$Ge_{4.06}I$, an Unexpected Germanium Subiodide—a Tetragermanioiodonium(III) Iodide with Clathrate Structure $[Ge_{46-x}I_x]I_8$, $x = 8/3$

By *Reinhard Nesper, Jan Curda,* and *Hans-Georg von Schnering**

The clathrate structures found for the nobel gas hydrates $Xe(H_2O)_{5.75} \triangleq Xe_8(H_2O)_{46}$[1] are characterized by a three-dimensional network of tetrahedrally bonded structural units, which enclose large and usually highly symmetric cavities. In the case of the nobel gas hydrates, the 46 H_2O molecules form a cubic E_{46} network, which is held together by hydrogen bonds and which contains (2+6) cavities of two different types, providing space for the eight Xe atoms. As was recently shown by the synthesis of the clathrasils,[2] this structural principle is also adopted by SiO_2 and may be modified in a variety of ways by the introduction of foreign substances. Further significant variants are the silicides and germanides of the alkali metals of the type K_8Si_{46}[3] and $Rb_8[In_8Ge_{38}]$,[4] respectively, and ternary halides of the type $[A_{38}B_8]X_8$ with A = Si, Ge, B = P, As, Sb, and X = Cl, Br, I;[5,6] in these cases, the E_{46} framework is

[*] Prof. Dr. H.-G. von Schnering, Dr. R. Nesper, Dipl.-Ing. J. Curda

Heisenbergstrasse 1, D-7000 Stuttgart 80 (FRG)

built up from Si and Ge/In and from $38\,A+8\,B^+$, respectively, while the alkali metal atoms and the halide ions fill the eight cavities. The formation of the nobel gas hydrates and the clathrasils, in particular, indicates that the clathrate structures, which are apparently topologically acceptable for tetrahedrally bonded units, allow the transfer of structural elements from solution to the crystalline state—even if it is metastable. For this reason, we have used high pressures of a foreign gas (Xe, CO_2; 80 atm) to influence the crystallization of Ge from the gas phase following thermal decomposition of GeI_2[7] and have indeed obtained a product with a clathrate structure. However, this product was not the desired $Ge_{46}Xe_8$ but rather the subiodide $Ge_{4.06}I$.

$Ge_{4.06}I$ is formed upon rapid thermal decomposition of GeI_2 at 660 K under extreme conditions of the chemical transport.[8] It is a black powder, which, under the electron microscope, consists of cubic crystals having edges of up to 10 μ (Fig. 1). According to inductively coupled phase (ICP) analyses, the chemical composition is $Ge_{4.1}I$, which, combined with the experimental density $\rho_{exp}=5.85$ g·cm^{-3} for the cubic unit cell ($a=10.814$ Å; $V=1264.6$ Å^3), gives the overall formula $Ge_{43.0}I_{10.5}$. Although this formula contains nearly 54 atoms, as one would expect for a clathrate structure, it includes more than eight I atoms (2+6 cages). $Ge_{4.06}I$ is a diamagnetic semiconductor ($\chi_{mol}=-114\times10^{-6}$ cm^3 per $Ge_{4.1}I$; $\Delta E\approx1$ eV). X-ray photoelectron spectroscopic (XPS) measurements reveal that two types of iodide 1s states are present in the ratio 3:1, at −619 and −623 eV, which, when compared with the known values for I^- (−619 eV) and I^{7+} in IO_3^- (−626 eV) indicate the presence of I^{1-} and I^{3+}.[9] $Ge_{4.06}I$ undergoes thermal decomposition above 780 K to give crystalline α-Ge, gaseous GeI_2, and I_2 (differential thermal analysis, thermogravimetry, mass spectra). All the findings indicate that $Ge_{4.06}I$ is thermodynamically metastable with respect to disproportionation into GeI_2 and α-Ge.

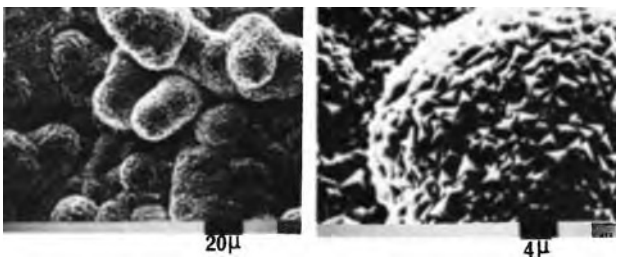

Fig. 1. Scanning electron micrographs of $Ge_{4.06}I$. The pictures show the typical dendrite-like, nodular growth of intergrown cubes around the starting compound GeI_2.

The structure elucidation was achieved by careful analysis of 80 reflections of a powder sample.[10] The surprising result is summarized in Table 1. 43.33 Ge atoms and 2.67 I atoms form the covalently bonded E_{46} framework, the cavities of which contain the remaining eight I atoms.

This distribution of the atoms was determined from the intensities of the reflections alone, independently of chemical analysis and density measurements. This is especially true for the statistical distribution of Ge1 and I3 at the position 6c (Table 1). Under the probable assumption that the I atoms in the cavities are I^- ions (cf. ref. [11]), the principle of neutrality requires that the 2.67 I atoms at 6c be I^{3+} ions, in good agreement with the results of the XPS measurements and also with the tetravalency of I^{3+}, which is necessary for a tetrahedral framework. Since each of these I atoms is coordinated by four Ge atoms, tetragermanioiodonium(III) centers are present. The overall structure may be described as a polygermanioiodonium(III) triiodide $[I(Ge_n)]I_3$ ($n=16.25$): $[I_4Ge_{65}]I_{12}$. The bond lengths (Table 1) and physical properties are in accordance with this description.

Table 1. $Ge_{43.33}I_{10.67}$; Structure parameters: space group $Pm3n$ (223); $a=10.814(3)$ Å; $Z=1$; powder sample; 80 reflections hkl; $R=0.087$. The larger U value of I1 probably results from defects (SOF = 0.85), which may also be the case for the Ge positions. On account of the method of synthesis, statistical defects in the structure are very likely. With SOF(I1) = 0.85 alone and assuming the validity of the electroneutrality rule, one obtains $Ge_{43.43}I_{10.27}\triangleq Ge_{4.23}I$, that is, only small differences from the chemical analysis. For this reason, we have preferred the composition of the fully occupied ideal structure.

Recently, it was again confirmed that only GeI_2 and GeI_4 exist as stable phases in the Ge/I system.[12] The discovery of the subiodide $Ge_{4.06}I$ in no way changes this situation insofar as it involves thermodynamically controlled reactions. The thermal decomposition of GeI_2 was carried out under conditions, however, under which $Ge_{4.06}I$ is only observed as an intermediate. Thermodynamic data for $Ge_{4.06}I$ are still not available. The equilibrium temperature for the reaction $GeI_2(g)=0.50\ Ge(s)+0.50\ GeI_4(g)$ is 670 K.[8] The value for the decomposition $GeI_2(g)=0.13\ Ge_{4.06}I(s)+0.47\ GeI_4\ (g)$ should be similar. In fact, the mean deposition temperature of $Ge_{4.06}I$ is $T_d=645$ K. Using the entropy increments for Ge and I (47.2 and 56.4 JK^{-1} mol^{-1}[13]) and the standard values ΔH_f^{298} and ΔS_f^{298} for $GeI_2(g)$ and $GeI_4(g)$ (+53.9 and −37.6 kJ mol^{-1} and 338 and 428 JK^{-1} mol^{-1}, respectively[14, 15]), one obtains at T_d the realistic value ΔH_f^{645} ($Ge_{4.06}I$,f) = +4 kJ mol^{-1}.

Experimental Procedure

$Ge_{4.06}I$ was synthesized by thermal decomposition of GeI_2 and by chemical transport. The thermal decomposition was carried out at $T=650$ K and $p=10^{-1}$ Pa in a glass ampule opened at one end. GeI_2 (0.5 g, 1.5 mmol) was converted into $Ge_{4.06}I$ in a yield of about 50% within 5 to 10 min. $Ge_{4.06}I$ was only formed in a vacuum. Under argon atmosphere (100 Pa), mixtures of GeI_2 and α-Ge were always obtained. The chemical transport was carried out in a sealed quartz ampule (28 cm × 0.27 cm) between $T_1=1070$ K and $T_2=625$ K. α-Ge (3.0 g, 0.04 mol) was transported with I_2 (0.25 g, 0.001 mmol) to the cold side within ca. 20 h. $Ge_{4.06}I$ appears as a black powder in a zone between ca. 635 K and 685 K. Despite numerous synthetic attempts, the crystal size could not be increased to more than 10 μ.

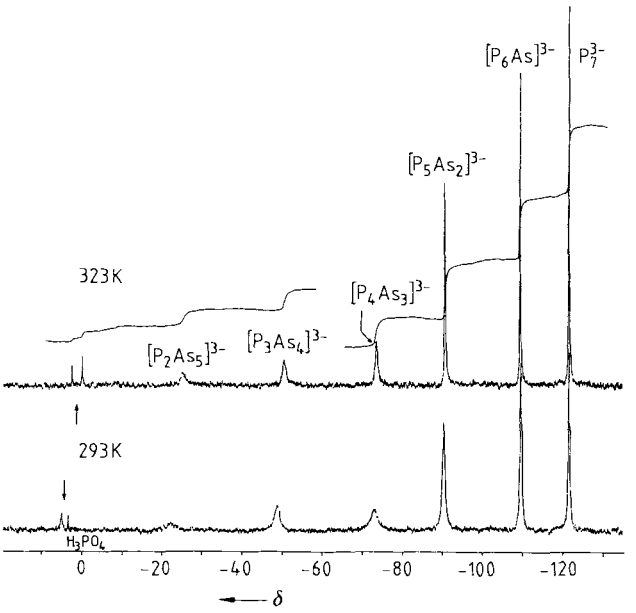

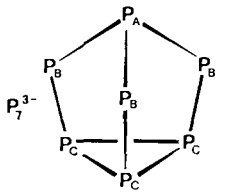

Fig. 1. $^{31}P\{^1H\}$-NMR spectrum of $Rb_3[P_{7-x}As_x]$ in en at 293 and 323 K ($x \approx 3$). The signals at $\delta \approx 5$ (arrow) are assigned to $H_2PO_4^-$ and HPO_4^{2-} [11], which are introduced inadvertently in the preparation procedure. The signal of $[PAs_6]^{3-}$ could coincide with these signals (cf. text).

Valence Tautomerism of the Heptaheteronortricycles $[P_{7-x}As_x]^{3-}$**

By *Wolfgang Hönle* and *Hans-Georg von Schnering**

Several years ago, *Baudler* et al.[1] described the valence tautomerism of the polycyclic heptaphosphane(3) anion P_7^{3-} in tetrahydrofuran solutions of solvated $Li_3P_7(solv)_3$ at 80 °C. Furthermore, we found that all solvent-free poly-

phosphides M_3P_7 (M = Li–Cs) dissolve in ethylenediamine (en) and, even at room temperature, undergo valence tautomerism.[2] The unequivocal identification of the arsenides M_3As_7 (M = Na–Cs) containing As_7^{3-} ions[3] was the motivation for undertaking an investigation of mixed crystals $M_3[P_{7-x}As_x]$, which we consider ideal for verifying the concept of topological charge stabilization.[4] According to *Gimarc* and *Joseph*, particularly stable structures are formed when the positions of highest charge density in a homoatomic isoelectronic reference system are replaced by heteroatoms with greater electronegativity.[4] In P_7^{3-}, the bridge P atoms have the greatest charge density.[5] According to *Allred* and *Rochow* as well as *Sanderson*, the electronegativity of arsenic is greater than that of phosphorus.[6] Accordingly, in mixed crystals $M_3[P_{7-x}As_x]$ the arsenic atoms should preferentially occupy the bridge positions, thereby favoring a polycycle $[P_4As_3]^{3-}$. The results of our investigations on the polymeric heptaphosphides $MP_{7-x}As_x$ (M = Li, Na)[7] fulfill these expectations, but not the results on the mixed crystals of the type $Eu[P_{3-x}As_x]$.[8]

Mixed crystals $Rb_3[P_{7-x}As_x]$ are synthesized from the elements in a stoichiometric ratio in sealed Ta ampules at 900 K. The dark red mixed crystals ($x \approx 3$) are air-sensitive and dissolve completely in en. The ^{31}P-NMR spectrum[9] of the intense red solutions exhibits six singlets at room temperature (Fig. 1), the halfwidths of which decrease with increasing temperature. The spectrum is surprisingly easy to explain if one assumes that a series of compounds are present, all of which can interconvert by valence tautomerism. The positions of the coalescence signals are derived from the weighted averages of the chemical shifts δ_i of the atoms involved in the rearrangement.

For the AB_3C_3 spin system of P_7^{3-}, the chemical shifts $\delta(P_A) = -57$, $\delta(P_B) = -103$, and $\delta(P_C) = -162$ are observed for the three structurally different P atoms P_A, P_B, and P_C, respectively.[1] Their weighted average $[\delta(P_A) + 3\delta(P_B) + 3\delta(P_C)]/7 = -121.7$ is in agreement with the signal of the highest shift at $\delta = -121.4$ (Fig. 1). The further coalescence signals are not equidistant, but their shifts in position to lower field correspond to the stepwise deshielding of the P atom by the As atom. If the signal at $\delta = 121.4$ is assigned to P_7^{3-}, in agreement with the observations of *Baudler* et al.,[1] the signals at $\delta = -109.5$, -90.2, -72.9, -48.7, and -22.4 correspond to the anions $[P_6As]^{3-}$, $[P_5As_2]^{3-}$, $[P_4As_3]^{3-}$, $[P_3As_4]^{3-}$, and $[P_2As_5]^{3-}$.

The chemical shifts are unequivocally correlated with the number of P atoms and are each separated by about 12–26 ppm with an average value of $\Delta\delta = 19.8$, which is close to the value $\delta(P_7^{3-})/7 = 17.3$. An analogous continuous series of shifts was observed by *Rudolph* et al.[10] for the heteronuclear clusters $[Sn_{9-x}Pb_x]^{4-}$; for $[Sn_{9-x}Ge_x]^{4-}$, however, a reversal in the shifts at $x = 4$ was observed. In specific cases, therefore, deviations should be expected. For this reason, it is also not possible to decide whether the anion $[PAs_6]^{3-}$ is absent or whether its chemical shift happens to coincide with the signal group at $\delta = 5$ (Fig. 1),

[**] The Chemistry and Structures of Phosphides and Polyphosphides, Part 40.—Part 39: H.-G. von Schnering, D. Vu, *J. Less-Common Met. 116* (1986) 257.

which would be in agreement with the (irregular) increase in the differences $\Delta\delta = |\delta(x) - \delta(x+1)|$ in the series $[P_{7-x}As_x]^{3-}$ with increasing x. It is also possible, however, that this heteroanion is unstable and decomposes into As_7^{3-} and, for example, $[P_2As_5]^{3-}$, because incorporation of the small P atom into the large As_7 cage is unfavorable. The ^{31}P-NMR spectra of solutions of mixtures of the pure compounds Rb_3P_7 and Rb_3As_7 exhibit, even after several weeks, only the signal of P_7^{3-}, so that no exchange between P_7^{3-} and As_7^{3-} occurs in solution.

The intensities of the ^{31}P-NMR signals—after correction with respect to the number of P atoms involved in the heteroanion—indicate a preference for the groups $[P_6As]^{3-}$ and $[P_5As_2]^{3-}$, but none for $[P_4As_3]^{3-}$, as would have been expected based on the concept of topological charge stabilization. With increasing content of arsenic, the valence tautomerism becomes slower, as shown by the increasing halfwidths of the signals. The question remains open, therefore, whether As_7^{3-} also has a fluxional structure in solution.

$[NbAs_8]^{3-}$, a Novel Type of Complex and an Unexpected One-Dimensional Chain Structure: $^1_\infty[Rb\{NbAs_8\}]^{2-}$

By *Hans-Georg von Schnering,* Juliana Wolf, Dieter Weber, Rafael Ramirez,* and *Teodoro Meyer*

In recent years, polyphosphides and polyarsenides of the alkali metals have been used, on the one hand, to synthesize a variety of polycyclic phosphanes and arsanes[1-3] and, on the other hand, to generate quasi-isolated ions such as P_7^{3-}, P_{11}^{3-}, As_7^{3-}, As_{11}^{3-}, and Sb_7^{3-}. This was achieved by complexation of the cations by large ligands (e.g., formation of cryptates) in order to prevent direct interactions between the cations and anions.[4-6] Pure metal compounds are required for both types of reaction. Alkali metal arsenides are usually synthesized from the elements in sealed quartz ampules. Recently, niobium ampules have been shown to be well suited for the suppression of reactions on the walls, in particular in the case of arsenic-rich polyarsenides.[7] However, here too, problems can arise as the amount of alkali metal is increased. Normally, such side reactions are undesired, although they often lead to especially beautiful compounds that are totally unexpected, to say nothing of being unpredicted. We report here one such case.

During the synthesis of Rb_3As_7 in a sealed niobium tube, rubidium was mistakenly added in too large an excess. The reaction product, primarily RbAs having helical $^1_\infty[As^-]$ chains,[8] was dissolved in a solution of 4,7,13,16,21,24-hexaoxa-1,10-diazatricyclo[8.8.8]hexacosane (2,2,2-crypt) in ethylenediamine (en). Red, transparent crystals separated out of the deep red solution and were identified as compound **1**:[9]

$[Rb(2,2,2\text{-crypt})]_2[Rb\{NbAs_8\}]$ **1**

In **1**, only two of the three Rb atoms are enclosed in the cryptands. The third forms a one-dimensional chain $^1_\infty[Rb\{NbAs_8\}]^{2-}$ with the complex anion $[NbAs_8]^{3-}$ (Fig. 1). The η^8-cyclooctaarsenidoniobate(v) trianion $[NbAs_8]^{3-}$ present in this chain, with the symmetry $\bar{8}2m$-D_{4d}, represents a novel type of complex, consisting of a monocyclic, crown-shaped polyanion $(As^-)_8$ with a Nb^V ion in the center. In accordance with the Zintl-Klemm rule (cf. ref. [1]), the ligand is isoelectronic and isostructural with the S_8 molecule (Nb-As 261.9, As-As 243.4 pm; bond angle at As: 93.7°; dihedral angle: 111.8°). The topology of the complex anion is unusual, because the donor functions of an $(As^-)_8$ crown should be directed outward, as has been observed up to now.[10] In this case, these donor functions bind the third Rb atom with formation of one-dimensional chains (Rb-As 392 pm). Evidently, the Rb-As interactions in these chains are able to compete with those between Rb^+ and the solvent en (ethylenediamine) as well as with those between Rb^+ and 2,2,2-crypt. This is remarkable since RbCl dissolves immediately in cryptand solutions, and sufficient 2,2,2-crypt was available in this reaction.

INDO calculations[11] afforded an insight into the electronic structure of the complex anion and the chain; for technical reasons, however, these calculations were carried out with K instead of Rb and V instead of Nb. The order of the energy levels obtained from the calculations and the distances between them should apply, in principle, to the $^1_\infty[Rb\{NbAs_8\}]^{2-}$ system. In particular, no essential differences between the isolated complex $[M^VAs_8]^{3-}$ and the one-dimensional chain $^1_\infty[M^I\{M^VAs_8\}]^{2-}$ with M^I, M^V = K, V and Rb, Nb are expected with respect to the 24 bonding energy levels. Important details are shown in Figure 1. The calculations reveal, among other things, that the compound is diamagnetic and that the band gap is 5 eV, which is in qualitative agreement with the observations.

The electronic states in the As_8 crown can be described practically exclusively in terms of pure 4s and 4p atomic orbitals, the latter of which form the σ bonds as well as the 4p π states of the electron lone pairs. The M^V-As bonds can largely be described by combinations of these 4p π states with functions of M^V having the symmetry e_2 and e_3. An important feature of the chain is the coupling of the $3a_1$ (As, 4p) state with $M^I(ns, np_z)$ functions. This results in

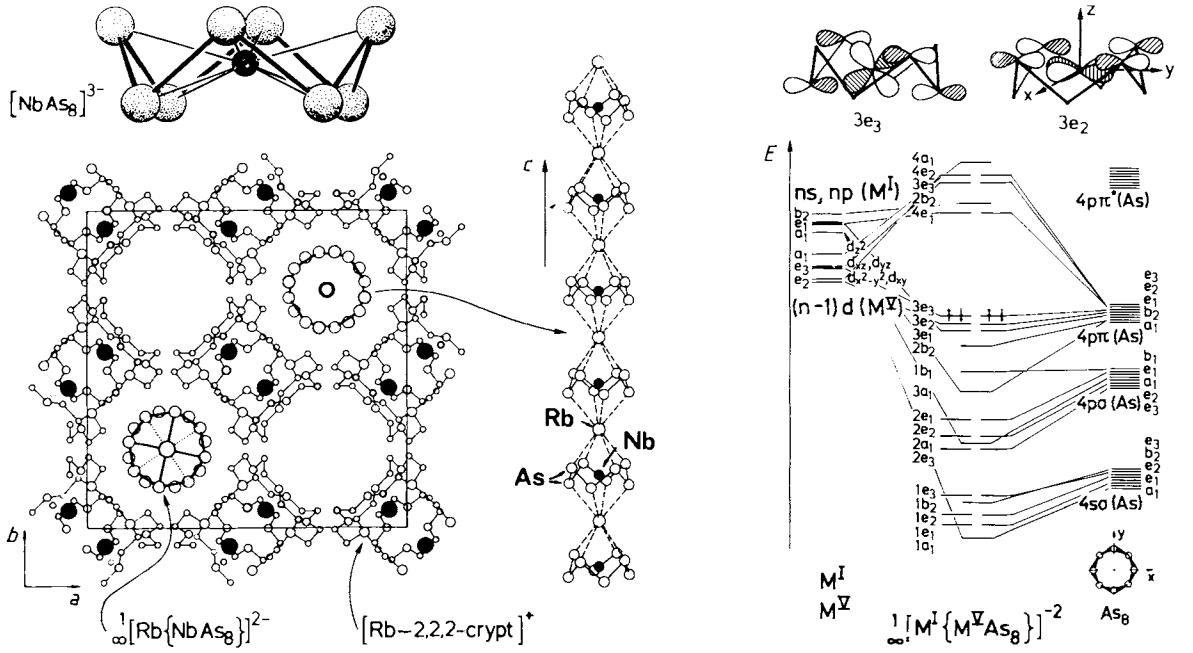

Fig. 1. Above: Structure of the complex anion $[NbAs_8]^{3-}$ in the crystal (left) and HOMOs $3e_2$ and $3e_3$ of the Nb-As bonds (one component of the e representation in each case, right). Below: Projection of the crystal structure along the chains $^1_\infty[Rb\{NbAs_8\}]^{2-}$ (left), a single chain (middle), and the electronic states of the chain $^1_\infty[M^I\{M^VAs_8\}]^{2-}$ with $M^I = K$, $M^V = V$ for the wave vector $k = 0$ (right). The irreducible representation corresponds to the point symmetry $\bar{8}2m$-D_{4d}. For technical reasons, the INDO calculations were carried out with K and V. The $3e_3$ HOMOs are indicated by arrows.

bonding M^I-As interactions along the one-dimensional chain. At the same time, the $4a_1$ orbital $(M^V, (n-1)d_{z^2})$ is destabilized and therefore direct metal-metal bonding along the chain is prevented.

With knowledge of the composition and structure of the new compound in hand, a direct synthesis was possible. To this end, Nb_2O_5 is added in the first step of the reaction.[12]

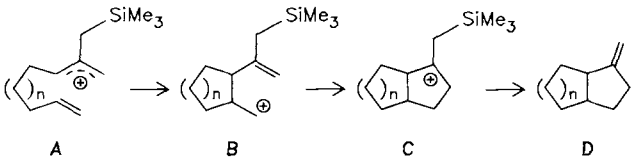
[12] Experimental procedure: **1**: Freshly distilled Rb (3.08 g), vacuum-annealed As (3.33 g), and Nb_2O_5 (0.74 g) (molar ratio 16 : 16 : 1) were fused under argon in an Nb ampule (1.5 cm × 10 cm). The ampule was then heated in an evacuated quartz tube for 35 h at 925 K. After annealing for 3 d at 925 K and cooling to room temperature over 48 h, 3.8 g of the product was obtained. This was allowed to stir with 1 g of 2,2,2-crypt in 100 mL of anhydrous, oxygen-free en under argon for 3 d at room temperature (three-necked flask). After filtration and concentration of the dark red solution, fine crystals of **1** separated out. Dark red prisms formed upon counter-current diffusion with tetrahydrofuran on both sides of a G3 frit. After decantation and drying under vacuum, the yield of **1** was ca. 700 mg (15% based on 2,2,2-crypt). The product of the thermal reaction is unknown.

Intramolecular Addition of 2-(Trimethylsilyl)methyl-substituted Alkyl Cations to Double Bonds—Synthesis of Bicyclo[3.3.0]octane Derivatives**

By *Junes Ipaktschi** and *Gerald Lauterbach*



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

The development of methods for the synthesis of cyclopentanoid compounds continues to be a subject of intensive study.[1] An important entry to carbocyclic five-membered ring systems consists in the coupling of a C_3 unit such as, e.g., a trimethylenemethane derivative,[2] to an electron-deficient olefin. The C_3 building blocks can be prepared in a Ni^0- or Pd^0-complex-catalyzed reaction from methylenecyclopropanes[2a] or 2-[(trimethylsilyl)methyl]-allyl acetates,[2b] or by pyrolysis of pyrazoline derivatives.[2c] These reactions can also be carried out intramolecularly with formation of bicyclo[3.3.0]octane and bicy-

clo[4.3.0]nonane derivatives.[2b,c] Such systems should also be accessible if it were possible to add allyl cations intramolecularly in a [3+2]-cycloaddition to double bonds. [3+2]-Cycloadditions of allyl cations as concerted reactions are forbidden.[3] On the other hand, a multistep mechanism (Scheme 1) requires a cyclization step (**B**→**C**), which according to the Baldwin rules[4] is unfavorable. That examples of reactions of this type are rare is not surprising.[5]

Scheme 1.

We have now found that the intramolecular [3+2]-cycloaddition of 2-trimethylsilylmethyl-substituted allyl cations of type **A** to alkenes does in fact lead to bicyclo[3.3.0]octane derivatives. When $TiCl_4$/*N*-methylaniline (1:1) is allowed to react with **1** in dichloromethane at −15 °C,[6] the bicyclooctane **2** (Scheme 2, Table 1) is obtained in 55% yield. Other products include **3** (25%) and an, as yet, unidentified hydrocarbon (5%).[7]

Scheme 2. a) $TiCl_4$, *N*-methylaniline (1:1), CH_2Cl_2, −15 °C, 1 h [10]; b) TosOH (cat.), $CHCl_3$, 50 °C, 5 min; c) $TiCl_4$/*N*-methylaniline (2:1), CH_2Cl_2, −20 °C, 1 h [10].

The influence of the trimethylsilylmethyl group on the cyclization is illustrated quite well by a comparison of the reactions of **1** and **4**. When **4** is allowed to react under otherwise the same conditions with Lewis acids, the *trans*-diisopropenylcyclopentane **3** is formed as sole product in 17% yield. The cyclization of **5** proceeds astonishingly smoothly.[6] **6** was isolated as sole product in 70% yield and was converted quantitatively in a proton-catalyzed reaction into **7**. This result is remarkable inasmuch as, as in **5**—after the reaction with Lewis acid—the allyl cation initially formed is highly substituted and the alkene is only monosubstituted. As expected, reaction of **8**,[6] in which the two geminal methyl groups are missing, affords **9** (15%) in an essentially unspecific reaction. **11** could be prepared in 45% yield from **10** in the same way.[6]

These results show that the cyclization **B**→**C** (Scheme 1) is greatly facilitated by the "β-effect"[8] of the silicon and by two geminal methyl groups in the β-position. Hence, the reaction can be regarded as an extension to the Pd-assisted cycloaddition of 2-[(trimethylsilyl)methyl]allyl acetates and electron-deficient olefins, since bicyclooctanes can also be synthesized in satisfactory yields from alkyl-substituted alkenes according to Scheme 1.

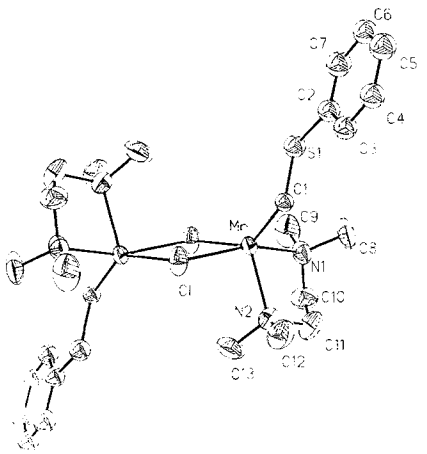
An α-Functionalized Organomanganese(II) Derivative: a Dinuclear Manganese(II) Complex with a σ-Bonded α-Thioalkyl Ligand**

By *Edouard Marc Meyer* and *Carlo Floriani**

Alkylmetal compounds M-CH_2X containing a functional group [X = OR, NR_2, SR] in the α-position are key reagents in organic synthesis.[1] In addition, knowledge of their chemistry is essential for an understanding of several well known metal promoted catalytic processes.[2] In this context, there are two important points that must be mentioned. First, the reactivity of α-functionalized alkylmetals is different from that of non-functionalized M-CH_2-R fragments. The M-CH_2-X unit not only functions as a precursor to metal carbenes, but is also a source of free CH_2.[2,6] Secondly, M-CH_2OX compounds are formed during metal-assisted reductions of carbon monoxide and formaldehyde;[3,4] and, insertion of CO into the M-CH_2OH bond is claimed to be the main route to the catalytic syntheses of ethyleneglycol from CO/H_2.[5] α-Thio-substituted organolithium compounds, which have been the subject of a number of chemical, structural, and theoretical studies,[7] are widely used in organic synthesis. However, only a limited number of examples of organometallic compounds containing the -CH_2SR residue have been reported.[8-11] When bonded,through various bonding modes, to soft transition metal ions, this fragment is stable.[8,9,12] Except in a few cases,[7c] however, attempts to bind this unit to hard metal ions in the absence of soft ancillary ligands,[10] resulted in decomposition, with loss of the CH_2 group.[11]

Herein, we report the synthesis and structural characterization of the manganese(II) Grignard reagent [{(tmeda)(PhSCH_2)Mn(Cl)}$_2$] **2** (tmeda = *N*,*N*,*N'*,*N'*-tetramethylethylenediamine), in which a σ-bonded thioalkyl residue is the only carbon ligand bonded to manganese(II). **2** was synthesized by addition of a solution of [(tmeda)$_2$Li$_2$(CH_2SPh)$_2$] **1**[7] in tetrahydrofuran (THF) to a suspension of [$MnCl_2$(thf)$_2$] in THF at −30°C.

Solubilization of $MnCl_2$ was observed as the reaction proceeded. After evaporation to dryness, partial dissolution of the residue in toluene and addition of *n*-hexane, colorless crystals were obtained (yield ca. 65%). All operations were carried out at temperatures below 35°C. Although complex **2** can be stored for months at room temperature in the solid state, it is thermally labile in solution at temperatures above 35°C. The colorless crystals of **2** contain one molecule of toluene per dimer. The magnetic moment of 5.91 BM per Mn at 298 K is consistent with two non-interacting high-spin d^5 centers, separated by 3.806(3) Å.



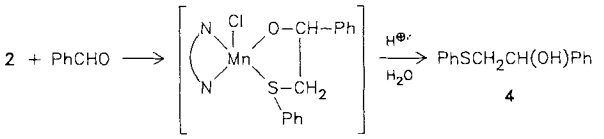


Fig. 1. ORTEP diagram of the structure of **2** in the crystal. Bond distances [Å]: Mn-N1 2.334(10), Mn-N2 2.234(9), Mn-Cl 2.701(4), Mn-Cl′ 2.411(2), Mn-C1 2.177(9), Mn···Mn′ 3.806(3), C1-S1 1.796(13), S1-C2 1.772(8); Bond angles [°]: N1-Mn-N2 79.0(3), Cl-Mn-Cl′ 83.9(1), N2-Mn-C1 110.0(4), Cl-Mn-Cl 89.6(4), Mn-C1-S1 110.5(6), C1-S1-C2 108.1(5).

The crystal structure of **2** is shown in Figure 1.[13] Mn^{II} is five coordinate with the two Mn-Cl bonds differing significantly in length (2.701(4) and 2.411(2) Å). Such an asymmetry was observed in carbon bridges in alkylmanganese(II) compounds.[14] Each Mn atom in **2** carries a σ-bonded phenylthiomethyl residue; the bond length of 2.177(9) Å, lies within the range of the few known Mn^{II}-C σ-bond distances.[14,15] Sulfur does not interact with the manganese atoms of the dimer. The structural parameters of the phenylthiomethyl ligand (C1-S1 1.796(13), S1-C2, 1.772(8) Å) compare with those found in complex **1** (1.779(2) and 1.792(2) Å)[16] and in the homoleptic derivative [{Pd(CH_2SPh)$_2$}$_4$] (1.82 and 1.80 Å),[8] in which, however, the thioalkyl ligand displays a C-S bridge-bonding mode. With regard to its coordination number of five for Mn^{II}, its single Mn-C σ-bond, and a coordination environment provided by the hard donor ligands, Cl and tmeda, complex **2** is unique in manganese(II) organometallic chemistry. Consequently, complex **2** represents an impor-

tant addition to the chemistry, developed by *Wilkinson* et al., of alkylmanganese(II) derivatives.[14, 15]

3 4

Furthermore, complex **2** may be viewed as a manganese(II) Grignard reagent, [RMnX]. Thus, reaction of **2** with benzaldehyde in toluene furnishes the adduct **4** (77% yield).[17] The intermediate **3** was not isolated.

[17] Benzaldehyde (0.49 g, 4.61 mmol) was added to a stirred and cooled (−78°C) solution of **2** (1.52 g, 2.31 mmol) in toluene (70 mL). After 30 min, the solution was allowed to warm up to, and to remain at room temperature for 24 hours. Hydrolysis was carried out under nitrogen at 0°C by adding 50 mL of degassed 1.4 N H_2SO_4 to the toluene solution. Separation of the two phases was followed by washing of the organic phase to neutrality, which, after drying and removal of the solvent, gave the crude product. Purification of the crude product was carried out by flash chromatography (silicagel, elution with *n*-hexane : ethylacetate 95 : 5). ^{1}H-NMR [$(CD_3)_2CO$]: $\delta = 7.10$–7.45 (m, 10H, Ph), 4.82 (t, 1H, CH), 3.26 (d, 2H, CH_2), 3.1 (bs, 1H, OH); MS: m/z 230 (M^+), 213 ($PhSC_7H_6$), 135 (C_8H_8S), 123 (C_7H_7S), 104 (C_8H_9).

η^3-1-Phosphaallyliron Complexes with Additional $W(CO)_5$-Coordination at the Phosphorus—the 1-Phosphaallyl Ligand as 5e-Donor

By *François Mercier, Jean Fischer,* and *François Mathey**

Whereas the initial claim for stable η^3-silaallyliron complexes[1] was subsequently discarded,[2] recently some genuine hetero analogues of the ubiquitous η^3-allyl(transition-metal) complexes have been reported in the literature. They include stable η^3-1-azaallylmolybdenum[3] and η^3-1,3-diphosphaallylcobalt[4] complexes, each of which were unambiguously characterized by X-ray crystal structure analysis. In the same vein, we wish to report here on the first characterization of a 1-phosphaallyl ligand acting as a bridging η^1,η^3 5e-donor. In a preceding paper,[5] we demonstrated that it was possible to prevent the self-condensation of secondary vinylphosphanes by complexation of the lone pair at phosphorus with $W(CO)_5$. Using this approach, we first prepared the two secondary vinylphosphane complexes **3** and **4** (an excess of $LiAlH_4$ must be used), which are quite stable and can be purified by chromatography on silica gel (hexane/toluene); in the case of **4** the yield is based on crude **2**.

Reaction of complex **3** with $[\{CpFe(CO)_2\}_2]$ (Cp = cyclopentadienyl) in boiling xylene then afforded the η^1,η^3-1-phosphaallyl complex **5** together with other products.

Complex **5** was completely characterized by NMR, IR, and mass spectroscopy (Table 1), but we were unable to obtain good crystals for a full X-ray crystal structure anal-

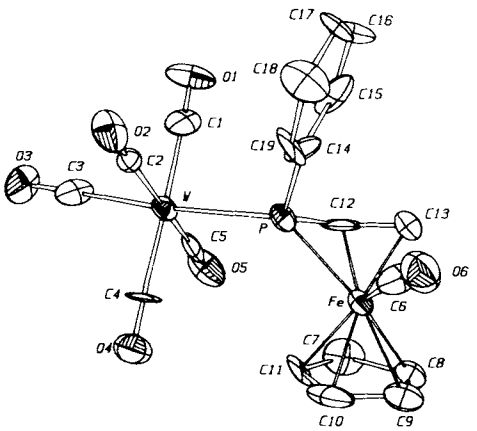
ysis.[6] Nevertheless, the collected data furnished valuable information concerning the stereochemistry of the compound (Fig. 1). The most notable features of the structure are the approximate coplanarity of the W–P–CH=CH_2 unit, the *cis* disposition of W and H^c (W–P–C–H^c dihedral angle ca. 6.6°) and the Fe–CO unit pointing in the opposite direction to C–H^c.



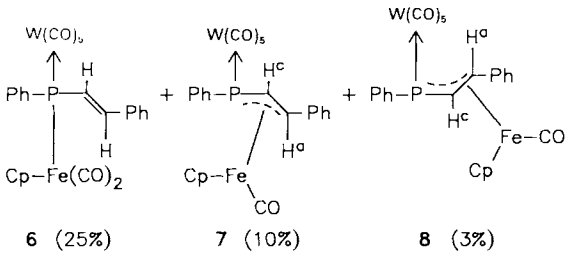


Fig. 1. Structure of **5** in the crystal [6]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity.

When we carried out the same reaction with **4**, we obtained the complexes **6**–**8**, which could be separated by chromatography. Complex **6** is a $W(CO)_5$-complexed, ferrio-substituted vinylphosphane, whereas **7** and **8** are η^1,η^3-phosphaallyl complexes like **5** (Table 1).

Complexes **7** and **8** were also obtained in 79% overall yield (ratio **7** : **8** ≈ 1 : 3) by brief irradiation of a CH_2Cl_2 solution of **6**. At room temperature in solution, an equilibrium between **7** and **8** takes place favoring the formation of **7**. (Since the equilibration is very slow, it is possible to separate **7** and **8** by chromatography.) According to an X-ray structure analysis,[6] complex **7** has the same stereochemistry as **5** (Fig. 2) with H^c *cis* to W and pointing away from the Fe–CO unit.

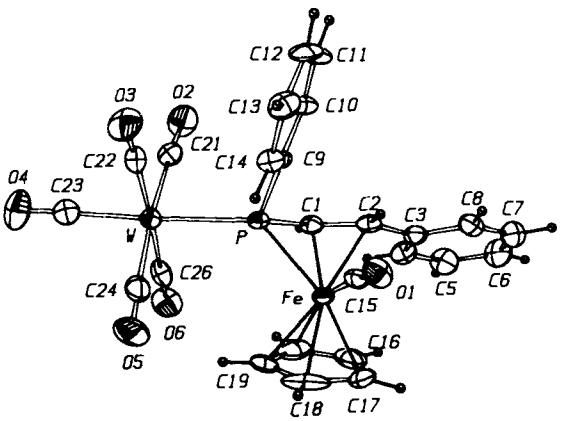

Fig. 2. Structure of **7** in the crystal [6]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances [Å] and angles [°]: W-P 2.511(1), Fe-P 2.270(1), P-C(1) 1.761(5), P-C(9) 1.819(4), C(1)-C(2) 1.380(7), C(2)-C(3) 1.489(7), $\langle$W-$C_{eq}\rangle$ 2.020(3), W-C_{ax} 1.992(6), $\langle$C-O$\rangle_W$ 1.158(3), Fe-C(15) 1.777(6), C(15)-O(1) 1.116(6), $\langle$C-C$\rangle_{Phe}$ 1.385(2), $\langle$C-C$\rangle_{Cp}$ 1.393(4), Fe-C(Cp) 2.056(6) to 2.098(6); W-P-C(1) 124.6(2), W-P-C(9) 111.7(1), W-P-Fe 130.11(6), C(1)-P-C(9) 106.5(2), C(9)-P-Fe 113.0(1), P-C(1)-C(2) 119.6(4), C(1)-C(2)-C(3) 126.4(4), $\langle$C-C-C$\rangle_{Phe}$ 120.0(1), $\langle$C-C-C$\rangle_{Cp}$ 108.0(3).

We assume that **7** and **8** equilibrate via a decoordination of the C=C double bond with subsequent 180°-rotation of the vinyl unit around the P–C(vinyl) bond. In **8**, H^c is probably *trans* to W and located close to the Fe–CO unit. This stereochemistry explains why H^c resonates at lower field than in **7**[7] and why no coupling is observed between H^c and P.[8] Finally, the short P–C(vinyl) bond of **7** [1.761(5) Å] is quite similar to those found in various η^5-phospholyl complexes[9] and in the recently described 1,3-diphosphaallyl complex.[4]

Experimental

All reactions were carried out under argon.

6–**8**: 4 (2.14 g, 4 mmol) was heated with [{CpFe(CO)$_2$}$_2$] (0.72 g, 2 mmol) in boiling xylene (25 mL) for 5 h. After filtration and evaporation, the residue

was chromatographed on a silica gel column (70–230 mesh Riedel de Haën) with a mixture of hexane and toluene (50:50). Complex **7** was eluted first ($R_f \approx 0.7$, yield 0.3 g), then complex **8** ($R_f \approx 0.5$, yield 0.1 g) and complex **6** ($R_f \approx 0.35$, yield 0.7 g).—**5** ($R_f \approx 0.6$, yield 0.75 g) was prepared from complex **3** (2.3 g, 5 mmol) by the same procedure.—**7** and **8** by irradiation of **6**: A stirred solution of complex **6** (0.7 g, 1 mmol) in 150 mL of dichloromethane was irradiated (125 W medium pressure mercury lamp) for 20 min at room temperature. After evaporation of the solvent, the residue was chromatographed. 140 mg of complex **7** and 400 mg of complex **8** were obtained.

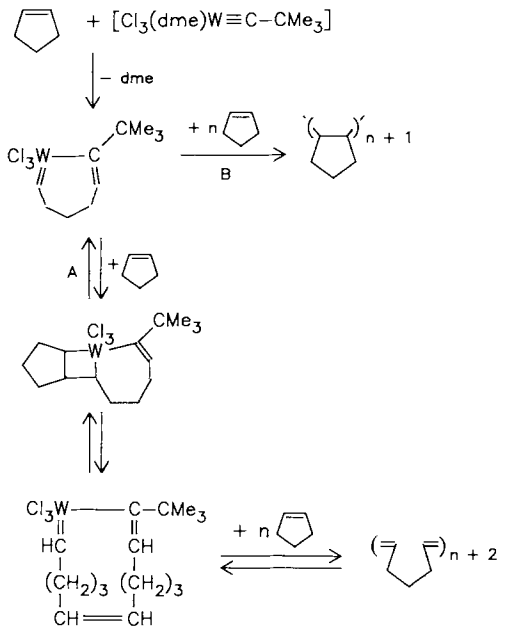
The Schrock Carbyne-Complex $[Cl_3(dme)W{\equiv}CCMe_3]$, a Highly Reactive Catalyst for the Metathesis of Alkenes**

By *Karin Weiss**

Fischer-type carbyne complexes such as *trans*-carbyne(tetracarbonyl)(halogeno)tungsten were already used by *Fischer* et al. as long ago as 1976 as catalysts for the ring-opening metathesis of cycloolefins. Metal chlorides, e.g. $TiCl_4$, WCl_6, or $SnCl_4$, were used as cocatalysts.[1] In 1984, *Katz* et al. investigated the activity of Fischer-type carbyne complexes in this reaction in the absence of metal halides. At room temperature (decomposition temperature), the carbyne complexes showed only slight activity, which, however, increased markedly in the presence of oxygen. Oxygen is also used as cocatalyst in other metatheses with transition metals.[3] That the cocatalysts have a decisive influence on the course of the reaction in the metathesis of cycloolefins follows from the stereochemistry of the polymers that are formed. For example, when using the same carbyne complex, *Fischer* et al.[1] obtained from cyclopentene a poly-1-pentenylene having predominantly *trans* double-bonds, whereas *Katz* et al.[2] obtained a poly-1-pentenylene having predominantly (70%) *cis* double bonds.

Metatheses of the W≡C triple bond of Schrock-type carbyne complexes with alkynes[4] and nitriles[5] are well known. Recently, the metathesis of the W≡C triple bond of $[Cl_3(dme(W{\equiv}CCMe_3]$ (dme = 1,2-dimethoxyethane) with the C=N double bonds of isocyanates[7] and carbodiimides[8] was also accomplished. In this metathesis, tungsten complexes with an imido ligand and a singly bonded ketenyl (X = O) or ketenimido ligand (X = NR) are formed initially. A further molecule of the heteroallene is then inserted into the W–C single bond (see Scheme 1).

Scheme 1.



This communication is concerned with the metathetic activity of $[Cl_3(dme)W{\equiv}CCMe_3]$ towards alkenes. Reaction of cyclopentene with catalytic amounts of the carbyne complex at room temperature affords poly-1-pentenylene with predominantly (75%) *trans*-configurated double bonds as sole product and in good yields. In view of the reaction pathway of the metathesis of the heteroallenes, the most likely course for the above reaction would appear to be that depicted in Scheme 2.

Metathesis of the W≡C triple bond with the double bond of cyclopentene could initially lead to formation of a tungstacycloheptadiene containing a W=C double bond and a W–C single bond. For further reactions with cyclopentene there exist two possible routes: insertion of cyclopentene in the W–C single bond according to a Ziegler-Natta-like mechanism, leading to poly(cyclopentene) (route B); metathesis of cyclopentene with the W=C double bond, leading to poly-1-pentenylene (route A), the reaction product actually obtained.

Each additional metathetic step increases the size of the metallacycle. The original carbyne ligand ($CCMe_3$) re-

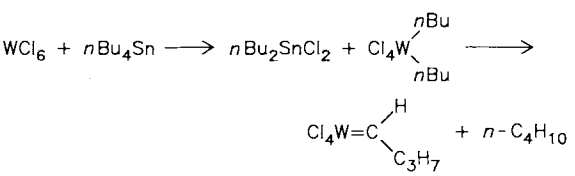
Scheme 2.



mains coordinated to the metal as an alkyl ligand in all reaction steps and can thus influence the steric course of the reaction. The metallacycle, concomitantly an alkyl- and a carbenetungsten-complex, is the active metathetic catalyst.

$[Cl_3(dme)W{\equiv}CCMe_3]$ catalyzes not only the metathesis of cycloalkenes, but also that of linear alkenes such as 1-octene (Scheme 3).[9] The products of the metathesis were found to be ethylene and 7-tetradecene (GC, GC-MS, NMR), of which the latter consisted predominantly of the *trans*-isomer.

Scheme 3.

For highly reactive metathetic catalysts, which mostly consist of WCl_6 and an alkylating agent such as nBu$_4$Sn as cocatalyst, carbene complexes, which should be formed according to the reaction formulated in Scheme 4 have been postulated as the active species.[3]

Scheme 4.

Reactions of WCl_6 with alkylating agents are often very complex.[10] However, in reactions of WCl_6 with alkyllithium or Grignard compounds no carbene complexes are formed, but only carbynetungsten complexes of the Schrock type.[6] The metathesis of alkenes with the catalyst system WCl_6/alkylating agent is therefore most likely initiated by carbyne complexes.

Since *Mayr*'s recent successful synthesis of Schrock-type carbyne complexes from Fischer-type carbyne complexes and Br_2,[11] there is now a further possibility that Schrock-type carbyne complexes are formed from Fischer-type carbyne complexes and metal chlorides (as chlorinating agent) or oxygen (as oxidizing agent), which then initiate the alkene metathesis.

[9] Procedure: Poly-1-pentenylene: A solution of $[Cl_3(dme)WCCMe_3]$ (100 mg, 0.22 mmol) in CH_2Cl_2 (5 mL) was treated at 20°C with 3 mL (32 mmol) of cyclopentene. The solution became viscous within a few minutes; after 3 h, the solution was diluted with 20 mL of CH_3OH and the poly-1-pentenylene precipitated by addition of 100 mL of CH_3OH. Yield: 1.6 g (70% referred to cyclopentene). Characterization by ^{1}H- and ^{13}C-NMR as well as IR spectroscopy. Concentration of *trans* configurated double bonds: 75% (^{13}C-NMR).—Metathesis of 1-octene: A solution of $[Cl_3(dme)WCCMe_3]$ (30 mg, 0.067 mmol) in CH_2Cl_2 (5 mL) was treated with 1 mL (6.4 mmol) of 1-octene at 20°C. The reaction was monitored by gas chromatography. After 30 min, 40% of the 1-octene was converted into 7-tetradecene (^{1}H- and ^{13}C-NMR as well as GC/MS) and ethylene (GC).

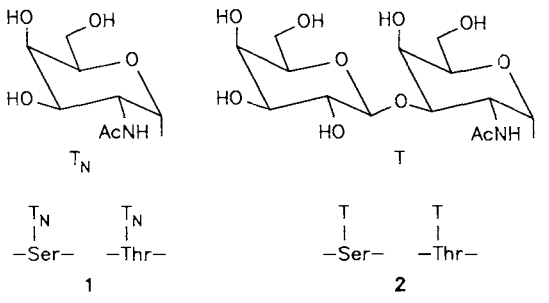
Synthesis of *O*-Glycopeptides of the Tumor-Associated T_N- and T-Antigen Type and Their Binding to Bovine Serum Albumin**

By *Horst Kunz** and *Stefan Birnbach*



Dedicated to Professor Siegfried Hünig on the occasion of his 65th birthday

Cellular biological and biochemical investigations have shown that glycoproteins perform important functions in cell differentiation and in the regulation of cell growth.[1] Normal cells and unregulated growing tumor cells differ very much in the glycolipid and glycoprotein profiles of their cell membranes.[2] The glycoproteins of the tumor cell membranes are regarded as tumor-associated antigens.

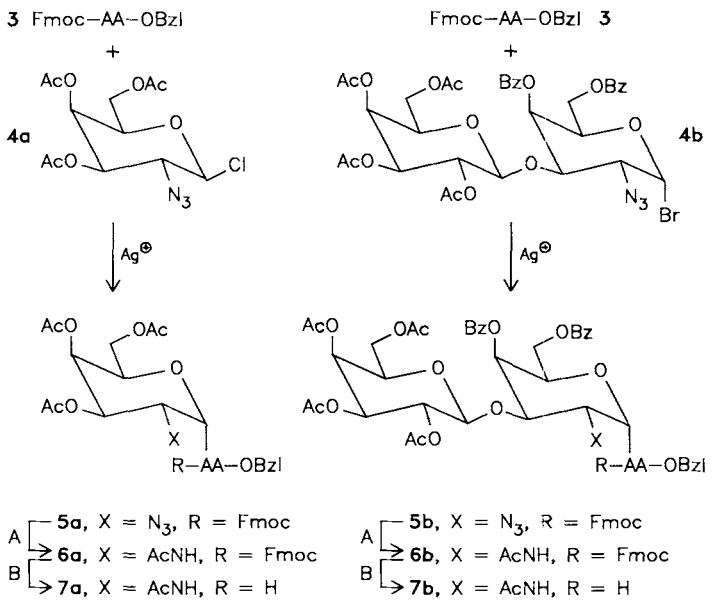
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

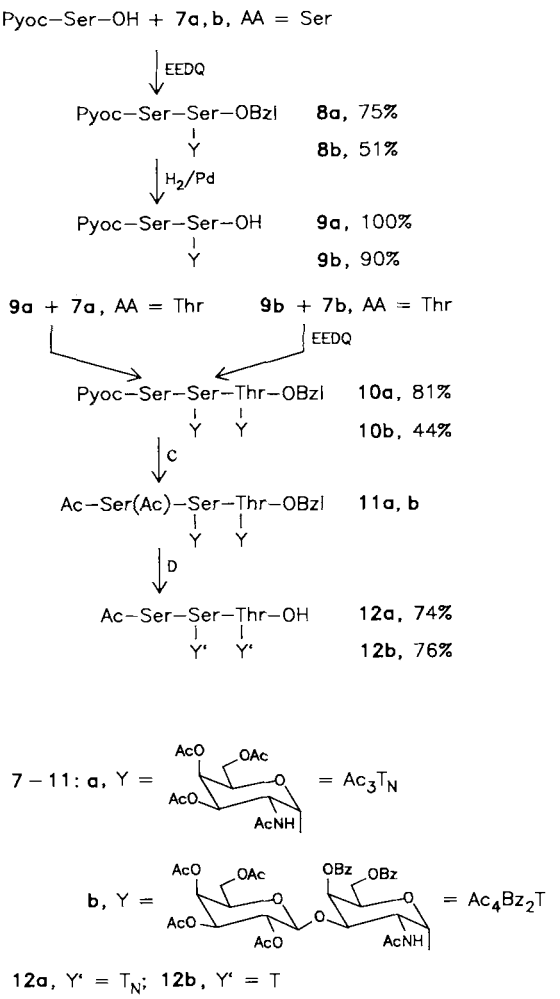


This property was demonstrated, in particular, for the T-antigen, an *O*-glycoprotein that is closely related to glycophorin A and contains the βGal(1-3)GalNAc disaccharide unit linked to serine or threonine as typical structural unit **2**.[3] Frequently, several such glycosylated amino acids are coupled together directly. The monosaccharidic structural unit **1**, the T_N-antigen, is also present in human epithelial tumor cells[3] and in the erythrocytic membranes of patients suffering from leukopenia and thrombocytopenia.[4]

Commensurate with the immunological importance of the structures **1** and **2**, glycopeptides of the T_N-[5] and T-antigen type[6,7] have already been the subjects of several studies. However, for the immunological application of synthetic antigens their conjugation with a biologically appropriate carrier is necessary.

Whereas the disaccharide β-Gal(1-3)GalNAc of the T-antigen could be bound to bovine serum albumin via artificial spacers,[8] the linking of glycopeptides of type **1** and **2** with biological carrier molecules has so far never been accomplished.

We describe here the synthesis of glycotripeptides of the tumor-associated T_N- and T-antigen type, which correspond to the *N*-terminus of glycophorin A with blood-group M activity,[9] and, for the first time, their binding to bovine serum albumin. Our synthetic strategy does not call for a spacer; that is, we can achieve a "natural" linking of the antigen structures to the biological carrier molecule.

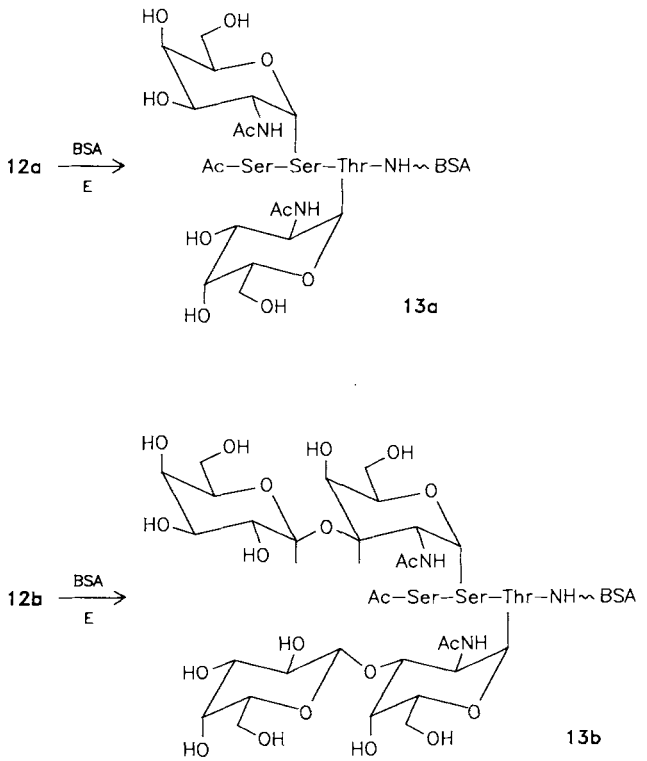


Scheme 1. AA = Ser or Thr. Bzl = benzyl, Bz = benzoyl. A: 1) $NaBH_4/NiCl_2$, 2) Ac_2O/pyridine; B: morpholine.

As protecting groups we used our tested combination[10] of *N*-terminal 9-fluorenylmethoxycarbonyl(Fmoc) group[11] and *C*-terminal benzyl ester in the glycosylation step, and in the chain-lengthening reactions the solubility-promoting 2-(4-pyridyl)ethoxycarbonyl (Pyoc) group.[12]

Table 1. Yields of compounds **5** and **6**.

Cpd.	AA	Yield [%]	Cpd.	AA	Yield [%]
5a	Ser	65 + 9% β	**6a**	Ser	86
5a	Thr	60 + 4% β	**6a**	Thr	85
5b	Ser	51 + 20% β	**6b**	Ser	70
5b	Thr	30 + 21% β	**6b**	Thr	60



Scheme 1 outlines the synthesis of the partially protected serine and threonine derivatives having T_N- **7a** or T-antigen structure **7b** (see also Table 1). Fmoc-serine benzyl ester **3**, AA = Ser,[10] and Fmoc-threonine benzyl ester **3**, AA = Thr, react with glycosyl donors **4a**[13] and **4b**[6] to give mainly the α-glycosides **5**. The accompanying β-glycosides, particularly those in the case of the disaccharide derivatives **5b**, can be separated chromatographically.

Scheme 2. C: 1) CH_3I/CH_2Cl_2, 2) morpholine/CH_2Cl_2, 3) Ac_2O/pyridine; D: 1) H_2/Pd, 2) hydrazine hydrate/methanol. The yield of **12** is based on **10**.

After reaction of the azido function with sodium boronate/nickel chloride[13, 14] and immediate acetylation, the fully-protected *O*-glycosylamino acid derivatives **6** are obtained. The Fmoc group can be selectively removed from these sensitive compounds with morpholine.[10] It is decisive for the further steps of the synthesis that the rate of reaction of the *N*-unprotected compounds **7** thus obtained is fast enough, since they otherwise decompose by self-destructing β-elimination of the glycan moiety. Fmoc-protected carboxyl components often react too sluggishly.

The chain-lengthening steps (Scheme 2) with formation of **8** and **10**, on the other hand, can be accomplished quite effectively with Pyoc-serine[15] or with the Pyoc-protected glycopeptides **9** in the presence of ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ).[16] In the selective deblocking of the carboxyl function on the fully-protected glycodipeptides **8**, the Pyoc group shows a further advantage: In contrast to the Fmoc group[17] it is stable towards hydrogenolysis. Prior to coupling with the albumin, the Pyoc residue is selectively removed from the fully-protected glycopeptides **10** by methylation to the pyridinium form and decomposition with morpholine in dichloromethane[12] without destroying the base-sensitive *O*-glycosidic bonds of serine and threonine. The free terminal serine residue is acylated to **11**, so that the free amino functions have no effect on the base-catalyzed destruction of the *O*-glycoside bonds, and, later, also do not influence the immunological recognition of the carbohydrate-peptide linkage region.[18] After hydrogenolysis of the *C*-terminal benzyl ester and gentle cleavage of all acetates using hydrazine in methanol,[10] the glycopeptides with T_N- and T-antigen structure (**12a** and **12b**, respectively) deblocked in the carbohydrate moiety are obtained in high yields. Their structure and purity has been unequivocally confirmed by ^{13}C-NMR spectroscopy.[20]

Scheme 3. E: Bovine serum albumin (BSA), (water soluble) $EtN{=}C{=}N{-}(CH_2)_3NMe_2$, 1-hydroxybenzotriazole, 4°C [21].

The coupling of the synthetic antigen-glycopeptides **12** to bovine serum albumin (BSA)—presumably at the ε-amino functions of the lysine residues—can only be carried out in aqueous solution (Scheme 3).

The conjugates **13a** and **13b** are freed from low-molecular impurities by dialysis against water. According to a photometric carbohydrate determination[18] (*N*-acetylgalactosamine/galactose as standard) they contain ca. 130 μg of carbohydrate/1 mg conjugate (**13a**) and 280 μg of carbohydrate/1 mg conjugate (**13b**), respectively. This means that, of the ca. 60 lysine residues of BSA, 25 and 38, respectively, are conjugated with the synthetic tumor-associated T_N- and T-antigen structures. The conjugates **13** are thus the first immunologically relevant bound synthetic glycopeptides with the tumor-specific recognition structures **1** and **2**, which, moreover, are only bound via natural peptide and amide bonds to the biological carrier molecule and should be suitable for inducing formation of antibodies against the structures typical for tumor cell membranes.

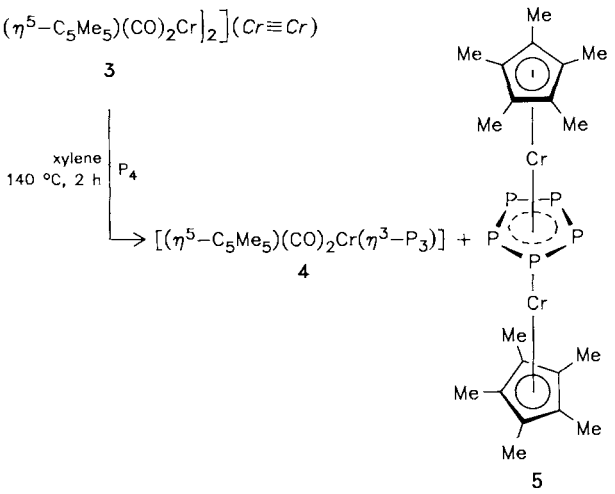
cyclo-P_5 as Complex Ligand—the Phosphorus Analogue of the Cyclopentadienyl Ligand**

By *Otto J. Scherer,* Joachim Schwalb, Gotthelf Wolmershäuser, Wolfgang Kaim,* and *Renate Gross*



Dedicated to Professor Rolf Appel on the occasion of his 65th birthday

The recently reported successful stabilization of *cyclo*-As_5 and *cyclo*-P_6 ("hexaphosphabenzene") as bridge ligand ("middle deck") in the triple-decker complexes **1**[1] and **2**[2] respectively, signaled the possibility of also stabilizing *cyclo*-P_5 in the same way.[3]

$[\{(\eta^5\text{-}C_5H_5)Mo\}_2(\mu,\eta^4\text{-}As_5)]$ **1**

$[\{(\eta^5\text{-}C_5Me_5)Mo\}_2(\mu,\eta^6\text{-}P_6)]$ **2**

If, in analogy to the synthesis of **2**, the Cr_2-complex **3** is allowed to react with P_4, then not only traces of the yellow η^3-P_3-complex **4** are formed but also the μ,η^5-P_5 triple-decker complex **5**, which can be isolated as blackish-red, shiny-metallic crystals (dec. 250 °C).[4, 17]

5,[4] which is only sparingly soluble in pentane but moderately soluble in benzene and dichloromethane (the solutions are very air-sensitive), is a paramagnetic triple-decker complex.[5] With 27 valence electrons (3×5 and 2×6), **5** closes a gap, since up to now only examples with 26 and 28 to 34 valence electrons were known.[6, 16] In the ^{1}H-NMR spectrum (200 MHz, 293 K, $CDCl_3$, TMS int.), a broad signal (halfwidth = 30 Hz) is observed at $\delta = -7.1$ (paramagnetic shift), in the $^{31}P\{^1H\}$-NMR spectrum (80.82 MHz, [D_6]benzene, 85% H_3PO_4 ext.), a sharp singlet at $\delta = 290.5$ ($^{13}C\{^1H\}$-NMR (50.28 MHz, [D_6]benzene, TMS int.): $\delta = 80.4$ (s, C_5Me_5), -2.2 (s, CH_3)). In the mass spectrum,[7] the line for the molecular ion is the strongest-intensity line.

The paramagnetism ($S = 1/2$) of **5** can be detected ESR spectroscopically at room temperature. Under high resolution conditions, a relatively narrow, unstructured signal[7] is obtained, from which the upper limiting values $a(^1H) \le 0.15$ mT, $a(^{31}P) \le 0.5$ mT, and $a(^{53}Cr) \le 0.9$ mT can be estimated for the coupling constants. With regard to reference compounds,[8, 9] this means, on the one hand, that the P_5 ring is situated in a nodal plane of the singly occupied molecular orbital[12] (cf. the well resolved ^{31}P-NMR spectrum), and, on the other, that the splitting of ca. 1.8 mT[9] by the isotope ^{53}Cr ($I = 3/2$, 9.54% natural abundance) observed for mononuclear paramagnetic Cr^I sandwich complexes is clearly lowered, at least halved. This was to be expected in the case of equal distribution of the unpaired electron between the two chromium centers.[10] **5** can therefore be regarded as a delocalized, mixed-valence complex of class III,[11] in which two equivalent chromium centers of oxidation state +1.5 (d^4/d^5 system) are bound by a *cyclo*-$P_5^{\ominus}$ bridge ($P_5^{\ominus} \triangleq C_5H_5^{\ominus}$).

The ESR results and the ratio $g_\parallel > g_\perp \approx g_{electron}$[10] are consistent with results of MO calculations on triple-decker complexes;[12a, b] nine electrons (d^4/d^5) are located in the predominantly metal-centered bonding orbitals e_2' (δ), e_2'' (δ), a_1' (σ), and a_2'' (σ), so a non-degenerated ground state $^2A_1$ can be assumed for **5**.

Electrochemical investigations on the 27-valence-electron system **5** (cf. also [5, 16]) gave a reversible one-electron oxidation step and reduction step[7] to the 26-valence-electron cation $\mathbf{5}^{\oplus}$ and 28-valence-electron anion $\mathbf{5}^{\ominus}$, respectively; calculations using $E_{ox} = +0.07$ V and $E_{red} = -0.97$ V gives a comproportionation constant $K_c = 4\times10^{17}$.

The accuracy of the X-ray structure analysis[13] is diminished by the crystallographically conditioned disorder of one of the two independent molecules (molecule 2) and the strong anisotropy of the temperature factors of the P atoms. Furthermore, the number of the reflections categorized as observed (2126) compared to the number of parameters to be determined is low and an anisotropic refinement of the temperature factors of the C atoms is therefore not justified. A detailed discussion of the bond lengths and angles quoted in Figure 1 is therefore out of the question. A refinement of the structures in the likewise conceivable acentric space groups $P2/n$ and $P2_1$ did not lead to any significant improvement.

5, with the three planar, parallel five-membered rings (Fig. 1), has a similar conformation as the triple-decker

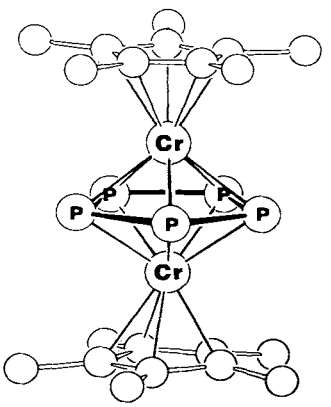


Fig. 1. Structure of **5** (molecule 1) in the crystal. Selected bond lengths [Å] and angles [°]: P-P 2.15(2)-2.21(2), P-Cr 2.29(1)-2.32(1), Cr-Cr 2.727(5); P-P-P 107.3(6)-108.9(6). Sum of angles 540, Cr-P-Cr 72.2(3)-72.7(3). The corresponding values for molecule 2 do not differ significantly.

complex $[\{(\eta^5\text{-}C_5H_5)Ni\}_2(\mu,\eta^5\text{-}C_5H_5)]^{\oplus}$.[14] In contrast to **1** (As_5 middle deck), in which a μ,η^4-coordination of the five-membered ring is discussed on the basis of the large differences in the As–As bond lengths (2.389(2)–2.762(3) Å),[1] in **5** the P_5 ring forms a regular pentagon (cf. the pentagonal columns of phosphorus atoms in Hittorf's phosphorus and the polyphosphides derivable therefrom[15]); the mean value of the P–P bond lengths differs very little from that in the P_6 middle deck of **2**,[2] and is of an order of magnitude which has also been found in the triple-decker complexes stabilized by triphosphorus ligands (triphos = for example 1,1,1-tris(diphenylphosphinomethyl)ethane) with μ,η^3-P_3 bridges.[16]

[4] Procedure: A solution of $Cr(CO)_6$ (3.5 g, 15.9 mmol) and pentamethylcyclopentadiene (2.9 mL, 16.6 mmol) in xylene (130 mL) was stirred under reflux for 60 h. The solution was then treated at room temperature with 2.0 g (16.1 mmol) of P_4 and heated to gentle boiling for 2 h. The blackish-brown solution was decanted and the residue extracted twice with CH_2Cl_2 (2 × 10 mL). The xylene solution was evaporated to dryness in a vacuum, and, after combination with the CH_2Cl_2 extract and addition of aluminum oxide (10 g, basic, 2% H_2O), re-dried under oil-pump vacuum until just pourable. Chromatographic separation (column: 2 cm × 35 cm, alumina (basic, 2% H_2O)) with pentane as first eluent gave a weak yellow phase (which was difficult to separate from the following broad, brown phase) which contained **4** (yield 10 mg, 0.2%, referred to $Cr(CO)_6$; $^{31}P\text{-}\{^1H\}$-NMR (C_6D_6): $\delta = -269.7$ (s); IR (*n*-heptane): $\tilde{\nu}(CO) = 1975$ (vs), 1928 (vs) cm^{-1}. Elution of the brown fraction with pentane/toluene (10 : 1), followed by evaporation to dryness and recrystallization from toluene afforded blackish-red crystals of **5** (yield 350 mg, 8.3%).

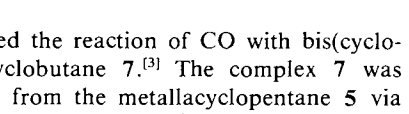
Reductive Coupling of CO: Formation of a 1 : 1 Adduct of η^2-Ketone- and Enediolato-Complex upon Carbonylation of Bis(cyclopentadienyl)hafnacyclobutane**

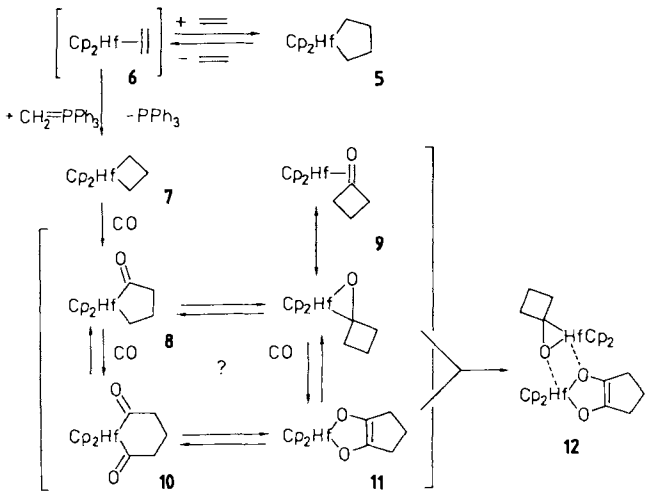


By *Gerhard Erker,* Peter Czisch, Rüger Schlund, Klaus Angermund,* and *Carl Krüger*

Dedicated to Professor Siegfried Hünig on the occasion of his 65th birthday

Alkyl and hydrido complexes of the bent metallocenes of oxygenophilic d- and f-elements can react with CO to give [(enediolato)MCp_2] compounds. Whereas the mechanism of this reductive coupling is basically understood in the case of multinuclear enediolate-bridged compounds (**1** → **2**) through the isolation of intermediates,[1] this is not so in the case of mononuclear compounds (**3** → **4**).[2]

1 **2**



3 **4**

We have examined the reaction of CO with bis(cyclopentadienyl)hafnacyclobutane **7**.[3] The complex **7** was synthesized starting from the metallacyclopentane **5** via formation of (ethylene)hafnocene **6**[4] by extrusion of one equivalent of ethylene and reaction with methylenetriphenylphosphorane. Upon carbonylation of this very reactive alkylmetal compound we expected that the following reactions might possibly take place: Initially, CO insertion into a Hf–C σ-bond leading to formation of the metallacyclopentanone **8**,[5] followed by direct rearrangement with CC coupling to give (η^2-cyclobutanone)hafnocene **9**, or, alternatively, further uptake of a CO molecule with formation of the bis(acyl)metallocene complex **10**. **10** would be a potential intermediate for intramolecular CC coupling to yield the enediolato complex **11** (see Scheme 1).

Scheme 1.

Indeed, the hafnacyclobutane **7** rapidly takes up 1.5 equivalents of carbon monoxide under ambient conditions. The compound **12**, a 1 : 1 adduct of the two hypothetical intermediates **9** and **11**, was isolated as the sole product in good yield.[6] The NMR spectra show two Cp absorptions, the complex splitting pattern of the substituted cyclobutane moiety, and—very characteristic—the signals of the enediolato moiety (e.g. ^{13}C-NMR ([D$_6$]benzene): $\delta = 135.0$, 144.7 (s, C5, C9); the apparent C_{2v} symmetry of the building block **11** is lowered to C_s by adduct formation. In the IR spectrum, the C=C stretching vibration band of the enediolate is observed at $\tilde{\nu} = 1690\ cm^{-1}$.

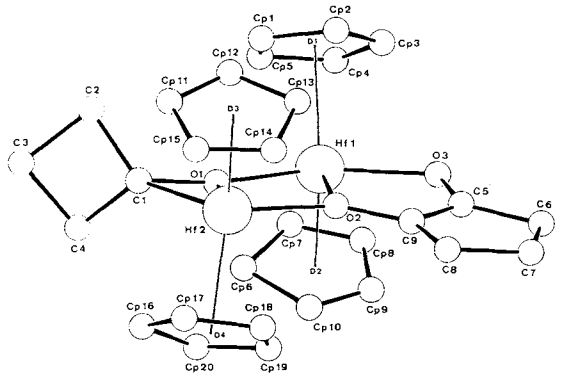

Fig. 1. Crystal structure of **12**. Selected bond lengths [Å] and angles [°]: Hf1-O1 2.138(6), Hf1-O2 2.234(5), Hf1-O3 2.097(7), Hf2-O1 2.103(6), Hf2-O2 2.163(5), Hf2-C1 2.266(8), O1-C1 1.46(1), O2-C9 1.40(1), O3-C5 1.35(1), C5-C9 1.33(1); O1-Hf1-O2 65.9(2), O2-Hf1-O3 74.2(2), O1-Hf2-O2 67.7(2), O1-Hf2-C1 38.8(3), Hf1-O1-Hf2 116.2(3), Hf1-O2-Hf2 110.0(2), Hf2-C1-O1 64.5(4).

An X-ray structure analysis of **12**[7] showed that the cyclobutane moiety is folded ($\theta = 35.8°$; C3 directed towards Hf2). As is usual for a (η^2-ketone)metallocene complex, the (η^2-cyclobutanone)hafnocene unit exhibits pronounced σ-complex character.[8] The adduct formation with the (enediolato)hafnocene substructure stabilizes in a very typical way the coordinatively unsaturated metallaoxirane moiety using both metal centers and two oxygen atoms. An almost planar Hf_2O_2 four-membered ring results, exhibiting almost equidistant Hf-O bond lengths (for further details of the structure see Fig. 1).

Adduct formation is neither unusual for the very reactive metallaoxiranes of the metallocenes of the titanium group[8] nor for metalladioxolene systems.[9] However, it is quite remarkable that we have only obtained the cross-over product **12**, and not the simple dimers of **9** and **11**. Presumably the reactive metallaoxirane traps the enediolate complex before substantial monomer concentrations of the two species are built up. As shown in Scheme 1 the monomers can, in principle, be formed via two routes. The assumption that **11** is a consecutive product of **9**, i.e., that it may be formed by a reaction path avoiding the frequently proposed bis(acyl)metallocene intermediate **10**, is an interesting mechanistic alternative.[9, 10]

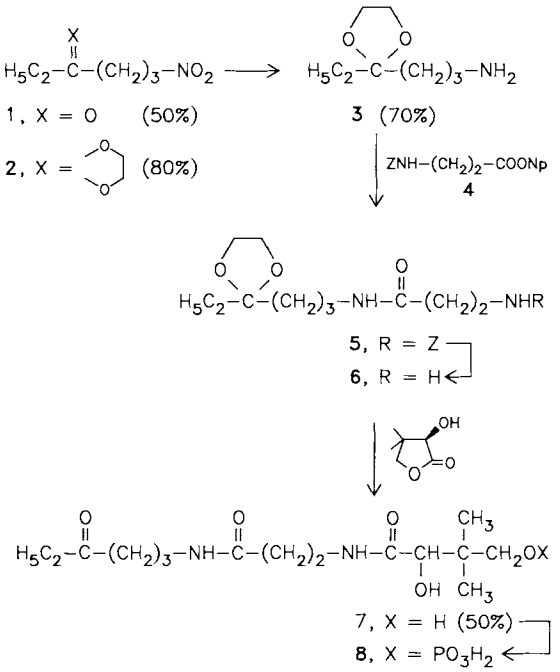
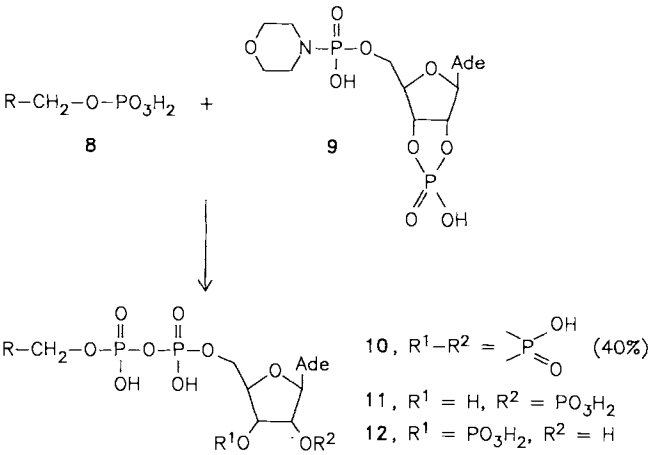
Methylmalonylcarba(dethia)-Coenzyme A as Substrate of the Coenzyme B_{12}-Dependent Methylmalonyl-CoA Mutase: Enzymatic Rearrangement of a β- to a γ-Keto Acid**

By *Martina Michenfelder* and *János Rétey**



Dedicated to Professor Hans Musso on the occasion of his 60th birthday

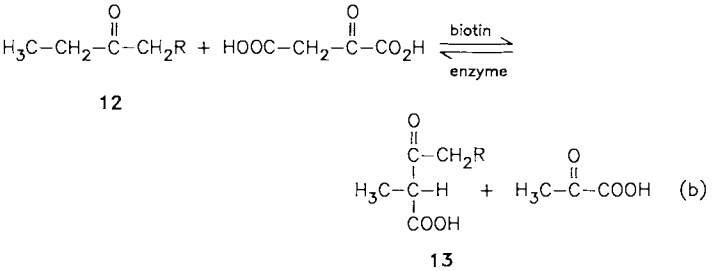
Methylmalonyl-CoA mutase[1] is the only well-characterized coenzyme-B_{12} (AdoCbl)-dependent enzyme occurring in animal and human tissues. It catalyzes the reversible rearrangement of methylmalonyl-CoA to succinyl-CoA [Equation (a)], an important step in the metabolism of propionic acid. In spite of the revelation of interesting details,[1] the mechanism of this unusual enzyme reaction is



(a)

still unclear. The behavior of enzymes towards substrate analogues can often make a valuable contribution to an understanding of their mode of action. We therefore synthesized by a combination of chemical and enzymatic methods methylmalonylcarba(dethia)-CoA **13**, an analogue in which sulfur is replaced by methylene (Schemes 1 and 2).[2]

Scheme 1. Z = benzyloxycarbonyl, Np = *p*-nitrophenyl.



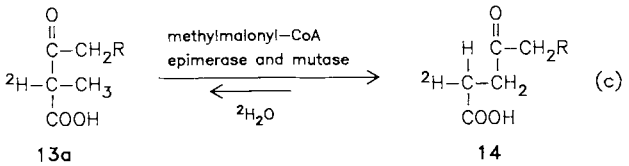
Addition of nitromethane to ethyl vinyl ketone in the presence of sodium methoxide furnished 6-nitro-3-hexanone **1**. The nitro group in the acetal **2** was reduced with Raney nickel to give **3**, which was condensed with protected β-alanine **4** according to the method described by *Stewart* and *Wieland*[2] to give the peptide **5**. The amine **6**, obtained by hydrogenolytic removal of the benzyloxycarbonyl protecting group, was condensed with (−)-(*R*)-pantolactone in the melt to give propionylcarba(dethia)pantetheine **7**.[3] The phosphorylation of **7** was accomplished with (cyanoethyl)phosphate in the presence of dicyclohexylcarbodiimide, and the cyanoethyl group was subsequently removed by alkaline hydrolysis. The barium salt of propionylcarba(dethia)phosphopantetheine **8** was characterized by ^{1}H- and ^{31}P-NMR spectra.[4]

Scheme 2. R see **8** in Scheme 1. Ade = adenine residue.

The final steps for the synthesis of the desired coenzyme A analogue **13** are outlined in Scheme 2. **8** was condensed with the known[2,5] adenosine derivative **9** to give the carba(dethia)-CoA derivative **10**, in which only the 2′,3′-phosphate ester ring had to be opened in order to obtain an almost 1:1 mixture of the 2′- and 3′-phosphates **11** and **12**. The 3′-phosphate is the target compound, namely propionylcarba(dethia)-coenzyme A **12**, while the ^{1}H-NMR spectroscopically distinguishable 2′-phosphate is the undesired propionylcarba(dethia)-isocoenzyme A **11**. The compounds **11** and **12** were almost completely separated by chromatography on DE-32 cellulose with a LiCl gradient and characterized.[6]

Whereas **11** is inert towards methylmalonyl-CoA pyruvate carboxylase (transcarboxylase), **12** reacts smoothly according to Equation (b). (The enzymatic carboxylation of **12** was not surprising since the analogous carboxylation of acetonylcarba(dethia)-CoA has already been reported.[7])

(b)



Removal of pyruvate from the equilibrium by reaction with lactate dehydrogenase led to complete conversion into (2*R*)-methylmalonylcarba(dethia)-CoA **13**, which was isolated and characterized by ^{1}H-NMR spectroscopy.[8]

Lehrstuhl für Biochemie im Institut für Organische Chemie der Universität
Richard-Willstätter-Allee, D-7500 Karlsruhe 1 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The pH-dependent epimerization of **13** can be observed directly in the NMR spectrometer, since it proceeds concomitantly with the replacement of the α-H atom by deuterium. The halftime of the epimerization at p^2H 7.1 is 140 min, and is thus shorter than that for a methylmalonic acid thiolester.[9] The epimerization of **13** to **13a** is accelerated by methylmalonyl-CoA epimerase.

13a is an excellent substrate for the coenzyme B_{12}-dependent methylmalonyl-CoA mutase. The enzymatic rearrangement [Eq. (c)] could be observed directly in the NMR

13a 14

spectrometer. Most striking was the disappearance of the methyl doublet at $\delta=1.21$.[10] In a preparative experiment, the enzymatic rearrangement was carried out in unlabeled solvent and the succinylcarba(dethia)-CoA **14** was isolated. With **14** and succinyl-CoA as substrates for methylmalonyl-CoA mutase the Michaelis constants were found to be $K_M=13.6\times10^{-5}$ M and $K_M=2.5\times10^{-5}$ M, respectively. The constant for **14** is somewhat higher (i.e. the affinity for the analogue is somewhat weaker), while the maximum reaction velocity (V_{max}) is practically the same.

The enzymatic rearrangement of a β-keto acid (**13**) to a γ-keto acid (**14**) is described here for the first time: the decomposition of model cobalt complexes with migration of an acyl group has already been observed.[11]

Nickel-Induced Cyclotetramerization of Cyclopropabenzene to 1,6 : 7,12 : 13,18 : 19,24-Tetrakismethano[24]annulene**

By *Richard Mynott, Richard Neidlein,* Harald Schwager,* and *Günther Wilke**

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

Ever since 1,6-methano[10]annulenes were first synthesized,[1] bridged annulenes have been the subject of intense theoretical and preparative interest. It seems surprising, however, that there has so far been no reported attempt at the synthesis of such compounds via organometallic intermediates. In catalytic cyclooligomerizations on "naked" nickel, numerous metallacycles—as catalytic intermediates—could be trapped and isolated.[2,3] Thus, reaction of 3,3-dimethylcyclopropene with 2,2′-bipyridyl-1,5-cyclooctadienenickel(0) affords a metallacyclopentane with two annelated three-membered rings.[4] We report here, an unusual two-step synthesis of tetrakismethano[24]annulene **7** by cyclotetramerization of cyclopropabenzene **1** via a metallacycle intermediate (Scheme 1).

Scheme 1. The (unsymmetrical) numbering merely serves for assignment of the spectra. cod = 1,5-cyclooctadiene.

1[5] reacts smoothly with 1,5-cyclooctadienenickel(0) **2** in pentane at $-20°C$ to give the bismethanonickelacyclotridecahexaene **3**.[6] Two cyclopropabenzene molecules are added oxidatively to **2** with displacement of the olefin ligand and C–C coupling. The liberated olefin can be removed in a high vacuum or by recrystallization. Compound **3** is stable at room temperature under argon.[7] The structure was essentially derived from a 2D-INADEQUATE ^{13}C-NMR spectrum: the chemical shift of C-7 ($\delta = 52.8$), the values of the coupling constants $^1J_{C\text{-}7,H\text{-}7} = 130$ and 140 Hz, and the geminal coupling $^2J_{H\text{-}7,H\text{-}7'} = 8.3$ Hz, indicated a bis(cycloheptatriene) system. This was confirmed by an X-ray structure analysis,[8] which, in addition, revealed a *trans* orientation of the methano bridges.

The Ni–C σ-bonds in **3** are amenable to insertion reactions with subsequent reductive elimination. Reaction of **3** with CO leads not only to formation of dicarbonylbis(trimethylphosphane)nickel(0) but also of the cyclopentanone derivative **4**,[7, 9] whose structure was determined by NMR, IR/Raman, and mass spectroscopy, and by an X-ray structure analysis.[8] The ^{13}C-NMR shift of C-8 ($\delta = 21.8$) and the values of the coupling constants $^1J_{C\text{-}8,H\text{-}8} = 168$ Hz and $^2J_{H\text{-}8,H\text{-}8'} = 3.9$ Hz, indicate that **4** is present as a norcaradiene isomer, and not—as expected—as a carbonylated bis(cycloheptatriene) derivative. The *trans* orientation of the methano bridges, which cannot be derived from the NMR spectra, was demonstrated by an X-ray structure analysis. Reaction of **3** with ethereal HCl, affords 1,1'-bi(1,3,5-cycloheptatriene) **5** in almost quantitative yield.[7, 10, 11] In contrast, when hydrolysis is carried out with H_2SO_4/H_2O, high yields of a 1:1 mixture of **5** and **6** are obtained.[7, 12] The methyl protons in **5** and **6** are, as expected, equivalent.

Upon reaction with trimethylphosphane, **3** undergoes reductive elimination to give tetrakismethano[24]annulene **7**;[13] the expected formation of 1,6:7,12-bismethano[12]annulene **8** was not observed. It follows from the NMR spectra of **7** that all four rings are in the cycloheptatriene form ($^2J_{H\text{-}1,H\text{-}1'} = 11.8$ Hz). This geminal coupling shows that, as in the case of **3** and **4**, the methano bridges do not invert. The UV spectrum of **7** points to an extended conjugated system.

With the synthesis of **7**, it has been shown for the first time that a methano-bridged annulene can be prepared by a two-step transition-metal-induced reaction. Formally, the reaction is a cyclotetramerization of cyclopropabenzene.

[12] **5** and **6**: A solution of **3** (600 mg, 1.53 mmol) in THF (20 mL) was treated under argon with 1% H_2SO_4 (10 mL) and, after 30 min, with pentane (50 mL). The organic phase was washed three times with H_2O (30 mL) and dried over $MgSO_4$. Flash chromatography on silica gel (15 cm × 3 cm Ø; eluent: pentane) yielded, besides 111 mg (0.61 mmol, 40%) of **5**, in the second fraction 153 mg (0.42 mmol, 55%) of red crystals of m.p. 114°C. **6**: ^1H-NMR (200 MHz, $CDCl_3$, TMS): $\delta = 2.51$ (d, 2H, H-1); 5.35 (br. q, 1H, H-2); 6.17 (m, 1H, H-3); 6.60 (m, 6H, H-4,5,9,10,11,12); 6.37 (br. d, 1H, H-6); 2.75 (s, 2H, H-14).—^{13}C-NMR (75.5 MHz, $CDCl_3$, TMS): $\delta = 30.6$ (t, C-1); 122.3, 123.0, 124.2, 124.5, 127.0 (d, C-2,3,6,9,12); 130.3 (d, C-4); 130.4 (2C), 130.8 (d, C-5,10,11); 132.5, 132.8, 132.9 (s, C-7,8,13); 33.2 (t, C-14).—MS: *m/z* 362 (M^+).—IR (KBr): $\tilde{\nu} = 1487$, 1518, 1577 (m) (C=C) cm^{-1}.—UV (*n*-hexane): $\lambda_{max} = 241$ nm ($\varepsilon = 37000$), 299 (20800), 340 (13500), 394 (10400).
[13] **7**: A solution of **3** (2.0 g, 5.11 mmol) in THF (300 mL) was treated at $-78°C$ under argon with 1 mL (10.22 mmol) of trimethylphosphane. The mixture was allowed to warm to RT over 4 d. After removal of the THF the residue was taken up in pentane and the resulting solution filtered through a frit; the filtrate and pentane washings were evaporated to dryness and subjected to work-up by HPLC. Crude yield: 75 mg (0.42 mmol, 8.2%). After HPLC separation: 41 mg (0.11 mmol, 4.5%) red crystals, m.p. 277°C.—^1H-NMR (400 MHz, CD_2Cl_2, TMS): $\delta = 0.65$ (d, H-1, $^2J(1,1') = 11.8$ Hz); 3.18 (d, H-1'); 6.33 (m, H-3, $^3J(3,4) = 6.8$ Hz); 6.68 (m, H-4).—^{13}C-NMR (75.5 MHz, CD_2Cl_2, TMS): $\delta = 31.0$ (t, C-1); 126.5 (s, C-2); 124.6 (d, C-3); 128.5 (d, C-4).—MS: *m/z* 360 (M^+).—IR (KBr): $\tilde{\nu} = 1570$ (m) (C=C) cm^{-1}.—UV (*n*-hexane): $\lambda_{max} = 263$ nm ($\varepsilon = 91100$), 338 (22600), 415 (3800).

Carbohydrate-Based Liquid Crystals: Mesogenic 1-*O*-Alkyl Derivatives of 2,5-Anhydrohexitols**

By *Peter Köll** and *Michael Oelting*

Although *Emil Fischer* had already reported on the perculiar melting behavior of some amphiphilic *O*-alkylglycosides at the turn of the century, and the first systematic investigations on the liquid-crystalline properties of these

[**] Carbohydrate-Based Liquid Crystals, Part 1.

compounds were carried out in the 1930s,[1] the field of thermotropic mesogenic carbohydrates can be considered as having been neglected.

Consequently, *Jeffrey*, in his recent review of the few sugar-based liquid crystals reported so far, restricted himself to *O*- and *S*-*n*-alkylglycosides.[2] There are, however, further isolated reports in the literature on mono-*O*-acyl derivatives of saccharides possibly exhibiting liquid crystalline properties.[3]

Recently, *Dahlhoff* introduced a new type of non-glycosidic stable carbohydrate mesogenes, namely 1-*O*-alkyl derivatives of sugar alcohols.[4] This prompted us to report our findings that are relevant in this connection.

Scheme 1. a) NaOMe in MeOH, 24 h, RT; b) ROH in $CHCl_3$, 48 h at 50°C in presence of trifluoromethanesulfonic acid as catalyst; c) Ac_2O in pyridine, 18 h, RT; d) 80% HOAc, 18 h, RT; e) TosCl in pyridine, 18 h, RT.

Table 1. Melting points (M.p.) and clearing points (Cl.p.) of **3** and **6**.

	R	3		6	
		M.p. [°C]	Cl.p. [°C]	M.p. [°C]	Cl.p. [°C]
a	n-C_6H_{13}	—	—	—	—
b	n-C_7H_{15}	<RT	42	<RT	32
c	n-C_8H_{17}	59	67	<RT	78
d	n-C_9H_{19}	61	82	<RT	81
e	n-$C_{10}H_{21}$	70	89	46	87
f	n-$C_{12}H_{25}$	74	115	58	102
g	n-$C_{14}H_{29}$	80	126	67	103
h	n-$C_{16}H_{33}$	87	210	74	104
i	n-$C_{18}H_{37}$	92	>210	80	101

The 1,3:2,5-dianhydrohexitols **2** and **5**, which can be synthesized from the known educts **1**[5] and **4**,[6] respectively (Scheme 1), undergo smooth reaction with alcohols to give the mono-1-*O*-alkyl ethers **3a–i** and **6a–i**, respectively.[7] Whereas the compounds of type **3** exhibit L-*ido* configuration, the derivatives **6** belong to the D-*gluco* series of the 2,5-anhydrohexitols.

When the chain length of the *n*-alkyl moiety in the 1-*O*-alkyl-2,5-anhydrohexitols **3** and **6** exceeds C_7, the latter show an anisotropic phase above the melting point that is transformed into the isotropic liquid at a distinctly higher clearing point (Table 1). The compounds **3b** and **6b–d** are already liquid-crystalline even at room temperature. We assume, on the basis of the birefringence observed under the polarizing microscope that smectic phases are formed in all cases.[8] Also in the other previously described liquid-crystalline carbohydrates, if one disregards the special case of some discotic hexa- and penta-*O*-acyl derivatives of inositols and hexoses,[9] smectic phases are presumed.[10] Aside from the phase transitions given in Table 1, further solid/solid transformations take place below the melting point in some cases.

Comparison of the two series of compounds **3** and **6**, with L-*ido* and D-*gluco* configuration, respectively, reveals in almost all cases that the *ido* derivatives **3** show higher melting and clearing points than the analogous gluco compounds **6**. This difference, which is said to be essentially due to deviating possibilities for the formation of hydrogen bridges, is already found in the parent compounds (R = H).

CC-coupled amphiphiles ("C-glycosides" of pentofuranoses) can also be synthesized from the oxetanes **2** and **5**.[11] Such compounds with alkyl chains beyond C_5 (i.e. C_6 with inclusion of the primary CH_2 group of the 2,5-anhydrohexitol) also form liquid-crystalline phases. The melting points of comparable derivatives, however, are in each case higher than in the case of the ethers **3** and **6** described here.

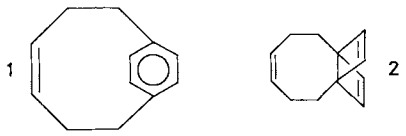
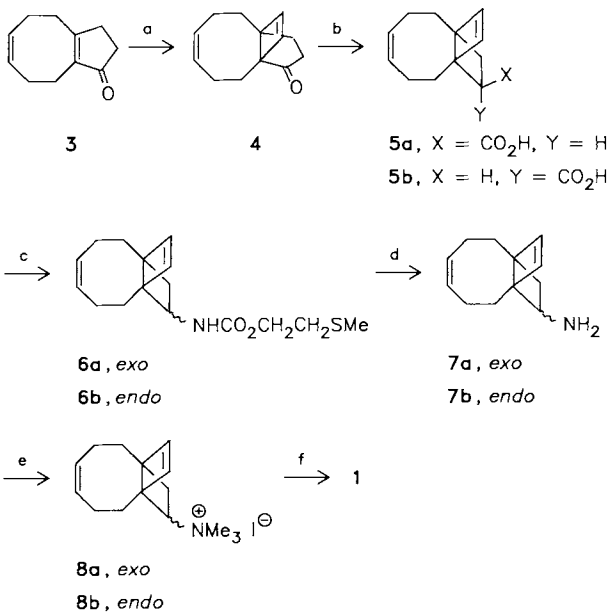
(*Z*)-[6]Paracycloph-3-ene**

By *Yoshito Tobe,** *Ken-ichi Ueda, Kiyomi Kakiuchi,* and *Yoshinobu Odaira*



Of the [n]paracyclophanes that have been isolated, [6]Paracyclophane has the smallest-bridge; its remarkable properties are due to the severe deformation of the benzene ring.[1] Although we as well as *Bickelhaupt* et al. have recently been able to characterize the next lower homologue, [5]paracyclophane, spectroscopically as an unstable intermediate,[2] it has so far eluded isolation.

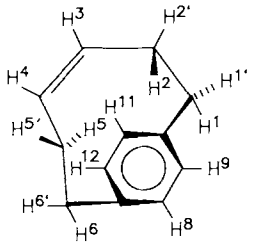
We now describe the synthesis of (*Z*)-[6]paracycloph-3-



[*] Dr. Y. Tobe, K. Ueda, Dr. K. Kakiuchi, Prof. Dr. Y. Odaira
Department of Applied Fine Chemistry, Faculty of Engineering
Osaka University, Suita, Osaka 565 (Japan)

[**] We are grateful to Dr. *Y. Takai* of the Institute of Scientific and Industrial Research, Osaka University for measuring the ^{1}H-NMR spectrum and for valuable discussions.

ene **1**, which, because of the length of its bridge—the bridge consists of six carbon atoms and has one *cis* double bond at the center[3]—must be allotted a place between [6]- and [5]paracyclophane. **1** is thus the smallest isolable paracyclophane known so far.



For the synthesis of **1**, we took advantage of the thermal valence isomerization of its Dewar-benzene isomer, [6.2.2]propellatriene **2**. The *exo*- and *endo*-propelladienecarboxylic acids **5a** and **5b**, respectively, were prepared from the bicyclic enone **3**[4] via the propelladienone **4** using our photocycloaddition and ring contraction strategy[1c] (yield: 26 and 17%, respectively). Reaction of **5a** with diphenylphosphoryl azide[5] and subsequent treatment with methylthioethanol afforded the methylthioethyl carbamate **6a** in 78% yield; alkaline hydrolysis[6] of the sulfonium salt of **6a** furnished the *exo*-amine **7a** (65%), which was converted into the ammonium salt **8a** (81%, m.p. 147–150°C). After conversion into the corresponding hydroxide and subsequent pyrolysis (120°C, 0.1 torr), **1** was obtained as a colorless solid (m.p. 29–33°C) in 44% yield. Although the Dewar-benzene isomer **2** was not detected at all, it is reasonable to assume that **1** was formed by thermal isomerization of **2** during pyrolysis. **5b** was transformed in an analogous way into the ammonium salt **8b** (m.p. 161–163°C), which on Hofmann degradation afforded **1** in lower yield (see Scheme 1).

Scheme 1. Synthesis of **1**: a) 1. ClHC=CHCl, *hv*; 2. $HOCH_2CH_2OH$, $H^{\oplus}$; 3. Na, NH_3; 4. $H^{\oplus}$. b) 1. HCO_2Et, EtONa; 2. $TosN_3$, Et_3N; 3. *hv*, MeOH; 4. KOH. c) $(PhO)_2PON_3$, $HOCH_2CH_2SMe$. d) 1. Me_2SO_4; 2. NaOH. e) MeI, $KHCO_3$. f) 1. Ag_2O, H_2O; 2. 120°C, 0.1 torr.

The spectroscopic properties of **1**,[7] especially its ^1H-NMR spectrum (360 MHz, $CDCl_3$, 25°C), are characteristic for the structure. The AA'XX' pattern of the signals of the aromatic protons appears at $\delta = 7.20$ and 7.07 ($^4J_{AX} = 1.0$, $^5J_{AX'} = 0.9$ Hz); decoupling and simulation experiments show that the vinyl protons exhibit an AA'BB'XX' pattern, formed by coupling to the allyl protons ($^3J_{AX} = 11.9$, $^4J_{AX'} = -0.8$, $^3J_{BX} \approx 5$, $^4J_{BX'} \approx -1$, $^3J_{XX'} = 12.2$ Hz); the signals of the two pairs of benzylic protons (H^1 and H^6, and $H^{1'}$ and $H^{6'}$) and of the two pairs of allylic protons (H^2 and H^5, and $H^{2'}$ and $H^{5'}$) appear at considerably different field strengths. Particularly noteworthy is the remarkably high-field shift (ca. 1 ppm) of the signals of the vinyl protons ($\delta = 4.68$) and one pair of the allylic protons (H^2 and H^5: $\delta = 1.01$) due to the shielding effect of the aromatic ring. Moreover, the sharp lineshapes and the temperature independence of ^1H- and ^{13}C-NMR spectra indicate conformational rigidity of the bridge in **1**.

1 exhibits a remarkable bathochromic shift in the UV spectrum (hexane, $\lambda_{max} = 310$ ($\varepsilon = 340$), 260 (3900), 227 (5400) nm) in comparison to [6]paracyclophane[8], suggesting a considerable increase in the out-of-plane deformation of the benzene ring in the former system relative to that in the latter. We are presently investigating the effect of the above strain on the reactivity of the aromatic ring and the double bond.

[Cp(CO)$_2$Mo{NR*[Rh(norbornadiene)]-CH(pyridyl)}], a Rhodium Complex with an Asymmetric Molybdenum Atom in the Chelate Skeleton**

By *Henri Brunner,* Joachim Wachter, Johann Schmidbauer, George M. Sheldrick,* and *Peter G. Jones*

Usually, in enantioselective catalysis, optically active chelate ligands are employed which coordinate via P or N atoms.[1] In some of these ligands the P atoms are the chirality centers; mostly, however, the inducing chirality is located in the chelate skeleton, as a rule in the form of asymmetric C atoms, but occasionally also as axial and planar chiral moieties. We now report on nitrogen chelate ligands and their rhodium complexes, which, for the first time, contain chiral transition metal atoms besides asymmetric C and N atoms in the chelate skeleton.

Reaction of the molybdenum complex **1** with sodium amalgam (20°C, 2 h, tetrahydrofuran) leads to formation of the complex **3** in 46% yield; its formation in the reaction of **1** with $LiCH_3$ has already been reported.[2,3] **3** has four chirality centers. One of them is already contained in R* [(*R*)-1-phenylethyl], the other three, at the Mo, N and C atoms of the three-membered ring, are formed during the reaction. Thus, eight stereoisomers are possible, of which only four have been detected (by ^{1}H-NMR spectroscopy) and only two isolated in pure form.

Regardless of whether one starts from the pure diastereomers **1a** and **1b** or from a **1a/1b** mixture, the reaction always leads to a 55:45 mixture of two products having different ^{1}H-NMR spectra, which can be separated chromatographically. The first red zone obtained upon chromatography on Merck-Lobar columns[4] contains the complexes **3a/3b**, while the second red zone contains the complexes **3c/3d**.

The isomers **3a** and **3b** rapidly interconvert in solution at room temperature; this manifests itself in the breadth of the ^{1}H-NMR signals. The high-temperature limiting spectrum for the **3a/3b** mixture was observed at 100°C and the low-temperature limiting spectrum with separate signals for **3a** and **3b** in the intensity ratio 96:4 at −70°C.[5] The isomeric pair **3c/3d** behaves analogously (at −70°C 90:10).[5]

At −20°C, ether/pentane solutions of **3a/3b** and **3c/3d**, afforded single crystals of **3a** and **3c**, respectively, whose absolute configurations were determined by X-ray

[**] Optically Active Transition Metal Complexes, Part 90. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. Part 89: I. Bernal, G. M. Reisner, H. Brunner, G. Riepl, *Inorg. Chim. Acta 103* (1985) 179.

crystallography[6,7] (Fig. 1 and 2). In both compounds, the substituents Cp on Mo, H on N, and pyridyl on C are located on the same side of the three-membered ring; the NH proton forms a hydrogen bridge to the pyridine N. The configurations of the chirality centers in the three-membered ring are $S_{Mo}S_NS_C$ in **3a** and $R_{Mo}R_NR_C$ in **3c**.[11]

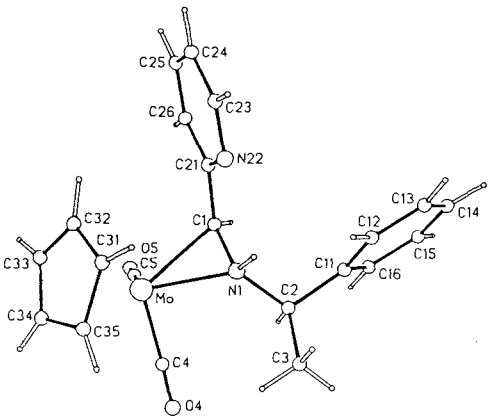

Fig. 1. Structure of **3a** in the crystal. Selected bond lengths [Å] and angles [°]: Mo-N1 2.174(4), Mo-C1 2.210(4), C1-N1 1.414(5), Mo-C4 1.921(5), Mo-C5 1.939(5), C4-O4 1.170(6), C5-O5 1.141(6), Mo-Cp 2.318–2.383, C1-C21 1.472(6), N1-C2 1.491(5), C2-C3 1.519(6), C2-C11 1.516(5), C-C(phenyl and pyridyl) 1.368–1.373, C-N22 1.339(6) and 1.340(6); N1-Mo-C1 37.6(2), Mo-N1-C1 72.6(3), Mo-C1-N1 69.8(3), N1-Mo-C5 107.4(2), N1-Mo-C4 90.7(2), C1-Mo-C4 110.9(2), C4-Mo-C5 77.3(3), C1-Mo-C5 81.1(3), Mo-N1-C2 126.2(3), Mo-C1-C21 116.3(3). Only one of two independent, very similar molecules is shown; in the second molecule the C11-C16 ring is rotated through ca. 30° compared to that in the first molecule.

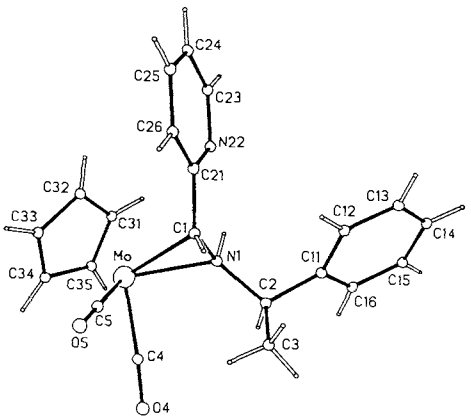

Fig. 2. Structure of **3c** in the crystal. Selected bond lengths [Å] and angles [°]: Mo-N1 2.172(3), Mo-C1 2.213(3), C1-N1 1.421(4), Mo-C4 1.938(4), Mo-C5 1.942(4), C4-O4 1.159(4), C5-O5 1.152(4), Mo-Cp 2.318–2.378, C1-C21 1.483(4), N1-C2 1.499(4), C2-C3 1.522(4), C2-C11 1.514(4), C-C (phenyl and pyridyl) 1.382–1.400, C21-N22 1.333(5), C23-N22 1.350(5); N1-Mo-C1 37.8(2), Mo-N1-C1 72.7(2), Mo-C1-N1 69.5(2), N1-Mo-C5 108.7(2), N1-Mo-C4 90.9(2), C1-Mo-C4 111.7(2), C4-Mo-C5 78.6(2), C1-Mo-C5 82.0(2), Mo-N1-C2 128.9(2), Mo-C1-C21 115.9(2).

Thus, the following picture emerges: In the reduction of **1**, the cation accepts two electrons. The anionic intermediate **2a** is formed in which the Mo–N(pyridyl) bond is broken. The chirality of the Mo atom disappears, and **1a** and **1b**, despite the contrary Mo configurations, give the same products. In the reaction **2a** → **2b** + **2c** the σ-bonded imine ligand becomes π-bonded and thereby the configuration at the C atom of the three-membered ring is established (S_C in **2b** and R_C in **2c**). The placement of the proton on **2b** and **2c** on the pyridine side via a preformed H bridge explains the *cis* orientation of the substituents H and pyridyl in **3a** and **3c**; there is no experimental evidence for a *trans* orientation. The isomer **3b**, which constitutes about 4% of the mixture with **3a** ($S_{Mo}S_NS_C$), is assigned opposite Mo configuration ($R_{Mo}S_NS_C$) whereby rapid isomerization **3a** ⇄ **3b** might arise by intramolecular rotation of the immonium ligand,[8] comparable with the rotation of an olefin in a π-complex. Correspondingly, **3c** and **3d** can be assigned the configurations $R_{Mo}R_NR_C$ and $S_{Mo}R_NR_C$, respectively. **3a** and **3c**, with *cis* oriented Cp, H, pyridyl substituents on the MoNC three-membered ring, are thermodynamically more stable than **3b** and **3d**.

Reaction of **3a/3b** with $[Rd(nbd)Cl]_2$ (nbd = norbornadiene) afforded the complex **4**, which after chromatography was isolated as a reddish-brown powder in 61% yield.[9] The same product is formed on using **3c/3d** as starting material. Crystallization from ether/pentane at −20°C furnished single crystals of **4a**, whose absolute configuration was determined by X-ray crystallography.[6,7] In **4a** the chelate ring formed via the two N atoms and the Rh atom lies on the side of the MoNC three-membered ring opposite to the cyclopentadienyl ring. This is surprising, since the substituents Cp, H and pyridyl are located on the same side of the MoNC three-membered ring in the complexes **3a** and **3c**. The reason for the chelate ring in **4a**, in contrast to the N–H–N hydrogen bridge in **3a** and **3c**, preferring that side of the three-membered ring with the CO ligands, may be sought in the formation of a bond between the Rh atom and C10 of the CO group C10-O10 (Fig. 3). This CO group (Mo-C10-O10 166.9°) deviates from linearity; the Rh-C10 distance (2.821 Å), however, points to only a weak interaction of the Rh atom with the C atom. The formation of this CO bridge is unusual, because semibridging CO groups normally only occur when metal–metal bonds are present.

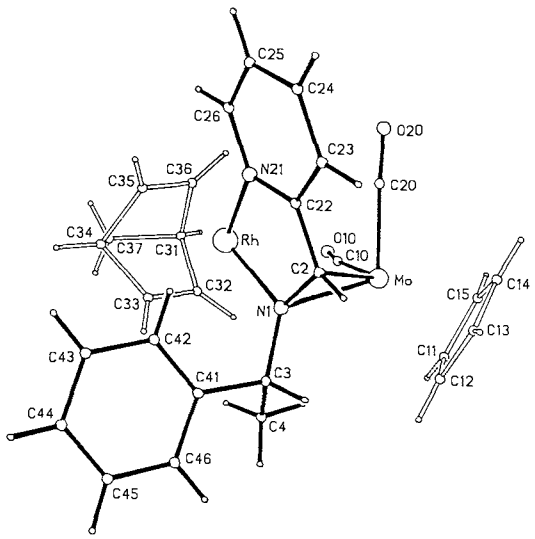

Fig. 3. Structure of **4a** in the crystal. Selected bond lengths [Å] and angles [°]: Mo-N1 2.221(5), Mo-C2 2.241(6), N1-C2 1.401(7), Mo-C10 1.966(6), Mo-C20 1.939(8), C10-O10 1.143(7), C20-O20 1.151(10), Mo-Cp 2.327–2.388, C2-C22 1.419(7), N1-C3 1.491(8), C22-N21 1.346(7), C26-N21 1.345(7), Rh-N21 2.117(5), Rh-N1 2.068(5), Rh-C32 2.122(6), Rh-C33 2.136(5), Rh-C35 2.110(6), Rh-C36 2.121(6); N1-Mo-C2 36.6(3), Mo-C2-N1 70.9(3), Mo-N1-C2 72.5(3), C10-Mo-C20 77.7(4), Mo-C10-O10 166.9(6), Mo-C20-O20 174.4(7), N1-Rh-N21 80.2(2), C22-C2-N1 118.1(5), Rh-N1-C2 109.8(4), Rh-N21-C22 112.3(4), N21-C22-C2 116.4(5).

The ^{1}H-NMR spectra show that **4** forms two diastereomers **a** and **b**, which rapidly interconvert in solution at room temperature. The high-temperature limiting spectrum for **4a/4b** is observed at 100°C, while the low-temperature limiting spectrum, with separate signals for **4a** and **4b** in the intensity ratio 98:2, is observed at −70°C.[10] It is not possible, as yet, to make any statements about the structure of **4b**.

The finding that the reactions of **3a/3b** and **3c/3d** with $[Rh(nbd)Cl]_2$ lead to the same product **4a/4b** can only be explained in terms of an intermediate **2a**. The intermediate **2a** is formed from both **3a/3b** as well as from **3c/3d**; the asymmetry of all former three-membered ring atoms is removed, leading under the strongly alkaline conditions used in the synthesis,[9] to establishment of the equilibrium **3a/3b** ⇄ **3c/3d**, even in the absence of $[Rh(nbd)Cl]_2$. It therefore follows that epimerization of the intermediates **2b** and **2c** (with π-coordinated imine ligand) via **2a** (with σ-coordinated imine ligand) is more rapid than the reaction with $[Rh(nbd)Cl]_2$: Otherwise, if the complex **4a** ($R_{Mo}R_NS_C$) is formed from **3a/3b**, then **3c/3d** would have to yield a Rh-complex **4c** with $S_{Mo}S_NR_C$ configuration, which is not observed.

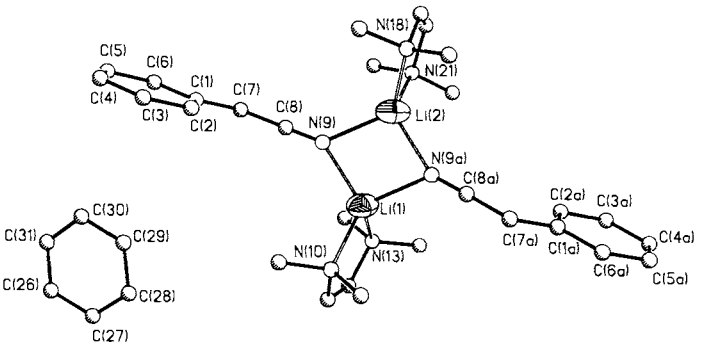
[(α-Cyanobenzyllithium · Tetramethylethylenediamine)$_2$ · Benzene]: X-ray Structure Analysis of an α-Nitrile "Carbanion"**

By *Gernot Boche,* Michael Marsch,* and *Klaus Harms*

The synthetic importance of α-nitrile-"carbanions" extends from dinitrile cyclization[1] to the umpolung of aldehydes with trimethylsilyl cyanide.[2] However, although numerous mechanistic investigations have been carried out,[3] and both mono- as well as di-alkali-metal compounds of acetonitriles and phenylacetylnitriles have been prepared and investigated IR spectroscopically,[4, 5] an X-ray structure analysis has so far never been carried out.[6] In the following, we report on such an analysis of [(α-cyanobenzyllithium · tetramethylethylenediamine (TMEDA))$_2$ · benzene] **1** · C_6H_6[7] (Fig. 1).



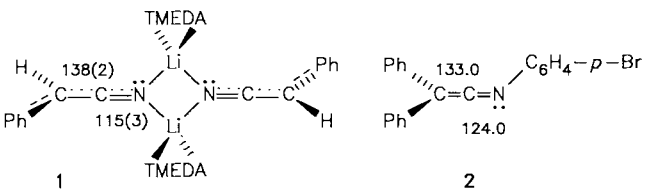


Fig. 1. Asymmetric unit of the crystal structure of **1** · C_6H_6. Space group $P2_1/n$, a = 968.0(2), b = 1583.4(4), c = 2402.9(6) pm, β = 99.46(2)°, Z = 4, R = 0.115 for 2292 reflections with $F > 3\sigma(F)$. The high R value is due to decomposition of the crystal in the X-ray beam. The H atoms on C-7 and C-7a were given a fixed C-H distance (96 pm) and a common isotropic temperature factor. All other H atoms were refined according to a riding model with C-H = 96 pm. All calculations were carried out with the SHELXTL (Rev. 5.1) program system (*G. M. Sheldrick*, Göttingen 1985). Selected bond lengths [pm] and angles [°] (mean values: Li-N(TMEDA) 205(4), Li-N(anion) 204(3), C1-C7 143(2), C7-C8 138(2), C8-N9 115(3), Li1-Li2 264(5); C1-C7-C8 124.5 (1.0), C7-C8-N9 178.4(1.0), N9-Li1-N9a 98.2(0.5), Li1-N9-Li2 80.9 (0.5), dihedral angle C6-C1-C7-C8 179.2 (0.7). Because of the small anisotropic vibration of the nitrogen atom, an analysis of the C8-C9 bond length according to a riding model [8] gave only a slight lengthening to 117(2) pm. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51841, the names of the authors, and the full citation of the journal.

1 · C_6H_6 crystallizes as a dimer, in which Li atoms are bonded to the N atoms of the nitrile groups and the TMEDA molecules. This solid state structure may corre-

spond to the structure in solution, since $PhCH(CN)^{\ominus}Li^{\oplus}$ is likewise dimeric according to molecular weight determinations in dimethoxyethane and in dimethyl sulfoxide.[5f,9] As in the recently described [$tBu_2C{=}NLi \cdot$ hexamethylphosphoric acid triamide]$_2$,[10] μ2-N-Li bonds are present in the slightly puckered Li_2N_2 ring (torsional angle $\pm 10.2(0.5)°$). The "anions" are almost planar (greatest deviation from the least squares plane: 2 pm), so the "anionic" C atoms C-7 and C-7a should also be planar coordinated.[11] The "anion" planes are at an angle of 95.7 and 103.5°, respectively, to the least squares plane of the Li_2N_2 ring. The co-crystallized benzene molecule fills the gaps between the orthogonally oriented planes of the "anion" and the Li-TMEDA five-membered ring; the nearest intermolecular distance is 378 pm (C30-C4).

Particularly interesting is the bonding situation in the almost linear CCN unit ($\sphericalangle = 178.4\ (1.0)°$). Thus, the C7-C8 distance is 138(2) pm, whereas the C8-N9 bond length of 115(3) pm is as short as in a nitrile.[11,12]

In comparable ketenimines such as **2** one finds shorter CC distances and longer CN distances,[13] which is also consistent with the IR spectra. Thus, $\mathbf{1} \cdot C_6H_6$ (in Nujol) shows an intense band at 2065 cm^{-1} ($\tilde{\nu}_{as}(C{=}C{=}N)$),[14] whereas ketenimines absorb at $\approx$1990–2010 cm^{-1}.[13c] Hence, the structural relationship between the lithium "keteniminate" $\mathbf{1} \cdot C_6H_6$ and normal ketenimines is less than that between a lithium enolate and enol ethers: In the latter series the C=C and C-O distances are almost the same.[15] The reason for this could lie in the different stabilization of a negative charge. Whereas a carbonyl group is predominantly mesomeric, in a nitrile group the (inductive) field effect also plays an prominent role.[3,16]

[7] $\mathbf{1} \cdot C_6H_6$: A solution of benzyl cyanide (100 mg, 0.85 mmol) in benzene (3 mL) was treated at room temperature with a solution of TMEDA (1.04 mmol) and BuLi (1.04 mmol) in hexane, and, after 1 h, with 1.2 mL of hexane. After 4 to 8 h, the whitish, needle-shaped crystals of $\mathbf{1} \cdot C_6H_6$ were freed from solvent with the aid of a drawn out pipette. They were then washed with hexane and dried at 10^{-3} torr.

[8] C. K. Johnson: *Crystallographic Computing*, Munksgaard, Kopenhagen 1970, p. 220–226.

[9] Quantum mechanical calculations gave an analogous structure; P. von R. Schleyer, private communication, April 18, 1985. Interestingly W. Bauer and D. Seebach (*Helv. Chim. Acta 67* (1984) 1972) and D. Seebach (private communication) January 6, 1986) found that $PhCH(CN)^{\ominus}Li^{\oplus}$ is present as a monomer in tetrahydrofuran at −108 °C and not, as at 18.5 °C, as a dimer [5f]. This finding is consistent with MNDO calculations by S. Schröder, Universität Marburg. Accordingly, $[PhCH(CN)^{\ominus}Li^{\oplus}(NH_3)_2]_2$ is, as model for **1**, only obout $\Delta\Delta H_f \approx 5$ kcal/mol more stable than the monomer $PhCH(CN)^{\ominus}Li^{\oplus}(NH_3)_3$; hence, entropy effects can favor the monomer at low temperatures. According to STO-3G calculations by *H.-U. Wagner*, Universität München (private communication, March 24, 1980), a bent monomer with a Li-1,3-bridge is the most stable one; see also J. B. Moffat, *J. Chem. Soc. Chem. Commun. 1980*, 1108.

[11] Since we could not localize the H atoms on C-7 and C-7a, a more suitable substitution is a prerequisite before a definite answer can be given. *Note added in proof (March 7, 1986):* A new measurement at ca. −35 °C gave the following important results: 1) The hydrogen atoms on C(7) and C(7a) could be located and refined. The sum of the bonding angles on C(7) is 359.9°, on C(7a) 359.7°. These atoms are thus planar coordinated. 2) The C(8)-N(9) was determined accurately. It is 117.4(7) pm, i.e. somewhat longer than the mean value measured at room temperature. A riding correction lengthened this bond to 119.5(10) pm. The cell constants at −35 °C are: a=968.9(2), b=1569.9(4), c=2391.4(6) pm, β=99.53(2)°. The R value is 0.094 (R_w=0.088) for 2469 reflections with $F > 3\sigma(F)$.

[12] CH_3CN: 115.7 pm; C.C. Costain, *J. Chem. Phys. 29* (1958) 864. Since the CN distance in nitrile complexes of Lewis acids is shortened to 113.5 pm, as in $CH_3CN \cdot BF_3$ (B. Swanson, D. F. Shriver, J. A. Ibers, *Inorg. Chem. 8* (1969) 2182) a similar effet caused by $Li^{\oplus}$. TMEDA could contribute to short CN-bonding in $1 \cdot C_6H_6$.

[13] a) J. J. Daly, *J. Chem. Soc. 1961*, 2801; b) R. R. Nagvi, P. J. Wheatley, *J. Chem. Soc. A 1970*, 2053; c) J. Lambrecht, B. Gambke, J. von Seyerl, G. Huttner, G. Kollmannsberger-von Nell, S. Herzberger, J. C. Jochims, *Chem. Ber. 114* (1981) 3751. d) abnormally short CN bonds ($\approx$115 pm) are found in linear(!) ketenimines such as $(CH_3SO_2)_2\overset{\ominus}{C}{-}C{\equiv}\overset{\oplus}{N}{-}CH_3$ [13a,b]; hence, their structure was compared with that of cyanamidinium salts $R^1R^2\overset{\oplus}{N}{-}C{\equiv}\overset{\oplus}{N}{-}R^3X^{\ominus}$; e) see also J. Lambrecht, L. Zsolnai, G. Huttner, J. C. Jochims, *ibid. 114* (1981) 3655.

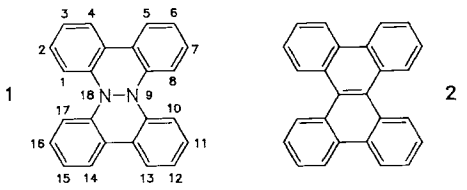
[14] 1175 cm^{-1} ($\tilde{\nu}_s(C{=}C{=}N)$); 570 cm^{-1} ($\tilde{\nu}(Li_2N_2$-Ring)). $PhCH(CN)^{\ominus}Na^{\oplus}$ shows a similar band as $\mathbf{1} \cdot C_6H_6$ at 2080 cm^{-1} [4], whereas completely different bands have been reported for $PhCH(CN)^{\ominus}Li^{\oplus}$ in Nujol [5f].

[15] Example: $H_2C{=}C(tBu)$-OLi: C=C 134, C-O 135 pm, enol ether: C=C 132, C-O 136 pm; R. Amstutz, W. B. Schweizer, D. Seebach, J. D. Dunitz, *Helv. Chim. Acta 64* (1981) 2617.

[16] This manifests itself in the low (high) activity of cyclopropyl ketones (nitriles); J. M. Motes, H. M. Walbossky, *J. Am. Chem. Soc. 92* (1970) 3697; H.-U. Wagner, G. Boche, *Z. Naturforsch. B 37* (1982) 1339, and references cited therein.

Benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline, a Chiral Hydrazine Derivative**

By *Hans Fischer, Claus Krieger,* and *Franz A. Neugebauer**



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

In benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline (**1**),[1] a triphenylhydrazine derivative with *ortho* linkage of the *N,N'*-phenyl substituents, the interaction of the lone-electron pairs on the nitrogen atoms with the connected π-electron system can lead to a flattening of the molecule. But even on extensive planarization the axial (*N-N*) chirality should be preserved because of the spatial requirements of the 1,17- and 8,10-hydrogen atoms; as in the case of dibenzo[*g,p*]chrysene (**2**)[2] one would expect a very low racemization barrier. Surprisingly, **1** crystallizes as separate enantiomers in the chiral space group $P2_1$. Prisms of up to a length of 4 mm (0.7 mg) were obtained on crystallization from ethyl acetate.

An X-ray structure analysis[3] of the crystals showed that the substituents on the nitrogen atoms are arranged pyram-

idally. As shown by the C-N-C angle (ca. 140°) of the Newman projection, the molecule as a whole is only slightly flattened. The torsional angle of the orbitals of the two lone pairs is 64°. The structure of **1** corresponds to a propellane skeleton in which a bridge is replaced by two vicinal lone pairs (Fig. 1).

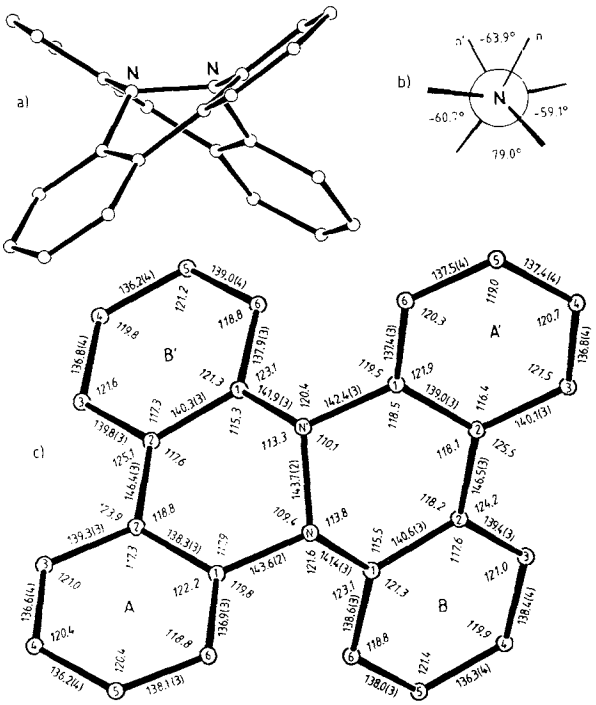

Fig. 1. a) Molecular structure of **1** in the crystal (*M* representation); b) Newman projection (*M*) with torsional angles; c) bond lengths [pm] and angles [°].

In dioxane, the enantiomers gave molar optical rotation values of $[\Phi]_D^{20}$ 2130±60 and $[\Phi]_{405}^{20}$ 24700±400 [enantiomer **A**: (+); enantiomer **B**: (−); concentrations 2×10^{-5} to 14×10^{-5} g mL^{-1}]. Figure 2 shows the respective CD spectra and the electronic spectrum. A definite assignment of the absolute configuration of the enantiomers could not be carried out, even after determination of several Cu-data sets, since the small dispersion effect of the nitrogen with $Cu_{K\alpha}$ radiation was too small compared to the error of measurement.

The rate constants for the racemization were determined by measurement of the optical rotations in decane; T [K] ($k\times10^4$ [min^{-1}]): 370 (642), 360 (233), 350 (75.6), 340 (24.7), 330 (7.34), 320 (2.01). The thermal racemization requires an activation energy of 27.1(±1) kcal mol^{-1} [113(±4) kJ mol^{-1}]; pre-exponential factor $A=6.52\times10^{14}$. Compound **1** can racemize both by rotation about the N-N axis as well as by double nitrogen-inversion. In both cases, a greater degree of planarization of the molecule is to be expected for the transition state. A comparable planarization can also be achieved by one-electron oxidation, which transforms the destabilizing interaction of the vicinal lone pairs into a bonding three-electron interaction, resulting in a planarization of the pyramidal arrangement of the substituents. $\mathbf{1}^{\odot\oplus}$ should therefore have a very low racemization barrier. This is in fact observed. Oxidation of the enantiomers affords an optically inactive radical cation.[4]

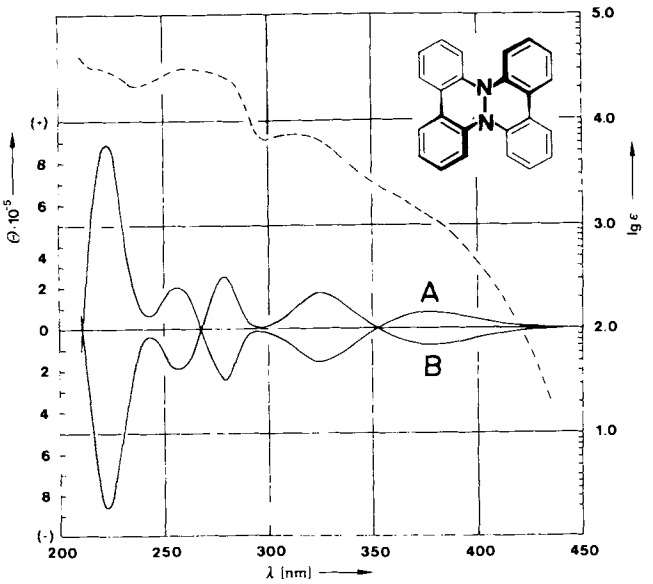

Fig. 2. Electronic spectrum (---) and CD spectra (—) (θ [grad cm^2 dmol^{-1}]) of **1** in dioxane (enantiomer **A**: $c=2\times10^{-5}$ g mL^{-1}; enantiomer **B**: $c=1.4\times10^{-4}$ g mL^{-1}; JASCO J 500).

The above findings indicate that the high racemization barrier of **1** is essentially due to the *gauche* effect[5] of the vicinal lone pairs. Their interaction with the coupled π-electron system proves to be surprisingly small.

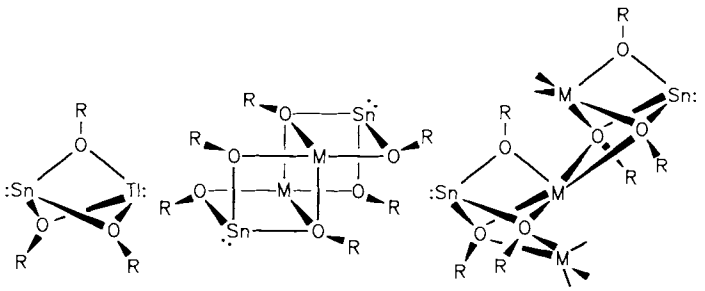
Strontium and Barium Alkoxostannates(II)—Molecules with S_6 Symmetry**



By *Michael Veith,* Dieter Käfer,* and *Volker Huch*

Tris(*tert*-butyloxo)stannates of the alkali-metals[1] and of monovalent thallium[2] exhibit a remarkable variety of structures. Whereas the stannates of thallium, **1**, as well as

[*] Prof. Dr. M. Veith, Dipl.-Chem. D. Käfer, Dr. V. Huch

[**] Alkoxostannates, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 2: [1].

those of lithium and sodium, **2**, form cage-like, molecular units, those of potassium, rubidium and cesium, **3**, form polymers. The structures are illustrated in formulas **1**–**3**, where the lines between the atoms represent, as usual, electron pairs, either in the sense of a two-center bond or a donor-acceptor bond (formal charges not shown). Our interest now turned to the question of whether these structural principles are preserved when two tris(*tert*-butyloxo)stannate ligands are available per "cation", i.e. on going to divalent metal "cations".

1 **2**, M = Li, Na **3**, M = K, Rb, Cs

R = *t*Bu

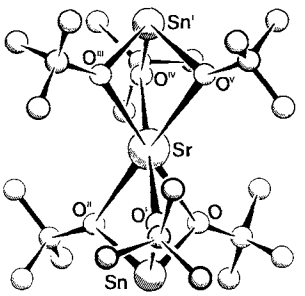
To check this we have examined the reaction of *tert*-butoxides of Mg,[3] Ca,[4] Sr,[5] and Ba,[5] which are insoluble in benzene, with a solution of tin di-*tert*-butoxide[6] [Eq. (a)]. $Mg(OtBu)_2$ and $Ca(OtBu)_2$ do not react, even in boiling benzene (^{1}H-NMR, quantitative recovery of the starting substances), whereas $Sr(OtBu)_2$ and $Ba(OtBu)_2$ undergo complete reaction in accord with Equation (a). The sharp distinction between the *tert*-butoxides of calcium and strontium is also demonstrated in the following experiment: A Ca/Sr alloy was converted into a mixture of the *tert*-butoxides, which was then treated with a benzene solution of $[Sn(OtBu)_2]_2$ (molar ratio 2:1); only the strontium salt was found to react! It dissolved completely, whereas the calcium salt remained undissolved. This procedure can be exploited without difficulty for the quantitative separation of Sr and Ca.

$$M(OtBu)_2 + [Sn(OtBu)_2]_2 \longrightarrow [Sn(OtBu)_3M(OtBu)_3Sn] \quad (a)$$

4, M = Sr; **5**, M = Ba

The compounds **4** and **5** are colorless, and crystallize isotypically (decomposition temperatures: 220 and 270°C, respectively). Both show a singlet in the ^{1}H-NMR spectrum (**4**: $\delta = 1.44$ (1.42), **5**: $\delta = 1.41$ (1.40) in benzene (toluene)), and the elemental analyses and mass spectra are consistent with the formula given in Equation (a). We have determined the structure of **4** by single-crystal X-ray structure analysis (Fig. 1).

The crystal lattice of **4** contains molecules of point symmetry $S_6(\bar{3})$, packed, internally interlocked, parallel to (001) within the layers and in the [001] direction with the layer sequence A,B,C... (the angle in the rhombohedric unit cell is 52.2°). If we consider only the skeletal atoms, then the polycycle can be built from two trigonal bipyramids connected via a common apex with retention of the threefold axis. This apical position, which at the same time is a center of inversion, is occupied by the Sr atom, which is situated in a distorted octahedral environment (O-Sr-O: 90 ± 24.4(1)°). The Sn atoms are, as in the related compounds **1**–**3**, trigonal-pyramidally coordinated (O-Sn-O: 82.3(1)°). The equatorial apices of the two bipyramids are occupied by the oxygen atoms, which, as expected, are at shorter distances from the Sn atoms than from the Sr atom (cf. Fig. 1). A striking feature is that the O atoms are not, as in **1**[2], located in a pyramidal, but in a trigonal-planar environment (sum of angles at the O atoms: 359.5°)—perhaps this arises as a result of intramolecular interactions. Actually, the *tert*-butyl groups in the molecule are in unusual close proximity (distance between the centers of the *tert*-butyl groups 511 and 550 pm); they completely shield the metal atom in the center of the molecule. If the central metal atom were to be even smaller than strontium, the *tert*-butyl groups would repel each other extremely strongly. The Ca atom is probably already too small (Ca–O in CaO: 240.5 pm[6]).



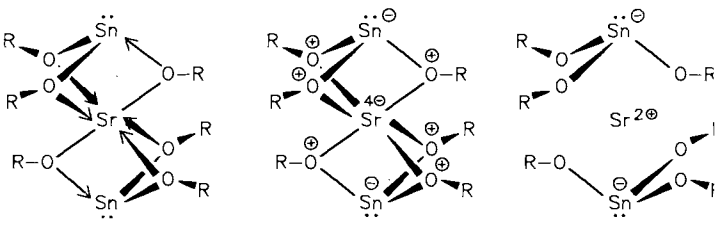


Fig. 1. Structure of **4** in the crystal. The unmarked atoms are C atoms; the H atoms are not shown. The point symmetry of **4** in the crystal is reduced from D_{3d} ($\bar{3}m$) to $S_6(\bar{3})$ by slight rotation of the *tert*-butyl groups. Cell dimensions: $a = 1017(1)$, $c = 2986(2)$ pm, space group: $R\bar{3}$; $Z = 3$. Four-circle diffractometer (Siemens) $R = 0.033$ (all atoms anisotropic) at a reflection-parameter ratio of 15.0:1. Some selected bond lengths [pm] and angles [°]: Sn-O 207.8(3), Sr-O 252.3(3), O-C 141.8(6); O-Sr-O' 65.6(1), Sn-O-C 124.9(3), Sr-O-C 142.8(3). Further details of the structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51786, the names of the authors, and the full citation of the journal.

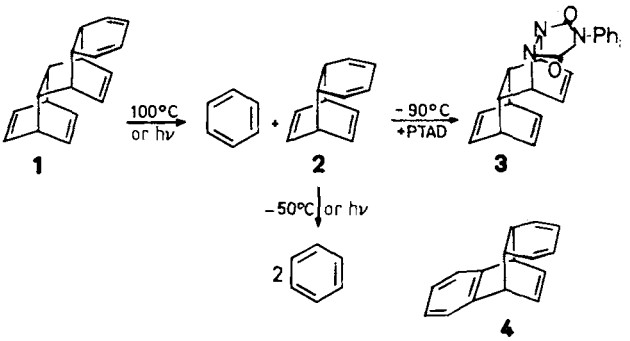
The structure of **4**, like that of **1**–**3**, is very difficult to formulate. Besides the formulation as the donor-acceptor complex **4**, other possible formulations are those with formal charges or ionic substructures **4'** and **4''**, respectively.

4 **4'** **4''**

In **4''** the two halves of the molecule are held together by electrostatic forces, with striking similarity to strontium oxide: The SrO_6 polyhedron in **4** could be regarded as a section of the SrO structure,[6] since the Sr–O distances are also very similar (in SrO: 258.0 pm; in **4**: 252.3(3) pm). Compounds such as **4** and **5** are therefore extraordinarily remarkable in that they contain alkaline-earth metal atoms yet nevertheless are molecularly structured. **4** and **5** are soluble in non-polar solvents such as hexane, benzene, and toluene.

Procedure



A solution of freshly sublimed $[Sn(OtBu)_2]_2$ [7] (1.2 g, 4.53 mmol) in benzene (25 mL) was added dropwise to a suspension of $M(OtBu)_2$, M = Sr, Ba (6 mmol) in benzene (10 mL). The mixture was stirred for 2 h, filtered, and the filtrate evaporated almost to dryness. The product crystallized out as colorless platelets. Yield: 1.59 g (92%) **4** or 1.71 g (93%) **5**.

recording the ^{1}H-NMR spectrum, signals other than that of benzene are observed, which first build up and then decrease during the course of the reaction. These signals correspond to those expected for *o,p'*-dibenzene (Fig. 1): upon heating of the sample to room temperature, they disappear in favor of the benzene signal. At −90°C, the intermediate photoproduct reacts with 4-phenyl-1,2,4-triazoledione (PTAD) to form the adduct **3**, the structure of which also confirms the presence of **2**.

Diels–Alder Adducts of Benzene with Arenes and Their [4 + 2] Cycloreversion**

By *Achim Bertsch, Wolfram Grimme,** and *Gerd Reinhardt*

A continuum of reaction pathways exists for the [4 + 2] cycloreversion, from the simultaneous breaking of two single bonds to stepwise bond cleavage. The retrocleavage of Diels–Alder adducts formed from two arenes should most closely resemble the ideal synchronous reaction. Both components lack the two singly occupied p-orbitals necessary to become aromatic, and only simultaneous formation of these two centers enables the transition state to acquire part of this stabilization. Having reported earlier the adduct **4** between benzene and naphthalene,[1] we now report the Diels–Alder adducts of benzene both with itself and with anthracene and naphthacene.

The Diels–Alder trimer **1** of benzene decomposes at 100°C to benzene without evidence for the formation of the intermediate *o,p'*-dibenzene **2**.[2,8] The retrocleavage of **1** also takes place upon irradiation with a high-pressure mercury lamp through quartz. If the reaction is carried out at −90°C in CD_2Cl_2 in an NMR tube and followed by

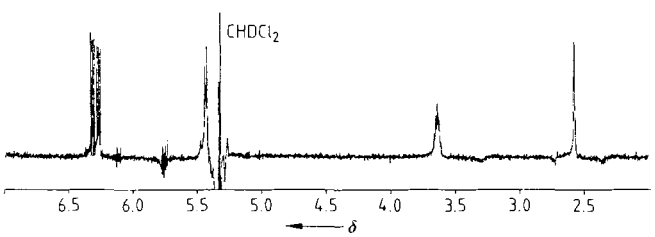

Fig. 1. 300-MHz ^{1}H-NMR spectrum of *o,p'*-dibenzene **2** in CD_2Cl_2 at −90°C. The $CHDCl_2$ signal has been truncated.

The kinetics of the [4 + 2] cycloreversion of *o,p'*-dibenzene **2** was determined by flash photolysis.[3] A solution of the tribenzene **1** in isooctane (8×10^{-5} M) was irradiated in a quartz cuvette ($l = 10$ cm) with a flash from a capacitor discharge and the transient UV absorption of the dibenzene formed, **2**, was recorded at 280 nm. The lifetime of **2** is ca. 0.5 s at room temperature; the kinetic parameters of the decomposition were derived from nine rate constants in the temperature range 20–55°C (see Table 2).

In order to synthesize the more stable adducts **5**–**7**, anthracene and naphthacene were allowed to react with *p*-benzoquinone. With anthracene, **5a** was the sole product, whereas with naphthacene a 1:1 mixture of the stereoisomers **6a** and **7a** was obtained. By hydrogenation with zinc in acetic acid, **5b** and a mixture of **6b** and **7b** were obtained; these compounds were then converted into the bistosylhydrazones **5c**–**7c**. Reaction with *n*-butyllithium in tetrahydrofuran/*n*-hexane at 0°C afforded the anthracene adduct **5**[4] and a 1:1 mixture of the isomeric naphthacene adducts **6** and **7**, respectively.

The adduct **10**, involving the outer ring of anthracene, was obtained from 4a,9,9a,10-tetrahydroanthracene **8**.[5] Cycloaddition of *p*-benzoquinone afforded the adduct **9a**, which, as described above, was converted into the hydrocarbon **9** via the intermediates **9b** and **9c**. Before dehydrogenation of the tetralin moiety in **9**, the cyclohexadiene ring must be protected by addition of 4-ethyl-1,2,4-triazoledione to give adduct **9d**. After formation of the naphthalene system in **10d** by heating with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in tetrachloroethane, the protecting group is removed by basic hydrolysis and oxidation with copper(II) chloride.

The adducts so obtained (Table 1) decompose cleanly into their aromatic components between 0 and 100°C; the nonseparated isomeric naphthacene adducts **6** and **7** have the same lifetime. In order to measure the rates of cycloreversion, a degassed solution of the compound in dodecane (10^{-5} M) was added to a thermostated polarimeter cuvette ($l = 5$ cm); the formation of naphthalene, anthracene, and naphthacene was followed by continuous re-

cording of their long-wavelength UV absorptions. The Arrhenius parameters of the cycloreversion and the temperature range in which they were determined are given in Table 2.

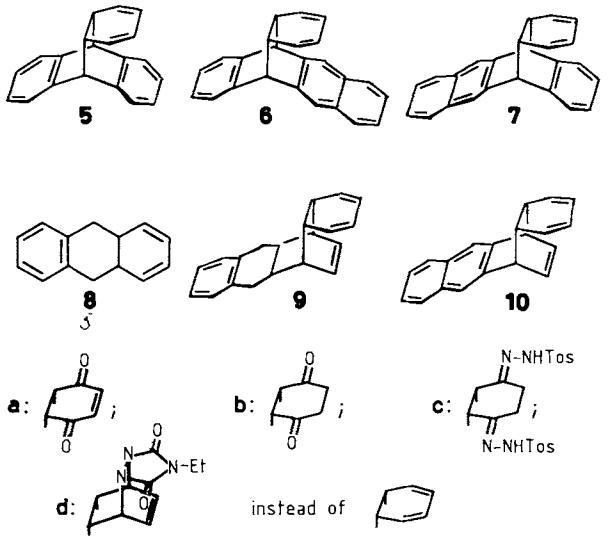

Table 1. Yields and some physical data for the compounds **2**, **3**, **5**, **6**, **7**, **9**, and **10**. The ^{1}H-NMR spectra (except for that of **2**, see Fig. 1) were recorded at 90 MHz in $CDCl_3$.

2, ^{1}H-NMR: $\delta = 6.32$ (q, 2H), 6.27 (q, 2H), 5.43 (m, 4H), 3.63 (sext, 2H), 2.58 (s, 2H)

3, M.p. = 156°C (dec.); ^{1}H-NMR: $\delta = 7.39$ (m, 5H), 6.52 (q, 2H), 6.07 (q, 2H), 5.90 (q, 2H), 4.80 (m, 2H), 3.52 (m, 2H), 2.58 (m, 2H)

5, Yield 8% from **5a**; m.p. = 150°C (dec.); ^{1}H-NMR: $\delta = 7.5$–7.0 (m, 8H), 5.38 (s, 4H), 4.21 (s, 2H), 3.06 (s, 2H)

6, **7**, Yield 4% from **6a**, **7a**; ^{1}H-NMR: $\delta = 7.8$ (m + 2s, 4H), 7.5–7.0 (m, 6H), 5.38 (m + s, 4H), 4.29 (s, 2H), 3.13 (s, 2H)

9, Yield 15% from **9a**; m.p. = 154°C; ^{1}H-NMR: $\delta = 7.1$ (m, 4H), 6.42 (q, 2H), 5.43 (AA'BB', 4H), 2.95 (s, 2H), 2.5 (m, 6H), 2.2 (m, 2H)

10, Yield 32% from **9**; m.p. = 156°C (dec.); ^{1}H-NMR: $\delta = 7.64$ (s, 2H), 7.63 (AA'BB', 4H), 6.70 (q, 2H), 5.63 (s, 4H), 4.10 (m, 2H), 2.92 (s, 2H)

The following linear relationship exists between the observed free energies of activation ΔG^+ for the cycloreversion of the adducts and the gain in resonance energy, ΔRE, calculated according to the SCF-MO method:[6]

Table 2. Activation parameters and resonance gain for the [4 + 2] cycloreversion of the adducts of benzene with arenes.

Compd	ΔT [°C]	lg$A$	E_a [kcal/mol]	ΔG^+ (77°C) [kcal/mol]	ΔRE [kcal/mol]
2	20–55	13.4 ± 0.2	16.5 ± 0.2	15.7 ± 0.1	40.0
4	0–14	12.1 ± 0.6	19.6 ± 0.8	20.8 ± 0.1	30.5
10	20–45	12.3 ± 0.2	21.8 ± 0.6	22.6 ± 0.1	26.4
5	56–80	15.5 ± 0.4	29.3 ± 0.7	25.3 ± 0.2	16.8
6, **7**	80–95	14.9 ± 0.4	30.8 ± 0.6	28.6 ± 0.2	11.5

$$\Delta G^+ = 33.3 \pm 0.9 - (0.43 \pm 0.03) \cdot \Delta RE$$

The correlation coefficient is $r = 0.995$ and the confidence level 99%. Thus, the transition state for the cycloreversion of the adducts is uniformly reduced in energy by 43% of the amount of resonance energy to be gained, ΔG^+ extending over a range of 13 kcal/mol. Structural parameters apparently have no influence on ΔG^+ in this series of closely related adducts. The linear relationship found is only in accordance with a synchronous process, since the breaking of only one bond in the rate-determining step would effect a gain of resonance energy in the intermediate diradicals over a range of only 2 kcal/mol.[7]

BOOK REVIEWS

The Chemist's English. By *Robert Schoenfeld*. VCH Verlagsgesellschaft, Weinheim 1985. xii, 173 pp., bound, DM 42.00/$ 17.95.—ISBN 3-527-26309-8 (VCH Verlagsgesellschaft), 0-89573-436-2 (VCH Publishers)

A large number of books on writing good English are available to the chemist—everything from college textbooks and usage dictionaries to handbooks and style manuals for authors of scientific papers and books. What recommends *The Chemist's English* is above all its readability. In a collection of short essays ranging from the correct use of hyphens and dashes ("Of Nuts, Muttons and Shotguns") and the choice between "that" and "which" ("On the Training of Old Dogs for Which-Hunting") to general questions of style ("Instant Stylistics," "An Investigative Examination of Driveliferous Jargonogenesis") and even "A Chemical Analysis of the English Sentence," *Robert Schoenfeld*, the former editor of the Australian Journal of Chemistry, discusses the many ingredients that go into making the chemist's English good.

Schoenfeld's avowed purpose is not to teach the skill of effective writing per se but rather to whet the appetite for good English. This modest goal he strives to achieve with a highly readable blend of fact, opinion, anecdote, and humor. What emerges from this unorthodox excursion through the English language is the amicably recounted story of one editor's experiences, filled with words of ad-

vice for the scientific author and pervaded with the message that language, like chemistry, can be fun.

The chapter on the overuse of strings of nouns ("Amazing Revelations: English Scientists Secretly Practise German Vice!") illustrates the ingenuity with which the author approaches problems of grammar. In order to explain why "ring junction carbon environment differences" is bad and "differences in the environment of the carbons at the ring junction" or "differences in the environment of the ring junction carbons" better, he introduces the "adjectival" and "genitive bonds" and proceeds to "hydrolyse" this "peptide chain of the order A_5." While perhaps a bit farfetched, the analogy is effective and certainly more entertaining than the dry discussions of most conventional books on grammar and style.

There is, unfortunately, one disturbing side to this book, namely, the inordinate number of errors (which this reviewer would like to assume are merely typographical). In the chapter "Of Nuts, Muttons and Shotguns," for example, the em dash, which may be used to set off parenthetic words or phrases, is discussed and—as in this sentence—printed correctly (i.e., it has roughly the width of a capital M and fills the space almost entirely). This is the first and only time the em dash is printed correctly in the entire book! Further examples are "undistinguishable" instead of indistinguishable (p. 50), "pronounciation" (footnote on p. 64), "commonsense" as a noun (p. 100), and "Oberhauser enhacement" (p. 127).

As the author notes in "Yes, Virginia, there *is* a Temperature," "he who writes about language skates on very thin ice indeed." *Schoenfeld,* like most editors, leaves behind a trail of opinions and pet peeves, but, fortunately, not too many cracks in the ice. Indeed, of all the books on English directed to the scientist, it is refreshing to find one that addresses the subject humorously and in terms the chemist is likely to enjoy. If *The Chemist's English* helps to elevate the chemist's appreciation of good writing, even to a small extent, it will have succeeded where many of its more pretentious relatives have often failed.

Angewandte Chemie, Weinheim

Spectral Atlas of Polycyclic Aromatic Compounds. By *W. Karcher, R. J. Fordham, J. J. Dubois, P. G. J. M. Claude,* and *J. A. M. Lighthart.* D. Reidel Publishing Company, Dordrecht 1985. 818 pp., bound, $ 94.00.—ISBN 90-277-1652-8

Polycyclic aromatic compounds (hydrocarbons and aromatic heterocycles) arise from the pyrolysis and incomplete combustion of organic material. Since such processes occur all over the place in our environment (e.g. in motor vehicles, furnaces and in forest fires), polycyclic aromatic compounds (PACs) are ubiquitous. Some PACs have turned out to be carcinogenic in experiments on animals. These two facts explain the enormous current interest in the analysis of PACs.

The samples that the analyst has to investigate generally comprise extremely complex mixtures of PACs. Therefore, combinations of separation (chromatographic) techniques and identification (spectroscopic) methods are usually, employed. Ideally, a laboratory that carries out PAC analysis would possess highly pure reference samples, for identification and standardization purposes, of all PACs in the mixtures to be analyzed. However, the authors justly observe that "due to the enormous number of compounds which are encountered, this situation is unlikely to be attained in the foreseeable future", and they conclude that "the widespread availability of high quality molecular spectra and related data represents a more realistic and practical alternative".

This work is seen by the authors as the beginning of the realization of this alternative. The spectral atlas deals altogether with only 42 compounds (25 polycyclic aromatic hydrocarbons (PAH), eight methyl-PAHs, five thiophene benzologs, three carbazole derivatives, and 10-azabenzo[a]pyrene). The spectra were recorded by the authors on their own instruments. Many of the compounds documented, and their spectra, could be found in any laboratory that carries out PAC analysis (carbazole, anthracene, phenanthrene, fluoranthene, pyrene, benzo[a]pyrene and others). Yet the authors intend—as indicated in their preface—that further volumes should follow this book. The production of an extensive, multivolume PAC spectral atlas would indeed be a welcome and useful enterprise and would increase the significance of this volume.

The conception and realization of the spectral documentation are excellent:

- In the form of graphs and tables, the following spectra are reproduced: the UV/VIS absorption spectra, fluorescence and fluorescence-excitation spectra (room temperature, energy-corrected), Shpol'skii-fluorescence and phosphorescence spectra (15 K), mass spectra (70 eV), ^{1}H-NMR spectra (80 MHz), ^{13}C-NMR spectra, and IR spectra (KBr disk and solution).
- All spectra have been recorded under stringently standard conditions with suitably pure (>99%) samples.
- The instruments used to make the measurements and the experimental conditions are comprehensively described.
- The chemical shifts in the NMR spectra are assigned by reference to literature data and by comparison with the spectra of related compounds.
- Likewise, the IR bands are assigned to important structural characteristics of the compounds.

Only one critical observation will be made here: such an extensive collection of the spectra of PACs should not have neglected the phosphorescence spectra in solid glasses measured at 77 K; at least for quantitative analysis these are appreciably more useful than the Shpol'skii phosphorescence spectra.

In addition, the book contains the melting points of the ultra-pure compounds. In some cases, literature values for the solubility in water (25 °C) are given.

The authors see the value of their work exclusively in connection with the environmental analysis of PACs (in the reviewer's opinion this is a fully unnecessary limitation; PACs are of significance, for example, in photo- and semiconductor physics, in coal chemistry, and many other fields). Thus, it is understandable that for every compound, indications are given as to "occurrence' and "biological activity". This information is presented in tabular form, with reference to the corresponding literature. These tables should, however, only be seen as a structured literature compilation (which the authors do not make explicitly clear) and their perusal cannot replace a comparative study of the works quoted. A critical evaluation, carried out by experts, of the carcinogenic potential of most of the compounds that appear in this volume can be found in Vol. 32 of the well known IARC monographs (International Agency for Research on Cancer). It is to be wel-

comed that the "IARC classification" has been followed in the tables of this book. Yet it could have been hoped, not least in view of the high reputation of the IARC monographs and their great significance as a source of information, that the authors of the PAC spectral atlas should quote accurately. Thus, we read in Vol. 32 of the IARC monographs "The available data provide *no evidence* that *anthracene* is carcinogenic to experimental animals", while the authors of the PAC spectral atlas remark of anthracene "IARC ranking: *inadequate data*".

Summary: A good spectral atlas, whose acquisition can be recommended, and which will be of use especially to laboratories that are beginning to institute PAC analysis. As far as occurrence and biological activity of PACs are concerned, the book can facilitate literature searching, but in no way replace it.

M. Zander [NB 734 IE]
Rütgerswerke AG, Castrop-Rauxel (FRG)

Biotechnology. A Comprehensive Treatise in 8 Volumes. Series editors: *H.-J. Rehm, G. Reed.* **Vol. 6a: Biotransformations.** *K. Kieslich.* VCH Verlagsgesellschaft, Weinheim 1985. xii, 473 pp., bound, Subscription price: DM 425.00.—ISBN 3-527-25768-3

Biotransformation is the broad term for chemical reactions carried out with the help of microbes or enzymes. These reactions may utilize the microbes or enzymes in an immobilized form or otherwise. The present volume is intended for anyone who wants an overview of the variety of biotransformations of commercial or academic interest.

The volume, which is divided into eleven chapters, begins, after an introductory remark by *K. Kieslich,* with an introduction to some of the methodologies for carrying out these transformations by *H. G. W. Leuenberger.* In the second chapter, *L. L. Smith* presents an excellent summary of the reactions involving steroids. The topic is continued by *C. K. A. Martin* who discusses the selective side chain cleavage of sterols for the synthesis of C-19 or C-22 steroids and the partial degradation of the sterol ring system. As is so often the case, biotechnology here succeeds only when it can surpass the chemical methods regarding conversion efficiencies.

Terpenoid transformations, of interest to the flavor and fragrance industries, are discussed by *V. Krasnobajew.* Optimal control of the transformation processes, such that no useless compounds are formed, and economical isolation of the products are the major challenges in this area. Acyclic, monocyclic, and bicyclic monoterpenoids and ionones and related compounds are discussed. In Chapter 5, *A. Kergomard* gives a comprehensive review of the reduction, oxidation, hydrolysis, hydroxylation, degradation, and synthesis reactions which are effected by bacteria and fungi on alicyclic and heterocyclic compounds. Microbial transformations involving natural and semisynthetic alkaloids (e.g. indole, isoquinoline, quinoline, colchicine, morphine, quinolizidine, nicotine, tropane, and ephedrine alkaloids) are reviewed by *P. J. Davis.* These reactions are of interest because microbial systems offer the first level of investigation into bioactivation, bioinactivation, and detoxification in mammals.

An excellent review of reactions involved in antibiotic compounds of both academic and practical interest is provided by *O. K. Sebek.* β-Lactams, aminoglycosides and rifamycins are discussed in some detail in this chapter, which is also sprinkled with some recent references.

The degradation reactions of arenes and five- and six-membered heterocyclic structures are reviewed in an excellent chapter by *P. R. Wallnöfer* and *G. Engelhardt.* While the emphasis here is on the degradation of pesticides and other industrial pollutants, the authors also cover the possibility of using the catabolism of microbes for the production of potentially useful intermediates. *M. Bühler* and *J. Schindler* contribute a fine review on the transformation of short chain *n*-alkanes, higher aliphatic hydrocarbons, and fatty acids by microbes. The role of the monooxygenase system is discussed in detail. Also included is a survey of patents issued during 1972 to 1982 in Europe, Japan, and the United States. Finally, the investigation of recombinant DNA is also discussed briefly.

The production of amino acids and peptides with the help of microbes and enzymes is reviewed by *G. Schmidt-Kastner* and *P. Egerer.* A brief but informative section outlines the economic aspects. In the last chapter, *A. Crueger* and *W. Crueger* conclude this volume with a discussion of carbohydrates. Aldose-ketose isomerizations such as, e.g., in high fructose corn syrup production, oxidations as in ascorbic acid and gluconic acid production are briefly but accurately highlighted, as are also reductions and the hydrolysis of glycosides, above all with a view towards commercial applications.

This volume is a welcome addition to the volumes that have already appeared.[*] The overall quality of the volume is very good. However, the reader should be cautioned that most of the references cover only up to about 1982. As in the case of the volumes reviewed so far, the contents of this volume also continue to fluctuate between the objective of reviewing the research on the topic and that of providing an overview of the relevant industrial aspects. The emphasis, more often than not, is on the former.

Electroorganic Chemistry as a New Tool in Organic Synthesis. By *T. Shono.* Springer Verlag, Heidelberg 1984. xi, 171 pages, hardback, DM 128.00.—ISBN 3-540-13070-5

Electroorganic synthesis has undergone rapid and continuous redevelopment in the past two decades. It now offers versatile possibilities for the preparation of synthetically valuable intermediates; it serves as a key reaction within complex synthetic sequences and, in addition, it offers easy access to synthetic equivalents with unusual reactivity by means of redox Umpolung. Considering the relatively rare application of this method by non-electrochemists, it must be concluded that it has not been satisfactorily propagated amongst preparative organic chemists. The fear of complex apparatus and electrochemistry's very theoretical presentation to students seem to weigh heavily against it.

T. Shono, one of the most active synthetic electrochemists, tries to dispel these inhibitions in his concise monograph on electroorganic chemistry as a tool in organic synthesis. He emphasizes in his foreword that he intends to present the field exclusively from a synthetic standpoint by means of selected examples. The book does not aim at being comprehensive, nor at penetrating mechanistic analysis.

[*] Cf. *Angew. Chem. Int. Ed. Engl. 24* (1985) 436.

The book consists of three chapters: introduction, anodic oxidations and cathodic reductions. These are followed by a short appendix in which it is demonstrated that the reactions can be carried out with very moderate apparatus.

In the introduction he discusses the principle and potential of redox Umpolung, unfortunately rather scantily. This is followed by a consideration of the consequences of the heterogeneous character of the reaction upon the stereochemistry of the conversion and upon the concentration relationships of the active species that are generated. The influence of the choice of electrode material and electrolyte on product distribution are missing here. The effect of the electrochemical procedure on the stereochemical course of a reaction could easily be overestimated through the presentation of three particularly impressive examples.

Anodic oxidation, with 120 pages, occupies two thirds of the book. This chapter is organized according to the structure of the substrates. Whether this arrangement is more accomodating to a synthetic chemist than organization by reaction type is to be left undecided. Yet, having chosen this system, it would have been more sensible to use it for the reductions too. The section on amine oxidation is, in spite of its great synthetic significance, clearly over-represented with 25 pages.

The chapter on cathodic reductions seems to be rather too brief with 35 pages only. It is organized by reaction type. Even if it is admitted that at present oxidation reactions show a somewhat greater synthetic potential, this abbreviated presentation of synthetic possibilities at the cathode does not meet ones expectations. For example, there is no room for the versatile cathodic heterocycle syntheses and conversions.

It is taken for granted that the author should give preference to his own work in the choice of examples; however, there are some places where a rather more balanced presentation would have been preferred. To meet the claims of the book to present organic electrochemistry as a synthetic tool, it would have to emphasize more strongly the principal synthetic possibilities at the beginning of each section and perhaps compare these with the chemical alternatives. That would offer welcome orientation to the chemist engaged in synthesis. Unfortunately, the index cannot supply this help since it lists, essentially, only compounds, classes of compounds or technical terms and does not link compound and methods or vice-versa. Unfortunately, it is incomplete.

In spite of these reservations, the book should provide valuable and stimulating reading for all synthetically oriented chemists. This presentation of organic electrochemistry as a synthetic tool should be a suitable way to dispel inhibitions about this technique. It can only be hoped that no potential reader will be deterred by the relatively high price.

Eberhard Steckhan [NB 705 IE]
Institut für Organische Chemie und Biochemie
der Universität Bonn (FRG)

Synthetic Organic Photochemistry. Edited by *W. M. Horspool*, Plenum Press, New York 1984. xvii, 534 pp., hardback, $ 75.00.—ISBN 0-306-41449-X

The renaissance of synthesis in organic chemistry has also had a stimulating influence on photochemistry. This welcome development cannot, however, disguise the fact that photochemical reactions still play only a minor rôle in organic synthesis. One reason for this surely lies in the inadequate communication between those engaged in synthesis and those investigating mechanisms.

Up to now, only a few have mastered the interdisciplinary transfer of results from physical chemistry to modern synthesis; thus, any attempt to make the synthetic potential of photochemistry accessible to a wider circle is very much to be welcomed. However, the question ought to be raised whether the prefix "Synthetic" suffices to differentiate this book from a well known series, of which six volumes have already appeared. As the foreword trenchantly comments, the selection of material in any single volume work is bound to be incomplete. If, on this account, however, particular stress has been laid on topicality and synthetic potential, then why are such significant classes of compounds as cyclohexadienones and di-π-methane systems not covered, while topical problems like chirality transfer in cycloadditions are treated comparatively briefly and incompletely? The list of such examples could be continued.

The book does, of course, contain useful information—in some cases very much so—on the photoreactions of arenes, enones, phthalimides, azirines, benzothiophenes and furans and indoles. The same applies for the Paterno-Büchi reaction, for electron transfer reactions in particular, and for photochemical methods with protecting groups. The final chapter, on experimental techniques, does indeed offer an introduction, but this is not exhaustive. Here, every reader is strongly recommended to refer back to textbooks or to "Houben-Weyl".

Around half the topics presented here have already been extensively described elsewhere in surveys, e.g. in the series referred to above. Since most of these contributions have been written from a synthetic standpoint and thus cite similar examples and, moreover, provide more mechanistic information, the editor of this book could easily have avoided repetition and thereby made room for other items. In summary, it can be said that this book provides an introduction to the subject. The reader should, however, have prompt recourse to other books on this topic.

Jochen Mattay [NB 711 IE]
Institut für Organische Chemie der
Technischen Hochschule Aachen (FRG)

Techniques in Organic Reaction Kinetics. By *P. Zuman* and *R. C. Patel*. John Wiley, Chichester 1984. 340 pp., hardback, £ 57.25.—ISBN 0-471-103556-4

This book is based on lectures given by the authors. In four chapters it gives an easily readable insight into the kinetic methods of physical organic chemistry. The theory of chemical reaction kinetics is only brought in to the extent required for the measurement of reaction rates. After a short introduction, the physico-chemical methods of measuring the rates of slow reactions are dealt with in chapter 2 (40 pages). Chapter 3 (201 pages) is concerned with the analysis of kinetic data. It is consciously modelled on the book by *Frost* and *Pearson* (A. A. Frost, R. G. Pearson: *Kinetics and Mechanism*). It contains formal kinetics with many examples from organic chemistry; the influence of ionic strength, solvent characteristics and substituent effects are discussed in depth. Chapter 4 (82 pages) handles the study of fast reactions; it follows *E. F. Caldin*'s book

(*Fast Reactions in Solution*) and is extended by the inclusion of examples from the electrochemical kinetic work of the authors.

This book offers the reader an instructive compilation of older books on kinetics, with a slant towards organic chemistry. The inescapable disadvantage, however, is that the techniques and applications of new developments in the last ten years could not be included. The book can be recommended to students as an introduction to this subject, alongside the thematically very similar book by *K. Schwetlick* (*Kinetic Methods for the Investigation of Reaction Mechanisms*).

^{15}N-NMR Spectroscopy—New Methods and Applications**

New Analytical Methods (28)

By Wolfgang von Philipsborn* and Raffaello Müller

The nitrogen nucleus is the third most important probe (after ^{1}H and ^{13}C) for structural investigations of organic and bioorganic molecules by NMR spectroscopy. For a long time, however, the insufficient sensitivity and low natural abundance of the ^{15}N isotope hampered detection of the ^{15}N nucleus, and the quadrupolar ^{14}N nucleus proved unsuitable for the study of larger molecules with several nonequivalent nitrogen atoms. The advent of new techniques, such as pulse sequences and polarization transfer, in conjunction with the use of high-field magnets and large-sample probe heads largely solved the detection problem. As a result, the last few years have seen a dramatic development of ^{15}N-NMR spectroscopy as a versatile method for studying molecular structure, both in isotropic (liquid) and anisotropic (solid) phases. The scope of chemical applications extends from inorganic, organometallic, and organic chemistry to biochemistry and molecular biology, and includes the study of reactive intermediates, biopolymers, enzyme-inhibitor complexes, and nitrogen metabolism. Two-dimensional NMR techniques offer additional possibilities for detailed studies of biological systems.

1. Introduction

Nitrogen belongs to the few elements that form the skeleton of organic and bioorganic molecules, and functional groups containing nitrogen atoms are of great importance in organic and biochemical reactions. Therefore, nitrogen NMR spectroscopy provides a sensitive method for the study of chemical structure and bonding, reaction mechanisms, biosynthesis, nitrogen fixation, and metal coordination, as well as for the study of active sites in biochemical systems.

In fact, *Proctor* and *Yu*[2] carried out nitrogen NMR studies in the very early days of nuclear magnetic resonance spectroscopy and thereby discovered the chemical shift phenomenon in NH_4NO_3. For a long time, the quadrupolar ^{14}N nucleus was preferred by NMR spectroscopists because of its high natural abundance (99.63%). The introduction of FT NMR spectroscopy, however, stimulated interest in the much less abundant spin-½ ^{15}N isotope. Although the NMR receptivity of the ^{15}N nucleus (0.37% abundance) is 280 times smaller than that of ^{14}N (Table 1), there are at least two factors that compensate for this deficiency. First, the line broadening of ^{14}N signals (up to several kHz) is absent in ^{15}N resonances, and, second, the large nuclear Overhauser effect (NOE) ($\eta_0 = -4.93$) enhances the ^{15}N signal intensities of proton-bearing ^{15}N atoms when proton noise decoupling is applied. Furthermore, it is sometimes possible to shorten the

long spin-lattice relaxation times (T_1) of tertiary N atoms by the use of high magnetic field strengths (superconducting magnets) or, alternatively, to circumvent the problem by the use of polarization-transfer from fast-relaxing, sensitive nuclei, such as ^{1}H or ^{19}F.

^{14}N-NMR spectroscopy has been employed to study relatively small organic[3] and inorganic molecules[4,5] and to study molecular motion;[6] the quadrupole moment is an especially important nuclear property for the investigation of dynamic processes. For larger molecules with several nonequivalent N atoms, including biopolymers, only the ^{15}N isotope yields satisfactory and interpretable NMR spectra. The results obtained up to 1980 are summarized in three monographs.[7] In many cases, ^{15}N-NMR spectra can also be recorded in the proton-coupled mode, thereby yielding both chemical shift and spin-coupling information (scalar coupling in solution and dipolar coupling in the solid). Finally, the use of large sample volumes in wide-bore high-field magnets has helped considerably to overcome the hitherto bad reputation of ^{15}N-NMR spectroscopy as being insensitive, time-consuming, and unsuitable for analytical applications in structural chemistry and biochemistry. It is the purpose of this review article to discuss the experimental progress and to illustrate the broad spectrum of present and future applications of ^{15}N-NMR spectroscopy in chemistry.

2. Experimental Techniques

2.1. Standard Pulse Experiments

Conventional FT NMR experiments with a pulse-modulated high-frequency field at the ^{15}N resonance are only feasible if the spin-lattice relaxation times (T_1) are reasonably short; this is true for N atoms with directly bonded protons, e.g., in NH_2 and NH groups. In such cases (nuclear-nuclear) dipole-dipole relaxation (DD) is the dominant relaxation mechanism, and T_1 values of less than 20 s are usually observed.[7a] Figure 1 shows the spectrum of the dication **1** of 6,7-dimethyltetrahydropterin. Each N atom is bonded to at least one H atom. Moreover, the N atoms have similar relaxation times, which results in comparable signal intensities. However, even tertiary N atoms may be detected with sufficient sensitivity if measurements are conducted in strong magnetic fields (9–11 tesla) generated by superconducting magnets. In this case, a chemical shift anisotropy dependent relaxation process (CSA), which increases with the square of the field strength, may contribute significantly to the spin-lattice relaxation rate (Section 3.3). Finally, otherwise long T_1 values may be reduced by electron-nuclear dipole-dipole interaction when paramagnetic species, so-called relaxation reagents, are added. A convenient and widely used compound is chromium(III) acetylacetonate, $Cr(acac)_3$,[8] which enhances ^{15}N relaxation rates without significant line shifts (< 1 ppm).

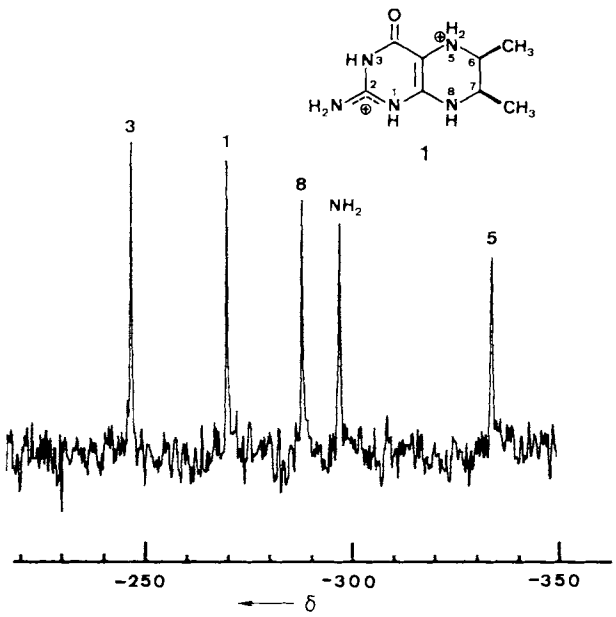

Fig. 1. Proton-noise-decoupled and phase-adjusted ^{15}N-NMR spectrum of the dication **1** of *cis*-6,7-dimethyl-5,6,7,8-tetrahydropterin (10.1 MHz; CF_3COOH, 0.7 M) [9].

^{1}H broadband-decoupling enhances the signal-to-noise ratio not only as a result of multiplet collapse but even more effectively by the large NOE factor ($\eta_0 = -4.93$) for the ^{15}N, ^{1}H system. From Equation (a) it is apparent that the full benefit of this (negative) signal enhancement is only obtained if T_1 is dominated by dipole-dipole interactions, which is the case for NH_2 and NH groups, and that it leads to signal inversion (Fig. 2) (M_z = z-magnetization; M_z^0 = z-magnetization at thermal equilibrium, T_1^{DD} = time constant of dipole-dipole relaxation).

$$\frac{M_z}{M_z^0} = 1 + 0.5\,\frac{\gamma_H}{\gamma_N}\,\frac{T_1}{T_1^{DD}} \qquad \text{(a)}$$

$$\eta_0 = 0.5 \cdot (-9.86) = -4.93$$

As shown in Figure 2a, inefficient dipolar relaxation for tertiary N atoms may result in loss of the signal. Such cases, frequently encountered in N-heterocycles, can be handled by deliberate suppression of the NOE; this is achieved by switching the decoupler power output on during acquisition and off during the pulse delay time (inverse gated decoupling). Since spin decoupling becomes effective almost instantaneously when the B_2 field is switched on whereas the NOE is built up more slowly with the time constant T_1^{DD}, ^{1}H-decoupled ^{15}N-NMR spectra may be recorded with a minimized Overhauser effect (Fig. 2b). This technique allows tertiary and proton-bearing N atoms to

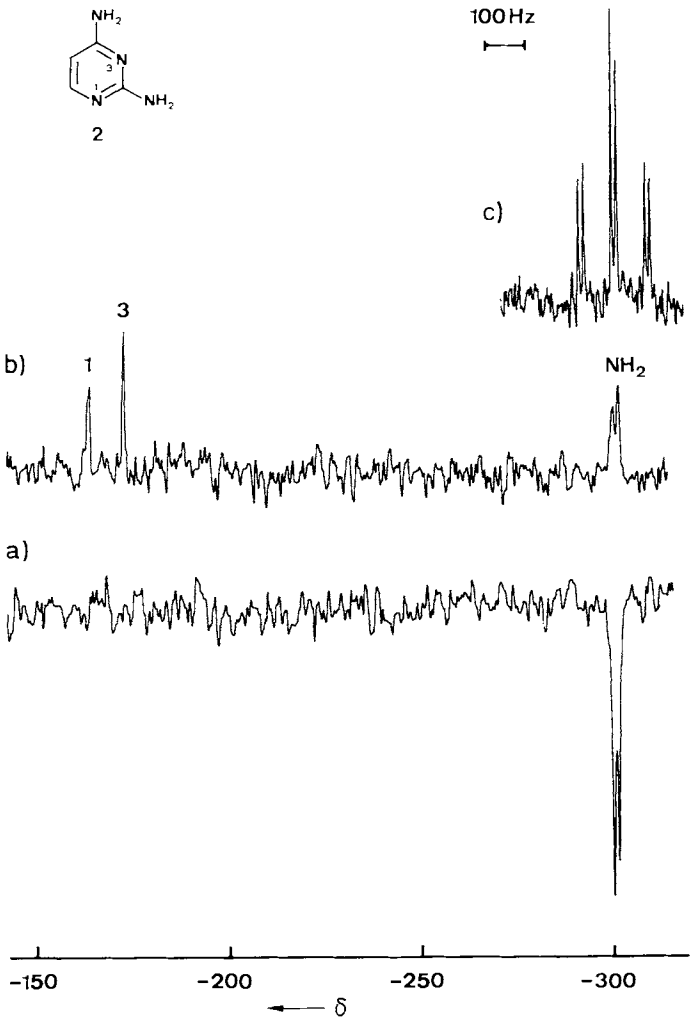

Fig. 2. ^{15}N-NMR spectra of 2,4-diaminopyrimidine **2** (10.1 MHz; $(CD_3)_2SO$): a) ^{1}H-noise-decoupled; b) "inverse-gated"-decoupled (decoupler output "on" during acquisition, "off" during acquisition delay time); c) no ^{1}H decoupling.

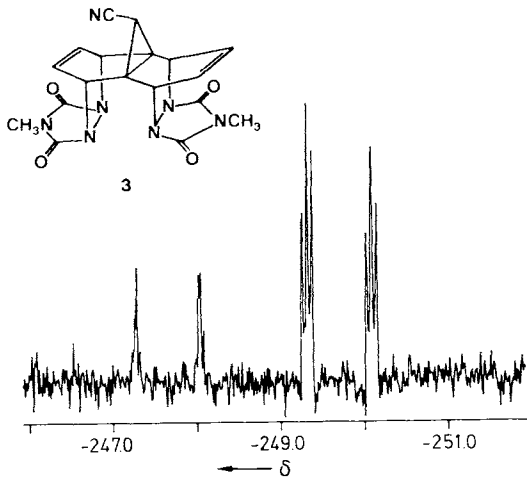

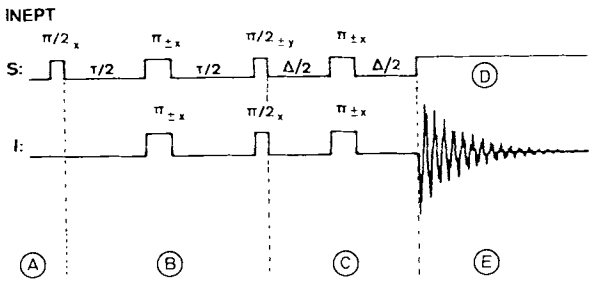

Fig. 3. Proton-coupled DEPT ^{15}N-NMR spectrum of the 1:2 adduct **3** of tricyclo[4.4.1.0^{1,6}]undeca-2,4,7,9-tetraene-11-carbonitrile with N-methyl-1,2,4-triazoledione) (40.6 MHz; $(CD_3)_2SO$). The cyano doublet ($\delta = -113.3$) is not shown. The assignment of the two weak and two strong signals to the NCH_3 and NCHCH groups, respectively, follows from the multiplicities and from the values of N,H coupling constants.

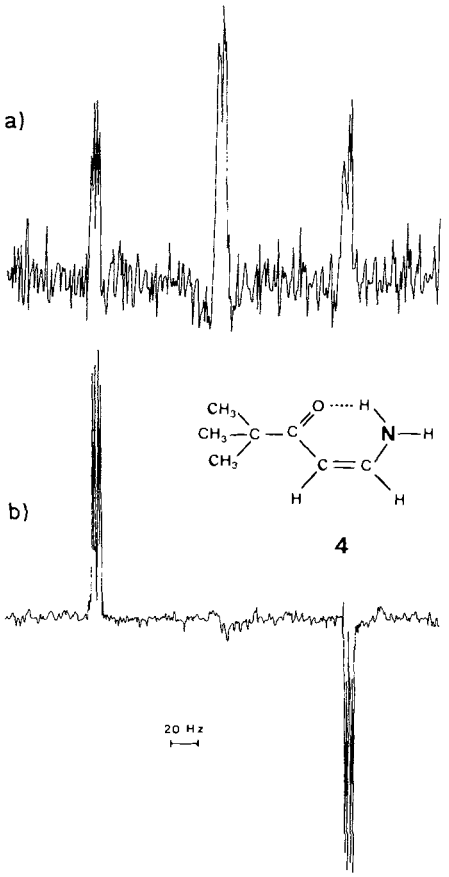
be simultaneously observed. Thus, the relative intensities of ^{1}H-decoupled ^{15}N resonances are dependent on the spin-lattice relaxation times T_1 *and* the nuclear Overhauser effects ($\eta \leq |\eta_0|$). Quenching of undesired, small Overhauser effects may also be achieved by the use of relaxation reagents.

The sensitivity of ^{15}N-NMR detection may be further enhanced by the use of large-diameter sample tubes (15–25 mm) and the application of strong magnetic fields (B_0). The excellent performance, in terms of field homogeneity and stability, of modern wide-bore superconducting magnets permits the routine measurement of ^{15}N-NMR spectra with natural isotope abundance with the techniques described above. A typical example is shown by the spectrum of the [4.4.1]propellane derivative **3** (Fig. 3).[10]



2.2. One-Dimensional Pulse Sequence Experiments (INEPT, DEPT)

The rapid development of pulse techniques and their implementation on modern spectrometers provides still more effective and versatile methods for sensitivity improvement in ^{15}N-NMR spectroscopy. In such experiments, application of a sequence of nonselective and simultaneous pulses on a scalar-coupled heteronuclear spin system leads to spin polarization transfer from the sensitive ^{1}H nuclei (large abundance, large γ) to the insensitive ^{15}N nuclei (small abundance, small γ) and a maximum enhancement factor of $|\gamma_H/\gamma_N| = 9.86$ for the intensities of the ^{15}N resonances. Furthermore, since the rate at which the entire pulse sequence can be repeated is governed by the short relaxation times of the ^{1}H nuclei, additional time is saved. A typical polarization transfer experiment, the INEPT pulse sequence (*I*nsensitive *N*uclei *E*nhanced by *P*olarization *T*ransfer) is shown in Scheme 1.[11] For a discussion of the mechanism of polarization transfer the reader is referred to the review by *Benn* and *Günther*.[12] After the polarization transfer (90° pulse) and following the ^{15}N detection pulse, antiphase signals can be detected or, by refocusing and decoupling during acquisition, the spin system can be "processed" further. Thus, proton-coupled, selectively decoupled, or fully decoupled ^{15}N-NMR spectra can be obtained, thereby increasing the information content of the spectra for structural studies.

Scheme 1. S, ^{1}H; I, ^{15}N; Ⓐ preparation, Ⓑ evolution, Ⓒ refocusing, Ⓓ ^{1}H-broadband decoupling, Ⓔ detection. See also [12].

The quality of such spectra, in terms of sensitivity and resolution, in comparison with standard pulse spectra, is exemplified in Figure 4. This example also demonstrates that the multiplicity and phases of the signals in INEPT

4

Fig. 4. ^{15}N-NMR spectra of the conformer shown of (*Z*)-1-amino-4,4-dimethyl-1-penten-3-one **4** (20.3 MHz; C_6D_6, 3.7 M): a) standard-pulse NMR spectrum (measuring time 10 h); b) INEPT ^{15}N-NMR spectrum (measuring time 1.9 h) [13]. $^1J(N,H) = 92.7$, $^2J(N,H) = 1.7$, $^3J(N,H) = 4.0$ Hz.

spectra differ from those in regular spectra. For instance, the relative intensities for NH doublets are +1 and −1, for NH_2 triplets +1, 0, and −1.[14] The phases can be adjusted by application of the above-mentioned refocusing procedure. In addition, selective ^{1}H-decoupling may lead to considerably sharper lines and, hence, to still better sensitivity. The ^{15}N-NMR spectra of 5-methylisoxazole **5** (Fig. 5) illustrate the accurate determination of $^2J(N,H)$ and $^3J(N,H)$ through selective ^{1}H-decoupling. Coupling of the ^{15}N nuclei to methyl protons often obscures the desired spin-coupling information, as shown in the case of 2-acetylpyridine **12** (Section 3.2.2), and increases the measuring time required.

Polarization transfer to an insensitive nucleus requires scalar-coupling to a sensitive nucleus. In addition to the ^{1}H nucleus, ^{19}F[17] and ^{31}P have been used; in particular, ^{31}P was used successfully to transfer spin polarization to ^{15}N,[16a] ^{57}Fe, ^{103}Rh, and ^{183}W.[16b] The substantial spin coupling between ^{19}F and ^{15}N is especially advantageous in polarization transfer experiments. Figure 6 shows the re-

5

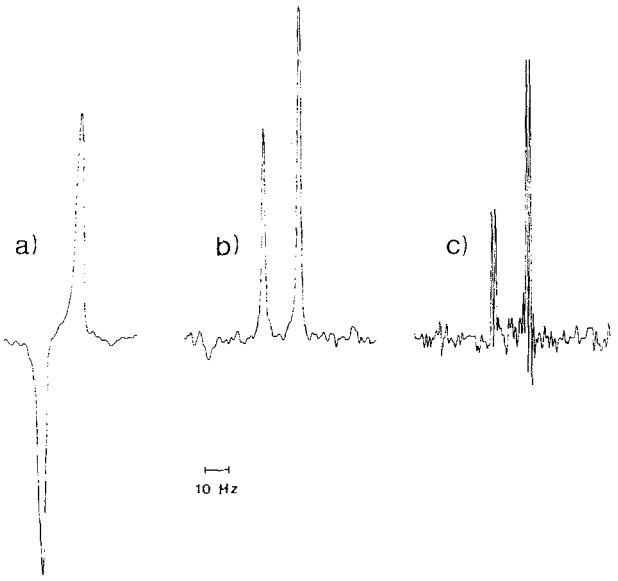


Fig. 5. INEPT ^{15}N-NMR spectra of 5-methylisoxazole **5** (20.3 MHz; $(CD_3)_2SO$): a) proton-coupled; b) refocused and selectively ^{1}H-decoupled (H-C4); c) same as b) but irradiated at the CH_3 resonance [15].

sult of such an INEPT measurement for perfluoropyridine **6**.[17] The large $^2J(N,F)$ coupling (−51.7 Hz) determines the pulse delay $\tau = 1/2J(N,F)$ in the INEPT pulse sequence (cf. Scheme 1). Here again, the central lines of the triplet are absent, so that the large splitting corresponds to $2 \times J(N,F)$.

The optimum setup of an INEPT experiment is less straightforward if there are no dominant heteronuclear

6

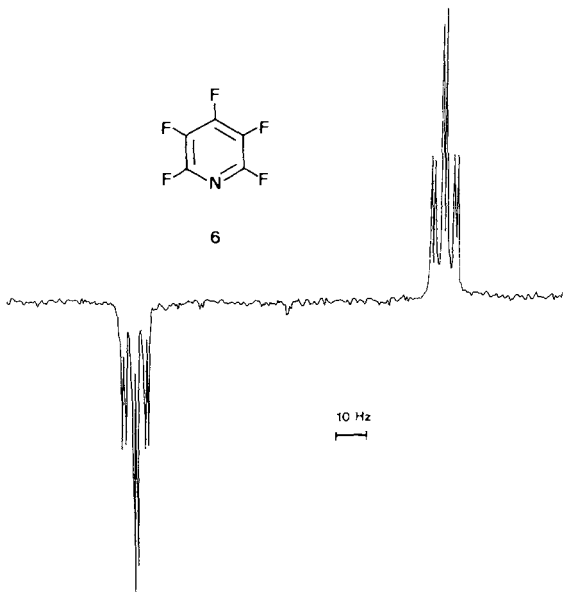

Fig. 6. INEPT ^{15}N-NMR spectrum of perfluoropyridine **6** (20.3 MHz; $(CD_3)_2CO$) with polarization transfer from the ^{19}F nuclei (188.2 MHz). The τ value for the INEPT sequence was calculated using $|^2J(N,F)| = 52$ Hz [17].

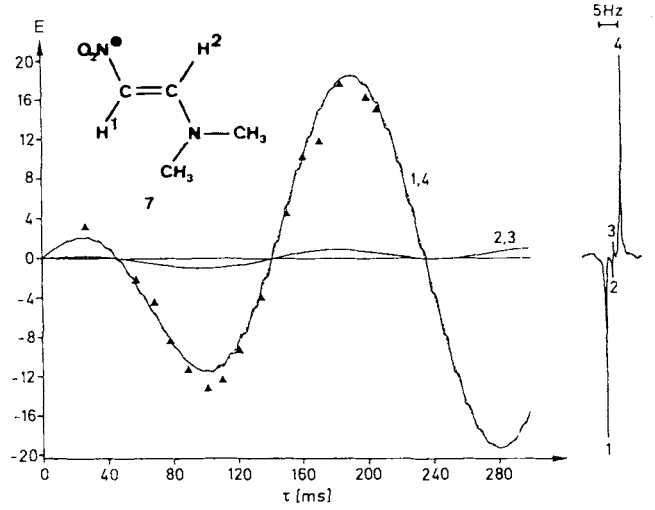
coupling constants. If the ^{15}N nucleus is coupled with several protons, which, in turn, are mutually coupled (spin systems of the type $IS^1S^2...S^n$), the optimal τ values can be determined by using analytical expressions.[18] This is shown for the nitroethene 7 in Figure 7. It should be noted



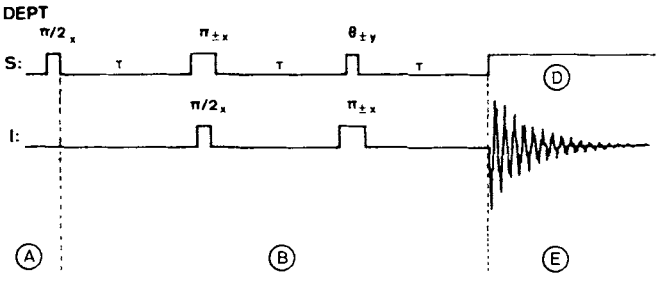


Fig. 7. Right: INEPT ^{15}N-NMR spectrum of the NO_2 group of (*E*)-*N*,*N*-dimethyl-2-nitrovinylamine 7; left: signal enhancements (E) as a function of τ. (—) calculated and (▲) experimental values [18]. $J(N,H\text{-}2)=2.2$, $J(N,H\text{-}1)=1.8$, $J(H\text{-}1,H\text{-}2)=10.6$ Hz; $\nu(H\text{-}1)-\nu(H\text{-}2)=-290$ Hz (20.3 MHz).

that τ_{opt} (190 ms) does not correspond to either $1/2J(N,H^1)$ ($\tau=278$ ms) or $1/2J(N,H^2)$ (227 ms), because the homonuclear coupling constant $^3J(H^1,H^2)$ is much larger (10.6 Hz) than the two heteronuclear values (1.8 and 2.2 Hz, respectively). Nevertheless, such spin systems are also amenable to an effective polarization transfer, which considerably extends the application of the INEPT technique beyond the detection of simple NH and NH_2 groups[14] (see also Section 4).

Scheme 2. S, I, Ⓐ, Ⓑ, Ⓒ, Ⓓ see legend to Scheme 1. See also [12].

The pulse sequence DEPT (*D*istortionless *E*nhancement by *P*olarization *T*ransfer) was developed[19] as an alternative polarization transfer technique in order to avoid the intensity and phase distortions inherent in the INEPT experiment. The DEPT sequence yields spectra (Scheme 2) with positive signals only, which thus resemble standard pulse spectra. In this technique, the sensitivity enhancement is described as a function of the delay time τ and the pulse angle θ. Only for simple spin systems of the type IS_n, however, are pure phase spectra obtained; spin systems $IS^1S^2...S^n$ with hetero- and homonuclear coupling are subject to phase distortions.[18] Further, when higher-order spin systems are involved, the intensities are also distorted. Decoupled DEPT spectra always show positive phase signals. DEPT ^{15}N-NMR spectra of thiazole **8** are shown in Figure 8. Selective decoupling allows the assignment of the small coupling constant (2.2 Hz) to the vicinal N,H interaction ($^3J(N,H)$).

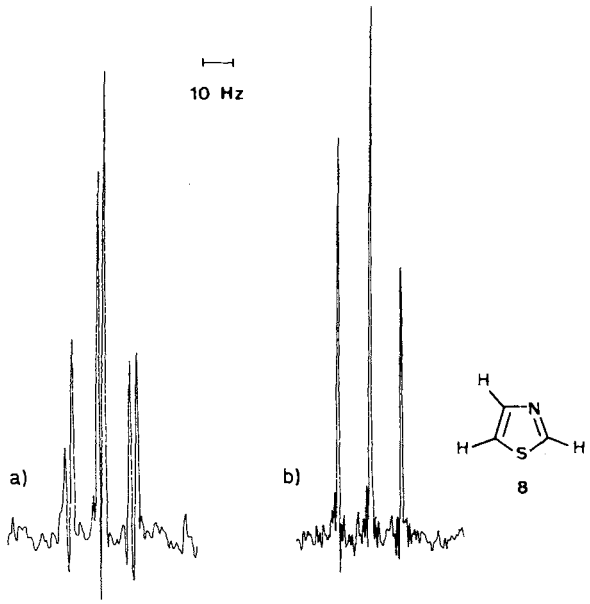

Fig. 8. DEPT ^{15}N-NMR spectra of thiazole **8** (20.3 MHz; $CDCl_3$): a) proton-coupled; b) selective irradiation of the H-5 resonance [15].

In terms of sensitivity enhancement, the INEPT pulse sequence has proven superior to the DEPT sequence;[19b] for the five-spin system of 2-methoxypyridine the enhancement is larger by a factor of 1.8.[18] The simple INEPT experiment (without refocusing) appears to be less prone to perturbation by additional homo- and heteronuclear couplings.

The advantage of the polarization transfer experiments discussed above is the nonselective nature of the ^1H-irradiation. Thus, polarization can be transferred to several nonequivalent N atoms, which allows the structural investigation of complex molecules (cf. Section 4).

An alternative way of achieving sensitivity enhancement is based on a *selective* population transfer (SPT), in which a single ^1H transition is irradiated, resulting in equalization or inversion of the populations followed by transfer to connected levels.[20] The ^{15}N sensitivity enhancement attained is the same as in the nonselective INEPT or DEPT experiments; however, the transition-selective nature of the experiment permits the determination of the relative signs of N,H coupling constants.[21] Similarly, for non-proton-bearing N atoms a modified INEPT sequence, which achieves a selective polarization transfer, was proposed. It largely suppresses homonuclear multiquantum coherence and allows neglect of N,H long-range coupling to other than the selectively irradiated proton.[22] For this purpose,

soft proton pulses (typical pulse duration 5 ms for a 90° flip angle) were used in the detection of the proline ^{15}N resonance of a hexapeptide. However, the enhancement is only large if the proton excitation is highly selective, which constitutes a serious limitation for complex molecules, even in high magnetic fields.

The largest sensitivity improvements are achieved when the ^{15}N resonance is detected indirectly via the proton resonance; theoretically, the sensitivity can be increased by a factor of $(\gamma_H/\gamma_N)^3$, i.e., by about 961. Such results have actually been obtained in multiple quantum coherence experiments on large peptides by the use of 1D and 2D data representations[23,24] (see also Section 2.3).

A critical evaluation of the advantages and disadvantages of the numerous one-dimensional pulse sequence experiments has recently been presented by *Turner*.[25]

2.3. Heteronuclear Correlated 2D NMR Spectroscopy

During the last decade, 2D NMR experiments have developed to a very high degree of versatility and sophistication and many of them can be routinely performed on commercial spectrometers. Nevertheless, the application to ^{15}N-NMR spectroscopy has been slow and, only recently, owing to improved general NMR instrumentation and the development of multiple quantum coherence experiments, has significant progress been achieved. Of the classical 2D experiments, only heteronuclear $^1H,^{15}N$ shift correlation has found application in the assignment of ^{15}N resonances via $^1J(N,H)$ and long-range $J(N,H)$. For a review of the classical 2D NMR methods the reader is again referred to the article by *Benn* and *Günther*.[12]

The correlation of ^1H and ^{15}N chemical shifts based on multiple quantum coherence has also led to a dramatic improvement in sensitivity, since determination of the ^{15}N frequencies is effected by detection of the scalar-coupled protons.[26] A third significant application of 2D NMR is found in the analysis of solid-state ^{15}N-NMR spectra with dipolar coupling.[27]

$^1H,^{15}N$ shift correlated (COSY) 2D NMR spectroscopy can be applied to oligopeptides and leads to an assignment of ^{15}N resonance lines based on known NH and $C_\alpha H$ proton frequencies.[28,29] Measurements of this kind, when carried out on nonenriched substrates, are rather time-consuming compared with $^1H,^1H$ and $^{13}C,^1H$ 2D NMR experiments. The complete assignment of all ^{15}N-NMR signals for the undecapeptide cyclosporin A has been achieved by using the COLOC pulse sequence[30] (Fig. 9). The proton shift assignments were obtained from additional COSY experiments, e.g., 2D homonuclear NH,H(α) and 2D heteronuclear C(α),H(α) correlation.

A 2D NMR experiment specifically designed for the detection of proton-coupled ^{15}N resonances utilizes the idea of a double transfer of polarization based on an INEPT pulse sequence and allows the determination of ^{15}N chemical shifts with the sensitivity of the proton resonance. The original pulse sequence used by *Bodenhausen* and *Ruben*[31] was subsequently modified and simplified by *Redfield*[32] (HAHNDOR pulse sequence) and *Bax* et al.[24] with the result that this 2D NMR multiple quantum

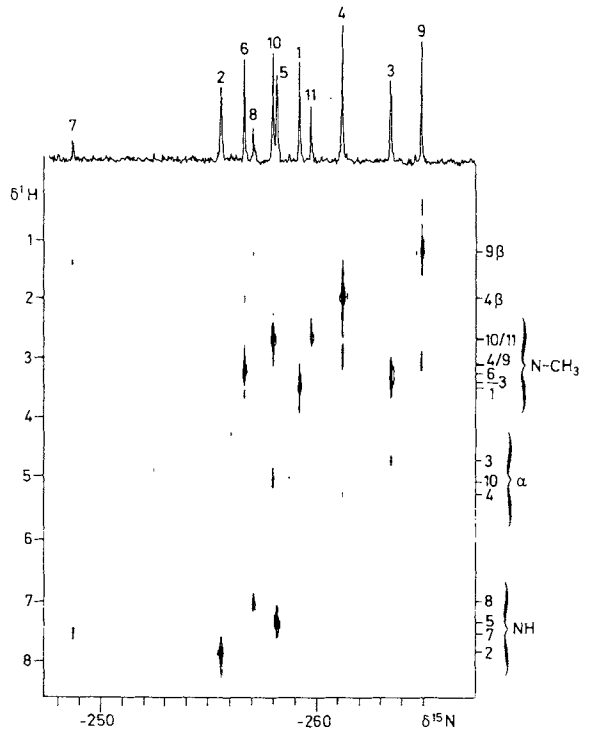

Fig. 9. COLOC $^1H,^{15}N$-heteronuclear shift correlated NMR spectrum of cyclosporin A (50.7 MHz; $CDCl_3$, measuring time 36 h). The spectrum shows correlation peaks for ^{15}N atoms with directly bonded protons (NH) and geminal protons ($N-C_\alpha-H$ and $N-CH_3$), thereby allowing a complete assignment of the eleven N atoms in one experiment [28c]. Cyclosporin A is an undecapeptide with the following amino acid sequence (MeBmt = *N*-methylbutenylmethylthreonine):

cyclo[MeBmt-Abu-Sar-MeLeu-Val-MeLeu-Ala-D-Ala-MeLeu-MeLeu-MeVal].
1 2 3 4 5 6 7 8 9 10 11

method has found wide practical use. The advantages of this experiment are a dramatic sensitivity gain by a factor of $(\gamma_H/\gamma_N)^3 = 961$ and the detection of only those ^1H resonances that are scalar-coupled to an ^{15}N nucleus. This permits detection of relevant NH groups in large biomolecules.[33a,23] The spectrum of ^{15}N-labeled *E. coli* $tRNA_f^{Met}$ (Fig. 10) demonstrates the use of this method to identify the six nucleotide units biosynthetically derived from uridine and, at the same time, the improved resolution obtainable in the 2D data representation. It was estimated that ^{15}N-NMR shifts for $^{15}N,^1H$ groups in nonenriched samples can be obtained in 2–4 h with a 100 mM sample of the biopolymer.

Recent developments in high-resolution ^{15}N-NMR spectroscopy of solids (see Section 4.6) permit the measurement of spectra of biomolecules which contain precise isotropic chemical shift and $^{15}N,^1H$ dipolar coupling information. Since such spectra may be very complex, 2D NMR spectroscopy and graphical representation of the spectra with $\delta(N)$ as the F_2 and D(N,H) as the F_1 coordinate is very useful. In one of the first applications, *DiVerdi* and *Opella*[34] reported N–H bond lengths in DNA based on the magnitude of dipolar $^{15}N,^1H$ couplings (Fig. 11). "D-resolved" $^{15}N,^1H$ spectra of oriented virus solutions, obtained by spontaneous alignment of these macromolecules in the external magnetic field B_0, have also been recorded.[35]

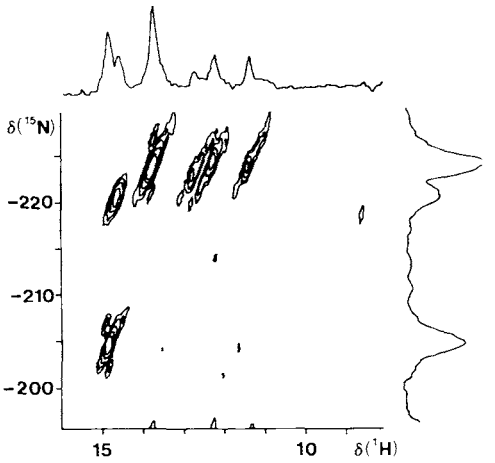

Fig. 10. Contour plot of $^{15}N,^{1}H$ heteronuclear chemical shift correlation NMR spectrum, derived from a multiple quantum coherence experiment, of ^{15}N-labeled $tRNA_f^{Met}$ from *E. coli* (36.5 MHz; $\nu(H)=360.1$ MHz; 65% enriched at N-3 of uridine and uridine-derived bases, 5 mg sample dissolved in 250 μL of aqueous buffer solution, measuring time 6 h). Projections of the ^{1}H- and ^{15}N-NMR spectra are shown opposite the respective chemical shift axes. For further experimental details and assignments of chemical shifts see [33a]. An improved method for the indirect detection of ^{15}N resonances was recently described[33b].

J-resolved 2D ^{15}N-NMR spectra are another powerful source for structure elucidation via long-range $^{15}N,^{1}H$ spin couplings. Such experiments have been performed in combination with an INEPT polarization-transfer pulse sequence applied during the preparation period of a selective 2D *J* pulse sequence.[36] In this way, long-range $^{15}N,^{1}H$ spin coupling constants have been determined, with excellent sensitivity and resolution, for aromatic and aliphatic

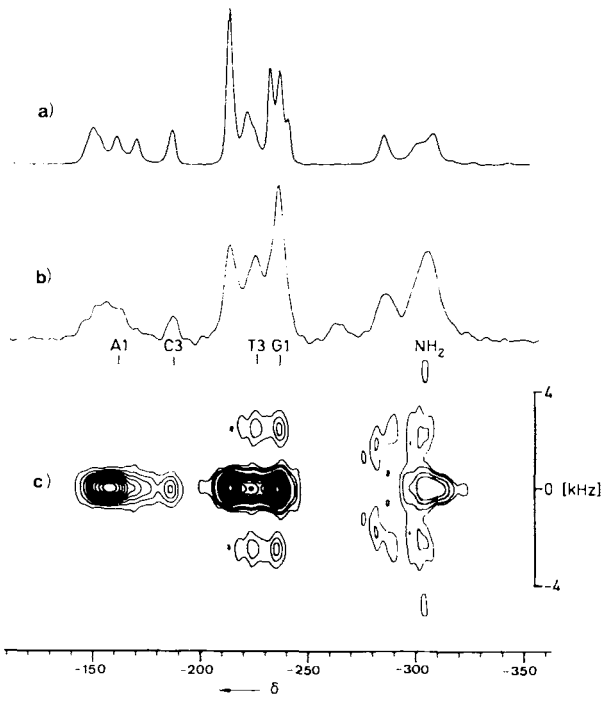

Fig. 11. CPMAS (cross polarization and magic angle spinning) ^{15}N-NMR spectra of DNA (15.24 MHz): a) isotropic chemical shifts of B-DNA; b) low-humidity DNA; c) $\delta(N)/D(N,H)$ 2D ^{15}N-NMR spectrum of low-humidity DNA. For assignments of chemical shifts see [34].

compounds, and the method has been suggested as a means to obtain precise values for $^{3}J(N,H)$ in peptides (see Section 3.2.2).

In conclusion, modern FT NMR spectroscopic techniques combined with high magnetic field strengths and large sample volumes have largely overcome the sensitivity problem and now permit the routine performance of ^{15}N-NMR experiments at natural isotope abundance. Nevertheless, depending on the type of ^{15}N resonance to be investigated, the most suitable detection technique has to be found and the experimental conditions carefully matched. This set-up procedure often requires more time than for conventional nuclei such as ^{1}H and ^{13}C. One major obstacle, the long T_1 relaxation times of tertiary N atoms and the small NOE, has been successfully removed by polarization transfer from a sensitive, fast-relaxing scalar-coupled nucleus, usually a proton. Even higher sensitivity can be achieved by indirect detection of the ^{15}N nuclei via the ^{1}H resonance, and corresponding 1D and 2D multiple quantum coherence experiments are particularly suited for large biomolecules. The ^{15}N resonance in nonlabeled low-molecular-weight compounds ($M_r<500$) can now be directly detected in a few hours with 0.1–0.2 M solutions. A variety of applications to organic and inorganic chemistry as well as to biochemistry will be discussed in Section 4.

3. Structural Dependence of Spectral Parameters

High-resolution ^{15}N-NMR spectra provide information on nuclear shielding constants (chemical shift), spin-lattice relaxation times (T_1), spin-spin relaxation times (T_2), and scalar heteronuclear spin coupling (e.g., $^{n}J(N,H)$). This constitutes a considerable improvement over ^{14}N-NMR spectroscopy, which mainly yields chemical shift information. Only in a few favorable cases can heteronuclear coupling constants be obtained and line-shape information be used to characterize exchange processes and molecular motion. In this section, the spectral parameters of ^{15}N-NMR will be discussed in terms of their structural significance and potential application in chemistry.

3.1. Chemical Shifts

The shielding range of the ^{15}N nucleus in diamagnetic molecules extends over 1000 ppm, corresponding to about 40 kHz in a field of 9.4 tesla ($\nu_0=40.5$ MHz). Taking into account a line width of 1–2 Hz and the smaller abundance of nitrogen atoms in organic and bioorganic molecules, this leads to an even better dispersion of the resonance lines than in ^{13}C-NMR spectra. This excellent dispersion is not attenuated by the fact that the resonances of the majority of N atoms in organic structures lie within a 500-ppm range. An example is provided in Figure 12 by the spectrum of a mixture of 1- and 2-methyltetrazole, **9** and **10**, respectively; well-separated lines for the eight nonequivalent N atoms are observed over a range of 170 ppm, but their assignment requires additional experiments (cf. Section 3.4).

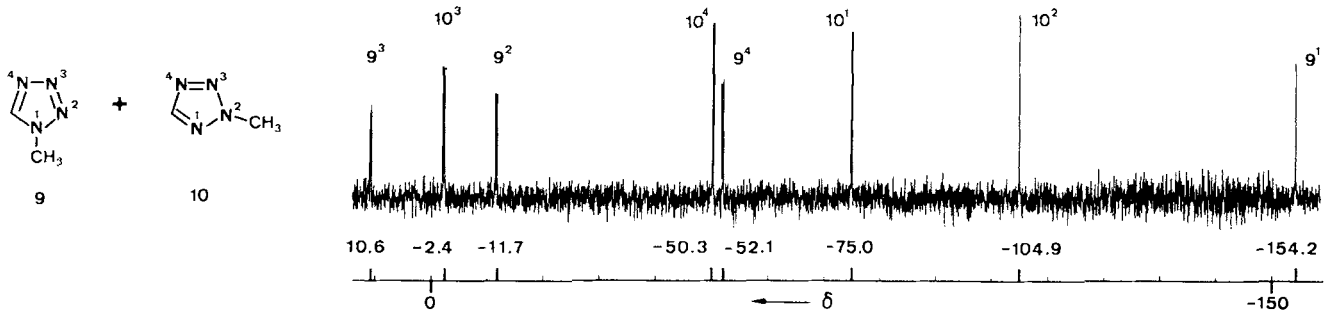

Fig. 12. ^{15}N-NMR spectrum of a mixture of 1- and 2-methyltetrazole, **9** and **10**, respectively (40.6 MHz; 200 mg in 2.5 mL of $CDCl_3$, 75 mg of $Cr(acac)_3$ added; measuring time 42 min).

3.1.1. *Standardization—Reference Compounds*

In this review, all chemical shifts (δ values) will be given relative to that of nitromethane ($CH_3{}^{15}NO_2$) as pure liquid in a capillary (external standard), without susceptibility correction and with negative signs for low-frequency and positive signs for high-frequency shifts. Literature data originally measured relative to other reference compounds, such as $NH_4{}^{15}NO_3$, $H^{15}NO_3$, or $^{15}NH_3$, are adjusted to the CH_3NO_2 scale.[7a] We have used nitromethane throughout our own work; its use allows direct comparison with the two extensive data collections compiled by *Martin* et al.[7a] and by *Witanowski* et al.[7b] The choice of CH_3NO_2 has the consequence that most δ values are negative. This fact, although quite common for other nuclei (e.g., metal nuclei), has induced some authors to adopt other references (e.g., NH_3(liq.) or $NH_4^{\oplus}$) at the low-frequency end of the nitrogen-shift scale, either as a primary reference (external standard) or as a secondary artificial reference. However, an arbitrary value for the $CH_3{}^{15}NO_2$ shift relative to NH_3 (liq.) (e.g., 380.2 ppm) should be used since the NH_3 resonance is strongly temperature dependent.[37] Moreover, as a consequence of concentration, solvent, and temperature effects, especially for different sample alignments in electromagnets and superconducting magnets, and usually neglected susceptibility corrections,[7a] the general reproducibility of ^{15}N chemical shifts is not better than ± 1 ppm. This value may be a lower limit in cases where relaxation reagents (>0.05 M) are used to measure the ^{15}N resonance.

3.1.2. *Main Trends in ^{15}N-NMR Shifts*

The ^{15}N-NMR shifts of N atoms with different oxidation states, coordination numbers, and hybridizations (sp^3, sp^2, sp) are summarized in Figure 13. As expected from the similarity of nitrogen and carbon in electronic structure and bonding, the ^{15}N-NMR shifts parallel the ^{13}C-NMR shifts in many respects. Thus, the tricoordinated N atoms (amines) appear at the low-frequency end of the scale; tetracoordinated N atoms (ammonium salts and *N*-oxides) absorb in the same range. The introduction of electronegative substituents leads to deshielding; the three principal hybridization states of nitrogen give rise to deshielding in the sequence $sp^3 < sp < sp^2$. The ranges for the resonance of carbon-substituted tricoordinated ($\delta = -400$ to -200) and dicoordinated N atoms ($\delta = -100$ to $+100$) are well separated. The carbonyl analogues $-$NO and $-NO_2$ exhibit resonance positions at the high-frequency end of the scale for organic nitrogen compounds. The characteristic position of functionalized N atoms is largely maintained when they act as ligands in metal complexes, i.e., the coordination shifts are fairly small[4] (see Section 4.4). An important feature of the N atom, the lone-pair electrons, have a pronounced influence on the shielding of ^{15}N nuclei if low-lying $n \rightarrow \pi^*$ transitions are available to affect the $(\Delta E)^{-1}$ term in the paramagnetic shielding expression. For example, protonation of the azine N atoms in pyridines and pyrimidines leads to low-frequency shifts of 100–120 ppm,[39] such effects being suitable for the study of protonation and hydrogen bonding in organic and bioorganic molecules (see Section 4.1). When the lone pair is involved in n,π-delocalization, e.g., in enamines and enamino ketones, high-frequency shifts are observed which can be correlated with the extent of conjugation in such systems.[40] Figure 14 illustrates the transition between amines, enamines, enamino ketones (vinylogous amides), and amides as reflected in the ^{15}N chemical shifts. An application of these principles to a conformational study of enamino ketones will be discussed in Section 4.3.

A less phenomenological and more detailed discussion of ^{15}N chemical shifts has to be based on the paramagnetic shielding term, σ^p, which dominates the relative line positions of the heavier nuclei. The observed ^{15}N chemical shifts have also been extensively discussed on the basis of quantum chemical calculations.[7b,41] In this context, it is important to note that the shielding values for the ^{14}N and ^{15}N isotopes may be readily compared with each other as well as with calculated data since the ratio of the resonance frequencies of a series of isotopomeric molecules was found to be constant within $\pm 8 \times 10^{-8}$.[3] All available data indicate that primary isotope effects are of the order of a few tenths of a ppm[7b] and may thus be neglected for practical purposes (see also ref. [78b]). In doing so, however, one must realize that the error limits of ^{14}N shielding data can be quite large (several ppm) depending on the line width (up to several kHz), whereas ^{15}N-NMR data are usually accurate to ± 0.5 ppm.

Both ^{15}N and ^{14}N chemical shifts are prone to medium effects, i.e., solvent, concentration, and temperature. Depending on the nature of the solvent and substrate, these effects may be as high as several tens of ppm. An example

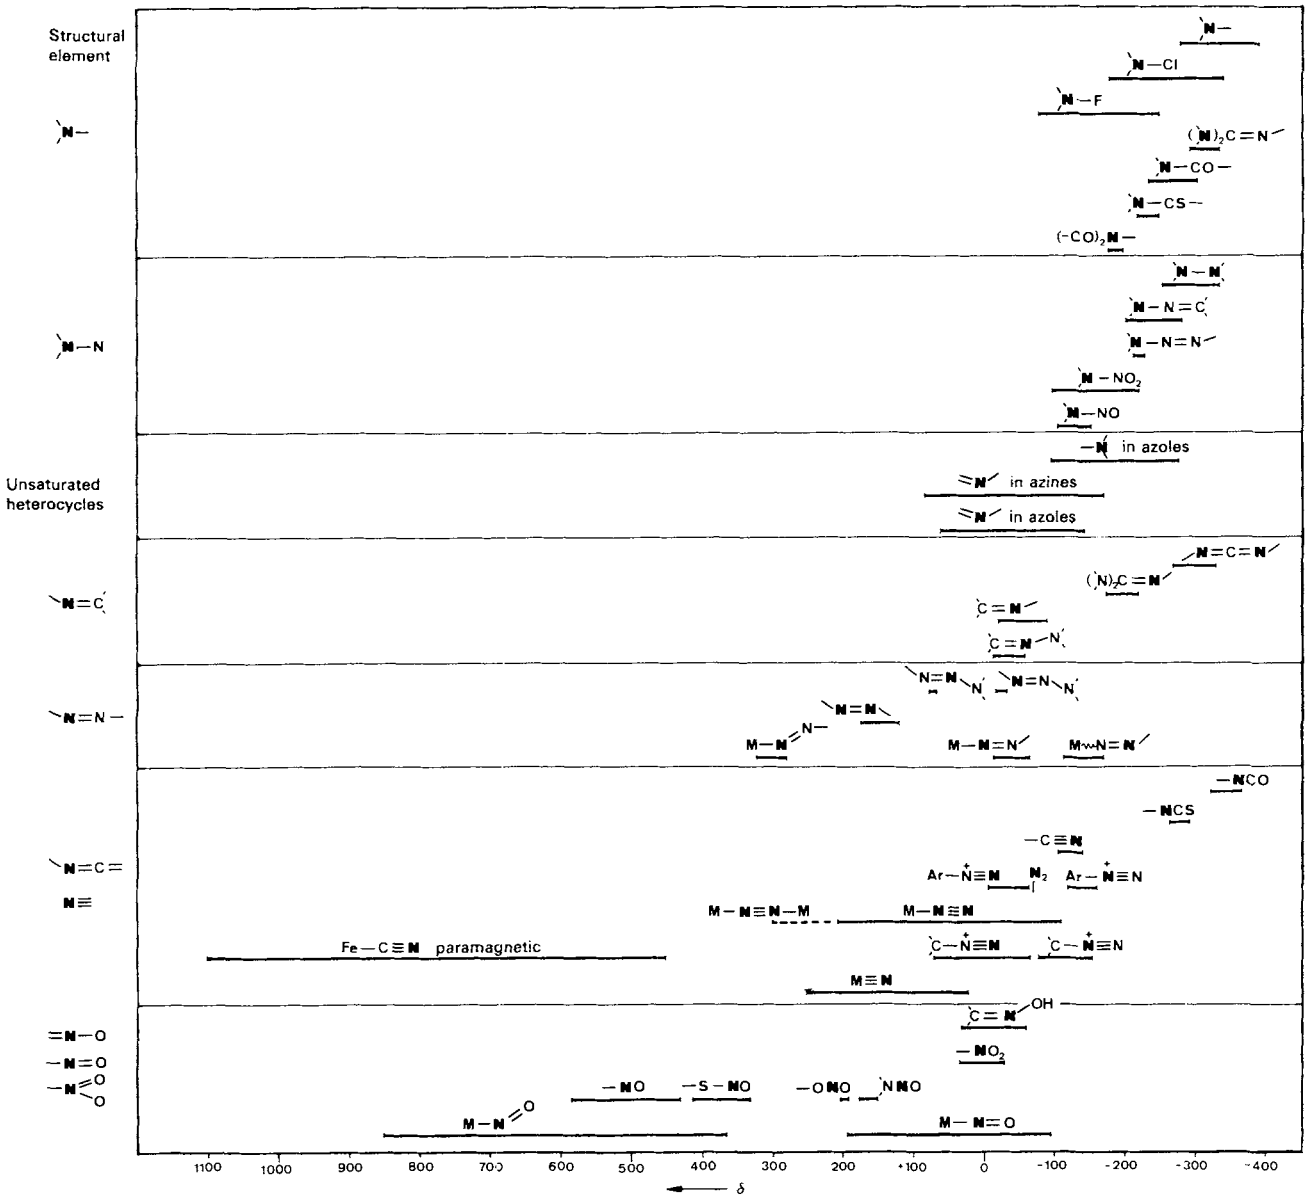

Fig. 13. ^{15}N chemical shift ranges in organic and inorganic compounds relative to CH_3NO_2; positive δ values correspond to ^{15}N resonances shifted to higher frequencies [38]. Ar = aryl.

is given in Figure 15. The substituent-induced shifts in *p*-substituted *N,N*-dimethylbenzaldehyde hydrazones **11** correlate well with Hammett substituent constants, and the slope is solvent dependent (which indicates the origin of the effects).[42] The dicoordinated N atoms of azines and azoles, frequently encountered in heterocyclic systems, are

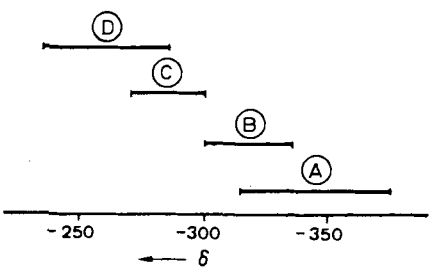

Fig. 14. ^{15}N chemical shift ranges for Ⓐ *tert.*-amines, Ⓑ enamines, Ⓒ enamino ketones, and Ⓓ amides.

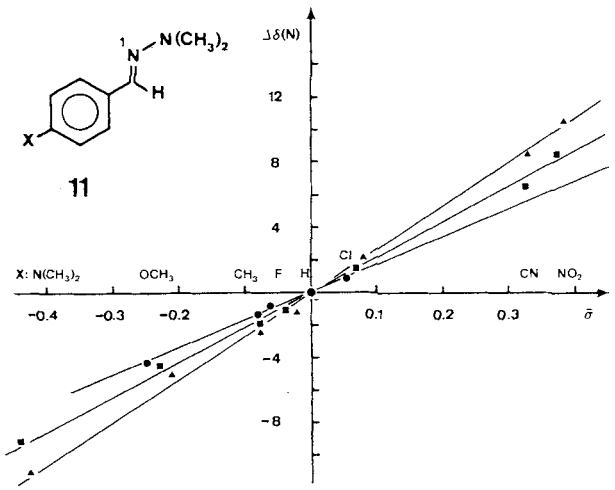

Fig. 15. Correlation between $\Delta\delta(N) = \delta_N^X - \delta_N^H$ and the substituent constants $\bar{\sigma} = (\rho_I\sigma_I + \rho_R\sigma_R)/(\rho_I + \rho_R)$ for the N-1 resonance of *p*-substituted benzaldehyde hydrazones **11**; measured in C_6H_{12} (●), $(CH_3)_2SO$ (■), and CH_3OH (▲) [42].

typical examples where the solvent-induced ^{15}N shift correlates well with the hydrogen bonding properties of the solvent[43] (Table 2). The limiting case, full protonation on the N atom, causes a low-frequency shift of approximately 120 ppm (see ref. [39] and references cited therein). An excellent overview of solvent effects on ^{15}N chemical shifts is given in ref. [7a], and some applications will be discussed in Section 4.1.

Several authors have investigated deuterium isotope effects on ^{15}N chemical shifts, although the data base is still rather small. In an early study, *Litchman* et al.[44] measured low-frequency shifts of 0.68, 1.29, and 1.96 ppm for mono-, di-, and trideuterated ammonia, respectively, and a value of −0.6 ppm per deuterium atom was observed in [^{13}C-2,3-$^{15}N_2$-guanidino]arginine.[45] Deuterium isotope effects over several bonds have been detected in enamino ketones, but they usually do not exceed 0.1 ppm.[46] If the deuteration affects a fast tautomeric equilibrium, as in 2-hydroxyazo compounds, much larger shifts (several ppm) can be observed.[47] Isotope effects may thus be useful for the detection and quantitative study of tautomeric systems.

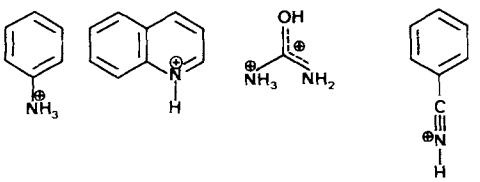
Because of the manifold influences on ^{15}N chemical shifts, the assignment of resonance lines for structure elucidations may become a difficult problem. A variety of assignment techniques, however, are available, which will be discussed collectively in Section 3.4. The possibilities have been considerably expanded by the inclusion of N,H coupling constants, which are obtainable from INEPT, DEPT, or 2D NMR heteronuclear correlation experiments. In the course of this development our knowledge of N,H couplings over several bonds (^nJ(N,H), n = 2, 3, 4) has progressed to a point where an application to structural analysis becomes possible.

3.2. Spin-Spin Coupling Constants

Contrary to the nearly identical chemical shifts of the two nitrogen isotopes, their coupling constants to an X nucleus depend on the gyromagnetic ratios $\gamma(^{14}N) = 1.9324$ and $\gamma(^{15}N) = -2.7107$. From Equation (b), it is apparent that the ^{15}N,X coupling constants are 40% larger than the ^{14}N,X coupling constants and have an opposite sign.

$$J(^{15}N,X) = \gamma(^{15}N)/\gamma(^{14}N) \cdot J(^{14}N,X) = -1.40 \cdot J(^{14}N,X) \quad (b)$$

It may be recalled that a "reduced coupling constant" $K(X,X')$ has been defined in order to allow a comparison of coupling energies of different nuclei (isotopes or elements)[48] [Eq. (c)].



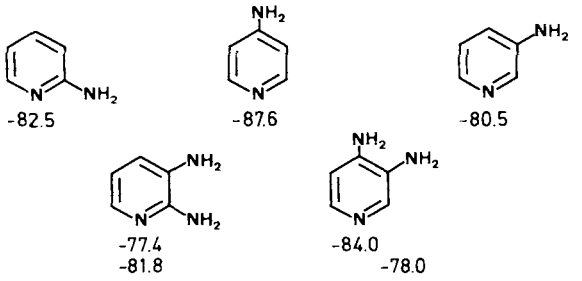
$$K(X,X') = \frac{4\pi^2}{h\gamma_X\gamma_{X'}} \cdot J(X,X') \ [N \cdot A^{-2} \cdot m^{-3}] \quad (c)$$

This definition eliminates the influence of the gyromagnetic ratio (magnitude and sign). Therefore, K reflects the coupling pathway and the mechanism of the scalar spin–spin interaction. In practice, coupling energies are always reported as J or $|J|$ values.

3.2.1. One-Bond $^{15}N,X$ Coupling (^1J(N,X))

As for C–H bonds in ^{13}C-NMR spectroscopy, the largest coupling constants in ^{15}N-NMR spectroscopy are observed for N–H bonds; moreover, they depend linearly on the s-character of the hybrid orbital involved in the N–H bond (see Scheme 3). There are several empirical equations that describe this dependence.

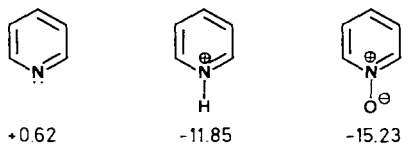
$$^1J(N,H) = -2.94 \cdot (\%s) \quad [Hz] \quad (d)[51]$$
$$^1J(N,H) = -2.33 \cdot (\%s) + 6 \quad [Hz] \quad (e)[52]$$
$$^1J(N,H) = -1.69 \cdot (\%s) - 17 \quad [Hz] \quad (f)[53]$$



^1J(N,H) [Hz]						
	found	−76.9 [49]	−96.0 [49]	−76.5	−96.8 [50]	−136 [49]
	calcd	−73.5	−98.0	−73.5	−98.0	−147
	%s	25	33	25	33	50

Scheme 3.

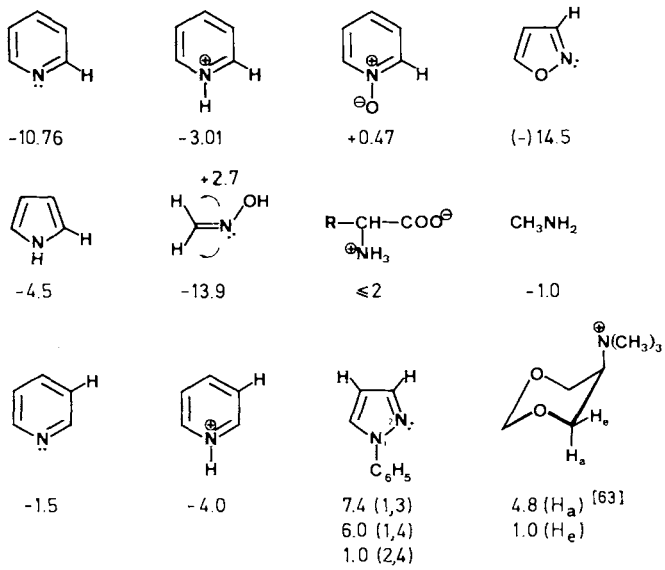
Equation (d) is preferably used for charged species and reproduces the ^1J(N,H) values in Scheme 3 within ±3.5 Hz with the exception of the value for protonated benzonitrile (−11 Hz). These correlations can be used to estimate the hybridization of the N atom. For example, compared with the ^1J(N,H) value for ammonia (62 ± 2 Hz),[7a] the small values for the 1,2-disubstituted triaziridines **24** and **25** (51.7 and 58.1 Hz, respectively, see Section 4.2)[54] indicate a pyramidal geometry at N-3.



^1J(N,H) coupling constants in aminopyridines and aminopyrimidines are dependent on the position of the NH_2 group, a manifestation of the extent of conjugation and, as a consequence, loss of pyramidal geometry at the N atom (Scheme 4). This result can be used for the assignment of amino groups in azines and is consistent with the conclusions drawn from chemical shifts.[39] The barriers to internal rotation about the N–C bond[55] are 22.1 and 31.3 kJ/mol for the 3- and 4-amino groups, respectively, in 3,4-diaminopyridine, which clearly supports the weaker conjugation and more pyramidal geometry of the 3-amino group. It should be added that N,H coupling in anilines is also solvent dependent. ^1J(N,H) increases with increasing tendency of the solvent to form hydrogen bonds to the NH_2 groups; for example, $\Delta J^{DMSO}_{CDCl_3}$ is 4–5 Hz.[56]

Scheme 4. The coupling constants $^1J(N,H)$ [Hz] are given below the formulas [39].

The $^1J(N,H)$ coupling shows no significant H/D isotope effect since the same value ($^1J(N,D) = 9.45 \pm 0.2$ Hz) was measured for the three species NH_2D, NHD_2, and ND_3. This value can be used to calculate $^1J(N,H)$ in ammonia, $^1J(N,H) = \gamma_H/\gamma_D \cdot J(N,D) = 6.494 \cdot J(N,D) = 61.4$ Hz, in good agreement with direct measurements.[44]



One-bond coupling of ^{15}N to other nuclei (e.g., ^{13}C, ^{15}N, ^{29}Si, ^{31}P) is expected to decrease with decreasing gyromagnetic ratio of the X nucleus since, for the lighter elements, the Fermi contact mechanism dominates this coupling.[57] In fact, $^1J(N,P)$ shows the largest values (50–95 Hz) in aminophosphanes.[58] The one-bond coupling between ^{13}C and ^{15}N nuclei is much smaller (for alkyl amines, absolute values of 2–5 Hz) but increases with increasing s-character in both the N- and C-orbitals and reaches values of -17.5 Hz in acetonitrile[59] and -20.2 Hz in diazomethane.[60] No general relationship, however, seems to hold between $^1J(N,C)$ and s-character, although the equation $^1J(N,C) = 0.0125 \cdot (\%s)_C \cdot (\%s)_N$[52] was proposed. It is evident from the extensive data collections on $^1J(N,C)$[7a,b] that factors such as the electronegativity of the substituents on nitrogen, the π-bond order, and the orientation of the lone-pair electrons contribute substantially to the coupling constant. For example, the lone-pair electrons make a positive contribution to $^1J(N,C)$ in pyridine, which results in a small coupling constant for the free base and a large, negative value for the pyridinium ion and the *N*-oxide[61] (Scheme 5). Furthermore, mechanisms other than the Fermi contact type can make considerable positive or negative contributions to coupling between ^{15}N and ^{13}C nuclei.[62]

Scheme 5. The coupling constants $^1J(N,C)$ [Hz] are given below the formulas [61].

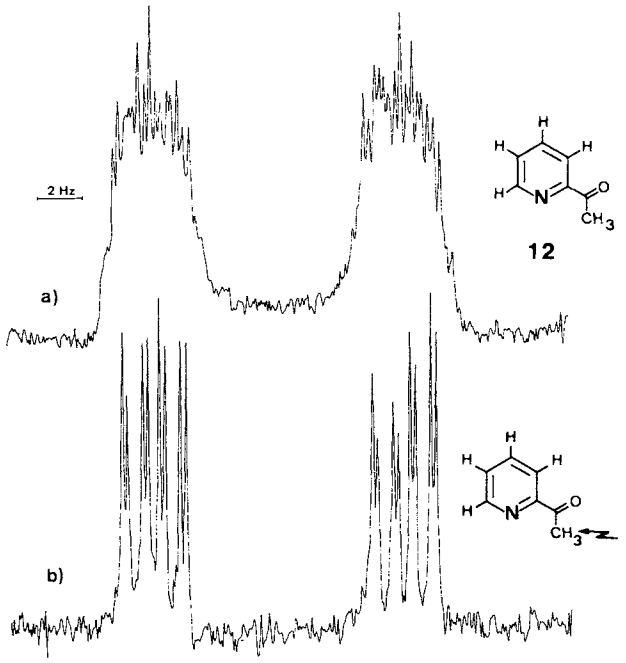
3.2.2. Long-Range $^{15}N,X$ Coupling ($^nJ(N,X)$, $n = 2, 3$)

In this section we will restrict ourselves to the discussion of $^{15}N,^1H$ and $^{15}N,^{13}C$ coupling constants and their application in structure elucidation. Values for these interactions are usually < 20 Hz and thus in the same range as corresponding $^1H,^1H$ or $^{13}C,^1H$ coupling constants. Whereas $J(^{15}N,^1H)$ can be determined for compounds containing a natural abundance of ^{15}N, the measurement of $^{15}N,^{13}C$ coupling constants requires ^{13}C- or ^{15}N-labeled components since both nuclei have a very low natural isotope abundance (1.1% and 0.37%, respectively). $^{15}N,^1H$ coupling constants are, therefore, useful for analytical purposes (e.g., spectral assignments, configurational and conformational studies), while $^{15}N,^{13}C$ coupling constants may be expected to aid mechanistic and biosynthetic investigations. With the advent of modern pulse sequences (cf. Section 2.2), a large number of $^{15}N,X$ coupling constants have become readily available, and major trends in their structural dependence have been worked out. Scheme 6 lists some typical examples for $^2J(N,H)$ and $^3J(N,H)$ in organic structures. Geminal N,H coupling is rather large in H–C=N– systems (10–20 Hz); a significant contribution to $^2J(N,H)$ originates from nonbonding electron transfer into the antibonding σ^* orbital of the C–H bond.[64] Protonation or quaternization of the dicoordinated sp^2-hybridized N atom leads to a drastic reduction of the value of $^2J(N,H)$, as seen in pyridinium and pyrimidinium compounds (Scheme 6).[65b]

Scheme 6. The coupling constants $^nJ(N,H)$, $n = 2, 3$ [Hz], are given below and, if necessary, above the formulas [7a, b].

When the INEPT and DEPT pulse sequences were first used to measure proton-coupled ^{15}N-spectra, it was recognized that $(2 \times {}^2J(N,H))^{-1}$ is the optimal τ value for azines[65] and azoles.[15] The following example illustrates the use of $^2J(N,H\text{-}6) = 11.1$ Hz in 2-acetylpyridine **12** to obtain a fully proton-coupled refocused INEPT spectrum. The very complex spectrum (Fig. 16a) can be simplified by applying selective ^1H-decoupling during the acquisition period. These experiments (Fig. 16b) permit the determination and assignment of all long-range N,H coupling constants; corresponding studies can help to elucidate the

substitution pattern in more complex nitrogen heterocycles (see Section 4).



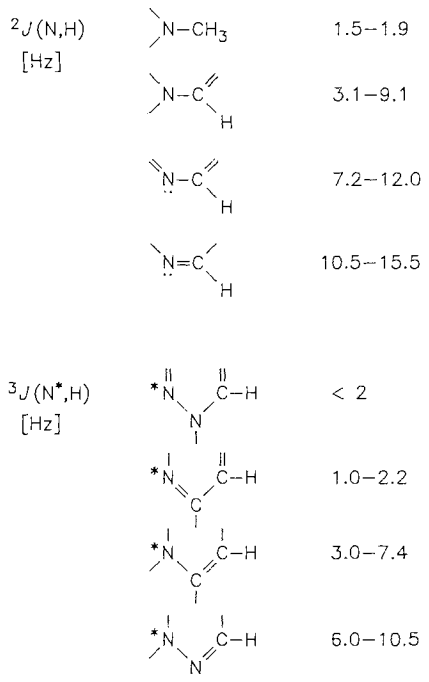


Fig. 16. INEPT ^{15}N-NMR spectra of 2-acetylpyridine **12** (20.3 MHz; 90% v/v in $(CD_3)_2CO$): a) proton-coupled, 11000 pulses; b) selective irradiation at the CH_3 resonance, 1500 pulses [65a].

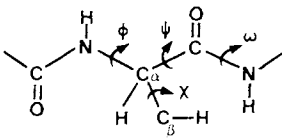
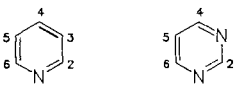
A detailed investigation of N,H coupling constants in azoles[66] has revealed a subtle dependence of ^2J(N,H) and ^3J(N,H) on the coupling pathway, i.e., connectivity, geometry, and bond order (Scheme 7). Such information, even if only semiquantitative, can be useful for structural assignments and for the estimation of coupling constants in order to optimize delay times for polarization transfer experiments and for heteronuclear 2D NMR.



Scheme 7.

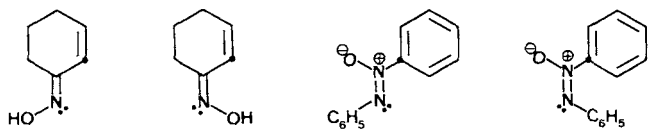
Long-range N,H coupling constants in aliphatic systems are usually small (<4 Hz) and, since the spin systems are often complex, the precise values cannot be readily determined. For example, the potential importance of ^3J(N,H) for the determination of the torsional angles ψ or χ in peptide systems has raised considerable interest (Scheme 8).[67] Although a torsional angle dependence of the type

$$^3J(N\text{–}CO\text{–}CH) = A\cos^2\psi + B\cos\psi + C$$



was demonstrated both theoretically[68] and experimentally,[69] the very narrow range of ^3J(N,H) is a serious limitation. The fact that small values may have either sign constitutes a further uncertainty in stereochemical applications.

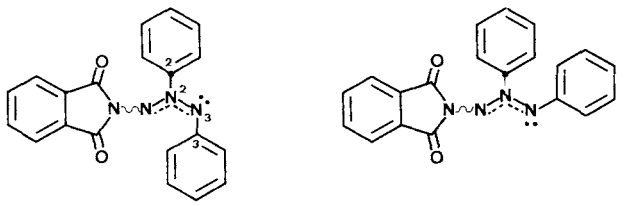
Scheme 8.



The relative signs of N,H coupling constants may be determined by standard double resonance techniques[70] or spectral analysis and simulation. As expected, the Fermi contact dominated coupling constants ^1J(N,H) are always negative, whereas ^2J(N,H) and ^3J(N,H) may show either sign; in general, N,H coupling constants > 10 Hz are negative.[71] The relative signs of all N,H coupling constants in pyridine and pyrimidine have been determined by SPT experiments[21c] and spectral simulation,[72] respectively. The consistent results are collected in Table 3.

Table 3. Magnitudes and relative signs of coupling constants ^nJ(N,H) [Hz] in pyridine [21c] and pyrimidine [72].

	H-2	H-3	H-4	H-5	H-6
Pyridine	−10.93	−1.48	+0.27	−1.48	−10.93
Pyrimidine	−14.42	—	+0.54	−1.07	−10.76



Long-range ^{15}N,^{13}C coupling constants are generally smaller than 10 Hz. The data can be best obtained from the ^{13}C-NMR spectra of ^{15}N-labeled compounds. ^2J(N,C), like ^2J(N,H), is known to depend upon the orientation of the lone-pair electrons on nitrogen relative to the geminal carbon atom, significantly larger values being observed for synperiplanar than for antiperiplanar arrangements[73] (Scheme 9). The geometrical dependence of the N-C-C coupling is not impaired by the presence of other heteroatoms, as shown by the spectra of (*E*)- and (*Z*)-azoxybenzene. This fact permitted the use of ^2J(N,C) in the structural proof of two stereoisomeric azimines, **13** and **14**, formed by addition of phthalimidonitrene to (*E*)- and (*Z*)-azobenzene, respectively (Scheme 10).[75] Since N-2 and N-3 have similar chemical shifts in **13** and **14**, their assign-

ments are based upon the very different values of ^1J(N,C), in analogy to the azoxybenzenes and on the basis of a theoretical treatment of ^1J(N,C).[62] The (*E*)- and (*Z*)-configurations clearly follow from the ^2J(N,C) values obtained from the ^{13}C-NMR spectra of the [2,3-N_2]-labeled substrates.

Scheme 10.

The use of N,C coupling constants in biosynthetic studies will be discussed in Sections 4.1 and 4.5.

3.2.3. $^{15}N,^{15}N$ Coupling Constants

For sensitivity reasons, ^{15}N,^{15}N coupling can only be observed in the spectra of ^{15}N-labeled compounds. Nevertheless, a considerable amount of data has accumulated and is summarized in several reviews.[76, 7a, b] The coupling constants are small (<25 Hz) since two nuclei with very small gyromagnetic ratios are involved. ^1J(N,N) does not seem to show correlations with either s-character in the bonding orbitals or N-N bond length (Scheme 11).

24.0 22 -12.9 [77a] 9.2 [Hz]

6.7 6.2 [78a] 5.6

2.5 [78b]

Scheme 11. The coupling constants ^1J(N,N) [Hz] are given below and, if necessary, above the formulas [7a, b]. The value for N_2 was calculated from the experimental value for $^{14}N^{15}N$ [78b] by means of Equation (b).

Quantum-chemical calculations have predicted that most ^1J(N,N) values should have a negative sign[79] owing to the dominant contribution of lone-pair electrons in "s-hybridized" orbitals. A pronounced dependence of the magnitude and sign of this coupling on the lone-pair dihedral angle was also predicted.[79b] A detailed interpretation of N,N coupling data should be based upon experimental determinations of the sign,[77] but such measurements are still lacking in most cases. Some structural applications of N,N coupling constants will be discussed in Section 4.

3.3. ^{15}N Relaxation Times

The two principal time constants of nuclear magnetic relaxation, T_1 and T_2, have very different significance for ^{14}N- and ^{15}N-NMR spectroscopy. For the quadrupolar nucleus ^{14}N, it is the transverse relaxation time T_2 that influences the ease of observation of the NMR signal. T_2 determines the line width $\Delta\nu_{1/2}$ of the signal, which may vary from a few Hz for a highly symmetrical electronic environment to several kHz for unsymmetrical environments and large molecules. Thus, sensitivity is lost as a result of *fast* relaxation, which results in line broadening ($T_2 = 1/\pi\Delta\nu \approx 65$ ms to 65 μs for $\Delta\nu = 5$ Hz to 5 kHz).

On the other hand, a very different situation arises for the spin-1/2 isotope ^{15}N, which lacks an effective internal relaxation mechanism. As a nucleus with a small gyromagnetic ratio, ^{15}N depends on the spatial proximity of a sensitive nucleus for fast dipolar spin-lattice relaxation rates, $(T_1^{DD})^{-1}$, or, alternatively, on high magnetic fields (B_0) to increase the contribution of the chemical shift anisotropy term to the rate of relaxation, $(T_1^{CSA})^{-1}$. The rate of spin-lattice relaxation $(T_1)^{-1}$ determines the pulse repetition rate in single-pulse experiments. Hence, it becomes evident that NH_2 and NH groups with efficient ^{1}H,^{15}N dipolar relaxation can be more readily detected than tertiary N atoms, which lack the dipolar interaction with a directly bonded proton, resulting in rather long T_1 values and the loss of a nuclear Overhauser effect (Section 2.1). With the availability of high-field magnets ($B_0 = 9.4$ or 11.7 tesla), the measurement of tertiary N atoms is less time-consuming. The CSA term, which contributes to $1/T_1$ for all larger molecules, increases proportionally to B_0^2 [Eq.(g)][80] and thus causes a significant decrease in T_1 (Table 4).

$$(T_1^{CSA})^{-1} = \tfrac{2}{15}\gamma_N^2 B_0^2(\sigma_\parallel - \sigma_\perp)^2 \cdot \bar{\tau}_c \qquad (g)$$

Table 4. Field dependence of ^{15}N spin-lattice relaxation times T_1/s.

	B_0=1.4	4.2	4.7	9.4 T
$NaNO_2$ [a]			19.0	17.5
KCN [b]	21.2	14.5		
2-chloro-pyrimidine [c]			170	114

[a] 99% ^{15}N, 1.1 M in D_2O, 25 °C [b]. 95% ^{15}N, 7.9 M in D_2O, 30 °C (from Table 2.3 in [7a]). [c] 99% $^{15}N_2$, 1.6 M in $(CD_3)_2CO$, 25 °C.

It should be mentioned that chemical shift anisotropy, $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$, is up to 4 times larger for ^{15}N than for ^{13}C nuclei and, consequently, the B_0^2-dependent CSA relaxation mechanism becomes more effective for ^{15}N nuclei in high-field spectrometers.

At lower field strengths very fast relaxation can be obtained by the addition of paramagnetic relaxation reagents, such as $Cr(acac)_3$, $Ni(acac)_2$, or $Gd(dpm)_3$ (dpm = dipivalomethanato)[81] or, for aqueous solutions, $[Gd(2:2:1)]^{3\oplus}$ cryptate.[82] An increase in the spin-lattice relaxation rate (T_1^{-1}) by a factor of 10-100 is frequently observed,[81] and measuring times are, therefore, dramatically reduced. The most recent and efficient technique to overcome the low sensitivity due to long T_1 relaxation times is the polarization transfer from an abundant, sensitive, fast-relaxing nucleus (e.g., ^1H, ^{19}F) to ^{15}N in the INEPT or DEPT pulse sequence experiments (Section 2.2). The repetition rate of the pulse sequence is governed by the (fast) proton relaxation and not by the (slow) ^{15}N relaxation.[11,12]

An intricate feature of spin-lattice relaxation is its dependence on molecular motion, specifically the reorientation times or correlation times τ_c. T_1 decreases linearly with increasing correlation time τ_c for small fast tumbling molecules in the so-called extreme narrowing condition ($\tau_c^2(\omega_N + \omega_H)^2 \ll 1$), approaches a minimum for $\tau_c = 10^{-9}$-10^{-8} s, and it increases again for longer correlation times (Fig. 17). This effect applies to large biomolecules, such as proteins and nucleic acids, and becomes more pronounced at high fields.

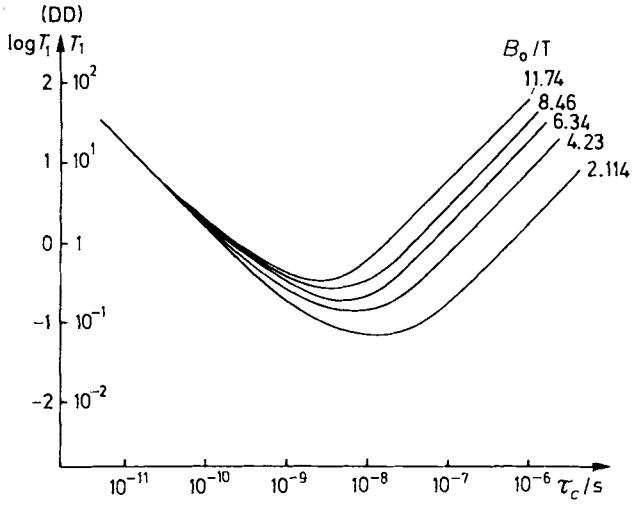

Fig. 17. Dipole-dipole relaxation (T_1^{DD}) as a function of the correlation time τ_c (for isotropic molecular reorientation) for different field strengths B_0 [7a].

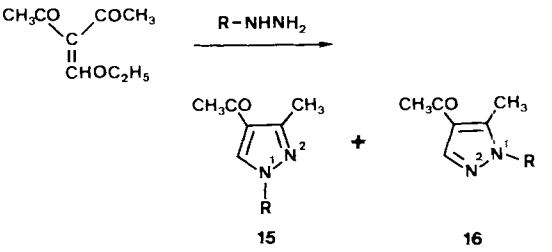
In conclusion it may be emphasized that a consideration of spin-lattice relaxation is a prerequisite for the optimization of ^{15}N-NMR experiments. Since T_1 values are strongly dependent on experimental conditions (field strength, concentration, solvent, temperature) and very sensitive to the structural environment, data compilations are only of limited value. T_1 values of some typical molecules are reported in ref. [7a, c, 4].

3.4. Assignment Techniques

The assignment of ^{15}N resonances may become a considerable problem for compounds with several N atoms, in particular when repeating structural units are involved, such as in polypeptides or polynucleotides. But even in small molecules the identification of the ^{15}N-NMR signals may become a challenging task. The first difficulty arises when the true signals have to be differentiated from spurious electronic signals in spectra with low signal-to-noise ratio. As a result of variable T_1 relaxation times and (negative) nuclear Overhauser enhancements, ^{15}N-NMR intensities can be very different, and weak signals are easily lost in the noise. Application of several of the detection methods outlined in Section 2 is often necessary to ensure that all resonances are indeed detected. In particular, experiments with and without NOE should be performed and, in the case of polarization transfer experiments with pulse sequences, the delay time τ should be varied.

The second problem concerns the assignment of lines to specific N atoms. Based on the discussion of the spectral parameters in Section 3, the following criteria can be applied:

- chemical shifts, including substituent effects
- protonation effects, N-H exchange rates
- lanthanide-induced shifts (LIS)
- nuclear Overhauser effects
- N,H and N,X coupling constants
- N,H and N,X correlation experiments (1D and 2D)
- spin-lattice relaxation times
- isotopic labeling



The most powerful assignment aid is the analysis of the proton-coupled ^{15}N-NMR spectra. It is this area of ^{15}N-NMR spectroscopy where rapid progress has been made in the past few years, owing to the development of modern 1D and 2D pulse sequence experiments. Paramagnetic shift reagents (lanthanide complexes) have also proven useful in several cases[83,39,84] to assign ^{15}N resonances. In oligopeptides, the different exchange rates of free and hydrogen-bonded NH groups are a useful criterion for their assignment. Moreover, additive empirical shift increments are available, e.g., for azoles[85] and azines.[86] Finally, extensive molecular orbital calculations have led to the prediction of a wide range of ^{15}N chemical shifts, which may be used for assignment purposes.[41,7b,87]

4. Chemical Applications

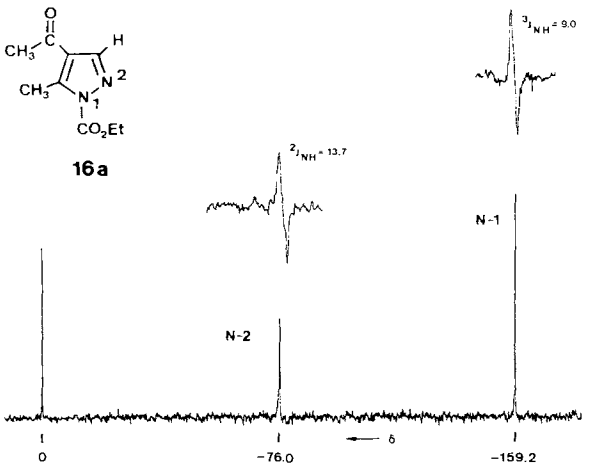
The increased sensitivity of ^{15}N-NMR spectroscopy together with the possibility of obtaining ^1H-coupled ^{15}N-NMR spectra has greatly enlarged the scope of applications in structural chemistry during the past few years. In this section, we will discuss selected examples from the fields of organic chemistry, biochemistry, and organometallic and coordination chemistry. They were chosen to illustrate the principles discussed in the previous Sections, the wide spectrum of applications, and the general potential of ^{15}N-NMR spectroscopy as a probe into molecular structure and reactions.

4.1. Structure and Bonding of Organic Molecules

^{15}N-NMR spectroscopy is particularly suited for studies of isomerism in nitrogen-containing heterocyclic systems. For example, isomeric acetylpyrazoles of the types **15** and **16**, which serve as precursors for biologically active substances,[88] are formed by the reaction of monosubstituted hydrazines with 3-(ethoxymethylene)-2,4-pentanedione, the product ratio depending on the nature of R (Scheme 12). Since the tricoordinated and dicoordinated nitrogen

Scheme 12.

atoms, N-1 and N-2, respectively, are readily distinguishable by their chemical shifts (Fig. 18), the geminal and vicinal N,H coupling constants obtained from an INEPT experiment allow an unambiguous assignment of the isomers.[15] As expected from the results discussed in Section 3.2.2, the pyrazoles **16** show large ^2J(N-2,H) and ^3J(N-1,H) values (e.g., **16a**, R = $CO_2C_2H_5$, 13.7 and 9.0 Hz, respectively), whereas the corresponding values for **15a** are 3.4 and 1.9 Hz, respectively. Very similar data were found for the *N*-benzyl derivatives.



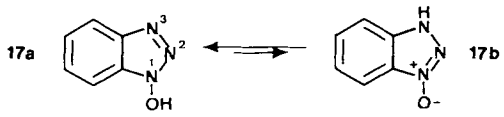


Fig. 18. Refocused and ^{1}H-decoupled INEPT ^{15}N-NMR spectrum of ethyl 4-acetyl-5-methyl-1-pyrazolecarboxylate **16a** (20.3 MHz; $(CD_3)_2SO$); without decoupling (insets) [15].

4- and 5-Nitroimidazoles present another case of regioisomerism, and their differentiation is of particular interest since *N*-substituted 5-nitro isomers are potent antiprotozoics.[88b] A reliable assignment was possible on the basis of the chemical shifts of the NO_2 group (4-NO_2, $\delta = -18 \pm 1$; 5-NO_2, $\delta = -25 \pm 1$) and ^{15}N,^{1}H coupling constants of N-1 and N-3.[15]

Intricate tautomeric equilibria are common in heterocyclic systems and their elucidation can often be achieved by ^{15}N-NMR spectroscopy. For example, the position of the fast tautomeric equilibrium of 1-hydroxybenzotriazole **17a** and its derivatives was determined as a function of solvent on the basis of the chemical shifts of N-3.[89] The range of chemical shifts for N-3 (-58 to -100 ppm) clearly shows that the *N*-hydroxy form **17a** dominates the equilibrium, the contribution of the *N*-oxide **17b** ranging from 6% (DMSO) to 26% (CH_3OH) (Scheme 13). 2-Hydroxyazines

Scheme 13.

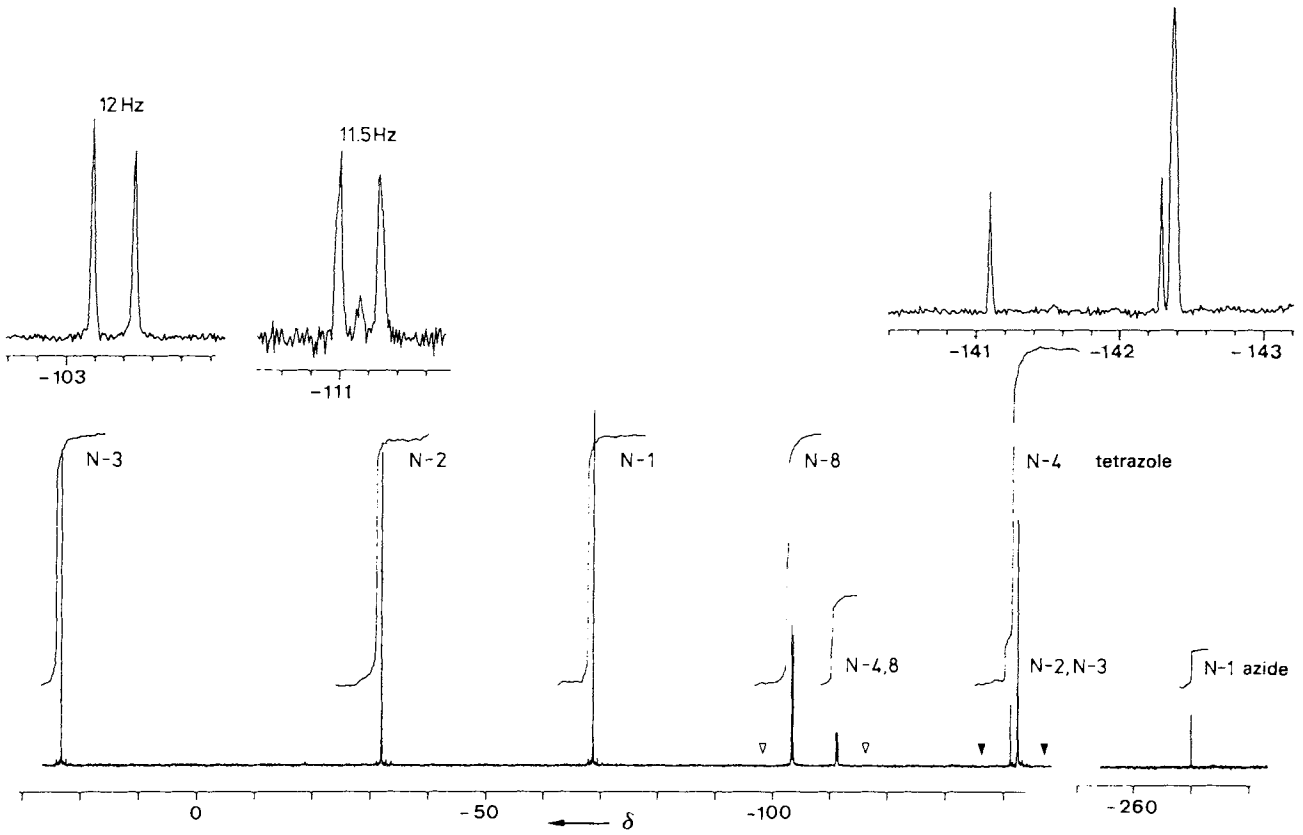
are known to exist in the tautomeric amide form. However, an unusual iminol-amide equilibrium was recently observed for the hydroxyaza[10]annulene **18** (Scheme 14). The averaged ^{15}N chemical shift of the tautomeric system ($\delta = -204.3$, $(CD_3)_2SO$, 37 °C) was compared with data of the *N*-methyl ($\delta = -240.6$) and *O*-methyl ($\delta = -115.9$) derivatives, the results indicating an **18a/18b** ratio of about 7:3.[90] The remarkable stability of the iminol form **18b** was also evident from the ^{13}C-NMR spectrum.

Scheme 14.

Similar studies have been carried out on a series of substituted azoles[91,92,7b] with special emphasis on imidazole[93] and nucleotides, which are important for the investigation of biological systems.[94]

Scheme 15.

Hull, Künstlinger, and *Breitmaier*[95] have reported on the tetrazolo[1,5-*a*]pyrimidine **19**/2-azidopyrimidine **20** valence isomerism, which lends itself to an investigation by ^{15}N-NMR spectroscopy (Scheme 15). This exchange, studied previously by ^{1}H-NMR spectroscopy,[96] is so slow that it is possible to assign all nine signals of the nonequivalent N atoms of the *n*-butyl derivative (as a neat liquid) (Fig. 19); the equilibrium lies on the tetrazole side (85%). The ^2J(N,H) values were crucial for the correct assignment. The equilibrium was shown to be strongly solvent dependent, the tetrazolo form **19** being favored in polar solvents, while the azido form **20** predominates in chloroform.



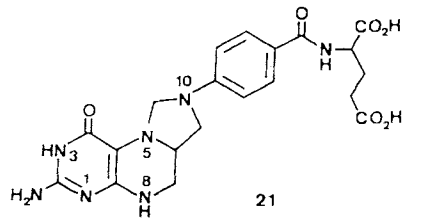


Fig. 19. ^{15}N-NMR spectrum of the equilibrium mixture of 6-butyltetrazolo[1,5-*a*]pyrimidine **19** and 2-azido-5-butylpyrimidine **20**, R = *n*-C_4H_9 (40.6 MHz; neat liquid, 15-mm sample tube). The numbering of the N atoms does not correspond to the systematic nomenclature (see Scheme 15) [95].

Substituent effects on the ^{15}N resonances were studied in pyridines,[97] pyrimidines,[97] and pyrazines,[98] and linear correlations with ^{13}C substituent effects could be established.

Extensive studies of the ^{15}N-NMR spectra of the biologically important pteridines[9] have led to a definite structure assignment of the so-called "activated formaldehyde" (Blakley cofactor), which is formed from (6*S*)-5,6,7,8-tetrahydro-L-folic acid and formaldehyde. This compound serves as a cofactor in the enzymatic conversion of glycine into serine.[99] Both the 5-hydroxymethyl- and the cyclic 5,10-methylene structure **21** have been proposed.[99, 100] The natural abundance ^{15}N-NMR spectrum of the (6*RS*) compound is shown in Figure 20. The assignments of the seven N atoms are based on the ^{15}N-NMR data of tetrahydrofolic acid derivatives,[9] but the signals of the two diastereoisomers (at 10.1 MHz) are not resolved.

The 20.3-MHz ^{15}N-NMR spectrum of the product labeled with ^{15}N in the 5- and 10-positions (Fig. 21) reveals clearly resolved doublets ($\Delta\delta = 0.24$) for the (6*R*) and (6*S*) diastereoisomers. Since the small ^{15}N-5,^{15}N-10 coupling of 2 Hz does not disprove the 5-hydroxymethyl structure, the 11-position was labeled by reaction with [^{13}C]formaldehyde. In the ^{1}H-decoupled ^{13}C-NMR spectrum the methylene carbon appears as a double doublet with $J(^{15}N,^{13}C) = 10.8$ and 4.7 Hz. Since the signal of ^{13}C-11 in the compound with natural ^{15}N isotope abundance is not split, the double doublet structure in the triply labeled product is due to ^{1}J(N,C) coupling only, thus clearly proving the *cyclic* methylene structure **21** for the activated formaldehyde[101] (cf. the other ^{13}C,^{15}N coupling constants in Scheme 16). As expected from the linear correlation between ^{1}J(N,C) and the s-character of the bonding orbitals (see Section 3.2.1), the aniline-type N-10 atom shows the largest ^{1}J(N,C) values, whereas N-5 shows smaller values, indicating a pyramidal (sp^3-type) geometry at this nitrogen

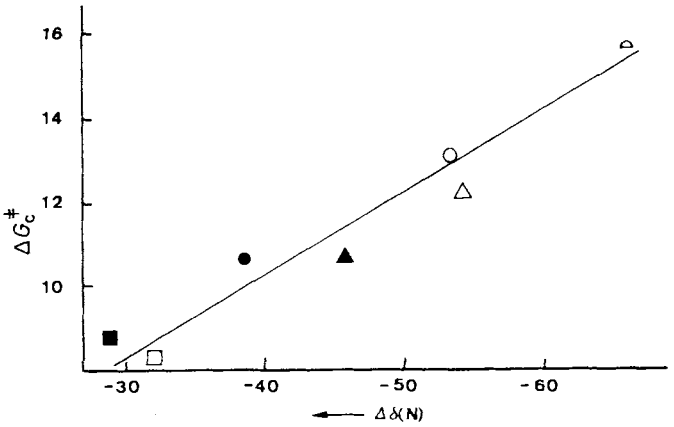

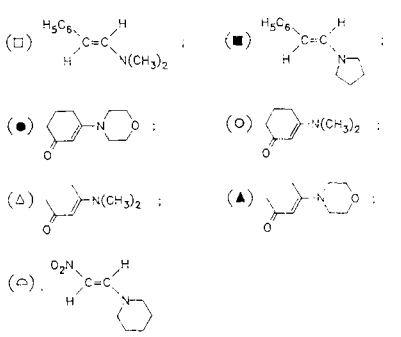

Fig. 22. Correlation of the free energy of activation $\Delta G_c^{\neq}$ for rotation about the N-C(α) bond with the differential chemical shift $\Delta\delta(^{15}N) = \delta$(amine) $-\delta$(enamine) [40].

The lone pair of electrons on the nitrogen atom is responsible for the dependence of ^{15}N chemical shifts on n,π-delocalization and hydrogen bonding. A further, directly related effect—most of the time annoying but occasionally useful—is the solvent dependence of ^{15}N shielding data (cf. Section 3.1.2). In the following discussion we will give specific examples for the successful use of ^{15}N-NMR spectroscopy in studies of electronic structure and hydrogen bonding.

The n,π-interactions in enamines and related compounds are largely responsible for the specific physical and chemical properties of enamines as synthons in organic synthesis.[103] In our laboratory, extensive studies have been carried out on ^{15}N chemical shifts in amines, enamines, enamino ketones, and other enamines with extended conjugation.[40, 46, 104, 13] The chemical shifts of ^{15}N nuclei in this class of compounds are found between those of tertiary amines (more shielded) and amides (less shielded) (Fig. 14). In order to separate the n,π-delocalization from electronic and steric substituent effects, it proved advantageous to define a differential chemical shift $\Delta\delta(^{15}N) = \delta$(amine) $-\delta$(enamine). $\Delta\delta(^{15}N)$ correlates well with the free energy of activation $\Delta G^{\neq}$ for restricted rotation about the N-C_α bond as determined from variable-temperature ^{13}C-DNMR measurements[40] (Scheme 17, Fig. 22).

Extrapolation of the data in Figure 22 gives a $\Delta G^{\neq}$ value of 15–20 kJ mol^{-1} for rotation about the N-C_α bond in a simple enamine; this is in good agreement with theoretical predictions for vinylamine (25.5 kJ mol^{-1})[105] and with experimental data on conjugative interactions in other simple enamines.[106]

In a similar study, *Martin* et al.[107] correlated activation energies E_a with ^{15}N chemical shifts in amides and thioamides and also advanced a semiempirical explanation for the validity of such correlations. Since enamino ketones may be considered as vinylogous amides, our results lend further support to this approach.

n,π-Delocalization was studied in a similar manner in substituted anilinostyrenes **22**; the $\Delta\delta$(N) values show excellent correlation with the Hammett σ constants for a series of donor and acceptor substituents (Fig. 23).[40] In this case, the ^{13}C chemical shift of C_β also exhibits a similar correlation with $\Delta\delta$(N), since this nucleus is in a similar electronic environment and no steric interactions with the substituents occur.

An excellent survey of correlations of $\delta(^{15}N)$ with E_a and $\Delta G^{\neq}$ for hindered rotation about N-X bonds and with σ values is given in ref. [7a] and covers the literature up to 1980. More recently, *Taft* et al.[108] analyzed ^{15}N-NMR shifts of amides in solution in terms of three solvent pa-

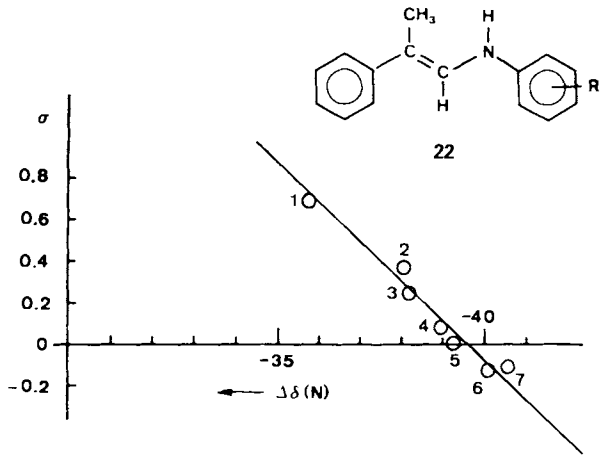

Fig. 23. Correlation of $\Delta\delta(^{15}N) = \delta_N^X - \delta_N^H$ with Hammett σ values for substituted anilinostyrenes **22**; (1) R = *m*-NO_2, (2) *m*-Cl, (3) *p*-Cl, (4) *m*-OCH_3, (5) H, (6) *p*-CH_3, and (7) *p*-OCH_3 [40].

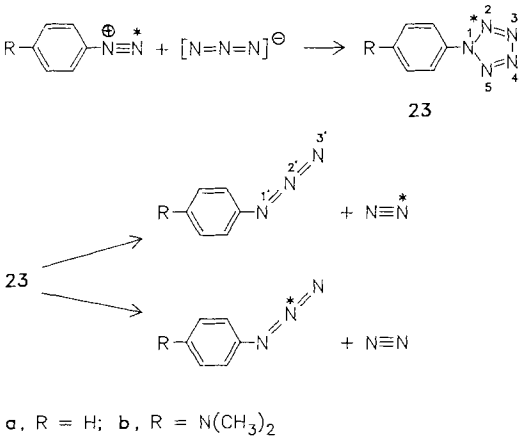

rameters, π^* (polarity/polarizability), α (hydrogen-bond donor acidity), and β (hydrogen-bond acceptor basicity) using multiparameter linear relationships with $\delta(^{15}N)$. Further linear free energy correlations involving Hammett σ constants have been reported for δ(NO) values in substituted *N*-methyl-*N*-nitrosoanilines,[109] for the three N atoms in *p*-substituted 1-phenyl-3,3-pentamethylenetriazenes,[110] and in a detailed study of ^{15}N- and ^{17}O-NMR shifts versus σ_I and σ_R constants as well as calculated electron densities in nitrobenzene derivatives.[111]

As expected from the foregoing discussion ^{15}N chemical shifts have been used successfully to monitor hydrogen-bond formation and protonation. Particularly large, low-frequency shifts are observed in systems containing the C=N group; pyridine has already been discussed in Section 3.1.2. Detailed studies on imines and oximes by *Roberts* et al.[112] showed that hydrogen-bond effects may become as large as 28 ppm (in going from $CHCl_3$ to CF_3CH_2OH as solvent), whereas full protonation (CF_3COOH) results in shifts of 110 to 150 ppm (to lower frequencies). ^{15}N chemical shifts were measured in *N*-retinylidenebutylamine and related Schiff bases as models for rhodopsin and bacteriorhodopsin in solvents of increasing hydrogen-bond donor acidity.[113] The protonation effects on the ^{15}N-NMR shifts increase with increasing length of the conjugated polyene, and it was concluded that ^{15}N-NMR spectroscopy is a most suitable method for the determination of the degree of protonation of the Schiff base linkage. In contrast, small high-frequency shifts (<25 ppm) are observed upon protonation (and hydrogen bonding) of aliphatic amines. In cases where hydrogen-bond shifts are too small to permit a reliable interpretation, ^{15}N spin-lattice relaxation times can be used to monitor restricted motion, as recently shown by *Yu* and *Levy* for 2,4-pentanediamine.[114]

The study of hydrogen bonds between NH and CO groups in peptides showed that ^{15}N chemical shifts are a sensitive indicator of *intra*molecular NH···O=C interactions and thus of the secondary structure of peptides. Gramicidin S, a cyclic decapeptide containing the sequence Phe-Leu-Orn-Val-Pro twice, is a particularly well-studied case investigated by several research groups.[115] The four hydrogen bonds between valine and leucine are indeed reflected in the ^{15}N chemical shifts of the two amino acids when the decapeptide is measured in solvents of increasing proton acidity; this is due to *inter*molecular hydrogen-bond formation between the solvent and the exposed carbonyl group of the respective peptide bond.[116] The four *intra*molecular hydrogen bonds are also demonstrated by reduced exchange rates for the protons involved, which is reflected in a distinct $^{15}N,^1H$ coupling even in basic medium. A comparison of the ^{15}N-NMR spectra of linear oligopeptides with that of gramicidin S led to the same conclusion.[117] *Inter*molecular hydrogen bonding in nucleosides, the predominant mechanism of self-association and base-pairing, is another domain in which ^{15}N-NMR spectroscopy has been successfully applied to structure elucidation.[118] An extension to the study of N-H bond lengths in DNA by solid-state ^{15}N-NMR spectroscopy has also been reported (cf. Section 4.6 and Fig. 11).

4.2. Reaction Mechanisms and Reactive Intermediates

In mechanistic studies ^{15}N-NMR spectroscopy has proven to be a powerful tool for the structure elucidation of unstable intermediates. Very recently, we reinvestigated the classic reaction of benzenediazonium chloride with lithium azide, which results in the elimination of nitrogen and the formation of phenyl azide.[1] This reaction, first described by *Hantzsch*,[119] was investigated mechanistically in 1956–1958 by *Huisgen* and *Ugi* et al.[120] They discovered that the reaction proceeds by two separate mechanisms. For one of them, it was proposed that phenylpentazole **23a** is an intermediate, since it accounts for the equal distribution of the ^{15}N-labeled, terminal N atom of the diazonium salt in the decomposition products phenyl azide and nitrogen (Scheme 18). Although a series of crystalline *p*-sub-

Scheme 18.

stituted phenylpentazoles was subsequently isolated[121] at low temperature (−30 °C) and despite the determination of the structure of *p*-dimethylaminophenylpentazole **23b** by X-ray crystallography,[122] a direct proof for the existence of the pentazole ring in solution was still lacking.

The natural abundance 40.56-MHz ^{15}N-NMR spectrum at −35 °C of **23b** is shown in Figure 24. Although even at this low temperature the pentazole had partially decomposed to the azide and N_2, its four resonance signals could be identified. The assignment was achieved by means of the ^{15}N-NMR spectrum of the [2(5)-^{15}N]pentazole **23b*** (Fig. 25a). The ^{15}N-NMR spectrum measured during decomposition of **23b*** (Fig. 25b) proves the exclusive formation of $^{15}N{\equiv}^{14}N$ and azide labeled in the N-2 position. The structural integrity and very slow decomposition of the pentazole ring at −20 °C is thus confirmed for the *p*-dimethylaminophenyl derivative **23b**.[1]

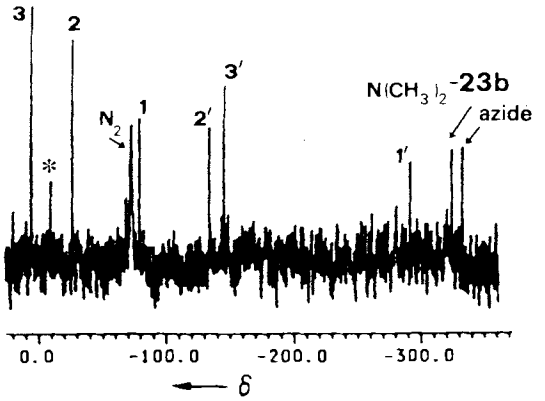

Fig. 24. ^{15}N-NMR spectrum of *p*-dimethylaminophenylpentazole **23b** (40.6 MHz; −35 °C; 0.04 M in $CDCl_3$ with 0.07 M $Cr(acac)_3$). The dashed numbers apply to the azide.

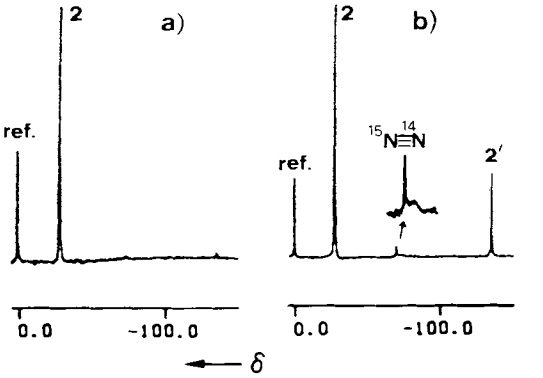

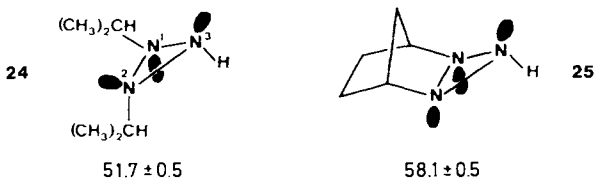

Fig. 25. ^{15}N-NMR spectra of the [2(5)-^{15}N]pentazole **23b** (40.56 MHz; −20 °C; 0.013 M in $CDCl_3$ with 0.06 M $Cr(acac)_3$); a) directly after preparation of the sample; b) during decomposition to the *N*-2-labeled azide and $^{15}N{\equiv}^{14}N$. ref = standard CH_3NO_2.

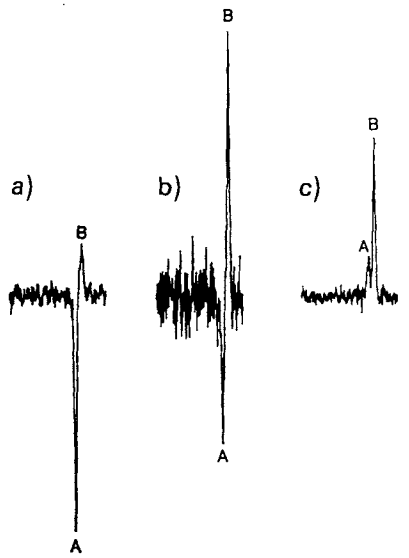
A considerably less reactive nitrogen homocycle, triaziridine, has been a target of organic synthesis for many years. *Dreiding* et al. achieved the photochemical cyclization of azimines to substituted triaziridines.[123] Subsequently, the stereochemistry of substituted triaziridines was investigated both experimentally and theoretically[124] and a series of compounds was characterized by ^{15}N-NMR spectroscopy.[54] The chemical shifts of 1,2-dialkyl-substituted triaziridines lie in the range of substituted hydrazines ($\delta = -240$ to -290) and are typical for pyramidal, tricoordinated N atoms. The N,H coupling constants, however, are unusually small (cf. Section 3.2.1 and Scheme 19). The significant increase in $|^1J(N,H)|$ in going from the 1,2-*trans*-diisopropyl derivative **24** to the *cis*-triaziridine **25** is consistent with a second hyperconjugative lone-pair effect from the inverted N-2 atom. The N,H coupling constant may thus provide a structural criterion for the still unknown all-*cis*-triaziridine, for which in the absence of any lone-pair effect a $^1J(N,H)$ value of approximately 45 Hz would be expected. These effects are in line with similar observations in N–C–H systems where a *syn*-orientation of the lone pair and the C–H bond leads to an increase of $^1J(C,H)$, e.g., in 1-methylaziridine[125a] and in peptides.[125b]

Scheme 19. The coupling constants $^1J(N,H)$ [Hz] are given below the formulas (in $CDCl_3$).

The existence of short-lived free radical intermediates in chemical reactions can be demonstrated by ^{15}N-CIDNP (*c*hemially *i*nduced *d*ynamic *n*uclear *p*olarization) effects in the stable products if radical pairs are involved.[126] This technique provided the first direct experimental proof for the formation of aromatic radical cations in the nitration of *N,N*-dimethylaniline with $H^{15}NO_3$ in 88% aqueous H_2SO_4[127] (Scheme 20). The radical cations are believed to originate in a reaction catalyzed by HNO_2.[128] As shown in Figure 26, polarization is only present in the *p*-nitro product (time-dependent negative signals), whereas the *m*-nitro product gives an absorption signal that steadily increases with time, since this product is not formed in the catalyzed reaction.



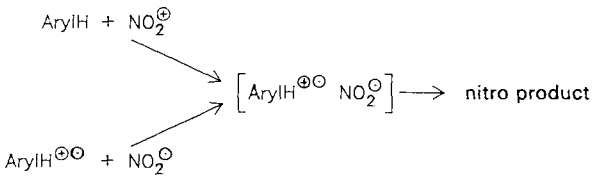


Fig. 26. ^{15}N-NMR spectra (25 °C; $H^{15}NO_3$ (0.53 M) in aqueous H_2SO_4 (88%)) as a function of time for the nitration of dimethylaniline (0.55 M): a) after 3 min; b) after 12 min; c) after 55 min; A = *p*-$O_2{}^{15}N$-C_6H_4-$N(CH_3)_2$, B = *m*-$O_2{}^{15}N$-C_6H_4-$N(CH_3)_2$ [127a].

The same authors have reported CIDNP effects in the ^{15}N-NMR spectra recorded during the acid-catalyzed rearrangement of *N*-nitroanilines to *p*-nitroanilines; their results support the intermediate formation of [ArylNH$_2^{\oplus\ominus}$NO$_2^{\ominus}$] radical pairs.[129] Because of the negative magnetic moment of the ^{15}N nucleus, a negative sign has to be inserted into Kaptein's formulas for the calculation of the sign of net polarization.[130]

Scheme 20.

^{15}N-CIDNP spectra have also been recorded during nucleophilic substitution of arenediazonium ions and indicate that the process is at least partially homolytic.[131] The ^{15}N-NMR spectrum of ^{15}N-labeled 4-chlorobenzenediazonium tetrafluoroborate subjected to decomposition in weakly alkaline aqueous solution (Fig. 27) clearly exhibits enhanced absorption and emission signals for diazonium

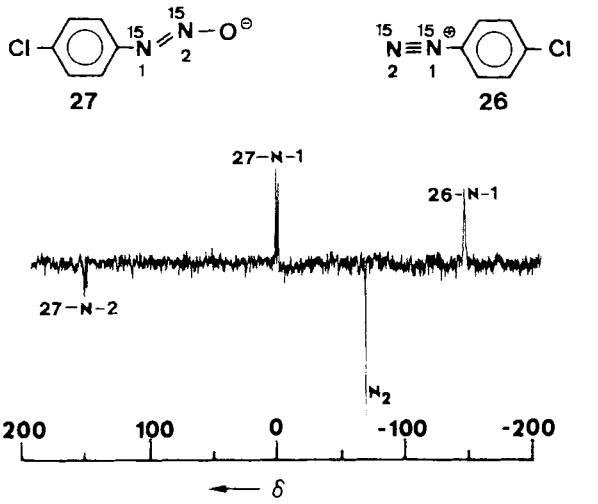

Fig. 27. ^{15}N-NMR spectrum of [1,2-^{15}N$_2$]-*p*-chlorobenzenediazonium tetrafluoroborate (9.1 MHz; 72°C, H_2O, pH 9.7) [131]. The signal for N-2 of **26** is not observed. ^1J(N,N) in **26** is <1 Hz (not resolved), whereas a value of 14.7 ± 0.5 Hz is obtained for **27**.

ion **26**, the *trans*-diazotate ion **27**, and molecular nitrogen. In a detailed interpretation, the authors conclude that the two radical pairs

[ArylN$_2^{\oplus\ominus}$ON$_2$Aryl] and [Aryl$^{\ominus\ominus}$ON$_2$Aryl]

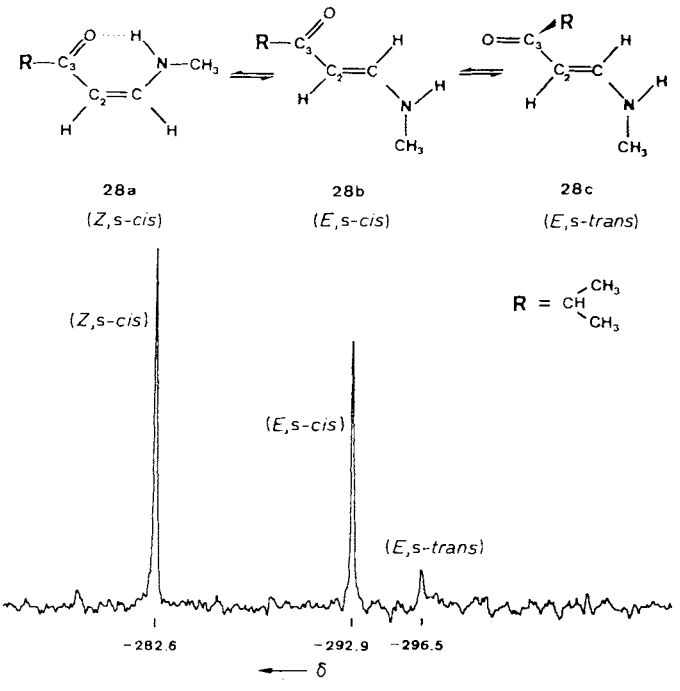
are formed in a very complex reaction sequence. However, other radical pairs cannot be excluded and, most importantly, the experiments "do not allow determination of the extent to which the homolytic pathway contributes to the total reaction." The last statement describes one of the major limitations of the significance of CIDNP experiments for quantitative mechanistic studies.

Several other applications of ^{15}N-NMR spectroscopy to reaction mechanisms have been published, e.g., detailed investigations of the Fischer indole synthesis,[132] the rearrangement of 1,3-oxazine-2,4-diones into pyrimidines and pyrazoles,[133] and the mechanism of formation of *N*-nitrosothiourea.[134]

4.3. Stereochemistry and Dynamic Processes

Variable temperature ^{1}H- and ^{13}C-NMR studies have proven very useful in investigations of intra- and intermolecular dynamic phenomena. Measurements of ^{15}N-DNMR parameters are still hampered by the low sensitivity of the ^{15}N nucleus. However, it can be anticipated that the experimental improvements discussed in Section 2 will surmount this difficulty. Furthermore, lowering of the temperature results in a more effective spin-lattice relaxation, at least for small molecules and in magnetic fields of moderate strength.

The high sensitivity of the ^{15}N chemical shift to delocalization of the lone-pair electrons makes it a useful configurational and conformational probe for conjugated molecules. Thus, different chemical shifts were observed for the (*E*) and (*Z*) isomers of enamino ketones, esters, and amides; moreover, different conformers could be detected in the slow exchange limit.[13, 104]



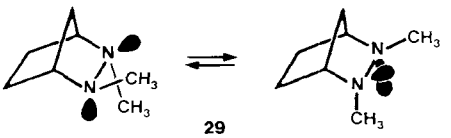


Fig. 28. INEPT ^{15}N-NMR spectrum of 4-methyl-1-(methylamino)-1-penten-3-one **28** (20.3 MHz; -65°C; [D$_8$]dioxane) [104].

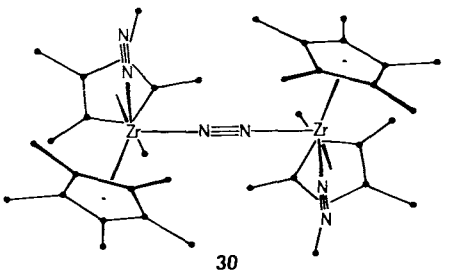
For example, the low-temperature spectrum of the enamino ketone **28** (Fig. 28) exhibits signals that can be assigned to s-*cis* and s-*trans* conformers on account of restricted rotation around the C(2)–C(3) bond.[104] Whereas the high-frequency signal ($\delta = -282.6$, hydrogen bonded

(*Z*,s-*cis*) isomer **28a**) remains narrow over the entire temperature range from +24 to −60°C, the two other lines exhibit dynamic behavior and, at −60°C, show the equilibrium **28b** ⇌ **28c** in the slow-exchange limit. The weak, low-frequency signal ($\delta = -296.5$) increases in intensity with decreasing size of the *C*-alkyl group and is therefore assigned to the nonplanar (*E*,s-*trans*) conformer **28c**. The higher shielding of the N atom in **28c** (−2.6 to −4.7 ppm relative to the N atom in the (*E*,s-*cis*) conformer **28b**) is in agreement with expectations based on the paramagnetic shielding term, $\sigma^P \approx -(\Delta E)^{-1}\langle r^{-3}\rangle_{2p}\sum Q$, since inhibition of conjugation in nonplanar **28c** is expected to result in a larger ΔE value (see also Fig. 14).

It should be noted that the dependence of the chemical shift differences on solvent and temperature requires careful consideration before small chemical shift effects can be interpreted.

Nomura and *Takeuchi*[135] observed slow double inversion at two N atoms in bicyclic hydrazines by low-temperature ^{15}N-NMR spectroscopy. At −45°C, the chemical shift difference of the two diastereotopic N atoms in **29** is 1.08 ppm (10.9 Hz at 10.1 MHz) and ΔG_c^{+} ($T_c = 269 \pm 1$ K) was determined to be 58.4 kJ mol^{-1}, a value that agrees well with the data obtained from ^{1}H- and ^{13}C-NMR measurements (55.2 kJ mol^{-1}) (Scheme 21). Further conformational studies on piperidine[136] and tetraazadecalins[137] as well as on restricted C–N bond rotation in the guanidino moiety of L-arginine[138] have also been reported.

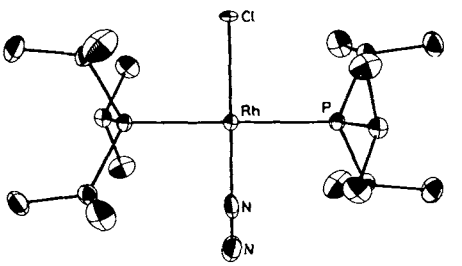
Scheme 21.



Although stereochemical applications of ^{15}N-DNMR studies are still scarce, the above-mentioned examples show that the considerable sensitivity of the ^{15}N nucleus to subtle stereochemical effects constitutes a promising basis for further investigations, particularly in biochemistry.

In this context, the ^{15}N-NMR spectroscopic investigations on chiral substances reported by *Roberts* et al.[139] are worth mentioning. The diastereotopic splittings in the ^{15}N-NMR spectrum of racemic 8-benzyl-5,6,7,8-tetrahydroquinoline in the presence of optically active carboxylic acids were found to be 3–12 Hz at 18.25 MHz and were strongly medium dependent, larger differential shifts being associated with less polar solvents and lower temperatures.

4.4. Coordination Chemistry



Although the number of significant structural applications of ^{15}N-NMR spectroscopy is much smaller in organometallic and inorganic chemistry then in organic chemistry, there are a few nitrogen-containing ligands that have been studied extensively with respect to metal binding, e.g., NO, CN and, most important, N_2. Whereas the differences in chemical shift due to coordination are relatively small (a few tens of ppm) for the majority of nitrogen ligands,[4] a wide range of shifts has been observed for N_2 and NO groups. In addition, the known ^{15}N chemical shifts for organic compounds are extended toward higher resonance frequencies (Fig. 13). Unsaturated ligands with direct metal–nitrogen bonds are observed between $\delta = 0$ and 900; additional deshielding effects are observed in paramagnetic molecules. Moreover, the coupling constants for ^{15}N nuclei directly bonded to metals may vary between a few and several hundred Hz. From a study of these parameters, information about the mode of coordination and the geometry of the complexed ligand can be obtained. The literature of this field up to 1980 is covered in a review by *Mason*.[4a]

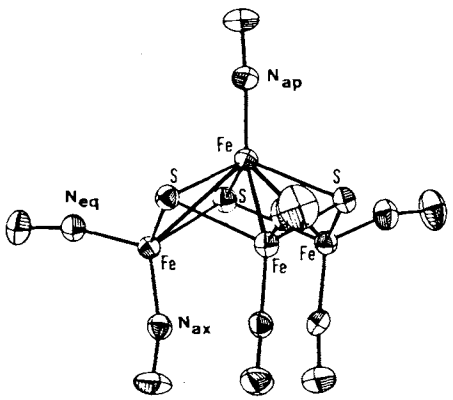
The fundamental biochemical problem of nitrogen fixation and reduction has stimulated the study of dinitrogen complexes of various transition metals, and ^{15}N-NMR spectroscopy has proven a powerful tool in their structural investigation.[140] Dinitrogen was found to coordinate either in a linear *dihapto* (M–N–N–M) or in a *monohapto* (M–N–N) fashion. The structure of the first complex containing both types of dinitrogen ligands, **30**, was established by X-ray diffraction analysis[141] (Scheme 22). The

Scheme 22. [{[η^5-$C_5(CH_3)_5$]$_2$ZrN$_2$}$_2$N$_2$] **30**.

^{15}N-NMR spectrum of the fully labeled compound exhibits a singlet at $\delta = 179$ for the 1,2-η^2-bonded N_2 (μ-N_2) and doublets at $\delta = 80$ and $\delta = 11$ ($^1J(N,N) = 6.2$ Hz) for the η^1-bonded N_2. The latter signals are temperature-dependent indicating dissociative exchange between bound N_2 and free, dissolved N_2.[78] The ^{15}N chemical shifts of 1,2-η^2-N_2 complexes extend from $\delta = 300$ to 50, whereas the η^1-bound N_2 is more shielded ($\delta = 200$ to -100) with the N_α atom resonating at lower frequencies.[140a] The ^{15}N,M coupling constants provide another important criterion for the differentiation of the two binding modes of N_2, as shown in the *trans*-chloro(dinitrogen)bis(triisopropylphosphane)rhodium complex **31** ($^1J(Rh,N(1)) = 28$ Hz, $^2J(Rh,N(2)) = 4$ Hz)[142] (Scheme 23).

Scheme 23. **31**

Reduction of coordinated dinitrogen leads to the diazenido complexes M–N=N–R, which can exist in a singly bent or doubly bent configuration (Scheme 24). The transoid form is characterized by a strongly deshielded N_α nucleus ($\delta \approx 300$), which allows a differentiation from the singly bent isomer[143] (cf. Fig. 13). Further reduction products, e.g., hydrazido, nitrido, and imido complexes, have also been characterized by ^{15}N-NMR data.[140,143]



Scheme 24. Left: singly bent; right: doubly bent.

The stereochemistry of nitroso complexes was also successfully studied by means of ^{15}N chemical shifts.[144] As in the case of the M–N=N–R system, bending leads to strong deshielding effects on the ^{15}N(O) signal, and available data allow a correlation between M–N–O bond angle and ^{15}N chemical shift. Linear nitrosyl complexes exhibit shielding values of $\delta = 0 \pm 80$ and strongly bent complexes (120°) $\delta = 350$–800; intermediate cases are also known. Since the strong deshielding parallels a bathochromic shift of the UV/VIS absorption maximum, the effect can be ascribed to a lower $n \rightarrow \pi^*$ excitation energy, which results in an increase in the paramagnetic shielding term. For nitroso complexes of cobalt(III) this is also reflected in decreased shielding of the ^{59}Co nucleus.[145]

^{15}N chemical shifts of nitroso ligands were used in the structure determination of the Roussin cluster anions, **32** and **33**[146] (Scheme 25). The presence of three resonances in the spectrum of ^{15}N-enriched (99%) **32** (Fig. 29), two of which are mutually coupled, suggests a threefold symmetry axis and the presence of $Fe(NO)_2$ and Fe(NO) subunits in the cluster molecule. The ^{15}N chemical shifts of the nitroso ligands in **32** and **33** are typical for linear Fe–N=O groups ($Fe(NO)_{eq}(NO)_{ax}$: $\delta = 30$–80; $Fe(NO)_{ap}$: $\delta = 7$–20).

Spin coupling of ^{15}N nuclei to complexed metal nuclei depends on the gyromagnetic ratio of the metal and is very sensitive to the bonding orbitals involved. An interesting

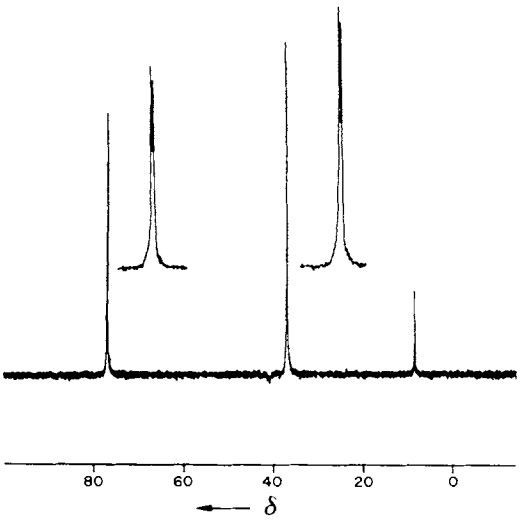
$[Fe_4S_3(NO)_7]^{\ominus}$ **32**
$[Fe_4Se_3(NO)_7]^{\ominus}$ **33**

Scheme 25.



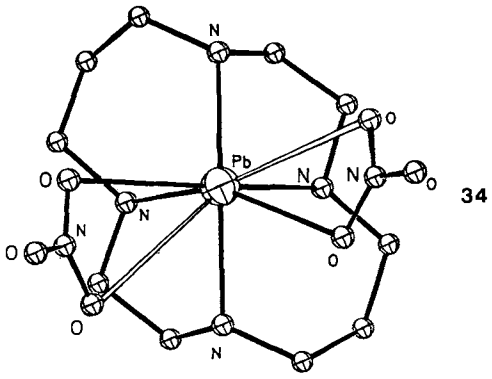


Fig. 29. ^{15}N-NMR spectrum (36.5 MHz) of the NO groups in $[(C_6H_5)_3PNP(C_6H_5)_3]^{\oplus}[Fe_4S_3(^{15}NO)_7]^{\ominus}$, a salt of the anion **32**; the equatorial and axial NO groups show a ^2J(N,N) coupling of 4.3 Hz [146].

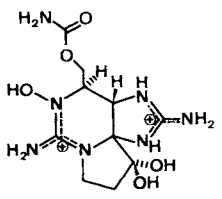
example is provided by the lead(II) nitrate complex of 1,4,8,11-tetraazacyclotetradecane, **34**, which forms a distorted octahedral structure (Scheme 26) with strikingly different ^{207}Pb,^{15}N coupling constants (207.5 and 19.8 Hz) for the two ^{15}N resonances at $\delta = -318.8$ and $\delta = -325.5$, respectively, at the low-frequency end of the ^{15}N-NMR shift scale. Since the lengths of the equatorial and axial Pb–N bonds (2.45 ± 0.02 and 2.50 ± 0.08 Å, respectively) are not appreciably different, the large difference in ^1J(Pb,N) is ascribed to differing contributions of the Fermi contact term as a consequence of the axially distorted octahedral geometry. Hence, the assignment of 207.5 Hz to equatorial N-donor ligands (normal octahedral bonds) and 19.8 Hz to axial N-donor ligands (distorted octahedral bonds) was suggested.[147] Such differences in ^1J(M,^{15}N) values were also reported for related Cd^{II}, Hg^{II}, and Pb^{II} complexes.[148]

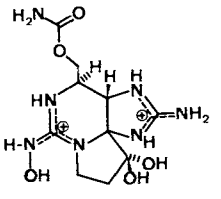
34

Scheme 26.



In favorable circumstances, i.e., very short electron spin relaxation times, ^{15}N resonances may even be observed in paramagnetic metal complexes, e.g., $^{15}N{\equiv}C^{\ominus}$ ligands in low-spin iron(III) cyanide complexes of porphyrin derivatives and hemoproteins. A further extension of the ^{15}N chemical shift range to higher frequencies is found for the $NC^{\ominus}$ resonance, $\delta = 450$ to 1100.[149] In low-spin iron(III)

tetraphenylporphin complexes extremely short T_1 and T_2 relaxation times (0.2–3.0 ms) were reported for the pyrrole N atoms.[150]



4.5. Biochemical Applications

The potential of ^{15}N-NMR spectroscopy for the study of biologically relevant molecules and molecular systems has been the major driving force for the rapid development of experimental techniques and for a steady improvement of ^{15}N-NMR sensitivity. The last few years, in particular, have seen a significant increase in biological ^{15}N-NMR studies. A recent review by *Blomberg* and *Rüterjans*[151] covers detection techniques, spectral parameters, and typical applications in the major biological fields. Further, *Kanamori* and *Roberts*[152] reported specific applications with particular emphasis on enzyme systems, nucleotides and nucleic acids, and intact cell systems. Intermolecular interactions in biomolecules were reviewed by *Kyogoku*,[153] and *Coxon* reported on ^{15}N-NMR studies of amino sugars.[154] Although not primarily biological in nature, a comprehensive account of the ^{15}N-NMR spectroscopic characterization of oligo- and polypeptides by *Krichel-dorf*[155] should be mentioned in this context. Very few studies of nonbiological polymers have so far been reported.[156]

We will focus our attention on a few examples from the recent literature in order to illustrate the possibilities and trends of ^{15}N-NMR spectroscopy in the study of biological systems. Studies of biosynthesis and metabolism are one field in which isotopic labeling combined with ^{15}N-NMR measurements allows detailed studies, which afford new insights into biochemical mechanisms. *Hori* and *Shimizu*[157] have investigated the structures of two related neurotoxins using biosynthetically enriched material. They succeeded in demonstrating that neosaxitoxin **35** is the N^1-hydroxy derivative of saxitoxin (Scheme 27). The ^{15}N-NMR spectrum (Fig. 30) of an ^{15}N-enriched (99%) toxin allows the identification and assignment of the seven N atoms, based on chemical shifts and N,H coupling constants, and the elimination of the alternative structure **36**. The correct assignment of the ^{15}N-NMR signals of complex molecules is an important prerequisite for biosynthetic studies. ^{15}N,^{13}C double labeling allows ^{15}N,^{13}C coupling constants to be measured, thus providing evidence for biosynthetic routes; for example, the biosynthetic formation of the N–C(5) bond in isopenicillin N (which is formed by cyclization of δ-(α-L-aminoadipoyl)-L-[3-^{13}C]cysteinyl-D-[^{15}N]valine) is demonstrated by the one-bond ^{15}N, ^{13}C coupling constant (4.4 Hz).[158]

35

36

Scheme 27.

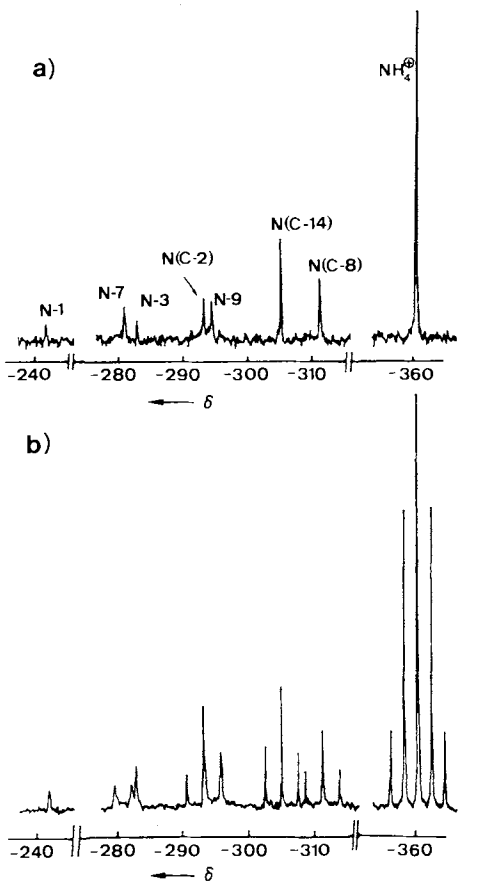


Fig. 30. ^{15}N-NMR spectra of 99% ^{15}N-enriched neosaxitoxin **35** (36.5 MHz; 1.8 mM in H_2O/D_2O 95:5): a) ^{1}H-decoupled; b) ^{1}H-coupled [157].

The in vivo study of amino acid biosynthesis in fungal and bacterial cells has proven a particularly successful domain for ^{15}N-NMR spectroscopy. In 1975 we observed that fast motion of *intra*cellular small molecules permits the measurement of narrow-line spectra in living cells of *Ustilago sphaerogena*.[159] Subsequently, the research groups of *Roberts*[160] and *Lapidot*[161] investigated the biosynthesis of amino acids in *Neurospora crassa* and *Brevibacterium lactofermentum*. The latter organism was used to monitor both nitrogen assimilation from $^{15}NH_4Cl$ and amino acid production throughout the growth cycle.[161] Under optimal growth conditions, i.e., high aeration and low biotin concentration, the glutamic-acid-producing bacteria convert about 50% of the ammonium salt into L-[^{15}N]glutamic acid. Spectra were recorded of intact cells and cell media at different stages of growth and production (Fig. 31). All ^{15}N-NMR signals can be clearly assigned to amino acids and metabolites, although a quantitative evaluation is hampered by different nuclear Overhauser effects and spin–lattice relaxation times. However, a semiquantitative comparison of the respective peaks in spectra recorded at various times in the growth cycle is possible. Two phases were distinguished during the fermentation process. At a very early stage (Fig. 31b) glutamic acid is accumulated in the cells, but practically no product is released into the growth medium. Later, the cell walls become permeable

and amino acids are excreted (Fig. 31a). The alanine/glutamic acid intracellular ratio depends on oxygen and biotin concentration; low oxygen supply leads to a release of alanine instead of glutamic acid. This sensitive and convenient ^{15}N-NMR technique has thus proven a powerful probe for monitoring both *intra-* and *inter*cellular amino acid concentrations in fermentation processes, and it may become an important analytical tool in biotechnology. Furthermore, the metabolic pathways of the intracellular amino acid pool can be followed and elucidated. A number of other studies on the metabolism of important biological precursor molecules have appeared recently.[162] The mobility and environment of intracellular glutamine, alanine, and arginine were studied using ^{15}N spin-lattice relaxation times T_1, and nuclear Overhauser effects.[163]

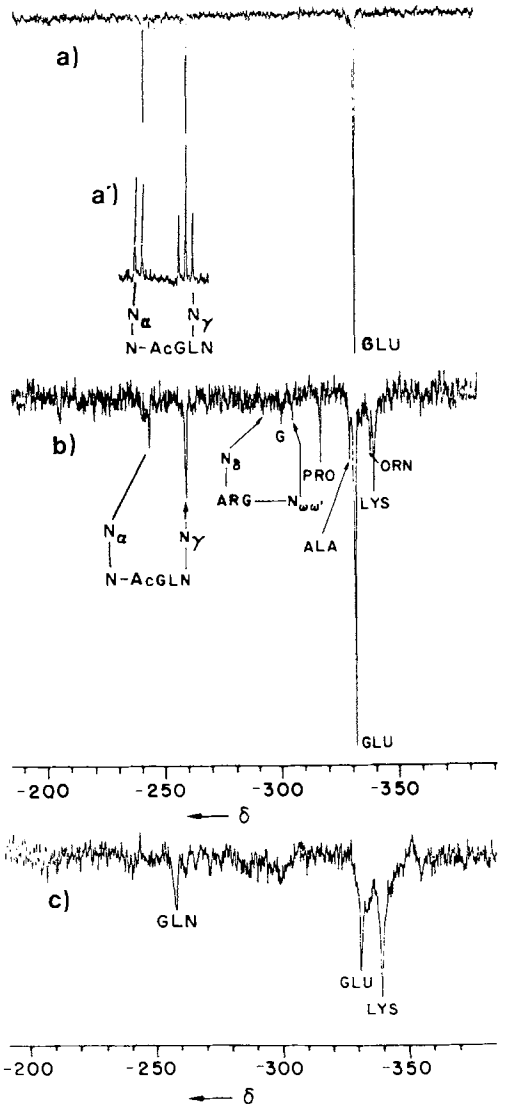

Fig. 31. Proton-decoupled ^{15}N-NMR spectra of 96.7% ^{15}N-enriched *B. lactofermentum* cells grown under conditions of high oxygen supply in normal biotin concentration (30.4 MHz). a) Spectrum of cell-free culture medium obtained after 31 h of fermentation; a') shows a spectrum from the same sample with gated ^{1}H-decoupling; b) spectrum of growth-phase cells (obtained after 10 h of fermentation); c) spectrum of early stationary phase cells (obtained after 16 h of fermentation) [161].

An important parameter characterizing the intracellular medium, the pH, can be determined from ^{15}N-NMR measurements. For example, the two ring atoms of histidine show substantial chemical shift changes between pH 4 and 8; this was used successfully to estimate the pH in the cytoplasmic and vacuolar environment of intact mycelia of *Neurospora crassa*.[164] In addition, pH-dependent line widths for the ^{15}N-NMR signals of the terminal NH_2 groups of arginine and the α-NH_2 group of alanine were used. Measurements on arginine and histidine yielded a pH value of 6.1 ± 0.4 for the vacuoles; the cytoplasmic pH determined by measurements on proline and alanine, on the other hand, was 7.2, in good agreement with other measurements.

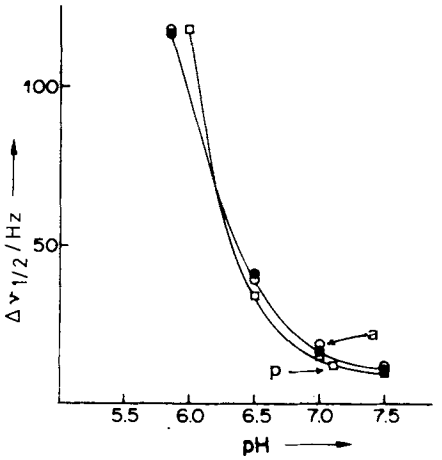

Fig. 32. Plots of the line width at half-height, $\Delta\nu_{1/2}$, of the ^{15}N-NMR signal versus pH for alanine in nitrogen-free medium: (●) 0.01 M, (○) 0.04 M, and (□) 0.005 M proline [164]. a = alanine, p = proline.

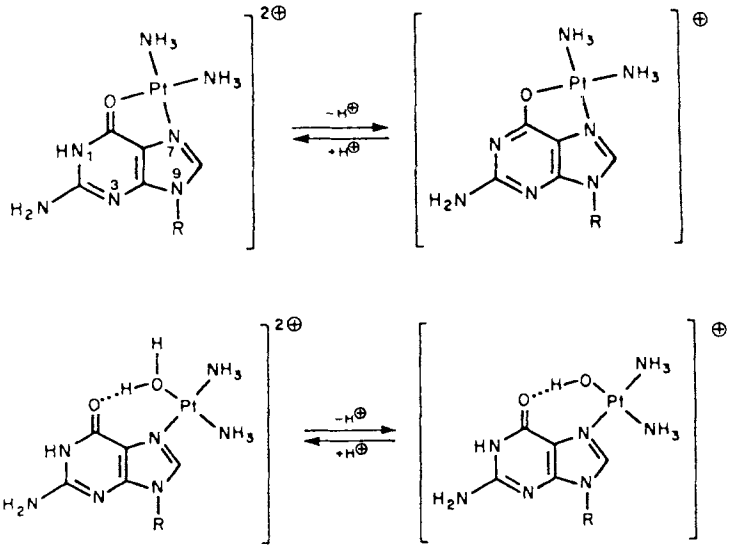
The pH dependence of the ^{15}N-NMR line widths for proline and alanine is due to base-catalyzed proton exchange between the NH_2 group and H_2O (see Fig. 32). ^{15}N-NMR experiments appear to offer definite advantages over other techniques, such as ^{31}P-NMR spectroscopy, since amino acids are regiospecifically distributed in subcellular units and their structure-dependent NMR parameters are more sensitive to pH changes in the weakly acidic region.



As a last example, we will discuss some ^{15}N-NMR studies on the binding of drugs to biomolecules, in particular, to proteins and nucleic acids. The antitumor activity of certain platinum(II)-amine complexes has stimulated the investigation of model systems for the presumed DNA complex.[165] Binding of ^{15}N-enriched *cis*-$[Pt(NH_3)_2Cl_2]$ to a nucleoside results in changes in the chemical shifts and (^{15}N,^{195}Pt) coupling constants in the ^{15}N-NMR spectrum. Interpretation of these spectra is facilitated by the large low-frequency shifts of the resonances for the azine nitrogen atoms (–N=, N-3) upon coordination (Table 5). Pt complexes containing one or two nucleoside ligands are formed. As expected, cytidine is complexed at N-3, whereas for guanosine, which has several possible sites of coordination, a mixture of mono-complexes is formed. Exchange of both chloride ligands affords a complex for which the structures in Scheme 28 were proposed in order

Table 5. ^{15}N chemical shifts δ of free nucleosides and of platinum-nucleoside complexes [165] [a].

	N-1	N-3	N-7	N-9	NH_2
cytidine 5'-phosphate	−227.9	−179.6			−287.6
cis-$[Pt(NH_3)_2(Cyd)_2]^{2\oplus}$	−228.0	−255.4			−276.8
guanosine 5'-phosphate	−233.5	−215.7	−145.6	−211.6	−307.9
cis-$[Pt(NH_3)_2(Guo)_2]^{2\oplus}$	−232.5	−215.8	−237.9	−207.1	−304.7

to explain the pH dependence of the resonance of the NH_3 ligand *trans* to the oxygen ligand. The low pK_a value of 4.9 for the acidic group suggests the incorporation of a water molecule in the complex rather than deprotonation of the amide function. The most complex coordination behavior was observed for adenosine and involves all four basic N atoms (N-1, N-3, N-7, and 6'-NH_2). A few relevant studies on ^{15}N-^{195}Pt interactions have also been reported[166] (see also references cited in ref. [165]).

Scheme 28.

The binding of small molecules to large biomolecules does not necessarily lead to broad resonance lines, as might be expected from the long correlation times of these macromolecules. An example of the application of ^{15}N-NMR spectroscopy to enzyme systems was provided by *Becker* and *Roberts* in their detailed investigation of a ternary inhibitor complex, liver alcohol dehydrogenase-NAD^+-pyrazole.[167] The ^{15}N-NMR spectrum obtained at 18.25 MHz (4.2 tesla) (Fig. 33) demonstrates the nonequivalence of N-1 and N-2 in the bound [1,2-$^{15}N_2$]pyrazole. The chemical shift of N-1 ($\delta = -146.5$) is relatively close to the corresponding resonance of the adduct between pyrazole and N-benzylnicotinamide ($\delta = -140.7$), whereas that of N-2 in the enzyme complex ($\delta = -122.2$) is shifted by 41.1 ppm to lower frequencies relative to the model compound. These results were interpreted in terms of covalent bonding between N-1 of pyrazole and C-4 of the nicotinamide group and coordination of N-2 by the Zn atom at the active site of the enzyme, in agreement with a structural model proposed by *Theorell* and *Yonetani* and with X-ray crystallographic studies (see ref. [167]).

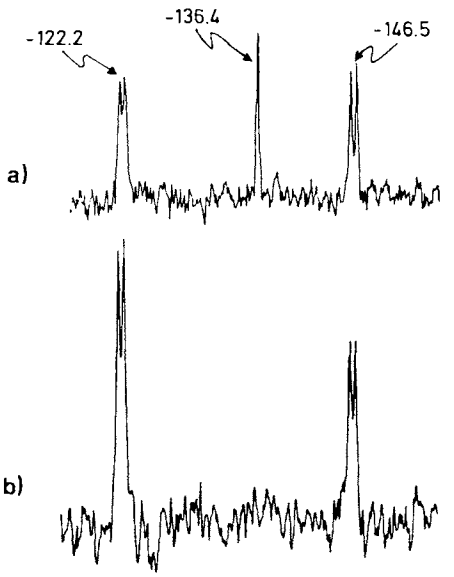

Fig. 33. ^{15}N-NMR spectra of the dehydrogenase-$NAD^{\oplus}$-pyrazole complex (18.25 MHz, prepared from 99% $^{15}N_2$-labeled pyrazole; 0.1 M sodium phosphate buffer; pH 7.0): a) before dialysis; b) after dialysis [167]. The signals at $\delta = -122.2$, -136.4, and -146.5 are assigned to N-2 of bound pyrazole, free pyrazole, and N-1 of bound pyrazole, respectively.

The formation of an enzyme-inhibitor complex is also responsible for the pharmacological activity of the dihydrofolate reductase (DHFR) inhibitors. Typical inhibitors are trimethoprim (2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine, TMP) and methotrexate (MTX), the latter of which has a modified folic acid structure. The binding mode of TMP and MTX to DHFR has been the subject of extensive investigations by several interdisciplinary research groups.[168] The ternary complex between *Lactobacillus casei* DHFR, trimethoprim, and $NADP^+$ exists in solution as a mixture of approximately equal amounts of two slowly interconverting conformational states, which have been characterized by multinuclear NMR experiments. The ^{15}N-NMR spectrum[168] of a triply ^{15}N-labeled TMP in its ternary complex with DHFR and $NADP^+$ is shown in Figure 34. Comparison of this spectrum with the spectra of the binary DHFR-TMP complex and with the free protonated trimethoprim confirms the presence of two species in aqueous solution. The chemical shifts of the N-1 and 2-NH_2 ^{15}N resonances in the inhibitor complex are typical for protonated trimethoprim, which had been studied earlier by our group.[39] In another study, binding of human carbonic anhydrase B with benzenesulfonamide and cya-

nate ion, typical inhibitors, was investigated by ^{15}N-NMR spectroscopy.[169a] Recently, ^{15}N-NMR spectroscopy has also been used to study whole enzyme systems, e.g., in the study of the flavin-apoenzyme interaction.[169b]

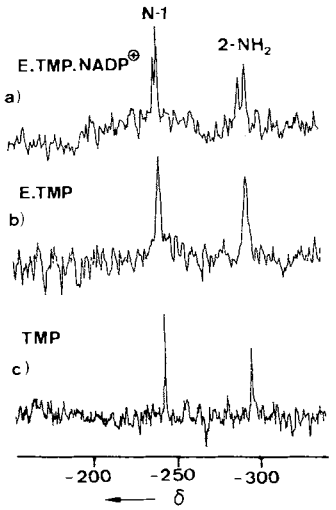

Fig. 34. ^{15}N-NMR spectra of (1,3,N^2-^{15}N$_3$)trimethoprim (TMP) (20.2 MHz): a) TMP in its ternary complex with dihydrofolate reductase (E) and NADP$^⊕$ (INEPT pulse sequence with ^{1}H-decoupling, 90% H_2O/10% D_2O); the signal of N-3 was not reported [168]. b) TMP in its binary complex with dihydrofolate reductase (conditions similar to a)). c) TMP in 0.1 M aqueous HCl.

4.6. High-Resolution ^{15}N-NMR Spectra of Solids

Whereas numerous structural studies have been concerned with ^{15}N-NMR spectroscopy of liquid samples of small, medium sized, and even large biomolecules, there are as yet only a few examples in which the ^{15}N nucleus has been used as a probe into molecular structure of the solid state, and most of these have dealt with biochemical problems. This fact is easily explained. The solid-state ^{13}C- and ^{1}H-NMR spectra of biomolecules are often difficult to interpret on account of the large number of nonequivalent ^{1}H and ^{13}C atoms. In contrast, nitrogen nuclei are favorable for solid-state NMR studies of biomolecules and biological systems since there are relatively few nonequivalent N atoms and the chemical shift differences are usually large. Thus, resolution problems are less severe. Sensitivity problems can be overcome by using selective ^{15}N isotopic enrichment and very effective cross-polarization experiments (polarization transfer from protons). The distances between N atoms in biomolecules guarantee that even with very high isotopic enrichment no problems due to homonuclear spin coupling arise. The inherent difficulties with NMR studies of solids have been successfully overcome by a combination of high-frequency magic angle spinning (MAS) to remove chemical shift anisotropy, broadband proton-decoupling to eliminate dipolar and scalar coupling, and cross polarization (CP) for sensitivity enhancement. These methods[170, 171, 27] and their chemical applications[172] have been reviewed recently. In addition, a survey of solid-state NMR as applied to biological systems has appeared.[173] Examples of CPMAS experiments on ^{15}N nuclei are given in this review.

Solid-state ^{15}N-NMR spectra have been obtained from single crystals, crystalline and amorphous powders, and whole biological systems, e.g., plant leaves. In all but the single-crystal studies, ^{15}N-enriched samples were used. The natural abundance ^{15}N-NMR single-crystal spectrum of histidine hydrochloride monohydrate is shown in Figure 35; well-resolved lines for the $NH_3^⊕$ groups and the N atoms in the ring can be recognized. Orientation-dependent NMR measurements may then be used to determine the chemical shift tensors.[174] The shift anisotropy, $\Delta\sigma$, was found to be 220 ppm for N-2 and 216 ppm for N-3, while the $NH_3^⊕$ group gave $\Delta\sigma < 12$ ppm. Since much larger $\Delta\sigma$ values were reported for unprotonated pyridine ($\approx$780 ppm),[175] such determinations of ^{15}N-NMR shift tensors can yield valuable information about the degree of protonation in solid biological systems. *Munovitz* et al.[27] have recently shown that chemical shift and dipolar tensors can be measured simultaneously with excellent resolution if the dipolar spin interaction is reintroduced and the spectra are analyzed by 2D NMR methods. The experimental techniques thus allow the study of dipolar interactions between nitrogen sites in solid biomolecules. ^{15}N and ^{13}C chemical shift tensors have been determined for the peptide bond in ^{15}N,^{13}C-labeled glycylglycine hydrochloride;[176] moreover, the authors give a discussion of $\Delta\sigma$(N) values known to date in terms of C–N π-bond order. The ^{15}N shift anisotropy for the peptide bond (155 ppm) reflects its partial double-bond character.

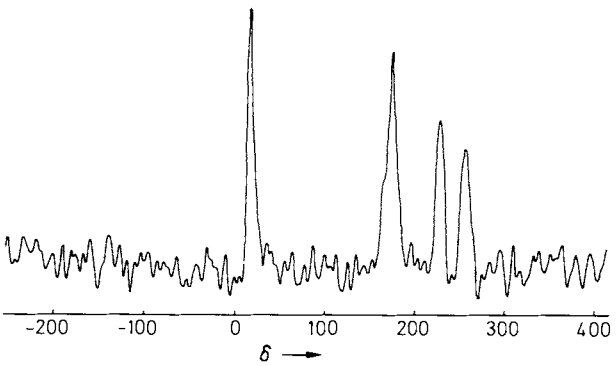

Fig. 35. ^{15}N-NMR spectrum of a single crystal obtained from L-histidine hydrochloride monohydrate. The unit cell *a* axis was approximately along the rotation axis of the NMR goniometer. Chemical shifts are relative to solid $(NH_4)_2SO_4$. The single line on the left is assigned to the $NH_3^⊕$ groups; it is indicative of very small shift tensors. The three lines on the right are due to the imidazole nitrogen atoms [174].

The protonation of and hydrogen bonding to nitrogen atoms is of central importance in many biochemical systems. A solid-state ^{15}N-NMR study of the Schiff base linkage in ε-[^{15}N]lysylbacteriorhodopsin, the only protein in purple membrane, has revealed, from the isotropic chemical shift ($\delta = -204.6$), that the imine N atom is protonated in the dark-adapted form.[177] The doublet structure of the signal (Fig. 36) suggests that the bacteriorhodopsin contains two stereoisomeric forms, which are tentatively assigned to 13-*cis*- and all-*trans*-retinal Schiff bases. The ^{15}N chemical shift of the lysylbacteriorhodopsin ($\delta = -204.6$) is similar to the values for the model all-*trans*-retinylidene-

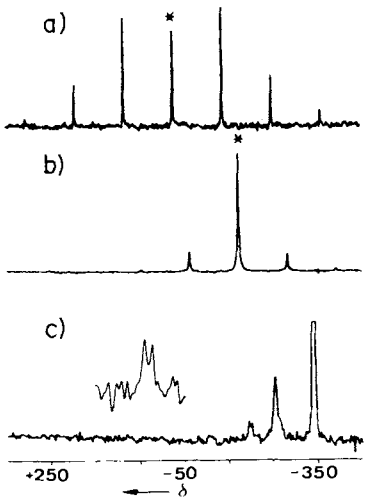

Fig. 36. Proton-decoupled MAS ^{15}N-NMR spectra of a) retinylidenebutyl[^{15}N]amine (^{15}N-RB); b) ^{15}N-RBH$^{\oplus}$Cl$^{\ominus}$; c) ε-[^{15}N]lysylbacteriorhodopsin (29.8 MHz). For clarity the center bands in a) and b) are marked with asterisks. The inset in c) is an expansion of the Schiff base signal showing the doublet structure ($\Delta\delta = 5.7$) tentatively assigned to the 13-*cis* and the all-*trans* stereoisomers. The two remaining lines in c) arise from the peptide backbone *N* atoms ($\delta = -259.3$) and the six lysine $NH_3^{\oplus}$ groups ($\delta = -344.5$). Chemical shifts originally referred to external, aqueous 5.6 M NH_4Cl [177] were recalculated relative to CH_3NO_2; conversion value −352.9 ppm [7a].

butyl[^{15}N]ammoniumchloride ($\delta = -181.2$), whereas the ^{15}N atom of the model base is strongly deshielded ($\delta = -37.6$). The chemical shift of the protonated solid is thus very similar to the one reported for the hydrochloride in solution ($\delta = -147$)[113] (see also section 4.1). Here, too, protonation of nitrogen results in a drastic narrowing of the chemical shift tensor, as shown in the ^{1}H-decoupled ^{15}N-NMR powder spectrum (Fig. 37), from $\Delta\sigma \approx 600$ ppm for the Schiff base to 270 ppm for the hydrochloride.

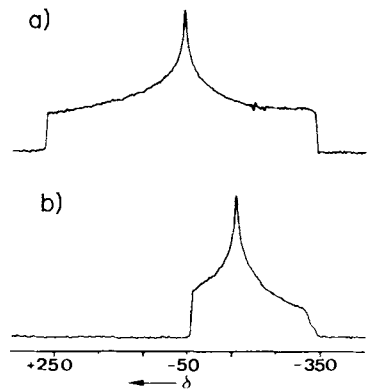

Fig. 37. Proton-decoupled ^{15}N-NMR powder spectra of all-*trans*-retinylidene butyl[^{15}N]amine; a) unprotonated; b) hydrochloride. In a) the powder pattern is ≈600 ppm (18 kHz) wide with an isotropic shift of $\delta = -38$. Protonation narrows the spectrum to a 270 ppm breadth and moves the chemical shift 142 ppm downfield. The chemical shifts were recalculated relative to CH_3NO_2 as standard (see legend to Fig. 36) [177].

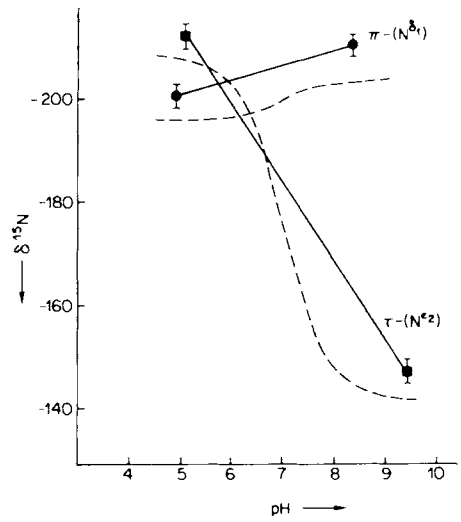
Solid-state NMR studies are particularly attractive since they permit a comparison of enzyme structures in anisotropic and isotropic phase (i.e., in solid and in solution, respectively) using the same physical method, in contrast to the usual comparisons between X-ray diffraction and NMR data. For example, the structure of α-lytic protease was studied by the CPMAS technique; initially, the N^{τ} atom of His^{57} was ^{15}N-labeled, and, in a subsequent experiment, both the N^{π} and N^{τ} atoms were ^{15}N-labeled.[178] The behavior of the ^{15}N chemical shifts as a function of the pH (Fig. 38) of the solution used to prepare the lyophilized samples was found to closely parallel that observed in earlier solution studies,[179a] except for the slower proton exchange at His^{57} in the solid state. The local environment at the His^{57} close to the active site of the enzyme is shown in Scheme 29. The unusual tautomeric form of



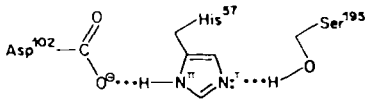


Fig. 38. The pH-dependence of the ^{15}N chemical shifts of the imidazole ring N atoms of histidine-57 in α-lytic protease in solutions (--) [179] and in lyophilized powders (—) [178].

Scheme 29.

histidine with an N^{π}–H bond was originally proposed[179a] and later confirmed[93c] on the basis of ^{15}N-NMR measurements on the enzyme in solution. The specific triad structure involving His^{57} with the closely spaced aspartate^{102} ion on the π-side and the OH group of Ser^{195} on the τ side is responsible for the stabilization of this tautomer. The good agreement between the new solid-state data and the solution results represents convincing structural evidence. A similar study employing ^{15}N-CPMAS and X-ray diffraction data was recently carried out on a carboxypeptidase A complex with glycyltyrosine.[179b]

The reduced proton exchange rates in the solid state allow the identification of protonated N atoms in biomolecules and ^{15}N-DNMR studies of proton transfer. A recent investigation by *Limbach* et al.[180a] on tautomerism in ^{15}N-enriched *meso*-tetra-*p*-tolylporphins **37** has shown that the process can be conveniently studied as a two-site exchange problem in the temperature range from 210 to 295 K. The CPMAS ^{15}N-NMR spectra are shown in Figure 39; a complete line-shape analysis gave first-order rate constants

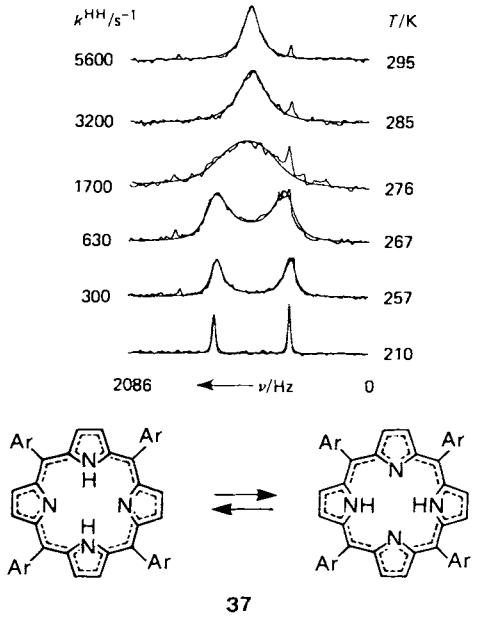

Fig. 39. CPMAS ^{15}N-DNMR spectra of *meso*-tetra-*p*-tolylporphin **37** (Ar = *p*-tolyl; 6.1 MHz; 95% ^{15}N-enriched **37**); experimental and calculated spectra are superimposed. The small sharp low-frequency line is attributed to an impurity [180].

(k^{HH}). Whereas the dynamic behavior of the *p*-tolyl- and phenylporphins was found to be the same in solution, they show very different solid-state spectra as a function of temperature. The complex cases of the arylporphins were also discussed in conjunction with the results from X-ray diffraction studies.[180b]

^{15}N-NMR spectroscopy of solids has also been applied to nucleic acids, e.g., to the study of N–H bond lengths in B-DNA[34] (see also Section 2.3, Fig. 11) and to the study of the DNA backbone structures of fd and Pfl bacteriophages.[181] The latter investigations were supported by 2D NMR analysis of the dipolar splittings in the spectra of oriented virus molecules.[35] From the same research group, several solid-state ^{15}N-NMR studies on proteins were also reported.[181, 182a]

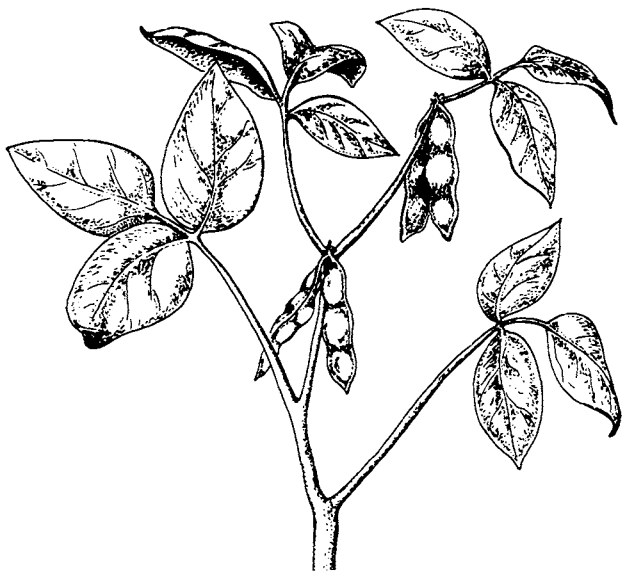

Fig. 40. Shoot of a soybean plant (Glycine soja) [184].

We will close this review by quoting a paper that demonstrates the almost unlimited potential of ^{15}N-NMR spectroscopy in biological studies.[182b] *Schaefer* et al.[183a] recorded the double cross-polarization MAS ^{15}N-NMR spectra of soybean leaves in order to determine the protein turnover number. This plant was also used to investigate the metabolism of allantoin in the early growth state.[183b] Figure 40 shows a soybean shoot as a symbol of the ever-growing applications of NMR spectroscopy to chemistry, biochemistry, and biology. New branches are expected to grow and will call for imaginative investigators.

5. Outlook

During the past few years ^{15}N-NMR spectroscopy has developed as a versatile experimental probe into the structure and reactivity of organic, bioorganic, and inorganic molecules. The majority of studies have been performed without isotopic enrichment of the substrates. Since the sensitivity of the ^{15}N-NMR technique is still improving, its application is expected to increase still further in the future. Modern 1D and 2D NMR experiments will undoubtedly make possible the structural investigations of larger molecules and more complex biomolecules in the liquid and solid states. For example, the heteronuclear "D-resolved" 2D NMR experiments recently described offer a new dimension for the quantitative study of hydrogen bonding in solids. Although many ^{15}N-NMR investigations of active sites in biological systems still require isotopic enrichment, the first successful attempts to study drug binding, i.e., the mechanism of drug action, have shown a considerable pharmacological potential. The fundamental problem of biological nitrogen fixation and metabolism may be investigated in the future by an extended use of ^{15}N-NMR techniques, and other applications may be envisaged. However, the realization of many chemical and biochemical ideas will finally depend on the availability of versatile multinuclear NMR instrumentation and flexible computing facilities. It is this area where the most significant advances can be expected for the near future.

The senior author (W. v. P.) wishes to express his gratitude and indebtedness to his co-workers who have contributed to the results from the Zürich laboratory that are described in this review: Dr. W. Schwotzer, Dr. W. Städeli, Dr. R. Hollenstein, Dr. P. Bigler, Dr. L. Kozerski, Dr. G. Cerioni, Dr. M. Tatò, B. C. Chen, C. Adams, and R. Müller. Their scientific enthusiasm, experimental skill, and endurance have had, and continue to have, a major impact on the research and spirit of our group. Generous financial support from the Government of the Kanton Zürich and the Swiss National Science Foundation is gratefully acknowledged.

Organic Synthesis at High Temperatures. Gas-Phase Flow Thermolysis**

New Synthetic Methods (57)

By Martin Karpf*

The preference for carrying out synthetic organic reactions at the lowest possible temperature is due to the expectation that the selectivity often increases with decreasing temperature, as is confirmed by many examples and also theoretically justified. Selectivity, however, is not the only problem at high temperatures; further factors include the frequently limited thermal stability of the functional groups and structural elements not directly involved in the transformation. In spite of these limitations, the advantages of high temperatures and the greatly improved knowledge of the mechanisms of dynamic gas-phase processes accumulated in recent years can be exploited in directed organic synthesis. In this review the synthetic potential of gas-phase flow thermolysis will be described from the viewpoint of the synthetic chemist with the aid of typical examples of application.

1. Introduction—Pyrolysis, Thermolysis, High Temperatures

The temperature is of decisive importance for the course of a chemical reaction. The majority of organic reactions are carried out between the sublimation point of dry ice (−78.5 °C) and the boiling points of high-boiling solvents (ca. 300 °C). There are two reasons for the lower limit of this range: the solubility of the reactants decreases and the reaction time increases with decreasing temperature. The upper limit, in contrast, is determined by the usually limited thermal stability of starting materials and products. Therefore, investigations outside this range of temperatures are often treated not as an extension of existing areas but rather as independent areas of research in organic chemistry.

Whereas the preparative development of the low-temperature realm, which hitherto has been largely dominated by spectroscopic studies, has made progress only in recent times,[1] high-temperature reactions have a longer tradition, as seen in the designation of the methods and transformations used, e.g., "Brenzreaktionen" (pyrogenic reactions) or *pyrolysis*.[2]

These terms originally meant the physical and chemical separation or decomposition of materials of mostly unknown composition by means of fire and heat. Later, they were extended to include the thermal behavior of well-defined chemical compounds. Thus, in 1929, *Hurd*, in the introduction to his classic work "The Pyrolysis of Carbon Compounds,"[3] described "pyrolysis" as "the transformation of a compound into another substance, or other substances, through the agency of heat alone," specifically including both isomerizations without decomposition and synthetic thermal processes. The expansion of knowledge in the area of mechanistic organic chemistry caused *Hurd*'s definition, which was based on molecular transformations to be supplemented or even replaced by separate, more specific terms of a mechanistic origin. As a consequence of this development, the application of the term "pyrolysis" has been restricted, in particular for nondestructive processes, to the induction of chemical reactions by means of high temperatures. Thus, *Brown*'s 1980 monograph "Pyrolytic Methods in Organic Chemistry"[4] treats organic gas-phase reactions at high temperatures according to mechanistic criteria. However, *Brown* retained the term "pyrolysis" in the broader sense introduced by *Hurd*,[3] in particular as a means to distinguish these reactions from reactions and methods carried out at "normal" temperatures. Without committing himself to a too-narrow distinction between "normal" and "high" temperatures, *Brown*[4] gave the temperature region between about 350 and 900 °C as typical for organic high-temperature reactions.

The use of the term "thermolysis" for purely thermally induced reactions has become more frequent in recent times and has, for example, been proposed by *de Mayo* et al.[5] for dynamic gas-phase processes (see Section 2.2.2). However, this concept is also used, e.g., by *Kametani*,[6] for pericyclic reactions under static conditions in the temperature range of ca. 100 to 300 °C. In contrast, modern textbooks of organic chemistry[7,8] and a well-known reference work[9] use the term "pyrolysis" in its original and narrower meaning, namely, the thermal decomposition of molecules; in this context both preparative and industrially important organic high-temperature processes are treated.

2. High Temperatures in Organic Chemistry

2.1. Analytical Investigations

The characterization of organic materials through analysis of their thermal decomposition products[10] comes close to the original goal of the use of high temperatures. The combination of special pyrolysis techniques (such as Curie point, pulsed, and laser pyrolyses) with modern analytical and spectroscopic procedures (such a gas chromatography,

[**] Part of the *Habilitationsschrift*, M. Karpf, Universität Zürich 1984.

mass and infrared spectroscopy) permits the reproducible, qualitative and quantitative analysis of small amounts of a material. The efficiency of these methods is further increased by the availability of electronic data processing (spectral comparisons, statistical analysis, etc.). In particular, slightly volatile substances may often be examined—e.g., synthetic and natural polymers, geologically and biologically interesting samples, and even microorganisms (in taxonomy studies).

2.2. Preparative Reactions at High Temperatures

Preparative organic reactions at high temperatures[11] can be divided, depending on the techniques used, into static and dynamic processes.

2.2.1. Static Processes

Static processes, i.e., those in which a substrate is heated continuously in the solid phase, in solution, or in the gas phase, have long been used for a large number of classical thermal reactions. For example, eliminations, fragmentations, and rearrangements, including many pericyclic processes, have been carried out under static conditions.[12-22] The transition from normal to high temperatures is, in many cases, necessary because of the low reactivity of the substrates, which cannot always be compensated for by an increase in the reaction time. Since static conditions at not too elevated temperatures are technically easy to accomplish (sealed tubes, autoclaves) and since large quantities can be handled without difficulty, these reactions are suitable not only for mechanistic studies but also for many preparative applications.

2.2.2. Dynamic Processes

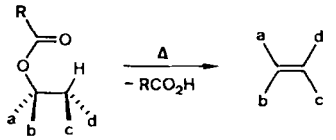
Dynamic processes, i.e., those in which a substrate is transported in its gaseous state through a heated zone, are characterized by a transient thermal excitation of the molecules in the gas phase, followed by rapid cooling of the products formed. Compared to static procedures, higher reaction temperatures are usually employed. This procedure, which was already used by *Berthelot*[23] in 1866 for the conversion of acetylene into benzene and other products, has experienced increasing popularity, especially during the past twenty years. Accordingly, a large number of variants of the method, which are united under the concept of "gas-phase flow thermolysis," are employed. These variants, which have different names, often differ only very slightly from one another.[24] Thus, in important reviews in this area the following expressions are found: "Flash Thermolysis" (*de Mayo*, 1972,[25] translated into German as "Kurzzeit-Thermolyse"); "Flash Vacuum Thermolysis" (FVT) (*Hageman* and *Wiersum*, 1973,[26] *Wiersum*, 1982[27] and 1984[28]); and "Blitzthermolyse" (*Seybold*, 1977[29]). However, in accordance with an earlier suggestion by *Hedaya*,[30] the same method is also described as "Flash Vacuum Pyrolysis" (FVP) (*Hedaya*, 1967[30] and 1963;[31] *Brown*, 1980[4]), "Flow Vacuum Pyrolysis," (*Brown*, 1980[4]), or "Flash Pyrolysis" (*Wentrup*, 1977[32]).

An important advantage of the dynamic over the static method is the possibility, through intense but transient thermal excitation of the starting materials followed by instant cooling of the products to low temperatures, of isolating and identifying by spectroscopic or chemical means even highly reactive thermal primary products. For investigations of this nature, which are usually mechanistically oriented, techniques such as matrix isolation and trapping reactions have proven to be particularly useful. The advantage of working at very low pressures using special techniques such as "Very Low Pressure Pyrolysis" (VLPP) developed by *Benson* et al.[33] is the avoidance of intermolecular secondary reactions in the hot zone. To distinguish the *flow* methods, operating at elevated, normal, or only slightly reduced pressures, from the low-pressure techniques, the latter are often called *flash* methods.

Dynamic conditions are also suitable, however, for the preparation of stable compounds. This is particularly true when product formation is hindered because of activation barriers that cannot be overcome at temperatures attainable in static systems, or when the starting materials or end products cannot withstand the thermal load. In addition, the problem of wall catalysis, which frequently arises in static systems is often less pronounced because of the short reaction times and high temperatures. For synthetic applications, gas-phase flow thermolysis methods also have the advantage that simple, often commercially available apparatus can be used,[34] which usually include an entry part for the substrate, a reactor part, and a cold trap to condense the products. In most cases the reactors consist of electrically heated, empty or packed quartz tubes.[4] Since the synthesis of stable products often permits working at normal or only slightly reduced pressure (flow conditions, see above), preparatively interesting rates of conversion can be achieved without difficulty in such apparatus. Furthermore, the method usually avoids the use of solvents and thus allows continuous operation.

2.3. Technical-Industrial Reactions at High Temperatures

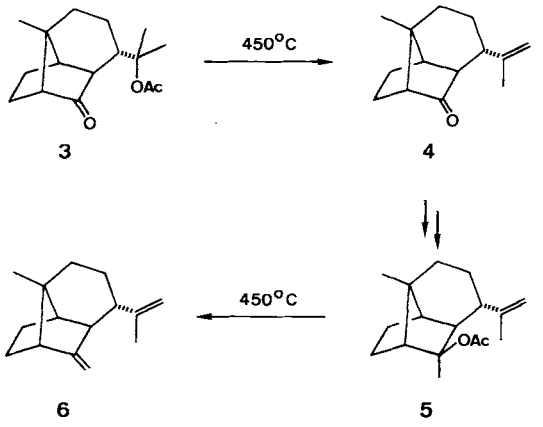
The decomposition of organic compounds at high temperatures forms the basis for many technical-industrial applications.[35-38] For example, the thermal cracking of certain mineral oil fractions is at present one of the most important sources of lower olefins, which are particularly useful as starting materials in the chemical industry. Furthermore, there are also many catalytic processes of industrial significance, such as dehydration, isomerization, oxidation, and reduction. These reactions are preferentially carried out in gas-phase flow systems, which permit a continuous reaction process as well as simple reaction control.



3. Gas-Phase Flow Thermolysis in Organic Synthesis

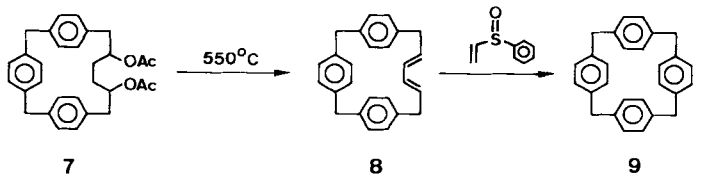
3.1. Eliminations

3.1.1. Ester Pyrolyses



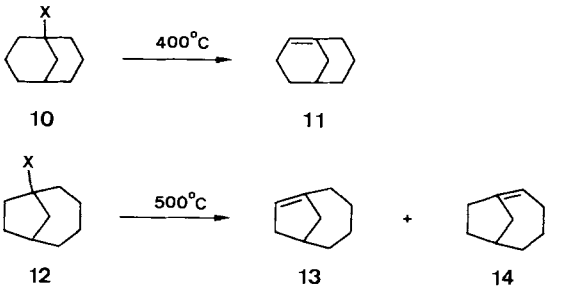
The ester pyrolysis **1** → **2** is the most common of the classical olefin-forming thermal eliminations carried out

under gas-phase flow thermolysis conditions; comparable reactions, such as the thermal decomposition of xanthate esters (Tschugaeff reaction) or amine oxides (Cope reaction), on the other hand, are usually carried out in solution at lower temperatures.[39,40] The pronounced *cis*-selectivity even at high temperatures (ca. 400–600 °C) can be explained by the intramolecular, cyclic transition state of a retro-ene type reaction (see Section 3.2.1). *Barton* et al.,[41] in the course of their classical work aimed at distinguishing between axial and equatorial substituents of cyclohexane rings, used the results of ester pyrolysis reactions as an argument for the assignment of the relative configuration of steroid hydroxyl groups.



1 2

A recent example of a synthetic application of the ester pyrolysis reaction is the synthesis of the tricyclic marine natural product sinularene **6** described by *Collins* and *Wege*,[42] whereby the introduction of the two carbon–carbon double bonds was achieved through acetate pyrolysis in a stream of nitrogen. The first thermal step (**3**→**4**) led preferentially to the less substituted olefin. Only 5% of the tetrasubstituted double-bond isomer of **4** was found in the product mixture.

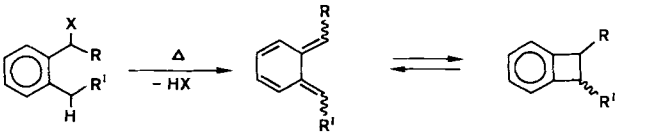


3 4 6 5

Miyahara et al.[43] succeeded in building the fourth aromatic ring in the synthesis of [1.1.1.1]paracyclophane **9** via a Diels–Alder reaction (**8**→**9**). The necessary starting diene **8** was obtained through double acetate pyrolysis of **7** at 550 °C in a yield of 38%.

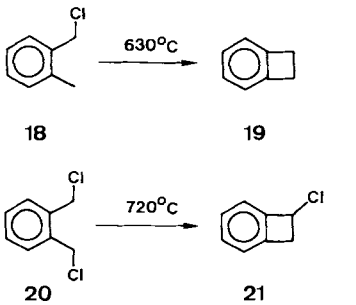
7 8 9

The acetate pyrolysis of **10** or **12** (X = OAc) as described by *Becker* and *Pfluger*[44] makes possible a very simple synthesis of the strained bridgehead olefins **11**, **13**, and **14** (**13** : **14** = 8 : 1). A double-bond shift from the bridgehead position was not observed.



10 11 12 13 14

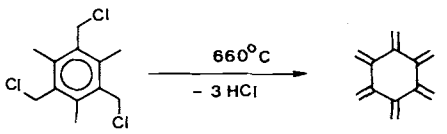
3.1.2. Elimination of Hydrogen Halides



The thermal β-elimination of hydrogen halides from organohalogen compounds usually occurs with low regio- and stereoselectivity and is, therefore, of only minor synthetic use.[45] An exception is the β-elimination of hydrogen chloride from **10** and **12** (X = Cl) (see Section 3.1.1), even at lower temperatures (**10** at 250 °C and **12** at 350 °C), to give the Bredt olefins **11** and **13** or **14**, respectively, in comparable or even better yields than from the corresponding acetates. The thermolysis tube was coated with calcium carbonate to remove the liberated HCl.

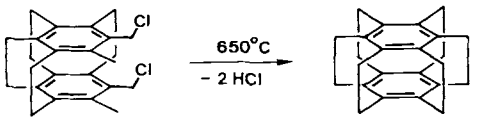
The specific 1,4-elimination of hydrogen halides from *o*-alkylbenzyl halides **15** to form benzocyclobutenes **17** (1,2-dihydrocyclobutabenzene derivatives) via *o*-quinodimethanes **16** has been intensively studied. Benzocyclobutenes are synthetically interesting intermediates since, already at lower temperatures, they are in equilibrium with the *o*-quinodimethane derivatives **16**, which are particularly reactive dienes for intramolecular Diels–Alder reactions.[6,12,15,17]

15 16 17



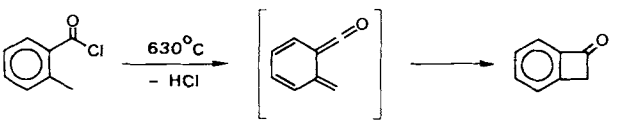
Benzocyclobutene **19** was first obtained by *Maccoll* et al.[46] from 2-methylbenzyl chloride **18** at 630 °C in 70% yield; the chloro derivative **21** was prepared by *Schiess* et al.[47] from the corresponding dichloro compound **20** in a yield of 53%. Grignard reaction allows the transformation of **21** into various benzocyclobutenes in good yields (e.g.,

18 19 20 21



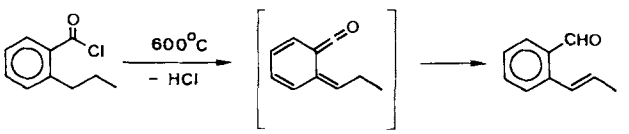
17, R=COOH, R'=H (72%) or R=CHO, R'=H (74%)),[47] which are of interest as synthetic building blocks.

A remarkable application of such 1,4-eliminations, reported by *Schiess* and *Heitzmann*[48] and by *Boekelheide* et al.,[49] is the synthesis of hexaradialene **23** from commercially available **22** by triple hydrogen chloride elimination at 660°C. Although **23** is only stable at low temperatures, the spectroscopic data and chemical behavior demonstrate that this compound exists exclusively in the tris-*o*-quinoid form and that, in spite of the presence of a cyclic 6π-electron system, no specific aromatic character is evident.



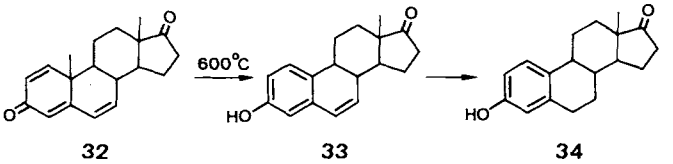
22 **23**

A further and particularly interesting example of this reaction was also reported by *Boekelheide* et al.[50] Double hydrogen chloride elimination from **24** allowed the preparation of the long-sought [2.2.2.2.2.2.](1,2,3,4,5,6)cyclophane **25** ("superphane") in a single step in a yield of 40% (see also Section 3.2.3).

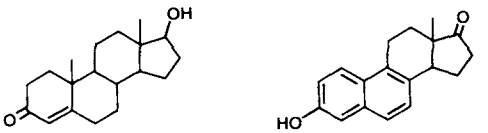


24 **25**

The synthesis of benzocyclobutenone **28** was achieved by hydrogen chloride elimination from 2-methylbenzoyl chloride **26**, whereby the *o*-quinoid ketene **27** was assumed to be the initial product.[51] Further evidence for such intermediates is provided by the thermolysis of 2-propylbenzoyl chloride **29**, which does not lead to the correspondingly substituted benzocyclobutenone. Instead, the assumed intermediate ketene **30** undergoes a [1,5]-hydrogen shift to give the aromatic aldehyde **31**.



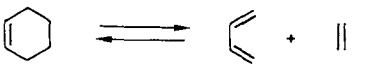
26 **27** **28**



29 **30** **31**

3.1.3. Dealkylations

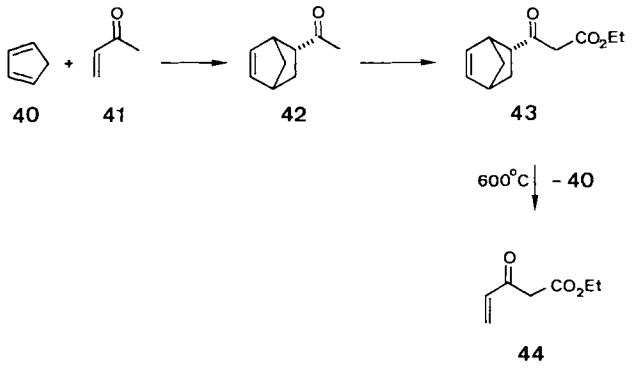
The aromatization of ring A is presumably the driving force for the loss of the C-19 methyl group in steroid-1,4-dien-3-ones upon gas-phase flow thermolysis. This dealkylation, discovered by *Inhoffen*[52] and mechanistically little investigated, has been used by *Djerassi* et al.[53] for the transformation of 1,4,6-androstatriene-3,7-dione **32**, obtained from the male sex hormone testosterone **35**, into 6-dehydroestrone **33**, which in turn was transformed into the female sex hormone estrone **34** by simple hydrogenation. Surprisingly, further aromatization of **33** to equilenine **36** did not take place under the conditions of flow thermolysis, although this transformation could be carried out at much lower temperatures in the condensed phase.



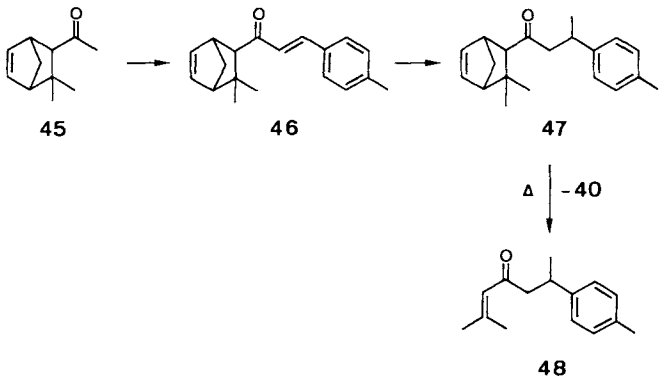
32 **33** **34**

35 **36**

3.1.4. Retro Diels–Alder Reactions

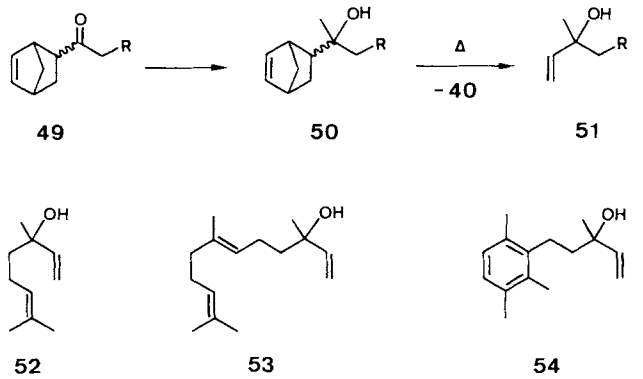


The synthetic value of the Diels–Alder reaction lies in the regio- and stereoselective addition of a diene **38** to a suitable dieneophile **39** to give a cyclohexene derivative **37**.[12-17,19] In contrast, the majority of retro Diels–Alder reactions, **37** → **38** + **39**, are used to regenerate "Diels–Alder protected" double bonds or 1,3-dienes.[54]

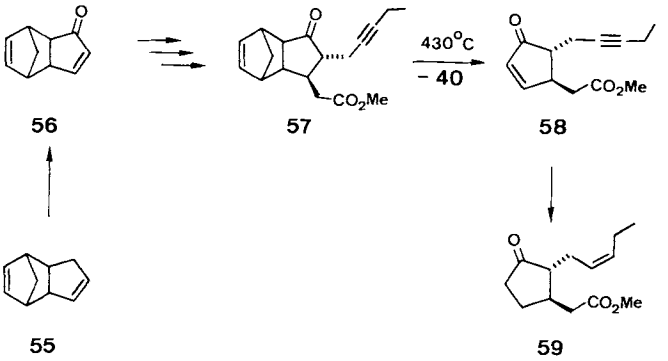


37 **38** **39**

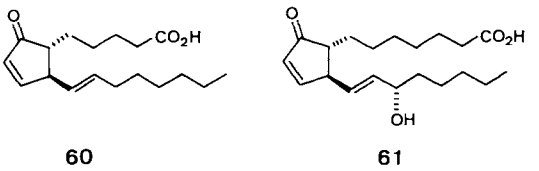
The use of high temperatures and reduced pressure has proven valuable in achieving a high degree of retro-reaction in the gas phase. Typical examples are the syntheses of α,β-unsaturated ketones, allylic alcohols, and sensitive nonconjugated polyenes. For instance, *Stork* and *Guthikonda*[55] reported a simple route to ethyl acryloylacetate **44**, which is used as a Michael acceptor for Robinson type annelations and as a diene precursor for Diels–Alder additions. The reactivity of the α,β-unsaturated system in **41** was masked by forming the Diels–Alder adduct **42** from cyclopentadiene **40** and methyl vinyl ketone **41**. The subsequent ethoxycarbonylation to **43** proceeded under strongly basic conditions. Regeneration of the α,β-double bond to give **44** was achieved at 600°C with concomitant elimination of **40**.



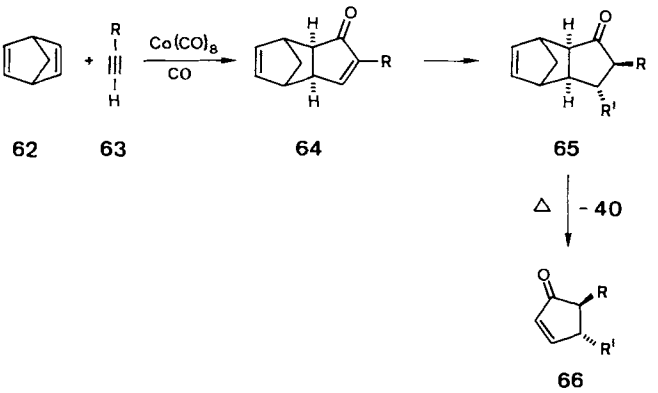
The same strategy was used by *Ho*[56] in the synthesis of turmerone **48**, in which cyclopentadiene **40** was eliminated in the last step by destructive distillation of **47** at reduced pressure. **47** itself was prepared by reaction of cyclopentadiene **40** with mesityl oxide to give the Diels–



Alder adduct **45**, followed by condensation of **45** with *p*-methylbenzaldehyde to give **46** and subsequent 1,4-addition of a methyl group.

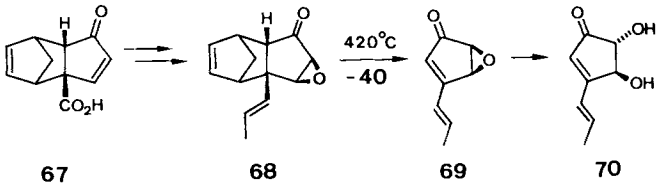


Bloch[57] used the above principle to synthesize allylic alcohols **51** starting from **49** (*endo/exo* mixtures), the alkylation products of **42**. Compounds **49** were treated with methylmagnesium iodide to give the tertiary alcohols **50** prior to thermolysis. In this way, linalool **52**, nerolidol **53**, and the sesquiterpene alcohol **54**, isolated from a Pacific algae species, were synthesized.

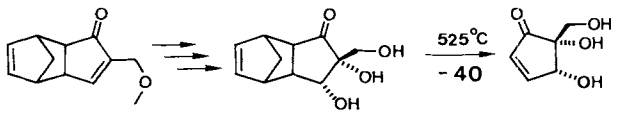


The strong tendency of cyclopentadienones to dimerize makes them less attractive for the synthesis of substituted five-membered rings.[58] An alternative to recent attempts to circumvent this problem in the condensed phase[59] is the use of **56** and its derivatives. These compounds can formally be regarded as "Diels-Alder protected" cyclopentadienones. In this manner, *Ducos* and *Rouessac*[60] succeeded in synthesizing the natural perfume component jasmone carboxylic acid methyl ester **59** starting from **56**, which is easily accessible from dicyclopentadiene **55**. After the introduction of the two side chains, which was facilitated by the 2-cyclopentenone partial structure, gas-phase flow thermolysis of **57** at 430°C led to the substituted 2-cyclopentenone **58**, which in turn was converted into the natural product **59** by selective reduction.

Wiel and *Rouessac*[61] also used **56** to synthesize other 4,5-substituted 2-cyclopentenones (e.g., **60**), which are possible intermediates for the synthesis of prostaglandins (e.g., prostaglandin A_1 **61**).

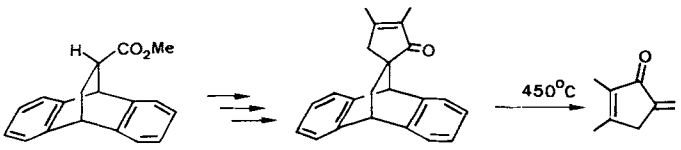


Schore,[62] with a similar goal in view, thermolyzed the compounds **65** (R = *n*Bu, R′ = H, Me, *t*Bu) to give **66**, whereby **65** was obtained by 1,4-addition of alkyl cuprates to the α,β-unsaturated system in **64**. The tricycle **64** was obtained using the Co^0-catalyzed cocyclization of acetylenes **63**, carbon monoxide, and norbornadiene **62** introduced by *Pauson* et al.[63]

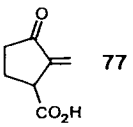


Zwanenburg et al.[66] used **67** and **71**, derivatives of **56**, for the synthesis of the cyclopentane antibiotics terrein **70** and pentenomycin **73**.[64,65] After transformation of the remaining α,β-double bonds to give **68** and **72**, respectively, the 2-cyclopentenone units of the natural products were obtained by gas-phase flow thermolysis. The fact that the free triol **72** could be directly transformed into penteno-

mycin **73** in 50% yield at 525°C demonstrates that this method can also be applied to substances with sensitive functional groups.

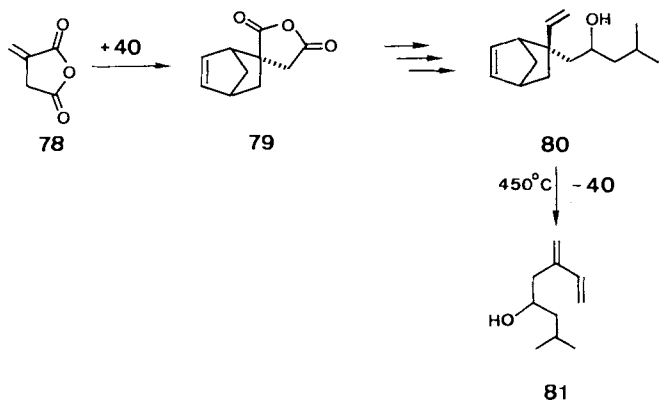


67 **68** **69** **70**

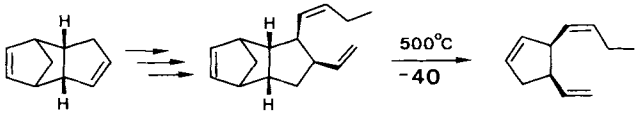


71 **72** **73**

Siwapinyoyos and *Thebtaranonth*[67] have described the synthesis of a further cyclopentane antibiotic,[64,65] methylenomycin B **76**, via the Diels–Alder/retro Diels–Alder route. After cycloaddition of anthracene with methyl acrylate to form **74** and subsequent elaboration of the dimethylcyclopentenone moiety, thermolysis of **75** furnished anthracene and the natural product **76**, which is sensitive in the condensed phase. The same principle was applied to the synthesis of sarkomycin **77**.[68]

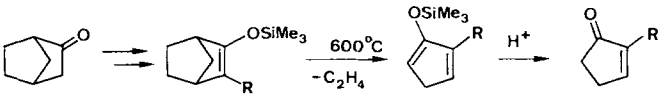


74 **75** **76**



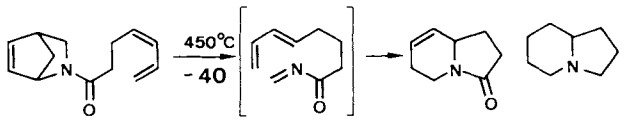
77

The cyclopentadiene adduct **79** was used by *Rouessac* and *Haslouin*[69] to protect the carbon–carbon double bond in itaconic anhydride **78** in the synthesis of the pheromone ipsenol **81**; compound **79** was converted via several steps into **80**, which underwent thermolysis at 450°C to give **81** in quantitative yield.



78 **79** **80** **81**

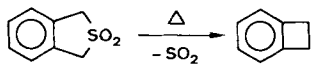
Boland and *Jaenicke*[70] synthesized the gynogamete sex attractant of a marine brown algae, multifidene **83**; dicyclopentadiene **55** was converted into the triene **82**, which underwent subsequent gas-phase flow thermolysis at 500°C to give the natural product **83** as a racemate with three nonconjugated carbon–carbon double bonds.



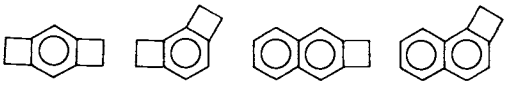
55 **82** *rac*-**83**

Bloch[71] has described an interesting variant of the application of the retro Diels–Alder reaction in which the 1,3-diene **86** formed in the thermal step is further used synthetically to give 2-substituted 2-cyclopentenones **87** (R = H, CH_3, $CH_2CH{=}CH_2$, or *n*-pentyl). Alkylation of 2-norbornanone **84** and silyl enol ether formation afforded **85**, which underwent thermolysis to furnish the cyclopentadiene derivative **86** and ethylene. The products **87** were then obtained by acid hydrolysis.

84 **85** **86** **87**



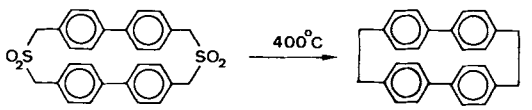
By gas-phase flow thermolysis of the azabicyclo[2.2.1]heptene **88**, *Ripoll* et al.[72] obtained the intermediate **89**, the *N*-acylimine moiety of which is extremely sensitive in the condensed phase. The formation of the lactam **90** in an intramolecular Diels–Alder addition upon warming of the thermolysate can be regarded as evidence for the intermediacy of **89**. Compound **90** in turn is a known intermediate in the synthesis of the alkaloid δ-coniceine **91**.



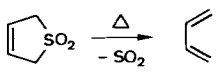
88 **89** **90** **91**

3.1.5. Elimination of Sulfur Dioxide

The thermal elimination of sulfur dioxide from cyclic sulfones under flow thermolysis conditions can be exploited synthetically in a variety of ways. Thus, in addition to the 1,4-elimination approach (see Section 3.1.2), the elimination of sulfur dioxide from dihydrobenzo[*c*]thiophene 1,1-dioxides provides a route to benzocyclobutenes. The fragmentation of the type **92** → **19** was first described by *Cava* and *Deana*[73] and was later used also in the synthesis of systems containing two four-membered-ring units such as **93**,[74] **94**,[75] and the dihydrocyclobutanaphthalenes **95** and **96**.[76] In this way *Smith* et al.[77] prepared the substituted benzocyclobutenes **17** (R = CH_3, R′ = H; R = R′ = CH_3; R = $CH_2C_6H_5$, R′ = H; R = $CH_2CH{=}CH_2$, R′ = H).

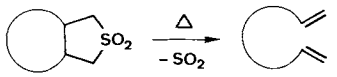


92 19



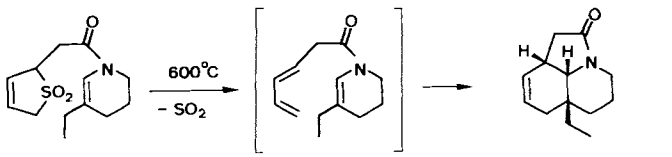
93 94 95 96

An SO_2 extrusion, possibly proceeding via benzyl radicals, was first used in the condensed phase by *Vögtle*[78] and in the gas phase by *Staab* and *Haenel*[79] for the synthesis of macrocyclic cyclophanes. Thus, the thermolysis of the disulfone **97** gave [2.2](4,4')biphenylophane **98** in 47% yield, a transformation that, in contrast to other examples,[78] was unsuccessful in both the condensed phase and in solution. Further examples of this type are found in the review by *Vögtle* and *Neumann*.[80]

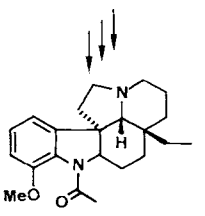


97 98

SO_2 eliminations can also be used in retro-cheletropic processes to synthesize dienes of the type **100** and **102** from di- and tetrahydrothiophene 1,1-dioxides **99** and **101**, respectively.

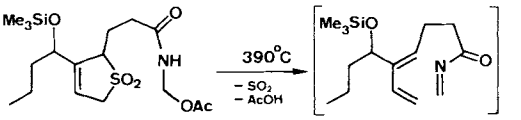


99 100

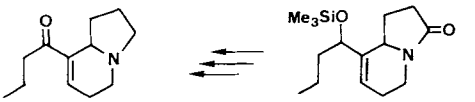


101 102

In the elegant synthesis of the indole alkaloid aspidospermine **106**, developed by *Martin* et al.,[81] the diene **104**, formed by thermal SO_2 elimination, reacts in an intramolecular Diels–Alder reaction to give the tricycle **105** selectively. In a series of steps (some already known) **105** was transformed into the natural product **106**.

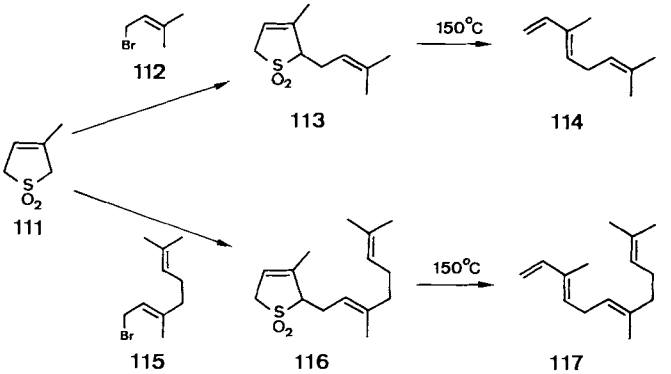


103 104 105



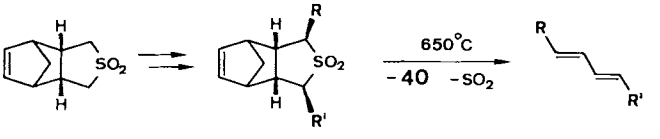
106

The same method was employed by *Weinreb* and *Schmitthenner*[82] in the synthesis of the elaeocarpus alkaloid elaeocanine A **110**, in which they succeeded in simultaneously generating the diene moiety and the acylimino moiety of **108** by SO_2 elimination and by acetate elimination, respectively.



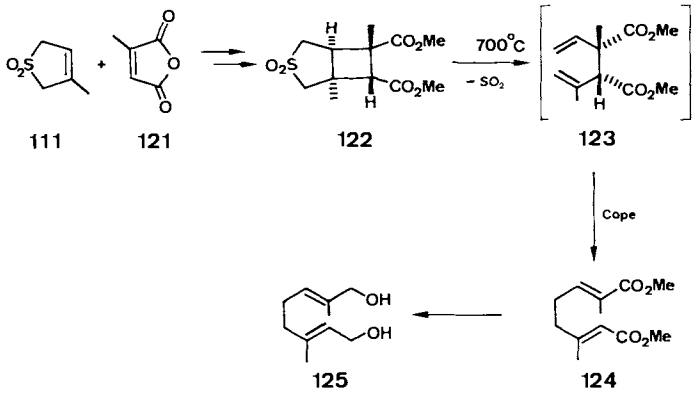
107 108

110 109



The use of 3-methyl-3-sulfolene **111** as an isoprene building block was demonstrated by *Chou* et al.[83] in the synthesis and thermolysis of the cyclic sulfones **113** and **116**, which were obtained from the anion of **111** by reaction with prenyl bromide **112** and geranyl bromide **115**, respectively. The SO_2 elimination took place already under preparative gas chromatographic conditions, leading stereoselectively to *trans*-β-ocimene **114** and α-farnesene **117**, respectively.

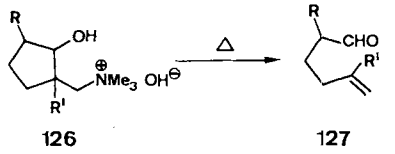
111 112 113 114 115 116 117



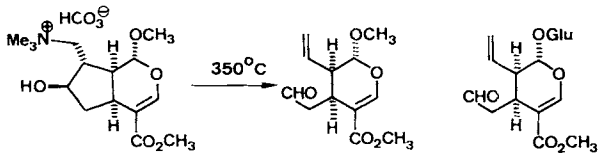
Bloch and *Abecassis*[84] effectively used a combination of retro Diels–Alder fragmentation and SO_2 extrusion to prepare the (*E,E*)-dienes **120** in a highly stereoselective manner and in good yields. Here, the exclusively *exo*-substituted tricyclic sulfone **119** was obtained by iterative alkylation of **118**. The method was applied to the synthesis of **120** (R = CH_3, R' = $(CH_2)_7OH$) and R = C_2H_5, R' = $(CH_2)_8OAc$), the sex attractants of two species of moths.

The sulfone **122**, obtained from **111** and **121** by photocycloaddition, was used by *Williams* and *Lin*[85] to prepare

118 119 120



the 1,5-diene **123** by thermolytic SO_2 elimination. Under the reaction conditions, a subsequent, stereoselective Cope rearrangement to give the diester **124** took place. Lithium aluminum hydride reduction of **124** opened a simple route to 10-hydroxygeraniol **125**.

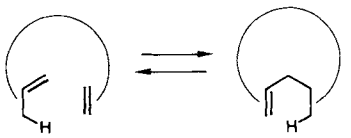


111 121 122 123 124 125

3.1.6. *Fragmentations*

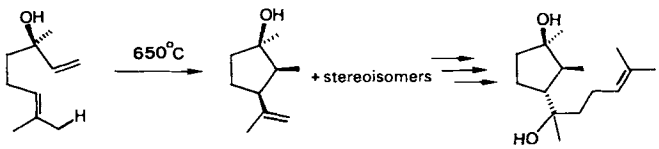
Terminally unsaturated aldehydes **127**, which readily undergo condensation reactions in the solid phase or in solution, were synthesized by *Tietze* et al.[86] through gas-phase flow thermolysis of γ-hydroxyammonium hydroxides **126** (R, R′=H; R, R′=CH_3; or R=H, R′=CH_3) at 350–450°C. This method was also successfully applied to the synthesis of **129**, the aglycone *O*-methyl ether of secologanin **130**, which in turn is an important intermediate in the biogenesis of many alkaloids and monoterpenes.[87]

126 127



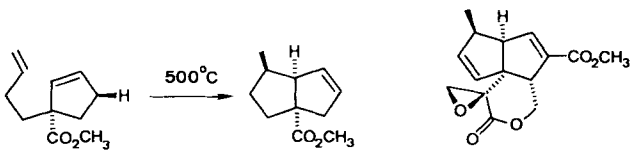
128 129 130

3.2. Rearrangements



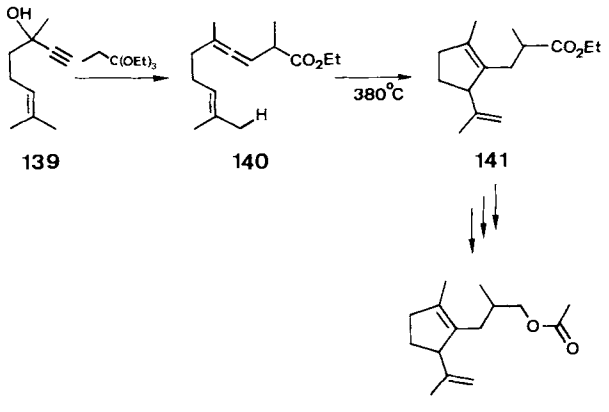
3.2.1. *Intramolecular Ene and Retro-Ene Reactions*

Cyclizations via ene reactions, i.e., involving the intramolecular addition of an olefin having an allylic hydrogen to a multiple bond (**131** → **132**), as well as the ring opening retro-ene reaction (**132** → **131**), are of particular synthetic interest and have been intensively studied in recent years by several groups.[12,13,18,22] Although the intramolecular ene addition is usually carried out under static conditions (e.g., in sealed tubes), gas-phase flow thermolysis has proven useful in some cases, particularly for retro-ene reactions.



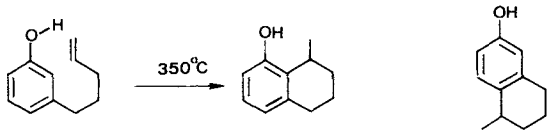
131 132

Intramolecular Ene Reactions: In experiments carried out by *Ohloff* et al.,[88] the cyclization of (−)-linalool **133** at 650°C led to a stereoisomeric mixture of plinols, the main isomer of which, (−)-plinol C **134**, was used as the starting material for enantioselective synthesis of the sesquiterpene cyclonerodiol **135**.[89]



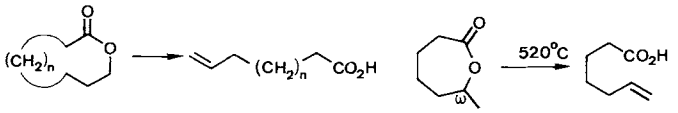
133 134 135

Searching for new ways to synthesize the ring skeleton of the antibiotic pentalenolactone **138**, *Plavac* and *Heathcock*[90] subjected the ester **136** to gas-phase flow thermolysis at 500°C and obtained an almost quantitative yield of the bicyclic product **137**. In spite of the high temperature, the ring methyl group remains in the thermodynamically unfavorable *endo* position, owing to the cyclic transition state of the ene reaction.



136 137 138

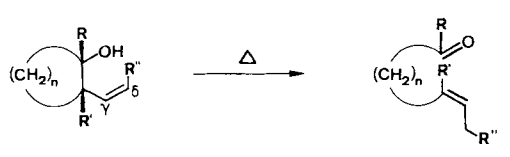
An industrial process consisting of a continuous gas-phase flow thermolysis at 380°C is used in the synthesis of **141**, a synthetic precursor of the cyclopentanoid perfume ingredient **142**.[18,91] The required starting material, the allene **140**, is also synthesized thermally, albeit under static conditions, from dehydrolinalool **139** and triethyl orthopropionate by Claisen ortho ester rearrangement.



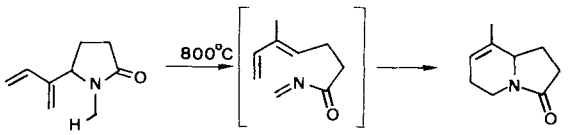
139 140 141 142

That the choice of reaction conditions used, static or dynamic, can have a considerable influence on the products of a reaction, is demonstrated by the cyclization of 3-(4-pentenyl)phenol **143**. This reaction, carried out by *Conia* et al.[91] using flow thermolysis at 350°C, led to exclusive formation of the *ortho* product **144**, whereas in the condensed phase the *para* product **145** was formed in roughly the same yield.

143 **144** **145**



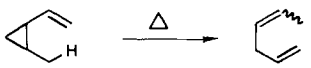
Retro-ene reactions: Apart from the eliminative retro-ene reactions such as the ester pyrolyses, which are most commonly carried out under gas-phase flow thermolysis conditions (see Section 3.1.1), there are many examples of the use of intramolecular reactions. For example, the pyrolysis of the lactones **146** has been studied by *Bailey* and *Bird*.[93] In agreement with the *syn*-specific reaction course discussed in Section 3.1.1 (**1**→**2**), the authors found that the intramolecular transformation of the lactone **146** into the terminally unsaturated acids **147** only occurred when medium-sized rings were employed (n = 4 and 6). Smaller lactones, such as **148**, reacted only when an additional methyl group was introduced into the ω-position, where it becomes available for the pericyclic process.



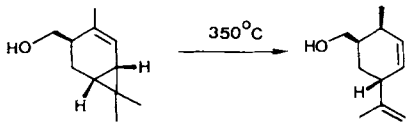
146 **147** **148** **149**

A further application of the retro-ene reaction under dynamic conditions involves the thermolysis of γ,δ-unsaturated alcohols such as **150**, which are used in the stereoselective synthesis of unsaturated aldehydes (**151**, R = H) or ketones (**151**, R = alkyl). *Arnold* and *Smolinsky*[94] found that 2-alkenylcycloalkanols (**150**, R, R′ = H, R″ = *n*-alkyl, n = 3, 4, or 5) smoothly rearrange at temperatures around 500°C to the corresponding aldehydes **151** with *E* configuration at the double bond. Later, *Marvell* and *Rusay*[95] used the same method in the thermolysis of 2-vinylcyclohexanols (**150**, R = H or CH_3, R′ = CH_3, R″ = H, n = 4) for a stereoselective synthesis of the corresponding trisubstituted unsaturated carbonyl compound **151** with E configuration.

Earl and *Vollhardt*[96] developed a process for the synthesis of bicyclic lactams (example **154**) in which the first thermal retro-ene step (**152**→**153**) gives rise simultaneously to both an acylimine and a diene partial structure, which in turn undergo an intramolecular Diels–Alder reaction to give the indolizidinone **154**. However, this reaction, in contrast to the thermolysis examples involving N-acylimines discussed in Sections 3.1.4 and 3.1.5, affords only moderate yields.

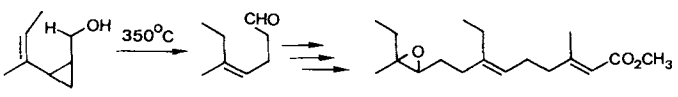


150 **151**



152 **153** **154**

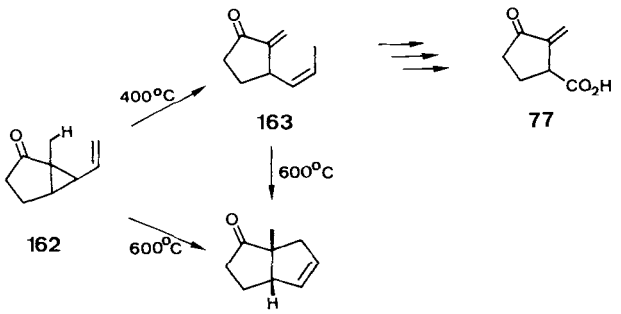
The most common synthetic intramolecular retro-ene reaction not involving heteroatoms is the rearrangement of methylvinylcyclopropanes **155** to give 1,4-hexadienes **156**. Because of its pericyclic character, this reaction, which is favored by release of ring strain, proceeds particularly easily when the two cyclopropane substituents involved are *cis* to each other.



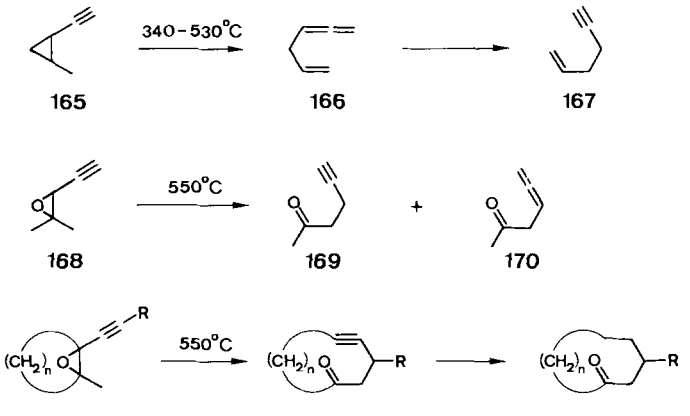
155 **156**

Already in 1960, while examining the thermal behavior of terpenes in the carane series, *Ohloff*[97] found that, upon thermolysis at 350°C, the carene derivative **157** gave the menthadiene derivative **158** stereoselectively in high yield. Later, *Gollnick* and *Schade*[98] described related examples.

157 **158**



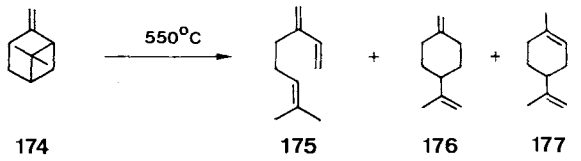
Corey et al.[99] used this transformation in the conversion of **159** into the δ-unsaturated aldehyde **160**, which is an important intermediate in the synthesis of the juvenile hormone JH-II **161**.



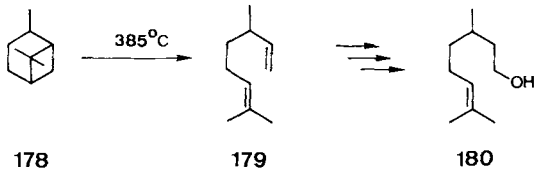
159 **160** **161**

A further example is the synthesis of the antitumor-active methylenecyclopentanone sarkomycin **77**. *Hudlicky* et al.[100] succeeded in transforming the bicyclo[3.1.0]hexanone **162** by thermolysis at 400°C into the retro-ene product **163**, which in turn was selectively oxidized to the natural product **77**.[101] At higher temperatures, **164** is formed from **162** by a vinylcyclopropane rearrangement (see Section 3.2.5); under the same conditions, **164** can also be obtained from **163**.[101] In addition to the temperature dependence of this reaction, the authors described the de-

pendence of the product ratio (**163/164**) on the surface treatment of the reactor material used.

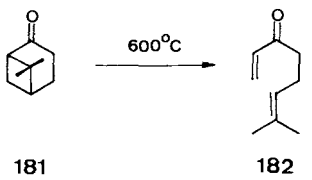


The retro-ene reaction of ethynylmethylcyclopropane **165** to give **166** followed by a Cope type rearrangement to the enyne **167**, reported by *Dalacker* and *Hopf*,[102] was applied by *Karpf* and *Dreiding*[103] to the three-atom ring expansion of acetylenic epoxides **171**. In order to demonstrate that such a transformation is possible, the reaction analogous to **165** → **167** was first carried out on **168** to give **169** and **170**. Similarly, the thermolysis of the epoxycycloalkanes **171** (R = H; n = 4, 10) gave, among other products, the corresponding ring-expanded alkynones **172**, hydrogenation of which furnished the cycloalkanones **173** (R = H; n = 4, 10). Attempted use of this reaction sequence in the synthesis of muscone **173** ($R = CH_3$, n = 10) starting from **171** ($R = CH_3$, n = 10), however, yielded only traces of the expected product.

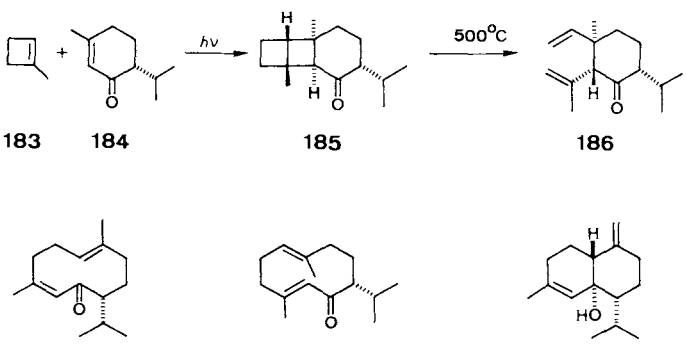


3.2.2. *Cyclobutane Ring Opening*

The use of the cyclobutane ring-opening reaction as a synthetic principle has been extensively applied to terpenes with a pinane backbone.[104] The technical process[105] for the flow thermolysis production of myrcene **175** (75–80%) from β-pinene **174** at 550°C is formally a [2+2]-cycloreversion. The pronounced regioselectivity of the cyclobutane ring opening and the simultaneous formation of the two limonenes **176** (3–4%) and **177** (10%) however, indicate a radical pathway for this transformation.

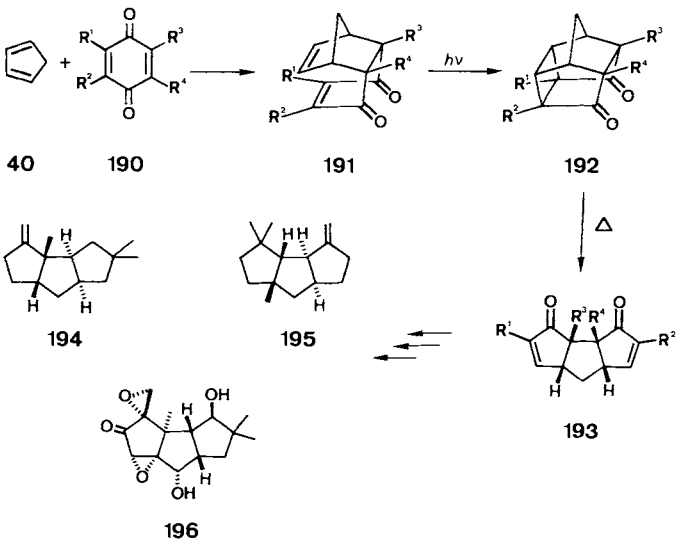


Rienäcker and *Ohloff*[106] applied this ring-opening reaction to the flow thermolysis transformation of pinane **178**



to the diene **179**. Subsequent hydroxylation of the monosubstituted double bond of **179** gave β-citronellol **180**, which is an important perfume component of ethereal oils. The use of the optically pure antipodes of pinane **178** made it possible to produce either of the known optical antipodes of the natural product **180**.

The thermal opening of nopinone **181** at 600°C was carried out in an analogous way by *Mayer* and *Crandall*[107] to yield the dienone **182**.



The thermal ring opening of bicyclo[2.2.0]hexanes, which in turn are formed through [2+2]-photocycloaddition reactions, can be used to advantage in synthetic sequences. *Williams* and *Callahan*[108] described the synthesis of (−)-shyobunone **186** in which the gas-phase flow thermolysis at 500°C of **185**, which itself was formed by the photochemical [2+2]-cycloaddition of methylcyclobutene **183** and (−)-piperitone **184**, led directly to products that included (−)-**186**. Three epimers of **186** were also formed as well as (+)-(*R*)-isoacoragermacrone **187**, which, according to a known reaction sequence, can be isomerized to (*R*)-acoragermacrone **188**. When **185** was heated under static conditions in the condensed phase for 30 min at 250°C, the only product isolated was the cadenane derivative **189** which is the product of an intramolecular ene reaction of **187**. This example clearly illustrates a com-

monly observed advantage of gas-phase flow thermolysis, namely, the possibility of isolating the primary thermal product.

An addition–rearrangement reaction sequence was developed by *Mehta* et al.[109] as a route to the linearly annelated triquinanes with the ring skeleton of **193**. The starting point of the sequence is the Diels–Alder addition of cyclopentadiene **40** to the substituted *p*-benzoquinones **190**. After the intramolecular photocycloaddition of **191** to give the pentacycle **192**, thermolysis, preferably under dynamic conditions, gave the *cis-syn-cis* isomer of the triquinane skeleton **193**. The two 2-cyclopentenone moieties then permitted further functionalization of the two lateral rings as well as isomerization to the known naturally occurring[110] *cis-anti-cis* configuration. So far, this strategy has led to the successful synthesis of hirsutene **194**,[111] $\Delta^{9(12)}$-capnellene **195**,[112] and the oxygenated triquinane corioline **196**.[113]

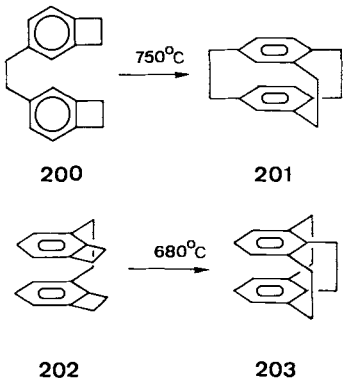
196

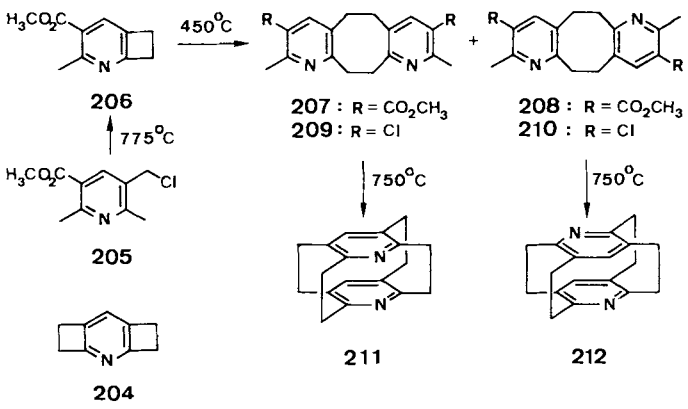
3.2.3. Benzocyclobutene Dimerizations



o-Quinodimethanes **16**, which are obtainable by thermolysis of benzocyclobutenes **17**, readily dimerize (see Section 3.1.2). *Boekelheide* and *Ewing*[114] were the first to recognize the importance of this property for the synthesis of cyclophanes. Thus, this group succeeded not only in synthesizing the "superphane" **25** (see Section 3.1.2) but also in transforming the benzocyclobutene derivative **197** into [2.2.2.2](1,2,4,5)cyclophane **198**. The intermediate formation of the bis-*o*-quinodimethane **199** is very probable since the retro-reaction **198** → **197** was also observed.

197 198

199



The same principle has been used by *Aalbersberg* and *Vollhardt*[115] in the flash thermolytic synthesis of the [2.2.2](1,2,4)cyclophane **201**. The bis-benzocyclobutene **200**, obtained by Co^0-catalyzed trimerization of 1,5-hexadiyne, gave **201** in 75% yield upon thermolysis at 650 °C. In benzene solution at 200 °C, on the other hand, **200** was transformed into a colorless polymer. *Neuschwander* and *Boekelheide*[116] synthesized the symmetrical [2.2.2](1,2,3)-cyclophane **203** by thermolysis of **202** at 680 °C.

200 201

202 203

The unusually strong tendency of *o*-quinodimethanes to dimerize was even applied by *Boekelheide* et al.[117] to the intermolecular synthesis of [2.2.2.2](1,2,4,5)cyclophane **198** by thermolysis of the dicyclobuta[*a*, *d*]benzene **93** (see Section 3.1.5) in a stream of nitrogen at 450 °C. The authors assume that this dimerization also proceeds via **199**. In contrast, an attempt to apply this method to the synthesis of the diaza[2.2.2.2](1,2,4,5)cyclophanes **211** and **212** by the gas-phase flow thermolysis of **204**, the aza analogue of **93**, failed.[118] The synthesis of **211** and **212** was accomplished, however, in three thermal steps. Starting from **205**, the dihydrocyclobutapyridine **206** was formed at 775 °C (10^{-2} torr) (see Section 3.1.2); **206** in turn gave the dimers **207** and **208** in a stream of nitrogen at 450 °C. After separation and transformation into **209** and **210**, respectively, thermolysis at 750 °C (10^{-3} torr) furnished the desired azacyclophanes **211** and **212**, respectively.

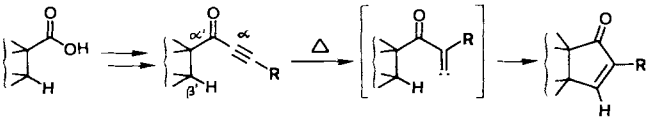
204

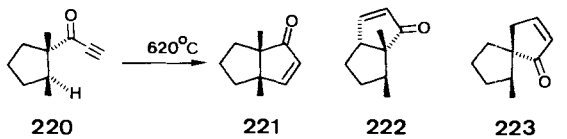
211 212

3.2.4. [1,2]-Rearrangements



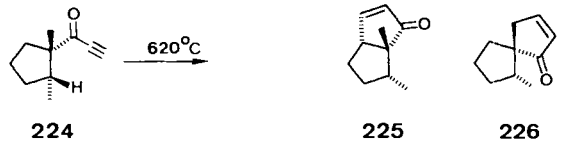
[1,2]-Rearrangements of acetylenes: The thermal [1,2]-rearrangement of acetylenes **213** to vinylidene carbenes

214, first demonstrated by *Brown* et al.[119] under gas-phase flow thermolysis conditions, can be used preparatively when the carbene **214** contains a suitable site for intramolecular insertion, e.g., an X–H bond.



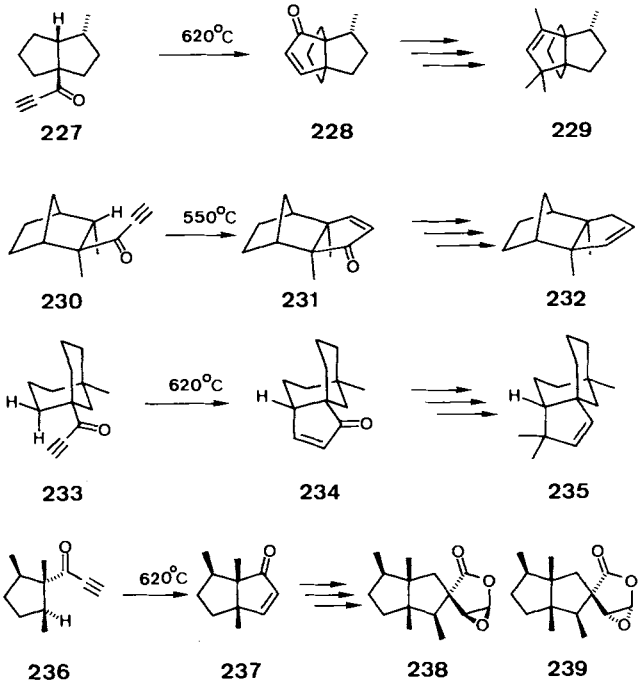
213 **214** **215**

Examples of species such as **214** are alkylidene carbenes conjugated with carbonyl groups, **218**, which are assumed to be intermediates in the flow-thermolytic isomerization of α-acetylenic ketones **217** to 2-cyclopentenones **219**. This "α-alkynone cyclization," discovered by *Karpf* and *Dreiding*,[120] is of interest as a cyclopentenone annelation sequence, because the required alkyl alkynyl ketones **217** are readily accessible from the corresponding carboxylic acids **216**; moreover, the 2-cyclopentenones **219** thus formed are synthetically useful intermediates.



216 **217** **218** **219**

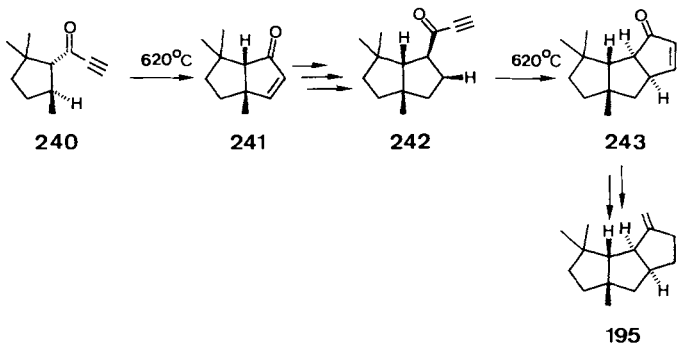
The selectivity of the cyclization step **217** → **219**, which usually takes place with good yields, in particular when R = H, allows predictions to be made about the products.[121] The cyclization takes place with exclusive five-membered-ring formation and occurs at the more highly substituted C(β′) atom, provided that the C(β′)–H bond can adopt a nearly synperiplanar relationship with the alkynone unit with respect to the C(α′)–C(β′) bond. Thus, bicyclo[3.3.0]octenone **221** was preferentially formed from the *cis*-dimethylalkynone **220** by insertion into the tertiary C(β′)–H bond, whereas in the thermolysis of the *trans*-dimethyl compound **224** a tertiary insertion product analogous to **221** was not obtained.



220 **221** (69 : 26) **222** **223** (5)

224 **225** (89 : 11) **226**

The "α-alkynone cyclization" permitted the construction, for example, of the carbon backbone of the cyclopentanoid natural products modhephene **229**,[122] albene **232**,[123] and clovene **235**,[124] as well as **238**,[125] a stereoisomer of ptychanolide **239**,[126] by the thermolysis of the α-alkynones **227**, **230**, **233**, and **236**, respectively.

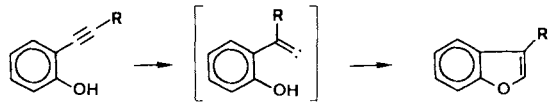


227 **228** **229**

230 **231** **232**

233 **234** **235**

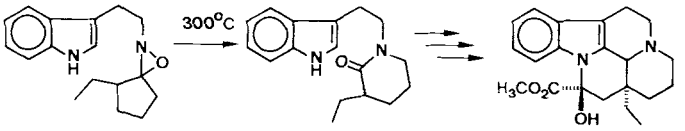
236 **237** **238** **239**



By consecutive application of this cyclopentane annelation, the synthesis of the linearly annelated marine triquinane sesquiterpene capnellene **195**[127] was achieved. In the first thermal step, the α-alkynone **240** gave exclusively the bicycle **241**. After introduction of the alkynone side chain to give **242**, a second cyclization step provided the secondary insertion product **243**, needed for the transformation to **195**, in 33% yield. **243** is the product of insertion into a secondary C–H bond.

240 **241** **242** **243**

195



The selective rearrangement of the 2-ethynylphenol **244** (R = H) to benzofuran **246** (R = H) was explained by *Bloch* and *Orvane*[128] as the insertion of the intermediate vinylidene carbene **245** (R = H) into the O–H bond. In support of this interpretation, *Barton* and *Groh*[129] observed the formation of **246** with R = $Si(CH_3)_3$, along with other

244 **245** **246**

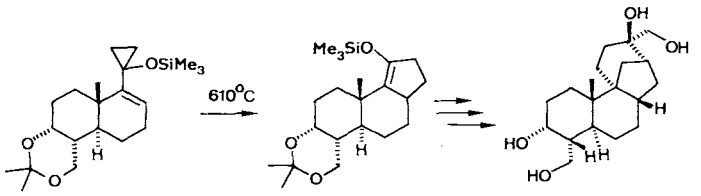
products, in the thermolysis of the trimethylsilyl derivative of **244** (R = $Si(CH_3)_3$).

Oxazirane-lactam rearrangements: The gas-phase thermal [1,2]-rearrangement of oxaziranes (example **247**) results in ring expansion to lactams (example **248**) and, according to *Kuehne* and *Parsons*,[130] represents an alternative to the photochemical reaction. Compound **248** is a known intermediate in the synthesis of the pentacyclic indole alkaloid vincamine **249**.[131]

247 **248** **249**

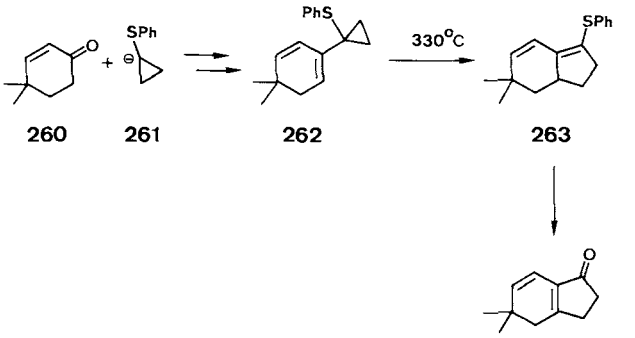
3.2.5. *[1,3]-Rearrangements*

Thermal [1,3]-rearrangements usually occur only at high temperatures and are, therefore, rarely useful for synthetic purposes.[132] One exception is the thermal rearrangement of vinylcyclopropanes **250** to cyclopentenes **251**. This rearrangement was first described by *Neureiter*[133] and shortly afterwards also by *Overberger* and *Borchert*[134] and has been thoroughly investigated by several groups.[135]



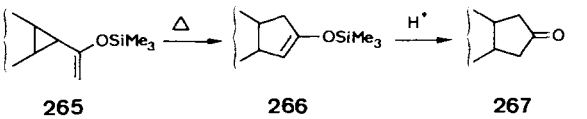
250 **251**

This reaction can be applied synthetically to the formation and annelation of five-membered rings, for example, the cyclopentane annelation sequence for cyclic ketones developed by *Trost* et al.[136] (example **252**). The reaction proceeds via addition of diphenylsulfoniocyclopropanide **253** to the ketone **252**, leading to the oxaspirononane **254**. After opening of the epoxide ring to give the trimethylsilyl ether **255**, flow thermolysis at 330 °C provided the bicyclic trimethylsilyl enol ether **256**.



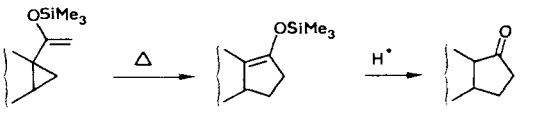
252 **253** **254** **255** **256**

The annelation of the five-membered ring of the antibiotically active compound aphidicolin **259** was achieved in this way; at 610 °C **257** was virtually quantitatively transformed into **258**.[137]

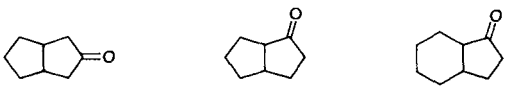


257 **258** **259**

Trost and *Keeley*[138] found an interesting variant of this oxaspiropentane route (**252** → **256**). Addition of the cyclopropyl phenyl sulfide anion **261** to **260** and subsequent dehydration yielded the vinylcyclopropane derivative **262**, which rearranged to the vinyl sulfide **263** upon gas-phase flow thermolysis. The ketone **264** was liberated in good yield by Ti^{IV}-catalyzed hydrolysis of **263**.

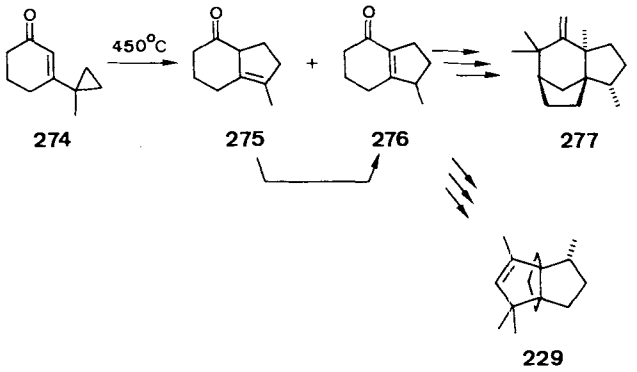


260 **261** **262** **263** **264**

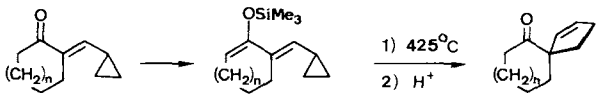


Cyclopropyl-substituted silyl enol ethers of the types **265** and **268**, respectively, have been synthesized by several pathways. Their thermolysis gives the vinylcyclopropane-rearrangement products **266** and **269**, respectively; hydrolysis furnishes the ketones **267** and **270**, respectively. The success of the thermal step developed by *Monti* et al.[139] is very strongly dependent on the particular structure of the silyl enol ethers. Thus, bicyclo[3.3.0]octanone **271** is formed by the path **265** → **267** in only 8% yield, whereas the ketones **272** and **273**, respectively, formed via **268** → **270**, are accessible in yields of 21% and 99%, respectively.

265 **266** **267**

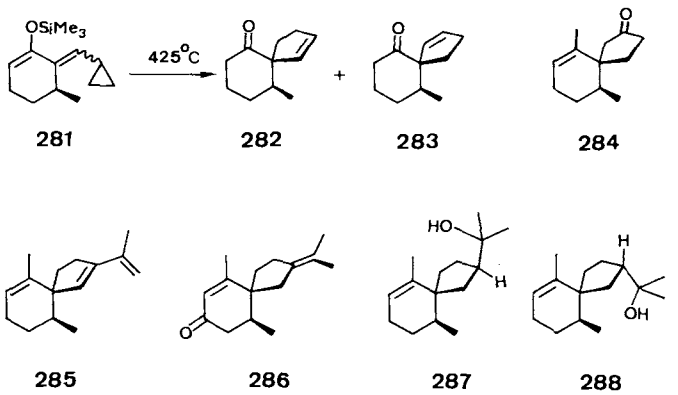


268 **269** **270**

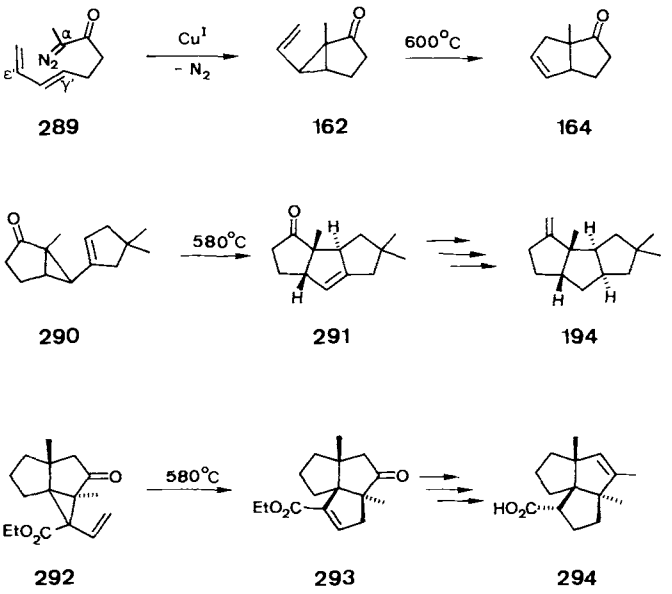


271 **272** **273**

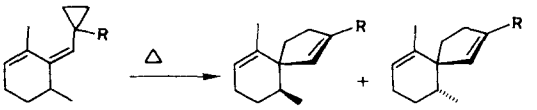
Piers et al.[140] have developed an efficient route for the synthesis and rearrangement of β-cyclopropyl-substituted α,β-unsaturated ketones. A typical example is the synthesis of the bicyclo[4.3.0]octenone **276** by thermal vinylcyclopropane rearrangement of **274**; the simultaneously formed **275** is also converted into **276** by isomerization of the β,γ-double bond. Compound **276** was then used for the syn-



thesis of the tricyclic sesquiterpene zizaene **277**. Moreover, *Smith* and *Jerris*[141] used **276** as the starting material in their synthesis of modhephene **229**, which is the first natural product with a propellane carbon skeleton.

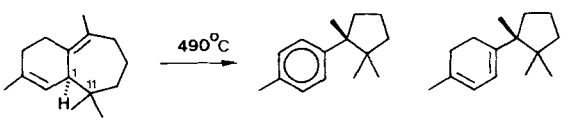


Piers et al.[142] have developed a spiroannelation of the silyl enol ether **279** (n = 1, 2) based on the vinylcyclopropane rearrangement. Acid hydrolysis of the crude thermolysate gave the spiroketones **280** in a total yield of 50–60%. Direct thermolysis of the ketones **278**, on the other hand, resulted in lower yields of the compounds **280** along with several other products.

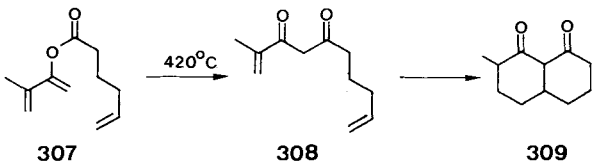


This method can be used to prepare a mixture of the diastereoisomeric spiro compounds **282** and **283** from **281**. Compound **282** is then used as starting material for **284**, thus making it possible to achieve the total synthesis of several sesquiterpenes of the spirovetivane type such as α-vetispirene **285**, β-vetivone **286**, hinesol **287**, and agarospirol **288**.[142]

The vinylcyclopropane rearrangement was used in the synthesis of polycyclopentanoid natural products by *Hudlicky* et al.[143] The required vinylcyclopropanes (example **162**) were obtained through Cu^I-catalyzed, intramolecular cyclopropanation of γ′,ε′-unsaturated α-diazoketones (example **289**). Gas-phase flow thermolysis then gave generally high yields of bicyclo[3.3.0]octenones (example **164**; cf. also Section 3.2.1). Compounds **291** and **293**, which are important as precursors in the synthesis of hirsutene **194**[144] and isocomenic acid **294**,[143] respectively, were obtained in this way.

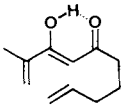


The gas-phase flow thermolysis of trimethylsilyl-substituted vinylcyclopropanes such as **295**, studied by *Paquette* et al.[145], led to synthetically interesting vinylsilanes such as **296** and **297** (6 : 1), relatively high temperatures (560 °C) being required for complete transformation. Since the vinylsilanes resisted transformation into sesquiterpenes of the spirovetivane type, **295** was transformed into the 1-methoxy-1-methylethyl derivative **298** or the cyano derivative **301**, respectively, the thermolysis of which provided the diastereoisomeric mixtures **299/300** (5 : 1) and **302/303** (4 : 1), respectively. The main components **299** and **302** opened up the way to α-vetispirene **285** and hinesol **287**, respectively, as well as β-vetivone **286**.



R = $SiMe_3$	: 295	560°C	296	297
R = CMe_2OMe	: 298	440°C	299	300
R = CN	: 301	470°C	302	303

A further example of the synthetic application of [1,3]-rearrangements under dynamic conditions is the thermal rearrangement described by *Sukh Dev* et al.[146] in which (+)-β-himalachene **304** yielded (+)-cuparene **305** at 490 °C, most probably via the dihydro derivative **306**. The opening of the doubly allylic 1,11-bond in **304** is particularly favored by the highly substituted intermediate radi-

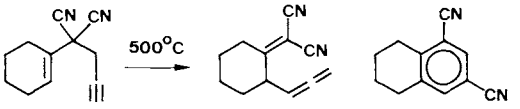


cals formed. The optical activity of the product **305** is retained to a degree of about 20%, which was interpreted with a partly concerted reaction path for the rearrangement.

Shea and *Wada*[147] observed a thermal [1,3]-acyl shift, described earlier in simpler vinyl ester systems, upon gas-phase flow thermolysis of the dienyl ester **307**. This compound is transformed at temperatures above 360 °C into the 1,3-diketone **308**, part of which reacts further to give the decalindione **309**, probably by an intramolecular Diels–Alder reaction via the enol **310**. Attempts at carrying out this transformation under static conditions failed.

307 308 309

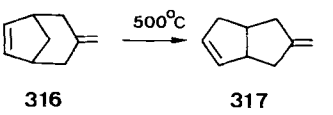
310



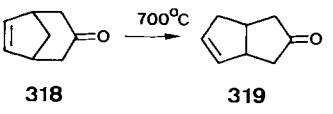
3.2.6. *[3,3]-Sigmatropic Rearrangements*

Among the preparatively most valuable pericyclic reactions, apart from Diels–Alder reactions,[12-17,19] are the [3,3]-sigmatropic rearrangements, namely, the Cope rearrangement (**311** ⇄ **312** with X = CR_2) and the Claisen rearrangement (**311** ⇄ **312** with X = O).[20,21,148] Although these processes are usually carried out under static conditions in the condensed phase or in the gas phase, there are examples known where gas-phase flow thermolysis is used.[149]

311 312



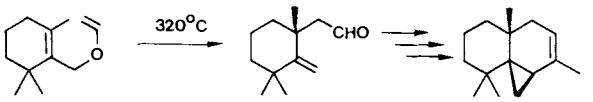
A rearrangement that gives rise to the Cope product **314** only in the gas phase, the thermolysis of the dinitrile **313**, was described by *Brown* and *McAllan*.[150] In the condensed phase **313** yielded exclusively the tetralin derivative **315**.



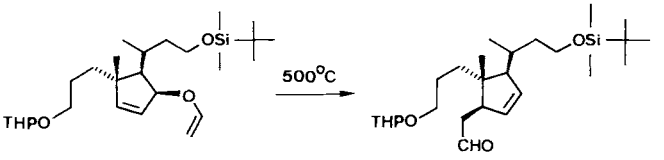
313 314 315

The bicyclo[3.2.1]octenes **316** and **318**, whose Cope systems are unfavorably arranged for a concerted rearrangement, only undergo transformation at high temperatures, according to *Klumpp* et al.,[151] to give the bicyclo[3.3.0]octenes **317** and **319**, respectively; this is indicative of a radical pathway.

An example of a synthetic application of the Claisen rearrangement under flow thermolysis conditions has been described by *Büchi* and *White*[152] in connection with the

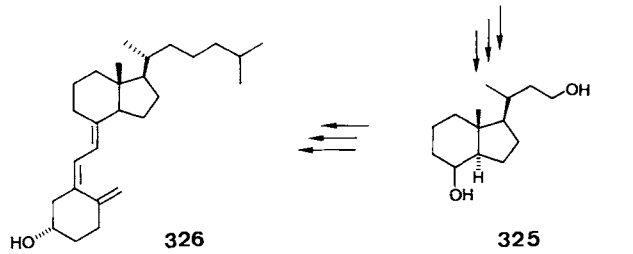


316 317



318 319

total synthesis of thujopsene **322**. The allyl vinyl ether **320** rearranged to the γ,δ-unsaturated aldehyde **321**. The vinyl ether **320**, which is readily accessible from β-cyclogeraniol, was subjected to continuous gas-phase flow thermolysis in quantities of over 100 g to give **321**.



320 321 322

Flow thermolysis of the allyl vinyl ether **323** at 500 °C led stereoselectively to the aldehyde **324** in a yield of 60%.[153] Compound **324** is a precursor for the Inhoffen-Lythgoe diol **325**, which in turn is a crucial reaction intermediate in the total synthesis of vitamin D_3 **326**. It should be noted that in spite of the high temperature used in this reaction both protecting groups remained unaffected.

323 324

326 325

3.3. Conclusion

The examples presented in this article show that organic reactions at high temperatures under gas-phase flow thermolysis conditions are synthetically useful. Several of the cases discussed emphasize the fact that, depending on the reaction conditions used, whether static or dynamic, different outcomes of the reaction can be expected. The choice of special conditions is, therefore, not only dependent on the intended thermal rearrangement, but also on the functional groups and structural elements of the starting material. Furthermore, it is important to study the compatibility of the reacting substructure with the functional groups that are not directly involved in the thermal step. The knowl-

edge so obtained will greatly expand the use of flow thermolysis methods in organic synthesis.

The Pentagonal Column and the ReO_3-Type Structure

By Bengt-Olov Marinder*

The pentagonal column (PC), consisting of MX_7 bipyramids sharing their equatorial edges with five MX_6 octahedra, is a structural feature frequently occurring in association with frameworks of the ReO_3-type, where it enables accomodation of an anion deficiency. The present article discusses the geometry of the PC and its compatibility with the ReO_3-type structure, which naturally emerges from the finding that a PC may result from twinning of an ReO_3-type structure on the unit cell level. A new symbolism is presented which facilitates visualization of a large variety of crystal and defect structures of MX_{3-x} stoichiometry. This symbolism may also serve as a convenient aid in deriving models of possible new structures that may be of value in the interpretation of HREM images.

1. Introduction

In his paper[1] that deals with the crystal structure of $W_{18}O_{49}$, *Magnéli* states that the arrangement of five W atoms close to the corners of a regular pentagon with a W atom situated in the center "is a very peculiar one". This structure is very likely the first known example of a transition metal oxide in which, according to present-day concepts of atomic arrangement, a central metal atom M is coordinated by seven oxygen atoms to form a pentagonal bipyramid [MO_7]. In turn, this bipyramid shares its equatorial edges with five [MO_6] octahedra (Fig. 1a). Further structural studies by means of X-ray diffraction techniques and High Resolution Electron Microscopy (HREM) on oxides, hydroxides and oxide fluorides of transition metals have revealed that this entity is quite common in several compounds with MX_{3-x} stoichiometry, $0.069 \leqslant x \leqslant 0.333$ (see Table 1). It has also been observed as a structural defect in a matrix of ReO_3-type structure. In all these structures such entities are linked to each other by their X vertices along a normal to the equatorial plane, and they thus form what has been called a pentagonal column or PC.[2] In the following we will also use the term PC to mean the repetitive unit of such a column.

The PC as a structure element in transition metal oxides and related compounds has been discussed by *Lundberg* et al.[2,3] *Hyde* and *O'Keeffe*[4] relate the PC to the ReO_3-type structure using the concept of cylindrical antiphase boundaries and concomitant interpolation of ...MXMX... rows in the resulting pentagonal tunnels. The ensuing structures are regarded as crystallographic shear (CS) structures with cylindrical rather than planar CS surfaces. The PC concept has been developed further by *Ekström*[5] and by *Ekström* and *Tilley*.[6]

The introduction of a PC into a matrix of the ReO_3 type always creates new types of tunnels running parallel with the PCs. Quite frequently three- or three- and five-sided tunnels are formed. If cations, appropriate in size and concentration, are inserted in the larger tunnels, these might serve as avenues for the transport of ions under the influence of an electric potential gradient, the substance thus acting as a solid electrolyte. In recent years we have been actively involved in the search for new substances of this kind;[7] those of current interest are listed in Table 1, with emphasis on substances of MX_{3-x} stoichiometry containing PCs and tunnels of various size and cross-section.

In what follows we will try to picture a PC in a convenient way, using a simple model of a PC as a building unit either alone, thereby following in the footsteps of *Lundberg*, or coupled with units of an ReO_3-type structure, i.e. with MX_6 octahedra. We shall also see how structural defects in transition metal oxides can be illustrated by the same model. First of all, however, we must discuss the geometry of a PC, and study in what way it is related to the ReO_3-type structure.

2. Some Geometric Properties of the Pentagonal Column

Figure 1a shows the idealized PC with five symmetry planes projected along a normal to the equatorial plane (which is also a symmetry plane) of the pentagonal bipyramid. In a real structure, such as that of $LiNb_6O_{15}F$[8] (see Fig. 1b) or Nb_2WO_8,[9] the five symmetry planes have been reduced to one. Figure 1c shows a slightly readjusted PC with one mirror plane perpendicular to the equatorial plane. The PC may be described in terms of a square having an edge equal to $d\sqrt{5}$, where d is the length of the diagonal of a regular MX_6 octahedron. Figure 1c also pictures the PC in an abbreviated way as a square with an inserted arrow. The same size of square will accommodate five ReO_3-type octahedra as shown in Figure 1d, which also depicts two mirror-related orientations of this grouping. The two sets are oriented at an angle of $2\,\mathrm{arctg}\,1/2$ ($=53.13°$) to each other.

Figure 2a shows squares with PCs and MO_6 octahedra joined together to form the characteristic part of a model of $4\,Nb_2O_5 \cdot 50\,WO_3$, $4\,Nb_2O_5 \cdot 22\,WO_3$,[10] and $W_{12}O_{34}$[3,11] structures. The model, in this particular case shows an intergrowth of $LiNb_6O_{15}F$- and ReO_3-type structures; the

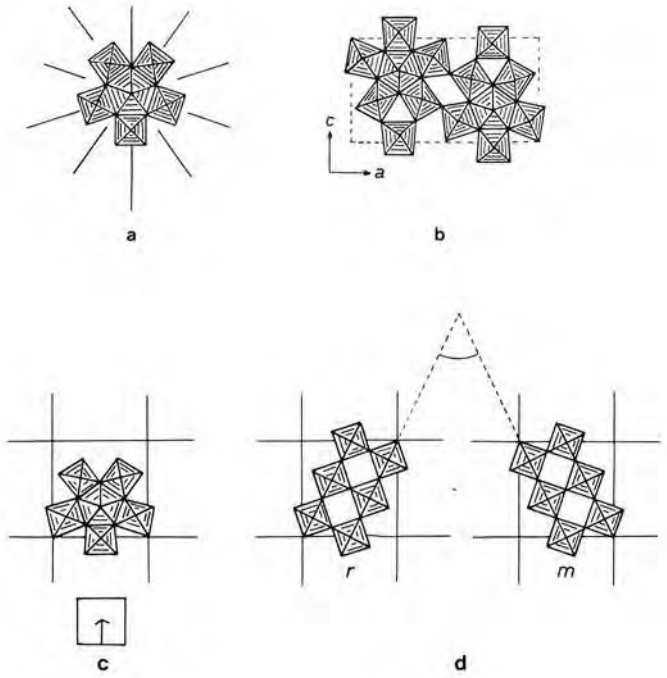

Fig. 1. a) A regular pentagonal column (PC) projected perpendicularly to its equatorial plane. Five symmetry planes are indicated. b) A structure model of $LiNb_6O_{15}F$. The unit cell contains two PCs. c) The slightly readjusted PC associated with a square, the length of whose edge is $d\sqrt{5}$; d is the diagonal of the MX_6 octahedron. A short-hand symbol of a PC is shown below: the arrow is pointing to the "top" of the PC. d) Two ReO_3 type structures, related by reflection and denoted r and m. Each of them has been assigned a square with an edge $= d\sqrt{5}$. The angle of 2 arctg 1/2 between them is shown.

two ReO_3 nets have the same orientation. As a consequence of the intergrowth, empty pentagonal tunnels (PTs)[3] are created, which render the structure a formal similarity to the tetragonal tungsten bronze (TTB) structure[12] (Fig. 2b). Figure 2c shows a model of an intergrowth between a $LiNb_6O_{15}F$-type structure and ReO_3 nets in two orientations indicated by r and m. It is a model of another kind of boundary sometimes observed as a defect in the Nb_2O_5/WO_3 system.[13] In the two models shown, both the top and bottom parts of a PC are involved in the intergrowth. Figure 2d shows two PCs joined by an isolated octahedron whose orientation, indicated by b, is halfway between m and r (see Section 3).

Figure 3 shows two PCs completely embedded in an ReO_3-type matrix. The occurrence of an $LiNb_6O_{15}F$-type structure in an ReO_3-type matrix has been observed in the system Nb_2O_5/WO_3 by *Iijima* and *Allpress*,[13] who regard it as a TTB element.

Further models of boundaries with yet other PCs participating in addition to those demonstrated in Figures 2a and 2c are shown in Figure 4. The ReO_3 structures to the left and to the right of a PC are twin related by reflection or glide. Whereas the boundaries in Figures 4a–c are made up of triangle linked PCs (for nomenclature see [3]), those in Figures 4d and 4e contain isolated PCs. PTs are formed at all boundaries except the one in Figure 4a. So far none of the structures shown in Figures 4a–d has been reported, while the one shown in Figure 4e has been found as a defect in the Nb_2O_5/WO_3 system.[10]

Before concluding this section some remarks should be

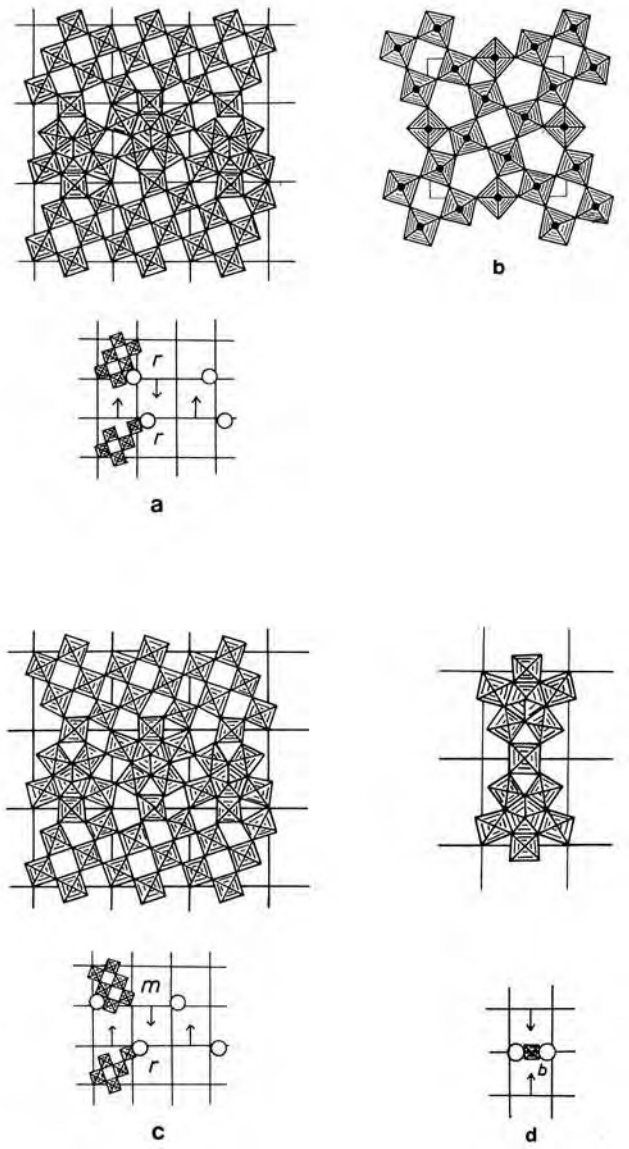

Fig. 2. a) Intergrown structures of the $LiNb_6O_{15}F$- and ReO_3-type. Below a schematic representation is given, where the rings denote pentagonal tunnels. The orientation of the ReO_3 net is the same throughout (r or m). b) A structure model of an empty, tetragonal tungsten bronze projected along the c-axis. c) As a), but with twin-related ReO_3 nets indicated by r and m; d) two PCs joined through triangle links to one octahedron whose orientation is b.

made about the structures of $LiNb_6O_{15}F$[8] (Fig. 5a) and $NaNb_6O_{15}F$[14] (Fig. 5b). In both types of structure the top of one PC is linked to the bottom of another, resulting in

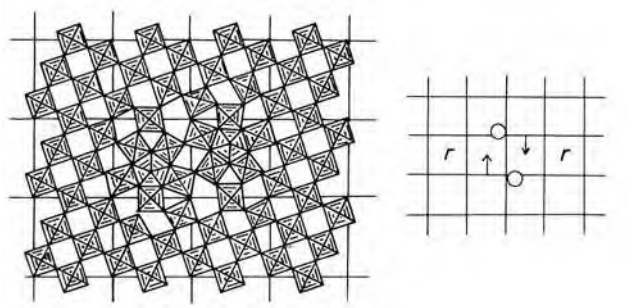

Fig. 3. A unit cell of $LiNb_6O_{15}F$ in a matrix of ReO_3 type in r orientation.

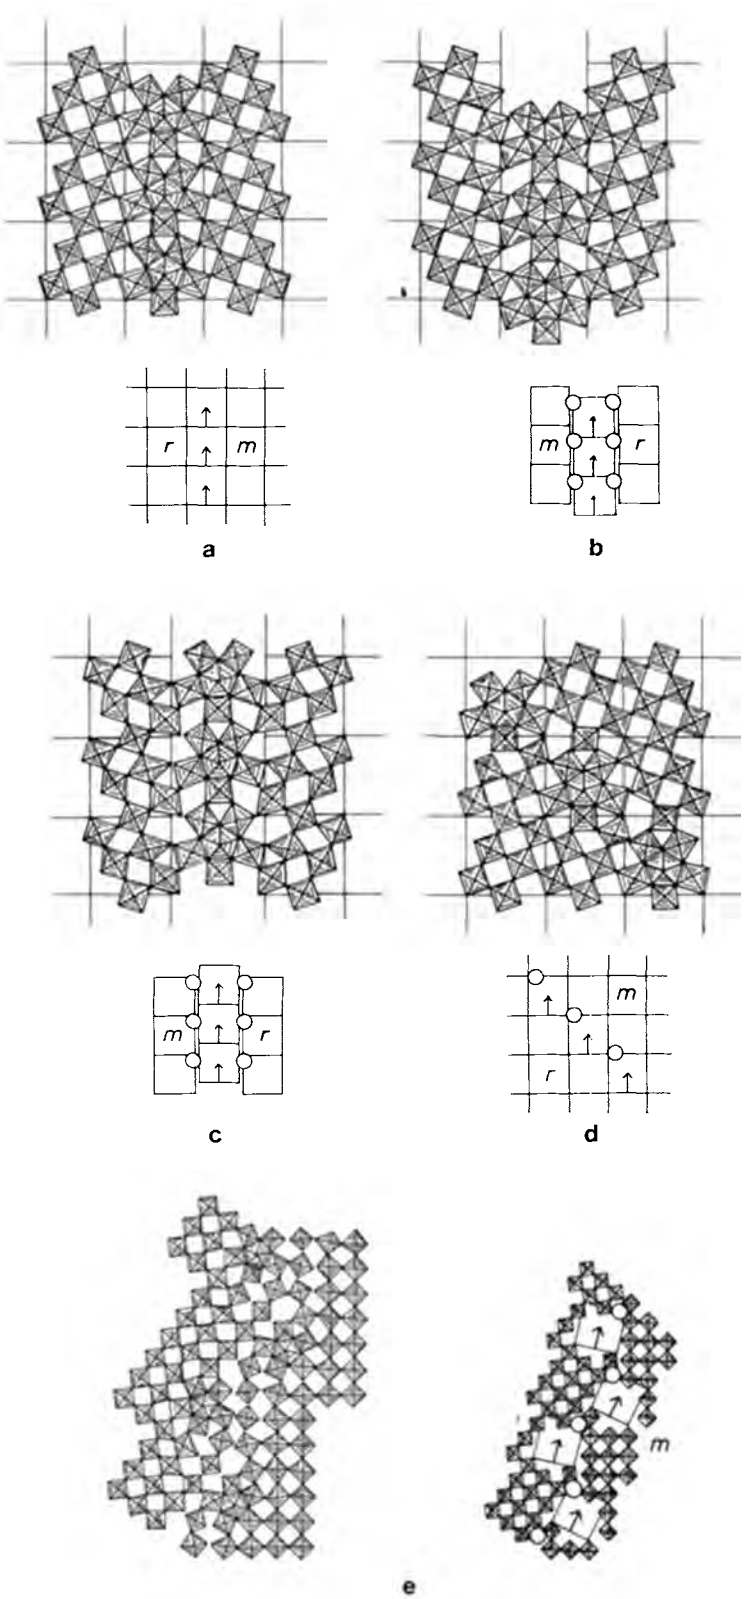

Fig. 4. Models of twin-related ReO_3-type structures with PCs. a)-c) PCs joined by triangle links; d) and e) show discrete PCs. A defect observed in $4\,Nb_2O_5 \cdot 22\,WO_3$ is shown in e).

straight slabs of triangle-linked PCs. In $LiNb_6O_{15}F$ the right edge of a square in such a slab is linked to the right edge of a square in another slab, the two slabs being antiparallel. The latter are linked among themselves in a diamond-like fashion. The idealized orthorhombic unit cell has the cell parameters[4]

$$a = 4a_R - 2c_R, \quad b = b_R \quad \text{and} \quad c = a_R + 2c_R$$

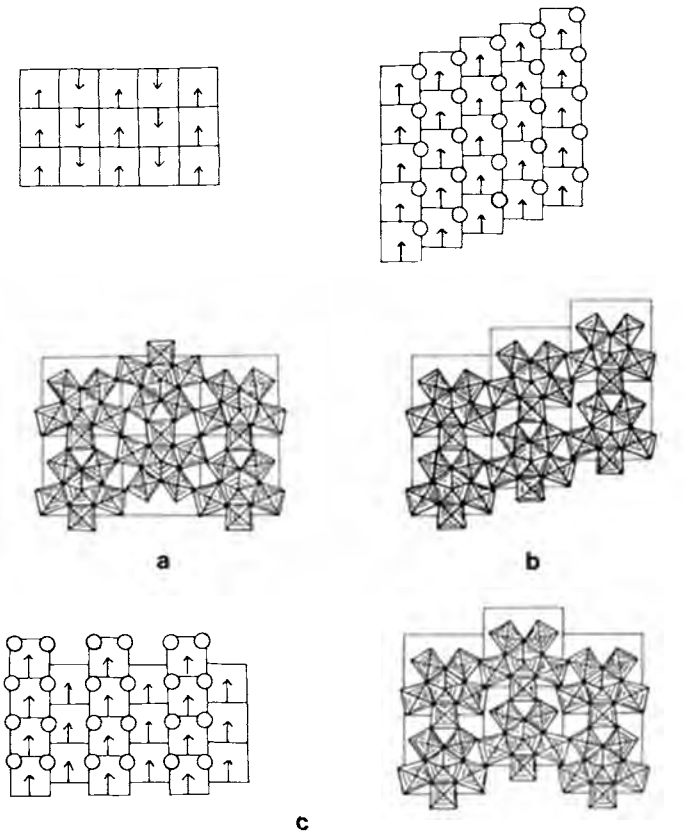

Fig. 5. Models of framework structures of a) $LiNb_6O_{15}F$, b) $NaNb_6O_{15}F$, and c) hypothetical AM_6X_{16}. Rings denote pentagonal tunnels.

(The subscript R denotes vectors of the ReO_3 subcell.) In $NaNb_6O_{15}F$ the slabs are parallel but displaced by a third of a square edge and the PCs thereby joined via a triangle link. The slabs are arranged in an abcabc... sequence. The cell parameters of the idealized monoclinic unit cell are

$$a = a_R, \quad b = 2(2/3)b_R + 1/3\,c_R \quad \text{and} \quad c = 2/3\,b_R - 3(2/3)c_R$$

In the real structure, however, the PCs are so assembled that orthorhombic symmetry is observed. It is obvious that an abab... arrangement should be possible (Fig. 5c); however, an example of such a structure has not yet been reported. The actual axial ratios are given in Table 1 and are commented on in Section 3.

3. Illustrating Structures with Pentagonal Columns

The present state of our knowledge of PCs and the ReO_3-type structure allows us to model PC-containing structures by means of the symbolism described above. We simply put together the symbols for PCs and octahedra in *m*-, *r*- or *b*-orientation. No attempt will be made to adjust the structures so as to make the polyhedra fit together properly. In most cases the adjustment needed would be

small. (When preparing the figures in this paper a template of a PC was often used. The fit between PCs or between a PC and an octahedron may therefore not always be perfect. In Figures 4e, 5b and 5c, for instance, the tunnels with a pentagonal cross-section are made up of octahedra with common corners. The actual, small misfit is in a way a measure of the adaptability of the PC to various surroundings.)

Let us now survey the structures according to the number N of octahedra per unit cell that are not part of a PC, and relate this to the number of PCs present. Let M be the number of metal atoms and P the number of PCs per unit cell. With six metal atoms in an ordinary PC, there are then $M-6P$ non-PC octahedra and $N=(M-6P)/P$ non-PC octahedra per unit cell. $M-P$ is the total number of octahedra per unit cell.

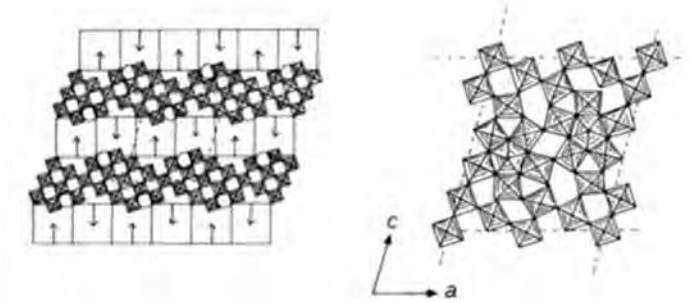

Fig. 6. Structure models of $W_{12}O_{34}$.

Figure 6 shows a model of the structure of $W_{12}O_{34}$.[11] With $M=24$ and $P=2$, N equals 6. The ideal structure has the cell parameters

$$a=4a_R+2c_R,\quad b=b_R\quad\text{and}\quad c=-a_R+5c_R$$

It can be regarded as an ordered intergrowth of structures of the $LiNb_6O_{15}F$- and ReO_3-type.[3] The structures of $4\,Nb_2O_5\cdot 50\,WO_3$, $N=23$, and $4\,Nb_2O_5\cdot 22\,WO_3$, $N=9$, are built analogously, as is immediately obvious from similarities in the unit cell parameters (see Table 1). All non-PC octahedra have the same orientation. The idealized unit cell parameters are[10]

$$a=12a_R-4c_R\quad\text{or}\quad 6a_R-2c_R,\quad b=b_R\quad\text{and}\quad c=2a_R+4c_R$$

Figures 7 and 8 show models of the structures of $2\,Nb_2O_5\cdot 7\,WO_3$, $N=5$,[15,16] and Mo_5O_{14}, $N=4$,[17] respectively. In both models non-PC octahedra are present in roughly two distinct orientations (r and m). Both structures have tetragonal symmetry and contain areas of TTB type, i.e. regions of a TTB unit cell with empty square and pentagonal tunnels. The structure of $2\,Nb_2O_5\cdot 7\,WO_3$ is an ordered intergrowth of structures of $LiNb_6O_{15}F$, ReO_3, and (empty) TTB. Its idealized unit cell parameters are[15]

$$a=6a_R+2b_R,\quad b=-2a_R+6b_R\quad\text{and}\quad c=c_R$$

The structure of Mo_5O_{14} also contains empty units of TTB, related to each other through a mirror plane. In the

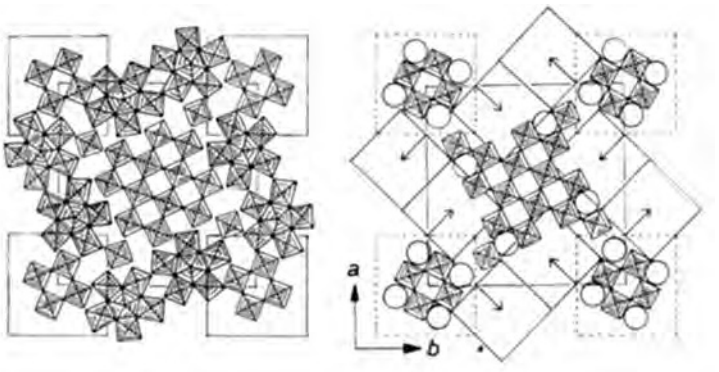

Fig. 7. Structure models of $2\,Nb_2O_5\cdot 7\,WO_3$. Note the areas of TTB structure type at the corners of the projected tetragonal unit cell.

idealized structure, the angle between the units is 2 arctg 1/2. The idealized unit cell has the lattice constants (cf. [4])

$a=6a_p$, $b=6b_p$ and $c=c_p$

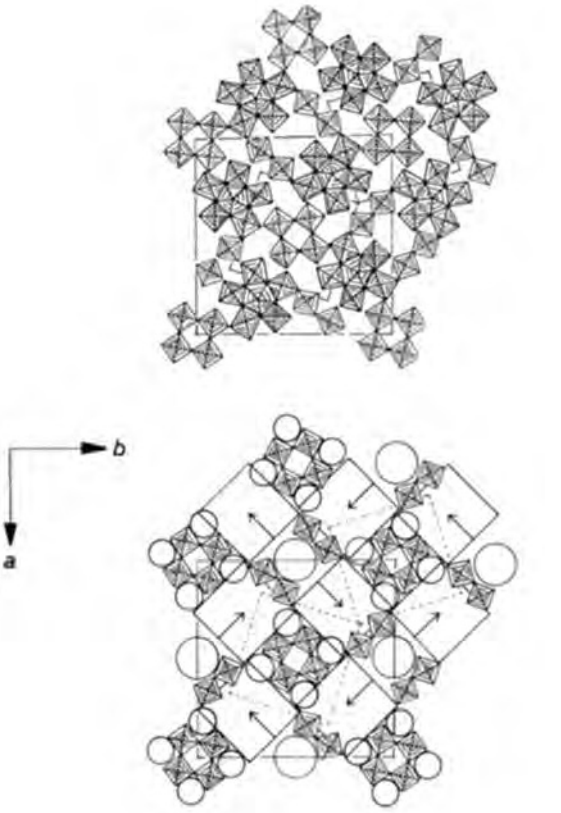

Fig. 8. Structure models of Mo_5O_{14}. Note the areas of TTB structure type at the corners and center of the projected tetragonal unit cell, and the diamond-like linked octahedra at the top of the PCs.

Note the large six-sided tunnels in Mo_5O_{14}.

In $W_{18}O_{49}$, $N=3$[1] (Fig. 9) all non-PC octahedra have the same orientation. According to the model, the structure can be described as built of slices; that is, of ordered intergrowths of the $LiNb_6O_{15}F$- and ReO_3-type structures. The slices are parallel to (100) of $W_{18}O_{49}$; the width of one slice is two squares or PCs. Between the slices, which are held together by edge-linked PCs, there are large, six-sided

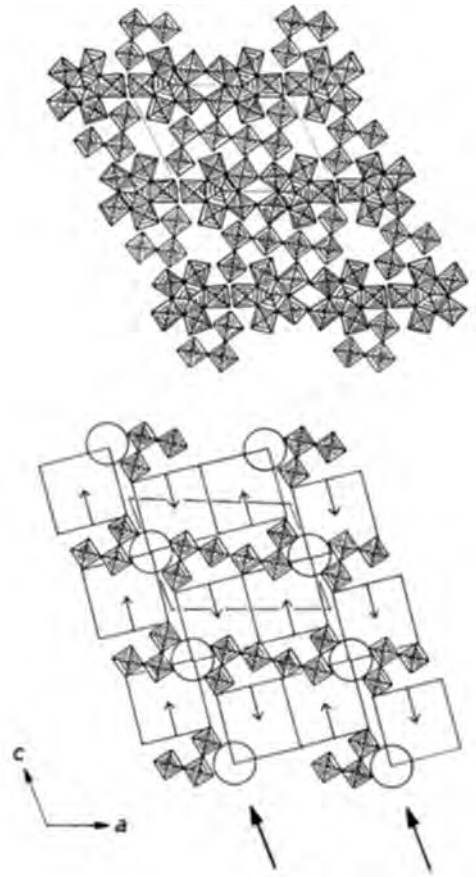

Fig. 9. Structure models of $W_{18}O_{49}$. The arrows (at the bottom) mark the width of a slice, which is made up of an $LiNb_6O_{15}F$-type structure intergrown with WO_3. The slices are parallel to (100). There are large, empty, six-sided tunnels running in the [010]-direction. The slices are held together by PCs united through edge links at the corners of the projected unit cell.

holes. The idealized monoclinic unit cell has the parameters

$$a = 5a_R + c_R, \quad b = b_R \quad \text{and} \quad c = -2a_R + 3c_R$$

In $Mo_{17}O_{47}$, $N = 2.5$[18,19] (Fig. 10), the non-PC octahedra are present in three orientations *m*, *b* and *r*. As in $W_{18}O_{49}$ the structure is built of slices parallel to (010) of $Mo_{17}O_{47}$, the slices being an ordered arrangement of PCs and MoO_6 octahedra. The width of a slice is one PC. Between the slices there are seven-sided holes; the slices are held together by edge-linked PCs. The idealized orthorhombic unit cell has the parameters

$$a = 4a_R + 4b_R, \quad b = -4a_R + 4b_R \quad \text{and} \quad c = c_R$$

Figure 11 shows a model of $Nb_8W_9O_{47}$, $N = 2.5$.[20] It is built of units of the type already discussed in Section 2 (Fig. 2d): two PCs are linked by a common MO_6 octahedron. These double PCs are then joined to each other in a diamond-like fashion. The result is a zig-zag arrangement of PCs forming slices which run parallel to (010). Between the slices there are further pentagonal holes and non-PC octahedra in *r*- and *m*-orientations. The idealized orthorhombic unit cell has[4]

$$a = 3a_R - b_R, \quad b = 3(a_R + 3b_R), \quad \text{and} \quad c = c_R$$

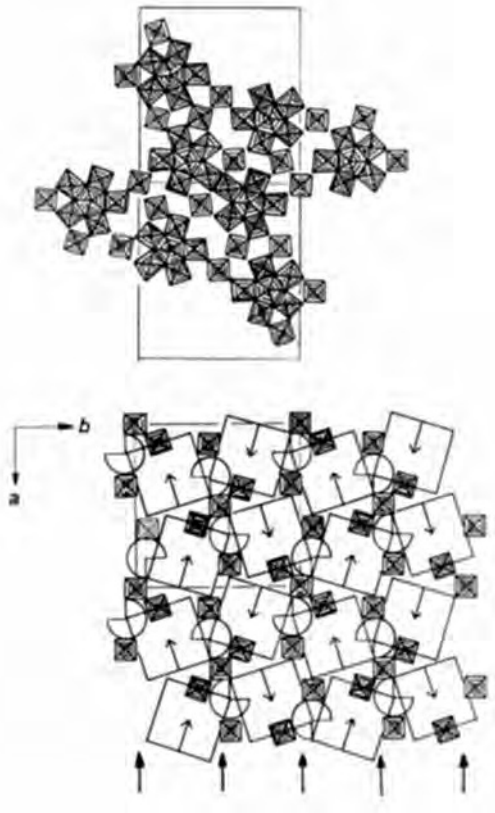

Fig. 10. Structure models of $Mo_{17}O_{47}$. The arrows (at the bottom) mark the width of a slice made up of PCs and MoO_6 octahedra. The slices are parallel to (010). Between them are seven-sided tunnels running in the [001]-direction. The slices are held together by PCs united through edge links at the midpoints of the *a* and *b* axes of the projected unit cell.

$Na_7Nb_{15}W_{13}O_{80}$, $N = 1$,[21] (Fig. 12a) is built of straight slabs consisting of PCs joined by a triangle link, just the same as in $LiNb_6O_{15}F$ and $NaNb_6O_{15}F$. The structure is

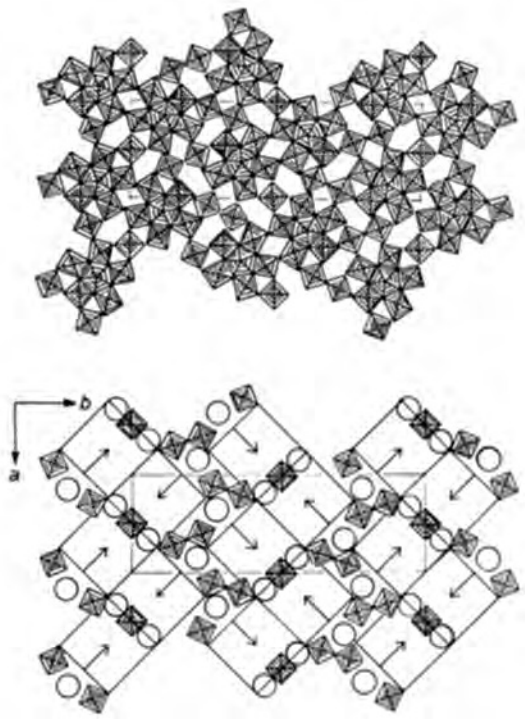

Fig. 11. Structure models of $4\,Nb_2O_5 \cdot 9\,WO_3$. Note the occurrence of two PCs united by triangle links to the same octahedron (cf. Fig. 2d).

analogous to that of lithium niobate; adjacent slabs are antiparallel. Non-PC octahedra in *r*- and *m*-orientation link the slices to each other. Between the slices tunnels with S-shaped cross-section are created, in which the sodium atoms are accomodated. A model commensurate with the ReO_3-type structure can be shown to have orthorhombic symmetry with

$$a = 6(4/5\,a_R + 2/5\,c_R), \quad b = 2(a_R + 2\,b_R), \quad \text{and} \quad c = c_R$$

Figure 12b shows a HREM image of the crystal structure of the isotypic potassium compound. The PCs are clearly recognizable, whereas the potassium atoms in the tunnels are hardly discernible.

Figure 13 surveys the various arrangements of PCs and MX_6 octahedra in the structures discussed in this section. Note that each PC is associated with N non-PC octahedra whose orientation may be *r*, *m* or *b*. In our description of the structures we find with one exception that the top part of a PC is triangle-linked either to an octahedron of another PC, as in Figures 5a and 12a, or to a non-PC octahedron. The exceptional case is the Mo_5O_{14} structure, where the top of a PC forms a diamond-like link with two non-PC octahedra (Fig. 8). The rest of the PC is bonded to four other non-PC octahedra by triangle links (Fig. 13e). This results in a structure with PCs completely separated from each other—a unique feature of the Mo_5O_{14} crystal structure. Similarly isolated PCs have been observed as defects (see Fig. 4e).

Table 1 lists some calculated cell parameters as a function of d together with the respective values observed in real structures. In order to compare these values the calculated and observed ratios of the parameters are also given. Note that in the structures discussed here there is always an observed short axis (3.8 to 3.9 Å) which corresponds to a diagonal in an MX_6 octahedron. The observed ratios are in most cases lower than the calculated ones. In general, however, the agreement seems fairly good; the largest deviations are found for $Mo_{17}O_{47}$ (*b* axis), $W_{18}O_{49}$ (*a* axis), $LiNb_6O_{15}F$ (*a* axis), and Nb_2WO_8 (*c* axis). The first and second structures are special cases in the sense that they contain edge-linked PCs with a short M–M bond across the common octahedron edge. This is likely to shorten the *a* axis of $W_{18}O_{49}$, in which the W–W bonds are parallel to this axis. The same is true in the case of $Mo_{17}O_{47}$, although the Mo–Mo bond is not quite parallel to the *b* axis. (Note also that the calculated unit cell volume (Table 1) is greater than $(M-P)d^3$ for these two compounds (see below).) As regards $LiNb_6O_{15}F$, the *a* axis is shorter than the corresponding distance in an ReO_3 structure, implying a more dense atomic arrangement and an ensuing stable configuration of the PC.

In our discussion of the geometric properties of a PC we have assumed that the volume of five octahedra and a pentagonal bipyramid equals that of five octahedra of an ReO_3-type structure (cf. Figs. 1c,d). We may now test the validity of this assumption in the following way: Given a real structure composed of PCs only or PCs and ReO_3-type units, we want to consider an average MX_3 unit cell of ReO_3 type whose volume is V_{av}. This is accomplished by dividing the unit cell volume (V) of the real structure by

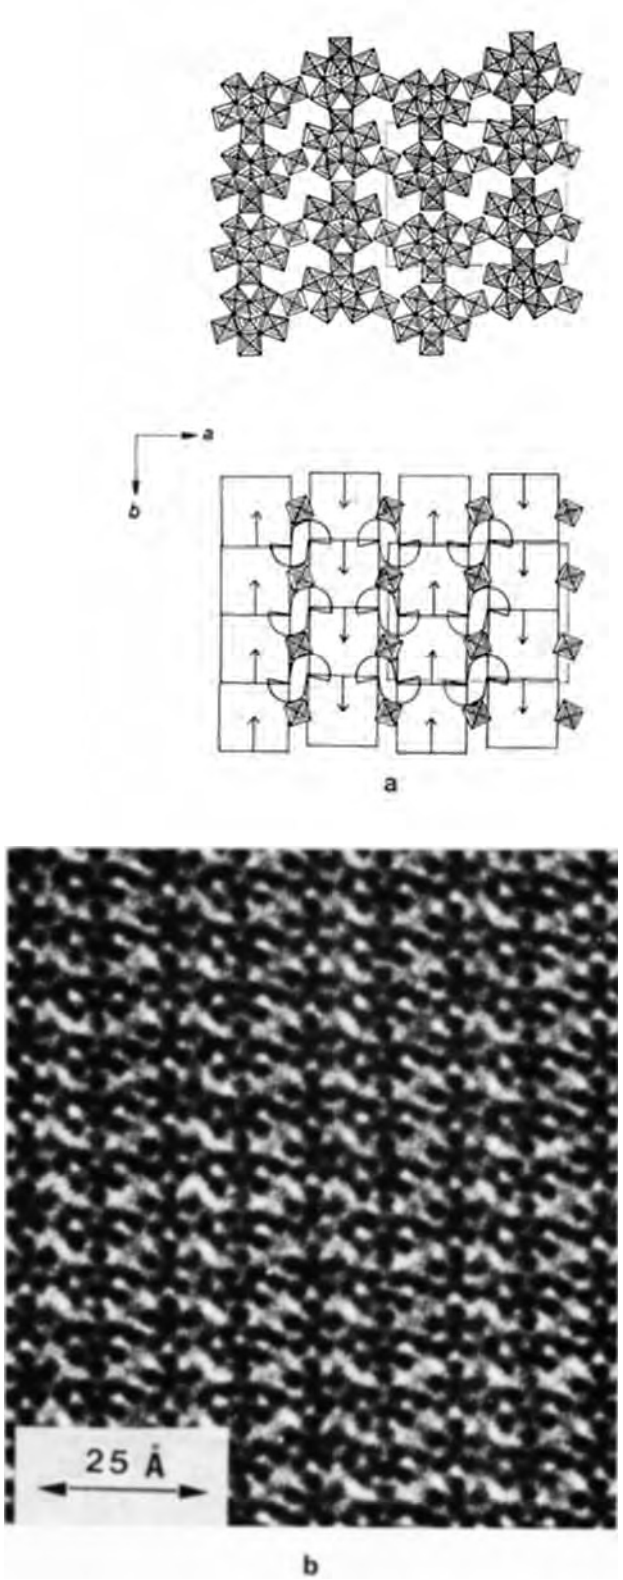

Fig. 12. a) Structure models of $Na_7Nb_{15}W_{13}O_{80}$ (sodium atoms not shown). b) HREM image of a thin crystallite of a potassium compound, isotypic with $Na_7Nb_{15}W_{13}O_{80}$. JEOL JEM 200CX microscope, accelerating voltage 200 kV, defocus ≈ -500 Å, objective-aperture 0.42 Å^{-1}. The electron beam is parallel to the (short) *c* axis.

the number M of M atoms in the unit cell, excluding those in the center of the pentagonal bipyramids. With the symbols used above this gives $V_{av} = V/(M-P)$ which has been listed in Table 1. The V_{av} values range from 54.6 Å^3 ($W_{18}O_{49}$) to 63.7 Å^3 ($Na_7Nb_{15}W_{13}O_{80}$). The values should

Survey of structure units involved in some PC-containing compounds: a) $4Nb_2O_5 \cdot 50WO_3$; b) $4Nb_2O_5 \cdot 22WO_3$; c) $W_{12}O_{34}$; d) $2Nb_2O_5 \cdot 7WO_3$; e) Mo_5O_{14}; f) $W_{18}O_{49}$; g) $Mo_{17}O_{47}$; h) $4Nb_2O_5 \cdot 9WO_3$; i) $Na_7Nb_{15}W_{13}O_{80}$. Small rings denote pentagonal tunnels and large rings six-sided tunnels. A three-quarter ring denotes a seven-sided tunnel in g) and part of an S-shaped tunnel in i).

be compared with the corresponding unit cell volumes of ReO_3 type, or related structures. Thus, the larger niobium atom in NbO_2F and $NaNbO_3$ leads to volumes of 59.4 Å^3 and 59.5 Å^3 ($V/8$), respectively, while the smaller tungsten atom in WO_3 results in $V/4 = 52.8$ Å^3.[22, 23, 16] The deviating structure is $Na_7Nb_{15}W_{13}O_{80}$. It contains tunnels with S-shaped cross-section, which apparently make the structure quite spacious.

4. Some Defects in Structures with Pentagonal Columns

This section deals with some structural defects reported to exist in some of the compounds discussed above. Thus, Figure 14 shows domains of $2Nb_2O_5 \cdot 7WO_3$ separated by a domain containing unit cells of $4Nb_2O_5 \cdot 9WO_3$.[15] Note the six PCs arranged as in the $LiNb_6O_{15}F$ structure that traverse the domain in between, starting and ending in the domains of $2Nb_2O_5 \cdot 7WO_3$, virtually keeping them together.

Some interesting defects have been observed in $W_{18}O_{49}$.[24, 25] Figure 15a shows a model of a defect parallel to (100) in $W_{18}O_{49}$. The ordinary diamond-like link between two PCs has been replaced by a corner link at the same time as two further octahedra have been introduced into the structure. Figure 15b shows a model of an expanded defect of the same type. The latter is from a slightly oxidized sample of $W_{18}O_{49}$, as is also the defect illustrated in Figure 16. Its stoichiometry is W_9O_{25}, with Z (the number of formula units) = 2 and N (defined above) = 3, intergrown with $W_{18}O_{49}$. The W_9O_{25} structure can be regarded as an ordered intergrowth of the $LiNb_6O_{15}F$- and the ReO_3-type structures (similarly to the structure of $W_{12}O_{34}$). Figure 16 clearly demonstrates that there exists a CS relationship between W_9O_{25} and $W_{18}O_{49}$, the CS proc-

Table 1. Calculated and observed unit cell parameters in some copounds M_mX_n containing pentagonal columns (PCs).

Z = Number of formula units per unit cell

ess taking place parallel to the (100) plane of $W_{18}O_{49}$. The W_9O_{25} structure contains two pentagonal tunnels. They are formed by octahedra, two of which are shared between the two tunnels.

The $Mo_{17}O_{47}$ structure might be discussed from a similar point of view. We must then assume a hypothetical structure of the kind shown in Figure 17a. Its stoichiometry is Mo_9O_{25}, $Z=4$ and $N=3$; the unit cell is indicated (broken lines). Due to a CS process the following "reaction" takes place:

$$Mo_{36}O_{100} = Mo_{34}O_{94} + 2\,MoO_3$$

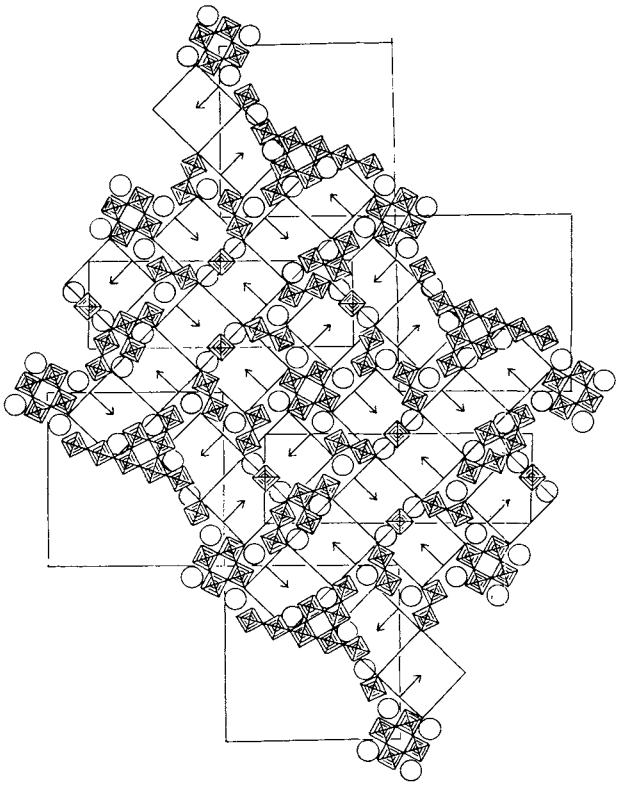

Fig. 14. Model of two domains (upper right and lower left) of $2\,Nb_2O_5 \cdot 7\,WO_3$ (see Fig. 7), in phase with each other but separated by a boundary of $4\,Nb_2O_5 \cdot 9\,WO_3$ unit cells (see Fig. 11). After the interpretation given in [15].

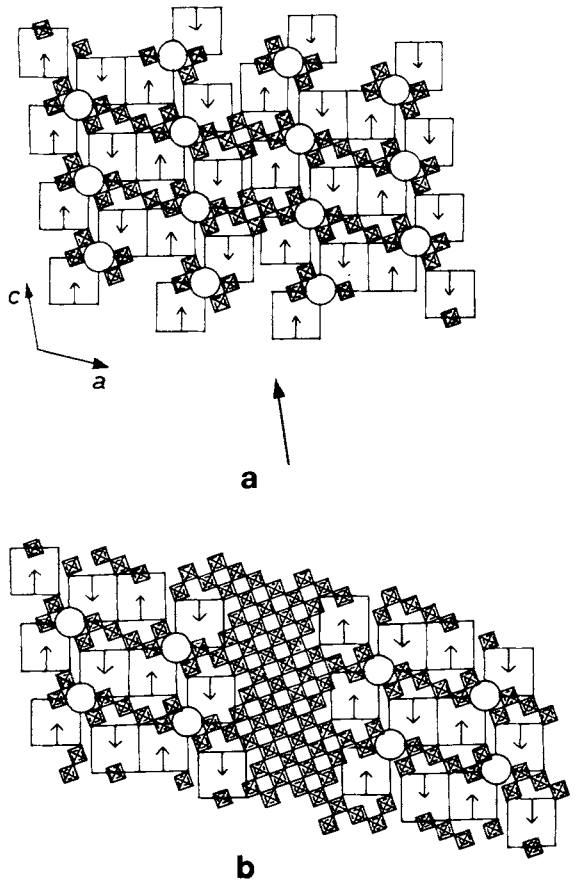

Fig. 15. a) Model of a defect (indicated by an arrow below the figure) parallel with (100) in $W_{18}O_{49}$ (cf. Fig. 9); b) Model of a wider defect of WO_3 type in $W_{18}O_{49}$. The defect is of the same kind as that shown in Fig. 15a.

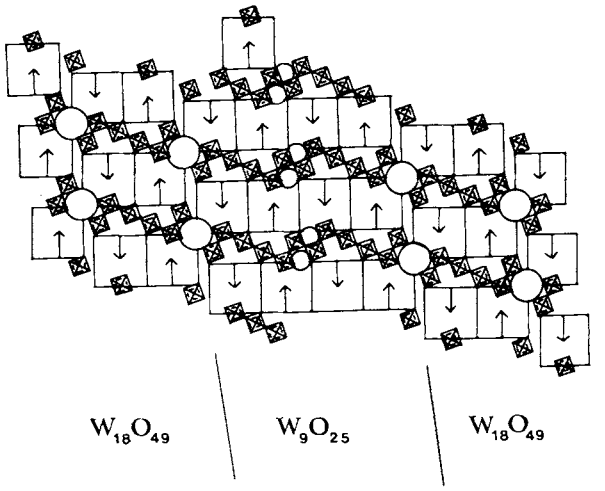

Fig. 16. Model of a structural defect in slightly oxidized $W_{18}O_{49}$. It shows an intergrowth of W_9O_{25} (in the center of the model) and $W_{18}O_{49}$. Note the pentagonal tunnels with two common octahedra in the W_9O_{25} structure.

The structural changes are modeled in Figure 17b. *Hyde* et al.[26] discuss a similar process when relating Mo_5O_{14} to $Mo_{17}O_{47}$.

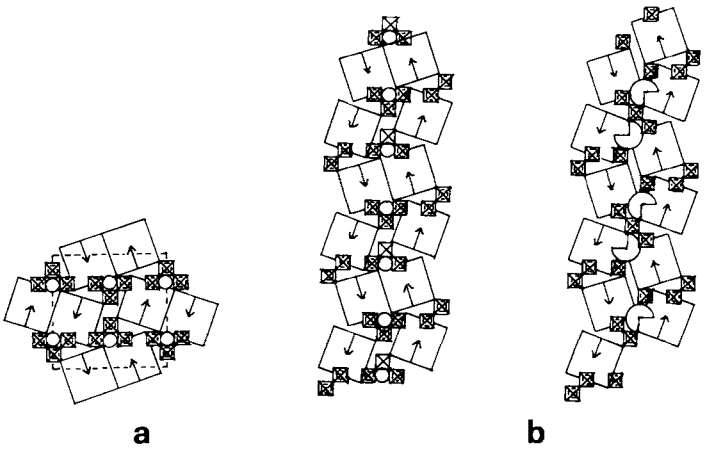

Fig. 17. a) Model of the hypothetical structure Mo_9O_{25}; b) a CS process converts the hypothetical Mo_9O_{25} (left) into $Mo_{17}O_{47}$ (right). The non-striated octahedra (left) are eliminated in the process.

5. Intergrowth of Pentagonal Columns with the ReO_3-Type Structure

It is apparent that two main structure types can be conceived when we consider the possibilities of intergrowths between PCs and the ReO_3-type structure. The first one has PCs joined by a triangle link in the direction of the arrow used in our symbolism. These slabs of PCs are straight and may be regularly interspersed with octahedra. We may interpret the structure of $Na_7Nb_{15}W_{13}O_{80}$[21] with $N=1$ in this way. Similar structures with $N>1$ can easily be imagined.

The second type of structure can be formed by joining slabs of PCs joined through a diamond-like link perpendicular to the direction of the arrow. MO_6 octahedra forming an ReO_3-type net may be regularly interspersed be-

tween these corrugated slabs.[3] This arrangement is found, e.g., in the structures of $W_{12}O_{34}$ and W_9O_{25}.

It is interesting to note that again two types of structures are possible, depending on the mutual arrangement of the slabs. When we project one slab onto a neighboring one in a direction parallel to an arrow we find that there is a more or less exact overlap of PCs (Figs. 18a, b). The emerging structure type depends on whether parallel or antiparallel PCs show the best overlap. Thus, in $4\,Nb_2O_5 \cdot 22\,WO_3$ and in the W_9O_{25} defects found in $W_{18}O_{49}$ parallel PCs overlap best, while in $4\,Nb_2O_5 \cdot 50\,WO_3$ and $W_{12}O_{34}$ the antiparallel PCs exhibit this feature. A special case is found in structures with $N=5$. Here the overlap is complete (see Figs. 18c, d). Further structural possibilities arise if *r*, *m* and *b* octahedra are included between the slabs (Fig. 19). Note the topological relationship with the TTB structure (Fig. 19b, bottom).

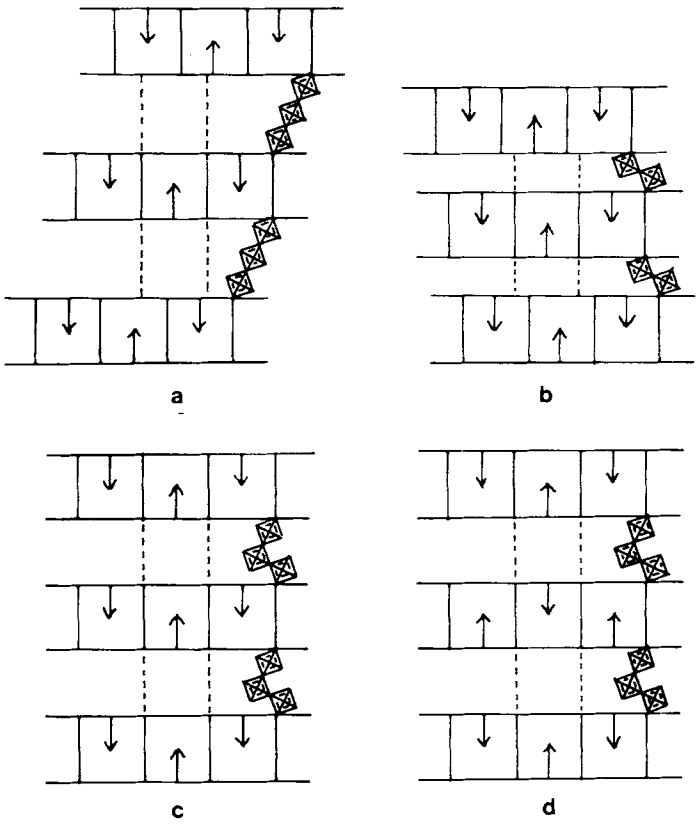

Fig. 18. Models of structures of a) $W_{12}O_{34}$ and b) W_9O_{25}. Indicated projections show best overlap of antiparallel PCs in a), while best overlap of parallel PCs is the case in b). Models of structures with $N=5$ with complete overlap of parallel PCs in c) and of antiparallel PCs in d).

The following observations are noteworthy: Given an intergrowth structure with parallel PCs overlapping, we may gradually decrease the value of N until we get the limiting structure which is that of the $LiNb_6O_{15}F$-type with $N=0$ (cf. Fig. 5a). An intergrowth with antiparallel PCs will give a limiting structure characterized by two PCs having one octahedron in common. So far, such an arrangement has not been reported, but PCs with two octahedra common with two other PCs have been found in $TlNb_7O_{18}$[27] and the isotypic rubidium compound.[28] Structure models are shown in Figure 20.

In concluding this section on intergrowth structures mention should be made of the possibilities of obtaining structures from the hypothetical Mo_9O_{25} structure discussed above (Fig. 17a). Further MoO_6 octahedra may be inserted into the structure, thereby increasing the value of N. No such structures seem to have been reported, however.

6. Some Remarks on the Formation of Pentagonal Columns

In this survey of models of ordered structures and defect structures we note that PCs may exist as isolated entities (Fig. 4e) or, as in Mo_5O_{14} (Fig. 8), surrounded by ReO_3-type elements. More common is the case, however, where PCs are coupled to each other by diamond-like, triangle or

The rings denote pentagonal tunnels. a)-c), bottom: Detailed structural models of the three structures shown at the top. Note the TTB type structure in b) (indicated by a unit cell).

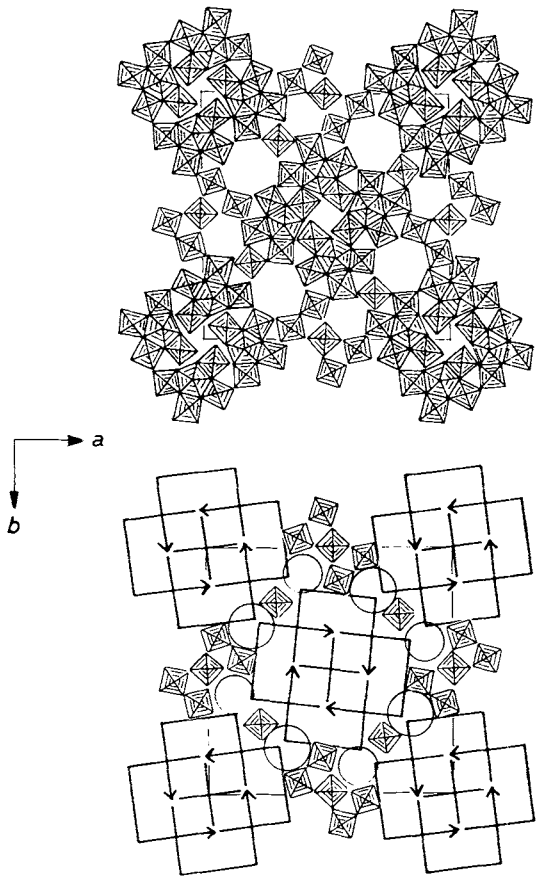

Fig. 20. Structure models of $TlNb_7O_{18}$. Note the ensembles of four PCs with common octahedra and the occurrence of six- and seven-sided tunnels in the structure.

edge links. As regards the formation of structures of this kind, it seems likely that a crystal grows in a matrix of composition MX_{3-x} to form an ReO_3-type structure with occasional dislocations in the form of PCs (and/or CS structures).[6, 29] Actually, a PC seems to be a very stable configuration of metal atoms and anions X. Due to its geometry, it is capable of attaching to itself other PCs or smaller or larger parts of an ReO_3-type structure, depending on the overall stoichiometry of the reactants. In the process, defects or ordered structures are created. In this connection it should be pointed out that the structures of $LiNb_6O_{15}F$ and $NaNb_6O_{15}F$ are examples of twinning on the unit cell level.[30] In Figure 21a a ReO_3-type structure is regularly repeated on $(2\bar{1}0)_R$. The twin blocks are $2.5d$ wide, measured along $[100]_R$. The resulting $LiNb_6O_{15}F$-type framework structure can then be symbolically written as

2.5, 2.5, 2.5, 2.5, ...

with a repeat distance of $5d$.

The structure of $NaNb_6O_{15}F$ can be derived analogously (Fig. 21b). Here the twin blocks are different, and the structure can be written as

1, 1.5, 1, 1.5, 1, 1.5, ...

The repeat distance is again $5d$. Note the angle of 2 arctg 1/2 between diagonals of octahedra in the twin sets of ReO_3 type. The hypothetical structure shown in Figure 5c can be written as

1, 1.5, 1.5, 1, 1, ...

also with a repeat distance of $5d$.

It has been emphasized that twin planes contain coordination polyhedra which are not found in the parent structure.[30] In fact, it can be stated that the PC is formed through a chemical twinning operation on the ReO_3 structure. Thus, we find the PCs centered on twin planes in $LiNb_6O_{15}F$ and $NaNb_6O_{15}F$. The coordination polyhedra

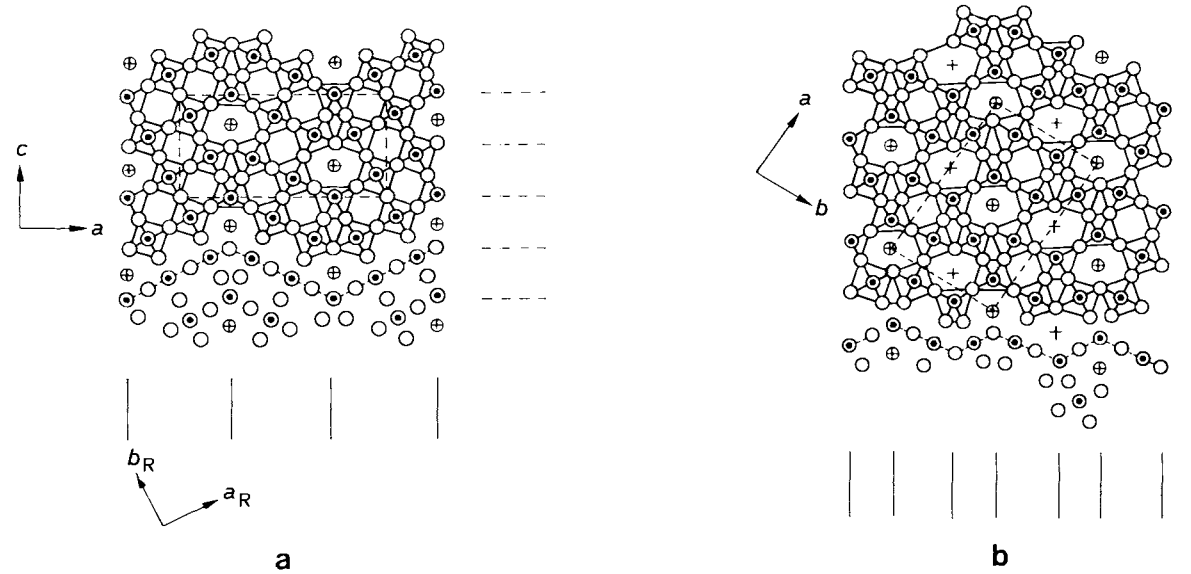

Fig. 21. The framework structures of octahedra of a) $LiNb_6O_{15}F$ and b) $NaNb_6O_{15}F$ as obtained from twinning of a parent structure of ReO_3 type. Small rings denote oxygen/fluorine, circled dots denote niobium atoms. A set of twin planes perpendicular to the plane of projection is indicated beneath the figures. The unit cells are shown. Note the glide planes indicated at the right in a). The orientation of an ReO_3 type subcell is also given in a). The center of a PC is marked with a crossed ring. The sodium positions in $NaNb_6O_{15}F$ are shown by crosses.

of the sodium atoms in the latter are also situated on these planes. The atomic arrangements shown in Figure 4 can also be easily derived through a chemical twinning operation on the ReO_3 structure.

As shown in Figure 21a, the MX_6 framework structure of $LiNb_6O_{15}F$ exhibits a set of *a*-glides perpendicular to the plane of projection. If every other glide plane is replaced by a reflection plane, the $LiNb_6O_{15}F$ structure converts into that of a TTB structure (Fig. 2b). It has been shown that the latter structure can be derived from the ReO_3-type structure through a chemical fourling operation, which is characterized by two sets of twin planes perpendicular to each other and circumscribing the fourling unit.[31] The idealized TTB unit cell dimensions have been derived from those of ReO_3.[4,32] The geometrical relation between the TTB and the $LiNb_6O_{15}F$ structures has been noted by *Lundberg* et al.[3] The intergrown structures illustrated in Figures 2a, 2c, and 3 may also be treated as chemical twinning.[33]

7. Conclusions

This paper describes a simple and general method for illustrating the structural relationships between the pentagonal column and the ReO_3-type structure. To the best of our knowledge all hitherto known compounds containing PCs and units of the ReO_3 type can be described in this way. The method enables us to discuss, in some detail, the similarities between PC-containing structures. It aids in their classification and in the search for new compounds with interesting structural features. It may also be very useful in the interpretation of lattice images of defects in such compounds.

The author wishes to thank Professors A. Magnéli and L. Kihlborg and Drs. M. Lundberg, M. Nygren and M. Sundberg for valuable discussions.—This study was supported by the Swedish Natural Science Research Council.

Synthesis and Redox Properties of Compounds with Several Separated Anthracene Electrophores**

By *Jürgen Fiedler, Walter Huber,* and *Klaus Müllen**

The through-space interaction of separated π-systems that are partly doped with electrons is of interest for theories of bonding[1] and for the material sciences.[2] The model dianthryl compounds **1a–c** can serve as efficient electron storage devices;[3] their ions exhibit π-system interactions[4] that are similar to those in the multilayered phanes.[5] As part of our studies directed toward the preparation of "polyelectrophoric" hydrocarbons,[6] we describe here the synthesis and reduction of the new compounds **1d**, **2a**,**b**, and **3**. Two questions arise: Is the electronic interaction between the anthracene moieties in **1** also possible for longer bridges (n = 11)? Are the electron-transfer properties of **1a–c** also evident in the higher homologues, e.g., **3**, with more than two redox groups?

1,11-Di(9-anthryl)-3,6,9-trioxaundecane **2a**[7] was prepared by reaction of the trioxaundecyleneditoluenesulfonate **7b** with the species **5** (2 equiv.) (obtained from 9,10-dihydroanthracene and *n*BuLi), followed by dehydrogenation of the tetrahydrodianthryl system.[8] The X-ray structure analysis of **2a** reveals a close approach of the anthracene moieties (preference of the *gauche* over the *anti* conformations of the CC bonds in the chain[9, 10]).[11] The C-9/C-9′ separation (ca. 10 Å) is significantly smaller than that expected for polymethylene chains with the CC *anti* conformation.

The synthesis of the hydrocarbon **1d**, which corresponds to the polyether **2a**, was achieved in an analogous manner. On account of the poor accessibility of **7**, n = 5, **2b** was prepared from **7a** and 2-(9-anthryl)ethoxide. In analogy to the synthesis of **1d** and **2a**, 9,10-bis[3-(9,10-dihydro-9-anthryl)propyl]anthracene **4** was prepared from **5** and 9,10-bis(3-bromopropyl)anthracene **6c**[12] (tetrahydrofuran, −80 °C) in 83% yield. Deprotonation of **4** (*n*BuLi/tetramethylethylenediamine, cyclohexane, 80 °C) followed by oxidation with cadmium chloride afforded the product **3**, which contains three separated anthracene moieties.[13]

1 a,b,c,d: n = 2,3,4,11 — **2** a,b: n = 3,4 — **3**

4 — **5** — **7** a,b: n = 3,4 — **6** a,b,c: X = H, OH, Br

The new compounds **1d**, **2a**,**b**, and **3** were reduced with alkali metals to the paramagnetic radical anions as well as to the polyanions. The distribution of spin density among the anthracene moieties in the radical anions (localization in one fragment or delocalization over all fragments) serves as an indication of the extent of through-space interaction. The most important experimental criteria are the size and multiplicity of the hyperfine coupling constants determined by ESR or ENDOR spectroscopy.

The coupling constants of the radical anion **1d**$^{\odot\ominus}$/$K^{\oplus}$ [a_H [mT] = 0.261 (H-1,8), 0.136 (H-2,7), 0.168 (H-3,6), 0.282 (H-4,5), 0.510 (H-10), 0.250 (α-CH_2), 0.029 (β-CH_2)] are the same as those in the 9-ethylanthracene radical anion. The spin density remains localized in one of the π-systems, as expected from the separation of the anthracene moieties. This result is independent of temperature and is valid for the solvent system dimethoxyethane (DME)/hexamethylphosphoric triamide (HMPT) as well as for 2-methyltetrahydrofuran (MTHF). As expected, solvent-separated ion pairs are present in DME/HMPT; MTHF, on the other hand, favors the formation of contact ion pairs.[3] In contrast, the hyperfine structure of the ESR spectrum of **2a**$^{\odot\ominus}$ depends markedly on the solvent, counterion, and temperature. The potassium salt proved to be "spin-localized" in MTHF. With lithium in MTHF or potassium in DME, however, the ESR line shapes were found to be reversibly dependent on temperature. At 20 °C, only a broad, S-shaped signal was observed. This exchange broadening is due to an intramolecular electron transfer between the anthracene moieties (K, DME, 60 °C: $k = 0.54 \times 10^6$ s^{-1}, $E_a = 15 \pm 2$ kJ/mol). The decrease in the electron-transfer barrier in **2a**$^{\odot\ominus}$ in comparison with that for the radical anion of the analogous hydrocarbon **1d** may be due to the helix-like chain conformation and, possibly, to the cation-coordination ability of the oxygen atoms; these factors fa-

vor a position of the counterion between the redox-active groups.[14, 15]

Reduction of **3** in MTHF leads to a radical anion [$K^{\oplus}$, 20°C; a_H [mT] = 0.262 (H-1,4,5,8), 0.155 (H-2,3,6,7), 0.117 (α-CH_2)], the coupling constants of which can be assigned to the protons of the inner anthracene fragment and to the protons of the two neighboring methylene groups. The coupling constants correspond to those in the radical anions of 9,10-dialkylanthracenes.[3] Under conditions that favor a strong interaction within the ion pair, the spin density of $\mathbf{3}^{\odot\ominus}$ remains localized in the central anthracene π-system.

In DME/HMPT (−85°C), $\mathbf{3}^{\odot\ominus}/K^{\oplus}$ exhibits only very small coupling constants (a_H [mT] = 0.02, 0.04, 0.06, 0.09, 0.11, 0.16). The largest of these hyperfine constants is less than one-third of the coupling constants of H-10 in $\mathbf{1d}^{\odot\ominus}$. On the time-scale of measurement, the spin density is delocalized over all the anthracene fragments of $\mathbf{3}^{\odot\ominus}$—a situation that, under the conditions of solvent-separated ion pairs, was also found for the dianthryl systems $\mathbf{1a}$–$\mathbf{1c}^{\odot\ominus}$.

Whereas in solution the primary ESR spectra of $\mathbf{3}^{\odot\ominus}$ are observed, the ESR spectra of triplet diradicals are observed in glassy rigid solutions; the latter can be assigned to the dianion $\mathbf{3}^{2\ominus}$. The zero-field splitting D measured in MTHF glass is 6.5 mT and agrees with that of the triplet dianion $\mathbf{1b}^{2\ominus}$.[3] This finding supports a structure with one electron in a terminal and one in the central anthracene moiety. In DME/HMPT glass two overlapping triplet-radical spectra are found (D = 6.5 and 9.2 mT); two structures are formed,[16] one of which agrees with the dianion structure also present in MTHF.

Upon further reduction, **1d** is converted into a stable tetraanion, the identity of which is established by NMR spectroscopy [$\mathbf{1d}^{4\ominus}/4\,Li^{\oplus}$, [$D_8$]tetrahydrofuran (THF), −50°C; δ_H = 3.58 (H-1,8), 4.38 (H-2,7), 4.18 (H-3,6), 3.36 (H-4,5), 1.90 (H-10), 0.60 (α-CH_2), 0.89 (β-CH_2), 1.00 (γ-CH_2), 1.20 ($\delta,\varepsilon,\varphi$-$CH_2$)]. Upon longer contact with the metal, the polyether **2a** undergoes reductive cleavage, as shown by the identification of ethylanthracene and anthrylethoxide fragments. In the case of **3**, the formation of a hexaanion can be shown by cyclovoltammetry (THF, sodium tetraphenylborate), i.e., each of the anthracene moieties can be charged with two electrons.[17]

This study shows that the rate of the intramolecular electron-transfer processes of compounds of type **1–3** can be specifically modified by the bridge and by the ion-pair structure and that the model system **3**, which contains three electroactive groups, behaves similarly to the "bis-electrophore" **1b**.

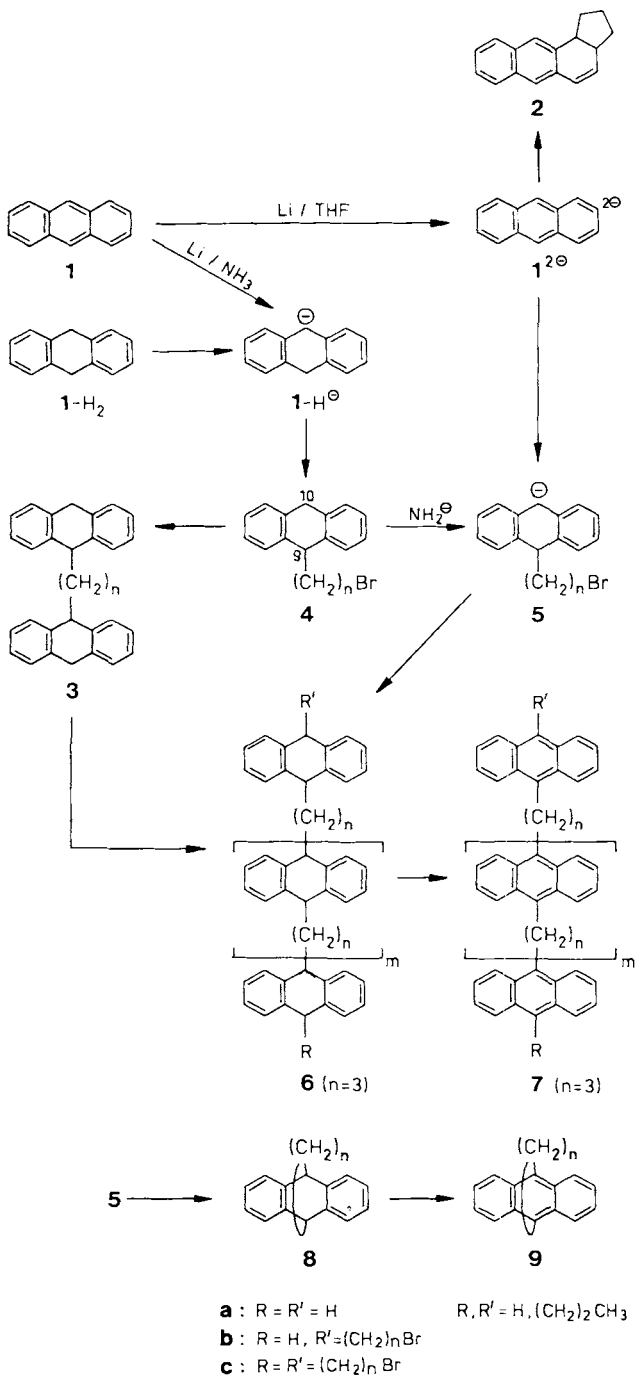
Poly(anthrylenetrimethylene) and 9,10-Bridged Anthracenes by Reductive Alkylation**

By *Dietmar Bender, Heinz Unterberg,* and *Klaus Müllen**

The synthesis of compounds consisting of several separated anthracene moieties and the study of their electron-transfer processes has directed attention to the polymer **7**.[1–3] The procedure for the synthesis of **7** and its precursor **6** consists in the alkylation of carbanions that are derived from anthracene **1** with 1,n-dibromoalkanes. Depending on the reaction conditions, this reaction can lead to the polymers **6** or to the monomers **8** (as well as their dehydrogenation products).



Key intermediates are 9-(n-bromoalkyl)-9,10-dihydroanthracenes **4** and the monoanions **5**. Their preparation from **1** or $\mathbf{1}\text{-}H_2$ and their reaction possibilities are summarized in Scheme 1.

When $\mathbf{1}\text{-}H^{\ominus}$[4] was generated by deprotonation of $\mathbf{1}\text{-}H_2$ and the 1,n-dibromoalkane was then added, the tetrahydrodianthrylalkane[5] **3** was formed (yield for n = 3: 80%). When the order of addition was reversed, i.e., addition of $\mathbf{1}\text{-}H^{\ominus}$ to a large excess of the alkylating agent, the substituted dihydroanthracene **4** (n = 3,[6] 60%; n = 6, 40%; n = 8, 38%; n = 10, 35%) was formed.

The isolated product **4** was then converted into the monoanion **5** by deprotonation [$LiNH_2$ or KNH_2 in NH_3/tetrahydrofuran (THF)]. The reactions of this species, which has both nucleophilic and electrophilic properties, is very much dependent on the chain length n and the concentration. If a solution of $LiNH_2$ (3 equiv.) in NH_3/THF (2:1, −33°C) was prepared and a 10^{-1} M solution of **4** (1

Scheme 1.

equiv.) in THF was added over 10 min, then the yields of cyclization product **8** were small for longer chain lengths (n = 3[7,8], 62%; n = 6, 8%; n = 8, 0%; n = 10, 8%). Reaction under dilution conditions proved more favorable. Separate solutions of **4** (THF, 2.5×10^{-2} M) and KNH_2 (NH_3, 3×10^{-2} M) were added synchronously over several hours to a NH_3/THF mixture (2:1, −33 °C). In this case, too, the smallest yield of the cyclization was obtained for n = 8 (n = 6, 34%; n = 8, 10%; n = 10, 38%). The higher homologues of **8** (n > 4) were previously unknown. **8** (n = 10) undergoes ready dehydrogenation to the known[9] anthracene derivative **9** (n = 10). The controlled conversion of **8** into **9** (n = 10) was achieved by oxidation ($CdCl_2$)[10] of the dianion obtained by deprotonation of **8**. On the basis of the ^{1}H-NMR chemical shifts of the methylene protons of **9** (n = 10) and $\mathbf{9}^{2\ominus}/2Li^{\oplus}$ (n = 10) it was possible to visually follow the anisotropy of the diamagnetic and paramagnetic ring-current effects, respectively [**9** (n = 10): $\delta_H = 3.8$ (α-CH_2), 1.8 (β-CH_2), 0.85 (γ-CH_2), 0.0 (δ,ε-CH_2); $\mathbf{9}^{2\ominus}/2Li^{\oplus}$ (n = 10), −50 °C: $\delta_H = 0.70$ (α-CH_2), 1.15 (β-CH_2), 1.70 (γ-CH_2), 2.35 (δ-CH_2), 2.70 (ε-CH_2); between −100 °C and −30 °C temperature-dependent line-shape changes are observed as a consequence of conformational transformations].

The third possible transformation of **4** and **5** consists in the polymerization to form **6**. This process can begin by bond formation between two monoanions **5** or by nucleophilic attack of the anions $\mathbf{1}\text{-}H^{\ominus}$ (in NH_3/THF) and $\mathbf{1}^{2\ominus}$ (in THF) on the bromoalkyl moiety of **4** and **5**, respectively. A high concentration of the nucleophile $\mathbf{1}\text{-}H^{\ominus}$ and $\mathbf{1}^{2\ominus}$ is guaranteed if **4** and **5**, respectively, are generated reductively from anthracene. Trapping of the dianion $\mathbf{1}^{2\ominus}$ (dilithium salt, 0.01 M in THF, −20 °C) with 1,3-dibromopropane affords the products **1**, **2**, and **8** and polymeric material (each n = 3) in 33, 20, 42, and ≤ 5% yield, respectively. The amount of polymer is small but can be increased by increasing the temperature and concentration; the reductive alkylation of anthracene is not regioselective under the conditions described above.[7,8] The relative yields of the monomeric cyclization products **2** and **8** could not be affected by varying the experimental conditions. In contrast, the reduction of **1** in NH_3 and alkylation with 1,3-dibromopropane gave up to 90% of poly(9,10-dihydroanthrylene-trimethylene) of type **6**. With 1,2-dibromoethane, instead of alkylation, oxidative coupling of $\mathbf{1}\text{-}H^{\ominus}$ occurred to give 9,9′,10,10′-tetrahydro-9,9′-bianthryl (46%).

For the fraction of the samples of **6** (n = 3) soluble in chloroform, molecular weight measurement by vapor pressure osmometry gave values between 1200 and 3500 depending on the synthesis conditions. These values are confirmed by gel-permeation chromatography[11] and FD mass spectroscopy.[12] According to the FD mass spectra, **6** (n = 3) consists of **6a**, **6b**, and **6c**. The structural proof of **6**[13,14] was accomplished by using ^{13}C-NMR spectroscopy; 9,10-dipropyl-9,10-dihydroanthracene, the tetrahydrodianthrylpropane **3**, its 10,10′-dipropyl derivative, and the model compound **6a** (m = 2, n = 3) containing four dihydroanthracene moieties (which was synthesized by us via an independent route[12]) were used as model compounds. The signals of these reference compounds agree with those of the corresponding polymers[13] within ±0.3 ppm. The NMR spectra do not provide evidence of interchain linkage by double alkylation at C-9 or C-10: the anthracene moieties are only linked through the positions 9 and 10. This is due to the high selectivity of the reductive alkylation in NH_3 (alkylation of $\mathbf{1}\text{-}H^{\ominus}$), which is not guaranteed in THF (alkylation of $\mathbf{1}^{2\ominus}$).[8,15]

The formation of **6** (n = 3) is a side reaction in the base-induced cyclization of **4** to **8**. The considerably better yields of polymer in the reductive alkylation of **1** in NH_3 confirm that the polymerization begins mainly by nucleophilic attack of $\mathbf{1}\text{-}H^{\ominus}$ on **4** or **5** and with less likelihood by reaction of two molecules of **5**. In agreement with this course of reaction is the finding that the polymer **6** (n = 3) can also be obtained from **3**, lithium amide, and dibromopropane.

The dehydrogenation of **6** to **7** (n = 3) was achieved (after removal of the bromine with $LiAlH_4$) with sulfur at 200 °C. The solubility of the brown material formed depends markedly on the molecular weight of the educt **6** and on the degree of dehydrogenation. Complete dehydro-

genation of higher-molecular-weight samples in organic solvents afforded insoluble products.[16]

This polymer synthesis can be considerably varied by the choice of the bridges and the reducible π-system.[12]

[16] The dehydrogenation was also achieved with chloranil as well as with *n*BuLi/tetramethylethylenediamine and iodine; however, the reaction mixtures were difficult to purify. The structural assignment of the insoluble samples of **7** was achieved by comparison of the IR spectra with those of model compounds (see **1–3** in [1]). For the partially dehydrogenated samples, the formation of anthracene π-systems could be followed by ^{1}H- and ^{13}C-NMR spectroscopy.

Evidence for Equilibria between μ-Alkyne and Alkylidyne Complexes of Tungsten Alkoxides: $[W_2(OR)_6(\mu\text{-}C_2R'_2)] \rightleftharpoons 2[(RO)_3W{\equiv}CR']$**

By *Malcolm H. Chisholm,* Brian K. Conroy, John C. Huffman, and Nancy S. Marchant*

The cleavage of alkynes to form two alkylidyne moieties has been observed at dinuclear,[1,2] trinuclear,[3–7] and tetranuclear[8] metal centers. The reverse reaction, the coupling of two alkylidyne ligands, is also known.[6,7] In certain instances a reversible process can be induced by CO elimination or uptake.[3,4] Recently, we suggested that a dynamic equilibrium between the μ-alkyne ditungsten complex **1a** and the alkylidynetungsten complex **2a**, involving the elimination or uptake of pyridine, exists in solution at room temperature [Eq. (a)].[2] Here, we present evidence for a general equilibrium of this type for which the equilibrium constant K is dependent upon the nature of R and R′, bulky combinations favoring the alkylidyne species.

$$[W_2(OR)_6(py)_n(\mu\text{-}C_2R'_2)] \overset{K}{\rightleftharpoons} 2[(RO)_3W{\equiv}CR'] + n\ py \qquad (a)$$

1 **2**

1, 2	a	b	c	d	e
R	*t*Bu	*t*BuCH$_2$	*t*BuCH$_2$	*t*BuCH$_2$	*t*BuCH$_2$
R′	H	H	Me	Et	Ph
n	1	2	2	1	1

The addition of sterically bulky alkynes to $[W_2(O\mathit{t}Bu)_6]$ results in the formation of alkylidyne species in high yields (i.e., alkyne cleavage).[11] By reducing the steric demands of the alkoxide ligands, we were able to prepare the stable μ-alkyne complexes **1b–e** [Eq.(a)].[2]

In principal the equilibrium (a) should be observable by UV/VIS spectroscopy since the alkyne adducts are blue or green whereas the alkylidyne species are yellow and do not show an absorption maximum in the visible region of the spectrum. The alkyne adducts **1c–e** do not obey the Beer–Lambert Law for their absorptions in the visible region. Hydrolysis by traces of water or oxidation by adventitious O_2 under the high-dilution conditions employed, which are necessary to drive the equilibrium to the right, may be responsible for such behavior. This precludes determination of the equilibrium constant K. Consequently, we have used trapping reagents to obtain chemical evidence for the existence of the equilibrium (a).

The alkyne adducts **1c–e** can be used as alkylidyne sources for the preparation of alkylidyne clusters **3** according to Equation (b).

$$2[W_2(OCH_2\mathit{t}Bu)_6(py)_2] + [W_2(OCH_2\mathit{t}Bu)_6(py)_n(\mu\text{-}C_2R'_2] \xrightarrow{25\,^\circ C,\ hexane} 2[W_3(\mu_3{-}CR')(OCH_2\mathit{t}Bu)_9] + (n+4)py \qquad (b)$$

1c–e **3**

R′ = Me, Et, Ph

Addition of the alkyne to $[W_2(OCH_2\mathit{t}Bu)_6(py)_2]$ (molar ratio 1:3) results in the direct formation of the alkylidyne-capped tritungsten compounds **3**. ^{1}H-NMR studies showed that the complexes **1** were formed initially [Eq. (b)]. The rate of formation of **3** follows the order Et ≈ Ph > Me, which probably reflects the magnitude of K in Equation (a). Interestingly, no μ_3-CH cluster could be prepared by this route. Furthermore, in a double labeling experiment involving $[W_2(OCH_2\mathit{t}Bu)_6(py)_2(\mu\text{-}{}^*C_2H_2)]$ and $[W_2(OCH_2\mathit{t}Bu)_6(py)_2(\mu\text{-}C_2D_2)]$, we found no evidence for formation of $[W_2(OCH\mathit{t}Bu)_6(py)_2(\mu\text{-}H{}^*CCD)]$ (*C represents 92.5 mol-% ^{13}C).

The new compounds **3** are analogous (^{1}H-, ^{13}C-NMR) to $[W_3(\mu_3\text{-}CMe)(O\mathit{i}Pr)_9]$, which was previously prepared by the comproportionation of $[(\mathit{t}BuO)_3W{\equiv}CMe]$ **4**[9] and $[W_2(O\mathit{i}Pr)_6]$ in the presence of *i*PrOH.[10]

Further evidence for equilibrium (a) is provided by the reaction of **4** with CO. Addition of CO (1 atm) to a hexane solution of **4** results in a color change (pale yellow to blue) and the quantitative formation of complex **5** (Eq. (c)].[11]

$$2[(\mathit{t}BuO)_3W{\equiv}CMe] + CO \xrightarrow{25\,^\circ C,\ hexane} [W_2(O\mathit{t}Bu)_6(CO)(\mu\text{-}C_2Me_2)] \qquad (c)$$

Reaction (c) is complete after 24 h (^{1}H-NMR). Under analogous conditions, the complexes [(tBuO)$_3$W≡CR′], R=Et, Ph, do not react, suggesting that, for these complexes, the equilibrium (a) lies far to the right.

Complex **5** can be isolated as dark blue crystals from hexane. ^{1}H- and ^{13}C-NMR spectroscopic studies support the existence of a static structure, having a mirror plane of symmetry, on the NMR time scale. The molecular structure deduced from a single-crystal X-ray study is shown in Figure 1. In the IR spectrum ν(CO) occurs at 1917 cm^{-1}, which is indicative of extensive W-to-CO back-bonding. It is this π-acceptor property of CO that stabilizes the μ-C_2Me_2 adduct relative to the alkylidyne species **4**.

Theoretical studies predicted[12] that there would be virtually no energy barrier for the interconversion of $L_3M(\mu\text{-}L)(\mu\text{-}CR)_2ML_3$ and $L_6M_2(\mu\text{-}L)(\mu\text{-}C_2R_2)$ complexes where the electron count on each metal was between d^4 and d^8 (the ligands L being counted as neutral rather than charged).

C_{phenyl}–H···O and C_{phenyl}–H···N Interactions: Crystal Structure of (*Z*)-4-Benzylidene-2-methyl-5(4*H*)-oxazolone, an Intermediate for Dehydropeptide Synthesis

By *Mohamed Souhassou, André Aubry, Guy Boussard,* and *Michel Marraud**

The spatial distribution of atoms in the environment of the phenylalanine aromatic rings in protein[1] and peptide[2] crystal structures has revealed that the carbonyl oxygen atoms are preferentially situated in the plane of these aromatic rings; ab initio calculations on benzene and formamide have suggested the existence of a favorable enthalpic interaction.[1] Moreover, *Taylor* and *Kennard* have presented crystallographic evidence, obtained by neutron diffraction experiments, for hydrogen bonds involving C–H bonds and O or N atoms.[3] A C–H···O contact can be described as a hydrogen bond when the H···O distance is shorter than 2.4 Å (i.e., C···O<3.5 Å for a linear arrangement of the three atoms) and the C–H···O angle is greater than 90°.

1

We report here on the crystal structure of **1**, which contains two short C–H···O and C–H···N contacts involving aromatic H atoms.

The existence of α,β-dehydro amino acid residues in naturally occurring microbial peptides exhibiting antibiotic activity has incited chemists to introduce these modified

residues into a number of analogues.[4] The expected advantages are a defined orientation of the unsaturated side chain due to the rigidity of the $C^{\alpha}C^{\beta}$ double bond and increased resistance to enzymatic degradation.[5] However, both (*Z*) and (*E*) configurations of the double bond are a priori possible and their characterization is not yet straightforward.[6, 7] According to *Kono* and *Stammer*,[8] one of the most promising procedures for the introduction of an α,β-dehydro amino acid into a growing peptide chain is to prepare an intermediate containing a *C*-terminal 5(4*H*)-oxazolone ring.

The crystal structure of the title compound **1**, obtained from α,β-dehydrophenylalanine,[9] is shown in Figure 1.[10] All the atoms were located, and the hydrogen atoms were moved along the observed C–H bonds until the C–H bond lengths were equal to the usual values found in neutron diffraction experiments.

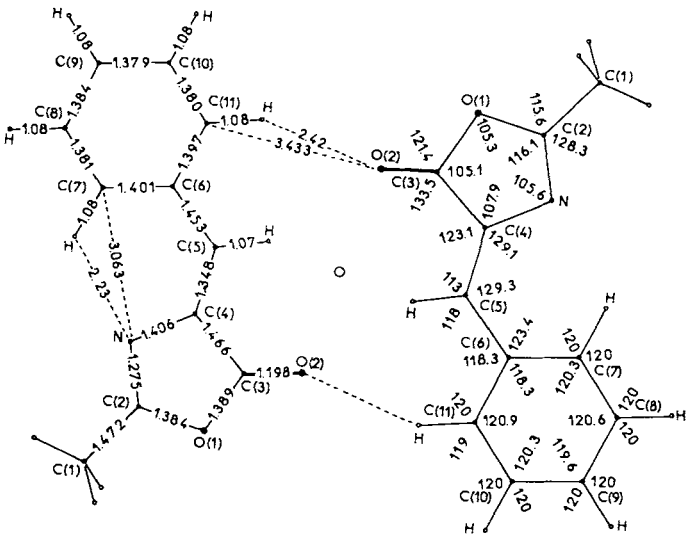

Fig. 1. Crystal structure of a "dimer" of **1** projected on the mean plane. Bond lengths (Å, left) and bond angles (°, right) are indicated, together with the C11–H···O2 and C7–H···N contacts.

The small thermal factors of the non-hydrogen atoms (B_{eq} = 3.0–4.8 Å^2) result in accurate bond lengths (σ = 0.002 Å) and bond angles (σ = 0.1°). The perfectly planar (*Z*) configuration of the molecules (maximum deviation from the mean plane: 0.027 Å) allows strong electronic conjugation, resulting in a rather short C5–C6 bond and a rather long C4–C5 bond compared to those of similar species with a twisted C5–C6 bond.[11]

In the unit cell (Fig. 2), the molecules are stacked two by two in an antiparallel disposition with the neighboring phenyl rings nearly orthogonal to each other. One intramolecular C7–H···N contact and one intermolecular C11–H···O contact are shorter than the van der Waals distances (Fig. 1). The former is probably responsible for the coplanar disposition of the oxazole and phenyl rings. In dehydropeptides, the accepting nitrogen atom of **1** is replaced by a proton-donating NH group and the C5–C6 bond is effectively rotated by an angle of up to 37°.[11] The C11–H···O interaction results in centrosymmetric "cyclic dimers" of two nearly coplanar molecules with a distance of 0.046 Å between the average planes.

We believe that these C–H···O and C–H···N interactions are not simply a consequence of the crystal packing forces; the low solubility of this molecule in an inert solvent such as CCl_4, however, prevents an NMR study of aggregation in solution. However, the low-field shift of the *o*-H signal (δ = 8.05) compared to that of the *m*- and *p*-H signals (δ = 7.40) suggests that the intramolecular C–H···N interaction is also present in solution.

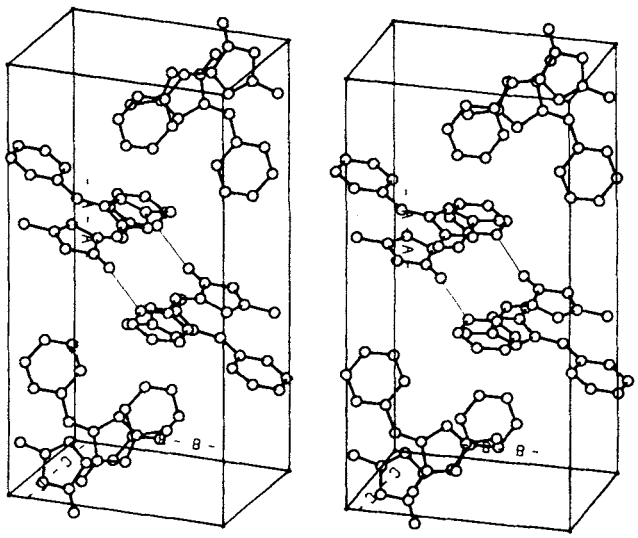

Fig. 2. Packing of the "dimers" of **1** (stereoview).

The crystal structure of **1** indicates that the phenyl ring not only experiences hydrophobic interactions and stacking forces, but is also capable of acting as a proton donor to atoms bearing a partial negative charge such as the oxygen of carbonyl groups. This type of interaction deserves to be taken into consideration in the analysis of aromatic side-chain folding in peptides and of molecular recognition in biological processes.

Synthesis of Cyclic, Vicinal Tetraketones**

By *Rolf Gleiter** and *Gerhard Krennrich*

Dedicated to Professor Edgar Heilbronner on the occasion of his 65th birthday

Whereas open-chain, vicinal tetraketones have long been known[1] and are well investigated,[2,3] only cyclic, vicinal tetraketones that bear strongly electron-donating substituents have been prepared to date (e.g., rhodizonic acid[4]). They are of interest because of their expected photochemistry[5] and on account of their physical-chemical properties (acceptor behavior, color).[2,3] Our initial goal was to synthesize cyclic compounds with 12 and 14 C atoms, since the syn-coplanar arrangement of the four CO groups in smaller rings results in the appreciable instability of such tetraketones. We report here the synthesis of simple, cyclic, vicinal tetraketones and bistetraketones.

The β,β′-tetramethyl diesters **2**[6] are obtained by conversion of the aliphatic α,α′-tetramethyl dicarboxylic acids **1a**[7] to the acid chlorides **1b**, followed by reaction of **1b** with diazomethane and irradiation of the products formed, the bis(diazo)ketones **1c** (Scheme 1). Subsequent acyloin condensation leads to the acyloins **3**,[6] which are oxidized with Cu^{II} to the yellow diketones **4**.[6] Reaction of **4** with sodium bistrimethylsilylamide followed by chlorotrimethylsilane[8] gives the monosilyl enol ethers **5**,[6] which smoothly react with lithium diisopropylamide (LDA) and

Institut für Organische Chemie der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF. We thank Priv.-Doz. Dr. *D. Spitzner* for recording the field desorption mass spectra and Mrs. *G. Rissmann* for recording the NMR spectra.

chlorotrimethylsilane to give the 2,3-bis(trimethylsiloxy)-1,3-dienes **6**.[6] Oxidation of **6** with *m*-chloroperbenzoic acid (*m*-CPBA) leads to the diols **7**[6] (*cis* and *trans* isomers), which are oxidized with *N*-bromosuccinimide (NBS) in CCl_4 in the presence of pyridine at 77°C to give **8** (violet-red oil).

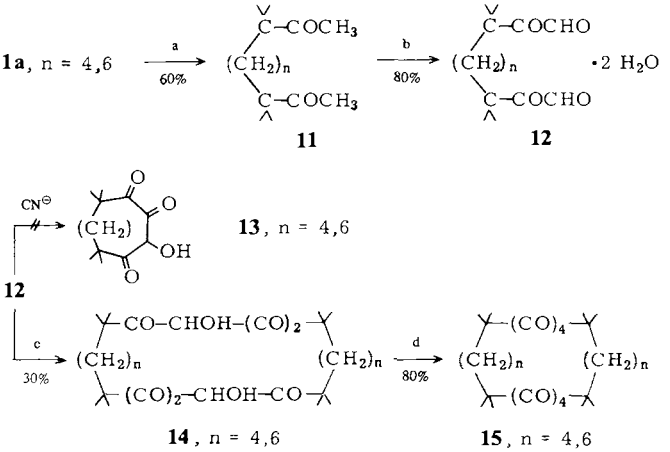
The tetraketones **8** react with *o*-phenylenediamine (*o*-PDA) to give the quinoxaline derivatives **9** (Scheme 2). Traces of water result in the ring contraction of **8** (n = 6) to **10**.[3,4,6] In contrast, **8** (n = 8) reacts with water at room temperature to give only the hydrate. The most important spectroscopic data for **8** and **9** are summarized in Table 1.

Scheme 2.

Table 1. Spectroscopic data for the compounds **8** (n = 6, 8), **9** (n = 6, 8), and **15** (n = 4, 6). ^{1}H-NMR: 300 MHz, $CDCl_3$; ^{13}C-NMR: 75.46 MHz, $CDCl_3$; UV: CH_2Cl_2. Correct elemental analyses were obtained for **9** (n = 6, 8) and for the hydrates of **15** (n = 4, 6).

8 (n = 6): IR (film): $\tilde{\nu}$ = 1710 cm^{-1}; ^{1}H-NMR: δ = 1.65–1.59 (m; 4H), 1.52–1.07 (m) 1.28 (s) (20H); ^{13}C-NMR: δ = 206.5 (s), 188.1 (s),47.2 (s), 35.9 (t), 25.1 (t), 24.4 (q), 21.6 (t); UV: $\lambda_{max}(\varepsilon)$ = 507 (43), 368 nm (97)

8 (n = 8): IR (film): $\tilde{\nu}$ = 1735, 1685 cm^{-1}; ^{1}H-NMR: δ = 1.60–1.55 (m; 4H), 1.41–1.06 (m) 1.28 (s) (24H); ^{13}C-NMR: δ = 207.3 (s), 185.2 (s), 46.1 (s), 37.8 (t), 27.3 (t), 26.0 (t), 24.4 (q), 23.7 (t); UV: $\lambda_{max}(\varepsilon)$ = 533 (87), 385 nm (94)



9 (n = 6): IR (KBr): $\tilde{\nu}$ = 1700, 1680 cm^{-1}; ^{1}H-NMR: δ = 8.14 (q, J = 6 Hz, 3 Hz; 2H), 7.88 (q, J = 6 Hz, 3 Hz; 2H), 1.64–1.58 (m; 4H), 1.53 (s; 12H), 1.26–1.22 (m; 4H), 0.9 (m; 4H); MS: *m/z* 352 ($M^{\oplus}$, 100%), 307, 227

9 (n = 8): IR (KBr): $\tilde{\nu}$ = 1680 cm^{-1}; ^{1}H-NMR: δ = 8.07 (q, J = 6 Hz, 3 Hz; 2H), 7.84 (q, J = 6 Hz, 3 Hz; 2H), 1.77–1.72 (m; 4H), 1.56 (s; 12H), 1.42–1.26 (m; 12H); MS: *m/z* 380 ($M^{\oplus}$), 335 (100%), 227

15 (n = 4): IR (KBr): $\tilde{\nu}$ = 1730, 1685 cm^{-1}; ^{1}H-NMR: δ = 1.69–1.64 (m; 4H), 1.30 (s) 1.39–1.16 (m) (16H); ^{13}C-NMR: δ = 204.9 (s), 187.8 (s), 46.1 (s), 38.4 (t), 29.0 (t), 23.6 (q); MS (FD): *m/z* 506, 505 ($M^{\oplus}$), 504; UV: $\lambda_{max}(\varepsilon)$ = 525 (165), 385 nm (149)

15 (n = 6): IR (KBr): $\tilde{\nu}$ = 1725, 1685 cm^{-1}; ^{1}H-NMR: δ = 1.73–1.68 (m; 4H), 1.28 (s) 1.38–1.19 (m) (20H); ^{13}C-NMR: δ = 204.4 (s), 188.1 (s), 46.1 (s), 39.1 (t), 29.6 (t), 24.1 (t), 23.8 (q); MS (FD): *m/z* 562, 561 ($M^{\oplus}$); UV: $\lambda_{max}(\varepsilon)$ = 522 (100), 380 nm (96)

A second reaction sequence, however, leads not to **8** but to the vicinal bistetraketones. Compounds **1a** (n = 4, 6)

Scheme 3. a) MeLi in THF, 0°C; b) 1. SeO_2, dioxane, 2. H_2O; c) KCN, EtOH/H_2O (1:1); d) CH_2Cl_2, HNO_3.

react with MeLi to give the ketones **11** (Scheme 3),[6] which are converted smoothly into the glyoxal derivatives **12**[6] with SeO_2. The benzoin condensation does not result in the expected 2-hydroxy-1,3,4-triketones (formoins) **13**, but rather in the dimers **14**.[6,9] Compounds **14** are oxidized with HNO_3 to the yellow dihydrates of **15**,[6] which, upon heating, afford the anhydrous, red bistetraketones **15** (data for **15**: see Table 1). The molecular weight determined by field desorption (FD) mass spectrometry supports the structure of **15**.

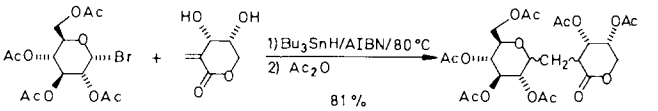
Synthesis of "*C*-Disaccharides" by Radical C–C Bond Formation**

By *Bernd Giese** and *Tom Witzel*

Disaccharides linked through a carbon atom ("*C*-disaccharides")[1] are of interest on account of their possible activity as enzyme inhibitors and for the investigation of carbohydrate metabolism. It has only been possible so far, however, to link pyranosyl building blocks directly[2] either through a hydroxymethylene[3] or a CH_2–CH_2 group.[1] We have now achieved the synthesis of a "*C*-disaccharide" in which the pyranosyl rings are linked to each other through a methylene group, employing a method developed by us earlier for the formation of C–C bonds, namely, the addition of radicals **1** to alkenes **2**.[4]



1 2

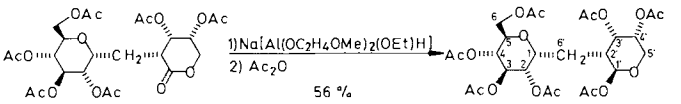
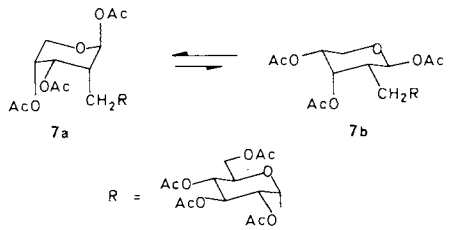
Institut für Organische Chemie und Biochemie
der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (FRG)

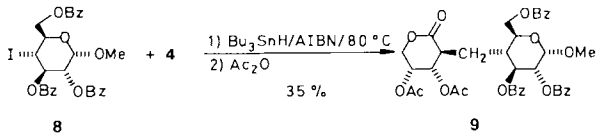


[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

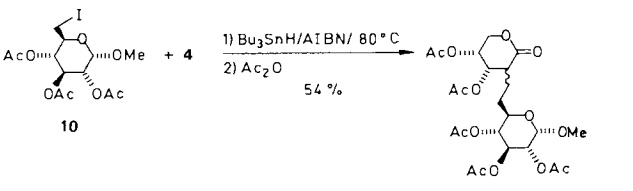
The glycosyl radicals required as reactants can be selectively generated from glycosyl halides such as **3**.[4] The second reactant is a "carbohydrate alkene" containing an exocyclic double bond, e.g., the methylene lactone **4**, which can be synthesized diastereoselectively starting from D-glyceraldehyde.[5]



3 4 5



The "*C*-glycosides" **5** were obtained in an α:β ratio of 10:1 from **3** in the presence of a catalytic amount of azoisobutyronitrile (AIBN). In contrast to the high stereoselectivity observed for the reaction of alkenes and glycosyl radicals,[4] the hydrogen transfer from tri-*n*-butyltin hydride to the adduct radical exhibits only low selectivity (60:40). Upon stirring the concentrated reaction mixture with ether, the isomer **6** precipitated out in analytically pure form in 22% yield.[6] Reduction of **6** with sodium ethoxybis(2-methoxyethoxy)hydridoaluminate[7] followed by acetylation afforded the "*C*-disaccharide" **7** in 56% yield.[8]



6 7

In order to determine the stereochemistry at C-1′, ^{1}H-NMR spectra were recorded at several temperatures. A doublet for H-1′ ($J(1',2')=5.1$ Hz) is observed at 20 °C, but is split up at −80 °C to give a doublet with a coupling constant of 8.5 Hz and a broad singlet. Such splitting is known for tetra-*O*-acetylribopyranoses[9] and indicates the *trans* geometry of the substituents at C-1′ and C-2′. At −80 °C, the ratio **7a** : **7b** is 70:30, i.e., the energy gain on account of the anomeric effect in **7a** is largely compensated by the energy loss on account of the axial arrangement of the CH_2R group on C-2′.

8 9

10 11

The advantage of this radical C-C bond formation is the variability of the radical building block, because it is possible to generate selectively carbohydrate radicals, with the radical center at any C atom, from xanthogenates, halides, selenides, and nitro compounds with the NO_2 group on a tertiary carbon atom.[4] Thus, the iodides **8** and **10** react with the alkene **4**, under conditions similar to those used for **3**, to give the C-C linked products **9** and **11**, respectively.

Experimental Procedure:

5: **3** (8.63 g, 21.0 mmol) and **4** (2.02 g, 14.0 mmol) were allowed to react in refluxing 1,2-dimethoxyethane with tri-*n*-butyltin hydride (6.11 g, 21.0 mmol) in the presence of a catalytic amount of AIBN. After acetylation, 6.30 g (81%) of **5** was isolated.

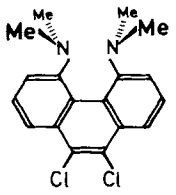
4,5-Bis(dimethylamino)phenanthrene and 4,5-Bis(dimethylamino)-9,10-dihydrophenanthrene: Syntheses and "Proton Sponge" Properties

By *Thomas Saupe, Claus Krieger,* and *Heinz A. Staab**

We have ascribed the fact that the basicity of 4,5-bis(dimethylamino)fluorene **1** is even higher than that of 1,8-bis(dimethylamino)naphthalene ("Proton Sponge")[2] to the stronger steric interaction of the two dimethylamino groups and to the formation of an especially strong, nearly linear N···H···N hydrogen bond in the monoprotonated **1a**.[3] Simple examinations of models (cf. ref. [3]) indicated that 4,5-bis(dimethylamino)phenanthrene **2** and 4,5-bis-(dimethylamino)-9,10-dihydrophenanthrene **3** might also be interesting as potential "proton sponges." In particular, a strong steric hindrance of the dimethylamino groups with unfavorable overlapping of the nitrogen lone-pairs was expected for **2**, and a nearly linear N···H···N hydrogen bond with an even shorter N···N distance than in **1a** was expected for the monocation **2a**.

In order to synthesize **2** and **3**, 2,2'-bis(bromomethyl)-6,6'-dinitrobiphenyl[4] was allowed to react with sodium sulfide (methanol/water, reflux, 5 h) to give the cyclic sulfide **4**[5] (m.p. = 173-174°C; 84% yield). Reduction of **4** with zinc dust in acetic acid (reflux, 140 min) gave the diamino compound **5**[5] (m.p. = 190-191°C; 80%), which was methylated with dimethyl sulfate in the presence of sodium hydride (tetrahydrofuran (THF), reflux, 1 h) to give **6** [5] (m.p. = 128-129°C; 36%). Oxidation of **6** with peroxytrifluoroacetic acid (trifluoroacetic acid, 0-25°C, 100 min) led selectively to the sulfone **7**[5] (m.p. = 265-266°C; 81%).



Vacuum gas-phase pyrolysis of **7** (625°C, 0.1-0.3 Pa) afforded (along with 20% of unreacted **7**) the product **3**[5] in 58% yield (m.p. = 82-84°C); ^{1}H-NMR (360 MHz, $CDCl_3$, 303 K): $\delta = 2.51$ (s, 12H), 2.57-2.74 (AA'BB', 4H), 6.75 ('d', $J \approx 7.3$ Hz, 2H), 6.85 ('d', $J \approx 8.1$ Hz, 2H), 7.08 ('dd', $J \approx 7.3$ and 8.1 Hz, 2H). The observation of an AA'BB' system for the protons in the 9- and 10-positions of **3** shows that the flipping-over of the "biphenyl moiety" in **3** is strongly hindered sterically. All attempts to dehydrogenate **3** did not lead—apparently owing to the required formation of significantly higher strain—to 4,5-bis(dimethylamino)phenanthrene **2** but rather to more or less complete decomposition of the starting material.

Although the synthesis of **2** by Ramberg-Bäcklund rearrangement of the α-chlorosulfone of **7** appeared futile in view of *Paquette*'s investigations,[6] the variant of the Ramberg-Bäcklund rearrangement described by *Meyers* et al.[7] was carried out on **7** [tetrachloromethane/*tert*-butyl alcohol (1 : 1), potassium hydroxide, 0-20°C, 1 h). Surprisingly, this reaction led indeed to the phenanthrene system of **2**;

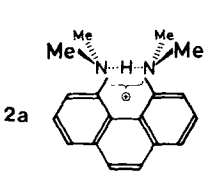
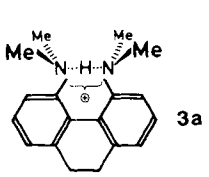
Jahnstrasse 29, D-6900 Heidelberg (FRG)
[**] New "Proton Sponges," Part 3.—Part 2: [1].



its 9,10-dichloro substitution product **8**[5] was obtained in 53% yield (m.p. = 160–161.5 °C). Halogen–metal exchange (excess lithium, THF, −55 to −35 °C, 1–1.5 h) and subsequent reaction with methanol gave **2**[5] (m.p. = 148 °C) in 27% yield (along with 10% of **3** and 46% of reisolated **8**).[8]



8

In the ^{1}H-NMR spectrum of **2** [(360 MHz, $CDCl_3$, 303 K): $\delta = 2.06$ (br. s, 6H), 3.13 (br. s, 6H), 7.08 ('d', $J \approx 7.8$ Hz, 2H), 7.24 ('d', $J \approx 7.5$ Hz, 2H), 7.39 ('dd', $J \approx 7.8$ and 7.5 Hz, 2H), 7.50 (s, 2H)] the pairwise nonequivalence of the methyl protons indicates a strong helical deformation of the phenanthrene system of **2**. From the coalescence of these signals ($T_c = 337$ K, $\Delta\nu_s = 370$ Hz), the enantiomerization barrier for **2** was determined to be $\Delta G^{\neq} = 64.0 \pm 0.4$ kJ/mol (in [D_5]pyridine). Similarly, for **8**, $\Delta G^{\neq} = 66.8 \pm 0.4$ kJ/mol at $T_c = 352$ K was found. These values are of the same order of magnitude as those determined for the enantiomerization of similar 4,5-disubstituted phenanthrenes.[9]

Both **2** and **3** react with perchloric acid—although used in excess—to form well-defined monoperchlorates, which contain the cations **2a** and **3a**. In the ^{1}H-NMR spectra[10] of **2a**-perchlorate[5] (m.p. = 190–191 °C) and **3a**-perchlorate[5] (m.p. = 221 °C), the strongly downfield shifted absorptions of the protons of the N···H···N hydrogen bond at $\delta = 18.37$ (**2a**) and 16.50 (**3a**) are particularly noticeable. The large positive isotope effect $\Delta\delta(^1H,^2H) = \delta(^1H) - \delta(^2H)$ that was observed for these protons supports, according to *Forsén* et al.,[11] the presence of strong but still unsymmetrical hydrogen bonds in **2a** and **3a**, as in **1a**-perchlorate. The coupling constants between the bridge proton and the methyl groups [monocation of 1,8-bis(dimethylamino)naphthalene, $J = 192$ Hz;[3] **1a**, $J = 2.03$ Hz;[3] **2a**, $J = 2.17$ Hz] also support the presence of an especially strong hydrogen bond in **2a**.

2a

3a

We obtained crystals of **2a**-perchlorate that were suitable for an X-ray structure analysis from acetone by addition of a layer of diethyl ether and subsequent slow crystal growth at the layer boundary. The structure of the **2a** part is characterized, above all, by the strong helical twisting of the phenanthrene system by 23° along the C12–C13 axis (Fig. 1B). The bond angles (Fig. 1A) at C12 and C13 reflect the considerable steric repulsion between the dimethylamino groups at C4 and C5. The bond lengths are similar to those of other phenanthrenes (with the exception of the especially short C1–C2, C7–C8, and C9–C10 bonds).[12] The hydrogen atom in the hydrogen bond is in a nearly linear arrangement (angle 168°) and unsymmetrically located between N4 and N5, which is connected with the only approximate C_2 symmetry of **2a**. The direct N···N distance in **2a** (254.4 pm) is significantly shorter than the corresponding N···N distance in **1a** (262.6 pm);[3] it is one of the shortest distances found so far for N···H···N hydrogen bonds.

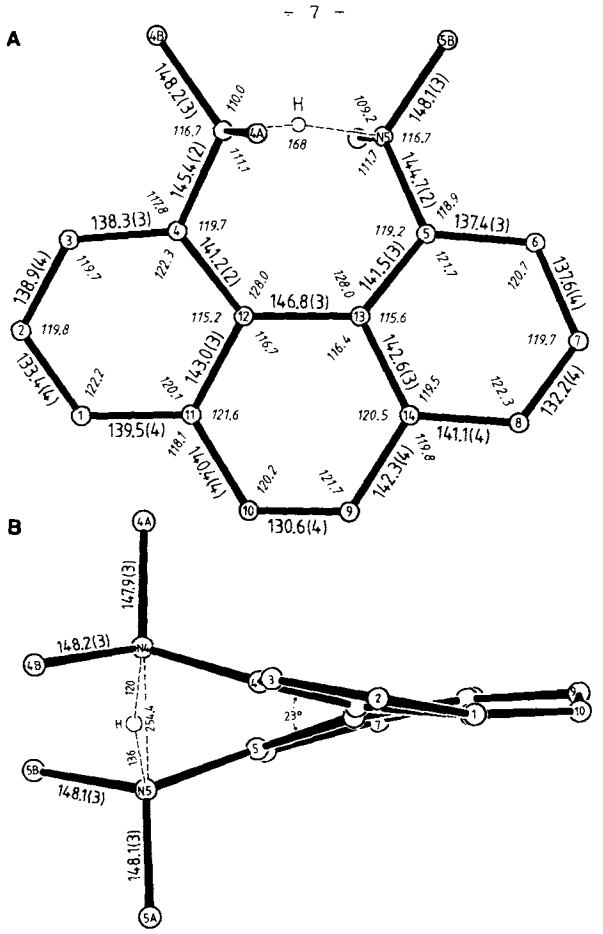


Fig. 1. Structure of the **2a** portion of **2a**-perchlorate as viewed looking down on the plane of the phenanthrene ring (A) and from the side (along the C2···C7 axis) (B). Crystal and measurement data: $a = 1293.4(3)$, $b = 1235.4(3)$, $c = 1218.4(3)$ pm, $\beta = 111.67(4)°$; space group $P2_1/c$, $Z = 4$; 4715 measured, 2402 observed reflections with $I \geq 1.96\sigma(I)$; $R = 0.058$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-51758, the names of the authors and the journal citation.

The data given indicate that the N···H···N hydrogen bond in **2a** is stronger than in **1a**. Furthermore, the free base **2** should also have a shorter N···N distance than **1** and therefore a stronger destabilizing interaction between the nitrogen lone-pair electrons,[13] which is removed upon protonation. For both reasons, we expected **2** to exhibit a higher basicity than **1**. Surprisingly, however, the determination of the pK_a values in 35% (v/v) dimethylsulfoxide/water ($I = 0.1$ mol/L, 25 °C)[14] gave a significantly lower pK_a value for **2** (11.5 ± 0.1) than for **1** (12.8 ± 0.1). We ascribe this result to the fact that the hydrogen bond in **2a** is less shielded on all sides by the flanking *N*-methyl groups than that in **1a**, as shown by comparison of the X-ray structure analyses of **1a**[3] and **2a** (Fig. 1). According to examination of models, this effect should be even more pronounced for **3a** than for **2a**; this is in accord with the estimated pK_a value of 10.9 for **3a** based on proton transfer experiments.

$[Pd_2S_{28}]^{4\ominus}$: A 30-Membered Cage Containing an Entrapped Cation**

By *Achim Müller,* Klaus Schmitz, Erich Krickemeyer, Michael Penk,* and *Hartmut Bögge*

Dedicated to Professor Marianne Baudler on the occasion of her 65th birthday

Novel, exciting metal–sulfur heterocycles and clusters can be formed from polysulfide ions and metal ions,[1] since, on the one hand, polysulfide ligands exhibit a wide range of coordination possibilities and, in addition, a large variety of combinations of rings is possible depending on the type of metal center.

We have now succeeded in obtaining orange-red crystals of **1** by reaction of palladium acetylacetonate in acetonitrile/dimethylformamide with an ethanolic solution of polysulfide in the presence of the cations $PPh_4^{\oplus}$ and $NH_2Me_2^{\oplus}$. **1** was characterized spectroscopically[2] and magnetochemically[2] as well as by elemental analysis and a complete X-ray crystal structure analysis.[3,4]

$(PPh_4)_2(NH_2Me_2)(NH_4)[Pd_2(S_7)_4]$ **1**

The anion of **1**, which exhibits approximate D_4 symmetry, has an unusual cage structure (Fig. 1). The cage is formed by linking two Pd atoms (or two PdS_4 planes, which form an approximate square antiprism) with four polysulfide chains. Alternatively, it can be described as being built up from two almost perpendicular tetradecathia-8,16-dipalladacyclohexadecanes having the Pd atoms in common. The coordination of the Pd atom corresponds to that expected for Pd^{II}-d^8.

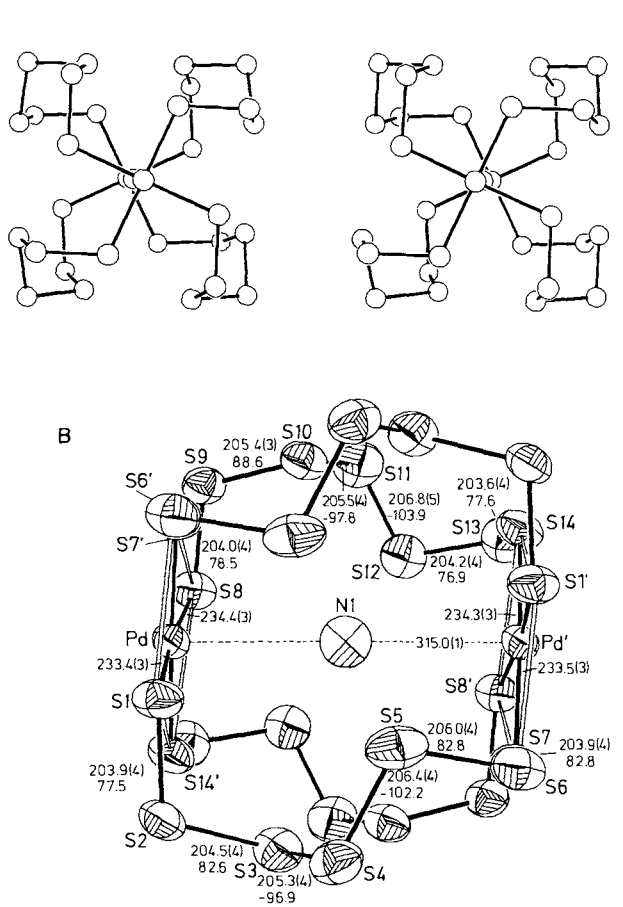

Fig. 1. Structure of the anion in crystals of **1**: A) stereoview along the Pd–Pd axis; B) viewed along the crystallographic C_2 axis with bond lengths [pm] and selected torsional angles [°]: S1-Pd-S(other ring) and S8-Pd-S(other ring) 89.5(1)–90.4(1), S1-Pd-S8 174.4(1), S7'-Pd-S14' 177.9(1), all Pd-S-S 112.5(1)–113.3(2), all S-S-S 105.6(2)–108.2(2); PdS_4 planes (S1-S14'-S8-S7' and S1'-S7-S8'-S14) in B specially marked. Definition of the rings: PdPd'S1···S14, "other" PdPd'S1'···S14'.

Since the Pd–Pd distance is 630.0(1) pm and the second coordination shell sulfur atoms lie roughly in the PdS_4 planes, the cage has a (relatively) large cavity. In its center is an $NH_4^{\oplus}$ ion, which most likely contributes to the stabilization of the cage system. The anion of **1** can, therefore, also be regarded as the "cation–anion complex" $[Pd_2\{NH_4\}(S_7)_4]^{3\ominus}$. The four equivalent $S_7^{2\ominus}$ ligands are so arranged that the sulfur atoms have alternatingly small (373.3–408.0 pm) and large (453.3–492.1 pm) distances from the center of the cage. The Pd–N distance is 315.0(1) pm. Remarkably, the cages are stacked parallel to the plane diagonals $\vec{a}+\vec{c}$ with a Pd–Pd distance of (only) 741.8 pm and the $NH_2Me_2^{\oplus}$ ions in between them.

A 2-Phosphonio-Substituted 1-Phospha-1-alkene: Resonance between P^{III} Alkene and P^{V} Ylide**

By *Hans H. Karsch,* Hans-Ulrich Reisacher,* and *Gerhard Müller*

Compounds with a P^{V}C "double bond" **I** have long been known, although they are best described by the ylide form **Ia**.[1] Compounds **II** with a P^{III}C double bond, on the other hand, have only become available in recent years and their PC double bonds are substantially less polarized.[2]

We have now studied whether the introduction of 2-phosphonio substituents on a 1-phospha-1-alkene leads to a resonance relationship as described by Equation (1). Such a bonding situation would have crucial consequences for the character and reactivity of the P^{III}C double bond. We have prepared the 2-phosphonio-substituted 1-phospha-1-alkene **4** both from the diphosphaallene **1**[3] and from the phosphino-substituted phosphaalkene **2**.[3b]

(1)

Compound **4** is formed via the presumed intermediate 1,3-diphosphaallyl cation **3** by the known C,H addition of a *tert*-butyl group to a proximal electropositive center, resulting in ring formation.[4] The yellow, crystalline compounds **4a**[5] and **4b**[6] dissolve surprisingly well in toluene.

The resonance relationship shown in Equation (1) follows from the NMR data: in the ^{31}P-NMR spectrum of **4**, the resonance signal of the P^{III} atom is found at unusually low field (cf. ref. [3b]) in the range observed for phosphenium ions.[7] On the other hand, the ^{13}C-NMR signal of the bridging sp^2 C atom has the lowest chemical shift found so far for phosphaalkenes:[8] δ = + 109.94 (**4a**) and + 116.25 (**4b**).[9] The alkene hydrogen atom is also correspondingly shielded ($\delta(^1H)$ = 6.84 for **4a** in comparison with 8.56 for **2**). The magnitudes of the ^1J(PC) coupling constants also agree with expectations. These results indicate that resonance structures B and C [Eq. (1)] are of considerable importance in describing the actual structure of **4**. Structure C is a resonance-stabilized bis(σ-organo)phosphenium ion.[11] The cation/anion interaction apparently has only a minor effect. Prototropism, i.e., the existence of tautomeric forms, was not observed (ylides with hydrogen on the phosphorus atom are rare).

Compounds **4a**, **b** are thus examples of compounds having a strongly polarized P^{III}C double bond, which may be described by P^{III}=C(sp^2)/P^V=C(sp^2) resonance structures. To the best of our knowledge, such a resonance relationship was unknown until now.[12] Polarization of the double bond is also observed for vinylphosphonium salts, resulting in a deshielded β-C atom that is highly electrophilic.[13] These observations further support the analogy between carbon and phosphorus expected on the basis of the diagonal relationship.

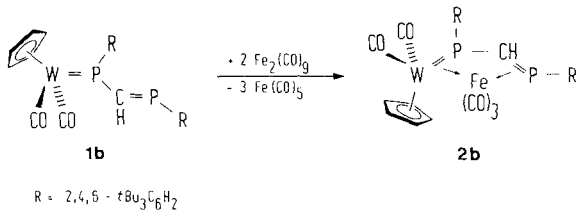
Phosphorus Analogues of Unsaturated Carbon Compounds: an (*s-trans*)-1,3-Diphospha-4-metallabutadiene and Its (*s-cis*)-Fe(CO)$_3$ Complex**

By *Hans H. Karsch,* Hans-Ulrich Reisacher, Brigitte Huber, Gerhard Müller, Wolfgang Malisch,* and *Klaus Jörg*

Analogies between phosphorus and carbon chemistry are well documented for saturated systems[1] and have been extended in recent years to the unsaturated systems.[2, 3] Until now, however, it has not been possible to isolate acyclic, conjugated 1,3-diphosphabutadienes.[3a] They are also unknown as complex ligands, even though a large number of complexes are known that contain an isolated PX multiple bond.[4] The incorporation of a metal into the heterobutadiene unit has only been achieved so far for cyclic compounds that are stabilized by complex formation.[5] Free 1,3-diphospha-4-metallabutadienes **1** and their metal complexes **2**, which contain **1** as an acyclic π-ligand, have not been described so far. They would be true analogues of butadiene **3** (which has the *s-trans* conformation in the ground state) and its *s-cis* metal complexes **4**, respectively.



We have now succeeded in obtaining compounds of the type **1** from the recently described 2-chlorophosphino-substituted 1-phospha-1-alkene **5**.[6a] **1a**, **b**[7, 8] can be isolated as green, air-stable crystals. According to an X-ray structure analysis of **1a** (M = Mo),[7] they can be described as *s-trans* heterobutadienes (Fig. 1). In **1a**, a 1,3-diphosphaallyl fragment[6b] (which is not obtainable in its uncomplexed

form) is bonded to the metal "end-on" through the planar-coordinated P1.[9] A (noncrystallographic) mirror plane passes through Mo, P1, C1, and P2. The MoP1 bond (2.268(2) Å) is only slightly longer than other MoP double bonds and significantly shorter than MoP single bonds.[10] The P–C bond lengths differ significantly. P1–C1 corresponds to a (slightly shortened) single bond and P2–C1 to a double bond.[2] The NMR data, especially the low-field shift of the signals of the phosphorus nuclei and the large $^1J(WP)$ coupling constant, are in good agreement with reference values.[2, 6, 10]

The tricarbonyliron complex (butadiene)Fe(CO)$_3$ may be considered as a "classical" butadiene complex of the type **4**. In order to test the butadiene analogy of **1**, we allowed **1b** to react with Fe$_2$(CO)$_9$[11] and thereby obtained reddish brown crystals of **2b**.[12] According to the ^{31}P-NMR spectrum, no intermediate is formed.

The butadiene-like coordination of **1b** to the Fe(CO)$_3$ fragment requires a rotation around the PC single bond. The NMR data are in accord with a π-coordination of the ligand **1b**; in particular, the high-field shifts of the ^{31}P- and ^{13}C-NMR resonances are typical for such a coordination.[4, 5, 11]

The X-ray structure analysis[12] confirms that **2b** is a heterobutadiene complex (Fig. 1). Characteristic are the nearly planar arrangement of the ligand framework

WP1C1P2 and the partial structure WP1C1C2, the distances of the iron atom from the donor atoms W, P1, C1, and P2,[5, 11] and the near equivalence of the two P-C1 bond lengths. The $Cp(CO)_2W$ fragment is only slightly changed in comparison with the $Cp(CO)_2Mo$ fragment in **1a**. The conformation found in the solid state requires a rotation around the WP double bond during the complexation with the $Fe(CO)_3$ fragment. This finding also supports the view that **2b** is a heterobutadiene complex. These results allow, for the first time, the direct use of an uncomplexed diphosphametallaheterobutadiene as a ligand in synthesis.[13]

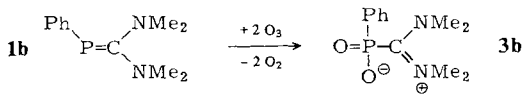
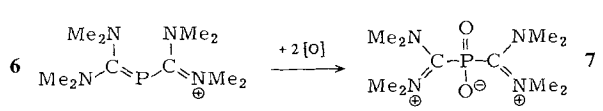
Dioxides of *C*-Amino-Substituted Phosphaalkenes and Phosphaallyl Cations**



By *Alfred Schmidpeter,* Karl-Heinz Zirzow, Angela Willhalm, Joan M. Holmes, Roberta O. Day,* and *Robert R. Holmes*

Dedicated to Professor Marianne Baudler on the occasion of her 65th birthday

Phosphaalkenes **1** react as nucleophiles and are converted by chalcogens into the P^V compounds **2** (Y = O, S, Se).[1] Thus, reaction of **1a** ($R^1 = C_6H_2tBu_3$, $R^2 = Ph$, $R^3 = SiMe_3$) with ozone at −78 °C affords a stable methyleneoxophosphorane **2a** (Y = O);[2] with an excess of ozone, secondary reactions take place,[2] most likely with cleavage of the P–C bond.[3]



We have now found that the electron-rich phosphaalkene **1b**[4] takes up two equivalents of oxygen smoothly and selectively upon reaction with ozone at room temperature, leading directly to formation of **3b**. **2b** (Y = O) is not observed as an intermediate, since a part of **1b** remains unchanged upon reaction with less ozone, and more ozone does not lead to secondary reactions.

In the ^{13}C-NMR spectrum (CD_3CN) of **3b**[5] the downfield shift of the sp^2 C-atom observed for **1b** ($\delta = 200$, $J_{PC} = 67$ Hz[4]) is essentially retained ($\delta = 180$, $J_{PC} = 91$ Hz). This is not consistent with the epoxide **4b** (oxaphosphirane oxide), and rather suggests formation of the zwitterionic amidiniophosphinate **3b**.[6] The thiaphosphirane sulfides **5** corresponding to **4b** can be synthesized from methylenethioxophosphoranes **2** (Y = S) by (reversible) uptake of sulfur.[1] **3b** is also accessible from dimethyl phenylphosphonite and tetramethylurea dichloride.[7]

The tetrakis(dimethylamino)-2-phosphaallyl cation **6**[8] is smoothly converted into the colorless dioxide **7**, not only by ozone, but also by hydrogen peroxide or dimethyl sulfoxide (DMSO).[9] Even the perchlorate counterion effects this oxidation already under mild conditions: colorless **7**·ClO_4 crystallizes from a solution of yellow **6**·ClO_4 in acetone or acetonitrile after heating to 60 °C.

The X-ray structure analysis of the perchlorate of **7** (Fig. 1)[10] confirms the bis(amidinio)phosphinate structure of the cation (C_2 symmetry). Compared to the phosphaallyl

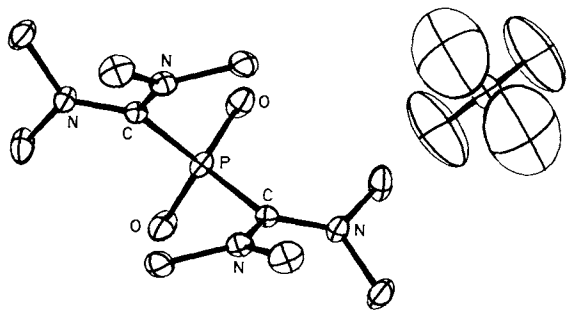


Fig. 1. ORTEP diagram of the structure of 7·ClO_4 in the crystal. The vibration ellipsoids are drawn at the 30% probability level. The hydrogen atoms have been omitted for clarity. Bond lengths [pm] and angles [°] (where necessary mean values): PO 147.8(3), PC 188.7(4), CN 133.5(5); OPO 122.5(3), OPC 102.5(3), CPC 103.8(3), PCN 119.6(3), NCN 120.6(4) [11].

cation **6**[8] the CPC angle is unchanged, while the PC bonds are lengthened from 179.6(4) to 188.7(4) pm and thus lie at the upper limit of known PC single-bond lengths. There is no contact between the $PO_2^{\ominus}$ and the $CN_2^{\oplus}$ groups; the amidinio C-atom is planar coordinated. In **6**, which has a conjugated allyl system, the spatial crowding of the two Me_2N groups turned towards each other results in the "internal" PCN angle being considerably greater than the "external" one.[8] In **7** the conjugation is no longer present, so the two amidinio groups are not kept coplanar; accordingly the two PCN angles of a group do not differ in **7**.

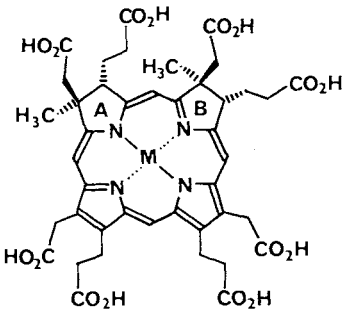
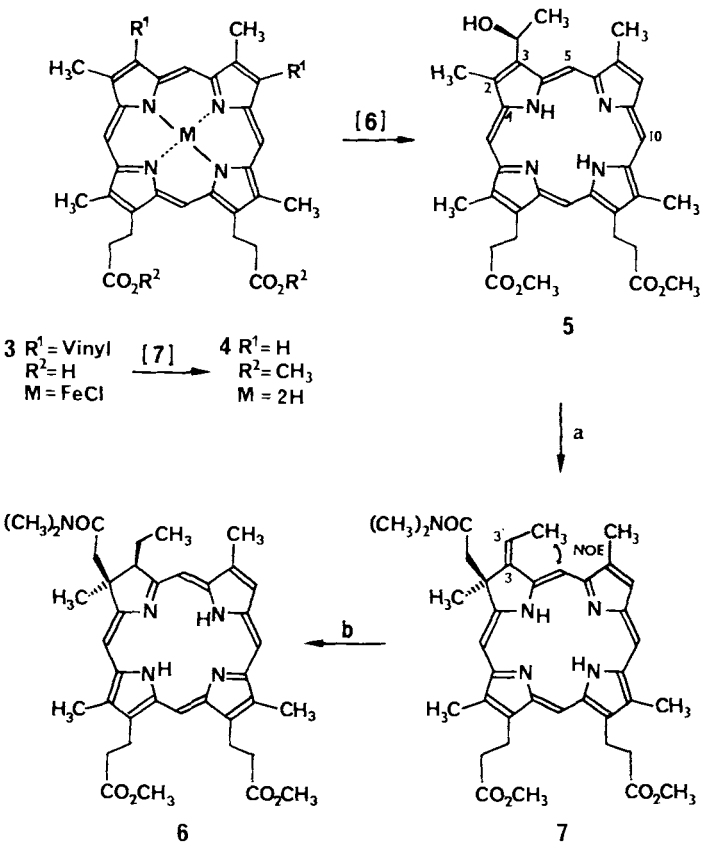
Facile Entry to Geminally Dialkylated Chlorins**



By *Franz-Peter Montforts** and *Gottfried Zimmermann*

Dedicated to Professor Burchard Franck on the occasion of his 60th birthday

Factor I **1** and sirohydrochlorin **2a** are novel porphinoid pigments with a chlorin and isobacteriochlorin structure, respectively. Their reduced derivatives occur as intermediates in the biosynthesis of vitamin B_{12} via uroporphyrinogen III.[1] Iron-containing sirohydrochlorin **2b**, moreover, functions as prosthetic group in sulfite- and nitrite-reductases of bacteria and plants.[2]



1

2a M = 2H
2b M = Fe

One of the main difficulties in model[3] and total syntheses[4] of these structure types is the construction of the geminally dialkylated moiety in the pyrrole rings A or A and B. We have now found that this moiety can be conveniently constructed starting from the readily accessible hydroxyalkylporphyrins by Claisen rearrangement with *N,N*-dimethylacetamide dimethyl acetal.[5]

A 3-hydroxyethylporphyrin **5**[6] suitable as starting compound can be obtained via deuteroporphyrin dimethyl ester **4**[7] from hemin hydrochloride **3** by a known pathway. Upon reaction with *N,N*-dimethylacetamide dimethyl acetal, **5** is converted into **7**. The *Z*-configuration of the exocyclic double bond in the product **7**, which is readily detectable by intramolecular ^1H-nuclear Overhauser effect (NOE), evidences the expected stereoselective course[8] of the rearrangement. Catalytic hydrogenation of **7** affords the chlorin **6**, whose *cis*-configuration likewise follows from a NOE experiment (Scheme 1).

Scheme 1. Reaction conditions: a) $CH_3C(OCH_3)_2N(CH_3)_2$, *o*-xylene, molecular sieve 3 Å, argon, 160°C, 1 h; flash chromatography; crystallization 76%. – b) H_2, Pd/C, CH_3OH, room temperature, 2 h; flash chromatography; crystallization 70%. – All the new compounds have been characterized by elemental analyses and UV/VIS, ^1H-NMR and mass spectroscopy. Selected spectroscopic data: **7**, UV/VIS ($CHCl_3$): $\lambda_{max} = 399$ nm ($\lg\varepsilon = 5.176$), 496 (3.99), 503 (3.95), 532 (4.03), 602 (3.56), 629 (3.48), 659 (4.61); ^1H-NMR ($CDCl_3$, 270 MHz): $\delta = -2.68$, -2.52 (2m, 2NH), 2.19 (s, 2-CH_3), 2.82 (d, $J = 7.5$ Hz, 3'-CH_3), 3.25 (AB system, 2-CH_2), 6.44 (q, $J = 7.5$ Hz, 3'-H), 8.86 (s, 20-H), 9.52 (s, 5-H); MS (200°C): *m/z* 651 (26%, M^+), 565 (100%, $M^{\oplus} - CH_2CON(CH_3)_2$). **6**, UV/VIS ($CHCl_3$): $\lambda_{max} = 392$ ($\lg\varepsilon = 5.195$), 489 (4.025), 496 (4.041), 522 (3.185), 532 (3.047), 592 (3.505), 616 (3.466), 645 (4.583); ^1H-NMR ($CDCl_3$, 270 MHz): $\delta = 1.18$ (t, $J = 7.4$ Hz, CH_3, 3-ethyl), 2.20 (s, 2-CH_3), 2.42 (m, $J = 7.4$ Hz, CH_2, 3-ethyl), 3.25 (AB system, 2-CH_2), 4.66 (t, 3-H), 8.79 (s, 20-H), 9.01 (s, 5H).

Since there are methods available for the efficient synthesis of porphyrins, and since hydroxyalkyl substituents can be readily introduced by acylation with subsequent reduction, the concept presented here should open up a route to the natural products **1** and **2**. Preliminary experiments show that hematoporphyrin dimethyl ester is converted by double Claisen rearrangement into the isobacteriochlorin structure type, but the stereochemistry involved thereby is complex and still requires clarification.

Thioketone *S*-Oxides by [2+2]-Cycloaddition of Ynamines to *N*-Sulfinyltosylamide

By *Steffen Kosack, Gerhard Himbert,** and *Gerhard Maas*

Ynamines undergo [2+2]-cycloaddition reactions with compounds that contain electrophilic C=C double bonds or carbonyl-, thiocarbonyl- or imino groups.[1] The resulting cyclobutenes are, as a rule, stable[1,2] (exceptions[3]), whereas the 1,2-dihydro-oxete, -thiete, and -azete derivatives that are formed initially isomerize by electrocyclic ring-opening to give α,β-unsaturated amides, thioamides, and amidines, respectively.[1,4]

In continuation of our studies on cycloadditions we have examined the reaction of ynamines **1a–f** with *N*-sulfinyltosylamide **2**.[5] We were able to isolate, in good yields (66–90%), the α-amidinothioketone oxides **4** (Table 1),[6] whose formation can be explained in terms of a spontaneous ring opening of the 1,2-dihydro-1,2-thiazete derivatives **3** (Scheme 1).

The constitution of the open-chain products **4** is substantiated, in particular, by their IR spectra; the *N*-sulfonylamide moiety is revealed by intense bands in the regions 1510–1560 cm^{-1} (C=N) as well as 1270–1305 and 1139–1152 cm^{-1} (SO_2), whereby the region of the asymmetric SO_2 valence vibration ($\tilde{\nu} \approx 1300\ cm^{-1}$) is especially characteristic.[7] We assign one of the intense absorptions between 1075 and 1139 cm^{-1} to the sulfinyl group.[8] Confirmation of the structure is provided by the chemical shift of the

thioaldehyde H-atom in the ^{1}H-NMR spectra of **4c** and **4f** ($\delta > 9$; see Table 1). The position of the signal and the magnitude of the coupling constants for the thiocarbonyl C-atom in the ^{13}C-NMR spectra of **4a** ($\delta = 183.77$; q, $^2J = 8.2$ Hz), **4b** (175.28, s), and **4f** (163.86; d, $^1J = 179$ Hz)

Table 1. Melting points, assignment of configuration, and selected ^{1}H-NMR data of **4**.

4	M.p. [°C]	Configuration	^{1}H-NMR ($CDCl_3$, δ values) NR^1R^2(alkyl)	R^3
a	110–111	*E*	1.19 (t; 6H) 3.43 (4H) [a]	2.54 (s; 3H)
b	127–128	*E*	1.13 (t; 3H) 1.26 (t; 3H) 3.20–3.90 (m; 4H)	7.40 (m; 3H) 7.95 (m; 2H)
c [b]	91–92	*E*	3.40 (s; 3H)	9.39 (s; 1H)
	155–156	*Z*	3.40 (s; 3H)	9.09 (s; 1H)
d [c]	133–134	*Z*	3.39 (s; 3H)	2.21 (s; 3H)
e	140–141	*Z* [d]	3.51 (s; 3H)	[d]
f [e]	160–161	*Z*	—	9.34 (s; 1H)

[a] Unstructured broad signal. [b] The *E* isomer is obtained upon addition of **1c** to **2** followed by rapid isolation; in solution, it transforms into the *Z* isomer (e.g. in $CDCl_3$ at room temperature in ca. 1 h). [c] New signals ($\delta = 2.27$ and 3.43 < 40%) appear in the ^{1}H-NMR spectrum within 5 h; these we assign to the *E* form. [d] Unequivocal assignment of configuration impossible owing to overlapping of the aryl-proton signals. [e] The ^{1}H-NMR spectra of some crystal fractions show a second, less intense singlet at $\delta = 9.50$, which we assign to the *E*-form.

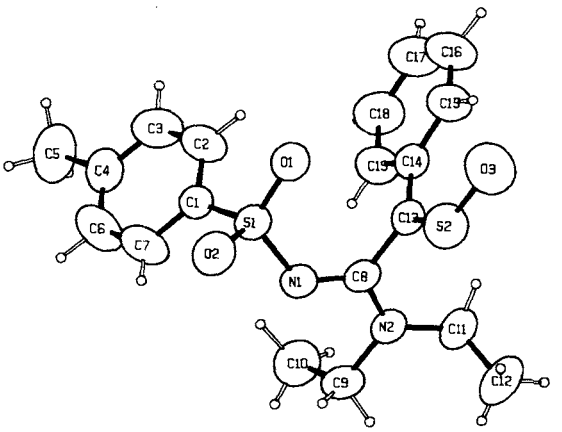

Fig. 1. ORTEP diagram of the crystal structure of **4b**. The vibration ellipsoids are drawn at the 50% probability level. Important bond lengths [Å] and angle [°]: S2-C13 1.629(3), S2-O3 1.470(4); C13-S2-O3 115.7(2) [9].

[*] Prof. Dr. G. Himbert, Dipl.-Chem. S. Kosack, Prof. Dr. G. Maas
Fachbereich Chemie der Universität
Postfach 3049, D-6750 Kaiserslautern (FRG)

are also consistent with the structure **4**. The adducts **4** exhibit the activity expected of a compound containing a sulfinyl group:[8] desulfurization on photolysis of **4a** and **4b**, Diels-Alder reactivity of the C=S double bond of **4c** and **4f** towards 2,3-dimethyl-1,3-butadiene, and hydrolysis of **4f** to the acetamidine derivative.

Assignment of configuration is based on the anisotropic effect of the sulfinyl group:[8] that the methyl protons of **4a** ($\delta = 2.51$, s) and the *ortho*-aryl protons of **4b** ($\delta = 7.93$ m) absorb at relatively low field shows that the oxygen of the SO group is near to these substituents, i.e. the C=S bond is *E*-configurated. In contrast, the *Z*-form seems to predominate in the aniline derivatives **4c-f** (see Table 1).

An X-ray structure analysis was carried out on **4b**. There is no conjugation between the π-systems of the amidine moiety and the C=S(O) bond, since the N1-C8-N2 and C14-C13-S2 planes are almost perpendicular (92.8°) to each other.

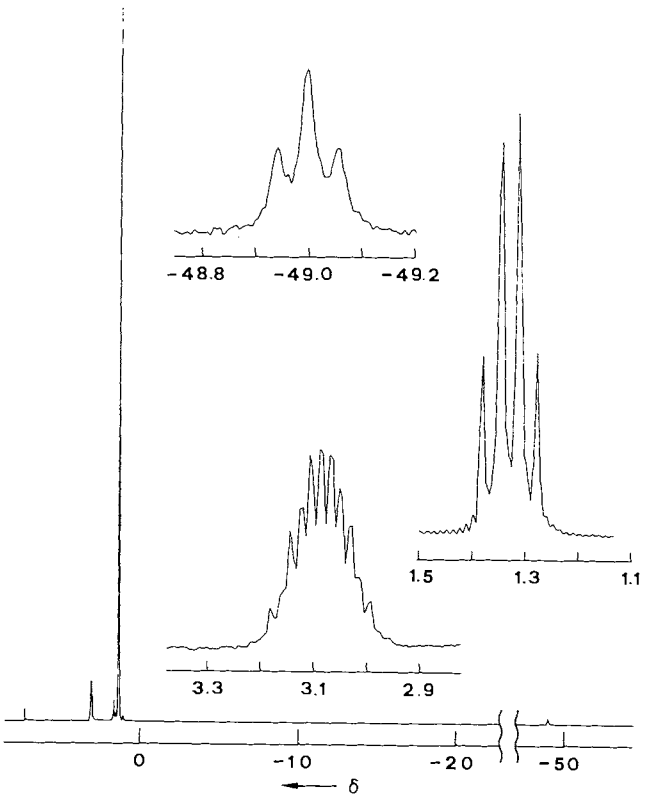
Unusual Behavior of the Stable Paramagnetic Dihydridoiridium(IV) Complex $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ in Solution**

By *Pasquale Mura** and *Annalaura Segre*

The title compound, *trans* $[Ir(H)_2(Cl)_2(iPr_3P)_2]$ **1**, whose preparation and X-ray crystal structure was reported recently,[1] failed to show any EPR signals both in the solid state and in solution, even when cooled to 110 and 193 K, respectively.

Consideration of electron spin relaxation times for systems with $T_{1e} \approx T_{2e} \lesssim 10^{-10}$ s led to the expectation that EPR lines would be so broad that they could not be readily detected, whereas the corresponding NMR line-widths should be only slightly affected by the unpaired electron.[2] Since we were unable to observe any EPR resonances for **1**, we undertook a study of its ^1H- and ^{31}P-NMR spectra.



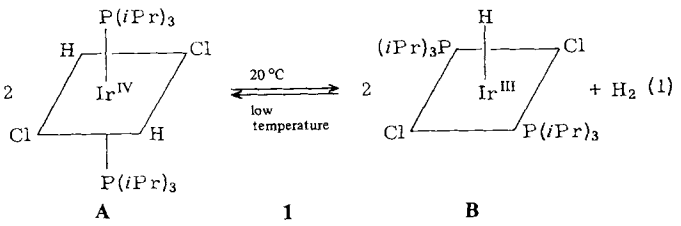


Fig. 1. ^1H-NMR spectrum of **1** at room temperature in $CDCl_3$; some sections have been enlarged.

The ^1H-NMR spectrum ($CDCl_3$, room temperature, TMS) of **1** (Fig. 1) contains three sharp, well-resolved multiplets (relative intensities 6:36:1); $\delta(PCH) = 3.11$ (m), $\delta(PCHCH_3) = 1.33$ (d, vt), and $\delta(IrH) = -49.0$ (t); $J(HH) = 7.3$ and $J(PH_{hydride}) = 11.1$ Hz. The broad-band decoupled $^{31}P\{^1H\}$-spectrum shows a sharp singlet at $\delta = 33.3$. Selective irradiation of the signals due to the CH and CH_3 protons in the region $\delta = 1$–3 converted this singlet into a doublet. Thus, it follows from the observed spectrum that a monohydride with a stereochemistry such as that of compound **B** is present in solution [reaction (1)].

[**] We are indebted to Prof. *L. M. Venanzi* for valuable suggestions and discussions, and to the NMR service of the Research Area of Rome.

A 1 B

Another broad peak, centered at $\delta \approx 2$ ppm and of very low intensity is also always present and will be discussed below.

It must be noted that the coupling constants, chemical shifts and relative intensities of the signals are reconcilable only with the presence of a *diamagnetic* monohydrido complex such as **B**—which is in complete contrast with the X-ray structure data and magnetic susceptibility measurements performed on solid **1**.[1]

However, on lowering the temperature all peaks of the ^{1}H- and ^{31}P-NMR spectra noticeably broaden and, at 223 K, the hydrido peak disappears.

In order to clarify this behavior, a study of the ^{1}H-NMR spectrum of **1** as a function of the temperature was undertaken. On lowering the temperature to 183 K the spectrum progressively broadens; in the meantime, also the solvent peak slightly broadens. This process is reversible. At the same time, on cooling, the signal of the hydrido hydrogen, as well as that of the methyne hydrogen, undergo a paramagnetic shift (Fig. 2a, b).[3] Thus, it is reasonable to postulate that an equilibrium between a paramagnetic and a diamagnetic species exists in solution,[4] in which the paramagnetic dihydrido species **A** is evident only at low temperature; i.e., NMR data obtained as a function of the temperature point to an equilibrium of type (1) in solution.

In order to verify this hypothesis a small quantity of H_2 gas was bubbled into the NMR tube. The intensity of the broad signal at $\delta \approx 2$ strongly increased, while the hydride signals underwent a strong paramagnetic shift (≈ 5 ppm) and broadened from ≈ 4 Hz to ≈ 50 Hz, indicating that equilibrium (1) moves in favor of species **A**.[5] When D_2 gas was bubbled into the NMR tube the broad peak at $\delta \approx 2$ disappeared. Thus, the proposed equilibrium (1) would appear to be consistent with and rationalize all solution and solid state data.[1]

One explanation why the molecular H_2 formed in (1) does not leave the solution could be that H_2 is in some way linked to the monohydrido species **B**, as has recently been reported for other complexes.[6] From this point of view the equilibrium (1) could be seen as an example of a temperature-dependent reversible ligand-to-metal charge transfer (LMCT)[7] $\rightleftarrows$ metal-to-ligand charge transfer (MLCT) [Reaction (2)].

$$2\,Ir^{IV}(H)_2 \underset{MLCT}{\overset{LMCT}{\rightleftharpoons}} 2\,Ir^{III}H\cdot(H_2) \qquad (2)$$

Extremely large chemical shifts ($\delta \cong -50$) have been reported by *Shaw* et al.[8] as well as by *H. Werner* et al.[9] for several monohydrido-Ir^{III} complexes. Given the similarity of the chemical shifts between **1** (δ(IrH) $= -49.0$) and the above compounds it is possible that their behavior is analogous to that what we observe for **1**, and that paramagnetic hydrido complexes may be present in solution at low temperature.

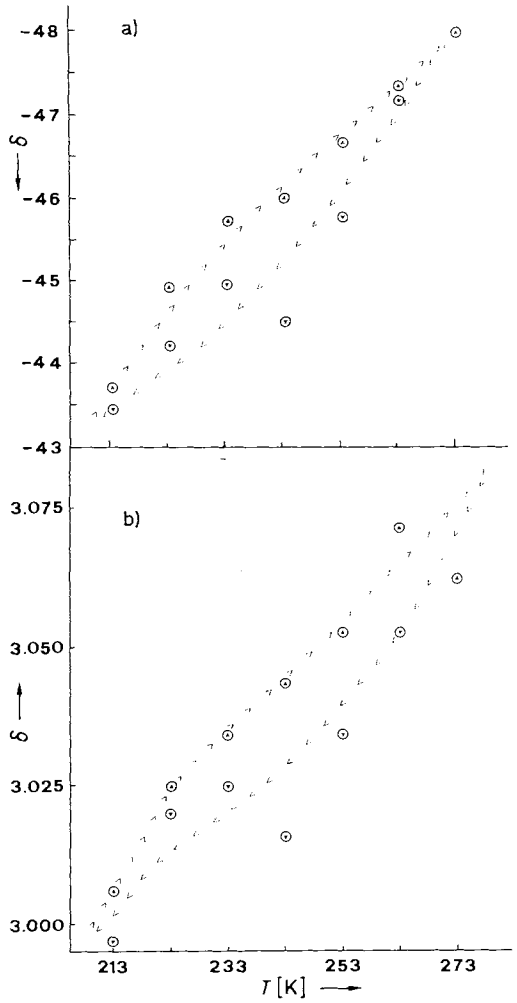

Fig. 2. Chemical shift behavior as a function of the temperature for the hydrido peak (a) and for the methyne peak (b) in the 200-MHz ^{1}H-NMR spectrum of **1**. In each case the measurements were made, starting from the lowest temperature. (The peak due to the methyl groups does not shift enough.)

The IR spectrum of **1** (in benzene at room temperature) shows one strong band at 2256 cm^{-1}, which is assigned to $\tilde{\nu}$(IrH). This value is very different from that observed for the solid compound,[1] $\tilde{\nu}$(IrH) $= 2003$ cm^{-1} (mw) (KBr pellets). Comparison of these two values strongly confirms the substantial difference between solid state and solution at room temperature.

[3] The hysteresis pattern apparent in Fig. 2a, b is most probably due to the fact that only 15 minutes dead-time were given between one NMR run and the other. In fact, solutions of **1** are not stable indefinitely; thus, as soon as the temperature was stabilized a new spectrum was run. Consequently, kinetic reasons can explain the apparent hysteresis cycle, which is observable only for signals due to **1** and not, for instance, for the H_2O signal; water was present as an impurity in solution. In the case of the analogue of **1** with cyclohexyl groups instead of isopropyl groups, the same experiment does not show any evidence of the hysteresis pattern, thus confirming that kinetic reasons can explain the behavior for **1**.

[4] Since we could observe a ^{31}P-NMR spectrum at -90 °C, even if rather broad, the equilibrium in solution must in any case be shifted towards the diamagnetic species; thus, the rate of the paramagnetic/dimagnetic equilibrium cannot be measured.
[5] Upon bubbling H_2 into an NMR tube containing $CDCl_3$ only, a sharp peak appeared at 4.61 ppm which disappeared in 60 s.

Stereospecific Reductions with Hydrogen Gas, Modified Metal Catalysts, Methyl Viologen and Enzymes or Microorganisms**

By *Iordanes Thanos* and *Helmut Simon**

Reductases which can take up electrons from reduced viologens such as methyl viologen ($MV^{\oplus\odot}$) can stereospecifically reduce numerous 2-enoates and 2-oxocarboxylates.[1-3] The methyl viologen, which is present in catalytic amounts, is recycled according to Scheme 1 between the oxidized and reduced state.

Scheme 1. Methyl viologen ($MV^{2\oplus}$) is the *N,N'*-dimethyl-4,4'-bipyridine dication.

We have hitherto reduced $MV^{2\oplus}$ in three ways:[1] 1) with hydrogen in combination with a hydrogenase, 2) with formate in combination with a formate dehydrogenase, and 3) electrochemically.

We have now found that methyl viologen and other viologens can also be reduced with palladium, platinum or Raney nickel and hydrogen gas when these catalysts are

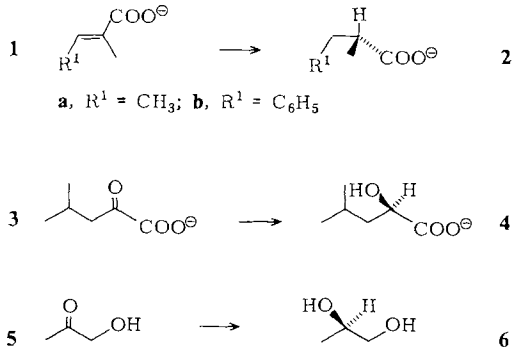

Table 1. Reduction of the substrates **1a**, **1b**, **3** and **5** with H_2, modified metal catalysts, methyl viologen, and biocatalysts (for further experimental conditions see caption to Fig. 1; enzymes, see [1]).

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 145), BASF, and the Fonds der Chemischen Industrie. We thank H. Costenoble GmbH & Co. KG, Eschborn/Ts. (FRG), for kindly supplying samples of Zonyl®. We also thank Mrs. *Christine Filser* for technical assistance and Mr. *A. S. Paxinos* for valuable discussions.

modified with fluorine-containing surfactants such as Zonyl®-FSC.[4,5] In the presence of such pretreated catalysts, 2-enoates or 2-oxocarboxylates are not reduced by hydrogen gas. When catalytic amounts of $MV^{2\oplus}$ and appropriate enzymes are added, however, the reduction proceeds exclusively enzymatically. Figure 1 shows a typical result. Tiglate **1a** is rapidly reduced by palladium and hydrogen. Palladium pretreated with surfactant was unable

to effect any hydrogen uptake from **1a**. On addition of the aforementioned $MV^{2\oplus}$ and enoate reductase, however, enantiomerically pure (*R*)-2-methyl butyrate **2a** was formed. Thus, we have here particularly simple systems containing only one enzyme, and resort to the relatively expensive electrochemical cell is circumvented. The results are listed in Table 1. For determination of the enantiomeric excess, the products **2a** and **2b** transferred to the organic phase were allowed to react with (*R*)-2-amino-2-phenylethanol according to the method described by *Helmchen*;[6] the unpurified reaction mixture was investigated by reversed phase HPLC or the optical rotation of the isolated products was measured. In each case base line separation could be achieved upon chromatography of the diastereomeric mixtures that were obtained in control experiments by reaction of *rac*-**2a** and *rac*-**2b** with (*R*)-2-amino-2-phenylethanol.

In the method previously used by us,[1,3] enoate reductase leads to products of the type **2a** and **2b** with an enantiomeric excess (*ee*) of >96–98%. (*ee* >96% means that *ee* can be practically 100%.) The experiments 1–5 show that the enantiomeric excess of the chiral acids is very high. It is irrelevant whether modified Pd, Pt or Raney nickel is used.

The catalyst pretreated with Zonyl®-FSC reduces methyl viologen at about the same rate as untreated catalyst. However, methyl viologen is more than 500 times more stable in the presence of pretreated palladium than in the presence of unmodified palladium. The modified palladium also attacks the pyridine nucleotide system. Unmodified catalysts destroy NAD(P) in ca. 1 h in a hydrogen atmosphere. This is very important if enzymatic NAD(P)H is formed with methyl viologen and is then consumed by a corresponding reductase. Experiment 6 shows that it is possible to couple yeast to hydrogen gas for bioreductions via modified catalysts and methyl viologen.

In some of the experiments listed in Table 1, relatively little biocatalyst was intentionally used in order to show that the systems have satisfactory long-term stability and that the chiral products do not racemize.

We envisage the following possible applications for the modified metal catalysts: 1) One-enzyme systems with simple regeneration of cheap mediators. 2) Coupling of many microorganisms not having any hydrogenase to hydrogen gas. This is possible, since many organisms can enzymatically reduce NAD and/or NADP with $MV^{\oplus\odot}$.[1,7] 3) Accelerating hydrogen uptake in the hydrogenation of substrates with hydrogenase-containing organisms, if the hydrogenase activity is limiting. It is, moreover, advantageous if the course of the reaction can be followed by the readily observable consumption of hydrogen.

Finally, the preparation of reduced methyl viologen with hydrogen and modified palladium or platinum in preparative enzymatic work is far superior to the methods with dithionite,[8] zinc,[9] or unmodified platinum with hydrogen as reducing agents. In the preparative application of these methods, high concentrations of sulfite or zinc ions, respectively, were introduced into the systems; both the viologen as well as the pyridine nucleotide are stable for only a short time in the presence of unmodified metal.

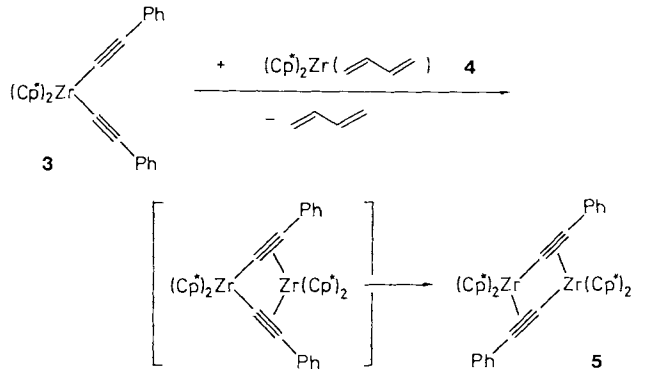
Unusual Bridging of the Metal Centers in Dimeric Bis(η-methylcyclopentadienyl)-phenylethynylzirconium**

By *Gerhard Erker,** *Wolfgang Frömberg, Richard Mynott, Barbara Gabor,* and *Carl Krüger*

The special bonding situation in bent metallocenes $[Cp_2M]$ often leads to rather unusual complex geometries upon interaction with organic π-systems.[1] *Teuben* and *de Liefde Meijer* observed that (phenylethynyl)titanocene **1a** spontaneously dimerized under the conditions used for its preparation.[2] *Stucky* et al. elucidated the unusual CC-coupled structure of the stable dinuclear reaction product **2b**

1 **2**



a, R=H; **b**, R=CH$_3$

by an X-ray structure analysis of the methylcyclopentadienyl analogue **1b**.[3] We have now tried to prepare the corresponding zirconium complex via a similar route. Surprisingly, we have observed that in this system the formation of the novel structure type **5** (Cp* = η-$C_5H_4CH_3$) is favored upon replacement of the 3d element titanium by the 4d element zirconium.

Reaction of the zirconocene derivative **3**[4] with **4**[5] at room temperature proceeds slowly, with liberation of butadiene, to give the sparingly soluble compound **5**. The IR spectrum immediately shows that **5** and **2** belong to different types of complexes. Whereas the titanium compound **2**

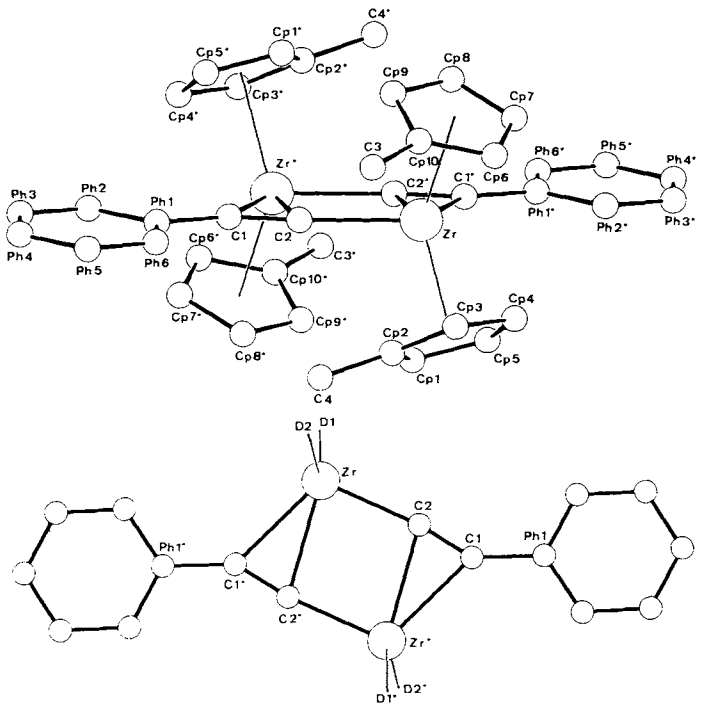
[**] This work was supported by the Fonds der Chemischen Industrie.

shows no IR absorption in the C≡C stretching vibration region,[2,3] in the case of **5** a strong band at 1780 cm^{-1} indicates the presence of a π-complexed alkynyl ligand.[6] In the ^{13}C-NMR spectrum the signal of one of the alkynyl C-atoms appears at unusually low field ($\delta = 228.9$, C2; 154.7, C1).



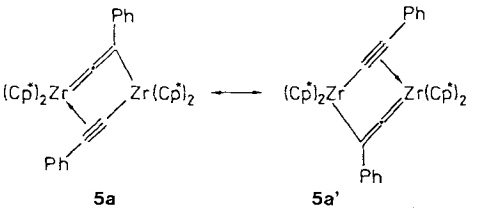


Fig. 1. Two views of the structure of **5** in the crystal. (D1 and D2 denote centroids of the cyclopentadienyl ligands.—Selected bond lengths [Å] and angles [°] C1-C2 1.261(2), C1-Ph1 1.467(2), Zr-C2 2.188(2), Zr-C2* 2.431(2), Zr-C(1*) 2.407(2); D1-Zr-C2 128.0, Zr-C2-Zr* 98.6(1), C2-Zr-C2* 81.4(1).

The X-ray structure analysis (Fig. 1)[7] shows that in the course of reaction one of the two σ-alkynyl ligands of **3** has been transferred to the $(\eta\text{-}C_5H_4CH_3)_2Zr$ fragment of **4**. Compound **5** may be regarded as a centrosymmetric dimer of formally d^1-configurated mono(alkynyl)zirconocene fragments. However, in contrast to the titanium system **2** no CC coupling of the alkynyl groups has occurred here. The two Zr centers in the diamagnetic complex **5** are neither coupled directly to each other nor by forming a CC bond but solely via the completely planar alkynyl ligand system. This can be regarded to a first approximation as a pair of bridging σ,π-alkynyl units. It should be noted, however, that the Zr-C2 bond is rather short.[8] Moreover, the Zr-C2* and Zr-C1* distances indicate that side-on coordination of the alkynyl ligands has led to metal-to-carbon bonds exhibiting a considerable σ-character.[1,8]

These findings indicate that a new type of bridging of two metal centers by alkynyl ligands is present in **5**.[9] **5** is a delocalized metallacyclic system. The bonding can be described in terms of an equivalent participation of the resonance structures **5a** and **5a'**.[10]

Superactive Alkali Metal Hydride Metalation Reagents: LiH, NaH, and KH**

By *Peter A. A. Klusener, Lambert Brandsma,* Hermann D. Verkruijsse, Paul von Ragué Schleyer,* Thomas Friedl,* and *Rafael Pi*

In principle, the hydrides of alkali metals should be ideal synthetic reagents for the metalation of active hydrogen compounds.[1-10] Hydrogen is the only by-product, and the course of the reaction can be conveniently followed by gas evolution. Addition reactions (e.g. of *n*-butyllithium (BuLi) to carbonyl groups) and electron transfer processes (e.g. by alkali metals) are largely (but not completely) avoided. The high lattice energies of the metal hydrides, particularly of LiH,[1] reduce their reactivity. Commercially available KH and NaH have both been used to some extent as bases,[1-6] whereas LiH has hardly been used at all.[7] Activated by tetramethylethylenediamine (TMEDA), commercial lithium hydride does metalate dibenzyl ketone, but the reaction takes four days.[8] *C. A. Brown* showed that commercial potassium hydride is more reactive than sodium hydride, but described LiH as "essentially inert".[1] We now report the preparation of extremely active NaH, KH and even LiH "superbase" reagents under mild conditions using simple procedures.

Gilman et al. found that a number of organolithium compounds as well as other organometallics could be reduced by hydrogen to give the corresponding metal hydrides.[11] Although these slow reactions can be accelerated by ethers or tertiary amines,[12] they remain "of no practical value".[9] *Bank* and others have prepared "exceedingly active" sodium hydride by hydrogen reduction of sodium naphthalene, but few reactions of this promising reagent have been reported.[13] Attempts by *Brown* to prepare KH in a similar way met without success.[1]

Enormous improvement in these procedures is achieved by hydrogenating BuLi in hexane in the presence of TMEDA. The finely suspended LiH which is produced metalates dibenzyl ketone and 1,1,2,2-tetraphenylacetone exothermically and almost instantly at room temperature; high yields (ca. 80%) of quench products (e.g. silylated enol ethers with $(CH_3)_3SiCl$) were obtained.

BuNa and BuK were prepared first by the reaction of NaO*t*Bu or KO*t*Bu with BuLi in hexane/TMEDA.[14, 15] Hydrogenation at $-25°C$ to $-10°C$ gave the highly reactive NaH and KH in suspension.[16] tBuCOCH$_3$ was metalated almost instantaneously by this KH reagent at $-20°C$; NaH reacts less vigorously, but at 0–20°C enolate formation was complete in 20 minutes. High (ca. 90%) yields of tBuC(OSiMe$_3$)=CH$_2$ were obtained in both cases with Me$_3$SiCl; only a slight amount (ca. 5%) of the addition product, tBuCH(CH$_3$)OSiMe$_3$, was formed. LiH with the same ketone gave comparable amounts of reduction and deprotonation products (after quenching with Me$_3$SiCl).

In contrast to these results, the reported yields with commercially available NaH and LiH are 20% and 2%, respectively.[1] With the difficultly enolizable dicyclopropyl ketone, reduction to the alcohol (95%) was achieved with both KH and LiH, but the rates of reduction were both much faster than those reported in the literature for commercial NaH.[7] Commercial LiH does not react at all. Our KH also metalated dibenzyl ketone instantly at $-20°C$ (80% yield of Me$_3$SiCl quench product), but refluxing for one day did not effect conversion into the known[10] dimetalated species.

Brown compared the reactivities of the alkali hydrides by measuring the rate of hydrogen evolution with, e.g., an excess of dimethyl sulfoxide.[1] At 25°C, KH reacted completely in 8 min; even at 50°C, NaH effected only partial conversion, while LiH was inert. Our reagents are indeed "superactive". Under the same conditions, but at 0°C, KH, NaH, and LiH all react within 1–5 minutes. With excess pyrrolidine at 20°C, our KH gave essentially complete metalation in one minute; LiH reacts somewhat slower and incompletely (70%). NaH leads to only 40% H_2 evolution; but this is essentially achieved in one minute. Incomplete reactions are due to solubility problems, especially with NaH. The metalated products appear to cover the metal hydride surface and prevent further reaction. Hence, use of excess hydride reagent may be needed.

Experimental

Preparation of NaH and KH Reagents. A mixture of 0.10 mol of NaO*t*Bu or KO*t*Bu and 50 mL of hexane (dried by distillation from LiAlH$_4$) was cooled to below $-20°C$. Dry TMEDA (0.10 mol) was added, and then a solution of 0.10 mol of BuLi in about 70 mL of hexane at $-30°C$ [14, 15]. After 15 min, hydrogen was introduced with vigorous stirring at such a rate that practically all gas was absorbed. Fine suspensions of KH and NaH were formed. The reactions were markedly exothermic; cooling was needed to keep the temperature between -20 and $-25°C$ (KH), and -10 to $-15°C$ (NaH). When the rate of absorption decreased, the flow of H_2 was increased to about 0.5 L/min, and the temperature allowed to rise gradually to $+10°C$ or somewhat higher. When no more hydrogen was absorbed, the reaction was stopped. ***Warning:** These active alkali hydrides are pyrophoric in air!*

Preparation of the LiH Reagent. An equimolar or small (1.2 times) excess of TMEDA was added to a solution of *n*-butyllithium in hexane at room temperature. Hydrogen was then introduced with vigorous agitation while keeping the resulting suspension between 30 and 35°C (30–60 min) until no more hydrogen was absorbed. The substrate to be metalated could then be added; the reaction could be followed by the rate and the amount of the H_2 evolved. Under the same conditions, H_2 does not react with BuLi in the absence of TMEDA.

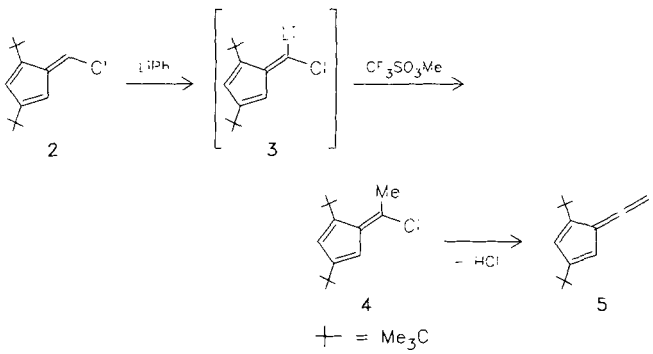
[16] In this procedure, LiO*t*Bu also is present. However, BuNa and BuK can be obtained pure by filtration and washing [14]; suspension in hexane/TMEDA and hydrogenation gives LiO*t*Bu-free NaH and KH. However, these reagents are less reactive and offer no preparative advantages.

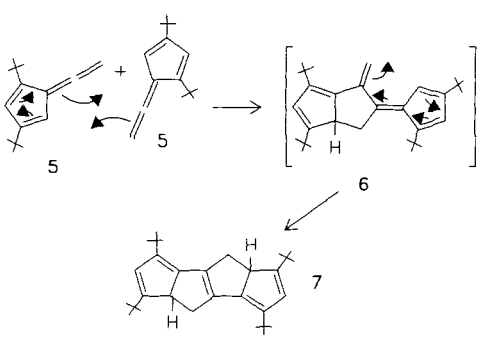
Synthesis of a Dicyclopenta[*a,e*]pentalene by [6 + 2]-Cycloaddition of 1,3-Di-*tert*-butyl-5-vinylidenecyclopentadiene and Consecutive 8π-Electrocyclic Reaction**

By *Bernd Stowasser* and *Klaus Hafner**

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday



Nonbenzenoid linear annelated [4n + 2]- and [4n]-π-electron systems can be formally regarded as annulenes perturbed by central σ-bonds. According to quantum chemical investigations the bonding behavior of these polycycles should be determined by the π-perimeter as well as by its partial structures.[1] Only three examples of linear annelated hydrocarbons containing more than two exclusively nonbenzenoid rings have so far been reported, namely cyclohepta[*a*]cyclopenta[*e*]- and cyclohepta[*a*]cyclopenta[*g*]azulene as well as azuleno[2,1-*a*]azulene.[2] The partial structures of these aromatic 18π-electron systems also contain [4n + 2]-π-electrons.[3] Consequently, the bonding situation in a representative of the hitherto unknown systems with [4n + 2]-perimeter having [4n]-π-partial structures is of special interest. These prerequisites are fulfilled by dicyclopenta[*a,e*]pentalene **1**. We report here on the synthesis of its tetra-*tert*-butyl derivative **11** by a surprising, novel dimerization of the "pentafulveneallene" **5**.[4] The synthesis concomitantly opens up an entry to the hitherto largely unexplored linear annelated tetraquinanes. The 14π-electron system of **1** formally consists of a pentalene and a



1A 1B

pentafulvene partial structure (**1A**) or two pentalene units (**1B**). According to π-SCF-MO calculations the perimeter of **1** should exhibit a pronounced double-bond fixation determined by a pseudo-Jahn-Teller effect and the π-bonding isomer **1A** (C_s symmetry) should be ca. 4 kcal·mol^{-1} lower in energy than **1B** (C_{2h} symmetry) with two overlapping pentalenoid partial structures. The delocalized 14π-electron system should have an enthalpy of formation ca. 14 kcal mol^{-1} higher than that of **1A**.[1a]

For the synthesis of the tetra-*tert*-butyl derivative **11** of the tetracycle **1** we used 1,3-di-*tert*-butyl-5-vinylidenecyclopentadiene **5** as educt. While "pentafulveneallenes" were hitherto only accessible from diradical generators by pyrolysis or photolysis,[4] we prepared **5** in 88% yield as pale yellow crystals of m.p. 43–44°C (after sublimation) by

metalation of the 6-chloropentafulvene **2**[5] with phenyllithium (tetrahydrofuran (THF), −78°C) to the carbenoid **3**, followed by methylation with methyl trifluoromethanesulfonate (−78°C) to give **4** (yellow leaflets, m.p. 71°C, yield 33%) and subsequent HCl elimination with lithium 2,2,6,6-tetramethylpiperidide (LiTMP) (−78 to 25°C).[6] **5** dimerizes in a solid-state reaction at ca. 10°C within approx. 14 days to give 1,3,5,7-tetra-*tert*-butyl-4,4a,8,8a-tetrahydrodicyclopenta[*a,e*]pentalene **7** (from *n*-hexane, pale-

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Dr.-Otto-Röhm-Gedächtnisstiftung.

yellow crystals, decomp. above 114°C; yield 35%). The formation of **7** could involve a [6+2]-cycloaddition of the terminal bond of **5** to the pentafulvene moiety of a second molecule of **5** to give the tetrahydropentalene derivative **6**, which subsequently undergoes an 8π-electrocyclization to **7**.

Whereas the direct dehydrogenation of **7** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in ether at 25°C affords only **8** (from *n*-hexane, brown crystals, sublimation >250°C; yield 63%),[7] the proton-catalyzed tautomerization ($CHCl_3$/HCl, 25°C) of **7** leads to the hydrocarbon **9** (from *n*-hexane, reddish-brown fine crystals, m.p. 182°C; yield 75%). Dehydrogenation with DDQ in the molar ratio 1:1 affords the dihydro compound **10** (greenish-brown powder, m.p. 131°C; yield 72%). Upon further dehydrogenation of **10** or reaction of **9** with DDQ in the molar ratio 1:2, the desired 1,3,5,7-tetra-*tert*-butyldicyclopenta[*a*,*e*]pentalene **11** is obtained as thermally stable brownish-violet crystals (chromatography on Al_2O_3 BII–III with pentane) of m.p. 136°C (decomp.) in 70% yield.

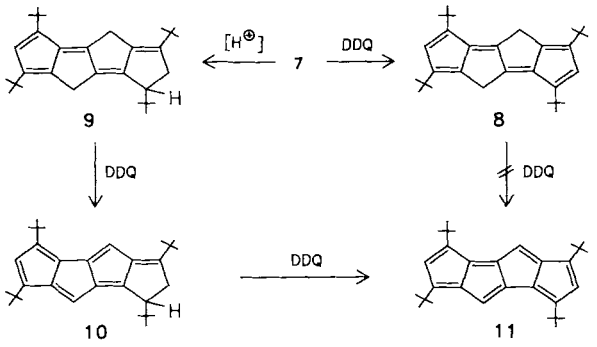

Table 1. Spectral data of **4**, **5**, **7**–**14**. ^{1}H-NMR at 300 MHz, *J* in Hz.

13: ^{1}H-NMR ([D$_8$]THF): δ = 1.01 (s; 9H, *t*Bu), 1.03 (s; 9H, *t*Bu), 1.20 (s; 9H, *t*Bu), 1.22 (s; 9H, *t*Bu), 3.51 (s; 2H, 4-H), 4.42 (s; 1H, 8-H), 5.06 (s; 1H, 2-H), 5.65 (s; 1H, 6-H)

14: ^{1}H-NMR ([D$_8$]THF): δ = 1.00–1.33 (*t*Bu signals masked by LiTMP/TMP signals), 4.64 (s; 2H, 4/8-H or 2/6-H), 5.13 (s; 2H, 2/6-H or 4/8-H)

Consistent with what was to be expected on the basis of quantum mechanical calculations, the ring-proton signals at δ = 6.58 and 6.72 (in $CDCl_3$) in the ^{1}H-NMR spectrum of **11** are shifted markedly upfield compared to those of bridged [14]annulenes such as *trans*-10b,10c-dihydropyrene[8] (δ = 7.98–8.67) or *syn*-1,6:8,13-bismethano[14]annulene[9] (δ = 7.1–7.9). In comparison to the ring-proton signals of 1,3,5-tri-*tert*-butylpentalene[10] (δ = 4.72–5.07) the ^{1}H-signals of **11** are shifted to lower field. The similarity of the ring-proton signals of **10** and **11** (Table 1) reflects the cyclopolyolefin character (extensive double-bond fixation) of the new hydrocarbon **11**. The absorptions in the electronic spectrum of **11** (Table 1) correspond favorably to the singlet electron transfers calculated by *Lindner*[1a,11] and by *Toyota* and *Nakajima*[1b] for **1A** with localized double bonds.

11 can be reversibly converted by protonation with trifluoroacetic acid in $CHCl_3$ at 25°C into the stable green cation **12**,[12] whose ^{1}H-NMR data are consistent with a delocalized 10π-electron system. Deprotonation of **8** with equimolar amounts of LiTMP in THF at 25°C affords the lithium salt of the deep-green anion **13**, which can be further deprotonated with LiTMP to give the brownish-yellow dilithium salt of the 1,3,5,7-tetra-*tert*-butyldicyclopenta[*a*,*e*]pentalene dianion **14**. A comparison of the ^{1}H-NMR signals of the ring protons of **11** and **14** shows that the conversion of the 14π-perimeter into the 16π-electron system—taking into account the negative charges in **14**—does not lead to the formation of a clearly paratropic system (upfield shift: Δδ = 1.5–2).[13]

Bicyclo[3.2.1]octa-2,6-dienyllithium**

By *Norbert Hertkorn, Frank H. Köhler,* Gerhard Müller,* and *Gabriele Reber*

The bicyclo[3.2.1]octa-2,6-dienyl anion **1** is an illustrious example for uniting differently orientated chemists in their ambition to understand a molecule. Although the existence of **1** in solution was first demonstrated more than twenty years ago[1] a lithium derivative thereof has so far never been reported; indeed, no alkali metal derivative has ever been isolated. The central question since its discovery has been: Does **1** experience a stabilization due to bishomoaromaticity or not? Many careful and elegant experiments as well as different computational methods gave diametrically opposed answers (for reviews see Refs. [2–4]). During the last five years *Grutzner* and *Jørgensen*[2a] as well as *Mayr, Schleyer* et al.[2b] concluded from their calculations that homoaromaticity should be negligible in **1**. Modified computations by *Brown* et al.[2c] were much in favor of homoaromaticity. The same was deduced by *Washburn*[3] from the experimental acidities of bicyclo[3.2.1]octa-2,6-diene **2** and similar compounds. *Christl* et al.[4a] and our group[4b] have published ^{13}C-NMR data which are in accord with (possibly slight) homoconjugation; at least, considerable charge transfer from the allylic to the olefinic part of **1** could be demonstrated. We have now been able to isolate the lithium derivative **1a** of the anion **1** as tetramethylethylenediamine (TMEDA) complex **1c**, and to obtain ^{13}C-NMR data of **1a**.

2 1b 3a,b 1a

As described earlier,[4b] **2** was converted into the potassium derivative **1b** of the anion **1**. Reaction with Me_3SnCl furnished a mixture of *exo/endo*-4-trimethylstannylbicyclo[3.2.1]octa-2,6-dienes **3a/b**,[5] and these were transformed into **1a** by methyllithium. **1a**, which according to its ^{13}C-NMR spectrum contained only small amounts of ether, was dissolved in various solvents in order to obtain the ^{13}C-NMR data listed in Table 1; new data for **1b** are also listed. The number of signals and their shifts show that in solution the anion has the same symmetry in **1a** and **1b**. We also wanted to establish how the charge transfer from the allylic to the olefinic part of **1** changes when the equilibrium between contact ion pairs and solvent separated ion pairs[6] is influenced by different alkali ions and/or solvents. As can be seen from Table 1 the average chemical shift δ^{av} is not constant. Hence the effect of the charge delocalization in the π-system on $\delta(^{13}C)$ is obscured by other effects like aggregation, participation of the σ-framework, and geometrical changes within **1**.

Table 1. ^{13}C-NMR data [a] of **1a** and **1b** in various solvents [b].

[**] This work was supported by the Fonds der Chemischen Industrie and BASF.

Upon cooling a saturated solution of **1a** in TMEDA we obtained yellow crystals that were suitable for an X-ray structure analysis.[7] Figure 1 shows that the crystals contain **1c**, bicyclo[3.2.1]octa-2,6-dienyllithium stabilized by one molecule TMEDA. **1c** is a monomer with a crystallographic symmetry (C_1) which is lower than expected for **1a** alone (C_s) because N1-N2 is not parallel to C1-C5. Lithium occupies an almost central position below the seven-membered ring, such that not only the allylic but also the olefinic part of the carbanion is engaged in metal–ligand bonding. Li-C6 and Li-C7 are even shorter than Li-C2 and Li-C4. A coordination number of seven, rarely observed for solvated lithium bound to a pure hydrocarbon,[8] is thus achieved.

According to the C_1 symmetry lithium is placed asymmetrically below the allyl part of **1**; this confirms NMR-results on allyllithium.[9] Li-C3 is the only "normal" lithium-carbon distance, the others being much longer than in most organolithium compounds.[8] In 1,3-diphenylallyllithium[10] similar Li-C distances are found for the outer allyl carbon atoms while the inner one is ca. 0.013 Å further away from lithium than in **1c**.

A still closer Li-C3 contact is to be expected in the case of an undistorted carbanion. However, the allylic plane is inclined towards C8 by 3.9° relative to the C1-C2-C4-C5 plane. This distortion is the first experimental verification that the inner substituents in an allyllithium compound are bent away from the metal, as predicted for the inner hydrogens of the parent compound C_3H_5Li.[11] There is also a similarity to the tricarbonyl(bicyclo[3.2.1]octa-2,6-dienyl)iron cation,[12] while in cyclopentadienyllithium (silylated in the five-membered ring) the π-system is planar.[13]

In view of the controversy about the homoaromaticity in **1** the results are especially enlightening. If the C1-C2-C4-C5, C1-C5-C6-C7, and C1-C5-C8 planes are termed A, B, and C then the interplanar angles A/B, A/C, and B/C are found to be 103.2°, 119.2°, and 137.6° respectively. While angles of about 120°, as for A/C, are expected,[14] it looks as if C6/7 moves towards the allyl system, thus increasing the angle for B/C and decreasing it for A/B. Correspondingly, C2 and C7 and C4 and C6 are separated by only 2.371 and 2.370 Å, respectively. The approach of the olefinic and the allylic part has been claimed to be crucial for the interaction in **1**.[2c] When the MNDO optimized geometry with C2-C7 = C4-C6 = 2.480 Å was used as a basis for ab initio calculations on **1** no homoaromatic stabilization could be found.[2a,b,15] In contrast, *Brown* et al.[2c] believe that substantial homoconjugative delocalization is responsible for the charge transfer in **1**. This follows from the orbital analysis at the equilibrium geometry of **1** with likewise 2.48 Å for C2-C7 and C4-C6. We find this distance to be even 0.11 Å shorter in **1c**. Such a shortening is expected[2b] for cyclic conjugation in **1**. On the other hand, the shortening is partly compensated by the interplanar angle A/allyl of 3.9°. As for an additional "lithium effect" on the geometry of **1**, theoretical work including the metal must be awaited.[16] Many X-ray structures[8] suggest that lithium rather accommodates itself to the constraint of ligands (cf. the long distances Li-C2/4/6/7 in **1c**) than vice versa.

[15] The C–C distance has not been given explicitly in Ref. [2a]; it should be very similar to that in Ref. [2b].
[16] After submission of this paper Prof. *Schleyer* informed us that he has carried out MNDO calculations on **1a**.

Synthesis and Structure of the First Arsaalkenyl Complex with FeAs Single Bond**

By *Lothar Weber,* Georg Meine,* and *Roland Boese*

The chemistry of phosphaalkenes has been the subject of intensive study in the past ten years.[1] Such compounds are not only of interest from the theoretical and preparative point of view but also because they exhibit a versatile coordination chemistry.[2] In contrast, very few arsaalkenes have so far been reported. Compounds of type **1** have been prepared by *Becker* et al. from disilylarsanes and pivaloyl chloride.[3] Further, the synthesis and spectroscopic properties of the substituted α-arsastyrenes **2**,[4] **3**,[5] and **4**[6] have been described, but without quoting any X-ray structure data. Coordination compounds of arsaalkenes have, with exception of the rhodium complex **5**, so far never been reported.[7]

5

We report here on the first arsaalkenyl complexes **9**, which can also be regarded as transition-metal substituted arsaalkenes. Complex **9a** is, moreover, the first compound to have been characterized by an X-ray structure analysis in which an As=C double bond does not belong to a conjugated system. The strategy used had previously proven successful in the synthesis of phosphaalkenyl complexes.[8,9] We obtained the title compounds **9a–c** by reaction of the disilylarsenido complex **6** with the carboxylic acid chlorides **7a–c**.

$$[(\eta^5\text{-}C_5H_5)(CO)_2Fe-As(SiMe_3)_2] \xrightarrow[-Me_3SiCl]{+RCOCl\ 7} [(\eta^5\text{-}C_5H_5)(CO)_2Fe-As(SiMe_3)(COR)] \longrightarrow [(\eta^5\text{-}C_5H_5)(CO)_2Fe-As=C(OSiMe_3)(R)]$$

6 **8** **9**

a, R = *t*Bu; **b**, R = 2,4,6-$Me_3C_6H_2$; **c**, R = 2,4,6-$tBu_3C_6H_2$

Postulated intermediates such as, e.g., **8a–c** could not be detected, either by IR or by ^{1}H-NMR spectroscopy.

The $Fe(CO)_2$ group of the complexes **9** is, in each case, recognizable by two intense bands. A medium intensity band occurs at 1180–1194 cm^{-1}; we assign this to the coupled $\tilde{\nu}$(SiOC) vibration. The characteristic downfield shift of the ^{13}C resonances of the As=C unit (δ = 216.4–232.7) is compatible with the monomeric structure of the complexes **9**. As in the case of the phosphorus analogues[8,9] of **9**, *Z*-configuration is assumed at the double bond for steric reasons.

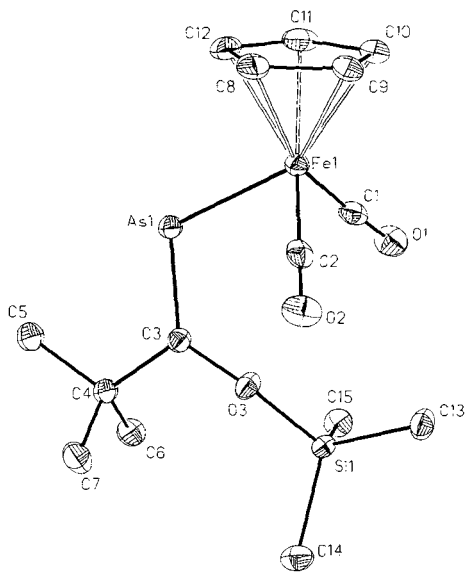

Fig. 1. Structure of **9a** in the crystal. Selected bond lengths [pm] and angles [°]: Fe-As 240.7(1), As-C3 182.1(2), C3-O3 135.6(3), C3-C4 153.3(4), Fe-C1 175.6(3), Fe-C2 176.1(3), C1-O1 114.6(4), C2-O2 114.2(3), Fe-C(Ring) 210.6(2) to 211.3(2); C1-Fe-As 88.0(1), C2-Fe-As 87.0(1), C1-Fe-C2 96.7(1), Fe-As-C3 111.4(1), As-C3-O3 124.1(2), As-C3-C4 120.6(2), C4-C3-O3 115.1(2), C3-O3-Si 144.1(2).

These assumptions were confirmed by an X-ray structure analysis of **9a** at −150°C (Fig. 1).[10] The As=C distance (182.1(2) pm) is distinctly shorter than in the arsabenzene 2,3,6-$Ph_3C_5H_2As$ (185.9, 188.4 pm)[11] and than the standard As–C single bond length (196 pm).[12] From the As=As distance in a diarsene (224.6 pm)[13] and the C=C bond length (130 pm), the length of an As=C double bond can be estimated to be 177 pm. The iron atom lies in a plane with the As, C3 and O3 atoms and is coupled to the arsenic atom by a single bond (240.7(1) pm).

The C3–O3 distance (135.6(3) pm) is significantly shorter than the calculated C(sp^2)O single bond length (141 pm).[14] We explain this in terms of delocalization of a lone electron pair of the oxygen and the electrons of the As=C double bond.

Experimental

^{1}H-NMR: In all cases 200-MHz, C_6D_6, 22°C; ^{13}C-NMR: in all cases C_6D_6, 22°C; EI-MS: in all cases 70 eV (Varian MAT 312).

6: The suspension of $[Cp(CO_3)Fe]^{\oplus}BF_4^{\ominus}$ (Cp = η^5-C_5H_5) (5.89 g, 20.2 mmol) in ether (170 mL) was treated at −55°C with 7.96 g (20.2 mmol) of solid $LiAs(SiMe_3)_2\cdot(THF)_{2.3}$ [15]; the solution immediately turned red. After 15 minutes stirring at −55°C and 30 minutes stirring at 0°C the solution was evaporated in a vacuum at 0°C. The oily dark-red residue was taken up in pentane (30 mL), filtered, and the filtrate concentrated to 10 mL and allowed to stand for 12 h at −78°C; yield 6.34 g (79%) of dark-red, crystalline **6**, m.p. 54–56°C.—^{1}H-NMR: δ = 0.48 (s, $SiMe_3$), 4.18 (s, Cp).—^{13}C{^{1}H}-NMR: δ = 4.7 (s, $SiMe_3$), 84.8 (s, Cp), 217.2 (s, Fe–C≡O).—IR (cyclopentane): 2009 s, 1956 s cm^{-1} ($\tilde{\nu}$(CO)).—EI-MS: *m/z* 399 (M^+).

9a: A solution of **7a** (0.33 g, 2.76 mmol) in THF (50 mL) was added dropwise within 1 h at 0°C to a solution of **6** (1.10 g, 2.76 mmol) in THF (100 mL). The dark-brown solution was evaporated to dryness in a vacuum. The oily, brown residue was taken up in *n*-pentane (25 mL), filtered, and the filtrate concentrated to ca. 10 mL. At −28°C, brown **9a** crystallized out; yield 0.31 g (27%), m.p. 61°C.—^{1}H-NMR: δ = 0.44 (s, $SiMe_3$), 1.42 (s, *t*Bu), 4.14 (s, Cp).—^{13}C-NMR: δ = 2.7 (s, $SiMe_3$), 30.1 (s, $C(CH_3)_3$), 48.3 (s, $C(CH_3)_3$), 85.0 (s, Cp), 215.9 (s, Fe–C≡O), 232.7 (s, As=C).—IR (cyclopentane): 2012 s, 1957 s cm^{-1} ($\tilde{\nu}$(CO)); IR (Nujol): 1194 m cm^{-1} ($\tilde{\nu}$(SiOC)).—EI-MS: *m/z* 412 (M^+ + 2H).

9b: Prepared analogously to **9a**. Brown crystals, yield 30%, m.p. 76°C.—^{1}H-NMR: δ = 0.11 (s, $SiMe_3$), 2.07 (s, *p*-Me), 2.61 (s, 6H, *o*-Me), 4.16 (s, Cp), 6.71 (s, 2H, Ph).—^{13}C-NMR: δ = 0.7 (s, $SiMe_3$), 21.2 (s, *p*-Me), 21.3 (s, *o*-Me), 84.5 (s, Cp), 128.8 (s, *m*-C–Ph), 135.3 (s, *o*-C–Ph), 137.4 (s, *p*-C–Ph), 142.0 (s, *i*-C–Ph), 215.5 (s, Fe–C≡O), 216.4 (s, As=C).—IR (cyclopentane): 2012 s, 1960 s cm^{-1} ($\tilde{\nu}$(CO)); IR (Nujol): 1180 m cm^{-1} ($\tilde{\nu}$(SiOC)).—EI-MS: *m/z* 474 (M^+ + 2H).

9c: Prepared analogously to **9a**. Dark brown crystals, yield 26%, m.p. 160–170°C.—^{1}H-NMR: δ = 0.15 (s, $SiMe_3$), 1.30 (s, *p*-*t*Bu), 1.87 (s, 18H, *o*-*t*Bu), 4.14 (s, Cp), 7.62 (s, 2H, Ph).—^{13}C-NMR: δ = 2.0 (s, $SiMe_3$), 31.5 (s, *p*-$C(CH_3)_3$), 32.6 (s, *p*-$C(CH_3)_3$), 35.0 (s, *o*-$C(CH_3)_3$), 39.0 (s, *o*-$C(CH_3)_3$), 84.9 (s, Cp), 123.7 (s, *m*-C–Ph), 139.8 (s, *p*-C–Ph), 148.2 (s, *o*-C–Ph), 149.6 (s, *i*-C–Ph), 215.2 (s, Fe–C≡O), 216.4 (s, As=C).—IR (cyclopentane): 2012 s, 1959 s cm^{-1} ($\tilde{\nu}$(CO)); IR (Nujol): 1181 m cm^{-1} ($\tilde{\nu}$(SiOC)).—EI-MS: *m/z* 600 (M^+ + 2H).

P_6tBu_4O and P_7tBu_5O— the First Polycyclophosphane Oxides**

By *Marianne Baudler,* Michael Michels, Manfred Pieroth,* and *Josef Hahn*

Dedicated to Professor Rolf Appel on the occasion of his 65th birthday

Polycyclic organophosphanes P_nR_m ($m<n$)[1] are generally susceptible to oxidative attack by atmospheric oxygen—especially in solution. But, so far, nothing has been reported about the polycyclophosphane oxides that are formed. Of particular interest is whether the oxygen reacts with insertion into the P_n-skeleton, as in the formation of P_4O_6 from P_4, or with exocyclic addition to the intact polycyclophosphane. We have now been able to isolate pure tetra-*tert*-butylbicyclohexaphosphane monoxide, **1**, and penta-*tert*-butylbicycloheptaphosphane monoxide, **2**; according to nuclear magnetic resonance investigations two constitutional isomers are formed in each case.

[**] Contributions to the Chemistry of Phosphorus, Part 165. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 164: M. Baudler, L. de Riese-Meyer, *Z. Naturforsch. B*, in press.

1 and **2** were obtained by reaction of excess P_6tBu_4[2] and P_7tBu_5,[3] respectively, in solution with dry air and were separated chromatographically from unchanged polycyclophosphane.[4] When stoichiometric amounts of atmospheric oxygen were used, the corresponding dioxides and further unidentified products were also formed, thus complicating work-up of the reaction mixture. **1a** and **1b** were separately isolable (abundance ratio 4.5 : 1), whereas **2a** and **2b** (abundance ratio approx. 1 : 1) could not be separated, even by high-pressure liquid chromatography.

1a, **1b**, and the mixture **2a**,**b** are pale yellow solids (**1a**: m.p. 132 °C; **1b**: m.p. 134 °C; **2a**,**b**: softening range 122–130 °C), which are stable at room temperature in the absence of air and light. They are readily soluble in hydrocarbons, tetrahydrofuran (THF), and methanol; the solutions are more sensitive to oxidation than the solid substances. The compositions of **1a**, **1b**, and **2a**,**b** were confirmed by elemental analyses and molecular mass determinations (MS). Each show an intense band in the IR spectrum in the region of the P=O valence vibrations.

Proof of the constitution of **1a**, **1b**, **2a**, and **2b** is provided by the ^{1}H-NMR data, and above all by the complete analysis of the ^{31}P{^{1}H}-NMR spectra (Tables 1 and 2). In the case of the ^{31}P{^{1}H}-NMR spectrum of the mixture **2a**,**b**, first a separation into the partial spectra of the isomers by selective population transfer experiments[6] was necessary, which also gave the signs of the coupling constants. Superposition of the calculated individual spectra very satisfactorily reproduced the experimental spectrum of the mixture **2a**,**b** (Fig. 1).

It follows from the ^{31}P-NMR parameters and especially from the ^1J(PP) coupling constants, that the oxygen in the monoxides is in each case bound exocyclically to the P_n skeleton of the parent compound. Which of the P atoms is present as λ^5-phosphorus follows from the drastic down-

field shift of the signal for the relevant P-nucleus compared to the starting compound (**1a**: $\Delta\delta(P^2)=46.3$; **1b**: $\Delta\delta(P^3)=41.5$; **2a**: $\Delta\delta(P^1)=62.2$; **2b**: $\Delta\delta(P^7)$[8] $=107.6$). In addition, the oxidized P atoms are recognizable by the magnitude and the sign of the $^1J(P^VP^{III})$ coupling constants.[7] Accordingly, **1a** and **1b** are 2,3,4,6-tetra-*tert*-butyl-2-oxo- and -3-oxo-bicyclo[3.1.0]hexaphosphanes, respectively, while **2a** and **2b** are 2,3,4,6,7-penta-*tert*-butyl-

1-oxo- and -6-oxo-bicyclo[3.2.0]heptaphosphanes, respectively.[8] The large positive P,P long range couplings (**1a**: $^2J(P^4P^6)$; **1b**: $^2J(P^2P^6)$, $^2J(P^4P^6)$; **2a**: $^2J(P^4P^6)$; **2b**: $^2J(P^4P^6)$) indicate that the lone electron pairs at the respective P atoms are directed towards each other;[2,3,9] i.e. the three-membered ring and four-membered ring are strongly inclined towards the five-membered ring. The organo-groups have the same spatial arrangement as in the starting compounds, as follows from the similarity of the corresponding coupling constants (e.g. **2a** (cf. [3]): $^1J(P^3P^4)$, $^2J(P^5P^7)$, $^3J(P^3P^6)$; **2b** (cf. [3]): $^1J(P^2P^3)$, $^1J(P^3P^4)$, $^3J(P^3P^6)$). As a result of the unsymmetrical substitution, the five-membered ring in **1a** is markedly distorted ($^2J(P^1P^3) \gg {}^2J(P^3P^5)$). **1a**, **2a**, and **2b** are present as enantiomeric pairs.

The findings clearly indicate that the attack of the oxygen at a polycyclic organophosphane is largely determined by steric factors. The observed isomeric abundance **1a** : **1b** = 4.5 : 1 (statistically 2 : 1) is an indication that the five-membered ring atom P^3 in P_6tBu_4 is more strongly shielded by the *tert*-butyl groups than the neighboring atoms P^2 and P^4. In P_7tBu_5 the exocyclic bonding of the oxygen at P^1 and P^7 is apparently equally favorable, but at P^2 or P^4, on the other hand, it is hindered by the *endo* position of the *t*Bu group on P^7. That no isomers with oxygen on the three-membered ring were found in the case of **1** could be due to the pronounced s-character of the lone electron pair on the respective P atoms of the parent compound.

[4] **1a**, **1b**: 6.24 L of dry air were passed into a stirred solution of P_6tBu_4 [2] (23.5 g, 56.7 mmol) in benzene (500 mL) within 2 h. The progress of the oxidation was monitored by ^{31}P-NMR spectroscopy. The solvent was removed under reduced pressure, and the residue (ca. 40% **1a**,**b**, 60% P_6tBu_4) dissolved in benzene (20 mL) and chromatographed under inert gas on Al_2O_3 (heated in vacuo). P_6tBu_4 was eluted with *n*-pentane and then **1a**,**b** with benzene/methanol (80 : 20). For separation of the isomers the solvent mixture was removed and the residue was rechromatographed with benzene on a short column (8 cm). The fractions containing the largest amounts of **1a** were combined and recrystallized from a small amount of pentane/THF (2 : 1) at −30 °C; yield 0.16 g of **1a** (0.7% referred to P_6tBu_4). A previously eluted fraction contained mainly **1b** (ca. 55%); this was isolated by preparative HPLC (Nucleosil 5-C18 column, acetonitrile, receiver −78 °C, rapid condensation of solvent at −30 °C); yield 0.11 g of **1b** (0.5%, referred to P_6tBu_4). — **2a**,**b**: The isomeric mixture was isolated as by-product (0.21 g) in the final purification of P_7tBu_5 by HPLC.[3] Separation of **2a** and **2b** was not possible because of their similar retention times.

[5] ^{1}H{^{31}P}-NMR ([D$_6$]benzene, 25 °C, 300.133 MHz): **1a**: δ = 1.44 (P^2tBu, P^4tBu), 1.21 (P^3tBu), 0.89 (P^6tBu); **1b**: δ = 1.55 (P^2tBu, P^4tBu), 1.37 (P^3tBu), 0.88 (P^6tBu); **2a**: δ = 1.62 (P^2tBu), 1.31 (P^3tBu), 1.36 (P^4tBu), 1.19 (P^6tBu), 1.40 (P^7tBu); **2b**: δ = 1.29 (P^2tBu), 1.46 (P^3tBu), 1.30 (P^4tBu), 1.36 (P^6tBu), 1.40 (P^7tBu).

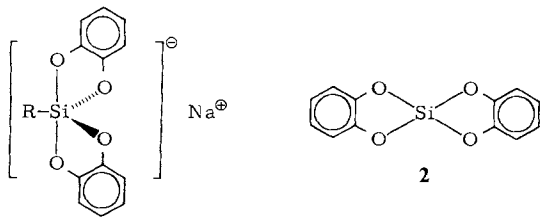
Reactivity of Anionic Pentacoordinated Silicon Complexes towards Nucleophiles

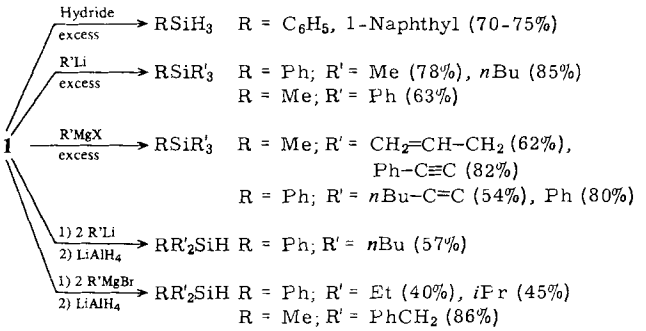
By *Alain Boudin, Geneviève Cerveau, Claude Chuit, Robert J. P. Corriu,* and Catherine Reye*

The reactivity of pentacoordinated anionic silicon species towards nucleophiles has attracted our interest for two reasons: 1) Hypervalent anionic silicon species have been known for a long time[1] and their structures have been investigated,[2] yet reactivity studies have been carried out only in isolated cases and mainly on hexacoordinated species.[1a,3] 2) Pentacoordinated silicon complexes are of interest in connection with mechanistic studies. Nucleophilic substitution at silicon in R_3SiX compounds can be activated by nucleophiles which are good coordinating agents for Si (e.g. $F^\ominus$, HMPA, $RCO_2^\ominus$).[4] These nucleophiles catalyze the nucleophilic substitution but they do not appear in the final product. The activation of organosilicon compounds with $F^\ominus$ is very useful in organic synthesis: the $F^\ominus$-activation of Si–H,[5a] Si–O,[5a,b] Si–N,[5c] Si–C,[5d] and even P–O[6a] and P–X[6b] bonds provided some new synthetic methods.



We have proposed a mechanism for the activation of Si–X bonds by nucleophiles[4a] in which the rate determining step is the attack of the nucleophile *Nu* at a pentacoordinated silicon center. This was formed in a first step by the reversible coordination of the activating nucleophile (cat) (Schema 1, top). However, at least in the case of SiCl and SiBr bonds,[7] this mechanism was considered unlikely since the silicon center of the pentacoordinated adduct should be both more sterically hindered and less electrophilic than the tetracoordinated one and consequently less susceptible to nucleophilic attack. An alternative mechanism (double displacement) was therefore proposed[8] (Scheme 1, bottom).

Scheme 1. Cat = $F^\ominus$, $RCO_2^\ominus$, HMPA, dimethyl sulfoxide (DMSO).



We now investigated the reaction of the complex anions **1** with nucleophiles (hydrides, R'MgX and R'Li, see Scheme 2). Stable ammonium salts and sodium salts of **1** are known.[9] Hydrides such as $LiAlH_4$, iBu_2AlH or Et_3Al/NaH react with **1** to give only trihydrogenosilanes $RSiH_3$, but Grignard reagents or organolithium derivatives are

1, R = Me, Ph, 1-Naphthyl

more selective and lead to two types of products depending on the amount of organometallic reagent: reaction of two equivalents of R'MgX or R'Li, followed by reduction with $LiAlH_4$ gives mainly silanes of type RR'_2SiH; excess of R'MgX or R'Li leads to the tetrasubstituted silanes $RSiR'_3$. Silanes of the type $RR'SiH_2$ (formation of one Si-C bond) are never obtained in yields better than 10%, whatever the experimental conditions may be. This means that the first substitution should be the rate determining step of the reaction.

Scheme 2. Hydride = $LiAlH_4$, iBu_2AlH, Et_3Al/NaH.

We have also compared the reactivity of **1** with that of the previously studied compound **2**.[10] **1** (R = Ph) reacts with 5 equivalents of PhMgBr at room temperature within 3 h to give Ph_4Si in 80% yield, whereas **2** gives only 35% of Ph_4Si after 20 hours in the presence of a large excess of Grignard reagent. Apparently the pentacoordinated anionic silicon species are more reactive than the tetracoordinated ones.

We thus have ample evidence that pentacoordinated anionic silicon species can undergo a nucleophilic attack and may be regarded as possible intermediates in nucleophilic substitutions at silicon. Hence, the mechanism proposed by us (Scheme 1, top) cannot be ruled out merely on the basis of arguments of steric hindrance or of reduced electrophilicity of silicon. These criteria do, of course, hold in the case of nucleophilic substitution at carbon, but may not be schematically extrapolated to silicon.

Experimental

RR'_2SiH: 2 equivalents of organometallic reagent were added dropwise to a suspension of 20 mmol of **1** in 100 mL of ether. The temperature of the mixture rose to 30 °C during the addition.

The mixture was refluxed for 1 h, then treated with an excess of $LiAlH_4$ and refluxed for a further hour. After hydrolysis with H_2SO_4 (25%), the silane was extracted with ether. The ethereal solution was washed with two portions each of 2 N NaOH, water, and brine, and then dried over $MgSO_4$. The ether was removed in a vacuum and the silane was purified by distillation and identified by IR, NMR, and mass spectroscopy.

$RSiR'_3$: The suspension of **1** in ether was treated with an excess (3.6 equivalents) of organometallic reagent. After the addition, the mixture was refluxed for 1 h and then hydrolyzed with H_2SO_4 (25%). The silane was then extracted as described above.

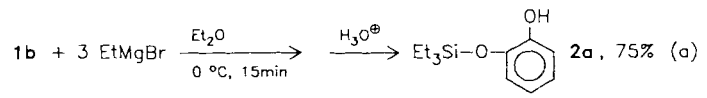
Reaction of Grignard Reagents with Dianionic Hexacoordinated Silicon Complexes: Organosilicon Compounds from Silica Gel

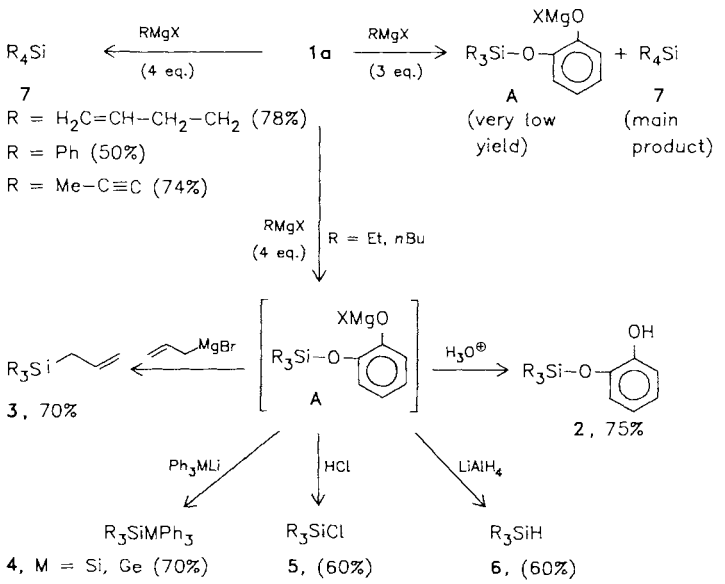
By *Alain Boudin, Geneviève Cerveau, Claude Chuit, Robert J. P. Corriu,** and *Catherine Reye*

Organosilicon compounds are nowadays of great importance in such diverse fields as organic synthesis[1] and ceramics.[2] Hitherto, they have been prepared from elemental silicon, either by "direct synthesis" (Rochow reaction),[3] by the organometallic route,[4] or by the hydrosilylation reaction.[5] In the search for new synthetic routes silica gel has also been used as starting material.[6] It was previously



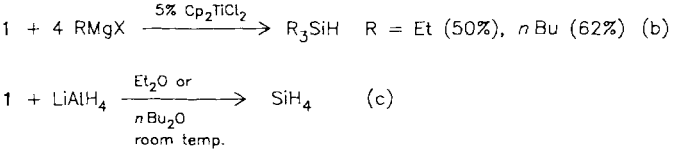
[*] Prof. Dr. R. J. P. Corriu, A. Boudin, Dr. G. Cerveau, Dr. C. Chuit, Dr. C. Reye
Institut de Chimie Fine, Université des Sciences et Techniques du Languedoc, Unité Associée C.N.R.S. U.A. 1097
Place Eugène Bataillon, F-34060 Montpellier Cédex (France)

reported that hexacoordinated silicon complexes of catechol, **1**, can be prepared directly from silica gel in water;[7] this reaction corresponds to a depolymerization of SiO_2 with formation of a monomeric silicon complex.



2 $M^{\oplus}$ **1a**, M = Na; **1b**, M = K

We have now investigated—as previously in the case of anionic pentacoordinated silicon complexes[8]—the reactivity of strong nucleophiles towards very stable sodium and potassium salts **1a** and **1b** prepared under anhydrous conditions.[9] We have found that these reactions lead to the formation of silicon-carbon bonds, thus providing an alternative route for the synthesis of organosilicon compounds. Compound **1b** is very reactive; for instance, it reacts with ethylmagnesium bromide to completion within 15 minutes at 0°C, giving triethylsiloxyphenol **2a** in 75% yield [Eq. (a)].



1b + 3 EtMgBr $\xrightarrow[0\,°C,\ 15min]{Et_2O}$ $\xrightarrow{H_3O^{\oplus}}$ Et_3Si-O-(OH) **2a**, 75% (a)

The reaction course depends on the nature of the Grignard reagent: When RMgX is an alkyl Grignard compound, three silicon-carbon bonds are directly formed irrespective of the ratio **1a**:Grignard compound. The siloxyphenols **2** can be isolated (Scheme 1). They react with nucleophiles to give further organosilicon compounds. Very interestingly, these products (**3**, **4**, and **6**) can also be obtained directly from the intermediate **A** (Scheme 1). In contrast, when RMgX is an allyl, phenyl, or alkyne Grignard reagent the tetraorganosilanes SiR_4 **7** are formed directly, once again independently of the ratio **1a**:Grignard compound. The intermediate **A** can also be cleaved with HCl, resulting in formation of a trialkylchlorosilane **5**.

Scheme 1.

We have reported[10] that Grignard reagents having an hydrogen atom in the β position and activated by Cp_2TiCl_2 (Cp = cyclopentadienyl) are reducing agents. Accordingly, silanes of the type R_3SiH can be prepared in one step directly from **1** and RMgX in the presence of Cp_2TiCl_2 [Eq. (b)]. Complexes **1** react with reducing agents such as $LiAlH_4$ under very mild conditions to give SiH_4 quantitatively [Eq. (c)].

1 + 4 RMgX $\xrightarrow{5\%\ Cp_2TiCl_2}$ R_3SiH R = Et (50%), *n*Bu (62%) (b)

1 + $LiAlH_4$ $\xrightarrow[n Bu_2O\ \text{room temp.}]{Et_2O\ \text{or}}$ SiH_4 (c)

The new methods enable the synthesis of organosilicon compounds directly from silica, thus circumventing the route via elemental silicon; the catechol that is employed can be quantitatively recovered and the complexes are easy to handle. Very important is the fact that the dianionic hypervalent species **1** are very reactive towards organometallic reagents. This demonstrates the synthetic potential of such hypervalent compounds, which hitherto were given very little attention.[11] Indeed, very little is known about the reactivity of hexacoordinated silicon complexes. Reports have merely been published on the basic hydrolysis of cationic species such as acetylacetone,[12] tropolone, and aminotropinimine[13] complexes. Our results and previous observations by *Kummer* et al.[14] on cationic bis-2,2′-bipyridine-, 1,10-phenanthroline- and pyridine-*N*-oxide-silicon complexes show that the reactivity of these species is unusual.

Experimental

1a: A solution of sodium methoxide (80 mmol) in methanol (40 mL) was treated with 45 mmol of silicagel (95%) and then with a solution of catechol (120 mmol) in methanol (40 mL); the resulting mixture was then heated under reflux with stirring for 18 h. After removal of methanol in a vacuum, the solid residue was washed with ether. The black solid was dissolved in 400 mL of tetrahydrofuran (THF) and the resulting solution heated for 1 h in the presence of activated charcoal. After filtration and removal of solvent **1a** was isolated as a white powder and identified by ^{13}C- and ^{29}Si-NMR spectroscopy.

2: Three equivalents of Grignard reagent were added to a suspension of 20 mmol of **1a** in 100 mL of ether at room temperature. The mixture was heated under reflux for 2 h, then hydrolyzed with H_2SO_4 (25%). After extraction with ether, the ethereal solution was washed with two portions of NaOH (2N), two portions of water, and with brine, then dried over $MgSO_4$. The ether was removed in a vacuum and the residue **2** was purified by distillation and identified by IR, NMR, and mass spectroscopy. The NaOH washings were acidified with HCl (4N), then extracted with ether. The ethereal solution was dried over $MgSO_4$ and the ether removed in a vacuum. The residue remaining was identified as crude catechol.

SiH_4: A suspension of **1a** (1 mmol) in *n*-butyl ether (10 mL) was treated with an excess of $LiAlH_4$ in *n*-butyl ether. 22.5 mL of a gas evolved, which was identified as SiH_4 by IR spectroscopy.

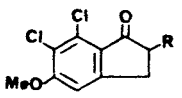
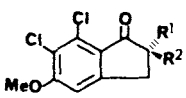
Enantioselective Robinson Annelations via Phase-Transfer Catalysis**



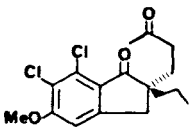
By *Apurba Bhattacharya,* Ulf-H. Dolling, Edward J. J. Grabowski, Sandor Karady, Kenneth M. Ryan,* and *Leonard M. Weinstock*

Robinson annelations have been one of the most widely used synthetic methods in organic chemistry, leading to such complex natural products as steroids, terpenes, and alkaloids.[1] However, only a few methods for accomplishing these reactions in a practical, efficient, and enantioselective manner exist to date.[2–4] Our interest in a chiral version of this reaction arose out of the need to synthesize the optically active tricyclic enone **4d**, which is currently undergoing clinical evaluation.[5]

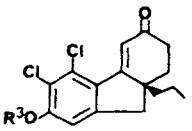


Earlier we described the first efficient, catalytic alkylation of a ketone via asymmetric phase-transfer catalysis mediated by substituted *N*-benzylcinchoninium salts.[6] 6,7-Dichloro-5-methoxy-2-phenyl-1-indanone **1a** was converted into its (*S*)-2-methyl analogue **2a** in 92% *ee* and 95% yield.[6] Herein we further demonstrate the application of this methodology to an asymmetric modification of the Robinson annelation employing 1,3-dichloro-2-butene (the Wichterle reagent[7]) as a methyl vinyl ketone surrogate.[11b]

Alkylation of **1b** with 1,3-dichloro-2-butene[8] in analogy to the procedure described earlier with *N*-(*p*-trifluoromethylbenzyl)cinchoninium bromide[9] as the chiral phase-transfer catalyst produced (*S*)-(+)-6,7-dichloro-2-(3-chloro-2-butenyl)-5-methoxy-2-propyl-1-indanone **2b** in 92% *ee*[10a] and 99% yield.[11a] On the basis of the tight ion-pair theory proposed earlier[6] we anticipated that the product resulting from the above reaction would be the (*S*)-enantiomer, which proved to be the case (see Fig. 1, **5**).[10b]

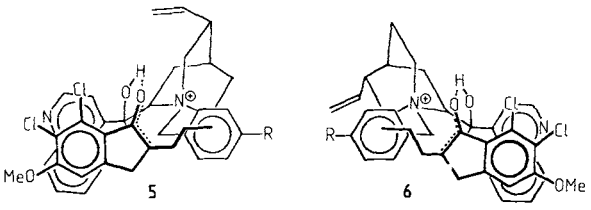


Since the enantiomorph of cinchonine is not available from natural sources, the diastereomer cinchonidine was used to synthesize the (*R*)-enantiomer **2c**. Chiral phase-transfer alkylation using *N*-(*p*-trifluoromethylbenzyl)cinchonidinium bromide[9] afforded **2c** 78% *ee* and 99% yield at 30 mol-% catalyst.[11b]



1a, R = C_6H_5
1b, R = *n*-C_3H_7

2a, $R^1 = C_6H_5$, $R^2 = CH_3$
2b, R^1 = *n*-C_3H_7, $R^2 = -CH_2CH{=}C(Cl)CH_3$
2c, $R^1 = -CH_2CH{=}C(Cl)CH_3$, R^2 = *n*-C_3H_7



3

4a, $R^3 = CH_3$
4b, $R^3 = H$
4c, $R^3 = CH_2COOEt$
4d, $R^3 = CH_2COOH$

After the alkylation, the extremely insoluble racemate was separated from the pure enantiomer **2c** by crystallization from hexane. Compound **2c** was converted into **4d** (83% overall yield based on **2c**) without isolation of intermediates by (1) hydrolysis with concentrated sulfuric acid (0 °C, 1.5 h) to **3**, (2) cyclization with concentrated sulfuric acid (H_2O:**3** = 2:1, 70 °C, 1 h) to **4a**, (3) demethylation ($AlCl_3$, toluene, 45 °C, 2 h) to **4b**, (4) alkylation ($ClCH_2COOEt$, K_2CO_3, KI, Triton X-405, toluene, reflux) to **4c**, and (5) hydrolysis by KOH (KOH:**4c** = 2.5:1, toluene, reflux) to **4d**.[12]

5 **6**

Fig. 1. Tight ion-pairs **5** and **6** of the enolate of **1b** with *N*-(*p*-trifluoromethylbenzyl)cinchoninium and *N*-(*p*-trifluoromethylbenzyl)cinchonidinium, respectively.

As proposed for the selective formation of **2a**,[6] a tight ion-pair, **5** (Fig. 1), also accounts for the formation of **2b**. Interestingly one of the attractive π–π interactions in the ion-pair leading to **2a** is replaced by an attractive non-bonded alkyl–π interaction[13] in **5** without loss in *ee*. The remaining ionic and π–π interactions and hydrogen bond proposed for the formation of **2a** also prevail in **5**. A Hammet plot of $\lg(ee/ee_0)$ vs. σ for catalysts with a *p*-substituted phenyl ring afforded a ρ value of 0.67 as op-

[**] Efficient Catalytic Asymmetric Alkylations, Part. 2.—Part 1: [6].

posed to 0.21 obtained for **2a**. The negative charge is delocalized into the phenyl ring in the enolate anion **1a**, whereas such delocalization is absent in the 2-propyl analogue **1b**. Accordingly, the latter responds toward substituent effects in the catalyst to a greater extent.[14] A similar tight ion-pair **6** (Fig. 1) can also account for the asymmetric induction in the formation of **2c**.[15] The decrease in enantioselectivity for **2c** vs. **2b** (78% vs. 92%) must result from the relative position of the vinyl group in the two tight ion-pairs. Study of the space filling models suggests that the vinyl group in **5** buttresses the hydroxyl group of the catalyst in a position to maintain the desired hydrogen bond. The vinyl group-hydroxyl interaction is absent in **6**, which may confer greater degrees of freedom to the system and hence lower the *ee*.

This chiral Robinson annelation offers potential as a pseudo-enzymic[16] process in organic synthesis in terms of simplicity, ease of operation, and enantiospecificity.

A Transition Metal Atom as Building Block of a Cyclic Phosphazene— Synthesis and Structure of $[Cl_3WN_3(PPh_2)_2]$**

By *Herbert W. Roesky,* Kattesh V. Katti, Ulrich Seseke, Michael Witt, Ernst Egert, Regine Herbst,* and *George M. Sheldrick*

Dedicated to Professor Marianne Baudler on the occasion of her 65th birthday

In 1983 we reported the synthesis and structure of $[Cl_2VN_3S_2]$, a 1,3-dithia-2,4,6-triazine containing a metal atom as the sixth member of the ring.[1] We describe here the first cyclic phosphazene containing a metal atom in the ring. Cyclic, trimeric phosphazenes have been known since 1834 and their chemistry has been the subject of numerous investigations.[2] To date, however, only derivatives with substituents on the ring, metal complexes, or polymers have been synthesized.[3] We have now succeeded in replacing one phosphorus atom in the six-membered phosphazene ring by a transition-metal atom. Tungsten hexachloride **1** reacts with $[H_2NPPh_2NPPh_2NH_2]Cl$ **2** in chloroform with elimination of HCl to give $[Cl_3WN_3(PPh_2)_2]$ **3**.[4]

In the solid state, **3** is probably present as a chlorine-bridged polymer. Evidence for the cyclic structure of **3** was provided by both a mass spectrum and a ^{31}P-NMR spectrum. Electron impact ionization gives rise to a peak at *m/z* 668 (relative intensity 100%) corresponding to the $[M-Cl]^{\oplus}$ ion. The ^{31}P-NMR spectrum contains a signal at $\delta = 39.2$ (85% H_3PO_4) with ^{183}W satellites and a $^2J(^{31}P\text{-}^{183}W)$ coupling constant of 63 Hz.

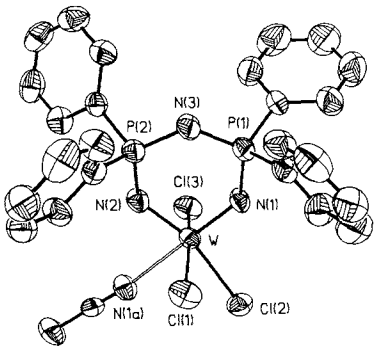

Fig. 1. Structure of **3**·$2CH_3CN$ in the crystal (without hydrogen atoms). Important bond lengths [pm]: W-N(1) 177.3(5), W-N(2) 179.8(6), W-N(1a) 236.4(6), N(1)-P(1) 166.3(7), N(2)-P(2) 164.0(7), P(1)-N(3) 158.7(7), P(2)-N(3) 159.6(6). Bond angles in central six-membered ring [°]: W 97.3(3), N(1) 134.5(4), N(2) 133.1(3), P(1) 113.4(3), P(2) 114.6(3), N(3) 126.4(5).

Crystals suitable for X-ray structure analysis were obtained by recrystallization from acetonitrile; two molecules of the solvent are incorporated into the crystal lattice. The single-crystal X-ray structure analysis[6] confirms the presence of a six-membered, planar ring (mean deviation of the ring atoms from the best plane: 3.4 pm) with pairwise equivalent bond lengths and angles (Fig. 1). A molecule of acetonitrile is weakly coordinated to the tungsten atom; it is surprising that the "*trans* effect" on the lengths of the W-N bonds is hardly evident. Compounds such as **3** should allow the synthesis of metal-containing polymeric phosphazenes.

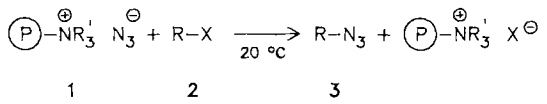
Synthesis of Alkyl Azides with a Polymeric Reagent**

By *Alfred Hassner** and *Meir Stern*



Nucleophilic substitution by azide ion is a well-established synthetic pathway to alkyl azides.[2] Some of the problems associated with this preparative method, such as the low solubility of inorganic azides in organic solvents, have been solved by the use of the more soluble tetraalkylammonium[3a] or guanidinium azides,[3] by phase-transfer conditions,[4] or by Lewis acid catalysis, the latter being mainly used with tertiary or activated alkyl halides or alcohols.[5]

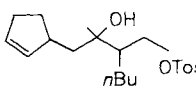
[**] Synthetic Methods, Part 22.—Part 21: [1].



Since azides are thermally and photochemically labile and are often explosive,[6] it is preferable to avoid heating during reaction or purification. Yet this is often required for the above-mentioned methods.

We now report the use of the polymeric quaternary ammonium azide **1** as a reagent for the preparation of azides; **1** permits clean nucleophilic substitution of activated as well as nonactivated alkyl halides **2** at room temperature. Since the insoluble polymeric reagent can be used in large excess, essentially complete conversion into alkyl azide can be achieved. The progress of the reaction can be monitored by GC, TLC, etc. After filtration of the polymer, a clean solution of alkyl azide **3** in organic solvent is obtained and can be used for subsequent reactions, either directly or after removal of solvent. The polymer **1** can be regenerated easily with NaN_3 solution.

In this manner we have succeeded not only in achieving clean conversion of benzyl halides but also of hexyl bromide **2b**, cyclohexyl bromide **2c**, α-halo esters and ketones, and dihalides into their corresponding azides (Table 1).

Table 1. Synthesis of the azides **3** from the educts **2** with the polymer **1** at 20°C.

	R–X **2**	Solvent	*t* [a]	Conversion (Yield)[%][b]
a	*n*-C_4H_9–Br	CH_3CN	3 h	100
	n-C_4H_9–I	CH_3CN	1 h	100
	n-C_4H_9–OTos	CH_3CN	24 h	100
	n-C_4H_9–Cl	CH_3CN	>7 d	100
b	*n*-C_6H_{13}–Br	ether	4 d	100 (71)
c	cyclohexyl-Br	ether	11 d	94
d	$PhCH_2$–Cl	CH_2Cl_2	2 h	98 (91)
	$PhCH_2$–Br	CH_2Cl_2	1 h	100
e	*p*-Br–$C_6H_4CH_2$–Br	CH_2Cl_2	2 h	100 (93) [c]
f	Ph–CO–CH_2–Br	CH_2Cl_2	1 h	100
g	EtO–CO–CH_2–Cl	CH_3CN	2 h	100
h	$PhCH_2O$–CO–Cl	ether	24 h	95
i	$C_6H_4(CH_2–Br)_2$–(*o*)	CH_3CN	16 h	100 [d]
j	Br–$(CH_2)_4$–Br	CH_3CN	24 h	100
k	CH_2Br_2	tetrahydrofuran	16 d	60
l		CH_3CN	3 d	100

[a] Reaction time. [b] All azides were identified by IR, NMR, and, in many cases, mass spectra. 100% conversion was indicated by the absence of **2** and the presence of only **3** (GC, TLC). It is assumed that some product remains adsorbed on the polymer **1**, accounting for lower yields than conversion. [c] Yield of a dimethyl acetylenedicarboxylate adduct of **3i** was 90%.

The solvents of choice are chloroform, ether, dichloromethane (caution! see below), or acetonitrile. As expected, the reaction proceeds faster in more polar solvents such as acetonitrile and dimethylformamide (Table 2), which are especially appropriate where solvent removal is not a problem.

For comparison with other methods, butyl bromide **2a** requires heating at 100°C for 3 h in the presence of methyltrioctylammonium chloride/NaN_3 under phase-transfer conditions for its conversion into the azide (which was purified by distillation).[4] In contrast, butyl bromide **2a** or

Table 2. Relative rate of conversion of *n*-hexyl bromide **2b** into *n*-hexyl azide **3b** with the polymer **1** (after 4 h in various solvents; determined by GC).

Solvent	Conversion [%]	Solvent	Conversion [%]
toluene	23	diethyl ether	54
chloroform	26	acetone	82
methanol	32	acetonitrile	>95
tetrahydrofuran	38	dimethyl-	
pentane	52	formamide	>95

even the more sluggishly reacting hexyl bromide **2b** are converted into their azides **3a** and **3b**, respectively, by reaction with **1** at 20°C within 3 h in acetonitrile or within 24 h in dichloromethane.

Most remarkably, this method allowed us, for the first time, to convert dibromomethane **2k** or, more slowly, dichloromethane into diazidomethane **3k**, an explosive compound.[7] Although dichloromethane is a convenient, low-boiling solvent for reactions of **1** with alkyl halides (usually complete within 4–24 h), the above results indicate caution when employing this solvent (conversion into **3k** requires over two weeks). The relative rate of reactivity with the polymer **1** is R–I > R–Br > R–OTos ≫ R–Cl, which is in accord with a nucleophilic substitution process.

Experimental Procedure

Polymer **1**: Amberlite IR-400 was washed with 20% sodium azide solution, then with water, methanol, and chloroform or ether. The polymer was dried at room temperature in vacuum and found to contain 2.55 mmol of azide per gram. The friction parameter of **1** as measured on a Julius-Peter apparatus was 14.4 kg, indicative of high friction stability.

Reaction of **1** with **2e**: To 4.9 g of **1** (12.5 mmol of azide) was added 4 mL of CH_2Cl_2 and 0.265 g (1.06 mmol) of *p*-bromobenzyl bromide **2e**. After 2 h of mixing, the polymer was filtered and washed with CH_2Cl_2. Evaporation of the combined solvent mixture gave pure *p*-bromobenzyl azide **3e** as an oil in 93% yield; ^{1}H-NMR: $\delta = 7.5$ and 7.2 (AA'BB', 4H); 4.29 (s, 2H). *m/z* 212.74, 210.84.

Diastereoselective Transformations on Heterometal Clusters**

By *Christine von Schnering, Thomas Albiez, Wolfgang Bernhardt,* and *Heinrich Vahrenkamp**

The phenomena of enantio- and diastereoselectivity, which are of current interest in catalysis and organic chemistry, have not yet been the objects of research in organometallic cluster chemistry; even simple isomerism has only seldom been observed for cluster frameworks.[1] Furthermore, there are only a few reported examples of isomerism in the coordination sphere of clusters,[2] and stereoselective reactions with clusters were unknown up to now. We report here reactions in which one of two possible isomers is preferentially formed.

The starting point of our studies was the acetylene–vinylidene rearrangement on trimetal clusters, which we have described for the compounds $[RuCo_2(CO)_9(\mu_3,\eta^2\text{-}L)]$, L = HC≡CR or C=CHR.[3] When the alkyne-bridged starting clusters are converted by metal exchange[4] into the chiral clusters **1**, which are then isomerized thermally to the vinylidene-bridged RuCoM′ clusters **2** (see Scheme 1), two isomers can be formed in each case, which differ in the positions of H and R. If M′ = NiCp, the isomers are formed in equal amounts regardless of the R group. If M′ = $MoCp(CO)_2$ or $WCp(CO)_2$ and R = *t*Bu, only one isomer is formed in each case.

Analogous results were obtained for FeCoM′ clusters **4**, which permit greater variation of the R groups (see Scheme 1). The alkyne-bridged binuclear complexes $[Co_2(CO)_6(HC{\equiv}CR)]$[5] react thermally with $Fe_3(CO)_{12}$, resulting in $Fe(CO)_3$ addition and H migration to give the vinylidene-bridged clusters **3**, which, in turn, can be easily converted into the corresponding clusters **4** by metal exchange.[6] In the case of the FeCoNi complexes, 1 : 1 mixtures of isomers are formed. For M′ = $MoCp(CO)_2$ and $WCp(CO)_2$, the isomers are formed in ratios of 1 : 3 to 1 : 4 when R is Me or Ph; only one isomer is formed when R is *t*Bu.

Scheme 1.

Clusters **2** and **4** each have two asymmetric centers, namely, the two vinylidene C atoms. Thus, for each of the two isomers, there exists an enantiomer, and two pairs of diastereomers are present. For R = *t*Bu, therefore, the transformations **1** → **2** and **3** → **4** are diastereospecific. However, it has not yet been possible to prepare optically active **1**.

In order to prove that the selectivity has a steric origin, an X-ray structure analysis was carried out for **2**, M′ = $WCp(CO)_2$, R = *t*Bu.[7] Surprisingly, the bulky *t*Bu group and C_5H_5 ligand were found to lie on the same side

[*] Prof. Dr. H. Vahrenkamp, Dipl.-Chem. C. von Schnering, Dipl.-Chem. T. Albiez, Dipl.-Chem. W. Bernhardt

of the molecule (Fig. 1). The shortest distance between *t*Bu and C_5H_5 (C44-C15 369 pm) indicates that practically no steric hindrance is present. This unexpected result compelled us to ascribe an electronic effect as the cause of the stereoselectivity.

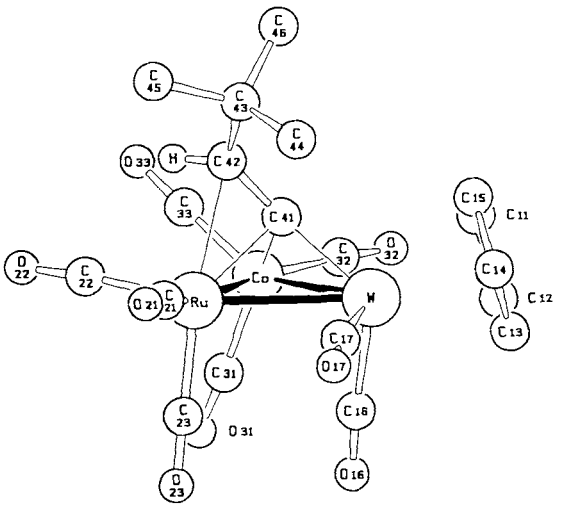

Fig. 1. Crystal structure of [RuCoWCp(CO)$_8$(μ_3,η^2-C=CH*t*Bu)] **2**. Important bond lengths [pm]: W-Ru 290.1(1), W-Co 272.3(3), Ru-Co 262.4(3), W-C41 201(1), Ru-C41 210(1), Co-C41 195(1), Ru-C42 235(2), C41-C42 129(2).

In view of the manifold possibilities for the transformation of organic multiple bond systems on clusters, for the release of transformed substrates from clusters, and for the preparation of clusters in optically active form, the results described here should point out a new way for the exploitation of variations in the inorganic part of cluster compounds, which, up to now, have been less investigated than those of the organic part.

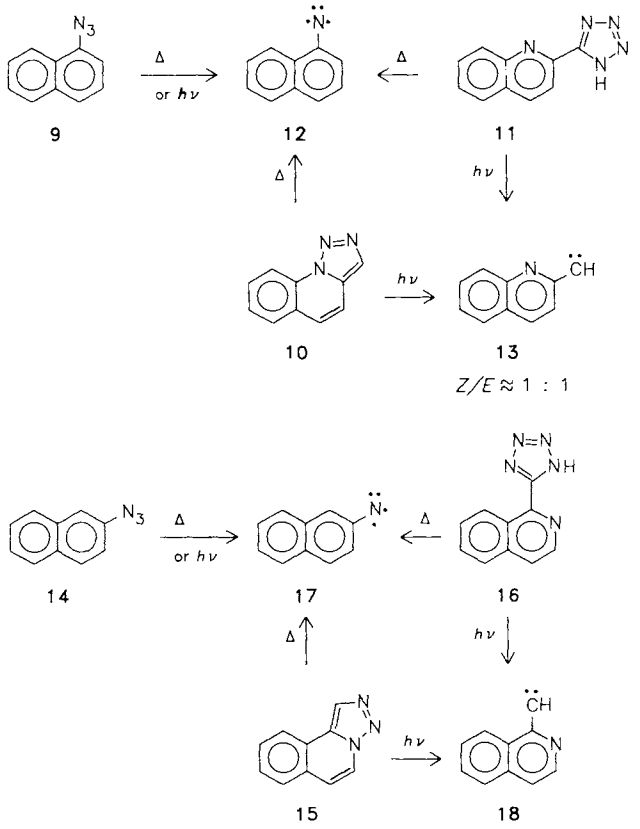
ESR Observation of Thermally Produced Triplet Nitrenes and Photochemically Produced Triplet Cycloheptatrienylidenes**

By *Martin Kuzaj, Holger Lüerssen*, and *Curt Wentrup**

To date all nitrenes observed by ESR[1,2] have been generated by photolysis in low-temperature glasses or matrices. We now report the thermal gas-phase production of nitrenes with subsequent matrix isolation,[3] which permits direct monitoring of thermal carbene and nitrene rearrangements that were previously only inferred from product studies.[4] Moreover, we describe the first observation of cycloheptatrienylidenes and their aza derivatives.

The pyrolysis of phenyl azide **1** at 500 °C gave a product with a strong ESR signal ($|D/hc| = 0.9896$; $|E/hc| = 0.00\ cm^{-1}$) typical of phenylnitrene **3**. The same signal was obtained on photolysis of matrix-isolated **1**. Phenylnitrene spectra were also obtained on pyrolysis of the *carbene* precursors **5** and **6**, thereby verifying the carbene-nitrene rearrangements **7** → **3** and **8** → **3**.[5,6] *p*-Tolylnitrene **4** was similarly generated from *p*-tolyl azide **2** (Table 1). The much debated thermal cycloperambulation[7] to *m*- and *o*-tolylnitrene did not take place to any measurable extent under these conditions.



The discrete nitrenes **12** and **17** were likewise obtained from the naphthyl azides **9** and **14**, respectively, as well as

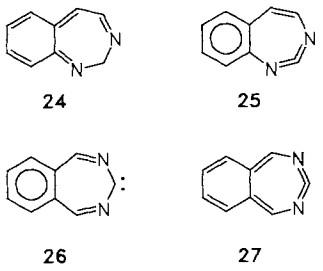
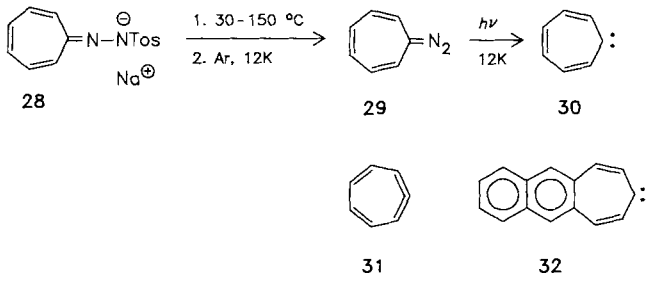
[**] This work was initiated at the University of Marburg (FRG) and supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the University of Queensland, Australia.



from the carbene precursors **10** and **11** or **15** and **16**. No interconversion of the 1- and 2-naphthylnitrenes **12** and **17** was observed. The *carbenes* **13**[8] and **18** were obtainable only on *photolysis* of the carbene precursors (Ar, 12 K). Both (*Z*) and (*E*) forms of **13** were observed, in a ca. 1 : 1 ratio. The fact that, in the thermal experiments, the *carbene* precursors rearrange entirely to *nitrenes* confirms our argument that nitrenes are intrinsically more stable thermodynamically than isomeric carbenes;[9] hence, the rearrangement of carbenes to nitrenes is virtually unidirectional in the gas phase.

The ring expansions interconverting carbenes and nitrenes are nowadays normally formulated in terms of cycloheptatetraenes/azacycloheptatetraenes.[2,4] The corresponding carbenes, the cycloheptatrienylidenes/azacycloheptatrienylidenes, have never been observed. If cycloheptatrienylidenes have triplet ground states,[10] it should be possible to generate such species by photolysis of triplet precursors. Indeed, this appears to have been achieved: Photolysis (200-W high-pressure Hg lamp) of thermally generated and Ar-matrix-isolated 2-pyridylnitrene **20** gave

a new triplet carbene characterized by unusually low *D* and *E* values (Table 1). These values are too low for a heteroarylcarbene, because aza substitution tends to *increase* the *D* value (Table 1); therefore, the new carbene may be 1,3-diazacycloheptatrien-2-ylidene **21**, which would be strongly delocalized, as expressed in canonical structure **22**. The *thermal* (singlet) rearrangement of **20** (as monitored by IR spectroscopy) gives only the carbodiimide **23**, which is presumably the lowest-energy form of this seven-membered ring system.[11]



The structural assignment of **21** was tested by irradiation of 2-quinolyl- and 1-isoquinolylnitrene; both gave the *same* carbene, **24**, which is also characterized by low *D* and *E* values (Table 1). 3-Isoquinolylnitrene gave a different carbene, **26**. The corresponding carbodiimides **25** and **27** have been observed by IR spectroscopy.[4,11]

[a] $H_0 = h\nu/g\beta \approx 3372.0$ Gauss; the exact value of ν was measured in each experiment. Uncertainties in *D* and *E* values in units of the least significant digit. [b] Number of experiments used in averaging *D* and *E* and determining the uncertainties. [c] Photochemically produced. [d] Thermally produced. [e] From annelated tetrazoles or azides. [f] By photolysis of phenyldiazomethane or by pyrolysis of 5-phenyltetrazole followed by photolysis. [g] From 4-quinolyl azide or by thermal rearrangement of 2-quinoxalylcarbene produced by pyrolysis of either 1,2,3-triazolo[1,5-*a*]quinoxaline or 2-(5-tetrazolyl)quinoxaline. [h] Photolysis of triazoloquinoxaline or tetrazolylquinoxaline.

The above results led us to attempt the direct generation of triplet cycloheptatrienylidene **30**. Mild pyrolysis of the salt **28** gave the diazo compound **29** (IR: 2048 cm^{-1}; Ar,

12 K). Photolysis of **29** at 12 K gave a carbene, different from phenylcarbene (Table 1) and characterized by a low *D* value. The ESR signal intensity did not follow the Curie law exactly, and, when the warmed sample was cooled again, the signals failed to return to their original intensities. One intriguing possibility is that **30** has a triplet ground state and, on warming, is partly converted into the lower-energy[10] allene **31**. Repeated warming and cooling should finally remove triplet **30** from the matrix.[12] Cyclohepta[*b*]naphthalen-8-ylidene **32**, a ground-state triplet,[13] was similarly generated and gave *D* and *E* values very close to those of **30** (Table 1).

BOOK REVIEWS

Analytical Solution Calorimetry. Edited by *J. K. Grime*. Wiley, Chichester 1985. xvi, 401 pp., bound, £ 69.40.—ISBN 0-471-86942-2

Calorimetry. Fundamentals and Practice. By *W. Hemminger* and *G. Höhne*. Verlag Chemie, Weinheim 1984. vi, 310 pp., bound, DM 135.00.—ISBN 3-527-25948-1

The book "Analytical Solution Calorimetry" edited by *J. K. Grime* and the English version of "Calorimetry" written by *W. Hemminger* and *G. Höhne* provide two extensive accounts of the experimental methods used in calorimetry. They describe the most important areas of calorimetric measurement techniques in accordance with the current state of development. As very few self-contained books have been published on this subject and all earlier review articles are out of date, these books make a welcome appearance. The selection and classification of their subject matter differ considerably however. The book "Analytical Solution Calorimetry" appears as volume 79 of the "Chemical Analysis" series and its concept is based on the requirements of the chemical-analytical applications of calorimetric measurement methods. The basic principles of analytical solution calorimetry, flow calorimetry and the determination of reaction enthalpies are accordingly described by competent experts and are presented in a form suitable for practical applications. This section is preceded by an introductory chapter on the thermodynamics, thermochemistry and principles of calorimetry. Further chapters provide a great deal of information on the selection of instruments and the evaluation of experimental data, as well as important examples of the applications of calorimetric methods in analysis and special studies performed in biochemical and clinical laboratories. The experimentalist will find important information for his daily work both in the text and in the large number of literature references.

"Calorimetry" is an extended English version of the book entitled "Grundlagen der Kalorimetrie" published in 1979. It summarizes the field of calorimetry including theoretical and methodological prerequisites and takes both historical development and the most recent methodological improvements into consideration. Six of the ten chapters (supplemented by an appendix) are dedicated to physical principles and evaluation procedures. Calorimeters with compensation for thermal effects are described in chapter seven and calorimetric measurements with registration of a temperature difference are treated in chapter eight. Chapter nine is especially important as regards practical applications and gives criteria for selecting suitable

calorimeters. The book is concluded by a few brief comments on possible future developments. Chapter nine has been extended in comparison with the original German edition by including sections on the influence of noise (short-term noise and long-term noise) and the functioning of the apparatus. The numbers assigned to two of the figures in section 9.2 have been corrected. This monograph written by *Hemminger* and *Höhne* is the only up-to-date book that gives a clearly presented account of methods for the determination of reaction enthalpies, procedures for measuring specific heats and applications in analytical and biophysical chemistry. Detailed examples of applications cannot, of course, be included in such a wide-ranging work but are to be found in the studies cited in the appendix. The book is a standard work which every natural science institute should have in its library, it can be recommended without any reservations to all scientists interested in thermodynamic measurements.

Methods of Enzymatic Analysis. Vol. 7. Metabolites 2: Tri- and Dicarboxylic Acids, Purines, Pyrimidines and Derivatives, Coenzymes, Inorganic Compounds. By *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grassl.* 3rd Edit. VCH Verlagsgesellschaft: Weinheim 1985. xxviii, 641 pp., bound, DM 325.00.—ISBN 3-527-26047-1

The five chapters of this volume[*] describe quantitative analyses for di- and tricarboxylic acids; purines, pyrimidines and nucleosides; nucleotides, coenzymes and related materials; nucleoside diphosphate sugars; and inorganic compounds.

Much of what separates this new edition from its predecessor of 10 years ago is the wealth of information which has been added in support of the assay procedure itself. Each assay has been extensively supplemented with concise information concerning the analyte's history, physical and biological properties, biogenesis and occurrence, special properties relevant in analysis, references and standards for the analyte, and alternate methods of analysis.

Some two dozen new assay procedures have been added to this edition; a similar number from the second edition have been omitted. Although most of the deletions are alternate procedures for analytes which are still represented in this edition, some metabolites appearing in the second edition will no longer be found.

Many of the procedures in this edition are the same as those in the second edition. Some of these procedures have been altered to incorporate new information and findings but others have been incorporated unchanged as they still represent the state-of-the-art—even after more than 10 years in a rapidly advancing area of science! That the content of the second edition has required only little change in a changing field is a strong statement about the durability of this new edition.

As in the previous edition, the assay itself is detailed and covers the Method Design (the assay principle and optimum measurement conditions), Equipment, Reagents and Solutions (purity, preparation, storage and stability of reagents and solutions), Procedure (specimen collection, treatment, preparation and stability; measurement and calculations) and Validation of the Method (precision, accuracy, detection limit and sensitivity, error, specificity, and reference range).

Accompanying each assay is a thorough list of references among which many citations from 1983 and 1984 can be found, thus attesting to the text's timeliness.

The first chapter contains analytical procedures for determining di- and tricarboxylic acids. Those familiar with the second edition of "Bergmeyer" will find that assays for both D- and L-tartrate, and for D-malate have been added to the procedures for the seven acids of the citrate cycle. Delections in this chapter include several fluorimetric procedures as well as the assay for maleate.

The chapter describing analyses for purines, pyrimidines and nucleosides has been extensively changed. Among the analyses for the purine and pyrimidine bases, those for guanine/adenine and for uric acid have been improved by using superior indicator reactions, the analysis for cytosine has been omitted while the procedures for orotate, hypoxanthine, and xanthine remain the same as those in the second edition.

For nucleosides, an analysis for total nucleosides has been added to those for adenosine, guanosine and inosine. Analyses for cytidine, deoxycytidine, deoxythymidine and deoxyuridine have all been omitted.

The third chapter, containing assays for nucleotides, coenzymes and related compounds, comprises more than 50% of the book. Analyses for pantethine, coenzyme A and a variety of acyl CoA derivatives—acetyl, acetoacetyl, long chain fatty acyl, 3-hydroxy-3-methyl-glutaryl, malonyl and succinyl—are described by a mixture of new, old and modified assays. Assays for six less-common CoA derivatives which appeared in the second edition are omitted.

The coverage of NAD(P)(H) cofactors is essentially unchanged from the second edition, however a luminometric method for determining NADH/NADPH is new. The assay for flavin-adenine dinucleotide has been revised and two assays for flavin mononucleotide have been added.

Assays for diadenosine tetraphosphate, *S*-adenosylmethionine, *S*-adenosylhomocysteine and two luminometric assays for the adenosine phosphates have been added to the nucleotide section. These assays, in addition to those which have been retained from the second edition for the adenosine phosphates, bring total coverage for this important group of materials to over 70 pages. The remainder of the chapter contains assays for the guanosine-, inosine-, cytidine-, and uridine 5′-mono-, di- and triphosphates in a streamlined manner. The chapter also contains the old UV-based assays for thiamine pyrophosphate and pyridoxal phosphate and new assays for pyridoxal phosphate (radiometric method) and tetrahydrofolate.

The chapter for nucleoside diphosphate sugars has been greatly expanded and now contains assays for 5-F-UDP-glucose/5-F-UDP-galactose, UDP-glucosamine/UDP-galactosamine, UDP-2-deoxyglucose/UDP-2-deoxygalactose, and thymidine 5′-diphosphoglucose in addition to assays for adenosine-, cytidine-, and uridine-5′-diphosphoglucose, uridine 5′-diphosphogalactose and guanosine 5′-diphosphomannose.

The chapter on inorganics has been expanded to include assays for lead, arsenic, zinc, magnesium, sulfite and bicarbonate as well as those for inorganic phosphate, inorganic pyrophosphate, inorganic peroxides and nitrate, of which the latter three have been improved since appearing in the second edition.

The improvements and additions made in this edition are significant and useful. As with previous volumes, the

editors and publisher have put together a high-quality reference which will find almost daily use among those involved in biochemistry, biology, chemistry and related areas. This series is strongly recommended to libraries and groups where analyses are routinely done.

Electroorganic Syntheses, Part I: Oxidations. By *S. Torii.* VCH Verlagsgesellschaft, Weinheim 1985. xi, 338 pp., bound, DM 138.00.—ISBN 3-527-26318-7

Shortly after the publication of *Shono*'s book, *S. Torii,* another important electroorganic chemist engaged in synthesis, has addressed the subject in a monograph. The first volume of this work has been published; the second part (on reductions) is planned. This volumed is based on a monograph of the author's, which appeared in 1981 in Japanese. It amounts to more than a simple translation into English, however, since it has been revised and extended. Literature references cover publications up to 1983; in a few cases there are even references from 1984. Since the author is not aiming at an exhaustive presentation of organic electrochemistry, literature from earlier than 1970 is considered only in a few cases.

This book, similarly to *Shono*'s, is directed at chemists engaged in synthesis, i.e., in the first place, at non-electrochemists. It is arranged in thirteen chapters, of which the first, "Electrooxidation and Product Selectivity", clearly gives the intention of the whole work from the outset. Chapters 2–10 and 12 deal with the electrooxidation of particular classes of compounds. Two chapters are concerned with catalytic phenomena which have achieved more and more significance lately: indirect electrooxidation and the use of electrochemically generated acids.

In these chapters, the author presents an abundance of synthetically interesting reactions, clearly arranged. Non-electrochemists are not put off by a lengthy explanation of the theoretical basis or exhaustive presentation of reaction mechanisms. Instead, the emphasis is placed on the discussion of selectivity and the steering of reactions. The author points out that high selectivity in the reactions can only be achieved through the right choice of the reaction parameters, especially of solvent, conducting salt and electrode material. Particularly in the first chapter, but also in all subsequent parts of the book, the influence of these parameters on the course of the reaction is repeatedly discussed in detail and possibilities for steering the reactions are worked out. Since this is done, to a large extent, on an empirical basis, it will appeal to synthetic chemists. It must be said, however, that this approach may perhaps distract those readers who want only to cast a quick glance at the synthetic potential of the method.

As the author points out in the foreword, he is attempting to present results in a form which makes plain the possibilities for their application in synthesis. An appendix to Chapter 1 contributes particularly to this end. Here, the possible conversions are set out schematically, arranged according to the kind of bond formation, bond splitting, rearrangement and functionalization, and linked with the appropriate reaction conditions and with references to pages and chapters of the book. Such a presentation is especially valuable, if information is required on a particular type of conversion. Synthetic chemists would surely, however, have welcomed a critical comparison of the pros and cons of electrochemical methods against current chemical alternatives. It would have been helpful for the evaluation of the potential of electroorganic synthesis by non-electrochemists had the author expounded the principle of redox-Umpolung, which underlies electrochemical reactions.

It is annoying, however, that in an otherwise very carefully edited book, the literature references in Chapter 1, contain some monographs in Japanese or translations into Japanese, while the English originals or equivalent works in English are not cited. Unfortunately, as frequently encountered, the index has not been given much attention. Not only is it incomplete, but it also suffers from the fact that the entries, mostly compounds, are not further qualified, so that their relationship to a method, type of conversion, or property is not established. This applies, for example, to the entry "anisaldehyde" in the index. If the reader were to be properly guided, the qualification "from methoxytoluene" would be necessary. As it is, the page number given refers only to the indirect electrochemical preparation, while the direct electrochemical synthesis, spanning almost two pages in Chapter 3, is not mentioned.

It is to be welcomed that, with these books by *Shono* and *Torii,* there are now two monographs available on the subject of electroorganic synthesis that are directly aimed at synthetic chemists. In both cases, it is not so much the electrochemical method itself which is given prominance to, but rather the great synthetic potential of this method, which is still underestimated. The books are written in a style which makes this fascinating area accessible to every reader. Thus, it is to be hoped that both books will achieve the largest possible circulation amongst synthetically oriented chemists. The length of the two books, in one case 171 pages and, in the other, 338 pages for volume 1 alone, shows quite clearly that the intended readership is different for each. *Shono*'s monograph is especially suitable for those who want a brief survey of the manifold possibilities of electrosynthesis, who want to kindle an interest or who are looking for new synthetic concepts. Students majoring in chemistry should belong to this group, if they are not put off by the relatively high price. On account of its strong emphasis on selectivity and the steering of electrochemical reactions, *Torii*'s book is not only suitable as a source of general information, but also offers a lot of concrete suggestions as to the most favorable procedure and the most suitable reaction conditions to those who want to incorporate electrochemical steps into their synthetic plans. It presents to the interested reader a good survey of the present state of the art and makes it clear that the high expectations on selectivity of modern synthetic operations can be fulfilled by electrosynthesis. It is, therefore, a book that can convince the synthetic chemist of the advantages of organic electrochemistry so that he will refer to it again and again.

Eberhard Steckhan [NB 705a IE]
Institut für Organische Chemie und Biochemie
der Universität Bonn (FRG)

Structure and Spectra of Molecules. By *W. G. Richards* and *P. R. Scott.* John Wiley, Chichester 1985. ix, 172 pp., paperback, £ 6.95.—ISBN 0-471-90575-0

In this brief introduction, the authors are principally concerned with illustrating the physical relationships of spectroscopic quantities with the electronic and geometric

structure of a molecule. The basic models are defined, energy values and quantum numbers are given, and eigenfunctions are qualitatively described. In contrast to some "practical" guides to instrumental analysis, this book does indeed contain many schematic, but only a few, simple, real spectra and hardly any empirical "rules".

53 pages serve for the introduction to the physical foundations of the subject. Proficiency in mathematics is not required: only the short section on symmetry and selection rules needs somewhat deeper understanding. A qualitative concept of H atom orbitals is taken for granted; antisymmetrized product eigenfunctions are illustrated. On this basis, the following topics are described: LCAO molecular orbitals and their symmetries, MO diagrams, term symbols, Walsh diagrams, the Jahn-Teller effect, hybridization, and crystal field splitting. These are followed by potential curves, then eigenvalues for the anharmonic oscillator, the non-rigid diatomic rotator and for the symmetric top.

In the spectroscopic part, the experimental methods are illustrated with block diagrams; term diagrams and spectra are mostly presented schematically. This part begins with pure rotational spectra, including the Stark effect and rotational Raman spectra. Then follow rotation-vibration spectra, Fortrat diagrams and classification aids for normal vibrations that are not, as such, more closely defined. Typical vibration-rotation structures of the electron bands of diatomic molecules are explained; predissociation, fluorescence, and Rydberg transitions are also mentioned. The following 18 pages deal with line intensities, transition probabilities, occupation numbers, Franck-Condon factors, symmetry selection rules, including hyperfine interactions, line widths and, finally, the laser principle. Alongside UV and X-ray photoelectron spectroscopy, spin-orbit coupling and the Auger effect are touched on and Koopman's theorem is critically illustrated. 12 pages are devoted to electronic spectra in the condensed phase (absorption, fluorescence, phosphorescence). Several types of chromophore are described here and a few empirical rules are stated. ^{1}H-NMR spectroscopy is more extensively handled, with references to temperature effects; solid state NMR spectra, ^{13}C-NMR spectra, Fourier techniques and double resonance methods are mentioned. The work concludes with the electron spin resonance of organic radicals.

The presentation is concise, informative and easily readable. I found no errors of fact. A few exercises are appended to each chapter. A good qualitative survey is given of the methods dealt with. Some important concepts are missing from the subject index, even though they are included in the text. The literature references at the end comprise 15 titles; apart from the three classical volumes by Herzberg, the rest are by British authors.

Stripping Analysis. Principles, Instrumentation, and Applications. By *J. Wang*. VCH Verlagsgesellschaft, Weinheim 1985. viii, 160 pp., bound, DM 120.00.—ISBN 3-527-26192-3

Voltammetric "Stripping Analysis" (inverse voltammetry) was introduced by *W. Kemula* in the mid 1950's. In spite of strong competition from atomic spectrometry and activation analysis methods it can no longer be dismissed from the arsenal of trace analysis. Not only does it allow, in its various forms, the determination of many elements with a very high power of detection, it also is capable of speciation. A further advantage lies in the fact that, with relatively modest instrumentation, most environmentally relevant elements (e.g. Hg, Cu, Pb, Cd, Bi, Tl, As, Se, Sb, Sn, Ni, Co) can be determined very reliably down to the pg/g region, above all in aquatic and biotic systems. If there are any reservations felt about the rôle of inverse voltammetry in analytical practice, these are certainly not objectively founded. Lacking in adequate information, many people unjustifiably regard electrochemical methods as more difficult and less reliable than, for example, oven-AAS, which is more intensively marketed by powerful manufacturers.

The author has based the book on established monographs (e.g. by *Neeb, Brainina* and *Vydra, Stulik, Julakova*). However, he discusses classical inverse voltammetric methods together with newer developments, e.g. "differential pulse stripping voltammetry", "square wave stripping voltammetry" and "potentiometric stripping analysis", which have enabled considerable improvements with regard to reproducibility and reliability.

All these established electrochemical methods of analysis, in which the actual determination step is preceded by electrolytic enrichment of the element in question, are clearly discussed. Modern types of instrumentation and their applications, above all in the fields of environmental, clinical and foodstuff analysis are included. Some 500 literature references, of which most are very recent, ensure that the work is thoroughly up to date.

Unfortunately, the author was not bold enough to highlight critically the advantages of inverse voltammetry, especially when these are obvious with respect to other possible methods. Admirably, much valuable information has been packed into 150 pages, but the high price will hamper wide circulation. This brief monograph is simply too expensive, especially for the purpose of education in analytically chemistry. Indeed, it may prove very difficult to introduce this work, whose content is very valuable, to those circles where its use would be most appropriate.

Analytical Methods in Human Toxicology. Part 1. Edited by *A. S. Curry*. VCH Verlagsgesellschaft, Weinheim 1985. x, 319 pp., hardback, DM 148.00.—ISBN 3-527-26284-9

In the past two decades enormous progress has been made in methods of separation and detection as well as in the qualitative registration of trace substances. This has been of especial value in toxicological practice and research. The field of toxicological investigation is so wide that it can scarcely be straddled by individual toxicologists. In consequence, the current state of knowledge can only be described by a group of experts in the form of a monograph.

In this, the first volume of a two volume monograph, specialists address the following subjects: *N. Morley* describes the detection of medicaments in cell samples, primarily with fluorescence or immunofluorescence methods. The following chapter by *R. J. Flanagan* and *B. Widdop* is concerned with the topic of poisoning through medicament overdoses. *R. J. Metcalfe* deals with the search for

drug receptors with the aid of labelled ligands and discusses "radioreceptor analysis". *J. S. Oliver*'s chapter describes the detection of solvent residues in those prone to solvent abuse. This is followed by *L. V. Jones*' treatment of mass spectrometry. *R. Whelpton* describes the analysis of tricyclic antidepressants and neuroleptics while *G. T. Tucker* and *M. S. Lennard* tackle the analysis of anesthetics. *A. V. Kovatsis* outlines the quantitative recovery of toxic compounds by chelation and subsequent determination of the metals by atomic absorption. In the following chapter *B. S. Thomas* and *E. Bailey* discuss the significance of glass capillary chromatography to toxicology. The final chapter of this volume, by *D. J. Harvey*, is concerned with the investigation of the constituents of hashish.

In my opinion the editor must have made things very easy for himself in compiling this book—he obviously ordered the chapters according to their date of arrival or some equally unfathomable system. How else could chapters on methodology be interspersed with those describing the analysis of particular classes of compounds? This external impression of disorganization is reinforced by the widely differing standard of the individual contributions: while Chapter 10, on cannabinoids, is comprehensive and profound, Chapter 5, on mass spectrometry, is concerned far too much, in my opinion, with the question of construction of the apparatus, surely of secondary importance to the toxicologist, and the crucial question of how and where the technique can be applied to toxicology is only marginally handled. This deficiency is evident in the scanty literature references.

In many of the chapters the specialists concerned to not make the comparative assessment of methods and their applicability which is important for the less experienced researcher. In my view this cannot be compensated for by a list of literature references, however extensive.

A few chapters, above all those on the analysis of individual classes of compounds, fulfil all requirements and expectations. Thanks to them this book is to be regarded as an important reference work for toxicology, in spite of the reservations expressed above.

Superacids. By *G. A. Olah, G. K. S. Prakash,* and *J. Sommer.* Wiley, Chichester 1985. xv, 372 pp., bound, £ 67.00.—ISBN 0-471-88469-3

This is a timely and very useful review of a fascinating and rapidly growing field of chemistry. It deals with acid systems that are stronger than 100% sulfuric acid, i.e. superacid systems, and their applications. The development since the early 1960s of $HFSO_3/SbF_5$ (Magic acid), HF/SbF_5 (fluoroantimonic acid) and related conjugate superacids which are 10^7 to 10^{19} times stronger than sulfuric acid have been truly spectacular. The discovery that stable, long-lived, electron deficient ions, such as carbocations, acidic oxonium ions, halonium ions and halogen cations can be obtained in these highly acidic systems has played an important role in this development in which *G. A. Olah* has been an outstanding leader. This work has provided a detailed insight into the structures and mechanisms of reactions of carbocations.

The superacid systems, which all contain superacid/very weak base pairs, allow the extension of acid catalyzed reactions to include substrates such as extremely weak basic substrates like hydrocarbons (including methane) in which σ-bonds are attacked. Applications of superacids are foreseen to expand in catalysis, synthetic chemistry, as well as in the preparation and study of reactive ionic intermediates.

The first two chapters (60 pages) of the book deal with general aspects including techniques for acidity measurements and the description of superacid systems, i.e. Brønsted superacids, Lewis superacids, conjugate Brønsted-Lewis superacids and solid superacids. Chapter 3 (112 pages) reviews some carbocations including tricoordinated as well as penta- and hexacoordinated and degenerate carbocations. A brief account of the methods and techniques used in the study of carbocations is also given. Heterocations are reviewed in Chapter 4 (66 pages). Ions included are onium ions, enium ions, homo- and heteropolycations and miscellaneous cations like $H_3^{\oplus}$. The last chapter (101 pages) is devoted to superacid catalyzed reactions: conversion of saturated hydrocarbons, alkylation of aromatic hydrocarbons, alkylation of aromatics, carboxylation, formylation, nitration, oxyfunctionalization, polymerization etc. Friedel-Crafts systems are not treated in the present book since they have already been reviewed.

Altogether, the chapters contain more than one thousand references to original publications. The overall impression of the authors' presentation is favorable despite some misreferencing, errors in structural formulas, misprints and that IUPAC-nomenclature is not strictly obeyed.

It is clear that the book will be most useful not only to the specialists but also to other chemists that want to enter the field or make use of superacids. Therefore, the book is strongly recommended and is expected to find a place on the book shelves of a large number of chemists as well as in the majority of the chemistry libraries.

Second-Sphere Coordination—a Novel Rôle for Molecular Receptors

By Howard M. Colquhoun, J. Fraser Stoddart,* and David J. Williams

Although it has been appreciated for most of this century that the coordinating influence of many transition metal complexes extends beyond their covalently-bonded first-sphere ligands to non-covalently bound chemical species in the so-called second-sphere, it is only recently that the fundamental importance of the phenomenon has been recognized and researched in its most general context. Rapid progress has been possible in this relatively new area of supramolecular chemistry by appealing to the symbiotic relationship that exists between X-ray crystallographic investigations and synthetic work. The gamut of non-covalent bonds, including electrostatic forces, hydrogen bonding, charge transfer, and van der Waals interactions are available for exploitation in choosing or designing suitable molecular receptors for particular transition metal complexes. Crown ethers are the synthetic macrocycles *par excellence* for forming adducts with neutral and cationic complexes carrying protic ligands (NH_3, H_2O, CH_3CN, etc.) in their first coordination spheres. Anionic complexes with electron-rich first-sphere ligands (e.g. $CN^{\ominus}$) form adducts with polyammonium macrocyclic receptors. In both situations, hydrogen bonds and electrostatic interactions provide the dominant sources of supramolecular stabilization. Spectroscopic studies (UV, IR, and NMR) reveal that the structural integrity of the adducts is usually maintained in solution. The transition metal complexes can be organometallic as well as inorganic. In complexes supporting organic ligands, such as 1,5-cyclooctadiene, norbornadiene, cyclopentadiene, 2,2′-bipyridine, and trimethylphosphane, the opportunity exists to match their steric and electronic characteristics with appropriate binding sites in the molecular receptor. With these ligands, the weaker categories of non-covalent bonding, e.g. charge transfer and van der Waals interactions, assume considerable importance. The phenomenon is also observable with naturally-occurring receptors such as the cyclodextrins and polyether antibiotics. Moreover, it extends beyond the territory of transition metal complexes to main group complexes such as ammonia-borane. As far as applications are concerned, it finds expression in areas as diverse as separation science and drug delivery systems.

1. Introduction

With the greater awareness amongst contemporary chemists of the importance of the non-covalent bond in chemistry, the opportunity exists to examine old concepts in new contexts. One concept, which has been around since almost the turn of the century, relates to the ability of transition metal complexes to confer some degree of struc-

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1986 0570-0833/86/0606-0487 $ 02.50/0

tural order beyond the first sphere of ligands directly coordinated to the metal. These marshalling influences, which invariably involve weak intermolecular interactions, are usually referred to under the umbrella of second-sphere coordination.[1] More recently, the rapidly expanding availability[2] of a wide range of low molecular weight molecular receptors, both natural[3] and synthetic,[4] has provided the potential for a range of interdisciplinary discoveries to be realized.[5] Although much of the story that follows has unfolded in our midst during the last five years, some advances of relevance to the theme of this tale happened in other places at different times. Presently, we reflect on our observations and experiences against the backcloth of historical and present-day activities that characterize this fascinating corner of chemical science.

The color code which has been employed in illustrating the X-ray crystal structures is as follows:

H (white)	B (green)	C	(grey)
N (blue)	O (red)	F	(green)
P (pink)	Cl (green)	All metals	(yellow)

The identity of the atoms in green is clear from their context in the structures.

2. Historical Background

The idea that ligands in the primary coordination sphere of a transition metal complex can interact in an ordered manner with neutral molecules or charged species to give a second-sphere or outer-sphere complex was first advanced by *Alfred Werner*[6] in 1912. He found the concept necessary in order to explain[7] a number of phenomena, which included (i) the formation of addition compounds between amines and coordinatively-saturated trisacetylacetonato complexes, (ii) the presence of solvents (e.g. H_2O) of so-called crystallization in complexes, such as $[Co(en)_3 \cdot 3H_2O][Cl]_3$, where $en = H_2NCH_2CH_2NH_2$, and (iii) the observation that the molar optical rotations of chiral complexes depend strongly on the nature of the solvents and the counterion, if present. Understandably, however, the nature of the forces involved in solvation were not at all well-understood at that stage.

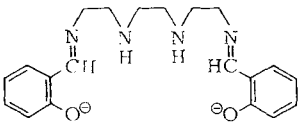
Since *Werner*'s original proposal, however, developments in optical, spectroscopic, crystallographic, and theoretical techniques have revealed a very wide range of other phenomena which can only be accounted for on the basis of second-sphere coordination either in the solid state or in solution, or indeed, in both. The forces responsible include the whole range of non-covalent interactions, i.e. hydrogen bonding—probably the single most important stabilizing interaction in second-sphere coordination chemistry, polar and dipolar attractions, dispersion forces, and charge-transfer interactions.

An early observation (1931) in the field of transition metal chemistry, which is now attributable to second-sphere coordination, is the so-called Pfeiffer effect.[8] One manifestation[9] of this effect is the ability of an optically-inactive transition metal complex—either achiral or a racemic modification—to display circular dichroism of one or more electronic transitions ($d \rightarrow d$), when it is dissolved in a medium containing an optically-active *environment* species, capable of interacting with its first-sphere ligands. Although the effect is independent of time for achiral and optically-stable racemic transition metal complexes, it is overlaid by an additional time-dependent change when an optically-labile transition metal complex is employed. This latter phenomenon is a result of the preferential second-sphere coordination of the *environment* species to *one* of the two enantiomeric complexes. In an optically-labile system, this second-sphere perturbation can disturb the enantiomeric equilibrium, shifting it away from its original 1 : 1 position to produce a slow increase in optical activity, a phenomenon which is generally referred to[9] as *anti-racemization*.

Although chiroptical methods are extremely sensitive tools for investigating second-sphere coordination by transition metal complexes, probing the phenomenon with other techniques, such as electronic and vibrational spectroscopes, has also proved to be very informative. Electronic spectroscopy provides[10] a straightforward method of distinguishing between second-sphere coordination and ligand-exchange. Thus, whereas the positions and/or intensities of charge-transfer bands are strongly affected by changes in both the first and second coordination spheres, *d-d* absorptions are normally shifted only by addition or exchange of ligands in the primary sphere. Vibrational spectroscopy has been employed by *Chatt* et al.[11,12] to detect hydrogen bonding associated with first-sphere coordinated ligands, both directly by the effect[11] on N-H stretching and deformation modes, and indirectly, by the effect[12] on co-ligand frequencies such as $\tilde{\nu}(C{\equiv}O)$ and $\tilde{\nu}(N{\equiv}N)$.

Kinetic data often indicate[13] the occurrence of second-sphere coordination in solution. In particular, the rates of certain anation reactions are found to be independent of anion concentration over a very wide range, suggesting rapid and extensive ion-pairing to give [Equation (1)] a second-sphere complex which is presumably stabilized by hydrogen bonding. This species can then undergo [Equation (2)] slow intramolecular rearrangement with loss of an aqua ligand.

$$[Co(NH_3)_5(H_2O)]^{3\oplus} + [SO_4]^{2\ominus} \overset{\text{fast}}{\rightleftharpoons} [\{Co(NH_3)_5(H_2O)\}\{SO_4\}]^{\oplus} \quad \ldots(1)$$



$$[\{Co(NH_3)_5(H_2O)\}\{SO_4\}]^{\oplus} \xrightarrow{\text{slow}} [Co(NH_3)_5(SO_4)]^{\oplus} + H_2O \ldots \quad (2)$$

Nuclear magnetic resonance spectroscopy has been employed extensively in the study of second-sphere coordination of transition metal complexes, particularly by *Nekipelov* et al.[14] Their investigations have depended heavily on ^{1}H-NMR spectroscopic measurements in solutions containing neutral, *paramagnetic*, transition metal complexes, since variations in chemical shifts and relaxation rates of solvent molecules in the second-sphere are then large enough to be measured reliably. Second-sphere stability constants, lifetimes, coordination numbers, and possible geometries have been estimated using this technique. However, as these results have been reviewed[14] recently in some detail, they will not be discussed further here.

An alternative ^{1}H-NMR spectroscopic technique uses the well-known aromatic-solvent-shift effect. This shift to

lower frequencies (i.e. to high field) of resonances associated with protons located within the aromatic ring-current shielding zone of solvating arene molecules has been used—to cite but one example—to study[15] the orientation of solvating benzene molecules with respect to the diamagnetic zinc complex, $[Zn(Me_2NCH_2CH_2NMe_2)Cl_2]$. It has also proved to be an extremely valuable tool in our investigations (see Sections 4 and 5) of second-sphere coordination by macrocyclic polyethers containing fused aromatic rings.

Second-sphere coordination has recently been shown[16] to have significant influence on the position of the high-spin/low-spin equilibrium for the complex, $[Fe(sal)_2(trien)]^{\oplus}$, and some related species. In the solid state, the equilibrium position is strongly dependent on the nature of the counterion and on the presence of solvents of crystallization which can hydrogen bond to the two NH groups of the hexadentate ligand, $[(sal)_2(trien)]$. In solution, the nature of the solvent influences the position of the spin-equilibrium in similar fashion. Low-spin is favored increasingly as the hydrogen bonding (electron donor) character of the solvent increases.

$(sal)_2(trien)$

In the past, second-sphere coordination has often been regarded simply as an aspect of solvation. Thus, it is relevant at this point to note that a *host*—or *receptor molecule*—has been *defined*[17] as one which provides "an assembly of solvation sites, tied together by covalent bonds". We therefore posed[5] the question: can we use molecular receptors to provide an insight into the nature of second-sphere coordination by studying their interactions with transition metal complexes, both in solution and in the solid state?

3. 3*n*C*n*-Type Crown Ethers as Receptors in the Second-Sphere

3.1. Adduct Formation involving Ammine Ligands

Macrocyclic polyethers such as [18]crown-6 (18C6) have long been known[18] to form[4,17-22] discrete hydrogen bonded complexes with primary alkylammonium ions, $[RNH_3]^{\oplus}$. It was the recognition[5] of a simple geometric and electronic analogy between an $[RNH_3]^{\oplus}$ ion and a transition metal ammine complex, $[ML_x(NH_3)]^{n\oplus}$, which led to our initial investigation of crown ether receptor molecules as second-sphere ligands. However, before discussing the interactions of $[ML_x(NH_3)]^{n\oplus}$ complexes with 18C6, we shall comment briefly on the binding of some complexes of main-group compounds by 18C6.

The borane complexes, $[BX_3NH_3]$ (X = H or halogen), are amongst the very simplest ammine complexes. In fact, $[BH_3NH_3]$ is strictly isoelectronic with the methylammonium ion, $[CH_3NH_3]^{\oplus}$. It follows that, just as $[CH_3NH_3][ClO_4]$ forms[23] a crystalline 1:1 complex with 18C6, so $[BH_3NH_3]$ affords[24] a well-defined crystalline 1:1 adduct[25] with 18C6. X-ray crystallographic studies reveal[23,24] the existence of a close structural relationship between the adduct and the complex—and, for that matter, most of the closely related $[RNH_3 \cdot 18C6][X]$ complexes.[26] In both cases, the 18C6 ring adopts an all-*gauche* conformation with pseudo D_{3d} symmetry, which is quite different from that found[27] in its free state. Figure 1 shows the X-ray structures of free 18C6,[27] of $[CH_3NH_3 \cdot 18C6]^{\oplus}$ as its $ClO_4^{\ominus}$ salt,[23] and of $[BF_3NH_3 \cdot 18C6]$ as its CH_2Cl_2 solvate.[24] In both $[CH_3NH_3 \cdot 18C6]^{\oplus}$ and $[BF_3NH_3 \cdot 18C6]$, three strong N-H···O hydrogen bonds ($[N \cdots O] \leqq 2.95$ Å) link the $NH_3^{\oplus}$ center to the alternate oxygen atoms in the 18C6 ring which are closer to the $NH_3^{\oplus}$ group. This geometry corresponds to the so-called[23] perching mode of binding.

The first adducts of transition metal complexes with 18C6 to be investigated[28,29] by X-ray crystallography involved the neutral ammine-platinum(II) complexes, [*trans*-$Pt(PR_3)Cl_2(NH_3)$] (R = Me or Et).[30] Unlike the ammineboranes, however, the platinum complexes form adducts with 18C6 in which both faces of the macrocycle are involved simultaneously in binding to the ammine ligands.

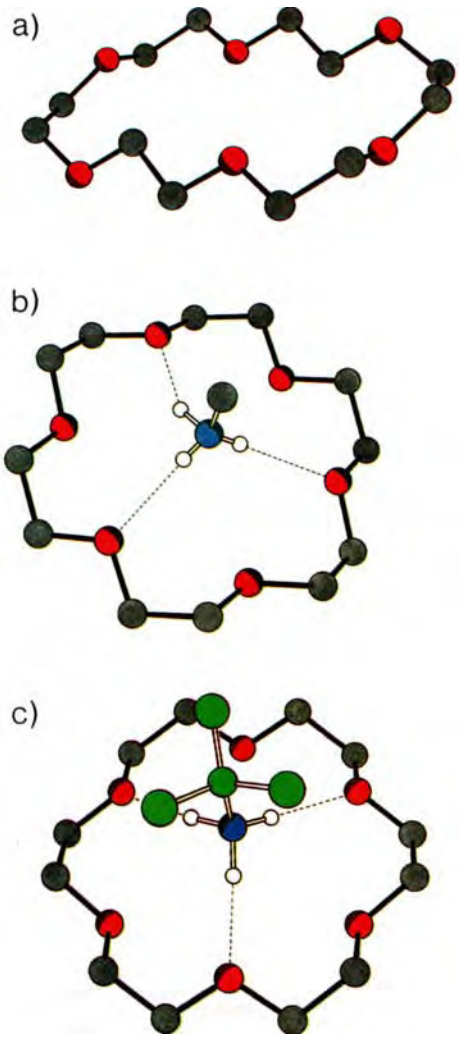


Fig. 1. Skeletal representations of the X-ray structures of (a) 18C6, (b) $[CH_3NH_3 \cdot 18C6]^{\oplus}$ ($ClO_4^{\ominus}$-salt), and (c) $[BF_3NH_3 \cdot 18C6]$ (CH_2Cl_2-solvate).

This phenomenon results in the crystallization of adducts having 2 : 1 (complex: 18C6) stoichiometry, even from solutions containing equimolar amounts of the transition metal complex and 18C6. As revealed[28,29] by the X-ray structure of [{*trans*-$Pt(PMe_3)Cl_2(NH_3)$}$_2$ · 18C6] (Fig. 2), the macrocycle still retains the familiar all-*gauche* conformation, characteristic[23,24,26] of $[RNH_3]^{\oplus}$ and $[BX_3NH_3]$ binding to 18C6. However, all six oxygen atoms in 18C6 are hydrogen bonded in approximately trigonal fashion via perching modes to the two NH_3 ligands on the neutral platinum complex. The [N···O] distances of the N-H···O hydrogen bonds (3.31, 3.21, and 3.04 Å) are significantly longer—by up to 0.4 Å—than in [BF_3NH_3 · 18C6]. Indeed, it will become increasingly apparent that long hydrogen bonds (3.0–3.4 Å) are a feature of many second-sphere complexes involving ammine-metal complexes and crown ethers.

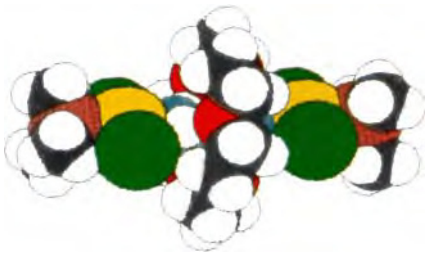

Fig. 2. Space-filling representation of the X-ray structure of [{*trans*-$Pt(PMe_3)Cl_2(NH_3)$}$_2$ · 18C6].

Although the factors favoring crystallization of either a 1 : 1 or 2 : 1 complex or adduct from a solution initially of 1 : 1 stoichiometry are not yet fully understood, it seems reasonable to expect that two $[RNH_3]^{\oplus}$ ions, in which the NH_3 groups carry essentially localized positive charges, should tend to repel one another as they approach each other from opposite faces of 18C6. This simple explanation accounts for the observed preference for discrete 1 : 1 stoichiometry. Conversely, a pair of *neutral* transition metal complexes with ligating ammonia [$M \leftarrow NH_3^{\delta\oplus}$] can obviously approach[31] within hydrogen bonding distances of each face of 18C6. Moreover, although 18C6 has an unfavorable conformation[27] for adduct formation in its free state, the unused face of a 1 : 1 adduct with its preorganized all-*gauche* conformation could provide an energetically-preferred binding site leading to adducts with the observed 2 : 1 stoichiometry. Alternatively, adduct solubilities and/or crystal packing forces may be more significant in dictating stoichiometries in the solid state.

The potential bireceptor nature of 18C6 suggested[28,29] that interaction with *trans*-diammines should generate a novel type of linear hydrogen bonded polymer. Indeed, this is so. On mixing dimethylformamide (DMF) solutions of 18C6 and [*trans*-$Pt(NH_3)_2Cl_2$], a highly insoluble 1 : 1 adduct is precipitated instantly. This material can only be dissolved in dipolar aprotic solvents (e.g. DMF) at high temperatures (e.g. 120 °C). Although crystallographic confirmation of the structure is not available because of crystal-twinning, the stoichiometry and extreme insolubility of the adduct strongly support a polymeric superstructure as indicated diagrammatically in Figure 3.

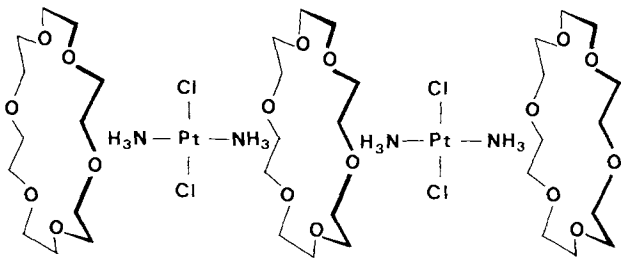

Fig. 3. Diagrammatic representation of the proposed structure of [*trans*-$Pt(NH_3)_2Cl_2$ · 18C6]$_n$.

In contrast, the isomer [*cis*-$Pt(NH_3)_2Cl_2$], the antitumor drug[32] Cisplatin, interacts with 18C6 in dimethylacetamide (DMA) to give[33] a soluble 2 : 1 adduct with a structure (Fig. 4) very similar to that described for [{*trans*-$Pt(PMe_3)Cl_2(NH_3)$}$_2$ · 18C6]. Again, both faces of 18C6 are involved in binding but, this time, the ammine ligands on platinum, which are oriented *cis* to those hydrogen-bonded in the normal trigonal manner to each face of 18C6, form additional N-H···O hydrogen bonds ([N···O] = 3.11 Å), also to each face. This additional hydrogen bonding tilts each complex with respect to the mean plane of the 18C6 macrocycle so that the Pt-N vectors of the two triply hydrogen bonded ammine ligands are no longer collinear nor, for that matter, orthogonal to the mean plane. The remaining ammine hydrogen atoms in this structure (Fig. 4) are, in fact, also involved in hydrogen bonds—one symmetry-related pair to solvating DMA molecules and the other pair to chlorine ligands in adjacent Cisplatin molecules.

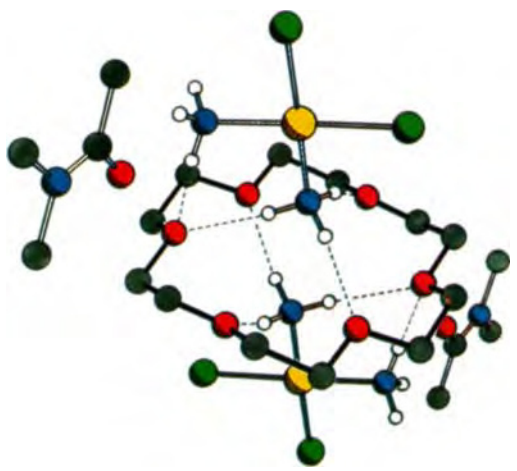

Fig. 4. Skeletal representation of the X-ray structure of [{*cis*-$Pt(NH_3)_2Cl_2$ · dma}$_2$ · 18C6].

A further increase in structural complexity is observed[29,34] when 18C6 interacts with the dicationic copper(II) complex, $[Cu(NH_3)_4(H_2O)]^{2\oplus}$ as its $PF_6^{\ominus}$-salt. The resulting polymeric 1 : 1 adduct crystallizes readily from aqueous solution, and an X-ray structural investigation (Fig. 5 and 6) has shown that the hydrogen bonding may be regarded as an extension of that already described above for [{*cis*-$Pt(NH_3)_2Cl_2$}$_2$ · 18C6]. Thus, each macrocycle not only interacts with two ammine ligands (one on each face) employing the normal three-point binding mode, but it also

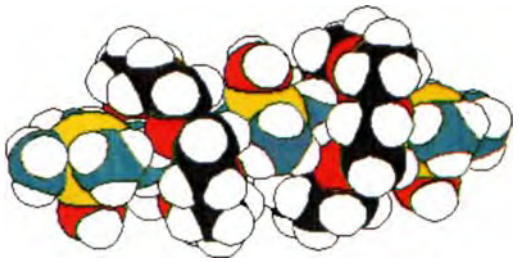

Fig. 5. Space-filling representation of the X-ray structure of $[Cu(NH_3)_4(H_2O)\cdot 18C6]_n^{2n\oplus}$.

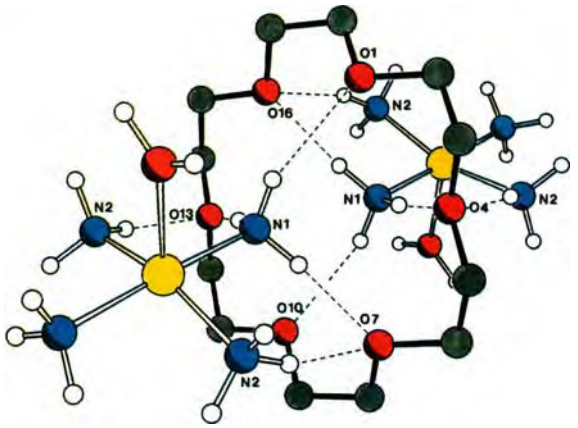

Fig. 6. Skeletal representation of the X-ray structure of $[Cu(NH_3)_4(H_2O)\cdot 18C6]_n^{2n\oplus}$ showing the hydrogen bonding pattern associated with an 18C6 ring.

forms single hydrogen bonds (two to each face) to ammine ligands which are oriented *cis* to the triply hydrogen bonded ammine ligands. The hydrogen bond distances are again relatively long (3.06–3.28 Å) and each macrocycle is involved in no fewer than ten hydrogen bonds. Oxygen atoms O1 and O10 each form one hydrogen bond with approximately trigonal approach geometry while O4, O7, O13, and O16 each accept two hydrogen bonds, one from N1 with approximately trigonal approach geometry, and the other from N2 with approximately tetrahedral approach geometry. The aqua ligand does not interact with 18C6 but it may hydrogen bond weakly to a $PF_6^{\ominus}$ counterion.

Clearly, simple metal complexes containing ammine ligands possess a strong affinity for 18C6. The examples of adduct formation quoted in this Section could probably be expanded upon almost indefinitely. However, given the limited range of hydrogen bonding patterns already established, it seems unlikely that many new binding modes will be uncovered for this particular class of adduct. For example, one might predict that the crystalline 1:1 adduct formed[35] between $[Pt(bpy)(NH_3)_2][PF_6]_2$ (bpy = 2,2′-bipyridyl) and 18C6, which has not yet been structurally characterized, will have a four-point binding pattern (Fig. 7) similar to that found in $[\{cis\text{-}Pt(NH_3)_2Cl_2\}_2\cdot 18C6]$.

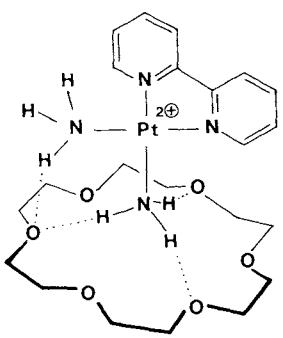

Fig. 7. Diagrammatic representation of the proposed structure of $[Pt(bpy)(NH_3)_2\cdot 18C6]^{2\oplus}$.

The opportunity remains (i) to alter the nature of the monodentate ammine ligands (e.g. to RNH_2 or R_2NH) and (ii) to examine a range (say n = 4, 5, 7, 8, etc.) of 3*n*C*n* crown ethers as potential second-sphere ligands. So far, we have not pursued these possibilities. However, we have examined[29,36] the ability of $[Pt(en)_2][PF_6]_2$, containing a bidentate diamino ligand ($en = H_2NCH_2CH_2NH_2$), to interact with 18C6 in aqueous solution. A colorless crystalline 1:1 adduct is formed and X-ray crystallography reveals (Fig. 8) a polymeric structure in which only one hydrogen atom of each NH_2 group and only four crown ether oxygen atoms are involved in hydrogen bonding. There are also weak interactions between the en ligands and $PF_6^{\ominus}$ counterions.

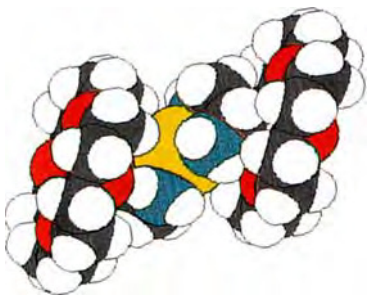

Fig. 8. Space-filling representation of the X-ray structure of $[Pt(en)_2\cdot 18C6]_n^{2n\oplus}$.

3.2. Adduct Formation involving Aqua Ligands

Just as ammine ligands on transition metals are activated towards second-sphere coordination of crown ethers, so aqua ligands coordinated to electropositive metals $[M{\leftarrow}OH_2^{\delta\oplus}]$ show an enhanced dipole and increased acidity. This phenomenon finds expression in the numerous crystalline adducts that have been isolated[37–44] between 18C6, other 3*n*C*n* crown ethers (e.g. 12C4 and 15C5)—as well as benzo[15]crown-5 and dibenzo[18]crown-6—and

Table 1. Some aqua complexes for which X-ray crystal data are available in the literature.

Structure	Repeating Polymeric Unit	Ref.
1	$[UO_2(NO_3)_2(H_2O)_2\cdot 18C6][H_2O]_2$	[37]
2	$[UO_2(NO_3)_2(H_2O)_2\cdot 18C6]$ [a]	[38]
3	$[Mn(NO_3)(H_2O)_5\cdot 18C6][NO_3][H_2O]$	[39]
4	$[Mn(H_2O)_6\cdot 18C6][ClO_4]$	[40]
5	$[Co(H_2O)_6\cdot 18C6][CoCl_4]$ [b]	[41]

aqua complexes of $U^{VI}O_2$, Mn^{III}, Co^{II}, Th^{IV}, U^{IV}, Sn^{IV}, etc. Although the characterization (Table 1) by X-ray crystallography of many of these polymeric adducts preceded our own investigations on transition metal ammines, there did not appear to be any widespread recognition of the generality of the phenomenon. The 18C6 rings in all the structures, except **8** listed in Table 1, adopt the normal all-*gauche* conformations with pseudo D_{3d} symmetry. With the exception of structure **7**, *trans*-aqua ligands are invariably hydrogen bonded to the macrocyclic ring faces to afford linear polymeric arrays of alternating metal complex and 18C6 macrocycle. An example (Structure **4**) is illustrated in Figure 9. Structure **7** (Fig. 10) is unique insofar as, although the H_2O molecules within the octahedral $[SnCl_4(H_2O)_2)]$ units are *cis* to each other, they still support a hydrogen bonded polymeric structure by involving non-coordinated H_2O molecules bound to each face of the 18C6 rings.

3.3. Adduct Formation involving Other Ligands

In addition to NH- and OH-acidic species, CH-acidic organic compounds form[31] crystalline complexes with 18C6. Since 18C6 is readily purified[45] as such a complex with CH_3CN, we reasoned that coordination of acetonitrile $[M \leftarrow N \equiv C - CH_3]$ to a transition metal should render the CH_3 group more acidic and hence more prone to hydrogen bonding with 18C6. Indeed, in marked contrast to [*trans*-$Ir(CO)(NH_3)(PPh_3)_2][PF_6]$ where the ammine ligand is sterically quite inaccessible to 18C6, [*trans*-$Ir(CO)(CH_3CN)(PPh_3)_2][PF_6]$ forms[46] a crystalline 2:1

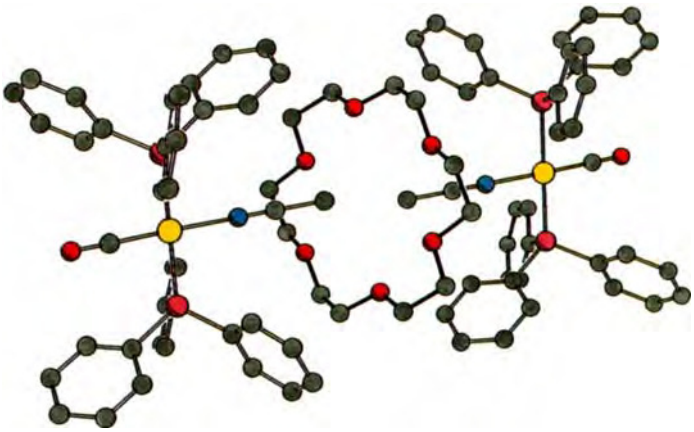

Fig. 11. Skeletal representation of the X-ray structure of $[\{trans\text{-}Ir(CO)(CH_3CN)(PPh_3)_2\}_2 \cdot 18C6]^{2\oplus}$.

complex with 18C6. X-ray crystallography has revealed (Fig. 11) the anticipated structure, with C–H···O hydrogen bonds ([C···O] = 3.24, 3.26, and 3.38 Å) between the more elongated CH_3CN ligands and the macrocycle in its ubiquitous conformation. Addition of excess of NaCl to equivalent amounts of $[Ir(CO)(CH_3CN)(PPh_3)_2][PF_6]$ and 18C6 in CH_2Cl_2 gave exclusively $[Ir(CO)(PPh_3)_2Cl]$. This promotion of the displacement of CH_3CN by $Cl^{\ominus}$ ion is reminiscent of a situation which exists in the reaction[47] of [*trans*-$Co(en)_2(CH_3CN)(NO_2)][ClO_4]_2$ with D_2O at pD 4.4 in the presence of either 18C6 or 15C5, where the small observed rate enhancements have been ascribed to adduct formation between the crown ether and the acidic CH_3 group of the CH_3CN ligand. However, it should be pointed out that the crown ethers will probably interact more strongly by N–H···O hydrogen bonding to the en ligands in this Co complex. Spectroscopic evidence also indicates interactions between CH_3CN ligands and crown ethers. Copper iodide reacts[48] in acetonitrile solution with dibenzo[18]crown-6 to form a crystalline adduct $[(CuI)_4(CH_3CN)_4 \cdot DB18C6]$: the luminescence spectrum of the adduct is red shifted, indicating some interaction between the crown ether and the acetonitrile copper iodide.

It is obvious that second-sphere coordination of transition metal complexes by 3*n*C*n* crown ethers could involve an extensive range of first-sphere ligands [e.g. PH_3, $CS(NH_2)_2$, $(H_2NCS)_2$, $H_2NCS_2^{\ominus}$, $CH_3N^{\oplus} \equiv C^{\ominus}$, CH_3, and even H] which are potentially able to enter into hydrogen bonding because of their acidic character.

4. Dibenzo Crown Ethers of Type DB3*n*C*n* as Receptors in the Second-Sphere

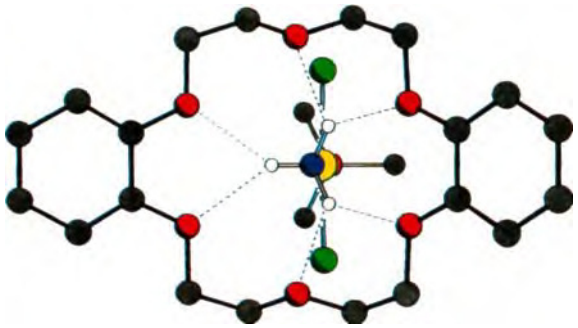
4.1. Adduct Formation involving Monoammine-Transition Metal Complexes

Our first evidence for interactions between crown ethers and ammine-metal complexes in solution was pro-

vided[5,29] by the shift to lower frequency of the two $\tilde{\nu}$(C≡O) bands in the IR spectrum of $[Fe(\eta^5\text{-}C_5H_5)(CO)_2(NH_3)]^{\oplus}$ when a molar equivalent of dibenzo[18]crown-6 (DB18C6) was added to a solution of the complex as its $BPh_4^{\ominus}$ salt in dichloromethane. This shift was not observed for $[Fe(\eta^5\text{-}C_5H_5)(CO)_2(C_5H_5N)][PF_6]$, thus confirming that hydrogen bonding to the ammine ligand was responsible for the carbonyl frequency shift. Since hydrogen bonding involves a net donation of charge to the metal complex, this change in frequency clearly reflects increased d→(C≡O)π* electron transfer as a result of the increased density at the metal center.

Although dynamic ^{1}H-NMR spectroscopic studies indicate an activation free energy of ca. 45 kJ mol^{-1} for dissociation of $[Fe(\eta^5\text{-}C_5H_5)(CO)_2(NH_3)\cdot DB18C6][BPh_4]$, no crystalline adduct could be isolated from solution. However, the neutral monoammines, [*trans*-$Pt(PR_3)Cl_2(NH_3)$]

Fig. 12. Space-filling representation of the X-ray structure of [*trans*-$Pt(PMe_3)Cl_2(NH_3)\cdot DB18C6$].



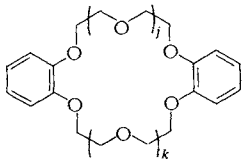


Fig. 13. Skeletal representation of the X-ray structure of [*trans*-$Pt(PMe_3)Cl_2(NH_3)\cdot DB18C6$] showing the three bifurcated hydrogen bonds.

(R = Me or Et) and $[W(CO)_5(NH_3)]$ do yield isolable 1:1 adducts with DB18C6. The tungsten derivative has been characterized spectroscopically (IR and $^{13}C\{^1H\}$-NMR) and the platinum derivative (with R = Me) crystallographically (Fig. 12 and 13). The benzene rings on the macrocycle in [*trans*-$Pt(PMe_3)Cl_2(NH_3)\cdot DB18C6$] are folded *away* from the Pt–N vector and the six oxygen atoms form three bifurcated hydrogen bonds to the ammine ligand (Fig. 13). The directions of approach of the hydrogen bonds result in approximately trigonal geometries at the aryl oxygen atoms, whereas the aliphatic oxygen atoms enter into essentially orthogonal hydrogen bonding interactions. Variable temperature ^{1}H-NMR spectroscopy in CD_2Cl_2 solution indicates a dissociation free energy of 33 kJ mol^{-1} for this neutral second-sphere adduct, i.e. it is a considerably weaker adduct than that formed in solution by the cationic iron derivative.

4.2. Adduct Formation involving Rhodium Complexes

Virtually all the results described so far in this review were obtained using commercially-available crown ethers with a ring size of 18 atoms or less. However, when a transition metal complex contains more than one protic ligand, larger macrocyclic polyethers with 21- to 36-membered rings become attractive second-sphere ligands, since one can envisage several ammine ligands, for example, being bound simultaneously within the extended cavities provided by the larger ring sizes. The dibenzo[3n]crown-n (DB3*n*C*n*) ethers (n = 6–12) are especially attractive candidates[49] for investigation as they are reasonably straightforward to synthesize and, moreover, have the potential for inducing aromatic ring-current shifts in the ^{1}H-NMR resonances of transition metal complexes containing organic ligands, thus providing a sensitive means of probing the stereochemical aspects of second-sphere coordination in solution.

DB3*n*C*n*	*n*	*j*	*k*
DB18C6	6	1	1
DB21C7	7	2	1
DB24C8	8	2	2
DB27C9	9	3	2
DB30C10	10	3	3
DB33C11	11	4	3
DB36C12	12	4	4

The cationic rhodium(I) complexes $[Rh(cod)(NH_3)_2]^{\oplus}$ (cod = 1,5-cyclooctadiene) and $[Rh(nbd)(NH_3)_2]^{\oplus}$ (nbd = norbornadiene) have been extensively studied by us[50] in this stereochemical context since they provide (i) a pair of *cis*-ammine ligands for hydrogen bond participation and (ii) an organic ligand with three sets of protons in heterotopic environments (Fig. 14). Any ring current shifts in-

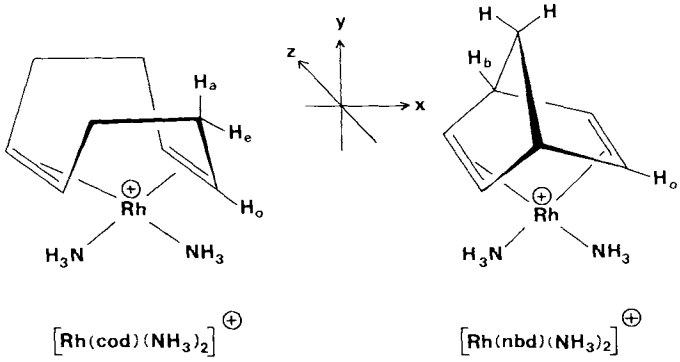

Fig. 14. Structural formulas of $[Rh(cod)(NH_3)_2]^{\oplus}$ and $[Rh(nbd)(NH_3)_2]^{\oplus}$

duced by a molecular receptor can therefore be related to the position of the shielding arene units relative to the heterotopic protons on the organic ligands.

The organometallic cations are readily isolated from aqueous solution as crystalline hexafluorophosphates. Both salts are insoluble in hydrocarbon and halocarbon solvents but dissolve freely in halocarbons on addition of crown ethers such as 18C6 or DB3*n*C*n* ($n=6$–12). The ^{1}H-NMR spectra of the complexes in CD_2Cl_2 solutions containing equimolar amounts of certain of the DB3*n*C*n* ethers—especially DB21C7 and DB24C8—show dramatic upfield shifts of the diene resonances relative to their positions when 18C6 is used as the solubilizing agent. The chemical shift data for both the cod and nbd complexes are summarized in Figure 15. It shows that the most dramatic

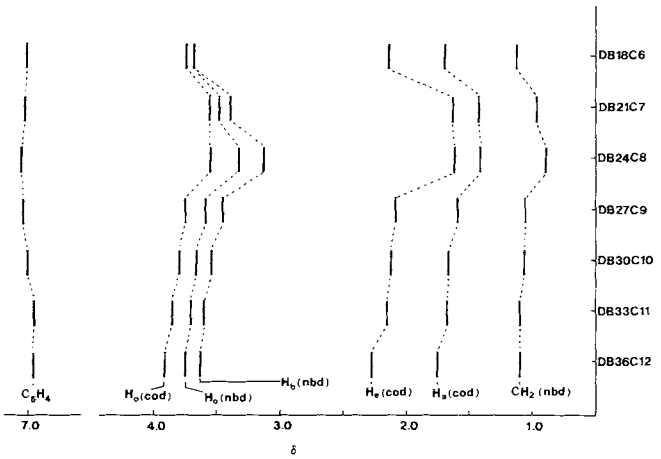

Fig. 15. The partial ^{1}H-NMR line spectra for the complexes [Rh(cod)$(NH_3)_2$·DB3*n*C*n*][PF_6] and [Rh(nbd)$(NH_3)_2$·DB3*n*C*n*][PF_6]. The signals (singlets) for the aromatic protons refer to [Rh(cod)$(NH_3)_2$·DB3*n*C*n*][PF_6] only.

shifts are experienced by the equatorial methylene protons of the cod ligand and the bridgehead methine protons of the nbd ligand. The olefinic protons are also shifted significantly upfield in both cases but the other ligand resonance in each case is influenced much less so. This difference in magnitude of the ring-current shifts of the probe protons strongly suggests an adduct geometry in which one or both aromatic ring systems of the receptor molecules approach the rhodium complexes "face on" along the sterically unhindered *z* axis (Fig. 14). In this super-structure, the olefinic, the equatorial methylene (cod), and the bridgehead-methine (nbd) protons, but not the remaining ligand protons, lie well within (Fig. 16) the aromatic ring-current shielding zones of the benzene rings in the molecular receptors.

Further evidence for a close association between the benzene rings in DB24C8 and the cod ligand in [Rh(cod)$(NH_3)_2$·DB24C8]$^{\oplus}$ was provided by the observation of intermolecular nuclear Overhauser effects (NOE's) between the aromatic protons on the receptor and the equatorial methylene and olefinic protons on the cod ligand. In accordance with the superstructure proposed (Fig. 16), intermolecular NOE's are *not* observed for the

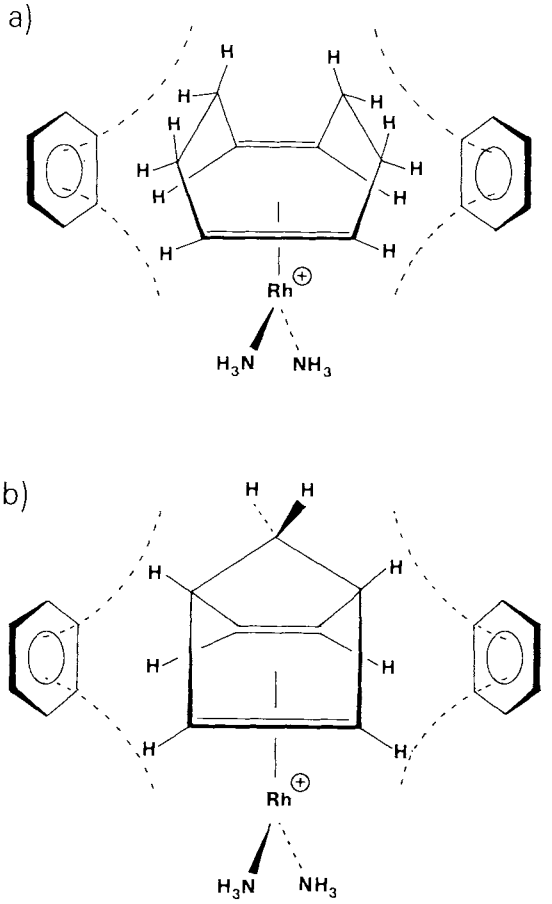

Fig. 16. A diagrammatic representation of the shielding effect of the annelated benzene rings of the dibenzo crown ethers DB3*n*C*n* ($n=7$–10) on (a) the cod ligand and (b) the nbd ligand of the Rh complexes of Figure 14.

axial-methylene protons on the cod ligand. This implies that these protons are more distant from the benzene groups of the crown ether than are the equatorial methylene and olefinic protons of the cod ligand.

The supramolecular structural features indicated by ^{1}H-NMR spectroscopic investigations have been amply confirmed by a series of X-ray structure determinations performed on adducts crystallized from halocarbon (CH_2Cl_2 or $C_2H_4Cl_2$) solutions. Four of the five adducts, which have been characterized in the solid state, are of 1 : 1 stoichiometry. They have many features in common, including a characteristic V-shaped conformation for the receptor, within which the rhodium complex is bound. Space-filling representations of the supramolecular structures of [Rh(cod)$(NH_3)_2$·DB21C7]$^{\oplus}$ and [Rh(nbd)$(NH_3)_2$·DB24C8]$^{\oplus}$ are shown in Figure 17. Figure 18 presents skeletal representations of the 1 : 1 adducts between [Rh(cod)$(NH_3)_2$]$^{\oplus}$ and the receptors, DB24C8 and DB30C10. These X-ray structural studies reveal that, without exception, the two *cis*-ammine ligands on the complexes straddle one chain of the macrocycle—the longer chain in the case of DB21C7—so that, in fact, only *one* ammine ligand is hydrogen bonded *within* the cavity while the other interacts with the oxygen atoms in the straddled chain. In both DB24C8 adducts, one of the four aryloxymethylene units is distorted from its customary coplanarity[51] with the benzene ring plane so

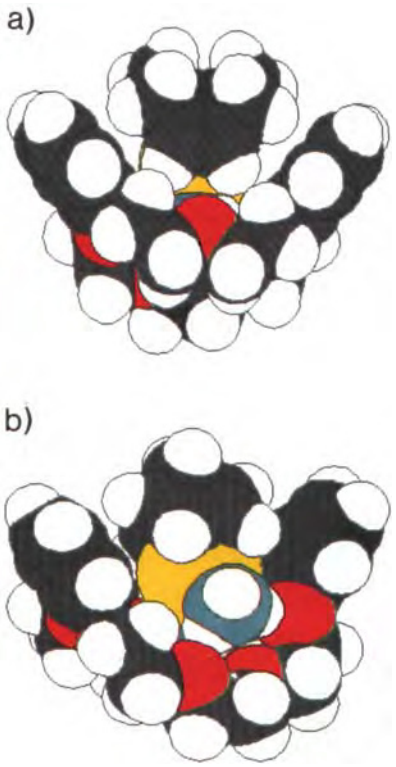

Fig. 17. Space-filling representations of the X-ray structures of (a) $[Rh(cod)(NH_3)_2 \cdot DB21C7]^{\oplus}$ and (b) $[Rh(nbd)(NH_3)_2 \cdot DB24C8]^{\oplus}$.

that the oxygen atom can form a hydrogen bond to one of the ammine ligands with an approximately trigonal approach to the oxygen. N–H···O hydrogen bond distances ([N···O]) in this collection of adducts are in the range 2.95–3.38 Å though the vast majority lie (Table 2) between 3.10 and 3.20 Å.

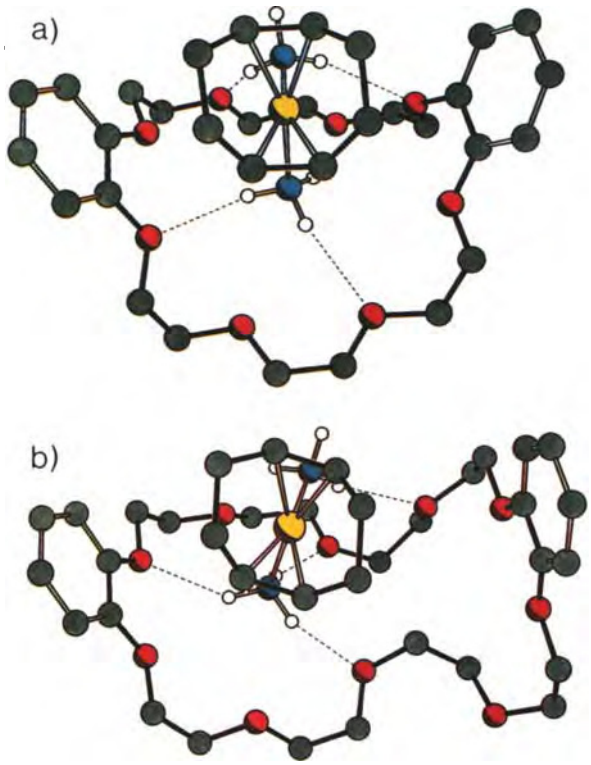

Fig. 18. Skeletal representations of the X-ray structures of (a) $[Rh(cod)(NH_3)_2 \cdot DB24C8]^{\oplus}$ and (b) $[Rh(cod)(NH_3)_2 \cdot DB30C10]^{\oplus}$.

Table 2. Selected hydrogen bond distances ([N···O]) in the 1:1 adducts of $[Rh(L)(NH_3)_2]^{\oplus}$ (L = cod or nbd) and DB3*n*C*n* (*n* = 7, 8 and 10).

$[Rh(L)(NH_3)_2 \cdot DB3nCn]^{\oplus}$ L	*n*	*R* [N···O] [Å]
cod	7	3.04, 3.12, 3.12, 3.17, 3.19, 3.19, 3.20, 3.22, 3.23, 3.31
cod	8	3.03, 3.13, 3.21, 3.34
nbd	8	2.95, 3.01, 3.27, 3.38
cod	10	2.96, 3.16, 3.18, 3.19

Although the primary binding forces between DB3*n*C*n* crown ethers (*n* = 7–10) and the rhodium complexes undoubtedly arise from hydrogen bonds, there also exist (Table 3) a large number of contacts ([Rh···O] and [Rh···C])

Table 3. Selected contact distances to rhodium ([Rh···O] and [Rh···C]) in the 1:1 adducts of $[Rh(L)(NH_3)_2]^{\oplus}$ (L = cod or nbd) and the aromatic O–C–C–O units of DB3*n*C*n* (*n* = 7 and 8) [a].

$[Rh(L)(NH_3)_2 \cdot DB3nCn]^{\oplus}$ L	*n*	*R* [Rh···O] [Å]	*R* [Rh···C] [Å]
cod	7	3.80, 3.87	4.04, 4.06
cod	8	3.59, 3.65, 4.01, 4.07	3.87, 3.87, 4.06, 4.12
nbd	8	3.50, 3.74, 3.78, 4.08	3.68, 3.86, 3.86, 4.06

[a] In $[Rh(cod)(NH_3)_2 \cdot DB30C10]^{\oplus}$, because of the larger ring size of the macrocycle, there are no contacts of less than 4 Å between the aromatic O–C–C–O units and the Rh atom.

at about van der Waals distances, which may provide weak, additional binding as a result of Coulombic and dispersion forces. Not only could these forces contribute to the overall stabilization of the adducts but they could also be largely responsible for ordering their superstructures. In particular, it is noticeable that, in all four adducts, the diene ligand is sandwiched between the two aromatic rings of the crown ether so that a number of allylic and vinylic C–H groups are brought into close contact with the π-arene systems of the receptor. As yet, there is no direct evidence that these contacts ([H···benzene ring plane] = 2.6–3.3 Å) enhance the stability of the adducts to any significant extent. However, there is considerable literature precedent for the existence of attractive [CH···arene] interactions at distances of 2.5–3.5 Å. The dimer of benzene, for example, has been shown[52] to have a T-shaped geometry in the gas phase with a binding energy of 14.7 kJ mol^{-1} derived almost entirely from dispersion forces between the C–H groups of one ring and the π-electron system of the other. An interaction of this type was, in fact, recently demonstrated crystallographically,[53] and more general evidence for attractive [CH···arene] interactions has been obtained for a wide range of different systems containing aromatic and aliphatic units from conformational studies,[54] gas-liquid chromatography,[55] molecular mechanics calculations,[56] and association constant measurements.[57] Whatever the form and relative strengths of these weak attractive interactions involving the benzene rings of the DB3*n*C*n* crown ethers and the rhodium(I) complexes, there is no doubt that both DB24C8[58] and DB30C10[59] undergo considerable conformational changes from their

rather flat extended structures (Fig. 19) in the free states[58, 59] to their V-shaped conformations in the 1 : 1 adducts.

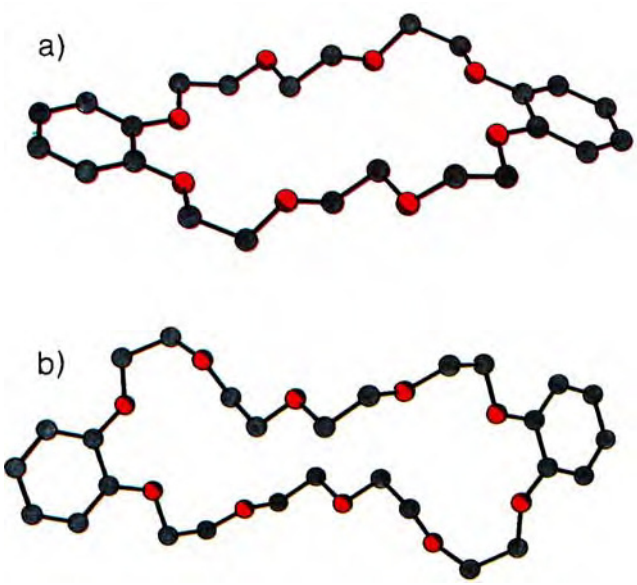

Fig. 19. Skeletal representations of the X-ray structures of (a) DB24C8 and (b) DB30C10.

In only one of the rhodium-based adducts is a significantly different solid state structure observed. DB36C12 forms a 2 : 1 (complex : receptor) adduct in which the macrocycle adopts a relatively flat, extended conformation (Fig. 20) with two $[Rh(cod)(NH_3)_2]^{\oplus}$ ions hydrogen-bonded centrosymmetrically to opposite faces of the receptor. Again, the characteristic straddling relationship of the two *cis*-ammine ligands with respect to the polyether chains is adopted. In accordance with the virtual absence (Fig. 15) of ring current shifts for the 1 : 1 adduct, the benzene rings of the receptor in the crystalline 2 : 1 adduct do not even begin to approach the diene ligand. The relatively flattened conformation adopted by the 36-membered ring in this adduct seems to be quite characteristic of DB36C12 (cf. its 2 : 1 complexes formed with sodium hexafluorophosphate[60] and lithium picrate).[61]

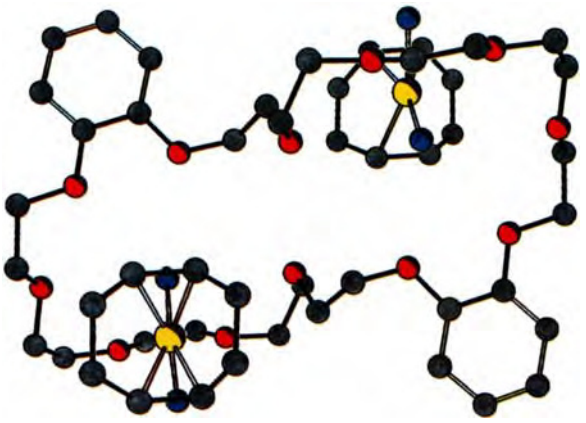

Fig. 20. Skeletal representation of the X-ray structure of $[\{Rh(cod)(NH_3)_2\}_2 \cdot DB36C12]^{2\oplus}$.

4.3. Adduct Formation involving a Platinum Complex

In view of the major rôle played by hydrogen bonding in second-sphere coordination we sought to enhance the hydrogen bonding potential of ammine ligands on transition metals by incorporation of π-acceptor co-ligands such as 2,2-bipyridyl into the primary coordination sphere of an ammine complex. It is known[62] that π-acceptor groups increase significantly the acidity of protic ligands on the same metal center by allowing partial delocalization of the increased electron density resulting from deprotonation. In this context, we may regard hydrogen bonding as a form of incipient deprotonation.

Although the square-planar platinum(II) complex, $[Pt(bpy)(NH_3)_2][PF_6]_2$ is insoluble in hydrocarbon or halocarbon solvents, it dissolves[35] in dichloromethane to give a pale yellow solution when a molar equivalent of 18C6 is added. A similar effect is produced by addition of the DB3*n*C*n* crown ethers ($n = 6$–12) to the complex. However, we noticed (eventually!) that solutions containing DB3*n*C*n* ethers (particularly $n = 7$–11) are markedly stronger in color than the solution obtained with 18C6 at the same concentration. Moreover, deep yellow, crystalline 1 : 1 adducts may be isolated from solutions containing the DB3*n*C*n* ethers when $n = 8$, 10, and 11. Single crystal X-ray diffraction studies[35] of two ($n = 8$ and 10) of these second-sphere adducts have revealed the source of this enhanced absorption in the visible region. Skeletal structures of the adducts are shown in Figure 21. A space-filling representation of $[Pt(bpy)(NH_3)_2 \cdot DB30C10]^{2\oplus}$ is given in Figure 22.

Three major features of the second-sphere coordination of the platinum complex are immediately apparent. Firstly, as anticipated, the ammine ligands lie within the cavity of the V- and U-shaped receptor and form hydrogen bonds to some of the crown ether oxygen atoms. Once again, the characteristic straddling disposition of the *cis*-ammine ligands with respect to one of the polyether chains is evident. Secondly, there is undoubtedly some stabilization provided by favorable electrostatic interactions of a charge-dipole type between the dicationic complex and the oxygen atoms of the macrocycle. Thirdly, the parallel arrangement and close contact (3.48–3.52 Å) between the relatively π-electron deficient bpy ligand and one or both of the π-electron rich catechol units of the receptor strongly suggest the existence of a $\pi \rightarrow \pi$ charge-transfer interaction. The associated electronic charge-transfer absorption, which was found to be centered at ca. 350 nm in acetonitrile solution, is clearly responsible for the enhanced depth of color of this type of adduct.

This charge-transfer absorption provides good evidence that the adduct-stereochemistry observed in the solid state is also retained in solution. Further proof of a close association of the crown ethers and the platinum complex in solution is provided by the observation (Fig. 23) of substantial upfield shifts (up to 0.7 ppm) for the ^{1}H-NMR resonances associated with the aromatic protons in both the complex and the receptor. As in the corresponding adducts involving rhodium-diene complexes, the shifts of the bpy ligand resonances can be ascribed to diamagnetic shielding by ring currents associated with the benzene rings of the macrocycle. On this occasion, however, the effect is recip-

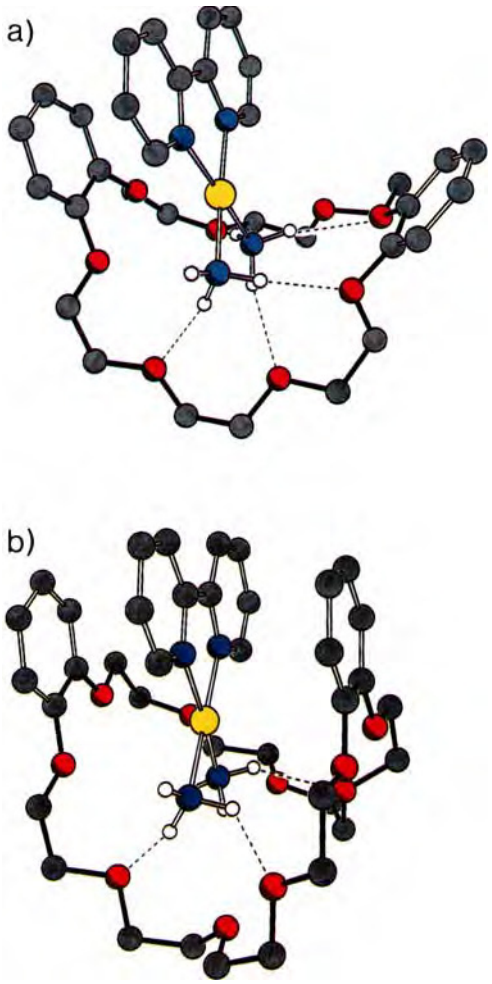

Fig. 21. Skeletal representations of the X-ray structures of (a) $[Pt(bpy)(NH_3)_2 \cdot DB24C8]^{2\oplus}$ and (b) $[Pt(bpy)(NH_3)_2 \cdot DB30C10]^{2\oplus}$.

Fig. 22. Space-filling representation of the X-ray structure of $[Pt(bpy)(NH_3)_2 \cdot DB30C10]^{2\oplus}$.

rocated and the aromatic protons of the receptor are also shielded by ring-currents associated with the bpy ligand in the complex. As shown in Figure 23, these upfield shifts increase with the ring size of the macrocycle up to a maximum for $n = 10$ or 11 and then decrease markedly for $n = 12$. The same general trend is followed by the intensity of the charge-transfer absorption band at 350 nm. This agreement is to be expected since the magnitudes of ring-current shielding and charge-transfer should both become

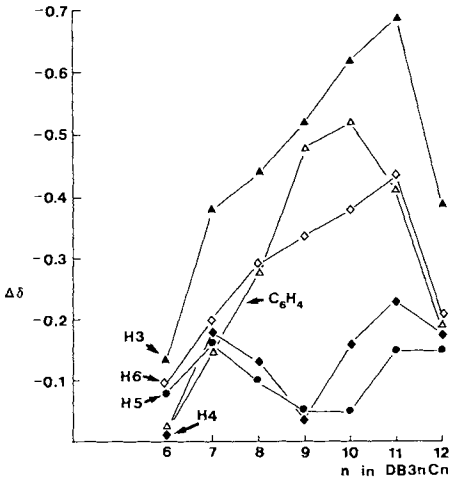

Fig. 23. A plot of ^{1}H-NMR chemical shifts ($\Delta\delta$) for crown ethers of the type DB3*n*C*n* in the formation of 1:1 adducts with $[Pt(bpy)(NH_3)_2][PF_6]_2$ in CD_2Cl_2 against the ring size ($n = 6$–12) of DB3*n*C*n*. Note that a negative $\Delta\delta$ value corresponds to an upfield shift.

optimal when the geometrical overlap of the π-systems is greatest and the inter-ring separations are least.

Analysis of the concentration dependence of the charge-transfer absorption can be used[63] to derive association constants (K_a) and free energies of binding (ΔG^0) for these adducts. The values for $n = 9$, 10, and 11 are $K_a = 66000$, 191000, and 69000 M^{-1} corresponding to $-\Delta G^0 = 27.7$, 30.2, and 27.7 kJ mol^{-1}, respectively. Thus, DB30C10 forms the most stable second-sphere adduct in solution. This particular receptor-complex match presumably reflects an optimum combination of hydrogen bonding and charge-transfer.

The relative significance of charge-transfer interactions in second-sphere coordination is probably best illustrated by examining the solid state structure of an adduct only recently obtained (Fig. 24) between $[Pt(bpy)(NH_3)_2][PF_6]_2$ and a dinaphtho[30]crown-10 (DN30C10) derivative.[64] This solid state structure reveals that the platinum complex is significantly tilted from its position in the corresponding

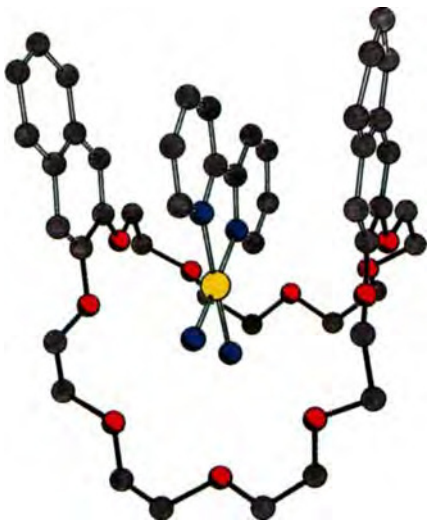

Fig. 24. Skeletal representation of the X-ray structure of $[Pt(bpy)(NH_3)_2 \cdot DN30C10]^{2\oplus}$.

DB30C10 adduct, apparently in order to maximize the overlap between the π-systems of the bpy ligand and those of the two naphthalene units. Clearly, a balance is being struck between N-H···O hydrogen bonding, pole-dipole interactions, and the dispersive forces that constitute a significant component of all charge-transfer interactions.

In conclusion, it should be mentioned that these investigations on the second-sphere coordination of $[Pt(bpy)(NH_3)_2]^{2\oplus}$ by DB3*n*C*n* crown ethers were directly responsible for initiating our research programme on the complexation of the bipyridinium herbicides, Diquat[49,65] and Paraquat[66] by the same and related molecular receptors.

5. Macrobicyclic and Macropolycyclic Polyether Receptors in the Second-Sphere

In the previous Section, we have witnessed, without exception, how the two ammine ligands in *cis*-diammine transition metal complexes straddle one of the polyether chains in the DB3*n*C*n* ether receptors. Thus, the receptor constitution is failing to make full use of the hydrogen bonding potential of these ammine ligands. For this reason, we decided to prepare macrobicyclic polyethers containing aromatic rings in which two crown ether rings are placed side-by-side such that each ring can bind one ammine ligand. The design concept and synthetic outcomes are summarized in Figure 25.

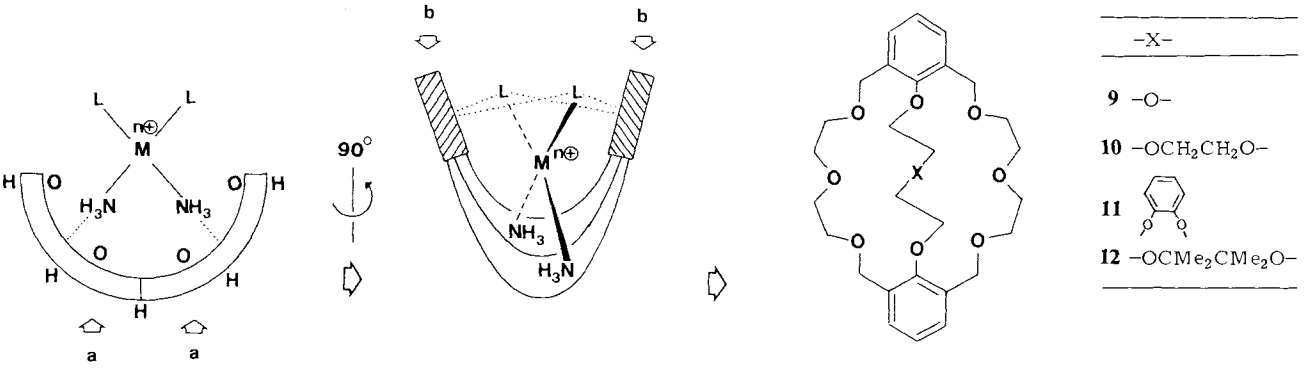

Fig. 25. The design concept behind macrobicyclic polyether receptors for *cis*-diammine transition metal complexes. a: receptor binding center; b: aromatic ring.

5.1. Adduct Formation involving a Rhodium Complex

The X-ray crystal structure analysis (Fig. 26) of the macrocycle **10** reveals[67] immediately that this receptor offers a more preorganized cavity for binding $[Rh(cod)(NH_3)_2]^{\oplus}$ than do the DB3*n*C*n* crown ethers. Although the three polyether chains have to undergo considerable conformational change prior to any adduct formation, the required V-shaped conformation of the receptor is already established. The suitability of the macrocycle **10**—and also the closely related derivative **11**—for adduct formation is confirmed by the solid state structures (Fig. 27 and 28) of their 1:1 adducts with the rhodium complex. The 24-membered macroring is clearly ideal for optimal hydrogen bonding of two *cis*-ammine ligands. The macroring encircles them by

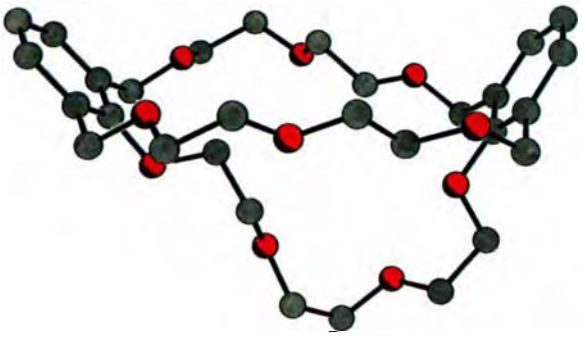

Fig. 26. Skeletal representation of the X-ray structures of the macrocycle **10**.

adopting a conformation with alternating *gauche* helicities for the C–C bonds and both structures are clearly stabilized by N-H···O hydrogen bonding: in each case, there are eight [N···O] distances lying within the range 3.00–3.26 Å and the N atoms of the ammine ligands are actually inserted below (0.53–0.63 Å) the mean planes of the six peripheral oxygen atoms. In both adducts, the middle two oxygen atoms in the central polyether chains are redundant as far as hydrogen bonding to the ammine ligands is

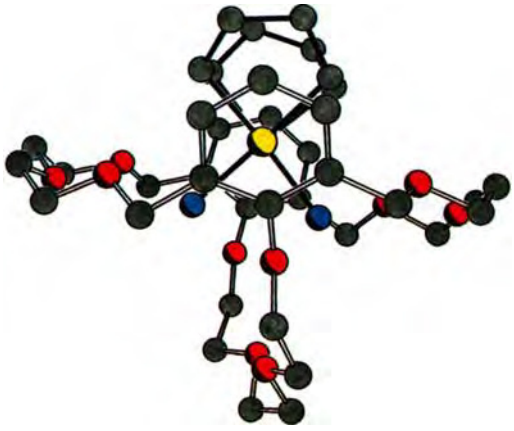

Fig. 27. Skeletal representation of the X-ray structure of $[Rh(cod)(NH_3)_2 \cdot \mathbf{10}]^{\oplus}$.

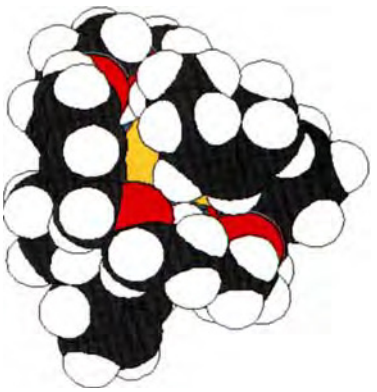

Fig. 28. Space-filling representation of the X-ray structure of $[Rh(cod)(NH_3)_2 \cdot \mathbf{11}]^{2\oplus}$.

concerned. Nonetheless, it has not been possible to obtain a crystalline 1:1 adduct of the macrocycle **9** and $[Rh(cod)(NH_3)_2]^{\oplus}$, and ^{1}H-NMR chemical shift data (Table 4) for all the 1:1 adducts in CD_2Cl_2 solutions suggest that binding is somewhat weaker in this case than it is in the $[Rh(cod)(NH_3)_2]^{\oplus}$ adducts of **10**, **11**, or **12**. As in the case of the $[Rh(cod)(NH_3)_2 \cdot DB3nCn]^{\oplus}$ adducts, upfield shifts of the signals for the cod protons were accompanied by downfield shifts in the signals for the aromatic protons in the receptors. Dynamic ^{1}H-NMR spectroscopy on the conformationally-mobile receptors **9** and **10** indicates that inversion of the receptors (i.e. passage of the central polyether chain through the middle of the 24-membered ring) is impeded on forming the 1:1 adducts with $[Rh(cod)(NH_3)_2][PF_6]$. The barriers to conformational inversion obtained from studying the temperature dependences of the signals—in each case, an AB system at low temperature coalescing to a singlet at higher temperature—for the benzylic methylene protons on the receptors are increased by 12.1 kJ mol^{-1} (from 32.6 to 44.7 kJ mol^{-1}) for **9**, and by 13.4 kJ mol^{-1} (from 43.5 to 56.9 kJ mol^{-1}) for **10**, respectively, on adduct formation. These values, which represent a minimum estimate of the binding free energies within the adducts reveal that **9** is a poorer receptor than **10** for $[Rh(cod)(NH_3)_2]^{\oplus}$.

Table 4. Selected ^{1}H-NMR data (δ- and $\Delta\delta$-values) for the 1:1 adduct of $[Rh(cod)(NH_3)_2][PF_6]$ and the macrobicyclic receptors **9**–**12** in CD_2Cl_2.

Resonance	**9**	**10**	**11**	**12**
NH_3 [a]	2.00	2.22	2.22	2.20
	(−0.39)	(−0.17)	(−0.17)	(−0.19)
(cod)-H_e [a]	2.00	1.32	1.52	1.48

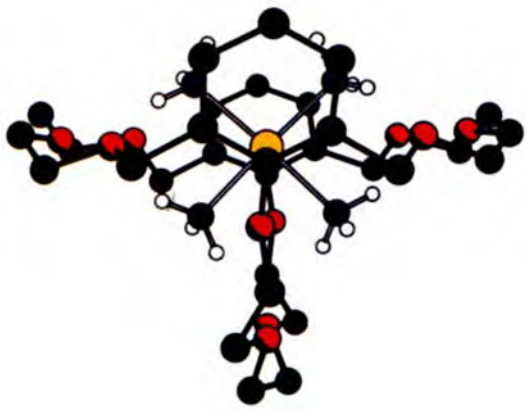
[a] The values in parantheses indicate the extent to which signals of the cod protons (H_e = equatorial methylene protons, H_a = axial methylene protons, H_o = olefinic protons) are shifted relative to the corresponding signals in $[Rh(cod)(NH_3)_2 \cdot 18C6][PF_6]$ where NH_3, (cod)-H_e, (cod)-H_a and (cod)-H_o have δ values of 2.39, 2.39, 1.85 and 4.07, respectively. [b] The values in parentheses indicate the extent to which the signals for *p*-H- and *m*-H are shifted relative to the corresponding signals in **9** (δ = 7.01 and 7.25, respectively), **10** (δ = 7.00 and 7.25, respectively), **11** (δ = 7.05 and 7.28, respectively), and **12** (δ = 7.02 and 7.28, respectively). [c] Signals obscured by signals for OCH_2 protons.

5.2. Adduct Formation involving a Platinum Complex

One of our objectives in this investigation was to encapsulate the antitumor agent, Cisplatin, in a molecular receptor. Although this goal still eludes us at the time of writing, we have discovered[68] that **10** forms a crystalline 1:1 adduct with $[Pt(NH_3)_4][PF_6]_2$. The X-ray structural analysis reveals that there are *two* independent adducts which differ subtly in the conformations adopted by the central polyether chain and in the relative orientations of the ammine ligands on platinum. One of the two independent adducts is illustrated in skeletal form in Figure 29. Compared with the monocationic $[Rh(cod)(NH_3)_2]^{\oplus}$ complex, the dicationic $[Pt(NH_3)_4]^{2\oplus}$ complex penetrates further into the receptor cavity, with all four ammine ligands involved in hydrogen bonding to the polyether chains. As a consequence, even the middle two oxygen atoms in the central polyether chain are no longer redundant as hydrogen bond acceptors.



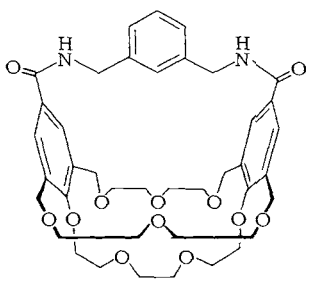


Fig. 29. Skeletal representation of the X-ray structure of $[Pt(NH_3)_4 \cdot \mathbf{10}]^{2\oplus}$.

In the knowledge that N–H···Cl hydrogen bonds exist[69] between adjacent Cisplatin molecules in the solid state, we have turned our attention to utilizing the hydrogen bonding potential of the Cl ligands in Cisplatin by synthesizing appropriately designed macropolycyclic polyether receptors. One of these is the bisamide **13**. The X-ray crystal structure (Fig. 30) of the free receptor confirmed[70] that there is indeed a cleft in the molecule into

13

which Cisplatin could fit. Alas, Cisplatin is not solubilized in halocarbon solvents containing the receptor despite the fact that $[Rh(cod)(NH_3)_2][PF_6]$ dissolves in CD_2Cl_2 in the presence of equimolar amounts of the bisamide receptor. However, the rhodium complex clearly does not enter the receptor cleft, since no significant changes in ^{1}H-NMR

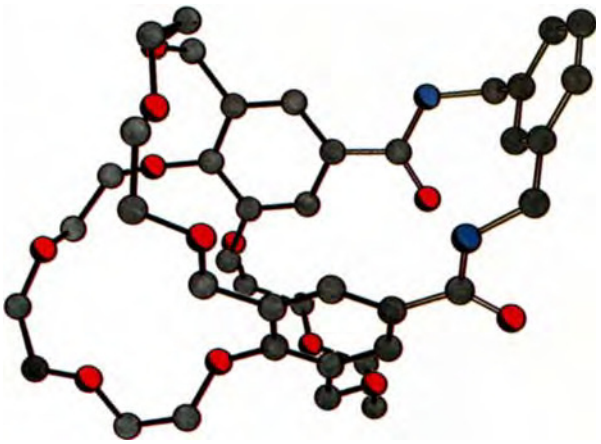

Fig. 30. Skeletal representation of the X-ray structure of the macrotricycle **13**.

chemical shifts are observed in the resonances for either the complex or receptor protons. Believing this to be for a simple steric reason, we examined the ability of $[Pt(NH_3)_4][PF_6]_2$ to form a crystalline adduct with the bisamide **13**. Crystals appeared almost immediately in methanol/acetone. However, X-ray crystallography revealed (Fig. 31) that, unexpectedly, a 2:1 (receptor:complex) adduct is formed in the solid state as an acetone solvate. Although this centrosymmetric adduct is undoubtedly stabilized by electrostatic interactions, N–H···O hydrogen bonds between *trans*-related ammine ligands and the amide oxygen atoms ([N···O]=2.90 and 3.01 Å) are obviously highly significant sources of adduct stabilization. The four ammine ligands are also involved in hydrogen bonding to oxygen atoms in one of the polyether chains of the bisamide receptor. This is the first example we have met where two receptor molecules coordinate simultaneously to the second-sphere of a transition metal complex in a discrete manner.

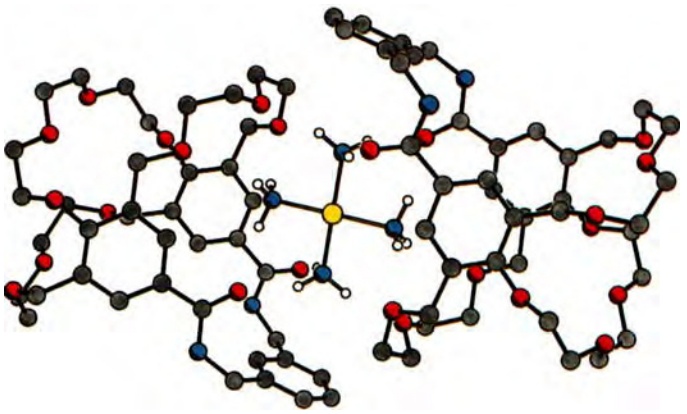

Fig. 31. Skeletal representation of the X-ray structure of $[Pt(NH_3)_4 \cdot \mathbf{13}]^{2\oplus}$.

6. Simultaneous First- and Second-Sphere Coordination

At present, there are only two well-characterized systems in which a receptor-type molecule interacts with a metal complex such that a ligand occupies sites in *both* the first *and* the second coordination spheres of the transition metal. The first such crystalline complex was reported[71] in 1974 as the product of a reaction between the phosphino-ether **14** and tetracarbonyldirhodium dichloride, followed by treatment of the neutral complex, **15**, in dichloromethane with silver tetrafluoroborate in the presence of adventitious water to give the salt **16**.

$$\underset{\mathbf{14}}{Ph_2P(CH_2CH_2O)_3CH_2CH_2PPh_2} \longrightarrow \underset{\mathbf{15}}{[Rh(CO)Cl \cdot \mathbf{14}]} \longrightarrow [Rh(CO)(H_2O) \cdot \mathbf{14}][PF_6]$$
$$\mathbf{16}$$

The X-ray crystal structure (Fig. 32) demonstrates the existence of a macrocyclic aqua-complex. The cavity formed by *trans*-coordination of the phosphino-ether is sterically and electronically perfect for binding a molecule of water, since coordination of the aqua-oxygen atom to a cationic metal center increases the polarization of the O–H bonds,

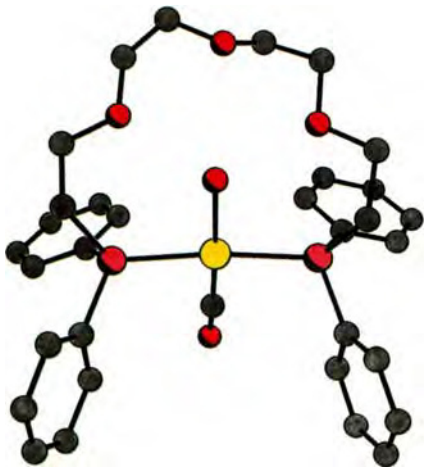

Fig. 32. Skeletal representation of the X-ray structure of $[RhCO(H_2O)\{Ph_2P(CH_2CH_2O)_3CH_2CH_2PPh_2\}]^{\oplus}$.

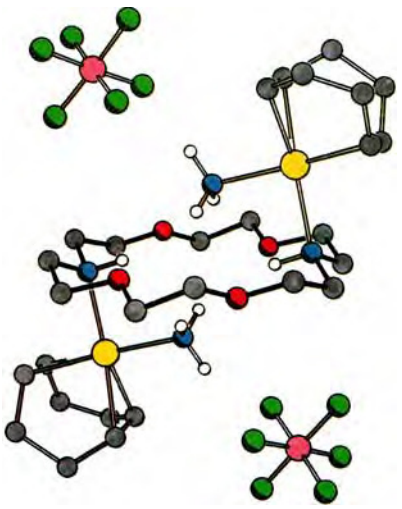
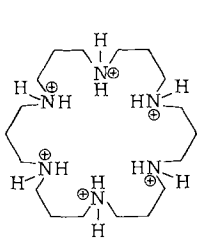
which are then directed to form strong linear O–H···O hydrogen bonds to two of the ether oxygen atoms ([O···O]=2.68 Å) in the chelate chain which adopts an almost ideal conformation. Although molecular modelling indicates that coordination of a polyether oxygen atom *directly* to rhodium is quite feasible, the water molecule is so strongly bound by the cooperative effects of first- and second-sphere coordination that it cannot be removed even after several cycles of dissolution in chloroform and evacuation at 10^{-3} torr. The second example[72] also emerged somewhat unexpectedly from an investigation of the second-sphere coordination 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane (diaza-18C6) to $[Rh(cod)(NH_3)_2][PF_6]$. The rhodium complex is readily solubilized in halocarbons by

18C6 and we anticipated that the diaza-18C6 analogue would form an even more strongly hydrogen-bonded second-sphere adduct. Indeed, rapid solubilization of the metal complex was observed in dichloromethane on addition of an equimolar amount of diaza-18C6. Initially, ^{1}H-NMR spectroscopic data were consistent with the formation of a 1:1 adduct. However, slow crystallization over 36 hours yielded a compound which was clearly *not* the expected adduct. Single-crystal X-ray analysis revealed that the first-formed second-sphere adduct had, in fact, decomposed with loss of ammonia to give a novel complex in which the amino groups of the diaza-18C6 are directly coordinated to rhodium. The structure (Fig. 33) shows that the macrocyclic ligands not only bind to rhodium in the first coordination sphere but also coordinate in the second sphere via N-H···O hydrogen bond formation to the remaining ammine ligand on the metal. Although the [N···O] distances are relatively long (3.22, 3.45, and 3.50 Å), the orientation of the ammine ligands directly over the faces of the macrocycle and the appreciable tilting of the Rh-N bonds in the same direction (Rh-N-C angles are 116° and 117° rather than the expected tetrahedral value) are both clearly indicative of significant interactions in the second sphere.





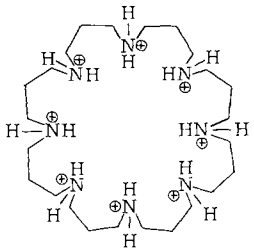


Fig. 33. Skeletal representation of the X-ray structure of diamminebis-(1,5-cyclooctadiene)(μ-1,4-10,13-tetraoxa-7,16-diazacyclooctadecane-N^7,N^{16})-dirhodium bis(hexafluorophosphate).

7. Other Synthetic Molecular Receptors as Second-Sphere Ligands

The binding of anions like $[Fe(CN)_6]^{4\ominus}$, $[Ru(CN)_6]^{4\ominus}$, $[Co(CN)_6]^{3\ominus}$, and other complex anions of transition metals by polyammonium macrocyclic receptors[73,74] such as 24-$N_6H_6^{6\oplus}$ and 32-$N_8H_8^{8\oplus}$ may be considered as yet another example of second-sphere coordination, since the central metal cation is complexed by cyanide anions, which are, in turn, bound to the receptors by multiple $N^{\oplus}$-H···NC-$M^{\ominus}$ hydrogen bonds. Although adduct formation does not influence the UV spectroscopic properties of the $[M(CN)_6]^{n\ominus}$ anions (cf. Section 2), it does affect the electrochemical properties of the anions by stabilizing the

24-$N_6H_6^{6\oplus}$

32-$N_8H_8^{8\oplus}$

more highly charged forms, i.e. the lower oxidation state of the metal. Electrochemical measurements show[75] that $[Fe(CN)_6]^{4\ominus}$ and $[Ru(CN)_6]^{4\ominus}$ both form 1:1 adducts with 24-$N_6H_6^{6\oplus}$ and 32-$N_8H_8^{8\oplus}$, and that the anions are more difficult to oxidize in the presence of the polyammonium macrocycles than in their absence. Changes observed in the redox potential of a given $[M(CN)_6]^{3\ominus}/[M(CN)_6]^{4\ominus}$ couple indicate that the resulting adduct exchanges one electron reversibly *without dissociation* of the complex. The lower stabilities (Table 5) of the adducts of the oxidized

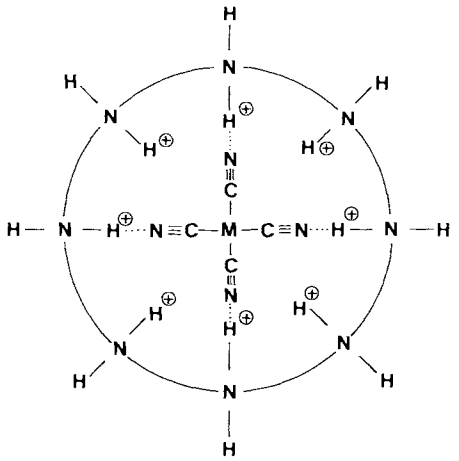
Table 5. Stability constants, log K_a (±0.2) for binding of complex anions by the polyammonium macrocycles in aqueous solution containing 0.1 M Me_4NCl.

	24-$N_6H_6^{6\oplus}$	32-$N_8H_8^{8\oplus}$
$[Fe(CN)_6]^{4\ominus}$	6.9	8.9
$[Fe(CN)_6]^{3\ominus}$	4.2	5.0
$[Co(CN)_6]^{3\ominus}$	3.9	6.0

anions in aqueous solution are consistent with the interactions between the anion and the protonated second-sphere ligand being mainly Coulombic in nature. Although second-sphere coordination of $[M(CN)_6]^{n\ominus}$ anions does not affect their spectroscopic energy levels, it does modify their photochemical properties by inhibiting those nuclear motions (i.e. metal-ligand stretching) responsible for chemical change. Thus, irradiation of $[Co(CN)_6 \cdot 32\text{-}N_8H_8]^{5\oplus}$ in aqueous solution at 313 nm results[76-78] in the same $CN^{\ominus}/H_2O$ photoaquation as undergone by free $[Co(CN)_6]^{3\ominus}$:

$$[Co(CN)_6 \cdot 32\text{-}N_8H_8]^{5\oplus} \xrightarrow[H_2O]{h\nu} [Co(CN)_5(H_2O) \cdot 32\text{-}N_8H_8]^{6\oplus} + CN^{\ominus} \ldots \quad (3)$$

However, the quantum yield of the reaction in Equation (3) is only one-third that for the photoaquation of free $[Co(CN)_6]^{3\ominus}$. This result implies that in the adduct two-thirds (i.e. four out of six) of the cyanide groups of the first coordination sphere cannot dissociate. This suggests a structure (Fig. 34) for the adduct in which four coplanar equatorial cyanide ligands are hydrogen bonded to alternate $NH_2^{\oplus}$ centers on the macrocycle leaving two axial cyanide ligands free to react. The practical importance of this finding will be discussed briefly in Section 11. To our knowledge, although a crystalline 1:1 adduct of $[Pt(CN)_4]^{2\ominus}$ and 32-$N_8H_8^{8\oplus}$ has been isolated,[73] an X-ray analysis in support of the above structural proposal has yet to appear in the literature.



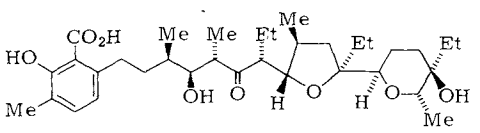


Fig. 34. A possible structure for the $[Co(CN)_6 \cdot 32\text{-}N_8H_8]^{5\oplus}$ adduct. The two $CN^{\ominus}$ ligands, which are perpendicular to the plane of the macrocycle, are not shown.

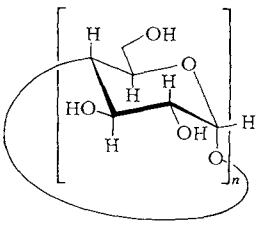
Just as anionic transition metal complexes can be coordinated by positively-charged macrocycles in aqueous solution, so it should be possible to coordinate cationic transition metal complexes with negatively-charged macrocycles in aqueous solution. Indeed, it has been claimed[79] that a macrocyclic hexacarboxylate receptor fulfils[80] this function.

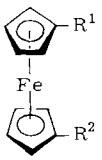
8. Second-Sphere Coordination of Ammine-Transition Metal Complexes by a Natural Ionophore

The acyclic carboxylic ionophore, Lasalocid A, not only has the ability to transport mono-, di-, and trivalent metal cations across natural and artificial membranes, but also is capable of binding and transporting substituted ammonium cations.[3] An X-ray crystallographic investigation of the Lasalocid A complex of (*R*)-1-(4-bromophenyl)ethylamine reveals[81] that an $NH_3^{\oplus}$ center binds the Lasalocid A anion via three N-H···O hydrogen bonds.



Lasalocid A

Very recently, crystalline adducts with the stoichiometry $[Cation^{n\oplus}][Lasalocid\ A^{\ominus}]_n$ have been isolated and characterized[82] for the inorganic cations, $[Co(NH_3)_6]^{3\oplus}$, $[Cr(NH_3)_6]^{3\oplus}$, $[Pt(NH_3)_6]^{4\oplus}$, $[Co(NH_3)_5Cl]^{2\oplus}$, and Δ- and Λ-$[Co(en)_3]^{3\oplus}$. The crystalline adducts are highly soluble in chloroform and dichloromethane. All the spectroscopic data (UV/visible and ^{13}C-NMR, and circular dichroism in the case of the Δ- and Λ-$[Co(en)_3]^{3\oplus}$ adducts) indicate that the structural integrity of the adducts is maintained in solution, a fact supported by vapor pressure osmometry in chloroform solutions. Adduct formation with Lasalocid A anions does not cause any rupture or rearrangement of the M-N bonds associated with the first coordination sphere of the cations, which are believed to interact with the anions through N-H···O hydrogen bonds involving one or two ammine ligands on the metal of the cation and possibly the oxygen atoms of the anion. Once again, Coulombic interactions presumably contribute substantially to adduct stabilities. No doubt, other transition metal complex adducts of natural ionophores await discovery and investigation.



9. Cyclodextrins as Second-Sphere Receptors

Although the cyclodextrins, α-, β-, and γ-CD are promiscuous in their role as receptors towards a wide range of chemical species,[3] only relatively few examples of adduct formation with organometallic compounds have been described in the literature. Since the initial brief report[83] in 1975 that ferrocene (FcH) forms a 1:1 adduct with β-CD in both dimethylformamide (DMF) ($K_a = 67\ M^{-1}$) and dimethyl sulfoxide (DMSO) ($K_a = 50\ M^{-1}$), no further investigations appear to have been carried out until quite recently when a range of crystalline adducts were characterized[84] in which FcH, acetylferrocene (FcAc) and, 1,1'-diacetylferrocene [$Fc(Ac)_2$] are believed to be included within the cavities of the cyclodextrins. Treatment of β- and γ-CDs with FcH and its derivatives, FcAc and $Fc(Ac)_2$, yielded only 1:1 adducts whereas α-CD formed 2:1 (CD:FcR) adducts with FcH and FcAc. It is of interest that the [FcH·(α-CD)$_2$] and [FcH·β-CD] are thermally stable and do not liberate FcH on heating *in vacuo* at 100°C. In addition, [FcH·(α-CD)$_2$] and [FcH·β-CD)] can be recrystallized from water giving yellow crystals. It would appear that, although FcH and FcAc are too large to be accommodated within a single α-CD cavity, they will fit into two juxtapositioned α-CD cavities. Additionally, circular dichroism spectra indicate that the orientation of FcH in β-CD is different from that of FcH in γ-CD. All these observations taken together have led to the general structural proposals for the adducts shown in Figure 35.

α-CD: $n = 6$
β-CD: $n = 7$
γ-CD: $n = 8$

The relatively strong binding of the ferrocene nucleus by β-CD in DMSO/H_2O (3:2) has encouraged[85] the use of the *p*-nitrophenyl esters **21** and **22** of ferrocene-2-acrylic acid and ferrocenepropiolic acid as suitably optimized substrates in studying the acylation of β-CD by bound substrates. The results in terms of the rate accelerations of acylation relative to hydrolysis have been quite spectacular. Further attempts at the optimization of metallocene substrates for β-CD acylation prompted the investigation of the ruthenocene analogue of **21** only to discover that it is an inferior substrate (ruthenocene is ca. 10% thicker than ferrocene) for the reaction. The oxidation of ferrocenecar-

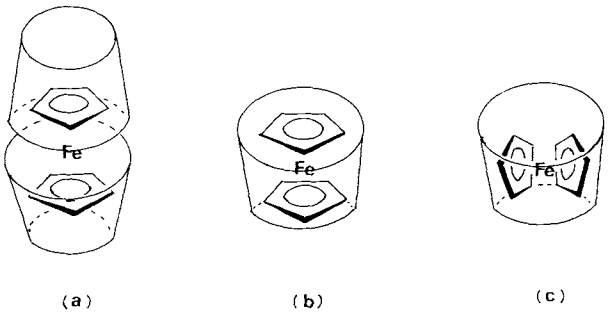

Fig. 35. The proposed structures for the adducts of (a) [FcH·(α-CD)$_2$], (b) [FcH·β-CD], and (c) [FcH·γ-CD].

boxylic acid (FcCA) in the presence of β-CD has been investigated[86] at pH 9.2 in aqueous buffer by cyclic voltammetry and the following conclusions were drawn: (i) the oxidation of the carboxyclic acid **20** proceeds by prior dissociation of the complex followed by electron transfer from free FcH, and (ii) there is no direct electron transfer from the complexed FcH within the accessible range of potentials.

The preparation and properties of several [rotaxane·CD] adducts have been described[87] in which α- or β-CD are threaded by α,ω-diaminoalkanes with a cobalt(III) complex coordinated to the terminal amino groups. The reaction yields (Scheme 1) were surprisingly high (1.9–19%) producing good evidence that the CDs are binding the α,ω-diaminoalkanes during the reactions.

It is only recently that a 1:1 crystalline adduct between a *cationic* transition metal complex and a CD has been characterized by X-ray crystallography. Despite the fact that [Rh(cod)$(NH_3)_2$][PF_6] undergoes slow hydrolysis of its ammine ligands in an aqueous solution of α-CD, it proved possible[88] to obtain good single crystals of the 1:1 adduct. A space-filling plan view of [Rh(cod)$(NH_3)_2$·α-CD]$^{\oplus}$ is shown in Figure 36. The cod ligand is inserted partly into the α-CD cavity and the complex is tilted so that the two ammine ligands can enter into N-H···O hydrogen bonding ([N···O]=3.24, 3.25, 3.31, 3.46 Å) with four of the secondary hydroxyl groups on two of the six α-D-glucopyranoside units in the receptor. ^{1}H-NMR spectroscopy indicates that the adduct exists in D_2O solution but decomposes slowly with time as ammonia is released from the first coordination sphere. Replacement of the two ammine ligands by a bidentate en ligand afforded a rhodium com-

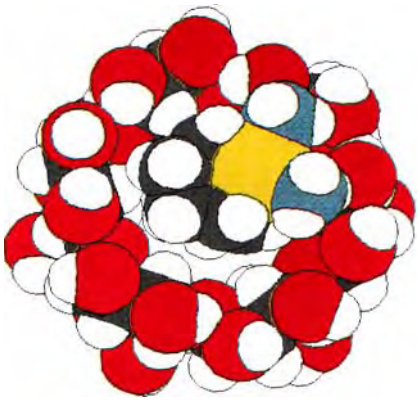

Fig. 36. Space-filling representation of the X-ray structure of [Rh(cod)$(NH_3)_2$·α-CD]$^{\oplus}$.

plex stable in aqueous solution in the presence of α-CD. A K_a value of 520±80 mol^{-1} kg was obtained from a quantitative ^{1}H-NMR spectroscopic analysis of the concentration dependence of [Rh(cod)(en)·α-CD][PF_6] in D_2O solution. Microcalorimetry and ^{1}H-NMR spectroscopy have also established[89] that the neutral antitumour drug diammine-1,1-cyclobutanedicarboxylatoplatinum(II) and α-CD form a 1:1 adduct in water with a standard free energy change ($-\Delta G^0$) in the region of 10.4–13.0 kJ mol^{-1} at 22–25°C. Slow cooling (starting from 80°C) of an aqueous solution of α-CD saturated with respect to the platinum complex afforded single crystals suitable for X-ray structural investigation.[90] A side-on view of the skeletal representation (Fig. 37) reveals that stabilization of the adduct is achieved by the cyclobutane ring of the complex penetrating into the α-CD cavity leaving the two ammine ligands to form two N-H···O hydrogen bonds ([N···O]=2.94, 3.14 Å) with secondary hydroxyl groups on neighboring α-D-glucopyranosidic units of the α-CD.

The binding of organometallic compounds to chemically-modified CDs awaits detailed investigations.[91] However, circular dichroism measurements show[92] that 6-deoxy-

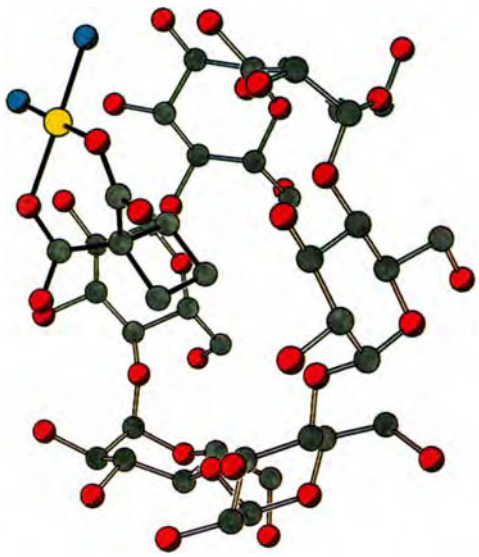

Fig. 37. Skeletal representation of the X-ray structure of [diammine-1,1-cyclobutanecarboxylatoplatinum(II)·α-CD].

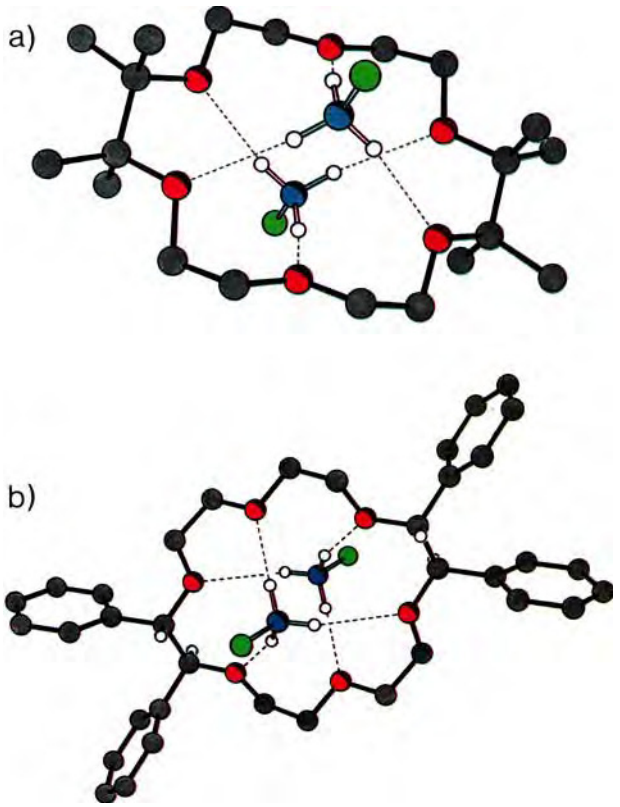
6-(2-methoxyethylamino)-β-CD has a strong binding ability ($K_a = 600 \pm 44\ M^{-1}$) for ferrocenecarboxylic acid **20** in DMSO because of a Coulombic [$-CO_2^{\ominus} \cdots {}^{\oplus}H_2N<$] interaction.

10. Adduct Formation involving Ammonia-Borane

We have already noted in Section 3.1 that the borane complexes $[BX_3NH_3]$ (X = H, F) form[24] crystalline 1 : 1 adducts with 18C6. Because of the formal positive charge on the nitrogen atom, we concluded that the formation of 2 : 1 adducts with two neutral $[BX_3NH_3]$ molecules binding to opposite faces might be disfavored by Coulombic repulsion. However, it transpires that this is not necessarily the case when the 18C6 ring carries substituents. Thus, both the octamethyl[18]crown-6 derivative[93] Me_8-18C6 and the *trans-syn-trans*-tetraphenyl[18]crown-6 derivative[94] (*RRSS*)-Ph_4-18C6 form crystalline 2 : 1 adducts. Their X-ray crystal structures (Fig. 38) reveal that, in each case, the two $[BH_3NH_3]$ molecules are hydrogen bonded in a centrosymmetric manner to the opposite faces of the macrocycle which adopts a characteristic all-*gauche* conformation.



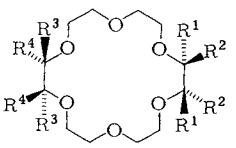


Fig. 38. Skeletal representation of the X-ray structure of (a) $[(BH_3NH_3)_2 \cdot Me_8\text{-}18C6]$ and (b) $[(BH_3NH_3)_2 \cdot (R,R,S,S)\text{-}Ph_4\text{-}18C6]$.

In $[(R,R,S,S)\text{-}Ph_4\text{-}18C6 \cdot (BH_3NH_3)_2]$, the four phenyl substituents are equatorially oriented. Interestingly, however, in the chiral *trans-anti-trans*-derivative (*R,R,R,R*)-{*p*-MeO−C_6H_4}$_4$-18C6,[95] although, once again, the characteristic all-*gauche* conformation—this time carrying two axial and two equatorial anisyl substituents—is adopted, only one $[BH_3NH_3]$ molecule is bound in the crystalline

adduct (Fig. 39). Clearly, the stoichiometry in the solid state varies, possibly reflecting the lattice requirements of the particular adduct. Nonetheless, high crystallinity is a feature of all the adducts involving $[BH_3NH_3]$ and crown ethers we have prepared and characterized in our laboratories.[95,96]

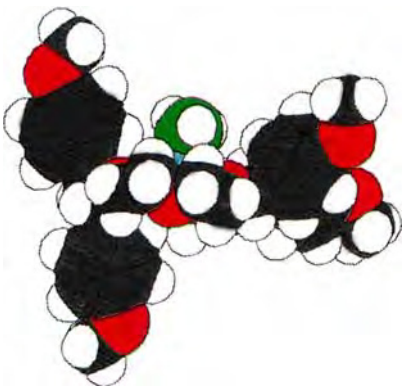

Fig. 39. Space-filling representation of the X-ray structure of $[(BH_3NH_3) \cdot (R,R,R,R)\text{-}\{p\text{-MeO}-C_6H_4\}_4\text{-}18C6]$.

11. Applications

These already exist and the potential for their growth is large and broad.

The purification of receptor molecules which are occasionally oils themselves can often be transformed from a difficult to an easy task by the formation of highly crystalline adducts. Thus, $[BH_3NH_3]$ has been used[96] successfully to purify and characterize a wide range of chiral crown ethers incorporating carbohydrate residues. Another *selective* crystallization procedure (Fig. 40) provides[29] a novel approach to the separation of *copper* from *cobalt*. The stability of the polymeric 1 : 1 adduct formed by $[Cu(NH_3)_4(H_2O)][PF_6]_2$ and 18C6 is such that it will precipitate almost quantitatively from aqueous solution, even in the presence of competing ions such as $[NH_4]^{\oplus}$ and $[Co(NH_3)_6]^{3\oplus}$.

Selectivity can also be observed in reactions of very different kinds. For example, enantioselective reductions of prochiral phenyl ketones PhCOR (R = Me, Et, *i*Pr, *t*Bu) with the chiral adduct (Fig. 40) formed between $[BH_3NH_3]$ and (*R,R,R,R*)-Ph_4-18C6 in toluene at −78 to −40 °C have afforded the corresponding secondary benzyl alcohols with 22–67% excess of the (*S*)-enantiomer. These re-

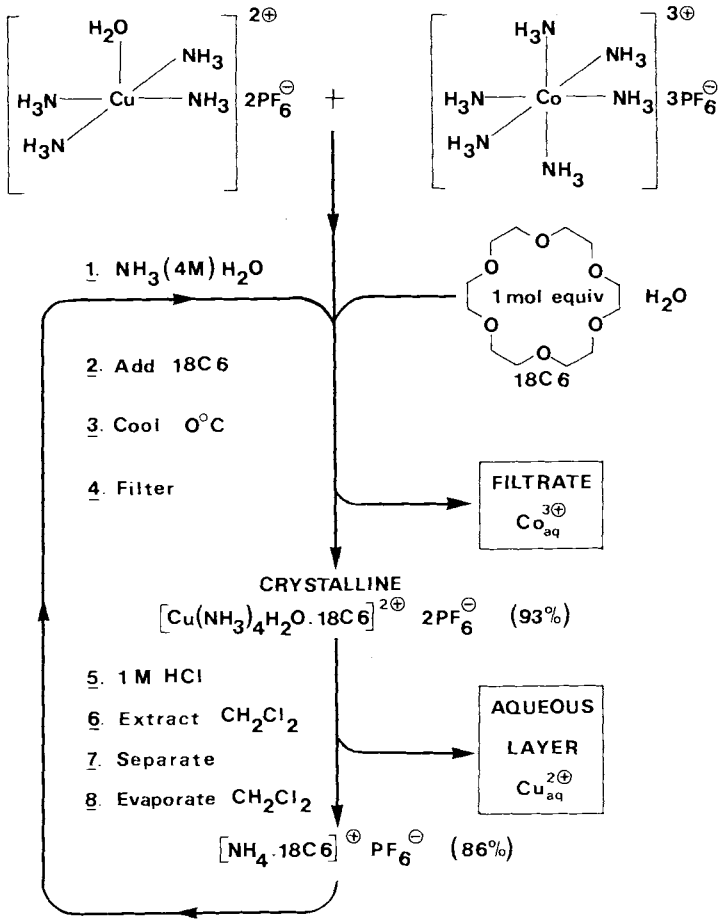

Fig. 40. A cyclic process for the separation of copper(II) from cobalt(III).

sults have been improved[97] by changing the reaction conditions. In a completely different context, the possibility exists of protecting coordinated $[M(CN)_6]^{n\ominus}$ anions against ligand photodissociation by using appropriate polyammonium macrocyclic receptors.[76–78] This combination of novel protecting group chemistry and photochemistry could be applied to the synthesis of substituted cyano complexes of transition metals.

Cyclodextrins have numerous and different applications. The interaction between β-CD and α-diimineruthenium(II) complexes containing phenanthroline ligands with phenyl substituents protects[98] the metal-to-ligand charge-transfer excited state from oxygen quenching and therefore modifies their properties as sensitizers. Perhaps most significantly of all, the formation of a 1 : 1 adduct between α-CD and Carboplatin provides an opportunity[99] for developing a drug delivery system for this promising anticancer agent.

12. Outlook

As in most interdisciplinary research areas, unexpected and exciting results are not difficult to come by, and pleasant surprises are often just waiting round the corner. Studying the second-sphere coordination of transition metal complexes by molecular receptors is proving to be a satisfying and rewarding pursuit. There is no doubt that, although the future in this field of chemistry offers many new challenges of a conceptual and practical nature, it also holds much promise of many new discoveries of technological importance. In a recent review article[100] where *Chatt* presents his reminiscences of scientific progress from academic backwater to industrial importance in the context of *A Half Century of Platinum Metal Chemistry*, he concludes:

> "Scientific discovery is not yet predictable. If you have an exciting road to follow do not be put off by those who say there is nothing at the end of it; they do not know. Persevere, and enjoy the excitement of exploring the unknown."

We draw strength and inspiration from the work of this scientist who, among his many pioneering contributions to coordination chemistry, sowed the seeds for the development of the second-sphere coordination of neutral and cationic metal complexes of the platinum group by molecular receptors.

We wish to thank our numerous students and coworkers for their contributions to the research program. Without their dedicated and enthusiastic involvement, only a very small part of the work we have reviewed here would have been accomplished. Their names are cited in many of the references. We thank ICI plc, Johnson Matthey plc, and the Agricultural and Food, and Science and Engineering Research Councils in the United Kingdom for their support. We are especially grateful to Dr. John Kendrick of the New Science Group at ICI Runcorn for his computer-assisted production of the color space-filling molecular illustrations.

[25] Second-sphere coordination of transition metal complexes affords complexes of complexes. We find it convenient to refer to these complexes of complexes as *adducts*.
[26] The X-ray crystal structures of $[PhCH_2NH_3 \cdot 18C6][SCN]$ (M. J. Bovill, D. J. Chadwick, I. O. Sutherland, D. Watkin, *J. Chem. Soc. Perkin Trans. 2 1980*, 1529) and $[PhCOCH_2NH_3 \cdot 18C6][PF_6]$ (J. M. Maud, J. F. Stoddart, D. J. Williams, *Acta Crystallogr. C41* (1985) 137) indicate face-to-face complexation in the perching mode of the $[RNH_3]^{\oplus}$ ions to 18C6 in its all-*gauche* conformation with pseudo D_{3d} symmetry. For a discussion of the crystalline complex formed between $NH_4^{\oplus}$ ions and 18C6, see O. Nagano, A. Kobayashi, Y. Sasaki, *Bull. Chem. Soc. Jpn. 51* (1978) 790 and D. A. Pears, J. F. Stoddart, M. E. Fakley, B. L. Allwood, D. J. Williams, unpublished.

[30] As an aside, it is an interesting historical fact that these complexes were prepared in 1980 at the ICI Corporate Laboratory from samples of $[Pt(PR_3)_2Cl_2]$, synthesized by *Chatt*'s Research Group working at The Frythe (ICI) some 25 years earlier!
[31] Later, in Section 7, we shall see that $[BH_3NH_3]$ can form 2:1 complexes with 18C6 derivatives. There are numerous examples (e.g. $[\{CH_2(CN)_2\}_2 \cdot 18C6]$ and $[(CH_3NO_2)_2 \cdot 18C6]$) of 2:1 complexes involving *neutral* organic molecules with 18C6 in the literature (J. A. A. de Boer, D. N. Reinhoudt, S. Harkema, G. J. Hummel, F. de Jong, *J. Am. Chem. Soc. 104* (1982) 4073; A. Elbasyouny, H. J. Brügge, K. von Deuten, M. Dickel, A. Knöchel, K. U. Koch, J. Kopf, D. Melzer, G. Rudolph, *ibid. 105* (1983) 6568; W. H. Watson, J. Galloy, D. A. Grossie, F. Vögtle, W. M. Müller, *J. Org. Chem. 49* (1984) 347). More often than not, the macrocycle adopts the familiar all-*gauche* conformation with pseudo D_{3d} symmetry, but not always (e.g. $[(PhSO_2NH_2)_2 \cdot 18C6]$). Organic cations can (B. L. Allwood, H. M. Colquhoun, J. Crosby, D. A. Pears, J. F. Stoddart, D. J. Williams, *Angew. Chem. 96* (1984) 806; *Angew. Chem. Int. Ed. Engl. 23* (1984) 824; B. L. Allwood, J. Crosby, D. A. Pears, J. F. Stoddart, D. J. Williams, *ibid. 96* (1984) 987 and *23* (1984) 977; D. A. Pears, J. F. Stoddart, J. Crosby, B. L. Allwood, D. J. Williams, unpublished) also form 2:1 complexes provided the formal positive charge is not directly associated with the binding group (e.g. $[\{Ph_3PMe\}_2 \cdot 18C6][PF_6]_2$, $[\{Ph_2SMe\}_2 \cdot 18C6][Hg_2I_6]$ and $[\{PhCOCHPhSMe_2\}_2 \cdot 18C6][PF_6]_2$). The bireceptor nature of 18C6 manifests itself structurally in yet another manner. Neutral (e.g. $MeO_2CC{\equiv}CCO_2Me$) and cationic (e.g. $[PhCOCH_2SMe_2]^{\oplus}$) organic molecules containing *two binding groups* can form polymeric hydrogen bonded structures with alternating 18C6 units.

[91] If the suggested structure of a binuclear copper(II) complex of α-CD involving cross-linking of contiguous glucose residues in the cyclodextrin by a $Cu(OH)_2Cu$ bridge (Y. Matsui, T. Kurita, Y. Date, *Bull. Chem. Soc. Jpn. 45* (1972) 3229; Y. Matsui, T. Kurita, M. Yagi, T. Okayama, K. Mochida, Y. Date, *ibid. 48* (1975) 2187; Y. Matsui, D. Suemitsu, *ibid. 58* (1985) 1658) is supported subsequently by firm structural evidence, then it could constitute an interesting example of simultaneous first- and second-sphere coordination of copper(II) by α-CD.

The Palladium-Catalyzed Cross-Coupling Reactions of Organotin Reagents with Organic Electrophiles

New Synthetic Methods (58)

By John K. Stille*

The cross-coupling of organotin reagents with a variety of organic electrophiles, catalyzed by palladium, provides a novel method for generating a carbon-carbon bond. Because this mild, versatile reaction is tolerant of a wide variety of functional groups on either coupling partner, is stereospecific and regioselective, and gives high yields of product, it is ideal for use in the synthesis of elaborate organic molecules. When the coupling reaction is carried out in the presence of carbon monoxide, instead of a direct coupling, carbon monoxide insertion takes place, stitching the two coupling partners together and generating a ketone.

1. Introduction

There are relatively few basic reaction types that generate a new carbon-carbon bond, although this is one of the most critical operations in the synthesis of organic molecules. Group VIII transition metals, particularly nickel and palladium, are effective in catalyzing the cross-coupling of organometallic reagents with organic halides and related electrophiles [Eq. (1)].[1-10]

$$RM + R'X \xrightarrow{M'} R-R' + MX \qquad (1)$$

In order for the coupling reaction to be useful, it should be relatively straightforward and require only a small amount of catalyst. Moreover, the reaction conditions and reagents, particularly the organometallic partner, should tolerate a wide variety of functional groups so that tedious protection-deprotection reactions are not necessary. Of the organometallic reagents available, many will not tolerate sensitive functionality on the coupling partners, are difficult to prepare, or are air or moisture sensitive, and few can be purified and stored.

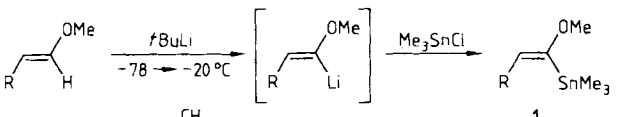
Various organometallic reagents, RM, have been used in coupling reactions with disparate success. High conversions often are not obtained with lithium or Grignard reagents, neither of which will tolerate a wide variety of functional groups on either coupling partner,[2,3] and often homocoupling of the organic halide is observed. The copper-promoted coupling of alkenyl or aryl compounds is more successful, but it often results in extensive homocoupling.[11] In addition, the methods of synthesis of copper reagents do not always allow the presence of the more reactive functional groups on the organocopper partner.

The use of organometallic reagents containing metals of intermediate electropositive character generally leads to higher yields of coupled product and fewer side reactions. Many of these organometallic compounds tolerate a wide range of functional groups in either or both of the coupling partners. Organozinc compounds are particularly good in this regard, although the methods of synthesis limit the variety of structures that can be incorporated into the organic portion of the organozinc reagent. Organomercurials also tolerate functionality, but the methods for their synthesis are somewhat limiting; moreover, methods for the alkylation of organomercurials are unfortunately limited to a few examples with organic halides.[12,13] Organometallic partners in which the metal is boron or aluminum often are not conveniently synthesized or the structure of the organic portion is limited by the methods of synthesis available, usually hydroboration or hydroalumination.[4-7] Organozirconium reagents have the advantage that ether or acetal groups are tolerated in the hydrozirconation reaction and carbonyl and ester groups may be present in the alkenyl halide partner.[14] In coupling reactions, low turnovers of catalyst are observed, however.

One of the most versatile organometallic reagents in palladium-catalyzed coupling reactions is the organotin reagent. Organotin compounds containing a variety of reactive functional groups can be prepared by a number of routes; moreover, these reagents are not particularly oxygen or moisture sensitive. Because of their value in coupling reactions, a brief survey of their syntheses, particularly some of the more recent ones, is presented.

In the palladium-catalyzed coupling of organic electrophiles with organotin reagents, essentially only one of the groups on tin enters into the coupling reaction [Eq. (2)].

$$RX + R'SnR''_3 \xrightarrow{[PdL_n]} R-R' + XSnR''_3 \qquad (2)$$



This is not a problem if a relatively simple organic group, for example, methyl, is to be transferred, since tetramethyltin can be used. If the group is more expensive or difficult to synthesize, however, then the utilization of only one of four identical groups would be a distinct disadvantage. Fortunately, different groups are transferred with different selectivities from tin, the simple alkyl group having the slowest transfer rate (see Section 3.1). Thus, an unsymmetrical organotin reagent containing three simple alkyl groups (such as methyl or butyl) is chosen; the fourth group, which undergoes transfer, is usually an alkynyl, alkenyl, aryl, benzyl, or allyl group.

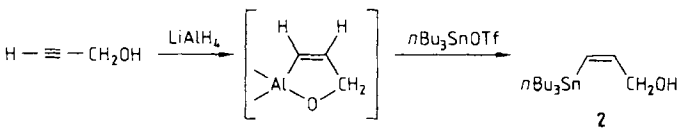
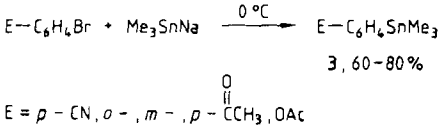
2. Synthesis of Organotin Reagents



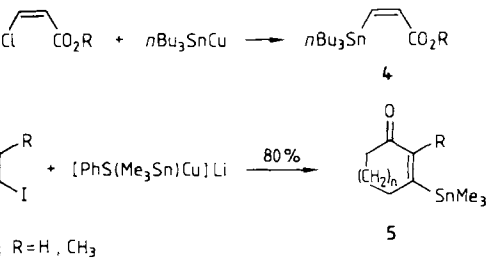
2.1. Synthesis from Electrophilic and Nucleophilic Triorganotin Compounds

A variety of methods for the synthesis of unsymmetrical organostannanes are known.[15-18] Although the reaction of a triorganotin halide with an organometallic compound is widely used, its scope of application is limited since the organometallic compound (usually M = Li, Al, Mg) does not allow a large variety of functional groups to be introduced into the organotin product. There are a number of valuable synthetic procedures involving organic anions, however. Lithiation of an enol ether followed by reaction with trimethyl- or tributyltin chloride gives a vinyltin reagent **1** that can serve as an acyl anion equivalent.[19,20]

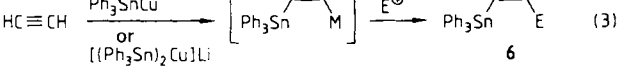


R = H, CH_2=CH, CH_2=C(CH$_3$), Ph

The reaction of propargyl alcohol with lithium aluminum hydride followed by tributyltin trifluoromethanesulfonate (triflate) yields the *Z*-vinyltin reagent **2**.[21] Cuprates also undergo *cis* addition to acetylenes, generating a vinyl metal compound, which reacts with tributyltin triflate to yield the (*Z*)-vinyltin compound.[22]

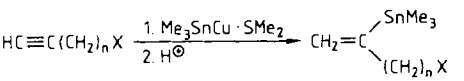


The inverse reaction of a trimethyl- or tributyltin anion with an organic electrophile is more versatile. The displacement of a halide or tosylate by a trimethyltin anion can be made to take place with inversion of configuration at an sp^3 carbon. Reaction of sodium trimethylstannate with an aryl bromide takes place under mild conditions, without reaction at other electrophilic substituents, to yield aryltin reagents **3**.[16,17]



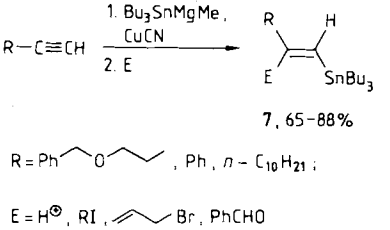
E = *p*-CN, *o*-, *m*-, *p*-C(=O)CH$_3$, OAc

The reaction of lithium tributylstannate with (*Z*)-β-chlorostyrene occurs with retention of configuration of the double bond. This reaction provides a method of synthesis of either pure (*E*)- or (*Z*)-β-tributyltin acrylates **4** from the corresponding (*E*)- and (*Z*)-β-chloroacrylates.[23] The reaction of a tin cuprate with an α,β-unsaturated β-iodo ketone gives high yields of the corresponding tin reagent **5**.[17,18]



n = 2, 3; R = H, CH_3

An especially useful reaction is the stereospecific addition of a complex containing a copper–tin bond across a triple bond. The stereochemistry of addition depends on the particular copper reagent and the reaction conditions. Acetylene undergoes a *cis* addition with the copper(I) reagents Ph_3SnCu and $[(Ph_3Sn)_2Cu]Li$ [Eq. (3)].[24] The initially



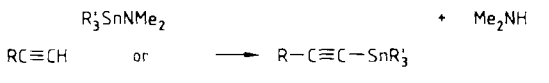
(3)

n = 1–4, 6; X = OH, OTHP, OSi*t*BuMe$_2$, Cl

formed anion can be trapped with a variety of electrophiles to yield the substituted vinyltin reagents **6**. When $Me_3SnCu \cdot SMe_2$ is used, the regiochemistry of addition to a monoalkyl-substituted acetylene is that expected for anionic addition; the alkyne can bear a variety of alkyl groups (THP = tetrahydropyranyl).[25] Methylmagnesium tributylstannate in the presence of copper(I) cyanide, however, yields product **7** of opposite regiochemistry. A variety of electrophiles may be used to trap the vinyl anion.[26]

R = Ph(THP), Ph, *n*-$C_{10}H_{21}$;

E = H$^{\oplus}$, RI, allyl bromide, PhCHO

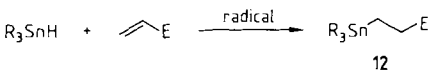


Either *cis* or *trans* addition of trimethylstannyl copper reagents to substituted and unsubstituted propiolate esters can be achieved to yield either (*E*)-**8** or (*Z*)-**9**, depending on the cuprate and the reaction conditions (THF = tetrahydrofuran).[27,28]

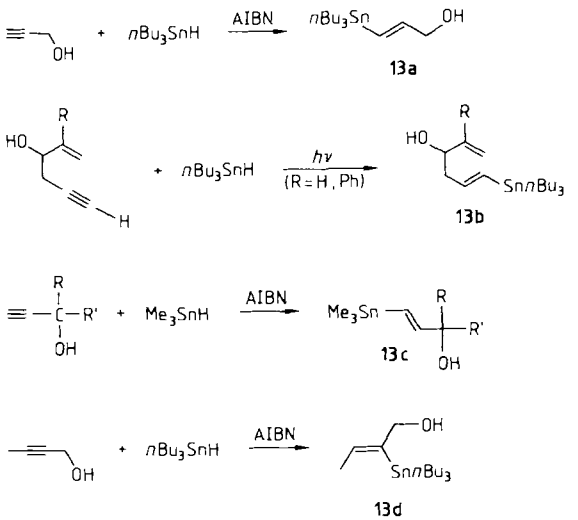
		8		**9**
R = Me	[$Me_3SnCuSPh$]Li, −78 °C, MeOH/THF	99	:	1
R = Me	[$Me_3SnCuSPh$]Li, −48 °C, THF	2	:	98
R = Me	[$Me_3SnCuC{=}CR$]Li or $Me_3SnCu \cdot LiBr \cdot Me_2S$, −48 °C, THF	99	:	1
R = H	[$Me_3SnCuSPh$]Li, −100 °C, EtOH/THF	97	:	3

2.2. Synthesis from Tin Amides and Oxides

Weakly acidic hydrogen can be replaced by tin in a reaction with tin amides or oxides.[15-17,29] This serves as a mild method for the synthesis of acetylenic tin reagents **10** and α-stannyl ketones **11**.

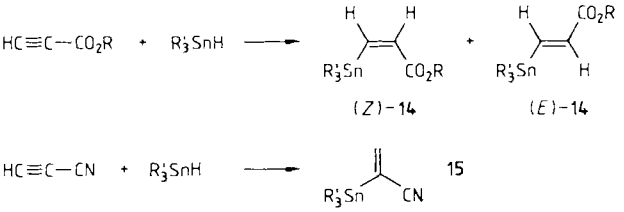


R = alkyl, aryl, CN, CH=CHOMe, OEt



2.3. Tin Hydride Additions to Alkenes and Alkynes

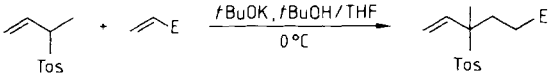
The free radical addition of triorganotin hydrides to olefins takes place regiospecifically.[15] This reaction has limited use, however, since the product **12** is a mixed alkyltin reagent, which will not necessarily transfer the newly added group exclusively in a catalytic coupling reaction.



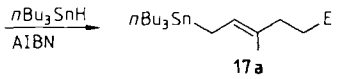
E = $CONH_2$, $CH(OEt)_2$, CH_2OH, CN

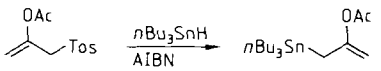
The radical addition of triorganotin hydrides to monosubstituted acetylenes to give substituted vinylstannanes **13** is mostly regiospecific, the (*E*)-isomer being favored, although an (*E*)/(*Z*) mixture is often obtained (AIBN = azobisisobutyronitrile).[30-34]

Radical addition to propiolate esters generally yields one regioisomer **14** as an (*E*)/(*Z*) mixture.[15,35] In the absence of catalyst, especially in polar solvents, cyanoacetylene yields the vinyltin reagents **15**.



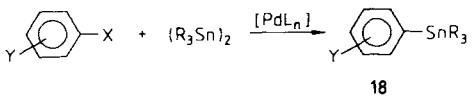
Triorganotin hydrides also react with diazoalkanes, giving the tin reagents **16** containing various functional groups.[15] However, these tin reagents will be useful in coupling reactions only if selective transfer of the added alkyl group is realized.





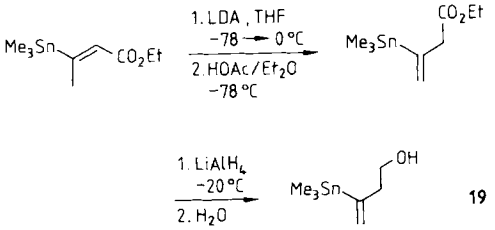
R' = CO_2Et, $COCH_3$, COC_6H_5, CN

The radical addition of tributyltin hydride to an olefin containing an allylic tosylate leaving group leads to the allyltin reagents **17a**, bearing a nitrile, ester, or tosyl group, or **17b**, bearing an enolacetate group.[36]

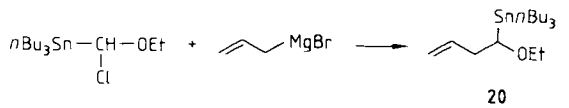


E = CN, CO_2Me, Tos

2.4. Reactions of Hexaalkyldistannanes with Organic Halides

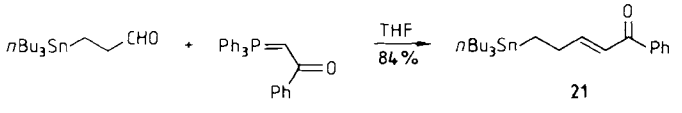


The mild, palladium-catalyzed coupling of hexaalkyldistannanes with aryl, benzyl, or allyl halides provides a unique method of synthesis of organotin reagents in which the organic group derived from the organic halide can have reactive substituents.[37-39] This synthetic procedure is especially valuable for the synthesis of trialkylaryltin reagents **18**.

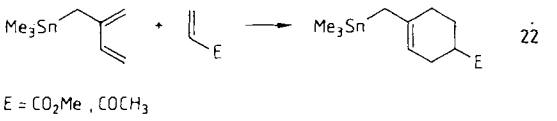


X = Br, I; Y = C(=O)-CH_3, CN, NO_2; R = Me, *n*Bu

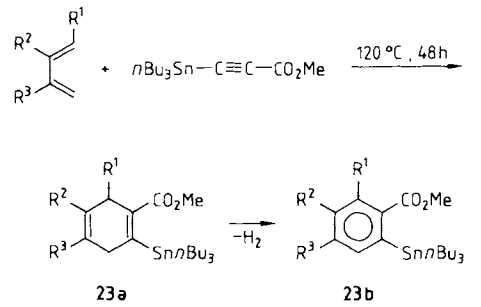
2.5. Elaboration of Organotin Reagents



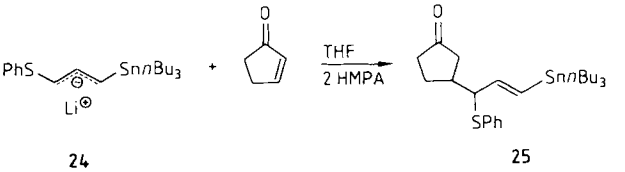
Tin–carbon bonds in organotin reagents are relatively stable, the bond energy being about 50 kcal/mol.[15] Thus, it is not surprising that a wide variety of reactions can be performed at other functional groups in the molecule without breaking the Sn–C bond. For example, the permanganate oxidation of primary alcohols to carboxylic acids[15] and the chromium trioxide oxidation of secondary alcohols to ketones,[16,17] as well as the lithium aluminum hydride reduction of esters, nitriles, and ketones to alcohols and amines,[15–17,40] can be carried out without cleavage of the carbon–tin bonds. Thus, the substituted vinyltin reagent **19**, containing a primary OH group, was obtained by an isomerization–reduction sequence (LDA = lithiumdiisopropylamide).[41]



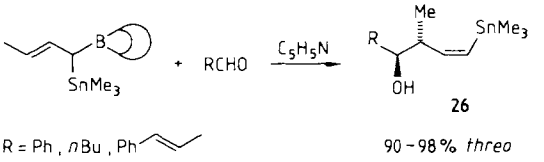
The Sn–C bond survives reactions of Grignard reagents, either when the Grignard reagent is allowed to react with an organotin compound containing an appropriate functional group or when a halogen-containing organotin compound is converted into a Grignard reagent.[15,17] Cyano and carbonyl groups on one of the organic groups of an unsymmetrical organotin reagent undergo Grignard reactions in the usual manner. An unsymmetrical organotin compound containing an α-chloroether function reacts with allylmagnesium bromide, for example, to yield the allylic tin reagent **20**.[42]



The NH_2 group undergoes typical reactions with various electrophiles;[43] for example, amines may be converted into isocyanates with phosgene.[16] Unsymmetrical organostannanes undergo the Wittig reaction, either by reaction of an aldehyde function on the organotin compound with methylenetriphenylphosphorane[15,16] or by reaction of an organotin-containing Wittig reagent with an aldehyde.[17] This reaction has been used in the synthesis of the organotin reagent **21** containing an α,β-unsaturated ketone.[44]

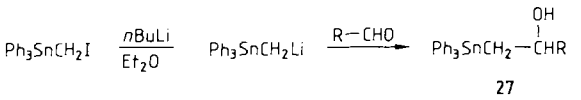


Olefinic groups on an organotin reagent can be hydroborated[17] and acetylenic groups add alkylboranes.[16] Cyclopropanation of an acetylenic group can be achieved with diazoalkanes.[16] A 1,3-diene containing a trimethylstannylmethyl group in the 2-position will undergo the Diels–Alder reaction with an electron-poor dienophile,[45] thereby providing a new allylic tin reagent **22**.

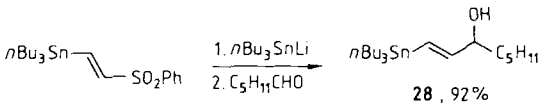


A Diels–Alder reaction between methyl tributylstannylpropiolate and substituted butadienes at 120 °C gives good yields of the 1,4-cyclohexadiene adduct **23a**, which can be dehydrogenated to the aryltin reagent **23b**.[46]

The ability to generate relatively stable anions on an organic group attached to tin, without carbon–tin bond cleavage, provides a versatile method of elaboration of organostannanes. The stabilized allyl anion **24**, for example, undergoes 1,4-addition to cyclopentenone to yield the vinyltin reagent **25** (HMPA = hexamethylphosphoramide).[47]



In a related reaction, aldehydes react with 9-borabicyclononane(9-BBN)-substituted organotin compounds with allylic rearrangement to yield the vinyltin reagents **26**.[48]



An anionic center in the α-position to tin reacts with a variety of electrophiles (such as aldehydes, ketones, and

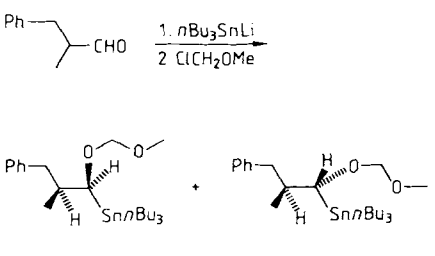
allyl bromides) to give the organostannanes **27**.[49] In the example shown, however, the alkyl group could not necessarily be expected to undergo selective transfer in transition-metal-catalyzed coupling reactions. A tributyltin-substituted vinyl anion also adds to aldehydes to give an al-

27

lylic alcohol **28** in which the Sn-C(sp^2) bond could be expected to undergo preferential cleavage in coupling reactions.[50]

28, 92%

2.6. Separation and Purification of Organotin Compounds

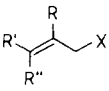


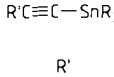
Since organotin reagents are relatively stable, it should not be surprising that some can be purified by distillation. Higher-molecular-weight compounds can sometimes be crystallized. Most importantly, many of the reagents withstand chromatography on silica gel.

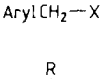
The separation of an (*E*)/(*Z*) mixture of benzyl tributylstannylacrylate **29**, obtained from the addition of tributyltin hydride to benzyl propiolate, can be achieved on a preparative scale by medium pressure liquid chromatography (MPLC) on silica gel. The (*Z*)-isomer elutes first and can be reisomerized to an (*E*)/(*Z*) mixture, thereby providing a means of converting nearly all of the product into the (*E*)-isomer.

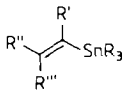
(*E*)-**29** (*Z*)-**29**

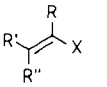
The reaction of 2-methyl-3-phenylpropanal with lithium tributylstannate followed by chloromethyl methyl ether yields two stereoisomers, **30a**, **b**, which also have been separated on an MPLC column.[51]

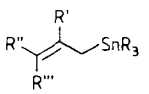


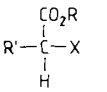


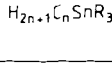












30a **30b**

3. Reactions with Organotin Compounds

The coupling reaction of organotin reagents with organic electrophiles catalyzed by palladium takes place under mild conditions in high yields. A wide variety of organic halides and organotin compounds can be coupled, either directly or in the presence of carbon monoxide (to yield a ketone, RCOR′, see Section 3.2) (Table 1). Moreover, a wide variety of functional groups (e.g., CO_2R, CN, OH, and even CHO) are tolerated on either partner. In addition, the reaction is regioselective in coupling reactions of allyl partners and occurs stereospecifically with inversion of configuration at sp^3 carbon centers bound to tin and/or halogen. Usually retention of configuration of the double bond is observed regardless of which reactant contains the double bond.

Table 1. Organotin reagents and electrophilic compounds suitable for coupling reactions.

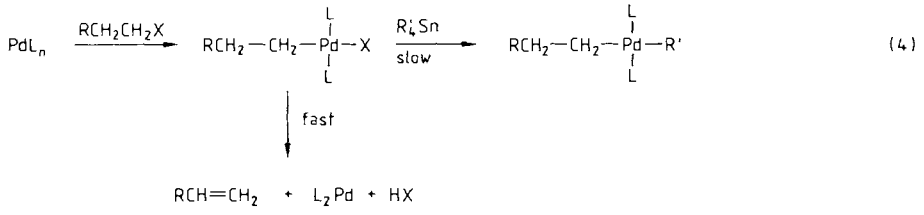
	[X = Br, I]	
	[X = Br, I]	
		

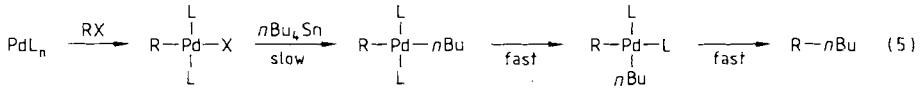
In the following discussion, the direct coupling reaction of organotin compounds with acid chlorides, organic halides, and vinyl triflates will be treated separately from the carbonylative coupling (Section 3.2).

3.1. Direct Coupling



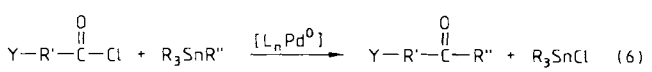
The catalytic cycle in Scheme 1 serves as a working model for the direct coupling reaction. Although this cycle has yet to be established for the coupling, many of the individual steps in the cycle have been documented;[52–57] a more detailed mechanistic discussion of certain of the coupling reactions is given in Section 4.

Notably absent from the list of electrophiles in Table 1 are those organic compounds with a hydrogen on an sp^3 carbon in the β-position to the carbon bearing the leaving group. This limitation is imposed because the slowest step



Scheme 1. Mechanism of the catalyzed, direct coupling.

in the catalytic cycle, the transmetalation step, is much slower than the β-elimination that takes place in the alkylpalladium halide complex [Eq. (4)]. This limitation is not imposed on the organotin partner, however, since the catalytic steps taking place after transmetalation—*trans/cis* isomerization and reductive elimination—are faster than β-elimination [Eq. (5)]. Nevertheless, the direct palladium-catalyzed coupling reactions of acid chlorides, benzyl halides, allyl halides, vinyl halides, vinyl triflates, and aryl halides with various organotin reagents have been reasonably well worked out.



(4)

(5)

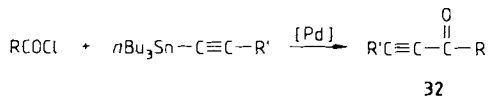
3.1.1. Acid Chlorides

The synthesis of ketones from acid chlorides [Eq. (6)] [58–61] is quite general with respect to the organotin reagent and the acid chloride.[60,61] Aromatic, aliphatic, and heterocyclic acid chlorides give high yields of product (75–100%) in 15 min–1 h under very mild (25 °C), neutral reaction conditions, and catalytic turnovers of 1000 have been achieved. Sterically hindered acid chlorides react normally and α,β-unsaturated acid chlorides do not undergo 1,4-addition; dicarboxylic acid dichlorides can also be employed. There is no further addition to the product ketone, and a wide variety of functional groups (Y) are tolerated, including nitro, nitrile, haloaryl, methoxy, ester, and even aldehyde groups.

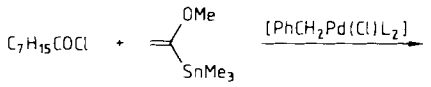
(6)

There are virtually no side reactions and the workup is simple. The end of the reaction is clearly visualized by the precipitation of palladium, and there is no need to run the reaction under an inert atmosphere.

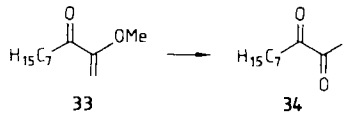
The tetraorganostannane transfers the first group rapidly, but the second leaves about 100 times slower from R_3SnCl. Thus, with a stoichiometric amount of tetraorganostannane, only one group is transferred. This single transfer of an organic group from tin is not a problem if a relatively simple organic group, for example, methyl, is to be transferred, since tetramethyltin can be used. If the partner on tin to be transferred is more expensive or difficult to synthesize, however, then the utilization of only one of those four partners would be a distinct advantage. Fortunately, different types of groups transfer selectively from tin, the simple alkyl group having the slowest transfer rate.[62] Thus, by using a trimethyl or tributylorganotin reagent, the group other than the methyl or butyl groups transfers exclusively:



In many cases, the trimethylorganostannane is preferred, since the by-product, trimethyltin chloride, can be easily removed from the reaction mixture by a water wash. Allyl transfer takes place predominantly with allylic rearrangement, coupling at a benzylic carbon takes place with inversion,[63] and coupling of an alkenyl group takes place with retention of double-bond configuration.[26,63] A number of trimethyltin derivatives of aromatic nitrogen heterocycles (pyridine, quinoline, isoquinoline) undergo transfer, leading to high yields of aromatic heterocyclic ketones such as **31**.[64] The conversion of alkynyltin reagents into

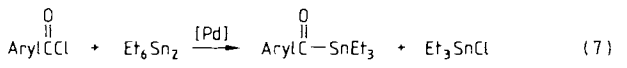


31

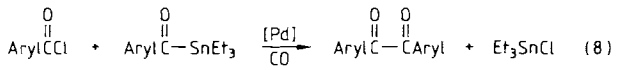


alkynyl ketones **32** is one of the best methods for the synthesis of these valuable intermediates.[65] The use of vinyltin reagents derived from enol ethers yields a vinyl ketone **33** that is easily converted into the 1,2-diketone **34**.[66] A variety of palladium catalysts have been used in these coupling reactions, including π-allylpalladium chloride dimer.

Symmetrical 1,2-diketones can be made from aroyl chlorides in a palladium-catalyzed coupling reaction that evidently involves conversion of half the acid chloride into an

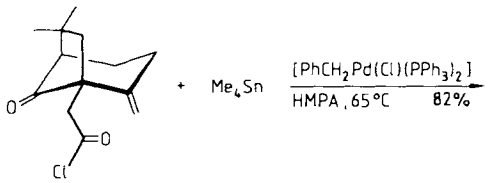


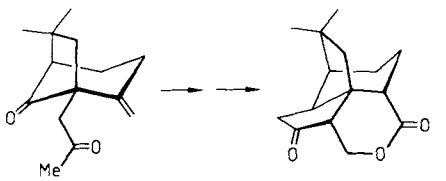
32



33 34

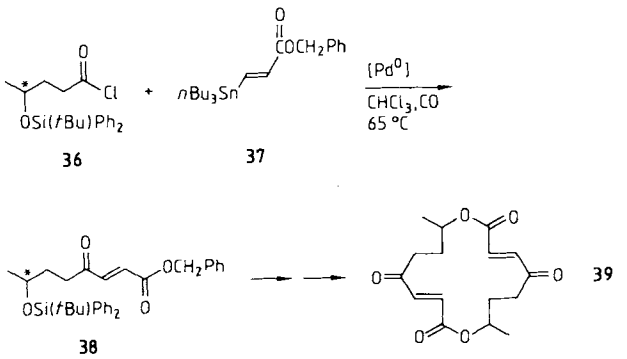
acyltin reagent [Eq. (7)], which then couples with the remaining acid chloride [Eq. (8)].[67] Decarbonylation of the intermediate aroylpalladium complexes is minimized by running the reaction under CO (8 atm).





(7)

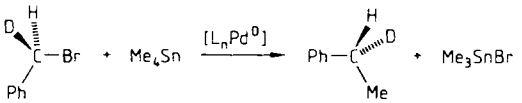
(8)

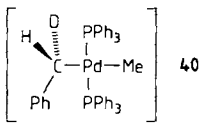


The conversion of an acid chloride into a ketone has been used in a number of syntheses of more complicated organic molecules, for example, in the synthesis of (±)-quadrone **35**.[68]

35

The coupling reaction of the acid chloride **36** with the substituted vinyltin reagent **37** gave the ketone **38**, which is a key intermediate in the synthesis of the antibiotic pyrenophorin **39** (Scheme 2).[69,70] Since the Mitsunobu coupling reaction proceeds with inversion of configuration at the chiral C atom and since the (*S*)-enantiomer of the starting lactone (precursor for **36**) is available, the synthesis of the naturally occurring (*R,R*)-pyrenophorin can be carried out. The synthesis illustrates the utility of the coupling reaction, even for the synthesis of more complicated ketones.





36 37 38 39

Scheme 2. Synthesis of pyrenophorin.

3.1.2. Benzyl Halides

In the direct catalytic coupling reaction between benzyl bromide and tetramethylstannane, an intermediate benzyl(methyl)palladium complex **40** is formed in the catalytic cycle.[71] The reductive-elimination reaction from this intermediate is stereospecific, proceeding with retention of configuration at the chiral center. Overall, inversion of configuration takes place as a result of inversion in the oxidative-addition step. High yields of cross-coupled products are obtained.[72]

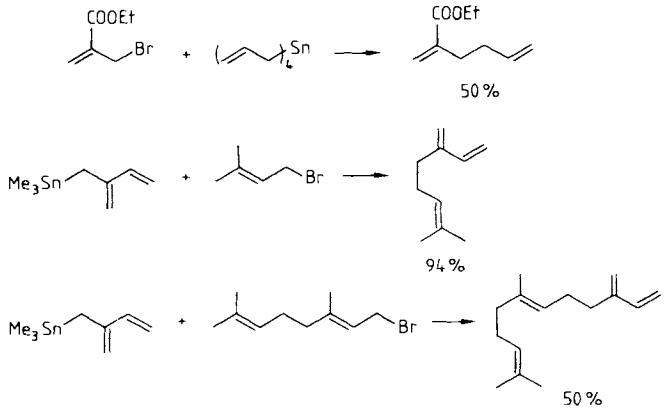
40

3.1.3. Allyl Halides and Acetates

The coupling of allyl bromides with allyltin reagents[73] takes place without homocoupling and allylic rearrangement takes place to a greater extent in the organotin reagent than in the allyl halide [Eq. (9) and (10)].[73,74] The ratios of coupled products are dependent on the R group of the tin reagent and on both the solvent and the catalyst. Generally, allylic acetates do not react, cinnamyl acetate[75] and allyl acetate[76,77] being exceptions.

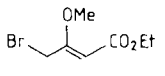
(9)

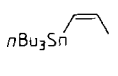
1 : 1.8

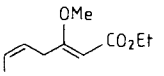


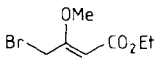
(10)

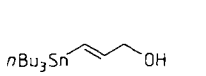
1 : 3

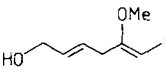


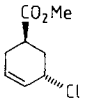


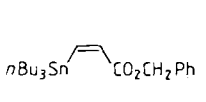


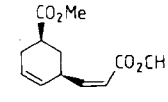


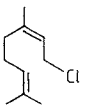


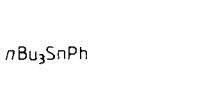


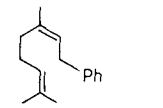


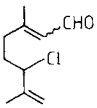


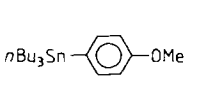


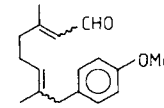


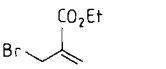


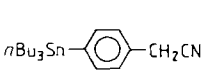


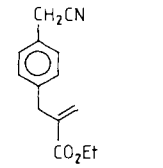












Nevertheless, with allylic bromides and particularly allylic tin reagents in which the product of allylic rearrangement is identical with the starting material, useful coupling reactions can be achieved (Scheme 3). In the latter two examples, coupling takes place more readily in the presence of zinc chloride[74] and no allylic rearrangement takes place in the allyl (prenyl-type) bromide.

The palladium-catalyzed coupling of allyl bromides or chlorides with alkenyl- or aryltin reagents leads to 1,4-dienes in high yields (Table 2).[78,79] The reaction is quite mild and is tolerant of a wide variety of functional groups,

Scheme 3. Coupling of two allyl compounds.

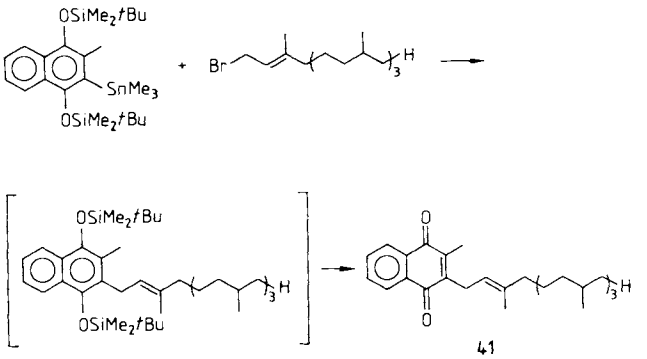


Table 2. Palladium-catalyzed coupling of allyl halides with alkenyltin compounds [a].

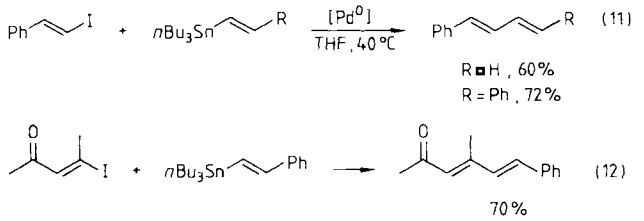
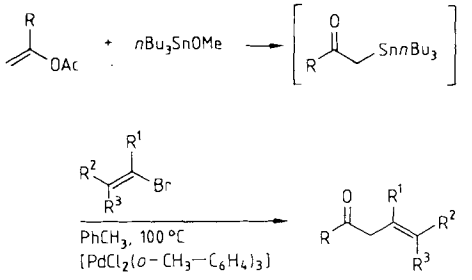
Reaction	Allyl halide	Organotin reagent	Product	Yield [%] [b]
1				86
2				82
3				80
4				90
5				87
6				81

[a] The reactions were carried out in dry THF at 50°C for 24–48 h, using equimolar amounts of allyl halide and alkenyltin reagent in the presence of 3 mol-% bis(dibenzylideneacetone)palladium(0) ([Pd(dba)$_2$]) and 6 mol-% PPh_3. [b] Isolated yields.

including CO_2R, CN, OH, and CHO. The reaction also proceeds with retention of double-bond configuration in the alkenyl compound (No. 1–3) as well as of the (*Z*)-configuration of neryl chloride (No. 4). The allyl halide undergoes regioselective coupling at the primary allylic carbon (No. 5; compare also No. 1, 2, and 4). Thus, this reaction exhibits stereospecific and regioselective carbon–carbon bond formation.



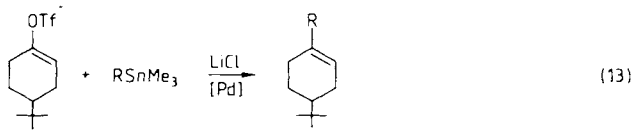
The coupling of allyl chlorides and bromides with aryltin reagents yields allyl-substituted arenes.[79,80] This reaction has been used in the synthesis of vitamin K_1 **41**; zinc chloride was again a better catalyst than palladium.[74]



41

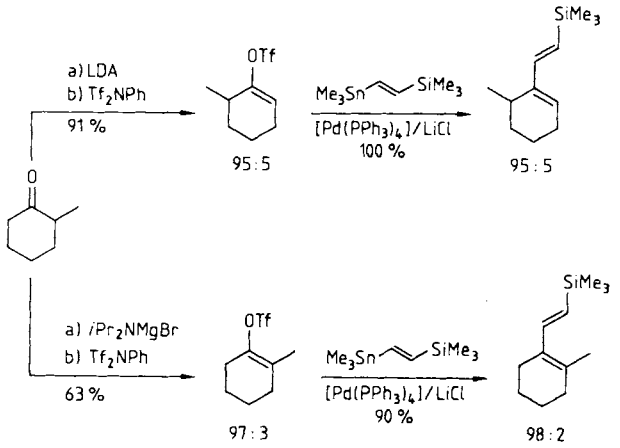
3.1.4. Substituted Vinyl Halides and Triflates

Substituted vinyl halides undergo direct, palladium-catalyzed cross-coupling with alkenyltin reagents to give good yields of conjugated dienes. Although the scope of this reaction has not been explored, it appears that retention of double-bond configuration in the vinyl partners occurs. Vinyl iodides [Eq. (11) and (12)] react readily at 25–40°C; vinyl bromides require higher temperatures (100°C) for the oxidative-addition step to take place readily.

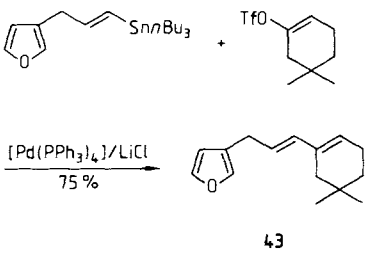


The palladium-catalyzed coupling of vinyl bromides with stannanes generated in situ from enol acetates yields allyl ketones **42**.[81]

42



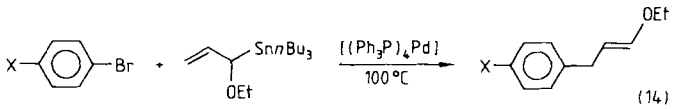
Vinyl triflates can be made to undergo palladium-catalyzed coupling reactions [Eq. (13)] provided lithium chlo-



R = H, $CH{=}CH_2$, $CH{=}CHSiMe_3$, *n*Bu, Me, $CH_2CH{=}CH_2$, $C{\equiv}C{-}SiMe_3$

ride is added to the reaction.[82] Apparently the vinyl palladium chloride complex is required for the transmetalation reaction, since the palladium triflates will not undergo transmetalation with vinyltin compounds.

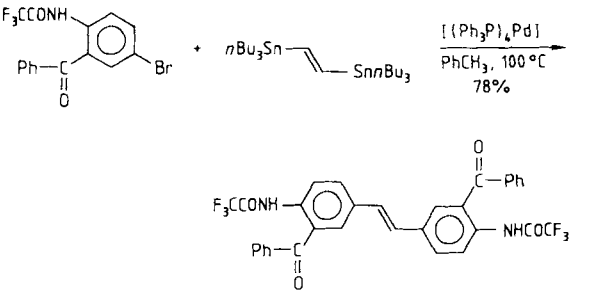
The discovery that vinyl triflates undergo coupling with a variety of tin reagents has proven to be very valuable. Since the triflates can be obtained from ketones, enolate chemistry is available and triflates are formed selectively from an unsymmetrical ketone by generating either the kinetic or thermodynamic enolate (Scheme 4).[82] This methodology has been used in a short synthesis of pleraplysillin-1 **43**.[82]



Scheme 4. Coupling of vinyl triflates.

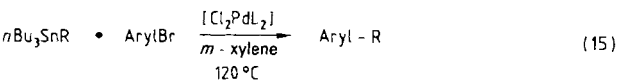
43

3.1.5. *Aryl Halides*



Because aryl iodides and bromides undergo oxidative addition to palladium(0) complexes at moderate temperatures, these halides are suitable for coupling with tin reagents; in contrast, aryl chlorides require activation with electron-withdrawing substituents on the ring. These coupling reactions take place with a wide variety of tin reagents.[83-89] Coupling reactions take place between aryl bromides and allyltin reagents at 100 °C with tetrakis(triphenylphosphane)palladium(0) as the catalyst [Eq. (14)].[42,83]

(14)

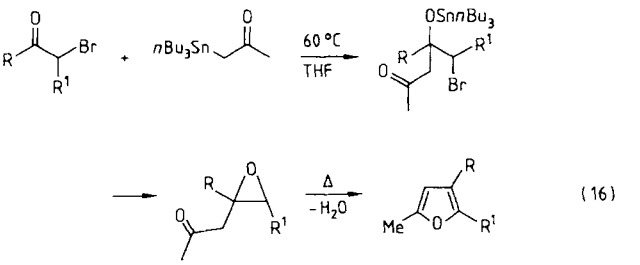


X = H, Cl, F 88–91 %

The bis-coupling of an aryl bromide with a vinylenedistannane proceeded at 100 °C to give a 78% yield of the stilbene derivative **44**.[89]

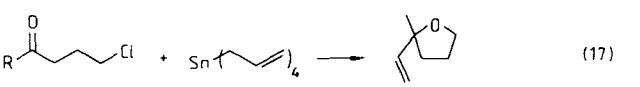
44

When ligandless catalysts generated from such palladium complexes as $LiPdCl_3$ or $[(CH_3CN)_2PdCl_2]$ in solvents that exhibit weak donor properties (such as HMPA, dimethylformamide (DMF), or acetone) are used, the coupling reactions with aryl iodides take place at ambient temperature as a result of a more facile oxidative addition with a coordinatively unsaturated d^{10} complex.[87] In addition to allyltin and vinyltin reagents, hydroxymethyl- and methoxymethyltin[90] compounds as well as α-acetonitrile-,[91] acetonyl-,[92] and cyanotin[93,94] compounds, can undergo the coupling reaction with aryl halides [Eq. (15)], although the mechanism of the reaction involving trimethyltin cyanide is evidently different from that shown in Scheme 1. Aromatic diazonium salts also undergo the palladium-catalyzed coupling with tetramethylstannane.[95]



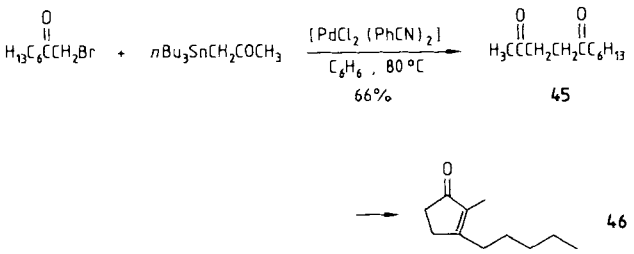
(15)

R = CH_2OH, CH_2OMe, CH_2CN, CH_2COMe, CN



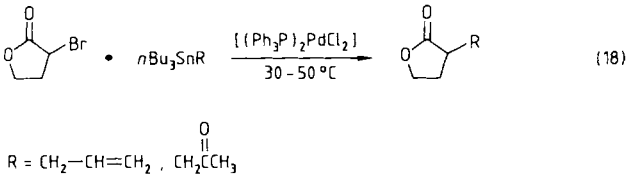
3.1.6. *α-Haloketones and α-Haloesters*

The reaction of a variety of α-haloketones with acetonyl- and allyltin reagents catalyzed by palladium gives cyclic ethers in good yield.[96] Oxiranes, oxetanes, and tetrahydrofurans can be obtained under mild conditions when the catalyst is introduced as benzyl(chloro)bis(triphenylphosphane)palladium(II) [Eq. (16) and (17)]. The catalyst is required both for the addition of the organotin reagent across the carbonyl group and for the epoxide generation. Thermal rearrangement of these initially formed acetonyl



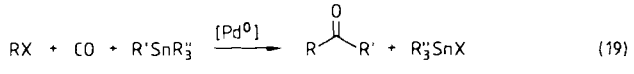
(16)

R = Me, Ph



(17)

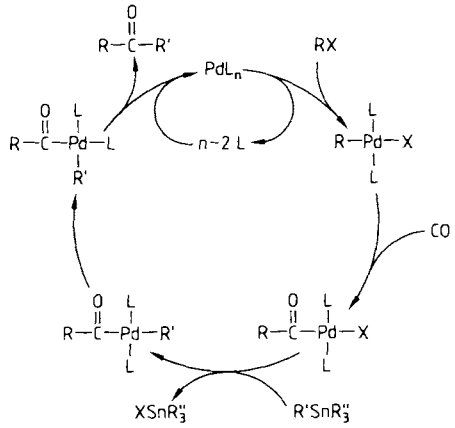
oxiranes leads to substituted furans. If a catalyst that does not contain phosphane ligands is used, a 1,4-diketone is formed, apparently through an initial oxidative addition step at the α-halo position.[97] The coupling reaction of 1-bromo-2-octanone with acetonyltributylstannane gives the 1,4-diketone **45**, a key intermediate in the synthesis of dihydrojasmone **46**.



α-Bromo-γ-butyrolactones undergo palladium-catalyzed coupling with allyl- or acetonyltin reagents to give good yields of α-allyl- or α-acetonyl-γ-butyrolactones [Eq. (18)].[98] Only moderate yields of coupled product could be obtained with ethyl α-bromoacetate, however. The coupling reaction of α-iodolactone involves a radical process and does not require a palladium catalyst.

(18)

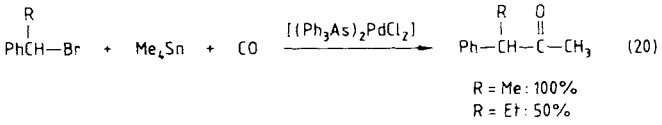
3.2. Carbonylative Coupling



The palladium-catalyzed carbonylative coupling reaction of organic halides with organotin compounds in the presence of carbon monoxide [Eq. (19)] is an especially valuable synthetic procedure for a number of reasons.

(19)

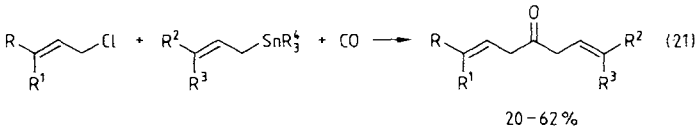
First, if the acid chloride is not readily available for a ketone synthesis by a direct coupling, then the organic halide having one less carbon can be used, since the same acylpalladium intermediate is generated. Second, since an acid chloride is not involved in the synthesis, presumably other functional groups such as OH and NH_2, suitably placed, can be present in the organic halide. Although our original efforts to achieve this transformation were not particularly successful,[60,61] this type of reaction was reported later to proceed with symmetrical tetraalkyltin reagents under severe reaction conditions (120°C, HMPA, 30 atm CO).[99]



The probable catalytic cycle for this carbonylative coupling reaction (Scheme 5) is analogous to the direct coupling except that carbon monoxide insertion takes place after the oxidative addition step and prior to the transmetalation step.

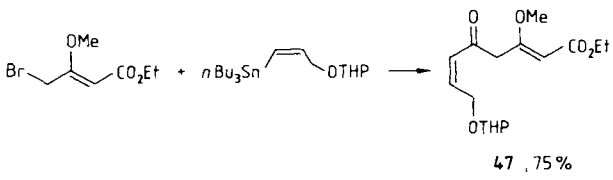
Scheme 5. Mechanism of the catalyzed, carbonylative coupling.

3.2.1. *Benzyl Halides*



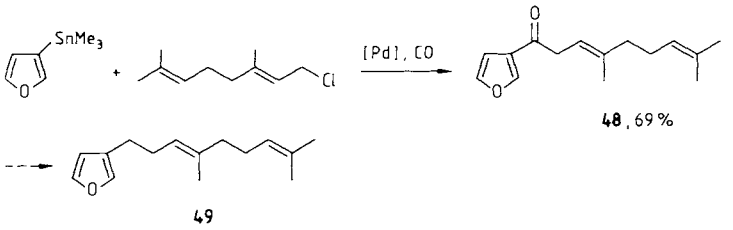
The carbonylative coupling of benzyl bromides and tetramethylstannane takes place to yield benzyl methyl ketones [Eq. (20)].[99,100] The insertion of carbon monoxide into the benzyl-palladium bond must be faster than β-elimination, at least under 20 atm of carbon monoxide.

(20)



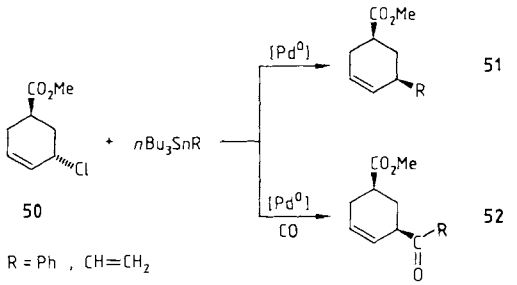
3.2.2. *Allyl Chlorides*

Bis-allylic ketones were synthesized by the reaction of allyl chlorides and allyltin reagents in the presence of CO (3 atm) at 25°C.[101] Higher temperatures resulted in the further addition of the allyltin reagent to the ketone to yield a tertiary alcohol (after hydrolysis). Rearrangement to give the α,β-unsaturated carbonyl compounds can be avoided. In contrast to direct coupling, carbonylative coupling occurs without allylic rearrangement of the organotin compound, and CO insertion takes place exclusively at the least hindered site of the allyl halide partner. This reaction [Eq. (21)] also tolerates other functional groups, including CO_2R, OH, and even CHO, at least on the allyl halide partner.



(21)

The use of alkenyltin reagents under 3 atm of carbon monoxide gives high yields of the carbonylated product **47**.[78,79]



47, 75%

Aryltin compounds also yield carbonylative coupling products. This reaction type was the basis for the high-yield synthesis of egomaketone and a precursor, **48**, to dendrolasin **49** by the carbonylative coupling between 3-furanyltrimethylstannane and prenyl chloride or geranyl chloride, respectively.[79]

The cross-coupling of **50** with either tributylphenyl- or tributylvinylstannane proceeded with inversion of configuration at the allylic carbon center to yield **51** (see also Table 2, No. 3). In the presence of carbon monoxide, the carbonylated *cis* product **52** was obtained.[78,79] Thus, the coupling of this allyl halide either in the absence or presence of carbon monoxide takes place with 100% net inversion of configuration at the allylic center.

3.2.3. *Substituted Vinyl Halides and Triflates*

The palladium-catalyzed reaction of substituted vinyl iodides with vinyl-, alkenyl-, alkynyl-, and phenyltin compounds in the presence of carbon monoxide (3 atm) proceeds under mild reaction conditions to yield the corresponding ketones[102] (Table 3).

The reaction tolerates carbonyl groups in both partners as well as an acetylenic group in the tin partner. Under these mild reaction conditions, no further addition of the tin reagent to the product ketone takes place. Generally, the preparation of unsymmetrical ketones by transition-metal-catalyzed cross-coupling reaction is severely limited, since the organometallic partners often react with the product ketone.

The (*E*)-configuration of the double bond, both in the vinyl iodide and in the stannane, is retained in the product. The (*Z*)-configuration of the double bond in the stannane, however, is lost under the usual reaction conditions and the (*E*)-isomer of the product predominates. (*E*)/(*Z*)-Isomerization of vinyl ketones is very facile, however.

Vinyl triflates also will undergo the palladium-catalyzed carbonylative coupling reaction provided lithium chloride is added to the reaction mixture (Table 4).[103] As in the direct coupling of vinyl triflates with organotin compounds, the lithium chloride apparently is necessary since the palladium triflate complex will not undergo transmetalation with the tin reagent. In coupling reactions with vinyltin reagents, the configuration of the double bond is maintained. An important aspect of this work is the ability to prepare a vinyl triflate regioselectively, using well-known enolate chemistry, and to couple the triflate with an organostannane under a carbon monoxide atmosphere to give only one regioisomeric product (Scheme 6).

The carbonylative coupling reaction followed by a Nazarov cyclization was used for a sequential annulation to assemble the fused five-membered-ring structure of (±)$\Delta^{9(12)}$-capnellene **53** (Scheme 7, L-Selectride = $LiBHsBu_3$).[103]

Table 3. Carbonylative coupling of vinyl iodides with organostannanes.

Scheme 6. Carbonylative coupling of vinyl triflates.

3.2.4. *Aryl Halides*

The carbonylative coupling reaction of aryl iodides and bromides can be carried out with a variety of palladium catalysts and tin reagents as coupling partners. The first reported aryl iodide carbonylative coupling reactions required high temperatures (120°C) and high pressures of carbon monoxide (30 atm),[99] even with nickel catalysts.[104] The reaction can be carried out under much milder reaction conditions (1 atm CO, 20°C) [Eq. (22)], particularly with ligandless catalysts.[105]

$$\text{Aryl I} + \text{RSnMe}_3 + \underset{1\,\text{bar}}{\text{CO}} \xrightarrow[72\,\text{h}]{[(C_3H_5)PdCl]_2} \text{Aryl}\overset{\overset{\text{O}}{\|}}{\text{C}}\text{—R} \qquad (22)$$

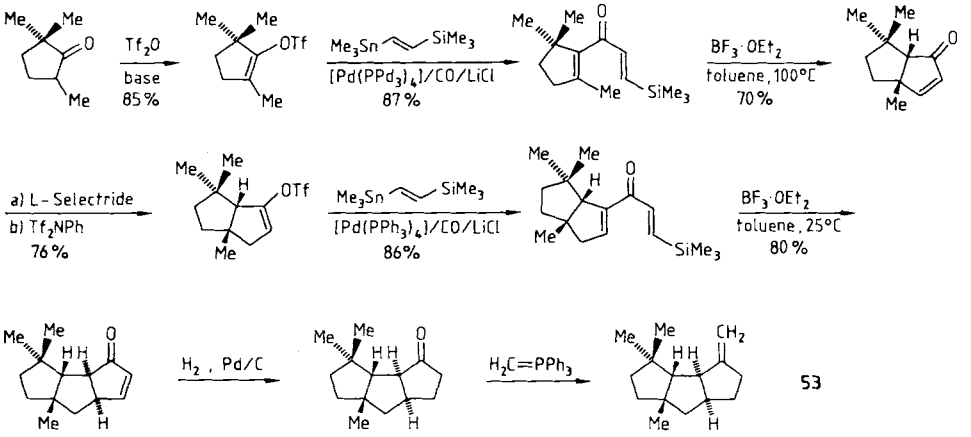
Aryl = *p*-C_6H_4X ; X = NO_2, CO_2Me, CN, Cl, I, H

R = Me, $CH{=}CH_2$,  , *p*-C_6H_4X, C_6F_5, C≡CPh,

(X = OMe, Me, H, Cl, NO_2)

3.2.5. *Aldehyde Synthesis*

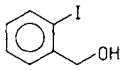
Organic halides may be converted into aldehydes in the presence of a palladium catalyst, carbon monoxide, and tributyltin hydride under mild reaction conditions [Eq. (23)].[106] Aryl, benzyl, alkenyl, and allyl halides can be

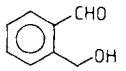


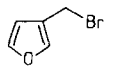
$$\text{RX} + \text{CO} + n\text{Bu}_3\text{SnH} \xrightarrow[50\,^\circ\text{C}]{[\text{Pd}^0]} \text{RCHO} + n\text{Bu}_3\text{SnX} \qquad (23)$$

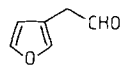
converted into aldehydes; other functional groups in the molecule remain unaffected under these reaction conditions (Table 5).

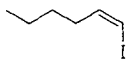
4. Mechanisms

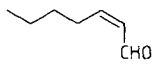


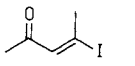


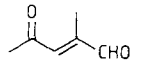


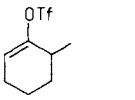


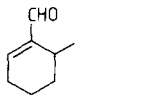


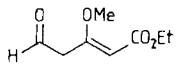


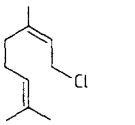


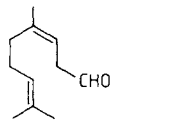






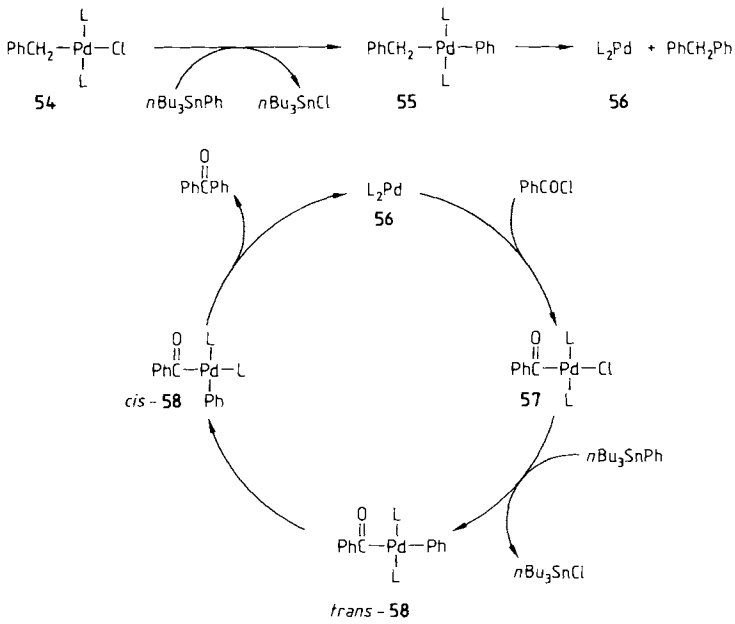






4.1. Coupling of Acid Chlorides with Organotin Compounds

The catalytic cycle for the coupling reaction of acid chlorides with organotin reagents is shown in Scheme 8.



Scheme 7. Synthesis of capnellene.

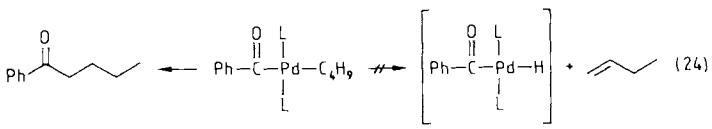
Halide	Solvent	Aldehyde	Yield [%]
	THF		87
	THF		91
	$PhCH_3$		55
	THF		67
	THF		88
	THF		95
	THF [b]		96
	THF		86
	THF		59

[a] 50°C, $[(Ph_3P)_4Pd]$. [b] LiCl added.



Scheme 8. Mechanism of the catalytic coupling of acid chlorides with organotin compounds. L = PPh_3.

Palladium was introduced into the reaction as benzyl(chloro)bis(triphenylphosphane)palladium(II) **54** (L = PPh_3) with the expectation that it would be reduced (via a transmetalation reaction to yield **55**, followed by a reductive elimination sequence) to reactive bis(triphenylphosphane)palladium(0) **56**.[62] The benzyl catalyst **54** was allowed to react with equimolar amounts of tributyl(phenyl)stannane and benzoyl chloride, and the reaction was followed at 65°C by ^{31}P-NMR spectroscopy. The signal for the benzyl catalyst disappeared concomitantly with the appearance of the acylpalladium species **57**.

When both benzoyl chloride and tributyl(phenyl)stannane are used in excess over the benzyl catalyst **54**, only the ^{31}P-NMR signals for **54** and **57** could be observed, those for **54** eventually disappearing. No additional signals for **56** or **58** could be detected, even though benzophenone was produced.

These results are consistent with the catalytic cycle shown in Scheme 8 if the transmetalation reaction is the slow step, with oxidative addition, isomerization, and reductive elimination occurring rapidly. The oxidative addition of benzoyl chloride to tetrakis(triphenylphosphane)palladium(0) in THF has a half-life of 10 min at 30 °C.[107] A fast reductive-elimination step is consistent with the observation that in coupling reactions with tetrabutylstannane, high yields of phenyl butyl ketone are obtained, and no butene resulting from a β-hydride elimination is observed [Eq. (24)].

Although the mechanisms of the oxidative-addition and reductive-elimination sequences have been individually studied, and are reasonably well understood,[52-57] much less is known about the transmetalation reaction. The existing data support an electrophilic cleavage of the Sn-C bond with the palladium(II) complex **57** acting as the electrophile. Several lines of evidence support this.

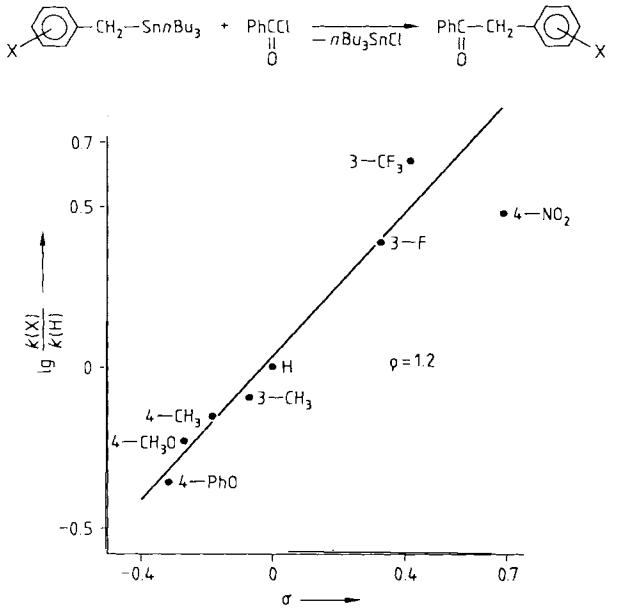
First, since the reductive elimination of an alkenyl group attached to tin is known[56] to take place with retention of configuration, overall retention of configuration in the coupling reactions of vinyltin compounds requires retention in the transmetalation step. Retention of configuration at the double bond is also observed in the cleavage reactions of alkenyltin compounds with electrophiles.[108]

Second, the order (relative rates) of transfer of organic groups is consistent with electrophilic cleavage. The reactions of trimethylorganotin compounds by mercury(II) chloride follow the order shown.[109] Further, the transfer order is the same as that observed for transmetalation reactions with platinum(II) complexes.[110, 111]

$PhC\equiv C$	>	$CH_2=CH$	>	Ph	>	Me
very fast		5		1		0.007

Third, the transfer of a benzyl group is accelerated by electron-withdrawing groups on the ring. A slightly positive ρ value (+1.2, Fig. 1) was obtained. These results are consistent with electrophilic attack at the benzylic carbon.

The relatively low ρ value indicates that there is little direct conjugation of the substituent group with the incipient benzyl anion and that carbon-palladium bond formation may precede carbon-tin bond breaking.



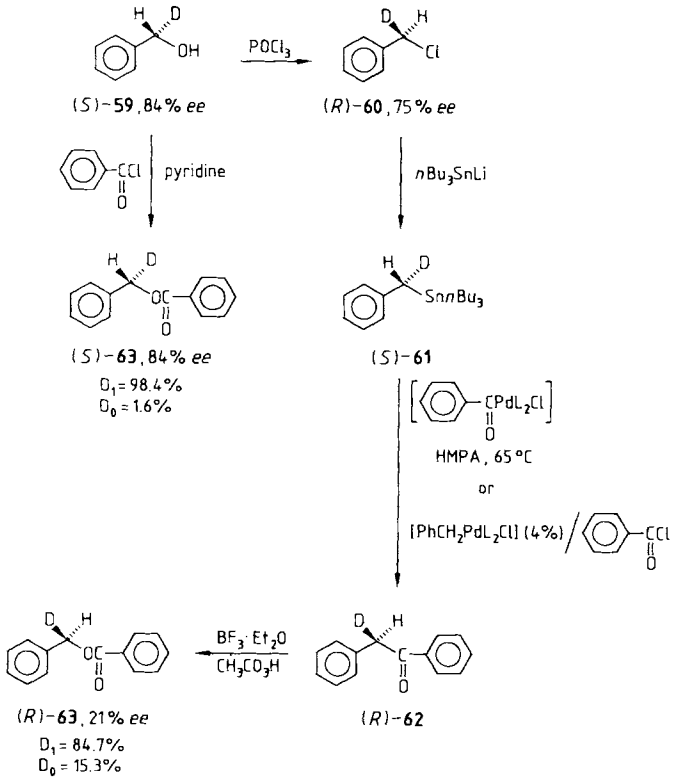


Figure 1. Linear free-energy relationship for the coupling of benzyltin compounds with benzoyl chloride.

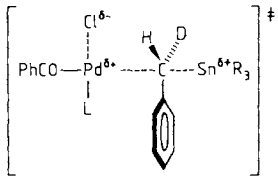
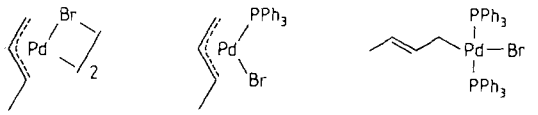


Finally, the inversion of configuration at an sp^3 carbon atom attached to tin is consistent with electrophilic cleavage and an open transition state (Scheme 9).[59-63] The reaction of (*S*)-(+)-[1-^{2}H]benzyl alcohol (*S*)-**59** (84% *ee*) with $POCl_3$ gave (*R*)-(−)-[1-^{2}H]benzyl chloride (*R*)-**60** (75% *ee*).

Scheme 9.

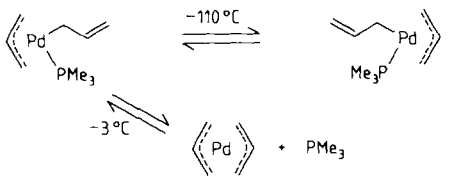
The addition of lithium tributylstannate to a solution of (*R*)-**60** gave (*S*)-**61** of unknown optical purity. Although there is controversy concerning the degree of nucleophilic vs. radical (electron-transfer) reaction,[112-116] the net inversion of configuration is high, often greater than 90%.[114-116]



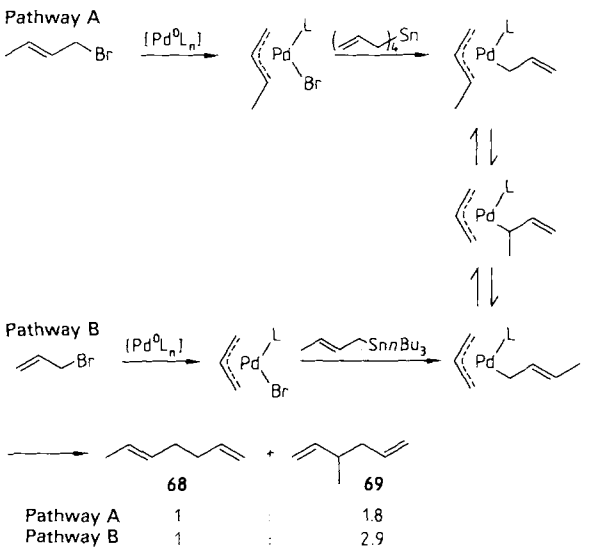
When the reaction of equimolar amounts of (*S*)-**61** with benzoyl chloride in the presence of catalytic amounts of benzyl(chloro)bis(triphenylphosphane)palladium(II) was carried out, desoxybenzoin (*R*)-**62** was obtained. The reaction of equal amounts of (*S*)-**61** and benzoyl(chloro)bis(triphenylphosphane)palladium(II) also gave **62**. The CD spectra of **62** are consistent with the (*R*)-configuration. The Baeyer-Villiger oxidation of **62** afforded the (*R*)-(−)-benzyl ester **63**; retention of configuration at the benzylic carbon atom occurs in this oxidation.[117] Conversion of (*S*)-**59** to the benzyl ester (*S*)-**63** and comparison of the optical rotation of the two esters allowed an assessment of the optical purity of (*R*)-**63**. Taking into consideration that the deuterium content in (*R*)-**63** is 85% compared to 98% in (*S*)-**63** and that any enolization would racemize **62** (independent of the deuterium content) and assuming a primary deuterium isotope effect of 2, it is possible to estimate at least 65% net inversion in the transmetalation reaction. This is based on the knowledge that reductive elimination takes place with retention of configuration at carbon[71,62] and that all steps other than the transmetalation step in proceeding from **60** to **62** take place without any racemization. This is not the case, of course, so the transmetalation reaction probably takes place highly stereospecifically, certainly with more than 65% net inversion. These results are consistent with a transmetalation reaction taking place by an S_E2 mechanism[118] and an open transition state **64** in which the electrophile is the palladium complex.

64

4.2. Allyl Coupling



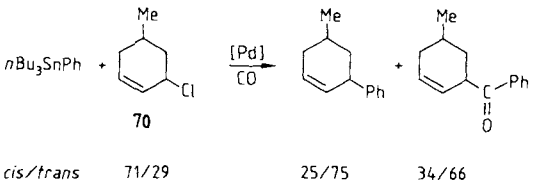
The mechanism of the coupling reaction of an allyl halide with an allyltin reagent is much more obscure, although presumably the same type of catalytic cycle as in the reaction of acid halides with organotin compounds is operative (see previous Section). In the reaction of allylpalladium complexes **65**–**67** with tetraallyltin, only **66** produced the yields observed in the catalytic coupling. The σ-complex **67** would be expected to be formed in the oxidative-addition reaction of $(CH_2{=}CH{-}CH_2)_4Sn$ with $[(Ph_3P)_2Pd]$ **56**, but excess crotyl bromide could be expected to scavenge an equivalent of phosphane to give **66** when only catalytic amounts of the palladium complex are used. Indeed, when a second molar equivalent of allyl bromide was present in the reaction with **67**, the yield of coupled products matched that of the catalytic reaction.[119]



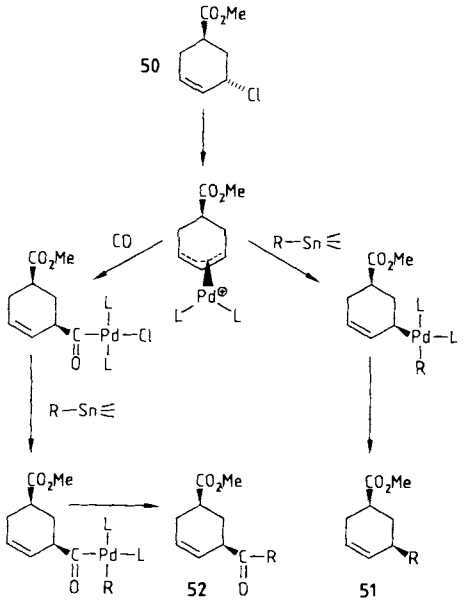
65 66 67

Unfortunately, the ratio of regioisomers **68** and **69** produced in the stoichiometric reactions of **66** with tetraallyl tin was different (5 : 4) from that obtained in the catalytic reaction (1 : 2).

Whether a bisallylpalladium species is the key intermediate leading to the coupled product also is not clear. It has been shown that a rapid equilibration takes place between η^1- and η^3-bound allyl groups in the bisallylpalladium complex (Scheme 10).[120] Thus, if bisallyl intermediates of this type are involved in the palladium-catalyzed coupling reactions, the reactions of either crotyl bromide and tetraallylstannane or of allyl bromide and tributyl(crotyl)stannane should lead to the same ratios of coupled products **68** and **69**. The ratios found, however, are different (Scheme 11).



Scheme 10. Isomerization of bisallylpalladium complexes.



Scheme 11.

The stereochemistry of the coupling reaction of allylic chlorides with vinyl- or phenyltin reagents is unequivocal, however. The reaction of *trans*-methyl 5-chloro-3-cyclohexenecarboxylate **50** with tributyl(phenyl)- or tributylvinylstannanes catalyzed by benzyl(chloro)bis(triphenylphosphane)palladium(II) gave the cross-coupled product **51** in which complete inversion of configuration had taken place.[78,79] Similarly, reaction of a *cis-trans* mixture (42 : 58) of **50** gave *trans*-**51** and *cis*-**51** in a 41 : 59 ratio. Under carbon monoxide (3 atm), both the products of direct coupling and of carbonylative coupling were obtained. Both products, **51** and **52**, had the *cis* configuration.

In order to ensure that the stereochemical course of the reaction with the chloride **50** was not due to participation of the methoxycarbonyl substituent in directing the approach of the palladium, the analogous 3-chloro-5-methylcyclohexene **70** was allowed to react with tributyl(phenyl)stannane in the presence of carbon monoxide. Similar results were obtained.

These results suggest a sequence of events outlined in Scheme 12. Oxidative addition, which takes place with inversion of configuration for allylic esters[121] and benzyl chloride[122], also takes place with inversion in the allylic chloride system. This is confirmed by the fact that carbon monoxide, which is known to insert into the Pd–C bond with retention of configuration at carbon,[123] freezes the stereochemistry of the oxidative-addition reaction. The presence of carbon monoxide does not modify the stereochemistry since both directly coupled products **51** and ketones **52** are produced at intermediate carbon monoxide pressures, and the *cis/trans* ratio of the cross-coupled product **51** is unaffected by the presence of carbon monoxide. Carbon monoxide simply diverts the allylpalladium (II) complex toward formation of the ketone **52**. Transmetalation and reductive elimination, which proceed with retention of configuration at carbon,[71,72] complete the sequence.

Scheme 12. Coupling of an allyl chloride.

The catalytic cycles shown (Schemes 1, 2, and 8) have made use of $Pd^0 \rightleftharpoons Pd^{II}$ oxidation states, although there is some evidence that coupling reactions take place via $Pd^{II} \rightleftharpoons Pd^{IV}$ states.[52, 71, 72] The stoichiometric coupling reactions between benzyl(iodo)bis(triphenylphosphane)palladium(II) and aryltrimethylstannane give coupled product, although higher yields are obtained when an equivalent of aryl iodide is present, suggesting some involvement of a Pd^{IV} complex.[124] Alternatively, the aryl halide, particularly iodobenzenes containing electron-withdrawing substituents, may promote reductive elimination by charge transfer.[125]

Our research in this area was supported by the National Science Foundation (Grant CHE-8305468), whose assistance is greatfully acknowledged. The research was carried out by a number of able graduate students and postdoctoral research associates, whose names appear in the references.

Orthophosphates in the Ternary System Al_2O_3-P_2O_5-H_2O

By Rüdiger Kniep*

Orthophosphates of aluminum have been the subject of numerous studies since the middle of the nineteenth century. They have acquired importance in such diverse fields as the earth sciences, chemical engineering, and medicine. The chemical problems associated with this Al_2O_3-P_2O_5-H_2O system mainly arise from the marked tendency to form polymeric aluminum orthophosphate complexes in solution; equilibrium is reached only with difficulty, and crystallization of single phases is the exception rather than the rule. However, the crystal structures of several aluminum orthophosphates (including minerals) have been elucidated, and it is now possible to give a systematic description of this class of compounds and the conditions necessary for their formation.

1. Introduction

The three-component system Al_2O_3-P_2O_5-H_2O encompasses several intermediate orthophosphates, the variety of which stems from the many ways of combining the cationic coordination polyhedra of aluminum with anionic phosphate species ($H_2PO_4^{\ominus}$, $HPO_4^{2\ominus}$, $PO_4^{3\ominus}$). Referred to the ternary system, these compounds occur only within the shaded area in Figure 1, with boundary conditions of 1 : 3 and 3 : 1 for the Al : P ratio. The Al : P ratio also determines the general classification into acid (Al : P < 1), neutral (Al : P = 1) and basic (Al : P > 1) phases.

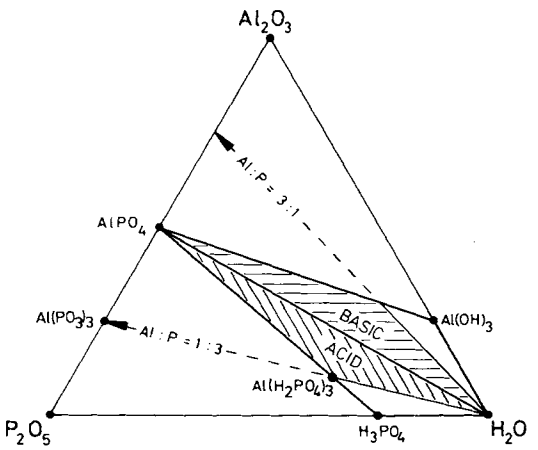

Fig. 1. The three-component system Al_2O_3-P_2O_5-H_2O; the shaded region comprises orthophosphate species.

Aluminum orthophosphates (henceforth AOPH) are of wide-ranging importance and application, and thus of interest over a wide spectrum of disciplines. Although this is a promising factor for the interdisciplinary exchange of information, such an exchange has not yet taken place to any great extent. In this article an attempt will be made to summarize current knowledge on the composition, structure and conditions of formation of AOPH.

Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

Many applications of AOPH are based on their capacity to lose water on heating, being converted into compounds on the Al_2O_3-P_2O_5 edge of Figure 1. Of these, neutral, anhydrous $AlPO_4$ is of especial importance because it is closely related to silicon dioxide, both chemically and structurally: $AlPO_4$ is isoelectronic with SiO_2 (formally Si-SiO_4) and is known in all SiO_2-analogous modifications (quartz, cristobalite, tridymite) including their α- and β-forms, which are reversibly interconvertible.[1-3] The low-temperature modification α-$AlPO_4$ (berlinite) can be obtained as large single crystals by hydrothermal methods[4] and is of interest because of its dielectric and piezoelectric properties.[5] At normal pressure, $AlPO_4$ shows negligible decomposition up to 1100 °C;[6] this fact, taken together with its insolubility and chemical inertness, accounts for its application in refractories, in ceramics, and in impregnating or insulating surface coatings.

The starting material for the preparation of such *inorganic binding or coating agents* is often aluminum dihydrogenphosphate $Al(H_2PO_4)_3$,[7-9] which undergoes a setting reaction with basic oxides such as $Al(OH)_3$ [Eq. (1)] or condenses by thermal dehydration[10] to $Al(PO_3)_3$ [Eq. (2)]; the reactions (1) and (2) are simplified limiting cases and do not take into account intermediate phases.

$$Al(H_2PO_4)_3 + 2\,Al(OH)_3 \longrightarrow 3\,AlPO_4 + 6\,H_2O \quad (1)$$

$$Al(H_2PO_4)_3 \longrightarrow Al(PO_3)_3 + 3\,H_2O \quad (2)$$

As can be seen from Figure 1, the course of reaction (1) intersects the regions of acidic, neutral and basic AOPH, whereas reaction (2) proceeds through the region P_2O_5-$AlPO_4$-H_3PO_4 (the condensed aluminum phosphates[11,12]); again it is not at all clear which particular compounds of this class actually exist. $Al(PO_3)_3$ is formed from aluminum dihydrogenphosphate via at least one intermediate (probably $Al_2(H_2P_2O_7)_3$[13]) and is obtained as either a cubic crystalline tetrametaphosphate[14] or as a monoclinic polyphosphate with hexameric chains,[15] depending on the reaction temperature (500° or 800 °C, respectively). Above 1300 °C the crystalline phase is converted into a molten glass, which is used as a ceramic binding agent[7-9] and in the preparation of optical fluorophosphate glasses.[16] At still higher temperatures the melt decomposes, releasing P_2O_5 and depositing $AlPO_4$, which at

temperatures up to 1800°C is converted into α-Al_2O_3, again with release of P_2O_5.[17] These decomposition reactions are of importance in the production of *highly refractory materials*.[18]

AOPH also find applications in the field of *corrosion protection*. Amorphous AOPH coatings, in contrast to corresponding oxide coatings, can be deposited from solution at relatively low temperatures;[19] undesirable hydration (boehmite formation) of oxide layers generated by anodic oxidation at aluminum can be extensively suppressed by surface phosphatization;[20,21] porous Al_2O_3 layers, required because of their good adhesion properties with respect to subsequently applied coatings,[22] are generated by anodic oxidation in the presence of phosphoric acid.

The adsorption properties and surface-active donor-acceptor centers of aluminum phosphates, and of phases generated from AOPH by reaction with Al_2O_3 or SiO_2, make these materials suitable for *catalysis* (cracking processes, hydrogenation, oxidation).[23-26] In this context a new group of substances should be mentioned, namely those containing neutral $AlPO_4$ networks with cavities of a specific size. These phases are analogous to zeolites; they find application as molecular sieves, catalysts, or catalyst supports and can be prepared hydrothermally in the presence of organic molecules (amines or quaternary ammonium salts) that determine the cavity size.[27] A recent report describes the synthesis and characterization of corresponding mixed silicon/aluminum phosphates.[28]

In the *medical and pharmaceutical field*, aluminum phosphate has been used for a long time as a regulator of stomach acidity.[29-31] Pure $Al(OH)_3$ is certainly a better neutralizer, but phosphate ions have a pharmacologically more favorable effect on the stomach lining.[32]

Neutral and basic AOPH occur naturally as (relatively scarce) minerals.[33] The formation of such mineral phases is of importance in *soil science*, since the effectiveness of phosphate fertilizers is considerably reduced by phosphate fixation (formation of sparingly soluble AOPH) to $Al(OH)_3$-containing soil components (e.g. clay minerals).[34-38] This effect can however be turned to advantage in the *purification* of phosphate-containing *waste water*.[39-41]

2. The Variety of Compounds

The AOPH in the ternary system Al_2O_3-P_2O_5-H_2O that have so far been identified are shown in Figure 2. Table 1 gives their chemical composition, the mineral names of the basic and neutral phases, and, where applicable, information concerning polymorphism. The large number of compounds and their abundance within a small segment of the complete system serve to demonstrate that the formation of single-phase products can only be realized by a precise knowledge of, and adhesion to, exact conditions for their synthesis. A further difficulty in the case of acid AOPH is that the solutions needed for crystallization experiments are highly viscous, because of the formation of "aggregation polymers"[69] (see also Section 4). Unambiguous characterization of single phases can only be achieved by studies of single crystals; it thus follows that the existence of those AOPH listed in Figure 2 and Table 1, but not confirmed by single crystal methods, cannot be regarded as absolutely certain.

The problem of identifying AOPH phases will be illustrated by some concrete examples: Only as recently as

Table 1. Orthophosphates in the ternary system Al_2O_3-P_2O_5-H_2O; XA = X-ray structure analysis, CA = chemical analysis, XP = X-ray powder studies, W = Weissenberg studies, EM = electron microscopy, DTA = differential thermal analysis, TG = thermogravimetry.

No.	Composition	Mineral name/Polymorphism	Crystal system	Ref.	Identification
Basic (Al:P > 1)					
1	$Al_4(OH)_3(PO_4)_3$	Trolleite	Monoclinic	[42]	XA
2	$Al_2(OH)_3(PO_4)$	Augelite	Monoclinic	[43]	XA

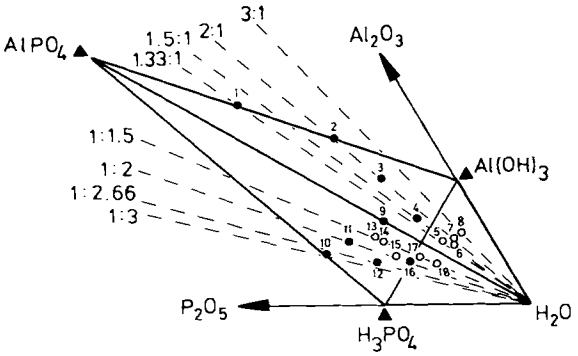

Fig. 2. Orthophosphates of the three-component system Al_2O_3-P_2O_5-H_2O. The chemical composition of the phases 1-18 is given in Table 1. Broken lines connect phases with equal Al : P ratio. Filled circles indicate phases for which crystal structure analyses have been performed.

1979 it was demonstrated[64] that the compounds $Al_2(H_2PO_4)_4(HPO_4)\cdot 2H_2O$,[70] $Al_4(H_2PO_4)_2(HPO_4)_5$,[70] $Al_2O_3\cdot 2P_2O_5\cdot 3H_2O$[71] and $Al_2(HPO_4)_3\cdot 2.5H_2O$,[72] formerly referred to in the literature as independent phases, in fact consist of mixtures of several phases. It must also be remembered that the presence of extraneous ions (such as alkali metal ions, which are added as their hydroxides to regulate the pH of the solution) can affect the preparation of AOPH by promoting the formation of quaternary compounds, of which the added ions form part. $AlH(H_2PO_4)_4\cdot 2H_2O$,[73] prepared in the presence of $Na^{\oplus}$, was later shown[64] to be a mixture of at least three phases (Na : Al : P = 1 : 1 : 4, 1 : 3 : 8 (see [59]), and 3 : 1 : 5), while $Al_3(H_2PO_4)_7(HPO_4)\cdot 6H_2O$,[73] crystallized from solutions containing $K^{\oplus}$, has been shown by X-ray powder methods[64] to be the potassium compound isotypic with phase 12 of Table 1. Non-existent compounds have also been introduced into the literature by simple transcription errors; the phases $Al(H_2PO_4)_3\cdot 1.5H_2O$ (see Addendum) and $Al_2(HPO_4)_3\cdot 3H_2O$[74] were mentioned as a result of an error in a list of AOPH.[64]

3. Crystal Structures and Their Classification

The classification of AOPH on the basis of the Al : P ratio into basic (> 1), neutral (= 1), and acid (< 1) phases finds its counterpart in structural studies.

The AOPH are not only classified according to the nature of the phosphate ions, but also according to the coordination polyhedra of aluminum (cation coordination polyhedra, CCP) and the types of linkage between them.[75-79] In all the AOPH investigated, excepting augelite and senegalite, $Al^{3\oplus}$ is octahedrally coordinated (see, however, Section 6); the oxygen donor atoms of the ligands may be defined as O_{H_2O} (from water), O_P (from phosphate anions) or O_{OH} (from hydroxyl groups). O_{OH} ligands always lead to further linkage between the CCP, whereas O_{H_2O} are always terminal. All non-protonated oxygen atoms of phosphate ions function as O_P ligands in the formation of CCP, the linkage type always being vertex-bridging. Protonated oxygens of phosphate groups are always terminal and do not contribute to further CCP-phosphate bridging (except for the formation of hydrogen bonds).

These general structural principles serve as a basis for the following summary of the fundamental differences between basic, neutral, and acid phases: basic AOPH contain condensed CCP aggregates and $PO_4^{3\ominus}$ units; neutral AOPH contain isolated CCP and $PO_4^{3\ominus}$ units; acid AOPH contain isolated CCP and protonated phosphate groups.

CCP linkages in basic AOPH are illustrated in Figure 3. Trolleite contains dimeric units $Al_2(O_{OH})_3(O_P)_6$; these face-bridged octahedra act as structure-generating CCP elements, being vertex-bridged to symmetry-equivalent dimers via O_{OH} and thus forming an infinite one-dimensional CCP double chain of composition $Al_2(O_{OH})_3(O_P)_{12}$. The CCP double chains are linked by common O_P-vertices of PO_4 tetrahedra, resulting in a dense three-dimensional network of octahedra and tetrahedra with even distribution of strong Al-O-P-O bonds. Augelite displays a less

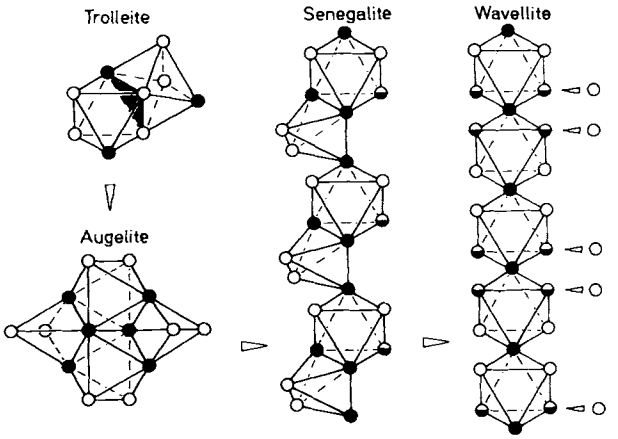

Fig. 3. Linkage of the coordination polyhedra of aluminum in basic AOPH. ●: oxygen atoms of hydroxide ions (O_{OH}); ○: oxygen atoms of phosphate ions (O_P); ◒: oxygen atoms of H_2O molecules (O_{H_2O}). The arrows to the right of the wavellite structure show the water positions which are replaced by O_P in the second chain-like structural unit. For the position of the fifth H_2O molecule, see text.

densely packed structure that contains tetrameric CCP units $Al_4(O_{OH})_6(O_P)_8$, in turn consisting of two $Al(O_{OH})_4(O_P)_2$ octahedra and two $Al(O_{OH})_3(O_P)_2$ trigonal bipyramids linked by common O_{OH}-O_{OH} edges. PO_4 tetrahedra bind the tetramers via O_P vertices to form the final three-dimensional structure. Senegalite contains coordination octahedra ($Al(O_{OH})_3(O_P)_2(O_{H_2O})$) and trigonal bipyramids ($Al(O_{OH})_3(O_P)_2$), condensed to dimeric units via common O_{OH}-O_{OH} edges; further bridging via O_{OH} vertices forms infinite chains of the dimers. Neighboring chains are united in a layer structure by vertices shared with PO_4 tetrahedra. Wavellite contains two different types of octahedra: $Al(O_{OH})_2(O_P)_3(O_{H_2O})$ and $Al(O_{OH})_2(O_P)_2(O_{H_2O})_2$, in the ratio 2 : 1; each type of CCP is incorporated into infinite one-dimensional chains via O_{OH} in *trans* positions. The chains are linked via common vertices shared with PO_4 tetrahedra, forming a three-dimensional structure with broad canals (Fig. 4) parallel to the crystallographic *a* axis. These canals contain disordered water molecules with relatively high mobility. The disorder can be reasonably described in terms of two half-occupied, mutually exclusive water sites. Between room

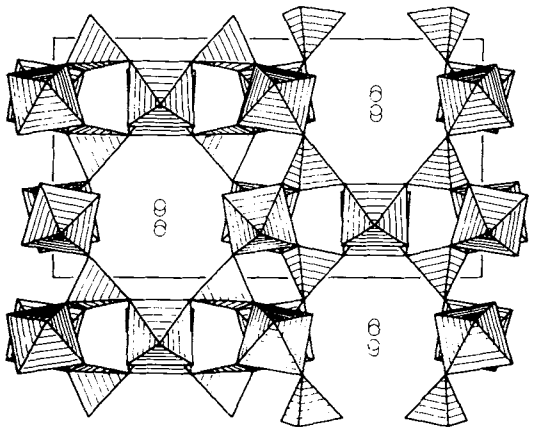

Fig. 4. Part of the crystal structure of wavellite (polyhedral representation). The double circles in the otherwise empty canals indicate disordered water molecules in mutually exclusive positions 0.88 Å apart.

temperature and 100 °C, this water can be completely removed; the process is reversible in single crystals, and wavellite thus shows a temperature-dependent phase range with respect to the water of crystallization.[79] Vashegyite and kingite have not yet been subjected to complete crystal structure analyses, because the crystals are extremely small. It is however clear that both are layer structures, and it has been suggested that they are structurally similar to kaolinite.[80] Bolivarite, whose average composition is given in Table 1, is amorphous to X-rays. Evansite is an opal-like, basic phosphate glass and displays the largest Al : P ratio yet observed (3 : 1). It may be assumed that this phase contains extensive aggregates of condensed CCP (fragments of the layer structures of gibbsite or bayerite[81]) that cannot be connected into a regular lattice structure because of the small number of phosphate tetrahedra available for bridging.

The tendency of basic AOPH to form crystalline phases decreases with increasing water content.[79,82,83] The AOPH that form well-characterized crystalline phases show a decreasing degree of CCP-condensation (Fig. 3) with increasing water content (in the order 1→4, see Fig. 2 and Table 1) and therefore also a decreasing density: trolleite (face- and vertex-bridging) 3.08 g cm^{-3}, augelite (edge-bridging) 2.70 g cm^{-3}, senegalite (edge- and vertex-bridging) 2.55 g cm^{-3}, wavellite (vertex-bridging) 2.35 g cm^{-3}.

The crystal structures of the neutral AOPH variscite-lucine (VL) and metavariscite contain $Al(O_P)_4(O_{H_2O})_2$ octahedra, connected via vertices shared with PO_4 tetrahedra to form a three-dimensional structure. The O_{H_2O} are mutually *cis* at aluminum. CCP polymerization, as is observed in the case of basic AOPH, does not occur in the neutral phases. Figure 5 shows comparable projections of the structures of VL and metavariscite; the linkage of CCP via phosphate tetrahedra is similar but not identical, as can be seen from the orientation of the shaded tetrahedron. Therefore, any interconversion of phases would, despite identical coordination polyhedra in both compounds, have to take place reconstructively.[84] No crystal structure analysis of variscite-messbach (VM) has been carried out, because this phase is only known in cryptocrystalline form. IR and X-ray powder investigations[53] suggest a close relationship to VL, with a doubled *b*-axis in VM but otherwise

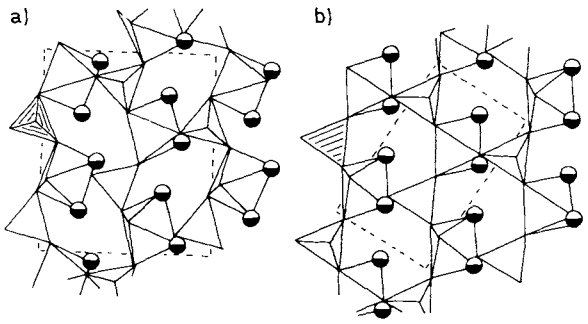

Fig. 5. Part of the crystal structures of (a) variscite-lucine (VL) and (b) metavariscite (polyhedral representation). The unit cells are indicated by broken lines. The shaded tetrahedra serve to emphasize the difference in the otherwise identical connectivities.

unchanged symmetry. VM can be regarded as a precursor in the formation of VL from amorphous neutral precipitates[53,79,85] (see also Section 4).

Thermal dehydration of the neutral AOPH variscite-lucine and metavariscite leads to tridymite-$AlPO_4$, but intermediate $AlPO_4$ phases, which correspond to none of the SiO_2-isotypic $AlPO_4$ modifications, are formed first.[79,85-88] Variscite-lucine is first converted under 600 °C to the crystalline phases $AlPO_4$-A and $AlPO_4$-B, the metric lattices of which are very similar to that of the starting hydrate. The dehydration of metavariscite leads below 450 °C to a phase $AlPO_4$-C. The fact that these primary dehydration products give sharp X-ray patterns and are capable of reversibly reabsorbing water—at least partially—suggests that the topology of the starting phases is largely unaltered by the initial dehydration; the coordination sphere of aluminum will however change from octahedral ($Al(O_P)_4(O_{H_2O})_2$) to tetrahedral ($Al(O_P)_4$). The simplification of the metavariscite crystal structure to its Al and P positions and their linear connections to each other results in the three-dimensional network shown in Figure 6,[79] which may be assumed to represent the topology of the three-dimensional structure of the phase $AlPO_4$-C. The structural model contains 4-, 6- and 8-membered rings of vertex-linked coordination tetrahedra, such as are found in the aluminosilicate framework of paracelsian;[89] the anion in paracelsian ($Al_2Si_2O_8^{2\ominus}$) is isoelectronic with the neutral aluminum phosphate

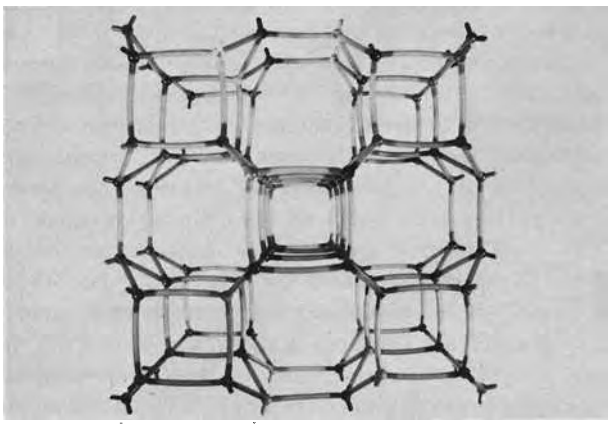

Fig. 6. Three-dimensional network structure assumed for $AlPO_4$-C; each "bond" corresponds to an ideally extended Al-O-P unit.

($Al_2P_2O_8$). The crystal structure of β-BeO[90,91] affords another topological model for comparison with that of $AlPO_4$-C; the linkage of tetrahedra as depicted in Figure 6 is precisely that of the Be-O bonding framework.[92]

Five phases of the group of acid AOPH (Nos. 10–18 in Fig. 2 and Table 1) have already been structurally analyzed. Figure 7 shows details of the crystal structures of

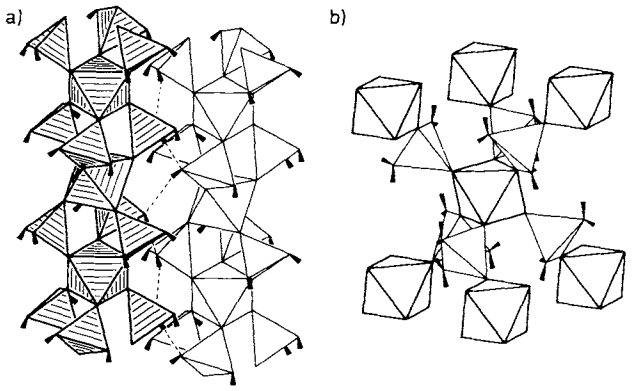

Fig. 7. Part of the crystal structures of (a) $Al(H_2PO_4)_3$-C and (b) $Al(H_2PO_4)_3$-A (polyhedral representation). One structural unit of $Al(H_2PO_4)_3$-C is indicated by shading. The hydrogen atom positions are shown by wedges; in $Al(H_2PO_4)_3$-A the hydrogen atoms are disordered, with two independent half-occupied sites at each P-OH group.

modifications A and C of $Al(H_2PO_4)_3$. Both structures contain $Al(O_P)_6$ octahedra, linked by common vertices to $O_2P(OH)_2$ tetrahedra; in $Al(H_2PO_4)_3$-C this results in an infinite one-dimensional structure, while in $Al(H_2PO_4)_3$-A a three-dimensional Al-O-P network results. With respect to their heavy atom positions alone, phases A and C are almost centrosymmetric. However, C is rendered significantly acentric (with a polar axis) by the observed directionality of the hydrogen atoms. In A, on the other hand, the hydrogen atoms are disordered at room temperature, with two half-occupied positions at each P-OH moiety, such that centrosymmetry is preserved. C is of interest because it may be ferroelectric; a phase transition observed at 60°C, associated with only minor changes in the X-ray diffraction diagram, could be considered as the transition to the paraelectric state. Whether the crystal structure of A thus represents a paraelectric state at room temperature, and A can become ferroelectric at lower temperatures, is still unclear.

Figure 8 shows details of the structures of the two-dimensional Al-O-P-linked phases $Al(H_2PO_4)(HPO_4)\cdot H_2O$ and $H_3O[Al_3(H_2PO_4)_6(HPO_4)_2]\cdot 4H_2O$. The former contains isolated $Al(O_P)_5(O_{H_2O})$ octahedra linked by common vertices to $O_2P(OH)_2$ and $O_3P(OH)$ tetrahedra, resulting in a macromolecular layer structure. Within each layer the octahedra are bridged in one dimension by both $H_2PO_4^{\ominus}$ and $HPO_4^{2\ominus}$ groups, in the other dimension only by $HPO_4^{2\ominus}$. Hydrogen bonds link the layers in the third dimension.

In $H_3O[Al_3(H_2PO_4)_6(HPO_4)_2]\cdot 4H_2O$, $Al(O_P)_6$ octahedra are linked by common vertices to $O_2P(OH)_2$ and $O_3P(OH)$ tetrahedra, forming layers with trigonal symmetry. The layers contain "holes", in the centers of which $H_3O^{\oplus}$ ions are located. Water molecules are held between the layers by hydrogen bonds. The trigonal symmetry of each individual layer is not a feature of the overall structure because of the particular displacements of the layers relative to each other. This oxonium salt could, according to the suggested transport mechanism of proton conduction in the solid state,[93] function as such a proton conductor. The particular position of the $H_3O^{\oplus}$ ions in the "holes" of the layers is a key to understanding the isotypy already suggested for compounds of the type $M^{I}M^{III}_3H_{14}(PO_4)_8\cdot 4H_2O$ ($M^{I}=H_3O^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$, $NH_4^{\oplus}$; $M^{III}=Al^{3\oplus}$, $Fe^{3\oplus}$).[94] It should be mentioned here that the compound $Al_2(H_2PO_4)(HPO_4)\cdot 2H_2O$ reported by *Erlenmeyer*[70] in 1878 is in fact none other than this oxonium salt, so that the true identity of the compound was finally determined more than a century after it was first described.

The structure of $Al_2(H_{2-x}PO_4)_3(H_{3x}PO_4)\cdot 6H_2O$ ($0\leq x\leq 1$) contains two different components stacked in the direction of the crystallographic *c* axis (Fig. 9): isolated PO_4 tetrahedra and larger groupings of two $Al(O_P)_3(O_{H_2O})_3$ octahedra linked through common vertices to three phosphate tetrahedra. The hydrogen positions could not be determined experimentally. If an ordered proton distribution is assumed, then two alternative limiting formulas are possible: $Al_2(H_2PO_4)_3(PO_4)\cdot 6H_2O$ and $Al_2(HPO_4)_3$-

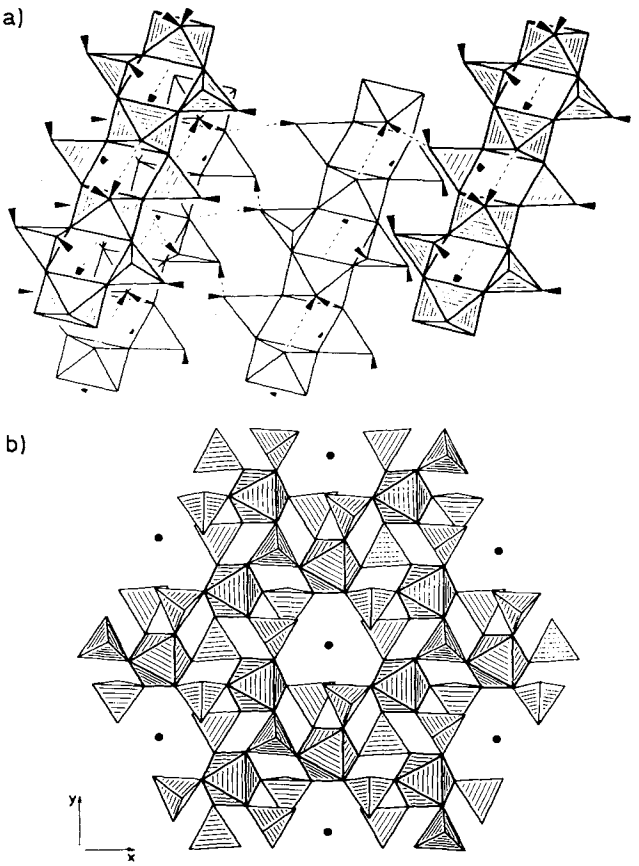

Fig. 8. Part of the crystal structures of two-dimensional Al-O-P connected acid AOPH (polyhedral representation). (a) $Al(H_2PO_4)(HPO_4)\cdot H_2O$; polyhedron linkages directed upwards in this projection are indicated by shading. The hydrogen sites are shown by wedges. Inter- and intramolecular hydrogen bonds are shown by broken lines. (b) $H_3O[Al_3(H_2PO_4)_6(HPO_4)_2]\cdot 4H_2O$; the filled circles in the middle of the "holes" represent the $H_3O^{\oplus}$ sites.

$(H_3PO_4)\cdot 6H_2O$. However, neither formulation seems very realistic, since they involve phosphate species differing by two in their degree of protonation. In addition, "free" phosphate oxygens, neither protonated nor coordinating, have never been observed, either in acid, neutral or basic AOPH. Since even a detailed analysis of the bond lengths and angles does not favor either of the limiting formulas, it is assumed that the true structure lies between both these states. Proton conduction was considered likely for this phase with its disordered protons,[67] but could not be confirmed experimentally;[95] our present understanding of the mechanism of proton conduction[93] in the solid state, however, suggests that such conduction here is not to be expected.

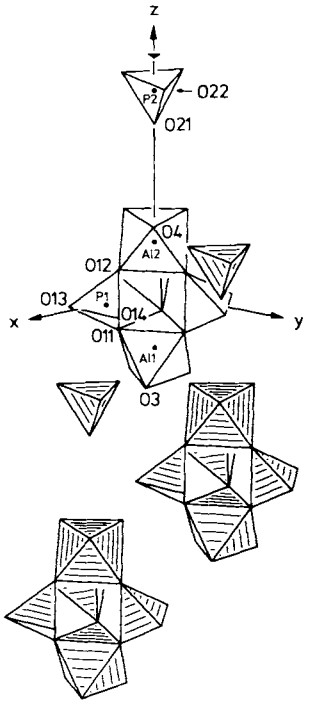

Fig. 9. Part of the crystal structure of $Al_2(H_{2-x}PO_4)_3(H_{3x}PO_4)\cdot 6H_2O$ (polyhedral representation).

Although only five crystal structures are known from the whole range of acid AOPH (see Fig. 2, Table 1), it is already clear that there is no restriction on the number of dimensions involved in the linking of the Al-O-P units: three-dimensional linking in $Al(H_2PO_4)_3$-A, two-dimensional in $Al(H_2PO_4)(HPO_4)\cdot H_2O$ and $H_3O[Al_3(H_2PO_4)_6(HPO_4)_2]\cdot 4H_2O$, one-dimensional in $Al(H_2PO_4)_3$-C, and isolated units in $Al_2(H_{2-x}PO_4)_3(H_{3x}PO_4)\cdot 6H_2O$. It remains to be seen to what extent further successful crystal structure determinations of acid AOPH are made possible by crystal-growing experiments; it has not yet proved possible to obtain suitable single crystals of acid AOPH with an Al : P ratio of 1 : 1.5 (phases 13, 14, 17, 18 in Fig. 2 and Table 1). In this connection it is interesting to note a recent high-field ^{27}Al-NMR study of solid aluminum phosphates,[96] which allowed definite conclusions concerning the coordination geometry of aluminum and also, to a certain extent, the nature of the ligands at aluminum; however, the AOPH with Al : P = 1 : 1.5 were not investigated in this study.

4. Stability Relationships and Conditions of Formation of AOPH

AOPH are obtained from aqueous solutions (pH ≤ 6). The conditions for the formation of trolleite, augelite, senegalite and wavellite correspond to hydrothermal syntheses, whereas all other AOPH can be obtained at normal pressure.

In aqueous solution, the aluminum cation exists in the form of an octahedral hexaaqua complex, which functions as a weak cation acid[97] and is subject to the dissociation equilibrium formulated in Equation (3) as a first step:

$$[Al(H_2O)_6]^{3\oplus} \rightleftharpoons [Al(OH)(H_2O)_5]^{2\oplus} + H^{\oplus} \quad (3)$$

The initially monomeric complexes condense via common OH groups (olation) to give polynuclear units; the dimeric, edge-bridged cation formed according to Equation (4) has been identified in the crystal structure of its sulfate salt.[98]

$$2[Al(OH)(H_2O)_5]^{2\oplus} \rightleftharpoons [(Al(OH)(H_2O)_4)_2]^{4\oplus} + 2H_2O \quad (4)$$

Further condensation, at pH values >4, leads mostly to ring-shaped hexanuclear cationic complexes with bridging along O_{OH}-O_{OH} edges,[99] which may be regarded as fragments of the layers of crystalline $Al(OH)_3$ phases. It may take several days to establish equilibrium, and intermediate phases, once precipitated, redissolve extremely slowly. Larger, probably metastable complexes have been isolated as their sulfate or selenate salts.[100, 101]

In phosphate-containing solutions the tendency of the aluminum octahedra to condense with each other is additionally influenced by complex formation with phosphate species. At the beginning of this century it was reported[102–104] that the mixing of $Al^{3\oplus}$- and $H_2PO_4^{\ominus}$-solutions causes a spontaneous lowering of the pH. The release of protons is consistent with the formation of stable, soluble aluminum phosphate complexes, in which (as Eq. (5) shows in schematic and simplified form) at least one ligand site of the octahedrally coordinated aluminum is occupied by the oxygen atom of a phosphate tetrahedron, forming an Al-O-P unit.

$$[Al(H_2O)_6]^{3\oplus} + H_2PO_4^{\ominus} \rightleftharpoons [Al(OPO_3H)(H_2O)_5]^{\oplus} + H_3O^{\oplus} \quad (5)$$

These complexes may be neutral, anionic or cationic depending on the nature and number of the phosphate ligands.[69, 103, 106–112] In concentrated solutions these complexes can form three-dimensional cross-linked "aggregation polymers",[69] thus leading to a highly viscous medium. Such highly viscous solutions may be obtained, for example, by dissolving aluminum in 60–85% H_3PO_4; the maximum attainable Al concentration in a still transparent solution corresponds to an Al : P ratio of ca. 1 : 2.[64]

Stock solutions with Al : P ratios $\leqq 1:2$ are used for the preparation and crystallization of acid AOPH; these solutions are themselves prepared by the reaction of $AlPO_4 \cdot 2H_2O$, $Al(OH)_3$ or aluminum with 60–85% H_3PO_4.[56, 59, 64, 113–117] Reproducible results in crystallization experiments (usually by evaporation between 25 and 100 °C) can only be obtained by the use of "matured" solutions that have been left untouched for a long time to reach equilibrium. The process by which equilibrium is reached is clearly an ordering or preliminary structure formation; the complex aggregates that are present in the crystalline materials are first formed in solution. Table 2 shows schematically which crystalline phases are preferentially

Table 2. Relationship between the Al : P ratios in concentrated solutions and those in the acid AOPH crystallizing from them. The phases are numbered as in Table 1.

	Al : P in solution							
T [°C]	1:7	1:6	1:5	1:4	1:3	1:2	Phase	Al : P
80							10-A	1:3
40–100							10-C	1:3
50–80							12	1:2.66
80–100							11	1:2
30–70							16	1:2
<65							14	1:1.5

formed for given Al : P ratios in solution; phase 10(C), $^1_\infty[Al(H_2PO_4)_3]$, can be regarded as a relatively stable, "everpresent" species, whereas the other phases crystallize only in restricted concentration ranges. Figure 10 shows the effect of temperature on the formation of crystalline phases from a stock solution with a constant Al : P ratio of 1 : 3.[116]

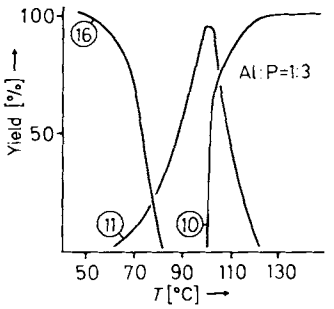

Fig. 10. Crystallization and yield of acid AOPH from solutions with an Al : P ratio of 1 : 3, as a function of temperature [116]. The phases are numbered as in Table 1.

The tendency to form products consisting of many phases (as already mentioned in the introduction) on crystallization from concentrated solutions can be observed in this system. The polymeric aggregates present in solution are responsible for this phenomenon, since they hinder the formation of crystallization centers and can cause supersaturation even to the extent of forming glasses. In addition, the high viscosity leads to marked concentration gradients in the neighborhood of growing crystals and thus to the crystallization of other phases around the crystal originally formed.

In contrast to the acid AOPH, which crystallize from highly concentrated solutions, the neutral AOPH are obtained from dilute aluminum phosphate solutions;[64, 85, 118–124] the temperatures required lie between 80 and 130 °C. When using solutions prepared from aluminum salts and phosphate salts it should be remembered that the presence of impurities (notably the cations $K^\oplus$ and $NH_4^\oplus$) can often have a serious effect on the products, sometimes leading to the precipitation of phases incorporating the impurities.[121] Metavariscite crystallizes directly from solution at $pH \approx 1$, whereas variscite-lucine is formed at pH 2-4 via an amorphous precipitate after long digestion. Many different intermediate stages with differing water content and degree of crystallinity are involved.[85] Variscite-messbach should be considered as a crystalline precursor of variscite-lucine (see Section 3).

Basic AOPH can be obtained at pH values of 4–6 and temperatures that increase with decreasing water content of the solid phases formed.[124–129] This is consistent with the expected increase of thermal stability, in the order $O_{(H_2O)} < O_{(OH)} < O_{(P)}$, of oxygen ligands coordinated to aluminum.[130, 131] In trolleite and augelite, $O_{(H_2O)}$ are not involved in the aluminum polyhedra, and these phases are thus the most thermally stable AOPH. Under hydrothermal conditions the stability ranges of trolleite and augelite are determined by various equilibrium processes[129] in which the even more stable phases berlinite ($AlPO_4$) and corundum (Al_2O_3) are involved [Eq. (6)–(9)].

$$\text{trolleite} \rightleftharpoons \text{augelite} + 2\,\text{berlinite} \quad (6)$$

$$\text{trolleite} \rightleftharpoons 3\,\text{berlinite} + 1/2\,\text{corundum} + 3/2\,H_2O \quad (7)$$

$$\text{augelite} \rightleftharpoons \text{berlinite} + 1/2\,\text{corundum} + 3/2\,H_2O \quad (8)$$

$$\text{augelite} \rightleftharpoons 1/3\,\text{trolleite} + 1/3\,\text{corundum} + H_2O \quad (9)$$

Figure 11 shows the course of the four univariant curves in the p/T diagram for reactions (6)–(9); the intersection of the equilibrium lines defines an invariant point at 4.70 kbar (p_{H_2O}) and 542 °C.[129]

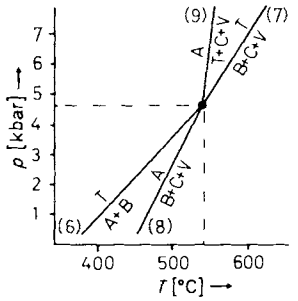

Fig. 11. p/T diagram showing the course of the equilibrium reactions (6)–(9) about their invariant point ($p_{H_2O} = 4.70$ kb; $T = 542$ °C) [129]. T = trolleite, A = augelite, B = berlinite, C = corundum, V = H_2O.

The thermal stability of the isolated "dry" AOPH (Fig. 12) varies over a wide temperature range according to the water content; the heavily hydrated phase 16 ($Al_2(H_{2-x}PO_4)_3(H_{3x}PO_4) \cdot 6H_2O$) decomposes at 70 °C, whereas the phase with the least water (trolleite,

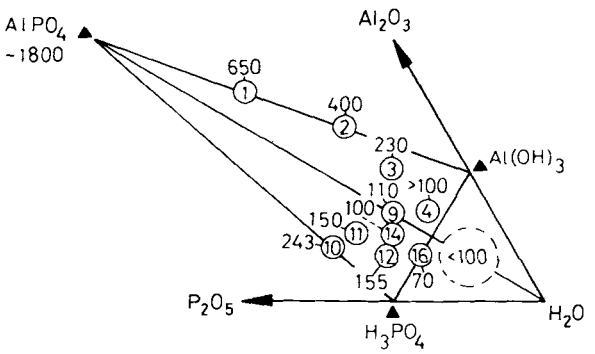

Fig. 12. The thermal stability of isolated ("dry") AOPH; temperatures in °C. The phases are numbered as in Table 1.

$Al_4(OH)_3(PO_4)_3$) is stable to 650°C. Higher hydrates can in general be converted into their corresponding less-hydrated phases by thermal dehydration. This preparative procedure is particularly suitable (given a constant Al : P ratio) when the higher hydrate decomposes below 100°C (generally by incongruent melting) and the lower hydrate decomposes at a temperature higher than the temperature of evaporation of water from the saturated solution. The principle of crystallization by evaporation finds an application here. In this way phase 16, for example, can be quantitatively converted into phase 11 [Eq. (10)].[60, 67, 113]

$$\underset{\text{Phase 16, m.p. (incong.)} = 70\,^{\circ}\text{C}}{Al_2(H_{2-x}PO_4)_3(H_{3x}PO_4)\cdot 6H_2O} \xrightarrow[-4\,H_2O]{120\,^{\circ}\text{C}} \underset{\text{Phase 11, decomp. temp.} = 150\,^{\circ}\text{C}}{2\,Al(H_2PO_4)(HPO_4)\cdot H_2O} \qquad (10)$$

Phase 15, which might occur as an intermediate (Fig. 2, Table 1), is in fact not observed in this thermal decomposition.

5. Summary and Concluding Remarks

The small segment $AlPO_4$–$Al(OH)_3$–H_2O–H_3PO_4 of the three-component system Al_2O_3–P_2O_5–H_2O encompasses several orthophosphate hydrates that can be classified as basic, neutral or acid phases according to chemical and structural principles. Their variety stems from the different condensation and linkage processes that are possible between the coordination polyhedra of aluminum and anionic phosphate species. The structural elements of the solid phases are preformed in concentrated aqueous solutions as complex "aggregation polymers"; if sufficiently extended, these may give rise to highly viscous solutions. This in turn leads to special problems in crystal growth, and single-phase products are the exception rather than the rule. Studies of single crystals are therefore of great importance for the identification of the AOPH phases.

The interest in, and applications of, AOPH extend to many regions of natural sciences, earth sciences, technology and medicine; a prominent role is played by single phases and their specific properties, such as behavior on heating, thermal stability, insolubility, chemical inertness, insulator properties, catalytic activity, acid or base capacity, ferroelectricity, and proton conduction.

On the basis of their peculiar structural characteristics and chemical composition, AOPH can be assigned to a wider group of compounds, to which iron(III) orthophosphate hydrates and also the corresponding arsenates belong; some are isotypic with AOPH. Thus variscite-lucine ($AlPO_4\cdot 2H_2O$) is isotypic with strengite ($FePO_4\cdot 2H_2O$), mansfieldite ($AlAsO_4\cdot 2H_2O$) and skorodite ($FeAsO_4\cdot 2H_2O$);[79, 132, 133] $Al(H_2PO_4)_3$-A and $Fe(H_2PO_4)_3$-A are also isotypic.[56, 57] In some cases isotypy in the strict sense is not observed, but the structural units display the same arrangement; for example, $Fe(H_2AsO_4)_3\cdot 5H_2O$[134] displays a one-dimensional structure type also seen in $Al(H_2PO_4)_3$-C, but with additional interstitial water molecules. The possible existence of an analogous pentahydrate of $Al(H_2PO_4)_3$ (possibly at low temperature) has not been investigated, and indeed the existence of further AOPH in general cannot be ruled out. It is however clear that AOPH represent the best-studied type of compound within this larger group of compounds. The main reason for this is that the arsenic compounds are too toxic, and the iron(III) compounds too susceptible to reduction, to have found wide application. An additional factor is that the hydrogen atom positions, although difficult to determine by X-ray methods, are generally more easy to determine in the absence of heavier elements.

6. Addendum

In the course of recent intensive work on $AlPO_4$-based molecular sieves[27] (see also Section 1) a neutral AOPH of composition $AlPO_4\cdot 1.5H_2O$ has been synthesized (probably under hydrothermal conditions).[62] The unusual crystal structure of this compound contains two different kinds of two-dimensional nets, which are stacked alternately and which are joined via common oxygen atoms to form a three-dimensional framework.[135] One kind of layer corresponds to an arrangement of $Al(O_P)_4(O_{H_2O})_2$-octahedra and PO_4-tetrahedra that is also present in variscite and metavariscite ($AlPO_4\cdot 2H_2O$) (see Fig. 5). The other kind of layer is built up from $Al(O_P)_4$- and PO_4-tetrahedra that are connected to four- and eight-membered rings, an arrangement proposed for the primary product ($AlPO_4$-C) of the metavariscite-dehydration (cf.[79] and Fig. 6). The resulting topology of the $AlPO_4\cdot 1.5H_2O$-framework is given schematically in Figure 13. The circles are $Al(O_P)_4(O_{H_2O})_2$-octahedra, and the composition of the four-connected net is thus $AlPO_4\cdot 1H_2O$; the remaining $0.5H_2O$ is loosely bonded within cavities of the structure and is readily released even at lower temperatures.

In an earlier work[85] on the dehydration and rehydration of neutral AOPH a low hydrate of composition $AlPO_4\cdot 1.67H_2O$ was described; this phase, however, is in fact the new 1.5-hydrate described here.[135] Generally, the reactions that take place upon dehydration and (partial) rehydration of neutral AOPH are rather complex, and involve a number of intermediate phases (see Section 3 and

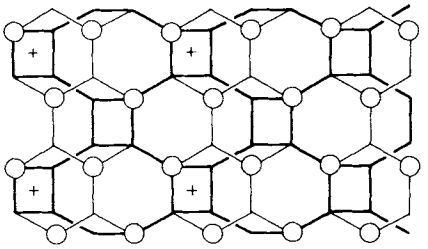

Fig. 13. Topology of the framework (linkage of the layers; projection along [100]) in $AlPO_4 \cdot 1.5\,H_2O$. Al- and P-positions (alternating) with tetrahedral coordination at the corners of the nets; open circles represent Al in octahedral coordination ($Al(O_P)_4(O_{H_2O})_2$) with terminal O_{H_2O}. Upper layer in the projection: net of condensed six-membered rings (6.6.6.-net); lower layer: net of condensed four- and eight-membered rings (4.8.8.-net). Linkage of the layers (coinciding edges of the nets) produces four-membered rings. The + sign indicates the corner point of the unit cell in this projection.

Ref. [105]), so that further investigations are necessary for definite clarification. Here again, the investigation of single crystals should be the most rewarding.

This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie. I wish to thank Prof. Dr. D. Mootz for cooperation and fruitful discussions.

High-Pressure Liquid Chromatography (HPLC) of Proteins

New Analytical Methods (29)

By Gerhard Seipke,* Hubert Müllner, and Ulrich Grau

The application of high-pressure liquid chromatography (HPLC) to proteins has undergone a dramatic development in recent years. Nowadays its many variants expand the repertoire of high-performance analysis methods available to the protein chemist, which, until now, have been dominated by electrophoretic techniques. The advent of gene technology has resulted in a renaissance of protein chemistry. The new analytical and preparative problems that have thereby emerged are often ideally solved by HPLC methods. HPLC has long since ceased to be solely a laboratory technique; HPLC systems are now being developed for the separation of proteins—particularly those of great pharmaceutical interest—on a 100-g scale. The range of applications of analytical and preparative HPLC will be illustrated by two examples of pharmaceutical importance—insulin and interleukin 2.

1. Introduction

Liquid chromatography has become one of the most important biochemical separation methods since its discovery more than eighty years ago. A differential distribution of biopolymers between a stationary and a mobile phase can be achieved by exploiting differences in molecular size, ionic properties, solubility, and polar or nonpolar character as well as specific interactions with other molecules (e.g., enzyme-inhibitor interactions). Earlier, however, the packing materials available precluded rapid high-resolution separations, so that these methods were mainly employed at low pressure for preparative purposes. The analytical sector was dominated by electrophoretic methods.

High-resolution chromatography requires microparticulate column packings with a narrow particle size distribution.[1,2] Although this concept was known very early, its realization in practice took decades since it was necessary to solve several technical problems:

- Pump systems providing constant flow rates at high pressures had to be developed.
- The "soft" gels previously used had to be replaced by pressure-stable materials.
- Columns had to be reproducibly and evenly packed with these fine particles.

Once the instrumental requirements had been fulfilled, the application of HPLC in biochemistry underwent a dramatic development. Within a few years a wide range of new analytical methods have become available to protein chemists. The applications of HPLC (Table 1) are not restricted to analysis, however. The new techniques are being increasingly employed preparatively as well—both in the laboratory and in industrial production.

2. The Construction and Operation of an HPLC Unit

HPLC is of itself not a new method, but rather a refinement of known methods combined with greater instrumental complexity and precision. The successful application of HPLC as a quantitative analytical method requires great care in the choice and purity of the solvent, a highly constant flow rate, and continual checks of column performance.

Table 1. Some applications of HPLC in the chemistry of amino acids, peptides, and proteins.

Analysis
— Amino acid analysis
— Purity control of synthetic peptides, optimization of reaction conditions
— Identification of multiple or mutant forms of proteins
— Molecular weight determination
— Analytical peptide mapping
— Sequence analysis (identification of degradation products)
— Chemical or enzymatic modification (process control and optimization, product characterization)
— Determination of enzyme specificity
— Metabolism studies, identification of prohormones
Preparative separation
— Isolation of natural products from extracts
— Purification of products obtained from chemical synthesis or gene technology
— Purification of modified peptides or proteins, for example, radioactively labeled substances
— Separation of diastereomers
— Isolation of protein fragments for sequence studies

A typical HPLC apparatus (Fig. 1) consists of a high-pressure pumping system, a sample applicator (injector and preinjector), a column, and a detector. It is also possible to include a fraction collector and/or a microcomputer for data processing. Automation is desirable if the instrument is to be employed for routine analytical or preparative purposes.

2.1. Pumps

All HPLC pumps on the market[3] are capable of delivering both organic solvents and aqueous buffer solutions with equally high precision. The pumps must provide a constant flow with little pulsation. These requirements are ideally fulfilled by a non-reciprocating pump resembling a large hypodermic syringe, whose delivery is free of pulsation and almost independent of the back pressure of the column and the viscosity of the solvent. Its use is relatively restricted, however, because of its design, which involves a fixed, relatively large internal volume.

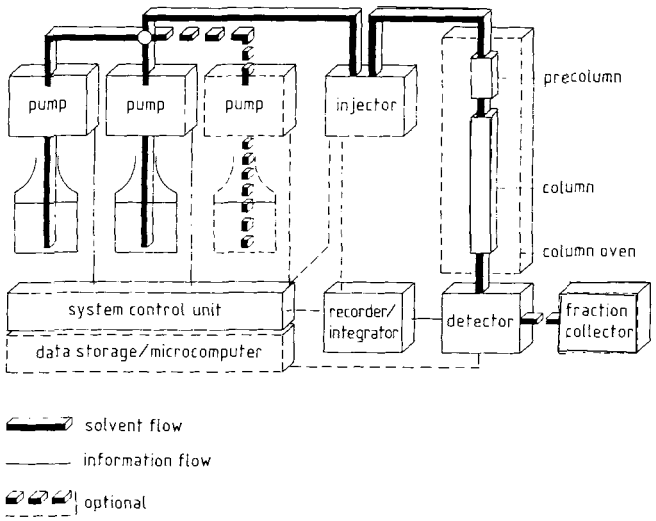

Fig. 1. Basic design of an HPLC system.

The delivery systems most frequently in use employ either short-stroke piston pumps or membrane piston pumps. Complex electronic controls are employed to ensure that the delivery volume set is maintained under changing back pressure (altered compressibility). Optimized pump design reduces the pulsation caused by the movement of the pistons. Further smoothing is usually achieved by hydraulic damping.

2.2. Gradient Formers

The composition of the mobile phase can be varied during the analysis by mixing two or more solvents continuously (gradient elution). This technique predominates in the separation of proteins by adsorption chromatography. Gradient elutions yield peaks of equal sharpness throughout the whole course of elution. In contrast to isocratic elution, in which the solvent composition remains unchanged, gradient elution results in the same detection sensitivity for strongly retarded components as well as a shorter analysis time.[47] Proteins bind cooperatively to more than one portion of the stationary phase.[5-7] Only the simultaneous effect of a corresponding number of molecules of the "displacing agent" (for example, salt in ion-exchange chromatography, organic solvent in reversed-phase chromatography) is able to displace them. From this it can be deduced that there will be an increasingly concave dependence of retention on the elution composition with increasing molecular weight.[4,8,9] In practice, if the displacer concentration is slowly increased, extremely strong adsorption (that is, minimal migration) of the proteins is initially observed. As the concentration is further increased, adsorption and thus retention strongly decreases within a range that becomes narrower with increasing molecular weight and whose position can be extremely different from protein to protein.[7-10] Gradient elution is therefore essential for the separation of complex mixtures of proteins, but its use places great demands on the precision of such delivery systems.

In the great majority of cases the solvents are mixed by employing two separate, adjustable pumps. Binary gradients are sufficient for most applications. A third solvent can be useful for the application of larger volumes of sample in preparative work or for the addition of a second, more strongly eluting solvent at the end of a gradient in reversed-phase chromatography.[11]

2.3. Eluents

The choice of eluents depends, above all, on the separation principle (see Section 3); further limitations are set by the compatibility of the eluents with the stationary phase (see Section 2.5) and with the materials from which the HPLC equipment is constructed. Warnings are often given against the use of buffer solutions containing halides. In practice, however, it is possible to avoid corrosion of the pumps and columns.[12] The choice of buffer components and organic solvents is also dictated by the method and required sensitivity of detection (see Section 2.6). The viscosity must also be taken into account since it not only contributes to the back pressure of the column, but also influences the separation efficiency of a column (measured in theoretical plates N[2,13]).

Filtration of all eluents through a 0.2- or 0.45-μm membrane filter not only protects the pumps, but also improves the long-term stability of the separation columns. Subsequent thorough degassing removes dissolved oxygen, which would make sensitive detection at low wavelengths impossible and could lead to problems when mixing gradients (formation of air bubbles). Sparging with helium is very effective and does not significantly affect the composition of the mobile phase.[14] In the case of pump designs that are sensitive to dissolved helium, degassing can be performed under vacuum or ultrasonically.

2.4. Sample application

The analysis of complex protein mixtures and the re-equilibration of the columns requires a relatively long time. Automatic injection of the samples ensures economical use of the expensive setup. As in the case of manual application, the choice is between fixed sample size (sample loop) and variable sample size (syringe).

2.5. Columns

The chromatographic column is the centerpiece of every HPLC unit. Its design and the type and quality of its packing are decisive for good separation and minimal dispersion of the sample components. In general, steel columns with minimal dead-volume, fixed end-fittings are employed. In addition, economically priced cartridge systems are available, in which ready-packed exchange cartridges are compressed in a corresponding module. Radially compressible plastic cartridges offer the additional advantages that wall effects[15] are avoided and that it is possible to repack the matrix after the formation of cracks.

Most of the commercially available analytical steel columns have a diameter of 4.0–4.6 mm and a length of 10–30 cm. Larger columns are sometimes employed for gel filtration, and, in the case of adsorptive techniques, signifi-

cantly smaller columns have been employed with success.[16-19] The resolution of a column (proportional to $N^{0.5}$[4]) is, in fact, not very greatly dependent on its length. However, from the special elution behavior of macromolecules (see Section 2.2) and simple trial separations, the conclusion should not be drawn that long columns generally fail to offer advantages for the separation of proteins using gradient elution.[20?] According to the gradient theory of *Snyder* et al.,[4] this is only true when short elution times (i.e., steep gradients) are chosen. However, when difficult separation problems require longer elution times (i.e., a shallower gradient), then there is a drastic increase in the influence of column length on the performance of the system.[2,22] If short columns can be employed, they have the advantage of less back pressure (higher long-term stability) and less dilution of the sample.

Theoretically, the column diameter has no influence on the separation performance of the column if the flow rate is suitably adjusted.[21] Because, in addition, the wall effect[15] is of less significance for larger diameters, there is a great potential for increasing the loading capacity for preparative work. Reducing the diameter leads to smaller peak volumes and, hence, to lower detection limits;[21] the "micro-bore" technique (column diameter < 1 mm) has found only occasional application in the protein field so far[23,24] and, like the use of short columns mentioned above, requires increased care with respect to possible peak broadening by the other system components. Suitable prepacked columns are only available with packing materials of low pore diameter (ca. 100 Å), which are less suitable than packing materials with larger pore-size particles (> 300 Å) for proteins with molecular weights of more than 20000.[25-27]

As far as the particle size of the packing is concerned, a compromise must be reached between the highest possible resolution, which improves as the particle size decreases, and the long-term stability of the column packing. At present, the minimum particle diameter is 5 μm for the large pore-size packings needed for the separation of high-molecular-weight biological samples.[21]

Silica gel largely fulfills the most important criteria for a packing material: very small particle size, high mechanical stability, and high porosity. However, it is only stable at pH values between 2 and 7. Organic polymers are suitable for use with basic buffers, but are not yet available with similar small particle sizes and with equivalent pressure stabilities. An easily exchangeable precolumn is highly recommended when working with complicated mixtures (such as cell homogenates). Filtrations or irreversible adsorptions take place at this stage, thus protecting the main column.

Many protein separations can be performed at ambient temperature. However, the temperature affects the resolution, retention, and recovery in all adsorptive techniques.[28-30]

Commercially available ready-packed columns, which are delivered with a test chromatogram, are employed most often. However, columns that are specially supplied for protein chromatography are seldom tested by the manufacturers with appropriate sample mixtures under relevant elution conditions. In practice each user has to test the quality of the column packing, the performance of the whole system, and, in particular, the recovery rate of the proteins. Various model mixtures have been proposed for this purpose in the literature.[31]

2.6. Detectors

UV detection is by far the most commonly applied method of detection in protein separation.[32] The peptide bond absorbs at $\lambda = 210$–230 nm, the absorbance being independent of the amino acid composition.[33] At 210 nm, moreover, the secondary structure is without influence.[34] The sensitivity is 10- to 20-fold higher than at $\lambda = 250$–280 nm, where only the aromatic amino acids absorb. However, working at lower wavelengths restricts the choice of solvent, places greater demands on its purity, and requires the effective exclusion of oxygen. It is scarcely possible to avoid a drifting baseline in gradient elution. Programmable detectors (e.g., diode arrays) can scan the whole available spectrum at various points (usually the peak maxima) in a very short time. This can be of particular value in the analysis of short peptides (e.g., from enzymatic or chemical degradations).[35-37]

In particular cases, the intrinsic fluorescence can be employed with sufficient sensitivity for the identification of peptides rich in aromatic amino acids.[38] Fluorescent detection with on-line, post-column derivatization is of more universal application.[39] With *o*-phthalaldehyde[40] or fluorescamine,[41] derivatives are formed that absorb at higher wavelengths and thus allow unhindered detection in the presence of strongly UV-absorbing buffers. For preparative work, only an aliquot is diverted for detection by means of a switching valve (splitting technique). A cysteine-specific method has also been described.[42]

3. Principles of Separation

3.1. Gel Filtration

Gel filtration occupies a special place among chromatographic separation methods. The separation does not take place on the basis of interaction between the sample, the stationary phase, and the mobile phase, but depends on "sorting" according to molecular size. In ideal gel filtration, proteins are separated on the basis of their distribution between mobile liquid phase and the liquid situated in the pores of the matrix.[43] The elution volume available for separation thus lies between two limiting volumes: the volume of liquid between the particles (V_o) and the total diffusion volume as the sum of V_o and the pore volume V_i. The peak capacity is, therefore, strictly limited. The elution volume V_e of a substance peak is given by

$$V_e = V_o + K_D \times V_i$$

The distribution coefficient K_D is virtually 0 for very large molecules. These cannot diffuse into the pores and are, therefore, eluted most rapidly. For small molecules K_D is 1; they migrate unhindered into all the available pores and are thus subjected to the greatest delay.

In general, a linear relationship between the distribution coefficient and the logarithm of the molecular weight exists in the range $K_D = 0.15$–0.80. Gel filtration can, therefore, be employed for the characterization of proteins when interactions between the protein molecules and the surfaces of the particles can be excluded and the protein is regular in form and not aggregated. Nonideal column behavior can be investigated by means of simple tests.[44]

The resolution of the column depends on its dimensions, the density of the packing, the pore volume, the pore-size distribution, and the peak width. Since the separation only takes place within a limited elution volume, efforts must be made to restrict the volumes of the individual peaks as much as possible.

The peak width is associated with the molecular transport between the phases and reaches its optimum at small particle sizes,[45] low flow rate and viscosity of the mobile phase, and high diffusion coefficient for the protein. From these relationships it can be understood that the limits for sample volume and concentration are lower (ca. 100 μg and 10 μL per mL of column volume) than is the case for adsorption methods.[46]

All the other parameters mentioned are fixed properties of the column packing. Spherical particles can be packed significantly more densely than can irregular ones, so that V_0—the column volume that is not available for separation—only makes up 37% of the total column volume.[44] The maximum volume available for separation is achieved by increasing the pore volume V_i. Here a compromise has to be reached between optimal pore volume and high mechanical stability.[44,46] A narrow pore-size distribution is advantageous for high resolution, but the packing process itself evidently also plays an important role in determining the efficiency of the column.[44]

Of the organic polymer particles developed for gel filtration, the TSK-PW series (Biorad) is finding increasing use; the hydrophobic interactions that are unavoidable in all materials of this type (see Section 3.3) are apparently minimized, thereby allowing very efficient protein separations, particularly in the high-molecular-weight range.[47]

Silica gels exhibit better separation performance in narrow molecular-weight ranges.[48,49] The surface may be treated with hydrophilic organosilanes[50,51] or organic polymers[52] to block silanol groups and prevent adsorption effects. However, the treatment is never complete for steric reasons,[53] so that these materials always exhibit residual ion-exchanger properties. This can be compensated for by the presence of salts in the eluent.[44] Too high a salt concentration should be avoided, however, since it would increase hydrophobic interactions. A new surface treatment variant that imparts greater pH stability to the support is also worthy of mention.[54]

Silica gels are also very stable in the presence of chaotropic salts and detergents. It is possible to employ guanidinium chloride, sodium dodecyl sulfate, urea, and organic solvents to denature the proteins before separation, thereby preventing self-association and increasing solubility.[55–58] However, this can greatly increase the hydrodynamic radius of the protein, which results in displacement of the fractionation range to lower molecular weight. Figure 2 shows the gel filtration chromatograms of two protein standards with two different eluents.

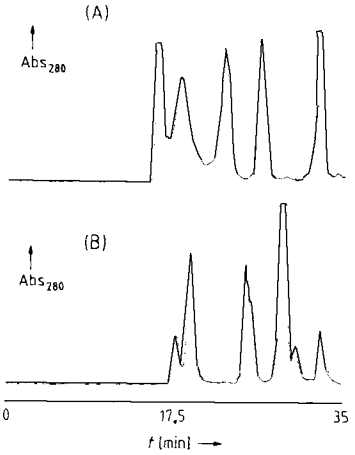

Fig. 2. Gel permeation chromatography of protein standards. HPLC system: Bio Sil TSK, 7.5 mm × 60 cm (Bio Rad), 0.7 mL/min, ambient temperature, Abs_{280} = absorption at $\lambda = 280$ nm; t = retention time. (A): 20 mM phosphate buffer, 0.1 M sodium sulfate, pH 6.8, peaks in the order of elution: thyroglobulin (MW 670000), γ-globulin (MW 158000), ovalbumin (MW 44000), myoglobin (MW 17000), vitamin B_{12} (MW 1350). MW = molecular weight. (B): 20% acetic acid/30% acetonitrile, pH 3.0, peaks in the order of elution: myoglobin (MW 17000), 17.8 min; cytochrome c (MW 12500), 19.1 min; insulin (MW 5850), 24.9 min; insulin B-chain (MW 3400), 25.5 min; phenylazo-Z-Pro-Leu-Gly-Pro-D-Arg (MW 777), 28.7 min; sodium azide (MW 65), 32.7 min). Z = benzyloxycarbonyl.

3.2. Ion-Exchange Chromatography

Because of its amphoteric character, a protein can exist in either cationic or anionic form depending on the pH. A characteristic parameter of proteins is, therefore, the isoelectric point at which the net charge of the protein is zero. The isoelectric point determines the pH of the medium and the choice of the type of ion exchanger. The strength of binding is determined by the number of cooperatively effective ionic groups on the protein, the charge density of the ion exchanger (theoretical capacity), and the ionic strength of the mobile phase. Thus, elution of the proteins can be brought about by a gradient of increasing ionic strength, a pH gradient, or a combination of both. The user has a wide range of possibilities available for influencing retention and selectivity.

Silica gel and its derivatives were the most commonly used ion-exchange supports for a long time and were used in the great majority of systematic investigations of ion-exchange HPLC of proteins.[59] Organic methacrylate-based polymers, which are only available in relatively large pore sizes and which are partially hydrophobic, did not prove to be as useful.[60] Recently, however, hydrophilic organic polymers, such as the above-mentioned TSK-PW series, have become available and provide good results in analytical and preparative separations, at a somewhat lower flow rate and pressure.[61–65] Their stability in the alkaline pH range allows a wide selection of buffer solutions and more efficient regeneration methods, thereby increasing the working lives of the columns, even when crude extracts are separated.[62]

Silica gels are available in a wide range of pore sizes and with a large variety of organic ligands. Strongly acidic and basic exchangers are usually characterized by higher resolution and detection sensitivity, because the better desorption leads to smaller peak volumes. The range of variation of the pH of the mobile phase does not affect the degree of ionization of the exchanger, so that the optimization problem is less complex.[29,66] A particularly stable and efficient masking of nonspecific binding sites on the silica gel surface and a high ion-exchange capacity is achieved when the ionic ligands are cross-linked within a thin polymer film.[67-70] The theoretical capacity in this case is proportional to the total surface area of the particles and, hence, highest for small pore-size material. However, ion-exchangers with wide pores are more accessible to high-molecular-weight proteins and, hence, exhibit a higher effective capacity. The optimization of peak sharpness also plays a crucial role, because diffusion is as unhindered as possible. The best choice for most protein separation problems is a pore size of 300 Å, whereas for molecules with a molecular weight larger than 150000 a pore size of 1000 Å or more is preferred.[16,27,66]

It is usual to elute by means of a salt gradient at a constant pH. Since the displacing power of a range of ions can be completely different for different proteins,[29] the exchange of one displacing ion for another can result in different selectivities. Thus, an astute choice of the salt type can optimize the distribution of all sample components and the resolution of early eluting components as well as improve the recovery of particularly strongly adsorbed proteins.[29]

The retention time of a protein increases as the difference between its isoelectric point and the pH of the buffer increases.[62] The selectivity can also be influenced by varying this parameter, since the shape of the titration curve is characteristic for each protein. A good starting point is often pH 7, which leads, on the average, to the best selectivity in anion- and cation-exchange chromatography.[29] A different pH can be more advantageous for the separation of a particular pair of proteins. This can often only be determined empirically and cannot necessarily be deduced from the titration curves of the proteins.[7]

Other conditions are easier to optimize than the composition of the mobile phase. The total volume of the salt gradient is generally between 5 and 15 column volumes. A reduction of the flow rate and of the steepness of the gradient improve the resolution considerably.[16,59] An increase in the temperature also has a positive effect.[16] The load that present-day columns can accept is high; 2–3 mg of protein per mL of packing volume can easily be separated without loss of resolution.[16,63] Apart from a few exceptions, the recovery rates are greater than 90%.[29,71]

3.3. Hydrophobic-Interaction Chromatography

Hydrophobic interactions play an important role in the folding of proteins and in the stabilization of their tertiary structures.[72] The nonpolar amino-acid side chains of soluble proteins are largely shielded inside the three-dimensional structure. Nonetheless, proteins possess a few hydrophobic points of contact on the surface, which lead to adsorption to a nonpolar stationary phase. This effect was at first observed as abnormal retention behavior in conventional affinity chromatography and then later deliberately exploited for the separation of proteins on alkylated agarose gels.[73-75] Hydrophobic adsorption of proteins on HPLC gel filtration columns has been observed under certain conditions.[44,76] Special phases based on silica gel[77-80] or organic polymer particles[81,82] were later developed for performing this type of separation by HPLC.

The hydrophobic interaction is strong in the presence of high concentrations of ions.[73,74] The type and concentration of the salt are decisive for the retention, which is greater for salts exerting a larger *salting-out* effect on proteins.[79,82-84] The strength of the hydrophobic interaction increases with increasing temperature;[30,79] on the other hand, the retention is reduced by the addition of small quantities of organic solvent or chaotropic reagents (urea, guanidinium chloride).[30,82] Theoretically, the bonding ought to be strongest at the isoelectric point;[85] in practice, however, the pH can affect the retention of different proteins, depending on the matrix, to differing degrees and in different ways, which is probably attributable to the effect of charges on the stationary phase.[82,83] The selectivity of the separation can also be strongly affected by changing the temperature and by addition of organic solvents to the eluent.[30,82,83]

The type of salt is also important for the resolution. Neutral salts with a high salting-out effect are preferred for hydrophilic (weakly binding) proteins, whereas those with a low salting-out effect are preferable for hydrophobic (strongly binding) proteins.[78] The resolution can also be improved by longer columns,[22,82] lower flow rates,[82] and shallower gradients (longer gradient elution time),[22,82] and by the addition of chaotropic agents or organic solvents.[30,82] Lower temperatures are also advantageous,[30,49] Denaturation caused by matrix contact is rare in this method.[22,86] The sample load that the columns can carry and the recovery rate are about the same as those in *ion-exchange chromatography*.

3.4. Reversed-Phase Chromatography

Reversed-phase (RP) chromatography was introduced as early as 1950[87] and has become the preferred method of HPLC because of its wide scope of application.[88] It is basically a variant of hydrophobic chromatography (see Section 3.3). In both cases binding takes place between a nonpolar surface of the protein and the stationary phase, thereby shielding the stationary phase from the polar (aqueous) mobile phase.[89-91] In contrast to hydrophobic chromatography, significantly more nonpolar, i.e., more heavily alkylated, stationary phases, are employed here, so that the proteins bind to the matrix even in aqueous buffers of low ionic strengths. Differential desorption is achieved by applying a gradient with an increasing concentration of organic solvent. On the one hand, this lowers the surface tension of the mobile phase and favors the formation of a solvent shell around the molecule that has been desorbed;[89-91] on the other hand, it favors desorption by means of direct competitive interaction with the protein and the matrix. Several theoretical models are un-

der discussion for the quantitative description of the complex thermodynamic and kinetic phenomena involved in the interaction between stationary phase, eluent components, and sample molecules and particularly the relationship between retention and solvent composition.[92-94]

Many binding sites can participate in the interaction of a protein with the matrix.[5,6,17,95] Hence, adsorption effects predominate rather than a distribution between stationary and mobile phases.[95,96] During gradient elution, the relatively more weakly binding solvent molecules first occupy free contact sites on the matrix and the protein surfaces not involved in binding. When a critical concentration is reached,[9,10,94,97] the protein is suddenly displaced from the matrix surface. This concept of a competitive interaction between matrix, protein, and solvent molecules is the basis of a newer stoichiometric displacement model[8] that explains very well the observed influences of molecular size and solvent composition and is in agreement with the general theory of gradient elution.[4]

The retention of a sample molecule depends on the ratio of the polar to nonpolar amino-acid side chains on the part of the surface that is involved in binding to the stationary phase. In the case of smaller polypeptides (<20 amino acids), it is possible to calculate the retention time accurately in advance from the sum of the relative hydrophobicities of the individual amino acids.[98-101] However, predictions are difficult for some proteins on account of the tertiary structure. Even in the case of B30 analogues of insulin (see Section 4.1 and Fig. 5), the incorporation of particular amino acids leads to a change in the retention time from the predicted value. In addition, under the usual elution conditions for RP-HPLC, possible conformational changes must also be taken into account,[105] which depend on the composition of the eluent and other parameters. In extreme cases they can lead to multiple peaks (native and denatured forms).[106-109]

The behavior of a silica-gel-based matrix is not just influenced by the nonpolar ligands but also, to a considerable extent, by the free silanol groups. This leads to the following phenomenon: with increasing organic solvent concentration, the retention of a given protein first decreases, as expected for nonpolar interactions, but then increases again owing to the silanophilic contribution.[97] Ionic components in the eluent suppress these interactions, leading to the formation of sharper peaks with higher resolution and, in the case of certain ion-pair reagents, allowing milder elution conditions. Only when these factors were included in the optimization of the separation conditions was it possible to overcome the initial difficulties[110] experienced in the RP-HPLC of proteins.

The HPLC user today finds himself confronted with a bewildering array of stationary phases, in which silica gel derivatives predominate. Two wide-pore materials based on organic polymers have recently appeared on the market.[112,113] Their advantage lies in the possibility of effective regeneration by washing with dilute sodium hydroxide solution. Stationary phases with a pore size of ca. 300 Å are best suited for proteins with molecular weights greater than 20000 with respect to loading capacity, resolution, and recovery.[25,26,96,104,114-116] The retention of most proteins is essentially independent of the chain length of the alkyl ligand for the same density of occupation.[115,117,118] The degree of alkylation, on the other hand, is critical for the resolving power and the gentle elution of proteins.[92,93,119-122] Wide-pore particles have the advantage that, because of the limited surface area, an optimal coating density (ca. 3–4 μmol alkyl residue/m^2) is obtained even at a low carbon content (2–4% wt-% C).[120,121] This allows the elution of proteins at low concentrations of organic solvent.[92,93,120] Octyl or octadecyl ligands lead to better masking of residual silanol groups than do ultrashort alkyl residues ($<C_4$).[120] It is recommended that silanophilic interactions be further suppressed by treating the alkylated silica gel with reactive silanes of small size ("end-capping").[93,120]

Electrostatic interactions with free silanol groups lead to very asymmetrical peaks or even to irreversible adsorption of the proteins to the RP matrix. Since the dissociation of the silanol groups is largely suppressed at low pH (<pH 4),[123] the best results are generally obtained in this region.[26,93,103,116,124] Thus, satisfactory protein separations are possible even in dilute hydrochloric acid.[12,23,104,116,117] Various buffer substances, however, are able to change the retention characteristics of proteins owing to ion-pair formation.[92,93,111,125] Examples include phosphoric acid, perchloric acid, perfluorinated carboxylic acids, and alkyl sulfonic acids and their salts. Phosphoric acid decreases[126] and perfluorinated carboxylic acids increase the retention time.[95,127] Cationic components in the eluent affect the matrix properties directly. Ammonium, alkylammonium, pyridinium, and morpholinium ions deactivate silanol groups by hydrogen bonding and electrostatic interactions.[92,128] High concentrations (>0.1 M) of chaotropic salts (e.g., $NaClO_4$, Na_2SO_4) lead to increased peak sharpness and improved elution, particularly on account of the electrostatic shielding of the silanol groups.[100,129-131]

Dilute trifluoroacetic acid has found the greatest application of all buffer systems,[17-19,83,95,96,132-137] whereas longer-chain perfluorinated carboxylic acids have been employed much more seldomly.[95,104,133,138] Trifluoroacetic acid is UV-transparent and easily evaporated and, hence, is also suitable for preparative work. It is particularly recommended, as is dilute formic acid,[139] for the separation of hydrophobic proteins or protein fragments.[95,127] On the other hand, the elution of the structural proteins of polio virus was not possible with any of these systems, but only with highly concentrated formic acid.[140] Pyridine acetate or pyridine formate are also volatile buffers, which have been employed with great success in the pH 3–5 range, that is, for work with acid-labile proteins.[141-145] A disadvantage is that their low UV-transparency necessitates detection at $\lambda = 280$ nm or post-column derivatization (see Section 2.6). Eluents with even higher pH values include ammonium hydrogen carbonate (pH 7.8)[147] and hexafluoroacetone/ammonia (pH 7.2).[148]

The most frequently reported nonvolatile buffer is phosphate,[28,98,100,103,111,149] very often in the form of the tri- or tetraalkylammonium salts[111,150-153] and with the addition of sodium perchlorate.[25,100,129-131] Usually the separations are performed below pH 4, more rarely at higher pH.[154] Separations have also been reported with Tris buffer at pH 7.5.[155]

The organic component must be sufficiently nonpolar to effect desorption of the protein from the matrix; on the other hand, it must be polar enough that the protein does not precipitate. This virtually restricts the choice to acetonitrile and alcohols. Dioxane has been used in the purification of interferon.[156] The eluting capacity increases in the order methanol, ethanol, acetonitrile, propanol, butanol.[93] Changing or combining the solvents allows different selectivities to be obtained.[98, 131, 148, 157–160] Small additions of methoxymethanol can improve the resolution.[92, 149] Propanol is recommended for larger, hydrophobic proteins. Since the concentration of the organic component in the eluate can be kept low, fewer problems are to be expected with precipitation and denaturation.[127, 141] Occasionally, however, peak broadening is observed,[100, 112, 148] which can be reduced by raising the temperature, provided that the proteins are sufficiently stable.[28] In general, both improvements[98] and deteriorations[103, 116, 128] in the resolution have been observed on raising the temperature. The resolution improves for reduced flow rates and shallower gradients.[26, 92, 119, 142]

The elution conditions of RP-HPLC not only reduce the solubility of many proteins, but also can result in conformational changes.[105] In the case of labile proteins this can lead to complete denaturation with irreversible adsorption or precipitation. This is not just a preparative problem, it can also bring into question the accuracy of a quantitative analysis. Examples are available for the successful isolation of functionally intact proteins by RP-HPLC in the presence of stabilizing cofactors or by special treatment of the fractions obtained.[136, 155, 161–163] In some cases, furthermore, certain proteins are eluted with low yield or are initially inactivated.[12] Recent investigations[86, 106, 122, 164, 165] of the mechanism of this process have revealed that, depending on the protein, denaturation processes can occur at various rates during column contact; the degree of denaturation depends on how long the protein is in contact with both the matrix and the solvent. Desorption initiates a refolding to the natural tertiary structure. The kinds of peaks obtained are determined by the relationship between the kinetics of unfolding and refolding and the separation kinetics: a) individual peaks of narrow width are observed when the protein is either especially stable (no denaturation) or the refolding is greatly inhibited (only denaturation product); b) multiple[106–109, 112, 165] or extremely asymmetrical[28, 112, 121, 122, 164, 165] peaks are observed when native and (several) denatured forms are present in equilibrium. Strongly eluotropic solvents, hydrophilic ion-pair reagents, reduced concentrations of the perfluorinated carboxylic acids, or steeper gradients inhibit the denaturation on the stationary phase.[106, 112] This leads to higher recovery rates and a high degree of retention of the native biologically active form.[28, 112, 116, 166] High salt concentrations, on the other hand, can have a negative effect[28, 116] since they intensify the interaction with the matrix. High flow rates and temperatures do not allow sufficient refolding to occur, so that, in the extreme case, only the denatured form is eluted[164, 165] or irreversible binding takes place (memory effect).[112, 165] In those cases high resolutions are obtained,[28] but the recovery is sometimes small.[116]

RP-HPLC is unquestionably one of the most efficient methods of separation. Its greatest potential lies in the separation of closely related proteins and protein derivatives, since selectivity and resolution can be manipulated in many different ways. However, the protein-chemical consequences of the elution conditions must be reevaluated in each case.

3.5. Other Techniques

Adsorption to hydroxylapatite is a central component of one system for the purification of monoclonal antibodies;[167] however, it can also be employed for other separation problems.[168] Affinity chromatography[169] involves biospecific selection from complex mixtures and, thus, places no great demands on elution techniques. The HPLC version of this method, therefore, emphasizes high speed rather than high resolution. Stationary phases are prepared by the user himself by coupling the appropriate ligand to glass,[170] silica gel,[171, 172] or organic polymers.[173] Some ligands have a variety of applications; these include adenosine monophosphate,[171] protein A,[170] lectins,[174] and the pseudo-affinity ligand Cibacron Blue.[175] Ready-to-use columns can be envisaged here. In view of the wide variety of other specific ligands, the use of self-made columns is inevitable. However, the process can be simplified by the use of a pre-packed, pre-activated column, which is then treated by allowing a solution containing the ligand to flow slowly through the column.[176] Chromatofocusing can be carried out with commercially available ion exchangers and buffer solutions.[177, 178] Like its electrophoretic counterpart, the separation depends strictly on the isoelectric point.

4. Insulin

The blood-sugar-lowering hormone insulin is a small protein. It has a molecular weight of 5800 and consists of two peptide chains: the A chain, with 21 amino acid residues, and the B chain, with 30. The two peptide chains are cross-linked by two disulfide bridges. A third disulfide bridge links the cysteine residues at positions 6 and 11 within the A chain.[179, 180]

Insulin has a relatively rigid structure[181] and therefore exhibits relatively high stability. Consequently, it poses a simple problem for HPLC analysis,[182–186] and insulins separated by HPLC generally remain biologically and immunologically active.[187–189] Moreover, insulin is of eminent importance in pharmaceutical research. For these reasons, insulin is ideal for demonstrating the scope of application of HPLC of proteins.

In this connection, it is important for preparative and analytical work that insulin is insoluble near to its isoelectric point at pH 5.4 and dissociates at acidic pH, whereas it forms dimers and hexamers at neutral pH. The hexamer is stabilized by zinc. Separations above the isoelectric point are only successful with zinc-chelating and dissociating additives such as ethylenediaminetetraacetate (EDTA) and alcohols,[190] urea,[191] or detergents.[192]

Insulin is nowadays produced by two important methods, isolation from animal pancreas[193] and genetic engi-

neering. The insulin from the pancreases of three pigs satisfies the requirements of one diabetic for about ten days. Insulin with human sequence can also be produced by semisynthesis from porcine insulin. In contrast to this, the production of human insulin by genetically altered microorganisms, whose carbon source is glycerin or simple sugars, is virtually unlimited.[194-197]

4.1. Semisynthesis of Human Insulin

Human insulin only differs from porcine insulin in the amino acid at position 30 of the B chain. Since lysine occurs at position B29, replacement of alanine (porcine insulin) by threonine (human insulin) is possible using the enzyme trypsin (Fig. 3). Although, in an aqueous medium at a neutral pH, trypsin catalyzes the cleavage of peptide bonds at basic amino acids, at a lower pH and in a suitable

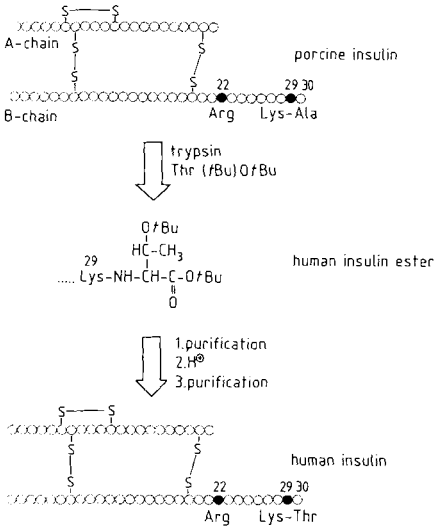

Fig. 3. Semisynthesis of human insulin from porcine insulin.

medium, it can also catalyze the formation of peptide bonds[198] or even directly catalyze the replacement of an amino acid without the formation of an intermediate hydrolysis product.[199-201] This replacement is formally equivalent to aminolysis of the acyl-enzyme intermediate. HPLC analysis of reaction mixtures suggests a direct exchange mechanism in human insulin semisynthesis (Fig. 4): After reaction with threonine *tert*-butyl ester, the OH group of which is protected by a *t*Bu group, des-(B30) insulin is not detectable; only the desired side-chain-etherified human insulin ester (III), nonconverted porcine insulin (II), and des-(B23-B30) insulin (I) are in evidence. The latter is an unwanted by-product originating from proteolysis at arginine (B22) and, for steric reasons, is apparently only formed in small amounts.[202]

A series of B30 derivatives, whose behavior in reversed-phase HPLC corresponds exactly with the change in hydrophobicity[100] of the *C*-terminal region of the B chain (Fig. 5), have been produced by semisynthesis.[201] However, two derivatives—thr(B30) insulin and tyr(B30) insulin—for which local structural changes (e.g., the presence of an additional hydrogen bond) can be postulated, do not follow the linear relationship.

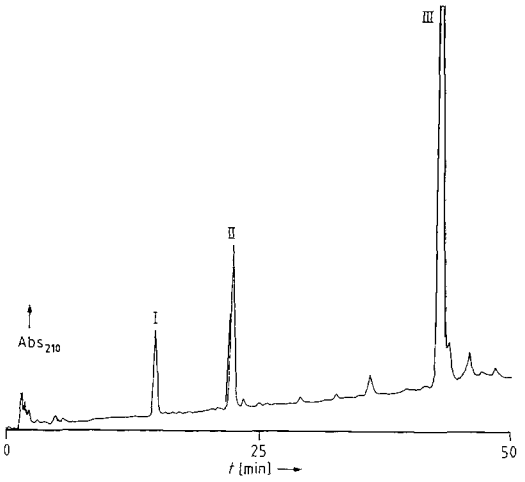

Fig. 4. HPLC chromatogram of the crude reaction mixture obtained in the semisynthesis of human insulin. HPLC system: Rad Pak C8, 10 μm, 8 × 10 mm (Waters), 50 mM tetraethylammonium phosphate, 0.25 M sodium perchlorate, 10% acetonitrile, pH = 3.0 (buffer A), and 50 mM tetraethylammonium phosphate, 90% acetonitrile, pH = 3.0 (buffer B), gradient from 28% to 40% B, 1.5 mL/min, ambient temperature, detection at $\lambda = 210$ nm; t = retention time. I-III: see text.

Retention time of various B30 derivatives of insulin as a function of relative hydrophobicity of the amino acid at position B30 in the following RP-HPLC systems: **TFA**: Nucleosil 300-7 protein-RP, 4.6 × 125 mm (Macherey-Nagel), 0.1% trifluoroacetic acid, pH = 2.1, gradient from 30% to 40% acetonitrile, 0.8 mL/min, ambient temperature. **TEAP**: Rad Pak C18, 5 μm, 8 × 100 mm (Waters), composition of buffers and other conditions as for Figure 4.

4.2. Production of Human Insulin by Gene Technology

Except for the final purification steps, the procedure used to produce human insulin from microorganisms by gene technology differs fundamentally from that used to isolate it from pancreas. The insulin from pancreas is present in the biologically active, native spatial structure in all isolation steps. The preliminary stages in gene technology, on the other hand, involve inactive and generally poorly soluble precursors, which, for instance in the *E. coli* cell, are deposited in large quantity in the form of inclusion bodies (Fig. 6). These precursors have to be converted into the native structure by sophisticated protein chemistry—supported by appropriate chemical analysis (Fig. 6). The proinsulin concept presented here exploits the natural folding tendency of the physiological insulin precursor,[203,204] in which the A and B chain are connected by a

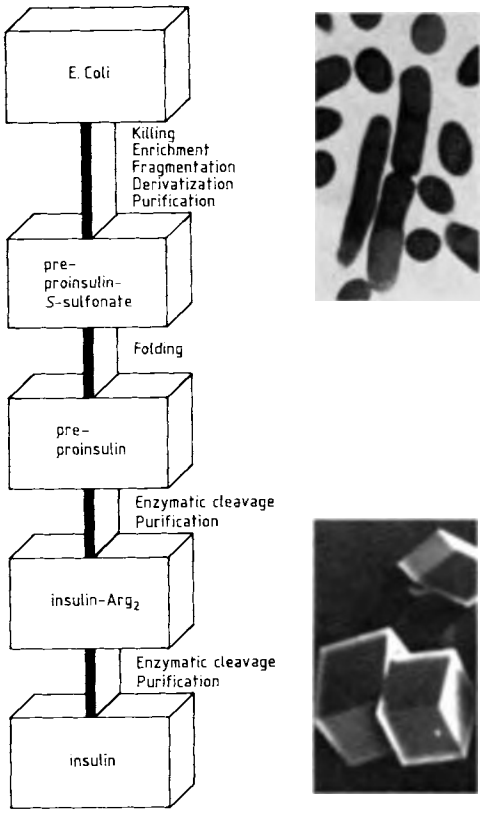

Fig. 6. Left: Principal steps in the production of human insulin from genetically engineered microorganisms. Right: Electron micrographs of *E. coli* cells (above) producing the insulin precursor and of the rhombohedral insulin crystals (zinc-stabilized hexamer) obtained by this process (below).

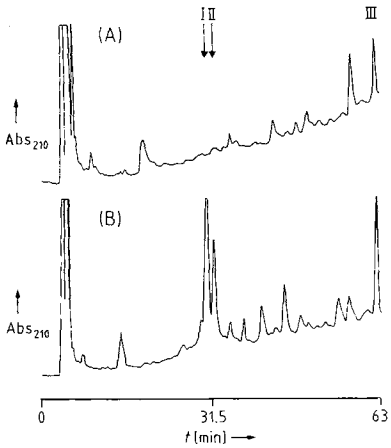

Fig. 7. HPLC chromatogram of the reaction mixtures obtained in the preparation of human insulin by gene technology: after chemical fragmentation of the insulin precursor (A) and after further modification by oxidative sulfitolysis and fractional precipitation (B). HPLC system: PLRP-S 300 A, 4.6 × 250 mm (Latek), 0.1 M hexafluoroacetone/NH_3, 2% butanol, 8% acetonitrile, pH = 7.0 (buffer A), 0.1 M hexafluoroacetone/NH_3, 9% butanol, 81% acetonitrile, pH = 7.0 (buffer B), gradient from 20% to 35% buffer B in 60 min, 0.8 mL/min, 40°C. I–III: see text.

peptide segment, the C peptide. The alternative concept, namely, separate production of the A and B chains, results, on recombination of these two chains, in a low yield and numerous by-products. Nevertheless, this was historically the first method for producing human insulin by gene technology and was also successfully used on a technical scale.[194]

For the isolation of insulin, the following procedure can be used: the microorganisms are harvested following fermentation, and the insulin precursor is enriched. The precursor is then cleaved chemically at methionine residues, thereby resulting in the formation of "preproinsulin"—a proinsulin with an *N*-terminal extension consisting of several amino acids. The six cysteine residues of preproinsulin, which are initially present in a form not precisely defined (*E. coli* lacks an enzyme system that specifically links the disulfides), are converted by sulfitolysis[205] to *S*-sulfonates. At this stage, the product is detectable by HPLC for the first time. In the reaction mixtures available prior to this, there are either too many by-products or the molecules of interest become irreversibly adsorbed on the reversed-phase support. This clearly demonstrates one of the limitations of HPLC analysis (Fig. 7A).

The preproinsulin *S*-sulfonate is a markedly acidic molecule. For reasons of solubility, the acid-mobile phases normally used in reversed-phase HPLC are therefore not feasible. A neutral hexafluoroacetone system,[148] in which the preproinsulin *S*-sulfonate (I) can be analyzed separately even from a precursor fragment (II) that is chemically very similar, is used instead (Fig. 7B). In contrast to fragments I and II, fragment III does not contain a cysteine residue and therefore elutes as a sharp peak without prior derivatization (Fig. 7A).

The preproinsulin *S*-sulfonate is not only an intermediate with a key role for purification and chemical analysis; the naturally folded preproinsulin is also available from it in high yields.[206,207] The folding and correct linking of the two interchain disulfide bridges can be examined by fingerprint analysis. The following requirements must be met:

- the formation of a limited number of fragments of interest
- a minimum of nonspecific reactions
- the identification of individual fragments
- a rapid and efficient method of separation and detection

Proteolytic fragmentation by *Staphylococcus aureus* protease V8 under special conditions in connection with HPLC analysis fulfills these requirements.[208] *S. aureus* protease V8 cleaves *C*-terminally at glutamate; the theoretical—and also experimentally verified—fragmentation pattern is shown in Figure 8. Fragments I, II, and III are of particular importance for the analysis. Fragment III contains the *C*-terminal region of the B chain and is present irrespective of whether preproinsulin *S*-sulfonate, disulfide-bridged preproinsulin or other species of the same sequence are present. It serves as internal standard for quantification purposes. In contrast, fragments I and II are only found in full amount when their disulfide bridges are present to the full extent. By-products, such as incorrectly disulfide-bridged species, would produce new peaks at the expense of peaks I and II. Fingerprint analysis of preproinsulin *S*-sulfonate does not produce either fragment I or II. Preproinsulin *S*-sulfonate, reduced with an excess of mercaptan, shows correspondingly low proportions of

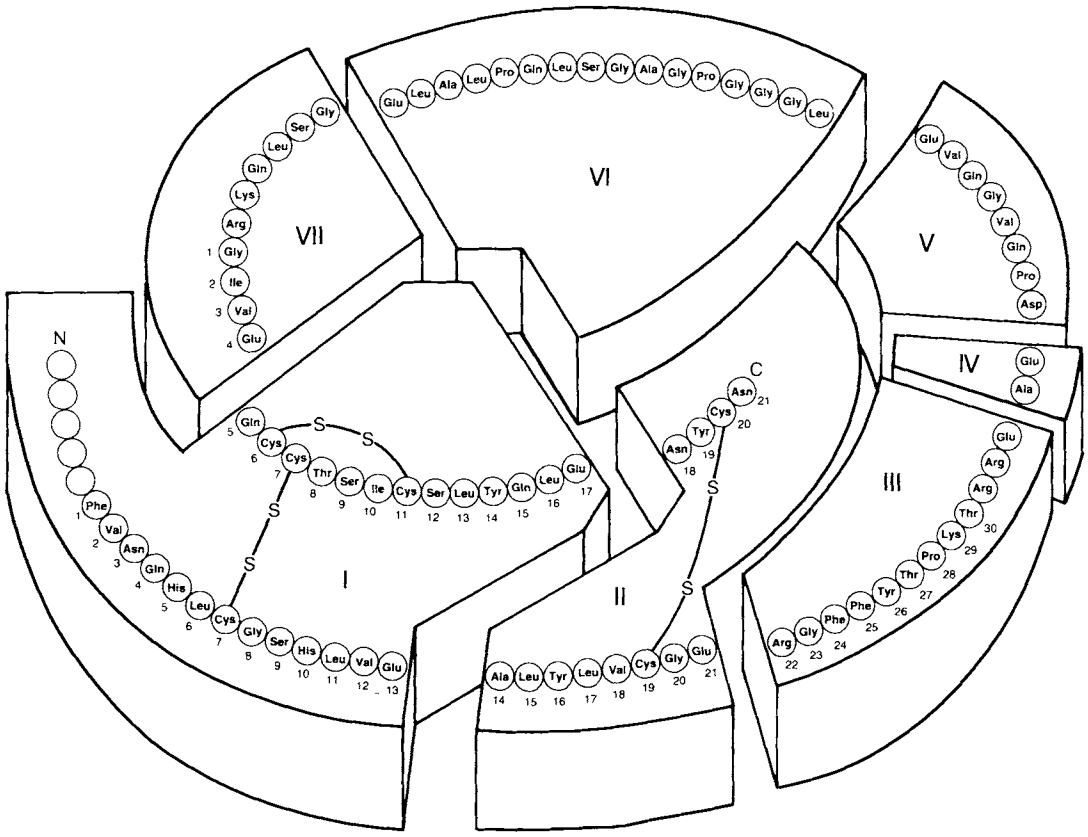

Fig. 8. Peptide fragments of preproinsulin formed by proteolysis with *S. aureus* protease V8. The prefix pre indicates that the proinsulin is lengthened at the *N*-terminal end by five amino acids (white circles).

both fragments. For comparison, an *S. aureus* protease V8 fingerprint of correctly folded preproinsulin is shown in Figure 9.

HPLC analysis is also essential in the next step, namely, in following the enzymatic processing of preproinsulin to insulin-Arg_2 and insulin-Arg (Fig. 10). Proteolysis of preproinsulin with trypsin occurs mainly at six arginine or lysine residues (see Fig. 8). However, cleavage at arginine(A0) at the *N*-terminal end of the A chain, at arginine(B0) at the *N*-terminal end of the B chain, and at arginine(B32) are preferred kinetically. Cleavage at lysine(B29) yields des-Thr(B30) insulin in small amount, while cleavage at arginine(B22) to give des-(B23-30) insulin—as found in semisynthesis—virtually does not occur, apparently for steric reasons.

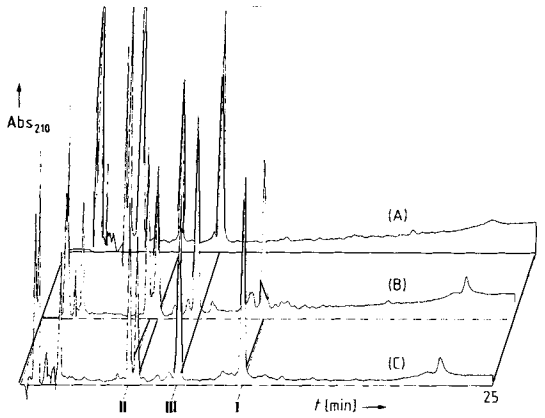

Fig. 9. HPLC analysis (fingerprints) of *S. aureus* protease V8 digests of (A) preproinsulin *S*-sulfonate, (B) preproinsulin reduced with excess thiol, and (C) correctly folded preproinsulin. HPLC system: Rad Pak C 18, 5 μm, 8 × 100 mm (Waters), buffers as in Figure 4, gradient from 20% to 45% buffer B in 25 min. I–III correspond to the fragments in Figure 8.

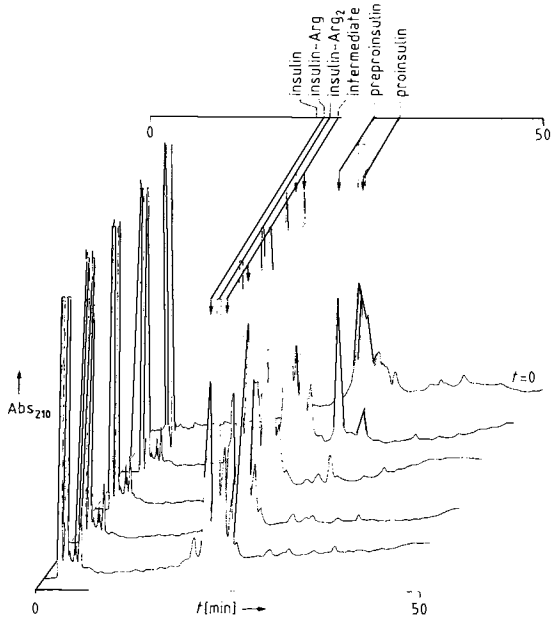

Fig. 10. HPLC chromatogram of samples taken at various times after incubation of preproinsulin with trypsin. HPLC system: Rad Pak C 18, 5 μm, 8 × 100 mm (Waters), buffers, gradients, and other conditions as in Figure 4.

Separation of des-Thr(B30) insulin, human insulin-Arg_2, and human insulin by reversed-phase HPLC is dependent to a large extent on whether perchlorate is present in the eluent. When a triethylammonium phosphate system without perchlorate is used as the mobile phase (Fig. 11), the sequence of the elution of these species is the reverse of that obtained when a tetraethylammonium phosphate system containing perchlorate is used (Fig. 10). However, HPLC analysis of the product mixture obtained by cleavage of purified human insulin-Arg_2 with carboxypeptidase B, which was performed using the perchlorate-free triethylammonium system (Fig. 11), affords distinctly less sharp peaks than analysis with the system containing perchlorate (see also Section 3.4).

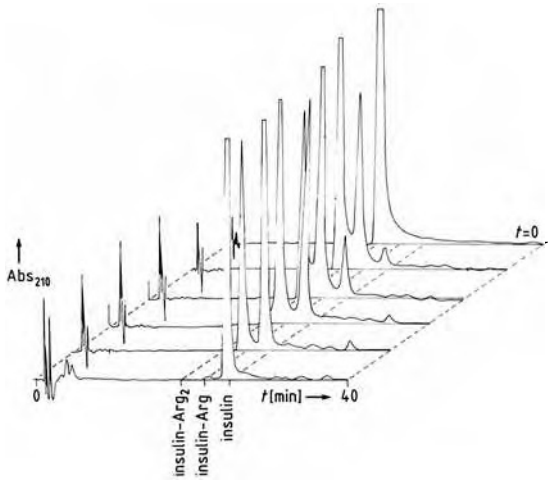

Fig. 11. HPLC chromatogram of samples taken at various times after incubation of human insulin-Arg_2 with carboxypeptidase B. HPLC system: Rad Pak C 18, 6 μm; buffer A: 0.25 M triethylammoniumphosphate, 20% acetonitrile, pH = 3.0; buffer B: 0.25 M triethylammonium phosphate, 50% acetonitrile, pH = 3.0, gradient from 19% to 32% buffer B in 40 min, 1.5 mL/min, 35 °C.

4.3. Purity Assessment and Quality Control

In order to ensure optimum tolerance and minimum immunogenicity, all insulins used in therapy nowadays are of high purity. In 1925, a few years after the discovery of insulin, a preparation containing 5 units per mg was used therapeutically; in 1935, the insulin content was about 20 units per mg. The highly purified insulin available at present has 28 units per mg. Foreign proteins in the end product are consistently in the ppm range or less and are only detectable by radioimmunoassay. The same applies to proinsulin, which is very efficiently separated by gel and ion-exchange chromatography. Ion-exchange chromatography (Fig. 12) yields a product that, moreover, is largely free of insulin derivatives formed during production and storage. For instance, under the acidic conditions of ethanol extraction, the acid amide groups of asparagines—in particular those of Asn(A21)—are hydrolyzed to aspartate, the desamido insulins[209] or their ethyl esters being formed.

HPLC permits identification of the individual products and the isolation of high-purity fractions (Fig. 12). It may likewise be used for quality control of the pure substance (e.g., with respect to species identity) or of the finished pharmaceutical as well as for checking the stability of insulins to storage at different temperatures and over several years.

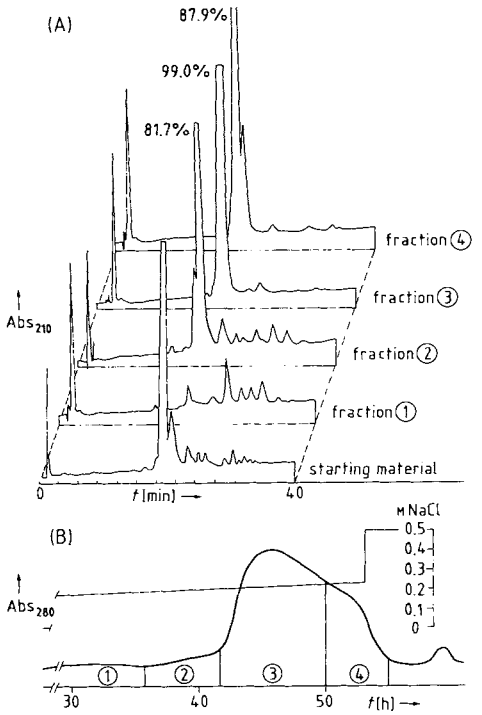

Fig. 12. Ion-exchange chromatography of crude, semisynthetic human insulin (B) and HPLC analysis of pooled fractions (A). The conditions of the ion-exchange purification on a diethylaminoethyl(DEAE)-cellulose matrix with detergent-containing eluents and a sodium chloride gradient are described elsewhere [192]. HPLC system: see Figure 4.

Gel-permeation HPLC is nowadays also used routinely for quality control and stability tests (Fig. 13); by this method, high-molecular-weight insulin derivatives, such as dimers originating as a result of transamidation, can be detected. For clinical therapy only highly purified insulins are used—for instance, they must not contain more than 10 ppm of proinsulin or more than 1% of high-molecular-weight derivatives.[210]

Detection of the absence of porcine insulin in semisynthetic human insulin poses a somewhat complicated analytical problem. Although it is possible to separate human and porcine insulin by HPLC, desamido(A21) human insulin, which can be a companion substance, coelutes with porcine insulin. Detection can be successfully carried out, however, at the preliminary stage of the human insulin es-

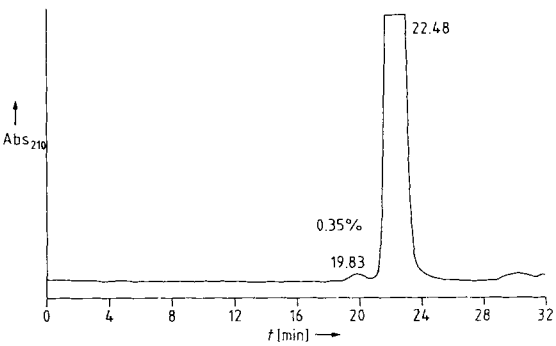

Fig. 13. Gel permeation HPLC of human insulin-Arg_2 obtained by gene technology. HPLC system: Bio Sil TSK 125, 7.5 × 600 mm (Bio Rad), 20% acetic acid, 30% acetonitrile, pH = 3.0, 0.7 mL/min, ambient temperature, detection at $\lambda = 280$ nm, sample load 200 μg.

ter,[199] or by the *S. aureus* protease V8 fingerprint method. If porcine insulin is present in the human insulin, fragment III (Fig. 8) will exhibit a small after-peak. On the other hand, if desamido(A21) human insulin is present, this after-peak will occur at fragment II (Fig. 14).

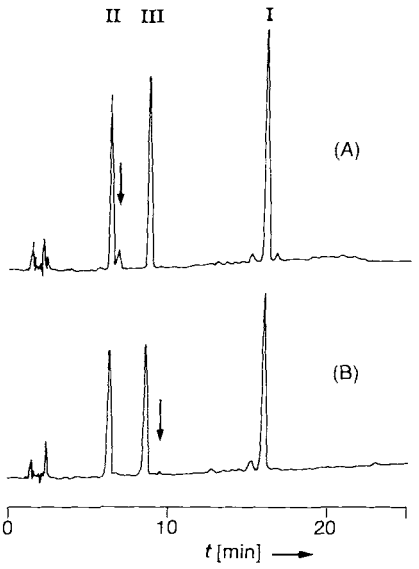

Fig. 14. HPLC chromatogram of *S. aureus* protease V8 digests of mixtures of (A) human insulin contaminated with desamido(A21) insulin and (B) human insulin contaminated with porcine insulin. HPLC system: see Figure 9.

4.4. Stability of Insulin in Dosage Devices

The pharmacokinetics of insulin in healthy individuals is extremely complex. The pancreas excretes a small amount of insulin as basal supply and larger amounts after glucose intake. Although the blood sugar then increases slightly, it settles down very rapidly at approximately 80 mg/dL. Substitution therapy with insulin administered subcutaneously can only very inadequately imitate these kinetics. Nowadays, a relatively constant blood-sugar level of 150–200 mg/dL is considered to be ideal. Such a profile (Fig. 15) is only possible when insulin preparation and food intake are well adapted to each other. Such high blood-sugar values, however, are considered at least partly responsible for various late complications of diabetes.[211–213]

The normal excretion of insulin in healthy individuals can be simulated by means of an infusion system (Fig. 15, right). Such infusion systems, in miniaturized form, are now in clinical trial. Externally worn devices, by means of which insulin is supplied subcutaneously via a catheter, are commercially available,[214] while implants are still at the development stage.[215] With implants, insulin is delivered into the abdominal cavity or vascular system, the reservoir being refilled from time to time through the skin.

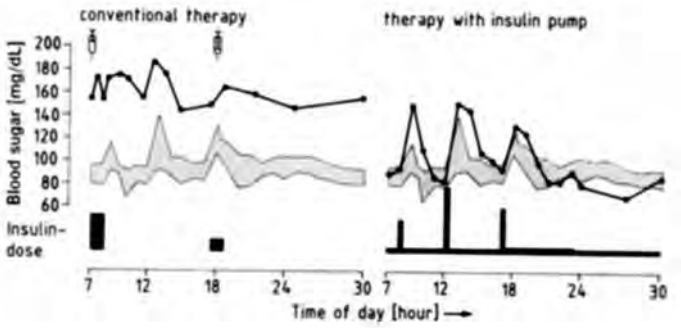

Fig. 15. Comparison of average blood-sugar levels of twelve type I diabetics under conventional therapy with Depot-H-Insulin Hoechst® (left, Prof. Skrabalo, Zagreb 1982) and of a different group of patients under therapy with external infusion devices (right, adapted from *Rizza* et al. [223]). The range of blood-sugar levels in healthy subjects is shown as shaded area.

Early in the development of these systems, however, a severe problem emerged: insulin is not stable in neutral solution under the conditions found in dosage systems. Denatured, biologically inactive insulin usually precipitates within a few days.[216,217]

Acidic insulin solutions (pH = 3) are comparatively stable physically (i.e., against denaturation). Under the conditions in implants, however, a number of modified products form within a refill cycle of four weeks; consequently, native insulin is ultimately only present in traces (Fig. 16). The stability of insulin in acidic solutions in dosage devices, as shown by HPLC analysis, is accordingly insufficient for human administration.[218]

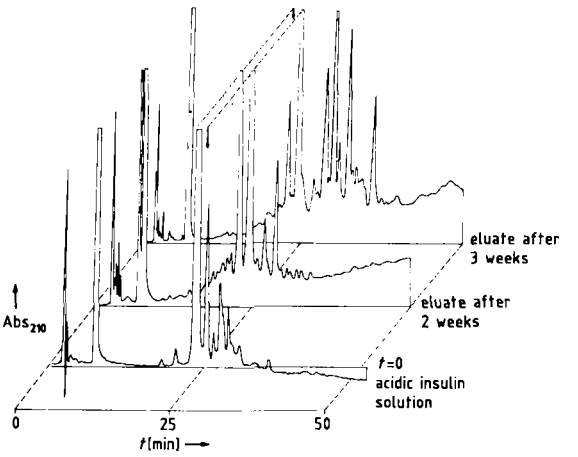

Fig. 16. HPLC chromatograms of acid porcine insulin (pH = 3.0) at refill and after passage through an implantable dosing device (240 μL/day) with 2 and 3 weeks of constant shaking at 37°C. The arrows indicate native (retention time 24 min) and desamido(A21) insulin (retention time 25 min). The latter is present in small amounts at $t = 0$ (arrow) and increases initially due to the acidic medium; native insulin decreases continuously, with the formation of several new species different from desamido(A21) insulin. HPLC system: see Figure 4.

Adsorption can be regarded as the initial step in surface denaturation of proteins.[219] Adsorption of insulin to hydrophobic interfaces can be prevented in neutral medium by the addition of a small amount of a surface-active substance.[219,220] Such an insulin solution is comparatively stable not only physically but also chemically, on account of the neutral pH. HPLC analyses have shown that insulin delivered through a pump at 37°C undergoes hardly any more changes than would be the case under conditions of elevated temperature alone (Fig. 17). A specific derivative eluting in HPLC with a retention time of 1.25 relative to insulin is thereby formed and can be isolated by preparative HPLC in a butanol/ethanol/water system.[208] It is a monomeric insulin, which is modified in the *N*-terminal region of the B chain, possibly at B3[221] and which has full biological activity and an immunogenicity as low as that of human insulin.[222]

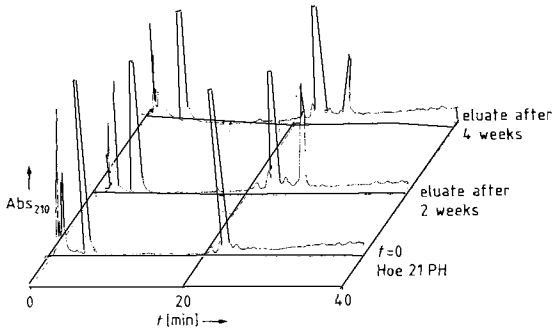

Fig. 17. HPLC chromatograms of a stabilized, neutral human insulin preparation (Hoe 21 PH) tested under identical conditions as described in Figure 16.

5. Further Applications of Analytical and Semipreparative HPLC in Protein Chemistry

At the present state of development, all conventional column-chromatographical methods are transferable to the HPLC version. Column materials and pumps also tolerate buffer systems such as those used in gel filtration, ion-exchange (Fig. 18), hydrophobic-interaction (Fig. 19), or affinity chromatography (Fig. 20). The resolution attainable is, in many cases, comparable in every way to that of the electrophoretic method. However, separation by HPLC is not restricted to size and charge differences. Furthermore, HPLC enables a smooth transition to the preparative scale with good recovery and, except in gel filtration, enrichment from very dilute solutions.

A good example is the isolation of colony stimulating factor (CSF) from human urine by hydrophobic-interaction HPLC.[224] Thymosin β4 could be detected in various cell culture extracts after rough preenrichment and subsequent RP-HPLC.[146] Several separation principles are generally combined; direct recovery of inhibin from follicular fluid was successfully carried out by gel filtration and RP-HPLC,[225] and ion-exchange and reversed-phase HPLC proved to be appropriate for isolating γ-interferon.[226] Semipreparative techniques are widely used for the characterization of proteins. The speed, reliability, and sensitivity of sequence analysis of proteins was decisively improved by HPLC methods; nowadays, the primary structure of proteins can be determined with sample sizes in the microgram range. Again, these amounts can be optimally obtained by HPLC.[18,23,227]

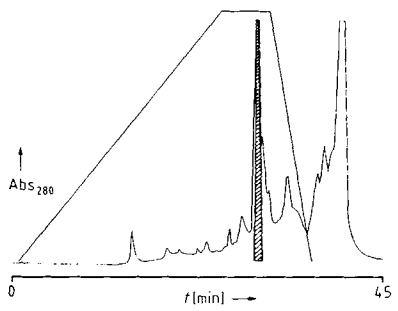

Fig. 18. Isolation of glucose-6-phosphate dehydrogenase by ion-exchange chromatography of a crude bacterial extract (300 μg). HPLC system: Protein Pak 5 PW, 7.5 mm × 7.5 cm (Waters), linear gradient from 0.02 M Tris/HCl, pH = 8.5, to 0.02 M Tris/HCl, 0.5 M NaCl, pH = 8.5, in 25 min, 5 mL/min, detection at $\lambda = 280$ nm; 0.1 absorption units full. Recovery of activity and protein was 100% and 81%, respectively (with permission of Millipore-Waters, Eschborn, FRG).

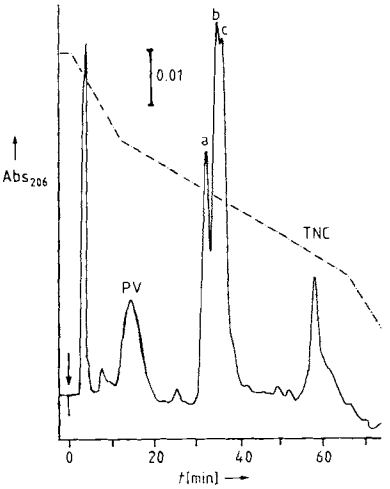

Fig. 19. Separation of various Ca^{2+}-binding proteins by hydrophobic-interaction chromatography. HPLC system: TSK-Phenyl-5PW, 7.5 mm × 7.5 cm (LKB), gradient from 1.5 M Na_2SO_4 in 0.1 M phosphate buffer, pH = 7.0, 1 mM Ca^{2+} to 0.1 M phosphate buffer, pH = 7.0, 1 mM Ca^{2+} in 74 min as indicated (---), 0.75 mL/min, detection at $\lambda = 206$ mm. Parvalbumin (PV), troponin C (TNC), and calmodulins from bovine brain (a), tetrahymena pyriformis (b), and paramecium (c) were recovered with more than 90% (from [258] with permission of Academic Press).

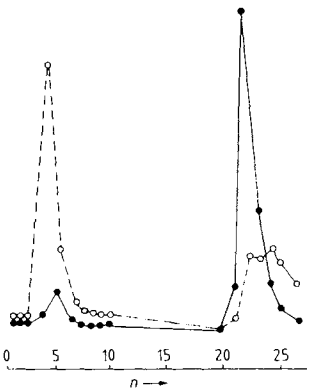

Fig. 20. Affinity chromatography of acetylcholinesterase (AChE) from a crude extract (1 mL). n = fraction number. HPLC system: Ultraaffinity-EP, 4.6 mm × 5.0 cm (Beckman), derivatized with procainamide (8 mg); sample loading (1 mL) with 0.1 M potassium phosphate, pH = 7.0; elution with 0.1 M decamethonium salt in 0.1 M potassium phosphate, pH = 7.0, 0.15 mL/min, detection at $\lambda = 280$ nm (○---○) or by measurement of AChE activity (●---●). Fivefold enrichment with 75% recovery in 2.5 h. (With permission of Beckman Instruments, Munich, FRG.)

The isolation of membrane-bound proteins is somewhat more problematic; the resolutions customarily obtained with water-soluble proteins are rarely achieved here. Successful use of ion-exchange chromatography in the presence of nonionic or zwitterionic detergents has been described.[228,229] Antigenicity is preserved by such mild separating conditions.[230] This can be of particular importance in isolating viral proteins, which are of use in obtaining antisera for diagnosing viral infections or in developing synthetic vaccines.[231,232] However, there are also reports that, under drastic RP-HPLC conditions, the isolated pro-

teins were still suitable for producing antisera to native viral proteins even though they could no longer be identified by antibodies to the native structure.[140,231,232]

HPLC is meanwhile also being widely used in the purification of radioactively labeled polypeptide hormones and antibodies for radioimmunological determinations. The high selectivity of RP-HPLC can be utilized to separate molecules labeled at different positions and, consequently, to optimize the reaction conditions, remove by-products, and isolate individual species.[233,234] A high degree of specific activity and stability is thereby obtained. The purification of antibodies can be carried out equally efficiently by hydroxylapatite[167] or hydrophobic-interaction chromatography,[49] or by ion-exchange chromatography alone[235] or in combination with gel filtration.[236]

The purely analytical application of protein HPLC is much less common. In the most recent European pharmacopeial directives, HPLC methods are included in the case of insulin only. This will definitely change, however, when, as a result of gene technology, a number of new pharmaceutically useful polypeptides and proteins become available. The insulin example shows what possibilities are offered by HPLC for process optimization and quality control, in particular for the separation of microheterogeneities caused by processing.

The wide range of applications in the diagnostic field have still not been fully explored. Interesting examples are the identification of abnormal insulins and proinsulins in hyperinsulinemic patients,[183,237] the analysis of genetically dependent hemoglobin variants,[238,239] the characterization of glycosylated hemoglobins caused by metabolic disorders,[240] the separation of receptor isoforms,[241] and the determination of immunoglobulin E in serum by affinity chromatography.[242] Certain isoforms of transferases may be connected with myocardial infarction;[243] specific growth factors were detected by HPLC in the sera of cancer patients.[244] In qualitative serum screening, electrophoresis, with its high sample throughput, is unparalleled; HPLC, however, may be employed irrespective of the sample concentration and is particularly of advantage where quantitative analyses are concerned.[239,240,242]

6. Preparative Separation of Proteins by HPLC

Large-pore silica gels with minimal carbon coating[92,93,115,116,119–222,245] are one of the basic prerequisites of preparative RP-HPLC.

The TP material from Vydac (TP = totally porous) particularly meets the requirements for the preparative separation of proteins.[17,246] Due to the minimal carbon coating and residual saturation of silanol groups by double bonding (i.e., a second derivatization with very short ligands), this material permits selective separations to be performed, and, despite low capacity, the yield obtained is good. The spherical 15–20-μm particles can be dry-packed. With radially compressible plastic cartridges, a simple but efficient separation system is obtained.

For preparative purposes, volatile buffers are most commonly used as solvent systems. The trifluoroacetic acid/acetonitrile system is most often used, with considerable success.[17,127,136] The counterion effect results in sharp peaks, and the products can be obtained salt-free after freeze drying. Relatively sensitive proteins can be separated by pyridine/acetic acid or by pyridine/formic acid[26,247] at pH 4–5. Here too, the proteins can be isolated salt-free. Although acetonitrile is one of the best eluents (sharp peaks), the less toxic propanol, which is stronger in eluotropic power, and mixtures of propanol and butanol are being used to an ever increasing extent[25,115,166] in order to keep the impact of the denaturing organic phase on the protein as low as possible.

Interleukin 2 will be used to exemplify that direct transference of an analytical separation to the preparative scale is possible.

6.1. Interleukin 2

Interleukin 2 (IL-2) is an immunologically active protein that, like γ-interferon, interleukin 1, and CSF, is now attracting great attention as a result of the progress achieved in gene technology. It plays a central role in the immune system during an immune reaction (Fig. 21). IL-2 is the proliferation factor that is necessary for the increase in activated T and B lymphocytes—the blood cells responsible for specific immune reaction. When the body comes in contact with an antigen, e.g., with a virus-transformed cell or fragments thereof, the antigen is first eliminated by the macrophages. The macrophages digest the antigen and express parts of it on their surface, together with other essential indicator proteins. At the same time, they release a signal protein, interleukin 1, which activates the lymphocytes. By means of interleukin 1 and the antigen on the macrophage surface, the T-helper lymphocytes specific to this antigen are activated; they react to this activation by production of a number of messenger substances, including interleukin 2. Interleukin 2 binds to the lymphocytes, which, subsequent to activation by the antigen and interleukin 1, express the receptor for interleukin 2. The binding of IL-2 to the receptor drives the cells to proliferation as long as IL-2 is present.

The cell division initiated by IL-2 binding leads to the specific defense reaction of the immune system. The number of reactive cells is increased by a factor of 100–1000. IL-2 is consequently an immunostimulator and is of interest for a whole series of therapeutic applications. Studies

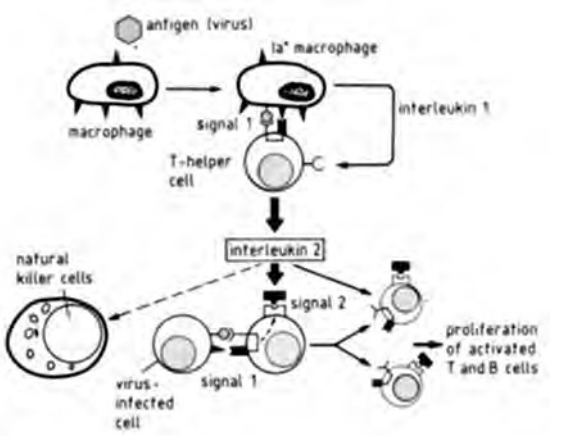

Fig. 21. Role of interleukin 2 in immune response (adapted from [259]).

performed at the National Cancer Institute of the United States of America have shown that IL-2 can also be successfully used in the treatment of tumors.

Human IL-2 was initially enriched in trace amounts from supernatants of activated lymphocytes and partially purified by RP-HPLC.[249-251] Elucidation of the nucleotide sequence by *Taniguchi* et al.[252] made possible the production of human IL-2 by gene technology. The protein consists of 133 amino acids with a molecular weight of about 15000. Two of the three cysteine residues form a disulfide bridge[253] (Fig. 22), which is essential for biological activity. After the nucleotide sequence—and hence the amino acid sequence—had been elucidated, human IL-2 was cloned and expressed[252, 254, 255] and has ever since been available in therapeutic quantities. IL-2 has also been obtained from yeast, as well as from *E. coli*. The specific activity of the natural molecule glycosylated at Thr3 (Fig. 22) is identical to that of glycosylated IL-2 from yeast and to that of nonglycosylated IL-2 from *E. coli*. It is clear from this that glycosylation is not essential to the activity.

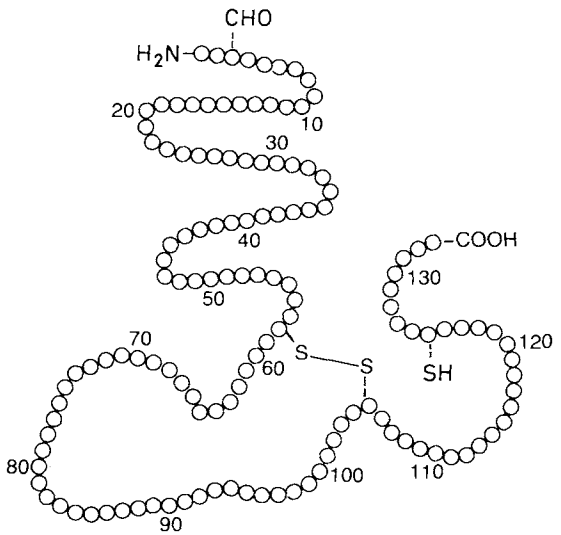

Fig. 22. Primary structure of IL-2 with the essential disulfide bond and the glycosylation site (CHO).

The physical properties of the nonglycosylated protein, however, complicate purification by traditional methods since, in *E. coli*, the protein is present as an aggregate in inclusion bodies. It is insoluble in conventional buffers and can therefore be relatively easily enriched. This is achieved by washing the material with buffers of different ionic strength, with and without detergents or organic solvents; foreign proteins and other cell constituents are thereby flushed out and IL-2 is enriched. This raw material is then extracted with a mixture of acetic acid and alcohols. Such an extract contains up to 40% IL-2, which is subsequently purified directly by RP-HPLC. Due to the considerable hydrophobicity of IL-2, the protein is only eluted after all impurities.

The initial studies using an analytical column and the trifluoroacetic acid/acetonitrile solvent system gave excellent separations and showed no memory effect (i.e., elution of protein, strongly bound in denatured form, in the subsequent runs) by precipitated IL-2, despite the large concentration of acetonitrile required for the elution. Rechromatography of 20 μg of IL-2 led to an elution of approximately 18 μg, i.e., a recovery of 90%.

The conditions of the analytical separation were first transferred to a semipreparative scale (2-cm column). After optimization of flow rate and elution gradient, we were already able to isolate IL-2 in milligram amounts. For preparative separation, we used radially compressible plastic cartridges (5.7 cm × 30.0 cm) filled with large-pore Vydac material. Despite the larger particles (15–20 μm), the quality of separation of IL-2 on such a cartridge is comparable to that on analytical columns (Fig. 23). About 60 mg of high-purity pyrogen-free interleukin 2 was obtained per run.

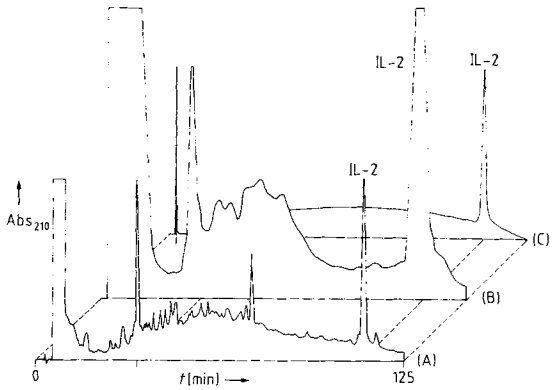

Fig. 23. Analytical and preparative HPLC separation of recombinant IL-2 from *E. coli*. (A) Analytical HPLC of an extract obtained with acetic acid/butanol. HPLC system: Hipore C18, 4.6 mm × 25.0 cm with guard column (Bio Rad); eluent A: 0.1% trifluoroacetic acid in water; eluent B: 0.1% trifluoroacetic acid/80% acetonitrile in water; gradient from 35% to 85% B in 60 min, 1.5 mL/min, detection at $\lambda = 210$ nm. (B) Preparative HPLC of 60 mg crude IL-2. HPLC system: Prep Pak radially compressed cartridge, 5.7 cm × 30.0 cm (Waters) with TP 218, 15–20 μ, 300 Å (Vydac), gradient as described for (A), 50 mL/min, detection with a 1/50 split. (C) Analytical HPLC of the material obtained in (B). HPLC system as in (A). The curved baseline results from an overlapping of the n-π* transition of the free acid with the π-π* transition of the $CF_3CO_2^{\ominus}$ anion [257].

It is well known that, in chromatography, the recovery of hydrophobic proteins can be increased when a coating of silica gel with relatively short alkyl chains, such as C_3, C_4, or C_6, is used. The proteins are less strongly bound and also often require a smaller proportion of organic phase for the elution.

The advantage of shorter alkyl chains could also be demonstrated in the case of IL-2. On C_{18} material, the yield decreased substantially after a single overload. The initial separating characteristics and initial yield could only be reestablished by regeneration with 60% acetic acid/guanidinium hydrochloride. In contrast, the C_4 material was relatively insensitive to overloading. Accordingly, for preparative, routine purification work, C_4 material should be given preference to C_{18} material.

6.2. Other Protein Purifications on a Preparative Scale

In contrast to IL-2, which can be obtained by means of preparative HPLC in pure and highly active form, many other proteins undergo partial unfolding and denaturation upon RP-HPLC owing to the pH conditions, organic eluents, and adsorption effects. By careful choice of the stationary phase and elution system and by appropriate

further treatment of the fractions, it is also possible, however, to purify enzymes such as trypsin and alkaline phosphatase without loss of activity.[135,256] For instance, a preparation of trypsin purified on RP-18 is free of other proteolytic activities to the extent that it can be used for highly selective peptide cleavages, as in sequence analysis.

Whereas the preparative separation of proteins with a molecular weight greater than 20000 is still limited to a few examples, the isolation and purification of antibodies with a molecular weight of around 180000 by high-pressure ion-exchange and hydroxylapatite chromatography has become generally accepted. A complete system for purifying monoclonal antibodies is available commercially under the name MAPS.[167]

7. Summary and Outlook

Within the last few years, HPLC versions of all conventional chromatographic techniques have been utilized in protein chemistry. Efficient separation systems have been developed and are now being used increasingly in fields that previously were a domain of electrophoretic methods. While the advantages of electrophoresis lie in the huge number of parallel analyses possible (e.g., in serum screening), HPLC impresses by the speed of the individual analyses with direct detection of the components. Newly developed supporting materials made of extremely small nonporous particles ($<2\,\mu m$) promise even further improvements. The high-resolution separations can also be extended to preparative HPLC. The development here is aimed at offering, at as reasonable a price as possible, stationary phases with relatively coarse particles, which can easily be packed into large columns by the user and can be operated with considerable long-term stability.

A crucial problem is the biocompatibility of stationary and mobile phase. Gel filtration and ion-exchange chromatography are carried out under approximately physiological conditions. Separations on reversed phase, however, still involve the risk of protein denaturation, even if considerable efforts have been made to reduce this problem, e.g., by using detergents. Solutions of this kind are often specific for a particular protein and can rarely be generalized. Hydrophobic-interaction chromatography separates according to criteria similar to those of RP-HPLC but, in principle, under milder conditions. By this means, higher recovery rates of biologically active proteins are achieved. For this reason, considerable further progress can be expected in this relatively new field.

We wish to thank Dr. H.-H. Schöne for his interest in these studies and for helpful discussions. We also wish to thank C. Müller and R. Lohfink for their help in preparing the manuscript.

Reduced Cobalt-*meso*-Tetraphenylporphyrin Complexes: Synthesis and Structure of $[Na(thf)_3]_2[Co(TPP)]$

By *Stefano Ciurli, Sandro Gambarotta, Carlo Floriani,* Angiola Chiesi-Villa,* and *Carlo Guastini*

In cobalt-porphyrin chemistry it is generally assumed that the diamagnetic anion $[Co(TPP)]^{\ominus}$ with d^8-Co^I is formed as sole reduction product of cobalt(II)-*meso*-tetraphenylporphyrin [Co(TPP)] **1**—independent of the amount and nature of the reducing agent and the reaction conditions.[1] This anion is one of the most popular metallic nucleophiles used in inorganic chemistry, and the experimental conditions under which it can be generated without forming other reduced species requires definition.[2] Only very recently an X-ray structure analysis of $[Co(TPP)]^{\ominus}$ in the salt $[(2,2,2\text{-crypt})K]_4[Co(TPP)]Cl_3 \cdot H_2O$ was reported.[3] We now report on the product that is formed upon reduction of [Co(TPP)] with two equivalents of sodium sand.

When a solution of **1** in tetrahydrofuran (THF) was stirred with two equivalents of sodium sand until all sodium disappeared, a brown solution formed; upon subsequent addition of Et_2O, $[Na(thf)_3]_2[Co(TPP)]$ **2** crystallized as a brown solid[4] (yield ca. 52%).

$$\underset{\mathbf{1}}{[Co(TPP)]} + 2\,Na \xrightarrow{THF} \underset{\mathbf{2}}{[Na(thf)_3]_2[Co(TPP)]}$$

At 298.0 K, complex **2** has a magnetic moment μ_{eff} of 2.22 BM, thus indicating one unpaired electron. Reaction of **2** in THF with an equimolar amount of **1** led to formation of a red-brown solution; upon addition of Et_2O and cooling at −8 °C, $[Na(thf)_3][Co(TPP)]$ **3** was obtained as a violet diamagnetic crystalline solid (yield ca. 83%).[5]

$$\underset{\mathbf{2}}{[Na(thf)_3]_2[Co(TPP)]} + \underset{\mathbf{1}}{[Co(TPP)]} \longrightarrow 2\underset{\mathbf{3}}{[Na(thf)_3][Co(TPP)]}$$

Complex **2** poses two fundamental questions: 1. Is the formulation of the Co^0 complex correct? 2. Which d-configuration describes the ground state? An analysis of the structural parameters can help in answering these questions.[6]

Figure 1 shows an ORTEP plot of complex **2**, which is isomorphous with the recently reported iron(0) complex $[Na(thf)_3]_2[Fe(TPP)]$.[7] The cobalt atom is a crystallographic center of symmetry; the two $[Na(thf)_3]^{\oplus}$ ions are located at equal distances above and below the plane of the porphinato ligand. Some bond lengths of the anion are given in Table 1.

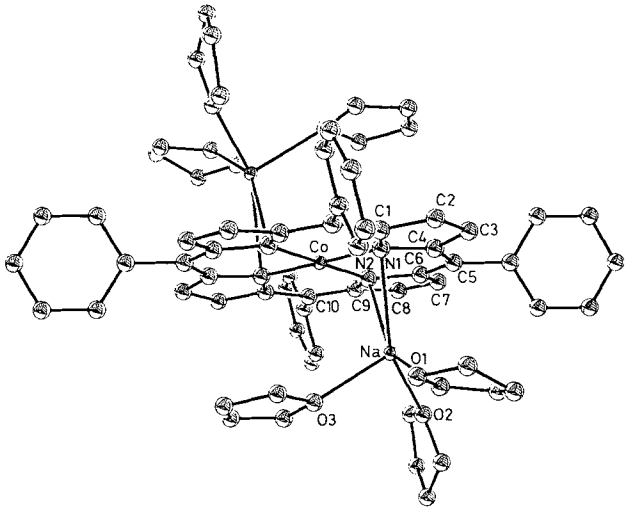

Fig. 1. Perspective ORTEP diagram of the structure of $[Na(thf)_3]_2[Co(TPP)]$ **2** in the crystal.

Table 1. Comparison of the bond lengths (average) [Å] of [M(TPP)] complexes (M = Co, Cu) [a].

Bond	$[Co(TPP)(Pip)_2]$ [10] [b]	$[Co(TPP)]^{\ominus}$ [3]	$[Co(TPP)]^{2\ominus}$	[Cu(TPP)] [11]
$M-N_p$	1.987(2)	1.942(3)	1.971(3)	1.981(7)
$N-C_\alpha$	1.380(2)	1.397(3)	1.400(5)	1.383(12)
$C_\alpha-C_\beta$	1.444(3)	1.434(3)	1.422(6)	1.427(16)
$C_\beta-C_\beta$	1.344(3)	1.337(7)	1.356(6)	1.335(23)
$C_\alpha-C_m$	1.393(2)	1.380(3)	1.390(6)	1.398(13)

[a] C_α and C_β are the α- and β-C atoms of a pyrrole ring; C_m is a methine C atom. [b] Pip = piperidine.

The conformation of the porphinato core in $[Co(TPP)]^{2\ominus}$, whose maximum deviation from planarity is −0.0105(6) Å for C2, is not unusual. The dihedral angles between the peripheral phenyl rings and the core are 75.7 and 76.1°. The interaction between the two $[Na(thf)_3]^{\oplus}$ ions and the $[Co(TPP)]^{2\ominus}$ ion is that of a contact ion-pair. The rather long Na-N distances (Na-N1, 2.766(5); Na-N2, 2.757(5) Å) are comparable with those in the iron(0) complex[7] and with those in a cryptate complex.[8] We can assume here also that they correspond to a bonding interaction.[7] The plane through Na-N1-N2 forms a dihedral angle of 83.4(1)° with that of the anion. The Na-O distances are unusual, ranging from 2.312(5) to 2.341(4) Å.[9]

In Table 1 averaged bond distances are compared for $[Co(TPP)(Pip)_2]$,[10] $[Co(TPP)]^{\ominus}$,[3] $[Co(TPP)]^{2\ominus}$, and [Cu(TPP)].[11] Following the arguments used by *Reed* et al.[7] for the reduced forms of [Fe(TPP)], complex **2** can be viewed as a resonance hybrid of a porphinate with d^9-co-

balt(0) at the center and a porphinate radical anion with d^8-cobalt(I) as central atom:

$$[Co^{0}(TPP)]^{2\ominus} \longleftrightarrow [Co^{I}(TPP^{\odot})]^{2\ominus}$$

For final confirmation of the radical anion character of complex **2**, further studies are necessary. Present considerations, however, suggest that the cobalt(0) designation should be used as a label of convenience only. The above findings closely parallel those in iron chemistry concerning the two reduced forms $[Fe(TPP)]^{\ominus}$ and $[Fe(TPP)]^{2\ominus}$,[7] though a significant difference exists between the stability of the reduced form as a function of the metal.[1,3,7] A significant aspect of these structures which can be deduced from the structural determinations of the doubly reduced species $[M(TPP)]^{2\ominus}$ [M = Fe, Co], is that the reduction products occur in tightly ion-paired forms in the solid state. Current efforts are aimed at finding a relationship between the structure in the solid state and in solution. Such ion-pairs have already been found to exist in salen-type compounds (salen = *N,N'*-ethylenebis(salicylideneaminato)) both in solution[12,13] and in the solid state.[7,9,13,14] In these complexes, the simultaneous presence of acidic (alkali cation) and basic (cobalt) sites close together in the same molecular structure is responsible for the so-called 'bifunctional' fixation of CO_2 and other reactions,[13,15] which are not observed in the case of such complexes with only a single reactive site.

Epoxidation of Olefins with Elemental Fluorine in Water/Acetonitrile Mixtures

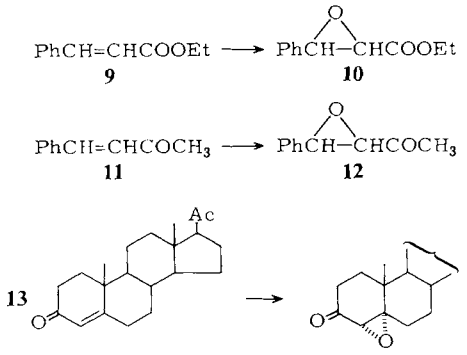
By *Shlomo Rozen** and *Michael Brand*

In the last few years we have shown that elemental fluorine, which, since its discovery one-hundred years ago, had been in a state of hibernation as far as organic chemistry was concerned, can in fact be a versatile fluorinating reagent.[1-7] We report here a general reaction of F_2 that leads, in contrast, to fluorine-free derivatives, namely, the facile synthesis of epoxides from olefins using fluorine in water/acetonitrile mixtures.

There are several methods for the synthesis of epoxides, including the reaction of olefins with peracids, H_2O_2, or XOH (X = Cl, Br; subsequent elimination of HX).[8] Most of these reactions, however, proceed slowly, need strongly basic or acidic medium, and often afford unsatisfactory yields.

When dilute fluorine (10% in N_2) is passed through dry acetonitrile or distilled water at 0°C, only a small amount of oxidizing agent is produced, which is inactive toward olefins. When a similar N_2/F_2 mixture is passed through a well-agitated solution containing 400 mL of acetonitrile and 20 mL of distilled water, however, an oxidizing solution is obtained. When it was added to *cis*-cyclooctene **1** in $CHCl_3$ at −15°C, reaction was complete within 1 min. After neutralizing the reaction mixture with $NaHCO_3$, we were able to isolate *cis*-epoxycyclooctane **2** in 85% yield. The epoxidation is stereospecific, as is evident from the conversion of *trans*- and *cis*-stilbene, **3** and **5**, respectively, into *trans*- and *cis*-2,3-diphenyloxirane, **4** and **6**, respectively.[9] Both reactions were complete within one minute in a yield of over 80%.

7 $CH_3(CH_2)_9CH{=}CH_2 \longrightarrow CH_3(CH_2)_9{-}CH{-}CH_2$ **8**



Terminal olefins are usually more sensitive toward strong oxidizing agents. However, even such olefins react

[**] This work was supported by the Fund for Basic Research of the Israel Academy of Science and Humanities.

practically instantaneously to give the corresponding oxiranes in high yields: for example, 1-dodecene **7** was converted into **8** in a yield of over 90%.

Conjugated enones, which are much more resistant to epoxidation, undergo oxidation if the ratio of oxidizing agent to alkene is increased from 1.2:1 to 2.5:1. Thus, ethyl cinnamate **9** was converted into the corresponding epoxide **10**[10] within one minute in 80% yield. Benzylideneacetone **11** and progesterone **13** underwent rapid epoxidation to give **12** (m.p. = 45 °C[11]) and **14** (m.p. = 177 °C[12]), respectively, in yields of 85% and 80%.

Acetonitrile is known to act as a carrier for an oxidizing agent. It reacts with H_2O_2 to form peroxyimidic acid **15**, an intermediate that has not been isolated, but which reacts with some olefins to form epoxides.[13] This epoxidation reaction, however, usually requires several hours at elevated temperatures, and electron-poor olefins such as enones do not react.

Since no oxidizing solutions are formed with fluorine unless both CH_3CN and H_2O are present, CH_3CN must be essential for the formation of the oxidizing agent. A crucial step is presumably the formation of hypofluorous acid, HOF,[14] which then reacts with CH_3CN. The $F_2/CH_3CN/H_2O$ system offers promise as a useful method for fast, low-temperature, high-yield epoxidations.

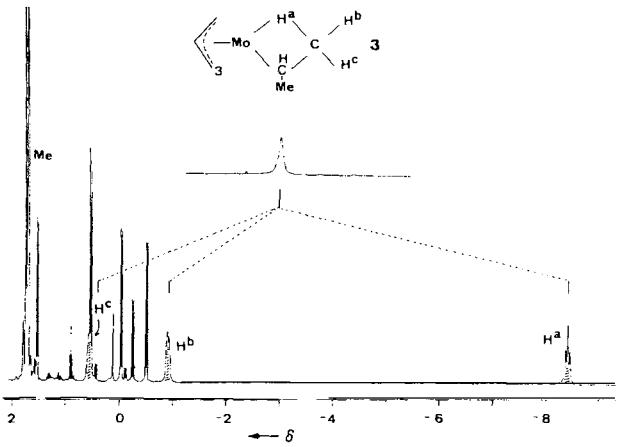
$[MoR(\eta^3\text{-}C_3H_5)_3]$, R = Alkyl: Alkylmolybdenum Complexes with Agostic C–H→Mo Bond**

By *Reinhard Benn, Sigrid Holle, Peter W. Jolly,* Richard Mynott,* and *Carlos C. Romão*

Earlier we reported the conversion of the binuclear molybdenum complex **1** into the ligand-stabilized alkylmolybdenum complexes **2** [Eq. (a)].[1,2] We discuss here the reactions of **1** with Grignard reagents in the absence of stabilizing ligands [Eq. (b)].

Treatment of **1** with isopropylmagnesium chloride in ether at −78 °C results in the formation of a yellow compound $[MoiPr(\eta^3\text{-}C_3H_5)_3]$ **3**, which decomposes in solution above ca. −10 °C. The ^{1}H-NMR spectra at various temperatures indicate that **3** contains an alkyl group having an agostic hydrogen atom (Fig. 1):[3] at −120 °C the three H atoms of one of the methyl groups are magnetically inequivalent with the agostic H atom absorbing at $\delta = -8.43$. At higher temperatures exchange of these protons occurs and at −50 °C only one signal is observed ($\delta = -2.90$). The second methyl group is not involved in this process (the associated doublet is sharp at all temperatures). Furthermore, there is no evidence for transfer of the agostic H atom to the metal—at least within the temperature range studied (−30 °C to −120 °C).



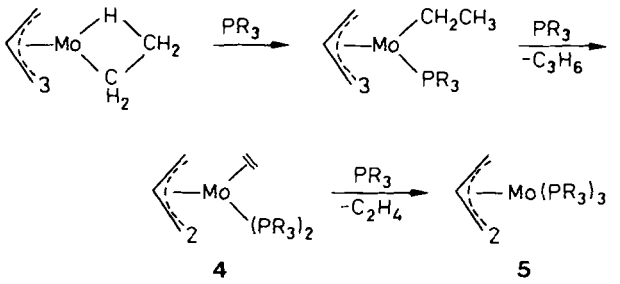


Fig. 1. Part of the ^{1}H-NMR spectrum of **3** (400 MHz, [D$_8$]toluene) at −120 °C (below) and −50 °C (above).

The effect of the agostic interaction is also observed in the ^{13}C-NMR spectrum of **3**: as expected, two signals are observed for the diastereotopic isopropyl methyl groups, but one of them experiences an unusually large upfield shift relative to the other ($\delta = 7.3$ and 27.5). The ^{13}C chemical shifts are not temperature dependent (down to $-115\,^{\circ}C$), but, whereas at $-60\,^{\circ}C$ in the proton-coupled spectrum a quartet is observed for the high-field group, ($^1J_{C,H} = 122$ Hz), at $-115\,^{\circ}C$ this becomes a triplet of doublets ($^1J_{C,H} = 138$ Hz (t), $^1J_{C,H} = 88$ Hz (d)).

We have prepared a series of related [MoR(η^3-C_3H_5)$_3$] complexes where R = Et, *n*Pr, *i*Pr, *n*Bu, *t*Bu, *cyclo*-C_6H_{11}, $(CH_2)_2CH{=}CH_2$, and $(CH_2)_3CH{=}CH_2$. In all cases the agostic interaction β-C-H → Mo is observed. In the absence of β-H atoms, either no reaction is observed (e.g., **1**/Me_3CCH_2MgCl) or a binuclear complex is formed (e.g., **1**/MeMgI or **1**/MeLi), while the reaction of **1** with 2-methylallylmagnesium chloride leads to the formation of [Mo(η^3-2-MeC_3H_4)(η^3-C_3H_5)$_3$].

R = CH_3, OCH_3

Scheme 1.

Treatment of the ethylmolybdenum complex with trimethylphosphane or trimethylphosphite leads to the cleavage of the agostic bond to give [(η^3-C_3H_5)$_3$Mo(L)Et], which reacts with a second ligand molecule to give the η^2-ethylenemolybdenum complex **4**,[5] as the result of what is presumably an intramolecular transfer of a β-H atom to an η^3-allyl group. The ethylene molecule can be displaced by a third ligand molecule to give **5**, which we previously prepared by reacting **1** with lithium in the presence of excess ligand.[2]

Experimental Procedure

3: **1** (3.2 g, 12.58 mmol) was dissolved in ether (50 mL) and *i*PrMgCl (12.58 mmol in ether) was added slowly at $-78\,^{\circ}C$. After the initially pink suspension had turned yellow, it was filtered to give a bright yellow solution, which was evaporated to dryness at $-78\,^{\circ}C$. Yield: 2.1 g (65%); correct elemental analysis. ^1H-NMR ([D$_8$]tetrahydrofuran (THF), $-60\,^{\circ}C$): allyl group 1: $\delta = 3.91$ (*meso*), 3.38 (*syn*, $^3J = 7.7$ Hz), 1.75 (*syn*, $^3J = 7.7$), 2.36 (*anti*, $^3J = 12.6$), -0.49 (*anti*, $^3J = 11.0$); allyl group 2: $\delta = 3.82$ (*meso*), 2.43 (*syn*, $^3J = 8.2$), 1.53 (*syn*, $^3J = 8.4$), 3.42 (*anti*, $^3J = 12.9$), -0.02 (*anti*, $^3J = 10.5$); allyl group 3: $\delta = 3.34$ (*meso*), 2.84 (*syn*, $^3J = 8.2$), 3.28 (*syn*, $^3J = 7.5$), 0.57 (*anti*, $^3J = 11.4$), 2.68 (*anti*, $^3J = 10.7$); isopropyl group $-120\,^{\circ}C$; $\delta = 2.49$ (C_α-H, ^3J(H,Me) = 6.6), 1.72 (Me), 0.54 (C_β-H^b), -0.93 (C_β-H^c), -8.43 (Mo-H^a); $^2J(H^a,H^b) = 8.0$, $^2J(H^a,H^c) = 8.4$.

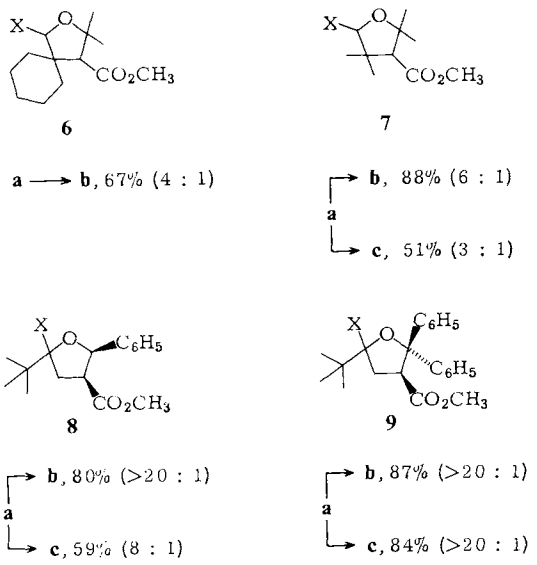
Diastereoselective Synthesis of Functionalized Tetrahydrofuran Derivatives from γ-Lactols**

By *Christiane Brückner, Hiltrud Lorey,* and *Hans-Ulrich Reissig**

Dedicated to Professor Siegfried Hünig on the occasion of his 65th birthday

Cyclic hemiacetals of type **1** (γ-lactols) can be smoothly reduced to the cyclic ethers **2** with triethylsilane/$BF_3 \cdot OEt_2$,[1] a method that we employed in the synthesis of methyl 3-tetrahydrofurancarboxylates.[2] Other silylated nucleophiles, such as allyltrimethylsilane **4**, cyanotrimethylsilane **5**, or silyl enol ethers, were only used in special cases for the direct reaction of hemiacetals according to **1** → **3**.[3]



The large number of recent reports in which the substitution of RO and RS groups as well as halogens on anomeric C atoms—especially of sugar derivatives—was described is evidence of the large interest in this type of reaction.[4] We show now that the free OH group can also be substituted effectively and sometimes with high diastereoselectivity.

When the readily available γ-lactols **6a**–**9a**[2,5] are allowed to react with allyltrimethylsilane **4** or cyanotrimethylsilane **5** in the presence of $BF_3 \cdot OEt_2$ (dichloromethane, $-78 \rightarrow 20\,^{\circ}C$), the 5-allyl- or 5-cyano-substituted meth-

Scheme 1. Synthesis of methyl 5-allyl-3-tetrahydrofurancarboxylates **6b–9b** ($X=CH_2-CH=CH_2$) and methyl 5-cyano-3-tetrahydrofurancarboxylates **7c–9c** ($X=C\equiv N$) from the γ-lactols **6a–9a** (X = OH) and allyltrimethylsilane **4** or cyanotrimethylsilane **5**, respectively, in the presence of $BF_3\cdot OEt_2$ as promoter. The *trans* : *cis* ratios of the products are given after the yields in parentheses.

yl 3-tetrahydrofurancarboxylates **6b–9b** and **7c–9c**, respectively, are isolated in good yields (Scheme 1).[6] Because boron trifluoride etherate has been successfully used until now, the effect of other Lewis acids on yields and on the stereochemical course of the substitution has not yet been investigated. The reaction of **7a** and **9a** with silyl enol ethers or with trimethylvinylsilane was unsuccessful even in the presence of $TiCl_4$. That both bicyclic compounds and simple tetrahydrofuran derivatives can be synthesized is demonstrated by the preparation of the allylated products **10–12**[6] (yields in parentheses), which were obtained analogously from the corresponding γ-lactols with allyltrimethylsilane **4**/$BF_3\cdot OEt_2$.

10 (85%) **11** (57%) **12** (40%)

The substitution might take place via oxonium ions, which are formed upon treatment of the γ-lactols with Lewis acids. Preferential attack of the nucleophile from the more accessible side would then lead to the observed products. Because the structural assignments of **6b**, **7b**, **7c**, and **8c** appear to be well established on the basis of the spectroscopic data,[7] we assume that the other main products in Scheme 1 also have the *trans* configuration. In the case of **7** and **8**, cyanotrimethylsilane **5** is less selective than allyltrimethylsilane **4** (even switching from **5** to *tert*-butyl(cyano)dimethylsilane does not change the *trans* : *cis* ratio in the case of **7c**).

Because γ-lactols are readily accessible[8] and allyl or cyano groups are easy to modify, the synthetic method described here should allow access to a variety of tetrahydrofuran derivatives.[9]

General Experimental Procedure

The γ-lactol was dissolved in dry dichloromethane (5 mL per mmol of γ-lactol) and treated first with 2 equivalents of **4** or **5** (1.1 equivalents are sufficient for **6** and **7**) under N_2 at −78 °C and then with 2 equivalents of $BF_3\cdot OEt_2$. The stirred reaction mixture was allowed to warm over ca. 16 h to room temperature. After aqueous workup, drying ($MgSO_4$), concentration, and distillation or chromatography, the substitution products shown in Scheme 1 as well as **10–12** were obtained.

[6] All new compounds isolated gave satisfactory elemental analyses and appropriate spectra.
[7] Characteristic is, for example, the low-field shift of the ^{1}H-NMR signals of 3-H and 5-H by 0.11 and 0.73, respectively, on going from *cis*- to *trans*-**7c**. This assignment is supported by the ^{13}C-NMR spectrum ($CDCl_3$, 22.6 MHz): *trans*-**7c**: δ = 169.7 (s, C=O), 117.4 (s, C≡N), 84.6 (s, C-2), 75.9 (d, C-5), 60.8 (d, C-3), 51.5 (q, OCH_3), 46.4 (s, C-4), 30.8, 25.7, 24.7, 21.7 (4q, $4CH_3$); *cis*-**7c**: δ = 169.3 (s, C=O), 117.4 (s, C≡N), 83.5 (s, C-2), 75.1 (d, C-5), 61.9 (d, C-3), 51.5 (q, OCH_3), 46.3 (s, C-4), 29.5, 25.5, 25.3, 19.3 (4q, $4CH_3$). Similar arguments hold also for **6b**, **7b**, and **8c**.
[8] γ-Lactols are most easily prepared by addition of nucleophiles (e.g., hydride from diisobutylaluminum hydride) to γ-lactones.

Complex-Induced Fragmentation of As_4S_4: Stabilization of an As_2S_3 Ligand

By *Henri Brunner, Heike Kauermann, Bernd Nuber, Joachim Wachter,** and *Manfred L. Ziegler*

The system arsenic/sulfur provides a treasure chest of new ligands for transition-metal complexes. As_2S_3 and As_4S_4 have been employed to obtain compounds with AsS_3,[1] AsS,[2] and As_2S[3] ligands. However, cage molecules as ligands were lacking, even though they are known in the phosphorus/sulfur system (P_4S_3[4]). During a search for complexes with AsS cage molecules as ligands, we allowed **1**, **4**, and **7** to react with As_4S_4. Of the products **2**, **3**, **5**, **6**, and **8**, complex **8** contains an As_2S_3 ligand, the largest fragment of the As_4S_4 cage reported so far.

The complexes **2** (green) and **3** (red-violet) can be prepared by reaction of As_4S_4 with $[(C_5Me_5)_2Fe_2(CO)_4]$ **1** in

[*] Dr. J. Wachter, Prof. Dr. H. Brunner, Dr. H. Kauermann
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (FRG)

boiling toluene. On the other hand, $[(C_5Me_5)_2Co_2(CO)_2]$ (*Co=Co*) **4** reacts with As_4S_4 in toluene (80 °C) to form the carbonyl-containing complex **5** and the black-brown cluster **6**.

$$[(C_5Me_5)_2Fe_2(CO)_4] + As_4S_4 \xrightarrow[115\,°C]{\text{toluene}} [(C_5Me_5)_2Fe_2As_2S_2] + [(C_5Me_5)_2Fe_2As_2S_3]$$

1 → **2** + **3**

$$[(C_5Me_5)_2Co_2(CO)_2] + As_4S_4 \xrightarrow[80\,°C]{\text{toluene}} [(C_5Me_5)_2(CO)Co_2As_2S_2] + [(C_5Me_5)_3Co_3As_2S_4]$$

4 → **5** + **6**

$$[C_5Me_5Co(CO)_2] + As_4S_4 \xrightarrow[h\nu]{\text{THF}} [(C_5Me_5)_2Co_2As_2S_3]$$

7 → **8**

The photochemical reaction of **1** and **7** with As_4S_4 in tetrahydrofuran (THF) gives **3** and the violet-brown complex **8**, respectively.[5] The compositions of the diamagnetic complexes **2**, **3**, **5**, **6**, and **8** were established by field-desorption mass spectroscopy and, for **2**, **6**, and **8**, by complete elemental analysis. The reaction of $[(C_5Me_5)_2W_2(CO)_4]$ (*W≡W*) with As_4S_4, on the other hand, affords solely the already known, exclusively sulfur-containing complexes $[(C_5Me_5)_2W_2(\mu\text{-}S_2)S_2]$ and $[(C_5Me_5)_2W_2(\mu\text{-}S)_2S_2]$.[6] Common to **2**, **3**, and **5** is a side-on bonded As_2 ligand as four-electron donor,[7] which, along with the sulfur ligands required for electron balance, appears to be better suited than mixed AsS ligands for the stabilization of lower metal oxidation states.

An X-ray structure analysis of **8**[8] revealed that in this complex a novel As_2S_3 ligand is present as a 4e donor with two *cis*-arranged η^2-bonded AsS units that are bridged by an S atom. This results in a "basket" with a C_2 axis through S(2) and the midpoint of the Co_2S_2 square. The structure differs from the sulfur-arsenic chains of the As_2S_3 layer lattice primarily in the all-*cis* geometry that is forced upon the molecule by the two C_5Me_5Co units. Comparison of the bond lengths for both kinds of As–S bonds reveals a surprisingly narrow range of variation of As–S distances. The mean value (2.231 Å) corresponds to that (2.237 Å) of the μ_2,η^2-AsS ligand in $[(C_5Me_5)_2Mo_2AsS_3Co(CO)_2]$[2] and is comparable to those in realgar (As_4S_4) and orpiment (As_2S_3).[9] The bond angles at S and As, although slightly expanded, more resemble those in As_2S_3 than in As_4S_4.

The results presented here underline the importance of As_4S_4 as a starting material for new As–S ligands, but also show the difficulties in controlling the complex-induced cage fragmentation, which appears to depend crucially on the transition-type complex used.

Heterogeneous Catalysis of Ammonia Synthesis at Room Temperature and Atmospheric Pressure

By *Ken-ichi Aika**

The artificial fixation of nitrogen at ambient temperature and under atmospheric pressure is one of the most important goals of chemical technology. The first step toward this goal has been achieved: for example, a large number of organometallic dinitrogen complexes have been prepared,[1] and the dissociative adsorption of N_2 occurs easily on a clean single-crystal surface of Mo[2] or Fe[3] at about room temperature. However, the catalytic synthesis of ammonia from N_2 and H_2 has not been achieved at am-

[*] Prof. Dr. K. Aika
Research Laboratory of Resources Utilization
Tokyo Institute of Technology
4259 Nagatsuta, Midori-ku, Yokohama 227 (Japan)

bient temperature and under atmospheric pressure. The solid catalyst described herein—potassium-containing ruthenium on active carbon—produces ammonia from N_2 and H_2 at room temperature under atmospheric pressure; however, its activity is much lower than that of nitrogenases.

Recently, several heterogeneous solids[4,5] and clean metal surfaces[6,7] have been reported to be efficient catalysts for the synthesis of ammonia. One of the most active catalysts,[4,5] ruthenium (4.5 wt-%) on active carbon with 32 wt-% metallic potassium (Ru-K/C), contains Ru particles with diameters of ca. 10 nm. In order to check the reproducibility of the catalytic activity, the ammonia synthesis was carried out with 1 g of Ru-K/C (2.5 cm^3) in a conventional glass circulation reactor for one week at 190 to 233 °C under a pressure of 600 torr (molar ratio $N_2:H_2=1:3$). The products were collected in a liquid nitrogen trap. For an estimated flow rate of 5.3 $dm^3\ h^{-1}$, the rate of NH_3 production at 190 °C was 3.4 $cm^3\ h^{-1}$ (g-catalyst)$^{-1}$ (gas analysis under standard conditions). The apparent activation energy was 22 to 23 kcal mol^{-1}, which agrees with the value reported earlier above 200 °C.[4,5] The reaction also occurs at 31 °C under atmospheric pressure (760 torr). The time course of the decrease in gas volume (measured with a gas burette) is shown in Figure 1. A constant rate of decrease was observed, although there was some fluctuation

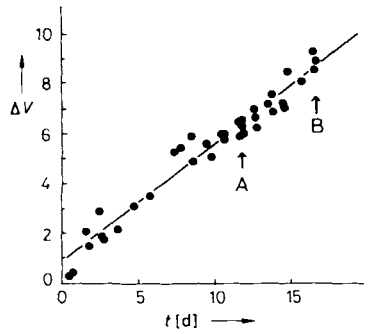

Fig. 1. Time course of the decrease of the volume ΔV [cm^3(g-catalyst)$^{-1}$] of the N_2/H_2 mixture (molar ratio 1:3) during reaction over the Ru-K/C catalyst at 31 °C under atmospheric pressure. The trapped product was identified to be ammonia.

owing to variations in the room temperature. At times A and B, the trapped gas was released and identified to be ammonia by mass spectrometry. The amount of ammonia produced between A and B (116 h) was 0.92 cm^3, which roughly corresponds to consumption of half of the N_2/H_2 mixture initially present (2.3 cm^3). The observed reaction rate, 0.23 $cm^3\ NH_3\ d^{-1}$ (g-catalyst)$^{-1}$, corresponds to 0.011 mmol $NH_3\ d^{-1}$ (g-catalyst)$^{-1}$ or 0.010 $cm^3\ NH_3\ h^{-1}$ (g-catalyst)$^{-1}$. The rate at 31 °C, calculated from the kinetic data above 190 °C, is approximately 1×10^{-5} $cm^3\ NH_3\ h^{-1}$ (g-catalyst)$^{-1}$, which was 10^3 times less than the observed result. Thus the reaction mechanism at ambient temperature might be different from that at higher temperatures, where the cleavage of the N–N bond is the rate-determining step. Nitrogenases have much higher activities: for example, the nitrogenase from *Klebsiella pneumoniae* has an activity of 0.25 mmol min^{-1} (g-protein)$^{-1}$,[8] which is 10^5 times higher than that of Ru-K/C. However, the results presented here demonstrate that a solid heterogeneous catalyst can also produce ammonia from H_2 and N_2 at room temperature under atmospheric pressure.

Reaction of Phosphonium Ylides with Alkyldichloroboranes**

By *Hans-Jürgen Bestmann** and *Thomas Arenz*

We recently reported on the reaction between phosphonium ylides **1**, $R^2=H$, and dialkylchloroboranes, which leads via transylidation to boron-substituted ylides and phosphonium salts such as **6**.[1] ^{31}P-NMR studies show that **3**, $R^2=H$, $^{\ominus}BClR^3_2$ instead of $^{\ominus}BCl_2R^3$, probably occurs as intermediate. It decomposes above 0 °C into the starting compounds and is not isolable.[2]

We have now examined the reaction of phosphonium ylides **1** with alkyldichloroboranes **2**. Compounds **1** and **2** react in the molar ratio 1:1 at −78 °C in ether to give the alkyltriphenylphosphonio-alkyldichloroborates **3** (for examples cf. Table 1). Unlike the chlorine-deficient analogues, these are stable at room temperature and are isolable under protective gas.

1 2 3 4

Table 1. Examples of alkyltriphenylphosphonioalkyldichloroborates **3** and -alkylborates **4**.

	R^1	R^2	R^3 [a]	Yield [%]	NMR (δ) ^{31}P [b]	^{11}B [c]	IR [cm^{-1}]	M.p. [°C] [d]
3a	H	H	*c*-C_6H_{11}	78	+26.5	+ 5.7		144–146
3b	CH_3	H	*c*-C_6H_{11}	86	+33.6	+10.1		170 (decomp.)
3c	CH_3	H	thexyl	71	+35.7	+10.1		75 (decomp.)
3d	CH_3	CH_3	*c*-C_6H_{11}	77	+40.8	+ 1.4		130
3e	H	H	thexyl	76	+27.9	− 8.4		[e]
4a	H	H	*c*-C_6H_{11}	73	+31.5	−19.8	2230	120
4b	CH_3	H	*c*-C_6H_{11}	75	+43.1	−15.0	2220	105–110

[a] *c*-C_6H_{11} = cyclohexyl, thexyl = $-(CH_3)_2C-C(CH_3)_2H$. [b] In $CDCl_3$, H_3PO_4 as external standard. [c] In $CDCl_3$, $BF_3\cdot OEt_2$ as external standard. [d] Under N_2 in sealed tube. [e] Still contains impurities.

The ate-onium complexes[3] **3** are crystalline compounds, some of which melt sharply, while others melt with decomposition. The ^{1}H-, ^{11}B-, ^{13}C-, and ^{31}P-NMR

spectra as well as the mass spectra of complexes **3** were consistent with what was expected for such compounds. With $LiAlH_4$ in slight excess,[4] the compounds **3** are reduced to the monoalkylborane-alkylidenetriphenylphosphorane adducts **4**[5] (for examples cf. Table 1).

We now allowed the adducts **3**, $R^2=H$, which were formed from **1**, $R^2=H$, and **2**, to react with one equivalent of **1***, $R^2=H$ (**1** and **1*** contain the substituents R^1 and R^4, respectively; $R^1 \neq R^4$). Transylidation to **5** and **6** occurred. Attempts to remove HCl from **5**, $R^1=H$, with bases, in order to obtain ylides with P=C=B-partial structure (cf. [6]), met without success. **5** is again transylidated with **1*** as base (molar ratio 1:2), and affords **7** and **6**. The boron-containing bisylides **7**, $R^1 \neq R^4$, obtained in this way (A) could be interesting complex ligands. Reaction of **1**, $R^2=H$, with **2** (molar ratio 4:1), leads via route (B) directly to **7**, $R^1=R^4$, and **6** (for examples cf. Table 2). The compounds **7** are sensitive toward atmospheric oxygen and moisture.

(A) 1, R^2=H + 2 ⟶ 3, R^2=H

(B) 4x1, R^2=H + 2 ⟶ 7, $R^1=R^4$ + 2x6

Table 2. Borandiylbis(triphenylphosphonioalkanides) **7** and triphenylphosphonio-1-[chloro(2,2,6,6-tetramethylpiperidineboryl]alkanides **5**.

	R^1	R^3 [a]	R^4	Yield [%]	NMR (δ) ^{31}P [b]	^{11}B [c]	Route
7a	H	*c*-C_6H_{11}	H	94.4	+17.37	+52.25	A, B
7b	H	*c*-C_6H_{11}	CH_3	82.8			A
					+21.07, +15.62	+49.2	
7b	CH_3	*c*-C_6H_{11}	H	76.7			A
7c	H	thexyl	H	89.8	+15.92	+44.13	A, B
7d	H	TMP	H	79.8	+11.64, +16.0	+45.57	A
5e	CH_3	TMP	—	90	+28.6	+40.9	
5f	C_2H_5	TMP	—	85	+27.6	+40.9	

[a] TMP=2,2,6,6-tetramethylpiperidino. [b] In C_6D_6, H_3PO_4 as external standard. [c] In C_6D_6, $BF_3 \cdot EtO_2$ as external standard.

The ^{1}H-, ^{11}B-, ^{13}C-, and ^{31}P-NMR and mass spectra as well as the elemental analyses were once again consistent with our expectations.[1] The intermediate **5**, which is sensitive to atmospheric oxygen and moisture, is isolable by reaction of **1**, $R^1 \neq H$, $R^2=H$, with dichloro (2,2,6,6-tetramethylpiperidino)borane **2**, R^3=TMP, in the molar ratio 2:1 (cf. Table 2). A transylidation with further **1** to give **7** is not observed in this case.

Experimental

7, $R^1=R^4$, route (B): A solution of **1**, $R^2=H$, (4 mmol) in ca. 100 mL of benzene was treated with 1 mmol of **2** and the resulting mixture stirred for 12 h at room temperature. After removal of the phosphonium salt **6** by vacuum filtration, the red filtrate was evaporated down to ca. one quarter of its original volume and then slowly covered with hexane (ca. 50 mL) and allowed to stand for about 12 h. The crystals of the bisylide **7** were filtered off and dried by suction (oil-pump vacuum) for 10 h at room temperature.

2-Substituted 1,3,2-Dioxaboroles as Synthetic Equivalents for the Glycolaldehyde Anion**

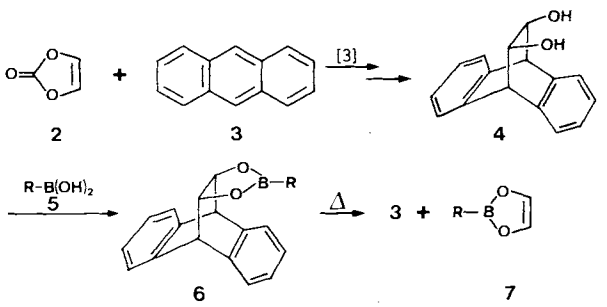
By *Günter Wulff** and *Achim Hansen*

Dedicated to Professor Leonhard Birkofer on the occasion of his 75th birthday

The glycolaldehyde anion $^{\ominus}$:CHOH-CHO plays an important role as a synthon since it can be exploited strategically through an Aldol reaction for the synthesis of α,β-dihydroxyaldehydes, in particular for carbohydrates.

1

1a, X=P(OMe)$_3$; **1b**, X=B–Ph; **1c**, X=Sn
R^1=alkyl, aryl
R^2=H, alkyl, aryl



Cyclic enediolates **1**, $R^1=R^2=H$, should be suitable as synthetic equivalents. So far, only their 4- and 4,5-substituted derivatives have proven to be useful from a preparative point of view. *Ramirez*[1] was able to prepare α,β-dihydroxyketones by the reaction of 1,3,2-dioxaphospholes **1a** with aldehydes and ketones. *Mukaiyama* et al.[2] have similarly prepared α,β-dihydroxyketones by Aldol reactions of the boron- and tin-enediolates **1b** and **1c**.

We have been interested in the application of the previously unknown 1,3,2-dioxaboroles **7a–e**, having substi-

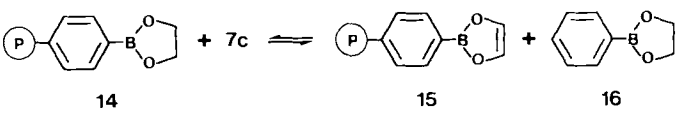
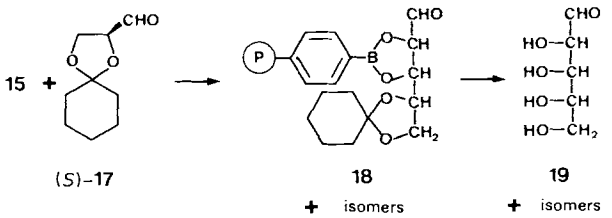
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

tuents only in the 2-position, as building blocks for the synthesis of carbohydrates. We have now been able for the first time to synthesize these interesting compounds in excellent yields in the following manner: esters **6a–e** were synthesized by reaction of the boronic acids **5a–e** with the diol **4**, which was obtained from vinylene carbonate **2** and anthracene **3** by Diels-Alder reaction and subsequent hydrolysis.[3] These were sublimable at 160–220°C/10^{-2} mbar and could be converted almost quantitatively by thermolysis in the gas phase at 550°C/10^{-2} mbar into the analytically pure 1,3,2-dioxaboroles **7a–e**.[4] The total yields with respect to **2** were over 80%.



a, R = cyclohexyl; **b**, R = methoxy; **c**, R = phenyl; **d**, R = 2-methylphenyl; **e**, R = 2,6-dimethylphenyl

The addition of 2-phenyl-1,3,2-dioxaborole **7c** to the aldehydes **8f–k** proceeds in a manner similar to the addition of the 4- and 4,5-substituted dioxaboroles **1b**, as described by *Mukaiyama* et al.[2a] We obtained a diastereomeric mixture of **9f–k** and **10f–k** in the ratio 1:2 to 1:3.[5] Unlike the products obtained from **1b** and aldehydes, these products contain a keto group instead of an aldehyde group and therefore could undergo further reaction with **7c**. Thus, in reactions with **8f–k**, mixtures of pyranoid (and furanoid) isomers **13**, which were formed from **11** by ring closure, were isolable in yields of 8–40%, in addition to larger amounts of not yet fully characterized, high molecular weight addition products **12**.



f, R = methyl; **g**, R = ethyl; **h**, R = isopropyl; **i**, R = *tert*-butyl; **j**, R = (*R*)-2,2-dimethyl-1,3-dioxolan-4-yl; **k**, R = phenyl. THF = tetrahydrofuran.

In order to restrict the reaction at a single addition to aldehydes, **7c** was immobilized on a cross-linked polymer; this strategy for site separation inhibits any further reaction of the primary addition products. Polymer bound **7c** (≡ **15**) could be obtained quite easily by triethylamine-catalyzed, rapid transesterification.

As a first example of the applications of **15** we describe here the synthesis of L- and D-ribose. 2,3-*O*-cyclohexylidene-L-glyceraldehyde (*S*)-**17** or the D-form (as 2,3-*O*-isopropylidene derivative (*R*)-**20**) was allowed to react with **15**[6] (CH_2Cl_2, room temperature, 12–36 h). The addition products could be isolated from the polymer using methanol/water. Removal of the protecting group (by ion exchanger) furnished the aldopentoses of the L- or the D-series in 70–95% yield with respect to the 1,3,2-dioxaborole units, or 75% with respect to (*S*)-**17** and (*R*)-**20**.

Product ratios:
L-Ribose : L-Lyxose : L-Arabinose : L-Xylose = 53.8 : 10.5 : 32.5 : 3.2
D-Ribose : D-Lyxose : D-Arabinose : D-Xylose = 56.0 : 6.6 : 35.2 : 2.2

Enantiomerically pure L-ribose was obtained by liquid chromatographic separation (LiChrosorb-NH_2, acetonitrile/water 85 : 15; $[\alpha]_D^{20} = +19.7$ ($c = 0.22$, H_2O)).[7] The nucleophilic attack of the enediolate **15** at the aldehyde group of **17** is controlled *ul*-selectively (1,2-induction ca. 9 : 1) by the diastereofacial influence of the isopropylidenedioxy- or the cyclohexylidenedioxy residue according to the Felkin-Anh model.[8] An enantiofacial control (1,3-induction) was seldom observed. The *threo-erythro* ratio at C-2 and C-3 was 1 : 2, similar to that found with achiral aldehydes.

The synthetic procedure described here enables the lengthening of sugar chains by two C atoms and thus offers a novel possibility for the synthesis of rare sugars.[9]

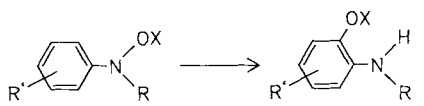
N-Aryl-*O*-(diphenylphosphinoyl)hydroxylamines: Electrophilic Amination of Amines to Hydrazines; a Model Reaction for the Carcinogenicity of Aromatic Amines**

By *Gernot Boche,* Reinhard H. Sommerlade,* and *Ferdinand Bosold*



The carcinogenicity of aromatic amines Aryl-NH_2 is due to their reactive metabolites, the *N*-arylhydroxamate esters **1** and the *N*-arylhydroxylamine esters **2**, which react with nucleophilic centers in nucleic acids and peptides.[1,2]

Aryl–N($COCH_3$)–OX Aryl–NH–OX

1 **2**

X = $SO_3^{\ominus}$, $COCH_3$, $PO_3^{2\ominus}$

The rearrangement of the species **3a–d** to the *o*-aminophenol derivatives **4a–d**[3a,4,5,6a–c] is regarded as confirmation[3a] that the nitrenium (aminylium) ion Aryl–$\overset{\oplus}{N}$–R is the ultimate carcinogen.[1] Furthermore, it is known that, upon solvolysis of **3a**, R′ = *p*-CH_3, in methanol[3b] and of **3e**, R′ = *p*-CH_3 or *p*-OCH_3, in water,[6d,e] the nucleophiles attack the phenyl ring of **3**.[8]

We report here on the reaction of the *N*-aryl-*O*-(diphenylphosphinoyl)hydroxylamines **5**[9] with the amines **6**. In contrast to **3a–e**, neither a rearrangement to the *o*-aminophenol derivatives nor a reaction of the nucleophile with the phenyl ring of **5** was observed. Instead, exclusive electrophilic amination to give the hydrazines **7** took place (Table 1).[10]

[a] The hydrazines **7** were characterized by ^{1}H-NMR spectroscopy—and, if they were new compounds—by elemental analysis and mass spectroscopy. [b] Isolated as the azo compound. [c] Isolated as *N*-benzylidene-*N*′-phenylhydrazine.

Notes to Table 1:

Reactions 1–5: Primary aliphatic amines **6** afford the hydrazines **7** in only moderate yields; branching at the α-C atom of **6** lowers the yields still further.

Reactions 6–13: Primary aromatic amines **6** give the hydrazines **7** (also called hydrazo compounds) usually in good yields. Since hydrazo compounds can be easily oxidized to azo compounds,[11] this provides a new route to symmetric and unsymmetric azo compounds.

Reactions 14–26: With secondary amines **6**, trisubstituted hydrazines **7** bearing virtually any substituents R^2 and R^3 are formed. In addition, deprotonation and subsequent alkylation can be used to introduce a fourth substituent R^4.[12] In this way, R^2, R^3, and R^4 can be introduced regioselectively without the use of protecting groups and *N*-nitroso compounds and without the formation of hydrazinium salts.

For the investigation of the carcinogenicity of aromatic amines, the *N*-aryl-*O*-(diphenylphosphinoyl)hydroxylamines **5** and the reaction of their electrophilic N atom with amines **6** are important for the following reasons:

1. The compounds **5** are the first models for the product **8b**, which is formed when the extremely carcinogenic *N*-(2-fluorenyl)acetohydroxamic acid **8a** (and related compounds) undergo in vivo activation with phosphate.[13]

2. *N*-arylhydroxamate esters such as **3a**, **c–e** and **8b**, **c** are in general considerably more stable that the corresponding hydroxylamine compounds; **3b** is not isolable. With the synthesis of **5a–d**, *O*-substituted *N*-arylhydroxylamines without second substituents on the N atoms are now easily accessible.[14] They are of interest, because, for example, **8a** can be enzymatically activated not only by transformation to **8b**, **c**, etc., but also by deacylation to **8d** or transacylation to **8e**.[1, 13]

3. The carcinogenic **8a** reacts with guanine-containing substances such as guanosine or DNA in vivo and in vitro under a variety of conditions, giving predominantly the fluorenylamino (or amido) guanine derivatives **9**, i.e., the products of an electrophilic amination. Precisely this reaction, which is apparently crucial for the carcinogenicity of **8a**,[1, 13] can be simulated by the reactions of **5a–d** described here.

Spontaneous Intramolecular Ring Opening of the Cyclopropyl Group at a Metal-Metal Double Bond**

By *Wolfgang A. Herrmann,* Eberhardt Herdtweck,* and *Cornelia Weber*

Cyclopropane occupies a special position among the alkanes even in organometallic reactions. Although systematic investigations of its behavior toward metal-complex fragments are lacking, it may be assumed as a working hypothesis that electron-rich metal centers cleave CH bonds by nucleophilic attack, whereas electron-deficient metal centers cleave CC bonds by electrophilic attack.[1–3] However, the latter reactions are only commonly observed for the C_3 structural unit as a building block of strained, polycyclic hydrocarbons; e.g., quadricyclane undergoes isomerization to norbornadiene at Rh^I and Pt^{II} centers.[3] We have now observed, for the first time, a spontaneous carbon–carbon bond breaking process at an (electrophilic) metal–metal double bond, namely, in a cyclopropyl group anchored to a binuclear μ-alkylidene complex.

Treatment of the binuclear rhodium complex **1** with the diazo compounds **2a** and **2b**, generated in situ from their hydrazone precursor compounds, results in the formation of the new dimetallacyclopropanes **3**,[4] once again confirming the generality of our well-documented synthetic strategy for the preparation of μ-alkylidene complexes.[5]

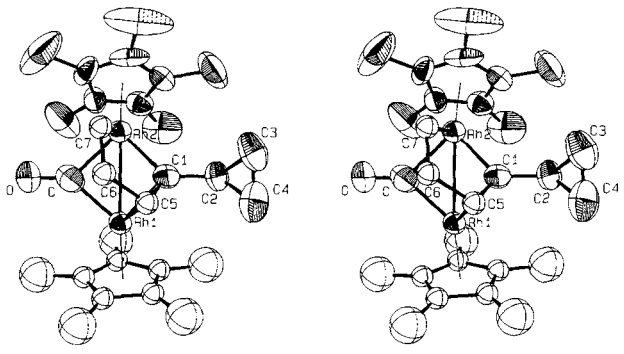
[**] Transition Metal Methylene Complexes, Part 62. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG, Hüls AG, DEGUSSA AG, and the Bundesministerium für Forschung und Technologie. Part 61: W. A. Herrmann, C. Weber, M. L. Ziegler, O. Serhadli, *J. Organomet. Chem. 297* (1985) 245.

According to the IR and NMR data, the complexes **3a**, **b** have the same constitution as the many other derivatives of this class whose structures have been established by X-ray diffraction analyses: characteristic are the two terminally bonded carbonyl groups and the two π-bonded pentamethylcyclopentadienyl ligands in *trans* positions with respect to the three-membered Rh_2C core structure.[5] In general, such compounds are thermally stable, but lose one of the two CO ligands rapidly upon irradiation. This results in the formation once again of a (highly reactive) double bond between the metal atoms (complexes of type **4**), to which small, reactive species may add (e.g., CO, CH_2, C_2H_2, Se, AgCl).[5,6]

The behavior of complexes **3a** and **3b** deviates fundamentally from this well-established reaction scheme. Although carbon monoxide is, in fact, cleaved off, the resulting species **4a** and **4b**, respectively, cannot be isolated. Even under mild reaction conditions (−50°C), a novel, spontaneous rearrangement takes place. The products **5a** and **5b**, respectively, having the same net composition as **4a** and **4b**, are isolated as deep red, lustrous crystals, which are stable to at least 250°C and are only soluble in very polar solvents such as acetone.[4] In contrast to its precursors **3b** (C_2 symmetry) and **4b** (mirror-plane symmetry), the stable end product **5b** is asymmetric. The absence of molecular symmetry is reflected in the ^{1}H-NMR spectra (300 MHz, $CDCl_3$, +28°C), not only in two different C_5Me_5 signals ($\delta = 1.68, 1.77, 2 \times d$; $^3J(Rh,H) = 0.6$ Hz) but also in numerous sets of signals for the CH and CH_2 protons. Of particular value in assignment of the structure is the group of signals centered at $\delta = 0.19$, which, on the basis of the chemical shift and the coupling ($^2J(Rh,H) = 0.8$ Hz) is assigned to the C5 protons. Without attempting a detailed interpretation of the spectra,[4] it is possible to locate an intact cyclopropyl group (C2, C3, C4) by spectral comparisons ($\delta = 0.46, 0.53, 0.90, 1.05, 1.30$; $5 \times m$).[6a] The molecule does not contain metal-bonded hydride ligands.

A single-crystal X-ray structure analysis of **5b** also revealed that the rearrangement involves cleavage of an α carbon-carbon bond of the cyclopropyl group, which was still intact in the precursor species **3a** and **3b**. As shown in Figure 1, a tricyclic Rh_2C_4 skeleton is formed in which C1 is the original μ-methylene carbon atom. Whereas the dimetallacyclopropane structure of the precursor species **3** is retained (Rh-C1 = 205.0(5) and 203.6(5) pm), the atoms involved in the CC bond cleavage form single bonds to the metal atoms (209(1) and 216(1) pm) in order to satisfy their valence requirements. This results in the formation of a dimetalladihydrobenzvalene structure. Since two possibilities exist for the α-cleavage of the cyclopropyl group, a disorder is observed for the tricyclic Rh_2C_4 skeleton, with C5 bonded to either Rh1 or Rh2; furthermore, the C_5Me_5 ligand of Rh1 is also disordered.[7] On account of the disorders, the structure alternatives that are in principle possible do not agree with the NMR data and are not reasonable in terms of bonding theory.



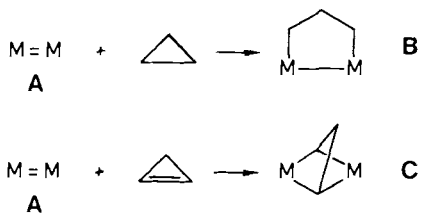


Fig. 1. ORTEP plot (stereoview) of the crystal structure of **5b** (50% probability; without hydrogen atoms; disordered atoms represented as balls). The compound was crystallized at −25°C from acetone; monoclinic, space group $P2_1/c$ ($Z = 4$), $a = 817.2(1)$, $b = 1766.8(3)$, $c = 1847.1(6)$ pm, $\beta = 98.14(2)°$, $V = 2640 \times 10^6$ pm^3.—Selected bond lengths [pm] and bond angles [°]: C1-C5 145(1), C1-Rh1 205.0(5), C5-C6 162(2), C6-C7 144(1), Rh2-C7 216.5(9), C1-C2 150.5(8), Rh1-C 195.4(7), Rh2-C 199.1(7); Rh-C-Rh2 85.0(3), Rh1-C1-Rh2 81.5(2); C5 lies 105 pm below the best plane of the atoms Rh1, C6, C7, and Rh2. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD 51873, the names of the authors, and the journal citation.

Particularly noteworthy is the simple formation of the dimetallapentane system **B**. It was achieved here, for the first time, by the ring-opening addition of a cyclopropane to a metal-metal double bond **A**, which in turn is transformed into a single bond (266.7(1) pm). Whereas dimetallacyclopentanes are usually thermally labile, either eliminating ethylene and undergoing ring contraction to form dimetallacyclopropane derivatives or undergoing β-hydrogen migration to form α-olefins (propene in the case of **B**),[8] complexes **5** probably owe their stability to the incorporation of the C_3 bridge into a polycyclic framework. Ring-opening of cyclopropene at the metal-to-metal double bond of **1** (type **A**) leads primarily to dicarbenoid species **C**, which, however, undergo rapid subsequent reaction (e.g., with CO insertion).[9] The ring opening of methylenecyclopropanes, which has been observed repeatedly, begins with π-complexation of the intact molecule;[10] in other cases, cyclopropyl groups remain intact, even at coupling-active compounds (e.g., allylidenecyclopropanes).[11]

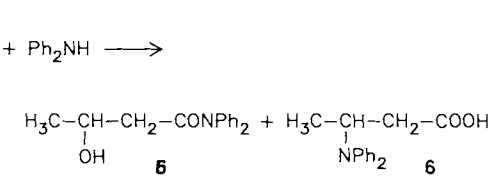
Direct Aminolysis of Unactivated Esters at High-Pressure**

By *Kiyoshi Matsumoto,* Shiro Hashimoto,* and *Shinichi Otani*

In memoriam Ryozo Goto



The direct conversion of esters into acid amides is known to be a difficult reaction,[1] though it potentially constitutes a useful synthetic strategy and several methods designed to facilitate it have been reported.[2–5] Uncatalyzed aminolysis with primary amines requires temperatures in excess of 200°C,[6] while the corresponding reaction with secondary amines has never been reported.

We have now found that even secondary amines **2** react in high yield at room temperature or 35–45°C with a wide variety of unactivated esters **1** to give acid amides **3** if the reactions are carried out under a few kbar (Table 1).[7] Neither an inert atmosphere nor dry solvents are required. The reaction is extremely clean and therefore the work-up procedure is straightforward; even the hydrolysis procedure used in the excellent method with alkylaluminum amide reagents is unnecessary. Usually, the solution of the products **3** contains only the esters **1**, if the yield is not quantitative, and excess amine **2**. Naturally, this method is also applicable to primary amines (see Table 1).

The reaction of β-butyrolactone **4** at 45°C with an extremely unreactive amine such as diphenylamine[8] further illustrates the utility and mildness of the method. The desired amide **5** is obtained in 28% yield, along with 35% 3-(*N,N*-diphenylamino)butyric acid **6**. Under conventional conditions at 180–190°C—without use of pressure—only 0.8% of the acid is formed.

College of Liberal Arts and Sciences, Kyoto University
Kyoto 606 (Japan)

[**] This work was supported by the Japanese Ministry of Education (No. 61840017).

Because of its broad applicability and the low temperatures, the method presented here appears to be superior to reactions with alkylaluminum amides.[9] Whereas these reagents often react with such a valuable functional group as a cyano group,[10] this is not the case in our method. The high acceleration of the aminolysis of esters by application of pressure would suggest that the formation of a tetrahedral zwitterion is rate-determining.[11]

Red, Transparent Alkali Metal Silicides with Si_4 Tetrahedrons

By *Hans Georg von Schnering,* Martin Schwarz,* and *Reinhard Nesper*

In memoriam Herbert Schäfer

The theoretically predicted structure of the fourfold μ_3-coordinated tetralithiotetrahedrane Li_4C_4[1] has not yet been experimentally confirmed. The homologous silicide is unknown,[2] and the germanide LiGe does not have Ge_4 tetrahedrons as anions.[3] The tetrahedral arrangement, however, has been long established for all higher homologues of the first and fourth main groups.[4–6] We have therefore attempted to determine, by the synthesis of ternary and quaternary silicides M*Si (M* = mixed alkali metal), whether lithium can at least be partially present as a μ_3-bonded metal atom on Si_4 tetrahedra. These experiments were successful and led, surprisingly, to the first red, transparent metal silicides.

Reaction of an alkali metal mixture, Li + M (M = Na–Cs) with silicon results in the formation of both red, transparent and metallic grey, opaque silicides. It is still unclear which conditions with respect to M* : Si and Li : M and which structures are characteristic for either of the two types. We have established, however, that the light absorption of the red silicides K_3LiSi_4 and $K_7Li(S_4)_2$ is an intrinsic property of these compounds. (*Preparation:* stoichiometric mixture of the elements; sealed Nb ampoule in a quartz ampoule; 4 h heating at 800 °C; 4 h annealing at 800 °C; slow cooling over 12 h.) These red silicides are also flammable in air and form flammable silanes with protic solvents.

The structures of the new silicides (Fig. 1) belong to the types already known or are variants of these. Thus, $K_7Li(Si_4)_2$ belongs to the $Rb_7Na(Ge_4)_2$ type,[7] and K_3LiSi_4 exhibits the polymeric chain $^1_\infty[M'(Y_4)]$ known for the $Cs_2Na_2Ge_4$ type.[8] In K_3LiSi_4, the Si_4^{4-} tetrahedra are linked by the Li atoms to form infinite one-dimensional chains $^1_\infty[Li(Si_4)]^{3-}$, thereby functioning twice as μ_3-ligands. Li is thus bonded to six Si atoms with d(Li–Si) = 258.8–294.7 pm ($\bar{d}$ = 272.9 pm), and, at the same time, two triangular faces of the Si_4^{4-} tetrahedron are capped by Li. In contrast to $Cs_2Na_2Ge_4$,[8] however, only one other face is capped by a K atom as μ_3-ligand; the other K atoms bridge only edges or coordinate only corners of the Si_4 tetrahedron (coordination number 6 and 7, respectively, with K–Si = 339.4–356.9 pm and 354.6–380.7 pm, respectively). The bond lengths in the anion are on the average $\bar{d}$(Si–Si) = 242.4 pm (236.3–244.9 pm) and are thus larger than in NaSi (240.9 pm[9]). The Si_4 tetrahedra in $K_7Li(Si_4)_2$, with the dumb-bell-shaped unit $[Li(Si_4)_2]^{7-}$, are also larger than in NaSi: $\bar{d}$(Si–Si) = 241.8 pm; $\bar{d}$(Li–Si) = 271.4 pm. In this structure, six of the K atoms serve as further μ_3-ligands (K–Si = 338.5–351.2 pm with $\bar{d}$ = 343.9 pm), whereas one of the K atoms exhibits no K–Si contacts.

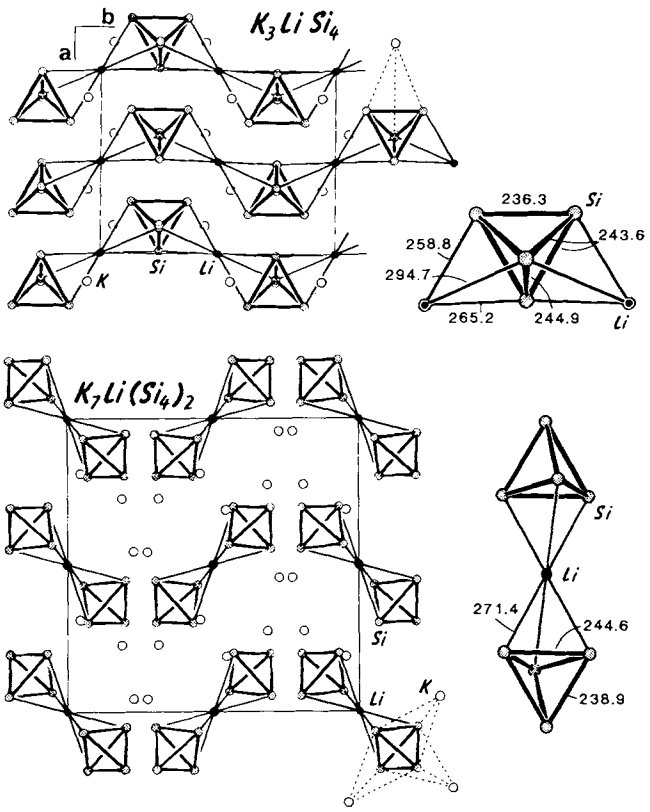

Fig. 1. Crystal structures of K_3LiSi_4 and $K_7Li(Si_4)_2$ with the bond lengths in the polymeric chain $^1_\infty[Li(Si_4)]^{3-}$ and in the dumb-bell-shaped structural group $[(Si_4)Li(Si_4)]^{7-}$. In both structures, the additional μ_3-coordinations by the K atoms are given on the right margin (hatched lines).—Crystallographic data: K_3LiSi_4: *Pnma* (No. 62); a = 765.1(4), b = 980.5(4), c = 1222.1(9) pm; Z = 4; 1253 reflections; R(aniso) = 0.033.—$K_7Li(Si_4)_2$: *Pa3* (No. 205); a = 1249.5(3) pm; Z = 4; 495 reflections, R(aniso) = 0.026. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD 51899, the names of the authors, and the journal citation.

Some of the structural details could be of importance for theoretical understanding. Thus, in $K_7Li(Si_4)_2$, the Si–Si distances in the tetrahedral faces bonded to μ_3(Li) are large (244.6 pm) and those in the faces bonded to μ_3(K) small (238.9 pm). In K_3LiSi_4, the Si_4^{4-} tetrahedra are also distorted. The one edge of the tetrahedron not involved in a μ_3(Li) cap structure has the smallest Si–Si distance (236.3 pm) and the edge involved in two μ_3(Li) cap structures the largest Si–Si distance (244.9 pm). Apparently, the strongly covalent Li–Si interaction of the μ_3-bonded Li atom weakens the Si–Si bonds of the Si_4^{4-} tetrahedron. Even the noted deformations due do incomplete μ_3-coordination can no longer permit a doubt as to the favoring of the T_d form for Li_4Si_4 as well.[10] Although *Ritchie* et al. predict a higher stability for the D_{2d} form,[11] more detailed

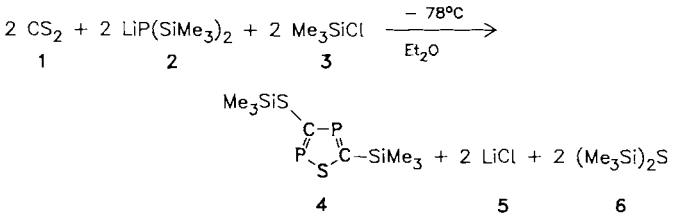
A Stable 1,2,4-Thiadiphosphole ("2,4-Diphosphathiophene")**



By *Rolf Appel** and *Rainer Moors*

Dedicated to Professor Marianne Baudler on the occasion of her 65th birthday

Investigations carried out in the past few years have revealed that there is a definite and, in some cases, amazing relationship between the P=C and C=C double bond.[1] This relationship manifests itself in the reaction behavior of the phosphaalkenes and alkenes as well as in the synthesis of phosphabenzene,[2] phosphaazulenes,[3] and various phospholes containing heteroatoms. Among these, only one incompletely characterized thiadiphosphole has been described as reactive intermediate[5] aside from aza-, oxaza-, and thiazaphospholes.[4]

We have now been able to synthesize the stable thiadiphosphole derivative **4** containing a conjugated P=C–P=C sequence by reaction of carbon disulfide **1** with lithium bis(trimethylsilyl)phosphide **2** and chlorotrimethylsilane **3**.

5-Trimethylsilyl-3-trimethylsilylthio-1,2,4-thiadiphosphole **4** is a yellow liquid that can be distilled under high vacuum (b.p. 75–78 °C/10^{-3} torr). Its composition has been confirmed by an elemental analysis and a molar mass determination; its constitution by an analysis of the spectroscopic data.

The ^{31}P-NMR spectrum shows an AB system at $\delta = 309.8$ and 304.3 in the characteristic PC double bond region with a PP coupling constant of 59.1 Hz. In the ^{13}C-NMR spectrum, the ring C-atoms appear as a doublet of doublets at $\delta = 194.84$ ($^1J_{CP} = 82.4$ Hz, $^2J_{CP} = 1.0$ Hz) and 189.96 ($^1J_{CP} = 88.5$ Hz, $^1J_{CP} = 87.5$ Hz) in the region for sp^2-hybridized carbon atoms. The signal at $\delta = 1.54$ (d, $^3J_{CP} = 5.3$ Hz) is assigned to the trimethylsilyl carbon atoms. Due to very similar coupling constants, the carbon atoms of the trimethylsilylthio group appear with the chemically different phosphorus atoms as a pseudo-triplet at $\delta = 0.66$ with a coupling constant $^4J_{CP} = 1.4$ Hz.

A double-doublet with two small Si–P coupling constants of 5.8 and 3.0 Hz is observed at $\delta = 18.32$ in the ^{29}Si-NMR spectrum. On the basis of the characteristic value of the shift, this signal can be assigned to the trimethylsilylthio-silicon atom. The silicon atom of the trimethylsilyl group bound to the carbon appears as a double doublet at $\delta = -2.03$ ($^2J_{SiP} = 25.8$ Hz, $^3J_{SiP} = 3.2$ Hz).

Experimental

All operations were carried out under inert gas using anhydrous solvents.

A solution of **2**·2THF (12 g, 37 mmol) in diethyl ether (80 mL) was slowly added dropwise to a solution of CS_2 (2.5 mL, 41 mmol) in 80 mL diethyl ether cooled with methanol/dry ice. After 15 minutes' stirring the dark-red mixture was treated with **3** (5.2 mL, 41 mmol) and allowed to warm to room temperature. The solvent was then removed and the residue was taken up in 50 mL of pentane, filtered, and the LiCl washed several times with pentane. After removal of the pentane under vacuum, the crude product **4** was distilled under vacuum (mercury diffusion pump); yield 2.5 g (45% referred to **2**); MS (70 eV 90 °C (selection)): *m/z* 296 ($M^{\oplus}$, 47.7%), 281 ($M^{\oplus} - CH_3$, 15.2%), 233 ($M^{\oplus} - PS$, 6.0%), 73 $(CH_3)_3Si$, 100%).

The thioether **6** was collected in a cold trap, distilled (b.p. 65 °C/15 torr), and identified ^{1}H-NMR spectroscopically by comparison with authentic samples.

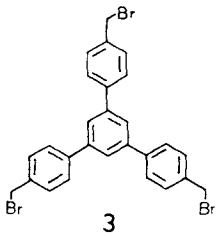
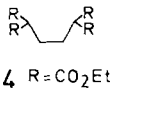
[**] We thank Prof. *F. W. Röllgen* and Dipl.-Chem. *S. S. Wong* (Bonn), Prof. *H. Egge* (Bonn), and Dr. *G. Eckhardt* (Bonn) for the mass spectra, and Dr. *B. Steffan* and Mr. *C. Schmidt* (Bonn) for the 400-MHz ^{1}H-NMR spectra.

compounds, such as **2**, have become known only recently.[2] The investigation of guest inclusion in molecules such as **1**, which has a disk-shaped cavity (Fig. 1), offers promise of progress in the preparation of artificial receptors and membrane channels and—by selection of appropriate functional groups—in the development of synthetic catalysts.[1]

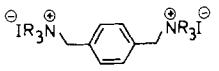


1



2

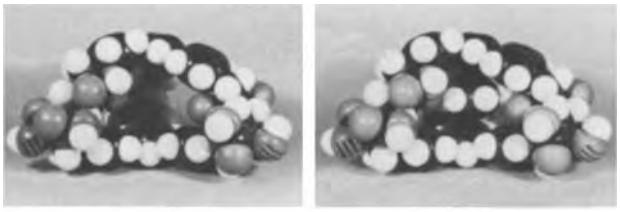
a R=CO_2Et
b R=CO_2H
c R=$CO_2^{\ominus}Na^{\oplus}$



We have now prepared the first example of this type of molecule, the dodecaester **1a** (m.p. = 285 °C),[3] from simple starting materials—the trifunctional bromo compound **3** and the tetraethyl carboxylate **4**[2]—in a single synthetic step under dilution conditions (sixfold bond formation; 0.6% yield). The dodecacarboxylic acid **1b**[4] (m.p. > 320 °C), obtained from **1a** by hydrolysis with KOH in ethanol, is particularly soluble in water at pH > 7. In aqueous NaOH, **1c** is formed.

3

4 R=CO_2Et

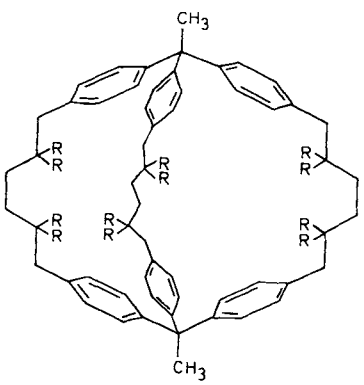


5 R=CH_3

On account of the macrobicyclic effect,[5] it was of interest to compare the strength and selectivity of the binding of guest substances by the new bicyclic host **1b** (as the sodium salt **1c**) with those of the monocyclic host **2b** (as the sodium salt **2c**).[2] In contrast to the findings for **2c**,[2] the doubly charged guest compound **5**, which, according to examination of molecular models, should fit into the cavity of **1b**, does not exhibit ^{1}H-NMR high-field shifts in aqueous solution. This points to an unexpected and significant difference in the recognition of guests by the macrobicyclic host **1c** compared with the macromonocycle **2c**. We propose that the guest dication is already "trapped" at the anionic periphery[6] of the sodium salt **1c** (cf. Fig. 1) and, owing to the formation of strong ion pairs as well as the relatively rigid skeleton, does not enter the cavity. In contrast, the conformationally more flexible host **2c** offers the same guest **5** both the possibility of analogous ion-pair formation and access to a directly neighboring cavity, which results in high-field shifts for the enclosed guest compound on account of anisotropy effects.

In view of these findings, it was at first surprising that an association constant of $\lg K_{ass} = 2.1$ (pH 11) was found by fluorescence spectroscopy for the reaction of **1c** (concentration between 0 and 10^{-3} mol/L) with 1,8-ANS (1,8-anilinonaphthalenesulfonate) in aqueous solution, since **1c** therefore binds this guest with an association constant ($\lg K_{ass} = 2.0$ at pH 7) similar to that of **2c** ($\lg K_{ass} = 2.3$ at pH 7). Examination of models provides an explanation for this finding; namely, neither cavity offers sufficient space for the entire ANS molecule. Only the anilino moiety of ANS fits into the cavity of **1c**. Presumably, the charges of the peripheral carboxylate groups have less effect on the guest ANS than on positively charged guest molecules.

Taking into consideration these results, we expanded the search for guests that fit into the cavity of **1c** to electrically uncharged guest molecules that, moreover, do not exhibit high-field shifts on association with the monocyclic host **2c**.[3] In fact, after addition of benzene to an aqueous solution of **1c** (and ultrasonication over several hours), we observed in the ^{1}H-NMR spectrum, in addition to the usual benzene absorption at $\delta = 7.34$, a strongly high-field shifted signal ($\Delta\delta = 0.65$ ppm!), which we assign to benzene enclosed in the cavity of **1c**. Evaporation to dryness and pumping at 50 °C removes all traces of benzene; subsequent addition of toluene and ultrasonication leads to inclusion of this guest, the aromatic and aliphatic protons of which appear at very high field besides in the usual region ($\Delta\delta(H_{aromat.}) = 0.5$, $\Delta\delta(CH_3) = 0.6$ ppm). Mesitylene also undergoes inclusion in **1c** in aqueous solution upon ultrasonication, as was demonstrated analogously ($\delta = 6.2$ and 1.8; $\Delta\delta(H_{aromat.}) = 0.6$ ppm, $\Delta\delta(CH_3) = 0.5$ ppm).



a) b)

Fig. 1. Space-filling model of the host **1b**: a) empty; b) with enclosed benzene.

Thus, whereas the monocycle **2c** does not bind uncharged guest molecules to a significant extent, **1c** does, owing to its ability to enclose the guest on all sides in a preformed cavity.

As demonstrated by the preparation of the analogous host compound **6a** (0.8% yield),[7] which contains a modified cavity, the one-step synthesis strategy chosen for **1a** is also applicable to other building blocks.

The differences observed in the binding of cationic, anionic, and uncharged guests by the bicyclic guest **1c** opens up possibilities for influencing the complexation in cavi-

6a R=CO_2Et
6b R=CO_2H
6c R=$CO_2^{\ominus}Na^{\oplus}$

ties by the use of pH-dependent charged groups on the periphery. Moreover, on account of their relevance for the control of the passage of molecules through membrane openings,[8] the host compounds described here appear to us to be of great interest with respect to guest selection.[9]

$[Cu_{36}I_{56}]^{20\ominus}$—a Novel Polyanion in the Compound $(pyH)_2[Cu_3I_5]$**

By *Hans Hartl** and *Joachim Fuchs*

Dedicated to Professor Georg Manecke on the occasion of his 70th birthday

In iodocuprates(I) $[Cu_mI_n]^{(n-m)\ominus}$, trigonal-planar and tetrahedrally coordinated Cu atoms are present; the CuI_3 units may be joined by common edges and the CuI_4 tetrahedrons by common corners, edges, and faces (!) to form higher condensed iodocuprate(I) ions. This results in a surprisingly wide range of possibilities in the structural chemistry of iodocuprates(I), from low-molecular-weight units such as $[CuI_3]^{2\ominus}$[1] or the binuclear ions $[Cu_2I_4]^{2\ominus}$, $[Cu_2I_5]^{3\ominus}$, and $[Cu_2I_6]^{4\ominus}$ and higher condensed units such as $[Cu_4I_6]^{2\ominus}$, $[Cu_4I_8]^{4\ominus}$, $[Cu_5I_7]^{2\ominus}$, $[Cu_6I_{11}]^{5\ominus}$, or $[Cu_8I_{13}]^{5\ominus}$ to polymeric anions such as $^1_\infty[CuI_2^{\ominus}]$, $^1_\infty[Cu_2I_3^{\ominus}]$, $^1_\infty[Cu_3I_4^{\ominus}]$, or $^2_\infty[Cu_2I_3^{\ominus}]$.[2] Such a variety of structures is not encountered for other iodometalates. The structure and degree of condensation of the iodocuprates(I) is determined by the size, form, and charge distribution of the cations involved.

[**] Synthesis and Structural Investigation of Iodocuprates(I), Part 7. This work was supported by the Fonds der Chemischen Industrie.—Part 6: [2].

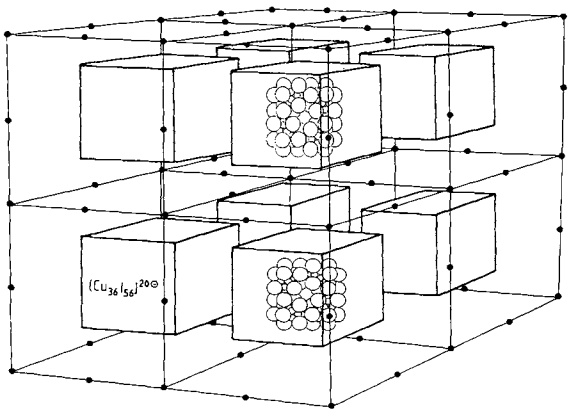

Fig. 1. Structure and arrangement of the anion $[Cu_{36}I_{56}]^{20\ominus}$ in the crystal.

In the system pyridinium iodide/CuI, it has now been possible to isolate the largest discrete iodocuprate(I) ion to date. The structural determination of a compound having the composition $(pyH)_2[Cu_3I_5]$ revealed that the correct formulation was $(pyH)_{24}([Cu_{36}I_{56}]I_4)$.[3] In addition to isolated $I^{\ominus}$ ions at the positions 8b and 24d of the cubic space group *Fm3c*, eight iodocuprate(I) ions $[Cu_{36}I_{56}]^{20\ominus}$ are present in the unit cell (Fig. 1). 36 CuI_4 tetrahedrons joined by two or three common edges form a structure having the extremely rare molecule symmetry 432 (=O). The 56 I atoms of the anion can be regarded ideally as a section of a cubic close-packing of spheres (Fig. 2a); eight cubes, face-centered on all sides, combine to form a larger cube, which lacks the I atoms in the middle of the faces and in the center. The Cu atoms occupy 36 tetrahedral gaps of the iodine partial lattice in such a way that 24 Cu atoms occupy the corners of a cube with octahedral habit, i.e., the positions formed by cutting off the corners of a cube. The 12 remaining Cu atoms lie at the middle of the edges of this cube; the centers of the faces and of the cube itself are unoccupied (Fig. 2b). If a van der Waals radius of 2.2 Å is assumed for $I^{\ominus}$, a diameter of approximately 7 Å is obtained for the cavity in the center of the anion. The holes in the centers of the faces have a diameter of about 1.5 Å and are therefore too small to allow guest molecules or cations to enter the cavity of the cube; the compound crystallizes without molecules of solvent.

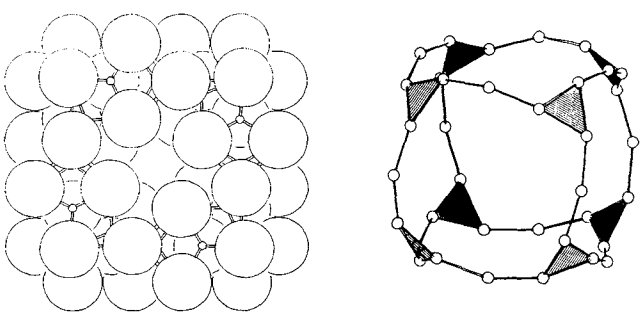

Fig. 2. a) View along an axis perpendicular to a face of the cube, showing the anion $[Cu_{36}I_{56}]^{20\ominus}$; large circles, I; small circles, Cu; distances [pm]: Cu-I 264.9(5)-270.8(5), Cu···Cu 278.9(5)-285.4(7); angle [°]: I-Cu-I 103.6(2)-113.7(1). b) Cu partial structure of the anion $[Cu_{36}I_{56}]^{20\ominus}$ (cube with octahedral habit). Hatched triangles: front side; black triangles: rear side.

The pyridinium ion $C_5H_6N^{\oplus}$, which is isosteric with benzene, often appears to have the high molecule symmetry of benzene on account of the disorder of the NH positions, which results in unusual crystal structures likewise exhibiting high symmetry.[4] In the present case, the 192 pyridinium rings of the unit cell are situated around their center of gravity in 0 0.19 0.11 and 0 0.22 0.23 and form, together with the 32 $I^{\ominus}$ ions, a suitable matrix for the eight $[Cu_{36}I_{56}]^{20\ominus}$ ions.

Experimental Procedure

Pyridinium iodide (1.38 g, 6.7 mmol) was allowed to react with CuI (1.9 g, 10 mmol) in 150 mL of acetone for 2–3 h at reflux and the reaction mixture was then filtered while still hot. Yellow-brown cube-shaped crystals precipitated upon slow cooling and addition of anhydrous ether or chloroform (1–2 drops/min).

Transition-Metal Clusters as Catalysts of Unconventional Reactions: Reductive C–N Coupling of Alkyl Isocyanates**

By *Georg Süss-Fink** and *Gerhard Herrmann*

Despite the great expectations that are placed in the catalytic potential of transition-metal clusters,[1] the use of such compounds has been limited up to now almost exclusively to conventional catalytic reactions.[2] An unconventional application, which we had found for the first time, was the spirocyclization of alkyl isocyanates to spiroheterocycles catalyzed by the cluster anion $[HRu_3(CO)_{10}(SiEt_3)_2]^{\ominus}$.[3]

Herein we report a novel reductive C–N coupling of alkyl isocyanates **1** to give *N*-formylureas **2**. The reaction takes place in the presence of the tetranuclear cluster anion $[H_3Ru_4(CO)_{12}]^{\ominus}$[4] as catalyst (precursor) (Table 1). The products **2a–c** can be isolated by preparative thin layer chromatography (silica gel, diethyl ether). When D_2 is used in place of H_2, the primary product formed from methyl isocyanate **1a** is presumably the expected product **2d**; chromatographic workup, however, affords the species **2e**, deuterated specifically in the formyl position. In every case, the reaction mixture contains the intact cluster anion, the catalytic activity of which remains unchanged.

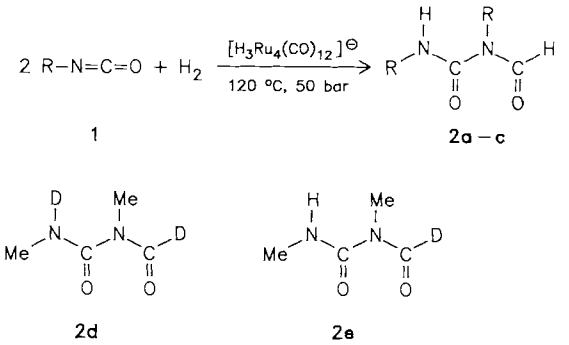

Table 1. Preparation of **2a–c**: **1a–c** (50 mmol) and $[N(PPh_3)_2][H_3Ru_4(CO)_{12}]$ (0.05 mmol) were allowed to react under 50 bar of H_2 in 25 mL of tetrahydrofuran at 120°C in a 100-mL autoclave.

	R	Reaction time [h]	Yield [%]	Turnover number [5]
2a	Me	20	46	230
2b	Et	40	41	205
2c	*n*Pr	40	56	280

The diphenyl derivative **2**, R = Ph, was assumed to be an intermediate in the protonolysis of the tetramethylethylenediamine adduct of 1,4-diphenyl-1,4-diaza-2-nickela-3,5-cyclopentanedione: instead of **2**, R = Ph, however, the decarbonylation product *N,N'*-diphenylurea was isolated.[6] In agreement with these results, exclusively *N,N'*-diphenylurea is found in the reductive C–N coupling of phenyl isocyanate in the presence of $[H_3Ru_4(CO)_{12}]^{\ominus}$; also isocyanates with branched alkyl groups, such as *i*PrNCO, give only the symmetrical urea. Whereas the corresponding ureas are always present as side products for EtNCO **1b** and *n*PrNCO **1c**, *N,N'*-dimethylurea is not observed in the reaction of MeNCO **1a**.

The composition of the new *N*-formylureas (*N*-carbamoylformamides) **2** was established by elemental analysis and (high-resolution) mass spectrometry. The IR and nuclear magnetic resonance data are in agreement with the given structures (Table 2).

Since, in all cases, the corresponding formamides can be detected in the reaction solution by gas chromatography, the role of the catalyst is possibly to hydrogenate the isocyanate.[7]

Bis(η^6-arsabenzene)chromium(0)**

By *Christoph Elschenbroich,* Jörg Kroker, Werner Massa, Martin Wünsch,* and *Arthur J. Ashe III*

Compared to the extensively documented organic chemistry of six-membered ring heterocycles only very few studies on the synthesis and properties of bis(η^6-heteroarene)metal complexes have so far been reported in the literature.[2] The reasons for this are the limited number of synthetic routes to such complexes as well as the ambident nature of many heteroarenes. The latter aspect requires for the synthesis of an η^6-complex the donor ability of lone pairs, which favors classical η^1-coordination, to be suppressed.[3] In the case of pyridine the lone pair on the nitrogen atom could be sterically blocked by 2,6-dialkyl substitution, thus enabling the synthesis of bis(2,6-dimethyl-η^6-pyridine)chromium as the first binary sandwich complex of a neutral heteroarene.[2e, f] In our attempts to prepare the unsubstituted parent compounds $(\eta^6\text{-}C_5H_5E)_2Cr$ (E = Group 5B element) we first selected arsabenzene **1** as ligand, since the σ-basicity of **1** is much lower than that of pyridine,[4] and, furthermore, the ability of **1** to undergo η^6-coordination has already been demonstrated in the formation of the complex $[(\eta^6\text{-}C_5H_5As)Mo(CO)_3]$ **2**.[5]

We have now synthesized bis(η^6-arsabenzene)chromium(0) **3** in 15% yield by metal atom-ligand cocondensation. The reddish-black, air-sensitive crystals of **3** are sublimable under high vacuum without decomposition.[6]

The cyclovoltammetrically determined redox potential $E_{1/2}(\mathbf{3}/\mathbf{3}^{\odot\oplus}) = -0.51$ V (reversible, at 25°C in 1,2-dimethoxyethane (DME)/tetra-*n*-butylammonium perchlorate (TBAP) versus saturated calomel electrode) displays an anodic shift of 0.17 V compared to that of bis(η^6-benzene)chromium. **3** can also be reduced, albeit not completely reversibly ($E_{1/2}(\mathbf{3}/\mathbf{3}^{\odot\ominus}) = -1.36$ V, 25°C, 100 mV s^{-1}, $\Delta E_p = 94$ mV, $I_{pa}/I_{pc} = 0.6$). Comparison with the electrochemical data for free arsabenzene **1** ($E_{1/2}(\mathbf{1}/\mathbf{1}^{\odot\ominus}) = -1.10$ V, irrev., $E_{1/2}(\mathbf{1}/\mathbf{1}^{\odot\ominus}) = -2.08$ V[8]) shows that the shifts of the redox potentials due to complexation are similar in magnitude for the transitions from the neutral molecule to the radical cation and to the radical anion (+0.59 V and +0.72 V, respectively).

An η^6-coordination of the two heteroarenes in **3** can already be inferred from the NMR spectra (Table 1): As has already been observed in the case of **2**, the unusually large difference in the shielding of the protons H-2,6 and H-3,4,5 in the free ligand **1** is reduced in the sandwich complex **3**. According to the ^{1}H-NMR data of $[(C_6H_5As)Mo(CO)_5]$ **5** this does not occur upon η^1-coordination.[9] The NMR spectra of **3** show no signs of freezing-in of ring rotation down to $T = -70$°C. Such a freezing-in could not be ruled out a priori, since a rotational barrier had been found for open metallocenes.[10]

To answer the related question as to whether a certain conformation is preferred, a single crystal of **3**, twinned along (001), was subjected to an X-ray crystallographic analysis (space group $P2_1/n$; $a = 658.8(5)$, $b = 783.1(5)$, $c = 963.8(4)$ pm; $\beta = 94.78(5)°$; $Z = 2$; $T = -90$°C). The analysis revealed a high degree of disorder of the whole complex. In this context, note that no refined crystal structure investigations of sandwich complexes with unsubstituted heterocycles have thus far been reported in the liter-

[**] Metal π-Complexes of Benzene Derivatives, Part 27. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 26: [1].

ature. In the case of **3**, the disorder can be described to a good approximation in terms of a model in which half of the As atoms occupy position 1 of the ring and the other half position 4 of the ring ($R_g = 0.086$ for 424 reflections). The chromium atom is located 25 pm from a crystallographic center of symmetry, so that the two alternative orientations of the complex are slightly displaced from each other. It is therefore impossible to infer structural details of the coordinated arsabenzene rings. However, from the positions of the As atoms it can be concluded that either the *cis*- or the *trans*-eclipsed form is present, and, from the maximum Cr–As distance of 252 pm that genuine η^6-coordination prevails.[11]

A first indication of the electronic structure of **3** is provided by the ESR spectra of the radical cation $\mathbf{3}^{\odot\oplus}$: Whereas the data obtained for $\mathbf{3}^{\odot\oplus}$ in fluid solution (dimethylformamide (DMF)/$CHCl_3$ = 1:1, 30°C, $\langle g \rangle = 1.9892$, $a(^{53}Cr) = 19.3$ G, ligand hyperfine structure only partially resolved) are consistent with the parameters of bis(η^6-arene)chromium(d^5) cations,[12] the spectrum of $\mathbf{3}^{\odot\oplus}$ recorded in rigid solution (DMF/$CHCl_3$ = 1:1, −135°C, $g_\parallel = 1.9730$, $g_\perp = 1.9980$, $A_\perp(^{53}Cr) \approx 20$ G) shows a g-anisotropy, typical for bis(η^6-arene)chromium anions.[13] In the latter, an MO with dominant π-ligand character is singly occupied. The similar g-anisotropy thus suggests that—in contrast to cations of the corresponding carbocyclic arene complex—the singly occupied HOMO in $\mathbf{3}^{\odot\oplus}$ has considerable ligand character.

[6] Procedure: The vapors of arsabenzene **1** (3 g, 36 mmol) [7] and chromium (0.3 g, 5.8 mmol) were cocondensed over a period of 1.5 h onto the walls of an evacuated, cooled (−196°C) reaction vessel. After warming to room temperature under N_2, the dark red co-condensate was taken up in tetrahydrofuran and the solution filtered over silanated silica gel. The solvent and unchanged **1**, which can be recovered in this way, were removed in a high vacuum. Recrystallization of the residue from toluene afforded **3** in the form of reddish-black, analytically pure crystals (yield: 290 mg (0.87 mmol), 15% referred to vaporized Cr). M.p. 253°C (dec.); MS (EI, 70 eV): m/z 332 (26%, $M^{\oplus}$), 192 (39%, $M^{\oplus} - L$), 140 (58%, $L^{\oplus}$), 52 (100% $^{52}Cr^{\oplus}$).

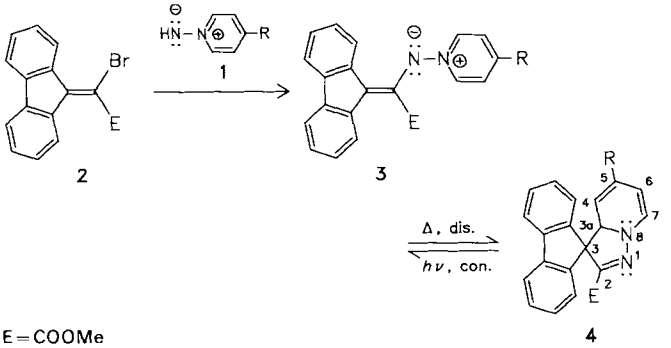
Dihydropyrazolopyridine and Bis(dihydroindolizine)—Novel Mono- and Bifunctional Photochromic Systems**

By *Heinz Dürr,* Charles Schommer,* and *Thomas Münzmay*



Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

Photochromic systems have long claimed worldwide interest.[1] They are not only of great importance in fundamental research but also in practice, where they find application as light-filters, chemical actinometers, silver-free materials for display devices in reprotechnology and more recently in computer chips.[1] We recently reported on a photochromic system based on a 1,5-electrocyclization of spirodihydroindolizine.[2] The aim of our present work is to prepare new systems that can undergo 1,5-electrocyclizations as well as molecules containing two chromophores.

We now report on the extraordinary reactivity of 1-pyridinioamides ("pyridin-*N*-imines") **1** towards pentafulvenes such as **2**. The deep-colored betaines initially formed are converted in a 1,5-electrocyclic reaction into the novel dihydropyrazolo[1,5-*a*]pyridines **4**; these are the first dihydropyrazole-based photochromic systems (Type 2,3-systems[3]).

For the synthesis of **4**, the *N*-imines **1** were generated from the corresponding *N*-aminopyridinium salts[4] with potassium carbonate in anhydrous dimethylformamide and allowed to react directly with **2** without prior isolation.[4d]

The deep-red to violet products transform within a few hours into the yellow title compounds **4**, whose structure

[**] Photochromic Systems, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 10: H. Dürr, V. Bach, *Tetrahedron Lett.*, in press.

Table 1. Some data of the dihydropyrazolo[1,5-*a*]pyridines **4** (UV/VIS data: see Table 2; for ^{1}H-NMR of **4a** see [5]).

	R	Yield [%]	M.p. [°C]	IR (KBr) [cm^{-1}] $\tilde{\nu}$(C=O)	$\tilde{\nu}$(C=N)
4a	H	67	154	1710	1505
4b	CH_3	30	150	1700	1505
4c	Ph	94	155	1715	1518
4d	CN	35	162	1702	1505
4e	COPh	15	176	1705 1650	1510

was derived from the spectroscopic data (Table 1). The assignment of the ^{1}H-NMR signals of the dihydropyridine protons (H-3a to H-7)[5] was accomplished by double resonance experiments, by a (^{1}H,^{1}H)-COSY experiment, and by comparison with the spectra of dihydroindolizines. The structure of **4** could be further verified by ^{13}C-DEPT spectroscopy and by a ^{13}C,^{1}H-correlated 2D-NMR experiment.—The structure of the intermediates **3** was elucidated by ^{1}H-NMR of the long-lived betaine **3g**. The conversion of **3** into **4** is a thermal disrotatory 1,5-electrocyclic ring-closure.

Table 2. Some UV/VIS data of **3** and **4**, as well as kinetic data [a] for the cyclization **3**→**4**.

	λ_{max} [nm] (lgε) **3**	**4**	10^3 k [s^{-1}]	$\tau_{1/2}$ [s]

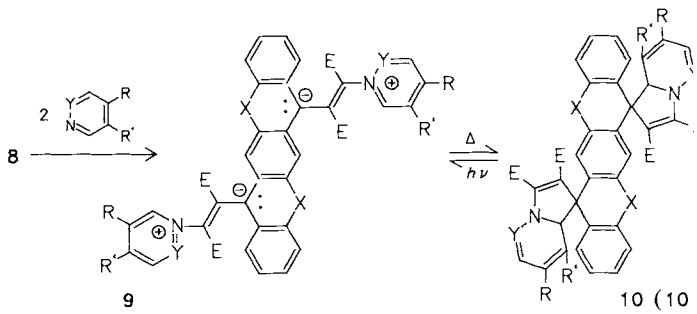
e	556	414 (3.81) 365 (3.80)	4.21	165

[a] At 25°C in CH_2Cl_2.

Table 2 shows the absorption maxima in the electronic spectrum of the betaines **3** and the dihydropyrazolopyridines **4**. The compounds **4** are converted in a photochemical controtatory 1,5-electrocyclic ring-opening reaction into **3**. The half-lives $\tau_{1/2} = \ln 2/k$ are also listed in Table 2. The compounds **3** and **4**, which can undergo reversible interconversion, thus form a novel photochromic system whose central reaction is 1,5-electrocyclic ring-opening.



We also report on the novel dichromophoric bis(dihydroindolizines) **10**. Based on the synthesis for monofunctional dihydroindolizines, the bifunctional 3*H*-pyrazoles **7** were generated first by 1,3-dipolar cycloaddition of the bis(diazo) compounds **6** to acetylenedicarboxylates **5**.[6a,b] The structure of **7** could be verified by ^{1}H-NMR, IR, and mass spectroscopy and by elemental analysis.

The bis(pyrazoles) **7** are cyclic *cis*-azo compounds, which can be converted photochemically with loss of nitrogen into cyclopropenes[6c] (in ether, pyrex filter, Hg high-pressure lamp HPK 125W; yield: **8a** 10%, **8c** 50%). Recrystallization of the solvent-free residue (ether) afforded the bis(cyclopropenes) **8**, which showed the strong IR bands characteristic for the cyclopropenes at 1850 cm^{-1}. For the synthesis of the photochromic bis(dihydroindolizines) **10**, the electrophilic bis(cyclopropenes) **8** were allowed to react with six-membered N-heterocycles in the molar ratio 1:2 (room temperature, ether). In all cases the deep-colored betaines **9** (or **9'**) occurred as intermediates which thermally cyclized to the yellow bis(dihy-

[a] At 25°C in CH_2Cl_2. [b] Determined by the Fischer method [7]. [c] Only **10c** and **10c'** could be separately isolated.

droindolizines) **10**. The adducts **10** were purified by column chromatography and recrystallized from ether. The assignment of the structures of **10** was possible on the basis of the ^{1}H-NMR, IR, and UV data.

The ^{1}H-NMR spectra of **10a, b** showed a sixfold splitting of the characteristic methyl ester signals and a complex splitting of the dihydropyridine and dihydropyridazine protons, respectively, thus indicating that both substances consist of inseparable diastereomers. **10c** and **10c'** (dihydropyridazine rings either *syn* or *anti* to the planar *trans*-fluoreneacene skeleton) could be isolated from the reaction mixture formed upon reaction of **8c** with pyridazine. According to the ^{1}H-NMR spectrum the isomers **10c** and **10c'** can interconvert by photochemical 1,5-electrocyclic ring opening and subsequent thermal cyclization.

The maxima in the UV/VIS region of **10a–c** lie between 378 and 396 nm (Table 3) and do not differ very greatly from those of the analogous monofunctional systems **12**[2a,b] (Table 3). The extinction coefficients of the bisadducts **10a–c** are about a factor of 1.5 to 1.7 greater than those of the monomers **12**. In solution, the compounds **10a, c** could be converted into the colored forms **9a–c** by irradiation with polychromatic light. A comparison of the bis(betaines) **9** with the analogous monobetaines **11** likewise shows good agreement of the maxima. The ε-values of **9a** and **11a** were determined from the degree of conversion using the Fischer method[7] (Table 3). Since the bisadduct **9a** has an ε-value 1.4 times higher for the longest-wavelength absorption than the monomer **11a**, it is very likely that both rings of the bisadduct can be opened. This photochemical ring opening **10** → **9'** → **9** should proceed in two one-photon steps (cf. also [8]). The rate constants of the cyclization of the betaines **9** → **10** points in all cases to a 1st order reaction; actually more complicated kinetics had been expected. The rate constants of the reaction **9** → **10** were increased in comparison to those of the monofunctional systems. The spiro bridge in **9c** causes a drastic increase in the rate constant compared to that of the mobile unbridged species **9a** and **9b**. The ΔH^+ values for the cyclization of **9** lie between 14 and 19 kcal/mol, the ΔS^+ values between -25 and -6 cal mol^{-1} K^{-1}. Hence, the ΔG^+_{298} values for all the compounds **9** are ca. 20 kcal/mol. That is, the novel bis(dihydroindolizines) **10** exhibit photochromic properties that are due to a 1,5-electrocyclic reversion to the betaines **9**.

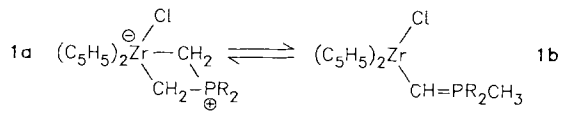
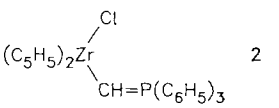
A Polyfunctional Dititanacyclobutane

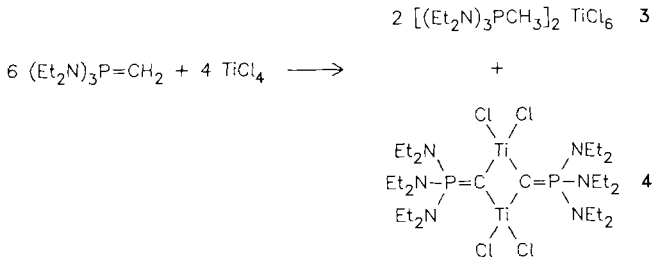


By *Hubert Schmidbaur,* Reinhard Pichl,* and *Gerhard Müller*



Whereas the chemistry of the metal complexes of phosphorus ylides (type **A**) has developed into a rapidly growing field of research[1] with important applications,[2] the chemistry of metal-substituted ylides (type **B**) has been relatively little investigated. All the examples that have been studied in detail are derived from the electron-deficient p- and d-block elements.[3]

Apparently, absolutely no compounds of type **B** containing electron-rich metal centers (such as the late transition-metal elements in low oxidation states) have been accessible. All attempts led only to isomeric products.[1] Moreover, even for the early transition metals, prototropism accompanied by the formation of a second metal–carbon bond between an R group of R_3P and the metal center is possible.



Thus, for example, an equilibrium mixture **1a/b** is found for the zirconium complex **1** ($R = N(C_2H_5)_2$) in solution. Only when no acidic H atom is present in the α-position to the P atom (e.g., in **2**) does the complex exist exclusively as an ylide.[4]

By the introduction of bulky diethylamino groups on the P atom, it has now been possible to replace both H atoms

[*] Prof. Dr. H. Schmidbaur, Dipl.-Chem. R. Pichl, Dr. G. Müller
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (FRG)

on the ylidic C atom by Ti atoms. Reaction of $(Et_2N)_3P{=}CH_2$ with $TiCl_4$ in diethyl ether results in immediate formation of a violet solution, from which the bis(phosphoranylidene)dititanacyclobutane **4** can be isolated in over 70% yield. The formation of the by-product tris(diethylamino)methylphosphonium hexachlorotitanate **3** (yield 80%) proves the stoichiometry of the transylidation. The structure of the analogous hexachlorozirconate was recently established by X-ray diffraction analysis.[5] The cyclic double ylide **4** is even soluble in solvents of low polarity. The $^{31}P\{^1H\}$-NMR spectrum of **4** in benzene exhibits a singlet at $\delta = 26.22$. The ^1H- and ^{13}C-NMR spectra establish the equivalence of all 12 ethyl groups.[6] The signal of the ylidic C atom could not be located with certainty. Black-violet crystals form from toluene at $-78\,^\circ C$; the X-ray structure analysis gave the centrosymmetric molecular structure shown in Figure 1.[7]

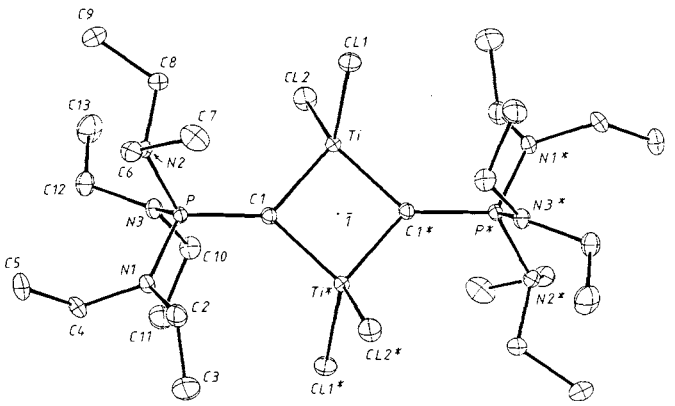


Fig. 1. Crystal structure of **4** (ORTEP, thermal ellipsoids 50%, without H atoms). Selected bond lengths [Å] and angles [°]: Ti-Cl1 2.278(1), Ti-Cl2 2.280(1), Ti-C1 1.957(2), Ti-C1* 1.957(2), P-C1 1.729(2), P-N1 1.656(2), P-N2 1.665(2), P-N3 1.644(2); Cl1-Ti-Cl2 110.69(3), Cl1-Ti-C1 116.32(7), Cl1-Ti-C1* 113.12(7), Cl2-Ti-C1 110.76(7), Cl2-Ti-C1* 117.04(7), C1-Ti-C1* 87.27(9), Ti-C1-Ti* 92.73(9), Ti-C1-P 128.0(1), Ti*-C1-P 136.9(1).

The most important detail of this structure, which has a nearly planar $PCTi_2CP$ framework, is the existence of four equal, remarkably short Ti–C distances (1.957(2) Å). This finding can be explained by the delocalization of the negative charge of the ylidic carbon atom into the Ti_2C_2 four-membered ring. The four Cl atoms are not completely symmetrically arranged with respect to the four-membered ring; this is revealed in part by the significantly different Cl-Ti-Cl1(2) angles.

The easily accessible complex **4** should prove to be an important starting material for numerous reactions.

Methylene-Bridged Dinuclear Gold(III) Complexes with Terminal and Bridging Ylide Ligands**

By *Hubert Schmidbaur** and *Christoph Hartmann*

Cyclic Au^I-ylide complexes **1**[1–3] are important model compounds for the oxidative addition of alkyl halides to multinuclear metal complexes.[4,5] Spectroscopic findings and structural data indicate the occurrence of an Au···Au interaction in **1**, which facilitates both metal atoms assuming the unusual oxidation state +II. Both monohaloalkanes as well as geminal di- and trihaloalkanes and even tetrahalomethanes add to the ring system in such a way that a genuine transannular metal–metal bond is first formed (**2**), which, in the case of polyfunctionalized halo-

1 2 3

alkanes is readily transformed in a subsequent step into a methylene bridge (**3**).[5] With suitable substrates these processes are at least partly reversible: thus, after methylation of the gold atoms in **3**, propane can be eliminated during the thermolysis.[6]

We have now tried to replace the substituents X in **3** by phosphorus ylides in order to obtain cationic complexes, which, with the exception of the CH_2-bridges, contain only onium-stabilized Au–C bonds. In the thermolysis of mononuclear cationic Au^{III} complexes the non-ylidic Au–C bonds proved to be the more labile centers [Eq. (a)].[7]

$$[R_2Au(CH_2PR_3)_2]^{\oplus} \xrightarrow{\Delta} [Au(CH_2PR_3)_2]^{\oplus} + R_2 \qquad (a)$$

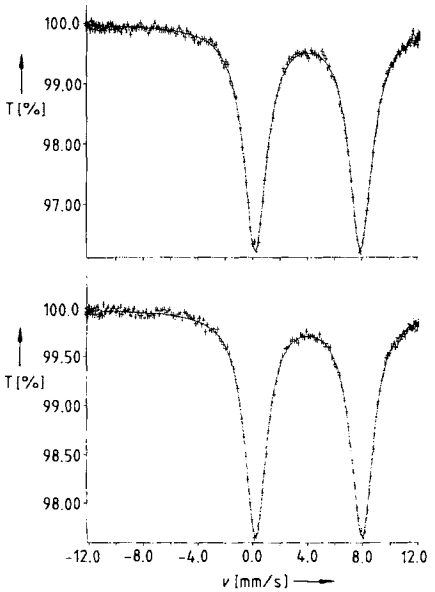
The reactions of **3a** (R = Me, X = I) and **3b** (R = Ph, X = Br) with $MePh_2P{=}CH_2$[8] and $Me_3P{=}CH_2$[9] smoothly afforded the products of double substitution **5a** and **5b**, respectively, in good yields. With reaction partners in the stoichiometric ratio 1 : 1, formation of the intermediates **4a** and **4b**, respectively, is also observed.[10]

3a, b 4a, b 5a, b

a, R = Me, R' = Ph, X = I

b, R = Ph, R' = Me, X = Br

5a, **b** are colorless, air stable salts which are soluble in chloroform and methanol, but insoluble in diethyl ether, toluene, and pentane. Since the structures of **1–3** were already known,[4,5] the constitution of **5a**, **b** could easily be deduced from the analytical and spectroscopic data: The signals of the high resolution ^1H-, ^{13}C-, and ^{31}P-NMR spectra can be unequivocally assigned to the individual structural units[11] and are consistent with a C_{2v} symmetry for the cations in solution (mirror planes through P*CH_2P and Au*CAu). An essentially rigid boat conformation can be assumed for the eight-membered ring.[4,5] This and the location of the *CH_2 bridge on one side of the eight-membered ring give rise to a non-equivalence of the H-atoms ($A_2A_2'B_2B_2'XX'$ system) and substituents R on the eight-membered ring (A_3B_3X system when R = CH_3). In contrast the H-atoms of the *CH_2 bridge and of the exocyclic CH_2 groups are in each case equivalent. Accordingly, the ^{197}Au-Mossbauer spectra of **5a**, **b** show in each case a doublet with almost equal values for the isomeric shift IS and the quadrupole coupling constants QS (Fig. 1), thus also providing proof of the equivalence of the metal atoms and their oxidation state (+III).[12]



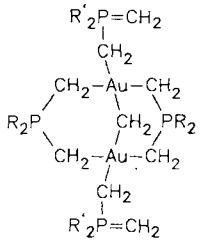


Fig. 1. ^{197}Au-Mössbauer spectra of **5a** (top) and **5b** (bottom) at 4 K (I = relative transmission, v = relative rate). **5a**: IS = 4.04 mm/s, QS = 7.72 mm/s. **5b**: IS = 4.10 mm/s, QS = 7.73 mm/s.

The constitutional isomerism of the complex cations of **5a**, **b** is recognizable in the field desorption mass spectra. In the case of **5a**, not only the dication (*m/z* 508) is observable, but also the monocation (*m/z* 1141) associated with an iodide ion. Observation of the unexpected cation $[Me_3PCH_2AuCH_2PMe_3]^{\oplus}$ demonstrates the ready formation and stability of these cations, which are also formed according to equation (a). The mass spectra of **5a**, **b** also contain the signals of the cations of the heterocycles **1** (R = Me and Ph, respectively). The IR spectra of **5a**, **b** do not show any typical bands for Au–X vibrations.

6a, R = Me, R' = Ph

6b, R = Ph, R' = Me

The corresponding ylides **6a**, **b** can be generated from the salts **5a**, **b** by reaction with strong bases under mild conditions. In solution the ylides are yellow, have different ^{31}P-NMR spectra, and can be reconverted into the salts by treatment with hydrogen haloacids. A rearrangement of the cation of **5a** into that of **5b** via an ylidic intermediate, with the terminal ylide taking up the bridge position and vice versa, could not be detected.

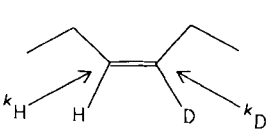
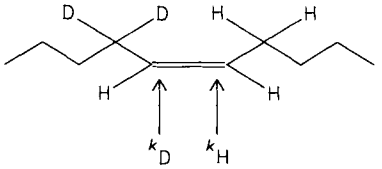
Secondary Deuterium Kinetic Isotope Effects in Enantioselective Hydroborations with (+)-Diisopinocampheylborane**

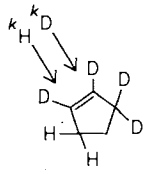


By *Brian E. Mann, Peter W. Cutts, James McKenna,* Jean M. McKenna,* and *Catriona M. Spencer*

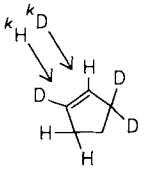
High degrees of regio- and/or stereo-selectivity in organic reactions are often achieved through the effect of differential strong non-bonded interactions in competitive transition states, where the geometrical arrangements of reacting bonds are controlled by stereoelectronic factors. The non-bonded interactions typically involve hydrogen atoms in alkyl or other groups. In such cases highly selective reactions would be expected to exhibit large inverse secondary hydrogen kinetic isotope effects associated with isotopic replacement at the compressed hydrogen atoms. A method for precisely locating the positions of important compressive interactions is therefore available, and we have successfully applied this method to investigate the relevant transition-state characteristics for enantioselective hydroborations of alkenes using (+)-diisopinocampheylborane, **1**, prepared from (−)-α-pinene.



1



Various detailed models, qualitative and (more recently) quantitative have been suggested[1] for this interesting reaction, which gives high enantioselectivity notably with simple acyclic non-terminal (*Z*)-alkenes, and which may be regarded as perhaps the most important early example[2] of the range of highly enantioselective reactions of great current interest in preparative organic chemistry. In every model, strong steric interactions between alkyl or other groups in the alkene and in the hydroborating reagent are envisaged, which serve to differentiate the free energies of competitive diastereoisomeric transition states. We now wish to report new and significant experimental evidence with which any satisfactory detailed model must accord.



2

3

4

5

The deuteriated (*Z*)-alkenes **2** through **5** were synthesized, hydroborated at −10°C in diglyme with **1**, and subsequently oxidized with aqueous Na_2O_2 at 25–40°C. The resultant reaction mixtures were analyzed by ^{1}H-NMR spectroscopy in presence of the lanthanoid shift reagent[3] $Eu(fod)_3$ to estimate in each case the relative proportions of structurally isomeric secondary alcohols. (Example: **6a** and **6b** were formed from **2**.) The enantiomeric purity of the isomers was not measured. The product ratios are equated to the competitive rate constant ratios, k_D/k_H, where k_D and k_H are defined as the overall rate constants for the attachment of the B-atom of **1** to the particular alkene C-atoms indicated by the arrows in the structural formulas. For substrates **2** through **5** we evaluate the kinetic isotope effects k_D/k_H as follows: **2**, 1.00 ± 0.17; **3**, 2.86 ± 0.24; **4**, 1.45 ± 0.16; and **5**, 1.41 ± 0.35. Precision limits quoted are standard deviations.

$$\mathbf{2} \longrightarrow \underset{\mathbf{6a}}{H_5C_2{-}CHOH{-}CDH{-}C_2H_5} + \underset{\mathbf{6b}}{H_5C_2{-}CH_2{-}CDOH{-}C_2H_5}$$

Hydroborations of simple acyclic non-terminal (*Z*)-alkenes with **1** are independently known[1,2] to be highly (up to 98%) enantioselective, so our results for **2** and **3**, and, by extrapolation for **4** and **5**, may be interpreted in terms of the characteristics of transition states leading to the expected[4] preferred enantiomers. Two important conclu-

[**] This work was supported by the Science and Engineering Research Council.

sions regarding the preferred transition states for hydroboration of such (*Z*)-alkenes emerge. Firstly, during the reactions there is no appreciable steric compression at the vinylic hydrogens; this conclusion follows from the absence of a secondary kinetic isotope effect for substrate **2** and from the similar values for this effect for **4** and **5**. Secondly, there is very strong steric compression at the allylic hydrogens during the reaction; this follows from the *exceptionally large* inverse kinetic isotope effect for **3**. The values for **4** and **5** are smaller (but still substantial), presumably because the allylic CH_2 (or CD_2) groups are partly bent back away from the reaction area by incorporation into the cyclopentene ring.

In an investigation of the enantioselective hydroboration of some deuteriated terminal alkenes, reaction of **1** with (*E*)- and (*Z*)-1-deuterio-1-hexene followed by oxidation had previously been reported[5] to yield active 1-deuterio-1-hexanols with 86% and 42% enantiomeric purity respectively, the enantiomeric ratios being assessed both biochemically and by asymmetric synthesis with ethylphenylacetic anhydride. We have repeated this work, but determined the enantiomeric purities by the more convenient modern procedure using NMR spectroscopy in presence of the chiral shift reagent[3] $Eu(hfbc)_3$. We found enantiomeric purities of 65% and 46%, respectively. This substantial difference is clearly due to a combination of several kinetic isotope effects, but it is not in this case algebraically possible to calculate absolute values of isotope effects, analogous to those given above, for enantioselective hydroboration in one or other chiral sense.

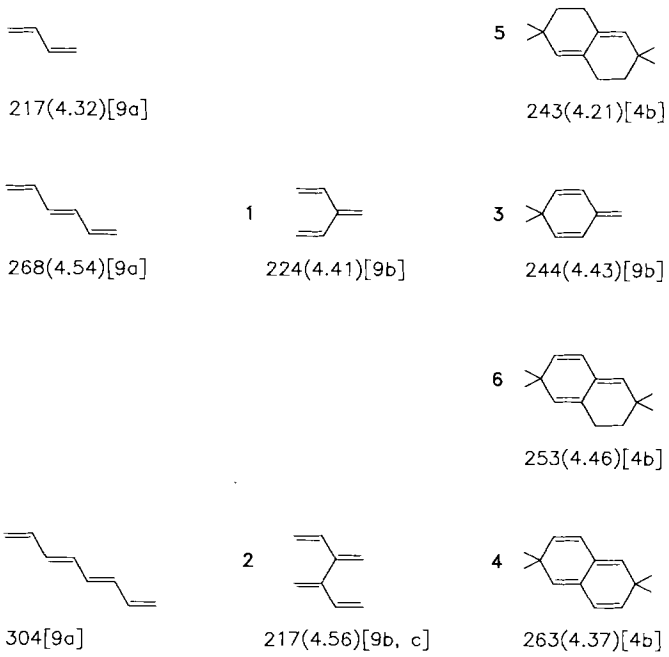
A Novel Entry to Dendralene Systems



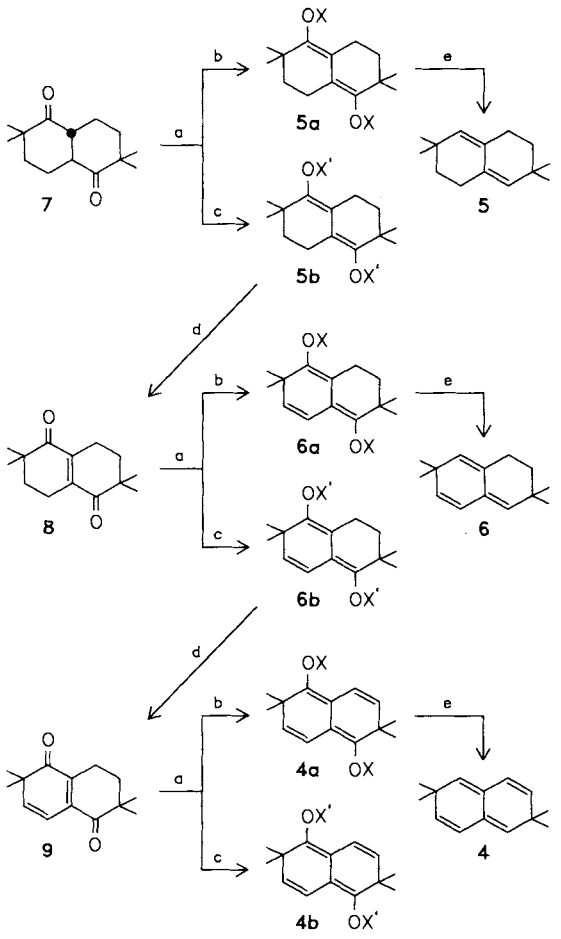
By *Thomas Loerzer, Ralf Gerke,* and *Wolfgang Lüttke**

Dedicated to Professor Edgar Heilbronner on the occasion of his 65th birthday

Of the four groups of polyenes—linear polyenes, annulenes, radialenes, dendralenes[1]—the parent compounds of the dendralenes have been the subject of very few studies, even though the clarification of their conjugative behavior and the properties determined by their topology[2] deserve interest. The first two known members **1** and **2** exhibit the light absorption of the butadiene chromophore (cf. Table 1); that is, they must be twisted, for steric reasons.

[*] Prof. Dr. W. Lüttke, Dr. T. Loerzer, R. Gerke
Institut für Organische Chemie der Universität
Tammannstrasse 2, D-3400 Göttingen (FRG)

Table 1. UV absorption data (λ_{max} (lg ε); cyclohexane) of linear polyenes and dendralenes.



In order to determine the "true" structural properties of the dendralenes we therefore had to prepare fixed planar compounds of this type. In the case of the triene **1** a corresponding substance **3** is already known.[3] We report here on the synthesis of the fixed tetraene **2**, the dendralene **4**, and its partially hydrogenated analogues **5** and **6**, each of which carry two pairs of geminal dimethyl groups for protection against hydrogen shifts.

The synthetic strategy chosen by us, which involves the use of tetramethyldiketone **7** as starting material, enabled successive incorporation of the double bonds, exploiting the trick of completely enolizing a carbonyl compound (step a). The resulting enediolate ions were either converted into the reducible enol phosphates **5a**, **6a**, **4a** (step b) or oxidized via the trimethylsilyl enol ethers **5b**, **6b** (steps c and d) (Scheme 1).

The starting compound **7** (m.p. 163 °C; overall yield 34%)[4] can be readily obtained by a previously described three-step synthesis[5] from 1,5-decalindione. For the complete enolization of **7** and its dehydro compounds **8** and **9** the base system potassium hydride/[18]crown-6[6] is, to our knowledge, the most suitable. The enolates are subsequently trapped in situ with chlorodiethyl phosphate and chlorotrimethylsilane, respectively; the enol ether derivatives **5a**, **6a**, **4a** and **5b**, **6b**, **4b** are obtained in yields of more than 60%. These compounds are stabilized by the geminal dimethyl groups to such an extent that they can be purified even by column chromatography (basic alumina; pentane).

The bistrimethylsilyl enol ethers **5b** and **6b** can—formally—be oxidatively desilylated at room temperature with *N*-bromosuccinimide.[7] We assume that this proceeds in each case via the 1-oxa-8a-bromotrimethylsilyl enol ether, which spontaneously loses bromotrimethylsilane. It is thus possible to dehydrogenate the dicarbonyl compounds

Scheme 1. a) KH/[18]crown-6, THF, RT, 15 h; molar ratio **7**, **8** or **9**: KH = 1:4. b) Reaction in situ with $(EtO)_2POCl/Et_3N$, RT, 3 h; 80–95%. c) Reaction in situ with Me_3SiCl/Et_3N, RT, 30 min; 60–85%. d) *N*-bromosuccinimide, THF, RT, 15 min; 95%. e) Ti^0, THF, reflux, 2 h; 5–20%. – X = $P(O)(OC_2H_5)_2$, X' = $Si(CH_3)_3$.

7 and **8** extraordinarily smoothly via the intermediates **5b** and **6b**, respectively.

Reduction of the enol phosphates **5a**, **6a**, **4a** with zerovalent titanium (prepared from titanium trichloride and potassium) afforded the diene **5** and the dendralenes **4** and **6**.[8] The yields decreased sharply with increasing number of double bonds. This is, in part, due to overreduction. **4**, **5**, and **6** could be isolated in pure form by gas-chromatographic separation (15% FFAP on Chromosorb W/AW-DMCS; 180°C) (**4**: m.p. 68°C, 5%; **5**: m.p. 44°C, 20%; **6**: m.p. 43°C, 15%).

For characterization of the bonding properties we consider here only the UV absorption data (Table 1). Other than in the case of the open-chain dendralenes **1** and **2**, in the fixed cyclic species **3**, **6** and **4** a bathochromic shift of the absorption maximum of ca. 10 nm per double bond is observed with increasing number of double bonds. The shift is—regardless of the alkyl substitution—essentially smaller than in the analogous linear polyenes. Consistent with PPP calculations[4b] and with the molecular topology[2] the π-delocalization in the dendralenes is obviously much more weaker than in the linear polyenes.

BOOK REVIEWS

Reductions in Organic Chemistry. By *M. Hudlicky*. Ellis Horwood Ltd., Chichester 1984. xvi, 309 pp., hardback, £ 35.00.—ISBN 0-85312-345-4

This book claims to present a comprehensive coverage of all types of reduction reactions. The author attempts to link the numerous classes of compounds and the various different methods of reduction in a sort of matrix in order to reach his difficult goal. With the choice of predominantly very simple model compounds, the neglect of stereochemical problems and the uncritical juxtaposition of important and unimportant methods, the author pays a high price to achieve his aim.

The introductory chapter covers catalytic hydrogenations, reductions with hydrides and hydrido-complexes, electroreductions, and reductions with metals and non-metallic reagents.

For the sake of clarity, it would have been better to dispense with experimental details and large-scale diagrams of apparatus at this point, especially since these are presented again, at some length, in an experimental appendix. The reductions of nearly all classes of compounds are listed in the main part of the book, accompanied by an abundance of examples. In this way completeness is achieved, but a discussion of problems of regio- and stereoselectivity and their basis in reaction mechanisms, which would have been appropriate, is lost. The field of reductions with chiral reagents, which has been the focus of much recent attention, is indeed broached here and

there in the book but surely deserves a more detailed treatment.

Preparative chemists will find useful the tables that follow the main chapter, in which are grouped important types of educt, reduction reagents and products. These tables refer back into the main body of the text and thence to an extensive literature index.

The last part of the book consists of fifty experimental procedures for the preparation of special reduction reagents and for the reduction of representative compounds. Since the compounds chosen have got quite simple structures, these procedures can serve only as a guide; for more complicated molecules it would certainly be advisable to consult the original literature.

This book does not, then, offer a critical view, but simply a superficial description of the extensive arsenal of reduction methods. For the practical chemist there is useful guidance, especially in the numerous tables and experimental procedures. The very high price is bound to stand in the way of purchase for everyday use.

Franz-Peter Montforts [NB 712 IE]
Institut für Organische Chemie
der Universität Frankfurt (FRG)

Handbuch der Gaschromatographie. Edited by *E. Leibnitz* and *G. Struppe*. Akademische Verlagsgesellschaft Geest & Portig, Leipzig 1984. 828 pages, hardback, DM 198.00. Order No. 669-628-5 (Sole distributors for the FRG: W & P Buchversand für Wissenschaft und Praxis, Weinheim, ISBN 3-89141-001-8)

This handbook, compiled by an authors' collective, amounts to a comprehensive treatment of all aspects of gas chromatography, which is certainly not lacking in detailed information. This is an area of chemistry which is rapidly developing and even a freshly published work is bound to be partly out of date at the time of publication; however, the new edition of this handbook does cover in supplements more recent techniques for sample introduction (e.g. "on column injection"), modern methods of coupling, column connections, flexible quartz capillaries, chemically immobilized stationary phases etc., even if not in close detail.

There are successful chapters on the principles and development of gas chromatography, capillary columns, detectors, quantitative analysis (albeit almost exclusively on "packed" columns) and the coupling of gas chromatography with spectroscopic methods. Packed columns, whose significance is diminishing these days, are rather overemphasized in two extensive chapters. It may be a drawback of this new edition that the increasing trend towards use of capillary gas chromatography is not sufficiently recognized. The admittedly difficult problems encountered in quantitative analysis with capillary columns are only briefly discussed.

The treatment of stationary phases is very comprehensive but a supplement covering newer literature on the use of chiral stationary phases would not have come amiss. Likewise, there is no reference to complexation gas chromatography and the work of *V. Schurig*. The chapter on derivatization reactions is also in need of supplementation: much of the newer literature is not included here. However, the handbook does contain chapters on such industrial aspects as process control, process regulation and automation. The physico-chemical basis of the different methods, the theory of temperature programming and many fundamental concepts are given detailed and comprehensible treatment.

This handbook not only offers the user, whether involved in industrial or academic research, many hints for the optimization and the solution of separation problems, it also provides fundamental knowledge in this area of physical chemistry.

Macrolide Antibiotics. Chemistry, Biology and Practice. Edited by *S. Ōmura*. Academic Press, Orlando 1984, 635 pages, hardback, $ 89.50.—ISBN 0-12-526450-X

Professor *Satoshi Ōmura* (Kitasato University Tokyo) is surely currently by far the best authority on the chemistry and biochemistry of macrolides. His book on the chemistry, biology and applications of macrolide antibiotics is correspondingly comprehensive. He has succeeded in gathering a group of renowned authors about him so that the content of this book goes far beyond his own field of interest, and even includes the application of macrolides in human and veterinary medicine.

A good half of the book is devoted to classical macrolides of the erythromycin and carbomycin type, the subgroup of macrolides which has found the broadest medical application. The chapters on the determination of constitution and configuration, on chemical modifications and structure/activity relationships, and on regulation of biosynthesis and the genetics of macrolide production are sound and contain extensive literature references. Especially penetrating is the description by *S. Masamune* of the total synthesis of macrolides. An easily grasped model of the structure and mode of function of ribosomes serves as the basis for *J. W. Corcoran*'s chapter on the mode of action and resistance mechanisms. This section gives some idea how much fundamental research in biochemistry and molecular biology owes to the use of antibiotics. The sections on macrolides in clinical *(I. Nakayama)* and veterinary *(R. C. Wilson)* use may be too brief for medical practitioners. However, they provide a valuable survey of the application of macrolide antibiotics for the chemist or biochemist.

The quite appreciable second part of the book is devoted to fungicidal polyene macrolides, of which some (e.g. amphotericin B, nystatin) have found medical application, albeit limited. This part is arranged similarly to the first and owes its completeness to the contributions of *H. Tanaka* (structure and fungicidal activity), *J. F. Martin* (biosynthesis, regulation and genetics), *E. F. Gale* (mode of action and resistance mechanisms) and *C. P. Schaffner* (clinical practice).

To keep the size of the book under control, the "macrolide-like" antibiotics from actinomycetes have been handled in a much more condensed way, even though a series of biogenetically and structurally most interesting compounds have recently been discovered here. To these belong, e.g., chlorothricin and nargenicin, as well as metabolites with high fungicidal and cytotoxic activity, like oligomycins, venturicidins and concanamycins. However, a good literature register enables access to these compounds as well. This applies too for the numerous fungal macrolides with quite diverse biological effects, for macrodiolides

(e.g. the boron containing boromycin), and for the macrotetrolides, which complex alkali metal ions specifically. In contrast, avermectins and milbemycins are dealt with in a chapter of their own (by *M. H. Fisher* and *H. Mrozik*), no doubt on account of their promising antiparasitic properties.

This book will be a useful aid, above all to natural products chemists, biochemists and microbiologists. It may also have much to offer medical personnel with an interest in chemistry.

Vom Würfelspiel zum Naturgesetz. Simulation und Modelldenken in der Physikalischen Chemie. By *G. Marsch*. VCH Verlagsgesellschaft, Weinheim 1985. x, 269 pp., bound, DM 58.00.—ISBN 3-527-26226-1

There has been no lack of attempts to present the difficult material of physical chemistry in a simple and didactically skillful manner in the past. The author has nevertheless been successful in finding a new approach which is particularly addressed to the mathematically less experienced reader. He presents a selection of dice and board games in order to illustrate some of the fundamental concepts of statistical thermodynamics and reaction kinetics.

Individual chapters deal with game models for the Maxwell distribution of velocities, the Boltzmann distribution, the concept of entropy, and various aspects of chemical reactions. The final chapter includes games for the illustration of several problems from different fields including the theory of chromatography, light absorption, crystallization, and phase separation of liquids.

The compilation under consideration is a success, reflecting the author's long experience in university instruction. Little more than a knowledge of the most elementary mathematical concepts and operations is assumed. The reader learns more difficult concepts, such as that of entropy, "as a player." Historical details of the development of statistical thermodynamics enrich the book decidedly. In the chapter on chemical reaction kinetics, the author also includes quite recent examples taken from oscillating reactions and processes of molecular selection. In this chapter, the algorism developed by *Gillespie* of the simulation of chemical processes would have fit in well, above all since it is well suited to illustrate the extrapolation from the extremely small numbers of statistical events in the games to the laws of kinetics in real systems. The section covering games played on a pocket calculator will surely be very useful to the reader. It is unfortunate that the author has not included microcomputers too, which are accessible almost everywhere nowadays, and on which many aspects of university instruction can be quickly demonstrated in a didactically effective manner.

On the whole, this excellent monograph is an enrichment of the literature used in physical-chemistry instruction. It can be warmly recommended to students and university teachers alike. Senior physicists and chemists will also discover much of interest in this work: old, familiar material appears in a new light when looked at through "game-glasses."

Orbital Interactions in Chemistry. By *T. A. Albright, J. K. Burdett,* and *M. H. Whangbo*. Wiley, Chichester 1985. xv, 447 pp., bound, £ 63.25.—ISBN 0-471-87393-4

As preface, let me say that in spite of the large number of books on the market dealing with the principles, methods, and applications of MO models in various fields of chemistry, the book under consideration could fill a gap that has been recognized not only by those who are engaged in teaching this area of theoretical chemistry, but also and especially by all those—whether advanced students or research colleagues—who want to learn MO theory as a "tool".

The content and presentation of this book are obviously strongly influenced by the theoretical approach and by the didactic example of the scientific mentor of the three authors, *Roald Hoffmann*, whose Preface to the book is well worth reading. Within the realm of the possible, this work comes very close to satisfying its very high aim: the transmission of a qualitative, sound understanding of the electronic structure, geometry, and reactivity of compounds, ranging from simple molecules to solids. This understanding is based on a model that is as universally useful as possible, the model of interacting orbitals. The consequent utilization of the fragment-orbital formalism runs like a red thread through the entire book. According to this formalism, the orbitals of complex molecules are built up from simple orbital building blocks, or fragments, using a few, straightforward interaction rules from perturbation theory.

In the beginning chapters, the theoretical foundations and formalisms are discussed in the necessary depth. Only little mathematical knowledge is required, a consideration that is not totally unimportant for a book's wide acceptance by chemists. The treatment is neither tiring nor unnecessarily extensive, considering the aims of the book. Here, chapters are found covering AO's and MO's, as well as the qualitative rules for orbital interactions and for the construction of correlation diagrams based on perturbation theory; group theory, orbital symmetry, and an introduction to the fragment-orbital approach are also included. In this section, hybridization, perturbations based on electronegativity and geometry, Walsh diagrams, and Jahn-Teller distortions are treated. In an extraordinarily thorough and detailed manner, and by means of many examples, the qualitative derivation of the "appearance" of molecular orbitals and of their relative energies is presented and made clear to the reader using qualitative, pictorial representations. Thus, he learns to "think in orbitals", progressing from simple, two-atom systems to complex molecules and finally to solids. The chapter on the electronic structure of solids is especially attractive: the correspondence between the MO picture of molecular entities, on the one hand, and the band structures of crystalline solids, on the other, as well as quasi analogous concepts and phenomena, are elaborated very well didactically. A bridge between molecular chemistry and solid-state physics can thus be recognized. A clearly written chapter, immediately accessible even to non-theorists, dealing with the limitations of the one-electron model in molecules, with electron-electron interactions, state energies, etc., including CI-wave functions, has not been overlooked. This is important, since most of the book is deliberately kept at the simple one-electron valence-MO level.

Whereas the basic theory and applications presented in the first half of the book are illustrated using organic molecules and light atoms as examples, it is predominantly the series of chapters on the application of MO theory to

inorganic and organometallic transition-metal compounds, following a chapter on so-called hypervalent species and their MO theory, that make the book worth reading. A survey like the one that the three authors give here has until now been lacking in the textbook field. A very thorough treatment, not only of the basic types of organometallic fragments, ML_n, and their bonding capability, but also of questions concerning the electronic structure, molecular geometry, structural dynamics, and reactivity of metal complexes, is provided using numerous qualitative MO and interaction diagrams. *Hoffmann's* Isolobal Analogy, treated at the end of this part of the book, serves to overlap and link inorganic with organic chemistry. This concept has recently received wide application as a structural and even as a synthetic guideline, especially in the organometallic field. It would have perhaps been useful if the authors had pointed out a little more clearly that transition-metal fragments and complexes with the same orbital characteristics may nevertheless differ in their chemistry, depending on the position of the respective metal atom within its group, on the actual charge, and on the appearance of special problems (relativistic effects, spin-orbit coupling, etc.) with the heavier transition metals. A chapter on cluster compounds closes the book.

The authors have chosen the subject matter and examples, especially in the section on transition metals, in such a way that the book can be considered a review at the textbook level of the research performed in this field by *Hoffmann* and his co-workers over the past ten years. Didactically, the book is a masterful achievement, and in this respect, the graphic work (formulas, MO diagrams, etc.) is in no way inferior to the text. Misprints, inevitable in a first edition, are not worth going into here. The references are sufficiently numerous and suitably chosen considering the aim of the book.

This book could be of great benefit to teachers and students alike. It could contribute to the understanding of modern chemistry as an integrated whole, rather than as a rigidly compartmentalized system. Much would be gained if university teachers gave this book the same attention as has been given to the original publications on which it is based. It is unfortunate that the book's price can only be regarded as an unreasonable demand and that students as a rule will be prevented from purchasing it. As is so often the case, a moderately priced, paperback edition would have been more appropriate and more conducive to the wider circulation and use of the book.

Common Fragrance and Flavor Materials. By *K. Bauer* and *D. Garbe*. VCH Verlagsgesellschaft, Weinheim 1985, 213 pages, hardback, DM 112.00.—ISBN 3-257-26038-2

In seven chapters of a monograph of 213 pages, the two authors try to give an overview of the chemistry of flavors and fragrances. The authors are predestined to do so by their profession, but succeed only partly. The classification of odorous compounds according to their structure is of course a possibility, but certainly not the clearest. This leads to curious situations. Macrocyclic odorants can thus be found in three different places, e.g. civetone on p. 56, 15-pentadecanolide on p. 104, and ambrettolide on p. 137. A classification by odors would have shown the reader the molecular similarities and structural variety that can cause a typical type of odor. Also elsewhere such present knowledge of the relationship between structure and odor is not covered. The relevant remarks in chapter 1 "Introduction" are totally insufficient. The information about the sources and the detailed descriptions of the odors of compounds that are listed in the voluminous chapter 2 "Single Fragrance and Flavor Compounds" are an agreeable surprise, but to give the boiling points, refractive indexes, and densities would have been justified 30 years ago, not today. This is aggravated by the fact that modern analytical data such as IR, NMR and MS are not given. As an extreme, chapter 3 "Essential Oils", lists the above "classical" physical constants of oils of different provenience in tabular form. Pages 152 and 171 could have been omitted together with another ten pages. Instead one would have wished modern analytical data and also information about important oils not treated at all. If physical data are to be compared, why not GC-fingerprints?

Specialists will miss the trade names for quite a number of odorants. 1,1,2,3,3,8-hexamethyl-6-oxa-2,3,5,6,7,8-hexahydro-1*H*-benzo[f] (p. 102) will be meaningless whereas the name Galaxolide® will recall the odorous power of an extraordinary musk substance. Lyral® (p. 58), Hedione® (p. 62) and Lilial® (p. 71) are some further examples. Even names that can be found in most textbooks like Exaltolide® are not given. Exaltone® and a number of other modern odorants are not treated at all. Flavor compounds have been specially neglected. The extraordinary richness of flavor compounds found, for example in the area of *N*- and *S*-heterocycles has been compressed into two pages. Literature references are cited in a very liberal manner. Half of them come from works called ISO and EOA, which will mean nothing to chemists, who, according to the introduction, are included in the potential readership. The layout and legibility are excellent, as is also the translation into English.

A Receptor-Mediated Pathway for Cholesterol Homeostasis (Nobel Lecture)**

By Michael S. Brown* and Joseph L. Goldstein*

In 1901 a physician, *Archibald Garrod*, observed a patient with black urine. He used this simple observation to demonstrate that a single mutant gene can produce a discrete block in a biochemical pathway, which he called an "inborn error of metabolism." *Garrod*'s brilliant insight anticipated by 40 years the one gene–one enzyme concept of *Beadle* and *Tatum*. In similar fashion the chemist *Linus Pauling* and the physician *Vernon Ingram*, through study of patients with sickle cell anemia, showed that mutant genes alter the amino acid sequences of proteins. Clearly, many fundamental advances in biology were spawned by perceptive studies of human genetic diseases.[1]

We began our work in 1972 in an attempt to understand a human genetic disease, familial hypercholesterolemia or FH. In these patients the concentration of cholesterol in blood is elevated many fold above normal and heart attacks occur early in life. We postulated that this dominantly inherited disease results from a failure of end-product repression of cholesterol synthesis. The possibility fascinated us because genetic defects in feedback regulation had not been observed previously in humans or animals, and we hoped that study of this disease might throw light on fundamental regulatory mechanisms.

Our approach was to apply the techniques of cell culture to unravel the postulated regulatory defect in FH. These studies led to the discovery of a cell surface receptor for a plasma cholesterol transport protein called low density lipoprotein (LDL) and to the elucidation of the mechanism by which this receptor mediates feedback control of cholesterol synthesis.[2,3] FH was shown to be caused by inherited defects in the gene encoding the LDL receptor, which disrupt the normal control of cholesterol metabolism. Study of the LDL receptor in turn led to the understanding of receptor-mediated endocytosis, a general process by which cells communicate with each other through internalization of regulatory and nutritional molecules.[4] Receptor-mediated endocytosis differs from previously described biochemical pathways because it depends upon the continuous and highly controlled movement of membrane-embedded proteins from one cell organelle to another in a process termed receptor recycling.[4]

Many of the mutations in the LDL receptor that occur in FH patients disrupt the movement of the receptor between organelles. These mutations define a new type of cellular defect that has broad implications for normal and deranged human physiology.

In this lecture we first discuss the peculiar problem of plasma cholesterol transport. We then present some historical aspects of FH and the origin of the LDL receptor concept. Next, we summarize current knowledge of this receptor and the mechanism by which it functions in cells. Finally, we relate these findings to the pathogenesis of FH and to the common clinical problem of high blood cholesterol levels and atherosclerosis in human subjects.

The Problem of Cholesterol Transport

Cholesterol is the most highly decorated small molecule in biology. Thirteen Nobel Prizes have been awarded to

scientists who devoted major parts of their careers to cholesterol.[5] Ever since it was first isolated from gallstones in 1784, almost exactly 200 years ago, cholesterol has exerted a hypnotic fascination for scientists from the most diverse domains of science and medicine. Organic chemists have been fascinated with cholesterol because of its complex four-ring structure. Biochemists have been fascinated because cholesterol is synthesized from a simple two-carbon substrate, acetate, through the action of at least 30 enzymes, many of which are coordinately regulated. Physiologists and cell biologists have been fascinated with cholesterol because of its essential function in membranes of animal cells, where it modulates fluidity and maintains the barrier between cell and environment, and because cholesterol is the raw material for the manufacture of steroid hormones and bile acids. And finally, physicians have been fascinated because elevated levels of blood cholesterol accelerate the formation of atherosclerotic plaques, leading to heart attacks and strokes. The studies of cholesterol therefore embrace almost all disciplines of modern biology. If the role of cholesterol in biomedicine is to be elucidated, all of these disciplines must be employed.

Cholesterol is a Janus-faced molecule. The very property that makes it useful in cell membranes, namely its absolute insolubility in water, also makes it lethal. For when cholesterol accumulates in the wrong place, for example within the wall of an artery, it cannot be readily mobilized, and its presence eventually leads to the development of an atherosclerotic plaque. The potential for errant cholesterol deposition is aggravated by its dangerous tendency to exchange passively between blood lipoproteins and cell membranes. If cholesterol is to be transported safely in blood, its concentration must be kept low, and its tendency to escape from the bloodstream must be controlled.

Multicellular organisms solve the problem of cholesterol transport by esterifying the sterol with long-chain fatty acids and packaging these esters within the hydrophobic cores of plasma lipoproteins (Fig. 1). With its polar hydroxyl group esterified, cholesterol remains sequestered within this core, which is essentially an oil droplet composed of cholesteryl esters and triglycerides, solubilized by a surface monolayer of phospholipid and unesterified cholesterol and stabilized by protein. The small amounts of unesterified cholesterol on the surface of the particle are maintained in equilibrium exchange with the cholesterol of cell membranes, but the larger amounts of cholesteryl esters remain firmly trapped in the core of the particle and leave the particle only as the result of highly controlled processes.

The major classes of plasma lipoproteins were delineated in the 1950s and 1960s through work in many laboratories, most notably those of *Oncley*,[6] *Gofman*,[7] and *Fredrickson*.[8] The four major classes are very low density lipoprotein (VLDL), intermediate density lipoprotein (IDL), low density lipoprotein (LDL), and high density lipoprotein (HDL). A schematic representation of LDL, the most abundant cholesterol-carrying lipoprotein in human plasma, is shown in Figure 1.

Packaging of cholesteryl esters in lipoproteins solves the problem of nonspecific partitioning of cholesterol into cell membranes, but it creates another problem, namely one of

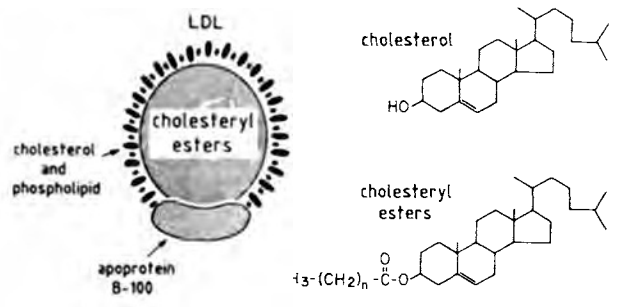

Fig. 1. Structure of plasma LDL (left) and its cholesterol and cholesteryl ester components (right). LDL is a spherical particle with a mass of 3×10^6 daltons and a diameter of 22 nanometers. Each LDL particle contains about 1500 molecules of cholesteryl ester in an oily core that is shielded from the aqueous plasma by a hydrophilic coat composed of 800 molecules of phospholipid, 500 molecules of unesterified cholesterol, and 1 molecule of a 387000-dalton protein called apoprotein B-100 [129]. Elevations in blood cholesterol are usually attributable to an increase in the number of LDL particles.

delivery. Cholesteryl esters are too hydrophobic to pass through membranes. How then can esterified cholesterol be delivered to cells? The delivery problem is solved by lipoprotein receptors, of which the prototype is the LDL receptor.[9] Strategically located on the surfaces of cells, these receptors bind LDL and carry it into the cell by receptor-mediated endocytosis. The internalized lipoprotein is delivered to lysosomes where its cholesteryl esters are hydrolyzed. The liberated cholesterol is used by the cell for the synthesis of plasma membranes, bile acids, and steroid hormones, or stored in the form of cytoplasmic cholesteryl ester droplets. Two properties of the receptor—its high affinity for LDL and its ability to cycle multiple times in and out of the cell—allow large amounts of cholesterol to be delivered to body tissues, while at the same time keeping the concentration of LDL in blood low enough to avoid the buildup of atherosclerotic plaques. When LDL receptor function is inappropriately diminished as a result of genetic defects or in response to regulatory signals, the protective mechanism is lost, cholesterol builds up in plasma, and atherosclerosis ensues.[10]

Familial Hypercholesterolemia: Origin of the LDL Receptor Concept

As a disease, FH has a rich clinical history. It was first described in 1938 by *Carl Müller*, a clinician at the Oslo Community Hospital in Norway, as an "inborn error of metabolism" that produced high blood-cholesterol levels and myocardial infarctions in young people.[11] *Müller* astutely concluded that FH is transmitted as a single gene-determined autosomal dominant trait. In the mid-1960s and early 1970s, *Khachadurian*[12] at the American University in Beirut, Lebanon, and *Fredrickson* and *Levy*[13] at the National Institutes of Health showed that FH exists clinically in two forms: the less severe heterozygous form and the more severe homozygous form.

FH heterozygotes, who carry a single copy of a mutant LDL receptor gene, are quite common, accounting for one out of every 500 persons among most ethnic groups throughout the world.[14] These individuals have a twofold

increase in the number of LDL particles in plasma from the time of birth. They begin to have heart attacks at 30 to 40 years of age. Among people under age 60 who suffer myocardial infarctions, about 5% have the heterozygous form of FH, a 25-fold enrichment over the incidence in the general population.[15-17]

The attractiveness of FH as an experimental model stems from the existence of homozygotes. These rare individuals, who number about one in one million persons, inherit two mutant genes at the LDL receptor locus, one from each parent. Their disease is much more severe than that of heterozygotes. They have six- to tenfold elevations in plasma LDL levels from the time of birth, and they often have heart attacks in childhood.[12-14] The severe atherosclerosis that develops in these patients without any other risk factors is formal proof that high levels of plasma cholesterol can produce atherosclerosis in humans. Experimentally, the availability of FH homozygotes permits study of the manifestations of the mutant gene without any confounding effects from the normal gene.

At the time that our studies began in 1972, it was generally felt that all important events in cholesterol metabolism take place in the liver or intestine.[18] It was obviously impossible to perform meaningful studies in livers of humans with FH. Our only chance to explain its mysteries depended on the mutant phenotype being faithfully manifest in long-term cultured cells such as skin fibroblasts. Techniques for growing such cells had been established over the preceeding two decades. Moreover, inherited enzyme defects were known to be expressed in cultured fibroblasts from patients with rare recessive diseases such as galactosemia, the Lesch Nyhan syndrome, and Refsum's syndrome. By 1970, *Neufeld*'s classic studies of the mucopolysaccharidoses, a form of lysosomal storage disease, were beginning to establish the value of cultured skin fibroblasts in elucidating complex cellular pathways.[19]

There was some reason to believe that the FH derangement might be manifest in cultured skin fibroblasts. Studies in the 1960s by *Bailey*[20] and *Rothblat*[21] had demonstrated that several types of cultured animal cells synthesize cholesterol and that this synthesis is subject to negative feedback regulation. When serum was present in the medium, cultured cells produced little cholesterol from radioactive acetate. When serum lipoproteins were removed from the culture medium, cholesterol synthesis increased.

Regulation of HMG CoA Reductase by LDL in Fibroblasts

We began our work by setting up a microassay for 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase), the rate-determining enzyme of cholesterol biosynthesis. This assay was used to measure HMG CoA reductase activity in extracts of cultured fibroblasts.[2,22] Earlier studies in rat livers by *Bucher* and *Lynen*[23] and by *Siperstein*[24] had shown that the activity of this enzyme was reduced when rats ingested cholesterol and that this reduction limited the rate of cholesterol synthesis. We soon found that the activity of HMG CoA reductase was subject to negative regulation in fibroblasts.[2,22] As shown in Figure 2A, when normal human fibroblasts were grown in the presence of serum, HMG CoA reductase activity was low. When the lipoproteins were removed from the culture medium, the activity of HMG CoA reductase rose by at least 50-fold over a 24-hour period. The induced enzyme was rapidly suppressed when lipoproteins were added back to the medium (Fig. 2B).

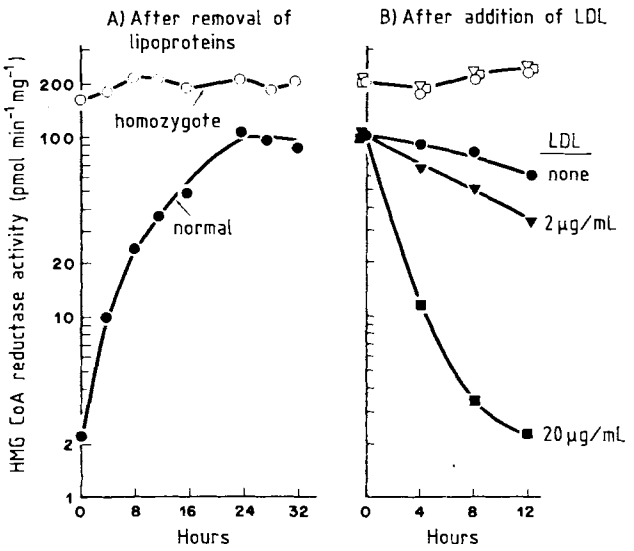

Fig. 2. Regulation of HMG CoA reductase activity in fibroblasts from a normal subject (●) and from an FH homozygote (○). A) Monolayers of cells were grown in dishes containing 10% fetal calf serum. On day 6 of cell growth (zero time), the medium was replaced with fresh medium containing 5% human serum from which the lipoproteins had been removed. At the indicated time, extracts were prepared and HMG CoA reductase activity was measured. B) At 24 hours after addition of 5% human lipoprotein-deficient serum, human LDL was added to give the indicated cholesterol concentration. HMG CoA reductase activity was measured in cell-free extracts at the indicated time. (Reprinted from ref. [2].)

Not all lipoproteins could suppress HMG CoA reductase activity. Of the two major cholesterol-carrying lipoproteins in human plasma, LDL and HDL, only LDL was effective.[22,25] This specificity was the first clue that a receptor might be involved. The second clue was the concentration of LDL that was required. The lipoprotein was active at concentrations as low as 5 µg of protein per milliliter, which is less than 10^{-8} M.[22,25] A high-affinity receptor mechanism must be responsible for enzyme suppression.

The key to this mechanism emerged from studies of cells from patients with homozygous FH.[2,25] When grown in serum containing lipoproteins, the homozygous FH cells had HMG CoA reductase activities that were 50- to 100-fold above normal (Fig. 2A). This activity did not increase significantly when the lipoproteins were removed from the serum, and there was no suppression when LDL was added back. Clearly, the genetic defect was expressed in cell culture (Figs. 2A and 2B).

The simplest interpretation of these results was that FH homozygotes had a defect in the gene encoding HMG CoA reductase that rendered the enzyme resistant to feedback regulation by LDL-derived cholesterol. This working hypothesis was immediately disproved by the next experi-

ment. Cholesterol, dissolved in ethanol, was added to normal and FH homozygote cells. When mixed with albumin-containing solutions, cholesterol forms a quasi-soluble emulsion that enters cells passively, apparently by diffusion through the plasma membrane. When cholesterol was added in this form, the HMG CoA reductase activities of normal and FH homozygote fibroblasts were suppressed at the same rate and to the same extent.[25]

Clearly, the defect in the FH homozygote cells must reside in their ability to extract cholesterol from the lipoprotein, and not in the ability of the cholesterol, once extracted by the cells, to act. But how do normal cells extract the cholesterol of LDL? The high affinity of the process suggested that a cell surface receptor was involved. The existence of cell surface receptors for protein hormones and other chemical messengers had been known for many years. It was generally thought that these receptors acted by binding the ligand at the surface and then generating a "second messenger" on the intracellular side of the plasma membrane. The classic second messenger was cyclic adenosine monophosphate (cyclic AMP).[26] Perhaps LDL was binding to a receptor and generating some second messenger that suppressed HMG CoA reductase.

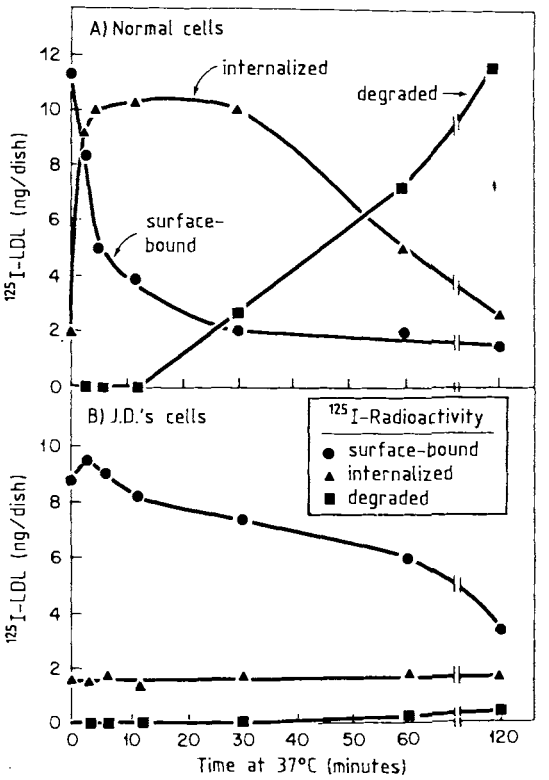

Fig. 3. Internalization and degradation at 37°C of ^{125}I-LDL previously bound to the LDL receptor at 4°C in fibroblasts from a normal subject (A) and from J. D., a patient with the internalization-defective form of FH (B). Each cell monolayer was allowed to bind ^{125}I-LDL (10 μg protein/mL) at 4°C for 2 hours, after which the cells were washed extensively. In one set of dishes, the amount of ^{125}I-LDL was determined by measuring the amount of ^{125}I-LDL that could be released from the surface by treatment with heparin. Each of the other dishes then received warm medium, after which they were incubated at 37°C. After the indicated interval, the dishes were rapidly chilled to 4°C, and the amounts of surface-bound (heparin-releasable) ^{125}I-LDL (●), internalized (heparin-resistant) ^{125}I-LDL (▲), and degraded (trichloroacetic acid-soluble) ^{125}I-LDL (■) were measured. (Reprinted with permission from ref. [41].)

Delineation of the LDL Receptor Pathway

The existence of an LDL receptor was confirmed when LDL was radiolabeled with ^{125}I and incubated with normal and FH homozygote fibroblasts. These studies showed that normal cells had high-affinity binding sites for ^{125}I-LDL, whereas FH homozygote cells lacked high-affinity receptors.[3,27] This seemed to explain the genetic defect in FH, but it did not reveal how LDL generated the signal that suppressed HMG CoA reductase. The answer came from studies of the fate of the surface-bound ^{125}I-LDL. Techniques were developed to distinguish surface-bound from intracellular ^{125}I-LDL,[28] and these revealed that the receptor-bound LDL remained on the surface for less than 10 minutes on average (Fig. 3A). Within this time most of the surface-bound LDL particles entered the cell; within another 60 minutes the protein component of ^{125}I-LDL was digested completely to amino acids and the ^{125}I, which had been attached to tyrosine residues on LDL, was released into the culture medium as ^{125}I-monoiodotyrosine.[27,28] Meanwhile, the cholesteryl esters of LDL were hydrolyzed, generating unesterified cholesterol which remained within the cell.[29]

The only cellular organelle in which LDL could have been degraded so completely and rapidly was the lysosome. Originally described by *de Duve*,[30] lysosomes were known to contain a large number of acid hydrolases that could easily digest all of the components of LDL. The hypothesis of lysosomal digestion of LDL was confirmed through the use of inhibitors such as chloroquine,[31] which raises the pH of lysosomes and inhibits lysosomal enzymes,[32] and through studies of cultured fibroblasts from patients with a genetic deficiency of lysosomal acid lipase.[29] Cells from the latter patients bound and internalized LDL but failed to hydrolyze its cholesteryl esters, even though they were able to degrade its protein component.

The cholesterol that was generated from LDL within the lysosome proved to be the second messenger responsible for suppressing HMG CoA reductase activity. We now know that cholesterol (or an oxygenated derivative that is formed within the cell) acts at several levels, including suppression of transcription of the HMG CoA reductase gene[33] and acceleration of the degradation of the enzyme protein.[34] The LDL-derived cholesterol also regulates two other cellular processes in a coordinated action that stabilizes the cell's cholesterol content. It activates a cholesterol-esterifying enzyme, acyl CoA: cholesterol acyltransferase (ACAT), so that excess cholesterol can be stored in the cytoplasm as cholesteryl ester droplets.[35] It also suppresses synthesis of LDL receptors by lowering the concentration of receptor mRNA.[36,37] The latter action allows cells to adjust the number of LDL receptors to provide sufficient cholesterol for metabolic needs without causing cholesterol overaccumulation.[9] Through these regulatory mechanisms, cells keep their level of unesterified cholesterol remarkably constant despite wide fluctuations in cholesterol requirements and exogenous supply.

Receptor-Mediated Endocytosis of LDL: Binding Coupled to Internalization in Coated Pits

The rapidity of internalization of receptor-bound LDL and the completeness with which the protein of LDL was hydrolyzed implied that fibroblasts have a special mechanism for transport of the lipoprotein from the cell surface to the lysosome. The likely mechanism was endocytosis, the process by which surface membranes pouch inward and pinch off to form vesicles that eventually fuse with lysosomes. Endocytosis was first demonstrated by cinematography of phagocytic cells in the 1930s, and its universal occurrence in all cells was established in the 1950s by the electron microscopic studies of *Palade*.[38] Endocytosis was felt to be a nonspecific process that transported bulk fluid and its contents into cells. There was no precedent for entry of specific receptors into cells by this route.

To determine whether endocytosis was involved in LDL uptake, we began in 1975 a collaboration with *Richard G. W. Anderson*, a cell biologist at our medical school in Dallas. Through the use of LDL coupled to electron-dense ferritin, we found that receptor-bound LDL was internalized by endocytosis. More important, however, these morphological studies explained the efficiency of internalization: efficiency was contingent upon the clustering of the LDL receptors in small pockets on the surface called coated pits.[39] Coated pits had been described in detail by *Roth* and *Porter*[40] in 1964 during electron microscopic studies of the uptake of yolk proteins by mosquito oocytes. These investigators showed that coated pits pinch off from the surface to form coated endocytic vesicles that carry extracellular fluid and its contents into the cell.

The finding that LDL receptors were clustered in coated pits raised the general possibility that these structures serve as gathering-places for cell surface receptors that are destined for endocytosis.[4] Other cell surface proteins, being excluded from coated pits, could not rapidly enter the cell.

This interpretation of coated-pit function was strengthened by study of fibroblasts from a unique FH homozygote. Cells from most of these subjects simply failed to bind LDL, but cells from one FH patient, whose initials are J. D., bound LDL, but failed to internalize it (Fig. 3B).[41,42] In collaboration with *Anderson*, we showed that the receptors in these mutant cells were excluded from coated pits.[43] This was an important finding, for it established the essential role of coated pits in the high-efficiency uptake of receptor-bound molecules.[4]

Figure 4 summarizes the sequential steps in the LDL receptor pathway as deduced from the biochemical, genetic, and ultrastructural studies performed between 1972 and 1976. Figure 5 shows the striking "all-or-none" biochemi-

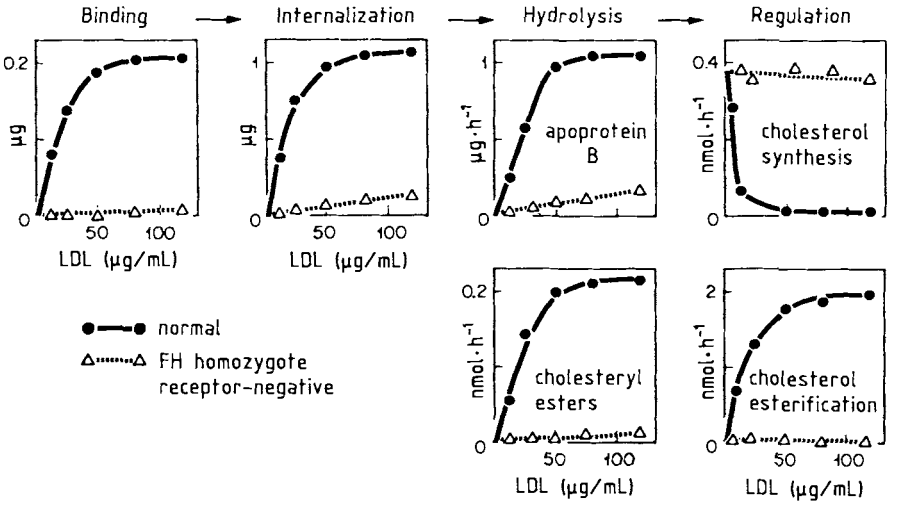

Fig. 5. Actions attributable to the LDL receptor in fibroblasts from a normal subject (●) and from a homozygote with the receptor-negative form of FH (△). The cells were incubated with varying concentrations of ^{125}I-LDL or unlabeled LDL at 37 °C for 5 hours. Assays were performed in growing cells in monolayers as previously described [128]. All data are normalized to 1 mg of total cell protein. The units for each assay are as follows: *binding*, μg of ^{125}I-LDL bound to cell surface; *internalization*, μg of ^{125}I-LDL contained within the cell; *hydrolysis of apoprotein B-100*, μg of ^{125}I-LDL degraded to ^{125}I-monoiodotyrosine per hour; *hydrolysis of cholesteryl esters*, nmol of [^{3}H]cholesterol formed per hour from the hydrolysis of LDL labeled with [^{3}H]cholesteryl linoleate; *cholesterol synthesis*, nmol of [^{14}C]acetate incorporated into [^{14}C]cholesterol per hour by intact cells; *cholesterol esterification*, nmol of [^{14}C]oleate incorporated into cholesteryl [^{14}C]oleate per hour by intact cells. (Reprinted from ref. [130].)

cal differences in the metabolism of LDL and its regulatory actions in fibroblasts derived from a normal subject and from an FH homozygote with a complete deficiency of LDL receptors.

Soon after the initial studies of the LDL receptor pathway, *Pearse*[44] purified coated vesicles and found that the cytoplasmic coat was composed predominantly of a single protein that she named clathrin. At the same time, *Cohen* and his collaborators performed their elegant studies of the action of epidermal growth factor (EGF) on cultured fibroblasts.[45] They found that this peptide hormone was internalized by cells in a manner that was indistinguishable from that of LDL. Similar observations were made by *Terris* and *Steiner*[46] with insulin in hepatocytes, by *Neufeld* and co-workers[47] and by *Sly* and co-workers[48] with lysosomal enzymes in fibroblasts, and by *Ashwell, Morell,* and co-workers[49] with asialoglycoproteins in hepatocytes. Moreover, *Helenius, Simons,* and their co-workers[50] showed that several lipid-enveloped viruses enter cells by this route. Clearly, receptor-mediated endocytosis did not exist solely for cholesterol delivery: it was a general process by which cells internalized and degraded many extracellular molecules.[4,51] In all instances in which adequate morphologic studies were performed, this internalization was attributable to clustering of receptors in coated pits. Indeed, *Pastan* and *Willingham*[51] and *Carpentier* et al.[52] showed that receptors for several different ligands colocalize in the same coated pit.

The early LDL receptor studies also exposed another feature of receptor-mediated endocytosis—namely, that receptors can be recycled.[4,28] After internalization the receptors dissociate from their ligands. From the work of *Maxfield*[53] and of *Helenius* and co-workers,[54] we now know that such dissociation is triggered by a drop in pH within a special class of endocytic vesicles called endosomes (discussed below). After dissociation, the receptors find their way back to the cell surface. The LDL receptor makes one round-trip into and out of the cell every 10 minutes for a total of several hundred trips in its 20-hour life span.[4,28]

The LDL Receptor: Structure Adapted to Function

The LDL receptor is a cell surface glycoprotein that contains approximately two asparagine-linked (*N*-linked) oligosaccharide chains of the complex type and approximately 18 serine/threonine-linked (*O*-linked) oligosaccharide chains.[55,56] About two-thirds of the *O*-linked sugars are clustered in one region of the molecule.[57] The LDL receptor binds two proteins: (1) apo B-100, the 387000-dalton glycoprotein that is the sole protein of LDL;[27] and (2) apo E, a 34000-dalton protein that is found in multiple copies in intermediate density lipoprotein (IDL) and a subclass of HDL.[58,59] *Innerarity* and *Mahley*[59] demonstrated that lipoproteins that contain multiple copies of apo E bind to LDL receptors with up to 20-fold higher affinity than LDL, which contains only one copy of apo B.

Figure 6 illustrates the circuitous itinerary followed by the LDL receptor from its site of synthesis to its site of internalization in coated pits and its site of recycling in endosomes. The receptor is synthesized in the rough endoplasmic reticulum (ER) as a precursor[60] that contains high-mannose *N*-linked carbohydrate chains and the core sugar (*N*-acetylgalactosamine) of the *O*-linked chains.[56] The *O*-linked core sugars are added before the mannose residues of the *N*-linked chains are trimmed, i.e., while the receptor is still in the endoglycosidase H-sensitive stage. Thus, the *O*-linked sugars must be added either in the ER or in a transitional zone between the ER and the Golgi apparatus. The receptor precursor migrates on sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis as a

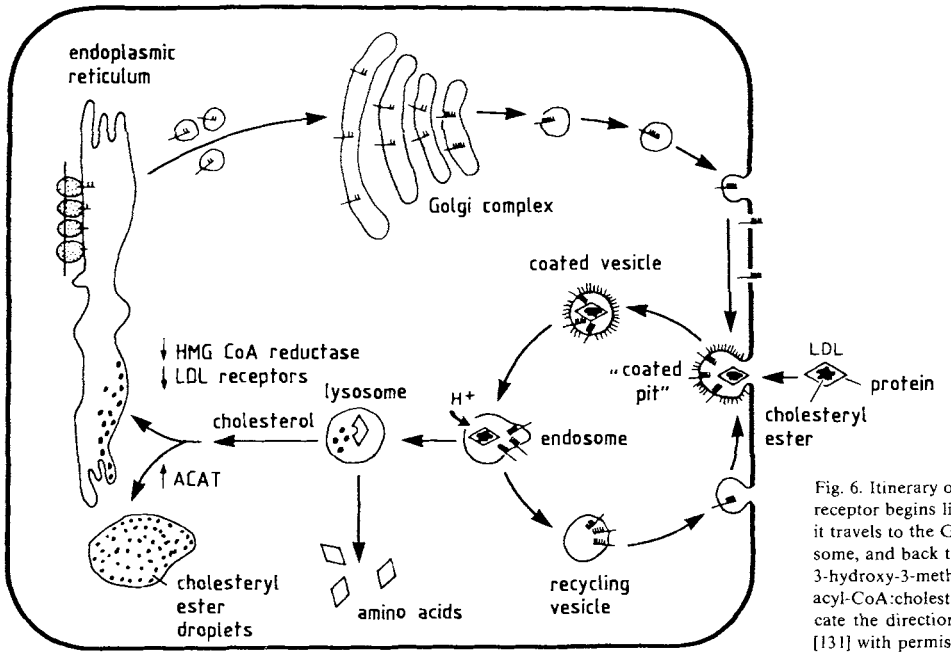

Fig. 6. Itinerary of the LDL receptor in mammalian cells. The receptor begins life in the endoplasmic reticulum from which it travels to the Golgi complex, cell surface, coated pit, endosome, and back to the surface. HMG CoA reductase denotes 3-hydroxy-3-methylglutaryl CoA reductase; ACAT denotes acyl-CoA:cholesterol acyltransferase. Vertical arrows indicate the direction of regulatory effects. (Reprinted from ref. [131] with permission.)

single band corresponding to an apparent molecular weight of 120000.[60]

Within 30 minutes after its synthesis, the LDL receptor decreases in mobility on SDS gels. The apparent molecular weight increases from 120000 to 160000.[60] This change is coincident with the conversion of the high-mannose *N*-linked oligosaccharide chains to the complex endoglycosidase H-resistant form.[56] At the same time, each *O*-linked chain is elongated by the addition of one galactose and one or two sialic acid residues.[56] The amount of carbohydrate is not sufficient to account for an increase in molecular mass of 40000 daltons. Rather, the decrease in electrophoretic mobility is primarily caused by a change in conformation of the protein that results from the elongation of the clustered *O*-linked sugars.[56,57]

About 45 minutes after synthesis, LDL receptors appear on the cell surface, where they gather in coated pits. Within 3 to 5 minutes of their formation, the coated pits invaginate to form coated endocytic vesicles. Very quickly, the clathrin coat dissociates. Multiple endocytic vesicles then fuse to create larger sacs of irregular contour called endosomes or receptosomes.[4,61] The pH of the endosomes falls below 6.5, owing to the operation of ATP-driven proton pumps in the membrane.[53,54,61] At this acid pH, the LDL dissociates from the receptor. The latter returns to the surface, apparently by clustering with other receptors in a segment of the endosomal membrane that pinches off to form a recycling vesicle. Once it reaches the surface, the receptor binds another lipoprotein particle and initiates another cycle of endocytosis.[4] Each LDL receptor makes one round-trip every 10 minutes in continuous fashion whether or not it is occupied with LDL.[4,62] The LDL that dissociates from the receptor is delivered to a lysosome when the membranes of the endosome and lysosome fuse. There the protein component of LDL is hydrolyzed to amino acids and the cholesteryl esters are hydrolyzed by an acid lipase, liberating cholesterol (discussed above).

The striking feature of this pathway is that it requires the continuous movement of a membrane-embedded protein from one organelle to another in a highly ordered fashion. Each time it moves, the receptor must be segregated from neighboring membrane proteins that do not follow the same route. This raises a crucial question: What are the signals that direct the highly selective movement of receptors from one membrane organelle to another? Clearly, the signals must lie in the structures of the receptors. What do we know about the structure of the LDL receptor?

The LDL Receptor: A Multi-Domain Protein

The LDL receptor was purified from bovine adrenal cortex by *Wolfgang Schneider* in our laboratory.[55] A partial amino acid sequence was obtained, and this sequence was used by *David Russell* and *Tokuo Yamamoto* to isolate a full-length cDNA for the human LDL receptor.[37,63] Biochemical studies of the receptor protein, coupled with the amino acid sequence that was deduced from the nucleotide sequence of the cDNA, have provided insight into the structural domains of the LDL receptor (Fig. 7).[63–65]

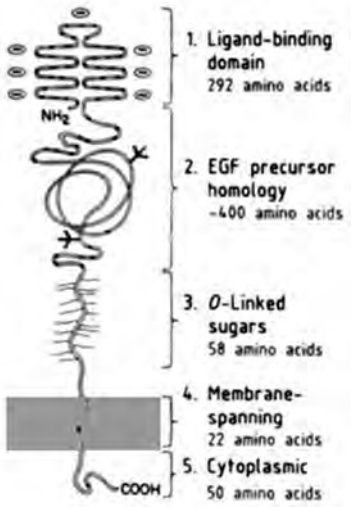

Fig. 7. The LDL receptor: a single protein with five domains. The significance of each domain is discussed in the text.

At the extreme NH_2-terminus of the LDL receptor, there is a hydrophobic sequence of 21 amino acids that is cleaved from the receptor immediately after it is translated. This segment functions as a classic signal sequence to direct the receptor-synthesizing ribosomes to the ER membrane. Because it does not appear in the mature receptor, the signal sequence is omitted from the structural domain that is described below. The mature receptor (without the signal sequence) consists of 839 amino acids.[63]

The *first domain* of the LDL receptor consists of the NH_2-terminal 292 amino acids, which is composed of a sequence of 40 amino acids that is repeated with some variation seven times.[65,66] Studies of anti-peptide antibody binding to intact cells revealed that this domain is located on the external surface of the plasma membrane.[67] Each of the seven 40-amino-acid repeats contains six cysteine residues, which are in register for all of the repeats. The receptor cannot be labeled with [^{3}H]iodoacetamide without prior reduction, suggesting that all of these cysteines are disulfide-bonded.[65] This region of the receptor must therefore exist in a tightly cross-linked, convoluted state. This explains the extreme stability of the binding domain of the receptor; the receptor can be boiled in strong denaturants and still retain its binding activity as long as the disulfide bonds are intact.[65]

A striking feature of each cysteine-rich repeat sequence is a cluster of negatively charged amino acids near the COOH-terminus of each repeat.[65,66] The charges on these sequences are complementary to a cluster of positively charged residues that are believed to occupy one face of a single α-helix in apo E, the best studied ligand for the LDL receptor.[68] Elegant studies by *Mahley* and *Innerarity*[68] with mutant and proteolyzed forms of apo E and with monoclonal antibodies against different regions of apo E showed that the positively charged region contains the site whereby this protein binds to the LDL receptor. It is therefore tempting to speculate that the negatively charged clusters of amino acids within the cysteine-rich repeat se-

quence of the LDL receptor constitute multiple binding sites, each of which binds a single apo E molecule by attaching to its positively charged α-helix.[65]

The *second domain* of the LDL receptor, consisting of approximately 400 amino acids, is 35% homologous to a portion of the extracellular domain of the precursor for epidermal growth factor (EGF).[63,64,69] The EGF precursor is a molecule of 1217 amino acids that appears to span the plasma membrane once, like the LDL receptor.[69-72] Analysis of the amino acid sequence of the EGF precursor, as revealed from the sequence of the cloned cDNA,[70,71] suggests that EGF, a peptide of 53 amino acids, is liberated from the EGF precursor by proteolysis. The sequence of EGF is not homologous to the LDL receptor. Rather, the homology involves a part of the EGF precursor that is on the NH_2-terminal side of EGF itself. The function of this region in either the LDL receptor or the EGF precursor is unknown.

The *third domain* of the LDL receptor lies immediately external to the membrane-spanning domain and consists of a stretch of 58 amino acids that contains 18 serine or threonine residues.[63,66] This domain is encoded within a single exon. Proteolysis studies reveal that this region contains the clustered *O*-linked sugar chains.[64]

The *fourth domain* consists of a stretch of 22 hydrophobic amino acids that span the plasma membrane, as demonstrated by proteolysis experiments.[63,64] Comparison of the amino acid sequences of the human and bovine LDL receptors reveals that the membrane-spanning region is relatively poorly conserved.[65] Of the 22 amino acids in this region, seven differ between human and cow, but all of the substitutions retain a hydrophobic character.

The *fifth domain* is the cytoplasmic tail. The human and bovine LDL receptors each contain a COOH-terminal segment of 50 amino acids that projects into the cytoplasm.[63,64] Localization of this domain to the cytoplasmic side of the membrane was determined through the use of an anti-peptide antibody directed against the COOH-terminal sequence.[64] When inside-out membrane vesicles containing receptor were digested with pronase, the antibody-reactive material was removed, and the molecular weight of the receptor was reduced by approximately 5000. The cytoplasmic sequence is strongly conserved among species. Of the 50 amino acids in this region, only four differ between human and cow, and each of these substitutions is conservative with respect to charge.[65]

The cytoplasmic domain of the LDL receptor plays an important role in clustering in coated pits, either through interaction with clathrin itself or with some protein that is associated with clathrin on the cytoplasmic side of the membrane.[4] This conclusion is based on a molecular analysis of three naturally occurring mutations at the LDL receptor locus that produce receptors that bind LDL normally but fail to cluster in clathrin-coated pits. All three of these mutations produce defects in the cytoplasmic tail (discussed below).[65,73]

The LDL Receptor: A Mosaic Gene

The haploid human genome contains a single copy of the LDL receptor gene[66] on chromosome 19.[74] Sequences representing almost the entire gene were isolated from bacteriophage lambda and cosmid libraries by *Thomas Südhof* and *David Russell*.[66] The position of each intron within the gene was mapped, and the sequence of each exon-intron junction was determined.

The LDL receptor gene spans approximately 45000 bases and is made up of 18 exons separated by 17 introns.[66] There is a striking correlation between the exons in the gene and the functional domains of the protein (Fig. 8). The first intron is located just at the end of the DNA encoding the cleaved signal sequence. The binding domain is encoded by exons 2 to 6. Within this domain (which contains the seven cysteine-rich repeats), introns occur precisely at the ends of repeats I, II, V, VI, and VII (Fig. 8). Repeats III, IV, and V are included in one exon. The binding domain is terminated by an intron at amino acid 292, the last residue in the seventh repeat. Thus, the binding domain is composed of a single exon that has been duplicated multiple times to produce seven repeats of a single 40-amino-acid sequence. Each of these seven repeats in the LDL receptor is strongly homologous with a stretch of 40 amino acids that occurs in the middle of the C9 component of complement, a plasma protein of 537 amino acids that participates in the complement cascade.[66,75]

The next eight exons in the LDL receptor gene (exons 7 to 14) encode the region that is homologous with the EGF precursor (Fig. 8). The gene for the EGF precursor con-

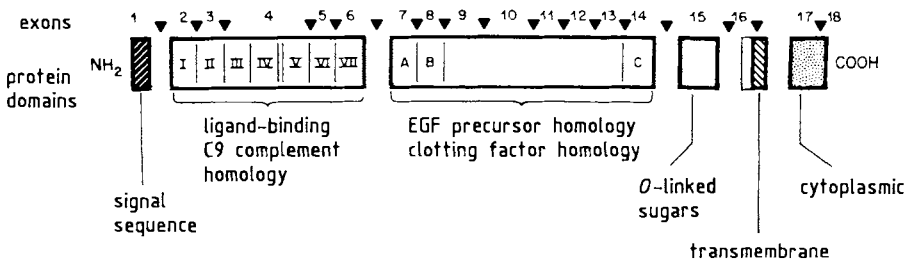

Fig. 8. Correlation of exon organization with protein domains in the human LDL receptor. The domains of the protein are delimited by thick black lines and are labeled in the lower portion. The seven cysteine-rich, 40-amino-acid repeats in the LDL binding domain (Fig. 7) are assigned roman numerals I to VII. Repeats IV and V are separated by eight amino acids. The three cysteine-rich repeats in the domain that is homologous with the EGF precursor are lettered A to C. The positions at which introns interrupt the coding region are indicated by arrowheads. Exon numbers are shown between the arrowheads. (Reprinted with permission from ref. [66].)

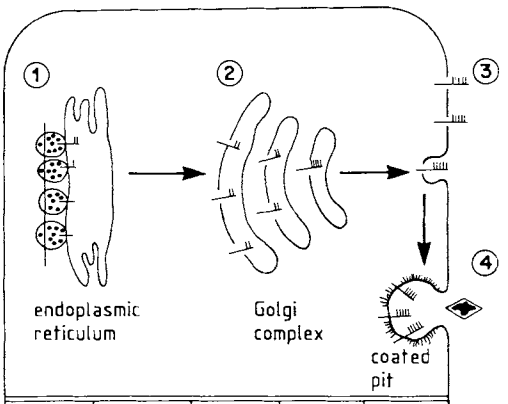

tains the same eight exons.[69] These exons form a cassette that has been lifted out of some ancestral gene during evolution and placed in the middle of the EGF precursor gene and the LDL receptor gene. Three of these exons have also been used by another class of genes. These exons encode a cysteine-rich sequence of 40 amino acids (labeled A, B, and C in Fig. 8) that is repeated three times in the LDL receptor and occurs once in several proteins of the blood clotting system, including factor IX, factor X, and protein C.[69,76] Thus, these exons have been used by members of at least three different gene families.

The *O*-linked sugar domain is also encoded by a single exon (exon 15). However, not all domains of the protein are encoded by single exons. Thus, the membrane-spanning region is encoded by parts of two exons (exons 16 and 17). The cytoplasmic tail is also encoded by two exons (exons 17 and 18) (Fig. 8).

The sharing of exons between the LDL receptor gene and other genes provides strong evidence to support *Gilbert*'s hypothesis concerning the nature and function of introns.[77] As originally proposed by *Gilbert*, introns permit functional domains encoded by discrete exons to shuffle between different proteins, thus allowing proteins to evolve as mosaic combinations of preexisting functional units. The LDL receptor is a vivid example of such a mosaic protein.[66,78] It seems likely that other cell surface receptors will also be found to be mosaic structures assembled from exons shared with other genes.

Genetic Defects in the LDL Receptor

The mutations in the LDL receptor gene in FH patients have helped to delineate the crucial steps of receptor-mediated endocytosis. So far, we have studied fibroblasts from 110 patients with the clinical phenotype of homozygous FH. All of them show evidence of defects in the LDL receptor, but not all defects are the same. At least ten different mutations can be distinguished by structural criteria.[65] These fall into four classes as shown in Figure 9. Many of the apparent FH homozygotes are actually compound heterozygotes who inherit different mutant alleles from each parent.

Class of mutation	Synthesis	Transport from ER to Golgi	Binding of LDL	Clustering in coated pits
1	X			
2	→	X		
3	→	→	X	
4	→	→	→	X

Fig. 9. Four classes of mutations that disrupt the structure and function of the LDL receptor and cause FH. Each class of mutation affects a different region in the gene and thus interferes with a different step in the process by which the receptor is synthesized, processed in the Golgi complex, and transported to coated pits. Each class of mutation can be further subdivided into different mutant alleles that are described in detail in ref. [65]. (Reprinted with permission from ref. [132].)

Class 1 Mutations: No Receptors Synthesized

This is the most common class of mutant alleles, accounting for approximately half of the mutations so far analyzed. These genes produce either no LDL receptor protein or only trace amounts as determined by reaction with polyclonal or monoclonal antibodies. One of these alleles has been analyzed by molecular cloning; the gene bears a large deletion that extends from exon 13 to an *Alu* repetitive element in intron 15.[79] This deletion is easily recognized on Southern blots of genomic DNA. We have not found evidence of a similar deletion in any other individual with the receptor-negative phenotype, so this particular deletion must be rare.

Class 2 Mutations: Receptor Synthesized, but Transported Slowly from ER to Golgi Complex

This is the second most common class of mutations. These alleles produce receptors that are synthesized as precursors whose apparent molecular weights vary from 100000 to 135000. Most have an apparent molecular weight similar to that of the normal precursor (120000). These receptors contain high-mannose *N*-linked sugars and the core *N*-acetylgalactosamine of the *O*-linked sugars.[56,80] However, the *N*-linked sugars are not converted to the complex endoglycosidase H-resistant form nor are the *O*-linked sugar chains elongated. These mutant receptors do not appear on the surface of the cell; rather, they seem to remain in the ER until they are eventually degraded. Some mutations in this class are complete, i.e., there is no detectable processing of carbohydrate. Others are partial, i.e., some of the receptors are processed and move to the surface at a rate that is one-tenth of normal.[80,81] The molecular defect in this class of mutations has not been determined.

Class 3 Mutations: Receptors are Processed and Reach Cell Surface, but Fail to Bind LDL Normally

In the mature form, these mutant receptors can have a normal apparent molecular weight of 160000 or aberrant apparent molecular weights of 140000 or 210000.[65] They are all synthesized as precursors that appear to be 40000 daltons smaller than the mature form. They all undergo normal carbohydrate processing and reach the cell surface, and they bind a variety of antibodies directed against the LDL receptor. However, they have a markedly reduced ability to bind LDL. We suspect that these mutations may involve amino acid substitutions, deletions, or duplications

in the cysteine-rich LDL binding domain or the EGF precursor region, but none has yet been fully elucidated at the molecular level.

Class 4 Mutations: Receptors Reach Cell Surface and Bind LDL, but Fail to Cluster in Coated Pits

Study of these internalization-defective mutations at the cellular level originally revealed the importance of coated pits in receptor-mediated endocytosis.[42,43] Three of the mutations have now been elucidated in molecular detail. All involve alterations in the cytoplasmic tail of the receptor, i.e., the 50 amino acids at the COOH-terminus that project into the cytoplasm (Fig. 10). The mutations have been unraveled through the preparation of genomic DNA libraries and the subsequent isolation and sequencing of exons 17 and 18, which encode the cytoplasmic domain. In the most drastic case, a tryptophan codon has been converted to a nonsense (stop) codon at a position that is two residues distal to the membrane-spanning region.[73] This produces a receptor with only two amino acids in the cytoplasmic tail. Another mutation involves a duplication of four nucleotides following the codon for the sixth amino acid of the cytoplasmic tail.[73] This duplication alters the reading frame and leads to a sequence of eight random amino acids followed by a stop codon. This receptor has only six of the normal amino acids in the cytoplasmic domain. Protein-chemistry studies have confirmed that these two proteins lack the normal COOH-terminus.[73]

The third mutation is the most informative. In this patient, who was the original internalization-defective subject to be described (J. D., see Fig. 3), a single base change leads to the substitution of a cysteine for a tyrosine residue at position 807, which is in the middle of the cytoplasmic tail domain (Fig. 10). We have recently reproduced this amino acid substitution in the normal LDL receptor cDNA by oligonucleotide-directed mutagenesis. When the altered cDNA was introduced into Chinese hamster ovary cells by gene transfer techniques, it produced a receptor that bound LDL but did not cluster in coated pits, confirming that the single base change is responsible for the internalization defect in J. D.'s cells.[82]

Inasmuch as all three internalization-defective mutations involve the cytoplasmic tail, this region must normally play a crucial role in the clustering of LDL receptors in coated pits. It is likely that the cytoplasmic tail binds to clathrin or some other protein that is itself linked to clathrin. The puzzling feature at the moment is that other cell surface receptors that cluster in coated pits do not show obvious homology with the LDL receptor in the amino acid sequences of their cytoplasmic tails.[65] Thus, the precise structure that links receptors to coated pits remains a mystery.

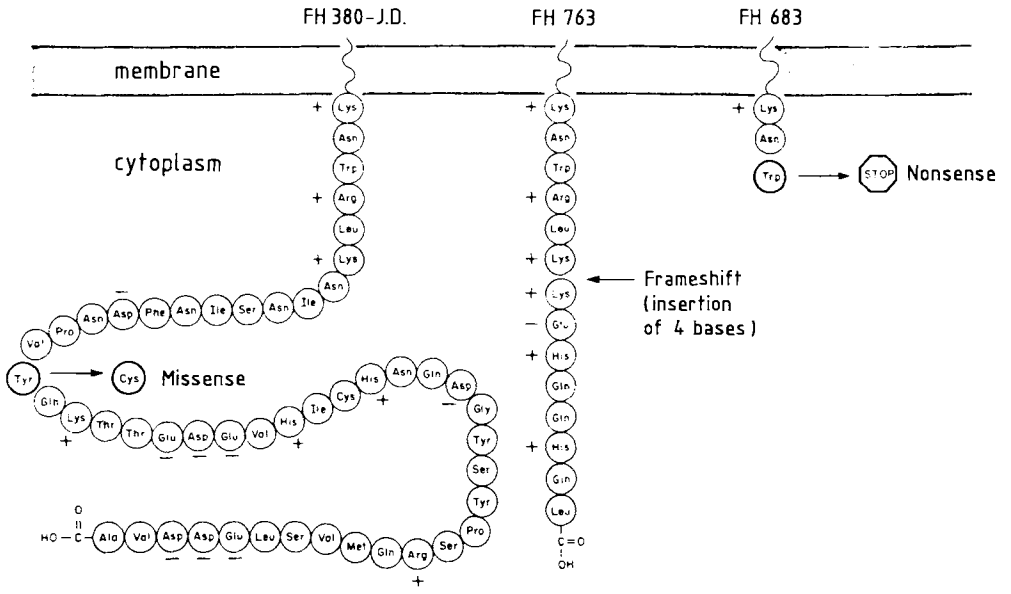

Fig. 10. Mutations affecting the cytoplasmic domain of the LDL receptor in three FH homozygotes with the internalization-defective form of FH.

We have identified several interesting variants of the class 4 mutations in which the mutant genes produce LDL receptors that are secreted into the culture medium. In two mutants of this class (each from an unrelated family), the responsible mutation is a large deletion that results from a recombination between two repetitive *Alu* sequences, one in intron 15 and the other in the 3′ untranslated region of exon 18. The deletion joints in the two mutants are similar but not identical, indicating that the two mutations arose by independent events (ref. [83] and unpublished observations). In each mutant, the deletion removes the exons encoding the membrane-spanning region as well as the cytoplasmic tail. Presumably these prematurely terminated proteins have a short random sequence of amino acids at the COOH-terminus, owing to read-through of an unspliced mRNA. The receptors are transported to the surface, where some of them remain bound to the membrane. The vast majority, however, are released into the culture medium (ref. [83] and unpublished observations). The few receptors that remain on the surface bind LDL, but do not

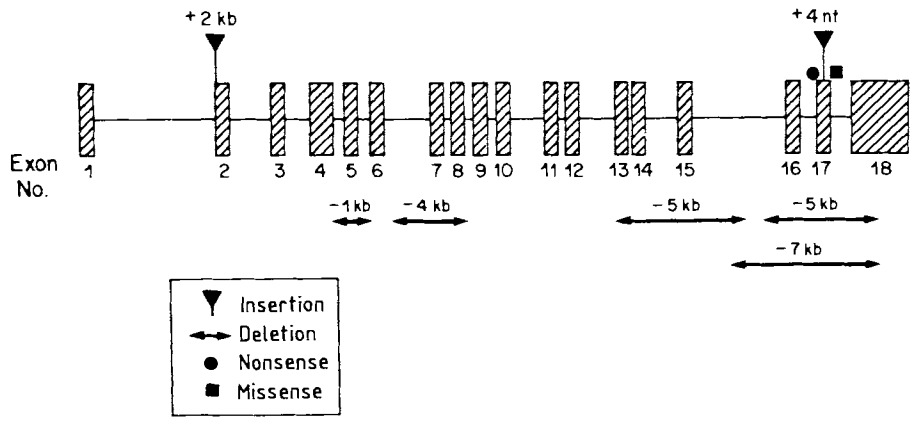

Fig. 11. Location of mutations in the LDL receptor gene. To date, nine mutations have been identified by molecular cloning and DNA sequence analysis or by restriction endonuclease analysis of genomic DNA. Five of the nine mutations are described in detail in refs. [73, 79, 82, 83]. kb denotes kilobases; nt denotes nucleotides.

migrate to coated pits, thus giving rise to an internalization-defective phenotype. These findings emphasize the importance of the membrane-spanning region in anchoring the LDL receptor to the plasma membrane.

Figure 11 shows the location of nine mutations in the LDL receptor gene that have been analyzed at the molecular level. Each FH family examined to date has had a different mutation, and multiple types of mutational events have occurred. Of the nine mutations, two involve single base substitutions, two involve insertions (one small and one large), and five involve large deletions. Many of the deletion joints occur in *Alu* repetitive elements.

Functions of the LDL Receptor in the Body

The LDL receptor was elucidated by an investigative route that is opposite to the one usually employed to uncover metabolic pathways in animals. These pathways are usually observed first in intact animals or tissues and then they are studied in isolated cells. The LDL receptor was first observed in a totally artificial environment—namely, tissue culture. The question immediately arose: What tissues express LDL receptors in the body, and how do they work? We knew at the outset that the receptor must play some role in the body as evidenced by the devastating consequences of LDL receptor deficiency in FH homozygotes and the proportionately less severe abnormalities in FH heterozygotes. Clearly, the receptor must be functioning somewhere. But where?

Detection of LDL Receptor Expression In Vivo

The first cells that were demonstrated to have LDL receptor activity in vivo were circulating blood lymphocytes. In the initial studies carried out with *Y. K. Ho* in 1975, we isolated lymphocytes from the bloodstream and incubated them for 67 hours in vitro in the absence of exogenous cholesterol so as to "derepress" receptor synthesis.[84] Under these conditions the lymphocytes expressed abundant LDL receptors as determined by measurements of the high-affinity uptake and degradation of ^{125}I-LDL (Fig. 12A). Lymphocytes from FH homozygotes did not express

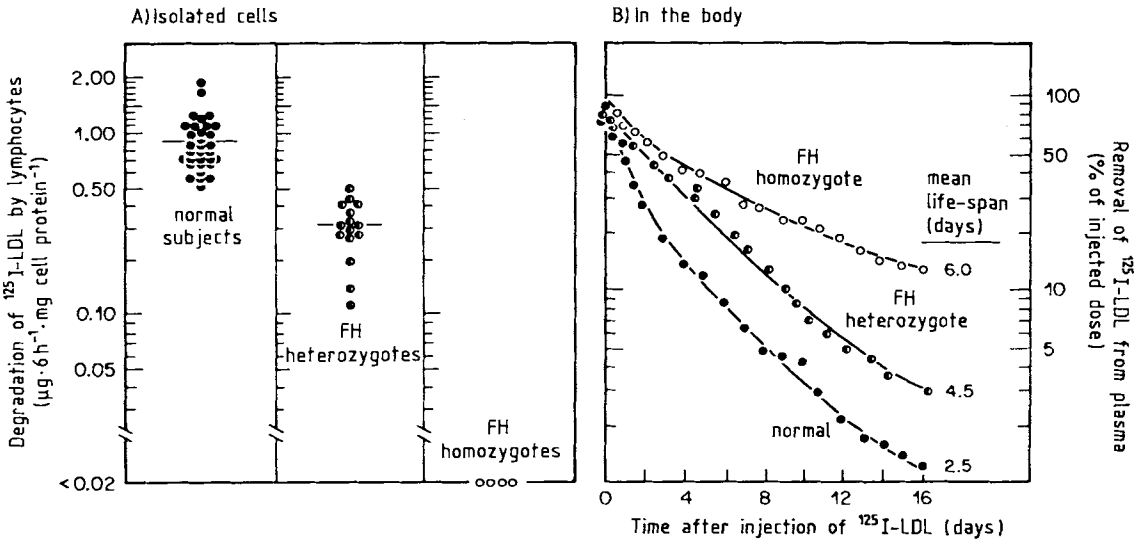

Fig. 12. Measurement of the number of LDL receptors in blood lymphocytes (A) and in living subjects (B). A) Lymphocytes were isolated from venous blood of 32 normal subjects (●), 15 FH heterozygotes (◐), and 4 FH homozygotes (○). After incubation for 67 hours at 37°C in medium containing 10% lipoprotein-deficient serum, LDL receptor activity was assessed by measurement of the high-affinity degradation of ^{125}I-LDL at 37°C. (Data replotted from ref. [85].) B) In the whole-body assay, a tracer amount of ^{125}I-LDL was injected intravenously, and the radioactivity remaining in the circulation over the next 16 days was measured in samples of venous blood [87, 89]. The higher the number of LDL receptors on body cells (A), the faster the removal of ^{125}I-LDL from the blood (B).

detectable LDL receptor activity, and lymphocytes from FH heterozygotes had an intermediate level consistent with the presence of only a single functional gene.[85] LDL receptors were also detectable on lymphocytes immediately after their isolation from the bloodstream, although the level of activity was lower than it was after derepression for 67 hours. Thus, LDL receptors were expressed in at least one cell type in vivo.

Another early clue to the function of LDL receptors in vivo came from studies of the rate of disappearance of intravenously injected ^{125}I-LDL from plasma (Fig. 12B). Such LDL is removed from the circulation more slowly in FH heterozygotes than it is in normal individuals.[86,87] In FH homozygotes the removal defect is even more profound.[87-89] The sluggishness of LDL catabolism in vivo correlates with the relative deficiency of LDL receptors as determined in isolated lymphocytes.

More detailed demonstrations of LDL receptor function in vivo have been obtained in experimental animals. Together with *Sandip K. Basu*, we established an assay for the binding of ^{125}I-LDL to membranes from homogenates of cultured cells and various tissues of the cow and other animals.[90] Using this assay, *Petri Kovanen* found that most tissues of the cow had detectable high-affinity ^{125}I-LDL binding; the adrenal gland and ovarian corpus luteum had the highest activity on a per gram basis.[91] When the weight of the organ was taken into consideration, the liver was found to produce by far the largest number of LDL receptors. Similar results were obtained in studies of human fetal tissues.[91] In collaboration with *Havel*'s laboratory, we showed that ^{125}I-LDL was taken up by perfused rat livers by a high-affinity receptor-mediated process that could be markedly accelerated by administration of the estrogenic hormone 17α-ethinyl estradiol.[92]

High levels of hepatic LDL receptors were also observed when radiolabeled LDL was injected into the circulation of experimental animals and its uptake into various tissues was compared. *Steinberg* and co-workers[93] and *Dietschy* and co-workers[94] showed that approximately 70% of the total-body uptake of radiolabeled LDL took place in the liver by LDL receptor-dependent pathways, but that the highest rates of uptake on a weight basis were seen in the adrenal gland. Various other tissues also showed receptor-mediated uptake of LDL in excess of that seen with nonspecific bulk-phase markers such as radiolabeled albumin.

Measurements of receptor-mediated LDL uptake by tissues of animals were made more practical as a result of two developments: (1) *Steinberg* and co-workers developed a method to label LDL with radioactive sucrose and later with tyramine-cellobiose.[95] In contrast to ^{125}I-labeling of tyrosines, the latter methods produced a radioactive marker that remained trapped in lysosomes after uptake and degradation, thus allowing slow rates of uptake to be quantified cumulatively over long periods. (2) *Shepherd* and *Packard*[96] showed that LDL whose arginine residues were modified by reaction with cyclohexanedione was cleared from the human circulation much more slowly than was native LDL. The rationale for these latter studies lay in previous work from our laboratory[97] and from *Mahley*'s laboratory,[98] which showed that modification of arginine or lysine residues on LDL abolished its ability to bind to the LDL receptor. These observations provided a crude estimate of the fraction of LDL clearance that was attributable to LDL receptors.

We had earlier estimated the fraction of total LDL clearance that was receptor-dependent by comparing the rate of catabolism of intravenously injected ^{125}I-LDL in normal individuals and in FH homozygotes.[99] The fractional catabolic rate for LDL, i.e., the fraction of the total plasma pool of LDL removed per unit time, was threefold higher in normal subjects than in FH homozygotes.[87] From this observation we reasoned that approximately two-thirds of LDL clearance is normally mediated through the LDL receptor.[99] This conclusion has generally been borne out by a number of studies comparing the degradation rates for native versus lysine-modified or arginine-modified LDL both in normal human subjects and in a wide variety of experimental animals.[100]

The WHHL Rabbit and the Role of the LDL Receptor in Clearance of IDL

One of the most important functions of LDL receptors in vivo was appreciated only in the past few years as a result of studies performed in Watanabe Heritable-Hyperlipidemic (WHHL) rabbits. This strain of mutant rabbits was discovered in the late 1970s by *Yosio Watanabe*, a veterinarian in Kobe, Japan.[101] These rabbits have a mutation in the LDL receptor gene that is similar to the class 2 mutations in human FH.[81,102] When present in the homozygous form, this mutation gives rise to extremely high LDL-cholesterol levels; the rabbits develop atherosclerosis early in life.[101,102]

The WHHL rabbits proved invaluable in explaining a previously puzzling feature of homozygous FH. Kinetic studies of ^{125}I-LDL metabolism by *Myant* and co-workers[88] and by *Bilheimer* and *Grundy*[87,89] indicated that FH subjects have a dual defect. In addition to degrading LDL more slowly, FH homozygotes and heterozygotes also appeared to overproduce LDL. How does a genetic defect in the LDL receptor lead simultaneously to overproduction and reduced degradation of LDL? The answer lies in the complex biosynthetic pathway for LDL.

Early studies by *Gitlin*[103] and later those of *Bilheimer, Levy*, and *Eisenberg*[104] suggested that LDL is not secreted directly from the liver, but rather produced in the circulation from a blood-borne precursor, very low density lipoprotein (VLDL) (Fig. 13A). VLDL is a large, triglyceride-rich lipoprotein that is secreted by the liver; it transports triglyceride to adipose tissue and muscle. The triglycerides in VLDL are removed in capillaries by the enzyme lipoprotein lipase, and the VLDL returns to the circulation as a smaller particle with a new name, intermediate density lipoprotein (IDL). The IDL particles have lost most of their triglyceride, but they retain cholesteryl esters. Some of the IDL particles are rapidly taken up by the liver; others remain in the circulation where they undergo further triglyceride hydrolysis and are converted to LDL. A distinguishing feature of the IDL particles is their content of multiple copies of apo E in addition to a single copy of apo B-100.

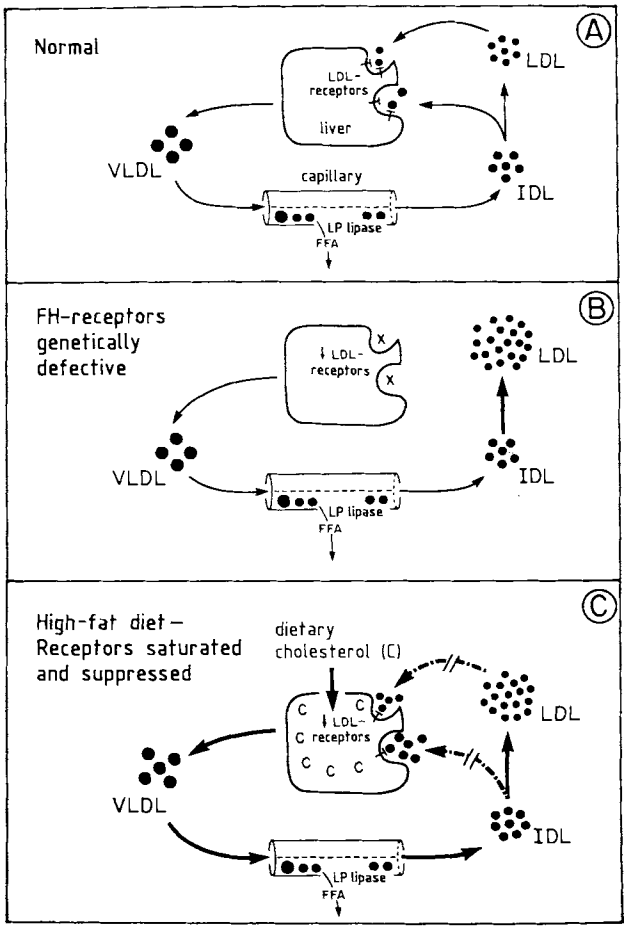

Fig. 13. Schematic model of the mechanism by which LDL receptors in the liver control both the production and catabolism of plasma LDL in normal human subjects (A), in individuals with FH (B), and in individuals consuming a diet rich in saturated fats and cholesterol (C). VLDL denotes very low density lipoprotein; IDL denotes intermediate density lipoprotein; FFA denotes free fatty acid. (Modified from ref. [132] with permission.)

The multiple copies of apo E allow IDL to bind to the LDL receptor with very high affinity. When IDL is converted to LDL, the apo E leaves the particle and only apo B-100 remains. Thereafter, the affinity for the LDL receptor is much reduced.[102]

With *Toru Kita*, we showed that the apparent overproduction of LDL in WHHL rabbits is due to the failure of IDL to be removed from the plasma[102, 105] (Fig. 13B). Thus, when ^{125}I-VLDL was administered to WHHL rabbits, the resultant IDL was not taken up by the liver, as it was in normal rabbits.[105] Rather it remained in the circulation and was converted in increased amounts to LDL. These findings strongly suggest that IDL is normally cleared from plasma by binding to LDL receptors in the liver. Although experiments of similar detail cannot be carried out in humans, the observations of *Soutar*, *Myant*, and *Thompson*[106] are consistent with the notion that enhanced conversion of IDL to LDL also occurs in FH homozygotes, thus accounting for much of the apparent overproduction of LDL.

Figure 13A illustrates the dual role of the LDL receptor in LDL metabolism as determined from the studies of WHHL rabbits. First, the receptor limits LDL production by enhancing the removal of the precursor, IDL, from the circulation. Second, it enhances LDL degradation by mediating cellular uptake of LDL. A deficiency of LDL receptors causes LDL to accumulate as a result both of overproduction and of delayed removal (Fig. 13B). By this quirk of dual functionality, LDL receptors become crucially important modulators of plasma LDL levels in humans and animals.

Perspectives

Receptor Regulation: Therapeutic Implications

Knowledge of the fundamental properties of the LDL receptor has important implications for the therapy of FH and other hypercholesterolemic states. This knowledge also provides fuel for certain speculations about the role of the LDL receptor as a protective factor against atherosclerosis in human beings.

The therapeutic implications of the LDL receptor studies center on strategies for increasing the production of LDL receptors in the liver, thereby lowering plasma LDL-cholesterol levels. In FH heterozygotes this goal can be attained by stimulating the normal gene to produce more than its usual number of LDL receptors, thus compensating for the defective allele.[107] The rationale for such therapy emerged from studies of cultured fibroblasts, which showed that the production of LDL receptors is driven by the cell's demand for cholesterol.[9, 36] When demands for cholesterol are high, the cells have high levels of mRNA for the LDL receptor. Conversely, when demands for cholesterol are reduced, excess cholesterol accumulates in cells, and the amount of receptor mRNA falls.[36, 37]

Inasmuch as the liver is the major site of expression of LDL receptors, the therapeutic problem is reduced to the development of methods to increase hepatic demands for cholesterol. This can be achieved by two techniques: (1) inhibition of the intestinal reabsorption of bile acids; and (2) inhibition of cholesterol synthesis. These techniques can be used alone or in combination, as illustrated in Figure 14.

The liver requires cholesterol for conversion into bile acids, which constitute the major route by which cholesterol is excreted from the body.[18] However, only a fraction

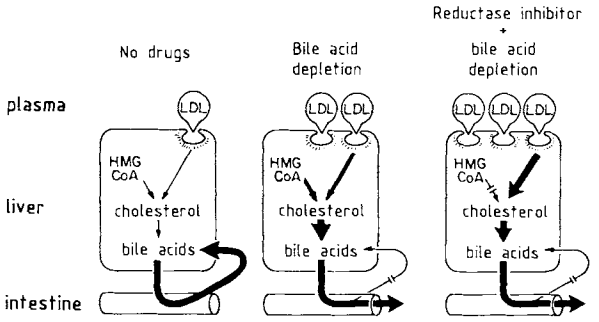

Fig. 14. Rationale for the use of a bile acid-binding resin and an inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A reductase in the treatment of FH heterozygotes. A detailed discussion of this figure is presented in the text.

of the bile acids secreted by the liver actually leaves the body. The vast bulk of bile acids are reabsorbed in the terminal ileum and returned to the liver for reutilization. As a result, the liver converts only a minimal amount of cholesterol into bile acids (Fig. 14, left). The liver's demand for cholesterol can be enhanced by the ingestion of resins that bind bile acids in the intestine and prevent their reabsorption. Since the liver can no longer reuse old bile acids, it must continually make new bile acids and the liver's demand for cholesterol increases. In order to obtain this cholesterol, the liver makes a dual response: (1) it synthesizes increased amounts of cholesterol through an increase in the activity of HMG CoA reductase; and (2) it attempts to take up additional plasma cholesterol by increasing the production of LDL receptors. The increased LDL receptor activity causes plasma LDL levels to fall (Fig. 14, center). The problem with bile acid resin therapy (and the physiologically equivalent procedure of ileal bypass surgery) is that the effects are not profound. The increase in cholesterol production partially offsets the hepatic demand for cholesterol and so there is only a 15 to 20% increase in the synthesis of LDL receptors and only a 15 to 20% drop in plasma LDL-cholesterol levels.

The second method for increasing LDL receptor production, namely, inhibition of hepatic cholesterol synthesis, is much more powerful than bile acid depletion. The technique emerged from the discovery in 1976 of a class of fungal metabolites that inhibit HMG CoA reductase. The original compound, discovered by *Akira Endo* at the Sankyo Drug Company in Japan, is called compactin.[108] A more recent version, developed by the Merck, Sharp and Dohme Research Laboratories in the United States, is called mevinolin.[109] These two agents are potent competitive inhibitors of HMG CoA reductase; the inhibitory constant is approximately 10^{-9} M.[108]

When given to experimental animals, compactin or mevinolin initially inhibit cholesterol synthesis in the liver, and this triggers a complex regulatory mechanism that lowers the plasma LDL-cholesterol level. With *Kovanen* and *Kita*, we showed that the inhibition of cholesterol synthesis elicits a dual compensatory response: (1) hepatocytes synthesize increased amounts of HMG CoA reductase; and (2) they synthesize increased numbers of LDL receptors.[110] When a new steady state is attained, the increase in HMG CoA reductase is almost sufficient to overcome the inhibitory effects of compactin. Total body cholesterol synthesis is only slightly reduced.[111] Meanwhile, the plasma LDL level has fallen as a result of the increase in LDL receptors. The fall in plasma LDL levels is balanced by the increase in LDL receptors, and so the absolute amount of cholesterol entering the liver through the receptor pathway is the same as it was earlier. The difference, however, is that this delivery is now occurring at a lower plasma LDL level.[107]

When given as a single agent to FH heterozygotes, mevinolin routinely produces a 30% fall in plasma LDL-cholesterol levels. When given together with cholestyramine, mevinolin blocks the compensatory increase in cholesterol synthesis, and the increase in LDL receptors is even more profound (Fig. 14, right). Plasma LDL cholesterol levels fall by 50 to 60%.[112]

The important principle to emerge from these studies is that stimulation of LDL receptor activity lowers the plasma LDL-cholesterol level without grossly distorting cholesterol delivery.[107, 111] At present mevinolin and related compounds are in the early stages of clinical testing. Their efficacy in lowering plasma LDL-cholesterol levels has been well established, but there is no information regarding long-term toxicity in man. If these drugs turn out to be nontoxic, they will have an important role in the therapy of FH heterozygotes and probably of other hypercholesterolemic individuals as well.

The principles applied to treatment of FH heterozygotes cannot, unfortunately, be applied to homozygotes, especially those who have totally defective LDL receptor genes. These individuals do not respond to the abovementioned drugs because they cannot synthesize LDL receptors.[113] Current therapy for these individuals involves removal of LDL from plasma extracorporeally through repeated plasmapheresis.[114] Such procedures, which must be repeated every two to three weeks, are technically difficult and are very demanding of patient and physician.

Recently, a more direct therapeutic approach was taken in an FH homozygote, whose initials are S. J. and who has two mutant genes at the LDL receptor locus. This six-year-old girl, who is a patient of our colleague *David Bilheimer* in Dallas, had a total plasma cholesterol level over 1,000 mg/dL (greater than six times above normal limits), and she sustained repeated episodes of myocardial infarction. After she failed to respond to two coronary bypass procedures plus a mitral valve replacement, she was subjected to combined heart-liver transplantation by a team of surgeons led by *Thomas E. Starzl* at the University of Pittsburgh.[115] The liver transplant was designed to provide a source of LDL receptors. The heart transplantation was necessitated because of the poor condition of her own heart as a result of the atherosclerotic process.

Immediately after the operation, S. J.'s total plasma cholesterol level fell from 1100 mg/dL to the range of 200 to 300 mg/dL, and it remained in that range for the succeeding 13 months (Fig. 15A). Thereafter she was started on the HMG CoA reductase inhibitor mevinolin, and her cholesterol fell further to the range of 150 to 200 mg/dL (Fig. 15A). Liver transplantation not only lowered the plasma cholesterol level but it also restored responsiveness to mevinolin, which requires a normal LDL receptor gene in order to act. Lipoprotein turnover studies performed six months after surgery confirmed that the new LDL receptors furnished by the transplanted liver were responsible for the dramatic drop in plasma cholesterol level (Fig. 15B). S. J. remains asymptomatic at the time of this writing, and her cutaneous xanthomas have resolved. However, she requires continuous therapy with cyclosporin to prevent rejection of the transplanted organs, and her long-term prognosis is uncertain.

The response to liver transplantation in S. J. underscores the importance of hepatic LDL receptors in vivo and raises the possibility that other FH homozygotes may respond to similar transplantation procedures. Hopefully, in appropriate cases liver transplantation can be performed before heart transplantation becomes necessary.

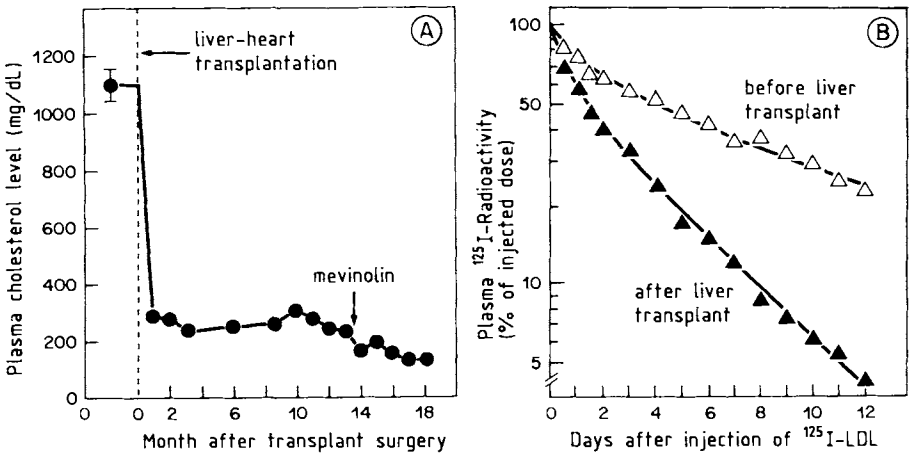

Fig. 15. LDL metabolism in S. J., a patient with homozygous FH, before and after liver-heart transplantation. A) Total cholesterol levels in plasma. B) Plasma decay curves of ^{125}I-LDL after intravenous injection of tracer amounts of ^{125}I-LDL before (△) and after (▲) liver-heart transplantation. (Data in B reprinted with permission from ref. [115].)

Speculations: LDL Receptors and the General Problem of Atherosclerosis

We now leave the realm of solidly established scientific fact and enter the much more controversial realm of speculation about the relation between cholesterol levels, LDL receptors, and atherosclerosis in the general population. After all, FH heterozygotes account for only 5% of myocardial infarctions in patients under the age of 60. What causes the other 95% of heart attacks?

Extensive epidemiologic studies performed in many populations in many countries over the past three decades have pointed strongly to a general association of high blood cholesterol levels with heart attacks. Among the most striking examples is the seven-country study of coronary artery disease directed by *Ansel Keys*.[116] A similar correlation has been observed within a single population in the extensive studies in Framingham, Massachusetts.[117]

These studies have all shown that the incidence of myocardial infarction rises in proportion to the plasma cholesterol level, more specifically the plasma level of LDL-cholesterol. When LDL-cholesterol levels are below 100 mg/dL (equivalent to a total plasma cholesterol level of approximately 170 mg/dL), heart attacks are rare. When LDL-cholesterol levels are above 200 mg/dL (equivalent to a total plasma cholesterol level of approximately 280 mg/dL), heart attacks are frequent. Controversy arises over the middle ground, i.e., individuals with plasma LDL-cholesterol levels between 100 and 200 mg/dL (total plasma cholesterol of 170 to 280 mg/dL). This is the range in which most heart attacks occur. Somewhere within this range there is a threshold value of cholesterol at which heart attacks begin to become more frequent. In this middle ground, how much of the heart attack burden is attributable to plasma cholesterol? There is no definitive answer. In addition to cholesterol, heart attacks in this group are aggravated by smoking, hypertension, stress, diabetes mellitus, and poorly understood genetic factors. However, it seems reasonable to propose that plasma cholesterol does have something to do with heart attacks in these subjects and that the incidence of heart attacks would be reduced if plasma cholesterol could be lowered.[10]

The LDL receptor studies lend experimental support to the epidemiologists' suggestion that the levels of plasma cholesterol usually seen in Western industrialized societies are inappropriately high.[9] This support derives from knowledge of the affinity of the LDL receptor for LDL. The receptor binds LDL optimally when the lipoprotein is present at a cholesterol concentration of 2.5 mg/dL.[28] In view of the 10-to-1 gradient between concentrations of LDL in plasma and interstitial fluid, a level of LDL-cholesterol in plasma of 25 mg/dL would be sufficient to nourish body cells with cholesterol.[118] This is roughly one-fifth of the level usually seen in Western societies (Fig. 16).[119] Several lines of evidence suggest that plasma levels of LDL-cholesterol in the range of 25 to 60 mg/dL (total plasma cholesterol of 110 to 150 mg/dL) might indeed be physiologic for human beings. First, in other mammalian species that do not develop atherosclerosis, the plasma LDL-cholesterol level is generally less than 80 mg/dL (Fig. 16).[120] In these animals the affinity of the LDL receptor for their own LDL is roughly the same as the affinity of the

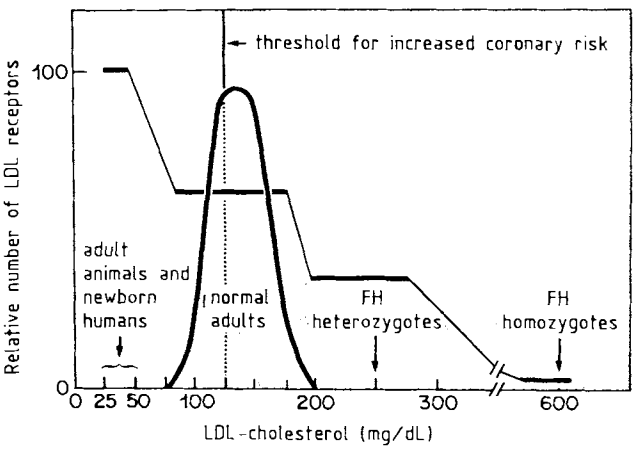

Fig. 16. Range of LDL levels in "normal" adults in Western industrial societies, indicated by the bell-shaped curve [127], is compared with the range in adult animals [120] and human infants [121] and with the levels seen in FH patients [14]. Levels in the shaded region of the chart are above the threshold associated with accelerated atherosclerosis; more than half of the adults have LDL levels above this threshold. The LDL level is inversely associated with the number of LDL receptors. (Modified from ref. [10] with permission.)

human LDL receptor for human LDL, implying that these species are designed by evolution to have similar plasma LDL levels.[9, 119] Second, the LDL level in newborn humans is approximately 30 mg/dL,[121] well within the range that seems to be appropriate for receptor binding (Fig. 16). Third, when humans are raised on a low-fat diet, the plasma LDL-cholesterol tends to stay in the range of 50 to 80 mg/dL. It only reaches levels above 100 mg/dL in individuals who consume a diet rich in saturated animal fats and cholesterol that is customarily ingested in Western societies.[116, 122]

What is the mechanism for the high levels of plasma LDL that are so frequent in Western industrialized societies? Extensive evidence implicates two major factors: diet and heredity. When people habitually consume diets low in animal fats, their plasma LDL-cholesterol levels generally tend to remain low. When even moderate amounts of animal fat are introduced into the diet, the plasma cholesterol level rises.[116, 122] However, the level does not rise equally in every person. Clearly, genetic as well as dietary factors play a role.

How might a diet rich in animal fats and cholesterol elevate the plasma LDL-cholesterol level? Here we believe that two properties of the LDL receptor play a role—saturation and suppression. As the plasma LDL level rises, the receptors become saturated. This saturation of receptors sets an upper limit on the rate at which LDL can be removed efficiently from plasma.[123] Each receptor can handle only one particle of LDL at a time. Once the receptors become saturated, the rate of removal of LDL can be accelerated only by an increase in clearance by non-receptor pathways that operate at low efficiency. In order to drive these alternate pathways, the LDL level must be quite high.[99] At ordinary levels of LDL, the major factor that limits the removal of LDL from plasma is saturation of the LDL receptor.[123]

Once LDL receptors become saturated, the removal rate of LDL is proportional to the number of receptors. Whenever the number of receptors is reduced, plasma LDL levels must rise. Experiments in animals indicate that the consumption of a high-fat diet decreases the number of LDL receptors in the liver.[123, 124] We believe that this mechanism operates through feedback suppression as described above. That is, when excess dietary cholesterol accumulates in the liver, the liver responds by decreasing the production of LDL receptors (Fig. 13C). The entry of dietary cholesterol into the liver is mediated by a receptor, termed the chylomicron remnant receptor, whose activity is genetically distinct from the LDL receptor.[125] The chylomicron remnant receptor is unaffected by cholesterol accumulation,[126] and it causes cholesterol to accumulate to high levels in liver when the diet contains excess fat.

The combination of saturation and suppression of hepatic LDL receptors contributes in a major way to the buildup of LDL in plasma when a diet rich in saturated fats and cholesterol is ingested. Insofar as such a diet also may increase production of LDL in the face of a fixed or declining removal capacity, the LDL level would rise even higher.

If the LDL receptor does limit the removal of LDL from plasma, then maneuvers that increase LDL receptor activity might be effective in individuals who have high plasma LDL-cholesterol levels, but who do not have defective LDL receptor genes. Such therapy seems feasible with the development of HMG CoA reductase inhibitors. However, it is still too early to tell whether such therapy would decrease the incidence of myocardial infarctions in individuals with moderately elevated plasma LDL-cholesterol levels in the range of 100 to 200 mg/dL. There is much circumstantial evidence to expect such improvement,[127] but unequivocal data are simply not there. Hopefully, with the availability of powerful receptor-stimulating drugs, the hypothesis should be susceptible to testing in the near future.

In considering the role of diet and drugs in treatment of high cholesterol levels, physicians and public health authorities must bear in mind the genetic variability between individuals. This variability exists at three levels: (1) The degree of increase in plasma cholesterol upon ingestion of a high cholesterol diet is variable. Not all people develop hypercholesterolemia. Some people, such as the Pima Indians, maintain low plasma cholesterol levels despite ingestion of a high-fat diet.[10] (2) Even when the plasma cholesterol level becomes elevated, the propensity for atherosclerosis varies. For example, a substantial proportion of FH heterozygotes (10 to 20%) escape myocardial infarction until the eight or ninth decade despite pronounced hypercholesterolemia from birth.[14] (3) Genetic susceptibility to contributory risk factors is variable. Some people can withstand hypertension and cigarette smoking for decades without developing atherosclerotic complications; others are highly sensitive.

In view of this genetic variability in susceptibility, dietary and drug recommendations must be individualized. The family history of the individual must be constantly borne in mind, particularly the familial incidence of premature heart attacks or strokes. An important goal of future research will be to dissect this genetic variability. Hopefully, it will become possible to identify the genes that determine such predispositions and to analyze them in each individual. For example, are there alleles that produce subtle defects in the LDL receptor that predispose to "garden-variety," diet-responsive hypercholesterolemia? Are there subtle abnormal alleles at other loci such as those governing cholesterol absorption, cholesterol synthesis, or bile acid synthesis? It seems likely that variability at such loci exists; the scientific challenge is to expose it.

Receptor Recycling: A Novel Cellular Pathway

The studies of the LDL receptor have revealed a new process by which membrane-embedded receptors cycle continuously into and out of cells. The receptors move from one organelle to another as a result of two sequential events: (1) segregation from other proteins by lateral movement in the plane of the membrane, and (2) pinching off of receptor-enriched membranes to form vesicles that eventually fuse with a different organelle. These receptors have been designated as "migrant" membrane proteins to distinguish them from "resident" membrane proteins that do not move in this fashion.[4] The purpose of such intracellular traffic is to integrate the behavior of multiple orga-

nelles to form coherent biochemical pathways. Thus, the movement of the LDL receptor links the cell surface to the endosome and to the lysosome. The cholesterol liberated from LDL in lysosomes exerts regulatory effects in two other organelles, the endoplasmic reticulum and the nucleus. Selective movement of membrane proteins from one organelle to another allows such multi-organelle regulation to occur.

What are the signals that dictate the path that each migrant membrane protein must follow? We are beginning to obtain some insight into the signals necessary for LDL receptors to be incorporated into one sorting structure, the coated pit. However, there is still no information with regard to signals that cause proteins to leave other organelles such as the endoplasmic reticulum and move to different organelles such as the Golgi complex. Delineation of these sorting signals is a major challenge facing the field of cell biology.

Concluding Remarks

In his Nobel Lecture of 1964, *Konrad Bloch* summarized his brilliant studies on the biological synthesis of cholesterol. At the end of his talk, Bloch predicted that the next era in cholesterol research would involve the elucidation of homeostatic control mechanisms.[128] A decade later, in 1973, the LDL receptor concept was advanced to explain the homeostasis of plasma cholesterol and to account for regulatory abnormalities in cholesterol metabolism that were observed in patients with familial hypercholesterolemia. During the next 12 years, the LDL receptor was transformed from a genetic abstraction to a well-characterized protein whose structural domains have been defined. Studies of this receptor taught us about receptor-mediated endocytosis and the novel route by which receptors cycle into and out of cells. We have learned that receptors contain multiple functional domains that direct each step in this movement and that these domains are encoded on exons that can be shared among many proteins. We have learned that genetic defects in the receptor can cause cholesterol to accumulate in plasma, producing premature atherosclerosis. Together with others, we have also learned that the liver is the most important site of action of LDL receptors and that liver replacement can offer a successful form of therapy for children with homozygous FH. Finally, we have learned that regulation of this receptor through drugs and diet can profoundly change the LDL-cholesterol level and that saturation and suppression of receptors may contribute to the high incidence of hypercholesterolemia in industrialized society. It is hoped that these insights will lead to a deeper understanding of the biology of cells and thereby to more effective forms of treatment for diseases such as familial hypercholesterolemia.

We wish to express our deepest appreciation to Dr. Donald W. Seldin, chairman of the Department of Internal Medicine at the University of Texas Southwestern Medical School for more than 30 years and creator of the intellectual environment that made our work possible. We are grateful for the contributions of many students, postdoctoral fellows, and faculty members who have advanced this effort over the past 12 years. Finally, we acknowledge the National Heart, Lung, and Blood Institute of the National Institutes of Health, the Moss Heart Foundation, and the Leland Fikes Foundation for their long-term financial support.

Direct Methods and Anomalous Dispersion (Nobel Lecture)**

By Herbert Hauptman*

1. Introduction

The electron density function, $\rho(\mathbf{r})$, in a crystal determines its diffraction pattern, i.e. both the magnitudes and phases of its X-ray diffraction maxima, and conversely. Since, however, only magnitudes are available from the diffraction experiment, then the density function $\rho(\mathbf{r})$ cannot be recovered. If one invokes prior structural knowledge, usually that the crystal is composed of discrete atoms of known atomic numbers, then the observed magnitudes are, in general, sufficient to determine the positions of the atoms, i.e. the crystal structure.

It should be noted here that the recognition that observed diffraction data are in general sufficient to determine crystal structures uniquely was an important milestone in the development of the direct methods of crystal structure determination. The erroneous contrary view, that crystal structures could not, even in principle, be deduced from diffraction intensities, had long been held by the crystallographic community prior to ca. 1950 and constituted a psychological barrier which first had to be removed before real progress could be made.

2. The Traditional Direct Methods

2.1. The Phase Problem

Denote by $\phi_{\mathbf{H}}$ the phase of the structure factor $F_{\mathbf{H}}$:

$$F_{\mathbf{H}} = |F_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}}) \tag{1}$$

where $\mathbf{H}$ is a reciprocal lattice vector (having three integer components) which labels the corresponding diffraction maximum. The relationship between the structure factors $F_{\mathbf{H}}$ and the electron density function $\rho(\mathbf{r})$ is then given by

$$F_{\mathbf{H}} = \int_V \rho(\mathbf{r}) \exp(2\pi i\, \mathbf{H}\cdot\mathbf{r})\, dV \tag{2}$$

and

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{H}} F_{\mathbf{H}} \exp(-2\pi i\, \mathbf{H}\cdot\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{H}} |F_{\mathbf{H}}| \exp i(\phi_{\mathbf{H}} - 2\pi\, \mathbf{H}\cdot\mathbf{r}) \tag{3}$$

in which V represents the unit cell or its volume. Thus the structure factors $F_{\mathbf{H}}$ determine $\rho(\mathbf{r})$. The X-ray diffraction experiment yields only the magnitudes $|F_{\mathbf{H}}|$ of a finite number of structure factors, but the values of the phases $\phi_{\mathbf{H}}$, which are also needed if one is to determine $\rho(\mathbf{r})$ from Eq. (3), cannot be determined experimentally. If arbitrary values for the phases $\phi_{\mathbf{H}}$ are specified in Eq. (3), then density functions $\rho(\mathbf{r})$ are defined, which, when substituted into Eq. (2) yield structure factors $F_{\mathbf{H}}$, the magnitudes of which agree with the observed magnitudes $|F_{\mathbf{H}}|$. It follows that the diffraction experiment does not determine $\rho(\mathbf{r})$. It was this argument which led crystallographers, prior to 1950, to the erroneous conclusion that diffraction intensities could not, even in principle, determine crystal structures uniquely. What had been overlooked was the fact that the phases $\phi_{\mathbf{H}}$ could not be arbitrarily specified if Eq. (3) is to yield density functions characteristic of real crystals.

Crystals are composed of discrete atoms. One exploits this prior structural knowledge by replacing the real crystal, with continuous electron density $\rho(\mathbf{r})$, by an ideal one, the unit cell of which consists of N discrete, non-vibrating, point atoms located at the maxima of $\rho(\mathbf{r})$. Then the structure factor $F_{\mathbf{H}}$ is replaced by the normalized structure factor $E_{\mathbf{H}}$ and Eq. (1) to (3) are replaced by

$$E_{\mathbf{H}} = |E_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}}) \tag{4}$$

$$E_{\mathbf{H}} = \frac{1}{\sigma_2^{1/2}} \sum_{j=1}^{N} f_j \exp(2\pi i\, \mathbf{H}\cdot\mathbf{r}_j) \tag{5}$$

$$\langle E_{\mathbf{H}} \exp(-2\pi i\, \mathbf{H}\cdot\mathbf{r})\rangle_{\mathbf{H}} = \frac{1}{\sigma_2^{1/2}} \left\langle \sum_{j=1}^{N} f_j \exp[2\pi i\, \mathbf{H}\cdot(\mathbf{r}_j - \mathbf{r})] \right\rangle_{\mathbf{H}}$$
$$= \frac{f_j}{\sigma_2^{1/2}} \quad \text{if} \quad \mathbf{r} = \mathbf{r}_j$$
$$= 0 \quad \text{if} \quad \mathbf{r} \neq \mathbf{r}_j \tag{6}$$

where f_j is the zero-angle atomic scattering factor, $\mathbf{r}_j$ is the position vector of the atom labelled j, and

$$\sigma_n = \sum_{j=1}^{N} f_j^n \quad (n = 1, 2, 3, \ldots) \tag{7}$$

In the case of X-ray diffraction the f_j are equal to the atomic numbers Z_j and are thus presumed to be known. From Eq. (6) it follows that the normalized structure factors $E_{\mathbf{H}}$ determine the atomic position vectors $\mathbf{r}_j$ ($j = 1, 2, \ldots, N$), i.e. the crystal structure.

In practice a finite number of magnitudes $|E_{\mathbf{H}}|$ of normalized structure factors $E_{\mathbf{H}}$ are obtainable (at least approximately) from the observed magnitudes $|F_{\mathbf{H}}|$, while the phases $\phi_{\mathbf{H}}$, as defined by Eq. (4) and (5), cannot be determined experimentally. Since one now requires only the 3N components of the N position vectors $\mathbf{r}_j$, rather than the much more complicated electron density function $\rho(\mathbf{r})$, it turns out that, in general, the known magnitudes are more than sufficient. This is most readily seen by equating the magnitudes of both sides of Eq. (5) in order to

obtain a system of equations in which the only unknowns are the 3N components of the position vectors $\mathbf{r}_j$. Since the number of such equations, equal to the number of reciprocal lattice vectors $\mathbf{H}$ for which magnitudes $|E_{\mathbf{H}}|$ are available, usually greatly exceeds the number, 3N, of unknowns, this system is redundant. Thus, observed diffraction intensities usually over-determine the crystal structure, i.e. the positions of the atoms in the unit cell. In short, by merely replacing the integral of Eq. (2) by the summation of Eq. (5), i.e. taking Eq. (5) as the starting point of our investigation rather than Eq. (2), one has transformed the problem from an unsolvable one into one which is solvable, at least in principle.

In summary then, the intensities (or magnitudes $|E_{\mathbf{H}}|$) of a sufficient number of X-ray diffraction maxima determine a crystal structure. The available intensities usually exceed the number of parameters needed to describe the structure. From these intensities a set of numbers $|E_{\mathbf{H}}|$ can be derived, one corresponding to each intensity. However, the elucidation of the crystal structure requires also a knowledge of the complex numbers $E_{\mathbf{H}} = |E_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}})$, the normalized structure factors, of which only the magnitudes $|E_{\mathbf{H}}|$ can be determined from experiment. Thus, a "phase" $\phi_{\mathbf{H}}$, unobtainable from the diffraction experiment, must be assigned to each $|E_{\mathbf{H}}|$, and the problem of determining the phases when only the magnitudes $|E_{\mathbf{H}}|$ are known is called the "phase problem". Owing to the known atomicity of crystal structures and the redundancy of observed magnitudes $|E_{\mathbf{H}}|$, the phase problem is, in principle, solvable.

2.2. The Structure Invariants

Equation (6) implies that the normalized structure factors $E_{\mathbf{H}}$ determine the crystal structure. However, Eq. (5) does not imply that, conversely, the crystal structure determines the values of the normalized structure factors $E_{\mathbf{H}}$ since the position vectors $\mathbf{r}_j$ depend not only on the structure but on the choice of origin as well. It turns out nevertheless that the magnitudes $|E_{\mathbf{H}}|$ of the normalized structure factors are in fact uniquely determined by the crystal structure and are independent of the choice of origin but that the values of the phases $\phi_{\mathbf{H}}$ depend also on the choice of origin. Although the values of the individual phases depend on the structure and the choice of origin, there exist certain linear combinations of the phases, the so-called structure invariants, whose values are determined by the structure alone and are independent of the choice of origin.

It follows readily from Eq. (5) that the linear combination of three phases

$$\psi_3 = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} + \phi_{\mathbf{L}} \tag{8}$$

and that the linear combination of four phases

$$\mathbf{H} + \mathbf{K} + \mathbf{L} = 0 \tag{9}$$

the linear combination of four phases

$$\psi_4 = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} + \phi_{\mathbf{L}} + \phi_{\mathbf{M}} \tag{10}$$

is a structure invariant (quartet) provided that

$$\mathbf{H} + \mathbf{K} + \mathbf{L} + \mathbf{M} = 0 \tag{11}$$

etc.

2.3. The Structure Seminvariants

If a crystal possesses elements of symmetry then the origin may not be chosen arbitrarily if the simplifications permitted by the space group symmetries are to be realized. For example, if a crystal has a center of symmetry it is natural to place the origin at such a center, whereas if a two-fold screw axis, but no other symmetry element is present, the origin would normally be situated on this symmetry axis. In such cases the permissible origins are greatly restricted and it is therefore plausible to assume that many linear combinations of the phases will remain unchanged in value when the origin is shifted only in the restricted ways allowed by the space group symmetries. One is thus led to the notion of the structure seminvariant, those linear combinations of the phases whose values are independent of the choice of permissible origin.

If the only symmetry element is a center of symmetry, for example (space group $P\bar{1}$), then it turns out (again from Eq. (5)) that a single phase $\phi_{\mathbf{H}}$ is a structure seminvariant provided that the three components of the reciprocal lattice vector $\mathbf{H}$ are even integers; the linear combination of two phases $\phi_{\mathbf{H}} + \phi_{\mathbf{K}}$ is a structure seminvariant provided that the three components of $\mathbf{H} + \mathbf{K}$ are even integers; etc.

If the only symmetry element is a two-fold rotation axis (or twofold screw axis) then one finds from Eq. (5) that the single phase ϕ_{hkl} is a structure seminvariant provided that h and l are even integers and $k = 0$; the linear combination of two phases

$$\phi_{h_1 k_1 l_1} + \phi_{h_2 k_2 l_2}$$

is a structure seminvariant provided that $h_1 + h_2$ and $l_1 + l_2$ are even and $k_1 + k_2 = 0$; etc.

The structure invariants and seminvariants have been tabulated for all the space groups.[13-15, 19, 21] In general the collection of structure invariants is a subset of the collection of structure seminvariants. If no element of symmetry is present, that is the space group is $P1$, then the two classes coincide.

2.3.1. Origin and Enantiomorph Specification

The theory of the structure seminvariants leads in a natural way to space group dependent recipes for origin and enantiomorph (i.e. the handedness, right or left) specification.

In general the theory identifies an appropriate set of phases whose values are to be specified in order to fix the origin uniquely. For example, in space group $P1$ (no elements of symmetry) the values of any three phases

$$\phi_{h_1 k_1 l_1},\ \phi_{h_2 k_2 l_2},\ \phi_{h_3 k_3 l_3} \tag{12}$$

for which the determinant Δ satisfies

$$\Delta = \begin{vmatrix} h_1 & k_1 & l_1 \\ h_2 & k_2 & l_2 \\ h_3 & k_3 & l_3 \end{vmatrix} = \pm 1 \qquad (13)$$

may be specified arbitrarily, thus fixing the origin uniquely. Once this is done then the value of any other phase is uniquely determined by the structure alone. For enantiomorph specification it is sufficient to specify arbitrarily the sign of any enantiomorph sensitive structure invariant, i.e. one whose value is different from 0° or 180° (for further details see ref. [6], pages 28–52).

In the space group $P\bar{1}$ one again specifies arbitrarily the value (0° or 180°) of three phases (see (12)), but now the condition is that the determinant Δ [defined by Eq. (13)] be odd. Similar recipes for all the space groups are now known and are to be found in the literature cited.

2.4. The Fundamental Principle of Direct Methods

It is known that the values of a sufficiently extensive set of cosine seminvariants (the cosines of the structure seminvariants) lead unambiguously to the values of the individual phases.[6] Magnitudes |E| are capable of yielding estimates of the cosine seminvariants only or, equivalently, the magnitudes of the structure seminvariants; the signs of the structure seminvariants are ambiguous because the two enantiomorphous structures permitted by the observed magnitudes |E| correspond to two values of each structure seminvariant differing only in sign. However, once the enantiomorph has been selected by specifying arbitrarily the sign of a particular enantiomorph sensitive structure seminvariant (i.e. one different from 0 or π), then the magnitudes |E| determine both signs and magnitudes of the structure seminvariants consistent with the chosen enantiomorph. Thus, for a fixed enantiomorph, the observed magnitudes |E| determine unique values for the structure seminvariants; the latter, in turn, lead to unique values of the individual phases. In short, the structure seminvariants serve to link the observed magnitudes |E| with the desired phases ϕ (the fundamental principle of direct methods). It is this property of the structure seminvariants which accounts for their importance and which justifies the stress placed on them here.

By the term "direct methods" is meant that class of methods which exploits relationships among the structure factors in order to go directly from the observed magnitudes |E| to the needed phases ϕ.

2.5. The Neighborhood Principle

It has long been known that, for a fixed enantiomorph, the value of any structure seminvariant ψ is, in general, uniquely determined by the magnitudes |E| of the normalized structure factors. In recent years it has become clear that, for a fixed enantiomorph, there corresponds to ψ one or more small sets of magnitudes |E|, the neighborhoods of ψ, on which, in favorable cases, the value of ψ most sensitively depends; that is to say that, in favorable cases, ψ is primarily determined by the values of |E| in any of its neighborhoods and is relatively insensitive to the values of the great bulk of remaining magnitudes. The conditional probability distribution of ψ, assuming as known the magnitudes |E| in any of its neighborhoods, yields an estimate for ψ which is particularly good in the favorable case that the variance of the distribution happens to be small.[7,8]

The study of appropriate probability distributions (compare Section 2.7) leads directly to the definition of the neighborhoods of the structure invariants. Definitions are given here only for the triplet ψ_3 and the quartet ψ_4, but recipes for defining the neighborhoods of all the structure invariants are now known.[3,10,11]

2.5.1. *The First Neighborhood of the Triplet ψ_3*

Let **H**, **K**, **L** be three reciprocal lattice vectors which satisfy Eq. (9). Then ψ_3 [Eq. (8)] is a structure invariant and its first neighborhood is defined to consist of the three magnitudes:

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\mathbf{L}}|. \qquad (14)$$

2.5.2. *Neighborhoods of the Quartet ψ_4*

The First Neighborhood

Let **H**, **K**, **L**, **M** be four reciprocal lattice vectors which satisfy Eq. (11). Then ψ_4 [Eq. (10)] is a structure invariant and its first neighborhood is defined to consist of the four magnitudes:

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\mathbf{L}}|, |E_{\mathbf{M}}| \qquad (15)$$

The four magnitudes in (15) are said to be the main terms of the quartet ψ_4.

The second Neighborhood

The second neighborhood of the quartet ψ_4 is defined to consist of the four magnitudes in (15) plus the three additional magnitudes:

$$|E_{\mathbf{h}+\mathbf{K}}|, |E_{\mathbf{K}+\mathbf{L}}|, |E_{\mathbf{L}+\mathbf{H}}| \qquad (16)$$

i.e. seven magnitudes |E| in all. The three magnitudes in (16) are said to be the cross-terms of the quartet ψ_4.

2.6. The Extension Concept

By embedding the structure seminvariant T and its symmetry related variants in suitable structure invariants Q one obtains the extensions Q of the seminvariant T. Owing to the space group dependent relations among the phases, T is related in a known way to its extensions. In this way the theory of the structure seminvariants is reduced to that of the structure invariants. In particular, the neighborhoods of T are defined in terms of the neighborhoods of its extensions. The procedure will be illustrated in some detail only for the two-phase structure seminvariant in the space group $P\bar{1}$ which serves as the prototype for the structure

seminvariants in general, in all space groups, noncentrosymmetric as well as centrosymmetric.

2.6.1. The Two-Phase Structure Seminvariant in $P\bar{1}$

It has already been seen (Section 2.3) that the linear combination of two phases

$$T=\phi_{\mathbf{H}}+\phi_{\mathbf{K}} \tag{17}$$

is a structure seminvariant in $P\bar{1}$ if and only if the three components of the reciprocal lattice vector $\mathbf{H}+\mathbf{K}$ are all even. Then the components of each of the four reciprocal lattice vectors $\frac{1}{2}(\pm\mathbf{H}\pm\mathbf{K})$ are all integers. Note also that in this space group the structure factors are real and all phases are 0° or 180°.

2.6.2. The Extensions of T

One embeds the two-phase structure seminvariant T [Eq. (17)] and its symmetry related variant

$$T_1=\phi_{-\mathbf{H}}+\phi_{\mathbf{K}} \tag{18}$$

in the respective quartets

$$Q=T+\phi_{-\frac{1}{2}(\mathbf{H}+\mathbf{K})}+\phi_{-\frac{1}{2}(\mathbf{H}+\mathbf{K})} \tag{19}$$

$$Q_1=T_1+\phi_{-\frac{1}{2}(-\mathbf{H}+\mathbf{K})}+\phi_{-\frac{1}{2}(-\mathbf{H}+\mathbf{K})} \tag{20}$$

From Eq. (17) and (18) and the space group-dependent relationships among the phases, it is readily verified that Q and Q_1 are in fact (special) four-phase structure invariants (quartets) and

$$T=T_1=Q=Q_1 \tag{21}$$

The quartets Q and Q_1 are said to be the extensions of the seminvariant T. In this way the theory of the two-phase structure seminvariant T is reduced to that of the quartets. In particular, the neighborhoods of T are defined in terms of the neighborhoods of the quartet.

2.6.3. The First Neighborhoods of the Extensions

Since two of the phases of the quartet Q [Eq. (19)] are identical, only three of the four main terms are distinct. The first neighborhood of Q is accordingly defined to consist of the three magnitudes

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\frac{1}{2}(\mathbf{H}+\mathbf{K})}| \tag{22}$$

(since $|E_{-\frac{1}{2}(\mathbf{H}+\mathbf{K})}|=|E_{\frac{1}{2}(\mathbf{H}+\mathbf{K})}|$)

In a similar way the first neighborhood of the extension Q_1 [Eq. (20)] is defined to consist of the three magnitudes

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\frac{1}{2}(\mathbf{H}-\mathbf{K})}| \tag{23}$$

2.6.4. The First Neighborhood of T

The first neighborhood of the two-phase structure seminvariant T is defined to consist of the set-theoretic union of the first neighborhoods of its extensions, i.e., in view of (22) and (23), of the four magnitudes

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\frac{1}{2}(\mathbf{H}+\mathbf{K})}|, |E_{\frac{1}{2}(\mathbf{H}-\mathbf{K})}| \tag{24}$$

2.7. The Solution Strategy

One starts with the system of equations (5). By equating real and imaginary parts of (5) one obtains two equations for each reciprocal lattice vector $\mathbf{H}$. The magnitudes $|E_{\mathbf{H}}|$ and the atomic scattering factors f_j are presumed to be known. The unknowns are the atomic position vectors $\mathbf{r}_j$ and the phases $\phi_{\mathbf{H}}$. Owing to the redundancy of the system (5), one naturally invokes probabilistic techniques in order to eliminate the unknown position vectors $\mathbf{r}_j$, and in this way to obtain relationships among the unknown phases $\phi_{\mathbf{H}}$ having probabilistic validity.

Choose a finite number of reciprocal lattice vectors $\mathbf{H}$, $\mathbf{K}$, ... in such a way that the linear combination of phases

$$\psi=\phi_{\mathbf{H}}+\phi_{\mathbf{K}}+\cdots \tag{25}$$

is a structure invariant or seminvariant whose value we wish to estimate. Choose satellite reciprocal lattice vectors $\mathbf{H}'$, $\mathbf{K}'$, ... in such a way that the collection of magnitudes

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, \ldots; \quad |E_{\mathbf{H}'}|, |E_{\mathbf{K}'}|, \ldots \tag{26}$$

constitutes a neighborhood of ψ. The atomic position vectors $\mathbf{r}_j$ are assumed to be the primitive random variables which are uniformly and independently distributed. Then the magnitudes $|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, \ldots; |E_{\mathbf{H}'}|, |E_{\mathbf{K}'}|, \ldots$; and phases $\phi_{\mathbf{H}}, \phi_{\mathbf{K}}, \ldots; \phi_{\mathbf{H}'}, \phi_{\mathbf{K}'}, \ldots$ of the complex, normalized structure factors $E_{\mathbf{H}}, E_{\mathbf{K}}, \ldots; E_{\mathbf{H}'}, E_{\mathbf{K}'}, \ldots$, as functions [Eq. (5)] of the position vectors $\mathbf{r}_j$, are themselves random variables, and their joint probability distribution P may be obtained. From the distribution P one derives the conditional joint probability distribution

$$P(\Phi_{\mathbf{H}}, \Phi_{\mathbf{K}}, \ldots | |E_{\mathbf{H}}|, |E_{\mathbf{K}}|, \ldots; |E_{\mathbf{H}'}|, |E_{\mathbf{K}'}|, \ldots), \tag{27}$$

of the phases $\phi_{\mathbf{H}}, \phi_{\mathbf{K}}, \ldots$, given the magnitudes $|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, \ldots; |E_{\mathbf{H}'}|, |E_{\mathbf{K}'}|, \ldots$, by fixing the known magnitudes, integrating with respect to the unknown phases $\Phi_{\mathbf{H}'}, \Phi_{\mathbf{K}'}, \ldots$ from 0 to 2π, and multiplying by a suitable normalizing parameter. The distribution (27) in turn leads directly to the conditional probability distribution

$$P(\Psi | |E_{\mathbf{H}}|, |E_{\mathbf{K}}|, \ldots; |E_{\mathbf{H}'}|, |E_{\mathbf{K}'}|, \ldots) \tag{28}$$

of the structure invariant or seminvariant ψ, assuming as known the magnitudes of (26) constituting a neighborhood of ψ. Finally, the distribution (28) yields an estimate for ψ which is particularly good in the favorable case that the variance of (28) happens to be small.

2.8. Estimating the Triplet in $P1$

Let the three reciprocal lattice vectors **H**, **K**, and **L** satisfy Eq. (9). Refer to Section 2.5.1 for the first neighborhood of the triplet ψ_3 [Eq. (8)] and to Section 2.7 for the probabilistic background.

Suppose that R_1, R_2, and R_3 are three specified non-negative numbers. Denote by

$$P_{1/3} = P(\psi | R_1, R_2, R_3)$$

the conditional probability distribution of the triplet ψ_3, given the three magnitudes in its first neighborhood:

$$|E_{\mathbf{H}}| = R_1, |E_{\mathbf{K}}| = R_2, |E_{\mathbf{L}}| = R_3 \tag{29}$$

Then, carrying out the program described in Section 2.7, one finds[11]

$$P_{1/3} = P(\Psi | R_1, R_2, R_3) \approx \frac{1}{2\pi I_0(A)} \exp(A \cos \Psi) \tag{30}$$

where

$$A = \frac{2\sigma_3}{\sigma_2^{3/2}} R_1 R_2 R_3 \tag{31}$$

I_0 is the modified Bessel function, and σ_n is defined by Eq. (7). Since $A > 0$, $P_{1/3}$ has a unique maximum at $\Psi = 0°$, and it is clear that the larger the value of A the smaller is the variance of the distribution (see Fig. 1, where $A = 2.316$; Fig. 2, where $A = 0.731$). Hence, in the favorable case that A is large, say, for example, $A > 3$, the distribution leads to a reliable estimate of the structure invariant ψ_3, zero in this case:

$$\psi_3 \approx 0 \text{ if A is large} \tag{32}$$

Furthermore, the larger the value of A, the more likely is the probabilistic statement (32). It is remarkable how useful this relationship has proven to be in the applications; and yet (32) is severely limited because it is capable of yielding only the zero estimate for ψ_3, and only those estimates are reliable for which A is large, the favorable cases.

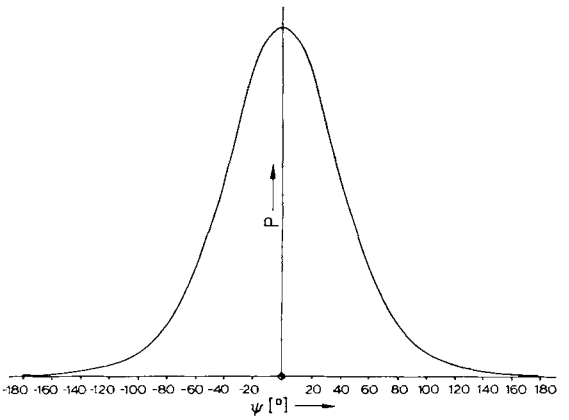

Fig. 1. The distribution $P_{1/3}$ [Eq. (30)] for $A = 2.316$.

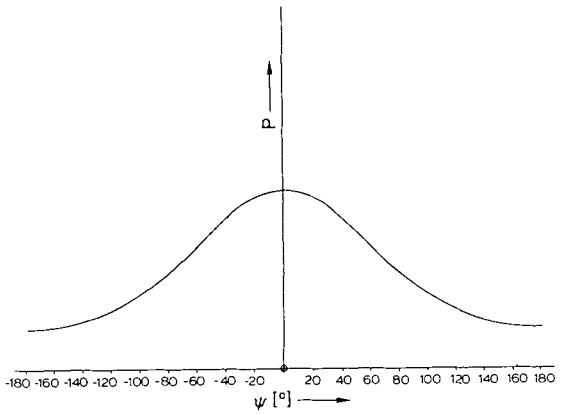

Fig. 2. The distribution $P_{1/3}$ [Eq. (30)] for $A = 0.731$.

It should be mentioned in passing that a distribution closely related to (30) leads directly to the so-called tangent formula[18] which is universally used by direct methods practitioners:

$$\frac{\sin\phi_{\mathbf{h}}}{\cos\phi_{\mathbf{h}}} = \tan\phi_{\mathbf{h}} = \frac{\langle |E_{\mathbf{K}} E_{\mathbf{h}-\mathbf{K}}| \sin(\phi_{\mathbf{K}} + \phi_{\mathbf{h}-\mathbf{K}}) \rangle_{\mathbf{K}}}{\langle |E_{\mathbf{K}} E_{\mathbf{h}-\mathbf{K}}| \cos(\phi_{\mathbf{K}} + \phi_{\mathbf{h}-\mathbf{K}}) \rangle_{\mathbf{K}}} \tag{33}$$

in which **h** is a fixed reciprocal lattice vector, the averages are taken over the same set of vectors **K** in reciprocal space, usually restricted to those vectors **K** for which $|E_{\mathbf{K}}|$ and $|E_{\mathbf{h}-\mathbf{K}}|$ are both large, and the sign of $\sin\phi_{\mathbf{h}}$ ($\cos\phi_{\mathbf{h}}$) is the same as the sign of the numerator (denominator) on the right hand side. The tangent formula is usually used to refine and extend a basis set of phases, presumed to be known.

2.9. Estimating the Quartet in $P1$

Two conditional probability distributions are described, one assuming as known the four magnitudes |E| in the first neighborhood of the quartet, the second assuming as known the seven magnitudes |E| in its second neighborhood.

2.9.1. The First Neighborhood

Suppose that **H**, **K**, **L**, and **M** are four reciprocal lattice vectors which satisfy Eq. (11). Refer to Section 2.5.2 for the first neighborhood of the quartet ψ_4 [Eq. (10)] and to Section 2.7 for the probabilistic background. Suppose that R_1, R_2, R_3, and R_4 are four specified non-negative numbers. Denote by

$$P_{1/4} = P(\Psi | R_1, R_2, R_3, R_4)$$

the conditional probability distribution of the quartet ψ_4, given the four magnitudes in its first neighborhood:

$$|E_{\mathbf{H}}| = R_1, |E_{\mathbf{K}}| = R_2, |E_{\mathbf{L}}| = R_3, |E_{\mathbf{M}}| = R_4 \tag{34}$$

Then

$$P_{1/4} = P(\Psi | R_1, R_2, R_3, R_4) \approx \frac{1}{2\pi I_0(B)} \exp(B \cos \Psi) \tag{35}$$

where

$$B = \frac{2\sigma_4}{\sigma_2^2} R_1 R_2 R_3 R_4$$

and σ_n is defined by Eq. (7). Thus $P_{1/4}$ is identical with $P_{1/3}$, but B replaces A. Hence similar remarks apply to $P_{1/4}$. In particular, (35) always has a unique maximum at $\Psi = 0°$ so that the most probable value of ψ_4, given the four magnitudes (34) in its first neighborhood, is zero, and the larger the value of B the more likely it is that $\psi_4 = 0°$. Since B values, of order $1/N$, tend to be less than A values, of order $1/\sqrt{N}$, at least for large values of N, the estimate (zero) of ψ_4 is in general less reliable than the estimate (zero) of ψ_3. Hence the goal of obtaining a reliable non-zero estimate for a structure invariant is not realized by Eq. (35). The decisive step in this direction is made next.

2.9.2. *The Second Neighborhood*

Employ the same notation as in Section 2.9.1 and refer again to Section 2.5.2 for the second neighborhood of the quartet ψ_4. Suppose that R_1, R_2, R_3, R_4, R_{12}, R_{23}, and R_{31}, are seven non-negative numbers. Denote by

$$P_{1/7} = P(\Psi | R_1, R_2, R_3, R_4;\ R_{12}, R_{23}, R_{31})$$

the conditional probability distribution of the quartet ψ_4, given the seven magnitudes in its second neighborhood:

$$|E_H| = R_1,\ |E_K| = R_2,\ |E_L| = R_3,\ |E_M| = R_4 \tag{36}$$

$$|E_{H+K}| = R_{12},\ |E_{K+L}| = R_{23},\ |E_{L+H}| = R_{31} \tag{37}$$

Then[7,9]

$$P_{1/7} \approx \frac{1}{L} \exp(-2B' \cos \Psi) \times I_0\left[\frac{2\sigma_3}{\sigma_2^{3/2}} R_{12} X_{12}\right] I_0\left[\frac{2\sigma_3}{\sigma_2^{3/2}} R_{23} X_{23}\right] I_0\left[\frac{2\sigma_3}{\sigma_2^{3/2}} R_{31} X_{31}\right] \tag{38}$$

where

$$B' = \frac{1}{\sigma_2^3}(3\sigma_2^3 - \sigma_2\sigma_4) R_1 R_2 R_3 R_4 \tag{39}$$

$$X_{12} = [R_1^2 R_2^2 + R_3^2 R_4^2 + 2 R_1 R_2 R_3 R_4 \cos \Psi]^{1/2} \tag{40}$$

$$X_{23} = [R_2^2 R_3^2 + R_1^2 R_4^2 + 2 R_1 R_2 R_3 R_4 \cos \Psi]^{1/2} \tag{41}$$

$$X_{31} = [R_3^2 R_1^2 + R_2^2 R_4^2 + 2 R_1 R_2 R_3 R_4 \cos \Psi]^{1/2} \tag{42}$$

σ_n is defined by Eq. (7), and L is a normalizing parameter, independent of Ψ, which is not needed for the present purpose.

Figures 3–5 show the distribution (38) (solid line —) for typical values of the seven parameters (36) and (37). For comparison the distribution (35) (broken line ---) is also shown. Since the magnitudes |E| have been obtained from a real structure with N = 29, comparison with the true value of the quartet is also possible. As already emphasized, the distribution (35) always has a unique maximum at $\Psi = 0°$. The distribution (38), on the other hand, may have a maximum at $\Psi = 0°$ or 180°, or any value between these extremes, as shown by Figures 3–5. Roughly speak-

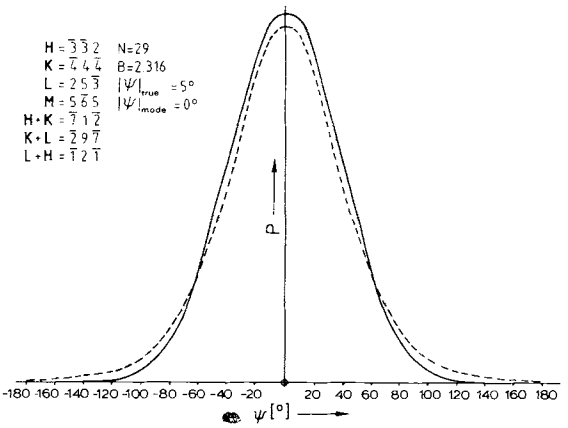

Fig. 3. The distributions (38) (—) and (35) (---) for the values of the seven parameters (36) and (37): $R_1 = 3.034$, $R_2 = 2.766$, $R_3 = 2.217$, $R_4 = 1.805$, $R_{12} = 2.918$, $R_{23} = 0.933$, $R_{31} = 2.863$. The mode of (38) is here $\Psi = 0°$, of (35) always $\Psi = 0°$.

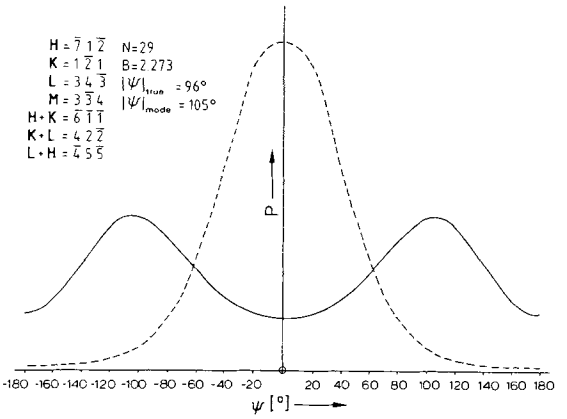

Fig. 4. The distributions (38) (—) and (35) (---) for the values of the seven parameters (36) and (37): $R_1 = 2.918$, $R_2 = 2.863$, $R_3 = 2.276$, $R_4 = 1.733$, $R_{12} = 1.631$, $R_{23} = 0.223$, $R_{31} = 1.540$. The mode of (38) is here $\Psi = \pm 105°$, of (35) always $\Psi = 0°$.

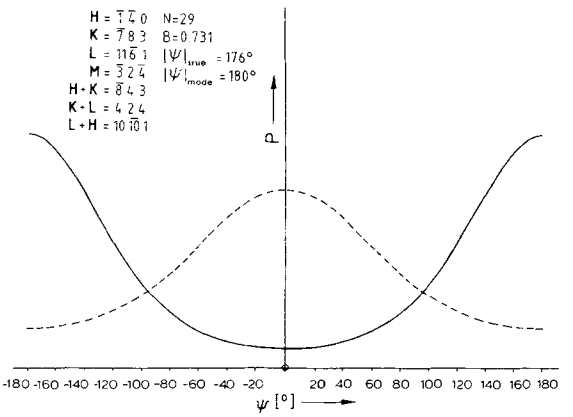

Fig. 5. The distributions (38) (---) and (35) (- ·) for the values of the seven parameters (36) and (37): $R_1 = 1.408$, $R_2 = 1.592$, $R_3 = 2.672$, $R_4 = 1.770$, $R_{12} = 0.157$, $R_{23} = 0.425$, $R_{31} = 0.385$. The mode of (38) is here $\Psi = 180°$, of (35) always $\Psi = 0°$.

ing, the maximum of (38) occurs at 0° or 180° according as the three parameters R_{12}, R_{23}, R_{31} are all large or all small, respectively. These figures also clearly show the improvement which may result when, in addition to the four magnitudes (36), the three magnitudes (37) are also assumed to be known. Finally, in the special case that

$$R_{12} \approx R_{23} \approx R_{31} \approx 0 \tag{43}$$

the distribution (38) reduces to

$$P_{1/2} \approx \frac{1}{L} \exp(-2B' \cos \Psi) \tag{44}$$

which has a unique maximum at $\Psi = \pi$ (Fig. 5).

2.10. Estimating the Two-Phase Structure Seminvariant in $P\bar{1}$

Suppose that **H** and **K** are two reciprocal lattice vectors such that the three components of $\mathbf{H} + \mathbf{K}$ are even integers. Then the linear combination T of two phases [Eq. (17)] is a structure seminvariant. Refer to Section 2.6.4 for the four magnitudes (24) in the first neighborhood of T and to Section 2.7 for the probabilistic background. Suppose that R_1, R_2, r_{12}, and $r_{1\bar{2}}$ are four non-negative numbers. In this space group every phase is 0° or 180° so that $T = 0°$ or 180° and the conditional probability distribution of T, assuming as known the four magnitudes in its first neighborhood, is discrete. Denote by $P_+(P_-)$ the conditional probability that $T = 0°$ (180°), given the four magnitudes in its first neighborhood:

$$|E_{\mathbf{H}}| = R_1,\ |E_{\mathbf{K}}| = R_2,\ |E_{\frac{1}{2}(\mathbf{H}+\mathbf{K})}| = r_{12},\ |E_{\frac{1}{2}(\mathbf{H}-\mathbf{K})}| = r_{1\bar{2}} \tag{45}$$

In the special case that all N atoms in the unit cell are identical, the solution strategy described in Section 2.7 leads to[2]

$$P_\pm \approx \frac{1}{M} \exp\left\{\mp \frac{R_1 R_2 (r_{12}^2 + r_{1\bar{2}}^2)}{2N}\right\} \cosh\left\{\frac{r_{12} r_{1\bar{2}} (R_1 \pm R_2)}{\sqrt{N}}\right\} \tag{46}$$

where upper (lower) signs go together and

$$M = \exp\left\{-\frac{R_1 R_2 (r_{12}^2 + r_{1\bar{2}}^2)}{2N}\right\} \cosh\left\{\frac{r_{12} r_{1\bar{2}} (R_1 + R_2)}{\sqrt{N}}\right\} + \exp\left\{+\frac{R_1 R_2 (r_{12}^2 + r_{1\bar{2}}^2)}{2N}\right\} \cosh\left\{\frac{r_{12} r_{1\bar{2}} (R_1 - R_2)}{\sqrt{N}}\right\} \tag{47}$$

It is easily verified that, under the assumption that R_1 and R_2 are both large, $P_+ \gg 1/2$ if r_{12} and $r_{1\bar{2}}$ are both large, but $P_+ \ll 1/2$ if one of r_{12}, $r_{1\bar{2}}$ is large and the other is small. Hence $T \approx 0°$ or 180° respectively (the favorable cases of the neighborhood principle for T).

3. Combining Direct Methods with Anomalous Dispersion

3.1. Introduction

The overview of the traditional direct methods described in Sections 1 and 2 is readily generalized to the case that the atomic scattering factors are arbitrary complex-valued functions of $(\sin\theta)/\lambda$, thus including the special case that one or more anomalous scatterers are present. Once again the neighborhood concept plays an essential role. Final results from the probabilistic theory of the two- and three-phase structure invariants are briefly summarized. In particular, the conditional probability distributions of the two- and three-phase structure invariants, given the magnitudes |E| in their first neighborhoods, are described. The distributions yield estimates for these invariants which are particularly good in those cases where the variances of the distributions happen to be small (the neighborhood principle). It is particularly noteworthy that these estimates are unique in the whole range from −180° to +180°. An example shows that the method is capable of yielding unique estimates for tens of thousands of structure invariants with unprecedented accuracy, even in the macromolecular case. It thus appears that this fusion of the traditional techniques of direct methods with anomalous dispersion will facilitate the solution of those crystal structures which contain one or more anomalous scatterers.

Most crystal structures containing as many as 80–100 independent nonhydrogen atoms are more or less routinely solvable nowadays by direct methods. On the other hand, it has been known for a long time[22–24] that the presence of one or more anomalous scatterers facilitates the solution of the phase problem; and some recent work[16,20] employing Bijvoet inequalities and the double Patterson function, leads in a similar way to estimates of the sines of the three-phase structure invariants. Again, some early work of *Rossmann*[25], employing the difference synthesis $(|F_{\mathbf{H}}| - |F_{\bar{\mathbf{H}}}|)^2$ in order to locate the anomalous scatterers and recently used[17] for the solution of the crambin structure, shows that the presence of anomalous scatterers facilitates the determination of crystal structures. This work strongly suggests that the ability to integrate the techniques of direct methods with anomalous dispersion would lead to improved methods for phase determination. The fusion of these techniques is described here. That the anticipated improvement is in fact realized is shown in Tables 1 and 2 and Figure 6. Not only do the new formulas lead to improved estimates of the structure invariants but, more important still, because the distributions derived here are unimodal in the whole interval from −180° to +180°, the twofold ambiguity inherent in all the earlier work is removed. It is believed that this resolution of the twofold ambiguity results from the ability now to make use of the individual magnitudes in the first neighborhood of the structure invariant and the avoidance of explicit dependence on the Bijvoet differences; the explicit use of the Bijvoet differences, as had been done in all previous work, leads apparently to a loss of information resulting in a twofold ambiguity in estimates of the structure invariants. It may be of some interest to observe that in the earlier work with anomalous dispersion only the sine of the invariant may be estimated; in the absence of anomalous scatterers only the cosine of the invariant may be estimated; as a result of the work described here both the sine and the cosine, that is to say the invariant itself, may be estimated. Since, in the presence of anomalous scatterers, the observed intensities are known to determine a unique enan-

tiomorph, and therefore unique values for all the structure seminvariants, formulas of the kind described here should not be unexpected; nevertheless not even their existence appears to have been anticipated.

3.2. The Normalized Structure Factors

In the presence of anomalous scatters the normalized structure factor

$$E_{\mathbf{H}} = |E_{\mathbf{H}}| \exp(i\phi_{\mathbf{H}}) \tag{48}$$

is defined by

$$E_{\mathbf{H}} = \frac{1}{\alpha_{\mathbf{H}}^{1/2}} \sum_{j=1}^{N} f_{j\mathbf{H}} \exp(2\pi i\, \mathbf{H}\cdot\mathbf{r}_j) \tag{49}$$

$$= \frac{1}{\alpha_{\mathbf{H}}^{1/2}} \sum_{j=1}^{N} |f_{j\mathbf{H}}| \exp|i(\delta_{j\mathbf{H}} + 2\pi\, \mathbf{H}\cdot\mathbf{r}_j| \tag{50}$$

where

$$f_{j\mathbf{H}} = |f_{j\mathbf{H}}| \exp(i\delta_{j\mathbf{H}}) \tag{51}$$

is the (in general complex) atomic scattering factor (a function of $|\mathbf{H}|$ as well as of j) of the atom labeled j, $\mathbf{r}_j$ is its position vector, N is the number of atoms in the unit cell, and

$$\alpha_{\mathbf{H}} = \sum_{j=1}^{N} |f_{j\mathbf{H}}|^2 \tag{52}$$

For a normal scatter, $\delta_{j\mathbf{H}} = 0$; for an atom which scatters anomalously, $\delta_{j\mathbf{H}} \neq 0$. Owing to the presence of the anomalous scatterers, the atomic scattering factors $f_{j\mathbf{H}}$, as functions of $(\sin\theta)/\lambda$, do not have the same shape for different atoms, even approximately. Hence the dependence of the $f_{j\mathbf{H}}$ on $|\mathbf{H}|$ cannot be ignored, in contrast to the usual practice when anomalous scatterers are not present. For this reason the subscript $\mathbf{H}$ is not suppressed in the symbols $f_{j\mathbf{H}}$ and $\alpha_{\mathbf{H}}$ [Eq. (52)].

The reciprocal-lattice vector $\mathbf{H}$ is assumed to be fixed, and the primitive random variables are taken to be the atomic position vectors $\mathbf{r}_j$ which are assumed to be uniformly and independently distributed. Then $E_{\mathbf{H}}$, as a function [Eq. (50)], of the primitive random variables $\mathbf{r}_j$, is itself a random variable and, as it turns out,

$$\langle |E_{\mathbf{H}}|^2 \rangle_{\mathbf{r}_j} = 1 \tag{53}$$

3.3. The Two-Phase Structure Invariant

The two-phase structure invariant, which has no analogue when no anomalous scatterers are present, is defined by

$$\psi = \phi_{\mathbf{H}} + \phi_{\overline{\mathbf{H}}} \tag{54}$$

3.3.1. The First Neighborhood

The first neighborhood of the two-phase structure invariant ψ [Eq. (54)] is defined to consist of the two magnitudes

$$|E_{\mathbf{H}}|,\ |E_{\overline{\mathbf{H}}}| \tag{55}$$

which, because of the breakdown of Friedel's law, are in general distinct.

3.3.2. Estimating the Two-Phase Structure Invariant

Define $C_{\mathbf{H}}$ and $S_{\mathbf{H}}$ by means of

$$C_{\mathbf{H}} = \frac{1}{\alpha_{\mathbf{H}}} \sum_{j=1}^{N} |f_{j\mathbf{H}}|^2 \cos(2\delta_{j\mathbf{H}}) \tag{56}$$

$$S_{\mathbf{H}} = \frac{1}{\alpha_{\mathbf{H}}} \sum_{j=1}^{N} |f_{j\mathbf{H}}|^2 \sin(2\delta_{j\mathbf{H}}) \tag{57}$$

where $f_{j\mathbf{H}}$, $\delta_{j\mathbf{H}}$, and $\alpha_{\mathbf{H}}$ are defined in (51) and (52). Define X and ξ by means of

$$X\cos\xi = C_{\mathbf{H}}, \qquad X\sin\xi = -S_{\mathbf{H}} \tag{58}$$

$$X = (C_{\mathbf{H}}^2 + S_{\mathbf{H}}^2)^{\frac{1}{2}} \qquad \tan\xi = -S_{\mathbf{H}}/C_{\mathbf{H}} \tag{59}$$

Suppose that R and $\overline{R}$ are fixed non-negative numbers. In view of (48) to (50) the two-phase structure invariant $(\phi_{\mathbf{H}} + \phi_{\overline{\mathbf{H}}})$, as a function of the primitive random variables $\mathbf{r}_j$, is itself a random variable. Denote by $P(\Psi|R,\overline{R})$ the conditional probability distribution of the two-phase structure invariant $(\phi_{\mathbf{H}} + \phi_{\overline{\mathbf{H}}})$, given the two magnitudes in its first neighborhood:

$$|E_{\mathbf{H}}| = R,\ |E_{\overline{\mathbf{H}}}| = \overline{R} \tag{60}$$

Then[5, 12]

$$P(\Psi|R,\overline{R}) \approx \left[2\pi I_0\left(\frac{2R\overline{R}X}{1-X^2}\right)\right]^{-1} \exp\left[\frac{2R\overline{R}X}{1-X^2}\cos(\Psi+\xi)\right] \tag{61}$$

where X and ξ, defined by (56)–(59), are seen to be functions of the (complex) atomic scattering factors $f_{j\mathbf{H}}$, which are presumed to be known. It should be noted that the distribution (61) has the same form as (30) but is centered at $-\xi$ instead of 0. Since (61) has a unique maximum at $\Psi = -\xi$, it follows that

$$\phi_{\mathbf{H}} + \phi_{\overline{\mathbf{H}}} \approx -\xi \tag{62}$$

provided that the variance of the distribution is small, i.e. provided that

$$A = \frac{2R\overline{R}X}{1-X^2} \tag{63}$$

is large. It should be noted that, while A depends on R, $\overline{R}$, and $|\mathbf{H}|$, for a fixed chemical composition ξ depends only on $|\mathbf{H}|$ (or $(\sin\theta)/\lambda$) and is independent of R and $\overline{R}$.

3.4. The Three-Phase Structure Invariant

It will be assumed throughout that $\mathbf{H}$, $\mathbf{K}$, and $\mathbf{L}$ are fixed reciprocal-lattice vectors satisfying

$$\mathbf{H} + \mathbf{K} + \mathbf{L} = 0 \tag{64}$$

Owing to the breakdown of Friedel's law there are, in sharp contrast to the case that no anomalous scatterers are present, eight distinct three-phase structure invariants:

$$\psi_0 = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} + \phi_{\mathbf{L}} \quad (65)$$

$$\psi_1 = -\phi_{\overline{\mathbf{H}}} + \phi_{\mathbf{K}} + \phi_{\mathbf{L}} \quad (66)$$

$$\psi_2 = \phi_{\mathbf{H}} - \phi_{\overline{\mathbf{K}}} + \phi_{\mathbf{L}} \quad (67)$$

$$\psi_3 = \phi_{\mathbf{H}} + \phi_{\mathbf{K}} - \phi_{\overline{\mathbf{L}}} \quad (68)$$

$$\psi_{\bar{0}} = \phi_{\overline{\mathbf{H}}} + \phi_{\overline{\mathbf{K}}} + \phi_{\overline{\mathbf{L}}} \quad (69)$$

$$\psi_{\bar{1}} = -\phi_{\mathbf{H}} + \phi_{\overline{\mathbf{K}}} + \phi_{\overline{\mathbf{L}}} \quad (70)$$

$$\psi_{\bar{2}} = \phi_{\overline{\mathbf{H}}} - \phi_{\mathbf{K}} + \phi_{\overline{\mathbf{L}}} \quad (71)$$

$$\psi_{\bar{3}} = \phi_{\overline{\mathbf{H}}} + \phi_{\overline{\mathbf{K}}} - \phi_{\mathbf{L}} \quad (72)$$

3.4.1. The First Neighborhood

The first neighborhood of each of the three-phase structure invariants [Eq. (65)–(72)] is defined to consist of the six magnitudes:

$$|E_{\mathbf{H}}|, |E_{\mathbf{K}}|, |E_{\mathbf{L}}|, |E_{\overline{\mathbf{H}}}|, |E_{\overline{\mathbf{K}}}|, |E_{\overline{\mathbf{L}}}| \quad (73)$$

which, again owing to the breakdown of Friedel's law, are not in general equal in pairs.

3.4.2. The Probabilistic Background

Fix the reciprocal-lattice vectors **H**, **K**, and **L**, subject to Eq. (64). Suppose that the six non-negative numbers R_1, R_2, R_3, $R_{\bar{1}}$, $R_{\bar{2}}$, and $R_{\bar{3}}$ are also specified. Define the N-fold Cartesian product W to consist of all ordered N-tuples $(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)$, where $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N$ are atomic position vectors. Suppose that the primitive random variable is the N-tuple $(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)$ which is assumed to be uniformly distributed over the subset of W defined by

$$|E_{\mathbf{H}}| = R_1, |E_{\mathbf{K}}| = R_2, |E_{\mathbf{L}}| = R_3 \quad (74)$$

$$|E_{\overline{\mathbf{H}}}| = R_{\bar{1}}, |E_{\overline{\mathbf{K}}}| = R_{\bar{2}}, |E_{\overline{\mathbf{L}}}| = R_{\bar{3}} \quad (75)$$

where the normalized structure factors E are defined by Equation (49). Then the eight structure invariants [Eq. (65)–(72)]

$$\psi_j, \psi_{\bar{j}} \quad (j = 0, 1, 2, 3) \quad (76)$$

as functions of the primitive random variables $(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)$ are themselves random variables.

Our major goal is to determine the conditional probability distribution of each of the three-phase structure invariants [Eq. (65)–(72)], given the six magnitudes (74) and (75) in its first neighborhood, which, in the favorable case that the variance of the distribution happens to be small, yields a reliable estimate of the invariant (the neighborhood principle).

3.4.3. Estimating the Three-Phase Structure Invariant

Denote by

$$P_j(\Psi | R_1, R_2, R_3, R_{\bar{1}}, R_{\bar{2}}, R_{\bar{3}}) = P_j(\Psi) \quad (j = 0, 1, 2, 3, \bar{0}, \bar{1}, \bar{2}, \bar{3}) \quad (77)$$

the conditional probability distribution of each ψ_j, assuming as known the six magnitudes (73) in its first neighborhood. Then the final formula, the major result of this article, is simply[5, 12]

$$P_j(\Psi) \approx \frac{1}{K_j} \exp[A_j \cos(\Psi - \omega_j)], \quad (j = 0, 1, 2, 3, \bar{0}, \bar{1}, \bar{2}, \bar{3}) \quad (78)$$

where the parameters K_j, A_j, and ω_j are expressible in terms of the complex scattering factors $f_{j\mathbf{H}}$, $f_{j\mathbf{K}}$, $f_{j\mathbf{L}}$, presumed to be known, and the observed magnitudes $|E_{\mathbf{H}}|$, $|E_{\mathbf{K}}|$, $|E_{\mathbf{L}}|$, $|E_{\overline{\mathbf{H}}}|$, $|E_{\overline{\mathbf{K}}}|$, $|E_{\overline{\mathbf{L}}}|$ in the first neighborhood of the invariant. Since the K_j and A_j values are positive, the maximum of distribution (78) occurs at $\Psi = \omega_j$. Hence when the variance of the distribution (78) is small, i.e. when A_j is large, one obtains the reliable estimate

$$\psi_j = \omega_j \quad (j = 0, 1, 2, 3, \bar{0}, \bar{1}, \bar{2}, \bar{3}) \quad (79)$$

for the structure invariant ψ_j. It should be emphasized that the estimate (79) is unique in the whole range from $-180°$ to $+180°$. No prior knowledge of the positions of the anomalous scatterers is needed, nor is it required that the anomalous scatterers be identical.

3.4.4. The Applications

Using the presumed known coordinates of the $PtCl_4^{2\ominus}$ derivative of the protein Cytochrome c_{550} from *Paracoccus denitrificans*[26] (molecular weight $M_r \approx 14\,500$, space group $P2_12_12_1$) some 8300 normalized structure factors E were calculated (to a resolution of 2.5 Å). In addition to the anomalous scatterers Pt and Cl, this structure contains one Fe and six S atoms which also scatter anomalously at the wavelength used ($Cu_{K\alpha}$). Using the 4000 phases ϕ_{hkl} corresponding to the 4000 largest $|E_{hkl}|$ values with $hkl \neq 0$, the three-phase structure invariants ψ_j [Eq. (65)–(72)] were generated and the parameters ω_j and A_j, needed to define the distributions (78), were calculated. All calculations were done on the VAX 11/780 computer; double precision (approximately 15 significant digits) was used in order to eliminate round-off errors. The A_j values were arranged in descending order and the first 2000, sampled at intervals of 100, were used in the construction of Table 1; the top 60000 were used for Table 2.

Table 1 lists 21 values of A_j, sampled as shown from the top 2000, the corresponding estimates ω_j of the invariants ψ_j, the true values of the ψ_j, and the magnitude of the error, $|\omega_j - \psi_j|$. Also listed are the six magnitudes |E| in the first neighborhood of the corresponding invariant.

Table 2 gives the average magnitude of the error,

$$\langle |\omega_j - \psi_j| \rangle \quad (80)$$

in the nine cumulative groups shown, for the 60000 most reliable estimates ω_j of the invariants ψ_j.

Tables 1 and 2 show firstly that, owing to the unexpectedly large number of large values of A_j, our formulas yield reliable (and unique) estimates of tens of thousands of the three-phase structure invariants. Secondly, the invariants which are most reliably estimated lie anywhere in

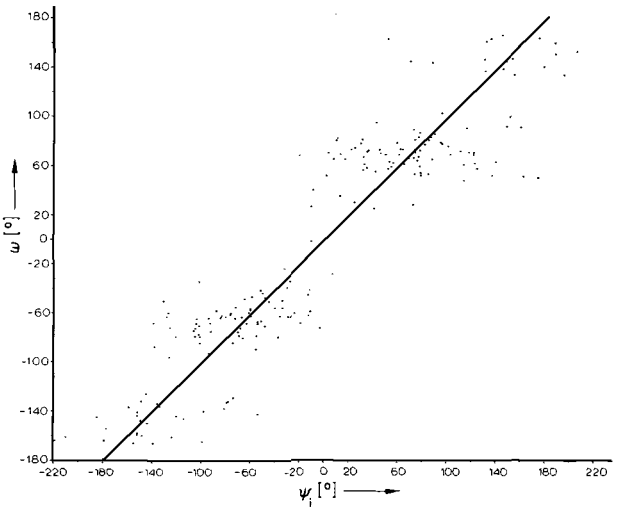

Fig. 6. A scatter diagram of ω_j versus ψ_j, using 201 invariants sampled at intervals of ten from the top 2000, for the $PtCl_4^{2\ominus}$ derivative of Cytochrome c_{550}, as well as the line $\omega_j = \psi_j$.

the range from -180 to $+180°$, and appear to be uniformly distributed in this range (Columns 9 and 10 of Table 1). Finally, in sharp contrast to the case that no anomalous scatterers are present, the most reliable estimates are not necessarily of invariants corresponding to the most intense reflections but of those corresponding instead to reflections of only moderate intensity (Columns 2–7 of Table 1).

Figure 6 shows a scatter diagram of ω_j versus ψ_j for the $PtCl_4^{2\ominus}$ derivative of Cytochrome c_{550}, using 201 invariants sampled at intervals of length ten from the top 2000, as well as the line $\omega_j = \psi_j$. Since the line falls evenly among the points, it appears that the ω_j are unbiased estimates of the invariants ψ_j.

3.4.5. Concluding Remarks

In this article the goal of integrating the techniques of direct methods with anomalous dispersion is realized. Specifically, the conditional probability distribution of the three-phase structure invariant, assuming as known the six magnitudes in its first neighborhood, is obtained. In the favorable case that the variance of the distribution happens to be small, the distribution yields a reliable estimate of the invariant (the neighborhood principle). It is particularly noteworthy that, in strong contrast to all previous work, the estimate is unique in the whole interval $(-180°, +180°)$ and that any estimate in this range is possible (even, for example, in the vicinity of $\pm 90°$ or $180°$). The first applications of this work using error-free diffraction data have been made, and these show that in a typical case some tens of thousands of three-phase structure invariants may be estimated with unprecedented accuracy, even for a macromolecular crystal structure. Some preliminary calculations on a number of structures, not detailed here, show that the accuracy of the estimates depends in some complicated way on the complexity of the crystal structure, the number of anomalous scatterers, the strength of the anomalous signal, and the range of $(\sin\theta)/\lambda$. With smaller

structures the accuracy may be greatly increased, average errors of only three or four degrees for thousands of invariants being not uncommon.

It should be stated in conclusion that the availability of reliable estimates for large numbers of the three-phase structure invariants implies that the traditional machinery of direct methods, in particular the tangent formula [Eq. (33)], suitably modified to accommodate the non-zero estimates of the invariants, may be carried over without essential change to estimate the values of the individual phases and thus to facilitate structure determination via anomalous dispersion. In view of the calculations summarized in Tables 1 and 2 and Figure 6, it seems likely that, in time, even macromolecules will prove to be solvable in this way. It is clear too, that, owing to the ability to estimate both the sine and cosine invariants, that is to say both the signs and magnitudes of the invariants, the unique enantiomorph determined by the observed intensities is automatically obtained. In fact the first application of these techniques using experimental diffraction data has already facilitated the solution of an unknown macromolecular structure.[4]

Recovering Phase Information from Intensity Data (Nobel Lecture)**

By Jerome Karle*

The concept of a crystal is that of a solid body in which the atomic or molecular units are so arranged as to form an array having three dimensional periodicity. Because of the periodicity, it is possible to describe the arrangements of the atomic composition by means of Fourier series. The type of Fourier series that is used in crystal structure analysis represents the electron density distribution in a crystal. This is indeed equivalent to representing the structure of a crystal since the atomic locations are represented by the regions of highest electron density in the electron distributions.

The experimental technique used for examining the structure of crystals is called diffraction. In a diffraction experiment, rays are made to impinge on a crystalline substance of interest and, given the proper geometric conditions, the rays are scattered as if they were bouncing off large numbers of different planes imagined to be cutting through the crystal. The collected intensities of scattering (often 5000–10000 in number) are called a scattering pattern or diffraction pattern and comprise the experimental data from which the structure of the crystal of interest is to be elucidated. The most commonly used rays are Roentgen rays or X-rays, as they are usually called. Other rays, composed of neutrons or electrons, also have their purposes.

It is possible to obtain an insight into the character and sense of a diffraction experiment by imagining some experimental circumstances on the macroscopic scale. Let us suppose that we would like to probe the shape of some large object, hidden from view, by using balls that are hurled in a precise way at the object of interest and interact with the surface with essentially perfect restitution. Let us also suppose that it is possible to minimize and correct for the gravitational effects on the impinging balls. We assume that we can observe the results of the bouncing of the balls from the surface of the object. If a large area were scanned perpendicular to the direction in which the balls were hurled and each time the bouncing pattern were essentially parallel but in the opposite direction to that of the impinging balls, we would conclude that the object had a face with a high degree of flatness that was perpendicular to the direction of the impinging balls. Evidently, by varying the orientation of an arbitrarily shaped object and observing the patterns of the bouncing balls or, equivalently, the scattering pattern, knowledge of the shape of the object could be developed in quite some detail. On the submicroscopic scale, the situation is somewhat different. Crystals are quite porous to X-rays and the interactions between the rays and the atomic composition of the crystal are different than that of a ball bouncing off a surface such that, as noted, certain geometric conditions need to be fulfilled before it appears that reflection of the rays has taken place. The nature of the interactions is understood, however, and the relevance of the comparison with the macroscopic thought experiment involving bouncing balls maintains. In the case of X-rays and a crystal, the X-rays replace the bouncing balls and the way the X-rays interact with electron density distributions within the crystal gives rise to a scattering pattern unique to each crystalline substance. The problem that the analyst faces is to be able to take the diffraction pattern and from it determine the atomic architecture of the crystal which cannot be observed directly.

There is a special problem in taking the intensity information from a diffraction pattern and calculating from it the electron density distribution of a crystal by use of the Fourier series. The coefficients in the Fourier series are, in general, complex numbers. Only the magnitudes of the complex numbers appear to be available from the measured intensities of scattering. The required phases of the complex numbers seem to be lost in an ordinary X-ray diffraction experiment. It was therefore generally thought that it was not possible to go directly from a diffraction pattern to a determination of a crystal structure. The impasse was overcome in a series of steps that involved recognition that the required phase information was contained in the experimental intensity information, the derivation of a foundation mathematics that displayed relationships between phases and magnitudes and even among phases alone and, finally, the development of practical procedures for structure determination, strategies that brought together in a more or less optimal fashion the mathematical relationships with suitably adjusted and refined experimental data.

The results of structure determinations have been playing a valuable role in a number of areas of scientific endeavor. Crystallization, for example, is a very common phenomenon and many types of substances form crystals ranging from metals and minerals to huge macromolecules such as viruses. Knowledge of structure allows one to relate structure to function, i.e., understand physical, chemical or biological properties and activities, provides the chemist with useful information for syntheses, modifications and reaction mechanisms and can also be used to identify very small quantities of scarce material. It often provides the theoretical chemist with a starting point for his calculations. Structural research provides a conceptual basis for many associated scientific disciplines and it is the opportunity to interact with a variety of such disciplines that has made structural research particularly appealing to me.

As this article proceeds, it will elaborate on a number of the items discussed in this introductory part, describe some interesting applications, and discuss briefly some research paths and opportunities for the future.

Electron Density Distribution

The electron density distribution, $\rho(\mathbf{r})$, is expressed in terms of the three-dimensional Fourier series

$$\rho(\mathbf{r}) = V^{-1} \sum_{-\infty \mathbf{h}}^{\infty} F_{\mathbf{h}} \exp(-2\pi \mathbf{h} \cdot \mathbf{r}) \tag{1}$$

where V is the volume of the unit cell of the crystal, the basic structural unit from which, through three-dimensional periodicity, the crystal is formed. The coefficients

$$F_{\mathbf{h}} = |F_{\mathbf{h}}| \exp(i\phi_{\mathbf{h}}) \tag{2}$$

are the crystal structure factors associated with the planes labeled with the vectors $\mathbf{h}$. The $\mathbf{h}$ have integer components, h, k and l, the Miller indices, whose values are inversely proportional to the intercepts on the x, y and z axes, respectively, of planes cutting through the crystal. The angle $\phi_{\mathbf{h}}$ is the phase associated with $F_{\mathbf{h}}$ and $\mathbf{r}$ labels the position of any point in the unit cell. $F_{\mathbf{h}}\mathbf{E}$ is the amplitude of the scattered wave associated with the plane labeled by $\mathbf{h}$, where $\mathbf{E}$ is the electric field vector of the incident beam. The measured intensities of X-ray scattering are proportional to $|F_{\mathbf{h}}|^2$. If the values of the $\phi_{\mathbf{h}}$ were also obtained directly from experiment, structures could be immediately calculated from equation (1). The seeming absence of this information gave rise to the so-called "phase problem".

The Fourier inversion of equation (1) followed by the replacement of the integral by the sum of contributions from the N discrete atoms in the unit cell gives, for the Fourier coefficient,

$$|F_{\mathbf{h}}| \exp(i\phi_{\mathbf{h}}) = \sum_{j=1}^{N} f_{j\mathbf{h}} \exp(2\pi i \mathbf{h} \cdot \mathbf{r}_j) \tag{3}$$

where $f_{j\mathbf{h}}$ represents the amplitude of scattering of the jth atom in the unit cell and $\mathbf{r}_j$ is its position vector.

Overdeterminacy

A system of simultaneous equations is formed by the definition of the crystal structure factors given by equation (3) since the values of the scattered intensities are measured for a large number of $\mathbf{h}$. The unknown quantities in equation (3) are the phases $\phi_{\mathbf{h}}$ and the atomic positions $\mathbf{r}_j$. The known quantities are the $|F_{\mathbf{h}}|$ obtained from the measured intensities and the $f_{j\mathbf{h}}$ which differ little from the theoretically calculated atomic scattering factors for free atoms. Since each equation (3) involves complex quantities, there are really two equations, one for the real and one for the imaginary part. In order to determine the overdeterminacy, a comparison is made of the number of unknown quantities with the number of independent data available. With the use of $Cu_{K\alpha}$ radiation, the overdeterminacy can be as great as a factor of about 50 for crystals that have a center of symmetry and about 25 for those that do not. In practice, somewhat fewer than the maximum available data are measured, but the overdeterminacy is still quite high.

Some Attempts, Some Successes

There were some early attempts to obtain structural information or phase information from the structure factor equations. *Ott*[1] made use of the structure factor equation (3) to derive relationships among the structure factors and atomic positions and he showed that in some simple cases atomic coordinates could be obtained directly from the relationships. *Banerjee*[2] devised a trial and error self-consistency routine based on *Ott*'s results for finding the phases of structure factors that are centric and therefore the phases have values that are limited to zero or π. The number of trials increased rapidly with complexity, limiting applications to rather simple structures. *Avrami*[3] worked with equations that relate intensities to interatomic vectors [eq. (4)]. Solutions to these equations were given in terms of the roots of a polynomial equation whose degree increases rapidly as the complexity of the crystal increases. In all these approaches, the increase in computational demands with complexity, sensitivity to experimental errors and inherent ambiguities in the results prevented their application to any but the simplest structures. Even though present day computational facility is enormously greater than when this work was done originally, the limitations cannot be suitably overcome even now.

A significant advance in the attempt to obtain structural information from the measured intensities was made in 1934 by *A. L. Patterson*. He developed a Fourier series which has as its coefficients the magnitude of the square of the structure factors rather than the structure factors themselves. The phases may be eliminated from equation (3) by multiplying by the corresponding complex conjugates to obtain

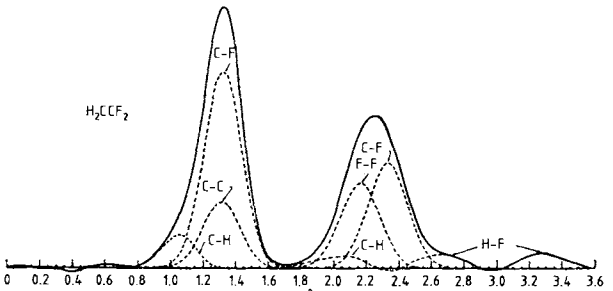
$$|F_{\mathbf{h}}|^2 = \sum_{j=1}^{N} \sum_{k=1}^{N} f_{j\mathbf{h}} f_{k\mathbf{h}} \exp[2\pi i \mathbf{h} \cdot (\mathbf{r}_j - \mathbf{r}_k)] \tag{4}$$

The Fourier transform of (4) is known as the Patterson function,[4,5]

$$P(\mathbf{r}) = \sum_{-\infty \mathbf{h}}^{\infty} |F_{\mathbf{h}}|^2 \exp(-2\pi i \mathbf{h} \cdot \mathbf{r}) \tag{5}$$

The maxima of a Patterson function represent the interatomic vectors in a structure. Evidently the values of the coefficients are directly obtainable from the measured intensities of scattering. This function has been very useful in locating the heavier atoms in a structure, if they are not too numerous, since the interatomic vectors associated with them would predominate in a map computed from equa-

tion (5) and the atomic positions for them could then be readily deduced. The coordinates for the heavy atoms may be used with equation (3) to compute an initial set of approximate phases. Depending upon the scattering power of the heavy atoms, such a computation may be suitable for structures containing up to a few hundred atoms. There are numerous procedures for developing a complete structure from the initial phase information obtained from the heavy atoms. The use of the Patterson function with structures containing heavy atoms has found widespread application and remains one of the major methods of crystal structure determination.



The difficulty with using the Patterson function with experimental data in a general way in the absence of heavy atoms arises from the lack of resolution that occurs for the $N(N-1)$ interatomic vectors as well as inaccuracies. The Patterson function becomes somewhat accessible when it is used in combination with known atomic groupings.[6-8]

The fact that the Patterson function could be used to solve simple structures made a positive contribution to the background atmosphere in which progress in phase determination was made. Once a structure was solved, it was possible to use equation (3) to calculate values for the phases. In effect then, phase values were determined from the measured intensities. In the case of the Patterson function, this happened through the intermediary step of first determining the structure. It was however conceivable that the process could be reversed, namely, to obtain phase information directly from the intensities and then to compute the structure by use of equation (1). This is indeed what happened. So far, except for special cases involving heavy atoms, it has turned out to be easier to obtain phase values directly from the measured intensities and then compute the structure than to obtain the structure directly from the intensities without the use of phases.

Relationships between phases and magnitudes that anticipated the later developments were the inequalities of *Harker* and *Kasper*.[9] They derived a number of inequalities by application of the Schwarz and Cauchy inequalities to the structure factor equations (3) in the presence of crystallographic symmetry. The Harker-Kasper inequalities have provided valuable insights. For example, the simple inequality expressions can provide useful phase information, as shown by *Kasper, Lucht* and *Harker*[10] in their solution of the structure of decaborane. In addition, work with the inequalities indicated that they may have probabilistic characteristics. *Gillis*,[11] for example, noted that the implication of an inequality was probably correct even when the magnitudes of the structure factors were too small to permit a definitive conclusion to be drawn. *Gillis* speculated that the smallness of the structure factor magnitudes may have been due to thermal effects and employed an appropriate function to increase the values of the structure factor magnitudes so that the inequalities could be applied. The probabilistic interpretation, however, remained a possible alternative, namely, that although an inequality does not quite determine the value of a phase definitively, it still does so with a high probability that the value is correct. This could be important because it would imply that the inequalities have probabilistic implications that could extend their range of usefulness.

Non-Negativity and General Inequalities

The initial motivation to investigate the mathematics of crystal structure determination arose from experiences in the development of an analytical procedure for obtaining accurate radial distribution functions for determining the structures of gaseous molecules by electron diffraction. A problem arose; namely, to find an accurate background intensity so that the molecular interference intensity could be accurately extracted from the total intensity of scattering. The Fourier transform of the molecular intensity can be interpreted as representing the probability of finding interatomic distances in a molecule. Therefore, this transform must be non-negative and the non-negativity imposed a very useful constraint on the shape of the background intensity.[12, 13] Figure 1 shows a radial distribution function for H_2CCF_2[14] derived from application of the non-negativity constraint and the component distances in the molecule. The attendant accuracy of the result permitted not only equilibrium interatomic distances to be determined but also estimates of the root-mean-square amplitudes of vibration associated with the interatomic distances.

Distance	C-H	C-C	C-F	C-H	F-F	C-F	H-F	H-F
nZ_iZ_j	4	12	36	4	27	36	6	6
Actual area	4.2	12.1	36.0	4.1	27.2	36.0	5.4	7

Fig. 1. The essentially non-negative radial distribution function (solid curve) for H_2CCF_2, computed from the experimental molecular intensity data extracted by use of a properly formed background intensity curve. The solid curve is a probability density that gives the probability of finding interatomic distances in some distance interval along the horizontal axis. The dashed lines represent the decomposition of the main peaks into their component individual interactomic distances. The individual peaks have a definite width related to the internal vibrations in the molecule. nZ_iZ_j are the theoretical values for the areas under the curves representing the various interatomic distances. Z_i is the atomic number of atom i and n denotes the number of times a particular distance occurs in the molecule.

At about the time this work in gas electron diffraction was proceeding, *Herbert Hauptman* joined our group at the Naval Research Laboratory and, in view of the success of the non-negativity criterion, we decided to explore the possibility that this criterion might be useful in other areas of structural research. This led us to investigate the determination of electron density distributions around free atoms,[15] which found a very fine application in the determination of the electron distribution about argon by *Bartell* and *Brockway*.[16]

We were also quite interested in seeing what the consequences of the application of non-negativity would be for crystal structure analysis, since the electron density distri-

bution defined in equation (1) is constrained not to be negative. This brought in the work of *Toeplitz*[17] early in this century on non-negative Fourier series and subsequent developments by others. We discussed the theory in three-dimensions and wrote it in a form that would have particular relevance to crystallographic data.

The fundamental result was that the necessary and sufficient condition for the electron density distribution in a crystal to be non-negative is that an infinite system of determinants involving the crystal structure factors be non-negative. A typical determinant is[18]

$$\begin{vmatrix} F_{000} & F_{-\mathbf{k}_1} & F_{-\mathbf{k}_2} & \dots F_{-\mathbf{h}} \\ F_{\mathbf{k}_1} & F_{000} & F_{\mathbf{k}_1-\mathbf{k}_2} & \dots F_{\mathbf{k}_1-\mathbf{h}} \\ F_{\mathbf{k}_2} & F_{\mathbf{k}_2-\mathbf{k}_1} & F_{000} & \dots F_{\mathbf{k}_2-\mathbf{h}} \\ \vdots & \vdots & \vdots & \vdots \\ F_{\mathbf{h}} & F_{\mathbf{h}-\mathbf{k}_1} & F_{\mathbf{h}-\mathbf{k}_2} & \dots F_{000} \end{vmatrix} \geq 0 \qquad (6)$$

The subscripts in the first column start with 0,0,0 but are otherwise arbitrary. The subscripts in the first row are the same but of opposite sign. The subscript of the element in the ith row and jth column is the sum of the subscripts of the elements of the ith row and first column and the first row and jth column. The third order inequality

$$\begin{vmatrix} F_{000} & F_{-\mathbf{k}} & F_{-\mathbf{h}} \\ F_{\mathbf{k}} & F_{000} & F_{\mathbf{k}-\mathbf{h}} \\ F_{\mathbf{h}} & F_{\mathbf{h}-\mathbf{k}} & F_{000} \end{vmatrix} \geq 0 \qquad (7)$$

contains a relationship among the structure factors that has played a most important role in direct crystal structure analysis. This may be seen by rewriting (7) in the form,[18]

$$\left| F_{\mathbf{h}} - \frac{F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}}}{F_{000}} \right| \leq \frac{\left| \begin{matrix} F_{000} & F_{-\mathbf{k}} \\ F_{\mathbf{k}} & F_{000} \end{matrix} \right|^{\frac{1}{2}} \left| \begin{matrix} F_{000} & F_{-\mathbf{h}+\mathbf{k}} \\ F_{\mathbf{h}-\mathbf{k}} & F_{000} \end{matrix} \right|^{\frac{1}{2}}}{F_{000}} \qquad (8)$$

For structure factors of unusually large magnitude, the right side of (8) becomes quite small, and then

$$F_{\mathbf{h}} \approx F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}} / F_{000} \qquad (9)$$

One evident conclusion from (9) is

$$\phi_{\mathbf{h}} \approx \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}} \qquad (10)$$

This states that for large structure factor magnitudes, the value of $\phi_{\mathbf{h}}$ may be defined in terms of the values of two other phases. This may also be seen from a construction based on (8), Figure 2, in which $\delta = F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}} / F_{000}$ and r is equal to the right side of (8). The form for (8) is then

$$|F_{\mathbf{h}} - \delta| \leq r \qquad (11)$$

It can be readily shown[18] that all determinants (6) can be written in the form of inequality (11). As the order of the determinants increases, there is a tendency for r to decrease in size, making the determination of $\phi_{\mathbf{h}}$ rather definitive.

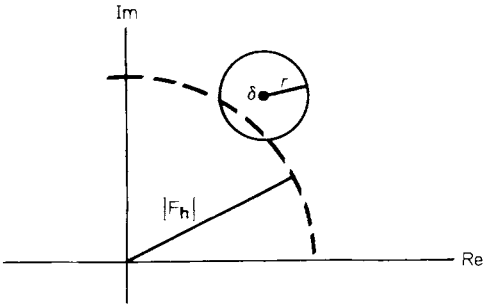


Fig. 2. The determinantal inequalities can be written in the general form $|F_{\mathbf{h}} - \delta| \leq r$. This means that $F_{\mathbf{h}}$ is bounded by a circle of radius r in the complex plane centered at δ. If $|F_{\mathbf{h}}|$ is known, then $F_{\mathbf{h}}$ is confined to a line within the circle.

Formula (10) has found wide application beyond the range of usefulness of inequality (8). This is because of the probabilistic characteristics of the inequalities[19] which imply that the most likely value of $\phi_{\mathbf{h}}$ is that of $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$ and the probability decreases the farther the value of $\phi_{\mathbf{h}}$ deviates from that of $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$. Therefore, even when the radius, r, of the bounding circle is large, the most likely value of $\phi_{\mathbf{h}}$ is $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$.

The structure factors in inequalities (6) can be replaced by quasi-normalized structure factors, $\mathscr{E}$, that represent point atoms (to an approximation when atoms of unequal atomic number are present) rather than atoms with electron distributions,

$$\mathscr{E}_{\mathbf{h}} = F_{\mathbf{h}} \Big/ \left(\sum_{j=1}^{N} f_{j\mathbf{h}}^2 \right)^{\frac{1}{2}} \qquad (12)$$

Structure factors representing point atoms are the type of quantity normally used in phase-determining procedures. Instead of formula (9), we have

$$\mathscr{E}_{\mathbf{h}} \approx \mathscr{E}_{\mathbf{k}} \mathscr{E}_{\mathbf{h}-\mathbf{k}} / \mathscr{E}_{000} \qquad (13)$$

For centrosymmetric crystals, we have

$$s\mathscr{E}_{\mathbf{h}} \approx s\mathscr{E}_{\mathbf{k}} \mathscr{E}_{\mathbf{h}-\mathbf{k}} \qquad (14)$$

where s means "sign of", a plus sign implying that the phase is equal to zero and a minus sign that it is equal to π. A one-term tangent formula also follows from (13),

$$\tan\phi_{\mathbf{h}} \simeq \frac{|\mathscr{E}_{\mathbf{k}} \mathscr{E}_{\mathbf{h}-\mathbf{k}}| \sin(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})}{|\mathscr{E}_{\mathbf{k}} \mathscr{E}_{\mathbf{h}-\mathbf{k}}| \cos(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})} \qquad (15)$$

The tangent formula composed of the sum of terms over **k** both in the numerator and the denominator is another formula that has played a major role in the practical applications of the theory for structure determination.

After the set of determinantal inequalities (6) were obtained on the basis of the non-negativity of the electron density distribution in a crystal, it was of interest to investigate their relationship to the inequalities derived by *Harker* and *Kasper*[9] from use of the Schwarz-Cauchy in-

equalities. It was shown that,[18] when the appropriate symmetry was introduced into the third order determinantal inequality by means of certain relationships among the structure factors, the Harker-Kasper inequalities could be derived. Examination of the derivation of the Harper-Kasper inequalities shows, as would be expected, that the nonnegativity of the electron density distribution is a requirement for their validity.

The variety of phase determining formulas contained within the determinantal inequalities (6) have their counterpart in probability theory, i.e., similar formulas can be derived with the use of probability theory. Their virtue is that measures of reliability can be attached to them and the judicious use of such measures was an important feature in bridging the gap between mathematical theory and practical application.

It had been pointed out that the determinants have inherent probabilistic characteristics[19] that can, in fact, be directly read out from inequality (11). This was not, however, how the first probability formulas were derived. The pursuit of such formulas was motivated by the expectation that the usefulness of the formulas from the inequalities could be extended because of the great overdeterminacy of the structure problem, the expectation that the points within the bounding circle of radius r and center δ (Fig. 2) would not be uniformly probable and the experience of *Gillis*[11] with structure factor magnitudes that were too small to elicit definitive conclusions from the inequalities but which, when made larger artifically, led to correct conclusions.

In order to characterize the probabilistic aspects of this subject, we initially decided to develop a facility in the use of the random walk,[20] but subsequently changed to the joint probability distribution,[21,22] which culminated in a monograph[23] that contained for the first time, a set of probabilistic formulas and measures for attacking the phase problem, in this case limited to crystals that have a center of symmetry. It was in this monograph[23] also that the theory of invariants and semi-invariants was introduced for the purpose of solving the problem concerning how many and what types of phases to specify to fix the origin in a crystal and what values are permitted. The practical aspects of solving crystals that lack a center of symmetry were developed later on and it was not until 1964 that the structure of the first crystal lacking a center of symmetry was solved[24] by the "direct method" for obtaining phase information by direct use of the measured intensities of scattering. It is interesting that fairly recent developments in the mathematics of the random walk have made this technique quite accurate, stimulating revived interest in its application to the probabilistic aspects of phase determining formulas.[25]

Formulas for Phase Determination

The main formulas for phase determination are now listed. They will suffice to characterize the nature of the phase determining procedures. There are additional formulas that play a variety of helpful roles and may be found in the referenced literature of this article.

Centrosymmetric Crystals

The Σ_2 formula is,[23]

$$s E_{\mathbf{h}} \approx s \sum_{\mathbf{k}_r} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}} \tag{16}$$

where s means the "sign of" and $\mathbf{k}_r$ represents restricted values of $\mathbf{k}$ for which the corresponding $|E_{\mathbf{k}}|$ and $|E_{\mathbf{h}-\mathbf{k}}|$ values are large. A plus sign refers to a phase of zero and a minus sign to a phase of π, the only two values possible for a centrosymmetric crystal when an origin in the crystal is properly chosen. The quantities, E, are normalized structure factors which arise as appropriate quantities to use with probability theory and are the same as the quasi-normalized structure factors, $\mathscr{E}$, except for a reweighting[26] of certain subsets of the E. The treatment of the intensity data to obtain normalized structure factors[27] arises from the work of *Wilson*,[28,29] the earliest application of probability methods to crystal structure analysis. Equation (16) is the probability equivalent of the set of inequalities (8) as $\mathbf{k}$ varies over the set $\mathbf{k}_r$. The appropriate probability function, $P_+(\mathbf{h})$, which represents the probability that the sign of $E_{\mathbf{h}}$ be positive was given in the above mentioned monograph.[23] It is conveniently applied in the form derived by use of the central limit theorem by *Woolfson*[30] and *Cochran* and *Woolfson*,[31]

$$P_+(\mathbf{h}) \approx \frac{1}{2} + \frac{1}{2} \tanh \sigma_3 \sigma_2^{-\frac{3}{2}} |E_{\mathbf{h}}| \sum_{\mathbf{k}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}} \tag{17}$$

where

$$\sigma_n = \sum_{j=1}^{N} Z_j^n \tag{18}$$

and Z_j is the atomic number of the jth atom in the unit cell containing N atoms.

Noncentrosymmetric Crystals

The sum of angles and tangent formulas are, respectively,

$$\phi_{\mathbf{h}} \approx \langle \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}} \rangle_{\mathbf{k}_r} \tag{19}$$

$$\tan \phi_{\mathbf{h}} \approx \frac{\sum_{\mathbf{k}} |E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}| \sin(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})}{\sum_{\mathbf{k}} |E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}| \cos(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})} \tag{20}$$

The expressions (19) and (20) are comparable to (10) and (15), respectively, and result from combining a number of individual terms as $\mathbf{k}$ varies over some chosen set. An appropriate measure of the reliability of (19) and (20) is a variance, V,[32] given by,

$$V = \frac{\pi^2}{3} + [I_0(\alpha)]^{-1} \sum_{n=1}^{\infty} (I_{2n}(\alpha)/n^2) - 4[I_0(\alpha)]^{-1} \sum_{n=0}^{\infty} [I_{2n+1}(\alpha)/(2n+1)^2] \tag{21}$$

where I_n is a Bessel function of imaginary argument,[33]

$$\alpha = \left\{ \left[\sum_{\mathbf{k}_r} \kappa(\mathbf{h},\mathbf{k}) \cos(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}) \right]^2 + \left[\sum_{\mathbf{k}_r} \kappa(\mathbf{h},\mathbf{k}) \sin(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}) \right]^2 \right\}^{\frac{1}{2}} \quad (22)$$

and

$$\kappa(\mathbf{h},\mathbf{k}) = 2\sigma_3\sigma_2^{-\frac{3}{2}} |E_{\mathbf{h}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}| \quad (23)$$

Expression (21) gives the variance of $\phi_{\mathbf{h}}$ as determined from a given set of $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$. This variance formula has its origin in a probability distribution (in somewhat different notation) of *Cochran*[34] for $\phi_{\mathbf{h}}$, given a particular $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$ and the accompanying |E| values. The tangent formula (20) can be derived in many ways. It has arisen, for example, in theoretical investigations of noncentrosymmetric space groups by use of the joint probability distribution[35] and can be shown to occur[32] in a generalization of the Cochran formula[34] for a particular $\phi_{\mathbf{h}}$ to take into consideration a set consisting of several or more $(\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})$ rather than just one.[32,34] The average in (19) is to be taken in the context of maximum clustering i.e. a minimum deviation of the contributions of individual addition pairs, $\phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}}$ from the average value. All ϕ are kept in a range $-\pi < \phi \leq \pi$ and maximum clustering requires the addition of 0, 2π or -2π to each addition pair. A practical method for effecting appropriate clustering has been described.[32]

Practical Phase Determination

In this part, the various aspects of practical phase determination will be outlined in terms of the first procedure that had broad practical applications to both centrosymmetric and noncentrosymmetric crystals, the symbolic addition procedure.[24,32,36,37] It arose mainly from the efforts of my wife, *Isabella Karle,* to bridge the gap between the mathematics of phase determination and the world of experimental data and practical application. By about 1956, we had acquired apparatus for carrying out X-ray diffraction experiments with crystals and *Isabella Karle* taught herself with the aid of a book written by *Martin Buerger* how to collect and interpret diffraction photographs. Working with crystal diffraction data was quite different then than now; computer-aided collection of diffraction data was essentially nonexistent and, by present standards, computers were very primitive. The thousands of diffraction data collected in the experiments were measured by eye with the use of a calibrated comparison strip. At the present time, data are collected by automatic diffractometers that measure and record the data after some modest, preliminary human intervention and the largest computers are many orders of magnitude superior in speed and capacity than thirty years ago. Technical advances in the recent past, as exemplified by synchrotron sources of X-radiation and area detectors, promise even greater advances in the near future in terms of the speed and facility with which data can be collected. They provide experimental opportunities that otherwise could not be contemplated.

Once the intensity data are collected, they are transformed into normalized structure factor magnitudes defined by,

$$|E_{\mathbf{h}}| = |F_{\mathbf{h}}| \Big/ \left(\varepsilon \sum_{j=1}^{N} f_{j\mathbf{h}}^2 \right)^{\frac{1}{2}} \quad (24)$$

where ε reweights certain subsets of the data.[26] A procedure for doing this is described in the International Tables for X-ray Crystallography.[38]

It is apparent on examining (16), (19) and (20) that it is necessary to know the values of some phases before additional ones can be evaluated. There are several sources of such information, from certain phase specifications associated with establishing an origin in the crystal,[38] the assignment of symbols to some phases for later evaluation and the use on occasion of auxiliary formulas, such as Σ_1 and Σ_3, that define individual phases in terms of structure factor magnitudes alone.[38] The number and types of phases to be used for specifying the origin in a crystal has been determined by use of the theory of invariants and semi-invariants that was developed for this purpose. Depending upon the type of space group involved, the number can vary from none at all to as many as three. Suitable tables[38] are available for carrying out this task.

The phase determining procedure is a stepwise one with few contributors to (16) or (19) at the start. Use at the start of phases associated with the largest possible values of the normalized structure factor magnitudes, |E|, will assure that the probability measures (17) and (21) will be as optimal as possible. The large overdeterminacy of the problem helps to ensure that initial probabilities will be large enough to proceed in a stepwise fashion to build up a sufficiently reliable set of phase values to effect a solution to the structure problem. Because the nature of phase determination is inherently probabilistic and contingent in a stepwise and interdependent fashion, the problem of establishing optimal procedures based on experimental data was not at all straightforward. There are a very large number of paths through a phase determination. Among many of them are pitfalls in which there arise, for example, temptations to take paths in which the interconnections between phase evaluations flow easily at the expense somewhat of the probability measures. Such paths are more likely to lead to missteps and cumulative errors that could damage or defeat a phase determination than ones that are based only on the highest values of the probability measures.

There is also an ambiguousness inherent in procedures for phase determination which is controlled by the use of symbols. The symbols can assume more than one value. For centrosymmetric crystals, they can have only two phase values, zero or π. For noncentrosymmetric crystals, experience has shown that whereas phase values for the general reflections can have any value in the range from $-\pi$ to π, it is usually sufficient to use only four possible values for the symbols spaced $\pi/2$ apart. One of the virtues

of using symbols is that, as the phase determination develops, relationships develop among the symbols reducing the number to be assigned values. Here again, one must proceed with caution so that reliable relationships are distinguished from those that are not. With centrosymmetric crystals, the entire phase determination is carried through before the remaining symbols are given alternative numerical values and tested to see which set yields a Fourier series that makes good chemical sense and reproduces the measured intensities well. For noncentrosymmetric crystals the symbolic addition procedure initially makes use only of equation (19). After about 100 phases have been evaluated, the remaining symbols are given alternative numerical values after which equation (20) is applied to further extend the phase set. Again, the correct phase set is the one whose Fourier series makes good chemical sense and yields a structure that is in fine agreement with the measured intensities. When a satisfactory result is not obtained, it is appropriate to try an alternative path through the phase determination.

An additional specification, whose character also derives from the theory of invariants and semi-invariants, is required for most noncentrosymmetric space groups. In making the specification, a choice is made of enantiomorph or axis direction or both. A good way in which this specification is achieved in the symbolic addition procedure is to find that a symbolic representation of a phase value most likely has a magnitude that differs significantly from 0 and π. The specification is accomplished by assigning a plus or minus sign arbitrarily to the magnitude of the phase. The enantiomorph ambiguity for noncentrosymmetric crystals arises from the fact that such a crystal gives the same diffraction pattern as its mirror image in the absence of detectable anomalous dispersion effects.

In the course of phase determinations, particularly in the case of noncentrosymmetric crystals, it may turn out that only a partial structure will appear in a Fourier map based on the determined phase values. This occurs because the phase determination went somewhat awry but not altogether so. The partial structure would be recognized as possibly being a correct fragment because it would make chemical sense, i.e., the fragment would have connectedness and acceptable interatomic distances and angles. A method has been developed for deriving a complete structure from a partial structure[39] that is based on the use of the tangent formula (20) and has been used in many applications. It may happen that a partial structure is not placed correctly with respect to a proper origin in the unit cell of a crystal. Under such circumstances, the use of a translation function[40–43] to place the fragment properly may be helpful.

The symbolic addition procedure[24, 32, 36, 37] was developed as an outgrowth of the experiences in applying the procedure for phase determination for centrosymmetric crystals described in the 1953 monograph.[23] In the monograph, the procedures proposed for sign determination involved the initial use of auxiliary phase formulas such as Σ_1 and Σ_3.[23] The application of preliminary phase information obtained from these formulas along with probability measures associated with individual indications from the phase-determining formulas facilitated the use of the Σ_2 relation (16). The combination of auxiliary formulas and probability theory greatly reduced to a practicable level the ambiguousness that would be obtained in the employment of the Σ_2 relation by itself along with some rather insensitive and often misleading criterion such as internal consistency.

In the course of applying the procedures of the monograph,[23] two important features were found that ultimately played an important role in the symbolic addition procedure. The first feature was that if probability measures were carefully employed at each step of a phase determination, it was possible to carry out the procedure with a small set of starting phases. It was also apparent that the use of symbols could greatly increase the efficiency of the procedure by carrying along in their alternative values a residual ambiguity that could not be easily overcome. A sufficient number of reliable relationships among the symbols usually developed in the course of a phase determination to reduce the alternative possible sets of phases to consider to just a few. A further reduction could be obtained, if desired, by applying auxiliary phase determining formulas at the end of a phase determination to help evaluate the remaining symbols. If an evaluation were incorrect, as occasionally happened with the auxiliary formulas, no great harm would be done. The alternative value could be tried without the necessity of repeating the phase determination. The symbolic addition procedure for centrosymmetric crystals is thus the procedure of the monograph[23] facilitated by the use of symbols and the application of auxiliary formulas at the end, if needed, instead of at the beginning of a phase determination.

The symbolic addition procedure for centrosymmetric crystals has several features in common with the procedure of *Zachariasen*.[44] The main distinction from the latter procedure was the application of probability measures to guide each step of the phase determination, especially in the beginning, the consequent use of a minimal number of symbols, and the resulting minimization of the ambiguousness of the determination and the optimization of the reliability of the result. There were efforts by others in the 1950's, e.g. *Rumanova*[45] and *Cochran* and *Douglas*[46] that met with some success. *Rumanova* developed a systematic method for using symmetry relations in the centrosymmetric space groups with equation (16). She used it in connection with *Zachariasen*'s procedure.[44] *Cochran* and *Douglas* used a variant of (16) based on a formula derived by *Sayre*[47] in a procedure that generated a very large number of sets of signs from which the correct one had to be selected under highly ambiguous circumstances.

The procedural features of the symbolic addition procedure for centrosymmetric crystals were extended, in the main by the efforts of *Isabella Karle*, to noncentrosymmetric crystals[24] with the use of equations (19), (20) and (21). Several problems arose in developing the technique for phase determination for noncentrosymmetric crystals concerning, for example, the assignment and handling of symbols, the use of the probability measure (21), the number of possible values to assign to the symbols that represent phase values that range continuously from $-\pi$ to π, the combined use of (19) and (20) for phase determination, the proper use of the tangent formula for the processes of

phase refinement and phase extension, the development of techniques for specifying an enantiomorph or axis directions or both, and special considerations such as the avoidance of certain troublesome triplet phase invariants involving one and two-dimensional centric reflections. These various aspects of the symbolic addition procedure are to be found in references [32] and [38] and in the papers concerning the applications described further on.

A considerable virtue of the symbolic addition procedure is that, because of its efficiency, a main part of the procedure for phase determination can be carried through by hand. For many years, the procedure for centrosymmetric crystals was carried out in our laboratory completely by hand. In the case of noncentrosymmetric crystals, the first stage, which involved the use of equation (19), was performed by hand until about 100 phases were evaluated and useful relationships developed among the symbols. Only after selected numerical values were assigned to the few remaining symbols was the tangent formula (20) applied with the aid of a computer. The benefits of this aspect of the efficiency of symbolic addition have been the opportunity for those with modest computing facilities to carry out structure determinations, the possibility of close interaction with the phase determination as it progresses, and the educational value for those newly learning about phase determination to be able to witness and carry through the procedure by hand.

As the application of direct phase determination began to increase during the 1960's and structure determination became more and more a part of research programs, there began to be developed at the end of the 1960's "program packages", software for determining structures from X-ray diffraction data. Among the ones that are widely used, alternative numerical values have been used instead of symbolic phases in the case of noncentrosymmetric crystals, although there are some programs that retain the use of symbols for such types of crystals. For those programs that use alternative numerical values for phases, large numbers of alternative phase sets are generated by use of the tangent formula (20) and the selection of the most likely solutions is dependent upon the use of an elaborate set of probability formulas, auxiliary formulas and acceptance criteria. Other computational techniques have also evolved. For example, random sets of phases have been used as starting sets to be refined by application of the tangent formula (20). By considering large numbers of alternative starting sets it is often practicable to obtain a correct answer, although a large amount of computing is involved. There are also special programs for specific purposes such as the development of a structural fragment into a complete structure.

The computer programs are quite successful with centrosymmetric crystals and also do fairly well with noncentrosymmetric crystals having up to 100 independent (nonhydrogen) atoms to be placed in the unit cell. On occasion an answer will not be forthcoming from the use of a program package. In that case, crystallographers may pursue the problem with special techniques and the application of insights and acumen that have been too special to be found in current programs.

Some names that have been associated with the preparation and dissemination of computer programs for various aspects of automated, direct structure determination are *Ahmed, Andrianov, Beurskens, Germain, Gilmore, Hall, Main, Schenk, Sheldrick, Stewart, Viterbo,* and *Woolfson.* Among them, some of their programs have enjoyed a broader range of popularity than others. Insight into the contents and philosophy of the programs can be obtained from several publications of the Commission on Crystallographic Computing of the International Union of Crystallography.[48, 49, 50, 51, 52]

Applications

This section will be devoted to illustrating the broad range of applications that have been made accessible by the development of direct structure determination. The examples will be mainly taken from my laboratory but will be seen to be representative of activities that now produce thousands of structural investigations each year.

The earliest applications after the publication of the monograph[23] were collaborations with colleagues at the U.S. Geological Survey on colemanite[53] and meyerhofferite.[54] This was followed by the initial investigations based on the experimental work of *Isabella Karle,* for example, on *p,p'*-dimethoxybenzophenone[55] and *N*-benzyl-1,4-dihydronicotinamide[56] that, in time, led to the symbolic addition procedure.

Early Applications of the Symbolic Addition Procedure

The first application of the symbolic addition procedure concerned cyclohexaglycyl, a synthetic polypeptide in which six glycine residues form an eighteen-membered ring. The polypeptide crystallizes as a hemihydrate in the triclinic space group $P\bar{1}$ with eight molecules in the unit cell[36] (Fig. 3). An interesting characteristic of this structure is that the eighteen-membered ring occurs in the unit cell in four different conformations. Another feature is that all hydrogen atoms capable of forming hydrogen bonds are so involved.

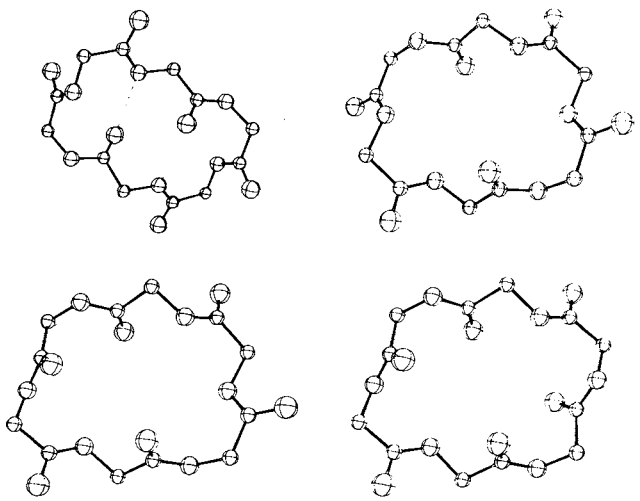

Fig. 3. The four co-crystallizing conformers of cyclohexaglycyl. The conformer at the upper left occurs four times in the unit cell, the one at the lower left occurs twice and the other two occur once.

Noncentrosymmetric crystals are quite common among substances of biochemical interest. The determination of the structure of the dihydrate of the amino acid L-arginine,[24] which crystallizes in space group $P2_12_12_1$, is the first noncentrosymmetric structure determined by the direct method. As seen in the diagram of the contents of the unit cell (Fig. 4), the hydrogen-bonding indicated by the dashed lines is extensive. As a consequence of this hydrogen-bonding the molecules of arginine form an infinite chain. In addition, water molecules also form hydrogen bonded infinite chains which are perpendicular to the plane of the figure.

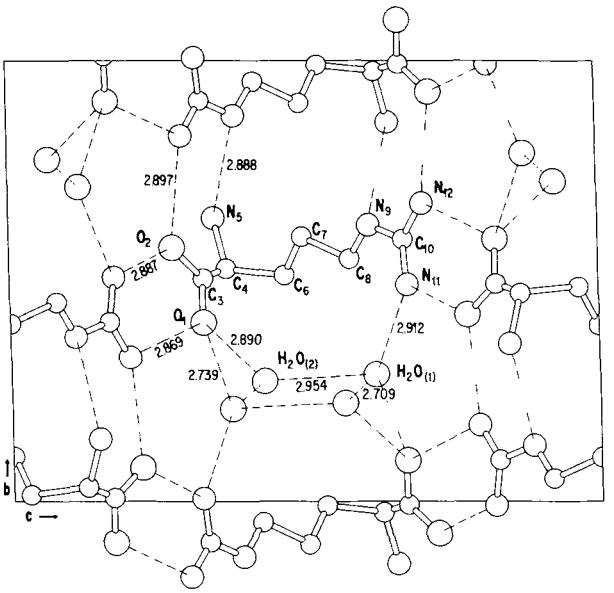

Fig. 4. The structure of L-arginine dihydrate viewed along the *a* axis. Hydrogen bonding is shown by the dashed lines.

The stereochemistry of reserpine, a drug that has been used to control hypertension and nervous disorders, had been determined by chemical means. It was of interest, however, to establish the spatial arrangement of the atoms in the molecule. Reserpine was found to crystallize in the noncentrosymmetric space group, $P2_1$.[57] In this investigation, the symbolic addition procedure yielded a partial structure which was developed into a complete structure (Fig. 5) by use of the recycling procedure[39] involving the tangent formula. Figure 5 shows sections from an electron density map projected down the *b*-axis. The trimethoxybenzoate group at the bottom is nearly perpendicular to the rest of the molecule. The indole group at the top of the diagram is planar and the dihedral angle between least-squares planes for the indole group and the benzoate group is 82°.

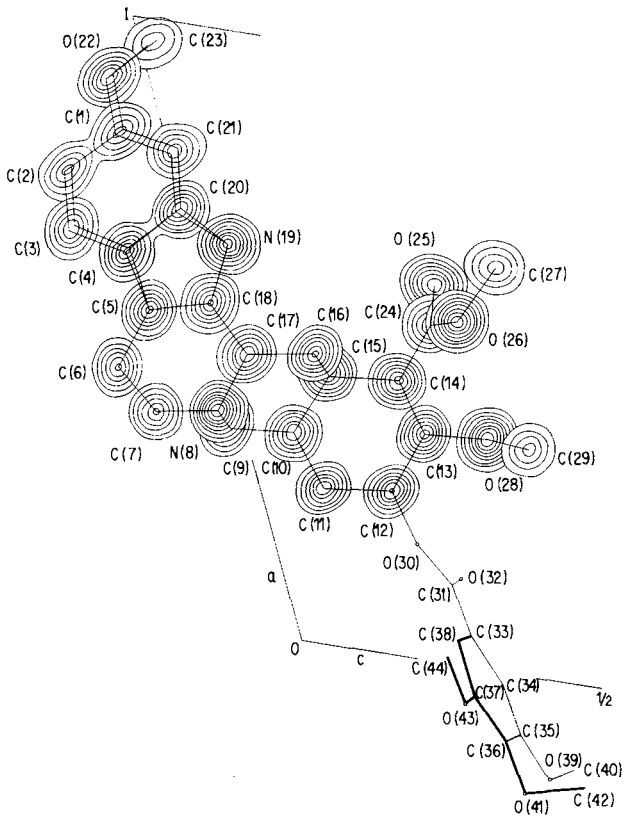

Fig. 5. Sections from a three-dimensional electron density map for the alkaloid reserpine projected down the *b* axis. The electron density contours are equally spaced at $1\,e\,Å^{-3}$ starting with the $1\,e\,Å^{-3}$ contour.

Identification and Stereoconfiguration

The problems concerning the determination of molecular formula and stereoconfiguration can become especially acute when the amount of sample available is very small, when the chemical linkages are new and unusual, or when the number of asymmetric centers is large. Under such circumstances, the use of crystal structure analysis can be not only quite helpful but also essential. An example of this is provided by batrachotoxin, a powerful neurotoxin that can be extracted from the skin of the frog, *Phyllobates aurotaenia*, from tropical America. It is used by native Indians to tip blow darts for hunting. Purified congeners were obtained from ethanol extracts of the skins of about 8000 frogs. The amounts were insufficient to permit the determination of the structural formulae by standard methods. A few, very small crystals of the *O-p*-bromobenzoate derivative of batrachotoxinin A, one of the congeners, were grown and one crystal was selected for structure analysis. It was found to crystallize in space group $P2_12_12_1$. The specialized position of the Br atom (at 1/5, 0, 0) and the restricted amount of data available limited the amount of information derivable from knowledge of the location of the Br atom. The structure was determined by use of the tangent formula to develop partial structural information into a complete structure. It showed that batrachotoxinin A was a steroidal alkaloid with several novel features[58] (Fig. 6). Other information obtained was the stereoconfiguration at the nine asymmetric centers, the conformations of the six rings, including the seven-membered ring containing the alkaloid function, values of bond lengths, bond angles and torsional angles, the location of intermolecular hydrogen bonds, and the packing of the models in the unit cell. The absolute configuration was established by mea-

urement of the anomalous scattering of the Br atom.[59] From the information obtained from the structural analysis, the structure and absolute configuration of batrachotoxin and many other congeners were readily deduced.[60]

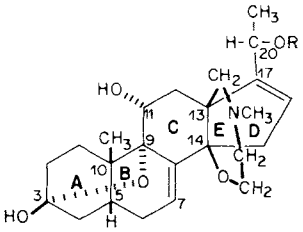

Fig. 6. The molecular formula and absolute stereoconfiguration for batrachotoxinin A (R = H) (heavy solid lines are above plane of paper and dashed ones behind).

Another small frog, *Dendrobates aurotaenia*, occurring in Columbia and Ecuador, secretes from its skin defensive substances among which are two major toxic alkaloids, histrionicotoxin and dihydroisohistrionicotoxin. These alkaloids are quite unique, having a spiropiperidine system with acetylenic and allenic moieties (Fig. 7). The molecular structures, stereoconfigurations and absolute configurations were established by crystal structure analyses of a hydrochloride and hydrobromide of the histrionicotoxin and a hydrochloride of the dihydroiso compound.[61,62] Space groups $C2$ and $P2_12_12_1$ were involved in the analyses. The histrionicotoxins appear to offer the first examples of the occurrence of acetylene and allene moieties in the animal kingdom. Other congeners that occur in smaller quantities were shown, subsequently, by means of mass and NMR spectra to differ only in the saturation of the two side chains.[63] The spiro ring system, with the intramolecular NH···O hydrogen bond, remained unchanged.

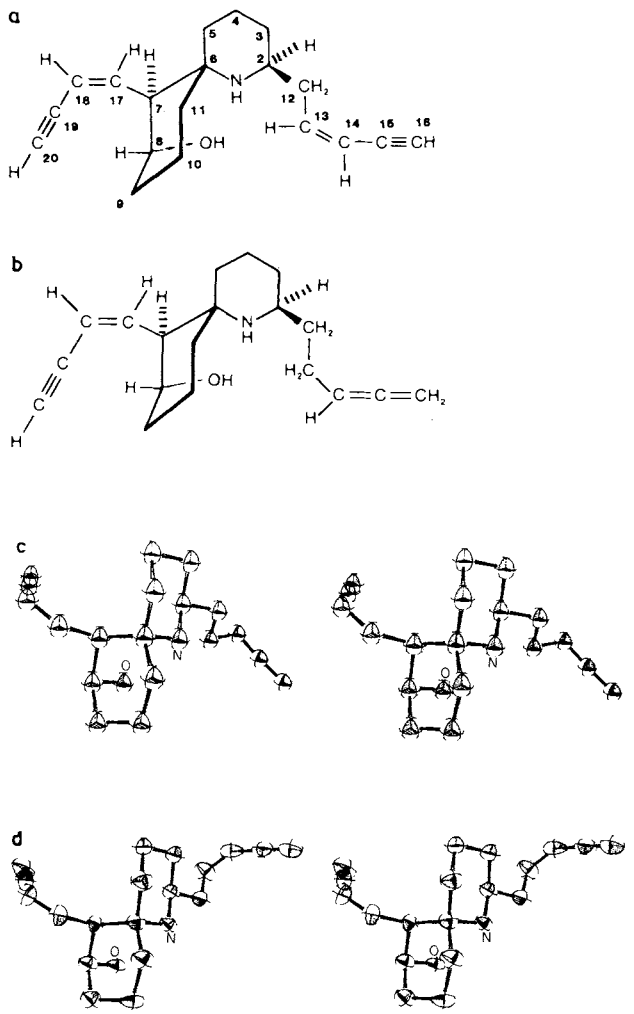

Fig. 7. Histrionicotoxin: a) structural formula; d) stereodiagram. Dihydroisohistrionicotoxin: b) structural formula; c) stereodiagram.

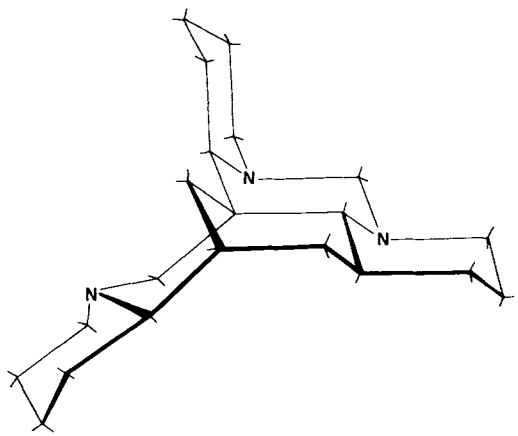

Fig. 8. The stereoconfiguration of jamine.

Another example of the application of X-ray crystal structure analysis to the determination of structural formula and stereoconfiguration of an unknown substance is illustrated by the investigation of an alkaloid derived from an *Ormosia* plant, namely the alkaloid jamine, which crystallizes in the triclinic space group $P\bar{1}$.[64] The configuration determined for the molecule is shown in Figure 8. The connectivity was found to comprise six six-membered rings, five of which were in the chair configuration and one in the boat configuration. There were six asymmetric carbon atoms and the stereoconfiguration about each was, evidently, readily apparent. The identification of the nitrogen atoms was also readily made in the course of the structure determination.

Brassinolide[65-67] is a very potent plant growth promoter. It is active in very small amounts, 1–10 ng/plant. Brassinolide generates cell enlargement and stimulates cell division in many food plants and plants grown in arid regions that yield oil and other energy related materials. The yield from extraction from plant pollen is very low and therefore large-scale testing awaited chemical synthesis. Evidently, chemical synthesis would be facilitated by structural information. A few crystals of brassinolide became available for crystal structure determination. The crystallization took place in space group $P2_1$ and the analysis[66] established that the steroid nucleus of the molecule had a seven atom B-ring lactone, an unprecedented feature for a natural ste-

roid (Fig. 9). The presence of the lactone appears to be responsible for promoting the plant growth. Subsequent synthesis has shown that compounds analogous to brassinolide are easier to prepare in large quantities and have adequate plant-growth regulating properties. Field evaluation of these regulators are currently under way.

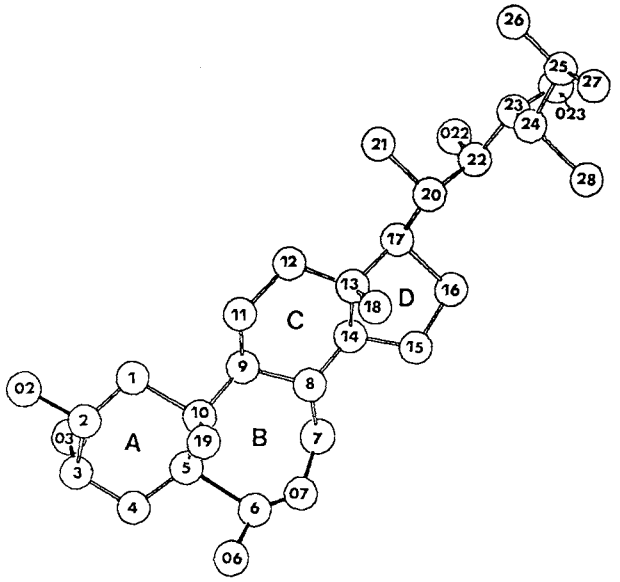

Fig. 9. The molecular formula (only C and O atoms) and stereoconfiguration of brassinolide. Note that the B ring is a seven-membered lactone ring.

There are very large numbers of examples that could be discussed under the heading of this section. It is noteworthy, however, that the implications of only a small number of definitive structure determinations can be extended far beyond the immediate results of the particular determinations. An outstanding example is given by some fundamental structural investigations on frog toxins which have provided the information on which was based the subsequent establishment of molecular formulas and stereoconfigurations of over 200 related frog toxins.[68,69]

Rearrangements

In the case of rearrangement reactions, crystal structure determination can again play a particularly useful role because many rearrangement reactions give products that are the result of vast and unanticipated changes in the starting materials. The following examples provide illustrations of such changes.

A photorearrangement reaction in which a major rearrangement takes place is illustrated by the reaction shown in Figure 10. A crystal structure investigation of a single optically active crystal, selected from a racemic conglomerate established the structural formula and configuration of the photoproduct.[70,71] The substance crystallized in space group $P2_12_12_1$. The structure analysis showed that the photoproduct consisted of four ring systems, namely two five-membered and two four-membered rings.

Ultraviolet irradiation of *N*-chloracetyltyramine, where there is a hydroxyl group on the phenyl ring in contrast to the two methoxy groups in the previous example, yields entirely different photorearrangement products. HCl was eliminated and two unusual photodimers, shown in Figure 11, were produced. Their molecular formulas and stereoconfigurations have been identified by use of crystal structure analysis.[72] It is interesting to note that dimer **II** is the more stable since it is produced from dimer **I** by use of additional ultraviolet radiation. Dimer **I** crystallizes in space group $P2_1/c$ and dimer **II** crystallizes in space group *Pbca*. Dimer **I** is seen to have a central cage bounded by four six-membered rings and two four-membered rings. Each four-membered ring is puckered, with the torsion angles around the ring bonds having values of about 20°. The six-membered rings assume distorted boat conformations. Dimer **II** is seen to have a more complex, partially open, cage bounded by one three-, two five-, two six-, and one seven-membered ring. The six-membered rings are again in a distorted boat conformation. Once the structural characteristics of the photoproducts are known, it is possible to

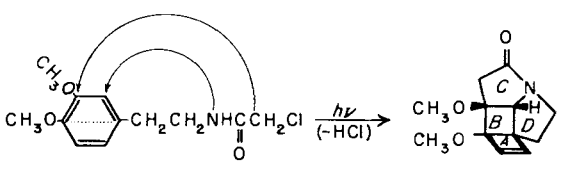

Fig. 10. The photorearrangement of *N*-(3,4-dimethoxyphenethyl)chloracetamide to a fused ring system consisting of two four- and two five-membered rings.

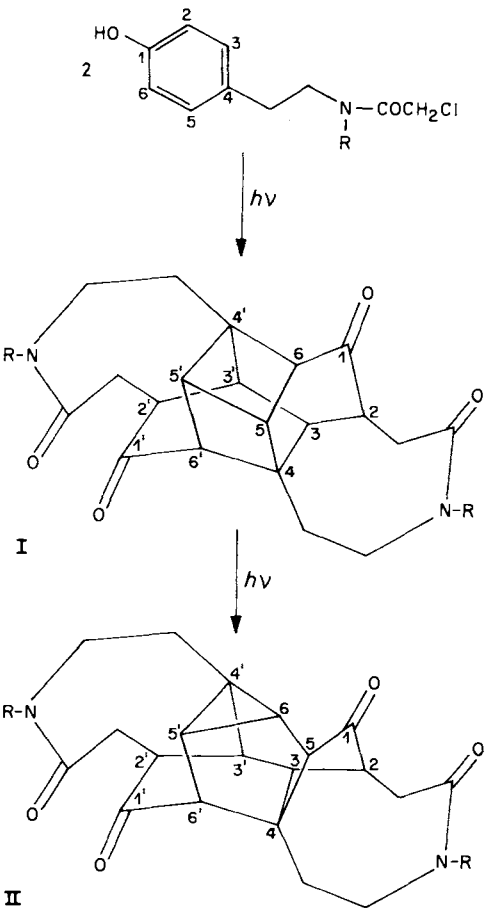

Fig. 11. The configurations of two dimers formed by photorearrangement from *N*-chloroacetyltyramine. Dimer **II** is seen to be formed from dimer **I** by continued irradiation with ultraviolet light (R = H or CH_3).

consider possible reaction mechanisms that describe the intermediate changes that occur in the rearrangements of the initial materials resulting in the final products. Postulated mechanisms for the formation of dimers **I** and **II** have been presented.[73]

Irradiation of a solution containing 5-methyl-1,2-diaza-4,6-cyclohexadien-3-one **III** and 2-propen-1-ol with ultraviolet light produces a cyclobutane addition compound **IV**, which, upon further irradiation, opens and switches bonds to form a tricyclic molecule **V** (Fig. 12). The crystal structure analysis[74] of **V**, which crystallizes in space group $P\bar{1}$, established that the final photoproduct was composed of a fused ring system, one three-membered ring, and two five-membered rings.

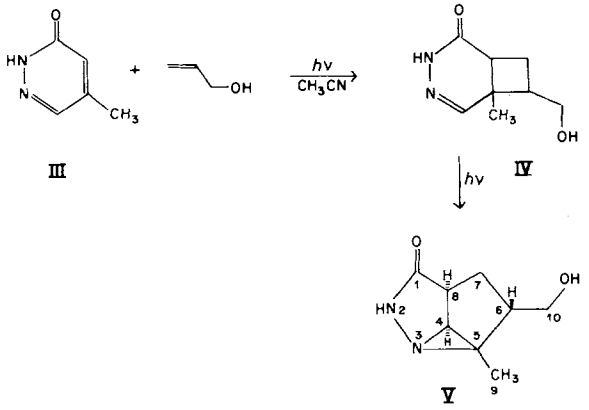

Fig. 12. Irradiation with ultraviolet light of a solution of 5-methyl-1,2-diaza-4,6-cyclohexadien-3-one **III** and 2-propenol leads to a cyclobutane addition product **IV**. On further irradiation, **IV** rearranges to a tricyclic product **V**.

Conformation

The conformations of molecules can be importantly related to their chemical and physiological behavior. Crystal structure investigations can be helpful in providing conformational information. It may be argued, and rightly so, that biologically active materials may assume conformations in the crystalline state that they would not assume in solution. There are, however, numerous instances of conformational studies in which the results of crystal structure analyses are either highly suggestive or rather definitive. The following examples are such instances.

One way in which the crystalline state can imitate the circumstances found in solution is to include in the crystallization relatively large amounts of solvent. Such a crystal is formed by [Leu^5]enkephalin (Tyr-Gly-Gly-Phe-Leu) grown from *N,N*-dimethylformamide (DMFA)/water. Endogenous enkephalin is a linear pentapeptide that occurs in the brain as [Leu^5]enkephalin and [Met^5]enkephalin in varying proportions depending upon the species.[75] Both are quite flexible and the structural study of [Leu^5]enkephalin was undertaken in the hope that insight into probable conformations would be so derived. The crystallization took place in space group $P2_1$ and it turned out that there were four molecules of the peptide in the asymmetric unit of the unit cell, each having a different conformation[76] (Fig. 13). The large amount of solvent surrounding the molecules suggests that the conformations may be relevant to the circumstances in solution. The four conformers with

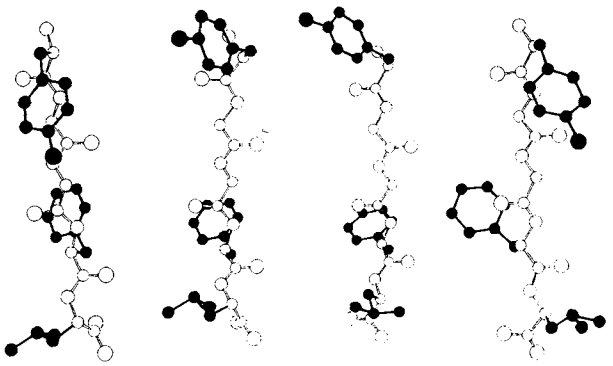

Fig. 13. Four conformations of [Leu^5]enkephalin that occur in *N,N*-dimethylformamide/water. Note the similarities in the backbone conformations and the differences in the (black) side chains.

extended backbones form an infinite antiparallel β-sheet. β-sheets related by the twofold screw axis are separated by a 12 Å spacing. Side groups protrude above and below the β-sheets and are entirely immersed in a thick layer of solvent that fills the volume between the β-sheets. The crystal was stable only in contact with the mother liquor. Structurally, it consisted of rather rigid sheets of peptide molecules separated by spaces filled with mobile solvent. Many of the solvent molecules appeared from the X-ray analysis to be completely disordered. An asymmetric unit of the unit cell contained four enkephalin molecules, eight water molecules, eight DMFA molecules, and an unknown number of disordered solvent molecules.

The crystal of enkephalin contains more than 210 independent C, N and O atoms and is of a size that lies between what is normally considered small-structure crystallography (up to 100 nonhydrogen atoms or so) and protein crystallography (about 500 nonhydrogen atoms or more).

The visual chromophores, 11-*cis*- and all-*trans*-retinal are present in both rod and cone cells of vertebrate retinas and in the corresponding organs of insects and crustacea.[77] The photochemical isomerization of the 11-*cis* isomer to the *trans* form is an important step in the visual process with the 11-*cis* isomer acting as a photochemical sensor. In the dark, 11-*cis*-retinal is covalently linked to proteins in the retina known as opsins. They differ in different species and may differ in different cells of the retina. The details of the geometry of the retinals had not been determined and, in view of their importance to biological function, a crystal structure investigation was undertaken on the 11-*cis* and all-*trans* forms. Special precautions had to be observed with the 11-*cis*-retinal. It is unstable towards light and oxygen and its stability is favored by lower temperatures. In solution, the *cis* isomer isomerizes to the *trans* form very readily at 20°C. Fortunately, crystals of the *cis* isomer are more stable than its solution. The diffraction data for the *cis* form were collected in a light-tight container that was continuously purged with dry nitrogen and maintained at 16–17°C. Crystal structure analyses[78,79] of

the 11-*cis* and all-*trans* forms revealed the detailed geometry of both (Fig. 14). An additional, independent structure

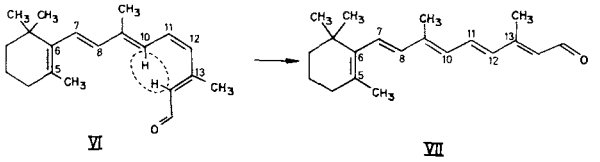

Fig. 14. Two isomers of retinal, the 11-*cis* (**VI**) and all-*trans* (**VII**) forms.

analysis of all-*trans*-retinal was also reported.[80] Of particular interest was the conformation of the *cis* form as there had been much speculation and theoretical work concerning its conformation. The 11-*cis*-retinal crystallized in space group $P2_1/c$ and the *trans* isomer in space group $P2_1/n$. The all-*trans*-retinal chain is planar with the six-membered ring inclined to the plane of the chain. The inclination is given by the torsional angle of the 5-6-7-8 segment, which is found to be 59°. The torsion angle of a planar *trans* conformation is 180° and that of a planar *cis* conformation is 0°. The conformation for the all-*trans* isomer is typical of carotenoids. In forming the 11-*cis*-retinal from the all-*trans* form, there is not only a rotation of 180° about the C11=C12 double bond, but also a rather unexpected rotation of 141° about the C12–C13 single bond. This additional rotation relieves the difficulty of too close a contact in the absence of the additional rotation between the hydrogen atom on C10 and the hydrogen atoms of the methyl group attached to C13 (see the diagram in Fig. 15). At the time that the manuscript concerning the crystal structure determination of 11-*cis*-retinal was being prepared, a theoretical calculation was published by *Honig* and *Karplus*[81] in which a ground-state configuration for 11-*cis*-retinal was proposed that closely resembled the result of the crystal structure determination.

The cyclic decapeptide antamanide acts as an antidote to the toxin phalloidin found in the deadly poisonous mushroom *Amanita phalloides*. Antamanide can also be isolated from the same mushroom but occurs in much smaller quantities. The synthetic analog of antamanide in which all four phenylalanyl residues are hydrogenated to cyclohexylalanyl residues (Cha), cyclic (ValProProAlaCha-ChaProProChaCha), has no antitoxic potency despite its ability to form ion complexes in the same manner as antamanide. A conformational analysis of the hydrogenated antamanide was carried out by means of a crystal structure analysis of Li-perhydroantamanide, which crystallizes in space group $P2_12_12_1$[82] (Fig. 16). The backbone encapsulates a Li ion in quite the same fashion as in Li-antamanide. In the Li-antamanide, however, the four phenyl groups are folded against the backbone, thus providing a hydrophobic surface for the complex, whereas in Li-perhydroantamanide the four cyclohexyl moieties are extended away from the folded backbone, with the consequent exposure of large portions of the polar backbone to the sur-

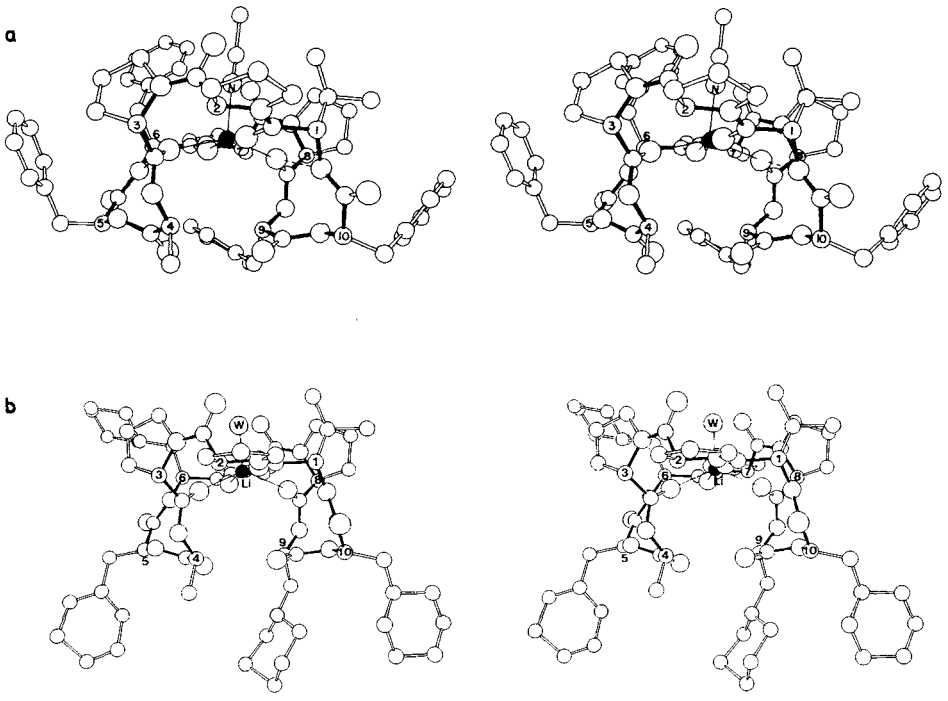

Fig. 16. a) Phenyl rings folded up around the backbone of a biologically active antamanide complex with Li^+ or Na^+ providing a lipophilic surface. b) In the inactive analogue, Li-perhydroantamanide, the cyclohexyl groups are folded down, thus exposing the peptide backbone to the environment.

rounding environment. As a result, elements of the backbone that would be otherwise shielded from the environment were found to make hydrogen bonds and ligands that would not occur in the Li-antamanide complex. It would appear that the large change of hydrophobicity around the backbone in the perhydroantamanide complex is related to the loss of biological activity.

These few applications represent only a minuscule portion of the broad range of topics and individual studies represented by the thousands of structural investigations performed each year. They do illustrate, however, how structure determination can play a useful and often indispensable role in the progress of many research disciplines.

Analysis of a Macromolecular Structure: Recent Interests

The analysis of structures of macromolecules, molecules that consist of at least about 500 nonhydrogen atoms and more, is facilitated by use of specialized heavy-atom techniques that have the titles anomalous dispersion and isomorphous replacement. Heavy atoms can often be soaked into a macromolecular crystal without seriously disturbing the structure. As a consequence, the technique of anomalous dispersion and isomorphous replacement have enjoyed considerable success in the determination of the structure of native (unsubstituted) macromolecules.

Anomalous dispersion effects arise from the fact that the atomic scattering factors, f, as would be used in equation (3), are in general complex numbers defined by

$$f = f^n + f' + if'' \tag{25}$$

where f′ and f″ are the real and imaginary parts, respectively, of the correction to f^n and are considered the contributions of anomalous dispersion. The scattering factor f^n is obtained from computations in which it is assumed that the frequency of the radiation is much larger than the absorption frequencies for the constituent atoms. The consequence of having atomic scattering factors with a significant imaginary part, as occurs with the heavier atoms at commonly used wavelengths, is that the intensity measured for an acentric reflection $\mathbf{h}$ is, in general, different than that for $-\mathbf{h}$. The fact that $I_{\mathbf{h}} \neq I_{\bar{\mathbf{h}}}$ has been the basis of a technique that has broad applications[83] in the field of structure research.

Crystals that have the same unit cell geometry but differ in chemical composition are called isomorphous. Since it is often possible to substitute heavy atoms into macromolecules with relatively minor perturbations on the structure, the criterion for isomorphicity can be fairly readily achieved to good approximation for such molecules. The method of phase determination based on one substituted isomorphous structure is called the single isomorphous replacement method (SIR) and if several isomorphous structure are available it is called the multiple isomorphous replacement method (MIR). If two isomorphous structures are centrosymmetric, the signs of the structure factors for both crystals can be determined. In practice, some signs would remain indeterminate because of experimental errors and the presence of structure factors of small magnitude. When two noncentrosymmetric crystals form an isomorphous pair, analysis shows that a twofold ambiguity occurs in the evaluation of the phases. It can be readily shown, however, that in the case of noncentrosymmetric crystals many individual phases can be unambiguously evaluated when the structure of the substituted atoms is known.[84] Such phases are either close to the value of the corresponding phases for the substituted atoms or are shifted by π from those values. There are a number of ways to resolve the ambiguity from isomorphous replacement. They involve, for example, the use of a second isomorphous substitution or, instead, the additional use of anomalous dispersion data.

Multiple isomorphous substitution with the occasional additional use of anomalous dispersion data has been the technique that has led to the enormous progress in macromolecular structure research of biological importance for the past 25 years. The early theoretical work that supported the advances in this field was that of *Patterson*[4, 5] and *Bijvoet*.[85] With the types of heavy atoms that are usually substituted into macromolecular structures, there can be significant effects from anomalous dispersion, so that data collection for both anomalous dispersion and isomorphous replacement can be, in effect, combined.

My interest in the techniques of anomalous dispersion and isomorphous replacement was rekindled by a development in my laboratory that demonstrated the considerable potential of the anomalous dispersion technique in structure determination. In an application of the anomalous dispersion technique to the structure determination of the protein, crambin, *Hendrickson* and *Teeter*[86] solved the structure by use of the anomalous scattering from six sulfur atoms occurring in three disulfide bridges. The experiment was performed as a single-wavelength experiment with $Cu_{K\alpha}$ radiation, which is far from the absorption edge for S at 5.02 Å. The success with the use of the relatively weak anomalous scattering from the S atoms coupled with the great span in wavelength between that of the absorption edge and the wavelength of $Cu_{K\alpha}$ radiation stimulated me to initiate a program to investigate various theoretical aspects of the single- and multiple-wavelength anomalous dispersion techniques and also, in time, isomorphous replacement.

One investigation concerned an exact algebraic analysis of single- and multiple-wavelength anomalous dispersion[87] by use of the structure factor equations (3) in which the atomic scattering factors are complex according to equation (25). The appropriate structure factor equations are treated as simultaneous equations and the key to obtaining the final form in which the equations were expressed was the separation of the contributions from the normal atomic scattering factors f^n from those of the real and imaginary corrections to f^n, f′ and f″, respectively.

A simple result of the algebraic analysis that concerns the case when a structure is composed of atoms that scatter normally and one type of atom that scatters anomalously is as follows,

$$\begin{aligned}|F_{\lambda\mathbf{h}}|^2 = {} & |F^n_{1,\mathbf{h}}|^2 + \{1 + (f^a_{\lambda 2,\mathbf{h}}/f^n_{2,\mathbf{h}})[(f^a_{\lambda 2,\mathbf{h}}/f^n_{2,\mathbf{h}}) + 2\cos\delta_{\lambda 2,\mathbf{h}}]\}|F^n_{2,\mathbf{h}}|^2 \\ & + 2[1 + (f^a_{\lambda 2,\mathbf{h}}/f^n_{2,\mathbf{h}})\cos\delta_{\lambda 2,\mathbf{h}}]|F^n_{1,\mathbf{h}}||F^n_{2,\mathbf{h}}|\cos(\phi^n_{1,\mathbf{h}} - \phi^n_{2,\mathbf{h}}) \\ & + 2(f^a_{\lambda 2,\mathbf{h}}/f^n_{2,\mathbf{h}})\sin\delta_{\lambda 2,\mathbf{h}}|F^n_{1,\mathbf{h}}||F^n_{2,\mathbf{h}}|\sin(\phi^n_{1,\mathbf{h}} - \phi^n_{2,\mathbf{h}})\end{aligned} \tag{26}$$

where $|F_{\lambda \mathbf{h}}|^2$ is the square of the measured magnitude of the structure factor at the wavelength λ, $|F^n_{1,\mathbf{h}}|^2$ is the square of the magnitude of the structure factor for the non-anomalously scattering atoms and $|F^n_{2,\mathbf{h}}|^2$ is the square of the magnitude of the structure factor for the anomalously scattering atoms, but scattering as if they were doing so normally. The measured $|F_{\lambda \mathbf{h}}|^2$ are corrected for vibrational effects and the latter are also absent from $|F^n_{1,\mathbf{h}}|^2$ and $|F^n_{2,\mathbf{h}}|^2$. The quantities $f^a_{\lambda j,\mathbf{h}}$ and $\delta_{\lambda j,\mathbf{h}}$ are defined for a particular λ,

$$f^a_{\lambda j,\mathbf{h}} = [(f'_{\lambda j,\mathbf{h}})^2 + (f''_{\lambda j,\mathbf{h}})^2]^{\frac{1}{2}} \tag{27}$$

and

$$\delta_{\lambda j,\mathbf{h}} = \tan^{-1}(f''_{\lambda j,\mathbf{h}}/f'_{\lambda j,\mathbf{h}}) \tag{28}$$

The f′ and f″ are tabulated in International Tables.[88] The phase angles $\phi^n_{1,\mathbf{h}}$ and $\phi^n_{2,\mathbf{h}}$ are the angles associated with $|F^n_{1,\mathbf{h}}|$ and $|F^n_{2,\mathbf{h}}|$, respectively.

Four equations can be formed from (26) by performing anomalous dispersion experiments at two different wavelengths and making measurements of the intensities of reflections associated with $\mathbf{h}$ and $-\mathbf{h}$. The equations are linear if the four quantities, $|F^n_{1,\mathbf{h}}|^2$, $|F^n_{2,\mathbf{h}}|^2$, $|F^n_{1,\mathbf{h}}||F^n_{2,\mathbf{h}}|\cos(\phi^n_{1,\mathbf{h}} - \phi^n_{2,\mathbf{h}})$ and $|F^n_{1,\mathbf{h}}||F^n_{2,\mathbf{h}}|\sin(\phi^n_{1,\mathbf{h}} - \phi^n_{2,\mathbf{h}})$ are chosen as the unknowns. It is worthwhile to add the quadratic relationship, $\sin^2\phi + \cos^2\phi = 1$, and treat the defining equations in a least-squares fashion.

A general analysis[87] has also been carried out which is appropriate for any number and type of anomalous scatterers. This general formulation has a number of favorable characteristics that are illustrated by the simple set of simultaneous equations formed from (26) by using multiple wavelengths and measuring the intensities at $\mathbf{h}$ and $-\mathbf{h}$. The unknown quantities are intensities of scattering and phase differences, all associated with the non-anomalous scattering. The intensities are those that would be obtained from individual types of atoms as if each type were present in isolation from all the rest. Knowledge of the intensities for the structure of an individual type of atom can facilitate the determination of the structure associated with this type of atom. Once this is known, the entire structure can be readily determined. The anomalous scattering enters the simultaneous equations as separate factors in terms of known, tabulated quantities. With appropriate definitions of unknown quantities, the simultaneous equations are linear. It is useful to introduce also quadratic relationships that exist among the unknown phase differences. The systems of simultaneous equations involve no approximations and remain exact for any number or type of anomalous scatterers.

There are some additional features of the equations (26). One concerns the fact that the usual analysis of single-wavelength anomalous scattering leads to the conclusion that there would be a twofold ambiguity in the evaluation of certain phase differences. It has recently been shown[89] that information that is inherent in the measured intensities $|F_{\lambda \mathbf{h}}|^2$ and $|F_{\lambda \bar{\mathbf{h}}}|^2$ that gives approximate information concerning $|F^n_{1,\mathbf{h}}|^2$ and $|F^n_{2,\mathbf{h}}|^2$ can be used with equation (26) for $\mathbf{h}$ and $-\mathbf{h}$ to obtain unique or essentially unique values for the phase differences that occur in (26) with potentially useful accuracy. This was specifically shown for a one-wavelength experiment for the case of one type or one predominant type of anomalously scattering atoms in the presence of essentially non-anomalously scattering atoms. It should be more generally true. *Hauptman*[90] showed earlier the uniqueness of a one-wavelength anomalous dispersion experiment in terms of unique values for triplet phase invariants.

A second feature of equations (26) and their generalization to many kinds of anomalous scatterers concerns the fact that anomalous scatterers in the form of heavy atoms are often substituted into a native substance that scatters essentially non-anomalously. In that case, intensity data for the native material corresponds to $|F^n_{1,\mathbf{h}}|^2$ in (26), thus reducing the number of unknown quantities.

Another type of theoretical study designed to elicit phase information from anomalous dispersion and isomorphous replacement concerns the development of formulas for evaluating the so-called triplet phase invariants. Triplet phase invariants are sums of three phases whose subscripts add to zero, e.g., $\phi_{\mathbf{h}} + \phi_{\mathbf{k}} + \phi_{\bar{\mathbf{h}}+\bar{\mathbf{k}}}$. In general, the sum of subscripts is carried out by attaching the sign associated with the corresponding phase to each subscript, e.g., $\phi_{\mathbf{h}} + \phi_{\mathbf{k}} - \phi_{\mathbf{h}+\mathbf{k}}$ is also an invariant. Note that there are triplet phase invariants in equations (10) and (19) forming the "sum of angles" formula.

Recently, there have been two main approaches to the evaluation of triplet phase invariants from isomorphous replacement and anomalous dispersion data. One involves the use of the mathematics of the joint probability distribution by *Hauptman* for isomorphous replacement[91] and for anomalous dispersion,[90] a similar theory for anomalous dispersion by *Giacovazzo*[92] and a theory for both techniques by *Pontenagel, Krabbendam, Peerdeman* and *Kroon*.[93] A recent investigation by *Fortier, Moore* and *Fraser*[94] of the evaluation of triplet phase invariants for isomorphous replacement when the heavy-atom structure is known indicates the potential of this approach for good accuracy.

A second approach to the evaluation of triplet phase invariants from isomorphous replacement and anomalous dispersion data has interested me for the past few years. It involved initially the development of formulas by use of approximate but simple algebraic manipulations that were based on certain mathematical and physical characteristics of the two techniques.[95,96] This was followed by algebraic analyses[84,97,98] that indicated a potential for good accuracy for many of a large number of formulas proposed.

The development of optimal strategies for the use of triplet phase invariants awaits practical experience. If the heavy-atom (anomalously scattering) substructure is known, there are a number of techniques for obtaining values for individual phases.[84,87,89] In that case, it is quite possible that the triplet phase invariants would be used mainly for phase extension and refinement. In those circumstances when the heavy-atom (anomalously scattering) substructure is not known and resists analysis, the triplet phase invariants may be able to play a primary role in reaching a solution to the structure, since the triplet phase invariants

can be evaluated without knowledge of the substructure.

The enhanced opportunities to carry out multiple-wavelength anomalous dispersion experiments with high intensity and tunable synchrotron X-ray sources should facilitate the development of applications of the new theoretical formulations. Coupled with the major advances in computing, the new theories have the potential to improve the facility with which macromolecular structure research is performed.

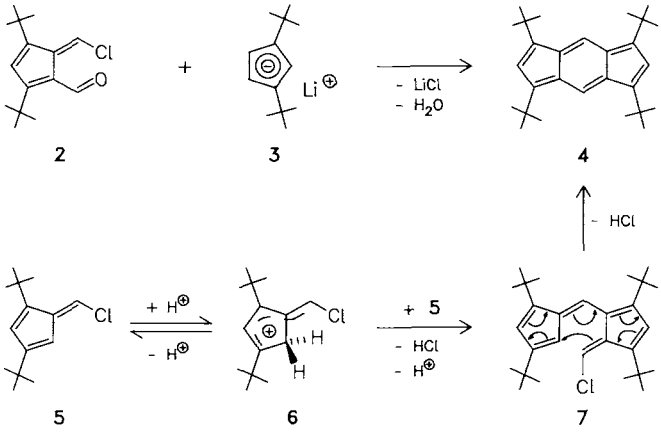
Synthesis and Properties of 1,3,5,7-Tetra-*tert*-butyl-*s*-indacene**



By *Klaus Hafner,* Bernd Stowasser, Hans-Peter Krimmer, Stefanie Fischer, Michael C. Böhm,* and *Hans Jörg Lindner*

According to quantum chemical calculations (MINDO/3 method) on *s*-indacene **1**[1]—a [12]annulene perturbed by two σ-bonds—substituents can be expected to have a strong influence on the bonding situation of the 12π perimeter. The enthalpy of formation for the localized structure **1A** with C_{2h}-symmetry and the corresponding structure of the 2,4,6,8-tetraalkyl derivatives is calculated ca. 10 kcal·mol^{-1} less than that for the delocalized structure **1B**

with D_{2h}-symmetry. For the 1,3,5,7-tetraalkyl-*s*-indacenes this energy gap should only be 2 kcal·mol^{-1}, whereas in the case of 4,8-diamino-*s*-indacenes a completely delocalized π-electron system should be preferred. Even nitrile groups in the 2- and 6-position can be expected to lower the energy difference between **1A** and **1B** to ca. 6 kcal·mol^{-1}. A similarly significant alkyl group effect, changing the bonding situation of the 12π perimeter of **1**, has so far never been reported in the case of other [4n]-π-electron systems. This effect is due to enhanced coupling between the π-electron system and the substituents in the case of the delocalized structure **1B**. The quantum chemical predictions could be experimentally established in the case of the stable 4,8-bis(dimethylamino)-*s*-indacene and the 4-dimethylamino-2,6,8-tri-*tert*-butyl derivative.[2,3] These results encouraged us to check the calculations also for pure alkyl derivatives of **1**, to gain more detailed information about the 12π-electron system. 1,3,5,7-Tetra-*tert*-butyl-*s*-indacene **4** seemed to be especially suitable for this purpose since it should be additionally stabilized kinetically by the bulky alkyl groups compared to the thermally extremely unstable **1**.[1]

In analogy to the synthesis of 4,8-bis(dimethylamino)-*s*-indacene, **4** can be obtained as red needles (decomp. 190°C; yield 30%)[3] by reaction of 2,4-di-*tert*-butyl-6-chloro-1-formylpentafulvene **2**[4] with lithium 1,3-di-*tert*-butylcyclopentadienide **3**[5] (CH_2Cl_2, 0°C). Recently we found an even more simple and rational entry to **4**, namely the protic acid-catalyzed condensation of 1,3-di-*tert*-butyl-6-chloropentafulvene **5**[6] in boiling methanol. The cation **6** formed on reversible protonation could be combined with **5** to give the 6-chloro-1-(6-pentafulvenyl)pentafulvene derivative **7**, whose 12π-electrocyclization with subsequent elimination of HCl led to **4** in 90% yield. Solid **4** is thermally stable as well as air-stable, but in solution it is extremely sensitive towards oxygen and traces of acid.[7]

The signals of the ring protons in the simple ^{1}H-NMR spectrum of **4** (see Table 1) are shifted to higher field in comparison to those of the dihydro derivative **9** ($\Delta\delta = 0.66$–0.81). This indicates a weak antiaromatic character of the *s*-indacene system. The ^{13}C-NMR spectrum, with four signals for the twelve perimeter C-atoms shows no temperature-dependence of the line shapes down to −130°C (in CS_2/COS (1 : 1)).[8] This suggests that either—in agreement with quantum chemical calculations—there is a low energy barrier between the two π-bond isomers, or the π-electron system is delocalized.

The crystal structure analysis of **4** at room temperature (see Fig. 1) gives CC-bond lengths for the perimeter that

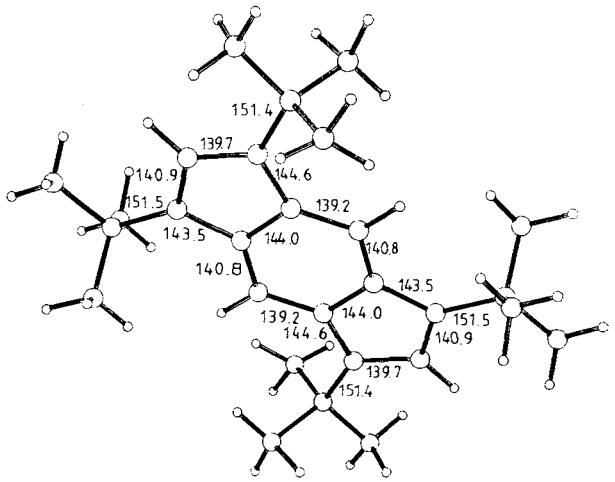


Fig. 1. Structure of **4** in the crystal at room temperature; bond lengths in pm (standard deviations $\sigma_r = 0.5$ pm). [10]

are consistent with a delocalized state. However, as in the case of tetra-*tert*-butylcyclobutadiene,[9] an unequivocal proof of the structure can only be expected from a diffraction experiment at low temperatures.

An electronic spectrum calculated for the localized structure of **4** according to a modified INDO variant[11] (CI method) is in good agreement with the measured data (see Table 1).[12]

Table 1. Spectral data of the compounds **4**, **8**–**10**, and **13**–**15**. ^{1}H-NMR ($CDCl_3$, 300 MHz), ^{13}C-NMR ($CDCl_3$, 75.47 MHz), UV (*n*-hexane).

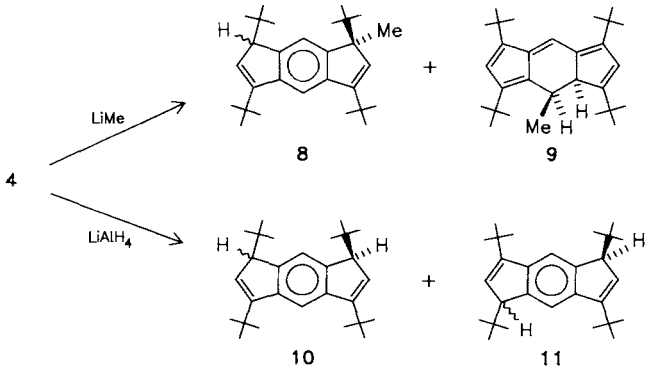
14: ^{1}H-NMR: $\delta = 0.99$ (s; 9 H, *t*Bu), 1.00 (s; 9 H, *t*Bu), 1.37 (s; 9 H, *t*Bu), 1.39 (s; 9 H, *t*Bu), 2.92 (s; 3 H, OMe), 3.09 (d, $J = 2.0$ Hz; 1 H, 7-H), 5.84 (s; 1 H, 2-H), 6.15 (d, $J = 2.0$ Hz; 1 H, 6-H), 7.48 (s; 1 H, 8-H), 7.60 (s; 1 H, 4-H); UV: λ_{max} (lg ε) = 227 (4.07) sh, 233 (4.23) sh, 240 (4.44), 248 (4.67), 257 (4.68), 281 (3.38), 288 (3.37) sh, 300 (3.27), 312 (3.20), 326 nm (3.03)

15: ^{1}H-NMR: $\delta = 1.12$ (s; 9 H, *t*Bu), 1.33 (s; 18 H, *t*Bu), 1.49 (s; 9 H, *t*Bu), 4.64 (s; 1 H, 2a-H), 6.41 (s; 1 H, 6-H), 7.31 (s; 1 H, 8-H), 7.74 (s; 1 H, 4-H); ^{13}C-NMR: $\delta = 26.0$–35.5 (*t*Bu), 60.5 ($C_{tert.}$), 67.4 ($C_{quart.}$), 111.2, 111.6 (C≡N), 121.4, 123.2 ($C_{tert.}$), 124.1, 129.5, 130.4 ($C_{quart.}$), 130.7 ($C_{tert.}$), 134.0, 137.8, 145.0, 145.4, 148.4, 155.3 ($C_{quart.}$); UV: $\lambda_{max} = 227$, 234 sh, 258 sh, 289, 308 sh, 358 sh, 369, 564, 582 sh, 650 nm sh

In its reaction with nucleophilic partners, **4** behaves—with exception of the formation of **9**—similarly to the 4,8-bis(dimethylamino)-*s*-indacene derivatives,[3] but contrary to these it is incapable of reversible protonation or Michael addition to electron-deficient alkynes. Whereas the addition of methyllithium (ether, 25 °C) leads to formation of 1,3,5,7-tetra-*tert*-butyl-1-methyl-1,7-dihydro-*s*-indacene **8** (colorless crystals, m.p. 200 °C; yield 46%) and its isomer **9** (brown crystals, m.p. 125 °C; yield 20%), the reduction with $LiAlH_4$ (tetrahydrofuran, 25 °C) gives 1,3,5,7-tetra-*tert*-butyl-1,7-dihydro-*s*-indacene **10** as major product along with 15% of the isomer **11** (both colorless crystals, subl. 218 °C). Protonation of **4** with methanesulfonic acid at room temperature affords the indenyl cation **12**,[13]



which rapidly undergoes a Wagner-Meerwein rearrangement in $CHCl_3$ to **13** (colorless crystals, m.p. 152 °C; yield 43%). In methanolic solution **12** can be trapped as the methyl ether **14** (colorless crystals, m.p. 195 °C; yield 62%). In boiling benzene, **4** combines with dicyanoacetylene to give

the [12+2]-cycloadduct **15** (blue powder, decomp. 40 °C; yield 9%), whose ring opening to the corresponding cyclohepta[*f*]indene has so far not been accomplished.

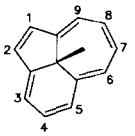
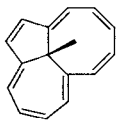
[13] Deuteration experiments show that **4** is protonated in the 2-position and the resulting cation then rapidly rearranges to **12**.

9b-Methyl-9b*H*-benzo[*cd*]azulene—A Novel Antiaromatic 12π-Electron System**



By *Klaus Hafner** and *Volker Kühn*

Dedicated to Professor Edgar Heilbronner on the occasion of his 65th birthday



Of the hitherto reported cyclic conjugated 12π-electron systems, only 1,7-methano-[12]annulene[1] allows conclusions to be drawn about the expected antiaromaticity of the planar 12π perimeter, since [12]annulene[2] and 1,6-methano-[12]annulene[3] are conformationally mobile and the π-perimeters deviate considerably from the planar geometry. In cycl[3.3.3]azine (9b-azaphenalene) and cycl[4.3.2]-azine[4] the properties of the perimeters are influenced by electronic interactions with the central nitrogen atom. Contrary to singly bridged annulenes multiple bridging of the perimeter should result in an increased planarity due to less transannular interactions and therefore allow a substantial delocalization of the peripheral π-electron system. In the case of the 10π-perimeter this expectation was confirmed by *Rees* et al.[5] with the synthesis of 7b-methyl-

1

3

7b*H*-cyclopenta[*cd*]indene **1**. An unexpected reaction of 4-alkylideneazulenide salts **4** with electrophiles recently opened up a simple access to 9b-methyl-9b*H*-benzo[*cd*]-azulene **2**, the first tricyclic [12]annulene,[6] which proves to be an antiaromatic [12]annulene *par excellence* among the 12π-electron systems. At the same time, **2** fills the gap between the tricyclic annulenes **1** and **3**.[7]

Whereas reaction of the resonance-stabilized lithium 4-methyleneazulenide **4**[8] with primary alkyl halides in diethyl ether affords exclusively the 4-alkylazulenes **5**, reactions with *sec*- and *tert*-alkyl halides as well as with dimethyl sulfate or methyl trifluoromethanesulfonate (TFA-Me) lead chiefly to 3a-alkyl-3a,4-dihydro-4-methyleneazulenes **6** and small amounts of **5**, with removal of the azulenoid 10π-electron system.[9] The different regiochemical course of these reactions could be due to competing substitution mechanisms (S_N, SET).[10]

Also 4,5-dihydro-3*H*-benz[*cd*]azulene **7**,[11] after deprotonation with lithium diisopropylamide (LDA), reacts, like **4**, with dimethyl sulfate or TFA-Me to give the tricyclic pentaene **8** (yellow oil, yield 52%).[12] Bromination of **8**

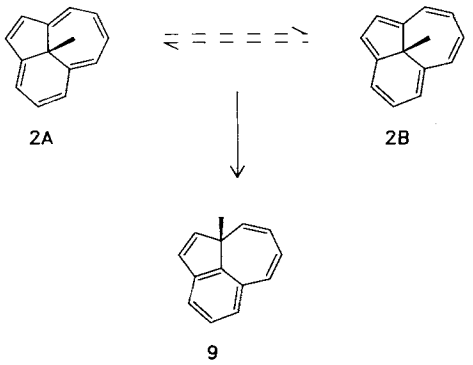
with *N*-bromosuccinimide (NBS) in CCl_4 at 0°C yields an unstable bromo-derivative (yellow, oil), which is dehydrobrominated to **2** with diisopropylethylamine in tetrahydrofuran at room temperature without further purification. Thereby, the blue hydrocarbon **2** is obtained in ca. 30% yield; **2** is stable in solution up to 80°C. Solid **2** rapidly transforms into yellow high molecular products, even at −30°C.

Table 1. Spectral data of **2**, **8**, and **9**.

2A: 300-MHz ^{1}H-NMR ([D$_6$]DMSO): $\delta=3.88$ (d, $J=7.1$ Hz; 1H, 6-H), 3.98 (d, $J=5.8$ Hz; 1H, 3-H), 4.01 (d, $J=9.5$ Hz; 1H, 5-H), 4.18 (d, $J=6.7$ Hz; 1H, 9-H), 4.27–4.41 (m: $\delta=4.30$ (7-H), 4.37 (8-H), 4.39 (4-H)), 4.67, 4.69 (AB system, $J=5.8$ Hz; 2H, 1,2-H), 4.75 (s; 3H, Me); UV (*n*-hexane) (qualitative): $\lambda_{max}=262$, 286, 351, 368, 387 sh, 491 sh, 559 sh, 567 nm

8: 300-MHz ^{1}H-NMR ($CDCl_3$): $\delta=0.76$ (s; 3H, Me), 2.42–2.56 (m; 2H, 3-H), 2.81–2.93 (m; 2H, 4-H), 5.86–6.05 (m; 4H, 6-H or 9-H and 5,7,8-H), 6.18 (dd, $J=1.7$ Hz, $J=2.0$ Hz; 1H, 2-H), 6.43 (d, $J=1.7$ Hz; 1H, 1-H), 6.66 (d, $J=10.7$ Hz; 1H, 6-H or 9-H); UV (*n*-hexane): λ_{max}(lgε) = 262 (4.25), 266 (4.25), 289 sh (3.23), 304 sh (3.04), 350 sh (3.39), 370 sh (3.53), 384 (3.59), 402 sh (3.45) nm

9: 300-MHz ^{1}H-NMR ([D$_6$]DMSO): $\delta=1.07$ (s; 3H, Me), 5.87 (d, $J=10.4$ Hz; 1H, 9-H), 6.15 (dd, $J=6.5$ Hz, $J=10.4$ Hz; 1H, 8-H), 6.44 (dd, $J=6.5$ Hz, $J=11.5$ Hz; 1H, 7-H), 6.71 (d, $J=5.5$ Hz; 1H, 1-H), 6.79 (d, $J=5.5$ Hz; 1H, 2-H), 7.03 (d, $J=11.5$ Hz; 1H, 6-H), 7.20 (dd, $J=1.1$ Hz, $J=7.7$ Hz; 1H, 3-H or 5-H), 7.28 (dd, $J=7.1$ Hz, $J=7.7$ Hz; 1H, 4-H), 7.44 (dd, $J=1.1$ Hz, $J=7.1$ Hz; 1H, 3-H or 5-H); UV (*n*-hexane): λ_{max}(lgε) = 211 (4.12), 257 (4.34), 265 (4.38), 375 (3.61) nm



Proof of the structure of **2** is provided, in particular, by its ^{1}H-NMR spectrum[13] (see Table 1), which, at the same time, provides interesting insights into the bonding structure of this [12]annulene, which according to model considerations has a rigid planar structure. From the spec-

trum, which is temperature-independent up to 80°C, the structure of the π-bond isomer **2A** could be deduced on the basis of the coupling constant $J = 5.8$ Hz for the AB system of 1 H and 2 H and the vicinal coupling constants of 3-H, 5-H, 6-H, and 9-H. In comparison to the spectrum of the dihydro derivative **8**, in the spectrum of **2** the signals of the central methyl group and of the peripheral ring protons appear in the opposite sequence. The signals of the perimeter protons exhibit a strong upfield shift of about 2 ppm in the range $\delta = 3.88$–4.69, whereas the methyl group singlet experiences a substantial downfield shift of about 4 ppm to $\delta = 4.75$. The extremely high-field resonances of the ring protons of **2** compared to the ^{1}H-NMR shifts of the perimeter protons of [12]annulene ($\delta = 5.91$), 1,7-methano[12]annulene ($\delta = 5.1$–5.8) and 1,6-methano[12]annulene ($\delta = 5.50$–6.17) are consistent with a pronounced paramagnetic ring current in the 12π-perimeter of **2**.

The electronic spectrum of **2** (see Table 1), like those of the mono- and bicyclic [12]annulenes and the dehydro[12]annulenes,[14] shows a strong absorption in the region of 260 nm and, in contrast to these, an additional long-wave absorption at 567 nm. The absorption corresponds to the singlet-electron transitions calculated by *Lindner*[15a] for the localized 12π-electron system **2A**.

According to π-SCF force field calculations,[15b] the standard enthalpies of formation of **2A** and **2B** should be about the same, and the activation enthalpies for the π-bond shift should be more than 25 kcal·mol^{-1}. However, contrary to expectations based on these calculations, isomer **2B** was not detected. Hence, the equilibrium may lie further to the side of **2A** than predicted by the calculations, or a higher barrier between **2A** and **2B** is involved. At elevated temperatures a, presumably sigmatropic, methyl-group shift takes place in **2** — as is found in the case of **1**;[5] the 9a-methyl-9a*H*-benz[*cd*]azulene **9** (yellow oil) having a benzenoid partial structure is formed. In contrast to **1**, this isomerization already occurs at 80°C (in dimethyl sulfoxide) in case of **2**, and proceeds quantitatively within 15 min in boiling xylene.

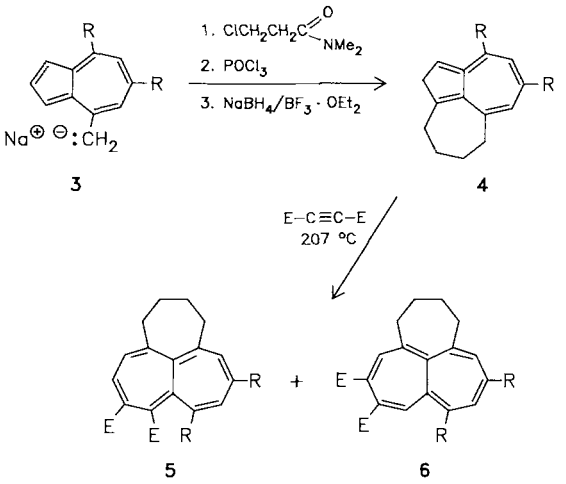
Synthesis and Dynamic Properties of Substituted Cyclohepta[*ef*]heptalene**

By *Klaus Hafner,* Günter L. Knaup,* and *Hans Jörg Lindner*

As in the case of the mono- and bicyclic [4n]-π-electron systems cyclobutadiene,[1a] cyclooctatetraene,[1b] pentalene[1c] and heptalene,[1d] which contain localized double bonds in the ground state, a π-bond shift should also be observed in polycyclic non-alternating [4n]-π-electron systems. However, all previously reported *peri*-annelated tri- and tetracyclic compounds[2] with [4n]-π-electrons contain either benzenoid or azulenoid partial structures, which impede this dynamic process. The still unknown tricycles cy-



clopenta[*cd*]pentalene **1** and cyclohepta[*ef*]heptalene **2**,[3,4] on the other hand, do not have any aromatic structural elements. In contrast to the mono- and bicyclic [4n]-π-systems, in the case of **1** and **2** three isodynamic structures with localized double bonds should be in equilibrium with each other. Furthermore, the seven-membered rings of cyclohepta[*ef*]heptalene (pleiaheptalene) **2** should prefer a boat conformation, so that a ring inversion also could occur as a further dynamic process in this tricycle, as in the case of cyclooctatetraene[1b] and heptalene.[5] With the synthesis of substituted cyclohepta[*ef*]heptalenes we have now

heptylenes **4a**[7] (blue platelets, m.p. 66°C; yield 39%) and **4b** (blue crystals, m.p. 52°C; yield 40%), respectively, whose reactions with dimethyl acetylenedicarboxylate (tetralin, 207°C) lead to the heptalene derivatives **5a** (yellow platelets; m.p. 128–129°C; yield 35%) and **6a** (yellow crystals, m.p. 133°C; yield 53%) as well as **5b** (yellow rhombs, m.p. 158°C; yield 23%) and **6b** (yellow crystals, m.p. 135°C; yield 1%), respectively. Since dehydrogenation of **5a** and **5b** with chloroanil or 2,3-dicyano-5,6-dichloro-*p*-benzoquinone proved unsuccessful, the missing double bonds were successively introduced by oxidation with selenium dioxide (dioxane, 90°C) to give the hydroxy compounds and subsequent elimination of water (TosOH/C_6H_6/80°C).[8] The completely unsaturated tricycles **7a** (orange-red platelets, m.p. 173–175°C; yield 18%) and **7b** (red crystals, m.p. 147–148°C; yield 7%) are stable towards heat and atmospheric oxygen.

7 8

a: R = H; b: R = Me; E = CO_2Me

As shown by the result of the X-ray structure analysis[9] of **7a** (Fig. 1), the achiral tricycle **2** has C_s symmetry and alternating bond lengths. Due to the puckering of the seven-membered rings, the molecule adopts a saddle shaped conformation.

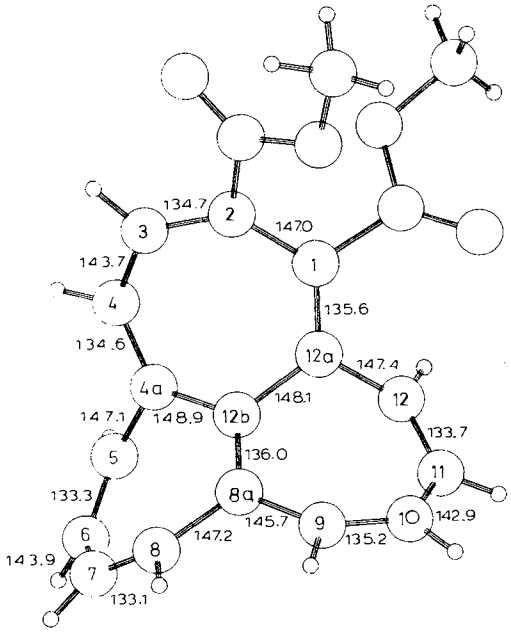
X-ray analysis of **7a** and low temperature ^{1}H-NMR spectra of solutions of **7a** and **7b**, prepared at low temperatures, indicate that, as in **5** and **6**, only the π-bond-shift isomers with a single bond between the ester-substituted positions exist in solution and in the crystalline state. On the other hand, at room temperature there are signals of other isomers in the ^{1}H-NMR spectra with ratios of 9 : 2 : 1 in **7a** and 12 : 1 in **7b**. The complexity of the spectra as well as the unfavorable isomer distribution have so far thwarted any unequivocal structural assignments of the additional isomers formed at room temperature.

Reduction of the diester **7b** with diisobutylaluminum hydride (DIBAH) (THF, 0°C) affords the pure π-bond-



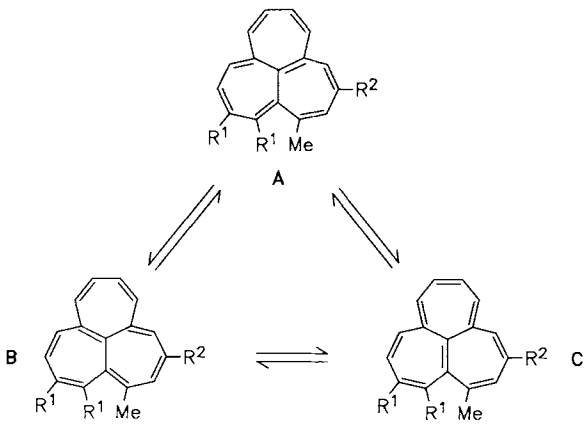


Fig. 1. Structure of **7a** in the crystal; bond lengths in pm (standard deviations: $\sigma_l = 0.4$ pm) [8].

shift isomer **A** of the diol **8b** (orange crystals, m.p. 178–179°C); in solution at room temperature an equilibrium is slowly established with the π-bond-shift isomer **B** (Table 1). Even at 150°C only the valence isomers **8bA** and **8bB** (1:1) are detectable in the ^{1}H-NMR spectrum. The free activation enthalpy for the isomerization **8bA** → **8bB** was found to be 24.1 kcal·mol^{-1} in [D$_6$]DMSO at 33°C.

8b: R^1 = CH_2OH, R^2 = Me; **9**: R^1 = Me, R^2 = H

These experimental results are consistent with π-SCF force field calculations[10] for the dynamics of the 1,2,12-trimethylcyclohepta[*ef*]heptalene **9**. Accordingly, the π-bond-shift isomer **9C**, in which the central double bond causes a partial planarization of the substituent-bearing carbon atoms, has an enthalpy of formation ca. 5 kcal·mol^{-1} higher than the other two isomers. Whereas the direct conversion of **9A** into **9B** should require an activation enthalpy of 38 kcal·mol^{-1}, the value for the isomerization of **9A** to **9C** is only 28 kcal·mol^{-1} and for the isomerization of **9C** to **9B** only 18 kcal·mol^{-1}. Hence, the observed conversion of **8bA** into **8bB** seems to proceed via the thermodynamically unstable isomer **8bC**. On the other hand, for a planarization of the tricycle **9**, i.e. for the transition state of the ring inversion, activation energies of ca. 70 kcal·mol^{-1} have been calculated. Consequently, a ring inversion in case of **7b** and **8b** may require temperatures at which these compounds are presumably no longer stable.

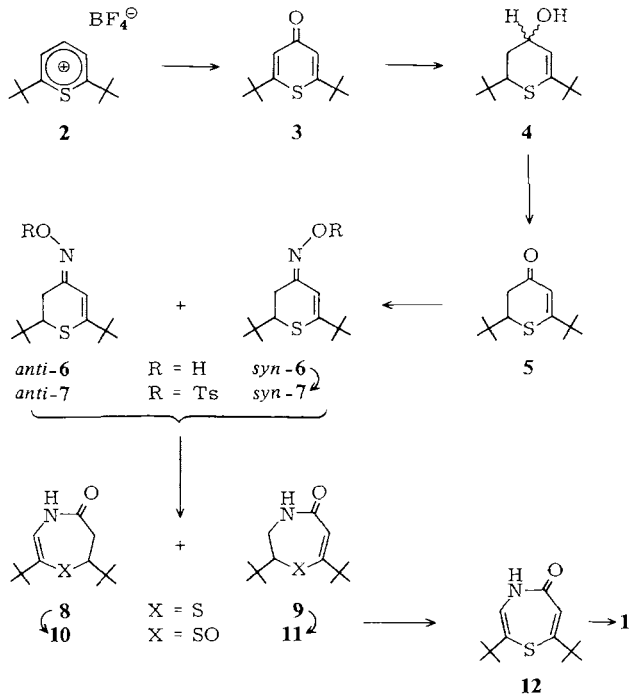
A Stable Monocyclic 1,4-Thiazepine: Synthesis and Characterization of 2,7-Di-*tert*-butyl-5-methoxy-1,4-thiazepine

By *Kagetoshi Yamamoto, Shoko Yamazaki, Hiroki Osedo,* and *Ichiro Murata**

Currently, there is a great deal of interest in seven-membered heterocycles such as oxepins, azepines, and thie-



[*] Prof. Dr. I. Murata, Prof. Dr. K. Yamamoto, Dipl.-Chem. S. Yamazaki, H. Osedo
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

pins.[1] Of these molecules, the parent thiepin still remains unknown owing to its thermal instability, although the parent oxepin[2] and azepine[3] have already been synthesized. We have recently demonstrated that monocyclic thiepins having two bulky groups at the 2- and 7-positions are surprisingly stable.[4,5] By comparison, 2,7-diisopropyl-5-ethoxycarbonyl-4-methylthiepin[6] extrudes sulfur even at −78 °C, whereas its 2,7-di-*tert*-butyl counterpart is stable up to 130 °C.[4,5] This increase in stability most likely rests on the severe nonbonding steric repulsion between the two *tert*-butyl groups in the corresponding thianorcaradiene proposed as an intermediate in the sulfur extrusion reaction.[7] Bulky groups may also stabilize the thiazepine ring system, the known examples of which have been confined to the annelated derivatives.[8,9] We report here the first synthesis of a stable monocyclic 1,4-thiazepine, 2,7-di-*tert*-butyl-5-methoxy-1,4-thiazepine **1**.

1

2,6-Di-*tert*-butylthiopyrylium tetrafluoroborate **2**, prepared from 2-*tert*-butyl-5-pivaloylthiophene in four steps by our previously reported procedure,[4] was oxidized by Sarett reagent to 2,6-di-*tert*-butylthiopyran-4-one **3**[10] in 56% yield. Formation of the seven-membered thiazepine ring by Beckmann rearrangement of the oxime of **3** (or its tosylate) failed.[11] It was necessary to reduce one double bond in **3** for the subsequent Beckmann rearrangement.

Reduction of **3** in tetrahydrofuran (THF) with a large excess of sodium borohydride gave a mixture of the dihydro alcohols **4**, which, without separation, were oxidized with Sarett reagent to dihydrothiopyranone **5** in 43% yield (based on **3**). Reaction of **5** with hydroxylamine gave a mixture of the oximes *syn*-**6** and *anti*-**6** in 92% yield in a ratio of 1:2 (comparison of the relative areas of the ^{1}H-NMR signals of the olefinic protons; see Table 1). The mixture was converted into the tosylates *syn*-**7** and *anti*-**7**, which underwent Beckmann rearrangement in 70% aqueous dioxane with Et_3N at 80 °C within 5 h to give a mixture of lactams, which could easily be separated into **8** (48%) and **9** (25%) by column chromatography on silica gel (deactivated with 5% H_2O) with benzene/ether.

Table 1. Some physical data of the compounds **1**, **3**, **5**, *syn*-**6**, *anti*-**6**, *syn*-**7**, *anti*-**7**, **8**, **9**, **12**, and **13**.

1: Pale yellow oil; ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.20$ (s, 9H; $C(CH_3)_3$), 1.21 (s, 9H; $C(CH_3)_3$), 3.73 (s, 3H; OCH_3), 6.02 (d, $^5J(6,3) = 1.0$ Hz, 1H; *H*-6), 6.78 (d, 1H; *H*-3); ^{13}C-NMR (22.5 MHz, $CDCl_3$): $\delta = 29.59$, 30.21, 37.99, 40.15, 52.91, 120.7 (*C*-6), 133.4 (*C*-3), 134.7 (*C*-5), 163.3 (*C*-7), 167.1 (*C*-2); IR (film): $\tilde{\nu} = 1640$ cm^{-1} (C=N); MS (70 eV): *m/z* 253 ($M^{\oplus}$, 28%), 238 ($M^{\oplus} - CH_3$, 24%), 211 (54%), 181 (100%); high-resolution MS: $M^{\oplus} = 253.1493$ (calcd. 253.1499). UV (cyclohexane): $\lambda_{max}(\log\varepsilon) = 244$ (3.77), 340 (2.36) nm

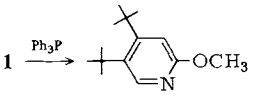
3: Colorless needles, m.p. = 97–99 °C (from hexane); ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 1.37$ (s, 18H; $C(CH_3)_3$), 6.87 (s, 2H); IR (KBr): $\tilde{\nu} = 1610$ cm^{-1} (C=O)

5: Colorless crystals, m.p. = 52.5–53.5 °C (from hexane); ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.04$ (s, 9H; 2-$C(CH_3)_3$), 1.24 (s, 9H, 6-$C(CH_3)_3$), 3.21 (dd, $^3J(2,3a) = 3.4$, $^3J(2,3b) = 13.5$ Hz; *H*-2), 2.71 (dd, $^2J(3a,3b) = 16.1$ Hz; *H*-3a), 2.42 (dd; *H*-3b), 6.20 (s, *H*-5); IR (KBr): $\tilde{\nu} = 1640$ cm^{-1} (C=O); MS (70 eV): *m/z* 226 ($M^{\oplus}$, 5%)

syn-**6** + *anti*-**6**: ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 6.84$ (s; *H*-5 of *syn*-**6**, relative intensity = 1), 6.22 (s, *H*-5 of *anti*-**6**, relative intensity = 2), the remaining signals are overlapped; MS (70 eV): *m/z* 241 ($M^{\oplus}$, 81%)

syn-**7** + *anti*-**7**: ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 0.97$ (s, 9H), 1.11 (s, 9H), 2.00–3.50 (m, 3H), 7.13–7.38 (m, 2H), 7.72–7.88 (m, 2H), 2.38 (s, aryl-CH_3 of *anti*-**7**, relative intensity = 2), 2.43 (s, aryl-CH_3 of *syn*-**7**, relative intensity = 1), 6.07 (s, *H*-5 of *anti*-**7**, relative intensity = 2), 6.55 (s, *H*-5 of *syn*-**7**, relative intensity = 1)

8: Colorless crystals, m.p. = 147–147.5 °C (from methanol); ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.04$ (s, 9H, 7-$C(CH_3)_3$), 1.22 (s, 9H, 2-$C(CH_3)_3$), 2.69 (d, $^3J(6,7) = 7.3$ Hz, 2H; *H*-6), 3.60 (t; *H*-7), 6.32 (d, $^3J(3,NH) = 3.6$ Hz; H-3), 7.15 (br. s, NH); IR (KBr): $\tilde{\nu} = 1665$ cm^{-1} (C=O); MS (70 eV): *m/z* 241 ($M^{\oplus}$, 100%)



9: Colorless crystals, m.p. = 141–142 °C (from hexane); ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.04$ (s, 9H; 2-$C(CH_3)_3$), 1.26 (s, 9H; 7-$C(CH_3)_3$), 3.32–3.64 (m, 3H; H-2,3a,3b), 6.15 (d, $^4J(6,NH) = 1.4$ Hz; *H*-6), 6.82 (br. s, NH); IR (KBr): $\tilde{\nu} = 1650$ cm^{-1} (C=O); MS (70 eV): *m/z* 241 ($M^{\oplus}$, 82%)

12: Colorless crystals, m.p. = 125–126 °C (from hexane); ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.18$ (s, 9H, $C(CH_3)_3$), 1.22 (s, 9H, $C(CH_3)_3$), 6.17 (d, $^4J(6,NH) = 1.8$ Hz; *H*-6), 6.27 (d, $^3J(3,NH) = 4.6$ Hz; *H*-3), 7.12 (br. s, NH); IR (KBr): $\tilde{\nu} = 1662$, 1640 cm^{-1} (−NH−CO−); MS (70 eV): *m/z* 239 ($M^{\oplus}$, 33%), 182 ($M^{\oplus} - 57$, 100%)

13: Colorless oil; ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 1.49$ (s, 9H; $C(CH_3)_3$), 1.52 (s, 9H; $C(CH_3)_3$), 3.92 (s, 3H; OCH_3), 6.91 (s, 1H; *H*-3), 8.35 (s, 1H; *H*-6); MS (70 eV): *m/z* 221 ($M^{\oplus}$, 16%), 206 ($M^{\oplus} - CH_3$, 68%); high-resolution MS: $M^{\oplus} = 221.1755$ (calcd. 221.1778)

In order to introduce the additional double bond, Pummerer reaction[12] of the sulfoxide **10**, derived from the major isomer **8** in 91% yield by oxidation with *m*-chloroperbenzoic acid, was examined. This reaction, however, resulted in the formation of a complex mixture of unidentified products. Unlike **10**, the sulfoxide **11**, obtained quantitatively from the lactam **9**, reacted smoothly under the same reaction conditions (F_3CCO_2H in H_2CCl_2, RT, 3 h) to give the desired diene **12** in 79% yield.[13] **12** was converted into the lactim **1**, a pale yellow oil, in 65% yield by treatment with $Me_3O^{\oplus}BF_4^{\ominus}$ in CH_2Cl_2. The elemental analysis and spectral data are in full accord with the thiazepine structure **1**. The thiazepine **1** is stable up to 130 °C; no detectable sulfur extrusion could be observed within 20 h (^{1}H-NMR monitoring in [D_8]toluene). However, thermolysis of **1** in benzene (110 °C, 7 h, sealed tube) in the presence of an equimolar amount of triphenylphosphane gave

4,5-di-*tert*-butyl-2-methoxypyridine **13** as a colorless oil in 77% yield.

13

The thermal stability of **1** is presumably due to the steric effect of two *tert*-butyl groups; however, the effect of the methoxy group on the thermal stability of **1** is still unclear.

$[U_3(\mu^3\text{-}Cl)_2(\mu^2\text{-}Cl)_3(\mu^1,\eta^2\text{-}AlCl_4)_3(\eta^6\text{-}C_6Me_6)_3][AlCl_4]$— A Trinuclear Arene Complex of U^{III}**

By *F. Albert Cotton,* Willi Schwotzer,* and *Charles Q. Simpson II*

The reaction of halides of early transition metals under reducing Friedel-Crafts conditions was successfully employed by *E. O. Fischer* et al. for the synthesis of trinuclear cluster compounds of the general type $[M_3(\eta^6\text{-}C_6Me_6)_3(\mu^2\text{-}Cl)_6]^{n+}$.[1] X-ray crystallographic and physicochemical studies have shown[2] that there is metal-metal bonding in these clusters. We have tried to emulate this seemingly generic reaction type in the chemistry of uranium and worked out reaction conditions for the synthesis of the first dinuclear and trinuclear arene complexes of U^{IV}, **1** and **2**, respectively.[3] **1** and **2** resemble the arene complexes of low-valent elements of the third and fourth main groups.[4]

$[U(C_6Me_6)Cl_2(\mu\text{-}Cl)_3UCl_2(C_6Me_6)][AlCl_4]$ **1**[3a]
$[U(C_6Me_6)Cl_2(\mu\text{-}Cl)_3UCl_2(\mu\text{-}Cl)_3UCl_2(C_6Me_6)]$ **2**[3b]

We now have found that a trinuclear cluster compound of U^{III}, **3**, can also be prepared under reducing Friedel-Crafts conditions [Eq. (a)].

$$3\,UCl_4 + 3\,AlCl_3 + 3\,C_6Me_6 + Al \longrightarrow [U_3(\mu^3\text{-}Cl)_2(\mu^2\text{-}Cl)_3(\eta^2\text{-}AlCl_4)_3(\eta^6\text{-}C_6Me_6)_3][AlCl_4] \quad (a)$$

3

The structure of the complex cation of **3** is depicted in Figure 1.[5] The three uranium atoms define approximately

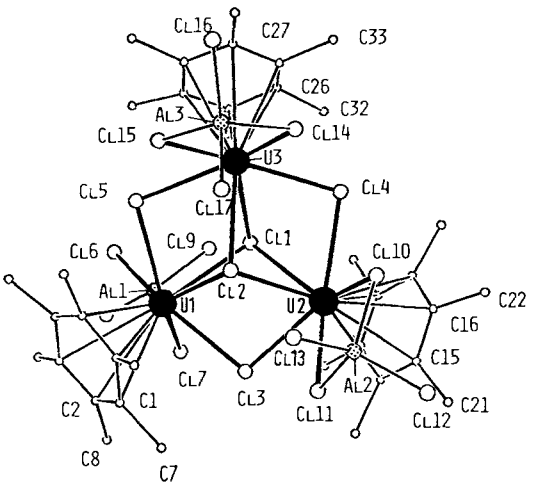

Fig. 1. Perspective drawing of the structure of the cation of **3** in the crystal.

an equilateral triangle. Three chlorine atoms bridge the edges of the triangle, while two additional chlorine atoms cap the triuranium fragment on each side in μ^3-fashion. The coordination polyhedron of each U atom is best described as a distorted pentagonal bipyramid. The equatorial plane is defined by two Cl atoms of the bridges, two Cl atoms of $AlCl_4$, and one μ^3-Cl atom of the caps. The apical positions are occupied by the other capping μ^3-Cl atom and the C_6Me_6 moiety. Important distances and angles of the structure of **3** are given in Table 1. For comparison, some selected structure data for the other known uranium arene complexes and for some uranium compounds with anionic π-ligands are summarized in Table 2. The U–C distances involving neutral π-ligands are systematically longer than those involving anionic ligands. This supports the view that the ionic contribution to the bonding of cyclopentadienyl, allyl, or cyclooctatetraenyl ligands is an im-

[a] η^2-$AlCl_4$. [b] Bridging. [c] Terminal. [d] Capping.

portant one, although our compounds with neutral π-ligands clearly indicate that covalent bonding is not to be neglected.[11] Moreover, while there is no simple correlation between bond length and bond strength, the large U–C separation is in agreement with our experience that the arene ligands are easily displaced by σ-donor molecules even though the arene complexes are fairly stable in a thermodynamic sense. The U–Cl distances vary according to the bonding situation (terminal, bridging, or capping) but fall into the expected ranges observed in many other uranium chlorides.

The relative orientation of the hexamethylbenzene ligands with respect to the triangular plane is *anti* for the ligands on U1 and U2 as well as for U1 and U3 but *syn* for the pair U2/U3. This could be explained by steric arguments assuming facile site interchange between hexamethylbenzene and $AlCl_4$ in solution and selective crystallization of the diastereomer with the most favorable steric interaction, including crystal packing. There is, however, an alternative explanation. The substructures containing the *anti* arrangement, for example, the fragment $[(C_6Me_6)(AlCl_4)U1(\mu^2\text{-}Cl)_3U2(C_6Me_6)(AlCl_4)]$, bear a very close structural resemblance to the dinuclear precursor **1**. All it takes to complete the trinuclear unit of **3** with correct stereochemistry is to attach, in our example, the fragment $[(C_6Me_6)(AlCl_4)U3(Cl)_2]$ via two of the bridging chlorine atoms, which consequently become caps. Unfortunately, NMR experiments to probe possible isomerization processes at the metal centers are not feasible because of paramagnetic line broadening.

The observed U–U distance (> 4.2 Å, Table 1) probably rules out a direct M–M interaction.[12] Therefore, the electron configurations of the U atoms are expected to be f^3, leading to a paramagnetic complex. This is in agreement with our observation that in the solid-state ^{13}C-NMR spectrum of **3** only very broad lines are observed, as opposed to the also paramagnetic (f^2-configuration) compound **2**.[3b]

Well-defined complexes of U^{III} and U^{IV} are thus accessible by a modified Friedel-Crafts procedure.[1,3,7] They represent the first examples of complexes of an actinide metal with neutral π-ligands. Meanwhile we have succeeded in extending our work to a lanthanide element and have isolated a hexamethylbenzene complex of samarium.[13] Such donor-acceptor complexes of f-block elements are gaining increasing attention. There are recent reports on compounds with other π-ligands, most notably CO[14] and olefins,[15] as well as with electron-rich transition metals.[16]

Experimental Procedure

All reactions were carried out under scrupulous exclusion of air and moisture in Schlenk-type glassware. Solvents were distilled under N_2 from appropriate drying agents. UCl_4 was prepared by published procedures [6].—**3**: Reaction of a mixture of UCl_4 (380 mg, 1 mmol), $AlCl_3$ (150 mg), and C_6Me_6 (200 mg) in refluxing toluene yielded a green solution with very little precipitate within 30 min. The green product, **1**, was isolated by slow cooling of the filtered solution. An excess (ca. 100 mg) of aluminum powder was then added from a dump tube without prior isolation of **1**. The solution gradually turned red-brown. It was then heated under reflux for 4 h and filtered hot; the residue was extracted twice with hot toluene. *Very slow* cooling of the combined extracts afforded the trinuclear compound **3**; yield: 410 mg (55%). On several occasions oily precipitates, which were converted into brown powders by washing with hexane, were formed. The precipitate, once formed, was no longer soluble in hot toluene or halocarbon solvents. It was soluble in polar donor solvents where it appeared to undergo chemical transformation. Crystalline products have been obtained from acetonitrile and are presently under investigation. **3** is exceedingly sensitive to air and moisture. Heating in vacuum (10^{-4} torr) leads to decomposition at ca. 160°C with concomitant sublimation of C_6Me_6.

[12] We estimate, based on M-M distances in similar clusters of d-transition elements [1b, 2], a U-U distance of 3.5 Å to be an upper limit for a bonding interaction. In a dinuclear uranium alkoxide with a U-U separation of 3.63 Å, the interaction is clearly repulsive (F. A. Cotton, D. O. Marler, W. Schwotzer, *Inorg. Chem. 23* (1984) 4211).

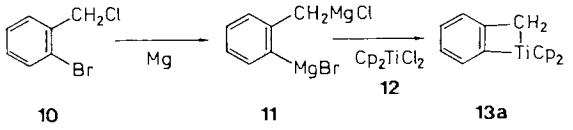
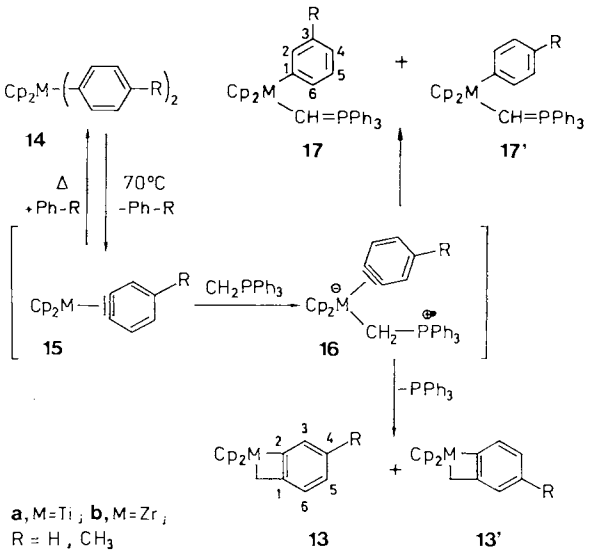
Metallacyclic Four-Membered Ring Systems: Two Independent Routes to Bis(cyclopentadienyl)titanacyclobutabenzene**



By *Henricus J. R. de Boer, Otto S. Akkermann, Friedrich Bickelhaupt,* Gerhard Erker,* Peter Czisch, Richard Mynott, Julian M. Wallis,* and *Carl Krüger*

Metallacyclobutanes of the early transition metals[1] are accessible via two routes (Scheme 1): by reaction of metal halides with suitably substituted 1,3-propanediyl dianion-equivalents [route (a)][2] or by the electrocyclic ring closure of carbene(olefin)metal complexes. The latter are usually obtained by reaction of carbene-metal complexes with olefins [route (b)],[1c] but more recently they have been prepared from organic alkylidene donors and reactive olefin-metal complexes [route (c)].[3] We have now found that



Scheme 1.

otherwise difficultly and rarely accessible metallacyclobutabenzene compounds[4] can be prepared by variants of routes (a) and (c). We have been able to demonstrate this, for example, in the case of bis(cyclopentadienyl)titanacyclobutabenzene **13a**.

The novel, double Grignard reagent **11** was obtained by reaction of *o*-bromobenzyl chloride with magnesium in tetrahydrofuran (THF). Reaction of a THF suspension of **11** with Cp_2TiCl_2 (**12**, equimolar amount) at -20 °C afforded the titanacyclobutabenzene **13a**.[5] **13a** can, however, also be prepared via the cycloaddition route (c) (Scheme 1). (Aryne)$ZrCp_2$ **15b**, generated thermally from diphenylzirconocene, reacts with $CH_2{=}PPh_3$ to give the metallocene-substituted ylide **17b**.[6] In the analogous titanocene system, transfer of the entire methylene group of the reagent with formation of **13a** and PPh_3 competes with H-transfer (**17a** : **13a** = 2 : 1).[7] A labeling experiment showed that both of the products are formed by an aryne mechanism[8] (Scheme 2).

Scheme 2. The (non-systematical) numbering merely serves for assignment of the NMR signals.

17a was characterized by an X-ray structure analysis (Fig. 1).[9] Like **17b**, in the crystal it exhibits a preferred conformation that allows for maximal π-interaction of the formally coordinatively unsaturated metal center[10] with the trigonal-planar ylide carbon atom. The Ti-C7 bond length (2.033(6) Å) is remarkably short.[11] The metal-C(ylide) π-interaction in the titanium compound **17a** ($\Delta d(M) = d[M\text{-}C1] - d[M\text{-}C7]$; $\Delta d(Ti) = 0.22$ Å) is stronger than in the zirconium compound **17b** ($\Delta d(Zr) = 0.18$ Å). **17a** and **17b** show dynamic NMR spectra in solution: In **17a** the activation barrier for rotation about the M-C7 bond ($\Delta G^{\ddagger}_{34\,°C} = 12.0 \pm 0.2$ kcal/mol) is considerably higher than in the case of **17b** ($\Delta G^{\ddagger}_{102\,°C} = 8.6 \pm 0.3$ kcal/mol),[6] suggesting a stronger π-interaction in **17a**. The methylene transfer to give **13** would be favored by a similarly enhanced M-C π-interaction in the intermediate **16**.

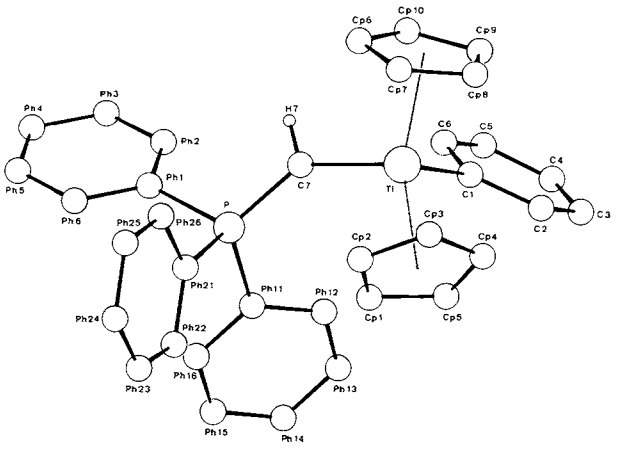

Fig. 1. Crystal structure of **17a**, R = H.

Experimental

A suspension of doubly sublimed magnesium (576 mg, 24 mmol, particle size 1–2 mm) in THF (4 mL) was treated with dibromoethane (21 mg, 0.1 mmol), and the mixture stirred for 15 min. A solution of **10** (492 mg, 2.4 mmol)[12] in THF (30 mL) was then added dropwise to the mixture within 2 h, and stirring continued for a further 1 h. To remove excess magnesium, the mixture was filtered through glass wool. This furnished a suspension of a green precipitate in a greenish-yellow solution, with the precipitate containing the greater part of the organomagnesium compound. The yield of **11** was almost quantitative. This was ascertained by hydrolysis and titration of the base and the magnesium ions with HCl and ethylenediamine tetraacetate (EDTA), respectively, and by determination of the α,*o*-dideuteriotoluene (99%) after deuteriolysis (GC/MS). Derivatization with CO_2, Me_3GeCl, and Me_3SnCl also afforded the expected disubstitution products in 92–94% yield.

For the synthesis of **13a**, **12** (198 mg, 0.795 mmol) was added to a THF-suspension of a molar equivalent of **11** (0.0199 M) at −20°C in a sealed glass system and stirred for 2 h. The grey precipitate dissolved and a deep red solution resulted. After removal of the THF by distillation at 4°C the solution was treated with dioxane (10 mL); after 15 minutes' stirring and removal of a white precipitate (magnesium salts), the filtrate was evaporated to dryness. The residue was virtually pure **13a** (red powder; 93% yield, determined by ^{1}H-NMR spectroscopy with cyclopentane as standard).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

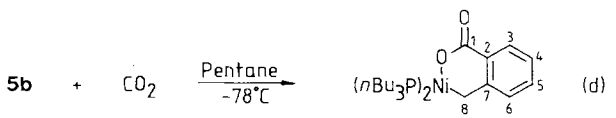
class of organometallic compounds on account of their importance as intermediates in olefin metathesis reactions.[2] Metallacyclobutenes, on the other hand, have not yet been isolated, although metallacyclobutabenzene compounds of some transition metals (but not of nickel) are known.[3] Higher-membered, multiply unsaturated metallacycles may be prepared, for example, by oxidative addition of biphenyls to nickel(0) compounds, whereby a CC σ-bond that is activated by ring strain undergoes cleavage.[4] As we recently showed, oxidative addition of cyclopropabenzene **1** to $[(Me_3P)_2Ni(cod)]$ (COD = *cis,cis*-1,5-cyclooctadiene) results in the formation of a bis-methano-bridged nickela[12]annulene.[5] Here we report a novel and flexible approach to metallacyclobutabenzenes, which was discovered in the course of those investigations.

When **1**[6] is allowed to react with the nickel(0) complexes **2**[7,8] and **3**[9] [Eq. (a) and (b), respectively] or with a 1:1 mixture of trisethenenickel(0) **4**[10] and tetramethylethylenediamine (TMEDA)[11] [Eq. (c)], the corresponding nickelaannulenes are not formed.[5] Instead, the crystalline nickel(II) compounds **5**, i.e., nickelacyclobutabenzene derivatives, are produced in high yields as the result of insertion of a Ni atom into one of the CC σ-bonds of the three-membered ring of **1**. The ligands thereby released can be removed by recrystallization or under high vacuum. The complexes with $(n\text{Bu})_3P$ and Ph_3P ligands (**5b** and **5c**, respectively) are stable at room temperature, whereas those with the ligands Et_3P and TMEDA (**5a** and **5d**, respectively) decompose slowly, turning black.[12]

The nuclear magnetic resonance spectra are in agreement with the structures given[13] (Tables 1 and 2). The following features were observed for each of the compounds **5a–c**. In the ^{31}P-NMR spectrum, the splitting pattern of an AX spin system is observed. In the $^{13}C\{^1H\}$-NMR spectrum, the signal of the Ni-bonded C atom of the methylene group (C-7) is a doublet of doublets at high field; the differing magnitudes of the coupling constants $^2J(P,C\text{-}1)$ and $^2J(P',C\text{-}1)$ (as well as $^2J(P,C\text{-}7)$ and $^2J(P',C\text{-}7)$) (see Table 2) indicate a square-planar geometry at the Ni atom. The C-6 atom of the aromatic ring gives rise to a signal at markedly low field ($\delta = 158\text{–}160$). In the ^1H-NMR spectrum, the nonequivalent, aromatic protons (H-2 to H-5) appear as an ABCD spin system, and the protons of the CH_2 group appear as a broad signal at $\delta = 0$. For **5d**, the chelating ligand assumes a preferred conformation at $T = -120\,^\circ C$. This causes the Ni atom to become a center of chirality, and the protons on C-7 are thus diastereotopic ($\delta = -0.24$ and -0.34, $^2J = 9$ Hz). The NMR spectra of **5d** differ clearly from those of **5a–c** in the high-field shifts of the atoms C-1 and C-7, which are directly bonded to the Ni atom, as well as of the proton H-7. We ascribe this to the stronger shielding of these nuclei on account of the large electron density at the Ni atom; the ligand TMEDA acts only as an electron donor without taking part in back bonding.

Table 1. ^1H-NMR data for the nickelacyclobutabenzene fragment of the compounds **5** (400 MHz [a], $[D_8]THF$, $-80\,^\circ C$ [b], δ values with respect to TMS).

	H-2 1H	H-3 1H	H-4 1H	H-5 1H	H-7 2H
5a	7.17(m)	6.58(m)	6.70(m)	6.24(m)	0.41(d)
5b	7.18(m)	6.59(m)	6.70(m)	6.23(m)	0.38(br. d)
5c	6.17(m)	6.57(m)	6.16(m)	5.99(m)	0.55(dd)
5d	7.03(dd)	6.34(dt)	6.53(dt)	6.00(dd)	−0.26(br. s)



[a] **5a** at 200 MHz. [b] **5c** at $-10\,^\circ C$.

Table 2. ^{13}C-NMR data for the nickelacyclobutabenzene fragment of the compounds **5** (75.5 MHz, $[D_8]THF$, $-80\,^\circ C$ [a]).

	5a	**5b**	**5c**	**5d**
δ values relative to TMS, $J(C,H)$ multiplicities in parentheses				
C-1	134.7 (s)	134.2 (s)	134.5 (s) [b]	128.6 (s)
C-2	122.4 (d)	122.5 (d)	122.8 (d)	121.7 (d)
C-3	124.3 (d)	124.2 (d)	124.3 (d)	122.3 (d)
C-4	125.4 (d)	125.6 (d)	123.8 (d)	123.4 (d)
C-5	129.4 (d)	129.5 (d)	— [c]	128.1 (d)
C-6	160.5 (s)	160.7 (s)	158.0 (s)	159.1 (s)
C-7	−6.3 (t)	−7.1 (t)	0.5 (t)	−17.8 (t)
$\lvert J(P,C)\rvert$ in Hz				
$^2J(P,C\text{-}1)$	25.0	24.9	−[b]	
$^2J(P',C\text{-}1)$	78.2	78.8	−[b]	
$^2J(P,C\text{-}7)$	23.0	23.4	18.3	
$^2J(P',C\text{-}7)$	55.4	56.0	50.9	

[a] **5c** at $-40\,^\circ C$, **5d** at $-60\,^\circ C$. [b] Signal not identified unequivocally. [c] Signal overlapped.

Evidence for the structures of **5a–d** is also provided by chemical reactions. Protolysis of **5b** with HCl in ether results in the nearly quantitative formation of toluene. As expected on account of the ring strain, **5a–d** readily undergo ring expansion: **5b** already undergoes reaction at $-78\,^\circ C$

with carbon dioxide to form the six-membered cyclic carboxylate **6** in high yield [Eq. (d)], which could be characterized unequivocally.[14] Protolysis of **6** with HCl in ether affords *o*-methylbenzoic acid in nearly quantitative yield.

[7] **5a**: **1** (0.5 mL, 4.85 mmol) was added to a vigorously stirred solution of **2a** (1.67 g, 4.14 mmol) in 60 mL of pentane under argon at −20°C. The reaction mixture was then allowed to warm to room temperature and stirred for 30 min. After the reaction mixture had been concentrated to 20 mL and a slightly amorphous precipitate removed, the filtrate was cooled slowly to −78°C and allowed to stand for 1 week at this temperature. The crystals that separated out were filtered off, washed once with cold pentane, and dried at a maximum temperature of −20°C under high vacuum. Yield: 1.21 g (3.14 mmol, 76%) greenish brown crystals.

[8] **5b**: Synthesized analogously to **5a**. Green crystals, yield 68%.

[9] **5c**: **1** (0.5 mL, 4.85 mmol) was added to a solution of **3** (1.92 g, 1.74 mmol) in 50 mL of toluene at −20°C under argon. The reaction mixture was then stirred over night at room temperature, during which time a finely crystalline, yellow precipitate separated out. After 1 d at −20°C, the yellow crystals were collected on a D_4 frit, washed with ether, and then dried at room temperature under high vacuum. Yield: 936 g (1.39 mmol, 80%) of yellow microcrystals.

[11] TMEDA (0.62 mL, 4.15 mmol) was added to a freshly prepared solution of CDT-Ni (CDT = all-*trans*-1,5,9-cyclododecatriene) [15] **4** in 20 mL of Et_2O at −78°C. **1** (0.75 mL, 5.03 mmol) was then added to the clear solution at −78°C and the reaction mixture was allowed to warm over 3 h to −20°C. The reaction mixture turned cloudy and ethylene evolved. In order to achieve complete crystallization, the mixture was cooled for 1 d at −78°C. The precipitate was filtered under suction while still cold, washed twice with cold Et_2O, and dried at −20°C under high vacuum. Yield: 770 mg (2.91 mmol, 70%) of greenish brown microcrystals.

[12] The elemental analyses are in agreement with the empirical formulas.

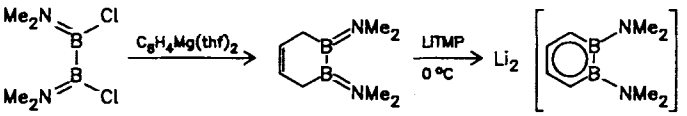
A 1,2-Diboratabenzene: Lithium Salt and Transition Metal Complexes**



By *Gerhard E. Herberich,* Bernd Hessner,* and *Martin Hostalek*

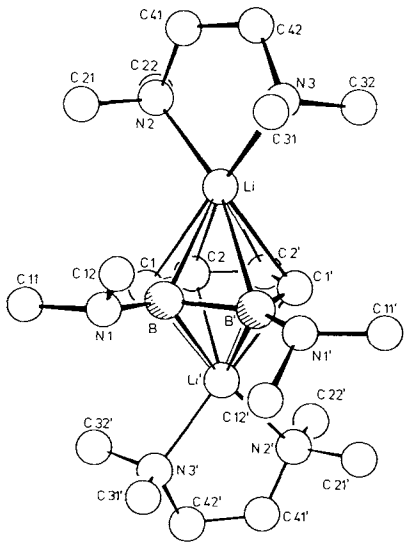
1,2-Diborabenzene **1** and its derivatives have so far never been reported in the literature. Possibly the most important representatives of **1** are the 1,2-dibora-3,5-cyclohexadienes **2**, the 1,2-diboratabenzene ions **3**, and transition-metal complexes in which **2** and **3** are stabilized as ligands. We report here on the first entry to 1,2-diboratabenzene derivatives.

1 **2** **3**

The diborane(4) $Cl(Me_2N)BB(NMe_2)Cl$[1] smoothly reacts with $C_4H_6Mg(THF)_2$[2] (THF = tetrahydrofuran) to give the liquid 1,2-dibora-4-cyclohexene derivative **4**.[3,4] Metalation of **4** with lithium 2,2,6,6-tetramethylpiperidide (LiTMP) affords the sparingly soluble lithium 1,2-diboratabenzene derivative **5**;[4,5] this can be converted by reaction with *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) into the readily crystallizable salt $[Li(TMEDA)]_2[1,2\text{-}C_4H_4(BNMe_2)_2]$ **6**, which is soluble in THF.

4 **5**

The salt **6** has a triple-decker structure with crystallographic C_2 symmetry (Fig. 1).[6] The structure can be interpreted as a contact ion triple. The 1,2-diboratabenzene ring is virtually planar (twist conformation; maximum vertical deviation 4.2 pm). The bonding pattern in the C_4B_2 ring is that of a delocalized 6π-electron system. As can be expected, the Li(TMEDA) groups are shifted from the B atoms in the direction of the atoms C2 and C2′; the acentricity of the bonding (slip distortion) is 14.9 pm.[7]



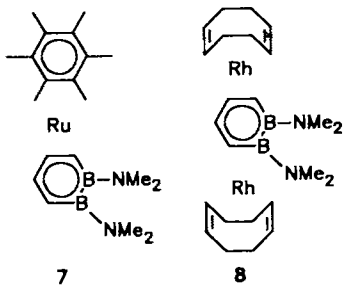


Fig. 1. Structure of **6**. Selected bond lengths [pm]: Li-C2 228.8(9), Li-C2′ 226.3(8), Li-C1 235.1(8), Li-C1′ 236.8(7), Li-B 247.1(8), Li-B′ 255.3(8), Li-N2 216.4(7), Li-N3 216.2(8); in the anion: B-B′ 170.6(8), B-C1 150.5(6), C1-C2 141.3(6), C2-C2′ 141.7(8), B-N1 149.5(5).

[**] Derivatives of 1,2-Diborabenzene, Part 1. This work was supported by the Fonds der Chemischen Industrie.

Reaction of **5** with transition-metal halides affords sandwich and triple-decker complexes. For example, reaction with $[\{(C_6Me_6)RuCl_2\}_2]$ furnishes the yellow 18e complex **7**,[4,8] while reaction with $[\{(1,5\text{-cod})RhCl\}_2]$ leads to formation of the dark-red, 30e triple-decker complex **8**.[4,9]

7 **8**

The constitution of the new compounds **4–8** follows from their NMR data. In **4**, the rotation of the Me_2N groups about the B–N bond is, as expected, slow, while in **6–8** it is rapid. The π-interaction between the lone pair on the nitrogen atom and the p_z orbital of the boron atom is thus reduced in **6–8**. The same interaction also weakens the boron–metal interaction in **7** and **8**. The ^{11}B-NMR resonances of **7** and **8** therefore lie on the low-field limit of the range expected for facially bonded boron heterocycles.[10]

Variable Electron-Donor Ability of Alkyne Ligands—Synthesis and Structure of Carbonyl(η^5-cyclopentadienyl)(η^2-1-diethylamino-1-propyne)(η^1-*p*-methylphenylketenyl)tungsten**

By *Fritz R. Kreissl,* Gabriele Reber,* and *Gerhard Müller*

Depending on the electronic requirements of the metal atom, the ketenyl ligand −C(R)=C=O in transition metal complexes is η^1-[1,2] or η^2-coordinated.[3] In both cases it characteristically exhibits pronounced electrophilicity. Consequently, electron-rich ynamines such as 1-diethylamino-1-propyne should undergo a cycloaddition reaction with the C=C or C=O double bond of the ketenyl ligand.[4] Surprisingly, however, the reaction of carbonyl(η^5-cyclopentadienyl)(*p*-methylphenylketenyl)(trimethylphosphane)tungsten **1** with the aforementioned ynamine leads via replacement of trimethylphosphane and concomitant opening of the WC_2 three-membered ring in **1** to the alky-

[**] Transition Metal-Ketene Compounds, Part 27. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Mr. *J. Riede* for assistance with the X-ray structure investigation.—Part 26: W. J. Sieber, D. Neugebauer, F. R. Kreissl, *Z. Naturforsch. B40* (1985) 1500.

neketenyl complex **2**, which, according to spectroscopic findings (IR, NMR), contains an η^1-bonded *p*-methylphenylketenyl ligand.

The ketenyl ligand in **2** ought to function as a 1e-donor, whereas the ynamine ligand should act as a 4π-electron donor, if one assumes an 18e-configuration at the tungsten atom. However, the X-ray structure analysis[5] surprisingly indicates a weaker donor action of the ynamine ligand and a stronger donor action of the ketenyl ligand. The pseudotetrahedral structure of **2** (Fig. 1) is characterized by a

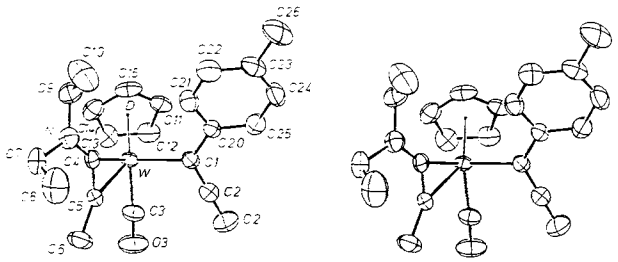

Fig. 1. Stereoplot of the molecular structure of **2** (ORTEP, thermal ellipsoids 50%, without H atoms). Important bond lengths [Å] and angles [°]: W-C1 2.171(6), W-C3 1.963(6), W-C4 2.032(6), W-C5 2.038(6), C1-C2 1.301(8), C2-O2 1.173(7), C1-C20 1.467(8), C4-C5 1.339(8), C4-N 1.354(7), N-C7 1.462(9), N-C9 1.459(8), C3-O3 1.158(7); W-C1-C2 107.3(5), W-C1-C20 129.7(4), C1-C2-O2 179.5(7), W-C3-O3 175.9(7), C20-C1-C2 122.9(6), C4-C5-C6 140.7(6), N-C4-C5 136.7(6).

short W-$C1_{ketene}$ bond (2.171(6) Å), whose length lies in the range found for W=$C_{carbene}$ bonds.[6,7] It is distinctly shorter than the W-C_{ketene} bond in the related *p*-methylphenylketenyl complex **3** (2.27(2) Å).[1]

3, R = *p*-MeC_6H_4

That the structure of **2** should be described in terms of the resonance structures **2a** and **2b** is underscored by the bond lengths C1-C2 (1.301(8) Å) and C2-O2 (1.173(7) Å), which are markedly longer and shorter, respectively, than the corresponding bonds in **3** (1.24(3) and 1.21(3) Å).[1] Moreover, the C1-C20 bond is also relatively short, and the aromatic ring is tilted by only 24.2° with respect to the W,C1,C2,C20 plane, so that an effective π-electron delocalization should be possible. The fact that the ketenyl ligand in **2** can donate more than one electron to the metal center is all the more surprising, since the planar geometry at the nitrogen atom and the interplanar angle C4,N,C7,C9/W,C4,C5 of only 7.3° in the ynamine ligand allow for optimal *p*-orbital overlap.[8]

It was hitherto usual, on the basis of an 18e-configuration for the central metal atom, to classify acetylene ligands as 2e- or 4e-donors.[9-11] It seems to us, however, that these are merely limiting cases, where the 4e-donor extreme could hardly ever be completely realized!

Experimental

A solution of **1** (0.48 g, 1 mmol) in toluene (30 mL) was treated under inert gas (argon) with 0.17 g (1.5 mmol) of 1-diethylamino-1-propyne and stirred for ca. 2 h at 25 °C. The solution slowly changed color from violet to reddish-orange. After removal of solvent, the residue was taken up in dichloromethane (10 mL); subsequent addition of pentane led to precipitation of the complex **2**. Repeated recrystallization from dichloromethane/pentane gave 0.42 g (81% yield) of the red crystals.

1,3-Diphosphacyclobutadienecobalt(I) Complexes from Phosphaalkynes**

By *Paul Binger,* Roman Milczarek, Richard Mynott, Manfred Regitz,* and *Wolfgang Rösch*

In the past few years the synthesis of a number of λ^5-1,3-diphosphetes **1** has been accomplished by dimerization steps which presumably involve participation of λ^5-phosphaalkynes.[1] In contrast, λ^3-1,3-diphosphetes ("1,3-diphosphacyclobutadienes"), which should be antiaromat-

[**] Phosphorus Compounds of Unusual Coordination, Part 11. This work was supported by the Fonds der Chemischen Industrie and the Landesregierung von Rheinland-Pfalz.—Part 10: H. Keller, G. Maas, M. Regitz, *Tetrahedron Lett. 27* (1986) 1903.

ic, have so far never been reported. They could possibly be prepared and stabilized by cyclodimerization of λ^3-phosphaalkynes such as **3** on suitable transition metal complexes. It is known, e.g., that **3**[2] forms side-on complexes with platinum[3] and can function as a bridging ligand in metal clusters.[4] We chose the cobalt complex **4**,[5] since its ethylene ligands can be replaced by alkynes and it is capable of undergoing alkyne-cyclooligomerization.[6]

When **4** is allowed to react with **3** in ether/pentane at -30°C, the monocobalt complex **5**, the dicobalt complex **6**, or the tricobalt complex **7** is obtained, depending upon the molar ratio of the reactants; **5**, **6**, and **7** are red to reddish-brown, crystalline compounds, a common feature of which is the novel λ^3-1,3-diphosphete structural unit. The complexes **6** and **7** can also be prepared by reaction of **5** and of **5** or **6**, respectively, with **4**.

The compounds **5**, **6**, and **7** gave correct elemental analyses. The molar mass of **5** was determined mass spectrometrically (*m/z* 324, 96% relative intensity). **6** and **7** are less stable: the first fragment in the case of **7** has *m/z* 572 (7%) and is formed by loss of two ethylene units.

Consistent with the structures of **5**[10] and **7**, the atoms of the four-membered ring each give rise to only one signal in the ^{31}P-NMR (**5**: $\delta = 38.1$; **7**: $\delta = 85.9$) and ^{13}C-NMR spectra (**5**: $\delta = 107.55$, t, $J(P,C) = 54.4$ Hz; **7**: $\delta = 99.38$, t, $J(P,C) = 22.1$ Hz). In contrast, the ^{31}P-NMR spectrum of **6** shows two resonance signals ($\delta = 134.9$, -32.0), the downfield signal being somewhat broadened (halfwidth 35 Hz, σ-bonded to Co). However, in the ^{13}C-NMR spectrum C-2/C-4 give rise to only one signal, a doublet of doublets [$\delta = 102.8$, $J(P,C) = 58.7$, 19.6 Hz].[7] Thus, it follows that for each phosphorus atom the bond to both former phosphaalkyne-carbon atoms in the dicobalt complex **6** must be the same. Alternative structures such as diphosphacobaltacyclopentadienes or complexes with σ- and π-bonded phosphaalkynes can therefore be ruled out. The signal multiplicities for C-2/C-4 in the ^{13}C-NMR spectra of **5** and **7** are also consistent with a diphosphete structure, but do not conclusively prove the chemical and magnetic equivalence of the two phosphorus atoms, since an ABX spin system (A, B = ^{31}P, X = ^{13}C) with a large coupling constant J_{AB} could also explain the splitting pattern.[8] (Since both phosphorus atoms would then not be directly bonded to the ^{13}C-atom, they would form an AB spin system with a very small chemical shift difference due to the isotope effect.)

Monocobalt complexes of the type **5** were also obtained from bisethylene(indenyl)cobalt and **3** or 2-methylpropylidinephosphane (**3**, $CH(CH_3)_2$ instead of $C(CH_3)_3$).[12]

Experimental

5: A solution of **3** [2] (2.0 g, 20.0 mmol) in ether/pentane (10 mL, anhydrous) was added dropwise with stirring (under argon) at -30°C to a solution of **4**[5] (1.4 g, 7.8 mmol) in ether/pentane (1:1; 20 mL, anhydrous). After stirring for one hour at -5°C, the mixture was evaporated to dryness, the crystalline residue dissolved in 10 mL of pentane (anhydrous), filtered over Florisil, and cooled to -78°C for 12 h, whereupon **5** crystallized out. The solvent was removed with a glass siphon and the crystals of **5** dried at 10^{-3} torr. Yield 1.70 g (67%) of reddish-brown crystals, m.p. 54°C.

6: As described for **5**; 0.7 g (3.7 mmol) of **4** [5] and 0.4 g (4.0 mmol) of **3** [2] furnish 0.4 g (50%) of **6** as reddish-brown crystals, m.p. 125°C (decomp.).

7: As described for **5**; 1.6 g (8.9 mmol) of **4** [5] and 0.6 g (6.0 mmol) of **3** [2] afford 0.8 g (43%) of **7** as red needles, m.p. 135°C (decomp.).

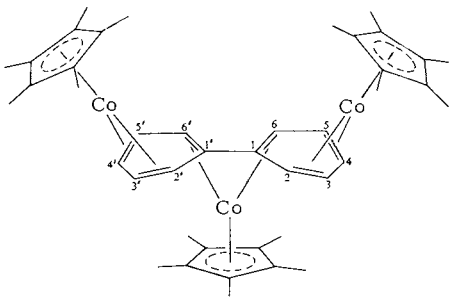
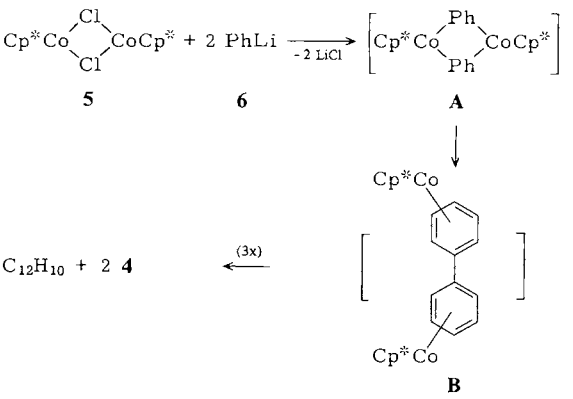
$[\{(\eta^5\text{-}C_5Me_5)Co\}_3C_{12}H_{10}]$—A Complex of Biphenyl with Kekulé Structure

By *Herbert Lehmkuhl,* Hans Nehl, Reinhard Benn,* and *Richard Mynott*



Only a few examples of transition-metal complexes with π-bonded biphenyl are known; in these compounds the biphenyl can function as a singly or, as in **1**-**3**,[1-4] as a doubly η^6-bonded ligand.

Complex **1** is obtained along with (η^6-biphenyl)tricarbonylchromium directly by heating $[Cr(CO)_6]$ with biphenyl,[1] but in the preparation of complexes **2** and **3**, the biphenyl is formed only in the course of the reaction. Compounds **2** are prepared starting from $[(\eta^6\text{-}C_6H_6)(\eta^6\text{-}C_6H_5Li)M]$ and $[(\eta^6\text{-}C_6H_6)(\eta^6\text{-}C_6H_5Br)M]$,[2,3] and compounds **3** are formed via the intermediacy of $[CpMn(C_6H_5)]$ (Cp = cyclopentadienyl).[4]



1 **2**, M = Cr, V **3**

We have now prepared a novel trinuclear metal complex, $[(Cp^*Co)_3C_{12}H_{10}]$ **4**, in which the 12-electron biphenyl ligand functions as three η^4-coordinated diene units ($Cp^* = \eta^5$-pentamethylcyclopentadienyl).

4

Complex **4** was obtained as black crystals in 69% yield along with free biphenyl upon reaction of dimeric (η^5-pentamethylcyclopentadienyl)cobalt chloride **5**[5] with phenyllithium **6**. In analogy to the formation of **3** from [CpMnPh], prepared in situ,[4] compound **5** probably reacts with PhLi in the first step to give **A** followed by reductive coupling of the two phenyl moieties to form **B**. However, in contrast to the stable complex **3**, containing the ligand η^6-coordinated to manganese, the cobalt in **B** has two additional electrons and will strive to achieve an η^4-coordination. Thus, **B** retains a free conjugated diene system, to which a third Cp*Co fragment is complexed when **B** disproportionates to form biphenyl and complex **4**.

Although it has not yet been possible to obtain suitable single crystals of **4** for an X-ray structure analysis, NMR investigations provide unequivocal confirmation of the structure shown. The ^{1}H-NMR spectrum (Table 1) exhibits five signals for the ten pairwise equivalent ligand protons (H2,2′ to H6,6′), which is in accord with a biphenyl ligand consisting of two identical phenyl moieties. In addition, two resonance signals with the intensity ratio 2:1 are observed for the methyl protons of the three Cp* groups, as expected for the suggested structure with three η^4-coordinated Cp*Co fragments, two of which are identical.

The assignment of the proton signals obtained from analysis of the chemical shifts and the H,H couplings was confirmed by observation of nuclear Overhauser effects (NOE) between the corresponding vicinal protons. On the other hand, no NOE signal enhancement was observed between the nonequivalent Cp* moieties, nor between H2 and H6′, as would have been expected if the inner diene moiety were s-*trans* (i.e., if the molecule had C_2 symmetry).[6]

The twelve pairwise equivalent C atoms of the ligand (C1,1′ to C6,6′) give rise to six ^{13}C-NMR signals (Table 1). All the C atoms are involved in the complexation. As is typical for (η^4-diene)metal systems, the terminal atoms (C2, C5, and C6) of the diene units are more strongly shielded, relative to those of noncoordinated ligands, than the inner atoms (C1, C3, and C4). Also consistent with the known properties of (η^4-diene)metal complexes is the find-

Table 1. NMR data of **4**.

[a] 400 MHz; [D$_8$]THF ($\delta \equiv 3.58$; α-H); 300 K. [b] Obscured by signals of residual [D$_8$]THF protons (β-H). [c] 75.4 MHz; [D$_8$]THF ($\delta \equiv 25.3$; β-C); 313 K. [d] The resonances C2 to C6 were assigned by transferring the ^{1}H-NMR assignment to the ^{13}C-NMR spectrum by means of a 2D ^{13}C,^{1}H-correlated spectrum. [e] Cp*′ is coordinated to the Co atom that is located above the center of the biphenyl fragment.

[*] Prof. Dr. H. Lehmkuhl, Dr. H. Nehl, Priv.-Doz. Dr. R. Benn, Dr. R. Mynott
Max-Planck-Instutut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

ing that the $^1J_{C,H}$ coupling constants for the inner atoms (C3, C4) are larger than those for the terminal atoms (C2, C5, and C6).[7] In analogy to the known CpCo(η^4-1,3-diene) compounds, we assume that each diene unit is planar[8] but that the two outer diene units are slightly bent with respect to the inner diene.[8]

The electron delocalization in **4** is essentially suppressed, which means that biphenyl in **4** is best described by a Kekulé structure. Although there are numerous examples of the reduction or suppression of the aromaticity of benzene, naphthalene, or anthracene by η^2-, η^3-, or η^4-complexation to a suitable metal complex fragment,[8-22] compound **4** is, to the best of our knowledge, the first example for the transformation of an aromatic system with 12 π-electrons into a system of three η^4-bonded dienes.

Experimental Procedure

A solution of **5** (4.9 g, 10.7 mmol) and **6** (1.8 g, 21.4 mmol) in 80 mL of ether was prepared at −80°C and then allowed to warm over several hours to 20°C. After 24 h, the ether was removed under vacuum and the residue was extracted with pentane. After filtration to remove the LiCl, the solvent was removed from the filtrate under vacuum. The remaining LiCl was removed by extraction with pentane, filtration, and removal of the pentane from the filtrate. This procedure was carried out three times. Finally, the residue was dried at 20°C/10^{-4} torr to remove the biphenyl. The residue was dissolved in 200 mL of pentane and filtered, and the filtrate was concentrated to 40 mL. Upon standing at −80°C, the concentrated solution slowly afforded **4** (3.6 g, 4.9 mmol, 69%) as black crystals. Correct elemental analysis and mass spectrum.

A Macrobicyclic Polyphenoxide as Receptor Analogue for Choline and Related Ammonium Compounds**

By *Hans-Jörg Schneider,* Detlev Güttes,* and *Ulrich Schneider*

The use of water-soluble, synthetic macrocycles as simple models for enzymes and receptors has been the focus of interest of many chemists in recent years.[1] We have now found that anions of the condensation products of resorcinol with aldehydes,[2] which have long been known and are preparable in large quantities, are by far the strongest complexing agents for methylammonium derivatives[3] discovered up to now. Interesting structural and salt effects influence the electrostatic interactions that are responsible for this behavior.

The reactions of resorcinol with aldehydes, which were already investigated by *Adolf von Baeyer*,[2a] lead, under certain conditions (for example, with acetaldehyde), to macrocyclic products such as **A**[2b-d] (Scheme 1). Their configuration and conformation has largely been elucidated for the esters (**A**, X = OOCR′ instead of OH) by means of NMR spectroscopy[2e,f] and X-ray crystallography.[2g,h] The system **A**, which was most recently studied by *Högberg*[2e] in the form of the octaacetate and octapropionate, exhibits

Scheme 1. R = CH_3, X = OH.

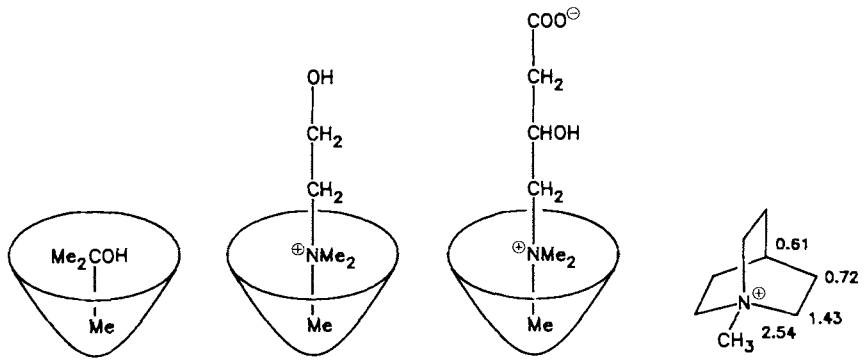
six ^{13}C-NMR and four ^{1}H-NMR signals in alkaline solution (e.g., 0.01 M **A**, 0.05 M NaOD in D_2O), besides signals for rapidly exchanging OH protons; the number and intensities of the signals are those expected for the highly symmetric host structure **H**.[4] That each of the four resorcinol units is only singly deprotonated, even with a large excess of NaOD, is confirmed by the deprotonation effect on the ^{13}C-NMR and ^{1}H-NMR chemical shifts, which are nearly the same for **A**/**H** and resorcinol. The high stability of the tetraphenoxide **H** is also reflected in the pK_a value, which is 11.4 in dimethylformamide (DMF)/H_2O (4:1) as opposed to 13.5 for resorcinol. The formation of four hydrogen bonds and the delocalization of the negative charge are responsible for the fact that even sodium methoxide is unable to deprotonate the tetraanion **H**.



By measuring the ^{1}H-NMR chemical shifts as a function of the ratio of **H** to substrate and by numerical simulation,[5] we obtained the chemical shifts of the completely complexed substrate **S** as well as the equilibrium constants K, which were converted to the corresponding $\Delta G°$ values (Scheme 2). The predominating electrostatic interactions are characterized by the marked decrease of $\Delta G°$ with increasing separation of the positive center in the substrate from the negatively charged macrocycle as well as by the small binding constants of electroneutral substances (cf. *tert*-butyl alcohol **5**).

As in the case of the electrostatically complementary complexes between cationic host and anionic guest molecules,[5] electrolytes such as NaOH (NaOD) (Scheme 2) or NaCl weaken the interactions considerably. The strong complexation of methylammonium ions such as **1** or **6** results, even at room temperature, in considerable line broadening, which, on the one hand, makes precise determinations of K difficult, but, on the other hand, allows the determination of the rate constants of dissociation, k_d, by means of line-shape analysis. The k_d value so obtained for **1**, $2000 \pm 200\ s^{-1}$, along with $K = 3 \times 10^4$ L/mol (in 0.5 N NaOD solution; in 0.01 N NaOD, $K \cong 3 \times 10^5$ L/mol), gives a rate constant of association for complex formation of $k_a \cong 10^8\ s^{-1}$, which indicates a diffusion-controlled reaction. The changes in ^{1}H-NMR shifts upon complexation, Δ (Scheme 2), are the result of ring current anisotropy and electrical field effects and support the geometry of the complexes shown in Scheme 2.

As shown by space-filling models, **H** has a relatively open, bowl-shaped structure; this explains the strong binding of **8** and the absence of strong hydrophobic or lipophilic interactions with electroneutral guest molecules such as **5**. These findings show that, *without* extensive enclosure, the electrostatic attraction between an anionic host molecule and a singly positively charged organic cation can lead to almost micromolar binding constants, even in water, taking into consideration the strong dependence of complexation on the concentration of electrolyte. The tetraphenoxide **H** is a highly effective complexing agent not only for choline derivatives such as **6** but also

	1	2	3	4
$\Delta G°$(0.5 N)	6.1	4.8	2.0	1.3

Diisopropyl(2,4,6-tri-*tert*-butylphenylimino)silane—a very Stable, Free Silaimine**

By *Michael Hesse* und *Uwe Klingebiel**

It has been known for several years that lithium salts of the aminofluorosilanes that are sufficiently sterically shielded are stable compounds, exhibiting no tendency to undergo cleavage of LiF.[1] The synthesis of a silaimine, therefore, requires a suitable salt with, for example, LiCl as leaving group. Such a LiCl elimination was recently used successfully for the preparation of a tetrahydrofuran (THF)-containing silaketimine.[2] Silaimines, moreover, have already been identified in solution at low temperature.[3]

We present here a four-step procedure for the synthesis of a stable, free silaimine. The lithium salt **2**[4] is formed in nearly quantitative yield by treatment of the aminofluorosilane **1**[5] with methyllithium; **2** is then converted into the lithiated aminochlorosilane **3**[6] by treatment with Me_3SiCl. Owing to the synthetic procedure used, **3** crystallizes as the THF adduct;[7] its ^{29}Si-NMR signal is shifted to high field with respect to $(CH_3)_4Si$ as expected for such lithium salts. These lithium salts react with carbonyl compounds and dienes as well as with unsaturated compounds.[8] In the field desorption mass spectrum of **3**, the molecular peak of the silaimine **4** is observed.

When **3** is heated in a vacuum at 0.01 mbar, it loses THF, and the silaimine **4**[9] sublimes at a bath temperature of approximately 80 °C. **4** is an orange, crystalline solid, which melts without decomposition to give a deep red liquid. This stability is due to the good steric shielding of the Si=N bond. Neither in solution nor as a solid does **4** exhibit the often common tendency to undergo dimerization.[10] However, **4** is very sensitive to water and air. The strongly low-field-shifted ^{29}Si-NMR resonance of **4** at $\delta = 60.3$ is significant for unsaturated silicon compounds. Thus, in contrast to the recently described THF-containing silaketimine,[2] **4** fits easily into the series of known silaethenes[11] and disilenes.[12] **4** is analytically pure and its structure is in agreement with the mass of $M^{\oplus}$ in the high-resolution mass spectrum. The large coupling constant, $^1J_{CC} = 58$ Hz, of the isopropyl substituents on silicon is further evidence of bonding to an sp^2-hybridized atom.

Experimental Procedure

$LiNHC_6H_2(CMe_3)_3$ (5.35 g, 0.02 mol) in 50 mL of THF/*n*-hexane was added quickly to 3.05 g (0.02 mol) of $(Me_2CH)_2SiF_2$. The reaction was followed by ^{19}F-NMR spectroscopy and was complete after 2 h. After purification by distillation, **1** (3.95 g, 0.01 mol) was lithiated with MeLi in diethyl ether. **2** was characterized by NMR spectroscopy and then treated with 50 mL of THF. The isolation of **2** was thereby circumvented. Immediately after addition of 1.09 g (0.01 mol) of Me_3SiCl, the signal of Me_3SiF ($\delta = 4.7$) was observed in the ^{19}F-NMR spectrum. The reaction was complete after 1 h. **3** was isolated and characterized as a crystalline THF adduct. Heating **3** at 0.01 mbar to approximately 80 °C results in loss of THF and LiCl and the sublimation of **4**. Compound **4** was purified by crystallization from *n*-hexane. The NMR spectra of **1**–**4** were recorded on a 250-MHz instrument.

Benzotri(imidazole)—a New Ring System Derived from Benzenehexamine**

By *Bernd Kohne, Klaus Praefcke,* Thomas Derz, Thomas Gondro,* and *Felix Frolow*

Recently, two research groups[1,2] reported the "rediscovery" of benzenehexamine **1**, a polyfunctional building block that was first reported over 50 years ago.[3] **1** has in the meantime become readily available[4] and has been used for the syntheses of new heteropolycycles (derivatives of a hexaazacoronene[1,5] and a hexaazatriphenylene[2]). We have now found that the ring-closure reaction for the synthesis of benzimidazole derivatives—condensation of, for example, carboxylic acids with 1,2-benzenediamine[6]—can be carried out three times with **1**. Condensation with, for example, hexanoic acid **2c** results in formation of the tripentyl derivative **3c** of the benzotri(imidazole) ring system, which has not been described previously.

The condensation steps leading to the formation of the symmetric, trigonal compounds **3** can take place either simultaneously or in an alternating fashion; in the latter case, the intermediate, unsymmetric analogue of **3** must undergo tautomerism in one imidazole segment.[7]

According to the elemental analysis, **3c** crystallizes with water in a molar ratio of 1 : 2. The crystals melt over a wide temperature range (138–154°C). According to the thermoanalysis,[4] **3c** has two sharp transition points (endothermic); the light yellow, highly viscous, glasslike melt does not undergo crystallization after cooling to room temperature, even after standing for several weeks.

a, R = CH_3; **b**, R = C_2H_5; **c**, R = C_5H_{11}

The mass spectrum of **3c**[4] exhibits, among other peaks, a very intense molecular ion peak ($C_{24}H_{36}N_6$, *m/z* 408) and a base peak at *m/z* 352 (β-cleavage of one side chain). A characteristic feature of the ^{1}H-NMR spectrum[4] is a very broad signal at δ = 12.64 (imino protons,[8] which are apparently strongly deshielded by the formation of hydrogen bonds). The ^{13}C-NMR spectrum[4] exhibits one singlet for the six central carbon atoms (δ = 123.20) and one for the three peripheral ring carbon atoms (δ = 150.44). The analytical and spectroscopic data are in accord with the results of an X-ray structure analysis[9] (Fig. 1).

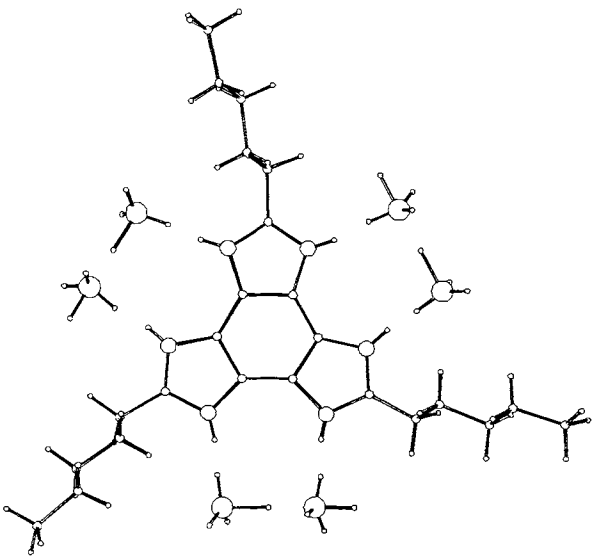

Fig. 1. Crystal structure of **3c**·2 H_2O [9]. The structure shows the disorder in the imidazole rings, resulting from tautomerism, and the statistical disorder of the hydrogen atoms of water.

The molecule has crystallographic C_3 symmetry. The thermal motions of the aliphatic side chains are large and increase toward the end of the chains. The N1–C2 and N3–C2 distances (1.33 and 1.34 Å, respectively) show that two tautomers are present in the crystal; this is supported by the presence of two hydrogen atoms with population parameters of 0.5 bonded to the nitrogen atoms (difference Fourier analysis). The central six-membered ring and the imidazole rings are nearly planar, with a deviation of 0.01 Å. The angles between the six-membered ring and the imidazole rings and between the imidazole rings themselves are 2 and 4°, respectively. The line joining the first

and the last carbon atom of the alkyl chains is at an angle of 118° to the plane of an imidazole ring. The molecule thus has a bowl or crown shape in the crystal. Each molecule of **3c** is surrounded in the crystal by six molecules of H_2O (water clathrate), which in turn each lie on a threefold symmetry axis and thus form hydrogen bonds both among themselves and with the nitrogen atoms of three molecules of **3c**.

Knaggs, *Proc. R. Soc. London, Ser. A 131* (1931) 612; c) H. J. Backer, S. van der Baan, *Recl. Trav. Chim. Pays-Bas 56* (1937) 1175.

[4] *Experimental procedure:* **3c**: Bright yellow 2,4,6-trinitro-1,3,5-benzenetriamine [2] (3.1 g, 12 mmol) in 150 mL of freshly distilled ethyl acetate was hydrogenated in a shaking flask for approximately 80 h at room temperature (approximately 4–5 bar H_2—cf. [1]—catalyst: 450 mg of 10% Pd/active carbon). The suspension, which contains **1**,—upon complete hydrogenation, the solvent is colorless—was evaporated first under water-aspirator vacuum and then under oil-pump vacuum to remove the ethyl acetate and the water of reaction. The Pd/active carbon-containing residue reacted with 11.6 g (0.1 mol) of hexanoic acid **2c** in 1 h at 160°C under pure nitrogen to give, after workup (dissolving in ether, neutralization with aqueous potassium hydroxide solution, washing with water, etc.), approximately 3.0 g of a reddish brown crude product. Column chromatography on silica gel with chloroform/methanol (50 + 1) afforded 45 mg (8.4%) of a yellow solid; purification by HPLC (Knauer HPLC pump 64 equipped with variable wavelength detector, $\lambda = 254$ nm; reversed phase column; $l = 250$ mm, $d = 16$ mm, Polygosil 10 μm; methanol: 40 mL/min) and recrystallization from ethyl acetate afforded 327 mg (6.1%, both yields are based on the trinitrobenzenetriamine) of pure **3c**·2 H_2O as yellowish needles [7]. Melting range 138–154°C (Leitz Laborlux 12 Pol polarization microscope with a Mettler hot stage FP 2); thermoanalysis (Mettler system TA 3000): two sharp phase transitions: 1) 144.9°C ($\Delta H = 42.7$ kJ/mol) and 2) 162.4°C ($\Delta H = 30.6$ kJ/mol).—^{1}H-NMR ($(CD_3)_2SO$, 270 MHz): $\delta = 0.85$ (t, CH_3), 1.2–1.45 (m, γ- and δ-CH_2), 1.8 (quin., β-CH_2), 2.83 (t, α-CH_2), 12.64 (s, very broad, N-H).—$^{13}C\{^1H\}$-NMR ($(CD_3)_2SO$, 20 MHz): $\delta = 13.85$, 21.88, 27.78, 28.46, and 30.86 (aliph.), 123.20 (s, central aromat.), 150.44 (s, peripheral aromat.). MS: *m/z* 408 ($M^{\oplus}$, 82%), 379 ($M^{\oplus} - C_2H_5$, 14), 365 ($M^{\oplus} - C_3H_7$, 36), 352 ($M^{\oplus} - C_4H_8$, 100), ≤350 no further peaks >10%.—A correct elemental analysis was obtained for $C_{24}H_{36}N_6 \cdot 2H_2O$.

[9] Cubic, space group $P2_13$, $a = 13.956(1)$ Å, $V = 2718.2(3)$ Å^3, $\rho_{calcd} = 1.067$ g·cm^{-3}, 3176 measured, 1062 independent and 1047 observed reflections, $R = 0.029$, $R_w = 0.031$. The measurement was carried out at 85°K with an Enraf-Nonius CAD-4 diffractometer ($Cu_{K\alpha}$ radiation, $\lambda = 1.5418$ Å). The structure solution was achieved by direct determination of the phases. All atoms except hydrogen were refined anisotropically. The hydrogen atoms were placed at newly calculated ideal positions after each refinement. All calculations were carried out with the SHELX program (G. M. Sheldrick: *SHELX 76 A Program for Crystal Structure Determination*, University Cambridge, England 1976). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD 51927, the names of the authors, and the journal citation.

Si_6H_6: Is the Aromatic Structure the Most Stable One?

By *Alexander Sax* and *Rudolf Janoschek**

The theoretical predictions prior to the first synthesis of a compound containing a Si=Si bond[1] encouraged theoretical chemists to study other, still unknown silicon compounds, especially those whose carbon analogues are known. Studies of silaaromaticity, which has long been a subject of theoretical speculation,[2] have regained importance since the discovery of the Si=Si bond.[3] Prior to 1981, a series of theoretical studies predicted the existence of a stable Si=Si bond:[4] the disilene molecule, H_2SiSiH_2, should be effectively planar, with a SiSi bond length of 215 pm and a π-bond energy of approximately 125 kJ mol^{-1}. The first synthesis of a compound containing this new double bond was then achieved[1]—despite the double-bond rule—and X-ray diffraction experiments confirmed the calculated structure.[5] Further calculations on Si_2H_4 also confirmed the known properties of the Si=Si bond and showed, in addition, that the silanediyl(silylene) structure, $HSiSiH_3$, is nearly isoenergetic with the ethylene-like structure.[6]

Theoretical studies of silaaromatic structures were restricted until now to silabenzene C_5SiH_6 and 1,4-disilabenzene $C_4Si_2H_6$; reliable theoretical predictions[7] and experimental confirmation[8] occurred more or less simultaneously. Only recently was a silaaromatic structure in pure form investigated for the first time:[9] for the system with the overall formula Si_6H_6, detailed quantum chemical calculations have given three stable isomers so far (Fig. 1), taking only the valence electrons into consideration. A set of three s- and three p-functions was employed for the val-

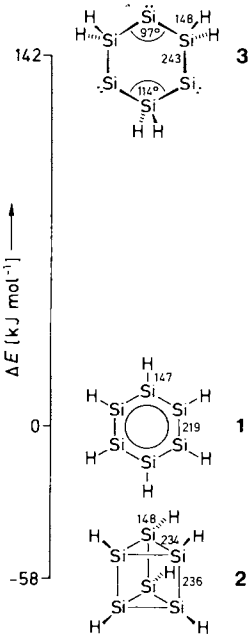

Fig. 1. Relative stabilities of three Si_6H_6 isomers; bond lengths in pm. For comparison with C_6H_6: prismane lies 543 kJ mol^{-1} higher in energy than benzene.

[*] Prof. Dr. R. Janoschek, Dr. A. Sax

Mozartgasse 14, A-8010 Graz (Austria)

ence shell of the Si atom (3s/3p); for those of the H atoms, a set of three s-functions was used. This basis set was extended with d-functions for the Si atoms and p-functions for the H atoms. The two lowest energy isomers were identified by calculation of the corresponding complete sets of vibrational frequencies as minima on the Si_6H_6 energy hypersurface.

Hexasilabenzene **1** should be planar (D_{6h} symmetry) with a SiSi bond length of 219 pm, which lies between those of disilane (236 pm) and disilene (215 pm) (analogous to C_2H_6, C_6H_6, C_2H_4). The extremely low wave number of 60 cm^{-1} was obtained for the ring-puckering vibration, so that a nonplanar molecule would almost be energetically equivalent. The stability of **1** with respect to alternation of the SiSi bonds (D_{3h} symmetry) is revealed in the relatively high harmonic vibrational frequency of 580 cm^{-1}.[*] In hexasilaprismane **2** (D_{3h} symmetry), the SiSi bond lengths in the three-membered rings (234 pm) are only marginally smaller than the SiSi bond lengths between the two three-membered rings (236 pm). In view of the isoenergetic structures H_2SiSiH_2 and $HSiSiH_3$, **3** would be an interesting candidate for an isomer that might be energetically comparable to **1**. For **3**, a relatively long SiSi bond length was found (243 pm), similar to that in $HSiSiH_3$. Other isomers, such as hexasila Dewar benzene, hexasilabenzvalene, and hexasilaoctahedrane are higher in energy according to preliminary calculations.

The pronounced difference between the structures of Si_6H_6 and C_6H_6 is revealed in the relative stabilities of the isomers **1** and **2**. Whereas benzene is by far the most stable form for C_6H_6, hexasilaprismane is the most stable isomer for Si_6H_6. Taking into consideration electron correlation does not change the energetic ordering of the isomers **1** and **2**. A qualitatively similar result was obtained by means of a theoretically less rigorous procedure.[11] Not the differences in ring strain energies of prismane and hexasilaprismane (606[12] and 418 kJ mol^{-1}, respectively) but rather the energy differences between sp^2- and sp^3-hybridized C and Si atoms are the essential causes of the differences in stability. The "resonance stabilization" of the π-electrons is only 30% smaller for hexasilabenzene (84 kJ mol^{-1}) than for benzene, the estimate being based on the following homodesmotic reaction:

$$Si_6H_6 + 3\,H_2Si{=}SiH_2 \longrightarrow 3\,H_2Si{=}SiH{-}SiH{=}SiH_2$$

This fact, together with the greater stability of hexasilaprismane, demonstrates once again how little aromaticity has to do with the resonance stabilization of a magic π-electron sextet. Crucial for the marked stability of the planar six-membered carbon ring is instead the energetic preference for sp^2-hybridized compared with sp^3-hybridized C atoms, both in bonding of the C atoms among themselves and in bonding to the H atoms. In the case of silicon, such a preference is absent.[13]

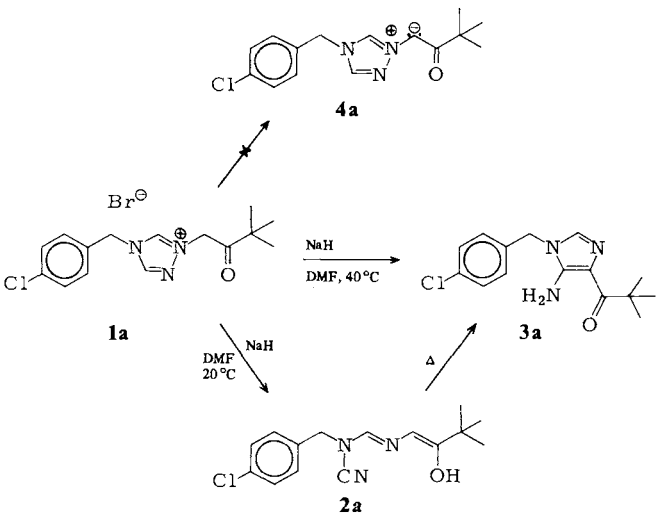
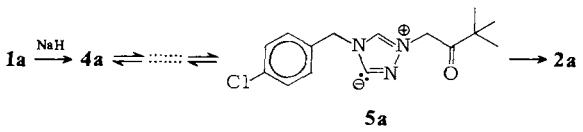
Rearrangement of 4*H*-1,2,4-Triazolium Salts to 4-Acyl-5-aminoimidazoles



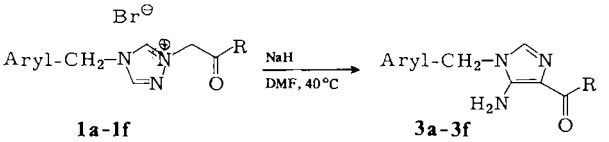
By *Costin N. Rentzea**

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday



The stable *N*-ylides[1] of *as*-triazoles[1,2] or *s*-triazoles[3] that are required for 1,3-dipolar cycloadditions are usually prepared from phenacyltriazolium salts with ammonia or amines in water, C_6H_6, CH_2Cl_2, or $CHCl_3$ at room temperature.[1-3] The attempt to generate the triazolium ylide **4a** from the *as*-triazolium salt **1a**[4] with NaH in dimethylformamide (DMF), however, led to a surprising result: instead of the expected reaction, the rearrangement of **1a** to 5-amino-1-*p*-chlorobenzyl-4-pivaloylimidazole **3a** was observed to take place at 40 °C in 25% yield.

At 20 °C, the *N*-cyanoformamidine **2a** (m.p. = 120 °C) could be isolated in 35% yield; it is present mainly in the enol form. After short heating to 120 °C, **2a** affords a quantitative yield of the Thorpe product[5] **3a** (*5-exo-dig*-cyclization[6]). Under the reaction conditions for **1a** → **3a**, it is possible that an equilibrium exists between the ylide **4a** and the dipole **5a**, which is formed by deprotonation of **1a** on C-3 of the triazole ring; on account of the facile ring opening[7] of **5a** to give the cyanoformamidine **2a**, the



[*] Dr. C. N. Rentzea
BASF Aktiengesellschaft, Hauptlaboratorium
D-6700 Ludwigshafen (FRG)

equilibrium would be continuously driven to the right. However, the direct deprotonation of **1a** to **5a**, followed by the ring-opening to **2a** is more plausible, since analogous deprotonations of cyclic =N–CH=N–N= systems with cleavage to a >N–CN derivative are known.[7]

The reaction **1a** → **3a** can be generalized: At 40°C, the triazolium salts **1a–1f** undergo direct rearrangement to the new aminoimidazoles **3a–3f** in yields of 20–60% (not optimized) (see Table 1).[8]

The novel rearrangement of 4*H*-1,2,4-triazolium salts reported herein makes possible a simple synthesis of 4-acyl-5-aminoimidazoles from readily accessible starting materials. 4-Acetyl-5-amino-1-methylimidazole[10] was previously synthesized, for example, by saponification of 6,9-dimethylpurine 1-oxide.

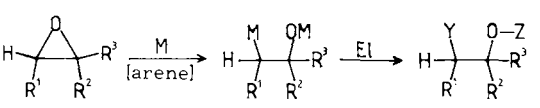
Organometallic Derivatives of Epoxides**



By *Ekkehard Bartmann**

Dedicated to Professor Rudolf Gompper on the occasion of his 60th birthday

Organometallic compounds RM, e.g. with M = Li, Mg, can be formed not only by the usual insertion of a metal atom into a carbon–halogen bond, but also by the cleavage of bonds between carbon and other leaving groups (even of less reactive bonds like those of ethers and amines).[1] It is especially remarkable, however, that in the case of such a reactive and frequently applied class of compounds as the epoxides no analogous reaction—with formation of β-metalated alkoxides **1**—has so far been reported in the literature,[2] except for a few specific systems with stabilizing substituents.[3]

The majority of these synthetically interesting organometallic compounds are stable only at low temperature and could be obtained by *Barluenga* et al. only via organomercury compounds or via β-chlorohydrins.[4]

[**] Experimental assistance: *Angelika Bartmann, Frauke Ettl,* and *Jutta Rausch.*

Although we have so far been unable to accomplish the direct conversion of epoxides into **1** at low temperatures with the metals themselves (even with highly activated forms[5]), we have had success on using the radical anion salts of aromatic hydrocarbons.[6] Table 1 contains the results of some of our experiments.

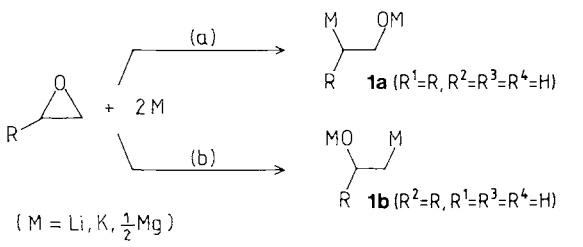

Table 1. Overview of the β-metallo-alkoxides **1** that have been prepared, and their reactions with electrophiles [d].

[a] Yield determined gas-chromatographically; [b] see 16; [c] metalation with addition of LiBr (equimolar amounts); [d] bi = biphenyl, na = naphthalene.

Thus, cyclohexene oxide (No. 8 and 9) is smoothly converted at −80 to −90°C by biphenyl- or naphthalene-lithium in tetrahydrofuran (THF) into the β-lithiated cyclohexanolate. Formally, two asymmetric centers are formed. The subsequent deuteration, however, is not stereoselective: according to the ^{13}C-NMR spectrum, *cis*- and *trans*-[2-D]cyclohexanol are obtained in the ratio of about 1 : 1.[7] On the other hand, with a more bulky electrophile such as diphenyl sulfide, apparently only the *trans* compound[8] is formed.

The regioselectivity of the ring opening can be investigated with the monosubstituted epoxides, since the two C–O bonds are now different (see Scheme 1). In all the experiments carried out so far, only one product could be detected: if the substituent is a phenyl or ester group, then only the neighboring C–O bond is cleaved (route (a));[9] this indicates a stabilizing effect of the substituents already during the formation of the carbanion.[10] Not only the lithium compounds but also the corresponding potassium compounds are accessible from these epoxides.

Scheme 1.

If, on the other hand, the substituent is an alkyl group, then exclusively the more distant C–O bond will be cleaved (route (b)): the formal primary alkyl anion thus formed is more stable than a secondary "alkyl anion" expected to be formed via route (a).[10] These epoxides readily undergo side reactions, which greatly reduces the yields of **1**.[11] A better yield is obtained by addition of lithium bromide (No. 1 and 2) or if naphthalenemagnesium[12] is used as metalating agent (No. 5 and 6).

Preparatively useful secondary reactions of **1** are naturally not limited to the derivatizations listed in Table 1:[13] In the reactions of these bifunctional anionic compounds with bifunctional electrophiles there emerges a novel ring expansion reaction of epoxides (see No. 13 as preliminary example).

[6] In the meantime this reaction has also been detected by *T. Cohen* et al.: T. Cohen, private communication, Pittsburgh.
[7] Two triplets of equal intensity appear at $\delta = 35.01$, 35.06 (rel. to TMS) for the deuterated C-atoms in the $^{13}C\{^1H\}$-NMR spectrum (in $CDCl_3$).
[8] ^1H-NMR (400 MHz, $CDCl_3$): $\delta = 1.15$–1.50 (m, 4H), 1.55–1.9 (m, 2H), 2.11 (mc, 2H), 2.78 (td, 1H), 3.33 (td, 1H), 7.2–7.4 (m, 3H), 7.4–7.6 (m, 2H).
[9] This regioselectivity was also observed (with other metalating reagents) in the cases described in the literature [3].
[10] Here, as in the cleavage of other carbon-heteroatom bonds,
$R{-}X \xrightarrow{+e^\ominus} R^\ominus + X^\ominus \xrightarrow{+e^\ominus} R^\ominus + X^\ominus$
the product might be formed in the second, non-rate-determining step. Important for the regioselectivity is that C–X bonds in general are more easily cleaved the more the C-atom is substituted. This, of course, is related to the stability of the radicals formed as intermediates[14]. The opposite regioselectivity in the case of alkyl epoxides, on the other hand, correlates with the ability of the respective C–O bond (i.e. its σ* orbital) to accept electrons, or in other words with the tendency of formation of the respective radical anion, which should be similarly influenced by substituents as the stability of the final product. In the case of acceptor- or phenyl-substituted systems a transfer of electrons into π*-orbitals of these substituents must also be taken into consideration.
[11] **1**: A solution of the epoxide (50 mmol) in THF (20 mL) is introduced within ca. 30 min by means of a syringe into the immediate neighborhood of the stirring bar in a vigorously stirred (magnetic stirrer) solution of biphenyllithium (prepared from 0.75 g (108 mmol) of lithium and 15.4 g (100 mmol) of biphenyl in 200 mL of THF [15]) at ca. −90°C. After stirring at −80°C for one hour a solution of the electrophile (quantity as calculated for reaction with **1**; in the case of H_2O and D_2O in large excess) in 20 mL THF was added dropwise to the solution, which was then warmed to RT and worked-up in the usual way by distillation or chromatography.
[12] Prepared by reaction of naphthalenepotassium [15] with magnesium bromide in THF at −70°C.
[13] For reactions of **1** with other electrophiles, especially carbonyl compounds, see [4].

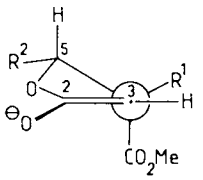
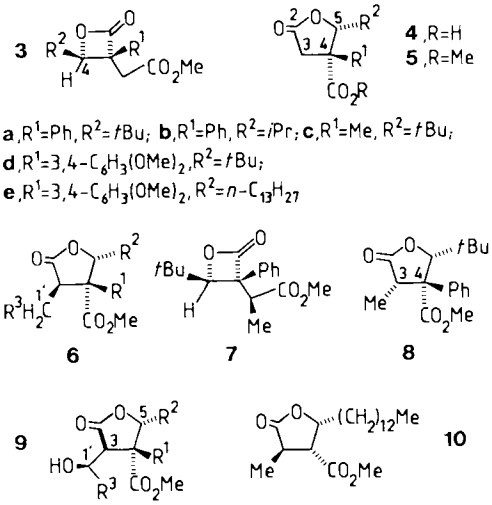
[16] The formation of the alcohol by side reactions prior to the protonation of **1** with H_2O can be ruled out. If addition of water takes place after warming to RT, the alcohol is detectable only in traces; in its place, olefin (elimination of metal oxide from **1** at temperatures above −70°C [4]) is formed.



Stereocontrolled Synthesis of Paraconates from β-Lactones; Stereochemistry of Electrophilic Additions to Endocyclic Paraconate-Enolates**

By *Johann Mulzer** and *Alexander Chucholowski*

The diastereoselectivity of electrophilic additions to ester-enolates of type **1** was recently a subject of intensive study; from the results it was concluded that a perpendicularly oriented *electron-donating* substituent Z directs the attack of an electrophile to the opposite face of the double bond.[1] The informational value of the experiments described in the literature, however, was considerably impaired by the conformational mobility of the systems and the undefined (*E*)/(*Z*) geometry of the enolates. In addition, the *syn*-directing influence of a perpendicularly oriented electron-withdrawing substituent Z also had to be demonstrated in order to support the postulated stereoelectronic effect. It occurred to us that the paraconate-enolates **2** would be suitable model systems for this purpose. Here, *Z* is the inductive electron-withdrawing CO_2CH_3 group; it is fixed perpendicularly to the rest of the molecule, such that the molecule as a whole assumes an envelope conformation with equatorial R^2.[2] The residue R^1 provides for unambiguous formation of the endocyclic (*Z*)-configurated enolate.



1

2

The paraconic acids **4** required for the generation of **2** were obtained diastereomerically pure by acid-catalyzed (conc. hydrochloric acid, dioxane, 120°C, 4 h) isomerization of the β-lactones **3**.[3] The driving force behind the isomerization, which proceeds with retention of configuration at C-4, is the release of strain in the four-membered ring. During the rearrangement, the orientation of the R^1/R^2 pair changes from the *cis*-vicinal to *trans*-vicinal, which in the case of R^1 = aryl is indicated by a downfield shift of the ^{1}H-NMR signals of protons in R^2 by ca. 0.3 ppm.[4] The esters **5**, obtained from **4** by reaction with diazomethane (Et_2O, 25°C), were converted with S_N2-active alkyl halides R^3CH_2X in the presence of hexamethylphosphoric triamide (HMPT) into the ^{1}H-NMR pure (>95%) products **6** (Table 1), via the enolates **2** (lithium diisopropylamide) (LDA), tetrahydrofuran (THF), −78°C).

We clarified the steric course of the methylation by unambiguous synthesis of the derivative **8**, which is 3-epimeric with **6a**. The enolate generated from **3a** (LDA, THF, −78°C) adds methyl iodide diastereoselectively to give **7**,[5] which can be isomerized to **8** in an analogous way to **3a–3f**. The ^{1}H-NMR signal of the methyl group in position 3 is characteristically different in the case of **6a** ($\delta = 0.73$) and **8** ($\delta = 1.13$); the values suggest *cis*- and *trans*-arrangements of 3-Me and 4-Ph, respectively. In a similar way, the 1′-CH_2 signals in **6b–6h** are clearly shifted upfield compared to their "normal position"[6] (Table 1).

[a] Correct elemental analyses were obtained for **6a–6h**.

In the reaction of **2** with aldehydes (R^3CHO) (Table 2), it is also clear that the 4-CO_2CH_3 group promotes a *trans* attack of the electrophile. That is, the adducts **9** do not close the second lactone ring, as is inevitable in the case of a *cis* arrangement;[5,7] this follows from the elemental analysis and the position of the ^{1}H-NMR signals of 1′-H, which are shifted ca. 1.7 ppm upfield compared to those of 5-H. The exocyclic chirality center is also configurationally uniform when R^3 = *i*Pr and Ph; on the basis of the small ^{1}H-NMR coupling constants $J_{3,1'} = 1.9$–4.3 Hz, a "*syn*" conformation can be assumed.[8] When R^3 = Me, both "*syn*" and "*anti*"-**9** are formed (**9c**: *syn*/*anti* = 77/23; **9g**: 69/31).

The diastereoselective formation of **6** and **9** from **2** can be explained in terms of the sum of the steric effects of the

substituents R^1, R^2 and CO_2CH_3; the attack is directed to the overall less-shielded ring plane. R^1 and R^2 are equatorial, and thus will contribute only slightly and almost compensatingly to the stereodifferentiation.[9] This is due, in the first place, to the influence of the 4-CO_2CH_3 group, which is clearly *anti*-directing. To postulate a *syn*-control on the basis of a stereoelectronic effect, as a logical consequence of what has been quoted in the literature,[1] is not defensible. The experiments described here, apart from being mechanistically informative, are also of preparative interest and open up a short, three-stereocenter-controlling entry to paraconic acids.[10] **6h** has been prepared as a 4-aryl derivative of the nephromopsinic acid methyl ester **10**.[11]

Isomorphism of Tris(cyclopentadienyl)lutetium(III) and Tris(cyclopentadienyl)scandium(III): An Unexpected Consequence of the Lanthanoid Contraction**

By *Stefan H. Eggers, Holger Schultze, Jürgen Kopf,* and *R. Dieter Fischer**

Dedicated to Professor Erwin Weiss on the occasion of his 60th birthday

It is known[1] that the "total hapticity" $\sum_i \eta_i^n$ of all four Cp ligands in the series of complexes Cp_4M **1** ($Cp=C_5H_5$) first passes through a maximum[2] in the case of **1b**, viz: **1a** 12, **1b** 16, **1c** 12. The drastic drop in the "total hapticity" in going from **1b** to **1c** is likely to result in part from the lanthanoid contraction, and in part from a theoretically well understood[6a] preference of the frequently formed[6b] complex type $[(\eta^5\text{-Cp})_2M(\eta^1\text{-X})_2]$ (M = transition metal, X = e.g. halide, pseudohalide, alkyl etc.). The occurrence of analogous changes in structure and hapticity is to be expected in related series of complexes.

Cp_4M **1**
a, M = Ti[3], **b**, M = Zr[4], **c**, M = Hf[5]

Indeed, within the series Cp_3M **2** (M = Sc, Ti, Y, La–Lu) where the "total hapticity" reaches a maximum of 17 for the structure type A ($[(\eta^5\text{-Cp})_2M(\mu\text{-}\eta^5:\eta^2\text{-Cp})]_\infty$) with M = La[7] and Pr,[8] this quantity decreases again, as we have now found for M = Lu (**2a**), to the minimum value of 12 as already observed for **2b** and **2c**.[12]

Cp_3M **2**
a, M = Lu[9], **b**, M = Sc[10], **c**, M = Ti[11], **d**, M = Tm, **e**, M = Yb

A single-crystal X-ray structure analysis of **2a**[13] confirms that here, as in the crystal of **2b**,[10] polymeric zig-zag chains of type B $[(\eta^5\text{-Cp})_2M(\mu\text{-}\eta^1:\eta^1\text{-Cp})]_\infty$ are present (Fig. 1).

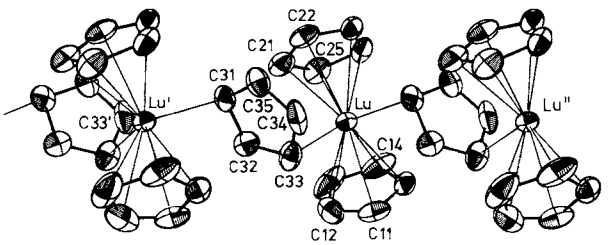

Fig. 1. ORTEP diagram of the structure of **2a** in the crystal. Selected bond lengths [Å] and angles [°]: Lu-Cent1 2.285, Lu-Cent2 2.321, Lu-Cent3 3.116, C31-C32 1.447(16), C32-C33 1.405(20), C33-C34 1.443(21), C34-C35 1.379(20), C31-C35 1.448(20), Lu-Lu' 6.163; C31-Lu'-C33' 89.0(8), Lu'-Lu-Lu'' 107.7 [25].

The structure of **2a** differs, on the other hand, from those of **2d** and Cp_3Er, whose crystals contain practically non-associated $(\eta^5\text{-Cp})_3M$ molecules ("total hapticity" 15, type C).[14]

The LuC distances found for the η^5-coordinated Cp rings (mean value 2.602 Å) and the cent1-Lu-cent2 angle (126.9(8)°) (cent = centroid of an η^5-coordinated Cp ring) resemble the corresponding data for the complex systems $[(\eta^5\text{-Cp})_2LuR(thf)]$ ($R=C(CH_3)_3$, $CH_2Si(CH_3)_3$, C_6H_4-4-CH_3, (thf) = tetrahydrofuran). Unlike in the polymers of type A[7,8] and in **2b**, the two shortest[16] LuC distances for the bridging Cp ring (Lu'-C31 2.519, Lu-C33 2.654 Å) are only slightly shorter and longer, respectively, than the two extreme $LuC(\eta^5\text{-Cp})$ contacts (Lu-C14 2.542 and Lu-C25 2.648 Å). The Lu'-C31 contact exceeds the longest hitherto known length of a LuC σ-bond (2.47 Å[15a]). The Lu'-C31 and Lu-C33 vectors form angles of 66.5 and 79.9° (**2b**: 61 and 73°,[10] respectively; **1b**: 49°[4b]) with the μ-Cp plane,

[**] Coordination Behavior in Base-Free Tris(cyclopentadienyl)lanthanoid(III) Compounds, Part 3. We thank Prof. *H.-D. Amberger* for supplying us with a sample of **4**. – Part 2: [7].

and the spatial arrangement of the μ-Cp ligands in **2a** and **2b** resembles that in the main group metal complex $[(\eta^1\text{-Cp})_2\text{In}(\mu\text{-}\eta^1\text{:}\eta^1\text{-Cp})]_\infty$.[17] The practically non-alternating C-C distances in the μ-Cp ligand (cf. Fig. 1) essentially rule out a diene character of this ligand.

Interestingly, the enthalpy of sublimation ΔH_{subl} of **2a** markedly exceeds the ΔH_{subl} values of the Cp_3M compounds with M = Y and Tb–Yb.[18] A further consequence of the comparatively strong self-association of **2a** is its noticeably sparing solubility in toluene, CH_2Cl_2 and THF, compared to that of **2e**,[19] which even facilitates the separation of Yb and Lu via their base-free triscyclopentadienyl complexes.—The temperature-dependent ^{1}H-NMR spectra of **2a** in CD_2Cl_2 and [D$_8$]toluene in the resonance range $\delta = 5.5$–6.5 (cf. Fig. 2) indicate the presence of at least one dissolved species with non-equivalent Cp ligands.[20]

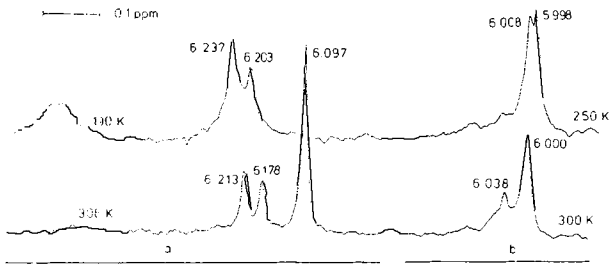

Fig. 2. ^{1}H-NMR spectra of **2a** in CD_2Cl_2 (a) and [D$_8$]toluene (b) at two temperatures (Bruker WP-80).

The difference $\Delta\{M\text{–}C(\eta^5\text{-Cp})\}$ in the MC distances (for the η^5-coordinated Cp rings in the case of **2a** and **2b**, mean value: 0.112 Å) correlates well with the difference in the metal-ion radii ($\Delta r(M^{3\oplus}) = 0.107$ Å[21]), while the corresponding MC distances for the μ-coordinated Cp ring (of **2a** and **2b**) are practically the same ($\Delta\{M'\text{-C31}\}$: 0.00 Å; $\Delta\{M\text{-C33}\}$: 0.025 Å). Hence, the MC(μ-Cp) distances in **2b** turn out to be relatively long, which feature might, in the first instance, be due to stronger interligand interactions in the coordination sphere of the smaller Sc^{III} ion.[22] Nevertheless, in view of the X-ray crystallographically confirmed existence of complexes of the type $[(\eta^5\text{-Cp})_3\text{Lu}\cdot\text{L}]$ with a "total hapticity" of 16, the observed isomorphism of **2a** and **2b** is completely unexpected.[23] The comparatively close relationship of Lu (instead of La) with Sc and Y, and the consequently more meaningful location of Lu in Group 3A of the Periodic System has, however, been hinted at on a number of earlier occasions.[24]

Remarks on the Review Article "Replication and Evolution in Inorganic Systems" by *Armin Weiss*[1]

By *Gustaf Arrhenius*,* *Alexander G. Cairns-Smith*,* *Hyman Hartman*,* *Stanley L. Miller*,* and *Leslie E. Orgel**

Professor *Armin Weiss* in a paper published in 1981 in *Angewandte Chemie* has claimed observations with potential importance for the origin and early evolution of life.[1] This paper has been widely cited since it claimed experimental proof of clay mineral replication, mutational variability in replicating clay crystals, and specific catalytic effects. The results have been invoked in support of the idea that an inorganic evolution through natural selection preceded the evolution of organic life.

The information given in the Weiss 1981 paper is altogether inadequate for others to repeat the key experiments that are said to be "proof of replication". A single reference in this section reads: "Unpublished results: published in part in *G. Mai*, Dissertation, Universität München 1969; *P. Brunner*, ibid. 1978; *S. Fritz*, ibid. 1978".

We have been unable to trace the first and third of these theses, while the second contains nothing which we consider of special relevance to clay replication. Nor have repeated attempts to obtain experimental protocol from Professor *Armin Weiss* been successful.

We now ask Professor *Armin Weiss* to provide us a published account of the procedures used to obtain the important results reported in his 1981 paper so that they can be confirmed or disproved. In the meantime, his conclusions should be accepted with caution.

BOOK REVIEWS

Applications of Dynamic NMR Spectroscopy to Organic Chemistry. By *M. Oki*. VCH Verlagsgesellschaft, Weinheim 1985. xii, 423 pp., bound, DM 208.00.—ISBN 3-527-26166-4

Why has a new book on dynamic NMR spectroscopy been published when, in addition to a number of review articles, three books are already available—the standard work by *Jackman* and *Cotton* (1975), *Kaplan* and *Fraenkel*'s more theoretically orientated book (1980) and *Sandström*'s recent introduction (1983) to DNMR analysis? The title of the present book indicates that it is concerned with applications in organic chemistry. Do the contents justify the need for a new publication?

The introductory section describes the exchange broadening phenomenon of NMR signals, gives methods (especially approximations) which can be used to determine rate constants, and provides typical examples of mechanisms that can result in spin exchange. Rotations around bonds (from sp^2-sp^2 to sp^3-sp^3) are then dealt with in detail (five chapters). The following sections concern flexible conformations in rings, the inversion and rotation of amines and imines, and applications for studying chemical reactions.

No such survey can hope to be complete, but the author has nevertheless managed to compile a surprising variety of examples from extremely different areas of organic chemistry. They reflect the current state of DNMR spectroscopy; only a few fundamental innovations have been introduced in the last decade, but the technique has become an important tool for the chemist. The book serves its purpose because it draws the reader's attention to possible applications in his own research work and can also be used as a reference work for literature published up to 1983.

Several topics are, however, missing. For example, ligand permutations at central atoms, DNMR phenomena in solids, comments on the mechanistic information obtained in multi-site exchange systems and 2D-DNMR techniques. The computer simulation of spectra is also dealt with very briefly, although six pages of the introductory chapter are dedicated to approximation solutions. This somewhat underestimates the flexibility of organic chemists as regards using new techniques.

A number of inaccurate formulations become evident on going through the book. In the first chapter, for example, "..., the lifetime of a nucleus in one site, ..., is a function of the external magnetic field.". This is impossible—what is meant is that the lower limit of the half-life times at which exchanging nuclei can still be separately observed is a function of the magnetic field. Later, the diastereotopic CH_2 protons in a molecule $XYZC\text{-}CH_AH_BW$ are considered and the three possible staggered conformations are illustrated. This is followed by the statement: "If the free energies of the three conformations are equal, it will be seen readily that the magnetic environments of H_A and H_B are completely equivalent on the average because ...". This

is incorrect; diastereotopic protons remain diastereotopic, the shift difference between H_A and H_B may be very small or almost zero depending on the population of conformers present, but equal energies of the conformers are neither necessary nor sufficient for this.

These criticisms should not, however, destroy the positive overall impression made by the book. The reader's first impression is of a useful compendium of literature. He may then be fascinated by a single topic and finally he is successfully made aware of the possibilities offered by DNMR spectroscopy for his own research.

Vibronic Coupling. By *G. Fischer*. Academic Press, London 1984. viii, 222 pp., bound, $ 42.00. - ISBN 0-12-257240-8

In recent years, the significance of vibronic coupling (i.e., the interaction between electronic and nuclear motion in molecules) for spectroscopy and for many dynamic processes has become increasingly evident, as reflected in the growing number of publications on this subject. Accordingly, there is keen interest in a book that documents the current status of research in this field and also gives the nonspecialist guidance.

The monograph under consideration is primarily intended for the nonspecialist. It therefore begins in Chapter 1 with an elementary demonstration of the separation of variables in several systems, which should facilitate an understanding of the adiabatic approximation. In the following two chapters, this approximation is discussed for di- and polyatomic molecules. In order to extend the treatment and be able to describe "intensity borrowing" and nonadiabatic effects, variants of the adiabatic approximation and other methods, mainly from perturbation theory, come up for discussion. Two approaches to the calculation of transition intensities in electronic spectra (that of dipole length and that of dipole velocity) are compared in Chapter 4. Chapter 5 concludes the general part of the book with a presentation of two symmetry-dependent degeneracies, the Jahn-Teller and the Renner-Teller effects, which are classical examples of vibronic coupling. In Chapters 6-8, the most important applications come up for discussion: the calculation of vibronic-coupling effects using semiempirical (CNDO) methods as well as the manifestation and detection of these effects in electronic spectra and in multiphoton processes. Important dynamic processes in which vibronic coupling plays a role—in particular, radiationless decay—are discussed in Chapter 9. The book closes with a survey of analogous effects in molecular crystals.

On the whole, one can recognize the effort that the author has made to present the manifold applications of vibronic coupling in a way that is also understandable to the nonspecialist. Nevertheless, this effort cannot be considered successful for several reasons.

First and foremost, attention must be called to the selection and organization of the material. Questions that are only very loosely related to the subject of the book, such as local modes, energy transfer, and unimolecular reactions, are discussed. On the other hand, important newer developments, such as the concept of the so-called diabatic electronic wave functions, the appearance of strong nonadiabatic effects when potential surfaces intersect conically, and the calculation of vibronic-coupling effects using truly ab-initio methods, are not even referred to. Furthermore, many standard references are missing, and only little experimental material is presented to illustrate the meaning of the effects discussed.

The material is not very clearly organized. Thus, the basic coupled equations of electronic and nuclear motion are newly derived in each of the Chapters 2, 3, and 5; the so-called Herzberg-Teller expansion for the transition moment in each of the Chapters 3, 4, and 6. Without cross-references, such repetitions are not only superfluous, but also, at least for the beginner, even disorienting. The assignment of the material to the individual chapters is in part illogical; Chapter 7, for example, seems out of place—thematically, it belongs to either Chapter 6 or 8. The unsystematic arrangement of the material makes it extraordinarily difficult to obtain a general view of the effects of vibronic coupling and of their connection. Why, for example, in Chapter 5, which is on the Jahn-Teller effect, is the opportunity not taken to make its relation to adiabatic potential surfaces clear by discussing calculated model spectra? On the whole, the book gives the impression (though unfounded) that one can almost always describe nonadiabatic effects using perturbation theory, and it is incomprehensible, for example, why an example is cited in Section 6.5 of the "Breakdown of the Born-Oppenheimer approximation," precisely where this approximation does *not* break down.

The list of shortcomings is rounded out by the numerous minor oversights and mistakes, which have crept into the text. One example is the false definition of the term "electrical anharmonicity" on p. 106; a more serious example is the discussion of the potential surfaces of a vibronic system with several nuclear vibrations, where the multimode effect is simply overlooked (p. 84). In summary, a book that is only marginally suited for the introduction of the beginner to the field in question.

Thermodynamik irreversibler Prozesse. Eine Einführung. By *H.-W. Kammer* and *K. Schwabe*. VCH Verlagsgesellschaft, Weinheim 1985. 114 pp., Brochure, DM 28.00.— ISBN 3-527-21104-7

This thin volume addresses physicists and chemists who wish to acquire first knowledge about thermodynamically irreversible processes. After the Introduction, which outlines the contents of the book very briefly, a short summary of equilibrium thermodynamics is given. Next, the fundamental concept of entropy production is introduced by means of two examples (solidification of supercooled water and thermal conductivity) and then generalized to processes with a single order parameter as well as to chemical reactions. In the short, fourth chapter, the dynamics of irreversible processes are discussed using the example of glass transitions in polymers. This chapter seems to me to be too complicated for an introductory text; furthermore, the mathematical treatment does not impart any knowledge that could not be equally well obtained in a simple qualitative manner. The next chapter deals with Onsager's reciprocal relationships. Thermoelectrical effects and thermodiffusion are thoroughly discussed; on the other hand,

the most important other interference effects are only briefly presented. Here, a more thorough treatment would have perhaps been appropriate. In the sixth chapter, stationary states are discussed. The theorem of minimal entropy production is derived, whereby the stability of the stationary state in the linear region is demonstrated. The last chapter is devoted to irreversible processes in the nonlinear region. Following a discussion of the general criteria for stability according to *Prigogine* and *Glansdorff*, the stability of simple, far-from-equilibrium, chemical reactions is dealt with in terms of the kinetic potential. Next, the Lotka model is presented as an example of an oscillating reaction. A qualitative discussion of several hydrodynamic instabilities closes this chapter. On the whole, this book is didactically successful and it can be recommended to every beginner.

Gruppentheorie für Chemiker. By *D. Wald*. VCH Verlagsgesellschaft, Weinheim 1985. ix, 234 pp., brochure, DM 48.00.—ISBN 3-527-26300-4

Group theory is an abstract branch of mathematics that is far from easy to understand. The chemist normally encounters it in vibrational and electron spectroscopy, quantum chemistry and crystallography. This book is intended "above all for chemistry students who have taken their Bachelor's degree" and, according to the advertising literature of the publishing company, "explains the group theory to the chemist in an understandable way".

The book is a direct copy of the original typewritten manuscript and contains rather simply presented figures. It is divided into six sections, the short introduction being counted as a separate chapter. Chapter 2 introduces basic group theoretical terms and deals with symmetry operations and point groups. Chapter 3 presents basic principles of the representation theory. Chapter 4 gives some applications of the material discussed in the previous chapters, the most important being the construction of character tables, the derivation of irreducible representations for various point groups, the selection rules used in vibrational spectroscopy of molecules and solids, the determination of the 230 space groups, the formulation of group-subgroup relationships in solid state chemistry and the Woodward-Hoffmann rules. Chapter 5 contains the solutions to the problems presented at the end of Chapters 2–4. Chapter 6 is a 13-part appendix.

I read the book with the intention of refreshing my memory and furthering my limited knowledge of group theory and its applications. It soon became apparent, however, that the book was not very well suited to my taste. It can be described as a collection of group theoretical definitions, rules and calculations supplemented by practice problems and (this is undoubtedly a positive feature) a large number of precalculated examples from the field of point and space groups, some of these having been performed in great detail. Proofs and explanations of mathematical (or physical) relationships have seldom been included with the comment that they can be looked up in a mathematics text book. I feel, however, that one of the purposes of a book of this type should be to explain these relationships to the non-mathematician, but this is certainly a matter of opinion.

More serious is the fact that sometimes important information is presented in such a way that it is almost unintelligible. The text is often simply too short, i.e. explanations are inadequate (e.g. p. 25, 73, 86, 120). The book also contains grammatical errors as well as a number of unclear formulations which miss the point in question (e.g. p. 32, 34, 115, 148). Furthermore the reader is unnecessarily harrassed by the appearance of symbols and terms in the text and tables which are then first explained pages or chapters later, if at all (e.g. p. 26, 29, 75, 116). A subjective "experimental" finding: I was only able to understand some of the topics dealt with in the book (e.g. cycles or a subject as important as irreducible representations) after I had consulted another text book (also intended for the chemist).

A few final remarks on individual points: a "slanted mirror plane" appears in a stereographic projection as a circle and not as an ellipse (p. 34); a factor of 1/2 is apparently missing on the left-hand side of some of the equations given on p. 110/111; Figure 2-21 (p. 37) is geometrically incorrect; whether the so-called "unit cell group" satisfies the group axioms or not surely depends on the formulation of the combination rules for the elements (p. 208); the statement that a group is isomorphic with the group of its inner automorphisms (p. 55) contradicts the statements presented on p. 60.

Enough fault-finding! It is also certainly true that the book contains a wealth of relevant material. In my opinion the book will be of value to the practicing chemist, especially the vibrational spectroscopist, in providing a compact summary of group theoretical facts, many detailed calculated examples, and a comprehensive list of references. I feel, however, that the book is less suitable as an introductory text on group theory and its chemical applications.

185-nm Photochemistry of Olefins, Strained Hydrocarbons, and Azoalkanes in Solution

By Waldemar Adam* and Thomas Oppenländer

Dedicated to Professor Dietrich Schulte-Frohlinde on the occasion of his 60th birthday

The possibility to excite *directly* at 185 nm chromophores that absorb in the vacuum-UV has stimulated increased activity during the last decade in this field of photochemistry. Whereas photochemical reactions at $\lambda < 200$ nm have been thoroughly investigated in the gas phase, only recently have intensive studies on the 185-nm photochemistry of organic compounds in *solution* provided new insights. Despite the high excitation energies, *selective* photoreactions are promoted in the short-lived singlet excited states (Rydberg photochemistry). In contrast to conventional photochemistry ($\lambda > 220$ nm), 185-nm irradiation preferentially results in *intramolecular* rearrangement, fragmentation, and isomerization reactions. Intermolecular radical couplings and abstractions as well as dimerizations (π,π^*-excitation) compete minimally. Besides the straightforward denitrogenation of photoresistant ("reluctant") azoalkanes, important applications of the short-wavelength photolysis are also found in technology (photolithography) and medicine (193-nm laser). Broadening the scope of the synthetic potential of the 185-nm photochemistry, which so far has been limited to direct *cis/trans* isomerizations, presents a challenge for the chemist.

1. Why 185-nm Photochemistry?

The photon as a "reagent" plays an important role in synthetic organic chemistry. During the last 15 years this has been particularly exemplified in the elegant syntheses of ring systems, especially four-membered rings and natural products.[1] The development of new photochemical equipment makes it possible to perform photoreactions over a wide range of wavelengths. For example, the continuous output of a synchrotron extends from the near infrared to X-ray radiation.[2]

For the organic chemist, however, it is essential to perform photochemistry as economically as possible. In 185-nm photochemistry this is accomplished by using Suprasil equipment and low-pressure mercury lamps. Such apparatus is comparably cheap and allows vacuum-UV photochemistry to be performed in solution[3] with *n*-pentane or other UV-transparent hydrocarbons as solvents. Despite the high excitation energy of 6.7 eV (647.8 kJ/mol), 185-nm photolysis of suitable substrates leads to defined products. Their formation can be rationalized according to defined mechanistic concepts. Besides the few preparative applications using 185-nm radiation, e.g., the syntheses of (*E*)-cyclooctene[4] and (*Z*)-2,2,5,5-tetramethyl-3-hexene ("di-*tert*-butylethylene"),[5] the main focus of research in

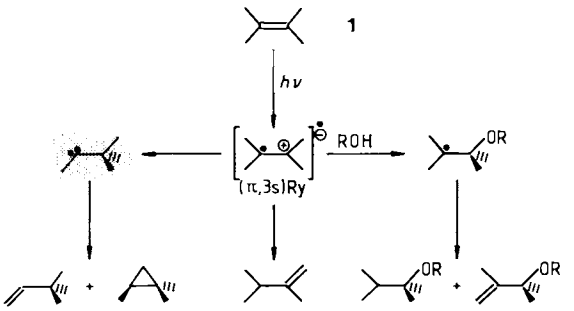
this stimulating field of organic photochemistry is on mechanistic studies. One of the principle goals of these studies is to describe the nature of the electronic states that are reached by high-energy excitation with 185-nm photons.

Recently, *Srinivasan* et al.[6] investigated whether UV radiation ($\lambda < 200$ nm) could be used for practical purposes. For example, laser photolysis (193 nm) might prove useful for photolithographic processes or in medicine. Since the excess energy can be converted into the translational energy of small molecular fragments, a process called ablation, the surrounding material is not burned. In medical applications, this should be of considerable advantage over the usual laser techniques.

2. Mechanistic Concepts in 185-nm Photochemistry



Organic photochemistry with vacuum-UV radiation is not limited to the well-examined alkenes[3a,7] and cyclopropanes.[8] Endoperoxides,[9] azoalkanes,[10] unsaturated ketones,[11] acetylenes,[12] alcohols, amines, ethers,[13] and trihalomethanes,[13f] and other bichromophoric systems such as oxacycloalkenes[14] and tetrahydropyridines[15] have been investigated in detail. Especially the degradation of halocarbons on 185-nm irradiation of aqueous solutions[13f] should acquire substantial significance in the treatment of waste water. The 185-nm photolysis of hexamethyldisiloxane[16] yields a multitude of photoproducts, the formation of which can be explained by means of radical intermediates. The gas-phase photolysis ($\lambda < 200$ nm) of olefins is described elsewhere.[17] However, there are significant differences[3c] between 185-nm photolyses in the gas phase and in solution.

The photoreversible $(Z)/(E)$ isomerization of cyclooctene,[18] which can be monitored by quantitative capillary gas chromatography, is the most commonly used chemical actinometer for the calibration of low-pressure mercury lamps. It is thereby possible to determine the absolute light output (I_0^{185}) of the UV lamp employed.[19] This method enables reproducible quantum yields Φ to be obtained for the diverse compounds employed in 185-nm photolyses.

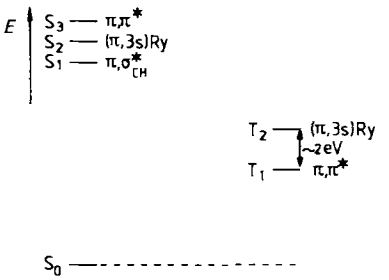
In this article we present the mechanistic knowledge acquired during the last decade on 185-nm photochemistry in liquid media. Because mainly photoinduced isomerizations, rearrangements, and fragmentations have been investigated, we will limit the discussion to the intensively investigated olefins, cyclopropanes, and azoalkanes.

2.1. Olefins

Since the early studies by *Kropp* et al.[3d,20] the formation of rearrangement products on 185-nm photolysis of olefins has been interpreted in terms of carbene intermediates. These are formed via a 1,2-carbon shift from the excited (π,3s) Rydberg state of the olefin (Scheme 1). Experimental evidence for the involvement of Rydberg states in vacuum-UV excitation of olefins is provided by nucleophilic trapping reactions[20,21] with alcohols, leading to ethers (Scheme 1), and by the remarkable pressure dependence of the vacuum-UV spectra of alkenes.[22] Furthermore, on excitation with 185-nm photons, olefins exhibit a weak, but measurable fluorescence[23] with quantum yields of about 10^{-4} to 10^{-6}. This fluorescence results presumably from the (π,3s) Rydberg state.

Scheme 1. Rearrangements and subsequent reactions of olefins such as 2,3-dimethyl-2-butene **1** on irradiation. Ry = Rydberg.

In contrast to the simple triplet-state photochemistry of olefins,[21] their photoreactivity on direct 185-nm excitation is often more complex. This is due to strong coupling of different excited states (Fig. 1). In spite of the similar energies of the π,π^*, (π,3s) Rydberg, and π,σ^*_{CH} singlet states of olefins (Fig. 1), distinct photoreactivity of each excited



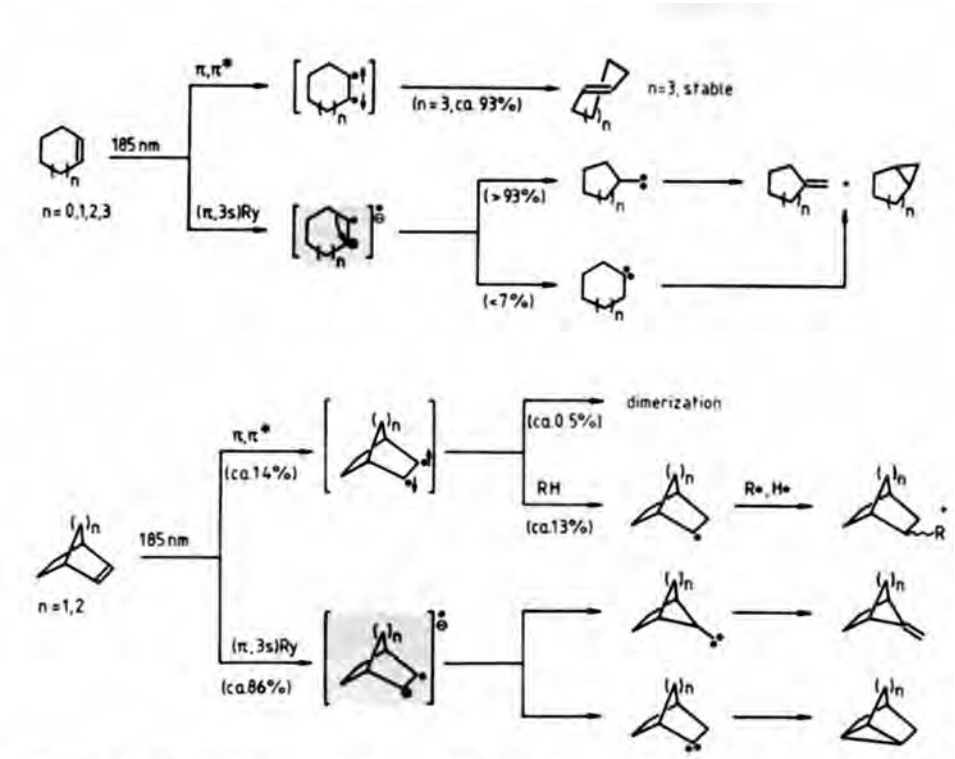


Fig. 1. Electronic states of olefins [21].

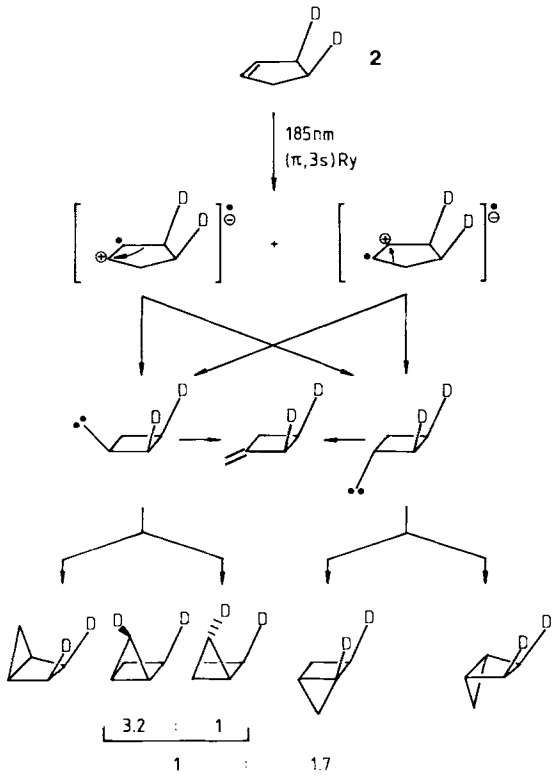
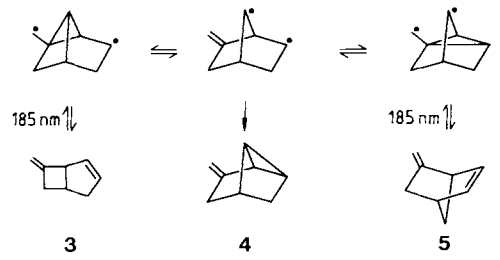
state can be observed. For example, the product distribution in the UV photolysis of 2,3-dimethyl-2-butene **1** is strongly dependent on the excitation wavelength.[24] Furthermore, there exists a direct connection between the wavelength dependence and the quantum yield of fluorescence[23] of the alkene. With increasing wavelength of excitation the chemical yield of the carbene products (Scheme 1) and the fluorescence quantum yield increase. This is a direct indication for the involvement of a Rydberg state as precursor to the intermediary carbene. The π,π^* excited state leads to $(Z)/(E)$ isomerizations and hydrogen abstractions.[24]

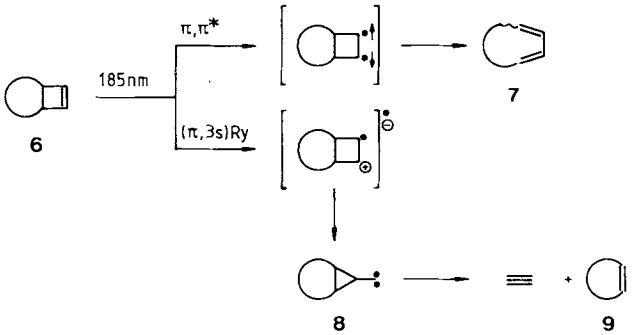


In general, the 185-nm photoreactivity of cyclic and bicyclic olefins can be summarized according to Scheme 2. Many examples that fit this scheme have been extensively investigated by *Inoue* et al.[3c,25] and by *Srinivasan* et al.[3a] In monocyclic olefins a 1,2-alkyl versus a 1,2-hydrogen shift is clearly favored (93%).[3a] A typical, recently studied[26] example is cyclopentene, which reacts with the formation of bicyclo[2.1.0]pentane and methylenecyclobutane.

A carbene intermediate is in accord with the recent results of the 185-nm photolysis of *cis*-3,4-dideuteriocyclo-



Scheme 2. 185-nm Photochemistry of mono- and bicyclic olefins [3a, 25].

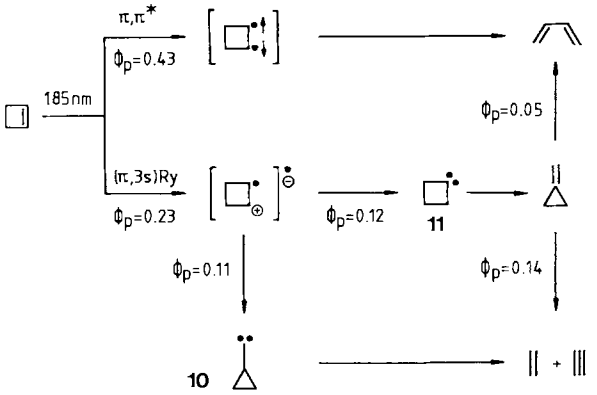


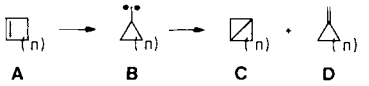
pentene **2** (Scheme 3).[26e] In bridged bicyclic olefins (Scheme 2), however, both processes compete.[7,25] The bichromophoric diolefins **3** and **5** represent exceptions, because they rearrange efficiently into one another on 185-nm irradiation and transform irreversibly to the tricyclic compound **4**.[27] This photoreactivity does not correspond to that of Scheme 2, but rather involves di-π-methane rearrangements.[28] Carbene reactivity seems to be of no importance for such dienes.

Scheme 3. 185-nm Photochemistry of *cis*-3,4-dideuteriocyclopentene **2**.

The 185-nm photochemistry of annelated cyclobutenes **6**[29] can again be described according to the general mechanism of Scheme 2. The π,π* excited state of cyclobutene **6** undergoes Woodward-Hoffmann allowed electrocyclic ring opening[30] to give the 1,3-diene **7**. On the other hand, the (π,3s) Rydberg state rearranges to the carbene **8**, which subsequently fragments into acetylene and the cycloalkene **9**.[31]

The 185-nm photolysis of cyclobutene[26a,d] provides important mechanistic insights into this process. The corresponding photoproducts can be rationalized in terms of the intermediacy of cyclopropylmethylene **10** and cyclobutylidene **11**.[31] Additional evidence for these carbenes comes from comparison of the behavior of the thermally generated carbenes with those resulting from the 185-nm irradiation of olefins (Table 1). The similar product ratios of methylenecycloalkane to bicycloalkane in the 185-nm photolysis of the homologous alkenes and the thermolysis of the corresponding tosylhydrazones proves convincingly this conjecture.





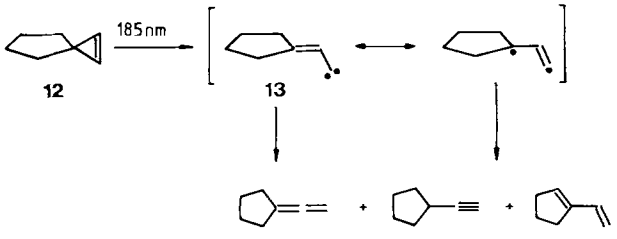


Table 1. 185-nm-Photochemistry of the homologous cycloalkenes **A**; formation of the bicyclic compounds **C** and the methylenecycloalkanes **D** from the cycloalkylmethylenes **B**.

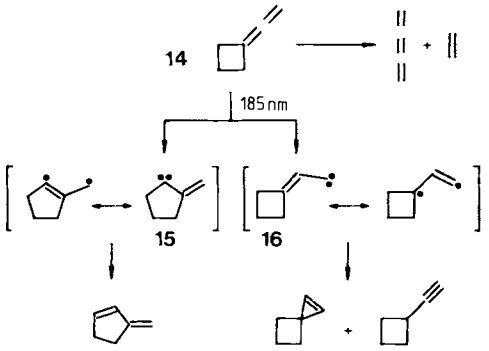
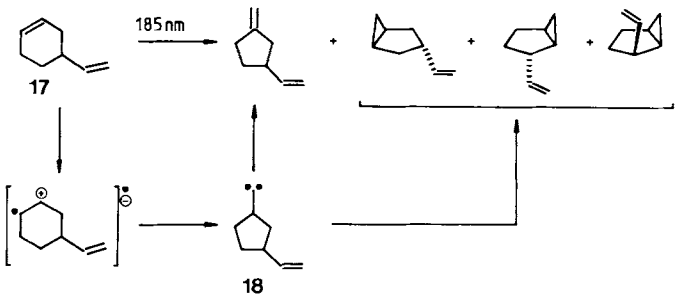
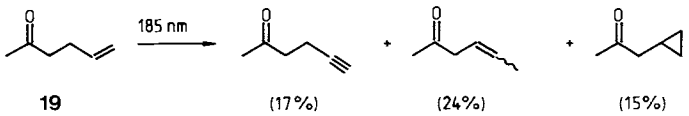


n	Quantum yields				Product ratios	
	Φ_S [a]	Φ_P [b] C	Φ_P [b] D	$\Sigma\Phi_P$	D/C 185 nm	D/C therm. [c]
5	—	0.008	0.007	0.015	0.9	—
4	—	0.02	0.10	0.12	5.0	11.5
3	—	0.07	0.05	0.12	0.7	0.4
2	0.15	0.03	0.04	0.07	1.3	1.4
1	0.71	[d]	0.12	0.12	—	—



[a] Φ_S = quantum yield of substrate consumption. [b] Φ_P = quantum yield of product formation. [c] The cycloalkylmethylenes (carbenes) **B** were generated via basic decomposition of the corresponding tosylhydrazones [31]. The basic decomposition of cyclopropylcarbaldehyde tosylhydrazone did not lead to bicyclo[1.1.0]butane **C**, n = 1 [31]. [d] Not formed.

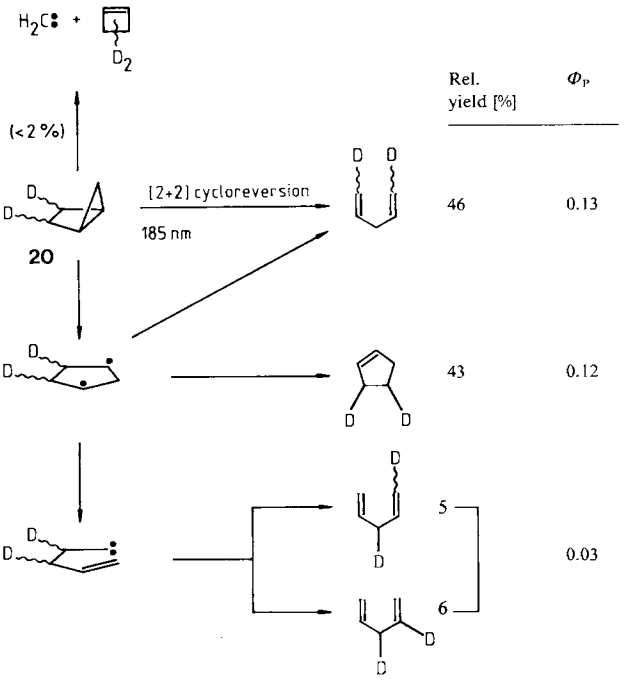
The essential step in the transformation of cyclopropenes such as **12**[32] and allenes such as **14**[33] on 185-nm irradiation corresponds to a cyclopropene–vinylcarbene rearrangement.[34] The UV photolysis of spiro[2.4]hept-1-ene **12**[32] yields as primary product the vinylcarbene **13**, which rearranges to the observed photoproducts. Similar intermediates have been proposed in the 185-nm photolysis of vinylidenecyclobutane **14**.[33] Besides the rearranged products that are formed from the two possible vinylcarbenes **15** and **16**, butatriene and ethene are produced via a [2+2] cycloreversion.



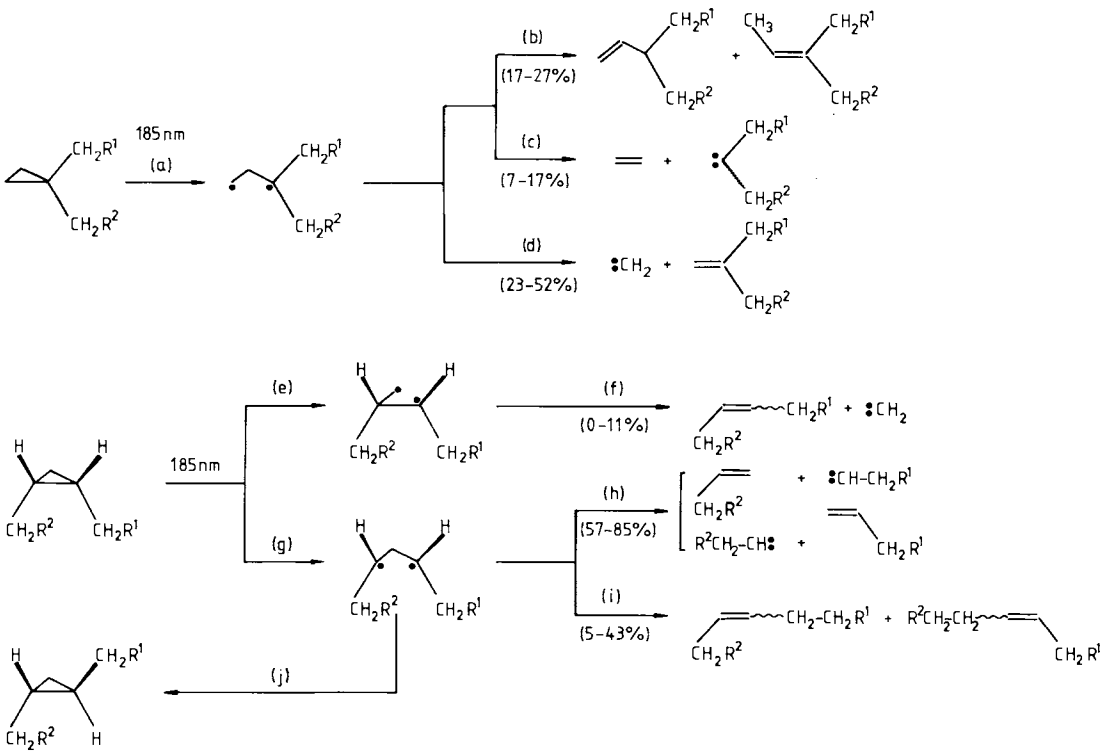
Intramolecular interactions between nonconjugated chromophores seem not to exist on 185-nm activation, but selective reactivity of the isolated chromophores can be observed. The 185-nm photolysis of 4-vinylcyclohexene **17**[35] leads to products that are formed by selective excitation of the endocyclic double bond. The photoproducts

can be explained in terms of carbene **18**. This carbene is formed from the (π,3s) Rydberg state of the cyclohexene double bond[35] since the photoproducts still contain the vinyl group intact. One would have expected a more complex product mixture had interaction between the chromophores in the excited vinylcyclohexene taken place.

Analogous selectivity can be observed in the 185-nm photolysis of γ,δ-unsaturated enones such as **19**.[11] Instead



of the usual carbonyl photochemistry, such as intermolecular formation of oxetanes, the products are mainly derived from excitation of the C=C bond with preservation of the carbonyl functionality. Therefore, intramolecular energy transfer from the C=C bond to the carbonyl group is unlikely.[11]

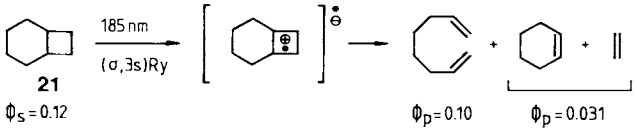


2.2. Cyclopropanes

Identification of the electronic state that is formed on 185-nm excitation of cyclopropanes is not easy. Besides very weak Rydberg transitions, cyclopropanes exhibit measurable σ,σ* transitions in the vacuum-UV region.[36] The gas-phase photolysis (147 nm and 163 nm) of cyclopropane[37] itself yields ethene and methylene (69%) via cleavage of two C–C bonds. This type of fragmentation is favored as the main reaction path in the direct 185-nm photolysis of substituted cyclopropanes in solution[8] (Scheme 4).

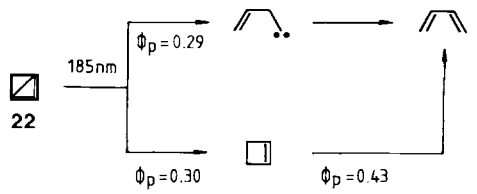
The photoreactivity of alkylcyclopropanes is a function of the substitution pattern. 1,1-Disubstituted[8] as well as 1,2-disubstituted[38] mono- or bicyclic alkylcyclopropanes react mainly via breakage of two bonds of the cyclopropane chromophore. Spirocyclopropanes[8] and 1,1-disubstituted cyclopropane derivatives cleave principally to form methylene (path a, d; 23–52%), whereas the related process in 1,2-disubstituted cyclopropanes[38] (path e, f; ≦11%) competes very little with fragmentation into the corresponding substituted carbenes (path g, h; 57–85%). The theoretical calculations of *Rossi*[39] show that the cleavage of two C–C bonds is not concerted, but follows a stepwise

Scheme 5. 185-nm Photochemistry of 2,3-dideuteriobicyclo[2.1.0]pentane **20**.



Scheme 4. 185-nm Photochemistry of 1,1- and 1,2-disubstituted alkylcyclopropanes [8, 38]. For (a)–(j) see text.

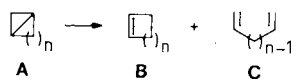
mechanism (paths a, c and a, d or paths e, f and g, h). Normally, the most substituted cyclopropane ring bond cleaves first. The stereoisomerization of *cis*-1,2-diethylcyclopropane[40] (path g, j; $R^1 = R^2 = Me$) takes place to about 10%, but it is of subordinate importance compared with the fragmentation process. Generally, the isomerization products, which are formed via cleavage of one C–C bond of the cyclopropane chromophore (paths a, b and g, i), are clearly disfavored compared with the corresponding fragmentation products.



Bicyclo[2.1.0]pentane (cf. **20**) behaves differently, because mostly (about 89%) homolysis of the bridge bond of the cyclopropane chromophore takes place (Scheme 5).[126a] This behavior was attributed to a Woodward-Hoffmann

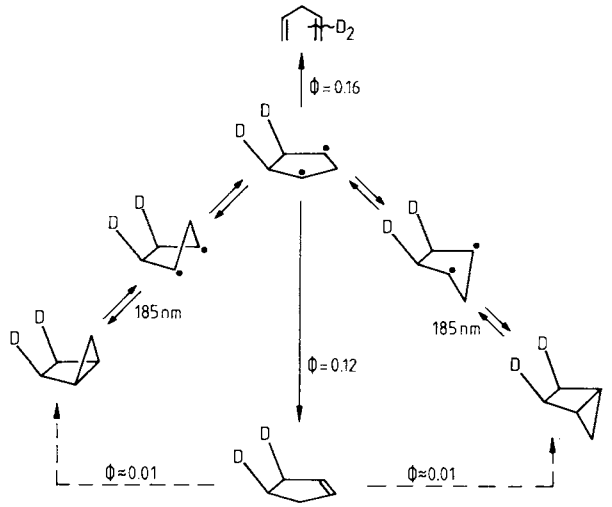
allowed [2+2] cycloreversion. Such a process is not possible in the higher homologous bicyclo[n.1.0]alkanes.

The efficient fragmentation of cyclobutanes on 185-nm excitation could be demonstrated for bicyclo[4.2.0]octane **21**.[26a,h] Possibly a radical cation mechanism can account for these fragmentations, because on 185-nm irradiation Rydberg transitions are possible. In contrast to bicyclo[2.1.0]pentane (cf. **20**), the homologous bicyclo[1.1.0]butane **22**[26a] fragments via one-bond and two-bond cleavages to the same extent.



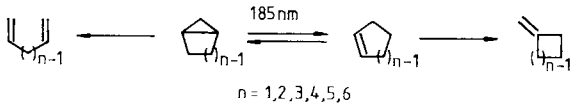
Srinivasan et al.,[26c] on the other hand, found by means of deuterium-labeling experiments a 10:1 ratio of butadiene and cyclobutene. Possibly, no corrections were made for the appreciable photolability of cyclobutene. However, the observed deuterium distribution in the photoproducts is in agreement with the results of *Adam* et al.[26d] and supports the mechanism shown in Scheme 6.

Scheme 6. 185-nm Photochemistry of bicyclo[1.1.0]butane **22**.



Comparison of the 185-nm photoreactivity of the homologous bicyclo[n.1.0]alkanes (Table 2) convincingly shows that bicyclo[2.1.0]pentane (n=2) is a special case. The *exo/endo* isomerization (Scheme 7)[26a] supports this fact. The isomerization is, however, quite inefficient ($\Phi_{iso}=0.03$) compared with the fragmentation into 1,4-pentadiene ($\Phi_p=0.16$) and with the formation of cyclopentene ($\Phi_p=0.12$). Already these few examples show that the conversion of bicyclo[n.1.0]alkanes into the corresponding cycloalkenes on 185-nm irradiation seems to be a general reaction.

Table 2. 185-nm Photochemistry of the homologous bicyclo[n.1.0]alkanes **A** to the cycloalkenes **B** and the 1,n+2-alkadienes **C**.



n	Quantum yields			Product ratio	Homolysis [a] [%]	
	Φ_S	Φ_P B	Φ_P C	C/B	one-bond	two-bond

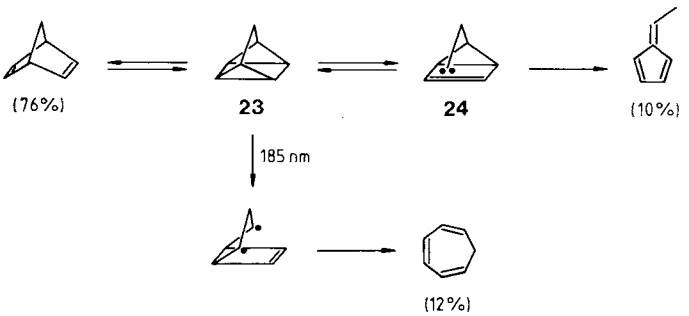
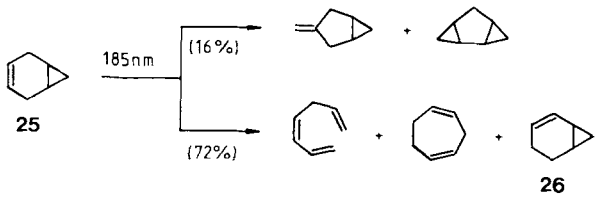
2	0.25	0.12	0.16	1.3	89	11
1	0.65	0.30	0.29	1.0	51	49

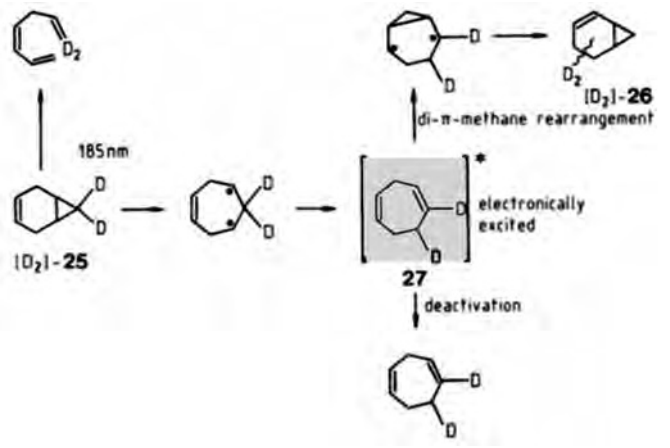


[a] One-bond and two-bond cleavages of the C–C bonds of the cyclopropane chromophore. [b] Not formed. [c] The fragmentation of two bonds of the cyclopropane chromophore seems to be the main reaction path [38].

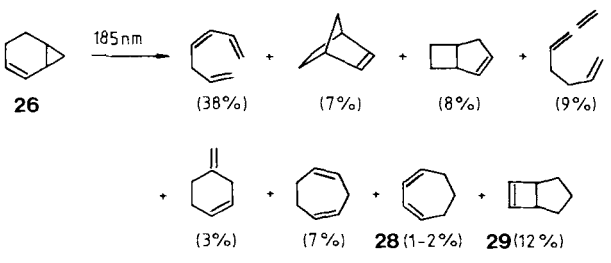
Scheme 7. Photochemical isomerization of *cis*-2,3-dideuteriobicyclo[2.1.0]pentane (cf. Scheme 3 and Scheme 5).



Surprisingly, the carbene elimination in quadricyclane **23**[41] plays an insignificant role, although **23** contains two cyclopropane chromophores. The formation of carbene **24** on 185-nm irradiation of quadricyclane could be reversible, so that re-addition to the double bond could regenerate the starting material and thereby account for the inefficiency ($\Phi=0.02$) of this process.[41] The side products, 6-methylfulvene and 1,3,5-cycloheptatriene, are also formed in traces in the direct 254-nm (<5%) and triplet-sensitized (<0.5%) photolyses of quadricyclane. Therefore, the use of the quadricyclane–norbornadiene system as an efficient solar energy storage system[42] has been questioned.[41]



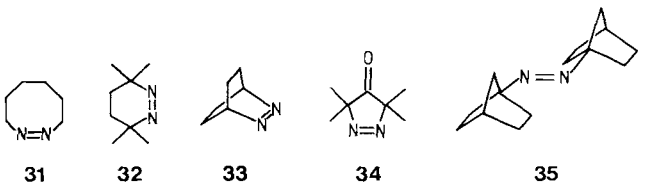
The 185-nm photolysis of compounds containing two different chromophores, e.g., cyclopropanes and olefins, provides evidence for intramolecular interactions between the excited chromophores and thus distinctive photochemical behavior of the excited states. The wavelength dependence of the UV photolysis of bicyclo[4.1.0]hept-3-ene **25**[43]



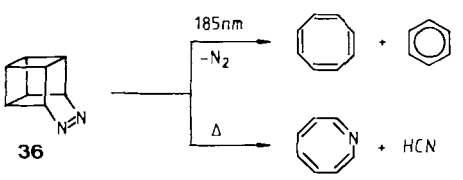
once again indicates that two or more different excited singlet states participate in one and the same molecule. Decreasing the photon energy ($\lambda = 185$, 193, and 214 nm) results in an increase of those products that are formed by selective excitation of the C=C bond of **25** and a corresponding decrease in the photoproducts derived from excitation of the cyclopropane chromophore. This observation becomes understandable when it is recognized that the first excited singlet state (S_1) of cyclopropanes lies higher in energy than the first singlet (π,3s) Rydberg state of olefins.[36]

The formation of product **26** during photolysis of the bichromophoric compound **25** can possibly be rationalized in terms of an intermediary electronically excited 1,4-diene (cf. **27**).[44] The excited intermediate **27** undergoes subsequent di-π-methane rearrangement to the isomer [D_2]-**26**. Indeed, these interesting speculations about the reaction mechanism of the 185-nm photolysis of **25** were verified through deuterium-labeling experiments.[44] Besides the formation of vibrationally excited or "hot" photoproducts,[40,45] an adiabatic reaction path is also possible.[46]

In contrast to these results, the product distribution in the 185-nm photolysis of bicyclo[4.1.0]hept-2-ene **26**[47] is independent of the excitation wavelength. In compound **26** the double bond is in conjugation with the cyclopropane ring. Therefore, no differentiation between the olefin and cyclopropane reactivity should be expected. Consequently, the 185-nm photochemistry of **26** is more complex than that of its isomer **25**.

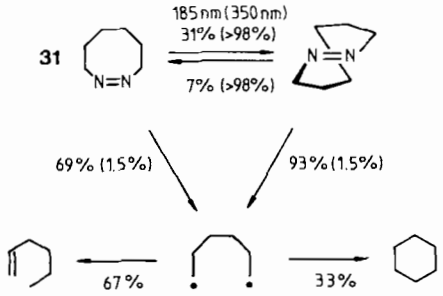


Analogous behavior is observed for 1,3-cycloheptadiene **28**,[47b] which, independent of the excitation wavelength ($\lambda = 185$, 229, or 254 nm), reacts mainly (88–99%) to give bicyclo[3.2.0]hept-6-ene **29**. However, substitution at C-7 in **26** with a methyl group (**30**) leads to *exo/endo* isomerization[48] as a side reaction.

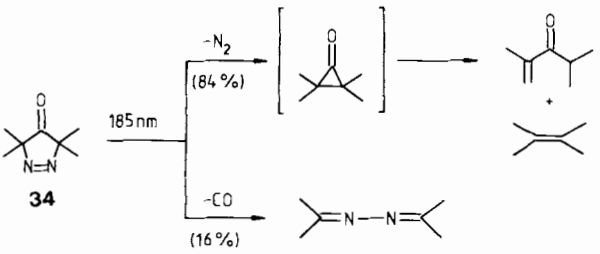


2.3. Azoalkanes

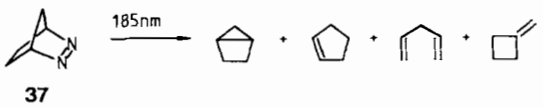
The thermal and photochemical reactivity of azoalkanes strongly depends on their structure.[49] Thus, to the group of photoresistant azoalkanes belong the structures **31** to **35**.[10,50] Their quantum yields of denitrogenation at the usual wavelengths ($\lambda > 300$ nm) are generally lower than



0.05.[51] In the case of six-membered azoalkanes, the quantum yield appears to be independent of whether the azo chromophore is part of a mono-, bi-, or polycyclic structure. The most important deactivation processes responsible for the photostability of these azoalkanes are fluorescence, radiationless deactivation, (*Z*)/(*E*) isomerization, intramolecular cyclizations, and phototautomerism.[52]



Photostable azoalkanes are of no synthetic value, because the crucial nitrogen elimination step cannot be realized to form the desired new C–C bond. A classical example for this is the attempt to synthesize cubane[53] by photolysis of diazabasketene **36**, which failed to undergo nitrogen elimination. As was shown in 1980,[51] the 185-nm photolysis of diazabasketene leads to efficient denitrogenation. However, instead of cubane,[54] cyclooctatetraene and benzene were formed. Moreover, the quantum yield of nitrogen elimination was about 1000 times higher at $\lambda = 185$ nm than at $\lambda > 300$ nm. 1,2-Diaza-1-cyclooctene **31**[26a,g] was recently shown to be effectively denitrogen-



ated on 185-nm excitation. Again, the efficiency of the denitrogenation was increased by about 26- to 42-fold, depending on the configuration about the N=N bond.

An interesting bichromophoric substrate is 3,3,5,5-tetramethyl-3,5-dihydropyrazol-4-one **34**.[55] The 185-nm irradiation of **34** leads to denitrogenation and decarbonylation.[55] In this case the nitrogen elimination is six times more efficient than the CO elimination. The intermediary tetramethylcyclopropanone rearranges via ring opening to the enone or eliminates carbon monoxide to form dimethyl-2-butene.

A definitive assignment of the excited states that are involved in 185-nm excitation of azoalkanes is difficult.[36,51] These may be π,π^*, n_+,π^*, n_+,σ^*, or diverse Rydberg transitions[56] (Fig. 2). Nevertheless, 185-nm photolysis of simple azoalkanes might enable predictions to be made about the excited states that are involved in such photochemistry. In this connection it is of interest that the 185-nm excitation of 2,3-diazabicyclo[2.2.1]hept-2-ene **37**[19a,26b] is quite

different from the 350-nm photolysis. In the latter case only traces (<1%) of cyclopentene could be identified, whereas bicyclo[2.1.0]pentane was formed in >99% yield. As shown in Figure 3, on 185-nm photolysis, denitrogenation affords considerable quantities of cyclopentene, presumably via zwitterionic species. Such intermediates should have a considerable influence on the product distribution.

From this perspective, the photochemistry of the bicyclic azoalkanes 2,3-diazabicyclo[2.2.1]hept-2-ene **38a**[57] and spiro[cyclopropane-1',7-2,3-diazabicyclo[2.2.1]hept-2-ene] **38b**[58] and of their *exo*-dideutero derivatives was examined in detail. Depending on the reaction conditions of the denitrogenation, the azoalkanes **38** preferred to undergo double inversion to give the bicyclo[2.1.0]pentanes **39**.[57]

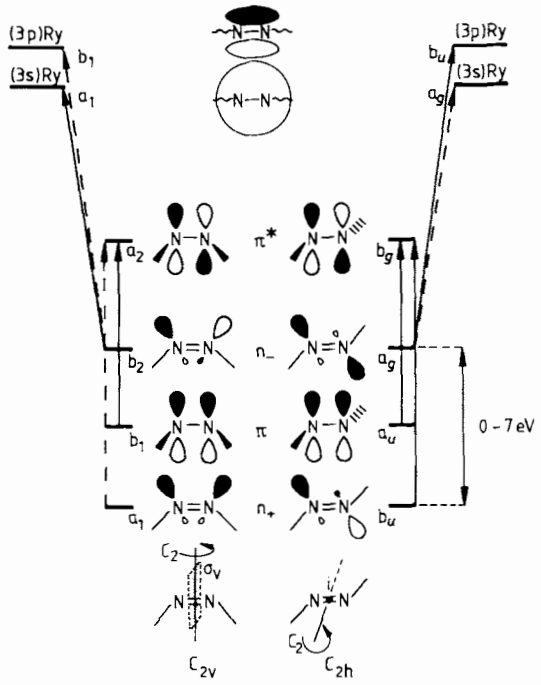


Fig. 2. High-energy electron transitions in (*Z*)- and (*E*)-azoalkanes. ——→, symmetry-allowed transition; – – →, symmetry-forbidden transition.

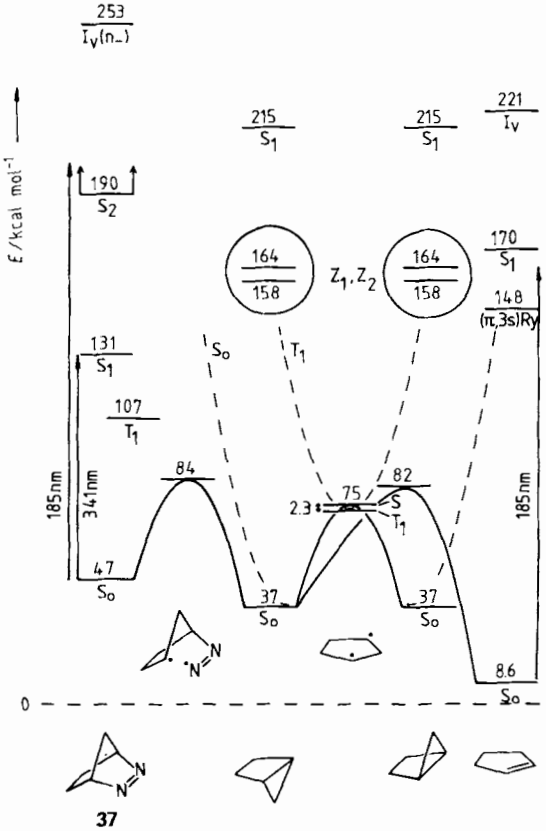

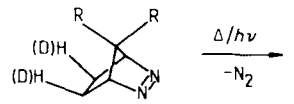

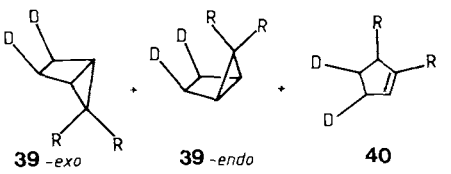

Fig. 3. Relative energies of 2,3-diazabicyclo[2.2.1]hept-2-ene, **37**, bicyclo[2.1.0]pentane, and cyclopentene.

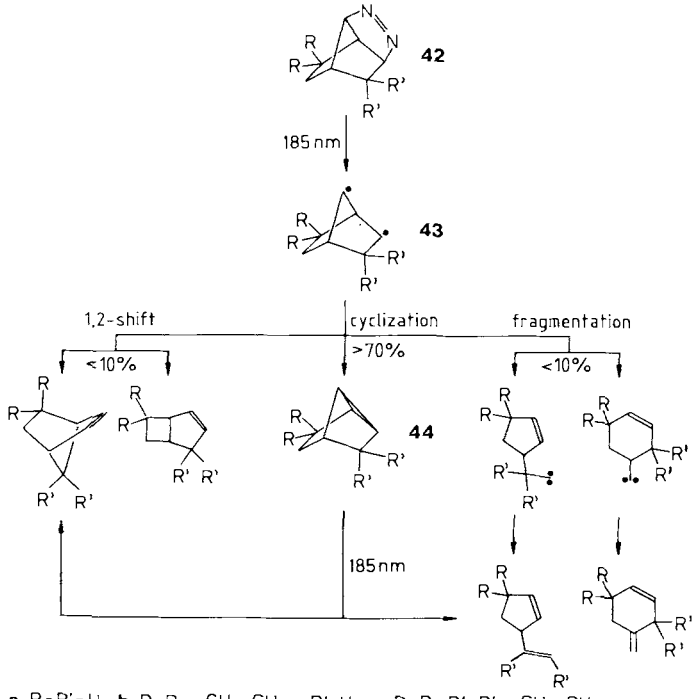
37, R=H
38, R+R=-CH_2-CH_2-

39-*exo* **39**-*endo* **40**
a, R=H; **b**, R+R=-CH_2-CH_2-



The rearrangement to the olefins **40** depends on the spin state and energy of the intermediary 1,3-cyclopentadiyl. In addition, the reaction path involving the zwitterionic species **41**, formed on 185-nm irradiation via concerted nitrogen elimination, might be possible.[26a]

41

In the long-wavelength ($\lambda > 300$ nm) photolysis of **38**, one-bond cleavage was postulated,[26f] the initially formed diazenyl diradical subsequently loses nitrogen, giving 1,3-cyclopentanediyl. Presumably, in the long-wavelength ($\lambda > 300$ nm) photolysis of azomethane,[26j] the primary step also involves one-bond cleavage to the corresponding diazenyl radical. Thus, the 185-nm photochemistry allows valuable mechanistic insights to be obtained into the denitrogenation of azoalkanes.

Attractive substrates for the examination of intramolecular interactions of distinct chromophores are the tricyclic azoalkanes **42**.[59] Their 185-nm photolysis results in denitrogenation and mainly formation of the tricyclic product **44**. In addition, the 1,3-diradical **43** undergoes a 1,2-carbon shift (<10%) and fragmentation (<10%), so that numerous photoproducts are formed.[59]

3. Prospects

On the basis of this brief review it is apparent that 185-nm photolysis *in solution*, still a rather young branch of organic photochemistry, offers a broad spectrum of challenging mechanistic problems. At first sight one gathers the impression that the complex product mixtures reflect a multitude of mechanistic processes. This is surely the case when hydrogen abstraction occurs and entry into the usual chemistry of free radicals ensues. However, the thorough mechanistic investigations of the last decade have shown that a definite regularity obtains in the behavior of the higher excited states that are reached on irradiation with 185-nm photons. The photochemistry of alkenes (Scheme 2), cyclopropanes (Scheme 4), and azoalkanes clearly supports this observation. However, when one considers what is still unknown about such complex photochemical processes, the gratifying progress appears quite modest. In order to motivate the interest of the novice as well as the expert, Table 3 summarizes those substances that have been investigated so far. Only a few purely radical processes have been included, because the main emphasis of this review concerns unimolecular transformations, such as isomerizations, rearrangements, and fragmentations, induced by means of 185-nm excitation.

Intensive efforts are required on all fronts before short-wavelength ($\lambda < 250$ nm) photochemistry achieves the status presently enjoyed by long-wavelength photochemistry ($\lambda > 250$ nm). Innovation is highly desirable, especially from the point of view of apparatus design. The present light sources (low-pressure mercury lamps) radiate mainly 254-nm light, so that many interesting problems, e.g., the behavior of substrates with coupled chromophores, can hardly be investigated. It is essential that convenient and efficient filters or monochromatic light sources with *sufficient* intensity be developed for such studies. Laser technology should provide important contributions. An ideal situation would obtain if a broad range of intense laser lines at regular intervals would become available in the 180- to 250-nm region, so that the wavelength dependence of the product formation could be assessed. Studies of this type are essential for recognizing the nature of the higher excited states, such as Rydberg, π-π^*, and σ-σ^* transitions.

This brings us to another problem, namely, the spectroscopy of the higher excited states. Despite some efforts,[36] our knowledge and understanding is rather modest in this area. Coupled with theoretical calculations, spectroscopic investigations (such as absorption, fluorescence, and photoelectron spectroscopy) on model substrates should be helpful.

Whether the 185-nm photochemistry will prove itself in preparative work is undoubtedly of interest to the organic chemist. Until now the utility has been modest, but 185-nm photochemistry represents presently the most direct and convenient entry into strained *trans*-cycloalkenes, e.g.,

Table 3. 185-nm Photoreactions in *n*-pentane as solvent. The quantum yield Φ_P or the product yield is given for each product.

trans-cyclooctene, or sterically congested *cis*-alkenes, e.g., *cis*-2,2,5,5-tetramethyl-3-hexene ("*cis*-di-*tert*-butylethene").

For such synthetic problems, which until now could only be realized by means of long-wavelength photochemistry in an indirect manner, short-wavelength photochemistry offers attractive possibilities. We regard the future of 185-nm photochemistry optimistically. Undoubtedly, the main sphere of action will lie in mechanistic studies.

We thank the Deutsche Forschungsgemeinschaft for generous financial support of our work and the Fonds der Chemischen Industrie for a fellowship (T. O.).

Understanding Reaction Dynamics in Coordination Chemistry—Application of High Pressure Techniques

By Rudi van Eldik*

In order to understand the dynamics of chemical reactions in general, detailed information on electronic, structural and kinetic properties is required. The key questions on how chemical reactions actually occur can in many cases only be answered in terms of information obtained from kinetic studies. In conventional kinetic studies of chemical reactions in solution, the variables usually selected include concentration, acidity, solvent, and temperature. In recent years, pressure has become an additional selected variable in such studies. It enables the measurement of the volume of activation and the construction of reaction volume profiles and thus assists in the elucidation of the underlying mechanism; it also completes the comprehension of reaction kinetics by adding another kinetic parameter that the suggested reaction mechanism must account for. Furthermore, the volume of activation is the only transition state property that can be correlated with the corresponding ground state property in an experimentally simple manner. In this paper, the insights so gained in our understanding of the dynamics of reactions involving coordination complexes will be presented. Such reactions are of fundamental interest to chemists since they often form the basis of catalytic, biological, environmental and energy related processes. Any additional information that will add to the understanding of the reaction dynamics is therefore of exceptional importance.

1. Introduction

1.1. Fundamental Principles

High pressure kineticists measure not only the usual kinetic parameters but also the pressure dependence of the rate constants. From this data and the partial molar volumes of reactant and product species, obtainable from density measurements, it is possible to construct a volume profile for the reaction investigated. For a reaction of the type

$$A + B \xrightarrow{k} AB$$

the simplest conceivable mechanism that can be formulated according to the transition state theory is

$$A + B \rightleftharpoons (A\text{---}B)^{\ddagger} \longrightarrow AB \qquad (1)$$

for which a possible volume profile is given in Figure 1. The magnitude and sign of the reaction volume, $\Delta\bar{V} = \bar{V}_{AB} - \bar{V}_A - \bar{V}_B$, and of the activation volume, $\Delta V^{\ddagger} = \bar{V}_{\ddagger} - \bar{V}_A - \bar{V}_B$, depend on the nature of the chemical species involved and their environment. The transition state volume (Fig. 1) does not necessarily have to be between that of the reactant and product states; it can be a minimum during a bond formation process (see, e.g., Fig. 5). Whereas $\bar{V}$ and $\Delta\bar{V}$ data are obtainable from partial molar volumes (density measurements) and dilatometric results, $\Delta V^{\ddagger}$ can only be determined from the pressure dependence of the rate constant k of the reaction under investigation, viz.

$$\Delta V^{\ddagger} = -RT(\partial \ln k/\partial p)_T$$

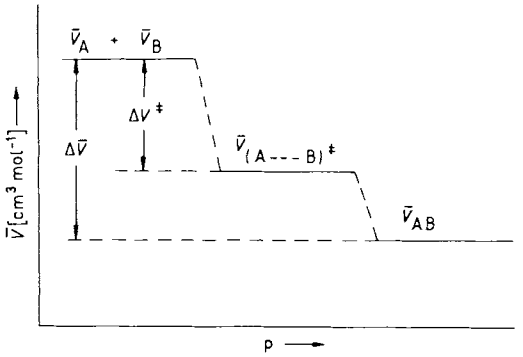

Fig. 1. Volume profile for reaction (1). $\bar{V}$ = partial molar volume, p = reaction coordinate.

In principle $\Delta V^{\ddagger}$ is not independent of pressure, i.e. the slope of $\ln k$ versus p plots depends on pressure, and the compressibility coefficient of activation, $\Delta\beta^{\ddagger}$, has been defined as

$$\Delta\beta^{\ddagger} = -(\partial \Delta V^{\ddagger}/\partial p)_T$$

Various mathematical descriptions to account for the pressure dependence of $\Delta V^{\ddagger}$ have been proposed.[1-3] However, for mechanistic purposes, the value of $\Delta V^{\ddagger}$ at ambient pressure alone is required for the above-mentioned correlation with partial molar volume data measured under such conditions. In most cases, $\Delta V^{\ddagger}$ is almost pressure independent up to 100 MPa (= 1 kbar).

In general, $\Delta V^{\neq}$ may be thought of as the sum of two components: an intrinsic part ($\Delta V^{\neq}_{intr}$), which represents the change in volume due to changes in bond lengths and angles, and a solvational part ($\Delta V^{\neq}_{solv}$), which represents the change in volume due to changes in the surrounding medium. An important part of this volume change is often due to changes in electrostriction, i.e. the interaction that occurs when an ion is submerged in a dielectric. It is of course principally the $\Delta V^{\neq}_{intr}$ part that is the mechanistic indicator in terms of changes in bond lengths and angles. Schematic representations of these components for typical bond formation and cleavage processes, are given in Figure 2. It follows that mechanistic assignments for processes in which no major solvational changes occur are very straightforward. In reactions with large polarity changes, $\Delta V^{\neq}_{solv}$ may be much larger than $\Delta V^{\neq}_{intr}$, and it can in fact counteract and swamp the $\Delta V^{\neq}_{intr}$ term; examples will be discussed. Nevertheless, a consistent picture arises from such studies, demonstrating the suitability of $\Delta V^{\neq}$ for mechanistic discrimination, even in extreme cases.

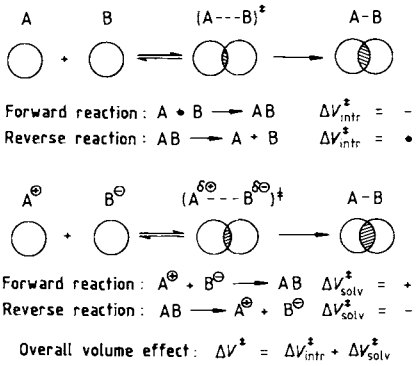

Fig. 2. Schematic presentation to illustrate the sign and components of $\Delta V^{\neq}$.

1.2. Instrumentation

Initial high pressure kinetic studies of coordination complexes in solution were conducted in a batch reactor (autoclave) either in situ, for instance by monitoring the reaction through optical windows and employing UV-VIS detection,[4] or by the use of a sampling technique. Advances in understanding the reaction dynamics of the coordination compounds described in this paper have resulted from developments in recent years which enable the pressure dependence of reactions to be studied on the milli-, micro- and nanonsecond time scales: stopped-flow[5–9] and T-jump methods[10–12], NMR spectroscopy,[13,14] and pulsed lasers.[15,16] With the increasing availability of such instrumental techniques, the output of high pressure kinetic information has increased significantly, as can be seen from a recent compilation of volume of activation data for reactions of coordination compounds.[17]

2. Reaction Dynamics in Coordination Chemistry

The effect of pressure on the reaction rates of coordination complexes has been studied for a variety of species and types of chemical reactions.[1,17] In general, such studies have been justified on the grounds that they can elucidate reaction mechanisms and resolve mechanistic discrepancies. In addition, however, pressure effects constitute important phenomena and complete our comprehension of chemical kinetics in that the suggested reaction mechanism must also account for these effects.[18] The examples selected in the following sections will clearly demonstrate both viewpoints. These include substitution, electron-transfer, and a series of miscellaneous reactions of coordination compounds. They are presented in this sequence, since substitution reactions form the basis for many of the other reaction types.

2.1. Substitution Reactions

Consider a substitution reaction of the type

$$[ML_nX] + Y \longrightarrow [ML_nY] + X \qquad (2)$$

in which M is the metal center, L the non-participating ligand, and X and Y the leaving and entering groups, respectively. Such reactions are generally discussed in terms of a dissociative (D), interchange (I) or associative (A) mechanism, depending on the degree of bonding of X and Y in the transition state of the process. The schematic presentation in Figure 3 is a useful aid to visualizing the nature of these mechanisms. If bond making is predominant, a significant decrease in molar volume of the reactants is expected (negative $\Delta V^{\neq}$); in contrast, a significant increase in volume will occur in a dissociatively activated process (positive $\Delta V^{\neq}$). In the case of an interchange process, bond breakage and bond formation occur simultaneously in varying degrees and small effects are expected, viz. a slightly negative $\Delta V^{\neq}$ for I_a and a slightly positive $\Delta V^{\neq}$ for I_d. These trends are predicted to show up in systems where no major solvational changes accompany the ligand substitution process, viz., in solvent exchange reactions; however, when charged ligands are substituted, major solvational changes are expected to influence the value of $\Delta V^{\neq}$.

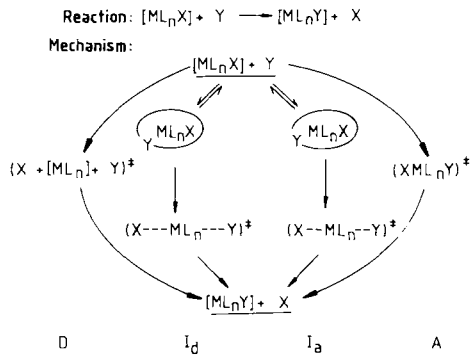

Fig. 3. Schematic presentation of the possible mechanisms of reaction (2).

2.1.1. Solvent Exchange Reactions

In a series of papers, *Merbach* and co-workers[19] reported $\Delta V^{\neq}$ data for solvent exchange reactions of diva-

Table 1. $\Delta V^{\ddagger}$ [cm^3 mol^{-1}] for solvent exchange on $[ML_6]^{2\oplus}$ ions [19]. DMF = dimethylformamide.

L \ M	$V^{2\oplus}$	$Mn^{2\oplus}$	$Fe^{2\oplus}$	$Co^{2\oplus}$	$Ni^{2\oplus}$

Mechanism:	I_a	I_a	I	I_d	I_d

lent octahedral first-row transition-metal ions. This information is of fundamental importance in understanding the general substitution behavior of such metal centers. The trend in the $\Delta V^{\ddagger}$ data (Table 1) was interpreted in terms of a gradual mechanistic changeover from I_a to I_d in this series.

A similar trend was observed for solvent exchange on high spin $[ML_6]^{3\oplus}$ ions by the use of NMR techniques.[19] The results are summarized in Figure 4. The trends can be rationalized according to the following complementary ideas:[19] A decrease in ionic radius (Fig. 4) will increase the dissociative character, due to steric crowding in the transition state. For an octahedral complex, the t_{2g} orbitals are nonbonding and the e_g orbitals σ^* antibonding. From $Mn^{2\oplus}$ to $Ni^{2\oplus}$ the t_{2g} orbitals are gradually filled, which makes the approach of a seventh ligand towards the face of the octahedron less favorable electrostatically, and could explain the tendency towards less associative behavior.

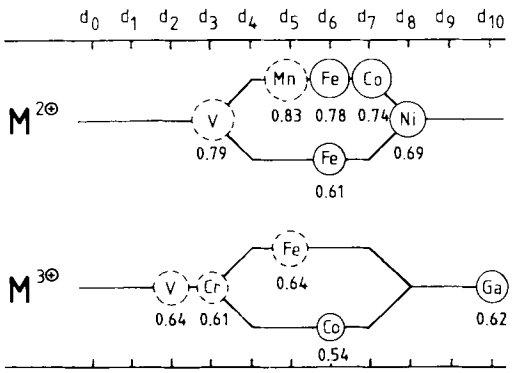

Fig. 4. First row octahedral transition metal ions (high and low spin) solvent exchange mechanisms (radii quoted in Å; Ⓜ = mechanisms A, I_a; Ⓜ = mechanisms D, I_d) taken from ref. [19].

2.1.2. Complex Formation Reactions

A logical question is whether complex formation reactions exhibit the same trend as discussed above for solvent exchange reactions. If this is indeed the case it will be of direct importance to all reactions involving such substitution processes at these metal centers. At the time the above mentioned solvent exchange work was reported,[19] only a few pressure dependence studies of fast complex formation reactions of these metal ions had been described, and the available data for complex formation with Ni^{II} and Co^{II}[20] seemed to be in good agreement with the solvent exchange data (Table 1). It was crucial to measure $\Delta V^{\ddagger}$ for complex formation of Mn^{II} or V^{II}, in order to determine whether a changeover in mechanism could be observed similar to that for the solvent exchange reactions. The first data came from a high-pressure temperature-jump study of the complexation of Mn^{II} with 2,2′-bipyridine (bpy) and 2,2′:6′,2″-terpyridine (terpy).[21,22] The presently available results (Table 2) clearly demonstrate that the activation volumes for complex formation reactions parallel those for solvent exchange, and underline the suggested changeover in mechanism along the first-row transition-metal ions.

Table 2. $\Delta V^{\ddagger}$ [cm^3 mol^{-1}] for complexation of first-row transition-metal elements in aqueous solution.

L \ M	$V^{2\oplus}$	$Mn^{2\oplus}$	$Fe^{2\oplus}$	$Co^{2\oplus}$	$Ni^{2\oplus}$	Ref.

$SCN^{\ominus}$	−2.1±0.8					[24]

[a] pada = 4-*N*,*N*-Dimethylaminobenzene-1-azo-2′-pyridine. [b] Experimental conditions such that $[L] \gg [M^{2\oplus}]$. [c] Experimental conditions such that $[M^{2\oplus}] \gg [L]$.

In one case, it was possible to measure $\Delta V^{\ddagger}$ for the reverse aquation process; this allowed the construction of a volume profile (Fig. 5). The reaction volume estimated from the activation volumes of the forward and reverse reactions is in close agreement with that determined directly from the pressure dependence of the equilibrium constant. The transition state is significantly denser than both the reactant and product states, emphasizing the associative nature of the process. Prior to this work the dissociative nature of such reactions, i.e., the traditional "Eigen-Wilkins" (or I_d) mechanism, had never been seriously questioned. The $\Delta V^{\ddagger}$ data, however, strongly support an I_a substitution mechanism for the earlier members of the first-row transition-metal elements.

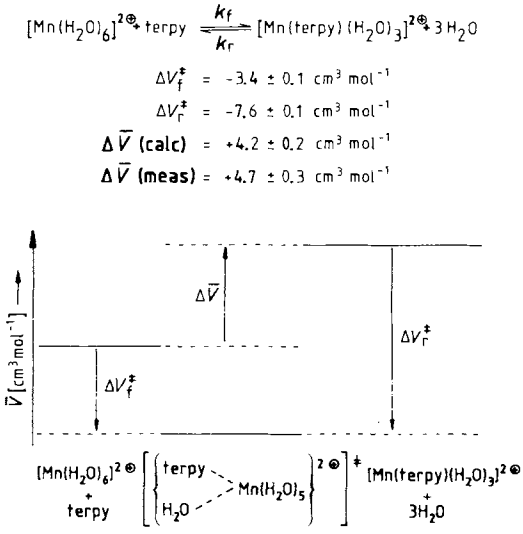

Fig. 5. Typical example of a volume profile for a complex formation reaction of Mn^{II}.

2.1.3. *Ligand Substitution Reactions of Square-Planar Complexes*

Such reactions are of general importance in the catalytic and cytostatic behavior of square-planar complexes. In general, substitution reactions of complexes of Pd^{II} and Pt^{II} follow an associative mechanism via a five-coordinate transition state. This is true for the solvolysis reaction (k_1), the subsequent rapid anation reaction (replacement of a H_2O ligand by another ligand), and the direct substitution (k_2) (see Fig. 6). The general question has been raised by

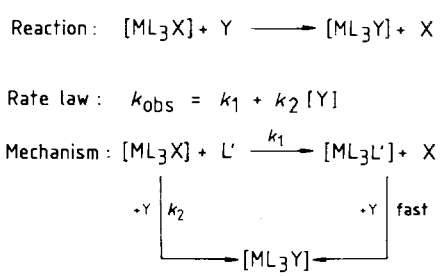

Fig. 6. A typical square planar substitution reaction; these reactions are usually associative (L' = solvent).

many investigators whether sterically hindered square-planar complexes could undergo substitution via a dissociative reaction mode. By increasing steric hindrance around the metal center, it may be possible to hinder the direct attack of the entering ligand or solvent molecule. Such a changeover in mechanism should clearly be seen in $\Delta V^{\neq}$ data. We have gradually increased the steric hindrance on a series of Pd^{II} complexes by introducing methyl and ethyl groups on the diethylenetriamine(dien) ligand. The data in Table 3 for the solvolysis/anation reaction of these complexes at 25 °C [Reaction (3)] nicely demonstrate that steric hindrance alone cannot induce a changeover in mechanism[25] even though the solvolysis rate constant decreases by up to five orders of magnitude. This reflects a gradual increase in $\Delta H^{\neq}$, but no trend is visible in $\Delta S^{\neq}$ and $\Delta V^{\neq}$.

$$[Pd(L)Cl]^{\oplus} + H_2O \xrightarrow[\text{slow}]{k_1} [Pd(L)H_2O]^{2\oplus} + Cl^{\ominus} \xrightarrow[\text{fast}]{+1^{\ominus}} [Pd(L)I]^{\oplus} + H_2O \quad (3)$$

$L = R^1R^2N-CH_2-CH_2-N(R^3)-CH_2-CH_2-NR^4R^5$

The average volume of activation (-12 ± 2 cm^3 mol^{-1}) is close to the maximum value expected for the associative entrance of a water molecule. This value, which is expected mainly to represent the intrinsic component, is significantly more negative than those (between -3 and -4 cm^3 mol^{-1}) reported[26] recently for similar solvolysis reactions involving NH_3 and pyridine as leaving ligands, and than those reported[27,28] for the solvent exchange on $[Pd(H_2O)_4]^{2\oplus}$ and $[Pt(H_2O)_4]^{2\oplus}$ (-2.2 and -4.6 cm^3 mol^{-1}, respectively). These tendencies in fact indicate that the values in Table 3 must arise partly from solvational changes probably involving dipole interactions with the charged leaving group. Such solvational contributions also show up in the data reported in Table 4 for the anation reaction (4), where partial charge neutralization during the associative reaction will result in a more positive $\Delta V^{\neq}$ value.[6,29,30] Furthermore, the volumes of activation become more negative with increasing size of the entering ligand, demonstrating the effect of the overlap of the van der Waals radii during the bond formation process.

2.1.4. Ligand Substitution Reactions of Octahedral Complexes

A number of reactions involving the substitution of ligands other than solvent molecules will be presented in this section. Such reactions occur mainly in non-coordinating solvents. For instance, the exchange of phosphane in the four-coordinated species $[Co(PPh_3)_2Br_2]$ in $CDCl_3$ exhibits a $\Delta V^{\neq}$ value of -12.1 ± 0.3 cm^3 mol^{-1}, which clearly underlines the associative nature of the substitution process.[31] Conversely, $\Delta V^{\neq}$ for the substitution of acetate in $Ni(OAc)_2$ by 2-hydroxynaphthalene-1-azo-2'-pyridine in acetic acid as solvent is $+15.5 \pm 2.6$ cm^3 mol^{-1}, demonstrating the dissociative nature of that process.[32] In the latter case, charge formation is involved so that $\Delta V^{\neq}_{intr}$ must be even more positive than the reported number. A recent study[33] of substitution reactions of the type

$$[cis\text{-}Mo(CO)_4(py)_2] + N\frown N \longrightarrow [Mo(CO)_4(N\frown N)] + 2\,py$$

where $N\frown N$ is bpy, 1,10-phenanthroline (phen) or *N,N'*-diphenyl-2,3-butanediimine (dab), resulted in $\Delta V^{\neq}$ values of $+3.6$ to $+4.5$ cm^3 mol^{-1}. These results are consistent with the rate-limiting step being the dissociation of pyridine:

$$[cis\text{-}Mo(CO)_4(py)_2] \rightleftharpoons [Mo(CO)_4py] + py$$

$$[Mo(CO)_4py] + N\frown N \longrightarrow [Mo(CO)_4(py)N\frown N] \longrightarrow [Mo(CO)_4(N\frown N)] + py$$

Many organometallic kineticists have run into problems with the interpretation of $\Delta S^{\neq}$ data in terms of the suggested reaction mechanisms. (The general fact that $\Delta S^{\neq}$ data are not very reliable for mechanistic assignments will be treated in the final section of this paper.) Positive volumes of activation have been found for systems in which other kinetic evidence, such as a negative $\Delta S^{\neq}$, points to an associative mechanism. Substitution of $[Cr(CO)_4(bte)]$ by $P(OEt)_3$ in 1,2-dichloroethane (bte = bis(*tert*-butylthio)-ethylene (2,2,7,7-tetramethyl-3,6-dithiaoctane)) is a typical example of such a case. The volume of activation of $+14.0 \pm 0.6$ cm^3 mol^{-1} clearly supports the dissociative nature of the process and emphasizes the value of this kinetic parameter. A similar value of $+14.7 \pm 0.7$ cm^3 mol^{-1} was found for the corresponding 3,6-dithiooctane complex.[34] In a recent study[35] a $\Delta V^{\neq}$ value of $+20.6 \pm 0.4$ cm^3 mol^{-1} was found for the rate-determining loss of CO in the reaction

$$[Mn(CO)_5Cl] + dab \longrightarrow [Mn(CO)_3(Cl)(dab)] + 2\,CO$$

This is indeed a very exciting result and motivates further study.

2.1.5. Base-Catalyzed Hydrolysis Reactions

Volumes of activation and volume profiles reveal significant mechanistic detail not only in the case of relatively simple chemical systems such as those discussed in the previous sections, but also for significantly more complicated processes. One of these concerns base-catalyzed hydrolysis reactions in which various complex species participate. In the case of Co^{III}-ammine complexes, base catalysis increases the rate of aquation from the hour to the millisecond time scale. Such reactions are generally accepted to proceed according to a S_N1CB mechanism which can be summarized as follows:

$$[Co(NH_3)_5X]^{(3-n)\oplus} + OH^{\ominus} \overset{K}{\rightleftharpoons} [Co(NH_3)_4(NH_2)X]^{(2-n)\oplus} + H_2O$$

$$[Co(NH_3)_4(NH_2)X]^{(2-n)\oplus} \xrightarrow{k} [Co(NH_3)_4NH_2]^{2\oplus} + X^{n\ominus}$$

$$[Co(NH_3)_4NH_2]^{2\oplus} + H_2O \xrightarrow{fast} [Co(NH_3)_5OH]^{2\oplus}$$

Net reaction:

$$[Co(NH_3)_5X]^{(3-n)\oplus} + OH^{\ominus} \longrightarrow [Co(NH_3)_5OH]^{2\oplus} + X^{n\ominus}$$

In this mechanism, formation of the conjugate base species is followed by rate-determining dissociation of $X^{n\ominus}$ to produce the five-coordinate $[Co(NH_3)_4NH_2]^{2\oplus}$ species, which rapidly reacts with the solvent to produce the hydrolysis product. The volume profile expected for this reaction scheme is given in Figure 7.

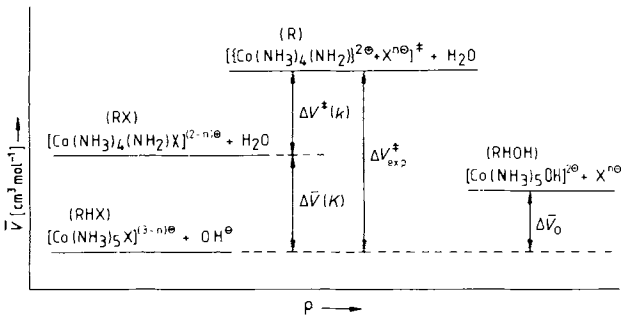

Fig. 7. Volume profile for the base hydrolysis of $[Co(NH_3)_5X]^{(3-n)\oplus}$ according to a S_N1CB mechanism.

Solvational effects are expected to significantly influence the values of $\Delta V^{\neq}_{exp}$ (consisting of $\Delta \bar{V}(K)$ and $\Delta V^{\neq}(k)$, since $k_{obs} = kK[OH^{\ominus}]$ for these reactions) and $\Delta \bar{V}_0$ (the overall volume change), since significant charge formation will be present when $X^{n\ominus}$ is a charged leaving group. This was indeed found to be the case,[36] and typical $\Delta V^{\neq}_{exp}$ values are ($X^{n\ominus}$): 40.2 ± 0.5 (Me_2SO); 31.0 ± 0.8 ($NO_3^{\ominus}$); 33.6 ± 1.0 ($I^{\ominus}$); 32.5 ± 1.4 ($Br^{\ominus}$); 33.0 ± 1.4 ($Cl^{\ominus}$); 26.4 ± 1.0 ($F^{\ominus}$); and 22.2 ± 0.7 ($SO_4^{2\ominus}$) cm^3 mol^{-1} at 25 °C. The decrease in $\Delta V^{\neq}_{exp}$ in this series is ascribed to the change in charge formation. A similar trend is seen in $\Delta \bar{V}_0$.[36] These data not only underline the validity of the suggested reaction mechanism, but reveal other interesting information. For instance, it is now possible for the first time to estimate the partial molar volume of the five-coordinate intermediate, on the assumption that the rate-determining step has a late (product-like) transition state in the case of a limiting dissociative mechanism. This volume should be independent of the nature of $X^{n\ominus}$. It turns out that the volume of the five-coordinate intermediate has an average value of 71 ± 4 cm^3 mol^{-1}, which is remarkably

close to the value of 68 $cm^3\ mol^{-1}$ for the six-coordinate $[Co(NH_3)_5OH]^{2\oplus}$ species. Furthermore, the quantity $\Delta V^{+}_{exp} - \Delta \bar{V}_0$ should also be independent of the nature of $X^{n\ominus}$ since it only involves the reaction of water with $[Co(NH_3)_4NH_2]^{2\oplus}$ to produce $[Co(NH_3)_5OH]^{2\oplus}$. It was found[36] that this volume difference is indeed constant and has an average value of 20 ± 2 $cm^3\ mol^{-1}$. This essentially equals the molar volume of water (viz. 18 $cm^3\ mol^{-1}$), which demonstrates that the water molecule is completely "absorbed" by the five-coordinate species during the final step of the reaction. In addition, this is also in line with the similarity found between the partial molar volumes of $[Co(NH_3)_4NH_2]^{2\oplus}$ and $[Co(NH_3)_5OH]^{2\oplus}$. Recent work[37] has demonstrated that similar trends exist for larger five-coordinate species, in which substituents were introduced on the ammine ligands.

2.2. Electron-Transfer Reactions

Mechanistic studies on electron transfer reactions of coordination complexes have been a popular research area for kineticists over the past decade, and the progress made and general importance of this work were recently emphasized by the award of a Nobel prize to *Henry Taube*. And yet, the mechanistic assignment in terms of inner- and outer-sphere mechanisms [Eq. (a)] has not been unambiguous. These mechanisms only differ with respect to the nature of the precursor intermediate species, Ox//Red, in the overall reaction scheme; it can be either an ion-pair or an encounter species in the case of the outer-sphere process, or a bridge intermediate in the case of an inner-sphere process. The electron-transfer [Eq. (b)] is then followed by dissociation of the successor complex [Eq. (c)]. In many systems, reaction (b) is rate-determining and in the presence of excess reducing agent, $k_{obs} = k_{ET} K[Red]/(1 + K[Red])$.

$$Ox + Red \overset{K}{\rightleftharpoons} Ox//Red \qquad (a)$$

$$Ox//Red \xrightarrow{k_{ET}} Ox^{\ominus}//Red^{\oplus} \qquad (b)$$

$$Ox^{\ominus}//Red^{\oplus} \rightleftharpoons Ox^{\ominus} + Red^{\oplus} \qquad (c)$$

The interpretation of the kinetic parameters is usually complicated by the fact that K is rather small, such that $k_{obs} = k_{ET} K[Red]$ and the observed second-order rate constant ($k_{ET} K$) is a composite quantity. However, the occurrence of bond formation and/or bond breakage in the inner-sphere mechanism should be clearly reflected in the volume of activation of the process as compared to that for outer-sphere reactions.

Halpern et al.[38] studied the pressure dependence of some typical inner-sphere electron-transfer reactions of the type

$$[Co(NH_3)_5X]^{2\oplus} + [Fe(H_2O)_6]^{2\oplus} \longrightarrow Co^{2\oplus} + 5\,NH_3 + [Fe(H_2O)_5X]^{2\oplus} + H_2O$$

They reported ΔV^{+} values of $+11$ (X = F), $+8$ (X = Cl, Br) and $+14$ $cm^3\ mol^{-1}$ (X = N_3). These values are expected to involve significant contributions from ΔV^{+}_{solv} and indeed, the data in Me_2SO as solvent were found to be $+10.3 \pm 0.4$ (X = F), $+3.8 \pm 0.7$ (X = Cl), 0.0 ± 0.4 (X = Br) and $+6.5 \pm 0.2$ $cm^3\ mol^{-1}$ (X = N_3).[39,40] In later work, *Stranks*[41] studied the effect of pressure on some typical outer-sphere electron-transfer reactions, and indeed found quite large negative values for ΔV^{+}. He developed a theoretical treatment based on the theories of *Marcus* and *Hush* and demonstrated that ΔV^{+} can be calculated by considering contributions from coulombic interaction, solvent rearrangement, internal metal-ligand rearrangement, and a Debye-Hückel component. His success is seen in the examples $[Co(en)_3]^{2\oplus}/[Co(en)_3]^{3\oplus}$ (en = ethylenediamine), for which ΔV^{+} is -19.8 ± 1.5 (exp.), and -18.4 (theor.) $cm^3\ mol^{-1}$, and $Fe(H_2O)_6^{2\oplus}/Fe(H_2O)_6^{3\oplus}$, for which ΔV^{+} is -12.2 ± 1.5 (exp.) and -14.4 (theor.) $cm^3\ mol^{-1}$. In contrast, the observed[41] ΔV^{+} values for inner-sphere electron transfer between $[Fe(H_2O)_5OH]^{2\oplus}$ and $[Fe(H_2O)_6]^{2\oplus}$ (-0.4 ± 0.4 $cm^3\ mol^{-1}$), and between $[Cr(H_2O)_5OH]^{2\oplus}$ and $[Cr(H_2O)_6]^{2\oplus}$ ($+4.2 \pm 1.1$ $cm^3\ mol^{-1}$) are significantly more positive than the values predicted for an outer-sphere electron-transfer process, viz. -11.4 and -11.6 $cm^3\ mol^{-1}$, respectively. This difference was ascribed to the dissociative release of a solvent molecule during the formation of the hydroxy-bridged inner-sphere intermediate. This trend is also in line with the data quoted above for the reduction of $[Co(NH_3)_5X]^{2\oplus}$ with $[Fe(H_2O)_6]^{2\oplus}$ and $[Fe(Me_2SO)_6]^{2\oplus}$.[38-40]

However, *Wherland*[42] recently pointed out that *Stranks*' theoretical treatment contained an error in the sign of the Debye-Hückel component, and that the close correlation between predicted and experimentally observed volumes of activation is only apparent. We[43] recently studied the outer-sphere electron-transfer reaction between $[Co(terpy)_2]^{2\oplus}$ and $[Co(bpy)_3]^{3\oplus}$ (terpy = 2,2′:6′,2″-terpyridine; bpy = 2,2′-bipyridine) in various solvents and found a ΔV^{+} value of -9.4 ± 0.9 $cm^3\ mol^{-1}$ for the reaction in water. This is in good agreement with the value of -7.3 $cm^3\ mol^{-1}$ theoretically predicted on the basis of *Wherland*'s treatment.[42]

The pressure dependence of a series of outer-sphere electron-transfer reactions in which significant ion-pair formation occurs, was also investigated.[44,45] In this case, K and k_{ET} can be determined separately.

$$[Co(NH_3)_5X]^{3\oplus} + [Fe(CN)_6]^{4\ominus} \overset{K}{\rightleftharpoons} ([Co(NH_3)_5X]^{3\oplus} \cdot [Fe(CN)_6]^{4\ominus}) \downarrow k_{ET} \quad Co^{2\oplus} + 5\,NH_3 + X + [Fe(CN)_6]^{3\ominus}$$

X = H_2O, Me_2SO, pyridine

The pressure dependence of k_{ET} results in large positive volumes of activation, viz., $+26.5 \pm 2.4$ (X = H_2O), $+29.8 \pm 1.4$ (X = py), and $+34.4 \pm 1.1$ $cm^3\ mol^{-1}$ (X = Me_2SO). Partial molar volume considerations showed[45] that these volume increases are due to the large volume increase in going from the precursor to the successor ion-pairs, e.g. 65 $cm^3\ mol^{-1}$ when $[Fe(CN)_6]^{4\ominus}$ is oxidized to $[Fe(CN)_6]^{3\ominus}$, and $[Co(NH_3)_5X]^{3\oplus}$ is reduced to

$[Co(NH_3)_5X]^{2\oplus}$. This means that on a volume basis the transition state for the electron-transfer step is approximately halfway between the two ion-pairs, and that the metal centers have a geometry halfway between the oxidation states involved. This simplified picture indicates how the molecular dimensions adjust prior to the actual electron-transfer step, which must obey the Franck-Condon restriction.

2.3. Miscellaneous Thermal Reactions

High pressure kinetic measurements have also assisted in the understanding of racemization and geometrical and linkage isomerization reactions of coordination compounds. Various mechanisms have been proposed for the racemization of octahedral complexes, and these are presented schematically in Figure 8. Although it is in many cases not possible to distinguish between all of these mechanisms, some racemization reactions exhibit very distinct pressure effects. For instance, $\Delta V^{\neq}$ for the racemization of $[Fe(phen)_3]^{2\oplus}$ (phen = 1,10-phenanthroline) is $+15.6 \pm 0.3$ $cm^3\ mol^{-1}$ compared to a value of -12.3 ± 0.3 $cm^3\ mol^{-1}$ reported for the racemization of $[Cr(C_2O_4)_2(phen)]^{\ominus}$.[46] The former result indicates a dissociative mechanism, and the latter an intramolecular one-ended ring-opening of the oxalate ligand. The large negative $\Delta V^{\neq}$ originates mainly from the increase in electrostriction during ring-opening of the oxalate chelate. A similar conclusion was drawn from the $\Delta V^{\neq}$ value of -16.6 ± 0.5 $cm^3\ mol^{-1}$ reported[47] for the geometrical isomerization of *trans*-$[Cr(C_2O_4)_2(H_2O)_2]^{\ominus}$. On the other hand, a $\Delta V^{\neq}$ value of $+14.3 \pm 0.2$ $cm^3\ mol^{-1}$ for the *trans* to *cis* isomerization of $[Co(en)_2(H_2O)_2]^{3\oplus}$ clearly supports the dissociative release of a water molecule to produce a five-coordinate intermediate.[48] A similar result was recently reported[49] for the *trans* to *cis* isomerization of $[Co(en)_2(CH_3COO)(H_2O)]^{2\oplus}$, in which the dissociation of the aqua ligand is believed to proceed according to an I_d mechanism since $\Delta V^{\neq}$ is between $+5.6$ and $+7.9$ $cm^3\ mol^{-1}$.

Linkage isomerization reactions are usually concerted intramolecular processes, and in general exhibit small pressure effects and volumes of activation.[1,17] This is understandable since such reactions, viz. M–ONO→M–NO_2, M–OSO_2→M–SO_3, and M–SCN→M–NCS, are expected to proceed via a transition state in which both coordination sites of the ligand are weakly bonded to the metal center. However, base-catalyzed isomerization reactions of $[Co(NH_3)_5ONO]^{2\oplus}$ and *cis*- and *trans*-$[Co(en)_2(ONO)_2]^{\oplus}$ exhibit large positive volumes of activation,[50,51] indicating that a S_N1CB mechanism is operative in these cases (see Section 2.1.5).

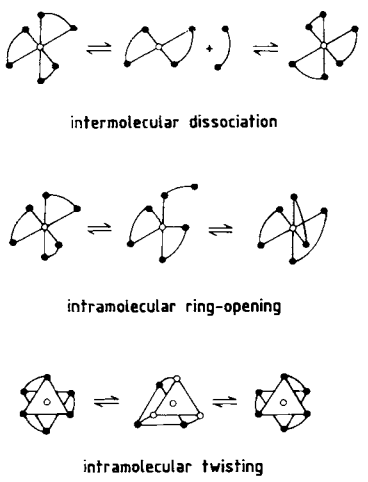

Fig. 8. Schematic representation of different racemization mechanisms of octahedral species.

Processes that involve addition or elimination reactions are expected mainly to exhibit intrinsic volumes of activation. For instance, CO_2 uptake by complexes of the type $[M(NH_3)_5OH]^{2\oplus}$ ($M = Co^{III}$, Rh^{III}, Ir^{III}) to produce the corresponding carbonato complexes, is characterized by negative volumes of activation.[52] Similarly, the reactions of [Ir(cod)(phen)]$^{\oplus}$ and [Ir(cod)(phen)I] (cod = cycloocta-1,5-diene, phen = 1,10-phenanthroline) with oxygen to produce $[Ir(cod)(phen)O_2]^{\oplus}$ exhibit volumes of activation of -31.1 ± 1.7 and -44.4 ± 1.6 $cm^3\ mol^{-1}$, respectively.[53] The more negative value for the reaction of the [Ir(cod)(phen)I] species is due to charge formation with the release of iodide. Large negative volumes of activation of this sort demonstrate the significance of bond formation in such addition reactions, and also demonstrate the significant catalytic effect pressure would have in such processes. On the other hand, decarboxylation reactions of complexes of the type $[M(NH_3)_5OCO_2H]^{2\oplus}$ all exhibit positive volumes of activation, in agreement with the release and elimination of CO_2.[52] A typical volume profile for such CO_2 uptake and elimination [Reaction (5)] is given in Figure 9, and the corresponding transition state for CO_2 uptake is illustrated schematically in Figure 10. These results are in good agreement with the volume profile reported[54] for the hydrolysis of CO_2 and the dehydration of carbonic acid.

$$[Co(NH_3)_5OH]^{2\oplus} + CO_2 \rightleftharpoons [Co(NH_3)_5OCO_2H]^{2\oplus} \quad (5)$$

Based on the results reported for organic systems,[55–57] homolytic and heterolytic decomposition reactions of coordination complexes are expected to exhibit character-

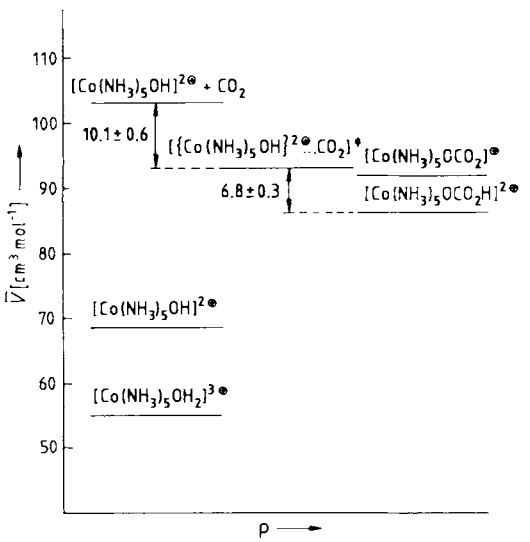

Fig. 9. Volume profile for the reaction (5).

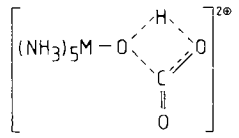

Fig. 10. Suggested transition state during CO_2 uptake and decarboxylation [Reaction (5)].

istic pressure dependencies. Such reactions were investigated for two organochromium(III) complexes of the type $[Cr(H_2O)_5R]^{2\oplus}$, where $R = C(CH_3)_2OH$ and $CH(CH_3)_2$.[58] The heterolytic decomposition path exhibited volumes of activation of $+0.3 \pm 0.2$ and -0.2 ± 0.2 cm^3 mol^{-1}, respectively. These small effects point to a transition state (I in Figure 11) which involves no net development of charge or major net changes in bond lengths. On the contrary, the volumes of activation for the homolysis reaction to produce $[Cr(H_2O)_6]^{2\oplus}$ and $R^{\odot}$ are $+15.1 \pm 1.6$ and $+26 \pm 2$ cm^3 mol^{-1} for the 2-hydroxyprop-2-yl and 2-propyl complexes, respectively. These large positive effects are ascribed to massive desolvation, i.e. breakup of the solvent cage, as the organic radicals separate from $Cr^{2\oplus}$ in the transition state (II in Figure 11).[55] Such mechanistic detail could not be obtained with conventional kinetic techniques.

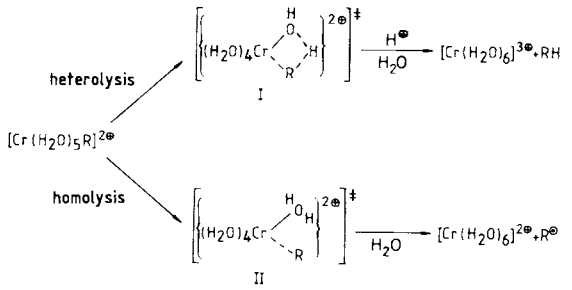

Fig. 11. Heterolytic and homolytic reactions of organochromium(III) complexes.

2.4. Photochemical reactions

The examples discussed in the preceeding sections have demonstrated how insight into reaction dynamics can be obtained from the pressure dependence of a rate constant. In photochemical reactions of coordination compounds we are dealing with the chemistry of excited state species. Since so little is known about the molecular dynamics of such reactions, the pressure dependence of the photochemical reaction step may help reveal the intimate nature of this process. The interpretation of such data can be expected to be more difficult than for ground state thermal processes.[56] Nevertheless, the results obtained so far for the photosolvolysis reactions of a series of rhodium(III)-ammine complexes are very reasonable and deserve to be mentioned in this paper.

The photosolvolysis reactions investigated all proceed according to the overall scheme:[16,60-62]

$$\begin{array}{l} [Rh(NH_3)_5X]^{(3-n)\oplus} \\ \quad + \\ \quad L \end{array} \xrightarrow[LF]{h\nu} \begin{cases} \longrightarrow [Rh(NH_3)_5L]^{3\oplus} + X^{n\ominus} \\ \longrightarrow \textit{trans}\text{-}[Rh(NH_3)_4(L)X]^{(3-n)\oplus} + NH_3 \end{cases} \quad (d)$$

LF = ligand field excitation

Earlier studies by *Ford* et al. (see literature cited in ref. [16]) indicate that the lowest energy excited state is a ligand field triplet state from which the primary photoreaction (k_p), nonradiative (k_n) and radiative deactivation (k_r) occur. Since $k_r \ll (k_p + k_n)$ it can be shown that $\Phi = k_p/(k_p + k_n) = k_p \tau$, from which it follows that the quantum yield Φ and the lifetime of the lowest excited state τ must both be measured to yield k_p at any pressure. A typical example of the pressure dependence of Φ is given in Figure 12, which clearly shows different dependencies for the two photosolvolysis reactions.

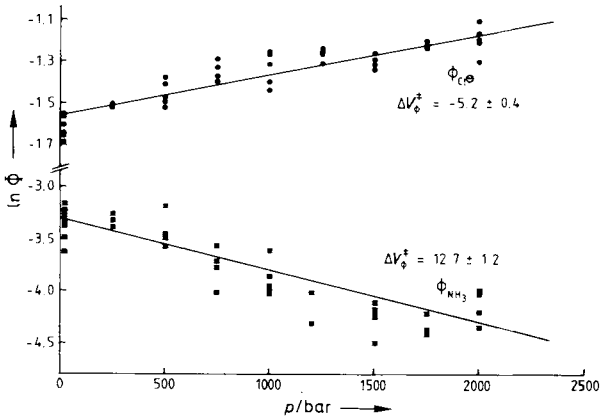

Fig. 12. Pressure dependence of the reaction (d). X = Cl, L = H_2O.

Pulsed laser techniques were employed to measure the pressure dependence of τ^{-1},[16,62] and the corresponding volumes of activation are summarized in Table 5. Throughout the series of complexes the solvolysis of NH_3 is accompanied by a positive $\Delta V_p^{\neq}$ value, which underlines the dissociative nature of the ligand substitution process. The negative $\Delta V_p^{\neq}$ values reported for the solvolysis of $X^{n\ominus}$ are attributed to electrostriction due to charge formation during the dissociative release of $X^{n\ominus}$. This is also in line with the more positive values found for the solvolysis of chloride in *trans*-$[Rh(NH_3)_4Cl_2]^{\oplus}$, for which significantly less electrostriction is expected to occur. These data also enable the calculation of $\Delta V_n^{\neq}$, the volume of activation for the non-radiative deactivation process, and throw more light on the nature of this step.[16,62] It follows that such studies can provide insight into the dynamics of the excited state processes.[59] The method can equally well be applied to study charge transfer photochemical processes, as illustrated by a series of studies[63-65] recently performed in our laboratories. The construction of volume profiles, however, is complicated by the lack of data on the partial molar volume of ligand field and charge transfer excited species.[59]

3. Concluding Remarks

We have described in the preceeding sections how the application of high pressure techniques can contribute to the understanding of thermal and photochemical reaction dynamics in coordination chemistry.[66] Such data can help

Table 5. Volumes of activation from photochemical and photophysical measurements on the photosolvolysis reactions of rhodium(III)ammine complexes at 25°C, FMA = formamide.

solve mechanistic questions by providing direct information on the size (volume) of transition state species. The interpretation of $\Delta V^{\neq}$ data offers a pictorial presentation of the chemical process on a volume basis that usually supports the mechanistic interpretation in an intuitive way. The occurrence of large solvational contributions may complicate the interpretation of $\Delta V^{\neq}$, and additional measurements in other solvents or for differently charged species are then helpful.

Some investigators have called attention to the apparent correlation between $\Delta V^{\neq}$ and $\Delta S^{\neq}$ data,[1,67-69] although there is no thermodynamic function that links these parameters directly. It would be misleading to use such a generalized correlation since there are numerous exceptions. In many of these $\Delta V^{\neq}$ and $\Delta S^{\neq}$ have opposite signs and it is therefore wrong to generalize this "correlation". It is important to note that $\Delta S^{\neq}$ is usually subject to large error limits since it is determined by extrapolating the experimental data to $1/T \rightarrow 0$. In contrast, $\Delta V^{\neq}$ can usually be determined with good accuracy since it results from the slope of the $\ln k$ versus p plot, similar to $\Delta H^{\neq}$.

Our present activities in this area are focussed on the thermal and photochemical dynamics of organometallic species, a research area in which many mechanistic uncertainties still persist. The advantage of such systems is the low oxidation states of the metal centers such that minor solvational contributions are expected to influence $\Delta V^{\neq}$ in most cases. The method described in this paper should also enable one to distinguish between the various reaction modes of metal clusters in solution.

Finally, these results find practical application in various areas. A better understanding of the intimate mechanism of a chemical reaction assists the design of modified systems with special behavior, for instance for use in catalytic cycles. Such information can also be applied directly in synthetic work where the application of pressure may favor a particular reaction product (see for instance Figure 12) or reduce the reaction time required; especially in organic chemistry there are numerous examples of the application of high pressure to assist the synthesis of particular species or isomers. In addition, such techniques are being applied to biochemical and environmental processes, in order to contribute to the understanding of the underlying mechanisms.

The author gratefully acknowledges financial support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Scientific Affairs Division of NATO. He sincerely appreciates the very fine collaboration with graduate students, post-doctoral fellows and visiting scientists during recent years; their names appear on the papers cited from this laboratory. This paper is dedicated to Prof. Dr. Hartwig Kelm in recognition of his pioneering work in this area, and for his continued interest and support over the last six years during which he served as President of the University.

Indirect Electroorganic Syntheses— A Modern Chapter of Organic Electrochemistry

New Synthetic Methods (59)

By Eberhard Steckhan*

The electrochemical formation and regeneration of redox agents for organic syntheses (*indirect electrolysis*) widens the potential of electrochemistry, as higher or totally different selectivities can often be obtained while at the same time the energy input can be lowered significantly. Higher current densities can also be obtained by preventing otherwise often encountered electrode inhibition. New types of redox catalysts can be formed in-situ and can be regenerated after reaction with the substrates. This principle is of increasing importance also for the application of already known redox agents with regard to environmental protection, since large amounts of a product can be generated in a closed circuit using only relatively small amounts of the redox reagent. Consequently the operation of such a process can be greatly simplified, and the release of ecologically objectionable spent reagents into the environment can be prevented. The broad spectrum of redox catalysts currently in use includes, inter alia, metal salts in very low or high oxidation states, halogens in various oxidation states, and, in particular, a wide variety of transition-metal complexes. A great deal of progress has recently been made in the application of organic electron transfer agents, since compounds have been found that are sufficiently stable in both the reduced as well as the oxidized state.

1. Introduction

In organic syntheses electrochemical reductions and oxidations offer numerous advantages over conventional methods: mild reaction conditions, which often guarantee a high selectivity; independence of a chemical redox reagent, which leads to a drastic reduction of environmental problems; better use of raw materials; easier isolation of products; simplification of continuous processing. One method that occupies a position between direct electrochemical and homogeneous-chemical redox processes and which under ideal conditions combines the advantages of both procedures is indirect electrolysis. Although at one stage almost forgotten this method has a long tradition,[1] and in some cases has found industrial application.[2,3] For example, one of the earliest electroorganic syntheses to be employed on an industrial scale was the oxidation of glucose to gluconic acid with bromide as redox catalyst [Eq. (1)]. In this process the bromine that is released at the anode is the oxidizing agent.[2]

$$2C_6H_{12}O_6 + CaCO_3 + H_2O \xrightarrow[\text{anode}]{Br^{\ominus}} Ca(C_6H_{11}O_7)_2 + CO_2 + 2H_2 \quad (1)$$

As shown in Figure 1, the indirect electrolysis combines a heterogeneous step (the production and regeneration of the redox catalyst (Med = mediator) in its active form) with the homogeneous redox reaction of Med and the substrate RH.

This electrochemical method has recently experienced a sudden revived interest,[4-10] stimulated in particular by its advantages in diminishing environmental hazards, lowering energy consumption, and, last but not least, by its ability to make extremely high selectivities possible. Moreover, the inhibition of the heterogeneous electron transfer that is often encountered in direct electrochemical processes can also be prevented by mediator-catalyzed electrochemical reactions, thus making useful current densities possible. The purpose of this article is not to summarize the scope and limitations of an already exhausted reaction principle, but rather to outline the changes and prospects of a field that is still developing and to encourage participation in its evolution and in the exploitation of its potential.

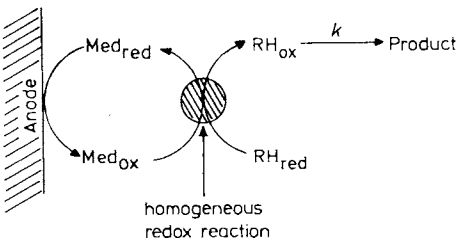

Fig. 1. The principle of indirect electrolysis exemplified by an oxidation.

2. Basic Principles

2.1. The Principle of Indirect Electrolysis

Indirect electrochemical processes are, in a certain sense, hybrids: They combine an electrochemical and therefore heterogeneous electron transfer reaction with a homogeneous redox process. The redox agent reacts with the substrate in a homogeneous reaction and is subsequently regenerated in its active form at the electrode (see Fig. 1).

The electrochemical regeneration can be performed in three different ways:[3,6,11] The most well known[12] consists

[*] Prof. Dr. E. Steckhan
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Str. 1, D-5300 Bonn 1 (FRG)

in separating and isolating the redox agent, which has been converted in the chemical reactor, and in regenerating it *externally* in an electrolysis cell. This so called "ex-cell" method[3,6] (see Fig. 2) possesses the following advantages:[7,13] chemical and electrochemical steps can be optimized independently of each other and neither substrates nor products can adversely affect the electrode reaction, nor can the electrode interfere with the homogeneous reaction. Despite this method being technically complicated most of the processes used on an industrial scale are two-stage processes of this kind, like, e.g. the external regeneration of chromic acid.

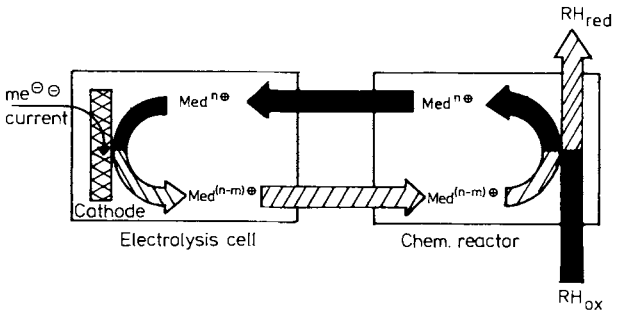

Fig. 2. Principle of indirect electrochemical synthesis with external regeneration of the redox catalyst ($Med^{(n-m)\oplus}$) exemplified by a reduction.

A second way of electrochemical regeneration consists in the continuous *internal* electrochemical retransformation of the electron transfer agent into its active form without isolating it, i.e. within the reaction vessel ("in-cell" process, Fig. 3).[3,6] The electron transfer agent, often also called mediator, that is inserted between electrode and substrate undergoes a homogeneous chemical reaction with the substrate and is subsequently regenerated at the electrode. Thus, it serves as a catalyst for the electron transfer between electrode and substrate.

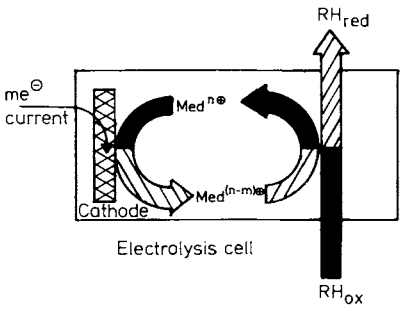

Fig. 3. Principle of indirect electrochemical synthesis with internal regeneration of the redox catalyst ($Med^{(n-m)\oplus}$) exemplified by a reduction.

Because of the coupling of two very different reactions in one reactor, however, the one-step process is much more difficult to realize than the two-step process, since conditions have to be found under which the organic substrates, reactive intermediates, and products do not hinder the electrochemical regeneration of the reagent or they themselves are not attacked electrochemically. That is why this method has only recently found more successful application. Aside from the advantage of lower investment costs, it is of great importance for the industrial application of this method that a continuous reaction processing is facilitated, since the products can be separated from catalytic amounts of the redox reagent far more easily than from an excess of reagent. It is, however, more advantageous if the process can be carried out in a two-phase system in which the product concentrates in the substrate phase.[14-16]

In the third type of indirect electrolysis the redox agent that is formed at the electrode does not react homogeneously in the solution, but remains fixed at the electrode surface, where it is continuously regenerated. Such an activation of the electrode surface can, on the one hand, take place "in-situ" by the continuous regeneration of the redox agent in its active form on the electrode surface during the electrolysis. This is the situation, e.g., both in the case of the nickel(III) oxide-hydroxide electrode, which is formed in alkaline medium during anodic polarization of a nickel electrode, and which is especially suited for the oxidation of primary alcohols to carboxylic acids and of primary amines to nitriles,[17] and in the case of the amalgam electrode, which is formed in the reduction of sodium or tetraalkylammonium salts at mercury cathodes and can, for example, be employed for the hydrodimerization of activated olefins.[5,18] On the other hand, the electrode can be chemically modified first by fixation of the redox catalyst to the electrode surface by adsorption, polymeric coating, or covalent binding. As the stability of such electrodes is not yet satisfactory enough for preparative purposes, and as this aspect of indirect electrochemical processes has already been extensively reviewed elsewhere,[19-23] it will not be discussed any further here.

2.2. The Redox Catalyst

The redox catalyst holds a key position in indirect electrolysis since it is involved in both the heterogeneous as well as the homogeneous redox reaction. To be suitable for both types of reactions the mediators must fulfill the following conditions:

1. Both reduced and oxidized forms must be chemically stable. Even a slight side-reaction to give compounds no longer convertible into the active form leads to a rapid loss of catalytic activity.
2. Electron exchange with the electrode and reaction with the substrate must be fast and as reversible as possible, otherwise larger and therefore more expensive electrode surfaces are necessary. In addition, side reactions are often favored.
3. Redox reactions with other than the desired compounds, for instance with the solvent, must not take place or must be suppressed.
4. Both redox states must be sufficiently soluble in the chosen supporting electrolyte (exception: two-phase systems).

Inorganic ions, metal salts and some metal complexes usually fulfill the condition of chemical stability more easily than organic mediators, however the electron transfer is often too slow, as it is in many cases connected with a change in the complex structure. On the other hand, metal

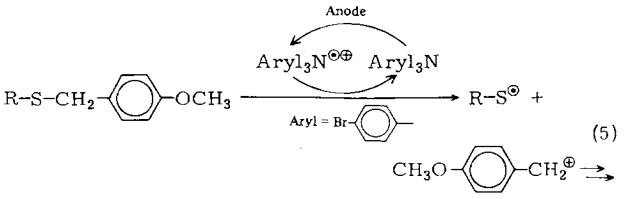
ions often have the advantage of moderating the reactivity of intermediates that are formed during the electron transfer by coordination or complexation and thereby enable specific and selective reactions. Moreover, in the case of transition metal complexes, the redox potential can easily be influenced by choice of the central atom or the ligands.

Organic mediators in their active form, e.g. as radical ions, are sometimes not sufficiently stable in many media. They often react irreversibly with the solvent, with the electrolyte, or with the intermediates that are formed during the redox reaction. The number of stable organic electron transfer agents is therefore limited and their availability is often restricted to certain electrolytes. Nevertheless, great progress has been made in this field recently.

In principle the redox catalysts can be classified into two groups according to the reaction mechanisms they undergo in the homogeneous redox step.

Mechanism A: The homogeneous redox reaction consists of a pure electron transfer. Such a process is called "redox catalysis" in its more stricter sense by *Savéant* et al.,[28] while *Shono*[8] has coined the expression "homomediatory system". This mechanism is represented schematically in equations (2) to (4). The radical anions and cations of aromatics, heteroaromatics and triaryl amines, for example, fall into this category of redox catalysts.

$$\text{Med} \xrightarrow[-e]{\text{anode}} \text{Med}^{\odot\oplus} \tag{2}$$



$$\text{Med}^{\odot\oplus} + \text{RH} \underset{\text{ET}}{\overset{K}{\rightleftharpoons}} \text{Med} + \text{RH}^{\odot\oplus} \tag{3}$$

$$\text{RH}^{\odot\oplus} \xrightarrow[\text{e.g. } -\text{H}^{\oplus}]{k} \text{R}^{\odot} \longrightarrow \longrightarrow \text{products} \tag{4}$$

ET = electron transfer

Electrode reactions that are often characterized by irreversible, i.e. slow electron transfer, can in this way be accelerated, and the more or less large overvoltages, that occur especially in conversions on a preparative scale, can be removed.[25] Hence, not only is the energy consumption thereby reduced but also the selectivity increased. With this type of reaction, electron transfer reactions in solution can often be carried out even with redox reagents whose potentials are up to 600 mV lower than the electrode potentials of the substrates. These redox reactions "opposite to the standard potential gradient"[25-27] can take place if a thermodynamically unfavorable electron transfer equilibrium [Eq. (3)] is followed by a fast and irreversible reaction step [Eq. (4)] that removes the product of the electron transfer from the equilibrium. In this case the overall reaction rate is determined by the equilibrium constant K, i.e. by the difference between the standard potentials of the partners of the redox step, and by the rate constant k of the follow-up reaction. In addition to the advantage of lowering the potential, which is accompanied by a gain in energy and selectivity, the number of the transferred electrons can be controlled by choice of the redox catalyst.

Decisive for the selectivity of the reaction are the potential differences between the various functional groups of the substrate and the mediator, as are also the rates of the respective chemical follow-up reactions. A typical example of such a reaction is the oxidative cleavage of a carbon-sulfur bond in *p*-methoxybenzyl sulfides with tris(*p*-bromophenyl)amine as mediator [Eq. (5)].[189]

(5)

The reductive and oxidative power, respectively, of the mediators and acceptors generated at low potentials can be enhanced by photochemical excitation during the electrochemical generation,[29,30] since a higher molecular orbital is occupied thereby, and an electron gap is generated in a lower orbital. The principle of this type of reaction is outlined in the following equations for an oxidation.

$$\text{Med} \xrightarrow[-e^{\ominus}]{\text{anode}} \text{Med}^{\odot\oplus} \tag{2}$$

$$\text{Med}^{\odot\oplus} \xrightarrow{h\nu} [\text{Med}^{\odot\oplus}]^{*} \tag{6}$$

$$[\text{Med}^{\odot\oplus}]^{*} + \text{RH} \underset{}{\overset{\text{ET}}{\rightleftharpoons}} \text{Med} + \text{RH}^{\odot\oplus} \tag{7}$$

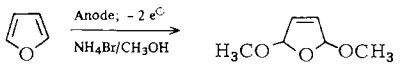
$$\text{RH}^{\odot\oplus} \xrightarrow[\text{e.g. } -\text{H}^{\oplus}]{} \text{R}^{\odot} \longrightarrow \longrightarrow \text{products} \tag{4}$$

Mechanism B: The homogeneous redox reaction is combined with a chemical reaction, for instance a hydrogen or hydride atom abstraction. In the terminology of *Savéant* et al.[28] this process is referred to as "chemical catalysis", while *Shono*[8] speaks of a "heteromediatory system." The following equations illustrate the principle of this type of reaction for a hydrogen abstraction (oxidation).

$$\text{Med} \xrightarrow[-e^{\ominus}]{\text{anode}} \text{Med}^{\odot\oplus} \tag{2}$$

$$\text{Med}^{\odot\oplus} + \text{RH} \longrightarrow \text{MedH}^{\oplus} + \text{R}^{\odot} \tag{8}$$

$$\text{MedH}^{\oplus} + \text{B} \longrightarrow \text{Med} + \text{HB}^{\oplus} \tag{9}$$



$$\text{R}^{\odot} \longrightarrow \longrightarrow \text{products} \tag{10}$$

B = base

If transition metal compounds are employed as redox catalysts, mechanism A can be regarded as outer-sphere and mechanism B as inner-sphere electron transfer. Here, the chemical step [Eq. (8)] determines the selectivity of the reaction. In addition, substantially higher potential differences can be overcome, as the chemical step [Eq. (8)] is not directly dependent upon the potential of the mediator.

The problem is, however, to find a chemical follow-up reaction in accord with equation (9) that can make the reagent electrochemically regenerable. In the case of organometallic reagents this is usually not easy to achieve, as mostly a ligand exchange has to occur first.[31,32] Some of the most frequently used redox catalysts in this category besides transition metal ions are halogen cations, hypohal-

ite ions, and molecular halogen, which are electrochemically generated from halide ions.[8] One of the oldest reactions, which is also used on an industrial scale, is the anodic methoxylation of furan in the presence of bromide ions [Eq. (11)].[33]

(11)

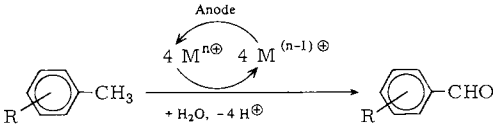
3. Indirect Electrochemical Syntheses with Inorganic and Organometallic Redox Catalysts

The largest group of inorganic redox catalysts comprises metal ions, especially transition metal ions, and their complexes. These reagents are often capable of undergoing selective redox reactions with a large number of organic substrates. By simply varying the reaction conditions a large variety of products can be obtained, since such redox processes are usually not simple electron transfer reactions. Rather, the substrates, reactive intermediates, or intermediate products are generally linked to the metal atom by complexation, coordination, or even by bond formation, so that their reactivity is reduced, and the selectivity thereby enhanced (mechanism B, Section 2.2).

In most cases the use of these reagents is reasonable from an economic and ecological point of view only if the redox catalysts can be regenerated. Regeneration by means of chemical reducing or oxidizing agents such as $LiAlH_4$ or $[Fe(CN)_6]^{3\ominus}$ is no solution, since it merely shifts the problem to another stage. Consequently, attempts were already made at a relatively early date to find ways of electrochemically regenerating the redox agents. In principle, it should be possible in all cases to use indirect electrolysis instead of stoichiometric amounts of inorganic redox agents. Prerequisite, however, is that the number of regenerative cycles is large and the current yield for the generation of the reagent remains constant at an acceptable order of magnitude over a long period of time.[13,24] Otherwise, the energy consumption is too high. But even in those cases where indirect electrolysis is more expensive than the comparable non-electrochemical process, the electrochemical regeneration can still be economically attractive, that is when a recycling of the reagent solution is necessary for ecological reasons, e.g. in the electrochemical recovery of chromic acid.[35]

In the meantime, results of electrochemical regeneration have been documented for the following inorganic oxidizing agents: Cr^{VI}-, Ce^{IV}-, Mn^{III}-, V^{V}-, Fe^{III}-, Hg^{II}-, Pd^{II}-, Tl^{III}-, Ag^{II}-, Os^{VIII}-compounds, $[Fe(CN)_6]^{3\ominus}$, Ru^{IV}-complexes, RuO_4, as well as the nonmetallic ions $BrO^{\ominus}$, $ClO^{\ominus}$, $IO_4^{\ominus}$, $I^{\oplus}$, $Br^{\oplus}$, $Cl^{\oplus}$, and the halogens I_2, Br_2 and Cl_2. The following electrochemically regenerated reducing agents have also been studied: Fe^{II}-, Ti^{II}-, Sn^{II}-, Sn^{II}-, V^{III}-, Cr^{II}-compounds, Pd^{0}-, Ni^{0}-, Ni^{I}-, Co^{I}-, Rh^{I}- and Fe^{0}-complexes, and the nonmetallic reagent $O_2^{\ominus\ominus}$. In addition, the alkali metal and alkaline earth metal amalgams[5,18] and solvated electrons fall into this category. An idea of the oxidative and reductive power of some of the redox agents can be gleaned from their standard potentials listed in Table 1.

Table 1. Standard redox potentials of some inorganic redox agents vs. the normal hydrogen electrode (NHE) [34].



Reduction			E° [V]
$Co^{3\oplus} + e^{\ominus}$	⟶	$Co^{2\oplus}$	1.83
$Ce^{4\oplus} + e^{\ominus}$	⟶	$Ce^{3\oplus}$	1.61
$Mn^{3\oplus} + e^{\ominus}$	⟶	$Mn^{2\oplus}$	1.54
$MnO_4^{\ominus} + 8H^{\oplus} + 5e^{\ominus}$	⟶	$Mn^{2\oplus} + 4H_2O$	1.51

$IO^{\ominus} + 2H^{\oplus} + 2e^{\ominus}$	⟶	$I^{\ominus} + H_2O$	1.31
$3HIO + 3H^{\oplus} + 4e^{\ominus}$	⟶	$I_3^{\ominus} + 3H_2O$	1.21
$IO^{\ominus} + H_2O + 2e^{\ominus}$	⟶	$I^{\ominus} + 2OH^{\ominus}$	0.49

3.1. Oxidations with Metal Salts as Redox Catalysts

3.1.1. *Oxidation of Aromatics in the Side-Chain*

The electrochemical recovery of inorganic oxidizing agents such as Cr^{VI}-, V^{V}-, Ce^{IV}- and Co^{III}-, and, to a smaller extent, Ag^{II}-compounds for the side-chain oxidation of aromatics has been the subject of very intensive studies.

Synthesis of benzaldehydes and substituted benzaldehydes: The use of electrochemically regenerated Mn^{III}- and Ce^{IV}-compounds as "oxygen transfer agents" for the formation of benzaldehydes from the corresponding methyl substituted aromatics was proposed at a very early date and later reviewed by *Fichter*[1] [Eq. (12)]. With the ions $Mn^{3\oplus}$,[36,39,44,46] $Ce^{4\oplus}$,[7,37,38,41-43] or $Co^{3\oplus}$ as redox

(12)

catalysts for the oxidation of alkyl aromatics, only the two-step process with recycling of the electrolyte has so far led to acceptable results, whereas in the catalysis by $Ag^{2\oplus}$ ions internal regeneration is especially favored, since the cur-

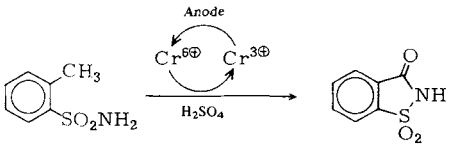
rent yield is reduced drastically when higher concentrations of $Ag^{2\oplus}$ ions are produced.[40] In a fundamentally different way alkyl-substituted aromatics can also be oxidized in the benzylic position with Fenton's reagent that is formed in situ [Eq. (13)–(19)].[45]

$$\text{Cathode: } Fe^{3\ominus} + e^{\ominus} \longrightarrow Fe^{2\oplus} \quad (13)$$

$$\text{Cathode: } O_2 + 2e^{\ominus} + 2H^{\oplus} \longrightarrow H_2O_2 \quad (14)$$

$$Fe^{2\oplus} + H_2O_2 \longrightarrow Fe^{3\oplus} + {}^{\ominus}OH + {}^{\ominus}OH \quad (15)$$

$$Ph{-}CH_3 + {}^{\ominus}OH \longrightarrow Ph{-}\overset{\ominus}{C}H_2 + H_2O \quad (16)$$

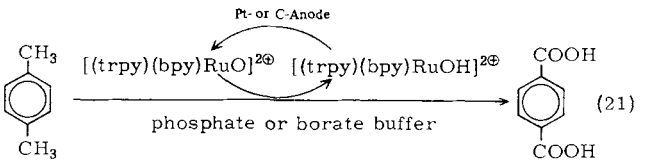


$$Ph{-}\overset{\ominus}{C}H_2 + O_2 \longrightarrow Ph{-}CH_2OO^{\ominus} \quad (17)$$

$$Ph{-}CH_2OO^{\ominus} \longrightarrow Ph{-}\overset{\oplus}{C}H{-}OOH \quad (18)$$

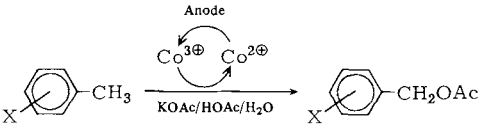
$$Ph{-}\overset{\oplus}{C}H{-}OOH + Fe^{2\oplus} \longrightarrow Ph{-}CHO + Fe^{3\oplus} + {}^{\ominus}OH \quad (19)$$

The redox pair $Fe^{2\oplus}/Fe^{3\oplus}$ can also be replaced by $V^{4\oplus}/V^{3\oplus}$ or $Cu^{2\oplus}/Cu^{\oplus}$.



Synthesis of aromatic carboxylic acids: The oxidation of arylalkanes to arylcarboxylic acids with electrochemically regenerated chromic acid[47] has been studied intensively by *Kuhn* et al. in the case of the transformation of *o*-toluenesulfonamide to saccharin [Eq. (20)].[24,28] The yields are about 80%. The main problems encountered are the incomplete separation of the organic material and the poisoning of the lead dioxide electrode, which leads to a decrease in the current yields. These problems are not only met with in this particular case but are characteristic for all processes in which an external electrochemical regeneration of chromic acid takes part.

(20)



The indirect electrochemical oxidation of *p*-nitrotoluene[49,50] and 2,4-dinitrotoluene[51] to the corresponding nitrobenzoic acids and the transformations of toluene as well as *p*-xylene, *p*-toluic acid and *p*-tolualdehyde into benzoic acid and terephthalic acid[11,52–54], respectively, by electrochemically generated chromic acid have also been studied.

Recently, great hopes have been put on the use of Ru^{IV}-complexes as mediators for the oxidation of arylalkanes to carboxylic acids with internal electrochemical regeneration. Thus, with the electrochemically produced complex $[(trpy)(bpy)RuO]^{2\oplus}$ (trpy = terpyridine, bpy = bipyridine) it is possible to convert *p*-toluic acid and *p*-xylene into terephthalic acid [Eq. (21)] and toluene into benzoic acid.[75] The current yield is almost quantitative. After 100 cycles, 75% of the redox catalyst can still be recovered, which corresponds to an estimated number of 400 possible cycles.

(21)

Side-chain acetoxylations: The selective side-chain acetoxylation of arylalkanes with internal electrochemically generated cobalt^{III} acetate to give monoacetoxylated products was already patented in 1969[55] [Eq. (22)]. Further patents have recently been granted for procedures using Cu-, Fe-, Co-, Mn- and Pb-acetates as catalysts.[56,57]

(22)

3.1.2. Oxidations at the Aromatic Nucleus

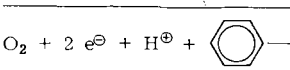
The oxidation of arenes to quinones, especially the oxidation of anthracene to anthraquinone, is usually performed with electrochemically regenerated Ce^{IV} or Cr^{VI}, even on an industrial scale,[2,3,58–60] but this method has lost importance since the development of catalytic processes. With regard to a hydroquinone synthesis, the oxidation of benzene to benzoquinone could be of industrial importance but the methods developed so far[40,61] are not yet competitive enough. Aside from the above-mentioned redox systems, Mn^{II} and Ag^{II} salts are also being investigated as catalysts.[62]

Another interesting application is the selective oxidation of benzene to phenol in the presence of iron salts, whereby the "in-situ" formation of Fenton's reagent is presumed to take place. Not only have reactions been studied in which hydrogen peroxide is added and the concentration of $Fe^{2\oplus}$ ions kept constant electrochemically[15] but also systems in which H_2O_2 is produced simultaneously at the cathode.[63–65] The addition of Cu^{II} salts is favorable, as $Cu^{2\oplus}$ ions are especially effective for the oxidation of carbon radicals [Eq. (23)–(29)]. A similar reaction sequence can also be achieved with the $Cu^{\oplus}/Cu^{2\oplus}$ redox pair alone.[66,67]

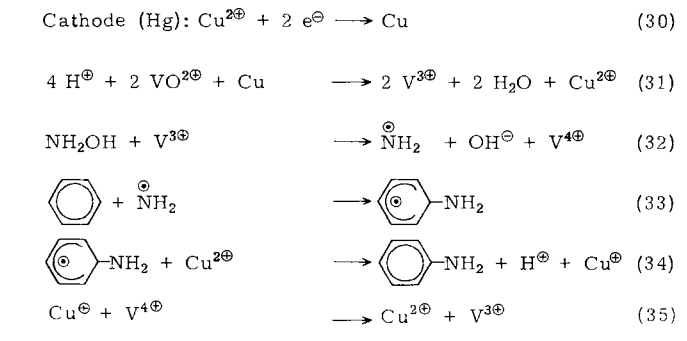
$$\text{Cathode: } Fe^{3\oplus} + e^{\ominus} \longrightarrow Fe^{2\oplus} \quad (23)$$

$$\text{Cathode: } O_2 + 2e^{\ominus} + 2H^{\oplus} \longrightarrow H_2O_2 \quad (24)$$

$$Fe^{2\oplus} + H_2O_2 \longrightarrow Fe^{3\oplus} + {}^{\ominus}OH + {}^{\ominus}OH \quad (25)$$



(26)

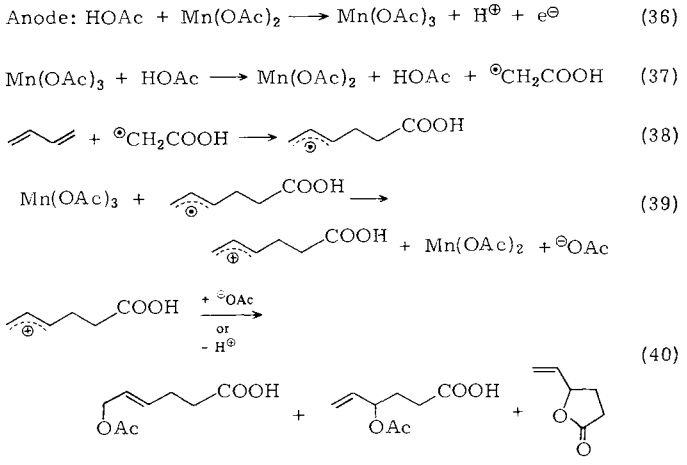


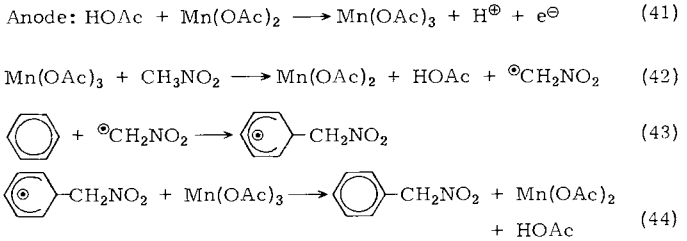
(27)

$$Cu^{\oplus} + Fe^{3\oplus} \longrightarrow Cu^{2\oplus} + Fe^{2\oplus} \quad (28)$$

(29)

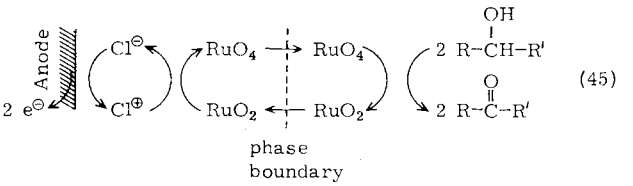
Phenol is obtained with a current yield of 60%,[63] and a material yield of 64% with respect to hydrogen peroxide,[15] whereby it is especially favorable to perform the oxidation in a two-phase benzene/water system.[15] Chlorobenzene, fluorobenzene and benzonitrile have been hydroxylated in this way as well.[15] Fluorophenol is formed in particularly high yields (80% material yield; *o*/*p* = 85 : 15).





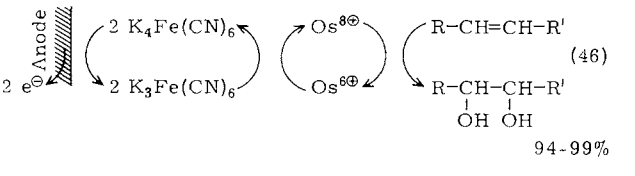
Aminations of aromatic compounds are possible in an analogous way by indirect electrochemical reduction of hydroxylamine [Eq. (30)–(35)].[68]

In a sulfuric acid/water/dioxane system, aniline is obtained from benzene with a 70% current yield and toluidines from toluene with a 50% current yield.



3.1.3. Oxidations with Electrochemically Generated Mn^{III}-, Ce^{IV}- or Ru^{VIII}-Compounds

The conversion of carbonyl compounds[69] and nitroalkanes[70] into carboxymethyl- [Eq. (37)] and nitromethyl-radicals [Eq. (42)], respectively, with Mn^{III}-salts is a preparatively very valuable method. These radicals are trapped by olefins such as 1,3-butadiene or by aromatics to give synthetically interesting products, whereby the in-situ regeneration of the $Mn^{3\oplus}$ ions is especially favorable. On the basis of this procedure a method was developed by Monsanto Co. for the synthesis of sorbic acid via γ-vinyl-γ-butyrolactone.[71,72] The decisive steps are summarized in equations (36)–(40). The nitromethylation of benzene can be carried out similarly [Eq. (41)–(44)][73] (current yield 78%).



Electrochemically produced and regenerated Ce^{IV}-sulfate is employed for the cleavage of D-gluconic acid to D-arabinose.[74] The electrochemically generated complex $[(trpy)(bpy)RuO]^{2\oplus}$ already mentioned in Section 3.1.1 is capable of converting 2-propanol into acetone (current yield 100%) as well as of oxidizing ethanol to acetaldehyde or acetic acid.[75] *Torii* et al. recently reported on the internal electrochemical production and regeneration of RuO_4.[76] A double mediator system is used in this case. RuO_4 is not formed at the anode directly, but via reaction with "$Cl^{\oplus}$" ions derived electrochemically from $Cl^{\ominus}$ ions [Eq. (45)]. The reaction takes place in neutral medium in a two-phase system. Secondary alcohols furnish ketones (90%), 1,2-diols are cleaved to carboxylic acids (75%), 1,4- and 1,5-diols afford lactones (75%), and amines are oxidized to amides.

3.1.4. Olefin Oxidations with Electrochemically Generated Metal Salts as Redox Catalysts

Electrochemically produced Tl^{III}-, Pd^{II}-, Hg^{II}- and Os^{VIII}-compounds are especially suitable for indirect electrochemical olefin oxidations; these preferentially lead to formation of carbonyl compounds ($Tl^{3\oplus}$-,[77–80] $Pd^{2\oplus}$-,[81–83] $Hg^{2\oplus}$-ions[84,85]), diols ($Tl^{3\oplus}$-, $Os^{8\oplus}$-ions[86]), or carboxylic acids ($Hg^{2\oplus}$-,[84,85] $Ru^{4\oplus}$-ions[75]).

OsO_4 can be generated internally at the anode most favorably by a double mediator system [Eq. (46)].[86] With the redox catalyst $[(trpy)(bpy)RuO]^{2\oplus}$, allylic methylene groups are oxidized to keto-groups while allylic methyl groups are converted into carboxylic groups.[75]

3.2. Oxidations with Inorganic Anions as Redox Catalysts

Of the various mediator systems the halide ions are of special importance, for they have a broad spectrum of applicability. The molecular halogens, hypohalite ions, and halide cations formulated as oxidizing agents can be generated without problem by the "in-cell" method. As the redox reaction with these mediator systems is generally coupled with a chemical reaction (mechanism B, Section 2.2), very high potential differences between mediator- and substrate-redox systems can be overcome. Thus, secondary alcohols with oxidation potentials of about +2.8 V (vs. SCE) can be oxidized to ketones at +0.6 to +0.8 (vs. SCE) via

anodically generated $I^{\oplus}$-ions, which corresponds to a potential gain of about 2.0 V.[108]

The dimethoxylation of furan and its derivatives to 2,5-dimethoxy-2,5-dihydrofuran [see Eq. (11)][33,87,88] and the oxidation of aldoses to saccharic acids [see Eq. (1)][2,90,91] have achieved industrial importance. The anodic coupling of activated methylene components like malonic esters and β-keto esters in the presence of 0.01 mol-% potassium iodide,[89] in which the cathodic generation of metallic potassium can be used for the anionization of the methylene component, has also proven very successful [Eq. (47)–(51)].

Cathode: $2K^{\oplus} + 2e^{\ominus} \longrightarrow 2K$ (47)

Anode: $2I^{\ominus} \longrightarrow I_2 + 2e^{\ominus}$ (48)

Solution: $2K + 2CH_2X_2 \longrightarrow 2K^{\oplus} + 2\,^{\ominus}CHX_2 + H_2$ (49)

$2\,^{\ominus}CHX_2 + I_2 \longrightarrow X_2CH{-}CHX_2 + 2I^{\ominus}$ (50)

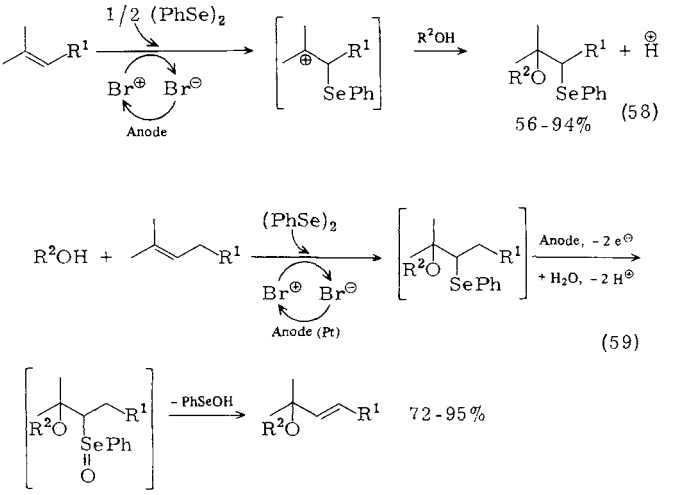
$2CH_2X_2 \longrightarrow X_2CH{-}CHX_2 + H_2$ (51)

The combination of this anode reaction with the cathodic hydrodimerization of acrylic acid esters[89] has also been the subject of numerous studies.

The synthesis of propylene oxide by way of heterogeneous catalysis has so far never been realized in satisfactory yield. Therefore the indirect electrochemical synthesis via intermediate formation of propylene chloro- or bromohydrin by anodically produced hypochlorite or hypobromite, respectively, was studied in great detail. The propylene halohydrins are saponified either externally or internally to propylene oxide by the sodium hydroxide formed at the cathode[92–94] [Eq. (52)–(57)]. This procedure, however, has not as yet been used on an industrial scale.

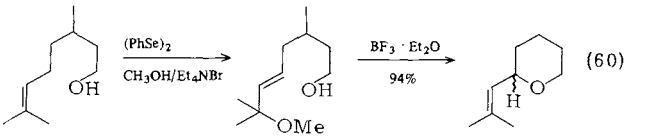
Anode: $2\,Br^{\ominus} \longrightarrow Br_2 + 2\,e^{\ominus}$ (52)

Cathode: $2\,H_2O + 2\,e^{\ominus} \longrightarrow H_2 + 2\,OH^{\ominus}$ (53)



Solution: $Br_2 + H_2O \longrightarrow HOBr + HBr$ (54)

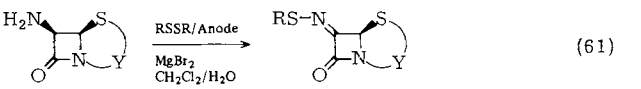
$H_3C{-}CH{=}CH_2 + HOBr \longrightarrow H_3C{-}\underset{OH}{CH}{-}CH_2{-}Br$ (55)



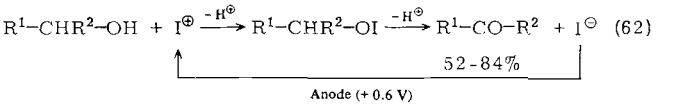
$H_3C{-}\underset{OH}{CH}{-}CH_2{-}Br + OH^{\ominus} \longrightarrow H_3C{-}\underset{O}{CH}{-}CH_2 + Br^{\ominus} + H_2O$ (56)

$H_3C{-}CH{=}CH_2 + H_2O \longrightarrow H_3C{-}\underset{O}{CH}{-}CH_2 + H_2$ (57)

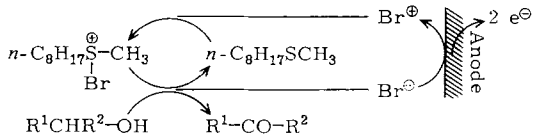
Polyisoprenoids can be epoxidized regioselectively in the ω-position to functional groups in a similar way; in this case "$Br^{\oplus}$" ions are formulated as the oxidizing species.[95] Polymer bound mediators such as anion exchange resins in their bromide form can also be employed for the synthesis of epoxides.[96] The bromide ion-catalyzed anodic oxyselenation of olefins with diphenyl diselenide [Eq. (58)] made it possible to dispense with the use of positively charged selenating reagents like PhSeBr.[97] Under certain conditions even the oxyselenation-deselenation sequence can be carried out in one step [Eq. (59)].[98,99]



For example, an effective synthesis of D,L-rose oxide is based on this method [Eq. (60)].[98]

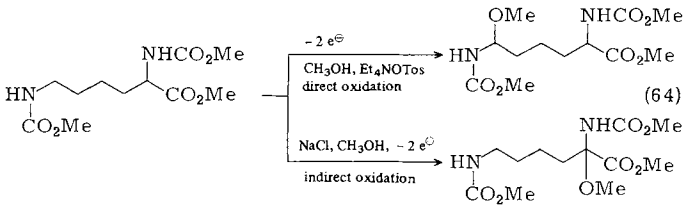


In a similar way carbonyl compounds can also be selenized in the α-position.[100]



Indirect electrochemical oxidation with sodium bromide or iodide not only enables the formation of carbon-hetero atom bonds, but also of hetero-hetero atom bonds, e.g. the nitrogen-sulfur bond in sulfenimides,[101] the phosphorus-sulfur bond in phosphoric acid monothiol esters,[103] and the phosphorus-nitrogen bond in N-substituted phosphoramidates,[104] as well as the sulfur-nitrogen bond in sulfenimines. The latter bond formation is of special importance for the sulfenylation of penicillin and cephalosporin [Eq. (61)].[102]

Since the direct electrochemical conversion of simple aliphatic alcohols occurs only at potentials of far more than +2.0 V (vs. SCE), indirect electrolysis is of great importance here. With sodium bromide or potassium iodide as mediator, oxidations can already be performed at +0.6 V (vs. SCE). Thereby, secondary alcohols produce ketones, while primary alcohols mainly furnish esters [Eq. (62)].[16,105–109]



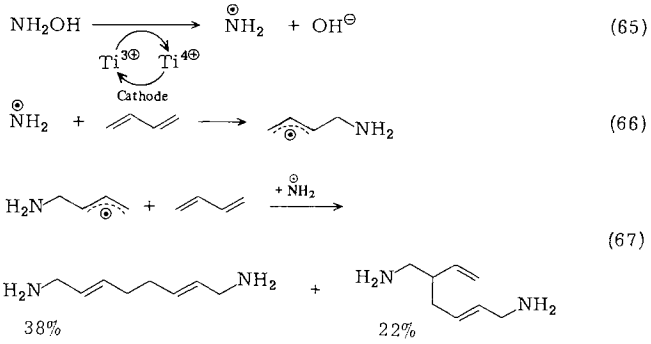
With the polymeric mediator poly-4-vinylpyridine hydrobromide it is possible to oxidize secondary hydroxyl groups selectively in the presence of primary ones.[107] The previously mentioned oxidation of alcohols with

(63)

$RuO_4/Cl^{\ominus}$[Section 3.1.3, Eq. (45)][76] is also possible with the double mediator system tetraethylammonium bromide and *n*-octylmethyl sulfide [Eq. (63)].[109] Primary amines can be converted into nitriles in an undivided cell with the system $NaBr/CH_3OH$.[110]

Methoxylation at the α-position to the nitrogen of an amide function can only be performed electrochemically in good yields, and affords valuable synthetic building blocks. This type of reaction is also possible by indirect electrolysis via catalysis by NaCl, but a decisively different regioselectivity is observed. This can be demonstrated quite neatly with a derivative of lysine methyl ester as example [Eq. (64)].[111]

(64)

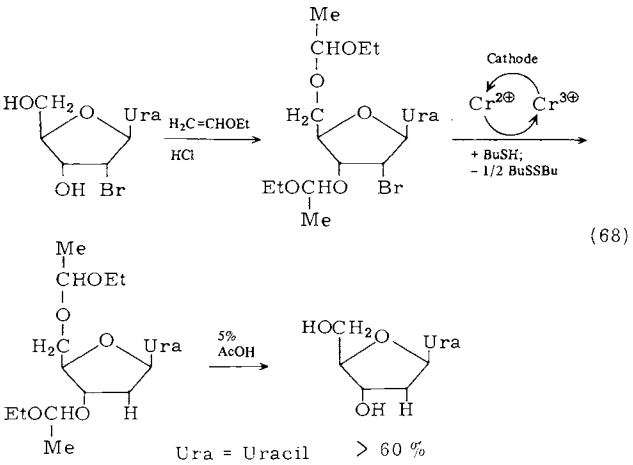


Indirect electrochemical oxidations with the nitrate ion proceed via the NO_3-radical and are suitable for the oxidation of secondary OH-groups[112] and of alkyl aromatic compounds in the side-chain.[113] The periodate regeneration has also been used on an industrial scale for the production of dialdehyde starch from starch[114] and has recently been employed for the generation of acetaldehyde from 2,3-butanediol.[115]

3.3. Reductions with Metal Salts and Metal Complexes as Redox Catalysts

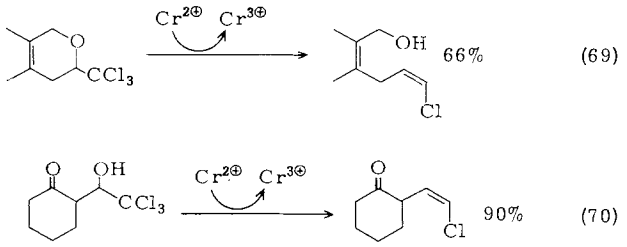
3.3.1. Reductions by Electrochemically Produced Low-Valent Metal Ions and Base Metals

Low-valent metal ions such as $Ti^{3\oplus}$, $V^{3\oplus}$, $Sn^{2\oplus}$ and $Cr^{2\oplus}$ are common reducing agents for many organic compounds.[122,123] Their use in stoichiometric amounts, however, gives rise to problems, especially if they are to be used on an industrial scale. The most important problem is the removal of spent metal salts in such a way that the environment is not endangered. But also the chemical formation of the low-valent ions gives rise to problems, since the reducing agents have to be separated after conversion, thus making a continuous reaction impossible. One way of circumventing these problems is resort to the indirect electrochemical reaction, and the ever increasing number of publications relating to this approach bear witness of the great interest now being shown in this method.



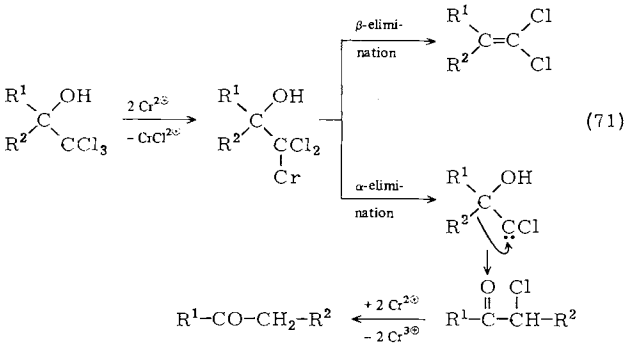
Thus, the reductive cleavage of hydroxylamine and its derivatives by electrochemically generated $Ti^{3\oplus}$- or $V^{3\oplus}$-ions with formation of aminyl radicals and hydroxide ions has been the subject of detailed investigations. The aminyl radical is preferably trapped with alkenes and aromatic compounds. Examples are the synthesis of aspartic acid from maleic acid[117] and of diamines with elongated chains from 1,3-butadiene [Eq. (65)–(67)].[116]

(65)
(66)
(67)



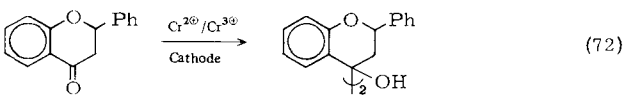
The reduction of aromatic nitro groups with electrochemically generated $Ti^{3\oplus}$ ions has also been investigated intensively, especially in India. Aniline derivatives can be generated in this way in high yields.[118–120] Because of the structure of the chemical industry in India this method evidently has some advantages compared with the otherwise conventional catalytic hydrogenation. Electrochemically produced $Sn^{2\oplus}$ ions are also used for the reduction of nitro groups. In the case of nitrobenzene the reduction can be stopped at the stage of phenylhydroxylamine,[121] which rearranges to *p*-aminophenol.

Cr^{II} reagents are known for their selectivity in organic reductions. With the in-situ formation and regeneration of Cr^{II}-chloride, allylic and benzylic halides could be coupled in anhydrous dimethylformamide (DMF) in yields comparable with those obtained by other coupling methods.[124] The dehalogenation of α-hydroxyhalides and their ethers can be realized in a similar way. The reagent, the ethylenediamine complex of $Cr(ClO_4)_2$, is electrochemically generated in moist dimethylformamide. Butanethiol acts as hydrogen donor for the trapping of the intermediate radicals.[125] To avoid elimination reactions, the α-hydroxyl group has to be protected. This method has proved to be a good alternative to the tributyltin hydride method for the synthesis of deoxynucleotides [Eq. (68)].

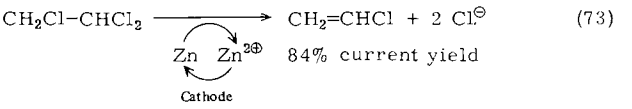


(68)

The α-trichloromethyl-substituted alcohols or ethers, which are readily accessible in a great structural variety, can be reduced to preparatively interesting products by $CrCl_2$ in water or water/DMF as electrolyte. In the case of secondary hydroxyl groups, the reaction leads to formation of (*Z*)-configurated alkenyl chlorides in one step [Eq. (69), (70)].[126] Should the alcohols have a hydroxyl group

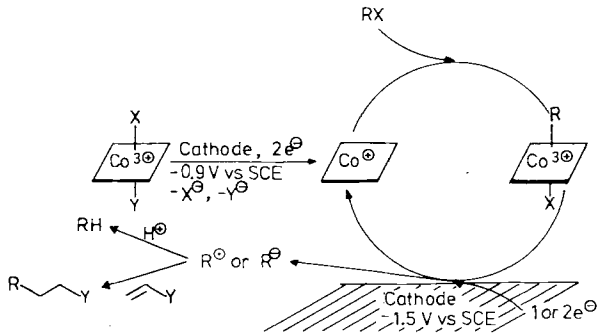


attached to a tertiary C-atom, then, depending on the reaction conditions, either formation of alkylidene dichlorides or rearrangement with formation of carbonyl compounds is preferred.[126]

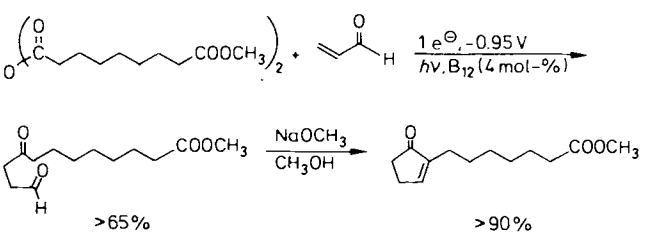


Geminal dibromocyclopropanes can be reduced to allenes in anhydrous DMF with externally generated and regenerated $Cr^{2\oplus}$ ions by an inner-sphere electron transfer mechanism.[127] If the reaction is carried out with internal regeneration, only monobromocyclopropanes are obtained via an outer-sphere electron transfer mechanism after the first regenerative cycle. This means that the Cr^{III} complex that is formed after the first conversion must contain different ligands than the originally employed chromium(III)-halogen dimethylformamide complex. Such problems also arise with other metal complexes as redox catalysts if the redox reaction proceeds via an inner-sphere electron transfer (mechanism B, Section 2.2).[31,32,128]

Electrochemically generated $Cr^{2\oplus}$ ions can even effect the pinacolization of otherwise unsatisfactorily dimerizing carbonyl compounds.[129,130] Here, the $Cr^{2\oplus}$ ions do not act as redox agent but catalyze the formation of a Cr^{III}-complex of the carbonyl compound, which is directly hydrodimerized at the cathode with formation of the pinacol. Thus, for instance, β-jonylideneacetaldehyde[129] and flavanone [Eq. (72)][130] can be pinacolized in 60% and 78% yield, respectively.

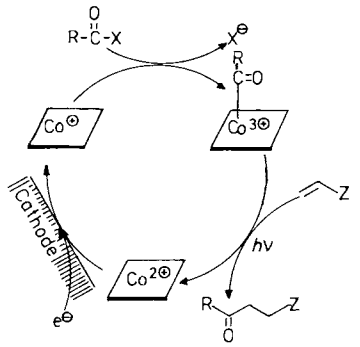


Suspensions of base metals can be generated at the cathode at high current densities (>0.5 A cm^{-2}) in two-phase systems. Since very small particles with oxygen-free surfaces are generated, the reactivity of these metal suspensions clearly surpasses that of the metals that are usually employed.[131,132] Thus, zinc, copper, iron, and tin powders have been generated in high current yields and have been used for the reduction of nitro compounds and halogenated hydrocarbons [Eq. (73)].



3.3.2. *Indirect Electrochemical Reductions with Transition Metal Complexes*

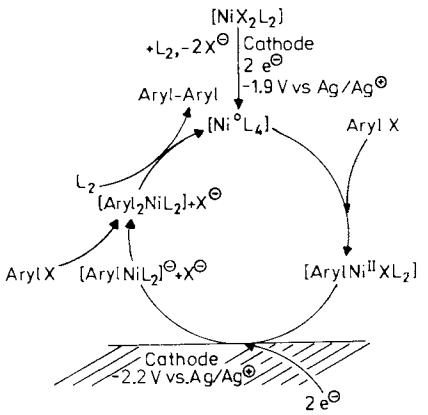
Transition metal complexes are finding increasing application as redox catalysts, especially for reductions. The cathodically generated active forms such as Ni^0-, Ni^I-, Co^I-, Sn^0-, Pd^0-, or Rh^I-complexes react with alkylating agents such as halides via oxidative addition. By electrochemical reduction of the alkyl complex the metal-carbon bond can be cleaved with regeneration of the active form of the complex. Such a catalytic cycle is presented in Scheme 1 for



Scheme 1. Principle of the indirect electrochemical reduction of alkyl halides by a Co^I/Co^{III}-complex system.

cobalt complexes, such as vitamin B_{12}.[133] In the case of the alkylcobalt(III) complexes the reduction potential can be lowered to a value of -0.9 V (vs. SCE) by irridiation with visible light, so that the generally highly selective and specific reaction can proceed under very mild conditions.[133–136,139]

A particularly suitable catalyst is vitamin B_{12}, which not only catalyzes allyl halide coupling[141] and the dehalogenation of alkyl halides,[133,138,142] but is also excellently

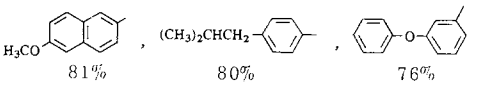


suited for the alkylation and acylation of Michael systems [Eq. (74)].[133, 134, 137] The latter proceeds via photochemically supported electrochemical cleavage of the intermediate acylcobalt(III) complex (Scheme 2).[135, 139]

Scheme 2. Nucleophilic acylation by photochemically supported electrochemical cleavage of acylcobalt(III) complexes (indirect electrochemical acylation).

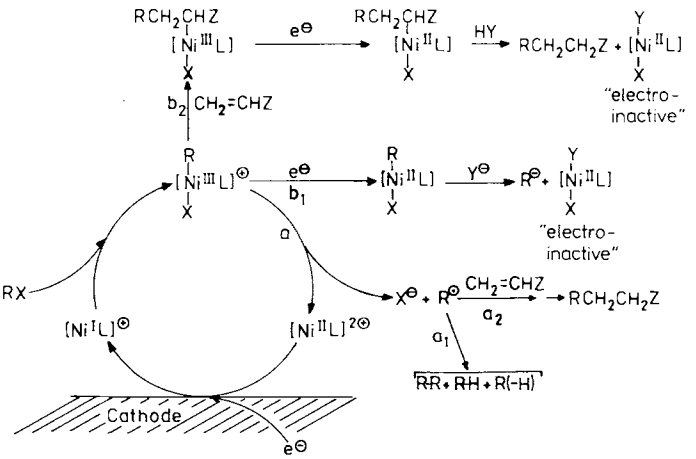
This technique can be used for the synthesis of natural products such as optically active pheromones, 3-substituted steroids, cyclopentanoids, sugars, etc.[139, 140]

Ni^0-complexes can be used in a similar way as the Co^I-complexes. Thus, e.g., the formation of bisaryl by reduction of aryl halides with electrochemically generated Ni^0-complexes has been reported on in detail. The reaction mechanism, which closely resembles that presented for the cobalt system (Scheme 1), is reproduced in Scheme 3. The reaction involves the intermediates $[ArylNiXL_2]$, which react at the electrodes. Phosphanes have proved to be useful ligands.[31, 143, 144]



Scheme 3. Bisaryl formation via electrochemically generated and regenerated Ni^0-complexes ($L = PR_3$).

Poly-*para*-phenylenes are obtained on a preparative scale when aromatic dihalides are used as starting compounds.[148] The electrochemical generation and reduction of $[ArylNiXL_2]$ in the presence of CO_2 or $H_2C{=}CH_2$ leads to the formation of benzoic acids,[145] or 1,1-diarylethanes[147] and styrene derivatives.[146] Ni^0-complexes also catalyze the reductive carboxylation of 1-arylethyl halides to 2-arylpropionic acids.[145] In this way, the pharmaceutically effective 2-arylpropionic acids are accessible in high yields with cycle numbers of 20 to 40 for the catalyst [Eq. (75)].[145]



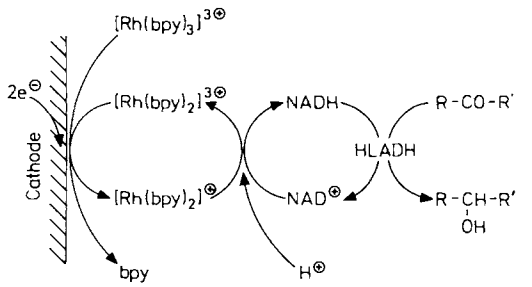
$$Aryl{-}CH(CH_3){-}Cl + CO_2 \xrightarrow[THF/HMPT/Bu_4NBF_4,\ +2\,e^{\ominus}]{NiCl_2/Ph_2P(CH_2)_3PPh_2/COD} Aryl{-}CH(CH_3){-}COOH \qquad (75)$$

COD = 1,5-cyclooctadiene, THF = tetrahydrofuran, HMPT = hexamethylphosphoric acid triamide

Aryl iodides and bromides can not only be reductively cleaved under catalysis by Ni^0-complexes but also by electrochemically generated and regenerated triphenylphosphanepalladium(0) complexes. Thus, bisaryls are obtained in material yields of 50–99%,[149] or, in presence of unsaturated compounds (styrene, 1,3-butadiene derivatives, phenyl acetylene), the products of ArH addition are obtained in yields of 20–78%.[150] The mechanism is in accordance with the one presented in Scheme 3, with palladium being substituted for nickel. Cycle numbers of 15 have been reported.

Besides phosphanenickel(0) complexes,[144] Ni^I-complexes are also suitable for the indirect electrochemical reduction of alkyl halides. They react via an organonickel(III) intermediate. The Ni^I-complexes are electrogenerated from the square planar Ni^{II}-complexes of macrocyclic quadridentate ligands[32, 151] (see Scheme 4).

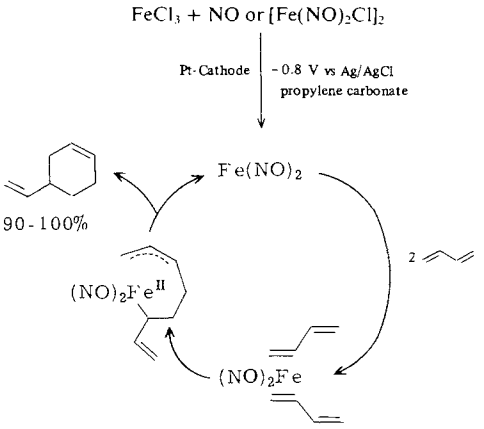
Scheme 4. Reduction of alkyl halides in presence (a_2, b_2) and absence (a_1, b_1) of activated olefins by electrochemically produced and regenerated Ni^I-complexes of macrocyclic quadridentate ligands.



The stability of the newly formed nickel–carbon bond is decisive for the subsequent course of the reaction: If it is not very stable, the complex decomposes into an alkyl radical and the original Ni^{II}-complex (path a); the result is a large number of cycles. This is the case, e.g., with secondary and tertiary alkyl bromides. If the bond is relatively stable, however, as for instance in the case of primary alkyl bromides, the alkylnickel(III) complex is reduced to an alkylnickel(II) complex, which loses an alkyl anion and is

converted into an *electroinactive* Ni^{II}-complex (path b); the cycle number is accordingly low. The structure of the ligand also influences the lifetime of the organonickel(III) complex. Thus, a less stable complex is formed with [*N,N'*-ethylenebis(salicylideneiminato)]nickel(II) ([Ni(salen)]) than with (5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane)nickel(II) ($[Ni(teta)]^{2\oplus}$); hence, [Ni(salen)] favors the reaction via the radical path with high cycle numbers, even with primary alkyl bromides (path a). Primary halides essentially afford dimers (R–R), whereas disproportionation (R–H + R(–H)) predominates in the case of tertiary halides.

The organonickel(III) complex that is formed from alkyl bromides and the electrochemically generated $[Ni(teta)]^{\oplus}$ complex can undergo insertion reactions with added activated olefins via path b_2 (Scheme 4) thereby forming a new nickel-carbon bond. Further reduction leads to cleavage of the complex with release of the Michael adduct and a Ni^{II}-complex that is no longer "electroactive". The more labile Ni(salen) complex, on the other hand, yields the Michael adducts via the radical path a_2 with regeneration of the original Ni^{II}-complex. In this case the reaction is catalytic.[39, 152]



The electrochemical allylation of carbonyl compounds by electroreductive regeneration of a diallyltin reagent from allyl bromide and an Sn^0 compound leads in methanol or methanol/water to formation of homoallylic alcohols in yields of 70–90%.[153]

Using a cathodically generated and regenerated bis(bipyridine)rhodium(I) complex as two-electron transfer agent it was possible for the first time to achieve the nonenzymatically coupled selective regeneration of NADH from $NAD^{\oplus}$. The direct cathodic reduction leads mainly to NAD dimers while the indirect electrochemical reduction by the rhodium complex as two-electron transfer agent provides almost exclusively enzymatically active NADH, and only traces of dimers. If the reaction is carried out in presence of alcohol dehydrogenase, carbonyl compounds can be transformed into the respective alcohols in-situ (Scheme 5).[154] With 2,2'-bipyridine-5-sulfonic acid as ligand, the electrode covering that would be otherwise observed can be avoided and the reduction potential can be shifted in an positive direction by 200 mV to a value of −720 mV vs. Ag/AgCl. The result is complete prevention of NAD-dimer formation.[155]

Scheme 5. Regeneration of NADH from $NAD^{\oplus}$ by electrochemically generated $[Rh(bpy)_2]^{\oplus}$ as electron transfer agent.

Indirect electrolysis is very useful for the in-situ generation of transition metal catalysts. Following the basic studies carried out by ***Lehmkuhl*** et al.,[156] some very interesting results have emerged recently. Thus, dinitrosyliron(0) complexes can be generated electrochemically and used for the cyclodimerization of conjugated dienes (Scheme 6).[157, 158]

Scheme 6. Electrochemical generation and application of the dinitrosyliron(0) complex as catalyst for the cyclodimerization of conjugated dienes.

The C_4-fraction obtained in petroleum cracking can thus be used directly as substrate. In the case of butadiene, turnover rates of 20000 per hour can be achieved with complete selectivity regarding the formation of 4-vinylcyclohexene.

Highly active catalysts for olefin metathesis can be obtained in a similar way by electrochemical reduction of WCl_6 or $MoCl_5$ [Eq. (76)].[159] Since the oxidation state of the catalyst generated in this way can be stabilized by potential control, these reactions are very highly selective. Aluminum is used as anode material because it furnishes the required Lewis acid with formation of aluminum trichloride. Hydroformylation reagents can also be generated electrochemically.[160]

$$n\,e^{\ominus} + WCl_6 \xrightarrow[\text{Al-anode, } CH_2Cl_2]{\text{Pt-Cathode, } -0.9\text{ V vs SCE}} n\,Cl^{\ominus} + WCl_{(6-n)} \quad (76)$$

$WCl_{(6-n)}$ —(2-pentene)→ 2-butene + 3-hexene, 2160 cycles/h

4. Indirect Electrochemical Syntheses with Organic Redox Catalysts

The most important prerequisite for the suitability of a compound as mediator is its stability in all the oxidation states being passed through, otherwise a rapid loss in catalytic activity will take place. This condition is rarily fulfilled by organic molecules, as their active forms, mostly radical cations or anions, react irreversibly in many media. Only in recent years has there been a distinct increase in the number of known stable organic mediators. Thus, radical anions and dianions of mostly aromatic compounds have been used for reductions in aprotic solvents, whereas

viologens and violens are suitable as electron transfer agents for reductions in protic solvents; however, they can only be used at potentials of up to about -1.0 V.

For oxidations, the radical cations of compounds like 9,10-diphenylanthracene, thianthrene, phenoxathiine or dibenzodioxine are likely candidates as one-electron acceptors; however, because of their reactivity they can only be used in media of low nucleophilicity. Triarylamines behave differently, if their reactive *para*-positions are blocked by substituents from attack by nucleophiles. Thus, many of these triarylamine radical cations show an excellent stability even in solvents like methanol. Aside from pure electron transfer agents, other mediators are being employed that react by way of a hydrogen or hydride abstraction (mechanism B, Section 2.2). Methods for the theoretical treatment of the homogeneous redox catalysis of electrochemical reactions were mainly developed by *Savéant* et al.[165]

4.1. Reductions with Radical Anions and Dianions of Organic Compounds

Radical anions and dianions of a great number of organic compounds, mostly aromatics, have been tested as mediators for reductions. Table 2 gives an overview of the potentials of some organic mediators frequently used for reductions.

Table 2. Reduction potentials of common mediator systems.

Compound	$-E_{1/2}$[V] (vs. SCE)	Ref.	Compound	$-E_{1/2}$[V] (vs. SCE)	Ref.

[a] C. K. Mann, K. K. Barnes: *Electrochemical Reactions in Nonaqueous Systems*, Marcel Dekker, New York 1970.

Alkyl and aryl halides, sulfonates, sulfonamides, sulfones, sulfides, onium compounds and epoxides can be cleaved by electrochemical reduction with organic mediators at potentials that can be much more positive than those of the substrates. The driving force of this reaction opposite to the standard potential gradient[26] is generally the fast and irreversible cleavage of the carbon-hetero atom bond. The essential reaction steps (77)–(87) correspond to those that are also observed with sodium naphthalenide.

As products, either the hydrocarbons RH or the coupling products RR are obtained via the carbanions $R^{\ominus}$ or via the radicals $R^{\odot}$. Second order reactions of the radicals such as dimerizations or disproportionations [Eq. (81)] are, however, unlikely under the conditions of indirect electrolysis, since the radicals are formed in homogeneous solution and therefore occur only in low stationary concentrations. The coupling of the radicals $R^{\odot}$ with the radical anions of the mediators [Eq. (84)] results in the alkylation products $MR^{\ominus}$, which are either protonated (HMedR) or form the bisalkylation product RMedR. With naphthalene as mediator the following alkylation products could be identified:[161]

$$\text{Cathode Med} \overset{+e^{\ominus}}{\rightleftharpoons} \text{Med}^{\odot\ominus} \quad (77)$$

$$\text{Med}^{\odot\ominus} + \text{RX} \overset{\text{ET}}{\rightleftharpoons} \text{Med} + \text{RX}^{\odot\ominus} \quad (78)$$

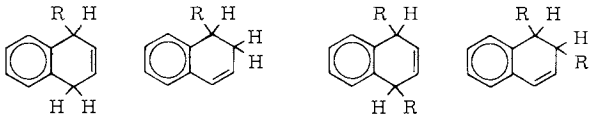
$$\text{RX}^{\odot\ominus} \longrightarrow \text{R}^{\odot} + \text{X}^{\ominus} \quad (79)$$

$$\text{Med}^{\odot\ominus} + \text{R}^{\odot} \longrightarrow \text{R}^{\ominus} + \text{Med} \quad (80)$$

$$2\,\text{R}^{\odot} \longrightarrow \text{R}-\text{R or RH} + \text{R}(-\text{H}) \quad (81)$$

$$\text{R}^{\odot} + \text{SolvH} \longrightarrow \text{RH} + \text{Solv}^{\odot} \quad (82)$$

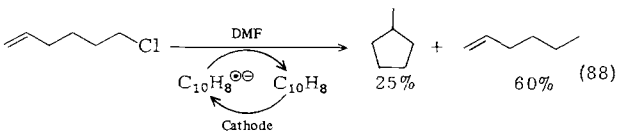
$$\text{R}^{\ominus} + \text{SolvH} \longrightarrow \text{RH} + \text{Solv}^{\ominus} \quad (83)$$



$$\text{Med}^{\odot\ominus} + \text{R}^{\odot} \longrightarrow \text{MedR}^{\ominus} \quad (84)$$

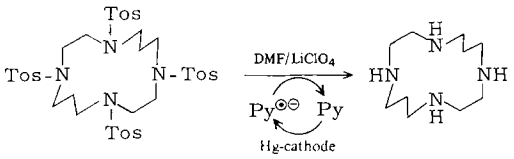
$$\text{MedR}^{\ominus} + \text{SolvH} \longrightarrow \text{HMedR} + \text{Solv}^{\ominus} \quad (85)$$

$$\text{MedR}^{\ominus} + \text{RX} \longrightarrow \text{RMedR} + \text{X}^{\ominus} \quad (86)$$



$$\text{R}^{\ominus} + \text{RX} \longrightarrow \text{RR} + \text{X}^{\ominus} \quad (87)$$

HMedR = monoalkylation product,
RMedR = dialkylation product of the mediator

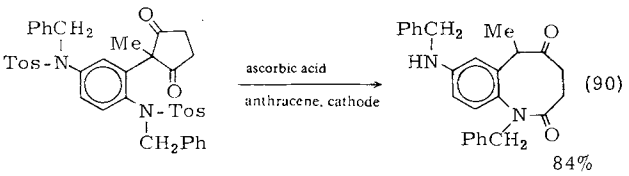


The indirect electrochemical cleavage of halides has been studied analytically in detail, especially by *Lund* and *Simonet* et al.[161–169] The course of the reaction strongly depends on the structure of the substrates. Thus, aryl and benzyl halides do not form alkylation products of the mediators, whereas these products dominate with aliphatic halides. In the latter case primary halides favor the formation of monoalkylation products, while tertiary halides favor the formation of dialkylation products. As a result of its alkylation, the mediator is naturally withdrawn from further reaction, so that stoichiometric amounts are required and the reaction sequence cannot be referred to as an "indirect electrolysis" in the fullest sense of the word. *Simonet* et al.[164] therefore coined the term "perturbed redox-catalysis".

In a number of cases the reductive halogen-hydrogen exchange has been studied on a preparative scale: If, for example, 6-chloro-1-hexene is reduced in the presence of naphthalene as redox catalyst, besides 1-hexene also methylcyclopentane is obtained as product of the radical cyclization [Eq. (88)].

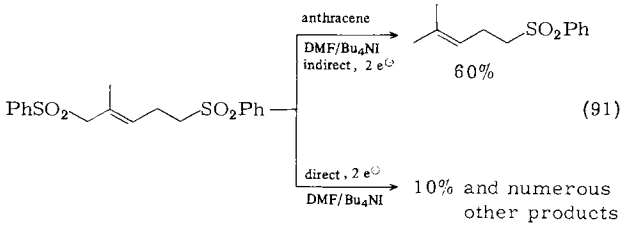
(88)

Also the indirect reductive deblocking of tosylamide, tosyl ester, benzyloxycarbonyl, *o*-nitrobenzyloxycarbonyl, benzyl ester, and benzyl ether groups have been studied in



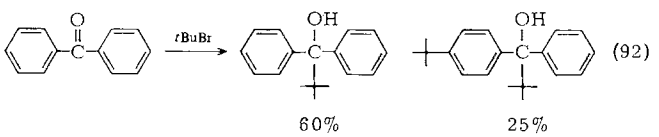
(89)

Py = Pyrene
Tos = *p*-toluene-sulfonyl



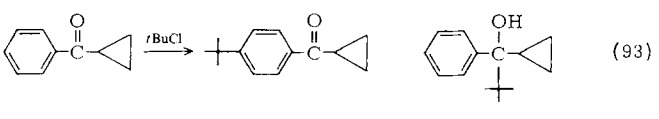
great detail.[26, 166-168] Thus, *Simonet* et al.[167] used pyrene as mediator for the release of polyaza-macrocycles from poly-*p*-toluenesulfonamides [Eq. (89)].

A very effective cleavage of a tosyl-nitrogen bond is apparently facilitated by the combined effect of the electrochemically generated anthracene radical anion as electron transfer agent with ascorbic acid as proton donor and additional reducing agent [Eq. (90)].[168]



(90)

The indirect electrochemical cleavage of sulfones convincingly demonstrates that the selectivity of this method is superior to that of the direct electrolysis [Eq. (91)].[169]



(91)

The perturbed redox catalysis, i.e. the mono- or bisalkylation of the electron transfer agent by the intermediary alkyl radicals [Eq. (77)-(79) and (84)-(86)], has been exploited for the production of arylalkanes that are difficult to obtain by Friedel-Crafts alkylation. The most suitable alkylating agent is *tert*-butyl chloride (or bromide),[161, 170-173] which can also be used for the alkylation of ketones. Tertiary alcohols and the compounds that are alkylated exclusively or additionally in the aryl moiety are formed [Eq. (92), (93)].[174]

(92)
