

(93)

Radicals which lead to the alkylation of the mediator can also be released by electron transfer from the mediator radical anion to sulfonium or ammonium ions.[175]

4.2. Reductions by Viologen Radical Cations

Viologens, i.e. *N,N*-dialkyl-2,2'- or -4,4'-bipyridinium salts, were already used some time ago as electron transfer agents in the coulometric titration of redox-enzymes.[176] Hence, it was a logical step to apply the same principle to reductions on a preparative scale. The electrochemical reduction of $NAD^{\oplus}$ to NADH presented itself as an especially interesting problem (see also Section 3.3.2). Since the direct electrochemical reduction of $NAD^{\oplus}$ never affords NADH exclusively, a number of authors chose the detour via an enzyme-coupled indirect electrolysis with methyl viologen ($MV = N,N'$-dimethyl-4,4'-bipyridinium dichloride) as mediator (see Scheme 7). The intercalated redox enzyme must be able to take up two electrons successively from the electrochemically generated $MV^{\odot\oplus}$ and then to transfer them at one and the same time to $NAD^{\oplus}$. It was possible to carry out the NADH and NADPH regeneration with the enzyme systems ferredoxin reductase,[177] lipoamide dehydrogenase,[178] as well as 2-oxocarboxylate reductase and enoate reductase.[179]

Scheme 7. Indirect electrochemical reduction of $NAD^{\oplus}$ assisted by a redox enzyme.

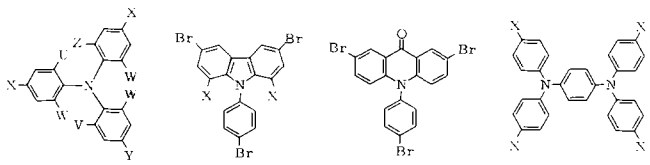
With enoate reductase, enoates can also be hydrogenated stereospecifically without intermediate NADH formation. This reaction also succeeds without isolation of the enzyme, by use of intact clostridium cells. *Simon* et al. were even able to generate (*R*)-1,2-propanediol "electromicrobially" from hydroxyacetone via indirect electrochemical formation of NADH using whole yeast cells [Eq. (94)-(97)].[179]

$$2\,MV^{2\oplus} \xrightarrow[+2e^{\ominus}]{\text{cathode}} 2\,MV^{\odot\oplus} \quad (94)$$

$$2\,MV^{\odot\oplus} + H^{\oplus} + NAD^{\oplus} \xrightarrow{\text{yeast}} NADH + 2\,MV^{2\oplus} \quad (95)$$

$$H^{\oplus} + NADH + CH_3COCH_2OH \xrightarrow{\text{yeast}} NAD^{\oplus} + CH_3CH(OH)CH_2OH \quad (96)$$

sum:



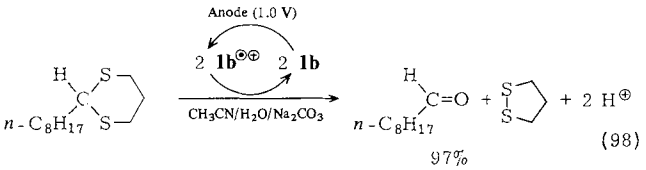
$$CH_3COCH_2OH + 2\,H^{\oplus} + 2\,e^{\ominus} \longrightarrow CH_3CH(OH)CH_2OH \quad (97)$$

4.3. Oxidations with Triarylamine Radical Cations

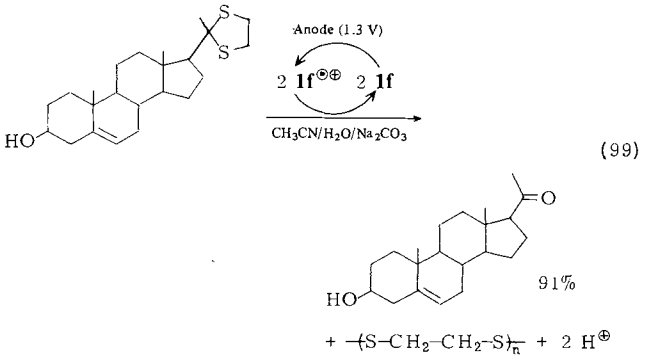
Oxidation reactions catalyzed by organic mediators attracted very little attention from chemists for some time, for it was a foregone conclusion that organic molecules would not be stable enough to reach an acceptable number of cycles. *Nelson* et al., however, were able to prove that the radical cations of triarylamines[180] and the related *N*-phenylcarbazoles[181] are very stable, if the *para* positions of the phenyl rings are blocked by substituents from attack

by nucleophiles. The suitability of triarylamines as mediators has for instance been demonstrated in the oxidation of cyanide ions with electrochemically generated trianisylamine radical cations as electron transfer agents.[182] We[183] and others[180, 184, 185] have in the meantime synthesized a large variety of substituted triarylamines and have tested their suitability as redox catalysts.[183] The compounds cover a potential range from +0.76 V to 1.96 V (vs. NHE), so that one should be able to find a suitable mediator for every reaction (see Table 3). It should be pointed out, however, that the stability of the triarylamine radical cations strongly depends on the reaction medium. Bromine- and chlorine-substituted compounds have proven to be especially reliable. Tris(2,4-dibromophenyl)amine, for example, is extremely stable. In methanolic solution 2500 cycles could be performed without any appreciable consumption of the mediator.[186]

Table 3. Standard potentials for the oxidation of triarylamines and related compounds to the radical cations.



1 2 3 4



Compound number	Substituents U	V	W	X	Y	Z	E^0 [V] vs. NHE
4a	—	—	—	H	—	—	0.75
1a	H	H	H	OCH_3	OCH_3	H	0.76
4b	—	—	—	Br	—	—	0.91

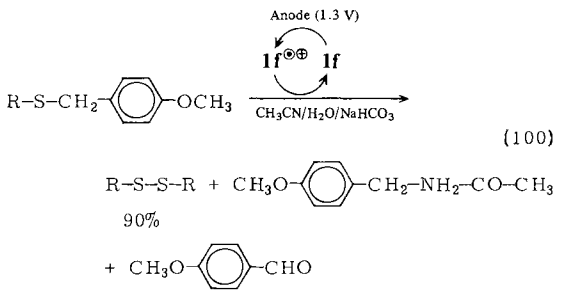
1v	Br	Br	H	Br	$COCF_3$	Br	1.86
1w	Br	Br	Br	Br	Br	Br	1.96

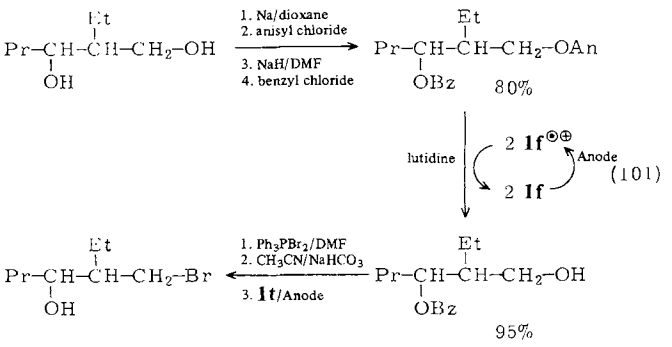
Compounds with potentials that are several hundered millivolts more positive than those of the mediators (electrochemical oxidation opposite to the standard potential gradient; see Section 2.2) can be oxidized with electrochemically generated triarylamine radical cations, since a fast and irreversible bond cleavage usually follows the primary electron transfer. Especially favorable follow-up reactions are deprotonations in the benzyl- or allyl-position or in the α-position to hetero atoms. The irreversible cleavage of carbon-sulfur bonds in sulfides also shifts the electron transfer equilibrium in favor of the products. In addition, in many cases the reaction between substrate and triarylamine radical cation does not proceed as a simple homogeneous electron transfer (mechanism A, Section 2.2), but presumably an interaction (complex formation or even bond formation) between mediator and substrate facilitates the electron transfer, so that potential differences higher than 600 mV can be overcome. *Eberson* came to the same conclusion in an analysis on the basis of the Marcus theory.[187]

In this way oxidation reactions are possible under very mild conditions and with high selectivity, which makes the method especially useful for the oxidative cleavage of protective groups. Thus, carbonyl compounds could be deprotected in high yields from 1,3-dithianes and 1,3-dithiolanes with **1b** or **1f** in moist acetonitrile in the presence of sodium carbonate [Eq. (98), (99)].[188] The cleavage conditions are so mild that hydroxy groups and double bonds can be tolerated without any problems.



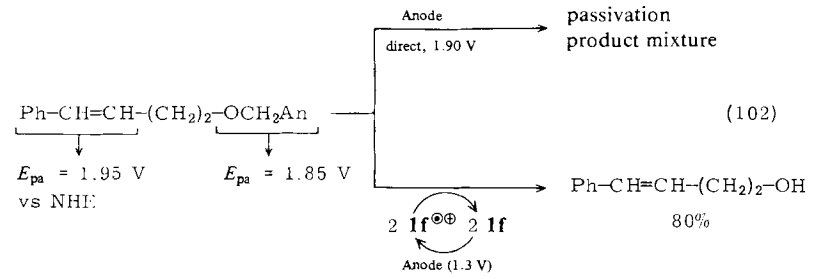
(98)

(99)



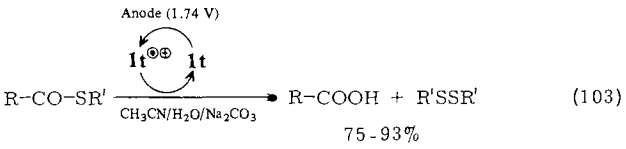
The cleavage of the carbon-sulfur bond in *p*-methoxybenzyl thioethers with formation of disulfides and secondary products of the *p*-methoxybenzyl cations [Eq. (100)] has been exploited for the directed incorporation of disulfide bridges in poly-cystinyl peptides via *S*-(4-methoxybenzyl)cysteine units in combination with *S*-tritylcysteine groups.[189]

Substituted benzyl ethers[190] and benzyl esters[191] can also be deblocked with formation of alcohols and carbox-



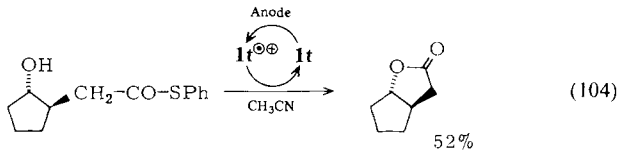
(100)

ylic acids, respectively. If a suitable mediator is selected these cleavages can be performed in a multifunctional molecule selectively and in a directed manner depending on the substitution pattern of the protective groups. Thus, the directed protection and selective deblocking of hydroxy groups attached to primary and secondary C-atoms in polyhydroxy compounds can be realized without any problem [Eq. (101)].[190b]



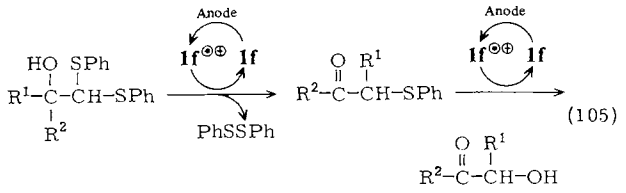
An = 4-methoxybenzyl, Bz = benzyl

Even substantially milder reaction conditions are possible, if the anisyl ether function as permanent protective group is combined with the 3,4-dimethoxybenzyl ether function as intermediate protective group.[190d] The selectivity of the reaction can be demonstrated with the anisyl ether of 4-phenyl-3-buten-1-ol [Eq. (102)].[190c] The educt contains two electrophores, whose potentials differ only by 100 mV. The direct electrolysis therefore proceeds unselectively, while the indirect electrolysis leads only to attack at the easier oxidizable function. Non-activated OH-groups are stable towards triarylamine radical cations with potentials up to 1.6 V (vs. NHE).



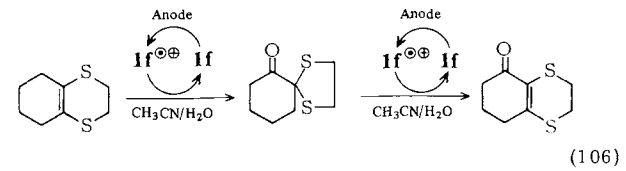
The indirect electrochemical deblocking of benzyl esters by triarylamine radical cations not only differentiates highly selectively between unsubstituted benzyl esters and 4-methoxybenzyl, 2,4-dimethoxybenzyl or benzhydryl esters, but, other than in previous methods, also between the acid labile 2,4-dimethoxybenzyl esters and the likewise acid labile 4-methoxybenzyl and benzhydryl esters.[191] The *N*-*t*-butoxycarbonyl(Boc)- and *N*-benzyloxycarbonyl(*Z*)-protective groups are stable under these conditions. In contrast, the *N*-*p*-methoxybenzyloxycarbonyl(MOZ)-protecting group can be cleaved smoothly by $\mathbf{1t}^{\odot\oplus}$. Thiol esters can also be cleaved by indirect electrolysis in good yield with **1t** as a mediator [Eq. (103)].[191b]

(103)



R' = Ph, $H_3CO-C_6H_4$, Ph–CH_2, n-C_8H_{17}

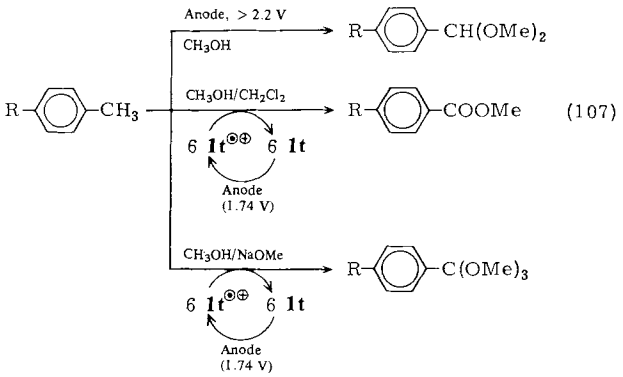
Starting from *S*-phenyl *trans*-2-hydroxycyclopentylthioacetate, this reaction can be used for the synthesis of an otherwise difficultly accessible cyclopentano-γ-lactone with the *trans*-configuration [Eq. (104)].[192] Rearrange-



(104)

ments can be initiated by the indirect anodic cleavage of carbon-sulfur bonds [Eq. (105) and (106)].[193]

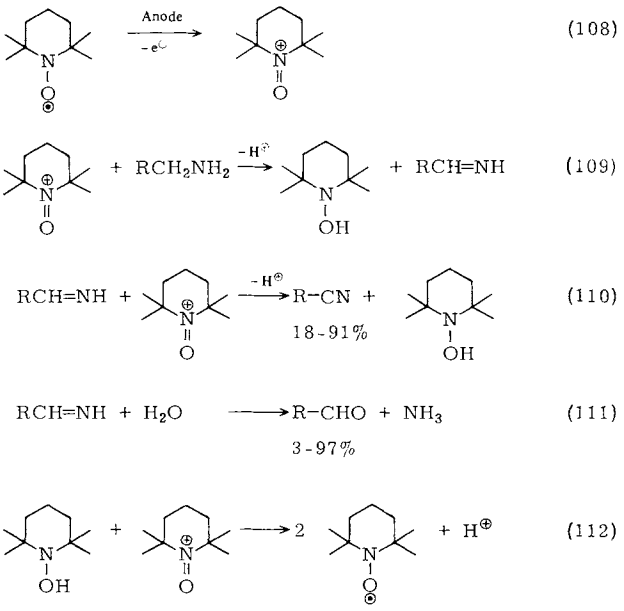
(105)



(106)

Interesting from the industrial point of view are the indirect electrochemical oxidations of benzylic alcohols, benzaldehyde dimethyl acetals and arylalkanes with **1t** as mediator. We were able to show that benzylic alcohols can be oxidized with high selectivity to benzaldehydes or their dimethyl acetals not only in acetonitrile in a divided cell but also in methanol in an undivided cell.[194a]

Arylalkanes that are oxidizable only to the stage of the benzaldehyde dimethyl acetals by direct anodic electrolysis in methanol are oxidized to methyl benzoates under mildly acidic conditions and at very low potentials with **1t** as mediator [eq. (107)].[186, 194b] Even toluene with a standard potential of 2.64 V (vs. NHE) can be transformed into



methyl benzoate in 95% material yield. If the reaction is carried out in presence of Na_2CO_3 or small amounts of NaOMe as base, trimethylorthobenzoates are obtained in good selectivity [Eq. (107)].[186, 194b] When benzaldehyde dimethyl acetals are used as starting compounds in a $CH_3OH/LiClO_4$ electrolyte in presence of low concentrations of NaOMe, orthoesters are obtained almost exclusively (selectivity > 90%). The current yields are especially good in all cases, if the substrate is used as a co-solvent.[186, 194b]

(107)

4.4. Oxidations with Electrochemically Regenerable Hydride or Hydrogen Atom Abstracting Reagents

As already demonstrated in Section 2.2, even those oxidation reagents that effect a hydrogen or hydride abstraction can be regenerated electrochemically. Hydrogen, for example, can be abstracted by in-situ electrochemically oxidized *N*-hydroxyphthalimide.[195] The presence of a base like pyridine is necessary. In this way alcohols, arylalkanes, benzyl ethers and olefins can be oxidized. The cycle numbers, however, are still very low. Electrochemically regenerable hydride abstracting agents are 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), as well as the oxoammonium ion accessible from 2,2,6,6-tetramethylpiperidyl oxide (TEMPO). DDQ has been regenerated both externally,[196] that is after the isolation of the hydroquinone, and internally.[197] TEMPO is oxidized in-situ in acetonitrile containing lutidine. Thus, primary alcohols can be converted into aldehydes, while secondary alcohols are scarcely attacked.[198] Under these conditions, primary amines preferably form nitriles; in the presence of water, hydrolysis of the intermediate azomethines with generation of carbonyl compounds is favored [Eq. (108)-(112)].[199]

5. Outlook

The optimism sparked off by euphoric predictions on the future development of electroorganic syntheses in the early sixties was suddenly displaced by a certain disillusionment during the seventies. In the meantime, however, there has been a gradual but distinct revival of interest in electrosynthesis, both in the laboratory and in industry. Responsible for this fresh impetus are new insights into chemical mechanisms and the development of new materials and new techniques.[201] One of these techniques, namely indirect electrochemical synthesis, has become a subject of intensive study and it is expected that a host of new possibilities for its application will emerge in the future. The particular advantages of this technique are its low burden on the environment, the favorable exploitation of energy because of the acceleration of electrode reactions, and the high selectivity of many of the syntheses. Special chances of development are foreseen for indirect electrolysis with transition metal complexes as redox catalysts, since these mediators are accessible in large variety, can easily be modified, and mostly undergo specific reactions. The in-situ regeneration of metal ions in low oxidation states opens up new possibilities for the use of reactive and highly sensitive reagents. Some organic mediators, in particular triarylamines, have proved to be surprisingly stable and even fulfill the prerequisites for use on an industrial scale, with cycle numbers of several thousands, Even some present day environmental problems can be reduced by resort to indirect electrochemical processes. Thus, the dehalogenation of polychlorinated biphenyls (PCB's) could be carried out with 9,10-diphenylanthracene as redox catalyst.[200] Entirely new reactions can be expected to emerge from the photochemical excitation of electrochemically generated and regenerated mediators. New insights into this field are also of great importance for the photoelectrochemical conversion of light into electrical or chemical energy.

My own results quoted in this article were only possible through the great efforts of motivated co-workers, which are mentioned in the references, and by generous support of the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Arbeitsgemeinschaft industrieller Forschungsvereinigungen, and the BASF Aktiengesellschaft. My sincere thanks to all of them!

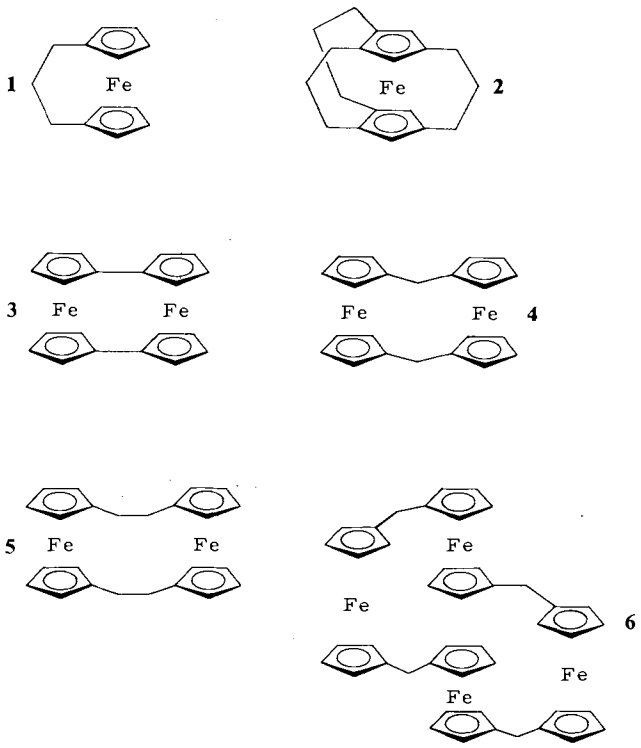
[m.m]Metallocenophanes: Synthesis, Structure, and Properties

By Ulrich T. Mueller-Westerhoff*

Metallocenophanes are metallocenes in which the cyclopentadienyl ligands are linked intramolecularly through C_mH_n or C_mH_nX (X = heteroatom) chains. Two main classes of metallocenophanes are known: in [m]metallocenophanes the ligands of *one* metallocene are connected by a bridge (or by several bridges); in [m.n]metallocenophanes *two* (or more) metallocenes are brought together into one molecule by bridging groups. This article briefly describes the first class (mononuclear complexes) and then concentrates on the second (binuclear complexes). The [1.1]metallocenophanes, which are produced by linking two metallocene moieties through two C_1 bridges, are of particular interest and are characterized by a variety of unusual and useful properties: they are very flexible conformationally; hydride abstraction from the CH_2 bridges produces carbenium ions that are greatly stabilized by the adjacent metallocene moieties; deprotonation of one of the CH_2 bridges is surprisingly easy and leads to the unusual situation that an intramolecular C–H···C hydrogen bond stabilizes a carbanion; protonation of both metallocene moieties causes the liberation of one mole of hydrogen per mole of [1.1]metallocenophane, thereby allowing the use of these compounds as catalysts for the formation of hydrogen in acidic aqueous solutions.

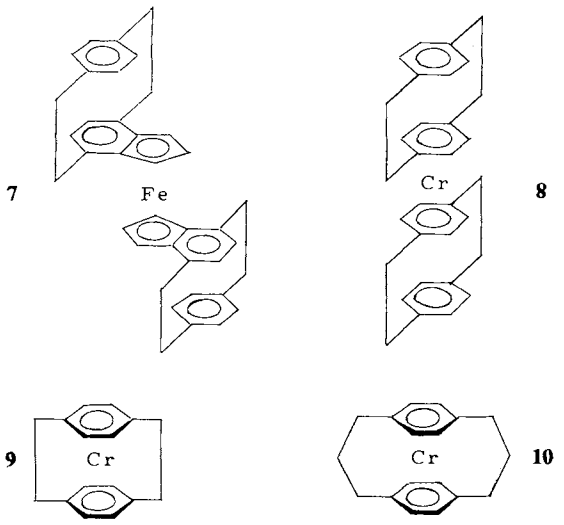


1. Introduction

1.1. General

Although some metallocenophanes have been known for close to twenty years, this class of compounds has been the subject of intensive studies only in the last few years. The development of specific syntheses and the associated study of the physical properties of the new compounds were the initial focus of investigations, which rapidly expanded to include such phenomena as metal basicity, the effects of structural deformation on the properties of metallocenes, intervalence transfer of electrons in binuclear species, electrical conductivity, and even the occurrence of intramolecular C–H···C hydrogen bonds.

There exist two main classes of metallocenophanes, exemplified here by derivatives of the classical metallocene ferrocene: the mononuclear complexes with one (**1**) or several (**2**) bridging groups and the multinuclear systems **3**–**6**, of which bis(fulvalene)diiron **3** is a special (and interesting) case because it contains no bridging groups. There also exist a large number of metallocenophanes with heteroatomic bridges, but they have been omitted from this discussion.



Loosely related to metallocenophanes in the sense of this definition are systems containing cyclic structures of a different type. For example, compounds **7** and **8** have been prepared[1,2] in which two cyclophane moieties coordinate a metal atom, resulting in the formation of a substituted ferrocene or bis(arene)chromium complex. Such compounds do not contain bridged metallocenes. Much more directly related are systems such as **9** and **10** in which paracyclophanes coordinate metal atoms in their cavities.[2,3] These systems are isoelectronic with similarly bridged ferrocenophanes, but they will only be mentioned here in passing.

The focus of this article is on binuclear metallocenophanes and their unusual properties; the most typical characteristics of related systems will only be discussed in connection with those of binuclear metallocenophanes. The fascination of organometallic compounds containing more than one transition-metal atom stems from the promise that these materials may show cooperative effects in which the metal centers may assist each other in redox processes and other reactions, with or without the existence of direct metal–metal interactions, and that this may

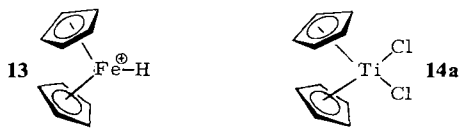
help our understanding of, for example, a variety of catalytic processes.

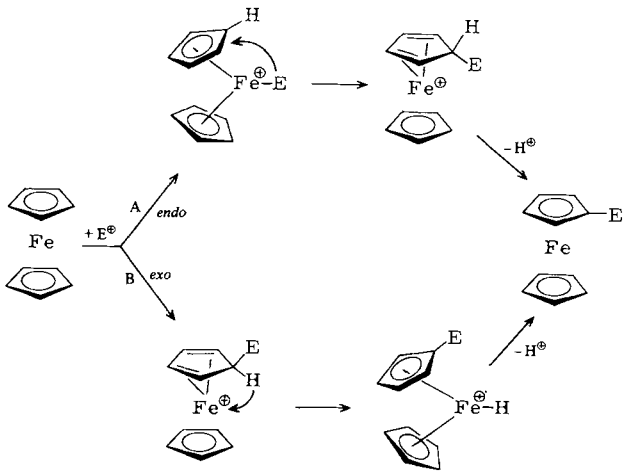
After several remarks concerning the nomenclature of these systems, we will discuss some of the important properties of metallocenes and of the mononuclear metallocenophanes and then focus on the chemistry and uses of the binuclear and multinuclear systems. The reader is referred to a review published nearly twenty years ago by *Watts*[4] on metallocenophanes, which emphasizes the mononuclear systems.

1.2. Nomenclature



The few examples in the previous section already indicate that there does not exist a uniform nomenclature for the metallocenophanes. A widely accepted nomenclature[5] for purely organic cyclophanes[6] was used[4,7-9] rather early for bi- and multinuclear ferrocenophanes.[10] This notation appears to be the choice of the majority of researchers in this area. The ferrocenophanes (FCPs) are designated [m][n][o][p]FCP and [m.n.o.p]FCP, where the numbers in square brackets denote the length of the bridges: **1**, [3]FCP; **2**, [3][3][3]FCP;[*] **3**, [0.0]FCP; **4**, [1.1]FCP; **5**, [2.2]FCP; **6**, [1.1.1.1]FCP. This system is not sufficient, however, to indicate the exact location of the bridges, a deficiency that causes problems only in the case of multibridged FCPs or of compounds with other ring substituents. Such cases require a slightly more complex system of nomenclature, which is exemplified for **2**, a triply bridged ferrocene: although **2** can be unambiguously named, according to the IUPAC rules, as 1,1′;2,2′;4,4′-tris(trimethylene)ferrocene, its name according to metallocenophane nomenclature is [3](1,1′)[3](2,2′)[3](4,4′)ferrocenophane. In the name for **4**, [1.1]ferrocenophane, the nature of the linkages is only specified by the number of carbon atoms in the bridges. Where needed, the more complete nomenclature can be used, namely, [1.1](1,1″;1′,1‴)ferrocenophane. Interesting examples where both types of metallocenophanes have been combined into one structure were recently described by *Hillman* et al.:[11] in **11** and **12** both the [3]FCP and the [1.1]FCP structures are found. The complete name of compound **11** is [3](2,2′)[1.1](1,1″;1′,1‴)FCP and of **12** [3](3,3′)[1.1](1,1″;1′,1‴)FCP, but here it seems indeed simpler to refer to these compounds as 2,2′-trimethylene[1.1]FCP and 3,3′-trimethylene[1.1]FCP, respectively.

1.3. Important Properties of Metallocenes



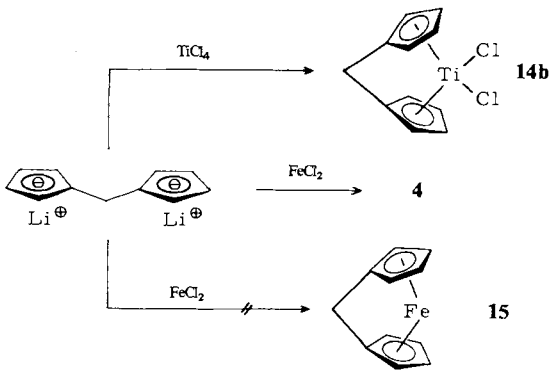
Ferrocene, known since 1952,[12] is the parent of all "sandwich" complexes. There exist many thousands today, predominantly with cyclopentadienyl ligands, although very interesting sandwich complexes are known with ligands ranging in size from C_3 (cyclopropenyl) to C_9 (cyclononatetraenyl) and with almost all of the main-group and transition metals, as well as lanthanides and actinides. The ligands in ferrocene are planar and lie in parallel planes with a separation of 330 pm;[13] this distance is comparable to the van der Waals thickness of an aromatic ring, e.g., the interplanar distance of approximately 340 pm found in crystalline arenes, so that ferrocene can roughly be thought of as a dimer of two aromatic systems within which an iron atom is "hidden," but still reveals its presence through the variety of properties of ferrocene. The C_5H_5 ligands are almost free to rotate with respect to each other: according to experimental and theoretical data,[14-17] the activation barrier to this rotation is of the order of 4-8 kJ/mol, the eclipsed conformation being slightly preferred over a staggered arrangement of the rings. Ferrocene is diamagnetic and has fully covalent bonds; it is stable toward air and nonoxidizing acids, sublimable, and soluble in most organic solvents. It can be reversibly oxidized to the deep green ferrocenium radical cation, which is more labile toward dissociation or exchange reactions than neutral ferrocene. Ferrocene acts as a very weak base: it undergoes protonation in extremely strong nonoxidizing acids to form a cation, which is slowly oxidized in air to the ferrocenium ion. In analogy to the known structures of other protonated metallocenes, the protonated ferrocene is assumed to have the bent structure **13**. Such bent structures are found frequently in compounds such as titanocene dichloride **14a**.

Related to the mechanism of protonation at the metal atom of metallocenes is the ease with which they—par-

[*] An alternative is to give the number of identical bridges in mononuclear complexes as subscripts, e.g., **2**, [3_2]FCP.

ticularly ferrocene—can undergo electrophilic substitution: compared with benzene, ferrocene is substituted several orders of magnitude faster. One of the most often (albeit incorrectly) cited reasons for this is that ferrocene coordinates the electrophile at the metal, thereby facilitating the ring substitution (path A in Scheme 1, *endo* attack). Alternatively, however, *exo* attack by the electrophile (path B) could explain the ease of substitution, because transfer of a proton of the ligand to the iron atom (the intermediate would be analogous to protonated ferrocene **13**) and its subsequent elimination are plausible; such a mechanism is not available to benzene.

Scheme 1. Alternative mechanisms for the electrophilic substitution of ferrocene (see text). Both pathways make use of the ability of the iron atom to coordinate an additional ligand.

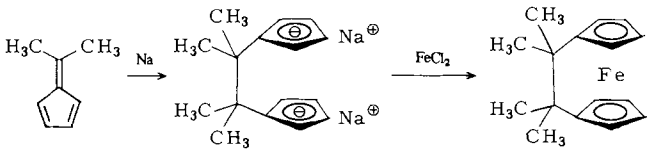


Ferrocene analogues of other transition metals show a wide range of properties. A few key properties of relevance to the discussion of metallocenophanes are related to the 18-electron rule: metallocenes with a total of 18 valence electrons (metal valence electrons plus ligand valence electrons minus total charge of the compound) are stable and have ferrocene-like sandwich structure: ruthenocene, osmocene, and the cobaltocenium ion are typical examples. The distance between the rings in ruthenocene (370 pm) is larger than in ferrocene; ruthenocene cannot be oxidized to a monocation, but a dication is known. The cobaltocenium ion is formed rapidly from its 19-electron precursor cobaltocene in aqueous acidic media upon exposure to oxygen (air). It is stable toward the strongest acids and does not undergo any of the typical electrophilic substitution reactions known for ferrocene.

2. [m]Metallocenophanes

When metallocenes and some of their simple derivatives were discovered, one of the more astonishing findings was that the cyclopentadienyl ligands lie in strictly parallel planes and can rotate easily about the symmetry axis. This is of course no longer true when the two ligands are joined by a bridge: the dihedral angle between the planes of the rings will depend to a large degree on the length of the bridge(s), and, instead of an almost free rotation, only vibration is possible. The ease of electrophilic substitution reactions should also be greatly influenced in going from ferrocenes to [m]ferrocenophanes: the tilt of the rings facilitates coordination to the metal, which in turn influences the reaction mechanism (path A or path B, see Scheme 1). Such considerations have prompted the study of [m]FCP systems having different bridge sizes and of ferrocenes with more than one bridge. Most of the present literature is still concerned with the synthesis and structural characterization of these compounds, only a few mechanistic studies having been reported. By far, most of the publications on [m]metallocenophanes concern ferrocene derivatives, although a comparison between systems involving different metals and thus varying distances between the rings is of great interest.

2.1. [1]Metallocenophanes

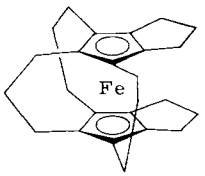


No examples exist of [1]ferrocenophanes such as **15**, because a C_1 bridge would presumably force the rings to tilt so much that the ferrocene system would no longer be stable. Precisely this tilt, however, is the preferred arrangement for the titanocene dichloride system **14a**. It is thus not surprising that the reaction of the dilithium salt of dicyclopentadienyl methane with iron(II) chloride does not lead to **15**, but instead produces **4** together with its oligomers;[9] its reaction with $TiCl_4$, on the other hand, cleanly produces **14b** (Scheme 2).[18]

Scheme 2. Reactions of dicyclopentadienylmethane dianion with $FeCl_2$ and $TiCl_4$.

2.2. [2]Metallocenophanes

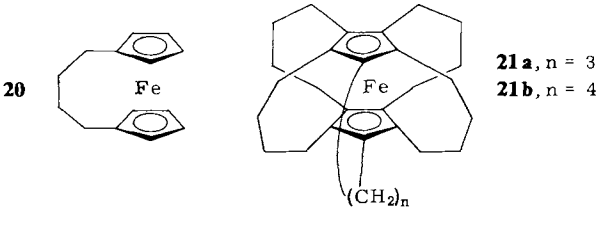
The first [2]metallocenophane, 6,6,7,7-tetramethyl[2]ferrocenophane **18**, was prepared in low yield by reacting 6,6-dimethylfulvene **16** with sodium to give the disodium salt **17**, followed by addition of $FeCl_2$. This reaction (Scheme 3), first reported by *Rinehart* et al.,[19] is typical of the approach by which many [m]metallocenophanes have been prepared. The rings in **18** are tilted with respect to each other, a structure that corresponds to the one assumed for protonated ferrocene **13**. It is not surprising, therefore, that [2]ferrocenophane is easier to protonate than ferrocene.[20]



16 17 18

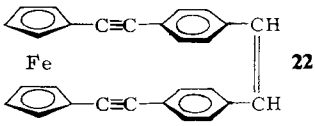
Scheme 3. Synthesis of 6,6,7,7-tetramethyl[2]ferrocenophane **18** from 6,6-dimethylfulvene **16**.

2.3. [3]Metallocenophanes



[3]Metallocenophanes are by far the best represented of the [m]metallocenophanes, both because these compounds are accessible by several routes (including some of the typical condensation reactions well-known in organic chemistry) and because the C_3 bridge causes relatively little distortion in the system. Although the C_3 bridge is too short to span the distance between the cyclopentadienyl ligands in ferrocene without any strain, the construction of multibridged systems is still possible. [3]Ferrocenophanes with one, two, three, or four bridges are known;[21,22] only the fully bridged [3][3][3][3][3]FCP ([3_5]FCP) has so far eluded all synthetic efforts. In several attempts to synthesize such a system, cyclization involving only one cyclopentadienyl ligand occurred instead of the desired bridge formation between the two sandwich moieties. Compound **19** is an example of such a product.[23]

19

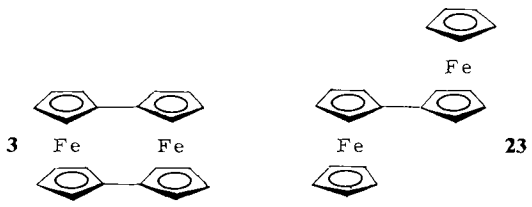


2.4. [4]Metallocenophanes and Larger Systems

The [4]ferrocenophane **20**, prepared by *Lüttringhaus* et al. in 1958,[24] was the first example of a bridged ferrocene. The synthesis, starting from a dicyclopentadienide reagent, produced a variety of oligomers. In the meantime, a large number of FCPs with C_n bridges ($n \geq 4$) have been prepared. Noteworthy are the homologues of **20**, such as the [4][4][4]- and [5][5][5]ferrocenophanes with bridges in the 1-, 2-, and 4-positions.[25] In 1982, *Hisatome* et al.[26a] reported the first example of a fully enclosed ferrocene system, [3][4][4][4][4]ferrocenophane, which contains one C_3 and four C_4 bridges. Its structure, despite disorder in the crystal, has been characterized. Recently, the same group reported the synthesis of the symmetrical [4][4][4][4][4]ferrocenophane ([4_5]FCP), which, in analogy to superphane, was named "superferrocenophane."[26b]

20 **21a**, n = 3 **21b**, n = 4

[m]Ferrocenophanes with extremely long bridges have also been prepared by *Hisatome* et al., but the current record, held by a Swedish group,[27] appears to be the synthesis of a partially conjugated [24]ferrocenophane. One further example from another Japanese group combines the [m]metallocenophane structure with that of a typical paracyclophane: compound **22** was reported by *Kasahara* et al.[28]



22

3. [m.m]Metallocenophanes

The concept of linking two or more metallocenes by simple hydrocarbon bridges offers a number of interesting possibilities, including various interactions between the two metallocenes, the nature and extent of which will clearly depend on the size and nature of the bridges. Such interactions may be transmitted either through the ligands (through-bond) or directly (through-space) or by combinations of the two possibilities. This concept thus allows, in principle, the construction of compounds with novel redox properties. Owing to the availability of two or more coordination sites and the existence of controllable cooperative effects in their redox chemistry, [m.m]metallocenophanes may find applications in catalytic processes where their mononuclear counterparts are of little or no use.

In any compound containing more than one metal center, the possibility exists that, through oxidation or reduction, different oxidation states of the metal may be present in the same molecule. Such "mixed valence" compounds are found in many areas of organometallic and coordination chemistry. However, the metallocenophanes have played an especially important role in contributing to our understanding of this class of substances. The presence of a mixed valence compound is revealed by usually broad but relatively intense near-IR (NIR) absorptions, often called intervalence transfer bands. These are exemplified in Figure 1 by the NIR spectra of the monocations of bis(fulvalene)diiron **3** and its singly bridged analogue biferrocene **23**.[41]

3 **23**

The electronic process giving rise to these absorptions is the transfer of an electron from the metal atom with the lower oxidation state to that with the higher oxidation state, thus reversing the order of oxidation states: in iron-containing species, for example, such an excitation corre-

sponds to the process $Fe^{II}/Fe^{III} \rightarrow Fe^{III}/Fe^{II}$. Because the local environment in different oxidation states is usually not the same, this electron-transfer process leaves both metals in a vibrationally excited state. In symmetric molecules, relaxation from this state leads to a ground state that is identical to the initial one. Metallocenophanes are excellent models for the investigation of such phenomena, because their structural parameters can be selectively varied.

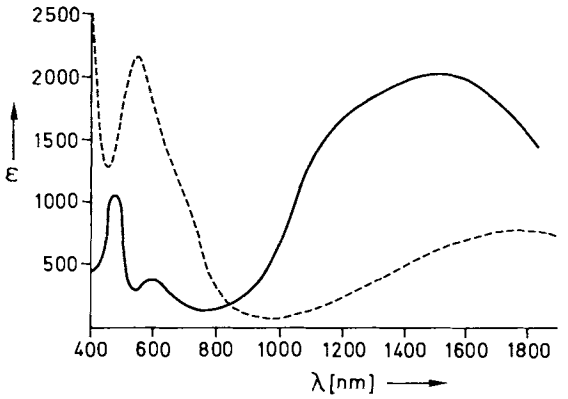


Fig. 1. The NIR spectra of the mixed valence monocations of **3** (solid line) and **23** (dashed line). Intervalence transfer bands are the broad, long-wavelength bands. For **3**, two absorptions with maxima at 1140 and 1550 nm overlap [41].

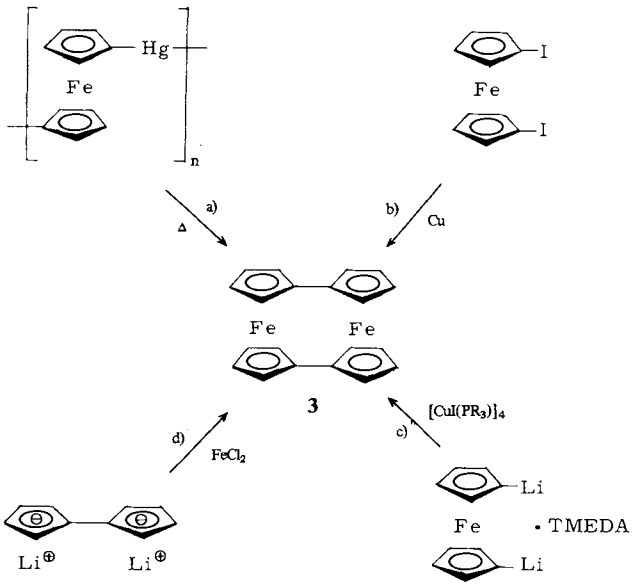
A classification of mixed valence systems based on the extent of intramolecular interaction was proposed very early by *Robin* and *Day*[29] and served as a guide to understand some of the phenomena. In compounds of class I, no interaction between the two metals exists, and such compounds show properties typical of the independent molecules. Compounds of class II show a moderate degree of interaction so that these compounds possess new properties in addition to those of their components. Class III refers to those compounds in which strong interactions between the two metals exist, so that none of the properties of the components remain and a new, delocalized species exists. This is reminiscent of the familiar picture of resonance in organic chemistry.



A theoretical model developed by *Hush*[30] provides a more quantitative parametrization of these systems. More recently, another model, based on the vibrational coupling of the two metals, was developed.[31] It is in good agreement with the experimental data for many systems. No clear borders exist between these classes; instead, many gradations of intramolecular exchange interactions can exist.

Most of the work on [m.m]metallocenophanes has focused on dimeric ferrocenes, but compounds containing other metals have begun to receive attention as the unique properties of these systems have been recognized. The focus on iron-containing species in this article is not an arbitrary limitation but reflects the current state of development. The [0.0]metallocenophanes are a major exception in this regard, because they are known for almost all first-row transition metals.

3.1. [0.0]Metallocenophanes

The first example of this type of binuclear metallocene was [0.0]ferrocenophane **3**, which has been named biferrocenylene, 1,1′-biferrocenylene, and, most frequently, bis(fulvalene)diiron. Many comparisons have been made between **3** and its singly bridged analogue biferrocene **23**.

There now exist four methods for the preparation of **3** (Scheme 4): pyrolysis of polymercury ferrocenes (path a),[32] Ullmann coupling of 1,1′-diiiodoferrocene (path b),[33] coupling of 1,1′-dilithioferrocene via organocuprates (path c),[34] and direct synthesis by reaction of the fulvalene dianion with $FeCl_2$ (path d).[35]

Scheme 4. Four synthetic routes to [0.0]ferrocenophane **3** (see text). TMEDA = *N,N,N′,N′*-tetramethylethylenediamine.

The yields obtained by paths a–c are low (11% for path c). The direct synthesis (path d) now affords a maximum yield of 40%.[41] This is surprisingly high in view of the potential of this reaction to produce oligomeric and polymeric material. Since polymeric materials are formed to a greater or lesser extent in all of these methods, separation of the only moderately soluble **3** was initially a problem. Indeed, the first syntheses were deemed to be failures, because such poor solubility was unexpected and the product **3** was assumed to be polymeric. Considering that biferrocene **23** can be recrystallized from hexane, it is indeed surprising that the solubility of **3** in benzene[32] is only 200 mg/L. The reason for this must be sought in the rigidity of **3**, which leaves little opportunity for adequate solvation.

The structure of **3** (Fig. 2) was expected to exhibit a larger Fe-Fe distance than a fully symmetric structure with two ferrocenes would dictate.[36] This expectation was based on the unusually large (1.5 ppm) chemical shift difference between the two kinds of protons.[32] Surprisingly, however, two completely "normal" ferrocenes were found in **3**: the two atoms lie at the center of the two ferrocene

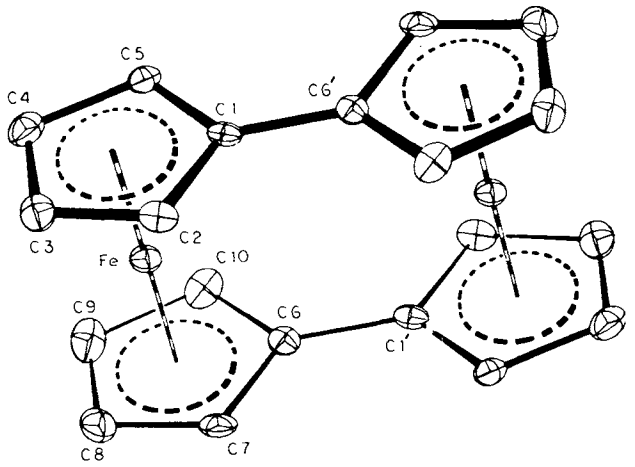


Fig. 2. The crystal structure of [0.0]ferrocenophane **3**. The ligands are coplanar and consist of regular, undistorted ferrocene moieties with a Fe-Fe distance of 398 pm. (Reprinted from ref. [36] with permission of the American Chemical Society.)

units and are 398 pm apart, the distance dictated by the C–C single bonds (148 pm) connecting the two units.

The difference between the singly connected biferrocene **23** and the doubly connected [0.0]ferrocenophane **3**, which already manifests itself in their differing solubilities, becomes very apparent when these two compounds are oxidized to their radical cations and dications. From electrochemical data[37,38] (with a saturated calomel electrode, SCE, as reference electrode, **23** is oxidized at 0.31 and 0.64 V, **3** at 0.13 and 0.72 V), it is apparent that **3** is much more easily oxidized to the monocation than **23**, but that the oxidation to the dications requires a similar, more positive potential. Why is $\mathbf{3}^{\odot\oplus}$ much more stable that $\mathbf{23}^{\odot\oplus}$? Mössbauer and X-ray photoelectron spectroscopy (XPS)[39,40] provide a first answer: whereas the iron atoms in $\mathbf{3}^{\odot\oplus}$ are identical, they are different in $\mathbf{23}^{\odot\oplus}$. The biferrocene monocation $\mathbf{23}^{\odot\oplus}$ is a typical example of a mixed valence compound of class II, according to the system of *Robin* and *Day*.[29] One iron atom has the environment of a neutral ferrocene, whereas the other is part of a ferrocenium cation; a limited degree of interaction between the two iron atoms occurs, giving rise to an intervalence transfer absorption (see Fig. 1). On the other hand, the cation $\mathbf{3}^{\odot\oplus}$ is a fully delocalized compound of class III with either a symmetric ground state or with such an extremely rapidly occurring intervalence transfer—faster than 10^{18} s^{-1} according to the XPS data—that this differentiation becomes meaningless. Of relevance, however, is the question whether the apparently very strong coupling of the iron atoms in $\mathbf{3}^{\odot\oplus}$ occurs by direct metal–metal interactions or occurs through the ligands.[41] A large number of studies and discussions suggest that both types of interactions are important.

That the ligands do play an important role is revealed by the finding that the two dications $\mathbf{3}^{2\oplus}$ and $\mathbf{23}^{2\oplus}$ are also very different: the biferrocene dication $\mathbf{23}^{2\oplus}$ is a diradical containing two noninteracting ferrocenium units,[42] whereas the [0.0]ferrocenophane dication $\mathbf{3}^{2\oplus}$ is diamagnetic (its NMR spectrum[43] is very similar to that of the neutral compound **3**). The initial explanation given for this diamagnetism was a strong intramolecular interaction through the ligands.[43] Direct metal–metal bonding was held to be unlikely on account of the accumulation of positive charge in this system, which would not be expected to allow a significantly close approach of the two iron atoms to facilitate such interaction.

That direct metal–metal interactions are also important is shown by the crystal and molecular structure of a complex salt of the [0.0]ferrocenophane radical cation $\mathbf{3}^{\odot\oplus}$ (Fig. 3).[44] The distance between the iron atoms is 364 pm (compared with 398 pm in neutral **3**); the ligands accommodate this shortening of the Fe–Fe distance by a tilting of 10°. However, the direct metal–metal interactions alone cannot account for the presence of two identical iron atoms. Arguments to the contrary have been given, but they were either shown later to be in error or repudiated by other evidence. For example, the delocalization found in the cation of [2.2]ferrocenophanediyne (see Section 3.3), in which the iron atoms are separated by more than 600 pm, can only be caused by interactions through the ligands. Molecular orbital calculations have indicated the importance of direct metal–metal interactions, but have not excluded interactions through the ligands.[45] Both interactions appear to be of varying significance in different cases, with the balance between them being dominated by structural factors which otherwise are not too obvious. This is also supported by the high degree of delocalization that some derivatives of biferrocene **23** exhibit.[46] The detailed reasons are not understood, but an analysis based on the vibronic coupling model[31] of *Piepho, Krausz,* and *Schatz* (PKS model) has once more emphasized that the differences are quantitative but not qualitative in nature.[47]

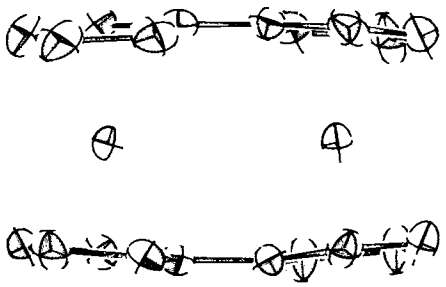

Fig. 3. Structure of the [0.0]ferrocenophane radical cation $\mathbf{3}^{\odot\oplus}$ in crystals of [0.0]ferrocenophanium picrate hemihydrate. The ligand rings tilt up toward the center, allowing the iron–iron distance to shrink by 34 pm compared with the distance in the neutral compound. (Reprinted from ref. [44] with permission of the American Chemical Society.)

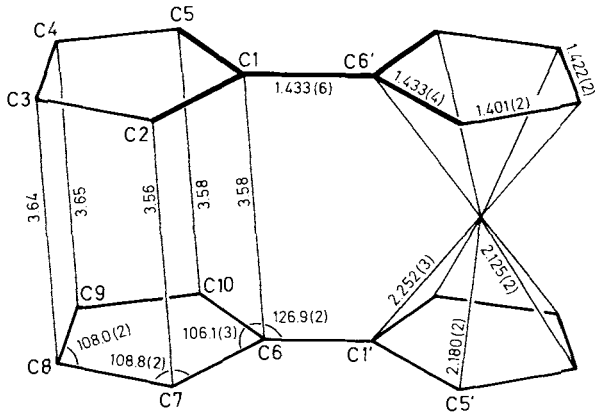
Through the work of *Smart* et al.[48] and others, [0.0]metallocenophanes are now known for almost all first-row transition metals. An X-ray structure of the nickel compound has been reported (Fig. 4).[49] The compound exemplifies well the 18-electron rule: in contrast to the [0.0]ferrocenophane with its two fully symmetric ferrocene ligands, the nickel atoms are coordinated predominantly to the butadiene units of the fulvalene ligands and are consequently further apart than the combination of two nickelocenes would predict; the central C–C bond takes on considerable double-bond character and the bond lengths in the cyclopentadienyl ligands alternate significantly.



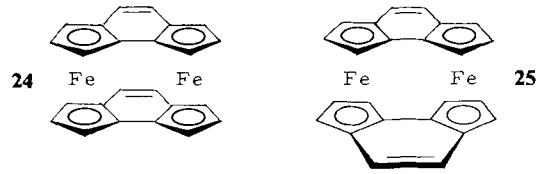


Fig. 4. Schematic drawing of the crystal structure of the ligand framework of [0.0]nickelocenophane [49] with distances [Å] and angles [°].

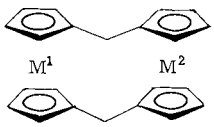
So far, no [0.0]metallocenophanes with two different metal atoms are known. Their preparation would require novel synthetic strategies.



A special case in the group of [0.0]metallocenophanes is the doubly bridged system with *as*-indacenyl dianions as ligands. Bis(*as*-indacenyl)diiron is a [0.0]ferrocenophane containing ethylene groups as bridges; it exists as a mixture of the *syn* and *anti* configurations **24** and **25**, respectively.[50]

The ease with which [0.0]metallocenophanes can be oxidized to stable radical cations allows such systems to react with electron acceptors such as tetracyanobenzoquinodimethane (TCNQ) to form ionic charge-transfer complexes. The TCNQ complexes of a large number of donors have been investigated, and many of them exhibit high and strongly anisotropic electrical conductivity.[51] The one-dimensionality of the electrical conductivity is related to the tendency of TCNQ to form segregated radical anion stacks, along which electrons can move throughout the entire length of the crystal, and to its tendency to impose such one-dimensional order onto the donors as well. The first such complex was that of TCNQ with tetrathiafulvalene (TTF). [0.0]Ferrocenophane reacts with TCNQ to form a salt of the composition [0.0]FCP$(TCNQ)_2$, in which [0.0]FCP exists as the radical cation. Two TCNQ molecules share one negative charge. Compressed pellets of this complex show the same electrical conductivity as that of pellets of TTF-TCNQ. This stimulated many attempts to grow large single crystals of [0.0]FCP$(TCNQ)_2$. However, a slight mismatch between the thickness of the donor molecule and the periodicity of the TCNQ stack results in felt-like, massively interwoven crystals. Although, for this reason, the exact magnitude of the electrical conductivity in this complex could never be established, the initial findings prompted the investigation of several related materials, such as the TCNQ complex of [0.0]FCP-containing polymers.[52] The work of *Katz* et al.[53] on helical metallocenophanes was also motivated in part by the search for electronically conducting complexes. It is surprising that many different salts of the organic donor TTF are known, but that only a few salts of [0.0]FCP have been investigated for their conductive properties in spite of the fact that a large spectrum of charge-transfer salts of ferrocene and other metallocenes are known, some of which show considerable electrical conductivity.

3.2. [1.1]Metallocenophanes

In addition to the system **4**, derived from ferrocene, the [1.1]metallocenophanes also include systems containing ruthenium and cobalt (**26**–**29**).

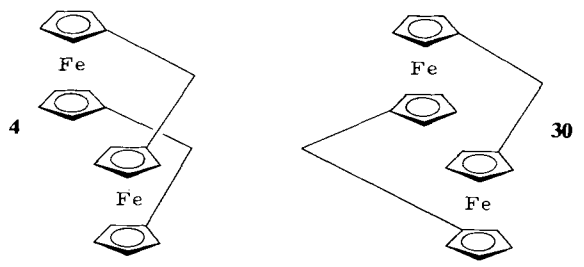
3.2.1. Syntheses

Two different and independent synthetic routes to [1.1]ferrocenophane **4** were reported in the late 1960s: *Watts*[8] prepared **4** via the corresponding diketone and *Katz* et al.[9] obtained it from the ligand dianion and iron(II) chloride; the latter route also leads to [1.1]FCP oligomers containing three, four, or five ferrocene units, including [1.1.1.1]FCP **6** cited in the introduction. Both of these routes afforded only very low yields, so that [1.1]FCP remained scarce in spite of some indications that it exhibited unusual properties. A derivative that was methylated once in each of the bridges was obtained by yet another route, but, unfortunately, also in only very modest yield.[8]

Because we required larger amounts of [1.1]FCP **4**, we developed a variant of the synthesis used by *Watts*[8] via the then unknown 1,1'-difulvenyl ferrocenes[54,55] (maximum yield 60%) (Scheme 5).[56] It's advantage is that one ferrocene unit and the entire carbon skeleton of the final product already exist in the precursor. In contrast to the original synthesis from dicyclopentadienyl methane, this route only allows the formation of oligomers with an even number of ferrocene units. Conversion of the difulvenyl ferrocene into the dicyclopentadienide was best achieved by using lithium triisobutyl borohydride. The relatively unreactive trialkyl borohydride is formed as by-product, but does not interfere with the subsequent addition of a transition-metal salt.

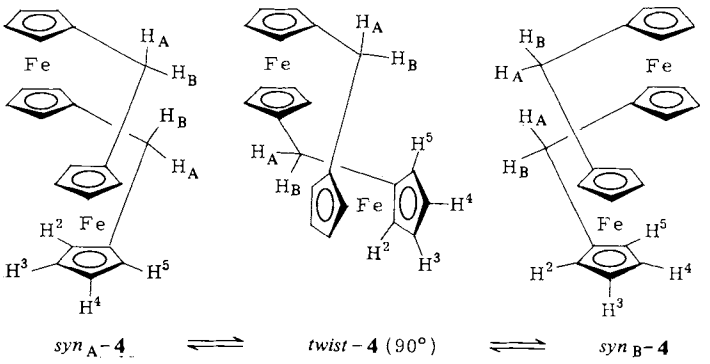
Since the reduction step may be followed by the addition of transition-metal salts other than iron(II) chloride, this route also offers the first useful entry to the class of metallocenophanes with different metals. In this way, the Fe/Ru and Fe/Co complexes **26** and **27**, respectively, were prepared. Bridge-substituted [1.1]FCP derivatives are also accessible. For example, reaction of the difulvenyl ferrocene with methyllithium, and $FeCl_2$ leads to a mixture of *endo,exo*- and *exo,exo*-dimethyl[1.1]ferrocenophanes (see



Scheme 5. The synthesis of [1.1]metallocenophanes via difulvenyl metallocenes, which are available by two different routes, both of them efficient. Their conversion to metallocenophanes involves reduction to the ligand dianion and reaction with metal(II) chlorides. Yields are surprisingly high. THF = tetrahydrofuran, R = *i*Bu.

Section 3.2.2). This route was also used for the synthesis of the [1.1]metallocenophanes **26** and **28** containing ruthenium.[57]

For [1.1]cobaltocenophane **29**, however, this route is not suited, because the lithiation of cobaltocene is not possible. Here, the original synthesis via the dianion of dicyclopentadienyl methane has to be used. The blue-green initial product **29** can be oxidized to a mixture of the more stable cobaltocenium salts, from which a salt of the dication $\mathbf{29}^{2\oplus}$ can be obtained by fractional crystallization. As expected, the yields are very low (maximum yield 2%).[58]



3.2.2. *Structure and Properties*

Dreiding models of [1.1]ferrocenophane **4** are helpful in understanding the structure of this compound. Intuitively, one would be tempted to assume that this compound should exist as two isomers: like bis(*as*-indacenyl)diiron, which exists in *syn* and *anti* forms, **24** and **25**, respectively, [1.1]FCP should also exhibit two configurations. In both

forms, **4** and **30**, the inner protons in the 2-position severely crowd each other (a problem that does not exist in the *as*-indacene complexes).

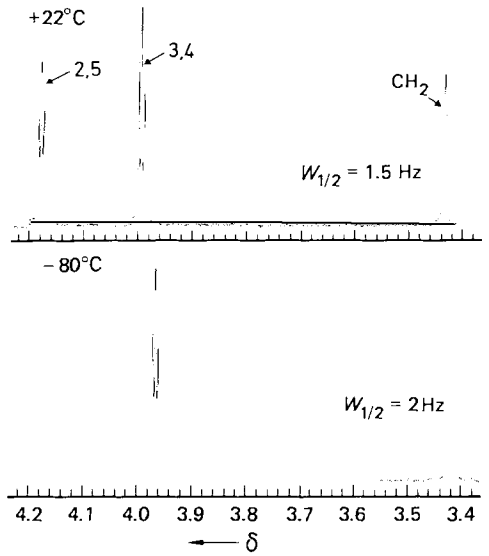
The models demonstrate that the *anti* isomer **30** is rigid and is not able to relieve the overcrowding, but that the *syn* isomer **4** is amazingly flexible and can easily twist to relieve all steric problems. This flexibility is directly linked to the low activation barrier for the rotation of the two ligands in the two ferrocene units. These rotations are coupled owing to the methylene links between the ferrocene units. This allows the molecule to undergo synchronized motion from one *syn* conformation to its mirror image. Although it is nearly impossible to give an adequate two-dimensional description of this motion, an attempt is made in Scheme 6.

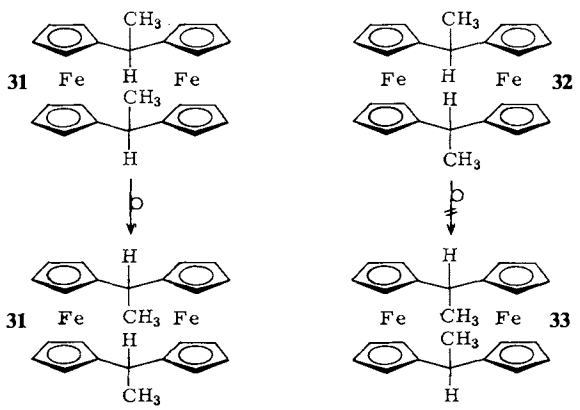
Scheme 6. Degenerate isomerization of [1.1]ferrocenophane **4**, which results in "exchange" of the *exo*- and *endo*-protons as well as the protons in the 2- and 5-positions as well as those in the 3- and 4-positions. This exchange is very rapid and has a low activation barrier.

The unprecedented conformational flexibility of [1.1]FCP **4** is also revealed in its ^{1}H-NMR spectrum,[7,8] which exhibits peaks for only three types of protons: the bridge protons appear as one sharp singlet; the eight protons in the 2- and 5-positions and the eight protons in the 3- and 4-positions each give rise to only one multiplet. Investigations in our laboratory have shown that this motion still occurs rapidly even below $-80°$ (Fig. 5), establishing an upper limit of 10 kJ/mol for the barrier to this *syn*–*syn* exchange.[56] The name "molecular acrobats" ascribed[59] to the [1.1]ferrocenophanes is thus not too much of an exaggeration.

The isomerization can be inhibited or even suppressed by substituents either on the rings or on the bridges. Whereas an ethyl group in the 3-position does not affect the isomerization, one in the 2-position completely suppresses it.[60] The conformational flexibility has also been studied in the hybrid metallocenophanes **11** and **12**.[11] Whereas in 2,2′-trimethylene[1.1]FCP **11** the *syn*–*syn* exchange is suppressed, it occurs in the 3,3′-isomer, although not as rapidly as in **4**.

Substitution at the bridges also affects the *syn*–*syn* exchange because the two *syn* conformations, syn_A-**4** and syn_B-**4**, are no longer equivalent. The *exo,endo*- and *exo,exo*-dimethyl compounds **31** and **32**, respectively, are good examples.[56] In **31**, the two conformations are identical; the methyl groups offer little steric hindrance to the





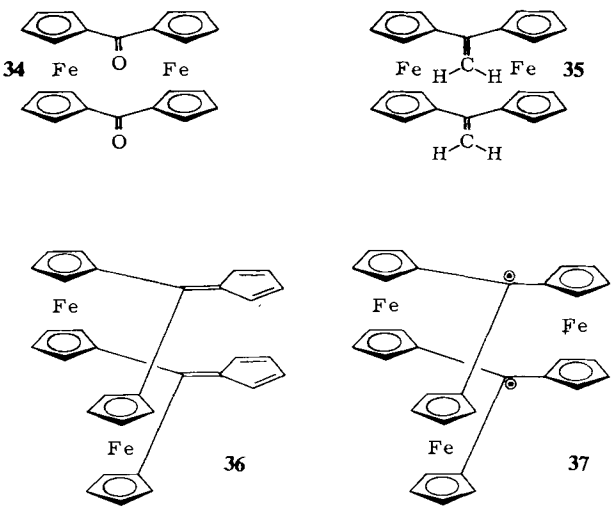


Fig. 5. 360-MHz ^{1}H-NMR spectrum of [1.1]ferrocenophane **4** in CS_2 at +22°C (above) and −80°C (below).

isomerization. For the *exo,exo* isomer **32**, on the other hand, the isomerization would give the sterically impossible *endo,endo* isomer **33**. Although the ^{1}H-NMR spectra reveal some motion in this system as well, it is limited to an opening of the *exo,exo* form to the transition state and a return to the starting conformation. As a consequence of rapid *syn,syn* exchange, there exist no isomers of the [1.1]FCP with a methyl group on only one of the bridges.

Electronic factors such as conjugation between the ferrocene units and unsaturated bridge substituents appear to be less important than steric factors in influencing this exchange. This becomes apparent from the ^{1}H-NMR spectra of the diketone **34** and the bis(methylene) compound **35**,[61] which both show the very simple two-multiplet structure for the ring protons. Even in the bis(fulvene) derivative **36**, which we recently prepared as a precursor to several trinuclear metallocenophanes, including the target "ferrous wheel" **37**, we see the same equivalence of these protons. The rapid motion of the fulvene substituents, reminiscent of the opening and closing of a crocodile's mouth, makes **36** useful for the synthesis of multinuclear metallocenes (**35** is also a potentially useful precursor).

The fact that [1.1]FCP **4** exists only in the *syn* conformation has been confirmed by X-ray crystallography. Since **4** tends to crystallize as very thin leaflets that are unsuitable for crystallography, the first structural characterization was carried out on the *exo,exo*-dimethyl derivative **32** and confirmed the expected arrangement, including a significant twist to eliminate the repulsion between the inner protons in the 2-positions.[62] We recently succeeded in obtaining suitable single crystals of the parent compound **4** and in carrying out its structure determination (Fig. 6). The ferrocene units are twisted to alleviate the steric repulsion, and the bridges are slightly opened from a fully parallel arrangement. Single crystals of the Fe/Ru system **26** were also investigated: a very similar structure was found, but with the expected dissymmetry imposed by the different ring–ring distances of the ferrocene and ruthenocene moieties.[63]

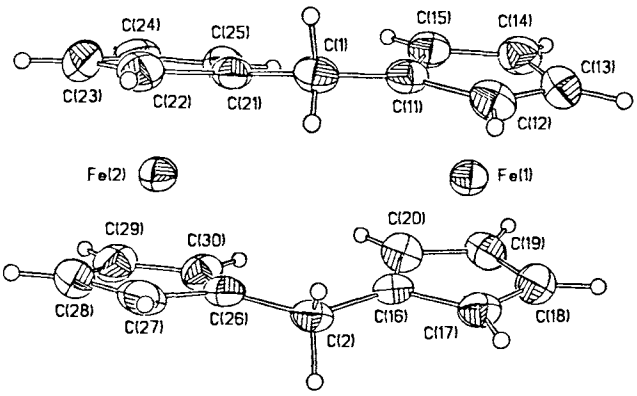

Fig. 6. Crystal structure of [1.1]ferrocenophane **4**. The molecule is twisted; this lengthens the distance between the bridge atoms and thereby avoids repulsion between the *endo*-protons of the bridge and between the ring-protons pointing toward the center of the molecule [63].

Although this article is not concerned with metallocenophanes whose bridges contain non-carbon atoms, one such compound must be mentioned here because of its direct relevance to the structure of the [1.1]metallocenophanes. In *Sn,Sn,Sn',Sn'*-tetrabutyldistanna[1.1]ferrocenophane[64] (Fig. 7), the steric bulk of the *n*-butyl groups prevents the normal *syn*-orientation; owing to the greater length of the

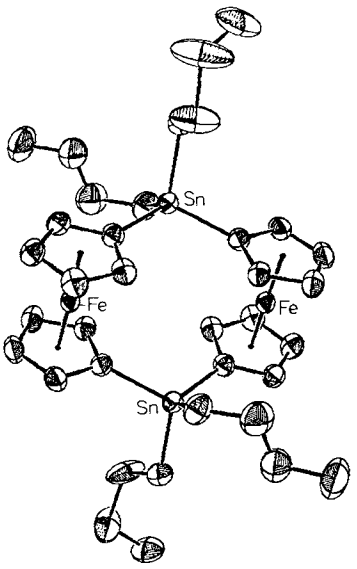

Fig. 7. Crystal structure of *Sn,Sn,Sn',Sn'*-tetra-*n*-butyldistanna[1.1]ferrocenophane (see text) [64]. The figure was taken from [64] with the permission of the authors and Elsevier Sequoia S.A., Lausanne.

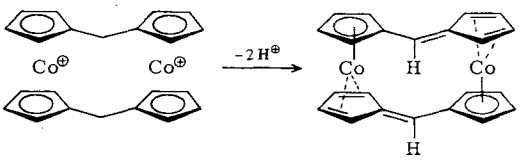
C–Sn bonds (215 pm vs. 148 pm for a C–C bond), the inner protons experience less repulsion than in the *syn*-[1.1]metallocenophanes. As a consequence, the tin analogue adopts the *anti*-configuration and a nearly coplanar structure of the ferrocene units. From the structural data,[64] the distance between the inner protons can be calculated to be approximately 185 pm. The ^{1}H-NMR spectrum, which was reported without further comment, shows only two triplets with $J = 1.8$ Hz at $\delta = 4.15$ and 4.37. This pairwise equivalence of the protons in the 2- and 5- as well as 3- and 4-positions is an enigma and contradicts the behavior of typical ferrocenophanes.

Rapid *syn-syn* exchange also occurs in the other unsubstituted [1.1]metallocenophanes **26**, **27**$^{\oplus}$, **28**, and **29**$^{2\oplus}$.[65] The NMR spectra of these compounds are very simple and show the typical sharp singlet of the methylene bridges.

The yellow-orange color of ferrocene is responsible for the color of the Fe/Fe and Fe/Ru [1.1]metallocenophanes **4** and **26**, respectively. Both ruthenocene and ruthenocenophane **28** are colorless. The [1.1]cobaltocenophane dication **29**$^{2\oplus}$ is isoelectronic with [1.1]ferrocenophane **4**, a fact reflected by its yellow color. While these metallocenophanes are stable under the usual conditions, they are easily oxidized, particularly in solution, to the mono- and diketones. The ketones can be sulfurized with P_4S_{10} to produce the synthetically useful thiones.[61]



Electrochemical oxidation follows, with one remarkable exception, the normal trends found in metallocenes (Table 1).[66] Ferrocene shows a reversible one-electron oxidation at relatively low potential; ruthenocene undergoes an irreversible two-electron oxidation at a much more positive potential. In [1.1]FCP **4** the oxidation waves of the two ferrocene moieties are separated by 200 mV; the first occurs at slightly lower potential than that for ferrocene, whereas the second is at a slightly higher potential on account of Coulomb repulsion. In the Fe/Ru system **26**, the ferrocene-based one-electron oxidation is observed first; the ruthenocene-based two-electron oxidation occurs at higher potential. Astonishing is the behavior of [1.1]ruthenocenophane **28**: instead of showing an irreversible oxidation at high potential, it exhibits a reversible two-electron oxidation at the surprisingly low potential of 380 mV. The reasons for this stabilization of the resulting dication are not fully understood. However, chemical oxidation of **28** leads to a diamagnetic cation, whose ^{1}H-NMR spectrum shows four multiplets ($\delta = 5.50$, 5.66, 5.93, and 6.14) for the ring protons and a sharp singlet ($\delta = 3.55$) for the four bridge protons. Since the latter signal indicates rapid isomerization between two *syn* conformations, the nonequivalence of the ring protons (one set of which is shifted downfield by 1.0 ppm and the other by 1.5 ppm from the values for ruthenocenophane **28**: $\delta = 4.41$ and 4.60) must stem from a dissymmetry in the dication.

Table 1. Cyclovoltammetric redox potentials of metallocenes and [1.1]metallocenophanes (C_6H_5CN solution with tetrabutylammonium fluoroborate as electrolyte; SCE reference).

	E_0 [mV]	$E_c - E_a$ [mV]	e

28	380	80	2

[a] Irreversible oxidation.

The dications of [1.1]metallocenophanes are strong CH acids, losing one or two protons from the bridge CH_2 groups.[58] The cobaltocenophane dication **29**$^{2\oplus}$, when treated with a weak base, loses two protons to form a diamagnetic, blue-green compound (λ_{max} 670 ($\varepsilon = 11300$), 450 (2800), and 260 (42300)), the ^{1}H-NMR data of which (two-proton singlet at $\delta = 4.22$ and four four-proton multiplets at $\delta = 4.90$, 4.99, 5.09, and 5.46) support the presence of **38** (^{1}H-NMR data of **29**$^{2\oplus}$: $\delta = 3.74$ (4H), 5.69, 5.75 (each 8H)). **38** is an 18-electron cobalt(I) species with one cyclopentadienide- and one butadiene-type ligand.

29$^{2\oplus}$ **38**

Deprotonation of the dication derived from [1.1]ferrocenophane **4** leads to a diamagnetic monocation **39**, identical to the one obtained from **4** by hydride abstraction using Ph_3CBF_4. This stabilized carbocation is described in the following Section.

3.2.3. Carbenium Ions

The bridge carbenium ion **39** is totally rigid, as shown by its room temperature ^{1}H-NMR spectrum (Fig. 8). The top and bottom halves of the cation are nonequivalent and there are now four types of protons in the rings; the proton of the carbenium ion center appears as a singlet, and the two protons on the now rigidly fixed second bridge are no longer equivalent and appear as doublets ($J = 22$ Hz).[67]

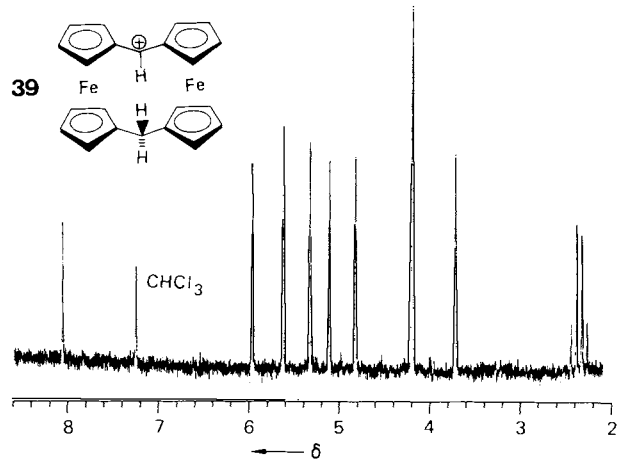

Fig. 8. 360-MHz ^{1}H-NMR spectrum of the [1.1]ferrocenophanylium ion **39** [67].

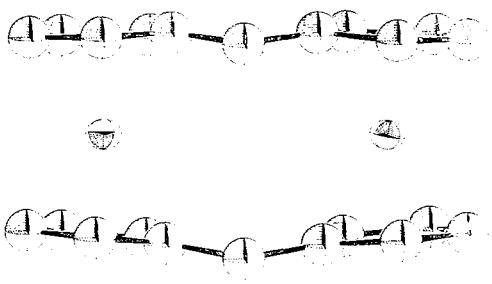
The X-ray structure analysis of **39** (Fig. 9) also revealed that direct interactions between the carbenium ion center and the two iron atoms are an important factor in the stabilization of this and, by extension, other α-ferrocenyl carbenium ions. These interactions contribute to the conformational rigidity of the carbocation. As shown by Mössbauer spectroscopy, each iron atom takes up one-third of the positive charge. This charge delocalization leads to a significant increase in the double-bond character of the bonds between the carbenium ion center and the neighboring ring carbons, resulting in a stiffening of the molecule and a dramatic reduction in the rate of isomerization. Although the spatial arrangement should favor hydride transfer between the bridges, the ^{1}H-NMR spectrum clearly shows that such a transfer does not occur. This is another consequence of charge delocalization.[67]



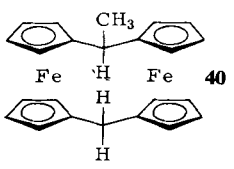


Fig. 9. Structure of the [1.1]ferrocenophanylium ion **39** in the crystal of the $BF_4^\ominus$ salt [67]. The positively charged bridge carbon is pulled toward the center of the molecule to allow direct Fe-C interactions. As in the bis(fulvalene)diiron radical cation $3^{\odot\oplus}$, the ligand rings tilt to allow a closer approach of the iron atoms. As a consequence of this, the CH_2 bridge is pushed away from the center.

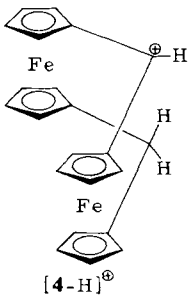
Since tertiary carbenium ions are more stable than secondary ones, it is not surprising that hydride abstraction from the [1.1]FCP **40**, having a methyl substituent in one

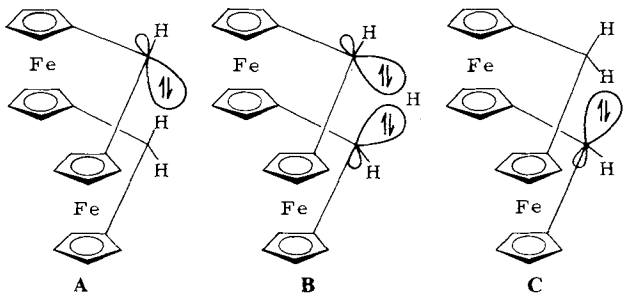
40



bridge, occurs from the substituted bridge. The dimethyl derivatives (both **31** and **32**) also undergo hydride abstraction to produce the same carbenium ion, which is particularly stable.[68]

Hydride abstraction from the Fe/Ru and Ru/Ru systems **26** and **28**, respectively, also leads to stable carbenium ions,[65] both of them rigid. Owing to the rigid, unsymmetrical molecular structure, the ^{1}H-NMR spectrum of $[\mathbf{26} - H]^\oplus$ exhibits a total of 16 different signals for the ring protons, the typical low-field signal for a proton at a carbenium ion center, and two doublets for the two nonequivalent protons of the methylene bridge. The carbenium ion derived from [1.1]ruthenocenophane **28** is very similar to the [1.1]FCP carbenium ion, but is clearly different from the dication $\mathbf{28}^{2\oplus}$ formed by oxidation of **28** (see preceding Section).

The carbocations discussed in this section have played an important role in understanding the structure of the mono- and dications derived from [1.1]ferrocenophane **4**. Early Mössbauer data[46] indicated the existence of diamagnetic *and* paramagnetic [1.1]FCP dications. This was taken as evidence for direct metal-metal interactions in the dications. However, it is now clear that the metallocenes in the mono- and dications are noninteracting: the monocations are trapped valence species, and the dications are paramagnetic with two unpaired electrons. The initial confusion[39,46] was a result of the very high CH acidity of the CH_2 bridges in the dications: as described in the preceding Section, diamagnetic monocations are formed by proton abstraction. The Mössbauer spectroscopic data for the carbenium ion formed from **31** or **32** agree closely with those of the diamagnetic species found to be present in the corresponding dication. The monocation of this system has recently been reinvestigated.[69] The X-ray structure shows the coexistence of one ferrocene and one ferrocenium ion unit, and there exists no intervalence transfer band in the NIR spectrum; thus, this compound should be placed into class I of the *Robin* and *Day* classification.[29] These results give a final answer to the question whether the interactions occur through the saturated ligands or through space in these compounds.[69]



3.2.4. Carbanions

When *n*-butyllithium is added to [1.1]ferrocenophane **4** in THF, the color of the solution turns from yellow (ferrocene) to intense red. Subsequent addition of methyl iodide gives the derivative **40**, which is methylated on the bridge. Under similar conditions, diferrocenyl methane does not react with *n*-butyllithium. Since the reactivity toward alkyllithium compounds should be comparable in these two systems, the apparent difference must be due to the stability of the products: the formation of the diferrocenyl methane carbanion is an uphill reaction, whereas the reaction of **4** leads to a stabilized species. This surprising finding has found an even more surprising explanation: the carbanion of **4** is stabilized by an intramolecular hydrogen bond between the carbon atoms of the methylene bridges (Scheme 7). Because such C–H···C/C···H–C bonds had not been documented before, we undertook a closer study of this situation.[70]

[4-H]$^{\oplus}$

[1.1]FCP carbenium ion

[4-H]$^{\ominus}$

[1.1]FCP carbanion

Scheme 7. Carbenium ion and carbanion of [1.1]ferrocenophane **4**. The charge in the carbenium ion is delocalized, only one-third of the charge remaining at the carbenium center; the cation is thereby rigidly fixed in the *syn* conformation and no intramolecular hydride transfer occurs. The carbanion contains a hydrogen bond between the two bridge carbon atoms, which gives this anion a rigid structure as well. The symmetric structure **B** may be the transition state between the extremes **A** and **C** or it may be the ground state of this system.

The essential bonding situation in these carbanions is best described by contrasting them with the previously discussed carbocations. We have seen that the carbocation is rigid both in solution and in the solid; this rigidity is attributed to delocalization of the positive charge into the ferrocene moieties and to direct Fe-C bonding. Like the structure of the carbenium ion, that of the carbanion is totally rigid, owing to the C···H···C bond and possibly also to delocalization. A detailed examination, based in part on ^{1}H- and ^{13}C-NMR coupling constants (Table 2), shows that the carbenium carbon atom is sp^2 hybridized and that the rigid CH_2 bridge gives rise to a doublet of doublets in the ^{1}H-NMR spectrum with a geminal coupling constant of 22 Hz. In contrast, the carbanion has two sp^3-hybridized bridge carbon atoms; the C,H_{exo} coupling constant corresponds to the normal sp^3 value, whereas the

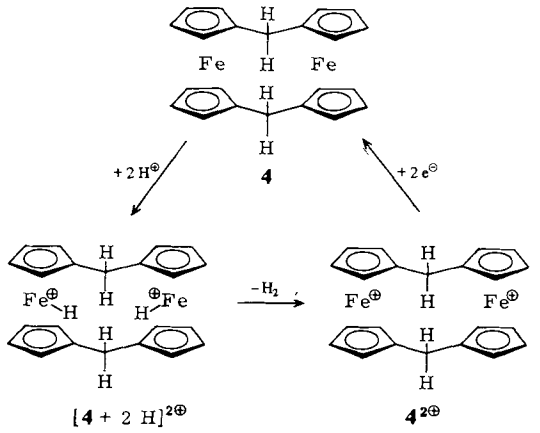
Table 2. Chemical shifts and coupling constants in the ^{1}H- and ^{13}C-NMR spectra of [1.1]ferrocenophane carbenium ion and carbanion (CO_2Cl_2 and [D$_8$]THF, respectively).

	δ Values		J [Hz]	
	C	H	C, H	H, H
carbenium ion				
$C^{\oplus}$–H	163.3 (d)	7.71 (s)	162.3	–
CH_2	20.4 (t)	2.05 (d)	127.0	22.0
		2.49 (d)		22.0
carbanion				
CH_{exo}	29.5 (dd)	3.09 (d)	130.4	9.0
CH_{endo}		4.51 (t)	63.9	9.0

endo-hydrogen atom, which is involved in the bridge, exhibits a C,H_{endo} coupling constant of only 63.9 Hz, about half the normal $J(C_{sp^3},H)$ value. The C···H···C bridge therefore appears to be symmetrical on the NMR time scale, but this does not allow any conclusion whether the symmetric form **B** is the ground state or the transition state for a rapid exchange between forms **A** and **C** (Scheme 7). Between +30 to −70°C, no change in the ^{1}H-NMR spectrum was observed. In the solid state, an unsymmetrical location of the THF-solvated lithium ion could induce a dissymmetry in the bridge; magic-angle-spinning ^{13}C-NMR spectroscopy has indeed shown an unsymmetrical structure, but conclusions about the structure of the carbanion in solution cannot be drawn from this result.

The carbanion formed by deprotonation of **40** shows an ^{1}H-NMR spectrum that is typical for proton exchange between two species (strongly asymmetric double-well potential). Since a negative charge is more stable on a secondary than on a tertiary carbon atom, most of the charge indeed resides on the secondary carbon atom. Proton decoupling experiments clearly show that a C···H···C bond exists in this case as well. Although this interaction does not lead to population of the higher-energy minimum (on the NMR time scale), this C···H···C bond is strong enough to introduce total rigidity into the anion. Reaction of this unsymmetric carbanion with methyl iodide leads to the exclusive formation of the *exo,exo*-dimethyl derivative **32**.

The same carbanion is formed from the *exo,endo*- and *exo,exo* dimethyl compounds **31** and **32**, respectively. Its bridging proton interacts equally with both methyl groups, which thereby give rise to one doublet in the ^{1}H-NMR spectrum. The bridging proton appears as a symmetric septet.



Since the ring–ring distance in [1.1]ferrocenophane **4** is 330 pm, this value is presumably also a favorable distance for the separation between the C atoms in a C···H···C bond. Extrapolation from the known distances of O···H···O, O···H···N, and N···H···N bonds further supports a value of about 330 to 350 pm. This finding explains the fact that the Fe/Ru analogue **26**, in which the bridge carbon atoms are separated by a distance of approximately 350 pm, reacts readily with *n*-butyllithium to form a bridge carbanion,[65] whereas [1.1]ruthenocenophane **28**, in which the ring–ring distance is 370 pm, does not. This result supports the suggestion that C···H···C bonds of this type are much stronger than expected. Previous estimates, derived from intermolecular hydrogen bonds between strong CH acids such as acetylenes and strong proton acceptors such as isocyanides, suggested a C···H···C bond strength of ≤8–10 kJ/mol. Although our results cannot provide an estimate of the upper or lower limits to the C···H···C bond strength, more than just a few kJ/mol are certainly involved.

3.2.5. Protonation

Ferrocene reacts with oxidizing acids to give the ferrocenium ion, a paramagnetic, green species; very strong non-oxidizing acids, on the other hand, lead to protonation without (subsequent) oxidation. In the protonated ferro-

cene **13**, the additional proton resides on the metal.[71] In the ^{1}H-NMR spectrum of ferrocene in, for example, boron trifluoride hydrate (HBF_3OH), the ten ring protons appear as a doublet ($J < 1$ Hz) at $\delta = 5.2$ (compared with $\delta = 4.1$ in ferrocene), and the proton on the iron atom appears near $\delta = -2$ as a broad signal. Although this signal should have eleven peaks resulting from the coupling to the ten ring protons, it is broadened by exchange with the solvent and shows only barely discernible structure. In the ^{1}H-NMR spectrum of ruthenocene in HBF_3OH, no coupling between ring protons and the hydridic H atom is observed; sharp singlets are observed for both types of protons. In contrast to earlier studies,[71] we found the integral ratio of the two types of signals to be exactly 10 : 1.

When [1.1]ferrocenophane **4** is added to HBF_3OH, double protonation is the main reaction, followed by immediate H_2 elimination to give $\mathbf{4}^{2\oplus}$ (Scheme 8).[72] While this reaction may not appear to be particularly unusual—Zn reacts with acids to produce H_2 and the $Zn^{2\oplus}$ ion—it is of considerable importance, because the dication $\mathbf{4}^{2\oplus}$ is easily reduced to neutral **4** and the system thus promises to be useful as a catalyst in processes where H_2 evolution is involved.[75]

Scheme 8. Catalysis of H_2 evolution in the system $\mathbf{4}/H^{\oplus}$. Double protonation of **4** leads to a dication with two almost neutral hydrogen atoms held close together. Elimination of H_2 results in the formation of $\mathbf{4}^{2\oplus}$, which can be easily reduced to neutral FCP.

A study of this reaction[73] has established the following facts: many protonation-deprotonation steps occur before a diprotonated species is formed; subsequent H_2 elimination is rapid; the resulting dication $\mathbf{4}^{2\oplus}$ can react with neutral **4**, undergoing synproportionation to form a monocation, which no longer participates in the hydrogen-producing steps; protonation of **4** does not occur directly, but rather proceeds through *exo*-attack on the ligands and subsequent proton transfer to the iron atom. These conclusions are supported by the following results. When **4** is dissolved in DBF_3OD (D_2O saturated with BF_3), the reaction product (after elimination of a mixture of H_2, HD, and D_2) contains, on the average, eight deuterium atoms in all possible ring positions, whereas the CH_2 bridges remain untouched.[73] If only direct deuteration of the iron atoms occurred, the gas evolved would be pure D_2 and no ring deuteration should occur. *Exo*-attack by deuterium on one of the rings leads to a transition state from which a proton can easily be transferred to the metal atom and ring deuteration can occur. This simple mechanism (see also Scheme 1) is complicated, however, by the low basicity of the ferrocene units. Only when the two metal atoms each bear a proton at the same time, which has a low probability, can H_2 evolution occur; many single protonations may occur in the meantime (deuteration). Addition of a small amount of a reductant such as tin leads to complete deuteration of all ring positions, because the dication is reduced to both the monocation and neutral **4**. The monocation can undergo many deuteration-dedeuteration steps without ever producing a diprotonated species that can eliminate H_2, HD, or D_2. Both pathways can lead to complete deuteration of **4**. Path B is thus the preferred one for the protonation of **4**. It is reasonable to assume that this path is not only limited to the case of the proton as electrophile, and that the generally accepted path A may not be as clearly established as some textbooks indicate. This reaction has been investigated by means of semiempirical quantum chemical methods.[74]

The reduction of the dication $\mathbf{4}^{2\oplus}$ by tin indicates that **4** can be of use as a catalyst in H_2-generating processes. Many metals such as tin and lead are more electropositive than hydrogen and should therefore react with acids, but, in fact, they are fully inert (lead acid battery!). This is a consequence of their overpotentials: the reaction is thermodynamically allowed, but one or several steps (for example, desolvation, adsorption and desorption, or the formation of an adsorbed H_2 molecule from two adsorbed H atoms) in the rather complicated reaction

$$2\,H^{\oplus}_{(solv)} + M_{(s)} \longrightarrow H_{2(g)} + M^{2\oplus}_{(solv)}$$

are inhibited. An additional potential is therefore required for the reaction to occur. Lead is a sufficiently strong reducing agent to effect the reduction of $\mathbf{4}^{2\oplus}$ to neutral **4**, which can reenter the cycle in Scheme 8. This process continues until all of the lead has dissolved. In several experiments we were able to dissolve 5 g of lead in HBF_3OH using as little as 10 mg of **4**. Compound **4** is therefore a catalyst for H_2-generating reactions where overpotentials would otherwise prevent the reaction from occurring.

For mercury, another metal with a significant overpotential to H_2 evolution, hydrogen can also be evolved from acidic media at much less negative potential in the presence of $\mathbf{4}^{2\oplus}$ (dropping mercury electrode).

Some results on the catalytic properties of **4** in H_2-generating processes are shown in Figure 10. Current flows in an electrolysis cell when the potential V (vs. SCE) is sufficiently negative to liberate hydrogen at the cathode. The amount of current at a given voltage is directly proportional to the amount of hydrogen generated. Cathodes made of polished platinum, having only a very small overpotential, will produce H_2 at potentials below -200 mV, but even this small overpotential can be eliminated by the addition of **4** to the solution. Of greater significance is the catalysis of H_2 evolution by **4** in systems involving silicon photocathodes (the use of solar energy).

The p-type silicon electrode is a poor conductor in the dark and cannot be used for the electrochemical formation of H_2. The irradiated photocathode is also unable to do so,

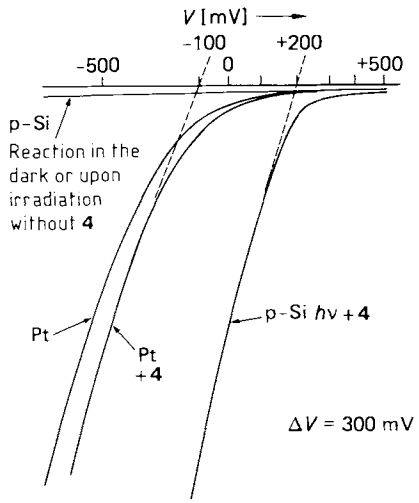


Fig. 10. Electrochemical data for HBF_3OH solutions with or without **4**. On a platinum cathode, hydrogen is evolved below -200 mV. The slight overpotential for hydrogen evolution on Pt is eliminated by the addition of **4** to the solution, which leads to current flow below -150 mV. A p-Si cathode in the dark does not evolve hydrogen and no current flows, whether or not **4** has been added. Hydrogen cannot be generated on an irradiated p-Si cathode unless **4** is added to the electrolyte solution.

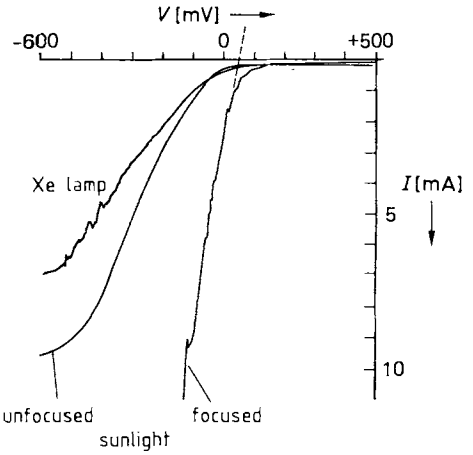

Fig. 11. H_2 evolution from a 1 M $HClO_4$ solution on p-type silicon photocathodes modified by polymer-bound **4** (see text). Noteworthy is the steep increase in current when the light is focused on the electrode. In the experiment with unfocused light, the current levels off because the number of light-generated charge carriers is small. Increasing the level of illumination increases the limiting current.

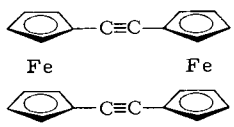

because silicon has a high overpotential. Irradiation of a p-type silicon cathode in a cell containing a Pt anode and a SCE reference electrode does not result in evolution of H_2 from HBF_3OH even at -1.0 V. If, however, **4** is added to the acid, hydrogen generation can be observed at potentials below $+200$ mV. The evolution of hydrogen at potentials more positive than those for reductions at platinum electrodes means that, through irradiation of the semiconductor electrode, light has been converted into an additional potential, which lowers the energy required for H_2 generation.

Using the [1.1]FCP carbanion (Scheme 7), we have been able to prepare a polymer-bound [1.1]FCP derivative: reaction of the carbanion with chloromethyl polystyrene produces a polymer containing enough [1.1]FCP structural units to make it catalytically active. Coating of silicon photocathodes with this polymer has led to active and stable, modified electrodes, which, in an electrochemical cell containing HBF_3OH as electrolyte, evolve hydrogen already at very positive potentials (400–450 mV) upon irradiation. Although the protonation of ferrocenes requires very strong acids, the polymer-modified silicon photocathodes, when irradiated either by a Xenon arc lamp or by sunlight, generate hydrogen efficiently even from 1 M acids (Fig. 11), although the potentials are more negative. The magnitude of the underpotentials (i.e., the difference between the potential required for H_2 generation at a Pt electrode and that required at other electrodes) is related to the efficiency of this conversion of solar energy into chemical energy in the form of hydrogen.

The reaction of [1.1]ferrocenophane **4** with acids to produce hydrogen is possible only because the dication $\mathbf{4}^{2\oplus}$ is energetically accessible. If in related systems a dication does not exist, hydrogen elimination from the diprotonated species should not be possible. This speculation has found experimental support in the case of the Fe/Ru system, for which a ferrocene-based one-electron oxidation to the monocation is followed by a ruthenocene-based two-electron oxidation to the trication. The reaction of the Fe/Ru system with HBF_3OH leads to a cationic species that can be observed by NMR spectroscopy and that indeed does not appear to lose hydrogen.[73] Protonation of [1.1]ruthenocenophane, which forms an unusually stable dication, has so far not been successfully achieved. New investigations of this compound are still needed.

3.3. [2.2]Metallocenophanes

To date, only [2.2]ferrocenophanes are known, although compounds containing other metals should be accessible. In **41**, the most interesting [2.2]ferrocenophane, the ferrocene units are connected through two acetylene bridges.[76] The diyne **41** was oxidized to a monocation and a dication. Of significance to the question of how electrons can

41

delocalize in mixed valence systems is the observation that the unpaired electron in the monocation is fully delocalized, even though the iron atoms are more than 600 pm apart.[77,78] This underlines the importance of interactions through conjugated ligands.

3.4. Larger [m.m]Ferrocenophanes

As the first [m.m]ferrocenophane to be prepared, [4.4]ferrocenophane has mainly historical significance. It was obtained in very small yield along with a variety of other products in the reaction of the ligand dianion with iron(II) chloride carried out by *Lüttringhaus* et al. in 1958.[24] Meanwhile, a number of [m.m]ferrocenophanes with long hydrocarbon bridges as well as with bridges containing heteroatoms have been prepared. No particularly

unusual properties appear to have been found in these systems.

3.5. [m^n]Metallocenophanes

The [m^n]metallocenophanes comprise the oligomeric systems in which more than two metallocene units are connected by hydrocarbon bridges (n is the number of bridges, m the number of CH_2 groups in the bridges). All synthetic routes to [1.1]metallocenophanes also produce these oligomers, but, except for the ferrocene-based systems, little effort has been made in characterizing these species. The [1^n]ferrocenophanes with n = 1 to 4 (for example, compound **6**) were described relatively early by *Katz* et al.,[9] but until recently not much new information was presented. In our work on heteronuclear metallocenophanes, we have obtained several Fe/Ru oligomers, of which the [1.1.1.1]metallocenophane containing two irons and two ruthenium atoms (analogue of **6**) is noteworthy: the two ferrocene units are on opposite sides of the ring and may approach closely. This is reflected in the ability of this system to generate H_2 upon protonation in strong acids. The reaction is slower than that of **4**. Similar studies of [1.1.1.1]FCP **6** have apparently not been carried out. The PF_6 salt of the analogous Fe_2Co_2 dication has been isolated as single crystals and its structure (Fig. 12) determined.[79] This salt was first thought to be the [1.1]metallocenophane because of its good solubility. It is formed by reduction of bis(fulvenyl) ferrocene and reaction of the dianion with hexamminecobalt(III) chloride. Undistorted ferrocene and cobaltocenium ions are arranged in such a way that Fe–Fe and Co–Co distances are minimized.

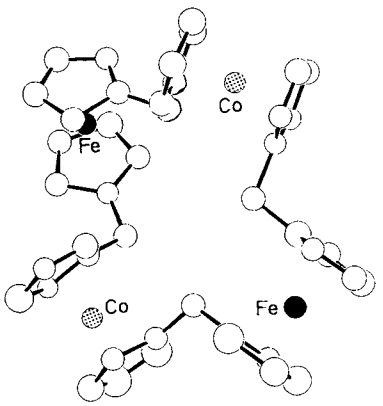

Fig. 12. Structure of the Fe_2Co_2 [1.1.1.1]metallocenophane dication in crystals of the PF_6 salt [79].

4. Summary

The chemistry of [m.m]metallocenophanes has proven to be interesting, instructive, and useful: not only have new synthetic approaches allowed the preparation of specifically tailored molecules, they have also produced materials with many unexpected properties. The structural features determined by the distance between the ligands of metallocenes, the ease with which the ligands can rotate, the availability of both flexible and rigid systems, and the presence of two or more metal atoms in an environment where interactions between them can be tuned make [m.m]metallocenophanes a fascinating class of potentially very useful materials. The first uses, for example, as catalysts for H_2 generation from acidic aqueous solution, have already been found, but many more applications of these materials can be expected, for instance in the area of conducting molecular solids and in the catalysis of C–C bond forming reactions. Only the first steps have been taken in this direction and many opportunities await to be explored.

In the work of our research group, we have benefited from very good and open communication with other groups. I would like to emphasize the importance of many discussions with Professors Cowan, Hendrickson, Watts, and Bitterwolf on many different aspects of this work. A large portion of our work was carried out at the IBM Research Laboratory in San Jose, California, where I have enjoyed the able cooperation of Adel Nazzal and of many postdoctoral fellows, whose work is acknowledged in the references. At the University of Connecticut, I enjoy the interaction with graduate students and postdoctoral fellows. Their so far unpublished contributions are noted with gratitude. I would also like to thank Professor Rheingold, University of Delaware, for his consent to include the structure of [1.1]ferrocenophane in this article before its publication.

[10] The name "metallocenophane" is somewhat misleading, because the suffix "phane" and its relative "phen" mean "like," "appearing," or "resembling" (as in Cellophane or epiphanie and in phenomenon and phantasy), so that "metallocenophane" has the unfortunate connotation of metallocene-like. The word cyclophane (*cyclo-phenyl-alkane*) was coined to describe cyclic structures consisting of arenes and aliphatic bridges, but its creators apparently were unaware of the coincidence that it also means "resembling a ring." Since "phane" is now the generic term for cyclic structures, the name metallocenophanes should be used.

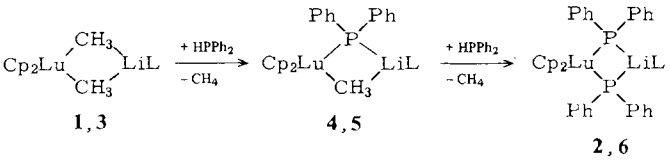
$[(Cp_2Lu\{\mu\text{-}PPh_2\}_2Li(tmeda)] \cdot 1/2\,C_6H_5CH_3$, the First Organolanthanoid-Phosphane Compound to be Characterized by X-Ray Structure Analysis**

By *Herbert Schumann*,* *Eftimios Palamidis*, *Günther Schmid*, and *Roland Boese*

Dedicated to Professor Georg Manecke on the occasion of his 70th birthday

The organolanthanoid-phosphane compounds $[Cp_2LnPtBu_2]$,[1,2] $[Cp_2LnP(C_6H_{11})_2]$,[3] $[Cp_2LnP(Ph)tBu]$,[2] and $[(H_3CC_5H_4)_2SmPPh_2]$[4] (Cp = cyclopentadienyl) are among the first compounds in which dicyclopentadienyllanthanoid fragments are bound to elements other than carbon or halogen. The structure of these compounds was hitherto derived from analytical and spectroscopic data alone, since all attempts to carry out X-ray structure analyses failed: either the compounds were too sensitive, or only disordered crystals could be obtained. Hence, the proposed structures have always been suspect, and an unequivocal elucidation of the bonding was therefore not only of theoretical interest, but also necessary in view of the potential use of such organolanthanoid-phosphane compounds in organic syntheses as mild and specific R_2P-transfer agents.

Excellently crystalline organolanthanoid-phosphane compounds are very conveniently accessible from the dicyclopentadienyllutetium-lithium complex **1**[5] and diorganophosphanes. The complex **1** reacts with $HPPh_2$ in toluene at room temperature with elimination of methane to give the dicyclopentadienyllutetium-phosphane compound **2** · $1/2\,C_6H_5CH_3$ [Eq. (a)].[6]



1 **2**

tmeda = *N*, *N*, *N'*, *N'*-tetramethylethylendiamine

In an analogous way, reaction of the tetrahydrofuran (THF) complex **3**[7] with $HPPh_2$ in ether at room temperature affords the complex **6**.[6]

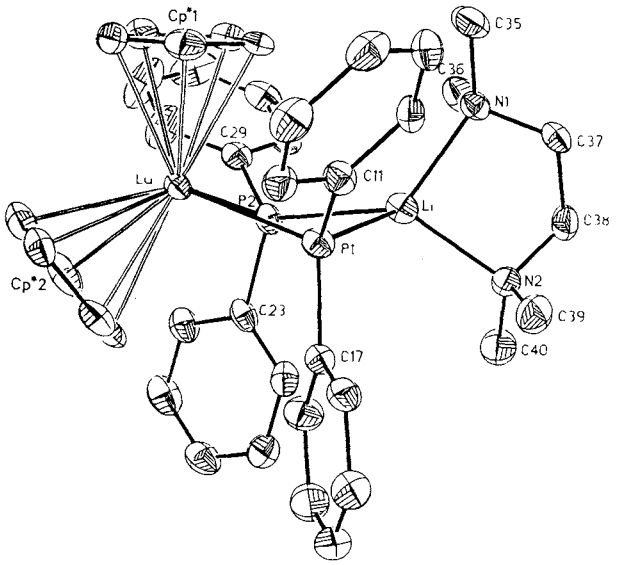
$HPtBu_2$ does not react with **1** or **3**, even in boiling benzene, whereas reaction of $HPMe_2$ with **1** or **3** not only leads to liberation of methane but also to cleavage of the cyclopentadienyl ligand.

When this reaction [Eq. (a)] was monitored by NMR spectroscopy, it was observed that only one CH_3-bridge is initially replaced by a Ph_2P group; the singlet for the ten cyclopentadienyl H atoms ($\delta = 6.26$ for **1**, 6.31 for **3**) is replaced by a doublet ($\delta = 6.22$, $J(HP) = 0.45$ Hz for **4**, $\delta = 6.24$, $J(HP) = 0.45$ Hz for **5**), which upon further addition of $HPPh_2$, is finally converted into a triplet, indicating the substitution of both CH_3 bridges [Eq. (b)].[6]

1, **3** **4**, **5** **2**, **6**

1, **2**, **4**: L = (tmeda); **3**, **5**, **6**: L = $(thf)_2$

According to the X-ray structure analysis, **2** is a bis(diphenylphosphino)-bridged, dinuclear lutetium-lithium complex (Fig. 1).[8] The lutetium atom is surrounded by a



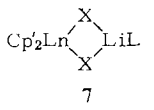


Fig. 1. Crystal structure of **2** (H atoms and solvent molecules omitted for clarity; vibration ellipsoids at the 50% probability level). Selected bond lengths [Å] and angles [°] (Cp* signifies the centroid of the cyclopentadienyl ligand): Lu···Li 3.771(1), P1···P2 3.845(2), Lu-P1 2.782(1), Lu-P2 2.813(2), Lu-Cp*1 2.311, Lu-Cp*2 2.299, mean value Lu-C(η^5) 2.602, P1-C11 1.844(3), P1-C17 1.851(4), P1-Li 2.692(14), P2-C23 1.857(3), P2-C29 1.859(4), P2-Li 2.691(8), Li-N1 2.098(12), Li-N2 2.124(12); Cp*1-Lu-Cp*2 131.2, P1-Lu-P2 86.8, Lu-P1-Li 87.1(2), Lu-P2-Li 86.5(3), P1-Li-P2 91.2(4), N1-Li-N2 87.8(5), dihedral angle between the P1-Lu-P2 and P1-Li-P2 planes 148.7.

[**] Organometallic Compounds of the Lanthanoids, Part 37. This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and by special funds from the TU Berlin. – Part 36: H. Schumann, I. Albrecht, J. Loebel, E. Hahn, M. B. Hossain, D. van der Helm, *Organometallics*, in press.

distorted tetrahedral array of the centroids of the two cyclopentadienyl rings and the two bridging phosphorus atoms. At the same time, these two phosphorus atoms together with the two nitrogen atoms of the tmeda ligand coordinate the lithium atom tetrahedrally. In addition, the crystal contains one molecule of toluene (disordered) per two molecules of **2**. The P1-Lu-P2 and P1-Li-P2 planes form an angle of 148.7°, i.e., a bent four-membered ring is formed, as observed in compounds with sulfur[9] or selenium ($[Cp_2Lu(\mu\text{-}SePh)_2Li(thf)]$[10]) in place of phosphorus, By contrast, in the already well-known complexes **7**, the

7

Ln	Cp'	X	L	Ref.
Yb	C_5Me_5	Cl	$(Et_2O)_2$	[11]
Yb	C_5Me_5	I	$(Et_2O)_2$	[11]
Er	C_5H_5	CH_3	tmeda	[7]
Lu	C_5H_5	CH_3	tmeda	[5]

$Ln(\mu\text{-}X)_2Li$ moieties are planar. The Cp*1-Lu-Cp*2 angle and the mean value of the ten Lu-C(η^5) distances in **2** lie in the expected range; the cyclopentadienyl rings are planar. The lengths of the organolutetium-phosphorus bonds (measured for the first time) are 2.782 and 2.813 Å.

Dihydroacepentalenediide, the Dianion of Acepentalene**

By *Thomas Lendvai, Thomas Friedl, Holger Butenschön, Timothy Clark,** and *Armin de Meijere**

Dedicated to Professor Edgar Heilbronner on the occasion of his 65th birthday

Dihydroacepentalenediide ($\mathbf{2}^{2\ominus}$), formally an ethenobridged dihydropentalenediide,[1,2] should, according to semiempirical calculations, in analogy to the latter be a closed-shell system.[3] However, the high strain energy in the cyclic and cross-conjugated skeleton with three angularly annelated five-membered rings could preclude its formation.[4] Apparently all attempts to generate $\mathbf{2}^{2\ominus}$ have thus far failed, despite the keen interest long shown by theoretical chemists in acepentalene (cyclopenta[*cd*]pentalene) **2**.[5] The most recent attempts to reductively eliminate the two dialkylamino groups from the potentially suitable precursor 4,7-bis(dialkylamino)tricyclo[5.2.1.0^{4,10}]deca-1(10),2,5,8-tetraenes[3] merely led to 1,4,7-tris(dialkylamino)-substituted monoanions.[3,6] It is therefore all the more surprising that $\mathbf{2}^{2\ominus}$ can be prepared quite simply and directly from triquinacene **1**.

1 $\mathbf{2}^{2\ominus}/2K^{\oplus}$ **2**

When **1** is added to a suspension of *n*-butyllithium and potassium *tert*-amyl alkoxide[7] in *n*-hexane,[8] the mixture turns deep red within 24 h at room temperature. To complete the reaction, the mixture is boiled under reflux for 24 h. The solvent is then removed from the mixture by suction through a fritted glass under nitrogen, and the excess base is then removed by washing five times with hexane.

The reddish-brown powder that is recovered along with potassium hydride on the filter (corresponding to 130–135% yield) can be dissolved in tetrahydrofuran (THF). Its ^{1}H-NMR spectrum shows only one singlet (Table 1), and,

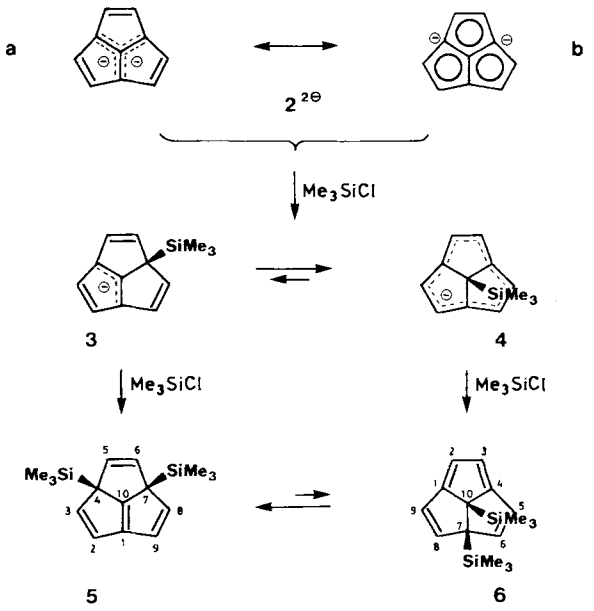

Table 1. Some characteristic data of the dipotassium acepentalenediide $\mathbf{2}^{2\ominus}/2K^{\oplus}$ and its trapping products **5** and **6**.

according to the ^{13}C-NMR spectrum, the constitution of the product recovered is indeed that of the dipotassium dihydroacepentalenediide $2^{2\ominus}/2K^{\oplus}$ (Table 1).[9] But the assignment of the very weak signal of C-10 is not absolutely certain because $2^{2\ominus}/2K^{\oplus}$ slowly decomposes in THF, even at $-40\,^{\circ}C$, and hence signals of other products appear in the spectrum. An unequivocal proof of the constitution was, however, provided by the trapping reaction with chlorotrimethylsilane. When a suspension of $2^{2\ominus}/2K^{\oplus}$ in *n*-hexane is stirred at room temperature for 48 h with an approximately equimolar amount of Me_3SiCl, decolorization of the mixture occurs, and, after the usual work-up, a product can be isolated (60–70% yield based on **1**) in which two components with $M_r = 272$ can be detected by combined GC-MS. According to the ^{1}H-NMR spectrum (Table 1) the components are the isomeric bis(trimethylsilyl)tricyclo[5.2.1.$0^{4,10}$]decatetraenes **5** and **6** (ratio 61:39).

It is especially remarkable that **6** is formed along with **5**, since the tricyclo[5.2.1.$0^{4,10}$]deca-1,3,5,8-tetraene skeleton of **6**, according to force field calculations, is about 18.2 kcal/mol more strained[4] than the skeleton of **5**, which is easily accessible in the form of 4,7-bis(dialkylamino)-derivatives.[3] According to MNDO calculations the charge distribution in dihydroacepentalenediide $2^{2\ominus}$ is best explained in terms of the structure **a**, a trisetheno-bridged trimethylenemethane dianion; structure **b** plays only a subordinate role.[3] Hence, the 4-trimethylsilyl anion **3** should be formed first in a kinetically controlled reaction of $2^{2\ominus}$ with Me_3SiCl; this could partially rearrange into the thermodynamically more stable 10-trimethylsilyl anion **4** with a 10π-perimeter by 1,2- or 1,5-silatropic shift,[10] before it reacts further to give the bis(trimethylsilyl) derivative. As expected, **5** is thermodynamically more stable than **6**; under modified conditions **5** and **6** are formed in the ratio 83:17 or 100:0. The isomer **6** rearranges into **5**, rapidly upon MeSiCl-catalysis at room temperature, but at best only slowly upon heating above 90 °C.[11]

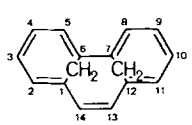
Bridged [14]Annulenes with a Phenanthrene-Perimeter: *syn*-1,6:7,12-Bismethano[14]annulene**



By *Emanuel Vogel,* Wilhelm Püttmann, Walter Duchatsch, Thomas Schieb, Hans Schmickler,* and *Johann Lex*

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

The *syn/anti*-isomeric 1,6:8,13-bismethano[14]annulenes **1**[1] and **2**[2] with an anthracene-perimeter are exemplary models for correlating aromaticity and molecular geometry.[3] On the basis of spectral[4] and structural chemical criteria, the *syn*-isomer **1** clearly qualifies as an aromatic compound, even though the annulene ring is noticeably bent—mainly as a result of steric repulsion of the internal bridge hydrogen atoms. In the *anti*-isomer **2**, on the other hand, the annulene ring is strongly puckered, so that the cyclic π-electron delocalization can no longer be sustained, and consequently **2** constitutes a highly reactive olefinic molecule.

1, *syn*
2, *anti*

3, *syn*
4, *anti*

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

A similar geometrically induced loss of aromaticity as observed with **1**/**2** should, according to model considerations, occur in the case of the *syn/anti*-isomeric 1,6:7,12-bismethano[14]annulenes **3** and **4** derived from phenanthrene. The annulene ring of **3** appears to be more deformed than that of its counterpart **1**, yet aromatic character should still be associated with **3**, since the torsional angles of the CC bonds do not exceed values of 40–50°.[5] In the case of **4** the annulene ring is puckered to about the same extent as that in **2**, so one can safely assume that **4** is also olefinic.[6] The experimental verification of this concept is the subject of this and the following communication.[7]

The stepwise coupling of terminally suitably substituted cycloheptatrienes, preferentially of—hitherto unknown—6-halogeno-1,3,5-cycloheptatriene-1-carboxylic acid derivatives (cf. **7**), promised a relatively simple entry to **3** and/or **4**. Using this strategy we succeeded, first of all, in synthesizing the *syn*-1,6:7,12-bismethano[14]annulene **3**, which, because of non-bonding interactions between the internal bridge hydrogen atoms, is a sterically very demanding species.

As cycloheptatriene synthetic building block we chose 6-iodocycloheptatriene-1-carbonitrile **7**. The preparation of **7** was based on our previous observation that cyclopropabenzene **5**[8] upon reaction with iodine affords 1,6-diiodocycloheptatriene **6**.[8a] As the yield of **6** reached in the original procedure is maximally 5%, advantage had to be taken of the efficient synthesis of **5** by *Billups*[8b] and of the finding that the iodination of **5** is a radical process optimizable by UV irradiation.[9] **6** is thus accessible on a preparative scale.

Upon heating the diiodide **6** together with copper(I) cyanide (molar ratio 1:1) in dimethylformamide (DMF) at 120 °C (6 h) a mixture of **7** and 1,6-cycloheptatrienedicarbonitrile[9] was obtained, from which **7** could be readily separated by chromatography on silica gel (pentane/ether 3:1) [colorless rhombs (from pentane/ether 1:1); m.p. 73 °C; yield 28%]. When **7** is slowly added to the Ni^0-reagent prepared from bis(triphenylphosphane)nickel(II) chloride, triphenylphosphane and activated zinc in DMF,[10] reductive CC coupling with formation of the dinitrile **8** is achieved [m.p. 188–189 °C; yellow needles (from methanol); yield 69%]. Reduction of **8** with diisobutylaluminum hydride (DIBAH) in toluene smoothly affords the dialdehyde **9** [m.p. 132 °C; orange-colored needles (from ether); yield 82%]. Upon reaction with titanium tetrachloride/zinc/pyridine[11] in tetrahydrofuran (THF) under high dilution conditions (the more advantageous method) or with tungsten hexachloride/butyllithium,[12] **9** undergoes annulene ring closure to give, surprisingly, the *syn*-isomer **3** stereoselectively in both cases (yield 35–40% and 10%, respectively). After work-up by chromatography on alumina (Brockmann act. IV; pentane) the annulene **3**, which is air-stable, is recrystallized from pentane thus furnishing orange-colored rhombs of m.p. 93–94 °C.

The ^{1}H-NMR spectrum of **3** (see Fig. 1 and Table 1) indicates—as would be expected for an aromatic compound—the presence of a diamagnetic ring current (signals for the annulene and bridge protons at relatively low and high field, respectively), which, however, is weaker than that in **1**, and even more so than that in bridged [14]annulenes with essentially planar annulene rings. Comparison of the mean positions of the signals of the annulene protons of **3** ($\delta = 7.19$), **1** (7.59) and **4**[7] (6.45) places **3** intermediate between **1** and **4**, which according to all its

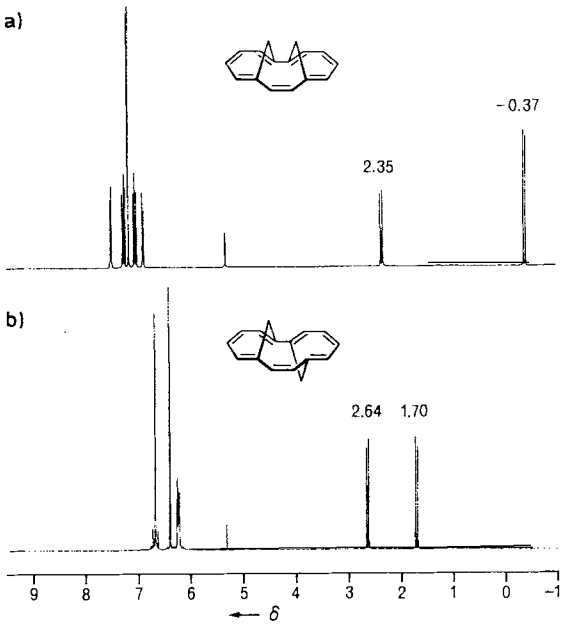

Fig. 1. ^{1}H-NMR spectra of a) *syn*-1,6:7,12-bismethano[14]annulene **3** and b) *anti*-1,6:7,12-bismethano[14]annulene **4** (300 MHz, CD_2Cl_2).

Table 1. ^{1}H-NMR data (δ values and vicinal coupling constants [Hz]) of the bridged [14]annulenes **3** and **4** and of phenanthrene [a] at 300 MHz in CD_2Cl_2.

3	6.91	7.06	7.27	7.52	7.18	−0.37	2.35
4	6.23	6.67	6.69	6.26	6.40	1.70	2.64
Phenanthrene	7.99	7.71	7.75	8.76	7.84	—	—

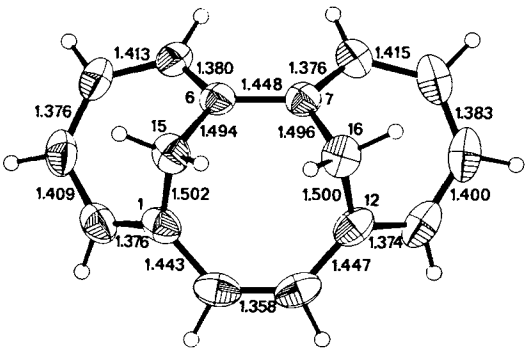
	J(2,3)	J(3,4)	J(4,5)	J(13,14) [b]
3	6.96	10.26	7.11	11.8
4	5.94	11.03	5.27	11.2
Phenanthrene	8.00	7.04	8.44	8.8

[a] For comparison, the annulene nomenclature has been used for phenanthrene. The NMR analysis was carried out in connection with this work; for data published earlier, see R. C. Fahey, G. C. Graham, *J. Phys. Chem.* **69** (1965) 4417. [b] The J(13,14) coupling could be determined from the ^{13}C-satellites of the ^{1}H-resonance.

properties is to be regarded as a purely olefinic compound. **3** also takes a position between **1** and **4** with respect to the ratio of the vicinal coupling constants $^3J_{H,H}$, that is a measure of the degree of bond alternation.[13] From the $^3J_{H,H}$ values it can be concluded that of the two nonequivalent resonance structures of the annulene **3** that with cycloheptatriene units has special weight. This finding conforms with the observation that the π-bonds in the olefinic species **4** are localized as shown in the structural formula.[7] The downfield position of the signals of the internal bridge protons (H-15i, H-16i) of **3** must largely be due to a proximity effect, which, as inferred from the analogous case of **1**, should cause a deshielding of the order of 1–2 ppm.[1]

The electronic spectrum of **3** (in cyclohexane, see Table 2) is of the same type as that of benzene and as the spectra of other delocalized [4n+2]annulenes.[14] Apart from the extinction of the most intense band being reduced and the longest wavelength band being relatively weak, it closely agrees with the spectrum of **1**, whereas it is markedly different[15] from the spectrum of its *anti*-isomer **4**.[7]

The X-ray structure analysis[16] of **3** (Fig. 2) not only provides unequivocal proof of the *syn* arrangement of the bridges, but also confirms the conclusion drawn from models that π-orbital overlap in the annulene ring is less favorable in **3** than in **1**. Torsional angles of up to 45° are observed for the CC bonds of the ring, as compared to 34° for those in **1** and 84° for those in **4**.[7] The bond alternation ensuing from the coupling constants $^3J_{H,H}$ locally varies in its degree quite noticeably. In the cycloheptatriene units the alternation lies within the range of lengths for aromatic CC bonds, whereas in the ring segment C12-C13-C14-C1 it approximates to those in polyenes, such as the *anti*-isomer **4**. This dichotomy apparently has its origin in the steric forces which the repulsion of the internal bridge hydrogen atoms (H,H distance ca. 1.87 Å) imposes on the annulene ring.



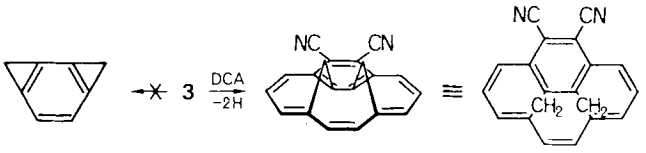


Fig. 2. Molecular structure of **3** in the crystal; selected bond lengths [Å]. Transannular CC distances: C1 ··· C6 ≙ C7 ··· C12 2.336 Å; bridge bond angles: C1-C15-C6 ≙ C7-C16-C12 102.6° (mean values for the four independent molecules in the unit cell).

From the investigations on the π-electron structure of **3** one arrives at the conclusion that the physical methods employed—especially ^{1}H-NMR spectroscopy, electron spectroscopy and X-ray structure analysis—respond with different sensitivity to the steric hindrance of resonance in **3** and other nonplanar (4n+2)π-electron systems.

The availability of **3** stimulated attempts to use this hydrocarbon, in analogy to the conversion of 1,6-methano[10]annulene to cyclopropabenzene,[8a] for a synthesis of the extremely strained di(cyclopropa)benzene **10**. The target molecule, however, did not materialize since **3** reacts

10 **11**

with acetylenedicarbonitrile (DCA) (in boiling acetone) with formation of **11** [decomp. above 235 °C; yellow rhombs (from chloroform); yield 85%].

Table 2. Some spectral data of the new compounds. ^{1}H-NMR: 300 MHz, ^{13}C-NMR: 75.5 MHz, both in $CDCl_3$ (exception: **3** in CD_2Cl_2); MS: 70 eV; UV/VIS in dioxane (exception: **3** in cyclohexane).

3: ^{1}H-NMR see Table 1; ^{13}C-NMR: δ = 33.51, 113.97, 115.98, 127.78, 128.27, 129.04, 130.53, 131.53; MS: *m/z* 206 ($M^{\oplus}$, 72%), 191 (100); IR (CsI): 3030, 1573, 1488 cm^{-1}; UV/VIS: λ_{max} = 245 nm (ε = 8300), 300 (47100), 367 (7400), 450 (340) sh

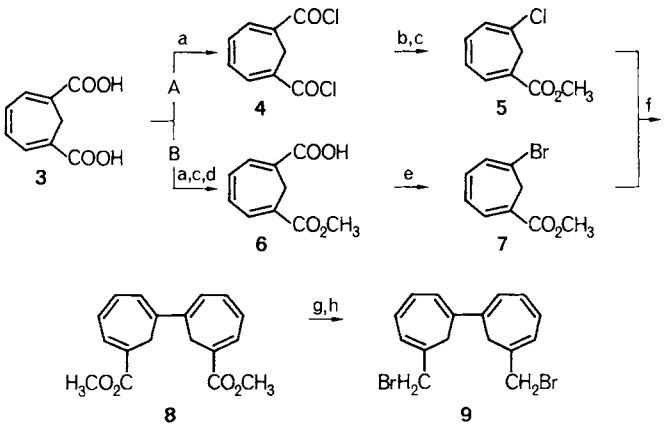
Bridged [14]Annulenes with a Phenanthrene-Perimeter: *anti*-1,6:7,12-Bismethano[14]annulene**

By *Emanuel Vogel,* Thomas Schieb, Wolfgang H. Schulz, Klaus Schmidt, Hans Schmickler,* and *Johann Lex*

The *syn*-1,6:7,12-bismethano[14]annulene **1** derived from phenanthrene, a bridged [14]annulene with a markedly bent annulene ring, is kind of a borderline case of an aromatic molecule regarding its π-electron structure.[1] In the case of the still unknown *anti*-1,6:7,12-bismethano[14]annulene **2** the predictions are that one is dealing with an olefinic molecule since, according to models, **2** possesses a puckered annulene ring in which the CC bonds are, in part, strongly twisted (maximum torsional angle 80–85 °). Following the successful synthesis of **1**[1b] we are now also able to report the synthesis of **2**.



1

2

The surprising observation that reductive coupling of 1,1′-bis(cycloheptatrienyl)-6,6′-dicarbaldehyde exclusively affords the *syn*-isomer **1** suggested the idea of approaching **2** by way of its dihydro derivative **11**. Compound **11** should be formed, albeit not necessarily stereoselectively, by reductive cyclization of 6,6′-bis(bromomethyl)-1,1′-bis(cycloheptatrienyl) **9**.

The diester **8** could be obtained—more advantageously than via the cyclopropabenzene route[1]—from the readily accessible cycloheptatriene-1,6-dicarboxylic acid **3**,[2] either A) via the dicarboxylic acid dichloride **4**, or B) via the methyl half ester **6**[2b] (Scheme 1).[3] Route A): The compound **4** (m.p. 63 °C; yield 80%), prepared by reaction of **3** with sulfinyl chloride, undergoes selective monodecarbonylation on heating with tris(triphenylphosphane)rhodium(I) chloride[4] as catalyst to give 6-chlorocycloheptatriene-1-carboxylic acid chloride, which after distillation from the reaction mixture is allowed to react with methanol yielding **5**. Upon chromatographic isolation (silica gel, ether/pentane 1:9), **5** is obtained as an NMR-spectroscopically pure oil, so that for practical purposes a distillation (yellowish liquid of b.p. 62–63 °C/0.2 torr; m.p. 26 °C; yield 65%) is not required. Treatment of **5** with bis(triphenylphosphane)nickel(II) chloride (catalytic amounts) and zinc in tetrahydrofuran (THF) in the presence of tetraethylammonium iodide,[5] brings about reductive CC coupling to give **8**, which after purification by chromatography (silica gel, ether) and recrystallization (from methanol) is obtained in the form of yellow rhombs (m.p. 126–127 °C; yield 70%). Route B): The half ester **6**, best prepared by hydrolysis of the dimethyl ester[2b] with aqueous methanolic sodium hydroxide (yield 45%), can be decarboxylatively brominated to **7** according to the method of *Barton*[6] (an alternative to the Hunsdiecker degradation) in that it is converted by reaction with *N*-hydroxypyridine-2(1*H*)-thione and dicyclohexylcarbodiimide into the thiohydroxamic ester and the latter then heated in bromotrichloromethane. After isolation by chromatography (silica gel, ether/pentane 1:9) and subsequent distillation, **7** is collected as a yellowish liquid (b.p. 75–76 °C/0.1 torr; m.p. ≈ 22 °C; yield 48%). Reductive coupling of **7**, carried out as in the case of **5**, affords **8** in 70% yield (no increase in yield on going from the chloro to the bromo

Scheme 1. compound). The diester **8** can be readily converted into the dibromide **9** [light-sensitive, yellow cubes (from hexane); decomp. above 115 °C; yield 85%] by reduction with diisobutylaluminum hydride (DIBAH) in ether [diol isolated: m.p. 132–133 °C; yellow platelets (from ether); yield 95%] followed by bromination with phosphorus tribromide in benzene.

For the intramolecular CC coupling in **9** (Scheme 2), we resorted to the use of new reductive methods based on low-valent derivatives of sub-group metals.[7] The most convenient method proved to be the reaction of **9** with titanium tetrachloride/zinc/pyridine in THF, since a hydrocarbon mixture consisting mainly of *syn*- and *anti*-13,14-dihydro-1,6:7,12-bismethano[14]annulene (**10** and **11**, respectively) is formed,[8] in which **11** predominates. The separation of the two isomers was accomplished by chromatography on alumina (pentane), whereby **11** was collected as first fraction and **10** as second fraction [**11**: m.p. 68–69 °C; colorless rhombs (from pentane); yield 52%; **10**: m.p. 75–76 °C; yellow needles (from pentane); yield 6%]. The assignment of conformation was confirmed by X-ray structure analyses of **10** and **11**.[9]

Scheme 2. **a**: $TiCl_4$, Zn, pyridine, THF, reflux, 15 h; **b**: DDQ, anisole, 120 °C, 15 h; **c**: *N*-bromosuccinimide, CCl_4, reflux, 25 h; **d**: NaI, acetone, 60 °C, 2 h.

The *anti*-isomer **11** is dehydrogenated (with considerable losses) to **2** by reaction with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) at 250 °C in anisole; surprisingly, **1** is also found to be a product (yields: in each case ca. 5%). In contrast, the *syn*-isomer **10** experiences DDQ-dehydrogenation already at 120 °C, the product being sterically uniform **1** (yield 75%) (likewise in anisole). These findings stimulated a study of the thermolysis of **10**/**11** and **1**/**2**. As it turned out, **10** and **11** interconvert with bridge inversion at 400 °C in the gas phase (flow apparatus) until an equilibrium (approximate composition: 25% **10** and 75% **11**) is established, whereas **1** and **2** are conformationally stable[10] under these conditions (above 400 °C irreversible rearrangements take place). In order to improve the introduction of the 13,14-double bond, **11** was allowed to react with *N*-bromosuccinimide (molar ratio 1:2.5) in carbon tetrachloride, and the resulting bromide mixture then heated with sodium iodide in acetone. Chromatography on silica gel (pentane), followed by short-path distillation (0.3 torr; bath temperature 80 °C) yielded **2** as a pale yellow liquid (yield 20%).

As expected, *anti*-1,6:7,12-bismethano[14]annulene **2** is borne out as an olefinic compound by spectral data and structural chemical findings. In the ^{1}H-NMR spectrum of **2** the signals of the annulene protons appear further upfield and those of the bridge protons further downfield than in the spectrum of **1** [$\Delta\delta$ (mean position of the signals) = 0.74 and 1.18 ppm, respectively] (Table 1). The relatively small shift of the signals of the internal bridge protons is understandable, since the signals of the corresponding protons in **1** appear at unusually low field as a result of the proximity effect.[11] In parallel with the changes in the chemical shifts one finds that the alternation of the vicinal H,H-coupling constants has increased markedly. In fact, the NMR parameters of **2** relevant to the π-electron structure of the molecule closely agree with those of its dihydro derivative **11**.

Table 1. ^{1}H-NMR data (δ-values and vicinal H,H-coupling constants [Hz]) of the [14]annulene derivatives **1**, **2**, **10**, and **11** at 300 MHz in CD_2Cl_2.

10	5.75	10.74	6.00
11	5.72	10.77	5.17

[a] The protons H-13/H-14 of **10** and **11** appear as an AA'BB' system (data refer to the mean position of the signals).

Especially informative is the electronic spectrum of **2**, for this, in contrast to that of **1**, no longer exhibits the three bands[12] typical for aromatic [4n + 2]annulenes, but shows only two pronounced bands (Table 2). On the other hand, the spectra of **2** and *anti*-1,6:8,13-bismethano[14]annulene[13] (polyene with fluctuating π-bonds) are strikingly similar.

For the X-ray structure analysis we used the oxime derivative of *anti*-1,6:7,12-bismethano[14]annulene-2-carbaldehyde.[14] The outcome of the structure determination[15] conforms with the image of the molecule that derives from an inspection of models (Fig. 1). The CC bonds of the annulene ring are, with few exceptions, twisted; the torsional angles of most of the bonds lie in the range of 22–35 °, but

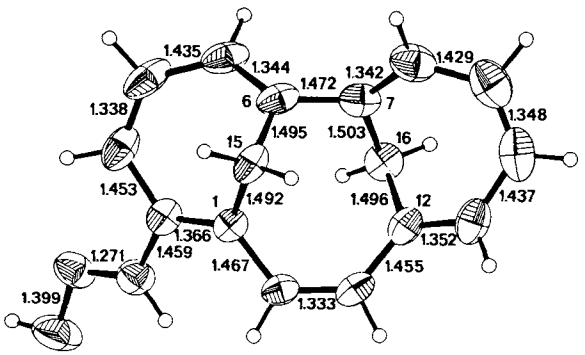

Fig. 1. Molecular structure of *anti*-1,6:7,12-bismethano[14]annulene-2-carbaldehyde oxime in the crystal; selected bond lengths [Å]. Transannular CC distances: C1 · · · C6 2.420 Å, C7 · · · C12 2.407 Å; bridge angles: C1-C15-C6 108.2°, C7-C16-C12 106.8°.

in the case of the C6-C7 bond the torsional angle reaches the extreme value of 84°. As a consequence, the 2p π-orbital overlap at the C6-C7 bond is only barely minimal, and this obviously accounts for the loss of aromaticity, which manifests itself in the pronounced alternation of single and double bonds. The existence of *anti*-1,6:7,12-bismethano[14]annulene as the double-bond isomer **2** with cycloheptatriene partial structures[16] follows equally so from model considerations and force field calculations.[17]

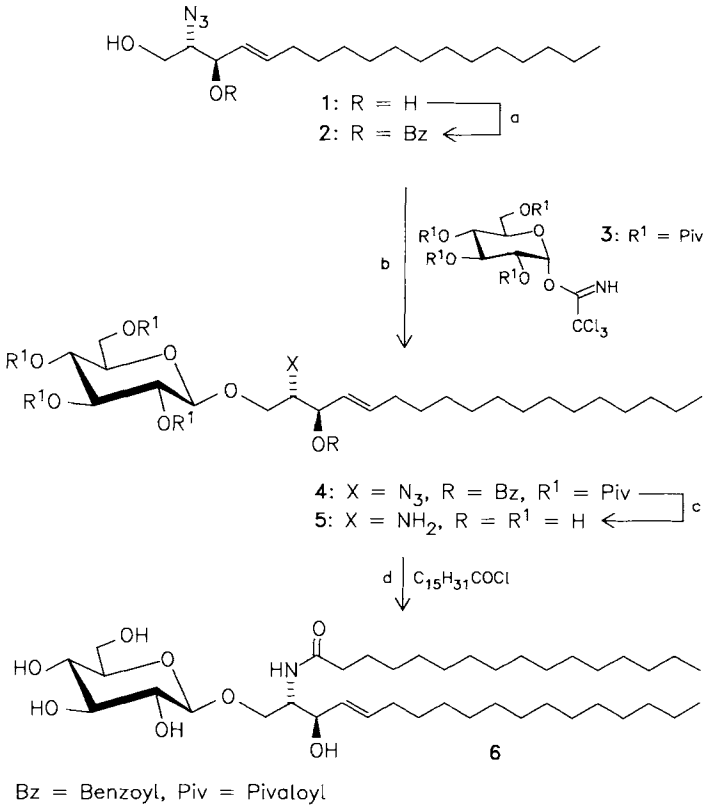
[14] Reaction of **2** with dichloromethyl *n*-butyl ether in the presence of tin tetrachloride [A. Rieche, H. Gross, E. Höft, *Chem. Ber. 93* (1960) 88] afforded mainly *anti*-1,6:7,12-bismethano[14]annulene-2-carbaldehyde, which was isolated by thin-layer chromatography (silica gel, pentane/ether 20:1) as an orange-colored oil (yield 13%). Reaction of the aldehyde with hydroxylamine hydrochloride/pyridine furnished the oxime; bright yellow rhombs (from dichloromethane) of m.p. 172–173 °C.

[15] *anti*-1,6:7,12-Bismethano[14]annulene-2-carbaldehyde oxime crystallizes monoclinically, space group $P2_1/c$, $a = 16.768(4)$, $b = 6.039(1)$, $c = 13.270(2)$ Å, $\beta = 99.99(1)°$, $Z = 4$; 1290 reflections, $R = 0.036$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51940, the names of the authors, and the full citation of the journal.

[16] See, however, the double-bond configuration of 1,6:9,14-bismethano[16]annulene: D. Tanner, O. Wennerström, E. Vogel, *Tetrahedron Lett. 23* (1982) 1221; E. Vogel, U. Kürschner, H. Schmickler, J. Lex, O. Wennerström, D. Tanner, U. Norinder, C. Krüger, *ibid. 26* (1985) 3087.

[17] According to calculations with a modified MM2 force field (W. R. Roth, F.-G. Klärner, G. Siepert, H.-W. Lennartz, unpublished) **2** is favored over its double-bond isomer by no less than 41.2 kcal/mol. In the case of **1**, this value drops to 3.6 kcal/mol (W. R. Roth, private communication).

Synthesis of Glycosphingolipids and Psychosines**



By *Richard R. Schmidt** and *Peter Zimmermann*

Glycosphingolipids have acquired great importance as components of biological membranes.[1] In order to explore their role and function in membranes, the synthesis of isomerically pure compounds that are otherwise only

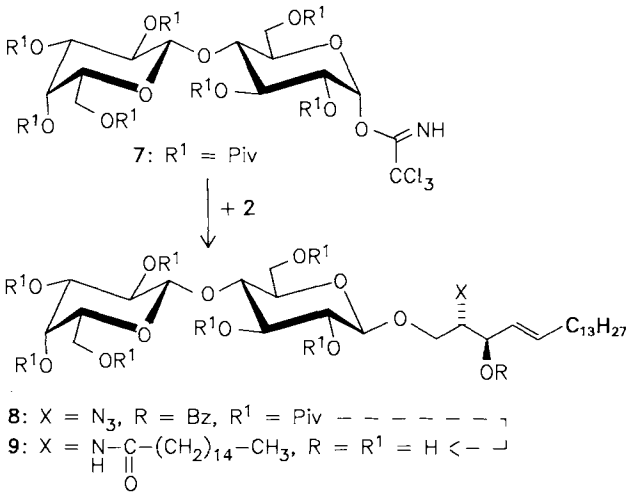
[**] Glycosylimidates, Part 23. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 22: R. R. Schmitt, G. Effenberger, *Carbohydr. Res.*, in press.



difficultly obtainable from biological materials is necessary.[1] For their synthesis, the reaction of *O*-glycosyltrichloroacetimidates (see **3** and **7**) as glycosyl donors with 3-*O*-protected or 3-*O*-unprotected ceramides as acceptors has proven to be the best approach,[2-4] but even then the yields are far from satisfactory.[2,3] We have therefore developed a new and productive entry to this class of compounds, based on our sphingosine synthesis,[5] in which the glycosylation takes place at the sphingosine stage and not, as previously, at the ceramide stage[6] (see Scheme 1).

Scheme 1. Synthesis of *O*-D-glucopsychosine **5** and D-glucocerebroside **6**. a) TrtCl (1.5 eq.), pyridine/$CHCl_3$/tetrahydrofuran (THF) (1:1:1), RT, 48 h (90%); BzCl (2 eq.), pyridine/toluene (1:4), RT, 12 h (91%); $BF_3 \cdot OEt_2$ (1.3 eq.), MeOH/toluene (1:3), RT, 5 h (90%). b) $BF_3 \cdot OEt_2$ (0.1 eq.), CH_2Cl_2, RT (94%). c) NaOMe (0.1 eq.), MeOH/CH_2Cl_2 (2:1), RT, 72 h (78%); H_2S, pyridine/H_2O (1:1), RT, 24 h (94%). d) 8 M NaOAc, THF/H_2O (1:1), RT, 1 h (81%).

The azido derivative **1** of the D-*erythro*-C_{18} sphingosine,[6] which is conveniently obtainable from D-galactose, was converted via 1-*O*-tritylation, 3-*O*-benzoylation and detritylation into the 3-*O*-benzoyl derivative **2** in high yields.[7] *O*-Pivaloylated *O*-α-D-glucosyl trichloroacetimidate **3**, which upon reaction with $BF_3 \cdot OEt_2$ as catalyst in dichloromethane affords the glucoside **4**[7] in 94% yield, proved to be most suitable for the β-specific 1-*O*-glycosylation. Removal of the *O*-acyl protecting groups with sodium methoxide/methanol and reduction of the azido group with hydrogen sulfide in pyridine/water gave as intermediate the glucopsychosine **5**, which plays an important role as metabolic product in Gauchers disease.[8]

The glucopsychosine **5** is a convenient starting compound for the synthesis of D-glucocerebrosides with different fatty acid residues on the amino group, as occur in nature.[1] For example, the D-glucocerebroside **6** previously prepared by us[2] was synthesized by reaction of **5** with palmitic acid chloride/sodium acetate. The lactosyl ceramide **9** could be prepared as the glycosphingolipid in a similar way and in comparable yields from per-*O*-pivaloylated

O-lactosyl trichloroacetimidate **7** and azidosphingosine **2** via the glycoside **8**[7] and the corresponding "lactopsychosine"; this compound, which had likewise been synthesized on a previous occasion by the "ceramide method" was characterized structurally by comparison with the authentic compound.[9]

ζ-$(ET)_2AuBr_2$, a New Type of Structure for the Organic Radical Cation Salts $(ET)_2AuX_2$**

By *Eberhard Amberger*,* *Kurt Polborn*, and *Helmut Fuchs*

In 1980 the first organic superconductor, the hexafluorophosphate of the radical cation of tetramethyltetraselenafulvalene $(TMTSF)_2PF_6$[1] was synthesized. The salts $(TMTSF)_2X$ ($X = PF_6^{\ominus}$, $AsF_6^{\ominus}$, $TaF_6^{\ominus}$, $ReO_4^{\ominus}$,[2] and $FSO_3^{\ominus}$[3]) become superconducting at approximately 10 kbar; only $(TMTSF)_2ClO_4$[4] is a superconductor at ambient pressure. Five normal-pressure superconductors of bis(ethylenedithio)tetrathiafulvalene 1 ("BEDT-TTF" or "ET") have been reported to date: β-$(ET)_2X$ ($X = I_3^{\ominus}$,[5] $IBr_2^{\ominus}$,[6] $AuI_2^{\ominus}$[6a,7]), γ-$(ET)_3(I_3)_{2.5}$,[5a,b] and ε-$(ET)_2I_3(I_8)_{0.5}$.[5a,b] The transition temperature T_c (transition from metallic to superconducting behavior) extends from 0.9 to 2.0 K in the $(TMTSF)_2X$ system and from 1.2 to 4 K in the β-$(ET)_2X$ systems at ambient pressure.[10] By subsequent treatment of $(ET)_2I_3$ crystals, it has even been possible to attain $T_c = 8$ K.[5a,b,8,9]

1

In contrast to the $(TMTSF)_2X$ compounds, the $(ET)_2X$ compounds display a wide variety of structures, owing to the following two factors: (1) On account of the ethylene groups, which do not lie in the plane of the molecule, ET does not form "face-to-face stacks," as is found for the one-dimensional organic conductors with planar donors and/or acceptors. The most noteworthy feature of the ET structure is the two-dimensional "side-to-side arrangement" of the ET molecules to form layers: weak S···S interactions are observed within the stacks and strong ones between the stacks. (2) The complex anions are located between the ET layers along with molecules of solvent in some cases. By variation of the anions (size), it is possible to study their effect on the electrical properties, on T_c, and on the structure of the salts.

ET is at present the most promising donor in the search for new metallic or superconducting radical cation salts. We report here the synthesis of ζ-$(ET)_2AuBr_2$ and *t*-$(ET)_2AuBr_2$ (*t* = *twist*) as well as the structure of the ζ-phase. The rods of ζ-$(ET)_2AuBr_2$, obtained by electrocrystallization from tetrahydrofuran, are formed under certain conditions instead of the preferentially formed *t*-$(ET)_2AuBr_2$ crystals with twistlike overlapping of the ET molecules.

The structure of ζ-$(ET)_2AuBr_2$ can be best described by referring to that of β-$(ET)_2IBr_2$. Both are triclinic: in ζ-$(ET)_2AuBr_2$, the *a* axis is ca. 0.7 Å shorter and thus the shortest of all triclinic ET radical-cation salts. The *c* axis is 1.2 Å longer, not shorter, as might have been expected for a smaller anion (Table 1). Replacement of the linear anions $AuI_2^{\ominus}$ (9.4 Å) and $IBr_2^{\ominus}$ (9.3 Å) by the $AuBr_2^{\ominus}$ anion (8.7 Å), which is ca. 7% shorter, therefore leads to two ET salts having the same stoichiometry but fundamentally different structures: a ζ-phase that is remotely related to the superconducting β-phase, and a t-phase with opposed twisting of the ET molecules.[19] This twist arrangement has only been observed to date in one $(ET)_2X$ salt with linearly symmetric interhalide or halometalate ions, namely, δ-$(ET)_2I_3$.[5b] Otherwise, it has only been found for $(ET)_2ClO_4(C_4H_8O_2)$[12] and $(ET)PF_6$[13] salts with tetrahedral or octahedral anions. All of these salts are semiconductors.

Table 1. Crystal data and T_c of superconducting and nonsuperconducting ET compounds with the anions $IBr_2^{\ominus}$, $AuI_2^{\ominus}$, and $AuBr_2^{\ominus}$.

In the crystal, the ET cations of ζ-$(ET)_2AuBr_2$ form stacks along the *b* axis (weak pair formation) (Fig. 1). The smallest S···S contact in the stack (<3.8 Å, average 3.797 Å and 3.777 Å) are larger than the S···S van der Waals distance (3.7 Å), as is the case for β-$(ET)_2IBr_2$. Still more important are the short S···S contacts between the stacks, which result in the formation of ET layers and give the compound a two-dimensionality (Fig. 2). Planes of $AuBr_2^{\ominus}$ ions join the ET layers. A view along the *c* axis into the two-dimensional network with S···S contacts smaller than 3.7 Å is shown in Figure 3. Between the side-to-side arranged ET molecules of a layer (Fig. 2: black ETs from the projection on the *a*,*c* plane), there are only two short

[**] We thank Dipl.-Phys. *C. P. Heidmann*, *H. Veith*, and Prof. Dr. *K. Andres*, Walther-Meissner-Institut für Tieftemperaturforschung, D-8046 Garching, for the measurement of the electrical conductivity and the T_c investigations.

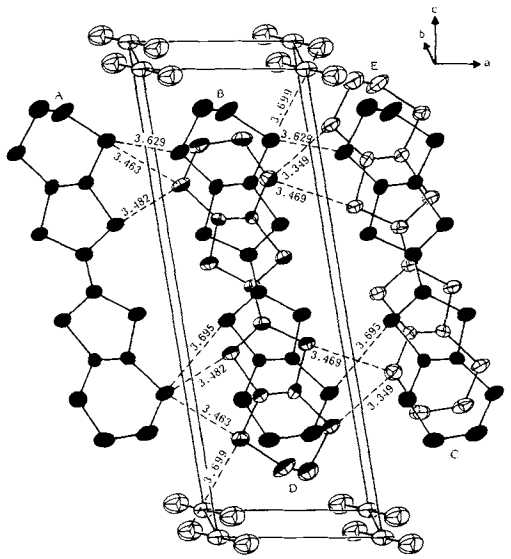

Fig. 2. "Side-to-side" layer arrangement of the ET molecules in ζ-$(ET)_2AuBr_2$ (50% ellipsoids) with unit cell. The molecules A, B, and C (black) form the upper layer of ET and the molecules, A, D (black-white), and E (white) the diagonal layer.

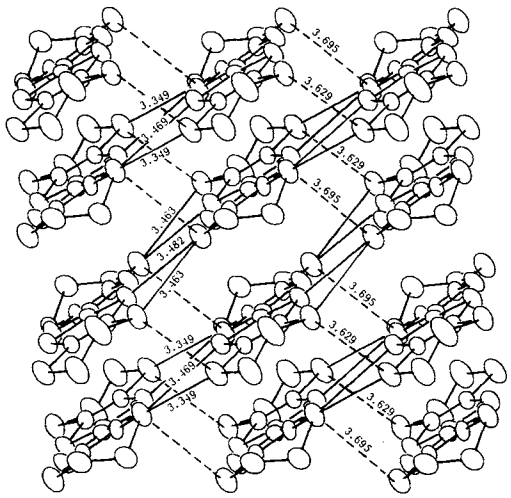

Fig. 3. Two-dimensional S···S network (distances <3.7 Å) in ζ-$(ET)_2AuBr_2$ (along the c axis).

S···S contacts (3.629 and 3.695 Å); in β-structures such as β-$(ET)_2IBr_2$, on the other hand, there are four (average value 3.587 Å).[14]

The crucial difference from the β-structure are the four very short S···S contacts between the stacks (3.349–3.482 Å, shown in Fig. 2 by the diagonal ET sequence black, black-white, and white). In β-$(ET)_2I_3$ and β-$(ET)_2IBr_2$, the short distances between the ET stacks are always larger than 3.56 Å, although the differences between the distances are less. That ζ-$(ET)_2AuBr_2$ is not superconducting could be due to the marked shortening of the S···S contacts. This results in weakening of the other S···S contacts in the plane of the layer of the ETs, which lie directly "side-to-side" (Fig. 2: linking of the black molecules), and reduces the two-dimensionality of the S···S network, which is important for electrical conductivity. In the side-to-side arrangement of the ET molecules, the sulfur atoms of the six-membered ring play an important role. All interstack distances between the S atoms of the five-membered ring are larger than 3.8 Å.

In examining the cation–anion interaction, so far only the $CH_2\cdots X$ contact (X = anion) has been considered.[15] One S···Br contact (3.699 Å) occurs per ET molecule in ζ-$(ET)_2AuBr_2$: this distance is shorter than the van der Waals distance of 3.8 Å. The twist stacks of t-$(ET)_2AuBr_2$[19] exhibit two short S···Br contacts (3.541 and 3.793 Å) per ET; however, the two-dimensional arrangement of the ET molecules, which is apparently necessary (but not sufficient) for superconductivity, is absent. These sulfur–halogen interactions could, along with the size, form, and symmetry of the anion, determine the type of structure and therefore the electrical properties.

As already observed in the case of α- and β-$(ET)_2I_3$, small changes in the experimental conditions for the synthesis of t- and ζ-$(ET)_2AuBr_2$ result in the growth of a non-superconducting and/or a superconducting phase. With the linear anions $I_3^\ominus$ (10.2 Å),[5d] $AuI_2^\ominus$ (9.4 Å), and $IBr_2^\ominus$ (9.3 Å), normal conditions of electrocrystallization (current density 1–5 μA/cm²) result in the growth of only α- and β-structures of $(ET)_2X$; with anions smaller than 9.3 Å ($Au(CN)_2^\ominus$: 9.2 Å,[19] $ICl_2^\ominus$: 8.7 Å,[11,15] $AuBr_2^\ominus$: 8.7 Å), only the β′-, ζ-, and t-structures are formed.

Experimental Procedure

ET [16] and n-Bu_4NAuBr_2 [17] were synthesized according to established procedures. Electrocrystallization: neutral ET (2×10^{-3} mol/L) in 25 mL of tetrahydrofuran (THF) or 1,1,2-trichloroethane (TCE) was galvanostatically oxidized in the presence of n-Bu_4NAuBr_2 (9×10^{-3} mol/L) with a current density of 0.5 μA/cm². After one week, thin black platelets (maximum $6\times0.5\times0.1$ mm³) were obtained at platinum electrodes from the TCE solution. These were identified by X-ray crystallography [19] as the twist phase. When THF solutions and gold or platinum electrodes were used, both the rodlike ζ-phase ($1\times0.5\times0.5$ mm³) and (usually) the twist phase (coffinlike or platelets, $1.3\times1.08\times0.18$ mm³) were obtained. Crystals obtained by a variety of procedures exhibited no volume superconductivity up to 0.5 K in a superconducting quantum magnetometer (SQUID).

t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$, Organic Radical Cation Salts with Twist Stucture**

By *Eberhard Amberger,* Helmut Fuchs,* and *Kurt Polborn*

Bis(ethylenedithio)tetrathiafulvalene (ET) (see **1** in ref. [3]) is currently the most promising organic donor for radical cation salts $(ET)_2X$ having metallic or superconducting properties.[1,2,11] Characteristic of the structures of all $(ET)_2X$ salts is the formation of layered structures of the ETs, whereby the π-systems overlap. The ethylene groups, which project from the planes, prevent close "face-to-face stacking," which would lead to undesired one-dimensionality. The size and shape of the anion X, as well as the "Pearson softness" of its periphery determine the kind of two-dimensional ET stack arrangement and thus the conductivity properties.

We report here the synthesis of t-$(ET)_2Au(CN)_2$ and η-$(ET)_2Au(CN)_2$[7] and the structures of the isotypic twist phases t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$. The lengths of the anions of these t- and η-phases and of ζ-$(ET)_2AuBr_2$[3] are related to those of the anions of the known β-$(ET^{0.5\oplus})_2X^{\ominus}$ normal-pressure superconductors (T_c)[1,2,4-6] as follows: $X = I_3^{\ominus}$: 10.2 Å (1.2-1.6 K); $AuI_2^{\ominus}$: 9.4 Å (3.2-4 K); $IBr_2^{\ominus}$: 9.3 Å (1.9-2.8 K); $Au(CN)_2^{\ominus}$: 9.2 Å; $AuBr_2^{\ominus}$: 8.7 Å.

Upon anodic oxidation of ET in the presence of $nBu_4NAu(CN)_2$ or nBu_4NAuBr_2 in tetrahydrofuran (THF) or 1,1,2-trichloroethane, the following new phases crystallize out (often together): monoclinic η-$(ET)_2Au(CN)_2$[7] and monoclinic t-$(ET)_2Au(CN)_2$;[8a] monoclinic t-$(ET)_2AuBr_2$[8b] and triclinic ζ-$(ET)_2AuBr_2$.[3] Triclinic β-phases are not formed with $Au(CN)_2^{\ominus}$ and $AuBr_2^{\ominus}$.

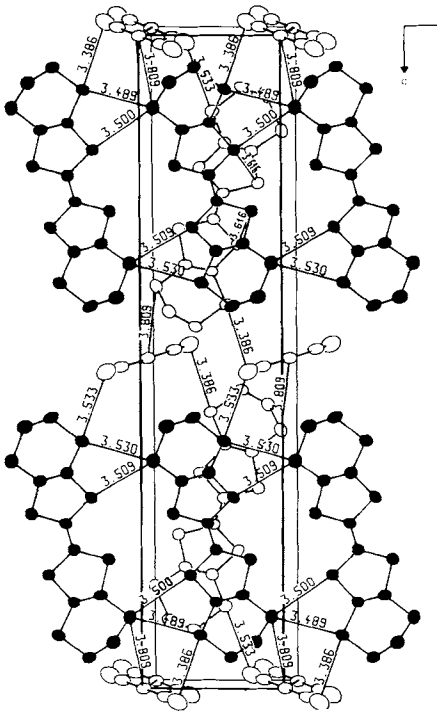

Fig. 1. Structure of t-$(ET)_2Au(CN)_2$; perpendicular to the plane of the ET molecules. "Side-to-side band arrangement" of the ET molecules along the *b* axis (S···S distances ≤3.7 Å and Au/N···S distances ≤4.0 Å). The black molecules form the upper band; only the ETs (white) in the unit cell are shown for the lower band.

In the β- and ζ-structures, the ETs are always parallel and arranged "side-to-side" (stacks and layers); they are characterized by short S···S distances between the stacks (i.e., within the layers) (≤3.7 Å; van der Waals distance 3.7 Å) and longer S···S distances within the stacks (>3.7 Å). In the new twist phases, on the other hand, the ETs are pairwise twisted in opposite directions with respect to the normals to the ET surfaces Fig. 1). These dimeric ET cations (S···S distances in the pair ca. 3.6 Å, Fig. 2, upper) are stacked parallel along the *a* axis (S···S distances between the pairs ca. 3.7 Å). Short S···S distances between the stacks (ca. 3.5 Å) of the ET molecules lying "side-to-side" parallel to the *b* axis result in an ET double band structure (Fig. 2, upper) in the twist phases. In the few known twist structures, δ-$(ET)_2I_3$,[4] $(ET)_2ClO_4(C_4H_8O_2)$,[9] and $(ET)PF_6$,[10] the twisting of the ET molecules only occurs in the direction of the stack. In t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$, the ETs are also oppositely displaced with respect to the long ET axis (Fig. 1, black and white ETs). Planes of $Au(CN)_2^{\ominus}$ and $AuBr_2^{\ominus}$ ions join these ET bands.

For comparison, Figure 2 shows the differing S···S distances of the semiconducting t-$(ET)_2AuBr_2$ (above) and the superconducting β-$(ET)_2AuI_2$ (below) as viewed approxi-

[**] We thank Dipl.-Phys. *C. P. Heidmann* and Prof. Dr. *K. Andres*, Walther-Meissner-Institut für Tieftemperaturforschung, D-8046 Garching, for the measurement of the electrical conductivity.

mately along the c axis. The two-dimensional structure that is necessary (but not sufficient) for superconductivity is not present in t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$.

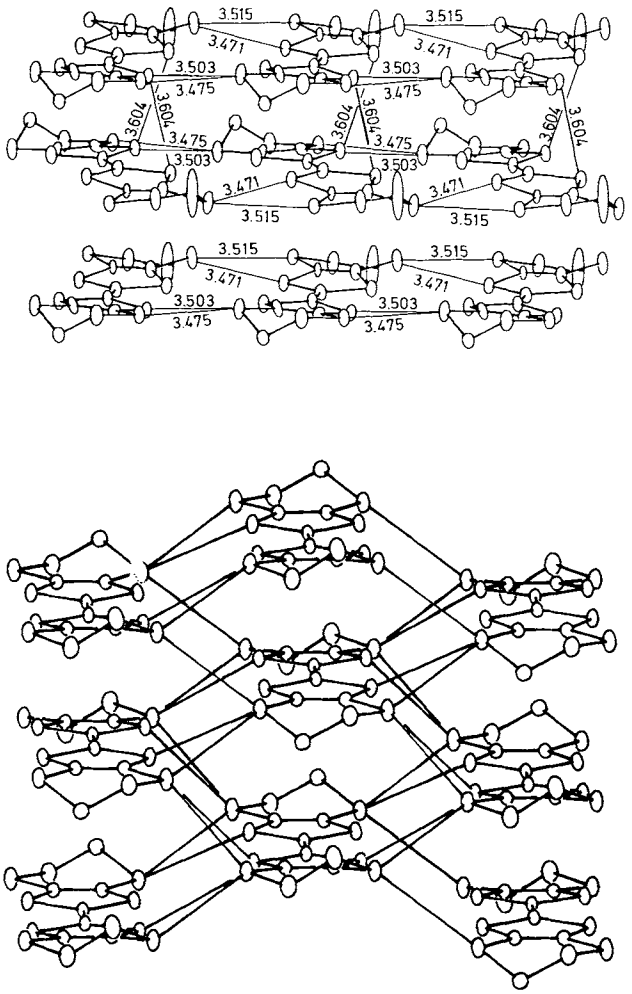

Fig. 2. Comparison of the quasi one-dimensional double band arrangement in t-$(ET)_2AuBr_2$ (above) with the steplike two-dimensional ET layers (two-dimensional network of S atoms) in β-$(ET)_2AuI_2$ (below). The view is along the c axis in each case (the S···S distances ≤ 3.7 Å are indicated).

In the highest occupied molecular orbital, the p_z orbital of sulfur predominates.[9, 10] The overlap integral of the wave functions of ET molecules having their S atoms in close proximity is therefore much larger when the S atoms of the "side-to-side" oriented ETs are arranged in a σ instead of a π configuration. The overlap in the direction of the stack (σ configuration) should be largest were it not hindered by the ethylene groups projecting from the molecular planes of the ETs. The smallest overlap occurs for the "side-to-side arrangement" (π configuration) of the ET molecules, as found for t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$ (Fig. 2, above). The "dimerization" in the direction of the stack, the twist stacking, and the weak overlap of the S orbitals (despite the short S···S distances) of the ET bands arranged in the π configuration are thus responsible for the nonmetallic character[11,12] of the twist structures. In β-$(ET)_2AuI_2$, the steplike (diagonal) arrangement of the ET molecules (Fig. 2, below) leads to a two-dimensional S···S network and superconductivity.

In the β-phases, the transition temperature T_c (transition from metallic to the superconducting state) increases in going from β-$(ET)_2IBr_2$ to β-$(ET)_2AuI_2$,[1,11] the anion of which is 0.1 Å longer. Replacement of $IBr_2^{\ominus}$ in β-$(ET)_2IBr_2$ by $Au(CN)_2^{\ominus}$, which is 0.1 Å shorter, does not lead to "β-$(ET)_2Au(CN)_2$" with a smaller T_c. In addition to the length of the anions, therefore, the lesser "Pearson softness" in the case of $Au(CN)_2^{\ominus}$ and $AuBr_2^{\ominus}$ could also be important for the formation of the new type of structure. No t-, η-, or ζ-structures are formed with the interhalide ions $IBrCl^{\ominus}$ (9.0 Å) and $ICl_2^{\ominus}$ (8.7 Å, same length as $AuBr_2^{\ominus}$); instead, α- and β'-phases are obtained.[5] The smallest Au···S distance in t-$(ET)_2Au(CN)_2$ (3.809 Å) is significantly shorter than in β-$(ET)_2AuI_2$ (>4.1 Å; van der Waals distance 4.0 Å). In t-$(ET)_2AuBr_2$, the smallest S···Br distance (3.541 Å) is significantly shorter than the van der Waals distance (3.8 Å). The cell volumes of the twist phases, unlike those of the β-phases, are not functions of the length of the anions. t-$(ET)_2AuBr_2$ has a cell volume that is 17 Å^3 larger than that of t-$(ET)_2Au(CN)_2$, even though the $AuBr_2^{\ominus}$ anion is ca. 5% shorter than $Au(CN)_2^{\ominus}$. The η-phase with four ET molecules in the unit cell and a similar steplike arrangement of the ET molecules along the b axis, which grows only seldomly, is not superconducting.[7]

Experimental Procedure

$Et_4NAu(CN)_2$ was synthesized from AuCN and Et_4NCN (molar ratio 1:1) in THF and was precipitated with Et_2O as colorless crystals (m.p. = 89 °C; yield 92%). Electrocrystallization: Galvanostatic oxidation was carried out on neutral ET (2×10^{-3} mol/L) and $Et_4NAu(CN)_2$ (13×10^{-3} mol/L) in 30 mL of THF with 0.5 μA/cm^2 current density (electrode voltage 0.5 V) at platinum electrodes (current yield 90%). After 5 d, distorted six-sided platelets of the η-phase along with coffinlike rods (maximum size $2.45\times0.43\times0.25$ mm^3) of the t-phase were obtained.

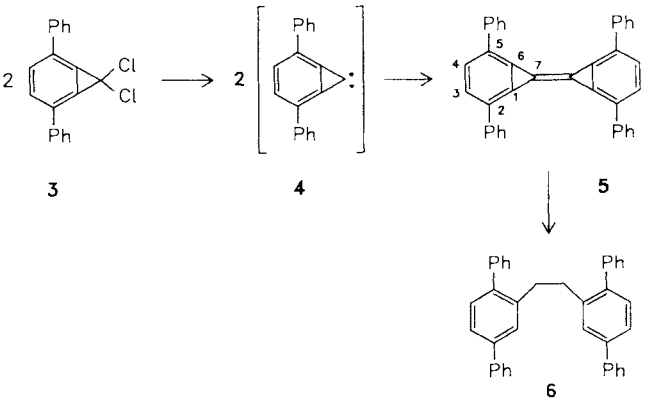
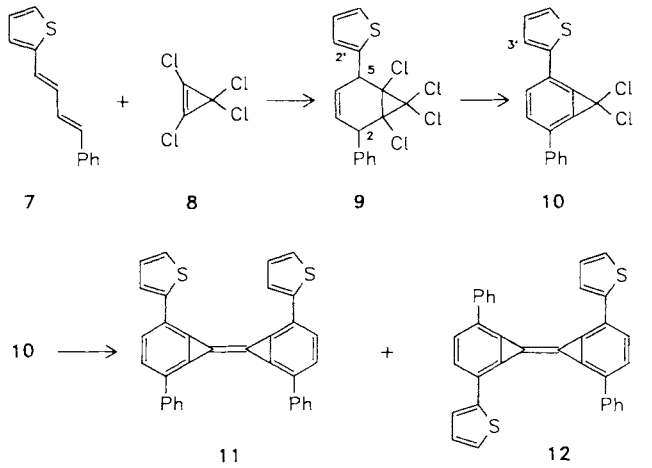
Syntheses and Spectroscopic Properties of Triafulvalene Derivatives**

By *Richard Neidlein,* Volker Poignée, Walter Kramer,* and *Christian Glück*



Dedicated to Professor Siegfried Hünig on the occasion of his 65th birthday

Although triafulvene **1**, the simplest cyclic cross-conjugated molecule, was recently synthesized,[1,2] triafulvalene **2** is still unknown.[3] Of its derivatives, only the benzophenanthrotriafulvalene radical cation has been postulated on the basis of mass spectrometric investigations.[4] In the course of our studies on new reactions of cyclopropabenzene and its derivatives, we have succeeded in synthesizing substituted dibenzotriafulvalenes.



We used 7,7-dichloro-2,5-diphenylbicyclo[4.1.0]hepta-1,3,5-triene **3**[5] as the starting material for the first synthesis. Treatment of **3** with a suitable base resulted in the formation of the carbene **4**, which undergoes dimerization to give 7,7′-bis(2,5-diphenylbicyclo[4.1.0]hepta-1,3,5-trienylidene) **5**. This reaction depends strongly on the base selected. With methyllithium, **3** reacts to give products that do not include the desired ones;[6] with *n*-butyllithium, on the other hand, the triafulvalene derivative **5** is obtained. Compound **5** is characterized by poor solubility. CS_2, in which the compound exhibits a strong yellow fluorescence, was used to record the ^{1}H-NMR spectrum, which is in agreement with the structure given. The aromatic protons are similar to those of **3**, H_2 instead of Cl_2, with respect to chemical shift and splitting pattern.[7] ^{13}C-NMR investigations of **5** failed on account of the low solubility.

Hydrogenation of **5** with Pd/C and hydrogen at room temperature gave a good yield of the expected 1,2-bis(1,1′:4′,1″-terphenyl-2′-yl)ethane **6**.

Two isomeric triafulvalene derivatives can be synthesized via 7,7-dichloro-2-phenyl-5-(2-thienyl)bicyclo[4.1.0]hepta-1,3,5-triene **10**. Compound **10** is obtained by allowing 2-(4-phenyl-1,3-butadienyl)thiophene **7** to react with tetrachlorocyclopropene **8**.

The Diels–Alder product **9** thereby formed is converted into **10** by treatment with potassium *tert*-butoxide at −78 °C. In analogy to **3**, treatment of **10** with *n*-butyllithium at −78 °C affords a 1:1 mixture of **11** and **12**. On account of their likewise low solubility, it was not possible to isolate the pure isomers **11** and **12**. The isomeric ratio was determined on the basis of ^{1}H-NMR spectroscopy.

Experimental Procedure

5: **3** (625 mg, 2 mmol) was dissolved in 50 mL of dry tetrahydrofuran (THF) under argon. *n*BuLi in hexane (0.65 mL, 1.6 M) was then added to the solution at −78 °C. After 15 min, the solution was allowed to thaw; the intense red precipitate was filtered under suction through a porcelain frit and washed with diethyl ether. After drying in air, **5** (110 mg, 23%) was obtained as a microcrystalline powder, m.p. = 240–242 °C (dec.); recrystallization from 1-bromonaphthalene gave fine deep-red needles, m.p. = 245 °C (dec.). ^{1}H-NMR (250 MHz, CS_2/CD_2Cl_2 4:1): δ(relative to $CDHCl_2$) = 7.34 (m, 4H, *p*-H), 7.45 (m, 8H, *m*-H, *m*′-H), 7.67 (s, 4H, H-3,4), 7.95 (m, 8H, *o*-H, *o*′-H). MS (100 eV, 280 °C): *m/z* 481 (32%), 480 (100, $M^{\oplus}$), 479 (24), 403 (22), 241 (26), 240 (7), 78 (25); M_r calcd 480.18780, found 480.18791.

6: A suspension of **5** (48 mg, 0.1 mmol) and Pd/C (10 mg) in THF was allowed to stir under H_2 at room temperature for 48 h, until the fluorescence had vanished. The reaction mixture was then filtered and the solvent was removed under vacuum. Recrystallization of the residue from $CHCl_3$/hexane (1:1 v:v) afforded **6** (46 mg, 95%) as colorless crystals, m.p. = 242 °C. ^{1}H-NMR (250 MHz, CD_2Cl_2): $\delta = 7.55$–7.09 (m, 26H, arom. H), 2.84 (s, 4H, CH_2). MS (100 eV, 180 °C): *m/z* 487 (3%), 486 (5, $M^{\oplus}$), 244 (23), 243 (100), 166 (9), 165 (25), 115 (12), 91 (23), 77 (2).

9: 7 (9 g, 42 mmol), **8** (5.2 mL, 42 mmol), and hydroquinone (100 mg) were dissolved in 60 mL of toluene. The reaction mixture was heated at 110 °C for 12 h. The solvent was then removed, the residue dissolved in methanol, and the insoluble matter separated off. The brown solid that crystallized was washed carefully with a small amount of acetone, dried, and recrystallized from 1-propanol. **9** (5.5 g, 33%) was obtained as almost colorless crystals, m.p. = 167 °C. ^{1}H-NMR (250 MHz, $CDCl_3$): δ = 4.1 (m, 1H, H-2), 4.5 (m, 1H, H-5), 5.77 (m, 2H, H-3,4), 7.2–7.43 (m, 8H, arom. H). ^{13}C-NMR (62.89 MHz, $CDCl_3$): δ = 41.67 (d, C-4 or C-3), 46.92 (d, C-3 or C-4), 56.40 (s, C-6 or C-1), 56.46 (s, C-1 or C-6), 70.11 (s, C-7), 125.73 (CH), 125.83 (CH), 126.58 (CH), 127.43 (CH), 127.57 (CH), 128.43 (CH), 128.50 (CH), 129.78 (CH), 140.28 (s, C-1′ or C-2′), 143.34 (s, C-2′ or C-1′).

10: KO*t*Bu (2.25 g, 20 mmol) was dissolved under argon in 100 mL of dry THF. The solution was cooled to −78 °C and a solution of **9** (3.9 g, 10 mmol) in 50 mL of dry THF was added over 15 min. After 1 h at −30 °C, the reaction mixture was allowed to thaw. The solvent was removed in vacuum and the residue was dissolved in 50 mL of $CHCl_3$. After filtration, the solution was concentrated to a third of its initial volume, treated with the same amount of *n*-hexane, and cooled to induce crystallization. **10** (890 mg, 28%) was obtained as colorless prisms, m.p. = 105–107 °C (dec.). ^{1}H-NMR (250 MHz, $CDCl_3$): δ = 7.19 (dd, 1H, H-4′), 7.45 (m, 2H, *p*-H, H-3′ or H-5′), 7.55 (m, 2H, *m*-H, *m*′-H), 7.65 (dd, 1H, H-5′ or H-3′), 7.71 (d, 1H, H-3 or H-4), 7.86 (d, 1H, H-4 or H-3), 7.91 (m, 2H, *o*-H, *o*′-H).

11, **12**: **10** (635 mg, 2 mmol) was dissolved in 50 mL of dry THF under argon. *n*BuLi in hexane (0.65 mL, 1.6 M) was then added to the solution at −78 °C. The reaction mixture was allowed to thaw and the violet microcrystals were collected under suction on a porcelain frit. After washing with diethyl ether and drying in the air, 95 mg (19%) of a 1:1 mixture of **11** and **12** was obtained, m.p. = 210 °C (dec.). ^{1}H-NMR (250 MHz, CS_2/CD_2Cl_2 4:1): δ (relative to $CDHCl_2$) = 7.17–7.78 (m, 32H), 7.98 (m, 4H, *o*-H (**11**), *o*′-H (**11**) or *o*′-H (**12**)), 8.07 (m, 4H, *o*-H (**12**), *o*′-H (**12**) or *o*′-H (**11**)). MS (100 eV, 240 °C): *m/z* 492 (2%, $M^{\oplus}$), 414 (1), 247 (2), 91 (2), 84 (6), 78 (4), 77 (4), 44 (100). M_r calcd 492.100646, found 492.1007767.

(*R*)-2-Isopropenylcyclopropane-1,1-dicarboxylic Acid: Absolute Configuration and Stereospecific Ring Expansion of Its Dimethyl Ester**

By *Gerhard Quinkert*,* *Hans-Günther Schmalz*, *Egon Walzer*, *Stefan Gross*, *Gerd Dürner*, and *Jan W. Bats*

Dedicated to Edgar Heilbronner on the occasion of his 65th birthday

Recently, we reported the preparation of enantiomerically pure (*R*)-2-vinylcyclopropane-1,1-dicarboxylic acid **6a** by chirality-inducing cyclopropanation.[1] The predicted but not yet proven (*R*)-sense of chirality of **6a** is based on an analysis of the stereoelectronic factors[2] for the formation of the three-membered ring (see Scheme 1) and for the ring expansion of the diester **8a**[1,2] leading to the enantiomerically pure five-membered ring ketones **13a** + **14a** (see Scheme 2) with known absolute configuration.

We now report the analogous preparation of enantiomerically pure (*R*)-2-isopropenylcyclopropane-1,1-dicarboxylic acid **6b** by chirality-inducing cyclopropanation (see Scheme 1) and the ring expansion of its dimethyl ester **8b** to give the enantiomerically pure five-membered ring ketones **13b** + **14b** (see Scheme 2) and provide proof of the absolute configuration of both **6b** and **13b**. What **13a** + **14a**[3] already are for the total synthesis of enantiomerically pure steroids without a methyl group at C(10),[1,2] **13b** + **14b**[3] could become for the total synthesis of enantiomerically pure pseudoguaianolides.[4]

The absolute configuration of *ent*-**6b**,[5] and thus also of **6b**, was determined by an X-ray structure analysis (see Fig. 1)[6,7] of the salt obtained from one equivalent each of *ent*-**6b** and (*S*)-(−)-1-phenylethylamine.

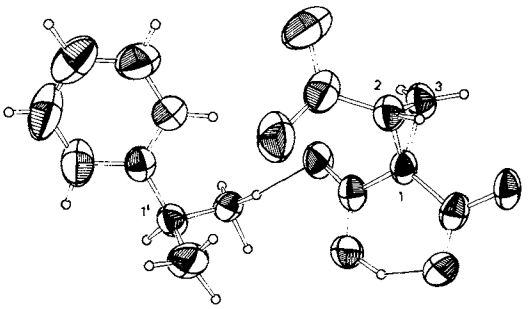

Fig. 1. Structure of the complex obtained from 1 equivalent each of *ent*-**6b** and (*S*)-(−)-1-phenylethylamine.

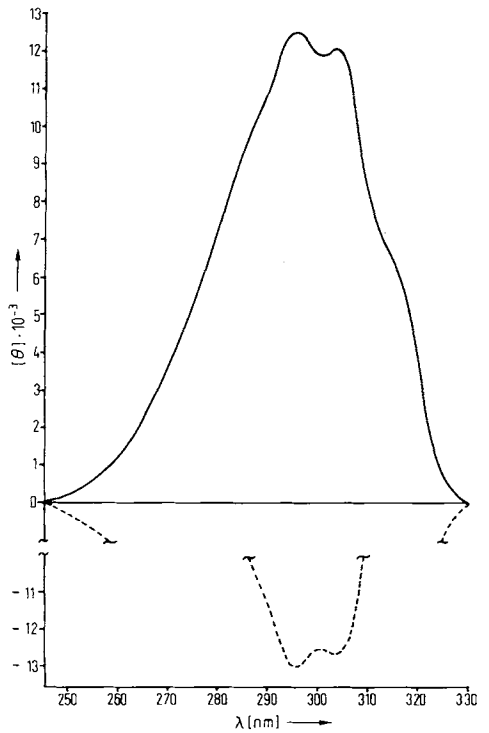
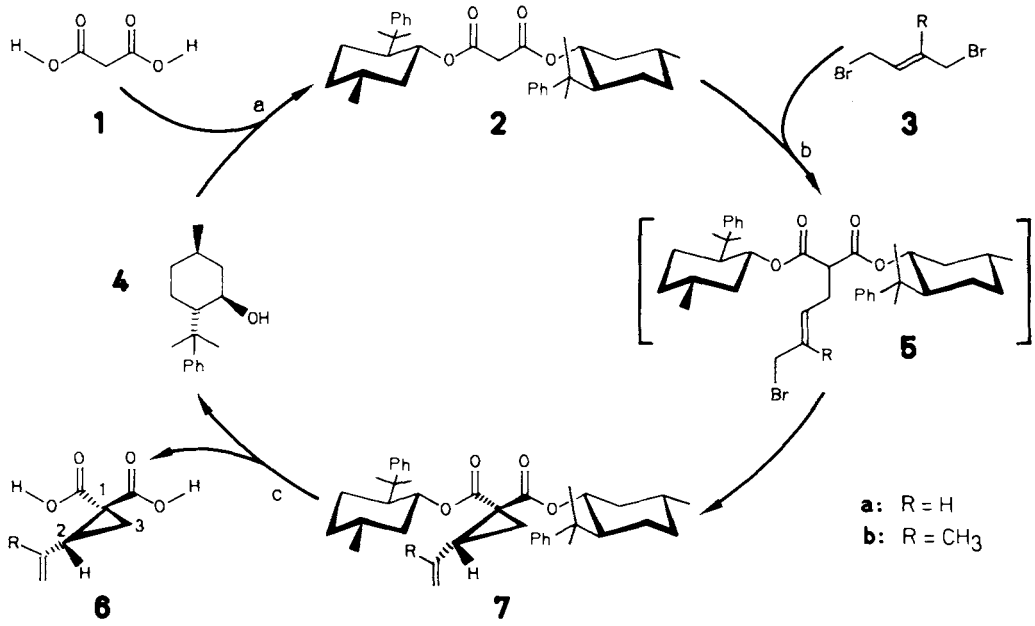
The absolute configuration of **13b** (obtained from **6b** according to Scheme 2) or of *ent*-**13b** (obtained from *ent*-**6b** according to Scheme 2) follows from a comparison of their CD spectra (see Fig. 2) with those of the configurationally





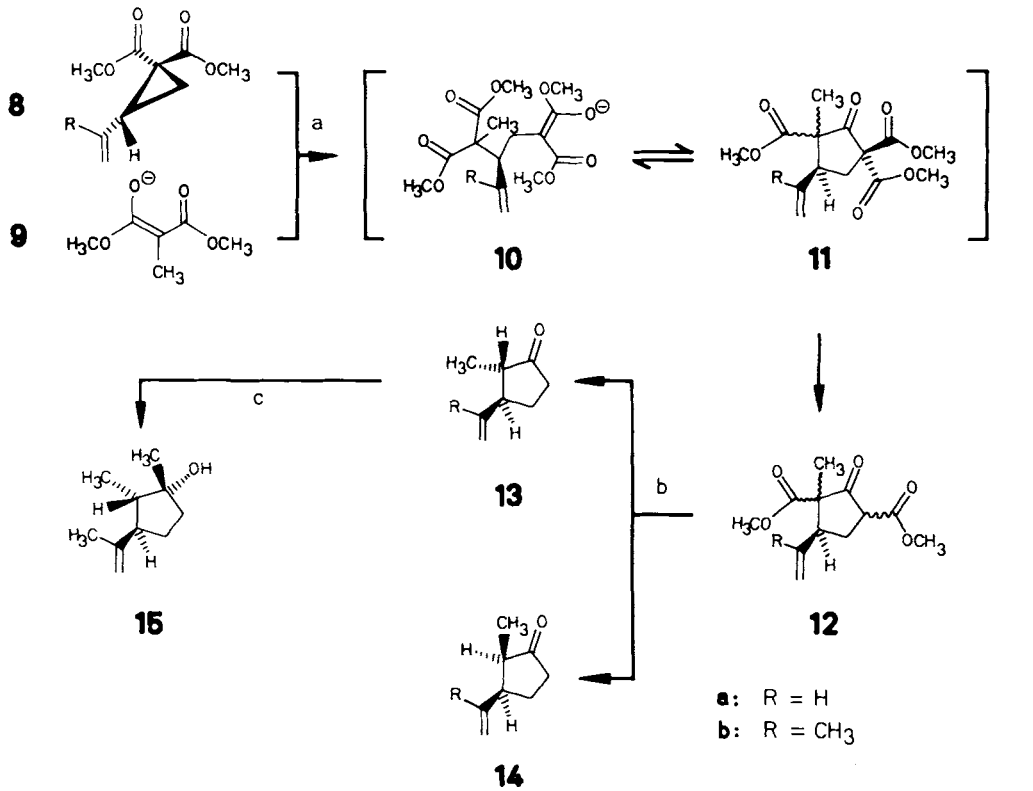


Fig. 2. CD spectra of **13b** (——) and *ent*-**13b** (----) in dioxane.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Project 15/21-1 and 2), the Fonds der chemischen Industrie, and Hoechst AG.

Scheme 1. Simple preparation of the enantiomerically pure three-membered ring building blocks **6a** and **6b** from **1**. Synthesis of **6a**: a) see [1]; b) 1 equiv. of **3a**, Aliquat 336, Fluka AG (catalytic), hexane/50% aqueous NaOH, 14h stirring at RT; **7a**:2-*epi*-**7a** = 98:2; preparative HPLC, **7a** (67%); c) KOH; hydroquinone (catalytic), EtOH/H_2O (4:1), 16h reflux, **6a** (65%) and **4** (72%).—Synthesis of **6b**: a) see [1]; b) 1.1 equiv **3b** (mixed with (*Z*)-isomer, 78:22), Aliquat 336, Fluka AG (catalytic), hexane/50% aqueous NaOH, 65 h stirring at RT; **7b**:2-*epi*-**7b** = 84:16; preparative HPLC, **7b** (63%); c) KOH, hydroquinone (catalytic), EtOH/H_2O (4:1), 100 h reflux, **6b** (71%) and **4** (70%).

Scheme 2. Simple preparation of the enantiomerically pure five-membered ring building blocks **13a** + **14a**, **13b** + **14b** and **15** from **8**. Synthesis of **13a** + **14a**: see [1].—Synthesis of **13b** + **14b**: a) 1 equiv. of **9**, MeOH; 1.5 h at 130°C; **12b** (78%); b) 10 equiv of LiCl, dimethyl sulfoxide, 4 equiv. of H_2O, 4h at 140°C; **13b**:**14b** = 92:8 (65%).—Synthesis of **15**: c) 2 equiv. of MeLi, ether, −10°C, 45 min; **15** (38%).

known[1] compounds **13a** and *ent*-**13a**, respectively. This assignment is supported by a comparison of the optical rotation of *ent*-**15** (obtained from *ent*-**13** according to Scheme 2; $[\alpha] = +44.6$ in CCl_4) with that of plinol A (**15**; $[\alpha] = -39.5$ without solvent[8]).

At the same time as having proven the absolute configuration of **6b** we have also established that the conversion of the chiral three-membered building block of type **8** into the chiral five-membered building block of type **13** + **14** takes place with complete inversion. Still more important, however, is the fact that the (*R*)-sense of chiralty predicted for the enantiomerically pure three-membered ring compounds of type **6** on the basis of stereoelectronic considerations[1] actually is correct.

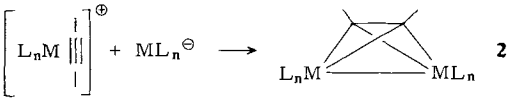
Directed Synthesis of Rhenamolybdatetrahedranes: Nucleophilic Addition of Pentacarbonylrhenate(1-) to Alkyne Ligands in Cationic Molybdenum Complexes**

By *Wolfgang Beck,* Hans-Joachim Müller,* and *Ulrich Nagel*

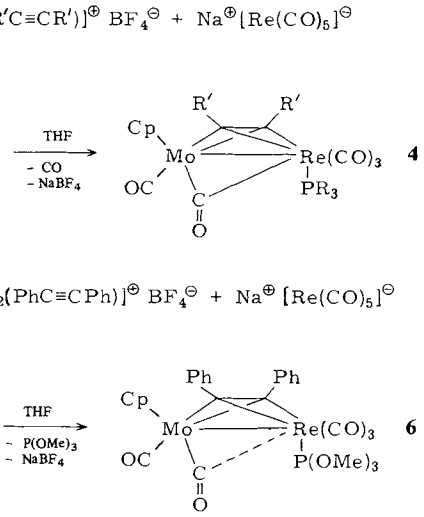


Dedicated to Professor Marianne Baudler on the occasion of her 65th birthday

The nucleophilic addition of carbonyl metalates to coordinated olefins (e.g., ethylene, butadiene) results in the formation of binuclear hydrocarbon-bridged complexes,[1] for example, of type **1**.

1

We have found, furthermore, that organometallic nucleophiles such as $Re(CO)_5^{\ominus}$ add to the coordinated alkyne of cationic molybdenum complexes with formation of dimetallatetrahedranes of type **2**.



2

The addition of organic nucleophiles to cationic alkyne complexes was reported earlier.[2]

The dimetallatetrahedranes **4** and **6** are obtained by reaction of **3**[3] and **5**,[3] respectively, according to Scheme 1.

The alkyne functions as a 4-electron donor in the educts **3** and **5**;[4] this explains the formation of the μ-η^2,η^2-alkyne-bridged complexes **4** and **6**, respectively, in which each of the metal centers has a nobel-gas configuration.

Scheme 1. Cp = η^5-C_5H_5; THF = tetrahydrofuran.

	PR_3	R'CCR'		PR_3	R'CCR'
4a	PPh_3	MeCCMe	**4d**	PEt_3	PhCCPh
4b	PPh_3	MeCCPh	**4e**	PMe_2Ph	PhCCPh
4c	PPh_3	PhCCPh	**4f**	PPh_3	MeCC*n*Pr

The migration of the PR_3 ligand from the Mo to the Re atom occurs for steric reasons. The structures of the compounds **4a** and **6** are shown in Figures 1 and 2.

The known dimetallatetrahedranes with two different metals, $NiCoC_2$,[5] $NiCrC_2$, $NiMoC_2$, $NiWC_2$,[6] and $NiFeC_2$[7], have been obtained from neutral carbonyl complexes and alkynes, along with other products, or, surprisingly, from alkylidyne complexes.[8] The type of reaction presented here, on the other hand, is, to the best of our knowledge, the first *directed* synthesis of dimetallatetrahe-

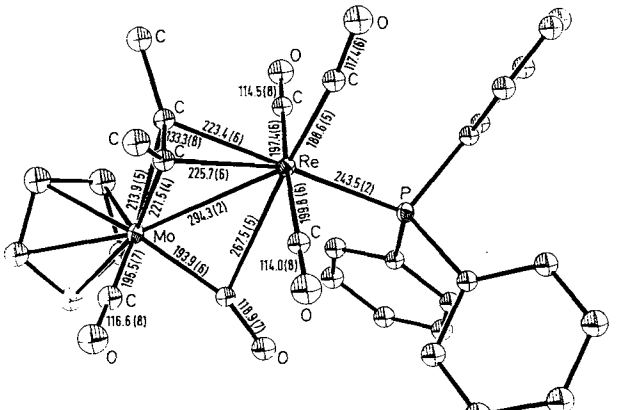


Fig. 1. Molecular structure of **4a** at −50 °C in the crystal, 20% probability level (H atoms omitted), interatomic distances [pm]. $P\bar{1}$, $a=852.4(2)$, $b=1160.2(3)$, $c=1605.0(4)$ pm, $\alpha=100.02(2)$, $\beta=104.76(2)$, $\gamma=100.88(2)°$, $V=1.4655(6)$ nm^3, $Z=2$. $\lambda(Mo_{K\alpha})=71.069$ pm; ω scan, $\Delta\omega=1.6°$, $4\leq\dot{\omega}\leq29.3°$ min^{-1}; $4°\leq2\theta\leq50°$; 10013 measured, 5120 unique reflections, of which 4904 were observed ($I\geq2\sigma(I)$), 131 parameters. The absorption ($\mu=46.9$ cm^{-1}) was corrected (crystal size $0.2\times0.1\times0.35$ mm^3, elipsoid, 250 measured values); $R=0.031$, $R_w=0.033$, $w=(\sigma^2(F_0)+0.0001\,F_0^2)^{-1}$. The hydrogen atoms are placed at calculated positons; the C_5H_5 and C_6H_5 rings were treated as regular rigid groups. Mo, Re, and P were anisotropically refined [13].

The absorption ($\mu=49.0$ cm^{-1}) was corrected (crystal size $0.45\times0.4\times0.3$ mm^3); $R=0.112$, $R_w=0.131$, $w=(\sigma^2(F_o)+0.001\,F_o^2)^{-1}$. One of two crystallographically independent molecules is shown; in the other molecule, the two methoxy groups are disordered. For further details, see the caption to Figure 1 [13].

dranes of this kind.[9] The use of unsymmetrical alkynes affords intrinsically chiral tetrahedranes such as **4b** and **4f**. Numerous chiral dimetalla-[5,6,10] and trimetallatetrahedranes[11] are known; in some cases, it has been possible to separate the enantiomers.[10,11]

As revealed by the ^{1}H-NMR (Table 1) and ^{31}P-NMR data, **4a**, **b**, **c** are formed as mixtures of configurationally stable diastereomers; the Mo and Re atoms are asymmetric.

Table 1. ^{1}H-NMR data for **4** and **6** in CD_2Cl_2 (int. TMS) and IR data [$\tilde{\nu}$ (CO) bands] for **4** and **6** in CH_2Cl_2 (in cm^{-1}).

4a: $\delta=7.23$–7.46 (m, 15H, 3Ph), α isomer: $\delta=5.24$ (s, 5H, Cp), 2.82 (s, 6H, Me), β isomer: $\delta=5.20$ (s, 5H, Cp), 2.73 (s, 6H, Me); α: β ≈ 10.—**4b**: $\delta=7.23$–7.38 (m, 20H, 4Ph), α isomer: $\delta=5.36$ (s, 5H, Cp), 3.07 (s, 3H, Me), β isomer: $\delta=5.27$ (s, 5H, Cp), 2.91 (s, 3H, Me) α:β ≈ 10.—**4c**: $\delta=7.28$–7.57 (m, 25H, 5Ph), α isomer: $\delta=5.47$ (s, 5H, Cp), β isomer: $\delta=5.34$ (s, 5H, Cp); α:β ≈ 10.—**4d**: $\delta=7.21$–7.29 (m, 10H, 2Ph), 5.25 (s, 5H, Cp), 2.03 (q, 6H, $3CH_2CH_3$), 1.01 (9H, $3CH_2CH_3$).—**4e**: $\delta=7.21$–7.36 (m, 15H, 3Ph), 5.26 (s, 5H, Cp), 2.02 (d, 6H, $2CH_3$, $^2J_{H,P}=9$ Hz).—**4f**: $\delta=7.27$–7.55 (m, 15H, 3Ph), 5.33 (s, 5H, Cp), 3.04 (s, br, 3H, Me), 2.84–3.17 (m, 2H, CH_2–C_2H_5), 1.43–1.79 (m, 2H, CH_2–CH_3), 0.96–1.16 (m, 3H, $(CH_2)_2$–CH_3).—**6**: $\delta=7.2$–7.32 (m, 10H, 2Ph), 5.26 (s, 5H, Cp), 3.61 (d, 9H, 3Me).
4a: $\tilde{\nu}=2060$ w, 2037 m, 2020 vw, sh, 1992 m, 1960 vs, 1898 s, br, 1756 m, br.—**4b**: $\tilde{\nu}=2084$ w, 2044 m, 2027 w, 2003 m, 1970 vs, 1928 s, 1902 s, 1770 m, br.—**4c**: $\tilde{\nu}=2083$ w, 2043 m, sh, 2025 m, 2003 m, 1973 vs, 1934 m, 1900 m, 1770 m.—**4d**: $\tilde{\nu}=2104$ vw, 2039 m, 2000 w, 1968 vs, 1925 m, 1893 s, 1747 m.—**4e**: $\tilde{\nu}=2083$ vw, 2041 m, 2029 w, sh, 1967 vs, 1905 s, br, 1738 m.—**4f**: $\tilde{\nu}=2079$ w, 2037 m, 2025 w, sh, 1989 m, 1958 vs, 1900 s, br, 1755 m.—**6**: $\tilde{\nu}=2114$ w, 2026 s, sh, 2012 s, 1976 vs, 1935 m, 1900 s, 1848 m, sh

The Mo–Re distance in **4a** and **6** is comparable to that in $[MoRe(CO)_3Cp_3]$[12] (296 pm). As expected,[9] the CC bond of the μ,η^2,η^2-alkyne in **4a** and **6** is lengthened to 136 pm, compared with the CC bond of an alkyne that is only coordinated to *one* metal center (ca. 130 pm), and lies orthogonally above the Mo–Re bond. Like $[Cp_2NiMo(CO)_2(\mu\text{-}\eta^2,\eta^2\text{-RCCR}]$,[5b,6] **4a** and **6** contain a semibridging carbonyl group [∢Mo-C-O: **4a** 160.6(4), **6** 166(2)°], which absorbs in the IR spectrum at 1756 and 1848 cm^{-1}, respectively (Table 1).

Experimental Procedure

All reactions were carried out under argon with carefully dried solvents.

4a: The orange solution (4 mL THF, −30 °C) of $NaRe(CO)_5$, obtained by reaction of 230 mg (0.35 mmol) of $Re_2(CO)_{10}$ with sodium amalgam, was added to a violet suspension of **3a** [3] (250 mg, 0.42 mmol) in 3 mL of THF (−30 °C). After 15 min, the solvent was removed from the brownish yellow suspension and the residue ($NaBF_4$) was digested with 5 mL of CH_2Cl_2. After centrifugation, the mother liquor was decanted and the residue was washed three times with 5 mL of CH_2Cl_2. The combined CH_2Cl_2 solutions were concentrated to 3 mL (vacuum) and a layer of Et_2O (10 mL) was added. The yellow precipitate of **4a** was centrifuged off, washed three times with 5 mL of cold Et_2O, and dried under high vacuum for several hours; yield 230 mg (68%), decomposition above 163 °C.—The yellow complexes **4b**–**4f** and **6** were obtained analogously in yields of 60 to 85%.

Pd^{II}-Catalyzed Regioselective Arylchlorination and Oxyarylation of Unsaturated Alcohols

By *Yoshinao Tamaru, Makoto Hojo, Hideyuki Higashimura,* and *Zen-ichi Yoshida**

Palladium-catalyzed arylation of olefins (Heck reaction)[1] is of great value, provided that the elimination and addition reactions of the hydridopalladium species HPdX can be regioselectively terminated. Arylation of norbornene[2] (no elimination of HPdX, since a strained olefin

Yoshida, Kyoto 606 (Japan)

endo methylene carbon atom does not bear the hydrogen atom *syn* to the Pd–C bond.[8] The tetrahydropyrans are presumably derived from **8** directly since **3** undergoes intramolecular ether formation very sluggishly under rather drastic conditions (e.g., **2f** was isolated in only 25% yield by treatment of **3f** with NaH, nBu$_4$N$^{\oplus}$I$^{\ominus}$ in refluxing THF for 10 h). This suggestion is further supported by the observation that the *trans*-2-(*p*-methoxyphenyl)-3-methyltetrahydropyrans **2g** and **2h** (reactions 8 and 9, respectively) are formed stereospecifically, whereas 6-chloro-2,5-dimethyl-6-phenyl-2-hexanol **3i** (reaction 10) is obtained as a 1:1 diastereomeric mixture. The stereospecific formation of **2g** and **2h** can be explained in one of two ways: either one of the two diastereomers **8** ($R^1 = CH_3$) which equilibrate via **7**, cyclizes to form the *trans* isomer **2g** or **2h** or

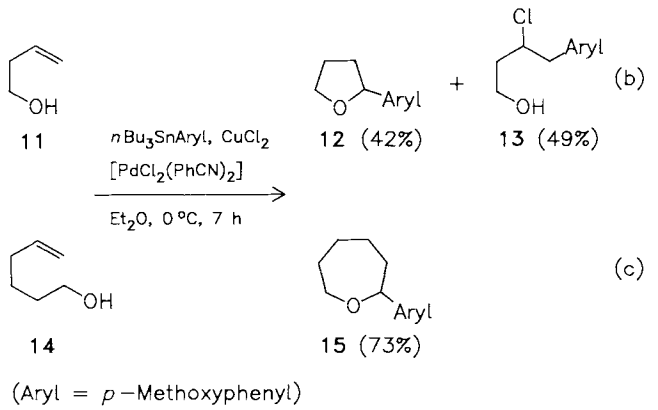
would thereby be formed) and of allylic alcohols[3] (formation of geminal hydroxypalladium complexes[4] or enols and thus carbonyl compounds) are typical examples. Here we describe a new type of regioselective termination of such reactions.

4-Penten-1-ols **1** [Eq. (a)] react, irrespective of their pattern of substitution (Table 1), with tri-*n*-butyl(*p*-methoxyphenyl)stannane (1.3–1.5 equivalents) and $CuCl_2$ (3 equivalents) in the presence of a catalytic amount of bis(benzonitrile)palladium(II) chloride (0.05 equivalents) to give 2-(*p*-methoxyphenyl)tetrahydropyrans **2** as the sole products (reactions 1, 3–5, 8, 9). The reaction of **1** with tri-*n*-butyl(phenyl)stannane, on the other hand, generally gives rise to two types of products (reactions 2, 6, 10): 1,1-difunctionalized products (**2** and **3**) and 1,3-difunctionalized products (**4**).[5,6] Phenylmercuric chloride (reaction 7) reacts analogously. The complete absence of 1,2-arylchlorination products contrasts sharply with the results of the Heck reaction (PhHgCl, Li_2PdCl_4, $CuCl_2$, 90% AcOH).[7] Indeed, under our reaction conditions ([$PdCl_2(PhCN)_2$], $CuCl_2$, ether), 1-aryl-1-chlorooctane was obtained from 1-octene almost exclusively, irrespective of the arylation agent (n-Bu$_3$SnPh, n-Bu$_3$Sn (*p*-MeOC$_6$H$_4$), PhHgCl).



The above regioselectivity may be rationalized according to Scheme 1. The primary adduct **5** equilibrates with intermediates **8** and **10** via a series of eliminations (to give **7** and **9**, respectively) and additions of HPdX. Further equilibration to form eventually an intermediate with the Pd atom in the α position to the hydroxyl group is presumably suppressed, because in the cyclic intermediate **10** the

Scheme 1. Postulated mechanism of the selective 1,1- and 1,3-difunctionalization of 4-penten-1-ols **1**.

both diastereomers react selectively, one with inversion and the other with retention of configuration.[9]

The difference in regioselectivity (1,1- and 1,3-arylchlorination in our system vs. 1,2-arylchlorination in the Heck reaction) may stem from the different polarities of the reaction media. In ether, the intermediate **5** is too stable to undergo a heterolytic cleavage of the Pd–C bond to form **6**.[10] In view of the similarity of the Pd–C bonds of **5** and **10**, the transformation of **10** to **4** might also be slow; therefore, a high concentration of **10** is presumably responsible for the formation of **4**. Other unsaturated alcohols with chain lengths of one less or one more C atom react in a similar fashion [Eq. (b) and (c)].[11, 12]

(Aryl = *p*-Methoxyphenyl)

The detailed mechanism responsible for the regioselectivity, stereoselectivity, and partition among **2**, **3**, and **4** and the application of this reaction to systems involving other nucleophilic heteroatoms or C atoms in the molecule remain to be investigated.

[9] Several precedents indicate that O and N atoms react *intermolecularly* with inversion of configuration. To the best of our knowledge, the stereochemical outcome of the *intra*molecular substitution reactions is not yet known: J.-E. Bäckvall, *Acc. Chem. Res. 16* (1983) 335.

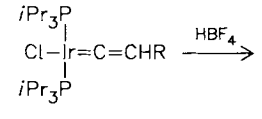
[10] A. Heumann, J.-E. Bäckvall, *Angew. Chem. 97* (1985) 228; *Angew. Chem. Int. Ed. Engl. 24* (1985) 207, and references cited therein.

[11] Formation of the 1,2-addition product **13** from **11** [Eq. (b)] appears to be an exception. These results, however, might be uniformly explained by selective chlorination of the C atom in the γ position to the hydroxyl group to form five-membered-ring intermediates analogous to **10**. Furthermore, it should be noted that the products shown in Equation (b), which are general for other homoallylic alcohols (unpublished), contrast with those obtained by the Heck arylation of homoallylic alcohols, namely, arylated ketones or aldehydes [3a].

[12] The 1,1-oxyarylation reported here, coupled with the Sharpless RuO_4-catalyzed oxidation of a phenyl to a carboxyl group, might be regarded as an equivalent to 1,1-oxycarbonylation of olefins: R. H. J. Carlsen, T. Katsuki, V. S. Martin, K. B. Sharpless, *J. Org. Chem. 46* (1981) 3936.

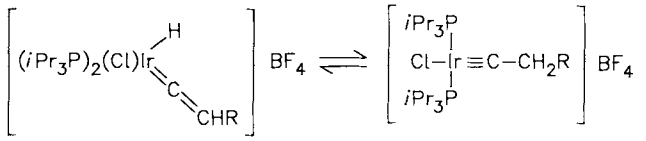
Carbyne-Iridium Complexes: Evidence for an Equilibrium between Alkenylidene(hydrido) and Carbyne Isomers

By *Arthur Höhn* and *Helmut Werner**



A number of mononuclear carbyne-metal complexes have been reported, particularly for the elements of the vanadium, chromium, and manganese subgroups.[1] A relatively new method of synthesis—as yet limited to octahedral complexes—has been reported which involves the conversion of an alkenylidene ligand into a carbyne ligand by addition of an electrophile.[2] MO calculations predict that the regioselectivity of the reaction, generally described by Equation (a) (where M is, e.g., $[(C_5H_5)Mo(P(OMe)_3)_2]^{\oplus}$ or $[W(CO)_{5-n}L_n]$), is governed by a significant charge localization on the β-C atom of the M=C=CHR unit, which should therefore undergo electrophilic attack.[3] We have now found that this pattern of reactivity does not hold true for square-planar alkenylidene-iridium complexes; instead, these complexes—at least for $E^{\oplus}=H^{\oplus}$—behave similarly to their carbonyl analogues and undergo electrophilic addition at the metal.

$$M{=}C{=}CHR \xrightarrow{E^{\oplus}} [M{\equiv}C{-}CH(E)R]^{\oplus} \qquad (a)$$

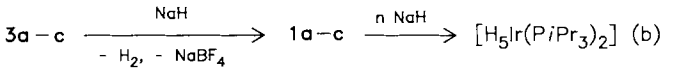


Treatment of a solution of **1a–c**[4] with HBF_4 in ether results in spontaneous formation of an orange-yellow precipitate.[5a] The ^{1}H-NMR spectrum, recorded immediately after dissolving the product obtained from **1c** in CD_3NO_2, shows a triplet at $\delta = -23.48$ ($J_{PH} = 13.2$ Hz), which is typical of a hydrido–metal bond. After 30 seconds (at room temperature), this signal, which we assign to compound **2c** has disappeared. The spectrum now corresponds to that expected for the carbyne complex **3c**.[5b] In the case of the corresponding compounds obtained from **1a** and **1b**,[5a] the ^{1}H-NMR spectra in either CD_3NO_2 or CH_3NO_2 showed no signal at high field. Nevertheless, we assume that an alkenylidene(hydrido) complex (**2a**, **b**) is also initially formed, because a characteristic band for an Ir–H stretching frequency (at ca. 2250 cm^{-1}) and a band for a C=C stretching frequency (at ca. 1640 cm^{-1}) are observed

[*] Prof. Dr. H. Werner, Dipl.-Chem. A. Höhn
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

in the IR spectra of the initially obtained products for both R=Ph and R=H, Me.[6] **2a, b** appear to be very labile in solution and smoothly rearrange by a 1,3-hydride shift to form the isomers **3a** and **3b**, respectively.

1a–c



2a–c **3a–c**

a, R = H; b, R = Me; c, R = Ph

The IR spectra of the solid products obtained from nitromethane solutions of **3** after removal of the solvent surprisingly also show the characteristic bands of **2**. This indicates that an *equilibrium* exists between the cationic alkenylidene(hydrido) complexes and the carbyne complexes, which in solution (CH_3NO_2) almost completely lies on the side of the carbyne complex. By removing the solvent, the equilibrium is shifted toward the alkenylidene(hydrido) isomers **2**, which precipitate together with **3**.

The transformation of **1** to **3** is *reversible*. Upon addition of NaH to a suspension of **3a**, **3b**, or **3c** in benzene, smooth evolution of H_2 begins and is complete after ca. 10 min [Eq. (b)]. From the intensely colored (red for **1a, b** and violet for **1c**) solutions, the alkenylidene complexes **1**[4] can be isolated in nearly quantitative yield. If an excess of NaH is used and the reaction mixture stirred for a longer period of time, compounds **1a–c** further react to give the pentahydrido complex $[H_5Ir(PiPr_3)_2]$ [Eq. (b)],[7] which is also obtained from **1a–c** and other hydride sources.[8] Deprotonation of **3** to form **1** also occurs with NaOMe in methanol or with MeLi in ether but these reactions are accompanied by decomposition.

Two important conclusions emerge from these studies: (1) It has been shown for the first time that alkenylidene metal complexes do not always react with electrophiles by attack at the β-C atom of the alkenylidene ligand. In contrast to octahedral complexes $[L_nM{=}C{=}CHR]$,[2] the corresponding square-planar iridium complexes behave—at least toward Brønsted acids—as Vaska-type complexes; the metal basicity dominates.[9] (2) The reactivity of the square-planar carbyne complexes **3** differs considerably from that of comparable Fischer-type carbyne complexes. Complexes **3** do not react with nucleophiles such as $MeO^{\ominus}$ by nucleophilic addition at the carbyne C atom (with formation of a carbene ligand);[1] instead, they undergo deprotonation and regeneration of the alkenylidene complexes **1** used as starting materials for the preparation of **3**. Whether soft Lewis bases behave in a similar way remains to be investigated.

Dimeric Chloro[dicyclopentadienyl(dimethyl)silyl]-ytterbium(III), a Rare Example of a Complex Involving Metal-Bridging instead of Chelating $[Me_2Si(\eta^5\text{-}C_5H_4)_2]$ Ligands**

By *Nils Höck, Wolfgang Oroschin, Gino Paolucci,** and *R. Dieter Fischer**

The ligands $[Me_2Si(\eta^5\text{-}C_5R_4)_2]^{2\ominus}$ (R = H, Me) are known to bond to early d-transition,[1] lanthanoid,[2] and actinoid[3] metals exclusively in a metal-chelating fashion. They are, however, metal-bridging in, e.g., the dimeric iron complexes **1**[4] and **2**.[5] We report here on the synthesis and the structure of the first correspondingly metal-bridged lanthanoid(III) complex **3**.

$[Fe_2L_2(\mu\text{-}CO)_2\{\mu\text{-}Me_2Si(\eta^5\text{-}C_5H_4)_2\}]$

1, L = CO; **2**, $L_2=(Ph_2P)_2(CH_2)_n$, n = 1–3

$[\{Yb(\mu\text{-}Cl)[\mu\text{-}Me_2Si(\eta^5\text{-}C_5H_4)_2]\}_2]$ **3**

[*] Prof. Dr. R. D. Fischer, Dipl.-Chem. N. Höck, Dr. W. Oroschin, Institut für Anorganische und Angewandte Chemie der Universität Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

Prof. G. Paolucci

Calla Large S. Marta 2137, I-30123 Venice (Italy)

[**] We thank the C.N.R. Institute (Padova, Italy) for allowing us to carry out the mass spectrometric measurements and Prof. *P. Traldi* for helpful discussions.

Reaction of $YbCl_3$ with $Na_2[Me_2Si(C_5H_4)_2]$ (1:1) in tetrahydrofuran (THF) affords primarily a THF-containing mixture of products. From its burgundy-red, saturated solution in toluene/cyclohexane, uniformly needle-shaped red crystals precipitate slowly at $-30°C$. [6] The single-crystal X-ray structure analysis[7] proves selective crystallization of the THF-free dimer, **3** (cf. Fig. 1); its isomer with chelating dicyclopentadienylsilyl ligands was not observed.

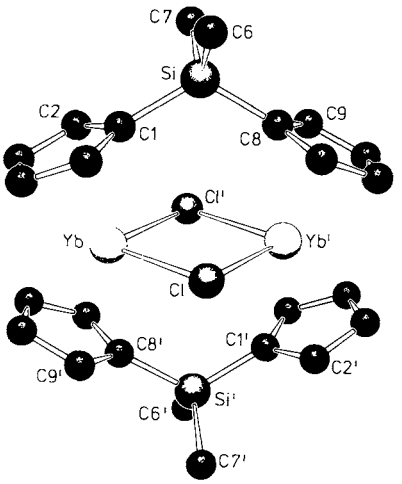

Fig. 1. SCHAKAL plot of the crystal structure of **3**. Selected angles: C(Me)-Si-C(Me) 106.6°; C(ring)-Si-C(Me) 111.4°; Cent-Yb-Cent' 135.3° (Cent and Cent': midpoints of unlinked C_5H_4Si rings); see also [10], [11], and text.

The Yb_2Cl_2 skeleton of **3** is practically a square (angles Cl-Yb-Cl' 89.3°, Yb-Cl-Yb' 90.8°), the Yb-Yb' distance (3.750 Å) being significantly shorter than in two $[\{Yb(\mu\text{-}Cl)Cp'_2\}_2]$ systems[8] with a rhombic Yb_2Cl_2 arrangement. Other remarkable features are the unusually widened C(ring)-Si-C(ring') angles of 118.7° (**1**: 105.7°[4b]), the Si-C(ring)-Cent angles (Cent: midpoint of Cp ring) of $174\pm0.5°$ which make the Si atoms point away from their Yb atoms, and a location of the C(ring)-Si-C(ring') linkages somewhat outside the $Yb_2(Cent)_4$ plane[10], so that this plane cannot function as a second mirror[9] plane of **3**. The Yb-C, Yb-Cl, and C-C distances in **3** correspond to those found in related complexes.[8]

Although the yield of pure **3** from the initially formed mixture of products[6] was rather poor, mass spectrometric findings[12, 13] indicate that **3** is preferentially formed in the reaction of $YbCl_3$ and $Na_2[Me_2Si(C_5H_4)_2]$ in toluene.[14] In contrast to the mass spectra of some exclusively Cl-bridged dimers, $[\{Yb(\mu\text{-}Cl)Cp'_2\}_2]$,[15] where the signals of mononuclear fragments ($m/z<450$) predominate,[16] the mass spectrum of **3**, prepared in toluene, exhibits numerous signals with $m/z>600$, but practically no signal in the region of mononuclear fragments. The B/E scan[17] of the ion with $m/z=790$ confirms its assignment to the most intense $M^{\oplus}$ signal ($M^{\oplus}$ with two ^{35}Cl atoms).[18] From this $M^{\oplus}$, the two binuclear primary fragments $M^{\oplus}-CH_3$ (m/z 775) and $M^{\oplus}-{}^{35}Cl_2$ (m/z 720) originate,[19] but none of the likewise conceivable fragments, $M^{\oplus}-{}^{35}Cl$, $M^{\oplus}/2$, $M^{\oplus}/2-CH_3$, and $M^{\oplus}/2-{}^{35}Cl$, could be observed.

Despite its apparently weak tendency to undergo thermal gas-phase isomerization, **3** readily adds $[D_8]THF$ in toluene (IR detection) — presumably accompanied by skeletal rearrangements.

[6] *Experimental procedure:* **3**: $YbCl_3$ (1.0 g, 3.57 mmol) and $Na_2[Me_2Si(C_5H_4)_2]$ (0.83 g, 3.57 mmol) were stirred in 45 mL of THF for ca. 3 h at −50°C. After removal of the solvent at room temperature, the residue was dissolved in toluene (60 mL). After filtration and removal of the solvent from the filtrate, an oily, red residue was obtained, which, after repeated "conditioning" with small amounts of *n*-hexane and drying under oil-pump vacuum, afforded a burgundy-red powder. Crude yield: ca. 50%. Recrystallization from toluene/cyclohexane (5:1) gave **3** in the form of red crystalline needles (dec. in high vacuum above 150°C).

[7] SYNTEX $P2_1$ four-circle diffractometer ($Mo_{K\alpha}$, graphite monochromator, $\lambda=0.71969$), crystal data for **3** (25°C, $0.1\times0.1\times0.1$ mm^3): monoclinic, space group $C2/c$, $a=20.15(1)$, $b=8.29(1)$, $c=15.96(3)$ Å, $\beta=108.0(1)°$, $Z=4$, $\rho_{calcd}=2.07$ g·cm^{-3}, range of measurement: $5.0\leq2\theta\leq50°$; 1667 reflections with $|F|>4\,\sigma(F_0)$, no absorption correction ($\mu=76.24$ cm^{-1}), SHELX 76, anisotropic temperature factors (H positions not determined); $R=0.047$, $R_w=0.039$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51886, the names of the authors, and the journal citation.

[8] a) $Cp'=C_5H_4Me$: $Yb\cdots Yb'=3.979$ Å (E. C. Baker, L. D. Brown, K. N. Raymond, *Inorg. Chem. 14* (1975) 1376); b) $Cp'=C_5H_3(SiMe_3)_2$: $Yb\cdots Yb'=4.06$ Å (M. F. Lappert, A. Singh, J. L. Atwood, W. E. Hunter, *J. Chem. Soc. Chem. Commun. 1981*, 1191).

[9] The only mirror plane of **3** coincides with the Yb_2Si_2 plane (point group C_{2h}).

[10] For example, Si-Cl ≠ Si-Cl' (4.169(7) and 3.890(9) Å, respectively, and Cl-Cl ≠ Cl-Cl' (3.65(1) and 3.55(1) Å, respectively); however, Si-Yb ≈ Si-Yb' (4.052(6) and 4.035(6) Å, respectively).—For the same reason, the $Fe_2(Cent)_2$ plane in **1** cannot be a mirror plane of this molecule [4a].

[11] $\overline{Yb\text{-}C}=2.617$, $(Yb\text{-}C)_{min}=2.572$, $(Yb\text{-}C)_{max}=2.647$ Å; $Yb\text{-}Cl=2.636$ Å; $(C\text{-}C)_{min}=1.411$, $(C\text{-}C)_{max}=1.452$ Å; C(ring)-Si = 1.892, C(Me)-Si = 1.905 Å.

[12] Electron impact ionization, 70 eV, source: 200°C, sample: 100°C, direct inlet technique, resolution (based on the "10% minimum") 20000.

[13] X-ray powder diffraction patterns of **3**, prepared in toluene, could not be used for identification because of the poor scattering ability of **3**.

[14] *Experimental procedure:* $YbCl_3$ (1.0 g, 3.57 mmol) and $Na_2[Me_2Si(C_5H_4)_2]$ (0.83 g, 3.57 mmol) were allowed to react in 20 mL of toluene at room temperature. After the reaction mixture had been stirred for 24 h, it was filtered and the solvent was removed under vacuum; the remaining wine-red solid (crude yield: 60%) was dried for 3 h under high vacuum. Elemental analysis: ($C_{12}H_{14}ClSiYb$): calcd: C 36.50, H 3.57%; found: C 36.3, H 3.6%.

[15] a) $Cp'=C_5H_5$: J. Müller, *Chem. Ber. 102* (1969) 152; b) $Cp'=C_5H_3(SiMe_3)_2$, cf. [8b]; c) $Cp'=C_5H_4SiMe_3$: M. F. Lappert, P. I. W. Yarrow, J. L. Atwood, R. Shakir, J. Holton, *J. Chem. Soc. Chem. Commun. 1980*, 987; prepared from $YbCl_3$ and $K[C_5H_4SiMe_3]$ in toluene for the mass spectrometric investigations. We thank *M. Adam* for a sample of the substance.

[16] Intense signals of $[\{Yb(C_5H_4SiMe_3)_2(\mu\text{-}Cl)\}_2]$: $(M^{\oplus}/2-CH_4)$, $(M^{\oplus}/2)$, $(M^{\oplus}/2-Cl)$.

A Radical Anion Salt of 2,5-Dimethyl-*N,N'*-dicyanoquinonediimine with Extremely High Electrical Conductivity**

By *Alexander Aumüller, Peter Erk, Gerhard Klebe, Siegfried Hünig,* Jost Ulrich von Schütz,* and *Hans-Peter Werner*

Tetracyanoquinonedimethane (TCNQ) and its 2,5-dimethyl derivative (2,5-DM-TCNQ) have hitherto played the most important role as electron acceptors for "organic metals".[1] In 2,6- or higher substituted TCNQs and naphthalene derivatives the rigid Y-shaped $=C(CN)_2$ group is tilted from the plane of the molecule to such an extent that the requisite stacking arrangement of the acceptor in the crystal is forestalled.[2] Furthermore, TCNQs are only obtainable via tedious multistep syntheses.[3] In contrast, a new class of acceptors, the *N,N'*-dicyanoquinonediimines (DCNQIs) with various substituents, are accessible in one step from the corresponding quinones.[4] Owing to the small angle formed by the =N—CN group in this class of compounds the planarity of the molecule remains virtually unaltered, even upon tetrasubstitution.[5] This is the reason, e.g., why *syn-N,N'*-dicyano-1,4-naphthoquinonediimine reacts with tetrathiafulvalene to give a charge-transfer (CT) complex that exhibits high electrical conductivity.[6] Herein we describe a radical anion salt with metallic character derived from DCNQI.

When acetonitrile solutions of 2,5-dimethyl-*N,N'*-dicyanoquinonediimine (2,5-DM-DCNQI) and copper(I) iodide are combined, a black crystalline powder of the composition $(2,5\text{-DM-DCNQI})_2Cu$[7] precipitates, which has a powder conductivity of 0.4 Scm^{-1}. Presumably the contact resistances between the crystallite surfaces limits the conductivity.

Single crystals of this composition are obtainable by electrolysis of 2,5-DM-DCNQI and copper(II) bromide in acetonitrile.[8] They already show a conductivity of 800 S cm^{-1} at 295 K, which *continually increases* as the temperature is lowered to 1.3 K (Fig. 1).[9] This behavior clearly demonstrates the metallic character of the salt, which is not interrupted by a phase transition (Peierls distortion) at any temperature.[10] Very pure crystals show a conductivity of 500000 S cm^{-1} at 3.5 K. Radical anions with such extremely high conductivities were hitherto unknown. The analogous $(TCNQ)_2Cu$ salt is only a semiconductor, whose conductivity drops from 1.5×10^{-5} S cm^{-1} at 530 K to 2×10^{-6} S cm^{-1} at 290 K.[11]

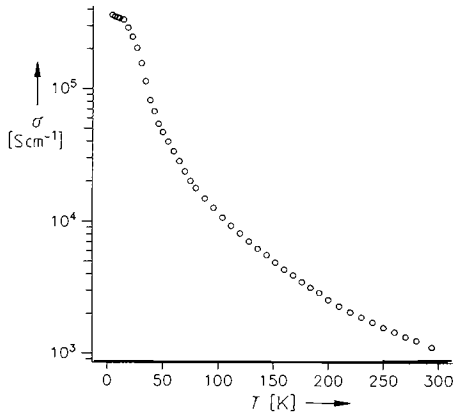

Fig. 1. Temperature dependence of the electrical conductivity σ of $(2,5\text{-DM-DCNQI})_2Cu$ single crystals [9].

As shown by a projection of the crystal structure onto the *a, b* plane, the copper atoms are coordinated in a slightly distorted tetrahedral fashion to the N-atoms of four *N*-cyano groups, with the Cu-N distances being almost equal (Fig. 2). A comparison with the stable tetrahedral complex $[(CH_3CN)_4Cu]ClO_4$[12] reveals that the bonding forces between the partners are almost the same in both cases (Table 1).

Table 1. Space groups, N-Cu distances, and N-Cu-N angles in the complexes $[(CH_3CN)_4Cu]ClO_4$ and $(2,5\text{-DM-DCNQI})_2Cu$.

Compound	Space group	Bond length N-Cu [pm]	Bond angle N-Cu-N [°]
$(2,5\text{-DM-DCNQI})_2Cu$	$I4_1$	198—199	101—126
$[(CH_3CN)_4Cu)ClO_4$ [12]	$Pn2_1a$	195—202	106—113

[**] This work was supported by the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen.

In the crystals of $(2,5\text{-DM-DCNQI})_2Cu$ the copper ions are arranged in chains, each surrounded by four stacks of the dicyanoquinonediimine (Fig. 3).[13] An electronic con-

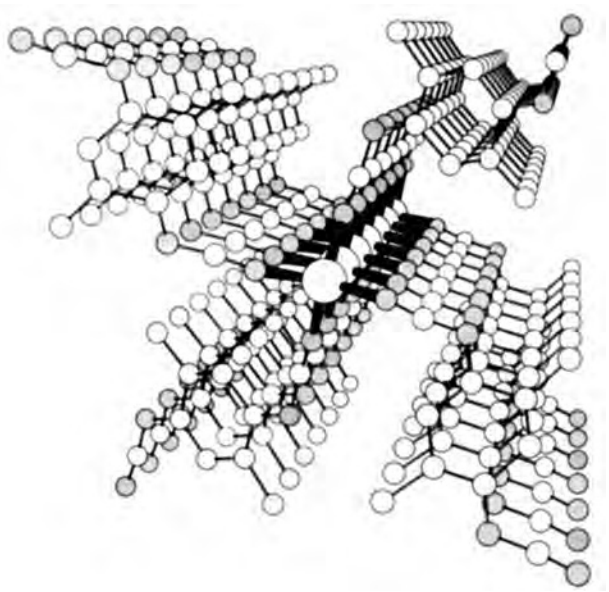

Fig. 3. Perspective view of the crystal structure along the c axis; the chain of copper atoms is surrounded by four stacks of 2,5-DM-DCNQI molecules (H atoms not shown). ○ = Cu, ○ = C, ○ = N.

ductivity along the chain of copper ions is most unlikely because of the large Cu-Cu distance (Cu-Cu 388 pm, Cu(metal) 256 pm). This could more likely take place along the stacks of the π-electron systems. The copper ions apparently take on the function of a conductivity bridge between the individual stacks. The fact that no ESR signal can be recorded (very large broadening) and the high conductivity with no phase transition both point to a multidimensional conductor.[14]

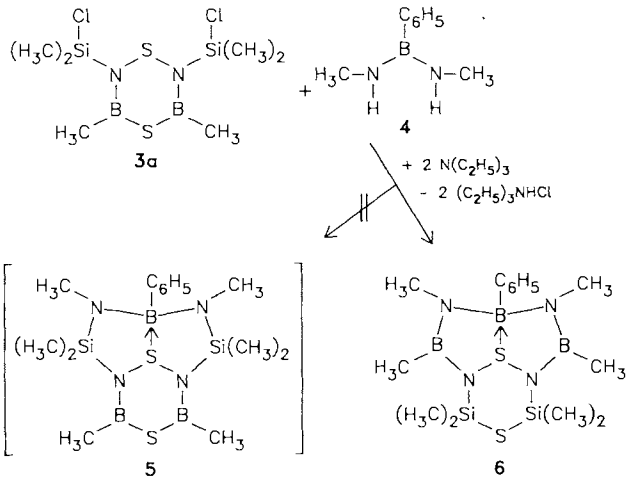
Synthesis and Molecular and Crystal Structure of a New Tricyclic $B_3N_4S_2Si_2$ System**



By *Carl Habben, Anton Meller, Mathias Noltemeyer*, and *George M. Sheldrick**

Acyclic sulfur diimides **1** undergo reaction with 1,2,4,3,5-trithiadiborolanes **2** to give the cyclic 1,4,2,6,3,5-dithiadiazadiborinane system **3**.[1,2]

1 2 3

The difunctional 2,6-bis(chlorodimethylsilyl)-3,5-dimethyl derivative **3a** reacts with bis(methylamino)phenylborane **4** to give not the product **5**, as might have been expected, but rather the tricyclic system **6**,[3] the structure of which was established by X-ray crystallography. The structure **6** (and **5**) is favored by the coordination of sulfur to boron; it is unclear whether **6** is a rearrangement product of **5**.

3a **4** **5** **6**

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The molecule **6** contains two nearly planar systems (the two five-membered rings with $Si(CH_3)_2$ and methyl groups), which form an angle of 111.4° to each other. If the phenyl groups are excluded, the molecule has a mirror plane through C11, B1, S11, and S6 (see Fig. 1).

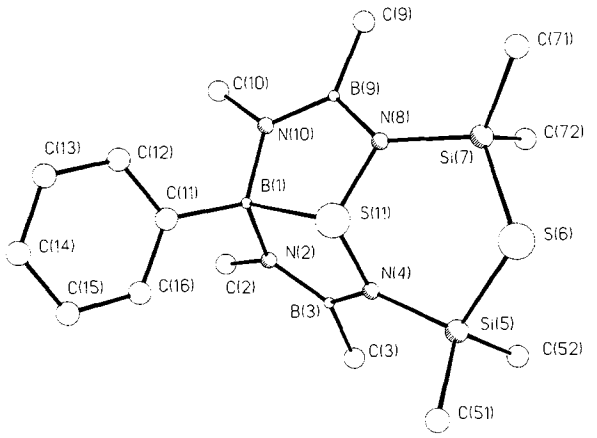

Fig. 1. Crystal structure of **6** (unsymmetrically numbered). Space group $P2_12_12_1$, $a = 715.4(1)$, $b = 1573.3(4)$, $c = 2017.0(5)$ pm, $V = 2.2702$ nm^3, $Z = 4$, $\mu(Mo_{K\alpha}) = 0.33$ mm^{-1}; $R_w = 0.046$, $R = 0.051$ for 1490 unique reflections with $F > 3\,\sigma(F)$; $Mo_{K\alpha}$ radiation, $2\theta_{max} = 45°$. Important bond lengths [pm]: B1-S11 204.4(8). S11-N4 168.1(5), S11-N8 167.8(5), B3-N4 147.6(9), B9-N8 148.1(9), N2-B3 140.0(9), N10-B9 139.2(9), B1-N2 152.4(9), B1-N10 152.4(9), N4-Si5 174.6(5), N8-Si7 176.3(5), Si5-S6 215.1(3), Si7-S6 214.6(3). — Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD 51938, the names of the authors, and the journal citation.

The B1–S11 distance (204.4 pm) is almost the longest so far found for tetracoordinated boron (186–207 pm[4]). Although the NS distances (167.8 and 168.1 pm) are shorter than those found in monocyclic compounds of type **3** (ca. 172 pm[1]), they are in good agreement with those in the bicyclic tetrasulfur hexanitrogen hexafluoroarsenates (168–169 pm[5]), which also contain three-coordinate sulfur. The BN bonds can be divided into three groups: single bonds between both N2 and N10 and the tetracoordinated B1 (152.4 pm); bonds having considerable double bond character when both atoms bear methyl substituents (139.2, 140.0 pm, compare 139–144 pm in borazines[6,7]); and the B3–N4 and B9–N8 bonds (147.6, 148.1 pm), which have intermediate lengths.

In the ^{1}H-NMR spectrum,[8] the methyl groups on the Si atoms give rise to two singlets; two types of $Si-CH_3$ groups are also apparent in the ^{13}C-NMR spectrum.[8] ^{11}B-NMR signals appear for three-coordinate boron[9] at $\delta = 35.7$ and for four-coordinate boron at $\delta = 13.7$ ($CDCl_3$/$BF_3 \cdot O(C_2H_5)_2$ ext., intensity ratio ca. 2:1; no changes in the chemical shifts or in the intensity ratios were observed at +60°C). The ^{14}N-NMR and ^{29}Si-NMR spectra show a broad singlet (^{14}N: $CDCl_3/H_3CNO_2$ ext., $\delta = -285.7$) and a sharp singlet (^{29}Si: $CDCl_3$/TMS int., $\delta = 19.39$), respectively. Compound **6** sublimes at 100°C and 2×10^{-3} mbar. Heating of **6** over several hours under argon in a sealed tube at 150°C results in partial decomposition. Protic solvents result in decomposition of **6** with the formation of H_2S.

Experimental Procedure

A mixture of **4** (1.90 g, 12.8 mmol) and triethylamine (5.18 g, 51 mmol), dissolved in 50 mL of CCl_4, was added to a solution of **3a** [2] (4.24 g, 12.8 mmol) in 150 mL of CCl_4. After 12 h of heating at reflux, the reaction mixture was filtered to separate the solvent, and **6** was sublimed at 100°C/2×10^{-3} mbar; colorless crystals, m.p. = 102°C, yield 33%.

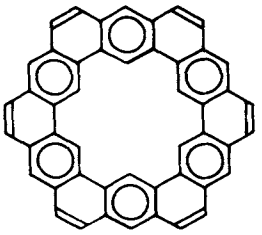
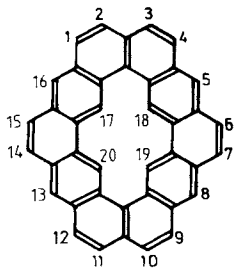
Cyclo[*d.e.d.e.e.d.e.d.e.e.*]decakisbenzene, a New Cycloarene**



By *Dirk J. H. Funhoff* and *Heinz A. Staab**

The only example known so far for the class of cycloarenes has been kekulene,[1] for which spectroscopic investigations and X-ray diffraction studies revealed a remarkably limited π-electron delocalization in the planar macrocyclic system (formula **1**).[2] Other cycloarenes, which are of interest with regard to their electronic structure, have not yet been prepared.[3,4] For instance, the attempt to synthesize cyclo[*d.e.d.e.e.d.e.d.e.e*]decakisbenzene **2**[5] by photocyclization of [2.2](3,10)benzo[*c*]phenanthrenophane-1,15-diene resulted only in ring closure on one side to give a helical system, the rigid structure of which presumably hinders the second ring closure to give **2**.[3] A modified synthetic strategy based on this assumption has now allowed us to prepare **2**, which contains the [14]annulene skeleton as the inner ring system and, as in the case of **1**, can be formulated with an outer and an inner [4n+2] π perimeter (**2a**).



The key reaction for the synthesis of **2** should be the double photocyclization of the partially hydrogenated [2.2](3,10)benzo[*c*]phenanthrenophanediene **3**, which would result in formation of the carbon skeleton of **2**; subsequent dehydrogenation should then give **2**. Compound **3** was obtained, starting from bis(4-chlorophenyl)chloromethane via the following 18-step route. The product (m.p. = 99–100°C; 70%)[6] obtained by reaction of the starting material with diethyl malonate (sodium hydride, dimethylformamide (DMF), 3 h, 100°C) was reduced with

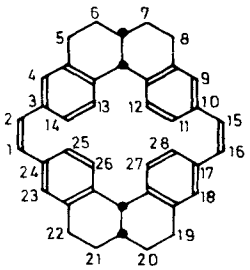
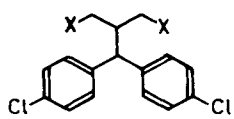
[**] Cycloarenes, a New Class of Aromatic Compounds, Part 5.—Part 4: [4].

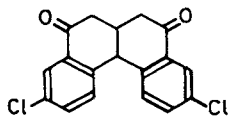
1



2

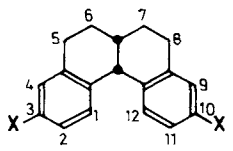


2a

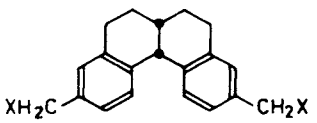


$LiAlH_4$ in tetrahydrofuran (THF) to give the diol **4** (m.p. = 118 °C)[6] in 78% yield; **4** was then converted, by reaction of the corresponding bis(methanesulfonate) **5**[6] (methanesulfonyl chloride, pyridine, −5 °C; m.p. = 143–144 °C; 89%) with potassium cyanide (DMF/water; 66%), into the dinitrile **6** (m.p. = 107–108 °C).[6] Hydrolysis (sodium hydroxide, ethanediol, 6 h, 160 °C; 90%) afforded the dicarboxylic acid **7** (m.p. = 118 °C),[6] which was cyclized with polyphosphoric acid to give 3,10-dichloro-5,8-dioxo-5,6,6a,7,8,12b-hexahydrobenzo[*c*]phenanthrene **8** (m.p. = 227–231 °C, dec.; *cis-trans* mixture 6a,12b-H)[6] in 90% yield.

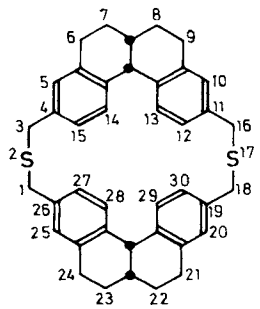
3



4: X = OH
5: X = OSO_2Me
6: X = CN
7: X = COOH



8



Reduction of **8** (red phosphorus, hydrogen iodide, glacial acetic acid, 5 d, reflux) gave a mixture of the *cis* compound **9** and its *trans* isomer (1:2, total yield 88%), which could be separated by crystallization (*cis*: m.p. = 138–139 °C; *trans*: m.p. = 151 °C).[6] When **8** was reduced and then heated with potassium hydroxide in ethanediol for 1 h at 160 °C, only the *cis* compound **9** was formed—as is the case for the Wolff-Kishner reduction of **8**. Compound **9** was converted into the dicyano compound **10** (m.p. = 181–183 °C)[6] by reaction with copper(I) cyanide in *N*-methyl-2-pyrrolidone (24 h, reflux; 78%); **10** reacted with hydrogen chloride in methanol/chloroform to give the dimethyl ester **11** (m.p. = 136–137 °C; 95%).[6] Reduction of **11** ($LiAlH_4$, THF; 93%) led to **13** (m.p. = 108–111 °C),[6] which was converted into the bis(bromomethyl) compound **14** (m.p. = 114–115 °C; 69%)[6] by treatment with hydrogen bromide/glacial acetic acid. Compound **14** is the first cyclization component required for the synthesis of the dithiaphane **17**. The double isothiuronium salt **15** (m.p. = 144 °C, dec.)[6], the second cyclization component, was obtained by treatment of **14** with thiourea (ethanol, 30 min, reflux; 84%).

9: X = Cl
10: X = CN
11: X = COOMe
12: X = CHO

13: X = OH
14: X = Br
15: X = $[SC(NH_2)_2]Br$
16: X = $[P(C_6H_5)_3]Br$

17

The cyclization was carried out by simultaneous addition of solutions of **14** in toluene and **15** in methanol to boiling methanol containing potassium hydroxide; a 30% yield of 6,7,7a,8,9,13b,21,22,22a,23,24,28b-dodecahydro-2,17-dithia[3.3](3,10)benzo[*c*]phenanthrenophane (m.p. = 267–269 °C, dec.)[6] was obtained. Only one of the two possible isomers was isolated, the assignment of which was not possible on the basis of the NMR spectra;[7] the X-ray structure analysis of the phanediene **3** obtained from this dithiaphane, however, showed that **17** must be present.

In order to synthesize **3**, compound **17** was converted into the 2,17-dimethyl-2,17-dithioniabis(fluorosulfonate) (m.p. = 189 °C, dec.) by reaction with methyl fluorosulfonate. The product then underwent rearrangement to give the carbocyclic 1,15- and 1,16-bis(methylthio)-substituted [2.2]phanes (m.p. = 161–175 °C, dec.; 96%)[6] upon treatment with potassium *tert*-butoxide in THF. Subsequent treatment with *m*-chloroperbenzoic acid in dichloromethane at −25 °C gave the double sulfoxide, which was pyrolyzed (sealed tube, 6 h, 170 °C, under argon atmosphere). [2.2](3,10)-5,6,6a,7,8,12b,19,20,20a,21,22,26b-dodecahydrobenzo[*c*]phenanthrenophane-1,15-diene **3** (m.p. = 226–230 °C)[6] was thereby obtained in 17% yield.

The synthesis of **3** was also attempted by double Wittig reaction (lithium hydroxide, dichloromethane/water[8]) of **12** (obtained from **13** with pyridinium chlorochromate, 55%)[9] with **16** (obtained from **14** with triphenylphos-

phane in DMF; 98%).[6] However, **3** was obtained in only 5% yield; in addition, the second possible isomer (m.p. = 295–302 °C, dec.)[6] was isolated in 2% yield.

The structure of **3** cannot be unequivocally established from the ^{1}H-NMR spectrum;[10] X-ray structure analysis, on the other hand, proved successful.[11] As revealed in Figure 1, the molecule is not strained; this was predicted from examination of models and force field calculations. In the crystal, the distance between the atom pairs C11/C28 and C14/C25 in the two *cis*-stilbene units is relatively short (342 pm); it is between these two pairs of atoms where bond formation is expected to occur photochemically.

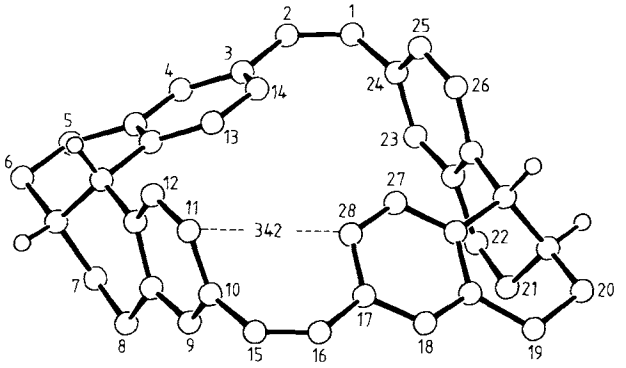


Fig. 1. Molecular model of **3** based on the X-ray structure analysis [11].

In order to carry out the photocyclization, **3** was irradiated in *n*-propylamine under argon for 6.5 h at −32 °C with a low-pressure mercury lamp; a mixture of various hydrogenated derivatives of **2** was obtained in 35% yield (after chromatography). Dehydrogenation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in *m*-xylene (54 h, 90 °C) afforded a 13% overall yield of **2** in the form of yellow crystals (m.p. > 330 °C, dec.). The mass spectrum exhibits the molecular ion peak *m/z* 500 as the base peak in addition to the peak of the multiply charged molecular ions [*m/z* 250 (M^{2+}, 15.5%), 166.7 (M^{3+}, 1.9) and 125 (M^{4+}, 7.0)]. The high-resolution mass spectrum confirms the composition (calcd 500.1565; found 500.1575). Of interest, moreover, is the $(M-4)^+$ peak (*m/z* 496, 13.6%; high-resolution spectrum: calcd 496.1252, found 496.1250); it apparently arises by cleavage of the four inner hydrogen atoms with transannular C–C bond formation.

The ^{1}H-NMR spectrum of **2** (360 MHz) was recorded at 150 °C in [D_2]1,2,4,5-tetrachlorobenzene. In accordance with the symmetry of **2**, only five signals of equal intensity are observed: $\delta = 8.11$ (s; 6,7,14,15-H), 8.11 (d, $J = 8.3$ Hz; 2,3,10,11-H), 8.29 (d, $J = 8.3$ Hz; 1,4,9,12-H), 8.65 (s; 5,8,13,16-H), and 9.56 (s; 17,18,19,20-H); the signals were assigned on the basis of NOE experiments. The low-field shift of the inner protons shows that, as in the case of kekulene, no significant diatropism of the macrocyclic system exists.

The UV spectrum is similar to the UV spectra of benzo[*c*]phenanthrene and pentaphene and is therefore in accord with the benzenoid character of **2**. The zero-field splitting parameter, $|D|$, determined from the phosphorescence emission by the ODMR method, is significantly smaller for **2** (0.0881 cm^{-1} in [D_2]1,2,4,5-tetrachlorobenzene, 1.3 K)[12] than for kekulene (0.10622 cm^{-1}). This indicates a less pronounced localization of sextets and double bonds than in kekulene. Indeed, it is possible to write more than one formula for **2** with the maximum number of possible sextets, whereas this is not so for kekulene in formula **1**. We hope to further clarify the electronic structure of **2** by X-ray structure analysis and by additional spectroscopic investigations.

An Isocyanide Radical as Complex Ligand**

By *Friedrich Seitz, Helmut Fischer,* Jürgen Riede, Thomas Schöttle,* and *Wolfgang Kaim*

Structurally, the $CNCR_2$ ligand in complexes of the type $[L_nM(CNCR_2)]^{\oplus}$ is unusually flexible. In the pentacarbonyl cations

$[(CO)_5M(CNCR_2)]^{\oplus}$ (M = W, Cr; compare **1** and **5**, respectively)

the M–C–N–C fragment is nearly linear;[1] these cations are best described as resonance hybrids of the structures **A** and **B**.

$$(CO)_5M{=}C{=}\overset{\oplus}{N}{=}CR_2 \quad \longleftrightarrow \quad (CO)_5M^{\ominus}{-}C{\equiv}\overset{\oplus}{N}{-}\overset{\oplus}{C}R_2$$
A **B**

$$[(CO)_5W{=}C{=}N{=}CR_2]^{\oplus}\,AlBr_4^{\ominus} \xrightarrow[-\ \text{"}AlBr_3\cdot THF\text{"}]{+\ THF} \begin{cases} \underset{\mathbf{2}}{trans\text{-}Br(CO)_4W{=}C{-}N{=}CR_2} + CO \\ + \\ \underset{\mathbf{3}}{(CO)_5W{-}C{\equiv}N{-}CR_2{-}CR_2{-}N{\equiv}C{-}W(CO)_5} + \ldots \end{cases}$$

1-$AlBr_4$

Increasing the back-bonding ability of the metal carbonyl fragment with M = W by exchange of the *trans* CO group for the weak π-donor $Br^{\ominus}$ results in a dramatic change in the bonding relationships. The $CNCR_2$ ligand of **2** is much more bent (C-N-C angle: 135.4° for CR_2 = 9-xanthenylidene = $C(C_6H_4)_2O$), and the W-C distance is typical for that of complexes with a formal W-C triple bond.[2]

The synthesis of **2** is accompanied by the formation of the binuclear diisocyanide complexes **3**, which are the products of a reductive dimerization of **1**. The product ratio **2**/**3** is strongly dependent on the reaction conditions—a preliminary indication for the involvement of paramagnetic intermediates. For R = mesityl, we have now been able to isolate and characterize such a radical intermediate.

7

R = 2,6-dimethylphenyl (mesityl)

The complex **5**-$AlBr_4$, which can be prepared from **4** and $AlBr_3$ in CH_2Cl_2,[3] reacts at room temperature in CH_2Cl_2 with tetrahydrofuran (THF) in 30 min to give the neutral, paramagnetic isocyanide complex **6**.[4]

The reduction of **5**-$AlBr_4$ is reversible, as shown by cyclovoltammetric measurements ($E_p = +0.58$ V versus sat. $Ag^{\oplus}/AgCl$, −30 °C, 0.3 M NBu_4BF_4 in CH_2Cl_2).

The violet compound **6** is surprisingly stable: the crystals are stable for days under nitrogen at room temperature. Analysis of the ESR spectrum (Fig. 1) and comparison of the results with published data[5] indicates that the unpaired electron is largely delocalized in the CNC(mesityl)$_2$ ligand. The X-ray structure analysis (Fig. 2) confirms that **6** is an isocyanide complex with the Cr-C, C-N, and N-C bond lengths characteristic of this class of compounds.[6] The C-N-C angle of 171.2° is similar to the values found for $(CO)_5Cr{-}C{\equiv}N{-}C{\equiv}N$ (168.5°)[7] and $(CO)_5Cr{-}C{\equiv}N{-}C{\equiv}NCo_3(CO)_9$ (176.0°).[8] The C7 atom is nearly planar coordinated, the sum of the angles being 348.3°. The planes of the two mesityl groups form angles of 31.9° and 64.4° with the C81-C7-C91 plane. The stability of this diarylmethyl(isocyano) radical complex is therefore presumably due to the effective steric shielding of C7 by the *o*-methyl substituents.

The reaction of the tungsten analogue of **5**-$AlBr_4$ (= **1**-$AlBr_4$, R = mesityl) with THF does not afford the radical

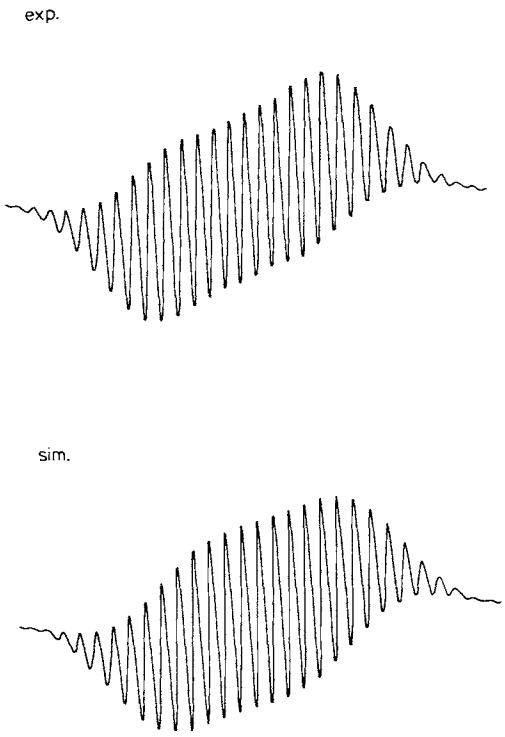

Fig. 1. ESR spectrum of **6** at room temperature in hexane (above) and simulated spectrum (below; $a(^{14}N) = 5.60$ G, $a(H)^{Me\text{-}p} = 2.30$ G, $a(H)^{Me\text{-}o} = a(H)^{H\text{-}m} = 1.15$ G; 0.77 G line width).

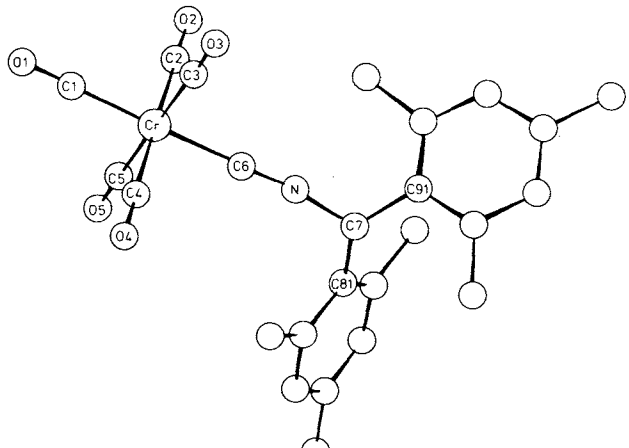

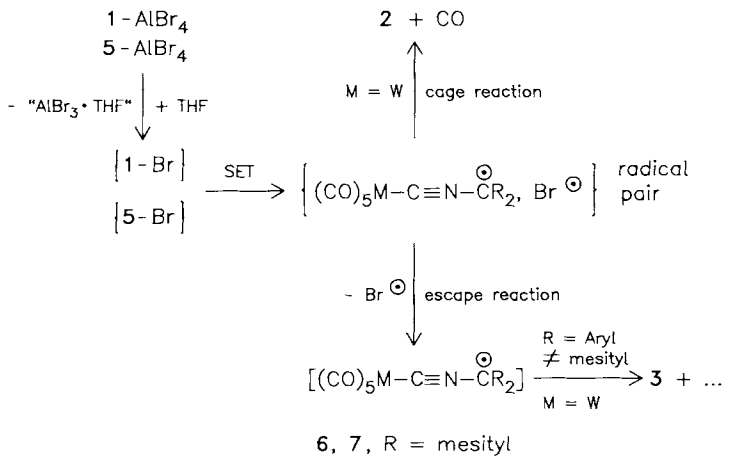

Fig. 2. Crystal structure of **6**. Selected bond lengths [pm] and angles [°]: Cr-C6 198.2(4), C6-N 115.7(5), N-C7 142.9(6), C7-C81 151.9(7), C7-C91 149.1(6); Cr-C6-N 179.0(4), C6-N-C7 171.2(4), N-C7-C81 110.5(4), N-C7-C91 116.4(4).

complex 7, which is analogous to **6**, but rather **2**, R = mesityl.[9] Compound 7, however, is formed as a by-product in the reaction of **1**-BF_4, R = mesityl, with diethyl ether and $Br^{\ominus}/CH_2Cl_2$.[10] Compound 7 can be generated cyclovoltammetrically by reversible reduction of the cation **1**, R = mesityl ($E_p = +0.66$ V versus sat. $Ag^{\oplus}/AgCl$, $-30\,^{\circ}C$, 0.3 M NBu_4BF_4 in CH_2Cl_2). At room temperature, 7 reacts rapidly (in less than one minute) with Br_2 to give **2**, R = mesityl; yield ca. 40% for $7:Br_2 = 1:1$. In contrast, 7 reacts with $Br^{\ominus}$ only very slowly upon prolonged standing of the solution at room temperature.

Scheme 1.

The reaction sequence summarized in Scheme 1 is thus an impressive example for SET (single-electron-transfer) reactivity:[11] the species **1**-Br and **5**-Br, formed by removal of $AlBr_3$ undergo an intramolecular SET reaction to form a radical pair, presumably on account of the very positive redox potentials of the cations and the easy oxidation of bromide in CH_2Cl_2; both cage products[11] (**2** in the case of the tungsten complex) and primary (**6, 7**) and secondary (**3**) escape products are detectable. We are currently investigating the fate of the $Br^{\ominus}$ species. To the best of our knowledge, **6** and **7** are the first complexes in which an isocyanide radical functions as complex ligand.[12]

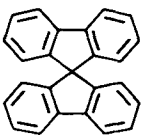
Selective Inclusion and Separation of Isomeric and Homologous Hydrocarbons by Hydrocarbon Host Lattices**

By *Edwin Weber,* Jochen Ahrendt, Mátyás Czugler,* and *Ingeborg Csöregh*



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

Crystalline inclusion compounds that only consist of hydrocarbons are rare.[1] We have now found new types of host compounds that make possible such "crystal inclusions" in many cases and with high selectivities.

Characteristic of compounds such as **1** and **2** is the scissor-like molecular shape and the absence of functional groups;[2] in the coordinatoclathrate-forming molecules described earlier by us, on the other hand, the presence of functional groups is essential.[3] The enclosure of guest molecules in the crystal lattices of **1** and **2** can therefore only occur by "lattice imprisonment" (clathrate formation in its original meaning).[1] The inclusion selectivity presumably depends to a significant extent on the spatial accommodation between the guest and the host molecule.

1

2

Apparently, 9,9′-bianthryl **1** and 9,9′-spirobifluorene **2** have a favorable molecular structure for the inclusion, in the crystal lattice, of isomeric and homologous hydrocarbons, as well as other uncharged organic molecules, with high selectivity. The inclusion compounds listed in Table 1 can be obtained selectively by simple crystallization of **1** or **2** from the guest compounds. As expected on the basis of the polarity of the host compounds **1** and **2**, the inclusion of aprotic and relatively nonpolar guest molecules, including alicyclic hydrocarbons as well as simple arenes and heterocycles, occurs as a rule.

[a] Guest molecules; van der Waals radii from space-filling models, taking into consideration the most probable conformations [4]. [b] Stoichiometry by ^{1}H-NMR integration; the substances were uniformly dried (12 h, room temperature, 15 torr). [c] Nonstoichiometric; inclusion compound decomposes under normal conditions. [d] Traces of solvent. [e] Estimated value.

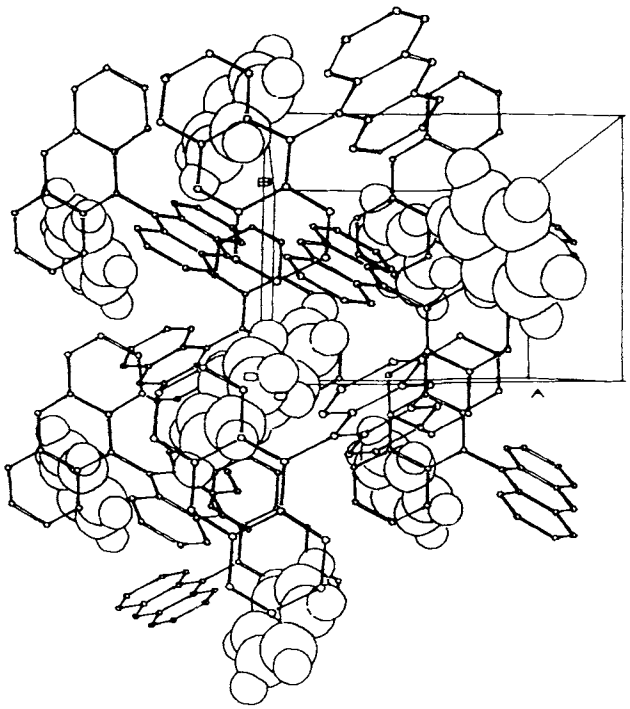

Fig. 1. Crystal packing of **1** · C_6H_6. Projection along the *c* axis. Host compound **1** represented as ball-and-stick model, guest compound benzene as space-filling model. For clarity, the H atoms of the host molecule are omitted. Important bond lengths [Å] in **1**: anthryl C-C 1.340–1.434, average 1.395(32); bianthryl C-C 1.480. Angles between the best planes [°] in **1** · C_6H_6: anthracene-A/-B 85.5, anthracene-A/benzene 48.2, anthracene-B/benzene 49.2.

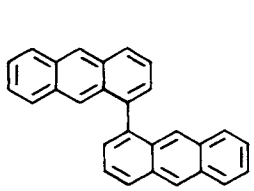
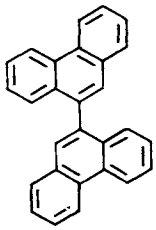
The unexpected thermal stability of some of the inclusion compounds formed from hydrocarbons as both guest and host components[1] (e.g., **1** · C_6H_6, dec. > 85 °C at 760 torr) and the pronounced selectivity of the host compounds (see below) prompted us to carry out a structure investigation. The X-ray structure analysis[5] of **1** · C_6H_6 (Fig. 1) shows that the benzene molecules are enclosed pairwise with nearly perfect fit in almost completely closed cages (edge length $\approx 6.5 \times 7 \times 12$ Å), which are formed by the flat fragments of a total of eight host molecules. Consequently, no disorder is found for the benzene molecules, as might have been expected.[6] The general structure of the heteromolecular lattice is similar to that found for aromatic hydrocarbons.[7]

The cage geometry appears to be typical for the host lattice of **1** and to exhibit only minor deviations, an observation supported by the inclusion selectivity and the van der Waals dimensions of the guest molecules (Table 1). Inclusion compounds with **2** presumably exhibit similar cavity dimensions (compare Table 1). Thus, with the exception of 2,3-dimethyl-2-butene (in the case of **1**), only cyclic guest molecules having a specific ring size (five- to eight-membered) and extension in the lattice of the host compounds **1** and **2** are enclosed. In the case of cycloheptane, the maximum allowable size of a guest molecule appears to have been just achieved or just exceeded, depending on the host. By the introduction of double bonds and the resulting flattening of the ring (compare cycloheptene, cycloheptatriene), the steric relations (molecular thicknesses) are gradually improved and inclusions (2:1 and 1:1 stoichiometries) are again possible. Thus, in the case of cyclic guest compounds, it is possible to distinguish between saturated and unsaturated (or aromatic) compounds (compare methylcyclohexane/toluene).



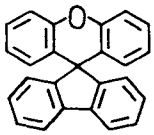
Differentiation is also achieved between substituted and unsubstituted alicyclic compounds (compare cyclohexane/methylcyclohexane and cyclopentane/methylcyclopentane), only the unsubstituted hydrocarbons being incorporated into the crystal lattices of **1** and **2**. This also holds true for cycloalkenes (compare cyclohexene/methylcyclohexene), but not for benzene. However, even in the latter case, only a limited number and arrangement of methyl groups are tolerated (Table 1). These findings open up interesting possibilities for separations, for example, of benzene from toluene or of isomeric xylenes.

A further important finding is that, for suitable van der Waals dimensions, cyclic ketones and cyclohexene oxide, but not the corresponding alcohols or amines, also form inclusion compounds with **1** and **2**. Also for the heterocyclic guest compounds, the exact fitting into the cage is presumably the crucial factor.



With respect to their host behavior, **1** and **2** are similar but not identical. For example, **2** is apparently capable of better spatial discrimination (compare benzene derivatives) and usually forms inclusion compounds that are more thermally stable (some of the inclusion compounds with **1** are already thermally labile under normal conditions, compare Table 1). We ascribe this observation to the rigid molecular geometry of **2**; compound **1**, on the other

hand, is capable, to a certain extent, of adjusting itself sterically on account of the flexible scissor-like hinge.[8]



The inclusion ability of the new host compounds opens up several practical uses, e.g., comparable to the crystal inclusions of urea.[9] Whereas urea is employed for the separation of unbranched from branched and cyclic hydrocarbons,[10] the advantage of the new inclusion-forming compounds **1** and **2** lies in the separation of cyclic hydrocarbons from mixtures containing chain-like hydrocarbons or of unsubstituted cyclic hydrocarbons from mixtures containing substituted cyclic hydrocarbons (e.g., cyclohexane from *n*-hexane or *n*-hexenes or from methylcyclopentane or methylcyclohexane; compare also Table 1).[11] They could thus provide a welcome addition to existing procedures. For future applications (e.g., encapsulation of labile substances, topochemistry), it is also of importance that the ready accessibility of the new host compounds opens up the possibility of synthesizing a wide variety of structures (compare **3**–**6**).[12]

Synthesis and Structure of $[(Ph_3P)_3Ir(\mu_3\text{-}H)(\mu\text{-}H)_2Ag_2(OSO_2CF_3)(H_2O)](CF_3SO_3)$, a Complex with a Bent Ag–Ir–Ag Chain**

By *Pierre Braunstein,* Tania Mara Gomes Carneiro, Dominique Matt, Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*

The $Ag^{\oplus}$ ion is often used for one-electron oxidations of transition-metal complexes, but it is also able to form stable adducts in which it is bonded to fragments of other transition-metal complexes.[1] Until now, such adducts have only been reported with Ag:M ≤ 1. This ratio was believed to be limited by the oxidative stability of the transition-metal fragment, which functions in these complexes as a Lewis base. We report here a unique reaction in which an Ir complex binds *two* $Ag^{\oplus}$ ions with metal–metal bond formation.

When *mer*-$[IrH_3(PPh_3)_3]$ **1** was allowed to react with two equivalents of CF_3SO_3Ag in acetone, a new complex was formed in quantitative yield.[2] Recrystallization from dichloromethane afforded the aqua complex $[(Ph_3P)_3IrH_3Ag_2(OH_2)](CF_3SO_3)_2$ **2**. Attempts to grow crystals from completely anhydrous media were unsuccessful.

The structure of **2** (Fig. 1)[3] shows a bent Ag1-Ir-Ag2 chain with the Ir atom coordinated by three PPh_3 ligands and with the Ag1–Ir–Ag2 plane almost orthogonal to the mean plane passing through Ir,P1,P2, and P3. From the structural and NMR results (see below), it appears that the Ir atom is octacoordinated, with the two Ag atoms inserted between the hydrido ligands in the H_3IrP2 plane. This results in longer Ir–P distances in **2** than in **1**.[4] Striking features of **2** include the presence of a monodentate $CF_3SO_3^{\ominus}$

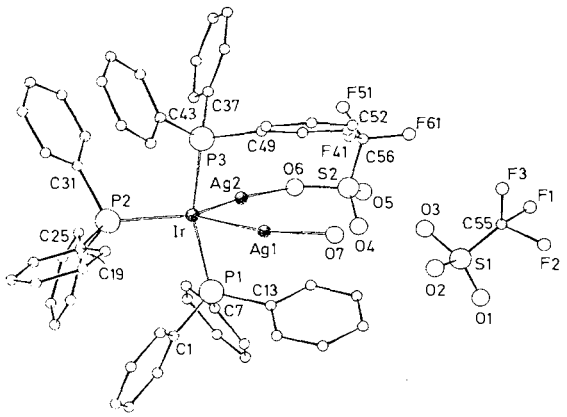

Fig. 1. Crystal structure of **2** (hydrido ligands omitted). Selected distances [Å] and angles [°]: Ir-Ag1 2.808(4), Ir-Ag2 2.764(4), Ag1 ··· Ag2 4.424(4), Ir-P1 2.357(10), Ir-P2 2.387(10), Ir-P3 2.329(9), Ag1-O7 2.23(3), Ag2-O6 2.14(4); Ag1-Ir-Ag2 105.1(1), P1-Ir-P2 99.2(3), P1-Ir-P3 161.0(4), P2-Ir-P3 99.0(3), P1-Ir-Ag1 80.8(3), P1-Ir-Ag2 82.6(3), P2-Ir-Ag1 130.9(2), P2-Ir-Ag2 123.7(3), P3-Ir-Ag1 83.3(2), P3-Ir-Ag2 91.7(3), Ir-Ag1-O7 162.6(9), Ir-Ag2-O6 164.7(9).

ion coordinated to Ag2 and of an H_2O molecule (probably hydrogen bonded with O3 and O6 according to ^{1}H-NMR and X-ray crystallographic results[5]) coordinated to Ag1.[6]

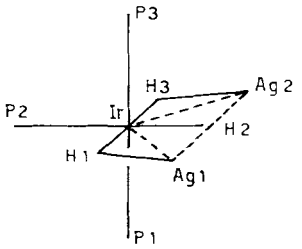

Fig. 2. Idealized positions of the hydrido ligands in **2**. Two of them bridge two different metal atoms, the third one bridges the Ir atom and the two Ag atoms (in an approximately T-shaped fashion).

The idealized positions of the hydrido ligands in Figure 2 were inferred from the ^{1}H- and ^{31}P-NMR results. At 25 °C, the ^{1}H-NMR spectrum of **2** in CD_2Cl_2 shows two resonances typical for hydrido ligands at $\delta = -9.11$ (br. s, H1 and H3) and -10.28 (br. d, $^2J_{P2H} = 88$ Hz, H2). The ^{31}P-{^{1}H}-NMR spectrum of **2** in CH_2Cl_2/CD_2Cl_2 consists of two broad signals at $\delta = 4.6$ (complex m, $\Delta\nu_{1/2} = 60$ Hz, P2) and 2.6 (s, $\Delta\nu_{1/2} = 45$ Hz, P1 and P3).[2] These data are consistent with the presence of a *mer*-[$IrH_3(PPh_3)_3$] moiety in **2**, reminiscent of **1**.[4] Upon decreasing the temperature, the ^{1}H- and ^{31}P{^{1}H}-NMR signals become more complex and at -50 °C a splitting of the H1,3 and P1,3 signals, respectively, is observed. Therefore, the equivalence of H1 and H3 and of P1 and P3 at 25 °C results from a dynamic behavior in solution during which H2 remains *trans* bonded to P2. This could occur, for instance, by an exchange of the *O*-bonded ligands at Ag1 and Ag2.

It is noteworthy that the reaction reported here does not involve $H^{\oplus}$ elimination from the hydrido complex, in contrast to other reactions between hydrido transition-metal complexes and cations of Cu, Ag, and Au.[7] This reaction also represents the first example of a double $Ag^{\oplus}$ addition to a *single* metal center. Although bimetallic Ag–Ir complexes have recently been reported,[8] we have been able to determine, for the first time, the precise Ag–Ir bond lengths.

[2] *Experimental procedure:* All reactions and operations, including the distillation of the solvents, were carried out under N_2. A solution of CF_3SO_3Ag (0.110 g, 0.43 mmol) in 3 mL of acetone was added to a suspension of **1** (0.210 g, 0.21 mmol) in 5 mL of acetone. After stirring for 20 min at room temperature, the solution was filtered and the solvent removed in vacuo. The solid was recrystallized from 5 mL of CH_2Cl_2 at -20 °C, affording **2** as colorless single crystals. Yield 0.261 g (83%); m. p. 145 °C (dec.) Correct elemental analysis. Since the integration of the observed ^{1}H-NMR H_2O resonance ($\delta = 1.63$, assigned by addition of D_2O) was always higher than predicted, traces of free water (which has a similar chemical shift) are presumably present. The occurrence of unresolved $^{107/109}$Ag coupling causes broadening of the hydride and phosphorus NMR resonances. ^{19}F-NMR (CD_2Cl_2, 84.67 MHz, 25 °C, external $CFCl_3$): $\delta = -76.2$ ppm.

the existence of common cores such as $Mo_2(\mu_2\text{-}S)_2$, $Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3$, and $Mo_4(\mu_3\text{-}S)_4$ in complexes of halides, cyanides, dithiocarbamates (dtc), and dithiophosphates.[1-2] Although there are abundant complexes with a Mo-O-Mo linkage, e.g., **1**,[4] we are aware of only one known species that contains a sulfido ligand bridging two Mo^{IV} atoms, namely, **2**.[5]

$[Mo_2(\mu\text{-}O)(dtc)_6]BF_4$ **1** $\quad$ $K_6[Mo_2(\mu\text{-}S)(CN)_{12}]$ **2**

Previously, we reported that the cubane-like complex **3**[2] was formed when a toluene solution containing $[Mo(CO)_6]$ and tetraethylthiuram disulfide was refluxed for an extended period in an inert atmosphere, whereas $[Mo_2(dtc)_6]$ was isolated if the reflux was carried out for only 3 h.[6] When the latter air-sensitive complex was dissolved in toluene and the stirred solution was aerated at 295 K, the title compound **4** was obtained.

$[Mo_4(\mu_3\text{-}S)_4(dtc)_6]\cdot$ **3** $\quad$ $[Mo_2(\mu\text{-}S)(dtc)_6]\cdot C_7H_8$ **4**

The IR, NMR, and UV/VIS spectra of **4** differ from those of the starting material. In particular, the sharp IR peak at 603 cm^{-1} beside a strong ν(CS) band at 581 cm^{-1} may be assigned to ν_{as}(Mo-S-Mo) by analogy to the corresponding band (620 cm^{-1}) in **2**[5] and the μ-oxo band (665 cm^{-1}) in **1**.[4] The ^{1}H-NMR spectrum of **4** (C_6D_6) showed that all dtc groups are equivalent: $\delta = 0.90$ ($J = 8$ Hz, CH_3), 3.35 (CH_2). Five bands were observed in the UV/VIS region: $\lambda = 526$ w, 461 ($\varepsilon = 13840$), 405 (14026), 375 (240), 280 nm (39710). The two weak bands may be due to d-d transitions, the others to charge transfer.

$[Mo(CO)_6]$ did not react with tetraethylthiuram disulfide in toluene at 295 K. When the mixture was refluxed in the atmosphere, $[Mo(dtc)_4]$ was always formed. The intermediate compound $[Mo_2(dtc)_6]$ seemed essential for the formation of the title compound **4** (major product, 60% yield). Aerating a chloroform solution of $[Mo_2(dtc)_6]$ yielded, instead of **4**, compounds **5** and **6**,[7] which were completely characterized. Redox reactions therefore occur between the solvent chloroform and the molybdenum dithiocarbamates; the use of inert toluene as a solvent seems critical for the formation of the compound containing the Mo-S-Mo core.

$[Mo(dtc)_4][Mo_6O_{19}]$ **5** $\quad$ $[Mo(dtc)_4](Cl\cdot H_2O)\cdot 0.88\ CHCl_3$ **6**

Complex **4** is insoluble in aliphatic hydrocarbons, sparingly soluble in benzene and toluene, but very soluble in chlorinated solvents such as chloroform. Black crystals of **4** grown by slow evaporation of a toluene solution quickly lost their crystallinity and solvent of crystallization upon exposure to air, yet the spectra of all samples exhibited IR bands due to the solvated toluene (700, 739, 1003 cm^{-1}). However, a freshly prepared crystal enclosed inside a 0.5-mm Lindemann glass capillary under a toluene atmosphere remained stable throughout the duration of the X-ray study.[8]

The partial crystal structure of **4** is shown in Figure 1. The preferred pentagonal bipyramidal geometry is retained by both seven-coordinated Mo^{IV} centers. The Mo-S(dtc) bond lengths range from 2.496(2) to 2.570(2) Å, the axial ones being the longest. The two Mo-S(bridging)

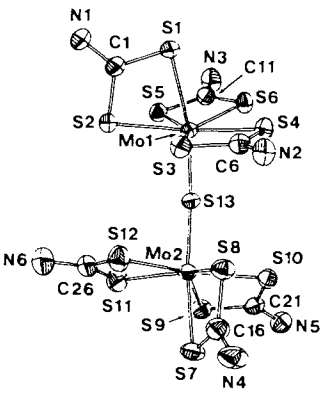

Fig. 1. ORTEP plot (35% probability thermal ellipsoids) of the crystal structure of $[Mo_2(\mu\text{-}S)(S_2CNEt_2)_6]\cdot C_7H_8$ **4**; ethyl groups and toluene are omitted. The crystals are monoclinic, space group $P2_1/c$, $a = 12.360(4)$, $b = 26.000(7)$, $c = 17.122(5)$ Å, $\beta = 92.42°$, $Z = 4$. The structure was refined to $R = 0.063$ using 8851 observed $Mo_{K\alpha}$ data [8].

bonds are 2.187(1) and 2.194(1) Å, and the Mo-S-Mo angle is 157.2°; the corresponding values for **2** are 2.173(1) Å (symmetric) and 169.5°.[5] The short Mo-S distances in the Mo-S-Mo system of **4** have been attributed to multiple bonding:

$$\sigma[Mo(d_{z^2}) + S(p_z)] + \pi[Mo(d_{xz}, d_{yz}) + S(p_x, p_y)]$$

The difference in Mo-S bond lengths in **4** and **2** is probably due to the degree of deviation of their Mo-S-Mo linkages from linearity, since the Mo atoms have the same oxidation state (+4) in both structures.

Although the symmetry of the molecule is not dictated by that of the space group, it approximates that of the point group C_2, with a twofold axis passing through S(13) and the midpoint of the line joining S(3) and S(12) (Fig. 1). The overall geometry is the same as that of the cation of **1**, which, however, has mixed Mo oxidation states and a nearly linear bridge (Mo-O-Mo = 175.7°).[4]

[8] Two methyl C atoms belonging to different ligands exhibit twofold positional disorder. The toluene molecule is also disordered, and most of its scattering was accounted for by two half-weighted benzene rings. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51900, the names of the authors, and the journal citation.

Bilayer-Immobilized Films Containing Mesogenic Azobenzene Amphiphiles—Electrically Controllable Permeability**

By *Yoshio Okahata,* Shinsuke Fujita, and Noami Iizuka*

Immobilization of synthetic or natural lipid bilayers facilitates their use as novel functional materials, such as permeability-controllable membranes.[1] Previously, we prepared a bilayer-corked capsule membrane[2] and a bilayer-immobilized film from dialkylammonium amphiphiles and polyanions,[3] and were able to control their permeability by application of an electric field across the membrane (Fig. 1, method B). The electrical field generates transient pores in the bilayer of the capsule membrane or film, resulting in a large increase in the permeability of the membrane. We report here the preparation of bilayer-immobilized films from the liquid-crystalline-type amphiphiles **1a–c** containing an azobenzene chromophore. The permeability of the film can be controlled by application of an electric field *parallel to the membrane* (Fig. 1, method A), which causes the orientation of the chromophores in the bilayer film to change.

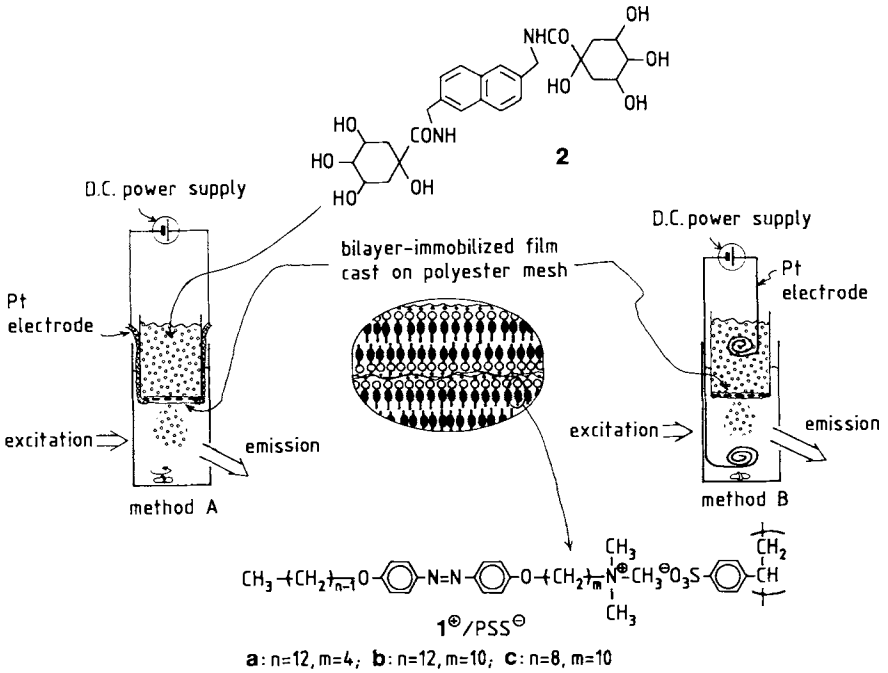

Fig. 1. Schematic drawing of the experimental setup (see text).

The preparation of the azobenzene-containing amphiphiles **1a–c** has been described elsewhere,[4] and the films were prepared according to the previously reported method.[3] An aqueous dispersion (2 mL) of azobenzene amphiphiles **1a–c** (3×10^{-5} mol) and an aqueous solution (2 mL) of sodium polystyrenesulfonate (NaPSS) ($M_r=2\times10^6$, 3×10^{-5} mol) were mixed at 70 °C. The precipitate was washed, dissolved in chloroform, and reprecipitated with ethanol. The dried, yellow powder (recovery: 80%) was dissolved in chloroform and cast on a polyester minigrid (270 mesh, 38 mm^2). The thickness of the cast film was estimated to be 100 μm from scanning electron microscopic observations. The polyionic film was transparent, mechanically stable, and water-insoluble.

The bilayer characteristics of the polyionic film were confirmed by X-ray diffraction analysis of **1a**: a strong diffraction pattern with 3.5-nm spacing was observed, which is consistent with the bimolecular length of tilted **1a**. The structural data are similar to those obtained for aqueous dispersions and cast films prepared from **1**.[5] These results clearly indicate that the films formed from azobenzene amphiphiles have extended lamellar structure like that observed for dialkylamphiphile-immobilized film.[3] The films obtained from the azobenzene amphiphiles were shown by DSC (differential scanning calorimetry) measurements to have the following phase-transition temperatures for transformation from the solid to the liquid-crystalline state: **1a**, 25 °C; **1b**, 56 °C; **1c**, 64 °C.

The permeation of the water-soluble, nonionic fluorescent probe **2**[6] (10^{-3} M) through the $1^{\oplus}/PSS^{\ominus}$ film cast on a polyester mesh was followed fluorophotometrically at $\lambda=340$ nm (excitation at $\lambda=280$ nm) (Fig. 1). Permeation rates were obtained both in the absence and presence of an electric field, which was applied either parallel (method A) or perpendicular (method B) to the film plane. The results are summarized in Table 1. The nonionic compound **2** was chosen to avoid the effect of electrostatic interaction with the electrodes and the polyionic, bilayer films.

The permeation of **2** through the $1^{\oplus}/PSS^{\ominus}$ film was very slow in the absence of an electric field, irrespective of both the chain length of the spacer and the alkyl end group of $1^{\oplus}$. When a potential of 4 V (250 μA) was applied between two electrodes with the field gradient parallel to the membrane (method A), however, the permeability was immediately increased by a factor of 5.0–10; it reverted to the original low value ($P=(1.8\text{–}2.2)\times10^{-9}$ cm^2 s^{-1}) when the potential was turned off, even after 5–10 min, irrespective

[**] Permeability-Controllable Membranes, Part 6. We thank Prof. *M. Shimomura*, Tokyo University of Agriculture and Technology, for helpful discussions.—Part 5: Y. Okahata, K. Ariga, O. Shimizu, *Langmuir*, in press.

Table 1. Permeation rates (P) of the water-soluble dye **2** across bilayer-immobilized films upon application of an electric field (4 V between two Pt electrodes) at 50 °C.

Film	P [10^{-9} cm^2 s^{-1}]					
	Method A			Method B		
	P_0 [a]	P	$\frac{P}{P_0}$	P_0 [a]	P	$\frac{P}{P_0}$
1a$^{\oplus}$/PSS$^{\ominus}$	2.0	10	5.0	2.0	3.5	1.8
1b$^{\oplus}$/PSS$^{\ominus}$	1.8	11	6.1	1.8	2.2	1.4
1c$^{\oplus}$/PSS$^{\ominus}$	1.6	16	10	1.6	2.1	1.3
$2C_{18}\overset{\oplus}{N}2C_1$/PSS$^{\ominus}$	12	12	1.0	12	120	10

[a] P_0 = permeation rate in the absence of an electric field.

of the chain length of the spacer and the alkyl end groups. The permeability change occurred within 30 s after application of the electric field, and there was no induction period due to swelling of the membrane. This permeability change could be observed at various temperatures (between 10 and 60 °C), irrespective of the phase-transition temperature of the bilayers, and could be reproduced repeatedly without damaging the films. The increase in permeability was observed only above 1.5 V (50 μA) and increased linearly with increasing potential in the range 1.5–8.0 V (50–500 μA).

When a potential of 4 V was applied across the membrane (method B), the permeability of the **1**$^{\oplus}$/PSS$^{\ominus}$ films was only slightly increased by a factor of 1.3–1.8. For films prepared from dimethyldioctadecylammonium ($2C_{18}N^{\oplus}2C_1$) amphiphile and PSS$^{\ominus}$, the permeability is largely enhanced (10 times) when the electric field is applied across the membrane (method B).[3a] In the latter case, the film acts as a capacitor because of its poor conductivity; the electric transmembrane potential can produce transient pores in the fluid bilayers by electrically induced "breakdown," which results in permeability enhancement. In contrast, the **1**$^{\oplus}$/PSS$^{\ominus}$ films contain highly conductive chromophores in the bilayers, so that a high transmembrane potential cannot form and no "breakdown" occurs.

When a potential is applied parallel to the **1**$^{\oplus}$/PSS$^{\ominus}$ films, the orientation of the azobenzene chromophore in the bilayers presumably changes, and the permeability of the resulting disordered bilayers increases. The orientation of mesogenic azobenzene chromophores in bilayers of **1**$^{\oplus}$ is well known to be sensitive to temperature changes; moreover, the UV/VIS spectra of the chromophores change upon phase transition of the bilayers.[5] The absorption spectra of the **1**$^{\oplus}$/PSS$^{\ominus}$ films, however, do not change, irrespective of whether the electric field is parallel or perpendicular to the film plane. The permeability of $2C_{18}N^{\oplus}2C_1$/PSS$^{\ominus}$ films does not change when the electric field is applied parallel to the membrane because the poorly conductive, "dialkyl" bilayers are not oriented by the electric field. Thus, the permeability of the bilayer-immobilized film containing the conductive, liquid-crystalline chromophores changes when the electric field is applied parallel to the membrane; on the contrary, the permeability of the film from the poorly conductive, dialkyl bilayers changes when the electric field is applied perpendicular to the membrane.

The fluid bilayer structure is very important for the electrically controlled change in permeability, because the change is not observed when rigid, polymeric liquid crystals such as poly(benzyl glutamate) are employed. The bilayers of **1**$^{\oplus}$ are immobilized at the hydrophilic head groups by contact with the polyanions, but still have the fluid bilayer properties. These artificial membranes, whose permeability is controllable by application of an electric field, may provide a new tool to study transport mechanisms in biological membranes.

E_3Te_3Hal, Mixed Valency Tellurohalides of Gallium and Indium with One-Dimensional Structural Units**

By *Sabine Paashaus* and *Rüdiger Kniep**

The ternary systems E-Te-Hal (E = Ga, In; Hal = Cl, Br, I) contain the phases ETeHal, having incongruent melting behavior, on the E_2Te_3–$EHal_3$ sections.[1] Along the sections from these ternary phases to the binary chalcogenides ETe[2] we have been able to identify thermodynamically stable, mixed valency compounds of the formula E_3Te_3Hal. The following compounds have so far been obtained in pure form: Ga_3Te_3Cl (m.p. = 718 °C, congruent), Ga_3Te_3Br (m.p. = 733 °C, congruent), and Ga_3Te_3I (m.p. = 692 °C, congruent) by crystallization from the melt according to the Bridgman method and In_3Te_3Br (m.p. = 381 °C, incongruent) and In_3Te_3I (m.p. = 394 °C, incongruent) by annealing of stoichiometric mixtures at 240 °C. The intense red crystals have high reflecting power and an acicular habit and are very easily cleaved along the fibers.

The first crystal structure analysis was carried out on $GaTe_3I$.[3] Figure 1 shows the macromolecular elements of the structure, in which $GaTe_{3/3}I$ tetrahedra and $Ga_2Te_{6/3}$ structural units (staggered conformation) are linked. The shortest Ga–Ga distances in the central six-membered rings (2.454(2) Å) are comparable to the corresponding bond lengths in Ga_2I_3 ($Ga^{I}_2Ga^{II}_2I_6$; 2.388(5) Å[4]) and GaTe (2.434 Å[2]), so that the oxidation state +2 has to be assumed for these Ga atoms; on the other hand, for the iodine-bonded Ga atoms (Ga-I: 2.536(1) Å) the oxidation

Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

state is +3. Thus, Ga_3Te_3I is the first mixed valency compound that contains an element of the third main group with the oxidation states +2 *and* +3. The macromolecular connection corresponds to the following structural formula:

$$^{1}_{\infty}\{(Te_{3/3}(Ga^{II})_2Te_{3/3})(Te_{3/3}Ga^{III}I)\}_2$$

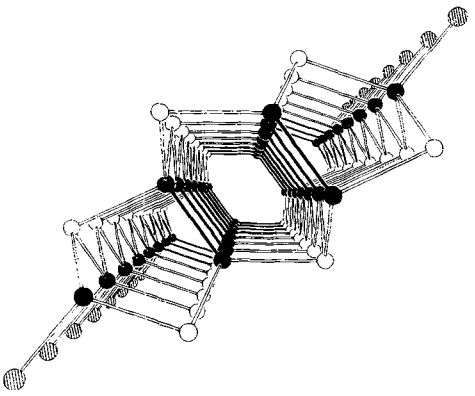

Fig. 1. View along [001] in the one-dimensional structural element of Ga_3Te_3I: Ga = ●, I = ⊘, Te = ○; each tellurium atom forms a trigonal pyramid with three gallium atoms (bond lengths Ga-Te: 2.633(1) to 2.693(5) Å).

In the structural arrangement, the strands that are extended parallel in the [001] direction are approximately hexagonally close-packed with respect to their central axes. The successive macromolecules are each translationally equivalent in the [100] direction. The shortest intermolecular distances (3.863(5) Å) are found between the terminal iodine atoms and between those tellurium atoms that are involved in the tetrahedral coordination of the Ga^{III} centers.

Nature of Ni and Cu Species in Reduced Bimetallic Ni–Cu/Al_2O_3 Catalysts

By *Gopinathan Sankar* and *C. N. Ramachandra Rao**

It is well known that $Ni^{2\oplus}$ ions in calcined Ni/γ-Al_2O_3 catalysts are in a spinel-like phase, occupying both tetrahedral and octahedral sites,[1-3] and are not reduced on treatment with H_2 even at high temperatures (770 K). In calcined Cu/γ-Al_2O_3 catalysts, copper is similarly present in a spinel-like phase,[1,2,4] CuO segregating out at high copper loadings;[5] in this catalyst, however, the $Cu^{2\oplus}$ ions are reducible on treatment with H_2. We considered it worthwhile investigating the nature of species in reduced samples of bimetallic Ni–Cu/γ-Al_2O_3, which are used as catalysts for hydrogenation and other reactions. It has been reported that the presence of copper favors the formation of Ni^0 in reduced samples.[6] Presence of nickel similarly seems to promote the reduction of supported copper. The actual nature of the nickel and copper species in reduced bimetallic catalysts has not been described hitherto except for the identification of the Ni^0 species in Ni23–Cu77/γ-Al_2O_3 samples by *Ertl* et al.[1]

We have investigated Ni–Cu/γ-Al_2O_3 catalysts over the entire composition range by means of X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES).[7] The total metal loading in the catalysts studied was 5 wt-%; samples with Cu to Ni ratios 75:25, 50:50, 25:75, were studied along with the catalysts containing only Cu and Ni. The catalyst samples were first calcined at 870 K for 8 h in air. The spectra of the catalysts were recorded after reducing them in situ in the sample preparation chamber of the spectrometer (720 K, 6 h, 300-torr hydrogen pressure). The 2p level of Al_2O_3 (74.0 eV) and the $4f_{7/2}$ level of Au (83.6 eV) were used as references for the XPS binding energies.

Calcined Ni–Cu/γ-Al_2O_3 catalysts show the presence of $Ni^{2\oplus}$ in the form of $NiAl_2O_4$ with a Ni($2p_{3/2}$) binding energy of ~856.6 eV. The Cu($2p_{3/2}$) binding energy in the calcined samples was close to that of $CuAl_2O_4$. On reduction, XPS in the core level region clearly reveals the nature of the nickel species. The Ni($2p_{3/2}$) spectra show the presence of both Ni^0 and $Ni^{2\oplus}$ with binding energies of 853.2 eV and 856.3 eV respectively, in samples with high copper content (Fig. 1). The relative concentration of Ni^0 increases with increasing copper content, the Ni^0 being totally absent in reduced Ni/γ-Al_2O_3. Variation of the rela-

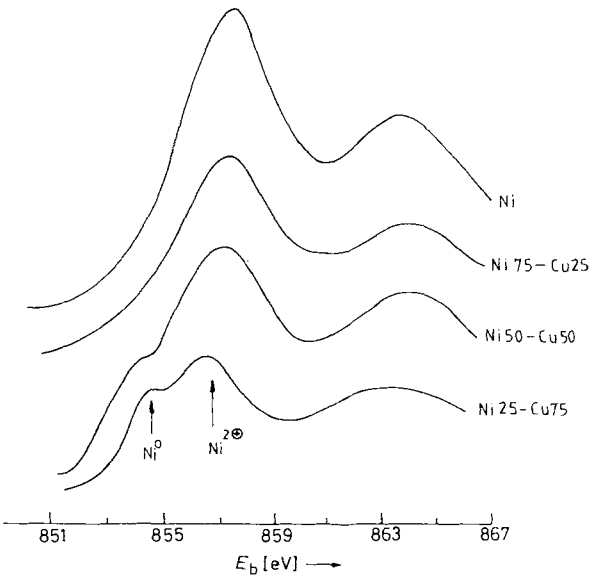

Fig. 1. Ni($2p_{3/2}$) spectra (ESCA) of reduced Ni–Cu/γ-Al_2O_3 catalysts; E_b = binding energy.

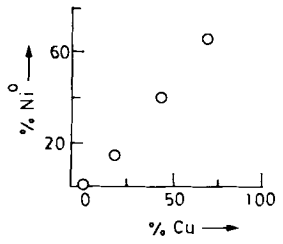

Fig. 2. Variation of the relative concentration of Ni^0 with copper content.

tive concentration of Ni^0 with copper content is shown in Figure 2. In contrast, the $Cu(2p_{3/2})$ spectra of the reduced $Cu-Ni/\gamma-Al_2O_3$ catalysts show little change with composition. From the XPS data it cannot be decided whether $Cu^{\oplus}$ is formed in addition to Cu^0, as noted earlier by *Ertl* et al.[1] Formation of $Cu^{\oplus}$ has been suggested in the literature[8] in the case of reduced $Cu/\gamma-Al_2O_3$ catalysts. We have employed Auger electron spectroscopy to examine the presence of $Cu^{\oplus}$ and Cu^0 in reduced $Ni-Cu/\gamma-Al_2O_3$ catalysts. The spectra do indeed show the presence of both species (Fig. 3). The relative proportion of $Cu^{\oplus}$ increases with the increasing copper content; accordingly, the AES spectrum of $Cu25-Ni75/\gamma-Al_2O_3$ does not show the presence of $Cu^{\oplus}$.

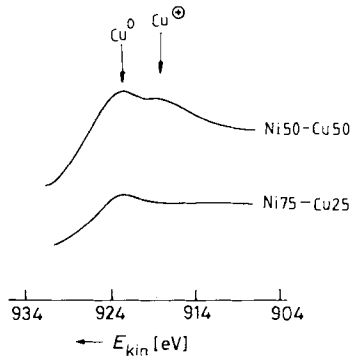

Fig. 3. $Cu(L_3M_{4,5}M_{4,5})$ Auger electron spectra of reduced $Ni-Cu/\gamma-Al_2O_3$ catalysts; E_{kin} = kinetic energy of the electrons.

The present study not only establishes the presence of Ni^0, $Ni^{2\oplus}$, Cu^0 and $Cu^{\oplus}$ in the reduced bimetallic $Ni-Cu/\gamma-Al_2O_3$ catalysts, but also shows how the relative proportion of Ni^0 increases with increasing copper content just as that of Cu^0 increases with increasing nickel content. We are presently carrying out EXAFS (*E*xtended *X*-ray *A*bsorption *F*ine *S*tructure) studies on these bimetallic catalysts.

Simple Synthesis of 1-Amino-1-cyclopropanecarboxylic Acids from *tert*-Butyl Isocyanoacetate and Epoxides; Synthesis of Alkyl 5,6-Dihydro-4*H*-1,3-oxazine-4-carboxylates

By *Ulrich Schöllkopf*,* *Bernd Hupfeld* and *Reinhold Gull*

1-Amino-1-cyclopropanecarboxylic acids **8** are currently attracting attention, mainly because of their proven or potential biological activity.[1] Although methods for the synthesis of this class of compounds have already been described in the literature,[1,2] a relatively simple, inexpensive and productive synthetic method is still lacking. We describe here a synthesis starting from *tert*-butyl isocyanoacetate **1** and from (inexpensive) epoxides **3**.[3] The lithiated ester **2** reacts with the epoxides **3** in the presence of boron trifluoride ether[4] to give the *tert*-butyl 4-hydroxy-2-isocyanoalkanoates **4**. The substitution takes place with inversion of configuration at the less hindered carbon atom of the epoxide. The compounds **4** are then mesylated to compounds **5**. The mesylates readily undergo base-induced cyclization to the *tert*-butyl 1-isocyano-1-cyclopropanecarboxylates **7**. Owing to the considerably large difference in size between the isocyano group and the *tert*-

butoxycarbonyl group, this cyclization via the anion **6** proceeds highly diastereoselectively. Thus, e.g., with cyclohexene oxide **3e** as starting compound, the ester **7e** with *endo* isocyano groups is formed almost exclusively. The conversion of the isocyano-*tert*-butyl esters **7** into the amino acids **8** was accomplished in good yields by heating **7** with concentrated hydrochloric acid. Herein lies one advantage of this method, for the hydrolysis of 1-amino-1-cyclopropanecarboxylates, usually the last step of most known methods for the synthesis of **8**,[1,2] is often problematic because of the ease with which the cyclopropane ring can be opened.

The *tert*-butyl 5,6-dihydro-4*H*-1,3-oxazine-4-carboxylates **9**, which are of interest as starting materials for the total synthesis of structural variants of the cephalosporins, are obtainable from **4** by heating with copper(I) oxide in toluene. This variant of the synthesis can be accomplished equally as well with methyl isocyanoacetate instead of **1**, whereas for the synthesis of **7**, the *tert*-butyl ester **1** is more advantageous.—As example we describe here the synthesis of *endo*-7-aminobicyclo[4.1.0]heptane-7-carboxylic acid **8e**.

Experimental

4e: *n*-Butyllithium (10.5 mmol; 6.6 mL of a 1.6 N solution in hexane) was added dropwise at −78 °C to a solution of **1**[5] (1.41 g, 10.0 mmol) in tetrahydrofuran (THF) (20 mL). The mixture was stirred for 10 min at this temperature then treated, first with 1.03 g (10.5 mmol) of **3e** and secondly dropwise with 1.3 mL (10.5 mmol) of boron trifluoride-ether. After a further 10 minutes' stirring, phosphate buffer solution (20 mL, pH 7) was added and the mixture was allowed to warm to room temperature. The solvent was removed in vacuo, and the residue shaken with water (20 mL) and ether (40 mL). The layers were separated and the water layer extracted with ether (2 × 40 mL). The combined extracts were dried over $MgSO_4$. After removal of the solvent in a vacuum the resulting **4e** was purified by Kugelrohr distillation. B.p. 90–95 °C/0.01 torr, yield 1.91 g (80%). IR (film): $\tilde{\nu}$ = 1740 (CO), 2130 (NC), 3200–3600 (OH) cm^{-1}. ^1H-NMR ($CDCl_3$): δ = 1.20–2.20 (m, cyclohexyl-H), 1.51 (s, C_4H_9), 2.40 (OH), 3.40–3.70 (m, CH and CHOH), 2.40 (d, CH−NC).

5e: Mesyl chloride (0.63 g, 5.5 mmol) was added dropwise at −10 °C to a solution of **4e** (1.25 g, 5.0 mmol) and triethylamine (7.5 mL) in anhydrous dichloromethane (20 mL). This mixture was stirred for 30 min at −5 °C, poured onto 30 mL of water/ice, and the phases separated. The organic phase was washed with 10% hydrochloric acid, then with saturated $NaHCO_3$ solution and saturated NaCl solution, and finally dried over Na_2SO_4. The solvent was removed in a vacuum and the resulting **5e** (1.47 g, 90%) used directly without purification.

7e: A solution of **5e** (0.98 g, 3.0 mmol) in THF (10 mL) was added dropwise at −78 °C to a suspension of KO*t*Bu (0.37 g, 3.3 mmol) in THF (20 mL). The mixture was stirred at this temperature for 2 h and then allowed to warm to −20 °C and treated with 20 mL of phosphate buffer (pH 7). After further warming of the mixture to room temperature, the solvent was removed in a vacuum. The residue was shaken with water (20 mL) and ether (40 mL), the phases separated, and the aqueous phase extracted twice with ether (2 × 40 mL). The ether solution was dried over $MgSO_4$, the solvent removed in a vacuum and the crude **7e** purified by Kugelrohr distillation. B.p. 75–80 °C/0.01 torr, yield 0.44 g (67%). **7e** solidifies on standing; m.p. 62–63 °C. IR (KBr): $\tilde{\nu}$ = 1730 (CO), 2120 cm^{-1} (NC). ^1H-NMR ($CDCl_3$): δ = 1.20–2.10 (m, cyclohexyl-H), 1.49 (s, C_4H_9).

8e: **7e** (0.44 g, 2.0 mmol) was added to conc. hydrochloric acid (20 mL) at 5 °C. The mixture was then stirred and heated under reflux for 2 h. The temperature was allowed to reach 50 °C and the hydrochloric acid was removed in a vaccum. The **8e**-hydrochloride remaining behind was dried at 60 °C/10 torr, dissolved in 10 mL of anhydrous ethanol, and heated under reflux with 2 mL of epoxypropane for 3h. Analytically pure **8e** precipitated, and was recovered by suction filtration. M.p. 185 °C (decomp.), yield 0.21 g (68%). IR (KBr): $\tilde{\nu}$ = 1580, 1690 (C=O), 2800–3200 cm^{-1} (NH_3). ^1H-NMR (D_2O): δ = 0.90–1.51 and 1.50–1.70 (m, cyclohexyl-H), 1.72–2.10 (m, H-1 and H-6).

[3] After completion of our studies, *M. C. Pirrung* and *G. M. McGeehan* reported in [1b] in a footnote (*J. Org. Chem.*, in press) on an analogous synthesis of 1-amino-2-alkylcyclopropanecarboxylic acids from 1,2-dibromoalkanes and methyl isocyanoacetate. However, our method has the advantage that epoxides (e.g. cycloalkene oxides) are usually more readily available than vicinal dibromides. Moreover, secondary vicinal dibromoalkanes or -cycloalkanes could react predominantly by E_2 with deprotonated isocyanoacetates.

[4] In the absence of BF_3-ether, **2** does not react with **3** (cf. U. Schöllkopf, R. Jentsch, K. Madawinata, *Justus Liebigs Ann. Chem. 1976*, 2105).

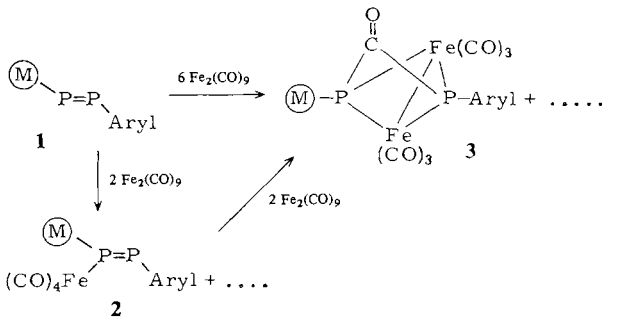
[5] Prepared from *tert*-butyl *N*-formylglycinate (I. Ugi, W. Betz, U. Fetzer, K. Offermann, *Chem. Ber. 94* (1961) 2814) by elimination of water according to the method of R. Obrecht, R. Hermann, I. Ugi, *Synthesis 1985*, 400.

Transition Metal-Induced CO-Insertion in the P=P Bond of Diphosphenes with Formation of Diphosphinomethanone Derivatives**

By *Lothar Weber,* Klaus Reizig,* and *Roland Boese*

SbSb multiple bonds in distibene transition metal complexes are cleaved by Lewis bases such as PPh_3 with formation of stibanediyl complexes.[2] A comparable reaction has so far not been observed in the case of the homologous diarsene and diphosphene complexes.[3] In contrast, the reverse process—the formation of a diphosphene complex in the thermolysis of a phosphanediyl complex—has already been described.[4]

We describe here the first transition metal-induced carbonylation of a stable diphosphene **1** with cleavage of the P=P bond. *P*-metalated diphosphinomethanones ("diphospho-ureas") **3** are obtained.



The iron-substituted diphosphene **1a**[1] reacts with $Fe_2(CO)_9$ in the molar ratio 1:6 in toluene at 20 °C to give the yellow complex **3a** in 45% yield together with small amounts of a brown byproduct identified as **2a**.

2a is formed as main product in the reaction of **1a** with $Fe_2(CO)_9$ in the molar ratio 1:2, and is to be regarded as the first intermediate in the conversion of **1a** → **3a**.[6] Logically, **2a** is converted by excess $Fe_2(CO)_9$ into **3a**. The ru-

Universitätsstr. 5-7, D-4300 Essen 1 (FRG)

[**] Transition Metal-Substituted Diphosphenes. Part 2. This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and Degussa AG, Hanau.—Part 1: [1].

thenium derivatives **2b** and **3b** can be prepared analogously.

Aryl = 2,4,6-tBu$_3$C$_6$H$_2$; **a**, Ⓜ = C$_5$Me$_5$(CO)$_2$Fe; **b**, Ⓜ = C$_5$Me$_5$(CO)$_2$Ru

The P–CO–P functions of **3a** and **3b** each give rise to a medium strength band at 1692 cm^{-1} in the IR spectrum cyclopentane); in the ^{13}C-NMR spectrum they give rise to double doublets at $\delta = 209.82$ and $\delta = 208.60$, respectively. The two nonequivalent phosphorus atoms are recorded in the ^{31}P-NMR spectrum as doublets at $\delta_{P_1} = 234.3$, $\delta_{P_2} = 155.1$ and $\delta_{P_1} = 202.7$, $\delta_{P_2} = 157.5$, respectively (see experimental).

The X-ray structure analysis underscores the diphosphinomethanone character of **3a** (Fig. 1).[5] The two phosphorus atoms no longer coupled directly to each other (d P(1)...P(2) 2.605 Å) are bridged by a carbonyl group with P–C single bonds. The C=O bond length in the bridge is 1.187(7) Å; the P1-C7-P2 angle at the sp^2-hybridized carbon atom with a value of 88.3(2)° is strongly compressed. The Fe–P bonds, as also the Fe1–Fe2 bond, may be interpreted as single bonds.[6]

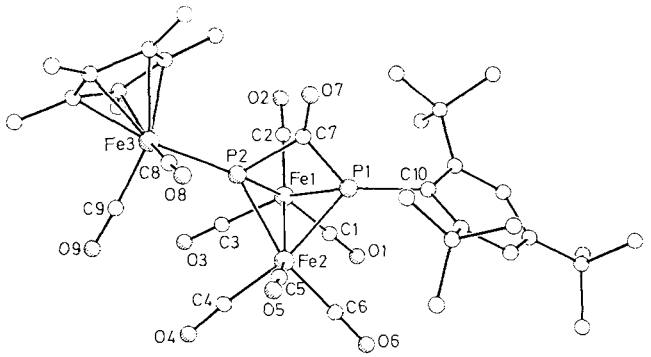

Fig. 1. Molecular structure of **3a**. Selected bond lengths [Å] and angles [°]: Fe1-Fe2 2.568(1), Fe1-P1 2.272(2), Fe1-P2 2.278(2), Fe2-P1 2.272(1), Fe2-P2 2.288(1), Fe3-P2 2.249(2), P1-C7 1.855(5), P2-C7 1.884(5), C7-O7 1.187(7); P1-C7-P2 88.3(2), P1-C7-O7 137.7(4), P2-C7-O7 133.9(4), Fe1-P1-Fe2 68.8(1), Fe1-P2-Fe2 68.4(1), P1-Fe1-P2 69.9(1), P1-Fe2-P2 69.7(1).

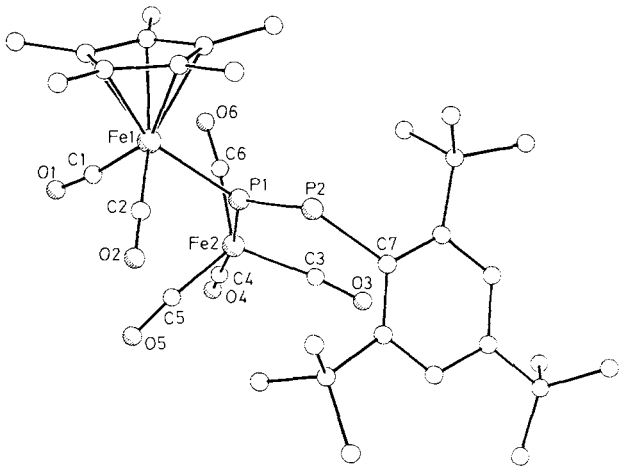
The complexes **2** are of interest as primary products in the formation of **3** from **1** and $Fe_2(CO)_9$. Their IR spectra show only the CO stretching vibrations of terminal ligands. The downfield shift of the ^{31}P-NMR signals ($\delta = 495.9$–546.3) and the coupling constants J of the AB spin systems (**2a**: 581.9 Hz; **2b**: 571.6 Hz) are typical for unsymmetrically substituted diphosphenes with free P=P bonding, thus suggesting coordination of the Fe(CO)$_4$ moiety to the lone pair of P1 in both compounds. This is confirmed by the X-ray structure analysis of **2a** (Fig. 2).[7] The P1-P2 distance of 2.032 Å is practically the same as that in **1a** and reflects the double bond character. The angle Fe1-P1-P2 is compressed to 106.0(2)° (in **1a**: 109.9(4)°) by the coordination of the Fe(CO)$_4$ group to P1 (P1 forms almost the apex of a trigonal bipyramid). The P1-P2-C7 angle (112.2(4)°) in **2a**, however, is considerably wider than that in **1a** (103.5(8)°).



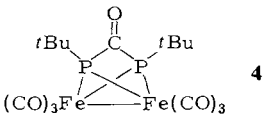


Fig. 2. Molecular structure of **2a**. Selected bond lengths [Å] and angles [°]: Fe1-P1 2.302(4), Fe2-P1 2.268(4), P1-P2 2.032(5), P2-C7 1.862(3); Fe1-P1-Fe2 122.8(2), Fe1-P1-P2 106.0(2), Fe2-P1-P2 130.3(2), P1-P2-C7 112.2(4).

The disphosphinomethanones have hitherto been the subject of very few studies. Recently, aside from the unstable $(Ph_2P)_2CO$,[8] the stable cyclic $(t\text{BuP})_4C{=}O$ was described.[9] Also only recently, complexes with diphosphinomethanone ligands analogous to **3** were surprisingly obtained upon reaction of Cl_2PNR_2 with $Na_2Fe(CO)_4$ ($NR_2 = N(i\text{Pr})_2$, $N(c\text{-}C_6H_{11})_2$, 2,2,6,6-tetramethylpiperidino).[10] Usually, reactions of Cl_2PR with carbonylmetalates lead to diphosphene- and/or phosphanediyl-complexes.[11] *Vahrenkamp* et al. synthesized the complex **4** some time ago from the corresponding diphosphene complex by carbonylation at 80 °C.[12]

Experimental

NMR spectra in C_6D_6 at 22 °C; ^{1}H-NMR: 200 MHz; IR: in cyclopentane.

2a: A mixture of **1a** (0.86 g, 1.56 mmol) and $Fe_2(CO)_9$ (1.01 g, 3.12 mmol) in toluene (80 mL) was stirred for 1 h at 45 °C. All volatile components were removed in a vacuum and the dark-brown residue was taken up in 80 mL of cyclopentane and filtered. The filtrate was evaporated down to 20 mL and stored for ca. 12 h at −28 °C. Dark-brown **2a** precipitated; this was isolated, and recrystallized twice from cyclopentane at −28 °C. Yield 0.62 g (55%), m.p. 150 °C (decomp.).—^{1}H-NMR: $\delta = 1.40$ (s, 9H, p-tBu), 1.45 (s, 15H, $C_5(CH_3)_5$), 1.73 (s, 18H, o-tBu), 7.65 (s, 2H, aryl).—^{31}P{^{1}H}-NMR: AB signal: $\delta_B = 546.26$ (P1); $\delta_A = 514.56$ (P2), $J_{AB} = 581.9$ Hz.—IR (cm^{-1}): $\tilde{\nu} = 2048$ s, 2025 s, 2018 s, 1980 s, 1973 m, 1961 m, 1948 m, 1942 m, 1927 m [$\tilde{\nu}$(CO)].—CI-MS (Varian MAT 312): m/z 723 ($M^+ + H$).

2b: 0.46 g (24%) of red, microcrystalline **2b**, m.p. 155 °C (decomp.) was obtained analogously from 1.52 g (2.53 mmol) of **1b** and 1.64 g (5.06 mmol) of $Fe_2(CO)_9$.—^{1}H-NMR: $\delta = 1.39$ (s, 9H, p-tBu), 1.58 (s, 15H, $C_5(CH_3)_5$), 1.76

(s, 18H, *o*-*t*Bu), 7.65 (s, 2H, aryl).—^{31}P-{^{1}H}-NMR: AB signal: $\delta_B = 503.86$ (P1), $\delta_A = 495.93$ (P2), $J_{AB} = 571.6$ Hz.—IR (cm^{-1}): $\tilde{\nu} = 2052$ vs, 2036 s, 1990 s, 1973 m, 1950 m, 1928 m, [$\tilde{\nu}$(CO)].—CI-MS: *m/z* 768 ($M^+ + H$).

3a: A mixture of **2a** (1.54 g, 2.13 mmol) and $Fe_2(CO)_9$ (1.50 g, 4.09 mmol) in toluene (50 mL) was stirred for 96 h at 22 °C and then filtered. The filtrate was evaporated to dryness and the residue chromatographed (alumina Woelm TSC). After elution of an orange-red front with petroleum ether/toluene (95:5), yellow **3a** was eluted with toluene (yield 1.13 g, 59%), m.p. decomp. above 215 °C.—^{1}H-NMR: $\delta = 1.18$ (s, 9H, *p*-*t*Bu), 1.44 (s, 15H, $C_5(CH_3)_5$), 1.72 (s, 18H, *o*-*t*Bu), 7.35 (d, 2H, $^4J_{PH} = 2.5$ Hz, aryl).—^{13}C{^{1}H}-NMR: 209.82 (dd, $^1J_{(PC)} = 81.5$ and 60.2 Hz, P_2CO), 211.99 (d, $^2J_{(PC)} = 13.8$ Hz, $C_5Me_5Fe(CO)$), 214.36 (m, br, $Fe_2(CO)_6$).—^{31}P{^{1}H}-NMR: $\delta = 234.3$ (d, $^2J_{(PP)} = 66.0$ Hz, P1), 155.1 (d, $^2J_{(PP)} = 66.0$ Hz, P2).—IR (cm^{-1}): 2060 vs, 2031 vs, 2013 vs, 1995 vs, 1977 s, 1957 m, 1943 s [$\tilde{\nu}$(CO)$_{term}$], 1692 m [$\tilde{\nu}$(CO)$_{acyl}$].—CI-MS: *m/z* 863 ($M^+ + 2H$).

3b: In the same way, reaction of 1.10 g (1.25 mmol) of **2b** with 0.81 g (2.50 mmol) of $Fe_2(CO)_9$ furnished 0.36 g (32%) of yellow, finely crystalline **3b**, m.p. 220 °C (decomp.).—^{1}H-NMR: $\delta = 1.18$ (s, 9H, *p*-*t*Bu), 1.58 (d, $^4J_{(PH)} = 1.6$ Hz, 15H, $C_5(CH_3)_5$), 1.71 (s, 18H, *o*-*t*Bu), 7.35 (d, 2H, $^4J_{(PH)} = 2.5$ Hz, aryl).—^{13}C{^{1}H}-NMR: 197.97 (d, $J_{(PC)} = 11.0$ Hz, Ru(*C*O)), 208.60 (dd, $J_{(PC)} = 79.5$, 57.5 Hz, P_2CO), 214.56 (m, Fe(*C*O)).—^{31}P{^{1}H}-NMR: $\delta = 202.7$ (d, $^2J_{(PP)} = 69.6$ Hz, P1, 157.5 (d, $^2J_{(PP)} = 69.6$ Hz, P2).—IR (cm^{-1}): $\tilde{\nu} = 2063$ vs, 2040 s, 2014 vs, 1979 s, 1957 m, 1942 m [$\tilde{\nu}$(CO)$_{term}$], 1692 m, [$\tilde{\nu}$(CO)$_{acyl}$].

$[C_6H_3(CH_3)_3][BiCl_3]$ and $[C_6(CH_3)_6][BiCl_3]_2$, Arene Complexes of Bismuth with Half-Sandwich and "Inverted" Sandwich Structures**

By *Annette Schier, Julian M. Wallis, Gerhard Müller,* and *Hubert Schmidbaur**

For a long time the coordination of neutral arenes to metal atoms appeared to be a domain of the d-block elements, where even simple valence theory models can give a plausible explanation of the nature of the interactions present[1]. For the p- and f-block elements, the few arene adducts of Sn^{II},[2] Pb^{II},[3] Sb^{III},[4], U^{III},[5a] and U^{IV}[5b] have remained rather as exceptions.

Meanwhile, with the systematic investigation of novel arene complexes of the earlier main group elements gallium, indium and thallium, it has been recognized that a large area of organometallic chemistry has lain neglected in the post-d-block elements. Even with the simplest of experimental methods, further rapid developments are possible.[6–9]

In the case of the heavier elements, theoretical considerations indicated, inter alia, that a relativistic effect probably also plays a role in the bonding.[10] A natural extension to the investigations already carried out on thallium[9] and lead[3] was to examine the ability of the element bismuth to form arene complexes. Not only the "Menshutkin complexes" of the antimony halides,[4, 11] known for more than a century, but also the results of experiments performed in the sixties would indicate such an ability; it was shown, for example, that BiX_3 compounds form arene adducts, the structures of which, however, were never elucidated.[12, 13] Indeed, simple dissolution of anhydrous $BiCl_3$ in mesitylene or in a solution of hexamethylbenzene in toluene produces homogeneous phases, from which the crystalline arene complexes **1** and **2**, respectively, can be obtained on cooling.[14]

$$BiCl_3 + 1,3,5\text{-}(CH_3)_3C_6H_3 \longrightarrow [1,3,5\text{-}(CH_3)_3C_6H_3][BiCl_3]$$

1

$$2\,BiCl_3 + (CH_3)_6C_6 \xrightarrow{\text{toluene}} [(CH_3)_6C_6][BiCl_3]_2$$

2

The crystals of **1**[15] consist of alternating, crystallographically independent sheets of $BiCl_3$ networks, which, in turn, each contain two non-equivalent bismuth atoms (Bi1, Bi3 and Bi2, Bi4). A section from one of the sheets is reproduced in Figure 1. Six $BiCl_3$ units are seen to form a ring structure. The coordination sphere of each Bi atom can be described as pseudo-octahedral, (Fig. 2): three strongly bound chlorine atoms (Cl11–Cl13), and two more loosely bound, bridging chlorine atoms (Cl13* and Cl32) occupy five of the coordination sites, while the sixth coordination site is screened by an η^6-bound mesitylene molecule. The angles between the ring normals and the metal-to-ring center vectors lie between 2.1 and 7.3°, thus confirming the

hexahapto nature of the bonding. Figure 1 also shows that the mesitylene rings are bound alternately above and below the $BiCl_3$ sheets.

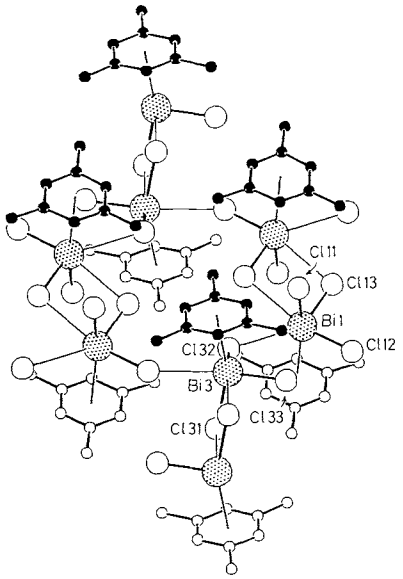

Fig. 1. Section from one of the two crystallographically independent $[(arene)BiCl_3]_n$ sheets in the crystal of **1**. In each sheet two non-equivalent centrosymmetric $[(arene)_2Bi_2Cl_6]$-units (Bi1, Bi3) are coupled via chloro bridges to each other to give strands, whereby the Bi3-dimers additionally cross-link the strands to give a sheet. Of the three Cl ligands of each Bi atom one (Cl13, Cl31) serves for the centrosymmetric coupling with an equivalent Bi atom, a second (Cl12, Cl32) forms the bridge to the nearest $[(arene)_2Bi_2Cl_6]$-dimer, while the third (Cl11, Cl33) is a terminal ligand. The mesitylene ligands are alternately bound above (black) and below (white) the sheet.

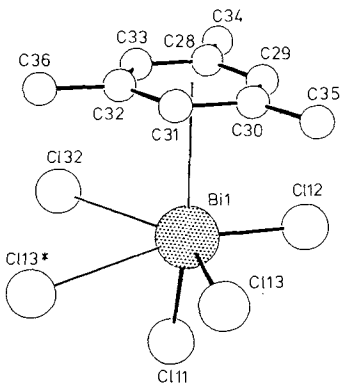

Fig. 2. Coordination sphere of one of the four crystallographically non-equivalent Bi atoms in **1** (Bi1). Bond lengths [Å]: Bi1-Cl11 2.465(5), Bi1-Cl12 2.489(4), Bi1-Cl13 2.483(5); Bi1-Cl13* 3.302(5), Bi1-Cl32 3.368(5); Bi-D4 (center of the arene) 3.11(2) Å. There is also a loose Bi1···Cl33 contact (4.050(7) Å, cf. Fig. 1).

1 is the first structurally characterized arene complex of bismuth. It differs fundamentally from the Menshutkin complexes of antimony, whose metal atoms are invariably acentrically η^2- or η^3-bound.[4]

In the crystals of **2**,[16] the centric η^6-coordination is further extended in a spectacular way. The structure consists of tetrameric $(BiCl_3)_4$ units of $\bar{4}2m$ (D_{2d}) symmetry, where each of the four crystallographically equivalent Bi atoms coordinate a hexamethylbenzene ligand (Fig. 3). Each metal atom is also bound to two nearest neighbor chlorine atoms (Cl1 and Cl2, Bi-Cl1 2.404(8), Bi-Cl2 2.438(8) Å), and to two symmetry-equivalent bridging chlorine atoms at greater distance (Cl3 and Cl3*, Bi-Cl3 2.887(6) Å). Two chlorine atoms from neighboring units also make loose contact (Cl2* and Cl2**, Bi-Cl2* 3.716(8) Å) (Fig. 4). The centers of the arene molecules form crystallographic inversion centers, so that the same bismuth halide unit is found on the other side of the ring (total symmetry $2/m$ (C_{2h}), Fig. 4; in Fig. 3 only the respective metal atoms Bi*, and not their halogen environments, are shown). Hence **2** can be regarded as an arene complex with an "inverted" sandwich structure, a structure which is extremely rare in the complex chemistry of neutral aromatic hydrocarbon compounds.[17] The tetramers in Figure 3 are coupled through the Bi(arene)Bi coordination, so that a three-dimensional framework results. Thus, the bonding between individual Bi_4Cl_{12} units is only maintained through the arene bridges.

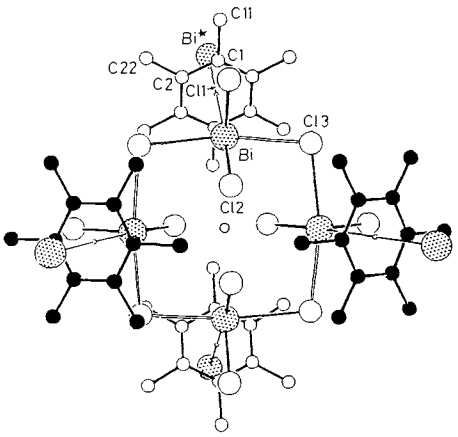

Fig. 3. Tetrameric units with $\bar{4}2m$ (D_{2d}) symmetry in the structure of **2**, as seen along the $\bar{4}$ (S4) axis, which generates the symmetry-equivalent $[(arene)Bi_2Cl_6]$ structural groups. The midpoints of the hexamethylbenzene rings are crystallographic inversion centers. The four symmetry-equivalent Bi-atoms are each components of four further tetrameric units which run screw-shaped with 4_2 symmetry through the crystal. The linkage is exclusively via mutual η^6-coordination to the arene ligand.

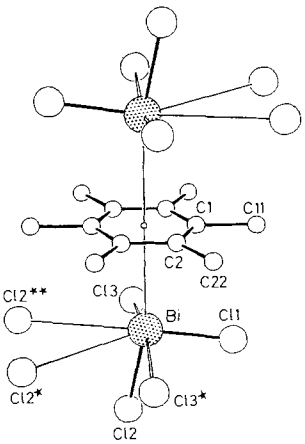
In this respect **2** is surprisingly similar to the complexes of the gallium subhalides with cyclophanes, where two metal atoms are not bound to one and the same arene (**A**), but



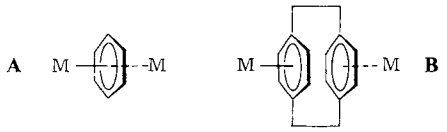


Fig. 4. The $[(arene)Bi_2Cl_6]$ unit of **2** with crystallographic $2/m$ (C_{2h}) symmetry. The Bi-Cl1/Cl2 (2.404(8)/2.438(3) Å) and Bi-Cl3 (2.887(6) Å) distances are strikingly different. In addition there are two further loose Bi-Cl2*/Cl2** contacts (3.716(8) Å). Bi-D (center of the arene) 3.07(2) Å.

to the parallel arene rings (which are inaccessible from the rear side) of the cyclophane (**B**).[6, 18]

By virtue of the η^6-bonding, **2** differs markedly from the analogous Menshutkin complexes, in which there is no central coordination.[4] The bonding in **2** can be explained quite well, however, in terms of the MO models already used in the case of the corresponding Tl^{I} and Pb^{II} complexes—dominance of the interaction between the HOMOs of the arenes and the p-orbitals of the metal atoms, which have the same symmetry.[6] It is significant that no stereochemical activity of the lone pair in the sense of ligand-free polyhedral corners is recognizable, either in **1** or in **2**. Here—and in the η^6-bonding—the stabilization of the $6s^2$ level, known as the inert pair effect, manifests itself. Due to the excessively long Bi—C bond lengths the new complexes must be classed among compounds with "weak interactions". The influence of the arene ligand is so great, however, that a relationship with the structure of $BiCl_3$ no longer exists in **1** and **2**.

Early Members of a Homologous Series Based on Linked GeM_2 Triangles, (M = Co, Fe): Structures of $[Ge_2Co_4Fe_2(CO)_{21}]$ and $[Ge_3Co_8(CO)_{26}]$

By *Skelte G. Anema, Kenneth M. Mackay,* Laurie C. McLeod, Brian K. Nicholson,** and *Jan M. Whittaker*

A spiro-linking of two GeM_2 triangles (M = transition metal) has been reported recently in the isoelectronic molecules $Ge[Co_2(CO)_7]_2$[1] and $Ge[Fe_2(CO)_8]_2$.[2, 3] Also known are a number of species containing two GeM_2 triangles sharing the M—M edge.[4]

Thus, it is possible to envisage a homologous series formed by extended chains of triangles linked alternately through Ge and M—M. There is good spectroscopic evidence[5] for such a structure in $Ge_2Co_6(CO)_{20}$, but so far we have been unable to grow any single crystals. In the iron series, linked-ring structures have been established[4] but these involve four-membered rings.

We report here on the structures of the title compounds **2**—isoelectronic with $Ge_2Co_6(CO)_{20}$— and **3**, which contain four and six GeM_2 triangles, respectively, and may therefore be regarded as the second and third members of the series headed by $Ge[Co_2(CO)_7]_2$.

Reaction[6] of $Co_2(CO)_8$ with the four-membered ring compound **1**[7] leads to the usual[1, 4] replacement of GeH_2 by the $GeCo_2$ triangle. The formation of the Fe—Fe bond, bridged by CO, across the Fe_2Ge_2 ring apparently occurs as a slower step since a second product was isolated which slowly lost CO to form **2**.

$$[Fe(CO)_4GeH_2]_2 + 2\,Co_2(CO)_8 \longrightarrow 2\,H_2 + 2\,CO + \text{intermediate}$$
1

$$\text{intermediate} \longrightarrow CO + Ge_2Co_4Fe_2(CO)_{21}$$
2

2 consists of the central $Fe_2(CO)_7$ unit with two links through Ge to $Co_2(CO)_7$ groups (Fig. 1a).[8]

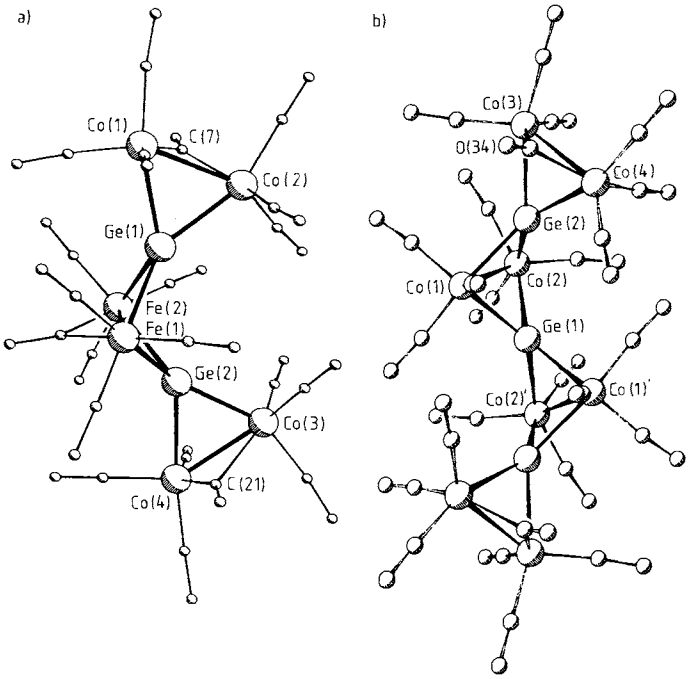

Fig. 1. a) Crystral structure of **2**. Bond lengths [pm]: Ge1-Fe1 236.5(1), Ge1-Fe2 243.7(1), Ge1-Co1 238.3(1), Ge1-Co2 235.1(1), Ge2-Fe1 242.1(1), Ge2-Co3 230.9(1), Ge2-Co4 240.0(1), Fe1-Fe2 267.8(1), Co1-Co2 252.8(1), Co3-Co4 249.1(1), Ge1···Ge2 330, Ge1···C7 260, Ge2···C21 271; Dihedral angles [°]: Ge1-Co1-Co2/Ge1-Fe1-Fe2 84, Ge2-Co3-Co4/Ge2-Fe1-Fe2 88, Ge1-Fe1-Fe2/Ge2-Fe1-Fe2 111.— b) Crystal structure of **3**, viewed down the crystallographic diad. Bond lengths [pm]: Ge1-Co1 236.1(1), Ge1-Co2 239.3(2), Ge2-Co1 238.8(2), Ge2-Co2 233.8(2), Ge2-Co3 240.7(2), Ge2-Co4 235.7(2), Co1-Co2 266.4(2), Co3-Co4 251.9(2), Ge1···Ge2 322, Ge2···C34 275. Dihedral angles [°]: Ge1-Co1-Co2/Ge1-Co1'-Co2' 70.7, Ge2-Co1-Co2/Ge2-Co3-Co4 85.3, Ge1-Co1-Co2/Ge2-Co1-Co2 110.4.

Reaction of any of the accessible germanes with $Co_2(CO)_8$[9] yields mixtures of the homologues **3**, **4** and **5**, with the yield of **3** optimized at a Ge:Co ratio of ca. 1:2.5. The reaction is cleanest with trigermane:

$$Ge_3H_8 + 4\,Co_2(CO)_8 \longrightarrow$$

$$4\,H_2 + 6\,CO + \underset{\mathbf{3}}{Ge_3Co_8(CO)_{26}} + \{\underset{\mathbf{4}}{Ge[Co_2(CO)_7]_2} + \underset{\mathbf{5}}{Ge_2Co_6(CO)_{20}}\}$$

The yields of recrystallized **3** were 30–60% based on Ge_3H_8. **3** consists of two central $Co_2(CO)_6$ and two terminal $Co_2(CO)_7$ units linked through three Ge atoms (Fig. 1b).[8]

The compounds **2** and **3** are sterically crowded with Ge···Ge and Ge···μ-C non-bonded distances less than the Van der Waals distances, and with a number of O···O interactions between adjacent $M_2(CO)_6$ moieties at distances of less than 3.0 Å. As a result of attempts to minimize these nonbonded interactions, the structures show (i) unsymmetric GeM_2 and $M_2(\mu\text{-C})$ triangles, (ii) dihedral angles between adjacent triangles linked at Ge of less than 90°, and (iii) dihedral angles between triangles with a common Co–Co edge which maintain Ge···Ge distances of 3.2–3.3 Å.

The simpler chain clusters readily lose CO and form closed clusters. Thus, $Ge[Co_2(CO)_7]_2$ loses CO at ca. 50°C to give quantitatively $(CO)_4CoGeCo_3(CO)_9$,[1,10] while $Ge_2Co_6(CO)_{20}$ similarly gives $[(CO)_4CoGe]_2Co_4(CO)_{11}$[5] with a pseudo-octahedral core. Similar rearrangements may be expected for **2** and **3**.

Finally, we note that these Ge species should have analogues with other elements of the carbon group; the first member of the Si series, $Si[Co_2(CO)_7]_2$ has been prepared,[11] and the related $Sn[Fe_2(CO)_8]_2$ has been known for years.[12] Wider correlations of this group of compounds have been explored in a recent view.[13]

The Alkylation of Epoxides with New Organoyttrium and Organolanthanoid Reagents

By *Ishita Mukerji, Andrea Wayda,* Gary Dabbagh*, and *Steven H. Bertz**

We wish to report that a new class of organoyttrium and organolanthanoid reagents, prepared from organolithium

[*] Dr. S. H. Bertz, Dr. A. L. Wayda, I. Mukerji, G. Dabbagh

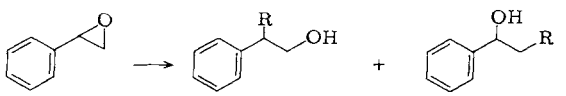
Murray Hill, NJ 07974 (USA)

[**] We thank *S. M. Vincent* for X-ray fluorescence analyses.

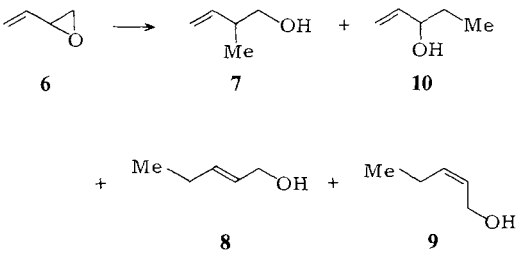
or Grignard reagents and yttrium or lanthanoid tris(isopropoxides) or tris[bis(trimethylsilyl)amides], alkylate epoxides with synthetically useful yields and regiochemistries. These reagents are especially interesting due to the observation that styrene oxide and butadiene monoxide are alkylated with regioselectivities complementary to those obtained with organocuprates, currently the standard reagents for epoxide alkylation. Previous work on C-C bond formation with organolanthanoids has involved principally the alkylation of carbonyl compounds with RYbI,[1a] RX/SmI_2,[1b] and RX/Ce(Hg) or $RLi/CeCl_3$.[1c]



The tris(isopropoxides), $M(OiPr)_3$,[2] and tris[bis(trimethylsilyl)amides], $M[N(SiMe_3)_2]_3$,[3] are easily prepared and handled by standard dry-box techniques. Addition of 1 equivalent of RLi or RMgBr at $-78°C$ gives the active reagent, to which is added 1 equivalent of epoxide. Reaction occurs upon warming to 25°C. Initial experiments with cyclohexene oxide (**1**) demonstrated that ether was much superior to pentane or tetrahydrofuran as a reaction solvent, and it was therefore used for all the experiments reported.

1 **2**

The yields of *trans*-2-methylcyclohexanol (**2**) obtained upon adding **1** to the reagent prepared[4] from MeLi and $Sm[N(SiMe_3)_2]_3$ or $Y[N(SiMe_3)_2]_3$ were 100% and 97%, respectively, after 2 h at room temperature. Under the same conditions, the corresponding isopropoxides gave 52% and 80% yields of **2**, respectively, after 23 h at room temperature. No significant amounts of **2** resulted when **1** was treated with MeLi or $CH_3Li/Al(OiPr)_3$, and no *cis*-2-methylcyclohexanol was detected by capillary GLC in any of the reaction mixtures.



In the case of an unsymmetrical epoxide such as styrene oxide (**3**), two products are possible: a methylating reagent can give either 2-phenyl-1-propanol (**4a**) or 1-phenyl-1-propanol (**5a**) and a butylating reagent can afford either 2-phenyl-1-hexanol (**4b**) or 1-phenyl-1-hexanol (**5b**). As far as the ratio of **4a/5a** is concerned, the best methylating conditions involved $MeLi/Sm[N(SiMe_3)_2]_3$ or $MeLi/Y[N(SiMe_3)_2]_3$. The yields of **4a** obtained after 2 h at ~25°C with these reagents were 71% and 73%, respectively, while the corresponding yields of **5a** were only 0.7% and <0.1%. The best butylating reagent was prepared from two equivalents of BuMgBr and one equivalent of $Y[N(SiMe_3)_2]_3$ and yielded 80% of **4b** and <0.1% of **5b** after 2 h at ~25°C.

3 **4a**, R = Me; **4b**, R = Bu **5a**, R = Me; **5b**, R = Bu

In contrast, organocopper reagents preferentially attack **3** at the least-hindered C of the epoxide, although the ratio of products is not nearly as high as we observe. For example, we have found that **3** is opened by $Me_2CuLi \cdot LiI$ to give 19% of **4a** and 44% of **5a**. Similarly, *Lipshutz* et al.[5] found that **3** is opened by $Bu_2CuLi \cdot LiCN$ to yield 8% of **4b** and 85% of **5b**. Further, *Ganem* et al.[6] recently reported that **3** is opened by $BuLi/BF_3$ to yield 36% of **4b** and 64% of **5b**. The more substituted product (benzylic attack) is observed upon treating **3** with two equivalents of trialkylaluminum reagent.[7] The utility of this chemistry is limited, however, by the availability of the Al reagent and the fact that five potentially valuable organic groups must be wasted in order to incorporate one into the product.

Butadiene monoxide (**6**) presents an especially challenging problem, as there are three potenital sites of alkylation. A priori, methylation could occur at the allylic carbon to give 2-methyl-3-buten-1-ol (**7**), at the terminus of the double bond (S_N2' displacement) to give *trans*-2-penten-1-ol (**8**) or *cis*-2-penten-1-ol (**9**), or at the least hindered epoxide carbon to give 1-penten-3-ol (**10**). Treatment of **6** with $MeLi/Sm[N(SiMe_3)_2]_3$ yielded 81% of **7** and 2% of **10**, in analogy with the styrene oxide result. No **8** or **9** were detected by capillary GLC. Essentially the same yield of **7** was obtained with $MeLi/Er[N(SiMe_3)_2]_3$ or $MeLi/Y[N(SiMe_3)_2]_3$, and with these reagents none of **8**-**10** was detected. The Sm- and Y-alkoxides produced mixtures of **7** and **8** also containing small amounts of **9** and **10** (see Table 1).

6 **7** **10**

8 **9**

Table 1. Methylation of butadiene monoxide **6** [a].

Reagent	Yield [%]			
	7	**8**	**9**	**10**
$MeLi/Sm[N(SiMe_3)_2]_3$	81	<1	<1	2
$MeLi/Er[N(SiMe_3)_2]_3$	78	<1	<1	<1
$MeLi/Y[N(SiMe_3)_2]_3$	77	<1	<1	<1
$MeLi/Sm(OiPr)_3$	31	19	2	3
$MeLi/Y(OiPr)_3$	23	31	3	<1
$MeLi/SmCl_3$	16	10	1	1
$MeLi/CeCl_3$	10	1	5	1
MeYbI	1	1	1	1
$2\,Me_3Al$	46	6	<1	<1
$Me_2CuLi \cdot LiI$	1	67	5	<1

[a] 23 h, room temperature.

For comparison: Treatment of **6** with $Me_2CuLi \cdot LiI$ yielded 67% of **8**,[8] along with 5% of **9** and 1% of **7**. Treatment of **6** with two equivalents of $AlMe_3$ in hexane[7] gave 46% of **7** and 6% of **8**. Other, previously known organolanthanoid reagents[1] proved unsatisfactory (see Table 1).

Several other substrates and reagents have also been investigated. For example reaction of 1,2-epoxybutane with $MeLi/Sm[N(SiMe_3)_2]_3$ furnished 3-pentanol in 74% yield. *Johnson* et al.[9] obtained an 84% yield when they used two equivalents of $Me_2CuLi \cdot LiI$ to effect this transformation. Finally, reaction of $PhLi/Y(OiPr)_3$ and cyclopentene oxide afforded *trans*-2-phenylcyclopentanol in 42% yield.

Namy, H. B. Kagan, *J. Am. Chem. Soc. 102* (1980) 2693; c) T. Imamoto, T. Kusumoto, Y. Tawarayama, Y. Sugiura, T. Mita, Y. Hatanaka, M. Yokoyama, *J. Org. Chem. 49* (1984) 3904.

[2] All isopropoxides were synthesized as described in S. N. Misra, T. N. Misra, R. N. Kapoor, R. C. Mehrotra, *Chem. Ind. (London) 1963*, 120, and were purified by repeated pentane extraction. The resulting products were free of Cl (X-ray fluorescence), gave satisfactory metal analyses and exhibited infrared and NMR spectra identical to those given in the literature (see K. S. Mazdiyasni, C. T. Lynch, J. S. Smith, *Inorg. Chem. 5* (1966) 342).

[3] All amides were prepared by minor modification of the original procedure: D. C. Bradley, J. S. Ghortra, F. A. Hart, *J. Chem. Soc. Dalton Trans. 1973*, 1021. Use of the lithium reagent, $LiN(SiMe_3)_2$ in the metatheses resulted in products which contained residual chloride. However, $NaN(SiMe_3)_2$ yielded chloride-free, pure amides which gave satisfactory analyses (see ref. [2]).

[4] *Procedure:* The reagents were prepared under Ar by adding the organolithium or Grignard reagent to 1 mmol of the lanthanoid amide or alkoxide suspended in 5 mL of ether at −78°C. After 15 min, the epoxide and internal standard (decane) dissolved in 5 mL of ether at −78°C was added. The reaction mixtures were sampled after stirring for 1 h at −78°C, 2 h at room temperature, and 23 h at room temperature. Quenching with 3 M aqueous ammonium chloride removed the inorganics and left a virtually colorless organic layer. Analysis by GLC calibrated with authentic materials gave the yields quoted.

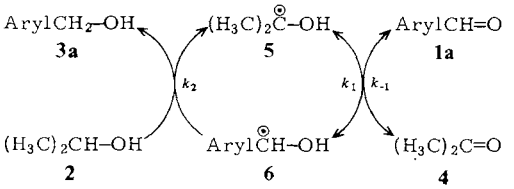
Thermally Induced Redox Reaction of Carbonyl Compounds and Alcohols in a Radical Chain Reaction: Comproportionation to Two Hydroxyalkyl Radicals

By *Dietmar Malwitz* and *Jürgen O. Metzger**

The reduction of carbonyl compounds to alcohols is a very important reaction in organic chemistry.[1] But reductions with alcohols also play an important role and, commencing with the Meerwein-Ponndorf-Verley reduction, numerous variants have been described in the literature.[2] *Ponndorf*[3] pointed out in his classical work more than half a century ago the possibility of a thermally-induced redox reaction, but so far no mechanism has been described for this reaction. Two routes are conceivable: a) a comproportionation of carbonyl compound and alcohol to two hydroxyalkyl radicals and their further reaction to give the products, or b) a pericyclic reaction in which two hydrogen atoms are transferred from the alcohol to the carbonyl group in one step.

We have found that aldehydes **1** are reduced by 2-propanol **2** in a thermal reaction to the alcohols **3**, whereby **2** is oxidized to acetone **4**.[4] Instead of **2**, methanol, primary alkyl alcohols and benzyl alcohols can also be used, whereas tertiary alcohols are not reducing.

$$\underset{\mathbf{1}}{RCH{=}O} + \underset{\mathbf{2}}{(H_3C)_2HCOH} \rightleftharpoons \underset{\mathbf{3}}{RCH_2OH} + \underset{\mathbf{4}}{(H_3C)_2C{=}O}$$



a, R = 4-*i*Pr-C_6H_4; **b**, R = C_6H_5

To elucidate the reaction mechanism we investigated the kinetics of the reaction of **2** and 4-isopropylbenzaldehyde **1a**. Preliminary experiments showed that the reaction proceeds as a radical chain reaction: active carbon as radical trapping agent completely inhibits it; radical formers such as di-*tert*-butyl peroxide[5] or atmospheric oxygen accelerate it; as soon as the radical formers are consumed, the rate is the same as for the reaction without radical former. Under the conditions used for the kinetic measurements,[6] no secondary reactions were observed. The rate law for the reaction is described by equation (1), and the Arrhenius equation is fulfilled quite well in the temperature range investigated (Eq. (2), $\Theta = 2.303\ [RT\ \mathrm{kJmol^{-1}}]$).

$$-\frac{d[\mathbf{1a}]}{dt} = \frac{d[\mathbf{3a}]}{dt} = k_{exp}[\mathbf{1a}][\mathbf{2}] \qquad (1)$$

$$\log k_{exp} = 7.56 \pm 0.05 - (125 \pm 1)/\Theta \qquad (2)$$

With deuteriated **2**, an almost temperature-independent kinetic isotope effect is obtained, both when **2** is *O*-deuteriated ($k_H/k_D = 2.06$), as well as *C*-deuteriated ($k_H/k_D = 2.61$). For perdeuteriated **2** one obtains $k_H/k_D = 5.34$.[7] A Hammet correlation gave a reaction constant $\beta = -0.62$.[8]

Start: **1a** + **2** $\xrightarrow{k_i}$ **5** + **6**

1a + **3a** $\xrightarrow{k_i'}$ 2 **6**

5 + **6** $\xrightarrow{k_t}$ chain termination

Aryl = 4-*i*Pr–C_6H_4

Scheme 1.

$$-\frac{d[\mathbf{1a}]}{dt} = \frac{d[\mathbf{3a}]}{dt} = (k_i'/k_t)^{1/2} \cdot (k_1/k_{-1})^{1/2} \cdot k_2[\mathbf{1a}][\mathbf{2}] \qquad (3)$$

All results are consistent with a radical chain reaction as shown in Scheme 1: Chain initiation starts with the formation of the hydroxyalkyl radicals **5** and **6** from **1a** and **2**. The radical **5** is converted by H-transfer to **1a** into the oxidation product **4**, a reaction which is already known from the analogous photochemical[10] and radical-induced[5] reactions, and which here is thermodynamically controlled; further reaction of the radical **6** to give the prod-

uct **3a** by H-abstraction from **2** is the rate-determining step in the radical chain reaction. Reaction of the two chain-carrying radicals **5** and **6** with each other leads to chain termination. After a relatively small conversion of ca. 5%, the comproportonation of **3a** and **1a** dominates as initiation reaction, since this reaction requires an activation energy about 45 kJ mol^{-1} less than the original initiation reaction because of the formation of two hydroxybenzyl radicals **6**.[11]

With this mechanism the experimental rate law is easy to simulate [Eq. (3)], both regarding the reaction order [Eq. (1)] as well as the Arrhenius parameter [Eq. (2)].[13] The isotope effect[14] and the reaction constant[15] are also consistent with this mechanism, a mechanism which is remarkable in two ways: 1) It describes a radical chain reaction with a "kinetic chain length" of ca. 10^7 at 200 °C.[16] In contrast, the analogous photochemical[10] and the radical-induced[5] reduction are not chain reactions. 2) The initiation reaction is the back reaction of the known disproportionation of hydroxyalkyl radicals and thus is analogous to the comproportionation of alkanes and alkenes to alkyl radicals.[17] Decisive is the "molecule-induced" homolysis[18] of a C-H bond [Eq. (4)] with a markedly reduced activation energy in comparison to the monomolecular bond cleavage.

$$RCH{=}O + HCR'_2OH \rightleftharpoons RCH{=}O\cdots H\cdots CR'_2OH \rightleftharpoons \overset{\oplus}{R}\overset{\ominus}{C}H{-}OH + \overset{\oplus}{C}R'_2{-}\overset{\ominus}{O}H \qquad (4)$$

In comparison, a pericyclic transfer of two H-atoms would be considerably slower[19] and, in view of the observed kinetics, highly unlikely, since according to equation (4) a radical chain reaction can be initiated. Our results are consistent with equation (4) most likely being the initiation reaction of the radical chain reaction.

[4] Typical reaction conditions: **2**:**1** = 100:1; 200 °C; 24-72 h; yields of **3** ca. 90%; increasing the temperature accelerated the reactions. Practically no secondary reactions occur up to 350 °C.

[5] E. S. Huyser, D. C. Neckers, *J. Am. Chem. Soc. 85* (1963) 3641.

[6] Duran glass ampules; exclusion of atmospheric oxygen; analysis: GC with on-column injection, mass balance referred to **1a** > 98%. a) Determination of reaction order at 200 °C; in the case of **1a**: 0.02–0.24 mol/L **1a** with 8.74 mol/L **2**; in the case of **2**: 8.74–1.7 mol/L **2** (variation by addition of *t*BuOH) with 0.02–0.05 mol/L **1a**. Evaluation according to pseudo 1st-order gave $k_{exp}/[\mathbf{2}] = k_{exp}$; b) temperature dependence: **2**/**1a** = 250:1; 175–230 °C (5 °C steps).

[7] The kinetics of the reactions of **1a** with $(H_3C)_2HCOD$, $(D_3C)_2DCOH$, and $(D_3C)_2DCOD$ were investigated in the temperature range 175–225 °C as described in [6].

[8] The following substituted benzaldehydes X-C_6H_4-CHO (X-**1b**) were measured for the Hammett correlation [9] in a competition reaction with **1b** at 160 °C: X = *p*-CN, *p*-Cl, *p*-Ph, *p*-*i*Pr, *p*-CH_3O. Conversions < 5 mol %; $\log([X\text{-}\mathbf{3b}]/[\mathbf{3b}]) = -0.62\sigma$ ($r = 0.999$).

[9] L. P. Hammett: *Physikalische Organische Chemie*, Verlag Chemie, Weinheim 1973, p. 352.

[10] D. I. Schuster, P. B. Karp, *J. Photochem. 12* (1980) 333.

[11] $\log(k_i/k_t) = \pm 0\text{-}217/\Theta$; $\log(k'_i/k_t) = -0.7\text{-}172/\Theta$; $\log(k_1/k_{-1}) = -1.4 + 52/\Theta$. Calculated for **1b** from thermochemical data according to *Benson* [12]. Substitution in equation (3) gives $\log k_2 \approx 8.6\text{-}65/\Theta$. The values of the A factor and of the activation energy are of the expected order of magnitude.

[12] S. W. Benson: *Thermochemical Kinetics*, Wiley, New York 1976.

[13] Other conceivable reaction sequences are not concomitantly consistent with both the observed rate law [Eq. (1)] and the experimental Arrhenius paramerers [Eq. (2)].

[14] The results evidence two different H-transfers: a) the cleavage of the O-H bond affects only k_1/k_{-1}; b) the cleavage of the C-H bond affects only k_2.

[15] In the competition reaction, the competition constant

$$k = \frac{k_1^X}{k_{-1}^X} \cdot k_2^X \Big/ \left(\frac{k_1}{k_{-1}} \cdot k_2\right)$$

is measured. A value of $\rho_1 > 0$ is to be expected for k_1/k_{-1} and $\rho_2 < 0$ for k_2, since electron-withdrawing substituents X in the aryl moiety stabilize the radical **6**. Since $\rho_{exp} < 0$ it follows that $|\rho_1| < |\rho_2|$.

[16] Kinetic chain lengths $= v_{exp}/v_i = k_{exp}[\mathbf{2}]/k'_i[\mathbf{3a}]$; $\log k'_i \approx 8.3\text{-}172/\Theta$; estimated from data in [11] with $\log k_t \approx 9.0 \pm 0/\Theta$ [12].

BOOK REVIEWS

Is Industrial Chemistry Still Presentable in Encyclopedic Form?

Ullmann's Encyclopedia of Industrial Chemistry has had a long and distinguished history beginning with the first edition which appeared in 1914. Since then, it has continued to be revised, updated and expanded at regular intervals leading to the fourth edition (1972–1984).[*] As is fitting, given the tremendous expansion in Chemistry and its impact on current technology, the time interval between successive editions has been decreasing and the number of volumes/edition has been increasing steadily. Now, less than two years after the publication of the last volume of the 4th edition, the first volumes of a new and updated 5th edition have appeared. This is a remarkable feat given the magnitude of the task.

[*] *Angew. Chem. Int. Ed. Engl. 23* (1984) 536.

Ullmann's Encyclopedia of Industrial Chemistry. 5th completely revised edition. Edited by *W. Gerhartz, Y. S. Yamamoto, F. T. Campbell, R. Pfefferkorn*, and *J. F. Rounsaville*. VCH Verlagsgesellschaft, Weinheim 1985. **Vol. A1: Abrasives to Aluminum Oxide:** xiv, 594 pp., bound, DM 430.00.—ISBN 3-527-20101-7

The 5th edition will ultimately include thirty six volumes and is divided into an A (Vol. A1–A28) and B (Vol. B1–B8) series. The latter series deals with a variety of basic knowledge topics, which by virtue of their general applicability

are not restricted to any single class of materials but are relevant to many different topics. An advantage of this "dual" volume approach is that it reduces the topical redundancy and permits more space to be devoted to the detailed description of specific products and processes.

One major difference in the 5th edition is that it is in English rather than German. This should greatly expand the audience and enhance its utility to scientists and engineers outside of the European technological community. This decision by the editorial board recognizes the truly international nature of industrial chemistry and technology. This trend is reflected not only by the composition of the editorial board, but also in the selection of contributing authors. For each topic discussed a specific location of previous and continuing expertise was selected and specific authors were chosen from that site. Where no single firm could be identified as dominant, authors have been selected from a number of competitive firms. This policy assures high quality, topical coverage and correctly recognizes the multinational contributions to Science and Technology.

I have personally reviewed the first volume of the 5th edition and was favorably impressed. The text is remarkably error free and maintains the high quality and standards of the previous editions. The subject matter selected for discussion is well organized and is treated in considerable detail. For highly specialized topics enough background data is provided to satisfy even the casual reader. Volume 1A provides a reasonably detailed and consistent treatment of twenty six separate topics ranging from Abrasives to Aluminum Oxide. All major compounds and most important derivatives are accompanied by the appropriate chemical abstract registry number to facilitate subsequent in-depth literature searches. Industrially important chemicals such as acetic acid, acetic anhydride, acetone, acetaldehyde, acetylene, etc. all receive a thorough treatment covering physical and chemical properties, manufacture and production engineering, major derivatives, reactivity, toxicology and industrial safety, transportation restrictions, economics, etc. The section on acetylene is particularly rich in details as befits a material with such a long chemical history and industrial importance. I was pleased to find a brief discussion of the formation of linear polymers by Ziegler Natta techniques, since these materials and their derivatives are of current scientific and industrial interest. Due to the industrial importance and diverse physical and chemical properties of aluminum compounds, this section is divided into a series of separate discussions of aluminum metal, aluminum alloys, inorganic aluminum compounds, organoaluminum derivatives and aluminum oxide. The last contribution describes the commercial uses of aluminum oxide except for its abrasive applications which are treated extensively in a separate section. In recognition of their considerable pharmacological importance there is a section on alkaloid derivatives. The major alkaloid groups are reviewed and many specific examples within each group are described. This section, which is quite long, is adequately indexed both by class and by compound. The organization of the sections dealing with acrylic materials (i.e. acrylic acid, acrylates, acrylonitrile) is unusual in that the respective polymers, which comprise the major industrial products, are not included in the same volume. While this makes the reading a little discontinuous, the location of the respective polymers and copolymers is adequately cross-referenced at the end of each subject article. One possible advantage of grouping the individual polymers under a broader more general polymer heading (e.g. fibers-synthetic organic, rubber-synthetic etc.) is that one can more easily see how each individual polymer product fits into the overall picture of a particular commercial polymer field.

Although I am admittedly not an expert in all of the twenty-six fields covered in volume 1A, I found all of the contributions to be quite readable and complete. Consistent with stated editorial board policy, the authorship of the first volume is internationally distributed to locations of demonstrated expertise. Although this often results in somewhat varying emphasis, the authors have all conformed to the basic editorial format which gives the volume consistency in spite of the great diversity of topics.

Regarding the format, I found the topical outline which precedes each contribution to be particularly valuable. If so desired, allows the casual reader to go easily and directly to sections of interest without wading through the entire article. This is particularly useful for someone who is interested in surveying related properties of a diverse group of materials. The text of each article is compiled in an appealing manner which seems to provide "something for everyone" whether they are interested in physical and/or chemical properties, chemical reactivity, production engineering, industrial safety or economics. I was particularly impressed with the extensive reference list provided for each topical discussion. In general these lists are composed of a mixture of accessible books, journals, patents, trade publications, etc. many of which are surprisingly current. In this regard, it was not unusual to find references as recent as 1982–83, which is somewhat unusual for a volume of this size. This currency will become increasingly important in future volumes dealing with emerging technologies in rapidly evolving fields such as genetic engineering, biotechnology, photoresists and microlithography, electronic materials etc., where reviews are often outdated by the time they appear.

In summary, I find that volume 1A of the 5th edition of Ullmann's Encyclopedia of Chemical Technology upholds in every fashion the high standards and traditions previously established. The concept is such that the articles provide something for both the casual reader as well as the skilled practitioner. The international authorship is a welcome innovation which is consistent with the multinational contributions to science and technology. The overall quality of this series is such that no Science and Engineering library should be without it.

Biotechnology. A Comprehensive Treatise in 8 Volumes. Edited by *H.-J. Rehm* and *G. Reed*. **Vol. 2. Fundamentals of Biochemical Engineering.** Volume Editor: *H. Brauer*. VCH Verlagsgesellschaft, Weinheim 1985. xvi, 819 pp., bound, subscription price: DM 425.00.—ISBN 3-527-25764-0

Biotechnology is an interdisciplinary field, the progress of which relies on close cooperation among professionals from various sub-disciplines within the areas of biology, chemistry, and engineering. The aim of this volume of the series[*] is to outline the fundamentals of biochemical engineering. It deals with the planning, design, and develop-

[*] Cf. *Angew. Chem. Int. Ed. Engl. 24* (1985) 436.

ment, as well as the optimization and operation of biochemical processes.

The volume contains 30 chapters in all, grouped in 5 sections. A relatively difficult philosophical question is, "what constitutes fundamentals for a diverse field like biochemical engineering". The editors seem to have decided to place a very strong emphasis on the fundamental concepts and the mathematics of transport phenomena, reaction kinetics, and reactors. About two-thirds of the book is devoted to these topics. The remaining one-third addresses the field from the practical point of view. Some very useful concepts are covered in stoichiometry, mechanical stress, measurement and control, and some selected unit operations. The quality of all the contributions is excellent; but at the risk of sounding parochial, I should share some additional observations. This volume is authored almost exclusively by experts from West Germany (19 of the 22 authors). In addition, most of the authors come from an academic environment (17 out of 22).

The first nine chapters give a review of momentum, mass, and heat transport phenomena, similarly as is to be found in *Transport Phenomena* by *R. B. Bird, W. E. Stewart,* and *E. N. Lightfoot* (Wiley 1960). The treatment is concise, but without omission of essential details. The philosophy and theory of reaction engineering form the subject of the following eight chapters. Concepts such as enzyme kinetics, batch and continuous fermentation kinetics, and reaction and mass transfer interactions are treated. Admittedly a difficult task to accomplish, yet it is a pity that practical examples of where and how these concepts are used are not presented to the reader in this volume.

Bioreactors are discussed in seven chapters. The present volume provides an extensive coverage of the "loop reactor"; interestingly, the type of reactor shown on the jacket of the volume. Loop reactors are typically fluidized reactors with at least one definitely directed circulation flow or "loop". The reader will note that there are some overlaps in what are considered "bubble" reactors, "tower" reactors, and "loop" reactors. Three chapters deal with the fundamental mathematics of stirred vessel reactors, bubble column reactors, and biochemical loop reactors. Fluid flow behavior, heat and mass transfer aspects, and gas dispersion are analyzed from a sound conceptual viewpoint. Several other chapters build on these fundamentals and provide a (somewhat redundant) comprehensive review of about 18 impressive installations, many in the Federal Republic of Germany. Examples are, the Imperial Chemical Industry's 2000–3000 m^3 (500000 to 800000 US gal) volume reactors for Single Cell Protein production; and smaller units of 20–40 m^3 at Mitsubishi and Hoechst-Uhde. Very large systems (several are 18–30 m high and 20–30 m diam) for wastewater treatment are the Hoechst BIOHOCH reactors and the Bayer "Tower Biology". Another concept presented is the "reciprocating jet" reactor which has shown promise in pilot-scale tests.

There are places in this volume where a fine attempt is made to link theory and practice. An example is a chapter on modeling and scale-up. Some important concepts are presented which are useful in determining whether kinetics or mass transfer is decisive in scale-up or other experiments. Such aspects deserve even more coverage.

Several chapters in this volume are of great practical value, and the editors are to be commended for the topics they have selected. There is an excellent chapter on the effect of mechanical stress on microbial cultures which also includes some micrographs. Gas solubility and stoichiometry are presented in two useful chapters for the reader interested in the practice of biochemical engineering. One should not, however, expect an in-depth treatment of these areas in this "Fundamentals" volume.

It must be mentioned that a chapter is included on "how to" run comparative tests for fermenters based on the recommendations of the DECHEMA working committee for biochemical engineering. Preparation of fermentation media is reviewed in another chapter that includes some 43 tables of information. The literature is a good blend of that from the US, Europe, and the USSR; and the chapter in itself constitutes a good practical starting point for the reader. In a chapter on "recovery operations," an account is given of those operations which are required in order to transform the (generally dilute) whole cell broth from the fermenter into the final product. Centrifugation and liquid-liquid extraction are dealt with very satisfactorily; however, the treatment of the other "downstream" operations is only cursory.

Finally, the editors are also to be commended for having included chapters on sterilization, measurement and control, as well as on process control and optimization. Here, the reader should expect an overview of the concepts involved and not a "how to" or "how it is done" discussion.

In summary, this volume provides a very good perspective on the kinds of activities in which the academicians and practitioners of biochemical engineering are engaged. The publication of this volume also takes us past the halfway point in this ambitious series. I wish those involved in its compilation continued success in this arduous task.

Dictionary of Organometallic Compounds. Edited by *J. Buckingham.* Chapman and Hall, London 1984. 3 Volumes, 2576 pp., £ 575.00.—ISBN 0-412-24710-0

Organometallic chemistry has increasingly developed into a discipline that, rather than being of interest only to the specialist, now attracts general attention. Therefore the appearance of an extensive compilation of the most important organometallic compounds, the brief description of their synthesis, characteristics, and physical properties, as well as (exemplary) applications, is of great interest. Entries on approximately 15000 compounds of the main-group and transition metals, including f-block elements, are presented in the *Dictionary of Organometallic Compounds* in a well organized and graphically clear manner. The editor showed his skill in not giving the authors of individual chapters any fixed rules for the selection of the compounds included. Thus, a balanced and useful presentation of the (sometimes very) different compound classes of the various metals was attained.

In general, the molecular formula, the name (often supplemented with common synonyms), the Chemical Abstracts Service Registry Number, and a very clearly drawn structural formula are given for every compound. These are followed by an enumeration of the more important physical and chemical properties. References to possible stereoisomers as well as derivatives (for which important data are in turn given) are well chosen. An important feature is that information concerning the toxicity and possible dangers of working with the given substance is provided. Finally, reference is made to important original papers and

to further literature; short statements of their contents reinforce the impression that the material presented has been carefully worked on.

The first two volumes of the "Dictionary" contain the entries on the individual compounds. These reports are organized into chapters according to the respective metal atom involved. As a result, the size of the chapters vary considerably (e.g., Fe, Ru, Os: ca. 3000; Si: ca. 2000; Cu, Ag, Au: ca. 200 entries). An index is provided at the beginning of each chapter, which in a compact form presents excellently drawn structural formulas of the compounds to be described. The corresponding entry is easily found on the basis of the simple code number that accompanies the formula. The third volume, which was prepared with great care, consists of separate name, formula, and CAS Registry Number indexes and contributes substantially to the good overall impression that the "Dictionary" makes.

The literature is covered until 1983. Yearly supplemental volumes are planned, which are to appear every eighteen months after the "copy dead-line." Unfortunately, it is to be feared that the imposing price will preclude the purchase of this useful reference work except by libraries. The announced publication of separate sections for the reader who is interested only in the compounds of a given metal is therefore very welcomed.

der Universität Würzburg (FRG)

Polymer Colloids. By *R. Buscall, T. Corner,* and *J. F. Stageman.* Elsevier Applied Science Publishers, London 1985. xii, 324 pp., bound, £ 38.00.—ISBN 0-85334-312-8

This book—which could equally as well have been entitled "Polymer Dispersions" or "Polymer Latexes"—discusses the synthesis, properties, and some of the methods of characterization of these materials.

In Chapter 1, methods of polymerization are briefly summarized, where the patent literature is also taken into account. In Chapter 2, using emulsion polymerization as an example, kinetic and mechanistic aspects of polymerization are considered in greater detail. The next two chapters, which are devoted to adsorption and adsorptive phenomena in polymer colloids, together with the discussion of the stability of polymer latexes (Chapter 5), constitute the most informative part of the book, at least from a scientific point of view. Rheological investigations (Chapter 6), designed to characterize flow behavior, are treated very briefly. After an explanation of the underlying principles, reference is made to equations, now considered almost classical, that take into account, inter alia, particle form. The discussion of the dependence of viscosity on concentration is followed by an account of non-Newtonian flow behavior. The introduction of dimensionless groups in order to reduce the number of variables necessary is very helpful; here electronically and sterically stabilized dispersions are handled separately. The last two chapters bring plastic materials into focus. Their great significance in technical applications is given detailed consideration using the examples of rubber and polyvinyl chloride.

To be sure, this book is not without weaknesses: this refers not only to the comprehensiveness of the literature references, but more importantly, to the scope of the individual topics, which has evidently been consciously restricted. The strength of the book lies in the broad treatment of polymer dispersions, especially with regard to the special features of their synthesis, characterization, and properties. The reader is thus given the possibility of rapidly becoming familiar with this interesting field. The reading and consultation of this book can be recommended for beginning and advanced students; for the specialist, however, only with reservation.

Protein Crystallography and Computer Graphics—toward Rational Drug Design

By Wim G. J. Hol*

"The coincidence of the ideal of progress with the advance of science is not a mere coincidence. Before this advance men placed the golden age in remote antiquity. Now they face the future with a firm belief that intelligence properly used can do away with evils once thought inevitable. To subjugate devasting disease is no longer a dream; the hope of abolishing poverty is not utopian."

John Dewey in
"Democracy and Education" (1916)

1. Introduction

Diseases have diverse origins. They may come from outside, for example, by infection with viruses, bacteria, protozoa, helminths, or other parasites. They may come from inside, for example, through hereditary diseases such as juvenile diabetes, sickle cell anemia, and Down's syndrome. Or they may arise from damage incurred during the course of life, as in the case of cancer.

For millennia people have depended on chance discoveries in their fight against disease. Keen observation led to the remarkable variety of useful herbs known to ancient man. In the last three or four centuries such observation has been supported by scientific reasoning. Nevertheless, the number of new drugs brought on the world market each year is perhaps not even half a dozen, even though such debilitating diseases as leprosy, leishmaniasis, and arthritis are still widespread. Moreover, malaria is making an incredible upsurge and cancer still slowly destroys the lives of many humans, both old and young.

Despite the many possibilities now available for abolishing disease, this goal remains elusive. One of the reasons is the intrinsic difficulty in developing safe and reliable drugs. However, the current explosion of knowledge in understanding the biochemical machineries of both man and pathogens, down to the atomic level, provides grounds for optimism that new drugs will indeed be discovered. This optimism is based on the tremendous progress being made in a number of disciplines: protein purification methods, gene and protein sequencing procedures, recombinant DNA techniques, oligonucleotide synthesis, protein crystallography, computer graphics, and theoretical biochemistry.

We will show in this overview that close and mutually stimulating collaborations between laboratories engaged in medicinal chemistry and those making advances in biochemical techniques open up fascinating possibilities for developing new drugs. Let us see how this may happen and, in fact, is already happening (see also ref. [1]), albeit on a limited scale.

2. A New Strategy for the Design of Drugs

Until recently the design or discovery of new drugs has largely been based on the following strategies:

1. in-depth investigations of active substances in herbs and plants traditionally considered to be of medical importance;
2. follow-up of the unexpected results of modern physiological and biochemical investigations;
3. massive screening programs;
4. exploitation of known key metabolic pathways, or other biochemical activities, in man and pathogens.

Penicillin is a prime example of the second category. The treatment of malaria provides examples of the other three categories. *Quinine* and *qinghaosu* (artemisin), from the Chinese herb *Artemisia annua*, are the active substances in plants traditionally used for medical purposes.[2,3] *Mefloquine*, commercial production of which may be too expensive, is the result of a major screening effort at the Walter Reed Army Hospital.[3] *Pyrimethamine* is a selective inhibitor of the dihydrofolate reductase of the malaria parasite. Its discovery resulted from biochemical investigations of a key step in parasite metabolism.[4]

Despite the ingenuity and sophistication often employed in these four approaches, they all suffer from the fact that their target is invisible. It is somewhat like boxing blindfolded—only by trial-and-error does one discover where the opponent is and how he can be knocked out. Being able to see one's opponent would be a big help (although one may still face a formidable problem!). This is precisely what the new strategy initiated in several laboratories aims to achieve.

The cornerstone of this new approach is the accurate knowledge of the three-dimensional structure of potential target proteins and other biomacromolecules, for example, DNA. This requires *X-ray crystallography*, which is the only method available so far to obtain accurate information regarding the three-dimensional structure of biomacromolecules ranging in molecular weight from a few thousand to more than a million. *Computer graphics* is also required, because it is the only way to visualize the complex structures so elucidated. This technique also provides a convenient interface with data bases of known structures and with hypothetical structures generated by *molecular mechanics* and *molecular dynamics* calculations.

If the potential of these recently developed techniques is to be fully exploited, there must be an ample supply of the proteins being studied. Until a few years ago this was a major bottleneck of the whole strategy because often only minute amounts of material were available. However, *recombinant DNA* and *gene cloning* techniques came to the rescue, assisted by powerful *protein microsequencing* procedures and a continual increase in the sophistication of *protein purification* methods. Although the details of each investigation differ, the overall process is illustrated by the following example. Biochemists succeed in isolating small amounts of a medically important protein. A gas-phase sequence analysis establishes the amino-acid sequence of the first 20 to 80 residues. This is followed by *oligonucleotide synthesis* of a series of DNA fragments that can hybridize with the gene encoding this particular protein. Once the gene has been identified, it is transferred into another organism where it is expressed, that is, this organism produces large quantities of the desired protein. Purification, which can sometimes be astonishingly simple if suitable *monoclonal antibodies* are available, affords gram amounts of the protein. This is the starting point for a full biochemical and kinetic characterization as well as for the growth of suitable crystals for X-ray crystallography.

This process, which is here grossly over-simplified, is the prelude to the application of X-ray crystallography, computer graphics, quantum mechanics, molecular mechanics, and molecular dynamics. These latter techniques result in numerous suggestions as to which kinds of molecules might be useful drugs. These molecules must then be synthesized and tested for their effectiveness. Although this route is little different from ongoing approaches to drug design, knowledge of the three-dimensional structure of target proteins allows an important feedback procedure. Because protein crystals contain roughly 50% solvent, small molecules can often diffuse through channels in the protein crystals and reach their binding sites. In such cases, the difference Fourier technique allows rapid determination of the structure of the complex formed between the protein and the small molecule. Even if complexes are not formed in the crystal, cocrystallization experiments may lead to formation of the complex in solution prior to crystallization. The structure determination of the complex is usually greatly speeded up by knowing the three-dimensional structure of the uncomplexed protein, since the so-called "molecular replacement method"[5] can then be used.

Accurate three-dimensional structures of a protein complexed with various small molecules provide a powerful starting point for the design of new molecules that will bind to this protein. This is especially true if the small molecules bind differently from predictions based on imperfect theories. Moreover, such structures may reveal major or minor conformational changes of the protein, which might be exploited in the design of new compounds. In this "rational drug design cycle" (Fig. 1), the structure of each new complex between the protein and a new compound expands the data base, resulting in the generation of ever better ideas for pharmaceutically active compounds. The ultimate goal is, of course, to leave the cycle as soon as possible by obtaining an effective new drug.

3. Three Cases

Three cases for the development of a new drug on the basis of potential target protein structures are possible.

1. A human protein is not functioning properly or its activity has to be modified for other reasons. In this case, only the three-dimensional structure of this particular protein is required. No proteins from infectious organisms need to be considered.

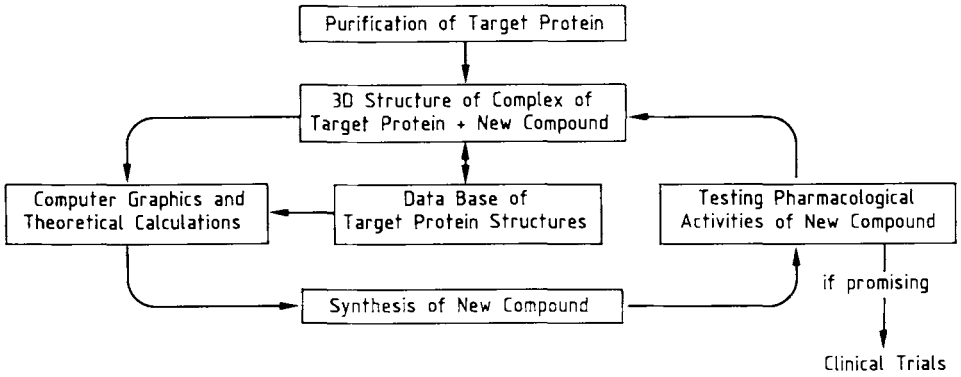

Fig. 1. A "rational drug design cycle" employing three-dimensional structures of complexes formed between target proteins and a range of small molecules (ligaands).

2. The potential target is a key protein from an infectious organism and has no counterpart in humans. In this case, the three-dimensional structure of the selected protein in the pathogen is the starting point and no human protein structures have to be taken into account.
3. The target is a protein from a harmful organism and a homologous human protein exists. In this case, the target protein must be inhibited selectively so that the human counterpart is not impaired. The three-dimensional structures of both proteins are required in order to design the desired selective inhibitors (Fig. 2).

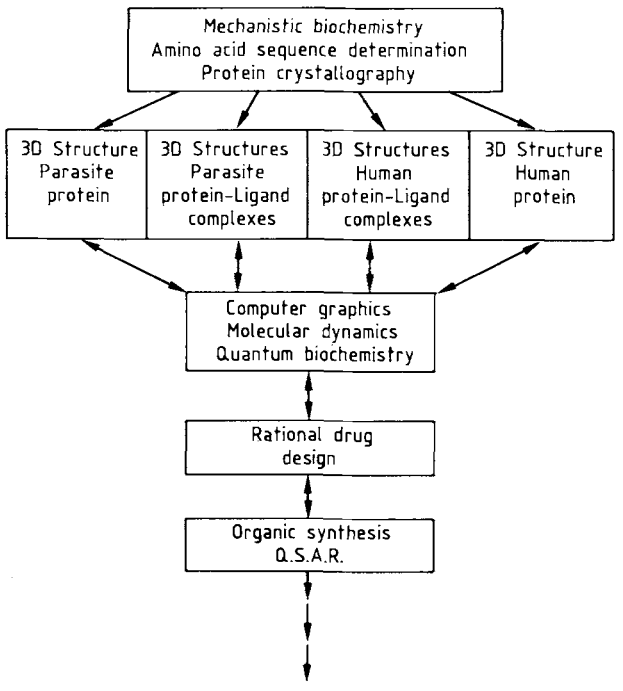

Fig. 2. Flow diagram of successive steps in a drug design strategy where detailed knowledge of the structure of key proteins plays a central role. Q.S.A.R.: quantitative structure-activity relationship.

The boundaries between these cases are by no means strict. Two of these cases are often considered simultaneously. Nevertheless, the distinction is quite useful, as shown in the following three sections.

4. Drugs that Affect Human Proteins

4.1. Sickle Cell Anemia

Hemoglobin was one of the first proteins to be structurally elucidated. Moreover, its structure was one of the first to be employed for designing new compounds that produce predicted physiological effects. The binding site for the natural effector substance, 2,3-diphosphoglycerate, in the deoxy conformation of human hemoglobin[6] was chosen as a model receptor site by *Beddell* et al.[7] They designed and synthesized a series of bibenzyl dialdehyde derivatives that produced the desired effect, namely, the stabilization of the deoxy conformation and the resulting right-shift of the oxygen saturation curve of hemoglobin.

These initial experiments were followed by an attempt to design compounds that alleviate the clinical symptoms caused by sickle hemoglobin, HbS.[8]. Substituted benzaldehydes were designed to bind preferentially to the oxy conformation of human hemoglobin at a site between the amino terminal residues of the α subunits. The compounds indeed produced the desired effect: left-shifting of the oxygen saturation curve of dilute hemoglobin solutions and of whole blood. Most interestingly, one of the predicted compounds is also a potent inhibitor of the sickling of erythrocytes of patients suffering from sickle cell disease. It may prove to be a clinically useful anti-sickling agent.[8]

Designing anti-sickling agents is difficult because a balance has to be struck between two somewhat conflicting requirements: (1) deoxy HbS fibers must not form, since they would thereby prevent the passage of erythrocytes through blood capillaries; (2) the oxygen transport capacity of the blood must not be diminished too severely.

Several groups, e.g., *Walder* et al.[9] and *Abraham* et al.[10], are using the three-dimensional structure of the hemoglobin molecule for designing anti-sickling agents. The work of *Abraham* et al. has already revealed the structures of a series of compounds complexed with hemoglobin, several of which appear to be bound in a rather unexpected manner.[11]

Future efforts to design anti-sickling compounds will be further assisted by the high-resolution structures of human oxy- and deoxy hemoglobin which are now available.[12] Also, the accuracy of the deoxy HbS structure has recently been considerably improved.[13,14] This is especially impor-

tant since the structure of the HbS aggregate in these crystals is believed to be closely similar to that of the polymer in the erythrocyte.[13, 14]

Hemoglobin is one of the very few human proteins of great interest for drug design for which an accurate three-dimensional structure is now known. However, even knowledge of the three-dimensional structure of a homologous protein from another organism may provide a starting point for obtaining the structure of a human protein—although one always has to bear in mind that more or less subtle changes in conformation may arise from amino-acid substitutions. Several such potentially useful structures are included in Table 1, a few of which are discussed further below.

Table 1. Proteins with known three-dimensional structures, which may be useful for the rational design of drugs that interact with human proteins only.

Protein	Source	Disease	Potential human target protein	Refs.
hemoglobin	human	sickle cell anemia	hemoglobin S	[8-14]
phospholipase A_2	pancreatic, snake venom	inflammation	intracellular phospholipase A_2	[55-59]
dihydrofolate reductase	bacterial	cancer	dihydrofolate reductase	[33]
carboxypeptidase A	bovine	hypertension	angiotensin-converting enzyme (ACE)	[15, 18-20]
thermolysin	bacterial			[16, 21-24]
aspartyl proteases	bacterial	hypertension	renin	[25-27, 30, 121, 122]
elastase	porcine	emphysema	leucocyte elastase	[123]
subtilisin: eglin	bacterial			
α_1-proteinase inhibitor	human	emphysema thrombosis	α_1-proteinase inhibitor anti-thrombin	[124]
calmodulin	rat	psychosis	calmodulin	[125, 126]
troponin C	chicken, turkey		troponin C	[127-129]

4.2. Hypertension

Hypertension is a major health problem in industrial societies, contributing to cardiovascular disease, stroke, and renal failure. Although its mode of action is not fully understood, the hormone angiotensin II is an important factor in regulating blood pressure, with higher concentrations of the hormone leading to higher blood pressures. The hormone is produced in the body via two steps (Fig. 3). First, the enzyme *renin* catalyzes the cleavage of angiotensin I from the inactive prohormone angiotensinogen. Second, the *angiotensin-converting enzyme* (ACE) catalyzes the removal of the carboxyl-terminal dipeptide from angiotensin I, releasing angiotensin II. Inhibition of either renin or ACE, or both, would lead to a smaller concentration of angiotensin II and contribute to lowering the blood pressure. No three-dimensional structure of ACE has been reported as yet, but the enzyme is known to be a zinc-peptidase and the structures of two such proteases have been determined with great accuracy: carboxypeptidase A and thermolysin.[15, 16]

The analogy between the active sites of ACE and carboxypeptidase A has been used by *Cushman* et al.[17] to guide the design of specific ACE inhibitors. The first carboxyalkanoyl amino acid synthesized, succinyl-L-proline, had an I_{50} value of 330 μM for inhibition of rabbit lung ACE. In the meantime, many modified compounds have been synthesized, the general architecture of the carboxypeptidase A active site having been kept constantly in mind. Replacement of the carboxyl group yielded 1-(3-mercaptopropanoyl)-L-proline with an I_{50} value of 0.2 μM. Further modifications gave the most potent inhibitor found, 1-(D-3-mercapto-2-methylpropanoyl)-L-proline, with an I_{50} of 0.023 μM.[17] This inhibitor is now on the market under the name Captopril and may be considered as the first generally available drug designed, albeit partly, on the basis of the known crystal structure of a protein molecule. This success has been one of the reasons for further investigations into the mode of binding of inhibitors to both carboxypeptidase A[18-20] and thermolysin.[21-24]

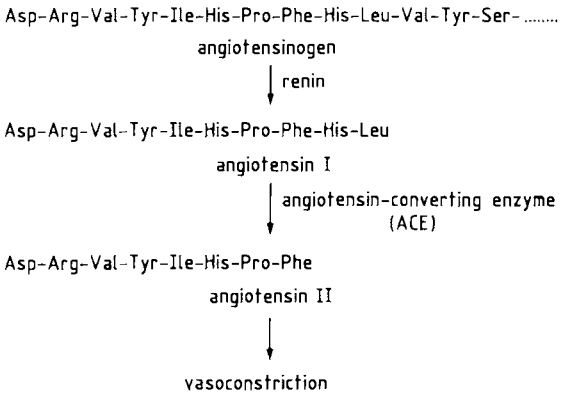

Fig. 3. Release of the oligopeptide angiotensin II catalyzed by the proteolytic enzymes renin and angiotensin-converting enzyme. Angiotensin II is involved in the regulation of blood pressure.

The aspartyl protease renin is considered a promising alternative target for inhibition of the conversion of angiotensinogen to angiotensin II, because the enzyme exhibits great specificity. Owing to the availability of high-resolution X-ray structures of several bacterial aspartyl proteases[25-27] and to the knowledge of the amino-acid sequence of human renin,[28, 29] it has been possible to use computer graphics methods to derive models of the human

enzyme. These models have formed the basis for making predictions of substrate binding.[30] Detailed crystallographic data on the structure of an aspartyl protease complexed with an inhibitor showed that the predictions made were essentially correct.[31]. The considerable activity going on in this area is further illustrated by the reported crystallization of mouse renin and renin-inhibitor complexes by a drug company in the United States.[32]

4.3. Cancer

Cancer falls squarely into the category of diseases for which successful drugs have to interact specifically with human proteins only. Although the detailed structure of a complex formed between the widely used anticancer drug methotrexate and bacterial dehydrofolate reductase is known,[33] it is hard to see how such knowledge can aid the design of better anticancer drugs: dihydrofolate reductase is too essential for *all* dividing cells. This key role of the target protein in nontransformed cells explains the serious side effects of methotrexate. For similar reasons, enormous problems exist with other anticancer drugs.

The "ideal" cancer drug should interact with a *specific* feature of the cancer cell crucial for its uncontrolled proliferation. Such a specific difference between normal and cancer cells may be provided by the point mutations observed in the *ras* "oncogene," which give rise to the transforming properties of its product, the p21 protein.[34-36] *Wierenga* and *Hol* observed an analogy between the amino-acid sequence of the first 30 residues of p21 and the sequences of a family of dinucleotide binding proteins and were able to construct a hypothetical model for this fragment of p21 (Fig. 4).[37] These residues might fold into a compact βαβ unit with the glycine at position 12 close to the phosphate group of a bound nucleotide. In several kinds of cancer cells, this glycine happens to have undergone mutation to form another residue.[34-36,38-41] In the hypothetical βαβ model[37] this would result in steric hindrance between the side chain of the non-glycine residue and the nucleotide phosphate and, therefore, in an altered mode of binding, improper functioning of p21, and loss of control of cell proliferation. If this model is correct then it might be possible to design compounds that bind to the mutated p21 of transformed cells in such a manner that their disastrous properties are suppressed. The mechanism of action of such compounds would depend on a crucial difference between cancer cells and normal cells and hence should not cause the side effects commonly associated with current anticancer drugs.

It is only fair to say that the prediction of *Wierenga* and *Hol* for the structure of p21 is by no means the only one.[42-46] Moreover, elegant site-directed mutagenesis experiments have shown that all non-glycine residues introduced at position 12, with the exception of proline, impart carcinogenic properties to p21.[47] This is difficult to reconcile with the predicted mode of binding of the dinucleotide to a βαβ unit. However, even if p21 has a structure different from all predictions made so far, the ideas discussed in the previous paragraph remain correct: a unique feature of a protein crucial for the rapid proliferation of a transformed cell provides, in principle, the basis for designing new and perhaps "ideal" drugs for certain kinds of cancer.

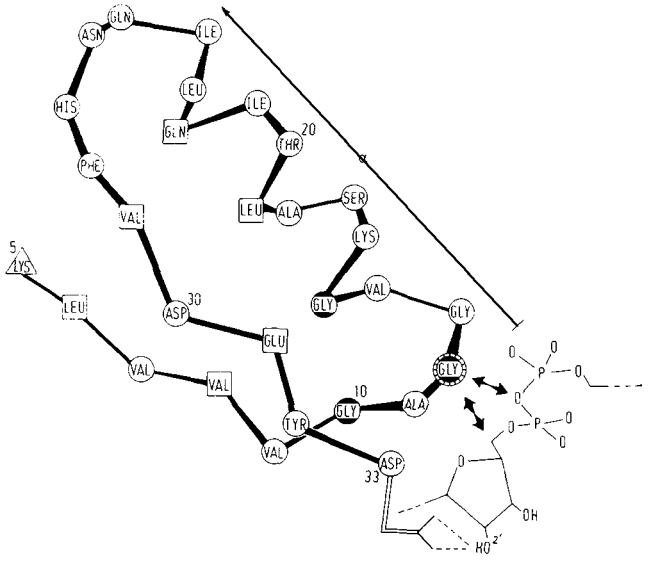

Fig. 4. Hypothetical model for the residues 5 to 33 of the p21 protein, encoded by the *ras* oncogene. Also indicated is the predicted ribose diphosphate moiety of a bound nucleotide. Mutations of glycine 12 would necessarily introduce a side chain at this position which would affect the postulated mode of binding of the nucleotide [37].

4.4. Inflammation and Asthma

Prostaglandins, thromboxanes, and leukotrienes are mediators of hypersensitivity reactions and inflammation.[48-52] They are formed via complex metabolic pathways in response to various stimuli; the formation of arachidonic acid is a central step (Fig. 5), which is catalyzed by the enzyme phospholipase A_2, or, more precisely, the intracellular $Ca^{2\oplus}$-dependent phospholipase A_2. In spite of its great importance, relatively little is known about this enzyme. However, *Okamoto* et al.[53] showed recently that the intracellular phospholipase A_2 is immunologically related to the secretory phospholipase A_2, several examples of which have been characterized in great detail (see, e.g., ref.

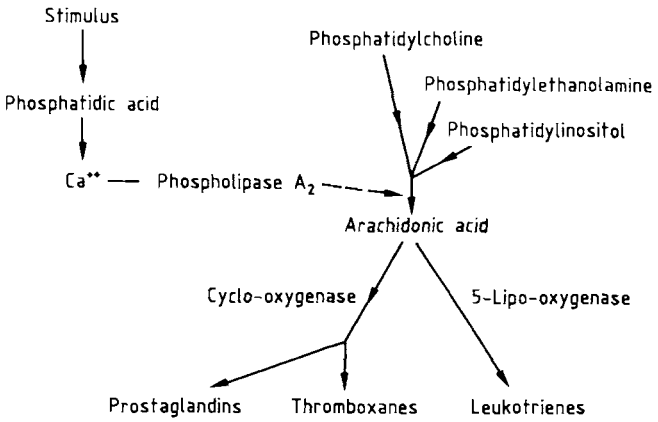

Fig. 5. Schematic drawing of the key step, catalyzed by cellular phospholipase A_2, in the biosynthesis of prostaglandins, thromboxanes, and leukotrienes.

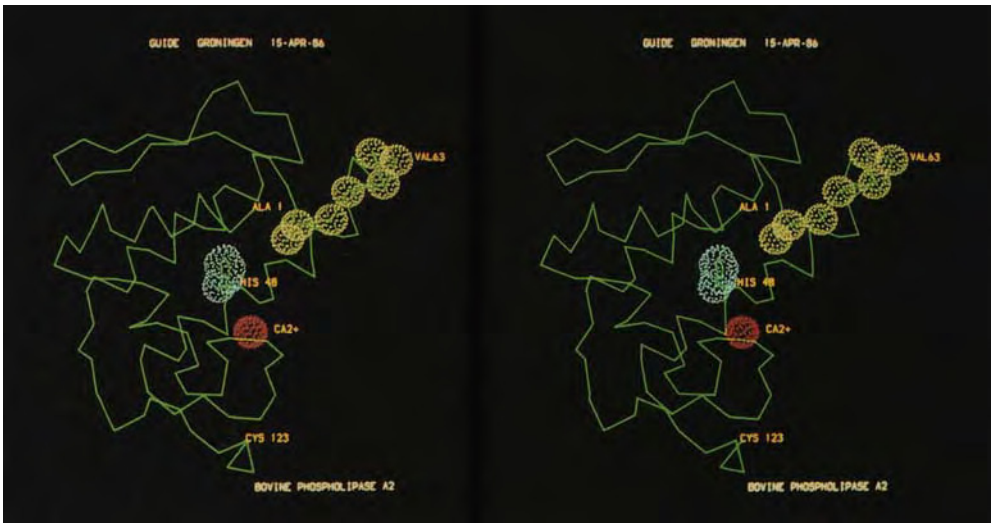

Fig. 6. Stereopicture of the structure of bovine pancreatic phospholipase A_2, which may resemble the cellular phospholipase A_2 to a considerable degree. The essential His-48 (blue) and the calcium ion (red), which is necessary for activity, are indicated. The "sixties-loop" is highlighted by yellow dot surfaces at the C_α positions. This loop has special properties: depending on the phospholipase, it is either disordered or adopts a conformation quite different from the one shown for the bovine enzyme [55–59].

[54]). The three-dimensional structures of pancreatic phospholipase A_2 from several sources are known (Fig. 6);[55–58] the structures of the snake venom and pancreatic enzymes are extremely similar.[59] Clearly, this structural information can be a starting point for designing inhibitors of intracellular phospholipase A_2, because the immunological relationship[53] almost certainly implies a considerable similarity in the active-site regions. It would be of great help if the structure of a phospholipase A_2 complexed with a phospholipid analogue were known, but this has not yet been achieved. A possible explanation is the surprising conformational sensitivity of the pancreatic enzyme to even minute alterations.[58] Nevertheless, the structure of the covalent inhibitor *p*-bromophenacyl bromide bound to the active-site histidine is currently known at 3.0 Å resolution—despite the fact that only a single suitable crystal was available.[60] This example of an inhibitor binding mode may provide an experimental starting point for designing specific inhibitors.

Even more recently, the amino-acid sequence of the protein macrocortin, or lipocortin,[61] an inhibitor of phospholipase A_2 induced by glucocorticoids,[48] was elucidated. The structure of a lipocortin:phospholipase A_2 complex would obviously be a marvelous source of inspiration for designing new compounds that interfere with arachidonic acid synthesis. A large number of laboratories are already engaged in attempts to design inhibitors using the information currently available for the structure of phospholipase A_2.

5. Inhibition of Proteins that are Unique to Infectious Organisms

5.1. Inhibition of Bacterial Cell Wall Synthesis

Penicillin is undoubtedly the best known example of a compound that inhibits, in an infectious agent, a vital metabolic step that has no counterpart in humans. The penicillin family has been enlarged by cephalosporins and other chemically related compounds (see, e.g., ref. [62]), so that a wide range of antibacterial compounds that interfere with cell wall synthesis is now available. This has caused a revolution in the treatment of bacterial infections in the twentieth century.[62] Nevertheless, drug resistance remains a severe problem. In several cases, this resistance is caused by enzymes such as β-lactamases that are able to degrade members of the penicillin family, rendering them harmless to the pathogen.

Penicillin interferes with the final steps of the synthesis of peptidoglycan, an important component of the cell wall:

$$\text{enzyme} + \text{R-D-Ala-D-Ala-COOH} \longrightarrow \text{enzyme—CO-Ala-R} + \text{D-Ala-COOH} \quad (1)$$

$$\text{enzyme—CO-Ala-R} + \text{R'NH}_2 \longrightarrow \text{R'NHCO-Ala-R} + \text{enzyme} \quad (2)$$

where R and R′ are the two polysaccharides to be cross-linked. Some of the enzymes involved are bifunctional. They can carry out both steps, acting as carboxypeptidase-transpeptidases, or they can accept water as the acceptor in step (2) and function as carboxypeptidases. Other enzymes are monofunctional and act solely as D-alanyl carboxypeptidases.[63]

The structure of a $Zn^{2\oplus}$-containing D-alanyl-D-alanyl carboxypeptidase from *Streptomyces albus* has been solved at 2.5 Å resolution by *Dideberg* et al.[64] This enzyme is penicillin-insensitive; only the β-iodopenicillinate binds irreversibly to its active site.[64] Once the structures of this enzyme and of complexes with its inhibitor are known in greater detail, they may suggest further possible modifications of the penicillin molecule, particularly those that would enable it to block a wide range of carboxypeptidases responsible for resistance.

The structure of a penicillin-sensitive D-alanyl carboxypeptidase-transpeptidase, solved by *Kelly* et al.,[65] is also of great interest. Moreover, these investigators reported the

first crystallographic binding studies of four species derived from penicillin: three β-lactams and a cyclobutanone.[66]

While this review article was being completed the first details of β-lactamase I from *Bacillus cereus* became available. Extensive regions of the tertiary structure of this enzyme are similar to those of the penicillin-sensitive D-Ala-D-Ala carboxypeptidase-transpeptidase.[67] Although details of the β-lactamase structure require further model building and refinement, it is evident that important structural information on penicillin-sensitive and penicillin-degrading enzymes is just becoming available. In due course it may become possible to design compounds that fit tightly into the active site of carboxypeptidases catalyzing the synthesis of cell walls and which, at the same time, have precisely tailored substituents that prevent inactivation by lactamases. Alternatively, efficient inhibitors of the β-lactamases may be designed. However, despite the detailed knowledge of the three-dimensional structures of proteins provided by X-ray crystallography, converting this knowledge into useful drugs, or combinations of drugs, remains a formidable challenge.

5.2. Virus Coats

High-resolution structures of viruses and of viral coat proteins are of tremendous importance for the development of new vaccines against several widespread human diseases. But also from the point of view of rational drug design, the crystallographic studies on rhino- and poliovirus,[68,69] as well as on the influenza virus coat proteins hemagglutinin[70] and neuraminidase,[71] are of potential practical use. For instance, inspection of the intricate subunit–subunit interactions of the viral coat proteins may reveal binding sites for small molecules that might interfere with the assembly of the viral particles. Alternatively, such knowledge may direct the design of precisely tailored cross-linking reagents—in analogy to the development of bivalent anti-sickling compounds.[8] Extensive cross-linking could render viruses into harmless entities. A third possibility is the design of compounds that fit tightly into the receptor binding sites of the rhino- and poliovirus and thereby prevent their entrance into the cell. The impressive results obtained by protein crystallography are therefore rich sources of inspiration for medicinal chemists designing new antiviral agents.

5.3. Bacterial Toxins

Some bacteria affect their hosts by the excretion of one or more toxins. The best characterized toxins include diphtheria toxin (DT), excreted by *Corynebacterium diphtheriae*, choleratoxin (CT), excreted by *Vibrio cholerae*, and the closely related, heat-labile enterotoxin (LT), excreted by enterotoxic *Escherichia coli* strains.[72–75]

Diphtheria toxin is synthesized as a single polypeptide chain of $M_r = 62000$, which is then split into an A chain of $M_r = 21000$ and a B chain of $M_r = 40000$. The A chain is an enzyme catalyzing the ADP-ribosylation of elongation factor 2, while the B chain is essential for entrance of the A chain into the cell. A similar mode of action has been observed for CT and LT, although their architecture and the precise point of cell deregulation differ from those of DT. CT and LT, like DT, consist of an A chain ($M_r \approx 27000$) and a B chain ($M_r = 13000$), but they form an AB_5 complex. The B chains are responsible for binding to the cell surface, where they interact with GM_1 gangliosides (Fig. 7). The A chain catalyzes an ADP-ribosylation, but the target is this time the regulatory G_s component of the adenylate cyclase system. This ribosylation sets the G_s protein in a permanent "on" state, which, in turn, stimulates adenylate cyclase to produce cAMP, resulting in a massive outflow of water and nutrients through the intestinal cell wall. This sequence of events has severe consequences, ranging from inconvenience in the northern hemisphere to child death in many less developed areas.

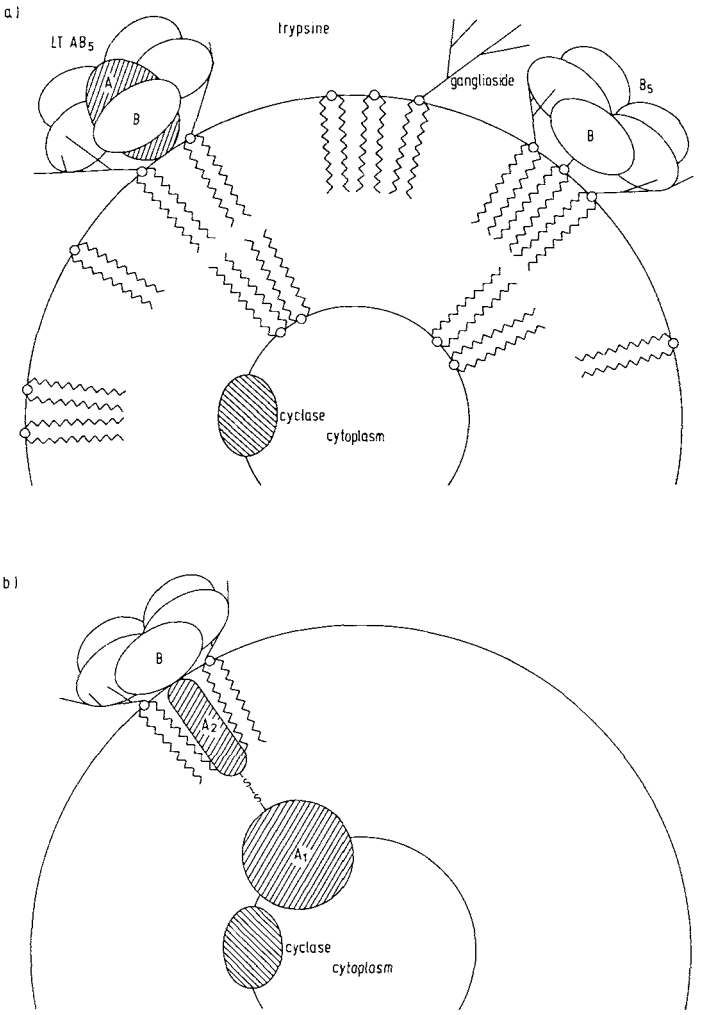

Fig. 7. The mode of action of the heat-labile enterotoxin from *E. coli*, which is virtually identical to that of choleratoxin. a) Attachment of AB_5 and B_5 complexes to gangliosides (GM_1) in the membrane of epithelial cells of the gut; b) translocation of the A1 fragment ($M_r = 22000$) across the membrane, followed by an ADP-ribosylation of the G_s component of the adenylate cyclase system (Drawing kindly provided by *Sylvia Pronk*). LT means heat-labile enterotoxin.

The amino-acid sequences of these toxins have recently become available,[76–80] and X-ray investigations are under way for DT, CT, and LT.[81–84] Once these investigations

have yielded high-resolution structures, compounds can be designed to interfere selectively with the key steps in the mode of action of these toxins; for example,

1. assembly of the AB_5 complex of CT and LT and the AB complex of DT;
2. binding to the cell surface receptors;
3. entry of the A chain into the cell;
4. ADP-ribosylation catalyzed by the A chain once it is inside the cell.

The rational design of drugs will have to compete, of course, with the development of vaccines, based either on recombinant DNA technologies or on fragment peptide synthesis, which is being carried out presently in a number of laboratories. Moreover, oral rehydration therapy appears to provide a cheap and effective method to combat child death due to enterotoxic *E. coli* and *V. cholerae* infections in developing countries. Nevertheless, accurate three-dimensional structures of the "moonlander-like" bacterial toxins, in particular the structures of their complexes with GM_1 and NAD analogues, may prove to be a starting point for the development of a variety of new pharmaceuticals.

6. Selective Inhibition of Proteins from Infectious Organisms

There are only a few examples in the literature of crystallographic projects involving the inhibition of an enzyme from a pathogen in cases where an analogous enzyme in the human host must be protected from inhibition. One well-known example is provided by the bacterial dihydrofolate reductases. Another example is that of the glycolytic enzymes from *Trypanosoma brucei*, the causative agent of sleeping sickness.

6.1. Dihydrofolate Reductase

Dihydrofolate reductase (DHFR) is a key enzyme in the metabolism of numerous organisms and the target protein of several widely employed drugs. The enzyme is vital for proliferating cells because it is required for maintaining adequate levels of fully reduced folate, which, in turn, is necessary for the synthesis of thymidylate (Fig. 8).

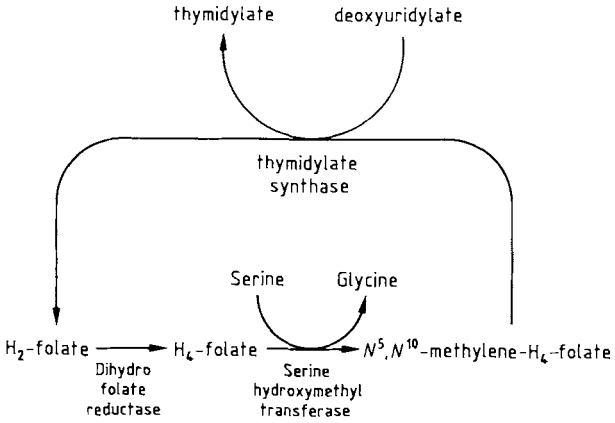

Fig. 8. Pathway involving three enzymes that are crucial for the synthesis of thymidylate and thus nucleic acids. The differences in the properties of dihydrofolate reductase from different organisms form the basis for several important antibacterial and antimalarial drugs currently in use. Human dihydrofolate reductase is, in addition, the target of the cancer drug methotrexate.

Three classes of dihydrofolate reductases have been described so far (see, e.g., refs. [85, 86] and references cited therein):

1. Chromosomal DHFRs have a molecular weight of about 15000 and, despite amino acid homologies of less than 30%, appear to share a common architecture (Fig. 9). Three-dimensional structures are known for the *E. coli*, *Lactobacillus casei*, and chicken enzymes.[33, 87, 88] A preliminary report on the structure of a second vertebrate DHFR, the enzyme from the L1210 mouse lymphoma, has appeared from the Wellcome Laboratories in the United Kingdom.[89]
2. Plasmid-encoded DHFRs occur in certain bacterial strains resistant to the antibacterial drug trimethoprim. Three types of resistant DHFRs can be distinguished:[85]
   - type I: dimeric molecules with subunits having molecular weights of about 17500; their resistance to trimethoprim is due mainly to a lowered affinity for the drug;
   - type II: a tetrameric molecule with a reported subunit molecular weight of about 8500;
   - type III: monomeric proteins with molecular weights of about 18000; their resistance to trimethoprim is due to a combination of weaker binding of the drug and enhanced affinity for the substrate.

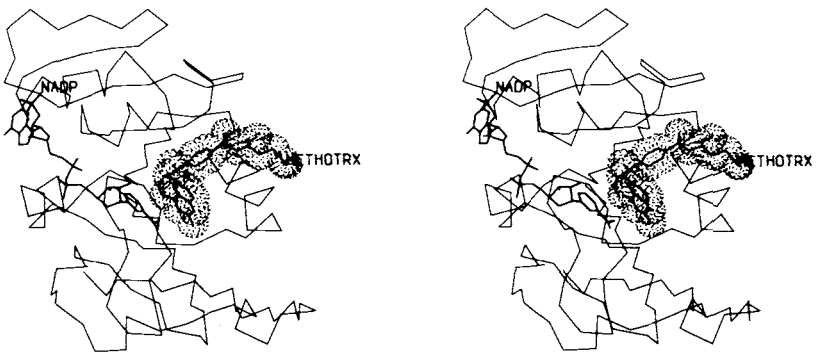

Fig. 9. Stereopicture of the structure of the complex of dihydrofolate reductase from *Lactobacillus casei* with the coenzyme NADP and the drug methotrexate (labeled METHOTRX) (coordinates kindly provided by *D. A. Matthews* and *J. Kraut*).

Amino acids crucial for the functioning of chromosomal DHFRs are conserved in type I and type III plasmid-encoded DHFRs, which suggests a common ancestry and similar overall architecture. The type II DHFRs have an entirely different folding pattern as shown by the crystal structure of apo R67 DHFR: each 78-residue subunit is folded into a six-stranded antiparallel β-barrel.[85]

3. Protozoal DHFRs have molecular weights of about 110000. These large enzymes have been found in the rodent malaria parasite *Plasmodium berghei*, in *Leishmania tropica*, and in *Trypanosoma cruzi*.[90-92] Most intriguingly, this protozoan enzyme is bifunctional, exhibiting both DHFR and thymidilate synthetase activities.[91-92] No structural information about this class of DHFRs is available yet, despite the great importance of such information for the treatment of several major tropical diseases. The need for new drugs is dramatically shown by the rapid increase of resistance against one of the most important antimalarial drugs, pyrimethamine.[2] This drug is a DHFR inhibitor, binding 1400 times more tightly to the *Plasmodium* enzyme than to the human enzyme;[93] however, the resistant malaria strains are somehow able to avoid the drug's action.

In a most interesting article, the group of *Matthews* and *Kraut* in San Diego recently described X-ray structures of complexes formed between dihydrofolate reductase and not less than ten compounds.[94] The structures of these complexes, together with the structures of the antibacterial drug trimethoprim bound to chicken and *E. coli* DHFR,[95] provided an explanation for the different binding of the drug to bacterial and mammalian DHFRs at the atomic level: amino acid residues on opposite sites of the active site cleft in the *E. coli* enzyme are approximately 1.5–2.0 Å closer to each other than the corresponding residues in the chicken enzyme.

Space does not permit further details to be presented regarding this series of DHFR structures; these studies have afforded marvelously detailed insight into the mode of action of drugs and their derivatives. They will almost certainly lead, via the rational drug design cycle (Fig. 1), to new antibacterial compounds in the near future. Reports on several investigations along these lines have already appeared (e.g., refs. [96–98]).

6.2. Glycolytic Enzymes and Sleeping Sickness

Sleeping sickness, or human trypanosomiasis, in sub-Saharan Africa is considered by the World Health Organization as one of the six most important current tropical diseases.[2] The disease is caused by the protozoal parasite *Trypanosoma brucei*. Only three drugs, each of which causes serious side effects, are presently available for treatment of the disease.[99] New and better drugs are therefore urgently needed.

Trypanosomes have several characteristic features, one of which is the variable surface glycoprotein (VSG), which enables the parasite to outwit the human immunological defense system.[100] The three-dimensional structure of a VSG has been reported at low resolution;[101] work at high resolution is in progress. The VSG structure shares a basic feature with that of influenza virus hemagglutinin, namely, long coiled α helices perpendicular to the membrane surface. Once detailed knowledge, in particular about subunit interactions, becomes available for the VSG protein, it may become possible to pursue strategies similar to those discussed above (Section 5.2) for the viral coat proteins. Compounds may be designed that either interfere with the assembly of the VSGs or bind to specific sites formed by two neighboring VSGs, thereby cross-linking them. The latter approach is not without problems, since damage to human macromolecules must be avoided.

In another project, three groups—in Amsterdam, Brussels, and Groningen—are collaborating in an attempt to design new drugs against sleeping sickness. These groups are focusing on another unique feature of *Trypanosomatidae*, namely, the presence of glycosomes. These peroxisome-like organelles are vital for the energy supply of the bloodstream form of the trypanosome.[102-104] The major glycosomal proteins are nine enzymes involved in glucose and glycerol metabolism. All nine enzymes are now available in pure form.[105, 106] Moreover, the amino acid sequences of five glycolytic trypanosomal enzymes have been determined by sequencing the corresponding genes.[107-110] Crystallization of trypanosomal enzymes is unusually difficult owing to the small amounts of material available. Nevertheless, high-quality crystals of the enzyme triose phosphate isomerase (TIM) were obtained from approximately 1 mg of protein,[110] and have allowed the solution of its three-dimensional structure.[111] Fortunately, TIM is also one of the enzymes for which the *T. brucei* sequence is available.[107] Moreover, the three-dimensional structure of the chicken enzyme[112] gives a good idea of the structure of the human enzyme owing to the high sequence homology. The *T. brucei* TIM structure still needs considerable refinement before it provides a solid basis for rational drug design. However, it is already obvious that the design of compounds that inhibit catalysis of the trypanosomal enzyme while leaving the human TIM undisturbed will not be trivial. The reason is the great similarity of the active site regions of the human and parasite proteins (Fig. 10). One of the differences closest to the active site resides in residues 101–103, which are Ala-Tyr-Tyr in *T. brucei* and His-Val-Phe in man.[107] To exploit this difference for the design of selective inhibitors, a distance of approximately 20 Å must be bridged between the substrate binding site and residue 102. This can certainly not be achieved in a single shot. However, via the rational drug design cycle, it might be possible to increase gradually the size of the compounds synthesized, see how they bind, and deduce new modifications which eventually may provide the necessary selectivity.

For another glycosomal enzyme, phosphoglycerate kinase (PGK), the amino-acid sequence is available;[108] moreover, three-dimensional structures of the horse and yeast enzymes are known.[113, 114a,b] Unfortunately, PGK from *T. brucei* does not show the slightest tendency to crystallize. However, model building on a computer graphics system coupled with energy minimization has given approximate models of the *T. brucei* and human en-

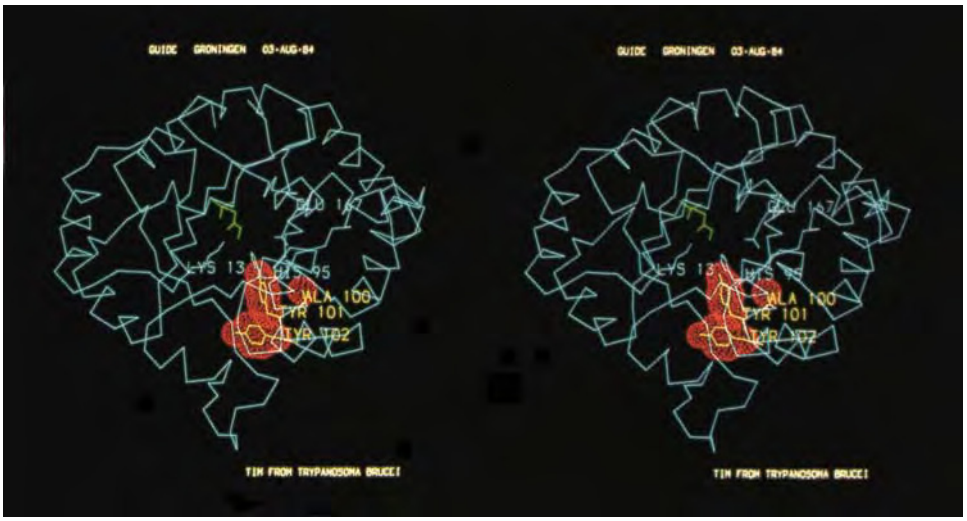

Fig. 10. Stereopicture of the structure of triose phosphate isomerase (TIM) from *Trypanosoma brucei* (coordinates kindly provided by *R. K. Wierenga*). Superpositions of TIM from *T. brucei* and yeast complexed with the substrate dihydroxyacetone phosphate (DHAP) (coordinates generously made available by *G. Petsko*) yielded an approximate position of DHAP bound to *T. brucei* TIM (center of the picture, green). For clarity, only C_α coordinates are shown except for six residues of which the side chains are outlined: the three catalytic residues Lys-13, His-95, and Glu-167, and the three residues near the active site that differ from those in the human enzyme, namely, Ala-100, Tyr-101, and Tyr-102 (yellow surrounded by a van der Waals surface in red). In the human enzyme, the latter three are His-100, Val-101, and Phe-102.

zymes.[114c] The active site regions appear to differ more from each other than in the case of triose phosphate isomerase and, hence, the design of selective inhibitors might be easier to achieve.

Selective enzyme inhibition is not the only way, however, by which the presence of glycosomes can be exploited for the rational design of drugs against sleeping sickness. Unlike their human counterparts, glycosomal enzymes have to enter the glycosome, thereby providing opportunities to interfere with the mechanism of import. Analysis of the sequences of glycosomal enzymes, together with the known three-dimensional structures of triose phosphate isomerase, phosphoglycerate kinase, and glyceraldehydephosphate dehydrogenase has led to a proposal for the mechanism of glycosome import:[115] two areas of high positive charge, approximately 40 Å apart, are considered to be essential elements of the import signal. Interestingly, this suggests a possible mode of action of suramin, one of the few drugs effective against sleeping sickness.[99] Suramin is a very complex molecule that has two trisulfonated naphthalene ring systems, which are approximately 40 Å apart in the extended conformation. The drug, which is known to interfere with glycolysis, might exert its therapeutic effect by preventing import of enzymes into glycosomes. Further investigations, currently in progress, are required, to prove these hypotheses. Whether or not these speculations are correct, the glycosomal import mechanism is an interesting target for rational drug design because there may be no closely analogous system in human beings.

7. Protein Crystallography

The methodology of X-ray crystallography of proteins is not given much attention in this article for two reasons. First, it would take up too much space. Second, several extensive accounts of the procedures required have been published (e.g., refs. [116, 117]). These monographs also give due attention to the major hurdle that has to be surmounted before a structure can be elucidated, namely, the growth of high quality crystals. This step is sometimes solved in a month, sometimes in one or two years, and sometimes not at all. Thus, it is hard to predict if and when a structure will be solved. However, with the gradual increase in the number of crystallization procedures and with the large amounts, up to grams, of very pure protein that are often made available by gene-cloning techniques, the prospects of obtaining crystals are becoming better all the time. The future may see the use of "protein-engineering-for-crystal-growth," that is, generating mutant enzymes that remain active but crystallize more readily. This will, obviously, have to be a trial-and-error process but it may be the only solution in cases where one absolutely needs to know a crystal structure. In difficult cases, it might be possible to crystallize proteins complexed with monoclonal antibodies. Once crystals are obtained, sophisticated software and hardware for data collection and phase determination allows structure determinations with increasing speed and accuracy.

8. Concluding Remarks

The drug design approach outlined here can be expanded in two ways. First, other biomacromolecules can be used as drug targets, which has already been alluded to in the introduction. In particular, X-ray crystallography of *oligonucleotides* has afforded detailed insight into the structure of DNA. For instance, the recent structure of a DNA:netropsin (congocidin) complex[118] may prove to be the starting point for the rational design of pharmaceuticals active against specific DNA sequences. It is also conceivable that differences in the tRNA, the ribosomal RNA, or the nuclear RNA structures of pathogen and host might be used for designing pharmaceutically useful compounds.

Second, the rational drug design strategy discussed here may be applied equally well to the design of new herbicides and pesticides. Indeed, the fantastic structure determination of the photosynthetic reaction center has already allowed the location of the herbicide terbutryn at its site of action.[119]

Amidst all this optimism it is good to remember the long list of obstacles to be overcome before a compound showing a desired activity in a test tube can be sold on the market as a useful drug. Drug delivery and safety, the possibility of metabolic alterations, and the economics of production all need to be given great attention and are, moreover, time-consuming. In this respect the approach outlined in the work described here and elsewhere (e.g., ref. [1]) differs little from existing procedures. However, in the initial stages of drug design, the approach discussed here is vastly different—not only because it allows one to "see" which compounds might be effective but also because three-dimensional structures of target proteins often immediately show which modifications of a compound *cannot* lead to a more active molecule, because the modified compound would simply not fit into the active site. *Freudenreich* et al.[120] give a beautiful example of these points in their rational design of alcohol dehydrogenase inhibitors on the basis of the three-dimensional structure of the enzyme.

In summary, a new drug design strategy has emerged during the last decade based upon accurate three-dimensional structures of biomacromolecules that have to be specifically affected by pharmaceutically active compounds. In view of the great advantage of this strategy over existing ones, it is not hard to predict that a considerable percentage of new drugs coming on the market by the turn of the century will be based on approaches outlined in this article.

It is a pleasure to acknowledge stimulating discussions with Rik Wierenga, Bauke Dijkstra, Jan Drenth, and Sylvia Pronk from the Groningen protein crystallography group, and Klaus Müller from Hoffmann-La Roche in Basel. I also would like to thank Randy Read for numerous suggestions for improving the text, and Dave Matthews for sending a preprint of the dihydrofolate reductase review. Roeline Hogenkamp has given excellent assistance in the preparation of the manuscript.

Microbial Degradation of Halogenated Hydrocarbons: A Biological Solution to Pollution Problems?

By Rudolf Müller and Franz Lingens*

In memoriam Konrad Bernhauer

Chlorinated hydrocarbons are widely used because of their chemical and thermal stability as well as their fungicidal, herbicidal, and insecticidal properties. Unfortunately, it is just this stability that makes the compounds persistent in nature; half-lives of more than 15 years are not uncommon. In many countries the use of some chlorinated compounds has been prohibited, even though many such compounds (e.g., DDT) exhibit exactly the desired spectrum of effects. Surprisingly, microbial systems that can degrade most chlorinated hydrocarbons have been found in nature. Indeed, it is possible, in many cases, to isolate pure cultures of bacteria that can utilize these compounds as the sole source of carbon and energy. Even polychlorinated compounds, such as the wood preservative and herbicide pentachlorophenol, can be utilized as a source of carbon by some bacteria. The study of the biodegradation of halogenated hydrocarbons has led to the discovery of novel catabolic pathways in which unusual and previously undescribed enzymatic activities have been detected. Bacterial enzymes have even been isolated that can replace halogen substituents in aliphatic and aromatic compounds with hydroxyl groups or hydrogen atoms. Improved understanding of the biodegradation of halogenated hydrocarbons, as described in this article, will almost certainly result in new biotechnological applications, especially in the area of waste-water treatment.

1. Introduction

Halogenated hydrocarbons are used in many aspects of our daily life. They have applications as solvents (e.g., chloroform, trichloroethylene, and chlorobenzene), as insulating liquids (polychlorinated biphenyls), as wood preservatives (pentachlorophenol), and as herbicides and fungicides. As a result, vast quantities of these compounds enter our environment both accidentally and intentionally. The sensitive methods for chemical analysis now available have revealed that few areas on earth remain uncontaminated.[1,2] Newspaper reports of the existence and associated dangers of chlorinated hydrocarbon pollutants are commonplace; consequently, the general public is aware and concerned about this issue. In contrast to most man-made compounds, which are rapidly degraded upon introduction into the environment, chlorinated hydrocarbons are often highly persistent.[3] This lack of degradation is thought by some biologists to reflect the inability of nature to adapt, through the evolution of appropriate biodegradative microorganisms, to the dramatic increase in the number of new compounds resulting from man's industrial activities in this century. However, since nature itself produces a variety of chlorinated compounds in large amounts, it would be surprising if mechanisms for their biodegradation did not exist. Indeed, microorganisms are known to play a major role in the degradation of organic compounds.

In this article we shall consider the extent to which chlorinated hydrocarbon pollutants can be degraded and thereby detoxified by microorganisms. We will first discuss the methods that are frequently used in the study of hydrocarbon biodegradation. The later sections will focus almost exclusively on the degradative activities of bacteria, since this group of microorganisms constitutes a major component of the soil and water microflora and since they have been the subject of most investigations of biodegradation. Comparable studies with fungi are rare, and the biodegradative potential of algae and protozoa remains virtually unstudied.

2. Methodological Approaches to Studying the Biodegradation of Pollutant Hydrocarbons

A prerequisite for examining the biodegradation of any compound is a reproducible, relatively sensitive and quantitative method for detection of the compound. The problems associated with the development of such analyses are familiar to chemists and, therefore, will not be described further.

Having selected a test substance whose degradation can be followed, the investigator has to find a suitable source of microorganisms capable of degrading the substance. For chlorinated hydrocarbons, the most promising sources are soil or water samples chronically polluted with these compounds. The samples are incubated in aqueous media containing varying concentrations of the selected chlori-

nated hydrocarbon. The incubations (often referred to as enrichments, since the investigator aims to enrich the sample with respect to specific degradative bacteria) are carried out under a wide range of conditions: for example, humidity, temperature, pH, trace element concentrations, and concentration of dissolved oxygen may be varied. Periodically, the concentration of the test substance, and possibly compounds derived from it, are monitored. If the test substance disappears, the investigator transfers a sample from the enrichment into fresh medium containing the test substance. By continuation of this procedure using either batch or continuous culture techniques, stable mixed populations of microorganisms, usually bacteria, can be obtained. Because it is usually simpler to work with pure cultures, the investigator will often aim to isolate single bacterial species capable of utilizing the test substrate as the sole source of carbon and energy. This may be done by plating out the mixed cultures on agar-based solid media in order to isolate single colonies (clonal populations) of bacteria.

Having isolated a single bacterial species, the investigator can attempt to identify the metabolic reactions that constitute the degradative pathway and to isolate the enzymes that catalyze these reactions. Ultimately, the degradative reactions may be carried out in vitro with purified enzymes, thereby allowing biotransformation of the test substance. Biotransformation, which is defined as the transformation of chemical substrates catalyzed by microorganisms, by cell-free extracts of microorganisms, or by isolated enzymes, can be carried out using a variety of techniques. For example, the test substance (the substrate) can be added to a growing bacterial culture so as to induce the synthesis of the enzymes catalyzing the desired reaction. Alternatively, biotransformations can be carried out using "resting cells," a technique in which the bacterial biomass is isolated from cultures growing under optimal conditions and then transferred into a special transformation medium containing the test substrate. An important variation of this technique is the immobilization of "resting cells" on an inert support. The advantage of using immobilized systems is that the biocatalyst is easily retained within a reaction vessel, facilitating continuous biotransformations. In some cases, undesirable interference from subsequent reactions as well as side reactions is best eliminated by the purification of the enzymes catalyzing the desired biotransformation and, where possible, their immobilization on inert supports.

In the following sections, the extent to which the methods described above have proved successful in studying biotransformations of the most important halogenated hydrocarbons will be described.

3. Halogenated Aliphatic Compounds

Halogenated aliphatic hydrocarbons are widely used as herbicides and solvents. In 1982, for example, more than 13 million tons of dichloromethane was produced throughout the world.[4] Some of these compounds are carcinogenic (e.g., vinyl chloride), whereas others (e.g., 1,2-dichloroethane) can be biologically or chemically converted into mutagenic products.[5,6] Repeatedly, contamination of ground and drinking water has resulted from careless handling of haloalkane-based solvents. Concern has also been voiced about the observation of chlorinated aliphatic hydrocarbons associated with chlorination of municipal water supplies.[7] Consequently, the biodegradation of these substances is of great interest. Two major groups of halogenated aliphatic compounds are of current importance: firstly, the haloalkanes used as intermediates in chemical syntheses and as solvents, and secondly, the haloalkanoic acids applied as disinfectants and herbicides.

3.1. Halogenated Alkanes

Brunner et al.[8] isolated a bacterium capable of utilizing dichloromethane as the sole source of carbon and energy, and *Stucki* et al.[9] have reported the isolation of a *Hyphomicrobium* species with the same degradative ability. The latter strain contains a glutathione-dependent dehalogenase, which was shown to catalyze the conversion of dichloromethane to formaldehyde. The disinfectant trichloronitromethane (chloropicrin) is another C_1 compound whose biodegradation has been studied:[10] this compound is converted, via a series of enzyme-catalyzed reactions, into nitromethane by a *Pseudomonas* species. Bacterial breakdown of carbon tetrachloride has also been demonstrated; chloroform and carbon dioxide were found as degradation products.[11]

Numerous C_2 haloalkanes have been reported to be subject to extensive biodegradation: e.g., 1,2-dichloroethane,[12,13] tetrachloroethylene, trichloroethylene, dichloroethylene, and vinyl chloride.[14] *Vogel* and *McCarthy*[14] have proposed a pathway for the degradation of tetrachloroethylene **1** by a mixed microbial culture grown under anaerobic conditions (Fig. 1). *Janssen* et al.[12] described the degradation of 1,2-dichloroethane **2** by a bacterium they classified as *Xanthobacter autotrophicus* strain GJ10. The first step in the catabolic sequence is the replacement of one halogen substituent by a hydroxyl group. The enzyme catalyzing this reaction has recently been purified.[15] The product, chloroethanol **3**, is oxidized, via the aldehyde **4**, to chloroacetate **5**, which undergoes hydrolytic removal of the second chlorine atom to give lactic acid **6** (Fig. 2). Interestingly, the two dehalogenation steps are catalyzed by two different enzymes.[12] *Jagnow* and coworkers[16,17] have described the biodegradation of the insecticide hexachlorocyclohexane (HCH, commercially available under the trade name Lindane) by obligate and facultative anaerobic bacteria. Although the complete degradative pathway remains to be elucidated, tetrachlorocyclohexane was identified as an intermediate.[17]

Long-chain haloaliphatic hydrocarbons have not assumed the same commercial importance as the substances discussed above; however, bacteria capable of dehalogenating and utilizing a number of such compounds (e.g., 1,5-dichloropentane, 1,6-dichlorohexane, 1,9-dichlorononane, 1,9-dibromononane, 1-chlorooctane, 1-chloro-, 1-bromo-, and 1-iodoheptane) have been isolated.[18]

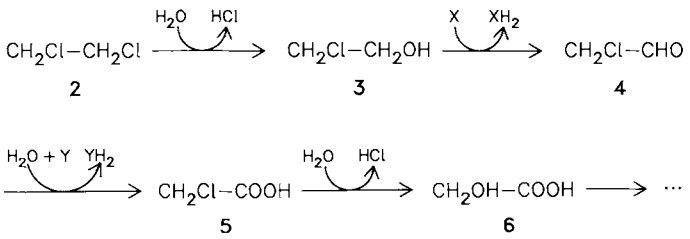

Fig. 2. The degradation of 1,2-dichloroethane **2** by *Xanthobacter autotrophicus* GJ10. The glyoxylic acid **6** so obtained is degraded by a known pathway.

3.2. Halogenated Alkanoic Acids

Chloroalkanoic acids, some of which are used as herbicides,[19] are toxic to a variety of organisms including mammals. As a group, the chloroalkanoic acids are relatively rapidly degraded by a variety of microorganisms. *Senior* et al. isolated several species from a mixed microbial culture that were capable of utilizing Dalapon (2,2-dichloropropionic acid) as the sole source of carbon and energy.[19] Several authors have reported the isolation of bacteria that can degrade chloroacetate,[21-23] fluoroacetate,[24,25] or chloropropionate[26] and their dichlorinated analogues. In all cases so far studied, the biodegradation is initiated by replacement of the halogen substituent of the α-substituted haloalkanoic acid with a hydroxyl group. Hydroxy acids are formed from monohalogenated acids and oxo acids from dihalogenated acids. Dehalogenating enzymes (dehalogenases) can be divided into two main groups: those that accept only halogenated acetic acids as substrates and those that can also dehalogenate longer chain substrates.[27] Both groups of dehalogenases accept only 2-substituted alkanoic acids as substrates. Optically active 2-haloalkanoic acids can react with either retention or inversion of configuration.[26] Some enzymes can only dehalogenate the L-isomer of the substrate, whereas others can transform both enantiomers. These different specificities can be exploited for the enzymatic synthesis of the two optically active forms of lactic acid from racemic 2-chloropropionic acid. The synthesis involves, first, the conversion of L-2-chloropropionate to D-lactate by the appropriate dehalogenase, followed by the separation of unconverted D-2-chloropropionate from the D-lactate and the conversion of the purified D-2-chloropropionate to L-lactate using an enzyme that can dehalogenate both isomers of the substrate.[28] Dehalogenases capable of converting D-2-chloropropionate exclusively into L-lactate, a reaction of commercial importance, have not yet been isolated.

4. Aromatic Hydrocarbons

4.1. Nonhalogenated Aromatic Hydrocarbons

The biodegradation of nonhalogenated aromatic compounds has long been intensively studied (for reviews see refs. [29-31]). The bacterial degradation of haloaromatic compounds involves the same basic principles as for the aerobic catabolism of corresponding unsubstituted compounds. These principles are exemplified below for the degradation of benzene by bacteria (Fig. 3). The first step is the formation of *cis*-3,5-cyclohexadiene-1,2-diol **7** by incorporation of both atoms of molecular oxygen into ben-

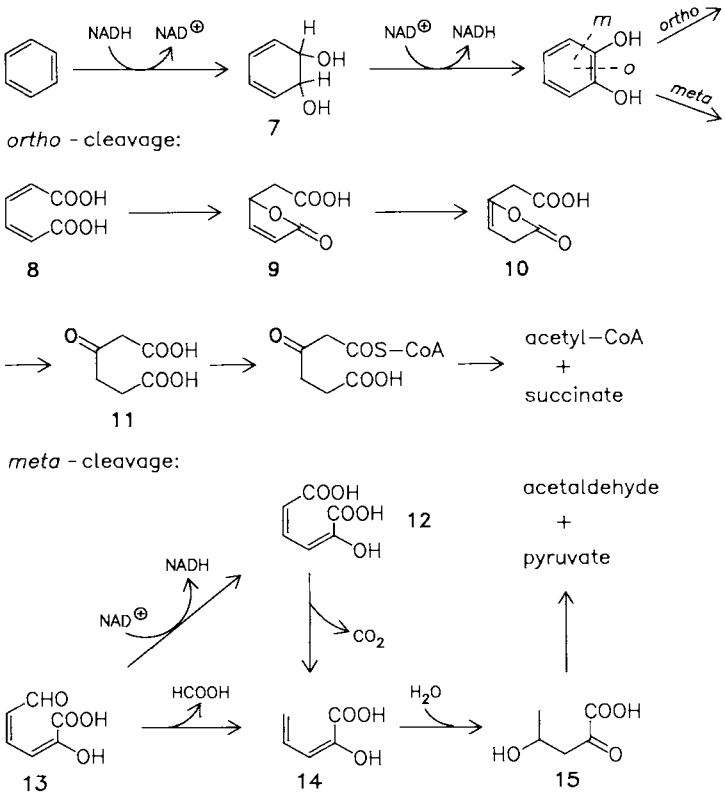

Fig. 3. The bacterial degradation of benzene.

zene. This reaction is catalyzed by a dioxygenase produced by benzene-degrading bacteria. The subsequent conversion of **7** to catechol is catalyzed by a dehydrogenase. At this stage a second molecule of oxygen is incorporated with cleavage of the aromatic ring. Two reaction pathways for aromatic ring cleavage of catechol are possible, each catalyzed by a distinct dioxygenase. Cleavage between the hydroxyl groups, called *ortho*-cleavage, produces *cis*,-*cis*-muconic acid **8**. Cleavage at a position adjacent to the two hydroxyl groups, called *meta*-cleavage, forms 2-hydroxymuconic semialdehyde **13**.

The first intermediate of the *ortho*-cleavage pathway, **8**, is converted by a cycloisomerase into muconolactone **9** which is further isomerized to form the enol lactone **10**. 2-Oxoadipic acid **11**, which is produced by hydrolase-catalyzed cleavage of the lactone **10**, is first esterified with coenzyme A and then cleaved into acetyl-CoA and succinate in an aldolase-catalyzed reaction.[32]

The product of the *meta*-cleavage pathway, **13**, can react further by either of two alternative routes. Dehydrogenase-catalyzed oxidation of **13** affords 2-hydroxymuconic acid **12**, which is then decarboxylated to 2-hydroxy-2,4-pentadienoic acid **14**. Hydrolase-catalyzed elimination of formic acid from **13**, on the other hand, results in direct conversion to **14**. Compound **14** is then converted into 4-hydroxy-2-oxovalerate by hydratase-catalyzed addition of water, and the product is cleaved by an aldolase to form pyruvate and acetaldehyde (Fig. 3).[31] Several enzymes involved in the catabolism of variously substituted aromatic hydrocarbons have been purified and characterized.[29,33-37]

4.2. Halogenated Aromatic Compounds

4.2.1. Polychlorinated Phenols

Polychlorinated phenols, in particular pentachlorophenol, are extensively used as fungicides, herbicides, disinfectants, and wood preservatives. Each year hundreds of thousands of tons are produced (wood preservatives constitute 80% of this production) and much of this enters the environment.[38] Bioaccumulation, a major problem associated with polychlorophenol pollution, has been highlighted by a study of the lake regions of Finland where these compounds were shown to be concentrated through food chains to high levels in fish.[39] Pentachlorophenol has been shown to be generally toxic[40] and may cause chloracne, irritation of the respiratory tract, and, in some cases, liver damage. Unequivocal association between exposure to pentachlorophenol and these symptoms is difficult to establish because technical-grade pentachlorophenol is contaminated with other chlorinated phenols and chlorinated dibenzo[1,4]dioxins, some of which are known to produce identical symptoms at low doses. New production methods are available for reducing the level of dioxin contamination in pentachlorophenol by about a hundredfold, but attempts to market this product have failed as a result of higher production costs.[38]

Anaerobic[41,42] and aerobic degradation[41,43-45] of pentachlorophenol by mixed microbial cultures has been reported. *Guthrie* et al.,[42] in a study of the anaerobic biodegradation of pentachlorophenol, found that the compound was undetectable ($< 5\ \mu g/L$) only ten days after its application to acclimated soil samples. Similar experiments were carried out by *Murthy* et al. with soil samples and radioactively labeled pentachlorophenol.[41] They found that CO_2 formation was severely reduced under anaerobic conditions but identified 2,3,5,6- and 2,3,4,5-tetrachlorophenol, 2,3,6-trichlorophenol, and pentachloroanisole as degradation products. In addition to these products, *Ide* et al.[46] identified 2,3,4,6-tetrachlorophenol, 2,4,5-trichlorophenol, 3,4- and 3,5-dichlorophenol, and 3-chlorophenol in acidic hexane extracts of soil samples taken from rice fields treated with pentachlorophenol and incubated for 30 days with the compound. These results strongly indicated that sequential reductive dechlorination reactions can be carried out by microorganisms degrading pentachlorophenol under anaerobic conditions.

Watanabe[47] and *Suzuki*[48] have both reported the isolation of a *Pseudomonas* species capable of utilizing pentachlorophenol as the sole source of carbon and energy. *Stanlake* and *Finn*[49] isolated a gram-positive *Arthrobacter* species with the same ability. In neither case was it possible to elucidate the complete pathways for the degradation of pentachlorophenol. However, *Suzuki*[48] and *Rott* et al.[50] identified tetrachlorocatechol and tetrachlorohydroquinone as aerobic biodegradation products, neither of which was a product of anaerobic degradation. In addition, *Rott* et al.[50] isolated tetrachlororesorcinol and corresponding derivatives in which either one or both hydroxyl groups were methylated or acetylated. Collectively, these results indicate that aerobic biodegradation of pentachlorophenol proceeds by replacement of a chlorine substituent by a hydroxyl group, although the reaction mechanism remains unclear. Both oxygenolytic and hydrolytic mechanisms are possible for the cleavage of the carbon–chlorine bond, but so far no enzymes have been isolated. The further steps in the aerobic degradation of pentachlorophenol also remain to be elucidated.

An interesting application of studies of pentachlorophenol biodegradation has been described by *Edgehill* and *Finn*,[51] who applied an inoculum of pentachlorophenol-utilizing bacteria, grown in a fermentor, to contaminated soil at a concentration of 10^6 cells (ca. 1 mg bacteria) per gram of soil (dry weight). The half-life of pentachlorophenol was thereby reduced from two weeks to less than one day. This and other studies strongly suggest that bacterial treatments could provide rapid, cheap, and effective methods for the decontamination of polluted soils.

4.2.2. Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs), which exhibit high chemical and thermal stabilities, have been widely used as insulating liquids for transformers, as greases for vacuum pumps and turbines, and as coolants. Moreover, they have found application in the production of wrapping paper, carbon paper, inks, paints, tires, and many other products. The commercial production of PCBs began in 1929 and today these compounds can be detected throughout the en-

vironment. Since PCBs are strongly hydrophobic, they are subject to bioaccummulation in the fatty tissue of humans and animals. For example, a variety of PCBs have been detected in fish, mussels, and birds living in and around the Rhine river.[1] Awareness of the environmental impact of PCBs has led to their replacement in industry by alternative, "safer" compounds, and to the relinquishment of PCB production in the Federal Republic of Germany.[52] Chloracne, skin pigmentation, hair damage, defective vision, fatigue, and liver damage are symptoms associated with acute exposure of mammals to PCBs.[53] Further studies on the biodegradation of PCBs are justified by the observation that most of the world's total production of PCBs still contaminates the environment.

Commercial formulations of polychlorinated biphenyls are made up of almost random mixtures of all 209 possible isomers. The degradation of both commercially available mixtures[54-59] and defined compounds[60-70] has been studied. Only the latter studies, however, can provide information on specific degradative reactions. Nonetheless, the former studies are of practical importance, especially with respect to the degradation of PCBs by mixed and pure microbial cultures. The most extensive studies of the biodegradability of specific chlorinated biphenyls have been carried out by *Furukawa* et al.,[65,70] who examined the degradation of 36 pure isomers, substituted with between one and five chlorine atoms, by an *Alcaligenes* species and an *Acinetobacter* species. Both the number and position of the chlorine atoms determined the extent of biodegradability. For example, the more highly substituted PCBs were metabolized less extensively than the mono- and dichlorinated biphenyls. Furthermore, the isomers bearing chlorine substituents on only one ring were more easily metabolized than those with substituents on both rings, and isomers doubly substituted in the *o*-positions (e.g., 2,2'- or 2,6-substitution) were generally recalcitrant to microbial degradation. Yellow *meta*-cleavage products were found to accumulate during the biodegradation of 2,4-dichlorobiphenyls,[70] whereas catabolism of other isomers (e.g., 4-chlorobiphenyl) led to the production of the correspondingly substituted chlorobenzoates.[65,67] A pathway for bacterial catabolism of PCBs is outlined in Figure 4. In agreement with this pathway, *Masse* et al.[64] identified 4-chlorobenzoate as a major product along with small amounts of other intermediates in the product mixture obtained by degradation of 4-chlorobiphenyl by an *Achromobacter* species. By adding a 4-chlorobenzoate-utilizing bacterium, *Pseudomonas* CBS3, a strain that was isolated and characterized in our laboratory, they observed that the mixed culture degraded not only the 4-chlorobenzoate but all other metabolites as well.[61]

An important general conclusion of investigations studying biodegradation of commercial PCB formulations is that the lower chlorinated isomers (one to three chlorine atoms) are rapidly degraded,[54,56,58] whereas those isomers substituted with between five and ten chlorine atoms are almost totally recalcitrant. *Kopecky*, however, has reported the isolation of bacteria capable of efficiently transforming Arochlor 1260, a commercial formulation containing highly substituted PCBs (five to nine chlorine atoms).[59] The involvement of plasmid DNA in the biodegradation of

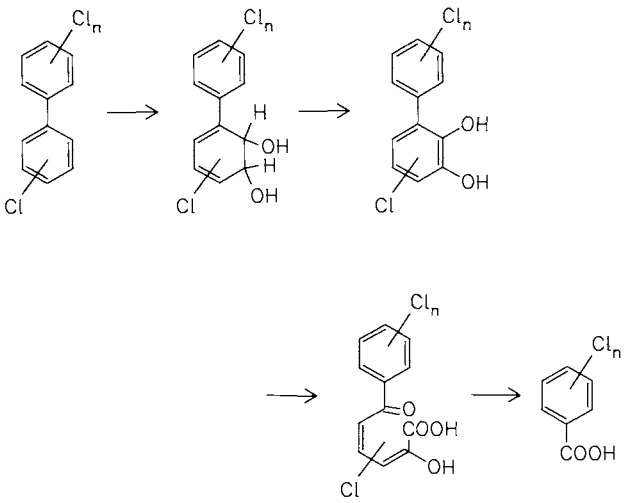

Fig. 4. The degradation of polychlorinated biphenyls by *Alcaligenes* sp. Y42 and *Acinetobacter* sp. P6. n = 1-5.

PCBs has been suggested by several investigators,[71,72] but the number of genes encoding the dehalogenating enzymes involved is unknown. In summary, polychlorinated biphenyls can be degraded by microorganisms, but the possibility remains that highly chlorinated isomers may be completely recalcitrant.

4.2.3. 1,1,1-Trichloro-2,2-bis(4-chlorophenyl)ethane (DDT)

Until recently, 1,1,1-trichloro-2,2-*bis*(4-chlorophenyl)ethane (DDT) was extensively used in the control of insect pests, especially in the fight against the spread of malaria. However, when DDT was found to be highly persistent in the environment (half-life more than 15 years)[3] and to undergo bioaccumulation through food chains, legislation banning its use was approved in North America and Western Europe.

Despite the persistence of DDT in the environment, it has been shown to be completely degraded by several different bacteria.[73,74] For example, *Golovleva* and *Skryabin*[74] reported the isolation of a *Pseudomonas* species that transformed DDT by "cometabolism."

The term cometabolism is used to describe the microbial transformation of a compound, in this case DDT, that does not serve as a source of carbon or energy. Alternative sources of carbon and energy, therefore, need to be supplied; in these experiments, lactic acid as carbon source and nitrate as electron acceptor were added to the medium. Phenylacetic acid, formed by bacterial cometabolism of DDT, was degraded by the producing organism aerobically (Fig. 5). Cometabolism of DDT by a *Hydrogenomonas* species to produce 4-chlorophenylacetic acid was reported by *Pfaender* et al.[73] These and other authors also showed that the product could be further degraded by a variety of microorganisms.[73,75] Yet, although DDT can be degraded by bacteria in the laboratory, it still persists in the biosphere. This paradox shows that the observation of extensive biodegradation of halogenated hydrocarbons by

bacteria in the laboratory does not guarantee that the corresponding degradative reactions occur to a significant extent in nature.

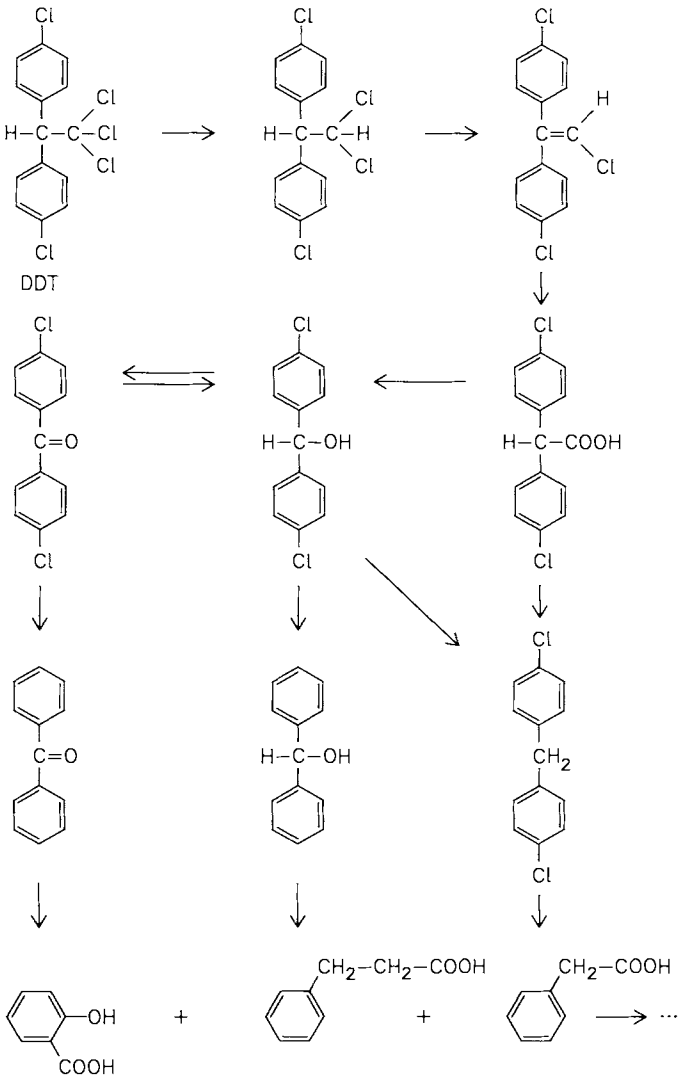

Fig. 5. The degradation of 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (DDT) by *Pseudomonas aeruginosa*.

4.2.4. *Chlorophenoxyalkanoic Acids*

The chlorophenoxyalkanoic acids constitute another economically important group of halogenated aromatic hydrocarbons. They are widely used as herbicides with hormone-like properties in the control of dicotyledonous weeds. The most important are 2,4-dichlorophenoxyacetic acid (2,4-D), its propionic acid and butyric acid homologues, 4-chloro-2-methylphenoxyacetic acid (MCPA), and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). The short half-life of 2,4-D in soils supports the idea that the herbicide is rapidly biodegraded. Further support comes from the ready isolation of microorganisms that utilize chlorophenoxyalkanoic acids as the sole source of carbon and energy or, at least, can cometabolize these herbicides. In all cases studied, aerobic biodegradation proceeds by removal of the aliphatic side chain with formation of the corresponding chlorinated phenol. Thus, formation of 2,4-dichlorophenol **16** from both 2,4-D and 4-(2,4-dichlorophenoxy)butyric acid, of 4-chloro-*o*-cresol from MCPA, and of 2,4,5-trichlorophenol from 2,4,5-T have been reported.[76,77] The subsequent degradative pathways differ in different microorganisms. For example, the biodegradation of 2,4,5-T by two bacterial species may involve the dehalogenase-catalyzed replacement of one chlorine substituent by a hydroxyl group, resulting in the formation of 3,5-dichlorocatechol.[78,79] The enzymes, however, have not been detected. Two pathways have been suggested for biodegradation of 2,4-dichlorophenol **16**: enzyme-catalyzed replacement of one chlorine substituent by a hydroxyl group gives 4-chlorocatechol,[76] and oxidation produces 3,5-dichlorocatechol.[77,80] Further degradation of 4-chloro- and 3,5-dichlorocatechol by one of these bacteria, a *Pseudomonas* species, involves dioxygenase-catalyzed cleavage of these intermediates between the hydroxyl groups to give the corresponding chloromuconic acids **17**.[77] By contrast, an *Achromobacter* species that cleaves chlorocatechols adjacent to the hydroxyl groups has been isolated (compare *ortho*- and *meta*-cleavage, Fig. 3).[81] Lactonization of **17** results in the removal of one chlorine substituent to form **18**, which is finally converted into 2-chloro-4-oxo-2-hexenedioic acid **19** (Fig. 6). Similar catabolic pathways[82]

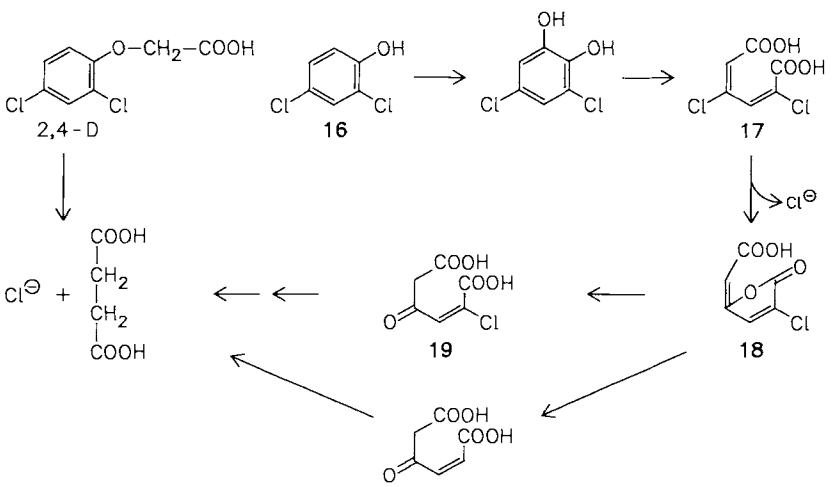

Fig. 6. The microbial degradation of 2,4-dichlorophenoxyacetic acid (2,4-D).

have been suggested for the degradation of the chloromuconic acids derived from 2,4-D and MCPA.[83-86]

4.2.5. Chlorobenzoic Acids

Chlorinated benzoic acids have been shown to be intermediates in the biodegradation of several chlorinated aromatic compounds; for example, 4-chlorobenzoic acid **20** is formed in the degradation of both PCBs[5,67] and the herbicide Bidisin.[87] These acids are relatively nontoxic and readily soluble in water. For these reasons, they are frequently used as model compounds for investigations of the mechanisms of biodegradation of chlorinated aromatic hydrocarbons.[88-91] Mixed microbial cultures, which have been studied by a number of groups, can, under aerobic conditions, degrade a wide range of chlorinated benzoic acids, including 2-, 3-, and 4-chlorobenzoic acid as well as 3,4-dichloro- and 2,4-dichlorobenzoic acid.[90] By contrast, under anaerobic conditions, only reductive dechlorination of *m*-substituted benzoic acids has been observed.[92-94] Cometabolism of chlorobenzoic acids in the presence of unsubstituted benzoic acids leads to the corresponding chlorocatechols in some pure cultures of bacteria.[95-98] These cultures were eventually poisoned, however, through accumulation of chlorocatechols, which could not be further catabolized and which polymerized to form toxic products. These results suggest that the enzymes involved in the conversion of unsubstituted benzoic acid to catechol can also transform some chlorobenzoic acids in an analogous manner. The critical step of these degradation reactions appears to be the ring cleavage. Conversion of 3-chlorocatechol to the corresponding acyl chloride and irreversible inhibition of a bacterial catechol 2,3-dioxygenase by the product (i.e., "suicide inactivation") has been reported by *Bartels* et al.[99] *Klecka* and *Gibson*,[100] who demonstrated reversible inhibition of the same enzyme in a different bacterium, suggested that the inhibition results from chelation of Fe(II), which is essential for the activity of the enzyme.

Several groups have isolated *Pseudomonas* species capable of utilizing 3-chlorobenzoate as the sole source of carbon and energy.[101-103] The *Pseudomonas* species described by *Johnston* et al.[101] degrades 3-chlorobenzoic acid via 3-hydroxybenzoic acid. This pathway indicates the involvement of an enzyme (not yet identified) that catalyzes the removal of the halogen substituent at an early stage of biodegradation. This enzyme allows the strain to avoid the problems associated with chlorocatechol degradation. *Dorn* et al.[102] and *Grishenkov* et al.,[103] on the other hand, found *Pseudomonas* species which convert 3-chlorobenzoic acid into 3- and 4-chlorocatechol, intermediates which are further catabolized via an *ortho*-cleavage pathway.

Kawasaki et al.[104] and *Knackmuss* and his co-workers[105-109] have studied the effects of various substituents upon enzymes catalyzing the individual reactions of the chlorobenzoate degradative pathway. In *Pseudomonas* sp. B13, for example, they detected two types of catechol 1,2-dioxygenase: one was mainly active in the ring cleavage of catechol and had low affinity for chlorinated catechols; the second enzyme could efficiently degrade chlorocatechols.[108] Furthermore, two cycloisomerases, catalyzing cyclization of the chloromuconic acids with cleavage of the chlorine substituent, were also isolated from strain B13. One was found to be specific for unsubstituted muconate, whereas the other was also capable of transforming chloromuconates.[109] These two enzymes, the dioxygenase and cycloisomerase, are responsible for the good growth of strain B13 on 3-chlorobenzoic acid.

From these studies, *Knackmuss* and his co-workers, using gene transfer techniques, were able to develop strategies that allowed *Pseudomonas* sp. B13 to degrade a wide range of halogenated aromatic compounds to the corresponding chlorocatechols. In this way, a gene encoding a broad-specificity benzoate 1,2-dioxygenase from *Pseudomonas* putida mt2, carried on the TOL plasmid, was transferred and expressed in strain B13. Since the TOL plasmid enzymes can also convert 4-chloro- and 3,5-dichlorobenzoic acids into the corresponding chlorocatechols, the hybrid strain B13 containing the plasmid was able to grow on these compounds as well. Genetic exchange between strain B13 and aniline-utilizing bacteria, containing plasmid-encoded enzymes that convert chloroanilines into chlorocatechols, allowed the construction of hybrid strains capable of degrading chloroaniline. Interestingly, in all of these genetically constructed hybrid strains production of plasmid-encoded enzymes catalyzing *meta*-ring cleavage was switched off by spontaneous mutations.[110,111] The prospects for constructing novel degradative pathways by means of genetic manipulation are interesting; however, it should be borne in mind that similar combinations can be obtained by developing continuous flow systems containing mixed cultures of the appropriate bacteria. Experience shows that genetic exchange can occur in these systems and, under appropriate selective conditions, can result in the formation of strains containing the desired degradative functions. Such strains are usually more stable than those produced by in vitro or in vivo genetic manipulations.

The biodegradation of 4-chlorobenzoic acid by pure cultures of bacteria has been described by American,[112] British,[113] Russian,[114] and German[115] groups. Work in our laboratory has resulted in the isolation of *Arthrobacter*, *Nocardia*, and *Pseudomonas* species capable of utilizing 4-chlorobenzoic acid as the sole source of carbon and energy.[115-117] In all of these bacterial strains, the first step of the catabolic pathway is replacement of the chlorine substituent by a hydroxyl group; the 4-hydroxybenzoic acid produced is converted into 3,4-dihydroxybenzoic acid **21** by oxygenase-catalyzed hydroxylation. Ring cleavage of this intermediate may be either of the *ortho*[117] or *meta*[116] type depending upon the bacterium. To date, enzymes catalyzing chlorine elimination from the aromatic ring have been identified in four different bacteria.[113,118,119] In vitro studies show that the enzymes catalyze the incorporation of ^{18}O-label, from $H_2{}^{18}O$, into the product of 4-chlorobenzoic acid dechlorination. They are, therefore, the only known examples of enzymes that have been unequivocally shown to catalyze direct substitution of the halogen on the aromatic ring by a hydrolytic mechanism.

The degradation of 2-chlorobenzoic acid by *Pseudomonas cepacia* also involves removal of the chlorine substituent in the first step,[122] but here the aromatic ring undergoes oxidation with elimination of CO_2. Catechol, which is

the first intermediate of this metabolic pathway, is further degraded by an *ortho*-cleavage pathway. An enzyme catalyzing the oxidative removal of the chlorine substituent from 4-chlorophenylacetic acid **22** has been isolated from *Pseudomonas* CBS3.[123] Expectations that this oxygenase, which converts 4-chlorophenylacetic acid into 3,4-dihydroxyphenylacetic acid, would be a nonspecific enzyme proved incorrect: only low activities were recorded in assays of the oxygenase with unsubstituted phenylacetic acid. Figure 7 outlines the catabolic pathways that have

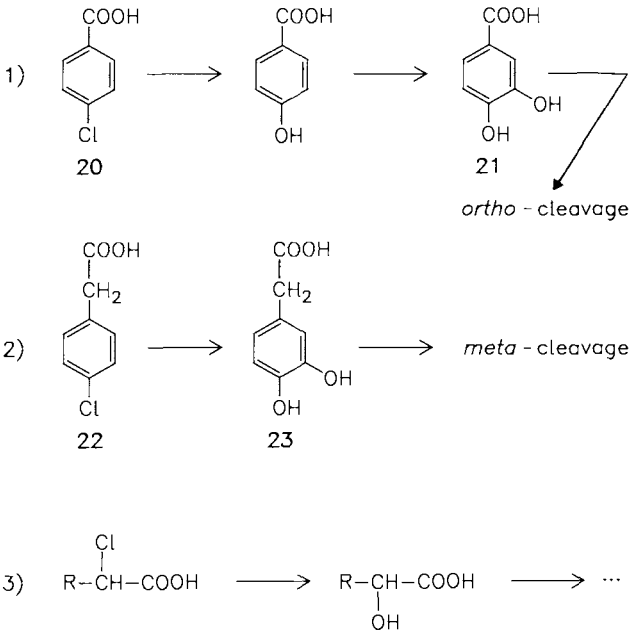

Fig. 7. Different dehalogenation mechanisms identified in *Pseudomonas* sp. CBS3. 1) Hydrolytic cleavage of the aromatic carbon-chlorine bond in the degradation of 4-chlorobenzoic acid **20**. 2) Cleavage of the aromatic carbon-chlorine bond and concomitant oxidation in the degradation of 4-chlorophenylacetic acid **22**. 3) Hydrolytic cleavage of the aliphatic carbon-halogen bond in the degradation of 2-haloalkanoic acids.

been shown to be responsible for the degradation of four kinds of halogenated aromatic compounds by *Pseudomonas* CBS3.

2-Fluorobenzoic acid can be degraded by a pathway entirely analogous to that described for 2-chlorobenzoic acid; oxygenase-catalyzed fluorine elimination produces catechol, which is then degraded by the β-oxoadipate pathway.[124-126] In contrast, degradation of 4-fluorobenzoic acid follows a pathway analogous to that described for the degradation of 3-chlorobenzoic acid by *Pseudomonas* sp. B13. Thus, 3- and 4-fluorocatechols are formed as intermediates, which, after *ortho*-cleavage to the corresponding fluoromuconates, may be defluorinated upon lactonization. Anaerobic degradation of 2-fluorobenzoic acid has recently been reported, although catabolic pathway intermediates and enzymes were not described.[128]

4.2.6. Polychlorinated Dibenzo[1,4]dioxins

Unlike the chlorinated hydrocarbons discussed so far, the polychlorinated dibenzo[1,4]dioxins have never been deliberately manufactured. Yet, they are dangerous environmental pollutants and have been detected even in the sediments of protected lakes situated in areas where no pollution should occur.[2] The question therefore arises as to the origin of dibenzodioxins. Polychlorinated dibenzodioxins are formed as side products during the manufacture of chlorinated phenols and biphenyls and are, for example, detectable in commercial wood preservatives that contain pentachlorophenol.[52] Another source of chlorinated dibenzodioxins is from the combustion of certain waste materials;[129] various isomers are, for example, formed during pyrolysis of chlorobenzenes, chlorophenols, and PCBs. Detection of chlorinated dibenzodioxins in biological samples sealed in 1933, well before the beginning of large-scale manufacture and use of chlorinated hydrocarbons, has led to the suggestion that the dibenzodioxins might have been produced by chlorination of domestic water supplies and by forest fires.[130] Analysis of sediment samples indicates that a rapid increase in the amount of chlorinated dibenzodioxins began in the 1940s and is likely to have been associated with commercial manufacturing of chlorinated hydrocarbons, which also began at about this time.

Public attention was focused on this group of compounds as a result of the disaster at Seveso,[52] where a reactor being used for production of 2,4,5-trichlorophenol exploded and showered the surrounding area with about 250 g of 2,3,7,8-tetrachloro[1,4]dibenzodioxin (TCDD), referred to erroneously as "dioxin" by the press. The extent of the damage at Seveso and the fears associated with the toxicity of TCDD prompted many detailed studies, both chemical and biological, of the compound and related isomers so that today it may be claimed that TCDD is one of the best studied chlorinated hydrocarbons.[131-136] TCDD is acutely toxic at low concentrations (< 1 μg per kg body weight), although carcinogenic effects associated with the compound probably result from induction of the enzymes involved in mammalian metabolism of xenobiotics. Thus, TCDD should be called a cocarcinogen.

What do microorganisms have to offer with regard to the biodegradation of this compound? Studies of microbial catabolism of TCDD and related compounds encounter two major obstacles from the outset: the compounds are almost insoluble in water and they adsorb strongly to surfaces. Consequently, quantitative analysis of chlorinated dibenzodioxins is complicated and the availability of the compounds as substrates for biodegradation is severely limited. Despite these problems, *Gibson* et al.[137,138] have shown that bacteria produce enzymes that catalyze the hydroxylation of TCDD at the 1-position, although it seems unlikely that these enzymes can be induced by the amounts of TCDD present in the biosphere. *Quensen* et al.[139] and *Philippi* et al.,[140] using media containing solvents to increase the solubility of TCDD, detected very low rates of degradation of ^{14}C-labeled TCDD by various bacteria. The products of biodegradation could only be detected by autoradiography after separation by thin layer chromatography. *Philippi* et al.[140] tentatively suggested that one of the polar metabolites produced during TCDD biodegradation was hydroxytetrachloro[1,4]dibenzodioxin, but further characterization of this product has not been forthcoming.

In summary, the notorious Seveso poison can, to some extent at least, be transformed by microorganisms. The concentrations of this compound in the environment, however, are too low and its water solubility and adsorptive properties are such that it probably would not induce the required enzymes in microorganisms. TCDD is, therefore, unlikely to be subject to extensive biodegradation. However, highly contaminated soils (such as those around Seveso) might be used to enrich for bacteria capable of detoxifying the compound if the TCDD can be solubilized so as to induce microbial degradative enzymes.

An alternative approach to the biodegradation of TCDD has been recently reported by *Bumpus* et al.,[141] who found that the enzymes involved in lignin degradation, excreted by fungi such as *Phanerochaete chrysosporium*, catalyze transformations of not only TCDD but also DDT, PCBs, and hexachlorocyclohexane. The fungus was incubated with the ^{14}C-labeled compounds, and, in all cases, $^{14}CO_2$ release was detected. The authors attributed this biodegradation to enzymes that produce carbon radicals capable of reacting nonspecifically with hydrocarbons in their vicinity. Applications of these studies to the control of environmental pollutants await further development.

5. Summary and Outlook

It has been the aim of this review to describe the range of degradative functions associated with microbial catabolism of halogenated hydrocarbons. Microorganisms capable of partially or completely degrading almost every pollutant known have been identified. However, the rates of degradation in the environment are often very slow and do not reflect the versatility of bacteria and fungi isolated in the laboratory. There might be several reasons for these conflicting observations. In some cases, the bacteria containing the appropriate enzymes might not be distributed widely enough. In others, natural conditions may not be optimal for biodegradation so that bacterial enzymes, although available, remain uninduced or inactive. Although the halogenated hydrocarbons discussed above are known to be degraded in the environment, the question remains, at what rate? Half-lives in aquatic and terrestrial environments of 15 years and more, as found for many halogenated compounds, are unacceptably high. What contribution to the solution of this problem might result from the isolation of microbes capable of degrading pollutant hydrocarbons and the elucidation of their degradative pathways?

The study of catabolic enzymes and biodegradative mechanisms in isolated microorganisms should reveal important pathways of biodegradation in the natural environment. Such pathways could be taken into consideration in the synthesis of new chemicals. Compounds that are liable to contaminate the environment (almost 100% of manufactured hydrocarbons) could be designed so as to combine efficacy with biodegradability. More direct applications may come from the use of isolated microorganisms or purifed enzymes for the decontamination of pollutant spillages. Such studies are currently being carried out in many countries, but the overall effectiveness of the approach is still in question. An example is the use of a bacterial inoculant to clean up pentachlorophenol contamination (Section 4.2.1). In some cases potential pollutants may be treated at the source before they enter the environment where dispersion creates problems. Thus, downstream waste treatments, either based upon domestic sewage plants or tailored for biodegradation of specific pollutant hydrocarbons, could be devised for detoxification of industrial effluents of known composition. Biological systems, comprising columns containing isolated bacteria and enzymes, are currently being used successfully for the degradation of dichloromethane and tetrachloroethylene. Mixed microbial cultures offer the best possibilities for efficient and robust treatments. In this respect, the results of laboratory-based studies with pure cultures growing in defined media under optimal conditions cannot immediately be applied to complex in situ and downstream treatments where considerations of fluctuating physico-chemical conditions and interactions between microorganisms may be as important as considerations of biodegradative mechanisms. Future research into these poorly understood aspects of biodegradation will be central to the development of treatment systems for toxic wastes.

Another exciting development of research into biodegradation of chlorinated hydrocarbons has been the biotechnological applications of novel enzymes as catalysts for commercial chemical syntheses. For example, dehalogenases are now being used for the production of optically active lactic acid from racemic 2-chloropropionic acid (Section 3.2). The synthesis of other optically active compounds is a future possibility.

Unfortunately, there are no obvious general biological solutions to the problems of environmental pollution by dispersed, low concentrations of halogenated hydrocarbons. We have little choice other than to continue to accept responsibility for controlling, at source or at production, the rate at which pollutants enter the environment. In the words of *Paracelsus von Hohenheim*, "prevention is better than cure."

The research described in this article that was carried out in the authors laboratory was supported by the Fonds der Chemischen Industrie.

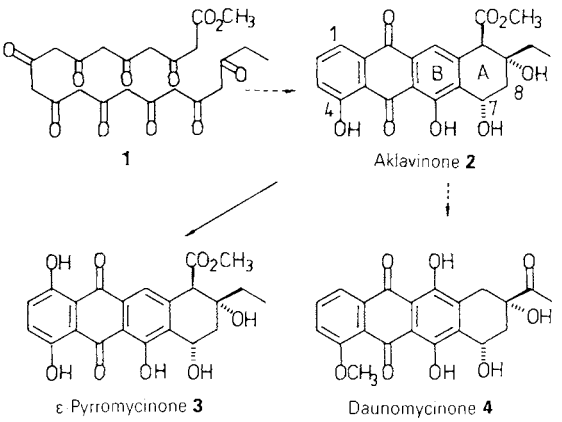
Total Synthesis of Anthracyclinone

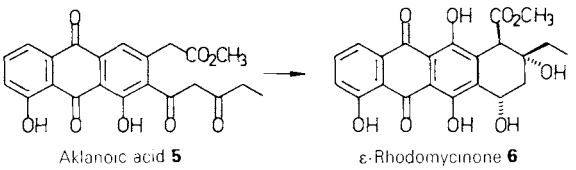
New Synthetic Methods (60)



By Karsten Krohn*

Dedicated to Professor Albert Mondon on the occasion of his 70th birthday

The remarkable antitumor properties of anthracycline antibiotics have motivated synthetic chemists, and a large number of groups have been active recently in this field. Initially, there was very little hope for this class of substances due to their extreme toxicity. However, the dividing line between toxicity and desired pharmacological effect has broadened to such an extent, partly through microbiological methods (new strains, mutants) and partly through semisynthetic modifications, that today anthracyclines take number one place (over 20% of the market) in the chemotherapy of (human) cancer. The demands made on modern cytostatica are extremely high, as may be seen from the fact that of the more than 600000 drugs tested in animals, only about 40 are in clinical use. In the meantime, some anthracyclines obtained by total synthesis are also in clinical testing. In this review it will hopefully be demonstrated that all those concerned in the chemotherapeutic use of these substances have also contributed to the general progress made in the solution of regio- and stereochemical problems of linearly annelated ring systems.



1. Structure and Nomenclature

Anthracyclinones are the aglycones of anthracyclines. The basic structure of the anthracyclinones has been elucidated by intensive investigations on the colored metabolites of *Streptomyces purpurascens* by *Brockmann* and his group.[1a] While the number of aglycones including other species of *Streptomyces*[1b,c] has increased only slightly, the number of the glycosidic anthracyclines, which contain up to eight sugar components, has in the meantime grown to over two hundred compounds.[2] The variety of structures encountered can be neatly underlined with a few examples of a biogenetic scheme (for further details compare reviews on the structure[1,2] and biological action of anthracyclinones[3]). The work of *Ollis* et al.[4a] on the biosynthesis of pyrromycinone[3] has shown that polyketides such as **1**, which consist of nine acetate units and one propionate unit, can be considered as precursors of anthracyclinones which are produced by *Streptomyces* species. Later works[4b-f] (review[4g]), including the labeling of precursors with ^{13}C, have presented further details of the biosynthetic pathway from aklavinone (**2**) to daunomycinone (**4**) (Scheme 1).

Scheme 1.

New findings have shown that aklavinone (**2**) (often in the form of its *O*-glycosides) is an early anthracyclinone precursor that is further transformed by certain *Streptomyces* species with hydroxylation of ring D into glycosides of ε-pyrromycinone (**3**) (*Actinosporangium sp.*[2f]) or with hydroxylation of ring B and oxidation of the side chain into daunomycinone (**4**) (*Streptomyces peucetius*[3c-f]). A particularly interesting variant is the incorporation of the tricyclic aklanoic acid **5** into ε-rhodomycinone **6** by certain mutants of *Streptomyces*.[4h] Although this finding—similarly as in the case of the tricyclic tetracycline precursors (pretetramides)[5]—must not necessarily correspond to the usual biosynthetic pathway, a number of new synthetic possibilities starting from tricyclic precursors are demonstrated (see, e.g., Section 4.1.1). Because of their different

position in the biogenesis and because of some chemical properties that influence the synthetic strategies, we have named anthracyclinones containing an ester group type B (e.g. **2**, **3**, **6**) and those without an ester group type A (e.g. **4**).[6] Otherwise, we follow the system proposed by *Brockmann*[1a] in the numbering and designation of the rings A–D because in this way both types A and B can be named uniformly. However, in many papers the systematic

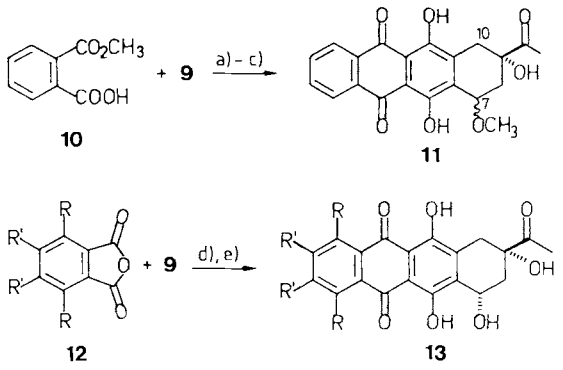
IUPAC nomenclature is used because the same numbering can be applied to natural as well as synthetic products (see for example[7, 8]). Furthermore, we also follow a ruling proposed by *Quinkert* et al.[9] for the designation of racemic mixtures and enantiomers so as to avoid confusion between optically pure products and racemic mixtures. For example, **4** represents the absolute configuration of daunomycinone, *ent*-**4** the enantiomer of **4** and *rac*-**4** racemic daunomycinone.

2. Total Syntheses

In the synthesis of anthracyclinones stereochemical problems of the hydroaromatic ring A with two, three, or four chiral centers have to be solved. Another equally exciting challenge is presented by the regiochemistry of the anthraquinone moiety. In the course of the synthesis, the relatively remote substituents of the rings A and D must occupy the correct positions (see Scheme 1). In a successful synthesis, both problems must be solved concomitantly, since a separation of isomeric tetracycles, which are often very sparingly soluble, can at best be achieved only on a very small scale. This additional difficulty, which often cannot be inferred from the synthetic schemes of a publication, is naturally solved with differing degrees of efficiency in subsequently reviewed methods. We follow a methodologically oriented earlier review by *Kelly*[10a] (for further reviews see [3e, 10]) with classification into cationic reactions (Friedel-Crafts reactions), Diels-Alder reactions, and anionic reactions (radical reactions have until now found no application in anthracyclinone synthesis).

2.1. Friedel-Crafts Reactions

The procedure shown in the retrosynthetic Scheme 2 is followed if a Friedel-Crafts reaction is used to construct the tetracylic anthraquinone skeleton via the usual method of anthraquinone synthesis.[11] It is well-conceived to choose the formation of the new bonds between rings B and C (disconnection "a" in **7**) to facilitate the Friedel-Crafts reaction by the donor-substituted, partially hydrogenated AB building block **9**. Basically, the acylation with the phthalic anhydride derivative **8** proceeds in two steps, whereby the first step deactivates the arene (the future ring B) for a second electrophilic attack; this holds, even if in practice one pot procedures (e.g. $AlCl_3$/NaCl melt[12]) are used. Consequently, vigorous reaction conditions can generally not be avoided.

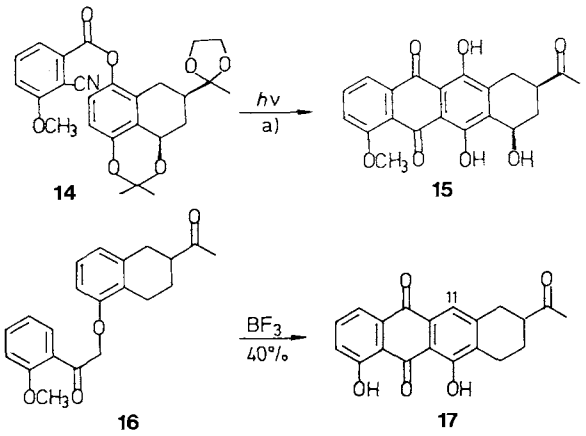


7 **8** **9**

Scheme 2.

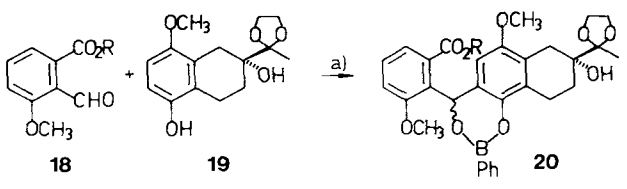
In contrast to most other anthracyclinones with ethyl or methyl side chains, daunomycinone and its analogues possess an acetyl side chain, which gives the molecule a special stability. The carbonyl group makes the development of a positive partial charge on the neighboring tertiary carbon atom difficult, and, this in turn, hinders the acid-catalyzed dehydration that occurs easily with the other members of the anthracyclinone family.[1] Due to this particular stability, the first synthesis of 7-*O*-methyl-4-demethoxydaunomycinone (*rac*-**11**) by *Wong* et al.[13] was possible in which the phthalic acid half ester **10** (DC-building block) and *rac*-**9** (AB-building block) were combined to give *rac*-**11** in a stepwise Friedel-Crafts reaction (Scheme 3).

The Friedel-Crafts reaction with symmetrically substituted phthalic acid anhydrides **12a–12f** can also occur in a one pot procedure. 4-Demethoxydaunomycinone (*rac*-**13a**) is now manufactured on a large scale by Farmitalia, in addition to the other derivatives *rac*-**13b** to *rac*-**13f**[12] (Scheme 3).



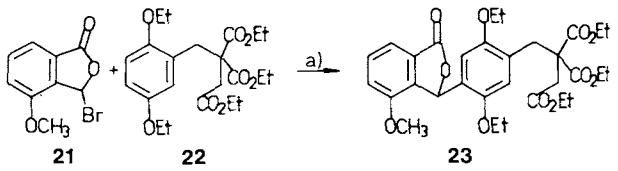
Scheme 3. a) 1) $(CF_3CO)_2O$; 2) HF. b) 1) $HOCH_2CH_2OH$, H^+; 2) *N*-bromosuccinimide (NBS); 3) CH_3OH. c) $AlCl_3$. d) NaCl/$AlCl_3$, 180°C, 2 min. e) Hydroxylation at C-7.—**a**, R = R′ = H; **b**, R = H, R′ = CH_3; **c**, R = H, R′ = Cl; **d**, R = CH_3, R′ = H; **e**, R = Cl, R′ = H; **f**, R + R′ = –CH=CH–CH=CH–.

The drastic conditions of the Friedel-Crafts reaction limit this method to daunomycinone-type anthracyclinones and do not allow the use of dihydroxylated AB building blocks. However, the introduction of a *cis*-hydroxy group at C-7 is of great importance, since the sugars that are essential for biological activity are bound at this position. Thus, the problem of hydroxylation at the benzylic position became evident at the very beginning of anthracyclinone synthesis. The decisive step that is still used today is the radical bromination of the benzylic position followed by solvolysis. *Wong* et al.[13] needed three steps to arrive at a mixture of the epimers *rac*-**11** starting from a 7-deoxy precursor. The reaction of daunomycinone precursors with silver trifluoroacetate likewise afforded a 5 : 2 mixture of epimers that could be equilibrated with trifluoroacetic acid to give a 6 : 1 ratio in favor of the natural 7,9-*cis*-configuration[14] (overall yield about 50%). In practice the scale of the reaction is limited by the low solubility of the hydroxylated tetracycles, both during the bromination in tetrachloromethane and also during the necessary chromatographic separation. Although the bromination of the more soluble 7-*O*-acetates leads stereoselectively to the *trans*-bromides (80–85%), a chromatographic separation of the solvolysis products (*cis* : *trans* = 41 : 20) cannot be circumvented.[15] A better *cis*-selectivity can be achieved via solvolysis with aqueous sodium hydroxide (43%).[16] Hy-



droxylation at C-7 seems to be a problematic reaction as long as the other position at C-10 is not blocked by a substituent such as a hydroxy or an ester group as in ε-rhodomycinone and all other type B anthracyclinones (see, e.g., Section 4.1.1).

A third limitation of Friedel-Crafts reactions is the lack of regioselectivity when using non-symmetrically substituted phthalic acid derivatives. Thus, an attempted regioselective synthesis of islandicin[17] failed due to Hayashi rearrangement as well as BF_3-catalyzed Fries rearrangement.[18] A chromatographic separation of regioisomers was also necessary in the first total synthesis of daunomycinone by *Wong* et al.[19] (cf. [20]), who closely followed the methods outlined in Scheme 3. However, a regioselectivity could be observed under the milder conditions of the photochemical Fries rearrangement of **14** to **15**[21] and with the BF_3 treatment of the precursor **16**, which led to an 11-deoxy compound **17**[22] (Scheme 4).

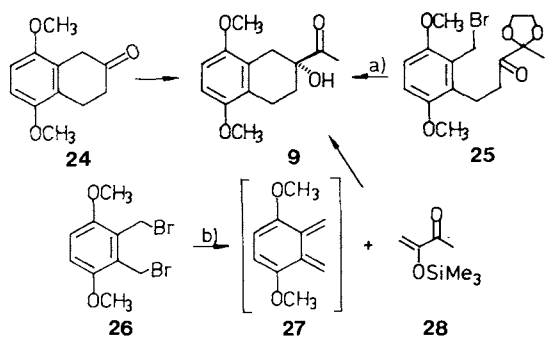


Scheme 4. a) Two further steps, 11%.

A regioselective coupling is also observed in the reaction of the aldehyde **18** with *rac*-**19** in the presence of phenylboronic acid to afford a mixture of diastereoisomers *rac*-**20**, which can be further transformed into *rac*-**4** in nine additional steps.[23] The preparative work necessary to achieve regioselectivity is largely shifted to the synthesis of the non-symmetrically substituted aromatic compounds **18** and **19** (Scheme 5). Obviously the phenylboronic acid prevents the usual rearrangements of the Friedel-Crafts acylation (cf. [24]).

Scheme 5. a) Phenylboronic acid, propionic acid, benzene, 20 h boiling.

A regioselective construction of the basic skeleton is also possible under the milder conditions of the Friedel-Crafts *alkylation* which was investigaged by *F. Johnson* et al.[25] The key step is the $SnCl_4$-catalyzed Friedel-Crafts alkylation of 3-bromo-4-methoxyphthalide (*rac*-**21**) in the *para*-position of the activating alkyl substituent in **22** to afford *rac*-**23**,[25a] which can be transformed into racemic daunomycinone (*rac*-**4**) in eleven additional steps[25b] (Scheme 6). This example clearly shows that the necessary regioselectivity in cationic cyclizations cannot be obtained without considerable synthetic effort!

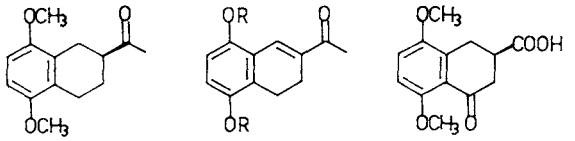


Scheme 6. a) $SnCl_4$, CH_2Cl_2, 25°C, 6 h.

A decisive criterion of modern total syntheses is the possibility of conducting reactions enantioselectively. Contradictory statements have been made in the literature concerning the racemization during conversion of the enantiomerically pure building block **9**. While *Arcamone* et al.[12] and *Rao* et al.[26] do not observe any racemization in the Friedel-Crafts reaction of **9** with phthalic acid anhydrides, *Terashima* et al.[27] and also *Russell* et al.[28] state that the same reaction is not free of racemization (70–81% *ee*). However, the coupling of the enantiomerically pure building blocks is possible with other methods. The synthesis of key intermediates, with emphasis on enantioselective methods, is therefore presented in this part of the review.

2.2. Synthesis of AB Building Blocks

Ready access to *rac*-**9** is possible by addition of organometallic compounds to β-tetralone **24**, which can be very easily obtained via Diels-Alder reaction of benzoquinone with 2-methoxy-[29] or 2-chloro-1,3-butadiene.[20] Ethynylmagnesium bromide,[20,30] 2-(trimethylsilyl)ethynylcerium(III) reagents,[31] lithiated 2-methyl-1,3-dithianes,[32] or methoxyvinyllithium[29] may serve as acetyl anion equivalents (Scheme 7). The key intermediate *rac*-**9** may also be obtained directly by Barbier reaction of **25**[33] or by Diels-Alder reaction of the intermediary *o*-quinodimethane **27** with 3-(trimethylsiloxy)-3-buten-2-one **28**.[34]

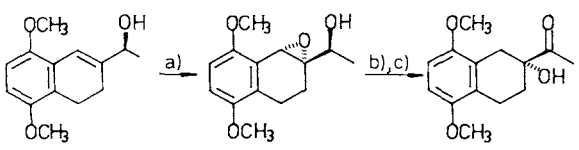


Scheme 7. a) Mg, 20°C, 6 h. b) 1) Zn, dimethylformamide (DMF) or $CrCl_2$; 2) HOAc, 45°C, 2 h.

The yields are especially high (85%) if **27** is generated from the dibromide **26** with chromium(II) chloride[35] (Scheme 7). The Barbier and Diels-Alder reactions can also be successfully applied to tetracycles (see Sections 3.1 and 4.1).

Frequently used building blocks are *rac*-**29**,[29,20,26,36-38] **30**,[26,27,39-42] R = $PhCH_2$, CH_3, and *rac*-**31**,[13,43,44] which can be obtained by cyclization of the corresponding open-chain precursors or their derivatives. The intermediates *rac*-**29** to *rac*-**31** can also be transformed into enantiomerically pure compounds by appropriate methods.

The missing tertiary hydroxy group in **29** or **31** can, as a result of activation by the neighboring center, be introduced via oxygenation of the corresponding enolate using the method of *Gardner* et al.[45] The reaction can be applied equally well to tetracyclic compounds (see Section 3.1). The replacement of one methoxy group in **30** by a selectively cleavable benzyloxy group is of great preparative value because it allows the synthesis of quinone monoacetals.[40,41]

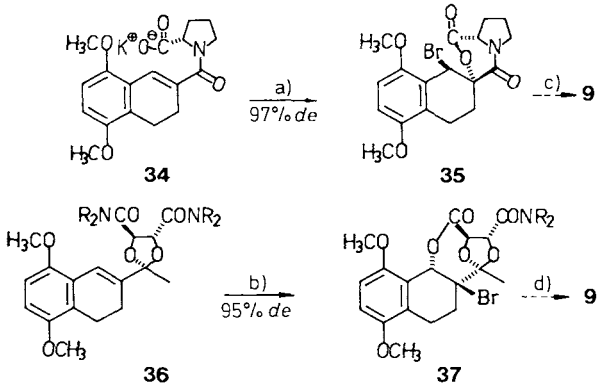


Special attention will be given here, however, to the preparation of enantiomerically pure AB building blocks. The classical methods of resolution of racemates may be employed for this purpose, which is especially easy with the brucine salt of an acid derived from **31**.[46] Precursors such as **9**, with acetyl side chains, can be resolved via diastereomeric Schiff bases obtained from (−)-1-phenylethylamine.[43,47]

29 **30** **31**

The Sharpless epoxidation can be employed for the kinetic resolution using the allyl alcohol **32** obtained from **30**.[48] The enantiomers of the racemic allyl alcohol **32** are epoxidized at different rates under the conditions defined by *Sharpless*. Unchanged *ent*-**32** remains in solution together with almost enantiomerically pure **33**. For the isolation of *ent*-**32**, the unstable epoxide **33** is reduced to a diol, which can be reoxidized with *Fetizon*s reagent[26] or dimethyl sulfoxide/sulfur trioxide[27] to the enantiomerically pure AB building block **9**. The "wrong" isomer *ent*-**32** can be recycled after inversion to **32** using the method of *Mitsunobu*[49] (Scheme 8).

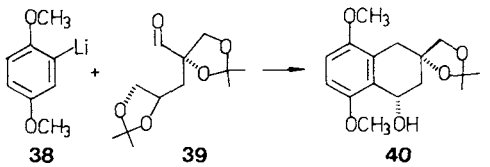
Alternatively, **9** can be prepared via stereoselective reduction of *rac*-**9** with bakers' yeast *(Saccharomyces cerevisiae)* to diastereoisomeric diols followed by chromatographic separation and reoxidation to **9**.[50]



32 **33** **9**

Scheme 8. a) *t*BuOOH, $Ti(OiPr)_4$, (+)-diisopropyl tartrate, −55 °C. b) $LiAlH_4$. c) Ag_2CO_3 or dimethyl sulfoxide (DMSO), SO_3.

Asymmetric syntheses using chiral auxiliaries have been investigated by *Terashima*'s group. Particularly successful was the reduction of the prochiral α,β-unsaturated ketone **30** (R = CH_3) with $LiAlH_4$ in the presence of (−)-*N*-methylephedrine at −78 °C to give **32** (92% *ee*), followed by stereoselective Sharpless epoxidation (90% *de*) to **33**,[27] which can be transformed into **9** as shown in Scheme 8.

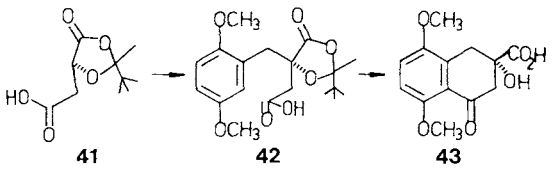


In another method, the decisive transfer of chirality to the tertiary center occurs during the bromolactonization of the proline derivative **34** to **35**[51] (cf. also [52]) or of the tartaric acid amide acetal **36** to **37**.[53a] In both cases the enantiomeric excess is greater than 95% (Scheme 9; for the extension of the latter method to tetracycles cf. [53b]).

34 **35** **36** **37**

Scheme 9. a) NBS. b) *N*-bromoacetamide. c) Four steps, 66%. d) Three steps, 47%.

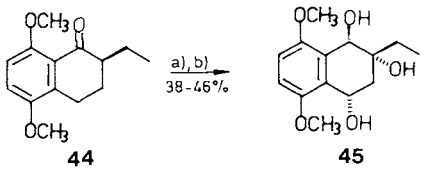
Another method for the synthesis of enantiomerically pure products consists in the incorporation of derivatives from the chiral pool of natural products. *Florent* et al.[54] obtained the AB building block by addition of the aldehyde **39**, prepared in five steps from α-D-isosaccharinolactone,[55] to the aryllithium compound **38** (Scheme 10; for similar reactions leading to tetracycles, see [55]).



38 **39** **40**

Scheme 10.

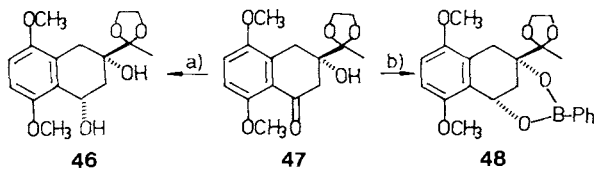
In our group we were able to prepare the highly functionalized α-hydroxy acid **43** in only three steps incorporating L-malic acid.[56] The chiral information of L-malic acid is transferred to a non-racemizable tertiary center of the five-membered acetal **41**.[57] Stereoselective alkylation of **41** yields **42**, and this is followed by cyclization to **43** (Scheme 11).



As already mentioned, the highly functionalized AB building blocks with benzylic hydroxy groups allow especially convergent anthracyclinone syntheses. Two hydroxy groups are introduced simultaneously during the oxygenation of the arene **44** at the positions activated by the car-

41 42 43

Scheme 11.

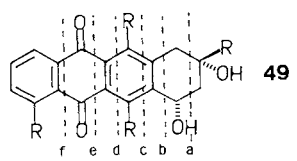


bonyl group. Reduction with $LiBH_4$ selectively affords the *trans*-1,2-diol **45** (8.6 : 1)[58] (Scheme 12; for further AB building blocks with *ethyl* side chains, see [59,60]).

44 45

Scheme 12. a) KO*t*Bu, $P(OEt)_3$, O_2. b) $LiBH_4$, toluene.

The reduction of the ketone **47** to the 1,3-*cis*-diol **46** with potassium selectride also proceeds with high stereoselectivity.[43] However, the much cheaper reducing agent $LiBH_4$ can be employed if the mixture of epimers is subsequently equilibrated with phenylboronic acid[44] (Scheme 13).

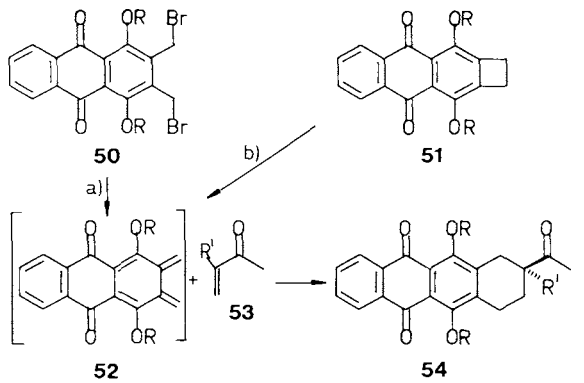


46 47 48

Scheme 13. a) K[*s*Bu$_3$BH] (potassium selectride). b) 1) $LiBH_4$; 2) phenylboronic acid, 18°C, 20 h.

3. Diels-Alder Reactions

[2+4]-Cycloadditions offer ideal possibilities for the construction of linearly annelated ring systems containing six-membered rings. It is thus not surprising that six of the eight possible ring couplings have been realized[3,10a] (disconnections "a–f" in **49**).

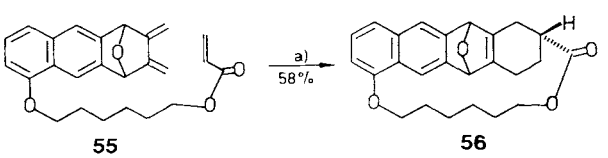


49

The specific conditions of the Diels-Alder reaction allow different degrees of control in the synthesis of various types of anthracyclinones. The control of the regiochemistry is, for example, less easy in compounds derived from rhodomycinone (1,4,5-trihydroxyanthraquinone) than in 11-deoxy compounds (aklavinone type). Problems of stereo- and enantio-control emerge, since the degree of functionalization of the building blocks varies considerably. However, elegant solutions to most problems have been found, making the use of Diels-Alder reactions an efficient method in anthracyclinone synthesis.

3.1. Construction of Ring A

The tricyclic DCB fragment can serve as a diene ("a" in **49**) as well as a dienophile ("b" in **49**) if ring A of the anthracyclinone is formed in a Diels-Alder reaction. *Cava* et al.[61,62] used the bis(bromomethyl)anthraquinones **50** for the generation of the tricyclic, highly-reactive intermediary *o*-quinodimethanes **52**, which are liberated on treatment of **50** with zinc[62] or sodium iodide.[61] The yield depends on the residue R; an optimum is attained in the reaction of methyl vinyl ketone **53**, R′ = H, with the methyl ether **50c** in the presence of zinc in dimethylformamide (DMF) or with the phenol **50a** in the presence of sodium iodide in dimethylacetamide (DMA) (69%).[34] More highly substituted dienes such as 1-acetylvinyl acetate **53**, R′ = OAc, or 3-(trimethylsiloxy)-3-buten-2-one **53**, R′ = $OSi(CH_3)_3$, can also be employed, but the yield of adduct *rac*-**54**, R′ = OH, is distinctly lower.[34,61]

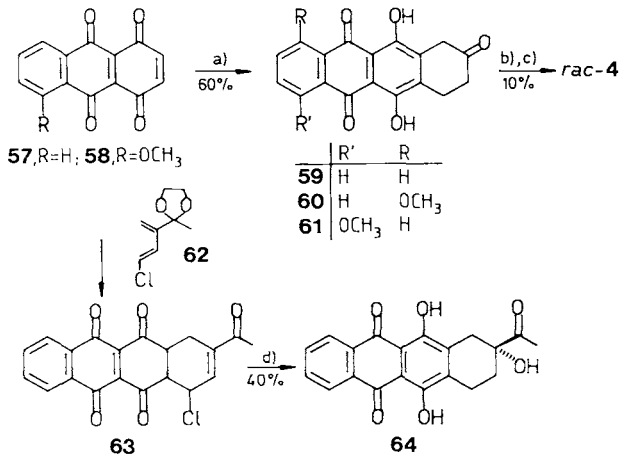


o-Quinodimethanes can also be generated thermolytically from the corresponding annelated cyclobutanes **51**, whereby the yields of *rac*-**54** are greatly improved[63] (Scheme 14).

50 51 52 53 54

Scheme 14. a) Zn, DMF or NaI, dimethylacetamide (DMA). b) 180–220 °C. **a**, R = H; **b**, R = Ac; **c**, R = CH_3; R′ = H, OAc, $OSi(CH_3)_3$, etc.

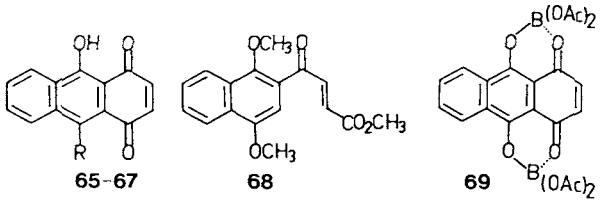
Attempts to conduct the reaction regioselectively with non-symmetrically substituted *o*-quinodimethanes have not been described in the literature. Interestingly, however, *P. Vogel* et al.[64] were successful in controlling the regioselectivity in the intramolecular Diels-Alder reaction of *rac*-**55** to give *rac*-**56**; diene and dienophile are linked by a spacer of appropriate chain length. This is reminiscent of the method described by *Breslow* for controlling the reaction in the case of steroids[65] (Scheme 15; cf. [66]).



55 56

Scheme 15. a) 170 °C, 24 h, xylene.

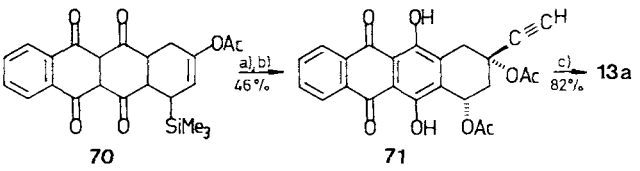
A number of 1,4-anthraquinones are suitable as starting material if the DCB tricycle does not serve as diene but rather as dienophile ("b" in **49**). In the most simple case 1,4,9,10-anthradiquinones such as **57** can be used. These are obtained by oxidation of the corresponding 1,4-dihydroxy-9,10-anthraquinones with lead tetraacetate. Thus, depending on the diene employed in the reaction, precursors with (e.g. *rac*-**63**) or without an acetyl side chain (e.g. **59**) can be synthesized.



Many authors choose the route used by *Kende* et al.[14] in their pioneering total synthesis of racemic daunomycinone (*rac*-**4**). The key step in this synthesis is the addition of 1-methyleneallyl acetate to the anthradiquinone **58**. The reaction is not regioselective and yields a 1:1 mixture of primary adducts, which are hydrolyzed to **60/61** and separated by crystallization.[14] The further transformation into daunomycinone (*rac*-**4**) was completed by ethynylation, hydration and hydroxylation at C-7 (Scheme 16). The direct incorporation of a side chain was achieved by reaction of **57** with diene **62** to afford *rac*-**63**, followed by a five step transformation to *rac*-**64**[67] (Scheme 16).

Scheme 16. a) 1) 3 equiv. (1-methylenallyl) acetate ("2-acetoxy-1,3-butadiene"), 25°C, 4 d; 2) C_2H_5OH, 6N HCl, reflux, 6 h. b) 1) $BrMgC{\equiv}CH$; 2) dil. H_2SO_4/HgO, 70°C, 4 h. c) 1) Br_2, CCl_4, *hv*; 2) SiO_2/H_2O. d) Five steps.

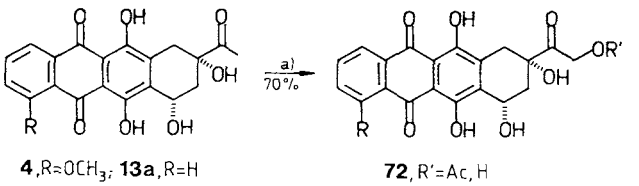
However, the relatively short route via anthradiquinones has the disadvantage that many highly functionalized dienes add to the inner double bond of these bisdienophiles.[68,69]



A conceptually interesting way to circumvent this problem is the Diels-Alder reaction of the 1,4-anthraquinones such as **65**,[70-72] **66**,[71] **67**[72] or the open-chain precursor **68**[73] with various dienes which must lead to linearly annelated products. The quinizarin boroacetate complex partly

65, R = Cl; 66, R = NH_2; 67, R = H

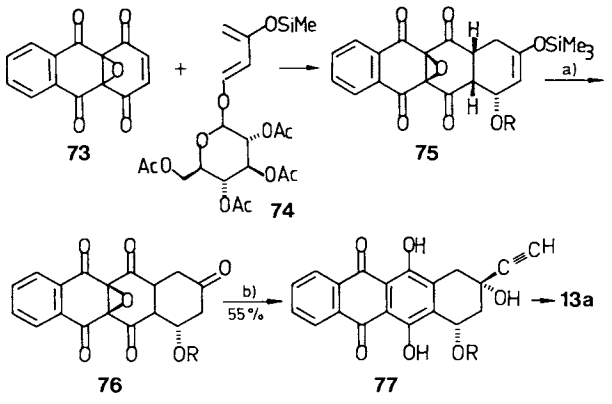
exists in the tautomeric form **69** and can also undergo Diels-Alder reactions.[74] However, the oxidation of the adducts proceeds under relatively drastic conditions and a synthesis of daunomycinone has not yet been realized in this way.



By contrast, the addition of *trans*-(1-methylene-3-trimethylsilylallyl) acetate to **57** affords the linearly annelated adduct *rac*-**70**. The decisive step in the further transformation of *rac*-**70** is the replacement of the trimethylsilyl group by an acetoxy group using fluoride and lead tetraacetate to yield *rac*-**71**[75] (Scheme 17).

Scheme 17. a) 1) H_2-Pd/$BaSO_4$; 2) CF_3COOH/H_2O; 3) $BrMgC{\equiv}CH$; 4) isopropenyl acetate, $H^{\oplus}$, 25°C, 16 h. b) 1) Oxidation and isomerization to the quinone; 2) 2 equiv. $Pb(OAc)_4$/HOAc, 18 h, $F^{\ominus}$; 3) $NaHSO_3$. c) HgO, $H^{\oplus}$, H_2O; $OH^{\ominus}$.

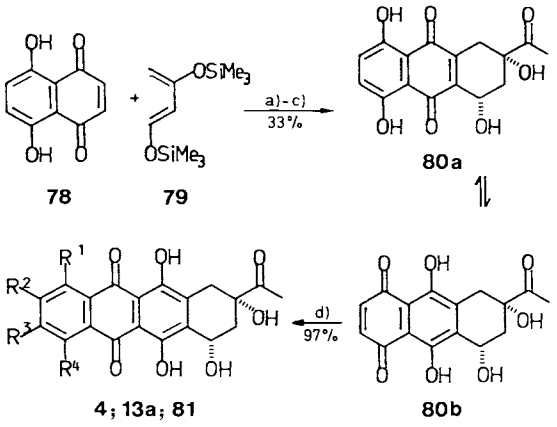
The use of the trimethylsilyl reagent, which enables the indirect introduction of the 7-hydroxy group, was later thoroughly investigated by *Bulman-Page* and *Ley*.[76] The authors also describe in detail the acetoxylation of the acetyl side chain of daunomycinone derivatives (e.g. *rac*-**13a**) to give the therapeutically even more important adriamycinone derivatives **72**, R = OCH_3, R' = Ac (Scheme 18).



In addition to the usual bromination followed by solvolysis, the direct transformation can also be achieved with the new generally applicable hypervalent iodine reagent [bis(trifluoroacetoxy)iodo]benzene.[77]

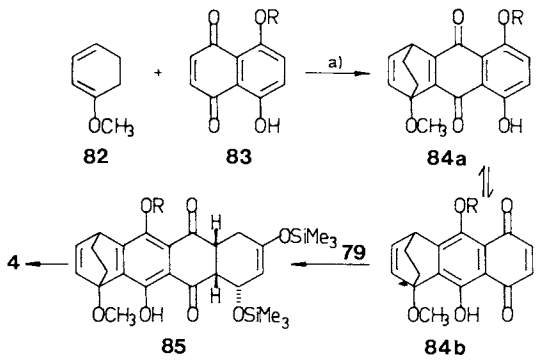
Scheme 18. a) 1) Br_2, CCl_4; 2) NaOAc, 30-45 min boiling in acetone.

Exclusive addition of dienes to the terminal double bond is also achieved by the use of the anthraquinone monoepoxide **73**, which is readily accessible from anthradiquinone **57** by epoxidation with *m*-chloroperbenzoic acid (MCPBA). An enantioselective synthesis of 4-demethoxydaunomycinone was achieved by employing a chiral diene.[79] The crucial step of the transfer of chirality occurs during the addition of the diene **74** to the quinone **73**, which proceeds in favor of the desired adduct **75** (4:1 ratio). After hydrolysis of the crude product and recrystallization, the epoxy pentanone **76** is obtained in 45% overall yield. For further transformation, the precursor **77** is reduced with dithionite or zinc, followed by ethynylation and oxidation with lead tetraacetate. The enantiomerically pure 4-demethoxydaunomycinone **13a** is obtained after



hydration and hydrolysis of **77**[79] (Scheme 19; for similar reactions with the epoxyquinone **73**, cf. [80,91]).

Scheme 19. a) Tetrahydrofuran (THF), 0.1 M HCl. b) 1) $Na_2S_2O_4$ or Zn/HOAc (71%); 2) 30 equiv. BrMgC≡CH, THF, 0°C, 30 min; 3) $Pb(OAc)_4$/HOAc (77%).

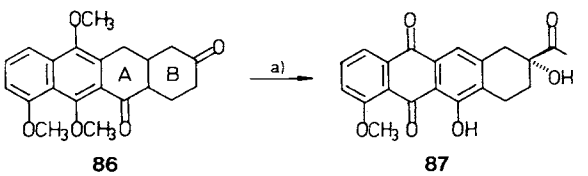


In our laboratories we have developed a method in which anthracyclinones are synthesized by two successive diene reactions with naphthazarin (**78**) (CB building block)[82] using bis(siloxy)butadiene **79**. Not only are both oxygen functions introduced simultaneously into ring A, but by variation of the second diene a large variety of substituents are easily introduced into ring D of daunomycinone. The synthetic strategy is based on the tautomerism of substituted naphthazarins such as **80a/80b** as described by *Fariña* and *Vega*.[83] The tautomeric form **80b** reacts with dienes to form linearly annelated ring systems. The flexibility of this synthetic principle is demonstrated by the variation of the open-chain and cyclic dienes used in the second Diels-Alder reaction: in addition to *rac*-**4** and *rac*-**13a**, four daunonomycinone derivatives not occurring naturally could also be prepared[82b] (Scheme 20).

Diels-Alder reactions with naphthazarin derivatives such as **80b** do not proceed regioselectively; however, they

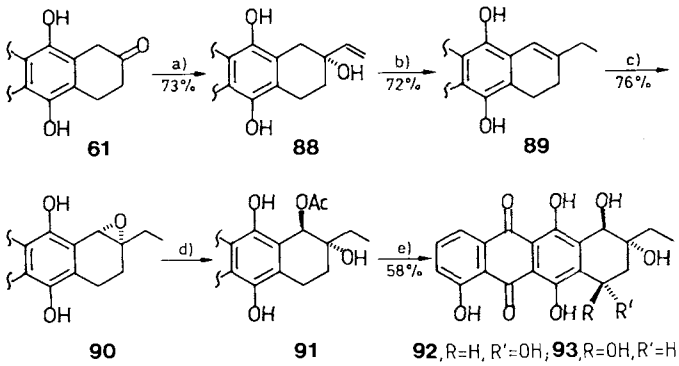
Scheme 20. a) CH_2Cl_2, 5 h. b) $CH_2Cl_2/(C_2H_5)_2O/CH_3OH/0.2$ N HCl, 5°C, 6 h. c) 1) 30 equiv. BrMgC≡CH; 2) acetone, 7% H_2SO_4/HgO, 60°C, 5 min. d) 1) 1-Methoxy-1,3-butadiene, 40°C, 7 h; 2) 1% NaOH, $H^{\oplus}$ (transformation to **81** not given).—**4**, R^1-R^3 = H, R^4 = OCH_3; **13a**, R^1-R^4 = H; **81a**, **81b**, **81c**, R^1 and R^2 and R^3 = OCH_3, other R = H; **81d**, R^1 = R^4 = H, R^2 = R^3 = CH_3.

do so when converted into monoacylnaphthazarins. In order to exploit this selectivity in anthracyclinone synthesis it was necessary to find a suitable acyl group that undergoes acyl migration during the reaction from *rac*-**84a** to *rac*-**84b** and is later on readily removable. *Kelly* et al.[84] found that the *p*-nitrobenzoxycarbonyl group fulfills these conditions: The mononaphthazarin **83** reacts with the cyclic diene **82** to give *rac*-**84a**. The addition of the diene **79** to the tautomeric form *rac*-**84b** occurred regioselectively to give exclusively the expected adduct *rac*-**85**. The subsequent transformation to *rac*-**4** was achieved by a method similar to those described earlier[84] (Scheme 21).



Scheme 21. a) 1) Without solvent, **82** : **83** = 2.5 : 1, 8 h; 2) THF, KH, PbO_2, 4°C, 12 h.—R = *p*-O_2N-C_6H_4-CH_2-O-CO.

The syntheses starting with naphthazarin require few steps and give excellent overall yields (29%,[82] 36%[84]), but the problems of enantioselectivity and *cis*-7,9-stereoselectivity are still to be solved. A possible solution to the latter problem is resort to the use of 1-*tert*-butoxy-3-trimethylsiloxy-1,3-butadiene.[81]

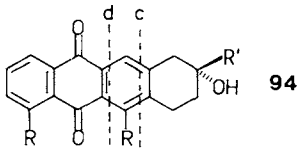


How general is the use of tetracyclic ketones of type **59**–**61** (Scheme 16) for the preparation of other anthracyclinone types (e.g. rhodomycinones) with alkyl or acetonyl side chains? The great tendency for enolization normally prevents the facile addition of organometallic reagents such as ethynylmagnesium bromide. Two solutions have been proposed: 1) prevention of aromatization using starting materials without aromatic ring B; 2) employment of organometallic compounds with less tendency to effect enolization. In the first approach *Sih* et al.[85] could prepare 7,11-dideoxydaunomycinone *rac*-**87** starting from **86** (Scheme 22).

Enolization occurred only slightly during the reaction of vinylmagnesium bromide with **61** to afford *rac*-**88**. Reduction with diimide and subsequent treatment with aluminum chloride effected both the cleavage of the C-4 methyl ether as well as the elimination of the tertiary hydroxy

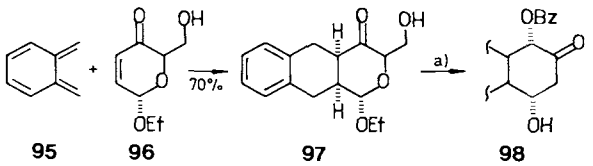
Scheme 22. a) 1) BrMgC≡CH, THF, −20°C; 2) $Hg(OAc)_2$; 3) Ce^{4+}, Br_2; 4) $NaOCH_3/CH_3OH$.

group to give the olefin **89**. After epoxidation, opening of the resulting oxirane *rac*-**90** with sodium acetate afforded the *trans*-acetate *rac*-**91** with a *cis/trans* selectivity of 1:9. The subsequent hydroxylation at C-7 via homolytic bromination and exchange with silver acetate gave a 1:1 mixture of the 7,9-*cis*-diol *rac*-**92** (β-rhodomycinone) and the 7,9-*trans*-diol *rac*-**93** (α-rhodomycinone; Scheme 23).



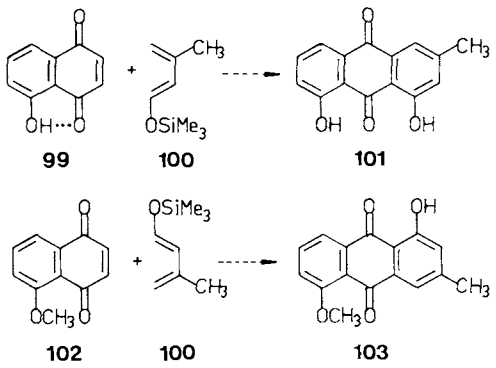
Scheme 23. a) $BrMgCH{=}CH_2$. b) HN=NH; 2) $AlCl_3$. c) *m*-Chloroperbenzoic acid (MCPBA). d) NaOAc/HOAc, 85°C. e) 1) Br_2, CCl_4, *hv*; 2) CF_3COOAg; 3) NaOH.

Little enolization is also observed in reactions with organomanganese compounds, which are generated in situ from alkenyl bromide, $MnCl_2$ and $LiAlH_4$. Thus, in the case of the allyl compounds, feudomycinone derivatives with acetonyl side chains are made available.[87]



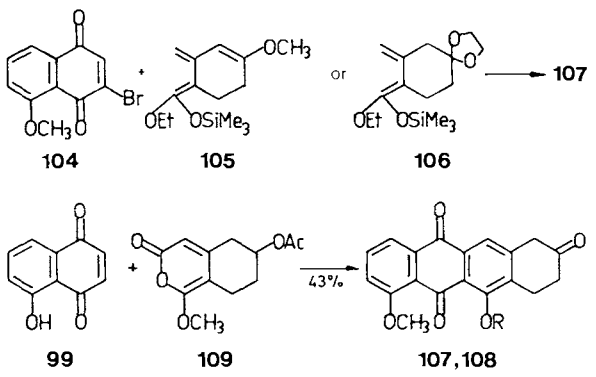
3.2. Formation of Ring B

The formation of new bonds in the construction of ring B can proceed via disconnection "c" (DC segment is the diene) or "d" (DC segment is the dienophile) in **94**.



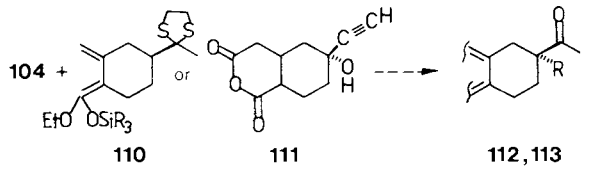
R = H, OH, OCH_3; R' = alkyl.

The disconnection "c" is only realized in a model reaction described by *Ferrier*[88] in which the tricycle **97** is formed by reaction of *o*-quinodimethane **95** with the pyranone **96**. The heterocycle **97** can subsequently be rearranged (Ferrier rearrangement[89]) to the carbocycle **98** in a six-step reaction sequence (Scheme 24). The potential importance of this method stems from the synthesis of enantiomerically pure anthracyclinones by addition of organometallic compounds to **98**.



Scheme 24. a) 1) $NaBH_4$; 2) tosylation; 3) benzoylation; 4) NaI; 5) AgF, pyridine; 6) $Hg(OAc)_2$, acetone, H_2O. — Bz = PhCO.

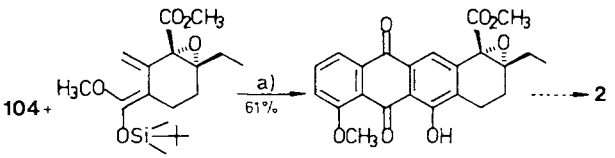
Much more important is disconnection "d" in the synthesis of 11- and 6-deoxyanthracyclinones, using mainly derivatives of juglone as the DC-dienophile. The regioselectivity of Diels-Alder reactions with juglone derivatives has been thoroughly investigated experimentally[90-94] and is in good agreement with frontier orbital considerations.[95] The strong hydrogen bridge in juglone **99** is responsible for the extremely different orbital coefficients in the LUMO of the quinone, which consequently leads to the formation of **101** in the reaction of **99** with diene **100**. By contrast, the juglone methyl ether **102** yields the adduct **103** with inverse orientation of the methoxy group[91-93,96] (Scheme 25).



Scheme 25.

The reaction of the bromojuglone methyl ether **104** with the ketene acetals **105**[96] or **106**[97] to give the tetracycle **107** also proceeds with formation of ring B. In these cases the bromine atom directs the regioselectivity. The presence of the bromine atom simultaneously facilitates the aromatization of ring B with elimination of HBr and alcohol. An aromatization with CO_2 elimination follows the addition of juglone (**99**) to the bicyclic 6-alkoxypyranone **109** to afford **108**[98] (Scheme 26).

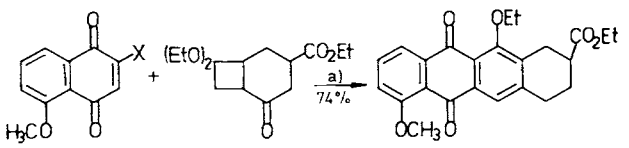
Scheme 26. **107**, R = H; **108**, $R = CH_3$.



The attachment of side chains to the tetracyclic ketones of type **107** or **108** is difficult due to the great tendency for enolization.[99,100] Alternative pathways using the AB building block with side chain *rac*-**110**[96,99] or *rac*-**111**[101] in the reaction with bromojuglone **104** lead to the formation of *rac*-**112** or *rac*-**113** (Scheme 27).

110 111 112,113

Scheme 27. 112, R = H; 113, R = OR'.

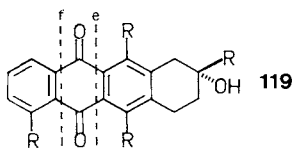


Rapoport et al.[102] were able to realize the use of the highly functionalized exocyclic diene **114**[102a] in a convergent synthesis of aklavinone via the intermediate *rac*-**115**[102] (cf. [97]). Carefully controlled reaction conditions (presence of triethylamine and molecular sieves to trap protons and methanol, respectively) were necessary in the Diels-Alder reaction so as to prevent aromatization of the primary adducts. Derivatives with a large variety of substituents in ring D are also available with the use of different naphthoquinones as dienophiles[102] (Scheme 28).

114 115

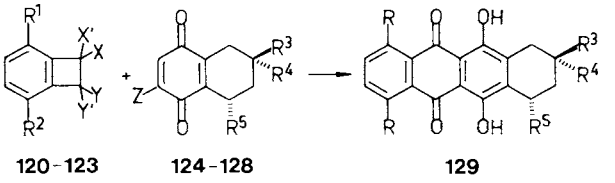
Scheme 28. a) 1) Benzene, 20 °C, 40 h, $N(C_2H_5)_3$, 4 Å molecular sieve; 2) nBu_4NF.

6-Deoxyanthracyclinones can also be obtained by this method by merely changing the position of the bromine atom in the juglone derivative. For example, the tetracyclic intermediate **118** is thus prepared by reaction of 2-bromo-*O*-methyljuglone **116** with the diene precursor **118**.[103] However, the intermediate **118** was in this case further transformed to daunomycinone (*rac*-**4**)[103] (Scheme 29; cf. [96]; for tandem Michael/Diels-Alder reactions or Claisen rearrangement/Diels-Alder reactions to 11-deoxyanthracyclinone precursors see [104, 105]).



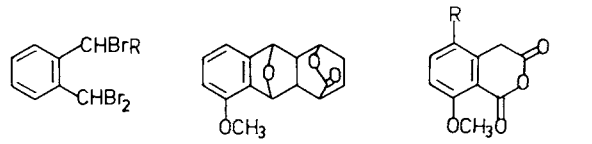
116 117 118

Scheme 29. a) 1) 185–190 °C, 1.5 h; 2) $NaOC_2H_5$, C_2H_5OH, O_2. – X = Br.



3.3. Formation of Ring C

Of the disconnections "e" and "f" in **119** only the first is of any importance because the AB building block can easily be incorporated in the form of tetrahydronaphthoquinones. However, following disconnection "e" only derivatives of rhodomycinones and no 6- or 11-deoxy compounds are available.



119

Intermediary *o*-quinodimethanes are also used as dienes. They can be generated thermolytically or photolytically from the cyclobutabenzenes **120–123**[60, 106–110] as shown in Scheme 30 (and also photolytically from *o*-methylbenzaldehydes[107]). Furthermore, the tri- or tetrabromides **130**[111, 112] or **131**[113] (generation of the *o*-quinodimethanes with NaI) can be used as precursors, as well as the isobenzofuran derivative **132**[30] or the homophthalic acid anhydrides **133**[114] or **134**[115] (treatment with strong bases). However, a general synthetic problem of this pathway is the subsequent oxidation of the 1,4-anthraquinone to derivatives of 1,4-dihydroxy-9,10-anthraquinone. An easy solution to the problem is only presented by the reaction of **123**[110] or **134**,[115] which directly yield 9,10-anthraquinones (Scheme 30).

120–123 124–128 129

130, R=H; **131**, R=Br **132** **133**, R=H; **134**, R=OAc

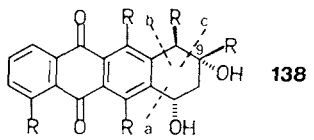
	R^1	R^2	X	X'	Y	Y'	Ref.
120	H	OMe	H	H	OH	H	[60, 106, 107]
121	OMe	OMe	H	H	–O–		[108]
122	H	H	OAc	H	OAc	H	[109]
123	H	OCH_2OMe	–O–		–O–		[110]

	R^3	R^4	R^5	Z	Ref.
124	$-O-(CH_2)_2-O-$		H	H	[106]
125	$-O-(CH_2)_2-O-$		H	Cl	[114]
126	Et	OH	OH	Cl	[60]
127	Ac	OH	H	H	[108]
128	Ac	–O–BPh–O–		H	[109]

The variety and different degree of functionality of AB quinones is shown in the examples **124–128**. Control of the regiochemistry is only possible with the corresponding chloro derivatives **125** and **126**. The quinones **124–128** can easily be prepared from the corresponding hydroquinone dimethyl ethers presented in Section 2.2; for instance, by oxidation with cerium(IV) reagents.[116] With chiral AB building blocks no racemization is observed under the conditions of the Diels-Alder reaction (Scheme 30).

A more unusual reaction is the addition of the Fischer carbene complex **136** to the acetylene *rac*-**135**. In this interesting reaction a molecule of CO is incorporated into ring B of *rac*-**137**[117] (for the mechanism see [117b]), which is then transformed (Scheme 31) in a further six steps to the known daunomycinone intermediate **61** (see Scheme 16).

Scheme 31. a) 1) THF, 45 °C, 12 h; 2) 2 equiv. $[Fe(dmf)_3Cl_2]FeCl_4$, THF. b) Six steps, 26–45%.



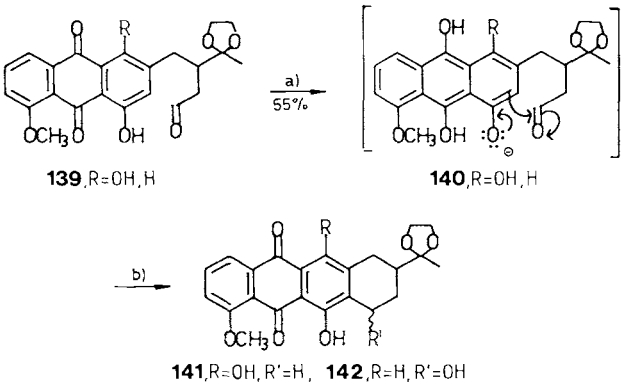
However, there are much shorter regioselective ways to **61** (see Section 4.1).

4. Anionic Reactions

The specific generation of anionic centers in one building block and acceptor centers in another enables selective bond formations and therefore an excellent control of regiochemistry. There are many possible methods for the first bond formation; however, Michael additions and the specific metalation of arenes certainly have priority. Although the coupling of the two building blocks is usually a two step process (the second step is often a Friedel-Crafts reaction) many condensations can in practice be conducted in a single reaction vessel.

4.1. Formation of Ring A

It is obvious that the tricyclic anthraquinones may be good starting materials for the synthesis of tetracyclic anthracyclinones. In many instances the syntheses starting from tricyclic precursors are much shorter and more efficient than the synthesis of AB fragments alone which must be coupled with further components to form tetracycles. The main reason for the success of this strategy stems from the fact that three excellent methods are available for the coupling of functionalized side chains to hydroxylated anthraquinones: 1) The Marschalk reaction; 2) nucleophilic additions to anthraquinones; and 3) the Claisen rearrangement.



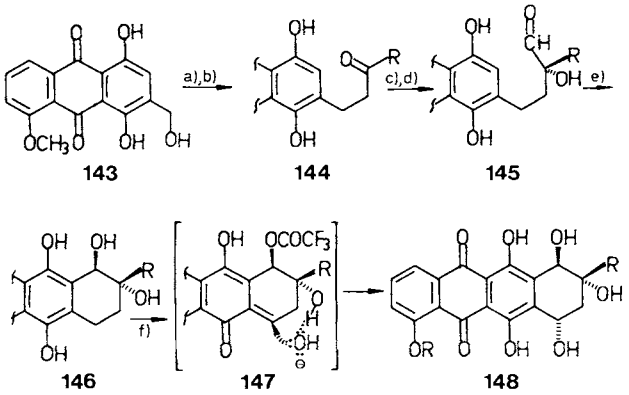
138

As shown in formula **138** the syntheses which proceed with formation of ring A can be divided into those which start from *mono*alkyl anthraquinones and those which require *di*alkylated anthraquinones. In the first case the ring of the arene is closed in the β-position ("a") or α-position ("b") to the tertiary center at C-9. In the second case, the formation of the bond leads, according to "c", via aldol reaction to anthracyclinones of type B or via Wittig reaction to anthracyclinones of type A.

4.1.1. Cyclization of Monoalkylanthraquinones

One of the earliest applications of the Marschalk reaction in anthracyclinone chemistry made use of disconnection "a" in **138**.[118] The strategy employed by *Sih* et al.[118] demonstrates the principles of this frequently used reaction. First the anthraquinone *rac*-**139** is reduced with dithionite in aqueous alkali to the hydroquinone *rac*-**140**, in which the electron density of the arene for an electrophilic attack of the aldehyde is considerably increased as compared to that in the anthraquinone *rac*-**139**. Thus, the reactive species *rac*-**140** is generated in a kind of "redox umpolung" from *rac*-**139**. Under the conditions originally employed by *Marschalk* (high temperatures) the benzylic hydroxy group that is formed during the addition is eliminated in an intramolecular redox process with regeneration of the anthraquinone,[119] as is shown by the cyclization to *rac*-**141** (Scheme 32). We have been able to demonstrate with many examples that the benzylic hydroxy group present in many anthracyclinones can easily be preserved by decreasing the reaction temperature.[120] This makes the Marschalk reaction an especially valuable tool in anthracyclinone chemistry. One example is the synthesis of 11-deoxydaunomycinone *rac*-**142** (R = H, R′ = OH) starting from aloe emodin, in which the benzylic hydroxy group is preserved during the cyclization of the aldehyde *rac*-**140** (R = H)[121] (Scheme 32).

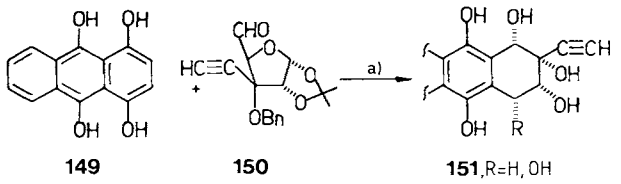
139, R=OH, H **140**, R=OH, H



141, R=OH, R′=H, **142**, R=H, R′=OH

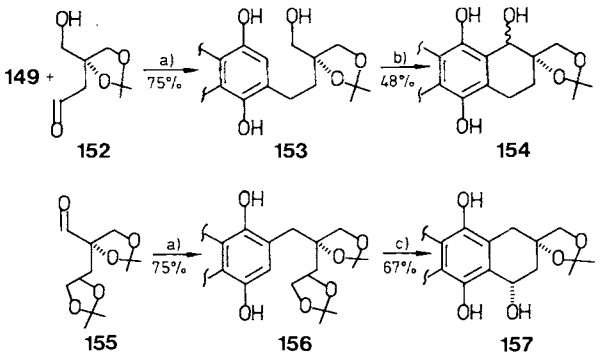
Scheme 32. a) NaOH, $Na_2S_2O_4$. b) O_2.

1,4-Dihydroxyanthraquinones not only react with aldehydes but also with other electrophiles such as α,β-unsaturated carbonyl compounds in a kind of Michael reaction[122, 123] (exceptions see [124a]), with halides[124b] and also intramolecularly with ketones.[120a, 125] A great advantage, moreover, is that with aldehydes (excepting formaldehyde) at low temperatures, directed *mono*alkylations can be achieved with 1,4-dihydroxyanthraquinones.[120] An intermolecular second alkylation is effected only under drastic conditions; however an *intra*molecular addition clearly occurs at −10 °C.[127] Aldehydes add *exclusively ortho* to the phenolic group, whereas halides also attack the *para* position.[124b] Esters do not react under the conditions of the Marschalk reaction; the products aromatize under more vigorous conditions.[118] According to *Whitlock* et al.,[128] a ring closure of esters can only be achieved by metalation of the arene.



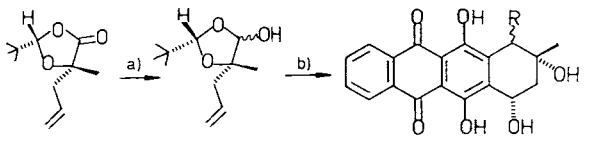
Excellent facilities to control stereo- and regiochemistry are also provided by disconnection "b" in **138** via α-hydroxyaldehydes such as *rac*-**145**. Starting from hydroxyme-

thylanthraquinone **143**, which is readily accessible from 1,4,5-trimethoxyanthraquinone[7] via selective cleavage of methyl ethers and Marschalk hydroxymethylation, it is possible to lengthen the side chain by standard methods to afford **144**. A further great advantage is that by reaction of **143** with 3-oxoesters, precursors with practically any side chain (e.g. CH_3, C_2H_5, C_3H_9) are available. The missing carbon atom can be introduced by reaction with acycl-anion equivalents. Lithiated 1,3-dithiane[129,130] and lithiated dichloromethane[7,127,131] have proven suitable for this purpose. The dichloromethane adducts are especially easily converted into the hydroxyaldehydes by treatment with aqueous alkali. Cyclization to the 9,10-diols **146** occurs in a one pot procedure after reduction with dithionite. The stereochemical outcome can largely be controlled by the choice of the reaction conditions: with non-chelating counter ions (e.g. Triton B), predominantly the *trans*-diols with the natural *trans* configuration are formed.[127] The synthesis is terminated by the hydroxylation at C-7. The benzylic hydroxy group is protected as trifluoroacetate prior to the usual bromination. The subsequent solvolysis with alkali yields almost exclusively the naturally configurated 7,9-*cis*-9,10-*trans* triols *rac*-**148**. The *cis*-selectivity is explained in terms of an elimination addition mechanism via an intermediate *o*-quinomethide *rac*-**147**, which is preferentially hydroxylated from the hydrophilic rear side.[132] Using this method, it was possible to prepare all the known natural rhodomycinones and feudomycinones of type A[7,127] (Scheme 33).



Scheme 33. a) SO_2Cl_2. b) 1) Alkylation with 3-oxo esters; 2) $OH^{\ominus}$; 3) $H^{\oplus}$; 4) $AlCl_3$ or BCl_3. c) Lithio-1,3-dithiane or dichlorolithiomethane, −100°C. d) NaOH, Triton B, CH_2Cl_2, 20°C. e) $Na_2S_2O_4$, −10°C, O_2, $H^{\oplus}$. f) 1) $(CF_3CO)_2O$; 2) Br_2, Azodiisobutyronitrile (AIBN) or *hv*; 3) $NaHCO_3$.

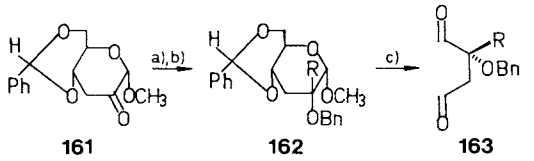
For the synthesis of enantiomerically pure natural products, the asymmetric synthesis of α-hydroxyaldehydes of type **148** with chiral auxiliaries is presently under investigation by our group. However, the Marschalk reaction also opens up ideal possibilities by incorporation of chiral derivatives from natural products, and both routes "a" and "b" (see **138**) are equally promising. Carbohydrates may be employed as natural products and *Shaw* et al.[133] have investigated the reaction of unbranched derivatives with leucoquinizarin **149**. The branched building block **150** was incorporated into the synthesis of the anthracyclinone **151** hydroxylated at C-8[133d] (Scheme 34).



Scheme 34. a) Five steps. Bn = $PhCH_2$.

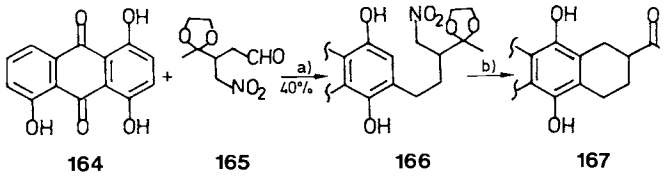
Both strategies "a" and "b" have been realized by *Monneret* et al.[55] The building blocks **152** and **155** were obtained in six steps from lactose. The first alkylation to **153** or **156** is carried out in boiling isopropanol with elimination of the benzylic hydroxy group (Lewis conditions[126]). Whereas cyclization of the aldehyde prepared from **153** under Marschalk conditions yields a 2:3 mixture of epimeric alcohols **154**, only the *cis*-diol **157** is obtained from **156** after partial cleavage of the terminal acetonide and cleavage of the diol to an aldehyde[55] (Scheme 35).

Scheme 35. a) 1) Isopropyl alcohol, Piperidinium acetate, 12 h boiling; 2) O_2. b) 1) DMSO, dicyclohexylcarbodiimide, pyridine, CF_3COOH; 2) $Na_2S_2O_4$, 0°C; 3) O_2. c) 1) 80% HOAc, 20°C, 1 h; 2) HIO_4; 3) $Na_2S_2O_4$, NaOH, −10°C; 4) O_2.



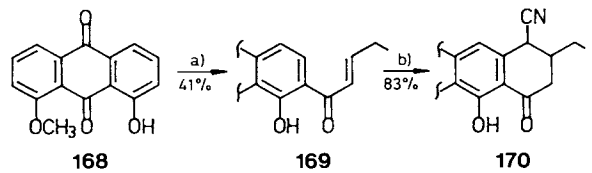
We in our group have been able to incorporate L-lactic acid into anthracyclinones **160** (R = H or OH) in a very short reaction sequence. The lactone **158** obtained by acetalation and alkylation[57] is easily reduced with diisobutylaluminum hydride to the relatively stable lactol **159**, which is transformed into **160** by a sequence of Marschalk reactions and ozonolysis[134] (Scheme 36).

Scheme 36. a) DIBAH, THF, −30°C. b) 1) **149**, NaOH; 2) O_3; 3) $Na_2S_2O_4$, NaOH.



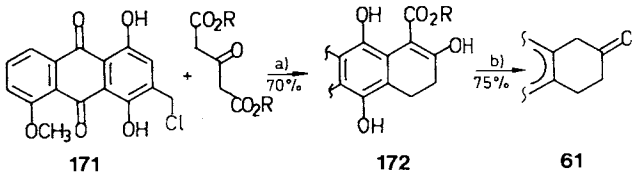
The incorporation of L-lactic acid is limited to the synthesis of anthracyclinones with methyl side chains. This restriction no longer exists when employing the 2-oxo-3-deoxy sugar **161** obtained from glucose, since a number of organometallic reagents can be added selectively to give **162** (R = ethyl, ethynyl). Benzylation, acetal cleavage and periodate cleavage affords the unstable dialdehydes **163**, which are added to leucoquinizarin **149** using the methods

outlined in Schemes 33–36[135] to give anthracyclinones (Scheme 37).



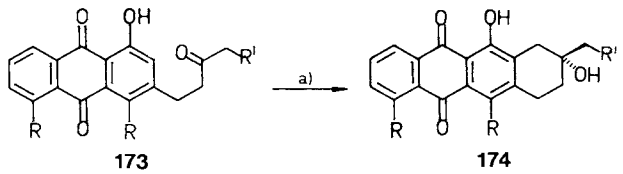
Scheme 37. a) BrMgR or LiR. b) Benzyl bromide, base. c) 1) HOAc, 60°C; 2) $NaIO_4$. — Bn = $PhCH_2$.

Anthracyclinone research has clearly shown that, in addition to electrophilic substitutions with hydroanthraquinones (Marschalk reaction), nucleophilic additions to anthraquinones are also possible. The additions are often surprisingly straightforward in *intra*molecular reactions. A combination of the Marschalk reaction with nucleophilic additions may be very advantageous, as has been shown by the work of *Sutherland* et al.[136] The nitroaldehyde *rac*-**165** is first added to the hydroquinone of **164** to give *rac*-**166**, which subsequently cyclizes with elimination of the nitro group[136] to give 7,9-dideoxycarminomycinone *rac*-**167** (Scheme 38). The C-3 selectivity (5 : 1) of the addition of *rac*-**165** to **164** under Lewis conditions is remarkable.[125, 126] The sequence of the reaction steps can also be reversed, whereupon nitroalkane building blocks add highly selectively at C-2.[136]



Scheme 38. a) Isopropyl alcohol, piperidinium acetate, 3 h boiling. b) 1) $NaOCH_3/CH_3OH$; 2) $H^{\oplus}$, H_2O, 10 h boiling.

Nucleophilic additions are a useful supplement to the Marschalk reaction insofar as the *ortho*-phenolic group is not a necessary prerequisite for the cyclization. This is demonstrated quite nicely in the synthesis of 11-deoxyaklavinone by *Cava* et al.[137] in which a kind of Michael addition of phenylthiomethyl cyanide to **169** is followed by ring closure to *rac*-**170** with elimination of phenyl sulfide[137] (Scheme 39).

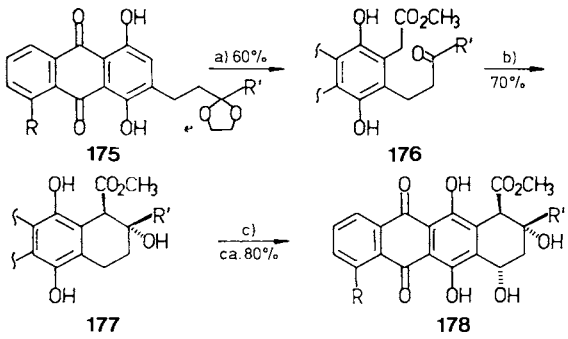


Scheme 39. a) Seven steps. b) $PhSCH_2CN$, $NaCH_2SOCH_3$/DMSO.

Unfortunately, the methods of *Sutherland* and *Cava* do not allow a direct introduction of an oxygen function at C-9. In our investigations we have paid special attention to this point. Thus, the daunomycinone precursor **61** (see Scheme 16) can be prepared regioselectively in only two steps from the tricycle **171**. The alkylation of acetonedicarboxylic ester leads under mild conditions via an open-chain intermediate directly to the tetracycle **172**, which is transformed into the ketone **61** by acid hydrolysis and decarboxylation[138] (Scheme 40).

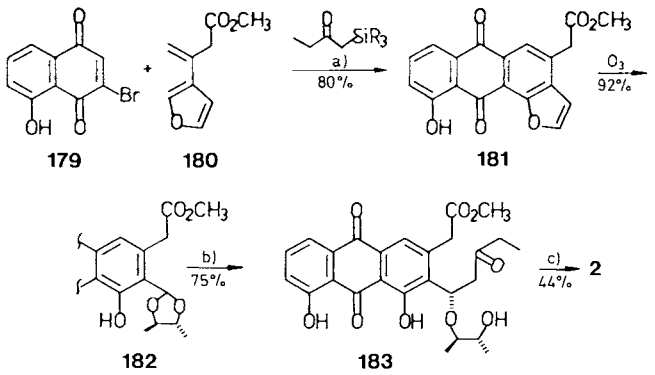
Scheme 40. a) K_2CO_3, DMF. b) HOAc, H_2SO_4.

Another example is the addition of nitromethane to the 3-oxoalkylanthraquinone **173**, followed by cyclization with elimination of the nitro group to form the tetracycles *rac*-**174** (66–92% overall yield). A prerequisite is the presence of a phenolic hydroxy group at C-4[139] (Scheme 41). The alcohols *rac*-**174** can either be converted into feudomycinones by hydroxylation at C-7[127] or into β-rhodomycinones via elimination.[86]



Scheme 41. a) CH_3NO_2, $C_2H_5O^-/C_2H_5OH$, 24 h boiling. R = H, OH, OCH_3; R' = H, CH_3.

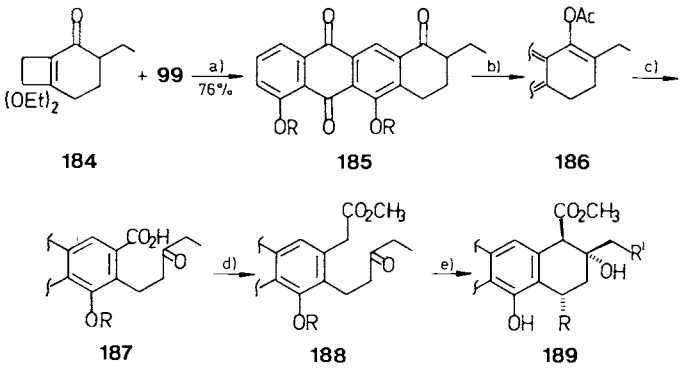
4.1.2. *Cyclization of Dialkylanthraquinones*



Anthracyclinone syntheses that start from bisalkylated anthraquinones are preparatively very profitable. Due to the specific substitution pattern of ring A, only the strategy based on disconnection "c" in **138** has so far been realized. One advantage of this pathway is the ready availability of the *ortho*-bisalkylated anthraquinones with differently substituted side chains. Two successive Marschalk reactions are ideal for the synthesis of the rhodomycinones with two *p*-hydroxy groups at C-6 and C-11, because a second, differently substituted side chain can only be introduced under more vigorous conditions. The procedure can be demonstrated with the synthesis of the ketoesters **176** which are made available from monosubstituted anthraquinones **175** via reaction with glyoxylic acid. In the subsequent treatment with base, the doubly activated benzylic position is deprotonated and the corresponding cyclic *p*-hydroxy esters are obtained almost quantitatively. The stereochemistry of the cyclization can easily be controlled: With lithium amides in aprotic medium, the *cis*-hydroxy esters are obtained exclusively, while treatment with Triton B in pyridine yields predominantly (at least 10 : 1) the 9,10-*trans*-anthracyclinones *rac*-**177** of natural configuration. The subsequent hydroxylation at C-7 is also highly selective and leads in good chemical yields almost exclusively to the 7,9-*cis*-diols *rac*-**178**[6, 140] (Scheme 42).

The two phenolic hydroxy groups at C-6 and C-11 are not available for the synthesis of aklavinone (**2**) or citromycinone (see, e.g., **194** and **205**), so another synthetic

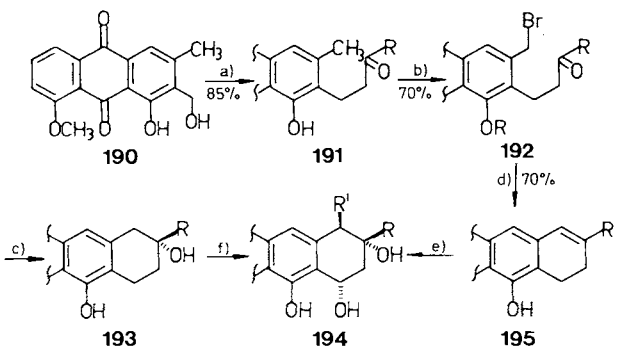
Scheme 42. a) 1) $Na_2S_2O_4$, NaOH, OHC–COOH; 2) H^+; 3) CH_2N_2. b) Triton B, pyridine, 0°C, 10–20 min. c) 1) Br_2, CCl_4, *hv*; 2) $NaHCO_3$, H_2O.



route has to be sought. The easiest approach is to generate the substitution pattern by Diels-Alder reaction, as demonstrated by the enantioselective synthesis of aklavinone by *Kishi* et al.[141] (Scheme 43). The Diels-Alder reaction of the bromojuglone **179** with the vinylfuran **180** affords the adduct **181**, which upon atmospheric oxidation and ozonolysis yields an ester aldehyde. The aldehyde group enables the introduction of a chiral auxiliary by acetalation with D-(−)-2,3-butanediol to give **182**. The decisive transfer of chirality is accompanied by chain elongation with 1-trimethylsilyl-2-butanone to give the keto alcohol **183** (selectivity 10:1 in favor of **183**). The cyclization with potassium carbonate in methanol yields 53% of a 7-*O*-methylaklavinone in addition to 43% of chromatographically separable *cis*-hydroxy esters. The intermediary ethers can be cleaved with trifluoroacetic acid to furnish the corresponding C-7 alcohols[141] (Scheme 43).

Scheme 43. a) Boiling in benzene, O_2, Hünig base. b) 2 equiv. CH_3CN, $SnCl_4$, −10°C, 5 h. c) 1) CH_3OH, K_2CO_3, 20°C, 2 h; 2) CF_3COOH, −78°C.

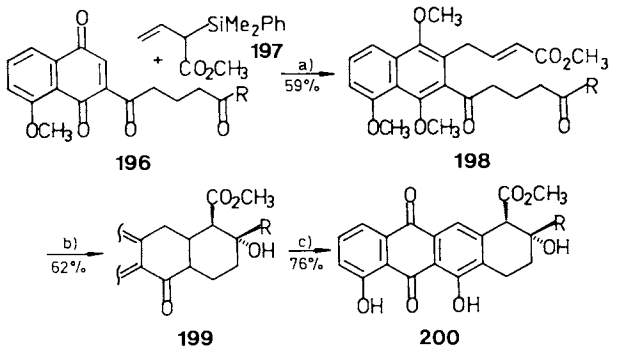
An enantioselective synthesis of 11-deoxydaunomycinone can be realized if the side chain of **183** contains an additional carbonyl group (initially masked as a methylene group).[142] The synthesis is completed by ozonolysis and decarboxylation (for further decarboxylations of type B anthracyclinones, see [143, 144]).



The advantage of the biogenetic type keto-ester cyclization is the generation of the acid-labile β-hydroxy ester under very mild conditions. It is therefore not surprising that seven of twelve published aklavinone or pyrromycinone syntheses follow this strategy, as was first resorted to in the synthesis of ε-rhodomycinones (see Scheme 42). However, the routes to the key intermediates are quite different. Most often an olefinic tetracyclic skeleton with ethyl side chain at C-9 is constructed by Diels-Alder reaction of juglone with diene precursors such as **184** (cf. Schemes 26–29), as may be seen in the synthesis of aklavinone by *Boeckman* et al.[145] (Scheme 44). The ozonolysis of **186** leads to a ketocarboxylic acid **187** lacking one carbon atom. Homologization of **187** via Arndt-Eistert reaction gives the keto ester **188**, subsequent cyclization and hydroxylation of which affords aklavinone (**2**),[145–147] pyrromycinone (**3**),[146] auramycinone (**189**)[147] (R′=CH_3) or 2-hydroxyaklavinone,[148] depending on the starting materials used (Scheme 44).

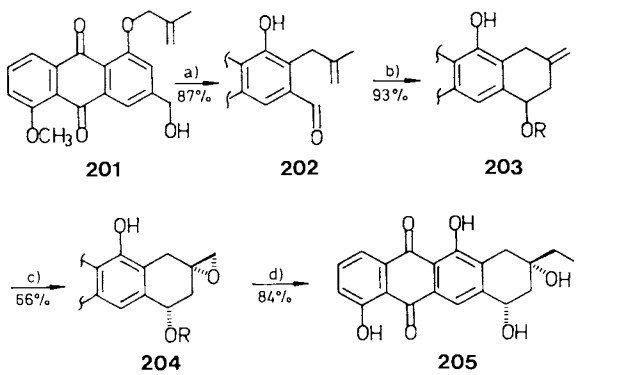
Scheme 44. a) 1) **184**:**99** = 4.4:1, 175–180°C; 2) methylation. b) Ac_2O, $HClO_4$. c) O_3. d) Arndt-Eistert homologization. e) Triton B, CH_3OH/CH_2Cl_2, −20°C; hydroxylation at C-7.

In our syntheses of aklavinone,[149] pyrromycinone and auramycinone[150] we have used the open-chain bromides **142**, which are accessible from the hydroxymethylanthraquinone **190** via the ketones **191**. Since a direct substitution of the bromide in **192** by carboxylate anion equivalents such as cyanide was not feasible (cf. [147]), we have also chosen the Arndt-Eistert reaction[149] or Grignardation at −78°C with highly reactive magnesium[151] to realize chain elongation.[150]



The reactive bromides **192** may also serve as starting materials for many 11-deoxyanthracyclinones of type A. They can be directly cyclized with magnesium to the alcohols *rac*-**193**[132] or by Wittig reaction, in excellent yields,

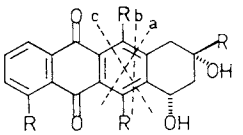
Scheme 45. a) Three steps see Scheme 44. b) 1) Pivaloyl chloride, dimethylaminopyridine (DMAP), pyridine; 2) NBS, CCl_4, *hv*. c) Activated Mg/THF. d) PPh_3, K_2CO_3, THF, [18]crown-6, 3 h boiling. e) 1) MCPBA; 2) NaOAc; 3) NaOH and finally hydroxylation. f) Hydroxylation.—R=CH_3, C_2H_5; R′=H, OH; R′+H-10=–O–.



to the olefins **195**.[152] Starting from the olefins **195**, the citromycines *rac*-**194** (R′=H or OH)[132] or the 8-deoxyaranciamycinones *rac*-**194** (with oxo group at C-10)[152] are obtained by the methods of epoxidation, nucleophilic epoxide opening, and hydroxylation, as has already been mentioned (see Scheme 23 and Scheme 45; for the synthesis of 10-oxoanthracyclinones cf. [153, 154]). With lactamide complexes of oxodiperoxomolybdenum, an enantioselective epoxidation of olefins of type **195** with 73% *ee*[155] was possible.

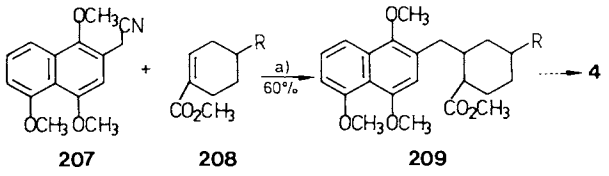
Similarly as in *Muxfeldt*'s tetracycline synthesis, in the aklavinone synthesis described by *Maruyama* et al.[157] both rings A and B are built up in a sequential reaction ("Zipper reaction").[156] The bicyclic compound **198** which resembles the tricyclic ketoesters is obtained by Michael addition of the silyl ester **197** to the naphthoquinone **196**. Three stereoisomeric tetracyclic products in addition to a tricyclic ketone are formed upon base-catalyzed cyclization of **198**. By extensive optimization studies, the yield of the desired product *rac*-**199** could be increased to 62% using [2.2.2]cryptands (kryptofix). Oxidation to the quinone and aromatization of ring B affords 7-deoxyauramycinone (*rac*-**200**, R=CH_3), deoxyaklavinone *rac*-**200** (R=C_2H_5), and the 13-methyl compound *rac*-**200** (R=*i*Pr)[157] (Scheme 46).

Scheme 46. a) CH_2Cl_2, $SnCl_4$, −78 bis −20 °C, 2 h. b) 1) KH, Kryptofix 222/hexamethylphosphoric triamide (HMPT), THF, −78 to −50 °C, 3 h; 2) *t*$BuMe_2SiCl$, imidazole. c) 1) $Ce^{4\oplus}$; 2) $NaHSO_3$; 3) Br_2, AIBN, CCl_4; 4) $N(C_2H_5)_3$; 5) $AlCl_3$.



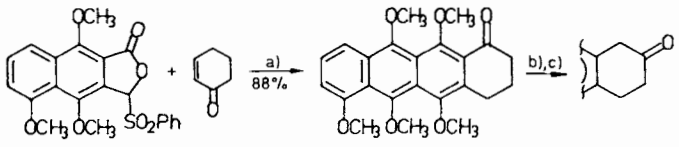
The synthesis of citromycinone by *Hauser* and *Mal*[158] also proceeds with formation of ring A. It is a beautiful example of the "reductive" Claisen rearrangement as introduced into anthracyclinone chemistry by *Rutledge* et al.[159] Thus, the reduced form of **201** rearranges to **202** at considerably lower temperatures than the quinoid form **201**. An interesting step is the $SnCl_4$-catalyzed cyclization of the unsaturated aldehyde **202** to the exocyclic olefin *rac*-**203**. The synthesis of γ-citromycinone (*rac*-**205**) is completed by epoxidation of *rac*-**203** to *rac*-**204**, opening of the oxirane with lithium dimethylcuprate, and ether cleavage[158] (Scheme 47).

Scheme 47. a) 1) $Na_2S_2O_4$, DMF, heating; 2) $BaMnO_4$, CH_2Cl_2. b) $SnCl_4$, CH_2Cl_2. c) Sharpless epoxidation. d) 1) 2 CuCN, 12 CH_3Li, THF, 0 °C; 2) $AlCl_3$.



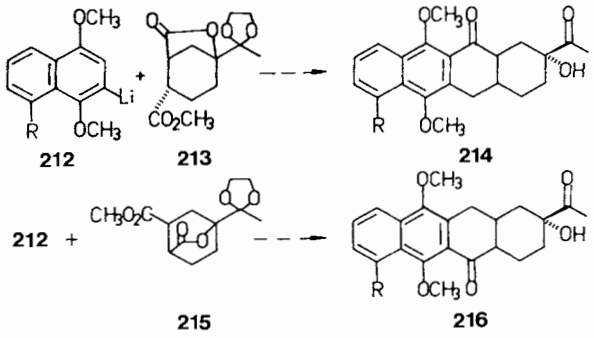
4.2. Formation of Ring B

Three of four possible pathways ("a", "b", and "c") are realized in the syntheses that proceed with construction of Ring B (see **206**). The anionic coupling of two unequal building blocks is also suitable for the synthesis of 6- and 11-deoxyanthracyclinones. The Michael addition and the nucleophilic addition of selectively lithiated arenes are most often employed.



206

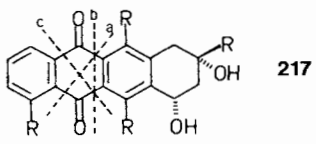
Parker et al.[160] as well as *Kende* et al.[161] make use of the Michael addition of the benzyl cyanide **207** to the cyclic α,β-unsaturated esters **208** for the regioselective synthesis of the precursors **209**. The further transformation to tetracycles is accomplished via an oxidative elimination of the cyano group and a Friedel-Crafts cyclization (Scheme 48).



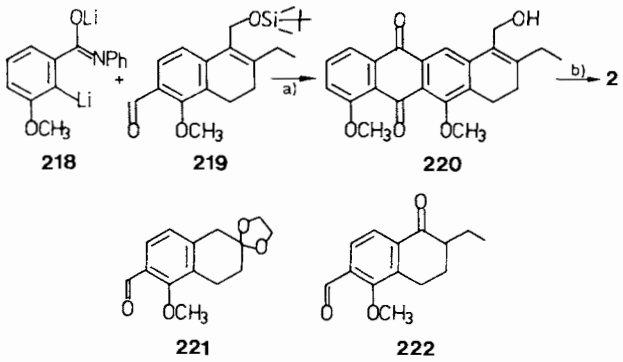
Scheme 48. a) Potassium enolate of **207**, −56 °C, 3 h.

The syntheses proceeding with formation of ring C following disconnection "b" in **206** have been systematically developed into a generally applicable synthetic method for linearly annelated ring systems, e.g. in the groups of *Hauser*,[162] *Kraus*,[163] *Staunton*,[164] *Swenton*,[43] and *Weinreb*.[165] The principle of the method is neatly demonstrated in the reaction of the tricyclic phenylsulfonylfuranone **210**.[166] A 1,4-dipole generated from **210** by deprotonation reacts sequentially with α,β-unsaturated carbonyl compounds such as cyclohexenone. A primary Michael reaction is followed by a nucleophilic addition of the intermediary enolate to the ester group to give the adduct **211**, which can be transformed into the daunomycinone precursor **61** by transposition of the carbonyl group from C-10 to C-9 as shown in Scheme 49.[166] Products with inverse substitution pattern can be obtained by regrouping the functional groups in the furanone **210**.[166] The reaction of bicyclic furanones with bicyclic enones leads to similar products[167] (Scheme 49).

Scheme 49. a) $LiNiPr_2$, THF, −78 °C, 30 min, then 0 °C. b) 1) $NaBH_4$; 2) $H^{\oplus}$. c) 1) $OsO_4/(C_2H_5)_3NO$; 2) $H^{\oplus}$, $HOCH_2CH_2OH$; 3) cerium ammonium nitrate; 4) AgO/HNO_3; 5) trifluoroacetic acid, HCl.



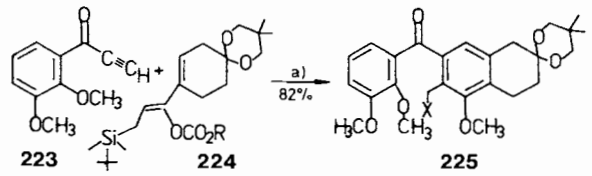
6-Deoxy-[168] as well as 11-deoxydaunomycinones[169] can be prepared in a very flexible manner by route "c" in **206**. Thus, *rac*-**214** can be prepared by coupling the lithiated naphthalene **212** with the ester lactone *rac*-**213**, while *rac*-**216** can obtained by reaction of **212** with *rac*-**215**.[170] It is remarkable that the ester group is attacked preferentially, thus controlling the regiochemistry of the adducts (Scheme 50). A disadvantage in the synthesis of 6-deoxy compounds is the low yield (26%) of the hydroxylation at C-7 due to the absence of the *peri* OH-group, which facilitates a twofold bromination of this position.[171] There is no such limitation when more highly functionalized AB building blocks are used (see Section 4.3).



Scheme 50. R = H, OCH_3.

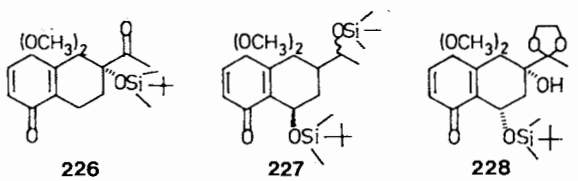
4.3. Formation of Ring C

The reactions proceeding with formation of ring B are very important because two equally large building blocks are coupled in a very convergent way, and ring D is introduced in the form of readily available benzene derivatives. Of four possible pathways, three ("a", "b", and "c") have been realized (see **217**).



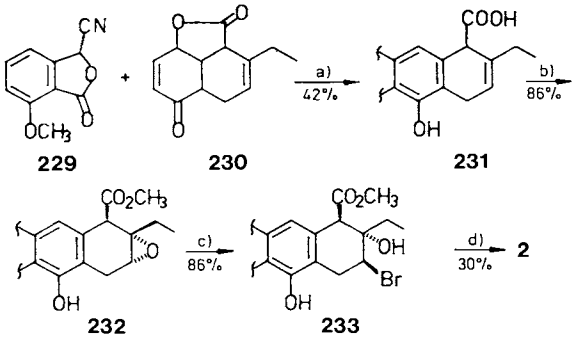
Disconnection "a" has been systematically investigated by *Kende* et al. for the synthesis of 11-deoxyanthracyclinones by coupling the lithiated benzamide **218** with the bicyclic aldehydes **221**,[100] *rac*-**222**[172] or **219**.[173] Especially elegant in the synthesis of aklavinone is the incorporation of the future ester group as hydroxymethyl group;[173] this enables the asymmetric epoxidation of the tetracyclic allyl alcohol by the method of *Sharpless*[48] (Scheme 51).

Scheme 51. a) *n*BuLi, tetramethylethylenediamine (TMEDA), four further steps. b) Sharpless epoxidation, Jones oxidation, esterification, five further steps.



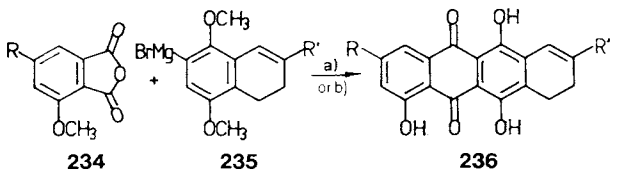
In a synthesis by *Vedejs* and *Nader*[174] the benzylic carbanion is not stabilized by a cyano group as in **207**, but by a silyl group. However, the replacement of the silyl group in **225** (X = SiR_3) by the cyano group (X = CN) is necessary in the nucleophilic cyclization step[176] via a kind of Hassall cyclization.[175] The adduct **225** (X = SiR_3) is accessible in a remarkably regioselective Diels-Alder reaction (11 : 1 in favor of the *meta* product) from the components **223** and **224**[176] (Scheme 52).

Scheme 52. a) 1) Toluene, 130 °C; 2) dichlorocyano-*p*-benzoquinone (DDQ), benzene, 50 °C. X = SiR_3 or CN.



The disconnection "b" in **217** has, as already mentioned, claimed fundamental importance in the synthesis of linearly annelated ring systems. In addition to the phenylsulfonylisobenzofurans developed by *Hauser*'s group,[162] the analogous cyanides such as **229** first synthesized by *Kraus*[163] are also used (for the synthesis of derivatized isobenzofuranones with cyano groups see [177]). The common principle of all these reactions is the Michael reaction of the phthalide anion derived from **229** with α,β-unsaturated systems such as **226**,[178] *rac*-**227**,[179] **228**[43] or *rac*-**230**, followed by spontaneous cyclization to tetracyclic anthracyclinone precursors.

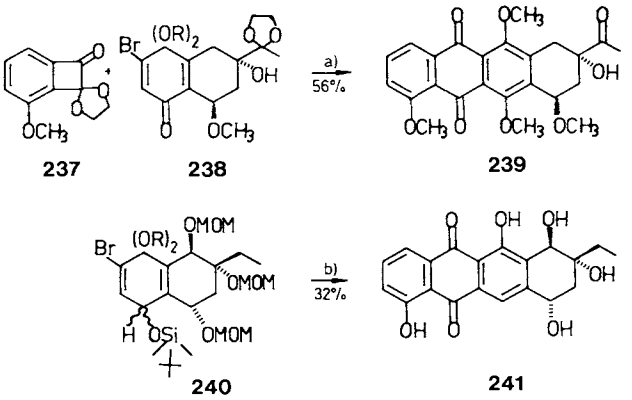
The quinone monoacetals are available from AB building blocks as mentioned in Section 2.2. The regioselectivity of the syntheses is determined by the efficient cleavage of the diacetals to the desired monoacetals. This cleavage in favor of the monoacetals was successfully performed in



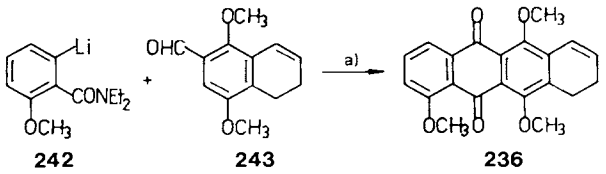
the ratios 87 : 13 and 9 : 2, respectively (cf. [180]) by *Swenton* et al.[43] and *Rodrigo* et al.[179] However, the cleavage is completely selective via the benzyl ethers **30** (R = OBn).[40,41,181]

The coupling of the phthalide **229** with the bicyclic Michael acceptor *rac*-**230** is the key step in the synthesis of aklavinone by *Li* et al.[182] For the hydroxylation in the tertiary position, the epoxide *rac*-**232** obtainable from *rac*-**231** is opened with hydrobromic acid and the bromine is removed reductively[182] (Scheme 53).

Scheme 53. a) 1) $LiNiPr_2$, THF/HMPT, + **230**, 20°C, 2 h; 2) O_2; 3) CH_2N_2. b) MCPBA. c) NaBr, TosOH, CH_3CN. d) Four steps.



Daunomycinones as well as rhodomycinones can be prepared by the procedure of *Braun*.[59] The key step is the regioselective addition of the Grignard compound **235** (R′ = H or CH_3) to the phthalic acid anhydride **234** (R = H or OCH_3), which is followed by Friedel Crafts cyclization to **236**. The olefinic derivatives without side chains (R = H or OCH_3, R′ = H) are transformed into daunomycinones, those with ethyl side chains (**236**, R = H, R′ = C_2H_3) into rhodomycinones[59] (Scheme 54).



Scheme 54. a) For R = R′ = H: 1) THF/TMEDA; 2) HF; 3) $AlCl_3$, epoxidation and ring opening. b) For R = H or OCH_3, R′ = C_2H_5: 1) THF/TMEDA; 2) HF, MCPBA; 3) $H^{\oplus}$; 4) see Schemes 30-32.

Swenton et al. also allowed metalated AB-building blocks derived from *rac*-**238** and *rac*-**240** to react with the monoacetal **237** and obtained the daunomycinone derivative *rac*-**239**[183] and β-citromycinone *rac*-**241**, respectively.[184] The difficult problem of hydroxylation at C-7 is neatly solved by use of the highly functionalized AB building block *rac*-**240** (see Section 2.2) (Scheme 55; for a synthesis of citromycinone via α-hydroxyaldehydes see [185]).

Furukawa et al.[186] obtained the olefinic daunomycinone precursor **236** (R = H) via route "c" in **217**. In this pathway the lithiated aromatic compounds **242** are allowed to react with the aldehydes **243** (Scheme 56). The lithiation to **242** is selectively directed by the neighboring benzamide group to the *ortho* position. This reaction has also been exploited by other authors for the synthesis of anthracyclinone precursors.[42,187]

Scheme 55. a) *n*BuLi, b) *t*BuLi. R = CH_3, MOM = CH_2OCH_3.

Scheme 56. a) THF, −78 °C, then 2 h at 20 °C.

5. Outlook

The present synthetic task is not terminated with the synthesis of the anthracyclinones: The aglycones must be coupled with sugars such as daunosamine or rhodosamine to afford the biologically active glycosidic anthracyclines. An efficient synthesis of new anthracyclines that contain several sugar residues still remains an enormous challenge. Larger amounts of synthetic enantiomerically pure aglycones are needed, which cannot be prepared by the derivatization of natural products. Not only are aglycones with "unnatural" substitution patterns (e.g. 4-deoxy compounds) being intensively investigated but also their heteroanalogues.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support and BASF, Bayer and Hoechst AG for gifts of chemicals. Special thanks are due to Dr. W. Priyono for help with the literature search.

Model Experiments on the Phytotoxicity of Halogenated Hydrocarbons

By *Gernot Grimmer* and *Werner Schmidt**

The proposals put forward thus far to explain the causes of the recent damage to forests are not totally satisfactory.[1] The forest damage that has occurred, to an increasing extent, during the last ten years in areas having clean air, especially at higher elevations with intense sunlight, has not been reproduced in the laboratory, either by exposure to SO_2 or by treatment with NO_x.[2] There is also considerable evidence that ozone is not a primary cause.[3] Besides microbes and insects, air-borne, anthropogenic photooxidants have been recently suggested as a source of the observed damage done to conifers, which is revealed by premature aging and loss of needles.[4]

Independently, *Frank*[5] and *Schenck*[6] recently suggested that halogenated hydrocarbons, upon exposure to light, might specifically damage the photosynthetic apparatus of conifers. In view of the large amounts of halogenated hydrocarbons produced annually (Table 1), their ubiquity, their persistence, and their good solubility in the cuticle layer of conifers, this hypothesis deserves closer scrutiny. *Frank* and *Frank*[5] were able to show, for example, that, upon treatment of a white pine with gaseous tri- and tetrachloroethylene and simultaneous irradiation with a high-pressure mercury lamp, the needles facing the light source turned yellow. In the extracts of such artificially aged needles, the amount of β-carotene and chlorophyll a had significantly decreased, as was the case for the extracts of "naturally" aged needles (HPLC). On the other hand, new products appeared, which were not found in the extracts of undamaged needles and which were not characterized further. They are possibly degradation products of these pigments. It is still unclear whether sunlight ($\lambda > 285$ nm) is able to activate halogenated hydrocarbons in vivo, since these compounds absorb at very short wavelengths ($\lambda_{max} \leq 230$ nm). We report here model experiments on β-carotene, which plays an important role as $^1O_2$ scavenger in all photosynthetically active organisms.[7]

Irradiation of a 1.6×10^{-5} M, air-saturated solution of β-carotene in cyclohexane with simulated sunlight[8] results in slow photodegradation (half-life $t_{1/2} \approx 540$ s) with loss of the conjugated double bond system (no absorption above 210 nm). This photodegradation is presumably the result of radical allyl oxidation with $^3O_2$ and ene reaction with $^1O_2$; it can be retarded by flushing the cuvettes with argon and degassing the solutions (four freeze-thaw cycles at 2×10^{-6} mbar) but not completely suppressed.[9]

Irradiation in the presence of a 150-fold molar excess of halogenated hydrocarbon, under the same conditions, leads, in the case of alkyl and aryl chlorides, to a significantly faster and, in the case of bromides and iodides, to a dramatically faster bleaching (Table 1). The chloroethylenes, which are important on account of the large amounts produced industrially and their good solubility, fall in the middle. This degradation can be inhibited neither by flushing with argon nor by degassing; even 1,4-diazabicyclo[2.2.2]octane, a good scavenger of $^1O_2$, has no significant effect. If the short-wavelength component of the light ($\lambda \leq 280$ nm) is eliminated by the use of normal glass instead of quartz cuvettes, then the bleaching is retarded ($t_{1/2} \approx 1600$ s) both in the absence and presence of a 150-fold excess of tetrachloroethylene. Moreover, selective irradiation in the long-wavelength absorption band ($\lambda_{max} = 454$ nm) of β-carotene in the absence and presence of tetrachloroethylene has no effect on the stability of the pigment.

Table 1. Half-lives, $t_{1/2}$, of the photodegradation [8] of β-carotene in cyclohexane (1.6×10^{-5} mol/L) in the presence of a 150-fold molar excess of halogenated hydrocarbons as well as the boiling points, long-wavelength absorption maxima in cyclohexane, distribution coefficients for olive oil/air [10], worldwide production [11], and tropospheric life-times, $\tau_{1/2}$ [12].

[a] Extrapolated on the basis of data for monochloro-, *o*-dichloro-, and *m*-dichlorobenzene. [b] Precursors in the production of polyvinyl chloride and its copolymers.

If the concentration of tetrachloroethylene is decreased, then the bleaching is retarded, but even for a molar ratio of tetrachloroethylene to β-carotene of 1 to 66, the bleaching takes place twice as fast as in the absence of tetrachloroethylene. These results are indicative of a radical chain reaction. The photochemical sensitivity of β-carotene toward anthropogenic halogenated hydrocarbons provides possible support for the validity of the Frank-Schenck hy-

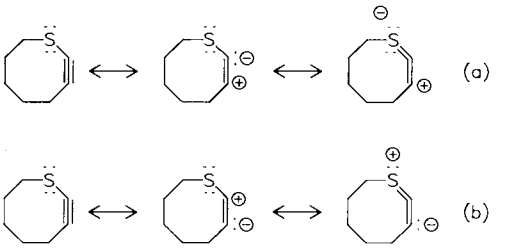
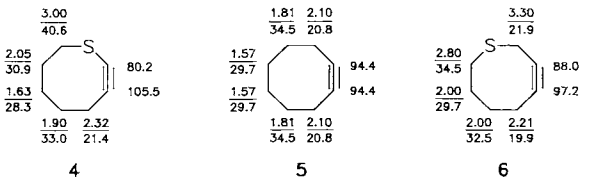
1-Thia-2-cyclooctyne—A Strained Cycloalkyne with Polarized Triple Bond**

By *Herbert Meier,* Evaggelia Stavridou,* and *Christiane Storek*



Dedicated to Professor Leopold Horner on the occasion of his 75th birthday

Very few representatives of strained heterocyclic alkynes have so far been reported in the literature.[1–3] We have now been able to synthesize the first molecule of this type, namely 1-thia-2-cyclooctyne **4**, whose triple bond is polarized by the heteroatom immediately adjacent to it. A preparative entry to **4** was accomplished by thermal fragmentation of the heterocycle **3**, which was obtained in good yields from the ketone **1**[4] via the semicarbazone **2**. Although the *E*-isomer dominates, the ring-closure reaction with selenous acid leads regioselectively to the 1,2,3-selenadiazole **3** (Scheme 1).

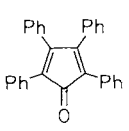


Scheme 1. Synthesis of **4**.

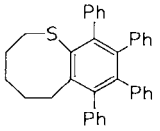
4, an oily liquid with a characteristic odor, is hardly less stable than cyclooctyne **5**. The crucial difference between **4** and **5** lies in the polarity of the triple bond. Aside from the −I effect of the sulfur atom, two mutual mesomeric effects are conceivable (Scheme 2).

Scheme 2. Possible mesomeric influence of the S atom in **4**.

The charge densities on the acetylenic C-atoms, which can be deduced from their ^{13}C-NMR shifts, confirm the above-mentioned mesomerism (a). The effect is strongly reversed in its direction to that in ynol ethers. The δ-values of C-2 and C-3 differ by ca. 25 ppm owing to the anisotropy and the polarization by the sulfur. The ^1H- and ^{13}C-NMR shifts of **4**, **5**, and the much more weakly polarized 1-thia-3-cyclooctyne **6**[5] compared to **4**, are given in Scheme 3.



Scheme 3. Comparison of the ^1H- and ^{13}C-NMR shifts of the compounds **4**, **5**, and **6**.



The polarity of the triple bond of **4** must confer remarkable chemical reactivity upon the molecule. Thus, on the one hand **4** undergoes reactions that are very common to other strained cycloalkynes, e.g. cycloaddition with tetracyclone **7** to give **8** (yield ca. 100% (80% for **3**→**8**), m.p. 234°C (decomp.)); on the other hand, however, it slowly adds water, even at room temperature. The regioselectivity

7

8

of the addition depends upon the pH (Scheme 4): In basic media C-3 is attacked nucleophilically, resulting in formation of **1**.[6] The direction of addition can be turned around by acid catalysis. However, the eight-membered ring thiolactone is not isolated, but the product of ring-opening, ethyl 7-mercaptoheptanoate **9**, in 40% yield. **9** reacts further in air to give the disulfide.[7]

Scheme 4. Addition of water to **4**.

The combined action of strain and polarization of the triple bond leads to **4** readily reacting both with electrophiles as well with nucleophiles. Thus, it not only differs significantly from other strained cycloalkynes, but also from open-chain alkynyl sulfanes containing a less reactive triple bond.[9]

[6] This behavior is reminiscent of that of the nonisolable 2-cyclooctyn-1-one: P. E. Eaton, C. E. Stubbs, *J. Am. Chem. Soc. 89* (1967) 5722.
[7] If one compares the reactivity of **4** and **5**, then, aside from reactions which are possible only with **4**, and reactions which proceed analogously to **4** and **5**, also reactions with **4** can be expected that lead to quite different products than with **5**. For example, upon twofold reaction with 4-phenyl-1,2,4-triazolindone (molar ratio 1:2), **5** undergoes a twofold ene reaction [8], while **4** undergoes a double cycloaddition.

CC Coupling of CO_2 and Butadiene on Iron(0) Complexes—A Novel Route to α,ω-Dicarboxylic Acids

By *Heinz Hoberg,* Klaus Jenni, Carl Krüger,* and *Eleonore Raabe*

Carbon dioxide is attracting increasing interest as a C_1 building block in preparative chemistry, particularly in synthetic methods involving its activation by transition metal complexes.[1] Stoichiometric (1 : 1) coupling reactions of CO_2 and systems containing multiple bonds have hitherto only been accomplished with Ni^0,[2a] W^0 and Mo^0 complexes.[2b] We have now also been able to induce such a CC coupling with Fe^0 complexes, whereby (η^4-butadiene)tris(trimethylphosphane)iron(0) **1**[3] has proven to be an especially suitable complex for this purpose.

Scheme 1. The (unsystematic) numbering in **2** and **6** serves only for assignment of the ^{1}H-NMR signals.

Treatment of a solution of **1** in tetrahydrofuran (THF) at 35°C with CO_2 (3 bar) leads to formation of the carboxylate complex **2** [diamagnetic, m.p. 110°C (decomp.)] in 75% yield.[4] Like most η^3-allyl-transition metal complexes **2** exhibits a dynamic behavior in solution, which manifests itself in the ^{1}H-NMR spectrum (25°C, [D$_6$]acetone) by very broad signals for the hydrogen atoms in the α-position to the carboxylate group. Whether this merely indicates a reorientation of the η^3-allyl moiety[5] or a dynamic equilibrium **2a** ⇌ **2** ⇌ **2b**, cannot be unequivocally decided from the available data. In contrast, at −80°C the compound is frozen-in in the η^3-allyl structure, and rotation of one of the three PMe_3 ligands is hindered. **2** also has the η^3-allyl

[*] Prof. Dr. H. Hoberg, Dipl.-Chem. K. Jenni, Prof. Dr. C. Krüger, [+] Dr. E. Raabe [+]

Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr 1 (FRG)
[+] Crystal structure analysis.

structure in the crystalline state, as has been confirmed by an X-ray structure analysis on a single crystal (Fig. 1).[6]

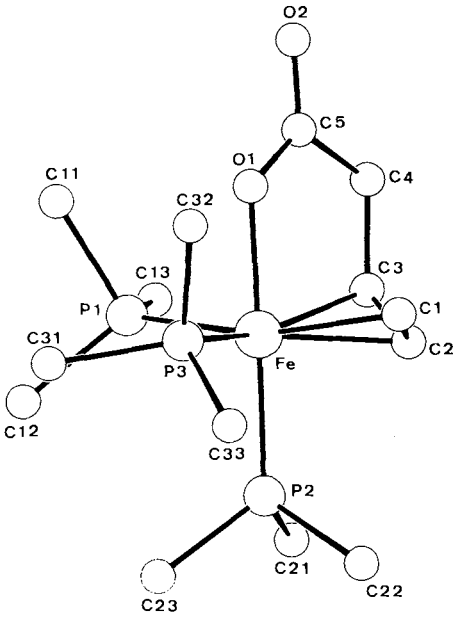

Fig. 1. Structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Fe-C1 2.124(2), Fe-C2 2.050(2), Fe-C3 2.152(2); Fe-O1-C5 121.3(1), O1-C5-C4 115.5(2), C5-C4-C3 114.0(2), C4-C3-C2 123.3(2), C3-C2-C1 124.4(2).

The coordination at the Fe-atom can be described as trigonal-pyramidal: the atoms P1 and P3 as well as the center of the allyl group C1-C2-C3 occupy equatorial positions, while the O1 and P2 atoms occupy axial positions. The Fe-C distances in the η^3-bonded allyl unit are as usually found in such units. The carboxylate group is coordinated monodentate to the Fe atom; consequently, the C-O bond lengths are markedly different: 1.274(3) (C5-O1) as compared to 1.235(3) Å (C5-O2). The coordination of the chain at both ends leads to a geometrically enforced disposition, which manifests itself in the magnitude of the bond angles. That the axial bond Fe-P2 with a length of 2.213(1) Å is noticeably shorter than the two equatorial Fe-P bonds (2.249(1) and 2.236(1) Å, respectively) can be explained in terms of a *trans*-effect of the O-atom of the carboxylate group.

The reaction behavior of **2** in solution can only be explained in terms of the η^1-allyl structures **2a** and **2b**: acid hydrolysis in methanol (−30°C) affords the methyl esters of the two carboxylic acids **3** and **4** in the molar ratio 10:1,[7] from which it follows that the reactivity of **2a** is greater than that of **2b**. Consistent with this finding, **2** also reacts with CO_2 (90°C, 5 bar) with preferential insertion in the Fe-C σ-bond of **2a** and not in that of **2b**: after hydrolysis, only 1,4- and no 1,2-dicarboxylic acids were isolated.[8] The *Z*-isomer expected from **2a** is obtained as main product. The *E*-isomer is presumably formed by isomerization of *Z*-**5** (molar ratio *Z*-**5**/*E*-**5** = 27:1).

Completely unexpected was the nature of the product obtained upon reaction of **2** and $FeCl_3$ (molar ratio **2**/$FeCl_3$ = 1:2) in THF: acid hydrolysis of the reaction mixture furnished the symmetrical, linear α-ω-dicarboxylic acid **6** containing two isolated double bonds in 93% yield.[9] The formation of **6** can be explained in terms of an intermolecular CC coupling of the allyl ligands of two molecules of **2**. Once again, only the Fe-C σ-bond of **2a** reacts and not that of **2b**, since the latter reaction would have to lead to branched α-ω-dicarboxylic acids.

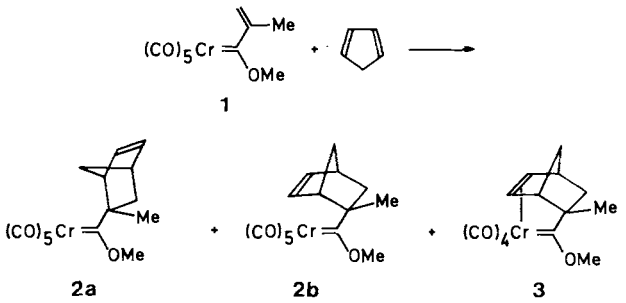
[6] Crystal structure analysis of **2**: space group $P2_1/n$, Z = 4, ρ_{calc} = 1.28 g cm^{-3}; $\mu(Mo_{K\alpha})$ = 9.94 cm^{-1}; a = 8.661(2), b = 15.248(3), c = 15.223(1) Å; β = 98.069(7)°. Solution of structure by the Patterson method. 4349 independent reflections with $I > 2\sigma(I)$, R = 0.033, R_w = 0.043. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51930, the names of the authors, and the full citation of the journal.

[7] Procedure for **3** and **4**: **2** (1.48 g, 3.88 mmol) was treated at −30°C with 5 mL of 6N methanolic HCl and the resulting solution, after 24 hours' stirring, was neutralized with $NaHCO_3$. The volatile components were then distilled off in a vacuum (2×10^{-4} bar). According to a GC analysis the distillate contained 314.0 mg (2.75 mmol; 70.8%) of the methyl ester of the acid **3** and 31.5 mg (0.28 mmol, 7.2%) of the methyl ester of the acid **4**. The products were unequivocally identified by combined GC-MS and comparison of the NMR spectral data with data given in the literature.

[8] Procedure for **5**: A solution of **2** (1.93 g, 5.05 mmol) in THF (80 mL) was treated at −78°C with 370 mL (15.2 mmol) of CO_2. The solution was transferred to a steel autoclave and stirred for 4 d at 90°C and 5 bar. The insoluble product was recovered by suction on a frit, dried, and worked-up as described for **3**, **4** in Ref. [7]. The quantitative GC analysis afforded the bis(methyl) esters of the acids *Z*-**5** (156.2 mg = 1.37 mmol; 27%) and *E*-**5** (1.37 mg = 0.05 mmol; 1%), which were identified as described in ref. [7] for **3**, **4**.



[9] Procedure for **6**: A solution of **2** (1.91 g, 5 mmol) in THF (150 mL) was treated at −78°C with 1.63 g (10 mmol) of $FeCl_3$ and the resulting mixture heated, with continuous stirring, to room temperature. After 24 h, the solvent was removed by distillation and the brown residue (3.36 g) remaining behind was hydrolyzed with ca. 5 mL of 2N H_2SO_4 in the presence of diethyl ether. The organic phase was dried over $MgSO_4$ and then purified by chromatography on silica gel 60 (toluene/diethyl ether 1:1). Yield of **6**: 461.3 mg (2.33 mmol; 93%). M.p. 52°C; correct elemental analysis; IR (KBr): ν = 1710 (C=O), 965 cm^{-1} (*E*-CH=CH); MS (CI, reactant gas NH_3): m/z 216 [$(M+NH_4^{\oplus})$, 100%]; ^{1}H-NMR ($CDCl_3$, 25°C, δ = 7.24, 200 MHz): δ = 8.62 (broad, 2H; H-1), 5.55 (m, 4H; H-3,4), 3.09 (dd, 4H, H-2), 2.12 (s, 4H; H-5).

Diels-Alder Reactions at Carbene Ligands: A Route to Olefin-Carbene Complexes**

By *Karl Heinz Dötz,* Werner Kuhn, Gerhard Müller, Brigitte Huber,* and *Helmut G. Alt*

Carbene complexes containing unsaturated carbene ligands have proved to be versatile synthetic building blocks.[2] In view of the isolobal relationship[3] between a pentacarbonylmetal fragment (M = Cr, Mo, W) and an oxygen atom, alkenyl(alkoxy)carbene complexes may be regarded as analogues of acrylic esters and thus as potential dienophiles in [4+2] cycloadditions.[1,4]

Pentacarbonyl[isopropenyl(methoxy)carbene]chromium **1** reacts with cyclopentadiene at room temperature to give the *endo/exo* cycloadduct **2a,b**. In the process, *the endo* compound **2b** already undergoes partial decarbonylation to form the olefin-carbene complex **3**.

The stereocontrol exerted by the $(CO)_5Cr$ fragment is revealed in the *endo/exo* ratio of (**2b** + **3**)/**2a** = 60/40. A similar ratio is observed for the isolobal methyl methacrylate in $AlCl_3$-catalyzed reactions;[5] however, the uncatalyzed reaction is known to satisfy poorly the Alder *endo* rule[6] and results therefore in a reversal of the product distribution.[7]

The olefin-carbene complex **3** belongs to a class of compounds that is important for the discussion of the mechanism of the olefin metathesis reaction.[8] To date only a few compounds containing other metals have been isolated;[9] **3** is the first example of a chromium compound. Complex **3** is preferentially formed in good yield by heating the mixture of isomers **2a,b** and can be separated from the unchanged *exo* isomer **2a** by column chromatography.

The structure of **3**[10] confirms the alkene coordination of the olefin-carbene ligand to the $Cr(CO)_4$ fragment, which is possible owing to the *endo* position of the carbene carbon atom C1 on the norbornene skeleton (Fig. 1). The alkene function is thereby bonded unsymmetrically to the metal; the Cr-C_{alkene} distances (2.286(3) and 2.366(3) Å[11]) are relatively long.[12] Both findings are a consequence of the rigidity of the norbornene skeleton and the short separation of the chromium-coordinated carbene and alkene functions by only two carbon atoms (C31, C36). The deviation from ideal octahedral symmetry at the central metal atom is due to the chelate structure. The Cr-C1 distance of 2.017(3) Å places **3** in the class of complexes with short Cr-$C_{carbene}$ bonds.[13]

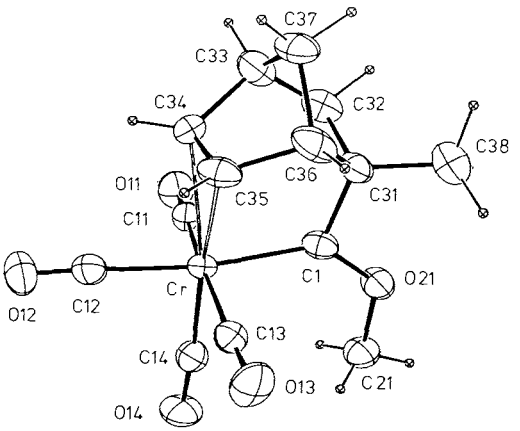


Fig. 1. Molecular structure of **3** in the crystal (ORTEP, thermal ellipsoids with 50% probability, H atoms with arbitrary radius). Selected bond distances [Å] and bond angles [°]: Cr-C1 2.017(3), Cr-C34 2.366(3), Cr-C35 2.286(3), Cr-C11 1.887(3), Cr-C12 1.902(3), Cr-C13 1.896(3), Cr-C14 1.842(3), C1-O21 1.312(4), C1-C31 1.523(4); C34-Cr-C1 86.1(1), C35-Cr-C1 79.2(1), C11-Cr-C1 91.4(1), C12-Cr-C1 168.8(1), C13-Cr-C1 85.4(1), C14-Cr-C1 102.8(1), Cr-C1-C31 118.0(2), Cr-C1-O21 134.0(2), C31-C1-O21 108.0(3).

Experimental Procedure

2a,b: A solution of **1** (0.68 g, 2.46 mmol) [14] in 10 mL of cyclopentadiene was allowed to warm slowly from −60 °C to room temperature. After 4.5 h, the solvent was removed and the residue was chromatographed at −30 °C on silica gel. The faster running orange-yellow band contained the mixture of isomers **2a,b** (0.57 g, 68%); the following fraction afforded **3** (0.13 g, 17%).—**2a,b**: IR (hexane): $\tilde{\nu}$(C=O) = 2061 m, 1983 w, 1960 s (sh), 1953 vs, 1938 s; MS: *m/z* 342 (M^+).—**2a**: ^{1}H-NMR (CD_3COCD_3): δ = 6.21 (m, 2H, =C*H*), 5.03 (s, 3H, OCH_3), 3.50 (m, 1H, C*H*), 2.82 (m, 3H, C*H*, CH_2), 1.42 (m, 2H, CH_2), 1.11 (s, 3H, CH_3); ^{13}C-NMR (CD_3COCD_3): δ = 371.7 ($C_{carbene}$), 224.2 (*trans*-CO), 217.6 (*cis*-CO), 140.9 (=CH), 135.1 (=CH), 73.1 (C_{quart}), 70.0 (OCH$_3$), 51.7 (CH), 50.3 (CH$_2$), 43.2 (CH), 42.4 (CH$_2$), 26.7 (CH$_3$).—**2b**: ^{1}H-NMR (CD_3COCD_3): δ = 6.02 (m, 2H, =C*H*), 4.96 (s, 3H, OCH_3), 2.97 (m, 4H, C*H*, CH_2), 1.44 (m, 2H, CH_2), 1.37 (s, 3H, CH_3); ^{13}C-NMR (CD_3COCD_3): δ = 373.5 ($C_{carbene}$), 224.3 (*trans*-CO), 217.3 (*cis*-CO), 137.2 (=CH), 136.8 (=CH), 74.3 (C_{quart}), 69.3 (OCH$_3$), 53.3 (CH), 47.2 (CH$_2$), 43.9 (CH), 43.2 (CH$_2$), 28.6 (CH$_3$).

3: A stream of N_2 was bubbled for 64 h through a solution of **2a,b** (0.48 g, 1.40 mmol) in 20 mL of *tert*-butyl methyl ether at 55 °C. After removal of the solvent, the residue was chromatographed at −30 °C with hexane on silica gel. Unchanged **2a** (0.22 g) was eluted initially, followed by a fraction that afforded orange-red crystals of **3** (0.21 g, 88%).—IR (hexane): $\tilde{\nu}$(C=O) = 2018 s, 1955 s, 1940 vs, 1905 s; MS: *m/z* 314 (M^+); ^{1}H-NMR (CD_3COCD_3): δ = 6.27 (m, 1H, =C*H*), 5.58 (m, 1H, =C*H*), 4.61 (s, 3H, OCH_3), 2.87 (m, 1H, C*H*), 2.55 (m, 2H, CH_2), 2.17 (m, 1H, C*H*), 1.41 (m, 2H, CH_2), 0.93 (s, 3H, CH_3); ^{13}C-NMR (CD_3COCD_3): δ = 363.6 ($C_{carbene}$), 238.0 and 226.9 (*trans*-CO), 226.2 and 224.4 (*cis*-CO), 102.4 (=CH), 95.2 (=CH), 69.5 (C_{quart}), 69.1 (OCH$_3$), 60.4 (CH$_2$), 53.6 (CH), 48.5 (CH$_2$), 42.2 (CH), 21.6 (CH$_3$).

Reductive Carbonylation of High-Valent Oxorhenium Complexes—a New Route to Low-Valent Carbonylrhenium Compounds**

By *Wolfgang A. Herrmann,* Ulrich Küsthardt, Adolf Schäfer,* and *Eberhardt Herdtweck*

The Re^{VII} complex trioxo(η^5-pentamethylcyclopentadienyl)rhenium **1** has proved to be a versatile, key compound in organorhenium chemistry, because its oxo ligands can be both functionalized and exchanged.[1] If complexes having rhenium in intermediate oxidation states are specifically accessible by redox processes, these complexes would be of interest with respect to olefin metathesis, the best catalysts of which are oxidic molybdenum, tungsten, and rhenium species.[2] With this goal in mind, we have investigated the stepwise reduction of **1** in the presence of ligands that are capable of stabilizing both higher and lower oxidation states of the metal.

$[(\eta^5\text{-}C_5Me_5)ReO_3]$ **1** $\quad$ $[(\eta^5\text{-}C_5Me_5)ReO_2]_2$ **2**

Suitable precursors are the metallacycles **3** and **5**, which may be obtained in smooth two-step reactions from **1** and, respectively, diphenylketene and phenyl isocyanate via the binuclear complex **2**.[3,4] The Re^V complex **3** can be reduced under CO (50 bar) at room temperature in tetrahydrofuran (THF), with cleavage of the terminal oxo ligand, to give quantitatively the chiral Re^{III} derivative **4**.

The air- and heat-stable compound **4** (m.p. = 171 °C), like its precursor **3**, contains a four-membered metallacycle (Fig. 1); the 1,1-ethenediolato ligand, which was *O,O*-

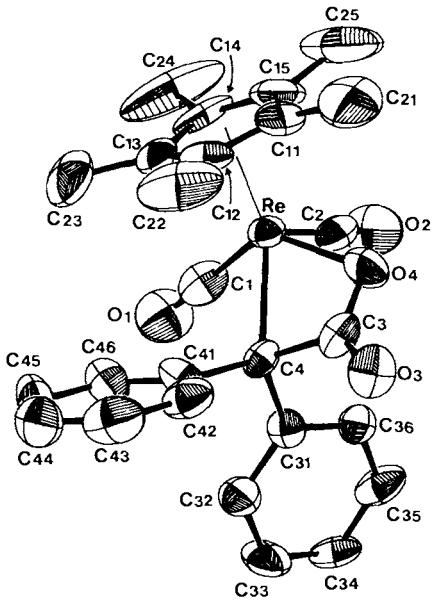

Fig. 1. Molecular structure of **4** in the crystal. Selected bond lengths [pm] and bond angles [°]: Re-C1 187.6(8), Re-C2 193.5(8), Re-C4 229.0(6), Re-O4 207.5(4), O4-C3 129.8(8), C3-C4 152.5(9), C3-O3 119.1(7), Re-C(11···15) 219–244; C4-Re-O4 62.4(2), Re-C4-C3 86.4(4), C4-C3-O4 106.6(6), Re-O4-C3 102.3(4), C1-Re-C4 80.9(3), C2-Re-O4 87.6(3), C1-Re-C2 79.4(3).—Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51877, the names of the authors, and the journal citation.

[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 29. This work was supported by the Bundesministerium für Forschung und Technologie, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Hoechst AG, and the Hermann Schlosser-Stiftung der Degussa AG (fellowship for *U. K.*). Part 28: [4].

bonded in **3**, is *C,O*-bonded in **4**.[5] At first sight, the isomerization that occurs upon reductive carbonylation of **3** is surprising, because the sterically demanding phenyl substituents are thereby placed in closer proximity to the metal center and to the terminal ligands; however, it may be understood by taking into consideration the greater electron density on Re^{III}. The metal in **4** is coordinated in a (very distorted) square-pyramidal fashion; the metallacycle (sum of angles 358°) is only slightly bent along the C4···O4 vector (164.6°). Upon reduction of **3** to **4**, the mirror plane is lost.[6]

Under CO pressure, the Re^{V} complex **5** is also reduced. In this case, too, the deoxygenation gives exclusively the Re^{III} derivative **6**, but without isomerization of the *N,O*-imidocarboxylato ligand. The carbonylation of **7** under pressure leads stereoselectively to the *trans* isomer of the compound **8**, which until now was only accessible in admixture with the *cis* isomer.[7]

$$\mathbf{1} + [(\eta^5\text{-}C_5H_5)_2Ti(CO)_2] \longrightarrow$$

9

$$[(\mu\text{-}O)\{(\eta^5\text{-}C_5Me_5)Re(CO)_2\}_2] + [(\eta^5\text{-}C_5Me_5)Re(CO)_3]$$

10 **11**

Besides carbon monoxide, carbonyltitanium reagents are also suitable for the deoxygenating carbonylation of Re^{V} and Re^{VII} complexes of the class of compounds discussed here. Thus, reaction of **1** with **9** affords mainly the Re^{II} derivative **10** (>80%) along with a small amount of **11**.

UV/VIS Laser Photochemistry: Intermediary Formation of Diazoalkanes versus Direct S_0,T_1 Transitions in the Photolysis of Azoalkanes**

By *Waldemar Adam,* Markus Dörr,* and *Peter Hössel*

Direct S_0,T_1 transitions[1] were reported some time ago to occur on irradiation of the azoalkanes **1**-**3**.[2] Thus, in the

1 **2** **3**

photolysis of **1**, besides traces of toluene and cycloheptatriene, norbornadiene **4** and quadricyclane **5** were observed as main products. The product composition was strongly dependent on the photolysis conditions (Table 1).

Table 1. Product composition obtained in the photolysis of azoalkane **1** to give norbornadiene **4**, quadricyclane **5**, 6-methylenebicyclo[3.1.0]hex-2-ene **6**, and toluene [a, b].

4 **5** **6**

No.	λ [nm]	Solvent	4	5	6	Toluene
1	350 [c]	pentane	53.4 (65)	37.7 (35)	7.8	1.1 (traces)
2	300 [c]	acetone	0.3 (5)	99.7 (95)	0.0	0.0
3	354 [d]	pentane	20.2	78.9	0.0	0.0
4	453 [e]	pentane	53.6 (10)	36.6 (90)	8.5	1.3
5	350 [c]	trifluoro-acetic acid	58.1	41.9	0.0	0.0

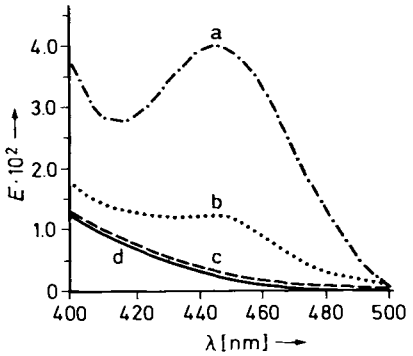
[a] The product composition was determined by means of capillary GC. GC conditions: OV 101, 50 m, column, injector, and detector temperatures of 150, 180, and 180°C, respectively, $p(N_2) = 0.5$ bar; products were calibrated against one another and were normalized to 100%. [b] Values in parentheses were taken from ref. [2]. [c] Irradiation in a Rayonet photoreactor; ca. 0.1 M pentane solutions were deaerated with nitrogen for 15 min; conversion ca. 100% for an irradiation time of ca. 30 min. [d] Laser photolysis at ca. 10 bar oxygen pressure; value in parentheses at ca. 100 bar. [e] Laser photolysis; average value of three runs (deviations ca. ±1.6%); conversion ca. 5% for an irradiation time of ca. 5 h.

Direct irradiation (singlet excitation) yielded mainly **4** (No. 1, values in parentheses), whereas acetone sensitization (triplet excitation) led almost exclusively to **5** (No. 2, values in parenthes). In view of the observation that in the direct photolysis with the 453-nm line of an argon ion laser the product composition corresponded to that of the triplet sensitization (No. 4, values in parentheses), the weak shoulder in the absorption spectrum of **1** (Fig. 1b) was assigned to the direct S_0,T_1 transition. However, our results (Tab. 1, Fig. 1) show that instead of the S_0,T_1 transition, the azoalkane **1** suffers photochemical cleavage to give the diazo compound **7**.

[*] Prof. Dr. W. Adam, Dipl.-Chem. M. Dörr, Dipl.-Chem. P. Hössel
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie (fellowships for *M. D.* and *P. H.*).

An aged pentane solution (exposed ca. 5 d to daylight) of **1** indeed exhibited a weak absorption at ca. 450 nm (Fig. 1b). However, this absorption completely disappeared, when freshly sublimed **1** (strict exclusion of light) was used (Fig. 1d). On the other hand, it could be augmented when the pentane solution of **1** was briefly (ca. 8 min) irradiated with the 354-nm line of the argon ion laser (Fig. 1a).



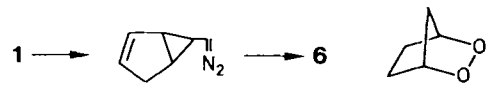


Fig. 1. Absorption spectra of the azoalkane **1** (all solutions ca. 0.1 M). a) **1** in pentane, after laser photolysis at $\lambda = 354$ nm for 8 min; b) **1** in pentane, after exposure to daylight for 5 d; c) **1** in trifluoroacetic acid, after exposure to daylight for 5 d; d) **1** in pentane, after sublimation under strict exclusion of light.

The IR spectrum exhibited a pronounced absorption at 2060 cm^{-1}, which is characteristic of diazo compounds. On addition of trifluoroacetic acid, the absorption at ca. 450 nm (Fig. 1c) disappeared. This absorption must be assigned to the diazo compound **7**, which was formed on direct photolysis of the azoalkane **1**.[3]

7 **8**

The photochemistry of **1** is also in agreement with this interpretation. Besides the already reported photoproducts (**4**, **5**, and toluene), a significant amount (ca. 8%) of 6-methylenebicyclo[3.1.0]hex-2-ene **6** was formed in the direct photolysis of **1** (Table 1, No. 1).[4] Analogous to other diazo compounds,[3] **7** extruded nitrogen under the photolysis conditions, leading to the bicyclic compound **6**, presumably via 1,2-hydrogen migration in the corresponding intermediary carbene.[5] Although an independent synthesis of **7** failed, it could be shown that the accumulated **7** led to increased amounts of **6** on subsequent photolysis (confirmed by capillary GC). Control experiments revealed that addition of trifluoroacetic acid led to formation of toluene via acid-catalyzed rearrangement of **6**. The direct photolysis of **1** in the presence of trifluoroacetic acid (No. 5) afforded only norbornadiene **4** and quadricyclane **5**. Apparently the diazo compound **7** was trapped, so that the formation of **6** and toluene was suppressed. That **7** was indeed produced by singlet excitation was supported by means of a triplet-sensitization experiment (No. 2). Besides traces of **4**, only **5** was produced.

The product composition obtained by laser photolysis at 453 nm (No. 4) proved that the 450-nm absorption must be ascribed to the diazo compound **7**. Within the limits of experimental error, the product composition was identical to that produced by direct photolysis at 350 nm (No. 1). In this context, the laser photolysis at 354 nm under oxygen pressure must be mentioned (No. 3). The product composition was unquestionably shifted toward that produced by triplet-sensitized photolysis (No. 2). Triplet oxygen catalyzes the $S_1 \rightarrow T_1$ spin inversion in the azoalkane **1**.[1]

Similarly, the reported experimental evidence[2] for direct S_0,T_1 transitions in the visible region (400–500 nm) of the azoalkanes **2** and **3** could not be confirmed. The laser photolysis of azoalkane **2** at 453 nm led to a product composition corresponding to that expected for singlet excitation. Mainly $(CH)_6$ products were formed and not 1,2-diazacyclooctatetraene, the product of the triplet sensitization. In the case of azoalkane **3**, the benzophenone-sensitized laser photolysis at 364 nm under oxygen pressure gave exclusively the endoperoxide **8**.[6] However, the laser photolysis of **3** at 453 nm under oxygen pressure (12 bar) did not afford even traces of **8**. Only bicyclo[2.1.0]pentane was detected. The absorption spectrum of an aged sample of **3** in pentane (0.75 M) exhibited a weak band at 410 nm. The long-wavelength spectrum ($\lambda > 400$ nm) of **3** in trifluoroacetic acid or of freshly sublimed **3** in pentane showed only the tail of the main absorption maximum at 349 nm.

On the basis of these results, we conclude that the weak absorption of aliphatic azo compounds in the visible region ($\lambda > 400$ nm) derives from impurities rather than direct S_0,T_1 transitions. In the case of azoalkane **1**, the impurity is the diazo compound **7**, produced via photochemical cycloreversion on n,π*-singlet excitation.[3] Experimental proof for direct S_0,T_1 transitions in azoalkanes is therefore still lacking.[1]

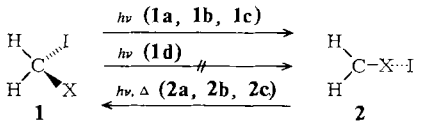
Photoisomerization of Dihalomethanes**

By *Günther Maier** and *Hans Peter Reisenauer*

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

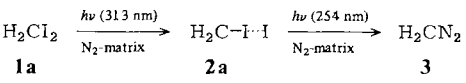


The first—flash photolytic—evidence of triplet[1a,b,d] and singlet methylene[1b,c] is to be found in the pioneering work

[*] Prof. Dr. G. Maier, Dr. H. P. Reisenauer
Institut für Organische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Giessen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of *Herzberg*. Furthermore, triplet methylene has been isolated in a nobel-gas matrix and characterized by ESR[2] and IR spectroscopy.[3] No information is available, however, on the isolation of singlet methylene. This is not surprising, since the singlet molecule is 9.05 kcal/mol higher in energy than the triplet ground-state molecule.[4b]



Is the failure to isolate $^1CH_2$ in matrix experiments perhaps due to the wrong choice of the precursor (diazomethane, diazirine)? In order to shed light on this matter, we have irradiated diiodomethane[5] in an argon or nitrogen matrix and observed a surprising result: when **1a** is irradiated in a matrix, a violet color is observed. However, this is only apparently an indication for the splitting off of iodine. We have now found that, upon irradiation, the dihalomethanes **1a**, **1b**, and **1c** undergo isomerization to form compounds of type **2**.

a, X = I; **b**, X = Br; **c**, X = Cl; **d**, X = F

Irradiation[6] of diiodomethane **1a** in argon at 12 K with 313-nm light leads within 1 to 3 min to a photoequilibrium between **1a** and a new species (ratio 70:30). This species exhibits a characteristic IR (see Table 1) and UV spectrum [$\lambda_{max}(\varepsilon)=370$ (≈ 10000), 545 nm (≈ 1300); see Fig. 2]. Upon irradiation with monochromatic light (366 or 545 nm), the matrix rapidly (< 1 min) loses its color, and both IR and UV spectroscopy reveal considerable—if not quantitative—re-formation of **1a**. This indicates that the compound formed upon irradiation of **1a** with light of wavelength 313 nm must be an isomer, which, on the basis of its spectra, can be assigned the structure **2a**.

If the irradiation of **1a** in a nitrogen matrix with wavelengths of 313 or 290 nm is not terminated after photoequilibrium has been attained, or if a low-pressure mercury lamp (254 nm) is used, then the new isomer **2a** reacts further photochemically. According to the IR spectra, diazomethane **3** is the main product (trapping of nitrogen by methylene[7]), along with the iodomethyl radical,[8] ethylene, and acetylene.

The photochemical interconversion **1a** $\rightleftharpoons$ **2a** can also be carried out in a polyethylene film, with the same results. In this way, it is possible to obtain a rough idea of the thermal stability of **2a**. Irradiation of the entrapped diiodomethane **1a** (313 nm, 13 K) leads once again to **2a** (IR: $\tilde{\nu}=3130.9$, 3005.8, 618.8 cm^{-1}; UV: $\lambda_{max}=560$, 385 nm). These absorptions vanish upon warming the film to about 100 K. In the process, partial re-formation of **1a** occurs, as revealed in the spectra.

The phenomena found for **1a** are also found for **1b** and **1c**. However, the isomerization of **1b** and **1c** to form **2b** and **2c**, respectively, upon irradiation of the matrix (313 nm), is slower. The photoequilibrium (ratio similar to **1a** : **2a**) is only attained after 40 min for **1b** and after 3 h for **1c**. The backward reaction can once again be induced by irradiation with light having the same wavelength as one of the UV maxima (see Fig. 2). The tendency to undergo a photochemical secondary reaction decreases in the series **1a**, **1b**, **1c**. In the case of **1b**, the IR bands of diazomethane **3** can be just barely perceived upon prolonged irradiation (5 h, 254 nm) in a nitrogen matrix. In the case of **1c**, trapping of nitrogen can no longer be observed. The thermal stability decreases markedly on going from **2a** to **2c**. The backward reaction **2c** → **1c** occurs already upon warming to 26–30 K. Finally, in accord with expectations based on the above results, fluoroiodomethane **1d**—despite its seemingly favorable absorption maximum at 255 nm ($\varepsilon=300$)—does not even afford traces of the photoisomer **2d** upon irradiation in a matrix at 12 K.

Only the IR spectra can be used to establish the structures of the new isomers. The bands of the educts **1** and the products **2** can be deduced by examining the difference spectra obtained from the irradiated and nonirradiated samples (forward reaction, Fig. 1) and from the

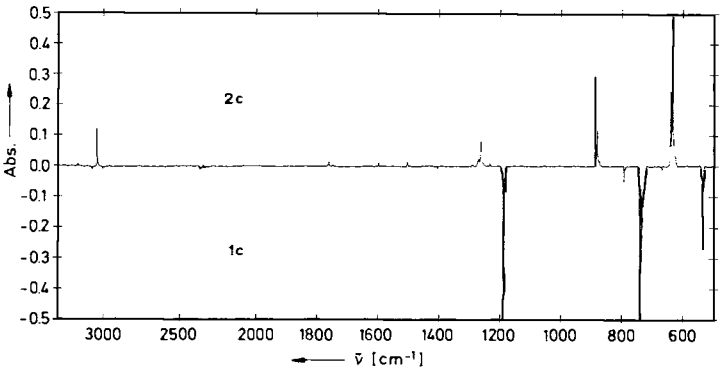


Fig. 1. Difference IR spectra (irradiated minus nonirradiated probe; Ar matrix, 12 K) of **2c** (upper) and **1c** (lower).

short-wavelength (313 nm) and long-wavelength irradiated samples (backward reaction). The spectra so obtained of the isomers **2** (Table 1) have the same appearance. Aside from the fact that the isomers must be more strongly polar than the educts (the bands of **2a–2c** are more intense), the following features are apparent: (1) A symmetric and an antisymmetric CH stretching vibration are observed for all species; these bands exhibit the expected shifts upon deuteration. A CH_2 group must therefore be present. (2) The most intense band is found for **2a**, **2b**, and **2c** at 610–640 cm^{-1}. The splitting is a result of matrix effects (annealing of the matrix changes the intensities within a group of bands). Upon deuteration, a strong shift is once again observed. Accordingly, this band may be assigned to a CH deformation vibration. The high intensity (in comparison with other examples) indicates a wagging vibration. (3) The question whether the methylene group also bears a halogen atom X can be answered by examination of the IR spectrum of **2c**. It shows a relatively intense double band at 886.2 and 879.4 cm^{-1} with the correct intensity ($^{35}Cl:^{37}Cl=3:1$) and frequency ratio, which only undergoes a small shift upon deuteration of the compound. These bands must therefore arise from the CCl stretching vibration.[9] (4) A band that could be assigned to an XI stretching vibration was not observed.

A normal coordinate analysis[10] for the pentaatomic molecule $H_2C{-}X\cdots I$ **2** and the pure cations $^{\oplus}CH_2{-}X$ with plausible geometries (C_{2v}, linear arrangement $C{-}X\cdots I$, shorter CX, longer XI separation), carried out on the basis of Table 1, affords good agreement between calculated

Table 1. IR spectra [Ar matrices, 12 K, [cm^{-1}] (E, rel. int.)] of the isomers **2a**, [D_2]**2a**, **2b**, **2c**, and [D_2]**2c**.

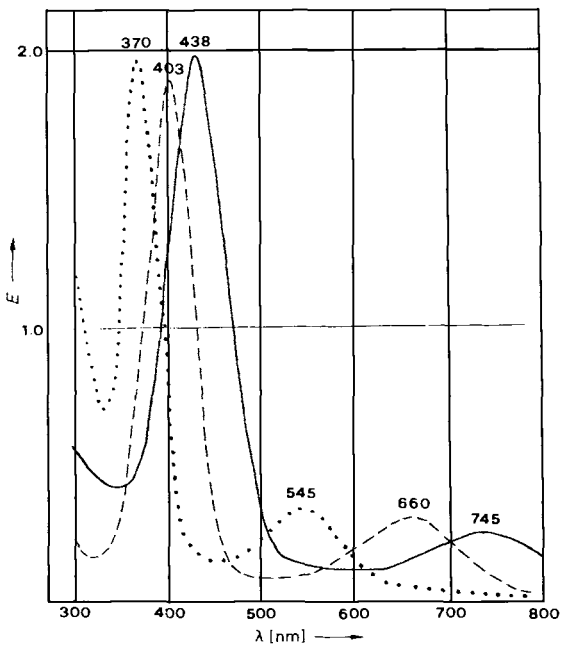
and experimental spectra. Furthermore, a relatively large force constant (4.48 for the pentaatomic model, or 4.66 for the tetraatomic model) is found for the CCl bond in **2c**. This gives a bond order of about 1.2 according to the procedure of *Siebert*.[11] Correspondingly, a value of 1.4 is found for the CI bond in **2a**.

The UV/VIS spectra of **2a–2c** are also similar.[12] Characteristic is the systematic bathochromatic shift of both absorptions. The long-wavelength maxima (possibly charge-transfer transitions of the "iodide ion" to the "carbenium ion") are responsible for the intense color of the isomers **2** and also for the fact that the backward reaction already takes place upon exposure to daylight.



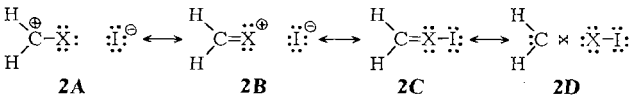


Fig. 2. UV spectra (N_2 matrices, 12 K) of the isomers **2a** [(——), 0.5 min irradiation, violet matrix], **2b** [(– – –), 10 min irradiation, green matrix], and **2c** [(· · · ·), 25 min, yellow matrix].

In summary, the photoexcitation of the dihalomethanes **1a–1c** leads to the isomers **2a–2c** (the weaker Cl bond is preferentially broken), which are best described as the contact ion pairs **2A** ↔ **2B**. Hypervalent resonances structures

such as **2C**[13,14] probably contribute less to the actual structure. It is evident, however, that the iodine must always exhibit, to a certain extent, bonding interactions with the heteroatom X. The resonance structure **2D**, corresponding to a carbene–halogen complex, is presumably even less important. A compound of this kind (having other bond lengths), however, may play a role in the transformation of **2a** into diazomethane **3**.

[7] The reaction of $^3CH_2$ with nitrogen upon irradiation of diazomethane **3** in a N_2 matrix was first suggested by *Pimentel* et al. [3b] on the basis of labeling experiments. The formation of **3** from **1a** via **2a** confirms the required type of reaction. This also explains why **3** and diazirine (which is converted into **3** before undergoing elimination of N_2 upon irradiation in a matrix) are very poor precursors for methylene in matrix isolation experiments. Under these conditions, **3** is apparently "photostable" for a long period of time because the N_2 formed is immediately trapped again by CH_2.

A Novel Electron Count and Metal–Metal Multiple Bonding in Trigonal Prismatic Clusters**

By *Ralph A. Wheeler* and *Roald Hoffmann**

Kryuchkov, Kuzina and *Spitsyn* recently synthesized two trigonal prismatic clusters, $[Tc_6Cl_{12}]^{2\ominus}$ **1** and $[Tc_6Cl_{14}]^{3\ominus}$ **2**, whose structures were determined by *Koz'min, Surazhskaya* and *Larina*. Both clusters have novel electron counts and unusually short metal–metal bonds.[1] **1** has 68 cluster electrons[2] (32 metal electrons), with Tc–Tc distances of 2.21 Å along the prism axis and 2.57 Å along triangular faces. **2** has two weakly μ_3-bound axial capping chloride ligands; if these are removed, $[Tc_6Cl_{12}]^{\ominus}$, with one electron less, is obtained. Relative to **1**, the short Tc–Tc distance in **2** is still shorter, and the longer one, in the triangles, still longer.

$[Tc_6Cl_{12}]^{2\ominus}$ $[Tc_6Cl_{14}]^{3\ominus}$

[**] This work was supported by the Cornell University Materials Science Center through grant number DMR 821722 from the National Science Foundation.

These clusters stand at the intersection of two strong currents of modern inorganic chemistry—metal–metal multiple bonding and cluster electron counting rules. The short prism dimensions indicate metal–metal multiple bonding,[3] and the cluster electron count is unique—compare, for example, octahedral $[Mo_6Cl_8]^{4\oplus}([Mo_6Cl_{14}]^{2\ominus}$, 24 cluster bonding electrons), $[Ta_6Cl_{12}]^{2\oplus}([Ta_6Cl_{18}]^{4\ominus}$, 16e), $[Zr_6I_{14}C]$(14e), $[Os_6(CO)_{18}]^{2\ominus}$(14e); and trigonal prismatic $[Rh_6C(CO)_{15}]^{2\ominus}$(18e).[4]

The Tc clusters thus have more electrons involved in metal–metal bonding than any other six-vertex clusters known. A detailed account of the bonding will be given elsewhere.[5] Here we focus on the metal–metal bonding, which is conveniently described by noting in the cluster the three Tc_2 units, each with well-defined σ, π, δ, δ*, π*, and σ* orbitals. Figure 1a shows the filled levels of **1**, labeled to indicate their bonding character within Tc_2 dimers.

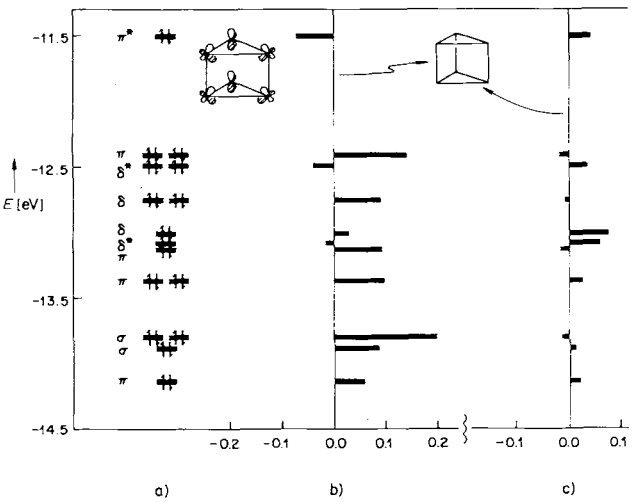

Fig. 1. a) Energy levels of the $[Tc_6Cl_{12}]^{2\ominus}$ cluster **1**. b) Orbital contributions to Tc–Tc overlap population within Tc–Tc dimers and (c) between them.

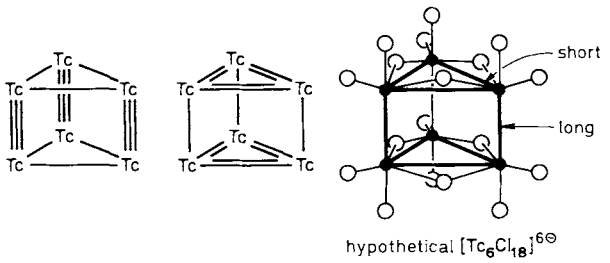

The lower 15 levels are three sets of σ, π_{xz}, π_{yz}, δ, and δ* orbitals. The HOMO of **1** (schematically drawn at the top of Figure 1a) has π* character within the Tc_2 units and π-bonding character between them. This description is consistent with electron-rich triple bonding ($\sigma^2\pi^4\delta^2\delta^{*2}$) within each Tc_2 unit, with two additional electrons in a π* orbital. Bonding between Tc_2 units is primarily through the HOMO of the cluster (π bonding between dimers) and localized δ and δ* orbitals (σ bonding between Tc_2 units).

The details of the bonding are neatly explored through examination of Figures 1b and 1c. The horizontal bars represent the contributions to the Tc–Tc overlap population of the corresponding levels in Figure 1a. Bonding within dimers (Fig. 1b) is much stronger than bonding between them (Fig. 1c). More levels are bonding in Figure 1b than in Figure 1c and their contributions to the overlap population are larger.

The observed bond-length changes on going from **1** to **2** (one-electron oxidation) are consistent with the composition of the HOMO. Figures 1b and 1c also show that the HOMO of $[Tc_6Cl_{12}]^{2\ominus}$ is net Tc–Tc antibonding, since its π* nature within Tc_2 units wins out over its bonding character between them.

In reply to the question, how many metal–metal bonding electrons are there in this cluster?, we would answer 30. As the syntheses of **1** and **2** show (and the calculations sup-

port), 32 and 31 electrons, respectively, are also satisfactory. We expect that 30-electron compounds in this system will also be synthesized.

3 **4** **5**

The 30 bonding electrons are in orbitals consistent with the localized description **3**. But since we know structures of the $[Re_3Cl_{12}]^{3\ominus}$ type,[3] an alternative trigonal prismatic valence structure of type **4** is possible, which is realizable perhaps as $[Tc_6Cl_{18}]^{6\ominus}$ **5**.

The interconversion of **3** and **4** is strongly (symmetry) forbidden. Will we ever see isomeric structures such as these?

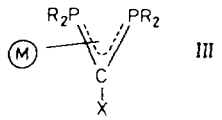
$[La\{(Ph_2P)_2CH\}_3]$— a Homoleptic Lanthanum Complex with π-Allyl-like Coordinated Diphosphinomethanide Ligands**



By *Hans H. Karsch,* Armin Appelt,* and *Gerhard Müller**

Investigations of the chemistry of carbon and of σ-bonded phosphorus have revealed an increasing number of parallels in unsaturated systems.[1] Also, for saturated systems, such parallels have been shown to be a valuable guide for structural comparison of molecules containing C–C and P–P bonds.[2] The reactivities of the two elements in molecules containing P–C bonds are expected to be similar when the two elements are isoelectronic, as, for example, in phosphinomethanides **I**. Indeed, in recent years a large number of ambident phosphinomethanides have been found in which carbon and phosphorus compete for electrophiles. Fine tuning of such systems may be effectively achieved by variation of the electrophile as well as of the number and kind of substituents on the carbanion.[3,4]

I **II**

With metals as electrophiles, coordination can occur in a variety of ways, including intermolecular interactions with formation of multinuclear complexes.[3,4] For di- and triphosphinomethanides **II** (X = H, $SiMe_3$, PMe_2), in particular, numerous coordination modes may be envisaged.[3,4] Already in the initial investigations,[5] the main question was whether diphosphinomethanides **II** (X = H) form π-type complexes **III** with fragments Ⓜ and thereby function as heteroallyl analogues. However, this type of coordination has not yet been unambiguously established. In comparing **II** with allyl ligands, it is important to realize that **II** (X = H) is a potential six-electron rather than a four-electron donor. A coordination of type **III** is opposed by the usually strong tendency of diphosphinomethanides to form M–P σ bonds in mononuclear complexes by coordinating both phosphorus atoms. Since lanthanoids and actinoids rarely form phosphane complexes,[6] a coordination of type **III** should be favored with these metals.

III

Indeed, by reaction of the potassium salt **1**[7] with $LaCl_3$, we have been able to prepare the lanthanum complex **2**[8] and to isolate it in pure form. Complex **2** is the first complex with π allyl-like η^3-coordinated diphosphinomethanide ligands.

$$LaCl_3 + 3\,K[(PPh_2)_2CH] \xrightarrow{THF} [La\{(PPh_2)_2CH\}_3]$$

1 **2**

The X-ray structure analysis of **2** · toluene[9] (Fig. 1) reveals that the La atom is trigonally planar coordinated by the diphosphinomethanide ligands. The midpoints of the PCP planes and the La atom lie in a plane (sum of angles at La: 360°, Fig. 1b). The distances between the central La atom and the coordinating atoms vary between 2.790(4) and 3.035(1) Å, the bonds to the C atoms being slightly *shorter* than those to the P atoms.[10] As a consequence of these nearly identical distances, the lines connecting the midpoints of the ligands with the La atom are not exactly perpendicular to the respective PCP planes, but form angles with their normals of 16.9, 6.5, and 17.0°. Of the possible conformations, which differ in the relative orientation of the ligands, **2** · toluene has that in which the ligands are arranged spokelike around the central atom.

The orientations of the phenyl substituents indicate that the lone pairs of electrons on the phosphorus atoms do not point optimally in the direction of the La atom. As is evident from Figure 1b, however, further rotation about the HC–P bonds, which would be required for a better posi-

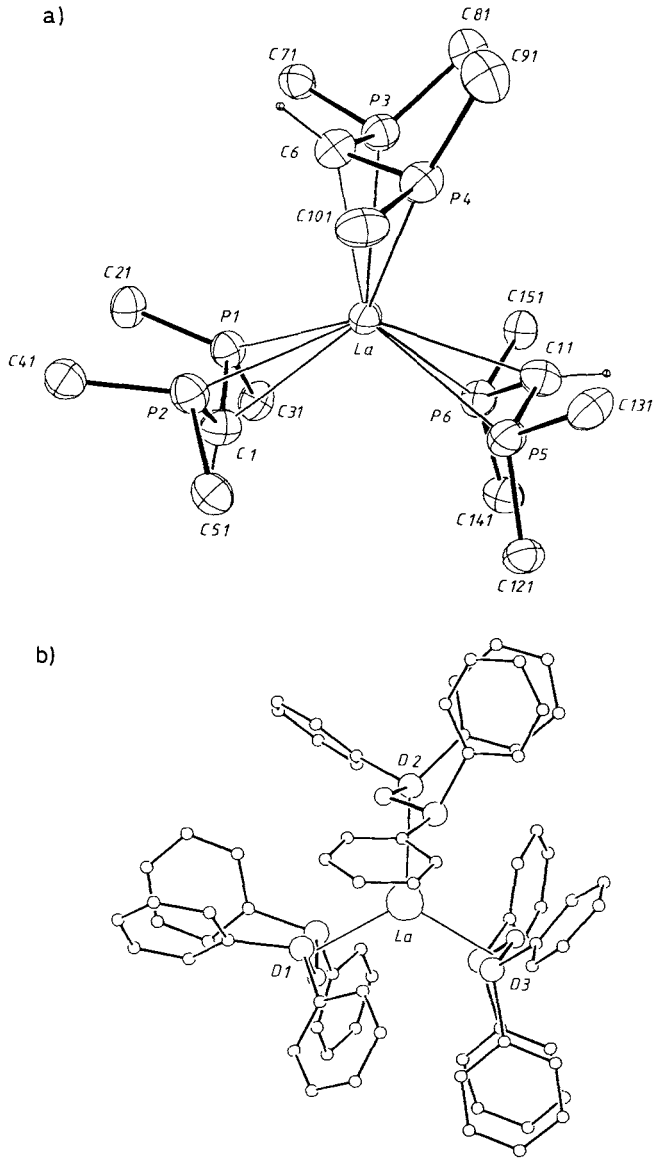

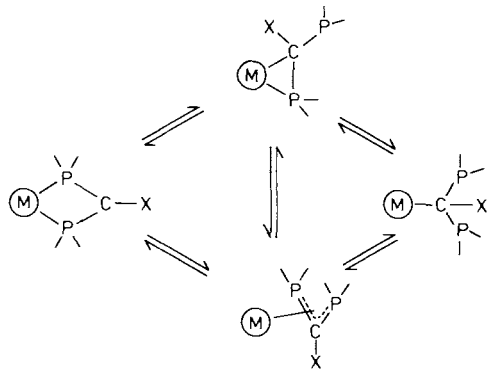

Fig. 1. a) Molecular structure of **2** (ORTEP), thermal ellipsoids at the 50% probability level, H atoms with arbitrary radii, only the *ipso*-C atoms of the phenyl rings are shown. Selected bond lengths [Å] and angles [°]: La-P1 2.955(1), La-P2 2.999(1), La-P3 2.965(1), La-P4 3.035(1), La-P5 2.940(1), La-P6 3.013(1), La-C1 2.890(5), La-C6 2.790(4), La-C11 2.908(5), C1-P1 1.771(5), C1-P2 1.768(5), C6-P3 1.778(5), C6-P4 1.764(5), C11-P5 1.769(5), C11-P6 1.780(5); P1-C1-P2 115.9(3), P3-C6-P4 111.2(3), P5-C11-P6 113.9(3). b) Conformation of the phenyl rings in **2** (ORTEP, atoms with arbitrary radii). D1, D2, and D3 are the midpoints of the PCP planes. The phenyl rings differ in their relative orientations with respect to the PCP planes ("axial", "equatorial"), the equatorial *ipso*-C atoms being 0.02–0.39 Å and the axial atoms 1.42–1.71 Å away from these planes. The respective C-P-C(phenyl) and La-P-C(phenyl) angles are significantly different. The La-arene distances are longer than 3.85 Å.

tioning of the electron pairs, would result in an increasingly close approach of the "axial" phenyl substituents.

The structure of **2** is in agreement with a more ionic character of the bonding, as is the case for organolanthanoid and -actinoid complexes.[11] The ^{31}P-NMR spectrum in benzene provides further support of this interpretation: the chemical shifts of the P atoms of the diphosphinomethanide in **1**[7] and **2** are nearly identical.

The coordination mode **III** found in **2** fills a gap in the coordination behavior of di- and triphosphinomethanides, which is important for a better understanding of the frequently observed fluxional behavior of these ligands in complexes with main-group and transition metals[3b,c,4a,b] (see Scheme 1).

$[Sb_3I_{10}^{\ominus}]_\infty$ — A Polymeric Anion with Transitions from Trigonal Pyramidal to Octahedral Coordination of Antimony(III)**

By *Siegfried Pohl,* Wolfgang Saak, Peter Mayer,* and *Alfred Schmidpeter**

The neutral and anionic halogen compounds of trivalent P, As and Sb include examples of three-, four-, five-, and sixfold coordination of the central atom, with the influence of the lone pair of electrons on the stereochemistry decreasing with increasing coordination number. The transitions between these coordination geometries are each characterized by a short bond and a long bond *trans* to each other.[1] In the anion $Sb_3I_{10}^{\ominus}$ these transitions can be observed within one and the same structure, since three forms of coordination of Sb[1] are present.

When a solution of tris(dimethylamino)cyclopropenylium iodide[2] and antimony triiodide (molar ratio 1:3) in acetonitrile was slowly evaporated to dryness, the complex $[C_3(NMe_2)_3]^{\oplus}Sb_3I_{10}^{\ominus}$ **1** crystallized (red prismatic crystals).[3] The compound was characterized by an X-ray structure analysis.[4] It contains a stoichiometrically and structurally novel anion.

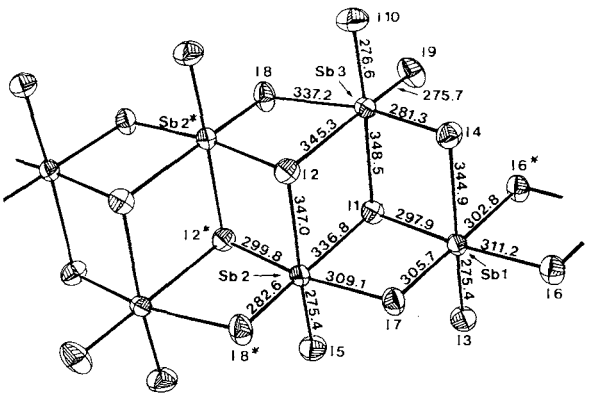

Fig. 1. Section from the structure of the polymeric anion $Sb_3I_{10}^{\ominus}$ in crystals of **1** (bond lengths in pm, vibration ellipsoids correspond to 50% probability).

The 18 independent Sb–I contacts (Fig. 1) lie in three clearly defined ranges: 275–282 (I), 298–311 (II) and 337–349 pm (III). If they are all considered as bond forming, then a distorted octahedral coordination results for all Sb atoms. The octahedra are linked edge-to-edge to give a polyanion whose structure can be regarded as a band-shaped section of the CdI_2 structure. However, adjacent bands are not bound together to form a layer structure analogous to CdI_2. The anionic bands and the planar cations are stacked alternately along the *b* axis.

The structure of the polymeric anion can plausibly develop if one consideres I6 (Fig. 1) as the original iodide, which now binds two SbI_3 molecules, and these in turn

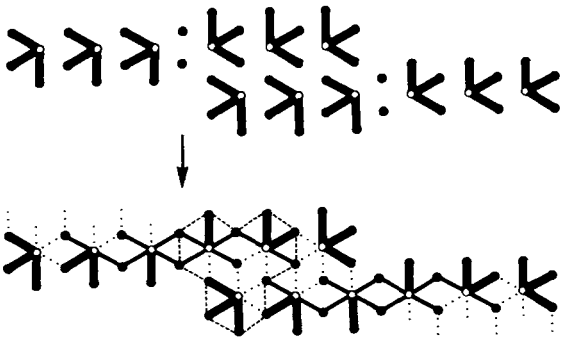

Fig. 2. Formation of four formula units of $Sb_3I_{10}^{\ominus}$ from I[⊖] and SbI_3; the distances in the ranges I, II and III are shown as thick lines, thin lines, and dotted lines, respectively (see text); the section corresponding to the 18 distances in Figure 1 is shown.

bind further SbI_3 molecules with decreasing strength (Fig. 2). If the bonding interactions are limited to Sb–I contacts in the ranges I and II, the reactivity of the lone pair will become manifest for each Sb atom: Sb1 is coordinated ψ-octahedrally, Sb2 almost ψ-trigonal pyramidally, and Sb3 ψ-tetrahedrally.

The larger the one of two *trans* contacts is, the smaller is the other (Fig. 1). This has indeed already been observed in the case of SbI_3[5] and the tetrameric tellurium(IV) halides[6] (further examples are given in refs. [1] and [7]), but the differences in these contacts in **1** vary remarkably, the consequence (or cause) of which is a divergence in the magnitude of the stereochemical effect of the non-bonding electron pairs at the three independent Sb atoms.

Oxygen Evolution by Water Oxidation Mediated by Heterogeneous Manganese Complexes

By *Ramasamy Ramaraj, Akira Kira,* and *Masao Kaneko**

Water oxidation is an important research topic, not only in connection with photosynthesis but also with regard to

The Institute of Physical and Chemical Research
Wako, Saitama 351-01 (Japan)

the conversion of solar energy into chemically stored energy.[1-5] Manganese ions play an important role as oxidation centers in photosynthesis.[1,6-8] Although a number of manganese complexes have been proposed as model complexes for water oxidation, the evolution of oxygen has hitherto never been observed.[9-12] *Calvin* reported that the di-μ-oxo-bridged binuclear complex **1** was able to decompose water photolytically,[9] but the initial claims of his success with photolytic dioxygen evolution soon had to be withdrawn.[13] *Renger* has proposed a model for the water-splitting complex that is in better agreement with the reported experimental findings.[14] It postulates a binuclear manganese complex in which water ligands are finally oxidized to O_2 via the stage of a bridging peroxy ligand.

$[(bpy)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(bpy)_2]^{3\oplus}$ **1**, bpy = 2,2′-bipyridyl

We have now found that the di-μ-oxo-bridged, binuclear manganese complex oxidizes water with the formation of visible oxygen bubbles when it is suspended in water as a heterogeneous catalyst in the presence of an oxidant such as Ce(IV) ion, although the same complex cannot oxidize water when used in homogeneous solution. The binuclear, cationic manganese complexes **1** and **2** have been prepared as the perchlorates[15] and characterized by UV-VIS and IR spectroscopy.

$[(phen)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(phen)_2]^{3\oplus}$ **2**, phen = 1,10-phenanthroline

Cyclic voltammograms were recorded for the binuclear complexes **1** and **2** in aqueous solution using a three-electrode cell arrangement (basal plane pyrrolytic graphite (BPG) working electrode, platinum wire auxiliary electrode, and a saturated calomel reference electrode (SCE)). The cyclic voltammogram of **1** exhibits two electrochemically reversible redox reactions. At a scan rate of 50 mV s^{-1} the binuclear manganese complex **1** is found to undergo a reversible redox process at 1.14 V vs SCE. Another wave is located at 0.98 V vs SCE, presumably corresponding to the reduction of the $Mn^{III}Mn^{IV}$ complex to the $Mn^{III}Mn^{III}$ complex. The cyclic voltammogram of **2** exhibits two reversible redox processes at 1.23 V and 1.09 V vs SCE. The electrochemical properties of the complexes **1** and **2** have mainly been studied in acetonitrile as solvent,[15,16] and it has been reported that the anodic electrolysis of **1** and **2** in acetonitrile at 1.45 V vs SCE causes decomposition, while the color of the solution changes from green to reddish-brown. We have carried out the anodic electrolysis of the complexes **1** and **2** in water at 1.45 V SCE with continuous reversible scanning between the potentials 0.4 V and 1.5 V vs SCE. The anodic electrolysis and continuous repeated scanning of the potentials did not bring about any noticeable change in the voltammograms. Absorption spectra were recorded for the solutions obtained from the cyclic voltammetric experiments. The absorption measurements also showed that the complexes **1** and **2** are highly stable in water, in contrast to their instability in acetonitrile.

Water-oxidation experiments were carried out with the binuclear manganese complexes using $(NH_4)_2[(Ce(NO_3)_6]$ **3** as oxidizing agent. When the complex **1** or **2** was dissolved in water containing excess **3**, no evolution of gas was observed, and analysis of the gas phase confirmed that no oxygen was formed. A water mixture containing the perchlorate of **1** or **2**, partly dissolved and partly as solid suspension, was deaerated by bubbling argon gas through it for two hours. After the deaeration, an excess of **3** was added to the mixture. Gas bubbles began to form on the surface of the undissolved manganese compound already after 1 minute of mixing. The gas evolved in the reaction was analyzed gas-chromatographically using a 1.5-m column of molecular sieve 5Å and argon carrier. The gas was identified as oxygen from its retention time. The amount of oxygen evolved was calculated by subtracting the oxygen content of the residual air contained in the reaction vessel from the total oxygen observed. According to the mass spectrum the gas evolved contained 1.9% $H_2{}^{18}O$. The ratio $^{18}O^{16}O^{\oplus}/{}^{16}O_2^{\oplus}$ was found to be 2.16%, whereas a value of 0.3% was found for the oxygen from air. That the theoretical value of 3.87% was not reached could have been due to the residual air in the mass spectrometer during the measurement.

Table 1. Oxygen evolution mediated by binuclear manganese complexes under argon at 20°C. In each case, the yields were determined after 4 h [a].

Complex	Solvent	Yield of O_2 [μL] without stirring	with stirring
1·$(ClO_4)_3$	water	94	148
	0.1 N HNO_3	101	171
	0.1 N NaOH	113	144
2·$(ClO_4)_3$	water	26	32
	0.1 N HNO_3	29	39
	0.1 N NaOH	14	32

[a] 1.81×10^{-4} **1**·$(ClO_4)_3$ or **2**·$(ClO_4)_3$, 3.6×10^{-3} mol **3**, volume of solution 10 mL.

The amounts of oxygen evolved in four hours under different experimental conditions are listed in Table 1. The time-dependence of the evolution of oxygen measured by a Warburg apparatus is shown in Figure 1. Repeated experiments show that the results are reproducible. The observed data show that stirring of the reaction mixture leads to formation of more oxygen, and that the pH of the solution does not affect the water-oxidation process. This observation shows that the species oxidized is a water molecule rather than the $OH^{\ominus}$ ion. Ce^{IV} is consumed during the oxidation, so that the rate of oxygen evolution decreases with time (Fig. 1). The finding that **1** is a more efficient catalyst than **2** (Table 1) is consistent with the easier oxidizability of **1** inferred from the cyclovoltammetric data. Since the standard potential of Ce^{III}/Ce^{IV} is not distinctly more positive than that of the $Mn^{III}Mn^{IV}/Mn^{IV}Mn^{IV}$ couple a large excess of **3** is needed for the oxidation of **1** or **2**.

The redox potentials of the complexes **1** and **2** show that they can be used only as 1e-transfer agents for water-

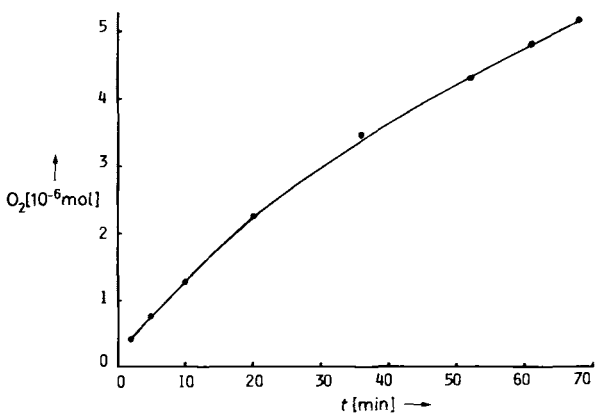

Fig. 1. Time-dependence of O_2-evolution at 25°C with stirring. 4.5×10^{-6} mol **1**·$(ClO_4)_3$, 1.82×10^{-4} mol **3**, 0.1 N HNO_3, volume of solution 1 mL.

oxidation. Since four electrons are required for the formation of an O_2-molecule, a water-oxidation can only be achieved if the 1e-processes can be efficiently coupled. This is obviously not the case in homogeneous phases, but is so in heterogeneous phases.

The heterogeneous water-oxidation system described here is of special interest with regard to the evolution of oxygen in photosynthesis. It has already been suggested[1,6-8] that the microheterogeneous environment around the manganese centers and the close proximity of the manganese atoms to one another are responsible for water-splitting in photosynthesis. This is supported by our finding that the complexes **1** and **2** are only catalytically active in the solid form. It is conceivable that four molecules of the binuclear manganese complex may be oxidized by four adjacent Ce^{IV} ions to produce a four-electron depletion center on the surface. This oxidizing center would then lead to the four-electron oxidation of two molecules of weakly bound water with subsequent evolution of oxygen.

Aminoacetylene and Its Mono- and Dication—Identification of Potentially Interstellar Molecules**

By *Ben van Baar, Wolfram Koch, Carlito Lebrilla, Johan K. Terlouw, Thomas Weiske,* and *Helmut Schwarz**

Dedicated to Professor Ferdinand Bohlmann on the occasion of his 65th birthday

More than 20% of all identified organic molecules in interstellar space contain either an amino moiety or a CC triple bond.[1] The simplest molecule which contains both these structural units is aminoacetylene (ethynamine) **1**. It follows from ab initio calculations of the C_2H_3N hypersurface[2] that **1**, which so far has not been generated and characterized, should be a stable species, at least in the gas phase.[2c] Inspired by our recent successful preparation of the neutral molecule, radical cation and dication of hydroxyacetylene in the mass spectrometer,[3] we have now succeeded in generating **1** and its mono- and dications (**1a** and **1b**, respectively).

Scheme 1.

Decarbonylation of $HC{\equiv}CCONH_2^{\oplus\ominus}$ (produced by 70-eV electron impact ionization) yields a $C_2H_3B^{\oplus\ominus}$ ion, which, under the conditions of tandem mass spectrometry,[4] upon collision activation (CA)[5] displays a mass spectrum[6] which differs uniquely from the spectra of all other presently known isomeric $C_2H_3N^{\oplus\ominus}$ ions[7] (such as, for example, $H_2C{=}C{=}NH^{\oplus\ominus}$, $H_3CCN^{\oplus\ominus}$, $H_3CNC^{\oplus\ominus}$ or $H_2C{=}N{=}CH^{\oplus\ominus}$), inter alia, by a weak-intensity but, for the proposed structure **1a**, characteristic signal at *m/z* 16 ($NH_2^{\oplus}$) (Fig. 1). The corresponding collisional activation spectrum of the $C_2HD_2N^{\oplus\ominus}$ species produced by decarbonylation of $HC{\equiv}CCOND_2^{\oplus\ominus}$ shows the mass shift *m/z* 16→*m/z* 18 ($NH_2^{\oplus}\rightarrow ND_2^{\oplus}$). This is in agreement with our proposal that $HC{\equiv}CNH_2^{\oplus\ominus}$ (**1a**), like $HC{\equiv}COH^{\oplus\ominus}$,[3] is a stable ion which is prevented by sizeable barriers from undergoing unimolecular isomerizations. Neutralization of **1a** with Xe followed by reionization (*N*eutralization *R*eionization *M*ass *S*pectrometry, NRMS[8]) yields a CA spectrum which is *identical* with that of **1a**. It must therefore be concluded that neutralization of **1a** produces the long sought aminoacetylene **1**; isomerization to thermodynamically more stable C_2H_3N species does not occur. It should also be mentioned that under the conditions of charge stripping,[9] **1a** can be oxidized to a $C_2H_3N^{2\oplus}$ dication, which we assume (by way of analogy to $HC{\equiv}COH^{\oplus\ominus}\rightarrow HC{\equiv}COH^{2\oplus}$[3]) to be the aminoacetylene dication **1b**.

Ab initio MO calculations (Table 1) confirm and extend the interpretation of our observations on **1** and **1a**. Calculations of the ground state potential energy surface give the

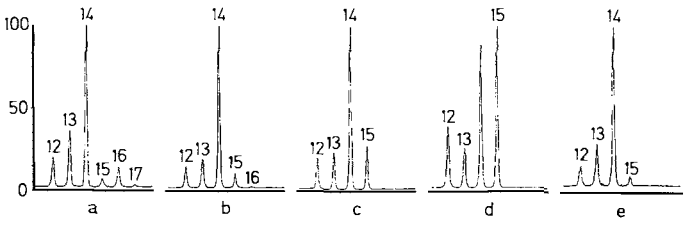

Fig. 1. Partial (*m/z* 12–*m/z* 17) CA mass spectra of $C_2H_3N^{\oplus\ominus}$ isomers. a) **1a** (generated from $HC{\equiv}COONH_2^{\oplus}$), b) $H_2C{=}C{=}NH^{\oplus\ominus}$ (from *n*-$C_3H_7CN^{\oplus\ominus}$), c) $H_3CCN^{\oplus\ominus}$, d) $H_3CNC^{\oplus\ominus}$, e) $H_2C{=}N{=}CH^{\oplus\ominus}$ (from *n*-$C_4H_9NC^{\oplus\ominus}$). The CA spectra were obtained with Vacuum Generators GmbH ZAB-3HF (TU Berlin) and ZAB-2F (Utrecht University) mass spectrometers.

[a] Taken from Ref. [2d]. [b] Calculated with a 3-21G//3-21G basis. c) $E_{tot}(H^{\odot}) = -0.49823$ Hartree. [d] $E_{tot}(NH_2^{\oplus}) = -55.55770$ Hartree. [e] Geometry optimization of **5a** demonstrated that this species does not correspond to a minimum of the potential hypersurface but rather rearranges to the azirine, $\overset{\frown}{CH{=}CHNH}^{\oplus\odot}$ (**6a**). The energy of **6a** was calculated to be −131.53174 Hartree. [f] $E_{tot}(NH_2^{\oplus}) = -55.20852$ Hartree [2d] and $E_{tot}(HCC^{\odot}) = -76.15009$ Hartree [2d].

following results: Isomerization of **1** to the ketenimine **2** (which is thermodynamically more stable by 16.1 kcal/mol) is computed at the 3-21G//3-21G level to involve a barrier of 155 kcal/mol; although this barrier may drop somewhat at a higher level of computation it will remain sufficiently high to prevent an isomerization **1** → **2**. Species **3–5** are thermodynamically quite unstable and thus isomerization of **1** to these can also be excluded. Similarly, we have calculated that the various dissociations of **1** which yield radicals as products will also be strongly endothermic. The MO calculations analogously confirm that the radical cation **1a** is also prevented by sizeable barriers from undergoing spontaneous isomerization or dissociation. Isomerization of **1a** to **3a–5a** is strongly endothermic (for that reason the barriers have not been computed), and, although isomerization to **2a** is exothermic (−21.1 kcal/mol), a spontaneous reaction is prevented by a barrier of ca. 90 kcal/mol. The dissociation of **1a** will also involve high energy barriers and it is therefore not surprising that **1a** and its neutral counterpart **1** are stable species in the gas phase. Finally, it is noted that theory predicts the vertical ionization of **1a** to the corresponding singlet dication **1b** to require an energy of 17.1 eV (MP3/6-31G(d)//6-31H(d)). For the generation of a triplet dication the calculated energy is 17.9 eV. Charge stripping[9] experiments yield a Q_{min} value for the ionization of **1a** to **1b** of 17.9 ± 0.1 eV.[11]

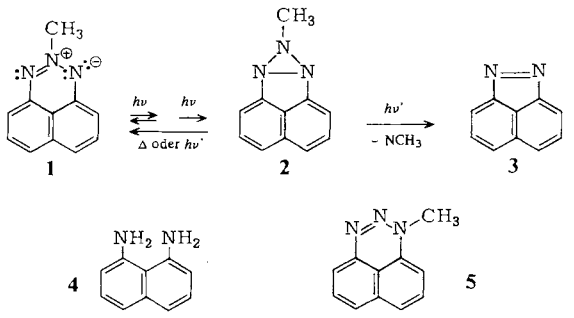
An Azimine-Triaziridine Transformation by Laser Photolysis**



By *Gerd Kaupp** and *Jens A. Döhle*

Up to now, only triaziridines that are stabilized by carbonyl[1] or trifluoromethyl groups[2,3] could be prepared. We now report on the synthesis and characterization of the first triaziridine, **2**, not modified by electron abstraction or by incorporation of *all* three nitrogen atoms in a polycyclic framework.[4] As starting material we used the blue azimine **1**,[6] which is of interest as an inhibitor of the photooxidation of polymers and as a trapping reagent for the detection of free radicals[5] and whose absorption spectrum covers the whole UV/VIS region.[7] Furthermore, according to crystal structure investigations, **1** is planar.[8]

The azimine **1** can be regarded as a derivative of nitromethane. Like the latter it is usually described in terms of dipolar resonance formulas and referred to as a so-called "1,3-dipole". **1** proves to be photostable upon long wavelength (Hg high-pressure lamp TQ700/pyrex)[9] or short wavelength (Hg low-pressure lamp TNN15/quartz)[9] irradiation in ether (298 K) or in the crystal (303 K, 213 K). Even at high dilution ($< 10^{-2}$ and $< 2 \times 10^{-3}$ mol/L) in 2-methyltetrahydrofuran (MTHF) glass, **1** survives prolonged and intense irradiation at 77 K or 10 K (full exposure to a Philips HPK-125W lamp through pyrex (30 min) or a Hanau TNN 15 Hg-low-pressure lamp (90 min) at a distance of 5 cm)[9] without any signs of alteration (UV analysis). Apparently, the electrostatic promotion of ring closure, which is enforced by substitution in the case of unsymmetrical, polar azimines,[1,2] is lacking in the case of **1**. Only multiple excitation of **1** with the super performance of excimer laser pulses[9] at 10 K or 85 K led to successful results. The blue color and the UV absorptions of **1** almost completely disappear and the structured UV spectrum of **2** is obtained, whose principle absorption ($\lambda = 328.5$ nm) has the same intensity as that of **1** (at $\lambda = 383$ nm). At low extinctions (MTHF-glass: $E = 0.3$, soft-

[*] Prof. Dr. G. Kaupp, J. A. Döhle

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ened MTHF: $E = 0.15$) the reaction comes to a standstill. Since, according to molecular models, the conjugation between the α-n-electron pairs and the π-electron system is reduced by the formation of the three-membered ring, the UV absorptions of **2** have shorter wavelengths ($\Delta\lambda = 27$ nm) than those of the reference compound 1,8-diaminonaphthalene **4**.[7] Further support for the formation of **2** is provided by the quantitative re-formation of **1** within 10–15 min upon heating to 150 K and the lasting stability of **2** in non-degassed (liquid) MTHF at 110 K (unchanged absorption spectrum after 2 d). All these experiments are also reproducible after warming to room temperature.

In contrast to **4**, the triaziridine **2** exhibits neither fluorescence nor phosphorescence. Nor can fluorescent or phosphorescent byproducts be detected. Since fluorescence and phosphorescence measurements are very sensitive at low temperatures, **2** must be formed free of byproducts despite (selective) multiple excitation. That **2**, which contains the intact naphthalene ring, usually a very effective fluorophore, does not fluoresce, would indicate that the N–N bonds are cleaved in high quantum yields in the single quantum excitation of **2**. Indeed, on brief exposure of **2** to the low-pressure lamp at 10 K, 65% of **1** and at least six colorless, fluorescing byproducts are formed. According to an HPLC analysis including stopped-flow UV spectroscopic measurements,[7] the major byproduct is **3**.[10] The isomer **5**[6] is not formed.

The high thermal and photochemical lability of **2** and the necessity of pulsed (14 ns) megawatt irradiation explain the failure of earlier attempts to synthesize triaziridines.[1–4] Our data are consistent with the formation of **2** by multiple (presumably two-photon) excitation[11] of **1**. If photolabile **2** were to be formed in the non-selective single-photon excitation of **1**, the short-wave proportion of light would have to lead very efficiently to the byproducts of the photolysis of **2**. But the complete stability of **1** in the polychromatic excitation indicates that no triplets of **1** with lifetimes in the ms range (or above) occur as intermediates, for these would encounter further photons. The reaction **1** → **2** already takes place at low pulse frequencies (5–50 Hz), so it is safely established that the two-photon absorption takes place within the duration of the pulse of 14 ns. Hence, only the electronically excited singlet of **1** can occur as very short-lived intermediate, which because of the naphthalene ring, can absorb a second photon at 351 nm. The intermediate no longer appears to absorb at $\lambda = 548$ nm, for prolonged irradiation with a pulsed dye laser at this wavelength does not lead to any trace of reaction of **1**.

We conclude that **1** is promoted by two-photon excitation within 14 ns into an excited state in which it has real 1,3-dipolar character, and from which it cyclizes to **2**, just like the above cited polar azimines do after one-photon excitation.

The results suggest that attempts should be made to convert suitable nitro compounds and ozone into the still unknown[12] dioxaziridines and trioxirane (*cyclo*-O_3), respectively, by laser photolysis.

Experimental

2: A solution of **1** in a 0.2-mm quartz cuvette (extinction at 355.5 nm ca. 2) was cooled to 85 K, 77 K or 10 K (cell sealed with Viton O-rings; clamping in an aluminum cold head of a cryostat (LH RG 210) to an indium foil with window; insulator vacuum of a turbomolecular pump; electronically regulated electric counter-heating) and irradiated through the quartz window of the cryostat with the excimer laser EMG 102 (cf. [13]) at 351 nm (Xe/F_2, 1.2–0.5 W/cm² average performance, pulse frequency 5–50 Hz). With 24000–36000 pulses, conversions of 84% (10 K) and 90% (85 K), respectively, were achieved. Doubling of the number of pulses did not lead to any higher yields. UV and fluorescence measurements (from the surface at an angle of 30°) in the large sample compartments of the Perkin Elmer 551S and Perkin Elmer 650-40 (with quantum-corrected computation) spectrometers at these temperatures and after electrical heating.—A solution of $E_{548} = 0.8$ was employed for the irradiation with the dye laser (FL 2000, cf. [13]) at 10 K with $\lambda = 548$ nm (coumarin 6, 30 Hz, ca. 0.13 W/cm² average performance). After 108000 pulses a congruent VIS spectrum is recorded.

Photolysis of **2**: After its generation in MTHF at 10 K or 77 K, **2** is irradiated at these temperatures for 10 min with the TNN 15 or HPK 125/Pyrex lamp at a distance of 5 cm. Prolonged irradiation (45 min) does not lead to any further change. The samples show bright fluorescence.

[4] A hexacyclic all-*cis*-triaziridine has recently been reported: G. Fischer, H. Fritz, H. Prinzbach, *Tetrahedron Lett. 27* (1986) 1269. Whether in fact a triaziridine or a rapidly equilibrating azimine was involved remains unclear, since only ^{1}H- and ^{13}C-NMR data were given which fit for both structures. In any case, according to molecular models the triaziridine is more strained than the azimine.

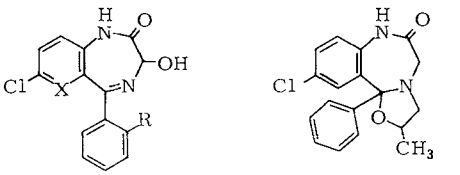
Enantiomeric Resolution by HPLC on Silica-Gel-Bound, Optically Active Polyamides**

By *Gottfried Blaschke,* Werner Bröker,* and *Werner Fraenkel*

Optically active polyacrylamides such as **2a**, with (*S*)-phenylalanine partial structures, and polymethacrylamides such as **2b** and **2c**, with (*S*)-1-phenylethyl and (*S*)-1-cyclohexylethyl moieties, respectively, have proved useful as adsorbents for direct chromatographic resolution of enantiomers.[1–6] These polymers, which are prepared by suspension polymerization in the presence of a cross-linking agent, swell in eluents to form gels and are therefore suitable for low-pressure liquid chromatography. However, they are not stable to pressure: at high pressure, they undergo compression and the rate of eluent flow decreases strongly. Further, the degree of swelling depends on the composition of the eluent. High-pressure liquid chromatography (HPLC) or gradient elution chromatography is therefore not possible.

These limitations can be circumvented by binding the optically active polyamides to silica gel; the separation properties are not thereby affected. To this end, commercially available silica gel that is substituted with diol groups (LiChrosorb® Diol) is esterified with methacrylic acid. The product is suspended in the solution of the monomeric acrylamide **1a**, without the addition of a cross-linking agent, and allowed to undergo radical polymerization to give **2a**-"Si." The acrylamide **1a** copolymerizes with the "methacryloyl silica gel" and is thereby bound covalently to the silica gel. Subsequently, the polyacrylamide that has not undergone copolymerization with the solid phase is solubilized in toluene and filtered off. The silica gel contains about 10 wt-% polyacrylamide. Likewise, copolymerization of the methacrylamides **1b** and **1c** with silica-gel-bound methacryloyl groups affords the polymethacrylamides **2b**-"Si" and **2c**-"Si," respectively.[7]



The silica-gel-bound adsorbents **2**-"Si" are suitable for direct enantiomeric resolution by HPLC.[8] Examples of chiral drugs that can be separated on the phenylalanine polymer **2a**-"Si" are the benzodiazepines oxazepam **3a**

c: $R^1 = c\text{-}C_6H_{11}$, $R^2 = R^3 = CH_3$

and oxazolam **4** and the diuretic penflutizide **5a** (Fig. 1a). Oxazolam **4** has two centers of chirality and is therefore resolved into two pairs of enantiomers or a total of four peaks. The 1-phenylethyl polymer **2b**-"Si" allows the separation of *N*-demethylchlormezanone **6a** (Fig. 1b), the thalidomide derivative **7a**, and the diuretic cyclopenthiazide **5b**. The 1-cyclohexylethyl polymer **2c**-"Si" allows the separation of thalidomide **7b** (Fig. 1c), the benzodiazepine ketazolam **8**, and the anticoagulant acenocoumarol **9**. These racemates have already been separated by low-pressure liquid chromatography on cross-linked polyacrylamide gels, albeit at great expense of time and energy and often only very poorly. As in the case of the cross-linked polyacrylamide gels, the silica-gel-bound polyamides **2**-"Si" separate the racemates listed with different degrees of success.

bents. However, apparently on account of nonspecific adsorption to the amide anchor groups that are additionally present, these preparations separate more poorly than do **2**-"Si."

If LiChrosorb® Diol is esterified with acetic acid instead of with methacrylic acid, then, as expected, no binding of the polyamide occurs upon polymerization of **1a** in the presence of this acetoxy-substituted silica gel. Similarly, polymerization of **1a** in the absence of a cross-linking agent affords a soluble polyamide that does not bind to LiChrosorb® Diol suspended in toluene solution upon heating. Surprisingly, however, polymerization of monomers such as **1a** in the presence of LiChrosorb® Diol or silica gel itself (LiChrosorb®) results, via an unknown mechanism, in anchoring of the polyamides (ca. 10 wt-%) to silica gel. Possibly, monomers and radical initiator are adsorbed by the silica gel. Upon heating, polymerization would then occur predominantly on the surface of the silica gel, whereby mechanical tangling of the growing polymer chain in the pores of the silica gel would result in anchoring. The polymer is not washed out by solvents such as *n*-hexane, toluene, dioxane, or 2-propanol.

The adsorbent[9] obtained by polymerization of **1a** in the presence of the diol phase is also suitable for direct resolution of enantiomers by HPLC. The studies carried out so far have shown that the separations obtained are at least as good as those with methacrylate-anchored polymerizates. For example, base-line separations have been achieved for the diuretic chlorthalidone **10** (Fig. 1d), the muscle relaxant chlormezanone **6b**, and the diazepine lopirazepam **3b**. The silica-gel-bound polyacryl- and polymethacrylamides of type **2**-"Si" described here exhibit unchanged separation ability even after repeated use.

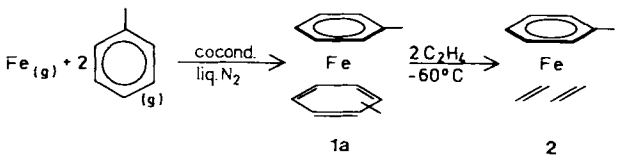
[6] G. Blaschke, J. Maibaum, *J. Pharm. Sci. 74* (1985) 438.
[7] *Experimental procedure:* **2**-"Si": A suspension of diol phase (2.50 g, LiChrosorb® 5 μm, Merck, Darmstadt, C = 6.64%, H = 1.59%) in 20 mL of anhydrous dioxane was treated under a stream of nitrogen with a solution of methacrylic anhydride (1.50 g) in 10 mL of anhydrous dioxane and with diisopropylethylamine (0.80 g) in 30 mL of anhydrous dioxane. The resulting reaction mixture was stirred for 30 min at room temperature (RT), allowed to stand for 24 h at RT, filtered under suction through a G-4 glass-frit filtering crucible and finally washed with 100 mL of dioxane. After drying under high vacuum at RT, a snow-white product was obtained (C = 8.27%, H = 1.76%). A suspension consisting of 2.5 g of this silica-gel-bound methacrylate in 10 mL of anhydrous toluene was treated under N_2 with a solution of 7.5 g of **1a** in 20 mL of toluene and a solution of 22 mg of azobis(isobutyronitrile) in 10 mL of toluene, and the resulting reaction mixture was allowed to stir for 15 min at 80 °C. The polymerization was terminated by addition of a solution of 200 mg of 4-*tert*-butylcatechol in 10 mL of toluene. The product mixture was filtered through a G-4 glass-frit filtering crucible and then washed with toluene, dioxane, *n*-hexane, and 2-propanol. After drying in vacuum, ca. 3.0 g of **2a**-"Si" was obtained as a white powder, C = 21.35%, H = 3.1%, N = 1.16%. **2b**-"Si" and **2c**-"Si" were synthesized analogously from **1b** and **1c**, respectively. However, in these cases, the polymerization took 30 instead of 15 min.
[8] *Experimental procedure:* The adsorbents **2**-"Si," as suspensions in 30 mL of 2-propanol, were poured into steel columns (250 × 4.0 mm) under 450–500 bar pressure. In each case, 3–15 μg of the racemate in dioxane solution was chromatographed. The solvent flow was maintained at 0.5–2.0 mL/min, a pressure of 20–100 bar being required, depending on both the eluents and the flow rate. The products were detected with a photodetector at 254 nm.
[9] *Experimental procedure:* A suspension of 2.5 g of LiChrosorb® 100 Diol 5 μm, used without further modification, was heated under N_2 in a stirred solution of 7.5 g of **1a** and 22 mg of azobis(isobutyronitrile) in 40 mL of anhydrous toluene [10] at 80 °C. The reaction was terminated by addition of 200 mg of 4-*tert*-butylcatechol in 10 mL of toluene and the products were washed as described in [7]. Approximately 2.8 g of a white powder was obtained (C = 12.48%, H = 2.06%, N = 0.65%). FT-IR: $\tilde{\nu}$ = 1680 (amide), 1732 (ester) cm^{-1}. The silica gel contained approximately 10 wt-% polymerizate.
[10] Note added in proof (June 17, 1986): If the less polar cyclohexane is used instead of toluene as solvent, only 0.75 g of **1a** is required to obtain the same loading of polymerizate.

Bis(η^2-ethene)(η^6-toluene)iron**

By *Ulrich Zenneck** and *Walter Frank*



Preparative cocondensation reactions of iron atoms with arenes, carried out at liquid nitrogen temperatures, afford mainly the (η^6-arene)(η^4-arene)iron complexes **1**, which decompose above approximately −60 °C.[2,3] Trapping reactions with ligands have made it possible to synthesize numerous stable complexes of the type [(η^6-arene)FeL_n].[4] We

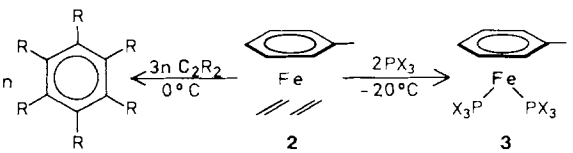
[**] Reactive π Complexes of the Group VIII Transition Metals, Part 2. This work was supported by the Land Baden-Württemberg (Project No. 31-Complex Chemistry) and by BASF AG. Part 1: [1].

have now exploited the pronounced lability of one of the arene ligands of **1** to synthesize new, reactive arene-iron complexes, which, in contrast to **1**, are easier to handle. These complexes open up a convenient approach to the study of the organic chemistry of iron(0).



We report here the synthesis and characterization of bis(η^2-ethene)(η^6-toluene)iron **2**. We reported earlier the first evidence of complexes of this type.[1] Bis(toluene)iron **1a** is synthesized in situ and allowed to react at $-60\,^{\circ}C$ with ethylene;[5] the title compound **2** is obtained as a solution in toluene. After addition of *n*-pentane, the substance undergoes partial crystallization at $-78\,^{\circ}C$. The synthesis of **2** from iron takes only a few hours and affords a high yield of product (57%).

1a **2**

Complex **2** decomposes in solution above $-20\,^{\circ}C$ and its crystals burst at $0\,^{\circ}C$; greater stability is observed at $-78\,^{\circ}C$ under ethylene. The decomposition products are the ligands and metallic iron. Complex **2** has been characterized by ^{1}H-NMR spectroscopy and an X-ray structure analysis. The NMR spectra of **2** are difficult to obtain, because the complex decomposes to form metallic iron under vacuum and upon short contact with wall surfaces above $-20\,^{\circ}C$;[6] even traces of iron particles cause line-broadening of 100 Hz or greater. The ^{1}H-NMR spectrum of **2** suggests that it is very similar to cyclopentadienylbis(ethene)cobalt[7] but considerably more reactive. Both ethene ligands are rigidly bound on the NMR time scale at $-50\,^{\circ}C$.

In contrast to (η^6-arene)diolefin-iron complexes, the olefin ligands in **2** are readily exchanged. Complex **2** undergoes rapid reaction with phosphites, phosphanes, and diolefins to give often good yields of complexes of the type (η^6-toluene)FeL_2.[8] The known complex (η^6-toluene)$Fe[P(OCH_3)_3]_2$ **3**[4c] is formed quantitatively, so that this reaction is also suitable for the determination of yields of **2** in solution.

2 **3**

Complex **2** catalyzes the cyclotrimerization of alkynes such as 2-butyne or 3-hexyne above $0\,^{\circ}C$, 4–8 moles of hexaalkylbenzene being formed per mole of **2**.

Crystal structure analysis: Although the orange crystals of **2** are stable under ethylene at $-78\,^{\circ}C$, under nitrogen surface decomposition begins above $-50\,^{\circ}C$, resulting in the formation of thin layers of iron. The methods employed for the manipulation of the crystalline material must therefore take this sensitivity into consideration.[9, 10] The results of the X-ray structure analysis confirm the composition of the compound inferred from its reactions.

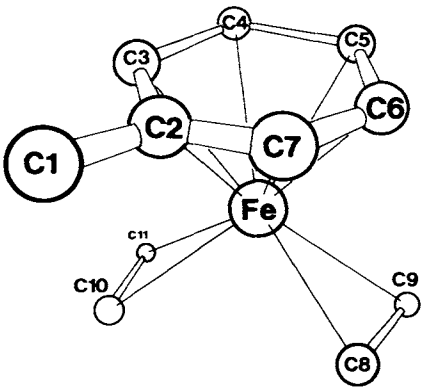


Fig. 1. Molecular structure of **2** in the crystal. Orthorhombic, space group $P2_12_12_1$, $a=811(2)$, $b=1038(2)$, $c=1148(2)$ pm at $T=-130\,^{\circ}C$, $Z=4$, $\mu(Cu_{K\alpha})=120.4\ cm^{-1}$, photometer data, 623 absorption-corrected unique reflections, 61 refined parameters, $R=0.087$. The solution of the structure could not be achieved by direct methods and the usual heavy-atom methods, but only after consideration of packing [13]. Selected distances [pm]: Fe-C2 215(2), Fe-C3 212(2), Fe-C4 211(2), Fe-C5 208(2), Fe-C6 211(2), Fe-C7 216(2), Fe-C8 207(2), Fe-C9 208(2), Fe-C10 202(2), Fe-C11 212(2), C1-C2 157(3), C-C(arene) 139(2) (averaged). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51975, the names of the authors, and the journal citation.

The crystal lattice of **2** is made up of discrete molecules (point symmetry 1 (C_1) (compare Fig. 1). The deviation from the higher point symmetry *m* (C_s), which was found for (toluene)Fe(bpy)[4e], the only (η^6-arene)FeL_2 complex whose structure was investigated previously, is considerable. The methyl group of the toluene ligand is twisted by about 30° from the symmetrical position relative to the ethene ligands. These ligands are thus approximately parallel to the hypothetical lines joining C2 and C4 as well as C5 and C7. Examination of the Fe-C_{arene} distances (cf. caption to Fig. 1) clearly reveals, furthermore, that the aromatic ring is "placed crookedly" upon the iron atom. The angle between the best planes of the ethene and arene ligands is 4°. All the indicated deviations from the "symmetrical" molecular structure can be ascribed to packing effects on the basis of an analysis of the intermolecular distances. The bond lengths of **2** do not exhibit unusual values (mean values [pm] for **2**, $[(C_2H_4)_4Fe]^{2\ominus}$[11] and $[(C_2H_4)Fe(CO)_3(PPh_3)]$[12]: C-$C_{ethene}$: 141, 142, 140; Fe-$C_{ethene}$: 207, 207, 210; Fe-$C_{arene}$ **2**: 212, [(toluene)-Fe(bpy)][4e]: 209).

[5] *Experimental procedure:* **1a** was synthesized from iron (5.5 g, 98 mmol) and toluene (300 g) within 2 h by cocondensation at 10^{-2} Pa and −196 °C. Ethylene (140 g, 5 mmol) was added to the mixture by condensation. After the mixture had been stirred for 2 h at −80 to −40 °C and then filtered at −30 °C through Al_2O_3/5% H_2O, an orange solution of **2** was obtained. The yield of **2** was determined to be 11.4 g (55 mmol, 57%), based on Fe, by oxidative destruction of an aliquot (O_2, air or acid) and titration with Titriplex III. Addition of 300 mL of *n*-pentane to the solution of **2** resulted in the crystallization of approximately 1 g of the complex in the form of orange parallelepipeds at −78 °C.—^{1}H-NMR (300 MHz, [D$_8$]toluene, −50 °C): δ = 5.06 (br, 1H), 4.28 (br, 2H), 4.12 (br, 2H), 1.84 (s, 3H) (π-toluene); 1.91 ("d", $4H_{outside}$), 0.44 ("d", $4H_{inside}$), AA'BB', J_{AB} = 10.3 Hz (π-ethene).

[6] *Sample preparation:* A solution of **2** in [D$_8$]toluene was filtered through a small amount of Al_2O_3/5% H_2O at −50 °C into an NMR tube. The tube was then exposed to air for a short time until the solution adhering to the walls of the tube was oxidatively decomposed without noticeable oxidation of the solution itself. Afterwards, the sample was frozen and the tube sealed. Line widths of 5 Hz were attained if the sample was transferred sufficiently fast to the spectrometer.

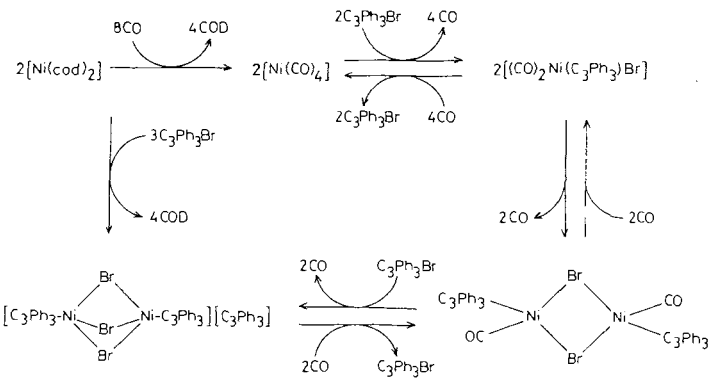
$[(C_3Ph_3)Ni(\mu\text{-}Br)_3Ni(C_3Ph_3)](C_3Ph_3)$— A Triple-Decker-like Complex with Triphenylcyclopropenyl as Ligand



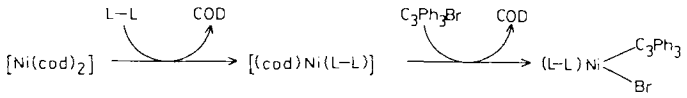
By *Franco Cecconi, Carlo A. Ghilardi, Stefano Midollini,* Simonetta Moneti,* and *Annabella Orlandini*

The cyclopropenylium system has recently attracted considerable interest in organometallic chemistry because it allows a variety of coordination types and reactions at transition-metal centers.[1] The cyclopropenyl complexes reported to date, however, contain strong donating ligands such as CO, C_5H_5, PR_3, and pyridine.[2] We now report the synthesis and the structural characterization of an organometallic compound containing triphenylcyclopropenyl as the only organic ligand.

In the course of repeated attempts to prepare the complex $[Ni_2(C_3Ph_3)_2Br_2]$, previously reported in a patent,[3] by the reaction of $[Ni(cod)_2]$ (COD = 1,5-cyclooctadiene) with C_3Ph_3Br in tetrahydrofuran (THF) solution, we succeeded in isolating deep-red crystals of a compound having the empirical formula $Ni_2(C_3Ph_3)_3Br_3$ **1**.[4] Complex **1** is only formed if the molar ratio between the reactants is $[Ni(cod)_2]/C_3Ph_3Br \geq 2/3$.[5] The X-ray structure determination[6] showed that **1** consists of $[(C_3Ph_3)Ni(\mu\text{-}Br)_3(C_3Ph_3)]^{\oplus}$ and $C_3Ph_3^{\oplus}$ ions (Fig. 1).

In the dimeric anion two eclipsed NiC_3Ph_3 fragments are linked together by three bridging Br atoms, which in turn are staggered with respect to the six C atoms of the η^3-coordinated cyclopropenyl ligands and lie on a plane that is parallel to those of the cyclopropenyl rings. The Ni atoms are thereby complexed in a double sandwich fashion between the cyclopropenyl rings and the three Br atoms. If the cyclopropenyl ring is considered to occupy one coordination site, then the Ni atoms are surrounded in a distorted tetrahedral fashion by three Br atoms and the cyclopropenyl ring, with angles around the nickel atoms of 91.8(2) to 125.4(10)°. The two Ni polyhedra are essentially similar, although corresponding bond distances and angles show some small deviations. The six Ni–Br bond distances range from 2.486(7) to 2.514(7) Å and are therefore essentially equivalent. The triphenylcyclopropenyl ion does not show any unusual features, displaying bond distances and angles in agreement with those reported for free $C_3Ph_3^{\oplus}$.[7]

Complex **1** is not air stable and is practically insoluble in THF, acetone and other polar organic solvents. It is slightly soluble in CH_2Cl_2, undergoing irreversible decomposition to yield a green solution.



Scheme 1.

Complex **1** can also be prepared by reaction of $[(C_3Ph_3)Ni(CO)Br]_2$ with C_3Ph_3Br under a stream of N_2. This reaction can be reversed by bubbling CO through the

ed Energetica dei Composti di Coordinatione, CNR
Via F. D. Guerrazzi 27, I-50132 Florence (Italy)

solution; if an excess of CO is used, $[Ni(CO)_4]$ is obtained as a final product. The interconversion in the nickel-cyclopropenyl-CO system, based on these results and those previously reported,[2a, e, 8, 9] are summarized in Scheme 1.

The addition of C_3Ph_3Br to [(cod)Ni(L-L)] complexes, which are easily prepared from $[Ni(cod)_2]$ and bidentate ligands, is a facile general method for the preparation of cyclopropenylnickel complexes. Two complexes have so far been synthesized in this way (Scheme 2).[10, 11]

Scheme 2. L-L = $Ph_2PCH_2CH_2PPh_2$ (DPPE), $Ph_2PCH_2CH_2CH_2PPh_2$ (DPPP).

Acid-Catalyzed Isomerization of the [2 + 1]-Cyclodimer of an Iminophosphane to the Diazadiphosphetidine**

By *Edgar Niecke,* Dietrich Gudat,* and *Erhard Symalla*

The cleavage of hydrogen halide or halosilane from aminohalophosphanes leads to diazadiphosphetidines, whose versatile chemistry has recently been the subject of intensive studies.[1] For this reaction, both a two-step condensation via a *N*-phosphanylbis(amino)phosphane as well as a dimerization by [2 + 2]-cycloaddition of initially formed iminophosphane could be demonstrated experimentally. We have now found a novel entry to the diazadiphosphetidine system via the acid-catalyzed isomerization of the [2 + 1]-cycloadducts of iminophosphanes.[2]

The iminophosphorane **1** is readily accessible by oxidation of **2**[2] with bromine.[3] However, on attempting the reverse of its formation, namely the reductive dehalogenation of **1**,[4] we surprisingly obtained the isomeric tetra-*tert*-butyl-1,3,2,4-diazadiphosphetidine **4** instead of the [2 + 1]-cyclodimer **3**. When the reaction of **1** with an excess of zinc or magnesium powder in tetrahydrofuran (THF) at 40°C was investigated ^{31}P-NMR spectroscopically it was

M = Mg, Zn; R = *t*Bu; X = F_3CSO_3

found that the iminophosphane **2** initially formed not only dimerizes to give **3**, as expected, but also that the latter is not stable in the presence of the Lewis acid $MgBr_2$ (or $ZnBr_2$) and reacts further to give **4**.

A further indication of the action of Lewis acids as catalysts in the isomerization **3** → **4**, is afforded by the vacuum thermolysis (120–140°C, 0.1 torr) of the stable adduct **5**: likewise, the four-membered ring compound **4** was obtained by cleavage of BF_3. Moreover, the direct conversion

[*] Prof. Dr. E. Niecke, Dipl.-Chem. D. Gudat, Dipl.-Chem. E. Symalla
Fakultät für Chemie der Universität
Postfach 8640, D-4800 Bielefeld 1 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of **3** into **4** could be accomplished with a catalytic amount of $ZnBr_2$ (THF, 4 h at 45°C; **3** : $ZnBr_2$ = 1 : 0.05).

A much better insight into the mechanism of the isomerization is afforded by the reaction of **3** with trifluoromethanesulfonic acid. When this reaction is carried out in CH_2Cl_2 at −40°C, protonation of the imino nitrogen leads to formation of the phosphonium salt **6**, which can be isolated in pure form by immediate addition of *n*-hexane. In solution, **6** rearranges within a few days at room temperature via a 1,2 H-shift into the stable diazadiphosphetidinium ion **7**, which can be deprotonated with bases to **4**. Since the deprotonation of **7** is also possible with **3** as base—this leads to re-formation of the phosphonium salt **6**—here too only a catalytic amount of the acid suffices for the complete conversion of **3** into **4**. In all the reactions described, only one isomer of **4** is formed.

The composition and constitution of the compounds **1** and **4**–**7** have been confirmed by elemental analyses and NMR data.[5] The spectroscopic findings for **5** ($\delta(^{31}P) = 0.1$ (P^{III}), 11.1 (P^{V}), $J_{PP} = 189$ Hz, IR: absence of the characteristic intense bands for a P=N double bond[6]) are consistent with coordination of the Lewis acid to the exocyclic nitrogen atom. The coupling constant J_{HP} of the H atom bound directly to P in **7** is 520 Hz. The isomerization **6** → **7** is accompanied by a drastic decrease in J_{PP}, which together with the shift of both resonance signals to higher frequencies, is indicative of the formation of 1,3,2,4-diazadiphosphetidine (**6**: $\delta(^{31}P) = -20.9$ (P^{III}), 40.8 ($P^{\oplus}$); $^1J_{PP} = 197$ Hz; **7**: $\delta(^{31}P) = 210.2$ (P^{III}), 79.2 ($P^{\oplus}$); $^2J_{PP} = 18$ Hz). From the position of the ^{31}P-NMR signal (δ: 191.2), a *cis*-configuration is assumed for **4**.[7]

Experimental

1: A solution of bromine (4.00 g, 25 mmol) in heptane (30 mL) was added dropwise within 1 h to a stirred solution of **3** (4.00 g, 13 mmol) at 60°C. The mixture was cooled to room temperature, filtered, and the solvent removed under vacuum. Distillation of the residue furnished 4.90 g (61%) of **1** as a colorless liquid (b.p. 55–60°C, 0.1 torr).

4: An ice-cooled solution of **3** (1.59 g, 5 mmol) in CH_2Cl_2 (30 mL) was treated with a catalytic amount of F_3CSO_3H (75 mg, 0.5 mmol) and stirred for 72 h at 30°C. After removal of the solvent in vacuo, the residue was treated with 30 mL of hexane, the solution filtered, the filtrate evaporated to dryness, and the residue recrystallized from ether/acetonitrile (1 : 5). **4** (0.95 g, 60%) was obtained in the form of colorless needles (m.p. 66°C).

5: A stirred, ice-cooled solution of **3** (0.95 g, 3 mmol) in Et_2O (20 mL) was treated with a solution of $BF_3 \cdot OEt_2$ (0.425 g, 3 mmol) in Et_2O (2 mL). The mixture was warmed to room temperature, the solvent removed, and the residue dried in a high vacuum. **5** was obtained as a colorless solid (m.p. 64–68°C (decomp.)).

6 and **7**: A solution of **3** (1.59 g, 5 mmol) in CH_2Cl_2 (30 mL) was treated at −40°C with F_3CSO_3H (0.75 g, 5 mmol). Immediate addition of 30 mL of hexane led to precipitation of **6**. Subsequent filtration, repeated washing with hexane, and drying in vacuum furnished 1.28 g (55%) of **6** as a colorless solid (m.p. 101–103°C). For the synthesis of **7**, the reaction solution was warmed to room temperature, stirred for 4 d, treated with 30 mL of hexane, and then evaporated down to 40 mL. Recrystallization of the precipitate of **7** from a small amount of toluene/acetonitrile (1 : 1) furnished 1.05 g (45%) of **7** (m.p. 98–100°C).

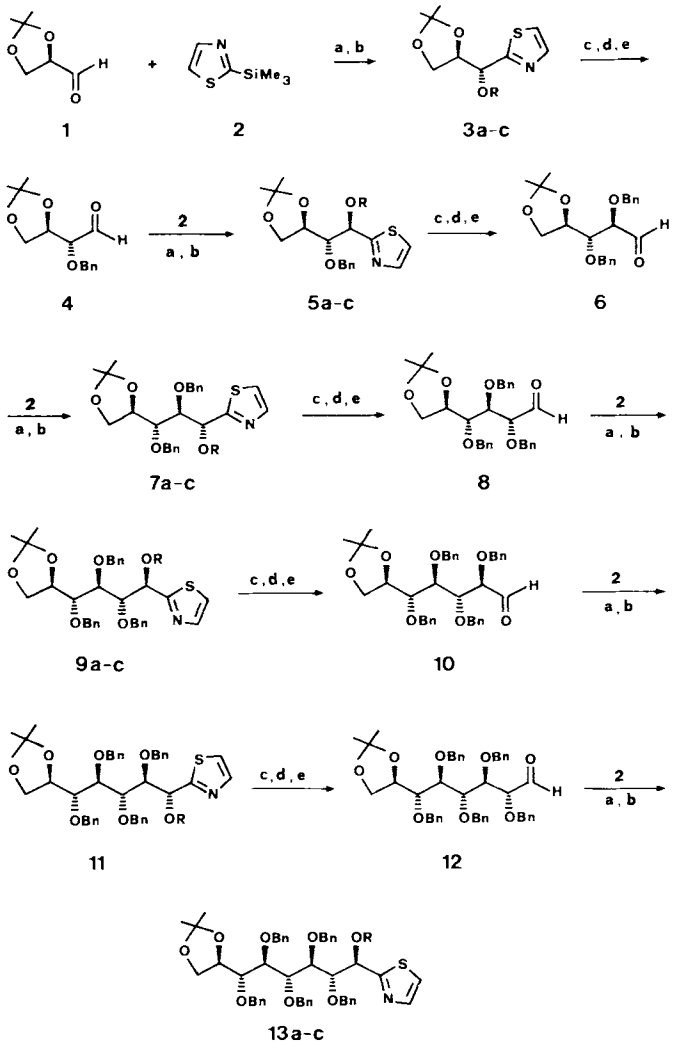
Synthesis of Long-Chain Sugars by Iterative, Diastereoselective Homologation of 2,3-*O*-Isopropylidene-D-glyceraldehyde with 2-Trimethylsilylthiazole**



By *Alessandro Dondoni,** *Giancarlo Fantin, Marco Fogagnolo,* and *Alessandro Medici*

There is ever-growing interest in the use of carbohydrates as chiral precursors to complex natural products[1] and in their preparation from nonsugar compounds.[2] However, efficient iterative methods for the preparation of carbohydrates from short-chain precursors are rare.[2] We report here a new procedure for the iterative, diastereogenic homologation of 2,3-*O*-isopropylidene-D-glyceraldehyde **1**[3] to form D-aldoses with up to nine C atoms in the chain and an *anti* configuration of vicinal hydroxyl groups (Scheme 1). Each iteration is based on two key steps, both of which employ a 2-substituted thiazole: the diastereoselective addition of 2-trimethylsilylthiazole **2** to a chiral α-hydroxyaldehyde and the facile conversion of the thiazole ring into the formyl group. Earlier, we showed that these steps could be carried out once.[4] Here, we describe improved conditions and a synthesis that involves six cycles of repetition, thus demonstrating the potential of the methodology for the synthesis of long-chain sugars.

The one-carbon homologation of the protected D-glyceraldehyde **1** to give the D-erythrose **4** exemplifies both the principle and the details of the sequence.[5] Treatment of **1** with **2** followed by desilylation of the resulting adduct **3a** afforded the (*R,R*)-thiazole **3b** as a single diastereomer (Table 1).[6] Benzylation afforded **3c**, which was transformed by thiazole-formyl conversion into the aldose **4** in good overall yield (Table 1). This transformation was carried out by a slight modification of the literature procedure:[4] (1) *N*-methylation to give the thiazolium halide; (2) reduction to the thiazolidine; (3) hydrolysis to the alde-

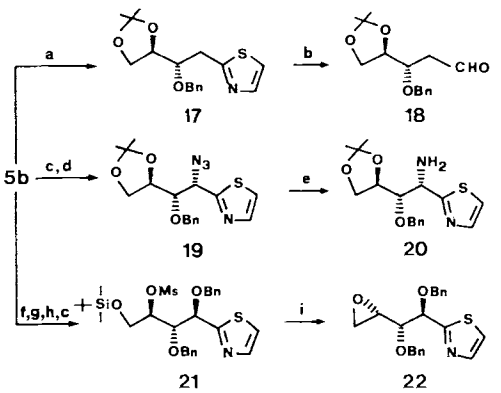
[**] This work was supported by the Ministero Pubblica Istruzione (Rome). We thank Prof. Dr. *S. Hanessian* (Montreal) and Prof. Dr. *V. Jäger* (Würzburg) for helpful discussions, and the High Field NMR Centre, CNR (Bologna), for recording the 300-MHz NMR spectra.

Scheme 1. Iterative homologation of **1**. **a**, R=$SiMe_3$; **b**, R=H; **c**, R=CH_2Ph. a) CH_2Cl_2, room temperature, then tetrahydrofuran (THF)/$F^{\ominus}$. b) NaH, $PhCH_2Br$, nBu_4NI, THF, room temperature. c) MeI, acetonitrile, reflux. d) $NaBH_4$, MeOH, −10°C. e) $HgCl_2$, acetonitrile/H_2O, room temperature.

hyde. The addition of **2** to the chiral aldehyde **1**, which takes place in good chemical yield and with a high degree of *anti*-diastereofacial selectivity, is the key step of the sequence, which could be repeated with equal efficiency five times (Scheme 1, Table 1).[7] In this way, the masked and protected pentoses **5** and **6** (D-riboses), the hexoses **7** and **8** (D-alloses), the heptoses **9** and **10**, the octoses **11** and **12**, and the nonose **13** were obtained. The synthesis of al-

Scheme 2. Conversion of **11b** into **16**. a) F_3CCO_2H (98%), 0°C. b) See c), d), and e) of Scheme 1. c) $NaBH_4$, MeOH, 0°C.

doses **9**–**13** having more than six C atoms is of especial relevance owing to the importance of long-chain sugars in natural products chemistry and the difficulty in preparing them by stereoselective methods from non-sugar precursors.[8,9]



Evidence for the repeated *anti*-diastereoselectivity in the addition of **2** was provided by the X-ray structure determination of the D-ribose precursor **5b**[10] and the elaboration of **11b** into the partially protected *meso*-octitol **16** (Scheme 2).[11] By inference, the formation of the *anti*-adduct **13** was also assumed in the homologation of **12**.

Table 1. Homologation of chiral α-hydroxyaldehydes according to Scheme 1 [a].

Aldehyde →	Adduct → (yield [%])	Aldehyde (yield [%])	$[\alpha]_{20}^{D}$ [b] (conc. [g/100 mL])
1	**3b** (96)	**4** (60)	29.5 (1.70)
4	**5b** (90) [c]	**6** (89)	45.1 (1.20)
6	**7b** (92)	**8** (73)	38.7 (1.45)
8	**9b** (90)	**10** (85)	32.2 (1.13)
10	**11b** (83)	**12** (72)	28.5 (2.79)
12	**13b** (75) [d]		

[a] The diastereomeric purity was determined by ^{1}H-NMR (80 MHz in C_6D_6 or $CDCl_3$). [b] In $CHCl_3$. [c] Lower yields (70–75%) were occasionally obtained owing to the formation of another product, which was isolated as the *O*-benzyl derivative. [d] $[\alpha]_D^{20} = 17.3$ ($c = 0.99$, $CHCl_3$).

Selective elaborations of the above carbohydrate precursors can be carried out owing to the possibility of selectively protecting their hydroxyl groups, as exemplified for **5b** (Scheme 3). Reactions involving the hydroxyl group at C-2 are the Barton deoxygenation[12] to give **17**, which can be readily transformed into the protected 2-deoxy-D-ribose **18**,[13] and the azidodeoxygenation to give **19**,[14] a precur-

Scheme 3. Synthetic elaborations of the pentose precursor **5b**. a) Thiocarbonyldiimidazole, THF, reflux; nBu_3SnH, toluene, reflux. b) See c), d), and e) of Scheme 1. c) $MeSO_2Cl$(MsCl)/Et_3N, CH_2Cl_2, room temperature. d) NaN_3, dimethylformamide, 80°C. e) $LiAlH_4$, THF, room temperature. f) See b) of Scheme 1. g) See a) of Scheme 2. h) $Me_2(t\text{Bu})SiCl$/imidazole, CH_2Cl_2, room temperature. i) nBu_4NF, THF, room temperature.

sor of the masked amino sugar **20**. A third elaboration of **5b** exploits the hydroxyl groups at C-4 and C-5. In a five-step sequence, the 1,3-dioxolane ring of **5b** was stereospecifically converted, via the silyl ether **21**, into the L-lyxose **22**, with an epoxy group having the opposite configuration at C-4.[15]

In conclusion, this iterative one-carbon homologation of chiral α-hydroxyaldehydes with 2-trimethylsilylthiazole **2**[16] should have numerous synthetic applications, particularly for the synthesis of the less common L-sugars and of deoxysugars and amino sugars.[17]

[5] *General experimental procedure:* a) Addition reaction: A solution of the aldehyde (0.5 g) and 1.5 molar equivalents of **2** in anhydrous CH_2Cl_2 (20 mL) was stirred for 10 h at room temperature. The solvent was evaporated under reduced pressure and the residue was treated with 1.5 molar equivalents of nBu_4NF in 30 mL of tetrahydrofuran (THF). After 2 h, aqueous work-up of the solution and chromatography (silica gel, cyclohexane/ethyl acetate) furnished the desilylated adduct. A solution of the latter in 30 mL of THF was added to a suspension of NaH (1.2 molar equivalents) in 50 mL of THF. After 30 min at room temperature, 0.1 molar equivalents of nBu_4NI and 1.1 molar equivalents of $PhCH_2Br$ were added in that order. After 3 h, the usual work-up furnished the *O*-benzylated adduct in quantitative yield. b) Conversion of the thiazole ring into the formyl group: A solution of the *O*-benzylated adduct (1 g) and MeI (10 molar equivalents) in 20 mL of acetonitrile was heated under reflux until the adduct was totally consumed (as monitored by TLC). After distillation of the solvent and excess MeI under reduced pressure, the crude thiazolium iodide was dissolved in anhydrous MeOH and treated with 1.5 molar equivalents of $NaBH_4$ at −10°C. After 30 min, 2 mL of acetone was added; the solvent was then removed by distillation and the residue treated with a concentrated aqueous solution of NaCl. Extraction with ethyl acetate and distillation of the solvent furnished the crude thiazolidine, which was dissolved in 3 mL of acetonitrile and slowly added to a solution of $HgCl_2$ (1.2 molar equivalents) in 30 mL of acetonitrile/H_2O (4:1). The mixture was stirred for 30 min and then filtered. The filtrate was evaporated to dryness and the residue treated with water and extracted with CH_2Cl_2. Distillation of the solvent furnished the aldehyde essentially pure.

[6] In this as well as in the other sequences of Scheme 1, the product distribution in the crude reaction mixture and the diastereomeric purity of the chromatographically isolated adduct were determined by 80-MHz NMR. All products were identified on the basis of their mass and NMR (80- or 300-MHz) spectra as well as elemental analyses.

[7] Benzylation of the newly formed hydroxyl group affords 5–10% of the epimer.

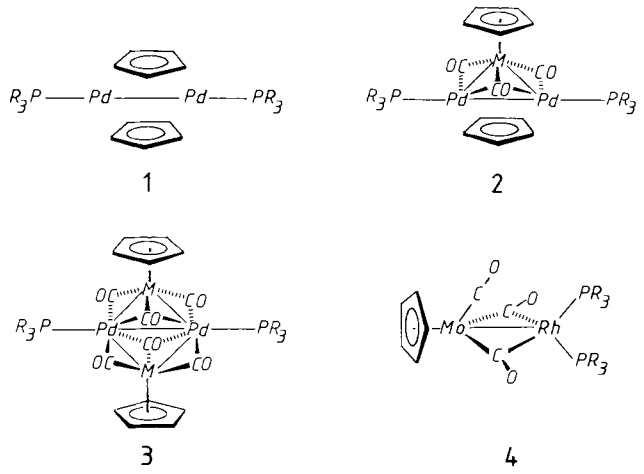
The Isolobal Analogy "d^6-$CpM(CO)_3^{\ominus}$ ⟷ $Cp^{\ominus}$"**



By *Peter Hofmann** and *Helmut R. Schmidt*

The isolobal concept[1] has proved to be a powerful principle in organometallic chemistry for the description of complex structures and the planning of synthetic strategies.[2] We show here an interesting isolobal analogy between the ubiquitous $C_5H_5^{\ominus}$ ($Cp^{\ominus}$) ligand and tricarbonyl(η^5-cyclopentadienyl)metalate ions $[(\eta^5\text{-}C_5H_5)M(CO)_3]^{\ominus}$ (M = Cr, Mo, W) having a d^6 configuration of the metal.

Recently, bimetallic sandwich compounds and clusters have been reported and structurally characterized in which $Cp^{\ominus}$ ligands and $CpM(CO)_3^{\ominus}$ fragments apparently can replace each other. Examples are **1**,[3] **2**,[4] and **3**.[5] A study of the electronic structure of **1** and its analogues has shown[6] that $Cp^{\ominus}$ functions only as a four-electron donor in these complexes, which apparently corresponds to M–Pd metal–metal interactions and μ_2- as well as μ_3-CO

bridges between the metals in clusters like **2** and **3**. The mononuclear groups $CpNi(CO)^{\oplus}$, $Ni(PR_3)_2^{\oplus}$, $Rh(PR_3)_2^{\oplus}$, and $Cu(PR_3)_2^{\oplus}$ are also known to function as binding partners toward $CpM(CO)_3^{\ominus}$ fragments,[7] displaying interactions between M and the second metal atom as well as between this metal atom and two carbonyl C atoms of the $CpM(CO)_3^{\ominus}$ fragment, as in **4**.[7c] Furthermore, a Pd_3Mo cluster was reported[8] recently, in which $CpMo(CO)_3^{\ominus}$ acts as a six-electron ligand. The isolobal relationship between $Cp^{\ominus}$ and d^6-$CpM(CO)_3^{\ominus}$ suggested[5b] by the existence of systems such as **2**, **3**, and **4**, and the general ability of such d^6 building blocks to replace $Cp^{\ominus}$ in a variety of bonding situations, is discussed in this communication.

Decisive for the electronic relationship to $Cp^{\ominus}$ are the highest occupied valence MOs of $CpM(CO)_3^{\ominus}$, $1a_1$ and 1e,[9] which display z^2, x^2-y^2, and xy character at the metal center ("pseudo-t_{2g} set")[1b] and contain π^* contributions from the three CO ligands mixed into these MOs in a bonding manner.

Figure 1, left, shows a qualitative drawing of these three MOs (for bent M–C–O units as in **2** or **3**); Figure 2, left, gives contour plots[10] of these orbitals in a plane below the three carbonyl C atoms, corresponding to those for the

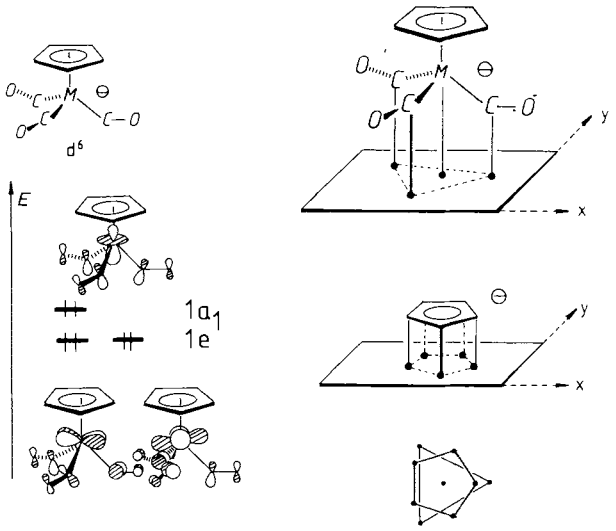

Fig. 1. Left: Qualitative depiction of the three highest occupied valence MOs of $CpMo(CO)_3^{\ominus}$ [10]; right (top to bottom): planes for plotting wave function contours for the MOs (see Fig. 2) of $CpMo(CO)_3^{\ominus}$ and of $Cp^{\ominus}$; comparison of the size of the Cp five-membered ring and the C_3 triangle of the carbonyl C atoms of $CpMo(CO)_3^{\ominus}$.

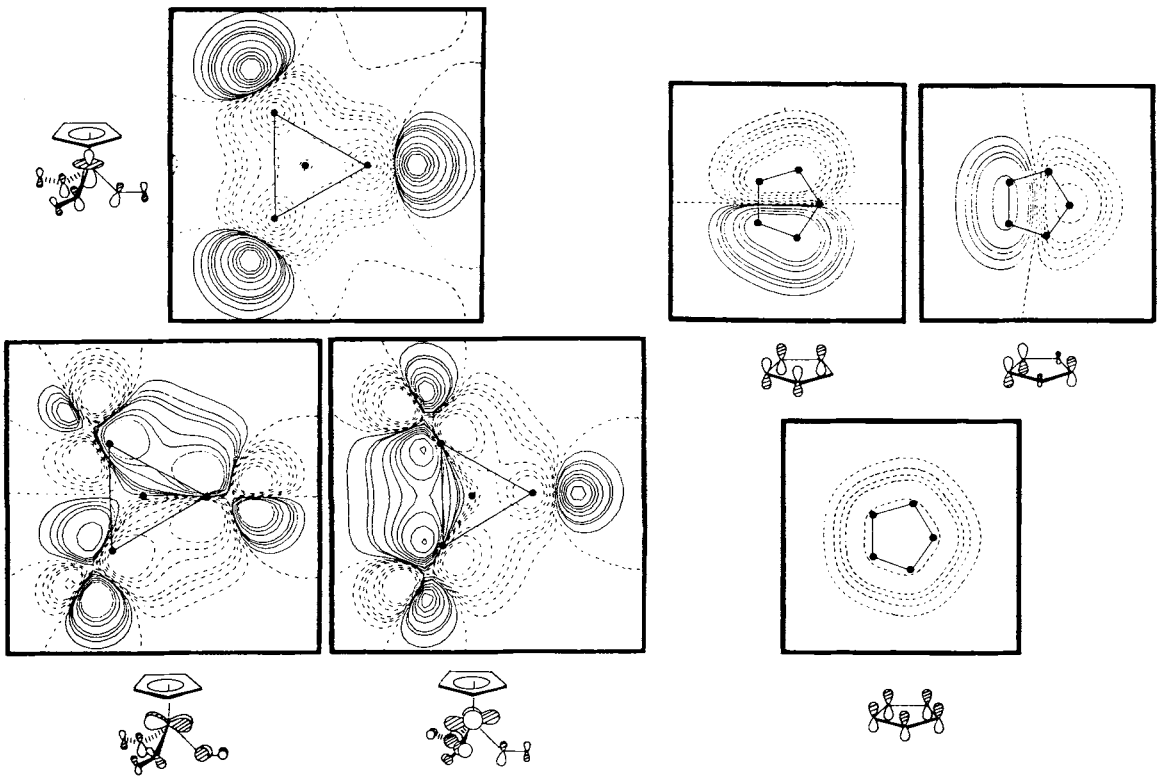

Fig. 2. Left: Representation of wave function contours for the three highest occupied valence MOs of $CpMo(CO)_3^{\ominus}$ [10] in a plane below the three carbonyl C atoms; right: corresponding representation for $Cp^{\ominus}$ (see Fig. 1).

three occupied π-MOs of $Cp^{\ominus}$ in Figure 2, right. The appearance and nodal properties of the three MOs for each of the two systems are very similar in the plane shown, that is, with respect to a potential binding partner in this position; moreover, the Cp five-membered ring and the C_3 triangle of the carbonyl C atoms have comparable dimensions (see Fig. 1, right).

Important is the fact that the areas of the wave functions of $CpM(CO)_3^{\ominus}$ that are available for bonding toward other fragments involve in each case the carbonyl C atoms *and* the metal center (in contrast to, for example, other "tripod" ligands[11]), so that overlap with a second metal fragment $M'L_n$ necessarily implies M–M′ interactions *as well*. Depending on the number and symmetry of the acceptor MOs[1] of a binding partner, $CpM(CO)_3^{\ominus}$ can formally provide two, four, or six electrons and, in analogy to η^1-, η^2-, ..., η^5-bonded Cp rings, can bind $M'L_n$ fragments more or less symmetrically to the carbonyl C atoms *and* M. As for the $Cp^{\ominus}$ rings in **1** and **2**, practically unhindered rotation of the $CpM(CO)_3^{\ominus}$ half-sandwich fragments in **2** and **3** is observed. Because the $1a_1$ and 1e MOs are nearly degenerate, the position of acceptor groups requiring less than six electrons (e.g., $Rh(PR_3)_2^{\oplus}$ or $Cu(PR_3)_2^{\oplus}$) can be adjusted quite flexibly. Of course, a direct bond to the metal atoms ("piano stool" structure) is preferred for pure σ-acceptors ($CH_3^{\oplus}$, $H^{\oplus}$). Interestingly, for $Cu(PR_3)_2^{\oplus}$ (d^{10}-ML_2) both structural alternatives are found.[7c] $M'L_n$ fragments with three acceptor MOs, such as $Mn(CO)_3^{\oplus}$, $CpFe^{\oplus}$, and $(\eta^6$-$C_6H_6)Mn^{\oplus}$, should bind $CpM(CO)_3^{\ominus}$ symmetrically and sandwichlike. *Härter* et al.[12] report the example of the complex composed of $(\eta^4$-$C_4H_4)Co^{\oplus}$ and $CpW(CO)_3^{\ominus}$.

It remains to be explored experimentally to what degree the isolobal analogy d^6-$CpM(CO)_3^{\ominus}$ ⟷ $Cp^{\ominus}$ discussed here, can be extended to analogous building blocks, such as the neutral species $(\eta^6$-$C_6H_6)Cr(CO)_3$ or $CpMn(CO)_3$ as binding partners of suitable, likewise neutral fragments. Undoubtedly, the redox compatability will also play a decisive role. The electronic structures specifically described[7b, 14] for $Ni(PR_3)_2^{\oplus}$ (one unpaired electron) and CpRh(CO) binding to d^6-fragments $CpW(CO)_3^{\ominus}$ and $(C_6H_6)Cr(CO)_3$ also emerge from the analogy d^6-$CpM(CO)_3^{\ominus}$ ⟷ $Cp^{\ominus}$. Its value—taking into account the known limitations[1, 2] of the isolobal principle and extending of alternative concepts—lies in the possibility of simply depicting electronic and structural relationships of complex molecules and of planning synthetic strategies.

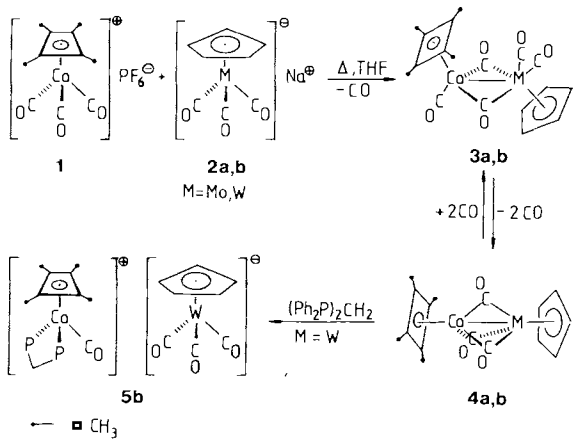
The Complex Ions $[C_5H_5M(CO)_3]^{\ominus}$ (M = Mo, W) as 6e-Ligands: Synthesis and Molecular Structure of $[(\eta^4$-$C_4Me_4)Co(\mu$-$CO)_3M(\eta^5$-$C_5H_5)]$ (M = Mo, W)**

By *Peter Härter,* Heike Pfisterer,* and *Manfred L. Ziegler*

The carbonyl metalates $[(\eta^5$-$C_5H_5)M(CO)_3]^{\ominus}$ of the chromium series display a wide range of bonding behavior toward acceptor molecules;[1, 2] they can coordinate directly through the metal without CO bridging, but they can also act as two-, four-, or six-electron ligands.[3–5]

On the basis of a theoretical analysis of this coordination behavior, *Hofmann* and *Schmidt* demonstrated the isolobal relationship of the organometallic fragment $[(\eta^5$-$C_5H_5)M(CO)_3]^{\ominus}$ with the cyclopentadienide ion $[C_5H_5]^{\ominus}$ in structurally related half-sandwich complexes.[6]



We have now found the first example of a symmetric coordination of $[(\eta^5$-$C_5H_5)M(CO)_3]^{\ominus}$ (M = Mo, W) in binuclear, sandwich-like complexes.

The cationic tetramethylcyclobutadiene complex **1**[7] reacts with the carbonyl metalates **2a**, **b** in tetrahydrofuran (THF) to give the new binuclear CoMo and CoW complexes **3a** and **3b**, which can be isolated in good yields by gentle column chromatography.[8] Upon heating, however,

they are converted into the derivatives **4a** and **4b**, with loss of two carbonyl groups.

The initially formed complexes **3a** and **3b** exhibit the usual carbonyl bridging ligands (ν_{CO} = 1843 and 1856 cm^{-1}, respectively, in *n*-hexane), whereas the derivatives **4a** and **4b** were presumed to have carbonyl bridges with unusual coordination because of the positions of the CO bands at 1803 and 1805 cm^{-1}, respectively. Also striking were the strong high-field shifts of the methyl signals in the ^{1}H-NMR spectra (δ = 1.05 and 0.92, respectively, in C_6D_6) in comparison to the spectra of similar or even isoelectronic complexes such as **6**,[9] in which these signals

$[(\eta^4\text{-}C_4Me_4)Fe(\mu\text{-}CO)_3Mn(\eta^5\text{-}C_5Me_5)]$ **6** $[(\eta^4\text{-}C_4Me_4)Co(\eta^5\text{-}C_5H_5)]$ **7**

usually appear in the range δ = 1.5–2.1.[10] Only in the mononuclear sandwich complex **7**,[11] which has been known for a long time but is quite different at first glance, is the methyl signal of the four-membered-ring ligand found at δ = 1.22.

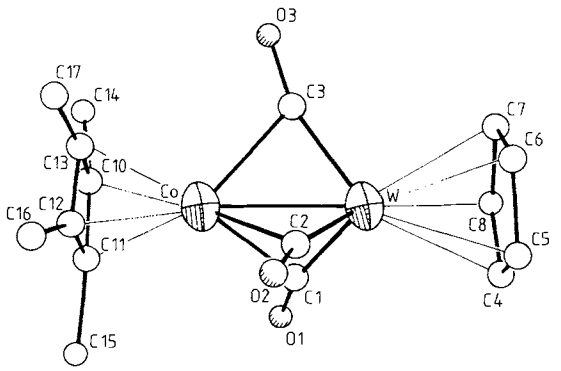

Fig. 1. Molecular structure of the CoW complex **4b** in the crystal (hydrogen atoms omitted). Monoclinic (from *n*-hexane/toluene, 98 + 2 vol.-%), space group C_{2h}^5-$P2_1/n$; a = 728.6(2), b = 2361.6(4), c = 1010.7(2) pm, β = 110.74(2)°, Z = 4; R_{aniso} = 0.071, R_w = 0.053. Selected bond lengths [pm] and angles [°]: W-Co 235.6(0), W-C1 196(3), W-C2 195(2), W-C3 188(3), Co-C1 219(3), Co-C2 215(4), Co-C3 204(2), C1-O1 115(3), C2-O2 121(3), C3-O3 121(4); W-C(1...3)-O(1...3) 162(2), Co-C(1...3)-O(1...3) 126(2), Co-W-C(1...3) 56.1–60.3, W-Co-C(1...3) 50.0–50.8, W-C1-CO 60(1), W-C2-Co 70(1), W-C3-Co 74(1).

In order to explain these observations, the crystal structure of **4b** was determined by X-ray diffraction analysis (Fig. 1).[12] The two ring ligands are parallel and form roughly a right angle with the CoW bond axis. The $(\eta^5\text{-}C_5H_5)W(CO)_3$ fragment has a slightly distorted trigonal-pyramidal structure and is held to the $(\eta^4\text{-}C_4Me_4)Co$ moiety through its carbonyl groups (interligand angle 94–97°); the metal atom of this moiety is thereby located in the center of a pyramidal structure. As a result of the metal binding of the $(\eta^5\text{-}C_5H_5)W(CO)_3$ partial structure, the W-C-O groups form an angle of ca. 162°. The M-CO distances also reflect the polar structure of the complex, the distances of the Co atom (the center of the acceptor portion), to C(1...3) are considerably larger than the W-C(1...3) distances. Similar differences have been observed in other polarized binuclear complexes.[13] Although the Co-W distance of only 235.6 pm can be correlated with a formal triple bond, it is more instructive, taking into consideration the isolobal analogy,[6] to view the new compounds discussed here as structural analogues of the sandwich complex **7**.

Preliminary investigations have shown that **4b** not only undergoes reversible CO addition to give **3b**, but also forms the ionic complex **5b** when it is allowed to react with chelating phosphanes such as methylenebis(diphenylphosphane).

Stabilization of Carbenium Ions in Liquid Crystals**

By *Gerhard R. Bauer, Franz Dickert,** and *Albert Hammerschmidt*

Dedicated to Professor Walther Jaenicke on the occasion of his 65th birthday

Carbenium ions are usually prepared in non-nucleophilic solvents.[1-3] In order to establish whether ordered phases are also capable of stabilizing carbenium ions, it appeared especially advantageous to investigate the formation of the almost planar trityl ion $Ph_3C^{\oplus}$ from the tetrahedral Ph_3CX in nematic liquid crystals. The influence of ordered phases as solvents on chemical reactions is usually limited to viscosity effects.[4,5] Other phenomena are seldom observed.[6,7]

The dissociation equilibrium (a) of 4-methoxytriphenylmethyl trifluoroacetate **1** in a nematic phase (Licristal 1052 Merck = eutectic mixture of **4** and **5**) was investigated.

$$\underset{\mathbf{1}}{MeOC_6H_4{-}CPh_2{-}O_2CCF_3} \rightleftharpoons \underset{\mathbf{2}}{MeOC_6H_4{-}\overset{\oplus}{C}Ph_2} + \underset{\mathbf{3}}{F_3CCO_2^{\ominus}} \quad (a)$$

$$\underset{\mathbf{4}}{C_6H_{13}OC_6H_4CO_2{-}C_6H_4{-}C_5H_{11}} \qquad \underset{\mathbf{5}}{MeOC_6H_4CO_2{-}C_6H_4{-}C_5H_{11}}$$

The equilibrium (a) can be monitored by way of the characteristic absorption of the carbenium ion at 481 nm.[8] The measurements were carried out in cuvettes with a layer thickness of 10^{-3} cm. To ensure uniform orientation of the liquid crystals, and thus to avoid light-scattering, the surface of the glass was treated with Me_2SiCl_2. The liquid crystal is then homeotropically oriented, i.e. the longitudinal axes of the molecules in the mesophase are arranged perpendicular to the surface of the glass.[9-13] This can be ascertained by inspection under a polarizing microscope. On inspecting the textures, schlieren of strength $s = \pm 1$ but not $s = \pm 1/2$ are observed.[14,15] Moreover, with these glass plates, in contrast to those treated with diamond paste (orientation of the liquid crystal parallel to the glass surface[10]), no light-dark effect is observed on rotating the crossed nicol prisms.

The extinction of the solutions investigated is shown in Figure 1 as a function of the temperature. The sudden increase in the extinction for the phase transition isotropic→nematic is indicative of an increase in the concentration of carbenium ions. Hence, it can be concluded that, compared to the isotropic solution, the directed phase stabilizes carbenium ions. The same effect is also observed in the presence of trifluoroacetic acid, but the extinction is altogether greater.[3] Apparently, as shown schematically in Figure 2, the almost planar carbenium ion is preferably incorporated in the rod-shaped liquid crystal structure. The concentration of carbenium ions is increased by ca. 10% by the isotropic→nematic phase transition.

The position of the maximum absorption of the carbenium ion is identical in the isotropic and anisotropic

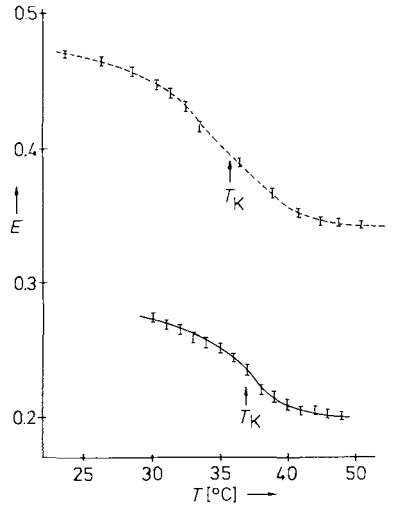

Fig. 1. Extinction of the 4-methoxytriphenylmethyl cation **2** (0.1 mol L^{-1}) in the nematic liquid crystals (——) and in presence of 10 mol-% F_3CCO_2H (----) as a function of temperature; corrected for residual scattering of the pure mesophase; T_K = clearing point for the nematic→isotropic transition.

phases, from which it can be concluded that the ion in both phases has the same electronic structure, particularly as regards twisting of the phenyl rings.[8] The free trifluoroacetate ion shows a typical, triplet-like structure in the ^{19}F-NMR spectra, because of the dipolar coupling in the nematic phase.

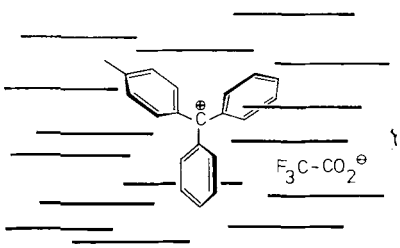

Fig. 2. Incorporation of the almost planar carbenium ion in the nematic liquid crystal (schematic).

The investigations showed that orientation phenomena favor ion formation even in hydrophobic media. Such effects could also be of interest for other directed phases such as micelles and membranes.

Tri-*tert*-butylazete—The First Kinetically Stabilized Azacyclobutadiene**

By *Uwe-Josef Vogelbacher, Manfred Regitz,** and *Richard Mynott*

Although a great deal has been published in the last few years about the chemistry of the cyclobutadienes,[1] our knowledge of the azetes (azacyclobutadienes) is still only scanty. Up to now only the two thermodynamically stabilized azetes **1**[2] and **2**[3] have been obtained, in admixture with other products, by flash pyrolysis of the corresponding triazines. All attempts to prepare electronically pure azetes have so far failed.

Thus, on low-temperature irradiation[4,5] or on flash pyrolysis[6] of 1,3-oxazin-6-ones, only nitriles and acetylenes, the formal decomposition products of the corresponding azetes, were obtained. The same holds for the thermal decomposition of Dewar-pyridazines[7] and for the photolysis of trimethylcyclopropenylazide.[8,9] Even the azide **5**, which has all the steric prerequisites for the generation of the kinetically stabilized azete **6**, afforded only N_2 and the fragments **3** and **4** under matrix conditions.[5,9] Despite these discouraging results, we have—based on experience gained in cyclobutadiene chemistry[10]—exploited the thermolysis of **5** as an entry to azete chemistry (Scheme 1).

Scheme 1.

When the azide **5**[11] was heated in the absence of solvent to 125°C and subsequently distilled under vacuum the azete **6** was obtained as the main product in the form of reddish-brown needles (m.p. 37°C) that are sensitive to oxidation. Chromatographic work-up of the residue from the distillation afforded the triazine **7**[11] (m.p. 130°C) as by-product. The "azete fragments" **3** and **4** could not be detected in the product by NMR spectroscopy, but they are formed quantitatively when **7** is photolytically ($\geq$280 nm) decomposed in pentane at 20°C. Since **6** is stable under these conditions, the formation of the fragments must start from tri-*tert*-butylcyclopropenylnitrene (presumably triplet). This explains why even matrix photolysis of **5**[5] fails to produce the target compound. The thermolysis **5**→**6** should therefore be interpreted as a synchronous reaction.

The azete **6** is characterized by its extreme thermal stability; no change was observed in its NMR spectra after several days in [D_8]toluene at 100°C. On the other hand, under flash pyrolysis conditions (700°C/5×10^{-6} mbar)—as in cyclobutadiene chemistry[12]—the cycloreversion **6**→**3**+**4** takes place (100%, 1:1). The same result is obtained upon thermolysis of the triazine **7** at 130°C or upon its flash pyrolysis.

The constitution of the azete **6** has been confirmed by elemental analysis, mass spectrometry, and NMR spectroscopy.[13] Only two *t*Bu signals in the intensity ratio 2:1 are observed in the ^{1}H-NMR spectrum at room temperature. Therefore, assuming that the ground-state is rectangular, it can be concluded that a rapid valence isomerization **6A**⇄**6B** is taking place. This has been proven by ^{13}C-NMR spectroscopy.[14] The resonance of C-3 at $\delta=134.4$ remains sharp in the temperature range from −110°C to +100°C. The other two ring carbon atoms, C-2 and C-4, however, give rise to one very broad signal at $\delta\approx181$ at room temperature; this signal becomes sharp at +100°C, while on cooling to −110°C it splits into two equally intense lines at $\delta=158.8$ and 203.7 (C-4 and C-2, respectively, in **6A**). The position of the latter line is comparable with that of the imino carbon atom of Dewar-pyridines.[15]

Experimental

6: 1.25 g (5 mmol) of **5** [11] was heated under argon for 90 min at 125°C (oil-bath temperature); the thermolysis product turned dark-brown (IR monitoring, disappearance of the azide absorption at 2090 cm^{-1}). Kugelrohr distillation at 60°C (oven temperature)/0.05 mbar afforded 0.61–0.72 g (55–65%) of a dark-brown oil, which immediately solidified; recrystallization from a small amount of pentane furnished reddish-brown needles of m.p. 37°C.

7: Obtained from the residue from the distillation by medium-pressure chromatography with petroleum ether (30–75°C)/ether (4:1). This afforded 40–60 mg (3–5%) of colorless crystals of m.p. 130°C (from pentane).

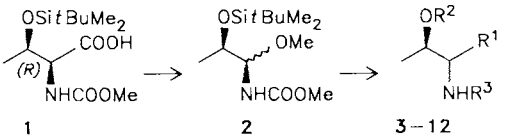
Preparation of Chiral Building Blocks from Amino Acids and Peptides via Electrolytic Decarboxylation and $TiCl_4$-Induced Aminoalkylation**

By *Philippe Renaud* and *Dieter Seebach**



Dedicated to Professor Vladimir Prelog on the occasion of his 80th birthday

In the anodic oxidation of *N*-acylated amino acids **A** in protic media, *N,O*-acetal derivatives **B**[1] are formed. These can be used as electrophilic amidoalkylating[2] reagents[3,4] (Scheme 1). When the groups R, R′ and/or R″ are chiral there is the possibility of performing stereoselective nucleophilic substitutions to give compounds **C**. Until now, this was only performed in the case of cyclization reactions[4,5] and with cyclic[6] acetals,[7] which upon opening with nucleophiles underwent inversion of configuration at the acetal center.[8] We have now shown with appropriate amino acid derivatives which possess chiral substituents in all the three positions of **A** — R, R′, and R″ (Scheme 1)— that we are able to carry out diastereoselective substitutions and to prepare interesting, and in some cases novel, enantiomerically pure building blocks.

Scheme 1.

In the first case (R in **A** chiral) we chose the threonine derivative **1**,[9] which, by electrolysis in methanol, was converted into a 1:1 mixture of *N,O*-acetals **2** in 75% yield. This mixture was subsequently converted by reaction with nucleophilic reagents (see Table 1) into the amino alcohol derivatives **3**–**12** (Scheme 2), which included phosphonothreonine and phosphonoallothreonine esters **7**. The diastereoselectivity was between 55 and 85%; however, in some cases the major diastereoisomer could be isolated by recrystallization (see Table 1).

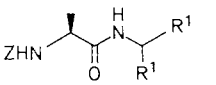
9	Me	COMe	**10**	Me
11	C_6H_{13}	COC_6H_{13}	**12**	C_6H_{13}



Scheme 2.

As examples for the second case (R′ in **A** chiral) we chose the N-protected dipeptides **13** and **14**, derived from the coupling of (*S*)-alanine with glycine and (*S*)-valine,[10] respectively, as our substrates. Electrolysis of the glycine derivative gave the acetal **15** in 95% yield. The anodic oxidation of the alanyl-valine dipeptide gave a mixture of two diastereoisomers **16** (95%, 1.2:1), the alkylation and phosphorylation of which gave the products **18** and **19** (see Scheme 3 and Table 1)[11]. 15) and **19** are of particular interest because of their biological activity.[12]

Finally, in the third case (R″ in **A** chiral) we investigated the *cis* acetals **20** and **21** which were derived from serine methyl ester via treatment with isobutyraldehyde/methyl chloroformate and pivalaldehyde/methyl chloroformate, respectively, in accordance with an earlier published procedure[13]. These gave after electrolysis in acetic acid the acetoxy derivatives **22** and **23** (85% and 87% yield, 90% and >97% *ds*), respectively, both products arising from re-

30: $[\alpha]_D^{25} = +121.7°$

[a] Signals of the three carbon atoms in the ring.

using NMR difference NOE measurements. The alkyne **25** can be hydrolyzed to the aminoalkynol **27**. Elimination of acetic acid from **23** gives access to the chiral glyoxal derivative **29**. In addition, alkaline hydrolysis of the acetates followed by oxidation (pyridinium dichromate) yields the chiral glycolic acid derivative **30**. Both of these compounds are starting materials for a large number of enantiomerically pure products.[15]

The fact that products of high diastereomeric purity are sometimes formed on starting from the diastereomeric mixture of *N,O*-acetals (cf. **2** → **3**) obtained by electrolysis indicates that an α-acylaminocarbocation is an intermediate.—Some characteristic physical data of the new compounds reported herein are given in Table 2.

Structures with Oligomeric Condensed Clusters in Indium Oxomolybdates

By *Arndt Simon,* Wilhelm Mertin, Hansjürgen Mattausch,* and *Reginald Gruehn*

In many cases the structures of metal-rich compounds of the transition metals are describable in terms of condensed clusters.[1] Thus, infinite chains of Mo_6-octahedra condensed via opposite edges are present in the structure of $NaMo_4O_6$, which are surrounded by O atoms, above all the free octahedral edges, in the same way as the known M_6X_{12} clusters.[2] Such Mo_4O_6 chains are found in a series of reduced oxomolybdates.[3]

The Mo_4O_6 chains can be interrupted by structural disorder in the crystal. $In_{11}Mo_{40}O_{62}$ is the first compound[4] where such structural "disorder" occurs at regular intervals with formation of defined fragments of the Mo_4O_6 chain. Discrete cluster anions with four or five condensed Mo_6-octahedra are arranged in layers, which are stacked in an alternating sequence (Fig. 1a). A single oligomeric cluster of five condensed octahedra is shown in Figure 1b. All (free) edges of the octahedra are bridged by O-atoms. The channels between the cluster anions are occupied by linear M–M bonded polycations (In_5^{7+} in the case of $(Mo_6)_4$-clusters and In_6^{8+} in the case of $(Mo_6)_5$-clusters). The layers seen in Figure 1a have the general composition $In_{n+1}Mo_{4n+2}O_{6n+4}$, where n indicates the number of Mo_6 octahedra in each cluster. The structure of $In_{11}Mo_{40}O_{62}$ is

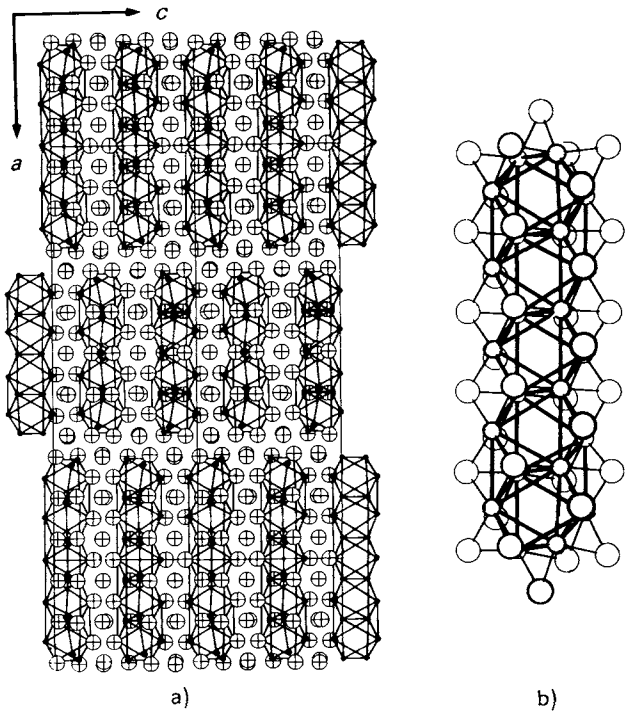

Fig. 1. a) Projection of the crystal structure of $In_{11}Mo_{40}O_{62}$ on (010). The oligomeric clusters containing four $(Mo_6)_4$ and five $(Mo_6)_5$ octahedra, respectively, are arranged in layers (small circles: Mo atoms; large circles with cross: O atoms). Between the clusters there are linear In_5^{7+} and In_6^{8+} ions (black circles), respectively. b) Oligomeric cluster with five edge-linked Mo_6 octahedra in $In_{11}Mo_{40}O_{62}$.

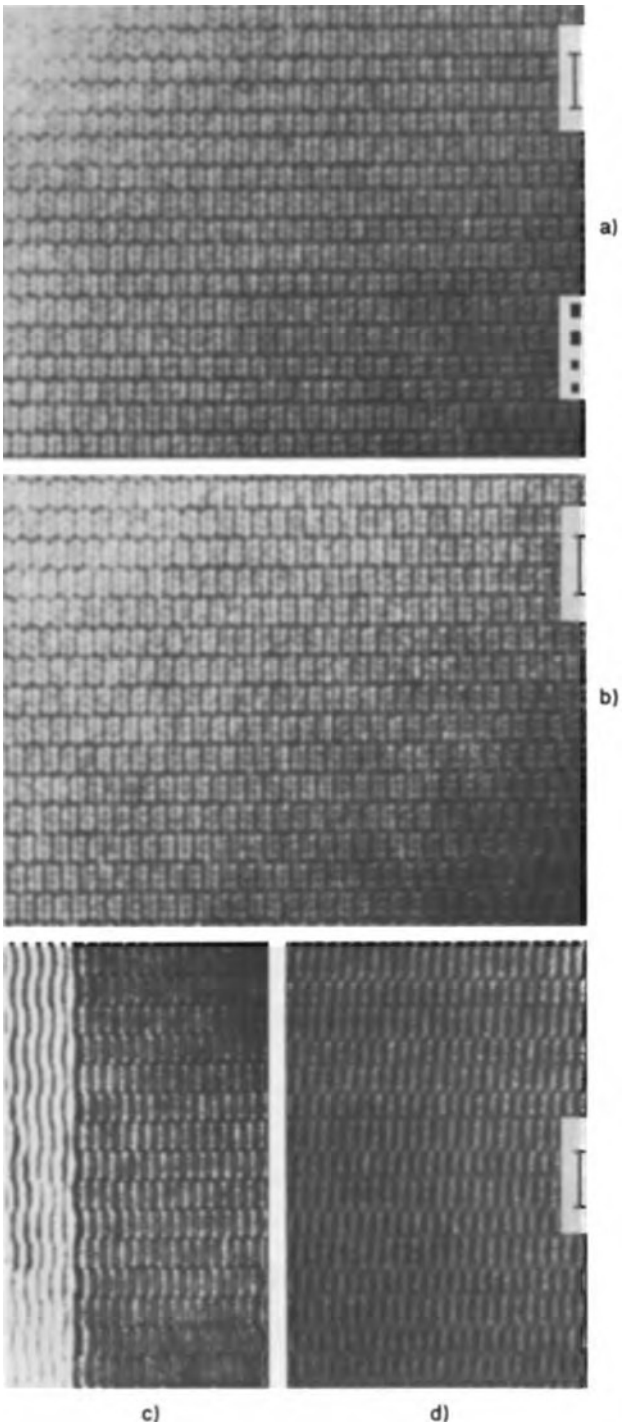

Fig. 2. Electron microscopic photographs of indium oxomolybdate with cluster layers of the general composition $In_{n+1}Mo_{4n+2}O_{6n+4}$. The lengths and orientations of the axes are indicated; cf. text (initial magnification 440000×, 120 kV; Philips EM 400 with HMG goniometer stage; LaB_6 electron source; computer simulations of the image contrast are presently under way. a) $In_{11}Mo_{40}O_{62}$ (h01); stacking disorders, which however do not lead to a change in composition, are shown by black rectangles (large, for two consecutive layers with $(Mo_6)_5$ clusters; small, with $(Mo_6)_4$ clusters. b, c) $In_3Mo_{11}O_{17}$: homogeneous sequences of layers with $(Mo_6)_5$ clusters viewed in two directions (*a* axis in the plane of the picture). d) $In_3Mo_{11}O_{17}$: modification with alternating sequences of $(Mo_6)_4$- and $(Mo_6)_6$-layers cluster (in the same direction as c).

formed by intergrowth of $In_5Mo_{18}O_{28}$ and $In_6Mo_{22}O_{34}$ layers in the ratio 1 : 1.

The number of Mo–Mo bonding states can be estimated by suitable fragmentation of the oligomeric cluster into $Mo_6O_{12}+(n-1)Mo_4O_6$.[5,6] Accordingly, one expects, besides "homogeneous structures" (i.e. structures with a single type of layers), also structures with clusters of other lengths. A first confirmation of their existence was provided by high-resolution transmission electron microscopy.[7] Figure 2a shows the alternating sequence of cluster layers in an $In_{11}Mo_{40}O_{62}$ crystal fragment. The thicknesses of the layers are 1300 ($(Mo_6)_4$) and 1580 pm ($(Mo_6)_5$), respectively; the difference corresponds exactly to the mean length of an Mo_6-octahedron edge (280 pm), and the sum corresponds to the lattice constant, determined more accurately by X-ray diffraction ($a=2887.8$ pm), of $In_{11}Mo_{40}O_{62}$. Such alternating layer sequences occur in ordered regions of 10^5 pm. In Figure 2a a section is intentionally reproduced in which stacking disorder is recognizable. The variation in the composition of the crystal through two consecutive $In_5Mo_{18}O_{28}$ layers is compensated by two immediately adjacent $In_6Mo_{22}O_{34}$ layers. In the same sample, regions are found (Fig. 2b) that are exclusively made up of identical $In_6Mo_{22}O_{34}$ layers over distances of 10^5 pm. In the meantime, the respective new compound $In_3Mo_{11}O_{17}$ has been isolated as a homogeneous phase and has been characterized by X-ray crystallography ($a=3160.8$, $b=948.9$, $c=983.9$ pm).

Another crystal zone of the $In_3Mo_{11}O_{17}$ fragment is shown in Figure 2c. In Figure 2d, an alternate stacking of layers with $(Mo_6)_4$ and the new $(Mo_6)_6$ clusters can be seen, which, having regular sequences, likewise leads to the composition $In_3Mo_{11}O_{17}$ with the same translational period $a=3160$ pm.

Thus, there is every indication of a similar diversity of oligomeric clusters with edge-linked Mo_6 octahedra in the case of oxomolybdates, like that already known in the case of metal-rich chalcogenides with face-linked Mo_6-octahedra.[8] Furthermore, there is the possibility of determining the lengths of the polycations of main-group metals between the clusters via the lengths of the clusters.

BOOK REVIEWS

With Chemistry into the Third Millenium

Opportunities in Chemistry. Edited by: The Committee to Survey Opportunities in the Chemical Sciences, National Research Council. National Academy Press, Washington, D.C. 1985. vii, 344 pp., bound, $ 24.75.—ISBN 0-309-03633-X

This book, which has become known as the "Pimentel Report," is the outcome of a study endorsed by the US National Research Council. A 26-membered "Committee to Survey Opportunities in the Chemical Sciences" set up by the NRC has compiled, under the leadership of *George C. Pimentel* and with the cooperation of more than 350 experts, a report documenting quite convincingly "the critical role played by chemistry in raising the quality of life, meeting the needs of society, and contributing substantially to a nations economic strength".[*] The main aim of the study was to answer the following questions:

- What opportunities are there in chemistry?
- How can chemists most effectively deploy the possibilities of chemistry for the future economic well-being of the community?
- How can we make the general public and their representatives in government aware of the importance of chemistry in solving economic problems and in satisfying the needs of society?
- How can we best inform the politicians such that they meet the correct decisions when granting financial support of research programs?

The experts who participated in this study come from all areas of chemical research, from academic, industrial, and national research institutes. The report is not meant primarily for the chemist but rather is directed at the interested public and the scientific policy makers.

The areas of chemistry which could become increasingly important in the future are outlined and used as a basis for recommending a reassessment of priorities in research investment. Thus, it is expected that chemistry will play an increasingly decisive role in the development of new processes and new materials in, inter alia, power supply, nutrition, hygiene, biotechnology, environmental protection, and will help in maintaining the competitiveness of the American industry and in contributing to the national security of the USA.

[*] Cf. also C & EN, January 6, 1986, p. 2.

Of particular interest to the scientist is the account of the current state of chemical research and technology and the developments to be expected in the innovative areas of chemistry. These include, in particular, the following areas: chemical kinetics, theoretical chemistry, catalysis, synthesis, the chemical fundamentals of life, and analytical methods.

From their account of the current state of and possible fields of development in chemistry the authors derive, from the American viewpoint, a number of scientific, industrial, and political recommendations, many of which might also be relevant for other industrial nations, and not least for the Federal Republic of Germany. The state of competitiveness of US chemistry is carefully brought into relief and attention is drawn to what other industrial nations are doing; thus, for example, it is pointed out that the Max-Planck-Society in Mainz has founded a new Polymer Institute.

This excellent work is concomitantly a concise account of our present chemical knowledge and, as such, also an avowal to research and industrial progress: "Chemistry is a central science that responds to societal needs" (P. 19). The "Pimentel Report" provides a scientifically sound and critical argument for all, who, despite the prevailing scepticism in our society, have faith in the future of chemistry.

The Chemistry of Natural Products. Edited by *R. H. Thomson*. The Blackie Publishing Group, Glasgow 1985. xii, 467 pp., bound, £ 46.00.—ISBN 0-412-00551-4

To produce a book about the progress made in the chemistry of natural products in the last ten years is by no means an easy task. The authors do not claim to have written a comprehensive work, but are concerned rather with giving an outline of progress in the main areas of the chemistry of natural products. As the foreword makes clear, the main emphasis in all the contributions is on structure, chemistry and synthesis, but each chapter also includes notes on biosynthesis. The book is divided into nine chapters.

Chapter 1 *(J. S. Brimacombe)* deals with the chemistry of carbohydrates. The applications of protecting groups are, of course, discussed in detail here. This is followed by a survey of the synthesis of sugars with antibiotic activity. The reader is also given a compilation of natural products syntheses which have employed sugars to transfer stereochemical information, and descriptions of some oligosaccharide syntheses. The chapter ends, with a survey of structure determination in polysaccharides.

In Chapter 2, *E. J. Thomas* describes syntheses of aliphatic natural products. Syntheses of fatty acids and their derivatives, of leukotrienes, marine natural products, pheromones, prostaglandins, polyether antibiotics, and macrolides are discussed in detail. The reactions described in the text are illustrated by detailed charts, thus ensuring that even very complex schemes are clearly presented. A feature deserving special mention is the inclusion of lists of review articles on each of the topics mentioned above, which should help the user to find further literature in a particular area.

In Chapter 3, *T. J. Simpson* has compiled information on syntheses of aromatic compounds. For biosyntheses the reader is referred to relevant books. Individual classes of compounds are briefly dealt with in turn, including coumarins, chromanes, cannabinoids, butenolides, lignans, flavonoids, naphthoquinones, ansamycins, and so on.

Chapter 4, by *J. R. Hanson*, is a survey of terpenoids. The terpenes are dealt with in order of increasing number of isoprene units, and the chapter concludes with a short section on carotenoids. Owing to the enormous number of compounds it is not possible to give complete details of all the syntheses and biosyntheses. Here too the reader is referred to review articles. An incidental point here is that the reactants given under Scheme 12 ought to be included in Scheme 14.

In Chapter 5, *B. A. Marples* gives a survey on steroids. A general introduction is followed by sections on rearrangements, biomimetic syntheses, polyene cyclizations, and more recent partial and total syntheses. Lack of sufficient space has prevented some aspects from being treated in detail, e.g. the synthesis of polyenes.

In Chapter 6 *(B. W. Bycroft* and *A. A. Higton)*, aminoacids, peptides and proteins are discussed. If in addition to their chemistry, the biochemical or biosynthetic aspects had also been covered, it would have exceeded the limits of such a chapter. The first section deals with various amino acids, with detailed descriptions of a small number of syntheses. In the sections on peptides and proteins too, the presentation is mainly concerned with structural aspects. Methods for sequence determination in peptides and proteins are touched on briefly. All the sections contain numerous references to biochemical studies.

The subject of Chapter 7, by *I. R. C. Bick*, is alkaloids, which have been classified according to their biogenetic origin. In this chapter the main emphasis is on synthesis, but numerous references to the biochemistry and biosynthesis of the compounds are included.

In Chapter 8, *J. B. Hobbs* covers recent developments in the area of nucleotide chemistry. The chapter begins with a section on nucleosides (synthesis, reactivity and alkylation), followed by a similarly organized section on nucleotides. Three sub-sections are devoted to chirality at the phosphorus atom. The final section of this chapter deals with syntheses of nucleic acids and techniques for sequence determination.

In Chapter 9, *A. H. Jackson* deals with porphyrins and related compounds. The emphasis is on synthetic methods, together with a few digressions into biosynthesis. Following a section on porphyrins, chlorophylls and their analogs are discussed. A comparatively large amount of space is given to syntheses of Vitamin B_{12} and related compounds. The chapter ends with sections on bile pigments and prodigiosins.

The book is a very successful cooperative effort by the various authors. It is not suitable as a beginner's introduction to the chemistry of natural products, since it assumes some specialist chemical knowledge, but because of the wealth of information which it contains on each group of substances it can be recommended for all research workers in the field, and for scientists who wish to keep up to date in these matters.

The book is very attractively produced, and contains remarkably few misprints in the text or errors in the diagrams. It is worth the price.

Asymmetric Synthesis—The Current State of the Art

Asymmetric synthesis was considered as an academic curiosity until the 1950's, when a better understanding of reaction mechanisms and the development of conformational analysis revived interest in the field. During that period much attention was given to the interpretation and prediction of the steric course of reactions (Cram's rule, Prelog's rule, nomenclature, ...). In these investigations the absolute configurations of many compounds were determined. At the same time, many asymmetric reactions leading to optically active products were studied, but their preparative value remained low. The now classical book of *J. D. Morrison* and *H. S. Mosher* "Asymmetric Organic Reactions"[1] fully reviewed the field up to the 1970's. In this book there are only a few reports of asymmetric syntheses with *ee*'s higher than 90%. During 1970–1982 there was a tremendous increase in the number and efficiency of asymmetric syntheses. Many stoichiometric or catalytic reactions which lead to chiral products with *ee*'s higher than 90% became routine. Moreover, the progress of modern technology rendered the setting up of reliable methods (based on NMR, or HPLC) for the measurement of enantiomeric excesses possible. It was therefore very appropriate that *J. D. Morrison* decided upon a new venture; namely, to edit a series of five volumes devoted to the progress of asymmetric synthesis in the seventies and early eighties. The complete work,

Asymmetric Synthesis. Edited to *James D. Morrison*. Academic Press, Orlando, FL, 1983–1985.

Vol. 1, xiv, 201 pp., bound, \$ 32.00.–ISBN 0-12-507701-7.

Vol. 2, xiv, 278 pp., bound, \$ 45.00.–ISBN 0-12-507702-5.

Vol. 3, xiii, 578 pp., bound, \$ 84.50.–ISBN 0-12-507703-3.

Vol. 4, xii, 380 pp., bound, \$ 85.00.–ISBN 0-12-507704-1.

Vol. 5, xiv, 391 pp., bound, \$ 85.00.–ISBN 0-12-507705-X

which was written in collaboration with some 60 authors, who are also major contributors to various aspects connected with the art of asymmetric synthesis, was published between 1983 and late 1985.

Volume 1 begins with a short chapter written by *J. D. Morrison* on the various ways to obtain optically active compounds. This volume is indeed useful for everyone working on optically active compounds prepared either by resolution, asymmetric synthesis or arising from natural products. It is exclusively devoted to the purpose of measuring enantiomeric excess (*ee*) by direct or indirect methods and is not primarily concerned with the measurement of diastereomeric composition. The analytical methods which are described cover the whole spectrum of techniques with many useful indications for the practitioner. In Chapter 2, *G. G. Lyle* and *R. E. Lyle* present various aspects of polarimetry, including details of commercial apparatus. Determination of maximum specific rotations by competitive reactions is then dealt with in Chapter 3 *(A. R. Schoofs* and *J. P. Guetté)*. In Chapter 4, *K. K. Andersen, D. M. Gash,* and *J. D. Robertson* explain how isotope-dilution techniques can be used to measure *ee* values. Gas chromatographic methods are presented by *V. Schurig* in Chapter 5, while *W. H. Pirkle* and *J. Finn* discuss the separation of enantiomers by liquid chromatographic methods in Chapter 6. The volume concludes with three chapters on NMR spectroscopic methods for the analysis of enantiomers using chiral derivatives (*S. Yamagushi,* Chapter 7), chiral solvating agents (*G. R. Weisman,* Chapter 8), and chiral shift reagents (*R. R. Fraser,* Chapter 9).

Subsequent volumes cover various chemical reactions in which one or several asymmetric centers are created under the control of either external chirality centers (in a reagent or catalyst), or internal chirality centers (in the substrate). The diversity of situations emphasizes the difficulty of defining the exact meaning of "Asymmetric Synthesis", which is the title of this work. Some reactions are clearly oriented towards the creation of asymmetric centers and isolation of chiral products after removal of the chiral auxiliary material. These fit the classical definition of asymmetric synthesis (Enantioselective Synthesis of Chiral Compounds). Another group of transformations is also discussed in the work. In these the chiral centers preexisting in the substrate are not detached after the controlled formation of new elements of chirality. They are diastereoselective reactions which are often of prime importance to the achievement of the total synthesis of natural products. Most of the strategies may be applied to the resolved or racemic substrate, and then fit with the proposed extended definition of asymmetric synthesis.[1] A third group of reactions is directly connected with the use of the chiral pool as source of chiral synthons. Fairly complex chiral molecules can be synthesized by combining small chiral building blocks obtained from cheap natural products (sugars, amino acids, ...). This approach does not necessarily create new asymmetric centers, but involves chemical reactions with specific protecting groups and reactions compatible with the stability of some key stereocenters.

Volumes 2 and 3 have the common title "Stereodifferentiating Addition Reactions". This title, which is not redefined here for the benefit of the newcomer to the field, originates from the classification of the steric course of reactions as proposed by *Izumi* and *Tai*.[2]

Volume 2 begins with a chapter on asymmetric hydroboration by *H. C. Brown* and *P. K. Jadhav*. These authors review the synthesis of chiral compounds by hydroboration of alkenes and further transformations leading to asymmetric C–H, C–OH or C–C bond formation with *ee* values often close to 100%. *M. M. Midland* then presents the asymmetric reduction of carbonyl groups by chiral boranes or modified borohydrides. A survey by *E. R. Grandbois, S. I. Howard,* and *J. D. Morrison* on asymmetric reduction by modified lithium aluminum hydrides follows, some examples being of great preparative interest. Chapter 4 *(Y. Inouye, J. Oda,* and *N. Baba)* includes reductions with chiral dihydropyridines, which can be considered as biomimetic reactions. Chapter 5 *(E. L. Eliel)* covers the addition of chiral nucleophiles to chiral substrates, mostly as an application of the Cram rule. In Chapter 6, *G. Solladié* presents asymmetric syntheses based on the addition of chiral nucleophiles to aldehydes and ketones. The chiral nucleophiles are either organometallic compounds used in a chiral environment, anions of chiral sulfoxides, or chiral ester enolates. Conjugated addition to α,β-unsaturated carbonyl compounds is discussed by *K. Tomioka* and *K. Koga* in Chapter 7 (in those cases where the "chiral help" is either part of the unsaturated carbonyl compounds or of the nucleophile). The specific topic of 1,4-addition of organometallic compounds to alkenyl sulfoxides with the sulfur atom as chiral center is dealt with by *G. Posner* in Chapter 8. Volume 2 is concluded by a review of the alkylation of imine and enamine salts by *D. E. Bergbreiter* and *M. Newcomb*. These are good methods for the asymmetric α-alkylation of aldehydes and ketones.

In Volume 3, four chapters are devoted to the creation of asymmetric centers via enolate chemistry and related processes. In Chapter I, *D. A. Evans* covers the stereoselective alkylation reaction of chiral metal enolates. The various facets of asymmetric aldol reactions are discussed by *C. H. Heathcock* in Chapter 2. A review of asymmetric synthesis via chiral oxazolines is given in Chapter 3 by *K. A. Lutomski* and *A. I. Meyers*, while in Chapter 4 *D. E. Enders* discusses the α-alkylation of chiral hydrazones. Olefin cyclization processes (mostly electrophilic reactions) are dealt with by *P. A. Bartlett* in Chapter 5 (C-C bond formation) and Chapter 6 (carbon-heteroatom bond formation). These processes allow good control to be introduced into the relative stereochemistry of monocyclic and polycyclic systems. In Chapter 7, *L. A. Paquette* deals with asymmetric cycloaddition reactions, particular attention being paid to the Diels-Alder reaction. The last chapter of the volume is devoted to chirality transfer via sigmatropic rearrangements *(R. K. Hill)*, with special emphasis on the Claisen rearrangement.

Volume 4 comprises various topics: reference is made to the chiral carbon pool and also to the use of chiral compounds with asymmetric S, N, P, and Si centers. Chapter 1 (226 pages of the 380 pages) is written by *J. W. Scott* on the readily available chiral carbon fragments and their use in synthesis. A large comprehensive table is included which should prove especially useful to the chemist who is planning a synthetic strategy. Practical information such as the approximate price is given, and many total syntheses using synthons from the chiral carbon pool are presented in detail. There follow four short chapters on the chemistry of chiral compounds with heteroatoms as asymmetric centers (presentation of the compounds and their use in syntheses): Chapter 2 by *M. R. Barbachyn* and *C. R. Johnson* summarizes the routes to various types of chiral sulfur centers and their use in asymmetric synthesis; Chapter 3 *(D. Valentine Jr.)* discusses the methods used to prepare compounds containing a chiral phosphorus center. This is an important field because of the use of phosphanes as ligands in homogeneous catalysis; Chapter 4 *(F. A. Davis* and *R. H. Jenkins Jr.)* then deals with the synthesis and utilization of compounds with chiral nitrogen centers; the final Chapter, Chapter 5, is written by *C. A. Maryanoff* and *B. E. Maryanoff* on the synthesis and utilization of compounds with chiral silicon centers.

Volume 5, on Chiral Catalysis, appeared only a few months ago. It is mostly concerned with organometallic catalysis. Chapter 1 is a general presentation by *H. Kagan* of various types of chiral ligands which can be introduced into a complex. These ligands are classified as mono- or polydentate as well as according to the nature of the heteroatom (P, S, N, O, ...) and location of chirality. In Chapter 2, *J. Halpern* discusses the mechanism of asymmetric catalytic hydrogenation with rhodium complexes. Special importance is given to kinetic data, which allow the location of the origin of enantioselectivity in the catalytic cycle to be determined. The application of homogeneous catalyzed asymmetric hydrogenation is the topic of the next chapter written by *K. E. Koenig*. One application is the Monsanto process for the synthesis of (*S*)-dopa. Efficient asymmetric reductions of various types of functionalized olefins are listed, suggesting some applications. In Chapter 4, *I. Ojima* and *K. Hirai* review asymmetric hydrosilylation and hydrocarbonylation. Asymmetric hydrosilylation can at present give high *ee* values for the reduction of aromatic ketones but the enantioselectivity of hydrocarbonylation must be improved if it is to be used technically. Chapter 5 deals with asymmetric coupling reactions *(T. Hayashi* and *M. Kumada)*. Most of the reactions involve the coupling of Grignard reagents to vinylic halides or allylic alkylations in the presence of chiral organometallic catalysts. In Chapter 6, *S. Otsuka* and *K. Tani* present catalyzed asymmetric isomerization of functionalized olefins. The class of reactions which is detailed is the transformation of achiral allylamines into enamines bearing an asymmetric center in the γ-position with respect to nitrogen. The most effective catalyst is a rhodium/Binap complex; it has recently been used for the industrial synthesis of citronellal and menthol. The next two chapters are devoted to the most efficient and reliable asymmetric synthesis discovered in the past five years. The Sharpless reagent for asymmetric epoxidation of allylic alcohols is now widely used in syntheses, and hundreds of references in the recent literature show the usefulness of this reaction for the preparation of functionalized compounds in 95–98% *ee*. In Chapter 7, *B. E. Rossiter* describes the synthetic aspects and applications of asymmetric epoxidation by various methods, and the author gives details of the results obtained with asymmetric epoxidation by the Sharpless reagent. Applications in the total synthesis of natural products are listed. In Chapter 8, *M. G. Finn* and *K. B. Sharpless* discuss the mechanism of asymmetric epoxidation with titanium-tartrate catalysts. In this relatively long chapter (114 pages) structural information on various Ti-complexes (tartrate derivatives as well as kinetic data) is given. A mechanism is proposed, and the kinetic resolution of racemic allylic alcohols is also considered. Unpublished data on the results obtained with ligands other than diethyl tartrate are given in a table. No major improvements were noticed for these fifty ligands, so that the tartrates, which were the first to be tested, still remain the best choice. A useful (and still unpublished) procedure is described in detail by the authors, namely the possibility of the routine use of catalytic amounts of titanium-tartrate complexes in the presence of molecular sieves. This places the Sharpless epoxidation (which is patented) on the brink of industrial application. Two short chapters bring the final volume of the series to a close. In chapter 9, *J. B. Jones* discusses enzymes as chiral catalysts. This chapter includes an introduction to enzymes (classification, main reactions) followed by many examples of various types of asymmetric syntheses, and is a short but excellent presentation of an extremely important area. A few examples of kinetic resolution are also given. In Chapter 10, asymmetric heterogeneous catalytic hydrogenation is discussed by *K. Harada*. Most of the examples given concern either chiral ketoesters, imino esters or enaminoesters which are hydrogenated in the presence of a metal catalyst. Stereochemical models, based on the interaction with the surface are proposed.

In spite of the large number of authors and topics the complete work appears quite homogeneous in its presentation. Some of the material presented has already been reviewed but, nonetheless, it is very convenient for the practitioner or newcomer to find all the basic information concentrated in one work. Most of the contributions are well written and very informative, and include the most important literature references. There are only a few mistakes. The volumes on stereodifferentiating addition reactions deal with a field which is almost mature and can be considered as textbook material. By way of contrast, Volume 5, Chiral Catalysis, is not so satisfactory, since some areas are not covered, presumably due to lack of space. This is unfortunate because asymmetric catalysis is developing rapidly and is on the verge of industrial application.[3] The

work by *Izumi* and *Tai* on catalytic hydrogenation with metals modified by tartaric acid is neglected and could at least have been discussed in Chapter 10. It is a pity that no section is devoted to catalysis by chiral amines, amino acids or small peptides, despite spectacular results being obtained such as, e.g., the proline-catalyzed cyclization of triketones,[4,5] the alkaloid-catalyzed ketene addition,[6] and the asymmetric alkylation with a chiral phase-transfer catalyst.[7] Moreover, enzymatic reactions are presented in only thirty pages. As stated by the author, this chapter should serve more as an introduction than a comprehensive coverage of the topic because of lack of space. Despite these criticisms, however, the work as a whole is an invaluable tool for the chemist already engaged in the field, and should become a reference work for everybody working on the stereocontrolled synthesis of organic molecules. The stereochemical nature of the series is well evidenced by the names to whom the five volumes are dedicated: *H. S. Mosher, A. Horeau, D. Cram, S. Yamada,* and *V. Prelog.* Asymmetric syntheses and stereocontrolled processes abound in the current literature and are the topic of many international meetings and symposia. This collected work should greatly stimulate the advance of asymmetric synthesis. Perhaps in a few years time a new set of volumes will be needed in order to reassess the state of the art.

Air Pollution and Plants. By *C. Troyanowsky*. VCH Verlagsgesellschaft, Weinheim 1985. x, 298 pp., bound, DM 120.00.—ISBN 3-527-26310-1

This book contains the papers presented at the Second European Conference on Chemistry and the Environment, held in London in 1984 under the auspices of the Federation of European Chemical Societies and the German Chemical Society. They are concerned with the atmospheric chemistry of pollutants (processes involving the formation of photo-oxidants, and photo-degradation processes occurring at aerosol surfaces), the direct and indirect effects of pollutants on plants, trees, and the ground and water systems, and the relevant analytical methods and monitoring programs.

The papers reflect the wide variety of views that exist concerning the effects of atmospheric pollution on terrestrial ecosystems, and also a degree of confusion on the subject, notably with regard to cause-effect relationships. Many of the contributions are informative, but the book is by no means representative of all European research in this field. In particular, there is insufficient information on the basic chemistry involved, and the fact that shortcomings in our understanding of the processes are largely caused by a lack of adequate analytical methods to provide specific evidence for individual pollutants does not come out clearly enough. Some of the papers are only reported as abstracts which are not very meaningful by themselves. The contribution by *B. Ulrich* (Göttingen) concerning the direct and indirect effects of pollutants on forests, and the resulting changes to the ecosphere, is especially well-written and informative. *Ulrich* expresses the view that, although man cannot destroy nature itself, he can destroy the ecosystems on which it depends, and therefore pollution of the atmosphere needs to be eliminated as quickly as possible. An opposite view is given by *E. Weise* (Leverkusen), who asks for further clarification and for priorities to be decided, so as to avoid hasty and mistaken actions.

Biological Oxidation of Nitrogen in Organic Molecules. Chemistry, Toxicology and Pharmacology. Edited by *J. W. Gorrod* and *L. A. Damani*. VCH Verlagsgesellschaft, Weinheim 1985. 445 pp., bound, DM 150.00.—ISBN 3-527-26299-7

Research into the metabolism of organic nitrogen compounds by *N*-oxidation began about 1920 with the isolation of *N*-acetylphenylhydroxylamine from the blood of cats which had been given acetanilide (Ellinger, *Hoppe-Seyler's Z. Physiol. Chem. 111* (1920) 86). Since then many nitrogen-containing xenobiotics have been studied, and in 1978 one of the editors of this book, *J. W. Gorrod,* reviewed progress up to then in this field of research. The present volume is concerned with the latest developments, some of which are extremely interesting, especially with regard to the biochemical pharmacology and toxicology of *N*-oxidations.

A short introductory chapter describes the possibilities of nitrogen oxidation in xenobiotics; the products consist essentially of hydroxylamines, hydroxamic acids, nitroso- and nitro-compounds, oximes, nitrones and *N*-oxides.

The rest of the book is divided into nine sections. The first describes the methods for analyzing *N*-oxidized compounds, especially those for arylhydroxylamines and tertiary amine oxides. Next, the flavin-containing monooxygenase ("Ziegler's enzyme") is discussed. A series of short chapters (about four or five pages each) then deal with pargyline, alicyclic amines, fomocaine, secondary aromatic amines, *N,N*-dimethylaniline, cimetidine, ranitidine and (*S*)-(−)-nicotine. The third section is concerned with oxidation and formation of aromatic amines, especially chemical carcinogens, and dietary control of the bacterial metabolism of the nitro group. The fourth section discusses the oxidation of amides and carbamates, especially of the known carcinogen 2-acetylaminofluorene. The next section deals with the *N*-oxidation of azaheteroaromatic compounds, and the following one with the oxidation of amidines, imines, triazenes, hydrazine and azo compounds.

The following two sections, on *N*-oxidations by prostaglandin-H-synthetase and by the peroxidase-H_2O_2 system, are highly topical and of particular biological interest ow-

ing to their close connection with the metabolism of polyunsaturated fatty acids and with the active hormones derived from these. The biological significance of these peroxidase-catalyzed reactions on model compounds is not yet known. In the final section dealing with toxicology, the interactions of the products of *N*-oxidation with nucleic acids, thiols, α-oxo-acids, hemoglobin, and fatty acids, and their mutagenic effects, are discussed.

On the whole, this collection of articles portrays very well the current state in this field of research. Most of the 47 contributions have been kept short, and give the essentials on their various topics. Readers interested in more detailed information will need to refer to the original papers listed, which may indeed have been the aim of the editors. In view of the flood of original papers that appear scattered through various specialized journals, this book is a good example of a manageable compilation of up-to-date information. The book should make it easier for chemists, toxicologists, pharmacologists and interested biochemists to quickly familiarize themselves with this expanding area of research.

Helmut Sies [NB 741 IE]
Institut für Physiologische Chemie
der Universität Düsseldorf (FRG)

Mass Spectral and GC Data of Drugs, Poisons and Their Metabolites. By *K. Pfleger, H. Maurer,* and *A. Weber.* VCH Verlagsgesellschaft, Weinheim 1985. **Part I: Introduction and Tables.** xxx, 208 pp., bound; **Part II: Mass Spectra and Indexes.** xii, 744 pp., bound, together DM 480.00.—ISBN 3-527-26303-9

The definitive identification of toxic substances by mass spectrometry has rapidly gained importance in recent years. *Karl Pfleger* is a pioneer of clinical toxicology who has used this work to pass on his experience to scientists in general.

These two volumes contain a wealth of clearly arranged GC and MS data which allow rapid identification of measured samples by comparison of spectra and data. Samples can be roughly classified by means of their retention indices, mass spectra are used for final identification. The line spectra are given in the form of computer print-outs and contain details of empirical and structural formulas, exact masses, retention indices and occurrence (urine, blood etc.). Reference spectra for purposes of identification are found primarily via the mass of the molecular ion. If the mass is not available the reference spectra can be located with the aid of the most intense peaks. Compounds are listed in an index so that a reference spectrum can also be found by looking up the name of the appropriate substance. The extensive tables are preceded by short sections on work-up, derivatization for GC analysis and artefacts that may appear in gas chromatographs.

Pfleger together with *Maurer* and *Weber* have created an extremely important work for practical purposes. It must however be mentioned that the book contains numerous errors: missing hydrogen atoms at the indole nitrogen (e.g. p. 200 and 201), missing double bonds in benzbromarone (p. 656) or a missing oxygen atom in the methylation of an alcoholic group (p. XXIV) are less serious but it is, however, very aggravating that computer print-outs that give incorrect masses due to incorrect calibration have been incorporated without any criticism. The key ion in the spectrum of stearic acid is, for instance, shifted from mass 60 to mass 61. The main ion of mass 56 shown in the spectrum of fatty acids is furthermore of minor intensity so that this compound would be difficult to identify. The main ion in the spectrum of bromopride (p. 599) is assigned a mass of 58 which is inconsistent with the structure of a diethylamino compound. As the molecular ion is missing and the other peaks cannot be correlated with the given structure, it seems likely that the spectrum shown belongs to another compound.

Despite this list of faults (which could be continued e.g. literature references are missing), this book written by *Pfleger* and co-workers is of great value for all toxicologists. Providing that it is read with an appropriate degree of criticism, it will be an important aid for helping to solve problems in all laboratories.

Molecular Semiconductors. Photoelectrical Properties and Solar Cells. By *J. Simon* and *J.-J. André.* Springer-Verlag, Berlin 1985. xiii, 288 pp., bound, DM 174.00.—ISBN 3-540-13754-8

An increasing amount of work has been published in recent years on organic, organometallic and polymeric compounds with unusual properties. The preparation of such materials and the study of their electrical, electrochemical, magnetic and optical properties has developed into one of the most attractive fields of research. In the next few years there will certainly be further important publications devoted to extending the range of these materials, and to understanding the phenomena of charge transport, charge interactions and charge storage at a molecular level. Because of the large number of publications in this field, the appearance of a monograph which critically reviews some aspects of materials of this kind is very welcome.

The first two chapters are concerned with the physical basis of charge transport in solids and of photoelectric phenomena. After first describing the behavior of inorganic solids, examples of various "molecular" crystals and polymers are discussed. On account of the wide variety of organic solids, this theoretical treatment is a useful starting point for understanding the processes concerned. These first two chapters will be of particular value to those who are just entering the field, because derivations have been avoided, and the understanding of the text is helped by the inclusion of many tables and figures.

In those classes of materials that are treated as "molecular" semiconductors, the authors have put the main emphasis on phthalocyanines and polyacetylenes. In each case the preparation and general physical properties of the materials are dealt with first, before describing the electrical and photovoltaic properties (including solar cell uses) which are chiefly of interest here. The sections on preparation and morphology are undoubtedly essential, in order to give the reader guidance in planning his own work. Studies of the properties of substances such as phthalocyanines in solution, e.g. their electronic spectra, photophysical properties, and redox behavior, could have been treated more briefly, as they do not really belong to the main subject of the book. It would have been better to increase the emphasis on solid state physical properties. In the chapter on the intrinsic conductivity of phthalocyanines, one would have liked to see a table of characteristic data on important in-

dividual phthalocyanines included. Under doped phthalocyanines, more detailed attention should have been given to the work of the Tübingen group led by *Hanack*. The description of the photochemical hole-burning technique for phthalocyanines, as an alternative method for storage at a molecular level, might also have been expanded. The topics covered in the chapter on polyacetylenes are appropriate to the objectives of the book, and are treated thoroughly.

The final chapter deals with other molecular semiconductors, but in most cases too briefly. Some of the latest "alternative" materials, such as polyphenylene sulfide, polyaniline and polythienylene, are regrettably not included at all. The reputation of the book could have been enhanced by looking at prospects for some of those molecular electronics developments (molecular conductors, storage devices, switches and transistors) which have been mentioned in several publications and at two conferences, but have not yet been achieved practically. The short chapter entitled "Conclusion" does not meet this need.

On the whole this book does fill a gap in the growing field of "alternative" materials. For scientists already working in the field the review is a useful addition to the literature, and it can also be recommended for those about to begin work in the area as a help in getting started.

Photochemical Conversion and Stabilization of Polymers. By *V. Y. Shlyapintokh*. Hanser-Verlag. München 1984. xiv, 470 pp., Hardbound, DM 168.00.—ISBN 3-446-13670-3

The photochemical and photooxidation reactions of polymers, including their photostabilization, are presented in this book in a fundamental manner on the basis of primary physical processes, energy transport, chemical reaction mechanisms, and kinetics. All subjects are discussed in full detail; the emphasis given to a thorough treatment of photostabilization, including the more recent methods of stabilization with hindered amines, qualifies this book as a valuable addition to the monograph literature. Since all its chapters (except for Chapter 4) are written by the same author, which nowadays is rarely encountered in this field, the book exhibits homogeneity in styling, much to the profit of the reader.

Each chapter offers a self-contained treatment of its particular topic. Chapters 1–5 are devoted to photoinduced changes in polymers, Chapters 6–10 to photostabilization: 1—Photophysical processes; 2—Some characteristics of photochemical and dark reactions in polymer matrices; 3—Photooxidation of polypropylene; 4—Photoaging of aliphatic polyamides (by *L. M. Postrekov* and *A. L. Margolin*); 5—Singlet oxygen and the photooxidation of polymers; 6—Protective mechanisms of photostabilizers in model systems; 7—Physical mechanisms of inhibition of the phototransformation processes of polymers in solution; 8—Physical mechanisms of inhibition of the phototransformation processes in solid polymers; 9—Photostability of UV absorbers; 10—Protective action of some photostabilizers. By their length, Chapters 9 and 10 may be considered as the main part of the book; this means that stabilization phenomena are presented in sufficient detail to allow thorough interpretation.

The author with his research group at the Institute of Chemical Physics of the Soviet Academy of Sciences counts among today's most competent contributors to this field in the Soviet Union. His presentation is based throughout on experimental data, partly from his own laboratories, which are being presented and interpreted with great care. A detailed list of references at the end of each chapter provides access to the original literature up to approximately 1979.

This book is a valuable collection of knowledge on the fundamental scientific facts of photoinduced aging and photostabilization of polymers; nevertheless, its aim is not advice on practical application. Though, e.g., in the treatment of photostabilizers, the book concentrates interest upon practically employed stabilizer substances, it may not be considered as a guidebook, neither to the proper choice of stabilizer systems, nor to their applicational properties. Present argument going on with respect to the interpretation of certain results (especially as to the rôle of singlet oxygen in photooxidation) is reflected in the book. This is without doubt one of the useful features of the book, making the reader familiar with currently open questions. On the other hand, some topics, however thoroughly presented (like the Fries photorearrangement in UV absorbers), are of less actual interest today, while certain important aspects (like the controlled photodecomposition induced by additives) are omitted.

On the whole, this book has to be classified as a largely comprehensive and highly informative publication. It is virtually indispensable for those who are scientifically concerned with questions of stability and stabilization of polymers. Furthermore, it is highly recommended for all those chemists, physicists, and students who are interested in questions of reaction kinetics, photochemistry and photophysics. Finally, tribute may be made to the book's excellent appearance.

Computer Graphics in the Study of Metal Cluster Compounds**

By Kim Henrick, Mary McPartlin,* and Jill Morris

Polynuclear carbonylmetal compounds provide convenient molecular analogues for the reactions occurring at metal surfaces during catalytic processes. Many properties of these cluster compounds are determined by the type and distribution of the ligands covering the metal polyhedral surface. Computer simulated space-filling models of these complicated molecules provide readily assimilated information about the arrangement of surface ligands, and in many cases lead to conclusions not readily deduced from other approaches.

1. Introduction

The importance of metal cluster compounds arises from the extra dimension to inorganic chemistry achieved by the presence of several metal atoms in one molecule. The challenge of these polynuclear systems lies not only in exploring their potential for reactions unknown for mononuclear compounds, but also in uncovering the range of possible polyhedral metal core geometries and the unusual bonding modes of the attached ligands. The present rapid expansion in transition metal cluster chemistry is a result of successful collaboration between the synthetic and crystallographic branches of chemistry. X-ray analysis is in most cases essential for complete characterization of a new cluster species, and has revealed discrete molecular structures with as many as 44 metal atoms.[1] The structural and chemical properties of these compounds are largely determined by the type and arrangement of the ligands on the cluster surface.[2,3] Such ligands also appear to play an important role in determining which of several alternative metal polyhedra is adopted by a particular cluster species with a given polyhedral electron count.[4,5] Examination of simulated 'space-filling' models using modern computer graphics techniques has proved a valuable tool in investigating these effects. Two types of surface ligand, apart from the carbonyl group, are particularly important and are being very widely studied. These are the single atom donors H and C (hydrido- and carbido-ligands, respectively), for which a wide variety of bonding modes has been observed.[6–9] Much of the current interest stems from a belief that formation of isolated H and C atoms on the surface of bulk metals is an important step in many catalytic processes.

2. Hydrido Cluster Derivatives

The interaction of hydrogen with transition metals plays a fundamental role in heterogeneous catalysis. Studies of the modes of bonding of H-atoms with polynuclear carbonyl-transition metal compounds are important in providing insight into reactions at bulk metal surfaces for which they are the nearest available molecular analogues. Location of hydrido ligands in transition metal compounds using X-ray analysis presents problems: the presence of metals of high atomic number makes direct location of the electron-deficient hydrogen atoms in a Fourier map very difficult. Even with the latest equipment and techniques there are very few examples in which the X-ray method has directly

located hydrido-ligands in a large cluster, particularly of a third row transition metal.[9]

Neutron diffraction is ideal for H-atom detection but involves equipment which is not readily available, and an equally serious drawback is that relatively large crystals are required. Consequently the most widely used methods for polynuclear metal cluster compounds are indirect; the hydrogen bonding site is deduced from the effect of the repulsive interaction between the 'invisible' hydrogen atom and the surrounding carbonyl ligands. In most cases the extra information about the hydrogen ligand which might be obtained from neutron diffraction studies, such as accurate M–H bond lengths, would be of limited value even if suitable crystals were available, and would certainly not justify the extra expense and time required. We have found that computer graphics can provide a simple and unambiguous method of routinely deciding the hydrogen site from X-ray data.

2.1. Conventional Indirect Methods for the Location of Hydrido-Ligands

In earlier work we have made considerable use of the indirect methods of H-location originally pioneered by *Owston* et al.[10] for mononuclear species and by *Churchill* et al.[11] for cluster compounds. For example, the μ_3-position of the hydrido ligand in the $[HOs_6(CO)_{18}]^{\ominus}$ monoanion (threefold bridging via Os1, Os2, and Os3), was readily deduced by the characteristic 'pushing back' of the neighboring CO ligands together with a lengthening of the respective Os–Os bonds (Fig. 1a).[12] Very similar effects were previously observed by *Churchill* et al. round the μ_3-H ligand sites in the dihydride $[H_2Ru_6(CO)_{18}]$ (Fig. 1b), where the H-ligands bridge opposite faces of the Ru_6-octahedron (Fig. 1b).[11]

Later a more quantitative indirect location of hydrogen atoms, the 'potential energy' technique, was developed by *Orpen* and is very useful for symmetrically bonded H-ligands. For a large range of cluster geometries, H-coordinates calculated from data using this method agree well with those obtained from neutron diffraction data.[13]

The reliability of qualitative indirect methods is illustrated by the results of the X-ray structure analysis of the $[(Ph_3P)_2N]^{\ominus}$ salt of $[HRu_6(CO)_{18}]^{\ominus}$ (cf. Fig. 1c).[14] In contrast to the case of the analogous osmium monohydride $[HOs_6(CO)_{18}]^{\ominus}$ (Fig. 1a) and the corresponding ruthenium dihydride $[H_2Ru_6(CO)_{18}]$ (Fig. 1b), in $[HRu_6(CO)_{18}]^{\ominus}$ no bond lengthening and no 'pushing back' of the CO ligands was observed. The structure in fact looks almost identical to that of the dianion $[Os_6(CO)_{18}]^{2\ominus}$ (Fig. 1d),[12] with none of the disturbance of the CO ligands that would be expected from a surface H-ligand. From these results we concluded that this was the first example of an interstitial H-atom in a carbonyl cluster.[14] This assignment was later strongly contested,[15] mainly because the ^{1}H-NMR data appeared to be more consistent with the direct coordination of hydrogen to a carbonyl group to give a 'formyl-like' ligand. However, a subsequent neutron diffraction analysis of the $[Ph_4As]^{\ominus}$ salt established beyond doubt that the H-ligand is in the center of the Ru_6 octahedron,[16] and vindicated this indirect method of interstitial H-atom assignment. Clearly a more readily assimilated method of presenting the facts about hydrido-ligand steric requirements, deduced from X-ray analysis, would prevent such controversies.

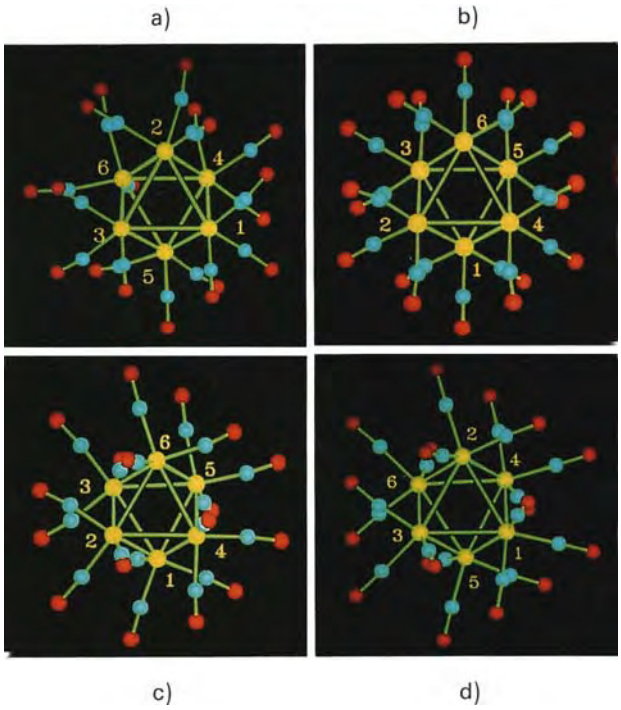

Fig. 1. A comparison of the carbonyl ligand distribution in hydrido and non-hydrido hexanuclear species, determined by X-ray structure analysis, illustrated using conventional computed 'ball-and-stick' models. a) $[HOs_6(CO)_{18}]^{\ominus}$, view onto μ_3-H site; b) $[H_2Ru_6(CO)_{18}]$, view onto one of the two μ_3-H sites; c) $[HRu_6(CO)_{18}]^{\ominus}$, with interstitial H; d) $[Os_6(CO)_{18}]^{2\ominus}$.

2.2. Hydrido-Ligand Location using Computer Graphics

Computer simulated space-filling models of the cluster molecules proved to be ideal for this purpose. We use a versatile program due to *Keller*,[17] which gives a computed model of the molecule, based on atomic coordinates established from X-ray analysis, with the atoms drawn as spheres of radius equal to the appropriate van der Waals value. In the original models the core metal atoms, which are not relevant to an examination of repulsion effects between ligands, partially obscured the surface atoms, and consequently it was difficult to deduce whether the ligands were in contact with each other. This effect arose from the relatively large size of the unnecessary metal van der Waals spheres and subsequent modification of the models by assigning covalent radii to these core atoms (Ru and Os 1.45 Å) allowed a clear view of the surface ligand contacts. Thus modified, the models proved a very valuable and powerful tool for the rapid location of hydrido-ligands in difficult cases.

The technique may first be demonstrated using well established clusters in which the H-site is undisputed. For example, in the space-filling model of the non-hydrido

dianion $[Os_6(CO)_{18}]^{2\ominus}$ (Fig. 2d) there is a symmetrical distribution of the carbonyl van der Waals spheres which are in tangential contact, efficiently covering the cluster surface and almost completely hiding the 'bonding' spheres of the core metal atoms.

In contrast, a similar view of the hydrido monoanion $[HOs_6(CO)_{18}]^{\ominus}$ onto the H-bridged face Os1, Os2, Os3 (Fig. 2a) shows a clear 'hole' in the carbonyl coverage through which the three Os atoms, bonded to the μ_3-H, can be readily seen. When this molecule is rotated in any direction from the bridged face a 'close-packed' array of CO ligands is obtained and the underlying metal atoms are completely obscured. The view of the dihydride $[H_2Ru_6(CO)_{18}]$ onto one of the H-bridged faces (Ru2, Ru4, Ru6, Fig. 2b) is similar to that of $[HOs(CO)_{18}]^{\ominus}$ but shows the three bridged Ru atoms through a more symmetrical 'hole' in the CO distribution. The models of these two hydrides demonstrate that the 'pushing back' of the CO ligands by the hydrido-ligand, and the resultant steric overcrowding, has produced a marked compression of the van der Waals spheres of the adjacent carbon atoms which are no longer in tangential contact as they were in $[Os_6(CO)_{18}]^{2\ominus}$. A contrast is evident in the structure of the analogous ruthenium monohydride $[HRu_6(CO)_{18}]^{\ominus}$ viewed down the C_3 axis onto the Ru2, Ru4, Ru6 face (Fig. 2c). The carbonyl ligands are once more in tangential contact with a distribution similar to that in the dianion $[Os_6(CO)_{18}]^{2\ominus}$ and from whatever direction this monohydride is viewed there is no sign of a 'hole' in the CO coverage and the 'bonding' spheres of the Ru atoms remain almost completely out of sight. Clearly the H-atom is not attached to the cluster surface. Had this type of model been used at the time of the original structure analysis of $[HRu_6(CO)_{18}]^{\ominus}$, the interstitial assignment of the H-atom at the center of the Ru_6 octahedron would probably have been undisputed.

The first application of the computer simulation technique to *location* of an H-ligand in a cluster, for which other methods had failed, was in the study of the neutral iodo-derivative $[HOs_8(CO)_{22}I]$. Indirect methods had allowed a ready assignment of the μ_2-H ligand site in the monoanion $[HOs_8(CO)_{22}]^{\ominus}$ from the ball-and-stick model shown in Figures 3a and 3b.[18, 19] The carbonyl ligands appear to be 'pushed back' from the Os7–Os8 bond, indicating that it is spanned by the H-ligand. In contrast the neutral compound, $[HOs_8(CO)_{22}I]$, obtained by reaction of the monoanion with iodine, has the complicated arrangement of core and surface atoms shown in Figure 3c, and this made it very difficult to apply the normal ligand displacement criteria in attempting to locate the H-ligand.[20]

Furthermore, no evidence could be obtained from the bond lengths nor from Orpen 'potential energy' calculations. In the dihydride $[H_2Os_7(CO)_{20}]$, characterized by *Holden* et al. (Fig. 3d), similar difficulties were experienced in locating the two hydrido-ligands.[21] Examination of computed space-filling models made the location of the H-ligands equally easy in all three cluster hydrides.

The computed Keller model of the monoanion $[HOs_8(CO)_{22}]^{\ominus}$ (Figs. 4a and 4b) shows only one 'hole' in the ligand coverage which is symmetrically located above the two atoms Os7 and Os8, where the μ_2-H site had earlier been deduced (Fig. 4b). Viewed from any other directions the carbonyl ligands are seen to be in close contact, com-

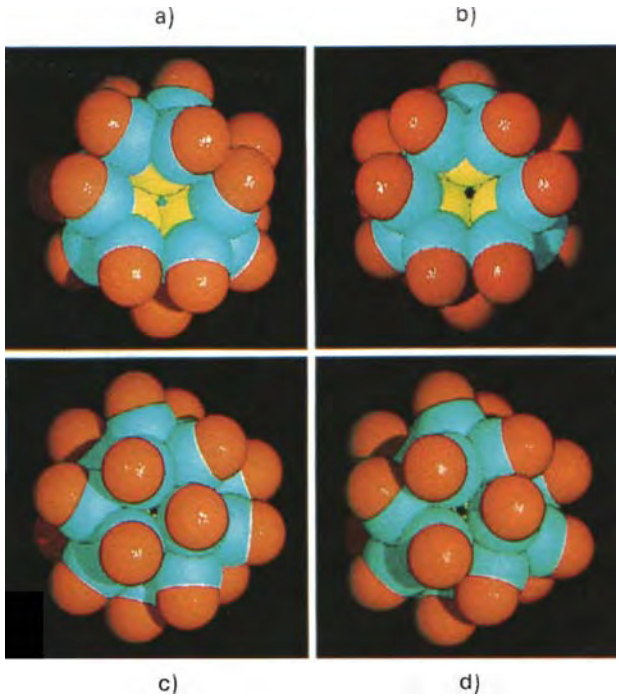

Fig. 2. The carbonyl ligand distribution of hydrido and non-hydrido cluster species (viewed as in Fig. 1) illustrated using computed 'space-filling' models. The van der Waals spheres of the carbonyl-C atoms (blue) are 'close-packed' except for clear gaps at the vacant H-atom sites where the underlying core of the metal 'covalent' spheres (yellow) is visible. a) $[HOs_6(CO)_{18}]^{\ominus}$ view onto the μ_3-H site; b) $[H_2Ru_6(CO)_{18}]$, view onto one of the two μ_3-H sites; c) $[HRu_6(CO)_{18}]^{\ominus}$, with interstitial H; d) $[Os_6(CO)_{18}]^{2\ominus}$.

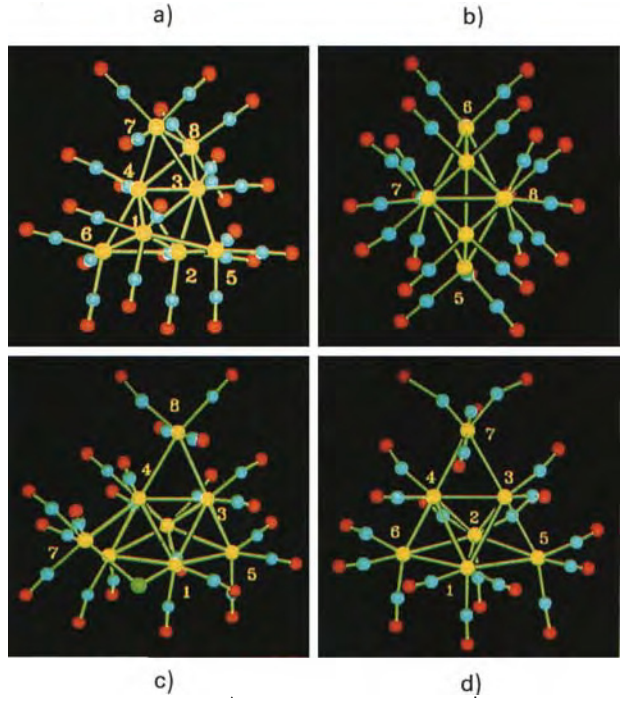

Fig. 3. Conventional computed 'ball-and-stick' models of some large hydridoosmium clusters, calculated using the atomic coordinates from X-ray structure analyses. a), b) $[HOs_8(CO)_{22}]^{\ominus}$, a general view and one onto the μ_2-H site, respectively; c) $[HOs_8(CO)_{22}I]$, view onto the μ_3-H site; d) $[H_2Os_7(CO)_{20}]$, view onto one of the two μ_3-H sites.

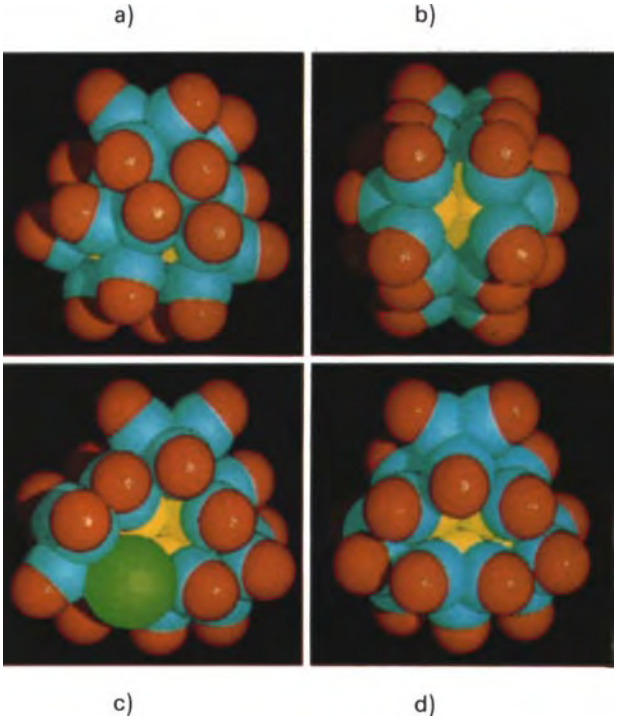

Fig. 4. The distribution of the non-hydrido surface ligands of the same large hydridoosmium clusters as in Fig. 3, illustrated using computed 'space-filling' models in which the ligand atoms (iodine: green) have been assigned van der Waals radii, but the underlying core osmium (yellow) atoms have been assigned covalent radii. a), b) $[HOs_8(CO)_{22}]^{\ominus}$, a general view and one onto the μ_2-H site, respectively; c) $[HOs_8(CO)_{22}I]$, view onto the μ_3-H site; d) $[H_2Os_7(CO)_{20}]$, view onto one of the two μ_3-H sites.

pletely obscuring the underlying osmium atoms of the core as shown, for example, in Figure 4a. The space-filling model of the neutral hydride $[HOs_8(CO)_{22}I]$ was equally unambiguous; there is only one gap in the surface ligand distribution (Fig. 4c).[19] Through this 'hole' in the carbonyl ligands the 'bonding' spheres of the three osmium atoms are visible, and it is apparent that the H-ligand is bridging these three atoms, Os1, Os3 and Os4. The areas of the three osmium atom spheres visible in this case are unequal, in contrast to the μ_3-bridged metal atoms in $[HOs_6(CO)_{18}]^{\ominus}$ and $[H_2Ru_6(CO)_{18}]$, so that it may be concluded that the H-ligand in $[HOs_8(CO)_{22}I]$ is not bonded symmetrically to the three osmium atoms. Very similar results were obtained from examination of the Keller model of the dihydride $[H_2Os_7(CO)_{20}]$. Here, two distinct 'holes' in the carbonyl distribution occur on opposite equivalent triangular faces of the cluster (Os1, Os3, Os4 and Os2, Os3, Os4). The view onto one of these H-bridged faces, Os2, Os3, Os4, is shown in Figure 4d. As in the case of the monohydride $[HOs_8(CO)_{22}I]$, an unusual asymmetric μ_3-H bonding mode is evident for both hydrogen atoms.

The asymmetry of the bridging modes observed in $[HOs_8(CO)_{22}I]$ and $[H_2Os_7(CO)_{20}]$, and the fact that the associated Os–Os bond lengths are not elongated but are in fact rather short in both structures, explains why the H-site could not be located readily by the normal qualitative indirect methods, nor by the Orpen 'potential energy' method which assumes symmetrical bonding of the H-ligands.

2.3. Computer-Generated 'Space-Filling' Models of Compounds with Directly Located Hydrido-Ligands

In the X-ray structure analysis[22] of the carbido(hydrido)nitrosyl cluster $[HRu_6C(CO)_{15}(NO)]$ (Fig. 5a) the hydrido-ligand was located directly, thus giving an opportunity to compare the results with those obtained with computer-generated space-filling models.

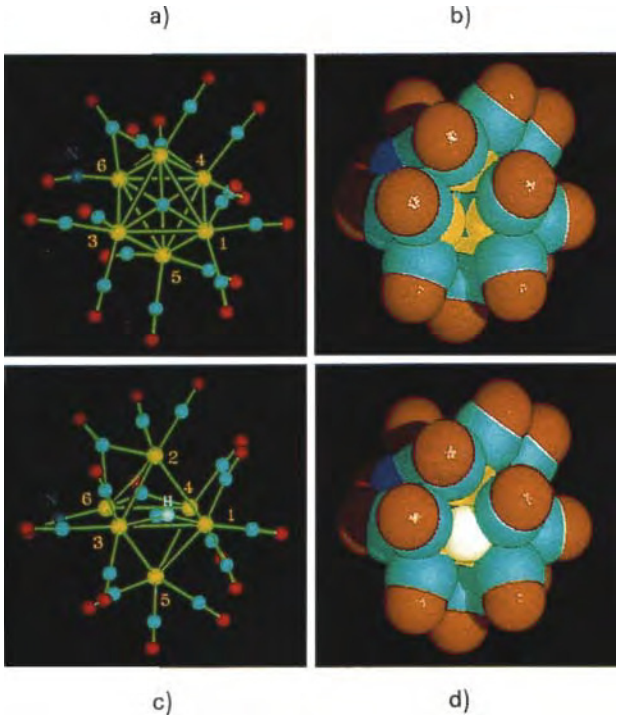

Fig. 5. A comparison of the ball-and-stick and space-filling models for illustrating surface ligand distribution using as example the structure of the carbido(hydrido)nitrosyl cluster $[HRu_6C(CO)_{18}(NO)]$, for which the H-atom was located directly from X-ray data. a) Ball-and-stick model computed without the H-atom; b) space-filling model with the metal atoms visible through the vacant H-site; c) ball-and-stick model including the H-atom; d) space-filling model, with the H-atom van der Waals sphere included (white).

Although the position of the H-ligand could not readily be deduced from the carbonyl distribution using conventional ball-and-stick diagrams, computed space-filling models of the molecule revealed only one gap in the close-packed surface ligands suitable to accommodate a hydrogen ligand (Fig. 5b). This 'hole', above the Ru1, Ru2, Ru3 face, was too asymmetric to be attributed to a μ_3-H atom and it was concluded that the H-ligand was in a μ_2-site bridging the Ru1–Ru3 bond but leaning over the face towards Ru2. After full refinement of the structure the highest peak in the final difference Fourier synthesis (ca. 1 e/Å^3) corresponded to the position of this μ_2-H atom, and the location is as predicted from the examination of the simulated model. Inclusion of the H-atom in the space-filling model (Fig. 5d) shows that the gap in the other surface ligands (Fig. 5b) exactly accomodates it. Figure 5c shows the hydrido-ligand at the observed site in the ball-and-stick model of the cluster.

2.4. Large Hydrido Clusters

As cluster size increases the ratio of surface area to number of metal atoms decreases so that interstitial ligands become important in preventing surface ligand overcrowding. Since the initial discovery of an interstitial H-ligand in a site of *octahedral* symmetry,[14] a number of polynuclear cluster compounds with ligands of this type have been characterized.[3,23] However, it was considered unlikely that H-atoms would be found in the smaller *tetrahedral* sites, except with metals of relatively large covalent radius.[9] Application of computer graphics to the study of some carbido(hydrido)decaosmium species, has indeed provided evidence for H-atoms in M_4 sites of this symmetry. For the dianion $[Os_{10}C(CO)_{24}]^{2\ominus}$, X-ray structure analysis (Fig. 6a) shows that the CO ligands are symmetrically arranged approximately perpendicular to the four flat surfaces of a giant tetrahedral osmium core;[24] this Os_{10}-cluster can, moreover, be regarded as a small fragment of a cubic close packed array of atoms, as is found in several metals.

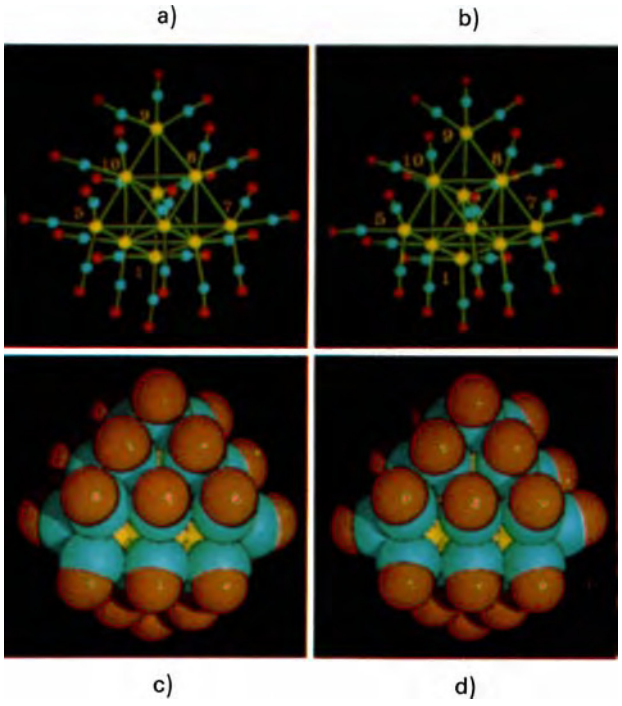

Fig. 6. Comparisons of the almost identical structures observed for the non-hydrido dianion $[Os_{10}C(CO)_{24}]^{2\ominus}$ and the hydrido monoanion $[HOs_{10}C(CO)_{24}]^{\ominus}$, which provide evidence that the H-ligand of the monoanion is not on the surface, but is the first example of an interstitial H-atom in a tetrahedral cavity of a cluster. a), c) Ball-and-stick and space-filling models, respectively, of $[Os_{10}C(CO)_{24}]^{2\ominus}$; b), d) ball-and-stick and space-filling models, respectively, of $[HOs_{10}C(CO)_{24}]^{\ominus}$.

The mono-hydrido derivative $[HOs_{10}C(CO)_{24}]^{\ominus}$ shows an almost identical ligand distribution to that of the dianion, with none of the characteristic displacement of the carbonyls expected if a surface H-ligand were present (Fig. 6b). This evidence together with a slight expansion of one of the capping Os_4 tetrahedra relative to the other three, led us to the conclusion that the H-atom in this cluster is in an interstitial tetrahedral site,[25] the only octahedral site being occupied by the carbido C-atom. The computed space-filling models of the dianion and the mono-hydride are shown for comparison in Figures 6c and 6d, respectively. The carbonyl atoms are 'close-packed' over each of the four 6-atom planar metal surfaces, with their van der Waals spheres in tangential contact. The carbonyls are eclipsed along all edges of both Os_{10}-tetrahedra in almost identical arrangements and remain in tangential contact. Overall, the two Keller models show a remarkable similarity and confirm the conclusion that there is no suitable site on the surface of $[HOs_{10}C(CO)_{24}]^{\ominus}$ to accomodate a hydrido-ligand. This was the first example of a hydrido-ligand in a tetrahedral site of a cluster compound, although this H-atom environment is well known in bulk metals. More recent evidence from X-ray structure analyses indicates that interstitial, tetrahedrally coordinated hydrido-ligands are also present in the non-carbido decaosmium species $[H_4Os_{10}(CO)_{24}]^{2\ominus}$,[26] where the absence of surface H-ligands is again indicated by the close contact of the surface ligands shown in computed space-filling models. It was very difficult to obtain crystals of these polynuclear hydrido-clusters suitable enough for X-ray analysis, and so far it has proven impossible to obtain the larger crystals needed for neutron diffraction studies. Consequently, the computer graphics method provides the best evidence to date for the presence of interstitial hydrogen atoms in these compounds.

3. Polynuclear Carbidometal Clusters

There is a great deal of interest in the chemistry of carbido(carbonyl)metal clusters, because it is widely believed that an important step in the Fischer-Tropsch hydrogenation of CO to produce hydrocarbons involves the formation of carbido species on the surface of the bulk metal catalyst.[6,7] Studies of the reactivity at the carbido-ligands in cluster compounds provide an insight into the reactions of similar atoms on bulk metal surfaces.

3.1. Clusters with μ_5-Carbido Ligands

The first carbido(carbonyl)transition metal cluster compound, $[Fe_5(\mu_5\text{-}C)(CO)_{15}]$ was reported in 1962,[27] and since then a large range of related compounds in which the carbido-C atom exhibits a number of different coordination geometries has been discovered. Many contain the carbido C-atom on the cluster surface in "semi-interstitial" sites. For example, in the series $[M_5C(CO)_{15}]$ (M = Fe, Ru, Os)[27,28,29,30] the C atom is 5-coordinate and lies slightly below the base of a square pyramidal M_5 arrangement as shown in Figures 7a and 7b for $[Os_5C(CO)_{15}]$.[29]

The reactions of the pentanuclear carbidoruthenium and -osmium species have been intensively studied by *Lewis, Johnson* et al.[7] They concluded that the dominant role of the semi-interstitial carbido ligand is to impart unusual stability to the metal framework. Although M–M bond cleavage takes place readily, reactions appear to be limited to those in which the M–C bonds are maintained throughout and any metal rearrangement occurs by swivelling

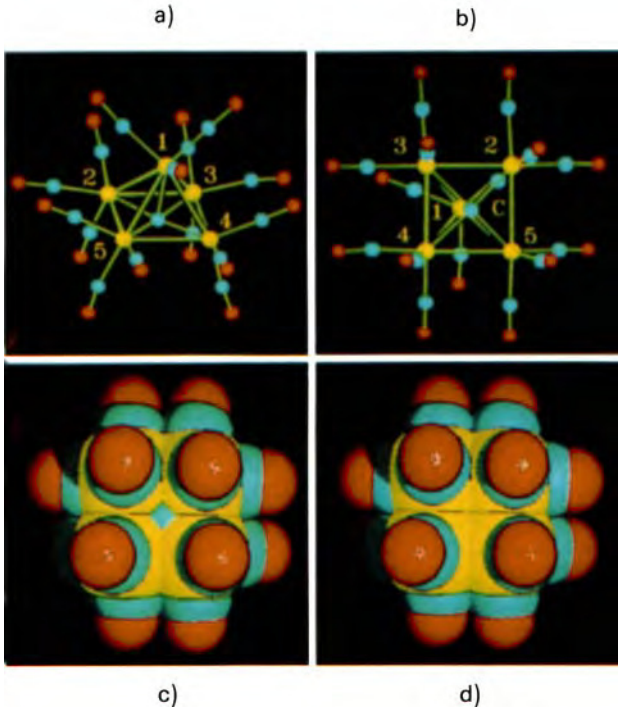

Fig. 7. Comparison of ball-and-stick models of the square-pyramidal structure of the carbido cluster $[Os_5(\mu_5\text{-}C)(CO)_{15}]$ (in which the carbido atom appears 'exposed') with space-filling models which show that in fact the 'bonding sphere' of the μ_5-C atom is completely covered by the van der Waals spheres of the four basal osmium atoms. a), b) Ball-and-stick models, viewed from the side and onto the square base, respectively; c), d) space-filling models, viewed onto the square base from below; the μ_5-carbido ligand is assigned a van der Waals sphere (small rectangle) and a covalent radius (not visible), respectively.

round the carbido-C atom. Significantly, they found no evidence of direct reaction at the μ_5-C atom.

Recent molecular orbital calculations indicate the involvement of the 'lone pair' electrons on the μ_5-C atom in the interaction with the basal metal atoms contributes to the lack of reactivity of the carbido ligand in $[Fe_5(\mu_5\text{-}C)(CO)_{15}]$.[31] Although non-bonded interactions of carbido substituents in clusters are thought to play a role in determining reaction pathways, and are currently being studied by interactive molecular graphics,[32] it has generally been accepted that unsubstituted C-atoms in pentanuclear cluster species are 'entirely exposed' and that there is no steric barrier to their reaction.[6,7,31] This assumption is proved wrong by computer simulated space-filling models of the $[M_5(\mu_5\text{-}C)(CO)_{15}]$ molecules which show that, although the surface ligands provide no steric barrier, the carbido-C atom is not as accessible as the usual ball-and-stick molecular models have indicated. For example the Keller model of $[Os_5(\mu_5\text{-}C)(CO)_{15}]$ (Fig. 7c), which is viewed onto the square-base shows that the van der Waals sphere of the carbido-C atom is almost completely 'swamped' by those of the four Os atoms. In considering the possibility of bond formation at the μ_5-C atom it is more appropriate to assign a covalent radius (0.77 Å) to it, as in Figure 7d. In this model the 'bonding' sphere of this atom cannot be seen because it is completely covered by the the van der Waals spheres of the metal atoms. Consequently, any reactant attempting a direct approach to within bonding distance of the carbido-C carbon atom would be repelled by the metal atoms. Clearly, in addition to the favorable bonding between the C-atom and the metal framework indicated by the MO calculations,[31] a kinetic contribution to the stability of this atom is important.[33] A group undergoing an initial bonding interaction with a metal atom would achieve a reaction pathway of lower energy, and it is significant that bond formation with the carbido atom has only been observed in the special case where a sixth metal adds to the four basal M atoms of $[M_5C(CO)_{15}]$ (M = Ru and Os) to form an octahedral cluster.[7]

3.2. Clusters with μ_4-Carbido Ligands

The first examples of four-coordinate carbido C-atoms were found in the tetranuclear species $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$,[34,35] and $[Fe(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$.[34,36] The 'butterfly' structure of the Fe_4 polyhedron in $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ (Fig. 8a)[35] allows a more exposed site for the μ_4-C atom than any alternative μ_4-arrangement that may be envisaged, such as, for example, that of the distorted square planar $Re_4(\mu_4\text{-}C)$ core reported recently for $[Re_4(\mu_4\text{-}C)(CO)_{15}I]$.[37] Protonation of the μ_4-C in $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ gives $[HFe_4(\eta^2\text{-}CH)(CO)_{12}]$ (Fig. 8b), and is the first example of such a reaction at a cluster carbido atom.[34]

This ready protonation has been attributed to the more accessible nature of the μ_4-bonding site in $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ compared to that of the unreactive μ_5-C atom

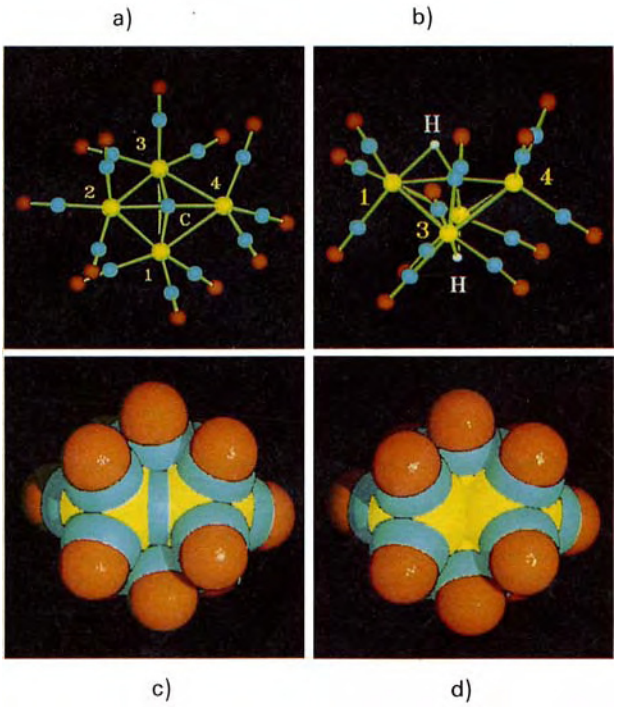

Fig. 8. Conventional ball-and-stick models showing the 'butterfly' structure of the carbido monoanion $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ and that of the product of its protonation, $[HFe_4(\eta^2\text{-}CH)(CO)_{12}]$, together with space-filling models of the reactive monoanion showing that the μ_4-C atom is not exposed but engulfed by the van der Waals spheres of the 'wing tip' iron atoms. a), b) Ball-and-stick models of $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ and $[HFe_4(\eta^2\text{-}CH)(CO)_{12}]$, respectively; c), d) space-filling models of $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$; the μ_4-carbido ligand is assigned a van der Waals sphere (visible as narrow strip) and a covalent radius (not visible), respectively.

in the widely studied $[M_5(\mu_5\text{-}C)(CO)_{15}]$ compounds. The computed space-filling models of the $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ monoanion (Fig. 8c) show that even in this apparently very exposed site the carbido van der Waals sphere is only visible as a narrow strip between those of the adjacent 'wing-tip' metal atoms, Fe2 and Fe4. In Figure 8d, calculated with the more appropriate carbido covalent radius, the 'bonding' sphere of the μ_4-C atom has disappeared completely beneath the van der Waals spheres of the metal atoms.

The (CH) ligand formed by protonation of this C-atom forms an unusual type of η^2-μ_4-bridge with the H-atom bonded to both the C-atom and a wing-tip Fe atom (Fig. 8b).[38] In view of the repulsion by the wing-tip Fe atoms, experienced by any incoming group directly approaching the C-atom of $[HFe_4C(CO)_{12}]^{\ominus}$, we concluded that the attack by the proton involves initial bonding interaction with the iron atom;[33] the available coordination sites on the wing-tip iron atoms are directed towards the uncoordinated side of the C-atom so that sequential bonding of the proton, firstly to an iron atom and then to the C-atom is reasonable. Recent molecular orbital calculations also indicate that it is orbitals associated with the metal atoms that are most probably involved in the initial reaction, and that direct attack on the C-atom is unfavorable.[39] It therefore appears that, as in the case of the μ_5-C atom, there are both kinetic and thermodynamic factors contributing to the stability of μ_4-C atoms.

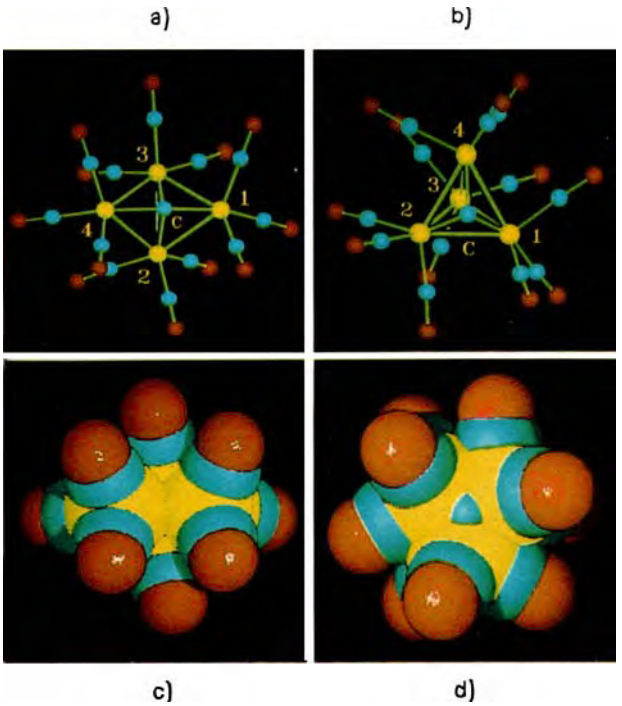

Fig. 9. A comparison of ball-and-stick and space-filling models for the observed 'butterfly' structure of $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$ with those of an estimated tetrahedral structure for "$[Fe_4(\mu_3\text{-}C)(CO)_{12}]$", the proposed intermediate in the reaction of the dianion with hydrogen, demonstrating that in a μ_3-site the carbido atom would be exposed. a), b) Ball-and-stick models of $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$ with a butterfly structure and "$[Fe_4(\mu_3\text{-}C)(CO)_{12}]$" with a tetrahedral structure; c), d) space-filling models of $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$ and "$[Fe_4(\mu_3\text{-}C)(CO)_{12}]$" the carbido ligand is represented as a non-visible and visible covalent sphere, respectively.

3.3. The Effect of Rearrangement of the Metal Polyhedron

The only example of direct hydrogenation of a cluster carbido atom by molecular hydrogen has been observed under oxidizing conditions for the 'butterfly' cluster dianion $[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2\ominus}$ (Fig. 9a) and it is thought that the reaction proceeds via a neutral species "$[Fe_4C(CO)_{12}]$", generated by loss of two electrons from the dianion.[34] The proposed intermediate has only 60 valence electrons in the cluster; consequently, a tetrahedral arrangement can be assumed for the four iron atoms.[40] The resultant metal core rearrangement would force the carbido C-atom to adopt a μ_3-bonding mode on the tetrahedral "$[Fe_4C(CO)_{12}]$" intermediate, illustrated in Figure 9b as a ball-and-stick model computed from estimated atomic coordinates.

In the space-filling model of the hypothetical tetrahedral '$[Fe_4(\mu_3\text{-}C)(CO)_{12}]$' cluster (Fig. 9d), the 'bonding' sphere of the carbido-C atom, previously submerged in the 'butterfly' conformation (Fig. 9c), can now be seen quite clearly above the van der Waals spheres of the iron atoms. Approach of a reactant to within bonding distance of the μ_3-C atom could therefore occur without any repulsion by these metal atoms. On reaction with H_2 the electron count of "$[Fe_4(\mu_3\text{-}C)(CO)_{12}]$" would again increase by two, causing a return to a 'butterfly' structure in the derivative $[HFe_4(CH)(CO)_{12}]$ (cf. Fig. 8b). The computer models therefore demonstrate a possible kinetic advantage from initial cluster oxidation which, by producing a metal geometry rearrangement, forces the C-atom into an exposed μ_3-site and hence lowers the activation energy of the hydrogenation process.

Finally, it should be mentioned that the findings presented here about the different accessibility of μ_5-, μ_4-, and μ_3-carbido ligands using rigid models also apply, in principle, even when it is taken into account that real molecules perform vibrational movements.

3.4. The Extension to Bulk Metal Surfaces

The exposed μ_3-C bonding mode deduced for the C-atom of the intermediate in the protonation of $[HFe_4(\mu_4\text{-}C)(CO)_{12}]^{\ominus}$ (Figs. 9b and 9d) is closely similar to the probable bonding mode which may be envisaged for C-atoms on the 'close-packed' (111) surfaces of cubic close packed or (001) surfaces of hexagonal close packed bulk metals, so that it may be anticipated that isolated C-atoms on these surfaces will be highly reactive. Although some evidence of discrete molecular species with μ_3-C atoms has been reported,[41] the very high reactivity which would arise from their exposed position (Fig. 9b) may account for the fact that none has yet been characterized in the solid state. The metal-protected μ_5-carbido species which have so far proved unreactive in isolated clusters have the type of coordination that is most probable for C-atoms on (100) surfaces of cubic close packed arrays, and the μ_4-C bonding mode would occur along 'steps' between layers; carbon atoms attached in the μ_5- or μ_4-mode at such sites may in

part account for the tenacity with which contaminating C-atoms bind to metal surfaces.[31]

We wish to thank Professor H. Vahrenkamp of the University of Freiburg who first suggested to us the use of computer simulated 'space-filling' models in examining cluster compounds, and Dr. E. Keller for supplying us with a copy of his program and for valuable discussions. We also wish to thank the staff of the North London Computing Centre for encouragement and advice.

High-Resolution Metal-NMR Spectroscopy of Organometallic Compounds

New Analytical Methods (30)

By Reinhard Benn* and Anna Rufińska

Great advances have been made in the past decade in the field of NMR spectroscopy. Apart from the development of completely new areas of application, such as in solid-state chemistry, in materials science, in physiological chemistry, and in medicine, with the introduction of new pulse spectroscopic methods and the application of high magnetic field strengths important progress has also been made in the traditional field of high-resolution NMR spectroscopy. Thus, among other things, the observation of metal resonances has been facilitated and new areas of application have been opened up in inorganic and organometallic chemistry. In this review, recent detection methods for spin-1/2 and quadrupolar metal nuclei are presented and discussed. The use of metal-NMR spectroscopy with respect to problems of a typical chemical nature, mainly from the field of organometallics, is demonstrated for a number of selected metal nuclei (^{25}Mg, ^{27}Al, ^{49}Ti, ^{57}Fe, ^{59}Co, ^{61}Ni, ^{91}Zr, ^{103}Rh, and ^{195}Pt). Relations found empirically between chemical shifts and coordination number, oxidation number, and electronic configuration of a metal bound in a complex are emphasized. Furthermore, cases in which the chemical shifts of metal nuclei can be interpreted in terms of the energy difference of frontier orbitals are presented. This aspect leads to the establishment of a relationship between chemical reactivity and NMR parameters for a series of related compounds.

1. Introduction

With the introduction of stable superconducting magnets and the development of new experimental techniques the last decade of NMR spectroscopy has seen the opening up of completely new areas of application, e.g. in the investigation of solids,[1] in physiological chemistry, and in medicine.[2] At the same time there has also been an active development in high-resolution Fourier transform NMR spectroscopy as it is used in chemistry for investigations of molecular properties. Consequently, a versatile repertoire of different techniques is available for structure determinations and reaction mechanism studies on molecules in solution. In this context the one- and two-dimensional pulse spectroscopic methods[3,4] warrant special mention. Initially, attention was focussed on ^{1}H and ^{13}C pulse NMR spectroscopy, later attempts were made to exploit improved sensitivity and greater signal dispersion for measurements on other magnetically active nuclei.[5] Naturally, these efforts concentrated first on those spin-1/2 nuclei which had already been investigated quite frequently, such as ^{31}P,[6] ^{15}N,[7] or ^{29}Si[8] as well as on some "friendly" quadrupolar nuclei such as ^{2}H,[9] ^{11}B,[10] and ^{17}O.[11] It was soon recognized that insensitive spin-1/2 metal nuclei like, e.g., ^{103}Rh which formerly were accessible only through special double resonance or pulse excitation techniques, could also be recorded directly within reasonable experimental times using the new high-field pulse NMR methods.[12]

Most metals, on the other hand, have a magnetically active isotope with a nuclear spin of quantum number $I > 1/2$. This can lead to resonances with large linewidths, thereby decreasing drastically the sensitivity. For such quadrupolar nuclei the new pulse techniques are only useful to a limited extent and the increase in sensitivity and signal selection available today results mainly from the more favorable Boltzmann distribution of the nuclear spins and the larger dispersion resulting from stronger magnetic fields.

It is mainly on the basis of these improved experimental conditions that the NMR spectroscopy of metal nuclei has been increasingly studied in recent years by several research groups.[5] In this review article it will be shown, primarily with organometallic compounds in solution as examples, how information on the structure, dynamics and chemical properties of metal complexes, which is difficult to obtain or not at all available from other sources, can be derived from the NMR spectroscopy of metal nuclei. Rather than a comprehensive and comparative review of all data already published, we present here a selection of typical results. Emphasis will be laid on such chemical aspects as coordination number, oxidation state, bonding situation and electronic configuration of the complexed metal. Although metal-NMR spectroscopy is only just beginning to assist solving problems regarding the chemical properties of complexes, we shall try to demonstrate these contributions and outline further lines of development.

We shall first give an introductory treatment of the various experimental aspects that originate from the magnetic properties of the metal isotopes. In two further sections we shall deal with the information that emerges from the NMR spectroscopy of metal nuclei. The primary source of such information is the chemical shift of the metal resonance, δ(M), while NMR parameters like relaxation times (T_1, T_2) and scalar spin-spin coupling constants involving metal nuclei, J(M,X), will be cited less frequently, although they are often extremely useful. As example of an

easily accessible spin-1/2 metal nuclei we shall discuss ^{195}Pt, while ^{103}Rh will serve to demonstrate the properties of the less sensitive spin-1/2 nuclei. From the quadrupolar nuclei of the main group elements of the Periodic Table, ^{27}Al and the ^{25}Mg serve as examples of a sensitive and an insensitive nucleus, respectively. As typical examples for the transition metals we have chosen ^{59}Co, ^{91}Zr, and ^{61}Ni.

2. Magnetic Properties of Metal Nuclei

The experimental requirements for NMR measurements as well as the suitability of a given isotope as NMR probe are primarily determined by the magnetic properties of the isotope. On the basis of the nuclear spin quantum number I, the magnetic isotopes can be divided into two classes: To the first one belong nuclei with $I = 1/2$, which usually yield sharp signals (in the case of small molecules the halfwidths $W_{1/2}$ lie between 1 and 10 Hz). The second class comprises nuclei with $I > 1/2$, which show considerably broadened lines with halfwidths of up to several kHz. This renders the observation of such resonances considerably more difficult.

2.1. Metal Nuclei with Spin Quantum Number 1/2

The sensitivity of a spin-1/2 nucleus depends upon its magnetogyric ratio γ, which determines the relative NMR sensitivity, and upon its natural isotopic abundance a (at constant magnetic field strength and constant temperature the intensity of the NMR signal is proportional to $a\gamma^3 I(I+1)$). Table 1 shows both properties for spin-1/2 metal nuclei. The absolute sensitivity or receptivity of a certain nucleus is the product of its relative sensitivity and its natural abundance. Since the signals in Fourier transform NMR spectroscopy[13] result from a summation of several free induction decays (FID), the repetition time for individual pulse experiments emerges as a further important factor which determines the total time of the experiment. A perturbation (for example, an excitation with a radio frequency pulse) changes the original z-magnetization, which is governed by the equilibrium Boltzmann distribution. The time necessary to re-establish the original equilibrium population is characterized by the longitudinal relaxation time T_1. It is proportional to the average lifetime of a spin in a certain energy state. The transport of spin population during the relaxation process to thermal equilibrium according to the Boltzmann theorem is achieved through interactions with fluctuating magnetic fields. These can originate from other magnetic moments present in the solution (the environment), the so-called lattice. However, since many of the magnetically active spin-1/2 metal nuclei only have a small magnetic moment, their interaction with the lattice is often very small and the relaxation times of such nuclei may become quite long. For instance, for silver ions in solution, T_1 of the silver isotope ^{109}Ag can be as large as 10^3 s.[14] This means that under conventional conditions the recording times for the measurement of insensitive spin-1/2 metal nuclei become prohibitively long. Therefore, besides the application of alternative experimental techniques, an estimate of the relaxation times and information about the mechanisms responsible for relaxation is of crucial importance for practical NMR measurements of insensitive spin-1/2 metal nuclei.

Table 1. Classification of spin-1/2 metal nuclei (except lanthanoids and actinoids) according to the magnitude of their elementary magnetic strength [a] and their natural isotopic abundance. Only the most favorable isotope of an element is listed.

Elementary magnetic strength	Natural abundance >90%	10-90%	<10%
strong		^{205}Tl	
medium		^{113}Cd, ^{195}Pt, ^{199}Hg, ^{207}Pb	^{119}Sn
weak	^{89}Y, ^{103}Rh	^{109}Ag, ^{183}W	^{57}Fe, ^{187}Os

[a] The elementary magnetic strength is defined here as the ration $\gamma(X)/\gamma(^1H)$ with $\gamma(^1H) = 26.7 \times 10^7$ rad T^{-1} s^{-1}. Isotopes of medium magnetic strength are those with $\gamma(X)/\gamma(^1H) = 0.9$ to 0.1 (see also ref. [5a]).

2.1.1. Longitudinal Relaxation Times of Spin-1/2 Metal Nuclei

Longitudinal relaxation times can be determined by various pulse techniques. For sharp signals that show no scalar coupling and that are distributed over a relatively narrow frequency range, relaxation time measurements present no problem and can be performed with high precision using the techniques known from ^{13}C-NMR spectroscopy.[13b,c] For nuclei that show scalar coupling to other magnetically active spin-1/2 nuclei, e.g. ^{195}Pt to ^{31}P in $[Pt(PMe_3)_4]$,[6a,15] difficulties may be encountered with T_1 measurements. Firstly, these are intrinsic, since relaxation in a coupled spin system (the spectrometers employed are often not equipped with the appropriate X nucleus decoupler for $X \neq {}^1H$) cannot be described in terms of a simple exponential behavior.[16] And secondly, they can arise from the experimental conditions employed. With the inversion-recovery method,[13b] for instance, it is difficult to invert all five lines of the ^{195}Pt spectrum of $[Pt(PMe_3)_4]$ completely by a single 180° pulse. This is because the lines are distributed over a frequency range of more than 15000 Hz (Fig. 1). The application of so-called composite pulses[17] can improve the inversion. With this technique the 180° pulse is replaced by a $90°_x\,180°_y\,90°_x$ sandwich pulse. Errors arising from imprecise adjustment of the pulse

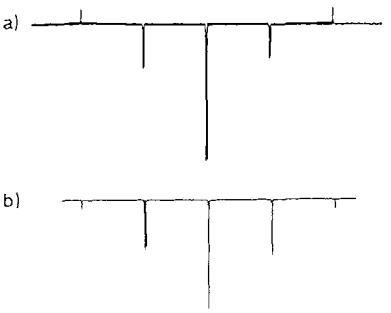

Fig. 1. Inversion of the ^{195}Pt quintet of $[Pt(PMe_3)_4]$ ($^1J(Pt,P) = 3835$ Hz) [15]: a) with a 180° pulse, and b) with a composite $90°_x\,180°_y\,90°_x$ pulse (duration of the 90° pulse 25 μs).

phases can be eliminated by additional phase cycling over all three directions in space.[18]

If spin-1/2 metal nuclei show scalar coupling to neighboring quadrupolar nuclei which have Zeeman states of only a short lifetime, fluctuating magnetic fields arise at the metal nucleus that contribute to its relaxation (scalar relaxation).[13c] This mechanism is, for example, observed for the relaxation of ^{195}Pt in platinum complexes with nitrogen ligands.[19] In the following we shall only rarely mention metal complexes with bonds between spin-1/2 metal nuclei and quadrupolar nuclei, and scalar relaxation as well as chemical exchange will not be considered further. Since only diamagnetic complexes are discussed, we shall also disregard relaxation through interactions with unpaired electrons, which can be very effective in solutions containing paramagnetic species. Brownian molecular motion together with dipole-dipole interactions (DD), spin rotation (SR) or chemical shift anisotropy (CSA)[13b] give rise to fluctuating magnetic fields which can contribute to relaxation of a spin-1/2 nucleus. The latter three of these mechanisms can be detected separately (see Table 2).

Table 2. Relaxation mechanisms of spin-1/2 metal nuclei in diamagnetic solutions (relaxation rate $R = 1/T_1$ under the following conditions: $\omega \cdot \tau_c < 1$, neglection of scalar couplings to quadrupolar nuclei and of chemical exchange, for details see Text) and quantities suitable for determining their contribution to the overall relaxation time.

Relaxation mechanisms	Detection
DD	experimental NOE faktor: $R_{DD}/R = \eta/\eta_{NOE}$
CSA	B_0 dependence: $R_{CSA} \sim B_0^2$
SR	temperature dependence: $\ln(R_{SR}) \sim -1/T$

Dipole-dipole relaxation results from the magnetic interaction of a spin-1/2 nucleus with neighboring magnetic dipoles. The strength of this interaction mainly depends upon the magnitude of the magnetic moments involved and upon the distance between them ($\sim r^{-6}$). The time dependence of the magnetic field at the position of the nucleus of interest follows from the fact that in solution all angles between the distance vector and the direction of the external magnetic field B_0 are possible. Dipole-dipole interaction is detected through the nuclear Overhauser effect.[20] For maximum NOE we have

$$\eta_{NOE} = 1 + \frac{\gamma_H}{2\gamma_X}$$

where η_{NOE} is the NOE enhancement factor (this holds if the correlation time for translations, τ_c, is small compared with the inverse Lamor frequency ω). From a comparison of the experimentally observed NOE enhancement factor η with the theoretical value η_{NOE} the contribution of dipole-dipole interaction to overall relaxation can be determined. While the maximum NOE factors for spin-1/2 metal nuclei are relatively large (Table 3), in practice frequently only small, or even no intensity increases due to proton NOE effects are observed at large magnetic fields (9.4 T) (see Fig. 2). Accordingly, other mechanisms contribute more effectively to the relaxation of spin-1/2 metal nuclei.

Table 3. Maximum signal enhancement factors η for nuclear Overhauser (NOE) and polarization transfer (PT) experiments (INEPT, DEPT), for pairs of protons and spin-1/2 metal nuclei.

X	^{13}C	^{57}Fe	^{103}Rh	^{109}Ag	^{183}W	^{187}Os	^{195}Pt
η_{NOE}	2.99	16.48	−16.89	−9.75	13.02	22.71	3.32
η_{PT}	3.98	30.95	31.77	21.50	24.04	43.42	4.65

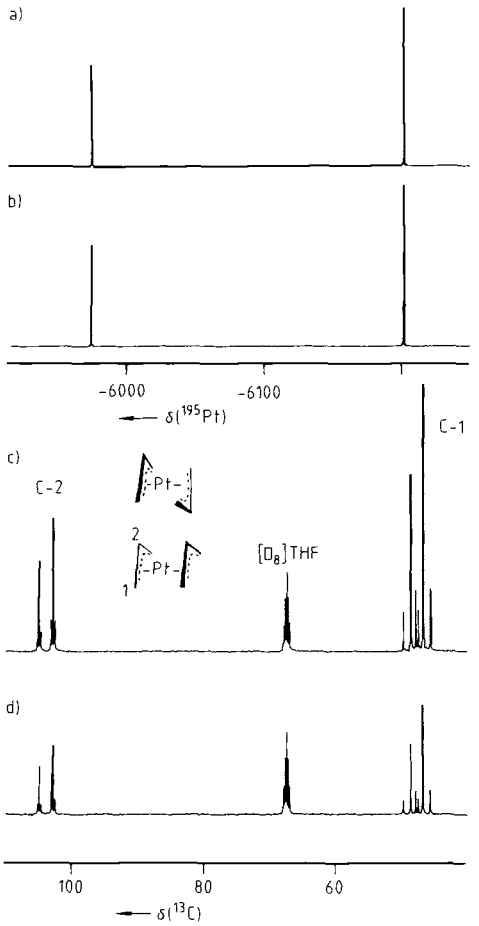

Fig. 2. Determination of the $^1H,^{195}Pt$- and $^1H,^{13}C$-NOE factors of *cis*- and *trans*-[Pt(η^3-allyl)$_2$] at 263 K and 9.4 T in the $^{195}Pt\{^1H\}$-NMR spectrum (a) with and (b) without ^1H irradiation; the $^1H,^{195}Pt$-NOE factor is zero. $^{13}C\{^1H\}$-NMR spectrum (c) with and (d) without ^1H irradiation. The $^1H,^{13}C$-NOE factor amounts to 2.3 for the central C-atoms and to 2.9 for the terminal C-atoms.

At high magnetic fields, and in particular for spin-1/2 metal nuclei with large chemical shift scales, relaxation is dominated by the CSA mechanism. The reason for this is that the nuclear shielding of metal isotopes depends on the relative orientation of the main molecular axis and the direction of the external magnetic field. Molecular motion creates a fluctuating magnetic field which induces transitions that restore thermal equilibrium for the population of nuclear spin states. This mechanism is characterized by the B_0^2-dependence of the relaxation rate. If the measurement of a relaxation time at different field strengths is not possible, then the contribution of this mechanism may, in favorable cases, be recognized by a comparison of T_1 (the longitudinal relaxation time) and T_2 (the transverse relaxation time). For CSA relaxation $T_1 = 7/6\,T_2$ holds[13b], while for the other mechanisms T_1 equals T_2, provided that $\omega\tau_c < 1$.

For certain complexes of Se,[21] Tl,[22] Pb,[23] Fe,[24] Hg,[25] Pt,[15,26,27] and Rh[28] it has been found that at high magnetic field strengths the CSA mechanism makes an important contribution to the relaxation of the spin-1/2 isotopes. For linear $[Pt(PR_3)_2]$ complexes, the ^{195}Pt relaxation rate depends upon B_0^2 for field strengths B_0 between 1.8 and 9.4 T, and extrapolation to $B_0 = 0$ yields a zero intercept (Fig. 3[15]). This demonstrates that ^{195}Pt relaxes exclusively

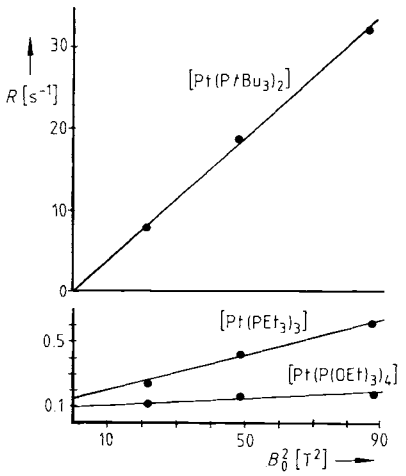

Fig. 3. B_0^2 dependence of the relaxation rate R of the ^{195}Pt nucleus in linear, trigonal, and tetrahedral (phosphane)platinum complexes at 310, 240, and 310 K, respectively. Spectra were measured at 9.4, 7.0, and 4.7 T (corresponding ^1H frequencies are 400, 300, and 200 MHz) [15].

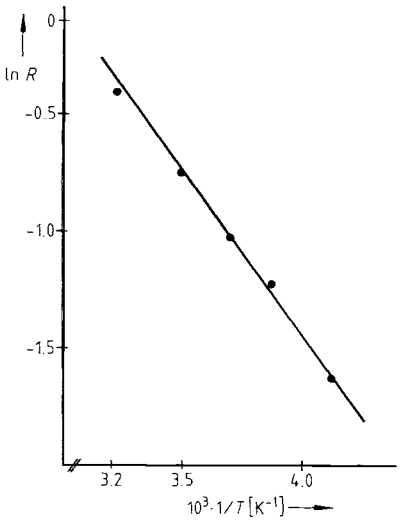
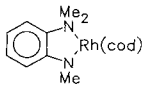
by this mechanism in these compounds. In such complexes the chemical shift anisotropy, $\Delta\sigma$, can amount to several thousand ppm (e.g. $\Delta\sigma(^{199}Hg)$ in $HgR_2 = 5600$ ppm;[29] $\Delta\sigma(^{195}Pt)$ in $[PtL_2] = 11\,140$ ppm).[15]

Relaxation by the CSA mechanism has two important practical consequences: Firstly, information about bonding between the metal and the organic ligand may be lost if, as a consequence of fast relaxation of the spin-1/2 nuclei, the metal satellites in the ^1H- and ^{13}C-NMR spectra are severely broadened, thus precluding their detection.[25b] Secondly, as a positive consequence, especially for insensitive spin-1/2 metal nuclei like ^{103}Rh,[28] ^{57}Fe,[24] and presumably also for ^{183}W, the relaxation times are considerably shortened at high magnetic field strengths (see Table 4). This reduces significantly the time necessary for conventional experiments because fast accumulation of individual free induction decays becomes possible at 9.4 T. However, in unfavorable cases the signal of the metal nuclei can be severely broadened, so that the sensitivity gained due to the high magnetic field is lost.

In addition to the CSA mechanism, the SR mechanism in particular also contributes to relaxation of spin-1/2 metal nuclei in small isotropic molecules. In this case the electrons surrounding the nucleus give rise to fluctuating magnetic fields as a consequence of molecular rotation. A special feature of this mechanism, as opposed to the dipole-dipole and CSA mechanism, is that the relaxation times (for $\omega \cdot \tau_c < 1$) are shortened at elevated temperatures (Fig. 4).





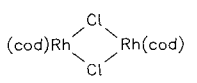


Fig. 4. Dependence of the natural logarithm of the relaxation rate R on the reciprocal of the temperature for $[Pt(PMe_3)_4]$ at 9.4 T [15].

To summarize, we can conclude that the most important relaxation mechanisms for spin-1/2 metal nuclei are spin rotation and chemical shift anisotropy. Their relative contributions depend on the one hand on molecular symmetry and on the other on the experimental conditions (magnetic field strength B_0, temperature, etc.). In the case of linear or anisotropic molecules, CSA is the dominant relaxation mechanism for spin-1/2 metal nuclei at high field strengths, whereas for metal nuclei in a tetrahedral, octahedral, or cubic environment at high temperatures, the SR mechanism is the most effective. It follows that in strong magnetic fields the relaxation times T_1 of insensitive spin-1/2 metal nuclei are shifted into a more favorable range enabling a faster detection of the metal resonances.

Table 4. Dependence of the ^{195}Pt- and ^{103}Rh-relaxation times and mechanisms on the geometry of the complexes. For the complexes listed, the ^1H-^{195}Pt- and ^1H-^{103}Rh-NOE factors are zero at 310 K (for $[Pt(PEt_3)_3]$ at 283 K) and 9.4 T, respectively. COD = cyclooctadiene.

Complex	$[Pt(PtBu_3)_2]$	$[Pt(PEt_3)_3]$	$[Pt(P(OEt)_3)_4]$			$[Rh(acac)_3]$
Complex geometry	linear	trigonal	tetrahedral	quasi square-planar		octahedral
T_1 at 9.4 T [s]	0.03	2.4	5.6	1.53	1.75	39
CSA [%]	100	ca. 50	10	96	80	10
SR [%]	0	ca. 50	90	4	20	90

2.1.2. *Methods for Improving the Signal Intensities*

Despite the shorter relaxation times in strong magnetic fields contributing to a reduction in the experimental time necessary to record NMR signals of spin-1/2 metal nuclei, in view of the low sensitivity of most of these nuclei further improvements for detection are still of interest. In this respect double resonance methods based on selective population transfer (SPT)[30,31] are of importance (Fig. 5). They have been used successfully before for the detection of a number of metal nuclei.[32] The intrinsic drawback of these methods is the fact that they rely on selective irradiation of a certain transition of a multiplet in the proton spectrum.

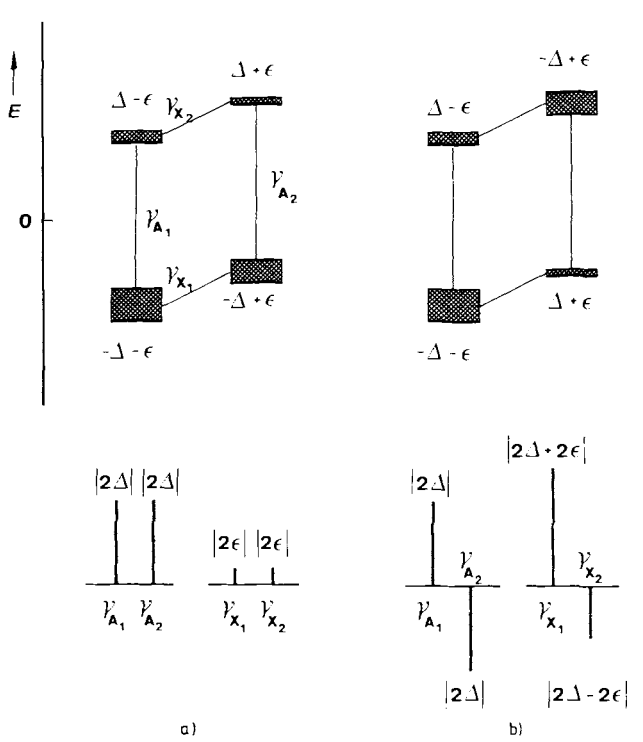

Fig. 5. Schematic representation of the SPT experiment [30] for sensitivity enhancement for a coupled AX spin system (e.g. A = ^{1}H, X = ^{103}Rh). Zeemann energies are $\pm\Delta = \pm\frac{1}{2}\hbar\gamma_A B_0$ for A and $\pm\varepsilon = \pm\frac{1}{2}\hbar\gamma_X B_0$ for X. In a) the relative signal intensities of the insensitive X-nucleus are proportional to ε, in b) to $\Delta \pm \varepsilon$.

In the case of complex and only partially resolved multiplets, as very often appear in the ^{1}H-NMR spectra of organometallic compounds, such a selectivity can seldom be achieved. This problem may be solved, however, by the use of the INEPT (*I*nsensitive *N*uclei *E*nhancement by *P*olarization *T*ransfer)[33] or the DEPT (*D*istortionless *E*nhancement by *P*olarization *T*ransfer)[34] sequence, since these polarization transfer methods allow all lines in the spectrum of the sensitive nucleus to be excited. Convincing applications of these techniques with ^{31}P as a source for polarization transfer have been presented by *Brevard* et al.[35] for the sensitivity enhancement of ^{57}Fe, ^{183}W, ^{109}Ag, and ^{103}Rh resonances in individual metal complexes. Protons can also be used for polarization transfer, as has been shown in the case of ^{109}Ag[36,37] and ^{103}Rh[37] nuclei. The success of such experiments is dependent mainly on the condition that the metal nucleus has a definite scalar coupling to neighboring protons and that these protons are not further coupled to other protons. Such simple cases are seldom encountered in organometallic compounds. For instance, in ^{103}Rh olefin complexes the metal-^{1}H coupling often amounts to only a few Hz[38] and therefore is smaller than the many vicinal inter-proton coupling constants. In such cases the use of the standard INEPT sequence may lead to difficulties and the expected gain in sensitivity is mostly not obtained.[39] If, however, only one multiplet of the ^{1}H-NMR spectrum that shows a metal-^{1}H coupling is inverted selectively, the experiment is known as the selective INEPT experiment (Fig. 6). This technique is of general

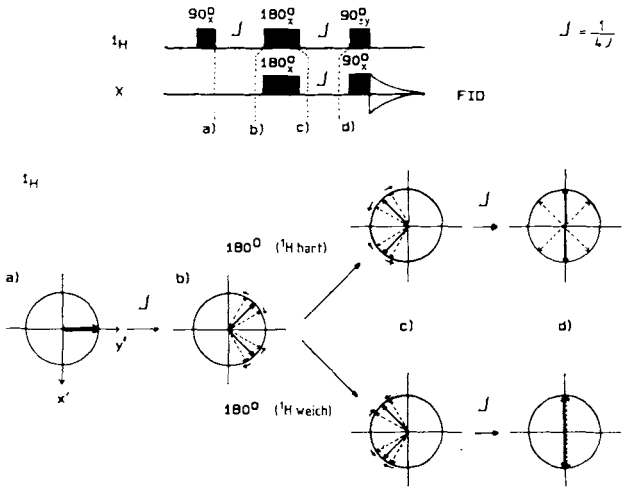

Fig. 6. Above: Pulse sequence of the INEPT experiment for a coupled AX spin system with hard and soft 180° proton pulse [28b]. Below: from the vector diagram in the rotating frame it is apparent that a non-selective (hard) 180° proton pulse does not lead to refocussing of the two proton magnetization vectors in the second time interval. In contrast, a selective (soft) 180° proton pulse only leads to a rotation around the x'-axis and does not interchange the precession frequencies. Consequently, the magnetization vectors which are further split due to coupling to other protons are refocussed at d). A complete polarization transfer is achieved through the 90°$_y$ pulse that follows.

applicability and allows considerable gain in sensitivity for the insensitive metal nucleus. It was first employed successfully in ^{15}N-,[40] ^{29}Si-,[41] and ^{13}C-NMR spectroscopy.[42,43] In particular, in the case of complexes which yield only one metal-NMR signal it is the method of choice, since polarization transfer from only *one* proton to the metal is already sufficient for sensitivity enhancement (Fig. 7).

For polarization transfer experiments a further gain in sensitivity results from the fact that the repetition rate of the pulse sequence is now governed by the relaxation time of the nucleus used as source of polarization transfer (^{1}H or ^{31}P) rather than by the T_1 value of the metal nucleus, which is usually longer. This aspect is of special importance for measurements made at low or intermediate magnetic field strengths.

Besides the improved possibility of recording metal resonances through direct detection by polarization transfer, the indirect detection of chemical shifts of spin-1/2 metal nuclei is of special importance. In their simplest form, indirect techniques are based on a heteronuclear spin-echo experiment designed for the detection of the sensitive nu-

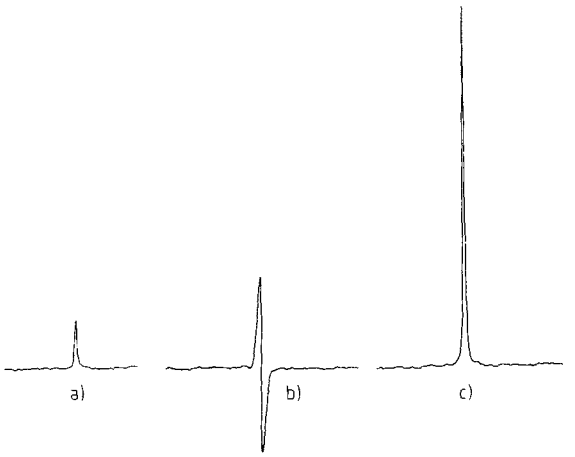

Fig. 7. Comparison of the intensity of the ^{103}Rh-NMR signal at $\delta = -6918$ in acetylacetonato(divinylcyclobutane)rhodium [Rh(acac)(dvcb)] for identical observation times [28b]. a) With proton-noise decoupling. b) In a selective INEPT experiment without proton decoupling. c) In a selective INEPT experiment followed by a refocussing period for the polarized transitions to a pure absorption signal and subsequent proton decoupling.

cleus. This technique was first reported for scalar coupled ^{199}Hg,^{1}H spin pairs.[44-46] The metal-NMR shifts are determined, with improved precision, by two-dimensional experiments (Fig. 8) in which the proton- and metal-NMR shifts are the two frequency axes and in which, in addition, the X,^{1}H coupling constants can also be determined. The important aspect of all these experiments is the detection of chemical shifts and scalar coupling constants of the insensitive spin-1/2 metal nucleus X with the sensitivity of the proton. Even for the two-dimensional version this amounts to an increase in signal intensity by several orders of magnitude.[47b, 48, 49, 137c]

The increased sensitivity achieved through faster relaxation at high field strengths and through application of various pulse techniques (INEPT, DEPT, selective polarization transfer, indirect one- and two-dimensional detection) have completely substituted the driven equilibrium (DEFT)[50] and Quadriga[51] techniques which had previously been used with success for this purpose.

2.2. Metal Nuclei with a Quadrupole Moment

There are many more magnetically active isotopes with $I > 1/2$ and thus with a quadrupole moment (Table 5) than there are with spin-1/2. Conclusions about the NMR sensitivity from a comparison of the individual data given in Table 5 are, however, less practical for quadrupolar nuclei than for spin-1/2 metal nuclei, since the linewidths of the

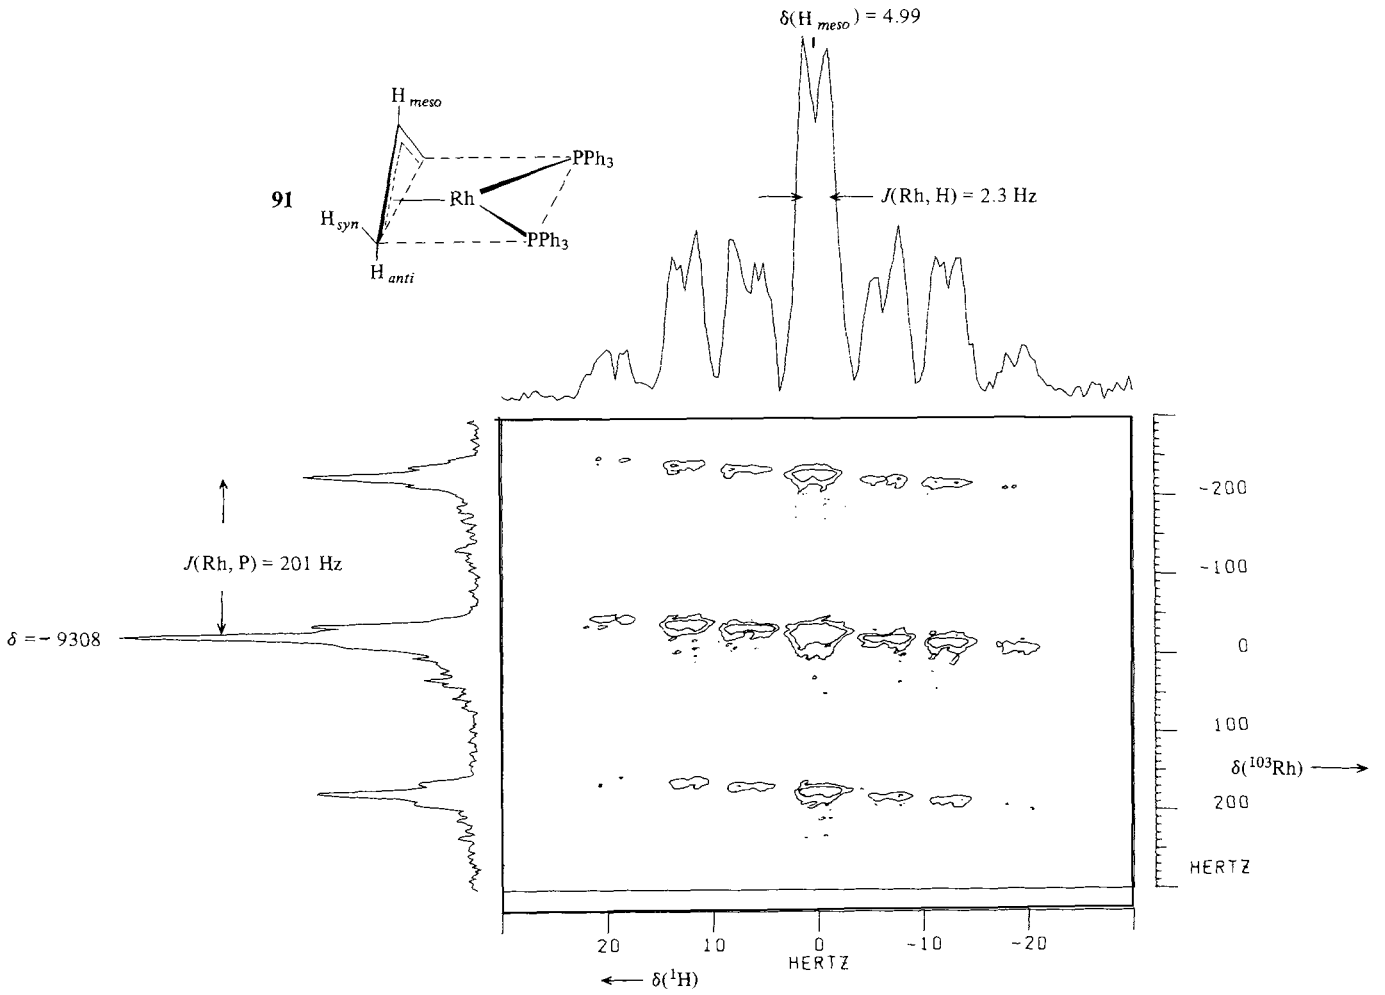

Fig. 8. Section from the two-dimensional ^{1}H{^{103}Rh}-NMR spectrum of [Rh(η^3-allyl)(PPh$_3$)$_2$] **91** in CD_2Cl_2 at $T = 310$ K (ca. 3% solution, 5 mm tube, WH 400). The F_2 dimension shows $\delta(^{1}H) = 4.99$, $J(H,H) = 7.0$ (*syn*), 12.4 (*anti*) and $J(Rh,H) = 2.3$ Hz of the meso protons (cf. horizontal protection). The F_1 dimension shows $J(H,H)$, $\delta(^{103}Rh) = -9308$ and $J(Rh,P) = 201$ Hz (cf. vertical projection) [47b].

Table 5. Classification of the quadrupolar metal nuclei of the main groups and subgroups of the Periodic Table (with the exception of the lanthanoids and actinoids) (see also Table 1). For each element only the nuclide with the highest absolute sensitivity is presented, neglecting the linewidth factor (including this factor, ^{99}Ru would be the more favorable isotope for NMR spectroscopy). Elements that possess a spin-1/2 isotope are also excluded. So far, resonances of ^{197}Au, ^{193}Ir, and ^{177}Hf have not been observed (see also ref. [5a]).

Elementary magnetic strength	Natural abundance >90%	10–90%	<10%
strong	^{7}Li		
medium	^{9}Be, ^{23}Na, ^{27}Al, ^{45}Sc, ^{51}V, ^{55}Mn, ^{59}Co, ^{75}As, ^{93}Nb, ^{115}In, ^{133}Cs, ^{181}Ta, ^{209}Bi	^{11}B, ^{63}Cu, ^{71}Ga, ^{87}Rb, ^{121}Sb, ^{137}Ba, ^{187}Re	
weak	^{39}K, (^{197}Au)	^{25}Mg, ^{91}Zr, ^{95}Mo, ^{101}Ru, ^{105}Pd, (^{177}Hf), (^{193}Ir), ^{189}Os	^{43}Ca, ^{49}Ti, ^{53}Cr, ^{61}Ni, ^{67}Zn, ^{73}Ge, ^{87}Sr

various isotopes can vary quite drastically (between several Hz and several kHz).

For a quadrupolar nucleus in a homogeneous magnetic field two energy terms have to be considered: the Zeemann energy and the energy resulting from interaction of the electrical quadrupole moment Q with electric field gradients q_{zz} that are due to the unsymmetrical charge distribution. For the NMR experiment (large B_0) the magnetic field determines the quantization, while the quadrupole interactions lead to further splitting of the Zeemann levels. In solution, the quadrupole interactions cause an uncertainty of the energy levels and this shortens the lifetime of the Zeemann states.[52]

Apart from its dependence upon the motion of the molecule, characterized in solution by the correlation time τ_c, the linewidth $W_{1/2}$ of a quadrupolar nucleus is also influenced by the magnitude of the spin quantum number I, by the electric quadrupole moment Q, and by the electric field gradient q_{zz}.

$$W_{1/2} = \frac{3}{10}\pi^2 Q^2 \frac{2I+3}{I^2(2I-1)} \frac{e^4}{\hbar^2} q_{zz}^2 \tau_c$$

For a certain nuclide, I and Q are already constant and they determine the linewidth factor $l = Q^2(2I+3)/[I^2(2I-1)]$ (Table 6).[5,52] In practice, this may however lead to a situation where a nuclide which is apparently less favorable for NMR detection because of its low natural isotopic abundance or relative NMR sensitivity is actually more readily detected because of its smaller linewidth. On the other hand, the dependence of the linewidth on q_{zz}^2 leads to very different linewidths for one and the same nuclide: relatively narrow signals are observed for nuclei in a cubic, tetrahedral, or octahedral environment or when τ_c is particularly small due to solvent effects[53] or high temperature.

Table 6. Linewidth factors l for quadrupolar nuclei and their dependence on I at constant Q. For the calculation of $W_{1/2}$, constant values for q_{zz} and τ_c have also been assumed.

I	1	3/2	2	5/2	3	7/2	4	9/2	5	11/2
l	5	1.33	0.58	0.32	0.2	0.16	0.098	0.074	0.058	0.046
$W_{1/2}$[Hz]	10	2.6	1.16	0.64	0.4	0.32	0.19	0.14	0.11	0.09

The broad lines frequently observed for quadrupolar nuclei lead to a number of difficulties in signal identification. The most important sources for errors are background signals and the phenomenon known as "acoustic ringing".[54] It is hardly possible to build a multinuclear probe head where the materials employed do not give rise to NMR signals of their own over the whole frequency range. Since these "probe head signals" are broad, they are especially misleading when trying to detect the resonances of quadrupolar nuclei (Fig. 9). It is therefore advisable (especially for insensitive nuclei and dilute solutions), to identify possible extraneous signals under identical experimental conditions with blank samples (i.e. the solvent only).

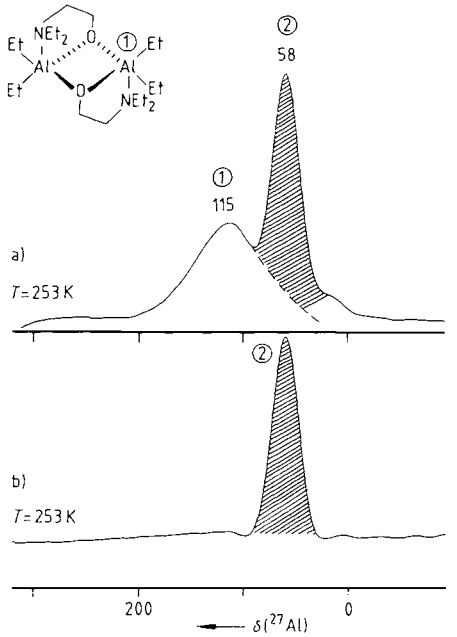

Fig. 9. Background signal (②) in the ^{27}Al-NMR spectrum of a multinuclear probe head. a) ^{27}Al-NMR spectrum of a 0.1 M solution of $[Et_2AlO(CH_2)_2NEt_2]_2$. b) Spectrum obtained with the test-tube filled with solvent only [95, 96a]. For resolution enhancement, the same Lorentz-Gauss transformation was used in both cases before Fourier transformation.

"Acoustic ringing" is caused by mechanical distortions that arise from Coulomb forces in the transmitter and receiver coils immediately after the high-power excitation pulse. In a static magnetic field these mechanical distortions give rise to high-frequency electromagnetic fields that cause broad signals, yielding spectra with "rolling base lines". Excitation pulses of reduced power or longer delays Δ between the end of the excitation pulse and the beginning of data acquisition can partly solve this problem.[55] Signals with linewidths larger than $1/\Delta$ are, however, suppressed by this technique and large phase errors arise over the entire spectrum. In the case of multiline spectra it is very difficult to correct the phase of all signals simultaneously. In a number of cases it is useful to nullify the first

points of the FID (Fig. 10); however, this method has the disadvantage that the signal intensity of fast relaxing quadrupolar nuclei is drastically reduced. Therefore, several pulse sequences[56] have been proposed to suppress error signals of the type discussed above. As a consequence of the proportionality between error signal intensity and pulse width, for application of the sequence $[(90°\text{-AQT})_3$ minus $(270°\text{-AQT})]_n$ (AQT = acquisition time) the error signals should be substracted and the sample signals added. Similar results are obtained on the basis of special sequences using spin-echo experiments.[57,58] The disadvantage of all these pulse techniques, however, is the fact that even with application of composite pulses it is not possible to produce perfect 90°, 180°, and 270° pulses over a spectral range of several 10 kHz.

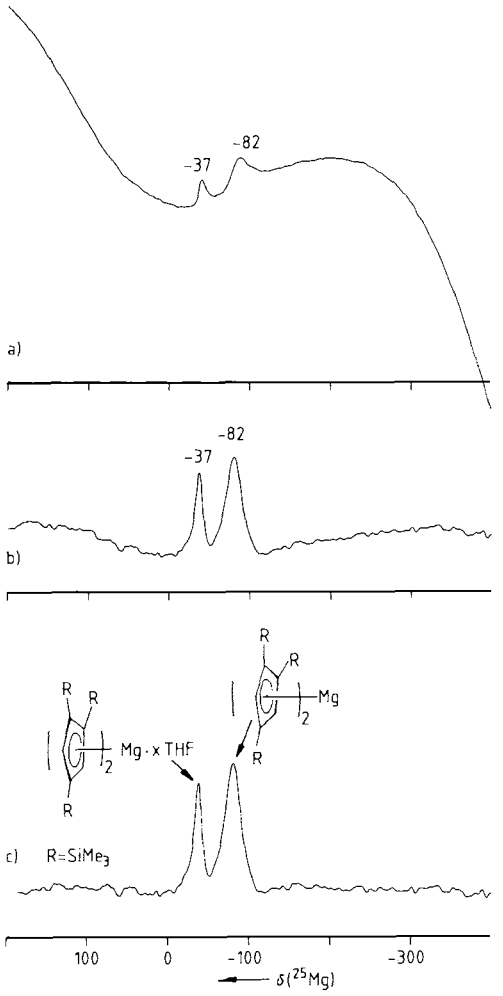

Fig. 10. ^{25}Mg-NMR spectrum of a solution of bis[1,2,4-tris(trimethylsilyl)cyclopentadienyl]magnesium in tetrahydrofuran (THF). a) Direct from the observed FID. b) After setting the intensity of the first six data points of the FID to zero. c) With additional baseline correction.

Pulse sequences aimed at sensitivity enhancement on the basis of polarization transfer experiments have also been proposed for the detection of quadrupolar nuclei.[59,60] Such enhancements have been realized in the case of ^{11}B,[61] ^{2}H,[62] ^{73}Ge[63] using ^{1}H and ^{11}B, respectively, as source for polarization transfer.[64] The short relaxation time of quadrupolar nuclei ($T_1 < 0.1$ s is not unusual for nuclei with $I > 1/2$) and the fact that the magnitude of the scalar spin-spin coupling constants is mostly unknown, however, severely limit the application of such experiments. For quadrupolar nuclei with linewidths of up to several 100 Hz the prospects of two-dimensional NMR experiments of the COSY- and NOESY-type[4] for the detection of connectivities or chemical exchange,[65] respectively, are somewhat more favorable, since they do not require a prior knowledge of J(X,X).

2.3. Metal-NMR Chemical Shifts

According to *Ramsey*,[66] chemical shifts are influenced by dia- and paramagnetic contributions to the shielding constant. In general it is assumed that for metal nuclei, where the chemical shift of even closely related complexes can easily vary by several 100 ppm, the paramagnetic contribution σ_{para} dominates.[67,68] It originates from the local anisotropic motion of the electrons surrounding the nucleus of interest. For related ligand fields, σ_{para} depends to a first (extremely rough) approximation on the average radius $\langle r \rangle$ of the valence orbital and the average electronic excitation energy ΔE:[69]

$$\delta \sim -\sigma_{para} \sim \frac{\langle r^{-3} \rangle}{\Delta E}$$

On this basis there emerges a relationship between NMR chemical shift and the effective nuclear charge of the metal atom, and the electronic energy states of the metal atom in a complex. This relationship will be used quite frequently in the following for a comparative interpretation of NMR shifts.

For practical reasons, because of the reactivity of many organometallic compounds, an internal reference often cannot be used. Calibration of δ-values is therefore frequently achieved by replacing the sample tube by a second tube that contains an appropriate reference, the signal of which is then measured under standard conditions ($\delta \equiv 0$) (Table 7).

All metal-NMR chemical shifts discussed in the following Tables are referred to the relevant standard listed in Table 7.[70] Since these shifts are strongly dependent on

Table 7. External standards for some metal nuclei. The Ξ-values hold for $T = 310$ K.

Nucleus	Compound	Solvent	Concentration	$W_{1/2}$ [Hz]	Ξ [MHz] (±10 Hz)
^{25}Mg	$MgSO_4 \cdot 7H_2O$	D_2O	0.18 mol/L	10	6.121636
^{27}Al	$[Al(acac)_3]$	$[D_6]$benzene	saturated	100	26.056908
^{49}Ti	$TiCl_4$	$[D_8]$toluene	80% (wt.)	4	5.639051[a]
^{57}Fe	$[Fe(CO)_5]$	neat			3.237792
^{59}Co	$K_3[Co(CN)_6]$	D_2O	saturated	100	23.727449
^{61}Ni	$[Ni(PMe_3)_4]$	$[D_8]$toluene	saturated	20	8.936408[b]
^{91}Zr	$[Cp_2ZrBr_2]$[c]	$[D_8]$THF/THF	0.25 mol/L	17	9.297303
^{103}Rh	$[Rh(acac)_3]$	$CDCl_3$	saturated	2	3.186447[d]
^{195}Pt	$H_2[PtCl_6] \cdot 6H_2O$	D_2O	0.50 mol/L	60	21.497151[e]

[a] The Ξ-value given in ref. [119] differs considerably from the value given here. [b] For $[Ni(CO)_4]$ $\Xi(^{61}Ni)$ is 8.936050 [173]. [c] Cp = cyclopentadienyl. [d] Considering the temperature coefficient of this standard (1.6 ppm/K), this value agrees well with the value given in ref. [144b]. [e] The value given in ref. [15] must be replaced by the present value.

concentration, temperature, and solvent, deviations in δ of several ppm for one and the same compound are not uncommon. Similar drawbacks hold for the Ξ-scale[71], which is, however, independent of the choice of a particular reference since all resonance frequencies measured are related to a magnetic field strength B_0 at which the protons of TMS resonate exactly at 100 MHz.

While it is clear from the foregoing discussion that experimental conditions and precision differ for the determination of chemical shifts of spin-1/2 and quadrupolar nuclei, the resulting information is, in principle, of the same type for both groups. In the following two sections we shall outline relations found experimentally between δ(M) and the coordination number, the formal oxidation state, and the average electronic excitation energy ΔE of organometallic complexes. In particular, we shall discuss the chemical shift ranges of the ^{27}Al and ^{25}Mg nuclei as well as those of the magnetically active metal isotopes of the fourth and eighth subgroups of the Periodic Table. With respect to the remaining metal nuclei, we shall refer to recent review articles[5,67,68] and a number of original papers: ^{6}Li, ^{7}Li, ^{23}Na, ^{39}K, ^{87}Rb, and ^{133}Cs;[72] ^{9}Be,[73] ^{43}Ca,[73a,74,75] ^{87}Sr,[73a] and ^{137}Ba;[73a] ^{45}Sc,[67,76] ^{89}Y,[67,77] and ^{139}La;[67] ^{51}V,[67,78] ^{93}Nb,[67] and ^{181}Ta;[67] ^{53}Cr,[67,80] ^{95}Mo,[67,79,80] and ^{183}W;[67,80] ^{55}Mn, ^{99}Tc, and ^{187}Re;[67] ^{63}Cu,[67,81] ^{109}Ag;[35b,36,67,82] ^{67}Zn,[67,83] ^{113}Cd,[67,84] and ^{199}Hg;[67] ^{11}B,[10] ^{71}Ga, ^{115}In,[85] and ^{205}Tl;[86] ^{29}Si,[8,87] ^{73}Ge,[63,87] ^{119}Sn,[87,88] and ^{207}Pb;[87] ^{75}As,[89] ^{121}Sb,[89] and ^{209}Bi.[90]

3. Organometallic Compounds of Main Group Metals

3.1. Relationship between ^{27}Al-NMR Shift and Coordination Number of Organoaluminum Compounds

In organoaluminum compounds[91] the metal can adopt different coordination numbers and undergo various types of bonding. In such compounds the ^{27}Al-NMR shifts correlate with the coordination number (CN) of the Al atom (Fig. 11[92]): The signals for organoaluminum compounds

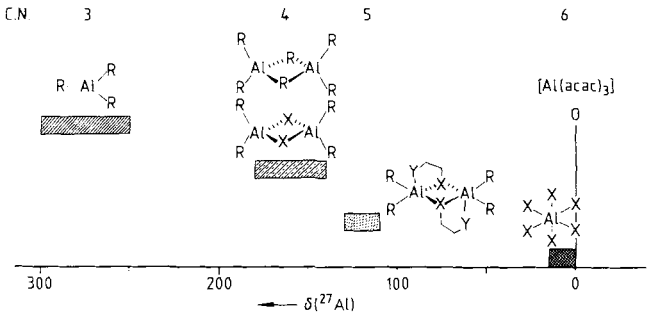

Fig. 11. Dependence of the ^{27}Al-NMR shifts on the coordination number of the Al-atom in organoaluminum compounds [92, 96].

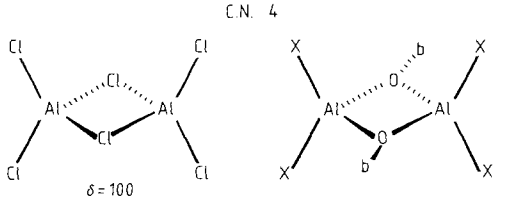

with CN = 3 resonate at the largest δ-values (250–300 ppm), while tetrahedrally coordinated aluminum atoms show $\delta(^{27}\text{Al})$ values of about 150 ppm. Apparently, these $\delta(^{27}\text{Al})$ values are more or less insensitive to the nature of the substituent in the multicenter bond, but are influenced quite strongly by substitution of the non-bridging alkyl groups by moieties with Cl, O, or N atoms (Table 8). Close to the region for tetrahedral organoaluminum complexes, the chemical shifts of aluminum compounds with fivefold coordinated aluminum atoms are found. Such organoaluminum compounds have so far been detected only rarely.[93] Apparently, this coordination number is preferred if bidentate ligands of a certain chain length (such as $O(CH_2)_2XR$, X = O, NR) are employed. In this way an optimal complexation of the second Lewis-base heteroatom can be achieved. The X-ray structure of the complexes **22**[92] and **26**[94] is known, and confirms the fivefold coordination of aluminum in the crystal. In the case of **25**, aside from the $\delta(^{27}\text{Al})$-value, the observation of diastereotopic α-CH_2 protons of the ethyl group in the low-temperature ^{1}H-NMR spectrum supports the existence of fivefold coordinated aluminum atoms. At elevated temperatures, these protons become enantiotopic due to the dissociation of the weaker Al donor bond. The ^{27}Al-NMR shift of the compounds, however, is temperature-independent between -40 and $+100$ °C, thus indicating that dissociation occurs only to a minor extent. The more readily soluble compound **24** yields a signal at $\delta(^{27}\text{Al}) = 123$,[95] which, due to its narrow linewidth, is easily identified even at -50 °C. As

Table 8. ^{27}Al-NMR parameters of **1–27**; measuring frequency: 104.2 MHz; external reference [Al(acac)$_3$] in [D$_6$]benzene (saturated); $T = 300$ K; 20–50% w/w solutions in [D$_8$]toluene; degree of association α, see ref. [91].

in the case of tetrahedral organoaluminum compounds, the variation of the non-bridging groups attached to aluminum leads to a considerable $\delta(^{27}Al)$ shift range for the complexes with fivefold coordinated Al atoms (Fig. 12).[97] Important here, however, is that there are still characteristic shift ranges for complexes with fourfold-, fivefold- and sixfold-coordinated aluminum atoms.

Fig. 12. ^{27}Al-NMR data of $[AlX_2(OBR_2)]_2$ [97] and $[AlX(OAlX_2)_2(OBR)_4]$ [97b] complexes and the 104.2-MHz ^{27}Al-NMR spectrum of $[AlCl(OAlCl_2)_2(OBEt)_4]$. The ^{27}Al-NMR signals of the four- and five-coordinated aluminum atoms, respectively, are clearly separated.

On the basis of their characteristic ^{27}Al-NMR parameters a number of structures proposed for organoaluminum compounds in the literature need reexamination (Fig. 13).[98–101]

The chemical shift region of aluminum atoms with coordination number 3, 4 and 5 is flanked at the high-field side by that of $\delta(^{27}Al)$ for octahedral aluminum compounds, as for instance aluminum tris-acetylacetonate $[Al(acac)_3]$. In accord with the coordination number 6 for Al, $\delta(^{27}Al)$ signals are found at lower frequencies and the lines have relatively small halfwidths. Associates that formally correspond to dialkoxy(alkyl)aluminum compounds have so far not been described in detail. They give signals in the region typical for four- and sixfold coordinated aluminum

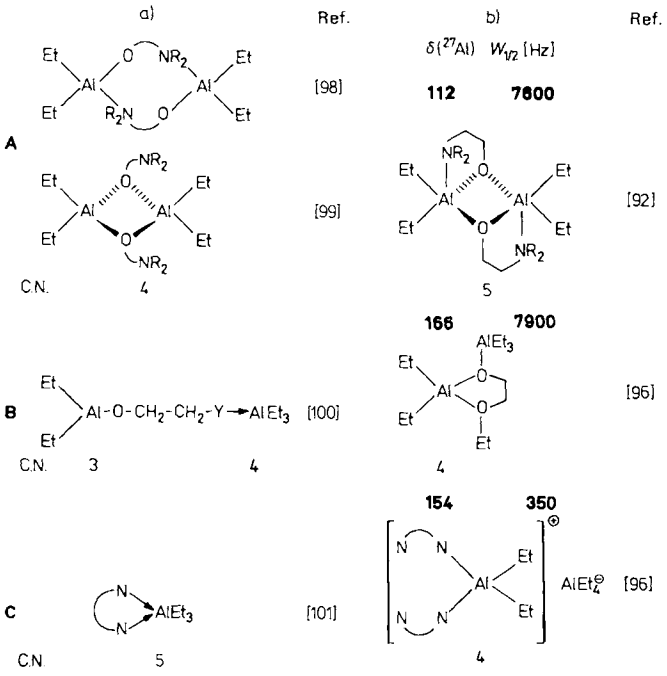

Fig. 13. Proposed structures for organoaluminum compounds. (a) From the literature (b) and on the basis of ^{27}Al-NMR data; **A** = $[Et_2Al(\widehat{O}NR_2)]$ ($\widehat{O}NR_2 = O(CH_2)_2NR_2$), **B** = $[Et_3Al(O(CH_2)_2Y)]\cdot AlEt_4$ (Y = OR, NR_2), **C** = $Et_3Al\cdot\widehat{N}\widehat{N}$ ($\widehat{N}\widehat{N}$ = 2,2'-bipyridyl).

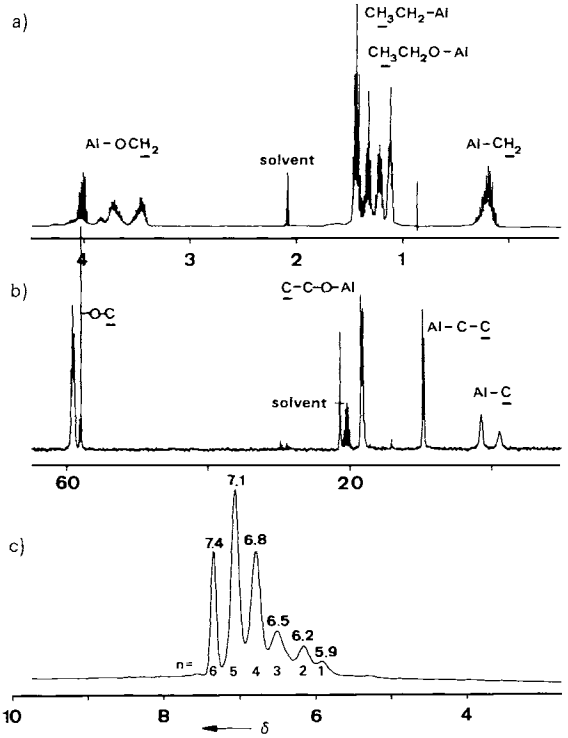

Fig. 14. ^1H-, $^{13}C\{^1H\}$-, and ^{27}Al-NMR spectra of dialkoxy(alkyl)aluminum compounds $[Et_nAl_4(OEt)_{12-n}]$ (n = 1,...6). (a) 400-MHz ^1H-NMR spectrum. (b) 100.6-MHz $^{13}C\{^1H\}$-NMR spectrum. (c) 104.2-MHz ^{27}Al-NMR spectrum in the region for octahedral coordinated aluminum.

atoms. For this reason and in agreement with mass spectroscopic results these compounds have been described as mixtures of $[R_nAl_4(OR)_{12-n}]$ (R = Et, n = 1...6) with a central, sixfold coordinated aluminum atom (Fig. 14),[92,96a] similarly to the tetrameric aluminum alkoxides.[102] Even though this structure proposal results from a combination of mass spectrometry and ^{27}Al-NMR spectroscopy, comparison of the non-resolved ^{1}H- and ^{13}C-NMR spectra with the ^{27}Al-NMR spectrum, which is well resolved in the region around 7 ppm, emphasizes immediately the practical importance of metal-NMR spectroscopy.

3.2. ^{25}Mg-NMR Spectroscopy for the Characterization of Organomagnesium Compounds

Organomagnesium compounds[103] play an important role in preparative organic chemistry. So far, ^{25}Mg-NMR investigations have concentrated on biological systems and inorganic complexes,[5] and only recently has the chemical shift range of organomagnesium compounds been determined.[104,105] In THF, the compounds R_2Mg, RMgX and MgX_2 (R = alkyl, aryl, X = halogen) are monomeric[106] over a wide range of concentrations and their $\delta(^{25}Mg)$ values lie between 0 and +100 ppm (Table 9).

The halfwidth of the ^{25}Mg-NMR signal of $MgBr_2$ in THF varies between 280 K (50 Hz) and 340 K (55 Hz) and reaches a minimum with 35 Hz at 330 K. This indicates a transition from a quasi octahedral[107] to a tetrahedral coordinated species as a consequence of the elimination of two THF molecules at higher temperatures.

From their characteristic signal positions at 310 K all three species present in the Schlenk equilibrium (Et_2Mg, EtMgBr and $MgBr_2$) can be detected.[104] One finds an average ^{25}Mg signal at $\delta = 54$, corresponding to an equilibrium shift in the direction of EtMgBr[106,108] at 340 K. Since the equilibrium constant for methylmagnesium bromide is larger than for ethylmagnesium bromide (K = 30 as compared to 5.1[108]), the first mixture of compounds already yields an average signal at $\delta = 67$ at T = 300 K.

The ^{25}Mg-NMR signals of bis(cyclopentadienyl)magnesium compounds appear outside of the range given above:[104,105] in unpolar solvents like toluene $\delta(^{25}Mg)$ values of about $\delta = -85$ have been measured for **32**, **34**, and **35** (Fig. 10).[109] The halfwidths of these resonances are unusually narrow (100–500 Hz), and have been interpreted in terms of a predominantly covalent bonding situation in η^5-Cp-Mg.[104,105] Here, ^{25}Mg-NMR spectroscopy provides a direct contribution to the controversal discussion of the bonding type in these systems (ionic or covalent).[110] For the elucidation of the bonding situation in allylmagnesium derivatives a number of complicated and subtle experiments and calculations have been performed:[111,112] The ^{25}Mg-NMR shift of **30**, with a value of $\delta = 70.4$, immediately demonstrates that the allyl groups are σ-bonded to magnesium.

The narrow linewidths of the ^{25}Mg-NMR signals of Cp-Mg derivatives also allow coordination compounds of Cp_2Mg with O-, N-, and P-containing Lewis-bases to be characterized with the help of ^{25}Mg-NMR spectroscopy.[104,105] In toluene, equilibria are established, from which, in some cases, defined complexes (1:1 adducts) could be isolated. For solutions of Cp_2Mg in different Lewis-bases a linear correlation between their ^{25}Mg-NMR shifts and ^{13}C-shifts of the corresponding Cp signals results (Fig. 15). The solutions of Cp_2Mg in anisole, diisopropyl ether and triethylamine show the same ^{25}Mg-NMR shifts as those of Cp_2Mg in toluene or cyclohexane (not shown). Complexation of Cp_2Mg by these Lewis-bases is therefore negligible. On the other hand, the ^{25}Mg-NMR shift of a solution of Cp_2Mg in PMe_3 is a direct proof for the coordination of phosphanes to organomagnesium com-

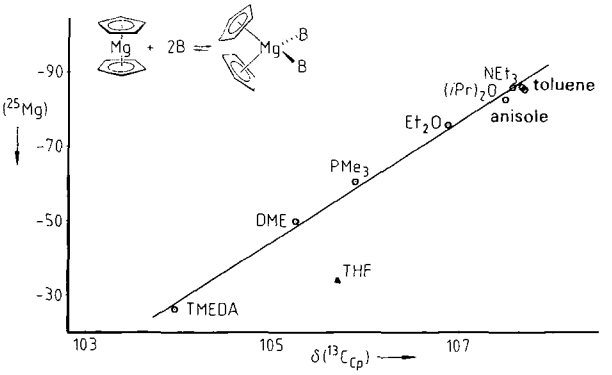

Fig. 15. Plot of the ^{25}Mg-NMR shifts of $[Cp_2MgB_2]$ complexes (solvents function as Lewis bases B) against the ^{13}C-NMR shifts of the Cp ligand in the given solvents [104, 105]. DME = 1,2-dimethoxyethane; TMEDA = tetramethylethylenediamine.

pounds. The ability of the Lewis-bases to coordinate increases in going from diethylether to tetramethylethylenediamine, a tendency which is reflected in a shift of the ^{25}Mg-NMR signal to higher δ values. The tetrahedral coordination of the metal atom has been confirmed in the case of the chiral 1,3-bis(dimethylamino)butane ligand by low-temperature ^{13}C-NMR spectroscopy (two Cp signals). The positions of the signals of Cp_2Mg in THF do not fit in the linear correlation of the ^{13}C- and ^{25}Mg-NMR data (Fig. 15). Hence, in agreement with chemical results, a coordination number five is proposed for Mg in THF through coordination of three THF molecules.[104, 105, 113] In substituted magnesocenes the ability of THF to coordinate to the metal is diminished: **35** exists in THF as a mixture of THF-free (**35**) and THF-complexed (**36**) compounds (see Fig. 10 and Table 9); in the case of **34** the ^{25}Mg-NMR shifts are nearly identical in THF and toluene, thus indicating negligible complexation by the solvent.

^{25}Mg-NMR spectroscopy is also useful for the detection and characterization of RMgR′ compounds (R = indenyl, cyclopentadienyl; R′ = alkyl, alkenyl, alkoxy) that are formed through comproportionation.[105] For instance, a 1:1 mixture of **32** ($\delta = -33.8$) and **30** ($\delta = 70.4$) in THF gives a ^{25}Mg-NMR signal at $\delta = -14.7$,[114a] which, through its deviation from the arithmetic mean of the chemical shifts of both individual components, immediately indicates the existence of a mixed compound **38**. This underlines the advantage of ^{25}Mg-NMR over the detection by ^{13}C-NMR spectroscopy.[114b]

4. Organometallic Compounds of Transition Metals

4.1. Metals of Group 4A

So far only very few NMR investigations have been carried out on the early transition metals. In the case of metals of group 4A there are presently only five publications dealing with titanium isotopes[115–119] and only three papers[120–122] on ^{91}Zr-NMR spectroscopy which focus upon chemical problems, while of the two magnetically active Hf isotopes no NMR investigations with any chemical relevance are known. As in the case of the MX_4 compounds (X = halogen) the metal resonances of $[Cp_2MX_2]$ complexes of Ti and Zr show an inverse halogen dependence[67] (Table 10). The reduced shielding of Ti in $TiBr_4$ as compared to $TiCl_4$ has been explained with the $1/\Delta E$ dependency of the paramagnetic shielding contribution.[115] The ^{49}Ti-NMR shifts of titanocene derivatives show an inverse correlation with Ti($2p_{3/2}$) bonding energies which were determined from photoelectron spectra.[117] A similar relationship was found upon comparison with the corresponding methyl-substituted titanocenes $[CpCp^*TiX_2]$ and $[Cp^*_2TiX_2]$. A considerable shift to higher frequencies has also been observed in the case of **62** (compared to **63**). These results show that a simple interpretation of metal resonances solely on the basis of charge density effects is not possible, but that the $1/\Delta E$ term of the paramagnetic shielding contribution can be of considerable importance.

For a further discussion of these relationships, a comparison of the $\delta(^{91}Zr)$ values in complexes of the type

Table 10. ^{49}Ti- and ^{91}Zr-NMR shifts and halfwidths of simple halometal compounds. For **51** and **52**, average electronic excitation energies ΔE of 34840 bzw. 28680 cm^{-1}, respectively, have been estimated [115]. $Cp^* = Me_5C_5$.

Compound	δ(M)	$W_{1/2}$ [Hz]	Lit.

$[Cp_2ZrBr_2]$ **64**	0	15–20	[122a]
$[Cp_2ZrI_2]$ **65**	126	134	[120]

$[Cp_2ZrX_2]$ with those in $[Cp_2Zr(diene)]$ complexes[124, 125] is of interest (Table 11), since for both systems ΔE can be estimated with the help of MO diagrams.[126–129] In $[Cp_2Zr(butadiene)]$ complexes, the diene can be coordinated in the *s-cis*-η^4-conformation (**73**) or in the *s-trans*-η^4-conformation (**72**).[124] For a ca. 1:1 equilibrium mixture of **72** and **73**, however, only a broad unresolved ^{91}Zr-NMR signal is observed at $\delta = -384$ ($W_{1/2} = 3100$ Hz), even at higher temperatures (T = 353 K). The high shielding of the ^{91}Zr nucleus correlates with the relatively large HOMO-LUMO gap (approx. 2.3 eV[128]) in these com-

Table 11. ^{91}Zr-NMR shifts and halfwidths of organozirconium complexes at 37.12 MHz [122, 123]. $T = 310$ K, external standard: **64**; COT = η^8-cyclooctatetraene. Cp = η^5-cyclopentadienyl.

plexes (Fig. 16), so that the paramagnetic contributions to the shielding constant via the $1/\Delta E$ term are therefore comparatively small. For **63**, qualitatively the same MO diagram can be assumed as for **55**.[126, 129] Consequently, in the bent metallocenes the frontier orbitals $1a_1$, b_2 and $2a_1$ possess mainly metal character, while the b_1 and a_2 orbitals have considerable ligand character. For two residues σ-bonded to Zr the respective n+n and n−n orbital combinations are bonding and a_1 constitutes the LUMO of the complex. The HOMO-LUMO gap in these 16e compounds can be assumed to be smaller than in the 18e-diene complexes discussed above.[129] It is therefore plausible that the $1/\Delta E$ contributions to the paramagnetic shielding term for the $[Cp_2ZrL_2]$ complexes with L=σ-ligand are rather large (cf. **61–65** in Table 10 and **72–75** in Table 11).

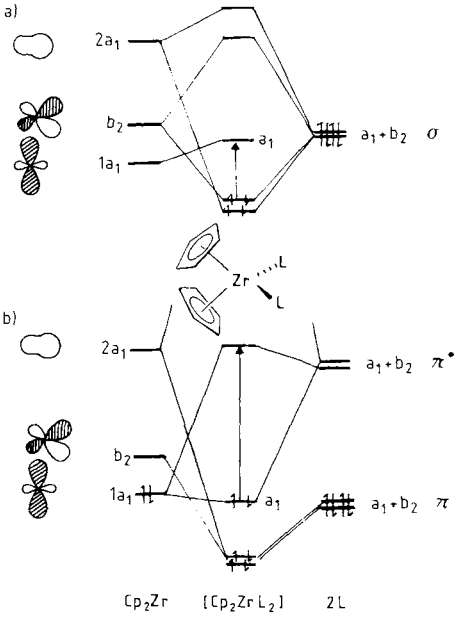

Fig. 16. Qualitative MO diagram for $[Cp_2ZrL_2]$ complexes [126]: (a) L=σ-ligand as halogen or alkyl and (b) L=olefin. For $[Cp_2Zr(\eta^4\text{-}C_4H_6)]$ a HOMO/LUMO gap of 2.3 eV was calculated [128]. For the σ-ligand, on the other hand, a smaller value can be assumed [129].

In the 16e complexes **67**[131] and **68**[130] $\delta(^{91}Zr)$ is about +100. As in the case of substitution at the η^5-Cp residue, methyl substitution at η^3-allyl and η^4-butadiene ligands leads to deshielding of the ^{91}Zr nucleus. Apparently these effects are additive: to a crude approximation the deshielding of Zr per methyl substituent amounts to 40 to 60 ppm. Similar effects are also observed upon methyl substitution in the 18e complexes of the $[Cp_2Zr(diene)]$ series.[122]

Since the shifts of Ti and Zr in organometallic compounds cover a large range and the signals are relatively narrow, high-field ^{49}Ti- or ^{91}Zr-NMR spectroscopy could be a valuable analytical method. The conversion of an 18e complex of the type $[Cp_2Zr(\eta^2\text{-}C_2H_4)_2]$ into a 16e metallacycle is symmetry-allowed,[126, 127] and on the basis of the different NMR shifts for Zr in both types of complexes the study of the relevant reactions with metal-NMR spectroscopy seems promising.

4.2. Metals of Group 8

4.2.1. The Elements of the Iron Group

The detection of magnetically active isotopes of the elements of the iron group (see Tables 1 and 5) is difficult, even with modern NMR techniques. However, the few ^{57}Fe-NMR investigations published so far[24, 35, 51c, 132–137] have clearly shown the potential of this spin-1/2 nucleus as a structural probe, inter alia, because it is important for chemical applications that in organo-iron $\delta(^{57}Fe)$ for Fe^{II} complexes is larger than for Fe^0 complexes (Fig. 17). This can be explained by the influence that electron density effects have upon the paramagnetic shielding contribution. In addition, the weaker shielding of the ^{57}Fe nucleus in ferrocene as compared to Fe^0 complexes might be caused by the $1/\Delta E$ term. A crude estimate for the ΔE term using the HOMO-LUMO gap shows that in $[Fe(\eta^4\text{-}C_4H_6)(CO)_3]$ it amounts to 2.9 eV[128] (extended Hückel MO calculations), while in $[Cp_2Fe]$ a value of 2.7 eV can be estimated from UV spectra.[138] As in the complexes $[Cp_2MX_2]$ (M=Ti, Zr), methyl substituents at the Cp-ring of the ferrocene cause a deshielding of the metal nucleus.[134] The great versatility of organoiron chemistry and the improved detection methods[137c] lead one to expect a broader application of ^{57}Fe-NMR spectroscopy in the near future. On the basis of the first measurements carried out on the ^{99}Ru quadrupolar nucleus[139–142] the same holds true for Ru complexes, since the halfwidths of these resonances are comparatively narrow even in unsymmetrical surroundings. In the case of the spin-1/2 nucleus ^{187}Os, apart from a paper dealing with the reference compound OsO_4,[143] only one publication concerning chemically relevant applications is known,[49] doubtlessly because of the low absolute NMR sensitivity of this nuclide. The quadrupolar nuclei ^{101}Ru and ^{189}Os seem to be less attractive from the point of view of chemical applications because of their insensitivity and the large halfwidths of their signals.[139]

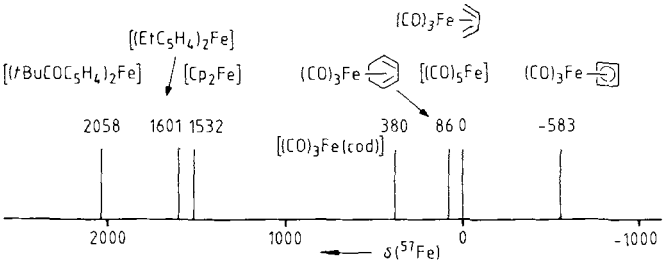

Fig. 17. ^{57}Fe-NMR shifts of organoiron compounds in which Fe has the formal oxidation state 2 or 0 [133, 134].

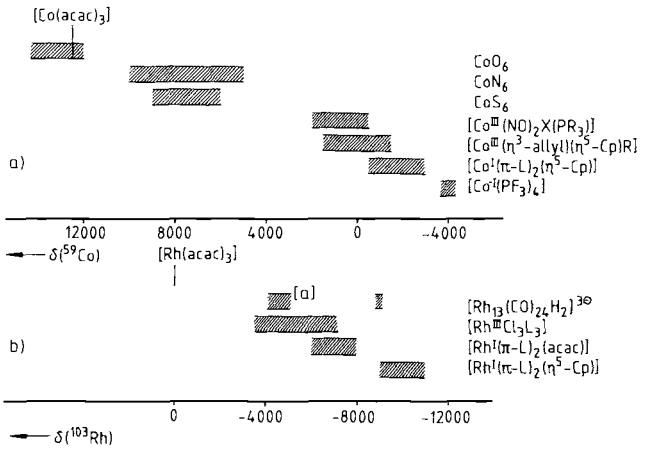
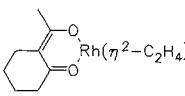
4.2.2. The Elements of the Cobalt Group

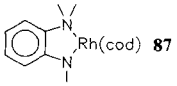
Of the magnetically active isotopes of the elements of the cobalt group, the ^{59}Co quadrupolar nucleus has been used since the advent of NMR spectroscopy for resolving various chemical problems.[5] Notwithstanding the natural abundance of 100% of the spin-1/2 nucleus ^{103}Rh, it is only because of the recent experimental techniques[47b, 144]

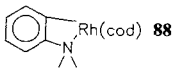
that this insensitive nucleus can be readily recorded.[144-147] In contrast, the magnetic properties of the two Ir isotopes exclude the general application of these nuclei in organometallic chemistry.

High-resolution metal-NMR spectra exist for diamagnetic Co- and Rh-complexes with the metals in the oxidation states +3, +1, 0, and −1 (Co).[133b, 148-152] The corresponding shift ranges cover more than 10000 ppm (Fig. 18).









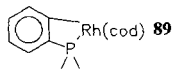


Fig. 18. M-NMR shifts of organometallic compounds [5a, 18, 148, 149]: a) M = ^{59}Co. CoO_6, CoN_6, and CoS_6 signify sixfold coordinated Co atoms via O, N, and S, respectively. b) M = ^{103}Rh. [a] Central Rh atom of the cluster.

It has been found empirically, that the shielding of the metal nucleus roughly correlates with the oxidation state of the metal atoms, even though individual subranges for the chemical shifts overlap. In octahedral Co^{III} complexes the shielding of the ^{59}Co nucleus increases in going from *O*- to *N*-, *S*-, *Se*-, *As*-, or *C*-bonded ligands.[5a] Here too, the shift ranges may in some cases overlap considerably. The chemical shifts of $[CpCo^{III}(\eta^3\text{-allyl})R]$ complexes lie within a range of ±1000 ppm around the standard $[Co(CN)_6]^{3\ominus}$.[148] Increasing donor properties of R lead to increased shielding of the ^{59}Co nucleus. Also extensive ^{59}Co-NMR investigations have been carried out on organocobalt(I) complexes with η^5-(Cp), η^3-(allyl), and η^2-bonded olefinic ligands as well as CO-ligands.[148-151] In addition, the ^{103}Rh-NMR shifts of many homologous Rh compounds[18b, 28b, 147] are known, thus permitting the question of which terms dominate the metal shifts to be discussed more broadly. Let us first compare only the ^{59}Co-NMR shifts of Co^I sandwich complexes with COD as one ligand and substituted cyclopentadienyl rings as second ligand.[148] Annelation of aromatic rings leads to a deshielding, while methyl substitution leads to a shielding, of a metal nucleus[148, 151] (if the cod ligand is replaced by two olefinic ligands, the changes for $\delta(^{59}Co)$ are similar). Such observations can be explained by charge density changes resulting from the −M and +I effects of the substituents. In $[(indenyl)Rh(\eta^2\text{-}C_2H_4)_2]$ the ^{103}Rh nucleus is more strongly deshielded by about 200 ppm than in $[CpRh(\eta^2\text{-}C_2H_4)_2]$.[153] Cyclopentadienylbis(π-L)cobalt complexes with substituted cyclopentadienyl ligands are powerful, homogeneous catalysts for the trimerization of alkynes and the cyclotrimerization of alkynes with nitriles to pyridine derivatives.[154] In the case of complexes with COD as π-ligand, a relationship between their activity and regioselectivity in catalysis and their ^{59}Co-NMR shifts has been established.[150]

As the ^{103}Rh-NMR shifts of rhodium(I) complexes[18b, 28b, 155] given in Table 12 show, the influence of the charge density on the paramagnetic shift term is here also decisive. Thus, the increasing donor properties of the ligands in the series COD, PPh_3, and *(cyclo*-$C_6H_{11})_2PCH_2CH_2P$(*cyclo*-$C_6H_{11})_2$ (DCPE) (**90**-**92**) effect an increased shielding of the ^{103}Rh nucleus.[18b]

Table 12. ^{103}Rh-NMR shifts of 16e organorhodium(I) complexes [18b] and $[Rh(\eta^3\text{-allyl})_3]$ [28b]; standard, see Table 7. dvcb = divinylcyclobutane, dcpe = (cyclo-$C_6H_{11})_2PCH_2CH_2P$(cyclo-$C_6H_{11})_2$.

Consistent with the strong influence of charge density on ^{59}Co- and ^{103}Rh-NMR shifts, the shifts known so far for Co^{III}, Rh^{III}, and Rh^I complexes show a normal dependence on halogen substitution. This property is in contrast to the expected decrease of ΔE with increasing atomic number of the halogen and the resulting increase of the paramagnetic shift term. The classical NMR spectroscopic investigations of octahedral Co^{III} complexes[69, 156] have shown, however, that the ^{59}Co-NMR shifts may also be dominated by the $1/\Delta E$ term of the paramagnetic shielding contribution. Such a relationship has also been demonstrated in the case of $[CpCo(\pi\text{-}L)_2]$ complexes (Fig. 19).[148] The parent compound of these Co^I complexes is $[CpCo(\eta^2\text{-}C_2H_4)_2]$,[157] from which further $CpCo^I$ derivatives are accessible by replacement of ethylene. In $[CpCo(C_2H_4)_2]$ the Co nucleus is strongly deshielded, in $[CpCo(CO)_2]$ strongly shielded. The shift difference of ca.

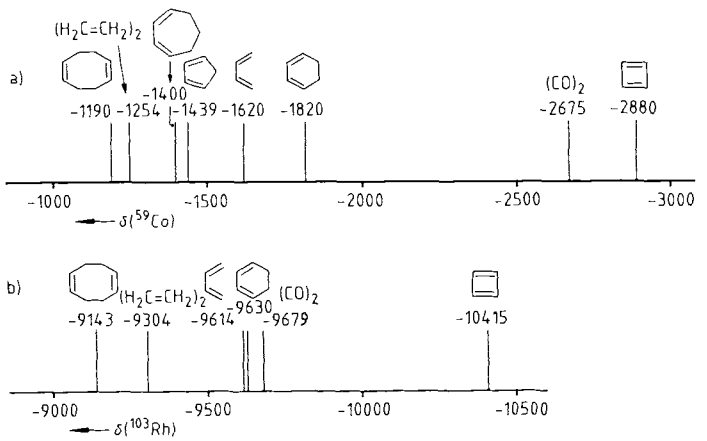

Fig. 19. Comparison of M-NMR shifts of $[CpM(\pi\text{-}L)_2]$ complexes: (a) M = ^{59}Co [148, 149]. (b) M = ^{103}Rh [18b, 149, 155]. The ^{59}Co-NMR shifts of the ^{59}Co-nucleus are referred to $[Co(CN)_6]^{3\ominus}$ as external standard, those of the ^{103}Rh nucleus to $[Rh(acac)_3]$ on the basis of the information given in [149]. The halfwidths of the ^{59}Co-NMR signals range from 7000 to 13000 Hz [148].

1500 ppm can be explained by the $1/\Delta E$ dependence of the paramagnetic shift contribution; ΔE was estimated[148] from quantitative EH-MO calculations (Fig. 20).[158] In these complexes the important interactions between the CpCo fragment and the other ligands are given by the combination of ligand orbitals ($\pi-\pi$, $\pi^*+\pi^*$, $n_{CO}-n_{CO}$, $\pi^*_{CO}+\pi^*_{CO}$) with the half-filled 2e-set of xz and xy CpCo-orbitals. In both cases the HOMO of the complexes, which is stabilized by back-donation, is of the type xz. The LUMO of the complexes is of the yz type and is destabilized by the antibonding combination with $n_{CO}-n_{CO}$ and $\pi-\pi$, respectively. As a consequence of better overlap between the donor orbitals n_{CO} (these are one-center orbitals of σ-type) the LUMO of the CO complex lies higher than that in the C_2H_4-complex. Since there is very little difference in the energies of the HOMOs of both complexes, the HOMO-LUMO gap in $[CpCo(C_2H_4)_2]$ is smaller by 0.31 eV than in $[CpCo(CO)_2]$. This result supports the conclusion that the ^{59}Co-NMR shifts in a series of CpCo complexes are influenced or even determined by the $1/\Delta E$ dependence of the paramagnetic shielding contribution. On the basis of the correlation between $\delta(^{59}Co)$ and $1/\Delta E$ which has been found by UV measurements on inorganic Co^{III} complexes,[69, 156] a decrease of ΔE by 2 cm^{-1} corresponds to a downfield shift of ca. 1 ppm. Consequently, the ^{59}Co upfield shift of 1448 ppm observed for $[CpCo(CO)_2]$ corresponds to a change in ΔE of 0.35 eV. This agrees surprisingly well with the calculated difference in ΔE of 0.31 eV.[148]

Since the ^{103}Rh-NMR shifts qualitatively show a trend similar to that of the ^{59}Co-NMR shifts of the analogous $(Cp)Co^{I}$ complexes (cf. Fig. 19), it may be assumed that

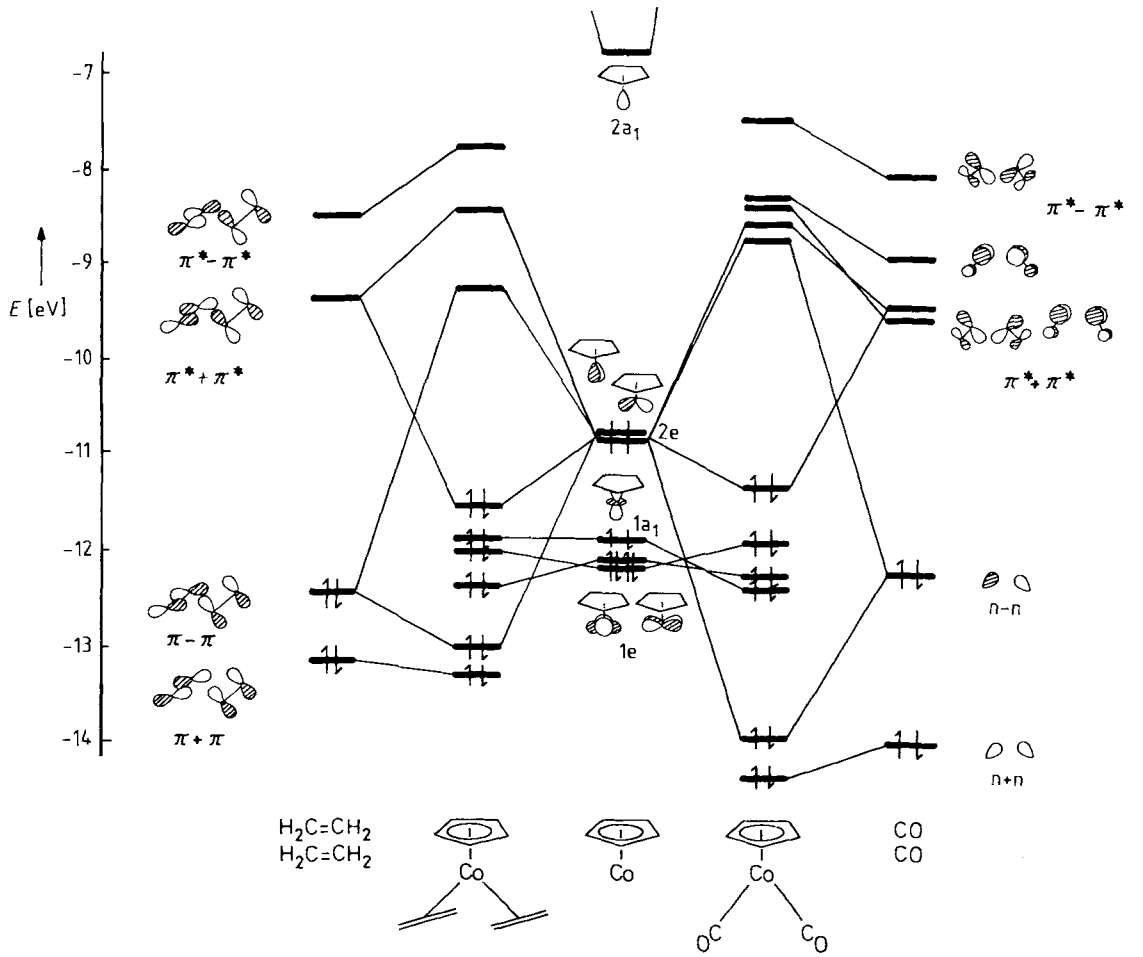

Fig. 20. Comparison of the EH-MO diagrams of $[CpCo(\eta^2\text{-}C_2H_4)_2]$ and $[CpCo(CO)_2]$ [148].

they are also affected by the $1/\Delta E$ term and the frontier orbitals of the complexes. Accordingly, the metal-NMR shifts reflect the strength of the interaction between CpM fragment and ligand, and therefore chemical shifts of a series of related complexes can serve as an indicator of complex properties. Indeed, for related Co-complexes the ^{59}Co-NMR shifts correlate with chemical properties.[148]

Of the isotopes of the elements of the nickel group, ^{195}Pt is the most attractive isotope for NMR investigations. As a consequence of its easy detectability a large number of ^{195}Pt-NMR data have already been reported in the literature.[5, 159, 160] The chemical shift range of the ^{195}Pt nucleus spans 16000 ppm;[5, 67, 159] that of the ^{195}Pt-NMR shifts of $[Pt^{IV}X_6]^{2\ominus}$ salts (X = F, Cl, I, Br) alone amounts to 13000 ppm.[67, 161] The dependence of the shifts on halogen substitution is quite normal. Anisotropic contributions to the paramagnetic shielding term may be considerably large. Depending on the geometry of the dissolved molecules, values between 1000 and 12000 ppm have been estimated for $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$.[15, 26, 27, 162]

So far, relatively little is known about $\delta(^{195}Pt)$ in Pt^0-compounds.[159, 160] Quantitative MO calculations and UV measurements on $[PtL_2(acetylene)]$ complexes showed that the $\delta(^{195}Pt)$ values in these compounds can be explained in terms of the $1/\Delta E$ dependence of the paramagnetic shielding term.[163] For phosphaneplatinum complexes $[Pt(PR_3)_n]$ (n = 2, 3, 4), of linear, trigonal and tetrahedral geometry, the order of the ^{195}Pt shifts ($\delta(Pt(PR_3)_2) < \delta(Pt(PR_3)_4) < \delta(Pt(PR_3)_3)$, see Table 13) has also been correlated with the $1/\Delta E$ term.[164] The average excitation energy ΔE has been estimated from qualitative MO diagrams and UV spectra.

Table 13. ^{195}Pt-NMR shifts of Pt^0 compounds and $[Pt(\eta^3\text{-allyl})_2]$ [15, 166]; dRpe = $R_2PCH_2CH_2PR_2$, standard, see Table 7.

As in the NMR spectroscopy of other spin-1/2 metal nuclei with large chemical shift ranges, important applications of ^{195}Pt-NMR spectroscopy in organometallic chemistry include the improved detection of isomers on the basis of the large signal dispersion of the ^{195}Pt resonances. Even a ^{195}Pt separation as small as 1 ppm is very often sufficient for exact integration. A particularly convincing example is the detection of optical isomers of square-planar Pt complexes with optically active ligands and prochiral π-bonded olefins.[159, 165] ^{195}Pt-NMR spectroscopy has also been used to elucidate the type of bonding between butadiene and a L_2Pt fragment[166] (see Fig. 21). This is of interest since butadiene can bind to transition metals in various ways.[167] Depending on the alkyl substituent R in the chelate-phosphane (dRpe), metallacyclopentene and $Pt(\eta^2$-diene) structures are found in the [Pt(dRpe)(butadiene)] complexes.[168] Their ^{195}Pt-NMR shifts are different by ca. 500 ppm.[166] This reflects the generally observed trend that for comparable ligands the ^{195}Pt-NMR signals of lower-valent Pt compounds resonate at lower frequencies. The shift ranges for complexes with Pt in different oxidation states are, however, not free of overlap.

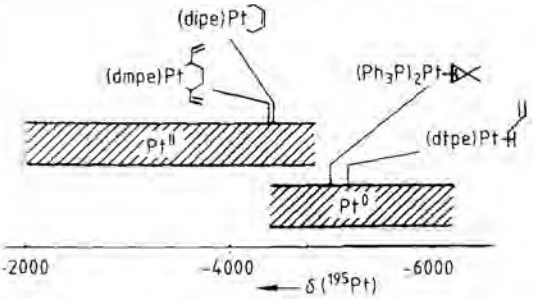

Fig. 21. ^{195}Pt-NMR shifts of bis(phosphane)platinum(0) and -platinum(II) complexes [166] relative to $[PtCl_6]^{2\ominus}$ as external standard. dmpe = $Me_2PCH_2CH_2PMe_2$; dipe = $iPr_2PCH_2CH_2PiPr_2$; dtpe = $tBu_2PCH_2CH_2PtBu_2$.

In the elucidation of the structures of clusters containing several chemically non-equivalent spin-1/2 metal nuclei, the NMR spectroscopy of metal nuclei is *a priori* superior to that of the traditionally measured nuclei. In the case of the compound $[Pt_9(CO)_{18}]^{2\ominus}$ it could be shown that quite different ^{195}Pt resonances are obtained for the inner and outer Pt cluster atoms.[169] The relatively high sensitivity of the ^{195}Pt nucleus and the comparatively large Pt-Pt spin-spin coupling constants should allow the connectivity of chemically nonequivalent cluster atoms to be determined with the aid of two-dimensional NMR techniques like COSY and INADEQUATE,[4] which have been used so successfully in the case of the ^{183}W isotope[170, 171] to determine the coupling pattern in Pt-clusters. These techniques should find widespread application.

In complete contrast, however, the low sensitivity and especially the large quadrupole moment of the ^{105}Pd nucleus leave little hope for its suitability for NMR investigations in the field of organopalladium complex chemistry. Similarily, the ^{61}Ni nucleus has unfavorable NMR properties and so far only two papers with chemically relevant ^{61}Ni-NMR data have been published.[172, 173] Organonickel complexes are, however, of great importance in preparative and mechanistic chemistry and in homogeneous catalysis.[174] The ^{61}Ni-NMR shifts already known[172, 173] and those determined by us[175] for complexes with tetrahedrally coordinated Ni span a range of ca. 2000 ppm (Fig. 22). These chemical shifts cannot be explained on the basis

of simple charge density arguments, since the shielding of the ^{61}Ni nucleus is strongest when ligands of high acceptor properties are coordinated. Ligands with good donor properties like COD, on the other hand, lead to a deshielding of ^{61}Ni. It is therefore reasonable to assume that the ^{61}Ni shift in tetrahedrally coordinated Ni complexes is determined by the frontier orbitals and in particular by the ΔE dependence of the paramagnetic shielding term (for MO calculations for these types of compounds cf. ref. [176]).

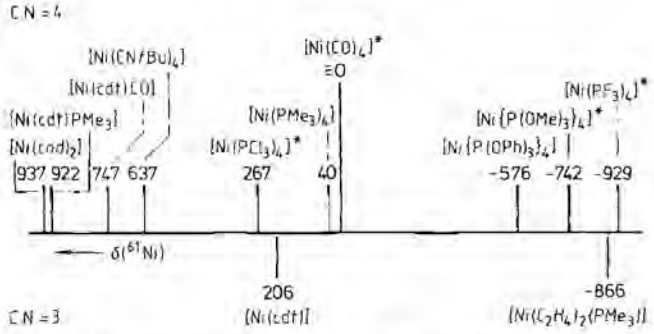

Fig. 22. ^{61}Ni-NMR chemical shifts of tetrahedral (upwards) and trigonal planar (downwards) Ni^0 complexes. The ^{61}Ni-data marked with (*) are from [173], the remaining data from [175]. cdt = all-*trans*-1,5,9-cyclododecatriene.

It would seem worth noting that for some $[NiL_4]$ complexes the strength of the Ni-L bond is reflected in an enhanced shielding of the ^{61}Ni nucleus. For example, $[Ni(PR_3)_4]$ complexes can be prepared from $[Ni(cod)_2]$ or $[Ni(CNtBu)_4]$ by ligand exchange, and the similarity of the ^{61}Ni-NMR shifts for $[Ni(CO)_4]$ and $[Ni(PMe_3)_4]$ are consistent with the finding that mixing of the complexes yields primarily the complexes $[Ni(CO)_n(PR_3)_{4-n}]$.[174] However, far more investigations will have to be carried out in order to establish a definite relationship between the ^{61}Ni-NMR shift and the strength of the Ni-L bond in NiL_4 complexes.

The ^{61}Ni-NMR shifts of the two trigonal-planar organonickel complexes known so far[175] differ by ca. 1000 ppm.

4.3. Metal-NMR shifts in Ally-Transition Metal Complexes

Most of the known pure allyl-transition metal complexes were synthesized more than 20 years ago[177] and since then have acquired great importance in preparative chemistry and in the catalytic transformation of olefins.[178] Even though the metal in $[M(allyl)_n]$ complexes formally has the oxidation number n, these compounds behave chemically very often like metal(0) complexes. The magnitude of the effective charge at the metal, for example in bis(η^3-allyl)nickel, has been the subject of numerous discussions and calculations;[179] a classification of such complexes according to their δ(M) shifts is therefore of great interest.

The following metal-NMR shifts in allyl complexes are already known: ^{195}Pt,[166] ^{59}Co,[148] and ^{103}Rh.[28b] An X-ray structure analysis of bis(η^3-allyl)platinum has shown that the allyl groups have a *trans*-arrangement in the crystal.[180] In solution, on the other hand, two isomers are observed, for which a *trans*- and a *cis*-arrangement of the allyl groups, respectively, is assumed.[181] The ^{195}Pt-NMR data support this assumption since the $\delta(^{195}Pt)$ values as well as the T_1 values for both isomers are considerably different.[166] The ^{195}Pt-NMR shifts of bis(η^3-allyl)platinum compounds fall in a range which, on the basis of data known sofar, is more typical for Pt^0-complexes (see Fig. 23). Application of the MO scheme for bis(η^3-allyl)nickel[176] to the homologous Pt-compound indicates almost a d^{10} configuration for the metal, so that the position of the ^{195}Pt-NMR shift in bis(η^3-allyl)platinum is not surprising.

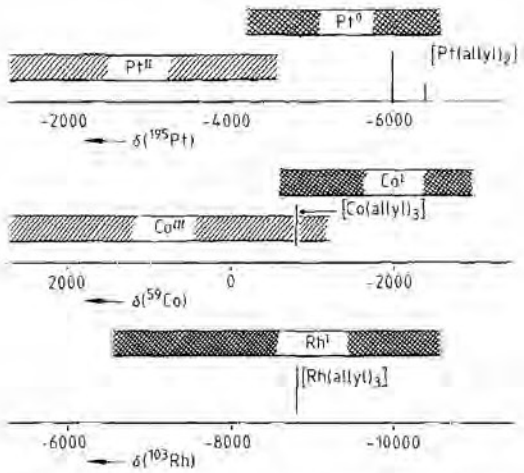

Fig. 23. M-NMR shifts in the allyl metal complexes *trans*-[Pt(η^1-allyl)$_2$], *cis*-[Pt(η^1-allyl)$_2$] [166], [Co(η^3-allyl)$_3$] [148] and [Rh(η^3-allyl)$_3$] [28b] (for reference compounds see Table 7). Characteristic ranges for the metal shifts of the respective organometallic compounds in different oxidation states are hatched.

Similar results are obtained for tris(η^3-allyl)cobalt and tris(η^3-allyl)rhodium, in which the metals are trigonal prismatic coordinated. Surprisingly, the halfwidths of the ^{59}Co-NMR signals of $[Co(\eta^3\text{-allyl})_3]$ and $[Co\{\eta^3\text{-}(H_2C{-}C(Me){=}CH_2)\}_3]$ are so small that the signals can be observed even at low temperatures.[148] (Relative to the nuclei in the respective $[CpM(\eta^4\text{-cod})]$ complexes (M = Rh, Co) those in the tris(allyl)metal complexes are strongly shielded, but the differences in the shifts are similar.) The metal shifts fall in a range which is more characteristic for the corresponding organometal(I) complexes. Qualitative MO considerations[176] show that the HOMO of $[M(\eta^3\text{-allyl})_3]$ is a pure ligand orbital, while the lower lying occupied orbitals still have considerable metal d-orbital character (Fig. 24). Therefore, the electronic configuration of Co and Rh, respectively, in the allyl complexes lies between d^6 and d^{10}, and the partial charges at the metal atoms are smaller than in normal M^{III} complexes. The stronger shielding ($\Delta\delta \approx 400$ ppm) of the ^{59}Co nucleus in $[Co\{\eta^3\text{-}(CH_2{-}C(Me){=}CH_2)\}_3]$, which has a structure (C_{3h} symmetry) similar to that of $[Co(\eta^3\text{-allyl})_3]$ but is thermally more stable than the latter, does not, however, fit into the qualitative picture described above.

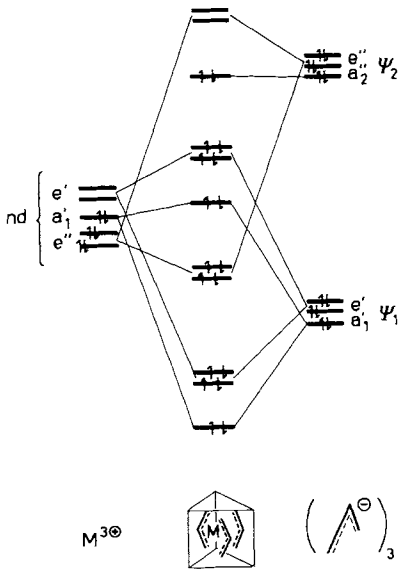

Fig. 24. Schematic MO diagram for $[M(\eta^3\text{-allyl})_3]$ complexes (M = Co, Rh) with trigonal prismatic coordination of the metal atom [176].

5. Conclusions

The examples discussed here show that NMR spectra of nearly all magnetically active metal nuclei can be obtained with reasonable effort. In particular, in the case of transition metals the chemical shift ranges are very often larger than 1000 ppm. Therefore, spin-1/2 metal nuclei and, within certain limits, also quadrupolar metal nuclei are very sensitive probes for investigating the chemistry of complexes. Since these nuclei are very often at or close to the center of the molecule of interest, the results obtained by high-resolution metal-NMR spectroscopy are mostly of a different nature from and complementary to the results obtained with nuclei at the periphery of the complex (as, e.g., ^1H and ^{13}C). Examples of where the NMR of metal nuclei is extremely useful are in investigations concerned with the coordination number, the oxidation state, the nature of the bonding and the electronic configuration of a metal atom in complexes.

Besides the possibility of determining the connectivity of magnetically active and chemically non-equivalent metals in polynuclear compounds and clusters, the relationship between the $\delta(M)$ values and the frontier orbitals of complexes deserves special attention, since this leads to a relationship between the chemical shift and the chemical properties of the complex.

Even if the examples discussed above can only partly demonstrate the present state of the art of the NMR spectroscopy of metal nuclei, it will be evident that the era of merely detecting NMR signals of metal nuclei is over, and that metal-NMR spectroscopy now constitutes a new, practical and useful method which will find application in many areas of inorganic and organometallic chemistry.

We are particularly indebted to the Director of the Max-Planck-Institut für Kohlenforschung, Prof. Dr. G. Wilke, for his generous support of our investigations. We are grateful to colleagues who have participated in joint projects (Prof. Dr. H. Lehmkuhl) or provided us with samples. R. B. thanks Dr. R.-D. Reinhardt for a number of investigations related to ^{195}Pt- and ^{103}Rh-NMR spectroscopy. R. B. gratefully acknowledges financial support by the Deutsche Forschungsgemeinschaft.

[45] For the indirect observation of ^{183}W see: G. T. Andrews, I. J. Colquhoun, W. McFarlane, S. O. Grim, *J. Chem. Soc. Dalton Trans. 1982*, 2353; for ^{1}H{X}-Spin-Echo-Difference Spectroscopy see: J. S. Cohen, C.-W. Chen, A. Bax, *J. Magn. Reson. 59* (1984) 181; indirect ^{31}P{^{107}Ag, ^{1}H}-NMR spectra: I. J. Colquhoun, W. Mc Farlane, *T. Chem. Commun. 1980*, 145.
[46] The inverse INEPT sequence (R. Freeman, T. H. Mareci, G. A. Morris, *J. Magn. Reson. 42* (1981) 341; M. R. Bendall, D. T. Pegg, D. M. Doddrell, J. Field, *J. Am. Chem. Soc. 103* (1981) 934) and the inverse DEPT sequence (M. R. Bendall, D. T. Pegg, D. M. Doddrell, J. Field, *J. Magn. Reson. 51* (1983) 520), which were suggested in particular for the overlap-free presentation of proton multiplets can also be used for determining the shifts of insensitive X-nuclei.
[47] a) The first two-dimensional ^{1}H,X-shift correlations were performed with proton observation A. A. Maudsley, R. R. Ernst, *Chem. Phys. Lett. 50* (1977) 368; A. A. Maudsley, L. Müller, R. R. Ernst, *J. Magn. Reson. 28* (1977) 463; b) application of this method for the indirect measurement of the ^{103}Rh-resonance via two-dimensional, correlated ^{1}H,^{103}Rh-spectroscopy: R. Benn, unpublished; see also R. Benn, H. Brennecke, A. Rufińska, *J. Organomet. Chem.* (1986), in press [137c].
[48] If the insensitive X-nucleus has a low natural abundance (e.g. ^{13}C, ^{57}Fe), the indirect detection of its signal through the ^{1}H FID has to cope with the problem of the elimination of intensive ^{1}H-NMR signals of sites with magnetically inactive X-nuclei. The suppression of such signals using phase cycling is described by G. Bodenhausen, D. J. Ruben, *Chem. Phys. Lett. 69* (1980) 185; A. Bax, R. H. Griffey, B. L. Hawkins, *J. Magn. Reson. 55* (1983) 301 and, using presaturation through proton noise decoupling, by D. Neuhaus, J. Keeler, R. Freeman, *ibid. 61* (1985) 553.

Geometric and Topological Thinking in Organic Chemistry

By Nicholas J. Turro*

The beginning student of organic chemistry is often bewildered by what appears to be an enormous maze of random structural variations and reactions that can be mastered only by tedious memorization. To the organic chemist, however, the same subject is often a beautifully ordered discipline of elegant simplicity. An important value of learning organic chemistry is the mastering of "organic thinking," an approach to intellectual processing whereby the "sameness" of many families of structures and reactions is revealed. This article offers the author's personal views of organic thinking and explores the intellectual and scientific foundations of organic chemistry and of the powerful methods that provide the field with a platform for making rapid conceptual and experimental advances. It is proposed that these methods involve a geometric and topological approach to scientific reasoning within the framework of scientific paradigms that guide experimental design and execution. The basis of this approach is considered in relation to day-to-day thinking, problem solving, and the psychological drive for intellectual closure. The power of the approach is illustrated by the analysis of several photochemical and chemiluminescent reactions.

1. Introduction—Intellectual Processing

1.1. Intellectual Processing, Problem Solving, and Closure

Normal day-to-day mental activity and learning involve a high degree of intellectual processing directed toward problem solving. Difficulties arise with the recognition of ambiguities that result from the existence of many possible solutions. These ambiguities and the recognition of potential deficiencies or conflicts associated with the selection of a single solution can give rise to anxiety and tension. On the other hand, the process of "closing out" a problem intellectually is a pleasant and reinforcing experience.

Figure 1 schematically depicts some relationships among the components involved in intellectual processing.[1,2] The phenomena (facts or events) in the world around us generate a set of beliefs. Intellectual processing involves preservation, rearrangement, or modification of these beliefs. Successful problem solving and concomitant closure reinforce beliefs and breed satisfaction. Failure to resolve problems breeds tension and conflict because of the implication that beliefs may be incomplete or incorrect. One may hypothesize that the dominant principle driving intellectual processes is a *Law of Intellectual Closure*:[2] intellectual processing is naturally driven toward as *closed* a mental state as circumstances permit. The origin of such a law could be traced to its survival value and the associated evolution of an appropriate genetic composition and constitution of the human brain.[3] The intellectual process of closure involves the goal of achieving a complete, stable, and self-consistent interpretation of a phenomenon or event. For example, an unfinished act tends to be mentally completed, an ambiguous object tends to be interpreted in terms of its familiar aspects, a word, an object, or a situation is perceived in a manner that allows achievement of a closed interpretation.

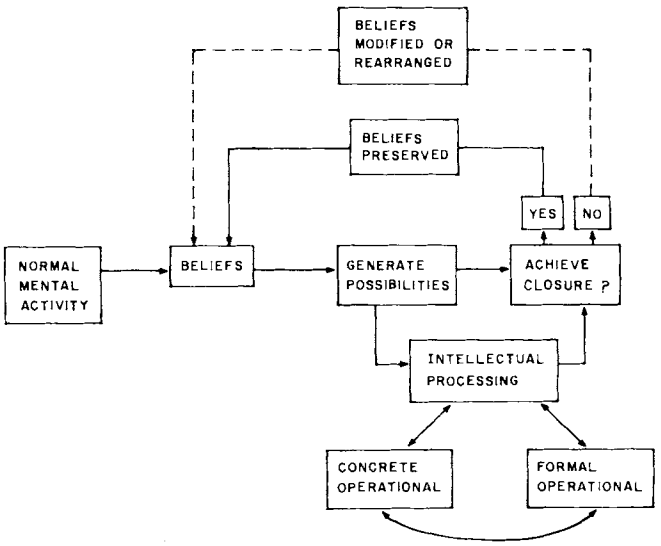

Fig. 1. A schematic representation of normal intellectual activity showing the interplay of beliefs, possibilities, closure, and intellectual processing (cf. Fig. 4).

Much of the learning experience consists of the process of resolving conflicts among related beliefs. Learning is facilitated and even made enjoyable by artificially creating intellectual conflicts that can be resolved to a high degree of closure. Students who learn to tolerate the tension that normally accompanies the process of resolving such intellectual conflicts often feel an excitement that is stimulating and rewarding in itself. Indeed, the development of an ability to tolerate tension during the activity of problem solving is important to the learning process. Intellectual processing that involves the achievement of problem definition and problem solution with a high degree of intellectual closure is naturally attractive and readily adopted. A

major aim of many motivational programs for learning is to promote the visibility of "living examples" of successful behavior or accomplishment and to suppress that of counterexamples.[2] This theme will reappear in the discussion of scientific paradigms (Section 3.3). Let us now consider two general and important classifications of intellectual processing that are employed in day-to-day thinking.

1.2. Concrete and Formal Operational Intellectual Processing

According to *Piaget*,[4] two distinct stages of intellectual development may be characterized, namely, *concrete operational* (typical of children from 6 to 12 years of age) and *formal operational* (typical of children from 11 to 16 years of age). In Figure 1, these stages may be viewed as alternative mechanisms for intellectual processing. During the concrete operational period, intellectual processing involving the logic of real (concrete) objects is mastered. This period is characterized by accepting concrete objects or events in the immediate present with little extrapolation to what hypothetically is possible in the future or was possible in the past. During the formal operational period, intellectual processing involving the generation and manipulation of possible combinations of objects and events is mastered. In this period, the mind becomes capable of extrapolating from objects and events in the immediate present to objects and events that are hypothetically possible.

At the concrete operational level, reality is accepted as it is found, perhaps without recognition that alternatives exist (for example, young children often may fail to acknowledge another's point of view because they do not consider the possibility that other points of view exist!). At the formal operational level, on the other hand, the recognition of competing possibilities often brings with it an ambiguity that may be psychologically unsettling. However, this uncomfortable feeling of ambiguity may be relieved and converted into a feeling of excitement by resorting to operations that solve problems effectively and thereby achieve intellectual closure. Let us now consider how geometry can assist thinking at either the concrete operational or formal operational levels.

1.3. The Role of Geometry in Intellectual Processing

Many of the beliefs that are employed in intellectual processing may be viewed as containing information, which, in turn, can be represented by concrete or abstract *forms*. According to *Thom*,[3a] there is a natural tendency of the mind to give the form or shape of an object some intrinsic meaning:

> ... our perceptual organs are genetically developed as to detect the living beings that play a large role, as prey or predators, in our survival and in the maintenance of our psychological equilibrium. It is clear that some forms have special value for us or are biologically important, for example, the shapes of foods, of animals, of tools. These forms are genetically imprinted into our understanding of space, and ... are narrowly and strictly adapted to them.

During the process of evolution of the brain, it is plausible that, since forms of information (beliefs) were generated from the stimuli provided by the environment in which we are embedded, the recognition of forms in terms of a three-dimensional (3-D) geometry had survival value and led to the development of perceptual receptors in the brain that are particularly suited to embrace and process 3-D geometric forms.[3] If so, facile recognition of 3-D geometric forms is genetically embedded into our ability to intellectualize and to understand space. It is easy to appreciate, therefore, how the use of geometry, with its powerful methods for processing geometric structures and its logical and internally consistent mathematical basis, both of which facilitate closure, can take on enormous importance as a vehicle for intellectual processing.

The notion that geometric thinking involves only 3-D forms, which correspond to figures in Euclidean geometry, is too restrictive, however. The geometric thinking that the author has in mind is much more "elastic" and general than that allowed by the rules of Euclidean geometry. An appreciation of what is meant by this elastic geometry may be obtained by considering some aspects of a branch of mathematics termed *topology*.[5]

2. Euclidean and Topological Geometry

2.1. Topology and Topological Geometry

Topology is a branch of mathematics concerned with the "sameness" of mathematical forms. Topology provides a basis for determining whether two mathematical forms are the same or not via a mapping procedure that attempts to place the topologically relevant properties of one form onto a second form.

Topology may be described as "rubber sheet" geometry.[6] This definition emphasizes the elasticity of the concepts of topology, which is concerned, in general, only with very fundamental geometric properties. Topological properties may be visualized as those geometric properties of a figure on a rubber sheet that are conserved upon twisting and stretching, such as the connectivity, the sequence, and the continuity of points. It is easy to visualize the continuous mapping of a figure on a rubber sheet onto the new image of the figure generated as a result of elastic twisting or stretching. No topological features of the figure are created or destroyed by the twisting or stretching process. However, tearing or joining parts of the original figure is not allowed, since this creates new topological properties and does not conserve the initial topological properties.

The model of the geometric figure on a rubber sheet provides the flavor of topological geometry, which emphasizes the possible rather than the concrete, an important feature of formal operational thinking. Euclidean geometry, on the other hand, emphasizes figures exactly as they are perceived, the essence of concrete operational thinking. Topological geometry considers geometric figures as they might be transformed by mapping procedures that conserve fundamental topological properties. To obtain a further appreciation for topological geometry, let us further compare

its essential features to the more familiar Euclidean geometry.

2.2. Comparison of Euclidean and Topological Geometry

Euclidean geometry is the study of certain properties of figures in space.[7] To a geometrician not all properties of a figure are of interest, only the geometric properties. What is a pertinent geometric property? In Euclidean geometry the key idea is that of *geometrically equivalent or congruent figures*. Two figures are called congruent if an intellectual transformation or mapping allows one figure to be "placed on the other" so that the two figures exactly coincide in all geometric properties. A geometric property of a figure is a property shared by every congruent figure.

Topological geometry also involves the study of certain properties of figures in space. Not all properties of a figure are of interest, only the topological properties. What is a pertinent topological property? In topology the key idea is that of *topologically equivalent or homeomorphic figures*. Two figures are called homeomorphic if an intellectual transformation or mapping allows one figure to be "placed on the other" so that the two figures exactly coincide in all topological properties. A topological property is one shared by every homeomorphic figure.

In Euclidean geometry, how do we "place one figure on another"? How can we move a figure? How can we conserve its geometric properties during the movement? The sameness or identity of geometric figures is established by transformations termed *isometries*. An isometry is an intellectual transformation that conserves the size and shape of a geometric figure. The three common isometries of Euclidean geometry are rotation, translation, and reflection. Shapes that are recognized to be the same by isometric transformations are termed *congruent*. In Euclidean geometry, we are allowed to move a figure only by applying motions that do not change the distance and angle relationships between any two points of the figure. Thus, the geometric properties of interest are those that are invariant during such motions. Euclidean geometric figures are characterized by rigidity owing to their characteristic metric (measurable) properties, such as the lengths and areas of sides and the angles between sides. A requirement of Euclidean figures is that motion of the figure in three-dimensional space cannot change its metric properties.

Euclidean figures may be similar but not identical, i.e., two figures may have the same shape but different sizes.

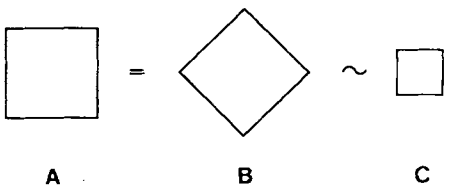

Fig. 2. Congruent (A and B) and similar (A and C, B and C) Euclidean geometric figures.

For example, **A** (Fig. 2) is a square whose sides are the same length as those of **B**. **A** and **B** are the same figure in Euclidean geometry, because they are congruent. **C** is a smaller square which is similar but not congruent to **A** and **B**.

Topological figures may be of different size and shape yet topologically equivalent (i.e., homeomorphic). For example, **D**, **E**, **F**, and **G** (Fig. 3) are all homeomorphic, because the points of any one figure may be continuously mapped onto those of the others by elastic motions that conserve sequence and connectivity. The differing size and shape of the figures is of no topological importance. Thus, **D**, **E**, **F**, and **G** are the same figures in topological geometry, because they are homeomorphic. Topological geometric figures are characterized by elasticity and complete lack of fixed metric properties such as lengths, areas, and angles. In terms of the rubber sheet analogy, elastic distortions of such figures do not change topological geometric properties such as the connectivity of points or the existence of an inside and an outside. Thus, in spite of the wide variation in appearance, **D**, **E**, **F**, and **G** are the same figures topologically in that they are closed simple curves, having an inside, an outside, and a boundary.

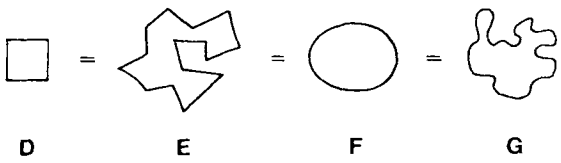

Fig. 3. Homeomorphic topological geometric figures.

The search for sameness in structural representations of objects is a crucial feature of geometric thinking. Given two structural representations of objects, how is it established whether the objects are identical or different? As may be inferred from the previous discussion, the terms identical and different need to be qualified. If we are interested in sameness in geometry, we must specify the level of sameness (topological or Euclidean, congruent or similar). In each case, however, the intellectual process of analyzing sameness can be viewed as a mapping procedure. In mathematics, the term *transformation* is used for such mapping. A mathematical transformation R→P (or its inverse R←P) may conserve certain topological properties or Euclidean properties. Sameness implies that the transformation (and its inverse) involves a one-to-one correspondence of the pertinent features of the structures. This observation is important because it implies, in turn, that if membership of a test structure within a topological family of homeomorphic structures can be established, then the test structure will share all the topological geometric features of the family.

The relationship of topological geometry and the elasticity of topological figures to formal operational thinking, that is, the extrapolation from the given to the possible, and the relationship of Euclidean geometry and the rigidity of Euclidean figures to concrete operational thinking are readily apparent.

3. The Scientific Method, Strong Inference, and Paradigms

3.1. The Scientific Method[*]

The scientific method is usually defined as an iterative inferential process involving the formulation of a hypothesis, followed by the devising of crucial experiments capable of a clean confirmation or rejection of the hypothesis and recycling as required by the outcome of the experiments. *Platt*[8] suggests that certain systematic methods of scientific thinking produce more rapid progress than others. He uses the term *strong inference* to describe a version of the scientific method that emphasizes the formal, explicit, and regular use of *alternative hypotheses and alternative crucial experiments*. The scientific method may be viewed as a specific form of intellectual processing.

Kuhn[9] takes the position that it is not the scientific method per se that leads to rapid progress, but rather the development of mature and effective *paradigms*, which are universally recognized scientific achievements that provide guidance to define scientific puzzles and to provide clues for their solution by a community of practitioners. Figure 4 is a transformation of the schematic description of normal mental activity (cf. Fig. 1) to that of normal science. In science, paradigms replace beliefs in the intellectual processing cycle. The role of geometric thinking in the scientific method is highlighted by replacing formal operational and concrete operational thinking with topological and Euclidean geometric thinking, respectively.

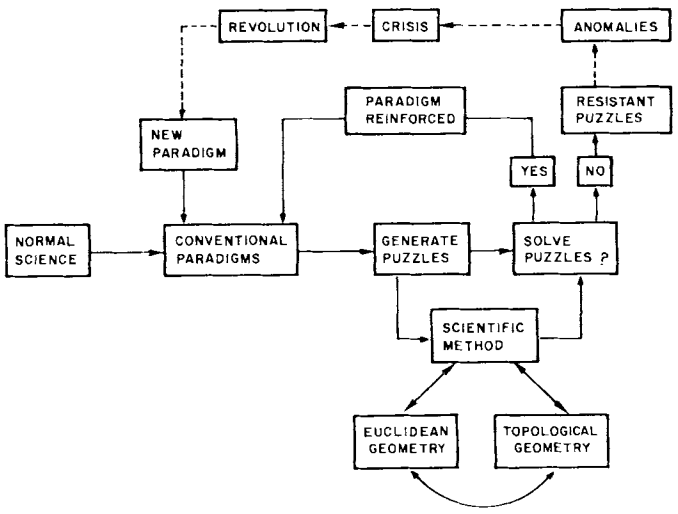

Fig. 4. A schematic representation of the activity of normal science showing the interplay of paradigms, puzzles, solutions, and the scientific method (cf. Fig. 1). Concrete and formal operational thinking "topologically map" onto Euclidean and topological geometry, respectively.

Thom[3] emphasizes the role of geometry in scientific analyses by suggesting that the human mind cannot be comfortable in a universe in which phenomena are governed by mathematic formulations that are coherent and quantitative but so abstract as to be impossible to visualize, that is, to interpret geometrically. The geometric interpretation allows the closure that drives intellectual processing. Furthermore, Euclidean geometry and topological geometry play an important role in structuring the thought processes involved in the scientific method.

The *Platt*[8] proposal of a strong inference methodology for solving puzzles scientifically raises two interesting questions: (1) Are there systematic and effective ways of generating alternative hypotheses and alternative crucial experiments?; (2) How does one best satisfy the Law of Closure in applying the strong inference approach (which inherently creates psychological tension by demanding the generation and consideration of possibilities and the resolution of the resulting conflicts)? We suggest that the use of paradigms and geometry can be effective in resolving these two issues.

3.2. Strong Inference

Some scientific fields appear to be capable of making more rapid advances than others. Clearly, development of instrumentation, funding, quality of practitioners, etc., all contribute to the speed of scientific advances in a field. *Platt*[8] suggests that an intellectual factor may also be important. He proposes that fields that systematically use and teach strong inference (the formal, regular, and explicit application of alternative hypotheses) are inherently better positioned for making rapid scientific advances.

The strong inference (scientific) method consists of the following steps: (1) creation of several alternative hypotheses; (2) devising of crucial experiments that exclude one or more of the hypotheses; (3) execution of experiments to allow "clean" exclusion of some hypotheses; (4) repetition of the cycle after refining the remaining hypotheses.

It is clear that observational knowledge must guide scientific ideas and that laboratory experiments must challenge and test the validity of the ideas. However, *Platt*[8] puts particular emphasis on the regular and explicit use of multiple hypotheses or possibilities. By embracing multiple hypotheses at the beginning of an inquiry, the scientist will exhibit less tendency to become attached to a single hypothesis (which may become a sort of intellectual offspring from the moment it is proposed as an original and satisfactory explanation of a phenomenon). The intellectual and experimental attempts to exclude hypotheses should provide an area of conflict, not between scientists, but between ideas. Excitement can be derived from the puzzles generated by alternative hypotheses. Which one will be right? Zeal and passion for experimental work surely can be derived from viewing the scientific method as requiring clever detective work in addition to experimental skill.

However, the question arises how scientists generate the formal schemata that guide them through the strong inference process without getting them bogged down in irrelevancies. The use of scientific paradigms provides such guidance.

3.3. Scientific Paradigms

The exact meaning of the term *paradigm*[9a] is a bit "fuzzy." A paradigm may be a constellation of beliefs, values, techniques, and methods that are shared universally by a community of practitioners. A paradigm may also be a smaller subset or a single element in such a constellation. In either case, the paradigms serve as models or examples that can replace explicit rules for generating and solving scientific puzzles. There is an implicit process of intellectual mapping of features of the paradigm onto the puzzle under analysis. Since topology is a branch of mathematics concerned with the identification of equivalences by mapping processes, we shall examine the possible interrelations of scientific paradigms and geometric methods, first considering the overall role of paradigms in scientific methodology.

According to *Kuhn*,[9a] paradigms provide a "mind set" for the execution of normal science. When scientific research is approached, questions of the following type arise commonly: How does one generate experiments to be performed? Of the many conceivable experiments that might be performed, how are priorities set? What aspects of a phenomenon are relevant for scientific examination? What questions may be legitimately asked and what techniques may be legitimately employed in seeking a scientific solution to a puzzle?

Effective paradigms, once established and accepted, provide a vehicle for the definition and solution of scientific puzzles. Successful paradigms prevent overt disagreements among practitioners concerning legitimate scientific problems and methods. As a result, practitioners spend little time involved in controversies over fundamentals. For example, a mature paradigm[9a] (1) generates an a priori ("intuitive") backdrop of expectations for the community by providing a common body of beliefs, (2) defines legitimate puzzles that may be addressed by the community of practitioners and legitimate methods for the solution of these puzzles, (3) guarantees that legitimate puzzles have solutions that are limited only by the cleverness and skill of the practitioner and the experimental technique used, and (4) allows the search for solutions to proceed rapidly, because irrelevancies and constant justification are avoided, since standards are universally accepted by practitioners.

The successful solution of a scientific puzzle within the protocol of the paradigm both demonstrates the skill of the practitioner and strengthens the authority of the paradigm. The iterative process of puzzle generation and puzzle solution also provides a high degree of closure to the intellectual processing involved in the scientific method and in this respect can be stimulating and fun for the successful practitioner.

Of course, the more powerful a paradigm becomes as the result of continuing successes, the deeper and more profound becomes its grip on scientific minds. Attempts to question an enshrined paradigm are typically dismissed out of hand. The scientist may become oblivious to even the existence of other possibilities. On the darker side, truly new paradigms are sometimes resisted because they challenge whole systems of scientific development which occurred over long periods of time and at great expenditure of energy and finances. A *scientific revolution*, as viewed by *Kuhn*,[9a] is the process of replacing an entrenched paradigm with a truly different one.

The course of a scientific revolution may be described by consideration of Figure 4. In normal science the conventional paradigms are employed to formulate legitimate puzzles which are solved by legitimate methods to reinforce the paradigm. However, according to *Kuhn*,[9b]

> ... sometimes a normal problem, one that ought to be solvable by known rules and procedures, resists the reiterated onslaught of the ablest members of the group within whose competence it falls ... when the profession can no longer evade anomolies that subvert the existing tradition of scientific practise—then begin the extraordinary investigations that lead the profession at last to a new set of commitments ...

Such resistant puzzles are typically viewed initially by practitioners as anomalies which will be resolved eventually within the framework of normal science. There is often an implicit suppression of such anomalies, because their existence reflects poorly on the operating paradigm. However, the accumulation of anomalies can lead to a vexation among practitioners because this raises doubts concerning the rules governing the prior practice of normal science and the scientific work already completed, that is, the occurrence of an anomaly implies that an error in the paradigm may have been propagated unknowingly at earlier times. If so, puzzles were solved incorrectly in the past. Eventually a crisis may develop among practitioners, who, in the face of paradigm collapse, are forced to seriously consider a tradition-shattering commitment to the new paradigm, that is, a scientific revolution is underway. Once a successful new paradigm has emerged, the practitioners are mercifully reinstated in the normal science loop (see Fig. 4). Candidates for new paradigms must resolve some outstanding and generally recognized puzzle that cannot be solved by the protocol of the existing paradigm. Furthermore, the new paradigm must preserve or replace the ability of the conventional paradigm to define and solve puzzles.

A true revolution (change of a paradigm) is much less common than an "articulation" of a paradigm (topologically speaking, an elastic distortion of the local rules within the global paradigm). Both, however, begin with the awareness of an anomaly that results from a disparity between paradigm-generated expectations and experimental or theoretical observations. This "opens" the paradigm and leads to a feeling of discomfort among the practitioners. Closure is sought and is only achieved when the paradigm has been replaced (rare) or the rules have been re-articulated (more common). The re-articulation of a paradigm often corresponds to merely a realization of some aspect of the conventional paradigm that had been previously ignored or overlooked.

It is important to note what organic chemists never do when confronted by a sudden and severe anomaly diagnostic of paradigm breakdown: they do not renounce the old paradigm out of hand. They almost always first con-

sider the anomaly to be the result of an artifact or to be interpretable in terms of a new articulation of the old paradigm. The old paradigm will survive until a viable alternative candidate is found. The decision to reject one paradigm is almost always coincident with the decision to accept another after comparison of both with the pertinent phenomena and with each other. Ad hoc modifications are usually a more preferable response than tossing out the conventional paradigm without a suitable replacement. Many of the paradigms of organic chemistry are retained, not because they are free of fault, or because they are infallible in their predictive ability, or because of their ineluctable logic. They are more often retained because they are useful for the understanding of observational knowledge at a qualitative level, because they are portable[10] and exploitable by practitioners, and because they provide the driving force for fast-developing experimental methodology.

The decision to employ a particular apparatus or a particular method to solve a chemical puzzle carries an assumption that certain chemical phenomena exist and can be investigated by means of the protocol set forth by the paradigm. Novelty and anomaly emerge against the backdrop of the expectation (intuition) provided by the paradigm. Since accepted paradigms are not readily surrendered, resistance guarantees that scientists will not be constantly distracted with irrelevancies and artifacts. So long as a paradigm continues to prove capable of identifying solvable problems, science moves fastest and penetrates most deeply through employment of the tools approved by the paradigm. In science as in industry, retooling is expensive and disruptive, and is reserved only for the special occasions that demand it.[9a]

It is the study of paradigms that prepares the student for admission to the scientific community. The practitioners share paradigms and are committed to the same rules and standards for scientific practice. By doing so, they can proceed rapidly in their research without having to start each time from first principles and to justify each basic concept that is used in an argument. Indeed, when we discuss research within a field, we usually assume that we are addressing colleagues who possess knowledge of a shared paradigm. The student is trained to attempt to "see" a new problem in the form of an old, solved problem and to replicate a solution by mapping the features of the "understood" problem onto the new problem. At the beginning of a scientific inquiry, the student is sometimes only vaguely aware of what he or she is expected to discover and may lack confidence in knowing what to look for. *Plato*[11] understood this dilemma when in the *Meno* he noted that if we know the solution to a puzzle there is no puzzle, but if we don't know the solution we do not know what we are looking for and can not expect to find anything. He concluded that problems are solved by remembering past incarnations. The protocol of scientific paradigms as a method of puzzle solving is somewhat akin to *Plato*'s reincarnations.

In organic chemistry there are numerous examples of revolutions in thinking that occurred as chemistry developed into a molecular science. First, the notion of composition (number and kinds of elements), then the notion of connectivity (the bonding between elements) and the concept of a three-dimensional representation (the stereochemical aspects of the array of bonded elements), and finally the concept of dynamic stereochemistry (the time-dependent conformational aspects of the array of bonded elements) were developed. At each of these stages in the development and refinements of the ideas of molecular structure a scientific revolution occurred because chemists changed entrenched paradigms which had previously determined the definition and solution of chemical puzzles.

4. The Relation of Euclidean and Topological Geometry to Chemical Structures

4.1. Mathematical Graphs, Forms, Figures, and Structures[*]

The scientific method often involves consideration of the information content of various mathematical objects. For the purposes of this article we wish to distinguish between mathematical graphs, forms, figures, and structures, which are used to model chemical objects. By a graph we shall mean a dimensionless but visualizable topological object that contains information concerning the components and connectivity relations of the chemical object to be modeled. By a form we shall mean an elastic topological geometric object that is embedded in Euclidean space. A figure shall mean a rigid Euclidean geometric object. We shall reserve the term structure for the mathematical object that models a chemical object (i.e., a molecule).

4.2. Transformation from Topological Objects to Euclidean Objects

We are all accustomed to analysis of concrete, readily visualized geometric figures embedded in Euclidean spaces of one, two, or three dimensions. We shall discuss briefly how objects in an abstract topological space can be transformed into objects in a concrete Euclidean space. In topology, sets (defined collections or families of objects) are employed for mathematical analysis. When relationships exist between members of the set, the objects of the set are said to constitute a topological space, T. How can one proceed from an abstract topological space to a concrete Euclidean space, R? In this section we suggest a pathway that uses topological structures, namely, graphs, as the bridge from T-space to R-space.

Topology involves the study of those properties of spaces that depend only on the "nearness" of the elements of the space and that are independent of geometric aspects such as distances and angles. A topological space,[6] $T(X, Y)$, is usually defined as a set, X, together with a family of subsets, Y, which satisfy certain conditions. Topological spaces have rich generality, but are completely abstract mathematical objects devoid of a visualizable geometric form. A finite topological space is said to have structure in the sets X and Y if there are some properties of the elements (members of the sets) that can be brought into

[*] See also I. Ugi, D. Marquarding, H. Klusacek, G. Gokel, P. Gillespie, *Angew. Chem. 82* (1970) 741; *Angew. Chem. Int. Ed. Engl. 9* (1970) 703.

correspondence. In order to "visualize" and eventually interpret a topological space geometrically, it is natural to speak of "points" rather than elements or members of the sets X and Y. The topological space can be visualized by imagining connections between the points of $T(X, Y)$. A *topological graph* is thereby produced. Among the most important fundamental properties of a topological space are neighborhood relations between points of the space. For an eventual chemical interpretation, it is natural to view the topological points in terms of atoms and the neighborhood relations in terms of chemical bonds. A finite topological space and its graph have the same number of components. A connected graph corresponds to a connected topological space.

A specific method of visualization, with powerful implications for chemistry, is to cast the topological space into the form of a connected graph, G, which is defined as an ordered pair, (V, E), where V is a set of points in a topological space and E defines the binary relations between the points. The points V are the vertices of the graph and the binary relations E are the edges connecting the vertices. The binary relations E can be viewed as the rules for a transformation that maps lines connecting elements of the abstract topological space $T(X, Y)$ to produce a visualizable graphical space, $G(V, E)$. Visualization is possible, for example, when the vertices are represented as small numbered circles and the connections are represented as lines. It is important to recognize that $G(V, E)$ is still a topological object, having no geometric parameters such as distances and angles. Chemists come into close contact with topological concepts when they use graphs to represent molecular structures. Indeed, in the usual mathematical sense, a graph, although it can be visualized, does not have dimensionality in the Euclidean sense.

As a concrete example of the conversion from a topological space to a connected graph let us consider the graph representing methane (Fig. 5). The members of the topological space $T(X, Y)$ represent carbon atoms and hydrogen atoms ($X = \{C, H\}$) and connections between carbon atoms and hydrogen atoms ($Y = \{C-H\}$). The degree of a vertex of a graph is the number of edges connected to the vertex. A connected graph of degree four is employed to represent the normal valence of carbon. In an abstract formulation of methane there are two different kinds of points in the topological space and one kind of connectivity relation. Embedding of the graph $G(V, E)$ into Euclidean space, R^n (R^1, R^2, and R^3 correspond to one-dimensional, two-dimensional, and three-dimensional spaces, respectively), produces an elastic object $R^n(V, E)$, which is a topological form having the flexible geometric properties of distance and angle.

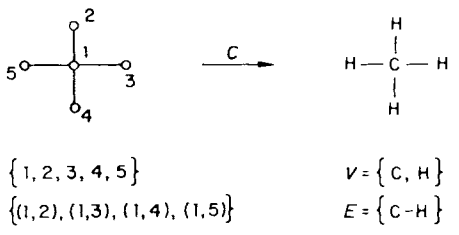

Fig. 5. A visualized connected graph (left) and a molecular graph (right) of methane. The molecular graph, which represents the molecular topology of methane, is produced by embedding the connected graph into the chemical paradigm for molecular structure, represented by the mapping process C. V is the set of points (left) or vertices (right); E is the set of binary relations between the points (left) or edges connecting the vertices (right).

In Figure 6, the visualized graph $G(V, E)$, which represents methane, is embedded in a dimensionless topological space to give a concrete Euclidean geometric figure. $R^3(V, E)$ represents any elastic distortion of the geometric form that conserves the constitutional properties of the figure. Application of a metric, M (corresponding to measurable distances and angles), to $R^n(V, E)$ produces a concrete object, $R^n(V, E, M)$, which is a rigid geometric figure that obeys the rules of ordinary Euclidean geometry.

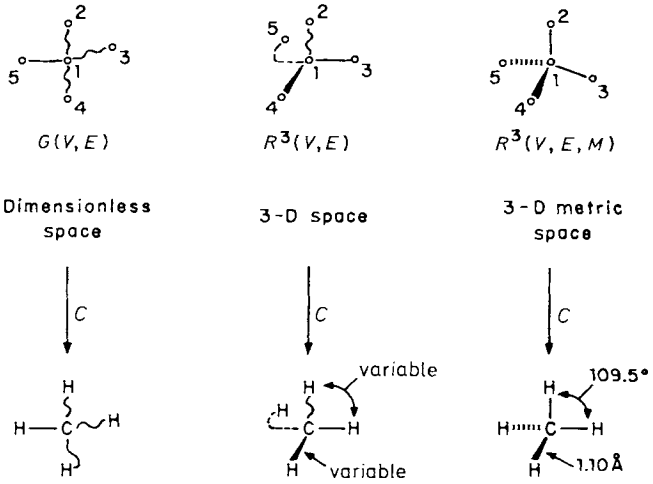

Fig. 6. Graphical topological, $G(V, E)$, topological geometric, $R^n(V, E)$, and Euclidean geometric, $R^3(V, E, M)$, representations of methane. The mathematical objects $G(V, E)$, $R^3(V, E)$, and $R^3(V, E, M)$ become models for the chemical object methane by embedding in the chemical paradigm, represented by the mapping process C. This produces a structural model at the graphical (left), topological (middle), or Euclidean (right) level of representation. V, points (vertices); E, lines (edges); M, metric (distances, angles).

4.3. Molecular Models

We have seen how mathematical objects may be used as models for molecular structures. The meaning of the term model, like that of the term paradigm, is a bit fuzzy. For the present purposes, a model is an alternative form of an object or concept, which is created with the expectation that it will provide some insight into the nature of the object or concept. The mind is a model builder par excellence as it seeks, with only fragmentary information, a closed interpretation of the surrounding world. To many organic chemists, models are the "pictures" on which imagination may be exercised and which enhance an intuitive understanding of the object or concept under consideration.

According to *Trindle*,[12a] in building a model we relinquish any claim to perfect truthfulness. Models are always different from the objects or concepts that are being represented. In science models are temporary aids, always subject to revision and usually destined for an intellectual junkyard. The best and most useful models have certain characteristic properties:[10] they are memorizable, port-

able, simple, self-consistent, elastic, and widely applicable. Models are particularly delightful when they produce surprises. Since it is now taken for granted that molecular objects in the real world can be faithfully represented by geometric objects, the wonderment of molecular models as representations of chemical reality is often no longer appreciated by the practitioner.

Up to this point we have considered purely mathematical (topological and geometric) objects, which can exist in intellectual processing but which do not require any relation to an ultimate reality. We now need a bridge from these objects to molecular structures, which are models[12] used to represent the reality of chemical systems. For our purposes we shall assume that the molecules we wish to model exist as real objects. *Mislow*[13] has provided a proper perspective for the approach we wish to embrace:

> The (geometric) figures which can be developed from molecules and which become their models are mathematical objects and intangible abstractions of the reality they are intended to represent ... Model and molecule are thus separate and distinct entities, one abstract, the other concrete ... By contrast, molecules and molecular ensemble exist entirely in the realm of observables.

The concepts of molecules and molecular structure, the so-called intellectual units of the chemist, are remarkably successful models of chemical reality. However, we should keep in mind the caution of *Hammond* et al.:[14]

> It is ... important to remember the fine distinction between ... models and physical reality. A good model can be so successful in ordering our thoughts and predicting the behavior of systems that we come to regard the model as real ... Trouble may arise when two scientists, using ... different models engage in a bitter conflict in which they try to prove, or disprove, the reality of their models ... We must remember that scientific thinking is really a branch of symbolic logic.

In Figure 7, the relationship of topological spaces, graphical forms, geometric forms, and geometric figures to molecular structure is shown schematically. A mapping process, C, which corresponds to the chemical paradigm, transforms mathematical objects such as spaces, forms, and figures into chemical objects such as molecular structures. We shall now discuss the nature of this mapping process.

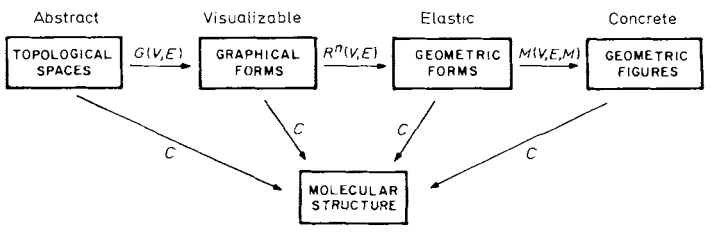

Fig. 7. A schematic representation of the interrelationship of topological spaces, graphical forms, geometric forms, and geometric figures. The embedding of any of these objects in conventional chemical paradigms produces a model of molecular structure. R^n, Euclidean space ($n = 1, 2, 3$). For other abbreviations, see Fig. 6 and text.

4.4. Transformation from Mathematical Objects to Chemical Objects

The transformation from mathematical objects (graphs, forms, figures) of topological geometry and Euclidean geometry may be viewed as the embedding of the mathematical objects into a chemical paradigm (see Fig. 7) to produce models for molecular structures. The paradigm provides the basis for the mapping process C that transforms mathematical objects into chemical objects. The historical pathway to modern chemical structure is related to that shown in Figure 7 except that Euclidean geometric figures (configurational stereochemistry) were accepted as the models for molecular structure before topological geometric forms (conformational stereochemistry).[15] The historical pathway is summarized in Figure 8 for cyclohexane as an example. Starting from the notion of composition (number and kinds of elements possessed by the chemical object), the notion of constitution[16] (bonding relations between elements) was introduced and visualization was achieved by creation of a molecular graph. The graph was then embedded in 3-D Euclidean space to produce a rigid configurational geometric model of the molecular structure of the chemical object.[17, 18] Finally, the molecular structure was allowed to be conformationally active by giving it an elasticity consistent with conventional chemical paradigms. The configurational level of representation may be viewed as corresponding to concrete operational thought and the conformational level of representation to formal operational thought.

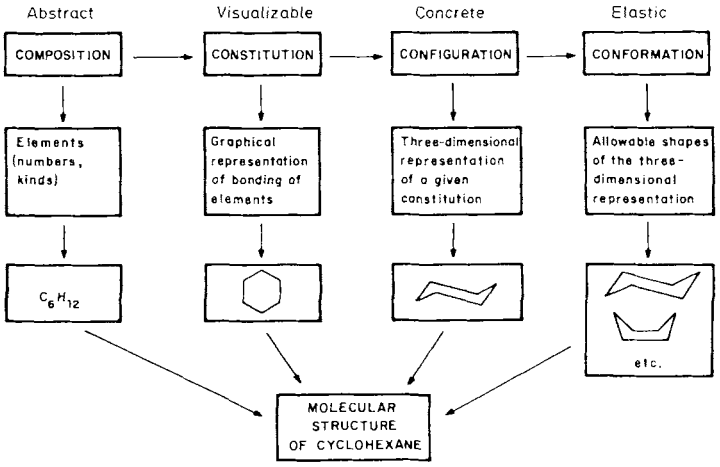

Fig. 8. The relationship between composition, constitution, configuration, and conformation in the mathematical and chemical sense. Molecular structure may be modeled at any of these levels. Cyclohexane is given as an example.

4.5. Molecular Graphs

Since chemists come into closest contact with topological ideas in the use of graphs to represent molecular struc-

tures, we now consider how graphs may be used to represent molecular topology and how these graphs are converted into geometric forms which model molecular structure.

The graphical method for representing molecules, which is nowadays taken for granted by organic chemists, represented a major intellectual breakthrough, since it provided a conceptual framework for further progress in organic chemistry. The informational content of a molecular graph and its ease of visualization are important reasons for its success among chemists. A special attraction of graphs is their power in handling combinational problems in chemistry. From a practical standpoint, the use of graphs and simple rules with pencil and paper, without need for lengthy calculation, allows representation and categorization of a large number of chemical systems. Let us analyze the basis for why graphs are so valuable in analyzing chemical systems and why these graphs appear to have such a broad and robust informational content.

In a molecular graph the vertices represent atoms (or groups of atoms considered as a unit) and the lines represent bonds. The points and the connections between points are topologically significant. The chemist would term the points the *composition* of the molecular graph, and the network of connections the *constitution* of the graph. To a topological chemist the composition and constitution of the graph are essentially global topological properties of the graph. The graph of a molecule may be viewed as an expression of the topological concept of special neighborhood relationships, which are chemically described by the valence of an atom (A). Only n atoms of the entire set of atoms in a molecule have a valency relationship with A, i.e., A has a valency of n. This topological notion of valency or bond order was the foundation of the first formulations of structural theory.[16] The actual arrangement of atoms in space, their bond lengths and bond angles, need not be specified. Indeed, at this level, bonded atoms may be drawn further apart than nonbonded atoms without reduction of the topological information, which is concerned only with the property of connectedness of atoms in the set with A.

Two graphs that have identical numbers of vertices connected in the same way are said to be *isomorphic*. The chemist recognizes two isomorphic molecular graphs as having identical composition and constitution. The type of line used to make the connection or the symbols used to represent the graph are not of topological significance.

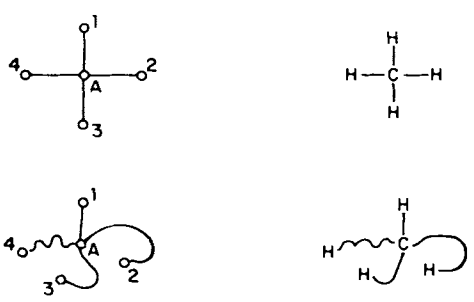

Fig. 9. Two isomorphic (mathematical) graphs of degree four (left) and two isomorphic molecular graphs representing methane (right).

Thus, a symmetrical, simple mathematical graph of degree four (see Section 4.2) is the same if it is written with a mixture of wiggly, straight, long and short lines (Fig. 9, left). The same holds true for the molecular graph of, for example, methane (Fig. 9, right). Because the points of the graph are abstract entities, the same molecular graph may represent many different molecules.

4.6. Stereochemistry in Euclidean and Topological Molecular Structures

Stereochemistry examines and categorizes relative spatial relationships between atoms and groups of atoms within a molecule and between different molecules.[15] From everyday experience, the chemist recognizes that, although the relative arrangements of atoms (configurations) and the relative shapes of networks of atoms (conformations) are of enormous importance, quantitative metric quantities such as bond lengths and bond angles may remain completely unspecified for many types of analyses. Within this framework, it is natural to employ an extension of topological ideas (which ignore metric relations) in stereochemical analysis.[19]

We have seen that graphs allow a topological representation of molecules in terms of the idealized entities that constitute geometry and that a molecular graph can be regarded as a representation of molecules in topological geometry. Examination of the stereochemical features of molecules requires the embedding of the molecular graph into Euclidean space, which produces geometric forms. This embedding is required because constraints, which are not fundamental to topology, are placed on the physical characteristics of molecular entities.

The step from geometric forms (topological) to geometric figures (Euclidean) involves the application of a metric. The introduction of distances and angles into *topological molecular structures* creates *geometric molecular structures*. The transition from topological to geometric structures is a profound one from the standpoint of intellectual processing; indeed, it is analogous to the distinction between formal operational and concrete operational thought! Thus, a geometric figure represents a concrete chemical object with fixed distances and angles, whereas a topological structure represents the chemical object only under the condition of conservation of topological properties. Finally, the labeling of the points of the geometric figure, which results in a fixed orientation of the figure, allows the representation of chemical objects such as enantiomers.[20]

The discovery of optical activity revealed a limitation of molecular graphs, which was overcome by introduction of the concept of configurational stereochemistry resulting from the arrangement of atoms in 3-D space. Optical isomerization could be understood in terms of the Euclidean 3-D geometry of n atoms connected to a central atom A. The key notion of the tetrahedral arrangement of valences about carbon is the same whether the configurational molecular figure representing the geometry is regular *(van't Hoff)*[17] or irregular *(Le Bel)*.[18] The neglect of metric relations, a fundamental feature of topological thinking, is apparent here. The bond lengths and bond angles of the te-

trahedral structure can vary over a wide range without changing the (nontopological) geometric property of configuration. Of course, in real systems a limit may be reached for which the configuration is not conserved (bond breaking, formation of an achiral structure, etc.).

In the light of scientific paradigms, the step from a graphical, abstract, hypothetical representation of real objects to the acceptance of atoms as real entities that may be modeled by molecular structures in 3-D space represented a scientific revolution because it profoundly changed the way the practitioners designed and interpreted chemical processes. The acceptance of the concept of stereochemistry met with the expected resistance of practitioners doing normal science under the guidance of entrenched paradigms. For example, *Kolbe*[21] castigated the new paradigm as a step backward:

> It is typical of the present time, when there is so little criticism and so much hatred of criticism, that two practically unknown chemists, one from a veterinary college, and the other from an agricultural institute, pass judgement on the loftiest problems of chemistry, those which will probably never be solved, particularly the question of the position of atoms in space, and they undertake to answer these problems with an impudence and assurance that absolutely astonish the true scientist.

Such a vitriolic attack on a paradigm that is now universally accepted brings to mind the skeptical but perceptive remark by *Planck*:[22]

> New scientific truth usually becomes accepted, not because opponents become convinced, but because opponents gradually die, and because the rising generation are familiar with the new truths at the outset.

4.7. Boundaries in Euclidean and Topological Molecular Structures

In mathematics a boundary implies a discontinuity, that is, the qualitative nature of a function changes as a "behavioral point" crosses from one side of the boundary to the other. In organic thinking, the notions of inside/outside and above/below are commonly used with reference to volumes or surfaces, respectively. For example, an organic molecule may be solubilized inside a micellar aggregate, outside the aggregate in the aqueous phase, or at the micellar/aqueous interface. A specific topological form that faithfully represents the inside/outside/boundary aspects of a micelle is a sphere. Of course, any geometric form that is homeomorphic with a sphere will also faithfully represent these topological aspects.

The wave functions of orbitals may or may not change sign when passing through a plane defined by certain nuclei of the molecule of interest, that is, the qualitative properties of the wave function either change or remain the same on passing through the plane. A specific topological form that faithfully represents the above/below/boundary aspects is a Euclidean plane. Of course, in topological terms, the plane is elastic and may be bent, twisted, and stretched without loss of the notion of above/below/boundary. The power and robustness of Hückel molecular orbital theory probably reflects its topological foundations and explains its remarkable ability to faithfully represent the qualitative features of molecules, even those with no apparent Euclidean geometric symmetry.[23]

5. The Use of Topological Thinking and Geometric Models to Examine Chemical Structures

5.1. Topological Thinking in Chemistry: A Qualitative but Precise Approach to the Scientific Method

Having given examples of geometric thinking and the use of topological concepts, we can suggest that there is a general procedure for structured intellectual processing that can be termed *topological thinking*. This method uses elastic mapping procedures for establishing the correspondence between a model, which can be expressed in topological form, and a phenomenon or observation. Geometric thinking emphasizes the concrete aspects of the model that relate to rigid forms and figures in space, whereas topological thinking emphasizes the elastic mapping process. Thus, the intellectual process by which a molecular structure is predicted to have a certain color or to be characterized by a certain NMR spectrum does not involve purely geometric components. The color or the spectrum can be related to a more general topological space in which the properties corresponding to color or the NMR spectrum can be defined.

Another way to view topological thinking is to consider it as an intellectual process that involves the pulling, stretching, and twisting of ideas in a search for sameness or correspondence in a manner reminiscent of the process involved in searching for homeomorphisms in topological geometry. Phenomena are imbued with properties that allow them to be converted into mathematical forms, which, in turn, can be mapped onto topological geometric forms.

Topological thinking is always qualitative, because, like topological geometry, it does not involve quantitative metric constraints. The term qualitative tends to have a pejorative connotation in the sciences. There is a tendency to assume that scientists are qualitative only when they are incapable of being quantitative; that is, qualitative is merely second best to quantitative. However, the history and incredible pace of progress in organic chemistry over the past two centuries is proof of the power of qualitative thinking in science. In most day-to-day organic research, what appears to be of greatest import is a qualitative result and not the precise value of a quantity; for example, is a rate slower or faster, is a yield higher or lower, does a structure contain a carbonyl or not. It is probable that the poor reputation of qualitative thinking is due to the naive and imprecise appearance of certain qualitative ideas. According to *Thom*,[3c] such need not be the case:

> (We can furnish) ... by a refinement of our geometric intuition ... our scientific investigations with a stock of ideas and procedures subtle enough to give satisfactory

> representations to ... phenomena ... we can now present qualitative results in a rigorous way, thanks to recent progress in topology ... for we know how to define a form and can determine whether two functions have or have not the same form or topological type.

Thom goes on to suggest that topological thinking is capable of releasing our intuition from the constraint of three-dimensional space and is capable of providing a more general, richer intuition for the examination of microscopic phenomena. Furthermore, topological thinking can be precise if only the topological aspects are considered in a geometric analysis. According to *Mislow*:[13]

> As chemists we often employ inexact terms such as fast/slow, strong/weak, concentrated/dilute, hot/cold, etc., yet we are confident that these words suffice to carry the desired message, unburdened by superfluous precision, within the context of the report.

Quantitative thinking, of course, plays a crucial role in the scientific method. However, quantitative, abstract mathematics may result in noncausal thinking that is mathematically precise, consistent, and rigorous, but chemically or physically irrelevant. *Thom*[3b] warns:

> The human mind would not be fully satisfied with a universe in which all phenomena are governed by a mathematical process that is completely coherent but totally abstract. Are we not then in wonderland? In the situation where man is deprived of all possibility of intellectualization, that is, of interpreting geometrically a given process, either he will seek to create, despite everything, through suitable interpretation, an intuitive justification of the process or he will sink into resigned incomprehension.

Perhaps *Platt*[8] best epitomizes the attitude of the topological thinker:

> Many—perhaps most—of the great issues of science are qualitative not quantitative, even in physics and chemistry. Equations and measurements are useful when and only when they are related to proof: but proof or disproof comes first and is in fact strongest when it is absolutely convincing without any quantitative measurement ... you can catch phenomena in a logical box or in a mathematical box. The logical box is coarse but strong. The mathematical box is fine-grained but flimsy. The mathematical box is a beautiful way of wrapping up a problem, but it will not hold the phenomena unless they have been caught first in a logical box.

In other words, a phenomenon should be mapped onto the correct topological form (logical box) before it is modeled in a quantitative fashion (mathematical box).

Topological thinking assumes that if the correct topological model for a phenomenon has been devised, then all of the topologically relevant aspects of the model can be "mapped onto" the phenomenon; that is, all the topological features of the model are enjoyed by the phenomena and vice versa. This potential relationship is extremely powerful when it exists because it automatically defines qualitative attributes that can be transferred from a given topological form to a wide range of chemical phenomena.

For example, the isoelectronic principle involves the mapping of the properties of a topological chemical structure having an array of valence electrons onto specific atoms. Thus, all atoms with octets of electrons "telescope down" to a single point in a topological space; the same is true for all atoms with sextets of valence electrons. In topological thinking, carbenes, nitrenes, oxygen atoms, etc., have the same qualitative chemical properties. This means that each reaction or physical property that is related to the topological aspects of a given chemical structure is shared qualitatively by every member or structure in the family. Other important examples of topological thinking in organic chemistry include the Hammond postulate,[24] the Woodward-Hoffmann rules,[25] and Salem diagrams.[26]

5.2. Tetrahedral Carbon: A Triumph of Topological Thinking

The first important step in the development of the structural theory of chemistry was probably the formulation of the concept of valency. This concept when mapped onto the concepts of graph theory naturally leads to the recognition of connectedness, the special chemical relationship that distinguishes the n atoms bound to an atom A from the rest of the set. The connectedness, in turn, is interpreted in terms of chemical bonds. Thus, at the earliest stages of development, the key concepts of bonding were topological and graphical.

Consider the following argument, based on the use of topological and geometric thinking, an experimental isomer count, and the assumption of the noninterconvertibility of isomers modeled by 3-D geometric figures. If the composition of methane is CH_4 and if it can be represented by a molecular graph and by a 3-D geometric figure, there are two distinct classes of possibilities (Fig. 10): either the vertices of the molecular graph are equivalent (class I) or they are not equivalent (class II). These two possibilities may be visualized with a molecular graph showing a C atom with four equivalent bonds to the H atoms, or by any other molecular graph with composition CH_4.

If I is the correct representation, then replacement of a single H atom by any equivalent atom will lead to one and only one isomer. If II is the correct representation, then replacement of a single H atom by any equivalent atom

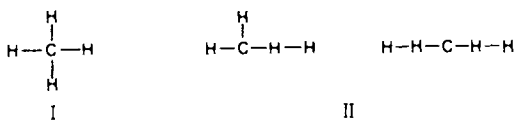

Fig. 10. Possible graphs for the representation of methane. Class I consists of a graph that shows four equivalent hydrogen atoms (and all isomorphous graphs) and class II consists of all other graphs of composition CH_4.

will lead, in principle, to two distinct isomers. Since all experimental examples have been consistent with I but would require an ad hoc explanation in each case to be consistent with II, strong inference suggests a molecular graph of CH_4 that has four equivalent H atoms and a C atom with a valency of four. By extrapolation, the valence of any member of the methane family is four. Any geometric figure that represents the molecular graph in 2-D or 3-D space and has four equivalent vertices and any molecular structure that has four equivalent H atoms bound to a C atom is consistent with the experimental finding that only one isomer is produced from methane by monosubstitution. In 2-D geometry the only such molecular graph places the H atoms at the corners of a square and the C atom at the center (square planar). In 3-D geometry the only such structures are a tetrahedron and a square pyramid. Thus, the experimental isomer count based on topological and geometric thinking reduces the choices to only three molecular structures (Fig. 11)!

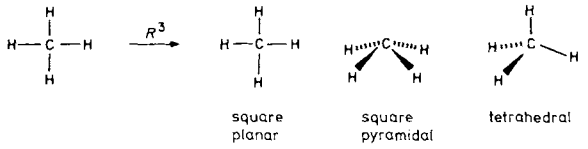

Fig. 11. Possible molecular structures produced by embedding the topological molecular graph for methane, deduced from the isomer count, into 3-D space (R^3). Three possible Euclidean molecular structures result.

By employing the isomer count criterion again (Fig. 12), the square-planar and square-pyramidal structures can be ruled out. Replacement of one H atom in a monosubstituted methane produces only one product, as expected for a tetrahedral structure. The square-planar and square-pyramidal structures, on the other hand, would have given two possible products (*cis* and *trans*).

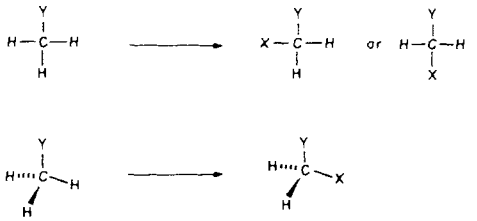

Fig. 12. Replacement of one H atom by a substituent X in square-planar or square-pyramidal (upper) and in tetrahedral (lower) monosubstituted methane, CH_3Y (see text).

The existence of enantiomers follows logically from the nonequivalence in 3-D space of mirror images of tetrahedral molecular figures having four different substituents. Moreover, these general conclusions are also valid for other molecular structures having a central atom of valence four.

A second example of topological thinking in organic chemistry is found in the use of the isomer count method to infer the structure of benzene (Fig. 13). If benzene has equivalent bonds, then only one type of 1,2-disubstituted benzene should exist; if benzene has alternating single bonds and double bonds, then two isomers of 1,2-disubstituted benzenes should exist. Since isomerism in 1,2-disubstituted benzenes has not been observed, it is inferred that the bonds in benzene are equivalent.

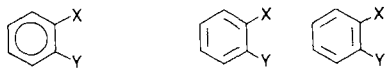

Fig. 13. Two representations of a 1,2-disubstituted benzene. Left: the bonds are equivalent (one possible structure). Right: alternating single and double bonds are present (two possible structures).

5.3. The Role of Time in Topological Thinking: Structural Stability and Chemical Reactivity

At the concrete operational level of thinking or the Euclidean geometric level of modeling, structures are rigid and do not change with time. At the formal operational level of thinking or the topological geometric level of modeling, structures are elastic and capable of changing with time. It is crucial to distinguish two types of time-dependent structural changes: those that conserve all topological properties and those that change the topological properties. For example, the former would correspond to the dynamic stereochemistry of a stable chemical structure and the latter to the dynamics of a chemical reaction.

Consider a structural model of a methane molecule. At any instant in time, a "snapshot" of the methane structure would not reveal a perfect tetrahedron, because vibrations will slightly change each bond length and bond angle (Fig. 14). Nevertheless, a chemist would not fail to recognize methane in any of its vibrational guises unless one of the C-H bonds becomes so long that it becomes unclear whether the observed structure corresponds to methane or to a methyl radical plus a hydrogen atom. The notion that methane, under "normal" conditions, can be modeled as a perfect tetrahedron derives from the premise that all experimental observations of methane correspond to a time-averaged structure and that the limiting time-averaged structure is a perfect tetrahedron. The time-averaged tetrahedral model is valid because, in a typical analysis, more than a trillion molecules are sampled.

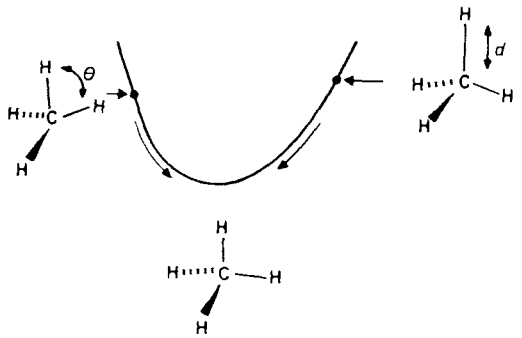

Fig. 14. Ideal tetrahedral representation of methane as an "attractor" structure for all homeomorphic representations of methane.

In topological terms the perfect tetrahedral structure represents an "attractor" structure toward which all other

topologically equivalent chemical structures tend. The chemical nature of methane does not change for sufficiently small deformations of its structure.

An experiment might be possible on a such short time scale, however, that most methane molecules would be "caught" in a nontetrahedral shape. Whatever the technical difficulties of such an experiment, it is topologically equivalent to an experiment for detecting cyclohexane conformers. Before fast methods of analysis were available, cyclohexane was considered as a single, static structure. Conformers were not detected because the time scale of the experiment was large relative to the time scale of the conformational change. With modern laser techniques, chemical structures may be examined on time scales of the order of 10^{-12} to 10^{-13} s. Many conformational systems in organic chemistry that are normally considered as being in dynamic equilibria are "static" on such a time scale.

6. The Use of Topological Thinking, Geometric Models, and Paradigms to Examine Chemical Reactivity

Are there archetypical graphs, topological forms, and geometric figures for modeling chemical reactivity? If we assume such models exist, we now have a recipe for anticipating their structure and the pathways for producing them; that is, we can map the pertinent aspects of the molecular graphs, molecular forms, and molecular figures used to model chemical structures onto reaction graphs, reaction forms, and reaction figures (i.e., a reaction network). It is natural to associate the points of the reaction network with the structures of reactants and products and the lines connecting the points with elementary reaction steps.

Topological thinking allows us to handle the multidimensionality of ground- and excited-state reactivity for a given structural transformation with a single reaction network generated by geometric procedures. Chemical paradigms guide the expression of specific geometric features of the reaction network.

6.1. Electronically Excited States and Diradicaloid Structures

Let us consider a chemical transformation of a reactant structure (R) to a product structure (P): R→P. The photochemist is concerned not only with the ground-state surface for this reaction but also with the excited-state surfaces associated with the same overall transformation. In constructing a reaction graph we need to establish the components (vertices) and connections (edges) of the graph. What are the components that correspond to the pertinent states of R and P? Using the highest occupied/lowest unoccupied (HO/LU) orbital paradigm for theoretical guidance,[27] there are four components or states, corresponding to the four possible electron occupancies of the HO and LU orbital of any R and P: S_0, S_1, S_2, and T_1 (Fig. 15). The energetic ordering of these states is invariably $S_0 < T_1 < S_1 < S_2$ for ordinary organic molecules.[28]

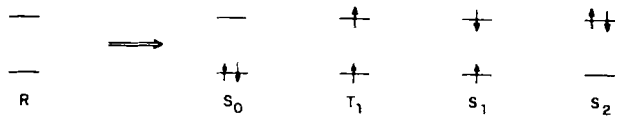

Fig. 15. The relationship between the HO and LU orbitals for a reactant structure R and its four lowest-lying electronic states: S_0, T_1, S_1, and S_2.

What are the connections between the components of R and P? If we can answer this question in a general way we will be able (as we are for molecular structures) to generate a visualizable reaction graph, which we can transform into a topological geometric form by embedding it in a Euclidean space, and which we can eventually transform into a Euclidean geometric figure with a metric, namely, the quantitative relationship of structure to energy. Before discussing examples of "reaction structures" (i.e., specific chemical reactions), we will discuss an important paradigm for the so-called "diradicaloid" structure that is commonly used for photoreactions.[26] This diradicaloid structure generally has four electronic states that are related to the S_0, S_1, S_2, and T_1 states of R and P. Importantly, we shall see that the diradicaloid structure is usually optimal for transformation from one energy surface to another, which occurs at the so-called "behavioral point" (corresponding to the change in atomic arrangement as R is transformed into P). Since getting from an excited-state surface to a ground-state surface is a critical aspect of all photochemical reactions, the diradicaloid geometry plays a crucial role in determining the possible "traffic patterns" at this behavioral point.

6.2. The Diradical/Zwitterion Paradigm

The important and extremely useful diradical/zwitterion (D/Z) paradigm for analyzing many photoreactions was proposed by *Salem*[26] as follows: If a molecular structure (having an even number of electrons) occurs along a reaction pathway for which the highest occupied orbital and the lowest unoccupied orbital are of comparable energy, the structure, termed a *diradicaloid or diradical/zwitterion structure*, will have four low-lying electronic states that will determine the chemical pathways leading to and from the structure. The diradical/zwitterion paradigm has the typical fuzziness of topological structures and qualitative organic thinking. The "composition" of the topology, namely, the set of four electronic states, is specified, but the energetic ordering of the states and the connectivity of the surfaces from R to P are not. We can proceed to the "constitutional" level of a reaction graph by assuming a common orbital situation for the reactant structure and then deriving the possibilities for the diradicaloid structure. By inspection, we can attempt to list the most probable state orderings of the diradicaloid structure and note the possible connections, thereby establishing the possible constitutional relationships between R and D/Z. We can then repeat the process to determine the connections between D/Z and P.

First, we consider a limiting situation in which the HO and LU orbitals have exactly the same energy at the D/Z structure (Fig. 16). Since composition is a topological property, we postulate that it must be conserved in an elementary, chemical step. Thus, there must be a one-to-one correlation between the number of electronic states for R and D/Z. What are the four lowest-lying states of the D/Z structure? How do they connect with the four lowest states of R?

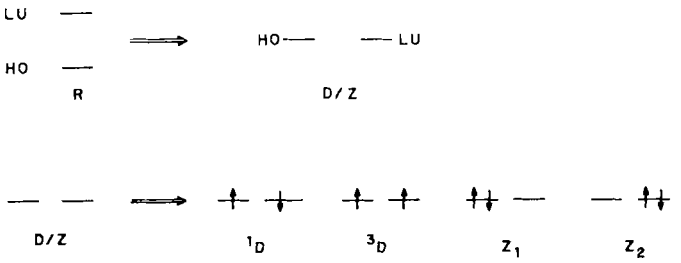

Fig. 16. The relationship between HO and LU orbitals and D/Z structures. Above: A chemical reaction results in transformation of the well-separated HO and LU orbitals of the starting structure R into a pair of orbitals of comparable energy for the diradicaloid structure D/Z. Below: The four electronic states (^1D, ^3D, Z_1, Z_2) of the D/Z structure.

In Figure 16, the states, (labeled ^1D, ^3D, Z_1, and Z_2) that are possible for the two electronic configurations of the D/Z structure, are shown. Let us now generate the possible connections that would constitute reaction graphs of a hydrocarbon system for which the state compositions are *only* S_0, T_1, S_1, and S_2 for R and ^1D, ^3D, Z_1, and Z_2 for D/Z. For hydrocarbons, the energy of the ^1D and ^3D states are expected to be similar, as are the energies of the Z_1 and Z_2 states.[29] The Z_1 and Z_2 states can be considered as a unit because of their similar energies and electronic and spin configurations. The ^1D and ^3D states, however, cannot be considered as a unit, because they have different spin configurations. In making connections between the states of R and D/Z, orbital occupancy and electron spin are used as descriptors at the topological level. In Figure 17, the transformation R→D/Z can be viewed as a reaction graph (termed a Salem diagram) for this structural change starting from any one of the four lowest-lying electronic states

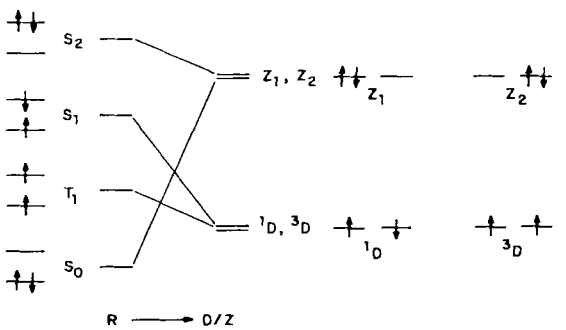

Fig. 17. Reaction graph for the transformation R→D/Z (see text).

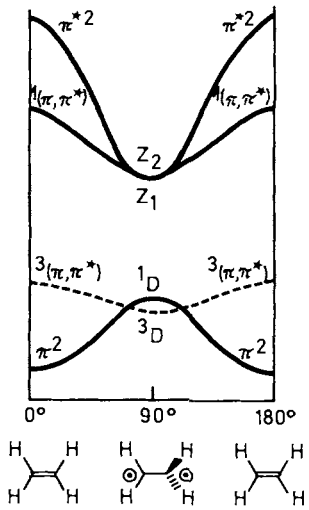
of R. The topological arguments are independent of the detailed chemical structure of R or D/Z. The next critical questions are how to map the reaction graph of Figure 17 onto plausible experimental examples and how, for a given system, to generate crucial experiments to eliminate by strong inference all candidates that cannot be mapped onto the reaction graph.

6.3. Some Archetypical Reaction Graphs Involving D/Z Structure

As examples of topological thinking in the use of reaction graphs, we shall consider two families of reactions involving D/Z structures along the reaction pathways. One family is typified by the *cis-trans* isomerization of a carbon-carbon double bond and the other family by a hydrogen-abstraction reaction.

The twisting and breaking of a carbon-carbon π bond may be imagined to occur as follows:[27] as an ethylene molecule is twisted, it eventually arrives at a structure in which the two methylene groups are mutually perpendicular (Fig. 18). At this diradicaloid geometry the π bond is completely broken. The resulting 1,2-diradical can be described by four electronic D/Z states. Twisting about the



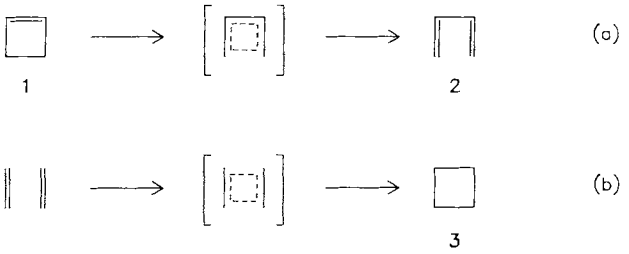


Fig. 18. State correlation diagram or reaction graph for the *cis-trans* isomerization of ethylene.

carbon-carbon bond of excited ethylene sharply relieves electron-electron repulsion, thereby lowering the energy of any ethylene state for which bonding is not important (because electronic excitation has already effectively broken the bond). As a result, the electronic energies of S_2, S_1, and T_1 drop rapidly as a function of the twist angle. At the same time, the electronic energy of S_0 increases as the molecule is twisted, because the π bond is being broken without any compensating bond formation. The breaking of a π bond by twisting is thus a prototype of a ground-state-forbidden concerted reaction, such as the disrotatory ring opening of cyclobutene **1** to give 1,3-butadiene **2** [Eq. (a)]

or the suprafacial-suprafacial [2+2] cycloaddition of two molecules of ethylene to give cyclobutane **3** [Eq. (b)].

(a)

(b)

The correlations $S_0 \rightarrow {}^1D$, $T_1 \rightarrow {}^3D$, $S_1 \rightarrow Z_1$, and $S_2 \rightarrow Z_2$ may be made on the basis of orbital-symmetry considerations.[26,27] The symmetry operation that brings the starting planar geometry into the twisted (diradicaloid) geometry is a rotation of one CH_2 group. The overall state symmetries must be definable in terms of this symmetry operation. Although the state correlation is best accomplished by use of group theory and point-group analysis, the following qualitative description indicates the basis of the correlation.

The wave function for the π^2 configuration (Fig. 18) at the planar geometry is essentially covalent in character, that is, there is very little ionic character to planar, ground-state ethylene; in terms of the p orbitals on the two carbon atoms, p_1 and p_2, the π^2 wave function has the form $p_1(\uparrow)p_2(\downarrow)$. This means that at all times there is only one p electron near each carbon atom, and the two electrons have paired spins. For the $^3(\pi,\pi^*)$ configuration at the planar geometry there can never be two electrons on one carbon in the same p orbital since the electrons have parallel spins (violation of the Pauli principle). The triplet (T_1) state is purely covalent and has no ionic character; its wave function has the form $p_1(\uparrow)p_2(\uparrow)$.

The wave functions for $^1(\pi,\pi^*)$ and π^{*2} must differ from that for π^2, because these two states are much higher in energy. They are best described by zwitterionic wave functions.[26,27]

The twisting of a π bond thus represents a prototype topological reaction surface. The state correlation diagram (Fig. 17) exhibits the following qualitative features:

1. The occurrence of minima in the S_2, S_1, and T_1 surfaces near the D/Z structure.
2. A maximum in the S_0 surface near the D/Z structure.
3. The close approach of the S_0 and T_1 surfaces near the D/Z structure.

The important topological features of these surfaces are the existence of four surfaces, their energetic ordering, and their electronic character. The closeness of approach of the ^1D and ^3D surfaces and of the Z_1 and Z_2 surfaces is not topologically significant but is geometrically significant, as shown for the examples discussed below.

6.4. Application of Prototype Surfaces to Experimental Examples

If they are to be useful, prototype reaction surfaces should be "topologically adjustable," that is, mappable onto different but related experimental examples. We shall start by considering the prototype surfaces for π-bond twisting, since we have just shown that the topological form of this surface may be viewed[26,27] as being equivalent to all thermally forbidden concerted ground-state reactions! This means that the twisting and breaking of the π bond of ethylene can be topologically mapped onto any 4n-electron concerted electrocyclic reaction or cycloaddition reaction.[25]

The mapping procedure can be simplified by invoking Kasha's rule,[30] which states that in solution only the S_0, T_1, and S_1 states are involved in organic photoreactions. Kasha's rule allows us to ignore S_2 (or any higher singlet state) and to consider only correlations involving the S_0, T_1, and S_1 states and the corresponding states of the D/Z structure. The movement of a representative point along each of the three lowest-energy surfaces (S_0, T_1, and S_1) in the prototype diagram is shown in Figure 19. Movement of the representative point along the S_0 and T_1 surfaces is chemically interesting in the region of the diradicaloid structure. At and near this structure, the S_0 and T_1 surfaces "come close together," so that there is a high probability for "jumping" from the S_0 to the T_1 surface (Fig. 19, left) or from the T_1 surface to the S_0 surface (Fig. 19, middle). Since jumping from one surface to another implies a topological change (in this case, change in the electron spin of the system), such jumps can only occur if the "topology" of the total experimental system is conserved. Therefore, somewhere in the experimental system a corresponding and compensating spin change must occur. Thus, an $S_0 \rightarrow T_1$ or $T_1 \rightarrow S_0$ jump is possible when the surfaces get close, but is not probable unless certain selection rules are obeyed. Chemically, the pertinent selection rules state that either strong electron spin-electron orbit (spin-orbit) coupling or electron spin-nuclear spin (hyperfine) coupling is needed for efficient $S_0 \rightarrow T_1$ or $T_1 \rightarrow S_0$ jumps near the diradicaloid structure.[31]

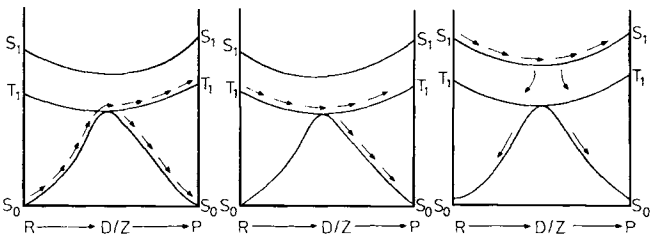

Fig. 19. Prototype reaction graph for a ground-state-forbidden concerted reaction showing various pathways for motions of a representative point along the reaction surfaces (see text).

The most important feature of the S_1 surface (Fig. 19, right) is the occurrence of a zwitterionic minimum near the D/Z structure; this minimum corresponds to the geometry at which $S_1 \rightarrow S_0$ transitions will occur. These transitions are spin allowed and can occur as rapidly as a means of "dumping" the electronic energy of the $S_1 \rightarrow S_0$ transition into vibrational or collision energy can be found. The position of the minimum is not a topological property of the system and may occur at the diradicaloid structure or at a

position corresponding to a structure "on either side" of the diradicaloid structure. Furthermore, other minima may occur owing to energetic features not explicitly considered.[32,33]

We have now developed a paradigm that can be used to generate experimental puzzles and to guide the search for solutions. To the extent that the paradigm is correct, only the experimentalist's ability to articulate the paradigm experimentally will determine whether the puzzle is solved. The paradigm has the following implications:

1. At diradicaloid geometries, $S_0 \rightarrow T_1$ and $T_1 \rightarrow S_0$ jumps are possible if an adequate mechanism for intersystem crossing is available and can operate. Since intersystem crossing can occur near the minimum of the T_1 surface, there is generally sufficient time for a spin-orbit or hyperfine interaction, which will promote the $T_1 \rightarrow S_0$ jump, to occur. A more remarkable possibility suggested by the paradigm (Fig. 19, left) is that an $S_0 \rightarrow T_1$ jump is possible, and, since this corresponds to a "chemiexcitation," it could result in chemiluminescence if phosphorescence can occur from T_1 of the product. The efficiency of the $S_0 \rightarrow T_1$ jump will depend on the efficiency of the spin change in the region of the diradicaloid structure.
2. An $S_1 \rightarrow S_0$ jump is possible from the minimum in the S_1 surface to the S_0 surface; the corresponding structure will reflect the nuclear geometry of the S_1 minimum. An intriguing possibility suggested by the paradigm is that the rapid removal of thermal energy will cause the representative point (Fig. 19) to "slide" rapidly toward the minimum on whichever side of the S_0 curve it lands.

We will now present experimental examples of photochemical and chemiluminescent reactions whose qualitative features can be readily interpreted in terms of "topological distortions" of the prototype energy surface.

6.4.1. The cis-trans Isomerization of Alkenes

An example of the archetypical reaction graph for a ground-state-forbidden reaction is shown in Figure 20, left, along with reaction graphs for the *cis-trans* isomerization of stilbene[34] (Fig. 20, middle) and 1-alkyl-2-anthrylethylenes[35] (Fig. 20, right). From experimental data the relative (and, in some cases, the absolute) positions of the S_0, S_1, and T_1 surfaces have been determined. The energy barrier indicated between the *trans*-stilbene structure and the D/Z structure on the S_1 and T_1 surfaces (Fig. 20, middle) is consistent with photochemical quenching data and temperature effects. There is no evidence for a barrier between the *cis*-stilbene structure and the D/Z structure on either the S_1 or T_1 surface. The representative behavioral points proceeding to *cis* and *trans* product starting from either *cis*- or *trans*-stilbene on either the S_1 or T_1 surface are consistent with the results of direct photoexcitation and triplet-sensitized excitation experiments.[34]

In the case of 1-alkyl-2-anthrylethylenes, e.g., *cis*- and *trans*-1-(2-anthryl)-3,3-dimethyl-1-butene,[35] the photoisomerizations are "one way" on both the S_1 and T_1 surfaces; that is, direct or triplet-photosensitized excitation of

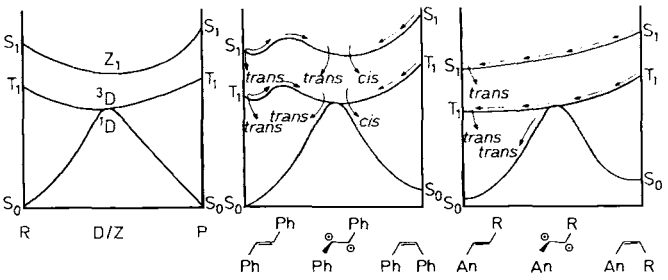

Fig. 20. Left: The prototype reaction graph of a ground-state-forbidden reaction. Middle: The "reaction structure" for *cis-trans* isomerization of stilbene. Right: The "reaction structure" for *cis-trans* isomerization of 1-alkyl-2-anthrylethylenes. An = anthryl. See text for discussion.

cis- or *trans*-1-alkyl-2-anthrylethylene results only in formation of *trans* product. This result is rationalized by postulating the lack of an effective attractor minimum at the D/Z structure on the S_1 or T_1 surface.

6.4.2. The Interconversion of Norbornadiene and Quadricyclane

The interconversion of norbornadiene (N) and quadricyclane (Q) is an example of a thermally forbidden concerted [2+2] cycloaddition reaction.[25,36] Accordingly, the prototype energy-surface diagram for thermally forbidden concerted reactions (cf. Fig. 20, left) can be used again as a paradigm to examine N and Q on the S_0, T_1, and S_1 surfaces.

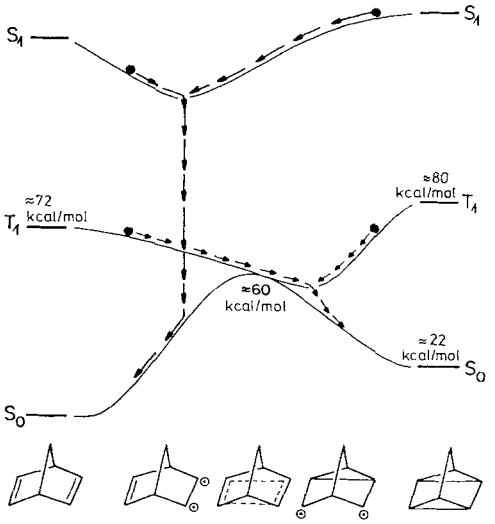

Fig. 21. Reaction graph for the norbornadiene to quadricyclane isomerization. See text for discussion. ● = representative point.

Mapping of prototype reaction graph for a thermally forbidden concerted reaction onto the N and Q systems produces the reaction graph shown in Figure 21. The prototype paradigm allows arguments to be made concerning the position of the minimum on the S_1 and on the T_1 surface relative to the ground-state maximum. Since the S_1 surface is expected to have zwitterionic character near the diradicaloid structure, a charge-separated zwitterionic

structure is expected. Of the two zwitterionic structures conceivably formed via approach from N or from Q, the one having a 1,2 arrangement of positive and negative charges, N_Z, is expected to be more stable than the one having a 1,3 arrangement, Q_Z, on account of simple Coulombic factors (Fig. 22, top). The structure corresponding to the S_1 minimum should therefore resemble the 1,2 charge-separated species N_Z; that is, the minimum on the S_1 surface should occur on the N side of the ground-state maximum.

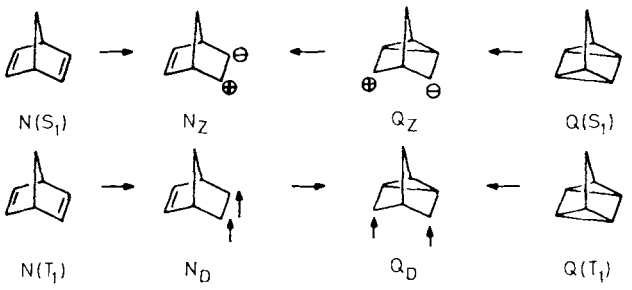

Fig. 22. Relationships of norbornadiene and quadricyclane structures to zwitterion species (top) and diradical species (bottom). See text for discussion.

A similar line of reasoning for the T_1 surface suggests that the species with a 1,3 separation of parallel spins, Q_D, should be more stable than that with a 1,2 separation, N_D (Fig. 22, bottom). The structure corresponding to the minimum on the T_1 surface should resemble the 1,3 diradical Q_D; that is, the minimum on the T_1 surface should occur on the Q side of the ground-state maximum.

Even though the above line of reasoning is qualitative, the paradigm leads to experimentally verifiable predictions; for example, either N or Q is the major product depending on the surface on which the representative point finds itself. Anytime a representative point is placed on the S_1 surface, N is the expected product, since the minimum on S_1 carries the point, via internal conversion, to S_0 on the N side. Anytime a representative point is placed on the T_1 surface, Q is the expected product, since the minimum on T_1, corresponding to Q_D, carries the point, via intersystem crossing, to S_0 on the Q side.

The paradigm has thus produced a framework to generate experimental puzzles and to articulate experimental solutions. How can the point be placed on the S_1 or T_1 surfaces? Experimentally the point can in principle be placed on the S_1 surface by direct photoexcitation of N or by direct photoexcitation of a precursor such as the azo compounds **4** and **5** (Fig. 23). The paradigm, if correct, predicts that, irrespective of precursor structure, the major product from the S_1 surface will be N and the major product from the T_1 surface will be Q. Thus, eight predictions can be made, each of which has been confirmed experimentally![37]

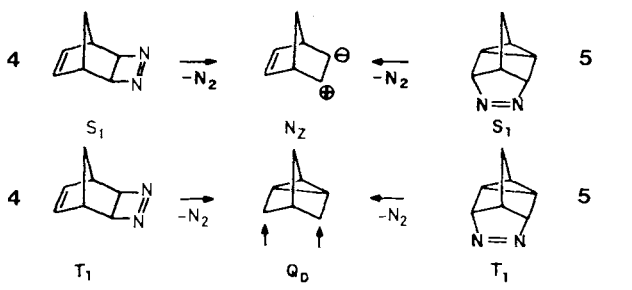

Fig. 23. Azo precursors **4** and **5** for N_Z (S_1 surface) and Q_D (T_1 surface). Top: On the S_1 surface both N and Q structures collapse to a zwitterionic structure, N_Z. Bottom: On the T_1 surface both N and Q structures collapse to a diradical structure, Q_D.

6.4.3. *The Chemiluminescent Electrocyclic Rearrangement of Dewar Benzene to Triplet Benzene*

The rearrangement of Dewar benzene to benzene may be viewed as a forbidden ground-state disrotatory electrocyclic reaction.[38] The prototype energy-surface diagram for thermally concerted reactions (Fig. 19) can therefore be used as a paradigm to examine the chemistry of Dewar benzene in its S_0, T_1, and S_1 states.

Initially, the prototype energy-surface diagram must be modified to accomodate any experimental data available for the Dewar benzene-benzene system. For example,[38] Dewar benzene is approximately 60 kcal/mol (ΔH_0) less stable than benzene, and the activation enthalpy, $\Delta H^{\neq}$, for the rearrangement of Dewar benzene to benzene is about 30 kcal/mol. The state energies for S_0, T_1, and S_1 for Dewar benzene and benzene are used to construct the energy-surface correlation diagram shown in Figure 24. The paradigm shows that three reactions are energetically conceivable: (1) the thermal production of triplet benzene; (2) the adiabatic conversion of triplet Dewar benzene to triplet benzene; (3) the adiabatic conversion of excited singlet Dewar benzene to excited singlet benzene.

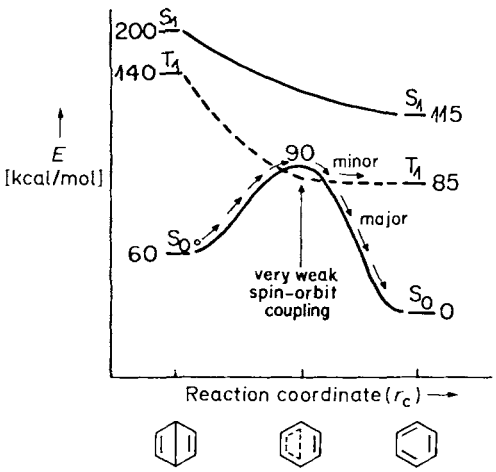

Fig. 24. Energy-surface correlation diagram ("reaction structure") for the Dewar benzene to benzene transformation.

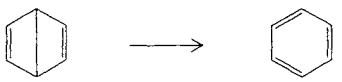
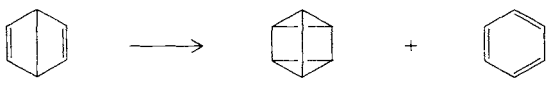


Experimentally, chemiluminescence is observed upon thermolysis of Dewar benzene and triplet benzene is produced, albeit in very low yield.[38] The reason for the low yield is readily explained by the paradigm in one of two ways: (1) The diradicaloid structure does not allow sufficiently strong spin-orbit coupling (which is expected to be

the only spin-flipping mechanism capable of causing an $S_0 \rightarrow T_1$ jump); (2) the time spent by the representative point in the region of the diradicaloid structure is too small to allow spin-orbit coupling to develop. Of course, a third possibility is that the paradigm is quantitatively incorrect with respect to the energetics; that is, the simplified two-dimensional representation may be misleading with respect to the energy of the diradicaloid structure.

The paradigm has thus created puzzles for the experimentalist: Is it the near absence of spin-orbit coupling, the too short time scale, or the energy that causes the low yield of triplet benzene? Can one devise a convincing test?

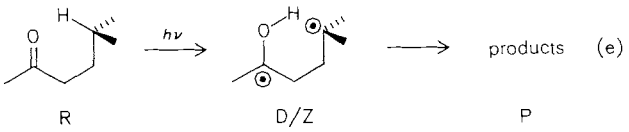


It is well established that certain "heavy atoms" such as halogens enhance spin-orbit coupling.[28] Thus, a specific test of the puzzle is to study the thermolysis of a Dewar benzene having a heavy-atom substituent. The paradigm suggests that thermolysis of a halogenated Dewar benzene should produce higher yields of triplet benzene if the near absence of spin-orbit coupling is the major factor in determining the yield of triplets. Experimentally, the thermolysis of 1,4-dichloro Dewar benzene produced a yield of triplets that was five times higher than that produced from Dewar benzene itself.[38]

The triplet state of Dewar benzene may be produced by triplet sensitization of Dewar benzene.[39] According to the paradigm (Fig. 24), an efficient adiabatic reaction along the T_1 surface is highly probable for the same reason that the $S_0 \rightarrow T_1$ jump is inefficient (i.e., the absence of an efficient spin-flipping mechanism). Experimentally, this prediction has been confirmed; triplet Dewar benzene **6**(T_1) produces triplet benzene **7**(T_1) [Eq. (c)].[39]

(c)

The paradigm further suggests that an adiabatic reaction along the S_1 surface is possible because S_1 of benzene is lower than S_1 of Dewar benzene and because the S_1 surface is separated from the S_0 surface all along the reaction coordinate. Experimentally, no evidence has been found for this adiabatic reaction. Instead, prismane **8** and ground-state benzene **7**(S_0) were produced by excitation of Dewar benzene **6** to the S_1 excited state [Eq. (d)].[38] This corresponds to a different process that is in competition with and evidently faster than the process leading to excited singlet benzene.



(d)

This paradigm has nothing to say directly about the formation of prismane **8**. The paradigm does, however, provide a possible explanation for the formation of ground-state benzene, since an attractor minimum on the S_1 surface is suggested as a possibility in the prototype surface (Fig. 19). Should the representative point be "captured" by this minimum, and if the minimum occurs on the benzene side of the ground-state maximum, internal conversion would lead to benzene.

6.4.4. *Reactions of n,π* Excited States*

The reactions of the n,π* excited states of carbonyl compounds are among the best understood of all photochemical processes. The n,π* state has topological features relative to a symmetry plane that allow the generation of topological reaction graphs that are applicable to a wide range of photoreactions.

(e)

A prototype reaction is intramolecular hydrogen abstraction by an excited carbonyl compound (Norrish type II photoreaction) [Eq. (e)]. The primary photochemical product is a diradicaloid structure, so that the overall transformation corresponds to an R→D/Z structural transformation. Application of the topological reaction graph for such transformations (Fig. 17) gives Figure 25. Starting from the $S_1(n,\pi^*)$ state there is an adiabatic connection to ^1D and starting from the $T_1(n,\pi^*)$ state there is an adiabatic connection to ^3D. Thus, both reactions are *topologically allowed* in the sense that the direct connections $S_1 \rightarrow {}^1D$ and $T_1 \rightarrow {}^3D$ exist.

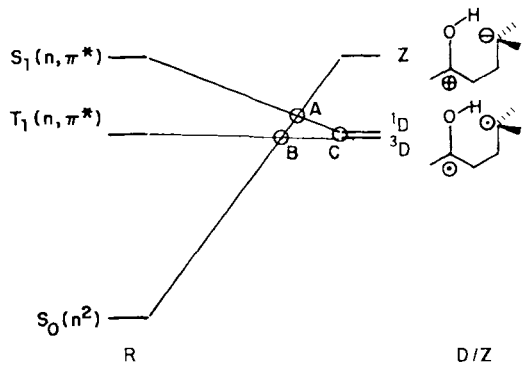


Fig. 25. Prototype reaction graph for the intramolecular hydrogen abstraction of photoexcited ketones. For A, B, and C, see text.

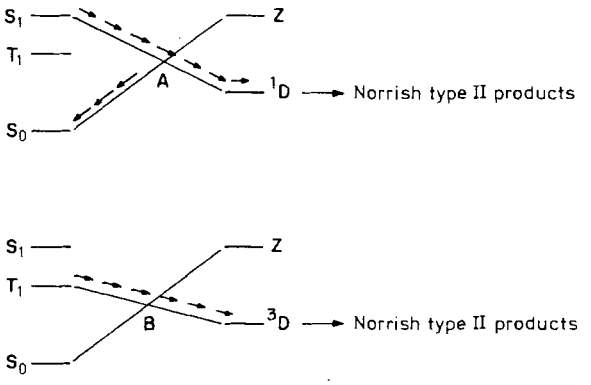
Since these arguments are topological, moreover, they are independent of the specific molecular structure we have selected to exemplify the reaction graph (i.e., S_0, T_1, S_1, ^1D, ^3D, and Z are merely symbols given to the abstract topological points!). Therefore, any conclusions derived for the specific example may be mapped onto all examples of H-atom abstractions from n,π* excited states of carbonyl compounds or n,π* states of compounds containing other functional groups. Furthermore, the reaction graph applies to any reaction that is topologically equivalent to (or homeomorphic with) hydrogen abstraction, that is, any

reaction involving low-lying $S_1(n,\pi^*)$ or $T_1(n,\pi^*)$ excited states in which the n orbital draws electron density from a substrate. Important examples are additions to alkenes, electron abstraction from amines, and the formation of exciplexes.[28]

Among the chemically interesting aspects of the reaction graph (Fig. 25) is the occurrence of three regions, A, B, and C, where different states have similar energies for the same structure. In these regions a transition from one state to the other is only expected to be favorable if a mechanism is available and if selection rules are obeyed. For example, the region A corresponds to structures for which the $S_1 \rightarrow {}^1D$ surface and $S_0 \rightarrow Z$ surface have comparable energies. This region is analogous to a traffic intersection. If a representative point moves down the $S_1 \rightarrow {}^1D$ surface relatively slowly, it may be driven by thermal collisions in one of three directions when it arrives in region A: toward Z, toward S_0, or toward ^1D. Since Z is higher in energy, this pathway is least likely. Thus, the plausible topological pathways are $S_1 \rightarrow A \rightarrow S_0$ and $S_1 \rightarrow A \rightarrow {}^1D$ (Fig. 26). In fact,



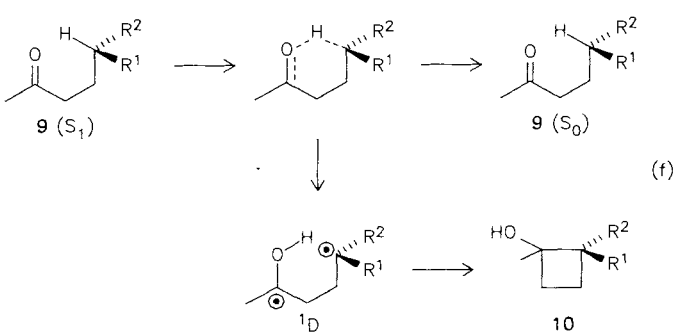


Fig. 26. Possible reaction pathways along the reaction graph for intramolecular hydrogen abstraction of photoexcited ketones.

experimental evidence in favor of the occurrence of both $S_1 \rightarrow A \rightarrow S_0$ and $S_1 \rightarrow A \rightarrow {}^1D$ pathways is available from the observation that an optically active ketone in the S_1 excited state, **9**(S_1), undergoes Norrish type II reaction both to form an optically active cyclobutanol **10** and to regenerate the starting structure **9**(S_0) without loss of optical activity [Eq. (f)].[40]

The situation is different for region B (Fig. 25), because the $S_0 \rightarrow Z$ surface is close to the $T_1 \rightarrow {}^3D$ surface and the surfaces differ in their spin characteristics. Transition from

(f)

one state to the other in region B requires a mechanism for intersystem crossing. In general, the rates of intersystem crossing in diradicals are relatively slow compared with motion (vibrational relaxation) along a surface. Nonetheless, the possibility of a jump from T_1 to S_0 is suggested by the reaction graph. Experimentally, it appears that only the $T_1 \rightarrow {}^3D$ pathway is followed (Fig. 26), since the quantum yield for product formation from T_1 can approach unity, that is, each molecule in the T_1 state produces products derived from the ^3D state.[41]

Region C (Fig. 25) is of interest from the standpoint of topology, because at geometries near C the ^1D and ^3D states are nearly degenerate. This means that weak magnetic forces whose energies are of the order of the energy difference between ^1D and ^3D can induce intersystem crossing between these states. There is considerable evidence that intersystem crossing from ^3D to ^1D is the rate-limiting step in reactions of triplet diradicals.[42]

7. Geometry, Intuition, and Imagination

In conclusion, we consider the possible relationships between geometry, intuition, and imagination. Intuition may be defined as an instantaneous comprehension or apprehension of an object or an event in the past, present, or future. In the spirit of the themes put forth in this article, some intuitions might be defined in terms of the instantaneous comprehension of a geometry representing an object or an event. Imagination may be defined as the power of creating or inventing mental images of what is not actually present and of perceiving the resemblances between apparently different objects and events. We can therefore view imagination as the manipulation of geometries, for example, in topological mapping.

In organic chemistry the classic figures of Euclidean geometry have provided the driving force for enormous efforts in organic syntheses. Of particular note is the role of the Platonic solids such as the tetrahedron,[43] the cube,[44] and the dodecahedron.[45] The belief in the reality of chemical objects that can be represented by these geometric figures and the realization of the syntheses of materials whose chemical properties correspond precisely to those expected from conventional scientific paradigms represents, in the author's opinion, a spectacular achievement of the highest order of intellect and scientific skill. Perhaps the future will bring comparable accomplishments involving the use of topological figures, especially those whose geometric properties are not revealed by an intuition that is provided by Euclidean geometry alone: for example, knots and Möbius strips.[46]

From time to time chemists create ideas that are judged by the profession to be imaginative, intuitive, and novel. Whether the values discerned in these ideas by the community of practitioners are intellectual, aesthetic, or practical, there is a consensus that such ideas increase the rate at which progress can be made in the field. It has been suggested that imaginative and creative thinking are distinguished from ordinary everyday thinking by a willingness to accept vaguely defined statements and to structure them, by a persistent preoccupation with puzzles before

solutions are apparent, and by extensive intuitive knowledge of the relevant aspects of puzzles.[47] The ability to achieve sudden insights into situations by recognizing similarities between new puzzles and solved puzzles would appear to depend on the ability of the brain to recognize familiar patterns and clues for the mapping of these patterns onto new puzzles.

Polanyi[48] has proposed that great scientific discoveries are made by practitioners who believe in the attribution of reality to scientific concepts, and that there can be an a priori knowledge of such underlying realities. He terms this knowledge a vision:

> ... the vision of a hidden reality, which guides a scientist in his quest, is a dynamic force. At the end of the quest the vision is becalmed in the contemplation of the reality revealed by a discovery; but the vision is renewed and becomes dynamic again in other scientists and guides them to new discoveries.

Polanyi[48] further notes that the vision is driven by the strength of imagination guided by intuition, which is homeomorphic with the view that the strengths of creativity in intellectual processing are guided by geometry.

The author thanks the National Science Foundation and the Air Force Office of Scientific Research for their generous support of this investigation. The author is also tremendously indebted to numerous friends and colleagues who over the past decade have participated with him in delightful discussions of the geometric and topological approaches to intellectual processing in the chemical sciences. A special thanks goes to Professor Lionel Salem for providing, over many years, a stimulating and revealing tutorial on seeking sameness in the solution of chemical puzzles.

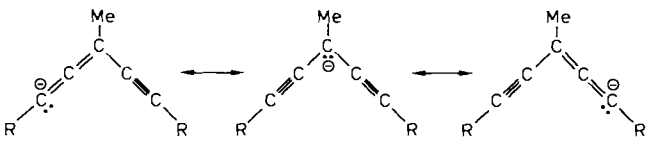
The Structure of an Allenylsodium Derivative—Competition between Carbanion Resonance Delocalization and Gegenion Charge Localization**



By *Christian Schade, Paul von Ragué Schleyer,* Maren Geissler,* and *Erwin Weiss**

Energies,[1] structures,[2] reactivities,[3] and reaction mechanisms[4] of the species often misleadingly designated "carbanions" may be influenced decisively by the alkali metal gegenions. A noteworthy example of the structural influence of such cations is provided by compound **1**, 3-[bis(tetramethylethylenediamine)sodium]-2,2,5,8,8-pentamethylnona-3,4-dien-6-yne,[5] the sodium salt of 2,2,5,8,8-pentamethyl-3,6-nonadiyne **2**. Concomitantly, compound **1** is the first allenylsodium derivative whose geometry has been determined by X-ray crystallography. The X-ray structures of two allenyllithium derivatives, one directly related to **1**, afford an interesting comparison.[8] Both of these are dimers, whereas **1** is a monomer.

1 **2**

Free carbanions (e.g. in the gas phase) may be stabilized by a group which delocalizes the negative charge. However, in the corresponding organometallic derivative in solution, the negative charge may be localized to a greater extent than in the free carbanion in order to maximize the electrostatic interaction with the alkali metal counterion. This principle[9] is demonstrated by the experimental results on **1**: a structure with a largely *localized* carbanion negative charge is favored over more *delocalized* alternatives.

3a, R=H; **3b**, R=Me; **3c**, R= *t*Bu

While qualitative theory (and MNDO calculations)[10] predict a resonance stabilized, symmetrical structure of the propargyl-type for the free carbanions, **3a** and **3b**, the crystal structure of **1** (Figure 1) shows the carbon skeleton to have an unsymmetrical allenyl anion topology. Hence, the resonance stabilization must have been reduced considerably. The sodium cation does not interact with the entire carbanion, as expected from the mesomeric formulations, but coordinates only with the end carbon, C_3. The bond lengths (Fig. 1) demonstrate **1** to be an allenyl derivative, with r(C3C4) = 124 pm and r(C4C5) = 138 pm. The ab initio bond lengths for allenylsodium, allenyllithium, and the allenyl anion are all about the same, 127 and 134 pm, and agree quite well with the experimental X-ray values not only for the sodium but also for both lithium derivatives (Table 1). In contrast, r(C5C6) = 144 pm and r(C6C7) = 119 pm in **1**; these bond lengths are close to those in propyne, 121 and 146 pm, as determined by microwave spectroscopy. The allene value is 131 pm.[11]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

As the pentadiynyl anion system was too large for an examination at adequate ab initio levels, MNDO was employed for the free anions, **3a** and **3b**. However, symmetrical geometries were favored in both cases, and no allenic structures could be located on the MNDO-hypersurfaces. Instead, bending a terminal RCC angle in **3a** or **3b** by fixed increments (to approximate the allenyl geometry) led to a steady increase in energy. For example, at $\sphericalangle RCC = 129°$ (the experimental value for **1**), the energies of **3a** and **3b** are 14 and 19 kcal/mol, respectively above the equilibrium values. This result suggests that charge localization due to electrostatic interaction with the counterion competes successfully in **1** with resonance stabilization.

Table 1. Comparisons of the ab initio (6-31G* opt) and experimental (X-ray) geometries of allenyl anion moieties ($RC_\alpha=C_\beta=C_\gamma R'R'')^\ominus M^\oplus$.

Species	Bond lengths [pm]		Bond angles [°]		
	$C_\alpha C_\beta$	$C_\beta C_\gamma$	$C_\alpha C_\beta C_\gamma$	$RC_\alpha C_\beta$	$MC_\alpha C_\beta$
Calculations: R = R′ = R″ = H					
Anion (free) [12] [a, b]	127.6	134.6	175.7	118.5	—
M = Na [a]	127.6	134.0	167.0	122.7	75.8
M = Li [14e]	127.3	134.4	161.4	127.9	71.5
X-ray structure analysis: R = *t*Bu, R′ = CH_3, R″ = C*t*Bu					
M = Na (**1**) [a]	124.4(14)	137.9(14)	172.9(9)	129.0(9)	86.2(6)
M = Li, dimer [8]	128.1(2)	136.5(2)	165.6(1)	121.9(1)	73.3(1)
R = C*t*Bu, R′ = *t*Bu, R″ = H					
M = Li, dimer [8]	128.5(3)	132.5(3)	165.6(2)	126.4(2)	73.9(1)

[a] This work. [b] 6-31+G* opt.

While we believe this conclusion to be valid, another factor must be considered: the inherent preference of such anions for a more localized (bent, C_s) allenyl rather than a π-delocalized (linear, C_{2v}) propargyl structure. The latter geometry permits the charge to be distributed to a greater extent, but the former benefits from the sp^2-hybridization (more s-character) at the carbanion center. Thus, ab initio calculations show the vinyl anion to be strongly bent, with an inversion barrier of 27 kcal/mol; this value is reduced to 7 kcal/mol in the allenyl anion, due to the conjugation.[12] A gas phase photodetachment study indicates $C_3H_3^\ominus$ to have an allenyl rather than a propargyl anion structure.[13, 14]

In contrast, MNDO incorrectly finds the propargyl (C_{2v}) structure of $C_3H_3^\ominus$ to be the most stable; this systematic error must be taken into consideration in evaluating the MNDO results with **3a** and **3b**. However, the additional conjugation afforded by the acetylene substituent in **1** and **3** should favor the propargylic form and there probably is very little energy difference between C_{2v} and less symmetrical geometries for **3a** and **3b**. Counterion charge localization effects must contribute to the structures adopted by **1** and by the corresponding lithium derivative.[7]

Although sodium pentacoordination is found frequently in crystal structures,[2b] the presence of the two TMEDA ligands in **1** is noteworthy. These inhibit association; the analogous lithium compound, Li(thf)-**3c**, is a dimer.[8] The influence of these TMEDA ligands also is responsible for restricting the $Na^\oplus$ interaction to a single carbon[15] instead of allowing even the dihapto coordination in allenyl sodium. This is shown by the bond angles, NaC3C4 = 86° and C3C4C5 = 173° in **1**, compared with the calculated values of 76° and 167°, respectively, for the unsolvated species. In the latter, the sodium interacts with both end carbons of the allenyl anion system since C3 (C5 in **1**) also is negatively charged to some extent. Because of the competition due to the external complexation with two TMEDA ligands, this does not take place in **1**.

There is another consequence of the metal cation interaction: the bending of the allenyl CCC angle in **1** (173°) is closer to that calculated for the free allenyl anion (176°) than for allenylsodium (167°). Table 1 shows that these trends continue with allenyllithium. The CCC angle is 161° in the monomer, but is somewhat larger (166°) in both crystal structures. Dihapto lithium bonding (bridging) is favored in the monomer and in both crystals where the LiCC angles are all about 73°. The larger interaction energy of the smaller $Li^\oplus$ is responsible for the greater tendency towards bridging and the greater CCC deformation than in allenyl sodium. We are finding this difference in sodium-lithium behavior to be general.[16]

Stepwise Addition of $MeS^{\oplus}$ to a Metal–Carbon Triple Bond— A New Type of Reaction in the Chemistry of Carbyne Complexes**

By *Fritz R. Kreissl** and *Hans Keller*

Nucleophilic attack on the carbyne carbon atom predominates for carbyne transition-metal complexes;[1–4] only a few examples have been reported of electrophilic attack, which results in the formation of carbene,[5–8] acyl,[9] or binuclear alkyne complexes.[10] We have now found a novel reaction sequence (a), which is characterized by a twofold electrophilic attack on the C atom of a MC multiple bond.

Dicarbonyl(cyclopentadienyl)(4-methylphenylcarbyne)-tungsten **1**[11] reacts in a stepwise, easily observed manner with dimethyl(methylthio)sulfonium tetrafluoroborate **2** to give first the cationic η^2-thiocarbene complex **3** and then the dicationic dithiatungstabicyclo[1.1.0]butane complex **4**.[12] Complexes **3** and **4** are obtained as red and yellow solids, respectively, and are stable at room temperature. The field desorption mass spectrum of **3** exhibits a peak at *m/z* 456 ($[M+H]^{\oplus}$), that of **4** one at *m/z* 251 ($M^{2\oplus}$). In the IR spectra of **3** and **4**, recorded in solution, two very intense CO absorptions are present, the positions of which are shifted to higher wave numbers relative to those of **1** ($\tilde{\nu}_{CO}$: **3** 2052, 1995; **4** 2105, 2065 cm^{-1}). Their intensity ratio in the case of both **3** and **4** supports a *cis* arrangement of the two carbonyl ligands. The ^1H- and ^{13}C-NMR spectra[13] are in accord with the suggested structures. The position of the signal for the alkylidene C atom of **3** ($\delta = 233.1$) is in very good agreement with the shifts normally found for heteroatom-containing η^2-carbene complexes;[14] for acyclic thiocarbene complexes, however, chemical shifts are found in the region around $\delta = 330$.[15]

The addition of the $MeS^{\oplus}$ ion to **1** establishes the nucleophilic character of the carbyne C atom, as has been suggested by *Fenske* et al. for cyclopentadienyl-substituted transition-metal carbyne complexes[16] and has been demonstrated in a carbyne/acyl transformation.[9] These addition reactions can be compared very well with the protonation of a thiocarbyne complex described by *Angelici* et al.,[7] in which an η^2-thiocarbene complex is likewise formed. Until now, however, few reactions of either this η^2-thiocarbene tungsten complex or of an analogous osmium complex[17] have been described and no examples demonstrating the nucleophilic character of the carbene C atom were known. The addition of a $MeS^{\oplus}$ ion to the WC double bond present in **3** represents the first example of the electrophilic attack of a cation on a Fischer carbene complex.

Isothermal Magnetic Phase Transitions Controlled by Reversible Electron/Ion Transfer Reactions

By *Robert Schöllhorn** and *Andreas Payer*

One of the most intriguing aspects of the intercalation chemistry of electronically conducting host lattices is the possibility of reversibly modifying and controlling the physical properties of solid materials by chemical reactions at ambient temperature.[1] So far, interest has focused mainly on changes of electronic properties, superconductivity, optical properties and structural transitions with the reaction state. We report here on the control of *magnetic* phase transitions via reversible electron/ion transfer reactions at 300 K with copper selenospinels $Cu_{1+y}Cr_2Se_4$ as the model system. The process is correlated with the change in the stoichiometric index y; at a critical concentration y_c the *isothermal* transition takes place according to the scheme

$$\text{ferromagnetic state} \underset{y<y_c}{\overset{y>y_c}{\rightleftharpoons}} \text{paramagnetic state} \qquad (T=\text{const.})$$

Spinel type structures formally provide an excess of vacant tetrahedral and octahedral lattice sites for the potential uptake and bulk transport of additional cations. In a recent publication we have demonstrated that copper chalcogenospinels with appropriate electronic properties and mobile $Cu^{\oplus}$ ions are, in principle, able to undergo topotactic redox reactions.[2] Since the copper chromium selenospinel $CuCr_2Se_4$ exhibits metallic properties as well as ferromagnetic behavior at room temperature[3] we investigated the electrochemical behavior of this compound in aqueous and aprotic electrolyte solutions ($Cu^{\oplus}/CH_3CN$, $Cu^{2\oplus}/H_2O$). Copper ions were found to be mobile in $CuCr_2Se_4$ and a chemical diffusion coefficient $\tilde{D}(300\,K) = 5\times10^{-11}\ cm^2\ s^{-1}$ was measured. The selenospinel participates in reversible electron/ion transfer reactions according to Equations (a) and (b), which apply to the case of $Cu^{\oplus}$ and $Cu^{2\oplus}$ electrolytes, respectively.

$$Cu_1Cr_2Se_4 + \ ye^{\ominus} + yCu^{\oplus} \rightleftharpoons Cu_{1+y}Cr_2Se_4 \qquad (a)$$

$$Cu_1Cr_2Se_4 + 2ye^{\ominus} + yCu^{2\oplus} \rightleftharpoons Cu_{1+y}Cr_2Se_4 \qquad (b)$$

The potential/charge transfer diagram under dynamic conditions (galvanostatic mode) as well as equilibrium potentials for the cathodic reduction of $CuCr_2Se_4$ in aqueous $Cu^{2\oplus}$ electrolyte are given in Figure 1a. An almost continuous change in potential is observed until the potential of copper deposition where the solid state reaction has reached its endpoint. The integral charge transfer value thus obtained is $n(e^{\ominus}/CuCr_2Se_4)=2$. For aqueous electrolytes containing $Cu^{2\oplus}$ ions the formal correlation between n and the stoichiometric index y corresponds to $y=n/2$. This was confirmed by analytical data, which agree perfectly with this correlation, i.e. no measurable side reactions appear and the intercalation of copper proceeds quantitatively according to Equation (b). The X-ray data (Fig. 1b) similarly indicate a one phase system with a continuous change in lattice parameters for the range $0\leqq y\leqq 1$. The products retain cubic symmetry with $a=10.57$ Å for the terminal phase with $y=1$; the total change in volume of the unit cell amounts to 7.0%. On anodic oxidation of $Cu_2Cr_2Se_4$ the process is reversed and the starting material ($y=0$) is obtained again after a charge transfer of $n=2$; the same result is found on chemical oxidation, e.g. with I_2/CH_3CN leading to $CuCr_2Se_4$ and (soluble) CuI.

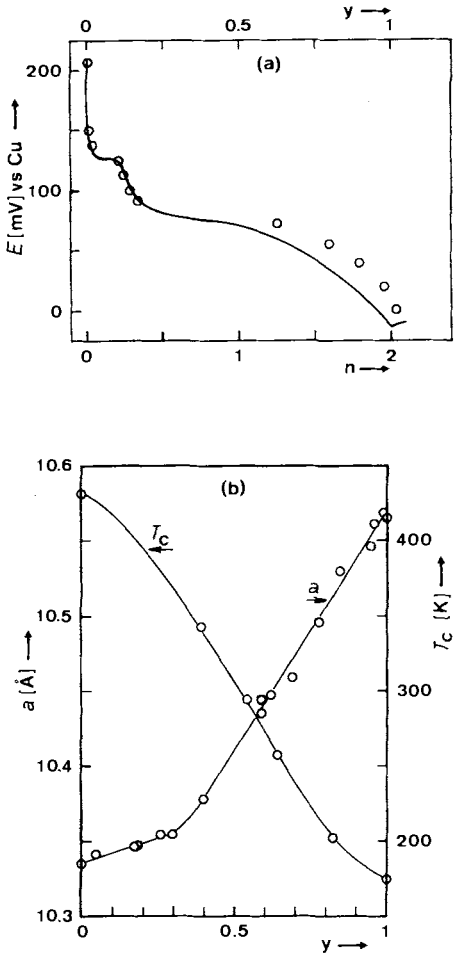

Fig. 1. a) Potential/charge transfer diagram for the galvanostatic cathodic reduction of $CuCr_2Se_4$ (pressed polycrystalline working electrodes, copper as counter electrode and as reference electrode) to $Cu_{1+y}Cr_2Se_4$ in aqueous electrolyte (0.5 M $CuSO_4$ + 0.5 M H_2SO_4); charge transfer $n(e^{\ominus}/CuCr_2Se_4)$; y = stoichiometric index; nominal current density = 1 A/m²; open circles refer to potentials measured under equilibrium conditions. b) Variation of cubic lattice constant *a* and Curie temperature T_c with the stoichiometry y of $Cu_{1+y}Cr_2Se_4$; the magnetic susceptibility was measured by means of a Faraday balance, T_c values were obtained from χ^{-1}/T plots. Results obtained for aqueous ($Cu^{2\oplus}/H_2O$) and aprotic ($Cu^{\oplus}/CH_3CN$) electrolytes are identical.

Figure 1b shows the change in Curie temperature T_c of the $Cu_{1+y}Cr_2Se_4$ phases as a function of composition in the range $0\leqq y\leqq 1$. With increasing copper content the critical temperature of the magnetic phase transition decreases significantly from 432 K ($y=0$) to 175 K ($y=1$). In the course of the *isothermal* electrochemical reaction at 300 K [Eq. (a), (b)] T_c is attained at a critical composition $y_c=0.52$ (Fig. 1b) which is correlated with a transition from the spin ordered ferromagnetic to the disordered paramagnetic state. The critical composition y_c is itself of course a function of the temperature at which the reaction proceeds. The chemical reaction is reversible and can thus be used to control the magnetic properties of the solid in

Strasse des 17. Juni 135, D-1000 Berlin 12

dependence of the reaction state. Systems of this type are of potential interest for practical application; experiments with permanent magnets in contact with a spring loaded $Cu_{1+y}Cr_2Se_4$ working electrode demonstrated that, in principle, it is possible to construct a magnetic switch operated isothermally by the chemical process under discussion. Conversely, the latter arrangement represents a magnetic sensor device for the reaction state of the chemical system.

The characteristic difference in reactivity *direction* between $CuTi_2S_4$[2] and $CuCr_2Se_4$ can be discussed qualitatively in terms of the relative stability in chalcogenospinel lattices of the formal oxidation states of the transition metal ions involved. Since copper has the oxidation state +1 in chalcogenides,[4] the compounds can be described in an ionic model as mixed valence phases $Cu^{\oplus}(Ti^{3\oplus}Ti^{4\oplus})(S^{2\ominus})_4$ and $Cu^{\oplus}(Cr^{3\oplus}Cr^{4\oplus})(Se^{2\ominus})_4$. While $CuTi_2S_4$ can only be *oxidized* to Ti_2S_4, $CuCr_2Se_4$ can only be *reduced* to $Cu_2Cr_2Se_4$ under the conditions applied:

$$\left.\begin{matrix}Cu_{1-y}Ti_2S_4\\ Cu_{1+y}Cr_2S_4\end{matrix}\right\}\ 0\leqq y\leqq 1\ \left\{\begin{matrix}Ti^{3\oplus}/Ti^{4\oplus} \rightleftharpoons Ti^{4\oplus}/Ti^{4\oplus}+e^{\ominus}\\ Cr^{3\oplus}/Cr^{4\oplus}+e^{\ominus} \rightleftharpoons Cr^{3\oplus}/Cr^{3\oplus}\end{matrix}\right.$$

This can be explained reasonably well in terms of the lower stability of $Ti^{3\oplus}$ and the higher stability of $Cr^{3\oplus}$ in relation to the coexisting quadrivalent states in chalcogen ligand fields.

The magnetic ordering in copper chalcogenospinels $CuCr_2X_4$ has been interpreted in terms of Cr^{III}/Cr^{III} (superexchange) and Cr^{III}/Cr^{IV} interaction (double exchange).[5a, b] We attribute the significant decrease in T_c of $Cu_{1+y}Cr_2Se_4$ with increasing degree of conversion (y) to the higher strength of ferromagnetic coupling of Cr^{III}/Cr^{IV} as compared to Cr^{III}/Cr^{III}.[5c]

Extended studies of the related ferromagnetic chalcogenospinels $CuCr_2S_4$ and $CuCr_2Te_4$ revealed a behavior quite similar to that of the selenide. Current work is related to the investigation of the influence of $Li^{\oplus}$ intercalation in these phases because of the strong difference in bond ionicity Cu/X and Li/X; the possibility of $Li^{\oplus}$ insertion in spinel type oxides and chalcogenides has been demonstrated in recent publications.[2, 6, 7]

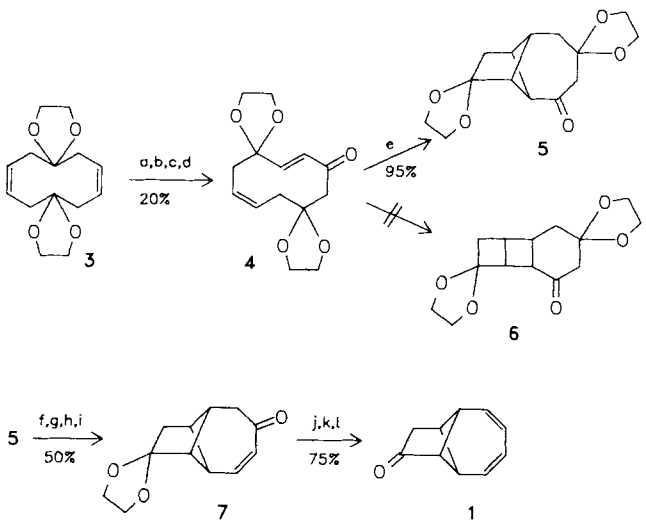
Tricyclo[5.3.0.0^{2,8}]deca-3,5-dien-9-one and a New Route to $C_{10}H_{10}$ Isomers**

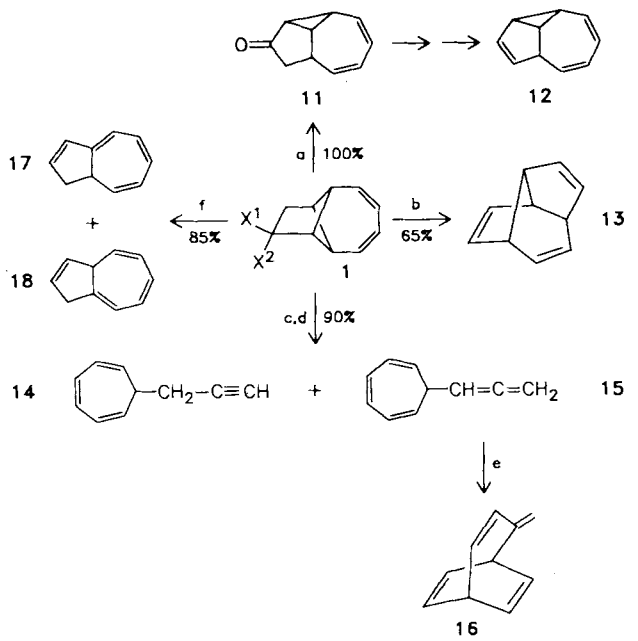


By *Rolf Gleiter,* Horst Zimmermann,* and *Wolfram Sander*

Tricyclo[5.3.0.0^{2,8}]deca-3,5-dien-9-one **1**, which is of interest as a precursor of tricyclo[5.3.0.0^{2,8}]deca-3,5,9-triene **2**, and its derivatives undergo unexpected rearrangements, which have allowed us to isolate several $C_{10}H_{10}$ isomers,

1 **2**

some of them previously unknown. Starting from 3,8-cyclodecadiene-1,6-dione bisethyleneacetal **3**, accessible in good yields from 1,4,5,8-tetrahydronaphthalene,[1] it is possible to synthesize the ketone **4** in three steps (oxidation with *m*-chloroperbenzoic acid (*m*-CPBA), reaction with PhSeSePh and then with H_2O_2 according to the Sharpless method,[2] and oxidation with CrO_3; Scheme 1). Irradiation of **4** affords only **5** (the other possible regioisomer, **6**, was not detected).



Scheme 1. Synthesis of **1**. a) *m*-CPBA, CH_2Cl_2. b) Ph_2Se_2, $NaBH_4$, *n*BuOH, 120°C, 24 h. c) H_2O_2, tetrahydrofuran (THF), 0°C, 20 h. d) CrO_3, pyridine. e) *hν*, H_3CCN, 0°C, 7 h. f) $NaBH_4$, EtOH. g) TsCl, pyridine. h) 1,5-Diazabicyclo[4.3.0]non-5-ene, H_3CCN, 70°C, 12 h. i) TsOH, H_2O/acetone. j) $LiAlH_4$, Et_2O. k) $(PhO)_3PCH_3I$, hexamethylphosphoric triamide, 80°C, 4 h. l) 1 N HCl, THF, 24 h.

The structure of the photoproduct was established from the ^{1}H-NMR spectrum and by comparison with the spectroscopic data for tricyclo[5.3.0.0^{2,8}]decane derivatives whose structures are known.[3] Reduction of the carbonyl group in **5** to the hydroxyl group, subsequent H_2O elimination, and acetal cleavage afford the ketone **7**, from which, in an analogous series of reactions, **1** is obtained.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. *W. S.* thanks the Studienstiftung des Deutschen Volkes for a fellowship. We thank Prof. *J. Dabrowski*, Dipl.-Chem. *M. Hauck*, and Dr. *P. Kunzelmann* for their help in recording and interpreting the NMR spectra.

Scheme 2. Reactions of **1** (X^1, X^2 = O; a), **8** (X^1, X^2 = N–NH–Ts; b), **9** (X^1, X^2 = N–NNa–Ts; c, d), and **10** (X_1 = H, X^2 = Me–SO_3; f). a) Al_2O_3. b) MeLi, Et_2O, 0°C. c) 125°C. d) *hv*, THF, 20°C. e) Preparative gas chromatography, Carbowax, 160°C. f) KO*t*Bu.

The rearrangements observed for **1** and its derivatives, such as the tosyl hydrazone **8** or the methanesulfonate **10**, are summarized in Scheme 2. Compound **1**, which is stable at room temperature, undergoes rearrangement within a few minutes in the presence of Al_2O_3 (neutral, activity I) to give quantitatively **11**,[4] from which the $C_{10}H_{10}$ isomer **12**[5] may be obtained. When **8** was allowed to react with excess MeLi in Et_2O at 0°C,[6] we obtained tricyclo[5.3.0.$0^{4,8}$]deca-2,5,9-triene **13**,[7] instead of the expected isomer **2**. The pyrolysis products obtained by heating **9** (sodium salt of **8**) without a solvent to 120°C were trapped at 10 K in an argon matrix on the window of an IR spectrometer; 7-(2-propynyl)-1,3,5-cycloheptatriene **14**[8] and 7-(1,2-propadienyl)-1,3,5-cycloheptatriene **15**, formed in a ratio of 2:1 (^{1}H-NMR spectrum), were detected. Compounds **14** and **15** were also obtained by irradiation of a solution of **9** in degassed THF at room temperature. Upon heating (GC), compound **15** undergoes rearrangement to give 2-methylenebicyclo[3.2.2]nona-3,6,8-triene **16**.[9]

The reaction of **10** with KO*t*Bu leads to the two unknown dihydroazulenes **17** and **18**, the structures of which were established from the spectroscopic data (Table 1) and from the observation that both compounds undergo oxidation with chloranil to give azulene. Two further isomeric dihydroazulenes were obtained in about 15% yield but could not be separated and identified.

Table 1. Spectroscopic data for the compounds **1**, **5**, **11**, **17**, and **18**. ^{1}H-NMR: 300 MHz, $CDCl_3$; ^{13}C-NMR: 75.46 MHz, $CDCl_3$.

Synthesis and Structure of $[(C_5Me_5)_2M_2Se_5]$: Formation of a μ,η^2-Tetraselenide Ligand at the M–M Double Bond of $[(C_5Me_5)_2M_2(\mu\text{-}CO)_2]$ (M = Co, Rh)**

By *Henri Brunner, Walter Meier, Bernd Nuber, Joachim Wachter,** and *Manfred L. Ziegler*

A rational synthesis of chalcogen-rich cyclopentadienyl transition-metal complexes has been achieved by addition of elemental sulfur or selenium to the M–M triple bond of the complexes $[(C_5Me_5)_2M_2(CO)_4]$ (M = Cr, Mo, W).[1] Substitution of all the CO groups leads, via labile addition adducts,[2] to complexes having one- and two-atom chalcogen ligands displaying a variety of coordinations. Bridging ligands with more than two atoms are not formed in these reactions, however, even though they are well documented for sulfur (but not for selenium).[3] We report here the synthesis of a complex containing a tetraselenide ligand by stepwise addition of selenium to the M–M double bond of $[(C_5Me_5)_2M_2(\mu\text{-}CO)_2]$ (M = Co, Rh).

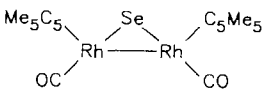
[**] Reactivity of the M–M Multiple Bond in Metal Carbonyl Derivatives, Part 12.—Part 11: I. Bernal, M. Draux, H. Brunner, B. Hoffmann, J. Wachter, *Organometallics 5* (1986) 655.

The reaction of the Co_2 and Rh_2 complexes **1** and **2**, respectively, with an excess of gray selenium in toluene (18 h, room temperature) affords, after chromatography on Al_2O_3, the carbonyl-free, diamagnetic complexes **3** (violet-brown) and **4** (dark green), respectively. Whereas the formation of **3** occurs surprisingly smoothly (80% yield), **4** (19% yield) is obtained along with two, as yet unidentified, likewise CO-free products. The ^{1}H-NMR spectra[4] of **3** and **4** support a symmetrical structure. Each of the ^{77}Se-NMR spectra[4] contains two groups of relatively broad signals having no fine structure (intensity ratio 3:2), the chemical shifts of which are strikingly similar to those of organic tetraselenides.[5] Less informative are the very weak IR absorptions between $\tilde{\nu}=300$ and 400 cm^{-1}, the region of M–Se–M and Se–Se vibrations.



$[(C_5Me_5)_2M_2(CO)_2] \xrightarrow{Se_x} [(C_5Me_5)_2M_2Se_5]$

1, M = Co
2, M = Rh

3, M = Co
4, M = Rh

5

6

An X-ray structure analysis[6] revealed the presence of two types of selenide ligands in **4**: a $Se^{2\ominus}$ and a nearly planar $Se_4^{2\ominus}$ ligand are situated in the same plane (deviation ≤ 0.009 Å), which intersects the midpoint of the Rh–Rh axis and is perpendicular to it (Fig. 1). Owing to the eighteen-electron rule, the two ligands contribute eight electrons to the electron count of the two Rh atoms, which thereby achieve a nobel-gas configuration when the five electrons of the C_5Me_5 ligands are included, without the necessity of a metal–metal bond. The Se–Se distances in the $Se_4^{2\ominus}$ ligands are nearly identical and their average value (2.37 Å) is similar to those in trigonal selenium.[7] The relatively small Se1–Se4–Se5 angle (98.6(1)°) appears to be determined by the size of the ring. Se1, Se2, and Se3 form a nearly equilateral triangle with separations of about 3.101 Å, which are much less than the sums of the van der Waals radii of two Se atoms (3.80 Å). Interactions of this order of magnitude are sufficient, for example, to dimerize two $[W(CO)_5(\eta^2\text{-}Se_2)]^{\oplus}$ molecules to form a molecule with $Se_4^{2\ominus}$ bridges.[8] This tendency is further revealed, albeit less strongly, in the molecular lattice of **4**, in which neighboring molecules are linked together to form chains by means of intermolecular interactions ($d_{Se\text{-}Se}=3.50$ Å) between Se3 of one molecule and Se4/Se5 of another.

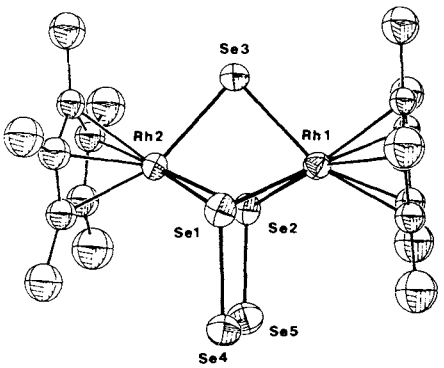


Fig. 1. Crystal structure of **4** (ORTEP plot). Selected bond lengths [Å] and bond angles [°]: Rh1-Se1 2.481(2), Rh1-Se2 2.460(2), Rh1-Se3 2.476(2), Rh2-Se1 2.479(2), Rh2-Se2 2.464(2), Rh2-Se3 2.473(2), Se1-Se4 2.373(2), Se2-Se5 2.370(2), Se4-Se5 2.368(2), Se1···Se2 3.115(2), Se1···Se3 3.102(2); Se1-Rh1-Se2 78.2(1), Rh1-Se1-Rh2 86.4(1), Rh1-Se2-Rh2 87.2, Rh1-Se3-Rh2 86.6(1), Rh1-Se1-Se4 105.2(1), Se1-Se4-Se5 98.6(1), Se2-Se5-Se4 99.5(1), Se2-Se1-Se3 60.3(0). Only one of the two independent, nearly identical molecules is shown.

These structural findings might explain the ready formation of the complexes **3** and **4**. The reaction of **1** with S_8 affords only a small yield of $[(C_5Me_5)_2Co_2S_4]$.[9] A Se analogue of the μ-η^1,η^2-S_2 ligand that characterizes this compound, namely, $[(triphos)_2Rh_2Se_4][PPh_4]_2$ (triphos = $H_3CC(CH_2PPh_2)_3$), is also known.[10] In the case of **3** and **4**, instead, a planar Se_4/Se ligand system is formed, which can be viewed alternatively as an η^3-Se_5 ligand. Comparable sulfur ligands are not planar.[11]

The stability of the polyselenide ligands in **3** and **4** is so pronounced that the dark brown diselenium adduct **5**,[4] obtained from **1** at 0°C, and the known monoselenium adduct **6**[12] undergo reaction at room temperature in toluene to afford mixtures from which **3** and **4**, respectively, may be isolated. Since **5** and **6** also undergo reaction with selenium in toluene to give **3** and **4** in appreciably better yields, the reactions **1**→**3** and **2**→**4** may be interpreted as occurring by stepwise addition of selenium to the M–M double bond with subsequent CO substitution.

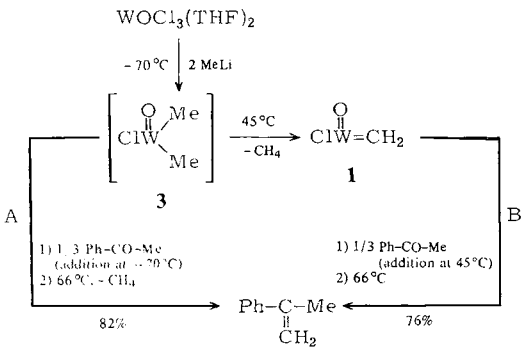
Carbonyl Olefinating Carbene-Tungsten Complexes and Their Suitability as Catalysts in Olefin-Metathesis**

By *Thomas Kauffmann,* Renate Abeln, Siegfried Welke,* and *Dorothea Wingbermühle*

Some readily accessible carbene-molybdenum complexes have proven to be suitable as reagents for carbonyl olefination. They are characterized by their high chemoselectivity (aldehyde-[2c] and grouping-selectivity[2d]) and low sensitivity towards hydroxy groups,[2b] but are so thermolabile that all attempts to isolate them have so far failed. In the hope of obtaining more stable complexes we allowed methyllithium to react with various tungsten halides and thus obtained complexes also suitable as reagents for carbonyl olefination.

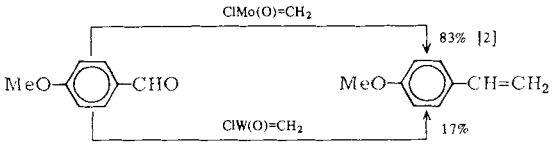
A) Formation: Reaction of 2 molar equivalents of methyllithium with $WOCl_3(THF)_2$ or with $WOCl_4$ in tetrahydrofuran (THF) leads—in each case with cleavage of about one molar equivalent of methane—to formation of brown solutions with which acetophenone and cyclohexanone undergo methylenation in very good yield (Table 1); the reagent obtained from $WOCl_3(THF)_2$ is also suitable for aldehyde olefination (Table 1). The reagents most likely have the structures **1** and **2**, or structures derived therefrom (associates or LiCl-adducts).



$$WOCl_3(THF)_2 + 2\,MeLi \xrightarrow[-0.9\,CH_4]{THF} ClW(O)=CH_2$$

1

$$WOCl_4 + 2\,MeLi \xrightarrow[-1.0\,CH_4]{THF} Cl_2W(O)=CH_2$$



2

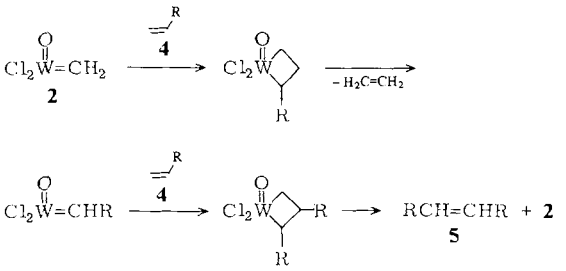
B) Comparison with carbonyl olefinating molybdenum complexes: The complexes **1** and **2**, to our knowledge the first carbonyl olefinating tungsten complexes, differ from the carbonyl methylenating molybdenum complexes[2], primarily in their greater activity towards ketones and in their greater thermal stability. Thus, it is possible in the case of carbonyl olefinations with $WOCl_3(THF)_2 + 2\,MeLi$ to prepare the carbene complex **1** first (heating to about 45 °C, *until evolution of methane subsides*) and thereafter to add the carbonyl component (Scheme 1, Method B), while in the case of carbonyl olefinations with the corresponding molybdenum compound the carbonyl compound must be added *before* the evolution of methane in order to ensure that the thermolabile molybdenum complex immediately has a reaction partner (Method A). In the carbonyl olefination with $WOCl_3(THF)_2 + 2\,MeLi$, Method A leads to yields of olefin that are equally as good as those obtained by Method B, and no methylation product is formed. Presumably, the dimethyl compound **3** is formed initially, and this cannot methylate the ketone employed in the reaction.

Scheme 1.

The tungsten complex **1**, which has been investigated in greater detail, is more reactive towards ketones than are carbene-molybdenum complexes. This, apparently, is the reason why **1** is less aldehyde-selective than the Mo-analogue in aldehyde/ketone competition experiments (cf. Table 1, Entry No. 7). A further difference appears to be less stability towards attack by water or ethanol: as can be seen from Entries No. 2 and 3, **1** is a much weaker carbonyl olefinating reagent in the presence of water and ethanol than in anhydrous THF. Scheme 2 shows that the complex $ClMo(O)=CH_2$ is significantly more effective in presence of water and ethanol than is **1**.

Scheme 2. Solvent THF/H_2O/EtOH (10:5:1); molar ratios, substrate : $ClMo(O)=CH_2$ = 1:2, substrate : **1** = 1:3.

Table 1. Carbonyl olefinations with carbene-tungsten complexes [a]. To obtain preparatively useful yields, a molar ratio of 3:1 of reagent and substrate was used in each experiment (in Entries No. 7 and No. 12, 3:1.1).



No.	Reagent	Substrate	Solvent	Olefin yield [%] [b]	Substrate recovered [%] [b]
1	**1**	Ph–CHO	THF	91	0
2	**1**	*p*-MeO–C_6H_4–CHO	THF	89	<3
3	**1**	*p*-MeO–C_6H_4–CHO	[c]	17	83
4	**1**	Ph–CO–Me	THF	82 (87)	11 (9)
5	**1**	cyclohexanone	THF	93	0
6	**1**	Ph–CO–Ph	THF	35	65
7	**1**	Ph–CHO + Ph–CO–Me	THF	90 (56) 27 (5)	0 (36) 65 (79)
8	**2**	Ph–CHO	THF	13	74
9	**2**	Ph–CO–Me	THF	77	17
10	**2**	Ph–CO–Me	cyclohexane	11 (6)	74 (81)
11	**2**	cyclohexanone	THF	96	0
12	**2**	Ph–CHO + Ph–CO–Me	THF	11 0 [d]	76 93

[a] The tungsten halide was treated at ca. −70 °C with 2 equivalents of MeLi. After 10 min, the carbonyl compound was added and the mixture heated to 66 °C (in Entry No. 10 to 80 °C) within 1.5 h. [b] Values in brackets apply for 20 °C. [c] THF : H_2O : EtOH = 10:5:1; for THF-dissolution of the reagent the carbonyl compound was added to a water/ethanol mixture. [d] The aldehyde apparently blocks the reagent.

C) Suitability as catalysts for olefin-metathesis: Since carbene-tungsten complexes have long been known to be suitable reagents for *olefin metathesis*,[3] we decided to check whether our *carbonyl olefinating* complexes are also suitable for this purpose; that is, whether they are suitable for both olefin metathesis as well as carbonyl olefination. In the presence of a tenfold excess of 1-hexadecene **4**, the reagent with the hypothetical structure **2** is converted into 15-triacontene **5** and ethylene (in cyclohexane/THF (9:1) at 80 °C, yield referred to **4**: 45% after 4 h; in THF-free cyclohexane, 20% after 14 h). It can be concluded, therefore, that the reaction proceeds as formulated in scheme 3.[4]

[**] Transition Metal-Activated Organic Compounds, Part 21. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 20: [1].

Scheme 3. R = n-$C_{13}H_{29}$.

The metathesis of **4** by **2** is almost completely suppressed in pure THF as solvent (ca. 2% **5**). Hence, we assume that a THF-solvate envelope around the Lewis acid **2** prevents access of the weakly basic olefin **4** to the central atom of **2**. In contrast, carbonyl compounds like acetophenone or benzaldehyde in THF can reach the central atom of **2**. This accessibility for carbonyl groups and the barrier to olefin groups makes it possible to carry out carbonyl olefinations without any interfering olefin metathesis, if THF is used as solvent.

No olefin metathesis could by achieved with the reagent **1**. Conversely, all attempts to carry out carbonyl olefinations with tungsten-containing compounds of well-defined structure known to catalyze olefin-metathesis[3] met without success.

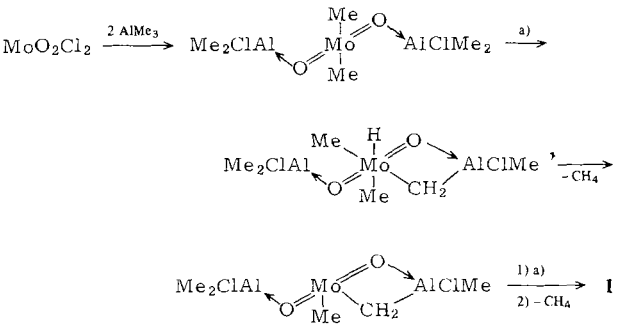
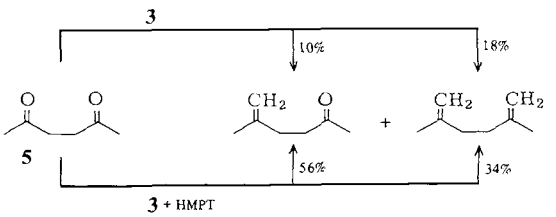
Carbonyl Olefinating Aluminum-Molybdenum Complexes and an Analogous Tungsten Complex**

By *Thomas Kauffmann, Manfred Enk, Wilfried Kaschube, Euripides Toliopoulos,* and *Dorothea Wingbermühle**



We have already reported on carbonyl olefinating molybdenum complexes that are formed on reaction of methyllithium with molybdenum halides via elimination of *one molar equivalent* of methane.[2] Since highly-active carbonyl olefinating reagents containing transition-metal atoms (Ti,[3a] Zr[3b]) and an aluminum atom are already known, our interest now turned to the possibility of preparing carbonyl olefinating aluminum-molybdenum complexes.

We found that reaction of two molar equivalents each of trimethylaluminum with MoO_2Cl_2 and with $MoOCl_3(THF)_2$ in tetrahydrofuran (THF) leads, via cleavage of *two molar equivalents* of methane, to the formation of complexes which in the course of a carbonyl olefination transfer about 1.5 CH_2 units per Mo atom to benzaldehyde present in excess (Table 1, Entries No. 1 and 6). We assume that bismethylene complexes are formed whose hypothetical structures **1** and **2** show similarities to the Tebbe reagent **4**.[3a] An analogous tungsten complex of hypothetical structure **3** was obtained from $WOCl_3(THF)_2$ (Scheme 1).

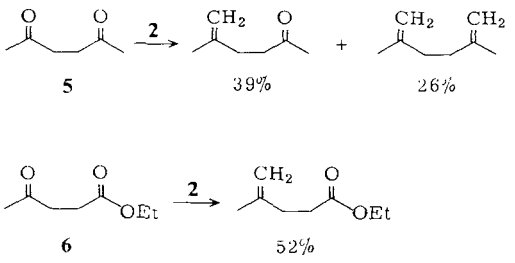


Scheme 1.

Our conception of the formation of **1** is outlined in Scheme 2; **2** and **3** could be formed analogously.

Scheme 2. a) denotes the cyclometalation step.

The carbonyl-olefinating activity of the Tebbe reagent **4** is enhanced by addition of base; this can be attributed to cleavage of the Al-CH_2 bond.[4] Analogous activations were observed in the case of **2** and **3** (Table 1, Entries 13 and 14; see also Schemes 3 and 4).



Scheme 3. Solvent: THF. Molar ratios: **5** : **3** = 1 : 1; **5** : **3** : HMPA = 1 : 1 : 2.

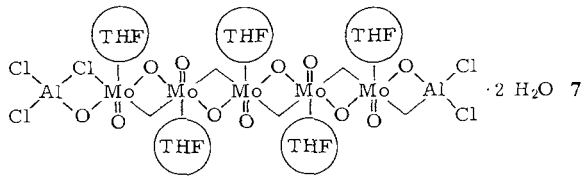
[**] Transition Metal-Activated Organic Compounds, Part 22. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 21: [1].

Since the reagent **2** is practically inactive towards monoketones (Table 1, Entries 10 and 11), we attribute the surprisingly good olefination of dicarbonyl compounds according to Scheme 4 to the effectiveness of the second carbonyl group as activating base.



Scheme 4. Solvent: THF. Molar ratios: **5** : **2** = 1 : 1; **6** : **2** = 1 : 1.

[a] In the experiments carried out in THF (Entries 1–11), the transition metal halide was allowed to react with 2 molar equivalents of $AlMe_3$ at −70 °C. After 2 h, the substrate was added and the solution heated to 20 °C within 14 h. In the case of the experiments carried out in *n*-hexane (Entries 12–14), $WOCl_3(THF)_2$ was allowed to react with 2 molar equivalents of $AlMe_3$. 1.4 molar equivalents of CH_4 were evolved. After 1 h, the substrate was added and the solution heated to 66 °C within 1 h. The addition of hexamethylphosphoric triamide (HMPA) immediately followed addition of the substrate. [b] 1.5 CH_2 groups were thus transferred per Mo-atom. [c] 2-Thiophenecarbaldehyde.

The hypothetical complexes **1** and **2** are thermolabile. Consequently, the products of carbonyl olefination are isolable in good yields only when the molybdenum halide is first allowed to react with trimethylaluminum at −70 °C before addition of the substrate at the same temperature, and the reaction mixture is then heated to 20 °C until evolution of CH_4 ceases. If the carbonyl compound is first added after evolution of gas ceases, then the yield of olefin is low. Apparently, the active carbonyl olefinating reagent initially formed undergoes decomposition when no carbonyl groups are available.[5] The decomposition has hitherto prevented the isolation of **1** and **2**, but enabled isolation of a primary product of the decomposition of **1**. This sparingly soluble, amorphous, air- and water-sensitive solid precipitates from the THF solution at 0 °C (stable only for a short time at this temperature) and can effect carbonyl olefination of benzaldehyde. According to elemental analysis, it would appear that one THF ligand is present per Mo atom, thus indicating a chain-like structure containing five $Mo(THF)O_2CH_2$ units. The Mo/Al ratio of 5 : 2 (i.e. large depletion of Al compared to **1**) suggests that the chain terminals are formed by $AlCl_2$ units, as tentatively formulated in **7**.—The moderate yield of olefin upon reaction of the yellow solid with benzaldehyde (31% per Mo atom of **7**) is understandable in view of the sparing solubility of this decomposition product.

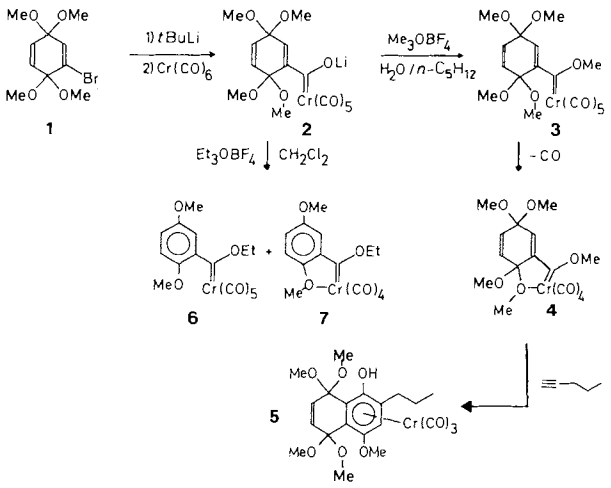
Carbene Complexes with Quinone Bisketal Functions**

By *Karl Heinz Dötz,* Michael Popall, Gerhard Müller,* and *Klaus Ackermann*

Carbene(carbonyl) transition-metal complexes are useful as synthetic building blocks for anthracyclinones.[1–4] For example, the rings B and C of the daunomycinone skeleton can be constructed by regiospecific annelation of arylcarbene complexes. In order to avoid the necessity of subsequent selective oxidation,[5] it would be useful to introduce the quinone ring C directly via the carbene complex. For this reason, we have investigated the synthesis and reactivity of carbene complexes having quinone bisketal functions.



The lithiated quinone bisketals that are obtained from **1** and **8** by halogen–metal exchange undergo addition to hexacarbonylchromium and -tungsten at low temperatures with formation of the ocher-colored acylmetalates **2** and

[**] Carbene Ligands as Anthracyclinone Synthons, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 3: [3].

9a, **b**. Their conversion into the neutral carbene complexes is strongly dependent on the transition metal, the alkylating agent, and the reaction medium. Whereas **2** undergoes methylation with Me_3OBF_4 in pentane/water to give **3**, it reacts with Et_3OBF_4 in dichloromethane to give **6** (aromatization), which partially undergoes immediate decarbonylation to give **7**.[6]

The bisketal compound **3** also undergoes facile elimination of a CO ligand in the *cis* position. The chelate carbene complex thereby formed, **4**, was shown by X-ray structure analysis[7] to have a five-membered metallacycle with short Cr–C(carbene) and long Cr–O bonds (2.226(2) Å) (Fig. 1, above). The five-membered ring has an approximate envelope conformation, while the quinone bisketal six-membered ring, owing to the coordination of O31 to the Cr atom, is not exactly planar. The molecular geometry provides an explanation for the rapid exchange of the Cr-coordinated methoxy group with the geminal, free methoxy group in acetone solution at room temperature. An activation enthalpy of 9 kcal/mol can be estimated for this process from the coalescence temperature of $-73\,^{\circ}C$.[8] The facile opening of the chelate ring under mild conditions allows the coordination of an alkyne, which—as exemplified by 1-pentyne—is incorporated into the hydroquinone skeleton, the annelation of the carbene ligand occurring regiospecifically.

The alkylation of the 1,4-naphthoquinone bisketal derivatives **9a**, **b** with oxonium salts in dichloromethane leads ultimately to aromatic products.[9] In the case of tungsten, the bisketal carbene intermediate **10b**[10] may be detected, although it undergoes slow aromatization in solution to form **11b**. In contrast to the cyclohexadienyl system **2**, the acylmetalate **9a** is transformed by even traces of $H^{\oplus}$ into the golden dihydronaphthylidene complex **12a**. This unexpected fragmentation is presumed to occur via an initially formed hydroxycarbene complex.

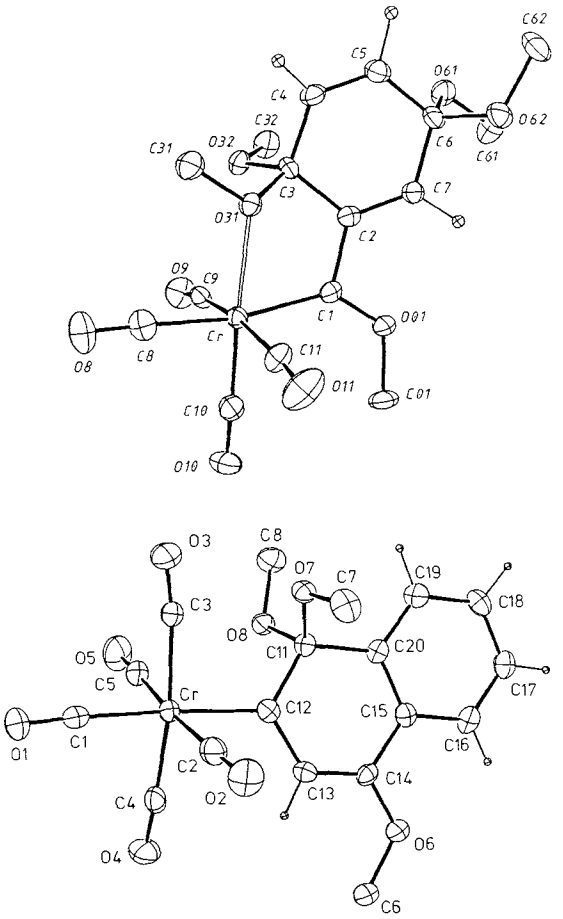

Fig. 1. Crystal structures of **4** (above) and **12a** (below) (ORTEP, thermal ellipsoids at the 50% probability level, H atoms with arbitrary radii, without methyl H atoms) [7]. Selected bond lengths [Å] and bond angles [°]: **4**: Cr-C1 1.978(3), Cr-C8 1.895(3), Cr-O31 2.226(2), Cr···O32 3.332(2), C1-O01 1.321(3), C1-C2 1.497(4), C2-C3 1.505(4), C3-C4 1.505(4), C4-C5 1.323(4), C5-C6 1.501(4), C6-C7 1.499(4), C2-C7 1.328(4), C3-O31 1.441(3), C3-O32 1.431(3); Cr-C1-C2 116.0(2), Cr-C1-O01 136.1(2), O01-C1-C2 108.0(2), C1-C2-C3 114.7(2), C2-C3-O31 103.6(2), C3-O31-Cr 109.6(1); torsion angle Cr-C1-C2-C3 −9.2, dihedral angle Cr, C1, C2, C3/Cr, O31, C3 44.3.— **12a**: Cr-C12 2.045(3), Cr-C1 1.897(4), C12-C13 1.410(4), C13-C14 1.376(4), C14-O6 1.333(4), C14-C15 1.460(4), C15-C20 1.403(4), C20-C11 1.532(4), C11-C12 1.541(4); Cr-C12-C13 121.4(2), Cr-C12-C11 122.8(2), C11-C12-C13 115.8(3).

In view of the absence of heteroatom substituents in α position at the carbene carbon atom, the thermal stability of **12a** is remarkable. It is due to conjugation of the carbene-metal and enol ether functions (vinylogous stabilization) as well as to the incorporation of the carbene carbon atom into a relatively rigid six-membered ring, as revealed by the molecular structure[7] (Fig. 1, below). The dihydronaphthylidene skeleton is nearly planar.

Experimental Procedure

2/9a, **b**: A solution of *tert*-butyllithium (30 mmol) in hexane was slowly added to a stirred solution of **1** or **8** (15 mmol) [11] in 60 mL of ether at $-75\,^{\circ}C$. The resulting orange suspension was stirred at this temperature for ca. 15 h and then added to a solution of $Cr(CO)_6$ or $W(CO)_6$ (15 mmol) in 150 mL of ether at $-60\,^{\circ}C$. The mixture was allowed to warm to room temperature over 4 h and the solvent then removed. After washing with pentane, the acylmetalate **2** or **9a**, **9b** was obtained.

3: **2** (5 mmol) was dissolved in 50 mL of ice water and a layer of 100 mL of pentane was added. After addition of Me_3OBF_4 (7.5 mmol), the mixture was extracted repeatedly with pentane and the extracts were dried over Na_2SO_4 and chromatographed on silica gel (Merck, type 60). Elution of the red, main zone with CH_2Cl_2 and recrystallization from ether/pentane afforded **3** in the form of light red needles (m.p. = 47 °C). Yield 58%. IR (pentane):

$\tilde{\nu}$(C=O) = 2064 (s), 1994 (s), 1955 (vs), 1942 cm^{-1} (vs). ^{1}H-NMR (CD_3COCD_3): δ = 6.07 (m, 3H; 3, 5, 6-H), 4.73 (s, 3H; carbene OCH_3), 3.33 (s, 6H; 1,1-OCH_3), 3.27 (s, 6H; 4,4-OCH_3). ^{13}C-NMR (CD_3COCD_3): δ = 355.5 ($C_{carbene}$), 225.4 (*trans*-CO), 216.1 (*cis*-CO), 153.5 (C-2), 130.7 (C-3), 126.1 (C-5,6), 96.4, 92.4 (C-1,4), 67.7 (carbene OCH_3); 48.8, 48.6 (1,1,4,4-OCH_3). MS: *m/z* 434 ($M^{\oplus}$).

4: **3** (5 mmol) was heated in 10 mL of *tert*-butyl methyl ether at reflux for 4 h. After recrystallization, **4** was obtained in the form of dark brown crystals (m.p. = 100°C). Nearly quantitative yield. IR (pentane): $\tilde{\nu}$(C=O) = 2019 (s), 1952 (s), 1938 (vs), 1865 cm^{-1} (vs). ^{1}H-NMR (CD_3COCD_3): δ = 6.34 (m, 3H; 3,5,6-H), 4.80 (s, 3H; carbene OCH_3), 3.36 (s, 6H; 1,1-OCH_3), 3.30 (s, 6H; 4,4-OCH_3). ^{13}C-NMR (CD_3COCD_3): δ = 341.5 ($C_{carbene}$), 233.1, 232.3 (*trans*-CO), 217.6, 216.9 (*cis*-CO), 145.1 (C-2); 133.8, 125.4, 119.6 (C-3,5,6), 100.0, 94.4 (C-1,4), 68.8 (carbene OCH_3), 56.5 (1,1-OCH_3), 50.3 (4,4-OCH_3). MS: *m/z* 408 ($M^{\oplus}$).

5: A solution of **4** (5 mmol) in 20 mL of *tert*-butyl methyl ether was heated to 55°C and, after addition of 5.5 mmol of 1-pentyne, allowed to stir for 0.5 h. **5** was precipitated by addition of pentane. IR (KBr): $\tilde{\nu}$(C=O) = 1938 (s), 1855 cm^{-1} (s). MS: *m/z* 474 ($M^{\oplus}$).

6/7: A solution of **2** (5 mmol) in 100 mL of CH_2Cl_2 was treated at 0°C with 7.5 mmol of Et_3OBF_4. After 1 h, the solvent was removed under high vacuum and the residue was dissolved in ether and quickly filtered over Al_2O_3 (neutral) at −20°C. Column chromatography on silica gel afforded **6** and **7** in a ratio of 10 : 1.

12a: A solution of **9a** (5 mmol) in 200 mL ether/water (1 : 1) was allowed to stir for 1 h at room temperature. After removal of the solvent (high vacuum), column chromatography on silica gel (Merck, type 60) with dichloromethane/pentane (2 : 1) followed by recrystallization from ether/pentane afforded **12a** in the form of golden crystalline platelets (m.p. = 100°C). Yield 56%. IR (pentane): $\tilde{\nu}$(C=O) = 2047 (s), 1988 (m), 1962 (vs), 1926 cm^{-1} (s). ^{1}H-NMR (CD_3COCD_3): δ = 8.91 (s, 1H; 3-H), 8.05 (m, 2H; 5,8-H), 7.62 (m, 2H; 6,7-H), 4.45 (s, 3H; 4-OCH_3), 2.78 (s, 6H; 1,1-OCH_3). MS: *m/z* 410 ($M^{\oplus}$).

Regioselective and Atropoisomeric-Selective Aryl Coupling to Give Naphthyl Isoquinoline Alkaloids: The First Total Synthesis of (−)-Ancistrocladine**

By *Gerhard Bringmann,* Johannes R. Jansen,* and *Heinz-Peter Rink*

Dedicated to Professor Burchard Franck on the occasion of his 60th birthday

(−)-Ancistrocladine **1**[1] is regarded as "the most unusual of all the isoquinoline alkaloids"[2] on account of the methyl group at C-3 of a tetrahydroisoquinoline, the two oxygen functions at C-6 and C-8 in mutual *meta* positions, and the peculiar naphthalene substituent at C-5. For a thorough investigation of the biological activity of **1**, as well as for a reexamination of the insufficiently established structures of several related natural products,[3] the molecular skeleton of **1** — with the highly substituted biphenyl system that is configurationally stable to above 200°C — represents an attractive synthetic goal.

1

Neither **1** nor other *Ancistrocladus* alkaloids could so far be synthesized. We recently reported the first synthesis of a naphthyl isoquinoline alkaloid, the less sterically crowded and fully aromatic, albeit racemic, *Triphyophyllum* alkaloid *O*-methyltetradehydrotriphyophylline.[4]

We describe here the first, and, at the same time, asymmetric, synthesis of the main alkaloid (−)-ancistrocladine **1**. The required starting material for the synthesis of the optically active tetrahydroisoquinoline building block **5** is the arylpropanone **2a**,[5] which may be regarded as a simpler analogue of the assumed[6,7] biosynthetic diketo precursor **2b** (Scheme 1).

Reductive amination[8] of **2a** with (*S*)-1-phenylethylamine (*de* 92%) and subsequent hydrogenolysis selectively affords the desired,[9] enantiomerically pure,[10] primary amine **3** [84% yield, m.p. of the hydrochloride = 151.5°C, $[\alpha]_D^{20}$ = +14.8 (*c* = 1.0, MeOH)]. After Bischler-Napieralski cyclization to the (3*S*)-configurated dihydroisoquinoline **4** [76%, m.p. of the hydrobromide = 202°C, $[\alpha]_D^{20}$ = −141 (*c* = 1.0, MeOH], the heterocyclic molecular half, e.g., of the spasmolytically active ancistrocladidine,[3] also the second center of chirality (C-1) can stereoselectively be built up. Reduction of **4** with $LiAlH_4$ in the presence of $AlMe_3$[11] affords the (1*S*)-configurated tetrahydroisoquinoline **5** [85%, m.p. of the hydrobromide = 293°C, $[\alpha]_D^{20}$ = +7.6 (*c* = 1.0, MeOH)] with remarkably good stereoselectivity (*de* 92%).[12] A *trans* arrangement of the two secondary methyl

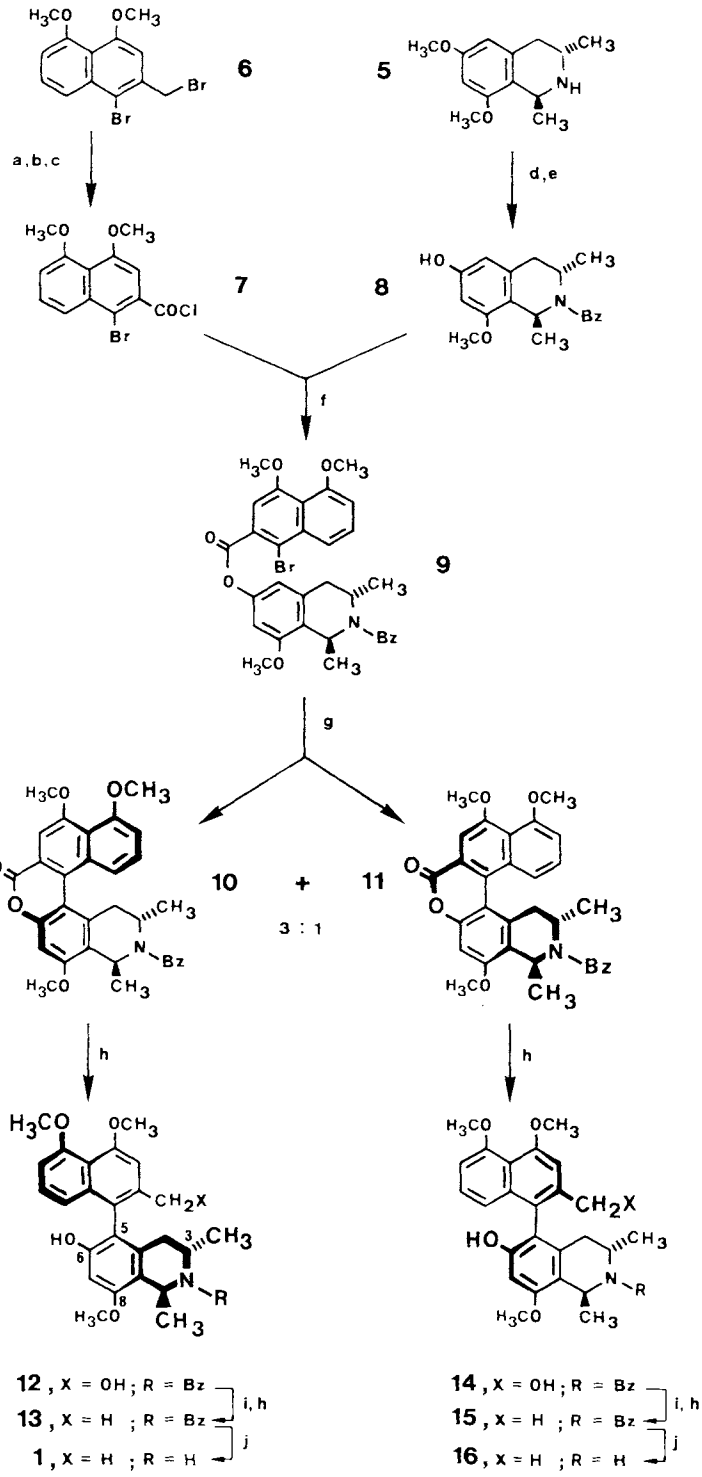
[**] Acetogenic Isoquinoline Alkaloids, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 10: [6].

groups, such as in **5**, is very common in the *Ancistrocladus* alkaloids,[3] but, up to now, could not be generated diastereoselectively.[4,6]



The subsequent procedure is summarized in Scheme 2. By *N*-benzylation and careful partial ether cleavage,[13] **5** can be converted regioselectively into **8** (65%). The coupling of the heterocyclic half of **1** thereby obtained with the naphthalene moiety—*inter*molecularly affording only very low yields—is performed *intra*molecularly, after the two coupling partners have been joined by an auxiliary bridge. Especially suitable for this purpose is an ester group, such as in **9**. The required difunctional naphthalene building block **7** is readily accessible (74%) from the dibromide **6**[4] and undergoes smooth esterification with the isoquinoline **8** to form **9** (86%).

Scheme 1. Stereoselective synthesis of the chiral isoquinoline building block **5**. a) (*S*)-1-Phenylethylamine, toluene, Δ; 5 bar H_2/Raney nickel W2, EtOH, 80 h. b) 5 bar H_2/10% Pd-C, MeOH, 120 h. c) H_3CCOCl, NEt_3, CH_2Cl_2. d) $POCl_3$, MeCN, reflux. e) $LiAlH_4/AlMe_3$, tetrahydrofuran (THF), −78°C→0°C, 3 h.

With the benzyl ether type auxiliary bridge, used by us earlier, the intramolecular aryl coupling, photochemically performed, occurred in maximum yields of only 15%—even in far simpler cases.[4] With **9**, under Pd^{II} catalysis, the coupling leads, in very satisfactory yields (49%) and with surprisingly high regioselectivity,[16] to the helicene-like atropoisomers **10** and **11**, which are difficult to separate. In this process, the diastereomer **10**, whose configuration corresponds to that of ancistrocladine, is preferentially formed. Reductive cleavage of the auxiliary bridge (95%) affords the atropoisomeric alcohols **12** and **14**, which, owing to the CH_2OH group on the naphthalene moiety, may be unusually easily separated in this state by chromatography (R_f of **12** = 0.26, R_f of **14** = 0.23; $CHCl_3$/MeOH = 100/7, silica gel). Mild deoxygenation and *N*-deblocking converts **12** into **1** [91%, m.p. = 261°C, $[\alpha]_D^{20}$ = −23 (*c* = 0.16, MeOH)], which is chromatographically and spectroscopically identical with authentic ancistrocladine.[17] The analogous transformation of the diastereomer **14**, via **15**, affords hamatine **16** [90%, m.p. = 250°C, $[\alpha]_D^{20}$ = +68 (*c* = 0.04, $CHCl_3$)],[17] the naturally occurring atropoisomer[18] of **1**. The atropoisomeric excess obtained in the aryl coupling of **9** is of the order of magnitude of that observed for these two alkaloids in the plants.

The presented first total synthesis of ancistrocladine **1** delivers the methodology for the stereocontrolled synthesis of further, related naphthyl isoquinoline alkaloids of

[12] Similarly high diastereomeric excess had previously been achieved in the reduction of tetrahydropyridines with $LiAlH_4/AlMe_3$ (see [11]). These results had been discussed in terms of the attack of "$H^{\ominus}$," occurring, on the one hand, as homosynplanar as possible to the axial CH_3 group on C-6 (dashed circle) and, on the other hand, as antiperiplanar as possible to the axial H atom on C-3 (circle) of the tetrahydropyridine ring, forced to adopt conformation **A** on account of the Al complexation. Since C-3 is no longer sp^3 hybridized in the dihydroisoquinoline system **B**, the latter effect is no longer present. As a result, such high diastereomeric excesses could not be expected. On the other hand, the results are stereochemically in agreement with the findings for iminium salts (and thus cationic systems). Cf. P. Deslongchamps: *Stereoelectronic Effects in Organic Chemistry*, Pergamon Press, Oxford 1983, Chap. 6.

Cyclodisalazane Cations—Synthesis and Crystal Structure**

By *Ursula Kliebisch, Uwe Klingebiel,* Dietmar Stalke,* and *George M. Sheldrick*

The nitrogen atom in silicon-nitrogen compounds is almost always in a structurally planar environment, and rarely exhibits basic properties;[1,2] adducts—which frequently undergo further reaction and consequently cannot be isolated—are formed only with very strong Lewis acids. Protonated silazanes have, to our knowledge, never been detected so far.

Hitherto, there have been two major objectives on carrying out reactions of aluminum trihalides with silazanes: First, the synthesis of aluminum silazanes,[3-5] and second, the synthesis of compounds with threefold coordinated silicon.[6-8] The stabilization of silicon ylides by adduct formation with aluminum trihalides[8] motivated us into investigating reactions of cyclosilazanes with Al_2Cl_6.

When the cyclosilazane **1**[9] was heated in *n*-hexane/dichloromethane (10:3 v/v), a phase separation was observed upon cooling the mixture. Evaporation of the dichloromethane phase to dryness furnished the salts **2** and **3** as solids: monoprotonated **1** with $AlCl_4^{\ominus}$ as counter-

ion,[10] and diprotonated **1** with the novel dianion $^{\ominus}Cl_3Al-O-AlCl_3^{\ominus}$ as counterion.[11] Repeated crystallization from *n*-hexane/dichloromethane afforded crystals of **3** sufficiently suitable for an X-ray structure analysis. Apparently the formation of **3** involves participation of traces of water during the reaction and/or during the work-up of the reaction mixture.[12]

1 does not react with Al_2Cl_6 in the absence of dichloromethane, and can be recovered without decomposition; consequently, CH_2Cl_2 functions as a reactant. Degradation products of dichloromethane were not detected. The stability of salts such as **2** and **3** can be ascribed to kinetic stabilization by the large substituents.

It follows from the ^{29}Si-NMR spectra of **1** ($\delta = 7.44$),[9] **2** ($\delta = 30.05$) and **3** ($\delta = 30.84$) that the Si atoms in **2** and **3** are strongly deshielded. The ^{15}N-NMR resonances of **2** and **3** appear in the region characteristic for quaternary ammonium salts. The Si–N bonds in **1** (174.7 pm)[9] are

Tammannstrasse 4, D-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

significantly shorter than in **3** (179.2 pm), i.e. they are weakened due to the sp^3-hybridization of the nitrogen. The existence of the NH-protons was confirmed by ^{15}N- and ^1H-NMR spectroscopy. Each of the N-C bonds subtend an angle of 16.8° to the $(SiN)_2$ plane. This unusual configuration at the nitrogen is indicative of protonation.

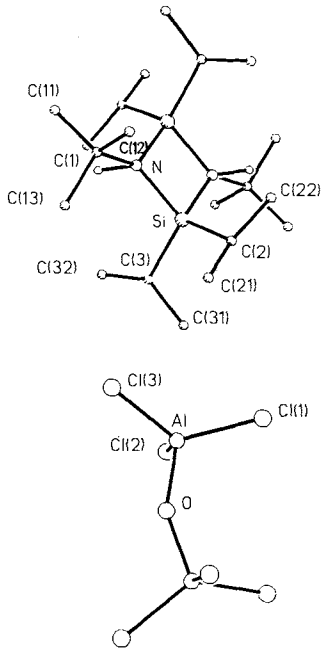

Fig. 1. Crystal structure of **3**. Stoe-Siemens AED diffractometer with graphite-monochromatized $Mo_{K\alpha}$ radiation ($\lambda = 71.069$ pm) at room temperature: size of crystal $0.46 \times 0.46 \times 0.77$ mm^3; 4652 reflections with $7° < 2\theta < 50°$, 1640 symmetry-independent with $F > 4\sigma(F)$. The structure was solved by direct methods. All atoms other than H were anisotropically refined. Geometrical placement of the nine H-atoms of the *tert*-butyl groups (C-H length: 96 pm, H-C-H bond angle 109.9°, U(H)-1.5 U_{eq}(C), U_{eq}(C) = 1/3 (trace of the orthogonal U_{ij} tensor)). The same holds true for the H atoms of the secondary-C-atoms of the isopropyl groups, but with $U(H) = 1.2\,U_{eq}(C)$. The H atoms on the nitrogen could not be unambiguously located, even by a high-angle refinement with subsequent difference Fourier synthesis. In the diagram they have been positioned according to their ideal geometry.—Space group $C2/c$, $Z = 4$, $a = 1482.5(2)$, $b = 1247.9(4)$, $c = 1866.7(3)$ pm, $\beta = 98.63(2)°$, $\mu(Mo_{K\alpha}) = 0.64$ mm^{-1}, $R = 0.055$, $R_w = 0.054$ ($w^{-1} = (\sigma^2(F) + 0.0002\,F^2)$). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52105, the names of the authors, and the full citation of the journal.

Experimental

A thick suspension of freshly sublimed Al_2Cl_6 (8 g, 0.03 mol) in *n*-hexane (100 mL) and CH_2Cl_2 (30 mL) was treated with 11.1 g (0.03 mmol) of **1** and the mixture heated for 2 h. Upon cooling, the mixture separated into two phases; the lower phase contained the aluminum salt. This phase was separated, covered with 10 mL of *n*-hexane, and cooled to −150°C. **3** crystallized out, while **2** was isolated as an amorphous powder after removal of the solvent. Yields: 7.3 g (45%) of **2** and 1 g (5%) of **3**.

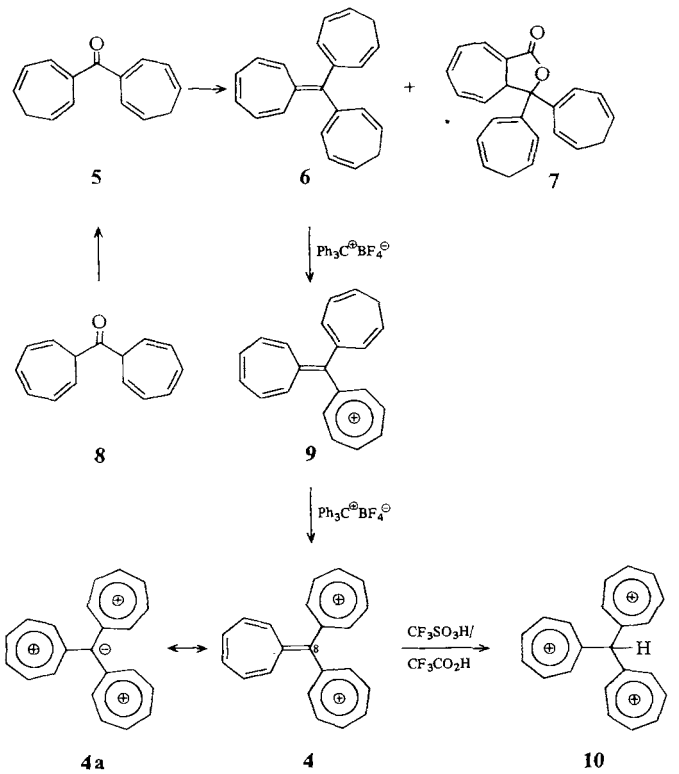
A Salt of the Dication Cycloheptatrienylidenemethyleneditropylium

By *Kiyoharu Mizumoto, Hideki Kawai, Keiji Okada,* and *Masaji Oda**

A number of ionic compounds having the bicyclic cross-conjugated structure **1** (m, n ≧ 1) have been synthesized as stable substances;[1–4] however, none of the tricyclic analogues **2** are known. These molecules would be of interest from both structural and physicochemical points of view. We wish to report the synthesis of cycloheptatrienylidenemethyleneditropylium **4**, a novel dication of type **2** (l = m = n = 3), which was isolated as the bis(tetrafluoroborate) salt, **4** · 2 $BF_4^\ominus$.

1
cation **3**, m = n = 3



2
dication **4**, l = m = n = 3

Thermal sigmatropic [1, 5] hydrogen shift of the ketone **8**[5] (140°C, xylene, 6 h) gave di(1,3,6-cycloheptatrienyl) ketone **5** and 1,3,6-cycloheptatrienyl 2,4,6-cycloheptatrienyl ketone in 47 and 33% yield, respectively (Table 1).[6] As the key step for the construction of the carbon skeleton of **4**, the ketone **5** was transformed into the heptafulvalene **6** employing *Kitahara-Asao*'s heptafulvalene synthesis with 7-carbonylcycloheptatriene.[7] Thus, dropwise addition of 7-cycloheptatrienecarbonylchloride (1.7 equiv.) into a refluxing benzene solution of **5** and triethylamine (2.0 equiv.) under nitrogen atmosphere provided **6** in 5–10% yield as a red, acid- and air-sensitive oil, in addition to the lactone **7** (50–70% yield). Treatment of **6** with triphenylmethyl tetrafluoroborate (2.2 equiv.) in dry acetonitrile (room temperature, 1 d) gave the dication **4** as the salt

[*] Prof. Dr. M. Oda, Dipl.-Chem. K. Mizumoto, Dipl.-Chem. H. Kawai, Dr. K. Okada
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

4·$2BF_4^{\ominus}$ (dark blue needles, m.p. = 245 °C (dec.)) in 60% yield. The hydride abstraction proceeded stepwise via the monocation **9** as monitored by thin layer chromatography (silica gel, acetone/trace of 42% HBF_4). Attempts to obtain **9** selectively using one equivalent of the reagent resulted, however, only in formation of a mixture with **4**.

5 **6** **7** **8** **9** **4a** **4** **10**

Table 1. Selected physical data for the compounds **4**–**7**, **9**, and **10**.

4: ^{1}H-NMR (100 MHz, CD_3CN): $\delta = 8.10$ (m, H-3,4), 8.55 (structured d, $J = 10$ Hz, H-2); ^{13}C-NMR (22.5 MHz, CD_3CN): $\delta = 133.2$ (s, C-8), 150.1, 150.3, 151.0 (each d, C-2–C-4 [8]), 168.5 (s, C-1)

5: ^{1}H-NMR ($CDCl_3$): $\delta = 2.36$ (t, $J = 7$ Hz, 4H), 5.49 (d, 9 Hz, 2H), 5.63 (dt, 9, 7 Hz, 2H), 6.28 (dd, 9, 6 Hz, 2H), 6.75 (d, 9 Hz, 2H), 7.15 (d, 6 Hz, 2H); IR (oil): $\tilde{\nu}_{C=O} = 1645$ cm^{-1}

6: ^{1}H-NMR ($CDCl_3$): $\delta = 2.29$ (t, $J = 7$ Hz, 4H), 5.2–5.6 (m, 6H), 5.75 (m, 2H), 5.9–6.3 (m, 6H), 6.51 (d, 6 Hz, 2H); UV (cyclohexane): $\lambda_{max} = 240$ nm ($\lg\varepsilon = 4.20$) sh, 270 (4.07) sh, 349 (3.93), tailing to 600 nm

7: m.p. = 89 °C; ^{1}H-NMR ($CDCl_3$): $\delta = 1.9$–2.6 (m, 4H), 3.05 (narrow m, 1H), 5.1–5.6 (m, 5H), 5.9–6.4 (m, 5H), 6.62 (d, $J = 6$ Hz, 1H), 6.78 (m, 2H), 6.94 (d, 6 Hz, 1H), 7.10 (structured d, 5 Hz, 1H); IR (KBr): $\tilde{\nu}_{C=O} = 1760$ cm^{-1}

9: ^{1}H-NMR (CD_3CN) (with a small amount of **4**): $\delta = 2.33$ (t, $J = 7$ Hz, 2H), 5.2, 6.4 (m, 4H), 6.60 (d, 6 Hz, 1H), 7.3 (m, 8H), 7.9 (m, 4H)

10: ^{1}H-NMR (CF_3SO_3H/CF_3CO_2H): $\delta = 7.92$ (s, 1H), 9.36 (m, 18H); ^{13}C-NMR (CF_3SO_3H/CF_3CO_2H): $\delta = 68.9$, 157.9, 159.2, 159.6, 166.4

The NMR spectra of **4** (Table 1), which showed little change down to −40 °C, are in accord with a C_3 symmetry of the molecule. The averaged chemical shifts of the ring protons and tertiary carbons ($\delta_{av} = 8.25$ and 150.5, respectively) lie between those of the bicyclic congener **3** ($\delta_{av} = 7.62$ and 141.4[4b]) and the tropylium ion ($\delta = 9.30$ and 155.4) in line with the number of charges per ring (**3**, 0.5; **4**, 0.66; tropylium ion, 1). Notably, the central carbon (C-8) is observed at the highest field in spite of being a quaternary carbon. This suggests some resonance contribution of the polar structure **4a**.[9] The absorption spectrum [$\lambda_{max}(CH_3CN) \approx 236$ nm ($\lg\varepsilon = 4.54$), 284 (4.15), 649 (4.39)] is redshifted by 53 nm in the visible region compared with that of **3**. The dication **4** gave two pK_{R^+} values (4.4 and 1.6), corresponding to the stepwise neutralization upon spectrophotometric measurements in 20% aqueous ethanol. These values are, however, considered to be somewhat smaller than the true values because **4** partially decomposed during the measurements. Cyclic voltammetry also showed two reduction potentials ($E = -0.36$ and -0.19 V vs. SCE, CH_3CN, $Bu_4N^{\oplus}ClO_4^{\ominus}$, 100 mV s^{-1}, 20 °C), which are ascribable to the two-stage reduction of the two tropylium groups to form a diradical. These pK_{R^+} values and reduction potentials lie between those of the tropylium ion (4.30[10] and −0.29 V, respectively) and **3** (7.49[4b] and −0.40 V, respectively). The poorer thermodynamic stability of **4** relative to **3** is perhaps associated with less coplanarity of **4** due to severer steric interactions among the three seven-membered rings.[11]

In agreement with the highest electron density shown in the ^{13}C-NMR spectrum, the dication **4** was protonated at the central carbon in CF_3SO_3H/CF_3CO_2H (1 : 1), though unchanged in CF_3CO_2H alone, to give the methylidynetritropylium ion **10**, which is the first trication in the methyltropylium series.[4b, 12]

[**] This work was supported by the Fonds der Chemischen Industrie.

quinones belong to one of the most thoroughly investigated classes of substances in organic chemistry. In organic synthesis, quinones have long played an outstanding role as oxidizing agents:[1] the synthesis of quinones having as positive a redox potential as possible has therefore always been of central interest,[2] 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) having thus far claimed special practical importance as one of the most powerful organic oxidizing agents.[3]

We now report the first synthesis of structurally novel poly-onio-substituted benzoquinones whose oxidative power clearly surpasses that of the known neutral systems. Reaction of trimethylsilyl trifluoromethanesulfonate (triflate) **1** with 4-dimethylaminopyridine **2** leads, in accord with equation (a), to formation of *N*-trimethylsilyl-4-dimethylaminopyridinium triflate in almost quantitative yield as thermally stable, colorless, hygroscopic crystals (for characteristic data see Table 1).[4]

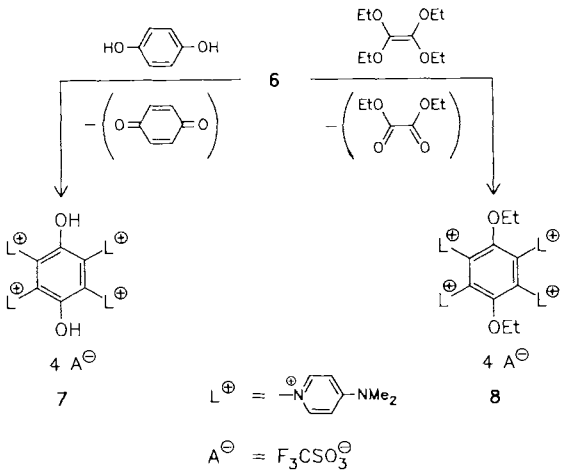
MNDO calculations show that the cation in **3** can, to a good approximation, be described as a silylated secondary amine.[5] Consistent with this description, **3** undergoes transamination reactions with numerous electrophilic organic halogen compounds, as are characteristic of silylamines.[5] Thus, on reaction of **3** with *p*-chloranil, **4**, in the molar ratio 2 : 1, the bispyridinio-substituted *p*-quinone **5** is obtained in quantitative yield as a vermilion crystalline powder (cf. Scheme 1 and data in Table 1). 2,5-Substitution is the rule in the case of nucleophilic difunctionalizations of *p*-chloranil, and will also be assumed here, although, according to the spectroscopic data, the equally possible 2,3-disubstitution pattern cannot be strictly ruled out. In no case, however, is the reaction product an isomeric mixture. Further reaction of **5** with 2 molar equivalents of **3** or direct reaction of **4** with 4 molar equivalents of **3** furnishes equally smoothly the dark red tetrakispyridinio-substituted quinone **6** in quantitative yield (cf. Scheme 1 and data in Table 1). In all cases the calculated amounts of Me_3SiCl could be detected in the mother liquor.

Scheme 1.



Mono-onio-substituted quinones have occasionally been postulated as strongly oxidizing, reactive intermediates, but in no case have they ever been isolated and convincingly characterized as such.[6] *Poly*-onio-substituted quinones have so far never been synthesized. Of central interest, aside from the reactivity of the new quinones **5** and **6**, is the influence of the pyridinio substituents on the redox potential. In Table 2 are listed, inter alia, the (reversible) redox potentials for the single and double reduction of salts **5** and **6**: It can be seen immediately that the dication in **5** is already a much stronger oxidizing agent than **4**. It ranks equal with DDQ, and even surpasses the latter when

Table 2. Reversible redox potentials of substituted 1,4-benzoquinones in CH_3CN.

Quinone	$E_{1/2}$ [V] 1st reduction step	2nd reduction step
1,4-Benzoquinone [a]	−0.51	−1.14
4 [b]	+0.089	−0.715
DDQ [a]	+0.51	−0.30
5 [b]	+0.49	−0.17
6 [b]	+0.73	+0.16

[a] M. E. Peover, *J. Chem. Soc. 1962*, 4540. [b] Cyclic voltammetry: Pt auxiliary and working electrodes; Ag/AgCl reference electrode: supporting electrolyte 0.1 N Et_4NBF_4.

the second reduction step is taken into consideration. On going to **6**, the redox potential increases even further. **6** exhibits the highest redox potential (+0.73 V) of all previously described quinone systems;[2] even the redox potential of the semiquinone form of **6** is comparable to that of **4**! As expected, **6** is easily reduced to tetrakispyridinio-substituted benzene derivatives—likewise a previously unknown class of substances. Thus, reaction with hydroquinone smoothly furnishes **7**, while reaction with tetraethoxyethylene affords the compound **8** by a previously undescribed reductive ethylation (cf. Scheme 2 and data in Table 1).

Scheme 2.

The finding that the redox potential is shifted by 1.24 V to more positive values on going from the parent *p*-benzoquinone to the salt **6** constitutes a very important facet of this investigation. This drastic effect could be attributed to an optimal electrostatic stabilization of the singly and doubly reduced forms of **6** by the four onio ligands. Undoubtedly, this finding will open up a new area of application in redox chemistry for **2**, which already finds frequent use in reactions catalyzed by Lewis bases.[7]

Reaction of **3** with *o*-chloranil instead of with **4** leads to the *o*-isomer of **6**; DDQ analogously affords a bis-onio-substituted product. In all cases, **2** can be replaced by *N*-methylimidazole; the substitution- and redox-chemistry of the new poly-onio-substituted quinones accessible in this way are presently under investigation.[8]

If the free *N*-bases are used instead of **3** or the analogous trimethylsilyl triflate adduct of *N*-methylimidazole in the reaction according to Scheme 2, then the stoichiometrically equivalent chlorides of the above triflates are obtained,[9] which, as a rule, can be converted with **1** into the triflates. As preliminary electrochemical measurements show,[8] the redox potential of the chlorides is distinctly less positive. Charge transfer interactions between the chloride ions and the electron-deficient quinone system might be responsible for this. The new oxidizing reagents presented here are especially attractive from the preparative point of view, in particular since they can be readily generated in situ; furthermore, in all three oxidation steps they are insoluble in the usual (aprotic) organic solvents, irrespective of the anion. Thus, they offer the same advantages in work-up procedures as immobilized (polymer-bound) reagents.[10]

Experimental procedures for 5 and 6

2,5-Bis[(4-dimethylamino)pyridinio]-3,6-dichloro-1,4-benzoquinone bis(trifluoromethanesulfonate) **5**: A solution of 4 mmol of **3** prepared in situ was added dropwise to a solution of **4** (0.492 g, 2 mmol) in anhydrous CH_2Cl_2 (25 mL). The mixture was stirred overnight at room temperature. The bright-red precipitate (**5**) that formed was filtered off, washed with CH_2Cl_2, and dried under vacuum (oil-pump). Yield: 96% of analytically pure **5**.

2,3,5,6-Tetrakis[(4-dimethylamino)pyridinio]-1,4-benzoquinone tetrakis(trifluoromethanesulfonate) **6**: A solution of **3** (4 mmol) in 25 mL of anhydrous CH_2Cl_2 prepared in situ was treated with 0.246 g (1 mmol) of solid **4**. A dark-red precipitate was immediately formed (**6**). The reaction mixture was stirred for 5 h and then worked up as described for **5**. Yield: 97% of analytically pure **6**. When using larger amounts of reagents it is advisable to heat the reaction mixture for a short while.

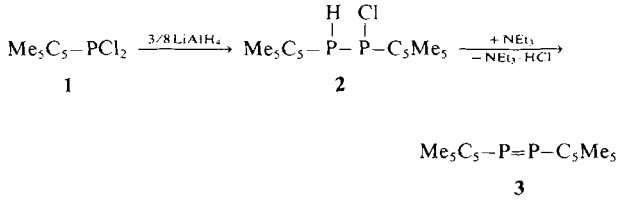
Bis(pentamethylcyclopentadienyl)diphosphene—a Molecule with Fluxional Structure and Reactive P-C Bond**



By *Peter Jutzi,* Udo Meyer, Bernt Krebs,* and *Mechthild Dartmann*

The σ-bonded pentamethylcyclopentadienyl (Cp*) ligand is, from our experience, of special interest for many reasons in the chemistry of the main-group elements: 1) the Cp* ligand enables the study of element-specific [1.5]-sigmatropic rearrangements;[1-3] 2) it is sterically demanding[4] and can thus kinetically stabilize reactive species; 3) element–Cp* bonds can be readily cleaved by nucleophilic or electrophilic agents, or even by reducing agents.[5] We now decided to test the potential of this ligand in the relatively new field of diphosphene chemistry.[6]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

We first obtained an indication of the existence of a bis(pentamethylcyclopentadienyl)diphosphene (**3**) that is stable under normal conditions during the reduction of Cp^*PBr_2.[7] At the time we were able to detect **3**, along with other products, in the reaction mixture by ^{31}P-NMR spectroscopy, but were unable to isolate it. In the meantime, however, we have succeeded in synthesizing **3** as an isolable compound via another route: Reduction of the dichlorophosphane **1** with $LiAlH_4$ furnished the chlorodiphosphane **2**,[8] which was dehydrohalogenated to **3** without prior isolation (Scheme 1).[9, 10]

Compound	4, 8	5, 9	6, 10	7, 11
R	$N(SiMe_3)tBu$	$N(SiMe_3)_2$	$CH(SiMe_3)_2$	$C(SiMe_3)_3$

Scheme 1. Synthesis and reactions of **3**.

3 was obtained in the form of air-sensitive, yellow crystals which can be stored without decomposition at -30 °C. The ^{31}P-NMR signal[10] lies in the region typical for diphosphenes. The crystal structure analysis carried out at -130 °C (Fig. 1)[11] confirms the presence of monohapto-bound cyclopentadienyl ligands. The P=P double bond has a length of 2.031(3) Å; the ligands are *trans*-oriented. The P–C single bonds are somewhat longer (1.893(7) and 1.883(7) Å, respectively) than in other diphosphenes (1.855–1.866 Å), but shorter than the P–C bond in Me_5C_5–P=C(SiMe$_3$)$_2$ (1.939 Å).[12] The P–P–C angles (103.4 and 103.9°, respectively) lie within the range of values typical for diphosphenes.[13]

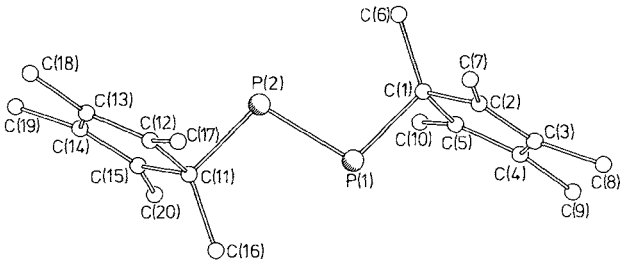

Fig. 1. Crystal structure of **3**.

The η^1-bonding of the Cp* ligand found in the crystal could not be detected in solution. Degenerate [1.5]-sigmatropic rearrangements at room temperature lead to a ^{1}H- and ^{13}C-NMR spectroscopic[10] equivalence, both of the ring carbon atoms as well as of the methyl groups. The ^{1}H- and ^{13}C-NMR signals exhibit the triplet structure to be expected because of coupling to P. We attribute the low activation energy for rearrangement (no change in the spectra down to -80 °C) to the stabilizing interaction of the Cp* ligands with the π^*-orbital of the (p-p)π bond in the η^2-transition state.[12, 14]

As anticipated, on grounds of the somewhat extended P–C bonds in **3**, the Cp* ligands can be readily substituted, e.g. stepwise by reaction with lithium-amides or -alkyls (Scheme 1). The unsymmetrical diphosphenes **4–7** are unequivocally characterized by the AX pattern in the ^{31}P-NMR spectra (Table 1). The diphosphenes **8–11** formed upon substitution of the second Cp* ligand and their ^{31}P-NMR data have already been reported in the literature.[6]

Table 1. ^{31}P-NMR data of the diphosphenes $R-P_A=P_B-C_5Me_5$ **4–7**. The spectra were recorded in solution with H_3PO_4 as external standard.

Compound	δP_A	δP_B	J_{PP}[Hz]
4	440.1	529.1	640
5	546.2	478.3	632
6	522.8	492.6	599
7	545.8	522.2	635

Summarizing, it has been established that the Cp* ligand kinetically stabilizes a P=P bond quite effectively, leads to a diphosphene with fluxional structure, and enables, for the first time, substitutions at a P=P bond.

Dimeric 1,4-Dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene, a Compound with Aluminum-Olefin π-Bonds**

By *Hansgeorg Schnöckel,* Manfred Leimkühler, Rainer Lotz,* and *Rainer Mattes*

π-Complexes of aluminum with olefins have long been regarded as intermediates in many reactions of organoaluminum compounds.[1] Results of IR and NMR spectroscopic investigations on alkenylaluminum compounds provided evidence of intramolecular interactions of the threefold coordinated aluminum with the C=C double bond.[2] We have now been able to prepare, for the first time, a compound containing the structural unit **I** and to characterize it by an X-ray structure analysis.

I

Treatment of the active species AlCl, generated at elevated temperature, with dimethylacetylene in a low-temperature reaction led, upon warming from -196 °C to room temperature, to formation of dimeric 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene **1**.[3]

$$4\,AlCl + 4\,H_3CC{\equiv}CCH_3 \longrightarrow Al_4Cl_4C_{16}H_{24} \quad \mathbf{1}$$

In 1968, *Timms* prepared 1,4-dibora-2,5-cyclohexadienes under similar conditions by reaction of boron subhalides with alkynes.[4] The decomposition of **1** in solution and the NMR spectra obtained for such solutions indicate a complex dynamic behavior.

The elemental analysis of **1** (Al : Cl = 1 : 1), the detection of *cis*-2-butene as the sole product of hydrolysis, and the occurrence of a singlet in the ^{1}H-NMR spectrum at $\delta = 2.08$ (90 MHz, C_6D_6) afforded the first indications of the structure of **1**. Surprisingly, the extremely air- and moisture-sensitive compound **1** can be vaporized at ca. 140 °C, and its mass spectrum shows the expected molecular peak with the characteristic fine structure for four chlorine atoms. A compound related to the monomer of **1** is 1,4-diethyl-2,3,5,6-tetraphenyl-1,4-dialumina-2,5-cyclohexadiene·2THF **2** (THF = tetrahydrofuran).[5]

The investigation of the structure of **1** at -130 °C[6] gave the following result: Two nonplanar 1,4-dialuminacyclohexadiene moieties, twisted through 90° with respect to each other, are coupled via four aluminum-olefin π-bonds of type **I** to give the dimer **1** (Fig. 1). In contrast, **2** is monomeric; the Al atoms are coordinatively saturated by THF, and the Al_2C_4 ring is planar.[5]

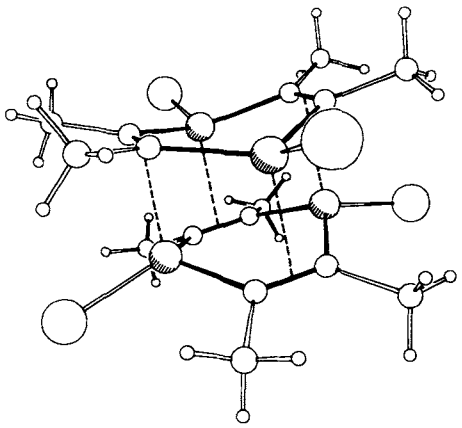

Fig. 1. Molecular structure of **1** in the crystal. Hatched, Al; large circles, Cl; dotted lines, Al-olefin π-bonds. Mean, selected distances [pm] and angles [°]: Al-Cl 210.9, Al-Al 300.5 and 337.0 (see text), Al-C (σ) 199.0, Al-C (π) 235.5, C=C 136.7; C-Al-C 115.1, C-Al-Cl 114.9, Al-C-CH_3 117.7 (standard deviations 0.1–0.3 pm). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52141, the names of the authors, and the full citation of the journal.

In **1**, the mean Al-C distance in the π-bonds is 235.4 pm, i.e. approximately 10% greater than the comparable distance in the Zeise salt $K[Pt(C_2H_4)Cl_3]$ (213.1 pm).[7] The average C=C distance in **1** is 136.7(3) pm (Zeise salt: 137.5(4) pm) and is thus longer than in an uncoordinated C=C bond. Other than in the Zeise salt, in which the C_2H_4 group is clearly no longer planar, the highly substituted double bonds of **1** are still almost planar. The interaction between the Al atoms and the C=C bonds is not optimal, since the Al,C=C vector deviates by 15.5° from the normal to the C=C group. The pyramidal coordination of the Al atoms by the Cl atom and the two C atoms clearly indicates presence of an aluminum-olefin π-bond.

The Al-Cl distance is 211 pm, and the length of the Al-C σ bonds is 199 pm (C-Al-C and C-Al-Cl: 114–116°). The distance between two Al atoms of different six-membered rings (ca. 300 pm) is relatively small. A closer proximity of two such atoms, which could lead to a shortening of the aluminum-olefin π bond, is therefore hindered. In contrast the distance between the Al atoms within the dialuminacyclohexadiene ring is 337 pm (in **2**, 347 pm); the transannular distance between the CC double bonds (334 pm) is of the same order of magnitude. The four Al atoms of **1** form a tetrahedron slightly compressed along the molecular axis.

Novel Modifications of Gold, Rhodium, and Ruthenium—M_{13} Clusters as Building Blocks of "Superclusters"**

By *Günter Schmid** and *Norbert Klein*

The unusual stability of transition-metal clusters with closed shells (so-called full-shell clusters) has already been demonstrated on a number of occasions.[1,2] They are compounds whose cluster skeleton is stabilized by a ligand shell. The question of the possibility of existence of closed shell clusters without protecting ligand peripheries, however, still remains unanswered. According to theoretical models by *Hoard* and *Pal*,[3,4] closed-shell clusters containing less than ca. 70 metal atoms should be incapable of existing; such aggregates form polytetrahedral structures. We have now succeeded, however, in converting ligand-stabilized M_{55} clusters into ligand-free M_{13} clusters and in identifying these as components of novel "superclusters".

Solutions of $[Au_{55}(PPh_3)_{12}Cl_6]$,[5] $[M_{55}\{P(tBu)_3\}_{12}Cl_{20}]$, M = Rh,[6] Ru,[7] and $[Pt_{55}\{As(tBu)_3\}_{12}Cl_{20}]$[7] in methylene chloride can be smoothly degraded on platinum electrodes at 20 V d.c. This type of degradation is not an electrolysis, since no discharging takes place. The compounds decompose upon contact with the cathode or anode, and the metals separate and are deposited on the platinum or are precipitated in the reaction vessel.[8] If contact of the clusters with the electrodes is prevented, e.g. by covering the methylene chloride solution with a layer of water, electrophoresis is observed, with the clusters migrating to the cathode. This process is reversible. The degradation of the M_{55} clusters gives, besides the metal, free phosphane and arsane and metal halide complexes that are soluble in CH_2Cl_2, in the case of gold $[(Ph_3P)_2AuCl]$, in the case of the other metals, complexes of unknown structure.

The cleavage of metal halide and phosphane (or arsane) leads to degradation of the whole external shell of 42 metal atoms of the M_{55}-cluster, thus leaving naked M_{13} cluster cores, which constitute the smallest conceivable closed-shell clusters. It may be assumed that they are not long-lived as isolated particles in solution, there being two routes open for their stabilization: a) degradation into small, e.g., tetrahedral particles, which, as predicted by model calculations could reassemble to form polytetrahedral structures, or b) the assemblage of M_{13} building blocks to give novel metal structures. It is found that the latter path is actually followed. If one imagines the M_{13} clusters in their simplest form as being spherically shaped, such clusters would try to adopt a cubic closest packed structure,which in the simplest case would be made up of thirteen M_{13} clusters. Even these $(M_{13})_{13}$ clusters could also aggregate in an organized way to form a second superstructure $[(M_{13})_{13}]_n$ consisting of closest packed $(M_{13})_{13}$ clusters.

This concept of novel metal modifications is confirmed by the Debye-Scherrer diffraction patterns ($Cu_{K\alpha}$, $\lambda = 1.5418$ Å) of the powders thus obtained. The metal atoms originating from the outer shell of the cluster upon degradation form "normal" metal (M_∞) which gives rise to the correspondingly well-known X-ray diffraction pattern. In addition, reflections are observed which are in very good agreement with the most important lattice planes to be expected for the superstructures illustrated below. Thus, for all metals, one finds three new lattice planes characterizing the superstructures which are integral multiples of the interplanar spacings of the metals. Rhodium, platinum, and gold crystallize in the cubic system, as do also the superstructures. Ruthenium, on the other hand, has a hexagonal structure; nevertheless, the reflections of the three superstructures observed even in the case of ruthenium are identical to those found with (the equally large) rhodium, i.e. ruthenium also forms $(Ru_{13})_{13}$ superclusters with cubic structure upon cluster degradation.

Table 1. *hkl* values, interplanar spacings *d* [Å] and 2θ-values of $(M_{13})_{13}$, $[(M_{13})_{13}]_n$ and, for comparison, M_∞-values.

M	$d(M_\infty)$	*hkl*	Occupation	$d(M_{13})_{13}$	$d[(M_{13})_{13}]_n$	2θ
Rh	1.902	200	$8 \times d(M_\infty) = 15.216$		15.3	5.8
	0.8725	331	$7 \times d(M_\infty) = 6.1075$	6.11 (d^2)		14.5
	1.0979	222	$3 \times d(M_\infty) = 3.2937$	3.24 (d^1)		27.5
Ru [a]					15.3	5.8
				6.11 (d^2)		14.5
				3.24 (d^1)		27.5
Au	2.039	200	$8 \times d(M_\infty) = 16.312$		16.8	5.3
	0.9358	331	$7 \times d(M_\infty) = 6.5551$	6.8(3) (d^2)		13.0(5)
	1.1774	222	$3 \times d(M_\infty) = 3.5322$	3.5(3) (d^1)		14.1(5)

[a] Ru_∞ crystallizes hexagonally; consequently, its structural data are not to be compared with those for $(Ru_{13})_{13}$.

In Table 1 the new 2θ-values and lattice planes are collected together with the corresponding values for the normal metals M_∞, where M = Rh, Ru, and Au. Figure 1 shows a model of the course of the lattice planes observed in the first superstructure $(M_{13})_{13}$, while Figure 2 shows a model of the second superstructure $[(M_{13})_{13}]_n$. All lattice planes necessary for characterization of the new metal structures are proven. That $[(M_{13})_{13}]_n$ is composed of closest packed $(M_{13})_{13}$ clusters is also confirmed by the occurrence of lattice planes with a separation of 15.3 and 16.8 Å, respectively. The magnitude of *n*, however, is still unknown.

[**] Large Transitioh-Metal Clusters, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG. We thank Dr. *R. Boese* for valuable discussions and Mrs. *G. Schmid* for help with the construction of the models. Thanks are also due to Dr. *H. Schweder* for the SEM photographs and to Mr. *W. Hüben* for the DMC measurements.—Part 4: [7].

Fig. 1. Model of a $(M_{13})_{13}$ cluster showing the interplanar spacings d^1 (3.24 Å for Rh/Ru and 3.5 Å for Au) and d^2 (6.11 Å for Rh/Ru and 6.8 Å for Au).

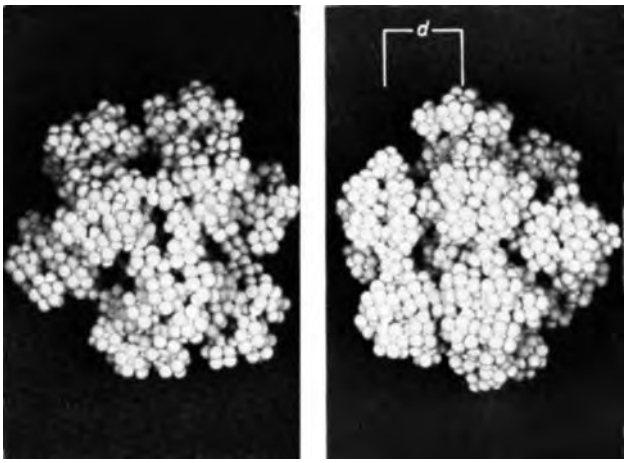

Fig. 2. Left: Model of a $[(M_{13})_{13}]_n$ cluster ($n = 13$) along a sixfold symmetry axis; right, model of a $[(M_{13})_{13}]_n$ cluster ($n = 13$), showing the interplanar spacing d (15.3 Å for Rh/Ru and 16.8 Å for Au).

Figure 3 shows a scanning electron (SEM) photomicrograph of $[(Ru_{13})_{13}]_n$ crystallites and Ru_∞, the latter of which appears amorphous. Platelet- and column-shaped crystallites of hexagonal morphology are indicated by arrows. The formation of hexagonal faces upon coupling of the $(M_{13})_{13}$ clusters as in Figure 2a is understandable. Crystallites of hexagonal morphology are also detectable by SEM in the case of gold and rhodium.

Preliminary DMC (differential microcalorimetry) measurements on $[(Au_{13})_{13}]_n$ show that phase-transitions take place irreversibly between 400 and 500°C, during which temperature range the superstructures are presumably destroyed. A great disadvantage regarding investigation of the physical properties of the new metal modifications is that they are formed in admixture with the normal metal.

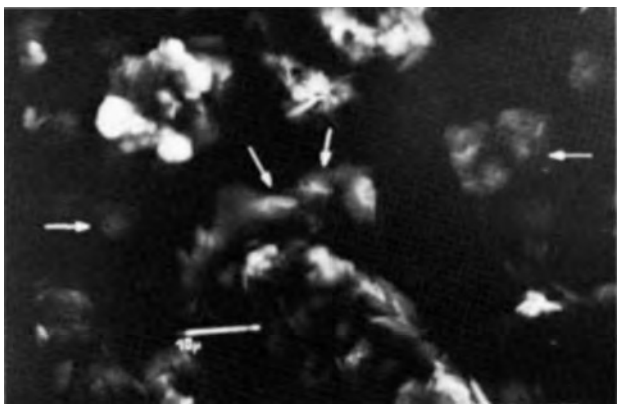

Fig. 3. SEM photograph of $[(Ru_{13})_{13}]_n$ crystallites mixed with Ru_∞. The arrows indicate particularly well formed six-membered ring faces.

[8] Elemental analysis of vacuum-dried precipitates show metal contents of between 95 and 99%. Preliminary DMC measurements indicate that traces of methylene chloride, water, or phosphanes are set free upon heating; these are apparently only loosely enclosed in the metal skeleton.

Heterometallic Dinuclear Complexes by Ethene Displacement with Grignard Compounds or Diorganomagnesium Compounds**

By *Klaus Jonas,** *Gerd Koepe,* and *Carl Krüger*

Cyclopentadienylbis(ethene)cobalt **1**,[1] a preparatively useful starting material which is a source of the synthetically versatile CpCo moiety,[1-4] reacts with phenyllithium with liberation of ethene to give the CpCo-complex salt **2** [Eq. (a)].[5,6] On the other hand, when **1** is treated with allyllithium, it reacts as one would expect of an ethene-cobalt(I) halide: the Cp ligand is smoothly replaced by an allyl group to form the lithium-cobalt compound **3a**. This ethene complex contains two π-allyl groups coordinated to cobalt and can be converted into the *N,N,N',N'*-tetramethylethylenediamine (TMEDA) complex **3b** [Eq. (b)].[2,5,6]

$$[CpCo(C_2H_4)_2] \xrightarrow[Et_2O,\ TMEDA]{LiC_6H_5,\ -C_2H_4} [Li(tmeda)_2][CpCo(C_2H_4)C_6H_5] \quad (a)$$

1 **2**

$$[CpCo(C_2H_4)_2] \xrightarrow[-LiCp,\ -C_2H_4]{2\,LiC_3H_5,\ Et_2O} Li[(C_3H_5)_2Co(C_2H_4)] \quad (b)$$

1 **3a**

$$\xrightarrow{TMEDA} [Li(tmeda)_2][(C_3H_5)_2Co(C_2H_4)]$$

3b

We have now found that the partial or complete removal of the ethene ligands in **1** can also be achieved with diorganomagnesium compounds [Eq. (c) and (d)], and that even Grignard compounds are reactive enough for this purpose [Eq. (e) and (f)]. A common feature of reactions (c)-(f) is that, unlike in reaction (b), the Cp group remains bonded to cobalt.[7] Reaction of **1** with $Mg(C_6H_5)_2$ in tetra-

Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)
[+] Crystal structure analysis.

[**] We thank Priv.-Doz. Dr. *R. Benn* and Dr. *R. Mynott* for the NMR spectra.

hydrofuran (THF) leads to formation of **4** [Eq. (c)], while reaction of **1** with $Mg(C_3H_5)_2$ leads to the ethene-free MgCo dinuclear complex **5** [(Eq. (d)]. **5** contains two different allyl ligands, one of which is π-coordinated while the other is σ-coordinated to the magnesium and shows dynamic behavior.[6] Attempts to synthesize trinuclear complexes by coupling two CpCo moieties to $Mg(C_6H_5)_2$ or $Mg(C_3H_5)_2$ failed: for example, upon reaction of **1** with $Mg(C_6H_5)_2$ in the molar ratio 2:1, only one equivalent of ethene is liberated

$$\underset{\mathbf{1}}{[CpCo(C_2H_4)_2]} \xrightarrow[-C_2H_4]{Mg(C_6H_5)_2,\ THF} \underset{\mathbf{4}}{[CpCo(C_2H_4)(C_6H_5)Mg(C_6H_5)(thf)_2]} \quad (c)$$

$$\underset{\mathbf{1}}{[CpCo(C_2H_4)_2]} \xrightarrow[-2C_2H_4]{Mg(C_3H_5)_2,\ THF} \underset{\mathbf{5}}{[CpCo(\pi\text{-}C_3H_5)Mg(\sigma\text{-}C_3H_5)(thf)_2]} \quad (d)$$

Methyl- and phenylmagnesium bromide do not react with **1** in diethyl ether at room temperature; only when THF is added or used as solvent are the Grignard compounds reactive enough to displace ethene. After addition of TMEDA, the ethene-complexes **6** are formed [Eq. (e)]. Reaction of allylmagnesium bromide with **1** in THF leads to the ethene-free dinuclear complex **7** [Eq. (f)].

$$\underset{\mathbf{1}}{[CpCo(C_2H_4)_2]} \xrightarrow[-C_2H_4]{RMgBr,\ THF,\ TMEDA} \underset{\begin{array}{l}\mathbf{6a},\ R=CH_3\\ \mathbf{6b},\ R=C_6H_5\end{array}}{[CpCo(C_2H_4)RMgBr(tmeda)]} \quad (e)$$

$$\underset{\mathbf{1}}{[CpCo(C_2H_4)_2]} \xrightarrow[-2C_2H_4]{H_2C_3MgBr,\ THF} \underset{\mathbf{7}}{[CpCo(\eta^3\text{-}C_3H_5)MgBr(thf)_2]} \quad (f)$$

The composition of the new CoMg-complexes has been confirmed by elemental analyses. In addition, like **2**, **3b**, and **5**, the complexes **6b** and **7** have been investigated by NMR spectroscopy.[6] Characteristic for the complex **6b** is the pronounced upfield shift of the ^{13}C-NMR signals of the ethene ligand compared to the ethene signal of **1**.[1] In order to obtain more detailed information about the structure and bonding in these compounds, crystal structure analyses of **6b** and **7** were carried out.

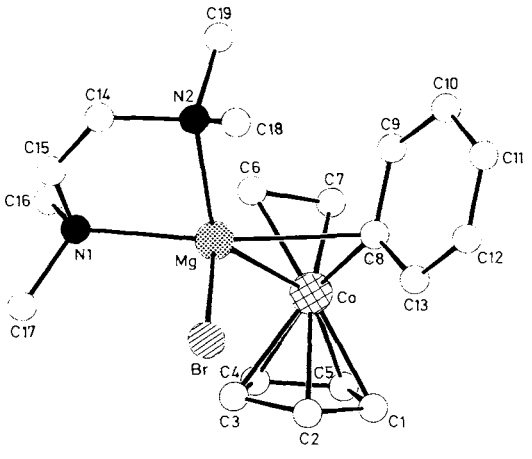

Fig. 1. Molecular structure of **6b** [8, 15].

A novel feature of the dinuclear complex **6b** is—apart from its formation upon reaction of a halogen-free transition-metal compound with a Grignard compound via liberation of ethene[9]—that it contains a TMEDA-modified, complete Grignard compound in the coordination sphere of a transition metal atom (Fig. 1). The central cobalt atom in **6b** is coordinated in an almost pseudo-tetrahedral fashion: ethene and the Cp ring each occupy a coordination site, while the other two coordination sites are occupied by magnesium and the carbanionic phenyl group. The phenyl group is σ-bonded to the cobalt atom and its ring plane is so oriented that, in addition to formation of a Co–Mg bond (2.565(3) Å), an ion pair interaction with the magnesium atom is also possible (Mg-C8 2.572(9) Å).[10] The presence of a Co–Mg bond is consistent with the finding that cobalt-containing 18e half-sandwich complexes such as $[CpCo(CO)_2]$ and $[CpCo(PMe_3)_2]$ have basic metal centers available and therefore can react with metal halides, for example $HgCl_2$, $ZnCl_2$, to give 1:1 adducts such as $[CpCo(CO)_2HgCl_2]$ and $[CpCo(PMe_3)_2HgCl_2]$ with metal-metal bonds.[12] Thus, **6b** can be regarded as a dinuclear complex which is formed by coupling of the singly negatively charged 18e anion $[Cp(C_2H_4)(C_6H_5)Co]^{\ominus}$ with the electrophilic $(tmeda)BrMg^{\oplus}$ ion (Lewis acid/Lewis base adduct with Co→Mg bond).

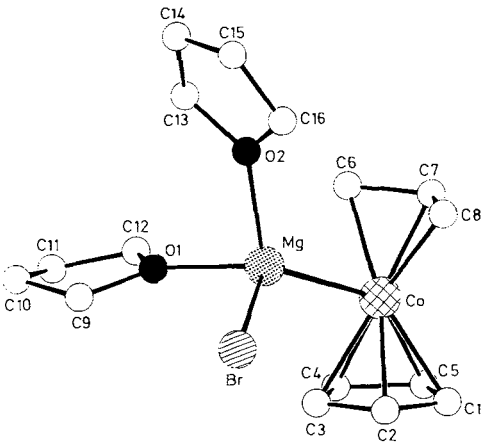

Fig. 2. Crystal structure of **7** [13, 15].

The distances between the Mg atom and terminal C atoms of the allyl group (Mg-C6 2.89(2) Å, Mg-C8 3.06(1) Å) in **7** (Fig. 2) are both significantly longer than the $Mg-C_{phenyl}$ distance in **6b**. Thus, in **7** there is no longer any bonding between the Mg atom and the allyl group introduced by the Grignard reagent; the C_3H_5-group is merely η^3-coordinated to the Co atom. As a result, the distance between the tetracoordinated Mg atom and the Co atom is shortened (2.480(4) Å).

$$L_nM + R{-}MgX \longrightarrow L_nM(R){-}MgX \quad (g)$$

There is no precedent for the insertion of ligand-transition metal fragments L_nM into the Mg–C bond of Grignard compounds [Eq. (g)] leading to stable heterometallic dinuclear complexes with RM–MgX moieties. The reactions of RMgX with $[Cp_2MoH_2]$ and with $[Cp_2WH_2]$ described by *Green* et al.[14] lead to cyclic hexanuclear complexes $[\{Cp_2MHMgR(\mu\text{-}Br_2)Mg(EtO)\}_2]$ (M = Mo, W), which likewise contain magnesium-transition metal bonds.

However, in these compounds the residues R are bound to the magnesium and not, as in **6b** and **7**, to the transition metal.

[7] Procedure for **4** and **5**: A solution of **1** in THF was treated at −78°C with Mg(C$_6$H$_5$)$_2$ or with Mg(C$_3$H$_5$)$_2$ (1:1); the reaction mixture was warmed to room temperature and finally recooled. **4** crystallized out at −30°C, **5** at −78°C.—**6** and **7**: **1** in THF was treated with (a) an equimolar amount of RMgX in Et$_2$O (R=CH$_3$, C$_6$H$_5$) or (b) with C$_3$H$_5$MgBr in THF at −78°C, respectively, and the reaction solution warmed to +20°C. After addition of TMEDA to (a) **6** crystallized out at −30°C, while on reducing the volume of (b) and addition of Et$_2$O 7 crystallized out at −30°C.—All cobalt-magnesium complexes were washed at 0°C with Et$_2$O and dried under oil-pump vacuum at 0°C.

[8] Crystal structure analysis of **6b**: Crystal size: 0.36, 0.36, 0.36 mm; space group $P2_1/n$, a=10.022(2), b=12.142(2), c=17.562(3) Å, β=101.26(1)°; Z=4, μ(Mo$_{K\alpha}$)=27.368 cm^{-1} (λ=0.71069 Å), 5072 reflections measured ($\pm h$, $+k$, $+l$), 1915 observed ($I>2\sigma(I)$), 225 refined parameters, R=0.0582, R_w=0.0519 ($w=1/\sigma^2(F_0)$), max. residual electron density 0.48 eÅ^{-3}, empirical absorption correction, max. 1.242, min. 0.655; see also [15].

[9] In contrast to this, the reaction of halogen-containing transition metal compounds with Grignard reagents is a classical type of reaction in which the halogen atoms on the transition metal are replaced by organic groups. Since MgX$_2$-salts are thus formed, these metathetical reactions lead to magnesium-free organo-transition metal compounds and not to compounds of type **6**, in which an entire Grignard compound is incorporated.

[10] The Mg-Fe distance in [CpFe(diphos)MgBr(thf)$_2$]·THF (diphos=1,2-bis(diphenylphosphino)ethane) is 2.593(7) Å: H. Felkin, P. J. Knowles, B. Meunier, A. Mitschler, L. Ricard, R. Weiss, *J. Chem. Soc. Chem. Commun. 1974*, 44.

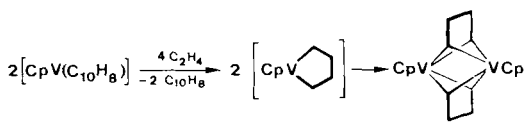
First Dinuclear Complexes with Fourfold Alkyl-Bridging

By *Klaus Jonas,* Wolfgang Rüsseler, Carl Krüger,* and *Eleonore Raabe*

The bridging of metal atoms by alkyl or aryl groups via multicenter bonds is an important means of stabilizing electron-deficient organometallic compounds.[1] Methyllithium, for example, exists as a tetramer in the solid state,[2] with each of the four methyl groups bound to three lithium atoms (structure type **I**). [{Cu(CH$_2$SiMe$_3$)}$_4$][3] was the first example of an organometallic compound in which neighboring metal atoms are present as singly alkyl-bridged centers and in which each organo-ligand is attached to only two metal atoms (structure type **II**). Prototypes of dinuclear compounds with double alkyl-bridging are, in the case of main-group elements, hexamethyldialuminum, the structure of which has been investigated by several groups (structure type **IIIa**),[4] and in the case of transition metals, the nickel(II) complex [{(π-C$_3$H$_3$Me$_2$)NiCH$_3$}$_2$] (structure type **IIIb**).[5] We now report on the first dinuclear complexes whose metal atoms are coupled via more than two alkyl bridges.



I **II** **IIIa** **IIIb**

For the synthesis of the new divanadium complex **3** we used the vanadium(I) complex **1**, which can be prepared according to reaction (a) by five-membered ring/six-membered ring exchange, and in which the naphthalene is markedly more loosely bound than the C$_6$H$_6$ ligand in the analogous benzene complex [CpV(C$_6$H$_6$)].[6, 7]

$$[Cp_2V] \xrightarrow[-KCp,\ -C_{10}H_8]{2\,K[C_{10}H_8]} K[CpV(C_{10}H_8)] \xrightarrow[-KCl,\ -1/2\,C_2H_4]{1/2\,Cl(CH_2)_2Cl} \underset{\mathbf{1}}{[CpV(C_{10}H_8)]} \quad (a)$$

We assume that the reaction of **1** with ethene (tetrahydrofuran (THF), 20°C, 15 bar), which leads to the dinuclear complex **3** in ca. 30% yield, proceeds via the metallacycle **2**. This coordinatively unsaturated 12e species stabilizes itself by dimerization. The four terminal methylene carbon atoms thereby take up bridging positions.

1 **2** **3**

The new divanadium complex **3** not only constitutes the first dinuclear complex with four pentacoordinated bridging carbon atoms, it also demonstrates that C$_4$H$_8$ ligands created by coupling of ethene molecules can function

as bridging ligands. In all other transition-metal complexes known to date which contain C_4H_8 ligands formed from ethene molecules, the butanediyl ligands are terminally bound,[8, 9] and in the hexanuclear complex $[Li_4Cr_2(C_4H_8)_4(thf)_4]$, obtainable from $CrCl_2$ and dilithiobutane, there is only double alkyl-bridging between each Li and a given Cr atom.[10]

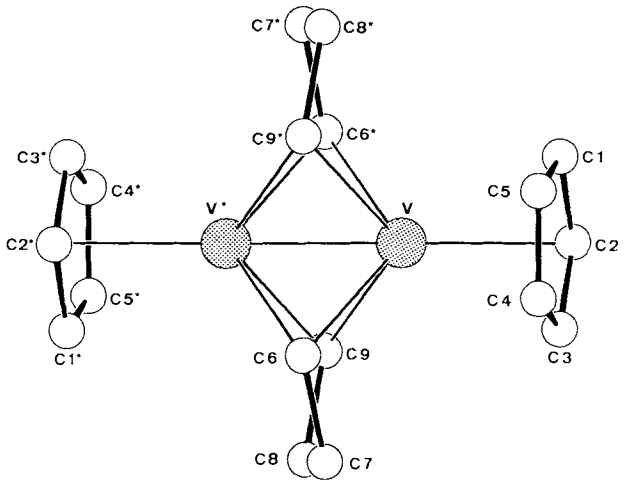

Fig. 1. Crystal structure of 3 [11].

In the dinuclear complex **3**, which has a center of inversion, the four methylene carbon atoms bridge the two vanadium atoms. At each of the two metal atoms there are two shorter and two longer V-C bonds: V-C6 2.211(2), V-C9* 2.202(2) Å; cf. V-C6* 2.299(2), V-C9 2.301(2) Å. The carbon chain C6-C7-C8-C9, in which the C-C distances fall in the expected range (mean value 1.53 Å), is slightly twisted (torsion angle 28.4°). The distances between the carbon atoms not coupled to each other (C6 and C9 2.618(3) Å and C6 and C9* 2.845(3) Å) are shorter than the sum of the van der Waals radii of two C atoms. The V-V distance of 2.315(1) Å is short and correspondingly the apical angles at the bridging carbon atoms (V-C6-V* 61.7(1)°, V-C9-V* 61.8(1)°), are unusually small even for three-center bonds. The cyclopentadienyl ring is oriented almost parallel to the plane through the four bridging carbon atoms (V-C mean value 2.347(3) Å).

Attempts to prepare the corresponding dinuclear compound with four bridging methyl groups have so far failed.[15] However, we discovered a reaction sequence which gives access to the structurally related dinuclear complex **8** with two pentamethylcyclopentadienyl (Cp*) ligands. For the synthesis of **8** we first prepared the chlorine-containing vanadium(II) complex **4** from vanadocene; **4** can also be prepared by degradation of the triple-decker sandwich complex $[(CpV)_2C_6H_6]$ with dichloroethane.[9] Reaction of **4** with LiCp* leads, in accordance with Equation (b), to formation of pentamethylvanadocene **5**, which can be converted in two steps into the new vanadium(III) complex **7** [Eq. (c)].

$$\underset{\mathbf{4}}{[CpVCl(thf)]} \xrightarrow[-LiCl,\ -THF]{LiCp^*} \underset{\mathbf{5}}{Cp^*CpV} \qquad (b)$$

$$\underset{\mathbf{5}}{[Cp^*CpV]} \xrightarrow[-1/2\,C_6H_{10}]{C_3H_5Br} \underset{\mathbf{6}}{[Cp^*CpVBr]} \xrightarrow[-LiBr]{LiCH_3} \underset{\mathbf{7}}{[Cp^*CpVCH_3]} \qquad (c)$$

As with many other transition metal compounds having Cp ligands,[9] the cyclopentadienyl ligand in **7** can be replaced by other organic residues by reaction with organolithium compounds. Upon reaction of **7** with $LiCH_3$ we obtained the divanadium complex **8** [Eq. (d)] in 70% yield, the composition of which was confirmed by elemental analysis and mass spectrometry [*m/z* 432 ($M^{\oplus}$, 68%)].

$$\underset{\mathbf{7}}{[Cp^*CpVCH_3]} \xrightarrow[-LiCp]{LiCH_3} 1/2\underset{\mathbf{8}}{[[Cp^*V(CH_3)_2]_2]} \qquad (d)$$

The crystal structure analysis of **8** revealed a constitution comparable with that of **3**; the disorder of the bridging carbon atoms, however, prevented an accurate determination of bond lengths and angles.

Experimental

1: A THF solution of naphthalenepotassium, prepared from 4.89 g (125.1 mmol) of potassium, 16.78 g (130.9 mmol) of naphthalene and 300 mL of THF at −15°C, was treated at −15°C with 11.41 g (63.0 mmol) of vanadocene. After two hours' stirring at 20°C, the reaction mixture was cooled to −78°C, allowed to stand for 8 h, and then filtered free of KCp. The filtrate was evaporated to dryness and the uncomplexed naphthalene was removed by sublimation at 20°C under high vacuum. The residue was dissolved in THF and the solution treated with 2.78 mL (34.7 mmol) of dichloroethane at 0°C. The mixture was evaporated to dryness, taken up in *n*-hexane, and filtered free of KCl. On cooling to −30°C, dark red crystals of **1** precipitated (yield 14.31 g, 93%). Correct elemental analysis. MS: *m/z* 244 ($M^{\oplus}$, 22%).

3: A solution of **1** (5.35 g, 21.9 mmol) in THF (300 mL) was treated with ethene in an autoclave at 20°C and 15 bar. The pressure was kept almost constant by repeated introduction of ethene under pressure. After 20 h the uptake of ethene noticeably slowed down, and, after 72 h, 229.6 mmol of 1-butene, 45.9 mmol of *trans*-2-butene, 193.9 mmol of 1-hexene, and 54.6 mmol of *trans*-2-hexene could be detected by mass spectroscopy and gas-chromatography. Evaporation of the contents of the autoclave to dryness and removal of the naphthalene by sublimation furnished a residue which was dissolved in hot toluene. Upon cooling the solution to −30°C, dark brown **3** crystallized out (yield 1.22 g, 33%). Correct elemental analysis. MS: *m/z* 344 ($M^{\oplus}$, 28%).

4: As in the case of **1**, naphthalenepotassium [19.11 g (149.1 mmol) of naphthalene, 5.71 g (146.0 mmol) of potassium] was first allowed to react in 300 mL THF with 13.02 g (71.9 mmol) of vanadocene and the mixture cooled to −78°C and filtered free of KCp. The filtrate was then allowed to warm to 20°C and treated with 2.88 mL (36.0 mmol) of dichloroethane. The resulting deep red solution was evaporated to dryness at 20°C. The residue was taken up in *n*-hexane and the solution filtered free of KCl. After treatment of the filtrate with 11.7 mL (143.9 mmol) of THF and 2.88 mL (36.0 mmol) of dichloroethane, violet crystals separated upon storage for 2 d at 20°C. These were washed with pentane and dried at 20°C under oil-pump vacuum (11.05 g, 69%). Correct elemental analysis.

Benzene as Bridging Ligand in Main Group Metal-Transition Metal-Arene Complexes

By *Klaus Jonas,* Wolfgang Rüsseler, Klaus Angermund,* and *Carl Krüger*

μ-Benzene(dicyclopentadienyl)divanadium **1**,[1] the first triple-decker sandwich complex with benzene as "middle deck", can be converted into the mesitylene analogue **2** by heating in mesitylene.[1,2] By way of analogy we have now treated **1** with lithium cyclopentadienide (LiCp) in tetrahydrofuran (THF) with the aim of replacing the bridging benzene ligand by the isoelectronic cyclopentadienyl anion. It was found, however, that this reaction resulted in rupture of the triple-decker sandwich structure and formation of the lithium-vanadium complex **3a** and vanadocene. That is, the C_5H_5-ring of LiCp attaches to a CpV unit, while the Li atom coordinates to the arene ligand of $[CpV(C_6H_6)]$ **4**.

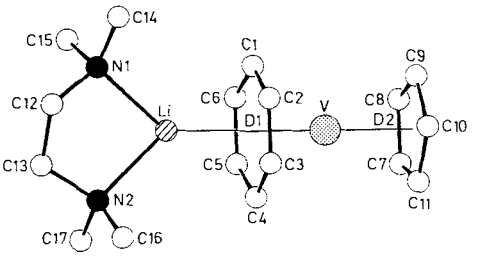
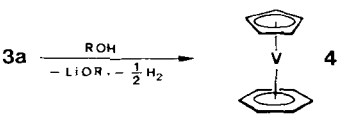
[+] Crystal structure analysis.

The novel lithium-vanadium complex **3a** is stable in toluene even at 100°C and is thus significantly more robust than the vanadium compounds that contain a second five-membered ring instead of the C_6H_6-ligand: $K[Cp_2V]$[2,3] and $K[(C_5Me_5)VCp]$.[2] The latter two complexes, which are obtained by reaction of the corresponding metallocenes with potassium and which are suitable starting compounds for the synthesis of half-sandwich complexes, are, like $M[Cp_2Co]$ (M = Li, K),[2,4] stable only at low temperatures.

Replacement of the THF ligands in **3a** by *N,N,N',N'*-tetramethylethylenediamine (TMEDA) affords crystalline $[(tmeda)Li(C_6H_6)VCp]$ **3b**. A novel feature of the structure of **3b** (Fig. 1) is that a transition metal atom and a main-group metal atom are bridged by a benzene molecule. The





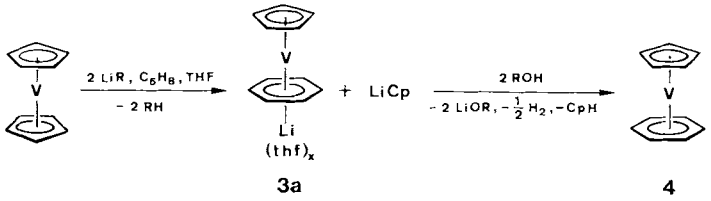


Fig. 1. Crystal structure of **3b** [5].

bridging ligand and the five-membered ring bound to the vanadium atom are parallel (angle between the least square planes through the carbon atoms C1–C6 (plane E1) and C7–C11 (plane E2): 1.1°); and are oriented almost perpendicularly to the line through the two metal atoms (angles between Li–V and E1 and E2: 89.0 and 88.6°, respectively). The benzene ligand is η^6-coordinated to both the lithium and the vanadium atom (angle between the normal of E1 and the line through the metal atom M and the center of the benzene ring: 1.4° for M = Li and 0.6° for M = V); the distances between the center of the benzene ring and the lithium and vanadium atoms are 1.938 Å and 1.590 Å, respectively. Taking into consideration the different ionic radii of lithium and potassium, it follows that the lithium-benzene distance in **3b** is ca. 0.5 Å shorter than the potassium-benzene distance in $[K(C_6H_6)Al(CH_3)_3NO_3]$.[6] The lithium atom is coordinated in a distorted pseudo-trigonal planar fashion, while the vanadium atom is sandwiched between the C_6H_6 ligand and the Cp ring (Cp-V-benzene angle: 179.3°). The V-Cp(center) distance (1.920 Å) is identical to that in **1**; the V-benzene (center) distance, on the other hand, is 0.11 Å shorter than that in the triple decker sandwich complex **1**.

The compounds **3a** and **3b** can be delithiated by alcoholysis. In both cases, this leads to evolution of H_2 and formation of the paramagnetic species benzene(cyclopentadienyl)vanadium **4**, which was thus prepared for the first time in pure form. In contrast, the reaction of $CpVCl_3$ with isopropylmagnesium bromide described by *Müller* and *Goll* furnished a product mixture, in which **4** was detected mass spectrometrically but could not be separated from $[Cp_2V]$ and $[(C_6H_6)_2]V$.[7]

The complex **4** can be prepared in pure form very much more easily and on a larger scale in a one-pot synthesis starting from vanadocene (Scheme 1).[8] Moreover, when methylcyclohexadiene is used in place of cyclohexadiene, the new vanadium complex cyclopentadienyl(toluene)vanadium is formed.

3a **4**

Scheme 1. One-pot synthesis of **4** from vanadocene (R = Me, Et, *n*Bu) [8].

That **4** reacts with lithium to give **3** is not surprising. Remarkable, however, is the reaction of **4** with magnesium: It leads in tetrahydrofuran to the novel trinuclear complex

$[(thf)_2Mg\{(C_6H_6)VCp\}_2]$

in which, analogous to the structure of **3b**, the benzene ligands probably form bridges between vanadium and magnesium.

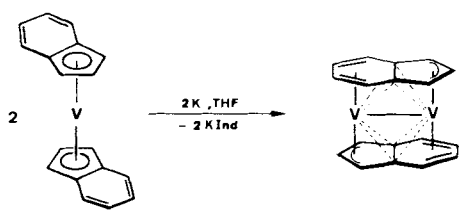
[8] Experimental procedure for **4**: A solution of vanadocene (13.18 g, 72.8 mmol) and 1,3-cyclohexadiene (10.4 mL, 109.2 mmol) in THF (200 mL) was treated with 69 mL of a 2.11 molar solution of *n*BuLi in hexane (145.6 mmol) at such a rate that the temperature of the solution increased to 50°C. After subsequent addition of 8.54 mL (145.5 mmol) of ethanol at 0°C and evaporation to dryness the resulting residue was sublimed under vacuum at 80–100°C. Dissolution of the sublimate in hot hexane furnished a solution from which the brown complex **4** crystallized at −30°C (yield 11.38 g, 81%). Correct elemental analysis. MS: *m/z* 194 ($M^{\oplus}$, 35%).
[9] Experimental procedure for **3b** (from **4**): A solution of **4** (2.42 g, 12.5 mmol) in THF (50 mL) was treated at 0°C with excess lithium sand. The mixture was stirred for 5 h and then filtered (to remove unchanged lithium). The filtrate was evaporated to dryness and the resulting residue treated, with vigorous stirring, with a mixture of Et_2O and TMEDA. Recrystallization of the solid product from Et_2O (36°C → −30°C) afforded 3.75 g (95%) of **3b** as red, needle-like crystals. Correct elemental analysis.

Synthesis of Diindenyldivanadium—a New Variant of the Reductive Degradation of Metallocenes and Related Compounds

By *Klaus Jonas,* Wolfgang Rüsseler, Carl Krüger,* and *Eleonore Raabe*



Partial or total degradation of metallocenes and related compounds with alkali metal in the presence of complexing agents such as olefins (reductive abstraction of five-membered ring ligands) produces reactive organometallic compounds with easily displaced ligands. Examples are ethene-transition metal complexes.[1–3] The ether soluble arene-alkali metal complexes such as naphthalenepotassium have also proven to be invaluable reducing agents. The arenes, which in these adducts act as alkali metal "carriers", can also become π-coordinated to the transition metal. Scheme 1 shows two such examples.[4,5]

1

Scheme 1. The double role of naphthalene in the synthesis of reactive vanadium complexes by reductive abstraction of five-membered ring ligands: alkali-metal carrier and π-bonded transition-metal ligand.

We have now found that alkali metal-reduction of diindenylvanadium **1** [$(Ind)_2V$], first prepared by us,[6] can be very easily converted into a diindenyldivanadium synthesis, in which reduction is carried out with potassium in tetrahydrofuran (THF) without addition of a complexing agent. By this simple trick one also uses the previously non-coordinated carbon atoms of the six-membered rings of two indenyl ligands to bind vanadium (Scheme 2 and Fig. 1). There is no other example of a dinuclear complex with one, let alone two, bridging indenyl ligands.

1 **2**

Scheme 2. Synthesis of diindenyldivanadium **2** [7].

Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)
[+] Crystal structure analysis.

In the paramagnetic dinuclear sandwich complex **2**, which has a center of inversion, the V-atoms (V-V* 2.351(1) Å) are each surrounded by a five-membered ring and six-membered ring. The bridging atoms C5 and C9 are located at an average distance of 2.274(6) Å from the central V atoms, a distance greater than all other V-C distances in the molecule. The same holds for the distances between C5/C9 and the neighboring C atoms. The C6-C7 (1.417(3) Å) and C7-C8 (1.411(2) Å) bonds in the five-membered ring are about 0.03 Å shorter than the other three C-C bonds, whereas a long-short-long sequence is observed for the C-C bond lengths between the C1-C4 atoms in the six-membered ring. The planar moiety C1-C4 ($V-C_{terminal}$ 2.166(2) Å, $V-C_{central}$ 2.236(2) and 2.239(2) Å, respectively) bound to vanadium like a diene forms an angle of 13.5° with the C1-C4-C5-C9 plane.

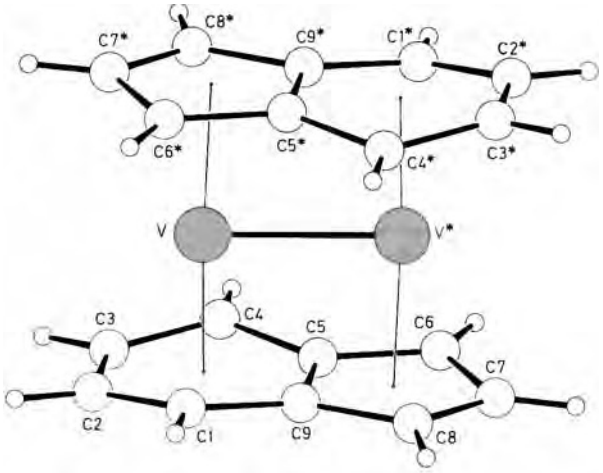

Fig. 1. Crystal structure of diindenyldianadium **2** [8]. Selected bond lengths [Å] and angles [°] (see text also): C1-C2 1.425(3), C2-C3 1.403(2), C3-C4 1.430(2), C5-C9 1.457(2); V-C6* 2.212(2), V-C7* 2.252(2), V-C8* 2.223(2).

Aside from **2**, there are only two other dinuclear complexes with two bridging ligands which are bicyclic annulated hydrocarbon systems. These compounds, which are formed in low yields (4% and 4–10%, respectively) upon reaction of $NiCl_2$ or $CoCl_2$ with dilithium pentalenide, have, on the basis of elemental analyses and ^{1}H-NMR and mass spectra, been characterized as $[(C_8H_6)_2Ni_2]$ and $[(C_8H_6)_2Co_2]$.[9, 10] *Katz* et al. have proposed a dinuclear sandwich structure for these two complexes, but such a structure has not, as yet, been confirmed by a crystal structure analysis.

[6] Experimental procedure for **1**: 20.31 g of the pale green product (43.1 mmol V, found 10.82% V), which was obtained by reaction of VCl_3 with zinc in THF [11], was added with stirring at 0°C to a solution of LiInd (prepared from indene and *n*BuLi in hexane) in THF (300 mL). After 15 hours' heating under reflux, the reaction mixture was evaporated to dryness and the residue sublimed under high vacuum at 120–140°C. Recrystallization of the sublimate from toluene/hexane furnished dark green crystals; these were washed and dried at 20°C under oil-pump vacuum (yield 10.34 g, 85%). Correct elemental analysis. MS: *m/z* 281 ($M^{\oplus}$, 100%). IR [cm^{-1}] (KBr): $\tilde{\nu}$(CH) = 3095 (w), 3074 (w), 3050 (m), 3008 (w); $\tilde{\nu}$(CC) = 1446 (m), 1326 (s), 1208 (m), 1149 (m); $\tilde{\nu}$(five-membered ring) = 1031 (s); π(CH) = 770 (vs), 730 (vs).
[7] Experimental procedure for **2**: to a stirred solution of **1** (17.48 g, 62.2 mmol) in THF (300 mL) at 0°C was added 2.41 g (61.6 mmol) of potassium pellets over a period of 3 h. After 10 hours' stirring at 20°C, the reaction mixture was evaporated to dryness and the residue taken up in boiling toluene. The hot solution was filtered free of insolubles. On cooling the filtrate to 20°C, dark purple crystals of **2** crystallized (4.74 g, 46%). Correct elemental analysis. MS: *m/z* 332 ($M^{\oplus}$, 100%). IR [cm^{-1}] (KBr): $\tilde{\nu}$(CH) = 3038 (m), 3049 (w), 3039 (w); $\tilde{\nu}$(CC) = 1457 (m), 1375 (m), 1294 (s), 1138 (m); $\tilde{\nu}$(five-membered ring) = 1030 (s); π(CH) = 736 (vs).
[8] Crystal structure analysis of **2**: space group $P2_1/n$, No. 14, $Z = 2$, $\rho_{calc} = 1.71$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 13.86$ cm^{-1}, $a = 7.7537(9)$, $b = 8.1145(7)$, $c = 10.8774(6)$ Å, $\beta = 109.541(6)°$, solution of structure by Patterson methods. 1654 observed reflections with $I > 2\sigma(I)$, $R = 0.025$, $R_w = 0.034$ ($w = 1/\sigma^2(F_o)$). Formal Insertion of the $HCO^{\oplus}$ Fragment into a Trinuclear Cluster Metal–Carbyne Bond: Synthesis, Structure and Reactivity of Cluster-bound Ethynol**

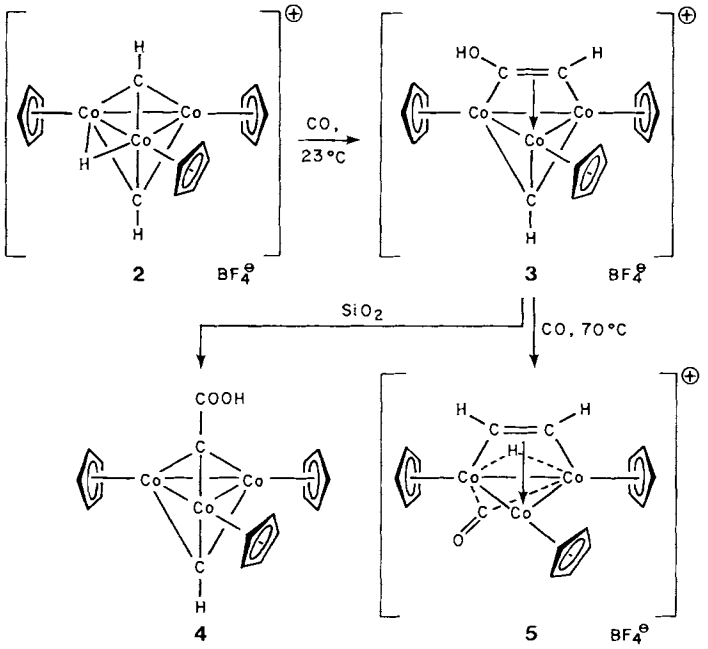
By *K. Peter C. Vollhardt** and *Matthias Wolfgruber*



A recent report of the observation of ethynol (hydroxyacetylene) in the gas phase,[1] prompts us to disclose the isolation of this usually unstable molecule as a ligand to a trinuclear cobalt cluster. Its formation proceeds by the novel formal insertion of the hydroxymethylidyne cation HO-C:$^{\oplus}$ into a cobalt–methylidyne bond, the isoelectronic carbon version of the related reaction of $NO^{\oplus}$.[2]

Addition of $HBF_4 \cdot OEt_2$ to a slurry of the cluster **1**[3] in CH_2Cl_2 caused an immediate color change from red to bright green and complete dissolution. Addition of pentane precipitated the edge-protonated[4] cluster **2** (94%),[5] characterized by a single ^{13}C-NMR signal (CD_2Cl_2) at $\delta = 87.61$ (methylidyne C-signal not observed), and three ^{1}H-NMR signals (CD_2Cl_2, −90°C) at $\delta = -27.49$ (s, 1 H), 4.99 (s, 15 H), and 16.79 (s, 2 H). The single Cp resonance indicates either accidental isochronism or a fluxional process around the trinuclear core.[4]

$[(\mu_3\text{-}\eta^1\text{-}CH)_2(CpCo)_3]$ **1**, $Cp = \eta^5\text{-}C_5H_5$

$[(\mu_3\text{-}\eta^1\text{-}CCO_2CH_3)(\mu_3\text{-}\eta^1\text{-}CH)(CpCo)_3]$ **6**

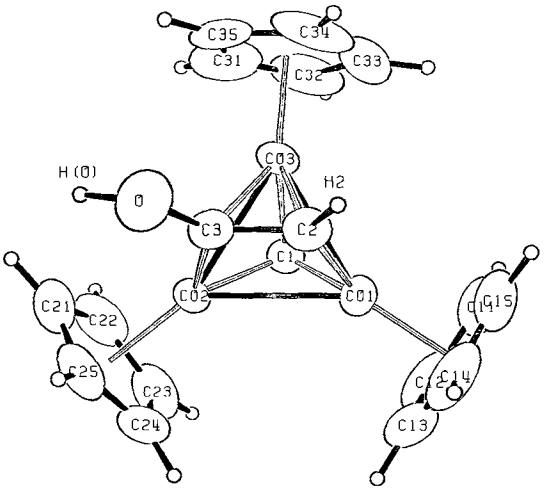

Fig. 1. ORTEP drawing of the crystal structure of the cation in **3**. Ellipsoids are scaled to represent the 50% probability surface. Hydrogen atoms are not refined and are represented by arbitrary spheres. H(O) and H2 are given in their positions as found on an electron density map. All other hydrogens are in idealized positions. Selected bond lengths [Å] and angles [°]: C2-C3 1.368(4), C2-H2 1.11, O-H(O) 1.02, Co1-C2 1.881(3), Co2-C3 1.886(3), Co3-C2 1.993(3), Co3-C3 2.036(3), Co1-Co2 2.501(1), Co1-Co3 2.392(1), Co2-Co3 2.435(1), Co1-C1 1.834(3), Co2-C1 1.830(3), Co3-C1 1.874(3), Co1-Cp1 1.695, Co2-Cp2 1.701, Co3-Cp3 1.677, Co1-C2-C3 108.1(2), Co1-C2-H2 131.2, C3-C2-H2 119.0, Co3-C3-C2 106.9(2), Co2-C3-O 128.1, C2-C3-O 123.6(3), C3-O-H(O) 107.8.

Remarkably, **1** is completely inert to CO at room temperature, whereas **2** is smoothly carbonylated (23 °C, 55 bar, CH_2Cl_2, 97%) to a new compound formulated as the ethynol complex **3**.[5] The composition of **3** is confirmed by elemental analysis. The ^{1}H-NMR spectrum ([D$_6$]acetone) exhibits signals at $\delta = 22.18$ (C–H of the intact methylydyne group), 11.16 (OH, assigned by deuterium exchange), 10.38 (C–H of the new ligand), and 5.10 (s, 15 H, Cp). Not unexpectedly,[2] the alkyne ligand is fluxional, leading to only a single peak for the Cp protons. The ^{13}C-NMR spectrum (CD_3NO_2) shows signals at $\delta = 197.52$ and 124.25 (ethynol C-atoms) and 87.69 (Cp); a methylidyne C-signal could not be observed. The IR spectrum (KBr) shows a broad peak at $\tilde{\nu} = 3380$ cm^{-1} and additional strong absorptions at $\tilde{\nu} = 1419$, 1266, 1070, 985, and 840 cm^{-1}. The mass spectrum contains characteristic fragments at m/z 426 ($M^{\oplus} - H$, 68%) and 398 ($M^{\oplus} - HCO$, 66%). Final structural confirmation of **3** was obtained by an X-ray structural analysis (Fig. 1).[6]

The alkynol ligand in **3** adopts a parallel[7] arrangement, and is bent and stretched as expected.[8] Its mechanism of formation by HOC$^{\oplus}$ coupling may be related to other acid-mediated methylidyne–CO couplings of interest as a fundamental step in hydrocarbon build-up by CO hydrogenation.[9] We have observed that this protonation-carbonylation sequence occurs also with other biscarbyne clusters of the type **1**.

On attempted chromatography (silica gel), **3** oxidized to the acid **4** in low yield,[10] synthesized independently from the cluster **6** (obtained by alkyne cleavage[3]) by hydrolysis (1. $HBF_4 \cdot OEt_2$, 2. H_2O; 94%). When **3** was treated with CO at 70 °C (CH_2Cl_2, 16 bar, 5 h, 73%) an unprecedented rearrangement to **5** occurred, involving apparent CO deinsertion and coupling of two methylidyne ligands! The IR spectrum of **5** (KBr) exhibits a strong peak at $\tilde{\nu} = 1845$ cm^{-1}, indicative of a bridging CO; the mass spectrum is identical to that of **3**, and the ^{1}H-NMR spectrum ([D$_6$]acetone) reveals the absence of the methylidyne signal and the presence of a peak at $\delta = 9.18$ (s, 2 H, ethyne H) in addition to two peaks at $\delta = 5.49$ (s, 10 H, 2 Cp) and 5.41 (s, 5 H, Cp). The hydride signal could not be detected. The ^{13}C-NMR spectrum (CD_3NO_2) shows absorptions at $\delta = 161.02$ (CO), 149.14 (ethyne), 91.48 and 87.52 (Cp). The elemental analysis and additional IR bands at 1000–1150 cm^{-1}[11] confirm the formulation of **5** as a $BF_4^{\ominus}$ salt. A related rhodium complex has been reported.[12] The transformation of **3** into **5** is analogous to the equally unprecedented base-induced NO-cleavage with CH/CH coupling of the related NO insertion products of **1**.[2]

S_4N_4 as Tridentate Ligand in $[IrX(CO)(PPh_3)(S_4N_4)]$ Complexes**

By *Frank Edelmann, Herbert W. Roesky,* Claudia Spang, Mathias Noltemeyer,* and *George M. Sheldrick*

In all the adducts of S_4N_4 and transition metal halides described in the literature so far, S_4N_4 is coordinated to the metal atom via an electron lone pair on a nitrogen atom.[1] The Vaska complex $[IrX(CO)(PPh_3)_2]$ **1** reacts with S_4N_4 with elimination of triphenylphosphane to give $[IrX(CO)(PPh_3)(S_4N_4)]$ **2**. The chloro complex **2a** has already been mentioned in the literature,[2] but so far has not been satisfactorily characterized.

$$[IrX(CO)(PPh_3)_2] + S_4N_4 \longrightarrow [IrX(CO)(PPh_3)(S_4N_4)] + PPh_3$$
1 **2**

a, X = Cl; **b**, X = Br; **c**, X = I

The intense red complexes **2a–c** are stable towards air and hydrolysis. Their purity was checked by thin-layer chromatography (silica gel, benzene; **2**: $R_f = 0.8$).[3] The IR spectra of **2a–c** show a distinct shift of the $\tilde{\nu}$(CO) band of more than 100 cm^{-1} to higher frequency compared to that of the starting compounds (**1a** 1951, **2a** 2065, **1b** 1955, **2b** 2069, **1c** 1975, **2c** 2075 cm^{-1}). The increased bond order can be attributed to oxidative addition of S_4N_4 to the Ir atom. It leads to reduction of the electron density at the iridium, and consequently to a weakening of the d_π–p_π back-bonding to the carbonyl group. In the EI-mass spectra, lines for the molecule ions with relative intensities between three and eighteen percent were observed for all three complexes, thus underscoring the kinetic stability of **2a–c**.

Single crystals for an X-ray structure analysis[4] were obtained by the diffusion method from benzene/hexane. The crystals contain two molecules of benzene per molecule of **2a**. The distinguishing feature of the structure of **2a** (Fig. 1) is that the $[IrCl(CO)PPh_3]$ fragment is inserted into a sulfur–nitrogen bond (S4–N1) of S_4N_4 while S2 is coordinated to the iridium atom, thus resulting in formation of a bicyclo[4.3.0]-skeleton. Of the two sulfur atoms coordinating the Ir atom, one (S4) has a C.N. (coordination number) of 2, the other (S2) a C.N. of 3. The S-atom with the lower C.N. should have the higher electron density and, consequently, the shorter Ir–S distance; this is indeed found to be the case: Ir–S4 233.5(3), Ir–S2 239.1(3) ppm. However, it should also be noted that the Cl-atom is *trans* to S4 while the PPh_3 ligand is *trans* to S2, and that these influence the bond lengths differently. In $[(Me_3P)_3OsS_7]$ with similar phosphane ligands, however, the S-atom with C.N. 3 has a shorter Os–S bond than the two S-atoms with C.N. 2.[5]

Synthesis of the First Triphosphabutadiene**

By *Rolf Appel,* Bärbel Niemann, Winfried Schuhn,* and *Falk Knoch*

Replacement of the carbon atoms of butadiene by dicoordinated phosphorus atoms has already been demonstrated on several occasions (mono- and diphosphabutadienes[1]). We now report the synthesis of the first 1,2,4-triphospha-1,3-butadiene, i.e. a compound in which a PP- and a PC-double bond are conjugated.

Aryl = 2,4,6-tri-*tert*-butylphenyl;
B = 1,8-diazabicyclo[5.4.0]undec-7-ene,
1,4-diazabicyclo[2.2.2]octane

We obtained the triphosphabutadiene **2** for the first time by reaction of the 3-chloro-substituted 1,3,5-triphospha-1,4-pentadiene **1**[2] with bases such as 1,8-diazabicyclo[5.4.0]undec-7-ene and 1,4-diazabicyclo[2.2.2]octane in toluene.[3] The reaction solution slowly changed color from yellow to red, with concomitant evolution of carbon monoxide and precipitation of the trimethylsilyl chloride adduct of the base. The red triphosphabutadiene **2** remained in solution, and, after removal of the solvent, could be isolated in crystalline form (m.p. 168 °C). It could also be prepared quite independently by condensation of the diphosphapropene **3**[4] and the dichlorophosphane **4**.[5,6]

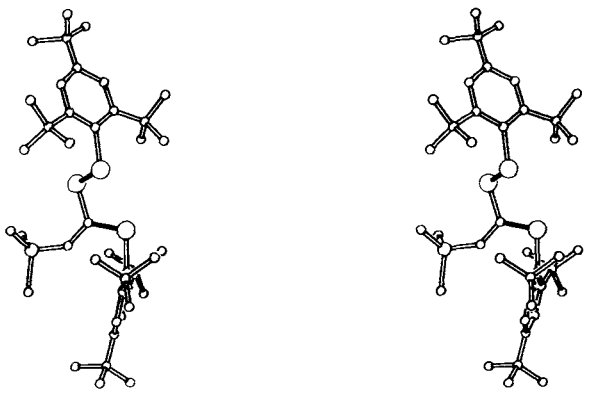

Fig. 1. Stereoview of the crystal structure of **2**.

[**] Low Coordinate Phosphorus Compounds, Part 52. This work was supported by the Deutsche Forschungsgemeinschaft and the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.—Part 51: R. Appel, C. Casser, F. Knoch, B. Niemann, *Chem. Ber. 119* (1986) 2609.

The constitution of **2** was confirmed by correct elemental analysis and by a molecular weight determination. According to the X-ray structure analysis,[7] the double bonds are arranged cisoid (Fig. 1). The ^{31}P-NMR spectrum shows the pattern expected for an ABX system with the AB part (PP double bond) shifted well downfield and an X part in the (PC)-double bond region.[8]

A Self-Replicating Hexadeoxynucleotide**

By *Günter von Kiedrowski**

Nonenzymatic, template-directed syntheses of oligonucleotides, first reported by *Naylor* and *Gilham* in 1966,[1] have been studied extensively by *Orgel* and colleagues[2] as an approach to model prebiotic condensation reactions using purine ribonucleoside 5′-phosphoimidazolides as activated monomers and oligomeric or polymeric ribo- and

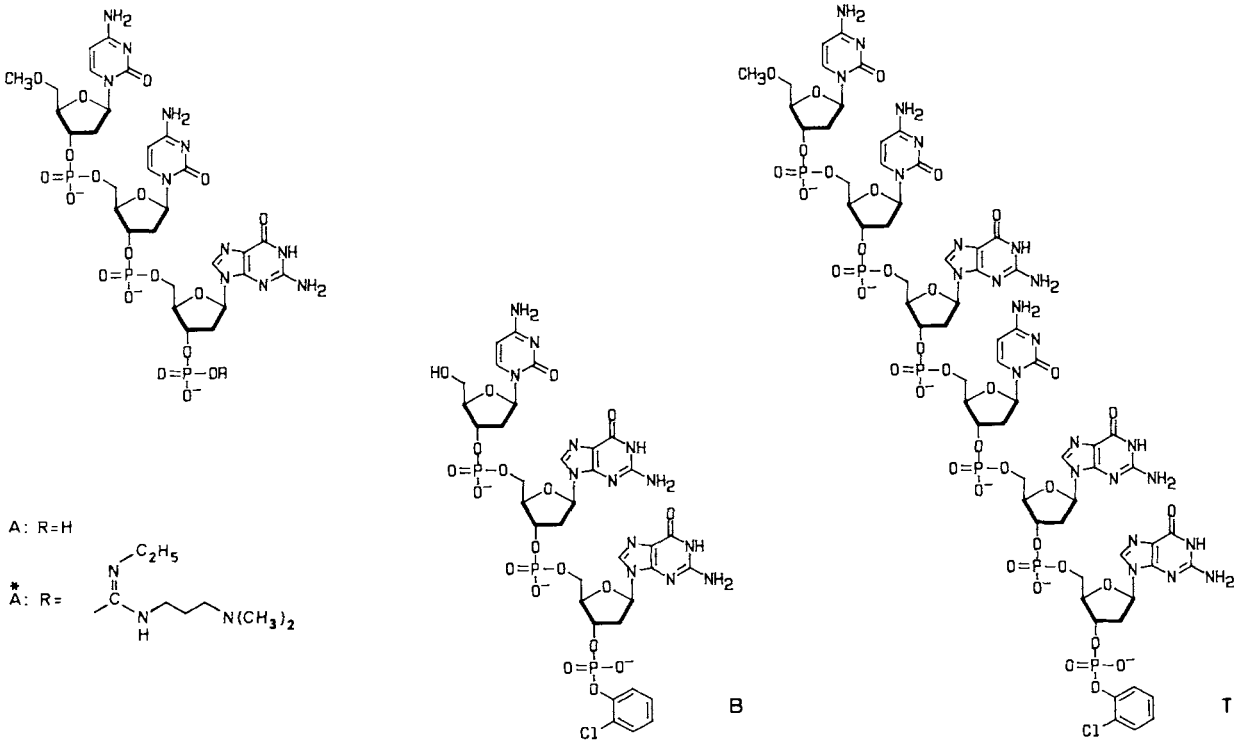
[**] This work was supported by the National Aeronautics and Space Administration (NASA) and the Deutsche Forschungsgemeinschaft. The author wishes to thank Professor *L. E. Orgel* for support and many helpful suggestions during the course of this work, *A. Hill* for technical assistance, Dr. *N. Assa-Munt* for recording the NMR spectra, and Dr. *C. K. Biebricher* for help in performing dynamic simulations.

deoxyribonucleotides as templates. *Inoue* et al. have reported a case of transcriptive information transfer: starting from a mixture of guanosine 5′-, and cytidine 5′-phospho-2-methylimidazolides, and C-C-G-C-C as template; pG-G-C-G-G was formed in 18% yield.[3] This was the first demonstration that a template with defined sequence can catalyze the formation of its complementary (−)-strand under nonenzymatic conditions. However, a full round of replication in which the synthesized (−)-strand separates from its template to direct the synthesis of the original (+)-strand has not been observed in nonenzymatic experiments. Such a process is autocatalytic and has been proposed as the key step for the transition from chemical to biological evolution in many theories on the origin of life.[4–6]

We now report on the case of autocatalysis in a template-directed condensation of two trinucleotides leading to a hexameric template with palindromic sequence. The oligonucleotide constituents—synthesized using the phosphotriester method in solution[7]—are a trideoxyribonucleotide 3′-phosphate with its 5′-terminus protected as its methyl ether (d(MeC-C-Gp), **A**), a complementary trideoxyribonucleotide 3′-phosphate with its 3′-terminus protected with an *o*-chlorophenyl group (d(C-G-Gṗ), **B**), and a self-complementary hexameric template protected with a methyl group at its 5′-end and an *o*-chlorophenyl group at its 3′-end (d(MeC-C-G-C-G-Gṗ), **T**).[8] In accordance with the commonly used method for the chemical coupling of oligodeoxynucleotide 3′-phosphates,[9] water-soluble 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (CDI) was used to activate in situ the 3′-phosphate of **A** as its carbodiimide adduct $\overset{*}{\mathbf{A}}$.

detected: the template T and a 3′-3′-linked pyrophosphate **pp**, obtained from **A** through self-condensation:

$$\underset{\overset{*}{\mathbf{A}}}{\text{d(MeC-C-Gp)}} + \underset{\mathbf{B}}{\text{d(C-G-Gṗ)}} \longrightarrow \underset{\mathbf{T}}{\text{d(MeC-C-G-C-G-Gṗ)}}$$



$$\underset{\overset{*}{\mathbf{A}}}{\text{d(MeC-C-Gp)}} + \underset{\mathbf{A}}{\text{d(MeC-C-Gp)}} \longrightarrow$$

$$\text{d(}^{5'}\text{MeC-C-G}^{3'}\text{pp}^{3'}\text{G-C-CMe}^{5'}\text{)}$$

pp

The same two reaction products were formed in experiments in which the 3′-phosphoimidazolide of **A** was used as activated material $\overset{*}{\mathbf{A}}$. An increase of temperature from 0 °C to 22 °C increases pyrophosphate formation and decreases template formation. Since an increase of temperature causes melting of double-stranded oligonucleotides, template formation should mainly proceed via double-stranded species, whereas pyrophosphate formation should predominantly proceed via single-stranded species.

In order to demonstrate autocatalysis in template production, reaction mixtures differing only in the initial concentration of template, c_o(**T**), were prepared. A 17-fold excess of CDI over **A** allowed repeated reactivation of **A**, since $\overset{*}{\mathbf{A}}$ is destroyed through hydrolysis. The trinucleotides **A** and **B** were introduced in at least 15-fold excess over **T** in order to determine the initial reaction order of template production with respect to template concentration. Figure 1, left, shows the time course of template production in the presence of differing values of c_o(**T**). An increase in c_o(**T**) clearly enhances the rate of production of **T**. Consequently, **T** acts as an autocatalyst for its forma-

The condensation reactions between $\overset{*}{\mathbf{A}}$ and **B** were performed in 1-μL capillaries at 0 °C and followed by HPLC.[2] In all experiments two reaction products were de-

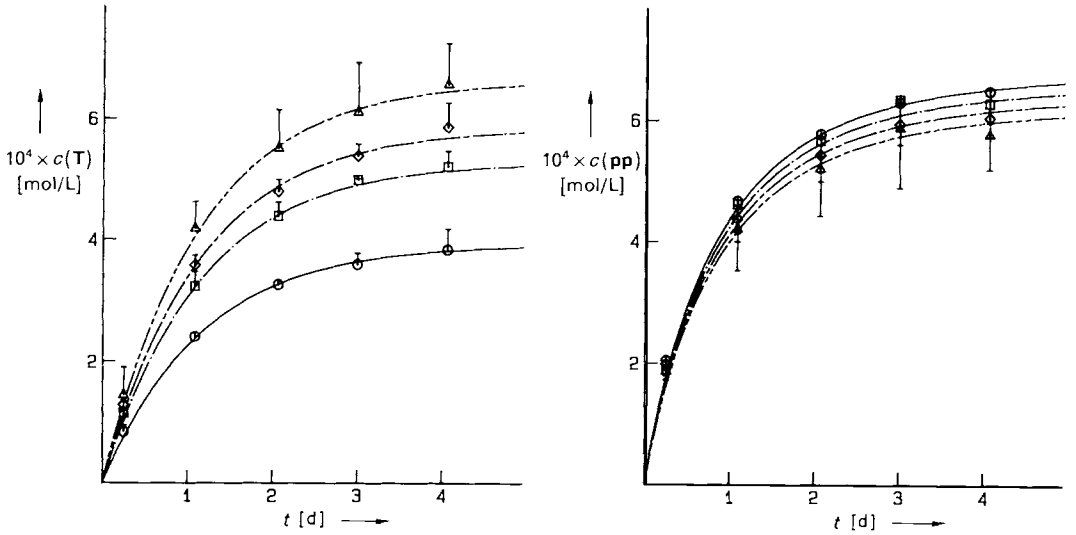


Fig. 1. Time course of template production (left) and pyrophosphate production (right) in reaction mixtures containing different initial concentrations of template. The points and error bars represent averaged concentrations and standard deviations, respectively, calculated from four series of experiments, each comprising four parallel experiments. Basic initial composition of reaction mixtures: 0.012 M **A**, 0.01 M **B**, 0.2 M CDI, 0.1 M 2-morpholinoethanesulfonic acid (pH 6.15), 0.05 M $MgCl_2$; initial template concentrations: ○ = 0 mM, □ = 0.2 mM, ◇ = 0.4 mM, △ = 0.8 mM. Each mixture (total volume: 10 μL) was prepared in a small test tube and then transferred into several 1 μL precision capillaries (Micro Caps). The capillaries were stored in a dessicator at 0°C and constant humidity for the reaction times given in the figure. HPLC samples were prepared by quenching the reaction mixtures with solutions of 10^{-3} M ethylenediamine-*N,N,N',N'*-tetraacetic acid at pH 11 (total volume, 4 mL; injection volume, 1 mL). Separations were performed on an RPC-5 column at pH 12 using a linear gradient of $NaClO_4$ (0–0.05 M, 50 min, flow rate: 1 mL/min) [2]. UV absorbance was monitored at 254 nm. Concentrations are calculated from peak integrals, no correction is made for hypochromicity.

tion. Under the same conditions, the rate of formation of the pyrophosphate **pp** (Fig. 1, right) is almost independent of $c_o(\mathbf{T})$. However, an increase in $c_o(\mathbf{T})$ slightly decreases the rate of formation of **pp**, simply because **T** and **pp** compete for the same activated species $\overset{*}{\mathbf{A}}$. As the combined yield of both products after four days is less than 12% (relative to **A**) in all experiments, the decreasing slope of the curves cannot be due to the consumption of the trinucleotides, but must be caused by the hydrolysis of the carbodiimide.

The initial rate of template formation, $[\mathrm{d}c(\mathbf{T})/\mathrm{d}t]_{\text{initial}}$, can be described using an empirical rate law which splits the rate of template formation, $[\mathrm{d}c(\mathbf{T})/\mathrm{d}t]_{\text{initial}}$, into a non-autocatalytic term (k_b) and an autocatalytic term comprising the constant k_a and the template concentration $c_o(\mathbf{T})$ with its reaction order p.

$$[\mathrm{d}c(\mathbf{T})/\mathrm{d}t]_{\text{initial}} = k_a c_o(\mathbf{T})^p + k_b$$

Using least-square approximation techniques, the constants k_a and k_b were calculated for varying reaction orders p from the initial rates of template formation. The best fit of parameters was obtained for p = .48. Assuming a reaction order of p = 1/2, approximation yields a set of parameters that fit the rates to only a slightly lesser extent: $k_a = 9.48 \times 10^{-8}\ \mathrm{M}^{1/2}\ \mathrm{s}^{-1}$, $k_b = 3.83 \times 10^{-9}\ \mathrm{M\ s}^{-1}$. As a consequence, the initial rate of template formation follows the square root of $c_o(\mathbf{T})$ as shown in Figure 2.

Autocatalysis in template production can be explained by the reaction mechanism shown in Figure 3, in which a mixed complex $\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}$ is reversibly formed from the trimer compounds $\overset{*}{\mathbf{A}}$ and **B** and the template **T** through complementary base-pairing. Template-directed condensation in $\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}$ yields a self-complementary duplex **T** : **T**. This duplex can dissociate to form two template molecules

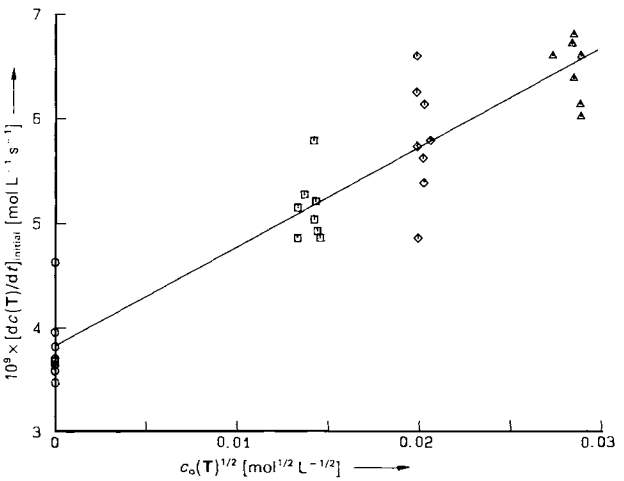

Fig. 2. Initial rate of template production, $[\mathrm{d}c(\mathbf{T})/\mathrm{d}t]_{\text{initial}}$, versus square root of initial template concentration, $c_o(\mathbf{T})^{1/2}$. Reaction conditions and analytical techniques as given in the legend of Figure 1. The initial rates shown are the slopes of template formation during the first 12-h period of linear evolution. The line drawn represents the solution of parameters k_a and k_b for a reaction order of p = 1/2, comprising all data-pairs given.

T, which again can undergo mixed complementary association with $\overset{*}{\mathbf{A}}$ and **B**, thus restarting the catalytic cycle. From thermodynamic and kinetic data for similar oligonucleotides[10] it can be concluded that, under the reaction conditions chosen, most template molecules should be present as **T** : **T**, a small fraction as $\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}$, and only a very small fraction as single-stranded species **T**. Furthermore, since the rates of all reversible steps (in particular the dissociation rate of **T** : **T**) are supposed to be fast compared with the rate of phosphodiester formation, the olig-

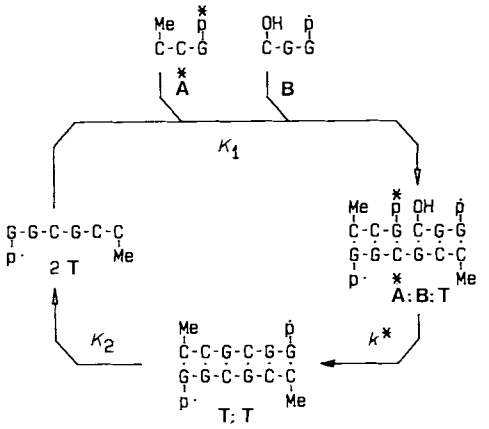

Fig. 3. Reaction mechanism of autocatalytic template production. Open arrows indicate reversible reactions, the closed arrow represents an irreversible reaction.

omers should be in equilibrium with respect to complex formation. Then, the equilibrium concentration of $\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}$ can be expressed in terms of the equilibrium concentration of $\mathbf{T}:\mathbf{T}$. With

$$K_1=\frac{[\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}]}{[\overset{*}{\mathbf{A}}][\mathbf{B}][\mathbf{T}]} \quad \text{and} \quad K_2=\frac{[\mathbf{T}:\mathbf{T}]}{[\mathbf{T}]^2}$$

the rate of template-directed condensation, which is first order in $\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}$, is given by

$$\frac{d[\mathbf{T}:\mathbf{T}]}{dt}=k^*[\overset{*}{\mathbf{A}}:\mathbf{B}:\mathbf{T}]=k^*K_1K_2^{-1/2}[\overset{*}{\mathbf{A}}][\mathbf{B}][\mathbf{T}:\mathbf{T}]^{1/2}$$

Accordingly, the reaction order for $\mathbf{T}:\mathbf{T}$ formation in terms of $\mathbf{T}:\mathbf{T}$ is expected to be 1/2. Since the equilibrium concentration, $[\mathbf{T}:\mathbf{T}]$, is supposed to be only slightly different from half of the total template concentration $c(\mathbf{T})$, the equation gives an approximate solution for k_a in the autocatalytic term of the empirical rate law.

The rationale of this work is to demonstrate that, in fact, self-replication occurs without the help of any enzyme[11] in a *chemical* model system composed of simple oligonucleotides. Although the system chosen is not very efficient in terms of its autocatalytic rate, autocatalysis is clearly evident. Further experiments must show whether autocatalysis also occurs when using other oligonucleotides, and whether autocatalysis can be enhanced employing appropriate "environmental conditions" and "energy sources." If so, it can be expected that, under certain conditions, some interesting self-organization phenomena might show up, similar to natural selection processes in biological systems.[12]

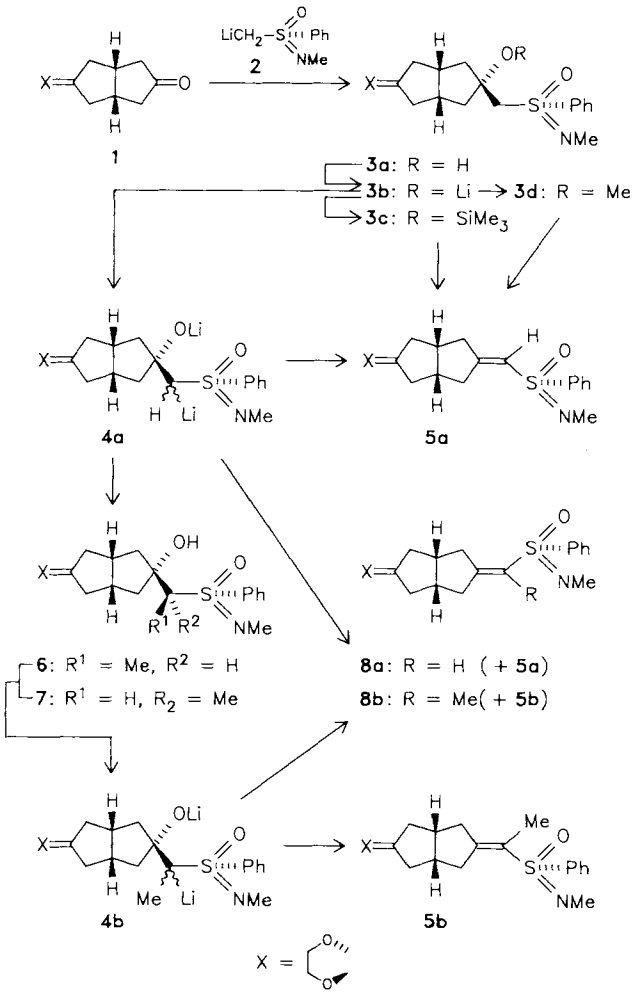
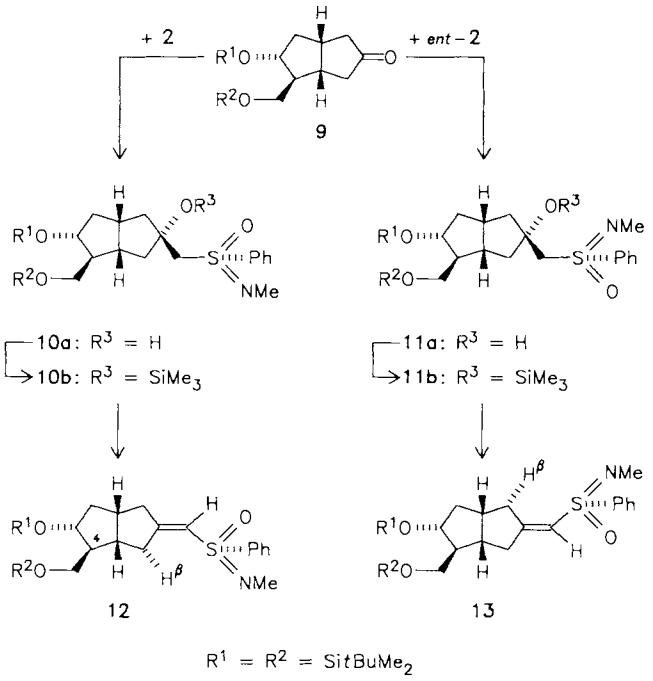
Asymmetric Elimination with High Induction: Synthesis of 1-Alkenylsulfoximides with Axial and Central Chirality**



By *Irene Erdelmeier, Hans-Joachim Gais,** and *Hans J. Lindner*



Asymmetric *eliminations* with high induction to give chiral alkenes are rarely observed;[1] the few known examples are characterized by removal of a chiral group with loss of chirality[1a,b] and/or transfer of chirality.[1c] We report here the synthesis of the axially chiral alkenylsulfoximides **5a**, **b** and **17** from the β-hydroxysulfoximides **3a**, **6/7**, and **15a**, respectively, which involves an asymmetric elimination that takes place with high diastereotopic differentiation and without loss of chirality. The stereoselective *carbonylolefination* of the ketone **9** to give either the (*Z*)- or the (*E*)-alkenylsulfoximide **12** or **13**, respectively, exemplifies the application of this reaction. Asymmetric carbonylolefinations with high and moderate selectivity to give axially chiral alkenes have been achieved previously by Horner–Emmons[2a] and Wittig reactions,[2b] respectively.

Selective *exo* addition [−78 °C, tetrahydrofuran (THF)] of the lithiosulfoximide **2**[3,4] to the ketone **1**[5] gave the β-hydroxysulfoximide **3a**[6a] in 96% yield and with ≥98% diastereoselectivity (*ds*). The surprisingly smooth silylation (−78 °C→25 °C, THF) of the lithium alkoxide **3b** with Me_3SiCl afforded the β-siloxysulfoximide **3c** in >95% yield. When this compound was treated with *n*-butyllithium (*n*BuLi) at −78 °C (molar ratio 1:1) in THF, asymmetric elimination of $LiOSiMe_3$ took place with high induction to give the (*S,aR*)-alkenylsulfoximide **5a**,[6b,7] which could be isolated in 91% yield and with ≥98% *ds*. From **1** and *rac*-**2**, *rac*-**5a** (90%) was also obtained with

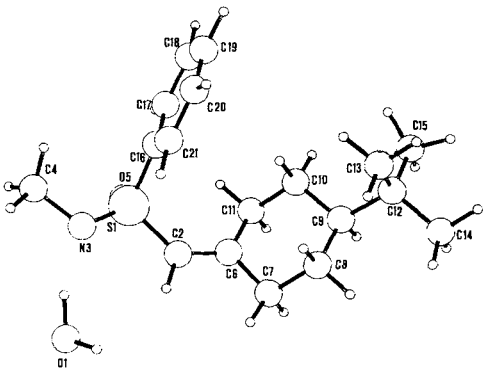
≥98% *ds*.[8] Interestingly, the extent and direction of the asymmetric induction observed in the elimination reaction of **3a** did not change when the dilithium compound **4a**, obtained by metalation of **3a** (2 *n*BuLi, −30°C, THF), was allowed to react with Me_3SiCl (−70°C); **5a** was isolated in 69% yield and with ≥98% *ds*. This was also true for the diastereomeric methyl derivatives **6**[6c] and **7**,[6d] which were obtained in 89% yield in a ratio of 3 : 1 by methylation (MeI, 0°C, THF, HMPA) of **4a**. The mixture of the two stereoisomers underwent metalation (2 *n*BuLi, 0°C, THF) to give the dilithium compound **4b** and subsequent reaction with Me_3SiCl (−30°C) to give the alkenylsulfoximide **5b**[6e] in 73% yield and with ≥98% *ds*. In contrast, we obtained mixtures of the diastereomers **5a/8a** (70%, 4 : 1) and **5b/8b** (75%, 1 : 1) when **4a** and **4b**, respectively, underwent titanation (−30°C, THF) with $Cl_2Ti(OiPr)_2$.

This asymmetric carbonylolefination also allowed us to selectively synthesize the (*Z*)- and (*E*)-alkenylsulfoximides **12** and **13**, respectively, which are potential precursors for the selective synthesis of the (5*E*) isomers of carbaprostacyclins,[9] from the ketone **9**.[10] Selective *exo* addition (−78°C, THF) of **2** to **9** to give the β-hydroxysulfoximide **10a**[6f] (93%, ≥98% *ds*), silylation (1 *n*BuLi, −78°C, THF; Me_3SiCl, −70°C→25°C) to give the β-siloxysulfoximide **10b**, and, finally, elimination (1 *n*BuLi, −78°C, THF) afforded the (*Z*)-alkenylsulfoximide **12**[6g,7] in 96% yield and with ≥98% *ds*. On the other hand, when *ent*-**2**[4] was added to **9** to give **11a**[6h] (93%, ≥98% *ds*) and this compound was then silylated to give **11b** and finally treated with *n*BuLi (−78°C, THF), the (*E*)-alkenylsulfoximide **13**[6i] was obtained, as expected, in 91% yield and likewise with ≥98% *ds*. Thus, the extent and direction of the asymmetric induction in the elimination reactions of **10b** and **11b** are independent of the chirality center in the 4-position and only determined by the choice of **2** or *ent*-**2** (reagent control). Unequivocal confirmation of the (*Z*) configuration of **12** (S(O)(NMe)Ph and R^2OCH_2 groups in *syn* positions) was achieved by NOE experiments and that of the (*E*) configuration of **13** (*anti* arrangement of the groups) on the basis of 2D ^{1}H-NMR spectra; in each case, the determination of configuration was based on the low-field shift of the resonance of H^β of the methylene group in the *syn* position, which is caused by the anisotropy effect of the sulfoximide functionality. Based on these results, the absolute configuration of the alkenylsulfoximides **5a** and **5b** was assigned.

Interesting differences in selectivity were found in the elimination reactions of the diastereomeric β-siloxysulfoximines **15b** and **16b**, which were obtained by addition[11a] of **2** to the ketone **14** to give the diastereomeric β-hydroxysulfoximines **15a** and **16a**[11b] followed by silylation. Whereas the elimination reaction of the *trans* diastereomer **15b** with *n*BuLi led to the (*S,aS*)-alkenylsulfoximide **17** (93%)[6j] with ≥98% *ds*, the elimination reaction of the *cis* diastereomer **16b** gave a mixture (94%) of the chromatographically separable (*S,aR*)- and (*S,aS*)-alkenylsulfoximides **18**[6k] and **17** in a ratio of 2.5 : 1.

The absolute configuration of **17** was determined by X-ray structure analysis,[12] in combination with the known (*S*) configuration of **2**,[13] to be (*S,aS*) (Fig. 1).



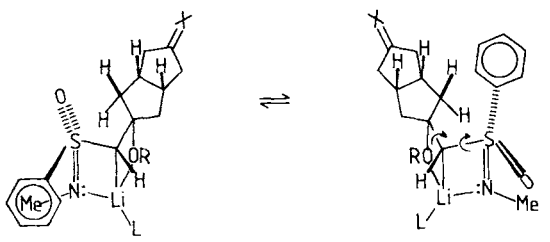


Fig. 1. Crystal structure of **17**·H_2O [12]. Selected bond lengths [Å] and bond angles [°]: S1-C2 1.741(7), S1-O5 1.427(5), S1-N3 1.534(5), S1-C16 1.804(5), C2-C6 1.353(8), C4-N3 1.504(8); C2-C6-C11 126.6(6), C2-C6-C7 119.4(7); N3-S1-C2-C6 −174(2), S1-C2-C6-C7 173(2), S1-C2-C6-C11 0(2).

We ascribe the similar directions and extents of asymmetric induction in the elimination reactions of **3**, **4**, **10**, and **15**—using **3c** and **4a** as examples and taking into consideration the crystal structure of **2** and the configurational stability of lithioalkylsulfoximides at the α-C atom[3]—to the following factors:

1. Initial metalation of **3c** to give the lithiosulfoximide **19** (Scheme 1), which is also presumably formed upon silylation of **4a** via *C/O* silyl migration[14] following *C*-silylation.

2. The establishment of a rapid equilibrium between the diastereomers **19A** and **19B**, even at low temperatures, on account of the low energy barrier for the configurational change at the anionic C atom in lithioalkylsulfoximides.[3]

Scheme 1. R = $SiMe_3$, X = $-OCH_2CH_2O-$, L = ligand.

3. The more rapid elimination of $LiOSiMe_3$ in **19A** than in **19B**, because the achievement of coplanarity of the p orbital on the anionic C atom and the siloxy group in **19B** is presumably more strongly hindered by the interaction between the phenyl and the *pro-R* methylene group than in the case of **19A** by the interaction between the O atom and the *pro-S* methylene group.[15]

Lithium-Coordinated α-Sulfonimidoyl Carbanions: Crystal Study of [(*S*)-(*N*-Methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$ · 2(tmeda) and Configurative Stability of [(*N*-Methyl-*S*-phenylsulfonimidoyl)isopropyllithium]**

By *Hans-Joachim Gais,** *Irene Erdelmeier, Hans J. Lindner,* and *Jürgen Vollhardt*

Lithioalkylsulfoximides such as **1** have become firmly established as analogues of lithioalkylsulfones such as **2**, with an optically stable center of chirality at the S atom, in the arsenal of methods used in asymmetric synthesis.[1] In contrast to **2**,[2] almost no information is available on the structure of **1**.[2b,c] This fact, along with investigations on

1a, $R^1 = R^2 = H$
1b, $R^1 = R^2 = Me$

2a, R = H
2b, R = Ph
2c, R = CH=CH$_2$

the asymmetric induction in the elimination reactions of β-siloxylithioalkylsulfoximides,[3] prompted us to determine the crystal structure of [(*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$ · 2(tmeda) **3** (tmeda = tetramethylethylenediamine) and the configurative stability of **1b** at the α-C atom. Compound **3** was prepared by metalation of (*S*)-*N*,*S*-dimethyl-*S*-phenylsulfoximide with *n*-butyllithium (*n*BuLi) in TMEDA.[4] The single-crystal X-ray structure analysis of **3**[5] (Fig. 1) revealed a tetramer of **1a** with approximate C_2 symmetry and having two pairs each of differently coordinated lithium ions and (*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyl anions. The coordination of two lithium ions by TMEDA and two oxygen atoms of two anions [average Li···N 2.10(5) Å, Li···O1 1.90(5) Å] corresponds to that found for **2a** and **2b**.[2a] The two other lithium ions in close proximity to each other [Li···Li 2.78(5) Å] are each coordinated by three nitrogen atoms of the sulfoximide groups [average Li···N 2.09(5) Å] and—in contrast to **2a-c**[2a]—by one carbon atom of each of the methylene groups [average Li···C 2.49(5) Å]: S1, N11, Li3, and C71 as well as S3, N13, Li4, and C73 each form four-membered chelate rings. Each of the two other methylene carbon atoms, C72 and C74, has contact to the two central lithium ions Li3 and Li4 [average Li···C 3.24(4) Å]. The S-$C_{methylene}$ bonds [average 1.64(2) Å], like the bond in **2a**[2a] [1.608(3) Å], are significantly shorter than that in *S*-methylsulfoximides (average of nine compounds: 1.74 Å[7]), thus pointing to the double-bond character of this bond. The methylene carbon, the sulfur, the nitrogen, and the methyl carbon atoms lie nearly in the same plane [average of the C7-S-N1-C8 dihedral angles 177(6)°].

Information about the structure of **1** in solution—especially about the nature of the bond between the anionic C atom and the sulfonimidoyl group—was expected to be obtained from the determination of the energy barrier for diastereotopomerization[8] ($\Delta G^{\ddagger}_{top}$) of the methyl groups in **1b**. The diastereotopomerization is effected by rotation around the C-S bond for a planar configuration of the carbanionic center and by rotation and inversion for a pyramidal configuration.

The 75.5-MHz ^{13}C-NMR spectrum of [^{13}C-9, ^{13}C-10]-**1b** (degree of labeling 99%) in [D$_8$]THF[9] is temperature dependent.[10] At room temperature, an averaged signal at $\delta = 20.5$, which is due to the rapid exchange of the diastereotopic methyl groups, is found for **1b**. Coalescence is observed at −70 °C; at −103 °C, separated signals are found at $\delta = 19.4$ and 22.4. From the line separation of the signals of 220 Hz, $\Delta G^{\ddagger}_{top}$ was calculated to be 9.2 ± 0.2 kcal/mol for **1b** at the coalescence point. This reveals that the carbanions of **1** with $R^1 \neq R^2$ are not configurationally stable at the anionic C atom, even at low temperatures.[11]

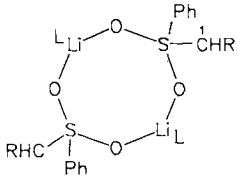
[9] [$Me^{10}(Me^9)C^7$–S(O)(NMe^8)Ph^{1-6}]Li **1b**, 75.5-MHz ^{13}C-NMR data [[D_8]THF, 25°C, [D_8]THF ($\delta = 25.3$) int.] of **1b**. Values in curly brackets: 75.5-MHz ^{13}C-NMR data ($CDCl_3$, 25°C, TMS int.) of *N*-methyl-*S*-isopropyl-*S*-phenylsulfoximide. $\delta = 20.5$ (C-9, C-10) {15.6, 16.3}, 30.4 (C-8) {29.5}, 38.2 [$^1J(^{13}C,^{13}C) = 38.3$ Hz] (C-7) {55.7 [$^1J(^{13}C,^{13}C) = 34.8$ Hz}, 142.0 (C-1) {135.7}, 128.5, 127.8 (C-2, C-3, C-5, C-6) {129.3, 130.3}, 127.9 (C-4) {132.7}.

[10] Line-broadening but not coalescence was observed in the 300-MHz ^{1}H-NMR spectrum of **1a** and of **1b** in [D_8]THF down to −100°C.



[11] The determination of the rate-limiting step in the topomerization of **1b** having a nonplanar configuration of the anionic C atom—rotation or inversion—is not possible on the basis of these results. However, on account of the reduced pyramidalization and the π delocalization of the carbanion, $\Delta G^{\neq}_{inv}$ should be smaller than $\Delta G^{\neq}_{rot}$ [2, 12].

Solid-State and Solution Structure of α-(Phenylsulfonyl)allyllithium**

By *Hans-Joachim Gais,* Jürgen Vollhardt,* and *Hans J. Lindner*

Monometalated allylsulfones play an important role as reactive intermediates in organic synthesis,[1] for example, in the preparation of specifically functionalized diquinanes,[1b] in the synthesis of *di*lithiated (phenylsulfonyl)allyl compounds,[1b] and in asymmetric CC bond formation in the presence of chiral amines.[1c] In contrast, the question of their structure, which is not only important for the interpretation of stereochemical results, has not yet been answered; thus, no X-ray structure analyses or NMR investigations are available.[2]

1, R = H, L = tmeda
2, R = Ph, L = tmeda
3, R = CH=CH_2, L = diglyme

4

The crystal structures of two lithiated *alkyl*sulfones—[(phenylsulfonyl)methyllithium·(tmeda)]$_2$ **1**[3a] and [α-(phenylsulfonyl)benzyllithium·(tmeda)]$_2$ **2**[3b] (tmeda = tetramethylethylenediamine)—as well as of several allyllithium[4] compounds not containing sulfonyl groups, such as **4**,[4c] have been reported. Whereas the former display no C–Li contacts, but only O–Li contacts and short C–S bonds, η^3-complexation of the lithium ion and bond equalization in the anion is observed for the latter—with one exception.[4a]

Which type of bonding dominates for the α-(sulfonyl)allyllithium compounds, that with C–Li or that with O–Li contacts?

We report here on the crystal structure of [α-(phenylsulfonyl)allyllithium·(diglyme)]$_2$ **3** (diglyme = diethyleneglycol dimethyl ether), an allyllithium compound with an acceptor substituent that is important for synthesis,[5] and on the NMR investigations of the structure of α-(phenylsulfonyl)allyllithium **5a**[6] in solution.

Compound **3** was prepared by metalation of allylphenylsulfone with *n*-butyllithium (*n*BuLi) in diglyme.[7] The X-ray structure analysis of **3**[8] reveals dimers with a crystallographic center of inversion (Fig. 1), such as are also found in **1** and **2**, despite the change in the chelate ligand. The arrangement of the diglyme molecules results in a distorted trigonal-bipyramidal pentacoordination of the Li atoms by the O atoms; C-1 to C-3 of the allyl group bonded to the S atom lie *outside* the coordination sphere of Li. An interaction of the η^3-π-allyl type is not observed.

The anionic C-1 exhibits clear pyramidalization. H-1 and C-2 are displaced toward the phenyl ring, as revealed by the dihedral angle around the S1–C1 bond (Fig. 2). Similar results were found for the anionic C atom of **1** (Fig. 2)—although in that case more pronounced flattening was observed. The configuration corresponds to a nearly middle position between sp^3 and sp^2 hybridization.[9] However, one might have expected further flattening at C-1 in going from **1** to **3** on account of the additional conjugation of the sulfonyl carbanion with the double bond.[2,3b,10] The S1–C1 bond (1.668(8) Å) is longer than that in **1** and approximately the same length as that in **2**, but considerably shorter than in sulfones.[3] Together with the length of the bond between C-1 and C-2, that between C-2 and C-3, and the dihedral angle around the C1–C2 bond (Fig. 1), this indicates the presence of a conjugated π-electron system. Interestingly, the C1–C2–C3 angle is widened, as is the case in allyllithium compounds,[4] although, in contrast to such compounds, **3** exhibits no C–Li contacts.

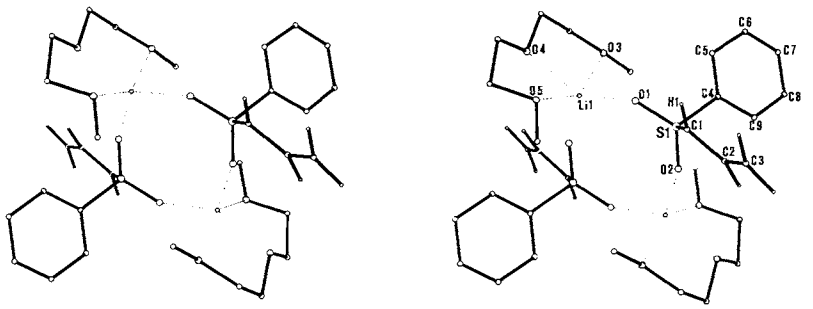

Fig. 1. Stereoview of the crystal structure of **3** (H atoms omitted with the exception of those on C-1 to C-3) [8]. Selected distances [Å] and angles [°]: S1-C1 1.668(5), S1-C4 1.791(5), S1-O1 1.451(4), S1-O2 1.426(4), C1-C2 1.445(9), C2-C3 1.352(9); C1-C2-C3 125.2(8); C4-S1-C1-H1 −78(3), C4-S1-C1-C2 76(1), O1-S1-C1-H1 36(3), O2-S1-C1-C2 −39(1), O1-S1-C1-C2 −171(1), S1-C1-C2-C3 −169(1).

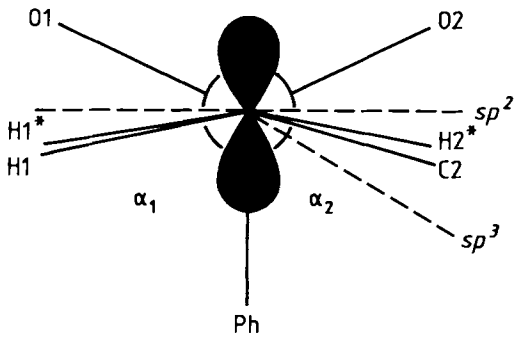
The S-O bonds of **3**, like those of **1** and **2**, are no longer than those in sulfones.[3] In the crystal, a conformation of the sulfonyl carbanion is favored (Fig. 1 and 2) in which



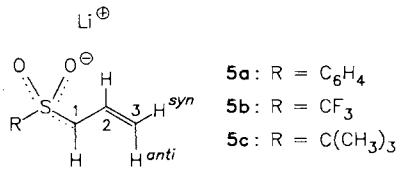


Fig. 2. Angles around the S-C1 bond in **1** (H1*, H2*) and **3** (H1, C2). O1, O2, and Ph apply to both compounds. **1**: $\alpha_1 = -81(3)°$, $\alpha_2 = 81(3)°$; **3**: $\alpha_1 = -78(3)°$, $\alpha_2 = 76(1)°$.

the lone pair of electrons at C-1, as in the case of **1**, is *gauche* to the two O atoms and periplanar to the S1-C4 bond.[9] Ab initio calculations carried out on (methylsulfonyl)methyllithium predict such a minimum energy conformation (n_C–σ^*_{SR} interaction).[11] Analogous conformations were also found for the isoelectronic sulfonamides in solution and in the crystal.[12]

Information on the structure of the title compound in solution is provided by the ^{13}C- and ^1H-NMR data (Table 1) (**3** ≡ [**5a** · diglyme]$_2$). The ^{13}C chemical shifts of **5a** and

especially the pronounced high-field shift of the signal of C-3, which is caused by the higher electron density, indicate the presence of a conjugated π-electron system in solution as well. This conclusion is also supported by the ^1H chemical shifts. The apparent constancy in the position of the C-1 signal may be ascribed to two effects acting oppositely: a high-field shift owing to the higher charge density and a low-field shift owing to the partial $sp^3 \rightarrow sp^2$ rehybridization. The latter is further confirmed by the significant increase of ^1J(C,H) at C-1.[13] The ^1J(C,H) value of C-3 undergoes only minor change, in contrast to that of C-2, which significantly decreases. In analogy to the interpretation[14a,b] of this effect in the case of allyllithium compounds,[14] we ascribe the cause of the decrease of ^1J(C,H) at C-2 in the case of **5a** also to the widening of the angle at C-2. The ^1H-NMR data, particularly the ^3J(1-H,2-H) value of **5a**, show[6] that **5a** also exists in solution preferentially in the transoid conformation with respect to the C1-C2 bond.[15] ^1H-NMR investigations on **5a** in [D_{14}]diglyme at higher temperatures revealed that $\Delta G^{\neq}$ must be greater than 19.5 kcal/mol (130°C) for the "rotation" around the C2-C3 bond, since, up to 130°C, no line-broadening, pointing to exchange phenomena, was observed in the 300-MHz spectrum. The structure of **5a** can therefore be best described as a vinyl-substituted α-sulfonyl carbanion with a lithium counterion.

Nitromethane as d^1,d^1 Multiple Coupling Reagent for the Carbonyl Dianion Synthon. Practical Synthesis of Chalcogran**

By *Goffredo Rosini,* Roberto Ballini, Marino Petrini,* and *Emanuela Marotta*

One of the major objectives of modern organic synthesis is the broadening of techniques for assembling collections of carbon atoms and functional groups. In order to increase the arsenal of practical routes for the synthesis of complex molecules, we recently reported new applications of functionalized nitroalkanes as reagents corresponding to alkyl anion synthons.[1]

The spiroacetal moiety occurs in many biologically active, natural products, including insect pheromones;[2] consequently, new methods for their preparation are becoming increasingly important. Herein, we present a novel strategy for the synthesis of 1,6-dioxaspiro[4.4]nonane derivatives based on the utilization of nitromethane as a d^1,d^1 multiple coupling reagent[3] corresponding to a carbonyl dianion synthon. To test this concept, we chose 2-ethyl-1,6-dioxaspiro[4.4]nonane (chalcogran **7**), the main component in the aggregation pheromone of the bark beetle *Pityogenes chalcografus* (L.), also named "Kupferstecker." Since the identification of chalcogran by *Francke* et al.[4] in 1977, several syntheses of racemic[4,5] and optically active[6] **7** have been reported.

The starting point for our synthesis was the 1,4 addition of nitromethane **1** to 1-penten-3-one **2** (without solvent, in the presence of alumina,[7] 6 h at room temperature). which afforded **3**[8] (62%). The 1,4 addition of **3** to acrolein **4** under identical conditions gave **5**[8] (53%). On reduction with $NaBH_4$ in EtOH, **5** furnished 1,7-dihydroxy-4-nitrononane **6**, the open-chain chalcogran precursor. Finally, the transformation of the nitro group into a carbonyl group by reaction with an aqueous solution of $TiCl_3$[9] led, via spontaneous cyclization, to the desired chalcogran ((*E*)-**7**/(*Z*)-**7** = 39/61).[8]

All four steps of this procedure, including purifications, are simple and require cheap starting materials. Thus, for the synthesis of 1,6-dioxaspiro[4.4]nonane derivatives, the use of nitromethane as a d^1,d^1 multiple coupling reagent can be considered more convenient than the use of the most popular masked acyl anions (dithioacetals,[10] *O*-protected cyanohydrins,[11] and *N,N*-diethylaminoacetonitrile[12]).

BOOK REVIEWS

The ACS Style Guide. Edited by *J. S. Dodd*. American Chemical Society, Washington, DC, 1986. xviii, 264 pp., hardback, $ 29.95 (export), 24.95 (USA and Canada), ISBN 0-8412-0917-0; paperback, $ 17.95 (export), 14.95 (USA and Canada), ISBN 0-8412-0943-X

The contents and format of *The ACS Style Guide* fully justify the new title of a book whose predecessors, the first and second editions of the American Chemical Society's *Handbook for Authors*, have long been valuable resources in the preparation of manuscripts for chemistry journals. Indeed, a detailed comparison of the *Style Guide* with the earlier *Handbook* would serve little purpose, so numerous are the changes, additions, and improvements.

Of the seven chapters, three ("The Scientific Paper," "Grammar, Style, and Usage," and "Illustrations and Tables") deal with the scientific manuscript itself, one discusses "Copyright and Permissions," and three treat new subjects, namely, "Manuscript Submissions in Machine-Readable Form," "The Literature: Becoming Part of It and Using It," and "Making Effective Oral Presentations." The last two chapters, in particular, reveal that the title *Style Guide* is somewhat of an understatement. In keeping with this broader intent, discussions of ACS editorial procedures and of ACS books, journals, and services, as well as of Chemical Abstracts Service, are relegated to the appendixes, which further include ethical guidelines to publication of chemical research; element symbols, atomic numbers, and atomic weights; symbols for commonly used physical quantities; hints to the typist; and proofreaders' marks.

One (well-drawn) picture is worth a thousand words, especially in the verbose manuscripts often delivered to overworked editors. The clearly written, copiously illustrated chapter "Illustrations and Tables" should therefore be very useful to authors doing their own artwork. Much greater attention than in the earlier *Handbook* is given to the practical aspects of drawing formulas and figures. Further improvements are the longer lists of abbreviations and symbols and the more detailed discussions of punctuation and editorial style. Moreover, the layout of the book, from the comprehensive table of contents and the all-inclusive index to the clear listing of the specific recommendations and numerous examples, facilitates enormously the use of this book as a quick reference source.

Only the first chapter, "The Scientific Paper," leaves something to be desired. Less than two pages treat writing style in general. Although suggestions such as "avoid slang and jargon," "use strong verbs," and "be brief" are good, a few examples of the more common such pitfalls in scientific manuscripts might have been more helpful. This is especially true in view of the wealth of examples given in later chapters to illustrate much finer points, such as the use of italics and commas or the location of quotation marks (curiously, while standard American practice is to place them after periods and commas, ACS practice is the hybrid called "logical placement," which is virtually identical with German practice). Whereas a good in-house copy editor can take care of typefaces and punctuation, only the author can ensure the clear, crisp style so essential to good scientific writing.

The ACS Style Guide is a welcome addition to the reference library of both scientific authors and editors. In fact, *Angewandte Chemie International Edition in English* recommends the *Style Guide* in its Notice to Authors.

David I. Loewus [NB 760 IE]
Angewandte Chemie, Weinheim (FRG)

Biochemistry of Alkaloids. Edited by *K. Mothes, H. R. Schütte*, and *M. Luckner*. VCH Verlagsgesellschaft, Weinheim 1985. 496 pp., bound, DM 194.00.—ISBN 3-527-26079-X

Following the earlier monograph "Biosynthese der Alkaloide" (Editors: *K. Mothes, H. R. Schütte*, 1969), there is now an updated version available in English by the same authors. This volume both fills the information gap existing between 1969 and the present in this specialized field, and treats in detail nearly all the biochemical ramifications of this fascinating group of natural products. It includes 247 figures and more than 1200 structural formulas, and for the reader needing further details there are over 2300 literature references ranging from classical work on alkaloids to the most topical problems.

The monograph is divided into 19 chapters. The topics covered by the first nine of these include methods in biosynthetic research, the genetic aspects of alkaloid metabolism and its regulation, the classification of metabolic sequences, and the localization of alkaloids in living cells and its ecological significance.

Chapters 8 and 9 are concerned with the metabolism of those amino acids which are important as alkaloid precursors. These chapters also introduce the principles of biosynthesis of alkaloids, leading up to that part of the book which treats the various classes of alkaloids. The classification is along biogenetic lines, treating in turn the alkaloid groups derived from ornithine, lysine, nicotinic acid, phenylalanine and tyrosine, tryptophan, anthranilic acid and histidine, together with purine bases and alkaloids derived from isoprene.

The clearly written and well organized text takes the reader easily and directly through each topic, and the many biosynthetic reaction schemes provided are a valuable help. It would, however, have been desirable for teaching purposes to clearly indicate in the diagrams those biosynthetic pathways which are not yet proven. This would show at a glance the existing state of knowledge, and might inspire young investigators to check these hypotheses by experimental work.

The external appearance of the monograph is attractive, though the type quality leaves a little to be desired. While the text, apart from the appendix, contains only a few printing errors, there are some mistakes in the structural formulas, which one hopes will be corrected in a second edition.

This book gives an excellent and detailed survey of the biochemistry of alkaloids, and is as up to date as is practicable in representing the current state of research. It is a welcome addition to the literature on alkaloids, and is strongly recommended for natural products chemists, pharmacists and biologists. Nevertheless, its readership is likely to be limited to some extent by the relatively high price.

J. Stöckigt [NB 754 IE]
Pharmazeutische Biologie
der Universität München (FRG)

Industrielle Anorganische Chemie. By *W. Büchner, R. Schliebs, G. Winter,* and *K. H. Büchel.* Verlag Chemie, Weinheim 1984. xxiii, 645 pp., hardback, DM 108.00.—ISBN 3-527-25069-2

"Industrial Inorganic Chemistry" is a textbook as well as a reference work on inorganic products. The clear organization and the extensive index enable the book to be used quickly and conveniently and make it possible for the reader to obtain a survey over a diverse and important area of chemistry.

The main chapters are: inorganic basic products, mineral fertilizers, metals and their compounds, silicones, inorganic solid state materials and the cycling of nuclear fuel. These chapters are subdivided according to chemical criteria. For example, the chapter on inorganic basic products contains the sections: water, hydrogen, hydrogen peroxide and inorganic peroxides, nitrogen and nitrogen compounds, phosphorus and its compounds, sulfur and its compounds and halogens and halogen compounds. In each of these sections the following topics are dealt with: *distribution of raw materials, production processes, purification of products, economic significance and technical applications.* At the end of each section references give access to more detailed literature.

Production processes are described in close detail, discussing such aspects as the disposition of raw materials, energy consumption and ecological problems. Metallurgical processes, with a few exceptions, are not discussed. Particular attention is paid to economic aspects and to the application of products. These are illustrated by numerous tables, albeit containing data that is partly rather old.

In summary it can be said that this book covers a broad scope in a clear and concise way. The excellent realization of the book and the design with main and marginal columns justify the price of DM 108.00. It can therefore be recommended to students, teachers, chemists, and colleagues from related disciplines.

Organomercury Compounds in Organic Synthesis. By *R. C. Larock.* Springer, Berlin 1985. xi, 423 pp., bound, DM 268.00.—ISBN 3-540-13749-1

In recent years organomercury compounds have, despite their toxicity, assumed increasing importance in organic synthesis, primarily because of their selectivity. The present monograph, written by an expert in this field, is a greatly extended version of an article in *Angewandte Chemie* (1978) and a 1982 "*Tetrahedron Report*". In addition to the preparation of organomercury compounds it deals with the substitution of the mercury atom by hydrogen or halogens, the synthesis of compounds containing heteroatoms, and with dimerization, alkylation, acylation, carbonylation, and addition to alkenes and alkynes. A newly added item is a particularly comprehensive chapter on carbene transfer reactions, a field in which much has occurred since the appearance twelve years ago of the "Houben-Weyl" work on organomercury compounds (Vol. XIII/2b).

Solvomercuration-demercuration reactions have been excluded, as these will be treated in a separate monograph by the same author. The advance notice of the latter book that is twice given in the preface would have been enough; the author did not really need to repeat the advertisement in twelve more places, including twice on p. 159, as his work advertises itself!

The book is truly a mine of information for all chemists engaged in preparative work, containing more than 2800 literature references, of which a considerable number are from the Russian-speaking world. Rather then merely listing the various reactions, their advantages and disadvantages compared with other methods of synthesis are thoroughly discussed. The book is also eminently suitable as a work of reference, especially on account of the twenty summary tables which are distributed through the text. Unfortunately an author index, which would also have been valuable in that respect, has not been included.

I could find very few typographical errors, although there are what I would describe rather as unattractive forms, e.g. the rendering of formulas for nitro compounds as NO_2-Ar instead of O_2N-Ar. The presentation is outstandingly good, and the printing really excellent com-

pared with that which nowadays we have come to expect with many books. This, together with the high-quality binding, is of course reflected in the price. Nevertheless, the book should not be missing from any departmental library, whether academic or in the chemical industry.

Stereochemistry of Heterogeneous Metal Catalysis. By *M. Bartók*. John Wiley, Chichester 1985. xxiv, 632 pp., bound, £ 85.00.—ISBN 0-471-90553-4

How does an organic compound behave when on the surface of a heterogeneous catalyst, especially with regard to stereochemistry? What is the mechanism involved in the hydrogenation of an olefin, the dehydration of an alcohol, or the hydrogenolysis of an amine?

M. Bartók felt that it was timely to summarize the literature in this field in the form of a book. A first glance through the list of contents and introductory remarks was not very promising: few concise headings, a series of misprints, an unfortunate choice of symbols (asterisks which are distinguished only by a slight difference in size signify either an active center on the surface or a chiral atom), and a careless use of *E* and *Z* as synonymous with *cis* and *trans*, which is quite surprising in a book on stereochemistry. The contents are divided into twelve chapters, and are arranged according to compound types: alkanes, cycloalkanes, alkenes, alkynes, aromatics, alcohols, carbonyl compounds, and nitrogen compounds. The literature up to the end of 1982 is covered, with 2956 references. The book concludes with a 50-page author index and a 40-page subject index.

Each chapter is arranged according to the following scheme. First, all the available review articles are listed, then the possible adsorbed species are given and their structures shown. This is followed by results on isotope exchange and isomerization, then a description of the reactions of the individual classes of compounds, illustrated by numerous diagrams. The longest chapter (116 pp.) deals with hydrogenation of olefins, including also unsaturated steroids.

The contributions of the various co-authors (nine in all) have turned out very differently. The chapters on alkanes and cycloalkanes with which the book begins are not good. There are long passages in which the presentation of the material is in the style of "one cited paper = one sentence", which does not make for an easily readable text. The sequence of facts is often unrelated, thus confusing the reader. There are numerous instances like that on p. 40. Here it is first stated that a study of the hydrogenolysis of cyclopropane derivatives provides considerable information towards understanding the mechanism. However, after thirteen equations and five lines of text it is concluded that more data are needed before any general rule can be established regarding the stereochemistry of the hydrogenolysis of the cyclopropane ring.

The basic fault of this book is that the route from the formulation of the problem to the final result is not explained. An illustration of this is the treatment of isotope exchange in cyclopentane and cyclohexane (p. 26). Here the reader is presented with five different mechanisms: repeated second-point adsorption, exchange of two adjacent equatorial hydrogen atoms, a π-allyl mechanism, a rollover mechanism, and a "rock and roll" mechanism. He is also told that one author prefers this mechanism and rejects that, whereas another sees it differently, but the grounds on which they base their different views are not explained. This way of presentation not to demonstrate how the mechanisms shown were arrived at leaves one feeling very dissatisfied. This is not the way to hold a reader's attention.

After a weak beginning, there follow some chapters which are better written and well organized, e.g. those on carbonyl and nitrogen compounds. In some of them the topics are treated too briefly, e.g. in Chapter XI, where some aspects of enantioselective hydrogenation using heterogeneous catalysts are presented in a very sketchy way.

Those working in this field will buy the book for its comprehensive coverage of the literature, but anyone who is not so close to the topic will not find the book very pleasant to read.

The Industrial Uses of Tin Chemicals. By *S. J. Blunden, B. A. Cusack,* and *R. Hill*. The Royal Society of Chemistry, London 1985. ix, 337 pp., bound, £ 36.00.—ISBN 0-85186-927-0

For about thirty years the industrial uses of a wide range of organotin compounds have continued to grow in importance. Various tin compounds are very effective in applications such as the thermal and light stabilization of PVC, as catalysts in polyurethane and silicone manufacture, and as biocides used in agriculture, the timber industry, shipping, etc. Over 40000 tonnes of organotin compounds are used each year throughout the world.

The number of people in industry who are concerned with organotin compounds—chemists, engineers and technicians—also continues to grow, and there has long been a need for an informative handbook to help them. This book now fills that gap.

The book is divided into 15 chapters: 1. Introduction, 2. Industrial manufacture, 3. Toxicology, 4. Antifouling systems, 5. Agrochemicals, 6. Wood preservatives, 7. PVC stabilizers, 8. Catalysts, 9. Glass applications, 10. Fire retardants, 11. Pharmaceuticals, 12. Ceramics, 13. Reducing agents, 14. Miscellaneous uses, 15. Environmental aspects. Finally there is an index of manufacturers. Each chapter contains a separate list of literature references. Altogether 1224 such sources are mentioned, covering literature up to and including 1984.

A complete review of the literature would have been out of place in a handbook such as this. On the other hand, a selection of key publications on significant advances corresponding to the relative importance of each field needed to be described. A comparison of Chapters 6 and 7 shows that the book does not meet this need. The literature covered in Chapter 6 (wood preservatives, where organotin compounds take a share of under 3%) consists of 118 references, which is about 90% of the existing publications on this topic. By contrast, in Chapter 7 PVC stabilizers, where organotin compounds have a share of more than 60%, are given a mere 42 references, i.e. about 10% of the available literature, and of the 100 or so known patents in this field

only three are mentioned. The use of organotin stabilized PVC films in food packaging is mentioned only in passing, and there is no discussion of the numerous publications on this topic.

A bare mention of the applications in each of the specialized areas is not enough for someone working in the field; he also needs information about how organotin compounds can most effectively and safely be used. It is true that toxicological studies have revealed no carcinogenic or mutagenic effects, but the compounds used for technological purposes are certainly not harmless: some are quite toxic and affect the eyes, mucous membranes, and liver. It would certainly have been appropriate to include in the book an account of the precautions needed.

Use of these substances also calls for reliable methods of analysis. The book includes nothing on this subject apart from a list of references on Mössbauer spectroscopy.

Since there is still no really good handbook available for those who use organotin compounds, "The Industrial Uses of Tin Chemicals" is recommended despite its shortcomings.

The Chemistry of the Metal-Carbon Bond. Vol. 2: The Nature and Cleavage of Carbon-Metal Bonds. Vol. 3: Carbon-Carbon Bond Formation using Organometallic Compounds. Edited by *F. R. Hartley* and *S. Patai*. John Wiley, Chichester 1985. Vol. 2: xiii, 904 pp., bound, £ 155.00.—ISBN 0-471-90282-9; Vol. 3: xiv, 489 pp., bound, £ 98.00.—ISBN 0-471-90557-7

Following the publication in 1982 of Volume 1 of this series, Volumes 2 and 3, covering the topics named above, appeared almost simultaneously during last year. To come immediately to the point, both these volumes are a good deal more integrated than the initial volume, which seemed to have been put together without a clear guiding concept, and they are consequently more useful. It is regrettable that Volume 2 still does not contain a chapter on the important topic of photochemical cleavage reactions, and this ought to be remedied in a later volume. As no precise information is given about the scope of the series, one must for the time being wait to see which other subjects are planned.

Volume 2 starts with a not very detailed chapter on the electrochemical cleavage of metal-carbon bonds (24 pp., 99 references). In addition to M-C σ-bonds, this also includes bonds between metals and C_5H_5, C_6H_6, CO, CNR, carbenes and carbynes. Unfortunately the literature references for this very topical theme do not extend later than 1982, a shortcoming which also applies to most of the other contributions. Chapter 2 is quite extensive (124 pp., 591 references), dealing with heterolytic cleavage of bonds between carbon and main group metals, a topic which has been worked on intensively for several decades. This reviewer does not feel competent to give an authoritative verdict either on this chapter or the following one (66 pp., 276 references), devoted to homolytic cleavage of M-C bonds (but excluding metals of the 3rd-8th subgroups, the lanthanides and actinides). Both chapters lack any recent references; Chapter 2 contains none later than 1981. Chapters 4 and 5 deal with insertion reactions of metal-carbon compounds, first for main group metals (Chapter 4, 118 pp., 556 references), then for transition metals (Chapter 5, 60 pp., 280 references). The information given here is mainly of interest to organic chemists, and despite the large amount of material it is all clearly presented, partly in the form of tables. Chapter 5 and Chapter 6 (which covers the reactivity of organic transition metal compounds with nucleophiles) are notable exceptions as regards being up to date, as they contain many references to work published in 1982, and in places even 1983. Chapter 6 (112 pp., 464 references) is well worth reading; one senses from the start that this is the work of a very competent author *(L. S. Hegedus)*. Chapter 7 (45 pp., 206 references), which examines electrophilic attack on M-C σ-bonds, is short by comparison, and omits consideration of some important reactions, such as those of carbenium ions with alkyl and aryl metal complexes; no references later than 1981 are given. The next chapter (65 pp., 206 references), however, deserves praise, as it contains everything of importance on the subject of β-hydride elimination (and to some extent too on α- and γ-hydride elimination). At the present time there is certainly nothing better available on this topic. Chapter 9 (163 pp., 829 references), on the highly topical theme of oxidative addition and reductive elimination, would have received a similar commendation, were it not for the fact that 95% or more of the references are from before 1981. This is a great pity, especially since it would be difficult to find a more competent author than *J. K. Stille*. The final chapter (37 pp., 272 references) treats structure and bond formation in organometallic compounds of main group metals. It clearly ought to be in Volume 1, and appears rather isolated here; moreover, one would have wished for rather more information on this subject than the chapter contains.

The better overall impression made by Volume 2 compared with the first volume is also continued into Volume 3. Almost throughout the ten chapters, the authors have a high reputation gained by having themselves made important contributions in the fields about which they write here. Chapter 1 (C-C bond formation using organotin and organolead compounds) is fairly extensive (97 pp., 322 references), and is clearly aimed at synthetic organic chemists. The same also applies to Chapter 2 (42 pp., 489 references), which is concerned with the use of organozinc, organocadmium and organomercury compounds. In neither case is there any literature later than 1982, although here the limitation is less serious. However, so far as topicality is concerned, Chapter 3 (C-C bond formation using η^3-allyl complexes) steps into the breach; there are even references to papers from 1984, and the reports by *G. P. Chiusoli* and *J. Tsuji* (on π-allyl compounds of nickel and palladium) are a genuine pleasure to read. A great deal of work is now in progress in this area, and the synthetic potential of other η^3-allyl complexes (see e.g. the recent work of *Trost*) are still far from being exhausted. The following two chapters deal with topics which are also of industrial importance: oligomerization of olefins (Chapter 4, 52 pp., 114 references) and oligomerization of alkynes (Chapter 5, 35 pp., 116 references). As the literature covered in Chapter 4 (with one exception) ends with 1979, this means that in particular the recent publications from the Mülheim group (especially by *Heimbach*) have not been included. Chapter 6, which discusses the applications of transition metal carbonyls in organic synthesis, is very thoroughly organized but amazingly brief (38 pp., 186 references). Many of the topics here are merely touched on, and some, such as the use of metal carbonyl-carbene complexes in the synthesis of natural products, are missing completely. Chap-

ters 7 to 10 again treat important industrial topics: carbonylation of olefins and alcohols in Chapter 7 (24 pp., 155 references), olefin hydroformylation in Chapter 8 (28 pp., 112 references), Fischer-Tropsch syntheses in Chapter 9 (43 pp., 143 references), and olefin carbonylation in Chapter 10 (10 pp., 69 references). Leaving aside the fact that there is some overlapping on these topics, it must be remarked that in all of them the literature survey is more up to date. An overall view is provided for the reader with limited time available, which is as much as the writers set out to achieve.

In the review of the first volume the question was raised as to who could afford to buy this series. As the situation in our libraries has not improved since then, the recommendation with regard to buying remains as before that caution is advisable. For anyone who has the money and for whom a survey is sufficient, the books can be recommended, but anyone who wishes to familiarize himself with the current position in one of the fields dealt with must choose more recent publications.

The Structure of Volatile Sulphur Compounds. By *I. Hargittai*. D. Reidel Publishing Company, Dordrecht 1985. viii, 316 pp., bound, HFl 135.00.—ISBN 90-277-1395-2

This monograph, which has already appeared in Hungarian in 1981, deals with organic and inorganic sulfur compounds whose structures in the gas phase have been determined by microwave spectroscopy or electron diffraction. The extensive material which it contains is arranged according to the coordination number of the sulfur atom. In some cases the structures of analogous oxygen, selenium or tellurium compounds are also discussed, and the content of the book is therefore wider than the title suggests. The range of compounds treated extends from simple molecules such as H_2S, $PSCl_3$, $Se(GeH_3)_2$ and $(SF_5)_2O$, through the many organic thiocarbonyls, isothiocyanates, thiols, thioethers, sulfoxides, sulfones, and sulfur–nitrogen compounds, up to exotic examples such as the gaseous species of B_2S_3, TeO_2 and K_2SO_4, and the van der Waals molecule ArOCS. The main emphasis is on organic compounds, which occupy about 75% of the formula index. The results are clearly presented in 105 diagrams and 101 tables, and are critically analyzed in the associated text. The extensive formula index (8 1/2 two-column pages) and author index (12 1/2 two-column pages) facilitate rapid access, despite the great wealth of data, based on nearly 1000 literature references, which are listed alphabetically at the end of the text. In addition to the ordinary structural information, conformational problems such as intramolecular rotation are thoroughly discussed, and relationships between molecular geometry parameters or other bond properties (force constants or IR wave numbers) and those in related molecules are given. In particular sulfoxides, sulfones, and related four-coordinated (pseudo-tetrahedral) sulfur compounds are thoroughly discussed, on the basis of the VSEPR model.

In this book the author, who is well known for his many publications on electron diffraction research, has produced a useful work of reference containing information which would be difficult to obtain elsewhere. There is much interest in such information, as the sulfur compounds dealt with here are of great importance in many technical processes, in problems of environmental chemistry, and for innumerable chemical reactions that arise in research. It is, however, difficult to understand why the text was not thoroughly up-dated for the English edition. By far the greater part of the references are from the sixties and seventies, with only a few publications from 1980–1981 reviewed, and none of more recent years. Furthermore, only in a few cases is reference made to the many theoretical structural calculations that exist for the smaller molecules. One might also have wished to see the reported gas phase structures systematically compared with results from X-ray structure analyses on the same compounds, rather than only occasionally. The criticism that molecular structures in the solid phase are affected by intermolecular interactions is countered by the fact that the bond angles determined by electron diffraction are usually subject to appreciable errors, so that it is useful to compare the results with X-ray data.

Notwithstanding these critical comments, this monograph by *Hargittai* is a valuable addition to the previous most recent major survey on the structures of sulfur compounds by *P. Laur* in 1972. No library should therefore be without this book, which is good value for the price.

Selective Synthesis by Use of Lewis Acids in the Presence of Organocopper and Related Reagents

New Synthetic Methods (61)

By Yoshinori Yamamoto*

Organometallic compounds with pronounced nucleophilicity such as organocopper and organolithium compounds, and powerful electrophiles, such as BF_3 and $AlCl_3$, are generally thought to be incompatible under normal, homogeneous reaction conditions. As a matter of course, it is anticipated that the two species cannot coexist and undergo transmetalation reactions. To our surprise, however, RCu and BF_3 are compatible at low temperature. $RCu \cdot BF_3$ and related organocopper-Lewis acid reagents exhibit new and unique reactivities and selectivities: in conjugate additions, e.g., not only activation but also high regio-, stereo-, and chemo-selectivity as well as very high asymmetric induction is observed; allylic derivatives are alkylated regioselectively, and reaction towards carbonyl groups, imines, epoxides, aziridines, ethers, acetals, orthoformates, and pyridinium salts is in each case found to be selective. $RLi \cdot BF_3$ and related organolithium-Lewis acid reagents also exhibit noteworthy selectivities and reactivities. These complex reagents are utilized in the key steps of the total synthesis of many important natural products, such as certain terpenes, steroids, and alkaloids.

1. Introduction

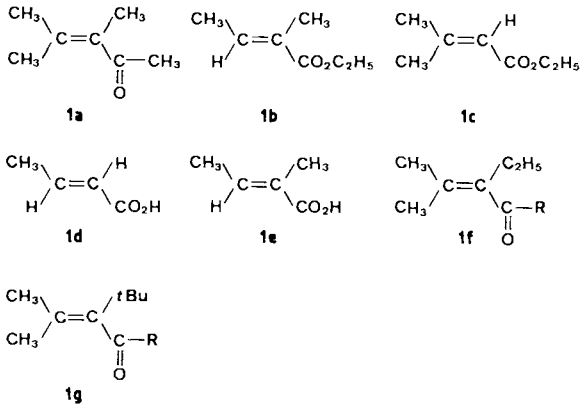
Both in aldol reactions with silyl enol ethers[1] as well as in allylation reactions with allylsilanes[2] Lewis acids are added in order to increase the reactivity of the only weakly nucleophilic silyl reagents. That this succeeds was already established in 1973 and 1976, respectively. What then is to be expected when much harder nucleophiles, such as alkyllithiums and Grignard compounds, are treated with BF_3

$$RLi + TiCl_4 \longrightarrow RTiCl_3 + LiCl$$

$$RMgX + TiX_4 \longrightarrow RTiX_3 + MgX_2$$

Scheme 1.

[*] Prof. Dr. Yoshinori Yamamoto
Department of Chemistry, Faculty of Science
Tohoku University, Sendai 980 (Japan)



or $AlCl_3$? Foreseen is a rapid transmetalation. Indeed, organotitanium compounds, which have often been used in modern organic syntheses since 1980, can be prepared in this way (Scheme 1).[3]

In 1977 we found that the combination of $BF_3 \cdot OEt_2$ with organocopper compounds, which are harder than silyl enol ethers and allylsilanes but softer than organolithium and magnesium derivatives, yields a new complex reagent, $RCu \cdot BF_3$. To our surprise, RCu and BF_3 are compatible at low temperatures, and the two species are not so easily transmetalated as RLi·TiLn.[4] Since this discovery, $RCu \cdot BF_3$ and related organocopper-Lewis acid reagents have found frequent use in selective organic syntheses. More recently, organolithium-Lewis acid reagents have been developed which also exhibit unique reactivities and selectivities. In this review, the scope and limitation of these complex reagents will be summarized.

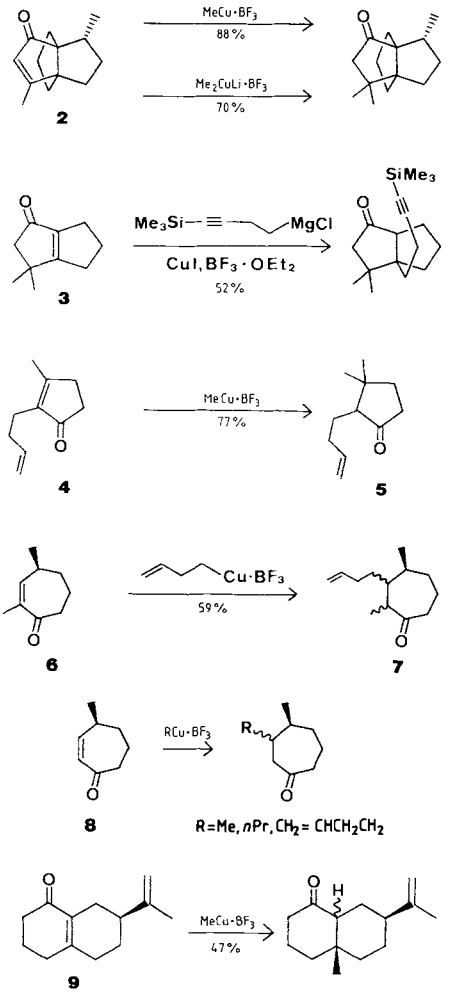
2. Activation in the 1,4-Addition to α,β-Unsaturated Carbonyl Compounds

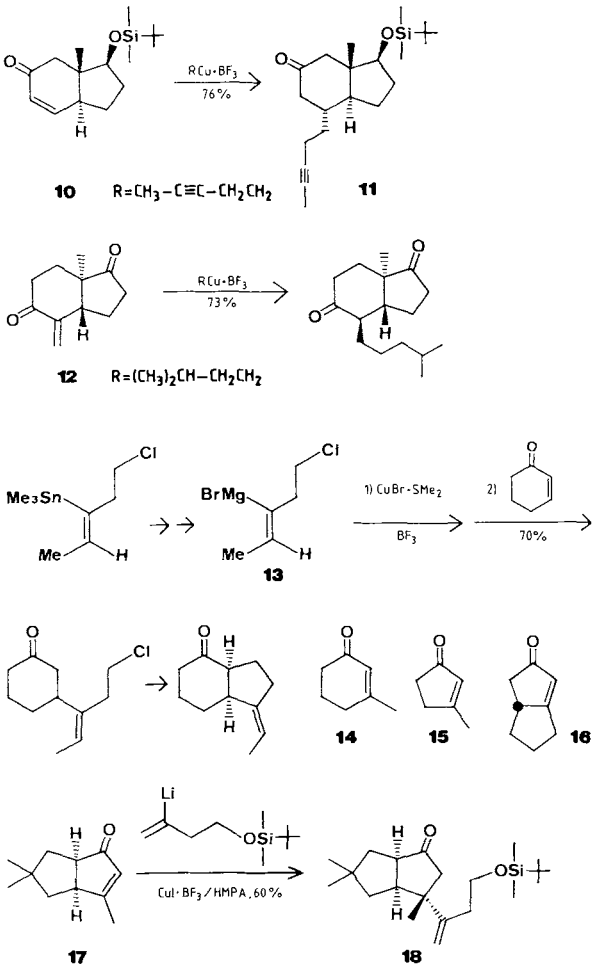


Although organocuprates (Gilman reagents) count among the most popular reagents for 1,4-additions (conjugate additions) there are still substrates with which they do not react as predicted. Thus, poor results are obtained with β,β-disubstituted acrylic ester derivatives, sterically highly crowded enones, and α,β-unsaturated carboxylic acids.[5] Organocopper-Lewis acid reagents have proven very useful for 1,4-additions to these previously "unreactive" substrates.[4,6] For example, $BuCu \cdot BF_3$ adds smoothly to **1a**–**1e**, whereas Bu_2CuLi does not. $MeCu \cdot BF_3$ is suitable for conjugate additions to the compounds **1f** and **1g** (Scheme 2).[7]

Scheme 2. **1f**, R = $CHEt_2$, *t*Bu; **1g**, R = Me, $CHEt_2$, *t*Bu, CMe_2*t*Bu, $CH(t\text{Bu})_2$.

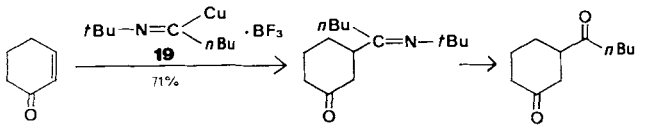
In the total synthesis of modhephen, a 1,4-addition to **2** was carried out either with $MeCu \cdot BF_3$[8] or with $Me_2CuLi \cdot BF_3$.[9] No addition took place at all with Me_2CuLi alone. Similarly, a conjugate addition to **3** was achieved with the propargylcopper·BF_3 reagent,[10] while $MeCu \cdot BF_3$ was the reagent of choice for the transformation **4** → **5**, a step in the synthesis of (±)quadrone.[11] In the course of the total synthesis of (±)parthenin, a step involving the conversion of the enone **6** into **7** was essential. This could not be accomplished with the cuprate reagent, whereas the organocopper·BF_3 reagent furnished **7** in satisfactory yields.[12] Furthermore, upon reaction with **8**, $RCu \cdot BF_3$ exhibited higher diastereoselectivity than R_2CuLi,[12] and the 1,4-addition to **9**, which was not achievable with Me_2CuLi alone, could be realized with $MeCu \cdot BF_3$ (Scheme 3).[13]

The conversion of **10** into **11** with $RCu \cdot BF_3$ proceeded in good yield, while with R_2CuLi the yield was only 46% (R = 3-pentynyl).[14] Reaction of **12** with isopentyl$Cu \cdot BF_3$ afforded the conjugate adduct in good yield,[15] while reaction of the $RCu \cdot BF_3$ complex prepared from **13** with 2-cyclohexenone furnished the 1,4-adduct in good to excellent yields.[16] Conjugate addition to the sterically hindered cyclic enones **14**–**16** proceeded equally smoothly. The transformation of **17** to **18** required in the total synthesis of (+)hirsutene was accomplished by means of the reagent



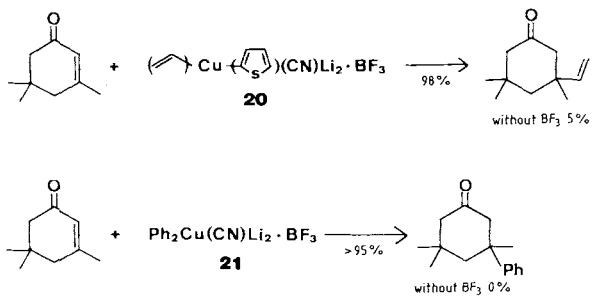
Scheme 3. Molecular ratio educt : reagent (from the top downwards): 1 : 5, 1 : 1.8; 1 : 2.8, 1 : 3, 1 : 2, no data, 1 : 3.

$RCu \cdot BF_3 \cdot HMPA$;[17] the addition took place exclusively from the α-side of **17** (Scheme 4).



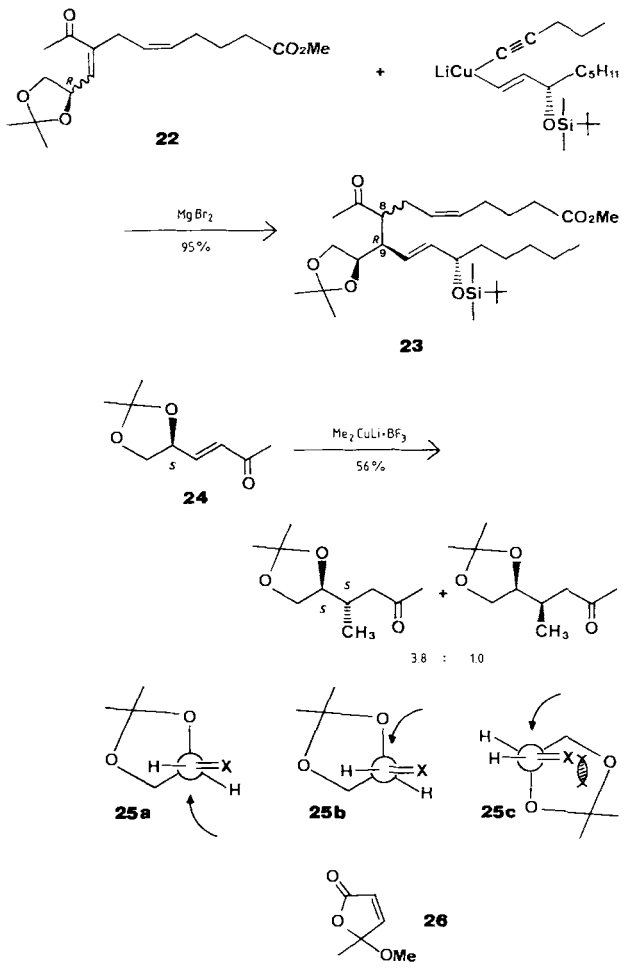
The 1,4-addition of copper-substituted Schiff bases to α,β-unsaturated enones could only be achieved by use of the corresponding BF_3-complex **19** (Scheme 5).[18] Other Lewis acids, such as $AlCl_3$, $TiCl_4$, $EtAlCl_2$, and Et_2AlCl, were also examined, but the results were very poor. The reagent **19** was prepared from the lithiated precursor and $CuI \cdot BF_3$; $CuBr \cdot SMe_2 \cdot BF_3$ and $CuI \cdot P(OMe)_3 \cdot BF_3$ likewise afforded good results. In the reaction according to Scheme 5, BF_3 presumably activates both the Schiff base **19** as well as the enone by coordination to the nitrogen atom.

The 1,4-addition of organocuprates such as $R_2Cu(CN)Li_2$ was also dramatically improved by $BF_3 \cdot OEt_2$.[19] Thus, the yield in the addition of **20** could be increased from 5 to 98% with BF_3, while **21** gave the conjugate adduct in >95% yield; without BF_3, however, no 1,4-adduct was obtained (Scheme 6). Other Lewis acids, such as $EtAlCl_2$, Et_2AlCl, $LiClO_4$, LiBr, $TiCl_4$, $SnCl_4$, $ZnCl_2$, $Ti(OR)_4$, $B(OR)_3$, and AlF_3, were ineffective.

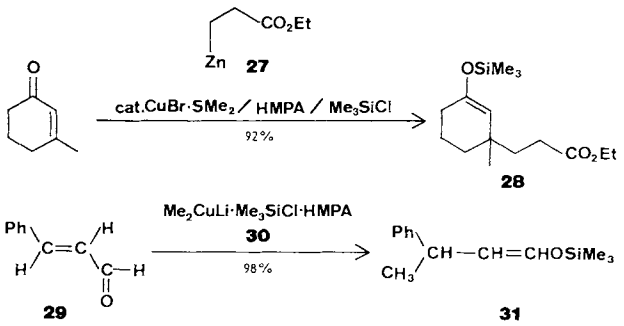


In the total synthesis of levuglandin E_2 (LG E_2), the conjugate addition of $R_2CuLi \cdot MgBr_2$ to **22** proceeded in ex-

Scheme 4. Molecular ratio educt : reagent (from the top downwards): 1 : 3.8, no data, 1 : 0.3, 1 : 1.4. HMPA = hexamethylphosphoric triamide.

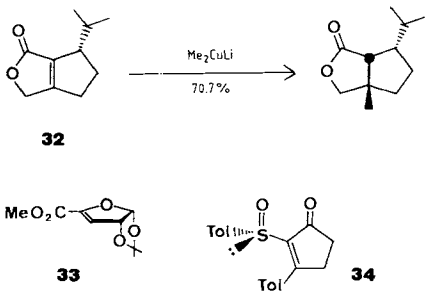


Scheme 5. Molecular ratio educt : **19** = 1 : 2.



Scheme 6. Molecular ratio educt : reagent (from top downwards): 1 : 1.4, 1 : 1.

cellent yields, whereas without $MgBr_2$ the adduct **23** was not obtained.[20a] Although epimerization was observed at C-8 of **23**, an (*R*)-configuration [(*R,R*)-**23**] was selectively generated at C-9, thus indicating that very high acyclic stereoselection can be achieved in the 1,4-addition. Similarly, the conjugate addition of $Me_2CuLi \cdot BF_3$ to **24** afforded the (*S,S*)- and (*S,R*)-adducts in the ratio 3.8 : 1.[20b] Presumably, **25b** and **25c** are less stable than **25a** owing to steric hindrance, which leads to the (*S,S*)-isomer (Scheme 7). Although $R_2CuLi \cdot MgBr_2$ adds to **22** in a 1,4-manner, it does not react with **26**.[21] This is reasonable, since the reactivity of α,β-unsaturated ketones is generally greater than that of α,β-unsaturated esters in conjugate additions.



Scheme 7.

A 1,4-addition of the zinc-substituted ester **27** can be realized in the presence of catalytic amounts of CuBr and Me_3SiCl.[22] In the absence of Me_3SiCl, no such addition occurs. HMPA presumably plays an important role in the transmetalation state from **27** to the copper analogue. This reagent system demonstrates that the organocopper-Lewis acid method can even be carried out catalytically. $R_2CuLi \cdot Me_3SiCl$ can also be used for the 1,4-addition to enones.[23] The reaction of lithium diallylcuprate with 2-cyclohexenone, e.g., gave a 82 : 18 mixture of the 1,4- and 1,2-adducts, while the lithium diallylcuprate-trimethylsilyl chloride complex increased the ratio to >98 : <2. Reagents of this type have also proven effective in the case of α,β-unsaturated aldehydes. Thus, e.g., reaction of **29** with **30** afforded the 1,4-adduct **31** in 98% yield; with Me_2CuLi itself the yield of adduct was only 74% (Scheme 8).

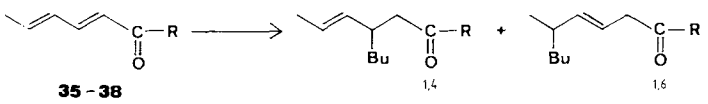
Scheme 8.

There are, however, a few examples in which the organocopper-Lewis acid reagents do not work well. Although the addition of Me_2CuLi to **32** proceeded smoothly, use of $Me_2CuLi \cdot BF_3$ or $MeCu \cdot BF_3$ gave dark resinous materials.[24] 1,4-Addition to **33** did not occur with Me_2CuLi nor with $MeCu \cdot BF_3$,[25] and, although $Me_5Cu_3Li_2$ added smoothly to **34** in the sense of a Michael addition, $MeCu \cdot BF_3$ and $Me_2Cu(CN)Li_2$ proved ineffective (Scheme 9).[26]

Scheme 9. Molecular ratio **32** : reagent = 1 : 5.

3. Regio-, Stereo-, and Chemoselective 1,4-Addition

In the conjugate addition of $BuCu \cdot BF_3$ to the α,β,γ,δ-unsaturated ester **35** the 1,4-adduct was obtained, whereas with Bu_2CuLi the 1,6-adduct was formed;[4,6] a similar trend was observed in the case of α,β,γ,δ-unsaturated ketone **36**.[27] On the other hand, reaction of the corresponding acid **37** with $BuCu \cdot BF_3$ afforded almost exclusively the 1,6-adduct.[4,6] Reaction of $Me_2CuLi \cdot Me_3SiCl$ with **38** likewise gave the 1,6-adduct in excellent yield;[23] the same regioselectivity was found with Me_2CuLi itself (Table 1).



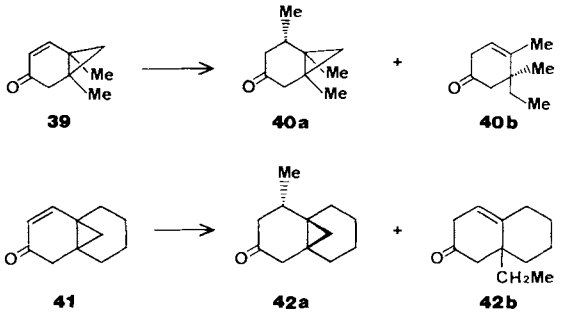


Table 1. Regioselectivity in the reaction of the diene derivatives **35**–**38**.

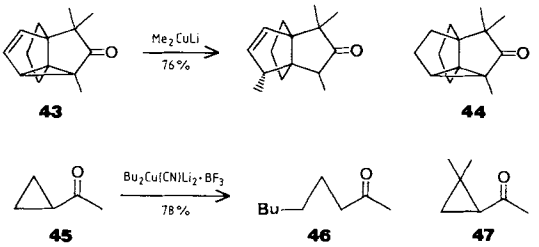
Educt	R	Reagent	Mol. ratio Educt : Reagent	Yield [%] 1,4 + 1,6	Yield [%] 1,4 : 1,6
35	OMe	$BuCu \cdot BF_3$	1 : 2	44	93 : 7
35	OMe	Bu_2CuLi	1 : 1	82	— 100
36	Me	$BuCu \cdot BF_3$		40	60 : 40
36	Me	Bu_2CuLi		60	— 100
37	OH	$BuCu \cdot BF_3$	1 : 3		14 : 86
38	Ph	$Me_2CuLi \cdot Me_3SiCl$			— 98[a]
38	Ph	Me_2CuLi			— 46[b]

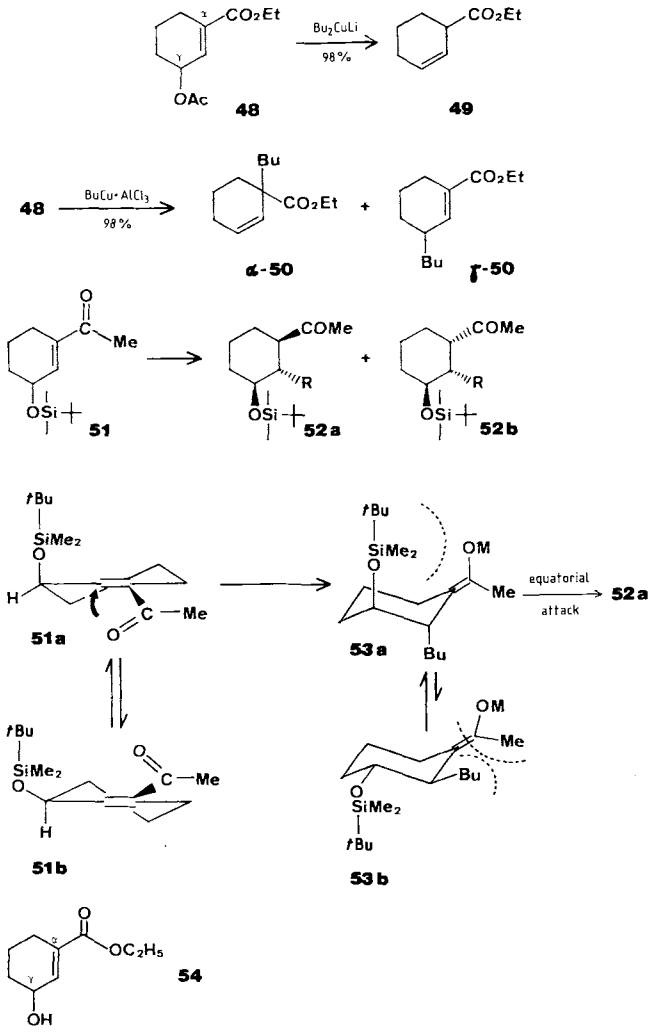
[a] Me instead of Bu. [b] Me instead of Bu. A polar byproduct is also formed, presumably the dienol derivative, by 1,2-addition to **38** [27].



As *Ibuka* has already demonstrated, $RCu \cdot AlCl_3$ is a useful reagent for regio- and stereoselective 1,4-additions to β′-cyclopropyl-α,β-enones such as **39** and **41**.[28,29] Thus, $MeCu \cdot AlCl_3$ selectively produced the 1,4-adducts **40a** and **42a**, while Me_2CuLi afforded the 1,6-adducts **40b** and **42b** as major products. No ring-opening takes place with $RCu \cdot AlCl_3$, thus indicating that no electron transfer step participates in conjugate additions with RCu-Lewis acid reagents (Scheme 10).

	Yield	40a	: 40b
Me_2CuLi [30]		48	: 52
$MeCu \cdot AlCl_3$	72%	100	–
	Yield	42a	: 42b
Me_2CuLi [31]	90%	40	: 55
$MeCu \cdot AlCl_3$	75%	100	—

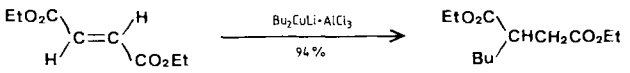
Scheme 10. Molecular ratio educt : reagent (from top downwards): 1 : 1, 1 : 5, no data, 1 : 5.



Cyclopropyl ketones, in which the cyclopropane ring is monoactivated by the carbonyl group, do not undergo homoconjugate addition (1,5-conjugate addition) with cuprate reagents, whereas diactivated cyclopropyl ketones do react with cuprates in this manner. For example, **44** was found to be completely resistant to 1,5-addition with Me_2CuLi and $Me_2CuLi \cdot BF_3$, while **43** diactivated with vinyl and carbonyl groups did undergo 1,5-addition.[32] The homoconjugate addition to monoactivated cyclopropanes was, however, realized with $Bu_2Cu(CN)Li_2 \cdot BF_3$.[33] The 1,5-adduct **46** was obtained from **45** in good yields; with $BuCu \cdot BF_3$, however, the 1,2-adduct was obtained as major product. Sterically bulky groups, such as *sec*- or *tert*-butyl, can be introduced in a similar way. In the case of **47**, the butyl group was regioselectively transferred to the less substituted carbon atom, indicating that the complexed reagent reacted in a concerted S_N2 manner (Scheme 11).

Scheme 11. Molecular ratio educt : reagent (from top downwards): 1 : 5, 1 : 3.

Both the γ-acetoxy-substituted α,β-unsaturated ester **48** as well as the related ketone **51** can, in principle, react in a 1,4-addition or allyl substitution. Exactly as in the case of the α,β-unsaturated ketone **22**, which readily undergoes 1,4-addition, and in the case of the α,β-unsaturated (cyclic) ester **26**, where this is not possible, one obtains with **51** a 1,4-addition, but with **48** a substitution at the allyl system. Whereas **48** was reduced with Bu_2CuLi to **49**, with $BuCu \cdot AlCl_3$ **α-50** and **γ-50** were obtained in the ratio 17:83.[34] The ratio increased to 3:97 on using $BuCu \cdot 5\,AlCl_3$. In the absence of $AlCl_3$, only the starting material was recovered. In the case of **51**, however, the conjugate addition took place.[35,37a] Although the reduced product, analogous to **49**, was again obtained as major product with R_2CuLi, reaction of the enone **51** with $RCu \cdot AlCl_3$ or $RCu \cdot BF_3$ gave the conjugate adducts **52a** and **52b**.[6]

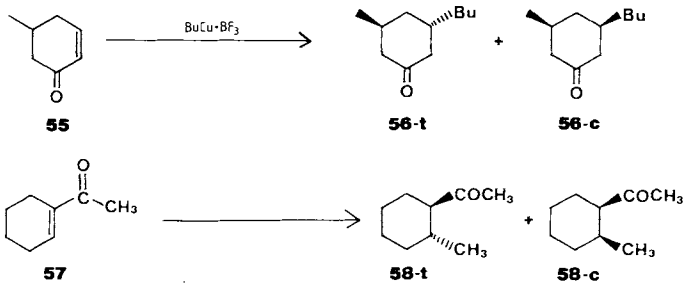


The preferential formation of **52a** can be explained as follows: Due to steric hindrance of the pseudoaxial siloxy group the butyl group of $BuCu \cdot AlCl_3$ or $BuCu \cdot BF_3$ attacks the planar enone system of **51a** from below, thus leading to **53a**. A similar attack in the case of **51b** is hindered by the bulky siloxy group. Although **53b** possesses two equatorial substituents, steric repulsion between the butyl group and the methyl substituent at the double bond of the enolate, which must occupy nearly the same plane, leads to preference of **53a**. Equatorial protonation then leads to **52a**, a reaction which was employed in the total synthesis of perhydrohistrionicotoxin.[36] As will be shown in Section 5, $BuCu \cdot BF_3$ can react with allylic alcohols to give predominantly the γ-substitution product.[38] Treatment of **54** with $BuCu \cdot BF_3$ in the molar ratio 1:4 afforded **α-50** (20%) and **γ-50** (55%).[6] Accordingly, the competition between conjugate addition and substitution in a single molecule leads, in the case of α,β-unsaturated ketones to 1,4-addition, and in the case of α,β-unsaturated esters to substitution (Scheme 12).

	Yield	52a	:	52b
$MeCu \cdot AlCl_3$	84%	90	:	10
Me_2CuLi	<7%	100		—
$BuCu \cdot AlCl_3$	87%	92	:	8
$BuCu \cdot BF_3$ [6]	75%	100		—

Scheme 12. Molecular ratio **48** : $BuCu \cdot AlCl_3 = 1:5$; **51** : $BuCu : BF_3 = 1:2$, in other reactions of **51** 1:1.

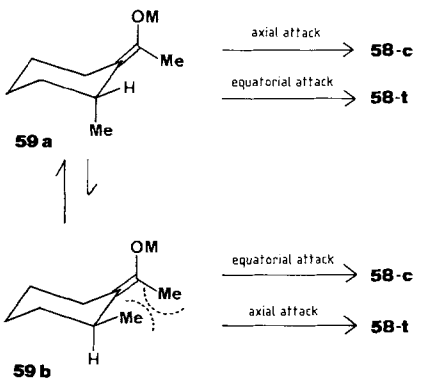
Reaction of electron deficient olefins, substituted with two carbonyl groups, with R_2CuLi leads to the reduced compound rather than to the conjugate adduct. The 1,4-addition to such olefins can, however, be accomplished with cuprate·Lewis acid reagents.[37b] Whereas reaction of diethyl fumarate with $Bu_2CuLi \cdot AlCl_3$ afforded the 1,4-adduct (Scheme 13), reaction of diethyl maleate gave



Scheme 13.

predominantly the reduction product under the same conditions. Reaction of triethyl ethylenetricarboxylate with $Me_2CuLi \cdot AlCl_3$ (or $Me_2CuLi \cdot BF_3$) furnished the conjugate adduct in 97% yield. As in the case of **39–42**, the Lewis acid complexes of organocopper compounds obviously do not react with α,β-unsaturated ketones and similar compounds via electron transfer. This is an advantage, since such an electron transfer often results in the reduction of substrates, and this can either be the main or side reaction.

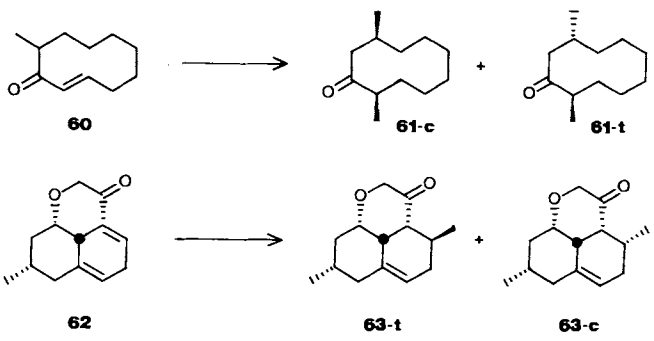
The stereochemistry of the 1,4-addition with RCu-Lewis acid reagents was investigated for the compounds **8–10**, **17**, **22**, **24**, **32**, **39**, **41**, and **51**, as well as for some simpler and more general systems.[6] Treatment of **55** with $BuCu \cdot BF_3$ afforded a mixture of **56-t** and **56-c** in the ratio 90:10. With Bu_2CuLi, almost the same ratio was obtained. The preferred formation of **56-t** can be explained in terms of an antiparallel attack, as described in the case of **51a**. The *cis*-isomer **58-c** was formed as main product in the conjugate addition of **57**. The highest stereoselectivity was realized with $MeCu \cdot BF_3$. Also $MeCu \cdot BF_3 \cdot PBu_3$, a colorless compound that is soluble in ether and stable at 0°C,[6] has already been used with success for high asymmetric induction reactions (see Section 4)[39] (Scheme 14).



The *cis*-preference of **57** can be explained as follows: whereas an equatorial attack is more favorable in the case of **59b**, in the case of **59a** an axial attack occurs more readily than the equatorial attack owing to the steric bulkiness of the methyl group. **59b** is presumably less stable

	Yield	58-t : 58-c
$MeCu \cdot BF_3$	63%	14 : 86
Me_2CuLi	93%	31 : 69
$MeCu \cdot PBu_3$	55%	36 : 64
$MeCu \cdot BF_3 \cdot PBu_3$	39%	18 : 82

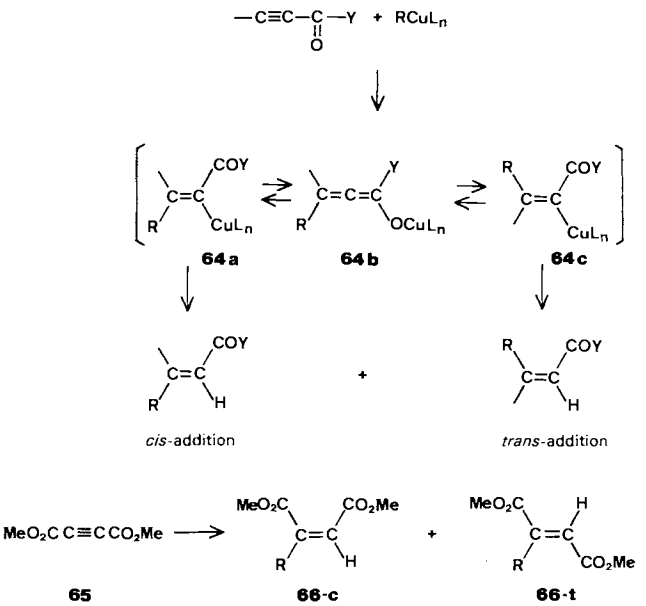
Scheme 14. Molecular ratio **57** : reagent, in all four examples 1 : 1.



than **59a** owing to the same reasons given in the case of **53b**. That **57** exhibits *cis*-preference and **51** *trans*-preference could be explained in terms of the sterically very bulky silyl group, which must prevent the axial protonation of **53a** (Scheme 15).

Scheme 15.

The high stereoselectivity of organocopper-Lewis acid reagents is also observed in the reactions of macrocyclic enones.[40] Thus, the conjugate addition of $MeCu \cdot BF_3$ to **60** gave the compound **61-c** with a stereoselectivity of >99%. Me_2CuLi was not quite as effective. **8**[12] also reacts with higher diastereoselectivity (5 : 1) with $RCu \cdot BF_3$ than with R_2CuLi (4 : 1). In the total synthesis of mevinolin, a stereoselective conversion of **62** into **63-t** was necessary. Among several reagents examined, $MeCu \cdot BF_3$ showed the best stereoselectivity (Scheme 16).[41]



Since the conjugate addition to α,β-alkynones proceeds via the copper-substituted enolate **64**, the geometry of the products strongly depends on the temperature and duration of the reaction before quenching. Highly stereoselective *cis*-additions are achieved with reagents of the type $RCu \cdot BR'_3$.[42] Of the reagents examined for the conversion **65** into **66-c**, $BuCu \cdot BEt_3$ exhibited the highest stereoselectivity. Presumably, in this case, the intermediate **64a** initially formed via the organocopper compound is stabilized (Scheme 17).

	Yield	61-c : 61-t
Me_2CuLi	82%	94 : 6
$MeCu \cdot BF_3$	98%	>99 : <1

	Yield	63-t : 63-c
Me_2CuLi	77%	86 : 16
$Me_2Cu(CN)Li_2$	78%	80 : 20
$MeCu(CN)Li$	61%	67 : 33
$MeCu \cdot BF_3$	79%	>98 : <2

Scheme 16. Molecular ratio educt : reagent (from top downwards): 1 : 8, 1 : 5, no data for the next three examples, last example 1 : 3.

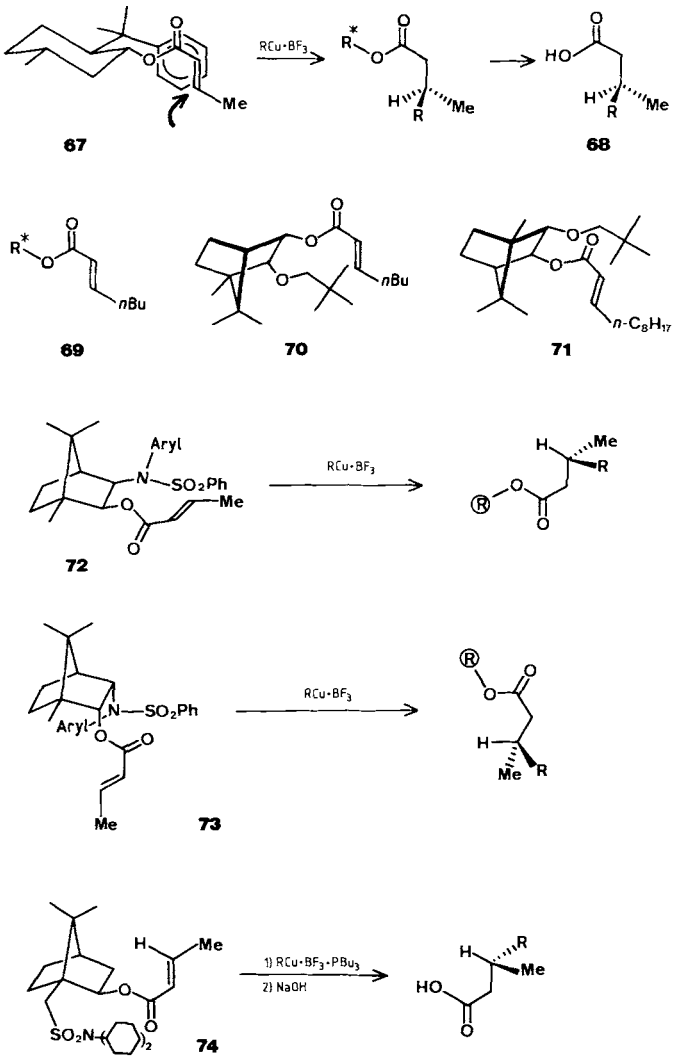
	Yield	66-c : 66-t
$BuCu \cdot BEt_3$	93%	>99 : <1
Bu_2CuLi	98%	60 : 40
$BuCu \cdot B(OMe)_3$	92%	91 : 9
$BuCu \cdot BF_3$	85%	87 : 13

Scheme 17.

4. Asymmetric Induction in 1,4-Additions

Very high asymmetric induction was achieved in the Michael addition to α,β-unsaturated esters by using $RCu \cdot BF_3$.[43] Thus, **67** reacts with $BuCu \cdot BF_3$ to give **68** in 99.5% *ee*. Presumably, the conformation of the enoate is fixed by the Lewis acid as indicated in **67**, and thus the R group is forced to attack from the direction depicted by an arrow. The enantiomer excess of 78% *ee* achieved by addi-

tion of $MeCu \cdot BF_3$ to **69** increased to 86.5% on using $MeCu \cdot BF_3 \cdot PBu_3$.[39] Me_2CuLi did not react with **70** at all, whereas reaction of $MeCu \cdot BF_3 \cdot PBu_3$ with **70** afforded the conjugate adduct in 94% *ee*. A very high asymmetric induction was similarly observed upon reaction of **74** with $RCu \cdot BF_3 \cdot PBu_3$.[44] Further examples are listed in Table 2.



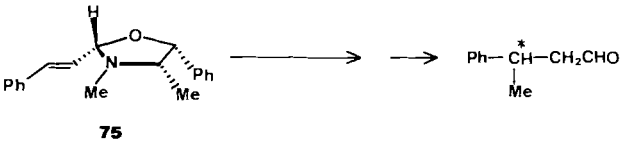


Table 2. Asymmetric induction in the reaction of the educts **67** and **69**–**73**. R*OH = 8-phenylmenthol; ®OH = sulfonamide-protected terpene alcohol.

Educt	Reagent	Mol. ratio Educt : Reagent	Yield [%]	*ee* [%] or Diastereomeric ratio	Ref.
67	$PhCu \cdot BF_3$	1 : 2	76	99.3	
67	$BuCu \cdot BF_3$	1 : 2	76	99.5	
69	$MeCu \cdot BF_3$			78	
69	$MeCu \cdot BF_3 \cdot PBu_3$			87	[39]
70	Me_2CuLi		—		
70	$MeCu \cdot BF_3 \cdot PBu_3$			94	
71	$MeCu \cdot BF_3 \cdot PBu_3$			98	
72	$EtCu \cdot BF_3$	1 : 5	90	>99 : <1	[45]

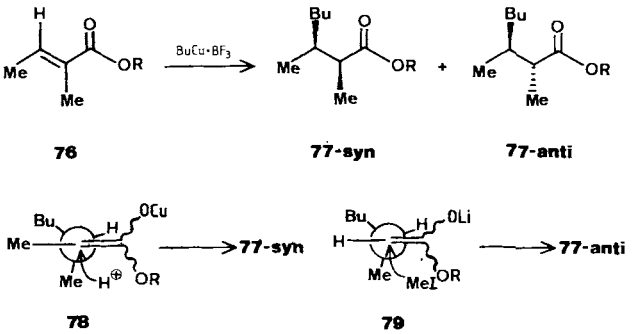
73	$EtCu \cdot BF_3$	1 : 5	84	>99 : <1	[45]
73	$iPrCu \cdot BF_3$	1 : 5	97	98 : 2	[45]
73	$CH_2{=}CHCu \cdot BF_3$	1 : 5	81	>99 : <1	[45]
73	$PhCu \cdot BF_3$	1 : 5	94	>99 : <1	[45]

A significant chiral induction was obtained upon addition of $Me_2CuLi \cdot BF_3$ to the chiral oxazolidine **75** in ether.[46] However, with hexane as solvent, high asymmetric induction was realized by use of Me_2CuLi itself. $MeCu \cdot BF_3$ in ether was ineffective (Scheme 18).

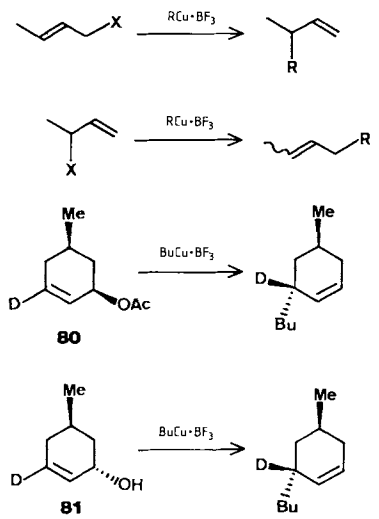


75

	Yield	*ee*
Me_2CuLi/THF	76%	10%
$Me_2CuLi \cdot BF_3$/Ether	88%	51%
Me_2CuLi/hexane	80%	80%
$MeCu \cdot BF_3$/ether	76%	9%

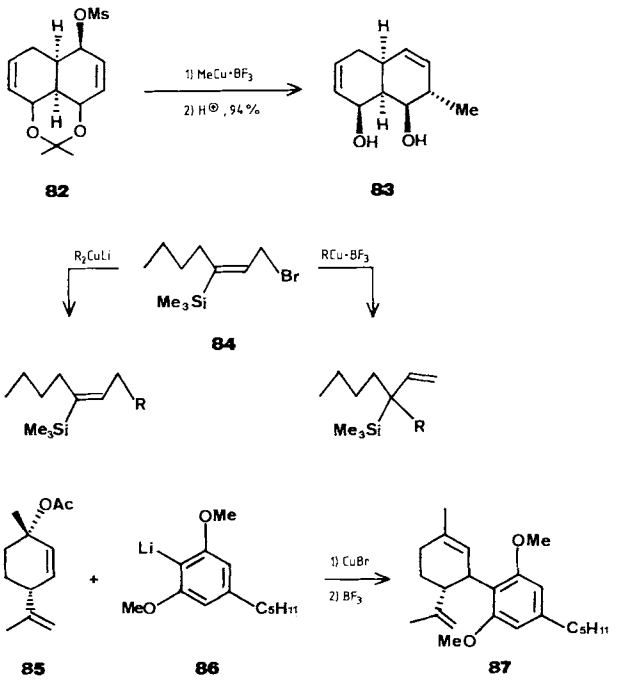
Scheme 18. THF = tetrahydrofuran.

Stereoselectivities in conjugate additions to α,β-unsaturated ketones and esters with chiral centers at their γ- or δ-positions have been investigated on **8**–**10**, **17**, **22**, **24**, **51**, **55**, and **60**. In addition, the stereochemistry of the protonation of enolates such as **53** and **59** obtained by conjugate addition have also been studied. Furthermore, the stereochemistry of the 1,4-addition of $RCu \cdot BF_3$ to the acyclic enoate **76** has also been studied;[47] reaction of **76** with $BuCu \cdot BF_3$ afforded **77** in good yields, though reaction with Bu_2CuLi gave poor results. The *syn*/*anti* ratio of **77** was ca. 7 : 3 regardless of the structure of R. The stereochemistry can be explained with the eclipsed model **78**: The protonation of the copper enolate occurs from the less hindered side, thus leading predominantly to **77-syn**. A similar eclipsed model can be applied to the methylation of the lithium enolate **79**; the methylation occurs from the less hindered side, leading to formation of **77-syn**/**anti** in the ratio 3 : 7 (Scheme 19).



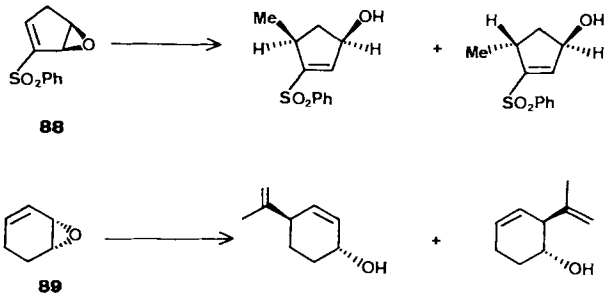
Scheme 19.

5. Regioselective Alkylation of Allylic Derivatives



The γ-alkylation of allylic halides, alcohols, and their derivatives with $RCu \cdot BF_3$ is a highly regioselective process.[4,48] As expected the substitution reaction of **80** with $BuCu \cdot BF_3$ proceeds via an *anti*-S_N2' mechanism, while that of **81** proceeds via a *syn*-S_N2' mechanism. The surprising *syn*-S_N2' mechanism observed in the reaction of **81** is

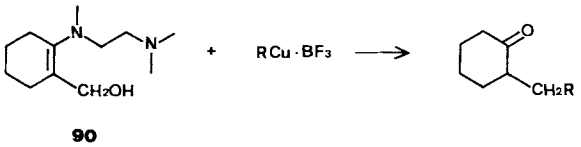
presumably due to the coordination of $RCu \cdot BF_3$ to the OH group. Other organocopper reagents do not react with allylic alcohols (Scheme 20).



Scheme 20. X = halide, OH, OAc, etc.

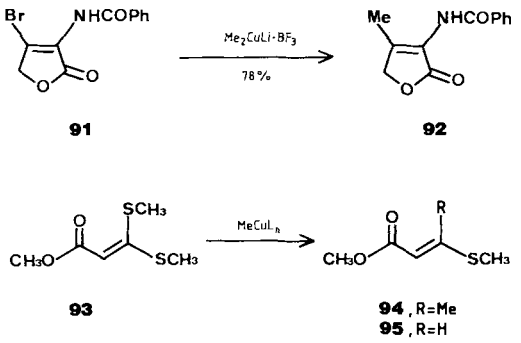
Although treatment of **82** with Me_2CuLi gave the S_N2-type product, the *anti*-S_N2' reaction took place with $MeCu \cdot BF_3$ to give **83**.[49] Similarly, **84** reacts with $RCu \cdot BF_3$ via an S_N2' mechanism, but with R_2CuLi via an S_N2 mechanism.[50] In this case, the γ-substitution product was also obtained with RCu itself. The cuprate, $aryl_2CuLi$, derived from **86** did not react with **85**, whereas the complex $aryl_2CuLi \cdot BF_3$ did so, to give the *anti*-S_N2' product **87** in 78% yield, which was further transformed into tetrahydrocannabinol (Scheme 21).[51]

Scheme 21. Ms = methanesulfonyl.



Reaction of the allylic epoxide **88** with $MeCu \cdot AlMe_3$ afforded the *anti*-S_N2' product, while reaction with $MeLi \cdot LiClO_4$ furnished the *syn*-S_N2' product.[52] Presumably the MeLi reagent coordinates to the epoxide oxygen, resulting in the *syn* attack; in contrast, such coordination is not observed in the case of $MeCu \cdot AlMe_3$ and **80**, **82**, or **85**. Treatment of **89** with $RCu \cdot BF_3$ again gave predominantly the *anti*-S_N2' product, along with the *anti*-S_N2 isomer; better regioselectivities were obtained with RCu(CN)Li than with $RCu \cdot BF_3$ (Scheme 22).[53]

	Yield			
$MeCu \cdot AlMe_3$	80%	<2	:	>98
$MeLi \cdot LiClO_4$	81%	95	:	5
	Yield			
$RCu \cdot BF_3$	26%	62	:	38
$RCu \cdot PBu_3$	23%	29	:	71
RCu(CN)Li	75%	75	:	25



Scheme 22. R = isopropenyl.

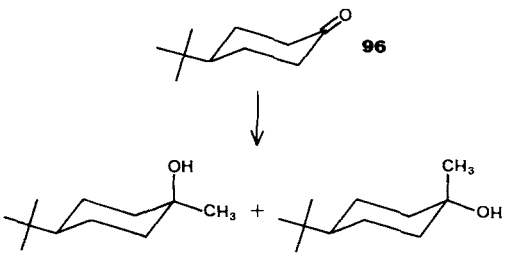
Although RCu · Lewis acid reagents generally react γ-regioselectively with allylic derivatives, α-substitution is also observed, e.g., in the case of the γ-acetoxy-α,β-enoate **48**.[34,35] In this respect, the α-selectivity of the γ-hydroxy-α,β-enoate **54** is also interesting. Further, the α-substitution of the enamine alcohol **90** with $RCu \cdot BF_3$ has been reported recently;[54] the α-alkylated ketone was formed in good yields (Scheme 23).

Scheme 23. R = *n*Bu, 76% yield; R = *t*Bu, 54% yield.

Replacement of halogen at the β-position of α,β-unsaturated γ-lactones such as **91** proceeded quite smoothly with $Me_2CuLi \cdot BF_3$.[55] With Me_2CuLi, on the other hand, **92** could be obtained only in low yield (<30%), and with Me_3CuLi_2 or $MeLi \cdot BF_3$ it could not be obtained at all. Treatment of **93** with Me_2CuLi afforded **94** (16%) and **95** (61%); the amount of **94** could not be increased even on using $MeCu \cdot BF_3$.[56] It is anticipated that the yield may be improved by use of $Me_2CuLi \cdot BF_3$ (Scheme 24).

Scheme 24.

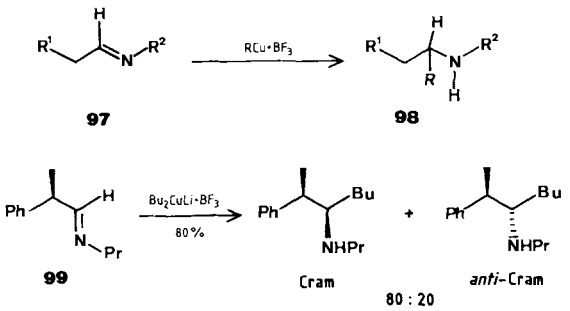
6. Selective Reactions with Carbonyl Compounds, Schiff Bases, Epoxides, Aziridines, Ethers, Acetals, Orthoformates, and Pyridinium Salts



Very high chemoselectivity towards carbonyl groups can be realized with $RCu \cdot BF_3$ (Table 3).[6] Thus, propanal undergoes butylation almost exclusively in the presence of cyclohexanone.

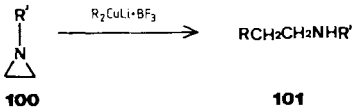
Table 3. Chemoselectivity of some reagents towards carbonyl groups: reaction of a 1 : 1 propanal/cyclohexanone mixture.

Reagent	Molar ratio Educt : Reagent	Yield [%]	Propanal derivative : Cyclohexanone derivative
$BuCu \cdot BF_3$	1 : 2	95	95 : 5
$BuCu \cdot BF_3$	1 : 1	70	99 : 1
Bu_2CuLi	1 : 1	92	76 : 24
BuMgBr	1 : 1	91	88 : 12
BuLi	1 : 1	88	46 : 54



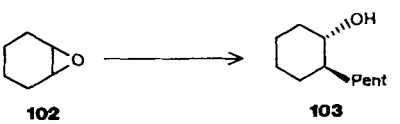
The stereoselectivity of the 1,2-addition was studied on the cyclic system **96**, but it was low in comparison to that observed in the reaction with MeLi or $MeLi \cdot AlEt_3$ (Scheme 25).

$MeCu \cdot BF_3$	68	:	32
MeLi	84	:	16
$MeLi \cdot AlEt_3$	87	:	13



Scheme 25. Molecular ratio **96** : reagent (from top downwards): 1 : 3, 1 : 1, 1 : 1.

In general, the alkylation of Schiff bases with conventional organometallic compounds does not proceed smoothly; the reaction is often accompanied by α-deprotonation. However, **97** could be smoothly converted into **98** in high yields with $RCu \cdot BF_3$;[57] with RMgBr, RCu, or R_2CuLi, the desired product (**98**) was not obtained. $R_2CuLi \cdot BF_3$ was effective for the alkylation of sterically bulky Schiff bases, which do not react with $RCu \cdot BF_3$. The diastereofacial selectivity of the chiral Schiff base **99** was investigated by reaction with $Bu_2CuLi \cdot BF_3$; the ratio of Cram to *anti*-Cram compound (4 : 1)[58] was very close to that found in the butylation of the corresponding aldehyde (Scheme 26).



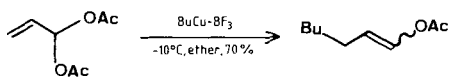
Scheme 26.

The alkylation of an ordinary aziridine with ring opening could not be accomplished with MeLi or RMgX. The alkylation of a strained tricyclic *N*-acylaziridine, however, was achieved with R_2CuLi in 15% yield. With $R_2CuLi \cdot BF_3$, the alkylation of **100** proceeded quite smoothly to give **101** in moderate to high yields (Scheme 27).[59]

Scheme 27. R = Me, Bu, Ph; R' = Me, Bu; yield 56–97%.

The stereoselective ring-opening alkylation of epoxides with $R_2CuLi \cdot BF_3$ takes place rapidly even at −78 °C.[60] For example, reaction of **102** with $R_2CuLi \cdot BF_3$ (R = pentyl) afforded **103** in 92% yield even at −78 °C, while the reaction with R_2CuLi or with $R_2Cu(CN)Li_2$ required higher temperatures and a prolonged reaction time (Scheme 28). $R_2Cu(CN)Li_2 \cdot BF_3$ was also found to be suitable for the stereoselective ring-opening alkylation of epoxides.[19] Unfortunately, however, **102** does not undergo such a ring opening reaction with $Me_3Si(PhS)CHCu \cdot BF_3$.[63]

			Yield
$R_2CuLi \cdot BF_3$	−78 °C, ether	10 min	92%
R_2CuLi	0 °C	2 h	97%
$R_2Cu(CN)Li_2$	−20 °C	2 h	95%

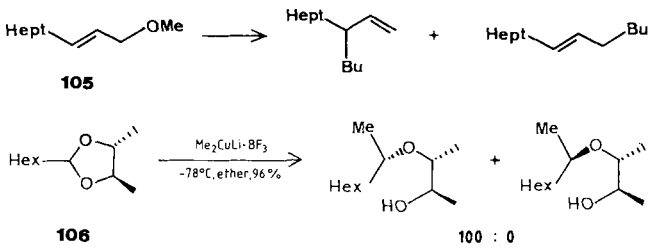


Scheme 28. R = *n*-pentyl. Molar ratio **102** : reagent (from top downwards): 1 : 1, 1 : 5, no data.

Whereas RCu and R_2CuLi are inert towards acetals, $RCu \cdot BF_3$ and $R_2CuLi \cdot BF_3$ react quite rapidly at low temperatures to give the monoalkylation product.[60] Ortho-

esters were likewise found to undergo monoalkylation at low temperatures. While reaction of the allyl acetate **104** with R_2CuLi furnished a mixture of S_N2- and S_N2'-type products, reaction with $RCu \cdot BF_3$ selectively afforded the S_N2' product (Scheme 29).[61]

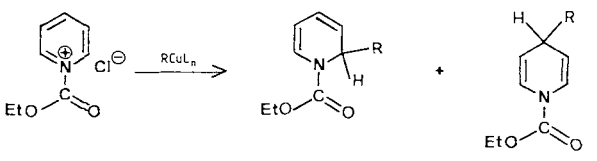
$$MeCH(OEt)_2 + PhCu \cdot BF_3 \xrightarrow[30\ min,\ 89\%]{-30\,^\circ C,\ ether} PhMeCHOEt$$



$$HC(OEt)_3 + n\text{-}C_7H_{15}Cu \cdot BF_3 \xrightarrow[20\ min,\ 88\%]{-20\,^\circ C,\ THF} n\text{-}C_7H_{15}CH(OEt)_2$$

104

Scheme 29.



Reaction of the allylic ether **105** with $RCu \cdot BF_3$ proceeded predominantly via an S_N2' mechanism, while the substitution with $R_2CuLi \cdot BF_3$ furnished the S_N2 product.[61] Generally, the reaction of common allylic acetals with $RCu \cdot BF_3$ preferably leads to the S_N2' product, while reaction with $R_2CuLi \cdot BF_3$ preferentially affords the S_N2 product.[61] The chiral acetal **106** reacts with $R_2CuLi \cdot BF_3$ quite smoothly with 100% diastereoselectivity (Scheme 30).[62]

	Yield			
$BuCu \cdot BF_3$	82%	87	:	13
$Bu_2CuLi \cdot BF_3$	35%	2	:	98

Scheme 30. Molar ratio **105** : reagent (from top downwards): 1 : 2, 1 : 1.

Organometallic compounds, such as RLi, RMgX, and RCdX, add preferentially at the 2-position of pyridine derivatives. In contrast, organocuprates react predominantly at the 4-position to give 4-substituted pyridines. The highest regioselectivity was realized in the reaction of **107** with $RCu \cdot BF_3$.[64] The alkylation products (**108** and **109**) were not obtained at all upon reaction with BuLi, while reaction with $BuLi \cdot BBu_3$ furnished a mixture of **108** and **109** in acceptable yield (Scheme 31).

107 **108** **109**

	Yield			
$PhCu \cdot BF_3$	94%	1	:	99
Ph_2CuLi		10	:	90
$BuLi \cdot BBu_3$	58%	38	:	62

Scheme 31.

7. Organocopper-Lewis Acid Reagents: Past and Present

Only two organocopper-Lewis acid reagents, $RCu \cdot BF_3$ and $RCu \cdot BR'_3$, appeared in *Posner*'s book in 1980.[5] Since then, a number of new types of complex reagents have been developed (Table 4). For highly selective transformations, the organocopper- and related organometallic-Lewis acid complex reagents will become increasingly important. In fact, $RLi \cdot BF_3$ and lithium enolate $\cdot BF_3$ reagents have recently been developed, which have already proven to be very useful.

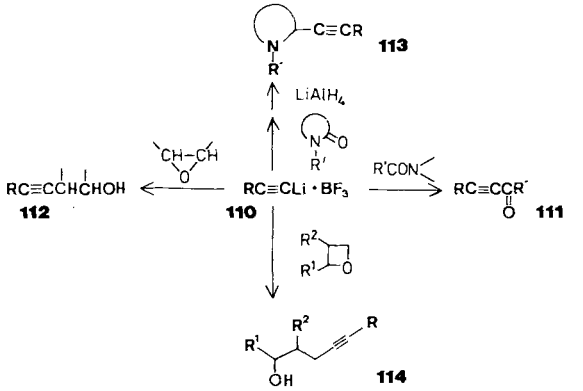


Table 4. Types of organocopper-Lewis acid reagents.

$RCu \cdot BF_3$,	$R_2CuLi \cdot BF_3$	$R_2Cu(CN)Li_2 \cdot BF_3$
$RCu \cdot BF_3 \cdot PBu_3$,	$RCu \cdot BF_3$(HMPA)	
$RCu \cdot BR'_3$

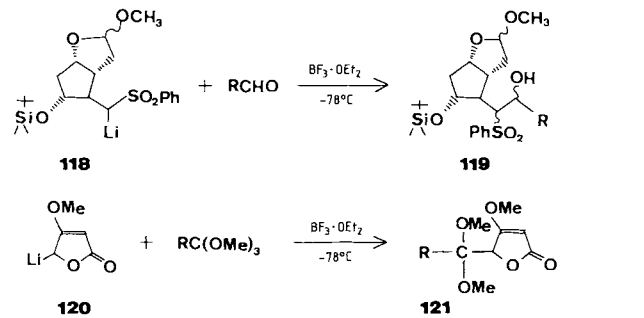
8. Organolithium $\cdot BF_3$ Reagents and Related Species

The complex reagents **110**, prepared in situ from lithium acetylides and BF_3 at $-78\,^\circ C$ in THF, react with tertiary amides at this temperature to give the corresponding alkynyl ketones **111** in high yields.[65] The formation of tertiary alcohols by further addition of the acetylide to the ketones was not observed. Oxiranes underwent ring-opening alkynylation under mild conditions to afford the alcohols **112** in high yields.[66] With other metal acetylides, the ring-opening reaction requires longer reaction times and/or higher temperatures and even then the yields are low. Alkynyl azacycloalkanes **113** were obtained in good yields by 1,2-addition of **110** to lactams followed by $LiAlH_4$ reduction of the adducts.[67] This transformation can not be achieved with the usual lithium or magnesium acetylides. Oxetanes react with **110** to give the compounds **114** in high yields.[68] Upon reaction with magnesium acetylides, considerable amounts of halohydrins were obtained as by-products; no reaction takes place with lithium acetylides (Scheme 32).

Scheme 32.

In the presence of catalytic amounts of trimethylgallium (0.08 equiv.) lithium acetylides react with epoxides to give **112** in good to excellent yields.[69] The addition of lithium acetylide to (20*R*)-20-hydroxypregnane-20-carbaldehyde **115** in the absence and in the presence of BF_3 gave predominantly **116** and **117**, respectively.[70] This finding provides a solution to the partial synthesis of either the ecdysone or the 22-epiecdysone side chain (Scheme 33). Formation of **116** can be explained in terms of a nucleophilic attack on the chelated substrate from the less hindered side (*Cram*'s cyclic model). In the presence of BF_3, the hydroxy group is presumably converted into an ate complex prior to nucleophilic addition. Consequently, the cyclic model is no longer applicable to the reaction of **110** with **115**; a non-cyclic mechanism (*Felkin*'s mechanism or *Cram*'s dipolar model) may be involved.



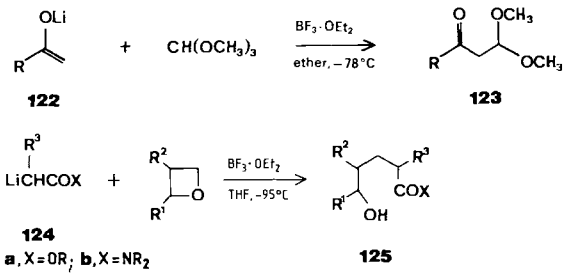
115 **116** **117**

	Yield			
RC≡CLi	91%	2.3	:	1
RC≡CMgBr	76%	6.9	:	1
110	40%	—		100

R = tetrahydropyranyl–O–CMe_2

Scheme 33.

Treatment of the lithiated sulphone **118** with aldehydes gave at best traces of the desired product **119**. Addition of $BF_3 \cdot OEt_2$ to **118** (1 : 1) prior to the addition of aldehydes resulted in formation of **119** in over 90% yield.[71] Similarly, the reaction of **120** with trimethyl orthoformate proceeded smoothly to give **121** in high yield; **121** was not obtained, however, when BF_3 was not present[72] (Scheme 34).

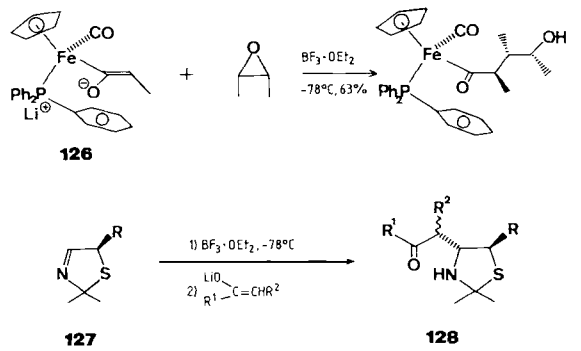


118 **119**

120 **121**

Scheme 34.

Reaction of the lithium enolate **122** with trimethyl orthoformate in the presence of BF_3 led to formation of the corresponding α-dimethoxymethyl ketone **123**.[73] The yield strongly depends on the manner and sequence of mixing of the reagents. BF_3 should be added in one portion to a solution of **122** and the orthoformate in ether. Prior mixing of **122** and BF_3 results in a drastic decrease in product yield. Oxetanes were allowed to react with compounds **124a** and **124b**, generated from esters and amides, respectively; in the presence of BF_3, the δ-hydroxyesters **125a** and amides **125b**, respectively, where formed in high yields (Scheme 35).[74]



122 **123**

a, X = OR; **b**, X = NR_2

125

Scheme 35.

(*Z*)- and (*E*)-2-Butene oxides underwent S_N2 ring opening upon reaction with the lithium enolate **126** obtained from $[(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_3)COCH_2CH_3]$ in the presence of $BF_3 \cdot OEt_2$.[75] Lithium enolates react with dihydrothiazolene **127** in the presence of $BF_3 \cdot OEt_2$ to give the 1,2-adducts **128** in good yields (Scheme 36).[76]

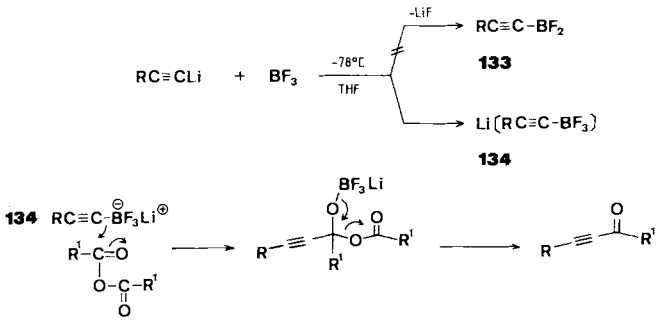
9. Mechanism of BF_3-Catalyzed Reactions of Organometallic Compounds



We have seen that combination of BF_3 with moderately basic main-group nucleophiles such as organocopper- and alkynyllithium compounds, lithium enolates, and stabilized lithium derivatives, leads to new reagents which exhibit synthetically useful selectivities and reactivities. However, the mechanisms according to which these new complex reagents react still remain unclear. With the aid of ^{11}B-NMR spectroscopy, *Ganem* et al. have recently established that RLi and $BF_3 \cdot OEt_2$ are reasonably stable together at low temperatures and react independently as potent nucleophile and strong Lewis acid, respectively.[77] In the reaction of RLi · BF_3 with epoxides and related electrophiles, coordination of the Lewis acid to give **129** takes place first and this is then followed by the nucleophilic addition of RLi to give the alkyltrifluoroborate **130**. The complex **130** undergoes attack by residual RLi much more rapidly than does $BF_3 \cdot OEt_2$; as a result tetraalkylborate **131** and lithium alkoxide **132** are formed. The intermediates **130** and **131** were detected by ^{11}B NMR spectros-

copy (Scheme 37). Substituted fluoroboranes such as RBF_2 or R_2BF would logically seem to be reactive intermediates; however, neither species convert epoxides into the corresponding alcohols, even in the presence of added LiF or $BF_3 \cdot OEt_2$.

Scheme 37.

Likewise with the aid of ^{11}B-NMR spectroscopy, *Brown* et al. have revealed that the real intermediate in the reaction of lithium acetylide with carboxylic acid anhydrides in the presence of $BF_3 \cdot OEt_2$ is not the alkynyldifluoroborane **133**, but the ate complex **134**.[78] Presumably the lithium alkynyltrifluoroborate **134** then reacts with anhydrides to give alkynyl ketones in very high yields (Scheme 38).

Scheme 38.

10. Conclusion

It is now clear from ^{11}B-NMR investigations that RLi and BF_3 can coexist at low temperatures, and that the coordination of BF_3 to heteroatoms (O, N, etc.) enhances the reactivity of nucleophiles (simple activation mechanism). As an alternative possibility, the ate complex like **134** may play a role in the BF_3-promoted reactions (ate-complex mechanism).

On the other hand, with regard to the $R_2CuLi \cdot Me_3SiCl$ reagent, *Corey* et al. state that the effect of the trimethylsilyl group is not due to prior complexation of Me_3SiCl with the carbonyl oxygen of the educt.[23] They suggest that the Cu^{III}–Si bond which would result from coupling is quite weak compared to the Si–Cl bond, making for a relatively low rate of replacement of chlorine by copper. Therefore, R_2CuLi and Me_3SiCl can presumably coexist in solution, but the activation of electrophiles as observed in the BF_3-promoted reactions is not expected since the coordination of Me_3SiCl is only very weak. Consequently, as a third possibility, the synergistic effect of substrate-Lewis acid-organometal complex should be considered (the synergistic mechanism or ternary-complex mechanism).[79]

From the synthetic point of view, the organometal-Lewis acid reagents are becoming increasingly important as a new synthetic tool; complex reagents other than organocopper-Lewis acid compounds should also be explored.[80] The types of complexes known so far are summarized in Table 5.

Table 5. Complex reagents formed by combination of nucleophiles and Lewis acids.

	Nucleophile		Lewis acid	Complex reagent
soft	$-C{=}C-O-Si$	hard	$TiCl_4$	[1]
↑	$-C{=}C-CH_2-Si$	↑	$TiCl_4$	[2]
	RCu		BF_3, $AlCl_3$ (solid)	$RCu \cdot BF_3$, $RCu \cdot AlCl_3$
	R_2CuLi			$R_2CuLi \cdot BF_3$, $R_2CuLi \cdot Me_3SiCl$
			BR'_3, AlR'_3	$RCu \cdot BR'_3$, $RCu \cdot AlR'_3$
	$-C{=}C-O-Li$		Me_3SiCl	$-C{=}C-O-Li \cdot BF_3$
	$-C{\equiv}C-Li$			$-C{\equiv}C-Li \cdot BF_3$
hard	RLi	soft		$RLi \cdot BF_3$

In the development of new complex reagents the following considerations can be used as a guideline: Combinations of soft nucleophiles and hard Lewis acids or of hard nucleophiles and soft Lewis acids seem to be compatible at low temperature, and to function as new complex reagents. Hard nucleophiles and hard Lewis acids readily undergo transmetalation reactions, even at low temperatures. Consequently, combinations along this line may produce a new complex reagent. Moreover, organometal-multidentate Lewis acid systems may exhibit interesting properties, since such Lewis acids could interact simultaneously with nucleophiles and with electrophiles.

Our work was supported primarily by the Ministry of Education (Japan). My thanks are due to my students for their intelligent questions and comments, especially H. Yatagai, S. Yamamoto, and Y. Ishihara. I would also like to thank Prof. T. Ibuka and Prof. R. W. Hoffmann for helpful discussions, and Mrs. T. Furuta and H. Azami for their help in the preparation of the manuscript.

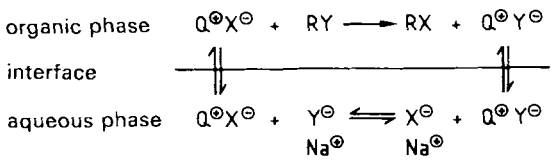
Hydroxide Ion Initiated Reactions Under Phase Transfer Catalysis Conditions: Mechanism and Implications

New Synthetic Methods (62)

By Mordecai Rabinovitz,* Yoram Cohen, and Marc Halpern

The development of Phase Transfer Catalysis (PTC) represents a major step forward in the employment of many organic reactions and renders them very convenient and useful processes. These reactions involve the application of nucleophiles in general, anions and bases in particular, in reactions carried out in a water-organic solvent system. They can be performed both in the laboratory and on an industrial scale. The ease of application of PTC processes is the main reason for their increasing utilization in industry. An outstanding achievement of this technique is the employment of aqueous bases in reactions which traditionally would otherwise require a strong base in a nonaqueous medium. The classical procedures that require severe anhydrous conditions, expensive solvents and dangerous bases such as metal hydrides and organometallic reagents are now replaced by aqueous solutions of, e.g., sodium or potassium hydroxides (PTC/OH processes). In contrast to the extensive synthetic applications of PTC/OH systems, the detailed mechanisms of these processes have been the subject of a great deal of controversy and various mechanisms have been suggested. However, it would seem that our knowledge concerning the mechanistic aspects of such reactions has now reached the stage where it can be used to advantage in synthesis planning. A better understanding of the various factors which influence the reaction would undoubtedly help to optimize PTC/OH processes such as to enable higher yields in shorter reaction times at lower temperatures. The importance of, inter alia, the catalyst will be pointed out and it is highly recommended that such catalysts be always available in the laboratory, for the range of organic reactions that they can efficiently, conveniently and safely catalyze is vast indeed.



1. Introduction

Phase transfer catalysis (PTC)[1] enables reactions between anions or molecules soluble in one phase (usually aqueous) with organic substrates soluble in an organic phase. Typical examples are listed in Table 1.

Table 1. Selected applications of phase transfer catalysis with hydroxide ions (PTC/OH) or other ions (PTC/X).

PTC/OH	PTC/X
Alkylation (C-, N-, O-)	Halide exchange
Carbene addition	Esterification
Elimination	Other nucleophilic Substitution
Condensations	($CN^{\ominus}$, $RS^{\ominus}$, $N_3^{\ominus}$, $SCN^{\ominus}$, etc.)
(Wittig, Aldol, Darzens)	Oxidation
Michael addition	Reduction
Hydrolysis	Benzoin condensation
Deuterium exchange	Asymmetric induction
Isomerization	
Organometallic applications	

The key factor in such PTC systems is the catalyst. The most commonly used catalysts are quaternary ammonium and phosphonium ions ("quats"),[1] crown ethers,[2] cryptates,[3] and open chain polyethers.[4] The action of the catalyst may be illustrated as in the elegantly simple Scheme 1 proposed by *Starks*.[1] The quat-anion ion pair, $[Q^{\oplus}X^{\ominus}]$, possessing ionic character may be soluble in an aqueous phase. On the other hand, the alkyl chains of the quat lend the ion pair an organophilic nature and therefore may be soluble in an organic phase as well. The quat is said to "extract" the anion from the aqueous phase into the organic phase in the form of an ion pair, via an equilibrium process. The anion, once in the organic phase, may react with an organic substrate. The negatively charged leaving group $Y^{\ominus}$ pairs with the quat cation $Q^{\oplus}$ forming an ion pair, $[Q^{\oplus}Y^{\ominus}]$, which may again equilibrate between the two phases. If the aqueous phase is charged with an excess of the reacting anion, $X^{\ominus}$, for example, the quat may preferably associate with $X^{\ominus}$ and another cycle, initiated by the presence of $[Q^{\oplus}X^{\ominus}]$ may follow.

Scheme 1. The extraction mechanism [1].

The extraction mechanism and its modified form, in which the quat need not enter the aqueous phase but rather exchange $X^{\ominus}$ for $Y^{\ominus}$ at the interface,[5] has explained the behavior of hundreds of reactions with scores of participating anions.

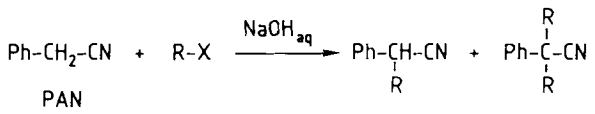
The concept of phase transfer catalysis is widely established in the literature and several excellent reviews[6–8] and monographs[9–11] have been published. Among the most outstanding achievements of PTC is the employment of aqueous sodium hydroxide as a base[12] in organic systems instead of the classical alkali metal alkoxides, amides and hydrides. However, it was realized quite early that the mechanism believed to operate for most PTC systems, i.e., the extraction mechanism (cf. Section 3) could not explain the behavior of those PTC systems involving the hydroxide ion. Therefore, another mechanism, namely the interfacial mechanism, was suggested (cf. Section 2). At present, PTC/OH systems operating via different mechanisms are known. In the present review, the characterization and implications of the mechanisms of hydroxide ion initiated reactions performed under phase transfer catalysis conditions ("PTC/OH systems") will be outlined. The favorable price and availability of the quaternary ammonium and phosphonium ions ("quats") renders them catalysts of choice, both in research as well as in industry. For this reason we chose to concentrate in this article on PTC/OH systems in which "quats", $Q^{\oplus}$, serve as catalysts. The two major PTC/OH mechanisms will be presented, together with supporting evidence drawn from the literature regarding their validity, and criteria for the determination of the mechanism valid for a particular reaction will be suggested. The implications of this knowledge will be discussed with the purpose of providing the synthetic organic chemist with a tool for evaluation and optimization of new potential applications of the PTC/OH method.

2. The Interfacial Mechanism

2.1. General

At first it was assumed that PTC/OH reactions proceed via a mechanism in which the hydroxide ion is extracted from aqueous NaOH into the organic phase.[13] Later, *Herriott* and *Picker* reported values for the distribution coefficients of various quaternary ammonium hydroxides between 2 M NaOH and benzene.[14] These values were determined by the HCl titration of the organic phase aliquots containing the quat and equilibrated with the aqueous NaOH. *Dehmlow* also employed this method for the determination of $[Q^{\oplus}OH^{\ominus}]$ concentrations in organic phases. However, *Brändström* warned that such determinations may be erroneous because of the possible presence of other contaminating bases in the medium (R_3HNX in R_4NX) resulting primarily from the catalyst's synthetic history or possible decomposition.[15] Reliable values for extraction constants of quaternary ammonium hydroxides, E_{QOH}, are thus hard to obtain, and, in benzene, cannot be precisely calculated even for lipophilic catalysts such as tetrapentyl or tetrahexylammonium hydroxide.[16] E_{QOH} for tetraheptylammonium hydroxide has been estimated to be 1.2 in benzene.[16] Tetrabutylammonium hydroxide (Bu_4NOH, TBA) is a quat frequently employed in PTC/OH reactions and does not exhibit a measurable ability to extract the hydroxide ion into benzene.[16] This would suggest that the classical catalyst for PTC/OH reactions, i.e. triethylbenzylammonium (TEBA), which is more hydrophilic than TBA, would extract hydroxide to an even lesser extent. Interestingly, TEBA induces enhanced reactivity in hundreds of PTC/OH reactions,[12] whereas nucleophilic substitutions performed in the presence of this catalyst proceed slowly if at all.[14] As these nucleophilic substitutions have been well characterized as extraction mechanism systems it was assumed that another mechanism must be involved in PTC/OH reactions with such hydrophilic catalysts as TEBA. Many other arguments were advanced against the hydroxide extraction mechanism, such as the complicated kinetics of PTC/OH reactions (compared to the simple pseudo-first or second order kinetics associated with the extraction mechanism) and the strong dependence of the reaction rate on stirring speed (compared to the independence of extraction systems on stirring speed). *Makosza* therefore proposed an alternative mechanism for PTC/OH systems called the "interfacial mechanism"[12] (see Scheme 2).

Scheme 2. The interfacial mechanism [12].



According to the interfacial mechanism a molecule of an organic substrate RH in the organic phase located near the interface, is deprotonated by the hydroxide ion, also located near the interface but within the aqueous phase (Step 1). An ion pair, $[Na^{\oplus}R^{\ominus}]$, is thus formed at the boundary and as such is insoluble in both phases. The anchored $[Na^{\oplus}R^{\ominus}]$ remains at the interface until the catalyst cation $Q^{\oplus}$ draws the organic anion deep into the bulk organic phase in the form of a new ion pair $[Q^{\oplus}R^{\ominus}]$. The quat's previous counteranion, $X^{\ominus}$, is simultaneously liberated into the aqueous phase (Step 2). Finally, $[Q^{\oplus}R^{\ominus}]$ reacts with a substrate R'Y to produce the product R-R' (Step 3) and the $[Q^{\oplus}Y^{\ominus}]$ thus formed may reenter a new catalytic cycle.

2.2. Evidence for the Interfacial Mechanism

Despite the relatively large number of reactions in which the interfacial mechanism is believed to be operative, only a few kinetic investigations have been carried out in this area. The reason for this may lie in the difficulty of per-

forming a comprehensive kinetic study due to the complexity of the kinetics of interfacial phenomena.

The importance of interfacial phenomena in the alkylation of phenylacetonitrile (PAN) was demonstrated by performing the reaction in the absence of catalyst (Scheme 3).[17] From the fact that the alkylation takes place, it may be concluded that the substrate is deprotonated at the phase boundary without the mediation of the catalyst.[17]

Scheme 3. Alkylation of phenylacetonitrile (PAN).

The resulting organic anion in this non-PTC system likewise reacts with the alkyl halide at the interface, as witnessed by the relative insolubility of $[Na^{\oplus}R^{\ominus}]$ in either phase (sodium ions are detected in the organic phase at a concentration of 5 ppm and PAN is detected in the aqueous phase at less than 2 ppm[17]). Under PTC/OH conditions, the deprotonation of PAN (Step 1, Scheme 2) was shown to be a fast equilibrium process. The absence of a kinetic isotope effect in the butylation of PAN in the presence of butyltriethylammonium bromide indicates that the acidic C-H bond is not ruptured during the rate determining step.[18a]

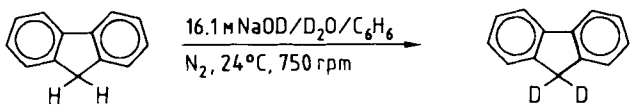


Figure 1 summarizes our results for the deuteration of fluorene. The results suggest that not only is Step 1 of the interfacial mechanism a fast equilibrium process, but also seems to constitute a necessary prerequisite for catalysis.[18a] This may be concluded from the observation that an induction period exists when the aqueous base is added last, but no induction period is observed when the catalyst is added last to a preequilibrated reaction mixture (Fig. 1).

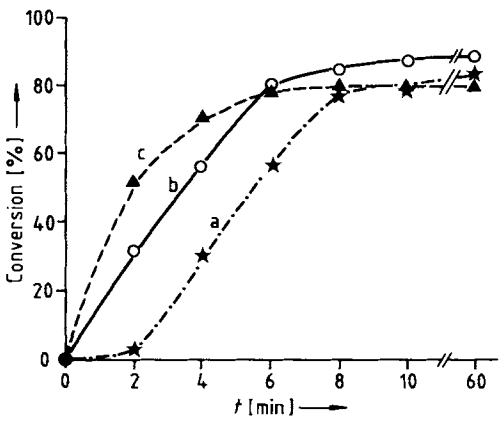

Fig. 1. Reaction profile of the deuteration of fluorene: a) $NaOD/D_2O$ added last; b) [TEBA] added after 20 minutes equilibration between organic and aqueous phase; c) as in (b) but for [TEBA] with $Br^{\ominus}$ instead of $Cl^{\ominus}$ as gegenion [18].

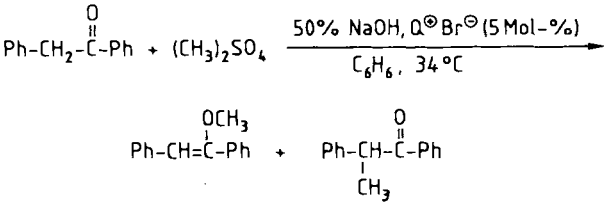
Indeed, it would seem that the role of the catalyst in this system (and probably in most PTC/OH systems) is to shift the equilibrium of fluorenyl anion formation at the interface to the right (Step 1, Scheme 2) by removing the organic anion into the organic phase (Step 2, Scheme 2). This would result in greatly increasing the quantity of fluorenyl anion in the overall system, and hence in increasing the rate of deuteration.

The dependence of the reaction rate on catalyst concentration was investigated for the ethylation of PAN.[19] A bilogarithmic plot of the reaction rate vs. the concentration of catalyst gave a straight line over a wide range of catalyst concentrations, but the slope was 0.6. This result suggests that the chemical reaction (Step 3, Scheme 2) is not the sole rate determining step. This is in contrast to simple nucleophilic substitutions in which the observed reaction rate is *linearly* dependent on catalyst concentration as found in the extraction mechanism (Section 3.2).[14,20-22] It was also found that, within a limited number of experiments (only three), the initial rate of reaction was linearly dependent upon both the PAN and the ethyl bromide concentrations. This may suggest that both the substrate and the alkylating agent participate in the rate determining step,[19] but it should be noted that only a very narrow range of molar ratios was investigated in this case.



It has been reported that the rate of an interfacial reaction is proportional to the speed of stirring in the range of 600 up to 1700 rpm.[23] This criterium is a powerful one in detecting interfacial phenomena because it is easy to measure; one has only to repeat an experiment while varying the speed of stirring. Indeed, in the reaction of dihalocarbenes in the presence of haloform, 50% aqueous NaOH and TEBA as catalyst, stirring speeds of 750–800 rpm were needed[24] in order to obtain reproducible results. That the rate strongly depends on the speed of stirring is a clear indication of the validity of the interfacial mechanism in this case.[19] The rate of ethylation increases continuously even up to stirring speeds of 1950 rpm.

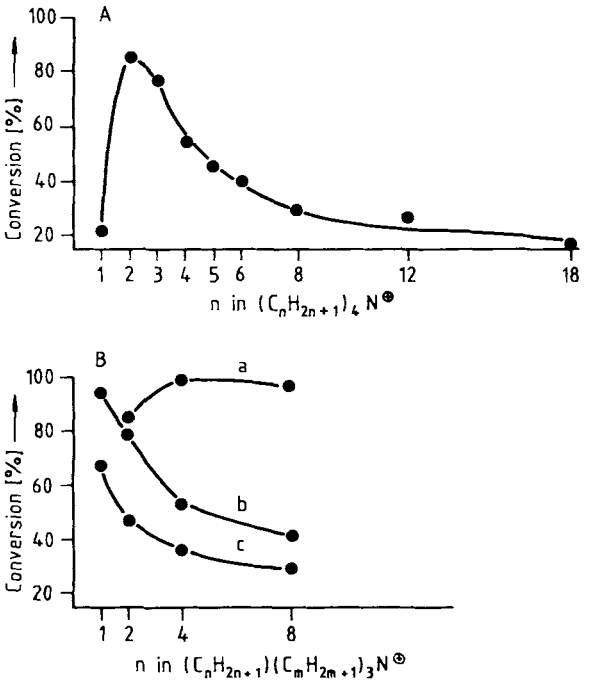
2.3. Effect of Catalyst Structure

The quaternary ammonium cations, "quats" ($Q^{\oplus}$), of the general class alkyltriethylammonium have been empirically found to induce maximum reactivity in PTC/OH systems.[12,24-27] Such small and frequently hydrophilic quats are known to be ineffective catalysts for most PTC reactions not involving the hydroxide ion.[14] Indeed, the enhanced reactivity observed for PTC/OH reactions in the presence of quats such as TEBA or methyltributylammonium encouraged the search for and acceptance of an alternate mechanism to the extraction mechanism.

The key role of the catalyst in the interfacial mechanism is believed to be detachment of the organic anion formed at the interface from its anchored position at the phase boundary by forming the ion pair $[Q^{\oplus}R^{\ominus}]$, which is subsequently drawn into the bulk organic phase. To do this the quat must successfully compete with the alkali metal cation for association with the organic ion. It has been suggested that as the alkyl chains of the quat decrease in length, the positive charge on the central nitrogen is more

electrostatically available (accessible) for interaction with the anion.[26] Thus, an ion pair consisting of an electrostatically available (accessible) quat and an organic ion will be of lower energy than a corresponding ion pair involving a quat having the positive charge buried deep within four long alkyl chains. Since the second and/or third step

(Scheme 2) of the interfacial mechanism is rate determining, the preferred interaction of the accessible quats with the organic anion promotes faster rates of reaction. Even when one of the four long alkyl chains of, e.g., tetraoctylammonium is replaced by one short alkyl group to produce, e.g., methyltrioctylammonium, a significant increase in the reactivity of the catalyzed system is observed (e.g., in the methylation of deoxybenzoin; see Fig. 2), testifying to



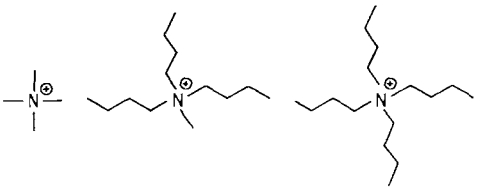


Fig. 2. Influence of quat structure on the reactivity of the alkylation of deoxybenzoin [26]. A) Conversions at 30 min for symmetrical quats of type $(C_nH_{2n+1})N^{\oplus}$; B) conversions at 30 min for nonsymmetrical quats of type $(C_nH_{2n+1})(C_mH_{2m+1})_3N^{\oplus}$, a) m = 2, b) m = 4, c) m = 8.

the importance of the accessibility of the positive charge of the central nitrogen. If the lengths of the alkyl chains are decreased to an extreme, e.g., tetramethylammonium, the ion pair $[Q^{\oplus}R^{\ominus}]$ will not be sufficiently organophilic to allow solubility of the ion pair in the organic phase. This will lead to a decreased rate of reaction similar to the case in which the non-catalyzed $[Na^{\oplus}R^{\ominus}]$ ion pair cannot enter the organic phase. Therefore, it may be concluded that the alkyltriethylammonium quats strike a near optimal balance between electrostatic availability (accessibility) of the positive charge and non-hydrophilicity. The structural demands of the optimal catalyst acting in an interfacial system are illustrated in Table 2.

Table 2. The structural demands of the quat in interfacial PTC/OH systems.

Catalyst			
Availability of positive charge	excellent	good	fair
Lipophilicity	very poor	moderate	good
Performance	poor	good	moderate

Enantioselective alkylations in the presence of chiral phase transfer catalysts have been reported showing some impressive results.[28-30] An enantiomeric excess of 92% has been achieved in the alkylation of an indanone derivative in the presence of benzylcinchoninium quats.[28] Consistent with the "three point interaction" theory for chiral recognition,[31] the planar indanone anion complexes with the chiral quat preferably on one side, on which two pi-complexation attractions and one hydrogen bonding provide a more stable ion pair. The correct stereopositioning of the hydroxy group is a necessary prerequisite for enantioselectivity. The presence of the hydroxy group in a related chiral phase transfer catalyst, benzylquininium, has been shown by comparing the asymmetric induction of reaction performed in the presence of this catalyst with the lack of asymmetric induction obtained in the presence of deoxybenzylquininium.[30] Thus, the effect of catalyst structure on the reactivity and selectivity of PTC/OH alkylations can be quite pronounced.

2.4. Effect of Water and Base Concentration

The role of water in interfacial PTC/OH systems is manifold, with two major effects particularly pronounced. First, the basicity of the hydroxide ion exhibited at the interface is strongly dependent on the aqueous base concentration.[19] As the concentration of base increases the extent of hydration of the hydroxide ion decreases and its basicity sharply increases. It has been estimated that the pK_a of water would be about 28 if the effect of hydrogen bonding of the surrounding hydration envelope could be isolated and removed.[32a] The proton affinity of the hydroxide ion at the interface is not totally uninfluenced by hydration, as water molecules are available for solvation from the nearby aqueous phase. The empirical upper limit found for substrate acidity in anionic reactions occurring via the interfacial mechanism lies at about $pK_a = 23$.[12] It is interesting to note that the following reaction (1) for NaOH[32b] happens to have an equilibrium constant of $K = 10^{-23}$:

$$2\,NaOH_{(s)} + H^{\oplus} \rightleftharpoons NaOH \cdot H_2O + Na^{\oplus} \qquad K = 10^{-23} \qquad (1)$$

This value hints at the upper limit of substrate acidity found, as it determines which substrates may form an ion pair, $[Na^{\oplus}R^{\ominus}]$, from thermodynamic considerations. Recently, a study on the efficiency of different bases for the alkylation of benzamide has been reported by *Dehmlow*.[33a] Although there is no clear-cut evidence for the reaction mechanism it seems reasonable that an interfacial process is operative as proposed by the authors.[33a] (The pK_a of benzamide is ≈ 20.[33b]) The main conclusion emerging from this publication is that the most effective base for carrying out dialkylation reactions is powdered KOH. It should be noted that for the above mentioned equilibrium for KOH the pK_a is about 31.[32b]

In the alkylation of PAN,[19] the effective kinetic order with respect to the hydroxide ion was found to be 5.3! This may be attributed to several factors, of which one is the strong dependence of the basicity of the hydroxide ion upon the extent of hydration. Undoubtedly, salting-out effects and other mass transfer effects are critical and result from the effect of water on the system.

The second factor is water of hydration, which can accompany organic anions as they are drawn from the interface into the organic phase,[34,35] just as inorganic anions carry with them hydration shells.[22] Hydration of organic anions in the organic phase may influence the reactivity and selectivity of alkylation reactions involving these anions.[34,35] The effect of water molecules on the reactivity of the fluorenyl anion has already been demonstrated.[35] Fluorene may be deuterated in the presence of TEBA, benzene, and 16.1 M NaOD at room temperature, but cannot be alkylated under the same conditions[18,35] (except in the presence of DMSO[36]). The fact that fluorene can be deuterated rapidly under these conditions suggests that the substrate is sufficiently acidic and that the interfacial deuteroxide ion is basic enough for interfacial deprotonation of the fluorene and that the catalyst is able to "detach" the organic anion from the interface. When fluorene is sugjected to the same alkylation conditions under which it is deuterated but substituting powdered NaOH for the base, alkylation proceeds in high yield.[35] The enhanced reactivity may be attributed to the decreased hydration shell of the fluorenyl anion in the system in which less water molecules are available, i.e. increased base concentration. Other alkylations have been credited with enhanced nucleophilicity due to decreased hydration.[36]

2.5. Effect of Anions

Many PTC/OH reactions are totally or partially suppressed by "catalyst poisoning".[13] This occurs in cases in which the deprotonated organic substrate[37] (when the interfacial mechanism is operative) or an extracted hydroxide ion[21,38] cannot compete successfully with a very lipophilic anion (e.g., iodide) for association with the quat in the organic phase. The lipophilic anion may have two sources: 1) as the counterion of the catalyst, or 2) as the leaving group eliminated from the substrate (for example in elimination reactions) or from an alkylating agent. In the second case, as the reaction progresses the concentration of the lipophilic anion increases. For this reason, one must carefully choose the leaving group liberated during the course of the reaction, i.e., one would prefer working with an alkyl chloride rather than an alkyl iodide, although the alkyl iodide is a better alkylating agent. The alkylation of PAN (which proceeds via the interfacial mechanism) was shown to be less sensitive to "catalyst poisoning" by two orders of magnitude relative to that expected theoretically if one assumes the extraction mechanism to be applicable in this case.[19] In general, it may be stated that in interfacial PTC/OH systems, the catalytic power of the quat is less hindered by the presence of lipophilic leaving groups than in the hydroxide extraction systems, since the organic anion $R^{\ominus}$ desired for reaction is inherently lipophilic in nature (much more than the hydroxide ion) and often competes successfully with other anions for association with the quat. Therefore, cases are known in which catalyst poisoning is not observed in the presence of the iodide anion.[39]

In the case of deuteration[18] it was shown that the initial rate of reaction was faster in the presence of bromide relative to chloride, as demonstrated in Figures 1b and 1c.[18a] This may have to do with the need to solubilize the hydrophilic TEBA in the organic phase in step 1 (Scheme 2).

3. The Extraction Mechanism

3.1. General

The extraction mechanism (Scheme 1) has been well characterized by several comprehensive kinetic studies of nucleophilic displacements involving many inorganic anions other than the hydroxide ion (halide ions, cyanide, azide, thiocyanate, etc.).[14,20,22] In the extraction of hydroxide the role of the catalyst is to carry the OH-anion into the depth of the organic phase where the reaction occurs. These systems are characterized by simple pseudo-first or second order kinetics, first order kinetics with respect to catalyst, increased reactivity in the presence of organophilic quats, independence of reaction rate on stirring speed (above ca. 300 rpm), strong dependence of the progress of the reaction upon the lipophilicity of the anions present, and the extent of hydration of the inorganic anion reacting in the organic phase.[5,14,20,22]

The hypothesis of an interfacial mechanism for PTC/OH systems by *Makosza*,[12] and the recognition, first by *Dehmlow* et al.[16] and then by others, that the extraction coefficients of $[Q^{\oplus}OH^{\ominus}]$ into organic solvents are very low, has aroused much skepticism regarding the possible validity of the extraction mechanism for such systems by the scientific community. But, despite the well documented low extractability of the hydroxide ion by quats, a growing number of reports have appeared in which synthetic achievements have been attributed to $OH^{\ominus}$ extraction.[38,40-42] Indeed, the kinetic and other parameters characteristic of the extraction mechanism have been identified as valid in several PTC/OH systems.

3.2. Evidence for the Hydroxide Extraction Mechanism

As mentioned earlier, the kinetics of the PTC/OH systems investigated have been found to be complicated and include fractional order dependency on catalyst concentration and non-simple general kinetic orders.[19,27] Much of the difficulty of deciphering the kinetics of these systems lies in their complexity, which includes the liberation of leaving groups and parallel and sequential reactions. Ideally, the optimum choice of a model reaction for kinetic characterization should be as simple a chemical system as possible. Systems such as isomerizations and deuterations alleviate the need to deal with added complicated equilibria due to constantly changing anionic compositions or additional competing reactions.

A comprehensive kinetic study of the isomerization of allylbenzene has been performed under PTC/OH conditions (see Scheme 4). The dependence of the reaction rate and induction periods on the substrate concentration, catalyst structure, catalyst concentration, speed of stirring, temperature, catalyst counterion and aqueous hydroxide ion concentration are consistent with a hydroxide ion extraction mechanism.[21]

$$\mathrm{Ph\text{-}CH_2\text{-}CH{=}CH_2} \xrightarrow[\text{toluene}\\ 75^\circ C,\ 850\ rpm]{Q^{\oplus}Br^{\ominus}\ (5\ Mol\text{-}\%)\\ NaOH_{aq}} \mathrm{Ph\text{-}CH{=}CH\text{-}CH_3}\ (trans/cis)$$

Scheme 4. Isomerization of allylbenzene [21].

The isomerization reaction constituted the first PTC/OH reaction to exhibit simple pseudo-first order kinetics with respect to substrate. Assuming the extraction mechanism to be applicable, one would expect the rate of reaction to be dependent on the concentration of substrate and the concentration of the quat-hydroxide ion pair in the organic phase since they both participate in the rate determining step (an energy of activation of ca. 17 kcal/mol was found indicative of chemical reaction control). Indeed, first order dependence with respect to both substrate and catalyst was observed (Fig. 3). The concentration of the quat-hydroxide ion pair is expected to be at a low steady state level and enters into the observed rate constant k_{obs}:[21]

$$\begin{aligned} rate &= k_{obs}[allylbenzene] \\ k_{obs} &= k_{chem}[Q^{\oplus}OH^{\ominus}]_{org} \end{aligned} \qquad (2)$$

Further evidence for the validity of the extraction mechanism is the independence of the rate of reaction on stirring speed above ca. 300 rpm (Fig. 4). Similar results have been obtained by *Starks* et al.[20] and others[13,22,43] and reflect kinetic control by the chemical reaction in which $[Q^{\oplus}X^{\ominus}]$ is at a steady state concentration. Below 300 rpm the requirement for sufficiently rapid mass transfer of the reacting anion is not met and diffusion controlled kinetics is observed. At these low stirring speeds the induction period of the isomerization which is observed, is stirring-speed dependent and is attributed to the need for attaining a steady state concentration of hydroxide in the organic phase.[21]

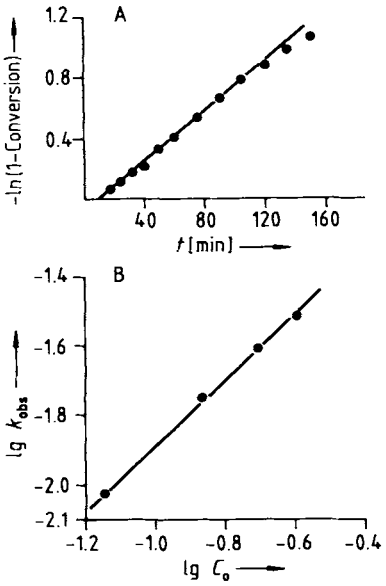

Fig. 3. A) Pseudo first order kinetics of the isomerization of allylbenzene under standard conditions [21] (cf. Scheme 4); B) determination of kinetic order with respect to the catalyst in the isomerization of allylbenzene (slope 0.97) [21]. C_0 = initial concentration of catalyst.

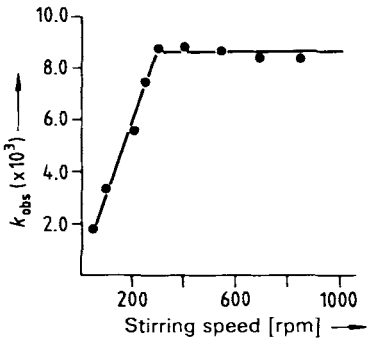

Fig. 4. Dependence of k_{obs} on stirring rate in the isomerization of allylbenzene [21] (cf. Scheme 4 and Table 3).

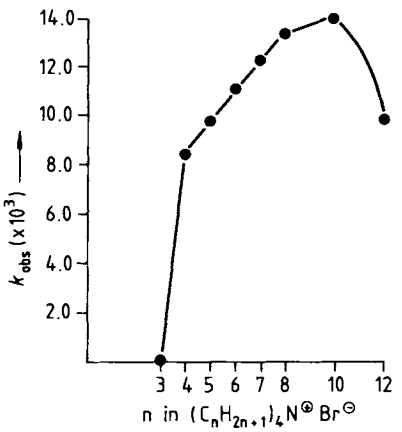
Other evidence in support of the extraction mechanism in this PTC/OH system lies in the dependence of the reaction rate on catalyst structure and the strong dependence of the reaction rate on the catalyst counterion (see Section 3.5). The behavior of this PTC/OH system with respect to the simple kinetics, catalyst structure and stirring-speed dependence is in direct contrast to the corresponding parameters which characterize the interfacial mechanism and is in direct correlation with the findings of the well documented extraction mechanism.[21]

3.3. Influence of Catalyst Structure

According to the extraction mechanism (Scheme 1) the main role of the catalyst is to extract the inorganic anion

into the organic phase. It has been shown that in S_N2-type reactions, the reaction rate increases as the organophilic character of the quat increases.[14,20,22] The extent of the extraction of the very hydrophilic hydroxide ion increases with the lipophilicity of the quat as demonstrated by *Dehmlow* et al.[16] In view of the above, it seems that the main structural demand of the quat in extractive systems is long alkyl chains. In the isomerization of allylbenzene a monotonic increase in the reaction rate was observed as the organophilicity of the symmetrical tetraalkylammonium quats increased (Fig. 5). The comparison of this observation with the effect of the catalyst structure in the interfacial mechanism (Fig. 2) is illustrative. This may be attributed to the increased solubility of the $Q^{\oplus}OH^{\ominus}$ ion pair in the non polar organic phase (e.g., tetrabutylammonium hydroxide may not be as soluble as tetraoctylammonium hydroxide in toluene). This would result in a greater observed rate constant since $[Q^{\oplus}OH^{\ominus}]_{org}$ enters into this term [see equation (2)]. Increasing the accessibility (electrostatic availability) and decreasing the organophilicity of a quat by replacing a long alkyl chain by a methyl group, e.g., by use of methyltrioctylammonium instead of tetraoctylammonium, results in a decrease in the rate of reaction. Again, this demonstrates the need for at least two PTC/OH mechanisms to be considered. Quats below a minimum organophilicity, such as tetrapropylammonium, are completely ineffective in this extractive system.[21]



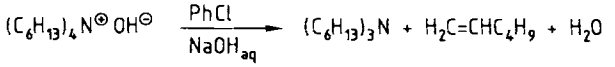


Fig. 5. Dependence of k_{obs} on quat structure in the isomerization of allylbenzene [21] (cf. Scheme 4 and Table 3).

3.4. Influence of Water and Base Concentration

Under liquid-liquid phase transfer catalysis conditions the anions transferred by the quats to the organic phase are solvated by a limited number of water molecules.[5,20,22,44] *Landini* et al. showed that the hydration number of the quat-anion ion pair depends largely on the nature of the anion.[5,20] The hydration number appears to be related to the size of the anion and its charge dispersion.[45] It has been suggested that hydration is one of the major factors that determines the nucleophilicity and reactivity orders of different inorganic anions in PTC systems. In anhydrous homogeneous solution the reaction rates are faster than in the two phase systems. It was possible to simulate these rate constants when the experiments were repeated in water-containing homogeneous systems.[22] The hydroxide ion is a small hard anion with barely any charge dispersion so one would expect it to be solvated to a great extent in water/organic solvent systems. At high NaOH concentrations only low concentrations of water molecules are available for concurrent transfer with the hydroxide ion into the organic phase. Varying extents of hydration of the hydroxide ion in the organic phase may significantly alter the basicity of the hydroxide ion. Indeed, the fact that allylbenzene ($pK_a = 34$[46]) may be deprotonated under PTC/OH conditions demonstrates the enhanced basicity of the extracted hydroxide relative to the interfacial hydroxide ion by a factor of at least eleven orders of magnitude. This assumption recently received strong support in a quantitative way in an elegant work published by *Landini* et al.[47] They examined the reactivity of $OH^{\ominus}$ as a function of its hydration sphere in the Hofmann elimination of tetrahexylammonium hydroxide in chlorobenzene (see Scheme 5). In the range of NaOH concentrations examined, the measured rate constants span up to four orders of magnitude. The basicity enhancements obtained by reducing the hydration sphere of the hydroxide ion from an average value of 11 to 3.5 molecules of water, is much more pronounced than those previously found in the dehydration of other anions.[48,49] This means that the basicity of the hydroxide ion may be dramatically increased when there are no water molecules available to solvate the hydroxide ion. In order words, we can say that we approach here the term "naked ion". The data presented by *Landini* and *Maia*[47] are comparable to those measured by *Bohme* et al.[50] on "real naked hydroxide ions" in the gas phase. The data confirm that gas phase reactivity can be approached by desolvating the anions in nonpolar organic solvents. This may explain, in part, the high sensitivity of the isomerization of allylbenzene[21] or H/D exchanges in weak CH-acids[51,52] to the NaOH concentration. In the case of the isomerization of allylbenzene, the effective kinetic order with respect to aqueous NaOH concentration was found to be 5.0. This result is similar to that obtained for the interfacial alkylation of PAN[19] and probably reflects similar phenomena (enhanced basicity, salting out, etc.), although it might be expected that enhanced basicity plays a special role in the deprotonation of very weak CH-acids.

Scheme 5. Hofmann elimination of tetrahexylammonium hydroxide [47].

3.5. Effect of Anions

The hydrophilicity of the hydroxide ion and the difficulty of its extraction into non polar organic solvents has been emphasized. It is a hard base and associates poorly

with the relatively soft quats, especially in the presence of other softer anions like bromide or iodide. It is therefore understandable that extractive PTC/OH reactions are subject to "catalyst poisoning" even more than the reactions which proceed via the interfacial mechanism. Such behavior has been demonstrated by the effect of counteranion on the rate of isomerization of allylbenzene. In the presence of a hundredfold excess of hydroxide over the catalyst counterion a change from $HSO_4^{\ominus}$ (effective ion: $SO_4^{2\ominus}$) to $Br^{\ominus}$ resulted in a fiftyfold decrease in the rate of reaction (Table 3). Despite the much greater solubility of tetrabutylammonium bromide in toluene, more hydroxide is

Table 3. Dependence of the rate constant k_{obs} on catalyst counterion in the isomerization of allylbenzene [21] (cf. Figs. 4 and 5) [a].

Catalyst	k_{obs} ($\times 10^3$)	Induction period [min]
$Bu_4N\ HSO_4$	114	<0.1
$Bu_4N\ Cl$	24	1.3
$Bu_4N\ Br$	2.4	10

[a] Reaction conditions: 1.42 M allylbenzene in toluene, 5 mol-% catalyst, 40% NaOH, 75 °C, 850 rpm.

extracted into the organic phase in the case of tetrabutylammonium hydrogensulfate. The order of lipophilicity $SO_4^{2\ominus} < Cl^{\ominus} < Br^{\ominus}$ also determines the ease of achieving the steady state concentration of $Q^{\oplus}OH^{\ominus}$ in the organic phase, as can be seen in a corresponding trend in the induction times.[21]

3.6. Examples of PTC/OH Extraction Systems

In Table 4 are shown some representative examples of synthetic applications that may proceed via a hydroxide ion extraction mechanism. The applications of PTC/OH under extractive conditions have been singled out since it

Table 4. Examples of reactions proceeding via a hydroxide ion extraction mechanism.

No.	Reaction	Conditions	Ref.
1	$R-CHBr-CHBr-R' \rightarrow R-C\equiv C-R' + 2HBr$	$Bu_4N^{\oplus}HSO_4^{\ominus}$ (300 mol-%), 50% NaOH, pentane, CH_2Cl_2, 20 °C	[38]
2	$R-C_6H_4OCH_2CH_2X \rightarrow R-C_6H_4OCH=CH_2 + HX$	$Bu_4N^{\oplus}HSO_4^{\ominus}$ (100 mol-%), 50% NaOH, benzene, 20 °C	[40]
3	As in reaction 1	$Octyl_4N^{\oplus}Br^{\ominus}$ (5 mol-%), solid KOH, petroleum ether, 80 °C	[41]
4	$ROOC-(CH_2)_n-COOR \rightarrow Na^{\oplus\ominus}OOC-(CH_2)_n-COO^{\ominus}Na^{\oplus}$	$Q^{\oplus}X^{\ominus}$ (1 mol-%), 50% NaOH, petroleum ether	[42]
5	Thiazole → 2-deuteriothiazole	$Bu_4N^{\oplus}HSO_4^{\ominus}$, NaOD/$D_2O$ (17 M)	[53]
6	$Ph-CH_2-CH_2-Br \rightarrow Ph-CH=CH_2 + HBr$	$Octyl_4N^{\oplus}Br^{\ominus}$ (5 mol-%), 50% NaOH, 75 °C, 750 rpm	[55, 56]
7	$p\text{-}Br-C_6H_4-CHCl-CH_3 \rightarrow p\text{-}Br-C_6H_4-CH=CH_2 + HCl$	$Q^{\oplus}X^{\ominus}$ (5 mol-%), solid or 50% NaOH, 75 °C, 1000 rpm	[35]

appears that general awareness to reactions proceeding via hydroxide ion extraction is not widespread.

One may identify the first three dehydrobromination[38,40,41] reactions as proceeding via a hydroxide ion extraction mechanism by examining the nature and the quantity of catalyst employed. In the first two cases the need for using stoichiometric amounts of catalyst[38,40] indicate that catalyst poisoning prevents extraction of hydroxide ion in the presence of catalytic amounts of quat. Indeed, when one mole-equivalent of tetrabutylammonium bromide was used in the dehydrobromination of 1,2-dibromo-1,2-diphenylethane (cf. No. 1 and 3) only monodehydrobromination occurred, affording α-bromostilbene[35] (the stereochemistry of the reaction under PTC/OH conditions indicates that the E2 elimination mechanism is valid in this case[35]). *Dehmlow* et al.[41] overcame the catalyst poisoning problem by employing a very organophilic quat, tetraoctylammonium.

The dependence of the reactivity of the hydrolysis of esters (No. 4) on the quat structure and the counteranion suggest the validity of the hydroxide extraction mechanism in this case.[42] In the case of the deuteration of thiazoles (No. 5), the authors suggest that the interfacial mechanism is operative.[53] But it would appear that the hydroxide ion extraction mechanism is the more valid assumption as the reaction follows first order kinetics with respect to substrate, the pK_a of the substrates are high (ca. 29, i.e. >23, the limiting pK_a for interfacial mechanism), and the hydrophilic catalysts seem to be less effective.[53,54]

The dehydrobromination of phenethyl bromide (No. 6) proceeds more rapidly in the presence of tetraoctylammonium bromide than in the presence of benzyltriethylammonium bromide.[55,56] But the zero order kinetics observed in the presence of the former catalyst and the low energy of activation (ca. 8 kcal/mol) possibly suggest a hydroxide ion extraction mechanism governed by diffusion control.[55]

In the dehydrohalogenation of a 1-phenethyl halide, chloride was chosen as the leaving group instead of bromide.[35] Despite the better capability of bromide as a leaving group, the chloride allows a greater extent of hydroxide extraction, and hence the reaction does not slow down as much as in the presence of bromide while the reaction progresses; indeed, chloride was in fact found to be the preferred choice.

We have employed the extraction mechanism to expand the scope of compounds which undergo H/D exchange under PTC/OH conditions (up to $pK_a = 37$).[58] The enhancement of the basicity of the hydroxide ion was achieved by using powdered NaOD, a lipophilic quat (TBA) with a very hydrophilic counter anion e.g. $HSO_4^{\ominus}$.[51,52]

4. PTC/OH Mechanisms: Determination and Implications

4.1. Determination of the Mechanism in PTC/OH Systems

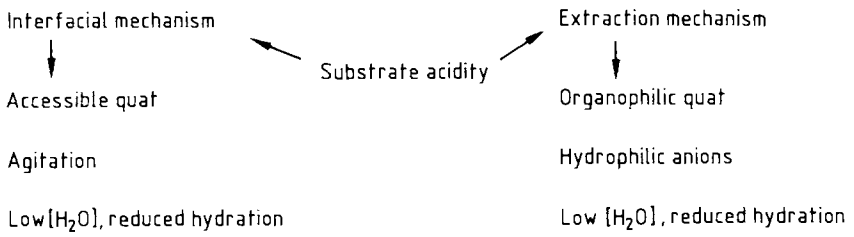
The properties that characterize the main PTC/OH mechanisms are summarized in Table 5. With the aid of

this table it is easily understood how one may determine the mechanism of a given PTC/OH reaction, and choose reaction conditions for new potential applications of PTC/OH reactions. In all cases in which the interfacial mechanism is operative, the accessible quats are the most efficient catalysts;[24,26,27] a strong dependence of rate on stirring speed may be observed,[19,24,39] and the kinetics are not simple with respect to substrate[18,19,27] or catalyst.[19,27] In contrast, the three characteristics of the extraction mechanism are: organophilic quats are the more efficient catalysts;[14,20,21] independence of rate on stirring speed above a low value;[14,20–22,37] and, very simple kinetics with respect to substrate and catalyst (cf. Fig. 5).[14,20–22]

Table 5. Characteristics of PTC/OH mechanisms.

Characteristic	Extraction Mechanism Controlled by		Interfacial Mechanism
	Chemical Reaction	Diffusion	
Quat structure	Organophilicity	Organophilicity	Electrostatic availability
Stirring speed	Independent (above need for mass transfer)	Varying dependence	Strongly dependent
General kinetic order	Simple (pseudo-first or second order)	Zero order	Complicated (must determine v_0)
Kinetic order catalyst	First order	Fractional	Fractional
Counterion effect (sensitivity to poisoning)	Strongly dependent	Strongly dependent	Moderately dependent
Aqueous $OH^{\ominus}$ concentration	Very strongly dependent	Very strongly dependent	Very strongly dependent
Substrate acidity	$23 \leqslant pK_a \leqslant 37$ $pK_a < 16$	$23 \leqslant pK_a \leqslant 37$ $pK_a < 16$	$16 < pK_a < 23$
Energy of activation	> 10 kcal/mol	< 10 kcal/mol	> 10 kcal/mol

[a] Above a limiting value necessary for minimal mass transfer.



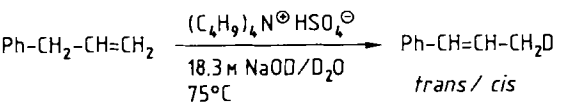
One may perform a simple experiment which allows for an educated guess in determining the valid PTC/OH mechanism of a given system. Two reaction vessels are set up next to one another under identical conditions, one containing an organophilic catalyst, such as tetraoctylammonium bromide or chloride, and the other containing an accessible (electrostatically available) catalyst, such as butyltriethylammonium bromide or chloride. If the organophilic catalyst induces the higher reactivity, then the extraction mechanism may be considered to be valid. One would expect to observe first order kinetics with respect to the substrate and the catalyst if the extraction mechanism is chemically controlled (not diffusion controlled). If the electrostatically accessible catalyst induces the higher reactivity, then the interfacial mechanism may be considered to be valid, and complicated kinetics are to be expected. An additional run at a significantly higher stirring speed would help differentiate between the two mechanisms, since the interfacial mechanism is strongly dependent on this parameter whereas the chemically controlled extraction mechanism is independent of the agitation efficiency (at least above a certain speed of stirring necessary for minimal extent of mass transfer). One may distinguish between the rare diffusion controlled mechanism and the other PTC/OH mechanisms by examining the kinetic order and energy of activation of the reaction. An energy of activation of above 10 kcal/mol suggests chemical control (etherification 14 kcal/mol,[37] alkylation 20 kcal/mol,[19] isomerization 17 kcal/mol[21]), whereas diffusion control exhibits an energy of activation under 10 kcal/mol (elimination 8 kcal/mol[55]).

4.2. Evaluation and Optimization of New Potential Applications of PTC/OH

In this section we would like to show how one can assess *a priori* whether or not a new potential application of PTC/OH is feasible, and, if so, how the reaction conditions can be optimized.

From Table 5 it may be concluded that it is possible to determine the mechanism of a given PTC/OH reaction with the aid of the first three criteria. But one additional critical parameter must be mentioned if an approach to the implementation of PTC/OH conditions is to be considered. This factor is the acidity of the substrate. It is possible to classify the substrates of PTC/OH reactions into four categories according to their pK_a values: a) $pK_a < 16$, b) $16 < pK_a < 23$, c) $23 < pK_a < 37$, d) $pK_a > 37$. In group (a) ($pK_a < 16$) the conjugate bases of the substrates are generally water soluble. In this case the deprotonation takes place in the aqueous phase and then the anion is extracted into the organic phase according to the extraction mechanism.[57] In group (b) ($16 < pK_a < 23$) we have two kinds of substrates: i) substrates that are water-soluble like alcohols; ii) substrates that are water-insoluble like PAN and fluorene. With water-soluble substrates, the extraction mechanism is usually operative. The $OR^{\ominus}$ anion formed in the aqueous phase is extracted into the organic phase and reacts with the electrophile. In contrast, if the pK_a of the substrate lies in the range between 16 and 23 and is not water soluble then it is likely that the substrate is acidic enough to be deprotonated by the hydroxide ion acting at the interface. An organic anion will then be produced which will subsequently react, and hydroxide ion extraction will be suppressed. If on the other hand, a stronger base is required to deprotonate the substrate ($23 < pK_a < 37$) then only the extracted hydroxide ion can be expected to be basic enough (due to its reduced hydration) to initiate the reaction (PTC/OH extractive mechanism is operative). If the pK_a of the substrate is greater than 37 it may be expected that the reaction will not succeed, judging by the data gathered hitherto; e.g., attempts to perform a deuterium exchange reaction of the benzylic protons of toluene have so far failed.[35]

Thus, we have experienced that the key to choosing initial reaction conditions for a PTC/OH reaction and deciding whether or not it is even worthwhile, is the acidity of the substrate (see Scheme 6). In our opinion, the acidity of the substrate should guide one to assessing which of the two PTC/OH mechanisms is likely to be valid for the PTC/OH reaction under consideration. Conversely, the synthetic implications of choosing one of the two mechanisms, result in totally opposite reaction characteristics.



Scheme 6. Approach to evaluation and optimization of new potential applications of the PTC/OH method.

If the pK_a of the substrate is between 16 and 23 and the substrate is not water soluble, the interfacial mechanism may be anticipated to be valid. In this case, an accessible (electrostatically available) quat should be chosen, preferably with one methyl group or three ethyl groups and the remaining residues butyl to octyl groups. One need not be too concerned about the nature of the counteranion, though one should avoid very lipophilic anions (e.g., iodide) unless the substrate to be alkylated is very lipophilic. Accordingly, secondary substrates such as alkylating agents may possess leaving groups as lipophilic as bromide or even in some cases iodide, but again, it is better to avoid the accumulation of ions that might compete with the organic anion for association with the quat. For a reaction expected to proceed via the interfacial mechanism one should choose a method of agitation which is as practical or economically feasible as possible. High nucleophilicity of the organic anion may be achieved by reducing the water content of the system (high $OH^{\ominus}$ concentration). One must be aware, though, of the increased sensitivity of the accessible (electrostatically available) quats to $OH^{\ominus}$-induced decomposition, especially at higher than ambient temperatures.

If a stronger base is required to deprotonate the substrate ($23 < pK_a \leq 37$), the extraction mechanism may be assumed to be valid. In this case, one should choose an organophilic quat, such as tetraoctylammonium. One should take great care in choosing a catalyst with hydrophilic counterion (e.g., $HSO_4^{\ominus}$), since hydroxide ion extraction is hindered by all but a few anions. A high NaOH concentration (even powdered NaOH) should be chosen so as to increase the basicity of the hydroxide ion. The choice of a bulky quat, such as tetraoctylammonium, will also decrease its susceptibility to Hoffmann elimination or nucleophilic degradation by the hydroxide ion. One need not invest great effort in maximizing mixing between the two phases, as this will not induce any additional reactivity above a certain easily attainable rate.

It may be noted that Aliquat 336 is an inexpensive commercially available catalyst (in tank-car quantities), which is electrostatically available enough to efficiently catalyze interfacial type reactions, and organophilic enough to efficiently catalyze extraction type reactions. The chloride counterion does not hinder the $OH^{\ominus}$ ion extraction very much. The disadvantages of Aliquat 336 lie in its difficulty of separation from the reaction mixture, since it is always soluble in organic phases and usually the product must be distilled out (industry) or separated by chromatography (laboratory). Its high molecular weight also reduces its cost effectiveness. Recently, methyltributylammonium chloride has been introduced commercially, and could prove to be a very efficient catalyst for interfacial type reactions.

PTC/OH conditions are subject to limitations. It is currently believed that the maximum pK_a for applicable substrates is ca. 37 (benzothiophene has been deuterated[58]). This limit may be illustrated by the fact that allylbenzene will isomerize and monodeuterate in the terminal position in the presence of 18.3 M NaOD/D_2O and tetrabutylammonium hydrogensulfate at 75°C.[51] This implies that allylbenzene is acidic enough to deprotonate under these conditions, whereas β-methylstyrene is not (cf. Scheme 7).

Scheme 7. Isomerization and deuteration of allylbenzene [51].

Another limitation of PTC/OH reactions is the temperature range in which quats may be used. Most PTC/OH reactions cease to be efficient at temperatures of 75–90°C due to catalyst decomposition. A possible solution to this problem may be the use of polyethylene glycols[59] or crown ethers,[2b] all of which are more thermally stable than the quats. Moreover, it has recently been reported that pyridinium salts are stable at high temperature and can act as phase transfer catalysts in the case of nucleophilic substitutions with phenoxide and thiophenoxide ions.[73]

Choosing a solvent still seems to be a matter of trial and error. Methylene chloride and aromatic hydrocarbons have generally proved to be suitable solvents, but it should be noted that solvents not commonly used have been quite efficient in certain systems (e.g., methyl isobutyl ketone).[35] It has been suggested that chloroform be avoided in reactions in which concentrated NaOH is used because of the possibility of carbene generation. Even methylene chloride has its drawbacks; it has been known to generate formaldehyde[16] or act as an alkylating agent in PTC/OH systems.[60] Esters are usually not suitable as they are subject to hydrolysis.

5. Summary and Outlook

Although many novel applications of PTC have been published, the great value of the PTC method lies in the

vast range of basic and common everyday reactions that can be performed in high yields, simply, inexpensively and with simple work-up procedures. In particular, PTC/OH applications are especially attractive to the chemist, and these have been reviewed extensively.[6,7,9,11]

In conclusion, we believe that an understanding of the mode of action of such a widely employed synthetic technique as PTC/OH is of great importance, for it can contribute greatly to the development of synthetic processes. In this review we have presented many specific aspects of PTC/OH mechanisms and have then endeavored to bring the accumulated knowledge into general perspective. Two major mechanisms are accepted for PTC/OH systems, the interfacial mechanism and the extraction mechanism. We consider it imperative to be aware that the two mechanisms have opposite characteristics, for, as we have seen, the outcome of many PTC/OH reactions may totally succeed or totally fail, depending on the reactions conditions employed. This holds true, in particular, regarding the great potential that lies uncovered in performing PTC/OH reactions under extractive conditions. Now that the distinction between the two mechanisms has been made we anticipate that the reaction of CH-acids of very low acidity under PTC/OH conditions will form the subject of numerous studies in the next few years.

Although a complete understanding of PTC/OH mechanisms is still far from having been reached we do at least now have a working knowledge of such systems. A knowledge of the mode of action of these systems has provided the chemist with a preliminary tool with which to evaluate and optimize new potential applications of these systems. Currently, there is a great momentum in the publications and patents relating to the application of PTC/OH conditions. We believe that the added mechanistic understanding presented in this review will help promote new avenues of application of PTC/OH in organic synthesis.

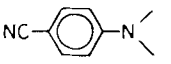
Charge Separation in Excited States of Decoupled Systems—TICT Compounds and Implications Regarding the Development of New Laser Dyes and the Primary Processes of Vision and Photosynthesis

By Wolfgang Rettig*

The understanding of the dual fluorescence of certain aromatic systems has greatly advanced in recent years. The accompanying large charge separation has been shown to be linked to a twisted (or small overlap) arrangement of the chromophores. Recent theoretical models are able to describe the excited-state twisting of both single bonds (TICT compounds) and double bonds (olefins) in a unified picture. These models can help to elucidate the photophysical behavior of many organic, inorganic, and biologically relevant compounds, and their application to laser dyes and fluorescent probes provides a route to new "tailor-made" fluorescent materials. Applied to the primary processes of vision and photosynthesis, these models can lead to a deeper understanding of basic photobiological processes.

1. Introduction

The separation of electrical charges is one of the processes upon which our existence depends and which is the basis for numerous present and possible future developments including organic conductors and superconductors as well as the production and storage of electricity. Most important, nearly all of earth's life forms use directly or indirectly the transformation of sunlight into chemical energy, which occurs via a charge-separation process.



Since charge separation on a molecular level is often involved, the study of model systems displaying charge separation is essential to understand the mechanisms involved. An especially powerful tool is provided if such charge-separated systems luminesce, because internal and environmental influences affect this luminescence in a characteristic way, yielding detailed information on thermodynamic, kinetic, and other photophysical and even photochemical properties of such species.

Some simple bichromophoric organic molecules form luminescent species that display the characteristic features of charge separation and are therefore well-suited model systems. For the majority of these systems, the charge separation is most favorable in a twisted conformation, where the two moieties involved in charge transfer, the donor D and the acceptor A, are orbitally decoupled, i.e., nearly perpendicular in the case of two π systems. Initially, this led to the notion of "twisted intramolecular charge transfer" (TICT) states.[1–4] Later, it was realized that many TICT states are nonluminescent and are responsible for the rapid nonradiative decay of numerous important dyes leading to intramolecular fluorescence quenching. Their involvement in excited-state processes of biologically important compounds is just beginning to be understood.

This article first gives a brief survey of the development of the concept of TICT states and of our present knowledge of the broad variety of systems that form such states. The properties of TICT states are then discussed and some important implications connected with the formation of TICT states are outlined.

2. The Concept of TICT States—A Historical Overview

More than twenty years ago, a simple benzene derivative, *p-N,N*-dimethylaminobenzonitrile 1 was discovered to behave peculiarly in fluorescence spectroscopy. *Lippert*

1

et al.[5] showed that it emits a dual fluorescence (Fig. 1) consisting of two bands, one being that "normal" for closely related benzene derivatives, the other, at considerably lower energy, being an "anomalous" one. *Lippert* et al.[5] proposed a solvent-induced reversal of excited states. The anomalous band was assigned to fluorescence from the more polar ^1L_a-type state, which is preferentially stabilized by solvation. This led to the nomenclature still in use today: A band for the "anomalous" emission from the ^1L_a-type state, B band for the normal short-wavelength emission from the ^1L_b-type state. The emitting states, also called A* and B* states, could be in thermal equilibrium. The kinetics of this process are summarized in Scheme 1,[1–2] which contains the equilibration rate constants k_{BA} (forward reaction) and k_{AB} (backward reaction) as well as the rate constants for radiative decay (k_f^B and k_f^A) and nonradiative decay (k_o^B and k_o^A) to the ground state. The scheme is very similar to that for excimer formation,[7] with the difference that three temperature-dependent rate

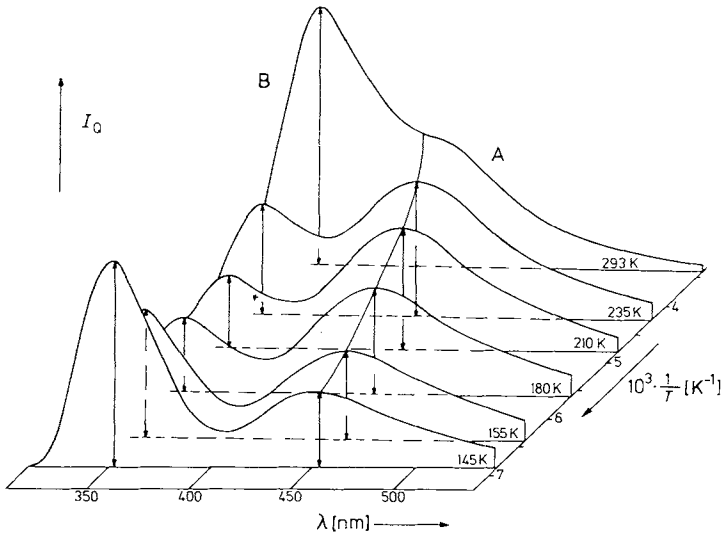
constants (k_{BA}, k_{AB}, k_f^A) are needed to explain the experimental observations.[1,2,6,8-10]



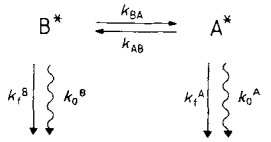


Fig. 1. Dual fluorescence of a 3×10^{-6} M solution of **1** in the medium polar, aprotic solvent *n*-butyl chloride as a function of temperature [6]. Both bands are independent of concentration and excitation wavelength over a large range. Upon increasing the solvent polarity, the longer-wavelength A band strongly shifts to the red and gains in relative intensity. The characteristic intensity minimum for the shorter-wavelength B band occurs at the temperature above which the excited B* and A* states reach a thermodynamic equilibrium B* $\rightleftharpoons$ A* during their nanosecond lifetime. Upon further increase of the temperature, this equilibrium is shifted toward B*, resulting in an increase of the total fluorescence quantum yield, because the deactivation of A*, unlike that of B*, occurs mainly via nonradiative processes. The slight increase of the quantum yield of the A fluorescence with temperature is due to the forbidden nature of this radiative process (hot fluorescence, see Fig. 10b). I_Q = number of quanta per nm and s.

Scheme 1.

As will be seen later, the above assignment to ^1L_a- and ^1L_b-type states is in fact true for **1** but breaks down for closely related compounds that emit a similar dual fluorescence. The excited-state reversal originally proposed by *Lippert* et al. is merely a manifestation of the underlying rules governing dual fluorescence of this type.

Rotkiewicz, Grellmann, and *Grabowski* were the first to suggest that these rules involved[11] a dynamic relaxation of **1** with internal twisting of the dimethylamino group, coupled with an electron transfer from the amino nitrogen to the far-away in-plane π_y^* orbital of the cyano group[11,12] or, in better agreement with later experiments, to the π_z^* orbital extending over the entire benzonitrile group.[1] Figure 2 shows schematically the two fluorescing species, the B* and the TICT state.

The suggestion of *Grabowski* et al. was at first mainly based on fluorescence polarization experiments in glycerol which showed that the two emission transition moments of **1** have the same polarization, along the axis connecting amino and cyano groups.[11] Thus, *Lippert*'s proposal of emitting ^1L_a- and ^1L_b-type states with perpendicular transition moments could not be true. For the same experiment in ethanol, however, the fluorescence polarization of the two bands is dissimilar, that of the B band being characteristic for a ^1L_b-type state with a transition moment perpendicular to the long molecular axis.[13] The B band in glycerol thus derives from a different state than in ethanol, namely from the ^1L_a-type state of the planar molecule, which is lower in energy than the ^1L_b-type one in this solvent. A similar case of solvent-induced level reversal in the nearly planar molecule has been found for a naphthalene analogue of **1**.[14-16] Level reversals of this type can also be induced by substituents. This is schematically shown in Figure 3.

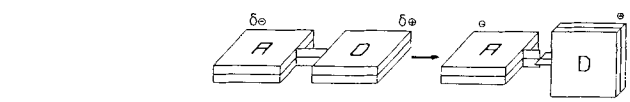

Fig. 2. Schematic representation of the change in geometrical arrangement of donor group D and acceptor group A upon going from the B* state to the TICT state. In the case of **1**, this transition involves (1) intramolecular rotation, (2) crossing of excited states and nonadiabatic coupling, (3) further charge transfer approaching a full electronic charge, and (4) relaxation of the polar solvent molecules around this increased dipole.

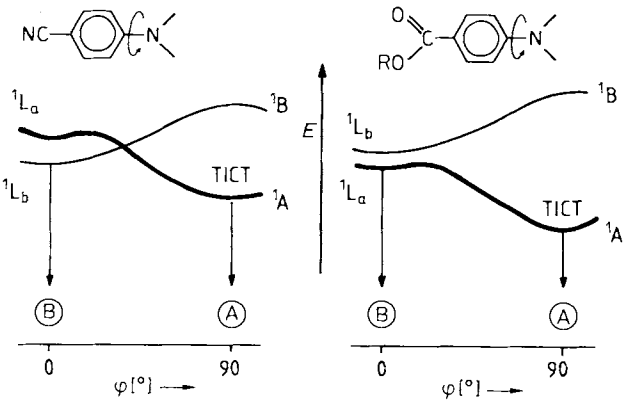

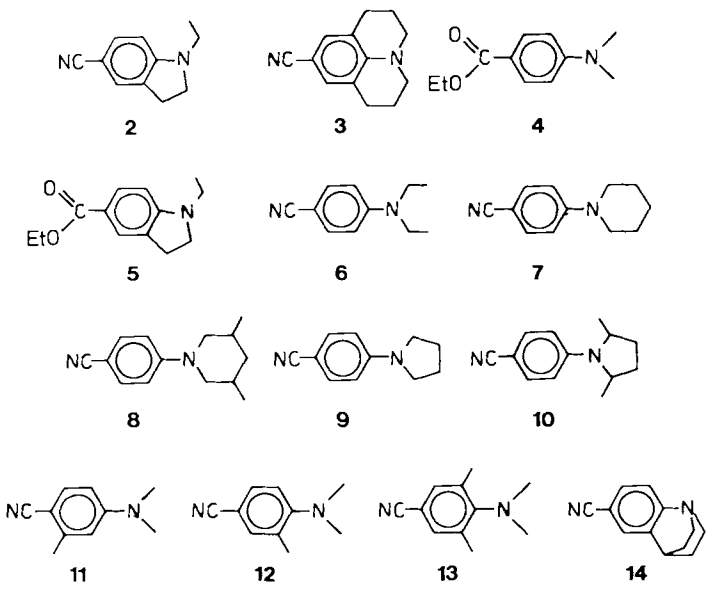

Fig. 3. *p*-Substituted dialkylanilines undergo substituent-induced level reversals for the excited states of the planar conformation. Upon going from the cyano to the alkoxycarbonyl derivatives, the ^1L_b-type state is shifted to higher energy, the ^1L_a-type state to lower energy compared with the nitriles [17]. Since both ^1L_a-type and TICT states are of symmetry species A (in the C_2 point group, which is valid for idealized nonpyramidal amino groups for any twist angle φ), they correlate without crossing (in the case of the alkoxycarbonyl derivatives) and with excited-state crossing (in the case of the cyano derivatives) [10, 15, 18]. As a result of the substituent-induced level reversal, the B fluorescence changes its nature. This can be followed by measurement of the fluorescence polarization and the rate constant for radiative decay [9, 10, 17]. Ⓐ = A band, Ⓑ = B band.

In a series of publications, *Grabowski, Rotkiewicz,* and co-workers presented convincing experimental proof for the twist hypothesis.[1-3,19,20] They synthesized model compounds for **1** where the dimethylamino group was rigidly held in the planar or perpendicular position, or where the planar arrangement of the dimethylamino group was increasingly hindered by *ortho* substituents in the benzene ring.[3] The bridged nitriles **2** and **3** as well as the ester **5** did not exhibit the A band in the fluorescence spectrum,[3,17,21] although they showed very similar absorption spectra. The fully perpendicular benzoquinuclidine **14**, on

the other hand, showed the A band but lacked the B band altogether.[19] Compounds with more flexible bridges were also synthesized by other groups.[22,23] These experiments clearly demonstrated that the possibility for reaching an orthogonal conformation of the dimethylamino group is a "sine qua non" for the occurrence of the A band.

In a different approach calling upon the dynamics of intramolecular twisting, the model compounds **7** and **8**[24] were found to exhibit similar electronic and steric properties, differing only in the size of the rotating volume. Figure 4 shows an example of such a "hydrodynamically" controlled dual fluorescence.

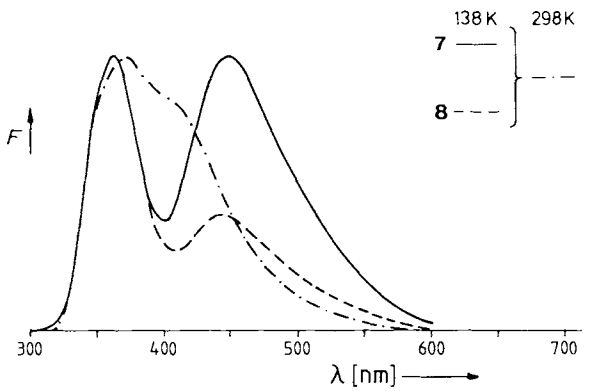

Fig. 4. Temperature dependence of the dual fluorescence of a pair of dynamically differing compounds, **7** and **8** (ca. 10^{-5} M in *n*-butyl chloride). At temperatures where the thermodynamic equilibrium $B^* \rightleftarrows A^*$ is established within the lifetime of the excited states, the dual fluorescences of **7** and **8** are identical. At low temperatures, however, the relative intensity of the TICT fluorescence of **8** is decreased considerably, which indicates slower formation of the TICT state A^* in **8** compared with **7** [24]. F = Fluorescence intensity in arbitrary units.

While these two approaches clearly show the necessity and the occurrence of intramolecular twisting in TICT formation, many factors are important in determining its actual rate. In a series of derivatives of **1** with different cyclic and open-chain alkyl substituents at the amino nitrogen (**6–10**), the rates (which differ by one order of magnitude) were shown to be governed by a complicated interplay of factors such as molecular flexibility, symmetry of the rotating moieties, the actual volume of solvent molecules displaced during rotation, and the mean ground-state twist angle (equal to the Franck-Condon twist angle, the starting angle for the relaxation in the excited state).[9,18,21,24]

The corresponding alkoxycarbonyl derivatives behave similarly.[18] However, the level crossing upon twisting, observed for **1**, is absent for the alkoxycarbonyl derivatives (Fig. 3), a fact that has profound effects on the potential hypersurfaces that ultimately govern all reaction dynamics. A qualitative drawing of these hypersurfaces is shown in Figure 5. Figure 6 displays the consequences for the dual fluorescence of these compounds.

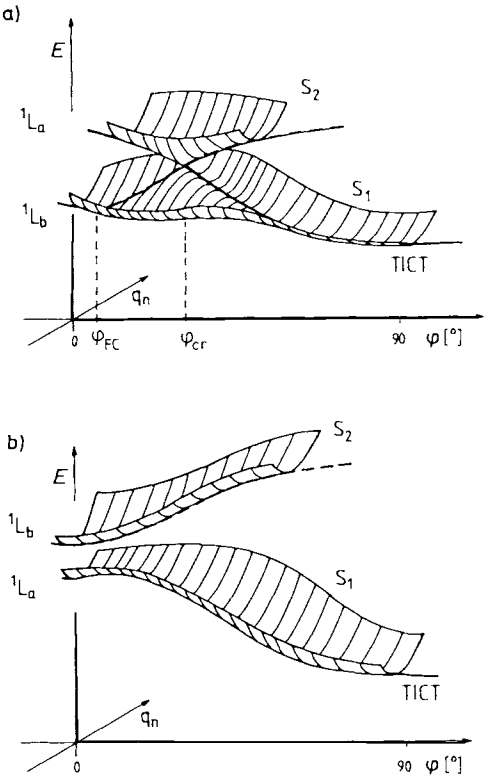

Fig. 5. Schematic representation of the potential hypersurfaces along the reaction coordinate toward the TICT state in *para*-substituted dialkylanilines [18]. a) In the cyano derivatives the crossing of ^1L_a- and ^1L_b-type states (cf. Fig. 3) causes a "conical intersection" at the critical twist angle ϕ_{cr} which necessitates the coupling with a non-totally symmetric vibration q_n or with solvent relaxation. b) For the alkoxycarbonyl derivatives, this coupling is not necessary; the reaction can proceed smoothly downhill (it is even possible that the indicated activation energy is not present). The experimental consequence is a readily observable TICT fluorescence even in nonpolar environments[9,18] and an increase of the rate constant k_{AB} for TICT formation by a factor of approximately 5 [18, 25]. A similar increase of k_{AB} should be expected for the CHO- and CRO-substituted anilines, but their weak fluorescence points to a complication by low-lying $n\pi^*$ states.

Recently, TICT emission in the gas phase was observed for **13**[26,27] and for an *N*-phenylpyrrole derivative (Fig. 7).[28] In each of these molecules, donor and acceptor are already strongly twisted in the ground state.

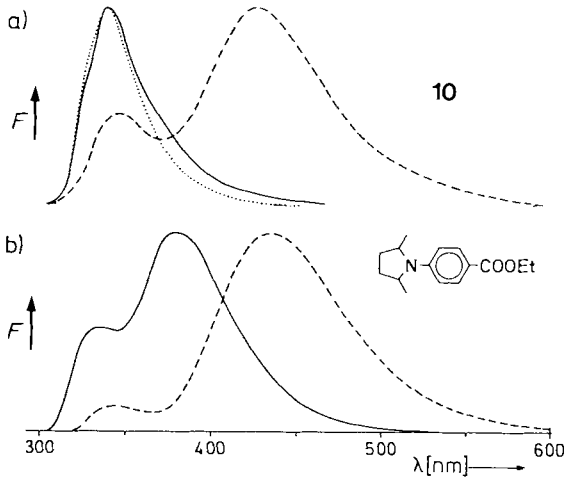

Fig. 6. Dual fluorescence spectra (a) of **10** and (b) of the corresponding alkoxycarbonyl derivative at room temperature [18] in *n*-hexane (——) and in *n*-butyl chloride (----). The TICT band for **10** in *n*-hexane is very weak (for comparison, the fluorescence spectrum of **1** in *n*-hexane is also shown, (·····)). The absence of the conical intersection, however, causes the TICT band to be the main fluorescence band for the corresponding alkoxycarbonyl derivative.

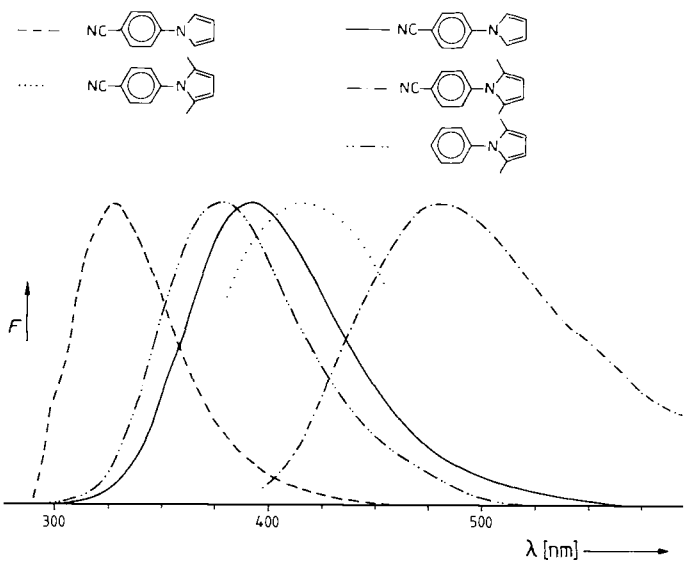

Fig. 7. TICT fluorescence bands of *N*-phenylpyrroles in *n*-butyl chloride (—, —·—, ··—··) and in *n*-hexane (----) at room temperature and in the gas phase at ca. 93 °C (···). The comparison of gas- and solution-phase spectra shows the stabilizing action of the solvent upon the fluorescent states. The concept of TICT states is not linked to the formation of specific solute-solvent interactions (ground-state complexes or exciplexes) and not even to the presence of a solvent at all. Increase of the acceptor strength (—·— versus ··—··) or of the donor capability (—·— versus ——) also lead to a lowering of the energy of the TICT state and a corresponding redshift of the emission (see Section 6).

3. Environmental Influences on TICT States

While it is perhaps most straightforward to learn more about the properties of TICT states by investigating them "naked" in the gas phase, most studies up to now have been done in solution, where the TICT molecule is surrounded by a swarm of more or less polar and polarizable solvent molecules, where specific solute-solvent interactions may play a role, and where the kinetics of formation may become strongly affected by cage effects (see Section 7 for the influence of free volume and microviscosity). In fact, because of these complications, the currently accepted notion of TICT states was slow to emerge.

In 1972, *Khalil, Hofeldt,* and *McGlynn*[29] repeated some of *Lippert*'s early experiments on **1** and found a third, longer wavelength emission band which they attributed to a ground-state dimer of **1**. The anomalous A band observed by *Lippert* et al. was assigned to an excimer, which was expected to form upon encounter of an excited molecule of **1** with a ground-state one.[29,30] Both the ground-state dimer and the excimer mechanisms would predict that the A band gains in relative importance if the concentration of **1** is increased. Although both mechanisms do actually take place for **1** and related molecules at high concentrations ($c \geq 10^{-4}$ mol/L),[31] or even for smaller ones at low temperatures,[32] *Mataga* et al.[33] showed that they are not the source of the anomalous A band. The ratio of fluorescence intensities of A to B, F_A/F_B, of a rigorously purified sample of **1** was independent of concentration over a range of more than two orders of magnitude. Moreover, the purified sample did not show the "dimer" emission reported by *Khalil* et al.[29] Thus, the latter was attributed to an impurity.

Kosower et al.[34] studied the effects of deuteration of the solvent on the ratio of the A to the B band in water and alcohols and concluded that the A band arises from a species protonated in the excited state. However, this mechanism could not explain the presence of the A band in rigorously dried aprotic solvents,[27,35] in saturated hydrocarbon solvents, or even in the gas phase. Although the deuterium effect has been observed by several other groups,[36,37] it does not necessitate a specific solute-solvent interaction for formation of the TICT state. For the deuterium effect to occur, it is sufficient that a competing kinetic process is isotope sensitive. A possibility for such a competing process is the photochemical reaction of excited **1** with an alcohol or water molecule to form a complex, which, in turn, decays to a thermally unstable ground-state product that rapidly reverts back to **1**. In fact, this possibility is supported by experimental data. Protic solvents strongly quench the total fluorescence yield of **1**, by a factor of about 10 for alcohols and even about 100 for water.[34] The quenching also takes place for the planar model compounds **2** and **5**.[17] Thus, it is not a feature specific for TICT states, but seems to be connected with the aromatic amine function. If substituent groups are absent altogether, as in TICT-forming biaryl systems, the quenching action of protic solvents is absent.[38,39]

Two additional ways in which the environment can affect the formation of a TICT state are outlined below. Both possibilities supplement but do not replace the twist mechanism and accompanying charge transfer accepted as the prerequisite for TICT-state formation.

Chandross[40] and later *Visser* and *Varma*[23,37,41] observed that the B band of **1** was strongly quenched as the amount of a polar solvent constituent in a mixture was increased. From a linear correlation of the F_A/F_B ratio with the concentration of polar solvent, the specific formation of a 1:1 exciplex of an excited molecule of **1** with one

polar solvent molecule was suggested.[23] This type of specific solute-solvent interaction may actually take place for certain solvents like alcohols[42-44] but is very unlikely to be a phenomenon generally linked with TICT emission on the following grounds: (1) There are some molecules that show TICT emission even in the gas phase. (2) The alkoxycarbonyl- and cyano-substituted dialkylanilines have fluorescence spectra in polar solvents that are similar,[18] and, moreover, the alkoxycarbonyl-substituted species show TICT emission even in aliphatic hydrocarbon solvents, where no specific interactions are possible (Fig. 6). (3) The fluorescence quenching of **1** by nitriles is of similar magnitude in high-viscosity paraffin as in low-viscosity hexane.[28] This suggests that the quenching phenomenon is not generally linked to diffusion kinetics, but that preferential ground-state solvation[45] (static quenching) plays an important role in mixed solvents. This is also suggested by the time-resolved measurements of alcohol/alkane mixtures.[42] (4) The redshift of the TICT fluorescence[5,46] (see also Fig. 9 in Section 5) is well correlated with solvent bulk-polarity properties for nearly all known molecules that exhibit TICT fluorescence, even though these species vastly differ in structure and electronic properties (see next section). A specific solvent interaction by overlapping electron clouds, however, should lead to stabilization energies that depend on properties other than the polarity of the interaction partners. Thus, the emission energy of exciplexes formed with ethers, chlorides, nitriles, ketones, or alcohols is not expected to correlate with solvent polarity. Some of the deviations from linearity of the solvatochromic plots (Fig. 9 in Section 5) are probably due to weak specific interactions of solute and solvent. (5) There are cases where true specific interaction has been observed and found not to correlate with polarity properties. One example is the quenching of TICT fluorescence by inorganic ions,[47] where the concept of hard and soft Lewis acids and bases is more important. Another example is the quenching of TICT fluorescence of **1** by interaction with trialkylamines.[48] A complex, $[^{\ominus}ArylMe_2N^{\oplus}:NR_3]$, is formed with a two-center three-electron bond; its rate of formation, however, is governed not by thermodynamic properties but by steric interactions.

Because of its strong response to environmental effects, **1** has been used as a fluorescence probe in micelles and in cyclodextrin inclusion complexes.[49]

4. TICT States and Dyes

The number of compounds able to form TICT states is rapidly increasing. Whereas the number of TICT-forming compounds known a few years ago filled one page,[4] a similar list (Fig. 8) is obtained today if one just takes one member of the various series of compounds that have been studied in this context. In the following, we will discuss very briefly some of the examples.

Of the three types of compound **15**–**17**,[1-3,5,6,8-10,23,24,50] **16** show the strongest TICT emission because the conical intersection is absent and because the $n\pi^*$ states are high in energy and do not lead to fast nonradiative decay. The dual fluorescence of **17**[31] is weaker on account of intramolecular quenching (nonradiative decay) by $n\pi^*$ states. Compared with **15**, compound **18**[14-16] contains a stronger acceptor group and **19**[46,51] a stronger donor group. Because of the increased donor capability of the pyrrole ring, even the parent compounds **20** and **21** show dual fluorescence.[46]

The carbazole group is also a good donor group, as seen from the TICT fluorescence of compounds **22**–**24**.[38,52,53] Therefore, one should expect the corresponding indole derivatives to behave similarly. In fact, recent experiments on **25** have shown that it exhibits a dual fluorescence. Other biologically relevant molecules like **26**[54] and **27**[55] also emit a dual fluorescence.

Very interesting examples are compounds that are nonpolar and highly symmetric in the ground state yet form a very polar TICT state upon excitation; examples include the biaryls **28**,[38,39,56-62] **29**,[63] **30**,[39] and **31**.[64] This symmetry breaking does not occur for all biaryls. The preconditions were first discussed by *Zachariasse*,[65] who correlated this property with the difference in oxidation and reduction potentials. In a more refined version (see also Section 6), this approach has been used to predict new TICT-forming members of the biaryl series.[39] Ionic biaryl derivatives like **32**[66] and possibly 9,9'-bisacridinium nitrate[67] show a similar dual fluorescence.

Diphenylmethane dyes like Michler's ketone **33** (X = O)[68,69] or Auramine O **33** (X = NH)[70] also exhibit multiple fluorescence. In the case of the sulfones **34**,[15,71] the TICT fluorescence is in fact strong, possibly due to p_π–d_π interaction at the sulfur atom.[71] In **33** and **34** and in **35**–**38**, the perpendicular TICT geometry is attained not by rotation around the N-aryl bond but by rotation around the S–C or C–C bond connecting the aniline moieties with the rest of the molecule. This has been concluded from the investigation of ring-bridged model compounds.[68,69,72-75]

For cationic triphenylmethane (TPM) dyes like Crystal Violet **35**·$Cl^{\ominus}$ or **35**·$ClO_4^{\ominus}$ as well as for the neutral fuchsone **36**, formation of the TICT state manifests itself by strong fluorescence quenching.[75] In this case, TICT states seem to be nonemissive, and have lifetimes of only a few picoseconds or less as judged from ground-state repopulation experiments.[76] If the system has two more π electrons, however, as is the case for neutral triphenylamines, long-lived emissive TICT states are possible (cf. results for **22**–**24**). The redshifted fluorescence of triphenylphosphane and its metal complexes[77] also seems to indicate the formation of TICT states.

If the energy of the TICT states is raised above that of the other "locally excited" (LE) states, TPM dyes fluoresce strongly. This is nicely shown for the Crystal Violet derivative **37**·$ClO_4^{\ominus}$, a xanthene dye that shows a fluorescence quantum yield of <0.01 in ethanol, owing to efficient formation of a weakly emissive or nonemissive TICT state by rotation around the C-anilino bond. Addition of a few drops of acid blocks the anilino lone pair by protonation and strongly reduces its donor capabilities. This results in an increase in the fluorescence quantum yield by more than two orders of magnitude.[70] Similar effects have been observed with the pyrenyl group as acceptor.[78] Such systems are potentially useful as fluorescent indicators.

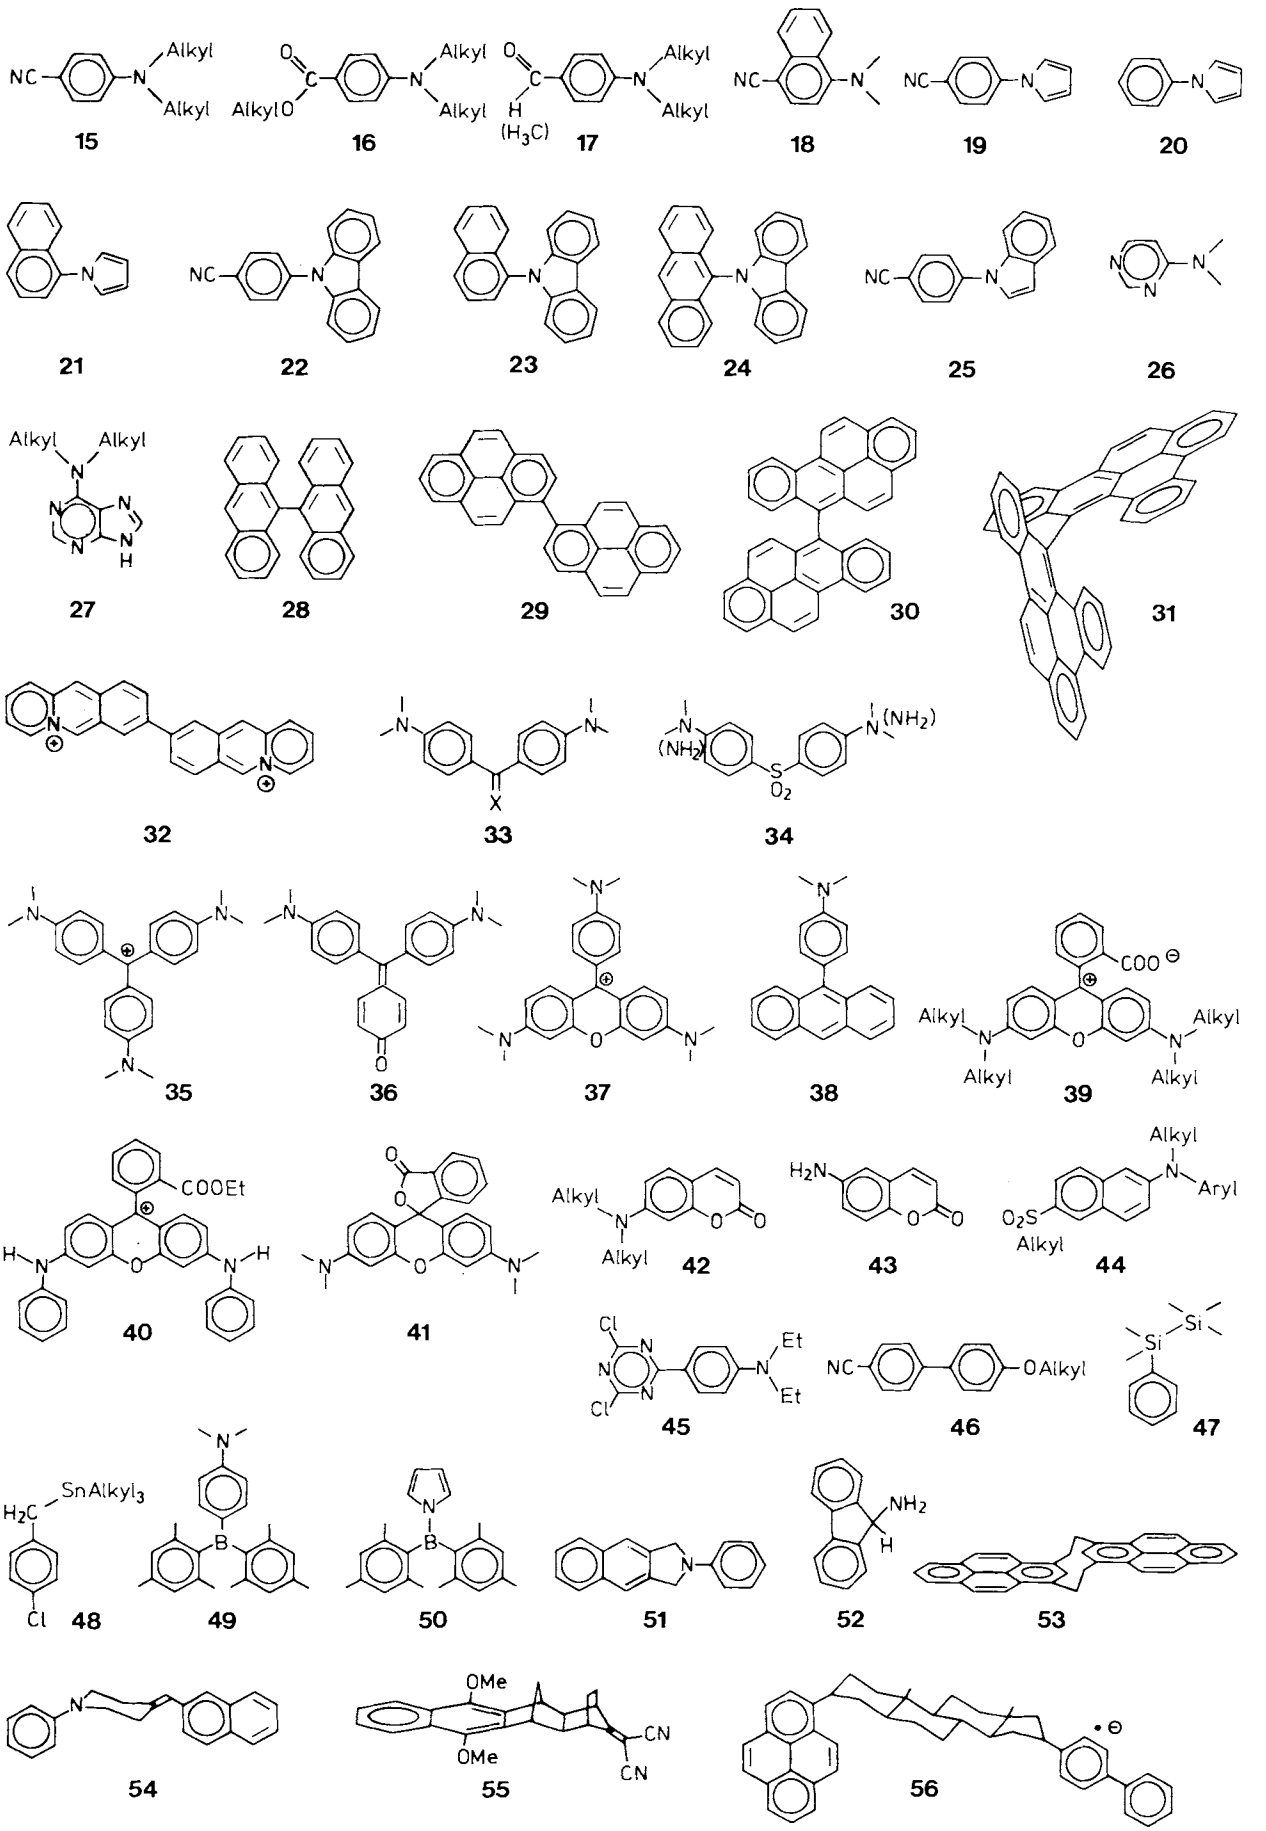

Fig. 8. A list of compounds known to form TICT states (or minimum overlap electron-transfer states). In many cases, one compound represents a large family of compounds with different substituents and/or substitution patterns. Since the notion of TICT states is spreading into organic as well as biochemistry, this list is expected to grow rapidly within the next few years.

Even for ordinary rhodamine dyes like **39**, in which the donor group is replaced by an acceptor group, TICT formation takes place, though only at higher temperatures and by rotation around the N-aryl bonds.[79] The rate of TICT formation is strongly increased by increasing the donor character of the amino groups, as in **40**·$Cl^{\ominus}$. Thus, Fast Acid Violet, a derivative of **40**·$Cl^{\ominus}$, has a strongly viscosity-dependent fluorescence lifetime in the subnanosecond range.[80]

In weakly polar solvents, compounds like **39** tend to exist in their lactone form **41**, a spiro compound with preformed TICT geometry. Emission spectra and lifetimes of these compounds do indeed indicate the population of a highly polar forbidden state.[81]

Also other laser dyes such as the coumarins **42** are strongly affected in their photophysical properties by a solvent-polarity-dependent decay toward a nonemissive TICT state.[82] In the case of **43**, this decay is so pronounced that even in saturated hydrocarbon solvents or in ethanol matrix at 77 K all excited molecules decay via the TICT state, which can be identified here by its weak emissive properties.[83]

Still another family of compounds is represented by **44**. These molecules have been used extensively as fluorescent probes in biology.[84] They decay like **40** by rotation of the anilino group around the N-naphthyl bond toward TICT states that are emissive in this case.[85]

Although biphenyl is predicted to possess only rather high-lying TICT states,[39] donor-acceptor-substituted biphenyls like **45**[86] and **46**[87] seem to decay via fluorescent TICT states. For sufficiently long alkyl chain lengths, the biphenyls **46** display liquid-crystalline behavior, and complicated phase transitions can be nicely probed by observing their unusual fluorescence properties.[88]

The range of TICT-forming compounds is not limited to pure organic chemistry. Some of the unusual fluorescence features observed in silicon or boron compounds, and even organometallic compounds, are in fact nothing else but a manifestation of TICT formation. Examples of such compounds are **47–50**. In **47**[89] and **48**,[90] a doubly occupied σ-orbital seems to act as the donor, because most of the unusual fluorescence is found when the Si-Si bond (a good donor[91]) is in the plane of the benzene ring, i.e., perpendicular to the benzene p_z orbitals. The boron compounds **49**[92] and **50**[93] are very similar to the triphenylmethane dyes (e.g., **35**·$Cl^{\ominus}$), but they are neutral, nonionic compounds.

Compounds **51**,[94] **52**,[95] **53**,[4,96] **54**,[97] and **55**[98] also undergo photoinduced charge separation, but no twisted bond is involved. Instead, a deeper principle is active here, which encompasses both TICT states and these molecules, that of "minimum overlap."[4,38,39] As discussed in Sections 8 and 9, flexible molecules spontaneously relax to a conformation with minimum interaction between LE and charge-transfer (CT) states (the "minimum overlap conformation"), which leads to full charge separation. If, however, one of the bridges is cut, say in **53**, and the sandwich-type conformation can easily be reached, the "maximum overlap rule" takes over, which describes the tendency for maximal LE-CT interaction.[99] Then, charge separation does not occur any more in symmetric systems.[38,100] The "minimum overlap rule" is probably also relevant for model systems (e.g., **56**) of photoinduced electron transfer over varying distances.[101]

As will be seen in Section 10, this notion of minimum overlap turns out to be a possible key for the understanding of the primary steps in photosynthetic charge separation. It probably also drives the very efficient *cis–trans* isomerization in the visual pigment rhodopsin (Section 9). Recent experiments indicate that TICT states may also be important in other fields of photobiology, for example in the photophysics of bilirubin.[102]

5. The Properties of TICT States

The most important feature of TICT states is their charge separation, which, neglecting σ–π interaction, amounts to transfer of exactly one electronic charge from donor to acceptor.[1–4] In more elaborate quantum chemical treatments,[20,103] the amount of charge transferred is still on the order of 0.8 of an electronic charge. This charge separation is detectable experimentally by measuring the dipole moment of the TICT state by means of the influence of an electrical field on the emission (*e*lectro*o*ptical *e*mission *m*easurements, EOEM).[27,35] Methods have even been developed which, in principle, allow the determination of the dipole moment of nonemissive TICT states (transient dielectric loss measurements).[41]

An experimentally much simpler approach is to measure either thermochromic shifts[104] or to probe the influence of the immense dielectric field set up by polar solvents. The emission bands in a series of such solvents are redshifted as polarity increases (Fig. 9a). A quantitative analysis of the spectra is shown in Figure 9b.

The dipole moment of the TICT state of **1** was determined to be about 12 D (40×10^{-30} Cm) by EOE measurements[27,35] and is compatible with the results of solvatochromic measurements if a so-called "harpooning mechanism"[28] is taken into account. This predicts that, upon charge separation, the molecule (and the cavity) should shrink in size, because the two oppositely charged molecular moieties attract each other. Quantum-chemical calculations on the CNDO/s level support this view.[55]

One of the main features of TICT states is their twisted geometry. It is interesting to ask, why, for planar molecules like **1** or **20**, a twisting to the perpendicular conformation should occur spontaneously in the excited stat. Quantum-mechanical calculations also predict this to occur (Fig. 10a). The answer can be given in terms of the valence bond model[109] (see Section 9) and leads to the "minimum overlap" rule.

Because the radiative transition TICT state → ground state (a back CT transition) involves two orbitals located on different π systems, perpendicular to each other on average, it is overlap forbidden (small transition probability) and thus expected to possess a small transition moment. A small TICT fluorescence quantum yield is therefore expected. However, by coupling to suitable vibrations, this transition can borrow intensity from higher-excited, more allowed states, which accounts for the many systems with

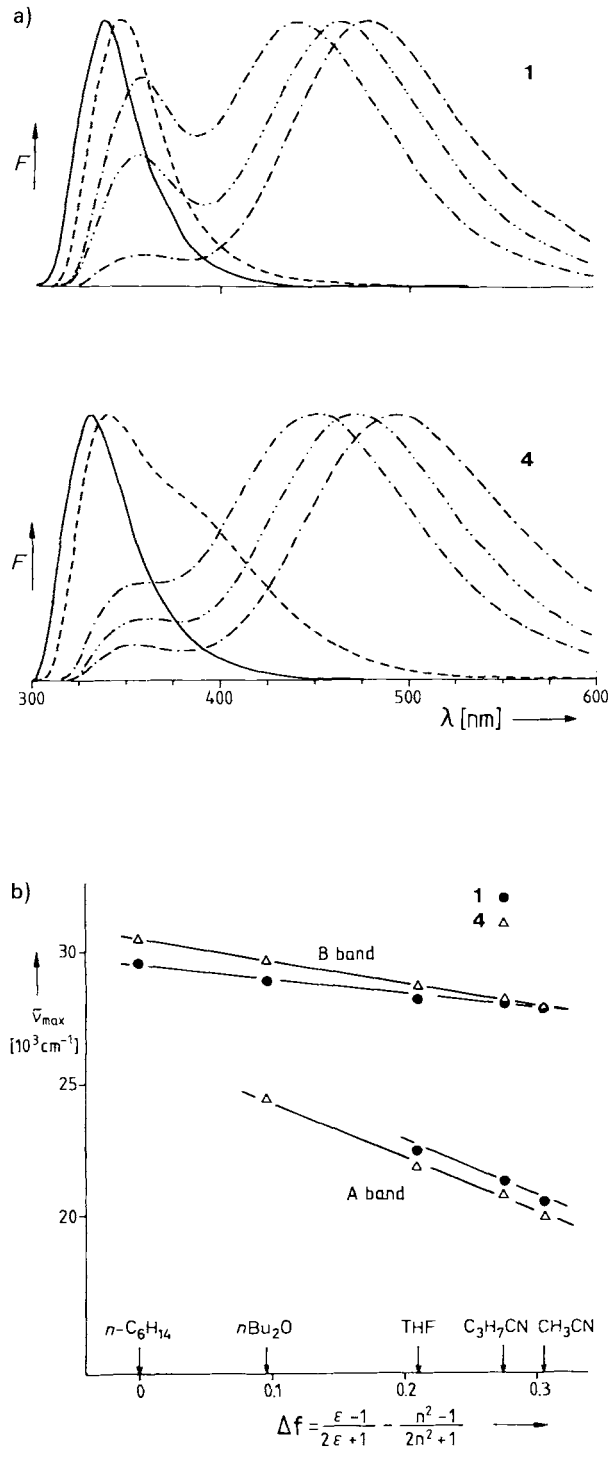

Fig. 9. a) Fluorescence spectra of **1** (upper) and **4** (lower) at room temperature in aprotic solvents of different polarity. The A band is strongly red-shifted and gains in relative intensity for increasing polarity. —— *n*-C_6H_{14}, --- nBu_2O, —·— tetrahydrofuran (THF), ··— C_3H_7CN, ·--· CH_3CN. b) Quantitative treatment by separation of the bands [9] and application of the solvatochromic equations derived by *Lippert* [105], *Mataga* [106], *Liptay* [107], or *Bilot* and *Kawski* [108]. The figure shows the fluorescence data derived from a) as a function of the solvent polarity parameter Δf [105], which depends on the dielectric constant ε and the refractive index n of the solvent. The point for THF is consistently slightly lower than the correlation line. This points to the existence of weak solvent-specific effects in addition to the strong bulk polarity ones. The B band of **4** is more strongly influenced than that of **1**, because B emission in **1** is from a ^1L_b-type state with a dipole moment smaller than that of the emissive ^1L_a-type state in **4**. The effect on the A bands is larger, but apparently similar for the two compounds. Precise relative TICT-state dipole moments may be determined if weak solvent-specific effects are excluded by using a series of homologous polar solvents, and if the variations in charge distribution and in molecular size and shape are taken into account [38, 39, 46].

appreciable TICT fluorescence quantum yields (**22–24**, **28**, **34**, **46**). Similar coupling effects may even lead to an unsymmetrical TICT equilibrium geometry in **12**.[43]

The fact that the rate constant for radiative decay of TICT states increases with temperature,[1,6,8,43,73] and that, therefore, a temperature-dependent fluorescence rate constant $k_f^{\wedge}(T)$ is required in Scheme 1, is in accordance with this picture of vibronic coupling. The major part of the observed TICT fluorescence is emitted from higher vibronic levels and is thus a "hot fluorescence" (Fig. 10b).

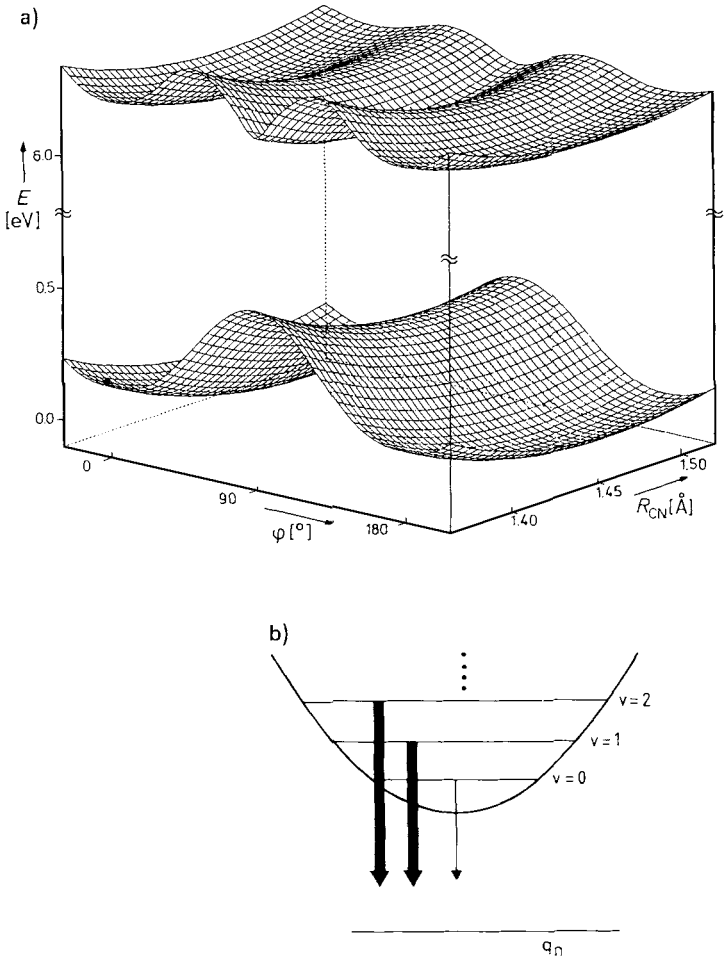

Fig. 10. a) Already a simple force field calculation for the ground and a higher excited state of **20** in the gas phase (S_5 at the planar geometry, i.e., $\phi = 0$, 180°) in the framework of the Pariser-Parr-Pople SCF-CI approximation predicts an energy minimum in the excited state at the twisted geometry ($\phi = 90°$, full charge separation), where the ground-state hypersurface possesses an energy maximum [51]. A polar environment will preferentially lower the excited-state minimum at 90° and may lead to the disappearance of the energy barrier between the conformations with $\phi = 0$ and $\phi = 90°$. b) Radiative decay from a TICT state with perpendicular conformation ($\phi = 90°$) is overlap forbidden (lowest vibrational level v = 0). For weak coupling, this level does not acquire much of the wave function of the upper allowed electronic state(s), quite different from the case for the higher-lying vibrational levels (v = 1, 2, ...) [1, 10, 17]. The TICT fluorescence therefore occurs mainly from molecules in excited vibrational states.

There are numerous similarities of TICT states to excimer or exciplex states. One of the main distinctions, however, is that excimers and exciplexes tend to follow the "maximum overlap rule," i.e., they assume sandwich-type structures if there are no geometric constraints.[99, 110–113]

Charge separation and symmetry breaking, however, are linked to a "minimum overlap" geometry (see Section 8). A more detailed discussion of the relation between exciplex, excimer, and TICT states can be found in a recent review by *Grabowski*.[114]

6. A Blueprint for Compounds with Energetically Low-Lying TICT States

Any bichromophoric system whose chromophores are linked by an essential single bond, like **15–50**, possesses, in the perpendicular conformation, several TICT states. Let us consider the simple case of dimethylaniline. The two most stable TICT states will be of different symmetries because they arise from the loss of an electron from the twisted amino group to one of the two lowest unoccupied benzene π^* orbitals. The energy of the lowest TICT state, however, is still unfavorable compared with that of the lowest excited state, LE1, of the planar conformation (Fig. 11b), and the twisting relaxation will not take place. If,

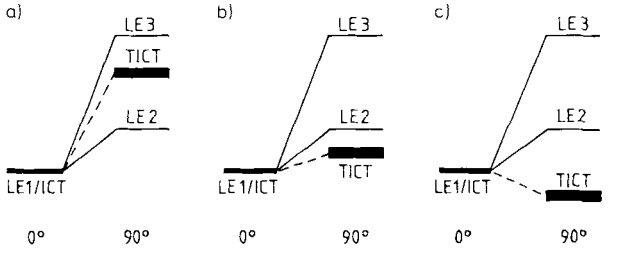

Fig. 11. Relative energy of the lowest TICT state in a twisted bichromophoric system. a) The TICT state is unfavorable with respect to the other states LE1, LE2 of both the perpendicular (90°) and the planar (0°) system. The term "locally excited" (LE) is somewhat misleading, because in a planar molecule like **1** the B* state (LE1) is delocalized over both acceptor and donor group and even contains quite substantial but never full intramolecular charge-transfer (ICT) character. In twisted **1**, however, the LE states are localized on the fragments, whereas the CT (TICT) states are still delocalized. b) The TICT state is unfavorable with respect to LE1, but favorable with respect to the LE states of the twisted conformation. c) The TICT state is lower in energy than the other excited states of both planar and perpendicular conformations.

however, the planar conformation cannot be reached because of steric hindrance, the lowest excited state is a TICT state. Benzoquinuclidine (**14** without the cyano group) actually shows such a TICT emission.[115] If the donor property of the dimethylamino group is weakened ($NMe_2 \rightarrow NH_2$), the situation in Figure 11a is expected, without TICT population even for rigidly perpendicular conformations. On the other hand, if the donor character is strengthened (e.g., the 2,5-dimethylpyrrolidino group in **10** is a better donor than the dimethylamino group in **1**[8]), and/or if the acceptor character is increased (*p*-cyano substituent), then the situation in Figure 11c arises, and the state LE1 can relax spontaneously to the lower-lying TICT state. This condition is given by Equation (a).

$$E(\mathrm{TICT}) - E(\mathrm{LE1}) < 0 \qquad \text{(a)}$$

The energy of the LE states can be determined by experiment. The energy of the TICT state can be approximated by Equation (b).[1,39,103]

$$E(\mathrm{TICT}) = IP(\mathrm{D}) - EA(\mathrm{A}) + C + \Delta E_{\mathrm{solv}} \qquad \text{(b)}$$

IP(D), the ionization potential of the donor moiety, and EA(A), the electron affinity of the acceptor, reflect the donor's capability to release an electron, and the acceptor's capability to bind it. Electron transfer results in the formation of a radical cation and a radical anion which attract each other, thereby stabilizing the system by the Coulomb energy C. Polar solvent molecules around the radical ion pair adjust to the increased electric field and stabilize the system by an amount ΔE_{solv}. A similar equation can be written in terms of oxidation and reduction potentials.[4]

Based on this equation, it is possible to rationalize the fluorescence behavior of biaryl compounds[65] and to predict new TICT-forming compounds.[39] Let us consider examples for each of the factors operating in Equation (b).

The first factor is the difference $IP(\mathrm{D}) - EA(\mathrm{A})$. Thus, for similar donors, the TICT state is lowered in energy with increasing acceptor strength. Examples are *N,N*-dimethylaniline and **1**, differently substituted TPM dyes like Crystal Violet **35**·$Cl^{\ominus}$ and Malachite Green (one NMe_2 group less than Crystal Violet),[75] or 7-dialkylamino coumarins **42**,[82] which are especially prone to form TICT states in polar solvents if they possess acceptor substituents on the coumarin skeleton. Examples for the variation of the donor capability are also found in the TPM series[75] and, particularly, for the phenylpyrrole derivatives (see **19**, **20**,[51] and Fig. 7), where the TICT emission is seen to follow the changes in the ionization potential of the donor group.

The Coulomb energy C can easily be calculated from the HOMO of the donor and the LUMO of the acceptor, as shown in Equation (c), where $c_{k,i}$ are the MO coefficients for atom i in the HOMO of the donor and $c_{l,j}$ those of atom j in the LUMO of the acceptor; e is the electronic charge and r_{ij} the internuclear distance.

$$C = -e^2 \sum_i \sum_j c_{k,i}^2 \cdot c_{l,j}^2 / r_{ij} \qquad \text{(c)}$$

C is an important factor in rationalizing and predicting which of a series of different isomers of the same D/A pair possesses the lowest-lying TICT state. Compare **1** with its *meta* isomer (Fig. 12a). The smaller absolute value for C for the *meta* isomer is one of the reasons why it does not show dual fluorescence. Similar arguments can be used for the behavior of naphthalene or coumarin as acceptor (Fig. 12b, c) or for different biaryl isomers (Fig. 12d).

ΔE_{solv} is given, in a simple form,[46,105] by Equation (d), where μ_T is the dipole moment of the TICT state, a the Onsager cavity radius, and ε the solvent dielectric constant.

$$\Delta E_{\mathrm{solv}} = -\mu_T^2 \cdot \frac{2}{a^3} \cdot \frac{\varepsilon - 1}{2\varepsilon + 1} \qquad \text{(d)}$$

There are cases where the condition in Equation (a) is met only above a certain threshold of the solvent polarity. Compound **1**, for example, shows a negligible amount of TICT fluorescence in nonpolar solvents;[18,116] this is also true for **34**[71] and **42**.[82,83] Polar solvents, however,

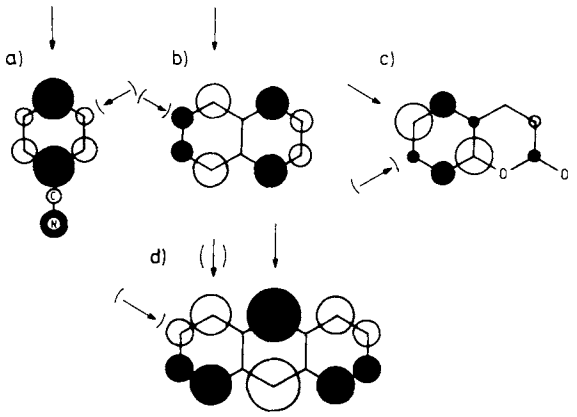

Fig. 12. LUMOs for some typical acceptor groups in TICT-forming compounds. The relative probability of finding the odd electron (negative charge) in the TICT state is given by the surface areas of the circles (square of the MO coefficients). The Coulomb stabilization C with an adjacent positive center is strongest if this center is next to an atom with a large MO coefficient (arrows) and less favorable for atoms with a smaller coefficient (arrow in brackets). a) Cyanophenyl: strongest stabilization is expected for the *para* isomer. b) Naphthyl: strongest stabilization for the α isomer; experimentally, **21** shows TICT fluorescence [46], whereas the corresponding β-naphthyl compound does not [55]. For better donors like carbazole, both α- and β-naphthyl derivatives show TICT fluorescence [53]. The behavior of isomeric coumarins [83] and of biaryl isomers [39] can also be rationalized in this way.

strongly enhance the TICT fluorescence. Such a change of the emitting state from ICT to TICT along a solvent polarity scale has been observed in several other cases. It usually shows up in a solvent polarity plot by a change in slope.[85]

ΔE_{solv} also depends on the size of the dipole moment of the TICT state, μ_T, which is mainly given by the distance between the center of gravity of negative and positive charge. For elongated systems such as anthracenes linked in the manner of **28** (in the 9-position), μ_T will be much smaller than if the linkage is in the 1- or 2-position; in the latter case, however, C is smaller (Fig. 12d); i.e., ΔE_{solv} and C can be compensating factors.[39]

Another interesting way for reaching TICT states is obviously not to lower E(TICT) but to raise E(LE) [Eq. (a)]. This is the case for sterically hindered dialkylanilines like **13** (twist ca. 60°) where the LE1/ICT state (Fig. 11) cannot be reached at the planar conformation and is thus raised in energy. This leads to the strong preference for TICT formation which even remains in the gas phase.[1,26,27]

For designing efficiently fluorescing systems, for example to obtain new laser dyes, it is important to control the formation of TICT states because these often act as intramolecular fluorescence quenchers. Two approaches are possible (Fig. 13). The first is to hinder the formation of the minimum overlap geometry, e.g., by bridging. Such "rigidized" systems are known to have substantially increased fluorescence quantum yields compared with their flexible counterparts.[17] The second way is to leave the system flexible but to increase the TICT energy relative to that of the LE1/ICT state. This second approach clearly invalidates an explanation of the decreased fluorescence quantum yield via a "loose bolt effect." In the case of infrared dyes, competing quenching processes without charge separation play an increasing role, too, because of the reduced S_0–S_1 energy gap.[79]

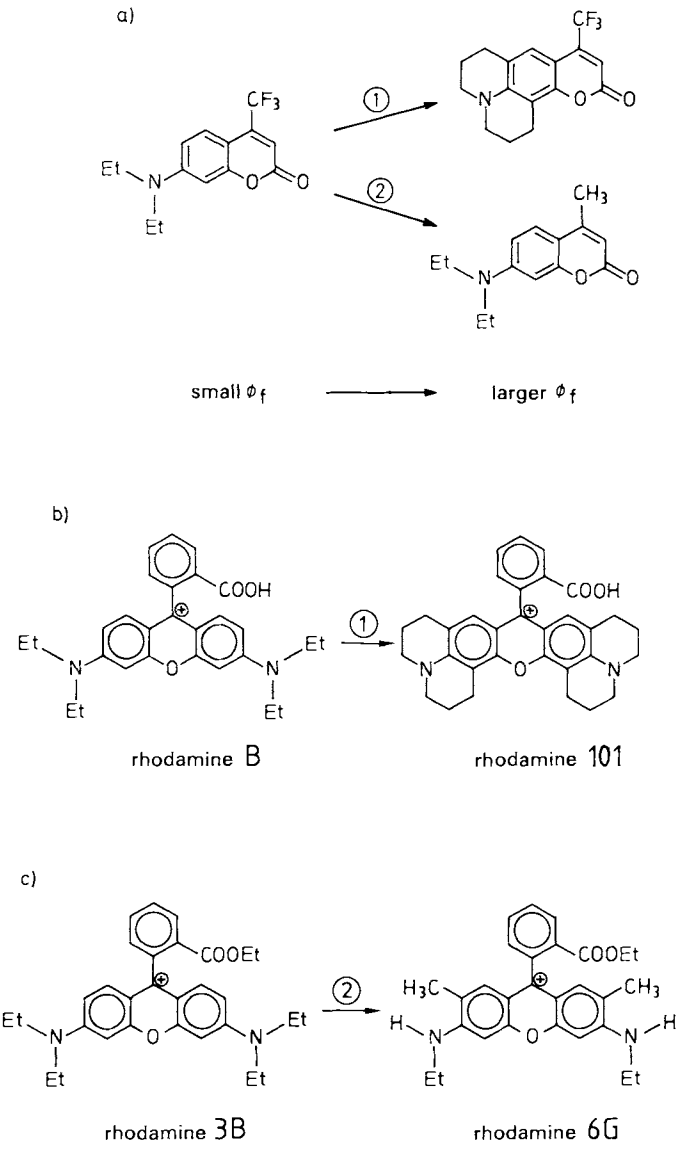

Fig. 13. a) The fluorescence quantum yield ϕ_f of certain coumarin dyes in polar solvents increases by a factor of nearly 10 if TICT formation is hindered by either "rigidizing" the system ① or raising the TICT energy ② (e.g., by reducing the acceptor strength) [82]. b, c) A similar approach explains the temperature dependence and reduced fluorescence quantum yield of flexible rhodamine dyes. The quenching effect disappears by a similar rigidization [117, 118] or by increasing the TICT energy (reduced donor strength of the amino groups [79]). In the case of rhodamines, also the phenyl substituent can act as a donor [75].

7. Kinetic Aspects of TICT Formation

Scheme 1 postulates the precursor-product relation of B* and A* states. This is experimentally supported by numerous nano- and picosecond studies on **1**,[12,25,42,119–124] which show that for the irreversible case (k_{AB} negligible) the A fluorescence builds up with a rise-time that is related to the decay time of the B fluorescence. Both solvent (viscosity, polarity) and solute parameters (structural: ground-state twist angle, rotating volumes, molecular shape and flexibility; electronic: state correlation, conical intersections) determine the rate k_{BA} for the formation of the TICT state.

In most cases, the temperature dependence of k_{BA} is weaker than that of the macroscopic solvent viscosity η [Eq. (e)].

$$k_{BA}^{-1} = C \cdot \eta^{x} \qquad 0.5 < x < 1 \qquad \text{(e)}$$

In the case of TPM dyes, the very well known Förster-Hoffmann model[125] gave $x = 2/3$. This value, however, does not even exactly hold for the case of the original study of relaxing TPM dyes in glycerol ($x = 0.8$[75]). In some cases, x depends on the type of solvent matrix (cross-linked versus *n*-alcohols),[126] in other cases (derivatives of **1**), on the size and shape of the rotating molecular moieties.[24] Microviscosity theory[127] can be used to describe these changes in x.[24, 128] The important points in this theory are, first, that the solvent environment is not a continuum but composed of discrete molecules which may even be larger than the solute itself and, second, that two types of diffusion exist: the diffusion that pushes away solvent molecules and the diffusion into holes between the solvent molecules (free volume). The free-volume effects become very important in polymers, where **1**, despite the very high macroscopic viscosity, shows a dual fluorescence in H-bonding[44] as well as in non-H-bonding matrices.[129] The small amino group in 6-aminocoumarin is even able to relax into the available free volume between the solvent molecules of a frozen ethanol matrix.[83]

The state crossing and conical intersection that occurs for **1** (Fig. 3 and 5) has very profound kinetic consequences. Figure 14 shows that the B decay (governed mainly by k_{BA}) is much slower for **1** than for the corresponding ester. The conical intersection (Fig. 5) seems to represent an "obstacle" on the lower surface. Its solvent dependence could explain the polarity-dependent activation energies as observed for **1**.[122]

Figure 14 also shows that the observed decays are non-exponential but can be described using a biexponential model. For the TPM dyes like **35**·$ClO_4^{\ominus}$, this has been known for some time.[130, 132] In **1**, the nonexponential decay is linked to a rise of the A fluorescence, which is *faster* than expected from the B decay.[25, 123]

A possible explanation is provided by the existence of broad rotational distribution functions in the ground state.[21, 25, 51, 130, 133] Projected onto the S_1 hypersurface by light absorption, these are transformed into broad relaxational distributions by the action of the coordinate-dependent driving force toward the TICT state (Fig. 15).[6, 18, 21] An alternative formalism uses a modified Smo-

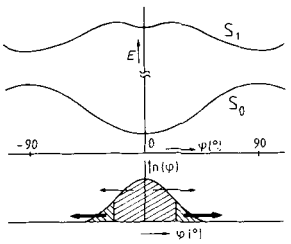

Fig. 15. Schematic potentials of ground and first excited states of a TICT-forming molecule with a planar ground-state geometry. By excitation, the broad angular distribution $n(\phi)$ is projected onto the S_1 hypersurface. Depending on its shape (the minimum at 0° may be actually present for **1** as shown, but in other cases the planar conformation may be a local maximum with regard to twisting), the different parts of the distribution are subject to different driving forces toward the TICT conformation (i.e., different slopes along the reaction coordinate). ● : large force; → : small force.

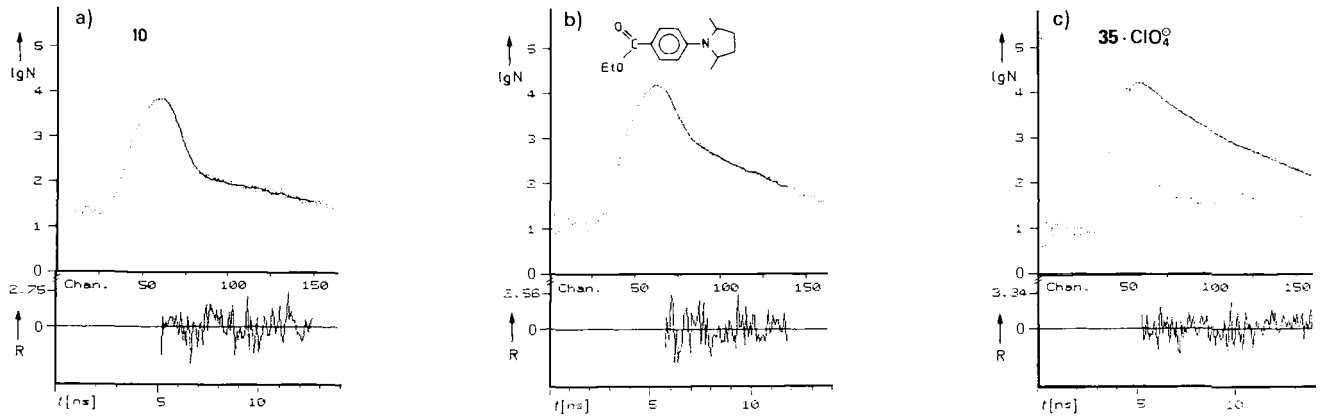

Fig. 14. Fluorescence decay curves of TICT-forming compounds. The excitation source was synchrotron radiation from the Berlin electron storage ring BESSY. (a, b) $\lambda_{ex} = 300 \pm 10$ nm. c) $\lambda_{ex} = 570 \pm 10$ nm) operated in the single bunch mode. Conventional single-photon counting equipment was used. a) **10** in *n*-butyl chloride at 234 K, b) the corresponding ester in the same solvent but at increased viscosity (at 152 K, just above the freezing point), both observed at 350 ± 10 nm. Both temperatures are in the range of irreversible kinetics ($k_{AB} \ll k_0^{\wedge} + k_f^{\wedge}$). The decays could be reasonably well fitted (——) by the iterative reconvolution method using a biexponential model. **10** and its ester are convenient kinetic model compounds for **1** and **4** because the irreversible temperature range extends up to room temperature [18] and because the decays are more easily monitored due to the reduced TICT formation rate (factor of about 4 [21]). The derived parameters are a) $\tau_1 = 0.21$, $\tau_2 = 3.6$ ns, $A_2/A_1 = 0.004$, b) $\tau_1 = 0.18$, $\tau_2 = 1.52$ ns, $A_2/A_1 = 0.02$. For these similar τ_1 times, the ester possesses a significantly increased weight of the second component [25]. For equal temperature (174 K) and viscosity, τ_1 for the ester is faster by a factor of 4.6. c) **35**·$ClO_4^{\ominus}$ in glycerol at 266 K, monitored at 620 ± 10 nm. The biexponential fit yields $\tau_1 = 0.59$, $\tau_2 = 1.67$ ns, $A_2/A_1 = 0.81$. The weight of τ_2 is considerably increased compared with a) and b). The prompt response function of the system (FWHM ≈ 800 ps) is also shown. R = deviation of the measured values from the average values. We consider these decays to be due to the combined effects of broad ground-state rotational distribution functions [25, 130] and of transient effects describable in a stochastic model [131] by means of time-dependent rate constants [123].

luchowski equation with sink terms[131] and leads to the time-dependent rate constants $k_{BA}(t)$.[123]

If the ground-state minimum is situated close to a conical intersection of excited states, then nonadiabatic effects will dominate the photo-physical properties,[134] and radiative and nonradiative decays of the excited states will be strongly coupled to nuclear motion. Such an example seems to be **13**[26] (Fig. 16). Depending on excitation wavelength, the relaxation is channeled toward different excited-state minima. Detailed picosecond kinetic investigations offer promise of shedding new light on nonadiabatic coupling phenomena.

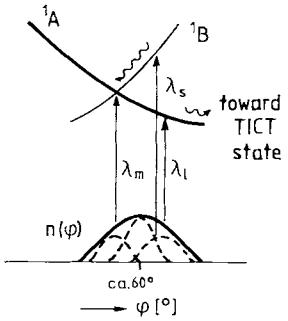

Fig. 16. Schematic excited-state potential surfaces for **13** as a function of twist angle [26]. At the point of crossing, a conical intersection, similar to that shown in Figure 5, occurs by vibronic coupling along a non-totally symmetric coordinate q_n (not shown). Steric hindrance by the two *ortho*-methyl groups shifts the ground-state minimum and the corresponding rotational distribution $n(\phi)$ below the crossing region. By varying the excitation wavelength, different parts of $n(\phi)$ can be excited. Upon excitation in the long wavelength tail (λ_l) of the absorption band, only the strongly redshifted TICT emission is observed, whereas exciting at shorter wavelengths (λ_m,λ_s) gradually results in the appearance of a second short-wavelength fluorescence band [26] probably derived from the relaxed ^1L_b state.

8. Symmetry Reduction and Charge Separation

Through coupling with nonsymmetric vibrational modes or with the environment, many symmetric molecules undergo a symmetry reduction. The most prominent example is the Jahn-Teller effect for coupling of degenerate states.[134] Other examples are nonadiabatic effects in cumulene radical cations, which lead to species twisted away from the symmetrical geometry by angles ranging from 25° (in $H_2C{=}CH_2^{\oplus\ominus}$) to 46° (in $H_2C{=}C{=}C{=}CH_2^{\oplus\ominus}$).[134] In 9,9′-bianthryl **28** and other symmetric biaryls, symmetry reduction is induced by a coupling with solvent fluctuations.[38,39] Symmetry reduction by the interaction of electronic and nuclear motion can occur only if the nonadiabatic coupling W exceeds a certain threshold (Fig. 17) given by Equation (f),[134,135] where E_2-E_1 is the energy difference between the unperturbed states, and f_n is the force constant of the coupling mode.

$$W^2 \geq 2f_n(E_2-E_1) \qquad \text{(f)}$$

In the highly symmetric **28**, the LE states (equal mixture of $\Psi(A^*-A)$ and $\Psi(A-A^*)$) and charge-resonance (CR) states (equal mixture of the CT wavefunctions $\Psi(A^{\oplus}-A^{\ominus})$ and $\Psi(A^{\ominus}-A^{\oplus})$) reflect this symmetry (dipole moment $\mu=0$). In CR states, which occur in symmetric excimers,[136] the coupling of the two CT wavefunctions with each other causes the symmetric equilibrium situation to be spontaneously restored every time external fluctuations disrupt the symmetry. To induce symmetry breaking, the coupling V_{CT} (equivalent to the right-hand side of Equation (f) has to be lowered below a certain threshold. The coupling occurs indirectly and is describable by the off-diagonal matrix elements $V_{CT}=\langle\Psi_{LE}|\hat{H}|\Psi_{CT}\rangle$ in a configuration-interaction treatment.[39] These matrix elements are strongly overlap dependent and vanish for the perpendicularly twisted conformation. At and close to this geometry, it is thus possible that the energy W_{solv} (interaction of CT wavefunctions with the fluctuating unsymmetrical solvent environment), which is equivalent to the left-hand side of Equation (f), exceeds that of V_{CT}. Then, spontaneous

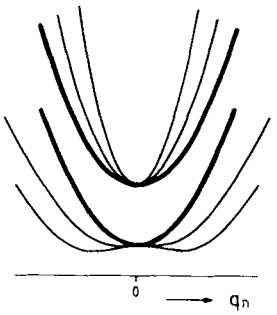

Fig. 17. Influence of a gradually growing vibronic interaction of two close-lying states (S_0 and S_1, or two excited states; bold lines) along a non-totally symmetric coordinate q_n. If the coupling W is below a certain threshold, both hypersurfaces change their shape, the higher one being steepened and the lower one flattened. The energy minimum, however, remains at the origin. Above this threshold, a double minimum develops for the lower state, and the energy minimum corresponds to an unsymmetric geometry (nonzero value of coordinate q_n). The upper state, however, retains its symmetric character [134, 135].

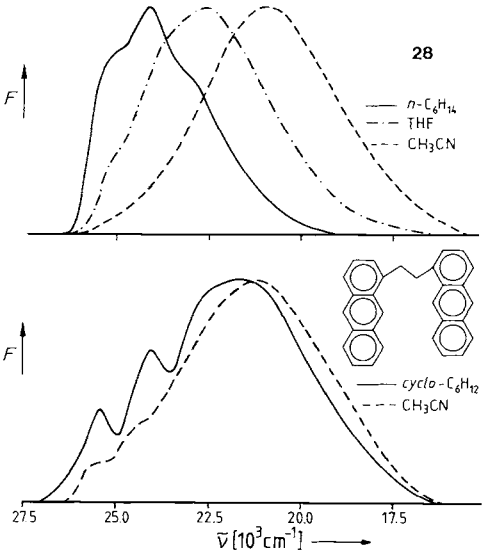

Fig. 18. The influence of polar solvents on the dual fluorescence spectra of **28** and 1,2-di(1-anthryl)ethane [100]. In both cases, the relative importance of the long-wavelength band increases with solvent polarity. Only for **28**, however, does it show a strong solvatochromic redshift indicative of an excited-state dipole moment (i.e., symmetry reduction). This is possible because the two CT wavefunctions are only very weakly coupled. In the case of 1,2-di(1-anthryl)ethane with sandwich-type overlap and strong coupling, the solvent fluctuation energies are not sufficient to induce the symmetry breaking, and a charge-resonance state with zero dipole moment is observed.

charge separation and symmetry reduction can occur, because the equal mixture of CT wavefunctions becomes unbalanced and is no longer restored. Figure 18 illustrates the effect of small and large overlap on the fluorescence spectra of **28** and 1,2-di(1-anthryl)ethane. The fact that **28**[61,137] and **30**[39] display TICT emission even in saturated hydrocarbons is evidence that even in these inert solvents non-negligible interaction energies W_{solv} are attained.

9. The Minimum Overlap Rule: A Bridge to Twisted Double Bonds

It was shown in the last section that for symmetry reduction to occur in symmetric biaryls, a perpendicular or minimum overlap-type conformation has to be adopted. A similar symmetry breaking can occur in olefins upon *cis–trans* isomerization. The phenomenon termed "sudden polarization" was discovered by quantum-mechanical calculations for pyramidalized ethylene, the simplest case.[138,139] Since then, the wide scope and applicability of this concept has been developed by very refined large-scale CI calculations.[109,140,141]

The calculations predict that substituted or pyramidalized ethylene, when electronically excited, spontaneously twists toward the perpendicular conformation, where the two charge-transfer or zwitterionic states $\Psi(C^{\oplus}-C^{\ominus})$ and $\Psi(C^{\ominus}-C^{\oplus})$ are very low lying. In contrast to the CT states of **28**, the subunits on either side of the twisted bond are closed-shell systems for ethylene. Nevertheless, the similarities are striking: Figure 19 compares the calculated excited-state dipole moment for **1** and ethylene. Charge separation and maximum dipole moment, as well as an energy minimum, occur in both cases at the perpendicular geometry.

Experimental evidence for the twisted state in olefins[143] is less well documented than for TICT states. In the case of the extensively studied stilbene, this state was termed a "phantom singlet" state.[144] It correlates with the S_4 state of *trans*-stilbene.[145] Its twisted geometry is experimentally established, but its dipolar nature awaits further experimental confirmation.

Recently, the characterization of MO wavefunctions by valence bond (VB)-like structures has greatly contributed to the rationalization of the "minimum overlap rule" for twisted single and double bonds.[109] Figure 20 shows the VB structures for two limiting cases, twisted ethylene and aminoborane. The states start to interact for twist angles different from 90°, causing a maximum in the ground state and a minimum in the excited state spaced by an energy separation ΔE (Fig. 21). For intermediate differences in

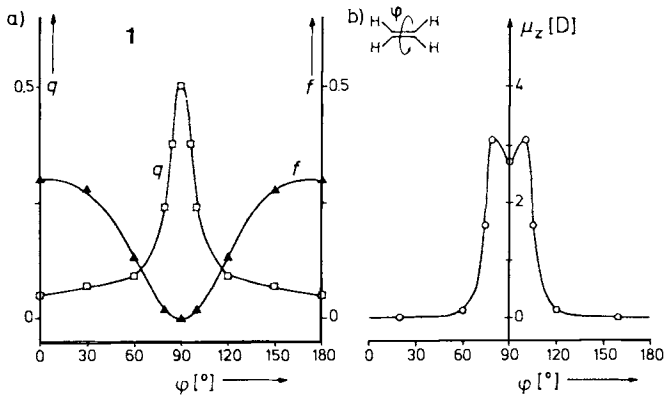

Fig. 19. Comparison of the calculated excited-state charge separation of **1** (CNDO/s-CI, 30 singly excited configurations) [15] and dipole moment of ethylene in the S_1 state for 10° pyramidalization (MRD-CI, ca. 8000 configurations) [139] as a function of twist angle. For ethylene, the calculations only lead to charge separation by introduction of a slight asymmetry (substitution or pyramidalization on one center). Such a symmetry breaking can also be brought about by a fluctuating solvent environment. Calculations on a variety of systems[140] indicate a less sudden nature of the "sudden polarization" than in the case of ethylene [142]. a) q = charge on the amino nitrogen atom; f = oscillator strength of the S_0–S_1 transition.

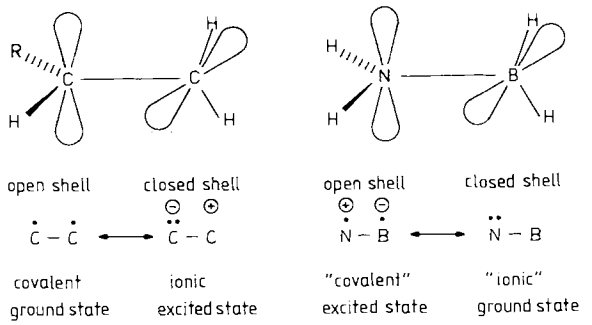

Fig. 20. The states of perpendicularly twisted substituted or pyramidalized ethylene (left) and of aminoborane (right) can be characterized approximately by VB-like structures [109]. The two states (covalent and ionic structures, open-shell and closed-shell character on the fragments) cannot interact for symmetry reasons. In substituted or pyramidalized ethylene, the ionic closed-shell state is the higher-energy one owing to charge separation. In aminoborane (different nuclear charges), the order is reversed. Charge separation occurs for the open-shell structure in this case.

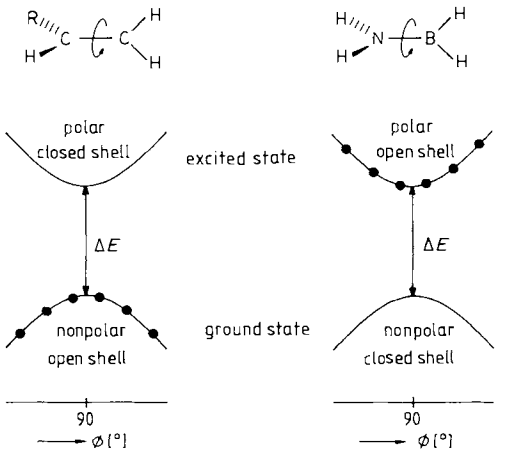

Fig. 21. Upon deviation from the perpendicular geometry, the states shown in Figure 20 start to interact and "repel" each other. An energetic maximum for the ground state and a minimum for the excited state results for the perpendicular geometry. The latter explains why compounds that undergo "sudden polarization" and compounds that form TICT states spontaneously twist toward 90° ("minimum overlap rule" [4]). The energy difference ΔE at the twisted geometry is given by the relative energy of the two VB-like structures. If ΔE is large, long-lived excited states are possible. If ΔE is very small, for cases intermediate between ethylene and aminoborane, nonadiabatic interactions are likely to lead to ultrafast nonradiative deactivation.

donor-acceptor strength, the potential surfaces are expected to get very close at a 90° twist and even to touch ($\Delta E = 0$)[109] (Fig. 22). Such borderline cases between TICT and "sudden polarization" behavior can lead to ultrafast nonradiative decay as observed for cyanine and TPM dyes.[76, 130, 132]

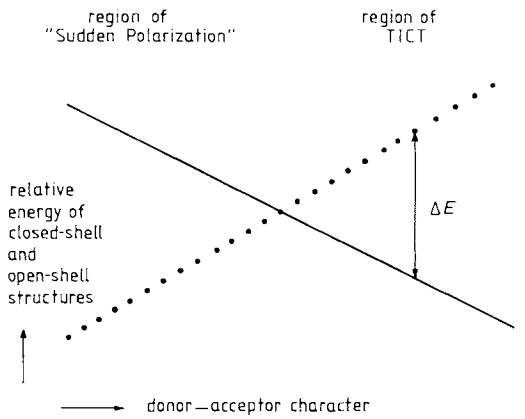

Fig. 22. If, for perpendicularly twisted compounds, the relative energy of the states characterizable by VB-like closed-shell and open-shell structures is changed continuously, these two states become isoenergetic. At this point, ground- and excited-state surfaces touch for 90° twist [109]. Compounds may be classified as belonging either to the region of "sudden polarization" with a closed-shell ionic excited state (left) or to the region of TICT states, where the ionic excited state is open-shell in nature (right).

The pigment of the visual process, the protonated Schiff base of retinal (Fig. 23), is probably also such a borderline case. Early calculations on "sudden polarization" in this

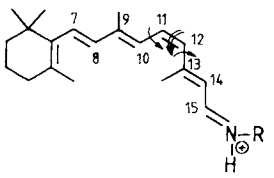

Fig. 23. In the protonated Schiff base of retinal (PRSB), the pigment of the visual process, light absorption leads to photoinduced *cis-trans* isomerization of the C11-C12 double bond. This occurs within a few picoseconds [146] or less [147], which seems impossible for large rotating parts. Concerted mechanisms involving the simultaneous twisting around several single and double bonds have therefore been developed ("bicycle-pedal" model [148] and "Hula-twist" model [149]). The extended polyene chain of PRSB possesses a strong acceptor ($=N^{\oplus}$) at one end, which leads to a behavior intermediate between "sudden polarization" and TICT states: small ΔE in the twisted geometry with charge separation, and large nonadiabatic effects.

polyene were connected with speculation whether the predicted charge separation is a key step in the primary process of vision.[150] Recent experiments,[147] as well as large scale CI calculations on model compounds,[109, 140] conclude that it is mainly the shape of the S_1 hypersurface (barrierless downhill transition from the planar to the perpendicular conformation) that drives the reaction toward the high-energy ground-state product in less than 1 picosecond (Fig. 24).

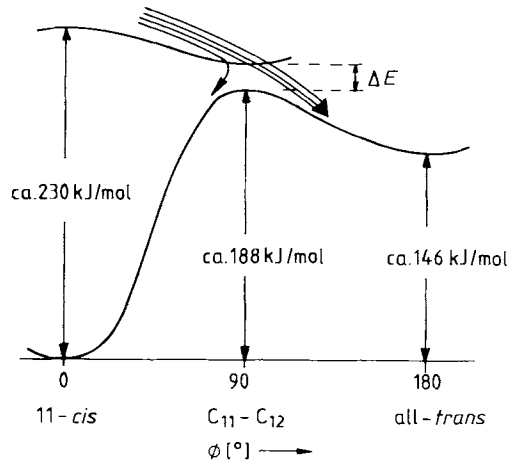

Fig. 24. Empirical ground- and excited-state potential energy surfaces for the primary step of the visual process (adapted from [147]). After initial excitation, an ultrafast, barrierless downhill transition toward the minimum at the perpendicular conformation occurs. There, the small ΔE leads to a strong coupling with the nuclear motions, so that the nonradiative transition to the ground state occurs preferentially in the "forward" direction [151], leading to highly efficient *cis-trans* conversion. The ground-state reaction is endothermic because the all-*trans* product has stored the energy needed for spatial separation of the $=N^{\oplus}$ end from its counterion [147, 152]. This energy is used to drive the ensuing chemical processes.

10. TICT States as Models for Photosynthetic Processes

The photosystems in green plants and photosynthetic bacteria store light energy by means of charge separation, which is subsequently used to drive chemical reactions (Fig. 25). Primary charge separation occurs in the so-called

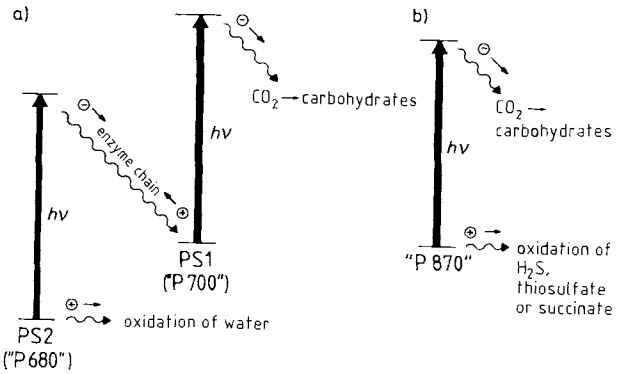

Fig. 25. a) In green plants, two quanta of light are used to pump an electron to a sufficiently high chemical potential so that CO_2 can be reduced and water oxidized (Z-Scheme [153, 154]). b) More simple photosynthetic bacteria possess only one photosystem, which resembles photosystem II (PS2) in green plants. They cannot oxidize water but need more easily oxidizable substrates like sulfides [154]. The secret of photosynthesis is connected with a problem of timing: The available energy stored by the charge-separation process has to be used chemically before the electron funnels back to the lower-energy level nonradiatively. Nature solved this problem by an electron-transfer chain.

reaction center (RC), and large progress has been made recently in elucidating its internal structure by an X-ray analysis of the RC of photosynthetic bacteria[155] (Fig. 26a). Before this, it was quite unclear whether the bacteriochlorophyll (BC) adjacent to the special pair (SP) was directly

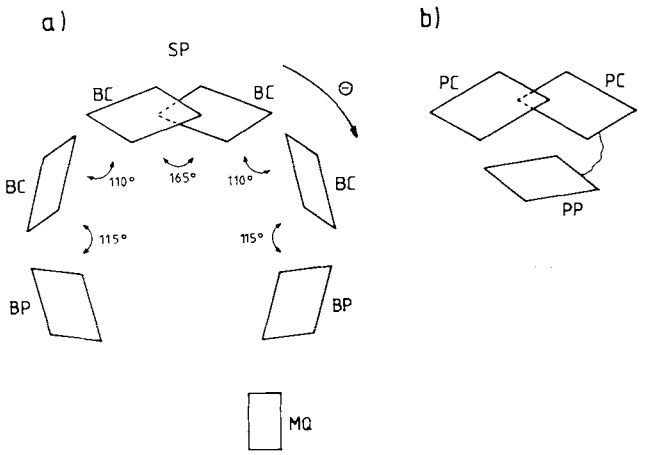

Fig. 26. a) Schematic drawing showing the spatial arrangement of chromophores of the electron-transfer chain in the reaction center of the photosynthetic bacteria *Rhodopseudomonas viridis*, according to an X-ray analysis [155]. The high degree of symmetry and the small-overlap arrangement between the chromophores is remarkable. From the antenna pigments (not shown), light energy is channeled to the "special pair" (SP), two nearly coplanar (deviation 15°) BC molecules overlapping with one of their pyrrole rings. There, the initial charge separation occurs. The electron is then transferred to a further BC molecule before it reaches a bacteriopheophytin (BP) (resembling in chemical structure the tetrapyrrole system of BC, but without a magnesium ion in its center). From there, transfer to menaquinone (MQ), the first stable intermediate species, occurs. b) Earlier photosynthetic model compounds [153] employed chromophores PC and PP, which are related to BC and BP, and used flexible linkages, which were not suitable to fix donor and acceptor in a small-overlap geometry.

involved in the electron-transport chain[156] or whether it played the role of "spectator chlorophyll."[154] Starting from SP, the chromophores are placed side by side in a two-ended symmetric chain, and not one on top of the other (Fig. 26b). They are rigidly held in this small overlap arrangement by proteins.

Several intriguing questions arise. (1) Why are the first members along the electron transport chain so similar chemically and electronically? (2) Why are the components of the RC disposed in a small overlap arrangement and not in a sandwich-type one? (3) Why is the back electron transfer to the ground state so remarkably slow[154]? (4) Why is the major part of the RC built up as an approximately symmetric double structure?

As the rate of both forward and backward electron transfer is slowed down with increasing charge separation distance,[154, 157] nature used several intermediate steps separating electron and hole further and further, until the deactivating processes become sufficiently slow (Fig. 27). A possible strategy for loosing as little energy per step as possible is shown in Figure 28. The smallest energy loss is obtained for nearly isoenergetic levels ($\Delta E \approx 0$), i.e., for electronically similar components, which answers question (1). But the small overlap arrangement (Fig. 28c) is by far superior both in the size of the actual energy loss and in the amount of charge transferred (question (2)). Moreover, a small overlap situation will automatically lead to a minimization of the back electron transfer rate for a given distance (question (3)).

The question remains why the RC is constructed in such a symmetrical manner. The primary charge separation in the SP is close to a symmetry-breaking process, resembling

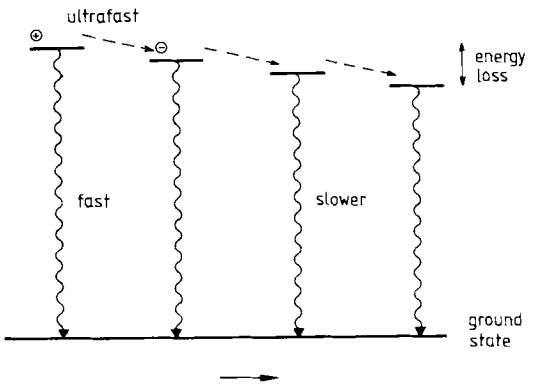

Fig. 27. The transfer of the electron along the chain has to be extremely rapid in order to prevent loss of quantum yield by the competing nonradiative decay to the ground state. As the separation between electron and hole increases, these decay processes slow down, and chemical reactions can compete with them. In order to retain enough chemically usable energy, the energy loss per single transfer step has to be kept to a minimum. A certain free-energy difference is, of course, necessary to drive the transfer. For simplicity, all the ground states have been drawn as a single level.

the situation in **28** (Section 8). Obviously, the perfectly symmetric situation is the best way for a minimal energy loss (compare Fig. 28c and d). In earlier evolutionary phases, the high symmetry of the RC seems to have included two MQ units.[155] Later, the two equivalent electron-transfer directions seem to have been given up in favor of the slightly biased system shown in Fig. 26a. It is conceivable that this biasing resulted in a considerable increase of the electron-transfer rates and thus efficiencies. A similar situation occurs in biased and nonbiased derivatives of BA,[38] which thus lend themselves to kinetic model studies.

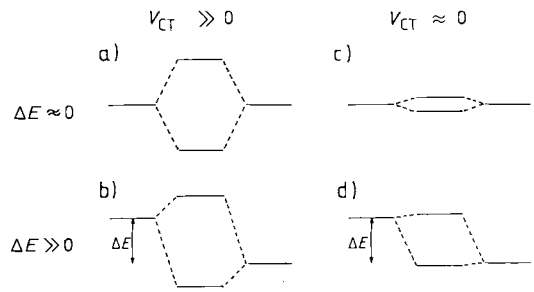

Fig. 28. Four types of interaction possible along the electron-transport chain. Left and right interacting levels, respectively, represent the situation before and after electron transfer, for infinitely separated chromophores; the center levels represent the energetic consequence of the interaction. a, b) In the large overlap case with strong interaction ($V_{CT} \gg 0$), the resulting wave functions always contain character from locally excited LE states; the CT character is thus "diluted" and never complete, especially in the case a of near degeneracy ($\Delta E \approx 0$). The resulting lower energy level is strongly stabilized (by an amount V_{CT} for case a, compared with the noninteracting levels). c, d) In the small overlap case ($V_{CT} \approx 0$), the charge separation is undiluted and complete, and the resulting lower energy level is not much stabilized, which is favorable for minimizing the energy loss per single transfer step.

11. Outlook

The notion of TICT states is just beginning to be understood as a basic mechanistic feature ("paradigm"[158]). As indicated in Section 4, the number of chemical species is rapidly growing in which unusual photophysical proper-

ties can be traced back to TICT states. The biological implications need to be explored more deeply, and the mechanistic concepts outlined may assist in the construction of more efficient model systems mimicking photosynthesis[159] and the development of new routes to artificial solar energy conversion.[160] These concepts are ready to be applied right now in the development of more efficient and versatile fluorescence and laser dyes and new fluorescent probes.

I wish to thank Prof. Z. R. Grabowski, Dr. K. Rotkiewicz, Prof. E. Lippert, Prof. J. Michl, Prof. M. W. Windsor, and Dr. D. F. Eaton for stimulating discussions. The organization of the "Workshop on the Nature of the so-called T.I.C.T. States" in June 1984 by Z. R. Grabowski and the physical chemistry group of the Polish Academy of Sciences, Warsaw, also gave a strong stimulus to this work. The skilful assistance of B. Burmeister, and Dr. H. Juds in synthesizing new TICT compounds, and of B. Dewald in the measurement of fluorescence spectra is gratefully acknowledged. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Heisenberg Foundation, the Fonds der Chemischen Industrie, and the Bundesministerium für Forschung und Technologie for support of the work.

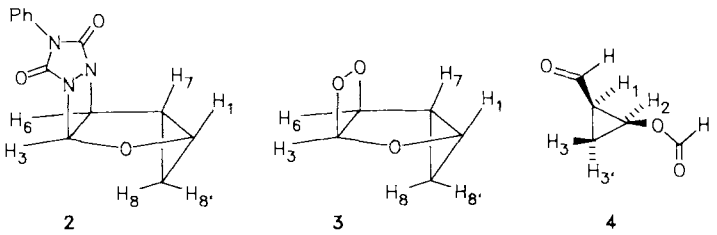
$[\pi^2+\pi^2]$ Cycloaddition of 4-Phenyl-4*H*-1,2,4-triazole-3,5-dione and Singlet Oxygen to Homofuran**

By *Waldemar Adam,* Axel Griesbeck, Frank-Gerrit Klärner,* and *Dietmar Schröer*



Homofuran **1** *can, in principle, undergo* $[\pi^2+\pi^2]$ *or* $[(\sigma^2+\pi^2)+\pi^2]$ cycloadditions with cyclophiles.[1] The latter possibility results in the opening of the central cyclopropane bond to give 8-oxabicyclo[3.2.1]oct-2-enes. In a broader sense, this cycloaddition mode is analogous to the well-known ene reaction.[2] For example, the reaction of **1** with typical dienophiles such as maleic anhydride or tetracyanoethylene (TCNE) affords quickly and in excellent yields the 8-oxabicyclo[3.2.1]octenes.

1

It was our goal, therefore, to prepare the diaza and dioxa bicyclic derivatives by using the established enophiles 4-phenyl-4*H*-1,2,4-triazole-3,5-dione (PTAD) and singlet oxygen, respectively. PTAD reacted already at -25 °C with **1** in solvents such as dichloromethane, chloroform, and Freon 11 to give quantitative yields of the $[\pi^2+\pi^2]$-cycloadduct **2**.[3] The ^{1}H-NMR data (Table 1) suggest that the cyclopropane and triazole rings are arranged *anti* to each other. For example, the missing coupling between 6-H and 7-H implies a dihedral angle of ca. 90°, as expected from Dreiding models.

Singlet oxygen, generated by photosensitization with tetraphenylporphine (TPP) or Rose Bengal (RB) also reacts with **1** to give the $[\pi^2+\pi^2]$ adduct, the dioxetane **3**. Compound **3** was formed independently of solvent polarity (chloroform, Freon 11, acetonitrile), and could be observed by means of ^{1}H-NMR spectroscopy. In most cases, *cis*-2-formyloxycyclopropanecarboxaldehyde **4**,[3,4] the decomposition product, could be isolated in high yields (up to 92%). However, when the photooxygenation was performed in a mixture of chloroform, Freon 11, and pyridine (2:1:0.1) at -30 °C, the solvent mixture removed by distillation at -20 °C/10^{-4} torr, and the residue allowed to warm up slowly at 10^{-4} torr, an 73:27 mixture of **3** and **4** could be distilled at ca. -5 °C. Comparison of the ^{1}H-NMR data of **3** (Table 1) with those of **2** clearly show formation of the *anti* product. The ^{13}C-NMR data of **3** are consistent with those of other known[5] tetrahydrofuran-annelated 1,2-dioxetanes; characteristic are the ^{13}C shifts of C-3 and C-6 (in order to facilitate comparison, structures **2** and **3** are not numbered systematically).

2 **3** **4**

Table 1. 400-MHz ^{1}H-NMR and 100-MHz ^{13}C-NMR data of the PTAD and the $^1O_2$ adducts **2** and **3**, respectively. *J* in Hz.

3, ^{1}H-NMR ($CDCl_3/CFCl_3$ 2:1, -50 °C): $\delta = 0.37$ (dd, $^2J(8,8') = 6.0$, $^3J(8,7) = 5.2$, H-8), 0.92 (ddd, $^3J(8',7) = 10.5$, $^2J(8',8) = 6.0$, $^3J(8',1) = 5.2$, H-8'), 2.16 (dt, $^3J(7,8') = 10.5$, $^3J(7,8) = 5.2$, $^3J(7,1) = 5.2$, H-7), 4.50 (br. m, H-1), 5.53 (d, $^3J(6,3) = 1.4$, H-6), 6.12 (d, $^3J(3,6) = 1.4$, H-3). — ^{13}C-NMR ($CDCl_3/CFCl_3$ 2:1, -50 °C): $\delta = 13.55$ (t, C-8), 20.82 (d, C-7), 60.32 (d, C-1), 88.83 (d, C-6), 109.02 (d, C-3)

[a] Confirmed by decoupling experiments.

Already at room temperature, solutions of **3** in toluene show a pronounced chemiluminescence. Determination of the dioxetane content by means of iodometry and application of known kinetic methods[6] afforded an activation energy of 19 ± 2 kcal/mol for the decomposition of the dioxetane. Thus, **3** belongs to the group of rather unstable dioxetanes.[7]

Homofuran **1** reacted only sluggishly with diethyl azodicarboxylate, dimethyl acetylenedicarboxylate, and (*E*)-1,2-bis(phenylsulfonyl)ethylene.[8] Even after one-day stirring of these dienophiles with **1** in dichloromethane, the starting materials could be reisolated. At 95 °C in benzene (ampoule), reaction with diethyl azodicarboxylate led to a low yield of the [2+2] adduct.

These results demonstrate that the quite reactive dienophiles PTAD and $^1O_2$ do not undergo the novel

$[(\sigma^2+\pi^2)+\pi^2]$ cycloaddition. While **1** reacts with maleic anhydride and TCNE presumably according to a classical, pericyclic mechanism,[1] reaction with PTAD or $^1O_2$ involves a $[\pi^2+\pi^2]$ cycloaddition, apparently via the dipolar intermediates **5** and **6**. These zwitterionic species appear to be sufficiently stable that exclusively $[\pi^2+\pi^2]$ adducts result. In contrast to the reaction of **1** with TCNE, for which increasing solvent polarity favors the $[\pi^2+\pi^2]$ mode over the $[(\sigma^2+\pi^2)+\pi^2]$ mode,[1] the reactions with PTAD and $^1O_2$ are not influenced by solvent polarity.

$[Cl_7Cu_5(ReS_4)]^{3\ominus}$, a Hexanuclear Complex Anion with Double Cubane-Like Structure

By *Achim Müller,* Erich Krickemeyer,* and *Hartmut Bögge*

Dedicated to Professor Oskar Glemser on the occasion of his 75th birthday

Although a large number of interesting coordination compounds containing thiometalates (such as $MoS_4^{2\ominus}$ and $WS_4^{2\ominus}$) are known,[1] no crystalline complexes containing the $ReS_4^{\ominus}$ ion, for which several crystalline salts have long been known,[2] have been reported. This is even more remarkable in that, owing to the strongly reducing $S^{2\ominus}$ ligands at the Re^{VII} center,[1] $ReS_4^{\ominus}$ should exhibit an interesting coordination chemistry. By reaction of $[NEt_4][ReS_4]$[3] with CuCl in CH_2Cl_2 in the presence of PPh_4Cl, we have now been able to obtain the diamagnetic, black Cu_5Re complex **1**, the first compound with a double cubane-like structure.[4] Compound **1** has been characterized by elemental analysis and by IR and UV/VIS spectroscopy,[5] as well as by a complete X-ray structure analysis.[6]

$[PPh_4]_2[NEt_4][Cl_7Cu_5(ReS_4)]$ **1**

[*] Prof. Dr. A. Müller, E. Krickemeyer, Dr. H. Bögge
Fakultät für Chemie der Universität
Postfach 8640, D-4800 Bielefeld 1 (FRG)

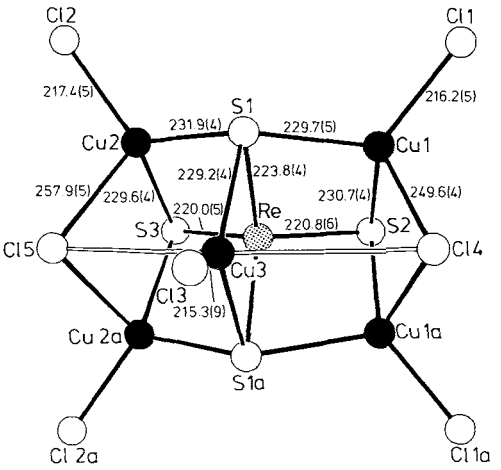

Fig. 1. Structure of the anion of **1** with bond lengths in pm. The atoms Re, S2, S3, Cu3, Cl3, Cl4, and Cl5 occupy a crystallographic mirror plane. Selected bond angles [°]: S-Re-S 106.4(2)–110.8(1), S-Cu-S 104.2(2)–105.8(2), S-Cu-Cl_{cube} 92.8(1)–100.0(2), S-Cu-$Cl_{term.}$ 119.4(2)–126.7(1), Cl-Cu-Cl 110.2(2), 110.4(2), Re-S-Cu 70.7(1)–72.2(1), Cu-S-Cu 84.4(2)–128.0(2), Cu-Cl-Cu 76.8(2)–79.5(2); further distances [pm]: Re-Cu1 263.8(2), Re-Cu2 263.7(2), Re-Cu3 266.8(4), Cu3···Cl4 331.8(6), Cu3···Cl5 293.9(6).

The anion of **1** is "rather symmetric" (Fig. 1); if the nonequivalence of the Cu3–Cl distances within the "double cubane" is ignored,[7,9] the anion has C_{2v} symmetry. Further notable features of the structure of the anion of **1** are the following: the arrangement of the six metal atoms, which form approximately a basal-plane-centered "rectangle pyramid"; the very short Re–Cu distances (263.7(2)–266.8(4) pm); the arrangement of fragments of a CuCl zigzag chain (a CuCl molecule and two Cu_2Cl_3 fragments); and, finally, the coordination number 4 for a sulfido ligand, which is relatively rare in inorganic complexes and enables the formation of the "double cubane." This coordination number has not been observed before for $MS_4^{2\ominus}$ (M = Mo, W) ligands.[1]

[2] A. Müller, E. Diemann, V. V. K. Rao, *Chem. Ber. 103* (1970) 2961. The earlier reported $TlReS_4$ (W. Feit, *Z. Angew. Chem. 44* (1931) 65) is a mixture of Tl_2S and Re_2S_7 (A. Müller, B. Krebs, *Naturwissenschaften 53* (1966) 178).
[3] A. Müller, E. Krickemeyer, H. Bögge, M. Penk, D. Rehder, *Chimia 40* (1986) 50.
[4] *Experimental Procedure:* A mixture of $[NEt_4][ReS_4]$ (0.22 g, 0.5 mmol), anhydrous CuCl (1 g, 10.1 mmol), and PPh_4Cl (1 g, 2.7 mmol) in 100 mL of CH_2Cl_2 (p.a.) was allowed to stir under argon in a closed flask for 2.5 h. After filtration, 50 mL of *n*-pentane/diethyl ether (1:1) was added to the deep red-black filtrate and the resulting solution was kept in a closed flask under argon at 20°C. Within 2–3 d, black crystals of **1** precipitated out. They were filtered off, washed with H_2O, isopropyl alcohol, and diethyl ether, and dried in air. Yield: 0.18 g (21%). **1** is slightly soluble in polar organic solvents such as CH_3CN.
[5] IR spectrum (solid, Nujol mull): 451/442 (m, $\tilde{\nu}$(ReS)), 335 cm^{-1} (w, $\tilde{\nu}_{as}$(CuCl/S)); for the assignment, see A. Müller, W. Jaegermann, W. Hellmann, *J. Mol. Struct. 100* (1983) 559. Solid-state reflectance spectrum (cellulose mull): $\lambda=700$ (charge transfer $Cu^I \rightarrow Re^{VII}$), 480, 350 nm (charge transfer $S^{2-} \rightarrow Re^{VII}$).

[6] 1 forms monoclinic crystals ($P2_1/m$, $a=950.7(7)$, $b=2453.2(9)$, $c=1395.1(8)$ pm, $\beta=99.12(5)°$, $V=3212.7\cdot10^6$ pm^3, $Z=2$). An empirical absorption correction was applied. The structure was solved by heavy atom methods ($R=0.098$, $R_w=(\Sigma w(|F_0|-|F_c|)^2/\Sigma w|F_0|^2)^{1/2}=0.095$ ($1/w=\sigma^2(F_0)+0.0002F_0^2$) for 4802 unique reflections ($F_0>3.92\sigma(F_0)$); Syntex $P2_1$ diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51954, the names of the authors, and the journal citation.

[7] The Cu-Cl distance in the "more closed" [Cu_3ReS_3Cl] cube (cf. Fig. 1) is roughly comparable to the larger Cu-Cl distance (276.4(4) pm) in [(Cu_3MoS_3Cl)(PPh_3)$_3$S] [8] with cubane structure (compare the discussions in [8] and [9]).

[8] A. Müller, H. Bögge, U. Schimanski, *J. Chem. Soc. Chem. Commun. 1980*, 91.

[9] By use of a thiomolybdate synthon, it was possible to prepare, "by unit construction," specific cluster and cage structures: a complete cubane and cubes with one or two missing corners; the latter structural unit then represents "half" of another prismatic cage system [10].

[10] A. Müller, U. Schimanski, J. Schimanski, *Inorg. Chim. Acta 76* (1983) L245.

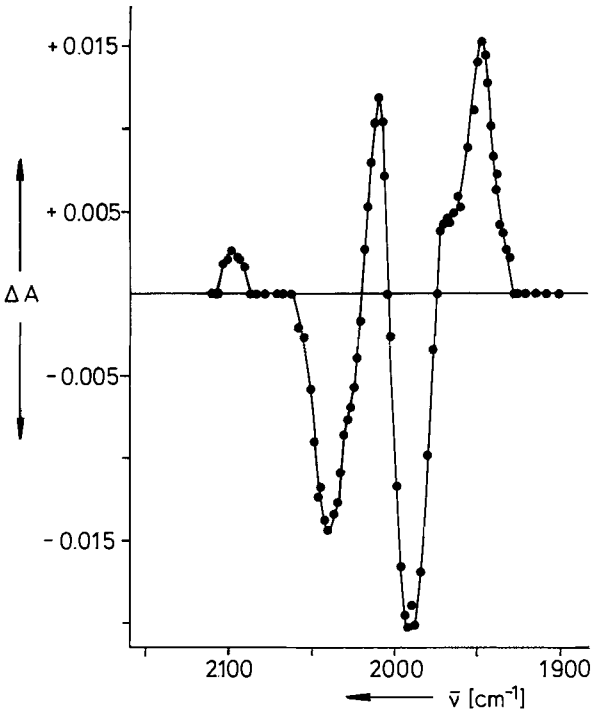

Figure 1. IR difference spectrum ca. 5 μs after flash excitation of $Os(CO)_5$ in CO-saturated C_6D_6. Positive bands correspond to $Os(CO)_4\cdot C_6D_6$, negative bands to photodepleted $Os(CO)_5$. The experimental setup for flash photolysis with fast IR detection has been described elsewhere [8, 9]. Instead of the previously used conventional flash lamps, an excimer laser (Lambda Physik EMG 200, operating on XeCl, $\lambda=308$ nm) was employed as the excitation source. For further details see text.

Flash Photolysis of $Os(CO)_5$ in Benzene Solution. Detection of $Os(CO)_4\cdot$benzene by Fast Time-Resolved IR Spectroscopy**

By *Stephen P. Church, Friedrich-Wilhelm Grevels,* Gong-Yu Kiel, William A. Kiel, Josef Takats,* and *Kurt Schaffner*

Although the photochemistry of $Fe(CO)_5$ has been extensively studied,[1] very little has been reported on the related photoreactions of $Os(CO)_5$.[2] Conversions to $Os_3(CO)_{12}$,[3] $Os_2(CO)_9$,[4] and $Os(CO)_4PPh_3$[5] are known. However, no mechanistic details have been published to date.

By means of fast time-resolved IR spectroscopy, we recently observed $Fe(CO)_4\cdot$benzene as an intermediate in the photochemistry of $Fe(CO)_5$ in benzene solution.[6,7] We now wish to report on the first experiments with the analogous osmium compound.

Flash photolysis of an 8×10^{-4} M solution of $Os(CO)_5$ in CO-saturated C_6D_6[10] yielded the transient difference spectrum shown in Figure 1, which exhibits four positive (2097, 2010, 1966 (sh), 1948 cm^{-1}) and two negative absorptions (2040, 1990 cm^{-1}) in the CO stretching vibrational region. The positive bands are different from those reported for $Os(CO)_4$ in a methane matrix[11] and are assigned to the species $Os(CO)_4\cdot C_6D_6$ formed through reaction (1).

$$Os(CO)_5 \xrightarrow[C_6D_6]{h\nu} Os(CO)_4\cdot C_6D_6 + CO \qquad (1)$$

The characteristic four-band pattern is in accordance with a C_{2v} structure of the $Os(CO)_4$ unit,[12] as has been proposed for the analogous $Fe(CO)_4\cdot C_6D_6$ complex.[6] The two negative absorptions, corresponding to photodepleted $Os(CO)_5$, occur in an intensity ratio of 1:1.4 as found in the IR spectrum of the pure compound, thus confirming that the absorptions of $Os(CO)_4\cdot C_6D_6$ are not overlapped by those of the starting material.

The transient $Os(CO)_4\cdot C_6D_6$ decays by first-order kinetics. The rate constant, k_{obs}, for the disappearance of $Os(CO)_4\cdot C_6D_6$ ([$Os(CO)_5$]$=8\times10^{-4}$ M; [CO]$=1.1\times10^{-2}$ M[13]) is 940 s^{-1}, i.e., two orders of magnitude faster than for $Fe(CO)_4\cdot C_6D_6$ under the same conditions.[6] $Os(CO)_5$ is regenerated concurrent with the decay of $Os(CO)_4\cdot C_6D_6$ and no other product is observed.[14] In a similar experiment, but with a CO concentration of only 10^{-3} M,[13] k_{obs} is markedly reduced to 150 s^{-1}. Furthermore, under these conditions the formation of $Os_2(CO)_9$ [$\tilde{\nu}$(CO)$=$2084 (s), 2042 (vs), 2032–2012 (unresolved), 1772 (m) cm^{-1}],[15] as a permanent product on the second time-scale, is also evident. Thus, the decay of $Os(CO)_4\cdot C_6D_6$ is CO-concentration dependent and the formation of $Os_2(CO)_9$ is favored at higher [$Os(CO)_5$]/[CO] ratios. Further, k_{obs} was shown to be inversely dependent on the C_6D_6 concentration in experiments performed in C_6D_6/cyclohexane mixtures. These observations are explained most simply in terms of reactions (2)–(4).

$$Os(CO)_4\cdot C_6D_6 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Os(CO)_4 + C_6D_6 \qquad (2)$$

$$Os(CO)_4 + CO \xrightarrow{k_3} Os(CO)_5 \qquad (3)$$

$$Os(CO)_4 + Os(CO)_5 \xrightarrow{k_4} Os_2(CO)_9 \qquad (4)$$

[**] This work was supported by the Alexander von Humboldt Foundation through a stipend (to *S. P. C.*). We thank Dr. *H. Hermann* for his collaboration, Miss *K. Fuchs* for technical assistance, and Johnson Matthey & Mallory Ltd. for a generous loan of osmium tetroxide.

For $[CO]=10^{-3}$ M and $[Os(CO)_5]=8\times10^{-4}$ M, further depletion of the $Os(CO)_5$ band at 1990 cm^{-1} occurs concurrent with the decay of $Os(CO)_4\cdot C_6D_6$; thus, $k_4>k_3$. However, at $[CO]=1.1\times10^{-2}$ M and $[Os(CO)_5]=8\times10^{-4}$ M, reaction (4) does not compete with reaction (3). Thus, a reasonable estimate is $k_4/k_3\approx2$.

$Fe(CO)_4$·benzene reacts with CO two orders of magnitude slower than does $Os(CO)_4$·benzene. This sharply contrasts with the behavior of the pentacarbonylmetal·benzene compounds of the chromium group, where the complex of the heavier metal, $W(CO)_5$·benzene, reacts significantly slower than $Cr(CO)_5$·benzene.[8a] The opposite behavior of the iron and osmium species might be due to the triplet nature of $Fe(CO)_4$[16] or to the involvement of other intermediates.

The Use of (+)-8-Phenylneomenthol in the Synthesis of Enantiomerically Pure (−)-Jasmonate Methyl Ester**

By *Gerhard Quinkert,* Hans-Günther Schmalz, Elmar M. Dzierzynski, Gerd Dürner,* and *Jan W. Bats*

Dedicated to Professor Vladimir Prelog on the occasion of his 80th birthday

(−)-8-Phenylmenthol **1**[1] has proved to be valuable as a chiral auxiliary reagent[3] for the synthesis of dimethyl (*R*)-(+)-2-vinyl-1,1-cyclopropanedicarboxylate **2b**,[4] a chiral building block for the synthesis of enantiomerically pure (+)-estrone[5] or (−)-norgestrel.[6] (+)-8-Phenylmenthol

ent-**1** would be a welcome chiral auxiliary reagent for the synthesis of enantiomerically pure (−)-jasmonate methyl ester **3**[7,8] via dimethyl (*S*)-(−)-2-vinyl-1,1-cyclopropanedicarboxylate *ent*-**2b**, but *ent*-**1** is difficult to prepare.[2b] Thus, up to now it has only been possible to obtain the chiral synthetic building block *ent*-**2b** via a detour by diastereomerization of **2c** to **4a**,[7,9] which is then converted into **3**.

As suggested by an analysis of the stereoelectronic requirements for cyclopropanation via an S_{cN} reaction,[10] (+)-8-phenylneomenthol **6** should act similarly to *ent*-**1**. Indeed, reaction of **6** (in the presence of imidazole and 4-(*N*,*N*-dimethylamino)pyridine in CH_2Cl_2) with malonyl dichloride gives the corresponding malonic diester (m.p. = 132 °C, $[\alpha]_{589}^{20}=+31.4°$; >80% yield), which, by reaction with (*E*)-1,4-dichloro-2-butene (analogously to the preparation of **2c** according to ref. [5]), affords the diastereomers **5** (in 57% yield based on the malonic diester) and **2d** in a ratio of 92:8.[11,12] The sterically congested three-membered ring compound **5**, which can be smoothly separated from **2d**, is converted into *ent*-**2b** by ester hydrolysis followed by treatment of the resulting dicarboxylic acid with diazomethane (analogously to the preparation of **2b** according to ref. [5]). This procedure considerably simplifies the synthesis of enantiomerically pure **3**.[7]

The new chiral auxiliary **6** can be conveniently and more easily prepared than the chiral auxiliary (+)-8-phenylisomenthol **11**[2a,3b] by reduction of a mixture of (−)-8-phenylmenthone **7** and (+)-8-phenylisomenthone **8** with $NaBH_4$, and, therefore, **6** may be prepared from (*R*)-(+)-pulegone **9**; overall yield of **6**: 47%, based on **9** (85%).

Table 1. Values of the specific optical rotation in $CDCl_3$.

Compd	1	6	7	8	10	11
$[\alpha]_D^{20}$ [°]	−32.8	+36.1	−63.7	+89.4	−46.3	+16.0
c [g/100 mL]	1.00	0.75	0.72	1.42	0.61	0.76

Table 1 shows the values of the specific optical rotation for the menthone and menthol derivatives mentioned.[14]

Experimental Procedure

The crude product (68 g) obtained by copper-catalyzed addition of phenylmagnesium bromide to **9** (≈85%, Fluka) and equilibration of the resulting mixture of **7** and **8** with a solution of ethanolic potassium hydroxide (before, 54/46; after, 84/16) [2a] was dissolved in 450 mL of dry methanol and 5.65 g of $NaBH_4$ was added in portions to the vigorously agitated solution at −7°C. The mixture was then stirred for 4 h, returning to room temperature. After addition of 85 mL of 2N hydrochloric acid and 70 mL of saturated aqueous ammonium chloride solution followed by the usual workup, 68 g of oily product was obtained, which, according to HPLC analysis, consisted mainly of the stereoisomeric alcohols **6**, **10**, and **1** (68 : 19 : 13). Preparative HPLC (isohexane/ethyl acetate = 10 : 0.8, repeated once) and kugelrohr distillation (0.04 torr/160°C bath temperature) afforded 32 g of **6**. [$[\alpha]_\lambda^{20}$ = +36.1 (589), +37.5 (578), +42.1 (546), +71.0 (436), +107.5 (365 nm) (c = 0.75 g/100 mL in $CHCl_3$)].

Crystal Structure of Cl_2O_6**

By *Klaus M. Tobias* and *Martin Jansen**

With the exception of iodine(v) oxide, the halogen oxides have positive enthalpies of formation. Despite (or because of?) the resulting instability (decomposition and disproportionation) this class of substances has been the subject of intensive investigation.[1] Nonetheless, there are still large gaps in our knowledge of the chemistry of such compounds. For instance, reliable data on the molecular structures are often lacking, so that systematic classification of these compounds and discussion of their bonding properties is not possible. To date, only the crystal structure of I_2O_5 has been determined.[2]

Of particular interest are halogen oxides with even-numbered oxidation states of the halogen atom, since these compounds have—at least for the monomer in each case—an odd total number of electrons. For the chlorine oxides, this is the case for ClO_3 (or Cl_2O_6) besides ClO_2. There is no uniform agreement as to the structure of Cl_2O_6. Depending on the state of aggregation and the method of detection, the following species have been proposed: a pyramidal monomer,[3] a symmetrical dimer which contains a Cl–Cl bond or is doubly μ-oxo-bridged,[4] an unsymmetrical dimer (mixed anhydride),[1a] and an ionic mixed-valent dimer ($ClO_2^+ClO_4^-$).[5] The ionic mixed-valent dimer formulation is supported, in particular, by the chemical action of Cl_2O_6 as a source of perchlorate groups, for example in the preparation of anhydrous perchlorates.[1a,6] We report here on the unambiguous structural characterization of Cl_2O_6 in the crystal.

Cl_2O_6[7] was prepared, according to a modified version of the classical procedure of *Bodenstein* et al.,[8] from ClO_2 and O_3. The yields can be significantly improved by combining the two gases by means of a Daniel's valve and by filling the reaction volume with Raschig rings, which results in good mixing of the two gases and a prolonging of the time the two compounds spend in the reaction zone. The crude product was purified by fractional condensation. The pure Cl_2O_6 so obtained is a crystalline, transparent red-brown solid. It reacts violently with water and with oxidizable substances, but can be stored safely at below −30°C. The crystallization was carried out by subliming pure Cl_2O_6 onto a cold finger (−2°C → −25°C), which results in the formation of coarse single crystals. For the X-ray structure analysis, the single crystals (m.p. = 3°C) were sealed under inert gas in Lindemann tubes.

The crystal structure analysis[9] shows unequivocally that Cl_2O_6 exists in the solid state as ionic chlorylperchlorate, $ClO_2^+ClO_4^-$. To a first approximation, the ions can be described as being "isolated." Their centers of gravity are arranged nearly as in the CsCl type of structure. The ClO_2^+ dipoles are oriented ferroelectrically. This polar arrangement is reflected in a similar orientation of the ClO_4 tetrahedra, one of the threefold axes being directed in each case toward [001] (compare Fig. 1).

Within the limits of error, the ClO_2^+ *ion has* C_{2v} symmetry (for structure data, see Fig. 1). Bond lengths and angles are in good agreement with those determined for ClO_2GeF_5;[10] compared with ClO_2 in the gaseous state (147.5(3) pm, 117.7(1.7)°), the Cl–O distance is considera-

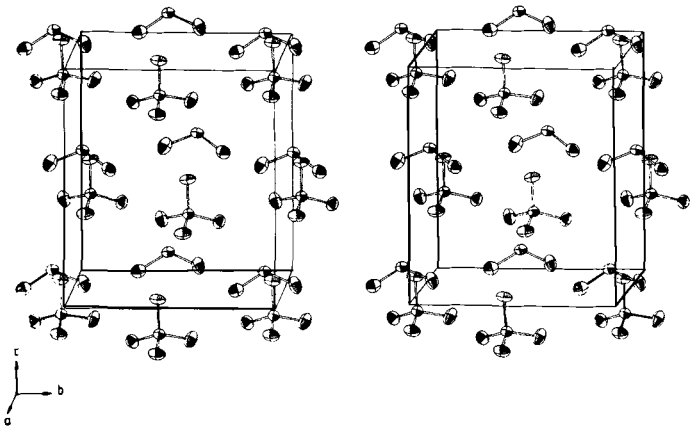

Fig. 1. Stereoview of the crystal structure of Cl_2O_6. Cl1 as well as O1 and O2 belong to ClO_2^+, Cl2 and O3-O6 to ClO_4^-. Selected bond lengths [pm] and bond angles [°]: Cl1-O1 140.6(2), Cl1-O2 141.0(2), Cl2-O3 146.7(2), Cl2-O4 143.0(2), Cl2-O5 145.7(3), Cl2-O6 141.7(3); O1-Cl1-O2 118.9(3), O-Cl2-O 108.0-110.8.

bly reduced. Since one electron is removed from an antibonding orbital in going from ClO_2 to ClO_2^+, a shortening of the Cl-O bond length would be expected, although not by this amount (Fig. 1). On the other hand, the widening of the bond angle relative to that in ClO_2—likewise expected[11]—is small (1.2°). The average of the bond lengths in the ClO_4^- ion (144.2 pm) is in agreement with expectations; however, the deviation of the individual values lies significantly above the experimental error. An association of cations and anions is suggested by the observation that precisely those oxygen atoms that have the smaller intermolecular distances to the chlorine atom in ClO_2^+ (250 and 251 pm) also have the (significantly) larger Cl-O distances in the ClO_4^- ion (146 and 145 pm). This certainly weak interaction cannot be viewed as a precursor for symmetrically μ-oxo-bridged dimers since each cation is linked with two anions (and vice versa) to form polymeric chains.

Since Cl_2O_6 undergoes sublimation, a transport as the ion pair $ClO_2^+ClO_4^-$ is unlikely, and a molecular monomeric or dimeric structure is therefore expected for gaseous Cl_2O_6. In fact, we found that a mixed anhydride of the chloric and perchloric acid is present in the gas phase.[12]

Optically Active Cyclopentanediol Synthetic Building Blocks from Tartaric Acid

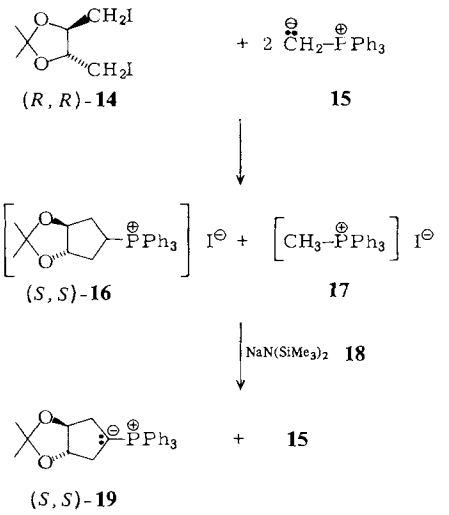
By *Hans Jürgen Bestmann** and *Thomas Moenius*

Dedicated to Professor Vladimir Prelog on the occasion of his 80th birthday

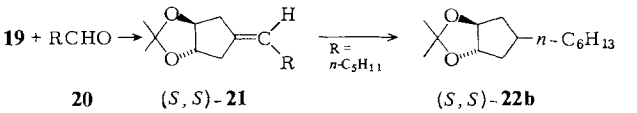
Optically active hydroxylated cyclopentanes are of general interest as building blocks for the synthesis of cyclopentanoid natural products.[1] We report here a route to enantiomerically pure cyclopentanediol derivatives starting from tartaric acid (Scheme 1).

Scheme 1. a) 1. NaH, 2. $ClSiMe_3$, 95% yield of **2**, $[\alpha]_D$ −53.7° (THF, $c = 0.5$ g/100 mL), b.p. = 65°C/0.05 torr. b) Elimination of $Me_3SiOSiMe_3$, 56% yield of **5**, $[\alpha]_D$ −59.0° (methanol, $c = 0.5$ g/100 mL), m.p. = 121°C. c) 56% yield (based on **5**) of **6**, $[\alpha]_D$ +50.0° (methanol, $c = 0.5$ g/100 mL), m.p. = 91°C. d) $H^{\oplus}$. e) Na_2CO_3.

[*] Prof. Dr. H. J. Bestmann, Dr. T. Moenius
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (FRG)



The known acetonide **1** of the monomethyl ester of (*R*,*R*)-(−)-tartaric acid[2] can be converted, via its sodium salt,[3] into the methyl trimethylsilyl ester **2**, which reacts in turn with the phosphorane **3** to give the acyl ylide **5**.[4] Heating of **5** for eight days in refluxing toluene leads to inversion at C4; the diastereomer **4** was detected by NMR spectroscopy. This diastereomerization is followed by an intramolecular Wittig reaction at the ester carbonyl group[5] to give the acetonide **6** of (4*S*,5*R*)-4,5-dihydroxy-2-cyclopentenone. The *cis* ring junction of the two five-membered rings in **6** could be shown by NOE ^{1}H-NMR experiments (identical interaction of a ketalic CH_3 group with both H atoms on C4 and C5). Further NMR investigations with optically active europium shift reagents show that, within the limits of error of this method, **6** is enantiomerically pure.[6] It is possible, in this way, to prepare **6** on a 5–10-g scale from inexpensive (*R*,*R*)-tartaric acid.—Starting from (*S*,*S*)-(+)-**1**, (4*R*,5*S*)-**6** may be prepared via (*S*,*S*)-**2** and (*S*,*S*)-**5**. The $[\alpha]_D$ values correspond to one another at each stage.



Compound **6** is a key synthetic intermediate. Regioselective 1,2 or 1,4 addition of organometallic compounds opens up the posssibility of obtaining the acetonide **12** enantioselectively from 3-alkyl-4,5-dihydroxy-2-cyclopentenones.

The reaction of **6** with strongly nucleophilic organometallic compounds **8** results in 1,2 addition to the carbonyl group to give compounds **11**. They are obtained as mixtures of diastereomers in which one component predominates; because of the lability of the compounds, it was not possible to make a definitive assignment of the main isomer. Proton catalysis results in the conversion of **11** into the compounds (*S*,*S*)-**12**, presumably via allyl rearrangement and the intermediacy of the nonisolable semiketal **10**.[7] The product was shown to be enantiomerically pure by NMR spectroscopy.[6] The results are presented in Table 1. Particularly noteworthy is the interesting change in $[\alpha]_D$ with increasing steric bulk of the group R. Proton-catalyzed elimination of water results in the formation of the ketene dithioacetal **13** from **11e** (Table 1).

Compound **6** undergoes 1,4 addition with the weakly nucleophilic lithium organocuprate **7**. Hydrolytic workup gives the compounds **9**, in which one diastereomer predominates. Base-catalyzed elimination of methanol leads once again to **12**. Since the allyl rearrangement does not occur in this case, one obtains the (*R*,*R*) enantiomer of **12**, whose optical purity was established by NMR spectroscopy.[6] The optical purity is also revealed in the $[\alpha]_D$ values of (*R*,*R*)-**12b** and (*R*,*R*)-**12d** (Table 1).

By selecting different nucleophilic organometallic compounds with the same R group—**7** or **8**—it is thus possible to synthesize selectively, via **6**, the optically pure enantiomers (*R*,*R*)- or (*S*,*S*)-**12** starting from inexpensive (*R*,*R*)-tartaric acid.

Scheme 2. (*S*,*S*)-**21a**, R = Ph, yield 38%, b.p. = 106 °C/0.05 torr (kugelrohr), $[\alpha]_D$ + 31.9° (methanol, *c* = 1.0 g/100 mL); (*S*,*S*)-**21b**, R = *n*-C_5H_{11}, yield 43%, b.p. = 80 °C/0.05 torr (kugelrohr), $[\alpha]_D$ + 113.8° (methanol, *c* = 1.5 g/100 mL); (*S*,*S*)-**22b**, yield 92%, b.p. = 75 °C/0.05 torr (kugelrohr).

Further, using the method described earlier by us,[8] we have carried out the reaction of the (*R*,*R*)-(−)-bisiodide **14**,[9] which is readily accessible from tartaric acid, with methylenetriphenylphosphorane **15** in a molar ratio of 1 : 2 (Scheme 2). This reaction resulted in the formation of a mixture of the phosphonium iodides (*S*,*S*)-**16**[10] and **17**, which are converted into the phosphonium ylides **19** and **15** by reaction with sodium bis(trimethylsilyl)amide **18**. Reaction of the mixture of **19** and **15** with the aldehydes **20** results in the formation, by Wittig reaction, of a mixture consisting of the cyclopentanediol derivatives **21**, with exocyclic double bond, and the unsaturated compounds (from **15**), which can be easily separated by distillation (Scheme 2). According to the ^{1}H-NMR spectra, only *one* diastereomer of **21** is present. On the basis of the optical activity of **21**, it is not possible to decide whether the two five-membered rings of **21** are *cis*- or *trans*-linked; the *trans* arrangement is demonstrated, however, by the formation of the hydrogenation product **22b** (Scheme 2). Compound **22b** is an optically active, diastereomerically pure acetal with $[\alpha]_D$ + 21.8° (methanol, *c* = 1.5 g/100 mL). For the *cis* arrangement, the hydrogenation product would have been achiral.

Table 1. Reaction of (4*S*,5*R*)-**6** to give (*S*,*S*)-**12** via **11** (above) and to give (*R*,*R*)-**12** via **9** (below).

$NaNb_3O_5F$—A Niobium-Niobium Triple Bond with "Side-On" Coordination by Nb Atoms

By *Jürgen Köhler* and *Arndt Simon**

The halides and chalcogenides of transition metals in low oxidation states often contain metal-metal bonds occurring in isolated or condensed clusters.[1] The number of such cluster compounds is still small in the case of oxides and fluorides. A relatively large number are known for molybdenum (e.g., $LiZn_2Mo_3O_8$, $Ba_{1.14}Mo_8O_{16}$, $NaMo_4O_6$, $Ca_{5.45}Mo_{18}O_{32}$, $Sc_{0.5}Zn_{1.25}Mo_4O_8$,[2] $In_{11}Mo_{40}O_{62}$,[3a,b] $In_3Mo_{11}O_{17}$[3c]), but only a few examples have been observed for the neighboring elements ($Mg_3Nb_6O_{11}$,[4] La_2ReO_5,[5] $La_4Re_6O_{19}$,[6] $Nd_4Re_2O_{11}$,[7] $Mn_3Nb_6O_{11}$,[8] $BaRuO_3$[9]). In the alkali-metal oxoniobates $LiNbO_2$[10a] and $NaNbO_2$,[10b] short Nb-Nb distances are found within the NbO_2^- layers (isostructural with MoS_2), suggesting M-M bonds.[11]

The occurrence of discrete Nb_6X_{12} clusters in Nb_6F_{15}[12] and in $Mg_3Nb_6O_{11}$ has prompted the search for comparable compounds with niobium oxide fluorides. To date, only $ANbO_2F$ (A = Li, Na, K)[13] and the always oxygen-containing "NbF_3"[14] have been described.

By addition of NaF to the repeatedly studied system Na_2O-Nb-Nb_2O_5,[10b,15] it is possible, among other things, to vary the number of electrons available for the Nb-Nb bonds by means of the O/F ratio. In this way, a new oxide fluoride is obtained as a crystalline component of an always heterogeneous reaction product (see Experimental Procedure). The reaction aimed at the composition $NaNb_3O_5F$ has the highest yields. A pure oxide, $NaNb_3O_6$, cannot be synthesized, even in traces, despite wide variation of the experimental conditions.

A differentiation between O and F atoms is neither possible by crystal structure analysis[16] nor by MAPLE calculations[17] or bond length-bond strength considerations[18] on the basis of the positional parameters found. For simplicity, therefore, the formula "$NaNb_3X_6$" with X = O, F will be used in the discussion of the crystal structure (compare Table 1).

Table 1. Motifs of mutual adjunction [a] in $NaNb_3O_5F$ ($NaNb(1)Nb(2)_2X(1)X(2)X(3)_4$). C.N. = coordination number.

	X(1)	X(2)	4X(3)	C.N.
Na	2/2	2/2	4/1	8
Nb(1)	—	—	4/1	4 + Nb(1) (261.4 pm)
2 Nb(2)	1/2	1/2	4/2	6
C.N.	4	4	4

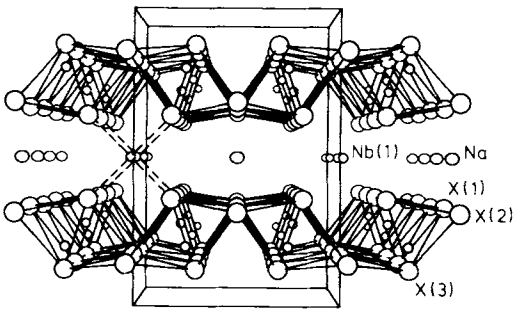

Fig. 1. $NaNb_3O_5F$, perspective drawing of the crystal structure along [001]. The layers formed from linked $Nb(2)X_6$ octahedra, as well as a $Nb(1)_2X_8$ arrangement, are graphically emphasized.

The structure (Fig. 1) contains chains of $Nb(2)X_6$ octahedra, which are *trans*-edge-linked via X(3) atoms and vertex-linked via X(1) and X(2) to form folded layers of composition $^2_\infty[NbX_{1/2}X_{1/2}X_{4/2}] = NbX_3$. Rows of Nb(1) and Na atoms are inserted between the layers. Whereas the Na atoms exhibit regular spacing, the distances between the Nb(1) atoms alternate along the chains leading to Nb-Nb pairs with the shortest distance known, $d_{Nb\text{-}Nb} = 261.4$ pm.

A $[Nb_2X_8]$ group (Fig. 2, left) is formed with the surrounding X(3) atoms. Such groups are found for molecular species, e.g., $[Re_2Cl_8]^{2-}$, as well as in the crystal structure of the ternary oxide $La_2ReO_5 = La_4O_2[Re_2O_8]$. Short Nb-Nb distances in Nb_2 pairs (though with intramolecular ligands) are known for $Cs_3Nb_2Cl_9$ (270 pm, double bond)[19] and $[Nb_2(CO)_2Cp_2(C_2R_2)]$ (R = CH_3CO_2) (273 pm, single bond).[20]

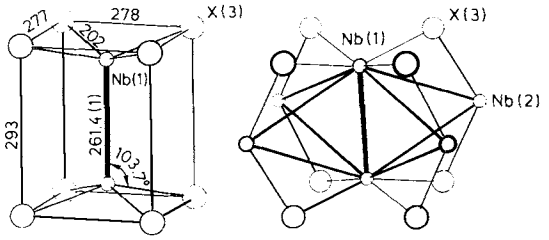

Fig. 2. Left: $[Nb_2X_8]$ subunit in $NaNb_3O_5F$. Interatomic distances are given in pm. Right: $[Nb_2Nb_4X_8]$ subunit in $NaNb_3O_5F$ with the $Nb(1)_2$ dumbbell [d(Nb(1)-Nb(1) = 261.4 pm] and the "side-on" bonded Nb(2) atoms [d(Nb(2)-Nb(1)) = 309 pm, d(Nb(2)-Nb(2)) = 327 pm and 456 pm].

Comparative bond length-bond strength calculations[18] for NbO_2 and $NaNb_3O_5F$ show that the Nb(2) atoms are present in the +4 oxidation state. Thus, a formal charge of −12 is obtained for the $[Nb_2X_8]$ unit with Nb(1) in the oxidation state +2. In analogy to molecular species, e.g., $Mo_2(OR)_6$,[21] a $\sigma^2\pi^4$ triple bond comes into question for the Nb–Nb dumbbell.

However, Figure 2, right, indicates that each Nb_2 pair in the structure of $NaNb_3O_5F$ is "side-on" coordinated by four Nb^{4+} ions. The Nb^{4+} ions are displaced by about 15 pm from the centers of gravity of the (distorted) coordination octahedra in the direction of an edge X(3)–X(3) toward the Nb_2 dumbbell [d(Nb(1)–Nb(2))=309 pm, distance to the center of gravity of the dumbbell 281 pm)]. The d^1 ion Nb^{4+} apparently tends to engage in metal-metal bonding as observed in the structures of the tetrahalides NbX_4 (X=Cl, Br, I).[1a,22] For $NaNb_3O_5F$ these bonds can be regarded as two-electron three-center bonds between Nb^{4+} ($d_{x^2-y^2}$) and π orbitals of the Nb_2 dumbbell; other configurations are also conceivable. The diamagnetism found for $NaNb_3O_5F$ is in agreement with the assumption of a spin pairing of all ten valence electrons in the resulting [1.1.1.1]propellane-Nb_6 cluster, but is not a proof for this idea of bonding, since $NaNbO_2F$[13] also does not show the magnetism for a d^1 configuration.

It is remarkable that the arrangement $M_2M_4X_8$ (Fig. 2, right) is also found in the structure of Gd_2Cl_3,[23] although as part of an infinite chain. The electronic band structure calculated for the chain can also be interpreted in terms of the presence of $\sigma^2\pi^4$-bonded Gd_2 pairs, which form Gd–Gd bonds in the direction of the chain via their π systems.[24]

Experimental Procedure

Dried NaF (p.A Merck) was ground into a mass with Nb powder (LAB, Merck) and Nb_2O_5 (Merck, Patinal®) and placed in a corundum crucible. This was fused under argon in a quartz ampoule and annealed for 3 d at 800°C. In addition to NbO, NbO_2, and oxide fluorides (e.g., $NaNbO_2F$), black, metallic appearing, parallelepiped-shaped single crystals of $NaNb_3O_5F$ were formed. By repeated grinding, compression, and annealing of a tablet containing NaF, Nb, and Nb_2O_5 (molar ratio 1.2 : 1 : 1; each 1 d at 750°C), $NaNb_3O_5F$ in ca. 80% yield was obtained. Such a product, washed with hydrochloric acid, contained 5.6% F. This value exceeds the calculated one for $NaNb_3O_5F$ (4.7%) by only 0.9% and can be explained by the higher F content for the side products, e.g., $NaNbO_2F$ (11.4% F).

Conformational Prerequisites for the in vitro Inhibition of Cholate Uptake in Hepatocytes by Cyclic Analogues of Antamanide and Somatostatin**

By *Horst Kessler,* Mechtild Klein, Arndt Müller, Klaus Wagner, Jan Willem Bats, Kornelia Ziegler,* and *Max Frimmer*

It is well known[1] that liver cells are protected by antamanide **1**[2] against poisons such as ethanol, dimethyl sulfoxide (DMSO), cysteamine, or phalloidin,[3] a toxin isolated from the mushroom *Amanita phalloides*. In recent years a similar cytoprotective effect has also been found for somatostatin **2**,[4] a naturally occurring peptide hormone.[5] Biochemical in vitro investigations of **1** and **2** as

antamanide **1** somatostatin **2**

well as of their derivatives have shown that the cause of this biological effect is the inhibition of a transport system.[6] This system is responsible for the transport of cholate from blood into the bile and also for the detoxification of the blood via the bile.[6] Searching for a common structural feature for the activity of antamanide and somatostatin, we found that cyclic peptides containing the modified

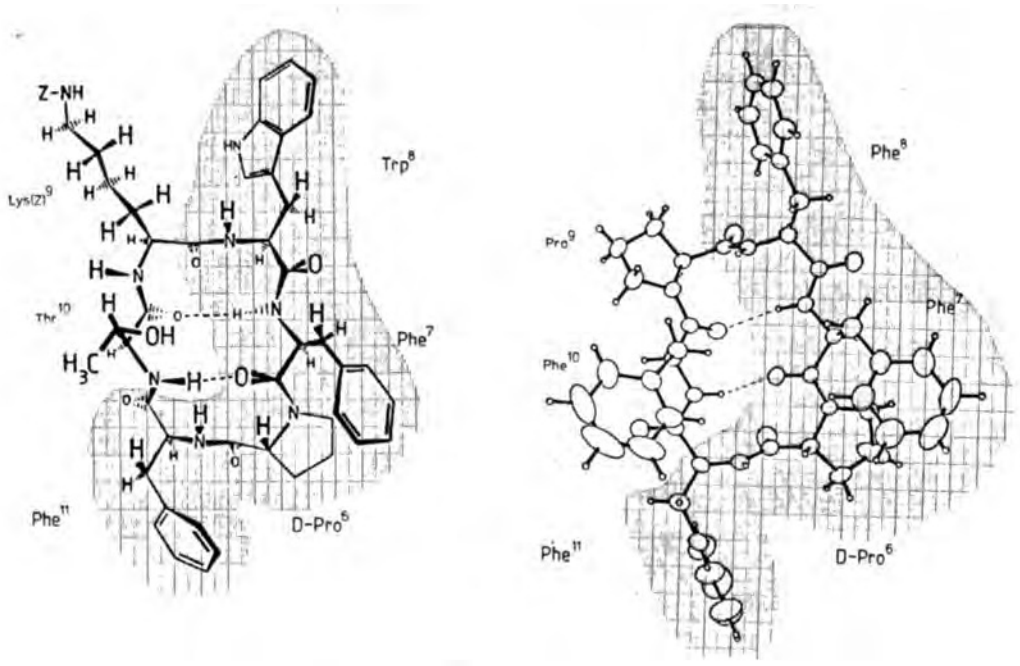

Fig. 1. Conformation of *cyclo*(-Phe-Thr-Lys(Z)-Trp-Phe-D-Pro-) **3** in DMSO (left) and *cyclo*(-Phe-Phe-Pro-Phe-Phe-D-Pro-) **5** in the crystal (right).

retro-sequence 6–11 of somatostatin[6] exhibit high cytoprotective activity. Figure 1 (left) shows the preferred conformation of the most effective peptide found so far

cyclo(-Phe-Thr-Lys(Z)-Trp-Phe-D-Pro-) **3**

(Z = benzyloxycarbonyl). The conformation was determined by means of 2D NMR methods[7] in DMSO solution.

The comparison of a number of cyclic peptides demonstrates that cytoprotective activity requires two adjacent aromatic amino acid residues. Activity is increased when an L-proline residue precedes this sequence or a D-proline residue follows (Table 1). Therefore, it was not surprising that cyclolinopeptide A **4**[8] (Table 1), which was isolated from linseed oil, also inhibits the uptake of cholate into hepatocytes. As far as we know, this is the first biological activity that has been found for this natural product.

Table 1. 50% Inhibition of cholate uptake in isolated hepatocytes by cyclopeptides [6].

However, in addition to the sequence homology the spatial structure is also crucial for the biological effect.[9] To determine the conformational requirements *cyclo*(-Pro-Pro-Phe-Phe-Gly-) was synthesized. The conformation of this homologue of antamanide and cyclolinopeptide A was studied in solution.[10] The spatial arrangement of the backbone and the side chains of the two phenylalanine residues strongly differs from the conformations of the bioactive cyclopeptides mentioned above.[11,12] As expected, this cyclopentapeptide does not exhibit cytoprotective activity. In contrast, the crystal conformation of the sequence analogue of antamanide, *cyclo*(-Phe-Phe-Pro-Phe-Phe-D-Pro-) **5**,[13] agrees to a large extent with the conformation of **3** in solution (Fig. 1, right). Thus, in this peptide the constitutional and conformational requirements for biological activity are excellently fulfilled. Indeed, this compound strongly inhibits the uptake of cholate into hepatocytes (Table 1). Therefore, there is good reason to localize the hatched regions of the molecules **3** and **5**, shown in Figure 1, as that part of the peptide which is responsible for the biological activity. Computer-assisted molecular modeling will show whether other compounds affecting the cholate transport system will have the same spatial structure.

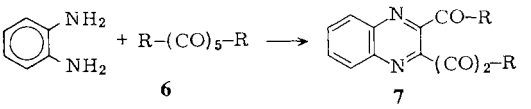
Vicinal Pentaketones**

By *Rolf Gleiter,* Gerhard Krennrich,* and *Michael Langer*

Dedicated to Professor Mordecai B. Rubin on the occasion of his 60th birthday

The kinetic stability decreases with increasing number of carbonyl groups in going from vicinal dicarbonyl to tricarbonyl to tetracarbonyl compounds. Vicinal tri- and tetraketones[1,2] react readily with water and rearrange in the presence of base, undergoing decarbonylation. Vicinal pentaketones have not yet been prepared. We report here on the synthesis (Scheme 1) and some properties of tBu(CO)$_5t$Bu **6a** and Ph(CO)$_5$Ph **6b**, the first vicinal pentaketones.



1 **2** **3** **4** **5** **6**

a, R = t-C$_4$H$_9$; **b**, R = C$_6$H$_5$

Scheme 1. a) NaH, monoglyme; b) p-CH$_3$–C$_6$H$_4$–SO$_2$N$_3$/Et$_3$N, CH$_3$CN; c) t-C$_4$H$_9$–OCl/HCOOH; d) P_2O_5, CHCl$_3$.

The readily available compounds 2,2,8,8-tetramethyl-3,5,7-nonanetrione **3a** and 1,5-diphenyl-1,3,5-pentanetrione **3b**[3] can be converted into the bisdiazo compounds **4a** and **4b**, respectively.[4] Reaction of these products with *tert*-butyl hypochlorite in formic acid[5] leads directly to the hydrates of the pentaketones **5a** and **5b**, respectively, which can be dehydrated to the deeply colored pentaketones **6a** and **6b**, respectively. Both pentaketones react smoothly with *o*-phenylenediamine to give the corresponding quinoxaline derivatives **7a** and **b**.

The most important spectroscopic data of **4**–**7** are given in Table 1. The electronic properties of the pentaketones fit in with their congeners having fewer CO groups. This is shown in Table 2 by comparison of the ionization energies of the lone pairs, the first reduction potentials, and the energies of the first bands of the UV/VIS spectra of the diphenylketones Ph(CO)$_x$Ph with x = 1–5. The first reduction potential decreases linearly with increasing x, while the first ionization energy and the energy of the first absorption band increase and level off to a final value.

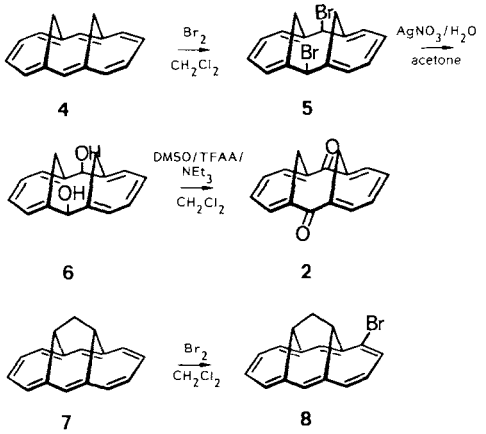
syn- and *anti*-Bishomoanthraquinone

By *Emanuel Vogel,* Stefan Böhm, Achim Hedwig, Bernd O. Hergarten, Johann Lex, Joachim Uschmann,* and *Rolf Gleiter**

Anthraquinone **1**, the parent substance of the anthraquinone dyes, is of great scientific and technical importance.[1] We therefore have undertaken the investigation of the bridged [14]annulenediones **2** and **3**, derived from the aromatic hydrocarbon *syn*-1,6:8,13-bismethano[14]annulene[2] and its olefinic *anti*-isomer,[3] respectively. In order to emphasize their structural relationship to **1**, these diones will henceforth be referred to as "bishomoanthraquinones."



1

2 : *syn*-isomer
3 : *anti*-isomer

Our interest especially focused on the *syn*-isomer **2**, since this molecule, constituting a diketo derivative of a Hückel-aromatic hydrocarbon, might be endowed with quinonoid properties, as is found to be the case with the diones of some other [4n+2]annulenes.[4] The preparation of **3** was already reported in 1966,[5a] but apart from its reaction with zinc/acetic anhydride in pyridine leading to reductive acetylation,[5b] no further studies bearing on its redox behavior have been carried out. We now report on the synthesis of **2** and on the electrochemistry of **2** and **3**.

4 **5** **6** **2** **7** **8**

A possible route to the elusive *syn*-bishomoanthraquinone **2** was suggested by the surprising course, with regard to both regio- and stereoselectivity, of the bromination of **4** with elemental bromine in dichloromethane at room temperature. Whereas the very rigid 1,6:8,13-propanediylidene[14]annulene **7**,[6] which almost perfectly matches **4** in the conformation of the annulene ring, experiences attack of bromine (same conditions as above) at the 2-position with formation of the substitution product **8**,[7] the hydrocarbon **4** reacts with the halogen to give the 7,14-diadduct **5** having the bromine atoms *syn* with respect to the bridges [m.p. = 165–166 °C (dec.); colorless needles from ethyl acetate; yield 90%; see Table 1]. The NMR spectra of the dibromide did not allow us to distinguish unequivocally between **5** and its stereoisomer, in which the two bromine atoms are *trans* with respect to the bridges; therefore, an X-ray structure analysis[8] was performed in order to prove the presence of **5** beyond doubt (Fig. 1).

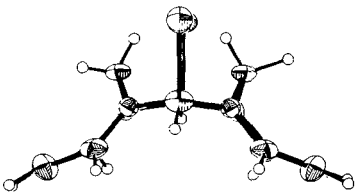


Fig. 1. Molecular structure of **5** in the crystal. Longitudinal profile of the molecule [8].

The findings on the bromination of **4** can be rationalized by an MO treatment, which shows that the chemical reactivity of **4** and **7**—like that of 1,6-methano[10]annulene[7b,9]—is influenced by π/σ interaction, leading to a rotation of the p_π atomic orbitals in the HOMO -1[10] as depicted in Figure 2. On the basis of the size of the orbital coefficients, electrophiles should attack the annulene ring at the sites adjacent to the bridges, addition to the outer positions (C-2, C-5, C-9, and C-12) being slightly preferred over addition to the central positions (C-7 and C-14). Sterically, *syn* addition (with respect to the bridges) should be favored, since the p_π orbitals of the HOMO -1, as a consequence of the rotation, are capable of overlapping with the vacant orbital of the electrophile more efficiently at the top side than at the bottom side of the molecule. The regioselective *syn* addition at the central positions observed with **4** becomes intelligible if one realizes that the rehybridization at C-7 and C-14 from sp^2 to sp^3 substantially reduces the nonbonding interaction between the internal bridge hydrogen atoms by causing folding of the C_{14} perimeter. Thus, the course of the bromination of **4**, which seems to be typical of the reactions of the hydrocarbon with electrophiles,[11] may be regarded as an unusual example of reaction control exerted by strain relief.

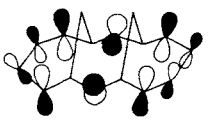

Fig. 2. Schematic representation, in the case of **4**, of the rotation of the p_π atomic orbitals in the HOMO -1 caused by π/σ interaction.

The dibromide **5**, which, contrary to expectation, is relatively stable thermally, exhibits no tendency to undergo elimination of HBr with formation of the 7-bromo derivative of **4**. As expected for an allylic halide, **5** is solvolytically very reactive, readily undergoing hydrolysis with silver nitrate in aqueous acetone (room temperature, 30 min) to give a sterically uniform symmetrical diol. Evidence that this diol possesses structure **6** [m.p. = 217–

[a] The coupling constants for **3** were measured in C_6D_6. [b] For nomenclature see: H. Günther, *Angew. Chem. 84* (1972) 907; *Angew. Chem. Int. Ed. Engl. 11* (1972) 861.

219°C; colorless rhombs (from ethyl acetate); yield 85%; see Table 1] was provided by an X-ray structure investigation.

The remarkable retention of configuration in the hydrolysis of **5** is most likely steric in origin, for a carbenium ion center at C-7 or C-14 is subject to shielding by the "cycloheptatriene wings" of the molecule in such a way as to leave no chance for the nucleophile to attack from the rear.[12]

In the last step of the synthesis, the oxidation of the sterically hindered diol **6** to **2**, the best results were achieved, as anticipated, when the reaction was carried out with the system dimethyl sulfoxide (DMSO)/trifluoroacetic anhydride (TFAA)/triethylamine[13] (in dichloromethane/DMSO; −78°C; 1 h). The dione **2**, isolated by chromatographic workup (silica gel; dichloromethane/ether 3:1) is a stable compound [m.p. = 198–199°C; yellow needles from dichloromethane/ether; yield 85%; see Table 1].

The ^{1}H-NMR spectrum of **2** (Table 1), consisting of an AA'BB' system for the vinylic protons and of an AX system for the bridge protons, exhibits chemical shifts and coupling constants indicative of an annulenedione (cycloheptatriene structural units). Apart from the observation that the internal bridge protons, owing to steric compression, resonate at unusually low field, this spectrum is in strikingly good agreement with that of the *anti*-isomer **3** (Table 1).

The electronic spectrum of **2** markedly differs from that of its colorless *anti*-isomer, but is similar to the spectrum of **1**, with which it has in common a band at relatively long wavelength, responsible for the yellow color of the compound.

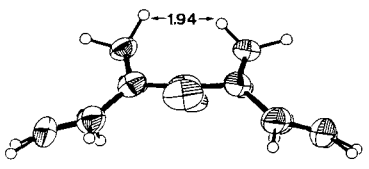

Fig. 3. Molecular structure of **2** in the crystal. Longitudinal profile of the molecule [14].

The molecular structures of **2** and **3**, as determined by X-ray investigations,[14] basically agree with those derived from an inspection of models. The CC bond lengths of the cycloheptatriene units of **2** and **3** strongly alternate, the degree of alternation being virtually the same in both compounds. That the steric repulsion of the internal bridge hydrogen atoms existing in **2**, (H,H distance 1.94 Å, compared to 1.78 Å in **4**) causes the C_{14} perimeter to be bent noticeably is revealed by the profile of the molecule given in Figure 3.[14]

On treatment with zinc/acetic anhydride in pyridine, the dione **2** undergoes reductive acetylation to give 7,14-diacetoxy-*syn*-1,6:8,13-bismethano[14]annulene [m.p. = 220°C (from dichloromethane/*n*-hexane); yield 76%], which, in contrast to its very reactive olefinic *anti*-isomer [m.p. = 135–136°C (from pentane/ether); yield 22%] is a stable aromatic compound.

The cyclovoltammetric investigation of **2** and **3** showed that both compounds undergo reduction by reversible one-electron transfers affording the corresponding semiquinone radical anions and dianions, respectively, as is typical of quinones.[15] The reduction potentials, including those of **1** and the reference compound *p*-benzoquinone, are listed in Table 2. As expected, **2**, which, in contrast to **3**, derives from an aromatic [14]annulene, is reduced to the radical anion and dianion more readily than **3**. In comparison with **1**, on the other hand, compound **2** is slightly less susceptible to radical anion formation; **2** and **1**, however, require about the same energy in order to be transformed into the corresponding dianions. Thus, **2** appears to be comparable to **1** with regard to quinonoid properties, yet noticeably differs in this respect from the planar [14]- and [18]annulenequinones (measured so far), which are more similar to *p*-benzoquinone in their reduction potentials ($E_1 + E_2$). This situation probably arises from steric factors, since the bent **2**, when reduced to the radical anion and dianion, will tend to flatten out, but can do so only at the expense of a sharp increase in the compression of the internal bridge hydrogen atoms.

Table 2. Comparison between the experimentally determined reduction potentials [a] and the orbital energies for the LUMO (ε_{LUMO}), calculated by the MINDO/3 method, the Coulomb integrals (J_{LUMO}), and the probability $A = \sum_{\mu} c_{\mu}^2$ of finding the electron at the CO groups.

Compound	E_1	E_2	$E_2 - E_1$	$E_1 + E_2$	ε_{LUMO} [eV]	J_{LUMO} [eV]	A [%]

[a] Measurement conditions: dimethylformamide as solvent, glassy carbon electrode, Ag/AgCl reference electrode, Pt counter electrode, Bu_4NPF_6 as conducting salt. All values in V. Under the same conditions, the oxidation potential of ferrocene was determined to be $E^{1/2} = 0.705$ V. The values for the reduction potentials of the reference compounds *p*-benzoquinone and **1** and that of 1,4-naphthoquinone deviate by ca. 0.25 V from the values given in [4b], presumably owing to different measuring arrangements.

From Table 2 it follows that the E_1 values of **1**–**3** correlate with the energies for the LUMO calculated by the MINDO/3 method. The remarkably small difference between E_1 and E_2 observed with **2** and **3** is assumed to result mainly from a decreased Coulomb interaction of the electrons in the LUMO as compared with the case for **1**.[16]

This explanation not only ensues from the values of the Coulomb integrals in the LUMO, but also derives support from the finding that the probability density of the electron at the carbonyl groups becomes smaller as one goes from either **2** or **3** to **1**. The carbonyl groups of **2** and **3** are thus more involved in conjugation than those of **1**. An important reason for this is that the two bishomoanthraquinones are subject to π/σ interaction—a phenomenon especially pronounced in nonplanar π systems such as bridged annulenes.

A $1\lambda^5,3\lambda^5,5\lambda^3$-Triphosphabenzene Derivative

By *Ekkehard Fluck,* Gerd Becker, Bernhard Neumüller, Robert Knebl, Gernot Heckmann,* and *Heinz Riffel*

Monophosphabenzene and a series of its derivatives were first described in the 1960s; later, diphosphabenzenes were also reported.[1] We report here the synthesis of the first 1,3,5-triphosphabenzene derivative. 1,1,3,3-Tetrakis(dimethylamino)-4-*tert*-butyl-$1\lambda^5,3\lambda^5,5\lambda^3$-triphosphabenzene **3** is the sole product formed upon reaction of 1,1,3,3-tetrakis(dimethylamino)-$1\lambda^5,3\lambda^5$-diphosphete **1**[2] with 2,2-dimethylpropylidynephosphane **2**.[3] The reaction can be regarded formally as an insertion. Mechanistically, it probably involves a cycloaddition, followed by spontaneous valence isomerization.[4]

Compound **3** forms air- and moisture-sensitive, pale yellow crystals, m.p. = 50–55 °C, which are soluble in benzene and *n*-pentane. In the $^{31}P\{^1H\}$-NMR spectrum (C_6D_6, standard 85% H_3PO_4) of **3**, the chemical shifts of the phosphorus atoms 1, 3, and 5 are $\delta = 57.5$, 59.0, and 295.5, respectively. In the $^{13}C\{^1H\}$-NMR spectrum (C_6D_6, standard TMS), the C atoms 6 and 4 exhibit the smallest chemical shifts ($\delta = 62.8$ and 100.8) so far recorded for phosphaalkenes. This is an indication of the significant ylide character of the C4–P5–C6 structural fragment. The ring structure of **3**, established by NMR triple resonance experiments, is in agreement with the results of an X-ray structure analysis (Fig. 1).[5]

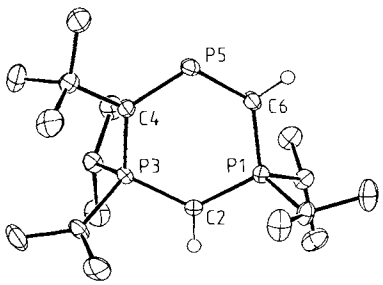

Fig. 1. ORTEP plot of the crystal structure of **3** (thermal ellipsoids at 50% probability). Bond lengths [pm] and angles [°]: P1-C2 168.8(2), C2-P3 169.7(2), P3-C4 175.8(2), C4-P5 170.9(2), P5-C6 170.0(2), C6-P1 171.5(2); P1C2P3 128.1(1), C2P3C4 111.9(1), P3C4P5 121.9(1), C4P5C6 113.7(1), P5C6P1 128.2(1), C6P1C2 109.4(1). The numbering of the atoms corresponds to the systematic name of **3**.

The six-membered ring is nearly planar and the distances between the ring atoms are nearly identical (170.2 ± 1.2 pm). An exception is the P3–C4 distance (175.8 pm). In the mass spectrum of **3**, the molecular-ion peak is very intense.

Experimental Procedure

All operations were carried out under argon. A solution of **1** [2] (2.07 g, 7.83 mmol) in 5 mL of dimethoxyethane was added dropwise over 20 min to a stirred solution of **2** [3] (1.06 g, 10.6 mmol) in 3 mL of dimethoxyethane at 0°C. The brown reaction mixture was allowed to warm slowly to room temperature and then stirred for 48 h. The solvent and excess **2** were removed under vacuum. The residual oil crystallized at −20°C and the solid was recrystallized three times from *n*-pentane. Yield of **3**: 1 g (35%).

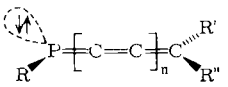
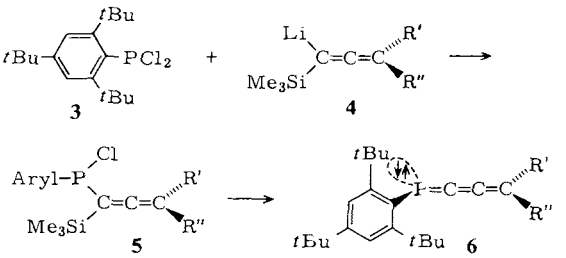
1-Phospha-1,2,3-butatrienes



By *Gottfried Märkl,* Hans Sejpka, Stefan Dietl, Bernd Nuber,* and *Manfred L. Ziegler*

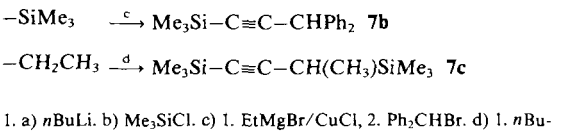
Whereas numerous open-chain, non-resonance-stabilized phosphaalkenes with kinetic or electronic stabilization have been prepared in recent years,[1] investigation of the phosphacumulenes began only recently with the synthesis of the phosphaallene **1a** by *Yoshifuji* et al.[2] and *Appel* et al.[3]

1, n = 1, 3, 5



1a, n = 1, R = 2,4,6-tBu$_3$C$_6$H$_2$, R′ = R″ = Ph

2, n = 1, 2, 3



As in the case of the cumulenes, it is useful to divide the phosphacumulenes into the species **1** with an odd number of atoms in the polyene chain and the species **2** with an even number. If phosphorus is stable to inversion, the phosphacumulenes **1** with R′≠R″ are chiral; the formation of *E/Z* isomers is expected for the analogues **2** with R′≠R″.

We describe here the synthesis of the 1-phospha-1,2,3-butatrienes **6**, the first phosphacumulenes of type **2**, n = 1. Reaction of the monolithiated allenes **4** with the dichlorophosphane **3** results in the formation of the coupling product **5**, which undergoes elimination of trimethylchlorosilane, in a reaction analogous to the Peterson–Wittig reaction, to give the 1-phosphabutatrienes **6**.

a, R′ = R″ = SiMe$_3$; **b**, R′ = R″ = Ph;
c, R′ = Me(SiMe$_3$), R″ = SiMe$_3$(Me)
Aryl = 2,4,6-tBu$_3$C$_6$H$_2$

The monolithiated allenes **4** are obtained by metalation of the corresponding alkynes **7** with *n*BuLi in tetrahydrofuran (THF) (2 h at room temperature, 2–4 h at reflux). The synthesis of **7a** is carried out by modification of the procedure of *West* et al.;[4] **7b** and **7c** (see ref. [5]) were obtained for the first time according to Scheme 1.

Scheme 1. a) *n*BuLi. b) Me$_3$SiCl. c) 1. EtMgBr/CuCl, 2. Ph$_2$CHBr. d) 1. *n*BuLi, 2. Me$_3$SiCl.

The phosphabutatrienes **6** are pale yellow oils (**6a**, **6c**), which undergo crystallization upon prolonged standing in the cold, or form, for example, a yellow solid (**6b**), which, in turn, crystallizes from ethanol in the form of shining yellow leaflets.

The spectroscopic data for **6a–c** (Table 1) are in agreement with the structure given. The marked low-field shift of the ^{31}P-NMR signal of **6a**, R′ = R″ = SiMe$_3$ ($\delta=+343.3$) corresponds to the values observed for phosphaalkenes of type **8**.[6] The $\delta(^{31}P)$ value of **6b**, R′ = R″ = Ph (+156.7), lies closer to the value found for **9** (+233[7]). Comparison with the chemical shift of **1a**, R′ = R″ = Ph (+72[2]), indicates an alternation of the values of **2**, n = 0, 1 (corresponding to **8** and **9** and to **6**, respectively) compared with those of **1**, n = 1, which is probably caused by the different orbital geometries.

8 R–P=C(SiMe$_3$)$_2$ mesityl–P=CPh$_2$ **9**

In the ^{1}H-NMR spectra of **6**, the signals of the *E* and *Z* moieties R′ and R″ have different chemical shifts, the signals of the *E* substituents R′ having the larger low-field shift and the larger P/H coupling.[8] The ^{1}H-NMR spectrum of crude **6c** corresponds, as expected, to the presence of an *E/Z* mixture of isomers (≈10:1). *E*-**6c** and *Z*-**6c** may be cleanly separated by chromatography on silica gel with petroleum ether (40–60°C). In the ^{1}H-NMR spectrum

[*] Prof. Dr. G. Märkl, Dipl.-Chem. H. Sejpka, S. Dietl

of *E*-**6c** ($R' = SiMe_3$), the $SiMe_3$ signal has a larger low-field shift and P/C coupling than that of *Z*-**6c**. The CH_3 signal of *Z*-**6c** shows analogous behavior.

Table 1. Selected physical data for the compounds **6a-c** and **5b**. All NMR spectra in $CDCl_3$; δ values, J in Hz, ^{1}H-NMR at 250 MHz.

5b, yield 50%; m.p. = 139-140°C (light yellow crystals from EtOH).—IR: $\tilde{\nu}$(allene): 1885 cm^{-1} (s).—^{31}P-NMR: 73.3.—MS (70 eV): $M^{\oplus\odot}$, 574 (< 1%); $[M - Me_2SiCl]^{\oplus\odot}$, 481 (≈ 1%); $[M - Me_3SiCl]^{\oplus\odot}$, 466 (< 1%); $[Aryl{-}P{-}Cl]^{\oplus}$, 311 (3%); $[Ph_2C{=}C{=}CSiMe_3]^{\oplus}$, 263 (100%)

The alternation observed in the ^{31}P-NMR spectra is also revealed in the ^{13}C-NMR spectra (Table 2).

Table 2. Comparison of the ^{13}C-NMR data of the compounds **9**, **1a**, and **6b**.

	α		α β		α β γ		
	mesityl−P=CPh$_2$		Aryl−P=C=CPh$_2$		Aryl−P=C=C=CPh$_2$		
	9		**1a**		**6b**		
			α	β	α	β	γ
$\delta(^{13}C)$	193.7	237.6	128.3	164.8	138.1	178.8[a]
J [Hz]	45.5	26.6	6.4	35.9	5.7	25.1

[a]The reverse assignment of C_α and C_γ cannot be ruled out.

In the mass spectra of **6a-6c**, the parent peak is the ion *m*/*z* 275, formed by cleavage of the P=C bond with elimination of $[R^1R^2C{=}C{=}CH]^{\oplus\odot}$.

The X-ray structure analysis of **6b** confirms the assumed rodlike structure of the phosphabutatriene structural unit (Fig. 1).[9]

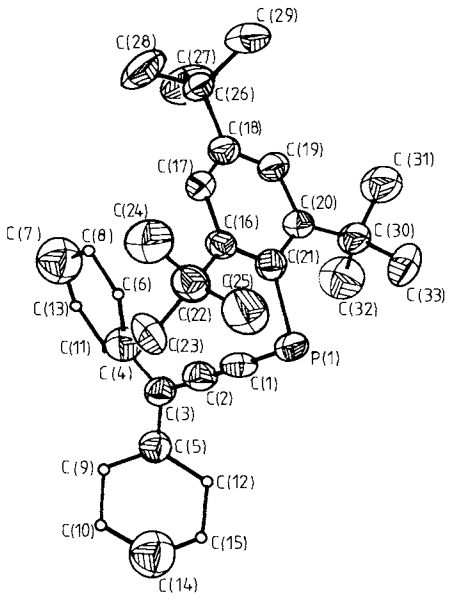

Fig. 1. Crystal structure of **6b** $P\bar{1}$, $Z = 2$, $a = 936.0(2)$, $b = 950.0(3)$, $c = 1840.0(7)$ pm, $\alpha = 80.91(3)$, $\beta = 85.59(2)$, $\gamma = 63.41(2)°$, $V = 1444.7 \times 10^6$ pm^3; 2074 of 5720 unique reflections, 313 parameters refined; $R_{aniso} = 0.068$, $R_w = 0.064$. Selected bond lengths [pm] and angles [°]: P1-C1 1.647(8), C1-C2 1.253(10), C2-C3 1.348(10), P1-C21 1.868(5), C3-C4 1.487(10), C3-C5 1.487(5), C21-P1-C1 98.4(3), P1-C1-C2 178.4(5), C1-C2-C3 178.3(6), C2-C3-C4 118.8(5), C2-C3-C5 121.9(6).

Experimental Procedure

4b: A solution of **7b** (3.97 g, 15.0 mmol) in 35 mL of dry THF was added slowly under inert gas to 15.0 mmol of *n*BuLi (1.6 N in *n*-hexane). The reaction mixture was then refluxed for 1 h.

6b: The dark red solution of **4b** was added to a solution of **3** (5.21 g, 15.0 mmol) in 45 mL of dry THF at −78°C. The reaction mixture was then allowed to warm over 4 h to room temperature and subsequently refluxed for 3 h [10]. After removal of the solvent, the residue was dissolved in petroleum ether (40-60°C) and filtered through silica gel to remove the salts. The clear yellow solution was chromatographed on oven-dried silica gel with petroleum ether/benzene (9/1). Recrystallization from dry ethanol afforded **6b** (3.15 g, 45%) as shining yellow crystals, m.p. = 156-158°C.

[10] If the reaction mixture **3** + **4b** is not heated to boiling, the chlorophosphane **5b** may be isolated in pure form.

Chiral Copper-Semicorrin Complexes as Enantioselective Catalysts for the Cyclopropanation of Olefins by Diazo Compounds**

By *Hugo Fritschi, Urs Leutenegger,* and *Andreas Pfaltz**

Metal-catalyzed reactions can be rendered enantioselective by complexation of the metal center with optically active ligands.[1] We report here the synthesis of enantiomerically pure, chiral ligands with structures of the semicorrin type **5**[2] and their use for enantioselective control of copper-catalyzed cyclopropanations of olefins by diazo compounds.

The synthesis is summarized in Scheme 1. Both halves of the C_2-symmetrical ligand skeleton are derived from pyroglutamic acid **1** and are joined by means of the iminoester-enamine condensation[3] method.[4] The overall yield of the crystalline, optically pure diester (−)-**5a**, based on L-pyroglutamic acid (−)-**1** is approximately 30%.

Scheme 1. a: MeOH, Dowex 50W X 8, reflux (yield >95%).—b: Et_3OBF_4, CH_2Cl_2, reflux (88% (+)-**2**).—c: 3 molar equiv. $NCCH_2CO_2tBu$, 100°C (81% (−)-**3**).—d: CF_3COOH, 23°C, 8 min; $NaHCO_3$, H_2O, 0°C (ca. 70% (−)-**4**).—e: 3 molar equiv. (+)-**2**, 3 molar equiv. CF_3COOH, 1,2-dichloroethane, 65°C (ca. 70% (−)-**5a**; m.p. 77°C, $[\alpha]_D = -140°$ ($CHCl_3$, $c = 2.2$, 23°C)). – f: $LiBH_4$, tetrahydrofuran (THF), 23°C; *t*$BuMe_2SiCl$, imidazole, dimethylformamide (DMF), 40°C (60% (−)-**5b**).—g: MeMgBr, Et_2O, 23°C (76% (−)-**5c**).—h: **6a**, **6b**: $Cu(OAc)_2$, MeOH, 23°C (91% **6a**, m.p. = 176°C; >95% **6b** (amorph.)); **6c**: $CuSO_4$, $NaHCO_3$, H_2O, CH_2Cl_2, 23°C (94% **6c**, m.p. = 196°C).

The semicorrins **5** possess several features that make them attractive candidates for enantioselective control of metal-catalyzed reactions. They are readily obtained in both enantiomeric forms from the commercially available starting materials (−)-**1** and (+)-**1** and form stable chelate complexes with a variety of metal ions (e.g., Cu^{II}, cf. Scheme 1).[5] Their structure is characterized by a rather rigid ligand skeleton and C_2 symmetry and may be modified in a variety of ways (cf. the derivatives **5b** and **5c**). In metal complexes, the two R substituents shield the metal center from two opposite directions and, therefore, are expected to have a pronounced effect on a reaction occurring in the coordination sphere.

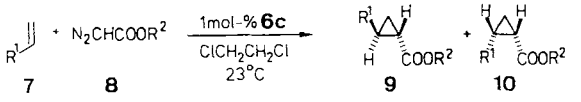

Table 1. Enantioselective cyclopropanation with the copper-semicorrin complex **6c** [a].

	R^1	R^2	Yields of **9** + **10** [%] [b]	Stereoselectivity **9** [% *ee*] [c]	**10** [% *ee*] [c]	**9** : **10**
a	Ph	Et	65	85	68	78 : 22
b	Ph	*t*Bu	60	93	92	84 : 16
c	Ph	*l*-menthyl	65–75	91	90	85 : 15
d	Ph	*d*-menthyl	60–70	97	95	82 : 18
e	$CH=CH_2$	*d*-menthyl	60	97	95	63 : 37
f	*n*-pentyl	*d*-menthyl	25–30	92	92	82 : 18

[a] The diazoester **8** was continuously injected over 10–16 h into a solution of **7** and 1 mol-% **6c** in 1,2-dichloroethane. The reaction was initiated by heating to reflux for a short time and then allowed to continue at 23°C. [b] After column chromatography: a–d, based on styrene; e, f, based on the diazo compound **8**. [c] Determined by gas chromatography after hydrolysis and reesterification with *d*- and *l*-menthol (reaction a–e) or with (*R*)- and (*S*)-2-octanol (reaction f). For **9** (R^1 = Ph, $CH=CH_2$) and **10** (R^1 = Ph), the values were confirmed by the optical rotation of the methyl ester [8]) and for **9** (R^1 = Ph, $R^2 = CH_3$) by ^{1}H-NMR spectroscopy with $Eu(tfc)_3$. In all cases, the products **9** and **10** have positive $[\alpha]_D$ values implying that the configuration at C1 is (*S*) [6–8].

As a possible application of the semicorrins **5**, we examined the metal-catalyzed cyclopropanation of olefins by diazo compounds. Chiral Cu^{II} and Co^{II} complexes have frequently been used as enantioselective catalysts for this type of reaction, some of them with considerable success.[6,7] We have found that the Cu^{II} complexes **6a**–**6c** efficiently catalyze the cyclopropanation of styrene with diazoacetates to give the diastereomeric 2-phenylcyclopropane carboxylates **9** and **10** in optically active form (cf. Table 1). The enantioselectivity and the reactivity of the catalysts increase in the order **6a** < **6b** < **6c** (for the reaction of **7** with **8** (R^1 = Ph, R^2 = Et) the temperature required and the *ee* of **9** were: with **6a**, ca. 60°C/23%; **6b**, 40°C/59%; **6c**, 23°C/85%). The selectivity of complex **6c** can be substantially improved by variation of the alkoxy group of the diazoacetate **8**. The optical yields of 95–97%, which we obtained with the *d*-menthyl ester, clearly exceed the selectivities previously observed in the cyclopropanation of styrene with other catalysts (81 and 78% *ee* for **9** and **10**, respectively, using Cu^{II}-salicylaldimine complexes (R^2 = menthyl);[6b] 88 and 81% *ee*, using Co^{II}-camphorquinone-dioximato complexes (R^2 = neopentyl)[7]). Butadiene and 1-heptene also react with high enantioselectivity. In the case of 1-heptene, however, the decreased reactivity of the double bond compared to styrene and butadiene results in lower chemical yields of cyclopropanes due to competing formation of other products such as menthyl fumarate and maleate. We are currently exploring the scope and limitations of the cyclopropanation catalysts **6**, as well as other applications of semicorrin ligands in enantioselective catalysis.

$[Ag(NCS)_2AsF_6]_n$—A Metal Complex with Dithiocyanogen as Ligand**

By *Herbert W. Roesky,* Jürgen Schimkowiak, Karen Meyer-Bäse,* and *Peter G. Jones*

Dedicated to Professor Oskar Glemser on the occasion of his 75th birthday

Söderbäck[1] reported the first synthesis of dithiocyanogen (dithiocarbonitrile), **1**, as long ago as 1919. The compound can be prepared quite simply from silver or lead thiocyanate and bromine. In the free state it polymerizes rapidly and irreversibly to a brick-red polythiocyanogen. Solutions of **1** in carbon tetrachloride are stable and are preparatively useful for the introduction of NCS groups into arenes or for addition to olefins.[2]

The thiocyanate ion, $NCS^{\ominus}$, is a good ligand, and numerous complexes are known in which $NCS^{\ominus}$ is bound via sulfur or nitrogen to a metal center.[3] We recently reported on the cycloaddition of hexafluoroacetone to **1** without cleavage of the S–S bond.[4] We have now succeeded, for the first time, in attaching **1** as ligand to a transition metal. This was achieved upon reaction of $AgAsF_6$ with **1** in liquid SO_2.

$$\underset{\mathbf{1}}{NCS{-}SCN} + AgAsF_6 \longrightarrow \frac{1}{n}\underset{\mathbf{2}}{[Ag(NCS)_2AsF_6]_n}$$

The title compound **2** is a white crystalline solid which decomposes with charring above 155 °C. The IR and Raman spectra indicate that **1** is coordinated to silver; the CN stretching vibration appears at 2196 cm^{-1}. In uncoordinated **1**, ν(CN) is observed at 2175 cm^{-1}.[5]

Crystals of **2** suitable for an X-ray structure analysis were obtained by recrystallization from liquid SO_2. The cation of **2** is a chain polymer (Fig. 1) with exactly linearly coordinated silver; the zig-zag chains display perpendicular dislocations at the S–S bonds.

The S-S distance (206.3(3) pm) lies in the usual range.[6] The upfield shift of the CN stretching vibration is consistent with the short N-C distance (111.6(9) pm). In accordance with the lower coordination number of the metal (2 as compared to 4), the Ag-N distance (211.7(6) pm) is significantly shorter than in polymeric $[Ag\{(CN)_2\}_2]^{\oplus}$ (239.9(6) pm)[7] and polymeric $[Ag\{S_n(CN)_2\}_2]^{\oplus}$ (227.4(11) for n = 3, 228.8(7) pm for n = 4).[6]

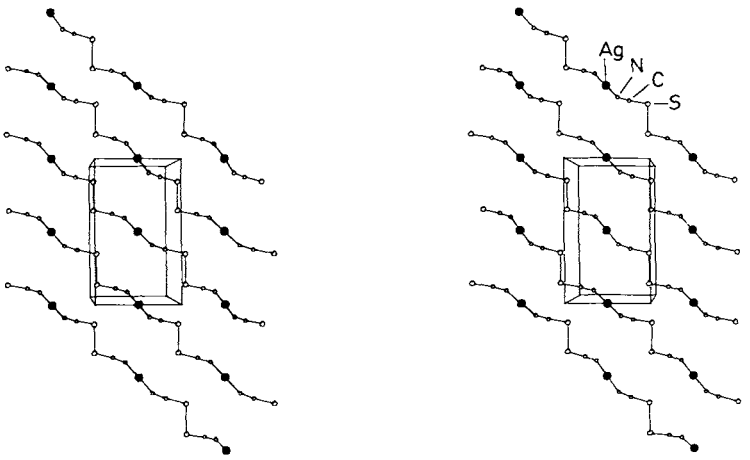

Fig. 1. Polymeric chains of $[Ag(SCN)_2]_n^{n\oplus}$ in **2**. View along y; the chains pass through the unit cell at $y = 0$ (shown here) and $y = \frac{1}{2}$ (omitted for clarity). Crystal data: orthorhombic, *Pbcn*, $a = 594.2(1)$, $b = 1608.0(4)$, $c = 1016(2)$ pm, $V = 0.9714$ nm^3, $Z = 4$ (monomers), $\rho_{calc} = 2.82$ g cm^{-3}, $Mo_{K\alpha}$ radiation, $\mu = 6.0$ mm^{-1}, $2\theta_{max}$ 50°, $R = 0.037$, $R_w = 0.039$ for 626 absorption- and extinction-corrected reflections with $F > 4\sigma(F)$. Ag lies on the symmetry center $\frac{1}{2}$,0,0 and As on the twofold axis 0,y,$\frac{1}{4}$. The anions (not shown) are disordered.—Bond lengths [pm] and angles [°]: Ag-N 211.7(6), N-C 111.6(9), C-S 170.8(7), S-S' 206.3(3); N-Ag-N' 180.0, Ag-N-C 154.4(6), N-C-S 174.6(6), C-S-S' 98.9(2). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik gmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51908, the names of the authors, and the full citation of the journal.

Experimental

1.93 g (6.5 mmol) of $AgAsF_6$ was added to 1.51 g (13 mmol) of **1** in a pressure vessel at −25 °C. After evacuation of the vessel, SO_2 (30 mL) was condensed into the reaction mixture at −80 °C. The mixture was allowed to warm to room temperature in the absence of light and then stirring was con-

tinued for 36 h. The clear bright yellow solution was filtered, and, after removal of solvent, the residue (**2**) was recrystallized from SO_2; yield 2.3 g (86%).

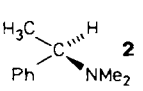
Recognition of Chirality by ENDOR Spectroscopy**

By *Hartmut B. Stegmann,* Helmut Wendel, Hoang Dao-Ba, Paul Schuler,* and *Klaus Scheffer*



The unequivocal detection of enantiomeric compounds and the determination of their relative concentrations and absolute configurations have gained increasing importance in the last few years. Hitherto, polarimetry and (with the use of chiral auxiliaries) NMR spectroscopy as well as chromatographic methods were mainly employed for chiral recognition,[1] whereas the use of electron nuclear double resonance[2] (ENDOR) spectroscopy for solving such analytical problems has so far never been described. The great advantages of this technique are that very little sample material is required and the spectra thus obtained are virtually solvent-independent. Moreover, proton-containing matrices (solvent, chiral auxiliaries or other diamagnetic components) do not interfere with ENDOR investigations through self-absorption, and, other than in NMR spectroscopy, no signal multiplets occur, which, quite frequently might afford important information but sometimes make the analysis of ^{1}H-NMR spectra very difficult.

Numerous natural products such as ascorbic acid, noradrenalin, adrenalin, isoprenalin etc. contain an asymmetric C-atom with an OH-group as part of the structure. The semidiones[3] or semiquinones[4] formed by oxidation of these compounds could be investigated ESR spectroscopically using the spin-stabilization technique,[5] but it was found that, in most cases, pyridine had to be used as solvent owing to solubility problems. In order to carry out measurements in inert solvents and thus definitely decide whether an ENDOR spectroscopic recognition of enantiomers using chiral auxiliaries is possible, we synthesized racemic 2,6-di-*tert*-butyl-4-(1-hydroxyethyl)phenol **1**.[6]

Oxidation of **1** with lead dioxide in toluene furnished the corresponding, hitherto unknown, phenoxyl radical

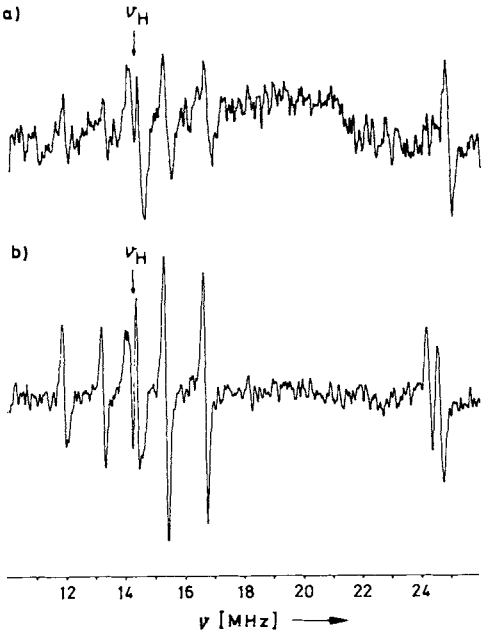

Fig. 1. ENDOR spectrum of **1**(−H) at 253 K. a) In toluene. b) In toluene after addition of **2**, molar ratio **2** : **1** = 9.2.

1(−H) which could be characterized by $a_{t\mathrm{Bu}} = 0.11$, $a_{3,5} = 1.75$, $a_{\mathrm{CH}} = 7.61$, and $a_{\mathrm{CH_3}} = 0.73$ G. Addition of (*R*)-(+)-*N*,*N*-dimethyl-1-phenylethylamine **2** did not alter the ESR spectrum, since the hyperfine structure is not fully resolved because of the small coupling to the protons of the *t*Bu groups. In the ENDOR spectrum (Fig. 1), on the other hand, the signal at ca. 25 MHz splits into two signals (intensity ratio about 1), which, on the basis of the ESR spectrum, we assign to the proton on the asymmetric C-atom. The corresponding low frequency absorption can hardly be detected according to the well known low signal-to-noise ratio at frequencies below 4 MHz. The distance between the two lines increases with increasing amine concentration, and at a molar ratio of **2** : **1** = 30 : 1 approaches a limiting value (Fig. 2). A similar behavior has already been observed in NMR investigations.[7]

A splitting of the remaining ENDOR signals was not observed. The linewidths merely increase with increasing amine concentration.

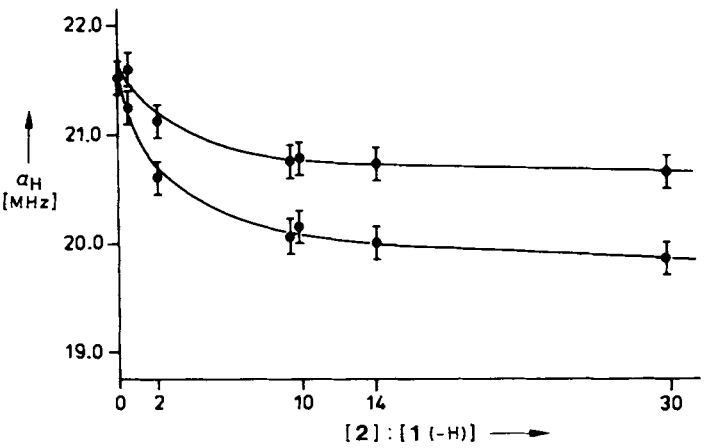

Fig. 2. Coupling of the proton at the asymmetric C-atom of **1**(−H) in both enantiomers as a function of the molar ratio **2** : **1**.

The intensity of the two lines at 25 MHz remained constant over the concentration range investigated, and, since the maximum line separation is ca. 0.4 MHz, that is the magnetic environment of the two protons is very similar, significantly different relaxation effects are highly improbable. For these reasons, differences in the solvation of the phenoxyl radicals can be ruled out as an explanation for the doublet at ca. 25 MHz. We therefore attribute the two signals to diastereomeric solvates.

The coupling of the proton at the asymmetric C-atom can be attributed to a hyperconjugation mechanism[8] corresponding to $a^{H}_{C-CH}=(B_0+B\langle\cos^2\Theta\rangle\rho C_\alpha)$. Whether B or the torsion angle Θ is responsible for the splitting will be explained by further systematic investigations of analogous systems. Since the couplings of the two ring protons $a_{3,5}$ remain constant no significant change in the spin density distribution can be expected during the formation of the diastereomers.

A Simple Route to Ruthenacycloalkanes**

By *Ekkehard Lindner,* Rolf-Michael Jansen*, and *Hermann August Mayer*

Metallacycloalkanes frequently occur as reactive intermediates in transition metal catalyzed organic syntheses such as olefin carbonylations, oligomerizations of olefins, or metathesis reactions.[1] In the past few years, such compounds have been described as model substances for numerous transition metals.[2] For lack of suitable synthetic methods, very few mononuclear carbonyl complexes of ruthenium containing metal-carbon σ bonds have been described in the literature.[3] By using the "nucleophilic elimination cycloaddition" method,[4] which has already been successful in the generation of tetracarbonylferracyclopentane,[5] we have now found a simple route to ruthenacycloalkanes.

$Na_2[Ru(CO)_4]$ reacts smoothly with the alkanediylbis(trifluoromethanesulfonates) $(YCH_2)_2$, $(YCH_2CH_2)_2$ and *cyclo*-$C_6H_{10}(CH_2Y)_2$ ($Y=CF_3SO_2O$) in dimethyl ether at −78°C to give the air-sensitive, thermolabile ruthenium compounds **1**–**3**, which are readily soluble in all the usual organic solvents.[6] Their composition and structures were established unequivocally from the IR, ^{1}H- and $^{13}C\{^1H\}$-NMR, and mass spectra (Table 1). **1** has already been detected before in solution by IR spectroscopy.[8] Due to the conformational mobility of **1**, only one signal each is observed for the two ethylene carbon atoms and for the four carbonyl carbon atoms; their position, as in the case of $[(\eta^2\text{-}C_2H_4)Fe(CO)_4]$,[5] is consistent with an ethylene complex rather than a ruthenacyclopropane.[9]

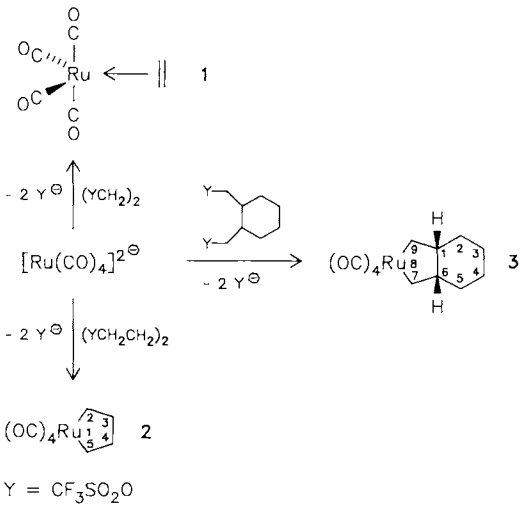

Table 1. Spectroscopic data and melting points of **1**–**3**.

Cpd.	IR ν(CO) [a]	^{1}H-NMR δ [b]	$^{13}C\{^1H\}$-NMR δ [b]	MS *m/z* [c]	M.p. [°C]
1	2107 (m)	2.16 (s)	25.15 (s)		−30 (decomp.)
	2025 (vs)		198.89 (s)		
	2000 (s)				
2	2119 (w)	1.58 (s)	11.63 (s, C2,5)	274	−20 (decomp.)
	2049 (s)		36.90 (s, C3,4)		
	2040 (vs)		189.70 (s, [d])		
	2023 (s)		197.28 (s, [e])		
3	2118 (s-m)	0.8–2.0 (m)	12.80 (s, C7,9)	326	− 3
	2048 (s)		23.34 (s, C3,4)

			189.39 (s, [d])		
			197.44 (s, [e])		
			198.47 (s, [e])		

[a] In *n*-hexane. [b] In $CDCl_3$, 80 and 20.115 MHz, δ values rel. $CDCl_3$, $T=233$ K. [c] ($M^{\oplus}$) referred to ^{104}Ru. [d] $Ru(CO)_2$ (*cis*). [e] $Ru(CO)_2$ (*trans*).

The appearance of four CO bands in the IR spectra of **2** and **3** is consistent with a pseudooctahedral coordination of the central atom. The ring skeleton of **2** and **3** gives rise to two and four signals, respectively, in the $^{13}C\{^1H\}$-NMR spectra. The carbonyl C-atoms absorb below $\delta=200$. The CO ligands oriented *cis* and *trans to each other* differ by virtue of the +I effect of the methylene groups. The signal appearing at lower field is *in each case* assigned to the *trans* CO groups in **2** and **3**. Due to their different environment the two carbonyl C-atoms oriented *trans to each other* in **3** give rise to two signals.

[**] Preparation and Properties of and Reactions with Metal-containing Heterocycles, Part 54. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 53: E. Lindner, K. Auch, G. A. Weiss, W. Hiller, R. Fawzi, *Chem. Ber.*, in press.

When stored under carbon monoxide, the ruthenacyclopentane **2** decomposes only above 60 °C. At this temperature a (formal) insertion of CO[5] into a Ru–C bond with formation of cyclopentanone is observed,[10] the latter being formed from the non-isolable six-membered intermediate $[(OC)_4\overline{Ru}C(O)CH_2CH_2CH_2\overline{C}H_2]$ by reductive elimination. The same results upon reaction of **2** with PPh_3. In the absence of CO, **2** already decomposes at −20 °C with cleavage of 1,3-butadiene and *trans*- and *cis*-2-butene in the molar ratio 3:3:1. Prerequisite for the occurrence of butadiene is a twofold β-hydride transfer, which requires a free coordination site at the metal by elimination of CO. This explains the unusual stability of **2** in the presence of carbon monoxide. The elimination of *cis*- and *trans*-2-butene from **2** probably takes place via an allylic intermediate.[5]

O_2-Generation by Oxidation of Water with Di- and Trinuclear Ruthenium Complexes as Homogeneous and Heterogeneous Catalysts

By *Ramasamy Ramaraj, Akira Kira,* and *Masao Kaneko**

Water-oxidation with generation of molecular oxygen was first realized only five years ago:[1] the strong one-electron oxidizing agent $Ru(bpy)_3^{3\oplus}$ (bpy = 2,2′-bipyridyl) is able to bring about the four-electron oxidation of water to oxygen on the surface of a suitable colloidal or powdered oxide catalyst such as RuO_2.[2] These catalysts are far from ideal, because the reaction is slow and there are many problems associated with their use in model systems. The main difficulty of constructing such models lies in the coupling of the one-electron oxidant with the four-electron formation of oxygen from water. We consider that the design of chemical models and the study of water-oxidation in non-biological systems are probably the best way of gaining an insight into the mechanism of the photosynthetic evolution of oxygen. It has already been shown[3,4] that dinuclear ruthenium complexes are capable of oxidizing water by a four-electron process without the addition of an external catalyst like RuO_2. However, the catalyst turnover number is not high and the total yield of oxygen obtainable from such systems remains low.[4] According to recent findings, not only homogeneous systems but also heterogeneous ones may be of importance.[5] We report here on the catalytic activity of oxo-bridged di- and trinuclear ruthenium complexes in the homogeneous and heterogeneous oxidation of water.

As trinuclear ruthenium complex we used commercially available ruthenium-red (Wako Chemicals); ruthenium-brown was prepared according to the procedure described in ref. [6] (with slight modification). The ruthenium-red cation is oxidized reversibly in acid solution to the ruthenium-brown cation.

$[(NH_3)_5Ru-O-Ru(NH_3)_4-O-Ru(NH_3)_5]Cl_6$
ruthenium red
abbreviation for the cation:
$Ru^{III}-O-Ru^{IV}-O-Ru^{III}$ or III, IV, III

$[(NH_3)_5Ru-O-Ru(NH_3)_4-O-Ru(NH_3)_5]Cl_7$
ruthenium brown
abbreviation for the cation:
$Ru^{IV}-O-Ru^{III}-O-Ru^{IV}$ or IV, III, IV

The dinuclear ruthenium complexes "Ru–Ru–H_2O" and "Ru–Ru–NO_2" were prepared and characterized according to previously reported procedures.[3,4]

$[(bpy)_2(H_2O)Ru-O-Ru(H_2O)(bpy)_2](PF_6)_4$
Ru–Ru–H_2O
abbreviation for the cation: $Ru^{III}-O-Ru^{III}$

$[(bpy)_2(NO_2)Ru-O-Ru(NO_2)(bpy)_2](PF_6)_2$
Ru–Ru–NO_2
abbreviation for the cation: $Ru^{III}-O-Ru^{III}$

The heterogeneous catalysts were prepared by mixing the di- or trinuclear ruthenium complex with commercially available kaolin (Nakarai Chemicals Ltd.) in deionized water and stirring the mixture until completion of adsorption (decolorization of the solution). The product was filtered, washed with deionized water, and dried in air. It has been reported[6,7] that the differences in the Mössbauer and electronic spectra of the cations of ruthenium red and ruthenium brown are consistent with the charge distribution indicated in Equation (1).

$$\underset{\text{Ru-red}}{Ru^{III}-O-Ru^{IV}-O-Ru^{III}} \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \underset{\text{Ru-brown}}{Ru^{IV}-O-Ru^{III}-O-Ru^{IV}} \qquad (1)$$

The absorption spectra show that ruthenium-red undergoes thermal and photochemical decomposition in aqueous solution. In contrast, ruthenium-brown does not show

[*] Prof. Dr. M. Kaneko, Dr. R. Ramaraj, Prof. Dr. A. Kira
Solar Energy Science Research Group
The Institute of Physical and Chemical Research
Wako, Saitama, 351-01 (Japan)

any noticeable thermal or photochemical decomposition in acidic aqueous solution. The higher thermal and photochemical stability in the latter case may be due to a charge delocalization in the linearly oxo-bridged cations of ruthenium-brown.[8]

Cyclovoltammograms of the trinuclear ruthenium complexes were recorded in aqueous solution using a basal plane pyrrolytic graphite (BPG) working electrode and a saturated calomel electrode (SCE). The oxidation of water interferes in the higher potential region. However, a well defined cyclovoltammogram could be obtained in the same potential region by using a BPG electrode coated with poly(styrene sulfonate). The reversible one-electron reduction of ruthenium-brown [Eq. (1)] and the reduction of ruthenium-red have already been investigated.[6] In the present investigation, the cyclovoltammograms of ruthenium-red showed six reduction peaks which are reversible in the oxidative scan in the potential region -0.5 V to 1.4 V vs. SCE. The wave shapes indicate that five one-electron-transfer processes occur at potentials which are fairly close to each other. The redox process which occurs at -0.24 V closely resembles the reactions observed in the case of the monomeric ammine-ruthenium(III) complexes.[9] The cyclovoltammogram is consistent with a series of one-electron oxidations [Eq. (2)];

$$\begin{aligned}&\mathrm{III,III,III} \underset{-0.24\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \underbrace{\mathrm{III,IV,III}}_{\text{Ru-red}} \underset{0.72\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \underbrace{\mathrm{IV,III,IV}}_{\text{Ru-brown}} \underset{0.84\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \\ &\mathrm{IV,IV,IV} \underset{0.95\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \mathrm{IV,V,IV} \underset{1.08\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \mathrm{V,IV,V} \underset{1.16\ \mathrm{V}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \mathrm{V,V,V}\end{aligned} \qquad (2)$$

From the cyclovoltammetric data it is evident that the trinuclear ruthenium complex exhibits multi-step reversible electron-transfer behavior and may be called an "electron sponge."

Oxygen evolution was investigated by adding excess ammonium ceric nitrate to a solution of the trinuclear ruthenium complex in a closed and degassed vessel. Gas bubbles were observed in the solution upon addition of excess cerium(IV) salt. The gas evolved was identified as oxygen by gas chromatography. When $H_2{}^{18}O$ was used, mass spectral analysis resolved the presence of $^{16}O_2$, $^{18}O^{16}O$ and $^{18}O_2$, respectively.

Table 1. Water oxidation by ammonium cerium(IV) nitrate in the presence of di- and trinuclear ruthenium catalysts in 1 h at 25°C under homogeneous and heterogeneous conditions (on Kaolin). Solution volume 5 mL. Molar ratio catalyst : cerium(IV) 1 : 400.

Catalyst		Homogeneous		Heterogeneous		Kaolin
		O_2	turnover	O_2	turnover	
	[mol]	[μL]	number	[μL]	number	[mg]
Ru-red	1×10^{-6}	1325	54.7	1022	42.2	300
Ru-brown	1×10^{-6}	1503	62.1	1084	44.8	300
Ru–Ru–H_2O	5×10^{-7}	88	7.3	55	4.5	250
Ru–Ru–NO_2	5×10^{-7}	30	2.5	18	1.5	250

The experimental results are summarized in Table 1, from which it is clear that the trinuclear ruthenium complexes are remarkably better catalysts for water-oxidation than are the dinuclear ruthenium complexes, both in homogeneous as well as heterogeneous phases. However, the trinuclear ruthenium complexes were found to undergo decomposition during the catalytic processes with a maximum turnover number of 62. Variation of the catalyst concentration in the homogeneous and heterogeneous phases had no influence on the catalytic activity. This finding suggests that a single molecule of the di- or trinuclear ruthenium complex is involved in the four-electron process of oxygen evolution. It has also been found that the addition of 0.1 M HNO_3 or 0.1 M NaOH does not affect the catalytic activity of the complexes. This shows that the oxidized species is a water molecule rather than a hydroxide ion. Ruthenium-red was converted into the stable ruthenium-brown in acidic solution. The anodic oxidation of ruthenium-red (+1.3 V vs. SCE) also led to the formation of ruthenium-brown; no formation of RuO_2 was observed.

The formation and stability of Ru^V in oxo-bridged dinuclear ruthenium complexes and its catalytic activity have been reported on just recently.[3,4,10] In the water oxidation experiment with ruthenium-red and Ce(IV) in the molar ratio 1 : 100, ruthenium-brown was observed spectrophotometrically at the end of the catalytic process. When, however, a molar ratio of 1 : 400 was used, the catalyst was found to undergo decomposition to a monomeric ruthenium complex at the end of the catalytic process. No formation of the black deposit characteristic of RuO_2 was observed.

From the observed data, it is concluded that the system ruthenium-red/ruthenium-brown catalyzes the water oxidation by Ce(IV). Ruthenium-red is converted into highly stable ruthenium-brown in acidic solutions as well as in the presence of anions such as $NO_3^{\ominus}$, $Cl^{\ominus}$ and $SO_4^{2\ominus}$; dinuclear ruthenium complexes, on the other hand, undergo decomposition to monomeric complexes.

$$\underbrace{\mathrm{Ru^{III}{-}O{-}Ru^{IV}{-}O{-}Ru^{III}}}_{\text{Ru-red}} + 5\ \mathrm{Ce^{IV}} \longrightarrow \mathrm{Ru^{V}{-}O{-}Ru^{V}{-}O{-}Ru^{V}} + 5\ \mathrm{Ce^{III}} \qquad (3)$$

$$\mathrm{Ru^{V}{-}O{-}Ru^{V}{-}O{-}Ru^{V}} + 2\ \mathrm{H_2O} \longrightarrow \mathrm{Ru^{V}(H_2O){-}O{-}Ru^{V}(H_2O){-}O{-}Ru^{V}} \xrightarrow{-4\ \mathrm{H^{\oplus}}} \qquad (4)$$

$$\mathrm{Ru^{III}}\begin{smallmatrix}\diagup\mathrm{O}\\ \mathrm{O{-}O}\diagdown\end{smallmatrix}\mathrm{Ru^{III}{-}O{-}Ru^{V}} \longrightarrow \underbrace{\mathrm{Ru^{IV}{-}O{-}Ru^{III}{-}O{-}Ru^{IV}}}_{\text{Ru-brown}} + \mathrm{O_2}$$

A trinuclear ruthenium complex in the oxidation state V,V,V [Eq. (2)] is formed upon addition of excess Ce(IV) to ruthenium-red [Eq. (3)]. Subsequent reaction with water yields oxygen and ruthenium-brown [Eq. (4)]. This ruthenium-brown is highly stable and catalyzes the oxidation of water in the presence of excess Ce(IV) in a cyclic process. In the case of dinuclear ruthenium complexes, the water-oxidation reaction is described by Equation (5).[4]

$$\mathrm{Ru^{V}{-}O{-}Ru^{V}} + 2\,\mathrm{H_2O} \longrightarrow \mathrm{Ru^{III}{-}O{-}Ru^{III}} + \mathrm{O_2} + 4\,\mathrm{H^{\oplus}} \qquad (5)$$

Earley and *Fealey*[6] studied the kinetics of the reduction of ruthenium-brown by hydroxide ion. They suggested that the attack of $OH^{\ominus}$ ion on the central ruthenium atom in ruthenium-brown would be the most probable step for which no symmetry restriction is to be anticipated, and that the reduction leads to the formation of ruthenium-red. According to *Endicott* and *Taube*[11] a spin-paired d^4 ion (Ru^{IV}) can accommodate seven groups in the coordination sphere; these authors assume that Ru^{III} also forms seven-

coordinate species as kinetic intermediates.[12] From these results we assume that two water molecules are involved in the formation of one molecule of oxygen. The first water molecule attacks the central Ru^V ion in the trinuclear ruthenium complex [Eq. (3)], the second one coordinates at one of the terminal Ru^V atoms. This intermediate may lead to the formation of an O–O bond between the two water molecules. This is followed by release of oxygen and the re-formation of ruthenium-brown. The formation of a peroxide intermediate and evolution of oxygen in the water-oxidation process with dinuclear ruthenium complexes has already been proposed by *Meyer* et al.[6] An analogous model for water-oxidation with manganese complexes in a heterogeneous environment could facilitate an understanding of the evolution of oxygen in photosynthesis.[13]

[α-(Phenylsulfinyl)-α-methylbenzyllithium-tetramethylethylenediamine]$_2$: Crystal Structure of an α-Sulfinyl "Carbanion"**

By *Michael Marsch, Werner Massa, Klaus Harms, Gerhard Baum,* and *Gernot Boche**

α-Sulfinyl "carbanions" $[R^1R^2\ddot{C}-\ddot{S}(O)R^3]^{\ominus}$ are important synthetic building blocks.[1] Thus, in reactions with electrophiles the chiral sulfoxide group determines the diastereofacial differentiation: oxygen-containing electrophiles E attack the anionic C-atom from the side of the S–O bond, whereas CH_3I approaches from the opposite side (Scheme 1).[2] On the basis of these, and other observations, an ion-pair structure (Scheme 1) was inferred for "α-lithiosulfoxides"[2b,e,f] and the diastereofacial differentiation was attributed to the attractive interaction of the electrophile E with $Li^{\oplus}$.

Scheme 1. Ion-pair structure model for α-sulfinylalkyllithium compounds [2b, e, f]. E = H_2O, D_2O, CO_2, RCHO, R_2CO, $(CH_3O)_3PO$.

We report here on the X-ray structure analysis of α-(phenylsulfinyl)-α-methylbenzyllithium-tetramethylethylenediamine **1a** (Fig. 1).[3] The diastereomer **1a** is formed from a ca. 1 : 1 mixture of the two diastereomeric α-methylbenzylphenyl sulfoxides **2** upon reaction with *n*-butyllithium in ether/TMEDA.[4]

$$\underset{\mathbf{2}}{PhCHMe-\ddot{S}(O)Ph} \xrightarrow[TMEDA/ether]{n\text{BuLi}} \underset{\mathbf{1a}}{[PhC\ddot{M}e-\ddot{S}(O)Ph]^{\ominus}Li^{\oplus}}$$

1a crystallizes as a dimer, with bonding occurring via a Li_2O_2 four-membered ring. Two further coordination sites on each $Li^{\oplus}$ are occupied by the TMEDA N-atoms. The

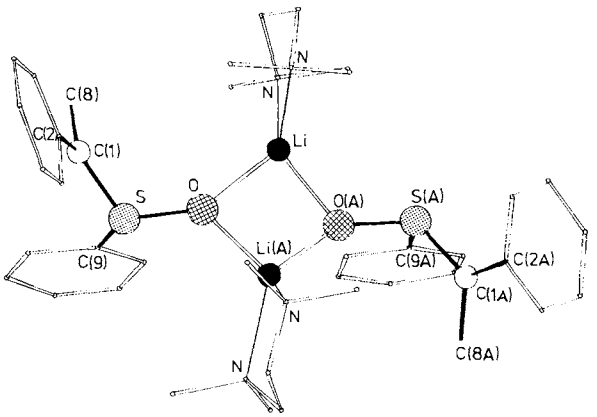

Fig. 1. Crystal structure of the dimer **1a** (H atoms omitted) at −65 °C. Space group $C2/c$, $a = 3855(2)$, $b = 1201.5(6)$, $c = 1813(1)$ pm, $\beta = 96.59(5)°$, $Z = 8$ (dimer). CAD4 (Enraf-Nonius) four-circle diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, ω-scans, $\theta = 2$–$20°$. Because of the small crystals, with broad reflection profile ($\Delta\omega \approx 2°$)—larger crystals were always deformed—only 1865 of 4050 observed independent reflections measured; 317 parameters (only S, phenyl residues bound to S, and methyl C-atoms of TMEDA molecules with anisotropic temperature factors; H atoms placed at calculated sites). $R_w = 0.083$. The two crystallographically independent molecules are bound perpendicularly to the slightly folded Li_2O_2 four-membered ring via a pseudo C_2-axis to give the dimer.—Important bond lengths [pm] and angles [°] (mean values of both molecules): Li-O 192(2), Li-N 213(2), Li-Li(A) 265(4), S-O 158(1), S-C(1) 163(1), S-C(9) 181(1), C(1)-C(2) 144(2), C(1)-C(8) 154(2); O-Li-O 91(1), Li-O-Li 87(1), Li-O-S 148(1), Li(A)-O-S 123(1), O-S-C(1) 117(1), O-S-C(9) 101(1), C(1)-S-C(9) 104(1), S-C(1)-C(2) 120(1), S-C(1)-C(8) 119(1), C(2)-C(1)-C(8) 118(1). [**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

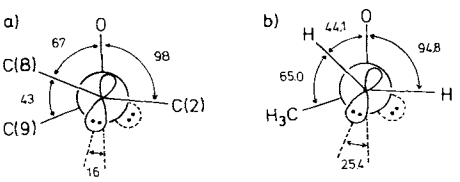
two phenyl rings on C(1) and S are *trans* oriented (dihedral angle C(2), C(1), S,C(9) = 152.1°). Since the protonation of **1a** in ether leads only to (*RR/SS*)-**2**[5] and the protonation of α-sulfinyl "carbanions" generally proceeds stereoselectively,[2] most likely only the one diastereomer **1a** found in the crystal is also present in solution.[6] The C(1)-S distance (163(1) pm) is distinctly smaller and the S-O distance (158(1) pm) somewhat larger than the corresponding distances in sulfoxides (dimethyl sulfoxide: 180 and 147 pm, respectively).[7] Such an alteration in bond lengths was also deduced from IR investigations on α-sulfinyl "carbanions".[2h] The torsion angle C(1),S,O,Li is 12(2)°. This means that the Li atom does not lie exactly in the C(1)-S-O plane. The C(1)-Li distance is exceptionally large (400(3) pm),[8] so C-Li bonding can be ruled out.[9]



It follows from Scheme 2 that the observed diastereofacial differentiation in the addition of the electrophiles E to α-sulfinyl "carbanions" can be explained, as before, in terms of an attractive O-Li interaction.[2b,e,f] As far as the diastereoselectivity[1a] in the reaction of α-sulfinyl "carbanions" with, for instance, benzaldehyde is concerned, the one observed in the case of **1b** can also be rationalized on the basis of the structure of **1a** (Scheme 2): as in the case of **1a**, in **1b** and in the transition state of the reaction the larger substituents avoid sterically unfavorable interactions. It is equally understandable that **1c**, which is unsubstituted at the anionic C-atom, does not react diastereoselectively.[10d] That the products upon reaction of **1d**[10e] indicate the existence of more than one diastereomeric "anion" remains a mystery; possibly this can be attributed to the (experimentally confirmed[10e]) reversibility of the reaction.

The bonding situation at the anionic C(1) atom and that along the C(1)-S axis of **1a** deserve special attention.

Scheme 2. Model of the addition of α-sulfinyl "carbanions" (with the bonding situation at C(1), S, O, and Li as in **1a**) to benzaldehyde. **1a**: $R^1 = CH_3$, $R^2 = C_6H_5$, $R^3 = C_6H_5$; **1b**: $R^1 = H$, $R^2 =$ S-*p*-tolyl, $R^3 =$ *p*-tolyl [10a, b]; **1c**: $R^1 = H$, $R^2 = H$, $R^3 =$ *p*-tolyl [10d]; **1d**: R^1, $R^2 = H$, C_6H_5, $R^3 = C_6H_5$ [10e].

Thus, C(1) is not planar coordinated but rises out from the S-C(2)-C(8) plane by 12(1) pm, *away* from the S-O (and thus the O-Li) bond! ^{1}H- and ^{13}C-NMR investigations on α-sulfinyl "carbanions" in solution were not informative in this respect; accordingly C(1) could be planar, or "not quite" planar.[2f-h] Furthermore, the lone pair on C(1) is tilted by 16° away from the antiplanar conformation to the S-O bond, so that there is reduced repulsion between the two lone pairs (Scheme 3a). The crystal structure of **1a** is thus fully consistent with the results of theoretical investigations on $[CH_3\ddot{S}(O)\ddot{C}H_2]^{\ominus}$ (Scheme 3b).[11] That the benzylic C(1) atom of **1a** is flattened and that the rotation is less than in the case of $[CH_3\ddot{S}(O)\ddot{C}H_2]^{\ominus}$ is not surprising.[12]

Scheme 3. Angles [°]: a) at C(1) and S in **1a** (experimental, except for the positions of the lone pairs) and b) in $[CH_2\ddot{S}(O)\ddot{C}H_2]^{\ominus}$ (calculated) [11].

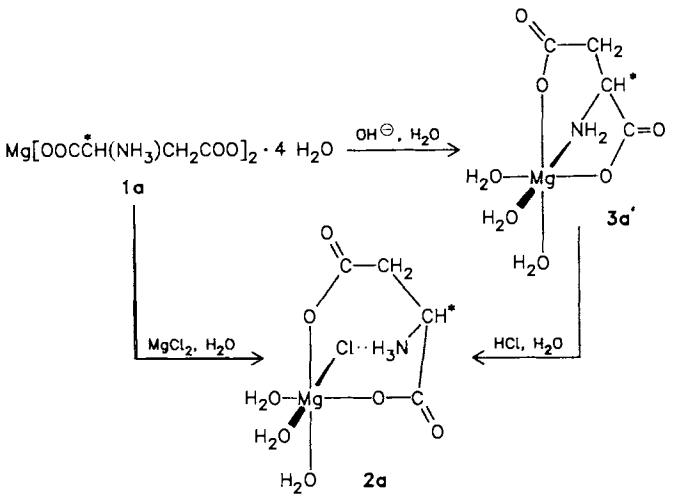
Kingsbury, *J. Org. Chem. 37* (1972) 102.

[11] S. Wolfe, A. Stolow, L. A. La John, *Tetrahedron Lett. 24* (1983) 4071, and references cited therein; the distances calculated for S-$\ddot{C}H_2^{\ominus}$ and S-O are 1.672 and 1.524 Å, respectively. In $[H\ddot{S}(O)\ddot{C}H_2]^{\ominus}Li^{\oplus}$, however, the *H atoms* are bent away from the S-O bond (S. Wolfe, L. A. La John, D. W. Weaver, *ibid. 25* (1984) 2863). Such a result could be due to the extremely short C-Li distance (216 pm) determined in the 3-21G* calculations.



[12] All the more surprising is that the benzylic C(1)-atom, which does not undergo C-Li bonding, is not planar coordinated. In α-(phenylsulfonyl)benzyllithium (G. Boche, M. Marsch, G. M. Sheldrick, K. Harms, *Angew. Chem. 97* (1985) 577; *Angew. Chem. Int. Ed. Engl. 24* (1985) 573), α-cyanobenzyllithium (G. Boche, M. Marsch, K. Harms, *ibid. 98* (1986) 373 and *25* (1986) 373), and α-nitrobenzyllithium (G. Klebe, K. H. Böhn, M. Marsch, G. Boche, *ibid.*, in press) the benzylic C-atoms are planar coordinated. To study the possible influence of packing effects, crystals of an enantiomer of **1a** are required. Enantiomers and racemates usually crystallize in different space groups.

Elucidation of the Structure of Pharmacologically Active Magnesium L-Aspartate Complexes

By *Hubert Schmidbaur,* Gerhard Müller, Jürgen Riede, Gebhard Manninger,* and *Joachim Helbig*

Magnesium therapy has gained increasing importance in several quite diverse areas of medical application in recent years.[1,2] Of particular interest are the magnesium salts of L-aspartic acid and L-glutamic acid, which are the frequently preferred forms of magnesium in chemotherapeutical treatment.[3,4] There are good resons for assuming that the two aminodicarboxylic acids form weak complexes with magnesium[5,6] which are decisive for the transport of magnesium through membranes as well as across the blood-brain barrier. At the same time, however, the magnesium ion is not irreversibly complexed, but is apparently readily released again.[7]

Besides the salts **1a** and **1b**,[8] which are readily obtainable by neutralization of $Mg(OH)_2$, MgO or $MgCO_3$ with the free acids (but whose structures are still unknown), the magnesium halide aspartates and glutamates also play an important therapeutic role, for it follows from in vivo experiments that, e.g., optimal physiological activities are achieved with the composition Mg : Cl : Asp (Glu) = 1 : 1 : 1.[9] These salts are not usually formed completely from **1a**, **b** and the hydrochloric acid of the stomach. They are, however, readily prepared from magnesium halides and **1a**, **b**.[10] In the course of studies on the nature of the interaction between $(Mg^{2\oplus})_{aq}$ and aspartate or glutamate ions in solution and in the solid state, a magnesium aspartate trihydrate **3a**, which exists only in strongly basic aqueous medium, has been obtained for the first time in the crystalline state and has been structurally characterized.[11]

Mg[OOCCH(NH$_3$)CH$_2$CH$_2$COO]$_2$

1b

It follows from Figures 1 and 2 that the L-aspartate dianion in **3a** is facially bound to the metal atom as a tridentate ligand. Two further sites of attachment of the octahedral coordination sphere are saturated by water molecules, and the sixth by an oxygen atom of a carboxy group of a neighboring complex (O4*). The strands of **3a** thus formed run parallel to the crystallographic *a*-axis (Fig. 2) and are held together by a complicated system of hydrogen bonds in which the third water molecule of the crystalline *tri*hydrate also participates. During the process of dissolution, one water molecule presumably occupies the sixth coordination site of the decoupled complex molecules (Formula **3a'**). All aspartate ions have the L-configuration.

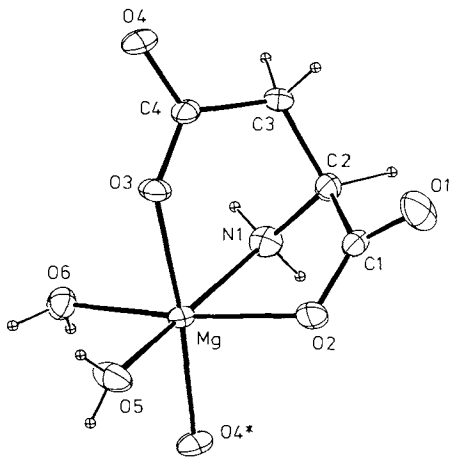


Fig. 1. Crystal structure of the complex **3a** (ORTEP, thermal ellipsoids 50%, H-atoms with arbitrary radius). O4* is the oxygen atom O4 of a neighboring molecule. All H atoms were located and refined; of the H atoms on O and N, only one on N does not participate in the three-dimensional hydrogen bonding network. Important bond lengths [Å] and angles [°]: Mg-O2 2.075(2), Mg-O3 2.066(2), Mg-O4* 1.999(2), Mg-O5 2.074(2), Mg-O6 2.090(2), Mg-N1 2.203(3); O3-Mg-O4* 174.1(1), O2-Mg-O3 90.0(1), O2-Mg-N1 77.2(1), O3-Mg-N1 84.4(1).

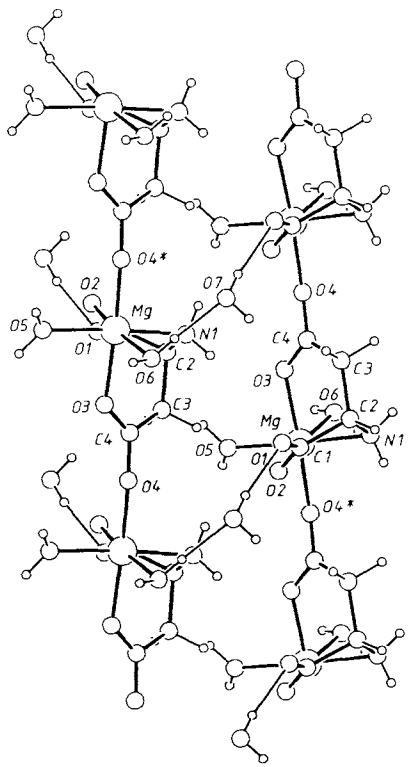

Fig. 2. Diagram of two strands of **3a** running parallel to the crystallographic *a*-axis of the crystal. The water molecule $H_2O(7)$ connects both strands through hydrogen bonds. There are further hydrogen bonds to other strands.

3a reacts basic in water (pH = 9.85 at 20°C, saturated solution) and exhibits only slight electrical conductivity ($\chi_M = 2.55\ \Omega^{-1}\ cm^2$). On neutralization with HCl, the chloride aspartate is formed (pH = 7.13 at 20°C). The conductivity of this salt in water ($\chi_M = 5.35\ \Omega^{-1}\ cm^2$) remains well below the value expected for a 1:2 electrolyte. Hence, it can be concluded that dissociation of the chloride ion from the magnesium is far from complete. This finding corresponds very well with the physiological observations, according to which the solution with 1:1:1 stoichiometry is particularly active. An ionic association in the sense of Formula **2a** had already been deduced from earlier measurements with ion-sensitive electrodes.[12] Apparently, the ammonium group in **2a** formed by protonation of the amino group in **3a** promotes the coordination (electrostatically or via weak hydrogen bonding) and represses the dissociation of the chloride ion.

Table 1. ^{1}H- and ^{13}C-NMR data of the complexes **2a** and **3a'** (solvent D_2O/D_3COD [30:1], c = 5 wt-%, 30°C; chemical shifts relative to TMS ext. and $D_3{}^{13}COD$ (δ = 49.00); J values in Hz).

		2a	**3a'**
^{1}H-NMR	δCH_2	2.60	2.65
	δCH	3.74	3.58
	$^3J(H_2CCH)$	5.6	4.7
^{13}C-NMR	δCOO	182.74, 179.95	178.71, 175.52
	δCH_2	53.19	52.73
	δCH	40.56	37.30
	$^1J(CH_2)$	128.9	127.4
	$^1J(CH)$	141.7	144.5

As expected, the transition **2a** → **3a'** is also revealed in the ^{1}H- and ^{13}C-NMR spectra of the aqueous solutions by a noticeable shift of the signals and by changes in the coupling constants (Table 1). The deviations are greatest at the atoms adjacent to the amino/ammonium groups, so that a protonation at the nitrogen atom is assumed to take place also in solution.

All the above findings support the concept that complexes of type **2** exhibit carrier properties for magnesium ions that are decisive for pharmacological activity.

The First Observation of the Equilibrium $2M{\equiv}M \rightleftarrows M_4$ (M = Transition Metal): Synthesis and Structure of Hexaisopropoxyditungsten and Its Dimer**

By *Malcolm H. Chisholm,* David L. Clark, Kirsten Folting,* and *John C. Huffman*

Only for certain elements of the first row are multiple bonds stable with respect to oligomerization at standard temperature and pressure; e.g., N≡N is stable with respect to N_x but P≡P will oligomerize to P_4 and then to P_x. Multiple bonds between metal atoms are stabilized with respect to clusters by ligand effects which may be steric or electrostatic or both.[1] Since our initial discovery of compounds of formula $[(RO)_3M{\equiv}M(OR)_3]$ for M = Mo[2] and W,[3] we have speculated about the dimerization of $[M{\equiv}M]^{6\oplus}$ units to give 12-electron M_4 clusters supported by alkoxide ligands. Although a variety of mixed halide-alkoxide Mo_4 12-electron clusters have been successfully characterized,[4–6] no compound of formula $[M_4(OR)_{12}]$ has been fully characterized because of either difficulties in obtaining crystals suitable for X-ray studies or the ease of oxidation of the $[M{\equiv}M]^{6\oplus}$ moiety.[7,8] An understanding of the factors facilitating the latter process allowed us to isolate a black crystalline compound of empirical formula $[W(OiPr)_3]$ (from elemental analysis), which appeared to be tetranuclear in benzene based on a cryoscopic molecular weight determination.[9] We now wish to report our characterization of $[W_2(OiPr)_6]$ **1** in equilibrium with its dimer, $[W_4(OiPr)_{12}]$ **2**. To our knowledge this is the first example of a reversible association of a dinuclear compound containing a multiple bond between metal atoms, though condensation reactions have been reported.[10,11]

$$2[W_2(OiPr)_6] \rightleftharpoons [W_4(OiPr)_{12}]$$

Bloomington, IN 47405 (USA)

[**] We thank the National Science Foundation and the Wrubel Computing Center at Indiana University for support.

Addition of isopropyl alcohol (>6 equivalents) to a solution of $[W_2(OtBu)_6]$[3] in dimethoxyethane (DME) yields a brown solution from which dark crystals are obtained upon cooling. The latter were found by X-ray analysis to contain a 1:1 mixture of **1** and **2**.[12]

A view of the dinuclear species is shown in Figure 1, above, and provides the first structural characterization of an unligated $[W_2(OR)_6]$ compound. The W≡W bond distance (2.315(2) Å) is just slightly shorter than that found for the ligated compound $[W_2(OiPr)_6(py)_2]$ (2.332(1) Å).[3] The W-O bond distances (1.86-1.88 Å) are indicative of significant O-to-W π-donation.[13]

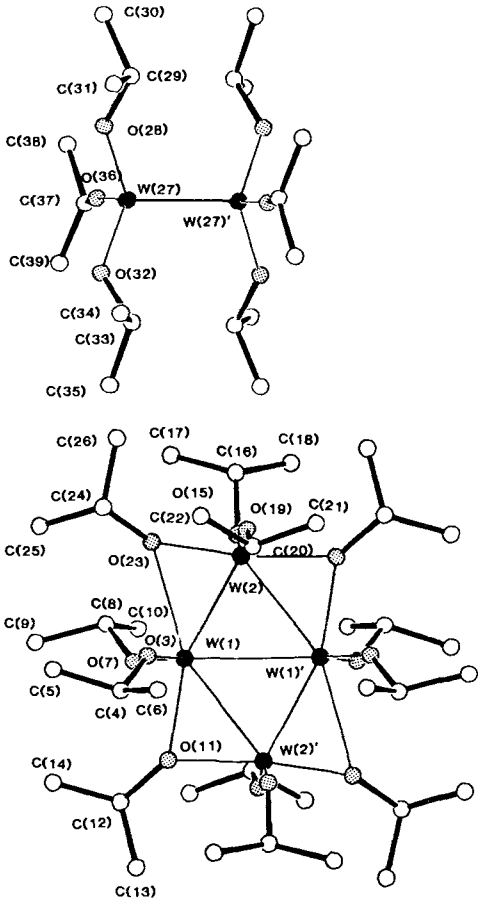

Fig. 1. Above: A ball- and-stick drawing of the centrosymmetric crystal structure of **1**. Bond distances [Å] and angles [°] (averaged where appropriate): W-W 2.315(2), W-O 1.87(1); W-W-O 106.7(7), O-W-O 112.1(9). Below: A ball-and-stick drawing of the centrosymmetric crystal structure of **2**. Bond distances [Å] and angles [°] (averaged where appropriate): W(1)-W(2) 2.502(1), W(1)-W(2)' 2.733(1), W(1)-W(1)' 2.807(2), W(1)-O(3) 1.91(1), W(1)-O(7) 1.89(1), W(1)-O(11) 2.18(1), W(1)-O(23) 2.59(3), W(2)-O(19) 1.99(1), W(2)-O(15) 1.89(2); W(2)-O(23) 1.87(2), W(2)-O(11)' 1.98(1), O(3)-W(1)-O(7) 122.9(6), O(11)-W(1)-O(23) 155.9(6), O(23)-W(2)-O(11)' 172(1), O(15)-W(2)-O(19) 150.2(7).

The W_4 cluster **2** (Fig. 1, below) consists of a rhombus of metal atoms having two short M-M distances (W(1)-W(2), W(1')-W(2') = 2.502(2) Å), and two longer distances, (W(1)-W(2'), W(2)-W(1') = 2.733(2) Å) with a short diagonal distance (W(1)-W(1') = 2.807(2) Å) still being worthy of mention with respect to M-M bonding interactions. There are four edge-bridging alkoxides whose oxygen atoms are contained in the W_4 plane; the remaining eight alkoxides are terminal, two per tungsten, with four lying above and four below the W_4 plane. The local WO_4 structural units may be viewed in terms of trigonal-bipyramidal fragments in which one equatorial OR group is missing. This site is directed toward the center of the cluster; the terminal and bridging alkoxide ligands make up the remaining equatorial and axial positions, respectively. It is possible to formulate the present distorted 12-electron W_4 rhombus as arising from a second-order Jahn-Teller distortion of a regular [W(1)-W(2) = W(1)-W(2)'] 10-electron $[W_4(OR)_{12}]^{2\oplus}$ cluster (compare 8- and 10-electron rhombs for $[W_4(OEt)_{16}]^{n\ominus}$, where n = 0 and 2).[14] Aside from the asymmetry within the W_4 unit, of particular note is the asymmetry in the $W_2(\mu\text{-}OR)$ moiety involving the short W-W distances: W(2)-O(23) = 1.87(2) Å, W(1)-O(23) = 2.59(4) Å.

Despite the fragility of the alkoxide bridges of **2** (noted above), the ^{1}H-NMR spectrum reveals a static structure on the NMR time-scale at 16 °C in [D$_8$]toluene. The CH resonances appear in a 2:2:1:1 ratio as expected based on consideration of the molecular structure found in the solid state. Upon heating the solution, the resonances assignable to **2** diminish as those associated with **1** increase, until at +65 °C only the latter are present. At this temperature the solution is pale yellow. Upon rapidly cooling to +16 °C, the resonances of **2** start to reappear only *slowly*, implying a significant energy barrier to dimerization of **1**.

Finally, it is worth mentioning that the pure compound **2**, as determined by ^{1}H-NMR spectroscopy, is obtained by crystallization from the reaction mixture of $[W_2(OtBu)_6]$ and *i*PrOH in hexane or toluene at 0 °C. The 1:1 mixture of **1** and **2** is obtained by crystallization from DME solutions. In hexane, toluene, or benzene at +65 °C only the dinuclear compound is present. Given the existence of a sizeable activation energy for the interconversion **1** ⇄ **2**, it should be possible under certain conditions to examine the separate reactivity of each species toward substrates of interest.

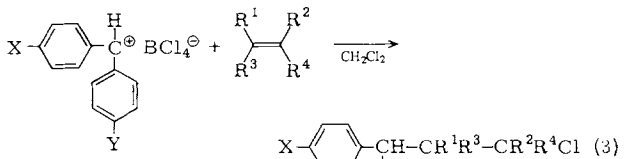
Direct Measurement of the "Isokinetic Rate Constant" in Additions of Diarylcarbenium Ions to 2-Methyl-2-butene**

By *Reinhard Schneider* and *Herbert Mayr**



In a series of reactions where the temperature (T) and the structure of the reagents (σ) are the only variables, the rate constant k can be considered as a function of these parameters [Eq. (1)].

$$k=f(T,\sigma) \quad (1)$$

It is possible that k becomes independent of one of these parameters, if the second parameter adopts a certain value.[1-4] The rate constant k will be independent of the temperature, if the structure (σ) is so selected that the Arrhenius activation energy (E_a) equals zero. If an isokinetic relationship [Eq. (2)] exists, the rate constant k will be independent of structure at the isokinetic temperature $T_{iso}=\beta$, since the alteration $\delta\Delta H^{\neq}$, which is affected by the structural variation, is completely counterbalanced by the $T\delta\Delta S^{\neq}$ contribution.[5]

$$\delta\Delta H^{\neq}=\beta\cdot\delta\Delta S^{\neq} \quad (2)$$

If $k=f(T,\sigma)$ becomes independent of any one of the two variables, it will adopt the same value: k_{iso}, the isokinetic rate constant, the logarithm of which has been termed the isoparametric value[1] or the isokinetic point.[2b]

OPh	H	$PopPh^{\oplus}CH$
H	OMe	$PhAn^{\oplus}CH$
Me	OMe	$TolAn^{\oplus}CH$
OMe	OMe	$An_2^{\oplus}CH$

We report here on a system which allows the direct measurement of k_{iso}.

Recently, we succeeded in determining the kinetics of the addition of diarylcarbenium ions to alkenes [Eq. (3)].[6] We found for the addition of *p*-substituted diarylcarbenium ions to 2-methyl-1-pentene that variation of the substituents affects only $\Delta H^{\neq}$, whereas $\Delta S^{\neq}$ remains constant within the limits of experimental error (-121 ± 4 J mol^{-1} K^{-1}). Table 1 shows a comparable situation for the addition of diarylcarbenium ions to 2-methyl-2-butene; variation of the substituents only influences $\Delta H^{\neq}$ while $\Delta S^{\neq}$ is almost unaffected.

As previously reported,[6] the log$k$ values of the additions of diarylcarbenium ions to alkenes are not linearly correlated with $\Sigma\sigma^{+}$. Steric effects inhibit the complete coplanarity of both aryl groups, and the individual torsional angles depend on the electron-releasing effects of both *p*-substituents with the consequence that the σ^{+} values are not additive. Figure 1b shows, however, that the reaction rates of the diarylcarbenium ions with 2-methyl-1-pentene (abscissa) and 2-methyl-2-butene (ordinate) are linked by a linear free enthalpy relationship (correlation coefficients 0.9995 to 0.99990).

Table 1. Activation parameters and rate constants for the addition of diarylcarbenium ions to 2-methyl-2-butene.

Carbenium ion	k_2 −70 °C [L mol^{-1} s^{-1}]	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J K^{-1} mol^{-1}]	E_a [kJ mol^{-1}]	log$A$
$Tol_2^{\oplus}CH$	6.8×10^{4}	−1.6	−157	0.2	4.89
$PopPh^{\oplus}CH$	3.8×10^{3}	5.3	−147	7.1	5.42
$PhAn^{\oplus}CH$	2.5×10^{2}	7.5	−159	9.3	4.79
$TolAn^{\oplus}CH$	1.8×10^{1}	13.6	−151	15.5	5.24
$An_2^{\oplus}CH$ [a]	8.7×10^{-2}	22.0	−154	23.7	5.02

[a] Determinations in presence of $PhCH_2NEt_3^{\oplus}BCl_4^{\ominus}$; probably because of the reversibility of the addition step, the rate constants of this reaction increase when $BCl_4^{\ominus}$ salts are added.

Figure 1b corresponds to a Hammett plot, in which the log$k$ values of the reactions with 2-methyl-1-pentene at −70 °C are defined as the temperature-independent substituent constants σ. The slopes of the correlation lines correspond to the reaction constants ρ, which decrease with increasing temperature and become zero at the isokinetic temperature (extrapolated horizontal line).

The correlation lines intersect at the position of the ditolylcarbenium ion, the rate of addition of which is not influenced by variation of the temperature.[7] The ditolylcarbenium ion, therefore, corresponds to the critical value of σ,[1,2] also termed the isokinetic substituent,[3] which reacts with the isokinetic rate constant $k_{iso}=6.9\times10^{4}$ L mol^{-1}

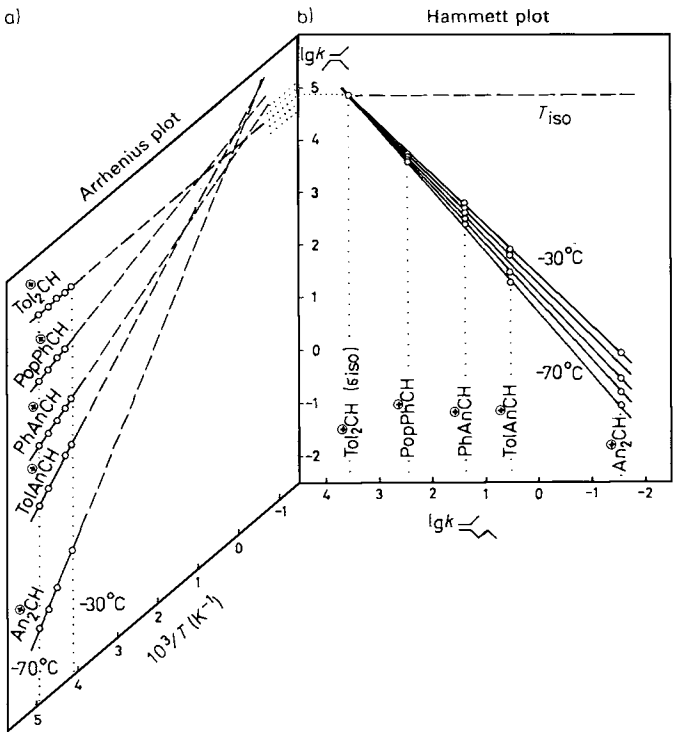

Fig. 1. Reactivity of the diarylmethyl cations towards 2-methyl-2-butene as a function a) of reciprocal temperature and b) of the reactivity towards 2-methyl-1-pentene at −70 °C (Ph = C_6H_5, Tol = *p*-CH_3–C_6H_4, An = *p*-CH_3O–C_6H_4, Pop = *p*-(C_6H_5O–C_6H_4).

$s^{-1} \pm 4\%$ at any temperature. As indicated in the Hammett plot, all cations of this series should react with this rate constant at the isokinetic temperature.

The same set of experimental data is plotted against the inverse temperature in Figure 1a[3] (Arrhenius plot). The slope of the lines ($=E_a$) decreases with increasing reactivity of the carbenium ions and adopts the value zero ($E_a=0$) for the ditolylcarbenium ion, the system with the isokinetic substituent.

As in the Hammett plot (Fig. 1b), it can be seen that the reactivity differences of the various carbenium ions decrease with increasing temperature. In the case of an ideal isokinetic relationship, all straight lines should intersect at one point (T_{iso}), at which the reactivity differences of the carbenium ions had vanished. A deviation from the ideal isokinetic relationship as well as the necessary extrapolation over a wide temperature range may be responsible for the fact that the points of intersection do not precisely coincide. It is evident, however, that the same order of magnitude of k_{iso}, which has been derived from the Hammett plot, is indicated by the points of intersection in Figure 1a.[3]

The ditolylcarbenium ion is the most reactive carbenium ion of this series which can be kinetically investigated with our present methods. The question arises, whether the linear free enthalpy relationships that have been described in this paper will also be valid beyond the isokinetic substituent, i.e., in the range of eventual negative activation energies.[8]

Linear Reactivity-Selectivity Correlations in Additions of Diarylcarbenium Ions to Alkenes; a Rebuttal of the Reactivity-Selectivity Principle**

By *Herbert Mayr,** *Reinhard Schneider,* and *Ute Grabis*

The selectivity of a species, at one time frequently used for classifying the relative life times of reactive intermediates,[1] has repeatedly been disproven as a criterion for the determination of reactivity.[2-4] The intuitive rule that an increase of reactivity is related with a decrease of selectivity was demonstrated by *Ritchie* to be invalid for many cation-anion combinations. Numerous cations of different reactivity reveal identical selectivity towards pairs of n-nucleophiles.[2] For frontier orbital controlled reactions an increase of selectivity with increasing reactivity was reported.[3] The impression was created that different classes of reactions are related with a certain reactivity-selectivity pattern, which may reverse if the isoselective temperature[3] comes into the experimental range.

We report here on the additions of diarylcarbenium ions to various alkenes. For the first time we demonstrate the coexistence of constant, proportional and inversely proportional reactivity-selectivity behavior within a group of closely related reactions.

1 2a-e

In the preceding communication we reported the existence of a linear free enthalpy relationship between the additions of the diarylcarbenium ions **1** to 2-methyl-1-pentene **2a** and 2-methyl-2-butene **2b**.[5] Figure 1 shows that the corresponding additions to methylenecyclopentane **2c**, isoprene **2d** and styrene **2e** are also linearly correlated with $\log k(\mathbf{2a})$.

Figure 1 represents a linear reactivity-reactivity relationship. Since selectivity arises from two reactivities ($S=\log k_1/k_2=\log k_1-\log k_2$), the combination of two linear reactivity-reactivity relationships necessarily yields a

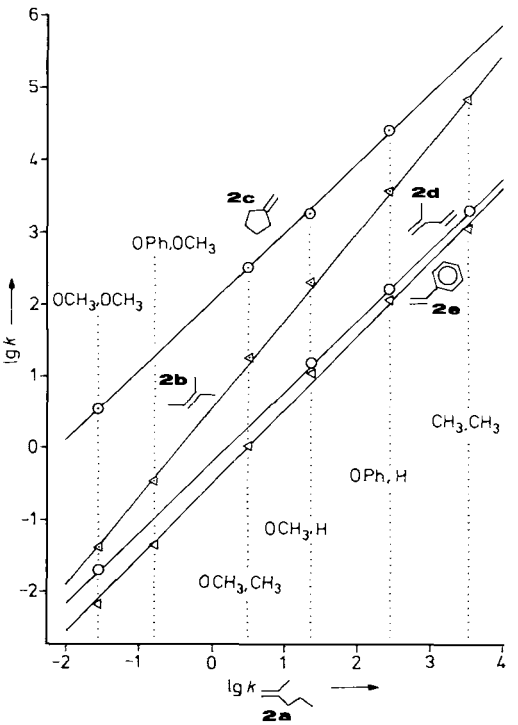

Fig. 1. Linear free enthalpy relationships between the rates of addition of a series of *p*-substituted diarylcarbenium ions **1** to alkenes **2** at $-70°C$ in CH_2Cl_2.

[*] Prof. Dr. H. Mayr, Dipl.-Chem. R. Schneider, U. Grabis
Institut für Chemie der Medizinischen Universität
Ratzeburger Allee 160, D-2400 Lübeck 1 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

linear reactivity-selectivity relationship. Since the selectivity scale has to be spread out for the graphical display in Figure 2, minor deviations from the linear reactivity-reactivity relationships lead to noticeable deviations from the ideal linear reactivity-selectivity relationship.

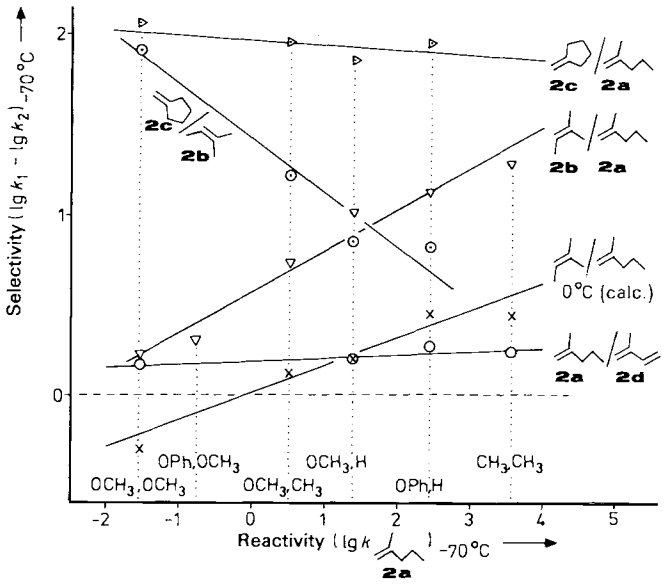

Fig. 2. Reactivity-selectivity relationships in the additions of *p*-substituted diarylcarbenium ions **1** to alkenes **2** at −70 °C in CH_2Cl_2.

Considering the pair **2c/2b**, one recognizes decreasing selectivity with increasing reactivity. The pairs **2c/2a** and **2a/2d** exhibit almost constant selectivity while the reactivity is varied, and the pair **2b/2a** shows even an increase of selectivity with increasing reactivity. If, finally, the pair **2b/2a** is considered at 0 °C, one finds the correlation line moving from bottom left towards the dashed zero selectivity level, i.e., in the range of low reactivity carbenium ions, the selectivity decreases with increasing reactivity[6] and is close to zero for the methoxyphenyl-tolyl compound. In the range of the more reactive carbenium ions, the selectivity increases with reactivity, but the relative reactivity of **2b** and **2a** is reversed compared with the left part of the correlation line.

Since it depends on the arbitrary selection of a pair of competing substrates whether constant, proportional or inversely proportional reactivity-selectivity behavior is encountered, we consider it to be impossible to derive reactivity sequences solely from competition experiments. Furthermore, our observation that all feasible types of linear reactivity-selectivity relationships are realized within a series of closely similar reactions indicates that a certain reactivity-selectivity behavior cannot be considered to be proof of a certain interaction mechanism.

The variety of reactivity-selectivity relationships in this system is due to the steeper correlation line of **2b** which is located *between* the almost parallel straight lines of the other alkenes (Fig. 1). Additional experiments should show whether the relation between ΔS^{+} and the slopes of Figure 1, as indicated by preliminary experiments, can be confirmed.

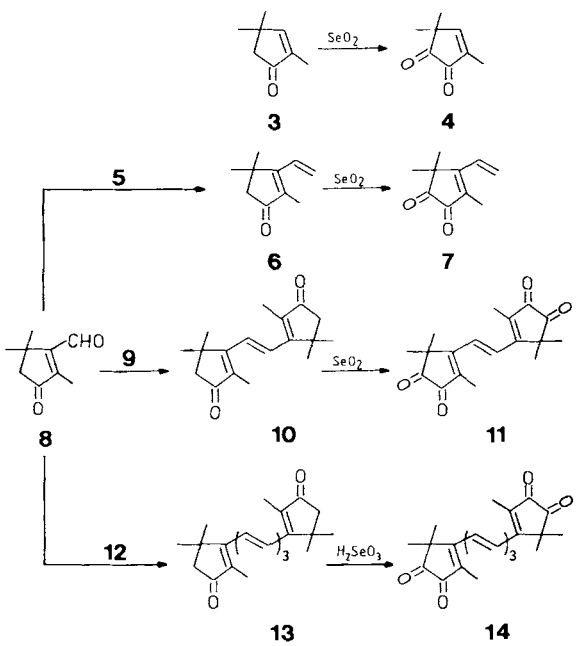
Mini-Violerythrins: Why can C_{38}-Carotinoids be Blue?**

By *Matthias Kummer, Georg Martin,* and *Hans-Dieter Martin**

Dedicated to Professor Siegfried Hünig on the occasion of his 65th birthday

Most carotinoids are yellow to red.[1] A number of years ago, a blue carotinoid, violerythrin **2**, was obtained by alkaline hydrolysis of actinioerythrin, the red pigment of the sea anemone *Actinia equina*.[2,3] This drastic change in color in going from dinorcanthaxanthin **1** (λ_{max} = 487 nm)[4] to violerythrin **2** (λ_{max} = 580 nm) has thus far remained unexplained.



It has been pointed out that the terminal five-membered rings containing the dicarbonyl moieties are oriented approximately planar to the polyene chain and could thus contribute to this bathochromic shift.[5] Since we have already demonstrated with several examples that α-dicarbonyl chromophores can exhibit considerable lone-pair splitting (in a $n_+ + n'_+$ and a $n_+ - n'_+$ combination) over longer distances,[6,7] the question now arises as to whether the same applies in the case of the bis(α-dicarbonyl) chromophore of violerythrin **2**. The UV/VIS spectrum of **2** provides no information about the position of the $(n_+ + n'_+)\pi^*$ or $(n_+ - n'_+)\pi^*$ transition (the broad $\pi\pi^*$ absorption masks the likely region). Herein we report experiments and calculations which answer this question and, at

[**] Small and Medium Sized Rings, Part 56. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der chemischen Industrie, and the BASF AG.—Part 55: R. Braun, M. Kummer, H.-D. Martin, M. B. Rubin, *Angew. Chem. 97* (1985) 1054; *Angew. Chem. Int. Ed. Engl. 24* (1985) 1059.

the same time, shed light on the cause of the deepening in color in the transition from **1** to **2**.

Oxidation of trimethylcyclopentenone **3**[8] with selenium dioxide afforded the 1,2-diketone **4**[9] in 60–70% yield ($\lambda_{max}=486$ nm, $\varepsilon=19$). Wittig carbonyl olefination of the aldehyde **8**[4] with methylenetriphenylphosphorane **5** led to formation of the colorless vinyl derivative **6**, which was oxidized with selenium dioxide to the orange-colored diketone **7** [m.p. 98°C, $\lambda_{max}=496$ nm, $\varepsilon=28$; ^{1}H-NMR ($CDCl_3$/TMS): $\delta=1.37$ (s, 6H), 2.06 (s, 3H), 5.97 (d, 1H), 6.05 (d, 1H), 6.83 (dd, 1H)]. A Wittig-Horner reaction of the aldehyde **8** with the phosphonate **9**[4] ($NaNH_2$/tetrahydrofuran, −15°C) furnished the mini-dinorcanthaxanthin **10** in 40–45% yield as pale yellow scaly crystals [m.p. 162°C, $\lambda=355$ (sh), $\varepsilon=15300$, $\lambda_{max}=336$ nm, $\varepsilon=22600$, ^{1}H-NMR ($CDCl_3$/TMS): $\delta=1.38$ (s, 12H), 1.93 (s, 6H), 2.41 (s, 4H), 6.92 (s, 2H)]. Twofold oxidation with selenium dioxide afforded the deep-red mini-violerythrin **11** [m.p. 208°C; $\lambda_{max}=520$ nm, $\varepsilon=180$, $\lambda=406$ nm, $\varepsilon=22300$, $\lambda_{max}=383$ nm, $\varepsilon=27100$; ^{1}H-NMR ($CDCl_3$/TMS): $\delta=1.45$ (s, 12H), 2.13 (s, 6H), 7.30 (s, 2H)]. Lengthening of the polyene chain by two further double bonds was achieved by reaction of the aldehyde **8** with the bisphosphonate **12**.[10] The dione **13** obtained, a mini-dinorcanthaxanthin, is a brilliant orange-colored solid, whose absorption maximum lies at 412 nm, $\varepsilon=48700$ [^{1}H-NMR ($CDCl_3$/TMS): $\delta=1.32$ (s, 12H), 1.89 (s, 6H), 2.37 (s, 4H), 6.52–6.94 (m, 6H)].

5: $(C_6H_5)_3P{=}CH_2$ **9**: $CH_2P(O)(OC_2H_5)_2$

12: $(C_2H_5O)_2(O)P{-}CH_2{-}CH{=}CH{-}CH_2{-}P(O)(OC_2H_5)_2$

A remarkable bathochromic shift is observed upon oxidation of **13** with selenous acid, whereupon the intense red-violet mini-violerythrin **14** is obtained [m.p. 265–267°C (decomp.); $\lambda=546$ nm (sh), $\varepsilon=340$, $\lambda_{max}=465$ nm, $\varepsilon=78000$; ^{1}H-NMR ($CDCl_3$, TMS): $\delta=1.41$ (s, 12H), 2.21 (s, 6H), 6.68–7.37 (m, 6H)].

A comparison of the UV data of the model violerythrin compounds **4**, **7**, **11**, and **14** is very interesting.

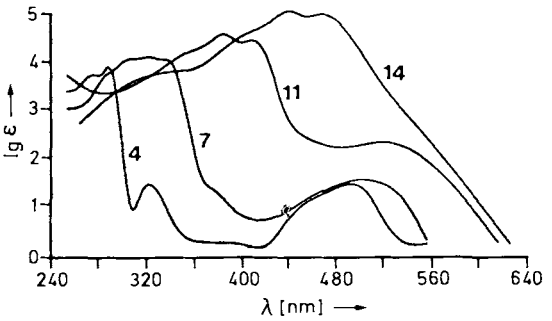

Fig. 1. UV/VIS spectra of the model violerythrin compounds **4**, **7**, **11**, and **14** (*in* $CHCl_3$).

The absorption spectra (Fig. 1) pose the following salient questions:

1. What gives rise to the bathochromic shift in the series of diones and tetrones **4** < **7** < **11** < **14**?
2. Why do the tetrones **11** and **14** absorb at longer wavelength than the precursors **10** and **13** (in analogy to **1** and **2**)?
3. Where are the $n_+\pi^*$ transitions to be located in those tetrones in which they are not recognizable under the broad $\pi\pi^*$ absorption.

To gain an insight into the energies of the occupied levels responsible for the observed electronic transitions, the He(I) photoelectron spectra of **4**, **7**, and **11** were measured. The MINDO/3[12] and HAM/3[13] calculations carried out with optimized MNDO[11] geometries, together with the ionization energies of other 1,2-diketones enable an unequivocal assignment. The splitting of the n-levels into an n_+- and n_--combination in **4** is $\Delta n=2.05$ eV, in good agreement with other data.[14] The additional conjugated double bond in **7** destabilizes the n_+-HOMO by 0.29 eV, whereas the π-SUBHOMO, however, is increased threefold (Fig. 2).

If the conjugated system is lengthened by a further violerythrin end group to give the tetrone **11**, the PE spectrum (Fig. 3) shows an almost constancy of the ionization energy for the HOMO compared to the ionization energies of the dione **7**. Whereas we have measured an n_+/n_+ splitting of ca. 1 eV in other tetrones,[6] in the case of mini-violerythrin **11** we obtained a value of ≤ 0.2 eV for Δn_+. It can be concluded, therefore, that there is no σ-orbital in the planar **11** to permit a clear discrimination of the two combinations $(n_+ + n'_+)$ and $(n_+ - n'_+)$. Aside from the HOMO/SUBHOMO energies, also the LUMO energies have to be taken into consideration for the drastic color change in the transition from the diones to the corresponding tetrones. The energy differences obtained by HAM/3 for $n_+\pi^*$ and $\pi\pi^*$ in the case of **4**, **7**, and **11** are: 2.31, 2.55, 1.66 eV and 3.34, 2.60, 2.05 eV, respectively. The strong bathochromic shift of both the $n_+\pi^*$ transition as well as the $\pi\pi^*$ transition of **11** is caused, in particular, by a drastic lowering of

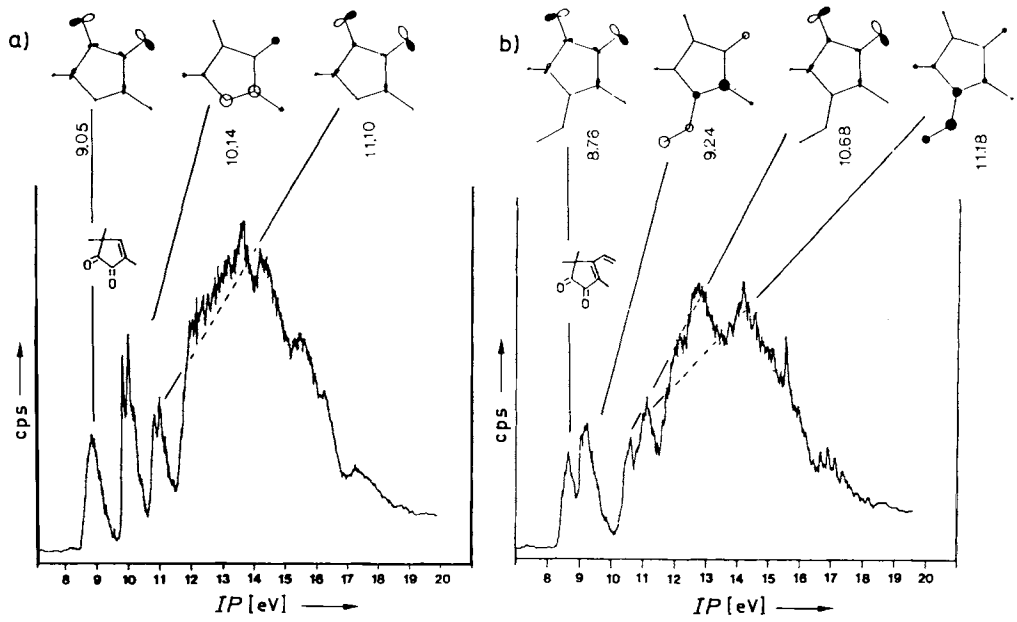

Fig. 2. He(I) photoelectron spectra and MO diagrams of the violerythrin end groups a) **4** and b) **7** (numerical values correspond to the maxima of the bands).

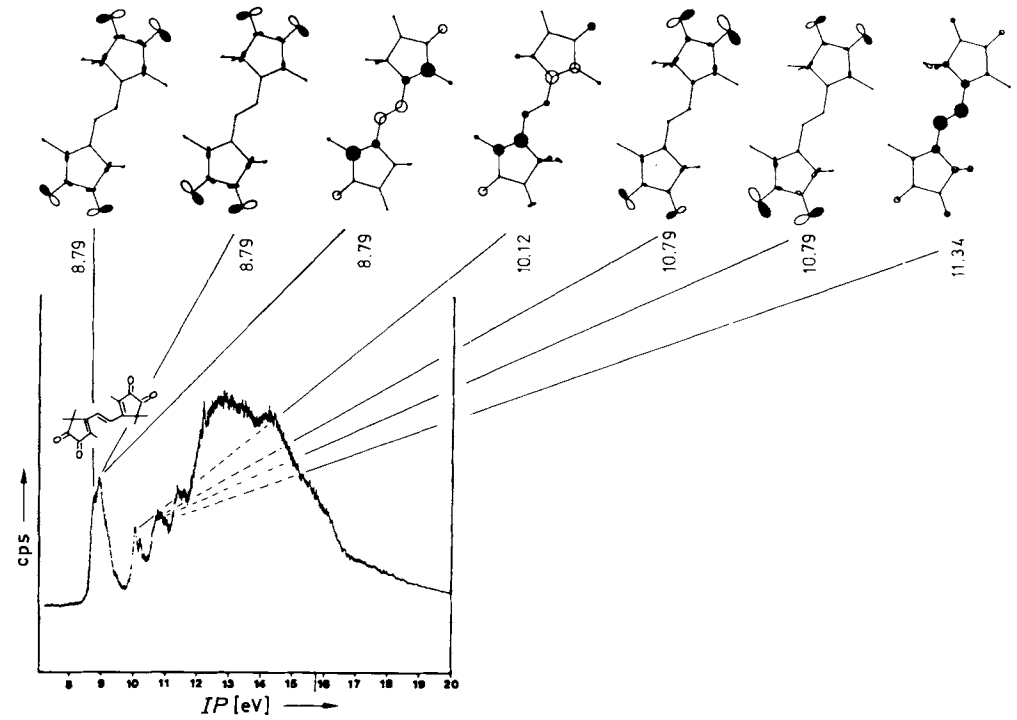

Fig. 3. He(I) photoelectron spectrum and MO diagram of mini-violerythrin **11** (numbers correspond to the maxima of bands).

the π^* LUMO level, besides a slight destabilization of the occupied n_+ level and, as a consequence, a substantial increase in the occupied π-level. A photoelectron spectrum of **14** could not be obtained. Calculations (MINDO/3, HAM/3), however, confirm the trend found in the case of **4**, **7**, and **11**.

Hence, the questions 1 and 2 can be answered as follows: The bathochromic shift in the series **4** < **7** < **11** < **14** is caused both by the increase of the occupied π level as well as by the lowering of the unoccupied π^* level, consistent with the lengthening of the π system. The dominant cause of the bathochromic shift upon oxidation of **10** to **11** and of **13** to **14** as well as of the red dinorcanthaxanthin **1** to the blue violerythrin **2**, however, can only be regarded as a lowering of the π^*-LUMO level.

Information about the $n_+\pi^*$ transition (question 3) can be deduced from Figure 1. Whereas the $n\pi^*$ transitions in the case of **4**, **7**, and **11** are well separated from the $\pi\pi^*$

transitions, the two $n_+\pi^*$ transitions of **14** are almost completely masked by the more intense and longer wavelength $\pi\pi^*$ transition, so that even in the case of **14** the more rapidly migrating $\pi\pi^*$ transitions have already caught up with the far less variable $n\pi^*$ transitions. As a result, a value of 580–600 nm can be extrapolated for the two $n_+\pi^*$ transitions in violerythrin **2**. Planar molecules with an *s-trans* conformation of the end groups to the ethene and hexatriene bridges were deduced on the basis of the calculations for **11** and **14**. The X-ray structure analysis of **11** confirms this geometry.[15] The torsion angles at the single bonds located between the double bonds are in each case 179.4°; hence, the end groups are coupled *s-trans* to the ethene bridge.

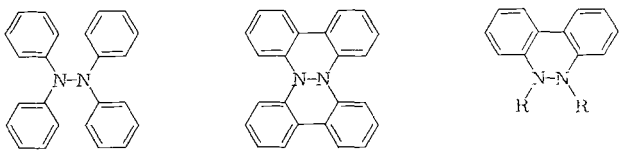
Unexpected "Two-Electron" Transfer in Cyclic Hydrazines—a Voltammetric Analysis**

By *Michael Dietrich, Jürgen Heinze,* Hans Fischer,* and *Franz A. Neugebauer**



Dedicated to Professor Walther Jaenicke on the occasion of his 65th birthday

Of the primary oxidation products of aromatic hydrazines, only the radical cations have so far been described as stable particles;[1–3] the dications, on the other hand, have been found to be extremely reactive, and consequently an unequivocal characterization of their redox properties is still lacking.

[**] This work was supported by the Stiftung Volkswagenwerk and the Fonds der Chemischen Industrie.

In a cyclovoltammetric investigation of the series tetraphenylhydrazine **1**, benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline **2**, 5,6-dihydro-5,6-diphenylbenzo[*c*]cinnoline **3**, and 5,6-dihydro-5,6-dimethylbenzo[*c*]cinnoline **4** we have now succeeded for the first time to carry out the reversible oxidation of **1**–**4** in liquid SO_2 ($T < -10$ °C) up to the dications (Table 1). In the case of **2**, even the reversible formation of the trication was observed. SO_2, purified by a new technique developed by us, proved once again to be an excellent solvent for the generation and investigation of highly charged cations.[4]

1 **2** **3**, R = C_6H_5; **4**, R = CH_3

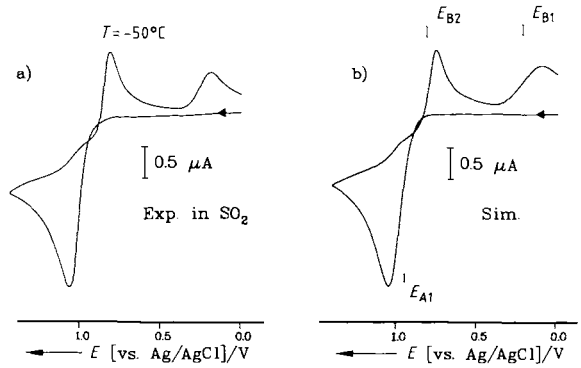
Table 1. Standard potentials of the compounds **1**–**4** [designated as X; cf. also reaction scheme (1)].

	E^0 ($X/X^{\oplus\odot}$) [V] [a]	E^0 ($X^{\oplus\odot}/X^{2\oplus}$) [V]	E^0 ($X^{2\oplus}/X^{3\oplus\odot}$) [V]
1	0.797	1.652	—
2	0.560	1.165	2.745
3	ee conf.: 0.240 [b] aa conf.: 0.990 [b]	0.840	—
4	ee conf.: 0.320 [b] aa conf.: 0.820 [b]	0.870	—

[a] The potentials were calibrated using an internal ferrocene standard and then referred to the standard Ag/AgCl reference electrode. [b] The standard potentials were determined by digital simulation.

Particularly suprising at first sight is the cyclovoltammogram of **3** at −50 °C (Fig. 1a): instead of the expected well separated oxidation steps for the formation of $\mathbf{3}^{\oplus\odot}$ and $\mathbf{3}^{2\oplus}$, the voltammogram shows only one, excessively large anodic wave, and in the reverse scan the rare trace crossing effect and a further wave shifted strongly cathodically.

Since **1** and **2** can be oxidized reversibly, a usual follow up reaction of $\mathbf{3}^{\oplus\odot}$ (e.g. addition or substitution) can be ruled out. Geometrical considerations based on the molecular model of **3** rather suggest that conformational trans-



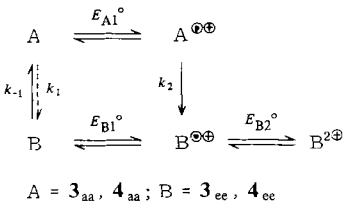


Fig. 1. Cyclovoltammogram of the oxidation of **3** ($c = 1 \times 10^{-3}$ M, $v = 100$ mV/s. a) Experimental voltammogram in SO_2 (working electrode Pt; 0.1 M Bu_4NPF_6). b) Simulated cyclovoltammogram (simulation data: $k^0(A/A^{\oplus\odot}) \cdot \sqrt{D} = 5.0 \times 10^{-6}$ cm^2 s$^{-3/2}$, $\alpha(A/A^{\oplus\odot}) = 0.39$, $k^0(B/B^{\oplus\odot}) \cdot \sqrt{D} = 3.1 \times 10^{-8}$ cm^2 s$^{-3/2}$, $\alpha(B/B^{\oplus\odot}) = 0.75$, $k^0(B^{\oplus\odot}/B^{2\oplus}) \cdot \sqrt{D} = 9.3 \times 10^{-6}$ cm^2 s$^{-3/2}$, $\alpha(B^{\oplus\odot}/B^{2\oplus}) = 0.35$, $k_1 \approx 0$, $k_{-1} = 100$ s^{-1}, $k_2 = 100$ s^{-1}).

formations take place after charge transfer. Due to steric factors, the two phenyl groups in uncharged **3** should be oriented axially to the predominantly sp^3-hybridized N-atoms (*aa* conformation).[5] Moreover, PE spectroscopic investigations on hydrazobenzenes closely related to **3** confirm that the antiperiplanar arrangement of the phenyl groups is, as a rule, preferred.[6] Oxidation to the radical cation $\mathbf{3}^{\oplus\ominus}$ leads, as shown by ESR investigations,[3] to a substantial planarization of the structural framework. The phenyl groups on the now sp^2-hybridized N-atoms are oriented equatorially (ee conformation) and acquire adequate space through an increase in the torsion angle about the N-C bond. *Nelsen* and *Evans* et al. have already been able to attribute the electrochemical behavior of cyclic aliphatic hydrazines to the existence of conformers.[7] Nevertheless, their findings and our results are not directly comparable.

We assume that **3** is oxidized to the dication in an ECE stepwise sequence,[8] whereby the C step leads to ee conformers. The conjugation between the two nitrogen centers is expanded to such an extent by planarization of the skeletal framework that the redox potential E^0_{B2} for the $\mathbf{3}^{\oplus\ominus}_{ee}/\mathbf{3}^{2\oplus}_{ee}$ pair lies on the negative side of E^0_{A1}. For this reason, only one wave is observed in the voltammetric experiment. In the reduction of the system, in the reverse scan, two well-separated reduction waves appear which lead from $\mathbf{3}^{2\oplus}_{ee}$ to the neutral $\mathbf{3}_{ee}$. The neutral species finally rearranges irreversibly again ($T=-50\,^\circ C$, $k_1\approx 0$, $k_{-1}\gg 0$) from the ee into the stable aa form (EEC).[8]

Thus, we have the simplified reaction scheme (1) (altogether eight conformers exist for the neutral species: two ee, two ae, and four ea forms[7]).

(1)

A = $\mathbf{3}_{aa}$, $\mathbf{4}_{aa}$; B = $\mathbf{3}_{ee}$, $\mathbf{4}_{ee}$

A formally analogous scheme has already been postulated by *Olsen* and *Evans* and by *Hammerich* and *Parker* for the reduction of bianthrone derivatives, whose radical anions likewise undergo conformational transformations.[9]

Two further results complete our interpretation. The distinctly visible trace crossing evidences a homogeneous disproportionation[10] of the type

$$B^{2\oplus} + A \longrightarrow B^{\oplus\ominus} + A^{\oplus\ominus} \qquad (2)$$

whereby the anodic current upon scan reversal results from the reoxidation of $B^{\oplus\ominus}$ to $B^{2\oplus}$ at the electrode surface. The digital simulation of the overall process including the disproportionation (Fig. 1b) excellently agrees with the experimental data. In principle, the experimental data at $-50\,^\circ C$ can also be simulated in terms of an E_iE_r mechanism[8] (i = irreversible, r = reversible) instead of the proposed ECE sequence. In this case, however, E^0_{A1} would have to be less than E^0_{B2}, and the transition $B^{\oplus\ominus}\rightarrow B$ at E^0_{B1} would be nonexistent. Measurements at $T>60\,^\circ C$ in benzonitrile, however, point to conformational transformations prior to charge transfer which, already in the neutral species, lead, even if only to a small extent, to the ee form and the ea forms ($k_1\gg 0$). In this case $\mathbf{3}^{\oplus\ominus}_{ee}$ is formed at the standard potential E^0_{B1}. The E_iE_r route can therefore be ruled out.

In a multisweep experiment in the range between $+0.6$ V and $+1.5$ V, an isopotential point (IPP) is observed at $+0.94$ V. The wave for the reversible redox pair $B^{\oplus\ominus}/B^{2\oplus}$ at $E^0_{B2}=0.840$ V continues growing at the same time as the wave for the formation of $A^{\oplus\ominus}$ at $E^0_{A1}=1.080$ V decreases. Isopotential points always occur when one electroactive species completely transforms into another electroactive species, i.e. in the present case axial $A^{\oplus\ominus}$ into equatorial $B^{\oplus\ominus}$.[11]

A reaction scheme very similar to that in the case of **3** is found for **4** at $-70\,^\circ C$ (Fig. 2). Due to less steric hindrance by the two methyl groups, E^0_{A1} remains less then E^0_{B2}, so there is no crossing effect. If the temperature is increased (Fig. 2), an anodic wave appears between $+0.3$ V and

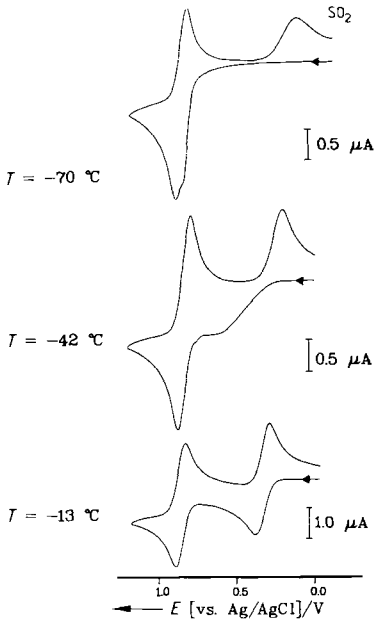

Fig. 2. Experimental cyclovoltammogram of the oxidation of **4** ($c=1\times 10^{-3}$ M, $v=100$ mV/s) in SO_2 at various temperatures (working electrode Pt; 0.1 M Bu_4NPF_6).

$+0.7$ V, and, at $-13\,^\circ C$, the normal form of a reversible peak-separated two-step oxidation is observed. **4** is transformed analogously to **3** from the aa or ea conformation into the ee conformation (CEE), but, because of the lower activation barrier at lower temperatures, before the electron transfer. Since there are eight conformations, the complete kinetic scheme is quite complex. NMR spectroscopic measurements over a very wide temperature range gave no indication of any change in conformation. It follows, therefore, that the thermodynamic equilibrium, consistent with the electrochemical findings, is on the side of the aa conformation. During the cyclovoltammetric experiment the ee conformer B is continually withdrawn from the equilibrium. Thus, this method allows an unequivocal detection of such thermodynamically less favored conform-

ers, provided that the rates of formation of B ($k_1 \gg 0$) are sufficiently high.

1,2,4,5-Tetrakis(dimethylamino)benzene, a New Electron Donor with Unusual Properties**

By *Karin Elbl, Claus Krieger,* and *Heinz A. Staab**

Because of its distinct donor strength, 1,4-bis(dimethylamino)benzene **1** is one of the best investigated electron donors in organic chemistry. Its oxidation to "Wurster's Blue" salts has been known for more than 100 years.[2] 1,2-Bis(dimethylamino)benzene **2**, too, was described in the last century.[3] Therefore, it is all the more surprising that 1,2,4,5-tetrakis(dimethylamino)benzene **3**, which combines the structural elements of **1** and **2**, had not been synthesized so far, even though 1,2,4,5-tetraaminobenzene—also known for 100 years—is a readily accessible compound.[4] We were interested in **3** on account of its expected donor properties and, besides that, in connection with investigations of compounds with dimethylamino groups in close spatial proximity ("proton sponges").[5]

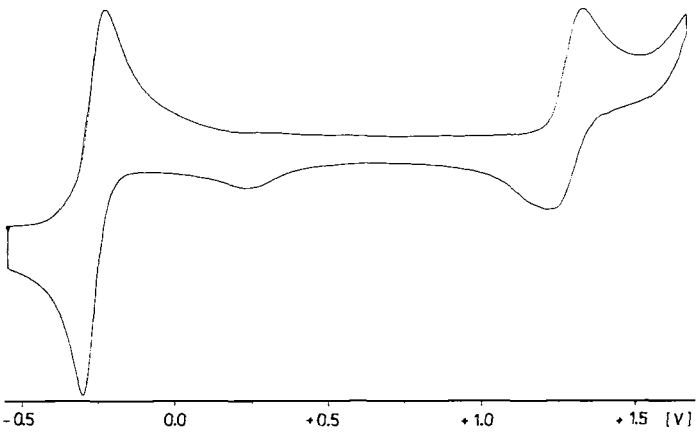
[**] Electron Donor-Acceptor Compounds, Part 42—Part 41: [1].

Conventional methods[6] did not allow the permethylation of 1,2,4,5-tetraaminobenzene, which was achieved, however, by treatment of the tetrahydrochloride in acetonitrile with 36.5% aqueous formaldehyde solution in the presence of $Na[B(CN)H_3]$ under argon according to the method of *Borch* and *Hassid*.[7] Sublimation afforded analytically pure **3** in the form of colorless crystals (m.p. = 95 °C, 27% yield). In solution, compound **3** is oxidized readily by agents such as oxygen, bromine, or iodine, yielding green oxidation products.

The ^{1}H-NMR spectrum of **3** ($CDCl_3$, 360 MHz) shows, as expected, only two singlets at $\delta = 2.76$ (24 H) and 6.56 (2 H). The mass spectrum [*m/z* 250 (100%, $M^{\oplus}$), 235 (6), 220 (12), 125 (3, $M^{2\oplus}$)] is in agreement with the structure. IR absorptions [$\tilde{\nu}$ = 2980 (m), 2940 (m), 2820 (m), 2790 (m), 1510 (s) cm^{-1}; KBr] and UV spectra [λ_{max} ($\lg\varepsilon$) = 320 (3.68), 278 (3.85), 242 (4.32) nm; acetonitrile] also support the assigned structure.

Cyclovoltammetry indicates that **3** is a very strong electron donor. Under the conditions given in the caption to Figure 1, the first two oxidation steps are not separable and correspond to $E_{ox} = -0.266$ V. A third electron is removed, likewise reversibly, at $E = +1.266$ V. Under analogous conditions of measurement, the first oxidation potential of **1**, which corresponds to the radical-cation formation of Wurster's Blue, was measured to be $E_{ox} = -0.206$ V and the second oxidation potential was determined to be $E_{ox} = +0.378$ V.



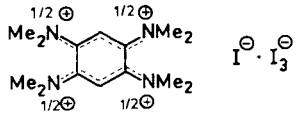


Fig. 1. Cyclovoltammogram of **3** [acetonitrile/0.1 M tetrabutylammonium perchlorate, "glassy carbon electrode" versus $Ag/Ag^{\oplus}$; ferrocene correction, $v = 220$ mV s^{-1}].

When **3** is treated with iodine in acetonitrile, lustrous black-violet crystals separate out of the dark green solution and can be recrystallized from acetonitrile: m.p. = 272 °C (development of iodine above 195 °C), elemental composition $C_{14}H_{26}N_4I_4$. This compound, in contrast to Wurster's Blue salts derived from **1**, is diamagnetic (ESR, acetonitrile). In the ^{1}H-NMR spectrum ([D_6]DMSO, 360 MHz), two singlets are observed, which with $\delta = 3.34$ (24 H) and 5.85 (2 H) show remarkable shifts compared to **3** ($\delta = 2.76$ and 6.56, respectively). The absorption spectrum in acetonitrile shows a long-wavelength absorption band at 573 nm ($\lg\varepsilon = 3.38$) along with additional bands at 368 and 290 nm ($\lg\varepsilon = 4.46$ and 4.74, respectively). All data are in accord with the structure of **4**, consisting of a dication of **3** with two mesomeric π-electron systems, which correspond to vinylogous amidinium units.[8]

4

An X-ray structure analysis confirmed that the product of the reaction of **3** with iodine is indeed **4**, in which the dication of **3** is present as the iodide-triiodide.[9] A remarkable feature of the bond lengths in the six-membered ring (Fig. 2a) is the fact that C(1)–C(1i) and C(1j)–C(1k) have nearly the lengths of single bonds. The remaining four C–C bond lengths are intermediate between standard single and double bond lengths.

In agreement with mesomeric systems of the polymethine type is the marked shortening of the C–N bonds compared with C–N single bonds. The side view (Fig. 2b) reveals that the two resonance-stabilized π-electron systems, each of which is roughly planar, are strongly tilted against each other so that the six-membered ring has a twist conformation. This conformation, which is made possible by the cancellation of the aromaticity of the six-membered ring, results in a largely strain-free structure.

In the crystal lattice of **4**, the organic dications are coordinated with iodide and triiodide as counterions. The lattice packing in the projection onto the *a*, *b* plane is shown in Figure 3. The iodide ions are hidden in the figure by the triiodide units lying in front of them on the *c* axis.

First results concerning the donor properties of **3** show that, because of the unique electronic structure of the dication, it is a strong *two*-electron donor, whose complexation with acceptors is of interest on account of a complex stoichiometry differing from that of **1** and other conventional donors. Thus, **3** forms a 1:2 complex (shining violet needles, m.p. = 213 °C, dec.) with tetracyanoquinodimethane

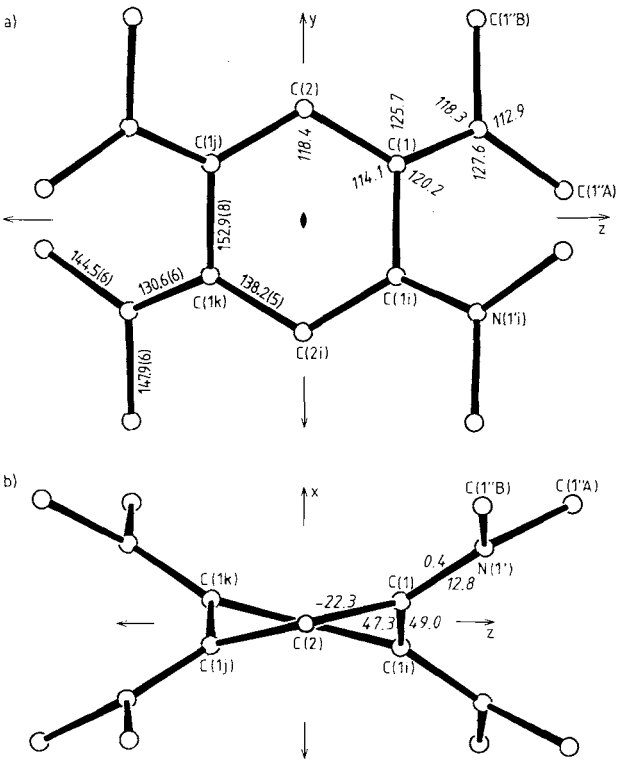

Fig. 2. Structure of the dication part of **4**; a) view from above; b) side view, with bond lengths [pm] and bond and twist angles (in italics) [°]. In parentheses: standard deviation in units of the last digit given.

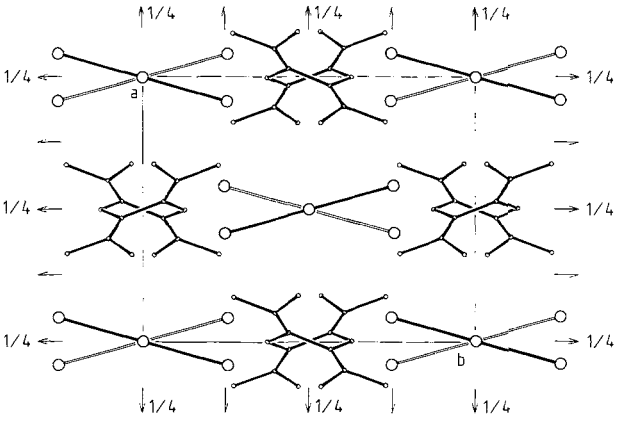
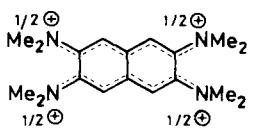
(TCNQ) in acetonitrile. Conductivity measurements (single crystals, four-contact method) gave $\sigma \sim 10^{-1}$ $(\Omega\ \mathrm{cm})^{-1}$





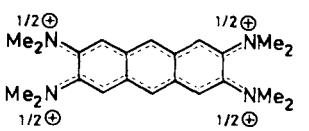


Fig. 3. Lattice packing of **4** in the projection onto the *a*,*b* plane.

for this complex; the temperature dependence of the conductivity showed that the behavior was that of a typical semiconductor.[10]

The dication **4**, derived from **3**, may be regarded as the first member of a series of vinylogous dications, to which **5** and **6** belong. The possibility of obtaining **5** and **6** from the corresponding, still unknown tetrakis(dimethylamino) derivatives of naphthalene and anthracene is currently the subject of investigation.

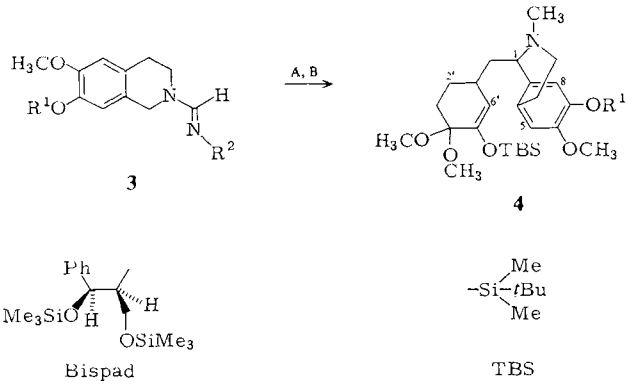
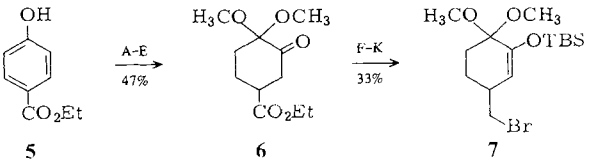
Total Synthesis of *rac*-Salutaridine and Sinoacutine ((−)-Salutaridine)— A New Route to the Morphine Skeleton**



By *Wolfgang Ludwig* and *Hans J. Schäfer**

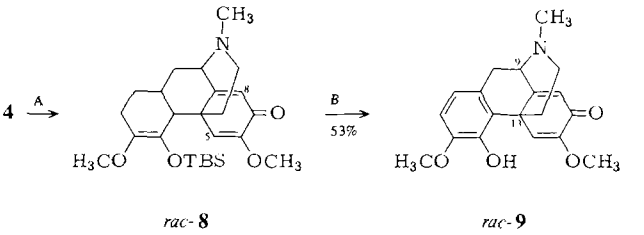
Despite its addicting side effects, morphine is of considerable importance as an analgesic.[1] It is isolated from *Papaver somniferum*; in addition, there exist several efficient total syntheses for the morphine skeleton involving various strategies.[2–6] Of these, the anodic coupling of the 1-benzyltetrahydroisoquinoline **1** is particularly attractive.[4] For steric and electronic reasons, however, morphinandienones of the flavinantine-type **2** are obtained, which, owing to the absence of the 4-hydroxy group, cannot be converted into morphine derivatives. Attempts to achieve the C6′-C4a coupling of **1** by blocking the C2′ position with halogen,[4a] nitro,[7] or *N*-acetylamino substituents,[7] however, have failed[8] (Scheme 1).

Scheme 1. A) 0.1 M $LiClO_4$, $CH_3CN/H_2O/NaHCO_3$ (99.5 : 0.5 : 2), electrolysis at Pt electrodes.



Prompted by work of *Evans* et al.,[9] we have now achieved the C6′ coupling by acid-catalyzed cyclization of **4**. Only C6′ is reactive in **4**, because the 1-benzyl moiety has been replaced by a tetrahydrobenzyl moiety.

a, R^1 = Me, R^2 = *t*Bu; **b**, R^1 = $PhCH_2$, R^2 = *t*Bu; **c**, R^1 = Me, R^2 = Bispad



Scheme 2. A) 1. $LiNiPr_2$, −78 °C; 2. **7**, −78 °C; B) $NaBH_4$, MeOH. Yields: **4a**, 49% from **3a**, 44% from **3c**; **4b**, 53% from **3b**.

Compound **4** may be prepared in a convergent synthesis starting from **7** and C1-lithiated **3** (Scheme 2). The bromide **7** is obtained in 15% yield in 11 steps from ethyl *p*-hydroxybenzoate **5** via the ketoester **6** (Scheme 3). The formamidines **3a** and **3b** may be prepared in 61% and 27% yield, respectively, from β-(3,4-dimethoxyphenyl)ethylamine and vanillin, respectively (for **3c** see below).

Scheme 3. A) H_2, Raney Ni, 110 bar, EtOH, 160 °C; B) $Na_2Cr_2O_7$, H_2SO_4, ether/H_2O; C) $HC(OMe)_3$, MeOH, cat. TosOH; D) *m*-chloroperbenzoic acid, MeOH, 8–10 °C; E) $CrO_3 \cdot 2C_5H_5N$, CH_2Cl_2, 20 °C; F) $Me_3SiCH_2CO_2Et$, cat. $Bu_4N^{\oplus}F^{\ominus}$, tetrahydrofuran (THF), 20 °C; G) $LiAlH_4$, ether, 15 °C; H) hexamethyldisilazane, Me_3SiCl, *n*-hexane; I) 1. $LiNiPr_2$, *t*BuMe$_2$SiCl, THF, −78 °C; 2. H_2O, 0 °C; J) MesCl, Et_3N, ether; K) LiBr, acetone.

The cyclization of **4** to **8** was achieved by variation of the reaction parameters: Lewis acid ($SnCl_4$, $BF_3 \cdot Et_2O$, $AlCl_3$, $(CF_3CO)_2O/CF_3CO_2H$), equivalents of acid, temperature, reaction time, and leaving group R^1. The best combination is 1.5 equivalents of $SnCl_4$ at 20 °C, R^1 = $PhCH_2$ (= **4b**, yield 46% **8**) (Scheme 4); with R^1 = CH_3 (= **4a**), under otherwise identical conditions, only 27% of **8** is obtained. Compound **8** may be dehydrogenated in 53% yield to *rac*-salutaridine **9**, the spectroscopic data of which agree with those reported.[10]

rac-**8** *rac*-**9**

Scheme 4. A) $SnCl_4$, CH_2Cl_2, 20 °C; B) 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in refluxing benzene.

Thus, *rac*-salutaridine **9** is available in an overall yield of 3% via a 15-step total synthesis; **9** may be converted via codeine[11a] into morphine.[11b]

The route described above also allows the enantioselective synthesis of sinoacutine ((−)-salutaridine).[12] According to the method of *Meyers* et al.,[13] it is possible to alkylate lithiated formamidines **3** with chiral auxiliary groups on the imine nitrogen to give (1*S*)-1-alkyltetrahydroisoquinolines with high enantioselectivity. We used this reaction for the formation of the (9*S*) and (13*R*) configuration in (−)-salutaridine. Reaction of 6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline with *N′*-bispad-*N*,*N*-dimethylformamidine gave **3c** (78%), which, like **3a**, was allowed to react with **7** to give, via **4c**, (−)-**9** in 6% yield (85.2% *ee*, see Table 1). Physical data for selected compounds are collected in Table 1.

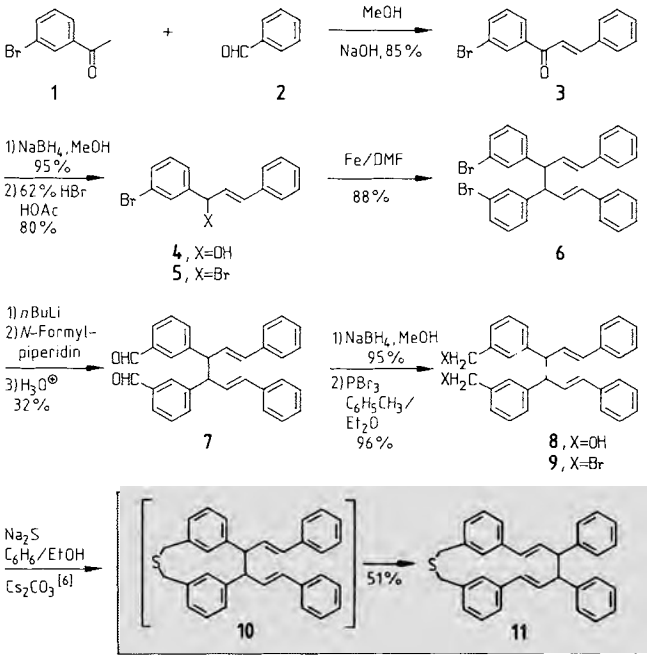
Cope Rearrangement Induced by Medium-sized Ring Strain**



By *Norbert Eisen* and *Fritz Vögtle**

In the case of small-ring compounds, Cope rearrangements can be facilitated considerably by Baeyer ring strain.[1] We recently reported on degenerated rearrangements of Cope systems which are bridged on both sides by long chains.[2] Attempts to achieve strained hydrocarbons in this way met with difficulties. By bridging only one side of the biallyl system we have now succeeded in carrying out a shorter bracketing and thus, for the first time, also a Cope rearrangement in which the educt I is completely converted—with ring expansion—into the product II by virtue of the ring strain of a medium sized ring (Scheme 1).

Scheme 1. B = bridge.

Starting from the simple chalcone **3**, readily obtainable from the ketone **1** and benzaldehyde **2**, the open-chain, substituted tetraphenyl Cope system **9** was obtained via the intermediates **4**–**8**[3] (data for the substances, see Table 1). Tetraaryl-substituted biallyl compounds of this type first start to rearrange sigmatropically at temperatures higher than are necessary for the synthesis (< 85°C),[4] i.e. it can be assumed that **9** and not the Cope rearrangement

[*] Prof. Dr. F. Vögtle, Dipl.-Chem. N. Eisen

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. *G. Eckhardt* and Mr. *C. Schmidt* for help with the spectroscopic studies.

product **14** is formed under the conditions chosen for the preparation of **9**. A comparison of the ^{1}H-NMR spectra (benzyl and vinyl protons) of **9** and otherwise substituted compounds prepared earlier[4a] show that **9** is formed as a mixture of the *meso*- and *d,l*-conformational isomers (ca. 1 : 1) (Table 1).

Cyclization of *meso-/d,l*-**9** with sodium sulfide in presence of cesium (Cs_2CO_3, in ethanol, benzene)[5] led to formation of the eleven-membered monosulfide **10**, which, however, could not be isolated; it isomerizes during work-up to give the 15-membered isomer **11**. This can be explained in terms of a ring strain-induced Cope rearrangement under the cyclization conditions (ca. 80 °C, 8 h).[6]

Desulfurization of **11** was achieved photochemically in triethyl phosphite as solvent (and thiophile),[7] albeit at higher temperatures than usual (60–80 °C). This afforded the 14-membered cyclic hydrocarbon **12**.

The constitution of **11** and **12** follow from the COSY-^{1}H-NMR spectra (Table 1). In the case of the sulfide **11** the H_i hydrogen atoms are not shifted upfield, whereas in the case of the [6.2]metacyclophane **12** they are found at somewhat higher field strength ($\delta = 5.7$). Signals are expected to be found at even higher field strength ($\delta = 4.6$) for the H_i atoms in the case of the constitutionally isomeric [2.2]metacyclophane **13**; in the case of the sulfide **10**, the signals for the H_i atoms should appear at $\delta \approx 5.3$, as indicated by a comparison with other cyclophane sulfides including the sulfide **15**.[8] These findings also suggest that a Cope rearrangement already takes place below 100 °C in the case of the sulfide **10**, and that **12** is formed by photochemical desulfurization of **11**.[9] Apparently, the comparatively low ring strain of an eleven-membered [3.2]metacyclophane already suffices in order to shift the equilibrium of the Cope rearrangement in favor of the larger, less strained 15-membered ring.

The configuration (*meso, d,l*) of the products of the Cope rearrangement cannot be derived with certainty from the ^{1}H-NMR spectra, since comparisons with known open-chain biallyl systems are difficult owing to the extremely different conformational possibilities. Molecular model considerations suggest that both diastereomers (*meso* and *d,l*) are possible with the size of the ring in **11**.

Thus, for the first time, it has been confirmed experimentally that a Cope rearrangement to the less strained product can be effected under mild conditions, not only by the ring strain of three- and four-membered rings ("small ring strain"), but also of medium sized rings. It now remains to explore the synthetic potential of this ring-expansion reaction (by four ring members). The possibility of 'fixing' conformations in the ground and transition state thus opens up new mechanistic aspects for sigmatropic reactions.

Table 1. Analytical data for the new compounds, all of which gave correct high-resolution mass spectra and C,H analyses.

Cpd.	M.p. [°C]	^{1}H-NMR (90 MHz, $CDCl_3$/TMS) [δ values]

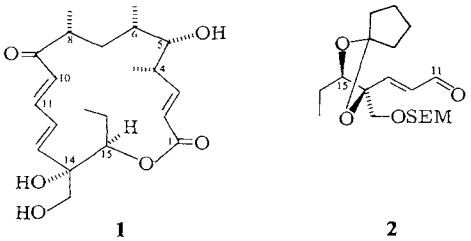
[3] On the basis of earlier studies and the conditions used we can rule out allylic rearrangements of these compounds: D. Brombach, *Dissertation*, Universität Würzburg 1977; cf. [4c].

[4] a) F. Vögtle, E. Goldschmidt, *Chem. Ber. 109* (1976) 1; b) the activation parameters of tetraarylbiallyl compounds are: E_A = 127 kJ/mol, $\Delta G^{\neq}$ = 127 kJ/mol, $\Delta H^{\neq}$ = 124 kJ/mol, $\Delta S^{\neq}$ = −8.5 J/K mol. See c) D. Brombach, F. Vögtle, *Synthesis 1977*, 800.

[5] W. Kissener, F. Vögtle, *Angew. Chem. 97* (1985) 782; *Angew. Chem. Int. Ed. Engl. 24* (1985) 794.

[6] These conditions hold for the overall dilution principle reaction (**9** → **11**). Solutions of the bis(bromomethyl) compound **9** (2.00 mol) in benzene (250 mL) and $Na_2S \cdot 9\,H_2O$ in ethanol (250 mL) were added dropwise concurrently from separate dropping funnels within 8 h into 1.2 L of boiling benzene/ethanol (2.5 : 1) containing 1.00 mmol of Cs_2CO_3. The educt **9** reacts, according to our previous experience with similar reactions, within a few minutes to give the cyclic sulfide. Neither time nor temperature suffice for a Cope rearrangement of the open-chain educt **9** [4b]. The [3.2]phane **10** formed initially, however, has adequate time to undergo Cope rearrangement under the reaction conditions.

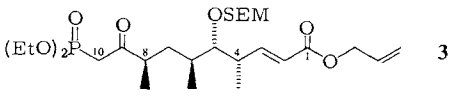
[7] K.-H. Duchêne, F. Vögtle, *Angew. Chem. 97* (1985) 867; *Angew. Chem. Int. Ed. Engl. 24* (1985) 885, and references cited therein.



[8] The bis-sulfide **15** was obtained by reaction of the corresponding tetrakis(bromomethyl) compound with $Na_2S \cdot 9\,H_2O/CsCO_3$ in benzene/ethanol (2 : 1) in a dilution principle reaction, cf [2]. Yield: 36%, for data see Table 1.

[9] In the meantime, **12** has been obtained in 5% yield by direct phenyllithium cyclization from the bis(bromomethyl) compound **9** at 80 °C. This structural change **13** → **12** is explained by an intermediate Cope rearrangement.

Total Synthesis of Mycinolide V, the Aglycone of a Macrolide Antibiotic of the Mycinamycin Series**



By *Klaus Ditrich, Tomas Bube, Rainer Stürmer,* and *Reinhard W. Hoffmann**

Of the mycinolides, a class of 16-membered macrolides,[1] only the simplest representative, the protomycinolide, has been synthesized so far.[2] Mycinolide V (**1**) is of interest insofar as it has a reversed configuration at the quaternary center C-14, compared to the majority of normal macrolide antibiotics. In the mycinolides the stereogenic centers are located in two separate regions of the molecule. Our synthesis of mycinolide V (**1**) takes this into account in that it involves coupling of the separately prepared enantiomerically-pure C-11–C-17 and C-1–C-10 building blocks **2** and **3**.

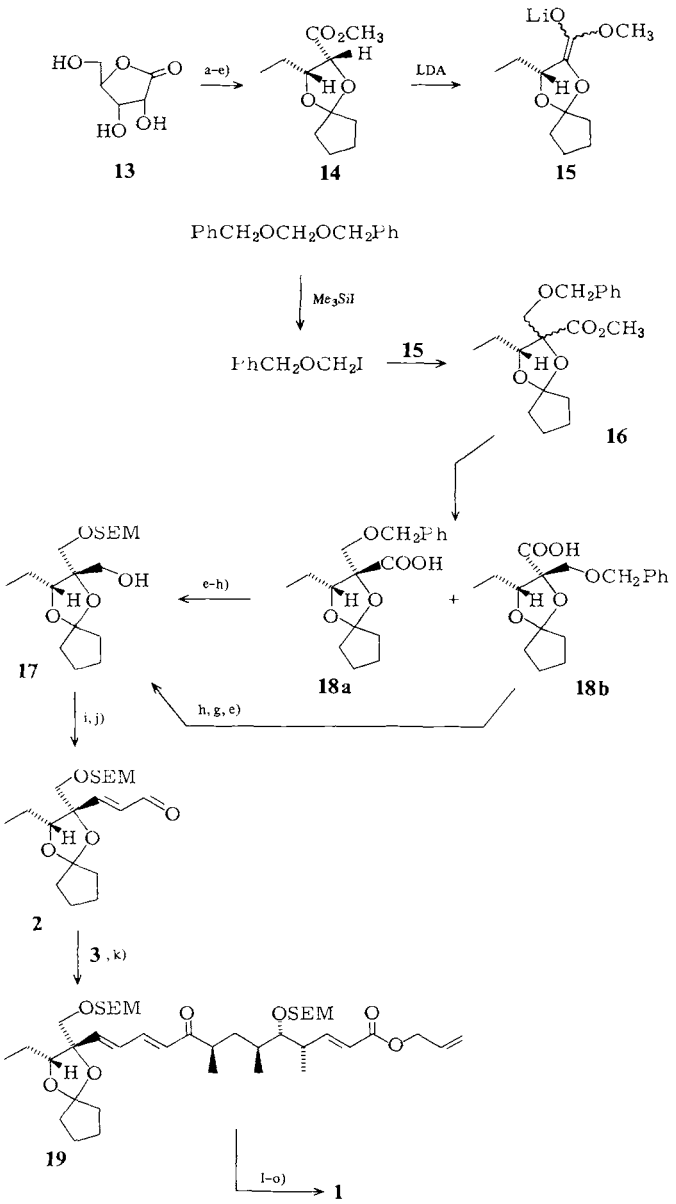
Table 1. Spectroscopic data of **1** and **2**.

1: ^{1}H-NMR ([D$_6$]acetone/D$_2$O, 400 MHz): δ = 0.80 (t, J = 7.4 Hz, 3H), 0.99 (d, J = 6.8 Hz, 3H), 1.01 (d, J = 6.7 Hz, 3H), 1.01–1.1 (m, 1H), 1.11 (d, J = 6.9 Hz, 3H), 1.37–1.46 (m, 1H), 1.54–1.63 (m, 1H), 1.68–1.78 (m, 2H), 2.40–2.46 (m, 1H), 2.48–2.56 (m, 1H), 3.19 (d, J = 9.6 Hz, 3H), 3.51 and 3.62 (AB system, J = 11.0 Hz, 2H), 4.92 (dd, J = 7.6 and 6.9 Hz, 1H), 5.88 (d, J = 15.5 Hz, 1H), 6.22 (d, J = 15.4 Hz, 1H), 6.47 (d, J = 15.1 Hz, 1H), 6.51 (dd, J = 15.5 and 10.2 Hz, 1H), 6.51 (dd, J = 15.4 and 11.1 Hz, 1H), 7.04 (dd, J = 15.1 and 11.1 Hz, 1H).—^{13}C-NMR ([D$_6$]acetone/D$_2$O, 100 MHz, internal standard: C$_3$D signal of the solvent at δ = 29.80): δ = 10.7, 17.6, 17.6, 19.6, 21.1, 32.1, 34.8, 41.0, 45.5, 65.6, 76.9, 78.4, 79.8, 121.8, 124.7, 130.8, 142.4, 144.8, 152.8, 167.3, 205.5

2: ^{1}H-NMR (CDCl$_3$, 400 MHz): δ = −0.01 (s, 9H), 0.90–0.94 (m, 2H), 1.03 (t, J = 7.4 Hz, 3H), 1.61–1.78 (m, 8H), 1.86–1.92 (m, 2H), 3.49 and 3.67 (AB system, J_{AB} = 9.8 Hz, 2H), 3.56–3.64 (m, 3H), 4.64 and 4.67 (AB system, J_{AB} = 6.8 Hz, 2H), 6.47 (dd, J = 15.6 and 7.0 Hz, 1H), 6.91 (d, J = 15.6 Hz, 1H), 9.59 (d, J = 7.0 Hz, 1H).—^{13}C-NMR (CDCl$_3$, 25 MHz): δ = −1.6, 11.3, 17.9, 21.4, 22.9, 23.7, 37.3, 37.4, 65.3, 68.6, 82.4, 84.3, 95.1, 118.3, 131.7, 155.4, 193.0

The synthesis of **3** (Scheme 1) concerns the construction of stereogenic centers in the region of C-4 and C-8. The partial structure of this segment of the molecule corresponds in its relative and absolute configuration to that of the Prelog-Djerassi lactone **7**. Numerous stereoselective syntheses have been described in recent years for this key building block in macrolide synthesis[3] which has set a standard for the degree of stereoselectivity that can be achieved. The present synthesis of mycinolide V (**1**) gave us the opportunity to establish the degree of stereoselectivity that can be achieved in the addition of chiral, α-substituted (*Z*)-crotylboronates to aldehydes. The boronate **5** required for this purpose was synthesized from **4** in a one-pot process using the method described by *Matteson* et al.[4] As chiral auxiliary we used 1,2-dicyclohexyl-1,2-ethanediol, which was obtained by hydrogenation (6–7 bar H_2, 5% Rh/Al_2O_3, CH_3OH, 60 °C) of enantiomerically pure hydrobenzoin.[5]

Scheme 1. a) 1 equiv. KOH, CH_3OH/H_2O, 12 h, 20 °C; b) 3 equiv. SEMCl, 4 equiv. ethyldiisopropylamine, CH_2Cl_2, 3 d, 20 °C; c) 25% aq. KOH, 6 h reflux; d) 1.2 equiv. $(CH_3)_2C{=}CCl[N(CH_3)_2]$, CH_2Cl_2, 3 h, 0 °C; e) 1.2 equiv. $(EtO)_2P(O)CH_2Li$, 1.2 equiv. CuI, tetrahydrofuran (THF), 12 h, 0→20 °C; f) 1. O_3, CH_2Cl_2, −78 °C; 2. Zn, AcOH, CH_2Cl_2, 2 h, 20 °C; g) 9 equiv. $(H_3CO)_2P(O)CH_2COOCH_2CH{=}CH_2$, 6 equiv. $KOC(CH_3)_3$, THF; reagent prepared at 0–20 °C (1 h), reaction at −78→20 °C, 12 h.



The diastereomeric purity of **5** could not be determined directly (^{13}C-NMR), but it was estimable from the extent of chirality transfer upon addition of **5** to benzaldehyde. This resulted in formation of the homoallyl alcohol **10** (68%) with an enantiomeric purity of 99.0% *ee*[6] (determined gas-chromatographically after derivatization with isopropyl isocyanate on a XE-60/*S*-valine/*S*-α-phenylethylamide column[7]). The absolute configuration of **5**—and thus indirectly that of **10**—followed from the reaction of the boronate **5** with the aldehyde **6**[8] (7 d, 20 °C). The hydroxy ester obtained thereby [in 85% yield and with a diastereoselectivity of >95% (^{1}H-NMR)] was converted into the lactone **8**, which was shown to have the same configuration as the Prelog-Djerassi lactone **7**. Assuming a cyclic transition state for the allylboronate-addition to aldehydes one can infer that the configuration of the new stereocenter in **5** is as shown, consistent with the results of *Matteson* et al.[4]

Thus, the stereogenic centers at C-4 to C-8 of the mycinolide skeleton have been constructed by coupling of the

boronate **5** with the aldehyde **6** to give the hydroxy ester **9**. In this reaction the use of a *chiral* boronate is decisive[9] for "reagent-control of selectivity".[10] For the subsequent conversion of the lactone **8** into the β-ketophosphonate **12** we followed the route used by *Yamaguchi* et al. in his synthesis of protomycinolide,[2] after the method originally developed by us[11] for this transformation proved unsuitable for production of the β-trimethylsilylethoxymethyl (SEM) derivatives. The carboxylic acid **11**, which was obtained in 78% yield after alkaline opening of the lactone, reaction with three equivalents of SEM-chloride, and alkaline hydrolysis of the SEM ester, was activated with an α-chloroenamine[12] and allowed to react with the cuprate of the methanephosphonate-anion to give the β-ketophosphonate.[13] This was followed by ozonolysis to give the aldehyde **12** (overall yield **8** → **12**: 40%). Finally, the building block **3** (cf. ref. [2]) was obtained in 84% yield by coupling of **12** with allyl phosphonoacetate. An intermolecular Horner-Emmons reaction was thereby realized with an external reagent on a substrate which is capable of undergoing by itself intra- or intermolecular Horner-Emmons reactions.

Scheme 2. a) 1,1-Dimethoxycyclopentane, cyclopentanone, $H^{\oplus}$, 12 h, 20°C; b) tosyl chloride, pyridine; c) 0.95 equiv. CH_3ONa, CH_3OH, cf. [14]; d) 3.2 equiv. Zn, 1.4 equiv. SEMCl, 4.5 equiv. ethyldiisopropylamine, CH_2Cl_2, 12 h 20°C; h) 2.5 equiv. $LiAlH_4$, ether, 0→20°C, 4 h; i) oxalyl chloride, dimethyl sulfoxide (DMSO); j) 1 equiv. $Ph_3P{=}CH{-}CHO$, benzene, 5 d, 20°C; k) 0.95 equiv. $KOC(CH_3)_3$, THF, 1 h, 0→20°C; −78°C, **3**, →0°C, 12 h; l) $Pd(OAc)_2$, Ph_3P, 1.1 equiv. morpholine, THF, 12 h, 20°C; m) HCl, CH_3CN, 4 h, 20°C; n) 1 equiv. 2,4,6-trichlorobenzoyl chloride, 1.1 equiv. Et_3N, THF, then 6 equiv. DMAP, benzene, 80°C [17]; o) 8 equiv. $LiBF_4$, aqueous CH_3CN, 5 h, 72°C. — LDA = lithium diisopropylamide.

Starting material for the preparation of the highly functionalized C-11–C-17 fragment **2** (Scheme 2) was the ester **14**, which was obtained from D-ribonolactone **13** in five steps (37%) analogous to those described earlier by us.[14] For construction of the stereogenic center at C-14, the enolate **15** was alkylated with benzyloxymethyl iodide, prepared in situ. In the alkylation product **16**, obtained with a selectivity[15] of only 3:2, the benzyloxymethyl group has been incorporated *cis* to the ethyl residue on the dioxolane ring, as shown by the ^{13}C-NMR spectrum.[14] After hydrolysis to the carboxylic acid, the main isomer **18a** (41% referred to **14**) could be crystallized as the cyclohexylammonium salt. Concomitantly, the isomer **18b** could be isolated in 12% yield. During the conversion of **18a** into **17** (78%) the benzyl protecting group was replaced by the SEM protecting group. The subsequent elongation of the chain in **17** to give **2** was accomplished in two steps with a yield of 84%.

The coupling of the building block **2** with the C-1–C-10 fragment **3** furnished the complete molecular skeleton **19** of mycinolide V (**1**) in 88% yield. Cleavage of the allyl ester with $Pd(OAc)_2$ (85%)[16] and of the cyclopentylidene residue with HCl (44%) led to the desired dihydroxycarboxylic acid. This was activated with trichlorobenzoyl chloride[17] and macrocyclized with *N,N*-dimethylaminopyridine (DMAP) to the protected mycinolide V (46%). In the last step, the SEM groups were removed with $LiBF_4$[18] (72%). The melting point (267°C) rotation (+36°), solubility, and ^1H-NMR spectrum of the free mycinolide V (**1**) thus obtained were in complete agreement with data given in the literature.[19]

Dinuclear Manganese(II,III,IV) Model Complexes for the Active Center of the Metalloprotein Photosystem II: Synthesis, Magnetism, and Crystal Structure of $[LMn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}L][ClO_4]_3$ (L = *N,N',N''*-Trimethyl-1,4,7-triazacyclononane)

By *Karl Wieghardt,* Ursula Bossek, Jacques Bonvoisin, P. Beauvillain, Jean-Jacques Girerd, Bernhard Nuber, Johannes Weiss,* and *Jürgen Heinze*

Although it has long been known that manganese, as essential trace element in green plants and algae, participates in the active center of the membrane-bound metalloprotein photosystem II in the light-induced oxidation of water to oxygen, little is known about the structure of the active center.[1] It was concluded from EXAFS and ESR investigations that there are two (or four)[2d] manganese atoms per metalloprotein molecule with a Mn-Mn distance of about 2.7 Å, and that only N,O-donor atoms form the first coordination sphere. The oxidation state of these manganese centers is believed to vary between +II and +IV on going through the five Kok states ($S_0 \rightarrow S_4$).[3] The chemistry of dinuclear manganese complexes with manganese(II,III,IV) and O,N-donor ligands has been intensively studied for some time with the object of comparing the structural, magnetic, and spectroscopic properties of model complexes with those of the active center of the metalloprotein.[4] We report here on the synthesis of **1**,[5] a novel dinuclear Mn^{II} complex, and on its oxidation products, the Mn_2^{III} complex **2**,[6] the Mn^{III},Mn^{IV} mixed-valent complex **3**, and a Mn_2^{IV} complex.

In the cation **1**, two Mn^{II}-centers are coupled to each other via one μ-hydroxo and two symmetric μ-acetato bridges. The IR spectrum shows a sharp band at 3620 cm^{-1} ($\tilde{\nu}$(OH) stretching vibration). From the measurements of the molar susceptibility between 98 and 293 K a spin-exchange coupling constant J of -9 cm^{-1} was determined for the two high spin Mn^{II} centers ($H = -2JS_1 \cdot S_2$ with $S_1 = S_2 = 5/2$; $g = 2.0$; TUP = 0). This weak antiferromagnetic coupling resembles that observed for the isostructural iron(II) complex ($J = -14$ cm^{-1}).[7] The cyclovoltammogram of **1** in acetonitrile (0.1 M tetrabutylammonium (TBA) hexafluorophosphate) shows a reversible one-electron transition at 0.61 V versus the normal hydrogen electrode (NHE). The mixed-valent Mn^{II},Mn^{III} complex is formed, which, so far, has remained unisolable.

The Mn^{III},Mn^{III} complex **2** already described elsewhere by us could be converted *electrochemically* by a reversible one-electron oxidation into the mixed valent Mn^{III},Mn^{IV} complex **3** ($E_{1/2} = 0.585$ V (Fc^+/Fc, acetonitrile)). We have now been able to carry out this oxidation *chemically*, and to isolate the complex **3** in crystalline form.[8]

Figure 1 shows the structure of the mixed valent cation of **3**.[9] The complex cation contains no crystallographic symmetry elements. The Mn-O and Mn-N distances at both manganese centers are, within the limits of error, equal—other than in the case of $[(bpy)_4Mn^{III}Mn^{IV}(\mu\text{-}O)_2][ClO_4]_3 \cdot 3H_2O$, in which an Mn^{III}(d^4-high spin) ion and an Mn^{IV}(d^3) ion have significantly different Mn-O and Mn-N distances, i.e. in which localized valences are present.[10] However, owing to disorder of the perchlorate ions, the accuracy of the crystal structure analysis of **3** is not satisfactory enough for an unequivocal observation of delocalization of the valence of the manganese centers.

Figure 2 shows the electronic spectra of **2** and **3** in acetonitrile. Interestingly, in the case of **3** an additional intervalence band (not discernible in Fig. 2) appears at $\lambda = 1400$ ($\varepsilon = 100$ L mol^{-1} cm^{-1}). Measurements of the magnetic susceptibility on crystalline **3** between 5 and 300 K show a ground state $S = 1/2$ (Fig. 3). The data could be adjusted with an isotropic Heisenberg model, $H' = -JS_1 \cdot S_2$ ($S_1 = 4/$

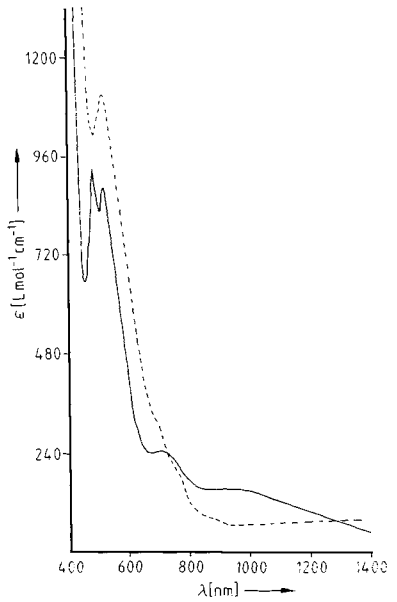

Fig. 2. Electronic spectrum of **2** (——) and **3** (----) in acetonitrile. In the case of **3**, a further broad band was observed at ca. 1400 nm ($\varepsilon = 100$ L mol^{-1} cm^{-1}).

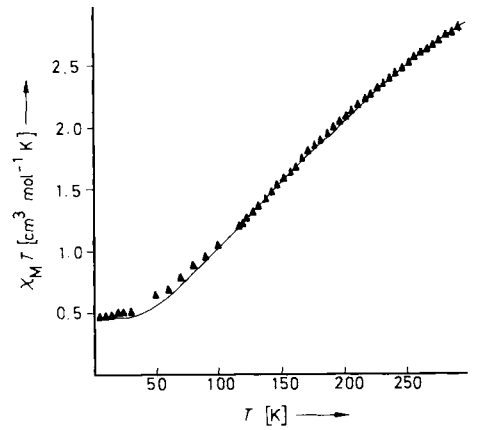

Fig. 3. Temperature dependence of the molar magnetic susceptibility of **3** (SQUID measurement) (▲: experimental data, —: calculated values).

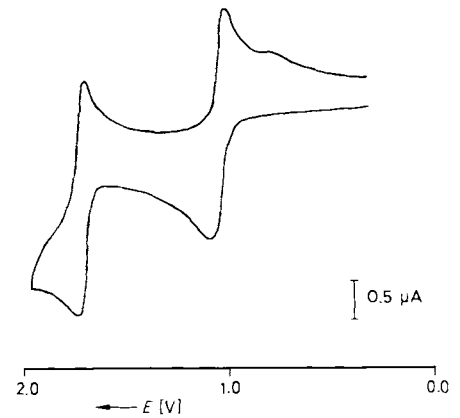

Fig. 4. Cyclovoltammogram of **2** (concentration ca. 10^{-4} mol/l) in liquid SO_2 (−40 °C, 0.1 M TBA-PF_6, $v = 50$ mV/s) vs. Ag/AgCl. Working electrode: Pt-button.

2; $S_2 = 3/2$) and $g = 2.2$ (TUP = 0). The spin-exchange coupling constant J is -80 cm^{-1}; i.e., the Mn^{III} (d^4-high spin) and Mn^{IV} centers in **3** are intramolecularly coupled antiferromagnetically. In **2**, on the other hand, the Mn^{III} centers are coupled ferromagnetically ($J = +18$ cm^{-1}).[6]

Finally, the oxidation of **3** to the Mn_2^{IV} complex was also accomplished electrochemically. Figure 4 shows the cyclovoltammogram of **2** in liquid SO_2 (0.1 M TBA-PF_6) at −40 °C. Two reversible one-electron transitions are observed at 1.25 and 1.92 V (NHE). The first transition corresponds to the reaction $\mathbf{2} \rightleftharpoons \mathbf{3}$, and the second to the oxidation of **3** to $[L_2Mn_2^{IV}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{4\oplus}$. This complex is stable only to a limited extent, even in liquid SO_2. From the two redox potentials, a comproportionation constant K of 7×10^8 can be calculated.

$$\mathbf{2} + [L_2Mn_2^{IV}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{4\oplus} \overset{K}{\rightleftharpoons} \mathbf{3} + \mathbf{3}$$

Thus, in the μ-oxo/(μ-hydroxo)-bis(μ-carboxylato)dimanganese system it is possible to vary the oxidation states of the manganese centers between +II and +IV by reversible one-electron transfers without destroying the coupling of the dinuclear complex.

The $[Mn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{III}]^{2\oplus}$ structural unit most likely occurs in the recently characterized manganese-containing metalloprotein of a pseudocatalase isolated from *Lactobacillus plantarum*; the electronic spectrum of this metalloprotein is remarkably similar to that of **3**.[11]

[8] *Procedure*: **3**: A solution of 1 g of $\mathbf{2} \cdot H_2O$ [6] in 50 mL of 1 M HNO_3 was treated at 25 °C with 2 g of $Na_2S_2O_8$ and 5 g of $NaClO_4$. Small greenish-black crystals of **3** precipitated out; these were recrystallized from acetonitrile (yield ca. 0.8 g). **3** was also obtained from a solution of $\mathbf{2} \cdot H_2O$ in 1 M $HClO_4$ (in presence of atmospheric oxygen) after addition of $NaClO_4$. **1** and **3** gave correct elemental analyses (C, H, N, Mn, ClO_4).

[9] Monoclinic $C2/c$, $a = 34.875(10)$, $b = 10.616(4)$, $c = 21.416(8)$ Å, $\beta = 113.98(3)°$, $Z = 4$, 5454 observed, independent reflections, $R = 0.090$. Complementary Epoxide Hydrolase- vs Glutathione S-Transferase-Catalyzed Kinetic Resolution of Simple Aliphatic Oxiranes—Complete Regio- and Enantioselective Hydrolysis of *cis*-2-Ethyl-3-methyloxirane**

By *Dorothee Wistuba* and *Volker Schurig**

Inspired by the fascinating stereoselectivity observed in the biosynthesis of steroids (e.g. formation of enantiomerically pure lanosterol from achiral all-*trans*-squalene via 2,3-squalene oxide[1]) we have investigated the enantioselectivity of the biotransformation of simple xenobiotic oxiranes with microsomal and cytosolic rat liver enzymes.

In the reaction sequences (a) and (b) enantioselectivity can arise by epoxidation of an alkene possessing enantiotopic faces ("*prochiral* recognition", *product* enantioselectivity[2]) and/or by kinetic resolution of the intermediary oxirane **2** ("*chiral* recognition", *substrate* enantioselectivity[3]). For the formation of highly enantiomerically-enriched products ($ee > 99\%$) at least *one* step, (I), or (II) and (III), respectively, must be highly enantioselective. In the case of incomplete asymmetric induction the product and substrate enantioselectivities can either be mutually increased to high *ee* or compensated to lower *ee*. While the microsomal epoxidation of *cis*-2-pentene in step (I) shows no significant product enantioselectivity,[2] in the epoxide-hydrolase-catalyzed ring-opening (II) of *rac. cis*-2-ethyl-3-methyloxirane to give 2,3-pentanediol we found complete substrate regioselectivity *and* substrate enantioselectivity ($ee > 99\%$) within the precision of the measurement.[4]

Complexation gas chromatography, which enables time-dependent measurements in the nanogram range, was employed for the determination of the enantiomeric excess (*ee*) and the absolute configuration:[5] *cis*-2-ethyl-3-methyloxirane is separated into the antipodes on nickel(II) bis(3-heptafluorobutanoyl-(1*R*)-camphorate)[6a] (Fig. 1a); the (2*R*,3*S*)-enantiomer,[5] which was prepared free of racemization[6b] from *erythro*-(2*S*,3*R*)-2,3-pentanediol,[6c] is eluted as the first peak. The four configurationally isomeric 2,3-pentanediols can be separated on nickel(II) bis(3-heptafluorobutanoyl-(1*R*,2*S*)-4-pinanonate)[6d] (Fig. 1b). Both *threo*-(2*S*,3*S*)-2,3-pentanediol (prepared in nine steps from (2*R*,3*R*)-tartaric acid via (2*S*,3*S*)-isopropylidenethreitol by C_1 chain extension[6c]) as well as *erythro*-(2*S*,3*R*)-2,3-pentanediol (prepared in six steps from (2*S*,3*S*)-allothreonine via (2*S*,3*S*)-dihydroxybutyric acid by C_1 chain extension[6c]) are eluted as second peak of each enantiomeric pair (Fig. 1b). The stereochemistry of the epoxide-hydrolase-catalyzed ring-opening of *cis*-2-ethyl-3-methyloxirane follows from Figures 1a and 1c: only the (2*R*,3*S*)-configurated oxirane[5] is biotransformed, and exclusively *threo*-(2*R*,3*R*)-2,3-pentanediol is formed as metabolite by regioselective ring opening with Walden inversion at C-3.[5]

This result shows that substrate enantioselectivity, which has been demonstrated for sterically hindered bicyclic epoxides such as 3-*tert*-butyl-1,2-epoxycyclohexane,[7a] already occurs in the case of the smallest aliphatic *cis*-oxirane consisting of oppositely configurated carbon atoms. Since practically no product enantioselectivity is observed in step (I),[2] the enantiomer (2*S*,3*R*)-2-ethyl-3-methyloxirane being inactive towards epoxide-hydrolases must be detoxified via another pathway *(vide infra)* in the *in-vivo*-metabolization of *cis*-2-pentene.

In the case of *trans*-2-ethyl-3-methyloxirane, which is formed from *trans*-2-pentene without appreciable product enantioselectivity (I),[2] *no* complete substrate enantioselectivity is observed during the hydrolytic ring-opening (II): although the *trans*-(2*S*,3*S*) enantiomer, which has been chemically correlated with *threo*-(2*S*,3*S*)-pentanediol,[6c] is preferentially metabolized (significantly slower, however, than the *cis*-(2*R*,3*S*) isomer), the *trans*-(2*R*,3*R*) antipode (in contrast to the inactive *cis*-(2*S*,3*R*) isomer) is also a substrate, even if a poor one, for epoxide-hydrolases.[8] *erythro*-(2*R*,3*S*)-2,3-Pentanediol, whose enantiomeric composition is turn-over-dependent ($ee = 58\%$ after 2 h), is preferentially formed as metabolite of *rac. trans*-2-ethyl-3-methyloxirane.

A complementary behavior in regard to substrate diastereoselectivity (*cis-trans* geometry of the oxirane ring) and substrate enantioselectivity with epoxide-hydrolases appears during conjugation of the four configurationally isomeric 2-ethyl-3-methyloxiranes at glutathione (γ-(L)-glutamyl-(L)-cysteinyl-glycine) catalyzed by glutathione S-transferases (III). The rate of the catalytic ring-opening of the oxiranes decreases in the order:

Epoxide-hydrolases:
2*R*,3*S* (*cis*) ≫ [2*S*,3*S* (*trans*) > 2*R*,3*R* (*trans*)] ≫ 2*S*,3*R* (*cis*) (no reaction)

Conjugation at glutathione catalyzed by glutathione S-transferases (Fig. 2a):

2*R*,3*R* (*trans*) ≫ [2*S*,3*R* (*cis*) > 2*R*,3*S* (*cis*)] > 2*S*,3*S* (*trans*) (very slow)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Presented in part at the International Symposium on Activation of Dioxygen Species and Homogeneous Catalytic Oxidations, Galzignano (Padua, Italy), June 25, 1984. Extract from the Dissertation by *D. Wistuba*, Universität Tübingen 1986.

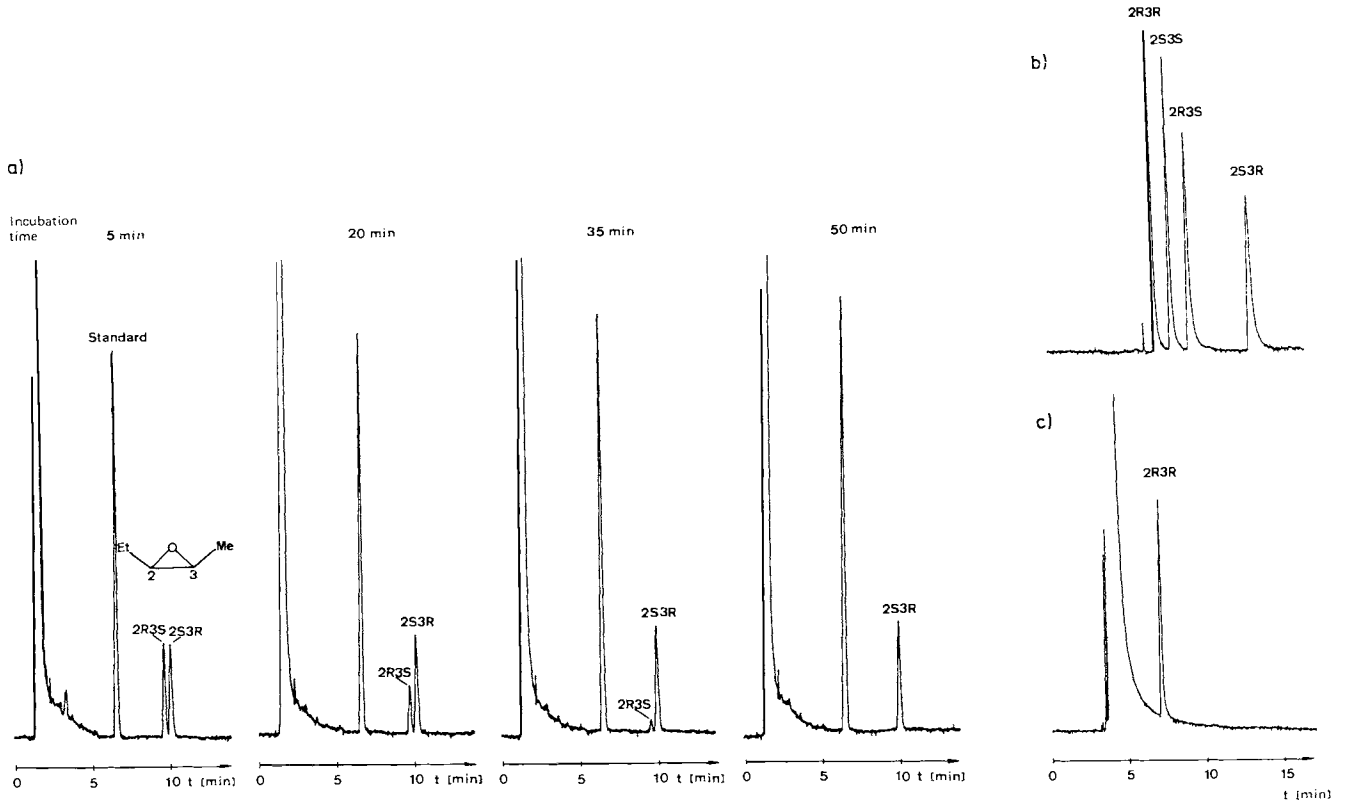

Fig. 1. a) Kinetic analysis of the enantiomeric composition of *rac. cis*-2-ethyl-3-methyloxirane during enzymatic hydrolysis by rat liver microsomes. Standard: 3-methyl-2-butanone (25 m × 0.25 mm glass capillary coated with 0.08 m nickel(II) bis(3-heptafluorobutanoyl-(1*R*)-camphorate) [6a] in OV 101, 80°C, 1.1 bar N_2). Incubation run (0.5 mL total volume): microsomes (1 mg protein/mL), 0.15 M phosphate buffer pH 7.4, *rac. cis*-2-ethyl-3-methyloxirane (4 mM), 37°C. Complexation gas-chromatographic head-space analysis of the oxirane. b) Quantitative complexation gas chromatographic separation of the four configurationally isomeric 2,3-pentanediols as acetonides [6d]. c) *threo*-(2*R*,3*R*)-2,3-pentanediol, formed in the enzymatic hydrolysis of *rac. cis*-2-ethyl-3-methyloxirane (36 m × 0.25 mm glass capillary coated with 0.075 m nickel(II) bis(3-heptafluorobutanoyl-(1*R*,2*S*)-4-pinanonate) in OV 101, 70°C, 1 bar N_2). Incubation run (cf. caption to Fig. 1a) (5 mL total volume): after cessation of reaction (−195°C) extracted six times with diethyl ether (0°C), concentrated, and diol converted into acetonide [6d].

Thus, the metabolites of the enzymatic epoxidation of *cis*/*trans*-2-pentene,[2] i.e. *cis*-(2*S*,3*R*)-2-ethyl-3-methyloxirane, which is completely inactive toward epoxide-hydrolases, is transformed by conjugation at glutathione, and *trans*-(2*S*,3*S*)-2-ethyl-3-methyloxirane, which is essentially inaccessible for conjugation, is a preferred substrate for epoxide-hydrolases.

The complementary chiral-recognition phenomena observed in the case of 2-ethyl-3-methyloxirane also occurs in a series of smaller, sterically less-demanding oxiranes. It follows from Table 1 that the *S*-configurated enantiomers are preferentially metabolized in the biotransformation of aliphatic oxiranes by epoxide-hydrolases while the *R* antipodes are preferentially metabolized by glutathione S-transferase-catalyzed conjugation at glutathione.

In the kinetic resolution of these substrates *in vitro* by glutathione S-transferase-catalyzed conjugation at glutathione we found a considerable substrate enantioselectivity that was dependent upon the degree of substitution and geometry of the oxirane (Fig. 2). Monoalkyl-substituted oxiranes **2** ($R^1=R^2=R^3=H$, $R^4=CH_3$, CH_2Cl, C_2H_5, $CH_2=CH_2$) of configuration *R* (*S* for the potential mutagen (chloromethyl)oxirane ≡ epichlorohydrin, cf. footnote [c] in Table 1) are conjugated significantly more rapidly than the antipodes at glutathione. Whereas (*R*)-ethyloxirane is completely conjugated after 30 minutes incubation time, the remaining (enantiomerically pure) *S* enantiomer was only consumed to the extent of 18%. 50% conversion is already observed after 5 min for the *R*-enantiomer of the cytotoxic 1,3-butadiene metabolite vinyloxirane,[9] and only after 25 min in the case of the *S* antipode (Fig. 2b). Dialkyl-substituted *trans*-oxiranes **2** ($R^2=R^3=H$, $R^1=R^4=CH_3$ and $R^1=CH_3$, $R^4=C_2H_5$) and trimethyloxirane **2** ($R^1=H$, $R^2=R^3=R^4=CH_3$) with *R* configuration are likewise conjugated more rapidly than

Table 1. Complementary *in vitro* substrate enantioselectivity of the biotransformation of racemic aliphatic oxiranes **2** during the hydrolysis to **3** catalyzed by epoxide-hydrolases and by the conjugation at glutathione catalyzed by glutathione S-transferases [a, b].

Oxirane **2**	Hydrolysis to **3** (epoxide-hydrolases)	Conjugation at glutathione (glutathione S-transferases)
Methyloxirane	*S* > *R*	*R* > *S*
(Chloromethyl)oxirane (epichlorohydrin)	*R* > *S* [c]	*S* > *R* [c]
Ethyloxirane	*S* > *R*	*R* ≫ *S*
Vinyloxirane	2*S*,3*S* > 2*R*,3*R*	2*R*,3*R* > 2*S*,3*S*
trans-2,3-Dimethyloxirane	2*S*,3*S* > 2*R*,3*R*	2*R*,3*R* ≫ 2*S*,3*S*
trans-2-Ethyl-3-methyloxirane	2*R*,3*S* ≫ 2*S*,3*R* (inactive)	2*S*,3*R* > 2*R*,3*S*
cis-2-Ethyl-3-methyloxirane	*S* ≫ *R*	*R* > *S*
Trimethyloxirane		

[a] Assignment of the absolute configuration of synthetic oxiranes of known chirality (K. Hintzer, Dissertation, Universität Tübingen 1983. Vinyloxirane: R. J. Crawford, S. B. Lutener, R. D. Cockroft, *Can. J. Chem. 54* (1976) 3364). [b] *S* > *R* means: the *S*-enantiomer reacts more rapidly than the *R*-antipode. [c] The chloro-substitution leads to a formal reversal of the descriptors *R* and *S*.

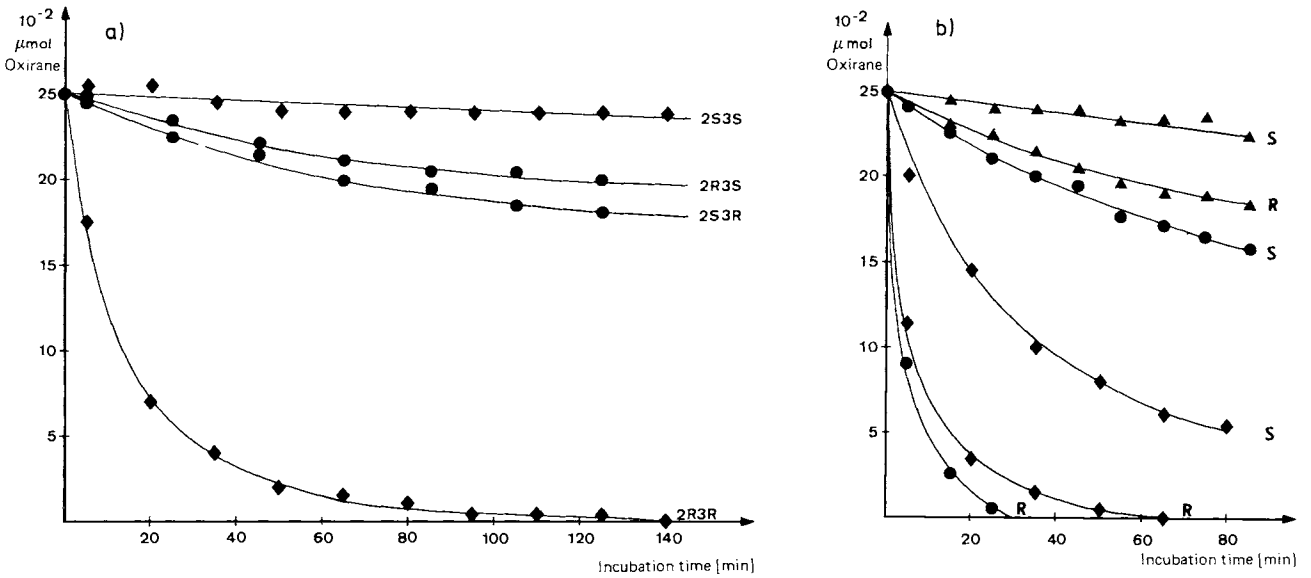

Fig. 2. Kinetic resolution by conjugation at glutathione catalyzed by glutathione S-transferases at 37°C. Incubation run (0.5 mL total volume): glutathione S-transferases (SIGMA, D-8024 Deisenhofen) (0.75 mg protein/mL; origin: rat); glutathione (SIGMA) (4 mM); 0.1 M phosphate buffer pH 6.5; oxirane (1 mM), (chloromethyl)oxirane (4 mM). Glutathione and glutathione S-transferases were pre-incubated in phosphate buffer for 5 min. Oxirane and standard (acetone or 3-methyl-2-butanone) were added as a solution in diethyl ether. The continuous determination of the oxirane enantiomers with respect to the standard was carried out by head-space analysis by means of complexation gas chromatography [2, 6a]. All incubations were repeated at least three times. a) *cis*- (●) and *trans*-2-Ethyl-3-methyloxirane (◆); b) ethyloxirane (●), vinyloxirane (◆) and trimethyloxirane (▲).

the *S* antipodes (50% conversion in 85 min in the case of *trans*-(2*R*,3*R*)-2,3-dimethyloxirane and 10 min in the case of *trans*-(2*R*,3*R*)-2-ethyl-3-methyloxirane, with less than 10% conversion in 20 min for (*R*)-trimethyloxirane and in 80 min for the *S*-antipode).

The occurrence of substrate enantioselectivity, arising from the chirality of the glutathione S-transferases and/or the configuration of the conjugation partner (L,L)-glutathione, has also been reported in the conjugation of phenyloxirane[10] and arene oxides.[11]

The chiral recognition phenomena found here for simple aliphatic oxiranes are of significance in the generalization of model concepts on the active center of the epoxide-hydrolases,[7b] for continuing mechanistic investigations on the conjugation at glutathione, and for the derivation of structure-activity relationships, which go beyond the uniform treatment of the antipodes in case of racemic substrates.[12] In conclusion, we have shown that the enzymatic kinetic resolution proves to be an efficient pathway for access to enantiomerically highly-enriched products of metabolization (*cf.* introductionary remarks).

Surveys of Organometallic Chemistry

Until a few years ago it was not possible to find a comprehensive textbook on organometallic chemistry. This may at first seem surprising, but it is in fact quite understandable in view of the hectic pace of growth and expansions into new topics which has occurred in this field of chemistry during the past four decades. Those who had made significant contributions to the development of organometallic chemistry, and where thus the main potential authors, held back because each new publication on the current state of knowledge was likely to become outdated by the time the printing was finished and the book bound. Over the years, however, the principles have become progressively better defined; compound classes, reactivity patterns, structural characteristics and possible applications have emerged more clearly and are better understood. Thus, several books have just become available whose titles promise a more or less comprehensive treatment of organometallic chemistry:

Fundamental Transition Metal Organometallic Chemistry. By *C. M. Lukehart*. Brooks/Cole Publishing Company, Monterey, CA 1985. xiv, 447 pp., bound, $ 28.00.—ISBN 0-534-03801-8.

Metallo-organic Chemistry. By *A. J. Pearson*. John Wiley, Chichester 1985. xi, 398 pp., paperback, £ 9.95.—ISBN 0-471-90446-5.

Basic Organometallic Chemistry. By *I. Haiduc* and *J. J. Zuckerman*. Walter de Gruyter, Berlin 1985. xxviii, 376 pp., bound, DM 169.00.—ISBN 3-11-007184-3.

I found the book by *Haiduc* and *Zuckerman* the most useful, as it is generally well written from a teaching standpoint, and gives a not unduly detailed survey of the organometallic chemistry of the main and transition group elements. Although the treatment of laboratory techniques is unfortunately not completely up to date, the book makes a good impression in all other respects. It presents in a clear way the most important classes of compounds arranged under groups for the main-group elements, and for the transition metals according to the electron balance in the complexing ligands. For advanced chemistry students the section on "Organometallic compounds of non-transition elements" (pp. 45–222) will be of great benefit, as the information is presented free from inessentials and with the emphasis on basic principles throughout. However, I feel that an accompanying discussion article is needed as much for this topic as for the comprehensive chapters on "Organometallic compounds of transition metals" (pp. 223–376), as the importance of the various classes of compounds for present-day chemistry in universities and industry is seldom treated as thoroughly as it ought to be. This book is especially valuable for teaching purposes since, by means of clear structural diagrams, it enables one to easily grasp the essential facts. The price of the book is reasonable in view of its content.

On comparing the above book with that by *Lukehart*, it is evident at the first glance that this is a distinctly more specialized work. As the title indicates, only the transition metals are covered, though with a corresponding increase in depth and thoroughness since the two books contain similar numbers of pages. In the division of the book into topics *Lukehart* has reached a good compromise between important classes of compounds, principles of reactivity, and—especially valuable for the industrial chemist—the technical applications of modern organometallic chemistry. Classifications according to method of preparation, spectroscopy and structure are, of course, clearly and fully presented, and in many places further developed by comparison tables which contain a lot of information. The author's tendency towards detail sometimes interferes appreciably with the flow of the text, especially when quite unnecessary data are added below the chemical equations (e.g. on pp. 95, 97, 143, 145...). On the other hand *Lukehart* gives with each chapter a selection of literature references for studying the topics more thoroughly. The book is a useful monograph for the research chemist rather than a textbook, as the advanced chemistry student would find the large number of individual compounds and their properties too much to cope with. I would refer them instead to "Collman-Hegedus", which is much easier and comprehensible for students, although at present it is unfortunately out of print.[*] The book by *Lukehart* will be useful to doctoral and post-doctoral students and academic staff engaged in the organometallic field, especially when a quick survey of a specialized topic is wanted. The book is not lying before me on the desk, but I do have it in the bookshelf behind me.

I have not yet made so much of a start with the 400-page work by *A. J. Pearson*. Although the book contains much basic material on mechanisms and compound classes, I find it lacks the overall guiding themes which make a book valuable and worth reading. An incidental comment: the title of the book promises more than is contained in the text, as the main-group metals are not treated. Numerous references to original literature are given, but these have been covered more fully and effectively in other publications. I cannot recommend the purchase of this book to any of the groups of readers mentioned earlier.

Boussingault. Chemist and Agriculturist. By *F. W. J. McCosh*. D. Reidel Publishing Co., Dordrecht 1984. xv, 280 pp., bound, Hfl. 140.00.—ISBN 90-277-1682-X

The French chemist and agronomist *Jean Baptiste Boussingault* (1802–1887) played a decisive role in determining the character of agricultural chemistry in the 19th century. A comprehensive biography in book form on his life and his scientific work has been lacking until now. The book under review fills this gap.

F. W. J. McCosh has compiled a very detailed account of the individual periods of *Boussingault*'s life, drawing upon all available source material. He thereby throws light on the manifold interrelations with political, social, and scientific communities.

[*] J. P. Collman, L. G. Hegedus: *Principles and Applications of Organo-transition Metal Chemistry*, University Science Books (Oxford University Press, Oxford 1982).

The focal point of the biography is *Boussingault*'s work as an agricultural chemist, above all his experimental activity at the Alsatian experimental farm Bechelbronn, where he carried out extensive laboratory and field experiments on mineral fertilization. *McCosh* has rightly given ample space to *Boussingault*'s experiments on the nitrogen requirements of plants. It was indeed *Boussingault* who in 1837 provided experimental evidence for the first time that leguminous plants can obtain the nitrogen that they need for growth from the air, even though this finding was acknowledged only fifty years later by the scientific community as a valid theory. 1986 is the 100th anniversary of *Hermann Hellriegel*'s disclosure of the basis for nitrogen binding in leguminous plants; in remembering this discovery, one must also think of *Boussingault*, the father of the idea of nitrogen fixation. Therefore *McCosh*'s biography appears at an opportune moment: it contains broad background information concerning the prehistory of *Hellriegel*'s discovery.

McCosh also gives proper attention to the significance of *Boussingault*'s major scientific work, his "Economie rurale" (first edition 1843/44) for the development of agricultural science. It thereby becomes clear that in this work, which was translated into several languages, *Boussingault* vigorously advocated the development of agricultural chemistry, soil science, and the science of plant cultivation into autonomous agricultural disciplines.

The reader is given an exhaustive survey of *Boussingault*'s many years of field studies in South America, his experiments on animal nutrition, his research work on photosynthesis, as well as his experiments in the field of metallurgy. This testifies to the versatility of this chemist, who in the brilliant period of French chemical theory did not rank among the theorists; on the contrary, he was at all times an advocate of applied chemistry.

The book's sources are conscientiously documented; numerous illustrations are included, as well as a bibliography of the scientific publications of *Boussingault* arranged by field. Many readers will perhaps generously overlook the infrequent misprints, which are noticeable above all in the German biographical and bibliographical references.

On the whole, this biography is a sound contribution, not only to the history of agricultural chemistry in the 19th century, but also to the general history of chemistry and science. It should not be absent from any private or public, specialized library.

Technology of Chemicals and Materials for Electronics. Edited by *E. R. Howells*. Ellis Horwood Ltd., Chichester 1984. 333 pp., bound, £ 39.50.—ISBN 0-85312-771-9

This book, published under the auspices of the Society of Chemical Industry (SCI), contains the papers presented at a joint symposium held in January 1984 by the SCI and the Institution of Electrical Engineers (IEE). The SCI has already occasionally concerned itself in the past with interdisciplinary areas where chemistry meets physics, biology or engineering. In the field discussed here the collaboration with the IEE has turned out to be particularly fruitful, as the electronics industry's need for chemicals and advanced materials is a topical theme, not only from a technical but also from an economic point of view. In Europe, where this meeting was held, the electronics industry faces a powerful challenge from the USA and the Far East, especially from Japan, but at the same time there is concentrated here a chemical industry which ranks as one of the most potent in world markets. Changes affecting the range of products supplied by the European chemical industry, and competition from oil-producing countries, have increased the importance of new markets such as the electronics industry, even though it appears that the quantities of materials needed annually are somewhat modest; these are mostly high quality specialty products of a sophisticated kind, whose prices are determined in a similar way to those of pharmaceutical products. Because materials for the electronics industry must meet very high specifications, a chemical industry that supplies them needs to have a very good infrastructure, so as to satisfy purity criteria, for example.

Although many aspects of the raw material requirements of the electronics industry have been discussed elsewhere, there has hitherto been no comprehensive treatment of this increasingly important field. The organizers of this symposium have provided here a clear and readable overview of the future materials needs of the modern electronics industry which, while it is by no means exhaustive, is useful and wide-ranging.

The first chapter looks at past trends and prospects for the future, mainly from an economic point of view, but also including readable accounts of some of the technical opportunities. The titles of the topics covered are as follows: Twenty-five years of molecular electronics (*D. H. Roberts*, General Electric); Advances in microelectronics via chemical and photoimaging innovations (*A. B. Cohen*, Du Pont); The anatomy of a discovery—biphenyl liquid crystals (*C. Hilsum*, General Electric); Electronic chemicals: a US view (*D. W. McCall*, AT & T Bell Laboratories); Future prospects of the Japanese electronics industry (*K. Odagawa*, Toshiba); New materials for electronics and electro-optics: some speculations and a peek into the future (*R. E. Schwerzel, R. L. Holman, G. P. Noel, V. E. Wood*, Battelle Memorial Institute); Trends in materials for modern electronic systems (*C. van de Stolpe*, Philips).

The second chapter is concerned with properties of materials, and consists of the following articles: The chemistry of polymer resists useful in microlithography (*A. Ledwith*, Pilkington Bros.); Molecular electronics using Langmuir-Blodgett films (*G. G. Roberts*, University of Durham); The influence of the electronics industry on the development of soft magnetic materials (*R. V. Major*, Telcon Metals); Gallium arsenide integrated circuit technology (*R. C. Eden*, GigaBit Logic); Growth technology of III-IV semiconductors for multilayer devices (*M. Razeghi*, Thomson-CSF); Ingegrated circuit packaging and lithography (*A. N. Broers*, IBM, New York); Materials cross-fertilization (*G. D. Pitt*, Standard Telecommunications Laboratories and University of Surrey); Electrochromic displays (*D. J. Barclay, D. H. Martin*, IBM, UK); The materials needs of optical communications (*M. J. Cardwell, R. C. Goodfellow*, Plessey Research).

An account of a panel discussion and a contribution by the editor give further insights in to the field, and some additional statistical data are included to round off the picture.

The appendix contains a list of the acronyms used, making the "computer Chinese" language a good deal more comprehensible. The list of the participants' addresses is a mine of information for all those who may want to ques-

tion the experts personally, or to send them advertising material.

The book fills a gap in a specialist area of growing importance. It is, moreover, highly recommended as bedtime reading for students seeking jobs, being an educational book on an otherwise neglected interdisciplinary field bordering on chemistry.

Oscillations and Traveling Waves in Chemical Systems. Edited by *J. R. Field* and *M. Burger*. John Wiley, Chichester 1985. xx, 682 pp., £ 98.30.—ISBN 0-471-89384-6

Chemical oscillations in time and space have been investigated extensively, especially in the last twenty years. The fascination with oscillating reactions following the discovery of the famous Belousov-Zhabotinsky reaction is reflected by the exponential growth in publications between 1965 and 1975. The study of chemical oscillators is also of interest from the standpoint of natural philosophy, namely in that the discussion of the significance of symmetry breaking and bifurcation in systems far from chemical equilibrium could affect the definition of time itself. There are still supposed to be skeptics who question the existence of chemical oscillations in a homogeneous system. They are in error! This book, written by several authors with strict organization by the editors, establishes unequivocally that chemical oscillations occur in inorganic reactions in a homogeneous system. This is also true for several biological systems, which are referred to only briefly, but which often motivated the study of the above reactions.

In general, chemical oscillations are possible only in thermodynamically open systems. The requirements for the occurrence of chemical oscillations are now adequately known and have been substantiated in a series of experimental systems. Chemical oscillators are non-linear oscillators. In addition to phenomena such as frequency-doubling, they show period-multiplication when "ideally" mixed. This may occur when the in-flow of reactants into a flow reactor is sinusoidally perturbed. Chaotic trajectories can also be produced; they are mentioned in this book, but are not dealt with further. In thin, liquid layers that are not stirred, spatial oscillations can appear in the form of chemical traveling waves and of standing waves. Here the coupling and interplay of the chemical reaction with diffusion or convection to form a spreading pattern prevail.

In the Introduction, *Zhabotinsky* reports on the interesting early history (1961–1969) and on the first mechanistic proposals for the Belousov-Zhabotinsky oscillations of a sulfuric acid solution of bromate, Ce^{III}/Ce^{IV}, and malonic acid, a reaction that also carries his name. The mathematically interested reader gets his money's worth, not only in the first chapter on the stability of steady states, on Hopf bifurcations, and on bilaterally coupled systems, but also throughout the entire book. The chapter on the inorganic Belousov-Zhabotinsky oscillator follows, in which the variations and subsystems are described in every detail. Except for chaotic movements, the well-known Field-Noyes "Oregonator" mechanism can account for almost all of the phenomena of the Belousov-Zhabotinsky reaction, such as bistability and traveling waves. It is given a comprehensive mathematical analysis in a separate chapter. Periodic gas-evolving and other chemical oscillators such as the Bray-Liebhafsky and the Briggs-Rauscher are discussed. The response of an oscillator to periodic perturbation is extremely varied. Mathematical methods of analysis are presented and also applied to non-isothermal oscillators. In this connection, the stability behavior of the system in the region of kinetic phase change is of great theoretical interest. The pattern formation produced by the crystallization of geological material, the propagation of reaction-diffusion fronts, or two- and three-dimensional periodic waves show a surprising abundance of forms. The chemical oscillations of carbon monoxide are treated in great detail in a further chapter. The last and somewhat curious chapter presents a statistical analysis and a "sociology" of the publications on chemical oscillations in the years from 1910 to 1981.

The references are very extensive and are carefully reported with titles. This book will surely be the standard work on inorganic chemical oscillations in the next years. Its purchase can be highly recommended, even though biological oscillators and chaos are not dealt with.

Über die Erhaltung der Kraft. Facsimile of the holograph text together with a commentated transcription. By *Hermann Helmholtz*. Physik-Verlag, Weinheim 1983. 124/67 pp., bound, DM 80.00.—ISBN 3-87664-071-7

The chemist *Döbereiner* who was appointed to the University of Jena at the instance of *Goethe* published a book in 1819 with the title "Anfangsgründe der Chemie und der Stöchiometrie". In § 5 of the introduction was the sentence "'Thorough study of chemistry begins, after mathematical and scientific preparation, with the study of the basic principles of chemistry in their most up-to-date form and then continues to the history of the same." The last portion of this sentence is applicable to all natural sciences. To know how scientific progress is made is extraordinarily instructive and useful for every representative of a science. Most important is to see on the basis of examples that science usually sprouts from the human endeavors of individual persons. This insight is excellently promoted by the publication of facsimile editions of manuscripts of great scientists. The publication reviewed here can be of great value to numerous scientists and particularly to physicists.

The essay by *Helmholtz* is particularly suited for the start of one's own involvement with the genesis of scientific ideas because the basic publication by *Julius Robert Mayer* the discoverer of the first main proposition appeared in *Liebig*'s "Annalen der Chemie" in 1842 and is relatively easy to include in a comparison. The reader will be able to establish that quite different avenues of thought can be of considerable importance for the achievement of new scientific insight.

As far as the technical representation of the present book is concerned it suffices to say that it consists of two part volumes; the first contains the facsimile of the holographic text and the second contains, after an introduction, the transcription and comments.

Discarding the Double Bond Rule?

A sentence in the table of contents concerning the communication of *H. Hesse* and *U. Klingebiel (Angew. Chem. 98* (1986) 638; *Angew. Chem. Int. Ed. Engl. 25* (1986) 649) prompts me to make several comments. On page A-134 of the July issue there is the following statement:

> Once again we have found bulky substituents that enable the synthesis of a stable compound with a moiety that ... contradicts the double bond rule.[*]

First, I would like to point out that there is not only one "double bond rule," for a large number of authors in this country and elsewhere have considered this aspect of bonding in detail and have arrived at various conclusions. Thus, there are several double bond rules. The question therefore arises whether all such rules should be discarded, or, which rules are meant? Since I have spent considerable time thinking about this problem and, in fact, have published two articles in *Angewandte Chemie* dealing with the problem ("Mehrfachbindungen in der anorganischen Chemie," [Multiple Bonds in Inorganic Chemistry] *Angew. Chem. 69* (1957) 77 and "Force Constants and Bond Orders of Nitrogen Bonds," *Angew. Chem. 78* (1966) 565; *Angew. Chem. Int. Ed. Engl. 5* (1966) 567), I was disturbed by the above statement.

Secondly, my reflections on this matter started with earlier considerations of isosterism. The first prerequisite for a double bond is a deficiency of electrons. It then turned out that the higher the sum of the electronegativities of the two atoms involved in bonding, the higher the probability for formation of a double bond. As an approximate limit, I gave a value of 5.0 for the sum of electronegativities. A sum of 4.8 is obtained for the Si–N pair in question, a value that is not far from this limit. Further, it was found that larger values of the difference in electronegativities oppose the formation of double bonds. Thus, in the second article cited above, I suggested that, for the combinations of Si–N, higher bond orders would be probable.

Furthermore, in discussing multiple bonds, it is important to note that not only are single and double bonds possible, but also bond orders with all possible values between 1.0, 2.0, and 3.0. These bond orders can be derived from bond distances and force constants. None of these values is given in the communication of *Klingebiel* et al., so that it is not clear whether a pure double bond is involved. Because of the large difference in electronegativity, I would like to suggest that the bond order lies below 2.0.

Thirdly, I have to admit that, in formulating my rules, I would never have imagined that the superb experimental talent of chemists would allow them to so suppress the reactivity of double bonds with bulky ligands that they would become stable at conventional temperatures, and even tolerate higher temperatures, without undergoing polymerization. I am referring to "cemented double bonds," the reactivity of which is strongly hindered. The use of bulky ligands, for example, has allowed the synthesis of stable compounds having Si–Si (sum of electronegativities 3.6!) or P–P double bonds (sum 4.2). In a discussion concerning Si–Si double bonds, the author reported that polymerization is observed when even one of the four *tert*-butyl groups is replaced by an isopropyl group. The rules that I formulated can easily accomodate this result. It is only necessary to add that the rules apply only when small ligands are bonded to the atoms in question or when the reactivity is not hindered by bulky substituents.

Moreover, the same issue of *Angewandte Chemie* and *Angewandte Chemie International Edition in English* contains a communication by *Alexander Sax* and *Rudolf Janoschek* (p. 634 and p. 651, respectively) in which the authors report that, in the case of Si_6H_6, not the benzene structure (with "double bonds") but rather the prismane structure with single bonds is preferred, in full agreement with my ideas.

Preorganization—From Solvents to Spherands

By Donald J. Cram*

Dedicated to Professor Vladimir Prelog on the occasion of his 80th birthday

This article assesses the importance of molecular preorganization to the rapidly developing field of complexation involving designed synthetic organic compounds. Since its birth as a science, organic chemistry has drawn heavily on biological chemistry as a vast storehouse of evolutionary structures, reactions, and control mechanisms that serve as inspiration for designed organic-compound mimics. Biological systems, through highly structured complexation, accomplish complicated tasks. The receptor sites of enzymes, the genes, the antibodies, and ionophores possess high degrees of preorganization. In other words, their functional groups act cooperatively as binding or catalytic sites which are largely collected and oriented prior to complexation.—The strength of the organic chemist derives from his ability to design organic compounds, organic reactions, synthetic sequences, and test systems to evaluate hypotheses. The design of highly structured complexes and the discovery of the rules that govern their behavior are described here. Research in this field is particularly rewarding because scientific and aesthetic content merge and become visible in the structures of many of the complexes.

1. Introduction

1.1. Definitions

Complexes are defined as two or more compounds bound to one another in a definable structural relationship by forces such as hydrogen bonding, ion-pairing, metal-ion-to-ligand attractions, π-acid-to-π-base attractions, van der Waals attractions, and the entropic component of desolvation. Complexing partners are conveniently classified as *hosts* and *guests*. In complexes, the binding sites of hosts converge. *Hosts* are the synthetic counterparts of the receptor sites of enzymes, genes, antibodies of the immune system, or ionophores. *Guests* possess divergently arranged binding sites, and are the counterparts of substrates, inhibitors, cofactors, drugs, or antigens.[1]

1.2. Structuring of Complexes

Complexes are structured by contacts at multiple binding sites between host and guest. The binding energy at a single contact site is at most a few kilocalories per mole, much lower than that of a covalent bond. Contacts at several sites between hosts and guests depend on complementary placements of binding sites, making use of the self-evident principle of complementarity: "to complex, hosts must have binding sites which cooperatively contact and attract binding sites of guests without generating strong nonbonded repulsions."[2]

1.3. Design of Complexes

The complexes discussed here were designed through extensive use of Corey-Pauling-Koltun (CPK) molecular models. These models were developed under the auspices of the U. S. National Institutes of Health, Education and Welfare, the National Science Foundation, and the American Society of Biological Chemists "for constructing macromolecules of biological interest." The models are based on crystal structures of biologically important compounds.[3] The crystal structures of over fifty complexes have been determined in our group alone.[4] We estimate that in about 95% of the crystal structures, the complexes turned out generally to have the structures anticipated based on CPK model building. Most of the complementary relationships between hosts and guests of our design could not have been anticipated without use of CPK models.

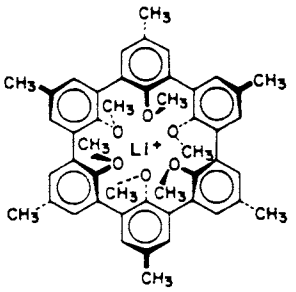
1.4. Solvent Effects

Binding forces between solvent and host, and solvent and guest, are frequently of the same type as those between host and guest. Thus, during complexation, solvent must be displaced from the binding sites needed to complete the complexation process. The solvation free energy is composed of an enthalpic term favoring solvent binding and an entropic term disfavoring solvent binding. Any net free-energy costs for this desolvation must be paid by decreasing the free energy of complexation. In effect, solvent competes with both host and guest for occupancy of the binding sites for each potential complexing partner. Host-guest complexes are formed in solution usually because of the *organization* of the binding sites of the host for complexation, and the lack thereof in the solvent.

1.5. Criteria of Structure

The criteria for host and complex organizations in the solid state are crystal structures. In solution, except for hosts rigidly preorganized for binding, conformational equilibria exist which complicate the structural picture, particularly since the relative populations of various conformations depend on the character of the solvent. Spectral techniques, particularly NMR, provide the most generally useful experimental criteria for solution structure. Correlations of binding free energies with structures of complexes, coupled with spectral data and expectations based on either CPK model building or molecular mechanical calculations,[5] are useful in assigning solution structures. Reasoning by analogy from crystal to solution structure is probably most sound when binding free energies are high, when solution spectra support the assignments, and when a series of related hosts and guests and their binding free energies are determined in the same medium under the same conditions.

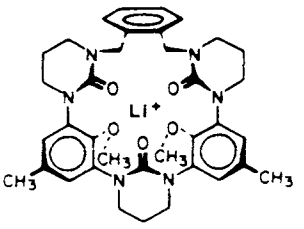
Solution structures of complexes tend to be much more free of conformational equilibria than those of hosts, since the contacts between the binding sites of the complexing partners severely limit the movements of the parts of the complex with respect to one another. Complexes are frequently easier to purify and crystallize, and their ^{1}H-NMR spectra tend to be simpler than those of their hosts. Many hosts crystallize as solvates in which a solvent molecule is employed as a guest (inclusion complex), and (or) with other solvent molecules packed between hosts. Often, obtaining suitable crystals is a greater task than determining their crystal structures.



1.6. Types of Complexes

Of the many types of complexes designed and synthesized, we will treat here only those families that provide correlations between structures and binding free energies, or that illustrate hypotheses, principles, and generalizations. Section 2 is concerned with the types and family names of complexes formed between hosts and cationic guests such as alkali-metal, ammonium, and alkylammonium ions. Section 3 treats complementarity, and the number and character of binding sites of hosts. Structure-binding relationships with ammonium and alkylammonium ions as guests are considered in Section 4. Section 5 deals with the central theme of the effects of host preorganization on binding free energies and rates of complexation. Section 6 relates preorganization of hosts to specificity in complexation. The structures of compounds are found essentially only in the Figures, which also contain most of the literature references to their study.

2. Types and Family Names of Hosts and Their Complexes with Guest Cations



The most extensive studies of complexes involve the alkali-metal, ammonium, and alkylammonium picrates as guests. The hosts and complexes treated in this article contain as binding sites ether oxygens, tertiary amine or pyridine nitrogens, or cyclic urea oxygens. These sites are separated from one another by hydrocarbon spacers such as dimethylene, trimethylene, *ortho*- or *meta*-phenylene, or *ortho*- or *meta*-xylene (phenylenebis(methylene)) units.

Hosts that bind alkali-metal and ammonium cations divide into families named according to structural features that are illustrated in complexes of hosts **1**-**9** (Fig. 1). *Corands*,[6] hosts first studied by *Pedersen*,[7] are macrocyclic polyethers whose oxygens are separated by $(CH_2)_n$ groups or groups of the *ortho*-phenylene type. The host of complex **6** · K^+ is a derivative of [18]crown-6. *Cryptands* are macrobicyclic polyethers, designed and studied by *Lehn*,[8] which are characterized by their polycyclic structures and whose bridgeheads are composed of $N(CH_2)_3$ units. The host of complex **4** · K^+ is a [2.2.2]cryptand. *Spherands*, designed and studied by the author, are macrocyclic or macropolycyclic systems that contain enforced cavities fully organized for complexation during synthesis, rather than during the complexing act. The host of complex **1** · Li^+ is a prototypical spherand.[9] *Hemispherands*, exemplified by **5** and **9**, are hosts whose cavities are at least half preorganized for binding by the rigidity of the hydrocarbon support structure and the spatial requirements of the appended groups.[4] *Cryptaspherands* **3** and **8** blend the cavity-enforc-

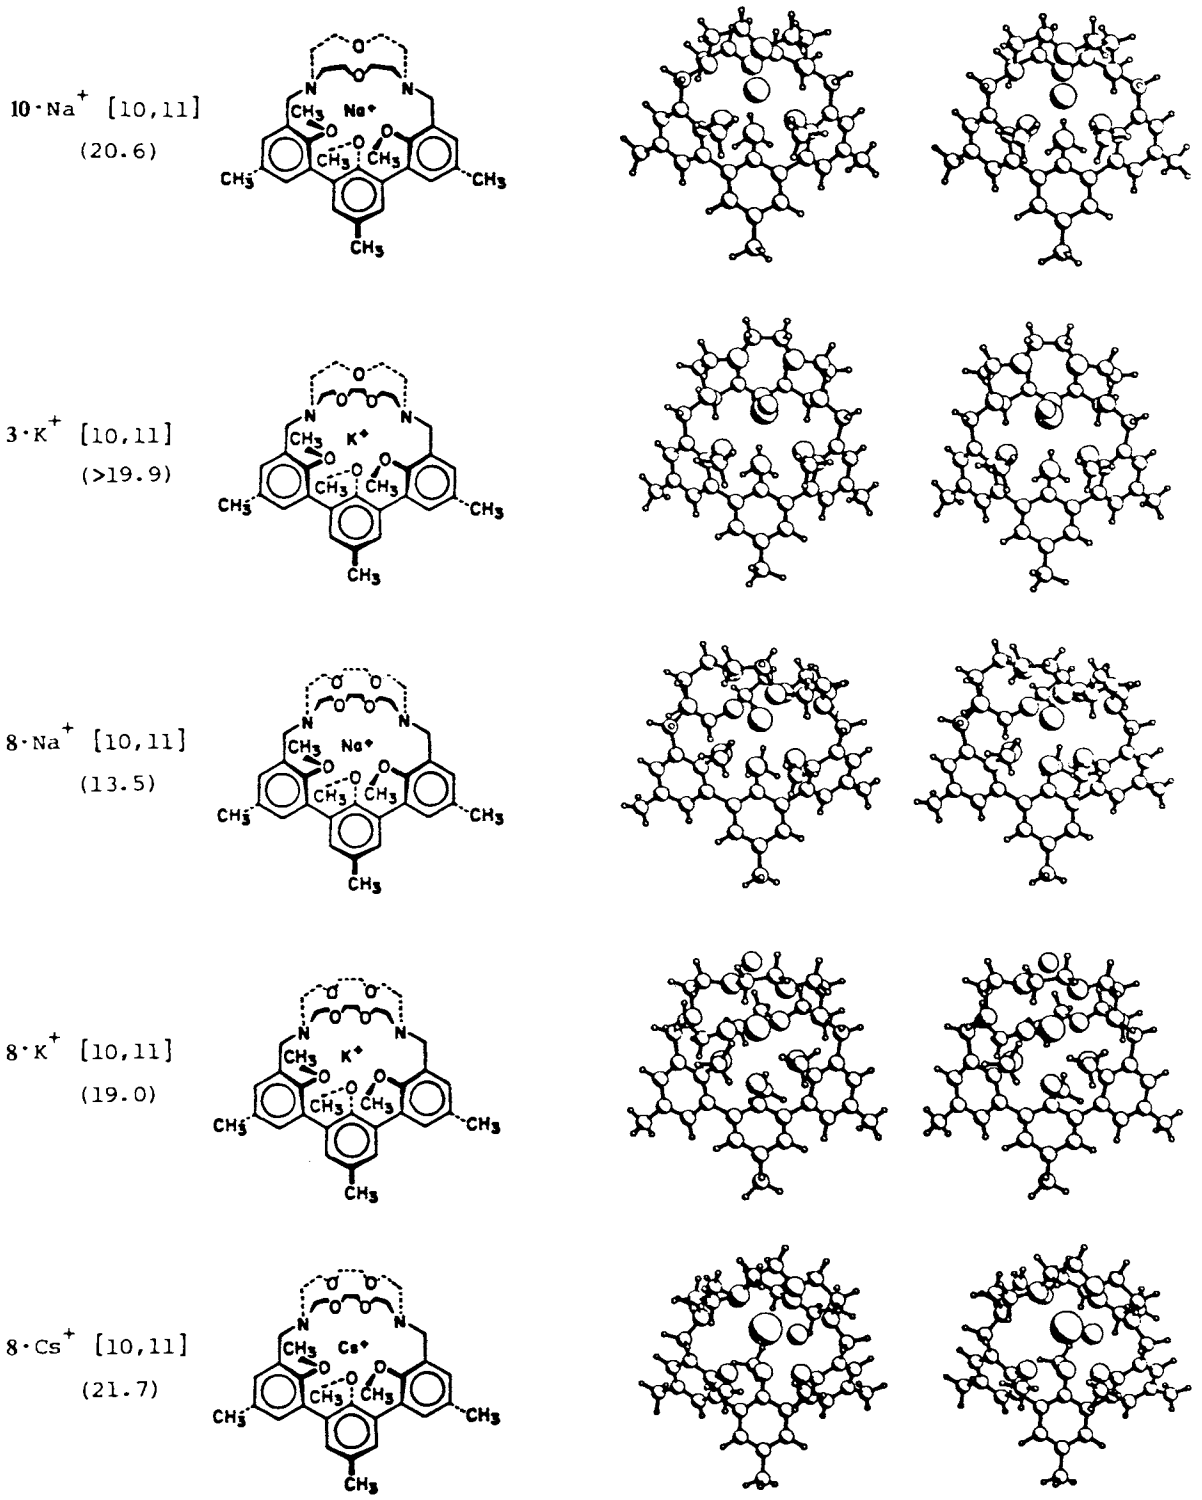
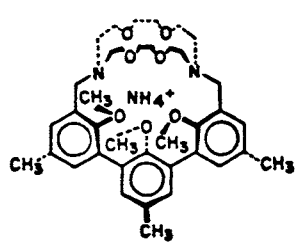
ing features of three *para*-methylanisole groups with the multiple ligand-gathering features of the cryptands.[10,11] Figure 2 provides stereorepresentations of the crystal structures of **10** · Na^+, **3** · K^+, **8** · Na^+, **8** · K^+, and **8** · Cs^+ complexes. *Podands*, named by *Vögtle* and *Weber*,[6] who provided the first examples, are noncyclic arrays of binding sites, in some cases terminated by groups capable of complexing each other to stabilize the cyclic conformations of the free hosts. Host **7** is a podand containing a binaphthyl unit, which somewhat limits its conformations.[18] The crystal structures of many complexes of the kind listed in Figure 1 have been determined, e.g., those of **1** · Li^+, **3** · Na^+, **4** · K^+, **8** · Cs^+, and **9** · Cs^+.

The suffix *and*, appropriately borrowed from the word *ligand*, is common to these family names. The suffix *ate*, found in the crystallographic words *solvate* or *clathrate*, has been suggested for the family names of complexes,[6] e.g., cryptate.[15] Use of this suffix suffers two disadvantages. One is that most crystalline solvates or clathrates cannot survive dissolution because their structures are too dependent on lattice forces. The other is that the suffix *ate* has been generally used in chemical names to denote innumerable anions, such as acet*ate* or perchlor*ate*. All of the complexes of Figure 1, however, carry a positive charge.

Instead of *ate*, we suggest the use of the suffix *plex*, de-





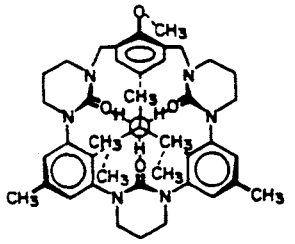


Fig. 2. Stereorepresentations of crystal structures of cryptaspheraplexes of alkali-metal ions, and binding free energies of their picrate salts ($-\Delta G^0$ [kcal·mol^{-1}]) under standard conditions. **3**·K^+, **8**·K^+, and **8**·Cs^+ also contain a water molecule.

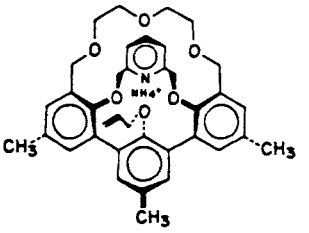

rived from the Latin word *plexus*, meaning an "interwoven arrangement of parts." The word *complex*, derived from the Latin word *complexus*, means a "weaving together of parts." The word complex is admirably suited as a class name for chemical entities such as those found in Figures 1 and 2, since the prefix *com* means "with or together." Transformation of the family names of the hosts to our suggested family names of their respective complexes provides the terms *spheraplex*, *cryptaplex*, *coraplex*, *podaplex*, *hemispheraplex*, and *cryptaspheraplex*, illustrated by **1**·Li^+, **4**·K^+, **6**·K^+, **7**·K^+, **5**·K^+, and **3**·Na^+, respectively, in Figure 1.

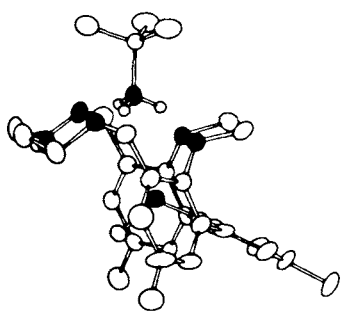
Fig. 3. Structures of selected complexes with ammonium and *tert*-butylammonium ions (cf. Table 1). Bu in **15**·$(CH_3)_3CNH_3^+$ means *tert*-butyl. For the complexes with **11**, **13**, and **15**–**17**, the crystal structures of various salts have been elucidated.



Many of the hosts that bind the alkali-metal cations also complex ammonium, methylammonium, and *tert*-butylammonium ions. Examples of the structures of some of the complexes of hosts **8** and **11**–**18** are listed in Figure 3. Those species for which crystal structures are known are indicated (for binding energies, see Table 1). In all of these crystal structures, the axis of the C–N bond of the guest is essentially perpendicular to the plane defined by the sites that form hydrogen bonds to the NH_3^+ group. The H–N–C–C dihedral angles are all 60°. The O···H–N or N···H–N bonds are nearly linear except for one of the hydrogen bonds in **15**·$(CH_3)_3CNH_3^+$, which is bifurcated.[4] In all of these structures, the $(CH_3)_3CNH_3^+$ guest perches on the electron-donating sites of the host to provide a tripod-type structure, as shown in Figure 4. The structures of the $CH_3NH_3^+$ complexes are probably similar.

3. Structure-Bonding Relationships Involving Alkali-Metal Cations

3.1. Complementarity

Binding free energies of hosts to their most complementary alkali-metal picrates are listed in Figure 1 below the

Table 1. Binding free energies ($-\Delta G^0$ [kcal·mol^{-1}]) of selected complexes as their picrate salts under standard conditions (cf. Fig. 3).

Guest \ Host	**8** [10, 11]	**11** [19, 20]	**12** [17]
NH_4^+	20.2	14.4	12.7
$CH_3NH_3^+$	—	14.4	11.9
$(CH_3)_3CNH_3^+$	—	13.2	11.7
Guest \ Host	**13** [4, 21]	**14** [17]	**15** [4, 22]
NH_4^+	10.5	9.2	9.9
$CH_3NH_3^+$	9.0	8.4	8.2
$(CH_3)_3CNH_3^+$	8.3	8.3	7.7
Guest \ Host	**16** [4, 18]	**17** [4, 18]	**18** [23]
NH_4^+	9.5	8.9	7.0
$CH_3NH_3^+$	7.5	6.9	7.4
$(CH_3)_3CNH_3^+$	6.9	6.4	8.6

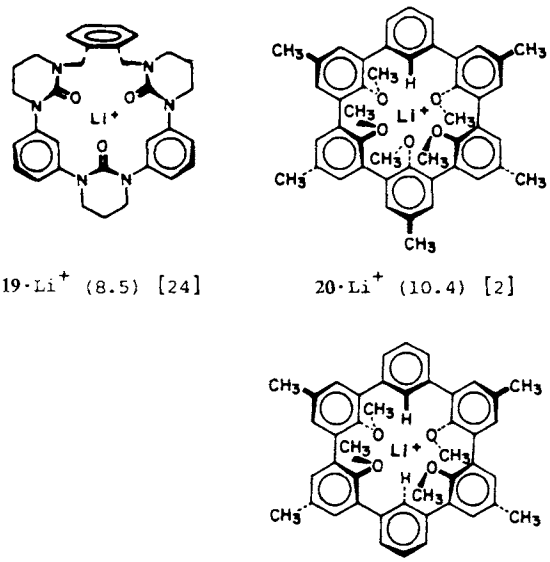

Fig. 5. Complexes of diminished spherands and the binding free energies ($-\Delta G^0$ [kcal·mol^{-1}]) of their picrate salts under standard conditions.

family names of the complexes. Notice that the $-\Delta G^0$ values range from a high of >23 kcal·mol^{-1} for spheraplex **1**·Li^+ to a low of 5.9 kcal·mol^{-1} for podaplex **7**·K^+. The structures of the complexes range from *capsular* (e.g., **1**·Li^+, **3**·Na^+, and **4**·K^+) to *nesting* (e.g., **2**·Li^+, **5**·K^+, and **6**·K^+) to *wrapping* (e.g., **7**·K^+). Values of at least 18 kcal·mol^{-1} of binding free energy have been realized for each of the alkali-metal ions by the appropriate design of the hosts. The $-\Delta G^0$ values provide a quantitative measure of the electronic and steric matching of the complexing partners, which is expressed by the term *complementarity*.

3.2. Number and Character of Binding Sites

The number of heteroatoms ligating the cations in the complexes of Figure 1 range from a high of nine for cryptaspheraplexes **8**·Rb^+ and **8**·Cs^+ to a low of five for spheraplex **2**·Li^+. Diminished spheraplex **19**·Li^+ in Figure 5 has a $-\Delta G^0$ value of 8.5 kcal·mol^{-1} and possesses only three host ligating sites, two less than **2**·Li^+ (Fig. 1), whose $-\Delta G^0$ value is 18.2 kcal·mol^{-1}. Spheraplex **1**·Li^+ with six ligating oxygens has a $-\Delta G^0$ value of >23 kcal·mol^{-1}; in comparison, **20**·Li^+, with five ligating oxygens, has a $-\Delta G^0$ value of 10.4 kcal·mol^{-1} and **21**·Li^+, with four ligating oxygens, a value of <6 kcal·mol^{-1}. These facts illustrate two important features of structure-binding correlation. First, in a series of hosts organized by a particular hydrocarbon framework, binding free energies decrease rapidly with a decrease in the number of ligating sites of the host. Second, the binding free energy is highly dependent on the electronic character of the ligating groups. Thus **19**·Li^+, with a $-\Delta G^0$ value of 8.5 kcal·mol^{-1} and only three binding sites, is much more stable than **21**·Li^+, whose four anisole oxygen binding sites provide a value of <6 kcal·mol^{-1}. The alternate placements of the three cyclic urea and the two anisole units to give five binding sites in the host **2** results in a $-\Delta G^0$ value of 18.2 kcal·mol^{-1} for **2**·Li^+, compared with the value of 10.4 kcal·mol^{-1} provided by the five anisole binding sites of **20**·Li^+. Clearly, the cyclic urea oxygen is a stronger ligating group than the anisole oxygen.[16]

Other interesting combinations of anisole and cyclic urea molecular units are illustrated by the crystal structures and binding free energies of the hemispheraplexes **22**·Na^+·H_2O, **22**·Cs^+·H_2O, **23**·Na^+·H_2O, and **11**·$(CH_3)_3CNH_3^+$. The structures suggested by CPK molecular model building and both face and side views of the crystal structures of these complexes are shown in Figure 6. For all four complexes, the general architectural features anticipated from CPK molecular model building were confirmed by the crystal structures. Notice the up-down-up arrangement of the alternate ligating oxygens as the eye passes clockwise around the face views of the macrocycles. The conformations of the bridging substituted *meta*-xylyl groups at "12 o'clock" are highly similar in the hosts of all four structures (see particularly the side views). As expected, **22**·Na^+·H_2O and **23**·Na^+·H_2O possess *nesting* structures, whereas **22**·Cs^+·H_2O and **11**·$(CH_3)_3CNH_3^+$ have *perching* structures, since the guests are too large to nest in the host.

The three metal-ion complexes in Figure 6 contain a molecule of water that ligates the metal ion from the side of the macroring opposite the methyl groups of the anisole units. The water molecules are held in place partially by hydrogen bonds to the bridging anisole oxygen in **22**·Na^+·H_2O and to the bridging aryl carboxylic carbonyl oxygen at "12 o'clock" in **23**·Na^+·H_2O. Surprisingly, these two oxygens do not directly ligate the nesting guests, although CPK models suggest that these contacts would put little strain on the support system. Other examples of a molecule of water ligating bound alkali-metal ions are found in the cryptaspheraplexes **8**·K^+ and **8**·Cs^+ in Figure 2. Water undoubtedly ligates the metal ions in solutions of $CDCl_3$ saturated with D_2O whenever the host structure in the complex provides an opening. The $-\Delta G^0$

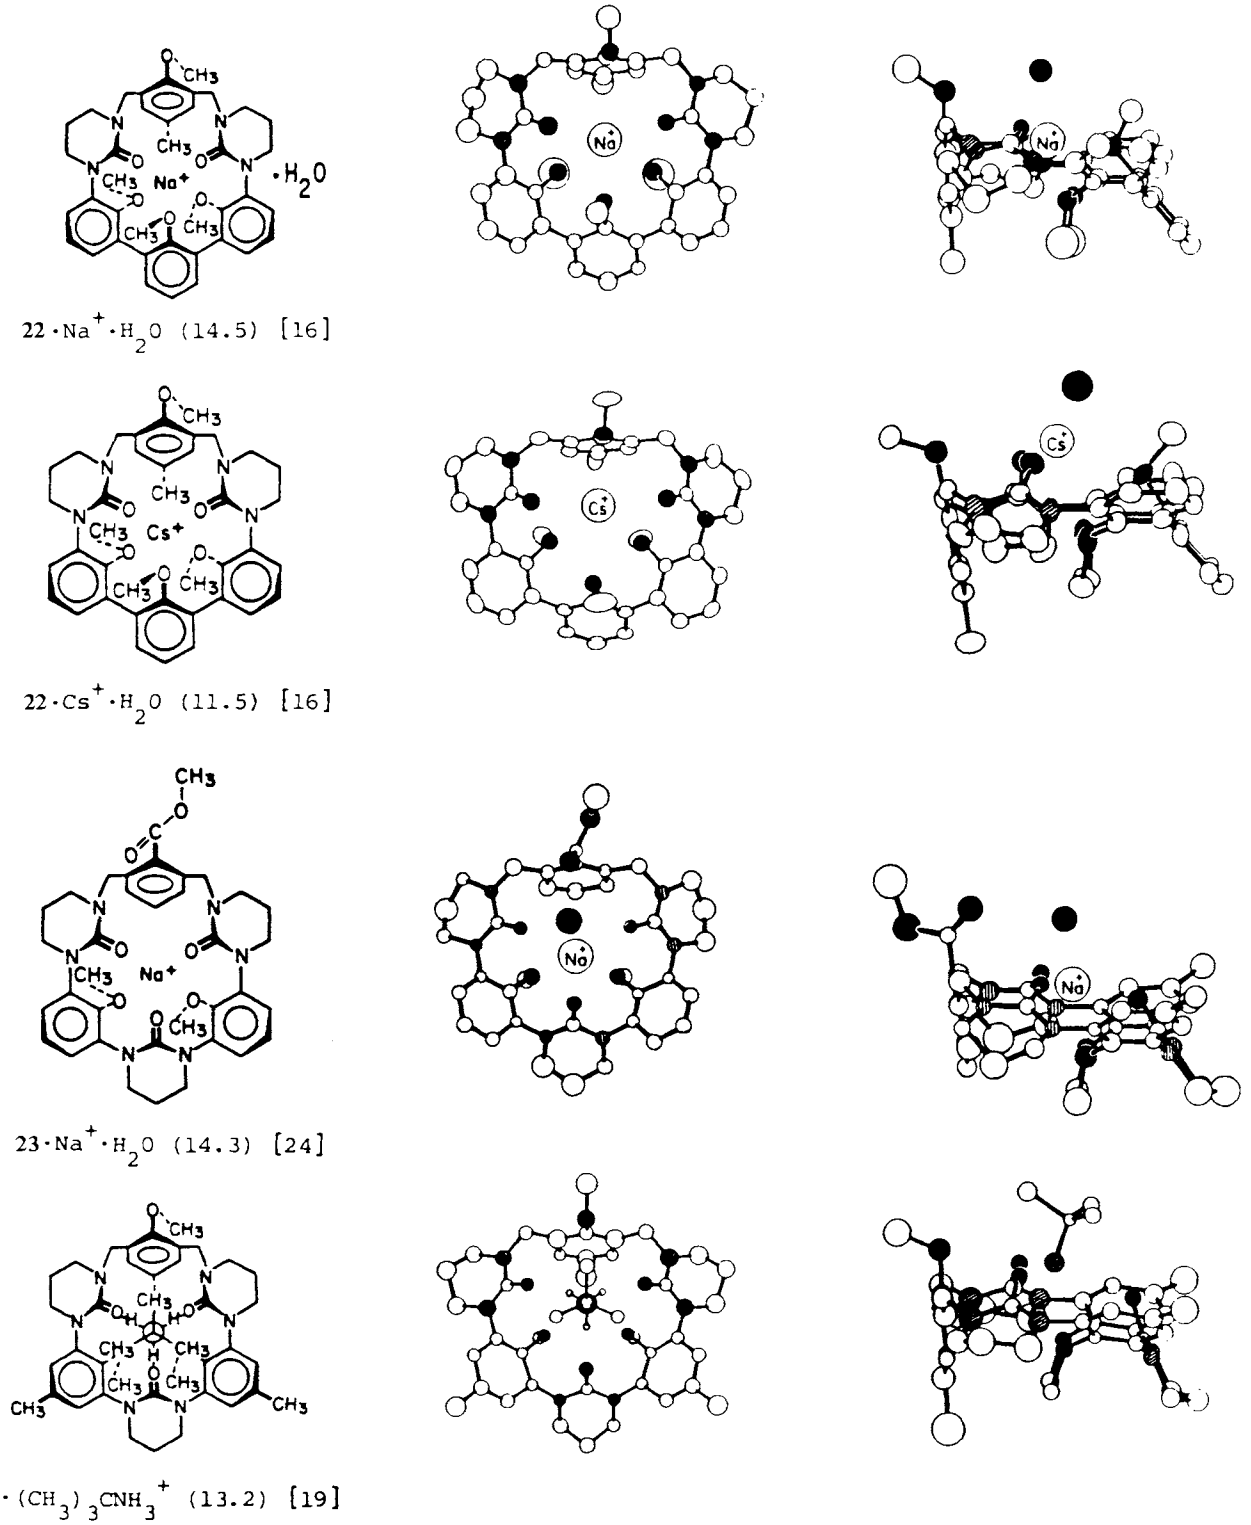

Fig. 6. Structural formulas of selected hemispheraplexes suggested by CPK models, face and side views of their crystal structures, and binding free energies ($-\Delta G^0$ [kcal·mol^{-1}], in parentheses) of their picrate salts under standard conditions.

values of the metal-ion complexes in Figure 6 are in the middle range (11.5 to 14.5 kcal·mol^{-1}), a fact discussed in Section 4.

The counting of the number of ligating sites used by a given host in binding a particular guest must be done cautiously. The problems are illustrated by the following comparisons. Host **8** complexing K^+ provides a $-\Delta G^0$ value of 19.0 kcal·mol^{-1}, and the crystal structure of **8**·K^+ in Figure 2 shows that all nine heteroatoms of the host ligate the K^+. Host **8** complexing Na^+, however, gives a $-\Delta G^0$ value of 13.5 kcal·mol^{-1}. Close scrutiny of the crystal structure of cryptaspheraplex **8**·Na^+ in Figure 2 indicates that although the orbitals of the unshared electron pairs of the heteroatoms are all pointing toward the Na^+ ion, only

five of the nine are actually within contact distance (those on the right of the drawing). The cavity is complementary to Na^+ in the sense that it is spherical, but its diameter is too large to match that of the Na^+ ion.

Somewhat different ligand-counting problems are encountered in spheraplexes **24** · Li^+ and **25** · Li^+, whose crystal structures are shown in Figure 7. Although host **24** contains six oxygens with inward-turned unshared electron pairs, the highly constrained *syn* bridges force the cavity to be somewhat elongated in one dimension so that the two methoxyl oxygens are more distant from each other than the pseudo-*para* pairs of oxygens found in the bridges. Thus, the Li^+ guest (effective diameter of 1.27 Å) is able to contact only five of the six oxygens in **24** · Li^+. A $-\Delta G^0$ value of 16.8 kcal·mol^{-1} results, considerably less than the $-\Delta G^0$ value of >23 kcal·mol^{-1} observed for **1** · Li^+ (Li^+ diameter of 1.48 Å). The $-\Delta G^0$ value for **24** · Na^+ is even lower at 13.3 kcal·mol^{-1}. The misshapen cavity is clearly visible in CPK models of **25**, modified by shaving the diameters of the four bridging oxygens, which violate one another's van der Waals volumes.

Host **25** contains eight oxygens with inward-turned electron pairs to provide a roughly spherical cavity. The crystal structure of **25** · Li^+ indicates that Li^+ (1.71 Å effective diameter) only contacts seven of the eight oxygens, the methoxyl oxygen at "6 o'clock" in the drawing being distant from the lithium ion. The $-\Delta G^0$ value for **25** · Li^+ is only 15.9 kcal·mol^{-1}, somewhat less than that for **24** · Li^+ with only five contacting ligands. As expected, the larger cavity diameter of **25** better matches the diameter of Na^+, so that **25** · Na^+ has a $-\Delta G^0$ value of 18.7 kcal·mol^{-1}, still somewhat less than the 19.2 kcal·mol^{-1} value for **1** · Na^+, whose host has only six available ligands.

We conclude from these results that the nearly perfect octahedral arrangement of the six oxygens in **1** more than compensates for the more rigid but somewhat misshapen oxygen cavity of eight oxygens in **25**. The nearly square-pyramidal arrangement of the five oxygens used by Li^+ in **24** · Li^+ provides slightly better binding than the seven more distant oxygens used in **25** · Li^+. These results further indicate that the effective diameter of Li^+ depends on the number of its ligands.[2, 12]

4. Structure-Binding Relationships Involving Ammonium and Alkylammonium Ions

4.1. Correlations of Binding Free Energies as Criteria of Structure

The structures and binding free energies for a variety of complexes of NH_4^+, $CH_3NH_3^+$, and $(CH_3)_3CNH_3^+$ are found in Figure 3 and Table 1. Of the many crystal structures known,[4] three are shown in Figure 4. Correlations of binding free energy with geometry for complexes of established crystal structure provide a basis for predicting structures of complexes from a combination of CPK molecular model examination and binding free energy measurements. For example, the highest $-\Delta G^0$ value we have measured (25 °C, $CDCl_3$ saturated with D_2O) for the binding of NH_4^+ picrate to a host is 20.2 kcal·mol^{-1} for **8** · NH_4^+ (Fig. 3). Complex **8** · Rb^+ has a $-\Delta G^0$ value of 20.3 kcal·mol^{-1} (Fig. 1), not far from that of **8** · K^+ (19.0 kcal·mol^{-1}) or **8** · Cs^+ (21.7 kcal·mol^{-1}) (Fig. 2). The crystal structures of **8** · K^+ and **8** · Cs^+ are both known to be *cap-*

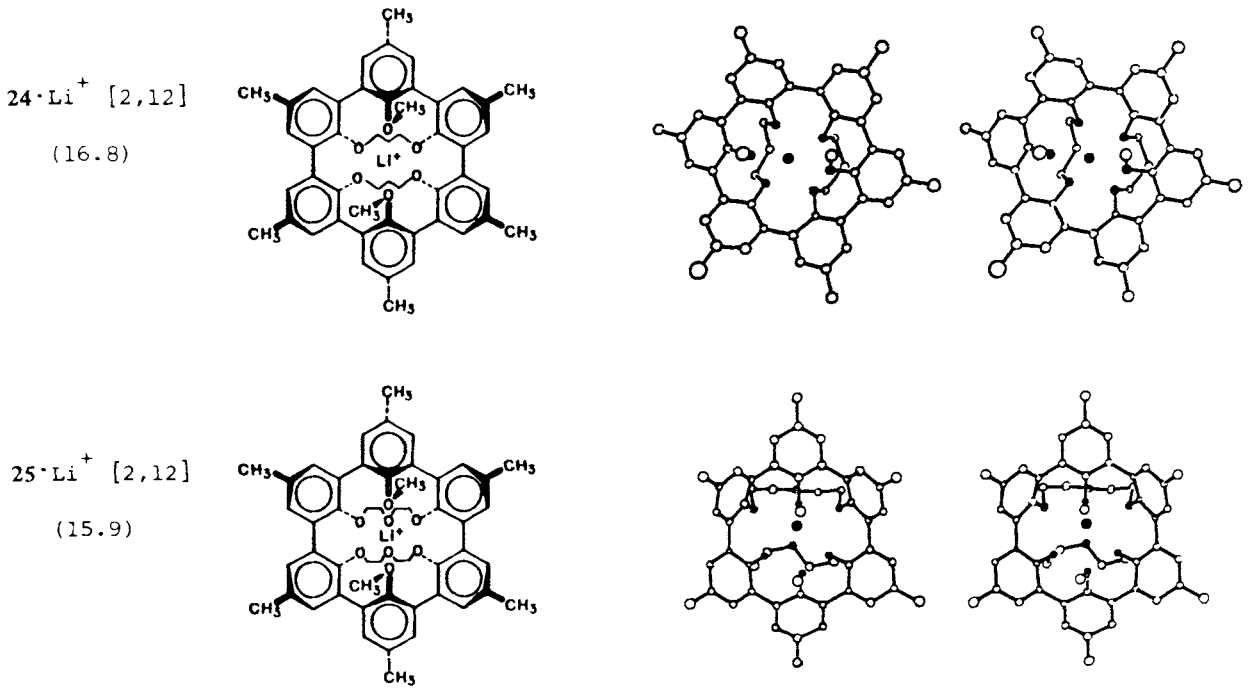

Fig. 7. Structural formulas of augmented spherands, stereodrawings of their crystal structures, and binding free energies ($-\Delta G^0$ [kcal·mol^{-1}], in parentheses) of their picrate salts under standard conditions. The stereodrawing of **24** · Li^+ is rotated by ca. 90° relative to its structural formula. The effective Li^+ diameter is 1.27 Å for **24** · Li^+ and 1.71 Å for **25** · Li^+.

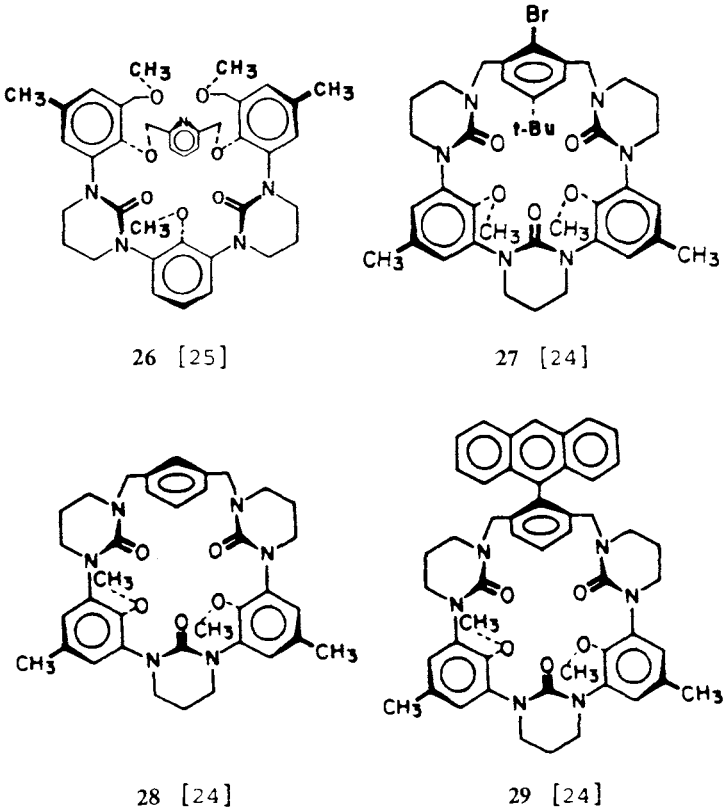

sular (Fig. 2), which strongly suggests **8** · Rb^+ to be capsular as well. The $-\Delta G^0$ values for the binding of NH_4^+ and Rb^+ picrates to a wide variety of hosts are within 1 kcal · mol^{-1} of one another. CPK molecular models indicate the potential cavity of **8** to be complementary to Rb^+ or NH_4^+ ions. We conclude that **8** · NH_4^+ is a capsular complex. Molecular models of **12** · NH_4^+ (Fig. 3) and **12** · Rb^+, with $-\Delta G^0$ values of 12.7 and 12.8 kcal · mol^{-1}, respectively, suggest that both probably have somewhat strained nesting structures. Models of **14** · NH_4^+ and **14** · Rb^+ ($-\Delta G^0$, 9.2 and 9.8 kcal · mol^{-1}, respectively),[17] and of **18** · NH_4^+ (Fig. 3) and **18** · Rb^+ ($-\Delta G^0$, 7.0 and 7.0 kcal · mol^{-1}, respectively) suggest that all four are perching.[23]

The patterns of $-\Delta G^0$ values (Table 1) for the complexes with NH_4^+, $CH_3NH_3^+$, and $(CH_3)_3CNH_3^+$ in Figure 3 suggest that most of them are of the perching-tripod variety, except for some of those discussed in Section 4.2. For hosts **11**–**17**, NH_4^+ is more strongly bound than $CH_3NH_3^+$, and $CH_3NH_3^+$ more strongly than $(CH_3)_3CNH_3^+$, the maximum differences of 2 kcal · mol^{-1} being between NH_4^+ and $CH_3NH_3^+$ complexes of **16** and **17** (Table 1). The low values of 6.9 and 6.4 kcal · mol^{-1} for the binding of $CH_3NH_3^+$ and $(CH_3)_3CNH_3^+$, respectively, to **17** are probably associated with steric encumbrance of the methyl groups of the guest by the methyl group of the host. In the crystal structure of **17** · $(CH_3)_3CNH_3^+$, the upward-thrusting methyl group of the host contacts the methyls of the guest at "7 and 12 o'clock" (see Fig. 3). The best plane of the macroring is folded away from the binaphthyl chiral barrier to accommodate the bulky guest perching on its top face.[4]

4.2. Di- and Tripodal Structures

In principle, guests such as RNH_3^+ can enter into tri-, di-, or monopodal binding with a host. Of these alternatives, tripodal binding provides a highly structured complex, dipodal binding a moderately structured complex, and monopodal binding a species with very little structure. The interesting question arises as to the relative $-\Delta G^0$ values for tripodal and dipodal binding. This question can be addressed in two ways. The first involves a comparison of $-\Delta G^0$ values for the binding of protonated primary amines to the hosts to form complexes having tripodal structures with the values for the binding of a protonated secondary amine, $(CH_2)_5NH_2^+$, to the same hosts to form complexes having dipodal structures (Fig. 8). The second requires a comparison of $-\Delta G^0$ values for NH_4^+, $CH_3NH_3^+$, and $(CH_3)_3CNH_3^+$ guests bound in a tripodal fashion by an unhindered host with the values obtained for a host whose CPK model suggests that, at least for $(CH_3)_3CNH_3^+$, only dipodal binding is sterically feasible. The relevant structures and $-\Delta G^0$ values are found in Figure 8 and Table 2, respectively.

The $-\Delta G^0$ values for **26** · $CH_3NH_3^+$ and **26** · $(CH_2)_5NH_2^+$ are 9.8 and 6.7 and those for **27** · $CH_3NH_3^+$ and **27** · $(CH_2)_5NH_2^+$ are 13.0 and 7.3 kcal · mol^{-1}, respectively. Thus, about a third of the total binding free energy is lost

26 [25] **27** [24]

28 [24] **29** [24]

Fig. 8. Structural formulas of selected hosts (cf. Table 2).

Table 2. Binding free energies ($-\Delta G^0$ [kcal · mol^{-1}]) of selected complexes as their picrate salts under standard conditions (cf. Fig. 8).

Guest \ Host	**26** [25]	**27** [24]	**28** [24]	**29** [24]
NH_4^+	9.5	13.8	13.9	10.3
$CH_3NH_3^+$	9.8	13.0	13.8	9.5
$(CH_3)_3CNH_3^+$	8.6	11.7	12.7	8.1
$(CH_2)_5NH_2^+$	6.7	7.3		

in passing from a tripodal to a dipodal structure. The $-\Delta G^0$ values for **28** · $CH_3NH_3^+$ and **29** · $CH_3NH_3^+$ are 13.8 and 9.5 kcal · mol^{-1}, and for **28** · $(CH_3)_3CNH_3^+$ and **29** · $(CH_3)_3CNH_3^+$ are 12.7 and 8.1 kcal · mol^{-1}, respectively. The results coupled with molecular model examination suggest the two complexes of **28** to be tripodal and those of **29** to be dipodal. The drop in $-\Delta G^0$ value of 3.6 kcal · mol^{-1} in passing from **28** · NH_4^+ to **29** · NH_4^+ is interpreted in terms of steric inhibition of solvation of the fourth and non-tripod-bound hydrogen in the tripodal structure of **29** · NH_4^+.

5. Effects of Preorganization of Hosts on Binding Free Energies and on Complexation-Decomplexation Rates

5.1. Families of Hosts Arranged According to Their Binding Powers

Families of compounds generally fall into the following order when arranged according to the $-\Delta G^0$ values with

which they bind their most complementary guests: spherands > cryptaspherands > cryptands > hemispherands > corands > podands > solvents. The structures and family names of twelve hosts are given in Figure 9. The $-\Delta G^0$ values are listed in Table 3. Spherand **1** shows peak binding with Li^+ ($-\Delta G^0 > 23$ kcal·mol^{-1}). Cryptaspherands show maximum $-\Delta G^0$ values for **10**·Na^+ (20.6), **3**·Na^+ (21.0), and **8**·Cs^+ (21.7 kcal·mol^{-1}). Cryptands provide maximal $-\Delta G^0$ values for **30**·Li^+ (16.6, probably the highest), **31**·Na^+ (17.7), and **4**·K^+ (18.0 kcal·mol^{-1}). Hemispherand binding power is strongest for **32**·Na^+ (12.2), **33**·Na^+ (13.5), and **34**·K^+ (11.6 kcal·mol^{-1}). Corand **6** peaks with **6**·K^+ (11.4 kcal·mol^{-1}). Podand **35** binds too poorly for its $-\Delta G^0$ values to be measured (< 6 kcal·mol^{-1} for all five ions), but it clearly binds better than *p*-methylanisole. In these particular hosts, the numbers of potential binding sites vary from a low of six for **1**, **30**, **32**, **33**, and **35** to a high of nine for **8**. Although the numbers of binding sites and their characters certainly influence the $-\Delta G^0$ values, as discussed in Section 3.2, a different factor appears to be overriding in providing the family order of binding power.

Table 3. Binding free energies ($-\Delta G^0$ [kcal·mol^{-1}]) of selected complexes as their picrate salts under standard conditions (cf. Fig. 9).

Guest \ Host	**1** [2]	**10** [10, 11]	**3** [10, 11]	**8** [10, 11]
Li^+	> 23	18.8	13.4	9.9
Na^+	19.2	20.6	21.0	13.5

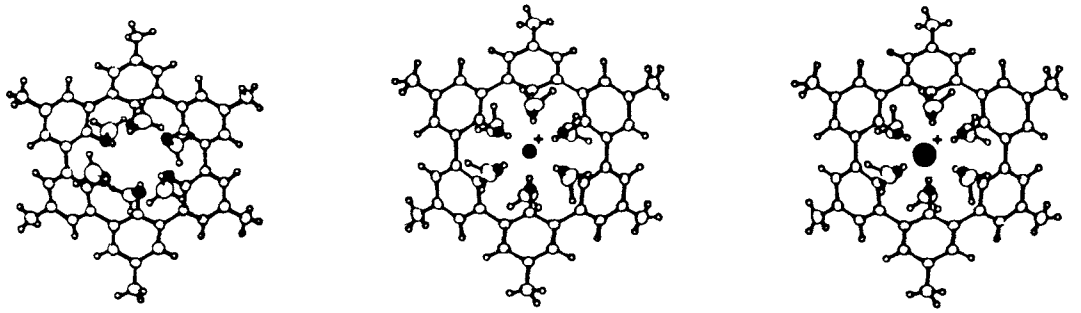
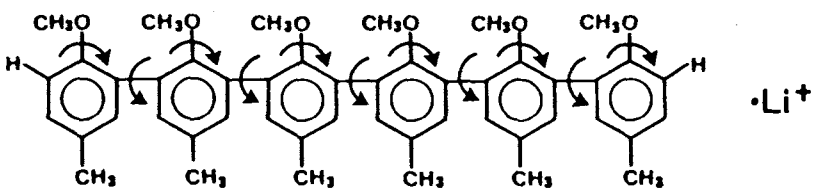
5.2. Preorganization as a Central Determinant of Binding Power



Crystal structures of **1**, **1**·Li^+, and **1**·Na^+ are shown in Figure 10. These three structures all resemble snowflakes and *possess the same conformation*. They differ mainly in the sense that **1** contains an empty cavity, which is filled in **1**·Li^+ and **1**·Na^+. Notice that the six oxygens of **1** are octahedrally arranged with the orbitals of their unshared electron pairs lining a roughly spherical hole whose diameter (1.62 Å) is between the diameters of Li^+ in **1**·Li^+ (1.48 Å) and of Na^+ in **1**·Na^+ (1.75 Å). The six oxygens are attached to six *equatorially* arranged *para*-tolyl groups and six *axially* arranged methyl groups. Thus, the oxygens are well buried within a hydrocarbon shell. The orbitals containing the unshared electron pairs of the oxygens are in a microenvironment whose dielectric properties are between those of a vacuum and those of a hydrocarbon. No solvent can approach the six oxygens, which remain unsolvated.[12]

Podand **35** differs constitutionally from spherand **1** only in the sense that **35** contains two hydrogen atoms in place of one aryl–aryl bond in macrocycle **1**.[27] The two hosts differ radically in their conformational structures. Spherand **1** possesses a single conformation ideally arranged for binding Li^+ and Na^+. Podand **35** can in principle exist in over 1000 conformations, only two of which bind Li^+ octahedrally. The free energy cost of organizing spherand **1** into a single conformation and of desolvating its six oxygens was paid for during its synthesis. Thus **1** is *preorganized* for binding. The free energy for conformationally organizing **35** into a binding conformation and desolvating its six oxygens must come from its complexation free energy. Thus **35** is not preorganized for binding, but is randomized to maximize the entropy of mixing of its conformers and to maximize the attractions between solvent and its molecular parts.[12]



The difference in $-\Delta G^0$ values for the binding of Li^+ to spherand **1** and podand **35** is > 17 kcal·mol^{-1}. The difference in association constant values (K_a) is $> 10^{12}$ M^{-1}. The difference in $-\Delta G^0$ values for the binding of Na^+ to **1** and **35** is > 13 kcal·mol^{-1} (i.e., $K_a > 10^{10}$ M^{-1}). These differences are dramatically larger than any we have encountered associated with other effects on binding power toward alkali-metal ion guests. We conclude that *preorganization is a central determinant of binding power*. The principle of preorganization states that "the more highly hosts and guests are organized for binding and low solvation *prior* to their complexation, the more stable will be their complexes." Both enthalpic and entropic components are involved in preorganization, since solvation contains both components. Furthermore, binding conformations are sometimes enthalpically very rich. For example, the binding oxygens of bridged spherands **24** and **25** (Fig. 7) severely violate each other's van der Waals volumes, and the systems are very highly strained.[2, 12]

The structuring of host–guest complexes depends on cooperativity between many contacting sites which, because of their organization, are able to compete with solvent. As measured by its ability to form hydrogen bonds, the anisole group is an intrinsically poor ligand.[28] Thus it is hardly surprising that podand **35** is such a poor binding system.

In Figure 11, representations of crystal structures of a prototypical corand, a cryptand, and a spherand are compared. Notice that corand **36** and cryptand **4** fill their own

1 **1**·Li^+ (>23) **1**·Na^+ (19.2)

35·Li^+ (<6)

Fig. 10. Snowflake-like crystal structures of **1**, **1**·Li^+, and **1**·Na^+, and binding free energies ($-\Delta G^0$ [kcal·mol^{-1}], in parentheses) of their picrate salts for **1**·Li^+, **1**·Na^+, and **35**·Li^+ under standard conditions.

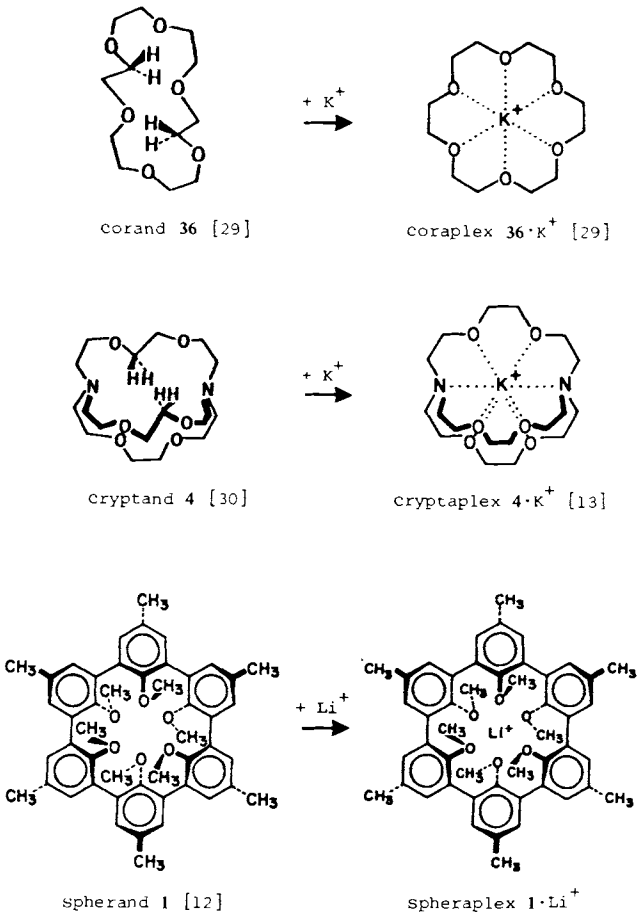


Fig. 11. Crystal structure comparisons of hosts and their complexes showing the relative states of preorganization of corands, cryptands, and spherands.

cavities with inward-turned methylene groups, which must be driven outward by the guest during complexation. In solution, the cavities are undoubtedly similarly unformed, either being filled with their own methylenes or with parts of solvent molecules, both of which must be displaced by a guest during complexation, and at some free energy cost. In contrast, spherand **1**, both in the crystalline state and in solution, is fully preorganized and its binding sites are nonsolvated. Crystal structures of cryptaspherands[10] and hemispherands[4] show that methylenes similarly fill their own potential cavities, but that their anisole parts are fully organized for complexation.[31]

When the families of hosts are arranged in decreasing order of their degrees of preorganization for binding, it is the same order observed when they are arranged in decreasing order of their $-\Delta G^0$ values. Thus spherands are completely preorganized. Cryptaspherands are largely preorganized by the anisoles and the conformational-solvation constraints of the bicyclic, cryptand part of the hosts. The bicyclic structure of the cryptands severely limits the number of their conformations and partially inhibits solvation of their binding sites. The anisole units of the hemispherands are self-organizing, whereas the corand portions are much more flexible, and their binding sites invite solvation. The corands are still more flexible in a conformational sense, and more of their binding sites are exposed to solvation than those of the hemispherands. Finally, the podands enjoy only the preorganization associated with the collection and potential spacing of their binding sites.

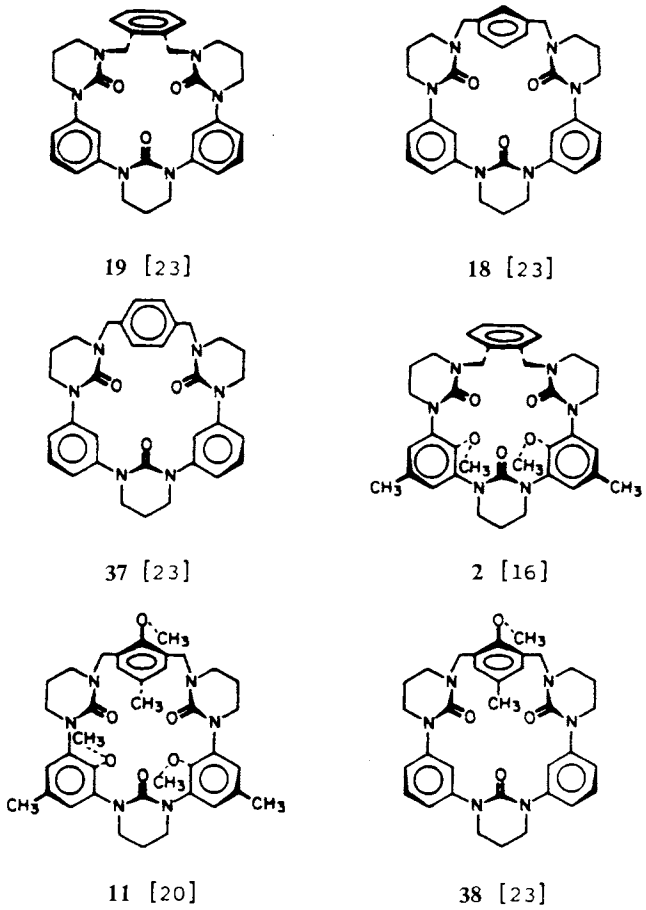

Fig. 12. Structures of selected hosts (cf. Table 4).

Table 4. Binding free energies ($-\Delta G^0$ [kcal·mol^{-1}]) of selected complexes as their picrate salts under standard conditions (cf. Fig. 12).

Guest \ Host	**19** [23]	**18** [23]	**37** [23]	**2** [16]	**11** [20]	**38** [23]
NH_4^+	7.0	7.0	8.0	11.8	14.4	8.4
$CH_3NH_3^+$	7.1	7.4	8.5	12.1	14.4	9.0
$(CH_3)_3CNH_3^+$	7.3	8.6	9.1	13.2	13.2	9.5

The power of preorganization is also evident in the binding of ammonium and alkylammonium guests by hosts. Comparisons of the structures and $-\Delta G^0$ values in Figure 12 and Table 4, respectively, indicate that hosts with anisole units separating their cyclic urea units are much stronger binders than the corresponding systems without the anisole units. For example, spherand **2** binds NH_4^+, $CH_3NH_3^+$, and $(CH_3)_3CNH_3^+$ with $-\Delta G^0$ values 5-6 kcal·mol^{-1} higher than those for **19**. Likewise, **11** binds the three ions with $-\Delta G^0$ values about 6 kcal·mol^{-1} higher than those for **18**. Even the one methoxyl and one methyl group attached to the bridging *meta*-xylyl unit in **38** enhance its binding by about 1 kcal·mol^{-1} over that of **18** without these substituents. All of the complexes in Figure

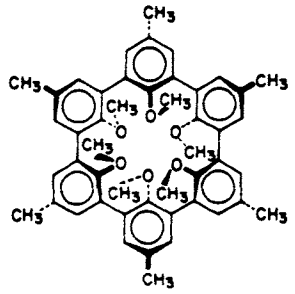
12 are probably held together by three NH···O=C hydrogen bonds as in the crystal structure of **11** · $(CH_3)_3CNH_3^+$ (Fig. 3). Thus the non-hydrogen-bonded oxygens account for about 40% of the free energy of binding for these hosts. We interpret this as being mainly due to the preorganizing effects that the space-occupying methoxyls exert on the cyclic ureas. The methoxyls not only organize the cyclic urea units for binding RNH_3^+ in a conformational sense, but they also partially shield them from solvation.

Comparisons of the $-\Delta G^0$ values for **19**, **18**, and **37**, on the one hand, and **2** and **11**, on the other, indicate that the larger the macrorings in this series, the stronger the binding. Model examination indicates that the NH_3^+ groups perch on orbitals deeper in the cavities of the larger macrorings, where microdielectric effects tend to stabilize charge. Interestingly, for **19**, **18**, and **37** (no anisole groups) the $-\Delta G^0$ values increase as the guest is changed from NH_4^+ to $CH_3NH_3^+$ to $(CH_3)_3CNH_3^+$. Molecular model examination of these complexes suggests that with $CH_3NH_3^+$ and $(CH_3)_3CNH_3^+$, the methyls contact the bridging xylene unit. These methyl protons are weakly acidic, and possibly form weak hydrogen bonds to the π systems of the bridging aryl group. The electrons of the bridging *para*-xylyl group of **37** · NH_4^+ can contact the fourth hydrogen of the NH_4^+ group in models, but those of the bridging units cannot without creating considerable strain in **19** · NH_4^+ and **18** · NH_4^+. This may account for the 1 kcal · mol^{-1} higher $-\Delta G^0$ value for **37** · NH_4^+ compared with **18** · NH_4^+ or **19** · NH_4^+.[16]

5.3. Preorganization and Rates of Complexation-Decomplexation

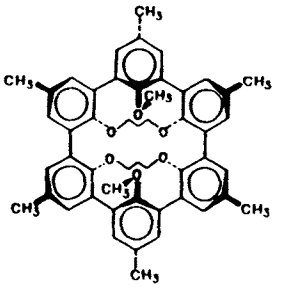
Equation (1) defines and relates the rate constants for complexation-decomplexation to the association constants (K_a) for complexation. The preorganized spherands **1**, **24**, and **25** (Fig. 13) complexed Li^+ and Na^+ picrates, at 25 °C in $CDCl_3$ saturated with D_2O, with rate constants (k_1 [M^{-1} s^{-1}]) that varied from $\approx 10^5$ for **1** · Li^+ to $\approx 10^6$ for **24** · Na^+ (Table 5). The decomplexation rate constants (k_{-1} [s^{-1}]) varied from $< 10^{-12}$ for **1** · Li^+ to $\approx 10^{-4}$ for **24** · Na^+. A plot of $\log K_a$ [M^{-1}] against $\log k_{-1}$ [s^{-1}] was

$$\text{Host} + M^+Pic^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Host} \cdot M^+ \cdot Pic^- \qquad K_a = \frac{k_1}{k_{-1}} \tag{1}$$



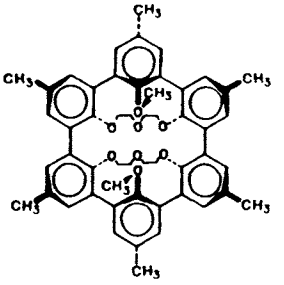
essentially linear for the six combinations of host and guest.[2] *Cox* et al. previously observed a linear correlation between $\log K_a$ and $\log k_{-1}$ for the binding of a variety of ions in several solvents to cryptands **31** and **4** (Fig. 9).[32] As with the spherands, the cryptands showed no correlation between k_1 and K_a. For the two cryptands **30** and **31** (Fig. 9), which are most complementary to Li^+ and Na^+, the k_1 values varied between 10^4 and 10^7 M^{-1} s^{-1} in a variety of solvents, most values lying in the same range as those mentioned above for the spherands.[32] The crystal structures of the spheraplexes and cryptaplexes show them to be capsular (Figs. 7, 10, and 11).

Values for k_1 and k_{-1} for the binding of K^+Pic^- to the hemispherands **39**–**41** under standard conditions are also given in Table 5. The k_1 values range from 10^7 to 10^9 M^{-1} s^{-1}, comparable to the range observed for the binding of K^+ to the least preorganized cryptand **4** (Fig. 9) in a variety of solvents at 25 °C. The k_{-1} values [s^{-1}] for release of K^+ from the three hemispherands varied only by a factor of 7, from 26 for **40** to 4 for **41**.[26] For binding of the relatively "soft" K^+ ion (compared with Na^+ and Li^+) to these partially preorganized and solvated hosts, the complexation rate constants play a larger role in determining K_a and $-\Delta G^0$ values than do the dissociation rate constants, in contrast to the results for spherands and cryptands. The hemispheraplexes of hosts **39**–**41** are undoubtedly nesting (CPK molecular model examination).



For the three hemispherands **11**, **38**, and **42**, the values of k_1 and k_{-1} for complexing and decomplexing of $(CH_3)_3CNH_3^+Pic^-$ are also listed in Table 5.[33] All three hosts undergo complexation with k_1 values [M^{-1} s^{-1}] of 10^{11} to 10^{12}, which indicates the reactions to be essentially diffusion controlled. Their decomplexation rate constants (k_1) vary from $\approx 10^3$ to $\approx 10^4$ s^{-1}. The hemispheraplexes of these hosts with $(CH_3)_3CNH_3^+$ have a perching structure (see crystal structure of **11** · $(CH_3)_3CNH_3^+$ in Fig. 4).

The three types of complexes referred to in Figure 13, when arranged in *decreasing* order of rate constant values for *either their formation or dissociation*, provide the same sequence: perching (**11**, **38**, **42**) > nesting (**39**–**41**) > capsular (**1**, **24**, **25**). These orders conform to expectations based on structure. The solvation shells of the cationic guests are least disturbed in forming a perching complex, more disturbed in forming a nesting complex, and the most disturbed in forming a capsular complex. Model examination of the transition states for Li^+ or Na^+ entering or leaving the preformed cavity of **1** indicates there is space available for only one ligand of the medium (H_2O or Pic^-) to contact the cation. Either cation is surrounded by a hydrocarbon sleeve of three methyl groups, capped at one end by the single ligand and at the other by the bulb of the preformed cavity. Thus it is hardly surprising that the rates of complexation and decomplexation for the spheraplexes are orders of magnitude slower than those for the hemispheraplexes. In the envisioned transition states for these complexation-decomplexation processes, both hosts and guests liberate or fix solvent at one binding site at a time, exchanging host-guest attractions for host-solvent and guest-solvent attractions, or the reverse. The transition states envisioned for complexation-decomplexation of the cryptaspheraplexes and the cryptaplexes are in between those for the spheraplexes and hemispheraplexes in their degrees of simultaneous stabilization by medium and by host-guest interactions. Those for the coraplexes and even more for the podaplexes should integrate stabilization by solvation with host-guest stabilization. Thus, *the more highly preorganized the host for complexation, the lower should be the rates for complexation and decomplexation.*



All of the complexation rates in homogeneous solutions are instantaneous on the human and ^{1}H-NMR time scales. The decomplexation rates of the hemispheraplexes and coraplexes are fast on the human and slow on the ^{1}H-NMR time scales. The decomplexation rates of the spheraplexes

and more stable cryptaspheraplexes are very slow on the human time scale at 25 °C.[11,12]

5.4. Preorganization and Solvation

The effects of changes in solvent on the $-\Delta G^0$ value for complexation have been the most thoroughly studied by *Cox* et al. with cryptand hosts and alkali-metal ion guests.[34] The solvents used were water, methanol, ethanol, acetonitrile, propylene carbonate, *N*-methylpropionamide, dimethylformamide, and dimethyl sulfoxide. The cryptaplexes are the most stable in the aprotic, least polar solvents, and are the least stable in aqueous and dipolar solvents. Examples of some of the highest values for $-\Delta G^0$ (kcal·mol^{-1}) are listed in Table 6 (see Fig. 14). A plot of the eight data points for $-\Delta G^0$ values in $CDCl_3$ saturated with D_2O against those in 95% CH_3OH–5% H_2O is roughly linear.[111] The $-\Delta G^0$ values in CH_3OH–H_2O are 5.2 ± 0.4 kcal·mol^{-1} lower than those in $CDCl_3$–D_2O. When the solvents are arranged in decreasing order of the observed $-\Delta G^0$ values, the sequence is $CDCl_3$–$D_2O \sim$ propylene-carbonate $\gg$ methanol $\sim$ methanol-water $>$ dimethyl sulfoxide $>$ water. The differences between $-\Delta G^0$ values in $CDCl_3$–D_2O and those in H_2O range from 6.4 to 11 kcal·mol^{-1}.[34] These large solvent effects on $-\Delta G^0$ indicate that solvent-host and solvent-guest attractions compete with host-guest interactions. Unfortunately, the $-\Delta G^0$ values for the binding of the alkali-metal ions to the spherands in solvents other than $CDCl_3$ saturated with water are not yet available. Since the binding sites of the spherands cannot be solvated for steric reasons, we expect solvent effects to be somewhat less important for this class of hosts than for the others.

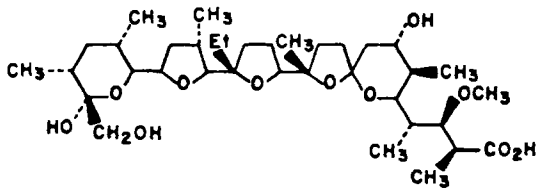
D_{4d} symmetry

Fig. 15. Fluorine analogues of spherands **1** and **9**.

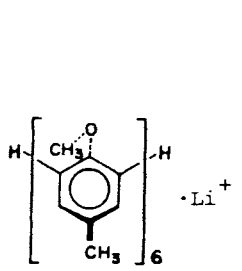
5.5. Highly Preorganized Nonbinding Systems



Spherand **1** is the strongest binder of Li^+ known, although its binding site is composed of the relatively weakly ligating anisole oxygens. The powerful binding of the ligand system is associated with its nearly perfect preorganization for binding. The question arises whether, by preorganization, the normally nonligating fluorobenzene might be made to ligate if six or eight of them are preorganized into a macroring analogously to **1** or **9** as in Figure 15. Accordingly, cavitands **43** and **44** were synthesized. Cavitand **43** is highly complementary in a geometric sense to Li^+, as is **44** to Cs^+. The crystal structure of **43** indicated it possessed the expected $\bar{3}$ (approximately D_{3d}) symmetry, with the fluorine atoms in an octahedral arrangement. The molecule has a roughly cylindrical cavity with a diameter of about 1.5 Å and a depth of ≈3.6 Å. However, the compound failed to complex Li^+.

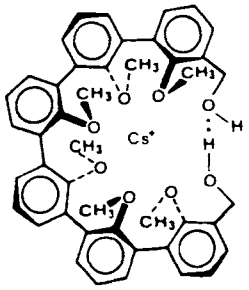
The ^{1}H-NMR spectrum of **44** at −15 °C indicated the compound to have D_{2d} symmetry, consistent with structure **44a**, rather than **44b**, which possesses D_{4d} symmetry. At 97 °C, **44a** and **44b** are in equilibrium, giving rise to an average signal. The compound turned out to be a nonbinder of Cs^+. Thus, the intrinsic ability of the fluorines of aryl fluorides to ligate the alkali-metal ions appears to be too low to be brought on scale by preorganization.

The volume of the cavity of **44a** was estimated to be about 60% of that of **44b**. We postulate that minimizing the volume of such systems provides some of the driving force for the dominance of **44a** at low temperature.

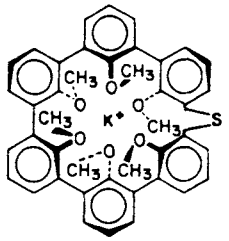


5.6. Partially Preorganized Podands

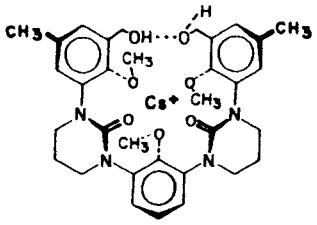
In a family of naturally occurring ionophores, rigid cyclic ether units are strung together in a chain terminated by hydrogen-bonding groups. When complexing, these chains wrap around the metal cations, their ends being held together by the hydrogen-bonded terminal functions. Monensin **45** is perhaps the most useful of these ionophores.



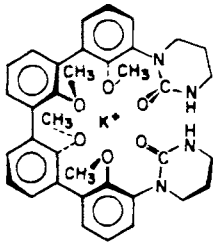
45



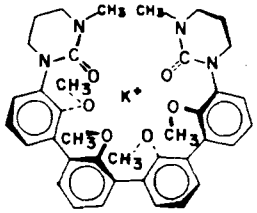
The question arises whether podands whose terminal groups can form hydrogen bonds to one another might preorganize themselves to form pseudomacrocycles having substantial binding potential. Although this possibility has not been systematically studied, the results of the few studies made thus far invite further investigation. In Figure 16 the structures of several podaplexes are shown, along with that of a hemispheraplex. The complex drawn in each case involves the alkali-metal ion that provides the maximum $-\Delta G^0$ value, which is listed in parentheses beneath each formula. A crystal structure of reference host **47** showed that the methyls of the two methoxyl groups flanking the sulfur are turned inward, effectively filling the cavity and reducing its preorganization for binding.



35·Li$^+$ (<6) [27]



46·Cs$^+$ (9.1) [27]



47·K$^+$ (10.1) [27]

48·Cs$^+$ (6.5) [25]

49·K$^+$ (8.3) [26]

50·K$^+$ (7.4) [26]

Fig. 16. The structures of podaplexes as pseudomacrocycles partially organized by hydrogen bonds between their terminal groups, along with the structures of model compounds. Their $-\Delta G^0$ values [kcal mol^{-1}] under standard conditions are listed in parentheses.

Podand **35** lacks terminal hydroxyl groups, and its $-\Delta G^0$ values for the alkali-metal ions were <6 kcal·mol^{-1} (Table 3). Podand **46** contains the same chain of six anisole groups but terminates in two CH_2OH groups. Molecular models indicate that these terminal groups can form hydrogen bonds to one another provided the methoxyl group possesses the alternate up-down conformational arrangement of **46**. Podand **46** binds Na^+, K^+, Rb^+, Cs^+, and NH_4^+ with $-\Delta G^0$ values that range from 6.2 to 9.1 kcal·mol^{-1}, the latter value being that of **46**·Cs^+. Model hemispherand **47** provides values for these same ions ranging from 7.3 to 10.1 kcal·mol^{-1}, the highest being that for **47**·K^+. We conclude that the CH_2OH groups terminating podand **46** substantially enhance the binding power of the system.[27] A less pronounced example of the same effect is observed with **48**, containing both anisole and cyclic urea units, whose $-\Delta G^0$ values for binding K^+, Rb^+, Cs^+, and NH_4^+ range from 5.8 to 6.5 kcal·mol^{-1}.[25]

Podand **49** is composed of four anisole units strung together and terminated at both ends with cyclic urea units each containing –CONH– moieties. The $-\Delta G^0$ values for the binding of the five alkali-metal ions and NH_4^+ to **49** range from 6.8 to 8.3 kcal·mol^{-1}. When the two NH groups are methylated as in **50**, these values drop to a range of 5.5–7.4 kcal·mol^{-1}. For both **49** and **50**, peak binding is reached with K^+. Thus, the hydrogen bonding possible with **49** but not with **50** is worth about 1 kcal·mol^{-1} in binding free energy.[26]

These meager results suggest that podands like their macrocyclic and bimacrocyclic counterparts are subject to design and are capable of providing substantial binding free energies. Central to such design is the limitation of the number of rotational degrees of freedom that must be frozen out during complexation. In other words, the principle of preorganization applies as well to podands as to other hosts.

6. Effect of Preorganization of Host on Specificity in Complexation

6.1. Specificity of Hosts in Binding Alkali-Metal Ions

This section is concerned with the connection between preorganization of hosts, their binding powers, and their selectivities (Fig. 17). The constants for distributing the five alkali-metal-ion picrate salts at 25 °C between D_2O and $CDCl_3$ differ from one another by factors of less than two for alkali-metal ions neighboring one another in the periodic table. The largest factor involving any of the five ions is only 3.8.[22] Thus, $K_a^A/K_a^{A'}$ ratios (K_a^A and $K_a^{A'}$ are association constants in $CDCl_3$ saturated with D_2O for complex formation involving alkali-metal ions A and A') provide a rough measure of ion selectivity in extraction, as well as in homogeneous media. The largest $K_a^A/K_a^{A'}$ values we have obtained for complexes at 25 °C in $CDCl_3$ saturated with water for neighboring alkali-metal ions are listed in Table 7. Interestingly, none of the hosts listed in Table 7 are either corands or podands.

Recall that when classes of hosts are arranged according to their states of preorganization for complexation, the sequence is spherands > cryptaspherands > cryptands > hemispherands > corands > podands. This same order is less rigidly followed when maximum ion selectivity is applied to the host classes, the sequence generally followed being spherands > cryptaspherands ~ cryptands > hemispherands > corands > podands. Thus the principle of preorganization is useful in designing both for selectivity and maximum binding power.

6.2. Effects of Small Structural Changes on Host Specificity

The question arises whether hosts can be designed which are strongly binding, but are indiscriminate in complexing a variety of guest cations. Hemispherand **11** exhibits $-\Delta G^0$ values in binding eight cations that range only from a low of 12.1 (for Li^+) to a high of 15.6 kcal·mol^{-1} (for K^+) (Fig. 18, Table 8). Furthermore, **11** binds $(CH_3)_3CNH_3^+$ ($-\Delta G^0 = 13.2$) almost as well as NH_4^+ ($-\Delta G^0 = 14.4$ kcal·mol^{-1}). Molecular model examination

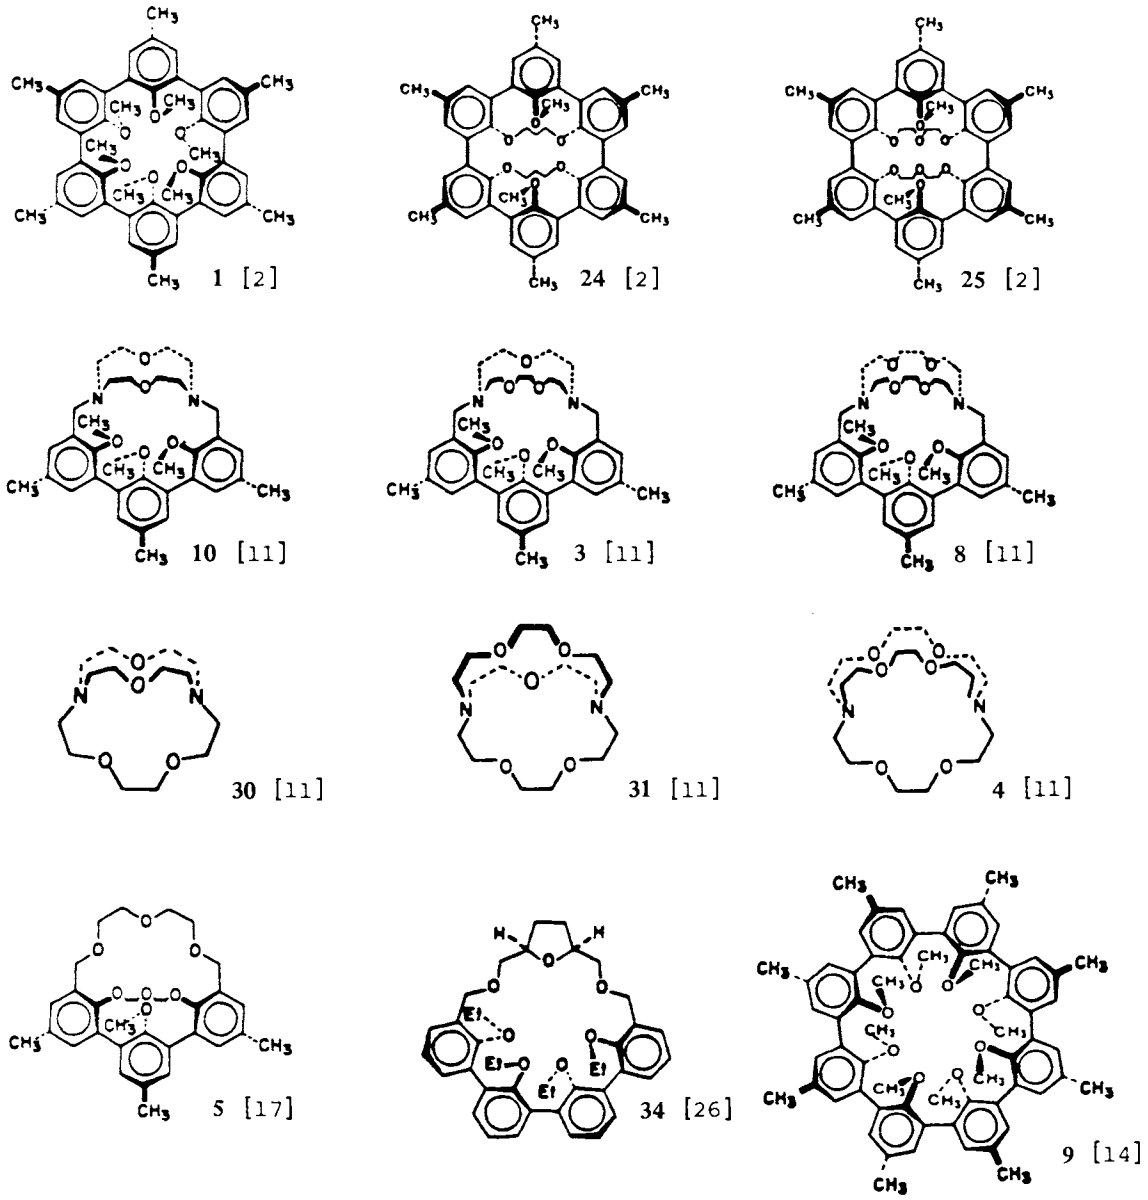


Fig. 17. Structures of selected hosts (cf. Table 7).

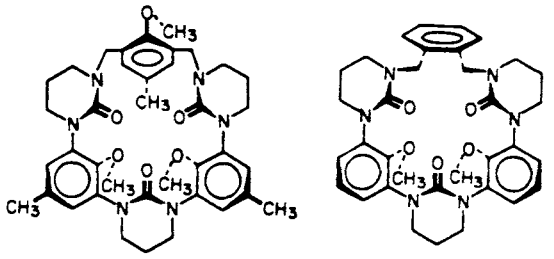

Table 7. Selectivity ($K_a^{\wedge}/K_a^{\wedge'}$) of selected hosts for pairs of alkali-metal picrates under standard conditions (cf. Fig. 17).

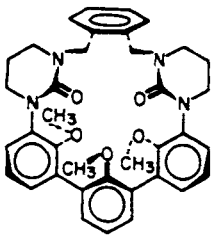
Host	**1**[2]		**24** [2]		**25** [2]	
Pair	Li^+/Na^+	Na^+/K^+	Li^+/Na^+	Na^+/K^+	Na^+/Li^+	Na^+/K^+
$K_a^{\wedge}/K_a^{\wedge'}$	>600	$>10^{10}$	360	$>10^5$	125	$>10^9$
Host	**10** [11]		**3** [11]		**8** [11]	
Pair	Na^+/K^+	Rb^+/Cs^+	Na^+/Li^+	Rb^+/Cs^+	Na^+/Li^+	K^+/Na^+
$K_a^{\wedge}/K_a^{\wedge'}$	13000	134	420000	900	440	11000
Host	**30** [11]		**31** [11]		**4** [11]	
Pair	Li^+/Na^+	Na^+/K^+	Na^+/Li^+	K^+/Rb^+	K^+/Na^+	Rb^+/Cs^+
$K_a^{\wedge}/K_a^{\wedge'}$	4800 [a]	260000 [a]	440000	81	440	58000
Host	**5** [17]		**34** [26]		**9** [14]	
Pair	Na^+/Li^+	K^+/Rb^+	K^+/Na^+	Rb^+/Cs^+	Rb^+/K^+	Cs^+/Rb^+
$K_a^{\wedge}/K_a^{\wedge'}$	9500	34	2000	5	14	370

[a] In propylene carbonate as solvent, which gives similar values to those in $CDCl_3$ [34].



of **11** indicates the macroring is large enough (20-membered) to provide a high degree of conformational flexibility with respect to oxygen placement and cavity diameter. As the diameter of the guest decreases, the diameter of the cavity becomes complementary by the anisole and cyclic urea units decreasing their dihedral angles with respect to one another, which shrinks the distance between their attached oxygens.

Hosts **2** and **51** exhibit much higher structural recognition in their complexation. The $-\Delta G^0$ values of **2** range from 18.3 (for Li^+) to 11.4 kcal·mol^{-1} (for Rb^+). Those of **51** are 16.6 (for Li^+) and 7.8 kcal·mol^{-1} (for $(CH_3)_3CNH_3^+$). Macrocycles **2** and **51** are 19-membered, and must accommodate the structural requirements of the rigid *ortho*-xylyl unit. Both show high structural recognition favoring the smaller ions. Thus the K_a ratio for **2** · Li^+ vs. **2** · Na^+ is 290 and for **2** · Na^+ vs. **2** · K^+ it is 725. The K_a ratio for **51** · Na^+ vs. **51** · K^+ is 2300. Molecular models

11 [16]

2 [16]

51 [16]

Fig. 18. Structures of selected hosts (cf. Table 8).

Table 8. Binding free energies ($-\Delta G^0$ [kcal·mol^{-1}]) for similar hosts of varying states of preorganization under standard conditions. The cations were present as picrates (cf. Fig. 18).

Guest \ Host	11	2	51
Li^+	12.1	18.3	16.6
Na^+	15.4	16.3	15.4
K^+	15.6	12.4	10.8
Rb^+	14.2	11.4	9.4
Cs^+	13.1	11.8	10.5
NH_4^+	14.4	11.8	10.4
$CH_3NH_3^+$	14.4	12.1	9.7
$(CH_3)_3CNH_3^+$	13.2	13.2	7.8

of **2** and **51** are rigidly preorganized for binding with a much lower degree of conformational flexibility with regard to oxygen placement than host **11**. The average binding powers of **11** and **2** are about the same. In contrast to the five oxygens of **2**, host **11** has a sixth oxygen available for either direct ligation of the guest or for hydrogen bonding a water that ligates the guest. Thus **2** makes up in preorganization what it lacks in number of ligands, and in so doing gains in specificity.[16]

7. Summary and Outlook

This article summarizes and rationalizes the structure-complexation free-energy relationships involving oxygens or amine nitrogens ligating alkali-metal, ammonium, or alkylammonium ions. The host structures are rich in alkoxyaryl, cyclic urea, pyridyl, *ortho*- and *meta*-phenylene, *ortho*- and *meta*-xylene, dimethylene, and trimethylene units. The design of hosts and their complexes was accomplished through CPK molecular model examination, and many of their structures were confirmed through crystal structure, NMR spectra, and correlations between structure and free energies of complexation.

The hosts and their complexes were designed and their free energies of complexation were measured to test the principles of complementarity and preorganization. The structure-binding relationships that were obtained are interpreted in terms of these two principles. Application of these principles to host design has led to high structural recognition factors for most of the alkali-metal ions adjacent to one another in the periodic table. These factors range from a high of $>10^{10}$ for Na^+/K^+ to a low of 15 for K^+/Rb^+. The free energies of binding the alkali-metal ions vary from >23 to <6 kcal·mol^{-1}, depending on the degree of preorganization of the host.

The importance of Li^+, Na^+, and K^+ to biological processes, the susceptibility of Rb^+ and Cs^+ to neutron activation, and the possible use of $^6Li^+$ as a fusion fuel combine to generate increasing interest in hosts that differentially bind these ions. High selectivity factors for Li^+, Na^+, and K^+ are particularly important to analytical methods for measuring concentrations of these ions in serum and urine. The wide distribution of NaCl in the environment and its ability to harm circuit boards of computers and increase corrosion rates makes sensitive and simple methods for its detection important.

The opportunities for fruitful research in the host-guest complexation field are boundless. Preorganized hosts that complex specifically all of the ions of the periodic table remain to be synthesized and tested. The use in hosts of highly preorganized assemblies of cyano, isocyano, amido, oxo, ester, carboxy, nitro, sulfide, sulfoxide, sulfone, sulfimide, sulfodiimide, pyridine oxide, phosphane oxide, and heterocyclic groups invites systematic investigation. Uranium and gold remain to be extracted by practical methods from sea water. The actinoides and lanthanoides, as well as certain isotopes, even might be separated by complexation.

The complexation of organic guests further excites the imagination. Racemic amino acids and their ester salts have already been resolved into their enantiomers by extraction involving complex formation with chiral hosts.[37,38] A variety of other organic guests, e.g., carbohydrates and fats, remain to be complexed. Particularly challenging are the possibilities of designing and preparing hosts that catalyze organic reactions through complexation and preorganization.[39,40]

We warmly acknowledge the skill and scholarship of my co-workers who helped to develop this field. Support for the research on systems dominated by the binding of alkali-metal ions by anisole groups was generously provided by the Division of Basic Sciences of the Department of Energy, and on the cyclic urea systems by the National Science Foundation and the United States Public Health Service. We heartily thank Drs. K. N. Trueblood, C. B. Knobler, E. Maverick, and I. Goldberg for the many crystal structure determinations, and Mrs. June Hendrix for the artwork.

Biochemistry of Oxidative Stress

By Helmut Sies

As a normal attribute of aerobic life, structural damage to organic compounds of a wide variety (DNA, proteins, carbohydrates and lipids) may occur as a consequence of oxidative reactions. Oxidative damage inflicted by reactive oxygen species has been called "oxidative stress". Biological systems contain powerful enzymatic and nonenzymatic antioxidant systems, and oxidative stress denotes a shift in the prooxidant/antioxidant balance in favor of the former. Diverse biological processes such as inflammation, carcinogenesis, ageing, radiation damage and photobiological effects appear to involve reactive oxygen species. This field of research provides new perspectives in biochemical pharmacology, toxicology, radiation biochemistry as well as pathophysiology.

1. Introduction

This review article is concerned with oxidative damage in biological systems. First of all, the nature of the damage to organic compounds will be discussed. It will then be shown that, despite being variable in terms of the different kinds of compound afflicted, oxidative damage is ultimately exerted only by a small number of different reactive oxygen species. Finally, some new aspects of defense and repair in biological systems will be presented, i.e. antioxidants *sensu stricto* as well as in a more general sense.

One-electron reduction of oxygen was widely studied early this century (see *Warburg*[1] and *Battelli* and *Stern*[2]). *Michaelis*[3] pointed out that one-electron steps of oxygen reduction, leading to intermediate radical formation, may be of general importance in biological chemistry. These radical forms of oxygen are $O_2^{\ominus\cdot}$ and $O^{\ominus\cdot}$ and their protonated forms, $HO_2^{\cdot}$ and $HO^{\cdot}$. The perhydroxyl radical $HO_2^{\cdot}$ and the hydroxyl radical $HO^{\cdot}$ were recognized by *Haber* and *Weiss*[4] in their study on the iron salt-catalyzed decomposition of H_2O_2 as being important in chemical, photochemical and electrochemical processes. Biological research on the superoxide anion radical $O_2^{\ominus\cdot}$ received exceptional stimulus after the discovery of superoxide dismutase by *McCord* and *Fridovich*.[5]

Other reactive species of oxygen are of a nonradical nature. Hydrogen peroxide (H_2O_2) as the two-electron reduction state became important in the development of enzymology after the discovery of catalase Compound I by *Chance*.[6] Further, the electronically excited states of oxygen such as singlet molecular oxygen or excited carbonyls are also worthy of note. *Kautsky*[7] realized quite early on the potentially important role of a "metastable active oxygen species" (singlet oxygen), while *Schenck*[8a] and Gollnick[8b] made important fundamental contributions to the photochemistry of photooxygenation reactions. *Foote*[9] identified the role of singlet oxygen in photooxygenation.

In recent years, much interest has been focused on the biochemistry of oxygen activation and on the biological significance of the reactive oxygen species.[10–14] More recent developments can be found in Refs. [15–20].

2. Oxidative Damage to Nucleic Acids

2.1. Causes and Effects

Oxidative damage to DNA can be initiated by ionizing radiation or photooxidation (UV light; visible light in the presence of photosensitizers), hydroperoxides, oxygen radicals or various other oxidizing agents. The nature of the damage is often complex. For example, a variety of radicals can be formed upon γ-irradiation of DNA, but only the radical **1** with a free electron on C-4 leads to strand breaks under anoxic conditions[21] (Fig. 1). In the presence of oxygen, the radical-mediated strand scission is more complex and proceeds via peroxy radicals of the bases and sugars. Base alteration has been studied most intensively with thymine and guanine. Thymine glycol **2** (Fig. 2) or 5-(hydroxymethyl)uracil are formed from thymine (cf. [23]). The base most readily lost upon γ-irradiation or photooxidation is guanine; some proposed reaction products are shown in Figure 3. Adenine and cytosine, on the other hand, appear to be more stable towards oxidation. Thymine dimers (Fig. 4) are also formed, and the chemical adducts upon reaction with epoxides, for example, usually involve guanine as shown for the adduct with aflatoxin epoxide (Fig. 5).

Strand scission by ionizing radiation is thought to be due to the hydroxyl radical (see [21, 22]). Likewise, the strand scission observed with superoxide is due to the hydroxyl radical formed from it.[26] However, in addition to this low-molecular weight molecule, other reactive species might be of interest; for example, the hydroperoxide of linoleic acid, 13-hydroperoxylinoleic acid, was found to cause the breakage of double-stranded DNA.[27] The breakage site was specific for guanine. The ultimate chemical agent interacting with the DNA, however, was not identified. Possibly a hydroxyl radical is generated from the hydroperoxide via homolytic scission, as has recently been found in the case of hydrogen peroxide.[28]

The damage to DNA (and possibly also to nucleoproteins) by ionizing radiation and by free radical oxidation also leads to chromosome damage. This is manifested by chromosome breaks and can be assayed by chromosome and chromatid aberrations. Chromosome breaks are particularly prevalent in diseases such as Bloom's syndrome,[29]

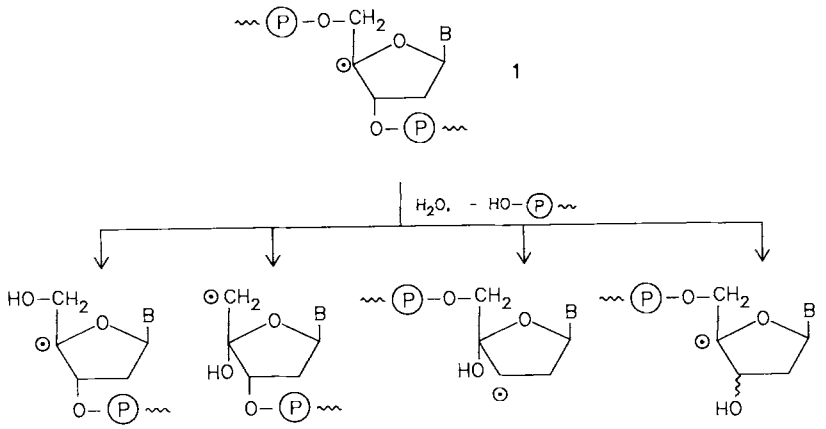

Fig. 1. Hydrolysis of the C-4'-radical **1** in DNA to yield strand breaks (anaerobic). The situation is more complex under aerobic conditions (modified after [21]).

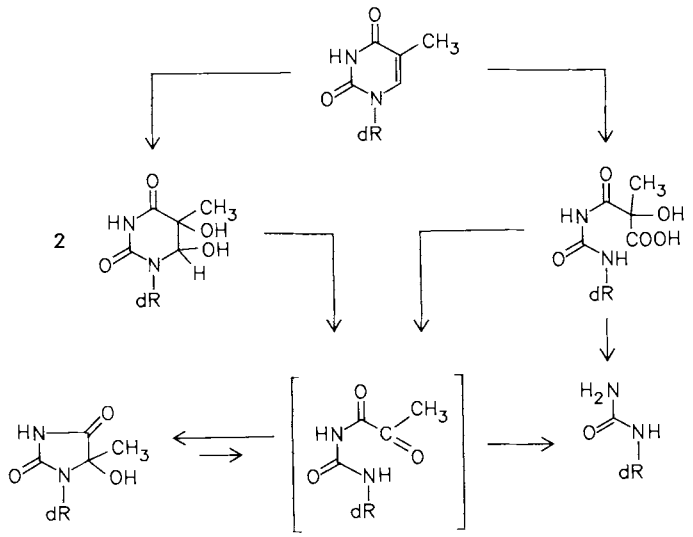

Fig. 2. Oxidative degradation of thymine residues in DNA. In addition to thymine glycol **2**, 5-hydroxymethyl uracil may also be formed (after [24]).

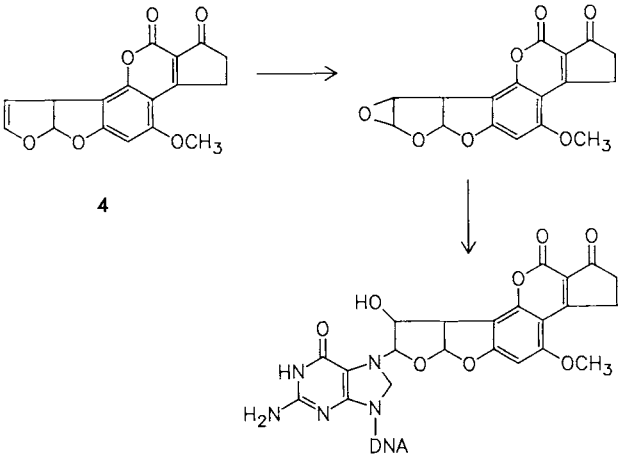

Fig. 5. Formation of the N-7 guanyl adduct of aflatoxin B_1 **4** from the 2,3-epoxide.

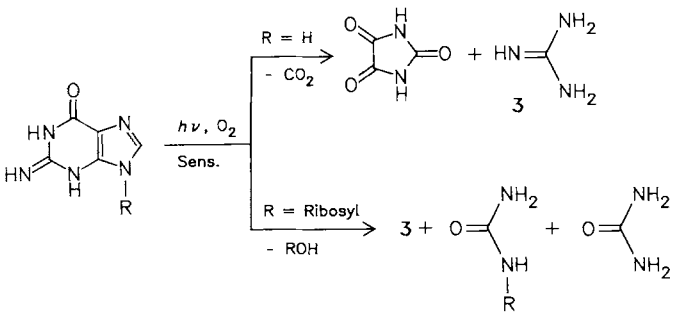

Fig. 3. Scheme for the oxidative degradation of guanine by photooxygenation. Sens. = sensitizer (after [25]).

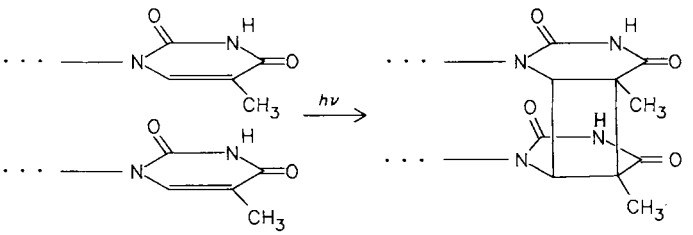

Fig. 4. Adjacent thymine residues in DNA can join upon irradiation to form a cyclobutylthymine dimer (sugar and phosphate residues omitted).

lupus erythematosus[30] or Fanconi's anemia.[31] Superoxide dismutase has an anticlastogenic (anti-chromosome-break) effect.[32] It is assumed that double-strand breaks of DNA are the initial lesion leading to chromosome breaks. The exact mechanism of chromosome breakage is not yet known.

2.2. Repair

Oxidized bases and strand breaks can be repaired enzymatically. It should be noted that oxidative damage is just one way of altering DNA; further routes of damage include errors in replication by recombination to produce mismatches, or by other ways of chemical alteration such as deamination. It has been estimated that the DNA of a mammalian cell probably loses 5000–10000 purine and 200–500 pyrimidine residues per 20 h generation time.[34] Nucleases involved in DNA repair have been shown to operate in several ways:[35,36] examples include nucleotide excision repair, base excision repair, recombinational repair, mismatch repair and error-prone repair. A given thymine glycol residue in DNA (cf. **2** in Fig. 2) may either be released as thymine glycol by a specific glycosylase, or it

may be released as thymidine glycol by an excision exonuclease (Fig. 6). These bases can be traced in the urine and have potential value for the screening of oxidative damage in man.[37] A similar pair of metabolites are 5-(hydroxymethyl)uracil and 5-(hydroxymethyl)-2′-deoxyuridine; a 5-hydroxymethyluracil glycosylase has recently been described.[38]

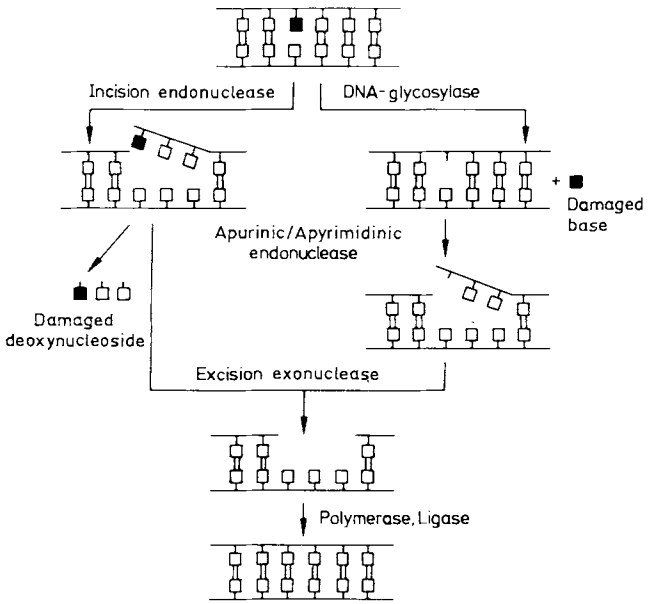

Fig. 6. Two pathways of excision repair. The left sequence is known as nucleotide excision repair, whereas the right sequence is base excision-repair (modified after [35]).

The intrastrand thymidine dimers that form as the predominant lesion in UV-irradiated DNA (Fig. 4) cannot only be repaired by the dimer-specific endonuclease, followed by DNA polymerase,[39] but also by a light-dependent repair reaction. This photoreactivation is catalyzed by a flavoenzyme.[40]

3. Oxidative Damage to Amino Acids and Proteins

The oxidation of amino acid side-chains in proteins has recently been recognized as being a potentially important signal in biological systems. The reversible oxidation-reduction of thiol groups is intimately linked to oxidative stress in a number of respects (see Sections 3.1, 3.4, and 3.5). Other types of oxidation of reactive groups are also reversible; for example, the oxidation of methionine to methionine sulfoxide and its enzymatic reduction back to methionine.[41] However, irreversible oxidative damage to amino acids may also occur; for instance, the ring cleavage in histidine or in tryptophan (see Fig. 7).

3.1. Methionine

Methionine can be oxidized by $HO^{\odot}$, $^1O_2$ or H_2O_2 to the sulfoxide and then further to the sulfone. This reaction sequence has now been established as an interesting metabolic signal.[42] Table 1 contains a list of enzymes in which a specific methionine residue has been shown to be oxidized. Oxidation to the sulfoxide can be associated with loss of function. A particularly striking example is that of α_1-antitrypsin. Oxidation of methionine-358 at the active site results in a dramatic decrease in inhibitory activity toward elastase.[43] This loss of control of elastase is thought to be responsible for the development of pulmonary emphysema.[44] Indeed, the development of emphysema can be limited by the intravenous injection of α_1-antitrypsin.[45] It is of interest to note that recently the problem of oxidative inactivation has been circumvented by producing an α_1-antitrypsin with valine at position 358 instead of methionine. This was achieved by site-directed mutagenesis and recombinant DNA techniques,[46] thus providing further evidence that critically targeted methionine oxidation

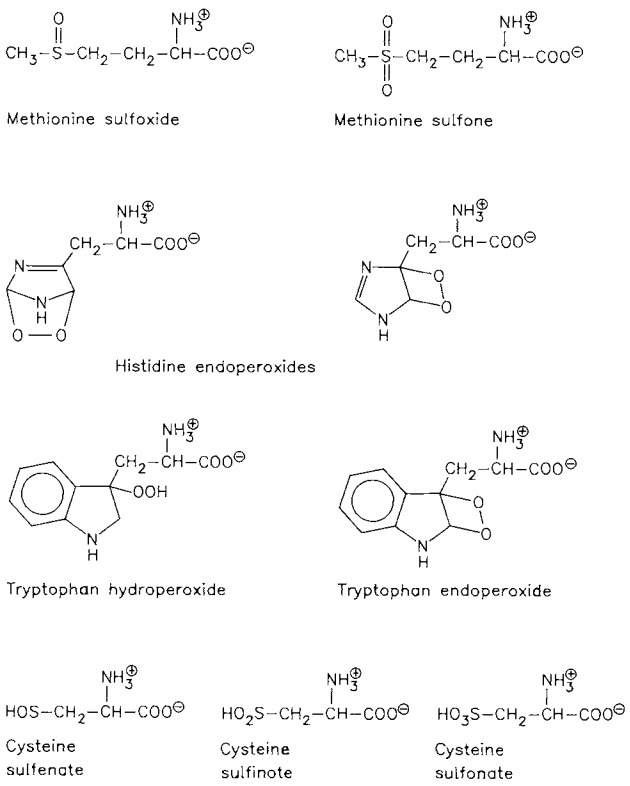

Fig. 7. End products or intermediates of the oxidative breakdown of some amino acids of biological interest.

Table 1. Some Proteins and peptides affected by oxidation.

Oxidized amino acid	Protein or peptide	Ref.
Methionine	Ribosomal protein L 12 (*E. coli*)	[42]
	Lysozyme	
	Pepsin	
	Ribonuclease	
	Phosphoglucomutase	
	α_1-Proteinase inhibitor

	Chemotactic factors	
	fMet-Leu-Phe	
	Complement C5A	
	α_1-Antitrypsin	[43]
Histidine	Glutamine synthetase (*E. coli*)	[48, 49]

is biologically significant. The mechanism of inactivation of the human α_1-proteinase inhibitor by gas-phase cigarette smoke has been investigated (for mechanism, see Ref. [47]).

3.2. Histidine

Histidyl residues in proteins can play a role similar to that described for methionine. The selective loss of one histidine residue from sixteen per subunit leads to the inactivation of glutamine synthetase from *E. coli*.[48,49] Several other enzymes of interest in cellular metabolism were also found to be inactivated upon exposure to oxidizing conditions, as established, for example, in a mixed-functional system consisting of NADPH, cytochrome P-450 reductase, and cytochrome P-450.[49] It has been discussed that this "marking" of the protein by histidine oxidation may serve for its recognition by proteases, thus serving a function in protein turnover.

The products of histidine oxidation have not yet been completely identified. Loss of histidine is accompanied by the introduction of a carbonyl group, detectable as a stable dinitrophenylhydrazone.[48] Singlet oxygen can lead to the products shown in Figure 7.[50]

3.3. Tryptophan, Lysine and Tyrosine

These amino acids are also subject to oxidation at appreciable rates, but no detailed study of their oxidation in proteins seems to have been carried out as yet. Dityrosine and isodityrosine are oxidation products of tyrosine.

3.4. Proline

Proline in proteins may constitute a preferential target for the hydrolysis of peptide bonds, yielding new *N*-terminal glutamate residues in the fragments[51] (Fig. 8). Collagen was found to be particularly susceptible to oxidative attack.[52]

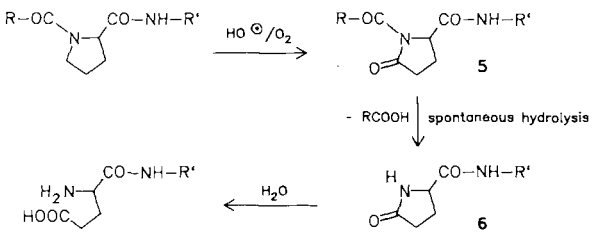

Fig. 8. Reaction scheme for cleavage of proteins at proline residues as proposed in [51]. In a first complex step initiated by hydroxyl radicals, hydrogen abstraction occurs and, in presence of O_2, leads to a 2-pyrrolidone intermediate **5** via an organic peroxy radical. This then undergoes hydrolysis at the peptide bond. The resulting pyroglutamate **6** may hydrolyze to a new *N*-terminal glutamate.

3.5. Cysteine

Although the formation of disulfide bonds as such cannot be considered as damage, because it is a reversible process, disulfide bridges in peptides and proteins may drastically alter biological functions. Alteration in the thiol/disulfide status, for example, has been found to lead to biological consequences,[53–57] including changes in enzyme properties (K_m or v_{max} effects) (see Table 2). Thus, the thiol redox status seems to serve as a metabolic signal. Intracellular proteins in general are predominantly present in the thiol form and have a low cysteine content (1.6%), whereas extracellular proteins (e.g. in blood plasma) are primarily disulfide proteins and have a high half-cystine content (4.1%).[58]

Table 2. Enzyme activities modified by thiol/disulfide exchange [55]. GSSG = disulfide of glutathione (GSH); cystamine = bis(2-aminoethyl) disulfide; DTNB = bis(3-carboxy-4-nitrophenyl) disulfide (dithionitrobenzoate).

Enzyme	Activation by
Glucose 6-phosphate dehydrogenase	GSSG
Collagenase (Leukocytes)	GSSG
Acid phosphatase (Spinach)	GSSG
Fructose 1,6-diphosphatase	Cystamine
δ-Aminolaevulinate synthetase	GSSG
Enzyme	**Inhibition by**
Pyruvate kinase	GSSG
Phosphorylase phosphatase	GSSG
Phosphofructokinase	GSSG
Glycogen synthase D	GSSG
HMG-CoA-reductase	GSSG
Adenylate cyclase (brain)	GSSG
Ribonucleotide reductase (*E. coli*)	GSSG
Hexokinase	Tetraethylcystamine
Tyrosine aminotransferase	Cystine
PDH kinase	DTNB
Fatty acid synthetase	DTNB
γ-Glutamylcysteine synthetase	Cystamine
Papain, trypsin	Dimethyl disulfide

Also of interest is the reversible formation of mixed disulfides between proteins and low-molecular weight thiols, in particular glutathione (GSH). ProtSSG have been observed in the soluble cytoplasm as well as in membranes.[54–57] The *S*-thiolation of proteins in heart cells treated with diamide and *tert*-butyl hydroperoxide showed distinct patterns, notably proteins with molecular masses of 23, 42 and 97 kD.[59] The levels of protein-glutathione mixed disulfides are low, for example, about 20–30 nmol/g of liver.[60,61] When the GSSG levels were increased, the concentration of mixed disulfides also increased,[60–62] possibly catalyzed by thiol transferases.[63]

There are also mixed disulfides of glutathione and coenzyme A (CoASSG). The fluctuations in their concentration can be metabolically significant; during oxidative challenge with *tert*-butyl hydroperoxide, the cellular free CoASH pool can be decreased to such an extent that coenzyme A-dependent processes are blocked:[64,65]

$$\text{CoASH} + \text{GSSG} \rightleftharpoons \text{CoASSG} + \text{GSH}.$$

In isolated mitochondria, respiration and ATP synthesis with CoA-dependent substrates such as pyruvate or 2-oxoglutarate are abolished, whereas there is little effect, for example, with β-hydroxybutyrate or succinate as substrate.[65]

Thiol groups may be further oxidized to alkylthio radicals and subsequently add oxygen:

$$RS^{\odot} + O_2 \longrightarrow RSO_2^{\odot}$$

Further rearrangements and oxidation steps lead to sulfenic, sulfinic, and, finally, sulfonic acids (cf. Fig. 7). The latter are stable enough to be detectable in assays of enzymatic oxidation; for example, glutathione sulfonate was detected in the enzymatic oxidation of glutathione by xanthine oxidase[66] and horseradish peroxidase.[67]

Alkylthio radicals have been detected by ESR methods in horseradish peroxidase-catalyzed reactions in vitro,[68,69] but no information is as yet available on the metabolic generation of these radicals in cells. Oxidation products of disulfides such as cystine *S*-monoxide or cystine *SS*-dioxide can also be formed, and they possibly occur in keratin fibers.[70]

3.6. Damage to Proteins by γ-Irradiation or Free Radical Attack

In radiation biochemistry, interest has recently focused on reactions of the hydroxyl radical ($HO^{\odot}$) and the peroxyl radical ($ROO^{\odot}$) with proteins (see [70b, 71]). Inactivation of yeast alcohol dehydrogenase and the protection of the enzyme by antioxidants[71] or the fragmentation of bovine serum albumin into peptides[72,73] are examples of studies in this area. As mentioned above, fragmentation via hydroxyl radicals is thought to occur preferentially at proline residues; reaction with a peroxyl radical leads to a 2-pyrrolidone intermediate, hydrolysis of which yields a new *N*-terminal glutamate residue[51] (cf. Fig. 8).

4. Oxidative Damage to Carbohydrates

As mentioned in Section 2, deoxyribose is prone to oxidative degradation. This property has even been exploited for the development of an assay of the formation of free-radicals. In the thiobarbiturate assay, deoxyribose yields a degradation product that is almost identical to the product obtained with malondialdehyde.[74]

Polysaccharides such as hyaluronic acid can be degraded by oxidative attack; superoxide dismutase was found to be capable of protecting hyaluronic acid against depolymerization in synovial fluid.[75,76] Proteoglycans may be subject to oxidative breakdown in a similar manner.[76]

5. Oxidative Damage to Lipids

5.1. Causes and Effects

Polyunsaturated fatty acids have become a central area of interest in the chemistry and biochemistry of oxidative reactions. These fatty acids, largely present in phospholipids of biological membranes, can be released into the pool of free fatty acids via the action of phospholipase A_2 before or after oxidative attack (Fig. 9). It is possible that oxidation before release from the phospholipid may serve as a marker for the phospholipase.

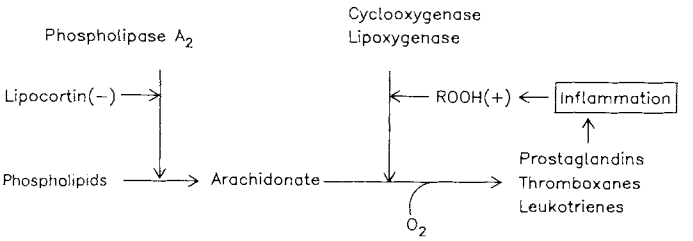

Fig. 9. Scheme of release of arachidonate from phospholipids and of eicosanoid formation. The inhibition of phospholipase A_2 by lipocortin, the inhibitory peptide inducible by glucocorticoids (see [77]) and the positive effect of organic hydroperoxides on cyclooxygenase [78] and lipoxygenase ("peroxide tone") are indicated.

The specific enzymatic oxidation of polyunsaturated fatty acids should not be considered as a damaging event, since it leads to a realm of extremely potent and biologically important signal compounds. The products of this specific oxidation are prostaglandins, thromboxane A_2, prostacyclin, and the leukotrienes (see [79]). Unspecific oxidation of polyunsaturated fatty acids is known as lipid peroxidation, a radical-mediated pathway (Fig. 10) leading to a number of stable degradation products (Table 3). The product pattern depends essentially on the nature of the initial fatty acid involved; for example, pentane is gener-

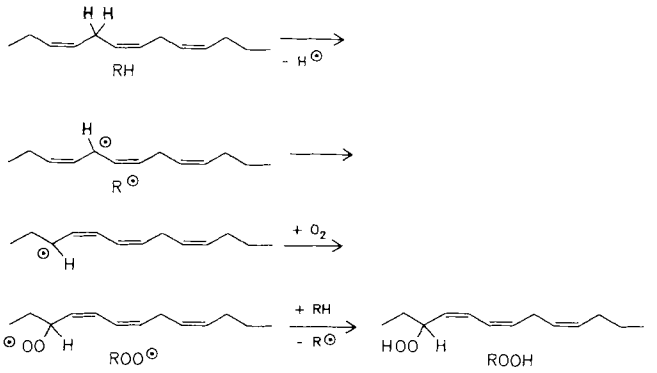

Fig. 10. Initial steps of lipid peroxidation, schematic for an unsaturated *n*-alkane (RH): H abstraction, diene conjugation, oxidation and reaction with RH (after [80]).

Table 3. Products of lipid peroxidation [81].

Chain cleavage and recurrent oxidation products:

Alkanes, alkenes, *n*-alkanals, 2-alkenals, 2,4-alkadienals, alkatrienals, hydroxyaldehydes, hydroperoxyaldehydes, 4-hydroxyalkenals, 4-hydroperoxyalkenals, malonaldehyde, dicarbonyl compounds, saturated and unsaturated ketones

Rearrangement and consecutive products:

Hydroxy acids, keto acids, ketohydroxy acids, epoxyhydroxy acids, dihydroxy acids, ketodihydroxy acids, trihydroxy acids

Further peroxidation products:

Cycloendoperoxides (prostaglandin G_2) and analogous compounds

Dimers and polymers

Dimers and polymers linked by –O–, –O–O–, –C–C– bridges

ated from an ω-6-polyunsaturated fatty acid, and ethane from an ω-3-polyunsaturated fatty acid. The chemistry of lipid peroxidation is complex, and will not be discussed here in detail (see Ref. [82]).

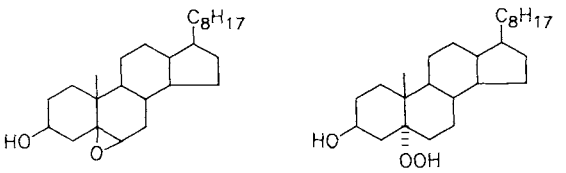

Fig. 11. Oxidation products of cholesterol: 5,6-epoxide and 5α-hydroperoxide.

The oxidation of cholesterol is of special biological interest, yielding a 5,6-epoxide and, in addition, the 5α-hydroperoxide (Fig. 11). This cholesterol epoxide occurs in high concentrations in human breast fluid[83] and has been identified as a directly acting mutagen.[84]

5.2. Atherogenesis

It has been suggested that lipid peroxidation is involved in the development of atherosclerotic lesions. It was found that modified forms of human low-density lipoprotein (LDL) cause an accumulation of large amounts of cholesterol esters in macrophages, e.g. after treatment of LDL with malonaldehyde.[85] 4-Hydroxynonenal is also capable of modifying LDL, and the concentrations required are one hundred to one thousand fold less than with malonaldehyde.[86] In addition to the enhanced accumulation of cholesterol esters, the binding of modified LDL to macrophages also leads to an increased release of a number of lysosomal enzymes.[87a] The molecular basis of modification of LDL by endothelial cells that leads to its enhanced uptake by macrophages remains to be defined.[87b]

6. Reactive Oxygen Species

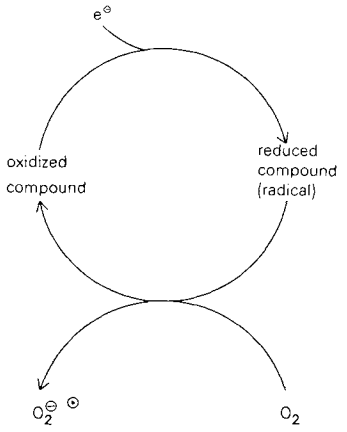
The reactive oxygen species involved in biological systems are listed in Table 4. Most of them are free radicals; the term oxygen-free radicals is used more or less synonymously with reactive or aggressive oxygen species. However, it should be noted that ground state (triplet) molecular oxygen as a diradical is much less reactive than molecular oxygen in the excited state ($^1\Delta_gO_2$ abbrev. $^1O_2$). This singlet oxygen is diamagnetic and not of a radical nature.[88] Thus, non-radical excited states of molecular oxygen and of oxygen in organic compounds, e.g. in excited carbonyl compounds and dioxetanes,[89] as well as ozone fall into the category of reactive oxygen species of biological interest. The kinetic constants of the reactions of $HO_2^{\ominus}/O_2^{\ominus\ominus}$ with more than 300 organic and inorganic compounds in aqueous solution have recently been compiled.[90]

These reactive oxygen species are formed via several pathways, enzymatic and nonenzymatic. One-electron reduction, initially leading to the formation of the superoxide anion radical $O_2^{\ominus\ominus}$, is a major source (Table 5). Direct two-electron reduction generates hydrogen peroxide; an example for this is given by the fatty acyl-CoA oxidase in the peroxisome. The formation of the hydroxyl radical may occur directly through radiolysis of water, and also via the Fenton reaction:

$$Fe^{2\oplus} + H_2O_2 \longrightarrow Fe^{3\oplus} + OH^{\ominus} + OH^{\ominus}$$

The sources of the radical $O_2^{\ominus\ominus}$ produced via one-electron reduction of molecular dioxygen in the cell include the mitochondrial and microsomal respiratory chains as well as the bactericidal activity of leukocytes and macrophages. The physiological importance of the cellular

Table 4. Reactive oxygen species of interest in oxidative stress.



Species	Name	Remarks
$O_2^{\ominus\ominus}$	Superoxide or hyperoxide	One-electron reduction state, formed in many autoxidation reactions (e.g. flavoproteins; redox cycling)
$HO_2^{\ominus}$	Perhydroxyl	Protonated form of $O_2^{\ominus\ominus}$, more lipid-soluble
H_2O_2	Hydrogen peroxide	Two-electron reduction state, formed from $O_2^{\ominus\ominus}$ ($HO_2^{\ominus}$) by dismutation, or directly from O_2
$HO^{\ominus}$	Hydroxyl	Three-electron reduction state, formed by Fenton reaction, metal(iron)-catalyzed Haber-Weiss reaction; highly reactive
$RO^{\ominus}$	R–oxyl, e.g. alkoxyl	Oxygen-centered organic (e.g. lipid) radical
$ROO^{\ominus}$	R–dioxyl, e.g. alkoxydioxyl	Formally formed from organic (e.g. lipid) hydroperoxide, ROOH, by hydrogen abstraction
ROOH	R–hydroperoxide	Organic hydroperoxide (e.g. lipid-, thymine-OOH)
$^1\Delta_gO_2$ (also O_2^* or $^1O_2$)	Singlet molecular oxygen	First excited state, 22 kcal/mol above ground state (triplet) $^3O_2$; red (dimol) or infrared (monomol) photoemission
^{3}R′R″CO (also R′R″CO*)	Triplet carbonyl	Excited carbonyl compound, blue-green photoemission (e.g., formed via dioxetane as intermediate)

sources is difficult to assess in a general fashion; they could contribute to a large extent in maintaining the cellular steady state concentration of the $O_2^{\ominus\cdot}$ radical. Autoxidation reactions such as redox cycling (Fig. 12) are certainly also growing in importance for explaining the oxidative stress caused by several xenobiotics; these include compounds such as quinones, which are used in cancer chemotherapy.[91]

The steady-state *oxygen concentration* is of particular importance. At low O_2 partial pressure, in the area of hypoxia, there is an optimum for damage by lipid peroxidation, since reductive steps such as the transfer of electrons in redox cycling (Fig. 12) or the reduction of haloalkanes by cytochrome P-450 occur simultaneously with O_2-dependent steps of lipid peroxidation (Figs. 10 and 13).[91] For example, the optimum O_2 partial pressure was found to be 2 mm Hg for liver microsomal lipid peroxidation by CCl_4 or halothane ($CF_3CHBrCl$) using an oxystat system.[91b]

Reoctive oxygen species
H_2O_2, $OH^{\cdot}$, $ROO^{\cdot}$, $RO^{\cdot}$, $^1O_2$

Fig. 12. Scheme of redox cycling. The superoxide anion radical, $O_2^{\ominus\cdot}$, is generated under aerobic conditions, driven by electrons coming from NADPH as catalyzed by various reductases.

It is of interest to note that reactive oxygen intermediates often seem to be metabolized according to the principle of dismutation (Table 6). Not only the one-electron reduction state is eliminated in a disproportionation reaction, but also two-electron reduction products. Whereas the dismutation of $O_2^{\ominus\cdot}$ and of H_2O_2 by superoxide dismutase and catalase, respectively, yield ground-state triplet oxygen, the dismutation of prostaglandin G_2 or of organic hydroperoxides as products of lipid peroxidation affords singlet molecular oxygen.

Table 6. "Dismutation reactions" of oxygen metabolites; PG = prostaglandin.

Reaction	Enzyme
$2\,O_2^{\ominus\cdot} + 2\,H^{\oplus} \longrightarrow H_2O_2 + O_2$	Superoxide dismutase
$2\,H_2O_2 \longrightarrow 2\,H_2O + O_2$	Catalase
$2\,PG\,G_2 \longrightarrow 2\,PG\,H_2 + {}^1O_2$	PG hydroperoxidase
$2\,ROOH \longrightarrow 2\,ROH + {}^1O_2$	Cytochrome P-450
$2\,PhI{=}O \longrightarrow 2\,PhI + {}^1O_2$	Cytochrome P-450

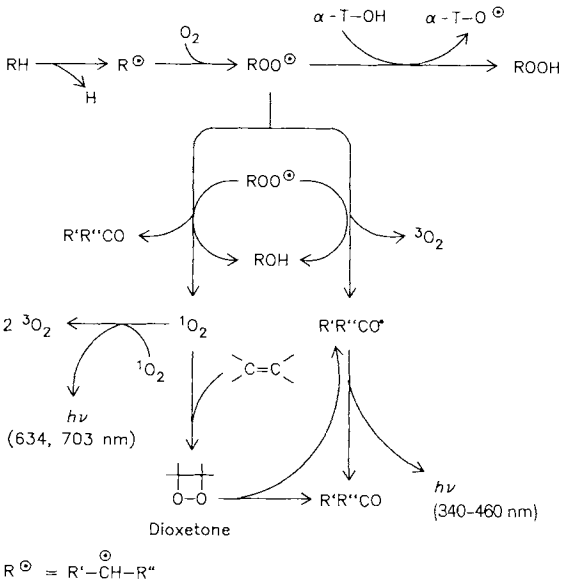

Fig. 13. Generation of excited oxygen (singlet oxygen; left-hand branch) or excited carbonyls R'R''CO* (triplet carbonyls; right-hand branch) from lipid peroxyl radicals, according to Russell's mechanism [92, 93]. α-T-OH signifies α-tocopherol (see Fig. 19).

Singlet oxygen is formed in biological systems (a) via photosensitization reactions, an appropriate sensitizer being electronically excited and then transferring energy to oxygen, and (b) via chemical excitation reactions. These latter pathways of singlet oxygen formation occur without activation by light, and are therefore also referred to as "photochemistry in the dark."[89]

In principle there are two pathways for the chemical excitation of oxygen. One proceeds via a radical-radical interaction[92,93] (Russell's mechanism) (see Fig. 13), the other via oxene transfer using heme iron (Fe^{3+}):[94]

$$(Fe^{3\oplus}) + ROOH \longrightarrow (Fe{=}O) + ROH$$

$$(Fe{=}O) + ROOH \longrightarrow (Fe^{3\oplus}) + ROH + {}^1O_2$$

$$2\,ROOH \longrightarrow 2\,ROH + {}^1O_2$$

Singlet oxygen may be of particular interest in biological systems, because it is capable of diffusing an appreciable distance in membranes. In stearate monolayers, the diffusion path for singlet oxygen for half-deactivation was estimated to be 115 Å (Fig. 14).[95] The formation of singlet oxygen in cellular systems has so far been demonstrated mainly by the detection of photoemission via the dimol reaction:

$${}^1O_2 + {}^1O_2 \longrightarrow 2\,{}^3O_2 + h\nu \quad (\lambda = 634\text{ nm}, 703\text{ nm}).$$

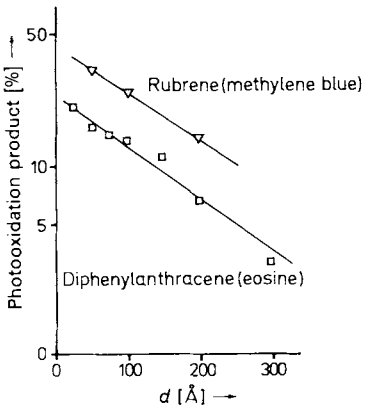

Fig. 14. Yield of photooxidation products in the reaction of rubrene and diphenylanthracene, respectively, in the presence of the sensitizers methylene blue and eosine. The photosensitizer was spaced by stearate monolayers of thickness d (after [95]).

Sensitive photon-counting equipment has made it possible to use this "low-level" chemiluminescence as an indicator of $^1O_2$ in intact cells and organs. The spectra as well as the enhancement of photoemission by diazabicyclooctane (DABCO) and the decrease of photoemission by azide indicate the occurrence of singlet oxygen in intact liver during the redox cycling of 2-methyl-1,4-naphthoquinone (menadione)[97] or 1,1'-dimethyl-4,4'-bipyridinium (paraquat).[98] Thus, singlet oxygen may be responsible for the toxic effects observed with these compounds. Menadione is mutagenic,[99] and singlet oxygen generated by microwave discharge has been shown to affect biologically active DNA, causing a loss of transforming activity in an assay system using the plasmid pBR 322.[100a] Similar results were obtained when $^1O_2$ was generated from a thermodissociable naphthalene endoperoxide.[100b]

In isolated enzymatic systems, the photoemission spectra resemble that of the H_2O_2/NaOCl reaction.[101] Two peaks near the 634-nm and 703-nm regions were observed with isolated ram seminal vesicle prostaglandin hydroperoxidase (cyclooxygenase)[94] (Fig. 15), or with cytochrome

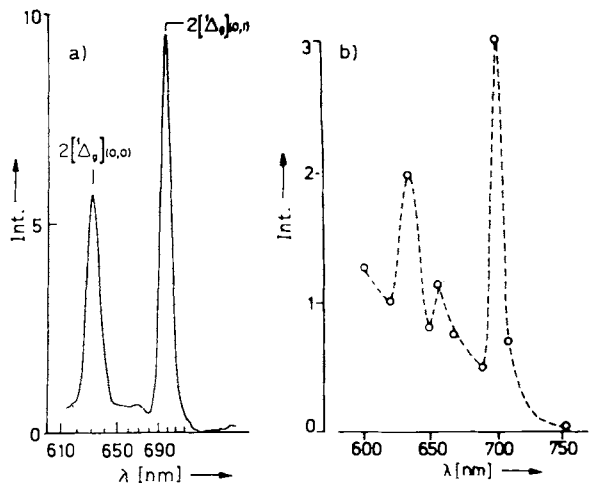

Fig. 15. Dimol emission spectrum of low-level chemiluminescence of singlet oxygen. Generation of $^1O_2$: a) in the hypochlorite-H_2O_2 reaction (after [101]); b) enzyme-catalyzed in the prostaglandin cyclooxygenase reaction (after [94]).

P-450 and iodosobenzene as substrate.[102] The monomol-photoemission of singlet oxygen occurs at $\lambda = 1270$ nm (in the IR). Recently, the lactoperoxidase reaction was shown to photoemit at $\lambda = 1270$ nm.[103]

7. Defense Against Oxidative Stress: Biochemical Antioxidants

The detoxication of reactive oxygen species is one of the prerequisites of aerobic life; the multiple lines of defense which have evolved form a veritable antioxidant defense system (Table 7). The repertoire to counteract the potentially hazardous reactions initiated by oxygen metabolites includes all levels of protection: prevention, interception, and repair. It comprises nonenzymatic scavengers and quenchers referred to under the term antioxidants in the more narrow sense, and also enzymatic systems.

Table 7. Anitoxidant defense in biological systems.

System	Remarks
Non-enzymatic	
α-Tocopherol (vitamin E)	Membrane-bound; receptors? Regeneration from chromanoxyl radical?
Ascorbic acid (vitamin C)	Water-soluble
Flavonoids	Plant antioxidants (rutin, quercetin, etc.)
Chemical antioxidants	Food additives, e.g. BHA (butylated hydroxyanisole), BHT (butylated hydroxytoluene) [a]
β-Carotene (vitamin A)	Singlet oxygen quencher
Uric acid	Singlet oxygen quencher, radical scavenger?
Plasma proteins	e.g., Coeruloplasmin
Enzymatic	
Superoxide dismutases	CuZn enzyme, Mn enzyme
GSH peroxidases	Selenoenzyme; non-Se enzyme; some GSH transferases, e.g., isoenzymes B and AA; cytosol and mitochondrial matrix
Catalase	Heme enzyme, predominantly in peroxisomal matrix
Ancillary enzymes	
NADPH-quinone oxidoreductase (DT-diaphorase)	Two-electron reduction, dicoumarol-sensitive
Epoxide hydrolase	
Conjugation enzymes	UDP-glucuronyl transferase Sulfotransferase GSH transferases
GSSG-reductase	
GSH synthesizing enzymes	
NADPH supply	Glucose 6-phosphate dehydrogenase 6-Phosphogluconate dehydrogenase Isocitrate dehydrogenases Malate enzyme Energy-linked transhydrogense
Transport systems	GSSG export Conjugate export
Semidehydroascorbate reductase	
Methionine sulfoxide reductase	
DNA repair enzymes	

[a] BHA = 2-*tert*-butyl-4-methoxyphenol; BTA = 2,6-di-*tert*-butyl-4-methylphenol (see **8** and **9** in Fig. 19).

7.1. Nonenzymatic Antioxidants

α-Tocopherol (vitamin E, cf. Fig. 19)[104] is the most important lipid-soluble antioxidant;[105] its unique function in

the membrane may be aided by the specific physicochemical interaction between the phytyl residue and the fatty acid residues of the polyunsaturated phospholipids in the membrane.[106] The proper insertion of the vitamin into the membrane increases its effectiveness by about 50-fold.[107]

Ascorbic acid (vitamin C), together with glutathione, is the important antioxidant in the aqueous phase. It can react with the vitamin E radical (chromanoxyl) and thus can regenerate tocopherol in the membrane. Further aspects of interest, e.g. in nutrition[109] (normal requirement: 12 mg of vitamin E and 75 mg of vitamin C per day[110]) cannot be discussed in detail here.

Further important antioxidants are listed in Table 7.

7.2. Enzymatic Antioxidants

The essential enzymes are the intensively studied *superoxide dismutases* and various hydroperoxidases such as *glutathione peroxidase, catalase,* and other hemoprotein peroxidases. They are characterized, in general, by high specific cellular content, by specific organ and subcellular localizations which often overlap in a complementary way, and by a specific form of metal involvement, especially of copper, manganese, iron (heme) and selenium, in the catalysis. These antioxidant systems have a wide distribution in nature, underscoring their importance for coping with the damaging effects of reactive oxygen metabolites in biological systems. Their distribution is crucial in target organ toxicity.[111] A comprehensive discussion of these central enzymes in antioxidant defense is beyond the scope of this article (see Refs. [13-20]). In the following, some more recent aspects of reactions involved more indirectly in antioxidant defense will be presented.

A novel protein which protects membranes from peroxidation and exhibits GSH peroxidase activity toward phosphatidylcholine hydroperoxides has been identified and characterized as a selenoenzyme.[112] Also new is a GSH-dependent heat-labile factor which inhibits lipid peroxidation in biological membranes.[113] Most recent findings indicate that this cytosolic protein is not one of the known GSH-dependent enzymes.[114a]

Some specific cell types may use extracellular GSH. The basolateral membrane of intestinal epithelial cells contains an $Na^{\oplus}$-dependent GSH uptake system, so that exogenous GSH protects these cells from oxidative injury.[114b] Most other cell types cannot utilize GSH as such, but have to synthesize their GSH intracellularly from the constituent amino acids.

It should be noted that a number of additional or ancillary systems are of crucial importance. For example, many of the radical or nonradical reactions in cells may lead to the oxidation of thiols to disulfides, i.e., the oxidation of glutathione (GSH) to form GSSG. Thus, the regenerative reaction of reduction to GSH as catalyzed by GSSG reductase can become pivotal in antioxidant defense. Naturally, the provision of reducing equivalents for this enzyme is also of importance. Thus, the NADPH regenerating systems (Table 7) are also of interest.

Diminution of the steady-state levels of reactive compounds capable of generating reactive oxygen species also results in a decreased expression of oxidative stress; in this respect, the two-electron reduction of quinones by NADPH:quinone oxidoreductase (DT diaphorase) and the subsequent conjugation reaction of the hydroquinone are part of the antioxidant defense.[97, 115]

Obviously, the export of reactive species in free or conjugated form also serves as a detoxication function, so that transport of conjugates as well as of GSSG from cells is of interest here. The binding of conjugates of glutathione to GSSG binding sites may have metabolic significance. It has been shown in kinetic and X-ray crystallographic studies that glutathione conjugates bind to the GSSG-binding site in the active center of GSSG reductase, causing inhibition of enzymatic activity[116] (Fig. 16). An increase in GSSG levels causes metabolic perturbations, including an inhibition of protein synthesis (see Ref. [53]).

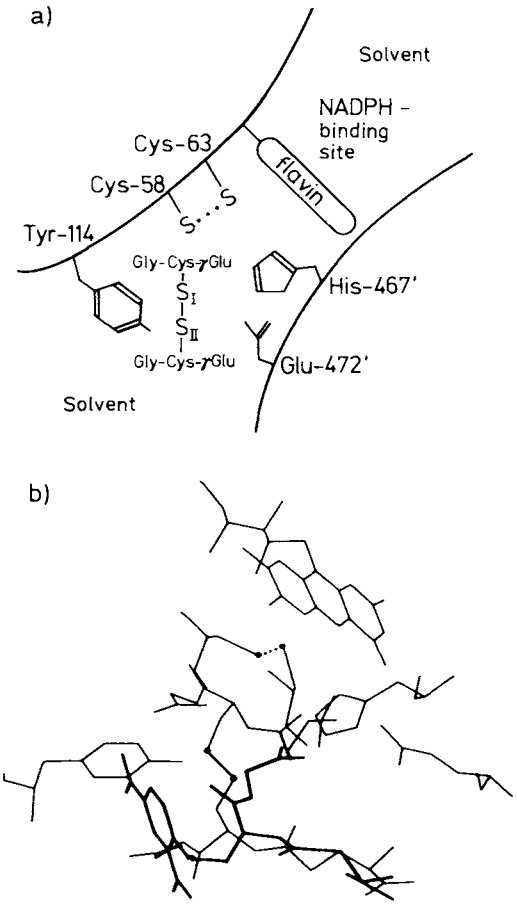

Fig. 16. a) GSSG binding site of glutathione reductase; b) the binding of *S*-(1,2-dinitrophenyl)glutathione (thick lines) at this site (after [116]).

The transport systems for GSSG and glutathione conjugates (thioethers) have been studied in some detail recently[117] (see Fig. 17). In liver, there is mutual competition of biliary export between these two types of glutathione derivatives,[118] indicating that the canalicular carrier system may accept both these substrates for transport. There appears to be a GSSG activatable ATPase in the hepatic plasma membrane.[119] Mutual competition for export of GSSG and GS-conjugates was also detected in the heart.[120] Using the creatine-kinase reaction as an indicator system, it was found that GSSG transport across the

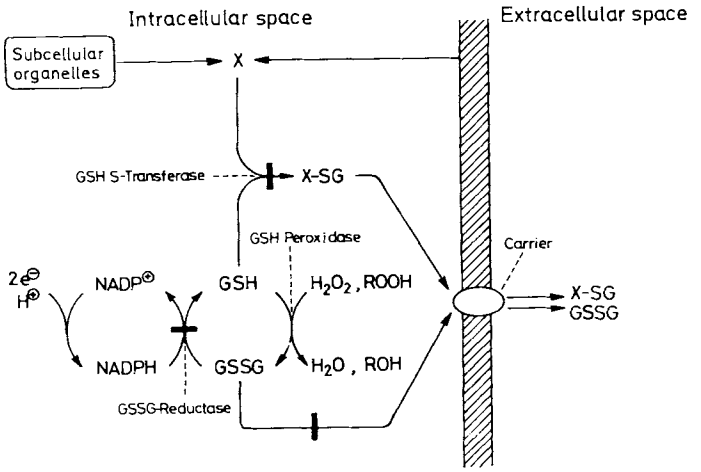

Fig. 17. Relations between GSH peroxidase and GSH transferase reactions. Glutathione disulfide (GSSG) and glutathione thioethers (X-SG) are exported from the cells, competing for transport. X-SGs inhibit GSSG reductase (after [120]).

cardiac plasma membrane was half-maximal at $(ATP/ADP)_{free}$ ratios of ≈ 10 in the intact perfused rat heart preparation.[121]

Interestingly, a prominent GSH transferase activity in the heart is isozyme 4-4, accepting 4-hydroxynonenal as a substrate[122] and, therefore, capable of detoxifying this biologically active product of lipid peroxidation.[123] Recently, another high-activity isozyme (8-8) was described.[122]

It should also be pointed out that some GSH transferase isozymes have the capacity to catalyze the GSH peroxidase reaction with organic hydroperoxides as substrate.[124] These non-selenium-dependent activities may become essential in states of selenium deficiency when the Se enzyme, GSH peroxidase, is very low in its cellular activity. However, since the GSH transferases do not accept H_2O_2 as substrate, there is no complete substitute for the selenoenzyme. This may explain why in Se-deficiency there can be overt clinical symptoms such as the cardiomyopathy known as Keshan disease.[125] This disease, which led to death in about one percent of the male population of school-age Chinese in the Keshan province, was found to be completely treatable by the oral application of 1 mg of sodium selenite per week.[125]

7.3. DNA Repair

Possibly the biologically most important line of defense for the organism consists in preserving the identity of the genetic material by repair after oxidative damage (cf. Fig. 6).[36] In addition, an equally important process for microorganisms is enzymatically controlled mutagenesis in order to ensure adaption to changing environmental conditions.

The repair system seems to be less sensitive to ionizing radiation than DNA. In yeast cells, the repair of single-strand breaks is dependent on the irradiation dose (up to high doses of 2400 Gy).[126] The repair enzymes are thus to be considered in a broad sense as a central component of the antioxidant enzymes for the cell.

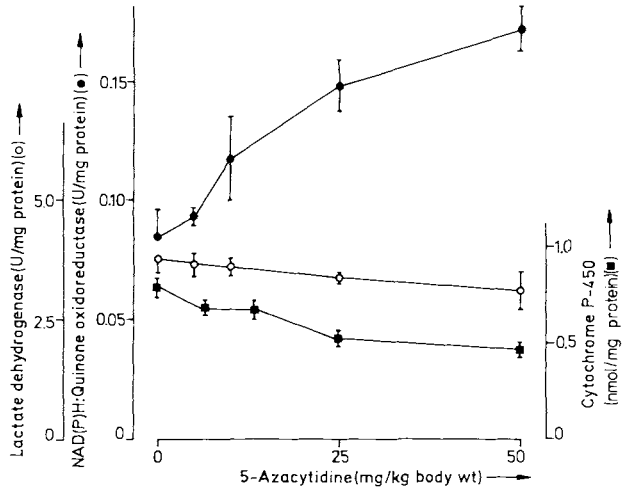
7.4. Control of the Antioxidant Capacity

The level of antioxidant defense is regulated. For example, the induction of catalase and superoxide dismutase (SOD) in microorganisms such as *E. coli* or *S. typhimurium* during anaerobic shifts[127] or by treatment with H_2O_2[128] has been observed; there are also adaptation phenomena.[129-131] A double mutant of *E. coli* devoid of the two SOD activities was unable to grow on minimal glucose medium.[132] During adaptation of *S. typhimurium* to H_2O_2, 30 proteins are induced, and it was shown that nine of them are under positive control of a regulon for defense against oxidative stress, called oxyR.[133] The oxyR regulon controls a global response to a DNA damaging agent, in addition to three other global responses (the SOS response, adaptation to alkylating agents, and heat-shock). In cells in which the oxyR regulon is deleted, the rate of spontaneous mutagenesis is dramatically increased, and the level of mutagenesis is less than in the controls if the oxyR gene is overexpressed[134] (Table 8). Similarly, the *E. coli* mutants lacking SOD exhibit oxygen-dependent mutagenesis.[135]

While control of the patterns of antioxidant enzymes, and also the control of the levels of antioxidants such as vitamin E, are not well-characterized in mammalian cells, it appears that adaptation phenomena of this nature may also be important in eukaryotes. In this regard, the changes in the biochemical pattern exhibited in cells in hepatic nodules may be considered as adaptive. These nodules contain clones of hepatocytes in which a new state of liver differentiation is acquired, and this is considered as a physiological response to environmental perturbations,[136] like the oxyR response mentioned above. The changes observed in the nodules refer to some of the ancillary antioxidant enzymes mentioned in Table 7; these consist of increases in the cellular activities of some isozymes of glucuronyl transferases, glutathione transferases, γ-glutamyl transferase, epoxide hydrolase, and NADPH : quinone oxidoreductase. These enzymes are classified as belonging to the Phase II group of enzymes involved in xenobiotic transformation. Interestingly, the enzymes of Phase I, namely cytochromes P-450 and b_5, have drastically decreased cellular activities. It appears that these changes in gene expression are related to DNA methylation (cf. [137, 138]). In experiments to decrease DNA methylation at the cytosine residues by treatment of animals with the drug analog, 5-azacytidine, the content of cytochromes P-450 and b_5 was found to drop,[139] whereas the content of several isozymes of the glutathione transferases as well as of NADPH : quinone oxidoreductase in mouse liver was in-

Table 8. Spontaneous mutagenesis in relation to the presence of the OxyR regulon in *S. typhimurium* tester strains. Strains with His G428 containing plasmid pKM101 and the oxyR regulon ($oxyR^+$) or overexpressed (oxyR1) or deleted (oxyΔ2) in oxyR were assayed for spontaneous mutations in the His reversion assay (Ames test). For description of phenotype, zones of inhibition by H_2O_2 on the agar plates are also shown [134].

Strain	Description	Colonies per plate	Zone of inhibition [mm]
TA 4117	$oxyR^+$	33 ± 6	18.0
TA 4118	oxyR1	12 ± 4	12.5
TA 4119	oxyΔ2	1408 ± 160	33.5



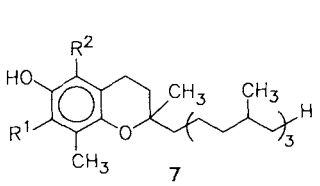


Fig. 18. Increase in NADPH : quinone oxidoreductase (DT-diaphorase) and decrease in cytochrome P-450 in mouse liver after injection of azacytidine for inhibition of DNA (cytosine-5) methyl transferase (after [140]).

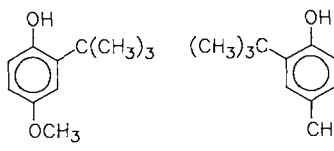
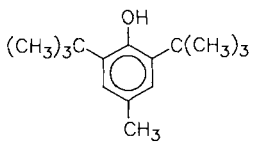
creased[140] (Fig. 18). Recently, NADPH : quinone oxidoreductase was cloned and was described to be hypomethylated in persisting liver noduli.[141]

Thus, there are interesting relationships between the status of DNA methylation and the expression pattern for some enzymes of importance in defense against oxidative challenge (see also [142]).



7.5. Synthetic Antioxidants

Numerous drugs serving as antioxidants have been synthesized and tested in biological environments, ranging from phenolic antioxidants added to foodstuffs to drugs used in medicine (Fig. 19). This subject cannot be treated here in detail. However, two selective aspects from our own research interest will be briefly mentioned.



7

	R^1	R^2
α-T	CH_3	CH_3

7.6. Ebselen, a Novel Organoselenium Compound

This synthetic organoselenium compound, 2-phenyl-1,2-benzoselenazol-3(2*H*)-one (ebselen), has been found to exhibit antioxidant capacity.[143] In an assay of lipid peroxidation using rat liver microsomes, the lag phase preceding the onset of ascorbate/ADP-Fe-induced lipid peroxidation is increased by the addition of ebselen, whereas the sulfur analog is inactive (Fig. 20); this pertains not only to the low-level chemiluminescence, but also to other parameters of lipid peroxidation like the evolution of ethane and *n*-pentane or the production of thiobarbiturate-reactive material.[94] In addition to this antioxidant activity, the compound acts catalytically in the GSH peroxidase reaction:[143, 144]

$$2GSH + ROOH \longrightarrow GSSG + ROH + H_2O$$

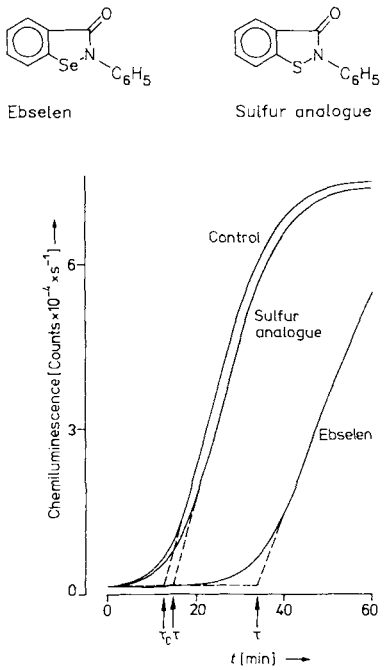

Fig. 20. Ebselen and its sulfur analog. The organoselenium compound exhibits antioxidant activity, shown by prolongation of lag phase in microsomal lipid peroxidation assay (after [143]).

This activity is thought to be responsible for the protection of isolated hepatocytes against oxidative challenge. Significant protection was afforded against ADP-Fe-induced cell damage in control cells, whereas cells previously rendered deficient in GSH were not protected by ebselen.[145a] The cytotoxicity of anticancer quinones in Ehrlich ascites cells was significantly decreased by ebselen.[145b] Recently, it was found that ebselen also exhibits an inhibiting activity in the lipoxygenase pathway.[146] Whether this can be explained by the removal of activatory hydroperoxide through the GSH peroxidase reaction (cf. Fig. 9), or by yet another site of action, is not clear.

Selenium displays a variety of biological effects (see [147]), a prominent one being its role as selenocysteine in the active center of GSH peroxidase.[148-150] It might be of interest to compare the mechanism of catalysis of the GSH peroxidase reaction identified for the enzyme with that of

ebselen. The role of selenium as an antioxidant[151] and as an anticarcinogen, as well as its potential as a carcinogen and as a cytotoxic agent, has been recently reviewed.[152a]

7.7. The Selenoenzyme GSH Peroxidase

This enzyme has recently been sequenced;[152b] its structure has been studied by X-ray crystallography.[152c] The gene from the mouse was cloned and it was found that the selenocysteine in the active site is encoded by the termination codon TGA.[152d] Likewise, this codon was found in formate dehydrogenase of *E. coli*.[152e]

7.8. Superoxide Dismutase as a Drug

The Cu,Zn-enzyme superoxide dismutase[5] has found a variety of applications as an antioxidant. In clinical medicine, the enzyme has been employed mainly in topical, e.g. intraarticular, applications, in the knee joint[153] and it was found to be active as an antiinflammatory agent. The enzyme has been cloned;[154] the recombinant human superoxide dismutase has been expressed in yeast.[155] The use of the human enzyme as obtained by gene-technological procedures may permit the systemic application and treatment of a variety of clinical conditions associated with oxidative stress. For example, there is evidence of free-radical involvement in ischemic myocardial[156] or intestinal injury or pancreatitis.[157] Recently, it was suggested that superoxide is involved in the breakdown of endothelium-derived vascular relaxing factor (EDRF).[158] However, this area of clinical research awaits further rigorous testing of the therapeutic benefits of oxygen radical scavengers.

8. Biology of Oxidative Stress: Some Aspects

The biological implications of oxidative stress have already been discussed at length (see, e.g., [13–20, 159]). It seems that almost all complex biological processes can be implicated with respect to reactive oxygen species and free radical involvement. Therefore, it seems that an in-depth treatment of such topics as the role of prooxidant states in *tumor promotion*[160] or in *spontaneous mutagenesis*[161] can only be referred to here. Similarly, the *ageing process*[162, 163] and the complex relations in *inflammatory states*[164] require a critical treatment from the biochemical standpoint. There is an intricate interorgan relationship in physiological and pathophysiological states; Figure 21 shows some of these for glutathione.

The biochemical events associated with radiation effects occur through free radicals (see Section 3.6). Recently, free radicals generated in brain, spleen and liver during γ-irradiation of mice (5 Gy) were detected by in vivo spin trapping.[165] Selenite and Vitamin E were found to inhibit radiogenic and chemically induced cell transformation in vitro[166] but, conversely, depletion of these antioxidants for six weeks had no effect on the radiation response in mice in vivo.[167] Radioprotectors and anticarcinogens should be viewed together.[168]

Biochemical-biological studies on oxidative stress have now reached a state where very careful and cautious use of

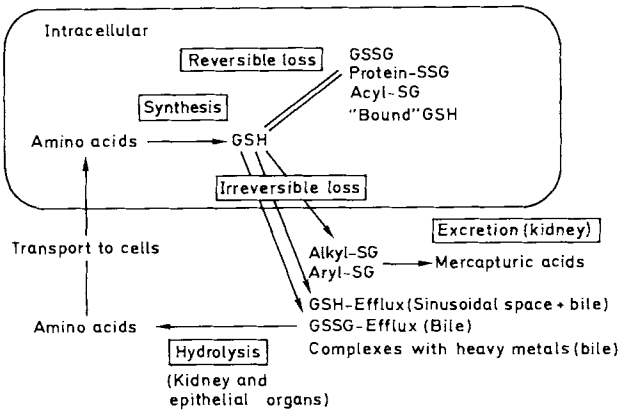

Fig. 21. Processes (chemical and translocation) that influence the intrahepatic and extrahepatic glutathione status (after [55]).

methods and concepts is called for. In this respect it should be mentioned that two volumes dealing with methods in this area of research have recently become available[169, 170] and should be consulted by workers interested in the biological effects of reactive oxygen species.

Finally, it should be pointed out that the term oxidative stress should not be interpreted solely in terms of a noxious challenge against which the organism must defend itself. As was recently pointed out,[171] numerous physiologically important chemical reactions occur in cells via reactive oxygen species and free radical reactions. These include the vital functions of macrophages[172] and neutrophils,[173] formate-pyruvate lyase,[174] ribonucleotide reductase necessary for deoxyribonucleotide production,[175a] and the vast area of selective oxidation of polyunsaturated fatty acids to produce the eicosanoids (see [79]) with far-reaching pathophysiological consequences, for example clinical states such as ischemia and shock.[175b]

The work carried out in the author's laboratory was supported by the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Mechanismen toxischer Wirkungen von Fremdstoffen"), by the National Foundation for Cancer Research, Washington, by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, and by the Fonds der Chemischen Industrie. Thanks are due to numerous colleagues for valuable discussions, and to my co-workers in the laboratory whose contributions are cited in the text.

Photochemistry of Transition-Metal Atoms: Reactions with Molecular Hydrogen and Methane in Low-Temperature Matrices

By Geoffrey A. Ozin,* John G. McCaffrey, and J. Mark Parnis

Reactions of metal atoms with molecular hydrogen and alkanes are prototypical of more complex systems involving metal-mediated reactions in solution, on supports, and on surfaces. The simplicity of metal-atom reactions makes them particularly attractive for fundamental experimental and theoretical studies. Following the first reports of H_2 and CH_4 activation by photoexcited metal atoms in cryogenic matrices, the behavior of a number of transition-metal atoms in their ground and selected electronically excited states has been examined with molecular hydrogen, methane, and ethane. A wealth of structural, electronic, reactivity, and selectivity information is emerging from these studies and it is now becoming possible to recognize the controlling factors at work in these fundamental chemical reactions. In this article, some experimental results for a number of metal-atom systems, in particular, those involving silver, copper, manganese, and iron atoms, are presented along with a discussion of the factors that are believed to be important in the understanding of the observed physical and chemical behavior.

1. Introduction

How can a metal atom have photochemistry? This is a question that a synthetic organometallic chemist might justifiably ask. One could respond by stating that it is expected that the chemical reactivity of a metal atomic species would be different for distinct electronic states of the metal atom. This general comment can be readily supported by thermodynamic and kinetic considerations. However, the exact nature of the resulting metal-atom reaction products cannot be so readily anticipated. In order to understand the types of photochemical processes initiated by the absorption of UV or visible light by isolated metal atoms entrapped at low temperatures with a co-reactant, it is necessary to use electronic, vibrational, and electron spin resonance spectroscopic studies of reaction intermediates and products.

The past decade has seen extensive development in the field of transition-metal vapor chemistry, although interest has been exclusively focused on the chemical reactivity of ground electronic state metal atoms in the condensed phase.[1] The analogous condensed-phase photochemistry of these systems has only recently been investigated.[2] On the other hand, extensive gas-phase photochemical studies have been performed on mercury and cadmium atoms since 1922, when *Cario* and *Franck*[3] discovered that photoexcited mercury atoms ($\lambda = 253.7$ nm) reacted with molecular hydrogen to produce free hydrogen atoms. A large body of data is available on the reactions of $^1P_1$ and $^3P_1$ mercury and cadmium atoms with hydrogen, methane, alkanes, and alkenes in the gas phase,[4,5] and results have recently been reviewed for similar reactions involving the analogous excited electronic states of magnesium and zinc atoms.[5]

Until recently, gas-phase investigations of electronically excited metal atoms have been limited to studies of relatively volatile metals, and hence only a small number of metal atomic species (alkali and alkaline-earth metals as well as metals of the zinc triad) have been studied in this way.[5] However, the advent of laser vaporization and molecular beam techniques has greatly extended the range of metals that are amenable to examination. Chemically interesting reactive intermediates such as RMH or HMH have not as yet been detected in the gas phase even by the highly sensitive laser-induced fluorescence technique, presumably because of their instability and transient nature and/or their low concentration.

In this paper the application of matrix isolation techniques to studies of certain classes of photochemical reactions of transition-metal atoms is described. Prior to our initial investigations in this field[6] there were apparently no studies of photochemical reactions of transition-metal atoms in low-temperature matrices.

It is now well-known that the matrix isolation spectroscopy (MIS) technique employs low-temperature solids as media for stabilizing relatively large quantities of reactive chemical species for long periods of time.[7] It is often the case that the interaction between the molecular guest species and the host matrix is sufficiently weak that electronic, vibrational, and ESR spectra differ insignificantly from what is predicted based on a simple model of a nonrotating but otherwise gaseous species with internal degrees of freedom (apart from rotation) equilibrated at the temperature of the matrix. Thus the low temperature of the matrix serves not only to stabilize the molecular species of interest but also to simplify its spectra. The number of chemical species for which MIS studies are possible is very large, being only limited by the requirement that the species itself, or a suitable photolytic precursor, be produced initially in a gaseous state. For the small quantities of material required in a MIS study (10^{-6} to 10^{-3} g) this presents no difficulty for all of the elements of the periodic table.

Therefore, the MIS technique can be easily applied to a wide range of metal-atom photochemical studies, and considerable potential exists for systematic investigations of the reactivity of photoexcited transition-metal atoms.

A large number of reactions involving ground-state metal-atom reagents can be conducted in the range 4.2–40 K. In these cases small activation energy barriers (0–5 kcal mol^{-1}) can be surmounted by thermal assistance from metal-atom translational energies, matrix/ligand condensation energies, and metal-source radiation energies, which are in the range 3–5 kcal mol^{-1}. The major products formed in these reactive systems usually arise from low-activation-energy, simple orbital-mixing processes, such as the following:

$$Pt + CO \longrightarrow Pt(CO)_4$$ [8]

$$Ni + N_2 \longrightarrow Ni(N_2)_4$$ [9]

$$Rh + O_2 \longrightarrow Rh(O_2)_2$$ [10]

$$Cu + C_2H_4 \longrightarrow Cu(C_2H_4)_3$$ [11]

$$Cr + Mo \longrightarrow CrMo$$ [12]

At the same time a large number of "unreactive" metal/ligand systems exist, which yield matrix samples comprised only of isolated metal atoms coexisting with unreacted ligands.

In particular, reactions involving ground-state metal-atom-induced bond-cleavage processes do not usually proceed at 4.2–40 K.[13] An example is oxidative addition to a C–H bond:

$$M + RH \longrightarrow RMH$$

It is specifically this class of ligands, namely, those that are unreactive toward ground electronic state metal-atom reagents at 4.2–40 K, that this article addresses. The large body of photochemistry of matrix-isolated molecules has recently been reviewed[14] and will not be discussed here.

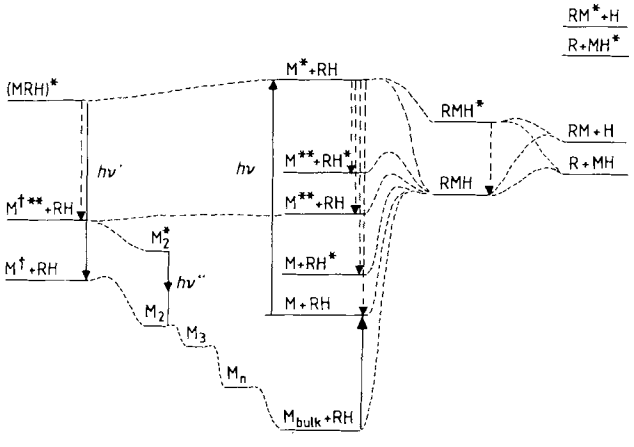

Fig. 1. A schematic view of condensed-phase energetics, dynamics, and reaction pathways of ground and excited electronic state metal atoms with alkanes and molecular hydrogen (R = H), $M^{\dagger}$ refers to a mobile metal atom; the asterisk denotes an electronically/vibrationally excited species; M_{bulk} is aggregate metal.

The basic physical and chemical mechanisms whereby fluorescence from the lowest M* and M** excited states of metal atoms is quenched by RH (R = H or CH_3) are shown in general terms in the energy-level scheme of Figure 1. The scheme shows that, in general, the reaction of the ground-state M with RH to give the insertion product RMH is sufficiently endothermic to not proceed at a measureable rate at 4.2–40 K. However, with respect to selected excited electronic states M* and M**, the situation can be quite different. Provided that there exist no insurmountable steric barriers, spin-selection restrictions, and/or orbital symmetry constraints, the reaction of M* or M** to yield RMH will likely be exothermic or at least thermoneutral, with either a negligible or a small activation barrier and hence will proceed at a measureable rate at 4.2–40 K. Whether RMH is directly formed in its electronic ground state or in an excited state (which may be unstable with respect to fragmentation) will depend intimately on the mechanism of chemical quenching of M* and M** as determined by the correlation of the electronic states of the metal atom plus reactant with those of the product.[15]

Another chemical quenching process of M* that can compete with the formation of the RMH insertion product involves vibrational relaxation of the matrix cage atoms or molecules around M* (Jahn–Teller effect, exciplex formation) followed by radiative and/or nonradiative decay to the ground-state M. The destabilization caused by producing a vibrationally excited ground-state "cage-complex" resulting from a Franck–Condon transition from the relaxed excited-state configuration can provide the driving force for photoinduced diffusion of ground-state M atoms and subsequent aggregation to M_2, M_3, M_4, etc. metal clusters (Fig. 1). Alternatively, M* can relax nonradiatively to a lower-energy electronically excited state M**. The energy thereby released into the matrix is thought to cause "local softening" of the surrounding cage resulting in photoinduced diffusion of M** (e.g., a long-lived mobile excited state) and reactive encounters with nearby ground-state M forming M_2, M_3, etc. metal clusters (Fig. 1). The metal-atom photoaggregation phenomenon (involving both ground-state and excited-state metal atoms) has been documented for Cu, Ag, Cr, Mo, and Rh atoms.[6]

Different behavior has been observed in recent studies of the quenching of electronically excited alkaline-earth metal atoms and atoms of the zinc triad (groups 2 and 12, respectively, of the periodic table) by alkanes or molecular hydrogen in the gas phase. These chemical quenching processes have a direct bearing on analogous processes involving electronically excited transition-metal atoms in low-temperature matrices. Three types of quenching processes have been identified in gas-phase studies based on the products observed:

(A) Photosensitization:

$$M^*RH \longrightarrow M + R^{\odot} + H^{\odot}$$

(B) Abstraction or insertion/fragmentation:

$$M^* + RH \longrightarrow MH + R^{\odot}$$

(C) Energy transfer:

$$M^* + RH(v=0) \longrightarrow M^{**} + RH(v=n)$$

Chemical quenching of the first $^1P_1$ excited states of certain group-2 and -12 metal atoms by H_2, CH_4, and alkanes is thought to occur by direct covalent chemical interaction between the excited metal atom and the quenching molecule.[4, 5, 16, 17] In this picture the reactions are envisaged as traversals of covalent potential energy surfaces, these surfaces correlating the separated reactants in their initial electronic states with the appropriate electronic states of the reactive complex and the final products. The reaction may or may not be adiabatic in the sense that the pathway may or may not involve a single potential energy surface exclusively.

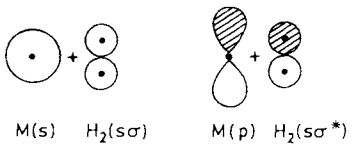

Fig. 2. Pictorial representation of the orbital interactions that are expected to be important in the quenching of excited P states of metal atoms by molecular hydrogen.

Callear et al.[4b] and *Breckenridge* et al.[16, 17] have considered reaction pathways including side-on attack on molecular hydrogen or on a C–H bond of an alkane molecule by the excited metal atom. The covalent chemical interactions that are expected to be important in the initial stages of such a reaction are illustrated in Figure 2 for excited electronic states derived from a ns^0np^1 or ns^1np^1 configuration. Here, the empty or singly occupied s and p metal atomic orbitals are available for bonding with the σ* antibonding molecular orbitals of H_2 or RH, respectively. Since the σ* orbital of H_2 or RH is unoccupied, the interaction with the singly occupied p orbital of the metal atom is believed to result in a transfer of charge from the metal atom to the antibonding orbital of H_2 or RH. At the same time the σ orbital of H_2 or RH is doubly occupied; therefore, it is expected that the M(s) + RH(σ) bonding interaction would lead to a transfer of electron density from the bonding molecular orbital of H_2 or RH to the metal atom. These metal-H_2 and metal-RH bonding interactions work in a synergistic sense and lead to a weakening of the H–H and R–H bonds, respectively. Considerations of this type may prove useful for deciphering the reactivity patterns of different electronic states of transition-metal atoms, in which the manifold of terms arising from a $(n-1)d^x ns^y np^z$ configuration is generally expected to be much more complex than the terms for s- and p-block metal atoms.

In what follows, selected physical and chemical aspects of the photochemistry of matrix-isolated transition-metal atoms, as well as of their reaction products, will be briefly illustrated by reference to some recent observations for electronically excited Mn, Fe, Cu, and Ag atoms with molecular hydrogen, methane, and ethane. For details of this work, the original literature references should be consulted.

2. Competing Photoinsertion and Photoaggregation Pathways in the Cu/CH_4, Cu/C_2H_6, Ag/CH_4, and Ag/C_2H_6 Systems

In all of the above systems, photoexcitation around 290–350 nm into the various components of the $^2P \leftarrow {}^2S$ atomic resonance transition of the entrapped Cu and Ag atoms causes rapid bleaching of the atomic absorption lines. Studies on the rate of loss of Cu atoms during photolysis in both CH_4[2c, 18] and C_2H_6[19] indicate that the quantum yield for chemical reaction does not vary with photolysis time and is essentially constant for CH_4, C_2H_6, CD_4, and CH_2D_2 matrices. For Cu/CH_4 and Cu/C_2H_6, no spectroscopic evidence for competing photoaggregation pathways to Cu_2, Cu_3, etc. clusters was obtained and no sign of Cu $^2D \rightarrow {}^2S$ fluorescence following $^2P \rightarrow {}^2D$ relaxation (easily observed in rare-gas matrices[20]) was apparent in CH_4 and C_2H_6 matrices. The UV/VIS spectroscopic and photochemical results, when taken in conjunction with IR, ESR, and isotope-labeling (^1H, ^2H, and ^{13}C) studies, serve to define the photochemical reaction of Cu atoms with CH_4 and C_2H_6 as one involving an initial insertion process to form RCuH followed by fragmentation to mainly R + CuH (see Section 3). With the Cu/CH_4 and Cu/C_2H_6 systems serving as control experiments, in that the excited-state Cu-atom reaction with the alkane can be considered to involve the direct reaction of the initially prepared ^2P state, we can now turn our attention to the corresponding Ag/CH_4 and Ag/C_2H_6 photochemical reactions.[21]

In the case of Ag/CH_4, using UV/VIS absorption and emission, IR, and ESR spectroscopy, one observes an insertion pathway to CH_3AgH with fragmentation of the intermediate to form $CH_3 + AgH$, but with an accompanying pathway to Ag_2 (Fig. 3). From UV/VIS spectroscopy, it is difficult to quantify the relative contribution of the photoinsertion and photodimerization pathways. However, the

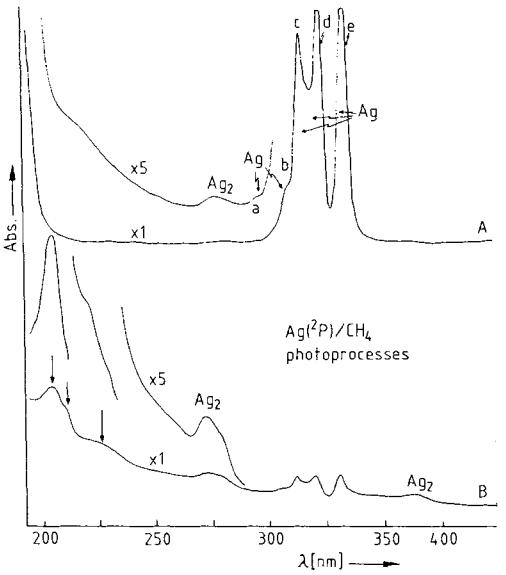

Fig. 3. UV/VIS spectrum illustrating competing 320-nm-induced photoinsertion and photodimerization matrix reactions of $Ag(^2P)/CH_4$ at 12 K. Absorptions due to Ag (maxima a–e) and Ag_2 are indicated; the arrows denote CH_3 and AgH absorptions. A) Spectrum before photoexcitation; B) spectrum following photoexcitation.

rate of Ag-atom loss observed for Ag/CH_4 was found to be roughly 60% as fast as that for Cu/CH_4 under similar photolysis conditions. The situation appears to be much the same for Ag/C_2H_6 matrices in terms of photodimerization yields, although the rate of Ag-atom loss with photolysis time diminished for excitation into all three major components of the $^2P \leftarrow {}^2S$ Ag atomic resonance absorption at 305, 320, and 347 nm, approaching the rate observed for Ag/Kr matrices (Fig. 4).

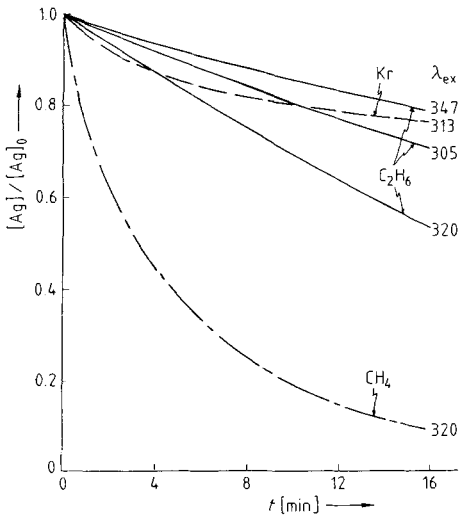

Fig. 4. Graphical representation of Ag(^{2}P) quenching behavior in Kr, CH_4, and C_2H_6 at 12 K. λ_{ex} = excitation wavelength. Identical concentration conditions were employed in these experiments.

In the following we attempt to provide a unified rationale for the above observations in terms of the ^{2}P- and ^{2}D-state energetics, dynamics, and cage structures for Cu and Ag atoms in CH_4 and C_2H_6 matrices.

2.1. Cage Structure of Cu and Ag Atoms in Solid CH_4

The p/T phase diagram of solid CH_4 has been well documented in the ranges 0–35 K and 0–5 kbar.[22] In this range, solid CH_4 exhibits the orientationally disordered phase I, the partially ordered phase II, and the ordered phases III and IV, which exist only under pressure. In phase II, which at low pressures exists between 10 and 20 K and is therefore pertinent to the present discussion, the carbon atoms are arranged in a face-centered cubic lattice with space group $Fm3c$. Three-quarters of the molecules are orientationally ordered with site symmetry D_{2d} and one-quarter are disordered with site symmetry O.

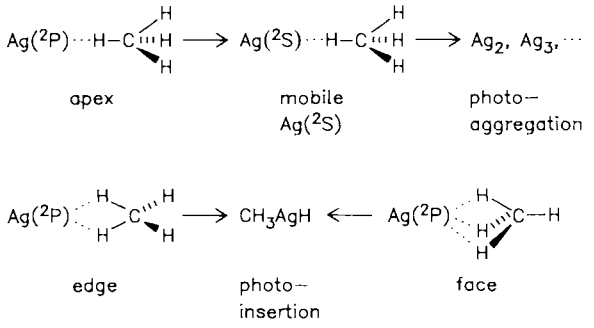
One can see that substitutional replacement of an ordered CH_4 molecule by a metal atom yields three kinds of nearest-neighbor $M \cdots CH_4$ interactions, two involving ordered CH_4 (face and apex aspects) molecules and one involving disordered CH_4 molecules. The latter may display face, edge, and apex aspects to the entrapped M atom. Alternatively, the $M \cdots CH_4$ interaction may freeze out the rotational disorder at the O sites and lock the CH_4 molecule in a preferred orientation with respect to the M atom. Substitutional replacement of a disordered CH_4 molecule by a M atom, on the other hand, results in just one kind of nearest neighbor $M \cdots CH_4$ interaction exhibiting a twofold edge aspect. Although differing in detail, similar considerations can be applied to the hexagonal close-packed lattice of solid C_2H_6, which exists in the range 10–20 K.

An examination of the $^2P \leftarrow {}^2S$ multiplet structure of Cu and Ag atoms in CH_4 and C_2H_6 matrices reveals five major components. From annealing studies,[18,21] this group of five observable lines can be divided into a group of three (major) and a group of two (minor), the origin of which can be traced to two different matrix trapping sites. It is proposed that Cu in CH_4 replaces a disordered CH_4 and thereby samples mainly edge aspects of the surrounding CH_4 molecules, whereas Ag in CH_4 replaces an ordered CH_4 and in doing so is able to sample face, edge, and apex aspects of the nearest-neighbor CH_4 molecules. Considerations of this type are thought to be important in discussions of the energetics, dynamics, and reactivity of metal atoms photoexcited in CH_4 and C_2H_6 matrices (see Sections 2.3 and 10).

2.2. C–H versus C–C Bond Insertion

In all cases one observes C–H bond-insertion pathways with fragmentation of the RMH intermediate to mainly R + MH.[2b,18,19] The disruption of RMH is more pronounced for C_2H_6 than CH_4 for both $^2P \leftarrow {}^2S$ Cu and Ag atoms. It is difficult to rationalize these results on the basis of C–C versus C–H bond energies or symmetry restrictions in C_2H_6 versus CH_4. One is obliged to consider a steric barrier for the attack of ^{2}P Cu or Ag atoms on the C–C bond of C_2H_6 (nonreactive site); such a barrier seems to be unimportant for the insertion into a C–H bond (reactive site). It is therefore to be expected that side-on attack of ^{2}P Cu atoms on the C–H bonds of CH_4 and C_2H_6 would involve similar $Cu(4s^0) + RH(\sigma)$ and $Cu(4p^1) + RH(\sigma^*)$ bonding interactions, which would lead to weakening of the C–H bonds in a comparable synergistic C–H bond activation process, resulting in essentially identical quantum yields, as observed experimentally through studies of rate of atom loss with photolysis time.

2.3. Photoinsertion versus Photodimerization



The observation of exclusive photoinsertion for ^{2}P Cu in CH_4 and C_2H_6 matrices yet competing photoinsertion/photodimerization pathways for ^{2}P Ag in CH_4 and C_2H_6 can be traced to differences in the cage geometries and relaxation dynamics for these metal atoms and matrices. In the case of Ag, it is the destabilization caused by formation of "ground state" Ag-atom-cage complexes in the relaxed ^{2}P excited-state configuration that provides the driving force for photoinduced diffusion of the Ag atoms.[6] In contrast, photoinduced diffusion of ^{2}P Cu atoms is promoted by $^2P \rightarrow {}^2D$ nonradiative transitions, allowing for reactive encounters of a long-lived ^{2}D Cu atom with nearby ground-state ^{2}S Cu atoms.[20,23] Thus, in the case of Cu, the ^{2}D state is intimately involved with both the photoinduced diffusion and dimerization mechanisms. Extending these ideas for ^{2}P Cu and Ag atoms in rare-gas

solids to the case of CH_4 and C_2H_6 matrices, one can propose the following:

(A) The ^2P state of the Cu and Ag atom is responsible for the insertion pathway for side-on approach to a C-H bond.

(B) In the case of Cu, the preferred cage geometry (major site replacing disordered CH_4, see Section 2.1) is such as to expose mainly C-H edge aspects of the CH_4 (or C_2H_6) molecule to the ^2P Cu atom, which inserts to form RCuH. The ^2D Cu state is never populated in this scheme and, therefore, the photodimerization route is completely quenched.

(C) In the case of Ag, the cage geometry is such that all face, edge, and apex aspects of the CH_4 (or C_2H_6) molecule are exposed (major site replacing ordered CH_4, see Section 2.1) to the ^2P Ag atom. Assuming that the apex approach represents a nonreactive encounter with respect to insertion, one can begin to appreciate how face and edge cage geometries can lead to photoinsertion, whereas apex geometries can lead to photodimerization (Scheme 1).

Scheme 1.

It remains to rationalize the more facile insertion of the ^2P Ag atom into the C-H bond of CH_4 compared with C_2H_6, remembering that the rates of the competing photodimerization appear to be about the same. A logical explanation stems from consideration of the number of reactive and nonreactive sites for Ag/CH_4 versus Ag/C_2H_6. For $Ag(^2P)/CH_4$ all face and edge encounters are productive for C-H bond insertion, whereas for $Ag(^2P)/C_2H_6$ only 25% of the face and 50% of the edge configurations can lead to C-H bond insertion, because of the proposed steric barrier to attack on the C-C bond. The less efficient C-H photoinsertion of $Ag(^2P)$ in C_2H_6 compared with CH_4 can be understood in this way although it is expected that other factors could also contribute to the overall scheme.

3. Fragmentation of CH_3CuH in the $Cu(^2P)/CH_4$ Matrix Reaction

Following $^2P \leftarrow {}^2S$ Cu-atom photolysis in 12-K CH_4 matrices, one observes by UV/VIS or ESR spectroscopy rapid depletion of the Cu-atom resonance lines with simultaneous formation of CH_3CuH, CH_3, CuH, CH_3Cu, and H.[18] Detailed kinetic and spectroscopic studies on the Cu/CH_4 system afford the following results: (1) the quantum yields for reaction in CH_4, CD_4, and CH_2D_2 are the same within experimental error. (2) The quantum yield does not vary with temperature between 12 and 25 K. (3) The $^2D \rightarrow {}^2S$ Cu-atom emission and Cu-atom photoaggregation processes seen in rare-gas matrices are completely quenched in solid CH_4. (4) As the photolysis proceeds, the concentration of CH_3CuH passes through a maximum and subsequently diminishes to zero (Fig. 5). At the same time, the concentration of $CH_3 + CuH$ and $CH_3Cu + H$ continue to increase and attain a constant value at very long photolysis times, the former pathway being favored over the latter by $>20:1$. (5) The measured [CuH]/[CuD] fragment ratio (IR absorbances corrected for the diatomic reduced masses) in the $Cu(^2P)/CH_2D_2$ reaction is unity within experimental error, implying that neither the formation nor fragmentation of CH_2DCuD compared with CHD_2CuH exhibits a measureable kinetic isotope effect. (6) Thermal annealing (12–40 K) of Cu/CH_4 matrices containing $CH_3 + CuH$ and $CH_3Cu + H$ leads to production of CH_3CuH, which itself decomposes above 40 K.

Of particular interest in the $Cu(^2P)/CH_4$ system is the mechanism of formation of fragments $CH_3 + CuH/$

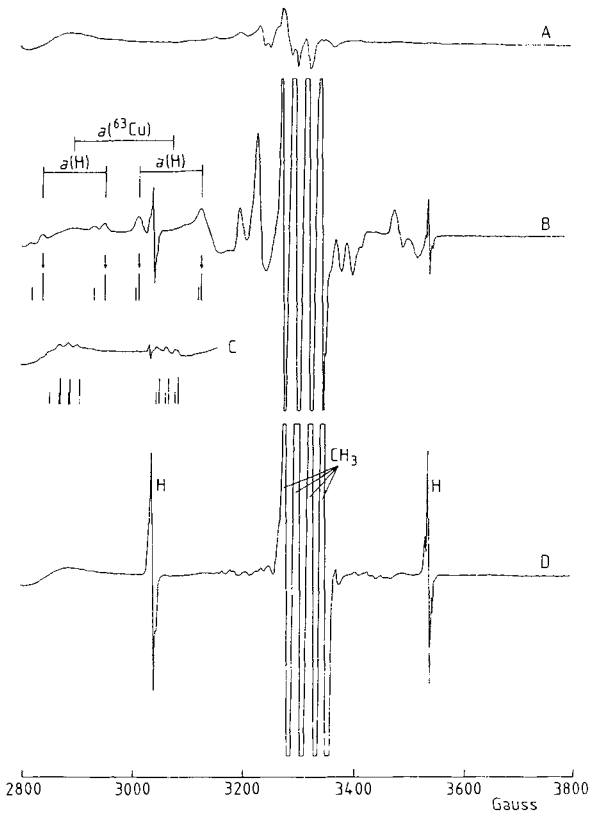


Fig. 5. ESR spectra showing changes caused by 320-nm photolysis of a Cu/CH_4 matrix ($\approx 1/10^4$) at 12 K. A) Freshly deposited matrix; B) after 2 min of 320-nm irradiation; D) after 15 min of 320-nm irradiation. The weak features near 3300 G in trace A are due to matrix impurities, mainly residual $Cu(O_2)$. Trace C shows a portion of the ESR spectrum of a Cu/CD_4 matrix ($\approx 1/10^4$) following 2 min of photolysis at 320 nm. The lines indicated by arrows in the upper stick spectrum show the positions of the lines in trace B that were used to measure the hyperfine splitting constants $a(^{63}Cu)$ and $a(H)$. The field positions of all other lines in the stick spectrum associated with ^{65}Cu hyperfine and H and D superhyperfine splitting represent calculated values using standard fitting procedures. The upper stick spectrum applies for CH_3CuH and should be compared with trace B, and the lower stick spectrum applies for CD_3CuD and should be compared with trace C. The microwave frequency was 9.280 GHz.

$CH_3Cu + H$. A broad UV/VIS absorption centered around 350 nm has been associated with CH_3CuH.[2c,18] Narrow-band excitation into this absorption causes rapid bleaching of all bands associated with CH_3CuH and concomitant production of CH_3, CuH, CH_3Cu, H, and Cu as seen by a combination of UV/VIS, vibrational, and ESR spectroscopy. Typical UV/VIS data for this photofragmentation are shown in Figure 6. Initial IR observations of the growth and decay characteristics of the intermediate and final products suggested that the reaction involves a two-step process in which the fragments $CH_3 + CuH$ and $CH_3Cu + H$ are formed exclusively from secondary photolysis of CH_3CuH. This is supported by the observation that final product distributions from 350-nm photolysis of CH_3CuH are similar to those obtained during 305–325-nm photolysis of Cu atoms, with the exception of regenerated Cu atoms in the former case.

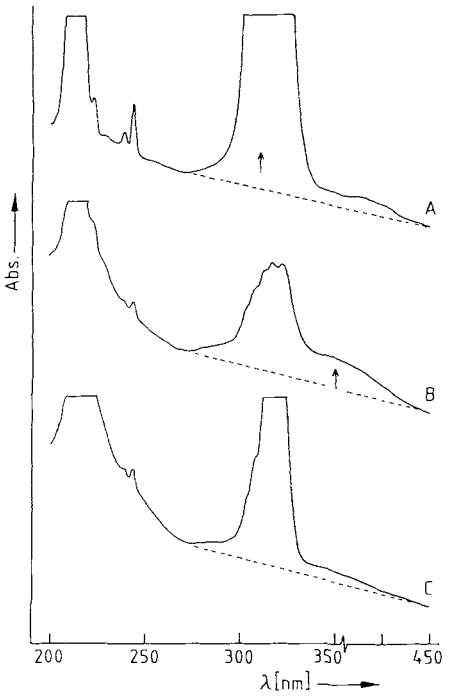

Fig. 6. UV/VIS spectrum of a Cu/CH_4 matrix: A) after deposition; B) following partial photolysis at 305 nm (60 min); C) following subsequent 350-nm photolysis (45 min).

A detailed study of the growth and decay behavior of the ESR signals due to Cu, CH_3, and CH_3CuH[28] has been done in order to establish the mechanistic routes by which the final products are formed. Theoretical growth and decay curves (Fig. 7) were generated by means of numerical integration of differential equations describing the routes for production and loss of these three species. The rate of change in the concentration of photochemically active species was related to the rate of photon absorption and the quantum efficiency for chemical reaction. From this analysis, it was clear that the growth of >90% of the final products is solely dependent upon the concentration of CH_3CuH, with only a small (<10%) amount that *may* be attributable to an abstraction or fragmentation process giving $CH_3 + CuH$ directly. Thus, it is established that the overall mechanism for the reaction of photoexcited ($^2P \leftarrow {}^2S$) Cu atoms in CH_4 is a two-step process involving the initial formation of CH_3CuH, which fragments photochemically to form all other products observed.

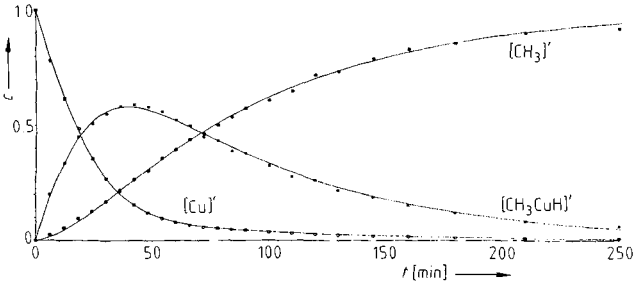

Fig. 7. Growth and decay behavior of Cu, CH_3CuH, and CH_3 during 305-nm photolysis. Points represent ESR experimental data and solid lines are the theoretically generated fit [18]. t = photolysis time.

To gain insight into the excited state(s) responsible for CH_3CuH fragmentation, SCF-Xα-SW MO calculations have been performed for linear CH_3CuH (Fig. 8).[24] Xα calculations show a low-lying $2a_1$ C–Cu–H σ-bonding level followed at higher energies by two near-degenerate and occupied levels designated 2e and 3e, corresponding to essentially pure $d_{x^2-y^2,xy}$ and $d_{xz,yz}$ Cu orbitals. Above these are two near-degenerate levels, designated $3a_1$ and $4a_1$, containing a single unpaired electron, thereby yielding a $^2A_1$ electronic ground state for CH_3CuH. The partial wave description of these $3a_1$ and $4a_1$ valence molecular orbitals is rather interesting. The $3a_1$ has mainly Cu and H σ-bonding character with a node between the Cu and C, while the $4a_1$ has mainly Cu and C σ-bonding character with a node between the Cu and H. These calculations indicate that 350-nm excitation of CH_3CuH probably involves the promotion of a σ-bonding electron from the $2a_1$ orbital to either one of the nearly degenerate $3a_1/4a_1$ pair of orbitals, which have σ*-antibonding character with respect to the Cu–C and Cu–H bonds, respectively (Fig. 8). If CH_3CuH in these $^2A_1$ excited electronic states has a linear geometry, then one can begin to understand why 305–325-nm photolysis of Cu atoms in CH_4 matrices leads not only to the production of CH_3CuH, but also to its destruction.

From the available data it is not immediately obvious whether the Cu atoms generated by photofragmentation of CH_3CuH arise by way of a concerted reductive-elimination pathway (as observed in the 420-nm photolysis of nonlinear CH_3FeH,[25] see Section 6) producing $Cu + CH_4$ or through complete photodissociation producing $Cu + CH_3 + H$.

An interesting perspective on the reactivity of atomic Cu toward CH_4 is afforded by a consideration of symmetry-based electronic-state correlations. A simple model for the $Cu + CH_4$ reaction considers the approach of the Cu atom in a C_{2v} side-on fashion to the CH_4 molecule, followed by insertion into a C–H bond, producing CH_3CuH initially with C_s symmetry. The $Cu \cdots CH_4$ bonding interactions that lead to a weakening of the C–H bond in a synergistic activation process have been described above. The symmetry species of the electronic states of the CH_3CuH mole-

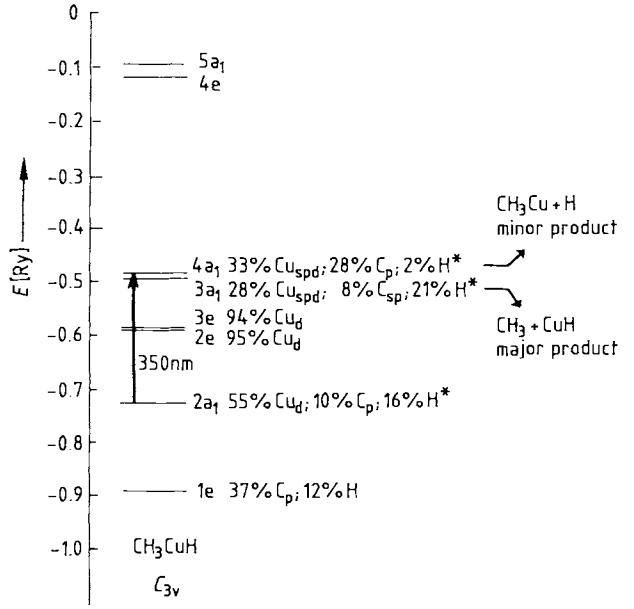

Fig. 8. Ground-state spin-restricted SCF-Xα-SW molecular orbital scheme for linear (C_{3v}) CH_3CuH: $\alpha_{Cu}=0.70697$, $\alpha_C=0.75928$, $\alpha_H=0.77725$, $r_{Cu-C}=1.94$ Å, $r_{Cu-H}=1.49$ Å, $r_{C-H}=1.12$ Å. The computed partial wave contributions to the various molecular orbitals are indicated in the energy-level diagram as well as the proposed 350-nm excitation responsible for secondary photolysis of CH_3CuH. The HOMO is the $4a_1$ orbital and contains a single unpaired electron, giving a $^2A_1$ ground electronic state to linear CH_3CuH.

cule that arise adiabatically from specified initial ^2S, ^2D, ^2P, and $^1A_1$ electronic states of Cu and CH_4, respectively, can be derived according to well-known correlation principles. In the same way a correlation may be made between CH_3CuH and CH_3+CuH and thus the electronic states of CH_3+CuH that arise adiabatically from the specified states of Cu and CH_4 may be ascertained. A correlation diagram of this type is shown in Figure 9. This diagram provides the basis for a qualitative discussion of the $Cu+CH_4$ photoinsertion step followed by dissociation of CH_3CuH to form the products CH_3+CuH. The ordering and relative energies of the electronic states shown for the $Cu+CH_4$ and CH_3+CuH positions of the correlation diagram were taken from UV/VIS spectroscopy data. It can be seen from the diagram that the reactants $Cu+CH_4$ in their ground electronic states correlate with the products CH_3+CuH in their ground electronic states. However, this reaction pathway is endothermic by about 38.5 kcal mol^{-1} and does not proceed from $Cu(^2S)+CH_4$ at 12 K. Reactions involving $Cu(^2D)$ or $Cu(^2P)$ and CH_4 in its ground electronic state lead to the products CH_3+CuH in combinations of ground and excited electronic states, designated $^2A_1+{}^1\Sigma^+$ in Figure 9. This combination of product states lies approximately 15 kcal mol^{-1} higher in energy than the highest-lying combination of reactant states $Cu(^2P)+CH_4(^1A_1)$ and thus all of the adiabatic reaction pathways considered in the diagram are endothermic by at least 15 kcal mol^{-1}. At the same time, the nonadiabatic reaction pathways leading from $Cu(^2D)+CH_4(^1A_1)$ and $Cu(^2P)+CH_4(^1A_1)$ to CH_3+CuH in their ground electronic states are nearly thermoneutral and exothermic, respectively. From the standpoint of energetics, therefore, and without regard for adiabaticity, the reaction is feasible at 12 K for either the directly excited ^2P state or the lower-lying ^2D state of $Cu(^2D_{3/2})$.

One can therefore deduce from these considerations that the initially formed excited state of CH_3CuH from $Cu(^2P)+CH_4(^1A_1)$ correlates adiabatically with CH_3+CuH excited states that are energetically inaccessible, but does not correlate directly with CH_3+CuH ground states because of avoided-crossing symmetry restrictions. Hence the reaction must proceed by way of a nonadiabatic transition corresponding to an electronic relaxation process of CH_3CuH in its initially formed excited state to its electronic ground state, as anticipated in the discussion above.

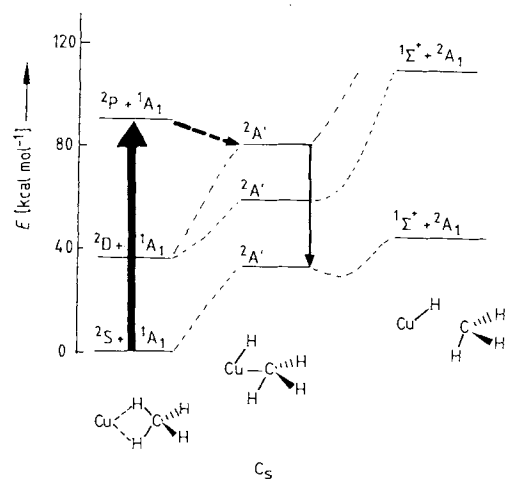

Fig. 9. Qualitative state correlation scheme for the reaction $Cu+CH_4 \rightarrow CH_3CuH \rightarrow CH_3+CuH$.

4. Thermal Reductive-Elimination: The CuH + H $\xrightarrow{h\nu}$ Cu + H_2 Matrix Reaction

The photochemical reaction of photoexcited Cu atoms ($\lambda=310$–320 nm) with H_2 in Kr and Xe matrices at 12 K shows some interesting differences from that observed for the similar Mn- and Fe-atom reactions.[26] This process exhibits pseudo-first-order photoinduced decay of Cu atoms and yields significant quantities of trapped CuH and H atoms as characterized by H_2, D_2, H_2/D_2, and HD isotopic substitution using IR and ESR spectroscopy.[27] The existence of a small ($k_H/k_D \approx 1.16$) kinetic isotope effect for the chemical quenching of photoexcited Cu atoms by H_2 and D_2 and the 2:1 [H]/[D] ratio observed for the reaction of photoexcited Cu atoms with HD are together indicative of the absence of a sizeable activation energy barrier. This is suggestive of a side-on attack[4] of the excited Cu atom on the H–H bond of H_2:

$$Cu + H_2 \xrightarrow[Kr,\ 12\,K]{h\nu} CuH + H$$

The end result of 310-nm $^2P \leftarrow {}^2S$ resonance excitation of Cu atoms in H_2/Kr ($\approx 1/10$) matrices at 12 K is thus an intimate mixture of immobilized CuH and H atoms, physically separated yet delicately poised to partake in a ther-

mal reaction which is the reverse of this photochemical step:

$$CuH + H \xrightarrow{\Delta} Cu + H_2$$

Such a reaction is of considerable theoretical interest since the ground state of, for example, NiH has been predicted to be unstable with respect to attack by H atoms, where the production of either NiH_2 or $Ni + H_2$ is dependent upon the geometry of approach of H to NiH.[28] In this study no activation energy barrier was found along the postulated reaction coordinates. Also, it is interesting to consider this process to be an analogue of the following, now classic gas-phase exchange reaction:

$$DH + H \longrightarrow D + H_2$$

Experimentally, one observes that careful annealing of matrices containing CuH + H at 18–20 K results in the regeneration of significant quantities of Cu atoms as observed by the monotonic reappearance of the $^2P \leftarrow {}^2S$ Cu atomic resonance absorption centered around 310 nm.[27b] A maximum of about 50% of the original Cu atoms can be regenerated using this thermal annealing technique, although the recovery rate is found to be very dependent on the choice of Cu/H_2/rare-gas concentrations, the type of matrix support, and the temperature at which CuH + H are photolytically generated. The inability to regenerate all of the original Cu atoms at 18–20 K can be traced to competitive H-atom recombination reactions forming H_2 and leaving behind unreacted CuH. This is thought to be most reasonable, since Cu-atom diffusion and agglomeration processes at 18–20 K in Kr/H_2 and Xe/H_2 matrices are found to be negligibly slow. The regeneration of Cu atoms follows a fairly well behaved second-order recombination rate law with respect to the reactants CuH + H and displays a kinetic isotope effect that is matrix dependent: $(k_H/k_D)_{Kr} \approx 3$, $(k_H/k_D)_{Xe} \approx 6$. The reaction rate appears to be diffusion controlled with a small but measureable activation energy barrier, with magnitude decreasing in the order Ar > Kr > Xe.

The regeneration of Cu atoms therefore appears to have its origin in the following thermal reaction:

$$CuH(^1\Sigma^+) + H(^2S) \xrightarrow[Kr\ or\ Xe]{18 \rightarrow 20\ K} Cu(^2S) + H_2(^1\Sigma_g)$$

This reaction can be considered to be the reverse of the photochemical reaction of $Cu(^2P)$ atoms with molecular $H_2(^1\Sigma_g^+)$.[27] In a series of careful IR and ESR experiments, no convincing evidence was obtained for a CuH_2 intermediate. It is therefore not possible to make any statement at this time as to whether the above reactions pass through an unstable copper dihydride species or proceed by way of an H-atom abstraction step. Nevertheless, it is quite clear that the activation energy for the production of $Cu + H_2$ from CuH + H has an upper limit of around 40 cal mol^{-1}, part or all of which might be associated with the barrier to thermal diffusion of H atoms in solid Kr or Xe at 18–20 K, and/or the rotational reorientation of CuH with respect to H to permit reaction.

Although the geometries, energy surfaces for different states, and atom–molecule state correlations for CuH_2, CuH + H, and $Cu + H_2$ have yet to be established and are not expected to be identical with those of the corresponding nickel–hydrogen system,[28] it is clear from the results of the present study that the reaction $CuH + H \rightarrow Cu + H_2$ proceeds with little or no barrier and is entirely downhill in energy.[27c]

5. Photoinsertion without Fragmentation: The $M + CH_4 \xrightarrow{h\nu} CH_3MH$ (M = Fe, Mn) Matrix Reaction

In this section the photochemical reaction of electronically excited Fe and Mn atoms with methane in a solid methane matrix will be described together since the behavior of the reaction in both metal-atom systems is similar. The UV/VIS spectra of Fe atoms and Mn atoms isolated in methane matrices of dilution ratios $1:10^4$ at 12 K can easily be correlated with their corresponding gas-phase spectra.[29,30] Photolysis at the 285-nm ($^6P, 3d^5 4s^1 4p^1 \leftarrow {}^6S, 3d^5 4s^2$) atomic resonance transition of Mn[26] and 300-nm ($^5P_3, 3d^6 4s^1 4p^1 \leftarrow {}^5D_4, 3d^6 4s^2$) atomic resonance transition of Fe[25] in neat methane matrices resulted in the bleaching of these absorptions in the UV/VIS spectrum and the growth of weak bands in the region of 300–339 nm and 420 nm (Fig. 10), respectively. IR experiments performed under similar metal/methane dilution ratios showed the growth of peaks upon photolysis at 285 nm and 300 nm for Mn/CH_4 and Fe/CH_4, respectively (for the frequencies of these peaks, see ref. [25, 26]). The Mn/CH_4 system is shown in Figure 11. With the exception of

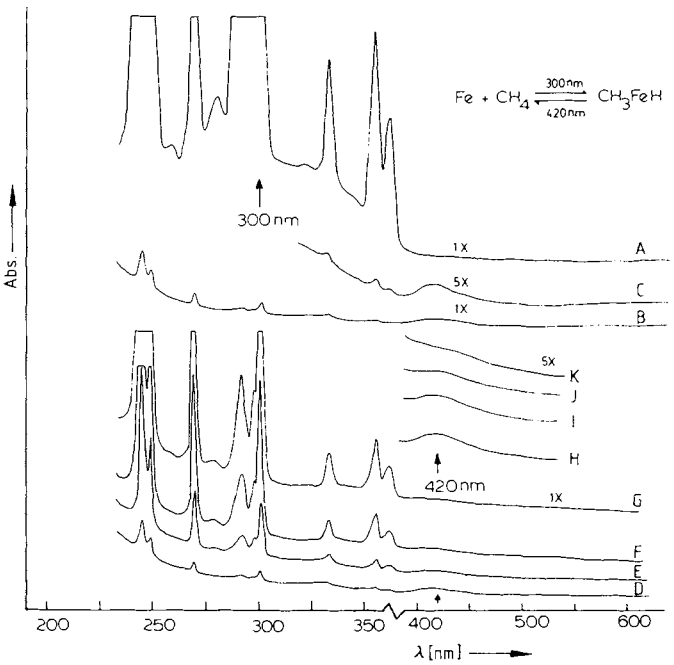

Fig. 10. UV/VIS spectra of Fe atoms isolated in solid CH_4 ($1/10^4$) at 12 K: A) after deposition; B) following 30 min of 300-nm photolysis; C) fivefold ordinate expansion of B in the 300–600-nm region; D)–G) samples similar to B after 0, 2, 7, and 12 min of 420-nm photolysis; H)–K) fivefold ordinate expansion of D–G in the 370–540-nm region [25].

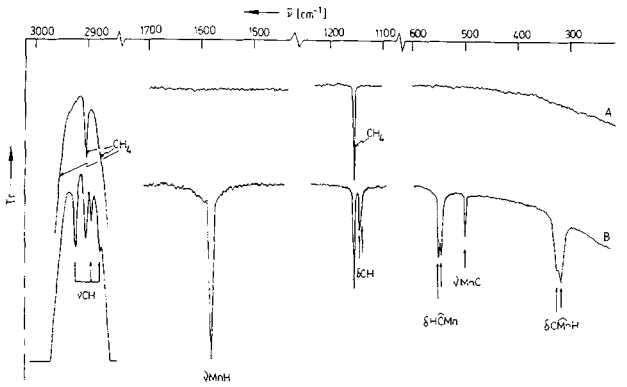

Fig. 11. IR spectrum of Mn/CH_4 (1/10⁴) at 12 K: A) following deposition, showing only CH_4 bands; B) following 120 min of photolysis at 285 nm, showing CH_3MnH product bands [32]. Tr = transmission; $\delta_{H\hat{C}Mn}$ and $\delta_{C\hat{M}nH}$ denote deformation modes.

the difference in frequencies of the bands for the Mn/CH_4 and Fe/CH_4 systems it is clear that the products resulting from the photolysis in both systems show distinct similarities. This is especially evident when it is noticed that the IR bands can be categorized as belonging to one of two types, namely, those arising from symmetrical stretching and bending modes (A_1) and those derived from doubly degenerate (E) modes for a linear C_{3v} molecule. From inspection of the spectra for both systems, it will be seen that the former modes appear as sharp singlets while the latter modes are split into doublets. This pattern of vibrational absorptions suggests that the product, CH_3MH, resulting from the atomic photolysis of Mn and Fe in neat methane matrices has a bent geometry.[25,26] No evidence is seen in the IR data to suggest that fragmentation of the intermediates CH_3MH (M = Mn or Fe) occurs during photolysis at the atomic resonance frequencies. This is in contrast to the Cu/CH_4 system where the fragmented products are observed. Such marked differences in behavior seem to arise from overlap of a dissociative molecular absorption of the product CH_3MH in the case of M = Cu with the atomic absorption, which is not present for the corresponding molecular absorption where M = Mn or Fe.

6. Photoreductive Elimination: The $CH_3MH \xrightarrow{h\nu} CH_4 + M$ (M = Mn, Fe) Matrix Reaction

As mentioned in Section 5 and as can be seen for iron in Figure 10, photolysis at the atomic resonance frequencies of Mn and Fe in solid methane results in the growth of weak absorptions in their UV/VIS spectra at 310 nm and 420 nm, respectively. Photolysis at the 420-nm absorption in the iron system resulted in the complete regeneration of the Fe-atom absorptions, while similar excitation at 310 nm in the Mn case resulted in the partial recovery of the original Mn atoms. In the IR spectrum the results of similar excitation at these optical frequencies resulted in a diminished intensity of the bands due to the insertion products CH_3MH. From this we can conclude that these weak optical bands correspond to absorptions into a dissociative molecular state of CH_3MH. It is particularly noteworthy that no evidence was seen in these IR studies or ESR experiments to suggest that any fragments such as $CH_3^{\odot}$, CH_3M, or $H^{\odot}$ were formed in the dissociation process. Thus it appears that dissociation of CH_3MH for M = Fe or Mn leads to the clean reverse of the atomic photolysis, i.e., the production of the metal atom and a methane molecule only. The nature of these excited states for CH_3MH are unknown but it seems reasonable to suggest that they have a large content of antibonding interaction between the metal atom and the hydrogen and carbon atoms. Detailed quantum mechanical calculations will be needed to provide suggestions as to the reasons for the difference in the photodissociation of the manganese and iron insertion products compared with that of the corresponding copper insertion intermediate.

7. Photoinsertion of Metal Atoms into Molecular Hydrogen: The $Fe + H_2 \xrightarrow{h\nu} FeH_2$ Matrix Reaction

The UV/VIS spectra of Fe atoms isolated in hydrogen/rare-gas (1/10) matrices can be readily correlated with those of Fe atoms in the gas phase.[29] The rate of loss of Fe atoms resulting from 307-nm ($^5P_3$, $3d^64s^14p^1 \leftarrow {}^5D_4$, $3d^64s^24p^0$) photolysis was found to exhibit a Beer–Lambert law dependence upon photon flux and to be roughly five times faster in H_2/Xe than in D_2/Xe matrices at 12 K.[30] Optical absorptions associated with photoproducts were observed to grow in at 400, 419, and 441 nm in H_2/Xe matrices (Fig. 12). The corresponding IR experiments led to the identification of an iron-hydrogen-containing species absorbing at 1636 and 323 cm^{-1} in H_2/Xe and at 1188 and 232 cm^{-1} in D_2/Xe matrices (Fig. 13). The analogous experiments in HD/Xe matrices show the respective stretching and deformational modes at 1665, 1198, and 280 cm^{-1}, which is the isotopic pattern expected for a FeHD insertion product rather than that of a molecular hydrogen complex, Fe(HD), thereby specifying the photochemical pathway leading to iron dihydride. The weak bands labeled a and a′ at 1660 cm^{-1} and 1204 cm^{-1} (Fig. 13), which are associated with FeH_2 and FeD_2, respectively, and which have slightly higher frequencies than the asymmetric νFeH_2 and νFeD_2 stretching modes, are *absent* in FeHD. They are therefore best ascribed to the symmetrical νFeH_2 and νFeD_2 stretching modes, rather than to a secondary matrix trapping site of iron dihydride, and hence provide evidence for a nonlinear geometry. On the other hand, the low-intensity shoulders denoted b and b′ (Fig. 13) do behave as multiple trapping sites of FeH_2 and FeD_2, respectively, and have been assigned accordingly. The ratio of the IR intensities of the stretching mode of FeH_2 is given in the bond dipole model by the following expression:

$$I_{B2}/I_{A1} = \tan^2\frac{\phi}{2}\,\frac{\left[m_{Fe} + 2m_H\sin^2\frac{\phi}{2}\right]}{\left[m_{Fe} + 2m_H\cos^2\frac{\phi}{2}\right]}$$

where ϕ is the apical angle. This yields a value of $\phi \approx 120°$ for FeH_2. The corresponding IR spectra recorded in Fe/

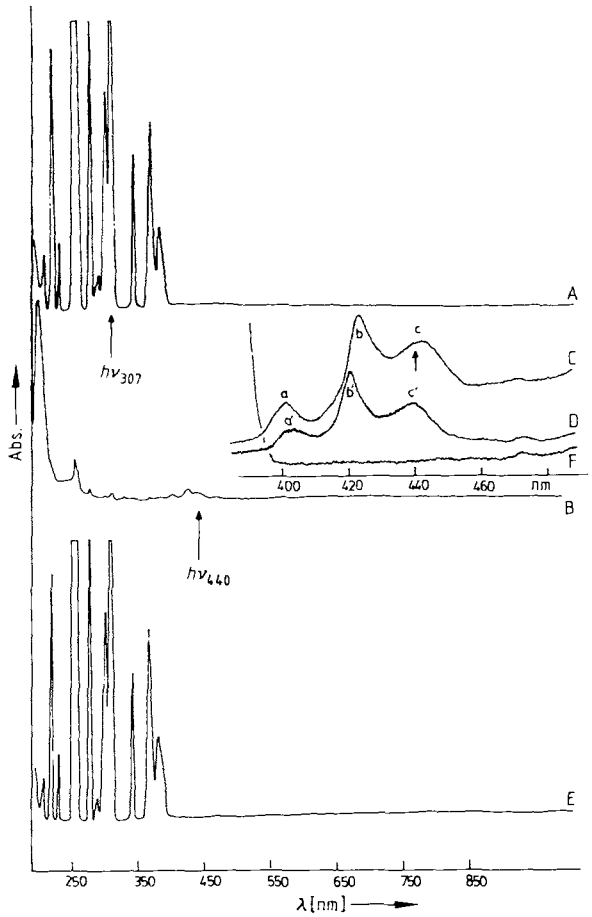

Fig. 12. Optical spectra of a $Fe/H_2/Xe$ ($\sim 1/10^3/10^4$) matrix at 12 K: A) freshly deposited; B) following 45 min of 307-nm atomic-Fe photolysis; C) scale expansion of 380–480-nm region of B; D) scale expansion of $Fe/D_2/Xe$ ($\approx 1/10^3/10^4$) analogue of C; E) the matrix sample shown in B following subsequent 15 min of 440-nm FeH_2 photolysis; F) scale expansion of the 380–480-nm region of E. The FeH_2 and FeD_2 product bands are denoted a, b, c and a', b', c', respectively [30].

$H_2/D_2/Xe$ mixed isotopic matrices display only those absorptions associated with FeH_2 and FeD_2 with no evidence for scrambling as seen by the absence of FeHD. In the $H_2/D_2/Xe$ matrices, FeH_2 is found to be formed preferentially over FeD_2 by a factor of 5.76 (IR absorbance measurements on the stretching modes, Fig. 13E). As expected, this parallels the approximately five times faster bleaching rate observed for 307-nm photoexcited Fe, reflecting the difference in the quenching cross section for this atom's excited state with H_2 and D_2 in Xe matrices (see Section 8). Note that for a pseudo-first-order competitive insertion reaction,

$$M^* + H_2 + D_2 \longrightarrow MH_2 + MD_2$$

the time dependence of the concentration of MH_2 and MD_2 photoproducts is given by the following expressions:

$$[MH_2] = \frac{k_H}{k_H + k_D}[M_0]\left(\exp\left[-\frac{1}{2}(k_H + k_D)t\right] - 1\right)$$

$$[MD_2] = \frac{k_D}{k_H + k_D}[M_0]\left(\exp\left[-\frac{1}{2}(k_H + k_D)t\right] - 1\right)$$

These lead directly to

$$k_H/k_D = [MH_2]/[MD_2]$$

These observations alert one to the existence of an activation energy barrier for the insertion step. Taking into account the low temperature at which the reaction was performed (zero point energy and possibly tunneling corrections), the observed k_H/k_D isotope ratio of around 5–6 for the $Fe^*/H_2(D_2)$ reaction translates into a k_H/k_D ratio of around 1.11–1.13 at ambient temperatures, which would indicate a small degree of H–H stretching in an "early"

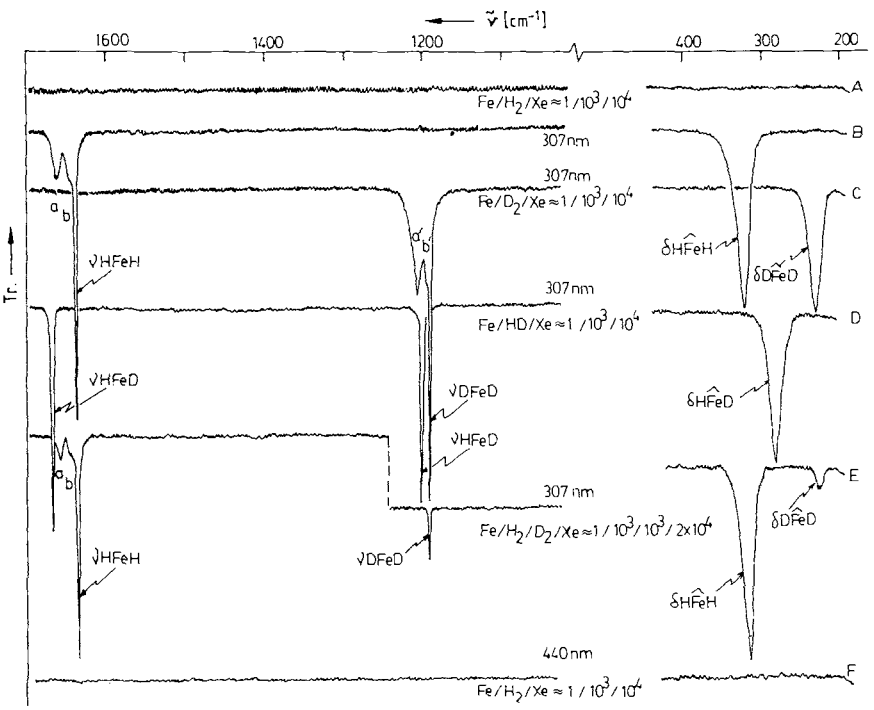

Fig. 13. IR spectra of a $Fe/H_2/Xe$ ($\sim 1/10^3/10^4$) matrix at 12 K: A) freshly deposited; B) following 120 min of 307-nm atomic-iron photolysis; C) as B for $Fe/D_2/Xe$ ($\approx 1/10^3/10^4$); D) as B for $Fe/HD/Xe \approx 1/10^3/10^4$; E) $Fe/H_2/D_2/Xe$ ($\approx 1/10^3/10^3/2\times10^4$); F) the matrix sample shown in B following subsequent 30 min of 440-nm FeH_2 photolysis. transition state and probably a low activation barrier for insertion. These observations are in line with (1) theoretical studies of H_2 oxidative-addition to $[Pt(PH_3)_2]$, which have indicated around 0–18% stretching of the H–H bond in the transition state with a 2–16-kcal mol^{-1} activation energy barrier in a reactant-like transition state;[31] (2) experimental data for H_2 addition to a metal center in molecular ML_n complexes, which show a k_H/k_D isotope ratio of 1–2;[32] and (3) neutron diffraction data for the H–H bond length in the first example of a molecular hydrogen complex, $[W(CO)_3(PiPr_3)_2(\eta^2\text{-}H_2)]$, the H–H bond length being 0.84 Å compared with 0.74 Å for gaseous H_2.[33] Finally, no sign of FeH or FeH_x ($x \geq 3$) could be detected in the IR experiments,[30] nor H atoms in the analogous ESR experiments.

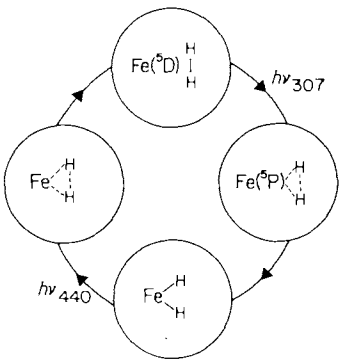
The accumulated spectroscopic and kinetic evidence therefore leans toward *concerted* insertion of a 307-nm photoexcited Fe atom into the hydrogen–hydrogen bond of H_2 to form FeH_2, having a nonlinear geometry, with no detectable participation of a molecular hydrogen complex,[34] nor indication of competing H-atom abstraction, secondary photolysis channels, or formation of higher iron hydrides, FeH_x ($x \geq 3$) (see Scheme 2). Similar, although not identical, effects have been discovered in the Mn/H_2/rare-gas system.[35]

8. Photoreductive Elimination: The $FeH_2 \xrightarrow{h\nu} Fe + H_2$ Matrix Reaction

In this section we will briefly consider the 440-nm photoreactivity of the FeH_2 insertion product generated cleanly and efficiently by 307-nm excitation of Fe atoms in the presence of H_2 in low-temperature matrices under rigorously mononuclear conditions.[30]



The UV/VIS and IR spectra both depict the monotonic bleaching of the FeH_2 absorptions with 440-nm irradiation time (Fig. 12, 13). Of particular note is the concurrent and rapid generation of atomic iron, clearly seen by the steady growth of the atomic resonance lines in the UV/VIS spectrum (Fig. 12E). During the photodissociation of FeH_2, neither IR nor ESR bands characteristic of FeH, H atoms, or FeH_x ($x \geq 3$) were ever observed. Furthermore, the 440-nm photobleaching of FeH_2 and FeD_2, with concomitant photoproduction of Fe atoms, was essentially quantitative (Fig. 12A, E), following a pseudo-first-order rate law and displaying no measureable kinetic isotope effect.

Collectively, the spectroscopic and kinetic evidence argues in favor of a *concerted reductive-elimination* of Fe atoms and H_2 from 440-nm photoexcited FeH_2 with no activation energy barrier, where FeH, H, $Fe(H_2)$, or FeH_x ($x \geq 3$) reaction intermediates, if involved, play only a minor role in the reaction since they remained below the detection limits of the analytical methods employed in this study. Again, the Mn/H_2/rare-gas system displays similar effects.[35]

It therefore seems likely that 440-nm photoexcitation of FeH_2 populates a low-lying electronic state having antibonding character between the iron–hydrogen bonds and bonding character with respect to the hydrogen–hydrogen bond. In a nonlinear configuration, this state is probably identical to or very closely resembles a three-center transition-state complex:

Such a complex could be responsible for the facile and concerted reductive-elimination of H_2 from FeH_2. This probably occurs in much the same way as that postulated to occur in the photoinduced reductive-elimination of H_2 from $[(\eta^5\text{-}C_5H_5)_2MoH_2]$, $[IrClH_2(PPh_3)_3]$, and $[IrH_3(PPh_3)_3]$ complexes.[36]

Scheme 2.

The photoinsertion of Fe atoms into H_2 leads to the first documented synthesis of FeH_2 and provides the first reported case of a "ligand-free," reversible, oxidative-addition, reductive-elimination reaction (Scheme 2).

$$M + H_2 \rightleftharpoons MH_2$$

This type of reaction is one of the most fundamental steps in homogeneous and heterogeneous catalysis involving molecular hydrogen.

9. SCF-Xα-SW MO Calculations for Nonlinear FeH_2: Relevance to the Photoreductive-Elimination Reaction

In order to gain a deeper understanding of the "ligand-free" photoreductive-elimination reaction, the electronic structure of some transition-metal dihydrides have been computed by the SCF-Xα-SW method. For illustrative purposes the MO energy level scheme for FeH_2 with an apical angle of 120° (IR intensity estimate) is shown in Figure 14.

It is significant that the optical spectra of FeH_2 show at least three low-energy absorptions around 400, 419, and 441 nm and that excitation into each of these leads to the clean and facile production of Fe atoms and H_2. Optical transitions that are computed to fall within this energy range are illustrated in Figure 14. One finds at best four possible transitions, calculated to occur at 396, 405, 414, and 509 nm. The latter two excitations involve promotion of FeH_2 σ-bonding electrons into essentially localized Fe 3d orbitals and are not expected to be effective in promoting reductive elimination to form Fe atoms and H_2. The

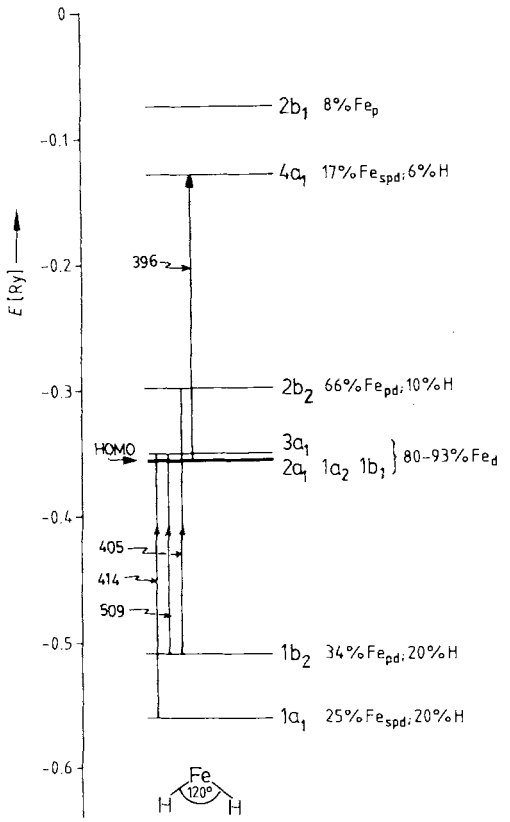


Fig. 14. Ground-state spin-restricted SCF-Xα-SW MO scheme for nonlinear (C_{2v}) FeH_2 ($\alpha_{Fe}=0.71151$; $\alpha_H=0.77725$; $r_{Fe\text{-}H}=1.77$ Å; H-Fe-H = 120°). The computed partial wave contributions to the various molecular orbitals are indicated in the energy-level diagram, as well as the proposed excitations in the 400–500-nm region thought to be responsible for the observed optical transitions in this range and the photoreductive-elimination pathway [26].

396-nm excitation involves promotion of Fe 3d localized electrons into a σ*-antibonding FeH_2 orbital and might be responsible for the Fe/H_2 elimination pathway. On the other hand, the 405-nm excitation takes a σ-bonding FeH_2 electron and places it in a σ*-antibonding orbital and could also be quite effective in promoting the observed photoreductive-elimination pathway. One or more of these excited states might turn out to closely resemble the three-center transition-state complex, proposed earlier to be responsible for the low activation energy and concerted reductive-elimination of Fe and H_2 from FeH_2. Further work is underway to explore this interesting result.

10. Factors Influencing the Reactivity of Electronically Excited Metal Atoms in Low-Temperature Matrices

It is worthwhile to briefly contemplate the factors that might affect the reactivity patterns of electronically excited metal atoms of the first transition series when co-isolated with different ligands in cryogenic matrices. As a first attempt at this, we will consider the photoinsertion reaction along a covalent chemical pathway in terms of what is currently known experimentally with respect to methane and molecular hydrogen.

For all of the cases studied so far, the initially prepared electronically excited metal atom (assuming this state to be reactive) was one of the following types:

$$3d^n4s^2 \longrightarrow 3d^n4s^14p^1;\ 3d^{n+1}4s^04p^1$$
$$3d^n4s^1 \longrightarrow 3d^n4s^04p^1$$

thereby presenting either an s^1p^1 or s^0p^1 orbital configuration to the CH_4 reactant.

The singly occupied 4s and 4p metal atomic orbitals are available for bonding with the σ-bonding and σ*-antibonding molecular orbitals of CH_4. Since the σ orbital of CH_4 is completely occupied, it is expected that the M*(3d/4s) + CH_4(σ) interaction would lead to a transfer of electron density from the $1t_2$ molecular orbital of CH_4 to the 3d/4s atomic orbitals of the excited metal atom. On the other hand, the σ* orbital of CH_4 is unoccupied and, thus, could result in a transfer of charge density from the singly occupied 4p atomic orbital of the excited metal atom to the $2a_1$ molecular orbital of CH_4. These combined interactions work in a "synergistic" sense and, overall, lead to a weakening of the C–H bond. Clearly the symmetry and energy matching of metal-atom valence orbitals in excited states with the ground-state σ($1t_2$) and σ*($2a_1$) orbitals of CH_4 are important factors in attempting to rationalize the reactivity patterns of excited metal atoms with CH_4. In the case of the first transition series, it has been observed that photoexcited[2a,21] Ti, V, Cr, and Ni atoms do not react with CH_4 at low temperatures whereas Mn, Fe, Co, Cu, and Zn atoms lead to CH_3MH insertion products.[2a,26] Similar reactivity patterns are also observed for reactions with H_2.[26] This series can be qualitatively understood in terms of the relative energies of the 3d, 4s, and 4p atomic orbitals of the excited metal atoms with respect to those of the $1t_2$ and $2a_1$ molecular orbitals of ground-state CH_4. Figure 15

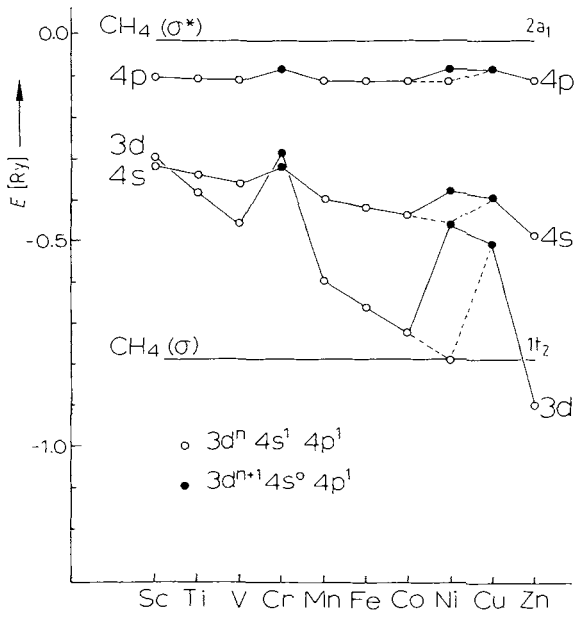

Fig. 15. SCF-Xα-SW spin-restricted orbital energies of CH_4 in its ground electronic state and the first-transition-series metal atoms in their low-lying excited states [26].

illustrates the variation of these energy levels across the first transition series, as determined by SCF-Xα-SW computations.[26] Except for Cr, Ni, and Cu, the energy levels were determined for $3d^n4s^14p^1$ excited-state configurations. For these three metals, however, a $3d^{n+1}4s^04p^1$ excited state configuration was considered, since this is the electronic configuration known to be populated for these metals. From Figure 15 it is clear that the nearly constant values of the 4p energy level for all the excited metal atoms, as well as its proximity to the energy value of the $2a_1$ level of CH_4, argue in favor of a similar $M^*(4p) \rightarrow CH_4(\sigma^*)$ interaction for the first-transition-series metal atoms. However, there is a dramatic difference among the metal atoms when one considers the $M^*(3d/4s)$-$CH_4(1t_2)$ energy separation. As one passes from Sc to Zn, the 3d and 4s orbitals are generally stabilized, becoming closer in energy to the $1t_2$ level of CH_4. Their interaction is thereby enhanced and, presumably, greater charge donation from CH_4 to M* is thereby promoted.

Both Cr and Cu have $3d^{n+1}4s^14p^0$ ground states in the gas and matrix phases. However, although Ni has a $3d^84s^24p^0$ ground-state configuration in the gas phase, recent studies[37] on its ground-state configuration in rare-gas matrices have shown that this changes to a $3d^94s^14p^0$ configuration. We have found this to be the case for CH_4 and H_2/rare-gas matrices as well. This has important consequences when one compares the $3d^84s^14p^1$ excited state of Ni (shown in dotted lines in Fig. 15) with the $3d^94s^04p^1$ excited-state configuration (solid lines in Fig. 15). In the former case, one would expect that the even closer proximity of the 3d and 4s levels of Ni* to the $1t_2$ level of CH_4 would result in the formation of reaction products, as observed for Mn, Fe, Co, Cu, and Zn. In the latter case, however, the dramatic *destabilization* of the 3d and 4s levels of the $3d^94s^04p^1$ excited state of Ni compared with the alternative excited-state $3d^84s^14p^1$ configuration, or with respect to Mn*, Fe*, and Co*, could result in anomalous behavior of Ni and might explain the lack of any observed reaction products when Ni is photoexcited in CH_4 matrices.[38]

The above discussion should only be regarded as a preliminary attempt to rationalize the reactivity patterns of electronically excited first-transition-series atoms with CH_4. Similar ideas seem to apply to the results so far obtained for H_2.[26] Clearly much more work needs to be done in this interesting area before one can fully appreciate the reactivity characteristics of selected metal-atom excited states with H_2 and CH_4 at low temperatures.

11. Conclusions and Outlook

The different kinds of photoprocesses accessible to metal atoms in selected excited states in the presence of hydrogen, methane, or ethane have been delineated and exemplified by experimental results. The photochemical and thermal behavior of reaction intermediates in these M/RH systems have also been considered, since they often play an important role in the scheme of events that correlate electronically excited metal-atom reagents with reaction products. Up to the present time these have included photooxidative-addition, photoaggregation, photoreductive-elimination and photofragmentation processes, most of which had not hitherto been observed with metal atoms in their ground electronic states.

In the case of methane and molecular hydrogen, this kind of metal-atom photochemistry has led to novel "ligand-free" CH_3MH and MH_2 insertion products as well as CH_3M and MH fragments. As a result of their inherent molecular simplicity, such species are ideally suited for detailed spectroscopic, photochemical, and structural investigations backed by quantum chemical calculations. This provides new opportunities for modeling CH_4 and H_2 chemisorption and desorption on metal surfaces and for probing CH_4 and H_2 oxidative-addition and reductive-elimination reactions in homogeneous catalysis in the absence of extraneous ligands.

Future studies are expected to focus attention on the photophysical and photochemical properties of transition-metal atoms and low-nuclearity metal clusters in selected excited states, as well as the reaction chemistry of RM_nH and M_nH_2 ($n = 1, 2, 3 \ldots$) with such ligands as N_2, CO, and C_2H_4, in an effort to secure ligand-free models of reactive intermediates in homogeneous and heterogeneous catalytic hydrogenations and alkylations of small molecules.

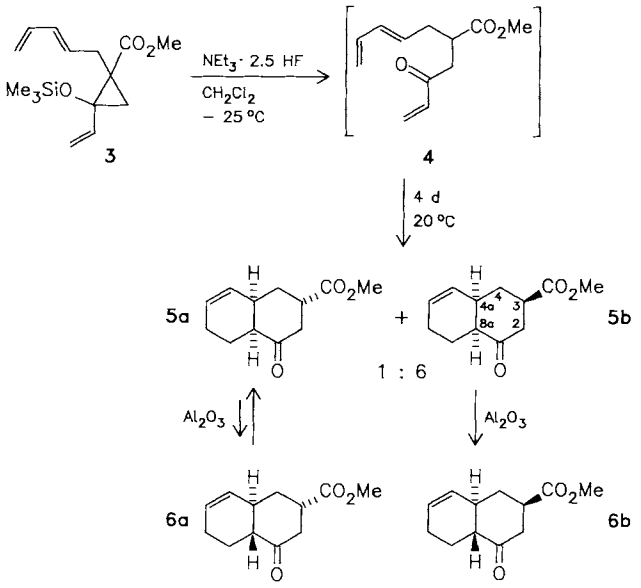
Intramolecular Diels–Alder Reactions with Methyl 2-Trimethylsiloxy-2-vinylcyclopropanecarboxylates as Key Building Blocks**



By *Ruth Zschiesche, Erich L. Grimm,* and *Hans-Ulrich Reissig**

Methyl 2-trimethylsiloxypropanecarboxylates with alkenyl substituents at C2 (e.g., **1**) can readily undergo reaction as masked vinyl ketones, resulting in C–C bond formation. We recently described efficient one-pot procedures for the ring-opening of **1** to give **2** and the subsequent Michael addition reactions of **2**.[1] The electron-poor C=C bond in **2** and in similar compounds should also undergo cycloaddition reactions.[2]

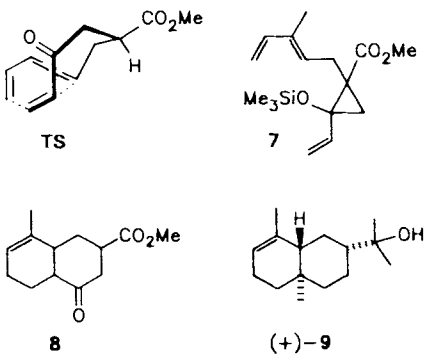
1 **2**

Of particular interest from a preparative and mechanistic standpoint is the intramolecular Diels–Alder reaction[3] starting from **3** (Scheme 1), which may be prepared in high yield (80%) by deprotonation of **1** followed by alkylation[4] with 5-bromo-1,3-pentadiene. Compound **3** is transformed by desilylation and subsequent ring-opening into the trienone **4**, which is ideally suited for a $[4\pi+2\pi]$ cycloaddition. The cycloaddition is complete after four days at room temperature. The crude product consists exclusively of the *cis*-octalone derivatives **5a** and **5b**, as shown by comparison of the NMR spectra with those of the separated isomers and by epimerization to give the *trans* compounds **6**. Pure **5b** (m.p. = 61–62.5 °C) can be isolated from the crude product in 47% yield by crystallization and **5a** can be obtained in 13% yield with a purity of > 90% (^{1}H-NMR) by chromatography (silica gel).

Scheme 1. Intramolecular Diels–Alder reaction of **4** to give **5a/5b** and isomerization providing **6a/6b**. For clarity, only one of the enantiomers of **5** and **6** is shown. All new isolated compounds (purified by recrystallization or kugelrohr distillation) gave appropriate spectra and correct elemental analyses.

When the crude product is chromatographed on alumina, however, the epimerized *trans*-octalone derivative **6b** is obtained in 57% yield as colorless crystals (m.p. = 90–92 °C). In this thermodynamically most stable isomer, all the substituents of the cyclohexanone portion are equatorial in the chair conformation. Compound **6b** is also formed upon treatment of pure **5b** with Al_2O_3, acids, or bases. However, the equilibrium between **5a** and **6a** lies on the side of **5a** (**5a** : **6a** = 2 : 1), since the methoxycarbonyl group in **6a** is arranged axially in a chair conformation. The relative configurations given in Scheme 1 are in accord with these equilibration experiments; moreover, they are supported by the comparison of the ^{13}C-NMR data[5] and are confirmed by selective proton decoupling experiments.[6]

As expected for trienones of type **4**,[3,7] the reaction proceeds via an *endo* transition state, which leads to the *cis*-linked bicyclic compounds **5**. The high selectivity with respect to the configuration at C3, however, is not obvious, since the folding of the chain joining the diene and the dienophile portions is crucial for the relative configuration of this center of chirality. Thus, the formation of the clearly preferred **5b** indicates a transition state **TS** with a boatlike conformation of this part of the molecule.



This short and efficient route to octalone derivatives is characterized by good stereocontrol and flexibility with respect to other substituents. For instance, the cyclopropane derivative **7** can be prepared in 90% yield by alkylation of **1** with 5-bromo-3-methyl-1,3-pentadiene; ring-opening of **7** results in rapid cycloaddition (compared with **4**) to give three diastereomers of 5-methyloctalone **8** in 79% yield. It has not yet been possible to separate these diastereomers (ratio of isomers corresponding to **5a**, **5b**, and **6b**, 3 : 6 : 1).

The synthetic route described here, involving intramolecular Diels–Alder reaction via **1**, should not only make

Fast Ionic Conduction in LiI·4 Methanol: $[Li(CH_3OH)_4]^+I^-$

By *Werner Weppner, Wilfried Welzel, Rüdiger Kniep,* and *Albrecht Rabenau**

A detailed knowledge of ionic transport in solids is of fundamental importance not only for a complete understanding of the properties of materials at the microscopic level but also for the development of solid-state galvanic cells.[1] Special attention is paid to solid lithium ionic conductors, because of the low atomic weight of lithium and the high negative Gibbs free energies of formation of many lithium compounds in view of energy storage devices with high energy densities. So far, only Li_3N has been found to exhibit an exceptionally high conductivity at room temperature. The use of Li_3N, however, is limited by a low decomposition voltage.[2] Lithium cells employing solid ionic conductors have only been commercialized with thin-layer electrolytes, for example, in pacemaker batteries[2] using a charge-transfer complex, e.g., in the cell combination Li/LiI/1-butylpyridinium polyiodide.

In an attempt to find fast solid lithium ion conductors, we have investigated compounds of the system lithium halide-alcohol.[3] An indication of high ionic conductivity at room temperature was provided by the earlier described high ductility and the low melting points of a series of solid phases of these systems.[4,5] We report here on the phase diagram of the system LiI-CH_3OH and on the conductivity and crystal structure of the highest conducting phase, LiI·4CH_3OH.

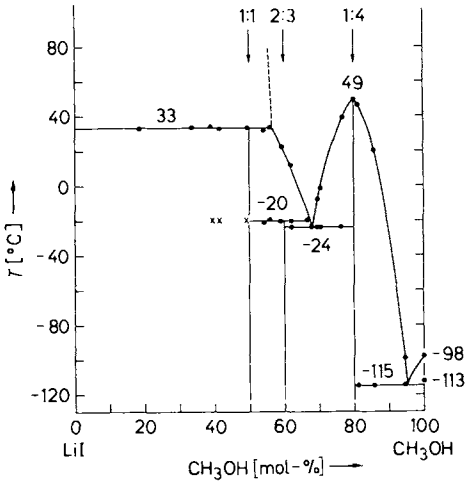

Fig. 1. Phase relationships in the system LiI-CH_3OH. See text and [6] for explanations.

Earlier studies had shown that lithium iodide reacts with methanol to form adducts having the molar ratios 1:1, 1:3, and 1:4.[4,5] Our determination of the phase equilibria along the section LiI-CH_3OH[6] (Fig. 1), carried out by differential thermoanalysis (DTA) and X-ray analysis, showed a quasi-binary section and confirmed the existence of the 1:1 (m.p. = 33 °C, incongruent) and 1:4 (m.p. = 49 °C, congruent) compounds. A compound having a 1:3 composition[5] was not observed; the investigations did, however, point to the existence of an additional (new) 2:3 phase (m.p. = −20 °C, incongruent).

Studies of the conductivity of polycrystalline samples of the compound LiI·4CH_3OH[7] (Fig. 2) gave a purely ionic conductance with the highest conductivity so far observed at room temperature (Fig. 3). The ionic conductivity has a value at room temperature of $2.7 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ with an activation enthalpy of 0.36 eV. For quenched (glasslike) samples, conductivities were measured that were one to two orders of magnitude less. The experimental galvanic cells, prepared with lithium anodes and various cathodes (TiS_2, PbI_2, and MnO_2), gave the expected emf values. The emf corresponds to that of a lithium concentration cell. In contrast to methanol, LiI·4CH_3OH does not appear to react with lithium.

Single crystals of the hygroscopic 1:4 compound were grown from the melt in Lindemann capillaries;[8] the crys-

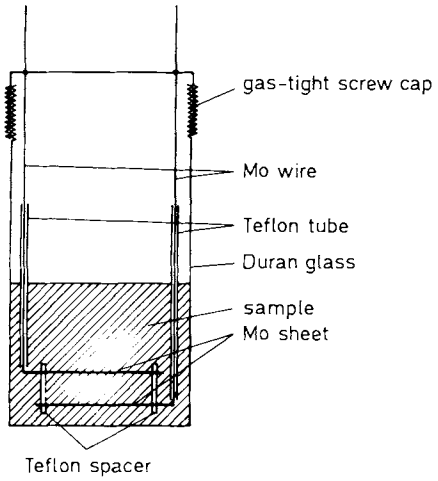

Fig. 2. Experimental setup for the conductivity measurement (cf. [7]).

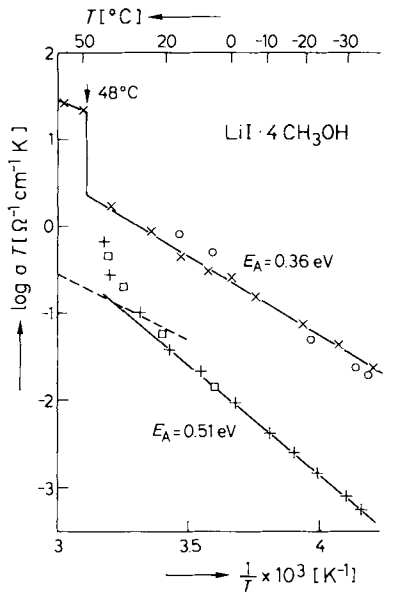

Fig. 3. Temperature dependence of the ionic conductivity of $LiI \cdot 4CH_3OH$ (cf. [7]). The product of the conductivity σ and the absolute temperature T is plotted logarithmically against the inverse of the absolute temperature (Arrhenius behavior). The values obtained for different samples are indicated by different symbols. The lower curve was obtained for quenched (glasslike) solids. For comparison, the conductivity of Li_3N (polycrystalline [2]) is shown. The arrow at the upper left points to the melting point.

tal structure[9] is shown in Figure 4. Lithium ions, are surrounded tetrahedrally by oxygen atoms of the methanol molecules with formation of the $[Li(CH_3OH)_4]^+$ units[10] (Li-O: 1.919(5) Å). The protons of the OH groups form hydrogen bonds with the iodide ions (O-H: 0.98(10) Å; H···I: 2.59(10) Å; angle O-H···I: 154(9)°). The arrangement of the anions and cations in this structure is similar to that of the zinc blende structure (corresponding unit cell shown by broken lines in Fig. 1; periodicity 13.301 Å); the c axis, however, is compressed by more than half (6.554 Å; direction of projection in Fig. 4). Compressed tetrahedral vacancies in the iodine matrix—alternately occupied and empty—therefore occur very closely one after the other in the [001] direction, thereby offering a preferred path for ion conductance in the crystal. The involvement of the protons of the OH groups in hydrogen bonds with the iodine

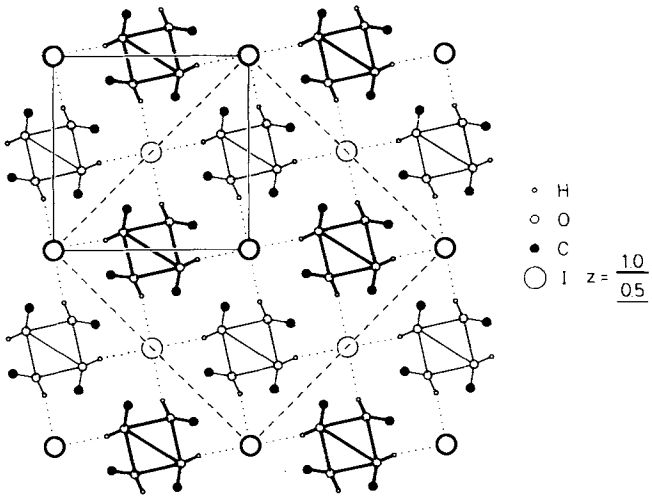

Fig. 4. Projection of the crystal structure of $Li(CH_3OH)_4I$ viewed along [001]. Centers of the $Li(CH_3OH)_4^+$ tetrahedra are in $z=0.75$ (thick) and $z=0.25$ (thin). The lithium ions in the centers of the tetrahedra are not shown. For further details, see text.

ions may explain the observation that the compound described here does not react with elemental lithium.

The results of the conductivity measurements and the crystal structure analysis are thus mutually consistent if one assumes that the ionic transport in the crystal is based on the mobility of the complex solvated cations $[Li(CH_3OH)_4]^+$.

[6] *Sample preparation and DTA measurements:* LiI (Cerac, 99%; dried at 250°C under vacuum) was added in known amounts to DTA ampoules made of Duran glass and having a thermocouple included internally. Methanol (Baker, >99.5%; distilled from magnesium) was then added with a calibrated syringe to ca. 80% capacity; sample volume ca. 1 cm^3. All operations were carried out under dried argon; the composition of the samples (see the data points in Fig. 1) was determined by re-weighing after sealing the ampoules. In order to achieve homogeneity the samples were melted and then quenched to liquid nitrogen temperature in a DTA apparatus (J. Oellers, *Diplomarbeit*, Universität Düsseldorf 1981). In order to achieve equilibrium the samples were heated repeatedly to the exothermic transition glassy→crystalline, until this effect was no longer observed. The rate of heating in the DTA measurements was 1.5°C/min (Ni/NiCr thermocouple; reference: aluminum oxide powder). The samples labeled with x in Fig. 1 could not be made completely homogeneous; the cause is presumably the marked incongruent melting behavior of the 1:1 phase.
[7] *For the conductivity measurements*, the compound was heated to melting in a sealed glass vessel equipped with plane-parallel molybdenum electrodes and then cooled (cf. Fig. 2). The electrodes (ca. 0.7 cm^2) were completely inserted, with appreciably larger separations from all surfaces than from each other. The molybdenum leads were electrically insulated by teflon tubings. Alternatively, samples consisting of compressed pellets were used. The conductivity was measured by impedance spectroscopy over a frequency range of 10 Hz-200 kHz using an HP 4192A low-frequency impedance analyzer. In the imaginary impedance plane, semicircles were obtained, which could be extrapolated to zero and were followed by a straight line forming an angle of about 45° with the axes. For the analysis, therefore, it was possible to use a simple De-

bye equivalent circuit. In order to check for ionic conductance, d.c. polarization measurements [11] were carried out in a potential range of 0 to 1 V.

[8] *For the growth of crystals*, $Li(CH_3OH)_4I$ was heated to melting in a Lindemann capillary (diameter 0.5 mm) by a perpendicularly applied stream of heated gas over a length of ca. 0.5 cm ($T_{max}=60°C$) and then cooled at 0.5°C/h.

[9] *Crystallographic data*: $Li(CH_3OH)_4I$; 517 (507) reflections (Syntex R3, $Mo_{K\alpha}$, room temperature; the authors thank Dr. *K. Peters* for the measurements on the single-crystal diffractometer). $R=0.030$; tetragonal, $I\bar{4}$; $a=9.405(5)$, $c=6.554(4)$ Å; $Z=2$. The proton of the OH group was located by a difference Fourier synthesis at $R=0.031$; the protons of the methyl groups could not be located. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52181, the names of the authors, and the journal citation.

Coordination-Polymeric Paracyclophane Complexes of Copper and Silver**

By *Hubert Schmidbaur*,* *Wolfgang Bublak*, *Brigitte Huber*, *Gabriele Reber*, and *Gerhard Müller*

Cyclophanes having short bridges between the benzene rings are highly strained molecules exhibiting strong repulsive interactions between the π systems.[1] In particular, for [2.2]paracyclophane this results in a strong deformation of the benzene rings and an increased donor effect of the external sides of the rings.[2] In cases with a deficiency or excess of electrons, the mutual interpenetration of the π systems leads to "spin communication," which is revealed by ESR spectroscopy or by magnetic anomalies.[3]

A

The number of transition metals[1,4] or appropriately configurated main-group metals ($d^{10}s^2$: Ga^I, Sn^{II}, Bi^{III}, etc.)[5] that form complexes with externally η^6-coordinated cyclophanes is increasing rapidly. With the coinage metals in the oxidation state +1 ($d^{10}s^0$ configuration), on the other hand, η^1- or η^2-coordinated arene complexes are expected to be formed for theoretical reasons.[6] In these complexes, the noncentric arrangement of the metal atoms should therefore dramatically affect the symmetry of the cyclophane moieties. In the presence of coordinating counterions, organometallic polymers similar to **A** might be formed, which, after partial oxidation (or reduction) should exhibit semiconducting or conducting properties.

With this goal in mind, we prepared the compounds $Cu[GaCl_4]$, $Ag[GaCl_4]$, and $Ag[GaBr_4]$ by reaction of CuCl, AgCl, and AgBr, respectively, with $GaCl_3$ or $GaBr_3$ in benzene, and then allowed them to react with equimolar amounts of [2.2]- and [3.3]paracyclophane in toluene. We thereby obtained nearly quantitative yields of the analytically pure, colorless crystalline products **1**–**4**, which have high melting or decomposition temperatures. The $AgClO_4$ complex **5** was prepared analogously.

	M.p. [°C]
1 $[Cu(GaCl_4)\cdot\{(p\text{-}C_6H_4CH_2CH_2)_2\}]$	230 (dec.)
2 $[Cu(GaCl_4)\cdot\{(p\text{-}C_6H_4CH_2CH_2CH_2)_2\}]$	225 (dec.)
3 $[Ag(GaCl_4)\cdot\{(p\text{-}C_6H_4CH_2CH_2)_2\}]$	223
4 $[Ag(GaBr_4)\cdot\{(p\text{-}C_6H_4CH_2CH_2)_2\}]$	185 (dec.)
5 $[Ag(ClO_4)\cdot\{(p\text{-}C_6H_4CH_2CH_2)_2\}]$	>300

Slow cooling of toluene solutions of **2** and **3** afforded transparent single crystals, whose structures could be determined by X-ray crystallography.[7] Both the copper complex **2** and the silver complex **3** are examples of organometallic coordination polymers. It was initially surprising to find that the metals differ in their hapticity: whereas Cu^I is η^2-bonded to each of the [3.3]paracyclophane units (Fig. 1a), Ag^I prefers η^2/η^3 coordination to the [2.2]paracyclophanes (Fig. 1b). Furthermore, the coordination sphere of the copper atom in **2** is saturated by a chelating $GaCl_4^{\ominus}$,

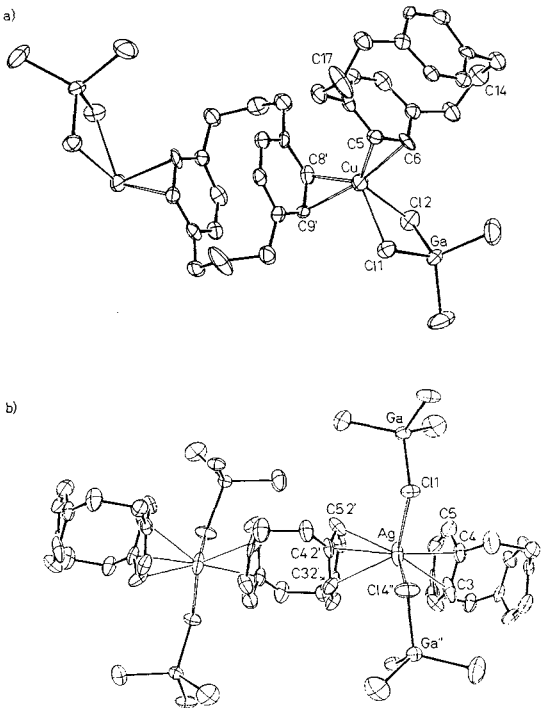

Fig. 1. Sections of the crystal structures of a) **2** and b) **3** (ORTEP, thermal ellipsoids at the 50% probability level, without H atoms; only one alternative for the disordered atoms C14/C17 in **2** is shown). The copper atom in **2** is, in each case, coordinated to the benzene ring through two nonbridging C atoms (η^2); in **3**, on the other hand, the silver atoms are also bonded to the bridgehead atoms (η^2/η^3). Important distances [Å]: **2**: Cu-C5 2.284(7), Cu-C6 2.139(7), Cu-C8' 2.230(7), Cu-C9' 2.163(7), Cu-Cl1 2.706(2), Cu-C12 2.718(2); **3**: Ag-C3 2.523(8), Ag-C4 2.434(7), Ag-C5 2.921(9), Ag-C32' 2.642(8), Ag-C42' 2.431(7), Ag-C52' 2.661(8), Ag-Cl1 2.719(2), Ag-Cl4'' 2.837(2).

[+] X-ray structure analyses.

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Professor *H. Hopf*, Braunschweig, and Priv.-Doz. Dr. *M. Haenel*, Mülheim, for the cyclophanes, *J. Riede* for the X-ray data collections, and *M. Barth*, *U. Graf*, and *B. Schuller* for the analyses.

whereas each silver atom in **3** is linked to two other silver atoms through two $GaCl_4^{\ominus}$ anions. Therefore, **2** forms screwlike chains; **3**, on the other hand, forms a layer structure that resembles somewhat the structure found for $Ga[GaCl_4]\cdot$[3.3]paracyclophane:[5c] in the latter, however, the Ga^I centers are twofold η^6-coordinated, as shown for **A**.

It remains an open question whether the different arene coordination of Cu^I and Ag^I in **2** and **3**, respectively, is due to the nature of the metal or to the difference in the cyclophane bridges.

It has often been observed that the coordination geometry of silver in its arene complexes is more variable than that of copper.[8] In certain cases, in fact, Ag^I is only η^1-bonded.[9] The considerable boat distortion of the benzene rings of the [2.2]cyclophane **3**, which is clearly visible in the structure (Fig. 1), necessarily leads to different donor properties, compared with those of **2**, in which the planarity of the benzene ring is better maintained.

The pure copper(I) compound **2** is electrically nonconducting; however, in air the compound turns slightly colored and becomes conducting. A partial oxidation to Cu^{II} can be assumed to have occurred, resulting in the formation of a mixed-valent organometallic polymer.[10] A detailed understanding of this phenomenon will only be possible if the properties of such polymers can be reliably controlled.

Experimental Procedure

$M[GaX_4]$: A solution of anhydrous $GaCl_3$ or $GaBr_3$ in benzene was treated with CuCl, AgCl, or AgBr (ca. 10% excess) and the resulting reaction mixture was refluxed for 10 h. Filtration of the hot solution and cooling of the filtrate resulted in the precipitation of the benzene complex $M[GaX_4]\cdot C_6H_6$, which, upon drying in a vacuum, was converted into the arene-free salt.

1–**4**: Solutions of $M[GaX_4]$ in toluene were treated with solutions containing equimolar amounts of cyclophane in toluene. The complexes **1**–**4** precipitated out at room temperature in the form of a colorless, microcrystalline, moisture- and air-sensitive powder in nearly quantitative yields. The products were washed with toluene and dried in a vacuum. By slow cooling (1°C/h) of the clear solutions from 100°C to room temperature, single crystals were obtained.

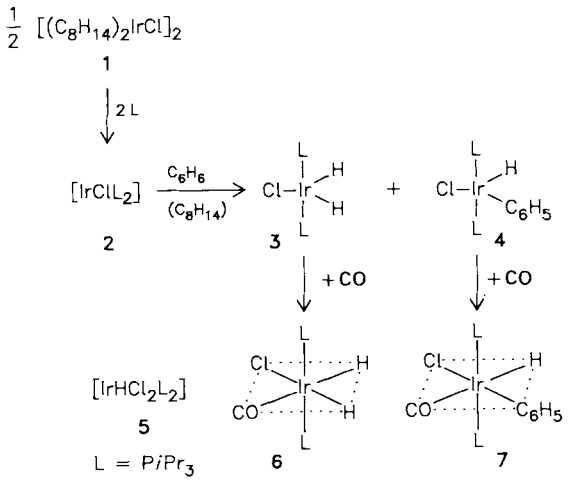
Thermolytically Induced C–H Activation Using a 14-Electron Complex: Synthesis and Molecular Structure of $[IrHCl(C_6H_5)(PiPr_3)_2]$**

By *Helmut Werner,* Arthur Höhn,* and *Michael Dziallas*

The presently known methods of *inter*molecular C–H activation of aliphatic and aromatic hydrocarbons, which have been developed in the last few years, generally make use of a high-energy (i.e., very reactive and short-lived) metal–ligand fragment.[1] Such species are usually generated by photolysis (e.g., by loss of H_2 or CO from a stable precursor), by reaction of "hot" metal atoms with appropriate ligands in a matrix, or by reduction of metal–halogen compounds (mostly by using strong reducing agents). Examples of *thermolytic* reactions, according to Eq. (1), which take place at moderate temperatures and use *stable* metal complexes, $[ML_n]$, are rare.[2]



$$L_nM + R{-}H \longrightarrow L_nM\begin{matrix}R\\H\end{matrix} \qquad (1)$$

Recently, we showed[3] that the 14-electron species **2** formed in situ from **1** and triisopropylphosphane,[4] reacts at room temperature with H_2 and with HCl to form **3** and **5**, respectively. Under the same conditions, no reaction occurs with benzene. We have now found, however, that reaction does occur at higher temperatures. If a solution of **1** and $PiPr_3$ (molar ratio $\approx 1:4$) in benzene is heated to 80°C, a mixture of **3** and the hydrido(phenyl)iridium compound **4** in an approximate ratio of 1:2 is obtained (Scheme 1).[5a] The separation of the two products can be achieved by repeated crystallization, but is more conveniently performed by allowing the mixture of **3** and **4** to react with CO to produce the octahedral compounds **6** and **7**, which can easily be separated.[5b] Complex **6** has been previously prepared (although not isolated) from **8** and H_2 and studied with regard to its catalytic properties.[6] A compound analogous to **7** having the composition **9** (with, however, the hydride and CO ligands in *cis* positions) is also known but has been obtained via a completely different route, namely by oxidative addition of HBr to **10**.[7]

The problem of how **3** is formed from **1**, $PiPr_3$, and benzene has not been finally solved. Compound **4** is definitely

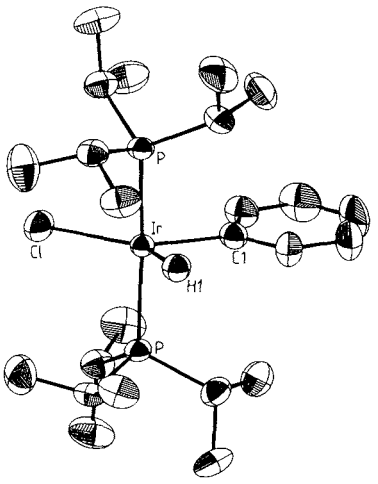
10

not a precursor of **3** since the hydrido(phenyl) complex **4** is quantitatively recovered after heating a benzene solution for several hours under reflux. Benzene is also not the source of the hydride ligands in **3**, because in C_6D_6 solution a mixture of **3** (not [IrD_2ClL_2]) and [IrDCl(C_6H_5)L_2] is produced, the latter being characterized by IR and mass spectra. We assume that cyclooctene formed in the reaction of **1** with $PiPr_3$ functions as the H_2-transfer reagent, which would be in agreement with very recent work by *Crabtree* et al.[8]

The spectroscopic data for **4**, **6**, and **7**[9] support the structural proposals for the complexes shown in Scheme 1. The most characteristic feature of the ^{1}H-NMR spectrum of **6** is the observation of *two* hydride signals in the high-field region that differ significantly in their chemical shift and thus reflect the differing *trans* influence of the Cl and CO ligands. A comparison of the NMR data of **6** and **7** led us to assume that in **7** the hydride ligand is in a *trans* position to CO.



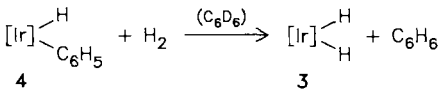


Fig. 1. Structure of **4** in the crystal. **4** has a mirror plane through Ir, Cl, and C1–C6. Selected bond distances [pm] and angles [°]: Ir-P 233.4(1), Ir-Cl 241.2(1), Ir-H1 144, Ir-C1 201.0(5); P-Ir-P 168.1(3), P-Ir-Cl 91.4(1), P-Ir-H1 85.5, P-Ir-C1 93.0(1), Cl-Ir-C1 136.1(1), Cl-Ir-H1 146.1, C1-Ir-H1 77.9.

The result of the X-ray structural analysis of **4** is shown in Figure 1.[10] The coordination sphere around the metal corresponds to a trigonal bipyramid with the phosphane ligands in axial positions. The P–Ir–P linkage is not completely linear (angle 168.1(3)°), presumably owing to steric hindrance between the isopropyl units and the phenyl group. The angles in the equatorial plane of the bipyramid differ significantly from 120°. Particularly noteworthy is the relatively small C1–Ir–H1 angle (77.9°), which possibly points to a still present (although weak) interaction between C1 and H1. This interaction may also explain the fact that in solution at room temperature there is no free rotation about the Ir–C1 bond as is proved by the appearance of *six* signals for the six phenyl carbon atoms in the ^{13}C-NMR spectrum.[9]

(2)

The hydrido(phenyl) complex **4** reacts with H_2 in C_6D_6 at room temperature in a few seconds to form **3** [Eq. (2)]. The rapid rate of this process is rationalized by supposing that one molecule of H_2 is oxidatively added to the coordinatively unsaturated metal center of the 16-electron complex **4** and the so-formed intermediate [$IrH_3(C_6H_5)ClL_2$] (a derivative of [IrH_5L_2][11]) preferentially eliminates C_6H_6 rather than H_2. It should be noted that the square-planar compounds *trans*-[IrR(CO)(PPh_3)$_2$] also react with H_2 by cleavage of the Ir–R bond and elimination of RH.[12]

1 → = CH_3 **2a** $(\eta^5\text{-}C_5Me_5)ReD_6$ **2b**

If the methanolysis is not carried out carefully, then the dark red, binuclear hydrido complex $[(\eta^5\text{-}C_5Me_5)ReH_3]_2$[7] is formed as a side product. The hexadeuteride **2b** (deuterium content ≧97%, ^{1}H-NMR) can be obtained analogously by treatment of **1** with $LiAlD_4$ and CH_3OD. The simple composition of **2a** is supported by elemental analysis, vapor pressure osmometric molecular-weight determination, and FD mass spectrometry. The structure of a half-sandwich complex having a π-coordinated pentamethylcyclopentadienyl ligand is shown by IR and NMR spectroscopy. In the IR spectrum, in addition to the typical band pattern for the $(\pi\text{-}C_5Me_5)Re$ fragment, five relatively intense bands at 2018, 980, 822, 620, and 458 cm^{-1} are observed. In the deuterio derivative **2b**, these bands are shifted to 1453, 704, 600, 458, and 345 cm^{-1}, which supports their assignment as ReH stretching vibrational (2018 cm^{-1}) and bending vibrational modes. The frequencies correspond to those of other rhenium polyhydrides.[1,2] Whereas the $^{13}C\{^1H\}$-NMR spectrum at room temperature supports the η^5 coordination of the C_5Me_5 ligand to the formally heptavalent rhenium, the six hydride ligands are

Hexahydrido(pentamethylcyclopentadienyl)rhenium, $[(C_5Me_5)ReH_6]$**

By *Wolfgang A. Herrmann** and *Jun Okuda*

The rhenium complexes $K_2[ReH_9]$ and $[ReH_7(PR_3)_2]$ have played a major role[1,2] in the development of transition-metal polyhydride chemistry.[3] In recent years, complexes of the latter type, in particular, have become increasingly interesting, because they are capable of activating C-H bonds in saturated compounds[4] and because they can be formulated as $[ReH_5(\eta^2\text{-}H_2)(PR_3)_2]$ with η^2-coordinated molecular hydrogen.[5] Whereas the majority of the metal polyhydrides are stabilized by triorganophosphane ligands, the number of hydrido complexes stabilized by π-aromatic ancillary ligands (e.g., cyclopentadienyl derivatives) is limited to a few examples.[6] In the course of our investigations into the coordination chemistry of the $(C_5Me_5)Re$ fragment containing rhenium in higher oxidation states, we have now surprisingly been able to synthesize the new polyhydride $[(C_5Me_5)ReH_6]$ **2a**.

The title compound **2a** is prepared by treatment of the Re^V complex **1** in diethyl ether with $LiAlH_4$ followed by extremely careful methanolysis of the aluminopolyhydride formed as an intermediate. Complex **2a** forms colorless crystals, which are hardly air-sensitive, undergo sublimation quickly and without decomposition at ambient temperature in high vacuum, and are even readily soluble in nonpolar (!) hydrocarbons.

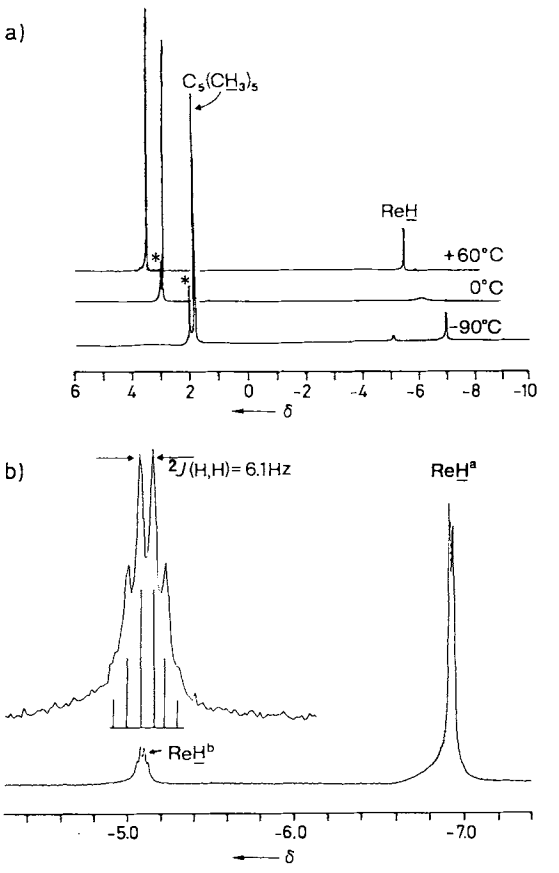

Fig. 1. a) ^{1}H-NMR spectra of the title compound **2a** at −90, 0, and 60°C (recorded in [D$_8$]toluene; 270 MHz, int. TMS); b) ReH region at −90°C, enlarged. The asterisks indicate signals due to solvent.

[**] This work was supported by the central research laboratory of Hoechst AG.

revealed as a sharp singlet besides the singlet for the CH_3 groups in the ^{1}H-NMR spectrum at 60°C.[9] We have also confirmed the number of hydride ligands by internal standardization with $[(C_5H_5)_2MoH_2]$.[8] Upon cooling of the probe, the high-field singlet undergoes significant line broadening. At −80°C, the low-temperature limit of the spectrum is reached, the practically unchanged singlet of the CH_3 groups being accompanied by a binominal sextet with a relative intensity of 1 ($\delta = -5.04$) and a doublet with a relative intensity of 5 ($\delta = -6.90$) (Fig. 1).[9]

These data show that the exchange of the six hydride ligands between two stereochemically independent positions is frozen at low temperature on the NMR time scale. If the C_5Me_5 ligand is placed at the corner of the coordination polyhedron, the coordination sphere around the rhenium atom can be regarded as a pentagonal bipyramid. On the other hand, the ring ligand can also be viewed as tridentate, and a polyhedron with nine edges can be used. In this case, the 3/3/3 coordination (tricapped trigonal prism) found in the $[ReH_9]^{2\ominus}$ ion is not preferred, but rather a 3/5/1 coordination derived from a monocapped square antiprism.

Since a pentagonal-bipyramidal structure with five hydrogen atoms in the equatorial plane has recently been found by neutron diffraction for the iridium hydride $[(PiPr_3)_2IrH_5]$,[10] we consider the above "classical" description of the coordination geometry of complex type **2** to be the most appropriate.

Experimental Procedure

A well-stirred suspension of **1** (200 mg, 0.49 mmol) in anhydrous diethyl ether (35 mL) was treated at −95°C with solid $LiAlH_4$ (190 mg, 5.0 mmol), added in portions. After 2 h, a nearly colorless mixture had formed and was allowed to warm slowly to 25°C. The mixture was cooled again to −95°C and methanol (1.0 mL, 24.8 mmol) in diethyl ether (10 mL) was added over 1 h, which resulted in violent evolution of gas. The reaction mixture was then stirred for 1 h at −95°C and allowed to warm to 25°C. After gas evolution had ceased, all volatiles were removed in vacuum, the white, powdery residue was extracted with 3 × 10 mL of toluene, and the extracts were filtered through a glass frit containing kieselguhr (dried by heating). After removal of the solvent from the yellowish filtrate in vacuum, the crude product was crystallized from a small amount of hexane at −30°C; colorless platelets, m.p. = 192°C (dec.), yield 120 mg (75%).—The derivative $[(\eta^5\text{-}C_5Me_4Et)ReH_6]$ (m.p. = 108°C, dec. above 170°C) was synthesized analogously.

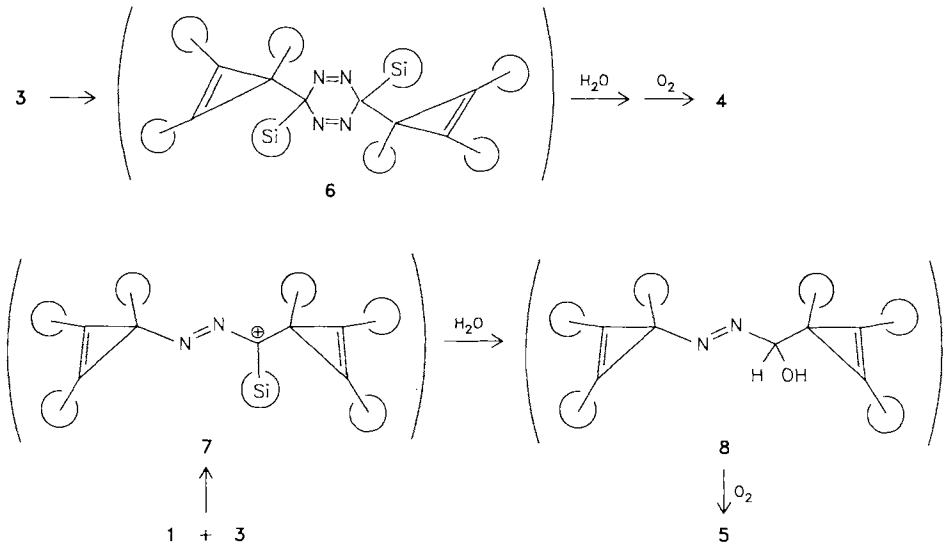
Tandem Walk Rearrangement of a Protonated Dicyclopropenyl Ketone**

By *Günther Maier,* Ines Bauer, Dieter Born,* and *Hans-Otto Kalinowski*



Tert-butyl tri-*tert*-butylcyclopropenyl ketone, upon protonation, undergoes a ring expansion to the corresponding hydroxyhomocyclopropenylium ion,[1] which, even at room temperature, undergoes a walk rearrangement.[2] The corresponding cyclopropenylcarbinyl cation represents the transition state of this process. If the *tert*-butyl group at the aliphatic C atom of the three-membered ring is not present in the starting ketone, the cyclopropenylcarbinyl system, initially formed upon treatment with acid, corresponds to an energy minimum and can therefore be observed directly.[3] How does a dicyclopropenyl ketone behave under similar conditions? To answer this question, we have synthesized bis(1,2,3-tri-*tert*-butyl-2-cyclopropenyl) ketone, which, to the best of our knowledge, is the first dicyclopropenyl ketone, and have investigated its behavior upon protonation by NMR spectroscopy.

The route to **13** is full of unique features: (a) **1** reacts with lithiated trimethylsilyldiazomethane **2** to give the cyclopropenyldiazomethane **3** (26%),[4] the tetrazine **4** (along with a small amount of the 1,4-dihydro derivative of **4**), and the acyl diimide **5**. The dimerization of **3**, leading ultimately to **4**, is unusual:[5] The initial product is probably the intermediate **6**, which undergoes hydrolysis followed by dehydrogenation by air to give the heteroarene **4**. The formation of **5** is still more surprising: The first step presumably involves attack of the terminal N atom of **3** on the cation **1**, resulting in the formation of **7**. Compound **7** un-

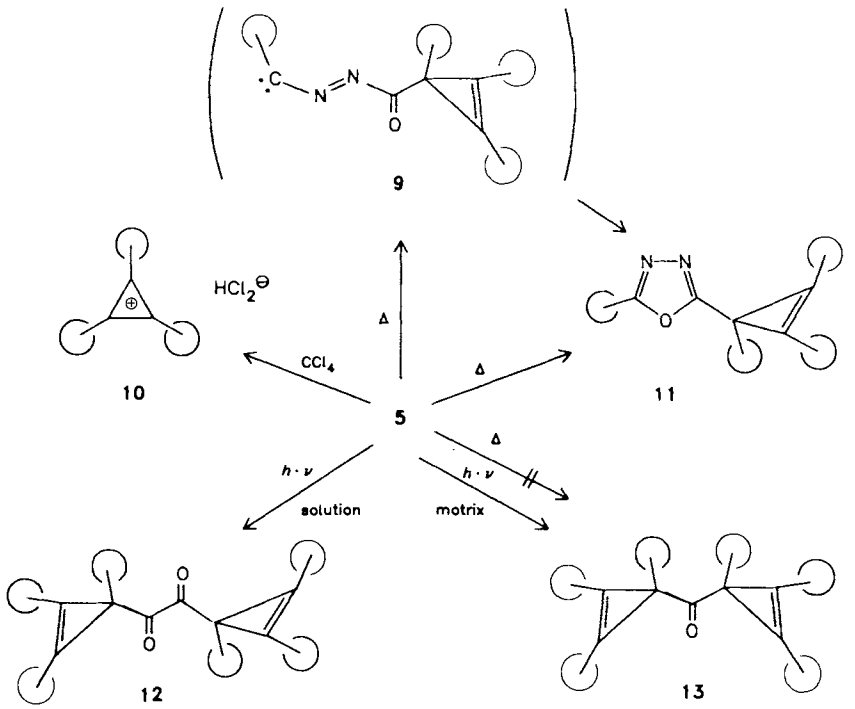
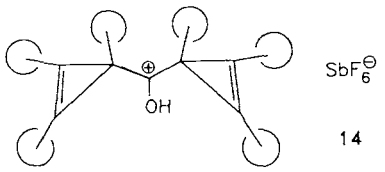
[**] Small Rings, Part 61. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 60: [3].



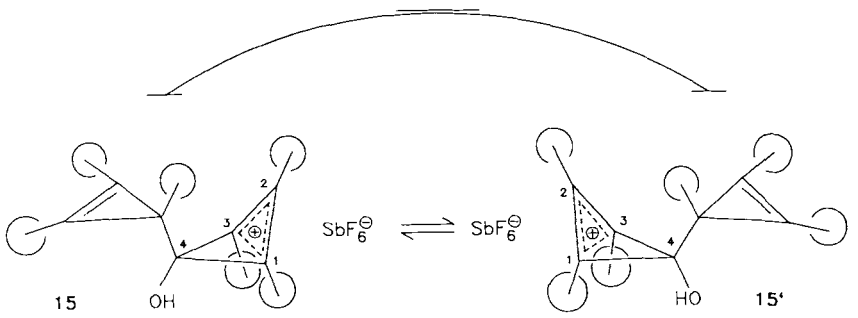
dergoes hydrolysis to give **8**, which, in turn, is oxidized by molecular oxygen to give the final product **5**.

(b) **5**, which is the potential precursor for **13**, also exhibits unusual behavior: Upon standing, a solution of **5** in tetrachloromethane forms beautiful crystals of the hydrogen dichloride **10**.[6] Heating of **5** does not result in elimination of nitrogen (and therefore formation of **13** does not occur), but rather in fragmentation to give di-*tert*-butylacetylene and the oxadiazole **11**. Thus, the cleavage begins on the C1–C2 bond of the cyclopropene ring adjacent to the nitrogen. Elimination of the alkyne affords carbene **9** (1,5 dipole), which, in turn, undergoes ring closure to give **11**.



Compound **12** is formed by dimerization of the acyl radical, which is less hindered than the cyclopropenyl radical. Upon irradiation of **5** in an organic matrix at $-196\,^{\circ}C$, the acyl radical formed has no other choice than to combine with the cyclopropenyl radical formed in the same solvent cage. Indeed, under these conditions, the ketone **13** is obtained.

Protonation of **13** with hydrogen chloride followed by ion exchange with silver hexafluoroantimonate results in the formation of a stable salt having temperature-dependent NMR spectra (^1H, ^{13}C). The low-temperature spectra (Table 1) support structure **15**. Free rotation of the *tert*-butyl group on the aliphatic C atom of the three-mem-



(c) The photochemical behavior of **5** is also unusual: Irradiation at room temperature (254 nm; benzene, cyclohexane, or tetrahydrofuran (THF)) results in gas evolution. However, instead of **13**, the α-diketone **12** is isolated.

bered ring is hindered, so that one observes two signals in the ratio of 2 : 1 for the methyl groups. If the changes in the ^1H-NMR spectra (100 MHz, CD_2Cl_2) are followed during warm-up of the sample, a first coalescence is observed at

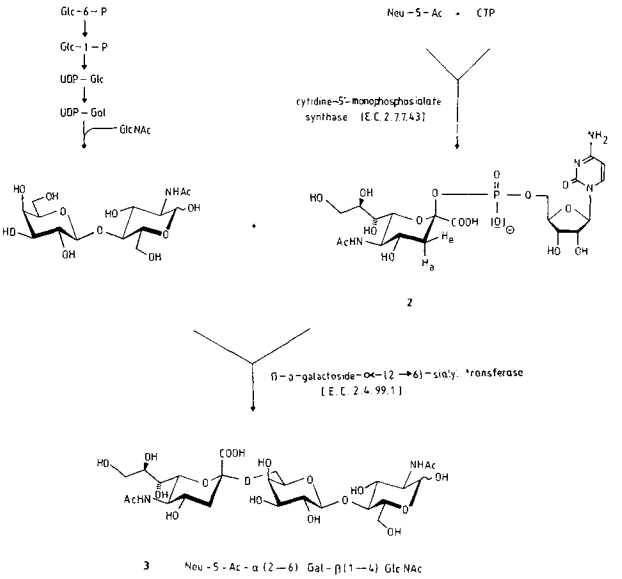
−53.5°C ($\Delta\nu$ = 48 Hz, ΔG^+ = 44.7 kJ/mol) as a consequence of the faster rotation of the *tert*-butyl group, which gives rise to only one signal (δ = 0.94) at −24.3°C. Further warming results in a second coalescence at +18.7°C ($\Delta\nu$ = 10 Hz, ΔG^+ = 63.9 kJ/mol), due to the merging of the signals of the *tert*-butyl substituents on C2 and C1/3. This means that at this temperature the walk rearrangement in the homocyclopropenylium portion of **15** (C4 moves around the fragment C1/2/3[2]) is sufficiently rapid. Accordingly, the room-temperature spectrum of **15** shows only three broad signals for the *tert*-butyl groups at δ = 1.62, 1.53, and 1.04 in a ratio of 3:2:1. At +42.5°C ($C_2D_2Cl_4$; $\Delta\nu$ = 62 Hz, ΔG^+ = 64.4 kJ/mol), a third coalescence is observed. The three signals collapse to give only one signal. At +80°C,[7] only one relatively sharp signal at δ = 1.5 is observed for the *tert*-butyl groups. Apparently, the positive charge is now transferred to the other half of the molecule as well, with contraction of the four-membered and expansion of the three-membered ring in the sense of **15** ⇌ **15'**. Compound **15** undergoes a tandem walk rearrangement via the symmetric transition state **14**, in the course of which the C atom bearing the hydroxyl group migrates around six "equivalent" ring positions.



Experimental Procedure

4/5: A 1.64-molar solution of methyllithium in diethyl ether (16.2 mL) was added at −78°C to a solution of (trimethylsilyl)diazomethane (2.73 g, 24 mmol) in 250 mL of dry THF. The resulting colorless solution was then stirred for 1/2 h and subsequently treated at −78°C with **1** (7.02 g, 24 mmol), added in portions. After 4 h, the temperature was allowed to rise

slowly to −10°C and the reaction solution was poured under vigorous stirring into a mixture containing 600 mL of saturated sodium chloride solution and 300 mL of diethyl ether. In order to remove the THF, the organic phase was washed several times with water and then dried with sodium sulfate. After removal of the ether, the product mixture was separated on 400 g of neutral alumina (activity III) at −20°C with pentane/ether (100:1) as eluent. It was thereby possible to elute four fractions: diazo compound **3**[4], tetrazine **4**, acyl diimide **5**, and a small amount (4%) of the dihydro derivative of **4**.

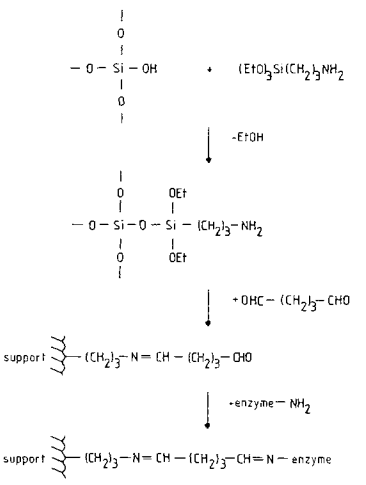
[5] It is known that ethyl diazoacetate undergoes a similar dimerization under basic conditions (review: R. Huisgen, *Angew. Chem. 67* (1955) 439). The same holds true for (diazomethyl)diphenylphosphane oxide (W. Disteldorf, M. Regitz, *Justus Liebigs Ann. Chem. 1976*, 225).
[6] Dr. *R. Boese* (Essen) is currently carrying out a detailed X-ray structure analysis of **10** in order to determine, in particular, the structure of the hydrogen dichloride anion.
[7] At this temperature, the irreversible decomposition of **15** is already complete after 30 min. For this reason, it was not possible with the apparatus at hand to confirm the results by parallel ^{13}C-NMR measurements.



Scheme 1.

Synthesis of the Trisaccharide Neu-5-Ac-α(2→6)Gal-β(1→4)GlcNAc by the Use of Immobilized Enzymes**

By *Joachim Thiem** and *Wolfgang Treder*

The trisaccharide 5-acetamido-3,5-dideoxy-α-D-glycero-D-galacto-2-nonulopyranolonic acid-(2→6)-β-D-galactopyranosyl-(1→4)-2-acetamido-2-deoxy-D-glucopyranose [Neu-5-Ac-α(2→6)Gal-β(1→4)GlcNAc **3**] is frequently bound to the terminus of glycoproteins, e.g., in glycophorin A, a surface glycoprotein of erythrocytes. The trisaccharide—bound to a solid support—would be of particular interest as a receptor for proteins and as an immunoabsorbent. The multistep chemical synthesis[1] is very laborious and affords only low yields. An alternative is an enzymatic synthesis[2] involving the use of immobilized enzymes, which follows, on a preparative scale, the biosynthetic route. This is accomplished by transferring *N*-acetylneuraminic acid (Neu-5-Ac) via the nucleotide cytidine 5'-monophosphosialate **2** to *N*-acetyllactosamine **1** using sialyl transferase (Scheme 1).

1 is prepared by a modification of the enzymatic synthetic cycle introduced by *Wong* et al.[3] for the first time on a preparative scale, involving regeneration of cofactors. Glucose-6-phosphate (1.43 g, 4 mmol) is first converted, via glucose-1-phosphate and UDP-glucose, into UDP-galactose, which is then transferred to *N*-acetylglucosamine (0.88 g, 4 mmol) using galactosyl transferase. The six enzymes required for this purpose are immobilized on functionalized silica gel by means of glutardialdehyde according to the method of *Wheetall*[4] (Scheme 2).[5] This procedure is, in particular, less expensive than that usually employed involving the use of organic supports (yield of **1**: 405 mg, 30%).

Scheme 2.

2 is prepared from Neu-5-Ac (60 mg, 19.5 μmol) by enzyme-catalyzed reaction with cytidine triphosphate (CTP, 600 mg, 123 μmol).[6] For the first time, it was possible to use the enzyme required for this synthesis, cytidine-5'-monophosphosialate synthase (E.C. 2.7.7.43, 600 U) from bovine *Glandula submandibularis*, in the immobilized form shown in Scheme 2. This approach appreciably simplifies the workup of the reaction mixture. Instead of ion-exchange chromatography with gradient elution and subsequent gel filtration of the reaction mixture, **2** can be obtained in pure form simply by separation of the reaction mixture on Sephadex G-15 (yield of **2**: 87 mg, 72%).

Conversion to the trisaccharide **3** was achieved by incubation of **2** (60 mg, 0.1 mmol) with **1** (32 mg, 0.1 mmol) in the presence of the enzyme β-D-galactoside-α(2→6)sialyl transferase (E.C. 2.4.99.1, ca. 2.5 U) in excess, which can be isolated from colostrum by affinity chromatography with cytidine diphosphate-agarose.[7] The reaction solution with albumin and magnesium chloride was allowed to stand for 24 h at 37°C and pH = 6.5 and then worked up by

elution with 5 mM sodium phosphate buffer on a phosphate-containing Dowex 1-X2 column. The free trisaccharide **3**, whose interglycosidic linkages were confirmed by ^{1}H-NMR spectroscopy,[8] was thereby obtained directly on a 50-μmol scale (yield: 31 mg, 52%).

exhibit greater anisotropy of the hyperfine interaction, whereby their relaxation behavior is strongly influenced. Therefore, for an optimal ^{13}C-ENDOR effect, an even higher microwave and radiofrequency power is required.[1]

Scheme 1.

^{13}C-ENDOR Investigation of an Organic Tetraradical in the Quintet State; Synthesis of a Fourfold ^{13}C-Labeled Tetrakisgalvinol**

By *Michael Grimm, Burkhard Kirste,* and *Harry Kurreck**

Dedicated to Professor Georg Manecke on the occasion of his 70th birthday

Organic compounds carrying several unpaired electrons exhibit, in addition to Zeeman splitting and hyperfine interaction, magnetic peculiarities that are characterized as scalar exchange interaction and dipolar coupling of the unpaired electrons. If the exchange interaction is large compared with the hyperfine interaction ($|J| \gg |a|$), the number of EPR (electron paramagnetic resonance) hyperfine components increases, since the unpaired electrons are formally delocalized over the whole molecule and therefore couple with all magnetic nuclei. This leads to an increase in spectral line density, while the overall splitting is retained and the resolution of the EPR spectrum becomes poorer. The dipolar electron interaction generates additional relaxation processes, which lead to both a line broadening as well as to a reduction of the electron nuclear double resonance (ENDOR) effect. This results in a diminution of the resolution and requires higher microwave powers. Compared with protons, ^{13}C nuclei generally

Organic multispin systems with weak dipolar electron interaction have so far been investigated by ^{1}H-ENDOR spectroscopy up to a tetraradical in the quintet state and by ^{13}C-ENDOR spectroscopy[2] to a triradical in the quartet state.[3] We now report on the first ^{13}C-ENDOR investigation on the quintet state of a fourfold ^{13}C-labeled tetraradical with tetrahedral symmetry. The key compound for the selective generation of mono-, di-, tri-, and tetraradicals is the diamagnetic ^{13}C-tetrakisgalvinol **9**, which was obtained as follows (Scheme 1): First, tetraphenylmethane **2** was prepared by Friedel-Crafts alkylation,[4] diazotization, and deamination.[5] Stirring of powdered **2** in bromine led to **3**, which was converted into the ^{13}C-tetranitrile **4** with ^{13}C-potassium cyanide using palladium(II) acetate as catalyst.[6] Alkaline hydrolysis of **4** afforded the ^{13}C-tetracarboxylic acid **5**, which upon reaction with diazomethane furnished the ^{13}C-tetraester **6**. Modifying the previously published galvinol synthesis,[7] (2,6-di-*tert*-butyl-4-bromophenoxy)trimethylsilane **8** was converted with *tert*-butyllithium into (2,6-di-*tert*-butyl-4-lithiophenoxy)trimethylsilane **7**, which was subsequently treated with **6**. Addition of water and slow thawing led to a gentle, alkaline elimination of the trimethylsilyl groups with formation of the ^{13}C-tetrakisgalvinol **9**.

Figure 1 (left) shows the experimental EPR spectra of the mono- and tetraradicals that are accessible from **9** by oxidation with alkaline potassium hexacyanoferrate(III).[8]

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

The well-resolved EPR spectrum of the monoradical consists of a doublet of quintets (one ^{13}C-nucleus, four *m*-protons). The EPR spectrum of the tetraradical **10** shows a quintet splitting by four ^{13}C-nuclei, while the expected 17-fold splitting by 16 *m*-protons is not resolved.

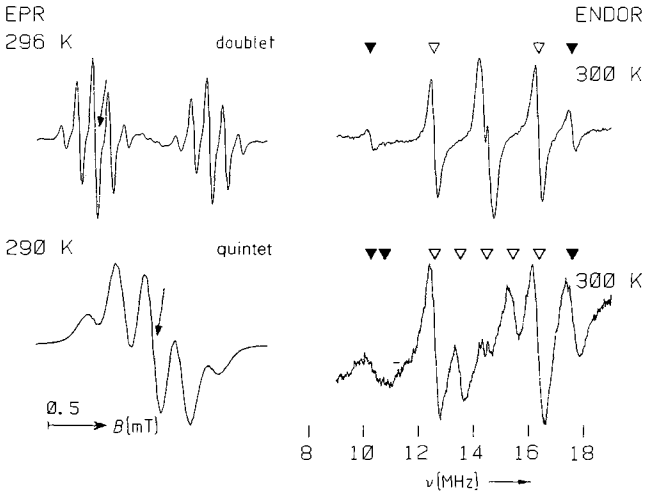

Fig. 1. EPR (left) and ENDOR spectra (right) of the monoradicals (top) and of the tetraradical (bottom) generated by selective oxidation of **9**. Also shown (left) are the field settings in the EPR spectra for recording the ENDOR spectra (arrows) and (right) the calculated ^1H-resonance frequencies (white triangles) and ^{13}C-resonance frequencies (black triangles).

In both cases, ENDOR spectra of the pure species (Fig. 1 right) can be obtained by appropriate positioning in the EPR spectra (arrows in Fig. 1 left). In Figure 1 (right), the ^1H-resonances (white triangles) and ^{13}C-resonances (black triangles) calculated on the basis of the ENDOR reson-

$$\nu_{ENDOR} = |\nu_n - M_S a^S| \qquad (a)$$

ance condition (Eq. (a); ν_n = free nuclear frequency, M_S = magnetic quantum number of the total electron spin, a^S = coupling constant for the electron spin quantum number S) are presented together with the experimental ENDOR spectrum. Whereas all the expected ^1H-ENDOR signals with the exception of those at the free proton frequency[2] can be observed in each case, only the ^{13}C-ENDOR line pairs belonging to $M_S = \pm S$ are clearly visible.[9] For experimental reasons, only the high frequency signal of the second ^{13}C-ENDOR line pair of the tetraradical ($M_S = \pm 1$) is accessible to the measurement. This signal, however, is broad or not present, which can be explained by the fact that the exchange interaction for the ^{13}C-tetraradical is of the order of magnitude of the ^{13}C-hyperfine interaction ($|J| \approx |a_C|$), whereas $|J| \gg |a_H|$ holds for the protons. The mixing of states due to the ^{13}C-hyperfine interaction should then strongly influence the relaxation behavior and the positions of the ^{13}C-ENDOR signals for $M_S \neq \pm S$.[10]

Procedure[11]

2: A mixture of **1** (52 g, 0.2 mol), aniline (28.5 mL, 0.3 mol), concentrated hydrochloric acid (90 mL), and glacial acetic acid (600 mL) was heated under reflux for 48 h; the intermediate product was isolated, dissolved in 1.5 L of ethanol and 100 mL of concentrated sulfuric acid, diazotized at −10°C with 60 mL of isopentyl nitrite, and, after 45 min, deaminated with 150 mL of 60% hypophosphorous acid under reflux; crude yield: 52.7 g (82.2%); after twofold recrystallization from 1,2-dichloroethane, 38.3 g of **2** (59.8%); m.p. 282–283°C.

3: 18 g (56.2 mmol) of powdered **2** was added to ca. 60 mL of pure bromine at room temperature; the mixture was stirred for 45 min and then diluted with ethanol in an ice-cooled vessel until no further crude product precipitated; the crude product was filtered off and washed with sodium bisulfite solution; crude yield 34.8 g (97.4%); after double recrystallization from chloroform/ethanol: 23.4 g of **3** (65.5%); m.p. 312.5–313°C.

4: A mixture of **3** (1.2 g, 1.89 mmol), ^{13}C-potassium cyanide (1 g, 15.13 mmol, 99 atom-% ^{13}C), potassium iodide (0.113 g, 0.68 mmol), palladium(II) acetate (0.026 g, 0.113 mmol), potassium hydroxide (0.21 mg, 3.8 μmol), and anhydrous hexamethylphosphoric triamide (12 mL) was heated under argon protective gas for 19 h at 85–95°C; the reaction solution was evaporated to dryness and the residue was taken up in methylene chloride and washed with water. Crude yield after removal of solvent: 0.83 g.

5: A mixture of **4** (0.8 g, 1.89 mmol), potassium hydroxide (1.88 g, 33.5 mmol), and ethylene glycol (20 mL) was heated under reflux for 18 h; after dilution with water, extraction with methylene chloride, and addition of diluted hydrochloric acid, **5** precipitated; crude yield after filtration by suction: 0.93 g.

6: **5** (0.93 g, 1.86 mmol) was esterified in an ethanol-methanol mixture at room temperature with diazomethane; crude yield: 1.2 g; purity determined by HPLC: 94.1%; a part of the sample was purified by HPLC (7 μm Polygosil 60 KN, 32 × 250 mm/methylene chloride + 0.25% 2-propanol); degree of labeling as expected within the accuracy of measurement (96% $^{13}C_4$, mass spectroscopy).

9: A solution of **7** (7.9 g, 22.11 mmol) in anhydrous tetrahydrofuran (100 mL) was cooled to −70°C under argon protective gas and treated within 45 min with a solution of *tert*-butyllithium (30.55 mL) in *n*-pentane (44.23 mmol); after 15 min a solution of **6** (0.4 g, 0.72 mmol) in anhydrous THF (20 mL) was added to the reaction solution; within 2.5 h the temperature was increased to −30°C. The solution was treated with a small amount of water and no longer subjected to cooling; it was then stirred for a further 12 h (cleavage of trimethylsilyl groups) and the organic phase separated, acidified with dilute hydrochloric acid, and washed with water; phenols (from **7**) were removed by flash chromatography[12] (silica gel 40–63 μm [Merck 9385], 80 × 80 mm/methylene chloride); yield: 1.47 g; purity determined by HPLC: 94.5%; a part was purified by HPLC (7 μm Polygosil 60 KN, 32 × 250 mm/methylene chloride).

[8] The EPR spectra of biradicals and triradicals, also accessible by oxidation, are however comparatively poorly resolved, inter alia, because of the unavoidable presence of other radical states due to redox equilibria. ENDOR spectra of the pure species can also be obtained in these cases by appropriate positioning in the EPR spectrum [9].
[9] Hyperfine coupling constants in toluene [MHz]: monoradical: $a^d_H = +3.78$, $a^d_C = -27.85$ (320 K); diradical: $a^1_H = +1.88$, $a^1_C = -13.92$ (310 K); triradical: $a^q_H = +1.25$, $a^q_H = -9.31$ (300 K); tetraradical: $a^q_H = +0.93$, $a^q_C = -6.97$ (300 K).

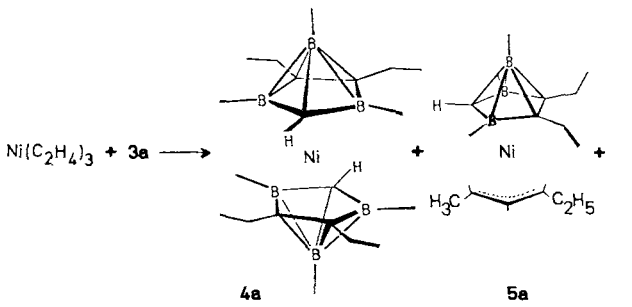
Bis(η^5-2,3,5-tricarbahexaboranyl)nickel, a Nickelocene Analogue**



By *Joachim Zwecker, Hans Pritzkow, Ulrich Zenneck,* and *Walter Siebert**

The oligodecker complexes **1** (n = 1–8) with terminal 2,3,5-tricarbahexaboranyl ligands are formed in an as yet unclear way from the bis(2,3-dihydro-1,3,4,5-tetraalkyl-1,3-diborole)nickel sandwich compounds **2**.[1] Decisive for the carbaboranyl formation and the stacking reaction is the reactive axial CH-bond at the pentacoordinated C2 atom of the ligands **3a**, **b** in **2**.[2]

Bis(η^5-2,3,5-tricarbahexaboranyl)nickel **4**, the parent member of the class of compounds **1** (for n = 0), is not observed in the conversion of **2**.[3] We now report the synthesis and characterization of the paramagnetic complex **4a** as the first bis(tricarbahexaboranyl)metal complex analogous to the metallocenes.

Reaction of excess **3a** with tris(ethene)nickel[4a] (prepared from nickel/toluene cocondensate and ethene[4b]) at low temperature in toluene leads to the formation of crystalline **4a** in 12.5% yield. The tricarbahexaboranyl(allyl)nickel complex **5a**[5a] is formed at the same time and can be isolated by distillation. Since this 18e-complex is not converted into **4a** under the reaction conditions, **4a** must be formed from another precursor of the reaction of **3a** with $[Ni(C_2H_4)_3]$. We assume that the replacement of two ethene ligands in $[Ni(C_2H_4)_3]$ by **3a** leads to a labile 2,3-dihydro-1,3-diborolyl(ethene)hydridonickel complex.[5b] By uptake of a H_3CB group from **3a**, a reactive ethene(hydrido)-η^5-tricarbahexaboranylnickel complex may then form as educt of **4a**.

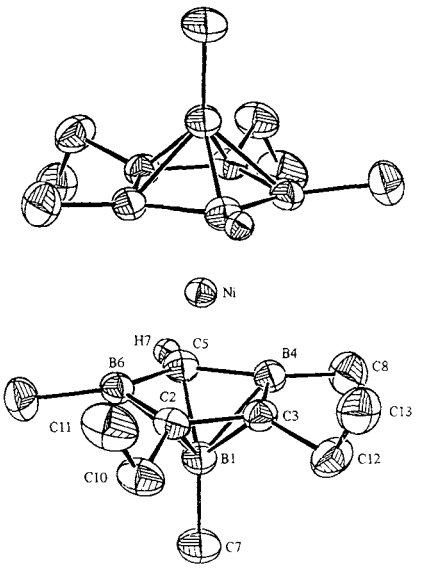


Fig. 1. Crystal structure of **4a**. Selected bond lengths [Å] (mean standard deviation 0.003 Å): Ni-B4(6) 2.198, 2.204; Ni-C2(3) 2.227, 2.240; Ni-C5 2.150; B1-B4(6) 1.802, 1.808; B1-C2(3) 1.711, 1.708; B1-C5 1.679; B4(6)-C3(2) 1.559, 1.551; B4(6)-C5 1.555, 1.566; C2-C3 1.484.

The structure proposed for **4a** is consistent with the analytical and mass spectrometric data and has been confirmed by an X-ray structure analysis (Fig. 1)[6]: In the crystal, the Ni atom is located at an inversion center; the molecule is therefore centrosymmetric. The structure of the carbaboranyl ligand does not differ from that in the triple decker **1**, n = 1.[1] The Ni-C and Ni-B distances are similar to those found for nickelocene[7] and the bis(dicarbollide)nickel dianion.[8] The distance of the nickel atom from the ring plane is 1.77 Å (maximum deviation of the ring atoms from the plane ±0.03 Å).

Both the cyclovoltammetrically determined electrochemical behavior of **4a** (Fig. 2a) and the ESR spectrum of the 19e-cation $4^{\oplus\ominus}$ (Fig. 2b) reveal the relationship between **4a** and nickelocene. Magnetic measurements on **4a** in the region of 120–300 K indicate Curie-Weiss behavior and give $\mu_{eff} = 3.06 \pm 0.2\,\mu_B$.[11] For nickelocene $\mu_{eff} = 2.89 \pm 0.15\,\mu_B$.[12] Thus, **4a** likewise occurs as triplet molecule. The results prove that the *nido*-2,3,5-tricarbahexaborate $C_3B_3R_5H^{\ominus}$ and the cyclopentadienide ion are isolobal.

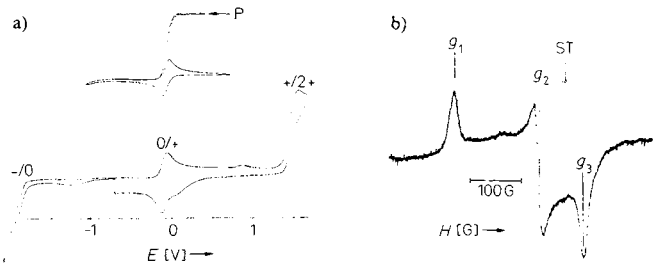

Fig. 2. a) Cyclovoltammogram of **4a** in $CH_2Cl_2/(C_4H_9)_4N^{\oplus}PF_6^{\ominus}$ at Pt wire electrodes vs. SCE; bottom: range +1.7 to −2.0 V, v = 200 mV/s; top: range +0.9 to −1.1 V, v = 200 mV/s; and P = polarogram at platinum rotating disc electrode (RDE): $E(0,+) = -0.11$ V (reversible), $E_p(+,2+) = 1.5$ V (irreversible), $E_p(-,0) = 2.0$ V (irreversible) [9]. b) X-band ESR spectrum of $\mathbf{4a}^{\oplus\ominus}$ (in closed ESR cell generated with $[(C_5H_5)_2Fe]BF_4$) in CH_2Cl_2 at $T = -160$ °C. Standard (ST): $Li^{\oplus}TCNQ^{\odot\ominus}$, $g_{ST} = 2.0025$. $g_1 \approx 2.14$, $g_2 = 2.03$, $g_3 = 1.98$; at room temperature $\langle g \rangle$ is not determinable [10].

[**] η^5-Carbaboranylmetal Complexes, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie, and BASF AG.—Part 1: [1].

Procedure

A solution of **3a** (0.9 g, 6.1 mmol) in toluene (40 mL) was treated at −50°C with 4 mL of a solution of tris(ethene)nickel in toluene (2.0 mmol $Ni(C_2H_4)_3$; titer determined by reaction with $P(OCH_3)_3$ and 1,5-cyclooctadiene). The stirred mixture was allowed to warm to room temperature in 30 min and the solvent was then removed under vacuum. At 45°C/10^{-2} torr, light green **4a** sublimed, which is colorless in thin layers (75 mg, 0.19 mmol, 12.5%). MS: m/z 403 ($M^{\oplus}$, 100%), correct isotopic distribution, hardly any fragmentation. Correct C,H analysis.

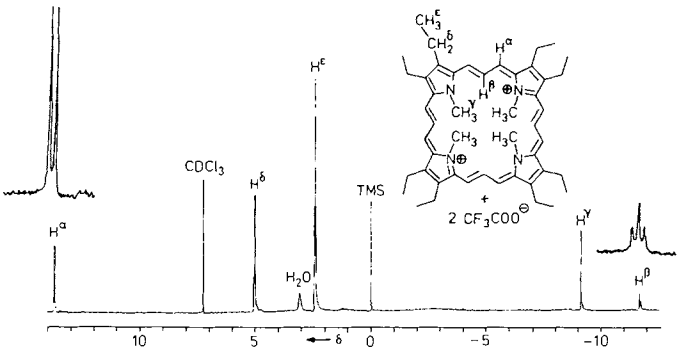
Synthesis of a Fourfold Enlarged Porphyrin with an Extremely Large, Diamagnetic Ring-Current Effect**

By *Martin Gosmann* and *Burchard Franck**

Porphyrins have an aromatic π-electron system of the [18]annulene type.[1] Like the annulenes, they exhibit a diamagnetic ring current in the ^{1}H-NMR spectrum, which serves as a qualitative criterion for aromatic character.[2] By cyclotetramerization of the pyrrylpropenol **3a**, we have now achieved the first synthesis of a fourfold enlarged porphyrin, **7**, having a [26]annulene structure.

The deep red-violet compound **7** is characterized by the largest ring-current effect found so far for a cyclic conjugated π-electron system (Fig. 1). The shift difference ($\Delta\delta$) of the resonances for the inner ($\delta=-11.64$) and outer ring protons ($\delta=+13.67$) is 25.3 ppm! This shift difference is twice as large as that found for the [18]annulene **1** ($\Delta\delta=12.1$ ppm).[7] Because **7** combines marked annulene behavior with the porphyrin structure, we refer to it as "[26]porphyrin."[3]



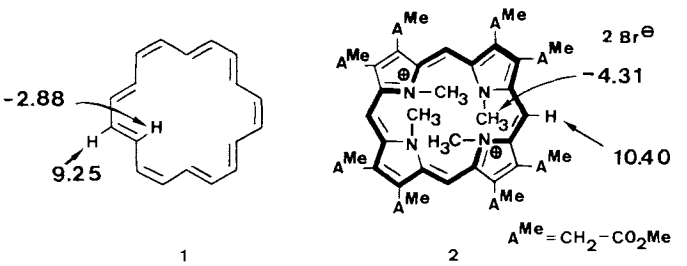


Fig. 1. 300-MHz ^{1}H-NMR spectrum of the [26]porphyrine **7b** in $CDCl_3$.

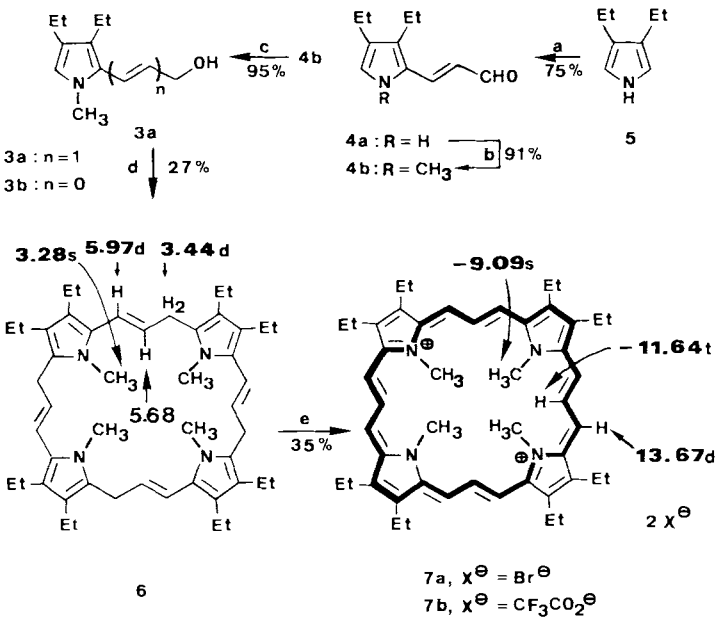
The motivation for the synthesis of **7** was the ring-current effect observed in the ^{1}H-NMR spectrum of the *N,N',N'',N'''*-tetramethylporphyrin **2**[4,5] (Scheme 1), which, despite the steric hindrance and nonplanar structure, exceeds that of the [18]annulene **1**. Since the steric hindrance in the ring center is reduced for the ring-enlarged [26]porphyrin **7**, an even larger ring-current effect was expected to be favored. On the other hand, according to several assumptions, a decrease in the ring-current effects was expected for larger annulenes.[6]



Scheme 1. ^{1}H-NMR signals (δ values) for inner and outer protons of the [18]annulene **1** (in $[D_8]$THF) [7] and of the *N,N',N'',N'''*-tetramethylporphyrine **2** (in CD_3CN) [5].

The *N*-methylpyrrylpropenol **3a** was selected as the key building block for the synthesis of the [26]porphyrin **7** (Scheme 2). It is known that 2-(aminomethyl)- and 2-(hydroxymethyl)pyrroles of type **3b** can be condensed, in analogy to the route of porphyrin biosynthesis, by acid-catalyzed cyclotetramerization to form porphyrinogens.[5,8] We were especially interested in whether the remarkable selectivity of this reaction (no oligomers, hardly any polymers) would also hold for the vinylogous compound **3a**.

For the synthesis of the very reactive compound **3a**, 3,4-diethylpyrrole **5**[9] was converted into **4a** by a vinylogous Vilsmeier formylation with 3-(dimethylamino)acrolein. Compound **4a** was *N*-methylated to **4b**, which, in turn, was reduced with $NaBH_4$ in situ to **3a**. Condensation of **3a** gave the colorless, non-cycloconjugated [26]porphyrinogen **6**[3] in 27% yield. Compound **6** was dehydrogenated with Br_2 to give the bisquaternary [26]porphyrin **7a**, chromatographically purified (silica gel, CH_3CN/trifluoroacetic

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Scheme 2. Synthesis of the [26]porphyrin **7** from 3,4-diethylpyrrole **5** [9]. For **6** and **7**, the ^{1}H-NMR data (δ, in $CDCl_3$) are included for comparison of the diamagnetic ring current. Reaction conditions: a) 3-(Dimethylamino)acrolein/$POCl_3$, CH_2Cl_2, −18°C, 90 min; **4a**: m.p. = 96°C; b) KOH, dimethyl sulfoxide, CH_3I, 20°C; **4b**: m.p. = 58°C; c) $NaBH_4$, methanol, 30 min; d) toluenesulfonic acid, acetic acid, 20°C, 30 min; **6**: m.p. = 250°C (dec.); e) Br_2/$CHCl_3$, 20°C.

acid = 250 : 1), and converted into the bis(trifluoroacetate) **7b** for elemental analysis.[11]

The remarkable ring-current effect of the [26]porphyrin **7** is presumably due to the flattening effect of the four pyrrole rings; the two cationic centers support this effect somewhat but are not decisive.[11] Thus, according to the ^{1}H-NMR criterion, **7b** contains a "superaromatic π-electron system." It demonstrates that the limits for aromatic behavior, so far expected to be reached with [26]annulenes, can be exceeded.

Apart from the ring-current effect of the [26]porphyrin **7**, its strong color intensity also deserves consideration. Thus, the molar extinction coefficient (ε) of its most intense absorption band at 547 nm (909600) is more than twice as large as that for the corresponding Soret band of porphyrins (maximally 400000). In the case of [26]porphyrin **7**, the visual effect of the color is increased still further by the fact that its most intense band lies in the middle of the visible range. In contrast, the Soret band of the porphyrins at 400 nm, compared with the longer-wavelength satellite maxima that are smaller by an order of magnitude, contributes little to the depth of color.

[1] The 18 π-electron system of the porphyrins can be viewed as a doubly bridged diaza[18]annulene or as a tetraaza[16]annulene dianion. The formulation as a dianion is in agreement with, among other characteristics, the spectroscopic properties of the metal complexes of the porphyrins: cf. H. Scheer, J. J. Katz in K. M. Smith (Ed.): *Porphyrins and Metalloporphyrins*, Elsevier, Amsterdam 1975; J. Griffiths: *Colour and Constitution of Organic Molecules*, Academic Press, London 1976.

[2] J. A. Elvidge, L. M. Jackson, *J. Chem. Soc. 1961*, 859; P. J. Garratt in D. H. R. Barton, W. D. Ollis (Eds.): *Comprehensive Organic Chemistry, Vol. 1*, Pergamon, Oxford 1979, p. 224.
[3] The term includes other enlarged porphyrins of this type, which we are currently studying [10]. In order to describe the structure more precisely, the number of C atoms between the pyrrole units can be included in the name; the skeleton of **7** would thus be a "[26]porphyrin-[3.3.3.3]."

Weak Pd···S Interactions in Palladium(II) Complexes with 1,4,7-Trithiacyclononane as Ligand**

By *Karl Wieghardt,* Heinz-Josef Küppers, Eleonore Raabe,* and *Carl Krüger*

The nine-membered rings of 1,4,7-triazacyclononane (tacn) and 1,4,7-trithiacyclononane (**L**) are especially suitable for occupying one or two faces in octahedral complexes of transition metals. The thermodynamic and kinetic stability of such complexes is very high (macrocyclic effect). It therefore appeared interesting to investigate the coordination behavior of these tridentate ligands toward metal centers, which, because of their electronic structure, prefer a square-planar coordination (e.g. Pd^{II},Pt^{II}). Thus we were able to show[1] that a square planar PtN_4 arrangement with two twofold coordinated macrocycles is indeed present in $[Pt(tacn)_2]Br_2 \cdot 2H_2O$.[2]

It is known that **L**[3] has *endo*-conformation, both in the solid state and in solution:[4] all three S-donors lie on the same side of the nine-membered ring, i.e. the conditions are ideal for the octahedral coordination of a metal center by two molecules of **L**. We report here on the complexation chemistry of **L** with Pd^{II} and on both the crystal struc-

ture and the electronic spectra of the complexes **1** (green), **2** (blue) and **3** (brown). *Schröder* et al.[5] recently detected two weak axial Pd···S interactions (Pd···S: 3.273(2) Å besides four normal, equatorial Pd–S bonds (Pd–S: 2.311(1) Å) in the yellow-brown complex $[PdL_1](BPh_4)_2$. The PdS_6 chromophore leads to a yellow-brown color, whereas **1** is green and **2** is blue.

$[PdL_2](PF_6)_2$ **1**

$[PdL_2](PF_6)_2 \cdot H_2O$ **2**

$[PdLBr_2]$ **3**

Pd^{II} acetate reacts with an excess of **L** in anhydrous methanol to give a clear, green solution, from which green crystals of **1** crystallize on addition of $NaPF_6$. In the presence of water, blue crystals of **2** precipitate out as well as the green crystals of **1**. The same products are also obtained from acetonitrile or acetone, whereupon a mixture of **1** and **2** or only **2** crystallizes out with increasing water content. **1** and **2** dissolve in water to give a blue solution. Addition of a solution of NaBr in methanol instead of $NaPF_6$ to the above reaction solution led to precipitation of orange-brown **3**. Measurements of the magnetic susceptibility between 100 and 300 K showed that **1**, **2** and **3** are diamagnetic.

Both **1** and **2** contain the cation $[PdL_2]^{2\oplus}$ and $PF_6^{\ominus}$ ions; in **2**, the asymmetric unit contains in addition one molecule of water of crystallization.[6] The structure of the $[PdL_2]^{2\oplus}$ ion in **1** and **2** is, within experimental error, the same (Fig. 1). In both structures it is located at a crystallographic inversion center. The central Pd atom is in a distorted octahedral environment: four short equatorial Pd–S bonds together with two weak axial Pd···S interactions. The axial Pd–S distances in $[PdL_1](BPh_4)_2$[5] are significantly longer than in **1** and **2**, while the four equatorial Pd–S bonds are comparable with those in **1** and **2**.[7] Paramagnetic complexes of Ni^{II} with NiS_6 polyhedra are octahedral.[8]

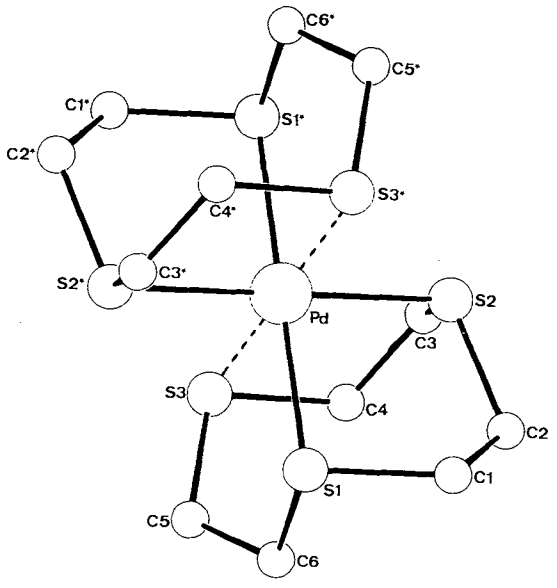

Fig. 1. Structure of the $[PdL_2]^{2\oplus}$ cation of **1** in the crystal. Important bond lengths [Å] and angles [°] (values for **2** in brackets): Pd-S1 2.333(2) [2.309(1)], Pd-S2 2.318(2) [2.314(1)], Pd-S3 2.957(2) [3.005(1)]; S1-Pd-S2 88.6(1) [89.2(1)], S1-Pd-S3 83.2(1) [83.9(1)], S2-Pd-S3 83.1(1) [82.5(1)]. In both structures the mean C–C bond length is 1.51(1) Å, the mean C–S bond length 1.82(1) Å.

The central Pd atom in **3** (Fig. 2) is surrounded by a distorted square-pyramidal array of two Br atoms and three S atoms. The Pd–S bond to the apical S atom is significantly longer than the bonds to the equatorial S atoms, each of which is oriented *trans* to a Br atom. Due to the *trans* influence of the Br atoms the equatorial Pd–S distance in **3** (2.66(3) Å) is 0.044 Å shorter than the corresponding distances in **1**, **2**, and $[PdL_1](BPh_4)_2$, whereas the Pd–Br distance is 0.02 Å longer than in $[PdBr_4]^{2\ominus}$.[9]

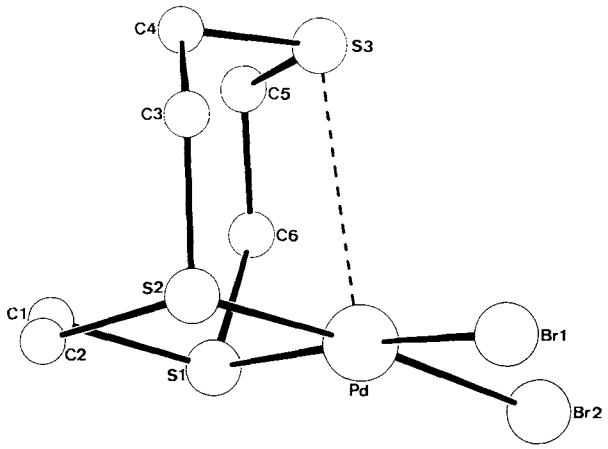

Fig. 2. Crystal structure of **3**. Important bond lengths [Å] and angles [°]: Pd-S1 2.275(2), Pd-S2 2.257(2), Pd-S3 3.125(1), Pd-Br1 2.456(1), Pd-Br2 2.468(1); S1-Pd-S2 89.3(1), S1-Pd-S3 78.7(1), S1-Pd-Br1 174.1(1), S1-Pd-Br2 89.3(1), S2-Pd-S3 81.7(1), S2-Pd-Br1 87.5(1), S2-Pd-Br2 175.5(1), S3-Pd-Br1 105.7(1), S3-Pd-Br2 102.2(1), Br1-Pd-Br2 93.4(1).

The reflection spectrum of **2** is identical with the spectra of **1** and **2** in water; an absorption maximum is observed at $\lambda = 620$ nm ($\varepsilon = 50$ L mol^{-1} cm^{-1}). In the reflection spectrum of **1**, this band is shifted to 575 nm. The change in color from blue (**2**) to green (**1**), however, is not due to this, but to the greatly enhanced intensity of the absorption between 400 and 470 nm (in **1**), which in **2** is additionally shifted to shorter wavelengths. The position of the metal-to-ligand charge-transfer bands is probably strongly dependent on the weak Pd···S interactions. In $[PdL_1](BPh_4)_2$, these are so weak that it can be assumed that only a square-planar PdS_4-coordination is present, whereas such a Pd···S interaction in **1** is relatively strong and in **2** only slightly weaker. Since the water of crystallization in **2** is not coordinated to the $[PdL_2]^{2\oplus}$ ions—weak hydrogen bonding with the $PF_6^{\ominus}$ ions cannot be ruled out—the different absorptions of **1** and **2** are attributed to different packing of the cations and anions.

Procedure

1, **2**: 0.1 g (0.45 mmol) of Pd^{II}-acetate was added at 20°C to a solution of **L** (0.18 g, 1.0 mmol) in anhydrous methanol (30 mL). Subsequent treatment of the green solution with $NaPF_6$ (1.0 g, 5.95 mmol) led to precipitation of **1** as green crystals. **1** dissolved in methanol/H_2O to give a blue solution, from which blue crystals of **2** [$\delta(CH_2)$ (80 MHz, D_2O) = 3.36 (s)] were obtained upon addition of $NaPF_6$. If a little water is present, **1** and **2** crystallize out together.

3: The above mentioned reaction solution was treated with a solution of NaBr (1.0 g, 9.72 mmol) in methanol (10 mL). Orange-brown crystals of **3** immediately separated out; these were recrystallized from acetonitrile.

All compounds gave correct elemental analyses (C, H, N, S (Br)).

2-Lithio-1-phenylpyrrole: X-Ray Structure Analysis and ^{6}Li-^{1}H 2D Heteronuclear Overhauser NMR Spectroscopy (2D HOESY)**

By *Walter Bauer, Gerhard Müller, Rafael Pi,* and *Paul von Ragué Schleyer**

Monolithiated organic compounds can often be converted further into synthetically useful dilithiated derivatives.[1] The first lithium substituent often determines the position of the second metalation.[2] Examples from our own work for such stereoselective second lithiation are 2,2′-dilithiobiphenyl,[3] 1,8-dilithionaphthalene,[4] and α,α′-dilithio-α,α′-diphenyl-*o*-xylene.[5] MNDO calculations indicate the presence of interactions between Li and the kinetically activated H atoms: the LUMO coefficients are largest at these atoms, and the corresponding C–H bond lengths are longest.[4] By means of the present example, 2-lithio-1-phenylpyrrole **1**,[6] we now show that the position of the second lithiation can also be predicted by X-ray and NMR analysis of the monolithiated precursor.

X-ray structure analysis[7] of **1** showed a dimer (**1**·TMEDA)$_2$ (TMEDA = *N,N,N′,N′*-tetramethylethylenediamine) with a central C2–Li–C2′–Li′ four-membered ring and crystallographic C_2 symmetry (Fig. 1), similar to that found for phenyllithium·TMEDA.[8] The two pyrrole rings are nearly orthogonal to the C_2Li_2 ring and *cis* to each another.[9] The angle between the pyrrole and phenyl rings is 26.1°. The C_2Li_2 four-membered ring is not planar (dihedral angle between the Li, Li′, C2 and the Li, Li′, C2′ planes 157.7°).

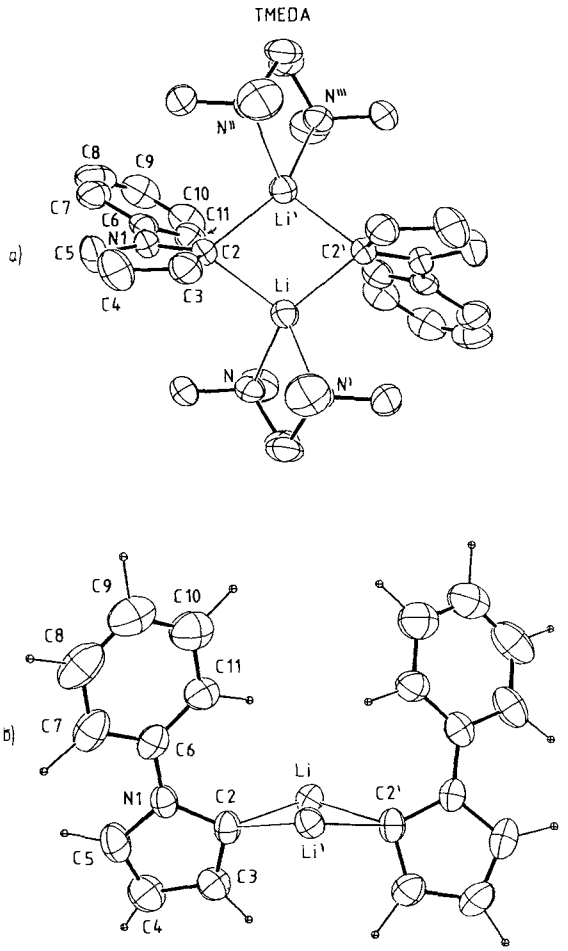

Fig. 1. Crystal structure of (**1**·TMEDA)$_2$ (ORTEP, thermal ellipsoids at the 50% probability level). a) View along the crystallographic C_2 axis (H atoms omitted). b) View when turned ca. 90° (TMEDA atoms omitted). Important distances [Å] and angles [°]: Li-Li′ 2.691(9), Li-C2 2.191(5), Li-C2′ 2.184(5), Li-N 2.304(5), Li-N′ 2.199(5), Li-H3 2.88(6), Li-H3′ 3.48(6), Li-H11 2.82(6), Li-H11′ 3.03(6); C2-Li-C2′ 101.4(3), Li-C2-Li′ 75.9(2). All other Li-H contacts are larger than 3.0 Å, the shortest of which are those to the Me groups (3.0–4.2 Å).

The position of the second metalation of **1** is expected to be indicated by a short distance between the lithium atom and the H atom that is thereby activated. As is clear from Figure 1, not only is the Li–H3 distance (average 3.2 Å) small, as expected, but also the Li–H11 distance (average 2.9 Å). MNDO calculations on **1**[10] are in good agreement with the crystal structure.

Through the use of a new NMR method, we have been able to find evidence *in solution* for the special activation of an H atom by a Li atom already present. Two-dimensional heteronuclear Overhauser NMR spectroscopy (2D HOESY) allows the spatial proximity of two heteronuclei, e.g., ^{13}C and ^{1}H, to be detected.[11] We have employed this pulse sequence for the first time to detect short ^{6}Li–^{1}H dis-

tances in a molecule with *isotopes in their natural abundance*.[12, 13] Figure 2 shows the results on **1** of a ^{6}Li-^{1}H 2D HOESY experiment in [D$_8$]tetrahydrofuran ([D$_8$]THF).[14] Short Li-H separations (< ca. 3.5 Å) are indicated through cross peaks. The short Li-H11 distance already shown in the crystal structure and by MNDO calculations is also found in solution by this method. In agreement with the crystal structure, the cross peak between Li and H11 is more intense than that between Li and H3; this reflects the distances found experimentally. Also as expected from the crystal structure (Fig. 1), an additional cross peak was found between Li and the methyl hydrogens of the TMEDA ligand; the TMEDA methylene protons are further away. The assumption that the structure of **1** in the crystal is similar to that in solution is thus supported by the ^{6}Li-^{1}H 2D HOESY experiment.

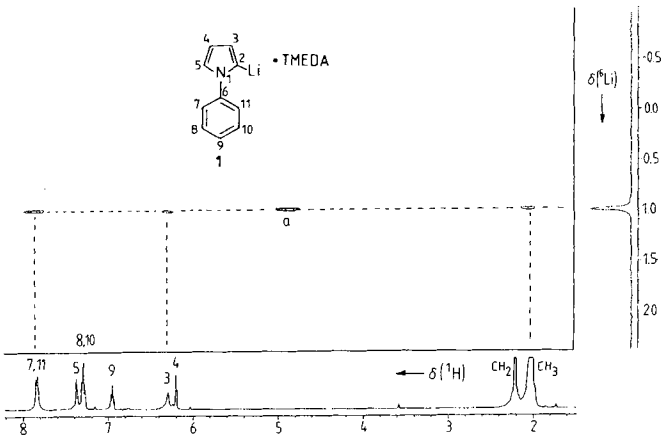

Fig. 2. ^{6}Li-^{1}H 2D HOESY spectrum of **1**·TMEDA in [D$_8$]THF, −70°C, natural abundance isotope distribution, contour plot; right: one-dimensional ^{6}Li-NMR spectrum; below: one-dimensional ^{1}H-NMR spectrum; mixing time [11] 1.5 s; a = axial cross peak at $f_1 = 0$.

As we have also found in numerous other instances, H atoms that are in proximity to the Li atom exhibit NMR signals with a significant shift to lower fields (Fig. 2). The ^{6}Li-^{1}H 2D HOESY method is thus demonstrated to be a new and useful method for the structural investigation of organolithium compounds in solution.

The introduction of a second Li atom takes place when **1** is treated with *n*BuLi. The product of this second metalation also can be obtained in crystalline form. In complete agreement with the expectation based on the evidence presented above, H11 undergoes substitution by Li.[15]

Experimental Procedure

1: *n*-Butyllithium in hexane (6.4 mmol) was added to a solution of *N*-phenylpyrrole (916 mg, 6.4 mmol) and TMEDA (1 mL, 6.6 mmol) in 25 mL of hexane under nitrogen. After 1 h at room temperature, the pale yellow solution was stored at −26°C for 2 days. The crystals formed were filtered, washed with hexane, and dried in vacuo.

[9] The reason for the unexpected *syn* geometry, which is of lower symmetry than the *anti* geometry, might be the origin of (**1**·TMEDA)$_2$ from a dimer-tetramer equilibrium. (D. Seebach, R. Hässig, J. Gabriel, *Helv. Chim. Acta 66* (1983) 308; R. Amstutz, W. B. Schweizer, D. Seebach, J. D. Dunitz, *ibid. 64* (1981) 2617.) Thus, the crystal geometry of **1** would reflect a "bisected" Li tetrahedron.

[12] The natural isotope abundance of ^{6}Li is 7.4%. Compared to ^{7}Li (92.6%), it has the advantage of a very small quadrupole moment and of large spin lattice relaxation times (T_1); this is a prerequisite for the application of the HOESY pulse sequence.
[13] NMR spectra were recorded on a JEOL JNM-GX400 spectrometer (^{1}H: 400 MHz). $(Me_4N)_3[Mo_4O_{12}F_3]\cdot 0.8H_2O$, A Salt with a Novel Fluorooxo Polyanion

By *Norbert Buchholz* and *Rainer Mattes**

A number of mono- and dinuclear as well as polymeric fluorooxo anions of molybdenum(VI) are known.[1] In the multinuclear anions, the coordination polyhedra are linked through common apexes or edges; the sole exception is the $[Mo_2O_6F_3]^{3\ominus}$ ion, for which two octahedra share a common face and the (formally) highly charged metal atoms are separated by 320.4 pm.[2] We have ascribed the stability of this anion and of the analogously structured $V_2O_4F_5^{3\ominus}$ and $V_2O_2F_7^{3\ominus}$ ions to the rigid crystal lattice of the $Cs_3[Fe_2F_9]$ type, in which the transition-metal atoms occupy octahedral voids in a close-packed lattice

[*] Prof. Dr. R. Mattes, Dipl.-Chem. N. Buchholz
Anorganisch-chemisches Institut der Universität
Corrensstrasse 36, D-4400 Münster (FRG)

made up of alkali-metal and oxygen or fluorine atoms.[2] Recently, the dimeric ions $V_2O_4F_5^{3\ominus}$ and $V_2O_2F_7^{3\ominus}$, having similarly short vanadium–vanadium distances (298 to 314 pm) were also obtained as the tetramethylammonium salts from nonaqueous solvents.[3] In contrast, the analogous reactions with molybdenum compounds did not lead to the compound $(Me_4N)_3[Mo_2O_6F_3]$ but rather to $(Me_4N)_3[Mo_4O_{12}F_3]\cdot 0.8\,H_2O$ **1**.

The anion of **1** is a novel fluorooxo polyanion (Fig. 1):[4] it has *mm* symmetry. Each molybdenum atom is surrounded in a distorted octahedral fashion by four oxygen and two fluorine atoms. Two coordination octahedra are joined through a common face, which contains one oxygen and two fluorine atoms, to form a double octahedron. Two double octahedra are joined through three apexes, which belong to two edges and are occupied by two oxygen atoms and one fluorine atom, to form a tetrameric anion. Thus, each of these oxygen atoms belongs to two molybdenum atoms and the fluorine atom to four molybdenum atoms. The linking of the octahedra in the anion of **1**, for which, to the best of our knowledge, no other examples are known, may also be described by the formula $[MoO_2O_{2/2}F_{1/2}F_{1/4}]_4^{3\ominus}$. The only fluorooxo polyanion reported thus far, $[Ta_4O_6F_{12}]^{4\ominus}$ has a Ta_4O_6 adamantane skeleton; all fluorine atoms are terminally bonded.[5]

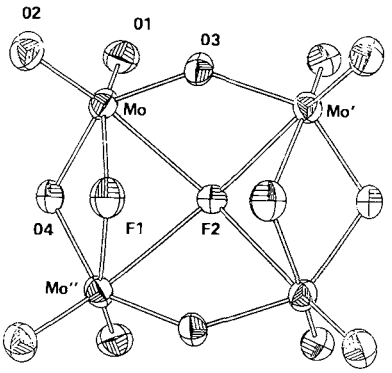

Fig. 1. Crystal structure of the anion of **1**. Selected bond lengths [pm] and angles [°]: Mo-O1 170.0(7), Mo-O2 169.3(7), Mo-O3 193.2(6), Mo-O4 192.3(6), Mo-F1 220.3(6), Mo-F2 244.6(6); O1-Mo-O2 104.3(1), Fe1-Mo-F2 69.4(1), Mo-O3-Mo' 109.5(1), and Mo-O4-Mo'' 122.9(1). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52162, the names of the authors, and the journal citation.

The metal-ligand distances in **1**—like those in comparable fluorooxo anions[1]—vary according to the type of ligand bonding: the terminal Mo–O bonds are 169.3(7) and 170.0(7) pm, the bridging 192.3(6) and 193.2(6) pm. The distance of the two-coordinate fluorine atom from the molybdenum atom is 220.3(6) pm. The longest Mo–F bonds are those to the unusual four-coordinate fluorine atom (244.6(6) pm), which lies 80 pm outside of the plane of the four metal atoms.

The longer Mo–F bonds are, as expected, opposite the shorter terminal Mo–O bonds (e.g., Mo–F2 and Mo–O2). The Mo–Mo distance inside the double octahedron (315.2(2) pm) is even shorter than that in $Cs_3[Mo_2O_6F_3]$.[2] The molybdenum atoms, like those in all polymolybdates,[6] are displaced from the center of the polyhedra toward the terminal oxygen atoms. Accordingly, the O/F–Mo–O/F bond angles vary from 69 to 104°. As in the other polymeric fluorooxomolybdates(VI), oxygen prefers the terminal and fluorine the bridging positions.

In the IR and Raman spectra, the Mo–O stretching vibrations give rise to bands at 955 ($\tilde{\nu}_s$) and 915 ($\tilde{\nu}_{as}$) cm^{-1} (terminal oxygen atoms) and at 842, 798, 713, and 686 cm^{-1} (bridging oxygen atoms). The Mo–F stretching vibrations could not be assigned unequivocally. They are expected to occur below 550 cm^{-1}.

Compounds having the same kinds of structures and compositions that are found for the iso- and heteropolyoxometalates are not expected to be found, however, for polymeric fluorooxometalates, because the positive charge built up in the interior of the polyanions by the highly charged metal atoms is not sufficiently compensated by the fluorine atoms.

Experimental Procedure

A suspension of MoO_3 in *N,N*-dimethylformamide was heated to reflux with a 25% methanolic solution of nBu_4NOH (molar ratio 4:3), until a clear solution formed. A stoichiometric amount of HF was then added in the form of a 20% ethanolic solution and the reaction mixture was heated to reflux for 30 min. Methanol, ethanol, and the water formed were removed by distillation. **1** was precipitated by addition of Me_4NCl in ethanol. Single crystals were obtained by the diffusion procedure. Yield: 67%.

Preparation of Ultrathin Layers of Molecularly Controlled Architecture from Polymeric Phthalocyanines by the Langmuir-Blodgett-Technique**

By *Ernst Orthmann* and *Gerhard Wegner**

The Langmuir-Blodgett (LB) technique enables the preparation of layered structures consisting of a sequence of monolayers, each one exactly one molecule thick.[1] A compound of conventionally amphiphilic character is dissolved in an organic solvent and spread onto the water surface of a Langmuir trough. A surface film is formed which is compressed by the mobile barrier of the film balance so as to achieve a well defined, solid-analogous layer of single molecules. This layer is now transferred to a solid substrate by repeated dipping of the substrate into the trough at constant surface pressure. The number of immersions determines the number of layers transferred to the sub-

[**] This work was supported by the Bundesministerium für Forschung und Technologie within the framework of the project "Ultrathin layers".

strate. Each single layer consists of domains which in total provide for a uniaxial texture of the layer system.[2] The size and orientation of the domains can be controlled only with difficulty. Thus, the orientation of the individual molecules or of the crystal axes of the domains with respect to an external reference system cannot be adjusted exactly. This constitutes one of the limiting factors for many of the potential applications of such systems as components in optical or electro-optical devices.[3]

We have now found a new class of compounds which allows for the preparation of homogeneous single layers on the substrate surface. The orientation of the molecules is uniquely fixed during transfer from the water surface to the substrate by the direction of immersion. The compounds concerned are unsymmetrically substituted polymeric phthalocyaninatosiloxanes, of which the tetramethoxy-tetraoctyloxy derivative **1** is the best example so far.

The polymer **1** is derived from the correspondingly substituted phthalocyaninatosilicon hydroxide **2** by $FeCl_3$-catalyzed condensation.[4] The monomer **2** is a mixture of the four positional isomers which are formed upon cyclization of 5-methoxy-6-octyloxy-1,3-isoindolediimine in the presence of $SiCl_4$ and subsequent hydrolysis to the dihydroxy compound.[4,5]

1, $R^1 = OCH_3$, $R^2 = OC_8H_{17}$

2, $(CH_3O)_4(C_8H_{17}O)_4$–phthalocyaninato–$Si(OH)_2$

Both monomer **2** as well as the polymer **1** (degree of polymerization $\bar{P}_w = 15$) are readily soluble in chloroform (solubility ca. 12 g L^{-1} at 20°C). **1** and **2** can be spread onto the water surface from such solutions. Figure 1 shows the force-area isotherms as measured by a Lauda-film balance.

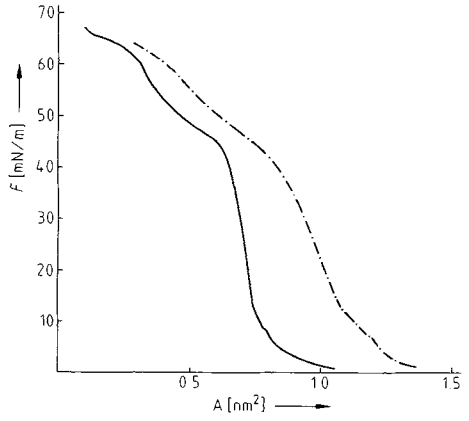

Fig. 1. Force-area isotherms of the monomer **2** (···) and of the polymer **1** (——) at 3°C.

The monomer **2** does not exhibit any sharp phase transition, whereas the polymer **1** gives rise to a solid-analogous phase with a characteristic area per repeat unit of 0.67 nm^2. This value corresponds to the cross-sectional area of the repeat unit as determined from X-ray and electron microscopic investigations of the multilayers. A distance of 0.34 nm is found for the chain repeat along the chain, and the average distance between adjacent chains and layers amounts to 1.96 nm.

Multilayers of the polymer can be built-up on hydrophobic substrates at constant pressure (usually 20 mN/m). Suitable substrates are, inter alia, glass with hydrophobic surface, polyethylene terephthalate films, or plates made of polytetrafluoroethylene, platinum or silicon. Transfer occurs to the same extent and proportional to the substrate area, both on immersion and on withdrawal of the substrate. Mixtures of **1** and **2** can be spread and transferred by the same technique.

The degree of orientation and the homogeneity of the layers can be examined with a polarizing microscope. When a glass plate covered with the polymer layers is viewed between crossed nicols the same birefringence and homogeneous extinction is observed over the whole area of a given preparation. Furthermore, the samples show dichroism. The absorption of a linearly polarized light beam impinging at right angles to the plane of the substrate depends on the angle between the plane of polarization and the direction of immersion, without any fluctuation over the whole surface of a sample of typically 2 cm^2 (Fig. 2a). The absorption increases linearly with the number of monolayers. The dichroic ratio is 2.7 at the maximum of the polymer absorption band (corrected for the self-absorption of the hydrophobic glass used as the substrate); this value is independent of the number of layers in a multilayer sample (cf. Fig. 2b). The dichroic ratio can be increased to 5.8 without changing the molecular orientation, which is uniquely determined by the direction of immersion, by annealing the freshly prepared multilayer sample at 140°C for 30 minutes. Intermediate values are obtained by variation of the annealing procedure. Once the

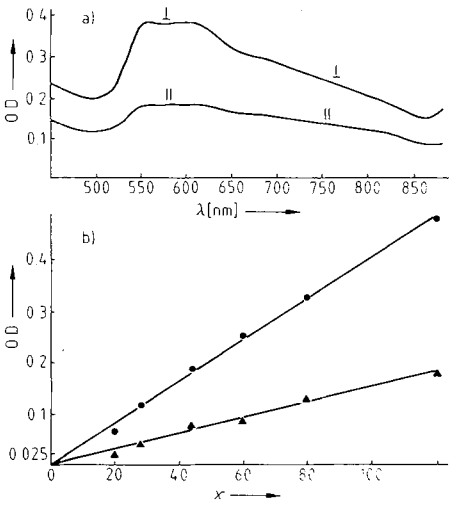

Fig. 2. a) UV/VIS absorption spectrum of the multilayer of polymer **1** (80 layers) on glass which had been pretreated with dichloromethylsilane (⊥) perpendicular to the plane of polarization, (∥) parallel to the direction of immersion of the substrate; -- self-absorption of the hydrophobicized glass. b) Optical density as a function of the number of layers (thickness of a single layer = 1.96 nm). (●) Perpendicular to the plane of polarization, (▲) parallel to the direction of immersion of the substrate.

dichroic ratio is fixed, either by annealing or by keeping the freshly prepared sample for two weeks at room temperature, it will stay constant, even if the sample is heated again (up to 260°C); thermal degradation of the sample will only occur above 280°C.

Multilayers transferred to platinum electrodes are electroactive. The polymer **1** showed its first reduction peak at -1.5 V and the first oxidation peak at $+0.25$ V vs. a Ag/AgCl reference electrode in a cyclovoltammetric experiment (acetonitrile, tetrabutylammonium perchlorate, 1 mmol).

The preparation of multilayers of unsubstituted or substituted phthalocyanines has been investigated by several authors.[6,7] However, in all cases the problem of formation of domains and of an ill-defined positioning of the ring plane with regard to the water surface was encountered. To the best of our knowledge, polymeric phthalocyanines have never been investigated by the LB-technique. Our results are very surprising for the following reasons:

1) the polymers investigated cannot be classified in the usual scheme as amphiphilic molecules;
2) the macrocycles are oriented with the molecular plane normal to the water surface, and normal to the plane of the substrate within the multilayer architecture. The latter is unambiguously derived from the force-area diagram and from the position of the diffraction peaks, which, together with the dichroic behavior, prove that the chain direction coincides with the direction of immersion;
3) the polymer exists at the water surface in a solid-analogous phase, which is mechanically deformable in the course of the transfer process, such that a unique orientation of all molecules results within the monolayer and domain formation can be suppressed; the dichroic ratio serves as the order parameter. Consequently, we assume that the polymer exists in a liquid crystalline state at the water surface and as monolayer at the substrate surface.[8] This is consistent with the observation that the molecular orientation can be improved by annealing subsequent to the preparation of the multilayer structure.

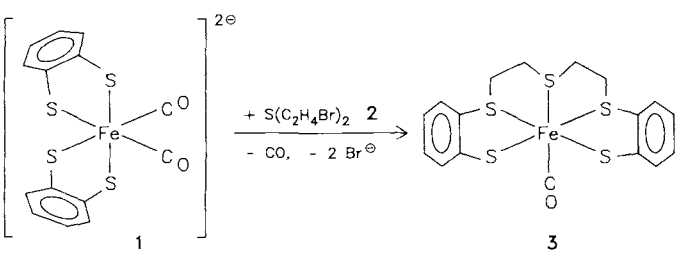
[7] D. W. Kalina, S. W. Crane, *Thin Solid Films 134* (1985) 109. These authors were able to produce a monolayer of octaalkoxy-substituted copper-phthalocyanines on the Langmuir trough; the macrocycles were reported to lay flat on the water surface initially, but are supposed to arrange like tiles on a roof in the course of the transfer to a solid substrate, where they form microstacks. These stacks show a preferential orientation similar to our results.

[8] We have so far been unable to obtain comparable results with polymers obtained from symmetrically substituted phthalocyanine monomers. We assume that the ability of the systems described here to be oriented relates to the fact that their structure cannot crystallize in a regular lattice.

A Simple Route to 2,3,11,12-Dibenzo-1,4,7,10,13,16-Hexathia-2,11-cyclooctadecadiene (Hexathiobenzo[18]crown-6)**

By *Dieter Sellmann** and *Peter Frank*

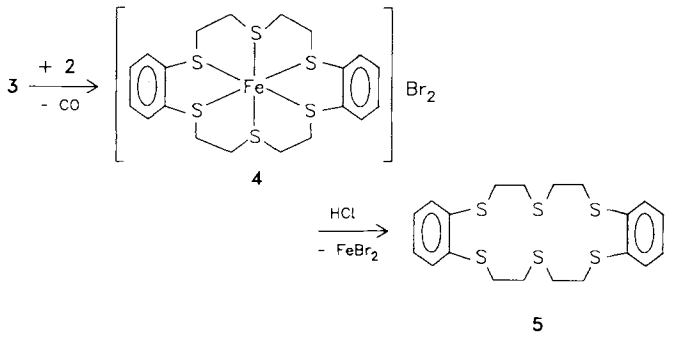


Cyclic polyethers are potentially strong ligands for many transition metals; consequently, they are important building blocks, inter alia, for model compounds of redox enzymes with sulfur-coordinated metal atoms at the active centers.[1]

However, a systematic study of the coordination chemistry of these ligands has been thwarted by the fact that in many cases they are accessible only with difficulty, if at all. The synthesis of such compounds by condensation reactions frequently affords, even according to the dilution or phase-transfer principle, only low yields of mixtures of products which require laborious separation.[2,3]

For 1,4,7-trithiacyclononane as example, it has recently been demonstrated how such compounds with suitable template centers can be obtained: reactions with 2,2'-thiodiethanethiol according to the dilution principle afford the desired product in only 0.04 to 4.4% yield,[3b] whereas reactions at $[Mo(CO)_3]$-centers afford up to 60% yield of the target compound.[4] Since template reactions are, in principle, catalytic reactions, it can be expected, in view of the course of the reaction and the substrate, that they are sensitively influenced by the properties of the metal template centers. We have now found that $[Fe^{II}CO]$ centers are exceptionally suitable for the synthesis of the novel ligand 2,3,11,12-dibenzo-1,4,7,10,13,16-hexathia-2,11-cyclooctadecadiene **5**; the compound **5** is the sulfur analogue of the well known cyclic polyether dibenzo[18]crown-6.

In the synthesis of the complex **3**,[5] the thiolate ligands of **1** are alkylated stepwise by **2** in tetrahydrofuran (THF) at room temperature. As has been observed with the corresponding ruthenium complexes, ligands such as those in **3** can be alkylated to polyethers under mild conditions only when substitution-labile (neutral) coligands are coordinated to the metal center. Replacement of these coligands by anions (from the alkylating agent) avoids formation of difficultly alkylatable complex cations.[6]



Since the CO ligand in **3** is inert to substitution at room temperature, we attempted to split it off under more drastic conditions (7 hours' reflux in THF) (**3** does not need to be isolated). A reddish-brown solid was obtained, an elemental analysis of which pointed to formation of the complex **4**. Hydrolysis of **4** with HCl afforded a yellowish solution, from which the title compound **5** could be isolated in 55% yield.

Procedure

5: A mixture of **3** (5.1 g, 11.17 mmol) and **2** (2.77 g, 11.17 mmol) was heated in 500 mL of boiling THF. This furnished a brown suspension, from which the solvent was completely removed. The reddish-brown residue was extracted with 2×50 mL Et_2O, taken up in 300 mL of THF, treated with 8 mL of conc. HCl, and heated to boiling for ca. 2 h until a yellow solution was obtained. Removal of the solvent furnished a yellow powder, which was washed with 2×25 mL of Et_2O and then dissolved in 200 mL of CH_2Cl_2. Extraction of the CH_2Cl_2 solution with 2×50 mL of H_2O, drying over Na_2SO_4, evaporation to a fifth of the original volume, and cooling, afforded a yellow solid. Recrystallization from 50 mL of CH_2Cl_2 at 30 °C → −30 °C yielded 2.85 g (55%) of analytically pure **5** in the form of colorless crystals; m.p. 161 °C; ^{1}H-NMR (270 MHz, CD_2Cl_2): $\delta(C_6H_4)=7.3$ (m, 4), 7.2 (m, 4); $\delta(CH_2)=3.1$ (m, 8), 2.7 (m, 8); MS (FD): m/z 456 ($M^{\oplus}$).

On using half the quantities of substrates mentioned above, yields of up to 75% could be obtained; the one-pot process with the educts $FeCl_2\cdot4H_2O$, $C_6H_4(SH)_2$, LiOH, CO and **2** afforded **5** in 45% yield.

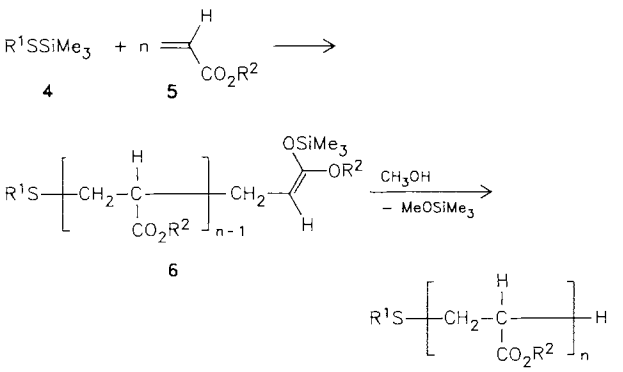
Group Transfer Polymerization of Acrylic Acid Esters with Alkylthio- or Arylthiosilanes as Initiators



By *Manfred T. Reetz,* Ralph Ostarek, Karl-Erwin Piejko, Dieter Arlt,* and *Bruno Bömer*

The polymerization of methacrylic acid esters to living polymers with narrow molecular weight distribution at room temperature has only recently been made possible by group transfer polymerization.[1] This industrially promising process is initiated by a Michael addition, e.g., of the *O*-silylketene acetal **1**, to methyl methacrylate **2** in the presence of anionic catalysts. Examples of such catalysts are $(Me_2N)_3S^{\oplus}Me_3SiF_2^{\ominus}$ (TASF) and $(Me_2N)_3S^{\oplus}HF_2^{\ominus}$ ($TASHF_2$). Chain growth is achieved by repeated Michael additions in which the silyl group is transferred to the end of the chain. This leads to formation of the living polymer **3** with an *O*-silylketene acetal end group, which can be desilylated, e.g. by methanolysis.

In the case of acrylic acid esters, polymers with narrow molecular weight distribution are obtained only with electrophilic catalysts such as ZnI_2 (at room temperature) or diisobutylaluminum chloride (at −78 °C).[2] However, the ZnI_2-catalyzed polymerization of ethyl acrylate fails to provide a living polymer.[2,3]

We report here on the first use of alkylthio- and arylthiosilanes **4** as initiators for the group transfer polymerization of acrylic acid esters **5**.[4] In order to perform the polymerization, a mixture of initiator and catalyst in the proper solvent is treated with the monomer, the reaction temperature being kept constant by a thermostat. After quantitative conversion, the polymers **6** are desilylated by methanolysis. In the case of initiation with **4b** and **4d**, the trimethylsilyl protective group at the front of the chain is cleaved with CH_3OH/HCl.

The results listed in Table 1 show that the anionic catalyst $TASHF_2$ leads to polymers with relatively broad molecular weight distributions (No. 1, 2). In contrast, use of electrophilic catalysts affords polymers with narrow molecular weight distributions[5] (No. 3–8). The somewhat high molecular weights of the polymers prepared with **4c**

[a] Concentration of the monomer ≈ 3 mol L^{-1}. [b] Calculated from monomer/initiator ratio. [c] Determined by gel permeation chromatography with universal calibration. [d] For the definition of polydispersity D see [5]. [e] Sample contained oligomers which were not taken into account in the calculation of the molecular weight distribution. [f] M_n from the sulfur content of the polymer, D not determined.

as initiator and diisobutylaluminum chloride as catalyst relative to the expected value (M_n(calc)) can be attributed to an incomplete initiation under the given conditions (No. 3 and 4, respectively). In combination with ZnI_2 as catalyst, however, the alkylthiosilanes **4a**, **4b**, and **4d** afford polyacrylates having molecular weights which correspond to the monomer/initiator ratio in the sense of a stoichiometric polymerization; the molecular weight distribution is also narrow (No. 5–7).

In the polymerization of **5b** with **4b** in the presence of ZnI_2 (22 °C), further monomer was added at room temperature three hours after termination of polymerization. This led to a continuation of the polymerization with quantitative formation of a polymer having a molecular weight distribution which is only slightly broadened ($D = 1.25$).

The polymers prepared with the functional initiators **4b** and **4d** have, after cleavage of the trimethylsilyl group, a hydroxy- and carboxy end group, respectively, which can be used for further reactions such as coupling reactions with other functionalized polymers.

The ethylenedi(thiosilane) **7** as initiator leads to a polymer **8** with two silylketene acetal end groups and narrow molecular weight distribution ($D = 1.07$; determined on the desilylated product; reaction with ZnI_2 as catalyst at 22 °C in toluene). In the case of the polymerization of the acrylate **5** (R^2 = 2-ethylhexyl) with **7**, anionic catalysts were also tested. $TASHF_2$ furnished only poor results, whereas $n\text{Bu}_4NF$ (THF/room temperature) afforded uniform polymers (e.g., $D = 1.07$; $M_n = 2.21$ kg mol^{-1}; M_n(calc) = 1.95 kg mol^{-1}).

In summary, alkylthiosilanes are excellent initiators for the polymerization of acrylates. In combination with ZnI_2 as catalyst, living polymers with narrow molecular weight distribution are obtained. The ready accessibility of functionalized initiators[6] enables the simple preparation of well defined functionalized polyacrylates which are suitable for the synthesis of block and graft polymers.

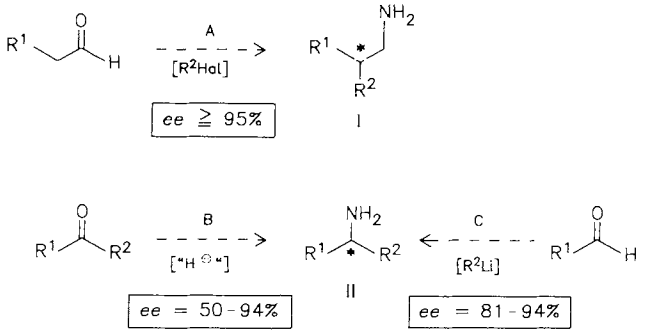
Enantioselective Synthesis of α-Substituted Primary Amines by Nucleophilic Addition to Aldehyde-SAMP Hydrazones**



By *Dieter Enders,* Heinrich Schubert*, and *Christoph Nübling*

The SAMP/RAMP hydrazone method enables highly diastereoselective and enantioselective CC couplings at the α-position to the carbonyl group of ketones and aldehydes.[1] We recently reported on the extension of this method to the enantioselective synthesis of β-substituted primary amines I by α-alkylating, reductive amination of aldehydes (reaction A),[2] and on the reductive amination of unsymmetrical ketones to α-substituted primary amines II (Reaction B).[3] We have now succeeded in opening up a very flexible entry to the amines II via a CC coupling reaction (Reaction C). The new method is based on a nucleophilic addition to SAMP (or the enantiomeric RAMP) hydrazones of aldehydes (Scheme 1).

The aldehydes **1**, after conversion into the SAMP hydrazones (*S*)-**2**, are treated with organolithium compounds in ether or tetrahydrofuran (THF) at −78 °C. The reductive N–N cleavage of the hydrazines (*SR*)-**3** or (*SS*)-**3**, formed by selective diastereofacial addition at the CN double bond, with Raney nickel affords the α-substituted primary amines (*R*)- or (*S*)-**4** together with ((*S*)-**5**) in total yields of

41–73% and enantiomeric excesses between 81 and 94% (Scheme 2, Table 1). The chiral auxiliary SAMP can be recovered from (*S*)-**5** as described in Refs. [1, 4].

Scheme 2. For experimental details see *Procedure*.

Table 1. Primary amines **4** prepared from the aldehydes R^1CHO **1** via the SAMP hydrazones (*S*)-**2** with orgaholithium compounds R^2Li. The amine (*S*)-**4a** was obtained with RAMP.

Product **4**	R^1	R^2	B.p. [°C/torr] [a]	Total yield [%]	$[\alpha]_D^{22}$ [°] (neat)	*ee* [%]
(*R*)-**4a**	C_6H_5	CH_3	80/20	47	+26.1	81
(*S*)-**4a**	C_6H_5	CH_3	87/25	48	−26.1	81
(*R*)-**4b**	t-C_4H_9	CH_3	55/95	41	− 4.5 [b]	81
(*S*)-**4c** [c]	c-C_6H_{11}	t-C_4H_9	39/0.4	64	−25.8	82
(*R*)-**4c** [c]	t-C_4H_9	c-C_6H_{11}	53/1	62	+27.4	90
(*R*)-**4d**	C_6H_5	n-C_4H_9	59/0.5	46	+14.1	85
(*S*)-**4d**	n-C_4H_9	C_6H_5	65/0.6	58	−13.9	83
(*S*)-**4e** [c]	i-C_3H_7	c-C_6H_{11}	39/0.6	63	+10.5	90
(*R*)-**4f**	i-C_3H_7	n-C_4H_9	76/40	57	+17.4 [d]	86
(*R*)-**4g** [e]	t-C_4H_9	n-C_4H_9	105/50 [f]	73	+31.9 [g]	93 [h]

[a] Data for short-path distillation. [b] $[\alpha]_D^{22} = 5.6°$ (neat) [9]. [c] The phenyl ring was hydrogenated during the N-N cleavage. [d] Measured in solution: $[\alpha]_D^{20}$ ($c = 3.3$, EtOH). [e] According to the GC retention time on a chiral stationary phase [6] **4g** has the (*S*)-configuration. [f] Oven temperature during Kugelrohr distillation. [g] Measured in solution: $[\alpha]_D^{22}$ ($c = 0.43$, benzene). [h] According to the ^{13}C-NMR spectrum **3g** is diastereomerically pure.

The *ee* values of the amines **4** were determined polarimetrically (**4b**), NMR spectroscopically by shift experiments with $Eu(hfc)_3$, and via the 3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid (MPTA)-amides[5] (^1H, ^{13}C, ^{19}F), as well as by gas-chromatography on a chiral stationary phase after conversion into isopropylurea derivatives[6] [XE-60-C-valine-(*S*)-α-phenylethylamide]. The racemic amines *rac*-**4** required for comparison were synthesized analogously from the corresponding achiral *N,N*-dimethylhydrazones.[7]

Both enantiomers of the amines **4** can be obtained as desired by use of SAMP or RAMP [example (*R*)-**4a**/(*S*)-**4a** in Table 1] or by exchange of R^1 and R^2 in the synthetic building blocks [examples (*S*)-**4c**/(*R*)-**4c** and (*R*)-**4d**/(*S*)-**4d**]. The absolute configurations were determined polarimetrically (**4a**[8] and **4b**[9]) and via the CD spectra of the *N*-salicylidene derivatives.[10] They suggest a uniform relative topicity during mutual approach of the reactants.

All attempts to improve the diastereoselectivity by varying the chiral auxiliary have so far failed. Thus, only a slightly higher enantiomeric purity of 94% *ee* was found for (*R*)-**4g** on using the sterically more demanding (*S*)-1-amino-2-(1,1-dimethylmethoxymethyl)pyrrolidine.[11]

The new method of amination of aldehydes by nucleophilic addition to SAMP (or RAMP) hydrazones thus provides an enantioselective entry to both optical antipodes of α-substituted amines **4**.[12, 13]

Procedure

4: A solution of (*S*)-**2** (15 mmol) in a small amount of ether or THF was added at −78 °C under argon to a solution of R^2Li (30 mmol) in 50 mL ether or THF (in the case of hydrazones **2** without α-H atoms in R′, 15 mmol of R^2Li suffices). The reaction mixture was allowed to warm to room temperature within ca. 12 h and then poured into 50 mL of water, and extracted twice with 25 mL of ether. The combined extracts were dried over $MgSO_4$ and concentrated by evaporation. Subsequent short-path distillation afforded the air-sensitive hydrazines **3**. These were dissolved in 30–50 mL of methanol and hydrogenated in a Parr hydrogenation apparatus with freshly prepared alkaline Raney nickel [14]/H_2 (3.5–3.8 bar, 20–40 °C, 24 h). The catalyst was then removed by filtration over Celite and the filtrate evaporated to dryness. The residue was taken up in ether, refiltered, and treated with 1.5 equivalents of *p*-nitrobenzaldehyde. After 12 hours' stirring at room temperature, the resulting Schiff bases ($R_f \geq 0.9$) were separated from (*S*)-**5** (→recycling, $R_f \leq 0.2$) by column chromatography (SiO_2, ether/pentane). The solution was evaporated down (50 mL), treated with 3–4 N HCl, and stirred for 2 h. After removal of the aqueous phase, the solution was rendered alkaline with conc. KOH solution and re-extracted with ether. After drying over $MgSO_4$ the extract was evaporated down and distilled.

A 1,3-Diboratacyclobutadiene and Its Dimer, a Sandwich Compound with a Li_4 Layer**

By *Günter Schmidt, Gerhard Baum, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Wilhelm Paul Neumann on the occasion of his 60th birthday

The 1,3-diboratacyclobutadiene (1,3-diboretanediide) **1** is formed, along with ca. 5% of products of unknown structure, upon reduction of the 1,3-dihydro-1,3-diborete **2**[1] with lithium powder in toluene. Compound **1** is isolated as the lithium salt, after a single recrystallization, in the form of pure yellow crystals. $[NiCl_2\{P(C_6H_5)_3\}_2]$ reoxidizes **1** to **2**. With bis(trimethylsilyl)amine in ethers, rapid monoprotonation of **1** occurs to give the 1,3-diboretanide **3**; with ethers, the reaction is slow. Compound **1** reacts with two equivalents of methyl iodide to give exclusively the—presumably *cis*-configurated—1,3-diboretane **4**.

R = $C(CH_3)_3$, R' = $Si(CH_3)_3$

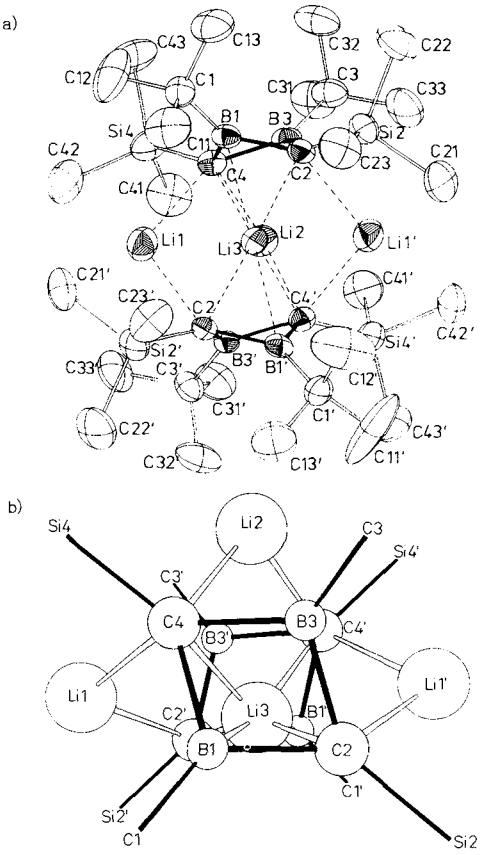

Fig. 1. ORTEP plot of the structure of dimeric **1** in the crystal (without H atoms). The ellipsoids of thermal vibration are at the 50% probability level. a) Projection roughly in the direction of the pseudo C_2 axis. b) Projection in the direction of the "sandwich axis." Arbitrary atomic radii, without methyl groups. Important distances [Å] and angles [°] averaged over both halves of the dimer: B1-C2 1.562(6), B1-C4 1.599(6), B3-C2 1.557(6), B3-C4 1.591(6) (average B-C(ring) 1.577), B1-C1 1.609(6), C2-Si2 1.832(4), B3-C3 1.619(6), C4-Si4 1.836(4), Li3-Li1 2.33(1), Li3-Li2 2.47(1), Li1-Li2 3.13(1); Li3-B1 2.237(8), Li3-C2 2.099(7), Li3-B3 2.454(8), Li3-C4 2.196(7), Li1-C4 2.346(8), Li1-C2' 2.276(8), Li2-C4 2.254(8); C2-B1-C4 101.3(3), B1-C2-B3 71.5(3), C2-B3-C4 101.9(3), B1-C4-B3 69.7(3) (average B-C-B 70.6, C-B-C 101.6).

The structures of the compounds **1**, **3**, and **4** were deduced from their ^1H-, ^{13}C-, and ^{11}B-NMR spectra[2] and from their pathway of formation; that of **1** was also derived from the reactions described and from an X-ray structure analysis. The strong shielding of the B atoms in **1** ($\delta(^{11}B) = 42$), compared with **4** ($\delta(^{11}B) = 81$) indicates considerable negative π charge at the boron atoms (1,3-diboratacyclobutadiene resonance structure **1A**). The ring C atoms in **1** ($\delta(^{13}C) = 93.5$) are shifted by 59 ppm to higher field in comparison with those of tetra-*tert*-butylcyclobutadiene ($\delta(^{13}C) = 152.7$);[4] this finding indicates considerable negative π charge at the ring carbon atoms (1,3-diboretanediide resonance structure **1B**).[5]

Compound **1** crystallizes as a dimer with a structure[6] that further expands the structural variety of organolithium compounds:[7] a layer of four Li atoms (greatest deviation from the common plane 0.013 Å) bridges two four-membered rings (Fig. 1). The separations of the Li atoms in the Li_4 layer are in part (Li3-Li1 2.33, Li3-Li2 2.47 Å) shorter than those found in the Li tetrahedra of tetrameric lithium compounds (average 2.56 Å[7]). The dimeric **1** possesses a pseudo C_2 axis in the Li_4 plane through Li2 and Li3. In the following discussion, therefore, average values of the geometric data for the two halfs of the dimer are given. The rings are arranged in an eclipsed fashion, a B atom lying above a C atom in each case; the lines drawn through the C2, C4 and C2', C4' atoms form an angle of 77° with each other. The separation of the centers of the four-membered rings is 3.84 Å. One Li atom (Li3) lies sandwiched between the rings, but—presumably owing to the unsymmetrical environment of the three Li neighbors—is displaced toward the Li-free side (angle formed between Li3 and the ring centers 155°). Apart from the two C atoms, therefore, only one of the two B atoms in each ring has a short distance from the Li atom (Li-C 2.09–2.20, Li3-B1 2.23, but Li3-B3 2.45 Å) (η^3 bond). Each of the remaining three Li atoms, which are situated in gaps between the bulky substituents, further bridges the rings from the outside through two C atoms (Li-C 2.25–2.38 Å). The atoms Li1 and Li1' have very short separations from methyl groups (Li1-C21 2.41, Li1-H212 2.19, Li1-H213 2.19 Å), which points to the existence of a metal-hydrogen interaction, as in the case for $LiB(CH_3)_4$ (Li-H 2.12 Å[8]).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The rings themselves are strongly puckered: the puckering angle along C2C4 (C···C 2.45 Å) is 132°, so that the B atoms approach each other to within 1.82 Å, which is little more than the distance of a B-B single bond (1.71–1.75 Å[9]). In contrast, the 1,3-bis(dimethylamino)-2,4-di-*tert*-butyl-1,3-dihydro-1,3-diborete **2′**[10] (**2**, with R = $N(CH_3)_2$ and R′ = $C(CH_3)_3$) described by *Siebert* et al. is puckered along the B-B diagonal (2.16 Å), so that the C atoms come to within 1.81 Å of each other. The different puckering of **2′** and the dimeric **1** is reflected in the bond angles CBC and BCB, which are 101.6 and 70.6° on the average for the dimeric **1** and 74 and 92°, respectively, for **2′**. The B-C bonds within the four-membered rings are significantly longer for dimeric **1** (1.56–1.60 Å) than for **2′** (1.50 Å). This is presumably a consequence of the strong electrostatic repulsion within the doubly charged four-membered rings.[11] The bonds from the ring atoms to the substituents are in part considerably bent with respect to the partial planes of the rings (C-Si 25.2–34.4° with respect to the BCB plane, B-C 8.0–12.7° with respect to the CBC plane), so that substituents on opposite sides avoid each other. The twisting and puckering of the rings also reduces the steric hindrance between the large substituents. The especially strong bending of the C-Si bonds might be caused in part by steric interaction with the outer Li atoms as well as by the electronic influence of the Li atoms on the anionic C atoms.[12] Overall, a compact, nearly spherical shape of the dimeric **1** is found.

Experimental Procedure

1: **2** (2.27 g, 7.4 mmol) was stirred in 15 mL of toluene at room temperature with lithium powder (0.58 g, ca. 80 mmol) containing 2% sodium. After 15 h, the excess metal was separated from the solution using a G3 filter tube for inert gas handling and washed three times with 5 mL of toluene, and the yellow reaction solution was concentrated until it turned cloudy. The crystals that precipitated out after 15 h at −30°C were crystallized once from toluene. 1.78 g (75%) yellow crystals, m.p. = 190–195°C (dec.).

A Puckered and a Planar 1,3-Diboretane**

By *Pia Hornbach, Manfred Hildenbrand, Hans Pritzkow,* and *Walter Siebert**

1,3-Diboretanes were described earlier by *Berndt* et al.[1] We now report the first structurally confirmed 1,3-diboretanes (**3b** and **4b**).

The 1,3-dihydro-1,3-diboretes **1a**[2] and **1b** react with Na/K alloy in tetrahydrofuran (THF) to give the corresponding radical anions.[3] $\mathbf{1b}^{\ominus\ominus}$ ($a(^{11}B) = 8.6$, $a(^{29}Si) \approx 8.7$ G, $g = 2.0029$) undergoes further reduction to give the diamagnetic dianion **2b**, which can be isolated in the form of the powdery, reactive dipotassium salt having only two coordinated THF molecules (NMR spectra). This finding indicates good shielding of the potassium ions by the anion (cf. ref. [4]).

Protonation of **2b** with weakly acidic compounds ($HCCl_3$, $HN(SiMe_3)_2$) results in the formation of colorless 1,3-bis(diisopropylamino)-2,4-bis(trimethylsilyl)-1,3-diboretane **3b** (65% yield), which is also accessible by hydrogenation of **1b** using Pd/active carbon (85% yield). Reaction of **2b** with iodomethane affords **3b** with Me instead of H. According to the NMR spectrum, the B atoms of **3b** are deshielded by 12.1 ppm relative to those of **1b**. A high-

a, $R^1 = NMe_2$, $R^2 = t$Bu; **b**, $R^1 = N$*i*Pr_2, $R^2 = SiMe_3$

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

field shift from $\delta = 37$ to $\delta = 26$ is found for the C atoms in the ring. These data are in agreement with the loss of π-electron density in the ring.

The X-ray structure analysis (Fig. 1)[5a] shows that the puckering of the four-membered ring along C1C2 (32°) is significantly smaller than for **1a** (52°)[2] and **1b** (59°);[5b]

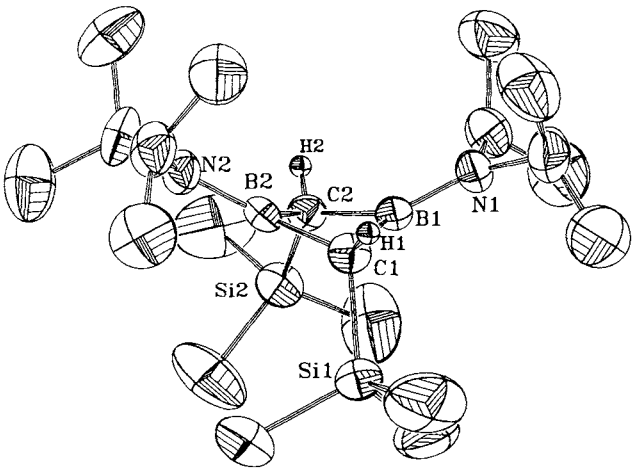

Fig. 1. ORTEP plot of the crystal structure of **3b** (thermal ellipsoids at 40% probability, methyl and *iso*-propyl H atoms omitted). Bond lengths [Å] and angles [°] (standard deviations 0.01 Å and 0.5°); calculated values for $C_2B_2H_6$ [6] in parentheses. BC 1.58–1.59 (1.587), BN 1.39, C(ring)Si 1.87; BCB 79.3 (78.6), CBC 96.8 (95.1); puckering angle 32.2 (36.2); for comparison **1b** (standard deviations 0.005 Å and 0.1°): BC 1.518 and 1.523, BN 1.388, C···C 1.805; BCB 89.0, CBC 72.8; puckering angle 59.

the value is in good agreement with that calculated for the 1,3-diboretane $C_2B_2H_6$ (36.2°).[6] The unsaturated ring (**1b**) and the saturated ring (**3b**) have different B–C distances (1.520 and 1.585 Å, respectively, (B–C) π bond in **1b**) and different angles (CBC = 72.8 and 96.8°, respectively). The structure of the four-membered ring in **3b** is similar to that in the dilithium-1,3-diboretanediide $[(Me_3C-B)_2(Me_3Si-C)_2]_2Li_4$,[4] in which the silyl groups are found in equatorial positions.

For further characterization, the dianion **2b** was allowed to react with Ph_3PAuCl. Brown and yellow crystals are formed which are not very air-sensitive but undergo decomposition upon sublimation. The brown crystals were identified as **4b**, which is formed by silyl group migration (cf. ref. [1]) and geminal substitution. According to an X-ray structure analysis (Fig. 2),[7] **4b** is surprisingly planar: The puckering of the four-membered ring along C1C2 is only 3°, presumably owing to the steric hindrance of the large substituents. Because of the different substituents on C1 and C2, the B–C distances are no longer the same: the B–C2 bonds are shorter than the B–C1 bonds.

The geometry of the Ph_3PAu substituents on C2 largely corresponds to that of other structures having geminal Ph_3PAu groups.[8] Only the Au–Au distance (2.98 Å) is larger, but still in accord with significant Au–Au interactions. Au1 and Au2 are not symmetrically arranged with respect to the four-membered ring; Au1 is closer to Si1. Thus, the silyl groups as well as P1 and P2 are no longer magnetically equivalent. A phenyl ring on P1 affects the methyl groups on Si1 via its anisotropy.

Our results confirm the structure calculated[6] for diboretanes. However, they also show that a planar structure is possible.

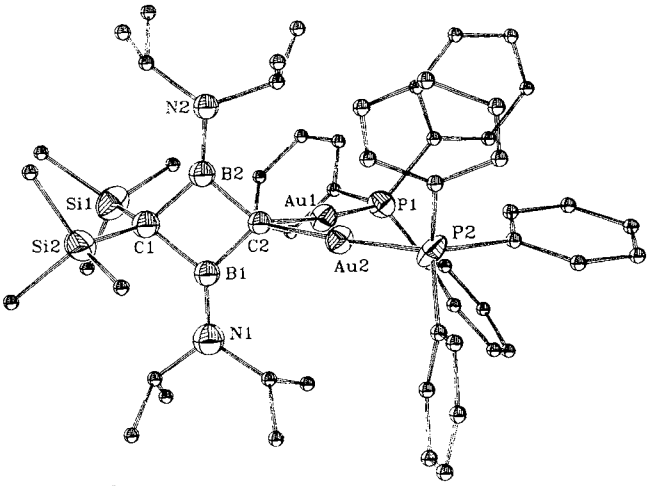

Fig. 2. ORTEP plot of the crystal structure of **4b** (thermal ellipsoids at 40% probability, phenyl, methyl, and *iso*-propyl C atoms with arbitrary radii). Bond lengths [Å] and angles [°] (standard deviations 0.03 Å and 1°): B1C2 1.53, B2C2 1.55, B1C1 1.62, B2C1 1.64; B1C1B2 81, B1C2B2 86, C1B1C2 97, C1B1C2 96; puckering angle 3.

Experimental Procedure

1b: $(Me_3Si)_2C=C(BCl_2)_2$ [3], obtained by addition of B_2Cl_4 to $Me_3Si-C\equiv C-SiMe_3$, was allowed to react with $HNiPr_2$ to give $(Me_3Si)_2C=C(BClNiPr_2)_2$. Its reaction, in turn, with Na/K alloy in THF or refluxing toluene (6–20 h), led, in analogy to the reaction of $(Me_3Si)_2C=C(BClt Bu)_2$ described in [1], to **1b**: 40% yield, b.p. = 120–130°C/0.01 torr, m.p. = 170°C (dec.). ^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 0.08$ (s, 18H; $SiCH_3$), 1.09, 1.12 (d, 12H each; $NCCH_3$), 3.44 (sept, 4H, $^3J(HH) = 6.6$ Hz; NCH); ^{11}B-NMR ($CDCl_3$): $\delta = 31.4$; ^{13}C-NMR ($CDCl_3$): $\delta = 1.20$ ($SiCH_3$), 23.13 ($NCCH_3$), 24.85 ($NCCH_3$), 37 (br.; CB), 49.47 ($NCCH_3$); MS: *m/z* 392 ($M^{\oplus}$, 93%), 319 ($[M-SiMe_3]^{\oplus}$, 47%).

2b: a) **1b** (392 mg, 1 mmol) was stirred with NaK_8 (74 mg, 0.2 mmol) in 10 mL of THF. After 15 h, the mixture was filtered, THF was removed, and the residue was washed with petroleum ether (PE). The white dipotassium salt of **2b** was dried in vacuum. Yield 16%. b) $(Me_3Si)_2C=C(BClNiPr_2)_2$ (4.62 g, 10 mmol) was treated with NaK_8 (1.48 g, 4.4 mmol) in THF. After 15–25 h, the reaction mixture was filtered, the THF was removed, and the residue was washed with PE and dried. Yield 65–80%. ^{1}H-NMR (90 MHz, C_6D_6): $\delta = 0.26$ (s, 18H; $SiCH_3$), 1.33 (d, 24H; $NCCH_3$), 3.11 (sept, 4H, $^3J(HH) = 6.5$ Hz; NCH); ^{11}B-NMR (C_6D_6): $\delta \approx 12$ (halfwidth ca. 1200 Hz); ^{13}C-NMR (C_6D_6): $\delta = 8.08$ (q; $SiCH_3$), 46.9 (br.; CB), 25.39 (q; $NCCH_3$), 67.88 (d; $NCCH_3$); ^{29}Si-NMR (C_6D_6): $\delta = -20.6$.

3b: **1b** (392 mg, 1 mmol) was stirred with Pd/active carbon (112 mg) in PE under H_2 for 2 d. After filtration of the reaction mixture, **3b** was sublimed at 100°C/0.01 torr. M.p. = 125°C. ^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 0.10$ (s, 18H; $SiCH_3$), 0.69 (s, 2H; BCH), 1.13 (d, 12H; $NCCH_3$), 1.14 (d, 12H; $NCCH_3$), 3.58 (sept, 4H, NCH); ^{11}B-NMR ($CDCl_3$): $\delta = 43.5$; ^{13}C-NMR ($CDCl_3$): $\delta = 3.93$ ($SiCH_3$), 23.46 ($NCCH_3$), 23.88 ($NCCH_3$), 26 (br.; CB), 47.94 ($NCCH_3$); ^{29}Si-NMR ($CDCl_3$): $\delta = 4.5$.

3b with Me instead of H: MeI (740 mg, 5.2 mmol) was added to **2b** (1.6 g, 2.6 mmol) in THF at −80°C. KI precipitated immediately. Sublimation at 125–130°C/0.01 torr afforded colorless crystals. M.p. = 118°C; yield: 494 mg (1.17 mmol, 45%). ^{1}H-NMR (90 MHz, C_6D_6): $\delta = 0.42$ (s, 18H; $SiCH_3$), 1.22 (s, 6H; $BCCH_3$), 1.37 (d, 24H, $^3J(HH) = 7$ Hz; $NCCH_3$), 4.18 (sept, 4H; NCH); ^{11}B-NMR (C_6D_6): $\delta = 48.7$; ^{13}C-NMR (C_6H_6): $\delta = 5.3$ (s; $SiCH_3$), 19.4 (s; $BCCH_3$), 26.3 (s; $NCCH_3$), 26.5 (s; $NCCH_3$), 49.9 (s; $NCCH_3$), 50.3 (s; $NCCH_3$); MS: *m/z* 422 ($M^{\oplus}$, 19%), 407 ($[M-Me]^{\oplus}$, 28%).

4b: **2b** (307 mg, 0.5 mmol) in 30 mL of THF was treated at −90°C with Ph_3PAuCl (494 mg, 1 mmol) in 10 mL of THF. The orange reaction solution turned dark red above −65°C. The THF was removed at room temperature; the residue was dissolved in PE, the resulting solution was filtered, and the combined filtrates were treated with toluene/pentane. Upon cooling, brown and slightly yellow crystals were formed. Yield: 230 mg **4b** (35%); m.p. = 154°C (dec.). (The constitution of the yellow crystals is not known). ^{1}H-NMR (300 MHz, C_6D_6): $\delta = 0.46$ (s, 9H; $SiCH_3$), 0.49 (s, 9H; $SiCH_3$), 1.26, 1.28, 1.52, 1.87 (d, 6H each, $^3J(HH) = 6.5$ Hz; $NCCH_3$), 3.59 (sept, 2H; NCH), 4.27 (sept, 2H; NCH); ^{11}B-NMR (C_6D_6): $\delta = 45.9$; ^{31}P-NMR (C_6D_6): $\delta = 37.8$, 41.2.

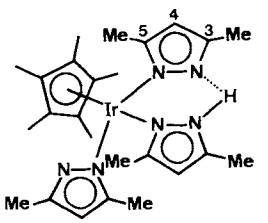
Prototropism in (Pentamethylcyclopentadienyl)iridium Complexes with Pyrazole Ligands**

By *Daniel Carmona, Luis A. Oro,* M. Pilar Lamata, José Elguero,* María del Carmen Apreda, Concepción Foces-Foces,* and *Félix H. Cano**

There is an increasing interest in (pentamethylcyclopentadienyl)iridium complexes because of their ability to activate the C–H bonds of alkanes.[1] Most of this work has been carried out on trimethylphosphane derivatives.[1a,b] In contrast, few (pentamethylcyclopentadienyl)iridium complexes with nitrogen donor groups as ancillary ligands have been prepared.[2,3] We now describe the preparation and characterization of new mononuclear (pentamethylcyclopentadienyl)iridium(III) complexes with pyrazole ligands, some of them showing very unusual ^{1}H-NMR behavior in solution.



2 [(C$_5$Me$_5$)Ir(pz)$_2$(Hpz)] **2**

When [{(C$_5$Me$_5$)IrCl}$_2$(μ-Cl)$_2$] **1**[4] was allowed to react with pyrazole (Hpz) and KOH in methanol, complex **2** was obtained and identified on the basis of ^{1}H-NMR, IR, and analytical data.[5] In particular, the ^{1}H-NMR spectrum (200 MHz, $CDCl_3$, 293 K) shows, in addition to the C_5Me_5 signal at $\delta=1.50$, thrice the characteristic AMX system of *N*-substituted pyrazole ($\delta=6.14$ (H^4), 6.99 (H^5), 7.61 (H^3); $J(H^3H^4)=J(H^4H^5)=2.0$, $J(H^3H^5)=0.6$ Hz), and an N–H proton at $\delta=11.24$ (intensity ratio 15:9:1).[6] Thus the three pyrazole ligands are identical; although an *inter*molecular proton exchange cannot be completely ruled out, an *intra*molecular exchange should be more favorable because the pyrazole ligands should be capable of attaining any rotational conformation around the Ir–N bonds, and therefore a dynamic hydrogen bonding between the three pyrazoles is likely.

A "chelated proton" structure with only two pyrazole rings was proposed by *King* and *Bond*[7] for [(C$_5$H$_5$)Co(C$_n$F$_{2n+1}$)(pz)(Hpz)] (n = 1–3). In the case of **2**, our representation does not mean necessarily that there is a "bifurcated" hydrogen bond but most probably that three "chelated proton" structures are equilibrating fast on the NMR time scale.

The IR spectrum (Nujol mull) of complex **2** shows a medium and very broad $\tilde{\nu}$(NH) band (3200–2000 cm^{-1}) which suggests that, also in the solid state, a strong N–H···N association is present,[8] most probably between two pyrazole ligands from the same molecule.

3 [(C$_5$Me$_5$)Ir(dmpz)$_2$(Hdmpz)] **3**

When the reaction was carried out with 3,5-dimethylpyrazole (Hdmpz), the mononuclear yellow complex **3** was obtained according to spectroscopic and analytical data.[9] Its ^{1}H-NMR spectrum ($CDCl_3$, 200 MHz, 293 K) shows, along with the signal of the C_5Me_5 group at $\delta=1.45$, two classes of 3,5-dimethylpyrazole ligands in a 2:1 ratio. The two identical dmpz ligands share an N–H proton as shown by the relative deshielding of H^4 ($\delta=2.33$ (Me^3), 1.50 (Me^5), 5.72 (H^4), whereas the remaining pyrazole ligand is unprotonated ($\delta=2.22$ (Me^3), 0.42 (Me^5), 5.39 (H^4).[10] Two

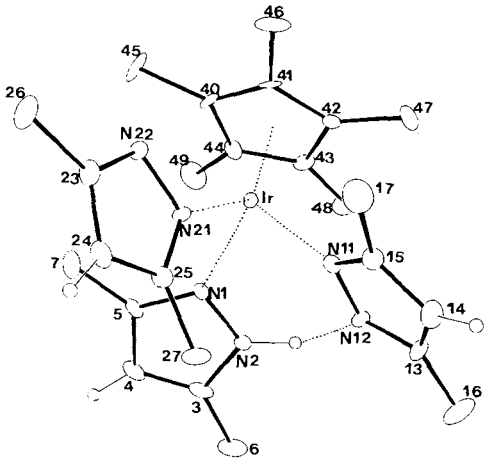
features are noteworthy in this spectrum: (1) there is no prototropic exchange with the third ligand; (2) the signal of the Me^5 group is at a very low frequency in the third ligand.



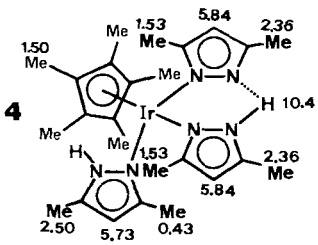


Fig. 1. ORTEP drawing of the crystal structure of complex **3**. Selected bond distances [Å] and angles [°]: Ir-C_5Me_5 1.800(7), Ir-N1 2.092(6), Ir-N11 2.078(6), Ir-N21 2.085(6), N2···N12 2.647(8); N1-Ir-C_5Me_5 125.3(3), N11-Ir-C_5Me_5 124.3(3), N21-Ir-C_5Me_5 131.9(4), N1-Ir-N11 89.2(2), N1-Ir-N21 84.8(2), N11-Ir-N21 87.8(2).

These observations prompted us to determine the X-ray structure of **3**.[11] Although the H atoms could not be located exactly, they are shown in Figure 1 for the sake of clarity. This structure explains both observations. (1) There is a short N2–N12 distance (2.647(8) Å) and the presence of an H atom between the two N atoms proves the existence of a strong hydrogen bond between the two ligands. The barrier for the proton transfer between N2 and N12 is certainly very low, and in solution, in accord with ^{1}H-NMR measurements, the proton exchange is fast. (2) The third ligand is in such a conformation that the nitrogen lone pair of N22 cannot participate in the prototropism and C27 lies just above one pyrazole ring, so that the Me^5 group is shielded by the ring current.

4 $[(C_5Me_5)Ir(dmpz)(Hdmpz)_2]$ **4**

Treatment of compound **3** in CH_2Cl_2/Me_2CO with an equimolar amount of aqueous HBF_4 afforded the yellow complex **4**.[12] The ^{1}H-NMR spectrum ($CDCl_3$, 293 K) of this complex clearly shows that the second proton is bonded to the nonchelated ligand, since its signals are the most affected. Consequently, a strong and sharp $\tilde{\nu}$(NH) band at 3410 cm^{-1} was observed in its IR spectrum (Nujol), along with the expected broad absorption in the 3200–2000 cm^{-1} region.[8]

Similarly, the addition of an equimolar amount of aqueous HBF_4 to complex **2** gives rise to the formation of $[(C_5Me_5)Ir(Hpz)_3](BF_4)_2$ **5**, which could also be prepared by the reaction of the solvated complex $[(C_5Me_5)Ir(Me_2CO)_3](BF_4)_2$ **6** with pyrazole.[13]

The strikingly different behavior of pyrazole and 3,5-dimethylpyrazole complexes is related to the steric hindrance of the 5-methyl group.[15] This substituent imparts to complex **3** a spatial structure in which a hydrogen bond links two ligands, while the third ligand does not participate in the prototropic exchange and remains, as expected, more basic when competing for a second proton.

[9] Complex **3** was prepared analogously to complex **2** [5], but using Hdmpz instead of Hpz. Yield: 70%; IR (Nujol): $\tilde{\nu}$=3200–2000 cm^{-1} (m, very broad; $\tilde{\nu}$(NH) [7]; correct elemental analysis (C, H, N).

[10] The ^{13}C-NMR spectrum (75 MHz, $(CD_3)_2CO$, 293 K) of compound **3** shows the following signals: δ=8.7 (C_5Me_5), 88.1 (C_5Me_5), 12.3 and 12.7 (Me^3 and Me^5), 149.9 (C^3), 106.0 (C^4), 144.4 (C^5) for the two Hdmpz ligands; 14.0 (Me^3), 11.1 (Me^5), 147.0 and 146.5 (C^3 and C^5) and 103.3 (C^4) for the third dmpz ligand.

[11] Crystal structure analysis of **3**: $P\bar{1}$, a=16.590(3), b=9.444(1), c=8.944(1) Å, α=100.97(1), β=75.95(1), γ=104.28(1)°, V=1034.7(3) Å^3, Z=2, R=0.044 for 4378 independent reflections with $I \geq 3\sigma(I)$ (Philips PW 1100 diffractometer, $Cu_{K\alpha}$). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52145, the names of the authors, and the journal citation.

[12] *Experimental procedure:* **4**: A solution of **3** (150.0 mg, 0.244 mmol) in 10 mL of CH_2Cl_2/Me_2CO (4:1, v/v) and 48.6 µL of aqueous HBF_4 (wt.-% 35%, 0.244 mmol) was stirred for 0.5 h at room temperature. After concentration of the solution, addition of diethyl ether yields yellow crystals which were filtered off, washed with diethyl ether, and air dried. Yield: 144.1 mg (84%); correct elemental analysis (C, H, N).

[13] *Experimental procedures:* **5**: From **2**: Complex **5** was prepared analogously to complex **4** from **3** [12] but using a molar ratio HBF_4:**2** = 2:1. Yield: 74%. From **6** [14]: To a solution of **6** (prepared in situ by treating **1** (150.2 mg, 0.188 mmol) with $AgBF_4$ (147.1 mg, 0.755 mmol) in acetone (10 mL)), pyrazole (102.4 mg, 1.504 mmol) was added. The resulting solution was stirred for 1 h. Complex **5** was isolated by partial vacuum-evaporation and subsequent addition of diethyl ether. Yield: 213.0 mg (80%); ^{1}H-NMR (200 MHz, $(CD_3)_2CO$, 293 K, TMS ext.): δ=1.64 (C_5Me_5), 6.72 (H^4), 8.06, 8.18 (H^3, H^5), $J(H^3H^4)$=$J(H^4H^5)$=3 Hz and 12.37 (broad, NH); correct elemental analysis (C, H, N).

Divinylglyoxal and Methylvinylglyoxal**

By *Roland Kramme, Hans-Dieter Martin,* Bernhard Mayer,* and *Ralf Weimann*

Dedicated to Professor Edgar Heilbronner on the occasion of his 65th birthday

The spectroscopic and conformational properties of 1,2-diketones have been the subject of numerous studies in the past few years.[1,2] Interrelated with these properties are the colors of such simple organic chromophores. Open-chain, aliphatic 1,2-diketones with unsubstituted vinyl groups, however, were hitherto preparatively inaccessible. Only in the case of the alkylvinyl derivatives were the diketones obtainable, albeit in poor yields (2–10%).[3a] Methylvinylglyoxal (4-pentene-2,3-dione) **2** has been postulated as a significant component of the dione fraction formed in the tropospheric photooxidation of aromatic hydrocarbons.[3b] As we had already successfully prepared cyclobutenedione by gas-phase pyrolysis,[4] we resorted to the same method for the synthesis of divinylglyoxal (1,5-hexadiene-3,4-dione) **1** and methylvinylglyoxal (4-pentene-2,3-dione) **2**.

The dione **5** required for pyrolysis was synthesized essentially according to the method described by *Stetter* et al.[5] The bicyclic aldehyde **3** was obtained as an *endo/exo* mixture from cyclopentadiene and acrolein by Diels-Alder reaction. Subsequent reaction of **3** with aldehydes in the presence of thiazolium salt as catalyst afforded the acyloins **4** and **4'**, which could be oxidized with Bi_2O_3 in acetic acid solution to the 1,2-diketones **5**.[6] Gas-phase pyrolysis of **5a** and **5b** at 600°C/0.01 torr furnished **1** and **2** in yields of 81 and 89%, respectively.[7]

The compounds **1** and **2** are excellent dienophiles. With cyclopentadiene, for example, the *endo* products are formed highly stereoselectively at room temperature: **5a** > 98% as a diastereomeric mixture of the *meso* and D,L forms; **5b** ≈ 90%.[6]

The UV spectra of flexible 1,2-diketones usually show a maximum between 350 and 450 nm; further bathochromic shifts caused by various effects are observed.[4] As a result, all these compounds are colorless or bright yellow to orange. The position of the $n\pi^*$ maximum is influenced substantially by the torsion angle between the two carbonyl groups. This effect can be exploited for the conformational analysis of glyoxal derivatives, since a correlation of the wave number of the transition and the torsion angle has already been well documented for aliphatic 1,2-diketones.[2] From Figure 1 it can be seen that the measured absorption at ca. 23000 cm^{-1} for **1** and **2** corresponds to a CO-CO torsion angle of ca. 165°, which in turn corresponds to an almost antiperiplanar dicarbonyl unit-consistent with the yellow color of **1** and **2**.

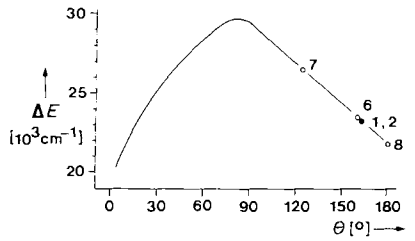

Fig. 1. Absorption maxima as a function of the torsion angle between the carbonyl groups: **1** and **2** ca. 165°, di-*tert*-butylglyoxal (2,2,5,5-tetramethyl-3,4-hexanedione) **7** 122° [2], dimethylglyoxal (biacetyl) **6** 160° [2], glyoxal **8** 180° [2]. (The left-hand side of the curve is ignored, since there is no synperiplanar arrangement in open-chain diones.)

Further insights into the electronic properties of **1** and **2** are provided by photoelectron spectroscopy (Fig. 2). The measured ionization energies are listed in Table 1 together with the energies assigned on the basis of MNDO,[8] MINDO/3[9] and HAM/3[10] model calculations, assuming the validity of Koopmans theorem.[11] A comparison with the data for known 1,2-diketones reveals that: the splitting between n_+ and n_- remains unaltered on going from biacetyl via **2** to **1** (n_+ and n_- are the n combinations formed by hyper- and homoconjugative interaction, respectively). The value of 1.9 eV for Δn lies in the middle of the usual range.[12] Noteworthy, is the intensity distribution in the PE spectrum of **1**: it is approximately 1 : 2 : 1. This would indicate that the ionization band at 10.78 eV is consistent with the theoretical predictions based on two π-ionization processes, which are not resolved in the spectrum. With respect to their ionization energy, the π orbitals of the two vinylglyoxals **1** and **2** are comparable with the π orbitals of acrolein. From the ionization energies I_j^m for **1** and **2** and the orbital energies of **1** calculated for two vinyl-CO torsion angles (0°, 51°) (Table 1), the following conclusion can be drawn: the vinyl group is comparable with a methyl group regarding its effect on the n_+ and n_- levels, and the n-ionization energies show no significant dependence on the vinyl-CO torsion angle.

Experimental

5a and **5b** were pyrolized at 600°C and 0.01 to 0.02 torr in a gas-phase pyrolysis apparatus (small tube furnace fitted with quartz tube and directly coupled to four cooling traps). The cooling traps directly adjacent to the furnace, and in which the products were collected, were cooled to −78°C (1st trap) and −178°C (2nd trap), respectively. The storage vessel for **5** was heated to 110°C in the case of **5a**, and to 60°C in the case of **5b**. After ca. 2 h, there was no longer any starting compound **5** in the storage vessel; the first cooling trap contained the dione **1** (81%) or **2** (89%), the second trap cyclopentadiene.

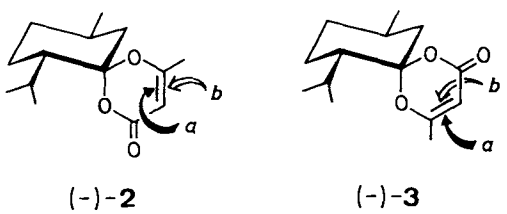
Asymmetric Photocycloadditions with Optically Pure, Spirocyclic Enones. Simple Synthesis of (+)- and (−)-Grandisol

By *Martin Demuth,* Albert Palomer, Heinz-Dieter Sluma, Ashesh K. Dey, Carl Krüger,* and *Yi-Hung Tsay*

Photochemical [2+2]-cycloadditions of enones and related chromophores to olefins have previously been the subject of numerous investigations from the standpoint of asymmetric induction.[1] In more recent studies of such cycloadditions based on a principle that has also been tested by us, enones[2] or compounds with enone-like photoreactive moieties[3] have been used which contain a chiral auxiliary group. After the cycloaddition the chiral auxiliary group is split off and can thus be recovered. The aim of our present investigation was to prepare an enone moiety in the simplest way from readily accessible materials and to couple it rigidly, i.e. spirocyclically, to the auxiliary material (novel principle of stereofacial differentiation) and to recover this under mild conditions after the cycloaddition (avoidance of isomerizations). The dioxacyclohexenones (−)-**2** and (−)-**3** have proven suitable for this strategy (Fig. 1).[4]



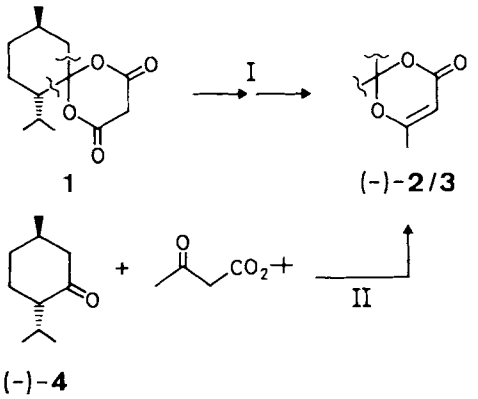


Fig. 1. Olefins add *a*-selectively to the dioxacyclohexenones (−)-**2** and (−)-**3**.

A mixture of (−)-**2** and (−)-**3** can be obtained via two routes: By rearrangement of the dioxacyclohexadione **1**[5] after acetylation (acetyl chloride, pyridine; analogously as in Ref. [6]) into a 1:1 mixture of (−)-**2** and (−)-**3** (diglyme, 120°C, analogously as in Ref. [7]) (Scheme 1, Route I; ca. 10% yield) or in *one step* by condensation of (−)-menthone, (−)-**4**, with *tert*-butyl acetoacetate in acetic anhydride in presence of sulfuric acid (Scheme 1, Route II; ca. 34% yield). The ratio in which the two isomers are formed can be varied: At −5°C, (−)-**2** and (−)-**3** are formed in the ratio 6:1, at 10°C in the ratio 1:1.

Scheme 1.

The products could be separated cleanly and easily by crystallization of (−)-**3** from *n*-hexane at −10°C and chromatography of the filtrate on silica gel [(−)-**2**]. The yields quoted for Routes I and II are the sum of the yields of pure (−)-**2** and (−)-**3**. The spectroscopic data are collected in Table 3.

Table 1. Photocycloadditions of the dioxacyclohexenones (−)-**2** and (−)-**3** with olefins [a]. The spectroscopic data of the products (+)-**5** and (+)-**8** are given in Table 3.

Expt.	Dioxacyclohexenone	Olefin	Photoproducts [b, c] [9] P′	P′
1	(−)-**2**		 (+)-**5**	
2	(−)-**2**			
3	(−)-**2**			
4	(−)-**3**		 (+)-**8**	

[a] Molar ratio dioxacyclohexenone:olefin = 1:4; $c((-)\text{-}2) = c((-)\text{-}3) \approx 0.2$ mol/L; experiments 1, 2, 4 in *n*-hexane, experiment 3 in acetonitrile. [b] Besides the regioisomers P and P′, small amounts of stereoisomers with complementary four-membered ring configurations are formed (cf. *a*:*b* values in Table 2). [c] Pure products after column-chromatographic separation.

The photocycloadditions of (−)-**2** and (−)-**3**[8] with the olefins listed in Table 1 (quartz vessel, medium-pressure mercury lamp) yielded products[9] which are *cis,anti,cis*-configurated at the new coupling sites (Table 2, experiments 1, 3, and 4).[10] The pronounced regioselectivity in additions with methylcyclobutene (experiments 1 and 4 at −78°C) decreases on using an acyclic olefin (experiment 2 at −78°C). The consistently high stereoselectivity (see *a*:*b* values in Table 2) lends support to the soundness of the spiro principle for stereofacial differentiation. Whereas a low reaction temperature is essential for a preparatively interesting stereoselectivity in the case of reactions 1, 2, and 4, considerable induction is already achieved at 5°C with

Table 2. Results of the reactions listed in Table 1.

Expt.	*T* [°C]	Yield [%] [a] P+P′	Regioselectivity P:P′	Stereoselectivity [b] *a*:*b*
1	−78	55 (70)	7:1	5:1

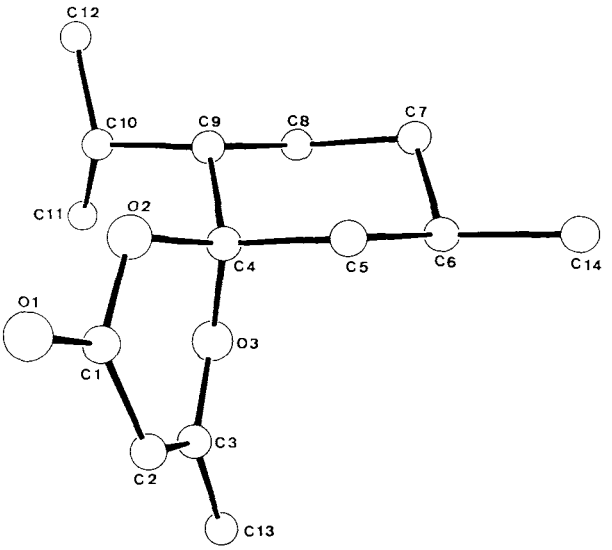
cyclopentene. Since attack from the *a*-side is preferred to the same extent in the case of (−)-**2** and (−)-**3** (experiments 1 and 4) they are suitable educts for selective entry to complementary series of enantiomers without—as is otherwise usual—the chiral auxiliary having to be changed (see, e.g., [2]).

The preferred addition of the olefins to the *a*-side of the enones (−)-**2** and (−)-**3** rules out any effective shielding by the isopropyl group, and is apparently determined conformationally. We presume that the dioxacyclohexenone ring could adopt a twisted boat conformation in solution, an arrangement that exposes the *a*-side and which has been found X-ray crystallographically in crystalline (−)-**3** (Fig. 2).



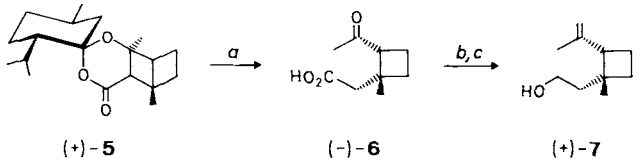


Fig. 2. Crystal structure of (−)-**3**. $a = 9.283(1)$, $b = 14.497(1)$, $c = 21.107(2)$ Å, $V = 2840.4$ Å^3, $\rho_{calc} = 1.11$ g cm^{-3}, $\mu = 0.72$ cm^{-1}, $Z = 8$, space group $P2_12_12_1$, 6640 reflections, 3976 observed ($I > 2\sigma(I)$), 307 refined parameters, $R = 0.056$, $R_w = 0.065$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51953, the names of the authors, and the full citation of the journal.

The value of the method presented here has been confirmed by the first example of its application (Scheme 2). The major product of experiment 1, (+)-**5**, was smoothly hydrolyzed with formic acid to give (−)-**4** and (−)-**6**[11b] (80% yield after column chromatography) without epimerization occurring at the acetyl group.[2] (−)-**6** was converted into (+)-grandisol, (+)-**7**,[11-13] by a procedure already described in the literature.[13d] A specific rotation of $[\alpha]_D = +20°$ was calculated for (+)-**7** ($c = 0.3$ g/100 mL, *n*-hexane; corrected literature values: $[\alpha]_D = +18.5°$[11a] and $+19.6°$[11b]). Thus, it has been possible for the first time to synthesize the boll weevil (*Anthonomus grandis*) pheromone in optically pure form. At the same time, this five-step synthesis is the shortest sequence so far for the preparation of this highly active natural product,[14] the enantiomer of which, (−)-grandisol, can be obtained analogously from (+)-**8**.

Scheme 2. Shortest synthesis of (+)-grandisol, (+)-**7**, reported so far. a) HCOOH, H_2O/Me_2CO, 40 °C, 20 h. b) Me_3SiCH_2MgCl, tetrahydrofuran, reflux, $SOCl_2$, room temperature; analogously as in [13d]. c) $LiAlH_4$, Et_2O, room temperature; analogously as in [13d].

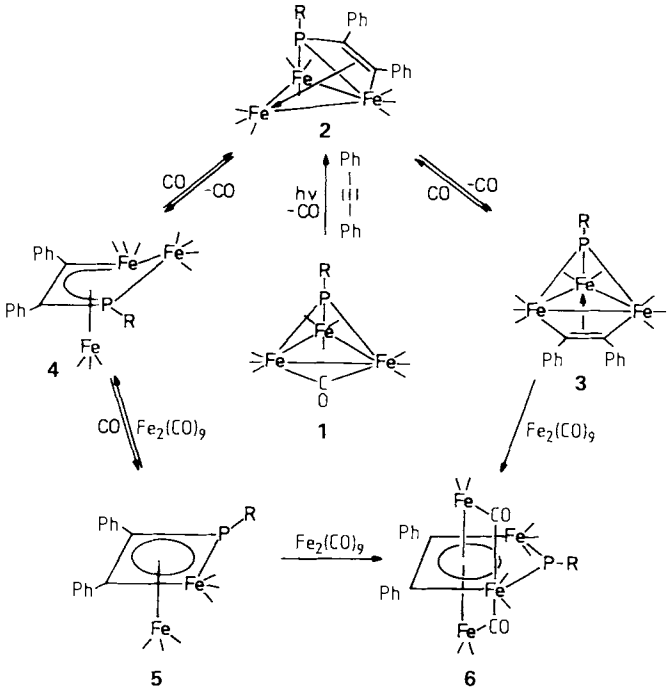
Skeletal Rearrangements on Clusters: The Reaction of [(*t*BuP)Fe$_3$(CO)$_{10}$] with Diphenylacetylene**

By *Konrad Knoll, Gottfried Huttner,* Laszlo Zsolnai,* and *Olli Orama*



μ_3-RP groups have proved useful as building blocks for clusters. The metal atoms that they bridge are held together in the course of a reaction in such a way that the mechanism of reactions that involve cleavage of metal-metal bonds can be studied in detail.[1-3] This application of

μ_3-RP groups in cluster chemistry is based on the fact that the bonds to phosphorus are not affected by the reaction. However, we recently showed that, under some conditions, the phosphorus-metal bonds can indeed be attacked.[4-6]

We have now found the reaction of $[(\mu_3\text{-RP})Fe_3(CO)_{10}]$ with alkynes[5a] to be a system in which the enthalpies of the P-Fe, C-Fe, and P-C bonds are apparently so similar that a variety of skeletal rearrangements are possible. We report here on the photochemical reaction of the cluster **1**[2,7] with diphenylacetylene to give **2** and on the subsequent reactions of **2** involving skeletal rearrangement. Since **2** reacts to give **3** upon irradiation, reaction of **1** affords, in addition to 47% of **2**, 11% of **3** (Scheme 1).

Scheme 1. The terminal CO groups are indicated by lines. R = *t*Bu.

One of the P-Fe bonds of the starting cluster **1** is opened in **2**. The coordination site that thereby becomes free is involved in interaction with the π system of the alkyne, which bridges one of the two remaining P-Fe bonds. The lengths of the P-Fe bonds are normal (Fig. 1);[8] the distance between phosphorus and the iron atom not directly bonded to it is 272.8(3) pm. The P-C bond in the ring is significantly shorter than the bond to the *tert*-butyl group. The skeleton of **2** thus corresponds roughly to a trigonal prism, one of whose square faces has an additional diagonal bond (Fe2-Fe3) (Fig. 1).

2 undergoes both photochemical and thermal decarbonylation with accompanying skeletal rearrangement to give **3**. In **3**, the RP group functions again as a μ_3 ligand. The P-C bond to the alkyne fragment is broken, and the Ph_2C_2 fragment bridges an edge of the iron triangle. The coordination site that becomes free upon decarbonylation is involved in π interaction with the bridging alkyne (Fig. 2).

In a reversal of its photochemical formation, **3** reacts at 20°C under 1 bar of CO to give **2**. The reaction does not stop there, however, since, under these conditions, **2** adds CO to form **4**. Complex **4** reacts, in turn, to give the binuclear complex **5**,[11] one of the iron centers being carbonylated to $Fe(CO)_5$. Complex **5** is the stable end product of the reaction of **3** or **2** with CO. The intermediacy of **2** and **4** in the conversion of **3** to **5** is revealed, on the one hand,

stitution product of **4** when, instead of CO, trimethylphosphite is used as ligand. One trimethylphosphite ligand is bonded to each of the ring iron atoms in the resulting product of type **4**.[10]

Elimination of the $Fe(CO)_4$ group of **4** produces **5**, which contains a conjugated cyclic 4π system that is stabilized by the coordination to a $Fe(CO)_3$ group.[11]

Complex **5** reacts with an excess of $Fe_2(CO)_9$ at 25°C, undergoing formal insertion of an $Fe(CO)_4$ fragment into the ring P–Fe bond, to give **4** once again. Complex **4**, in turn, undergoes rapid decarbonylation to give **2**. At 60°C, **5**, as well as **3**, reacts with $Fe_2(CO)_9$ to give the triple-decker complex **6**.[10]

The closed sequence of reactions described here, in which the opening and formation of Fe–Fe, P–Fe, C–Fe, and P–C bonds occur alternately and sequentially, implies very similar enthalpies for these bonds. Overall, the observed pattern of reactions is strongly reminiscent of the chemistry of carboranes.[12]

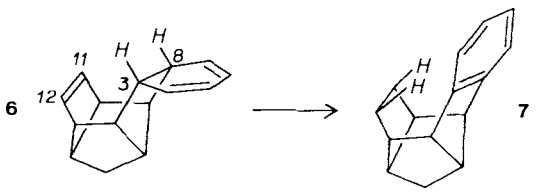
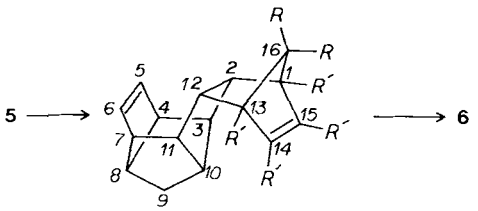
Dyotropic Hydrogen Migration in Pentacyclo[7.6.0.0^{2,13}.0^{3,8}.0^{10,14}]pentadeca-4,6,11-triene

By *Tahsin J. Chow** and *Mei-Fang Ding*



Nonbonding interactions between the two closely spaced ethylene bridges on an isodrin skeleton (cf. **11**) have been extensively analyzed. One of the most interesting phenomena is the dyotropic migration of two hydrogens from one bridge to the other.[1] Primary and secondary orbital effects of such transformations have been ana-

lyzed by *Reetz*.[2] Refluxing a toluene solution of **1** induces its smooth transformation to **2**. Two other derivatives, **3** (for example, Aryl = C_6H_5 or *p*-Me–C_6H_4)[3] and **4** (R = COOMe)[4], have also been shown to react in a similar fashion, and their thermodynamic parameters have been calculated. The energy of aromatization in **1** and **3** contributes part of the driving force, but the degree of orbital overlap between the *endo*-H atoms of the ethane bridge and the C atoms of the ethylene bridge also plays a determining role in these processes. The carbon-to-carbon dis-



tance between the ethylene bridges of homohypostrophene, **5**,[5,6] is very close to that of isodrin,[7] but the two compounds have different directional angles between the π lobes and the C–H bonds of the opposite bridge.

A derivative of **5**, the title compound **6**, has now been prepared by us. Gas-phase flash pyrolysis of **6** at 400°C through a Vycor tube packed with glass beads was examined and shown to produce a high yield (ca. 70%) of **7**.[8] The presence of an aromatic ring in **7** was obvious since the ^{1}H-NMR spectrum showed a multiplet at $\delta=7.0$ (4H) and two upfield-shifted protons at $\delta=0.9$ for H-11 and H-12 due to a strong shielding effect from the proximately

located aromatic ring. The reaction **6** → **7** is thus a rare example of an intramolecular dyotropic hydrogen migration between two nonconjugated ethylene moieties.

8, R=OMe; R'=Cl
9, R=OMe; R'=H
10, R,R=O; R'=H

Scheme 1.

The synthesis of **6**[8] is outlined in Scheme 1. Refluxing a xylene solution of **5** and 2,3,4,5-tetrachloro-1,1-dimethoxycyclopentadiene (molar ratio 1:1) for 24 h produced the [4+2] adduct **8**[8] in 50% yield. Dechlorination of **8** was effectively carried out in sodium/ethanol to give **9** in 60% yield. In the 200-MHz ^{1}H-NMR spectrum of **9**, H-2 and H-12 appear as a doublet of doublets at $\delta = 1.9$, which is 0.5 ppm more upfield than the signals of H-3 and H-11 ($\delta = 2.4$). The shift is believed to be due to the shielding caused by the ethylene bridge (C-5, C-6). Acidic hydrolysis of **9** (10% H_2SO_4, 20 °C, 2 h) gave **10**[8] quantitatively, which was then decarbonylated to form **6** by heating it in a sealed tube at 125 °C (2 h in CCl_4, quantitative yield). The triene **6** is a colorless solid (m.p. = 50–51 °C) with the vinylic protons appearing as three multiplets at $\delta = 5.5$, 5.7, and 6.1 (2H each).

11 **12** **13**

The distance between the two ethylene bridges of dechlorinated isodrin, **11**, is ca. 2.8 Å.[9] The corresponding distance for homohypostrophene, **5**, is also about 2.8 Å.[5] However, since the double bonds of **11** are nearly parallel to each other, the through-space interaction is maximized to produce a 1.26-eV energy gap between IP_1 (8.08 eV) and IP_2 (9.34 eV) in its photoelectron spectrum.[10] In **5**, the π lobes are not parallel but instead form an angle bending outward. The small difference between its IP_1 (8.6 eV) and IP_2 (8.8 eV) indicates a very weak interaction.[11] Moreover, a comparison based on the hydrogenated products **12** and **13** is also revealing. The ethane bridges of **12** and **13** are pushed apart by steric repulsions between the *endo* hydrogens but to different extents. The distance between the *endo* hydrogens (d_1) is 1.85 Å for **12**[12] and 2.14 Å for **13**.[6] However, the carbon-to-carbon distance (d_2) between the bridges increases by 0.4 Å to a value of 3.2 Å[12] in going from **11** to **12**, and by only 0.2 Å to a value of 3.0 Å in going from **5** to **13**.[6] These data clearly show that introduction of *endo* hydrogens induces a more severe distortion in **12** than in **13**. The same criterion can be equally applied to **1** and **6** (i.e., nonbonding interactions of **6** should be much weaker than those of **1**). The transannular strain of **1** has been calculated as ca. 0.3 eV;[13] thus, the corresponding value in **6** is expected to be much smaller. Nevertheless, our observation of double hydrogen migration suggests that orbital interactions across the bridges of **6** are still of significance.

Large Molecular Cavities for Small Ions—Double Bridging of Three Bipyridine Units**

By *Smaragda Grammenudi* and *Fritz Vögtle**

We recently reported on a $Fe^{3\oplus}$-selective ligand of the siderophore-type, in which three pyrocatechol units are bridged symmetrically.[1] With the synthesis of the macrobicyclic ligand **10**, we have now been able to achieve for the first time an analogous bridging of three bipyridine units via two 1,3,5-substituted benzene rings as spacers. Compared to cryptands with two-membered chains between the donor centers and the coordinating bridgehead nitrogen atoms,[2] **10** has the great advantage that complexation and decomplexation are less sterically hindered because of the size of its cavity, which is of importance in chemical and biological applications.[3]

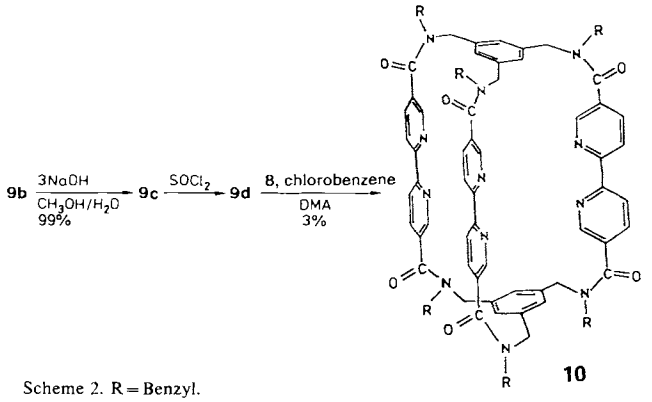
[**] Presented in part at the Fourth International Symposium on Inclusion Phenomena in Lancaster (England), July 20–25, 1986. This work was supported by the Deutsche Forschungsgemeinschaft. We thank Dipl.-Chem. *W. Calaminus*, Dipl.-Chem. *R. Thomessen* and *W. M. Müller* for assistance, and Frau Dr. *J. Peter*, Institut für Physiologische Chemie der Universität Bonn, for recording and evaluating the FAB mass spectra.

The synthesis of **10** starts from the nicotinate **1** and proceeds via the intermediates **2**–**9** shown in Scheme 1 (for data for the new compounds see Table 1). Since the *N*-unsubstituted intermediate **9a** presents solubility problems, the more readily soluble tribenzyl derivative **9b** was synthesized.[4] The decisive cyclization of **9d** and **8** to give the hexabenzyl-substituted ligand **10** was accomplished after numerous optimization experiments—other than usual[5]—in chlorobenzene/dimethylacetamide at room temperature under dilution principle conditions (yield 3%) (Scheme 2).[6]

The R_F value of the purified[6] ligand **10** (TLC plates Al_2O_3 neutral, $CHCl_3$/isopropyl alcohol/C_2H_5OH (100 : 1 : 0.6) is 0.43. Further data for **10** are listed in Table 1.

In the ^{1}H-NMR spectrum of **10** (400 MHz, [D_6]dimethyl sulfoxide) all the signals are broadened at room temperature. At 120°C, however, sharp absorptions appear: all benzyl CH_2-resonances centered at $\delta = 4.5$ overlap at 20°C, whereas at 120°C, two singlets are observed at $\delta = 4.51$ and 4.75. Because of hindered rotation about the amide bonds[7] the free ligand **10** shows limited free mobility, whose barrier ΔG^+ is approximately 60 kJ/mol assuming a coalescence temperature $T_c \approx 20$°C and a splitting of $\Delta\nu \approx 20$ Hz.

Although the 34-membered cavity[8] has to shrink drastically for the complexation of small metal ions, the macrobicyclic ligand **10**, which is strongly lipophilic because of the six benzyl residues, is an unusual complex ligand: the characteristic red color of the $Fe^{2\oplus}$-complex **12** is already observed during the cyclization reaction **9d** + **8**. Upon chromatographic separation, **10** always forms—other than in the case of the open-chain ligand **9b**—a red-violet zone at the upper rim of the column. Since the ligand **10** was not intentionally brought into contact with iron salts in these experiments, the formation of a complex had to be attributed to traces of iron in the reagents and/or parts of the apparatus. With $Fe^{3\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$, $Cu^{2\oplus}$ and $Cu^{\oplus}$, **10** forms only almost colorless solutions so that $Fe^{2\oplus}$ can be visually recognized even in the presence of these cations. Furthermore, the complex can be extracted with chloroform from aqueous alcoholic solution.



Scheme 1. W_7 = activity of Raney nickel used; DMA = dimethylacetamide.

Table 1. Data of the new compounds. All compounds except **8** gave correct elemental analyses. In the case of **8** the R_F value was determined: $R_F = 0.24$ (TLC aluminum foil Al_2O_3 neutral, CH_2Cl_2/CH_3OH 100 : 1). Because of its sensitivity towards hydrolysis, the triacid chloride **9d** was used as raw product.

Scheme 2. R = Benzyl.

The absorption maximum of the red $Fe^{2\oplus}$-complex **12** of **10** in the visible region (in hexafluoroisopropyl alcohol/water 1 : 1) lies at $\lambda = 524$ nm, that of the violet open-chain complex **11** of **9b** at longer wavelength at $\lambda = 546$ nm. The intensity of the absorption of the $Fe^{2\oplus}$-complex **12** ($\varepsilon = 6426$) exceeds that of the complex **11** of the open-chain "tripod"[9] **9b** ($\varepsilon = 5748$) (Fig. 1).

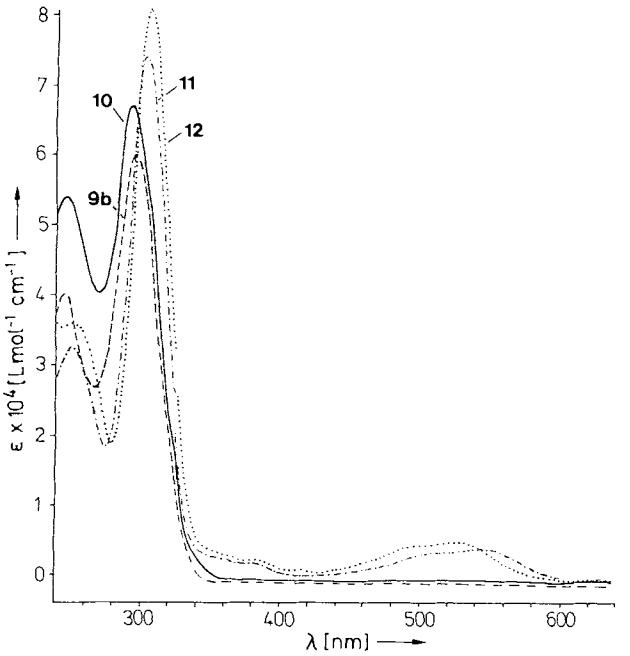
UV/VIS spectra of freshly prepared mixtures of **10** and $Fe^{2\oplus}$ salt solutions [$(NH_4)_2Fe(SO_4)_2$] in water/hexafluoroisopropyl alcohol (1 : 1) recorded after various intervals of time show that formation of the $Fe^{2\oplus}$-complex in dilute solution is complete after ca. one hour at 20 °C. Titration of the ligands **9b** and **10** with $Fe^{2\oplus}$-solutions indicated 1 : 1 stoichiometry of the complex in each case.

It follows from competition experiments between the three ligands **10**, **9b**, and **2** (molar ratio 1 : 1 : 3) that **10** is capable of taking over the central ion ($Fe^{2\oplus}$) from the other ligands. The $Fe^{2\oplus}$-complex **12** of **10** cannot, however, be decomplexed, not even with ethylenediaminetetraacetic acid (disodium salt) or the bipyridine ester **2** in 1000-fold excess or with hydrochloric acid at pH = 1. In contrast, the $Fe^{2\oplus}$-complex of **2** is decolorized with excess EDTA.

The unusual stability of the oxidation state 2 in the $Fe^{2\oplus}$-complex **12** of **10** follows from the fact that 10^{-4} M solutions in dimethyl sulfoxide are not decolorized—by oxidation to $Fe^{3\oplus}$ or ligand removal—even after several days, whereas this already takes place in the case of the open-chain $Fe^{2\oplus}$-complex of **9b** after a few hours under analogous conditions, and much more rapidly so in the case of the $Fe^{2\oplus}$-complexes of the diester **2** and of unsubstituted bipyridine. The $Fe^{2\oplus}$-complex **12** survives drastic conditions, such as addition of aqueous H_2O_2, considerably longer than the above-mentioned comparison complex **9**.

It can be concluded from the high stability of the complex and the stabilization of the oxidation state that the $Fe^{2\oplus}$-ion is bound at the center of the cavity of **10**. Such a stability could not be explained in terms of an intermolecular bonding of $Fe^{2\oplus}$. As can be shown on the basis of molecular models, upon coordination of $Fe^{2\oplus}$ the ligand **10** assumes a helical conformation in which the bipyridine rings are inclined at almost 54° to the threefold molecular axis.

The intense red color of the $Fe^{2\oplus}$-complex can, in view of the negligible color reaction with $Fe^{3\oplus}$, be exploited for the sensitive photometric determination of $Fe^{2\oplus}$ in the presence of other ions. **10** (and **9**) can be useful for the complexation of ions of the noble metals Pd, Pt, Rh, etc.,[10] e.g. with respect to indirect electrochemical redox reactions[11] and photochemical cleavage of water. Similarly structured cation selective ligands with other spacer groups,[12] other donor units, and more than three bridges[13] can also be prepared via the route described here.



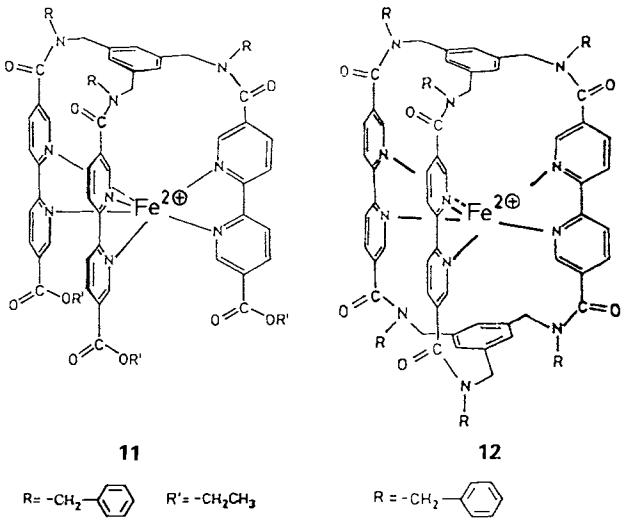


Fig. 1. UV/VIS spectra of the ligands **10** and **9b** (for comparison) and their $Fe^{2\oplus}$-complexes **12** and **11**, respectively [iron salt employed: $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$] (in hexafluoroisopropyl alcohol/water 1 : 1).

[4] This strategy had proven useful in a previous case: U. Werner, W. M. Müller, T. Merz, H.-W. Losensky, F. Vögtle, *J. Incl. Phenom. 4* (1986), in press.
[5] In this case the use of benzene as solvent, as was used previously [1], met without success.
[6] *Procedure:* **10**: Solutions of **9d** (5.00 g, 4.25 mmol) in chlorobenzene (200 mL) (dried over P_4O_{10}), dimethylacetamide (50 mL, 99% Janssen), and **8** (3.72 g, 8.55 mmol) in chlorobenzene (250 mL) were added concomitantly and dropwise under nitrogen within 12 h at room temperature to 1 L of chlorobenzene. A colorless flocculent precipitate formed; this was removed from the red solution by filtration, and then the solvent was removed from the filtrate by evaporation. After stirring of the residue with dichloromethane (with heating) and filtration, the dichloromethane solution was chromatographed on a silica gel column with chloroform/methanol (20:1). **10** crystallized from the eluent as the clathrate with $CHCl_3$ (1:2). The chloroform was completely removed at 100°C/0.05 torr (6.6 Pa) within a few days (see Table 1).

Synthesis of a Macrobicyclic Thiazolium-Host and Supramolecular Catalysis of the Benzoin Condensation**

By *Heinz-Dieter Lutter* and *François Diederich**

Dedicated to Professor Vladimir Prelog on the occasion of his 80th birthday

Thiamine pyrophosphate (TPP) participates as the essential cofactor in numerous enzymatic reactions involving formation and breaking of carbon–carbon bonds.[1] The catalytic action of TPP is mainly due to the thiazolium ring, and simple thiazolium salts catalyze many of the enzymatic transformations in the absence of the enzymes.[2]

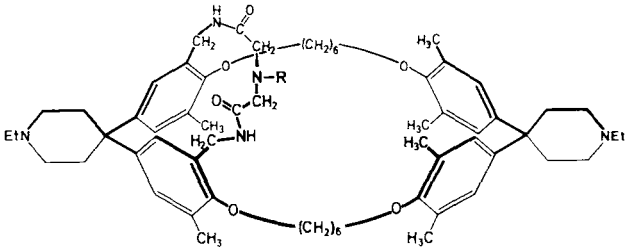
[**] This work was supported by the Deutsche Forschungsgemeinschaft.



We report here for the first time on the preparation of a fully synthetic thiazolium-macrocycle (**1**) and its use as an efficient catalyst in the benzoin condensation.[3,4] Compound **1** was designed to provide in aqueous[5] and in organic solution[6] a binding cavity for the two benzaldehyde molecules that react to give benzoin. A thiazolium residue is connected by two side arms to the macrocyclic binding site of **1**. This double fixation atop the cavity was expected to limit the number of unproductive conformations of the catalytic residue and to prevent its competitive binding to the macrocyclic cavity. Favorable proximity and orientation of the reacting partners has been recognized as a major principle of enzymatic catalysis.[7] We therefore expected higher rates of benzoin formation in the presence of **1** than in the presence of thiazolium derivatives lacking the macrocyclic binding cavity.

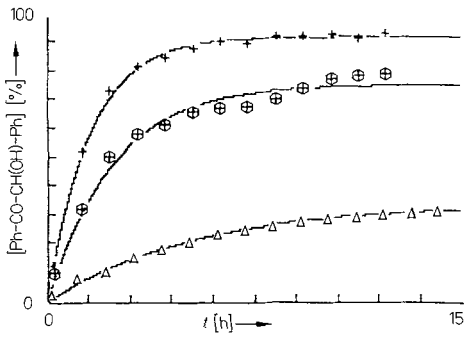
3

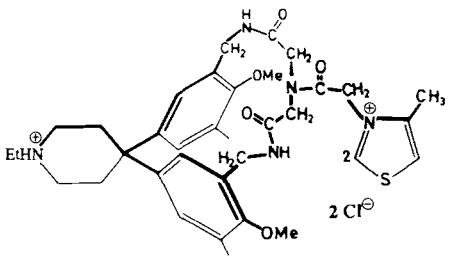
4, R = -C(=O)-O-CH$_2$-C$_6$H$_5$
5, R = H
6, R = COCH$_2$Br

In the synthesis of macrobicycle **1**, the macrocyclic tetramine **2**[8,9] was cyclized in chloroform with the activated diester **3**[10] to give the macrobicycle **4**[9] in 50% yield. The *N*-protective group of **4** was removed catalytically [H_2/Pd on C (10%); 95%], and the secondary amino residue of **5**[9] was acetylated with α-bromoacetyl bromide in chloroform to give **6** (37%).[9] Reaction of **6** with excess 4-methylthiazole followed by ion exchange chromatography ($Cl^{\ominus}$) provided in 69% yield the target molecule **1**, which was analyzed as a dihydrate.[11] 1D- and 2D-(COSY) ^{1}H-NMR analysis of **1** shows that the bridge with the thiazolium residue takes several conformations as a consequence of the restricted rotation around the three amide linkages.[11] The contour plot of a 2D-NOESY ^{1}H-NMR experiment under

the same conditions indicates the location of the thiazolium ring on the cavity side in proximity to the tetramethyl-substituted diphenylmethane unit. Revealing connectivities are observed between 2′-*H*,5′-*H*, and 4′-CH_3 of the thiazolium ring and 31,35-CH_3, 32,34-*H*, and N–CH_2–CH_3 of the diphenylmethane unit.

We studied by ^{1}H-NMR (500 MHz) the catalysis of the benzoin condensation by **1** in [D_4]methanol in the presence of triethylamine as base (initial concentrations of: [**1**] = 20 mmol·L^{-1}, [PhCHO] = 400 mmol·L^{-1}, [NEt_3] = 60 mmol·L^{-1}; T = 323 K, under N_2). After 8 h, the signals of the benzaldehyde protons had almost completely disappeared and all new peaks could be assigned to benzoin. Chromatographic work-up of the reaction after 12 h afforded unchanged catalyst and analytically pure benzoin in 93% isolated yield. For kinetic analysis, we monitored the decrease in integrated intensity of the singlet for the aldehyde proton of benzaldehyde at $\delta = 9.97$ and the increase in integrated intensity of the isolated doublet at $\delta = 7.93$ for the two aromatic protons *ortho* to the carbonyl group of benzoin.[12] A plot of benzaldehyde disappearance and of benzoin formation versus time (Fig. 1) is best evaluated by assuming that the reaction is first order in benzaldehyde and the first order rate constant is calculated as $k = 2.0 \times 10^{-4}$ s^{-1}.[13] Under initial reaction conditions, **1** shows a turnover rate of 15 per hour.[13]





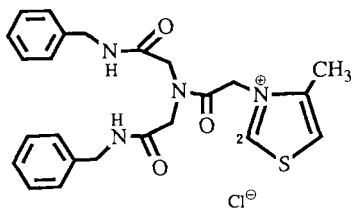


Fig. 1. Increase in benzoin concentration versus time followed by ^{1}H-NMR. [PhCHO]$_0$ = 400 mmol·L^{-1}, [NEt_3] = 60 mmol·L^{-1}, T = 323 K in [D_4]methanol. +: [**1**] = 20 mmol·L^{-1}, ⊕: [**7**] = 20 mmol·L^{-1}, Δ: [**8**] = 20 mmol·L^{-1}.

Using the above mentioned conditions, we compared the catalytic activity of **1** and of thiazolium derivatives lacking the macrocyclic binding site (Fig. 1): Reaction in the presence of macromonocycle **7**,[9] which was prepared following the procedures described above for **1**, led to a 74% isolated yield of benzoin after 12 h. We explain the considerable activity of **7** by the fact that this macromonocycle, according to examinations of CPK models, can provide a niche-binding site for benzaldehyde. The non-macrocyclic thiazolium-derivative **8**[9] gave only a 27% yield of benzoin after 12 h. Considerably smaller yields were also obtained in the presence of simple thiazolium salts like *N*-benzylthiazolium bromide, *N*-phenacylthiazolium bromide or thiamine (vitamin B_1). Macrobicycle **1** being a better catalyst than thiazolium derivatives without a macrobicyclic binding cavity demonstrates the importance of collecting and orienting the reacting partners by complexation prior to the catalytic event.

We have now started investigating in detail the mechanism of the benzoin condensation in the presence of **1**. From the dependence of the initial reaction rates on the aldehyde concentration we have obtained evidence for saturation kinetics. In dimethyl sulfoxide ([**1**] = 20 mmol·L^{-1}, [NEt_3] = 160 mmol·L^{-1}, and [$NHEt_3^{\oplus}Cl^{\ominus}$] = 100 mmol·L^{-1}) at 323 K the maximum rate of benzoin formation is observed at [benzaldehyde] ≈ 3.5 mol·L^{-1}.[14] We also observed that the molecular cavity binding site of **1** has a large effect on the rate of H/D-exchange at C-2′ of the thiazolium ring.[15] In a KCl/DCl buffer at pD = 1.84, T = 303 K, the rate of H/D-exchange observed by ^{1}H-NMR is $k_{obs} = 1.48 \times 10^{-3}$ s^{-1}.[16] Under the same conditions the rates of H/D-exchange at C-2 of the thiazolium rings in **7** ($k_{obs} = 4.88 \times 10^{-5}$ s^{-1}) and in **8**

7

8

($k_{obs} = 2.25 \times 10^{-5}$ s^{-1}) are considerably smaller. We tentatively explain the enhanced rate of H/D-exchange by a micropolarity effect of the cavity of **1** on the acidity of 2′-H of the thiazolium ring. The macrobicycle **1** also catalyzes the reverse reaction: With [**1**] = 20 mmol·L^{-1} and [Ph–CO–CH(OH)–Ph] = 800 mmol·L^{-1} in Me_2SO ([NEt_3] = 160 mmol·L^{-1} and [$NHEt_3^{\oplus}Cl^{\ominus}$] = 100 mmol·L^{-1}) at 323 K, we observed formation of benzaldehyde in 15% yield after 23 h. Under these conditions, the reaction starting with benzaldehyde leads to 50% yield of benzoin after 24 h.

In conclusion, **1** exhibits many features that are typical of the natural, TPP dependent enzymes and it is the most efficient molecular catalyst for the benzoin condensation known today. With **1**, we are currently investigating cross acetoin condensations[2e] between aromatic and alicyclic aldehydes with different affinity to the binding site as well as Stetter additions[17] of active aldehydes to complexed unsaturated carbonyls. The synthesis of molecular hosts with more enforced binding sites and with suitably located functional groups that provide intramolecular general acid-base catalysis as well as the preparation of chiral thiazolium-macrocycles for asymmetric acetoin condensations[2b, 3b] are now under way.

[11] Compound **1**·2 H_2O: m.p. 265°C (dec.). FAB-MS (*m*-nitrobenzyl alcohol) for **1**: *m/z* 1139.8 (33.7%, $M^{\oplus}-3$Cl), 1138.8 (68.2%, $M^{\oplus}-H-3$Cl), 1137.8 (100%, $M^{\oplus}-2H-3$Cl), 1136.8 (15.8%, $M^{\oplus}-3H-3$Cl). IR (KBr): $\tilde{\nu}=1670$ cm^{-1} (C=O). ^{1}H-NMR (1D- and 2D-COSY, 500 MHz, [D_6]Me_2SO, 303 K): $\delta=1.15$–1.25 (m, 6H, $^{\oplus}NCH_2CH_3$), 1.45–1.60 (m, 8H, 4-, 5-, 25-, 26-*H*), 1.60–1.85 (m, 8H; 3-, 6-, 24-, 27-*H*), 2.11 (s, 6H; 14-, 20-CH_3), 2.16 (s, 12H; 31-, 35-, 39-, 41-CH_3), 2.31 (s, 3H; 4′-CH_3), 2.30–2.35 (m, 4H; 3″-5″-, 3‴-, 5‴-H_{ax}), 2.55–2.80 (m, 4H; 3″-, 5″-, 3‴-, 5‴-H_{eq}), 2.85–3.15 (m, 8H; $^{\oplus}NCH_2CH_3$, 2″-, 6″-, 2‴-, 6‴-H_{ax}), 3.40–3.50 (m, 4H; 2″-, 6″-, 2‴-, 6‴-H_{eq}), 3.55–3.75 (m, 8H; 2-, 7-, 23-, 28-*H*), 4.10–4.55 (m, 8H; CH_2NCH_2, aryl-CH_2NH), 5.30–6.15 (m, 2H; $CO-CH_2-N^{\oplus}$), 6.80–7.05 (m, 8H; 11-, 13-, 17-, 21-, 32-, 34-, 38-, 42-H), 7.98 (s, br, 1H; 5′-H), 8.68, 8.82, 9.26, 9.35 (4 "t", 2H; N–*H*), 10.12 (s, 1H; 2′-*H*). The spectrum of **1** at 303 K corresponds to a mixture of an unknown number of conformers since the rotations around the three amide bonds and the chair inversions of the two protonated spiro piperidinium rings [6a] with equatorially positioned *N*-ethyl groups are slow. In [D_6]Me_2SO at $T=418$ K (200 MHz) the rotations around the amide bonds and the chair inversions are fast on the NMR time scale and a considerably simpler spectrum corresponding to one homogeneous compound is obtained.

[12] The change in integrated intensity of the proton signals of substrate and product was followed relative to the intensity of the methyl signal of triethylamine as internal standard. A pulse width of 2 μs and a delay time of 3.6 s assured very reproducible integrations.

[13] The first-order rate constant was calculated using a computer program which fits the experimental data for the disappearance of the aldehyde proton according to the equation $y=a\cdot e^{-k\cdot t}+b$. A fit over all data points gives the empirical equation $y=14.83\cdot e^{-0.749\cdot t}+0.65$ and $k=0.75$ h^{-1}. No significant b-value is obtained, if only the four first data points are fitted. The experimental data could not be fitted according to an integrated second-order rate equation. The turnover rate is expressed as molecules of substrates (initial concentration) reacting per hour per molecule of catalyst; see H. R. Mahler, E. H. Cordes: *Biological Chemistry*, 2nd edit., Harper-Row, New York 1971, p. 277.

[14] A more detailed analysis will have to show whether the observed saturation kinetics corresponds to a 1:1 or to a 1:2 (catalyst: benzaldehyde) Michaelis-Menten complex.

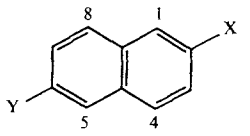
Electron Donor-Acceptor Interactions in Host-Guest Complexes in Organic Solutions**

By *Stephen B. Ferguson* and *François Diederich**

The role of electron donor-acceptor (EDA) interactions in molecular complexation has attracted much interest over the past decades.[1] These weak intermolecular interactions may be a major driving force for specific complexation in biological systems.[2] Major components of the interaction energy in EDA complexes are defined as electrostatic interaction, polarization interaction, and charge-transfer interaction in addition to dispersion energy.[1a] In the growing field of host-guest chemistry, which mimics biological complexation, several researchers have discussed contributions of EDA interactions to the stability of complexes formed in solution and in the solid state.[3] We now report the first quantitative evidence for these interactions in designed host-guest complexes.



1

Our studies compare the strength of complexation between macrocycle **1**[4] as host and a series of sixteen 2,6-disubstituted naphthalene derivatives **2a**–**p** as guests. The binding cavity of **1** has high steric complementarity to all of these guests which have a similar size and shape but differ in their electronic properties. These guests can be divided into three categories: a) naphthalene derivatives with two donor substituents (e.g. CH_3-, CH_3O-, $HO-$, H_2N-; **2a**–**e**), b) naphthalene derivatives with two acceptor substituents (e.g. $-CN$, $-COOR$, $-NO_2$; **2l**–**p**), and c) naphthalene derivatives with one donor and one acceptor substituent (**2f**–**k**).

^{1}H-NMR complexation studies in [D_4]methanol ([host]$_0$ = [guest]$_0$ = 5.0 mmol·L^{-1}) indicate that all 2,6-disubstituted naphthalene guests form highly structured 1:1 complexes of similar geometry with **1**. Complexed guests prefer a pseudoaxial position in the cavity of **1**; Figure 1 shows the averaged geometry of the complexes as deduced from the NMR complexation shifts.[5] This geometry of the complexes allows for π-π interactions between the guest and the benzene rings of the host.[6] Due to the rapid equilibrium of complexation, ^{1}H-NMR titrations provided quantitative determination of the binding between **1** and **2a**–**p** in [D_4]methanol (500 MHz, $T=303$ K, methyl peak of the solvent taken as reference). Concentrations of host and guest were chosen to vary the percentage of complexation from about 10–80% (e.g. [**2p**] = 1.1 mmol·L^{-1}, [**1**] = 3.0 to 22 mmol·L^{-1}). The association

constants of the 1:1 complexes were determined from the titration curves by using a computer-assisted non-linear curve-fitting procedure.[7] Table 1 gives the observed maximum complexation shift ($\Delta\delta_{max.obs.}$) of the guest proton whose signal can be best observed over the entire titration, the calculated complexation shift of this proton at saturation binding ($\Delta\delta_{sat}$), the association constants (K_a), and the free energies of complexation (ΔG).

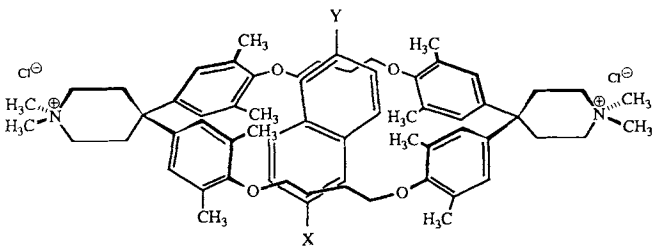

Fig. 1. Averaged geometry of complexes formed between host **1** and guests **2a-p**.

The K_a values in Table 1 show that electron-deficient (acceptor) guests (**2l-p**) form more stable complexes with host **1** than electron-rich (donor) guests (**2a-e**), while guests having one donor and one acceptor substituent (**2f-k**) demonstrate an intermediate stability of complexation. Differences in free energies of complexation can be as large as 1.59 kcal·mol^{-1}. We explain these differences by the major contribution of intermolecular EDA interactions to the stability of complexes. With its four trialkylsubstituted anisole units, compound **1** can be considered a donor host. Corresponding to the expectation that EDA interactions are a driving force for selective complexation, the acceptor guests (**2l-p**) form the most stable complexes with the donor-host **1**. Interestingly, these interactions also affect the geometry of complexes: the analysis of the complexation shifts of the protons of donor-acceptor substituted guests (**2f-k**) shows that in the averaged geometry of the complex the naphthalene moiety bearing the acceptor substituent is located more deeply in the cavity of **1** than the moiety with the donor-substituent. Further evidence that attractive interactions rather than entropically favorable desolvation represent the major driving force for selective complexation was provided by examining the temperature-dependence of the binding. For the **1**·**2p** complex in [D$_4$]methanol, the enthalpic and entropic contributions to the free energy of complexation ΔG are $\Delta H = -7.6$ kcal·mol^{-1} and $\Delta S_{303\,K} = -14.1$ cal·mol^{-1}·K^{-1}.

The conclusion that the differences in complexation, observed in [D$_4$]methanol, result from EDA interactions and not from special solvation effects of the polar protic solvent is clearly demonstrated by studies in [D$_6$]dimethyl sulfoxide. While considerably weaker binding of guests is observed in this solvent than in methanol, we find the same trends in complexation strength. Acceptor-acceptor guests form the strongest complexes with **1** while donor-acceptor and donor-donor guests form progressively weaker complexes. From the complexation shifts with [host]$_0$=20 mmol·L^{-1} and [guest]$_0$=5.0 mmol·L^{-1} and the saturation shifts obtained from methanol titrations, the association constants in dimethyl sulfoxide are estimated.[8,9] Examples of K_a values in [D$_6$]Me$_2$SO (T=303 K) are: for the **1**·**2d** complex $K_a \approx 1.6$ L·mol^{-1} ($-\Delta G \approx 0.28$ kcal·mol^{-1}), for the **1**·**2k** complex $K_a \approx 6.4$ L·mol^{-1}, and for the **1**·**2p** complex $K_a \approx 11.5$ L·mol^{-1} ($-\Delta G \approx 1.47$ kcal·mol^{-1}).

The electronic complementarity between host and guest is not as crucial for the strong complexation of substituted aromatic guests in aqueous solution. In D$_2$O/CD$_3$OD (60:40) with [host]$_0$=[guest]$_0$=5 mmol·L^{-1} (T=303 K), strong complexation between **1** and *all* naphthalene guests is evidenced by complexation shifts approaching the saturation shifts observed in [D$_4$]methanol.[10] In aqueous solution the entropically favored desolvation ("hydrophobic effect") rather than attractive EDA interactions provides the major driving force for complexation.[11]

In conclusion, our study demonstrates that electronic complementarity between host and guest is of special importance for the complexation of aromatic guests in organic solvents.[12] We were able to give quantitative evidence that electron donor-acceptor interactions can be a major driving force of complexation. The additional stabilization of donor host-acceptor guest complexes involves electrostatic and polarization interactions rather than charge-transfer (electron delocalization) interactions, since the complexes do not give any charge-transfer bands in the electronic absorption spectra.[13,14] We are currently preparing hosts with donor properties far superior to those of **1** as well as highly electron-deficient hosts. We expect to find significantly larger differences in the association constants of complexes formed by these new hosts and naphthalene guests with high and low electronic complementarity than we observed for the complexes of **1**.[15] It will be interesting to see if charge-transfer interactions can be observed in these complexes and if, as a consequence of par-

tial electron delocalization in the ground state, these complexes are more stabilized.

[4] F. Diederich, K. Dick, D. Griebel, *Chem. Ber. 118* (1985) 3588.

[5] For an extensive analysis of the ^{1}H-NMR complexation shifts of host and guest supporting a preferred time-averaged pseudoaxial inclusion of 2,6-disubstituted naphthalenes in cavities of hosts with two diphenylmethane units, see ref. [4] and F. Diederich, D. Griebel, *J. Am. Chem. Soc. 106* (1984) 8037; see also: K. Odashima, A. Itai, Y. Iitaka, Y. Arata, K. Koga, *Tetrahedron Lett. 21* (1980) 4347. The analysis of the ^{1}H-NMR complexation shifts indicates that in the complexes of the symmetrical guests, each ring of the naphthalene unit is located equally deep in the cavity; in the complexes of the donor-acceptor guests the naphthalene moiety bearing the acceptor substituent is, in the time average, enclosed more deeply in the cavity.

[6] The X-ray analysis of a benzene complex of a very similar host also supports the possibility of π-π interactions in the complexes of **1**: C. Krieger, F. Diederich, *Chem. Ber. 118* (1985) 3620.

[7] The function of $\Delta\delta_{obs}$ in terms of the initial host concentration is solved by a non-linear least squares curve fitting procedure to determine the two parameters $1/K_a$ and $\Delta\delta_{sat}$ for each titration. For a previously reported use of this method, see H. J. Schneider, K. Philippi, J. Pöhlmann, *Angew. Chem. 96* (1984) 907; *Angew. Chem. Int. Ed. Engl. 23* (1984) 908.

[8] The use of the saturation shifts obtained in [D$_4$]methanol for estimating the association constant of the same complex in [D$_6$]dimethyl sulfoxide is valid, since the geometries of complexes, according to ^{1}H-NMR, are almost identical in both solvents. For identical geometries of complexes, very similar complexation shifts at saturation binding can be assumed. For further discussions and support for this rapid method of estimating association constants of the same complex in various solvents, see: F. Diederich, K. Dick, D. Griebel, *J. Am. Chem. Soc. 108* (1986) 2273. From the detailed analysis provided in this paper, the error of the ΔG-values is estimated as ±10%.

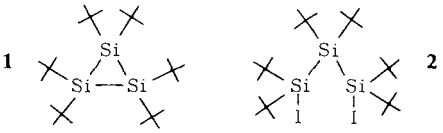
[9] A series of nine complexes have been analyzed in [D$_6$]Me$_2$SO; the sequence of complexation strength is the same as in [D$_4$]methanol.

[10] Stoichiometric complexation in pure water could not be studied since the critical micelle concentration of **1** is too low (< 0.02 mmol·L^{-1}; [4]). The observation of near saturation binding of all guests in D$_2$O/CD$_3$OD (60/40) under our experimental conditions interferes with the estimations of association constants as described in ref. [8]. Therefore, differences in complexation strength in aqueous solutions due to EDA interactions can only be shown by further studies.

[11] These findings are in full agreement with previous studies in aqueous solution, see F. Diederich, K. Dick, *J. Am. Chem. Soc. 106* (1984) 8024.

[12] It is obvious that the steric complementarity between host and guest has to be optimal if weak attractive interactions that are extremely distance dependent are the major driving force of complexation. The importance of steric complementarity for complexation of neutral guests in organic solvents had been shown in a previous study with arenes of different size; see ref. [8].

[13] In the electronic spectrum of **1**·**2p** in methanol ([host]$_0$ = 5 mmol·L^{-1} and [guest]$_0$ = 1 mmol·L^{-1}), the bands of the complexed dinitrile at longest wavelength (λ_{max} = 328 and 342) that are not overlapped by bands of the host show small bathochromic shifts (2–4 nm), hypochromicity, and broadening indicating transannular interactions.



[14] Contributions to the observed binding differences from steric and polarization interactions of the various guest substituents with the host as well as contributions from the different solvation of the polar groups cannot be completely ruled out. To minimize these effects, we chose the 2,6-disubstituted naphthalenes as guests which locate the substituents more outside the cavity of **1**.

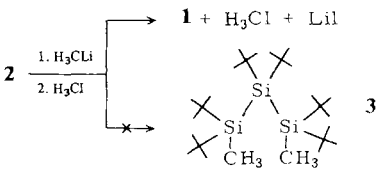
[15] In the meantime, we have prepared the *bis*(N-acetylpiperidine) derivative of a host very closely related to **1** with eight methoxy groups instead of eight methyl groups attached to the two diphenylmethane units. In preliminary studies, we observed almost complete absence of complexation of **2d** in [D$_4$]methanol, whereas considerable complexation occurs with **2p**; P. Inocencio, F. Diederich, unpublished results.

Hexa-*tert*-butyl-1,3-diiodotrisilane, a Molecule with Two Neighboring Very Long Si–Si Bonds**

By *Manfred Weidenbruch,* Bolko Blintjer, Karl Peters,* and *Hans Georg von Schnering**

About two years ago we reported the preparation of hexa-*tert*-butylcyclotrisilane (**1**), a molecule containing the longest intramolecular bond distances known at that time, namely d(Si–Si) = 251.1 pm, i.e. 16 pm longer than a normal Si–Si single bond (235 pm). This corresponds to a reduction of the Pauling bond order (PBO) to 0.54 and thus to a C–C bond length of 170 pm. Moreover, the stretching of the Si–C bonds to 198 pm (mean value in carbosilanes 188 pm) and the widening of all β(Si–C–C) bond angles at the central C atoms of the substituents impressively bear witness of the enormous intramolecular steric interactions in such a strained molecule.[1]

The remarkable stability of **1** has been attributed to optimal shielding of the Si–Si bonds by the closely packed substituents. Furthermore, the enforced conformation of the substituents on the three-membered Si$_3$ ring contributes quite significantly to a reduction in the repulsive interactions.[1] Namely, one can show, e.g., that the van der Waals contacts between Me-groups of neighboring C atoms in permethylated open-chain hydrocarbons are increased from 1.67 d in eclipsed conformations to 1.92 d in staggered conformations; in contrast, in hexamethylcyclopropane such contacts reach 2.00 d (d = C–C bond length).



Opening of the cyclotrisilane ring of **1** should lead to formation of molecules with a staggered arrangement of the substituents, with bond angles β(Si–Si–Si) > 109.5° and, possibly, with even longer Si–Si bonds. With suitable reagents, such reactions take place in thermal equilibrium. They lead, on the one hand, to ring insertion,[2] and, on the other, also to open-chain trisilanes.[3] Of the latter, 1,1,2,2,3,3-hexa-*tert*-butyl-1,3-diiodotrisilane (**2**) is especially interesting because the steric influence of iodine is

[**] Silicon Bonds with Strong Intramolecular Steric Interactions, Part 25. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 24: M. Weidenbruch, K.-L. Thom, *J. Organomet. Chem. 308* (1986) 177.

still considerable, even in presence of *tert*-butyl groups. **2** is formed as a colorless, crystalline product (m.p. 112°C) upon reaction of **1** with iodine.[3] The X-ray structure analysis confirms the above predictions (Fig. 1). Again the bond distances d(Si-Si) = 258.1 pm and 264.4 pm are drastically enlarged and correspond to Pauling bond orders[4] of 0.41 and 0.32, respectively. The β(Si-Si-Si) bond angle (115.8°) is widened considerably, despite the elongated Si-Si bonds. Here also, the Si-C bonds afford no compensation for the loss in bond strength; on the contrary, the stretching of the peripheral distances to $\bar{d}$(Si-C) = 198.9 pm and $\bar{d}$(Si-I) = 255.1 pm (instead of 188 and 246 pm, respectively) also indicate weakening of these bonds to PBO = 0.66 and 0.71, respectively. Finally, the strain also manifests itself in the increased bond angles $\bar{\beta}$(Si-C-C) = 112°.

The sum of the PBOs for the bonds to the Si atoms (nine in **1** and ten in **2**) are 5.70 and 6.11, respectively; i.e. the loss in bond order compared with Σ(PBO) = 9 and 10, respectively, increases from 3.30 to 3.89, thus indicating greater stability of the cyclic molecule **1**. An interesting observation in this respect is that the attempted formation of 1,1,2,2,3,3-hexa-*tert*-1,3-dimethyltrisilane **3** by dimetalation of **2** followed by methylation with iodomethane did not succeed, but led once again to the cyclic compound **1** [Eq. (a)]. Besides the presumably greater stability of **1**, the formation of crystalline LiI and volatile H_3CI is also important for the observed reaction.

(a)

In solution, both halves of the molecule **2** are equivalent, since the ^{1}H-NMR spectrum [δ = 1.38 (s, 36H) and 1.48 (s, 18H)] shows no splitting, even at −80°C. The remarkably large chemical shifts (downfield) in the ^{29}Si-NMR spectrum (79.47 MHz) are δ = 45.980 ppm for the two terminal Si atoms and δ = 32.945 ppm for the central Si atom.[5] In the crystal, the molecule **2** is unsymmetrical. The conformation and bond lengths in the two halves are different (Fig. 1 and Fig. 2); this could be due to the packing in the crystal. However, there are also arguments in favor of the observed deformations being an intrinsic property of **2**. Thus, we have found by a series of calculations that, on allowing for acceptable bond angles and stepwise rotation of the substituents, the spectrum of all non-bonding distances (van der Waals contacts) limits the allowed conformations considerably. In particular, it emerges that no twofold conformation with completely equivalent halves (C_2 axis) would lead to tolerable intramolecular distances, and, furthermore, that the observed deformations of the bond angles are necessary. According to these calculations it actually appears as though the observed conformation is at the same time the optimal one. However, one can only assume that unequal stretching of the two Si-Si bonds represents the optimal solution for internal strain.

In the meantime, *Wiberg* et al.[6] have described the synthesis of the thermally remarkably stable compound tBu$_3$SiSitBu$_3$, **4**, which exhibits an even larger intramolecular Si-Si bond distance (269.7 pm, PBO = 0.26[4]) than **1**. The stretching of the Si-C bonds and the angle deformations are similar to those observed in **1** and **2**. The d(Si-Si) bond lengths in **1**, **2**, and **4** are linearly correlated with n (the average number 2, 2.5, or 3 of bulkyl substituents per Si atom):

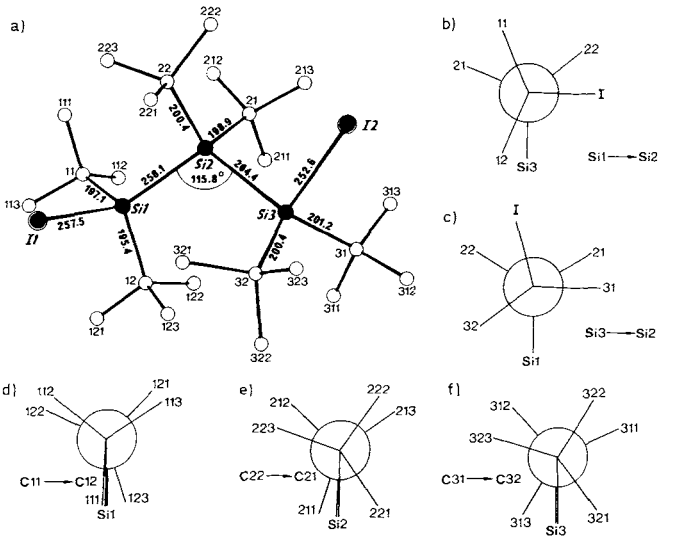

Fig. 1. a) Crystal structure of **2** (without H atoms) with bond distances in pm and the angle Si1-Si2-Si3. Standard deviations: σ(Si-I) = 0.1, σ(Si-Si) = 0.1, σ(Si-C) = 0.4 pm; σ(Si/Si/Si) = 0.1°. The numbers are the crystallographic denominations of the atoms. Si1, Si2, and Si3 each form the bridge atoms in the projections C11→C12, C22→C21, and C32→C31 (below), respectively. The compound crystallizes triclinically: $P\bar{1}$ (No. 2), a = 1094.2, b = 1827.8(5), c = 931.1(2) pm; α = 93.04(2), β = 111.39(2), γ = 99.88(2)°, Z = 2, ρ_{calc} = 1.360 g cm^{-3}, 6306 hkl with $F > 3\sigma(F)$, R = 0.030. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51754, the names of the authors, and the full citation of the journal. b) + c) Newman projections. d)-f) In these projections along the vector of two indirectly bound C atoms, in each case one Si atom is the center coupling the two C atoms.

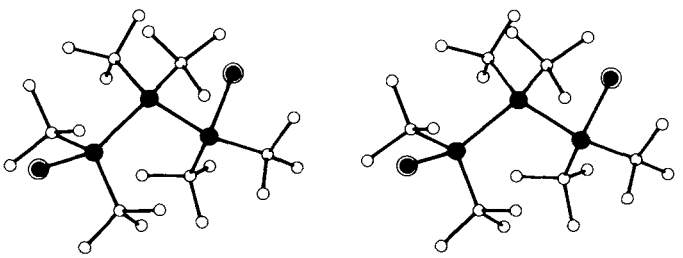

Fig. 2. Stereoview of **2** (Si = ●; I = ◉; C = ○; H atoms omitted). The orientation corresponds to that in Figure 1a.

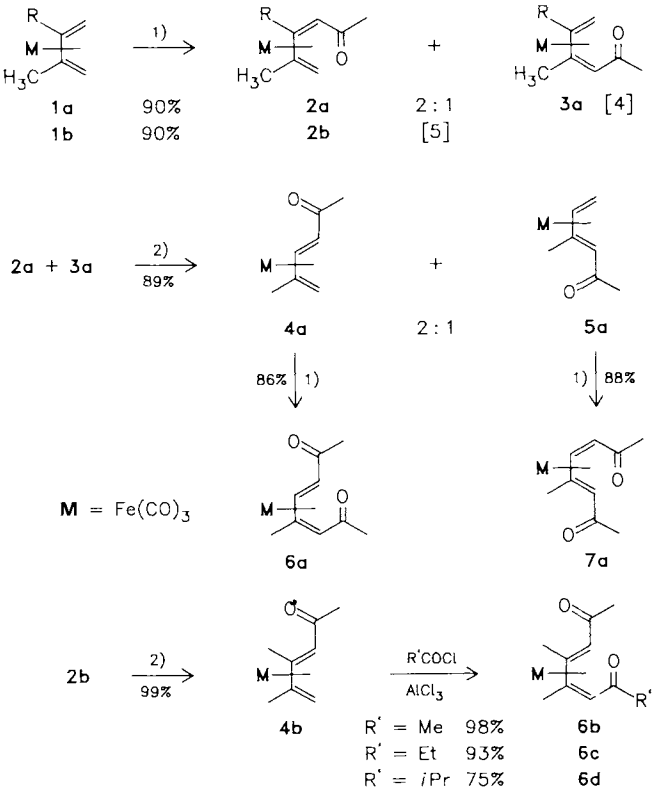
$$d(\text{Si–Si}) = (18.6\,n + 214)\ \text{pm} \qquad \text{(b)}$$



With n = 1.5 one obtains d = 245 pm, the mean value for the bond lengths in the *cis-cis*- and *cis-trans*-isomeric 1,2,3-tri-*tert*-butyl-1,2,3-trimesitylcyclotrisilanes.[7] This means that the steric influence of a mesityl group is about half as large as that of a *tert*-butyl group. The normal length of a single bond (235 pm) is expected with n ≤ 1.1, that is in a cyclotrisilane with six substituents, whose steric influence is half that of *tert*-butyl groups, or in a disilane with six substituents which have only a third of the influence of *tert*-butyl groups. That is, one could use the aforementioned relation (b) for the classification of the steric influence of substituents.

A further aspect emerges from a comparison of the Si–Si bonds in **1**, **2**, and **4**: if one assumes that the bonds of the Si_3 ring in **1** are arched, then the "analog calculation" with a model kit[8] using the Si–Si distance of 251 pm gives a value of 265 pm for the linear bond. This would then be the "normal" length of an Si–Si bond between two atoms with *tert*-butyl groups as substituents.

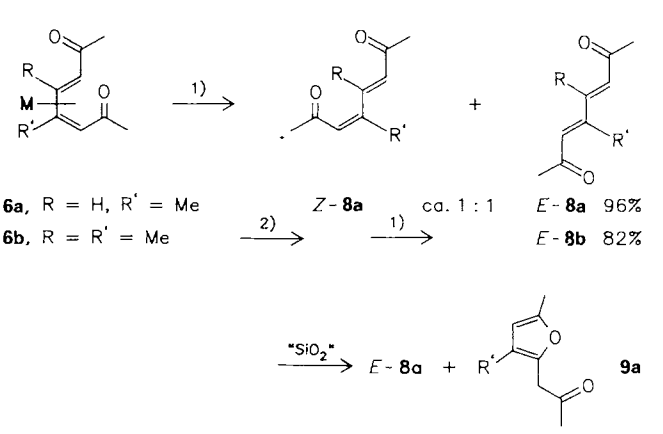
2,4-Diene-1,6-diones and 2-Acyl-3-cyclopenten-1-ols by Double Friedel-Crafts Acylation of Tricarbonyl(diene)iron Complexes



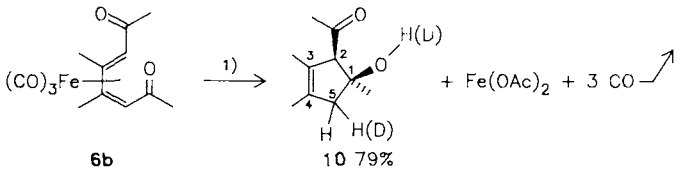
By *Michel Franck-Neumann,* Madjid Sedrati,* and *Mohamed Mokhi*

Dienes in tricarbonyl(diene)iron complexes (diene = unsubstituted, methyl- or aryl-substituted butadiene) are known to be acylated in the 1- or 4-position by Friedel-Crafts reagents.[1] The acyl residue is bonded *cis* to the diene moiety at the C-atom with the least number of substituents. A second acylation should not be possible, even after previous *cis-trans* isomerization.[1b,2]

As reported in a recent communication,[3] this does not apply in the case of the 2-triethylsilylbutadiene complex, which is successively acylated in the 4- *and* in the 1-position. This exception from the "rule" prompted us to reinvestigate the Friedel-Crafts acylation of dienone complexes. We found that exclusively carbon-substituted dienes such as isoprene **1a** or 2,3-dimethylbutadiene **1b** bound in complexes can also be acylated twice. The best yields are achieved at a molar ratio of *trans*-dienone complex/acyl chloride/aluminum chloride of 1/2/3 (Scheme 1).

For the *cis-trans*-isomerization, the diene complexes **2a** and **3a** as well as **2b** are dissolved in acetyl chloride; the solution is treated with ice-water and subsequently extracted with Et_2O.[6] The second acylation in dichloromethane at room temperature is a slow reaction, i.e. yields of 75–98% are achieved only after 20 h.[8] A terminal acyl substituent is thus not completely deactivating.

With few exceptions[9] the Friedel-Crafts acylation of tricarbonyl(diene)iron complexes has never been used for the synthesis of purely organic molecules, presumably since the methods for the cleavage of the dienone are not generally applicable. The usual cleavage methods proved unsuitable in particular in the case of the new dienedione complexes.[10] Finally, it was found possible to cleave the diketones by oxidation with H_2O_2 in methanolic NaOH[11] at −15°C (Scheme 2, Route 1).



Scheme 2. 1) H_2O_2, NaOH, MeOH, −15°C, 0.5 h. 2) MeONa/MeOH, 20°C, 15 h.

Under these conditions the *cis-trans*-complexes **6** are partly converted into the *trans-trans*-isomers, so mixtures

1, rue Blaise Pascal, F-67008 Strasbourg (France)

of the dienediones *Z*-**8** and *E*-**8** are obtained. The isomer *Z*-**8a** is quantitatively cyclized to the furan derivative **9a** by chromatography on silica gel or, better, by slowly slurrying with silica gel. If the isomerization is carried out prior to the cleavage (Scheme 2, Route 2+1), only the dienediones *E*-**8** are obtained.

Another possible way of cleaving tricarbonyl(diene)iron complexes is by reductive photolysis in acetic acid.[12] Whereas β,γ-unsaturated ketones are obtained from dienone complexes, the photolysis of dienedione complexes leads stereospecifically[13] to *cis*-2-acyl-3-cyclopenten-1-ols (**6b** → **10**, Scheme 3).

6b **10** 79%

Scheme 3. 1) *hv*, AcOH(D), 15 °C [13].

Intermediates could not be detected. Upon irradiation in deuterated acetic acid and work-up with D_2O only a product deuterated at C5 is formed. This rules out formation of a β,γ-unsaturated 1,6-diketone as an intermediate.[14]

The double Friedel-Crafts acylation of tricarbonyl(diene)iron complexes with subsequent cleavage of the metal thus provides a new method for the direct synthesis of 2,4-diene-1,6-diones and 2-acyl-3-cyclopenten-1-ols.

Table 1. Spectroscopic data of the compounds **6b**, *E*-**8b**, and **10**. IR (CCl_4), ^{1}H-NMR (200 MHz, $CDCl_3$, TMS). All the compounds gave correct elemental analyses.

6b: $\tilde{\nu}$(C≡O) = 2060, 2005, 2000 cm^{-1}, $\tilde{\nu}$(C=O) = 1655, 1665 cm^{-1}; δ = 1.95 (1H, s), 2.17 (3H, s), 2.19 (3H, s), 2.20 (3H, s), 2.47 (3H, s), 3.22 (1H, s).

E-**8b**: $\tilde{\nu}$(C=O) = 1683 cm^{-1}, $\tilde{\nu}$(C=C) = 1602, 1588 cm^{-1}; δ = 2.23 (6H, d, J = 1.2 Hz), 2.28 (6H, s), 6.37 (2H, br. s); UV (CH_3CN): λ_{max} (ε) = 277 nm (18500)

10: $\tilde{\nu}$(OH) = 3200-3600 cm^{-1} (associated OH), no bands for free OH, $\tilde{\nu}$(C=O) ≈ 1700 cm^{-1}; δ = 1.44 (3H, s), 1.61 (3H, m), 1.66 (3H, m), 2.19 (3H, s), 2.36 (1H, br. d, J = 16 Hz), 2.46 (1H, s, exchange with D_2O), 2.62 (1H, br. d, J = 16 Hz), 3.33 (1H, br. s)

Procedure

6b: A suspension of anhydrous $AlCl_3$ (2.00 g, 15 mmol) in dichloromethane (10 mL) was treated dropwise at 0 °C, first with a solution of AcCl (0.78 g, 10 mmol) in dichloromethane (5 mL) and then with a solution of **4b** (1.32 g, 5 mmol) in dichloromethane (10 mL). The temperature of the stirred mixture was allowed to increase slowly to 20 °C, and stirring was then continued for a further 16 h. After dropwise addition of the reaction mixture to ice-water and extraction with ether, the organic phase was washed with aqueous $NaHCO_3$ and dried over $MgSO_4$. After removal of the solvent by evaporation, the residue was taken up in a little *n*-hexane, and the resulting solution filtered through a short silicagel column (*n*-hexane with 10% Et_2O): 1.50 g of **6b** (98%), yellow crystals, m.p. 71 °C.

E-**8b**: 1. Isomerization: A solution of **6b** (1.40 g, 4.6 mmol) in methanol (10 mL) was added to a solution of NaOMe (0.50 g (21.7 mmol) Na in methanol (15 mL)). After 15 h at 20 °C the mixture was diluted with water, extracted with ether, and, after removal of solvent, filtered over silica gel (*n*-hexane with 20% Et_2O): 1.29 g *trans-trans* complex (92%), m.p. 86 °C.—2. Cleavage of metal: A solution of 0.20 g (5 mmol) of NaOH in 0.2 mL water and 5 mL of methanol was added dropwise at −20 °C to a solution of 0.90 g (2.9 mmol) of the *trans-trans* complex and 1.50 mL of 30% H_2O_2 in 3 mL of methanol. After 0.5 h at 15 °C the mixture was treated with a saturated NH_4Cl solution and extracted with Et_2O. The extract was washed with water, dried over $MgSO_4$, and, after removal of solvent the residue was filtered over silica gel (*n*-hexane with 20% Et_2O): 0.44 g of *E*-**8b** (89%), pale yellow crystals, m.p. 78 °C.

10: A solution of **6b** (1.20 g, 3.9 mmol) in acetic acid (50 mL) was transferred to a Pyrex glass apparatus, flushed with argon, and then irradiated with a Philips HPK 125 mercury lamp until evolution of CO ceased (ca. 1 h). After dilution with 100 mL of water and neutralization with Na_2CO_3 powder, the mixture was extracted with Et_2O. The organic extracts were dried over $MgSO_4$; the solvent was removed by evaporation and the residue chromatographed on silica gel (*n*-hexane with 20% Et_2O): 0.52 g of **10** (79%), colorless liquid [13].

[6] The conditions for this isomerization of dienone complexes were found in the acetylation of tricarbonyl(2,3-dimethylbutadiene)iron (M. Franck-Neumann, D. Martina, F. Brion, unpublished); the method is not limited to acetylated complexes, however, and is at least comparable with other methods [1, 7]. The isomerization proceeds rapidly and without decomposition, such that the *trans*-dienone complexes are recovered almost quantitatively. Only when a chromatographic separation is necessary (**4a/5a**) is the yield somewhat lower. The separation of the *trans*-dienone complexes is much simpler than that of the original *cis*-dienone complexes.
[7] J. S. Frederiksen, R. E. Graf, D. G. Greshan, C. P. Lillya, *J. Am. Chem. Soc. 101* (1979) 3863.
[8] The parent compound (*trans*-1-acetylbutadiene)tricarbonyliron is converted to only about 60% even after this time, and *cis-trans*- and *trans-trans*-1,4-diacetylbutadiene complexes are formed besides the products of metal-cleavage.
[9] See, e.g. G. R. Knox, I. G. Thorn, *J. Chem. Soc. Chem. Commun. 1981*, 373.
[10] Cerium(IV) ammonium nitrate and trimethylamine oxide act as oxidizing agents, but only mixtures of complexes are formed—as also in the ligand-exchange experiments with phosphanes. With manganese dioxide in boiling benzene, and even with iron(III) chloride in boiling methanol, the complexes either remain unchanged or are isomerized to the *trans-trans* form only!

[13] The *cis*-compounds **10** are solely obtained in ca. 80% yield by neutralization of the acetic acid with Na_2CO_3. With NaOH, the yield is increased considerably (95%), but partial epimerization is observed at the same time.
[14] Upon irradiation of 2-silyl-substituted dienedione complexes in acetic acid the corresponding β,γ-unsaturated diketone could be isolated as by-product. It is stable under the conditions of the photolysis and workup (M. Mokhi, *Dissertation*, Strasbourg 1985).

Valence Isomers of Compounds with Geminal Aryldiazene and Isocyanate Functions Stabilized by Protonation**

from the static point of view but also from the dynamic point of view.[1,2] 1-Aryl-2-(1-isocyanato-1-methylethyl)-diazenes **1a–d**[3] react with HBF_4 to give stable 1-aryl-4,5-dihydro-3,3-dimethyl-5-oxo-3*H*-1,2,4-triazolium tetrafluoroborates **2a–d** (Table 1). The structure of the compounds **2**, which corresponds to a protonated form of the non-isolable, highly reactive intermediates **3**, which are valence isomers of **1**, was confirmed by an X-ray structure analysis of **2a**.[4] **2a** can be described as an intermediate **3a** stabilized by protonation.

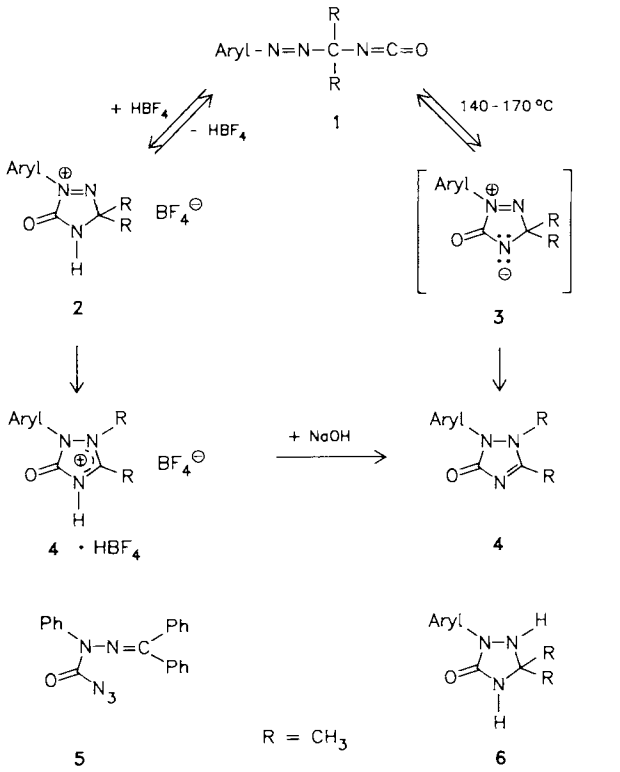

Table 1. 1-Aryl-4,5-dihydro-3,3-dimethyl-5-oxo-3*H*-1,2,4-triazolium tetrafluoroborates **2a–d**.

[a] KBr pellet. [b] Acetonitrile.

The isocyanate function of **1**, revealed by IR spectra (ν(NCO) = 2200 cm^{-1}), is characterized by an unusual stability towards O- and C-nucleophiles. An interaction between the geminal aryldiazene function and the isocyanate function leading to **3** explains both the sluggish reactivity of the isocyanate group in addition reactions[5,6] as well as the enhanced electrophilicity of the diazene group.[7] Presumably **3** occurs as an intermediate in the thermolysis of the compounds **1**[8] and of *N*-aryl-*N*-azidocarbonylhydrazones such as **5**[9] to give 1,5-disubstituted 2-aryl-1,2-dihydro-1,2,4-triazol-3-ones **4**. It is also to be discussed as an intermediate in the synthesis of **1** by oxidation of **6**.[5,6]

In solution (e.g. in acetonitrile), the triazolium salts **2a–c** rearrange, slowly at room temperature but within a few minutes at 70 °C, with 1,2-shift of a methyl group to give the salts **4a–c** · HBF_4. The donor-substituted 4-methoxyphenyl derivative **2d**, on the other hand, is stable in solution at room temperature. The carbonyl function of **2** is not attacked by nucleophiles such as water or 2 N NaOH, but instead a deprotonation occurs, shifting the equilibrium from **2** to **1**.

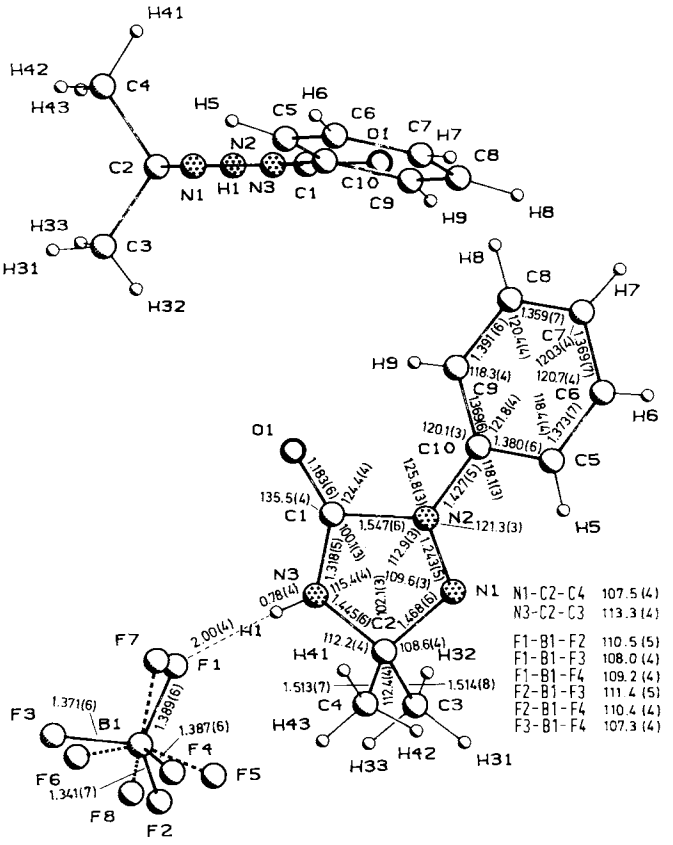

Fig. 1. Molecular structure of **2a** with two views of the cation. The $BF_4^{\ominus}$ ion is disordered. Bond lengths in Å, bond angles in degrees.

The cation of **2a** (Fig. 1) is almost planar. The planar five-membered ring and the phenyl substituent form an angle of only 17°. The molecular structure is characterized by an extremely long CN bond between the CO and the diazene group (C1–N2: 1.547(6) Å), which is 0.08 Å longer than the C2–N1 single bond, and an extremely short C=O bond (1.183(6) Å). This bonding geometry draws the molecule—consistent with the tendency shown by the bond angles at C1 of the isocyanate fragment to assume linearity—near to the transition state of the nucleophilic addition of a diazene nitrogen to the electrophilic carbon of a N-protonated isocyanate group. The geometry described is determined by intramolecular steric hindrance in the *all cis*-system O1 to H9, and possibly is one of the main reasons for the high reactivity of the compounds **2**. The extraordinarily high carbonyl frequency of **2a** at $\tilde{\nu}$ = 1860 cm^{-1} is readily explained by the extremely short C=O distance. This also holds for the finding that the C=O function is not a proton acceptor in the crystal but that instead a N–H···F bridge is present between cation and anion.

Procedure

1 mL of **1a–d** was dissolved in 75 mL of ether. The solution was cooled to 0 °C and, 10 mL of HBF_4 (50% w/w in water) were added dropwise with

stirring, during 5 min. The crystalline products were filtered off, washed twice with 40 mL of ether and dried (30°C/4×10^{-1} Pa); crystallization of **2c** necessitated cooling to −40°C. **2a**–**2d** gave correct elemental analyses.

^{1}H-NMR ([D$_6$]acetone, TMS): **2a**: $\delta = 1.90$ (s, 6H, CH_3), 4.50–6.50 (1H, NH), 7.37–8.10 (m, 5H, aromatic H).—**2b**: $\delta = 1.90$ (s, 6H, CH_3), 5.00–7.10 (1H, NH), 7.60–8.26 (AA'BB' system, 4H, aromatic H).—**2c**: $\delta = 2.03$ (s, 6H, CH_3), 5.10–7.10 (1H, NH), 7.60–8.39 (m, 4H, aromatic H).—**2d**: $\delta = 1.89$ (s, 6H, CH_3), 4.00 (s, 3H, OCH_3), 4.50–6.50 (1H, NH), 7.13–8.40 (AA'BB' system, 4H, aromatic H).

BOOK REVIEWS

Synthetic Polymer Membranes. A Structural Perspective. 2nd edition. By *R. E. Kesting*. Wiley, Chichester 1985. xi, 348 pp., bound, £ 55.75.—ISBN 0-471-80717-6

This book provides an extensive survey of the application of synthetic membranes for separation processes in the chapters on *Membrane Separation Processes* (Chapter 2) and *Miscellaneous Uses of Membranes* (Chapter 3). The properties and solubility behavior of membrane specific polymers as well as the preparation and properties of various synthetic membranes are dealt with in chapters on *Membrane Polymers* (Chapter 4), *Polymer Solutions* (Chapter 5), *Dense Membranes* (Chapter 6), Phase Inversion Membranes (Chapter 7), *Other Porous Membranes* (Chapter 8), and *Liquid and Dynamically Formed Membranes* (Chapter 9). The final chapter 10 on *Biological Membranes* supplies a condensed overview of the structure and function of biological membranes.

The author is an internationally recognized expert in the field of synthetic membranes who has been concerned with the design and production of synthetic membranes for more than 20 years. His great experiences in this field are reflected, in particular, in Chapters 4, 6, and 7, which are really worth reading.

However, the vivid and interesting description of knowledge on synthetic membranes cannot obscure the fact that the treatment of the physico-chemical foundations of transport across membranes, of equilibria at solution/membrane interfaces, of the solubility of polymers, and of the water structure in membranes suffer from at least a one-sided view and from inaccuracies in some respects. Thus, the attempt at a purely kinetic explanation of the osmotic pressure fails (p. 24). A clear theoretical background is lacking with the presentation of electrochemical membrane processes. As a consequence of this, individual processes are treated independently without clearly elaborating the interrelations. As a result, an analytical relationship is given only for the diffusion potential whereas the streaming potential is discussed only qualitatively. Furthermore, a theoretical treatment of desalination is presented in the paragraph on hyperfiltration (pp. 64–78) which is essentially unaccepted till today. This biased presentation, which unfortunately extends throughout the whole book and also prevents a systematic classification of synthetic membranes according to their formation, results in a not really scientific and clear presentation of the membrane field.

Despite the shortcomings mentioned, the book is a valuable extension of the literature on membranes since the author is at least familiar with, and quotes, the published literature from the beginning of membrane research which was mainly published in German. Consequently it should be available in every library aiming at a reasonably complete coverage of the literature on membranes.

SUBJECT INDEX

(R) = Review Article (C) = Short Communication (B) = Book Review (L) = Correspondence

AB INITIO STUDY, 1,2-Dilithioethylene isomers and their mechanisms of interconversion: an ab initio study (C) 169

Acepentalene, Dihydroacepentalenediide, the dianion of acepentalene (C) 719

Acridine dyes, Physicochemical and cytochemical investigations on the binding of ethidium and acridine dyes to DNA and to organelles in living cells (R) 115

Activation, Thermolytically induced C-H activation using a 14-electron-complex: synthesis and molecular structure of $[IrHCl(C_6H_5)(PiPr_3)_2]$ (C) 1090

4-Acyl-5-aminoimidazoles, Rearrangement of 4*H*-1,2,4-triazolium salts to 4-acyl-5-aminoimidazoles (C) 652

1-Adamantyl cation, First crystal structure analysis of an aliphatic carbocation—stabilization of the 3,5,7-trimethyl-1-adamantyl cation by C-C hyperconjugation (C) 349

Addition, Intramolecular addition of 2-(trimethylsilyl)methyl-substituted allyl cations to double bonds—synthesis of bicyclo[3.3.0]octane derivatives (C) 354
Stepwise addition of $MeS^{\oplus}$ to a metal-carbon triple bond—a new type of reaction in the chemistry of carbyne complexes (C) 904
Vicinal dilithioalkenes by addition of lithium to simple cyclic and acyclic alkynes (C) 167

1,4-Addition, Selective synthesis by use of Lewis acids in the presence of organocopper and related reagents (R) 947

Agostic C-H→Mo bond, $[MoR(\eta^3\text{-}C_3H_5)_3]$, R = alkyl: alkylmolybdenum complexes with agostic C-H→Mo bond (C) 555

Alcohols, Preparation of optically active alcohols from 1,3-dioxan-4-ones. A practical version of the asymmetric synthesis with nucleophilic substitution at acetal centers (C) 178

Alkali metal hydride metalation reagents, Superactive alkali metal hydride metalation reagents: LiH, NaH, and KH (C) 465

Alkali metal silicides, Red, transparent alkali metal silicides with Si_4 tetrahedrons (C) 566

Alkaloids, Biochemistry of alkaloids (B) 942
The first evidence of endogenous pyridoxyl isoquinoline alkaloids in mammalian organisms (C) 177

Alkenylsulfoximides, Asymmetric elimination with high induction: synthesis of 1-alkenylsulfoximides with axial and central chirality (C) 935

Alkyl aryl ketones, Asymmetric bromination of enantiomerically pure acetals of alkyl aryl ketones (C) 259

Alkylation, The alkylation of epoxides with new organoyttrium and organolanthanoid reagents (C) 760

Alkyl azides, Synthesis of alkyl azides with a polymeric reagent (C) 478

Alkylmolybdenum complexes, $[MoR(\eta^3\text{-}C_3H_5)_3]$, R = alkyl: alkylmolybdenum complexes with agostic C-H→Mo bond (C) 555

Alkyl radicals, Metathesis of alkyl radicals and alkenes—a novel elementary reaction of alkyl radicals (C) 80

Alkyne ligand, Variable electron-donor ability of alkyne ligands—synthesis and structure of carbonyl(η^5-cyclopentadienyl)(η^2-1-diethylamino-1-propyne)(η^1-*p*-methylphenylketenyl)tungsten (C) 643

Allenylsodium derivative, The structure of an allenylsodium derivative—competition between carbanion resonance delocalization and gegenion charge localization (C) 902

Allyl cations, Intramolecular addition of 2-(trimethylsilyl)methyl-substituted allyl cations to double bonds—synthesis of bicyclo[3.3.0]octane derivatives (C) 354

Allylic hydroperoxides, A simple access to 2-epoxy alcohols: titanium(IV)-catalyzed oxygen transfer from allylic hydroperoxides (C) 269

Allyllithium compound, Crystal structure of the η^3-allyllithium compound [1,3-diphenylallyllithium·diethyl ether]$_n$ (C) 104

Allyl rearrangement, Optically active α-chloro-(*E*)-crotylboronate esters by allyl rearrangement (C) 189

Allylsulfones, Solid-state and solution structure of α-(phenylsulfonyl)allyllithium (C) 939

Aluminum-molybdenum complexes, Carbonyl olefinating aluminum-molybdenum complexes and an analogous tungsten complex (C) 910

Aluminum-olefin π-bonds, Dimeric 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene, a compound with aluminum-olefin π-bonds (C) 921

Aluminum phosphates, Orthophosphates in the ternary system Al_2O_3-P_2O_5-H_2O (R) 525

Amination, *N*-Aryl-*O*-(diphenylphosphinoyl)hydroxylamines: electrophilic amination of amines to hydrazines; a model reaction for the carcinogenicity of aromatic amines (C) 562

Amines, Enantioselective synthesis of α-substituted primary amines by nucleophilic addition to aldehyde-SAMP hydrazones (C) 1109

Aminoacetylene and its mono- and dication—identification of potentially interstellar molecules (C) 827

Amino acid derivatives from *N*-(Arylmethylene)dehydroalanine methyl esters (C) 90

Amino acids, Simple synthesis of 1-amino-1-cyclopropanecarboxylic acids from *tert*-butyl isocyanoacetate and epoxides; synthesis of alkyl 5,6-dihydro-4*H*-1,3-oxazine-4-carboxylates (C) 754
Synthetic equivalent for aminocarboxycarbene; synthesis of 1-amino-1-cyclopropanecarboxylic acid methyl esters (C) 192

Amino acid synthesis, Enantiomer separation of (*R,S*)-2-(*tert*-butyl)-3-methyl-4-imidazolidinone, a chiral building block for amino acid synthesis (C) 345, 766

Aminocarboxycarbene, Synthetic equivalent for aminocarboxycarbene; synthesis of 1-amino-1-cyclopropanecarboxylic acid methyl esters (C) 192

1-Amino-1-cyclopropanecarboxylic acids, Simple synthesis of 1-amino-1-cyclopropanecarboxylic acids from *tert*-butyl isocyanoacetate and epoxides; synthesis of alkyl 5,6-dihydro-4*H*-1,3-oxazine-4-carboxylates (C) 754

1-Amino-1-cyclopropanecarboxylic acid methyl esters, Synthetic equivalent for aminocarboxycarbene; synthesis of 1-amino-1-cyclopropanecarboxylic acid methyl esters (C) 192

Aminolysis, Direct aminolysis of unactivated esters at high-pressure (C) 565

Ammonia synthesis, Heterogeneous catalysis of ammonia synthesis at room temperature and atmospheric pressure (C) 558

Amorphous solids, The chemistry of the noncrystalline state (R) 31

Analytical chemistry, Methoden der Analytischen Chemie. Eine Einführung. Band 2: Nachweis- und Bestimmungsmethoden, Teil 2 (B) 294

Analytical methods, High-pressure liquid chromatography (HPLC) of proteins (R) 535
High-resolution metal-NMR spectroscopy of organometallic compounds (R) 861
^{15}N-NMR spectroscopy—new methods and applications (R) 383
Resonance Raman spectroscopy and its application to inorganic chemistry (R) 131

Ancistrocladine, Regioselective and atroposelective aryl coupling to give naphthyl isoquinoline alkaloids: the first total synthesis of (−)-ancistrocladine (C) 913

Angiotensin converting enzyme, Synthesis of *N*-(1-carboxy-5-aminopentyl)dipeptides as inhibitors of angiotensin converting enzyme (C) 277

Anhydrohexitols, Carbohydrate-based liquid crystals: mesogenic 1-*O*-alkyl derivatives of 2,5-anhydrohexitols (C) 368

Anions, [2.2]Indenophane dianion: a novel double-layered dianion (C) 174

[14]Annulenes, Bridged [14]annulenes with a phenanthrene-perimeter: *anti*-1,6:7,12-bismethano[14]annulene (C) 723
Bridged [14]annulenes with a phenanthrene-perimeter: *syn*-1,6:7,12-bismethano[14]annulene (C) 720

Anomeric effect, Solvent polarity and the anomeric effect (C) 287

Antamanide, Conformational prerequisites for the in vitro inhibition of cholate uptake in hepatocytes by cyclic analogues of antamanide and somatostatin (C) 997

Anthracene electrophores, Synthesis and redox properties of compounds with several separated anthracene electrophores (C) 443

Anthracenes, Poly(anthrylenetrimethylene) and 9,10-bridged anthracenes by reductive alkylation (C) 444

Anthracyclinones, Simple synthesis of anthracyclinones by cyclization of an intermediate hydroxynitronate (C) 339
Total synthesis of anthracyclinones (R) 790

Antibiotics, Macrolide antibiotics. Chemistry, biology and practice (B) 580

Antimony(III) compounds, $[Sb_3I_{10}^{\ominus}]_\infty$—a polymeric anion with transitions from trigonal pyramidal to octahedral coordination of antimony(III) (C) 825

Arene C-H activation, Metal dependence of cyclometalation and arene C-H activation in the photolysis of *cis*-$H_2M[P(CH_2CH_2CH_2PMe_2)_3]$ (M = Fe, Ru) in benzene (C) 260

Arene complexes, Benzene as bridging ligand in main group metal-transition metal-arene complexes (C) 927
$[C_6H_3(CH_3)_3][BiCl_3]$ and $[C_6(CH_3)_6]$-$[BiCl_3]_2$, arene complexes of bismuth with

half-sandwich and "inverted" sandwich structures (C) 757

Flash photolysis of $Os(CO)_5$ in benzene solution. Detection of $Os(CO)_4$·benzene by fast time-resolved IR spectroscopy (C) 991

Arene-iron compounds, Bis(η^2-ethene)(η^6-toluene)iron (C) 831

Aromaticity, Bridged [14]annulenes with a phenanthrene-perimeter: *anti*-1,6:7,12-bismethano[14]annulene (C) 723

Bridged [14]annulenes with a phenanthrene-perimeter: *syn*-1,6:7,12-Bismethano[14]annulene (C) 720

9b-Methyl-9b*H*-benzo[*cd*]azulene—a novel antiaromatic 12π-electron system (C) 632

Novel synthesis of the angular [3]phenylene (terphenylene) by cobalt-catalyzed cyclization of bis(2-ethynylphenyl)ethyne: a molecule with an internal cyclohexatriene ring (C) 266

syn- and *anti*-Bishomoanthraquinone (C) 1000

Synthesis of a dicyclopenta[*a,e*]pentalene by [6+2]-cycloaddition of 1,3-di-*tert*-butyl-5-vinylidenecyclopentadiene and consecutive 8π-electrocyclic reaction (C) 466

Synthesis of a fourfold enlarged porphyrin with an extremely large, diamagnetic ring-current effect (C) 1100

Arsaalkenyl complex, Synthesis and structure of the first arsaalkenyl complex with FeAs single bond (C) 469

Arsabenzene ligand, Bis(η^6-arsabenzene)-chromium(0) (C) 571

Arsaethyne, 2-(2,4,6-Tri-*tert*-butylphenyl)-1-arsaethyne—the first compound containing an arsenic-carbon triple bond (C) 264

Arsenic-carbon triple bond, 2-(2,4,6-Tri-*tert*-butylphenyl)-1-arsaethyne—the first compound containing an arsenic-carbon triple bond (C) 264

Arsenic-cobalt-compounds, $[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]$, a product of the reaction of $[CoCl_2(PPh_3)_2]$ with $PhAs(SiMe_3)_2$ (C) 175

Arsenic-iron single bond, Synthesis and structure of the first arsaalkenyl complex with FeAs single bond (C) 469

Arsenic-niobium anions, $[NbAs_8]^{3-}$, a novel type of complex and an unexpected one-dimensional chain structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (C) 353

Arsenic-phosphorus compounds, Valence tautomerism of the heptaheteronortricycles $[P_{7-x}As_x]^{3-}$ (C) 352

Arsenic/sulfur system, Complex-induced fragmentation of As_4S_4: stabilization of an As_2S_3 ligand (C) 557

Arylchlorination, Pd^{II}-catalyzed regioselective arylchlorination and oxyarylation of unsaturated alcohols (C) 735

Asymmetric bromination of enantiomerically pure acetals of alkyl aryl ketones (C) 259

Asymmetric elimination with high induction: synthesis of 1-alkenylsulfoximides with axial and central chirality (C) 935

Asymmetric induction, Asymmetric photocycloadditions with optically pure, spirocyclic enones. Simple synthesis of (+)- and (−)-grandisol (C) 1117

Asymmetric molybdenum atom, $[Cp(CO)_2Mo\{NR^*[Rh(norbornadiene)]\text{-}CH(pyridyl)\}]$, a rhodium complex with an asymmetric molybdenum atom in the chelate skeleton (C) 371

Asymmetric synthesis (B) 848

Preparation of optically active alcohols from 1,3-dioxan-4-ones. A practical version of the asymmetric synthesis with nucleophilic substitution at acetal centers (C) 178

Attraction of similarly charged solutes, Ordering of ionic solutes in dilute solutions through attraction of similarly charged solutes—a change of paradigm in colloid and polymer chemistry (R) 323

1-Azabutadienes, A facile synthesis of a new class of eight-membered heterocycles from 1-azabutadienes (C) 181

Azacyclobutadiene, Tri-*tert*-butylazete—the first kinetically stabilized azacyclobutadiene (C) 842

Azete, Tri-*tert*-butylazete—the first kinetically stabilized azacyclobutadiene (C) 842

Azides, Synthesis of alkyl azides with a polymeric reagent (C) 478

Azimine-triaziridine transformation, An azimine-triaziridine transformation by laser photolysis (C) 828

Azirines, Nitrile ylides and azirines: gas-phase generation from 2,3-dihydro-1,4,2λ^5-oxazaphospholes and matrix isolation (C) 85

Azoalkanes, UV/VIS laser photochemistry: intermediary formation of diazoalkanes versus direct S_0,T_1 transitions in the photolysis of azoalkanes (C) 818

185-nm photochemistry of olefins, strained hydrocarbons, and azoalkanes in solution (R) 661

BACTERIAL ENDOTOXIN, Chemical, biological, and clinical aspects (B) 293

Bacteriorhodopsin pigments, Influence of external negative charges on the absorption maxima of symmetrical cyanines. A study with model compounds and artificial bacteriorhodopsin pigments (C) 284

Baeyer, Adolf von Baeyer's scientific achievements — a legacy (R) 297

Barium alkoxostannates(II), Strontium and barium alkoxostannates(II)—molecules with S_6 symmetry (C) 375

Benzene as bridging ligand in main group metal-transition metal-arene complexes (C) 927

Benzene oligomers, Diels-Alder adducts of benzene with arenes and their [4+2] cycloreversion (C) 377

Benzo[*cd*]azulene, 9b-Methyl-9b*H*-benzo[*cd*]-azulene—a novel antiaromatic 12π-electron system (C) 632

Benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline, a chiral hydrazine derivative (C) 374

Benzoin condensation, Synthesis of a macrobicyclic thiazolium-host and supramolecular catalysis of the benzoin condensation (C) 1125

Benzophenone *O*-oxide (C) 255

Benzotri(imidazole)—a new ring system derived from benzenehexamine (C) 650

(*Z*)-4-Benzylidene-2-methyl-5(4*H*)-oxazolone, $C_{phenyl}\text{-}H\cdots O$ and $C_{phenyl}\text{-}H\cdots N$ interactions: crystal structure of (*Z*)-4-benzylidene-2-methyl-5(4*H*)-oxazolone, an intermediate for dehydropeptide synthesis (C) 447

Benzyllithium compounds, [α-(Phenylsulfinyl)-α-methylbenzyllithium-tetramethylethylenediamine]$_2$: crystal structure of an α-sulfinyl "carbanion" (C) 1011

Bicyclo[3.2.1]octa-2,6-dienyllithium (C) 468

Bicyclo[3.3.0]octane derivatives, Intramolecular addition of 2-(trimethylsilyl)methyl-substituted allyl cations to double bonds—synthesis of bicyclo[3.3.0]octane derivatives (C) 354

Bilayers, Bilayer-immobilized films containing mesogenic azobenzene amphiphiles—electrically controllable permeability (C) 751

Bimetallic catalysts, Nature of Ni and Cu species in reduced bimetallic Ni-Cu/Al_2O_3 catalysts (C) 753

Bio-inorganic chemistry (B) 291

Biological oxidation of nitrogen in organic molecules. Chemistry, toxicology and pharmacology (B) 850

Biotechnology, A comprehensive treatise in 8 volumes (B) 764

A comprehensive treatise in 8 volumes. Vol. 6a: Biotransformations (B) 380

Biotransformation von Arzneimitteln. Band 4 (B) 293

Biphenyl ligand, $[(\eta^5\text{-}C_5Me_5)Co]_3C_{12}H_{10}]$—a complex of biphenyl with Kekulé structure (C) 646

Bis(η^6-arsabenzene)chromium(0) (C) 571

Bis(cyclopentadienyl)hafnacyclobutane, Reductive coupling of CO: formation of a 1:1 adduct of η^2-ketone- and enediolato-complex upon carbonylation of bis(cyclopentadienyl)hafnacyclobutane (C) 364

Bishomoanthraquinone, *syn*- and *anti*-Bishomoanthraquinone (C) 1000

Bishomoaromaticity, Bicyclo[3.2.1]octa-2,6-dienyllithium (C) 468

anti-1,6:7,12-Bismethano[14]annulene, Bridged [14]annulenes with a phenanthrene-perimeter: *anti*-1,6:7,12-bismethano[14]annulene (C) 723

syn-1,6:7,12-Bismethano[14]annulene, Bridged [14]annulenes with a phenanthrene-perimeter: *syn*-1,6:7,12-bismethano[14]annulene (C) 720

Bis(η-methylcyclopentadienyl)phenylethynylzirconium, Unusual bridging of the metal centers in dimeric bis(η-methylcyclopentadienyl)phenylethynylzirconium (C) 463

Bismuth compounds, $[C_6H_3(CH_3)_3][BiCl_3]$ and $[C_6(CH_3)_6][BiCl_3]_2$, arene complexes of bismuth with half-sandwich and "inverted" sandwich structures (C) 757

Bismuth-sulfur cluster, $[Bi_2^{III}S_{34}]^{4-}$, the hitherto sulfur-richest complex (C) 273

Bis(pentamethylcyclopentadienyl)diphosphene—a molecule with fluxional structure and reactive P–C bond (C) 919

Bisporphyrinates, Remarkable ease of ring oxidation in cerium(IV) bisporphyrinates with double-decker structure (C) 286

10,10′-Bi(trispiro[2.0.2.0.2.1]decylidene): a highly nucleophilic olefinic hydrocarbon (C) 335

Bond cleavage, Evidence for equilibria between μ-alkyne and alkylidyne complexes of tungsten alkoxides: $[W_2(OR)_6(\mu\text{-}C_2R_2')] \rightleftharpoons 2[(RO)_3W{\equiv}CR']$ (C) 446

Metal dependence of cyclometalation and arene C–H activation in the photolysis of *cis*-$H_2M[P(CH_2CH_2CH_2PMe_2)_3]$ (M = Fe, Ru) in benzene (C) 260

Bond length, Hexa-*tert*-butyldisilane—the molecule with the longest Si-Si bond (C) 79

Hexa-*tert*-butyl-1,3-diiodotrisilane, a molecule with two neighboring very long Si–Si bonds (C) 1129

π-Bonds, Dimeric 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene, a compound with aluminum-olefin π-bonds (C) 921

Boranes, Reaction of phosphonium ylides with alkyldichloroboranes (C) 559

Boronate esters, Optically active α-chloro-(*E*)-crotylboronate esters by allyl rearrangement (C) 189

Boron heterocycles, A 1,2-diboratabenzene: lithium salt and transition metal complexes (C) 642

A 1,3-diboratacyclobutadiene and its dimer, a sandwich compound with a Li_4 layer (C) 1111

A puckered and a planar 1,3-diboretane (C) 1112

Polymeric (η^5,μ-2,3-dihydro-1,3-diborolyl)-nickel—the first polydecker sandwich compound (C) 105

Boron-nitrogen-sulfur compounds, Synthesis and molecular and crystal structure of a new tricyclic $B_3N_4S_2Si_2$ system (C) 741

Boussingault. Chemist and agriculturist (B) 1035

Bridging, Large molecular cavities for small ions—double bridging of three bipyridine units (C) 1122

Bridging ligands, Benzene as bridging li-

gand in main group metal–transition metal–arene complexes (C) 927
CF_2-bridged metal complexes (C) 185
Dimeric chloro[dicyclopentadienyl(dimethyl)silyl]ytterbium(III), a rare example of a complex involving metal-bridging instead of chelating $[Me_2Si(\eta^5\text{-}C_5H_4)_2]$ ligands (C) 738
Evidence for equilibria between μ-alkyne and alkylidyne complexes of tungsten alkoxides: $[W_2(OR)_6(\mu\text{-}C_2R'_2)] \rightleftharpoons 2[(RO)_3W{\equiv}CR']$ (C) 446
First dinuclear complexes with fourfold alkyl-bridging (C) 925
Unusual bridging of the metal centers in dimeric bis(η-methylcyclopentadienyl)phenylethynylzirconium (C) 463
Butterfly structure, $[(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_4(PPh)_2]$, a diphosphene complex with a butterfly structure (C) 338
(*R,S*)-2-(*tert*-Butyl)-3-methyl-4-imidazolidinone, Enantiomer separation of (*R,S*)-2-(*tert*-butyl)-3-methyl-4-imidazolidinone, a chiral building block for amino acid synthesis (C) 345, 766

CADMIUM COMPOUNDS, The three-dimensionally non-molecular polyadamantanoid structure of $Cd(SPh)_2$ (C) 165
Cage structure, $[Pd_2S_{28}]^{4\ominus}$: a 30-membered cage containing an entrapped cation (C) 453
Calorimetry, Analytical solution calorimetry. Fundamentals and practice (B) 482
Carbanions, Bicyclo[3.2.1]octa-2,6-dienyllithium (C) 468
[(α-Cyanobenzyllithium·tetramethylethylenediamine)$_2$·benzene]: X-ray structure analysis of an α-nitrile "carbanion" (C) 373
Lithium-coordinated α-sulfonimidoyl carbanions: crystal study of [(*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$·2(tmeda) and configurative stability of [(*N*-methyl-*S*-phenylsulfonimidoyl)isopropyllithium] (C) 938
Solid-state and solution structure of α-(phenylsulfonyl)allyllithium (C) 939
The structure of an allenylsodium derivative—competition between carbanion resonance delocalization and gegenion charge localization (C) 902
Carbene complexes, Carbonyl olefinating aluminum-molybdenum complexes and an analogous tungsten complex (C) 910
Carbene complexes with quinone bisketal functions (C) 911
Carbenes, Diels-Alder reactions at carbene ligands: a route to olefin-carbene complexes (C) 812
ESR observation of thermally produced triplet nitrenes and photochemically produced triplet cycloheptatrienylidenes (C) 480
Carbene-tungsten complexes, Carbonyl olefinating carbene-tungsten complexes and their suitability as catalysts in olefin-metathesis (C) 909
Carbenium ions, Direct determination of rate constants for the addition of carbenium ions to alkenes (C) 89
Direct measurement of the "isokinetic rate constant" in additions of diarylcarbenium ions to 2-methyl-2-butene (C) 1016
Linear reactivity-selectivity correlations in additions of diarylcarbenium ions to alkenes; a rebuttal of the reactivity-selectivity principle (C) 1017
Stabilization of carbenium ions in liquid crystals (C) 841
Carbocations, First crystal structure analysis of an aliphatic carbocation—stabilization of the 3,5,7-trimethyl-1-adamantyl cation by C–C hyperconjugation (C) 349
Carbohydrate synthesis, 2-Substituted 1,3,2-dioxaboroles as synthetic equivalents for the glycolaldehyde anion (C) 560
Carbon-carbon bond formation, The palladium-catalyzed cross-coupling reactions of organotin reagents with organic electrophiles (R) 508
Carbon-carbon coupling, CC Coupling of CO_2 and butadiene on iron(0) complexes—a novel route to α,ω-dicarboxylic acids (C) 810
Carbon monoxide, The chemistry of the catalyzed hydrogenation of carbon monoxide (B) 195
Carbon monoxide reduction, Synthesis and structure of the Co_3Ti_2 complex$[\{\mu_3\text{-}[(C_5H_5)_2TiOC]\}_2\{(C_5H_5)_3Co_3\}]$: CO reduction by two different metal centers (C) 254
Carbon-nitrogen bond formation, Transition-metal clusters as catalysts of unconventional reactions: reductive C–N coupling of alkyl isocyanates (C) 570
Carbon suboxide, Wittig reaction with carbon suboxide: synthesis of dimethyl 1,5-diphenyl-1,2,3,4-pentatetraenedicarboxylate (C) 93
Carbonylation, Reductive coupling of CO: formation of a 1:1 adduct of η^2-ketone- and enediolato-complex upon carbonylation of bis(cyclopentadienyl)hafnacyclobutane (C) 364
Carbonyl dianion synthon, Nitromethane as d^1,d^1 multiple coupling reagent for the carbonyl dianion synthon. Practical synthesis of chalcogran (C) 941
Carbonyl olefination, Asymmetric elimination with high induction: synthesis of 1-alkenylsulfoximides with axial and central chirality (C) 935
Carbonyl olefinating aluminum-molybdenum complexes and an analogous tungsten complex (C) 910
Carbonyl olefinating carbene-tungsten complexes and their suitability as catalysts in olefin-metathesis (C) 909
Carbonyl oxides, Benzophenone *O*-oxide (C) 255
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: the nucleophilic character of carbonyl oxides (C) 101
N-(1-Carboxy-5-aminopentyl)dipeptides, Synthesis of *N*-(1-carboxy-5-aminopentyl)dipeptids as inhibitors of angiotensin converting enzyme (C) 277
Carbyne-complexes, The Schrock carbyne-complex $[Cl_3(dme)W{\equiv}CCMe_3]$, a highly reactive catalyst for the metathesis of alkenes (C) 359
Stepwise addition of $MeS^{\ominus}$ to a metal-carbon triple bond—a new type of reaction in the chemistry of carbyne complexes (C) 904
Carbyne-iridium complexes: evidence for an equilibrium between alkenylidene(hydrido) and carbyne isomers (C) 737
Carcinogenicity, *N*-Aryl-*O*-(diphenylphosphinoyl)hydroxylamines: electrophilic amination of amines to hydrazines; a model reaction for the carcinogenicity of aromatic amines (C) 562
Carotinoids, Mini-violerythrins: why can C_{38}-carotinoids be blue? (C) 1018
Catalysis, Heterogeneous catalysis of ammonia synthesis at room temperature and atmospheric pressure (C) 558
Synthesis of a macrobicyclic thiazolium-host and supramolecular catalysis of the benzoin condensation (C) 1125
Catalysts, Nature of Ni and Cu species in reduced bimetallic Ni–Cu/Al_2O_3 catalysts (C) 753
C–C bond formation, Synthesis of "*C*-disaccharides" by radical C–C bond formation (C) 450
C-Disaccharides, Synthesis of "*C*-disaccharides" by radical C–C bond formation (C) 450
Cerium(IV) bisporphyrinates, Remarkable ease of ring oxidation in cerium(IV) bisporphyrinates with double-decker structure (C) 286
C–H Activation, Thermolytically induced C–H activation using a 14-electron-complex: synthesis and molecular structure of $[IrHCl(C_6H_5)(PiPr_3)_2]$ (C) 1090
Chain elongation, Synthesis of long-chain sugars by iterative, diastereoselective homologation of 2,3-*O*-isopropylidene-D-glyceraldehyde with 2-trimethylsilylthiazole (C) 835
Chain reaction, Thermally induced redox reaction of carbonyl compounds and alcohols in a radical chain reaction: comproportionation to two hydroxyalkyl radicals (C) 762
Chain structure, $[NbAs_8]^{3-}$, a novel type of complex and an unexpected one-dimensional chain structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (C) 353
Chalcogran, Nitromethane as d^1,d^1 multiple coupling reagent for the carbonyl dianion synthon. Practical synthesis of chalcogran (C) 941
Chalcose, Synthesis of deoxyhexoses from divinylglycols—the synthesis of D- and L-chalcose (C) 89
Charge localization, The structure of an allenylsodium derivative—competition between carbanion resonance delocalization and gegenion charge localization (C) 902
Charge separation in excited states of decoupled systems—TICT compounds and implications regarding the development of new laser dyes and the primary processes of vision and photosynthesis (R) 971
Charge transfer, Unusual behavior of the stable paramagnetic dihydridoiridium(IV) complex $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ in solution (C) 460
Charge-transfer interactions, A simple route to the intramolecular quinhydrone of [2.2]paracyclophanediene (C) 171
Electron donor-acceptor interactions in host-guest complexes in organic solutions (C) 1127
Chemical bonding, Kristallstruktur und chemische Bindung (B) 112
Chemical oscillations, Oscillations and traveling waves in chemical systems (B) 1037
Chemical technology, Kirk-Othmer concise encyclopedia of chemical technology (B) 194
Chiral building blocks, Preparation of chiral building blocks from amino acids and peptides via electrolytic decarboxylation and $TiCl_4$-induced aminoalkylation (C) 843
Chiral hydrazine derivative, Benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline, a chiral hydrazine derivative (C) 374
Chirality, Recognition of chirality by ENDOR spectroscopy (C) 1007
Chirality transfer, α-Deprotonation of an α-chiral 2-alkenylcarbamate with retention and lithium-titanium exchange with inversion—the homoaldol reaction with 1,3-chirality transfer (C) 160
Optically active α-chloro-(*E*)-crotylboronate esters by allyl rearrangement (C) 189
Chiron approach, Total synthesis of natural products: the "chiron" approach (B) 113
Chlorine oxides, Crystal structure of Cl_2O_6 (C) 993
Chlorins, Facile entry to geminally dialkylated chlorins (C) 458
Chloro-(*E*)-crotylboronate esters, Optically active α-chloro-(*E*)-crotylboronate esters by allyl rearrangement (C) 189
Chlorosilyl-*N,N*-dimethylamine, The structure of chlorosilyl-*N,N*-dimethylamine in the gaseous and solid phases (C) 107
Cholesterol homeostasis, A receptor-mediated pathway for cholesterol homeostasis (Nobel lecture) (R) 583
Choline, A macrobicyclic polyphenoxide as receptor analogue for choline and related ammonium compounds (C) 647

Chromatography, High-pressure liquid chromatography (HPLC) of proteins (R) 535
Clathrate structure, $Ge_{4.06}I$, an unexpected germanium subiodide—a tetragermaniodonium(III) iodide with clathrate structure $[Ge_{46-x}I_x]I_8$, $x = 8/3$ (C) 350
Cluster beam chemistry—from atoms to solids (R) 197
Clusters, A novel electron count and metal-metal multiple bonding in trigonal prismatic clusters (C) 822
$[Bi_2^{III}S_{34}]^{4-}$, the hitherto sulfur-richest complex (C) 273
$[Cl_7Cu_5(ReS_4)]^{3\ominus}$, a hexanuclear complex anion with double cubane-like structure (C) 990
Computer graphics in the study of metal cluster compounds (R) 853
$[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)(PPh_3)_4]$, a product of the reaction of $[CoCl_2(PPh_3)_2]$ with $PhAs(SiMe_3)_2$ (C) 175
Diastereoselective transformations on heterometal clusters (C) 479
Directed synthesis of rhenamolybdatetrahedranes: nucleophilic addition of pentacarbonylrhenate(1-) to alkyne ligands in cationic molybdenum complexes (C) 734
Formal insertion of the $HCO^{\oplus}$ fragment into a trinuclear cluster metal-carbyne bond: synthesis, structure and reactivity of cluster-bound ethynol (C) 929
Heteronuclear 'star clusters': $[Ni_2Pt_2W_4(\mu_3\text{-}CPh)_4(CO)_8(\eta\text{-}C_5H_5)_4]$ and $[Ni_2Pt_2W_4(\mu_2\text{-}CR)(\mu_3\text{-}CR)_3(CO)_8(\eta\text{-}C_5H_5)_4]$ (R = Ph or *p*-C_6H_4Me) (C) 190
Multiple bonds between transition metals and "bare" main group elements: links between inorganic solid state chemistry and organometallic chemistry (R) 56
$[Re_4^{IV}S_{22}]^{4-}$, a highly symmetrical metal-sulfur cluster with six S_3^{2-} ligands (C) 272
Reversible interconversion of C-C and C-N multiple bond systems on clusters (C) 279
Skeletal rearrangements on clusters: the reaction of $[(t\text{Bu}P)Fe_3(CO)_{10}]$ with diphenylacetylene (C) 1119
Structures with oligomeric condensed clusters in indium oxomolybdates (C) 845
Synthesis and structure of $[(Ph_3P)_3Ir(\mu_3\text{-}H)(\mu\text{-}H)_2Ag_2(OSO_2CF_3)(H_2O)](CF_3SO_3)$, a complex with a bent Ag-Ir-Ag chain (C) 748
Synthesis of $[Cu_3Os_3H_9(PMe_2Ph)_9]$, a bimetallic raft, by reductive elimination of alcohol or H_2 (C) 262
The $\sigma^2\pi^4$ triple bond between molybdenum and tungsten atoms: developing the chemistry of an inorganic functional group (R) 21
Cobalt-germanium triangles, Early members of a homologous series based on linked GeM_2 triangles, (M = Co, Fe): structures of $[Ge_2Co_4Fe_2(CO)_{21}]$ and $[Ge_3Co_8(CO)_{26}]$ (C) 759
Cobalt-magnesium compounds, Heterometallic dinuclear complexes by ethene displacement with Grignard compounds or diorganomagnesium compounds (C) 923
Cobalt-porphyrins, Reduced cobalt-*meso*-tetraphenylporphyrin complexes: synthesis and structure of $[Na(thf)_3]_2[Co(TPP)]$ (C) 553
Cobalt-titanium compounds, Synthesis and structure of the Co_3Ti_2 complex$[\{\mu_3\text{-}[(C_5H_5)_2TiOC]\}_2\{(C_5H_5)_3Co_3\}]$: CO reduction by two different metal centers (C) 254
Coenzyme A analogue, Methylmalonylcarba(dethia)-coenzyme A as substrate of the coenzyme B_{12}-dependent methylmalonyl-CoA mutase: enzymatic rearrangement of a β- to a γ-keto acid (C) 366
Colloid chemistry, Ordering of ionic solutes in dilute solutions through attraction of similarly charged solutes—a change of paradigm in colloid and polymer chemistry (R) 323
COLOC technique, The elucidation of the constitution of glycopeptides by the NMR spectroscopic COLOC technique (C) 342
Complexation, Preorganization—from solvents to spherands (R) 1039
Computer graphics in the study of metal cluster compounds (R) 853
Protein crystallography and computer graphics—toward rational drug design (R) 767
Conformation, Conformational prerequisites for the in vitro inhibition of cholate uptake in hepatocytes by cyclic analogues of antamanide and somatostatin (C) 997
Conjugation, Laticyclic 1,5-conjugation between parallel, neighboring azo-groups and phenyl groups (C) 187
Coordination, Crystal structure of the η^3-allyllithium compound [1,3-diphenylallyllithium · diethyl ether]$_n$ (C) 104
Dimeric 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene, a compound with aluminum-olefin π-bonds (C) 921
$(Me_4N)_3[Mo_4O_{12}F_3]\cdot 0.8H_2O$, a salt with a novel fluorooxo polyanion (C) 1104
$NaNb_3O_5F$—a niobium-niobium triple bond with "side-on" coordination by Nb atoms (C) 996
$[NbAs_8]^{3-}$, a novel type of complex and an unexpected one-dimensional chain structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (C) 353
Novel octahedral Si and Ge complexes with a hexadentate diphenol ligand (C) 162
[α-(Phenylsulfinyl)-α-methylbenzyllithium-tetramethylethylenediamine]$_2$: crystal structure of an α-sulfinyl "carbanion" (C) 1011
Polymeric paracyclophane complexes of copper and silver (C) 1089
Reaction of Grignard reagents with dianionic hexacoordinated silicon complexes: organosilicon compounds from silica gel (C) 474
Reactivity of anionic pentacoordinated silicon complexes towards nucleophiles (C) 473
$[Sb_3I_{10}^{\ominus}]_\infty$—a polymeric anion with transitions from trigonal pyramidal to octahedral coordination of antimony(III) (C) 825
Second-sphere coordination—a novel rôle for molecular receptors (R) 487
Structures with oligomeric condensed clusters in indium oxomolybdates (C) 845
S_4N_4 as tridentate ligand in $[IrX(CO)(PPh_3)(S_4N_4)]$ complexes (C) 931
Trithiometaphosphate PS_3^-—an anion with phosphorus of coordination number 3 (C) 82
Coordination chemistry, Understanding reaction dynamics in coordination chemistry—application of high pressure techniques (R) 673
Coordination number, A 2-phosphonio-substituted 1-phospha-1-alkene: resonance between P^{III} alkene and P^{V} ylide (C) 454
2-Dewar phosphinines—a new class of compounds containing two-coordinate phosphorus (C) 280
$H_3C{-}{-}P{=}CH_2$: an ylide with two-coordinate phosphorus? (C) 265
Cope rearrangement induced by medium-sized ring strain (C) 1026
Copper iodides, $[Cu_{36}I_{56}]^{20\ominus}$—a novel polyanion in the compound $(pyH)_2[Cu_3I_5]$ (C) 569
Copper-osmium cluster, Synthesis of $[Cu_3Os_3H_9(PMe_2Ph)_9]$, a bimetallic raft, by reductive elimination of alcohol or H_2 (C) 262
Copper-semicorrin complexes, Chiral copper-semicorrin complexes as enantioselective catalysts for the cyclopropanation of olefins by diazo compounds (C) 1005
Coupling reactions, The palladium-catalyzed cross-coupling reactions of organotin reagents with organic electrophiles (R) 508
Transition-metal clusters as catalysts of unconventional reactions: reductive C-N coupling of alkyl isocyanates (C) 570
Coupling reagent, Nitromethane as d^1,d^1 multiple coupling reagent for the carbonyl dianion synthon. Practical synthesis of chalcogran (C) 941
Crown ethers, A simple route to 2,3,11,12-dibenzo-1,4,7,10,13,16-hexathia-2,11-cyclooctadiene (hexathiobenzo[18]crown-6) (C) 1107
Palladium(II) and platinum(II) complexes of 1,4,7,10,13,16-hexathiacyclooctadecane (C) 274
Cryptates, $[NbAs_8]^{3-}$, a novel type of complex and an unexpected one-dimensional chain structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (C) 353
Crystal structure, Kristallstruktur und chemische Bindung (B) 112
$[NbAs_8]^{3-}$, a novel type of complex and an unexpected one-dimensional chain structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (C) 353
Periodic potential surfaces in crystal structures (C) 110
The pentagonal column and the ReO_3-type structure (R) 431
Crystal structure determination, Direct methods and anomalous dispersion (Nobel lecture) (R) 603
Recovering phase information from intensity data (Nobel lecture) (R) 614
Cubane-like structure, $[Cl_7Cu_5(ReS_4)]^{3\ominus}$, a hexanuclear complex anion with double cubane-like structure (C) 990
Cumulenes, Structure determination of pentatetraenes—comparison of the structures of cumulenes (C) 340
Wittig reaction with carbon suboxide: synthesis of dimethyl 1,5-diphenyl-1,2,3,4-pentatetraenedicarboxylate (C) 93
Cyanine dyes, Influence of external negative charges on the absorption maxima of symmetrical cyanines. A study with model compounds and artificial bacteriorhodopsin pigments (C) 284
Cyanosulfanes, The polymeric silver complexes $[Ag\{S_n(CN)_2\}_2][AsF_6]$ (n = 3, 4): stable coordination compounds of dicyanotri- and dicyanotetrasulfanes (C) 84
Cycloaddition, [3 + 2] Cycloaddition approaches to five-membered rings via trimethylenemethane and its equivalents (R) 1
$[_\pi 2 + _\pi 2]$ Cycloaddition of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione and singlet oxygen to homofuran (C) 989
[4 + 2] Cycloadditions with transition-metal-coordinated selenoaldehydes and selenoketones as heterodienophiles (C) 78
Organic reactions at high pressure: cycloaddition reactions of 11-methylene-1,6-methano[10]annulene (C) 346
Synthesis of a dicyclopenta[*a,e*]pentalene by [6 + 2]-cycloaddition of 1,3-di-*tert*-butyl-5-vinylidenecyclopentadiene and consecutive 8π-electrocyclic reaction (C) 466
Thioketone *S*-oxides by [2 + 2]-cycloaddition of ynamines to *N*-sulfinyltosylamide (C) 459
Tricyclo[5.3.0.$0^{2,8}$]deca-3,5-dien-9-one and a new route to $C_{10}H_{10}$ isomers (C) 906
1,3-Dipolar cycloaddition chemistry (B) 112
Cycloalkynes, 1-Thia-2-cyclooctyne—a strained cycloalkyne with polarized triple bond (C) 809
Cycloarene, Cyclo[*d.e.d.e.e.d.e.d.e.e.*]decakisbenzene, a new cycloarene (C) 742
Cyclo[*d.e.d.e.e.d.e.d.e.e.*]decakisbenzene, a new cycloarene (C) 742
Cyclodisilazane cations—synthesis and crystal structure (C) 915
Cyclohepta[*ef*]heptalene, Synthesis and dy-

namic properties of substituted cyclohepta[*ef*]heptalene (C) 633
Cycloheptatrienylidenemethyleneditropylium, A salt of the dication cycloheptatrienylidenemethyleneditropylium (C) 916
Cycloheptatrienylidenes, ESR observation of thermally produced triplet nitrenes and photochemically produced triplet cycloheptatrienylidenes (C) 480
Cyclohexatriene, Novel synthesis of the angular [3]phenylene (terphenylene) by cobalt-catalyzed cyclization of bis(2-ethynylphenyl)ethyne: a molecule with an internal cyclohexatriene ring (C) 266
Cyclohexatriene structure, $[\{(\eta^5\text{-}C_5Me_5)Co\}_3C_{12}H_{10}]$—*a complex of biphenyl with* Kekulé structure (C) 646
Cyclometalation, Metal dependence of cyclometalation and arene C-H activation in the photolysis of *cis*-$H_2M[P(CH_2CH_2CH_2PMe_2)_3]$ (M = Fe, Ru) in benzene (C) 260
Cyclopentane derivatives, Intramolecular addition of 2-(trimethylsilyl)methyl-substituted allyl cations to double bonds—synthesis of bicyclo[3.3.0]octane derivatives (C) 354
Cyclopentanediols, Optically active cyclopentanediol synthetic building blocks from tartaric acid (C) 994
Cyclophosphane oxides, P_6tBu_4O and P_7tBu_5O—the first polycyclophosphane oxides (C) 471
Cyclophosphanes, *cyclo*-P_5 as complex ligand—the phosphorus analogue of the cyclopentadienyl ligand (C) 363
New products from PCl_3, $P(NMe_2)_3$, and $AlCl_3$ (C) 253
Cyclopropabenzene, Nickelacyclobutabenzene compounds by oxidative addition of cyclopropabenzene to nickel(0) compounds (C) 640
Nickel-induced cyclotetramerization of cyclopropabenzene to 1,6:7,12:13,18:19,24-tetrakismethano[24]annulene (C) 367
Cyclopropanation, Chiral copper-semicorrin complexes as enantioselective catalysts for the cyclopropanation of olefins by diazo compounds (C) 1005
Cyclopropenylium salts, *cyclo*-C_3I_4—the first saltlike halocarbon (C) 103
Cycloreversion, Diels-Alder adducts of benzene with arenes and their [4 + 2] cycloreversion (C) 377
Cycloselanes, Selenium-rich chalcogen rings Se_5S, Se_5S_2, and Se_7 from titanocene pentaselenide (C) 99
Cyclosilanes, The tetrasilabicyclo[1.1.0]butane system: structure of 1,3-di-*tert*-butyl-2,2,4,4-tetrakis-(2,6-diethylphenyl)tetrasilabicyclo[1.1.0]butane (C) 173
Cyclotetradepsipeptide, Synthesis of the all-L-configurated cyclotetradepsipeptide *cyclo*[-L-Val-L-Lac-]$_2$ by the combined protection/activation method with the 2,4-bis(methylthio)phenoxycarbonyl group (C) 170
Cyclotetramerization, Nickel-induced cyclotetramerization of cyclopropabenzene to 1,6:7,12:13,18:19,24-tetrakismethano[24]-annulene (C) 367
Cytochrome P-450 (B) 294

DECAMETHYLSILICOCENE—synthesis and structure (C) 164
Dehydroalanine, Amino acid derivatives from *N*-(Arylmethylene)dehydroalanine methyl esters (C) 90
Dehydropeptide synthesis, $C_{phenyl}\text{-}H\cdots O$ and $C_{phenyl}\text{-}H\cdots N$ interactions: crystal structure of (*Z*)-4-benzylidene-2-methyl-5(4*H*)-oxazolone, an intermediate for dehydropeptide synthesis (C) 447
Dendralenes, A novel entry to dendralene systems (C) 578
Deoxyhexoses, Synthesis of deoxyhexoses from divinylglycols—the synthesis of D- and L-chalcose (C) 89
Depsipeptides, Synthesis of the all-L-configurated cyclotetradepsipeptide *cyclo*[-L-Val-L-Lac-]$_2$ by the combined protection/activation method with the 2,4-bis(methylthio)phenoxycarbonyl group (C) 170
2-Dewar phosphinines—a new class of compounds containing two-coordinate phosphorus (C) 280
Diastereoselective synthesis of functionalized tetrahydrofuran derivatives from γ-lactols (C) 556
Diastereoselective transformations on heterometal clusters (C) 479
Diazadiphosphetidine, Acid-catalyzed isomerization of the [2 + 1]-cyclodimer of an iminophosphane to the diazadiphosphetidine (C) 834
Diazenes, Valence isomers of compounds with geminal aryldiazene and isocyanate functions stabilized by protonation (C) 1132
Diazoalkanes, UV/VIS laser photochemistry: intermediary formation of diazoalkanes versus direct S_0,T_1 transitions in the photolysis of azoalkanes (C) 818
1,2-Diboratabenzene, A 1,2-diboratabenzene: lithium salt and transition metal complexes (C) 642
1,3-Diboratacyclobutadiene, A 1,3-diboratacyclobutadiene and its dimer, a sandwich compound with a Li_4 layer (C) 1111
1,3-Diboretanes, A puckered and a planar 1,3-diboretane (C) 1112
α,ω-Dicarboxylic acids, CC Coupling of CO_2 and butadiene on iron(0) complexes—a novel route to α,ω-dicarboxylic acids (C) 810
Dichlorine hexaoxide, Crystal structure of Cl_2O_6 (C) 993
Dicyclopenta[*a,e*]pentalene, Synthesis of a dicyclopenta[*a,e*]pentalene by [6 + 2]-cycloaddition of 1,3-di-*tert*-butyl-5-vinylidenecyclopentadiene and consecutive 8π-electrocyclic reaction (C) 466
Diels-Alder adducts of benzene with arenes and their [4 + 2] cycloreversion (C) 377
Diels-Alder reaction, Intramolecular Diels-Alder reactions with methyl 2-trimethylsiloxy-2-vinylcyclopropanecarboxylates as key building blocks (C) 1086
Mechanism of the thermal 1,3-cyclohexadiene dimerization: a non-concerted Diels-Alder reaction leading to the *exo*-[4 + 2] adduct and a novel [6 + 4]-ene reaction (C) 108
Diels-Alder reactions at carbene ligands: a route to olefin-carbene complexes (C) 812
Difluoromethylene bridge, CF_2-bridged metal complexes (C) 185
Dihalomethanes, Photoisomerization of dihalomethanes (C) 819
Dihydroacepentalenediide, the dianion of acepentalene (C) 719
Dihydroazulenes, Tricyclo[5.3.0.0^{2,8}]deca-3,5-dien-9-one and a new route to $C_{10}H_{10}$ isomers (C) 906
Diindenyldivanadium, Synthesis of diindenyldivanadium—a new variant of the reductive degradation of metallocenes and related compounds (C) 928
Diisopinocampheylborane, Secondary deuterium kinetic isotope effects in enantioselective hydroborations with (+)-diisopinocampheylborane (C) 577
Diketones, 2,4-Diene-1,6-diones and 2-acyl-3-cyclopenten-1-ols by double Friedel-Crafts acylation of tricarbonyl(diene)iron complexes (C) 1131
Dilithioalkenes, Vicinal dilithioalkenes by addition of lithium to simple cyclic and acyclic alkynes (C) 167
Dilithioethylene isomers, 1,2-Dilithioethylene isomers and their mechanisms of interconversion: an ab initio study (C) 169
Dimerization, The first observation of the equilibrium $2M \equiv M \rightleftarrows M_4$ (M = transition metal): synthesis and structure of hexaisopropoxyditungsten and its dimer (C) 1014
Dinuclear complexes, First dinuclear complexes with fourfold alkyl-bridging (C) 925
Heterometallic dinuclear complexes by ethene displacement with Grignard compounds or diorganomagnesium compounds (C) 923
Dioxaboroles, 2-Substituted 1,3,2-dioxaboroles as synthetic equivalents for the glycolaldehyde anion (C) 560
Dioxan-4-ones, Preparation of optically active alcohols from 1,3-dioxan-4-ones. A practical version of the asymmetric synthesis with nucleophilic substitution at acetal centers (C) 178
Dioxepins, Asymmetric double-bond isomerization of 4,7-dihydro- to 4,5-dihydro-1,3-dioxepins (C) 274
Dioxirane, Benzophenone *O*-oxide (C) 255
Diozonides, A stable diozonide of a conjugated diene by ozonolysis of 2,3,4,5-tetramethyl-2,4-hexadiene on polyethylene (C) 81
Dipeptides, Thin layer chromatographic separation of stereoisomeric dipeptides (C) 278
1,3-Diphosphacyclobutadienecobalt(I) complexes from phosphaalkynes (C) 644
1,3-Diphospha-4-metallabutadiene, Phosphorus analogues of unsaturated carbon compounds: an (*s-trans*)-1,3-diphospha-4-metallabutadiene and its (*s-cis*)-$Fe(CO)_3$ complex (C) 455
Diphosphathiophene, A stable 1,2,4-thiadiphosphole ("2,4-diphosphathiophene") (C) 567
Diphosphene complex, $[(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_4(PPh)_2]$, a diphosphene complex with a butterfly structure (C) 338
Diphosphenes, Bis(pentamethylcyclopentadienyl)diphosphene—a molecule with fluxional structure and reactive P-C bond (C) 919
Transition metal-induced CO-insertion in the P=P bond of diphosphenes with formation of diphosphinomethanone derivatives (C) 755
Diphosphinomethanide ligands, $[La\{(Ph_2P)_2CH\}_3]$—a homoleptic lanthanum complex with π-allyl-like coordinated diphosphinomethanide ligands (C) 823
Diphosphinomethanone derivatives, Transition metal-induced CO-insertion in the P=P bond of diphosphenes with formation of diphosphinomethanone derivatives (C) 755
Dipolar cycloaddition, 1,3-Dipolar cycloaddition chemistry (B) 112
Disilane, Hexa-*tert*-butyldisilane—the molecule with the longest Si-Si bond (C) 79
Disorder, The chemistry of the noncrystalline state (R) 31
Disulfur dioxide, Complex stabilization of disulfur dioxide in the fragmentation of thiirane *S*-oxide on bis(triphenylphosphane)platinum(0) (C) 261
Dithiocyanogen, $[Ag(NCS)_2AsF_6]_n$—a metal complex with dithiocyanogen as ligand (C) 1006
Dititanacyclobutane, A polyfunctional dititanacyclobutane (C) 574
Divinylglyoxal and methylvinylglyoxal (C) 1116
DNA, Physicochemical and cytochemical investigations on the binding of ethidium and acridine dyes to DNA and to organelles in living cells (R) 115
Double-bond isomerization, Asymmetric double-bond isomerization of 4,7-dihydro- to 4,5-dihydro-1,3-dioxepins (C) 274
Double bond localization, $[\{(\eta^5\text{-}C_5Me_5)Co\}_3C_{12}H_{10}]$—a complex of biphenyl with Kekulé structure (C) 646
Synthesis and dynamic properties of substituted cyclohepta[*ef*]heptalene (C) 633

Double bond rule, Discarding the double bond rule? (L) 1038
Drug design, Protein crystallography and computer graphics—toward rational drug design (R) 767
Drugs, Biotransformation von Arzneimitteln. Band 4 (B) 293
Dyotropic hydrogen migration, An intramolecular dyotropic hydrogen migration in pentacyclo[7.6.0.0^{2,13}.0^{3,8}.0^{10,14}]pentadeca-4,6,11-triene (C) 1121

ELECTRICAL CONDUCTIVITY, A radical anion salt of 2,5-dimethyl-*N,N'*-dicyanoquinonediimine with extremely high electrical conductivity (C) 740
Electrochemistry, Ferrocene-modified polypyrrole films by electrochemical copolymerization (C) 180
Indirect electroorganic syntheses—a modern chapter of organic electrochemistry (R) 683
Unexpected "two-electron" transfer in cyclic hydrazines—a voltammetric analysis (C) 1021
Electron acceptors, Poly-onio-substituted quinones as strong electron acceptors (C) 917
Electron-donor ability, Variable electron-donor ability of alkyne ligands—synthesis and structure of carbonyl(η^5-cyclopentadienyl)(η^2-1-diethylamino-1-propyne)(η^1-*p*-methylphenylketenyl)tungsten (C) 643
Electron donor-acceptor interactions in host-guest complexes in organic solutions (C) 1127
Electron donor, 1,2,4,5-Tetrakis(dimethylamino)benzene, a new electron donor with unusual properties (C) 1023
Electronics, Technology of chemicals and materials for electronics (B) 1036
Electron/ion transfer reactions, Isothermal magnetic phase transitions controlled by reversible electron/ion transfer reactions (C) 905
Electron-transfer, Poly(anthrylenetrimethylene) and 9,10-bridged anthracenes by reductive alkylation (C) 444
Synthesis and redox properties of compounds with several separated anthracene electrophores (C) 443
Electroorganic chemistry as a new tool in organic synthesis (B) 380
Electroorganic syntheses, Part I: oxidations (B) 484
Electrophilic addition, Stereocontrolled synthesis of paraconates from β-lactones; stereochemistry of electrophilic additions to endocyclic paraconate-enolates (C) 655
Elementary reactions, Metathesis of alkyl radicals and alkenes—a novel elementary reaction of alkyl radicals (C) 80
Elements, Chemistry of the elements (B) 194
Enantiomerically pure C_2 units, Preparation of chiral building blocks from amino acids and peptides via electrolytic decarboxylation and $TiCl_4$-induced aminoalkylation (C) 843
Enantiomerically pure cyclopentanediols, Optically active cyclopentanediol synthetic building blocks from tartaric acid (C) 994
Enantiomeric resolution by HPLC on silica-gel-bound, optically active polyamides (C) 830
Thin layer chromatographic separation of stereoisomeric dipeptides (C) 278
Enantiomerization, Synthesis of *erythro*-D- and -L-4-pentenetriols. Selective epoxy allyl alcohol hydrolysis with retention or twofold inversion (enantiomerization) (C) 87
Enantiomer separation of (*R,S*)-2-(*tert*-butyl)-3-methyl-4-imidazolidinone, a chiral building block for amino acid synthesis (C) 345, 766
Enantioselective catalysts, Chiral copper-semicorrin complexes as enantioselective catalysts for the cyclopropanation of olefins by diazo compounds (C) 1005
[$Cp(CO)_2Mo$\{NR*[Rh(norbornadiene)]-CH(pyridyl)\}], a rhodium complex with an asymmetric molybdenum atom in the chelate skeleton (C) 371
Enantioselective hydroborations, Secondary deuterium kinetic isotope effects in enantioselective hydroborations with (+)-diisopinocampheylborane (C) 577
Enantioselective Robinson annelations via phase-transfer catalysis (C) 476
Enantioselective synthesis of α-substituted primary amines by nucleophilic addition to aldehyde-SAMP hydrazones (C) 1109
ENDOR spectroscopy, ^{13}C-ENDOR investigation of an organic tetraradical in the quintet state; synthesis of a fourfold ^{13}C-labeled tetrakisgalvinol (C) 1097
Recognition of chirality by ENDOR spectroscopy (C) 1007
Ene reaction, Mechanism of the thermal 1,3-cyclohexadiene dimerization: a non-concerted Diels-Alder reaction leading to the *exo*-[4+2] adduct and a novel [6+4]-ene reaction (C) 108
Enzymatic analysis, Methods of enzymatic analysis. Vol. 6. Metabolites 1: carbohydrates (B) 291
Methods of enzymatic analysis. Vol. 7. Metabolites 2: Tri- and dicarboxylic acids, purines, pyrimidines and derivatives, coenzymes, inorganic compounds (B) 483
Enzymatic hydrolysis, Complementary epoxide hydrolase- vs glutathione S-transferase-catalyzed kinetic resolution of simple aliphatic oxiranes—complete regio- and enantioselective hydrolysis of *cis*-2-ethyl-3-methyloxirane (C) 1032
Enzymatic rearrangement, Methylmalonyl-carba(dethia)-coenzyme A as substrate of the coenzyme B_{12}-dependent methylmalonyl-CoA mutase: enzymatic rearrangement of a β- to a γ-keto acid (C) 366
Enzymatic synthesis, Synthesis of the trisaccharide Neu-5-Ac-α(2→6)Gal-β(1→4)Glc-NAc by the use of immobilized enzymes (C) 1096
Enzyme inhibitors, Synthesis of *N*-(1-carboxy-5-aminopentyl)dipeptides as inhibitors of angiotensin converting enzyme (C) 277
Enzyme reagents, Stereospecific reductions with hydrogen gas, modified metal catalysts, methyl viologen and enzymes or microorganisms (C) 462
Epoxidation of olefins with elemental fluorine in water/acetonitrile mixtures (C) 554
Epoxides, Organometallic derivatives of epoxides (C) 653
The alkylation of epoxides with new organoyttrium and organolanthanoid reagents (C) 760
2-Epoxy alcohols, A simple access to 2-epoxy alcohols: titanium(IV)-catalyzed oxygen transfer from allylic hydroperoxides (C) 269
Equilibria, Evidence for equilibria between μ-alkyne and alkylidyne complexes of tungsten alkoxides: [$W_2(OR)_6(\mu\text{-}C_2R_2')$] ⇌ 2[$(RO)_3W{\equiv}CR'$] (C) 446
Ethanedithiolate complexes, [Et_4N][$M(SCH_2CH_2S)_3$] (M = Nb, Ta), homoleptic 1,2-ethanedithiolate complexes of niobium and tantalum (C) 86
Ethene displacement, Heterometallic dinuclear complexes by ethene displacement with Grignard compounds or diorganomagnesium compounds (C) 923
Ethidium dyes, Physicochemical and cytochemical investigations on the binding of ethidium and acridine dyes to DNA and to organelles in living cells (R) 115
Ethylene oxide —X-ray structure analysis (at 150 K) and ab initio calculations (C) 276
cis-2-Ethyl-3-methyloxirane, Complementary epoxide hydrolase- vs glutathione S-transferase-catalyzed kinetic resolution of simple aliphatic oxiranes—complete regio- and enantioselective hydrolysis of *cis*-2-ethyl-3-methyloxirane (C) 1032
Ethynol, Formal insertion of the $HCO^{\oplus}$ fragment into a trinuclear cluster metal-carbyne bond: synthesis, structure and reactivity of cluster-bound ethynol (C) 929
Evolution, Remarks on the review article "replication and evolution in inorganic systems" by *Armin Weiss* (C) 658

FERROCENE, Ferrocene-modified polypyrrole films by electrochemical copolymerization (C) 180
Ferrocenylmethyl(Fem) group, The ferrocenylmethyl(Fem) group as a highly lipophilic and chromophoric group for the masking of peptide bonds (C) 159
Fischer-Tropsch synthesis, The chemistry of the catalyzed hydrogenation of carbon monoxide (B) 195
Flash photolysis of $Os(CO)_5$ in benzene solution. Detection of $Os(CO)_4$-benzene by fast time-resolved IR spectroscopy (C) 991
Flavor materials, Common fragrance and flavor materials (B) 582
Fluorescence, Charge separation in excited states of decoupled systems—TICT compounds and implications regarding the development of new laser dyes and the primary processes of vision and photosynthesis (R) 971
Fluorine, Epoxidation of olefins with elemental fluorine in water/acetonitrile mixtures (C) 554
Fluoroorganic compounds, Di- and trifluoro-substituted dilithium compounds for organic syntheses (C) 98
Fluorooxo polyanion, $(Me_4N)_3[Mo_4O_{12}F_3]\cdot 0.8H_2O$, a salt with a novel fluorooxo polyanion (C) 1104
Fluxional structure, Bis(pentamethylcyclopentadienyl)diphosphene—a molecule with fluxional structure and reactive P-C bond (C) 919
Forest damage, Model experiments on the phytotoxicity of halogenated hydrocarbons (C) 808
Friedel-Crafts acylation, 2,4-Diene-1,6-diones and 2-acyl-3-cyclopenten-1-ols by double Friedel-Crafts acylation of tricarbonyl(diene)iron complexes (C) 1131
Full-shell clusters, Novel modifications of gold, rhodium, and ruthenium—M_{13} clusters as building blocks of "si perclusters" (C) 922
Fulvalene derivatives, Novel fulvalene derivatives of zirconium: a facile entry into organozirconium(III) chemistry (C) 289

GAS CHROMATOGRAPHY, Handbuch der Gaschromatographie (B) 580
Gas-phase flow thermolysis, Organic synthesis at high temperatures. Gas-phase flow thermolysis (R) 414
Germanium subiodide, $Ge_{4.06}I$, an unexpected germanium subiodide—a tetragermanioiodonium(III) iodide with clathrate structure $[Ge_{46-x}I_x]I_8$, x = 8/3 (C) 350
Glass, The chemistry of the noncrystalline state (R) 31
Glycolaldehyde anion, 2-Substituted 1,3,2-dioxaboroles as synthetic equivalents for the glycolaldehyde anion (C) 560
Glycopeptides, Synthesis of *O*-glycopeptides of the tumor-associated T_N- and T-antigen type and their binding to bovine serum albumin (C) 360

The elucidation of the constitution of glycopeptides by the NMR spectroscopic COLOC technique (C) 342

Glycosides, New methods for the synthesis of glycosides and oligosaccharides—are there alternatives to the Koenigs-Knorr method? (R) 212

Glycosphingolipids, Synthesis of glycosphingolipids and psychosines (C) 725

Gold-gold distances, Synthesis and structure of 1,3-Diphenyltriazenidogold(I), a tetrameric molecule with short gold-gold distances (C) 95

Gold(III) complexes, Methylene-bridged dinuclear gold(III) complexes with terminal and bridging ylide ligands (C) 575

Grandisol, Asymmetric photocycloadditions with optically pure, spirocyclic enones. Simple synthesis of (+)- and (−)-grandisol (C) 1117

Grignard reagents, Reaction of Grignard reagents with dianionic hexacoordinated silicon complexes: organosilicon compounds from silica gel (C) 474

Group theory, Gruppentheorie für Chemiker (B) 660

Group transfer polymerization of acrylic acid esters with alkylthio- or arylthiosilanes as initiators (C) 1108

HAFNIUM COMPOUNDS, Reductive coupling of CO: formation of a 1:1 adduct of η^2-ketone- and enediolato-complex upon carbonylation of bis(cyclopentadienyl)hafnacyclobutane (C) 364

Halogenated hydrocarbons, Microbial degradation of halogenated hydrocarbons: a biological solution to pollution problems? (R) 779

Model experiments on the phytotoxicity of halogenated hydrocarbons (C) 808

Hepatocytes, Conformational prerequisites for the in vitro inhibition of cholate uptake in hepatocytes by cyclic analogues of antamanide and somatostatin (C) 997

Heptaheteronortricycles, Valence tautomerism of the heptaheteronortricycles $[P_{7-x}As_x]^{3-}$ (C) 352

Heterocycles, A facile synthesis of a new class of eight-membered heterocycles from 1-azabutadienes (C) 181

Synthesis and molecular and crystal structure of a new tricyclic $B_3N_4S_2Si_2$ system (C) 741

Heterogeneous catalysts, O_2-Generation by oxidation of water with di- and trinuclear ruthenium complexes as homogeneous and heterogeneous catalysts (C) 1009

Oxygen evolution by water oxidation mediated by heterogeneous manganese complexes (C) 825

Heterometallic dinuclear complexes by ethene displacement with Grignard compounds or diorganomagnesium compounds (C) 923

Hexadeoxynucleotides, A self-replicating hexadeoxynucleotide (C) 932

Hexaethynylbenzene (C) 268

Hexahydrido(pentamethylcyclopentadienyl)rhenium, $[(C_5Me_5)ReH_6]$ (C) 1092

Hexaisopropoxyditungsten, The first observation of the equilibrium $2M{\equiv}M \rightleftarrows M_4$ (M = transition metal): synthesis and structure of hexaisopropoxyditungsten and its dimer (C) 1014

Hexasilabenzene, Si_6H_6: Is the aromatic structure the most stable one? (C) 651

Hexathiacyclooctadecane, Palladium(II) and platinum(II) complexes of 1,4,7,10,13,16-hexathiacyclooctadecane (C) 274

High-pressure liquid chromatography (HPLC) of proteins (R) 535

High-pressure reactions, Direct aminolysis of unactivated esters at high-pressure (C) 565

Organic reactions at high pressure: cycloaddition reactions of 11-methylene-1,6-methano[10]annulene (C) 346

High pressure techniques, Understanding reaction dynamics in coordination chemistry—application of high pressure techniques (R) 673

History of chemistry, Adolf von Baeyer's scientific achievements — a legacy (R) 297

History of science, Boussingault. Chemist and agriculturist (B) 1035

Über die Erhaltung der Kraft (B) 1037

2D HOESY, 2-Lithio-1-phenylpyrrole: X-ray structure analysis and ^6Li-^1H 2D heteronuclear Overhauser NMR spectroscopy (2D HOESY) (C) 1103

Homoaldol reaction, α-Deprotonation of an α-chiral 2-alkenylcarbamate with retention and lithium-titanium exchange with inversion—the homoaldol reaction with 1,3-chirality transfer (C) 160

Homofuran, $[_\pi 2 + _\pi 2]$ Cycloaddition of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione and singlet oxygen to homofuran (C) 989

Homoleptic complexes, $[Et_4N][M(SCH_2CH_2S)_3]$ (M = Nb, Ta), homoleptic 1,2-ethanedithiolate complexes of niobium and tantalum (C) 86

Homologation, Synthesis of long-chain sugars by iterative, diastereoselective homologation of 2,3-*O*-isopropylidene-D-glyceraldehyde with 2-trimethylsilylthiazole (C) 835

Host-guest chemistry, Bicyclic host cavities derived from triphenylamine—guest selectivity and redox properties (C) 336

Electron donor-acceptor interactions in host-guest complexes *in organic solutions* (C) 1127

Large molecular cavities for small ions—double bridging of three bipyridine units (C) 1122

Preorganization—from solvents to spherands (R) 1039

Host molecules, Anionic host molecules with bicyclic carbon skeletons—synthesis and guest inclusion in aqueous solution (C) 567

HPLC, Enantiomeric resolution by HPLC on silica-gel-bound, optically active polyamides (C) 830

High-pressure liquid chromatography (HPLC) of proteins (R) 535

Hydrazines, *N*-Aryl-*O*-(diphenylphosphinoyl)hydroxylamines: electrophilic amination of amines to hydrazines; a model reaction for the carcinogenicity of aromatic amines (C) 562

Benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline, a chiral hydrazine derivative (C) 374

Unexpected "two-electron" transfer in cyclic hydrazines—a voltammetric analysis (C) 1021

Hydride reagents, Superactive alkali metal hydride metalation reagents: LiH, NaH, and KH (C) 465

Hydrides, Hexahydrido(pentamethylcyclopentadienyl)rhenium, $[(C_5Me_5)ReH_6]$ (C) 1092

Hydrido compounds, Unusual behavior of the stable paramagnetic dihydridoiridium(IV) complex $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ in solution (C) 460

Hydrocarbon host lattices, Selective inclusion and separation of isomeric and homologous hydrocarbons by hydrocarbon host lattices (C) 746

Hydrogenation, The chemistry of the catalyzed hydrogenation of carbon monoxide (B) 195

Hydrogen bonds, C_{phenyl}-H···O and C_{phenyl}-H···N interactions: crystal structure of (*Z*)-4-benzylidene-2-methyl-5(4*H*)-oxazolone, an intermediate for dehydropeptide synthesis (C) 447

Hydrogen migration, An intramolecular dyotropic hydrogen migration in pentacyclo[7.6.0.0^{2,13}.0^{3,8}.0^{10,14}]pentadeca-4,6,11-triene (C) 1121

Hydroxyacetylene, generation and characterization of the neutral molecule, radical cation and dication in the gas phase (C) 282

Formal insertion of the $HCO^{\oplus}$ fragment into a trinuclear cluster metal-carbyne bond: synthesis, structure and reactivity of cluster-bound ethynol (C) 929

Hydroxylamines, *N*-Aryl-*O*-(diphenylphosphinoyl)hydroxylamines: electrophilic amination of amines to hydrazines; a model reaction for the carcinogenicity of aromatic amines (C) 562

Hyperconjugation, First crystal structure analysis of an aliphatic carbocation—stabilization of the 3,5,7-trimethyl-1-adamantyl cation by C-C hyperconjugation (C) 349

IMIDAZOLE, Benzotri(imidazole)—a new ring system derived from benzenehexamine (C) 650

Iminophosphane, Acid-catalyzed isomerization of the [2 + 1]-Cyclodimer of an iminophosphane to the diazadiphosphetidine (C) 834

Immobilized enzymes, Synthesis of the trisaccharide Neu-5-Ac-α(2→6)Gal-β(1→4)-*Glc*NAc by the use of immobilized enzymes (C) 1096

Inclusion compounds, Selective inclusion and separation of isomeric and homologous hydrocarbons by hydrocarbon host lattices (C) 746

Indacene, Synthesis and properties of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene (C) 630

Indenophane dianion, [2.2]Indenophane dianion: a novel double-layered dianion (C) 174

Indium oxomolybdates, Structures with oligomeric condensed clusters in indium oxomolybdates (C) 845

Indolizines, Dihydropyrazolopyridine and bis(dihydroindolizine)—novel mono- and bifunctional photochromic systems (C) 572

Industrial chemistry, Industrielle Anorganische Chemie (B) 943

Ullmann's encyclopedia of industrial chemistry (B) 763

Influenza A viruses, Molecular biological background of the species and organ specificity of influenza A viruses (R) 47

Inorganic polymers, $[Ag(NCS)_2AsF_6]_n$—a metal complex with dithiocyanogen as ligand (C) 1006

$[Sb_3I_{10}^{\ominus}]_\infty$—a polymeric anion with transitions from trigonal pyramidal to octahedral coordination of antimony(III) (C) 825

Insecticides, Synthesis of bis(trifluoromethyl)-analogues of the pyrethroids (C) 184

Insertion, Transition metal-induced CO-insertion in the P=P bond of diphosphenes with formation of diphosphinomethanone derivatives (C) 755

Intellectual processing, Geometric and topological thinking in organic chemistry (R) 882

Ionic conduction, Fast ionic conduction in LiI·4methanol: $[Li(CH_3OH)_4]^+I^-$ (C) 1087

Iridium compounds, Prototropism in (pentamethylcyclopentadienyl)iridium complexes with pyrazole ligands (C) 1114

Thermolytically induced C-H activation using a 14-electron-complex: synthesis and molecular structure of $[IrHCl(C_6H_5)(PiPr_3)_2]$ (C) 1090

Unusual behavior of the stable paramagnetic dihydridoiridium(IV) complex $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ in solution (C) 460

Iridium-silver compounds, Synthesis and structure of $[(Ph_3P)_3Ir(\mu_3\text{-}H)(\mu\text{-}H)_2Ag_2(OSO_2CF_3)(H_2O)](CF_3SO_3)$, a complex with a bent Ag-Ir-Ag chain (C) 748

Iron(0) compounds, Bis(η^2-ethene)(η^6-toluene)iron (C) 831
CC Coupling of CO_2 and butadiene on iron(0) complexes—a novel route to α,ω-dicarboxylic acids (C) 810
Isocyanates, Transition-metal clusters as catalysts of unconventional reactions: reductive C–N coupling of alkyl isocyanates (C) 570
Valence isomers of compounds with geminal aryldiazene and isocyanate functions stabilized by protonation (C) 1132
Isocyanide radical, An isocyanide radical as complex ligand (C) 744
Isokinetic rate constant, Direct measurement of the "isokinetic rate constant" in additions of diarylcarbenium ions to 2-methyl-2-butene (C) 1016
Isolobal concept, The complex ions $[C_5H_5M(CO)_3]^{\ominus}$ (M = Mo, W) as 6e-ligands: Synthesis and molecular structure of $[(\eta^4\text{-}C_4Me_4)Co(\mu\text{-}CO)_3M(\eta^5\text{-}C_5H_5)]$ (M = Mo, W) (C) 839
The isolobal analogy "d^6-$CpM(CO)_3^{\ominus}$ ⟷ $Cp^{\ominus}$" (C) 837
Isomerization, Acid-catalyzed isomerization of the [2+1]-Cyclodimer of an iminophosphane to the diazadiphosphetidine (C) 834
An azimine-triaziridine transformation by laser photolysis (C) 828
Asymmetric double-bond isomerization of 4,7-dihydro- to 4,5-dihydro-1,3-dioxepins (C) 274
Carbyne-iridium complexes: evidence for an equilibrium between alkenylidene(hydrido) and carbyne isomers (C) 737
Diastereoselective transformations on heterometal clusters (C) 479
Reversible interconversion of C–C and C–N multiple bond systems on clusters (C) 279
Isomorphism of tris(cyclopentadienyl)lutetium(III) and tris(cyclopentadienyl)scandium(III): an unexpected consequence of the lanthanoid contraction (C) 656
(*R*)-2-Isopropenylcyclopropane-1,1-dicarboxylic acid: absolute configuration and stereospecific ring expansion of its dimethyl ester (C) 732
Isotope effects, Secondary deuterium kinetic isotope effects in enantioselective hydroborations with (+)-diisopinocampheylborane (C) 577

KEKULENE, Cyclo[*d.e.d.e.e.d.e.d.e.e.*]decakisbenzene, a new cycloarene (C) 742
Ketenyl ligand, Variable electron-donor ability of alkyne ligands—synthesis and structure of carbonyl(η^5-cyclopentadienyl)(η^2-1-diethylamino-1-propyne)(η^1-*p*-methylphenylketenyl)tungsten (C) 643
Ketones, Synthesis of cyclic, vicinal tetraketones (C) 449
Kinetic isotope effects, Secondary deuterium kinetic isotope effects in enantioselective hydroborations with (+)-diisopinocampheylborane (C) 577
Kinetic resolution, Complementary epoxide hydrolase- vs glutathione S-transferase-catalyzed kinetic resolution of simple aliphatic oxiranes—complete regio- and enantioselective hydrolysis of *cis*-2-ethyl-3-methyloxirane (C) 1032
Kinetics, Direct determination of rate constants for the addition of carbenium ions to alkenes (C) 89
Direct measurement of the "isokinetic rate constant" in additions of diarylcarbenium ions to 2-methyl-2-butene (C) 1016
Linear reactivity-selectivity correlations in additions of diarylcarbenium ions to alkenes; a rebuttal of the reactivity-selectivity principle (C) 1017
Techniques in organic reaction kinetics (B) 381
The phenol ⇌ 2,4-cyclohexadienone equilibrium in aqueous solution (C) 344
Kirk-Othmer concise encyclopedia of chemical technology (B) 194
Koenigs-Knorr method, New methods for the synthesis of glycosides and oligosaccharides—are there alternatives to the Koenigs-Knorr method? (R) 212

γ-LACTOLS, Diastereoselective synthesis of functionalized tetrahydrofuran derivatives from γ-lactols (C) 556
Langmuir-Blodgett-technique, Preparation of ultrathin layers of molecularly controlled architecture from polymeric phthalocyanines by the Langmuir-Blodgett-technique (C) 1105
Lanthanoid contraction, Isomorphism of tris(cyclopentadienyl)lutetium(III) and tris(cyclopentadienyl)scandium(III): an unexpected consequence of the lanthanoid contraction (C) 656
Lanthanum compounds, $[La\{(Ph_2P)_2CH\}_3]$—a homoleptic lanthanum complex with π-allyl-like coordinated diphosphinomethanide ligands (C) 823
Laser dyes, Charge separation in excited states of decoupled systems—TICT compounds and implications regarding the development of new laser dyes and the primary processes of vision and photosynthesis (R) 971
Laser photochemistry, UV/VIS Laser photochemistry: intermediary formation of diazoalkanes versus direct S_0,T_1 transitions in the photolysis of azoalkanes (C) 818
Laser photolysis, An azimine-triaziridine transformation by laser photolysis (C) 828
Laticyclic 1,5-conjugation between parallel, neighboring azo-groups and phenyl groups (C) 187
Layer systems, Preparation of ultrathin layers of molecularly controlled architecture from polymeric phthalocyanines by the Langmuir-Blodgett-technique (C) 1105
Ligands, $[Ag(NCS)_2AsF_6]_n$—a metal complex with dithiocyanogen as ligand (C) 1006
An isocyanide radical as complex ligand (C) 744
$Me_3SiNPNSiMe_3^{\ominus}$, the monophosphorus analogue of a triazenido ligand (C) 96
$[\{(\eta^5\text{-}C_5Me_5)Co\}_3C_{12}H_{10}]$—a complex of biphenyl with Kekulé structure (C) 646
$[La\{(Ph_2P)_2CH\}_3]$—a homoleptic lanthanum complex with π-allyl-like coordinated diphosphinomethanide ligands (C) 823
$[(C_3Ph_3)Ni(\mu\text{-}Br)_3Ni(C_3Ph_3)](C_3Ph_3)$—a triple-decker-like complex with triphenylcyclopropenyl as ligand (C) 833
Complex-induced fragmentation of As_4S_4: stabilization of an As_2S_3 ligand (C) 557
Formal insertion of the $HCO^{\oplus}$ fragment into a trinuclear cluster metal-carbyne bond: synthesis, structure and reactivity of cluster-bound ethynol (C) 929
$[Et_4N][M(SCH_2CH_2S)_3]$ (M = Nb, Ta), homoleptic 1,2-ethanedithiolate complexes of niobium and tantalum (C) 86
cyclo-P_5 as complex ligand—the phosphorus analogue of the cyclopentadienyl ligand (C) 363
η^3-1-Phosphaallyliron complexes with additional $W(CO)_5$-coordination at the phosphorus—the 1-phosphaallyl ligand as 5e-donor (C) 357
Novel octahedral Si and Ge complexes with a hexadentate diphenol ligand (C) 162
Prototropism in (pentamethylcyclopentadienyl)iridium complexes with pyrazole ligands (C) 1114
S_4N_4 as tridentate ligand in $[IrX(CO)(PPh_3)(S_4N_4)]$ complexes (C) 931
The complex ions $[C_5H_5M(CO)_3]^{\ominus}$ (M = Mo, W) as 6e-ligands: Synthesis and molecular structure of $[(\eta^4\text{-}C_4Me_4)Co(\mu\text{-}CO)_3M(\eta^5\text{-}C_5H_5)]$ (M = Mo, W) (C) 839
The isolobal analogy "d^6-$CpM(CO)_3^{\ominus}$ ⟷ $Cp^{\ominus}$" (C) 837
Weak Pd···S interaction in palladium(II) complexes with 1,4,7-trithiacyclononane as ligand (C) 1101
Ligand-to-metal charge transfer, Unusual behavior of the stable paramagnetic dihydridoiridium(IV) complex $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ in solution (C) 460
Liquid crystals, Bilayer-immobilized films containing mesogenic azobenzene amphiphiles—electrically controllable permeability (C) 751
Carbohydrate-based liquid crystals: mesogenic 1-*O*-alkyl derivatives of 2,5-anhydrohexitols (C) 368
Stabilization of carbenium ions in liquid crystals (C) 841
Lithioalkylsulfoximides, Lithium-coordinated α-sulfonimidoyl carbanions: crystal study of [(*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$·2(tmeda) and configurative stability of [(*N*-methyl-*S*-phenylsulfonimidoyl)isopropyllithium] (C) 938
2-Lithio-1-phenylpyrrole: X-ray structure analysis and ^6Li-^1H 2D heteronuclear Overhauser NMR spectroscopy (2D HOESY) (C) 1103
Lithium compounds, Vicinal dilithioalkenes by addition of lithium to simple cyclic and acyclic alkynes (C) 167
1,2-Dilithioethylene isomers and their mechanisms of interconversion: an ab initio study (C) 169
Lithium iodide, Fast ionic conduction in LiI·4methanol: $[Li(CH_3OH)_4]^+I^-$ (C) 1087
Lithium ketenimides, [(α-Cyanobenzyllithium·tetramethylethylenediamine)$_2$·benzene]: X-ray structure analysis of an α-nitrile "carbanion" (C) 373
Lithium-titanium exchange, α-Deprotonation of an α-chiral 2-alkenylcarbamate with retention and lithium-titanium exchange with inversion—the homoaldol reaction with 1,3-chirality transfer (C) 160
Living polymers, Group transfer polymerization of acrylic acid esters with alkylthio- or arylthiosilanes as initiators (C) 1108
Low-temperature matrices, Photochemistry of transition-metal atoms: reactions with molecular hydrogen and methane in low-temperature matrices (R) 1072
Lutetium-phosphane compounds, $[(Cp_2Lu\{\mu\text{-}PPh_2\}_2Li(tmeda)]\cdot 1/2\ C_6H_5CH_3$, the first organolanthanoid-phosphane compound to be characterized by X-ray structure analysis (C) 718

MACROBICYCLES, Large molecular cavities for small ions—double bridging of three bipyridine units (C) 1122
Macrobicyclic molecules, Anionic host molecules with bicyclic carbon skeletons—synthesis and guest inclusion in aqueous solution (C) 567
Synthesis of a macrobicyclic thiazolium-host and supramolecular catalysis of the benzoin condensation (C) 1125
Macrocycles, A macrobicyclic polyphenoxide as receptor analogue for choline and related ammonium compounds (C) 647
Bicyclic host cavities derived from triphenylamine—guest selectivity and redox properties (C) 336
Cope rearrangement induced by medium-sized ring strain (C) 1026
Electron donor-acceptor interactions in

host-guest complexes in organic solutions (C) 1127
(*Z*)-[6]Paracycloph-3-ene (C) 369
Porphycene—a novel porphin isomer (C) 257
Preorganization—from solvents to spherands (R) 1039
Macrolide antibiotics. Chemistry, biology and practice (B) 580
Total synthesis of mycinolide V, the aglycone of a macrolide antibiotic of the mycinamycin series (C) 1028
Magnesium L-aspartate complexes, Elucidation of the structure of pharmacologically active magnesium L-aspartate complexes (C) 1013
Magnesium therapy, Elucidation of the structure of pharmacologically active magnesium L-aspartate complexes (C) 1013
Magnetic phase transitions, Isothermal magnetic phase transitions controlled by reversible electron/ion transfer reactions (C) 905
Manganese(II) complexes, An α-functionalized organomanganese(II) derivative: a dinuclear manganese(II) complex with a σ-bonded α-thioalkyl ligand (C) 356
Manganese(II,III,IV) complexes, Dinuclear manganese(II,III,IV) model complexes for the active center of the metalloprotein photosystem II: synthesis, magnetism, and crystal structure of $[LMn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}L][ClO_4]_3$ (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) (C) 1030
Mangenese compounds, Oxygen evolution by water oxidation mediated by heterogeneous manganese complexes (C) 825
Mass spectrometry, Aminoacetylene and its mono- and dication—identification of potentially interstellar molecules (C) 827
Hydroxyacetylene: generation and characterization of the neutral molecule, radical cation and dication in the gas phase (C) 282
Mass spectral and GC data of drugs, poisons and their metabolites (B) 851
Materials science, 3-Chloropropyltrialkoxysilanes—key intermediates for the commercial production of organofunctionalized silanes and polysiloxane (R) 236
The chemistry of the noncrystalline state (R) 31
Membranes, Bilayer-immobilized films containing mesogenic azobenzene amphiphiles—electrically controllable permeability (C) 751
Synthetic polymer membranes. A structural perspective (B) 1134
Metabolites, The first evidence of endogenous pyridoxyl isoquinoline alkaloids in mammalian organisms (C) 177
Metal atoms, Photochemistry of transition-metal atoms: reactions with molecular hydrogen and methane in low-temperature matrices (R) 1072
Metal-carbon bond, The chemistry of the metal-carbon bond. Vol. 2: The nature and cleavage of carbon-metal bonds. Vol. 3: Carbon-carbon bond formation using organometallic compounds (B) 945
Metal-carbon triple bond, Stepwise addition of $MeS^{\oplus}$ to a metal-carbon triple bond—a new type of reaction in the chemistry of carbyne complexes (C) 904
Metallacycles, A simple route to ruthenacycloalkanes (C) 1008
Metallacyclobutanes, Metallacyclic four-membered ring systems: two independent routes to bis(cyclopentadienyl)titanacyclobutabenzene (C) 639
Metallaspiro compounds, Early members of a homologous series based on linked GeM_2 triangles, (M = Co, Fe): structures of $[Ge_2Co_4Fe_2(CO)_{21}]$ and $[Ge_3Co_8(CO)_{26}]$ (C) 759
Metal-ligand interactions, Weak Pd···S interaction in palladium(II) complexes with 1,4,7-trithiacyclononane as ligand (C) 1101
Metallocenophanes, [m.m]Metallocenophanes: synthesis, structure, and properties (R) 702
Metal-metal bond, The $\sigma^2\pi^4$ triple bond between molybdenum and tungsten atoms: developing the chemistry of an inorganic functional group (R) 21
Metal-metal bonds, Multiple bonds between transition metals and "bare" main group elements: links between inorganic solid state chemistry and organometallic chemistry (R) 56
Metal-metal double bond, Spontaneous intramolecular ring opening of the cyclopropyl group at a metal-metal double bond (C) 563
Synthesis and structure of $[(C_5Me_5)_2M_2Se_5]$: formation of a μ,η^2-tetraselenide ligand at the M-M double bond of $[(C_5Me_5)_2M_2(\mu\text{-}CO)_2]$ (M = Co, Rh) (C) 907
Metal-metal multiple bonding, A novel electron count and metal-metal multiple bonding in trigonal prismatic clusters (C) 822
Metal-metal triple bonds, The first observation of the equilibrium $2M{\equiv}M \rightleftarrows M_4$ (M = transition metal): synthesis and structure of hexaisopropoxyditungsten and its dimer (C) 1014
Metal-NMR-spectroscopy, High-resolution metal-NMR spectroscopy of organometallic compounds (R) 861
Metal-sulfur cluster, $[Re_4^{IV}S_{22}]^{4-}$, a highly symmetrical metal-sulfur cluster with six S_3^{2-} ligands (C) 272
Metaphosphate, Trithiometaphosphate PS_3^-—an anion with phosphorus of coordination number 3 (C) 82
Metathesis, Carbonyl olefinating carbene-tungsten complexes and their suitability as catalysts in olefin-metathesis (C) 909
Metathesis of alkyl radicals and alkenes—a novel elementary reaction of alkyl radicals (C) 80
The Schrock carbyne-complex $[Cl_3(dme)W{\equiv}CCMe_3]$, a highly reactive catalyst for the metathesis of alkenes (C) 359
Methylene, Photoisomerization of dihalomethanes (C) 819
11-Methylene-1,6-methano[10]annulene, Organic reactions at high pressure: cycloaddition reactions of 11-methylene-1,6-methano[10]annulene (C) 346
(−)-Methyl jasmonate, The use of (+)-8-phenylneomenthol in the synthesis of enantiomerically pure (−)-methyl jasmonate (C) 992
Methylvinylglyoxal, Divinylglyoxal and methylvinylglyoxal (C) 1116
Microcrystals, Cluster beam chemistry—from atoms to solids (R) 197
Mini-violerythrins: why can C_{38}-carotinoids be blue? (C) 1018
Mixed valence compounds, Dinuclear manganese(II,III,IV) model complexes for the active center of the metalloprotein photosystem II: synthesis, magnetism, and crystal structure of $[LMn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}L][ClO_4]_3$ (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) (C) 1030
Mixed valency gallium tellurohalides, E_3Te_3Hal, mixed valency tellurohalides of gallium and indium with one-dimensional structural units (C) 752
Molybdenum compounds, $(Me_4N)_3[Mo_4O_{12}F_3]\cdot 0.8H_2O$, a salt with a novel fluorooxo polyanion (C) 1104
Molybdenum-rhodium compound, $[Cp(CO)_2Mo\{NR^*[Rh(norbornadiene)]\text{-}CH(pyridyl)\}]$, a rhodium complex with an asymmetric molybdenum atom in the chelate skeleton (C) 371
Molybdenum-sulfur compounds, Synthesis and crystal structure of μ-thio-bis[tris(diethyldithiocarbamato)molybdenum(IV)-toluene 1:1, a compound containing a rare Mo-S-Mo core (C) 749
Morphine skeleton, Total synthesis of *rac*-salutaridine and sinoacutine ((−)-salutaridine)—a new route to the morphine skeleton (C) 1025
Multiple bonds between transition metals and "bare" main group elements: links between inorganic solid state chemistry and organometallic chemistry (R) 56
The $\sigma^2\pi^4$ triple bond between molybdenum and tungsten atoms: developing the chemistry of an inorganic functional group (R) 21
Mycinolide V, Total synthesis of mycinolide V, the aglycone of a macrolide antibiotic of the *mycinamycin* series (C) 1028
NAPROXEN, Asymmetric bromination of enantiomerically pure acetals of alkyl aryl ketones (C) 259
Natural compounds synthesis, Regioselective and atropoisomeric-selective aryl coupling to give naphthyl isoquinoline alkaloids: the first total synthesis of (−)-ancistrocladine (C) 913
Natural products, [3+2] Cycloaddition approaches to five-membered rings via trimethylenemethane and its equivalents (R) 1
The chemistry of natural products (B) 847
Total synthesis of natural products: the "chiron" approach (B) 113
Nickelacyclobutabenzene compounds by oxidative addition of cyclopropabenzene to nickel(0) compounds (C) 640
Nickelocene, Facile synthesis of pentaphenylnickelocene and other pentaphenylcyclopentadienylnickel and -cobalt complexes (C) 97
Nickelocene analogue, Bis(η^5-2,3,5-tricarbahexaboranyl)nickel, a nickelocene analogue (C) 1099
Niobium-niobium triple bond, $NaNb_3O_5F$—a niobium-niobium triple bond with "side-on" coordination by Nb atoms (C) 996
Nitrenes, ESR observation of thermally produced triplet nitrenes and photochemically produced triplet cycloheptatrienylidenes (C) 480
α-Nitrile "carbanion", [(α-Cyanobenzyllithium·tetramethylethylenediamine)$_2$·benzene]: X-ray structure analysis of an α-nitrile "carbanion" (C) 373
Nitrile ylides and azirines: gas-phase generation from 2,3-dihydro-1,4,2λ^5-oxazaphospholes and matrix isolation (C) 85
Nitrogen, Biological oxidation of nitrogen in organic molecules. Chemistry, toxicology and pharmacology (B) 850
Nitrogen fixation, Heterogeneous catalysis of ammonia synthesis at room temperature and atmospheric pressure (C) 558
Nitrogen-phosphorus ligands, $Me_3SiNPN\text{-}SiMe_3^{\ominus}$, the monophosphorus analogue of a triazenido ligand (C) 96
Nitrogen-silicon double bond, Diisopropyl(2,4,6-tri-*tert*-butylphenylimino)silane—a very stable, free silaimine (C) 649
Nitrogen-sulfur compounds, S_4N_4 as tridentate ligand in $[IrX(CO)(PPh_3)(S_4N_4)]$ complexes (C) 931
Nitromethane as d^1,d^1 multiple coupling reagent for the carbonyl dianion synthon. Practical synthesis of chalcogran (C) 941
NMR Spectroscopy, Applications of dynamic NMR spectroscopy to organic chemistry (B) 658
High-resolution metal-NMR spectroscopy of organometallic compounds (R) 861
The elucidation of the constitution of glycopeptides by the NMR spectroscopic *COLOC technique* (C) 342
2-Lithio-1-phenylpyrrole: X-ray structure

analysis and ^{6}Li-^{1}H 2D heteronuclear Overhauser NMR spectroscopy (2D HOESY) (C) 1103
^{15}N-NMR spectroscopy—new methods and applications (R) 383
Nobel lecture, A receptor-mediated pathway for cholesterol homeostasis (Nobel lecture) (R) 583
Direct methods and anomalous dispersion (Nobel lecture) (R) 603
Recovering phase information from intensity data (Nobel lecture) (R) 614
Nucleic acid structure, Principles of nucleic acid structure (B) 290
Nucleophilicity, 10,10'-Bi(trispiro[2.0.2.0.2.1]-decylidene): a highly nucleophilic olefinic hydrocarbon (C) 335

OLEFIN, 10,10'-Bi(trispiro[2.0.2.0.2.1]decylidene): a highly nucleophilic olefinic hydrocarbon (C) 335
Olefin-carbene complexes, Diels-Alder reactions at carbene ligands: a route to olefin-carbene complexes (C) 812
Olefin-iron compounds, Bis(η^2-ethene)(η^6-toluene)iron (C) 831
Oligonucleotides, A self-replicating hexadeoxynucleotide (C) 932
Oligonucleotide synthesis. A practical approach (B) 296
Oligosaccharides, New methods for the synthesis of glycosides and oligosaccharides—are there alternatives to the Koenigs-Knorr method? (R) 212
Opportunities in chemistry (B) 846
Orbital interactions, An intramolecular dyotropic hydrogen migration in pentacyclo[7.6.0.0^{2,13}.0^{3,8}.0^{10,14}]pentadeca-4,6,11-triene (C) 1121
Orbital interactions in chemistry (B) 581
Ordering of ionic solutes in dilute solutions through attraction of similarly charged solutes—a change of paradigm in colloid and polymer chemistry (R) 323
Organic chemistry, Geometric and topological thinking in organic chemistry (R) 882
Organic syntheses, Di- and trifluoro-substituted dilithium compounds for organic syntheses (C) 98
Strategies and tactics in organic synthesis (B) 292
Organocopper compounds, Selective synthesis by use of Lewis acids in the presence of organocopper and related reagents (R) 947
Organolanthanoid reagents, The alkylation of epoxides with new organoyttrium and organolanthanoid reagents (C) 760
Organomanganese(II) derivative, An α-functionalized organomanganese(II) derivative: a dinuclear manganese(II) complex with a σ-bonded α-thioalkyl ligand (C) 356
Organomercury compounds in organic synthesis (B) 943
Organometallic chemistry, Basic organometallic chemistry (B) 1035
Fundamental transition metal organometallic chemistry (B) 1035
Metallo-organic chemistry (B) 1035
Organometallic compounds, Dictionary of organometallic compounds (B) 765
Organometallic derivatives of epoxides (C) 653
Organotin reagents, The palladium-catalyzed cross-coupling reactions of organotin reagents with organic electrophiles (R) 508
Orthophosphates in the ternary system Al_2O_3-P_2O_5-H_2O (R) 525
Oxazolidines, Preparation of chiral building blocks from amino acids and peptides via electrolytic decarboxylation and $TiCl_4$-induced aminoalkylation (C) 843
Oxidation, Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: substrate complexation in oxidations with transition metal peroxides (C) 188
Oxidative stress, Biochemistry of oxidative stress (R) 1058
Oxirane, Ethylene oxide—X-ray structure analysis (at 150 K) and ab initio calculations (C) 276
μ-Oxo complexes, Dinuclear manganese(II,III,IV) model complexes for the active center of the metalloprotein photosystem II: synthesis, magnetism, and crystal structure of $[LMn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}L][ClO_4]_3$ (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) (C) 1030
Oxygen, Biochemistry of oxidative stress (R) 1058
Oxygen transfer, A simple access to 2-epoxy alcohols: titanium(IV)-catalyzed oxygen transfer from allylic hydroperoxides (C) 269
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: substrate complexation in oxidations with transition metal peroxides (C) 188
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: the nucleophilic character of carbonyl oxides (C) 101
Ozonides, A stable diozonide of a conjugated diene by ozonolysis of 2,3,4,5-tetramethyl-2,4-hexadiene on polyethylene (C) 81
Ozonolysis, A stable diozonide of a conjugated diene by ozonolysis of 2,3,4,5-tetramethyl-2,4-hexadiene on polyethylene (C) 81
Benzophenone *O*-oxide (C) 255

PALLADIUM-SULFUR COMPOUNDS, $[Pd_2S_{28}]^{4\ominus}$: a 30-membered cage containing an entrapped cation (C) 453
Paraconates, Stereocontrolled synthesis of paraconates from β-lactones; stereochemistry of electrophilic additions to endocyclic paraconate-enolates (C) 655
Paracyclophane complexes, Coordination-polymeric paracyclophane complexes of copper and silver (C) 1089
Paracyclophanediene, A simple route to the intramolecular quinhydrone of [2.2]paracyclophanediene (C) 171
(*Z*)-[6]Paracycloph-3-ene (C) 369
Pentagonal column, The pentagonal column and the ReO_3-type structure (R) 431
Pentaketones, Vicinal pentaketones (C) 999
Pentaphenylnickelocene, Facile synthesis of pentaphenylnickelocene and other pentaphenylcyclopentadienylnickel and -cobalt complexes (C) 97
Pentatetraenedicarboxylate, Wittig reaction with carbon suboxide: synthesis of dimethyl 1,5-diphenyl-1,2,3,4-pentatetraenedicarboxylate (C) 93
Pentatetraenes, Structure determination of pentatetraenes—comparison of the structures of cumulenes (C) 340
Pentenetriols, Synthesis of *erythro*-D- and -L-4-pentenetriols. Selective epoxy allyl alcohol hydrolysis with retention or twofold inversion (enantiomerization) (C) 87
Peptide synthesis, The ferrocenylmethyl-(Fem) group as a highly lipophilic and chromophoric group for the masking of peptide bonds (C) 159
Periodic potential surfaces in crystal structures (C) 110
Phanes, A simple route to the intramolecular quinhydrone of [2.2]paracyclophanediene (C) 171
Coordination-polymeric paracyclophane complexes of copper and silver (C) 1089
[2.2]Indenophane dianion: a novel double-layered dianion (C) 174
Pharmacology, Physicochemical and cytochemical investigations on the binding of ethidium and acridine dyes to DNA and to organelles in living cells (R) 115
Phase-transfer catalysis, Enantioselective Robinson annelations via phase-transfer catalysis (C) 476
Hydroxide ion initiated reactions under phase transfer catalysis conditions: mechanism and implications (R) 960
Phenanthrene derivatives, 4,5-Bis(dimethylamino)phenanthrene and 4,5-bis(dimethylamino)-9,10-dihydrophenanthrene: syntheses and "proton sponge" properties (C) 451
Phenol ⇌ 2,4-cyclohexadienone, The phenol ⇌ 2,4-cyclohexadienone equilibrium in aqueous solution (C) 344
[3]Phenylene, Novel synthesis of the angular [3]phenylene (terphenylene) by cobalt-catalyzed cyclization of bis(2-ethynylphenyl)ethyne: a molecule with an internal cyclohexatriene ring (C) 266
(+)-8-Phenylneomenthol, The use of (+)-8-phenylneomenthol in the synthesis of enantiomerically pure (−)-methyl jasmonate (C) 992
α-(Phenylsulfonyl)allyllithium, Solid-state and solution structure of α-(phenylsulfonyl)allyllithium (C) 939
1-Phospha-1-alkenes, A 2-phosphonio-substituted 1-phospha-1-alkene: resonance between P^{III} alkene and P^{V} ylide (C) 454
Phosphorus analogues of unsaturated carbon compounds: an (*s-trans*)-1,3-diphospha-4-metallabutadiene and its (*s-cis*)-$Fe(CO)_3$ complex (C) 455
Phosphaalkenes, Dioxides of *C*-amino-substituted phosphaalkenes and phosphaallyl cations (C) 457
Phosphaalkynes, 1,3-Diphosphacyclobutadienecobalt(I) complexes from phosphaalkynes (C) 644
Phosphaallyl cations, Dioxides of *C*-amino-substituted phosphaalkenes and phosphaallyl cations (C) 457
η^3-1-Phosphaallyliron complexes with additional $W(CO)_5$-coordination at the phosphorus—the 1-phosphaallyl ligand as 5e-donor (C) 357
1-Phosphaallyl ligand, η^3-1-Phosphaallyliron complexes with additional $W(CO)_5$-coordination at the phosphorus—the 1-phosphaallyl ligand as 5e-donor (C) 357
Phosphabenzene derivative, A $1\lambda^5,3\lambda^5,5\lambda^3$-triphosphabenzene derivative (C) 1002
Phosphabutadiene, Synthesis of the first triphosphabutadiene (C) 932
1-Phospha-1,2,3-butatrienes (C) 1003
Phosphanes, New products from PCl_3, $P(NMe_2)_3$, and $AlCl_3$ (C) 253
2-Phosphapropene, $H_3C{-}P{=}CH_2$: an ylide with two-coordinate phosphorus? (C) 265
Phosphates, Orthophosphates in the ternary system Al_2O_3-P_2O_5-H_2O (R) 525
Phosphazene, A transition metal atom as building block of a cyclic phosphazene—synthesis and structure of $[Cl_3WN_3(PPh_2)_2]$ (C) 477
Phosphinines, 2-Dewar phosphinines—a new class of compounds containing two-coordinate phosphorus (C) 280
Phosphinoallenes, Tetrakis(diphenylphosphino)allene (C) 348
Phosphonium ylides, Reaction of phosphonium ylides with alkyldichloroboranes (C) 559
Phosphorus homocycles, *cyclo*-P_5 as complex ligand—the phosphorus analogue of the cyclopentadienyl ligand (C) 363
Phosphorus-tungsten double bond, Synthesis, structure, and addition reactions of $[Cp(CO)_2W{=}PR_2]$, R = *i*Pr, *t*Bu (C) 92
Photochemistry, Flash photolysis of $Os(CO)_5$ in benzene solution. Detection of $Os(CO)_4$·benzene by fast time-resolved IR spectroscopy (C) 991
Photochemistry of transition-metal atoms: reactions with molecular hydrogen and

methane in low-temperature matrices (R) 1072
Synthetic organic photochemistry (B) 381
185-nm photochemistry of olefins, strained hydrocarbons, and azoalkanes in solution (R) 661
Photochromic systems, Dihydropyrazolopyridine and bis(dihydroindolizine)—novel mono- and bifunctional photochromic systems (C) 572
Photocycloaddition, Asymmetric photocycloadditions with optically pure, spirocyclic enones. Simple synthesis of (+)- and (−)-grandisol (C) 1117
Photoisomerization of dihalomethanes (C) 819
Photolysis, UV/VIS Laser photochemistry: intermediary formation of diazoalkanes versus direct S_0,T_1 transitions in the photolysis of azoalkanes (C) 818
Photosynthesis, Remarkable ease of ring oxidation in cerium(IV) bisporphyrinates with double-decker structure (C) 286
Phthalocyanines, Preparation of ultrathin layers of molecularly controlled architecture from polymeric phthalocyanines by the Langmuir-Blodgett-technique (C) 1105
Physical chemistry, Vom Würfelspiel zum Naturgesetz. Simulation und Modelldenken in der Physikalischen Chemie (B) 581
Phytotoxicity, Model experiments on the phytotoxicity of halogenated hydrocarbons (C) 808
Polarity, Solvent polarity and the anomeric effect (C) 287
Pollution, Air pollution and plants (B) 850
Pollution problems, Microbial degradation of halogenated hydrocarbons: a biological solution to pollution problems? (R) 779
Polyadamantanoid structure, The three-dimensionally non-molecular polyadamantanoid structure of $Cd(SPh)_2$ (C) 165
Polyanions, $[Cu_{36}I_{56}]^{20\ominus}$—a novel polyanion in the compound $(pyH)_2[Cu_3I_5]$ (C) 569
Poly(anthrylenetrimethylene) and 9,10-bridged anthracenes by reductive alkylation (C) 444
Polycations, Poly-onio-substituted quinones as strong electron acceptors (C) 917
Polycyclic aromatic compounds, Spectral atlas of polycyclic aromatic compounds (B) 379
Polycyclophosphane oxides, P_6tBu_4O and P_7tBu_5O—the first polycyclophosphane oxides (C) 471
Polydecker sandwich compounds, Polymeric (η^5,μ-2,3-dihydro-1,3-diborolyl)-nickel—the first polydecker sandwich compound (C) 105
Polyenes, A novel entry to dendralene systems (C) 578
Polylithium compounds, 1,2-Dilithioethylene isomers and their mechanisms of interconversion: an ab initio study (C) 169
Polymer chemistry, Ordering of ionic solutes in dilute solutions through attraction of similarly charged solutes—a change of paradigm in colloid and polymer chemistry (R) 323
Polymerization, Group transfer polymerization of acrylic acid esters with alkylthio- or arylthiosilanes as initiators (C) 1108
Polymers, Photochemical conversion and stabilization of polymers (B) 852
Polyphenoxide, A macrobicyclic polyphenoxide as receptor analogue for choline and related ammonium compounds (C) 647
Polypyrrole films, Ferrocene-modified polypyrrole films by electrochemical copolymerization (C) 180
Polysiloxanes, 3-Chloropropyltrialkoxysilanes—key intermediates for the commercial production of organofunctionalized silanes and polysiloxanes (R) 236
Polysulfanes, The polymeric silver complexes $[Ag\{S_n(CN)_2\}_2][AsF_6]$ (n = 3, 4): stable coordination compounds of dicyano-tri- and dicyanotetrasulfanes (C) 84
Polysulfido complexes, $[Bi_2^{III}S_{34}]^{4-}$, the hitherto sulfur-richest complex (C) 273
$[Pd_2S_{28}]^{4\ominus}$: a 30-membered cage containing an entrapped cation (C) 453
Polythioethers, A simple route to 2,3,11,12-dibenzo-1,4,7,10,13,16-hexathia-2,11-cyclooctadiene (hexathiobenzo[18]crown-6) (C) 1107
Porphin isomer, Porphycene—a novel porphin isomer (C) 257
Porphycene—a novel porphin isomer (C) 257
Porphyrin analogue, Synthesis of a fourfold enlarged porphyrin with an extremely large, diamagnetic ring-current effect (C) 1100
Porphyrinates, Remarkable ease of ring oxidation in cerium(IV) bisporphyrinates with double-decker structure (C) 286
Porphyrins, Reduced cobalt-*meso*-tetraphenylporphyrin complexes: synthesis and structure of $[Na(thf)_3]_2[Co(TPP)]$ (C) 553
Potential surfaces, Periodic potential surfaces in crystal structures (C) 110
Preorganization—from solvents to spherands (R) 1039
Protecting groups, Synthesis of the all-L-configurated cyclotetradepsipeptide *cyclo* [-L-Val-L-Lac-]$_2$ by the combined protection/activation method with the 2,4-bis(methylthio)phenoxycarbonyl group (C) 170
The ferrocenylmethyl(Fem) group as a highly lipophilic and chromophoric group for the masking of peptide bonds (C) 159
Protein crystallography and computer graphics—toward rational drug design (R) 767
Proteins, High-pressure liquid chromatography (HPLC) of proteins (R) 535
Proton sponge, 4,5-Bis(dimethylamino)phenanthrene and 4,5-bis(dimethylamino)-9,10-dihydrophenanthrene: syntheses and "proton sponge" properties (C) 451
Prototropism in (pentamethylcyclopentadienyl)iridium complexes with pyrazole ligands (C) 1114
Psychosines, Synthesis of glycosphingolipids and psychosines (C) 725
Pyrazolopyridine, Dihydropyrazolopyridine and bis(dihydroindolizine)—novel mono- and bifunctional photochromic systems (C) 572
Pyrethroids, Synthesis of bis(trifluoromethyl)-analogues of the pyrethroids (C) 184
Pyridoxyl isoquinoline alkaloids, The first evidence of endogenous pyridoxyl isoquinoline alkaloids in mammalian organisms (C) 177

QUINHYDRONES, A simple route to the intramolecular quinhydrone of [2.2]paracyclophanediene (C) 171
Quinone bisketals, Carbene complexes with quinone bisketal functions (C) 911
Quinones, Poly-onio-substituted quinones as strong electron acceptors (C) 917
Quintet state, ^{13}C-ENDOR investigation of an organic tetraradical in the quintet state; synthesis of a fourfold ^{13}C-labeled tetrakisgalvinol (C) 1097

RADICAL ANION SALT, A radical anion salt of 2,5-dimethyl-*N*,*N*′-dicyanoquinonediimine with extremely high electrical conductivity (C) 740
Radical cation salts, ζ-$(ET)_2AuBr_2$, a new type of structure for the organic radical cation salts $(ET)_2AuX_2$ (C) 727
t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$, organic radical cation salts with twist structure (C) 729
Radical chain reaction, Thermally induced redox reaction of carbonyl compounds and alcohols in a radical chain reaction: comproportionation to two hydroxyalkyl radicals (C) 762
Radical reaction, Synthesis of "*C*-disaccharides" by radical C–C bond formation (C) 450
Radicals, ^{13}C-ENDOR investigation of an organic tetraradical in the quintet state; synthesis of a fourfold ^{13}C-labeled tetrakisgalvinol (C) 1097
Raft structure, Synthesis of $[Cu_3Os_3H_9(PMe_2Ph)_9]$, a bimetallic raft, by reductive elimination of alcohol or H_2 (C) 262
Raman spectroscopy, Resonance Raman spectroscopy and its application to inorganic chemistry (R) 131
Rate constants, Direct determination of rate constants for the addition of carbenium ions to alkenes (C) 89
Reaction dynamics, Understanding reaction dynamics in coordination chemistry—application of high pressure techniques (R) 673
Reaction mechanism, Mechanism of the thermal 1,3-cyclohexadiene dimerization: a non-concerted Diels-Alder reaction leading to the *exo*-[4+2] adduct and a novel [6+4]-ene reaction (C) 108
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: substrate complexation in oxidations with transition metal peroxides (C) 188
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: the nucleophilic character of carbonyl oxides (C) 101
Reactive intermediates, Reactive molecules. The neutral reactive intermediates in organic chemistry (B) 295
Reactivity-selectivity correlations, Linear reactivity-selectivity correlations in additions of diarylcarbenium ions to alkenes; a rebuttal of the reactivity-selectivity principle (C) 1017
Rearrangements, Rearrangement of 4*H*-1,2,4-triazolium salts to 4-acyl-5-aminoimidazoles (C) 652
Skeletal rearrangements on clusters: the reaction of $[(tBuP)Fe_3(CO)_{10}]$ with diphenylacetylene (C) 1119
Tandem walk rearrangement of a protonated dicyclopropenyl ketone (C) 1093
Tricyclo[5.3.0.0^{2,8}]deca-3,5-dien-9-one and a new route to $C_{10}H_{10}$ isomers (C) 906
Receptor analogue, A macrobicyclic polyphenoxide as receptor analogue for choline and related ammonium compounds (C) 647
Receptors, Second-sphere coordination—a novel rôle for molecular receptors (R) 487
Redox agents, Indirect electroorganic syntheses—a modern chapter of organic electrochemistry (R) 683
Redox properties, Synthesis and redox properties of compounds with several separated anthracene electrophores (C) 443
Redox reaction, Thermally induced redox reaction of carbonyl compounds and alcohols in a radical chain reaction: comproportionation to two hydroxyalkyl radicals (C) 762
Reductions in organic chemistry (B) 579
Stereospecific reductions with hydrogen gas, modified metal catalysts, methyl viologen and enzymes or microorganisms (C) 462
Reductive carbonylation of high-valent oxorhenium complexes—a new route to low-valent carbonylrhenium compounds (C) 817
Reductive coupling of CO: formation of a 1:1 adduct of η^2-ketone- and enediolato-

complex upon carbonylation of bis(cyclopentadienyl)hafnacyclobutane (C) 364
Regioselective arylchlorination, Pd^{II}-catalyzed regioselective arylchlorination and oxyarylation of unsaturated alcohols (C) 735
Replication, A self-replicating hexadeoxynucleotide (C) 932
Resonance Raman spectroscopy and its application to inorganic chemistry (R) 131
Retinal, Influence of external negative charges on the absorption maxima of symmetrical cyanines. A study with model compounds and artificial bacteriorhodopsin pigments (C) 284
Reversible interconversion of C-C and C-N multiple bond systems on clusters (C) 279
Rhenamolybdatetrahedranes, Directed synthesis of rhenamolybdatetrahedranes: nucleophilic addition of pentacarbonylrhenate(1-) to alkyne ligands in cationic molybdenum complexes (C) 734
Rhenium compounds, Reductive carbonylation of high-valent oxorhenium complexes—a new route to low-valent carbonylrhenium compounds (C) 817
Rhenium hydrides, Hexahydrido(pentamethylcyclopentadienyl)rhenium, $[(C_5Me_5)ReH_6]$ (C) 1092
Rhenium-trioxide type structure, The pentagonal column and the ReO_3-type structure (R) 431
Ring expansion, (*R*)-2-Isopropenylcyclopropane-1,1-dicarboxylic acid: absolute configuration and stereospecific ring expansion of its dimethyl ester (C) 732
Ring opening, Spontaneous intramolecular ring opening of the cyclopropyl group at a metal-metal double bond (C) 563
Robinson annelations, Enantioselective Robinson annelations via phase-transfer catalysis (C) 476
Ruthenacycloalkanes, A simple route to ruthenacycloalkanes (C) 1008
Ruthenium compounds, O_2-Generation by oxidation of water with di- and trinuclear ruthenium complexes as homogeneous and heterogeneous catalysts (C) 1009

SALUTARIDINE, Total synthesis of *rac*-salutaridine and sinoacutine ((−)-salutaridine)—a new route to the morphine skeleton (C) 1025
SAMP Hydrazones, Enantioselective synthesis of α-substituted primary amines by nucleophilic addition to aldehyde-SAMP hydrazones (C) 1109
Sandwich anions, Synthesis of anionic triple-decker complexes having closed 30e valence shells by stacking of sandwich anions with $Cr(CO)_3$ fragments (C) 165
Sandwich complexes, Bis(η^5-2,3,5-tricarbahexaboranyl)nickel, a nickelocene analogue (C) 1099
$[C_6H_3(CH_3)_3][BiCl_3]$ and $[C_6(CH_3)_6][BiCl_3]_2$, arene complexes of bismuth with half-sandwich and "inverted" sandwich structures (C) 757
Polymeric (η^5,μ-2,3-dihydro-1,3-diborolyl)nickel—the first polydecker sandwich compound (C) 105
Synthesis of diindenyldivanadium—a new variant of the reductive degradation of metallocenes and related compounds (C) 928
Schrock carbyne-complex, The Schrock carbyne-complex $[Cl_3(dme)W{\equiv}CCMe_3]$, a highly reactive catalyst for the metathesis of alkenes (C) 359
Second-sphere coordination—a novel rôle for molecular receptors (R) 487
Selectivity, Bicyclic host cavities derived from triphenylamine—guest selectivity and redox properties (C) 336
Regioselective and atropoisomeric-selective aryl coupling to give naphthyl isoquinoline alkaloids: the first total synthesis of (−)-ancistrocladine (C) 913
Synthesis of deoxyhexoses from divinylglycols—the synthesis of D- and L-chalcose (C) 89
Synthesis of *erythro*-D- and -L-4-pentenetriols. Selective epoxy allyl alcohol hydrolysis with retention or twofold inversion (enantiomerization) (C) 87
Selenide ligand, Synthesis and structure of $[(C_5Me_5)_2M_2Se_5]$: formation of a μ,η^2-tetraselenide ligand at the M-M double bond of $[(C_5Me_5)_2M_2(\mu\text{-}CO)_2]$ (M = Co, Rh) (C) 907
Selenium-sulfur compounds, Selenium-rich chalcogen rings Se_5S, Se_5S_2, and Se_7 from titanocene pentaselenide (C) 99
Selenoaldehydes, [4+2] Cycloadditions with transition-metal-coordinated selenoaldehydes and selenoketones as heterodienophiles (C) 78
Selenocarbonyl ylides, Stable selenocarbonyl ylides (C) 183
Selenoketones, [4+2] Cycloadditions with transition-metal-coordinated selenoaldehydes and selenoketones as heterodienophiles (C) 78
Selenonium ions, Tris(pentacarbonylrhenium)-sulfonium, -selenonium, and -telluronium ions: synthesis and structure of $[\{(OC)_5Re\}_3E]^{\oplus}BF_4^{\ominus}$ (E = S, Se, Te) (C) 270
Self-replication, A self-replicating hexadeoxynucleotide (C) 932
Semiconductors, Molecular semiconductors. Photoelectrical properties and solar cells (B) 851
Semiochemistry, Mammalian semiochemistry. The investigation of chemical signals between mammals (B) 296
Signal agents, Mammalian semiochemistry. The investigation of chemical signals between mammals (B) 296
Silaaromaticity, Si_6H_6: Is the aromatic structure the most stable one? (C) 651
Silaimine, Diisopropyl(2,4,6-tri-*tert*-butylphenylimino)silane—a very stable, free silaimine (C) 649
Silanediyl, Decamethylsilicocene—synthesis and structure (C) 164
Silanes, The tetrasilabicyclo[1.1.0]butane system: structure of 1,3-di-*tert*-butyl-2,2,4,4-tetrakis-(2,6-diethylphenyl)tetrasilabicyclo[1.1.0]butane (C) 173
3-Chloropropyltrialkoxysilanes—key intermediates for the commercial production of organofunctionalized silanes and polysiloxanes (R) 236
Silica gel, Reaction of Grignard reagents with dianionic hexacoordinated silicon complexes: organosilicon compounds from silica gel (C) 474
Silicocene, Decamethylsilicocene—synthesis and structure (C) 164
Silicon complexes, Novel octahedral Si and Ge complexes with a hexadentate diphenol ligand (C) 162
Reaction of Grignard reagents with dianionic hexacoordinated silicon complexes: organosilicon compounds from silica gel (C) 474
Reactivity of anionic pentacoordinated silicon complexes towards nucleophiles (C) 473
Silicon compounds, Si_6H_6: Is the aromatic structure the most stable one? (C) 651
Silicon-silicon bonds, Hexa-*tert*-butyl-1,3-diiodotrisilane, a molecule with two neighboring very long Si-Si bonds (C) 1129
Hexa-*tert*-butyldisilane—the molecule with the longest Si-Si bond (C) 79
Silicon tetrahedrons, Red, transparent alkali metal silicides with Si_4 tetrahedrons (C) 566
Silver complexes, The polymeric silver complexes $[Ag\{S_n(CN)_2\}_2][AsF_6]$ (n = 3, 4): stable coordination compounds of dicyano-tri- and dicyanotetrasulfanes (C) 84
Silver oxide, Ag_3O_4, the first silver(II,III) oxide (C) 77
Silylamines, The structure of chlorosilyl-*N*,*N*-dimethylamine in the gaseous and solid phases (C) 107
Singlet oxygen, $[_\pi2+_\pi2]$ Cycloaddition of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione and singlet oxygen to homofuran (C) 989
Sinoacutine, Total synthesis of *rac*-salutaridine and sinoacutine ((−)-salutaridine)—a new route to the morphine skeleton (C) 1025
Skeletal rearrangements on clusters: the reaction of $[(t\text{BuP})Fe_3(CO)_{10}]$ with diphenylacetylene (C) 1119
Solid state chemistry, Cluster beam chemistry—from atoms to solids (R) 197
Fast ionic conduction in LiI·4methanol: $[Li(CH_3OH)_4]^+I^-$ (C) 1087
Isothermal magnetic phase transitions controlled by reversible electron/ion transfer reactions (C) 905
Multiple bonds between transition metals and "bare" main group elements: links between inorganic solid state chemistry and organometallic chemistry (R) 56
Solution structure, Ordering of ionic solutes in dilute solutions through attraction of similarly charged solutes—a change of paradigm in colloid and polymer chemistry (R) 323
Solvent polarity and the anomeric effect (C) 287
Somatostatin, Conformational prerequisites for the in vitro inhibition of cholate uptake in hepatocytes by cyclic analogues of antamanide and somatostatin (C) 997
Spectral atlas of polycyclic aromatic compounds (B) 379
Spectroscopy, Structure and spectra of molecules (B) 484
Spherands, Preorganization—from solvents to spherands (R) 1039
Stacking, ζ-$(ET)_2AuBr_2$, a new type of structure for the organic radical cation salts $(ET)_2AuX_2$ (C) 727
E_3Te_3Hal, mixed valency tellurohalides of gallium and indium with one-dimensional structural units (C) 752
t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$, organic radical cation salts with twist structure (C) 729
Star clusters, Heteronuclear 'star clusters': $[Ni_2Pt_2W_4(\mu_3\text{-}CPh)_4(CO)_8(\eta\text{-}C_5H_5)_4]$ and $[Ni_2Pt_2W_4(\mu_2\text{-}CR)(\mu_3\text{-}CR)_3(CO)_8(\eta\text{-}C_5H_5)_4]$ (R = Ph or *p*-C_6H_4Me) (C) 190
Stereochemistry of heterogeneous metal catalysis (B) 944
Stereocontrolled synthesis of paraconates from β-lactones; stereochemistry of electrophilic additions to endocyclic paraconate-enolates (C) 655
Stereospecific reductions with hydrogen gas, modified metal catalysts, methyl viologen and enzymes or microorganisms (C) 462
Stereospecific ring expansion, (*R*)-2-Isopropenylcyclopropane-1,1-dicarboxylic acid: absolute configuration and stereospecific ring expansion of its dimethyl ester (C) 732
Strain theory, Adolf von Baeyer's scientific achievements — a legacy (R) 297
The concept of strain in organic chemistry (R) 312
Stress, Biochemistry of oxidative stress (R) 1058
Stripping analysis. Principles, instrumentation, and applications (B) 485
Strontium alkoxostannates(II), Strontium and barium alkoxostannates(II)—molecules with S_6 symmetry (C) 375
Structural comparison, The structure of chlorosilyl-*N*,*N*-dimethylamine in the gaseous and solid phases (C) 107
Solid-state and solution structure of α-(phenylsulfonyl)allyllithium (C) 939
Style guide, The ACS style guide (B) 942
Style manual, The chemist's English (B) 378

Sugars, Synthesis of long-chain sugars by iterative, diastereoselective homologation of 2,3-*O*-isopropylidene-D-glyceraldehyde with 2-trimethylsilylthiazole (C) 835
α-Sulfinyl "carbanions", [α-(Phenylsulfinyl)-α-methylbenzyllithium-tetramethylethylenediamine]$_2$: crystal structure of an α-sulfinyl "carbanion" (C) 1011
Sulfones, Solid-state and solution structure of α-(phenylsulfonyl)allyllithium (C) 939
α-Sulfonimidoyl carbanions, Lithium-coordinated α-sulfonimidoyl carbanions: crystal study of [(*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$·2(tmeda) and configurative stability of [(*N*-methyl-*S*-phenylsulfonimidoyl)isopropyllithium] (C) 938
Sulfonium ions, Tris(pentacarbonylrhenium)-sulfonium, -selenonium, and -telluronium ions: synthesis and structure of $[\{(OC)_5Re\}_3E]^{\oplus}BF_4^{\ominus}$ (E = S, Se, Te) (C) 270
Sulfoximides, Asymmetric elimination with high induction: synthesis of 1-alkenylsulfoximides with axial and central chirality (C) 935
Lithium-coordinated α-sulfonimidoyl carbanions: crystal study of [(*S*)-(*N*-methyl-*S*-phenylsulfonimidoyl)methyllithium]$_4$·2(tmeda) and configurative stability of [(*N*-methyl-*S*-phenylsulfonimidoyl)isopropyllithium] (C) 938
Sulphur compounds, The structure of volatile sulphur compounds (B) 946
Superacids (B) 486
Superclusters, Novel modifications of gold, rhodium, and ruthenium—M_{13} clusters as building blocks of "superclusters" (C) 922
Superconduction, ζ-$(ET)_2AuBr_2$, a new type of structure for the organic radical cation salts $(ET)_2AuX_2$ (C) 727
Supramolecules, Second-sphere coordination—a novel rôle for molecular receptors (R) 487
Surface reactions, Reversible interconversion of C–C and C–N multiple bond systems on clusters (C) 279
Synthetic building blocks, Optically active cyclopentanediol synthetic building blocks from tartaric acid (C) 994
Synthetic methods, [3 + 2] Cycloaddition approaches to five-membered rings via trimethylenemethane and its equivalents (R) 1
Hydroxide ion initiated reactions under phase transfer catalysis conditions: mechanism and implications (R) 960
Indirect electroorganic syntheses—a modern chapter of organic electrochemistry (R) 683
New methods for the synthesis of glycosides and oligosaccharides—are there alternatives to the Koenigs-Knorr method? (R) 212
Organic synthesis at high temperatures. Gas-phase flow thermolysis (R) 414
Selective synthesis by use of Lewis acids in the presence of organocopper and related reagents (R) 947
The palladium-catalyzed cross-coupling reactions of organotin reagents with organic electrophiles (R) 508
Total synthesis of anthracyclinones (R) 790

TANDEM WALK RERANGEMENT of a protonated dicyclopropenyl ketone (C) 1093
T-antigen, Synthesis of *O*-glycopeptides of the tumor-associated T_N- and T-antigen type and their binding to bovine serum albumin (C) 360
Technetium cluster anions, A novel electron count and metal-metal multiple bonding in trigonal prismatic clusters (C) 822
Telluronium ions, Tris(pentacarbonylrhenium)-sulfonium, -selenonium, and -telluronium ions: synthesis and structure of $[\{(OC)_5Re\}_3E]^{\oplus}BF_4^{\ominus}$ (E = S, Se, Te) (C) 270
Terphenylene, Novel synthesis of the angular [3]phenylene (terphenylene) by cobalt-catalyzed cyclization of bis(2-ethynylphenyl)ethyne: a molecule with an internal cyclohexatriene ring (C) 266
Tetra-*tert*-butyl-*s*-indacene, Synthesis and properties of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene (C) 630
Tetrahydrofuran derivatives, Diastereoselective synthesis of functionalized tetrahydrofuran derivatives from γ-lactols (C) 556
Tetraiodocyclopropene, *cyclo*-C_3I_4—the first saltlike halocarbon (C) 103
Tetraketones, Synthesis of cyclic, vicinal tetraketones (C) 449
Tetrakis(dimethylamino)benzene, 1,2,4,5-Tetrakis(dimethylamino)benzene, a new electron donor with unusual properties (C) 1023
Tetrakis(diphenylphosphino)allene (C) 348
Tetrakisgalvinol, ^{13}C-ENDOR investigation of an organic tetraradical in the quintet state; synthesis of a fourfold ^{13}C-labeled tetrakisgalvinol (C) 1097
Tetrakismethano[24]annulene, Nickel-induced cyclotetramerization of cyclopropabenzene to 1,6:7,12:13,18:19,24-tetrakismethano[24]annulene (C) 367
Tetraselenide ligand, Synthesis and structure of $[(C_5Me_5)_2M_2Se_5]$: formation of a μ,η^2-tetraselenide ligand at the M–M double bond of $[(C_5Me_5)_2M_2(\mu\text{-}CO)_2]$ (M = Co, Rh) (C) 907
Tetrasilabicyclo[1.1.0]butane system, The tetrasilabicyclo[1.1.0]butane system: structure of 1,3-di-*tert*-butyl-2,2,4,4-tetrakis(2,6-diethylphenyl)tetrasilabicyclo[1.1.0]-butane (C) 173
Thermodynamics, Thermodynamik irreversibler Prozesse. Eine Einführung (B) 659
Thermolysis, Organic synthesis at high temperatures. Gas-phase flow thermolysis (R) 414
Thiacyclooctadecane, Palladium(II) and platinum(II) complexes of 1,4,7,10,13,16-hexathiacyclooctadecane (C) 274
1-Thia-2-cyclooctyne —a strained cycloalkyne with polarized triple bond (C) 809
Thiadiphosphole, A stable 1,2,4-thiadiphosphole ("2,4-diphosphathiophene") (C) 567
Thianthrene 5-oxide as mechanistic probe in oxygen transfer reactions: substrate complexation in oxidations with transition metal peroxides (C) 188
The nucleophilic character of carbonyl oxides (C) 101
Thiazepine, A stable monocyclic 1,4-thiazepine: synthesis and characterization of 2,7-di-*tert*-butyl-5-methoxy-1,4-thiazepine (C) 635
Thiazolium compounds, Synthesis of a macrobicyclic thiazolium-host and supramolecular catalysis of the benzoin condensation (C) 1125
Thiepin, A stable monocyclic 1,4-thiazepine: synthesis and characterization of 2,7-di-*tert*-butyl-5-methoxy-1,4-thiazepine (C) 635
Thiirane *S*-oxide, Complex stabilization of disulfur dioxide in the fragmentation of thiirane *S*-oxide on bis(triphenylphosphane)platinum(0) (C) 261
Thin layer chromatography, Thin layer chromatographic separation of stereoisomeric dipeptides (C) 278
Thioethers, A simple route to 2,3,11,12-dibenzo-1,4,7,10,13,16-hexathia-2,11-cyclooctadiene (hexathiobenzo[18]crown-6) (C) 1107
Thioketone *S*-oxides by [2 + 2]-cycloaddition of ynamines to *N*-sulfinyltosylamide (C) 459
Thiometalates, $[Cl_7Cu_5(ReS_4)]^{3\ominus}$, a hexanuclear complex anion with double cubane-like structure (C) 990
TICT Compounds, Charge separation in excited states of decoupled systems—TICT compounds and implications regarding the development of new laser dyes and the primary processes of vision and photosynthesis (R) 971
Tin chemicals, The industrial uses of tin chemicals (B) 944
Titanium compounds, A polyfunctional dititanacyclobutane (C) 574
Metallacyclic four-membered ring systems: two independent routes to bis(cyclopentadienyl)titanacyclobutabenzene (C) 639
Topology, Geometric and topological thinking in organic chemistry (R) 882
Toxicology, Analytical methods in human toxicology (B) 485
Mass spectral and GC data of drugs, poisons and their metabolites (B) 851
Transition-metal clusters as catalysts of unconventional reactions: reductive C–N coupling of alkyl isocyanates (C) 570
Novel modifications of gold, rhodium, and ruthenium—M_{13} clusters as building blocks of "superclusters" (C) 922
Transition metal complexes, Second-sphere coordination—a novel rôle for molecular receptors (R) 487
Triafulvalene derivatives, Syntheses and spectroscopic properties of triafulvalene derivatives (C) 731
Triazadiphosphatungstacyclohexatriene, A transition metal atom as building block of a cyclic phosphazene—synthesis and structure of $[Cl_3WN_3(PPh_2)_2]$ (C) 477
Triazenido complexes, Synthesis and structure of 1,3-Diphenyltriazenidogold(I), a tetrameric molecule with short gold-gold distances (C) 95
Triaziridine, An azimine-triaziridine transformation by laser photolysis (C) 828
Triazolium ions, Valence isomers of compounds with geminal aryldiazene and isocyanate functions stabilized by protonation (C) 1132
Triazolium salts, Rearrangement of 4*H*-1,2,4-triazolium salts to 4-acyl-5-aminoimidazoles (C) 652
Tri-*tert*-butylazete —the first kinetically stabilized azacyclobutadiene (C) 842
Tricarbahexaboranyl ligand, Bis(η^5-2,3,5-tricarbahexaboranyl)nickel, a nickelocene analogue (C) 1099
Tricyclo[5.3.0.$0^{2,8}$]deca-3,5-dien-9-one and a new route to $C_{10}H_{10}$ isomers (C) 906
Trifluoromethyl group, Synthesis of bis(trifluoromethyl)-analogues of the pyrethroids (C) 184
Trimethylenemethane, [3 + 2] Cycloaddition approaches to five-membered rings via trimethylenemethane and its equivalents (R) 1
Triphenylcyclopropenyl ligand, $[(C_3Ph_3)Ni(\mu\text{-}Br)_3Ni(C_3Ph_3)](C_3Ph_3)$—a triple-decker-like complex with triphenylcyclopropenyl as ligand (C) 833
Triphosphabenzene derivative, A $1\lambda^5,3\lambda^5,5\lambda^3$-triphosphabenzene derivative (C) 1002
Triphosphabutadiene, Synthesis of the first triphosphabutadiene (C) 932
Triple bond, The $\sigma^2\pi^4$ triple bond between molybdenum and tungsten atoms: developing the chemistry of an inorganic functional group (R) 21
Triple-decker complexes, $[(C_3Ph_3)Ni(\mu\text{-}Br)_3Ni(C_3Ph_3)](C_3Ph_3)$—a triple-decker-like complex with triphenylcyclopropenyl as ligand (C) 833
Synthesis of anionic triple-decker complexes having closed 30e valence shells by stacking of sandwich anions with $Cr(CO)_3$ fragments (C) 165
Trisaccharides, Synthesis of the trisaccharide Neu-5-Ac-α(2→6)Gal-β(1→4)GlcNAc

by the use of immobilized enzymes (C) 1096
Trithiometaphosphate PS_3^-—an anion with phosphorus of coordination number 3 (C) 82
Tropylium salts, A salt of the dication cycloheptatrienylidenemethyleneditropylium (C) 916
Tumor cell membranes, Synthesis of *O*-glycopeptides of the tumor-associated T_N- and T-antigen type and their binding to bovine serum albumin (C) 360
Tungsten alkoxides, Evidence for equilibria between μ-alkyne and alkylidyne complexes of tungsten alkoxides: $[W_2(OR)_6(\mu\text{-}C_2R_2')] \rightleftharpoons 2[(RO)_3W{\equiv}CR']$ (C) 446
Tungsten compounds, The first observation of the equilibrium $2M{\equiv}M \rightleftarrows M_4$ (M = transition metal): synthesis and structure of hexaisopropoxyditungsten and its dimer (C) 1014
Twist structure, t-$(ET)_2Au(CN)_2$ and t-$(ET)_2AuBr_2$, organic radical cation salts with twist structure (C) 729
Two-electron transfer, Unexpected "two-electron" transfer in cyclic hydrazines—a voltammetric analysis (C) 1021

ULLMANN'S ENCYCLOPEDIA of industrial chemistry (B) 763
Uranium compounds, $[U_3(\mu^3\text{-}Cl)_2(\mu^2\text{-}Cl)_3(\mu^1,\eta^2\text{-}AlCl_4)_3(\eta^6\text{-}C_6Me_6)_3][AlCl_4]$—a trinuclear arene complex of U^{III} (C) 637

VALENCE ISOMERISM, Valence isomers of compounds with geminal aryldiazene and isocyanate functions stabilized by protonation (C) 1132
Valence tautomerism of the heptaheteronortricycles $[P_{7-x}As_x]^{3-}$ (C) 352
Vanadium compounds, Benzene as bridging ligand in main group metal–transition metal–arene complexes (C) 927
First dinuclear complexes with fourfold alkyl-bridging (C) 925
Synthesis of diindenyldivanadium—a new variant of the reductive degradation of metallocenes and related compounds (C) 928
Vibronic coupling (B) 659
Vicinal pentaketones (C) 999
Vinyl ketones, Divinylglyoxal and methylvinylglyoxal (C) 1116
Intramolecular Diels-Alder reactions with methyl 2-trimethylsiloxy-2-vinylcyclopropanecarboxylates as key building blocks (C) 1086
Violerythrins, Mini-violerythrins: why can C_{38}-carotinoids be blue? (C) 1018
Viruses, Molecular biological background of the species- and organ-specificity of influenza A viruses (R) 47
Vitamin B_{12}, Facile entry to geminally dialkylated chlorins (C) 458

WALK REARRANGEMENT, Tandem walk rearrangement of a protonated dicyclopropenyl ketone (C) 1093
Water oxidation, Oxygen evolution by water oxidation mediated by heterogeneous manganese complexes (C) 825
O_2-Generation by oxidation of water with di- and trinuclear ruthenium complexes as homogeneous and heterogeneous catalysts (C) 1009
Wittig reaction with carbon suboxide: synthesis of dimethyl 1,5-diphenyl-1,2,3,4-pentatetraenedicarboxylate (C) 93

YLIDES, $H_3C{-}P{=}CH_2$: an ylide with two-coordinate phosphorus? (C) 265
A 2-phosphonio-substituted 1-phospha-1-alkene: resonance between P^{III} alkene and P^{V} ylide (C) 454
A polyfunctional dititanacyclobutane (C) 574
Nitrile ylides and azirines: gas-phase generation from 2,3-dihydro-1,4,2λ^5-oxazaphospholes and matrix isolation (C) 85
Reaction of phosphonium ylides with alkyldichloroboranes (C) 559
Stable selenocarbonyl ylides (C) 183
Ylide ligands, Methylene-bridged dinuclear gold(III) complexes with terminal and bridging ylide ligands (C) 575
Ytterbium compounds, Dimeric chloro[dicyclopentadienyl(dimethyl)silyl]ytterbium (III), a rare example of a complex involving metal-bridging instead of chelating $[Me_2Si(\eta^5\text{-}C_5H_4)_2]$ ligands (C) 738

ZIRCONIUM COMPOUNDS, Unusual bridging of the metal centers in dimeric bis(η-methylcyclopentadienyl)phenylethynylzirconium (C) 463
Novel fulvalene derivatives of zirconium: a facile entry into organozirconium(III) chemistry (C) 289
