pair potential curves derived by the Sogami theory as a function of interparticle distance R. The numerical calculation was carried out for $\kappa x=1$, where κ is the screening parameter and x is the radius of the particle. ε is the dielectric constant of the solvent and Z is the number of charges the particle carries. U^E is the potential referred to the electrostatic energy; the curve shows a very strong attractive component. U^F is the potential corresponding to the Helmholtz free energy of interaction and indicates that there is only repulsive interaction between two similarly charged particles. The difference between U^E and U^F is due to entropic contributions of the counterions as discussed by *Verwey* and *Overbeek* [40]. U^G was calculated taken into account the volume contraction from V to v', which is not negligible for highly charged particles, and indicates the existence of a weak but definite attractive contribution, namely a secondary minimum. It should be remembered that this minimum is created by the equilibrium between electrostatic repulsion and electrostatic attraction; it is not due to the presence of a van der Waals type attraction. (Taken from Ref. [42] by courtesy of the American Institute of Physics.)

It is self-evident then that the experimental data obtained under isobaric conditions should be referred to dG, and not to dF. Hence, the presence of an electrostatic attraction between similarly charged ionic species can be claimed as having been proven by *Sogami*'s theory. Once again, it should be emphasized that attraction is possible through the intermediary of counterions; as expected, the attraction is particularly large when the particles are highly charged.

Therefore, the widely accepted view that colloidal particles or macroions in solution should repel each other as a result of having the same charge cannot be totally correct. It may be correct for particles of low charge density, because the "compression" is then negligible. In other words, the DLVO theory holds for the limiting case of colloids with low charge density.

The following example will serve to illustrate the results of the Sogami theory: For particles with a charge of 4×10^3 and a diameter of 1700 Å, the U^G minima lie at 1.8×10^4 and 7.2×10^3 Å at concentrations of 0.004 and 0.04 g/mL, respectively. The $2D_{exp}$ values for latex particles having similar properties[22] are 1.8×10^4 and 8.0×10^3 Å, respectively (for detailed quantitative tests see[41,42]).

One question remains to be answered: Why has the DLVO theory been regarded as satisfactory in interpreting various colloidal phenomena? One of the reasons could be that, in most cases, low charge density particles have been studied. With such particles, the attraction is usually weak, so that the particles are situated at close to the largest possible separation, namely at $2D_0$. Indeed, the value $2D_{exp}$ for *Hachisu*'s sample agrees with $2D_0$ (Table 3). A neutron-scattering study of lithium dodecyl sulfate (LDS)[48] gave 62 Å and 52 Å for the intermicellar spacing at LDS concentrations of 0.598 and 1.107 M, respectively, while $2D_0$ was found to be 66 Å and 54 Å, respectively. The agreement appears to be in favor of an interpretation of the results in terms of Coulombic repulsion. This conclusion, however, is erroneous. Particles carrying a small number of charges (such as ionic micelles) are not suitable for exploring the true nature of interactions between colloidal particles.

8. General Discussion

8.1. Conformation of Linear Synthetic Macroions

The $2D_{exp}$ and $2D_0$ values (Table 1) were calculated without any assumptions concerning the geometry of the macroions. For this reason, we find it necessary to make a brief comment on the conformation of linear synthetic macroions. It is generally believed and often claimed that linear macroions are stretched like a rod. We also have been able to demonstrate good agreement of various experimental data on soluble polyelectrolyte solutions with the Manning theory,[49] which assumed rod-like models for macroions.[50] The justification for this assumption is that α has a value close to 2 for salt-free polyelectrolyte solutions. α is the exponent in the relation $[\eta]=KM^{\alpha}$, where $[\eta]$ is the intrinsic viscosity and K a constant.[51] It should be remembered that $[\eta]$ refers to infinite dilution. *Fuoss* clearly stated that "the configuration of a polyelectrolyte at infinite dilution is an extended rod",[51] but it seems that this boundary condition is completely ignored or neglected in recent work on polyelectrolytes. The fully stretched model is justified only at infinite dilution. It may be correct, because the degree of dissociation may be large at infinite dilution. In other words, the counterions might diffuse away from the macroion domain at such a dilution, so that the ionized groups of the macroion repel each other. However, there remain two problems: The first is a technical one related to the determination of $[\eta]$ in *salt-free* polyelectrolyte solutions, which is a formidable task. As clearly demonstrated by *Conway* et al.,[52] *Fujita* and *Homma*,[53] *Eisenberg*,[54] and *Butler* et al.,[55] the η_{sp}/C–C curve (C=polymer concentration) has a maximum at a very low concentration (C_1) and a minimum at a much higher concentration (C_2).

The minimum is widely recognized, whereas the maximum has been completely ignored in recent papers on polyelectrolyte solutions. This appears to be unavoidable, since the experimental determination of the maximum is difficult, except when the highly-developed techniques of the experts such as mentioned above are available. As a matter of fact, C_1 lies at $2\text{-}3 \times 10^{-4}$ g/L, for example, for polystyrenesulfonate samples having a molecular weight of about 10^6.[55] This range is not easily accesible. Hence, the "experimental" value of $[\eta]$ that was obtained by ignoring the maximum point at C_1 must be carefully reevaluated, and the conclusion that α assumes a value close to 2 and that the macroions are consequently stretched out like rods, must be reconsidered. We believe that the linear macroions are *probably* stretched below C_1; but this is not the case above C_1. The well-known sharp drop in the η_{sp}/C value with increasing concentration in the concentration range between C_1 and C_2 might be caused by a rapid shrinking of the macroions. This in turn could be caused by an interaction between ionized groups in the same macroion, as occurs in higher ionic aggregates.

The second problem concerns the fact that the macroion domain corresponds to a very highly concentrated solution of a simple electrolyte. This point is likewise very often ignored or neglected. For example, the distance between two ionized groups of vinyl-type polyelectrolytes such as, e.g., polyacrylates or polystyrenesulfonate is ca. 3 Å, even if one supposes that the molecules are stretched. This is surprisingly small, if one recalls that the interionic distance for 1-1 type electrolytes at a concentration of 10 M is about 4 Å. Since 75% of the counterions are bound to macroions,[56] the macroion domain corresponds very roughly to a 10 M or more concentrated soution of a simple electrolyte. How can we expect, under such conditions, that the ionizable groups of a macroion are dissociated in such a way that the ionized groups repel each other to cause the stretching? It would be reasonable and meaningful to accept that the dissociation does not take place to such an extent. On the other hand, ionic association phenomena, which are known to occur in concentrated simple electrolyte solutions, may be expected in the macroion domain. For example, triple ions may be formed under such conditions. If this were to happen between two ionized groups of the same molecule and a counterion, or if one triple ion were to be formed intramolecularly, the polymer chain would not be stretched out but form a loop. For loop formation it suffices if only *0.2%* of the total ionizable groups inside a molecule of 1000 repeating units participate in the triple ion formation.

Once again, it should be emphasized that macroions are plausibly almost completely dissociated at very low concentrations (below C_1), whereby the macroions assume a rod-like structure. Probably the steep, positive slope of the η_{sp}/C-C curve observed by the above-mentioned authors[52-55] reflects this situation; above C_1, however, this is not at all certain. Such an argument of ours may be criticized as being too speculative. If this criticism were justified, however, then the reverse view, namely that such an ionic association does not take place and that the macroions are stretched out at relatively high concentrations accessible to X-ray or neutron scattering experiments, is no less speculative than ours. Under such circumstances, it is first necessary to carry out further detailed studies on the geometry and conformation of the linear macroions at the concentrations usually employed in X-ray or neutron scattering (much higher than C_1 and C_2). Secondly, we hesitate using the so-called C^* concept,[13] which is defined by the maximum length of the stretched chain, and we also hesitate adopting the rather artificial division of the concentration range into "semidilute" and "dilute" regions on the basis of C^*, since the C^* concept is in no way certain.

In this context, a recent study by *Yanagida* et al.[57] on DNA using fluorescence microscopy is quite informative. These authors successfully and directly photographed the dynamic movement of the helical strand in solution with the aid of a video system. The helix structure was clearly seen to fluctuate in shape, between that of a flexible rod, compact sphere, and prolate ellipsoid, within a short period of about 6 s. Such a dynamic situation is surprising, since we have been led to believe in the stiffness of the helical structure. The fluorescence microscopy was mainly carried out in a buffer solution, which contained a relatively high concentration of salt. Similar dynamic behavior was also observed at much lower salt concentrations.[58] It would now be less plausible to assume a highly stretched conformation for the much more flexible vinylic macroions at such concentrations as employed in X-ray and neutron scattering experiments.

8.2. The Correlation Hole Concept

There is a counterinterpretation[59] for the occurrence of a single broad peak of scattered X-rays from solutions of macroions, namely the correlation hole concept. *Weil* et al. have criticized the interpretation advanced by *Chu* et al.[7] and by us[6] (see Section 3). They stated that, "The maxima are not reminiscent of an order in the particle distribution. They are simply due to the correlation hole produced by the strong repulsive interaction both from hard sphere and electrostatic potentials." This criticism can however be refuted as follows: First, if the maximum originates from the hole by the (repulsive) interaction, it must be shifted toward smaller angles, in other words the spacing must become larger with increasing valency. This, however contradicts the experimental facts (see Tables 1 and 2). The contradiction is very definite in the case of bovine serum albumin, whose molecular conformation is more well-defined than that of the linear macroions. Specifically, for bovine serum albumin, $2D_{exp}$ decreases from 133 Å to 105 Å when the pH is raised from 8.08 to 12.2 (in other words when the (negative) charge number is increased from 20 to 80). Secondly, the correlation hole theory gives a negative scattering intensity in the small angle regions at the high BSA concentrations employed in the X-ray scattering experiments. This is particularly true when their charge number parameter is small.[60] Experimentally, positive scattering intensity was observed. Furthermore, when the charge number parameter (or the charge number) is assumed to be as high as those of typical polyelectrolytes such as sodium polystyrenesulfonate with a molecular weight of 74000, the theory shows no scattering peak for physically reasonable values of macroion radius, which is again in contradiction

to that observed in practice. Thirdly, *Weil* et al. assumed only repulsive interaction between macroions, which was claimed to produce the correlation hole. This seems to be a fundamental error, since condensed systems with free boundaries cannot physically exist without net attractive interaction. Such an assumption could be correct—if at all—only at extremely low concentrations, when counterions may diffuse away from the macroions. This basic error is probably responsible for the above mentioned discrepancy between theory and experiment. For these reasons, and also in light of the observed dependence of the scattering behavior on molecular weight, the correlation hole theory should be viewed with extreme caution, at least for ionic macromolecules.

9. Summary and Outlook

Ever since *Bernal* and *Fankuchen* postulated an equidistant distribution of rod-like tobacco mosaic virus particles in very concentrated solutions,[61] several authors such as *Oster* et al.[62] have proposed a similar ordering of other biological and synthetic macromolecules. At that time, the apparatus available for X-ray scattering experiments were not sensitive enough for the study of dilute solutions. Recent technical developments now enable us to investigate relatively low concentrations. The development of new techniques such as neutron scattering and dynamic light scattering and the refinement of well-established techniques have now provided more powerful methods for the analysis of the distribution of particles in dilute solutions. For example, *Schmitz* et al.[63] have carried out dynamic light scattering measurements on poly-L-lysine at very low polymer and salt concentrations and have concluded that there exist "regions of correlated polymer motions for sufficiently high "local" concentrations and regions of "isolated" particles for sufficiently sparse local concentrations". It is difficult to find the essential difference between this statement and terminology such as the two-state structure proposed by us some time ago.[1,6] They further describe the role of counterions as screening of the direct repulsive interaction between the polyions and providing a "fluctuating dipole" interaction. In our opinion this interaction and the intermacroion attraction through the intermediary of counterions describe one and the same situation, except of course that the former emphasizes the dynamic character of the counterions. Recent studies by *Nemoto, Kurata* et al. also appears to provide positive support for the two-state structure.[64] Classical light scattering experiments on salt-free polyelectrolyte solutions at very low concentrations showed that the scattered intensity was characterized by a single broad peak, which is quite similar to the maxima obtained by X-ray and neutron scattering at much higher concentrations.[65] *Drifford* and *Dalbiez* concluded therefrom that their result was consistent with a short and local ordering. We are of the opinion that, if paracrystalline distortion is taken into consideration, this light scattering data is also consistent with the concept of a relatively long-range ordering of macroions, which would be stretched out fairly strongly at the concentrations employed.

It becomes increasingly clear that ionic solutes are structurally organized in dilute solutions under suitable conditions. Depending on the size, shape, and weight of the solutes, the experimental techniques to be used vary from solute to solute. The mode of ordering, the lifetime, and the size of the ordered structure also varies. When the fact that an ordered structure can exist in liquid states is fully comprehended, both the static and dynamic aspects of the ordering phenomena become equally important. Ignoring either of them would lead us to completely erroneous conclusions. The study of the trajectory of latex particles in ordered structures is an important advance, though much detailed study remains to be done in the future. The polymer latex has provided much valuable information, not directly accessible from X-ray or neutron scattering.

The ordering phenomena is obviously of great significance in the physical chemistry of ionic solutions; adequate knowledge about the nature of ordering is indispensable for a complete understanding of dilute ionic solutions. Furthermore, we believe that such a phenomenon might also be relevant to some of the activities of biological macromolecules. In this connection, for example, *Srere* has pointed out that the activity of Krebs cycle enzymes might be affected by their spatial relationships in the mitochondrial matrix.[66] From kinetic data, it has been concluded that ordered enzyme arrays are able to achieve higher throughputs than random arrays of enzymes at the same substrate concentration. To date, enzymologists have mostly analyzed the behavior of individual enzyme molecules in the test tube. The kinetics of enzymes in organized states may turn out to be an interesting subject in the future.[67]

The author expresses his gratitude to his co-workers, whose names are referred to in the references. He also expresses his thanks to Professor Ikuo Sogami for helpful discussions, Dr. von Korff, Michigan Molecular Institute, for having drawn attention to Ref. [66], and Professors J. Th. G. Overbeek and Shiro Akabori for valuable comments and for calling the author's attention to the relationship between "Intermacroionic" attraction and the coacervation phenomena. This work was generously supported by the Ministry of Education, Science and Culture (Grant-in-Aid for Specially Promoted Research), the Toray Science Foundation, the Mistubishi Foundation, and the Nissan Science Foundation, to whom sincere thanks are due.

[10] Neutron scattering on macroion solutions also shows a single broad peak [11, 12], which was interpreted by an isotropic model proposed by *de Gennes* et al. [13]. The observed molecular weight dependence mentioned in the text indicates that the isotropic model is not generally valid. It should be mentioned that *Gennes* et al. did not carry out experiments on the molecular weight dependence. The statement that the scattering behavior is molecular weight independent is therefore unfounded.

[27] By assuming an hexagonal or face-centered cubic distribution we obtained slightly larger $2D_0$ values. However, the difference in the distribution modes is small in comparison with the values of $2D_{exp}$, so it does not affect our arguments [17].
[28] The $2D_{exp}$ value for latex solutions is affected by the column height of the solution. However, our experiments were designed to make the uncertainty in $2D_{exp}$ smaller than 10%, by taking into account previous results [29].

[33] The activity coefficient of simple ionic species is assumed to be unity at infinite dilution. However, in the case of macroions, interaction still persists between the ionic groups even at infinite dilution, because the ionic groups are bound to each other by covalent bonds. In the light of this property, the activity coefficient of the macroion cannot be set equal to unity at infinite dilution. In Figure 4 the a_{2p} value was conveniently assumed to be unity at 0.1 equiv./1000 g. Since we are interested in the concentration dependence of the activity, the choice of the standard does not matter. In this reference system, $\ln a_{2p}$ at 1.2 equiv/1000 g is about -8.5×10^5, whereas at 0.1 equiv/1000 g it is 0. Such a surprisingly sharp drop in $\ln a_{2p}$ is due to the fact that the stoichiometric valency (z) of the latex particle under consideration is 3.5×10^5 and a_z is defined by the thermodynamic relation $a_z^{1+z} = a_{2g}^z \times a_{2p}$. Similar drastic decreases in $\ln a_{2p}$ were also noted earlier [34] in the case of synthetic macroions.
[34] N. Ise, T. Okubo, *J. Phys. Chem. 70* (1966) 2407.
[35] The tendency for solute activity to decrease with increasing concentration is not peculiar to macroions. As a matter of fact, the activity of a neutral polymer decreases with concentration in a limited concentration range when the so-called interaction parameter χ is large according to the Flory-Huggins theory (cf. Ref. [36] and [37]).

[67] *Note added in proof:* In 1984, *Schellman* discussed the forces stabilizing the DNA lattice [68] and pointed out that the electrostatic interaction is one of the major factors. He states, "The repulsion of one molecule by another has been overemphasized in discussions of condensed phases containing DNA. An analogy with ionic crystals is not unreasonable. This [repulsive energy] is more than compensated for by the attractive interactions of Cl^+ lattice with the Na^+ lattice. The key point is that ions of opposite charge are nearer to one another than ions of the same charge." The situation described in this statement is basically the same as that discussed in the text.

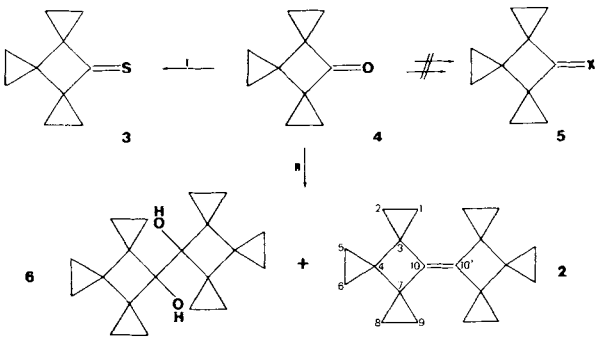
10,10'-Bi(trispiro[2.0.2.0.2.1]decylidene): a Highly Nucleophilic Olefinic Hydrocarbon**



By *Horst Wenck, Armin de Meijere,* Fabian Gerson,* and *Rolf Gleiter*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

No other substituent without a heteroatom is as capable of enhancing the nucleophilicity of an olefin as the cyclopropyl group,[1] which exhibits a unique donor ability toward electron-deficient centers.[2] Tetracyclopropylethylene **1** has until now held the potential for the greatest effect of this kind, since it contains the largest number of such substituents.[3] However, because the short diagonal distance in a four-membered ring allows a 1,3-interaction,[4] both the four α- and the two β-spirocyclopropyl groups in the bi(cyclobutylidene) **2** should be able to exercise a donor effect on the double bond during electrophilic attack.

Our strategy for the synthesis of **2** started with readily available trispiro[2.0.2.0.2.1]decanone **4**.[5] Although conversion of **4** with *Lawesson*'s reagent[6] into the thioketone **3**[7] (85%) was achieved without difficulty, the preparation of the diazo compound **5a** could not be realized, despite the use of several methods. The hydrazone **5b** was very prone to azine formation, and the Bamford–Stevens reaction of the tosylhydrazone **5c** yielded only thermolysis products of the labile **5a**.[8] Thus, the "double-extrusion" route via the 2,5-dihydro-1,3,4-thiadiazole prepared from **3** and **5a**,[9] could not be employed, although this method has frequently been successful in the preparation of sterically demanding tetrasubstituted alkenes.

Scheme 1. **5a**, X=N_2; **5b**, X=NNH_2; **5c**, X=NNHTos. **I**: *Lawesson*'s reagent [6], toluene, reflux, 4 h; **II**: $TiCl_3$, $LiAlH_4$ (1:0.5), tetrahydrofuran, room temperature, 3d.

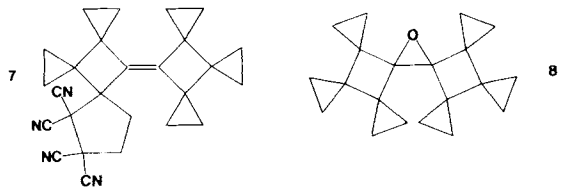
The titanium-induced reductive coupling of **4**,[10] on the other hand, was surprisingly easy, even though the yield was low. Based on a 60% conversion of **4**, the yield of **2**[7] was 8%, the major product being the pinacol **6**. The structure of **2** is unequivocally established by its spectral and physical data (see Table 1).

Table 1. Spectroscopic and physical data for **2** and **8**.

2: ^{1}H-NMR (270 MHz, $CDCl_3$): δ(TMS)=0.10 (s, 5,6,5',6'-H_2), 0.52 and 0.66 (AA'BB', 1,2,8,9,1',2',8',9'-H_2).—^{13}C-NMR (100.62 MHz, C_6D_6): δ(TMS)=5.32 (C-5,6,5',6'), 12.64 (C-1,2,8,9,1',2',8',9'), 29.77 (C-4,4'), 30.37 (C-3,7,3',7'), 136.22 (C-10,10').—IR (KBr): $\tilde{\nu}$=3160, 3010, 2870, 1460, 1425, 1010 cm^{-1}.—High-resolution MS: calcd for $C_{20}H_{24}$ 264.1878, found 264.1883 (±0.01).—M.p.=193 °C

8: ^{1}H-NMR (270 MHz, C_6D_6): δ=−0.31 (mc, 2H), −0.13 (mc, 4H), 0.02 (mc, 2H), 0.13 (mc, 4H), 0.31 (mc, 4H), 0.65 (mc, 2H), 0.77 (mc, 4H), 1.10 (mc, 2H).—IR (KBr): $\tilde{\nu}$=3060, 2980, 2920, 2850, 1760, 1660, 1460, 1370, 1280, 1255, 1100, 1010, 1000, 985, 940, 920, 870, 700, 850, 610 cm^{-1}.—High-resolution MS: calcd for $C_{20}H_{24}O$ 280.1827, found 280.1747 (±0.01)

As expected, **2** is very easily oxidized. The ESR spectrum of the radical cation $2^{\oplus\ominus}$, which was electrochemically produced at −80 °C in CH_2Cl_2 with n-Bu_4NClO_4 as the conducting salt, shows three hyperfine splittings with a_H=0.207, 0.048, and 0.014 mT, one for each set of eight equivalent protons. One of the splittings is caused by coupling with the eight protons on the β-spirocyclopropyl groups.[11]



The oxidation potential of **2** ($E^{\circ\prime}$=0.74 V, determined cyclovoltammetrically vs. SCE) is far lower than that of **1** (1.13 V), let alone that of vinylcyclopropane (2.24 V).[13] This cannot be due to a twisting of the double bond in **2**, since the sterically comparable 2,2,2',2',4,4,4',4'-octamethylbi(cyclobutylidene) and the strongly twisted 2,2,2',2',5,5,5',5'-octamethylbi(cyclopentylidene) have $E^{\circ\prime}$ values of 1.81 and 1.37 V (vs. SCE), respectively.[14]

The He(I) photoelectron spectrum of **2** confirms the strong tendency to form $2^{\oplus\ominus}$. The π-ionization potential (IP(π)) of 7.3 eV for **2** is the lowest measured value for a monoolefin without heteroatom substituents;[15] the corre-

sponding values for tetracyclopropylethylene **1** and tricyclopropylethylene are IP(π)=7.9 and 7.48 eV, respectively.[16] Accordingly, **2** reacts smoothly with tetracyanoethylene in acetonitrile at room temperature. Presumably for steric reasons, however, attack occurs predominantly at one of the α-cyclopropyl groups to give **7** (64%), as observed for **1**.[3b] The question whether some addition also occurs at the double bond or at a β-cyclopropyl group remains open.

The oxidation of **2** with *m*-chloroperbenzoic acid (CH_2Cl_2, $NaHCO_3$) gave epoxide **8** (Table 1) without skeletal rearrangement. Compound **2** is also attacked by singlet oxygen ($^3O_2$, *hν*, tetraphenylporphin), but not by triplet oxygen, despite its low oxidation potential.

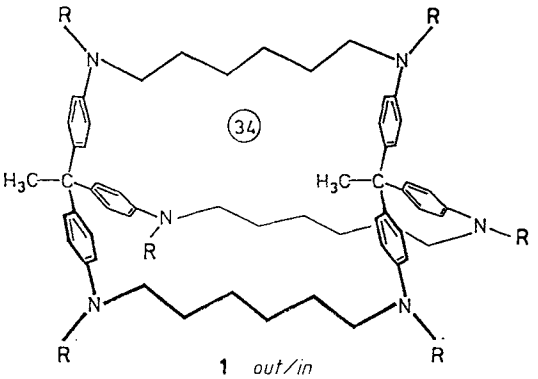
Bicyclic Host Cavities Derived from Triphenylamine—Guest Selectivity and Redox Properties**

By *Heinrich Schrage, Joachim Franke, Fritz Vögtle,** and *Eberhard Steckhan*



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

The host compounds (*out/out*)-**1** and (*out/in*)-**1**, which are derived from 1,1,1-triphenylethane are capable of forming complexes with guest molecules of varying size in aqueous acidic solution.[1] As revealed by models, the corresponding isomers of the triply bridged triphenylamine compounds **2** and **3** can undergo conformational interconversion, which obviates the necessity of separating them. Therefore, compounds **2** and **3** should be easy to synthesize and, moreover, should exhibit modified guest selectivities on account of their different bond angles. Furthermore, the triphenylamine unit is of interest because it is capable, via its radical cation, of serving as a redox catalyst that is incorporated into the ring system.

The yield obtained for the triple chain extension of **4**, Y=N, with 1,6-dibromohexane to give **5**, X=N, is slightly higher (21%) than that obtained for the synthesis of the

isomers **1** (17%). The crucial multiple ring closure to give the hexatosyl compound **2b** (24%) and **3b** (29%) from **4**, Y=C-CH_3, and **5**, Y=N, respectively, proceeded, however, in lower yield than that in the carbon series of equal chain length (79%). This result is presumably due to the less bent–trigonal instead of tetrahedral[2]—structure of the triphenylamine skeleton, which is less favorable for the cyclization.[3] Detosylation of **2b** and **3b** to give **2a** and **3a**, respectively, was achieved with HBr/phenol.[4]

4

5

6

Molecular models suggest that the cavities of **2** and **3** are shallower than the spherical cavity of (*out/out*)-**1** owing to the trigonal geometry of the triphenylamine nitrogen. This is confirmed by their different complexation properties. Thus, variously substituted naphthalene diols (2,7-, 2,6-, 2,3-) undergo complexation by **2a** and **3a**; however, adamantane, which undergoes complexation by (*out/out*)-**1a**, does not. The ^{1}H-NMR high-field shifts observed ($\Delta\delta$=0.25 ppm) for the host/guest complexes with **2a** are not dramatic; however, the signals of the guest undergo strong line broadening, which indicates dynamic exchange processes that are slow on the NMR time scale. With the host **3a** and 2,7-naphthalenediol as guest, on the other hand, sharp signals with marked shifts to high field are found for the guest protons ($\Delta\delta \approx 0.5$ ppm).[5]

Fluorescence spectroscopic measurements permit the study of the complexation of ANS (8-anilino-1-naphthalenesulfonate) by **2a** and **3a**:[6] the constants for complex formation so determined in each case are less than those for (*out/out*)-**1a** (lg K=4.6),[1a] and the difference between **2a** and **3a** (lg K=3.1 and 3.2, respectively) is minor within the limits of experimental error. The hydrophobicity of the cavity is supported by the observed blue shift in the wavelength maximum of emission to λ=485 nm (**2a**) and 440 nm (**3a**).[7]

The electrochemical properties of the host compounds **2** and **3** are of interest in connection with their model character for redox enzymes. Triarylamines are well known as electron-transfer reagents (mediators).[8] In these reactions, the electrochemically generated and regenerated, stable radical cations serve as the oxidizing agent. The oxidation potentials are very sensitive to the steric effects of substituents, which result in twisting and/or bending of the aryl groups.[9] Accordingly, the redox behavior of the bicyclic compounds **2** and **3**, in comparison to that of the open-chain compound **6**, may be used as a probe for steric effects.

The cyclovoltammograms of the new bicyclic compounds **2b** (Fig. 1), **3b**, and **6b** are very similar.[10, 11] They all show two redox pairs, Ox1/Red1 and Ox2/Red2, during the first potential scan; moreover, during the second potential scan, a new redox pair, Ox3/Red3, is observed at lower potentials, which, with increasing number of potential scans, increases at the expense of Ox2/Red2. The first redox step, the formation of the radical cation, exhibits electrochemical and chemical reversibility for all compounds and is diffusion controlled (Fig. 1b). The second step corresponds to the formation of a dication, which, in a chemical follow-up reaction, forms the third redox pair, Ox3/Red3, which is presumably a quinoid system. The potentials of the first oxidation steps of **2b** and **3b** are shifted by about 135 mV and 110 mV, respectively, to more positive values in comparison with the open-chain compound **6b** (see Table 1). This clearly reflects the differing steric environment, which will cause the bending or twisting of the aryl groups in the bicyclic compounds. Likewise, the slight release of strain upon replacement of a triphenylamine unit by a triphenylmethane unit is reflected in the potential. In contrast, steric factors have less effect on the potential of the second redox step.

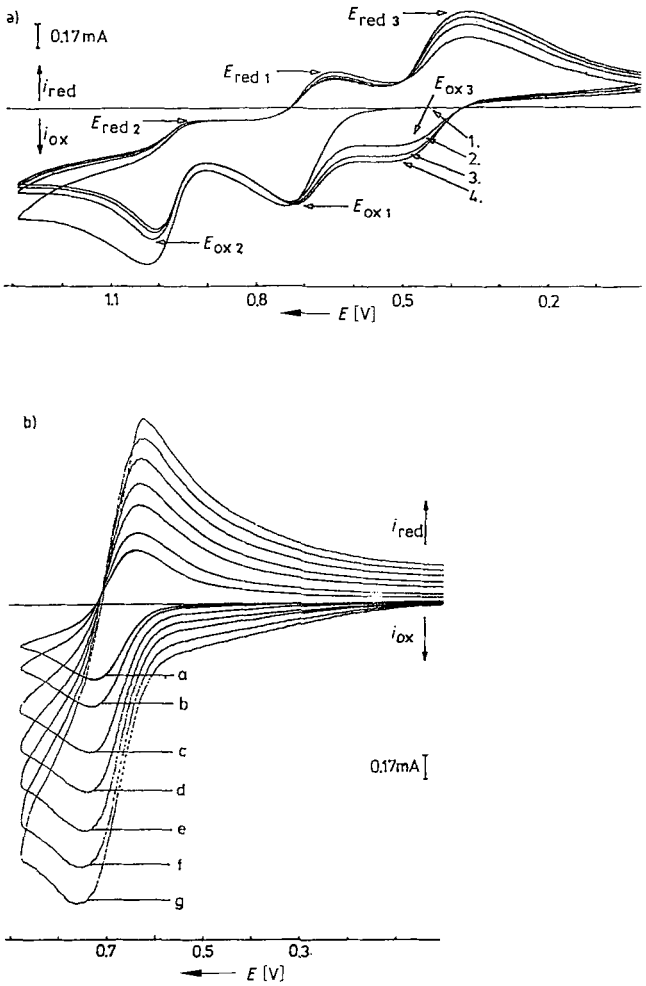

Fig. 1. Cyclovoltammogram of **2b**: a) Potential range 0–1.3 V [Ag/$AgNO_3$ (0.1 M in CH_3CN)], potential scan rate 40 mV/s, the numbering corresponds to the sequence of the scans; concentration of **2b**: 2×10^{-3} M in CH_3CN/CH_2Cl_2 (1:1) (0.1 M $LiClO_4$). b) Potential range 0–900 mV [Ag/$AgNO_3$ (0.1 M in CH_3CN)], potential scan rate (a–g): 20, 40, 90, 160, 250, 360, 490 mV/s, concentration as in a). The Ag/$AgNO_3$ reference electrode has a potential of 590 mV versus the normal hydrogen electrode (NHE).

Table 1. Potentials of compounds **2b**, **3b**, **6b** [a].

	E_{ox1}/E_{red1}	E_{ox2}/E_{red2}	E_{ox3}/E_{red3}
2b	725/660	1010/– [b]	525/370
3b	700/640	1030/– [b]	500/350
6b	590/530	965/880	445/380

[a] Potentials in mV relative to the $Ag/AgNO_3$ reference electrode. [b] Reduction signal too weak for exact determination.

Compounds **2** and **3** are, therefore, two of the most easily prepared water-soluble hosts with a high inclusion ability whose electronic state and reactivity and, possibly, cavity shape, can be influenced electrochemically. Since **2** and **3**, as well as guest compounds, are capable of undergoing redox reactions, possibilities exist for novel substrate-selective redox reactions.[12]

$[(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_4(PPh)_2]$, a Diphosphene Complex with a Butterfly Structure**

By *Dieter Fenske** and *Kurt Merzweiler*

We recently described the reaction of $PhE(SiMe_3)_2$ (E = P, As) with [2,3-bis(diphenylphosphino)-*N*-methylmaleimide]nickel(II) chloride,[1] which results in migration of two $SiMe_3$ substituents to the CO groups of the maleimide and formation of the complex **1** as well as its analogue with $(AsPh)_2$ instead of $(PPh)_2$, the $(EPh)_2$ ligands having a *trans* configuration. In attempts to prepare heterometallic clusters, we allowed **1** to react with $[\{CpMo(CO)_3\}_2]$ in toluene. This resulted in the evolution of CO and the formation of an insoluble nickel-containing precipitate of unknown structure. When pentane was added to the filtrate, the dark brown, diamagnetic diphosphene complex **2** crystallized in a yield of 30%.[2]

1 **2**

The IR spectrum (KBr) of **2** exhibits four $\tilde{\nu}$(CO) bands (1950, 1930, 1861, and 1845 cm^{-1}). The P atoms of the $(PPh)_2$ ligands give rise to a singlet at $\delta = -94$ in the ^{31}P-NMR spectrum (tetrahydrofuran); the ^{1}H-NMR spectrum exhibits a multiplet at δ = 7.10 (Ph) and a singlet at δ = 5.50 (Cp).

According to the crystal structure analysis,[3] **2** (Fig. 1) consists of a *cis*-diphosphene unit, which bridges two Mo atoms. In addition, two terminal CO groups and an η^5-C_5H_5 ligand are bonded to each Mo atom. The Mo–P bond lengths are significantly different (Mo1–P1, Mo2–P1: 246.6, 247.0; Mo2–P2, Mo1–P2: 254.2, 254.6 pm).

Most of the $(ER)_2$ complexes known to date contain the ligands in the *trans* configuration.[4] However, compounds containing a *cis*-$(PR)_2$ group, e.g., **3**–**5**, are also known.[5]

Engesserstrasse, Geb. Nr. 30.45, D-7500 Karlsruhe (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank the Institut für Kristallographie der Universität Karlsruhe for measurement of the crystal data.

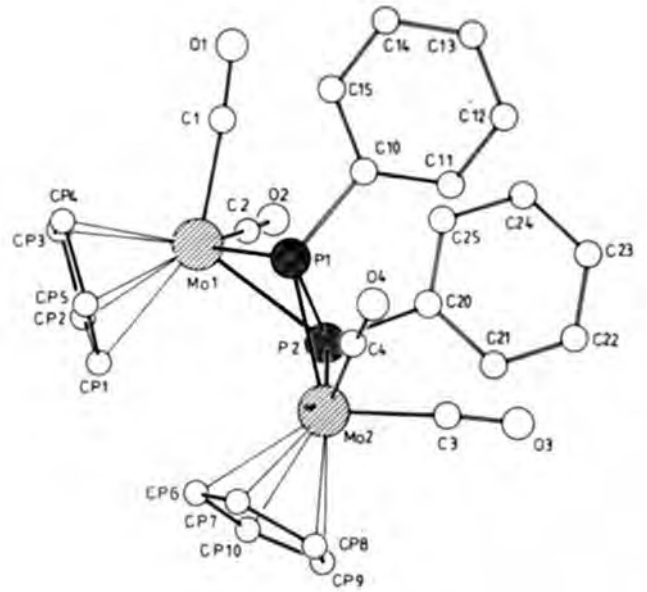

Fig. 1. Structure of **2** in the crystal. Important bond lengths (±0.2 pm) and bond angles (±0.1°): Mo1-P1 246.6, Mo1-P2 254.6, Mo1-C1 193.1, Mo1-C2 196.2, C-O 114.2-114.8, Mo-C(Cp) 229-238, C(Cp)-C(Cp) 138.5-142.2, P1-P2 213.6, Mo2-P1 247.0, Mo2-P2 254.2, Mo2-C3 193.6, Mo2-C4 195.9; P1-Mo1-P2 50.4, Mo1-P-Mo2 110.8-116.0, P-P-Mo 62.9-66.7, Mo-C-O 174.1-177.6, P1-Mo2-P2 50.4.

The P1-P2 distance (213.6 pm) is significantly shorter than a P-P bond and is similar to the values that have also been found for other "side-on"-coordinated $(PR)_2$ complexes.[4] It is noteworthy that the P-P bond in **2** is longer than that in **3** (205.9 pm), **4** (208.5, 209.8 pm), and **5** (202.6 pm). The angle between the planes Mo1, P1, P2 and Mo2, P1, P2 is 135°. The distance between the Mo atoms is 418.7 pm; i.e., they are not bonded to each other.

M_2P_2 clusters with tetrahedral structure were found, e.g., in **3** and in **6**.[6] In these cases, 14e and 15e complex fragments are bridged by a 6e donor $(PR)_2$ and a 4e donor (P_2), respectively. In order to attain a filled 18e shell at the metal center, a metal-metal bond is formed (Fe-Fe in **3**: 274.0 pm, Mo-Mo in **6**: 302.2 pm). In contrast, the 18e rule is fulfilled for **2** without the formation of a Mo-Mo bond. Comparison of **2** and **6** clearly shows that the Mo_2P_2 cluster in **2** is formed by opening of the Mo-Mo bond in **6**, resulting in a butterfly structure for the Mo_2P_2 skeleton.

According to the isolobal terminology of *Roald Hoffmann*, **3** and **6** can be regarded as derivatives of tetrahedrane.[7] **2** is then a derivative of bicyclobutane. Accordingly, a formal analogy exists between **2** and E_2 complexes (E = P, As) such as $(diphos)_2Ni_2P_2$ (diphos = bis(diphenylphosphino)ethane and $[\{(C_5Me_5)(CO)_2Mn\}_2As_2]$.[8,9] The formation of **2** is one of the first examples for the transfer of a coordinated diphosphene to another metal.

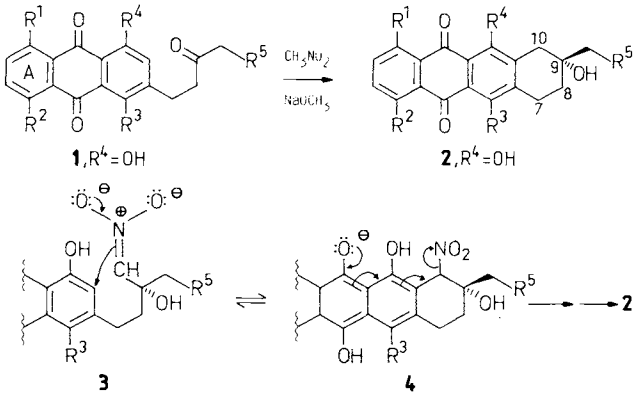
Simple Synthesis of Anthracyclinones by Cyclization of an Intermediate Hydroxynitronate**



By *Karsten Krohn** and *Wahyudi Priyono*

The possibility of introducing side chains regioselectively by the Marschalk reaction or the Claisen rearrangement has made hydroxylated anthraquinones valuable starting materials in the synthesis of anthracyclinones.[2] Thus, the oxoalkyl anthraquinones **1b-f**, for example, can be prepared in over 50% yield from industrially manufactured 1,4,5-trihydroxy-9,10-anthraquinone.[3,4] The C atom required for the cyclization to anthracyclinones was introduced previously via acyl anion equivalents such as lithio-1,3-dithiane[3] or lithiodichloromethane[4] in a multistep reaction sequence. We have now found that the condensation of the ketones **1a-f** with nitromethane offers a preparatively simple, one-pot procedure for the synthesis of the anthracyclinones **2a-f**.

Sutherland et al.[5] have employed the addition of a long-chain nitroalkane building block for the synthesis of 9-deoxydaunomycinone. In our method, the incorporation of the C_1 building block into the ketone **1** and the formation of the 9-OH group of the anthracyclinone are carried out simultaneously. The procedure is generally applicable to a wide variety of substituted 1,4-dihydroxy anthraquinones, such as **1b-e**. Compounds without hydroxyl groups on C-4 cyclize equally well, as shown by the conversion of **1f** into the new anthracyclinone **2f**. However, the presence of the phenolic hydroxyl group on C-1 is necessary: compounds of type **1** ($R^1 = R^5 = H$, $R^2 = R^3 = OH$, $R^4 = H$ or OCH_3) cannot be converted into tetracycles with nitromethane. These findings reveal at the same time the mechanism of this remarkable cyclization. We propose that the ketones **1** exist in equilibrium with the nitromethane adducts **3**, which, as indicated by the arrows, undergo intramolecu-

lar *nucleophilic* addition resulting in cyclization to the quinones **4**. Tautomeric forms of the anthraquinones, in which the quinoid function is shifted to the outer ring A, may play a role in this reaction.[6] In the final step, the primary cyclization product **4** stabilizes itself by elimination of the nitro group and simultaneous reoxidation to the products **2**. This intramolecular redox process with elimination of leaving groups in the benzylic position is well established for the anthrahydroquinones.[2,7,8]

By hydroxylation at C-7 of **1b**,**c** and **1d**,**e**, the racemic natural products belonging to the rhodomycinones and feudomycinones, respectively, are obtained;[4b] **1c** or **1e** can be converted into β-rhodomycinones via elimination of the tertiary hydroxyl group on C-9.[9]

Experimental Procedure

2: A solution of sodium (92 mg, 4 mmol) in 100 mL of anhydrous ethanol was treated with 3 mL of nitromethane and 1 mmol of **1** [4, 10] and then refluxed under nitrogen for 24–48 h until all the starting material had reacted (as followed by tlc). After neutralization with acetic acid, the solution was concentrated, and the residue was dissolved in ca. 50 mL of dichloromethane, washed with water, and dried over sodium sulfate. The solution was then concentrated again and the product recrystallized from a small amount of dichloromethane/ether. **2f**: m.p. = 183 °C; IR: $\tilde{\nu}$ = 3400 (OH), 1675, 1662, 1621 (C=O); UV (CH_3OH): λ_{max} (lg ε) = 224 (4.20), 259 (4.11), 286 (3.85), 431 (3.66), 450 nm (3.62); ^{1}H-NMR (400 MHz): δ = 1.29 (s; 1H, 9_{ax}-OH), 1.45 (s; 3H, 9_{eq}-CH_3), 1.80 (ddd, $J(8_{ax,eq})$ = 13.4 Hz, $J(8_{ax},7_{ax})$ = 10.5 Hz, $J(8_{ax},7_{eq})$ = 6.0 Hz; 1H, 8_{ax}-H), 1.95 (dddd, $J(8_{eq,ax})$ = 13.4 Hz, $J(8_{eq},7_{ax})$ = 6.5 Hz, $J(8_{eq},7_{eq})$ = 4.5 Hz, $J(8_{eq},10_{eq})$ = 2.0 Hz; 1H, 8_{eq}-H), 2.77 (d, $J(10_{ax,eq})$ = 18.5 Hz; 1H, 10_{ax}-H), 2.90 (ddd, $J(7_{eq,ax})$ = 18.5 Hz, $J(7_{eq},8_{ax})$ = 10.5 Hz, $J(7_{eq},8_{eq})$ = 4.5 Hz; 1H, 7_{eq}-H), 2.95 (dd, $J(10_{eq,ax})$ = 18.5 Hz, $J(10_{eq},8_{eq})$ = 2.0 Hz; 1H, 10_{eq}-H), 1.16 (ddd, $J(7_{ax,eq})$ = 18.5 Hz, $J(7_{ax},8_{ax})$ = 10.5 Hz, $J(7_{ax},8_{eq})$ = 6.5 Hz; 1H, 7_{ax}-H), 7.28 (dd, $J(2,3)$ = 8.3 Hz, $J(2,4)$ = 1.0 Hz; 1H, 2-H), 7.63 (s; 1H, 6-H), 7.66 (t; 1H, 3-H), 7.28 (dd, $J(4,3)$ = 7.1 Hz, $J(4,2)$ = 1.0 Hz; 1H, 4-H), 12.15 and 12.48 (each s; each 1H, each OH); MS (180 °C): *m/z* 324 (70%, M^+), 306 (55, $M^+ - H_2O$), 296 (100, $M^+ - CO$), 291 (49, $M^+ - CH_3 - H_2O$), 281 (83), 266 (61).

Structure Determinations of Pentatetraenes—Comparison of the Structures of Cumulenes**

By *Hermann Irngartinger** and *Wolfgang Götzmann*

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

For our studies on the structures of cumulenes,[1] we synthesized the pentatetraene **4a**.[2] The addition of dichlorocarbene to the butatriene **3a** (phase-transfer conditions (PTC)[3]) did not afford the expected[2b,4] adduct **1a** but rather the rearranged enynol **6a**. The X-ray structure analysis[5] revealed a lengthening of the double bond to 1.348(3) Å, which is due to strong repulsive interactions between the chlorine atom and the two neighboring methyl groups (Cl···C 3.170(3) and 3.213 (3) Å). In comparable enyne units the double bonds are 1.305–1.338 Å long.[6] Because the chlorine atom is locked in place by the two methyl groups, twisting of the double bond is not possible (torsional angle only 4.5°). The weakening of the bond is also shown by the C=C vibrational absorption, which is shifted to longer wavelengths (IR 1540, Raman 1544 cm^{-1}). The pentatetraene **4a** was ultimately obtained by exchange of the OH group of **6a** for Cl followed by cleavage of chlorine from **7a** with zinc dust.[7]

The structures of **4a**[7] and its tetraphenyl analogue **4b**[8] were determined by X-ray diffraction. Both cumulenes are

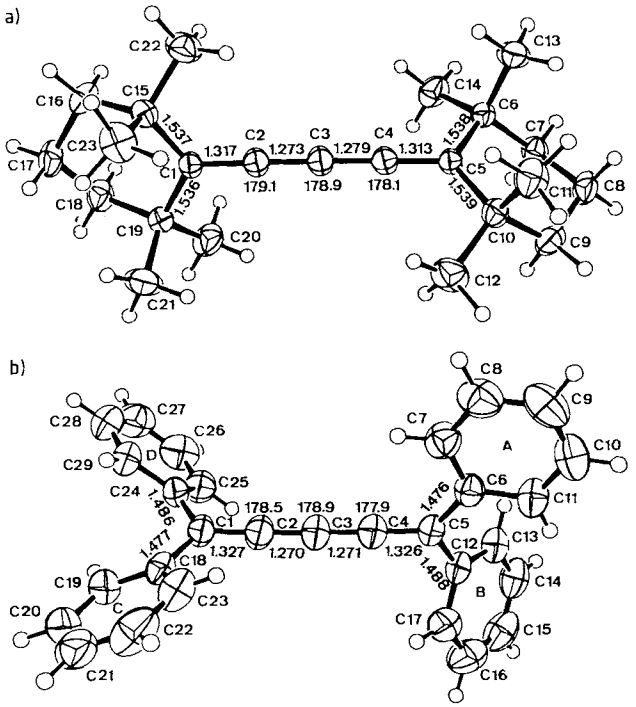
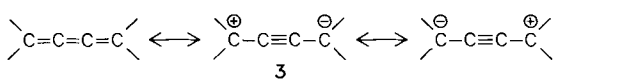
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

linear (Fig. 1). In each case, the terminal substituents are oriented perpendicularly to each other (with the exception of a deviation of 10° in **4a** caused by packing effects). Owing to the differing hybridization of the C atoms, the terminal C(sp^2)=C(sp) double bonds in both molecules are longer than the central C(sp)=C(sp) bonds. The terminal double bonds of **4b** are significantly lengthened by conjugation with the phenyl rings; in contrast, the central double bonds in **4a** and **4b** have approximately the same lengths (Fig. 1). Only *one* of the phenyl groups at each end of the tetraene system **4b** adopts an orientation that is favorable for the conjugation. The twist angles of the phenyl rings with respect to the plane of the terminal double bonds are 16.4° and 28.2° for rings **A** and **C**, respectively (51.3° and 42.5° for rings **B** and **D**, respectively, Fig. 1).





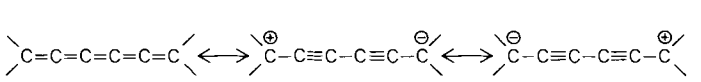


Fig. 1. Molecular structure of pentatetraenes in the crystal. Bond lengths [Å], bond angles [°]. a) **4a**: Standard deviation 0.002 Å and 0.1°; b) **4b**: standard deviation 0.002 Å and 0.1–0.2°.

Comparison of the cumulative double bonds of homologous systems reveals a clear difference between cumulenes with an even number and those with an odd number of double bonds. In the cumulenes with an odd number of double bonds (trienes **3**, pentaenes **5**; Table 1), the terminal bonds are approximately 0.02 Å longer and the neighboring bonds about 0.02 Å shorter than the corresponding bonds in cumulenes with an even number of double bonds (allenes **2**, tetraenes **4**; Table 1). Accordingly, the bonds marked x in cumulenes with an odd number of double bonds have some single-bond character and the bonds marked y have some triple-bond character.

5

Table 1. Bond lengths [Å] of the double bonds in **2a–5a** and **2b–4b** (averaged in the case of multiple determinations).

2a–5a, > = ⟨⟩; **2b–4b**, > = Ph/Ph

Compd.	x	y	z	Ref.
2a	1.305			[1]
3a	1.328	1.256		[1]
4a	1.315	1.276		
5a	1.329	1.259	1.299	[1]
2b	1.310			[9]
3b	1.345	1.246		[10]
4b	1.327	1.271		

These cumulenes contain a 1,3-butadiene system (trienes **3**) or 1,3,5-hexatriene system (pentaene **5a**) with resonance along the entire length of the cumulene chain, so that a phenyl ring at either end of the chain can also participate in the resonance. Therefore, the x bond in the triene **3b** is about 0.02 Å longer and the y bond 0.01 Å shorter than the corresponding bonds in the triene **3a** with aliphatic substituents.

For the cumulenes with an even number of double bonds, resonance involving triple bonds is not possible. Such systems have two perpendicular π systems, which cannot interact. The substituents of the allene **2** have no significant effect on the length of the double bonds. In the tetraene **4b**, which has two perpendicularly oriented 1,3-butadiene systems, the x bond is lengthened by a small amount (ca. 0.01 Å) compared with that in the aliphatic substituted tetraene **4a** on account of the substituent effect of the phenyl ring.

The Elucidation of the Constitution of Glycopeptides by the NMR Spectroscopic COLOC Technique

By *Horst Kessler,* Wolfgang Bermel, Christian Griesinger,* and *Cenek Kolar*

In the elucidation of the constitution of organic compounds by NMR spectroscopy, it is usually easy to identify the scalar-coupled proton spin systems, e.g., by means of H,H-COSY[1] or H-relayed H,H-COSY.[2] If these spin systems are separated by quaternary carbon atoms or heteroatoms that bear no protons, however, the determination of the connectivity is difficult. Frequently, interpretation of the nuclear Overhauser effects is useful (e.g., to assign the NMR signals of biopolymers such as peptides[3] and oligosaccharides[4]); however, in order to avoid circular reasoning, these should only be used to elucidate the stereochemistry (configuration and conformation).[5] As we recently found, the two-dimensional heteronuclear correlation via long-range coupling (COLOC) may be employed for the determination of the sequences of amino acids in peptides.[6] We show here the potential of this technique as applied to the disaccharide derivative **1** (see Fig. 2), for which it was possible to solve simultaneously three structural problems:

—The 3-1′ connectivity of the sugar moieties was established by means of the detection of a $^3J_{H,C}$ coupling through the oxygen atom.[7]

—The connectivity of C-1 of the sugar with the amino group of the amino acid through a urethane carbonyloxy group was confirmed.

—The positions of the acetyl and benzoyl groups were established by means of the couplings of the carbonyl C atoms of the acyl group to the protons of the sugar and acyl moieties. At the same time, it was possible to assign the ^{13}CO signals and the ^{1}H signals of the acetyl groups.

Upon attempted glycosylation of Ddz-serine benzyl ester (Ddz=α,α-dimethyl-3,5-dimethoxybenzyloxycarbonyl), a surprising migration of the α,α-dimethyl-3,5-dimethoxybenzyl group to the β-hydroxyl group of the serine took place with the formation of a glycosyl urethane.[8] Although this connectivity was suggested by a signal of a urethane carbonyl C atom in the ^{13}C-NMR spectrum of the substance *after* cleavage of the putative Ddz protecting group and by the unusual low-field shift of the ^{1}H-NMR signal of H-1 as well as by mass spectroscopic analysis of the glycosyl urethane,[8] unequivocal proof of the structure of **1** was desired.

The assignment of the sugar protons and the determination of the relative configuration of both pyranose rings was achieved by analysis of the ^{1}H-NMR spectrum of **1** (Fig. 1a) and of an H,H-COSY spectrum.[11] The nonquaternary C atoms were, as usual, assigned by means of an H,C-COSY spectrum.[9] In order to establish the connectivity of the sugar moieties, a COLOC spectrum for the aliphatic C

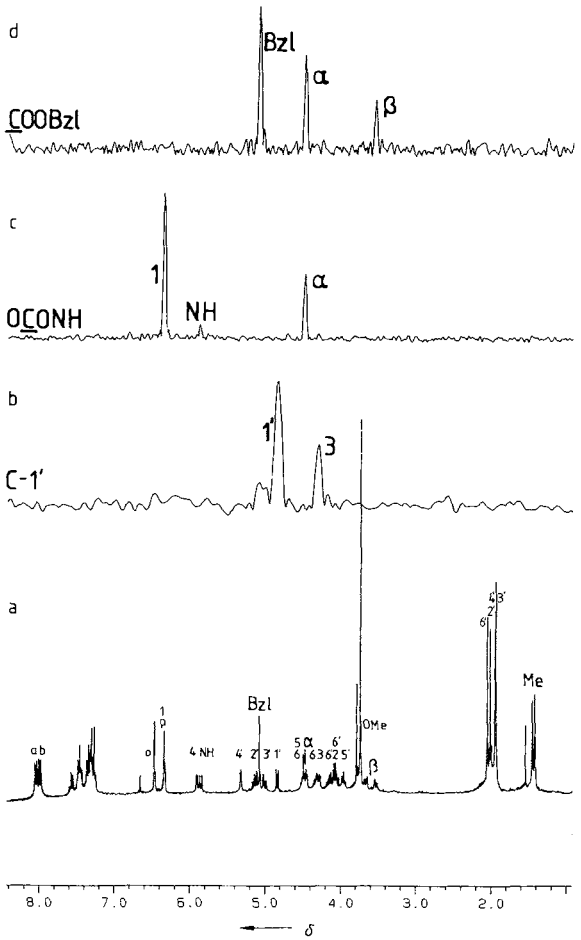

Fig. 1. 300-MHz ^{1}H-NMR spectrum of **1** (440 mg in 3 mL of $CDCl_3$) (a) and cross sections through the COLOC spectra (b–d). b: Cross section at the signal of C-1′. The signal to H-3 gives information on the connectivity of the sugar moiety. c: Cross section at the signal of the urethane C atom. In addition to a weak $^2J_{C,H}$ correlation to the NH proton, the proximity of H-1 and the α-proton of the serine in clearly observed. d) Cross section at the signal of the carbonyl C atom of the ester.—The COLOC spectrum was recorded with the following pulse sequence: $\pi/2(^1H)(t_1/2)\pi(^1H, ^{13}C)(\Delta_1 - t_1/2)\ \pi/2$ (^{1}H, ^{13}C) Δ_2 acquis. (^{13}C) ^{1}H-broadband decoupling. Measuring conditions: b: 140 experiments, 128 scans each with 8 K data points; acquisition time, 0.45 s; relaxation delay; 1.5 s; $\Delta_1 = \Delta_2 = 63$ ms; total measuring time, 13 h. Spectral width in F2, 9091 Hz; in F1, 2994 Hz; ^{1}H measuring frequency, 300 MHz.—c, d: 330 experiments, 64 scans each with 4 K data points; acquisition time, 0.5 s; relaxation delay, 1.5 s; $\Delta_1 = \Delta_2 = 90$ ms; total measuring time, 13 h. Spectral width in F2, 4032 Hz; in F1, 2439 Hz; ^{1}H measuring frequency, 270 MHz.

atoms[10] was recorded. The cross section at the chemical shift of C-1′ shows a coupling from C-1′ to H-3 ($^3J_{CH}$ coupling, Fig. 1b) in addition to a correlation between C-1′ and H-1′. For the signal of C-3, on the other hand, only $^2J_{CH}$ and $^3J_{CH}$ couplings to protons of the same sugar ring are observed. Furthermore, the COLOC spectrum exhibits a large number of cross signals to each carbon atom, thereby providing independent confirmation of the assignment of the ^{1}H-NMR and ^{13}C-NMR spectra.

The ^{13}C-NMR signal of the urethane carbonyl group at $\delta = 153.38$ was identified in a second COLOC spectrum for quaternary carbon atoms[6, 11] by means of its coupling to the NH and α-proton of the serine (Fig. 1c). The α-proton is coupled to only one additional quaternary C atom at $\delta = 169.86$, which, however, could be characterized as the signal of the ester carbonyl group by means of its coupling to a β-proton of the serine and to a methylene proton of the benzyl moiety (Fig. 1d). Of particular importance is the coupling of the urethane carbonyl C atom with H-1 of the sugar moiety (Fig. 1c).

All remaining carbon atoms can be assigned unequivocally in this spectrum (Table 1). The positions of the acetyl and benzoyl protecting groups can be determined by couplings of their carbonyl C atoms to the protons of the sugar moiety *and* the acyl groups (CH_3 and C_6H_5, respectively) (Fig. 2). Hence, the COLOC technique allows the easy determination of the positions of protecting groups, which is of use in the characterization of intermediates and in the structural elucidation of natural products.

We have thus demonstrated that the ^{13}C-NMR signals of quaternary and nonquaternary C atoms can be assigned unequivocally with the COLOC spectra. Further, the assignment of the signals in the ^{1}H-NMR spectra is considerably facilitated; even protons that show no resolved couplings to other protons or that are separated by non-proton-bearing carbon atoms or heteroatoms can be connected with one another by means of the COLOC experiment.

The Phenol ⇌ 2,4-Cyclohexadienone Equilibrium in Aqueous Solution**

By *Marco Capponi, Ivo Gut,* and *Jakob Wirz**

Cyclohexadienones were long ago proposed[1] and were recently detected[2,3] as transient intermediates in electrophilic substitution reactions of phenols. Keto tautomers of phenols are frequently postulated to occur as intermediates in the isomerization of arene oxides, and an important criterion to determine the routes of metabolism of aromatic compounds ("NIH shift"[4]) relies on indirectly determined kinetic isotope effects attributed to the enolization of α-H isotopomeric ketone intermediates. It is therefore surprising that the equilibria and mechanisms of phenol tautomerization have so far hardly been investigated,[5] in sharp contrast to the reverse enolization of simple ketones, which is one of the most documented reactions in organic chemistry.[6]

If a thermodynamically unstable tautomer can be generated photochemically from a suitable precursor, its rate of conversion to the stable isomer can be determined directly by the method of flash photolysis. By combining the rate constants for the forward and back reactions, we have recently obtained the first purely experimental and accurate equilibrium constants both for the enolization and for the acid dissociation (enolate formation) of simple ketones in aqueous solution.[7] We have now developed a method to monitor the tautomerization of 2,4-cyclohexadienone **1** to phenol **2** and report here the pH profile of the rate constant $k_{1\to2}$ (H_2O, 25 °C) as well as preliminary estimates for the equilibrium constant of tautomerization, K = [**1**]/[**2**], and for the acidity constant K_a of the carbon acid **1**.

The phenol tautomer **1** is formed by a retro-Diels-Alder reaction in the gas phase pyrolysis of suitable bicyclic ketones.[8] Bicyclo[2.2.2]oct-7-ene-2,5-dione **3** yields phenol upon irradiation in solution.[9] It seemed likely that this reaction also proceeds via **1**. This was confirmed by photolysis of **3** (λ = 313 nm) in a glassy solution at 77 K. In agreement with a previous observation,[10] very little **1** accumulated under these conditions because of its highly efficient conversion into the dienyl ketene **4** by secondary photolysis, a reaction with ample precedent.[11] Compound **4** was characterized by its absorption spectrum [λ_{max} (rel. int.) = 284 (1), 274 (1.2), 265 nm (1.0, sh.)] and identified by trapping with ethanol upon thawing of the rigid glass.

Flash photolysis of **3** at 25.0 ± 0.5 °C in aqueous solution, using either an excimer laser operated on XeCl (200 mJ, 25-ns pulses at 308 nm) or a conventional electric discharge flash lamp (1000 J, 20 μs), produced a weak transient absorption in the wavelength range of 280 to 330 nm, as expected for **1**.[11] The decay of the intermediate obeyed first-order kinetics. The rate constants $k_{1\to2}$ as a function of pH are shown in Figure 1. The points within the pH range of 4 to 6 were obtained with sodium acetate buffer solutions by extrapolating to zero buffer concentration; the ionic strength was kept constant at I = 0.1 M by the addition of sodium chloride. Plots of the observed decay rate constants $k_{1\to2}$ vs. the total buffer concentration at a given buffer ratio were linear and the slopes indicated general base catalysis, $k_{AcO^-} = (9.2 \pm 0.5) \times 10^3\ M^{-1}\ s^{-1}$, but no significant contribution by general acid catalysis, $k_{HOAc} < 5 \times 10^2\ M^{-1}\ s^{-1}$. Similar measurements with α-amino-α-(hydroxymethyl)-1,3-propanediol (Tris)/HCl buffers in the pH range of 7 to 9 gave $k_{Tris} = (2.0 \pm 0.1) \times 10^5\ M^{-1}\ s^{-1}$.

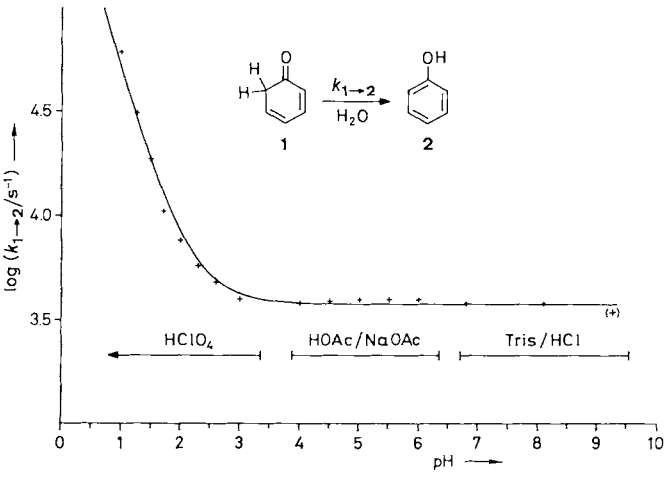

Fig. 1. Measured rate constants $k_{1\to2}$ in aqueous solution at 25 °C as a function of pH. The ionic strength was kept constant at I = 0.1 M by the addition of NaCl. The solid line was found by least-squares fitting of the function $k_{1\to2} = k_0 + k_H \cdot [H^+]$ (see text).

[**] This work was supported by the Swiss National Science Foundation. We thank Priv.-Doz. Dr. *M. Demuth*, and Prof. Dr. *C. A. Grob* for kindly providing samples of 5,7-dioxobicyclo[2.2.2]octane-2,3-dicarboxylic acid.

As is evident from Figure 1, the tautomerization of **1** is dominated by an uncatalyzed reaction, $k_0=(3.8\pm0.2)\times10^3$ s^{-1}, in the pH range of 3 to 9. A reaction rate of this order of magnitude is expected for the *protonation of water by the strong carbon acid* **1**: inserting k_{AcO^-} and k_{Tris} into the Brønsted relation

$$\log(k_{Tris}/k_{AcO^-})=\beta[pK_a(HTris^+)-pK_a(HOAc)]$$

yields $\beta\approx0.4$ and, assuming $pK_a(H_3O^+)=-1.74$, one obtains $k_{H_2O}\approx30\ M^{-1}s^{-1}$ or $k_0\approx2\times10^3\ s^{-1}$. At pH values below 3, the reaction rate is dominated by acid catalysis, $k_{H^+}=(4.6\pm0.2)\times10^5\ M^{-1}s^{-1}$.

The rate of deuteration of phenol in 1 N D_2SO_4 at 80 ± 1 °C was measured by intermittent ^{1}H-NMR analysis at 25 °C. On a 400-MHz spectrometer the NMR signals of the *ortho* and *para* hydrogen atoms could be integrated separately yielding $k(ortho)=(1.1\pm0.1)\times10^{-5}\ s^{-1}$ and $k(para)=(2.3\pm0.2)\times10^{-5}\ s^{-1}$. In order to derive the rate constant of ketonization, $k_{2\to1}$, from the observed rate of *ortho*-deuteration, several isotope effects and statistical factors need to be accounted for. A comparison with isotope effects observed in related reactions[3, 12] yields the prediction $k_{2\to1}\approx5k(ortho)$. This estimate is likely to be correct within one order of magnitude (±0.5 log units); experimental investigations of the kinetic isotope effects of the reaction **1** $\rightleftharpoons$ **2** are in progress. The rate constant of the reverse reaction under similar conditions (1 N $HClO_4$, 80 °C) was determined by the method of flash photolysis: $k_{1\to2}=(5.6\pm0.6)\times10^6\ s^{-1}$.

The ratio of these rate constants then gives $pK\approx11.0\pm0.8$ for the equilibrium **2** $\rightleftharpoons$ **1** at 80 °C. The equilibrium constant at 25 °C may be estimated by neglecting the contribution of entropy to the highly exothermic reaction **1** → **2** (for an estimate of the error involved in this approximation we assume $|\Delta S_{1\to2}|\leq20\ J\ mol^{-1}\ K^{-1}$). Thus, $d(T\cdot pK)/dT\approx0$ and $pK(25\,°C)=13\pm1$. Finally, the acidity of **1** as a carbon acid in water (25 °C) is $pK_a(\mathbf{1})=-pK+pK_a(\mathbf{2})\approx-3\pm1$.

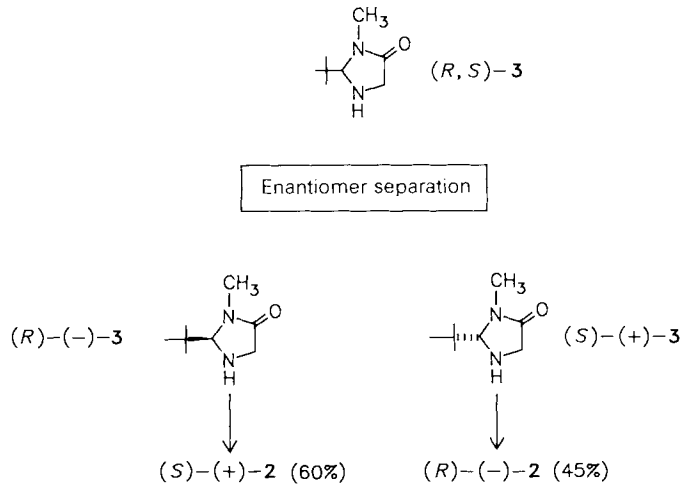
Enantiomer Separation of (*R,S*)-2-(*tert*-Butyl)-3-methyl-4-imidazolidinone, a Chiral Building Block for Amino Acid Synthesis**

By *Robert Fitzi* and *Dieter Seebach*



Owing to their possible biological activity, enantiomerically pure nonprotein α-amino acids have become increasingly important. For their preparation various methods have been employed.[2-4] These afford a 1:1 mixture of enantiomers or—if additional chirality centers are present—diastereomeric pairs of enantiomers, thereby necessitating enantiomer separation.[5, 6]

Among the recently developed stereoselective α-amino acid syntheses, the α-alkylation of chiral glycine derivatives is especially attractive.[7] The highest selectivities have been observed with the bislactim ethers **1**[8] and with the imidazolidinone **2**.[9]

The six-membered heterocycle **1** is obtained from glycine and another amino acid via the diketopiperazine, which is *O*-methylated by Meerwein salt. Its use requires the separation of two amino acids in the final step. When the five-membered heterocycle **2** is employed, it is only necessary to separate the desired product from benzoic acid, methylamine, and pivalaldehyde, and almost all derivatives of **2** can be conveniently purified by crystallization. So far, enantiomerically pure **2** was only available by degradation of a substituent in the 5-position.

We have now succeeded in separating the enantiomers of the nonbenzoylated glycine derivative **3** by crystallization of the mandelate salt. *Both* enantiomers of **2**, and thus the (*R*)- *or* (*S*)-amino acids, thereby become readily available on a preparative scale.

The (*R,S*)-aminal **3**, prepared from glycine methyl ester hydrochloride, methylamine, and pivalaldehyde,[10] was treated with 14 chiral carboxylic or sulfonic acids. In two cases one of the two possible diastereomeric salts crystallized selectively: the salt from (−)-2,3:4,6-di-*O*-isopropylidene-2-ketogulonic acid [(−)-diacetone-2-ketogulonic acid] and (*S*)-**3**, and that from (*S*)-(−)-mandelic acid and (*R*)-**3**. For preparative resolution a single crystallization with mandelic acid gave enough enrichment so that *N*-benzoylation and recrystallization of **2** produced the two enantiomers with greater than 98% *ee*. Mandelic acid is recovered in 95% yield without detectable racemization.

Experimental Procedure

(*R,S*)-**3**: Glycine methyl ester hydrochloride (125.6 g, 1 mol) was added to 375 mL of 8 M ethanolic methylamine (ice-cooled) with stirring. After 15 h at room temperature, the suspension was concentrated in a rotatory evaporator (water aspirator). A slurry of the resulting viscous material in 200 mL of CH_2Cl_2 was prepared and concentrated three times. A solution of the residue, pivalaldehyde (235 mL, 1.5 mol, Fluka pract.), and triethylamine (209 mL, 1.5 mol) in 1 L of CH_2Cl_2 was then heated at reflux for 10 h with separation of water. After cooling, the mixture was filtered through a sintered-glass filter and the filter cake was washed with 500 mL of ether. Concentration of the filtrate gave an oil, which was dissolved in 300 mL of CH_3OH. The resulting solution was combined (with cooling and stirring) with 600 mL of methanol that had been saturated with HCl gas at 0 °C. After 30 min of stirring at 0 °C and 2 h at room temperature, the mixture was concentrated to a syrup, dissolved in 800 mL of CH_2Cl_2, washed with 670 mL of 3 M aqueous NaOH, and then evaporated to give the crude product **3** (107.5 g, 69%; yellow oil, which crystallizes upon cooling; for characterization of (*R,S*)-**3** see [10].

Enantiomeric resolution: A mixture of (*R,S*)-**3** (70.0 g, 0.448 mol) and (*S*)-(−)-mandelic acid (70.0 g, 0.460 mol) was dissolved in boiling acetone (ca. 170 mL, saturation!). The solution was stirred in order to spread the initially formed crystals in the insulated flask, which was then allowed to cool slowly (in ca. 6 h to ambient temperature), resulting in the separation of the (*R,S*)-diastereomeric salt. After 15 h in a refrigerator (5 °C), the crystal cake was pressed and filtered. Drying in vacuo afforded 54.5 g of light yellow, fine crystals.

(*S*)-(+)-**2**: A suspension of the (*R,S*)-diastereomeric salt (54.5 g, 0.177 mol) in 200 mL of CH_2Cl_2 was shaken with 92 mL of 2 M aqueous NaOH. For recovery of mandelic acid, the aqueous layer was acidified with 50% H_2SO_4, whereupon the acid crystallized and was filtered off or extracted into ethyl acetate. The aminal **3** remaining in the CH_2Cl_2 layer was *N*-benzoylated by addition of benzoyl chloride (20.1 mL, 0.173 mol) and 195 mL of 1 M NaOH with ice cooling. This afforded 45.8 g of a yellow crystalline material with $[\alpha]_D$ +107 (c=1, CH_2Cl_2).

(*R*)-(−)-**2**: The mother liquor from the crystallization above was concentrated (syrup, ca. 0.27 mol of diastereomeric salts) and then dissolved in 300 mL of CH_2Cl_2. The resulting solution was first treated with 2 M NaOH (140 mL) and then with benzoyl chloride (30 mL, 0.26 mol)/1 M NaOH (280 mL) for removal of mandelic acid and *N*-benzoylation, respectively, as described above for the (+)-enantiomer. The lumps of brown crystals obtained upon concentration of the CH_2Cl_2 phase were recrystallized from 45 mL of ethanol to give 33.6 g of a brownish material with $[\alpha]_D$ −109 (c=1, CH_2Cl_2).

Further purification of **2**: Each enantiomer was recrystallized twice from ethanol. Although the crystals were pulverized, the material dissolved only very slowly in refluxing ethanol (ca. 1.43 mL/g). Finally, the product was precipitated from a CH_2Cl_2 solution by addition of pentane and dried for at least 12 h at 60 °C/0.1 torr. This afforded 34.7 g (0.133 mol) of (*S*)-(+)-**2** (60%) with $[\alpha]_D$ +127 (c=1, CH_2Cl_2) and 26.4 g (0.101 mol) of (*R*)-(−)-**2** (45%) with $[\alpha]_D$ −126 (c=1, CH_2Cl_2). A sample was recrystallized several more times and sublimed (135 °C/0.01 torr) to give material with $[\alpha]_D$ +127.5 and m.p. = 143–144 °C. For spectroscopic data of (*R,S*)-**2** and (*R,S*)-**3** see [9, 10]. The enantiomeric excess of the derivatives was therefore greater than 98% and 99%, respectively.

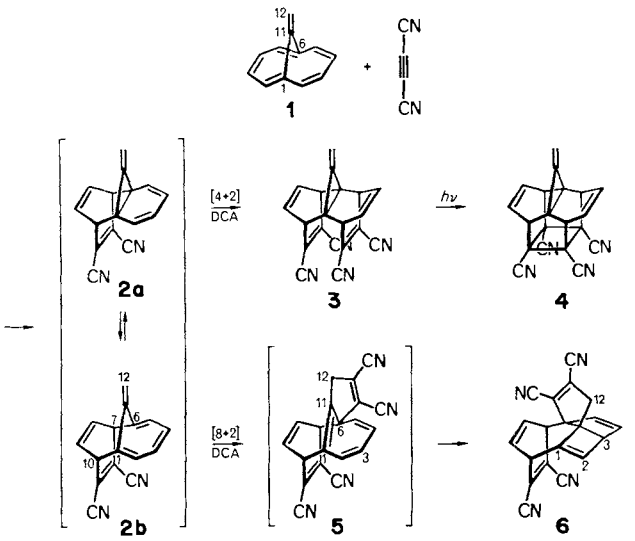
Organic Reactions at High Pressure: Cycloaddition Reactions of 11-Methylene-1,6-methano[10]annulene**



By *Frank-Gerrit Klärner,* Barbara M. J. Dogan, Richard Weider, David Ginsburg*, and *Emanuel Vogel*

The 1,6-methano[10]annulene route to cyclopropabenzenes[1] suggests 11-methylene-1,6-methano[10]annulene **1**[2] as a suitable starting material for the preparation of the still unknown methylenecyclopropabenzene[3] via cycloaddition of **1** with dicyanoacetylene (DCA) and Alder-Rickert cleavage. However, **1**, unlike the parent 1,6-methano[10]annulene, exhibits little tendency to react with DCA.[4] For this reason, we attempted to favor the cycloaddition by increasing the pressure (to 7000 bar). We report here the partly unexpected results for the reaction of **1** with DCA (Scheme 1).

At normal pressure, reaction of DCA with **1** (60 °C, pentane, 24 h in a sealed glass ampule) affords, in addition to polymers, a 3–4% yield of a crystalline 1:1 adduct (m.p. = 158 °C), which was identified as **2** by its spectral properties.[5] According to the ^{13}C-NMR spectrum (cf. Table 1), **2** exists in solution as the fluxional methylenenorcaradiene-heptafulvene system, **2a/2b**, with both components present in similar amounts. The chemical shift of C-1,6 (δ = 73.9, 32 °C) of **2** takes an intermediate position between symmetrically substituted methylenecyclopropanes (e.g., **3**: δ(C-1,6) = 39.9)[5] and heptafulvene (δ(C-1,6) = 138.3).[6] To the best of our knowledge, **2a/2b** is the first example of its kind. In contrast to **2**, the DCA adduct of 1,6-methano[10]annulene (δ(C-1,6) = 38.1) is only present as a "frozen" norcaradiene, that is, **2a** with $>CH_2$ instead of $>C=CH_2$.[1a] The similar energy content of **2a** and **2b** is presumably due to the fact that the strain energy of the methylenecyclopropane subunit,[7] which is 13.4 kcal/mol higher than that of cyclopropane, is able to compensate for the constraining effect of the 1,6-bridge. **2b** does not exhi-

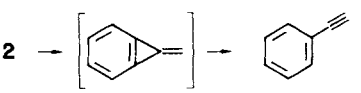
[a] The assignment of the ^{1}H-NMR signals was made on the basis of a COSY 2D NMR spectrum. The coupling constants were determined by double resonance experiments (irradiation of the signals of H-3, H-7, and H-10 with a second RF field). A NOESY 2D NMR experiment allowed the determination of the spatial proximity of the noncoupled atom H-3 with H-2 and H-12 (*endo*) and a ^{13}C,^{1}H correlation the C,H connectivities. [b] Hydrogenated on the centers marked 1 and 2 in **6**.



bit any significant heptafulvene character, which is understandable since the conjugation of the methylene group with the cycloheptatriene system is sterically strongly hindered.

When **1** is allowed to react with DCA at high pressure (7000 bar, 80°C, toluene, 4 h), two 2 : 1 adducts, which can be separated by fractional crystallization, are obtained in the ratio of 1 : 4 as determined by ^{1}H-NMR spectroscopy [yields of the isolated adducts: 11 and 16%, respectively; m.p. = 223°C (dec.) and 242°C, respectively].

According to its spectral and chemical properties, the high-pressure product formed in lower yield was characterized as the symmetrical 2 : 1 adduct **3**.[5] This adduct is very sensitive to light; it rearranges to the cage compound **4**, partly upon recrystallization in daylight and quantitatively upon short irradiation with a sunlamp.[5] The photochemical transformation of **3** into **4** proves that both dicyanovinylene bridges in **3** are in *anti* position with respect to the methylenecyclopropane ring.

The structural elucidation of the second 2 : 1 adduct proved to be more difficult insofar as an X-ray structure analysis led to no definitive result (presumably on account of crystallographic disorder).[8] By high-resolution ^{1}H- and ^{13}C-NMR spectroscopy along with the use of homo- and heteronuclear decoupling and 2D NMR experiments, it was possible to assign structure **6** to this adduct,[5] significant parts of which proved to be identical with those of the trapping product of 1,6-methano[10]annulene-11-ylidene with 1,3-diphenylisobenzofuran.[9] The presence of **6** is also revealed by the reduction with diimine, which gives the dihydro compound[5] (selective hydrogenation at C-1 and C-2, see Scheme 1).

The 1 : 1 adduct is formed by Diels–Alder reaction, the question remaining open whether the [10]annulene or its norcaradiene valence tautomer serves as the diene partner of DCA. The low yield of **2**, which could not be improved by high pressure, thus far has not allowed a detailed study of the thermolysis. Preliminary investigations show, however, that **2** fragments upon heating (130°C in benzene (1 h) or 400°C in a flow system), but, aside from phthalonitrile, mainly phenylacetylene is formed, which is probably a secondary product of the primarily formed methylenecyclopropabenzene.

In order to elucidate the mechanism of formation of the 2 : 1 adducts **3** and **6**, we showed by reaction of isolated **2** with DCA at 7000 bar that both adducts could arise from **2**. The course of the addition of DCA to **2** is apparently controlled by the valence tautomeric equilibrium **2a** ⇄ **2b**. As expected, **2a** reacts with DCA in a Diels–Alder type reaction, resulting in the formation of **3**. The ease with which **3** cyclizes photochemically to give **4** is a consequence of the small distance of the cyano-substituted double bonds, which, according to force-field calculations of *Ermer*[8] is only 2.98 Å. The unpredictable formation of the unsymmetrical 2 : 1 adduct **6** can only be explained by the reaction of **2b** with DCA via the intermediate **5**. The initial step **2b** → **5** may be regarded as an [8 + 2] cycloaddition, which is known to occur in the parent heptafulvene system.[10] That this cycloaddition occurs in the case of the geometrically unfavorable **2b**, however, is surprising. According to the inspection of models, the double bond between C-1 and C-11 of **5** exhibits a torsional angle of almost 90° (anti-Bredt compound). Accordingly, **5** has significant diradical character and apparently takes advantage of the sterically favorable possibility to stabilize itself by formation of **6**. Examples of such a butadiene–cyclobutene isomerization are known for *cis,cis,trans*-cycloheptatrienes[11] and related, extremely strained compounds.[12]

The preferential formation of the 2 : 1 adducts **3** and **6** upon reaction of **1** with DCA at high pressure is presumably due to the different activation volumes for the compet-

ing reactions of **2**. The bimolecular [4+2] and [8+2] cycloadditions are certain to have appreciably more negative activation volumes than the monomolecular Alder-Rickert cleavage.[13] Thus, an increase in pressure should enhance the rate of the association process strongly in comparison with the dissociation and the former process should dominate. The example described here clearly reveals the different effects of pressure and temperature on the rate of the reaction, which can result, as shown here, in the formation of unusual compounds that are not observed under normal conditions.

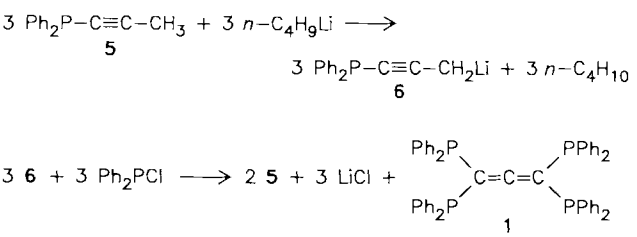
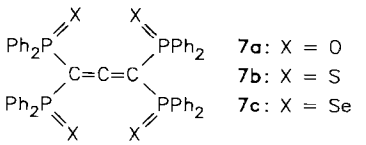
Tetrakis(diphenylphosphino)allene**



By *Hubert Schmidbaur** and *Thomas Pollok*

Little is known about phosphinoallenes at present,[11] and examples with four phosphino substituents (**1**) are totally lacking. Owing to the partly unexpected reaction behavior of 1,1-bis(diphenylphosphino)ethene **2**, R = Ph,[2] -cyclopropane **3**, R = Ph,[3] and -methane **4**, R = Ph,[4] upon quaternization,[5,6] oxidation,[7] and complex formation,[8] we have synthesized the title compound **1**, R = Ph.



1 **2** **3** **4**

Compound **1** was prepared surprisingly easily by lithiation of 1-diphenylphosphinopropyne **5**[9] to give **6**, followed by reaction of **6** with chlorodiphenylphosphane, and isolated in highly pure form in satisfactory yield (60%).[10] The molar ratios given in the two reaction equations clearly show that several transmetalations occur. Apparently, the CH acidity of the intermediates increases with increasing number of phosphino substituents, thereby favoring the complete replacement of all propyne/allene H atoms by Ph_2P groups. In contrast, the reactions of lithium or magnesium propynide (Li_4C_3 and Mg_2C_3) with chlorodiphenylphosphane afforded only tetraphenyldiphosphane.[11]

The allene **1** forms colorless crystals with a melting point (dec.) of 224 °C, which are only sparingly soluble in halogenated hydrocarbons. The allene structural unit is revealed in the IR spectrum by an absorption at 1890 cm^{-1}. The presence of the isomeric tetrakis(diphenylphosphino)propyne is also excluded by the observation that the ^{31}P-NMR spectrum contains only one signal ($\delta = -6.9$). In the ^{13}C-NMR spectrum, the central allene C atom gives rise to a quintet ($^2J_{PC} = 9.8$ Hz) at $\delta = 209.7$; the flanking C atoms, on the other hand, give rise to a singlet at $\delta = 89.1$. In solution the Ph_2P substituents are apparently free to rotate around the P-C bonds (such as in **2**, R = Ph[2]), so that only one set of signals results from the eight phenyl groups. In the mass spectrum (electron ionization, 70 eV), the peak at *m/z* 776 is due to the molecular ion.

The allene **1** can be converted into the tetraoxide **7a** by careful oxidation with bis(trimethylsilyl)peroxide in tetrahydrofuran (THF) (87% yield, m.p. = 258–260 °C); **7a**

7a: X = O
7b: X = S
7c: X = Se

forms beautiful single crystals.[12] Sulfur and selenium also add to **1**, giving the chalcogenides **7b** and **7c**, respectively. Table 1 gives spectroscopic data for **1** and **7**. Moreover, an X-ray structure analysis is available for **7a**.[12]

Other reactions often proceed in a complex manner—as observed for the vinyl derivative **2**, R = Ph[5]—since the propyne/allene isomerism allows several possible sites of attack. Thus, whereas the mild quaternization with iodomethane (in benzene at 0°C) indeed gives the monophosphonium salt **8**,[13] the use of the reagent in excess leads, even at 20°C, to the totally unexpected formation of the butynylphosphonium salt **9**.[14] Presumably, ylidic intermediates play a role in the lengthening of the allene/propyne chain. The Ph_2P unit that is lost is found in the reaction mixture as $[Ph_2PMe_2]I$.

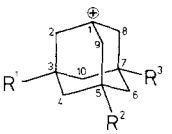
[10] *Experimental Procedure*: **1**: A solution of **5** (1.99 g, 8.87 mmol) in 15 mL of THF was metalated at −70°C with the equivalent amount of *n*BuLi (in hexane). The reaction mixture was allowed to warm up to 20°C and then cooled again to 0°C after 2 h. After slow addition (1 h) of Ph_2PCl (1.96 g, 8.86 mmol) in 10 mL of THF, the mixture was stirred for ca. 15 h and the solvent was then removed; the oily residue was crystallized from ethanol and dried; yield: 1.3 g (56%). Correct elemental analyses were obtained for **1**, **7a–c**, **8**, and **9**.

[11] We thank SKW Trostberg for chemicals and advice.

[12] G. Reber, G. Müller, unpublished results.



[13] The reaction of **1** (1.17 g, 1.51 mmol) with 2 mL (32.1 mmol) of iodomethane in 50 mL of benzene at 0°C affords, after 3 h, 1.20 g of **8** (87%), decomposition temperature: 203°C. IR: ν(C=C=C) = 1880 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ = 2.25 (br. d, J = 12.4 Hz, 3H, CH_3), 6.9–7.9 (m, 40H, C_6H_5). ^{13}C-NMR ($CDCl_3$): δ = 10.1 (d, J = 55.7 Hz, CH_3), 99.0 (m, CP_2), 117.9 (d, J = 86.9 Hz, C1), 207.3 (m, CC_2), signals of C2–C6 overlap.— ^{31}P-NMR ($CDCl_3$): AB_2X multiplet δ = −7 and +22. MS (FD): m/z 792 ($M^{\oplus}$).

[14] A solution of **1** (1.34 g, 1.73 mmol) and 2 mL (32.1 mmol) of iodomethane in 50 mL of THF was refluxed for 30 min. Upon cooling, **9** separates out as a yellow precipitate (yield: 1.52 g, 99%, m.p. = 225°C (dec.)). IR: ν(C≡C) = 2120 cm^{-1}. MS (FD): m/z 764 ($M^{\oplus}$ − I, 100%), 319 ($M^{\oplus}$ − 2I, 40.5). ^{1}H-NMR ($CDCl_3$): δ = 2.5–2.9 (m, 9H), 7.4–8.2 (m, 30H). ^{13}C-NMR ($CDCl_3$): δ = 13.3 (t, ^2J(PC) = 48.3 Hz, CH_3C), 18.2 (dt, ^1J(PC) = 110.3, ^3J(PC) = 4.4 Hz, CP_2), 65.4 (dt, ^1J(PC) = 191.4, ^3J(PC) = 6.3 Hz, P–C≡), 120.3 (d, ^1J(PC) = 99.6, C1 of PPh_2), 120.7 (AXX', N = 91.8 Hz, C1 of PPh_2Me), signals of C2–C6 overlap; 125.6 (dt, ^2J(PC) = 36.0, ^2J(PC) = 2.4 Hz, C–C≡). ^{31}P-NMR ($CDCl_3$): δ = 1.1 (t, ^3J(PP) = 7.3 Hz, P^{III}), 22.7 (d, P^V).

First Crystal Structure Analysis of an Aliphatic Carbocation—Stabilization of the 3,5,7-Trimethyl-1-adamantyl Cation by C–C Hyperconjugation**

By *Thomas Laube**

The 1-adamantyl cation **1a** and its derivatives **1b** and **1c**, bridgehead cations with high stability, have been the subject of numerous NMR spectroscopic,[1] theoretical,[2] and solvolytic[3] studies, because many observations can only be interpreted by assuming that the γ carbon atoms 3, 5, and 7 bear partial positive charges. Although *Olah* et al.[4] described the synthesis of solid **1a**-SbF_6 in 1973, no X-ray structure analysis of the salt of an adamantyl cation or, for that matter, of a cation that is not stabilized by a π-system or a heteroatom has been reported. By reaction of 1-fluoro-3,5,7-trimethyladamantane[5] with antimony pentafluoride (modification of the procedure in ref. [4]), it has now been possible to synthesize the salt **1c**-Sb_2F_{11}, which, after recrystallization, afforded suitable crystals[7] for the X-ray structure analysis.[6]

	R¹	R²	R³
1a	H	H	H
1b	CH_3	CH_3	H
1c	CH_3	CH_3	CH_3

No interaction between cations and anions is found in the crystal lattice, since, even though the shortest C⊕···F distance (C1···F25) is only 2.88(2) Å,[8] the Sb2–F25 bond is not lengthened[9] (Fig. 1). The bent structure of the anion does not differ from that in other Sb_2F_{11} salts.[10] The cation **1c**, however, exhibits drastic differences from the idealized structure[11] (Fig. 2).

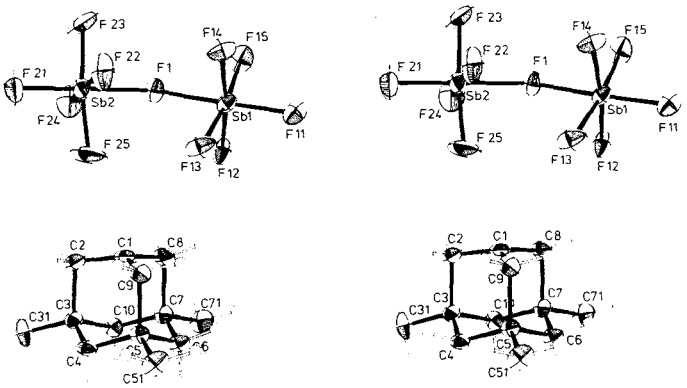


Fig. 1. ORTEP stereo plot of the crystal structure of **1c**-Sb_2F_{11}. The ellipsoids are drawn at the 50% probability level. Within the limits of error of the structure, the cation belongs to the point group C_{3v}, the anion approximately to the point group C_2. The ion pair shown forms the asymmetric unit.

The cationic center C1 is clearly flattened (the "pyramidalization"[12] is 0.21 Å); the bonds emanating from C1 are on the average 1.44(2) Å, the subsequent bonds to the qua-

C6-C7	1.52	C6-C7-C10	113	C6-C7-C10-C3	+54
C7-C10	1.51	C7-C10-C3	111	C7-C10-C3-C4	−53
C10-C3	1.55	C10-C3-C4	110	C10-C3-C4-C5	+55

The structure of the cation reflects the effect of hyperconjugative resonance structures of type **1c'**. Homohyperconjugation appears to play no or at most a very minor role, because resonance structures of type **1c''** are not able to explain the extreme differences in bond lengths[13] and the bonds to the methyl groups are not lengthened (Table 1). The very small C-C-C bond angles (99(1)°) around the methylene carbon atoms 2, 8, and 9 show that these atoms, like C1, are approximately sp^2 hybridized, the p-like orbital contributing in each case to the bond to the quaternary C atom.[14]

Position of the Sb atoms determined with the Patterson option of SHELX84, all other atoms, except hydrogen atoms, by subsequent difference Fourier synthesis with SHELX76. Refinement by the least-square method (all atoms except hydrogens anisotropic, H atoms on C2 and C9 isotropic, the other H atoms were calculated and refined according to the riding model) with unit weights, finally in the XRAY system: $R = 0.070$. The tensor component U_{11} is large for F23 and F25: 0.18 and 0.28 Å^2, respectively.

[7] The X-ray structure analyses of **1a**-Sb_2F_{11} and **1b**-Sb_2F_{11} gave only poor R values on account of disorder (**1a**-Sb_2F_{11}: *C2/c*, $a = 17.072(7)$, $b = 13.263(5)$, $c = 9.017(4)$ Å, $\beta = 121.90(4)°$ at −30°C; **1b**-Sb_2F_{11}: $Pmn2_1$, $a = 14.486(8)$, $b = 7.692(4)$, $c = 8.51(1)$ Å at −40°C).
