The cyclic voltammogram of **2** shows two reversible one-electron transitions at −0.10 and −0.56 V (THF, 0.1 M tetrabutylammonium hexafluorophosphate, gold electrode versus Ag/Ag$^{\oplus}$). So far only the diaza-*s*-indacene **5** could be isolated in the reduction of **2**. On reaction of **2** in liquid ammonia with sodium in the ratio 1 : 2 a violet solid is ob-

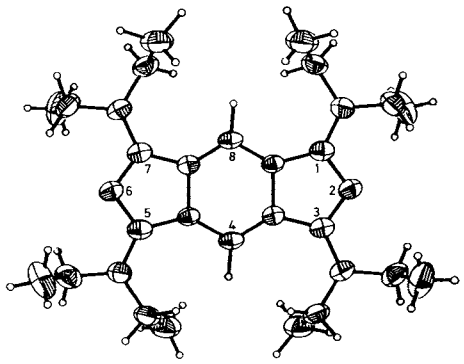

Fig. 1. Crystal structure of **5** at 0 °C; bond lengths (in pm, standard deviations: 0.5 pm [17]) [MNDO results]: C1-N2 136.0, [139.9], N2-C3 135.8 [137.9], C3-C3a 142.5 [144.0], C3a-C4 138.8 [139.8], C8-C8a 139.2 [139.8], C3a-C8a 148.7], C1-NEt_2 136.4 [136.6], C3-NEt_2 136.6 [136.6].

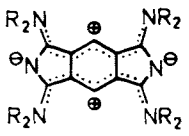
tained from which **5** can be extracted with *n*-pentane under argon (yield 47%). The X-ray structure analysis (Fig. 1; measurement at 0°C) shows **5** to be a planar molecule (apart from the methyl groups) with approximate D_{2h} symmetry.

The observed bond lengths are in good agreement with the MNDO results for 1,3,5,7-tetraamino-2,6-diaza-*s*-indacene and also with the bond lengths found in the case of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene.[12, 13] The dipolar resonance structure **12** illustrates the bonding situation in **5**. However, further investigations are necessary in order to clarify whether **5** has a delocalized structure or whether a very rapid valence isomerization between two localized structures takes place.



12, R = Et

As an electron-rich π-electron system, **5** is a strong reducing agent and air-sensitive, even in the crystalline state. Solutions in hexane or THF show traces of radicals (ESR signal). A radical cation salt has so far not been isolated. **5** can be oxidized to **2** in good yields with nitrosyl tetrafluoroborate. **5** and **2** show consistent cyclovoltammograms.

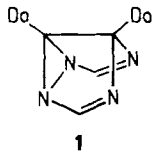
Propellanes of the Glycoluril Series and Bridged Tetrazocines**

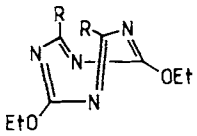
By *Rudolf Gompper,* Heinrich Nöth,* Wilfried Rattay, Marie-Luise Schwarzensteiner, Peter Spes,* and *Hans-Ulrich Wagner*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

The search for semibullvalenes and diazasemibullvalenes with bishomo-aromatic ground states[1, 2] has hitherto been virtually unsuccessful (cf. Ref. [3]; surprisingly, tetramethyl 1,5-hexamethylenesemibullvalene-2,4,6,8-tetracarboxylate has previously been reported to have a symmetrical structure with a delocalized electron system[4]). We had attempted the preparation, not of the hitherto inaccessible 2,4,6,8-tetracyanosemibullvalenes[5] but of the structurally related 2,4,6,8-tetraazasemibullvalenes **1** (Do = donor) (cf. 2,6-diazasemibullvalenes[6]). A bishomoaromatic ground



1



2

state should be formed in the case of **1** due to the tendency of the NN bond in the diaziridine ring to undergo cleavage. Instead of tetraazasemibullvalenes, however, we obtained 1,3,5,7-tetrazocines **2**[7] on oxidation of glycoluril derivatives. Apparently, either the 3a–6a bond of the glycoluril derivative or the 1–5 bond of intermediary tetraazasemibullvalenes (bishomoaromatic structure?) is cleaved during the course of the oxidation. In order to prevent this cleavage we have now synthesized 3a,6a-bridged glycolurils and investigated their oxidation.

The reaction of cyclic α-diketones **3** (cyclopentane-, cyclohexane-, cycloheptane-1,2-dione, *cis*-5-cyclooctene-1,2-dione, acenaphthenequinone, camphorquinone; benzocyclobutenedione reacts differently[8]) with urea in ethanol-water in the presence of some hydrochloric acid (**4a** is obtained by heating the components in benzene in the presence of ethereal tetrafluoroboric acid) affords the sparingly soluble, bridged glycolurils **4** in good yields (only **4b** was known[9]), which can be converted by reaction with triethyloxonium tetrafluoroborate (cf. Ref. [10]; 110°C; after cooling the melt, addition of 50% aqueous potassium carbonate solution and extraction with chloroform) into the bisimidates **6** (cf. Table 1). The bisimidates **6** can be oxidized in various ways: 1) with one equivalent of *tert*-butyl hypochlorite in dichloromethane and subsequent addition of potassium *tert*-butoxide; 2) successive addition of two equivalents of potassium *tert*-butoxide and iodine in tetrahydrofuran; 3) heating in carbon tetrachloride with *N*-bromosuccinimide in the presence of azobisisobutyronitrile; 4) reaction with two equivalents of *tert*-butyl hypochlorite to give the dichloro compounds **7** and their reduction with naphthalene-sodium. All these methods, howev-

er, do not give 1,5-bridged tetraazasemibullvalenes, but 2,6-bridged 1,3,5,7-tetrazocines **5** (cf. Table 1). That the products **5** are in fact tetrazocines and not tetraazasemibullvalenes follows from the X-ray structure analysis of **5c** (Fig. 1).[11] It should be emphasized that the distance between the atoms C-2 and C-6 is 278 pm; the corresponding distance in 2,6-diethoxy-4,8-diphenyl-1,3,5,7-tetrazocine is 301 pm;[7] i.e., in comparison to the monocyclic compound, the eight-membered ring of **5c** is slightly distorted in the manner expected in a tetraazasemibullvalene.

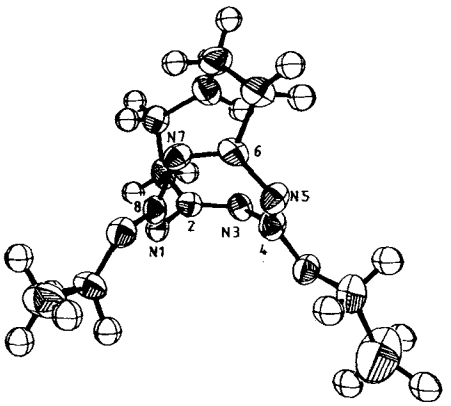

Fig. 1. Crystal structure of **5c**; bond lengths (in pm, standard deviations 0.8–0.9 pm [11]): N1-C2 128.0, C2-N3 140.9, N3-C4 125.3, C4-N5 139.1, N5-C6 127.9, C6-N7 140.8, N7-C8 130.0, C4-O 134.6, C8-O 134.5; sum of angles at C2 and C6 359.9°.

The NMR data of **5a** and **5b** compare with those of **5c**, thus indicating that **5a** and **5b** are also tetrazocines. In the ^{13}C-NMR spectra of **5** the signals of C-3a/6a of the starting substances **6** at $\delta \approx 90$ have disappeared and in their place the signals of the bridgehead C-atoms appear at $\delta = 160$–170. Most surprising is that the tetraazasemibullvalene structure does not even occur in **5a**. Actually, it is a derivative of bicyclo[3.3.3]undec-1-ene, which is counted among the "isolable" bridgehead olefins (cf. Refs. [12, 13]), but which, aside from 2-azabicyclo[3.3.1]nonene[14] is the only "anti-Bredt" bridgehead imine isolated so far (cf. Ref. [15]). The greater ring strain in **5a** compared to that in **5b** and **5c** is evidenced by the shift of the C=N stretching vibration to lower frequencies ($\nu_{C=N} = 1560$ cm^{-1} vs. 1610 and 1614 cm^{-1}, resp.), as has also been observed in 4-aza-

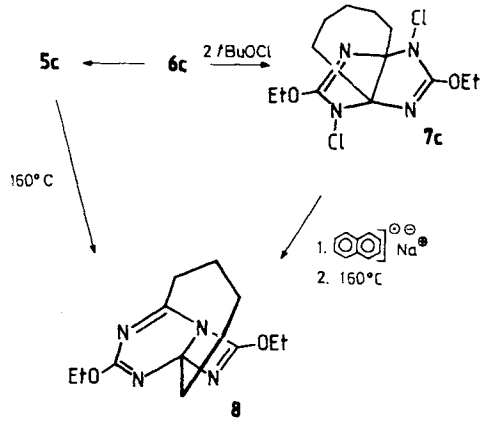

Table 1. Selected data of the compounds **5**, **6**, and **9**–**11**. ^1H-NMR spectra: 60/80 MHz, $CDCl_3$; ^{13}C-NMR spectra: 20 MHz, $CDCl_3$; IR spectra: KBr.

5a: b.p. 160°C (0.1 torr); ^1H-NMR: $\delta = 1.42$ (t; 6H, OCH_2CH_3), 2.26, 2.80 (mc; 6H, $(CH_2)_3$), 4.46 (q; 4H, OCH_2CH_3); ^{13}C-NMR: $\delta = 14.27$ (OCH_2CH_3), 23.00, 37.54 ($(CH_2)_3$), 64.14 (OCH_2CH_3), 171.98 (C-4/8), 182.38 (C–OEt); IR: 2934, 1560 cm^{-1}

5b: m.p. 50–52°C; ^1H-NMR: $\delta = 1.40$ (t; 6H, OCH_2CH_3), 2.21, 2.43 (mc; 8H, $(CH_2)_4$), 4.28 (q; 4H, OCH_2CH_3); ^{13}C-NMR: $\delta = 14.30$ (OCH_2CH_3), 28.77, 39.25 ($(CH_2)_4$), 64.94 (OCH_2CH_3), 158.47 (s; C-4/8), 178.83 (C–OEt); IR: 2960, 1610 cm^{-1}

5c: m.p. 64°C; ^1H-NMR: $\delta = 1.35$ (t; 6H, OCH_2CH_3), 1.87, 2.36 (mc; 16H, $(CH_2)_5$), 4.21 (q; 4H, OCH_2CH_3); ^{13}C-NMR: $\delta = 14.09$ (OCH_2CH_3), 23.89, 28.90, 38.49 ($(CH_2)_5$), 64.55 (OCH_2CH_3), 159.19 (C-4/8), 177.20 (C–OEt); IR: 2985, 2933, 1614 cm^{-1}

6a: m.p. 217°C; ^1H-NMR: $\delta = 1.30$ (t, 6H, OCH_2CH_3), 1.86 (mc; 6H, $(CH_2)_3$, 4.16 (q; 4H, OCH_2CH_3), 5.16 (s; 2H, NH); ^{13}C-NMR ($CDCl_3/CF_3CO_2H$): $\delta = 13.96$ (OCH_2CH_3), 24.96, 39.98 ($(CH_2)_3$), 74.97 (OCH_2CH_3), 91.08 (C-3a/6a), 164.35 (C–OEt); IR: 3156, 1616 cm^{-1}

6b: m.p. 219°C; ^1H-NMR: $\delta = 1.31$ (t; 6H, OCH_2CH_3), 1.53, 1.80 (mc; 8H, $(CH_2)_4$), 4.15 (q; 4H, OCH_2CH_3), 5.29 (s; 2H, NH)

6c: m.p. 225°C; ^1H-NMR: $\delta = 1.33$ (t; 6H, OCH_2CH_3), 1.46, 1.83 (mc; 10H, $(CH_2)_5$), 4.12 (q; 4H, OCH_2CH_3), 5.20 (s; 2H, NH); ^{13}C-NMR: $\delta = 14.27$ (OCH_2CH_3), 25.26, 30.54, 36.22 ($(CH_2)_5$), 75.39 (OCH_2CH_3), 88.35 (C-3a/6a), 164.80 (C–OEt); IR: 3150, 2923, 1630 cm^{-1}

6d: m.p. 195–197°C; ^1H-NMR: $\delta = 1.33$ (t; 6H, OCH_2CH_3), 2.31 (mc; 8H, CH_2-Brücke), 4.20 (q; OCH_2CH_3), 5.50 (s; 2H, NH), 5.90 (mc; 2H, CH=CH)

6e: m.p. 208–210°C; IR: 3250, 1726, 1605 cm^{-1}

6f: m.p. 178–180°C

8: m.p. 130°C; ^1H-NMR: $\delta = 1.23$ (t; 3H, OCH_2CH_3), 1.40 (t; 3H, OCH_2CH_3), 1.73, 2.63 (mc; $(CH_2)_5$), 4.26 (mc; 4H, OCH_2CH_3); ^{13}C-NMR: $\delta = 14.63$ (OCH_2CH_3), 22.63, 22.86, 23.11, 23.44, 32.44 ($(CH_2)_5$), 62.52 (OCH_2CH_3), 116.95 (sp^3 bridgehead), 158.20 (C=N bridgehead), 161.44 (four-membered ring C–OEt), 165.98 (six-membered ring C–OEt); IR: 1630, 1560 cm^{-1}

9a: ^{13}C-NMR ([D$_6$]DMSO): $\delta = 18.02$ (OCH_2CH_3), 20.81, 38.89 ($(CH_2)_3$), 61.09 (OCH_2CH_3), 100.83 (C-3a/6a), 167.92 (C–OEt)

9c: ^1H-NMR ([D$_6$]DMSO): $\delta = 1.20$ (mc; 6H, OCH_2CH_3), 1.46, 1.80 (mc; 10H, $(CH_2)_5$), 4.01 (mc; 4H, OCH_2CH_3); ^{13}C-NMR ([D$_6$]DMSO/18-crown[6]): $\delta = 15.08$ (OCH_2CH_3), 25.23, 31.05, 36.53 ($(CH_2)_5$), 61.00 (OCH_2CH_3), 96.11 (C3a/6a), 167.50 (C–OEt)

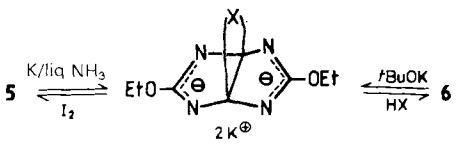
10a/11a: ^1H-NMR: $\delta = 1.30$ (mc; 6H, OCH_2CH_3), 1.50, 1.86 (mc; 10H, $(CH_2)_5$), 2.73, 2.83 (s; 6H, NCH_3), 4.20 (mc; 4H, OCH_2CH_3); ^{13}C-NMR: $\delta = 14.57$ (OCH_2CH_3), 24.26, 24.38, 25.96, 27.75, 29.80, 31.11, 34.71, 39.16 ($(CH_e)_5$), 64.27, 64.49 (OCH_2CH_3), 89.29, 91.81, 96.29 (C-3/6a), 161.23, 161.71 (C–OEt)

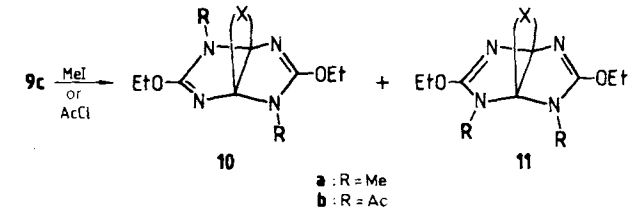
10b/11b: ^1H-NMR: $\delta = 1.40$ (t; 6H, OCH_2CH_3), 1.56, 1.91 (mc; 10H, $(CH_2)_5$), 2.36, 2.53 (s; 6H, $NCOCH_3$), 4.43 (q; 4H, OCH_2CH_3)

homoadamant-3-ene[15] as a result of twisting of the C=N bond. Although no pyramidalization of the N atoms is observed in **5c**, $\nu_{C=N}$ is somewhat smaller in the case of **5c** than in the case of 2,6-diethoxy-4,8-dimethyl-1,3,5,7-tetrazocine ($\nu_{C=N}$ = 1648, 1625 cm^{-1}).[7] On heating to 160°C (Kugelrohr distillation), **5c** is converted into **8** (cf. Table 1), which is also obtained when the N^1,N^4-dichloro compound **7c** (88%; m.p. 133°C; obtained by chlorination of **6c** with two equivalents of *tert*-butyl hypochlorite in dichloromethane) is reduced with naphthalene-sodium and the resulting product distilled.

The X-ray structure analysis of **7b**[16] (m.p. 131°C) affords insights into the bonding situation in a tetraazapropellane. The N-atoms are pyramidalized; the 3a–6a distance (154.9 pm) is much smaller than the distance between the bridgehead C-atoms in **5c**.

Reduction of **5** with potassium in liquid ammonia leads to dipotassium salts **9** (cf. Table 1), which can also be generated from **6** by treatment with potassium *tert*-butoxide. According to the ^{13}C-NMR spectra of **9** these salts contain dianions of **6**. The signals of the bridge C-atoms of **9** are shifted significantly upfield but still appear downfield compared to those of **5**. Decisive, however, is that the signals of *C*-OEt in **9** and **6** appear at practically the same field strength. Had tetrazocine dianions been present then the signals would have been shifted significantly upfield.





The formation of **9**, which can be regarded as a bishomoantiaromatic[17] 12π-electron system, instead of an aromatic 10π-electron tetrazocine dianion is in no way associated with the 3a,6a bridge. The disodium salt obtained by reduction of 2,6-diethoxy-4,8-dimethyl-1,3,5,7-tetrazocine[7] with sodium in liquid ammonia is, according to the ^{13}C-NMR data, a salt of 2,5-diethoxy-3a,6a-dimethyl-3a,6a-dihydro-1,4*H*-imidazo(5,4-*d*)imidazole and not, as originally presumed,[18] a tetrazocine dianion salt. Dianions of tetrahydropentalenes normally rearrange into cyclooctatetraene dianions.[6, 19–21] The formation of dianions of the type **9** from **5** or **6** now affords examples for the opposite case (MNDO heats of formation also show that donor-acceptor substituted bicyclo[3.3.0]octadiendiyl dianions are generally preferred over the corresponding cyclooctatetraene dianions).

The fact that no tetrazocine derivatives have been found in any of the reactions with electrophiles, apart from the oxidation with iodine leading to **5**, can also be considered as evidence for the tricyclic structure **9**. In the reaction of **9** with methyl iodide a 1:1 mixture of **10a** and **11a** is formed, in that with acetyl chloride a mixture of **10b** and **11b** (cf. Table 1).

[8] So far we have been unable to prepare compounds of the type **6** with smaller 3a,6a bridges. Reaction of benzocyclobutenedione with urea (12 hours' heating under reflux in benzene in the presence of trifluoroacetic acid; water separator) did not afford a glycoluril derivative but surprisingly 4-amino-6-(2-carboxyphenyl)-*s*-triazin-2-one (34%; m.p. 250°C), which can be converted—by heating with triethyloxonium tetrafluoroborate to 110°C and treatment of the cold melt with 50% aqueous potassium carbonate solution—into 2-amino-4-(2-carboxyphenyl)-6-ethoxy-*s*-triazine (36%; m.p. 219°C (decomp.); the constitution has been confirmed by an X-ray structure analysis).

IR Emission Analysis of Temperature Profiles in Pt/SiO_2 Catalysts during Exothermic Reactions**

By *George Georgiades, Valerie A. Self,* and *Paul A. Sermon**

Although the excess temperature of the active sites in supported catalysts during catalysis could be several hundred degrees higher than that measured by a thermocouple,[1] theoretical and experimental results have been contradictory. Indirect evidence may come from catalyst sintering[2] (attributed to local heating and consequent Pt mobility during oxidation-reduction) and the fact that in CO oxidation a Pd/SiO_2 catalyst without external heating remained at 150–190 K above the temperature of the reactant stream.[3] Unfortunately, 150-K temperature excursions of Pt/SiO_2 are probably representative of the support rather than the active sites (see Ref. [4]).

Infrared emission can, however, provide direct evidence of the temperature of the more important supported phase if at the relevant wavelengths the "black" active metal emits more strongly than the support. It has been shown that (1) the temperature of Ni crystallites exhibits an average transient increase of 165 K above that of the silica support within 3 s on O_2 chemisorption,[5] (2) during CO oxidation at 573 K the temperature of Pd is at least 190 K above that of its SiO_2 support,[3] and (3) temperature variations of 28 K exist across Pt/Al_2O_3 catalysts during H_2 oxidation.[6] However, it is now necessary to concentrate on temperature profiles produced under flow conditions using porous impregnated catalysts, operating in flow reactors with residence times of a few seconds, at partial pressures close to the stoichiometric composition of reactants[7] and to consider their significance for analysis of the kinetics of heterogeneous reactions.[8] We report here on the Pt/SiO_2-catalyzed oxidation of H_2 and hydrogenation of cyclohexene.

This particular catalyst (see *Experimental Procedure*) was selected because (1) the size of its pores might be large enough to reduce pore diffusion limitation, (2) the support would increase thermal and chemical isolation of the Pt active sites, (3) the activity of Pt was high and well known in the reactions selected, and (4) the Pt was finely dispersed (i.e., hydrogen chemisorption revealed[10] that it existed as 4-nm particles) throughout the internal pore structure of the support with sizes much smaller than the support pore size, thereby possibly allowing relatively ready access of reactants and release of products.

Platinum is one of the most active metals for H_2 oxidation[11] ($-\Delta H = 241.8$ kJ/mol H_2O) and has been studied in the unsupported[12] and supported[13] states. On supported catalysts a thermal feedback from the heat generated by the reaction may affect the chemical rate and cause oscillations and bistability.[14, 15] Interestingly, the higher activity for smaller SiO_2-supported Pt particles during H_2 oxidation[13] could not be explained by their heating up more than the larger ones. In cyclohexene hydrogenation ($-\Delta H = 117.8$ kJ/mol[16]) supported and unsupported Pt have been found[17–20] to show structure insensitivity (i.e., the turnover numbers remained constant at 2–3 cyclohexane molecules produced per Pt site per second[21] and independent of Pt particle size) with an activation energy of about 30 kJ/mol.

In the past many surface reactions have been probed by IR spectroscopy.[22] However, here IR emission analysis during catalysis has been carried out (see *Experimental Procedure*). Temperature profiles within catalysts during use can be predicted,[23] but precise catalyst parameters[24, 25] define the magnitude of the temperature rises of microscopic active centers and, inevitably, such analyses require assumptions concerning rates of generation, conduction, radiation, and convection of heat. As a result, widely varying excess temperatures[26] have been calculated and measurement[1] by IR emission[27] must be preferable (noting when external gas-film mass-transfer limitation[28] or stagnant gaseous boundary layers adjacent to the catalyst particle[29] are significant).

Figure 1 shows the temperature profiles of the Pt particles at the external surface of the Pt/SiO_2 catalyst particle during catalysis of H_2 oxidation (above) and cyclohexene hydrogenation (below), where the catalyst particle was initially at 294 K and 300 K, respectively. In view of the par-

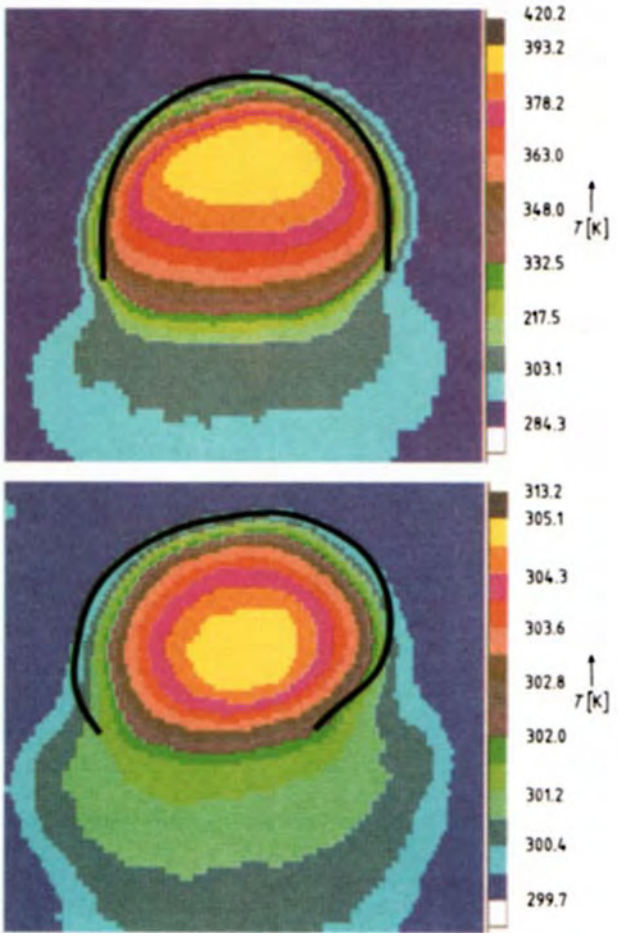

Fig. 1. Thermal profile observed for a 2.5-mm spherical particle of the Pt/SiO_2 catalyst, whose position is indicated by the dark line. The temperature of the SiO_2-supported Pt crystallites is predominantly assessed by IR emission. Above: Catalyst (which was predominantly at 293.7 K before reaction in flowing N_2) 13.0 min after initiation of hydrogen oxidation. Clearly, the temperature of the supported Pt crystallites rises as a result of the reaction to a maximum of 393.2 K. Interestingly, the gas stream temperature hardly appears to rise at all.—Below: Catalyst (which was predominantly at 300.3 K before reaction in flowing N_2) 3.25 min after initiation of cyclohexene hydrogenation. Here, 21% of the cyclohexene was hydrogenated by this catalyst particle. The temperature of the SiO_2-supported Pt crystallites clearly rises as a result of the reaction, but only modestly to 305.1 K.

ticle position indicated (black outline), there is no evidence of a stagnant boundary layer[29] surrounding the catalyst particle. However, there are a number of notable features which require comment. First, the temperature of the SiO_2-supported Pt crystallites (which is preferentially assessed by the IR emission method used here, unlike thermoelectric methods used previously,[13-14] which measure essentially the insulator support temperature), does increase as a result of sustained catalysis for both exothermic reactions, but to a much greater extent for H_2 oxidation than for cyclohexene hydrogenation. It should, however, be noted that excess temperatures of the obscured Pt particles within the catalyst pores may be higher than those noted at the external surface. Second, such excess Pt temperatures are stable as a function of reaction time. Third, there is a very wide range of Pt temperatures on the catalyst particles (which are not affected by the direction of reactant flow, but which are affected a little by the presence of the Pyrex pedestal which produces a vertical thermal asymmetry).

Despite the trend to design reactors with minimal concentration and temperature gradients, these temperature distributions are those that may exist during real heterogeneous catalysis. It has been shown here that the excess temperature of the SiO_2-supported Pt increases during catalysis of exothermic reactions to an extent which appears to vary from one reaction to another. This is unexpected for reactions whose overall enthalpies differ by only a factor of about two. Why it should be so remains uncertain. It is possible that in H_2 oxidation energy released is dissipated by radiation and so transfer to the gas phase is minimized, but that the reverse is the case for cyclohexene hydrogenation. If the reactant flow within the catalyst pores is a Knudsen flow, then the effective diffusion coefficients of oxygen and cyclohexene (0.025 and 0.015 $cm^2\ s^{-1}$ at 300 K) are significantly lower than in the bulk gases. However, turnover numbers of both reactions are approximately one product molecule per surface Pt atom per second. Therefore, the entire catalyst surface appears active and so with the present catalyst the differences in temperature are unlikely to result from larger cyclohexene molecules being hydrogenated at the outer edge of the catalyst and H_2 being oxidized through the porous structure catalyst particle, with radiation losses being greater in the former case. Bearing in mind the catalyst pore size, it is more likely to be attributable to the mechanisms of the two reactions being radically different, leading to different predominant modes of energy release. Thus, H_2 oxidation will result in formation of surface OH groups and adsorption of product water under these conditions is also quite likely.

The fact that the temperatures of the active crystallites in heterogeneous catalysts during exothermic reactions are raised relative to those of the support and of the gas phase is bound to affect the kinetics of catalyzed reactions. This means that measurement of the kinetics of reactions promoted by heterogeneous catalysts are made more complex by being a summation of the kinetics of processes occurring at reaction centers having a distribution of temperatures.[8] At least it may now be that these excess temperatures can be measured and controlled better than previously during catalysis under realistic conditions. They may then be found to affect the activity, selectivity, and reactivity of catalysts.

Experimental Procedure

Catalyst: A representative spherical particle (0.0124 g; 2.5 mm diameter) of 3% Pt/SiO_2 was used. This catalyst had been prepared by impregnation of SiO_2 (Shell, 2.5 S980-2.5 3; 211 m^2/g by N_2 BET analysis; 83% of its pore volume (0.94 cm^3/g) within the range 6-10 nm) with an aqueous H_2PtCl_6 (Johnson Matthey, Secpure) solution to the point of incipient wetness at 373 K and drying at the same temperature, calcining in air (543 K, 3 h), and reducing in flowing hydrogen at (713 K, 1 h) [9]. Since the catalyst had only a slightly lower pore volume (but a very similar surface area (205 m^2/g) and pore size range) compared to the support itself, support pore blocking on introduction of Pt was not great.

Methods: IR emission analysis was carried out using an Agema Thermovision 782 instrument (operating at 3-5.6 μm using a 7° lens and extension rings and image analysis on an IBM XT P/C with TIC 8000 cats software) and a Pyrex flow reactor. The emissivity of the supported metal particles was assumed to be 1 here and previously [5]. The catalyst sphere was placed in the reactor (in the center of an IR transparent window on a Pyrex pedestal) and around this flowed the reactant stream at constant flow rate and temperature (294 K or 300 K). The prepurified [7] reactant streams selected were (1) 4.05 kPa H_2 and 2.03 kPa O_2 (with the balance to 101 kPa being N_2) at a total flow rate of 100 ± 0.1 cm^3/min and (2) 4.05 kPa H_2 and 2.03 kPa cyclohexene (with the balance to 101 kPa being N_2) at a total flow rate of 40 ± 0.1 cm^3/min. These catalytic conditions were selected because of their previous use[7] and the prediction that they would result in identical excess temperatures of Pt in these reactions.

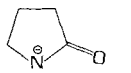
Novel Bimetallic Macrocyclic Polymer Structures Incorporating Deprotonated 2-Pyrrolidone Bridges: The Crystal Structures of $[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ ($X = NO_3$ or ClO_4)**

By *David M. L. Goodgame,* David J. Williams,** and *Richard E. P. Winpenny*

Polynuclear complexes involving different metal ions are currently of appreciable interest because, *inter alia*, of their possible role in catalysis, their involvement in metalloenzyme activity, and the unusual magnetic and electron transfer behavior they often exhibit. In the case of heterobimetallic complexes, easy electron transfer and the formation of metal centers with less-common oxidation states should be favored by the use of metals capable of ready redox behavior. With this in mind, we have been studying the formation of new polynuclear complexes involving combinations of mercury(II) ions with various transition metal ions.

Herein we report the syntheses and structural characterization of polynuclear complexes of stoichiometry $[Hg_2Cu(C_4H_6NO)_4X_2]$ with $X = NO_3$ (**1**) and ClO_4 (**2**); where C_4H_6NO = deprotonated 2-pyrrolidone **3**.



3

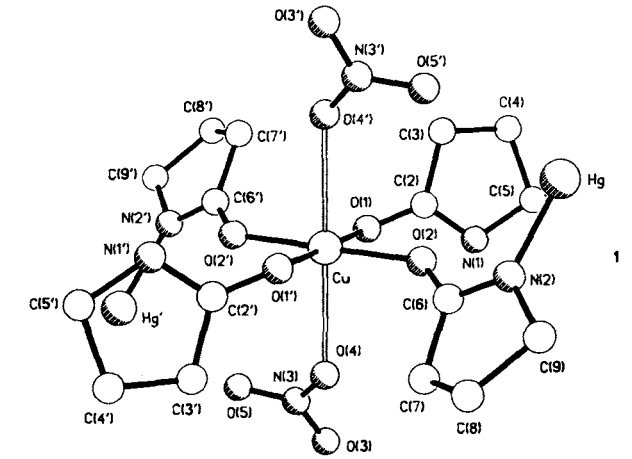
In both cases the X-ray structure analyses[1] show the Cu atoms to be coordinated to four 2-pyrrolidone units and two counterion oxygen atoms in an elongated octahedral arrangement (Fig. 1). The distances to the apical (counterion) oxygen atoms are significantly longer (ca. 2.6 Å) than those to the equatorial, pyrrolidone oxygens (ca. 1.9 Å). Additionally, the Hg atoms form strong bonds to the pyrrolidone nitrogen atoms,[2] producing linear N–Hg–N units linking pyrrolidone rings.

The consequence of these combined interactions is the formation of a unique polymeric, bimetallic, macrocyclic array (Fig. 2). The array is comprised of contiguous 32-membered macrocyclic rings, each ring being formed of 4 Cu, 4 Hg, 8 O, 8 N, and 8 C atoms. Within each macrocycle there are two counterions. In addition to their role of occupying the apical coordination sites on the Cu atoms, these form, in **1**, stabilizing ONO-bridges between opposite Hg atoms within each macrocycle, but in **2** they bridge only between the mercury and copper atoms.[3] In both structures the corrugated macrocyclic arrays are two-dimensional with, in each case, no significant inter-layer interactions.[4]

The formation of these structures may be thought to arise from the pronounced tendency of mercury(II) to favor deprotonation of the ring nitrogen atom of the 2-pyrrolidone and adoption of a linear N–Hg–N arrangement, accompanied by coordination of the exocyclic oxygen atom to copper(II). Conceptually, this behavior is related to that in some trinuclear species of the type

$[(NH_3)_2Pt^{II}L_2Cu^{II}Pt^{II}_2(NH_3)_2]^{n\oplus}$

where L represents 1-methylcytidine, or the anions of 1-



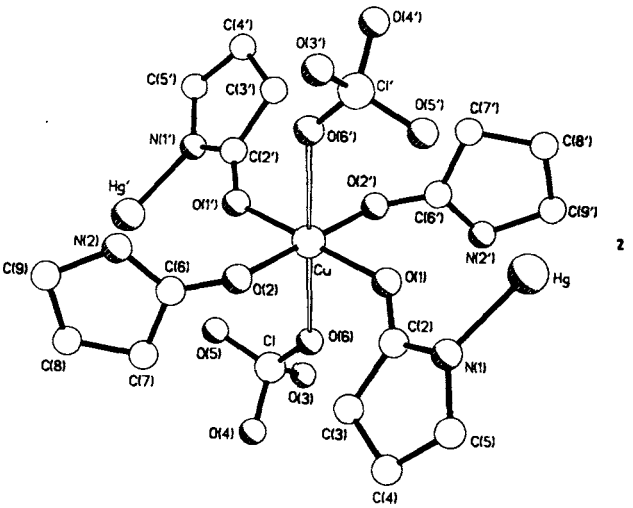


Fig. 1. The structures of **1** and **2** in the crystal. In **1** Cu-O1 = 1.960(7), Cu-O2 = 1.920(8) and Cu-O4 = 2.552(7) Å. In **2** Cu-O1 = 1.931(10), Cu-O2 = 1.955(10) and Cu-O6 = 2.681(10) Å.

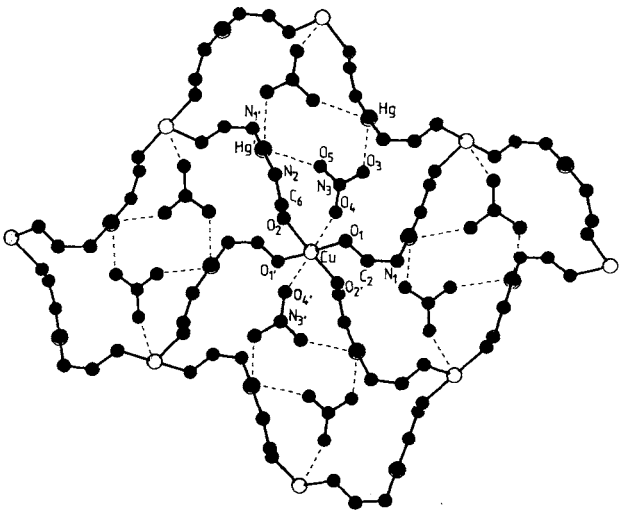

Fig. 2. Part of the contiguous macrocyclic array in the crystal structure of **1** showing also the $NO_3^{\ominus}$ stabilizing bridges. For clarity, only the atoms comprising the macrocyclic skeleton are shown (the pyrrolidone carbon atoms C3 to C5 and C7 to C9—see Fig. 1—have been omitted).

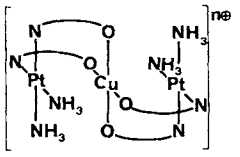
methyluracil or 1-methylthymine,[5] in which Pt^{II} binds to the ring nitrogen atom and Cu^{II} to the exocyclic oxygen atoms of the heterocyclic ligand (see **4**). In **1** and **2**, however, discrete units of low nuclearity are not formed.[6] Instead, the described contiguous, polymeric ring structure results.



4

Magnetic and spectral measurements[7] show that there is no strong coupling between the unpaired electrons on the copper(II) centers. There is evidence for a small degree of copper–copper interaction in **1**, as its g_z band in the ESR spectrum shows no evident Cu hyperfine coupling; this is in contrast to that observed in **2** (Fig. 3). However, no 'half-field' ($\Delta M_s = 2$) line, often observed for strongly coupled binuclear Cu^{II} systems,[8] was detected. The distance between nearest copper centers in both **1** and **2** is similar and is > 8 Å, so direct Cu–Cu interaction is unlikely. The poorer magnetic dilution in **1**, compared with **2**, may originate via a weak Cu–nitrate–Hg–nitrate–Cu mediated interaction (Fig. 2). Rhombicity is apparent in both spectra but is noticeably better resolved in the spectrum of **1**.

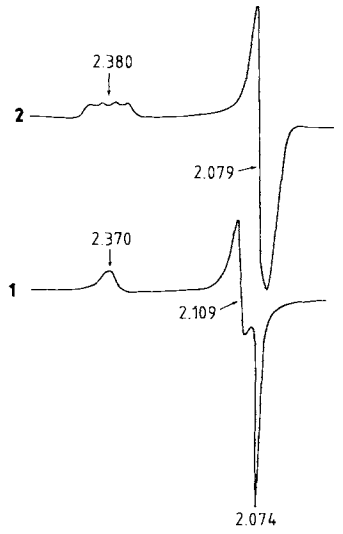


Fig. 3. Q-Band (≈34 GHz) ESR spectra of polycrystalline samples of **1** and **2**.

It is also of interest that the ν(C=O) bands, due to the bridging 2-pyrrolidones, in the IR spectra of **1** and **2** are much lower than those in complexes in which these ligands bind in monodentate fashion,[9] and this may provide a useful diagnostic guide for related compounds not amenable to single crystal X-ray analysis.

In view of the fairly loosely bound environment of the counterions in these structures there is potential for the development of analogous systems, with the possibility for anion exchange. It is perhaps noteworthy that the acetate used in the preparation of these complexes is not incorporated into either structure.

Experimental

Mercury(II) acetate (2 mmol), 2-pyrrolidone (8 mmol) and the appropriate ($X = NO_3$ or ClO_4) hydrated copper(II) salt (2 mmol) were refluxed in methanol (120 cm^3) for 3 d. The solutions were concentrated to ca. 20 cm^3, filtered and allowed to evaporate at room temperature when pale blue crystals suitable for X-ray analysis were obtained. Yields of **1** and **2** 49 and 56%, respectively. Both compounds gave satisfactory elemental analyses.

Spherical Mixed-Valence $[V_{15}O_{36}]^{5\ominus}$, an Example from an Unusual Cluster Family

By *Achim Müller,* Erich Krickemeyer, Michael Penk, Heinz-Jürgen Walberg,* and *Hartmut Bögge*

Intramolecular electron transfer processes in $M_xS_yM'_z$ clusters (M = V, Mo, W, Re; M′ = Fe, Co), and especially in the thioanions $VS_4^{3\ominus}$, $MoS_4^{2\ominus}$, $WS_4^{2\ominus}$ and $ReS_4^{\ominus}$, are of interest regarding a knowledge of the component 1 of the enzyme system nitrogenase[1] and HDS catalysis.[2] Remarkably, reduction of V^V by the $S^{2\ominus}$ ligands *and* rapid S–O exchange already take place on gently heating $VS_4^{3\ominus}$ (in contrast, e.g., to $MoS_4^{2\ominus}$) in H_2O. We have now been able to prepare black

$[NMe_4]_6[V_{15}O_{36}]\cdot Cl\cdot 4H_2O$ **1**

[*] Prof. Dr. A. Müller, E. Krickemeyer, M. Penk, H.-J. Walberg, Dr. H. Bögge

in high yields by this reaction[3] and to characterize it by elemental analysis, manganometric titration of the V^{IV}, DTA/TG analysis, IR spectroscopy,[4] magnetic measurements, and single-crystal X-ray structure analysis.[5]

The spherical anion $[V_{15}O_{36}]^{5\ominus}$ (Fig. 1), which has the high crystallographic symmetry $\bar{6}m2(D_{3h})$, is formed by linkage of fifteen tetragonal VO_5 pyramids. The different V-O distances ($V\text{-}O_{term} < V\text{-}(\mu_2\text{-}O) < V\text{-}(\mu_3\text{-}O)$; Fig. 1) are in the expected range. The 15 V atoms are arranged on the surface of a sphere at a distance of 343 ± 10 pm from the center of the cluster, where the $Cl^{\ominus}$ ion resides. Eighteen V-V distances in the range 293 to 300 pm indicate spin-spin interactions. Owing to significant spin coupling and the delocalized electronic ground state, the 8-electron cluster can *only formally* be referred to as a $V_7^V V_8^{IV}$-system[6] ($\mu_{eff} = 3.9\,\mu_B$ at room temperature). Probably the electronic interaction of the metal centers is optimized on a spherical surface.

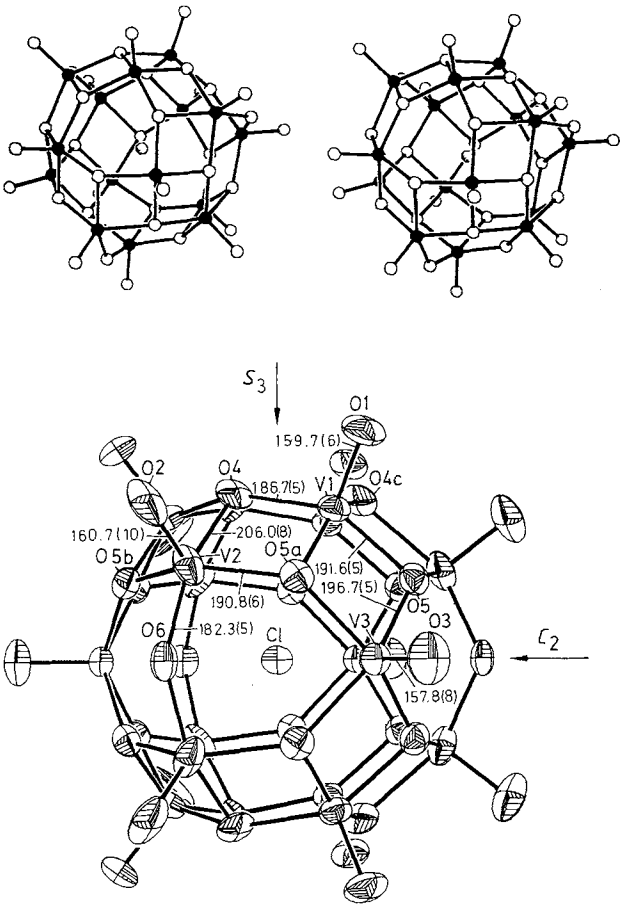

Fig. 1. Structure of the $[V_{15}O_{36}]^{5\ominus}$ anion with entrapped $Cl^{\ominus}$ ion in the crystals of **1**. Top: stereodiagram for clarification of the geometry: six VO_5 pyramids are each linked via three edges and two corners, six further are each linked via two edges and three corners and three are each linked via two edges and four corners. All μ_3-O atoms concomitantly participate in two edge linkages and one corner-linkage; the μ_2-O atoms form a corner linkage (V = black, O = white, Cl = shaded). Bottom: Ellipsoid plot with view perpendicular to the crystallographic S_3 and to one of the C_2 axes with bond lengths [pm]. Symmetry operations *a*: $-y, -x, z$; *b*: $y-x, -x, z$; *c*: $-y, x-y, z$; V-V distances [pm]: V1···V2 293.3(2), V1···V3 300.0(2); Bond angle ranges [°]: O_{term}-V-(μ-O) 101.0(4)-110.7(2), (μ-O)-V-(μ-O) 77.3(3)-93.0(6), 136.1(4)-156.1(4), V-(μ_3-O)-V 96.5(2)-101.2(2), 138.7(3)-140.8(5), V-(μ_2-O)-V 130.2(6).

The mixed-valence isopolyanions of vanadium probably form a structurally unusually versatile cluster family, since the metal-metal interaction is not very marked (in contrast to clusters of the 4d and 5d metals such as e.g., Mo with d^n configuration, in which the number of the d-electrons is structure-determining due to the formation of strongly covalent metal-metal bonds[7]), but can be highly modified by variable amounts of V^{IV} and V^V, and, moreover, the coordination geometries at the V centers are highly variable (tetrahedral (V^V), tetragonal-pyramidal (V^{IV}/V^V), and octahedral (V^{IV}/V^V)).

A Non-Stereospecific Diels-Alder Reaction**

By *Herbert Meier,* Heinz-Ludwig Eckes, Hans-Peter Niedermann,* and *Heinz Kolshorn*

Dedicated to Professor Ernst Bayer on the occasion of his 60th birthday

Since its discovery some 60 years ago[1] the Diels-Alder reaction has been a major subject of study in organic chemistry both from the preparative as well as mechanistic point of view.[2] At an early stage, *Diels* and *Alder* highlighted stereospecificity as a very important aspect of this [4+2] cycloaddition. According to present-day textbooks by far the majority of such cycloadditions involve a concerted mechanism. Very few cases are known in which the configuration of diene or dienophile is not retained during product formation.[3]

On the basis of frontier orbital theory it can be assumed that large energy differences HOMO(diene)-LUMO(die-

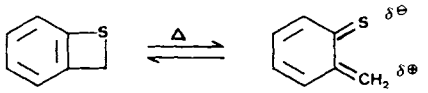
nophile) and HOMO(dienophile)-LUMO(diene) can be a decisive prerequisite for a two step mechanism being able to compete with the concerted mechanism.[2] *Huisgen* et al. recently demonstrated with an impressive example that this effect together with a strong steric hindrance reduces the stereoselectivity in the closely related 1,3-dipolar cycloaddition.[10] All the more surprising is that the heterodiene **2** reacts *stereo-unspecifically*—despite energetically favorably lying frontier orbitals and the absence of significant hindrance.



1 **2**

Because of its ease of thermal ring-opening to **2**, benzothiete **1** is suitable as synthon for the synthesis of numerous heterocycles.[11] According to MNDO calculations the *o*-quinoid form **2** has a low-lying LUMO and a relatively high-lying HOMO (Fig. 1); it can therefore be used as 4π (or 8π) component in cycloadditions with electron-rich or electron-deficient olefins **3** (2π components).

From the orbital coefficients it is clear that **2** should be attacked at the exocyclic positions; also evident in Figure 1 is the mode of addition for electron-rich olefins. The substituents X should assume the α-position to the sulfur in the cycloadduct (correlation A). In the case of electron-deficient olefins both modes of addition appear to be possible, whereby a slight preference for the β-position in the adduct can be assumed for the substituents Z (correlation B).

While the predicted periselectivity is rigidly retained, only in case A do the reactions proceed completely regioselectively; in case B, apart from the predicted main product, a by-product with inverse orientation of the dienophile is observed. In all cases the cycloaddition of **2** to **3** to give the products **4** and/or **5** competes with the cyclodimerization of **2** to **6**.

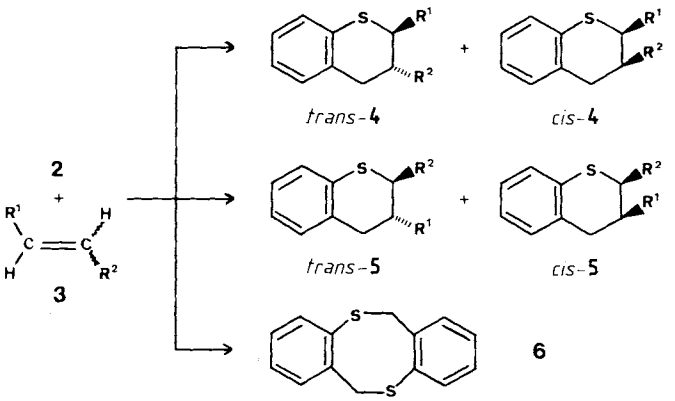


Table 1. Yields in the cycloadditions of **2** (from **1**) to **3** (toluene, 80–110°C, molar ratio **1** : **3** = 1 : 1.5).

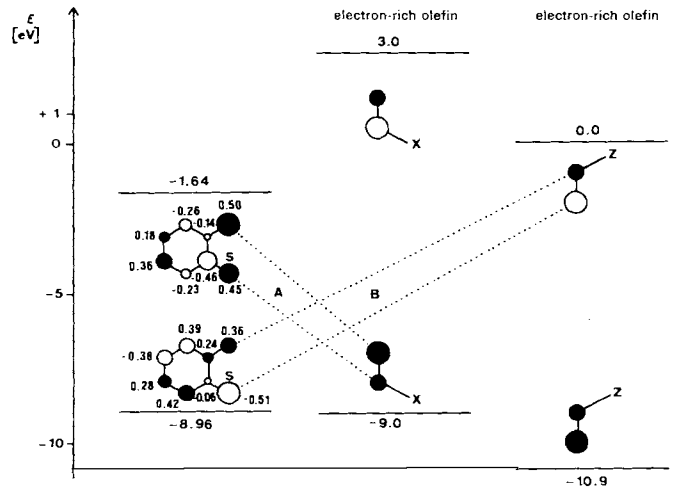

Fig. 1. Frontier orbitals of **2**, calculated according to the MNDO method [12], and estimation of the regio- and peri-selectivity of $[\pi 4_s + \pi 2_s]$ cycloadditions. (A, B: see text.)

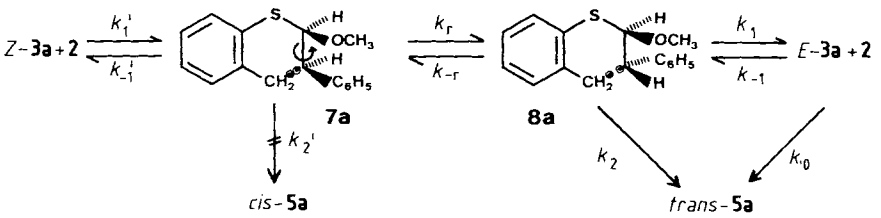
Table 1 lists the total yields and the percentage distribution for the products of the reaction of **1** (via **2**) with the *E*- and *Z*-configurated dienophiles **3a–c**. It can be seen that the *E*-olefins are added strictly stereospecifically; in the case of the more sluggishly reacting *Z*-olefins the amount of **6** is larger and the configuration of the olefin can even be completely inverted. This is so in the case of *Z*-**3a**, which affords exclusively *trans*-**5**. In the case of *Z*-**3b** the configuration is up to 93% retained and in the case of *Z*-**3c** 68% retained.

A mechanistic explanation for these observations is given for the example **2** + **3a** (Scheme 1). In its behavior **2** is reminiscent of a weakly polar diradical.[13] It adds *Z*-**3a** with formation of *one* bond (C–S or C–C). **7a** should be more stable than the 1,6-diradical, which is formed by primary C–C linkage. When $k_r \gg k_2'$ the *Z*-configuration is lost by rotation prior to the CC coupling. The isomeric diradical **8a** can cyclize to *trans*-**5a** ($k_2 \gg k_2'$), but also be cleaved to *E*-**3a** and **2** ($k_1 \gg k_2'$). In the case of unused *Z*-**3a** a partial isomerization to *E*-**3a** is indeed observed. Under these circumstances the reaction path to *cis*-**4a** is not followed at all. At the beginning of the reaction the concentration of *E*-**3a** is very low, and it follows from the rate of formation of *trans*-**5a** that the process *Z*-**3a** + **2** → **7a** → **8a** → *trans*-**5a**



Scheme 1.

dominates. It is still unclear to what extent *E*-**3a** reacts in a concerted reaction (k_0) or via **8a** to give *trans*-**5a**. If one starts with *E*-**3a** no isomerization to *Z*-**3a** can be observed (k_0 or $k_2 \gg k_{-r}$). In any case, in the process *Z*-**3a** + **2** → *trans*-**5a** a *Diels–Alder reaction takes place via a non-concerted reaction with loss of the Z-configuration of the added olefin*; in control experiments it can be unequivocally demonstrated that neither a direct isomerization *Z*-**3a** ⇄ *E*-**3a** nor an isomerization *cis*-**4** ⇄ *trans*-**4** or *cis*-**5** ⇄ *trans*-**5** is possible under the given reaction conditions.

The degree of stereoselectivity in the other examples likewise depends on the ratio of the partial rate constants. Apparently, favorable HOMO(diene)–LUMO(dienophile) or LUMO(diene)–HOMO(dienophile) interactions still do not suffice to ensure a concerted reaction. The asymmetry of the transition state may here be crucial: the C–S and C–C bonds to be formed have quite different lengths and therefore have different resonance integrals $\beta = f$ (distance *d*) on approach of **2** and **3**. This explanation is supported by the finding that the related *o*-quinodimethane system reacts stereospecifically with fumarates and maleates.[14]

Table 2. ^{1}H-NMR data of the cycloadducts **4** and **5** (δ values, TMS, vicinal *trans*- or *cis*-coupling $^3J_{2,3}$ in Hz). Solvents in brackets in the first column.

Imaging Oxygen Vacancies in Superconducting $YBa_2Cu_3O_{7-\delta}$ by High Resolution Electron Microscopy**

By *Dong Tang, Wuzong Zhou,* and *John M. Thomas**

Recent studies by high-resolution powder diffractometry[1,2] indicate that, in the perovskite-based superconductor $YBa_2Cu_3O_{7-\delta}$, there is a tendency for the oxygen anion vacancies to be preferentially ordered. It is thought that the arrangement of vacancies in the *ab* plane is such that CuO_4 planar groups constitute one-dimensional chains running parallel to the *b* axis (Fig. 1). High-resolution electron microscopic studies have also been brought to bear on the question of oxygen vacancy ordering;[3,4] but, owing to the inherent features of this technique (summarized below), less firm conclusions have hitherto been drawn concerning the preferential nature of these vacancies. Extensive computations, using the multislice procedure for coping with multiple electron scattering, along with high-resolution electron microscopic imaging, is shown here to yield strong supportive evidence for the recently proposed structural model.[2] In particular, we show that under certain well-defined conditions of imaging—sample thicknesses 60 to 80 Å, defocus settings of +600 to −1800 Å and resolutions close to 2.0 Å—the ordering of oxygen vacancies

[**] We thank the Royal Society for an Elizabeth Scholarship to enable one of us (*D. T.*) to come from the Institute of Physics, Academia Sinica, Beijing to London and Cambridge, Fudan and Cambridge Universities for support (to *W. Z.*) and the SERC for an equipment grant (to *J. M. T.*).

can be experimentally identified. Images projected along either [010] or [100] zone axes reveal direct evidence for the alignment of vacancies; those along either [001] or [110] do not. Such vacancies are crucially implicated in proposed[2,5] interpretations of the superconductivity of these mixed oxides.

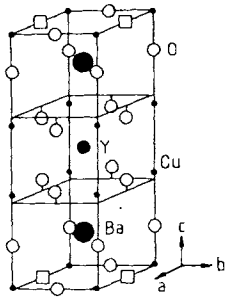

Fig. 1. Representation of the idealized structure of $YBa_2Cu_3O_{7-\delta}$ with the oxygen vacancies designated by □.

Experimental determinations of the structure of the high-temperature superconductor $YBa_2Cu_3O_{7-\delta}$ by X-ray and neutron scattering or by high-resolution electron microscopy leave little doubt as to the location of cations in the unit cell (Fig. 1). The arrangement of the anion vacancies in the oxygen sub-lattice is, however, more difficult to determine. And although there can be certain circumstances when the presence or absence of light atoms may be unambiguously detected either from superlattice spots[6,7] in electron diffraction patterns or by rather special conditions of high-resolution imaging,[8] it is no mean task unambiguously to characterize the nature of the arrangement of light atoms or vacancies by electron microscopy. We have tested the currently accepted structural model by comparing our observed images—recorded under conditions described in an earlier paper[9] dealing with crystalline defects in $YBa_2Cu_3O_{7-\delta}$—with the results of several hundred image computations covering a wide range of observational conditions.

High-resolution electron microscopy can nowadays achieve point-to-point resolutions of better than 1.6 Å. But there is no ready intuitive way of reading off structural detail from projected images of relatively tightly packed structures. Why this is so has been amply described elsewhere.[10,11] One of the main reasons stems from the multiple scattering of electron waves so that, even with ideal electron lenses, the structural information transferred to the Gaussian image plane is complex, and is, in any case, further affected by imperfections in the lenses and by processes other than diffraction which occur when the monochromatic electron waves pass through the sample. Fortunately, a well-tried method—the multislice procedure—of image computation is available. It transpires that, depending upon the suspected feature in the sample that one seeks to characterize, a specific imaging condition, or 'window' of conditions is found, by numerical computation, to be appropriate. Thus, in endeavouring to locate exchangeable cations, for example, in zeolitic catalysts, it is found[12] that a lower rather than higher resolution (fewer diffracted beams) is advantageous.

Samples of the material $YBa_2Cu_3O_{7-\delta}$ were kindly supplied by Dr. *W. Y. Liang* of the Cavendish Laboratory, University of Cambridge. The preparation, composition, superconducting properties ($T_c \approx 93$ K; $\Delta T_c \approx 1$ K) of this material and our electron-microscopic and computational procedures have been described elsewhere.[9]

Using the atom coordinates given by *David* et al.,[2] we have computed images projected along all the principal high symmetry directions. Sample thickness has been varied systematically up to 120 Å, lens defocus from 400 to −2300 Å and image resolutions from 1.90 to 2.40 Å, the accelerating voltage being 200 keV throughout.

Not surprisingly, with thin specimens, computed projected images of the structure containing aligned vacancies show no difference as between the [010] and [100] projections for a resolution of 1.90 Å. At 80 Å thickness, however, significant differences begin to emerge for the [010] and [100] projections (see Fig. 2). But images along [001] and [110] do not yield any information about oxygen vacancies. When the oxygen occupancy factors are all set equally at

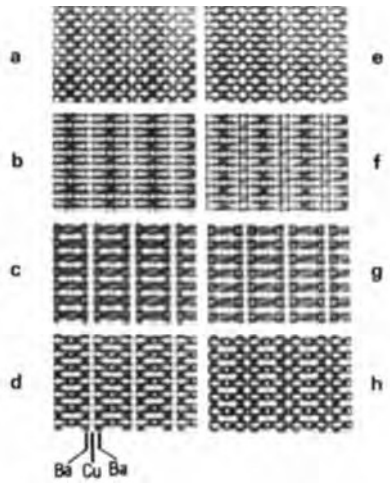

Fig. 2. Computed images along [010] (*a*, *b*, *c*, *d*) and [100] (*e*, *f*, *g*, *h*) zone axes. From top to bottom, specimen thickness: 20, 40, 60 and 80 Å; resolution = 1.90 Å; defocus = −600 Å. Note the difference between *d* and *h*. Along [010], the Cu-O "plane" is imaged to be more as a continuous line than in *h*, where discrete white spots are visible.

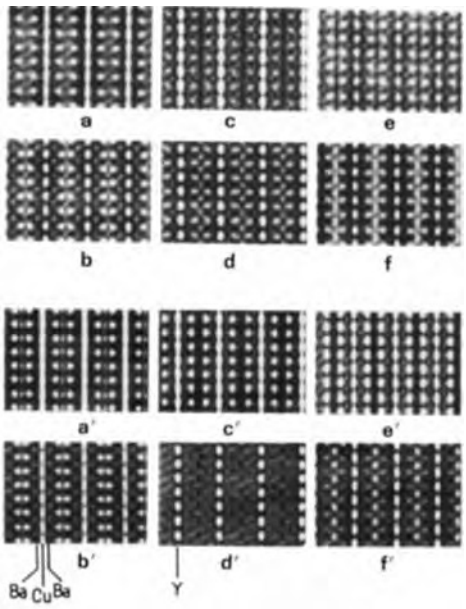

Fig. 3. Computed images along [100] projection (*a* to *f*) and [010] projection (*a'* to *f'*). Resolution = 1.98 Å; defocus = −600 Å (*a*, *b*, *a'*, *b'*), −1200 Å (*c*, *d*, *c'*, *d'*) and −1800 Å (*e*, *f*, *e'*, *f'*); thickness = 60 Å (*a*, *c*, *e*, *a'*, *c'*, *e'*) and 80 Å (*b*, *d*, *f*, *b'*, *d'*, *f'*).

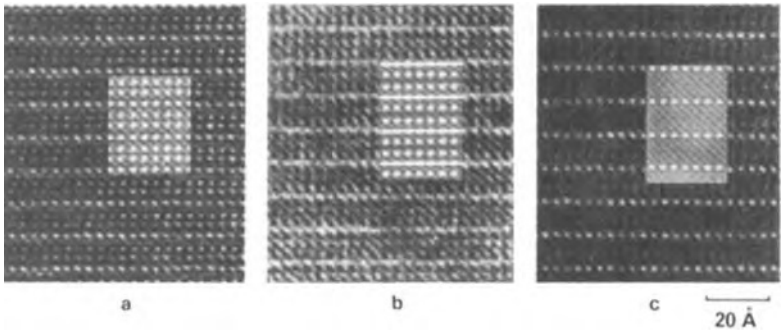

Fig. 4. Experimental images of $YBa_2Cu_3O_{7-\delta}$. a) [100] projection, the computation conditions of the inset: resolution of 1.98 Å; defocus of −1800 Å and thickness of 60 Å; b) und c) [010] projection, the computation conditions of the insets: resolution of 1.98 Å; defocus of −1200 Å; thickness of 60 Å (b) and 80 Å (c).

0.5 at the four sites on the *ab* plane, the differences in the images along the [010] and [100] directions is much reduced.

By choosing a resolution for the computed image close to that used by us experimentally (1.98 to 2.00 Å) we find that there are now clear-cut differences between the computed images of the structure containing aligned oxygen vacancies for the [100] and [010] projections (see Fig. 3).

Our experimental results, Figure 4a from one particle and Figures 4b,c from other regions of another particle, show different details of image contrast. The inset of Figure 4a is identical to that shown in Fig. 3e. None of the images calculated along [010] matches this experimental result. The insets of Figures 4b and c are identical to those from Figures 3c′ and d′ respectively. The sample-thickness dependence of these two images match only with those found experimentally for projections along [010].

In summary, we have demonstrated that, in principle, it is possible by high resolution electron microscopy, to observe contrast effects arising from the presence of a given oxygen vacancy arrangement in the *ab* plane of $YBa_2Cu_3O_{7-\delta}$. Further studies of this system, with larger[13–15] values of δ, are underway.

BOOK REVIEWS

Clusters and Catalysis

The above title has in recent years become a catchphrase used in support of research on clusters, especially in the USA. Although opinions may differ about the use of a phrase which contains such promises, it has nevertheless gained attention and funding for cluster research, and led to increased activity in this area. Consequently the appearance of monographs on the theme "Clusters and Catalysis" was only a question of time. That has now occurred in the two books

Metal Clusters in Catalysis. Edited by *B. C. Gates, L. Guczi,* and *H. Knözinger.* Elsevier, Amsterdam 1986, xxv, 648 pp., bound, HFl 195.00.—ISBN 0-444-42708-2, and **Metal Clusters.** Edited by *M. Moskovits.* Wiley, Chichester 1986. ix, 313 pp., bound, £ 47.95.—ISBN 0-471-89388-9

and more will probably follow. In both cases the editors do not come from the field of preparative cluster chemistry, which is mostly associated with inorganic chemistry, but instead come from physical chemistry. The book of over 600 pages edited by *Gates, Guczi,* and *Knözinger*

states its aims in the title, whereas in the volume of 300-odd pages edited by *Moskovits* the definition of subject matter first appears in the list of contents. Both books are priced at a level which today is normal for monographs of this kind, both give about the same amount of paper in relation to the price, and both can be described as collections of review articles. In both cases the editors have enlisted a competent team of authors (seventeen in "Metal Clusters in Catalysis" and ten in "Metal Clusters"), from whose names specialists in the field will be able to predict the subjects covered, and also those that receive little attention. Altogether one can say of both these books that they deal with the essential highlights of the chemistry of cluster compounds, mainly those without organic ligands.

"Metal Clusters in Catalysis" is divided into three sections, which can be defined as molecular cluster chemistry, clusters in and on supports, and some analogies between clusters and surfaces. In the first part *G. L. Geoffroy* gives a short but complete survey of synthetic methods for molecular clusters, which is followed by a very brief article by the same author on cluster structures. Likewise very brief is the article by *J. A. Connor* on thermochemistry and binding energies in clusters. The essay on reactivities of molecular clusters by *G. Lavigne* and *H. D. Kaesz* which comes next is well organized and essentially complete. The article by *L. Markó and A. Vizi-Orosz* on homogeneous catalysis by metal clusters is the fullest review yet to appear on this topic. The second part of the book contains its main emphasis, in accordance with the editors' chief area of interest. The chapter by *H. Knözinger, L. Guczi,* and *R. F. Pettifer* on characterization by physical methods is very detailed, carefully written, and longer than all the preceding five chapters put together. The chapter by *G. A. Ozin* and *M. P. Andrews* on clusters produced by the condensation of metal vapors is authoritative and comprehensive. The treatment by *P. A. Jacobs* of clusters in zeolites emphasizes the great hopes which are held for developments in this area. This is followed by the second principal chapter of the book, to which *B. C. Gates, R. Psaro, R. Ugo, G. Maire,* and *H. Knözinger* have contributed; this is concerned with clusters immobilized on surfaces, their preparation from molecular clusters, and the associated organometallic surface chemistry. The following chapter by *L. Guczi* on surface bound bimetallic catalysts is actually a sub-chapter of the preceding one. The third section of the book consists of only a single essay, in which *G. Ertl*—impressive as always—discusses relationships between clusters and surfaces. Although the book, with 648 pages, is by no means thin, it cannot be said that any of the eleven chapters is unduly long.

In "Metal Clusters" the emphasis is very unevenly distributed between individual topics. General themes are treated very briefly: bonding theory considerations (by *R. C. Baetzold*), structures (by *D. H. Farrar* and *R. J. Goudsmit*), organometallic chemistry involving clusters (by *J. S. Bradley*), and catalysis by surface bound clusters (by *B. C. Gates*). In contrast, two chapters on individual special topics, namely reaction kinetics of metal carbonyl clusters (by *A. J. Poë*) and optical methods for identifying cluster compounds in the gas phase (by *J. L. Gole*), are very detailed. The book is rounded off by an account of methods for identifying matrix-isolated clusters (by the editor, *M. Moskovits*), and two applications-oriented chapters, on clusters in zeolites (by *P. Gallezot*) and on a comparison of the catalytic activities of surface bound clusters (by *A. Brenner*). Thus the book's rather general title conceals a collection of essays on particular aspects of cluster chemistry, determined by the choice of authors, the main emphasis being on describing the properties of metal atom aggregates.

The field of cluster chemistry as a whole is already so large that these two books, even when taken together, can present only a selection from it. Regarding the selections that have been made, they are to some extent complementary, but they overlap on matrix isolation, clusters in zeolites, structure geometry, and clusters on supports. On the last topic we also find the same author, *B. C. Gates,* in both books. Both books are attractively produced; the detailed index in "Metal Clusters in Catalysis" is an additional good feature. Both books have their strengths and weaknesses, of course, since they can be no better than the individual contributions of their authors. As monographs, however, they offer a very good account of the present state of knowledge on the topics treated, and therefore should not be omitted from any library. So far as purchase by individuals is concerned, though, they will only be of interest to specialists, particularly in the case of "Metal Clusters". Even when one accepts that the very brief treatment of molecular cluster chemistry is in accord with the editors' stated aims, it would nevertheless have been desirable to include some discussions of the chemistry of soluble cluster compounds with inorganic ligands, the redox properties of clusters, the extensive topic of clusters in solid state compounds, and the biological importance of clusters. Since the phase of frantic activity in cluster chemistry is coming to an end and the matter is becoming somewhat settled now, perhaps some author should risk writing a textbook type monograph on the subject.

Analytical Methods in Human Toxicology, Part 2. Edited by *A. S. Curry.* VCH Verlagsgesellschaft, Weinheim 1986. x, 354 pp., bound, DM 170.00.—ISBN 3-527-26285-7

The second volume of "Analytical Methods in Human Toxicology" deals with HPLC, fluorescence analysis and radioimmunoassay methods, and their application to solving toxicological problems. In addition it familiarizes the reader with pharmaco-kinetic investigations. Using examples from the literature, the large differences often found in metabolization of pharmaceutical substances are discussed, together with the related concept of the "effective dose". Lastly, procedures used to test for the presence of some toxicologically important classes of compounds, such as narcotics and combustion gases, are described in detail; other classes of substances, e.g. barbiturates, benzodiazepines and tricyclic antidepressants, are included in the discussion of practical examples.

The book includes references to a considerable amount of literature which is important to the toxicologist. Some chapters contain a wealth of very useful advice, e.g. in the section on the elimination of errors in HPLC. Unfortunately, though, the editor has not succeeded in this second volume in avoiding some duplication of material, e.g. the analysis of tricyclic antidepressants has already been treated thoroughly in volume 1. Despite this lack of complete coordination, every toxicological laboratory will find that this second volume too is a valuable addition to its library.

Schrödinger. Centenary Celebration of a Polymath. Edited by *C. W. Kilminster*. Cambridge University Press, Cambridge 1987. 253 pp., bound, £30.00.—ISBN 0-521-34017-9

To mark the centenary of the birth of *Erwin Schrödinger* a conference was held in the spring of 1987 at Imperial College, London. Most of the papers presented at the meeting are contained in this volume. They are all, without exception, written by internationally recognized scientists.

Schrödinger, who, together with *Einstein* and *Planck*, is one of the best known of the founders of twentieth century physics, was born in Vienna and studied physics at the city's university. Towards the end of an eventful life, he returned in 1957 to his native country. The places where *Schrödinger* did his most important work were Zürich (1921–1927), where his achievements included the publication of his six famous papers on wave mechanics, Berlin (1927–1933) and Dublin (1940–1957), where, after years of fleeing from the Nazis, he found a secure intellectual home in the Institute of Advanced Studies. In 1933 he was awarded a Nobel Prize in physics for his work on wave mechanics.

This collection of articles is, by the nature of its theme, very heterogeneous. There are two contributions (by *Flamm* and *McCrea*) on biographical aspects and on the background to *Schrödinger*'s scientific works, while the rest of the articles are mainly concerned with the current state of knowledge in those fields which were given a new theoretical basis by the *Schrödinger* equation. Readers unfamiliar with the methods of theoretical physics will find considerable difficulty with many of the articles. Nevertheless, even the layman will be impressed by the enormous range of influence that *Schrödinger*'s work has on modern physics.

Schrödinger, like *Einstein*, was never entirely satisfied with the then generally accepted interpretation of quantum mechanics according to the Copenhagen school. For this reason the three papers (by *Dorling, Bell,* and *Yang*) that are concerned with the modern view of *Schrödinger*'s interpretation of wave mechanics, are especially interesting. I have the impression that the front of resistance to "unconventional" interpretations of the quantum theory is gradually beginning to weaken.

From the chemist's point of view the greatest interest lies in the significance of the *Schrödinger* equation for questions of chemistry, to which four papers are devoted (*Karplus, Fukui, Buckingham, Pauling*). Understanding of chemical bonding and chemical reactions would be highly inadequate without the basis provided by *Schrödinger*'s work. Further, the numerical methods of calculation that are based on the *Schrödinger* equation are now an indispensable source of exact data on molecules and molecular aggregates. Molecular dynamics too has its origins in quantum mechanics. In this field laborious quantum-mechanical calculations are nowadays often replaced by classical approximations which are sufficiently accurate. Some of the most important modern applications are to understanding chemical reactions of small molecules in the gas phase, to the structure and dynamics of liquids, and to the study of biologically important macromolecules.

The little book "What is Life?", which *Schrödinger* wrote during his time in Dublin, undoubtedly introduced many young physicists to interesting unsolved problems in biology. The reservations expressed by those experts (*Perutz, Pauling*) who criticize the eminent physicist for superficiality and insufficient knowledge of the literature were therefore somewhat unexpected, though justified on closer scrutiny. These minor complaints, though, cannot shake the overall picture of *Schrödinger* as a widely ranging scholar. This book is written mainly with physicists in mind, but the chemist or biochemist with interests in this field will also find it profitable reading.

Trace Analysis. Spectroscopic Methods for Molecules. Edited by *G. D. Christian* and *J. B. Callis*. Wiley, Chichester 1986. XII, 406 pp., hard cover, £ 52.75.—ISBN 0-471-87583-X

The identification and quantitative analysis of molecular trace components in (usually) complex mixtures belongs to the most important tasks in modern Analytical Chemistry, particularly in areas like environmental, clinical, agricultural, food and biochemistry. In order to obtain reliable and accurate results, separation methods (like GC, HPLC) are often combined with spectroscopic techniques which enable one to obtain qualitative and quantitative information.

This volume presents four of these spectroscopic techniques—photometry, luminescence spectroscopy, IR spectrometry and NMR spectroscopy. The most important technique for trace analysis of molecules, mass spectrometry, is not included, obviously to keep the number of pages limited. The limitation of the content to these four techniques should have been stated in the title!

The chapters have been written by different authors, consequently the chapters differ somewhat in style and structure: While the chapter on IR (*A. L. Smith*, Dow Corning Corp.) does not cover the fundamentals of IR spectrometry but centers on aspects of trace analysis with this technique, the other chapters on photometry (*K. L. Ratzlaff*, University of Kansas), luminescence spectroscopy (*R. J. Hurtubise*, University of Wyoming) and NMR (*D. L. Rabenstein*, University of California, and *T. T. Nakashima*, University of Alberta) provide more a presentation of fundamentals, instrumentation and application of the individual techniques. Relation to trace analysis is provided to a variable extent. The chapter on NMR shows a particular emphasis on the fundamental principles of the technique: only 10 out of 108 pages are devoted to trace analysis.

Nevertheless—all of the chapters are of interest for those who want to make themselves acquainted with the principles and basic potential of these spectroscopic techniques. The presentations are clear and illustrative and much specific information about measurement techniques etc. is given. Major recent progress in each area—e.g. the use of lasers in photometry—is included as well as a list of references (between 86 and 395 per chapter) which refers either to fundamental literature or specific information.

The general impression can be summarized as follows: a good presentation of four major spectroscopic techniques for trace analysis of molecules. The book is useful for separation scientists who want to get to know such spectroscopic techniques. It may also serve as a rather good textbook on photometry, luminescence spectroscopy and NMR for analytical chemistry courses.

Inorganic High Pressure Chemistry. Kinetics and Mechanisms. Edited by *R. van Eldik*. Elsevier, Amsterdam 1986. x, 448 pp., bound, HFl 280.00.—ISBN 0-444-42682-2

High pressure kinetics has become more and more important in the last years. Especially in coordination chemistry it brought new insights into the reaction mechanisms. The editor *Rudi van Eldik* is one of the leading experts in high pressure kinetics of coordination compounds. The reader will notice his experience and competence. He himself has written a large part of the book, thus making it very coherent. There are almost no repetitions.

The introductory chapter by *van Eldik* describes the high pressure techniques and methods of analysis comprehensively. The experimental results are arranged according to reaction types: Solvent Exchange Reactions (*Y. Ducommun* and *A. E. Merbach*); Substitution, Isomerization and Related Reactions of Octahedral Complexes (*R. van Eldik*) and of Four-Coordinate Complexes (*M. Kotowski* and *R. van Eldik*); Electron Transfer Reactions (*T. W. Swaddle*); Photochemical and Photophysical Processes (*P. C. Ford*); as well as Bioinorganic Systems (*K. Heremans*). The final chapter by *van Eldik* demonstrates how much the subject is in a state of flux. Simple transition state theory is used to discuss the high pressure data almost all over the book. It is only in the last chapter that *van* Eldik shows what consequences the simplifications have and which extensions were suggested. These difficulties become evident especially in high pressure photochemistry. Here, the application of transition state theory is not justified a priori. In the introduction to his chapter *Ford* explicitly stressed this point: "the processes subsequent to photoexcitation have to be treated somewhat differently". However, he also uses the simple transition state theory to discuss the experimental results. Obviously there is nothing better.

I am sure this monograph will remain the standard work on high pressure kinetics for years. Everyone working in this field will use it and quote from it. The nonspecialist might be discouraged by size and price. But there is hope, its contents will get into text books on reaction kinetics and thus will become widely known. For, the pressure dependence of rate constants will soon become as important as the Arrhenius diagram is to-day.

Stereoselective Synthesis. By *Mihály Nógrádi*. VCH Verlagsgesellschaft, Weinheim 1987. xiv, 356 pp., bound, DM 168.00.—ISBN 3-527-26467-1

The area of stereoselective synthesis has been intensively studied for a good decade, and has thus reached some degree of maturity. Therefore both outsiders and those working in the field have an equal need for a critical review which sets out the principles and highlights the reliable methods. We already have, from the years 1983-1985, the five volume work "Asymmetric Synthesis", edited by *J. D. Morrison* (see *Angew. Chem. Int. Ed. Engl. 25* (1986) 848), which describes the essence of the more important methods. What can the present book offer us?

The introduction, which discusses the basic concepts of stereochemistry, shows the author to be a scientist who proceeds in a systematic way. This is followed by chapters on stereoselective catalytic hydrogenations, stereoselective non-catalytic reductions, stereoselective oxidations and stereoselective C-C bond-forming reactions. Finally there are two shorter chapters on stereoselective pericyclic reactions and stereoselective carbon-heteroatom bond formation. However, the critical evaluation which we had hoped for constitutes only a small insignificant part of the book, which being simply a collection of data is scarcely more exciting to read than a telephone directory. The author has, however, assembled, under types of reactions, all the important factual information on stereoselective syntheses from recent years, and a large amount of additional data. Is this book then to be regarded as the "Beilstein" of stereoselective synthesis? The scandalously long time interval between the end of literature coverage in 1984 and the book's publication in 1987 is reminiscent of that. But that is the only resemblance—whereas Beilstein is recognized for the proverbial reliability of the data, *Nógrádi*'s book contains many incorrect structural formulas. These, regrettably, include quite a number of errors which alter the intended meaning. Worse still, some reactions which superficially look correct are in fact given wrongly, e.g. because the configuration of a stereogenic center in a product is shown wrongly, or the description of the reaction as a whole does not correspond to that in the papers cited. Of course, the reader only notices such errors in those topics with which he is familiar. It is unfair, but understandable, to draw conclusions from this about the treatment of other topics. In short, viewed in this light the book is a source of irritation.

Despite these criticisms I must give the author credit where it is due. Behind this collection of data there lies an immense amount of work, and the book is certainly of value insofar as it contains a wealth of well organized data on stereoselective syntheses. This includes much factual information and examples which the reader interested in this field could not otherwise readily find. Nevertheless, all users of the book are strongly advised to check the data by consulting the original papers!

It may occur to the reader of this review that minor defects of presentation and inaccuracies, which one would usually criticize, have not been mentioned here. Such faults pale into insignificance compared with the lack of care in presenting structural information. It is perhaps typical of the book that the page devoted to advertising by VCH Verlagsgesellschaft shows an sp^2 hybridized carbon atom with tetrahedral bond angles!

Reinhard W. Hoffmann [NB 838 IE]
Fachbereich Chemie
der Universität Marburg (FRG)

Transient Techniques in NMR of Solids. An Introduction to Theory and Practice. By *B. C. Gerstein* and *C. R. Dybowski*. Academic Press, New York 1985, xi, 295 pp., bound, $59.00.—ISBN 0-12-281180-1

As the authors state this book is written for students working in the field of high resolution NMR spectroscopy of solids, who wish to gain a thorough understanding of this specialized topic. They have sought to convey to the reader their own, quite individual view of this subject, the fascination which it generates, and their own pleasure in the scientific concepts involved. To this end they use a very lively style of language rich in individual idioms and expressions. They treat at length with very detailed calculations the fundamental topics, including some rather trivial ones. Time and again the authors feel obliged to lead the reader into digressions, e.g., into complex numbers, alter-

nating current circuits, selected topics in magnetostatics, some of the fundamentals of quantum mechanics and linear algebra, and into the mathematics of exponential operators.

However, accuracy sometimes becomes lost in the authors' enthusiasm for the subject. Thus, for example, they talk about "decoupling of differential equations," where what they actually mean are *linear first-order* differential equations. A more bizarre example is seen on p. 21, where the symbol τ is used with two different meanings within the same simple equation. The misprint demon has struck in a particularly malicious way on p. 167, where, as a result of a "0" (zero) having been converted into the letter "O", the whole thing has turned into a hopeless mess.

In a sense the impression is conveyed that the book has been compiled in such a way as to make it superfluous for a student working on solid state NMR spectroscopy to study any other text. The essential problem of the book is, though, that it is addressed to a fictitious readership.

At the beginning of Chapter 5, on p. 198 (of a total of 275 pages), the authors state that all that has gone previously is only a preparation for the real objective, which is to understand the mechanism of multipulse cycles. I am sorry to have to say, though, that the heyday of multipulse cycles took place ten years ago. Throughout the world there are now only a few groups working in this particular field and their number is decreasing rather than growing. *Gerstein* and *Dybowski* mainly ignore the successes of the multipulse technique, which in my view are best seen in single crystal studies. It thus seems an ironic accident that in the one example relating to single crystal measurements, data containing systematic errors are used. It is casually stated that in any case most samples are in the form of powders. The hope is expressed that a combination of multipulse cycles with rapid rotation of the sample about the "magic angle" (here dealt with only briefly) will yield a method equivalent in information content and ease of interpretation to true high resolution liquid state NMR spectroscopy, which is so outstandingly successful as an analytical technique. However, one hardly finds in this volume any convincing example to support such a hope.

The final chapter is devoted to heteronuclear pulse experiments. The style here is different. We no longer have detailed analyses and a complete understanding, but instead a more or less traditional presentation of well-known techniques. It is clearly apparent that the authors are here no longer drawing on their own store of experience and knowledge to the extent that they are in the earlier chapters.

The literature citations are a peculiar feature of the book. On the grounds that this is a textbook, *Gerstein* and *Dybowski* avoid citing original papers so far as possible. In some places, however, original work is deliberately cited. The reader may easily guess at the system which is used. Writing a whole chapter on multipulse cycles and homonuclear pulse experiments in solids without mentioning the name of *J. S. Waugh* even once in the text, is, to say the least, a strange thing—and this is by no means an isolated example.

Research libraries concerned about full coverage will not be able to avoid buying this book, but I fear that there will not be many students, at least in Germany who will give themselves the "pleasure" of studying it systematically.

U. Haeberlen [NB 801 IE]
Max-Planck-Institut für medizinische Forschung,

Low Energy Electrons and Surface Chemistry. By *G. Ertl* and *J. Küppers*. VCH Verlagsgesellschaft, Weinheim 1986. XII, 374 pp., hard cover, DM 168.00.—ISBN 3-527-26056-0

If *Irving Langmuir* were to appear again on the scene in surface science he would be captivated by many things, not the least important of which is the ability we now have of being able to probe the composition and structure of solid surfaces with great dexterity and precision. To test the theory of monolayer saturation in adsorption, proposed by *Langmuir*, it was necessary to use high-area solids, typically activated charcoal or silica gel which have areas ranging from 20 to 400 $m^2 g^{-1}$. Only by boosting the extent of the adsorbed phase in this way was it possible to cope experimentally with the reliable measurement of adsorption from the gas phase or solution. Nowadays, however, it is routinely possible to monitor the build-up of monolayer volumes, Vm, from fractions of coverage of 10^{-4} to unity when the surface area is no more than a few $cm^2 g^{-1}$. The principal cause of the revolutionary advance has been the use of electron, and other beams (including soft X-rays, and ions of light elements) as primary probes for arriving at the composition, stoichiometry and structure of two dimensional ordered or disordered two-dimensional structures at solid surfaces. Low-energy monoenergetic electrons (1 to 5 eV) beams are ideal for exciting the vibrations of chemisorbed and physically adsorbed layers; and from the diffraction of monoenergetic electrons of energy in the range 60 to 300 eV, a great deal can be inferred about the atomic disposition of the exterior surface of a bulk solid and of overlayers that can form upon it.

It would be difficult to overemphasize the importance of the study of such systems: they are deeply implicated in the phenomenology of catalysis, corrosion, epitaxy, and the vast ramifying technologies that hinge upon these including the fashioning of new devices from quantum well lasers to fast transistors. At the fundamental level, too, a great deal needs to be learned about the basics of surface science. Why does the sticking coefficient of a given gaseous species vary so enormously from one crystal face to another on a simple solid such as tungsten. For graphite, for example, the 'anisotropy' in sticking coefficient of oxygen as between the prismatic and basal faces is a factor of some 10^{15}.

In the last two decades major progress has been accomplished in enlarging our understanding and control of the properties of surfaces. There have been dramatic improvements ever since the first edition of this very fine monograph appeared in 1974. The reader is given concise, expert guidance in numerous facets of surface science, and, in particular, is introduced to all the principal ways in which the strong interaction of electrons with matter are turned to good advantage in gaining further insights into surface properties and behavior. Only a fastidious concern for perfection leads one to discover minor almost trivial, faults with this book. The reviewer is a little disappointed (and perhaps a few students who will read this text avidly, will be too) that a more specific definition of work function (introduced on page 101) is not spelled out. The work function is a notion that often causes confusion for those that encounter the surface properties of solids for the first time. A minor omission is a detailed discussion of low-resolution, high-energy electron energy loss spectroscopy which is currently finding increasing relevance as a tool in the science of catalysts. But this is understandable if the title is to be interpreted literally.

The book is lavishly illustrated with the important points

of theory, experiment and, where appropriate, instrumentation is thoroughly discussed. It is moreover, up-to-date, as evidenced by the treatments of topics as fast-moving and disparate as inverse photoemission, Auger neutralization and extended- and near-edge X-ray absorption fine structure.

Drs. *Ertl* and *Küppers* are to be complimented on producing an excellent monograph, the lifetime of which should, on present trends, substantially exceed that of the first edition.

John M. Thomas [NB 849 IE]
The Royal Institution, London

Gaseous Ion Chemistry and Mass Spectrometry. Edited by *J. H. Futrell.* Wiley, Chichester 1986. xii, 335 pp., bound, £ 57.50.—ISBN 0-471-82803-3

A workshop, from which this book takes its title, took place in 1983, organized by the Department of Chemistry of the University of Utah along the lines of a Gordon Conference. The participants wished to put the contributions on record by publishing a book, lest the matters discussed should be forgotten. However, it is open to doubt whether that was a useful aim, and whether it has been achieved.

The papers, written by scientists who in some cases are of the first rank in their fields, cover thirteen topics, and are arranged under four groups. They vary greatly in their length, content, presentation, and coverage of literature for further study. Some of the papers, such as that by *Futrell* on ion cyclotron resonance (11 pages with 23 references), are concise but informative; on the other hand some are quite weak, such as those by *Morrison* on photoionization and multiphoton ionization (11 pp., 33 refs.), and on instrumentation (18 pp., 35 refs.). The paper on clusters by *Castleman* and *Märk* (44 pp., 160 refs.) is well worth reading, and also has the advantage that the bibliography is up-to-date, although it is marred by too much emphasis on the authors' own published work, and insufficient coverage of important contributions from other groups. In fact it seems to be a general shortcoming of the book that the attention given to papers from other research groups is inadequate and unduly selective. Considering the level of competence and the high standing of the authors, one might have expected a more balanced presentation of the various topics. Two examples may suffice to illustrate this: in the treatment of doubly charged cations there is not a word about *Beynon*'s charge-stripping experiments, and in the discussion of laser-induced fluorescence in ions one looks in vain for a reference to the work of *J. P. Maier* and collaborators.

All the authors are either physicists or physical chemists, with only one exception (*D. C. Smith*, who contributes a chapter on biochemical applications which is inappropriate for this book, and is also too superficial). I am afraid that the book will not appeal to chemists, and it would have been more appropriate if the title had mentioned ion physics rather than ion chemistry. It is doubtful whether students of chemistry or physics will be able to follow the text easily without some guidance, and since the specialists have access to other sources of information, I fear that the effort expended on this book will turn out to have been in vain.

Mikrobiologische und biochemische Verfahrenstechnik; eine Einführung. By *A. Einsele, W. Samhaber,* and *R. K. Finn.* VCH Verlagsgesellschaft, Weinheim 1985. x, 248 pp., bound, DM 88.00.—ISBN 3-527-26117-6

The appearance of this book constitutes a highlight in German scientific literature. The authors have succeeded in drawing together the interdisciplinary character of biotechnology into a single textbook. The book is in eight chapters. After an introduction to microbiology and a survey of microbial processes, we reach the subject of the kinetics of such processes. The chapters on "Mass transfer in biological systems", "Sterilization", "Bioreactors" and "Process control" lay the foundations for the technology of these processes, by enabling the reader to understand the process engineering principles which are followed by the discussion of Downstream processing.

Each chapter is a complete unit in itself, so that the reader, depending on his interests and previous knowledge, can concentrate on individual topics, without being tied to a particular sequence. Readers already familiar with microbiology will skip the first three chapters, as these provide a short introduction to the topics of metabolization and regulation, and classify microbial processes so as to illustrate the many possibilities offered by microorganisms. From their complex nutritional requirements and the main growth-determining factors we come to the determination of biomass. This section on the kinetics of biological processes concludes with the kinetic description of a batch and a continuous culture.

The supply of oxygen plays a key role in bioreactors, and the fourth chapter therefore deals with mass transfer. The fundamental aspects are the solubility of oxygen in water (Henry's law), and the oxygen transport coefficient K_La; three methods for calculating the latter are described, with their advantages and disadvantages. The theoretical relationships are explained by means of several examples. The effects of other hindrances to transport, such as cell agglomerates, biofilms, and the rheological properties of the system, are also considered.

The excursion into sterilization which follows is comparatively brief; besides two examples of calculations it covers continuous steam sterilizing and sterilization of gases.

Much space is given to the bioreactor and techniques of measurement and control. The reader has to work through a good 100 pages on the aeration, mixing and oxygen transfer rates, and on the more important of the dimensionless numbers (e.g. the Newton number). This is followed by other reactor systems, problems of scaling up the process, and the uses of special types of reactors (carrier immobilization, animal cell culture). The essential peripheral devices such as sensors, gas probes, enzyme electrodes, analytical instruments, and the introduction of computers, which are covered under process control technology, are absolutely essential for monitoring the complex reactions occurring in the fermenter. There is a particularly detailed examination of the types of electrodes. Downstream processing in biotechnology is a topic large enough to justify a textbook by itself; consequently in the final chapter here only general considerations and the principles of the methods can be given. Certain unit operations are common to the various work-up processes used, e.g. the separation of solids from liquids as a first step. Filtration methods are central to this topic, as they have recently undergone much development. The book describes the potential applications of these and the difficulties. Sedimentation, centrifugation and chromatographic separation are also discussed.

The instructional style of the book makes it easier for the newcomer to biotechnology to quickly and easily familiarize himself with the subject matter, so as to gain an understanding of the field or assimilate new knowledge. For those already working in the field this book will serve as a work of reference, and it is therefore suitable as an addition to one's personal library. The good organization of the contents and the excellent typographic presentation contribute to this favorable impression. As a reviewer I have read this book with interest, as the text is clear, comprehensible, and very readable in style. In scarcely 250 pages it is, of course, only possible to present a small section of the field of biotechnology. Those who wish to go into the subject in greater depth will need to consult more detailed works. If this book should later form the basis for a considerably more extensive work, it is to be hoped that its good qualities will not be lost in the "scale-up". I wish to recommend this book, though its price gives some cause for concern, the ratio of usefulness to price being very unfavorable compared with other textbooks.

Polymer Synthesis. By *P. Rempp* and *E. W. Merrill.* Hüthig & Wepf Verlag, Heidelberg 1986. 315 pp., bound, DM 96.00.—ISBN 3-85739-116-2

This textbook has arisen out of the notes for lectures given by the two authors during the past twelve years in the Department of Chemical Engineering at the Massachusetts Institute of Technology. As the title indicates, it is principally concerned with polymer synthesis. Problems of characterization (structure and properties), and the physico-chemical aspects of polymer science, are dealt with only insofar as they are important in synthesis.

The authors have divided the writing between them. *P. Rempp* has prepared the first part of the book, which is concerned with polymer synthesis on a laboratory scale. It deals with reaction mechanisms, kinetic aspects, and their consequences as regards molecular weight distribution and molecular structure. *E. W. Merrill* has written the second part of the book, dealing with industrial polymerization processes, in which heterogeneous systems and continuous processes assume special importance.

The first part of the book follows the classical pattern of subdivision of an excellent lecture entitled "Introduction to Macromolecular Chemistry". After a general chapter introducing the basic concepts, there follows a relatively short section on addition polymerization. Next come chapters on free radical polymerization (including copolymerization), anionic and cationic polymerization (including polymerization-depolymerization equilibria), and finally stereospecific polymerization. The book concludes with chapters on chemical reactions involving polymers, and on functional polymers, including block and graft copolymers and model networks.

The second part of the book is concerned with reactors and processes for the homogeneous phase and multiphase free radical polymerization (including suspension polymerization and emulsion polymerization), heterogeneous ionic polymerization, reaction injection molding, and polymerization in the presence of heterogeneous catalysts. This part of the book is unusual for a textbook, at least in its orientation towards industrial processes, though in Germany too this ought to be an essential part of a training in macromolecular chemistry. Here one finds descriptions not only of the polymerization of ethylene with heterogeneous catalysts in the fluidized bed process, but also of the manufacture of a glass fiber reinforced polyester and of motor tires.

Appendices are provided which, for example, make it easier to understand the derivation of molecular weight distribution functions. Problems included at the ends of the chapters, in the well-established style of American textbooks, allow the reader to test the knowledge which he has gained. Altogether this is a useful and convenient book, but one which regrettably includes no references to original literature, nor to material for further reading. Surprising is the small number of polymer pioneers' names the authors require.

Affinity Chromatography: A Practical Approach. Edited by *P. D. G. Dean, W. S. Johnson,* and *F. A. Middle.* IRL Press, Oxford 1985. xv, 215 pp., paperback, £ 11.00.—ISBN 0-904147-71-1

As a result of the progress in genetic engineering, effective methods for separation of proteins are becoming increasingly important. In addition to the conventional methods of ion exchange and gel chromatography, HPLC has in recent years come into use as a preparative technique to an ever greater extent. Affinity chromatography, on the other hand, plays only a subsidiary role, as it has hitherto been regarded as a complicated technique which is only useful in special cases.

These reservations concerning affinity chromatography are certainly not justified, for it is an outstandingly effective method, and there are many proteins whose isolation could not have been performed without it. The principle of affinity chromatography is very simple. Specific enzyme inhibitors, ligands or antibodies are covalently bonded to a gel matrix. Under optimal conditions only the desired protein then bonds to the column, with the result that a very high degree of enrichment can be obtained in a single stage of purification. Affinity chromatography has become an indispensable tool for isolating proteins which occur in very low concentrations and those that are attached to membranes. It is also of great interest as a means of isolating proteins made by genetic engineering methods, since here the separation of the desired protein from a mixture of intermediate products, which have the same amino-acid sequence but different chain folding, can be achieved very neatly, and often in a single step, by using a suitable ligand or antibody which is bonded to the gel matrix.

Against this background the book under review is greatly to be welcomed. It is a strongly application-orientated handbook which includes a reasonable amount of directly applicable instructional content, while not neglecting the theoretical aspects, and it forms a good contribution to making affinity chromatography more widely known. The book is divided into eight main chapters, and consists of contributions from 25 authors. It is to the credit of the three editors that the book nevertheless reads well, and there are only a few instances of repetition.

The first chapter is a useful survey of the more important gel matrices now in common use, with their properties and methods of preparation. In most cases, though, it is more sensible and economical to buy ready prepared gel

materials; newcomers to the field are particularly advised against preparing their own.

The strongest features of the book are in Chapters 2, 3, and 5, which deal in detail with techniques of activation and bonding. The methods given are mostly within the capabilities of any biochemical laboratory with the usual facilities. It has, of course, not been possible to describe every special case, but the methods given here can be adapted by analogy to cover many of them. Chapter 4 describes particular chromatographic procedures, and the associated methods for determining the degree of substitution of the stationary phase material. Chapters 6 and 7, which are concerned with affinity chromatography as a method of quantitative analysis, seem rather too long. The use of affinity chromatography for separating cell populations is an economical alternative to installing cell sorting equipment. This application, discussed in the final chapter, is, however, limited to only a few cell types.

Altogether this is a very interesting book, which gives valuable guidance on planning and setting up affinity chromatography methods. An additional reason for recommending its purchase is the comparatively low price.

Computer-Aided Chemical Thermodynamics of Gases and Liquids—Theory, Models, Programs. By *P. Benedek* and *F. Olti*. Wiley, Chichester 1985. xxvii, 731 pp., bound, £ 86.95.—ISBN 0-471-87825-1

To begin with, the title of this book is annoying. Too much of what is published lately is given the honor of being described as "computer-aided". One might well have guessed that thermodynamics, the classic discipline of physical chemistry, would not escape this treatment.

It has also become the practice in chemistry to treat complex problems by computer modelling calculations, so that the calculations are used in a sense to carry out "experiments", to define limits, or to test particular approximations. The unique step forward which computers have brought is in facilitating the solution of lengthy and complex problems by appropriate fast mathematical techniques. A great deal can now be achieved with personal computers, which is especially important for the chemist because he likes to be able to do the work himself and understand its details.

The chemist therefore welcomes books which provide him with an introduction to practical work on physicochemical calculations using computers. The present book claims to do this for chemists and chemical engineers, mainly in the field of classical thermodynamics, and certainly it should be able to meet this objective within its considerable space of more than 700 pages. In classical reversible thermodynamics the requirements for the numerical mathematical toolkit are relatively modest, being limited to the solution of algebraic equations and expansions in infinite series, both of these operations being easy to program in any of the common computer languages.

In its subtitle "Theory, Models, Programs", the book makes sweeping claims with regard to the depth of treatment. This may well be justified for certain chapters (equations of state, phase equilibria, systems of one substance). However, the chapter on chemical equilibria, which is particularly important for the chemist, treats this topic in a rather offhand way, and the only example given in the chapter (methane conversion) ought to have been complemented by including other types of reactions.

The theory is treated in a very formal way, without any descriptions of related phenomena of practical importance. This may be sufficient for the working chemist who has already covered this material in his previous studies, but for chemistry students the treatment will certainly seem too dry and uninteresting. Nevertheless, it is sufficiently detailed and thorough, so that the student need seldom refer to more comprehensive works on thermodynamics.

The programs for calculating thermodynamic quantities are written in BASIC, and are rather odd in appearance, as they have been written for a computer which has only 32 characters per line. Unfortunately too the programs are not structured conventionally, especially with regard to repeat loops, which makes them less easy to follow. This again is probably a result of using an obsolescent computer. No explanatory notes are provided with the programs, which means that the user needs either to have the required knowledge of BASIC beforehand, or to acquire it elsewhere. On the other hand, a lot of examples are provided with the programs, though here the authors have perhaps given us too much of a good thing. The examples are often set out at great length without attention to economy of space, and consequently they take up a not inconsiderable proportion of the book. The thermodynamic data needed in conjunction with the examples are given alongside. In addition the data for more than 200 substances are collected together in an appendix, which also has its own index.

By "models" the authors apparently mean the equations whereby the values of the various thermodynamic quantities and functions are calculated. For this purpose they reproduce well-known and proven formulas. The authors are to be complimented in this on having produced an exhaustive compilation.

The book is definitely of considerably more value to the chemical engineer than to the chemist. It is well suited for the training of chemical engineers, and as additional material on which to base a course in engineering thermodynamics. The chemist could more appropriately use it as a reference book and additional source of information when he is looking for a quick solution to a practical problem in thermodynamics, and does not want to have to write his own program.

Biotechnology. A Comprehensive Treatise in 8 Volumes. Series Editors: *H.-J. Rehm* and *G. Reed*. **Vol. 4. Microbial Products II.** Volume Editors: *H. Pape* and *H.-J. Rehm*. VCH Verlagsgesellschaft, Weinheim 1986. XIII, 673 pp., bound, subscription price: DM 425.00; series price: DM 495.00.—ISBN 3-527-25766-7

This is the 6th volume to be published in the series.[*] Its publication helps complete the sequence from Volume 1 to Volume 6a. Volumes 3 and 5 covered a number of "microbial products" that are compounds for the food and feed production industries. The primary focus of Volume 4 is on secondary metabolites from microorganisms represented by the actinomycetes which are gram positive fil-

[*] Cf. *Angew. Chem. Int. Ed. Engl. 22* (1983) 893; *22* (1985) 436.

amentous bacteria, and to a lesser extent, fungi. The intent is to cover the era after the development of industrial production of penicillin in the 1940's during which other medically useful metabolites were sought.

The first three chapters are an excellent introduction to the concepts and genetics of secondary metabolism by *R. Hütter, L. C. Vining,* and *V. S. Malik.* Factors affecting production of the secondary metabolites, control mechanisms, and the strategies used for isolation of *Streptomyces* genes are discussed. A discussion of recombinant DNA work with fungi such as *Aspergillus, Penicillium,* and *Cephalosporium* is also presented. Most readers would find this section highly useful.

Five chapters are devoted to the so called "complex" products. The term "complex" is used for nucleic acids and related compounds, vitamins, coenzymes, lipids, and iron-complex compounds (siderophores). The emphasis varies from chapter to chapter depending on the author's background. Those with private industry have tended to provide at least a very cursory commercial research perspective. This reviewer feels perhaps more should have been done along those lines. Generally, the style in each chapter is that of a research review article. Most of these chapters are very readable. With bacteria and yeast as the source, the production of nucleic acids, nucleotides, nucleosides, and pyrimidine compounds is reviewed by *A. Kuninaka.* Vitamins B12, B2, C, provitamins A and D2, and biotin are discussed by *J. Florent.* ATP gets some coverage twice, once in the nucleotides chapter and once in a chapter on coenzymes. The latter chapter also touches upon NAD, NADP, and Coenzyme A.

A very readable chapter from a "practice" viewpoint on lipids is presented by *C. Ratledge*, who reviews the patterns and pathways of lipid synthesis with examples for triacylglycerols, sterols, carotenoids, esters, and the use of esterases and lipases. The isolation and characterization of siderophores from bacteria and fungi is reviewed by *G. Winkelmann* in the last chapter on "complex" compounds.

The last twelve chapters in this volume deal with secondary metabolites. These chapters generally review compounds that are either considered antibiotics or are "bioactive" in some sense. By "bioactive" we mean the compounds have one or more of the following activities: antimycobacterial, antifungal, antibacterial, antitumor, antiviral, or immunomodulatory. Those interested in this area should find this group of chapters quite useful. Penicillins, cephalosporins, clavams, carbaphenems, nocardicins, monobactams, peptide antibiotics, aminoglycoside antibiotics, macrolide antibiotics, tetracyclines, rifamycins, chloramphenicol, lincomycin, novobiocin, fusidic acid, vancomycin, griseofulvin, blasticidin S, polyoxins, cycloheximide, feed additive antibiotics, antitumor substances such as actinomycin D, bleomycin etc., are covered in several chapters.

The last four chapters attend to a slightly different group of secondary metabolites other than antibiotics. Inhibitors of glycosidases such as acarbose, including their isolation procedures, are presented by *L. Müller.* These compounds have potential as antihyperglycemic compounds.

The physiology, genetics, and commercial production of ergot alkaloids is covered by *H. Kobel* and *J.-J. Sanglier.* Metabolites from *Streptomyces* known to be inducers (factors A, L, B), immunomodulators, enzyme inhibitors for use as antihypercholesterolemic drugs, plant growth regulators such as gibberellic acid, compounds useful as insecticides and as animal growth promoters are reviewed in another chapter in this set. As a preview of soon to come Volume 6b, the subject of plant cell culture is introduced. Here, *J. Berlin* covers cinnamic acid derivatives, naphtho- and anthraquinones, alkaloids, pigments, steroidal compounds, ubiquinone-10, and nicotine as well as compounds tissue culturists would *like to make* via plant cultures. An important point is made here that conventional techniques of screening for highly productive variants are not sufficient and new approaches must be found on the way to commercial success. Anyone starting out in plant cell culture would find this chapter very insightful.

How Nature Adapts Chemical Structures to Curved Surfaces

By Hans Georg von Schnering* and Reinhard Nesper

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

Guided by the symmetry in a natural way, periodic potential surfaces partition the space in solid crystalline compounds. The arrangement of atoms, clusters and molecules obviously follows the (in general) curved shape of these 'space partitioners'. In structures, the atoms therefore choose only a very limited subset of the infinite set of possible positions. In collective structures the periodic surfaces separate areas of different interactions between atoms, clusters, and molecules. In a certain sense, they can be considered as inner surfaces, a knowledge of which reveals insights into the organization of crystalline matter. There are many good indications that the weakly bonded electrons in the highest occupied orbitals are preferably localized in the region of the space partitioners. Dynamic processes as well can be correlated to the shape of the periodic surfaces. Moreover, the surfaces are didactically very helpful in making accessible the complicated three-dimensional relations in collective structures because the main features are projected onto (although curved) two-dimensional creations. The application of periodic potential surfaces to such a variety of compounds as quartz, brass and alpha-amylose underscores their general significance. Simple qualitative considerations already reveal the manifold relations to animate and inanimate nature through to mathematics, art and architecture. It appears that, in a very universal sense, the adaption of structures to a collective order finds a natural solution through curvature.

1. How Do Structures Organize Themselves?

The recognition, generalization and utilization of relationships between structures of compounds and their properties has long ranked as one of the great tasks in chemistry. Simple concepts (8-electron rule, Zintl-Klemm rule, radii ratios etc.) and complex methods (e.g. force field, MO and band structure calculations) are qualified for manifold, far-reaching statements. They can be tested, and if necessary improved by means of a large number of precisely determined structures. On the other hand, one feels that, despite the elucidation of many details, decisive comprehensive correlations are not yet recognized or cannot be formulated clearly. Besides, a big obstacle arises by frequently using very different terms for the description of the facts.

Three years ago, while preparing a seminar about *periodic minimal surfaces* (PMS), we conceived the idea of investigating, whether in electrostatic charge distributions of a given crystal symmetry coherent potential surfaces exist, and what they might look like. In the meantime new insights into the comprehensive correlations essential for the organization of crystalline solids are occurring daily,[1–5]

[*] Prof. Dr. H. G. von Schnering, Dr. R. Nesper
Max-Planck-Institut für Festkörperforschung
Heisenbergstr. 1, D-7000 Stuttgart 80 (FRG)

making a detailed representation appropriate. Above all, there emerges a notably close relationship between the course of potential surfaces and the spatial distribution of electrons in crystals.[6] Close collaboration with *S. Andersson* (Lund) and *S. T. Hyde* (Canberra) has given us many fruitful ideas.[7-12] It is not yet certain, whether the things seen through the authors spectacles[*] will be bearing in the long run. However, even if only the beauty in the structures of solids should remain, it will have been worth it.

Chemical structures of molecules and crystals are fascinating, not only because of their local symmetry but also because of the symmetry of the periodical translational patterns extending into crystal space. In a comprehensive sense, it is the symmetry that unites chemical structures with objects of inanimate and animate nature, the architecture and the art by virtue of governing mathematical relationships. This is not a new discovery, and in all areas one repeatedly finds the phenomenon of *optimal form*, apparently dominant over all and a challenge to an interdisciplinary bridging. From the manifold literature, the monographs of *Pearce*,[13] *Duarte*,[14] *Frei Otto* et al.,[15] *Stevens*,[16] as well as of *Hildebrandt* and *Tromba*[17] are highly recommended.

Quite frequently, the symmetry of single objects does not fit the symmetry of an arrangement of such objects. However, by the development of curved structures, an adaption is then possible. Just as hexagons and pentagons are arranged in a nearly unconstrained way to form the cover of a soccer ball, a chemical molecule of the corresponding structure can be formed. In both cases the local symmetry of the building units remains, however without appearing in the arrangement. It can be shown that also in chemical structures in a very general way, the curvature plays an important role in the adaption of parts to the whole!

Atoms with four bonds are regarded as centers of local tetrahedral symmetry. Objects of such a symmetry cannot be connected for example to a three-membered ring (ring tension) without loss of the local symmetry. Usually, in the theoretical treatment the local symmetry of the bonding functions is then adapted to the total symmetry. However, if the local symmetry is retained, the arrangement of the three-membered ring can only be produced by a curvature of the bonds. The curvature of bonds, following the symmetry only locally at the centers has a significant consequence: The usual bond angles are only of topological meaning, but the "true" values can be obtained by a measurement on non-euclidean surfaces, which are spanned by the curved bonds. This concept can also be extended to certain collective crystal structures and contributes to the understanding of peculiar experimental observations.

In the crystalline state, the topology of chemical structures is substantially influenced by the symmetry of the periodical translations. While the latter organize the packing of the building units in molecular crystals, in true collective structures primary connections between the atoms of the collective arrangement are also produced by the translation (in collective structures molecular units cannot be delimited informally). Also, in these arrangements, the point symmetry of local aggregations in general does not correspond to the crystal symmetry. In the structures, the adaption of local aggregations to the demand of the crystal symmetry then seems to take place by nestling the periodically curved surfaces. Let the building units be atoms, molecules, clusters or even blackberries (Fig. 1a) [even humans?]; their aggregations are to some extent regulated similarly by a balance between the rigidity of the individual and the force of the collective law. The self-similarity, e.g. between a single blackberry (packet of tiny blackberries) and a pile of blackberries (packet of blackberries), is called *fractal* in mathematics.[18,19] In nature it appears in multifarious ways and is also found in the combination of curved single building units and their collective.

S. Andersson is credited with recognizing the general significance of periodic minimal surfaces as being curved space partitioners.[7-9] Such surfaces are creations of extraordinary harmony and fascination, which one can hardly escape. Also *Mackay*[20] had already alluded to connections between PMS and the macrostructure of silicate membranes. Recently, a number of papers have been published which refer to the general application of PMS to crystal structures.[21-31]

We were able to show that *p*eriodic *e*qui-*p*otential *s*urfaces (PEPS) and, of these, especially the *p*eriodic *zero p*otential *s*urfaces (POPS) of appropriate Coulomb fields are very similar to such minimal surfaces. They are of more comprehensive importance, because they contain the PMS, and, moreover, permit space partitions for which corresponding PMS do not exist. With PEPS and POPS direct correlations to physical properties result. In addition, we can show that the concept of periodic potential surfaces (PEPS) generates a general relationship between crystallography and PMS, which is also important for mathematicians. This is because PEPS are determined by symmetry-adapted distributions of points and point charges. Such distributions are known by the term *point configurations* (PK),[32,33] and they represent the fundamental point patterns in the corresponding symmetry groups. According to *Fischer* and *Koch* some of these PK's form so-called sphere packings, which means graphs of spheres touching each other.[34-36] POPS are connected in a natural manner with such sphere packings, because they span the space partitioner between non-touching interpenetrating sphere packings. Thus, e.g., as in Figure 2c, where the bridging Nb-Cl-Nb bonds (yellow) of one partial structure (violet side) never touch those of the other (blue side). This is especially important for the fragmentation of space into unequal parts, because the mathematical prerequisites for the derivation of PMS are still missing in this case. The same is true for sphere packings with spheres of different size.

We believe that with PEPS and POPS we have put aside a real component to the fascination which comes from the idea of space partitioning periodic minimal surfaces and their curvature properties. Numerous examples demonstrate the surprising consequence by which nature obviously correlates chemical structures with the topology of periodic equi-potential surfaces and with the curved labyrinths generated by the latter acting as space partitioners.

[*] Cf. Figure 16 in H. G. von Schnering, *Angew. Chem. Int. Ed. Engl. 20* (1981) 33.

2. Generation and Representation of Periodic Equi-Potential Surfaces PEPS

Periodic equi-potential surfaces PEPS, and among these also the periodic zero-potential surfaces (POPS), are quite simply obtained using a Coulomb ansatz. For this, in a defined three-dimensional (3D) distribution of point charges $q_1=(m+)$ and $q_2=(n-)$ the electrostatic potentials $P(xyz)=\sum_i q_i \cdot r_i^{-1}$ are calculated for a large number of mesh points (xyz) (q_i = given point charges; r_i = distance between q_i and (xyz)) and then the equi-potential contours are determined and plotted. The distribution of the generating point charges q_i is selected according to typical point configurations, as they are characteristic for the symmetry of the given space groups.[33] In the simplest case two symmetry equivalent point configurations are occupied by the charges (+) and (−). Such arrangements are especially important, because the charge distributions are *commutable*, i.e., with an exchange of (+) and (−) the trace of the POPS does not change. The chosen point configurations are connected with each other by a translation vector $-\vec{s}$, whose sign takes into consideration the change in the charges. For the CsCl structure type, e.g., $-\vec{s}$ is $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$ [space group $Pm\bar{3}m$, (+) at position 1a (000), (−) at position 1b $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$].

For the mathematical evaluation the program system OBERFLEX[37] was developed, which combines a whole series of different functions. First of all the program MADKUG[38] calculates the lattice potentials according to the Ewald-method,[39] whose convergence behavior is controlled by the eligible numerical accuracy *GN*. The accuracy is selected after test calculations ($4 \leqq GN \leqq 7$ valid digits) and it essentially determines the computing time. Crucial for the determination of the entire potential space $P(xyz)$ is the introduction of a probe S_0 with the charge $q_s=0$[38] which is suitable for the calculation of vacancy potentials, especially on those positions (xyz) which are *not* occupied by one of the generating point charges q_i. The probe S_0 moves through the 3D space in chosen steps,[37] whose width is a compromise between the desired accuracy and computing time. Usually 20–40 steps along the main lattice directions are sufficient, and this rather rough mesh yields around 8000 potentials to be calculated per asymmetric unit.

The following interpolation using the program LINES[37] or POLYGON,[37] supplies sufficiently smooth PEPS and POPS surface elements in the asymmetric unit, which can be expanded if desired via the symmetry elements of the appropriate space group within a chosen parallelepiped or a sphere of any size (program EXPAND[37]). The representation is done in the form of open nets or closed polygons (POLYGON[37]), which allows graphical and topological evaluations, e.g. the determination of the surface area. The complete representation of the surfaces is stored explicitly and can be used in modules. In this way the modular assembly of surfaces with correspondingly scaled and stored structures and convex polyhedra is possible (STRUKTUR[37]; KVEXPOL[37]). Two new graphic programs finally allow the preparation and interactive alteration of the pictorial representations on a two-dimensional graphic terminal (AED767[*]; FNETZ[37]) and on a three-dimensional RASTER graphics station (RASTER TECHNOLOGIES, MODEL ONE/380[*]; RAPTURE[37]).

Finally, by means of a scenario, the graphical representations can be recorded as a movie picture. The automatic recording of single pictures is controlled by the program FNETZ[37] for SUPER 8 film, 16 mm film and/or videocamera (U-MATIC). A further option allows to display suitable representations (without undercuts) of closed surfaces and structures to such an extent that they can be used by numerically controlled milling machines for an automatic generation of molds for models (FNETZ[**], FRAES[37]).

3. Topology of Zero-Potential Surfaces

In the following we will point out the properties of POPS in connection with the generating point configurations (PK) of the symmetry groups and also the relationships between POPS and periodic minimal surfaces PMS. First of all, two completely different types of POPS have to be distinguished, namely those which are based on *commutable* PK's and those which are based on *non-commutable* PK's.

3.1. POPS of Commutable Point Configurations

Independently of the actual symmetry, POPS of commutable point configurations fulfill some boundary conditions: a) The symmetry of the charge distribution and the potential space obey a so-called *black-white symmetry group*.—b) Positive and negative partial spaces are topologically exchangeable and therefore have the same volume.—c) Thus, the respective POPS divide the space into equivalent halves, and POPS are therefore *invariant* against an exchange of the generating charges and contain exactly those symmetry elements which perform the exchange of complete partial spaces.—d) Therefore, these POPS belong to a supergroup (normalizer) of the generating symmetry group (space group) and in the limiting case to the corresponding Cheshire group. If we take $Cs^{\oplus}Cl^{\ominus}$ as the generating structure with the symmetry $Pm\bar{3}m$ then the POPS ($Cs^{\oplus}Cl^{\ominus}$) has the higher symmetry $Im\bar{3}m$; if we choose $Na^{\oplus}Tl^{\ominus}$ with the symmetry $Fd\bar{3}m$, again POPS ($Na^{\oplus}Tl^{\ominus}$) has the higher symmetry $Pn3m$ ($a'=a/2$).—e) Among all equi-potential surfaces PEPS of a given charge distribution, POPS has the smallest maximum curvature and also the smallest average curvature *at each point* of the surface.—f) The integral curvature taken over the asymmetric unit is $\bar{H}=0$, because of the interchangeability of the partial spaces.

These particular properties make POPS very similar to the mathematical periodic minimal surfaces PMS of the same symmetry. In certain cases they presumably are even

[*] CIS Graphic & Bildverarbeitung, D-4060 Viersen (FRG).

[**] Uses the DI 3000-graphic package, Precision Visuals, D-8000 München (FRG).

exactly identical (which has to be proven separately). For PMS, the average curvature, e.g. the sum of both principal curvatures *at each point* of the surface, vanishes: $H=(\kappa_1+\kappa_2)=0$ and trivially $\overline{H}=0$, just like the POPS, for which exact conditions for the average local curvature cannot be given; here, only positive and negative curvatures of the same absolute value must appear at any but not necessarily at identical points of the POPS. Nevertheless, PMS and POPS are exactly identical in special points (xyz) and at certain straight lines, because of the relationships mentioned in (c) and (d) above, which are valid for both PMS and POPS. Thus, twofold axes form straight lines on PMS and POPS, which are needed as boundary conditions for the mathematical derivation of the PMS. Inversion centers at both types of surfaces are always flat points, however not saddle points.

3.2. POPS of Non-Commutable Point Configurations

If POPS are generated from non-commutable PK's then the listed (a priori) conditions in 3.1a) - f) are not applicable. For POPS of this type (type 2) only the following holds: They belong to the symmetry group of the generating charge distribution; they separate the two *unequal* partial spaces in such a manner that the volume integrals over the potentials of both partial spaces have the same absolute value but opposite sign $\left(\int_0^{V(-)} P(-)\,\mathrm{d}V = -\int_0^{V(+)} P(+)\,\mathrm{d}V\right)$. The more the volume difference between both partial spaces increases the more the average potentials of both parts differ. In general, for $V(+)>V(-)$ in the (larger) positive partial space a family of PEPS should exist which show smaller average and integral curvatures than POPS. Again, among the PEPS, there has to be a PEPS_{min} for which the integral curvature vanishes ($\overline{H}=0$). Their space partitioning properties are also worth further investigations, which, however, we could not carry out systematically, because the determination of such PEPS turned out to be very difficult.

No mathematical boundary conditions for the derivation of equivalent PMS can be given because PEPS of type 2 do not contain any symmetry elements—a substantial difference when compared to the surfaces of type 1. Nevertheless, today one knows some PMS of this type which divide space into non-equivalent parts such as the surfaces *I-WP* and *OC-TO*.[40] As a rule they were obtained empirically by stochastic methods.

Of course these surfaces also obey—even if not parameter-free—boundary conditions if they are intersected by symmetry elements. For example, all rotation axes and mirror planes intersect the POPS and PMS of type 2 perpendicular to the surface. Each twofold axis perpendicular to the surfaces generates at least one saddle point on the intersection point, all rotation axes of higher order produce a flat point. However, these points are not fixed along the rotation axis (cf. the mobility of a soap bubble along a penetrating straw). Intersection lines of POPS (PMS) with mirror planes are plane lines, because all their normal vectors lie in one plane, namely the mirror plane.

3.3. Topology

Very important topological information is obtained from the POPS and PMS about the existence, shape and orientation of tunnel connections between cavities *of the same* potential (cf. Fig. 1c, CsCl). They show the direction in which structure elements of the same type "can see each other" and therefore show the direction in which interactions between such units may occur. We also believe that these tunnels define symmetry determined polarization directions, which always exist (if symmetry allowed) but become more or less effective depending on the type of participating atoms and aggregates. Especially strong interactions between units of the same kind correspond to covalent bonds with short distances between neighboring atoms. Such structures often belong to space groups whose symmetry generates POPS with marked tunnel systems (e.g. D^* with NaTl or diamond (Fig. 1b); Q^* with quartz or α-amylose (Fig. 1j)).

In contrast to this only a few POPS exist *without* any tunnel connections, i.e. "positive" and "negative" areas are optimally shielded. Typical examples are the F^* surface of the $Na^{\oplus}Cl^{\ominus}$ charge distribution or the W^* surface (Table 1; Fig. 1g, h), which contributes to an understanding of the substitutional behavior of certain clathrate structures (cf. Section 5.7). A POPS with this exceptional property was also found with hexagonal symmetry (cf. E^*, Table 1, Fig. 1k).

Finally, a family of surfaces exists among the POPS of type 2 which contains neither tunnel nor shielding planes but bubbles (*F-P*$_2$; *I-W*). For these, the Gaussian curvature is always positive, a fundamental difference to the continuous surfaces. However, even in these cases there exists between the bubbles a PEPS with vanishing integral curvature. POPS with the bubble structure correspond to strained PMS, perhaps a regular structure of isolated soap bubbles.

3.4. How Many POPS can Be Generated?

The answer to this important question is disillusioning at first: There are infinitely many! Let us take a charge distribution corresponding to the NaTl structure and generate the D^* surface in the space group $F\bar{4}3m$ with the parameters: (1+) at 000, (1+) at $\frac{1}{4}\frac{1}{4}\frac{1}{4}$, (1−) at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ and (1−) at $\frac{3}{4}\frac{3}{4}\frac{3}{4}$. By reducing the charges at $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ (+) and at $\frac{3}{4}\frac{3}{4}\frac{3}{4}$ (−) one *continusouly* reaches the F^* surface of NaCl. Beginning (D^*) and end (F^*) of this transformation differ drastically! However, in the course of this continuous transformation *no topological new* type appears (cf. Section 7). This must be explained in more detail: The topology distinguishes bodies by their *genus*, namely the amount of tubes (tunnels, channels) which originate from the bodies. Therefore, each sphere has the genus = 0, spheres with a handle have the genus = 1 (= 2/2) etc. Each periodic infinite surface which divides the space in any form has the genus = n, which is just the number of channels leading from one unit cell to neighboring cells (e.g. "CsCl", n = 6/2 = 3, Fig. 1c). The surface D^* mentioned above has a four-armed tunnel system which envelops the diamond structure and according to the Cheshire group $Pn\bar{3}m$ ($a'=a/2$), to which the D^*

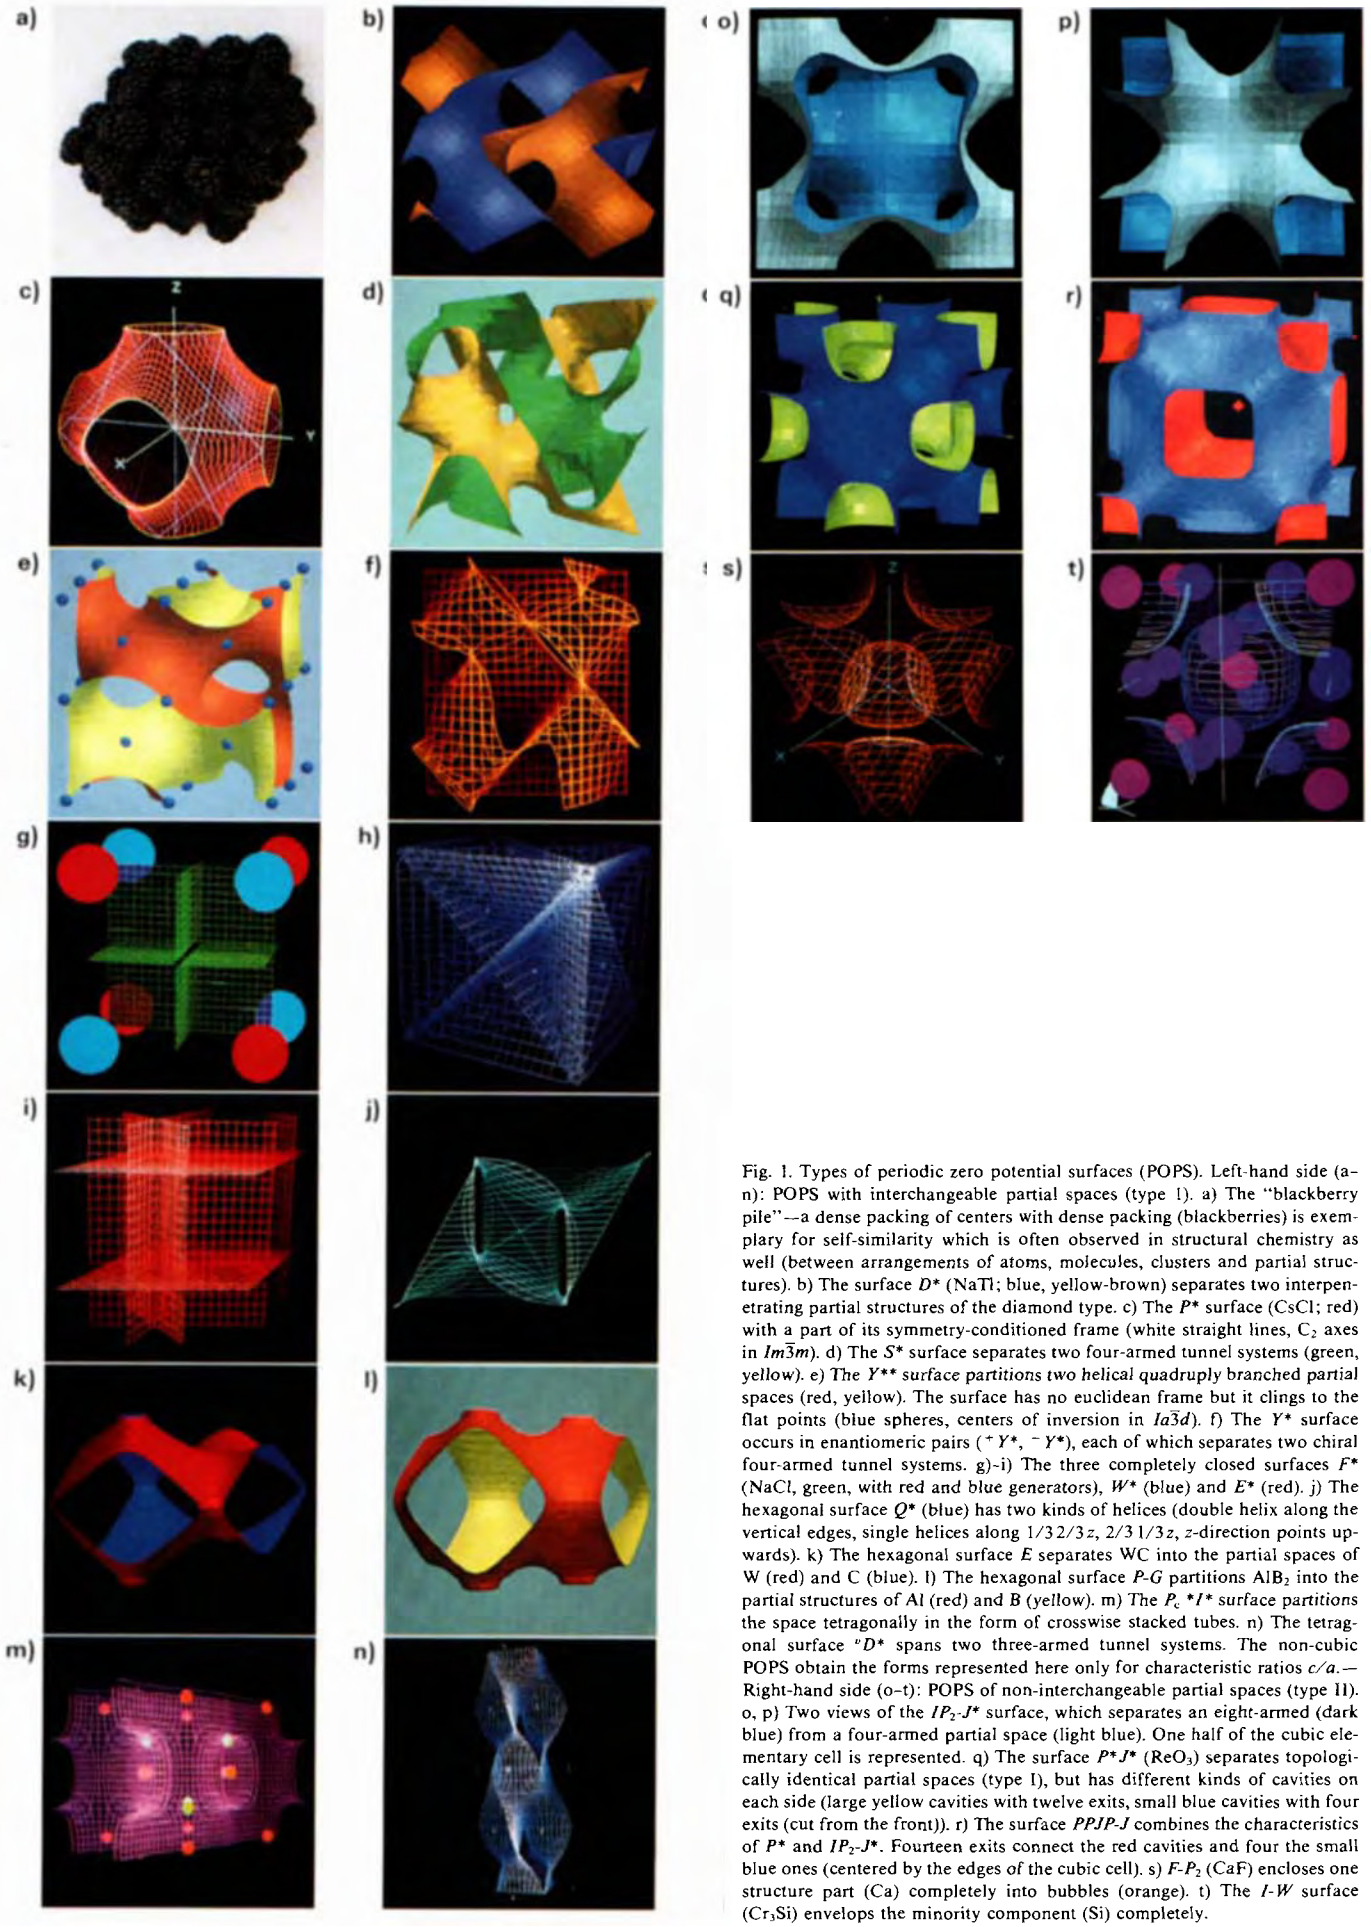

Fig. 1. Types of periodic zero potential surfaces (POPS). Left-hand side (a–n): POPS with interchangeable partial spaces (type I). a) The "blackberry pile"—a dense packing of centers with dense packing (blackberries) is exemplary for self-similarity which is often observed in structural chemistry as well (between arrangements of atoms, molecules, clusters and partial structures). b) The surface D^* (NaTl; blue, yellow-brown) separates two interpenetrating partial structures of the diamond type. c) The P^* surface (CsCl; red) with a part of its symmetry-conditioned frame (white straight lines, C_2 axes in $Im\bar{3}m$). d) The S^* surface separates two four-armed tunnel systems (green, yellow). e) The Y^{**} surface partitions two helical quadruply branched partial spaces (red, yellow). The surface has no euclidean frame but it clings to the flat points (blue spheres, centers of inversion in $Ia\bar{3}d$). f) The Y^* surface occurs in enantiomeric pairs ($^{+}Y^*$, $^{-}Y^*$), each of which separates two chiral four-armed tunnel systems. g)–i) The three completely closed surfaces F^* (NaCl, green, with red and blue generators), W^* (blue) and E^* (red). j) The hexagonal surface Q^* (blue) has two kinds of helices (double helix along the vertical edges, single helices along $1/3\,2/3\,z$, $2/3\,1/3\,z$, z-direction points upwards). k) The hexagonal surface E separates WC into the partial spaces of W (red) and C (blue). l) The hexagonal surface P-G partitions AlB_2 into the partial structures of Al (red) and B (yellow). m) The P_c $^{*}I^*$ surface partitions the space tetragonally in the form of crosswise stacked tubes. n) The tetragonal surface $^{v}D^*$ spans two three-armed tunnel systems. The non-cubic POPS obtain the forms represented here only for characteristic ratios c/a.—Right-hand side (o–t): POPS of non-interchangeable partial spaces (type II). o, p) Two views of the IP_2-J^* surface, which separates an eight-armed (dark blue) from a four-armed partial space (light blue). One half of the cubic elementary cell is represented. q) The surface P^*J^* (ReO_3) separates topologically identical partial spaces (type I), but has different kinds of cavities on each side (large yellow cavities with twelve exits, small blue cavities with four exits (cut from the front)). r) The surface $PPJP$-J combines the characteristics of P^* and IP_2-J^*. Fourteen exits connect the red cavities and four the small blue ones (centered by the edges of the cubic cell). s) F-P_2 (CaF) encloses one structure part (Ca) completely into bubbles (orange). t) The I-W surface (Cr_3Si) envelops the minority component (Si) completely.

surface belongs, has the genus = 4 (for the entire NaTl unit cell as generator, the genus = $32 = 4 \times 2^3$; $a = 2a'$). The $Na^{\oplus}Cl^{\ominus}$ distribution, on the other hand, yields the POPS F^* without any tunnels: genus = 0. But all intermediate stages in the above described transformation maintain the genus = 4 typical for the D^* surface, i.e. the infinite set of POPS of this transformation only belongs to *two* topologically different types.

It is obvious that only the discussion of topological *types* is of general interest in the investigation of structures and their properties. Only these provide a small and surveyable group of principally different forms: A very encouraging discovery!

3.5. Distinctions between POPS and PMS

It should be pointed out that for certain symmetry groups no PMS can be generated, e.g. for the space group $Fd\bar{3}m$. If, e.g., in the space group $F4\bar{3}m$ a charge distribution $\langle F^{(+)}|\frac{1}{4}\frac{1}{4}\frac{1}{4}|F^{(-)}\rangle$ is chosen, then without any difficulties the POPS D of the symmetry $Fd\bar{3}m$ (Table 1) is obtained. It has the same genus = 4 as the surface D^* (= PMS "D" of *Schwarz*) and also the same system of C_2 axes, which lie on the surface as straight lines. If this system of straight lines were to be dipped into a soap solution, *only one* stable PMS would be obtained, namely PMS "D" which corresponds to POPS D^*. In a given framework only that surface which produces an additional set of C_2 axes perpendicular to the surface is also a PMS, because this is the only way to obey the condition $H = 0$ at all points of the surface (the symmetry of this PMS is therefore $Pn\bar{3}m$ with $a' = a/2$). Consequently, the $Fd\bar{3}m$ frame, built from C_2 axes, cannot generate a PMS equivalent to the POPS D. On the other hand, the POPS D only has to fulfill the weaker condition $\overline{H} = 0$ and, therefore, in the given frame, equivalent surface elements (just like, e.g., a sail) can be alternately more or less inflated without losing the character of the tunnel structure. This is due to the fact that, for the generation of the POPS, not all equivalent positions have to be occupied by charges (and usually they are not), and the POPS is able to respond topologically, which is impossible for a PMS under the same boundary conditions. The family of POPS is therefore larger than the family of PMS. Analyzing in detail the topological changes during the transition from D^* to D one gets the impression that the D surface ($Fd\bar{3}m$, ZnS) might be a variant of D^* modulated by a periodical variation of pressure in the labyrinths.

Another important difference is that POPS are always orientable surfaces. Because of their construction, namely the separation of positive and negative space, a situation like on a Möbius strip can never occur, i.e. one cannot move continuously from the positive to the negative side of the surface. However, PMS with this particular property are well-known.

4. The Periodic Zero-Potential Surfaces POPS

Table 1 compiles the current state of our knowledge of such surfaces. The graphical representations are illustrated in different figures and are each given abbreviated symbols. One always has to keep in mind that the POPS only reflect the symmetry of the corresponding space group and by that also characterize the space partitioning properties of the related point configurations PK. They are generated from only a few special point positions xyz, which with a few exceptions don't have anything to do with a real structure. Primarily they also have nothing to do with structures that may be connected with the generating charge distribution. Characterizations such as 'CsCl surface' are merely used as obviously short symbols. The striking similarities of POPS and PMS show again that the electrostatic ansatz only represents a well manageable procedure to determine the space partitioning surfaces ($P(xyz) = 0$). There can be no doubt that in principle the same forms would be reached if it were possible to formulate mathematically where a "blue" partial space switches into a "red" one. The same holds for other potential ansaetze. If for instance balloons are pumped up, which are fixed at constant distances according to a cubic body centered structure, then the partitioning skin finally has the form of the so-called P surface (= POPS P^*).

To label the POPS (Table 1) we have chosen symbols which follow the well-known PMS or produce other simple relationships (Q^* for the symmetry group of *quartz*). Furthermore, a detailed symbol will be used to establish the connection to the generation of the surfaces. Example D^*: Generating symmetry group is $Fd\bar{3}m$ with the equivalent positions (8a) and (8b), which both have the point configuration D (cf. Ref. [33]). $D_{(8a)}$ is occupied by (1+) and $D_{(8b)}$ by (1−). The resulting POPS symmetry is $Pn\bar{3}m$, and accordingly, the symbol $cP\ \langle D|\frac{1}{2}\frac{1}{2}\frac{1}{2}|D\rangle$ is chosen because the POPS has cubic P translation and separates two D configurations from each other shifted by $\frac{1}{2}\frac{1}{2}\frac{1}{2}$. The latter fact is described by the symbol D^*, and simultanously the analogy to *Schwarz*'s minimal surface D is set up (D is by the way a wrong symmetry declaration).

Today, all cubic space groups are investigated systematically for the existence of PMS and POPS of type 1, for which all pairs of generating PK's show the same point symmetry, even if more than one PK belongs to the same partial space. In contrast, only minimal information is available for surfaces of type 2, even for the cubic systems. As already mentioned, especially for the PMS, systematic statements are missing for the mathematical boundary conditions. However, with the help of suitable POPS it would seem that there is the possibility of expanding our knowledge of this subject.

Leaving the cubic systems, from the variable axial ratios additional free parameters are gained for the lower crystal classes. Because of such anisotropy effects in certain directions, tunnels can merge and in other directions they can completely break off. Related crystal structures as a rule also show the character of layer structures (cf. Section 7). However, all in all our knowledge of POPS and PMS for these 194 symmetry groups is, at present, very limited.

How is the topology of POPS's affected by the splitting of a high symmetry position occupied by a charge? This question is equally important for structural chemistry and crystallography. This process corresponds to the replacement of an atom by a cluster or a molecule respectively.

Table 1. Periodic zero potential surfaces POPS, their correspondence to point configurations PK and known periodic minimal surfaces PMS. The charges of the PK's are in the upper parentheses, the Wyckoff positions of the space group are in the lower parentheses. c, h and t indicate cubic, hexagonal and tetragonal Bravais lattices ($\wedge$ = logical 'and').

POPS	POPS symmetry	Generating SG for POPS	Generating PK	Complete POPS symbol	Synonym	PMS

$^vD[x]$	$I4_1$/amd	$I4_122$	$^vD2xx^{(1+)}_{(8d)}[x] \wedge {}^vD2x\bar{x}^{(1-)}_{(8e)}[x]$	$tI\langle {}^vD2xx\vert 000\vert {}^vD2x\bar{x}\rangle$	—	

One may for example think of the transition $CsCl \rightarrow CaB_6$. The invariant symmetry-controlled boundary conditions (space group $Pm\bar{3}m$) are maintained in any case and independent of the choice of the multipole. From some selected examples it can be assumed[41] that the topology might in fact change locally, but it still keeps its essential features, i.e. the type. Finally, we would like to point out the important relations between POPS and PMS on the one hand and the Dirichlet partitions with the conception of the convex polyhedra on the other.[31,42-49] Often the facet surfaces, which were determined by the polyhedra method, represent very good approximations for POPS and PMS (Fig. 2p), and with this method even partitions of the 3D space in *four* interpenetrating labyrinths (four colors) can be derived, for which equivalent PMS and POPS cannot as yet be given.

5. POPS and Structures

What do zero-potential surfaces POPS (or periodic minimal surfaces PMS) have to do with chemical structures? In this section we would like to show how the surfaces, which are solely formed by the symmetry, separate chemical structures in crystals in an almost natural way, and how this partitioning accounts for the obviously different interactions between the partial structures. Figures 1-6 show the most important POPS presently known, together with an arbitrary selection of structures of completely different character, which are adjusted solely by a scaling factor into the affiliated POPS.

5.1. The P^* Surface

This surface, besides those of the type IP_2-J^* and P^*J^* (Table 1), is a representative of the symmetry group $Im\bar{3}m$, and at the same time it is suitable for the topology of structures in the subgroups $I\bar{4}3m$, $I432$, $Im\bar{3}$, $I23$, $Pm\bar{3}m$, $P\bar{4}3m$, $P\bar{4}3n$, $P432$, $Pm\bar{3}$, $P23$, etc. In Figure 2a a part of the structure of the zeolite sodalite is shown ($Na_4Al_3Si_{12}O_{26}Cl$; $P\bar{4}3n$). Na and Cl form a partial structure of the type of the intermetallic phase $PtHg_4$. The entire aluminosilicate framework lies, in very good approximation, on the P^* surface, while the few $Na^{\oplus}$ cations are centering the cavities and the $Cl^{\ominus}$ anions lie above the twelve-membered rings of the silicate framework. The O atoms are bonded such that the lone electron pairs are on both sides of the surface, and directed towards the cations in the cavities. They practically form a double layer along the P^* surface, which primarily participates in the polar interactions with the cations, while the more covalent partial structure matches the surfaces. The sodalite structure can be described analogously with the help of the surfaces IP_2-J^* (group-subgroup relationship: $Im\bar{3}m$-$I\bar{4}3m$-$P\bar{4}3m$).

Because Al and Si fulfill equivalent functions, they can be unified in $Pm\bar{3}m$ symmetry. Indeed the aluminosilicate framework coincides with the intersection lines of the surfaces P^* and IP_2-J^*. The latter one possesses tunnel openings in the region of the twelve-membered rings and is closed where the openings of P^* lie, namely above the eight-membered rings. Both surfaces are topologically combined in the surface *PPJP-J* (Fig. 1r); however, their symmetry group is only $Pm\bar{3}m$. For the latter the $(Al,Si)O_2$ framework lies on the surfaces and all tunnel passages are open. Apparently all three POPS (PMS) belonging to the above mentioned symmetry branch describe in the same way the spatial separation of the different chemical interactions.

In the CaB_6 structure ($Pm\bar{3}m$, Fig. 2b) $Ca^{2\oplus}$ and the three-dimensional net of connected B_6 octahedra form two cubic primitive partial structures, which are separated by P^*. Here P^* apparently represents an inner surface, which to some extent centers the ionic interactions between $Ca^{2\oplus}$ and the electrons of the boron framework. Because of the larger expansion of the B_6 net into the volume, the curved surface also marks the area in which the weakest bonded electrons of the entire structure are found, namely those between the Ca and B atoms.[6] The important perovskite structure ($CaTiO_3$, $Pm\bar{3}m$) can be described analogously with the help of P^*.

At first glance the complicated α-Mn structure ($I\bar{4}3m$) seems to be somewhat obscure. A topological classification of different atoms is difficult for the element even though it is known that the four distinguishable crystallographic positions are occupied by Mn atoms of different magnetic moments. About 60 binary and ternary phases are known with this structure, and for a few of them exact structure information has been documented.

Obviously nature separates the four crystallographic positions in analogy to a POPS into such positions which lie close to the POPS (position 24(g), 24(g)) and into such which are further away (positions 2(a), 8(c)). As a result $A_{17}B_{12}$ structures are observed (A = Mg, Ta, Re; B = Al, Ta),[50] in which the more electronegative element often forms Friauf polyhedra (Fig. 2d) that are separated by P^*. However, in compounds like Ti_5Re_{24},[50] the electropositive element forms the Friauf polyhedra and occupies the positions on the P^* surface. The fragmentation of $Li_5Mg_{12}Al_{12}$[5] is an especially good example. Here Al forms the Friauf polyhedra, Mg occupies the surface, and Li lies in the cavities.

The metal cluster compound Nb_6F_{15}[52] (Fig. 2c) is an impressive example for two interpenetrating identical structures. The $[Nb_6F^i_{12}]$ clusters are linked via six bridging F atoms forming two independent three-dimensional nets ${}^3_\infty[Nb_6F^i_{12}]F^{a-a}_{6/2}$, which are inserted into each other just like a catena-compound. Mainly covalent forces predominate within the complex networks, but the interaction between the two independent nets is exclusively of van der Waals type. The linked clusters are large octahedra with triangular faces formed by six F atoms (Fig. 2c). Caused by the organization of the interpenetrating partial structures, two large triangular faces of neighboring cluster nets always meet in all cubic space diagonals, and they are separated by a layer of empty F_6 octahedra. This is the van der Waals gap, typical for layer structures, but in the present structure these layers change their orientation in space, going from one layer piece to the next. Therefore the Nb_6F_{15} structure is a non-euclidean layer structure whose van der Waals layers completely follow the course of the POPS P^*,[9] and again the highest occupied orbitals of the covalent bonded structure units are facing the P^* surface.

5.2. The D^* Surface

Up to now the D^* surface (Fig. 1b) is the only representative of the space group $Pn\bar{3}m$ and of the respective symmetry branch with the subgroups $Fd\bar{3}m$, $F\bar{4}3m$, $F4_132$, $Fd\bar{3}$, $F23$, $Fd\bar{3}c$, $F\bar{4}3c$, $F4_132$, etc. The large zeolite structure of faujasite ($Fd\bar{3}m$, $M^1_{57}Al_{57}Si_{135}O_{384}$[53]) can be understood with the help of D^*. The few isolated cations occupy cavities or at most tunnels while the covalent aluminosilicate network nestles closely to the surface. By doing this, the lone electron pairs of the O atoms are again aligned towards the surface in the direction of the cations.

The cubic Laves phase $MgCu_2$ ($Fd\bar{3}m$) is a typical representative of the intermetallic compounds. In Figures 2g, h the structure is shown together with the D^* surface. The Mg atoms center that partial space (Fig. 2h) which is enclosed by the green side of the surface. In the "blue" part the Cu atoms form a network of linked tetrahedra, and their centers set up a diamond structure which is equivalent to the arrangement of the Mg atoms. This structure is especially interesting, because it directly refers to the above discussed question about the splitting of point charges distributed at high symmetry positions into multipoles. If we choose for the generation of the POPS the real $MgCu_2$ structure ($Mg^{2\oplus}Cu^{\ominus}$, $D^{(2+)}_{(8a)} \wedge T^{(-)}_{(16d)}$) instead of the high symmetry ansatz ($Na^{\oplus}Tl^{\ominus}$, $D^{(+)}_{(8a)} \wedge D^{(-)}_{(8b)}$) then the resulting POPS hardly looks different. Therefore the splitting of the generating charges (cf. Section 4) into multipoles causes only marginal changes of the POPS! Apparent relations exist between structures formed by single atoms and structures formed by clusters, particularly because these often show the same basic patterns. Does the topological space partitioner therefore have a chemical meaning, too? In fact one can assume that the weakest bound electrons (in a metal the conduction electrons) reside close to the affiliated surface.[54] The expression 'interstitial' is almost a synonym for a weak bond with a flat course of the potential at points located *as far* away as possible from the atomic cores. Quantum mechanical investigations for this are in progress.

$Li_{21}Si_5$ is a γ-brass phase built of main group elements ($F\bar{4}3m$,[55] see Figs. 2i-l). The 416 atoms of the huge structure form as fundamental units 16 A_{26} clusters of two different types, namely $[Li_{22}Si_4]$ and $[Li_{20}Si_6]$. The centers of each of the eight clusters of both kinds form two interpenetrating structures of the diamond type. In other words, a NaTl structure of higher order (A_{26} clusters instead of atoms) is formed for which the D^* surface is likewise the space partitioner.[55] The periphery of the clusters is built by twelve Li atoms forming a cuboctahedron, and the mutual spatial arrangement leads to an interlocking of all cuboctahedra in such a way that all (!) these Li atoms lie on

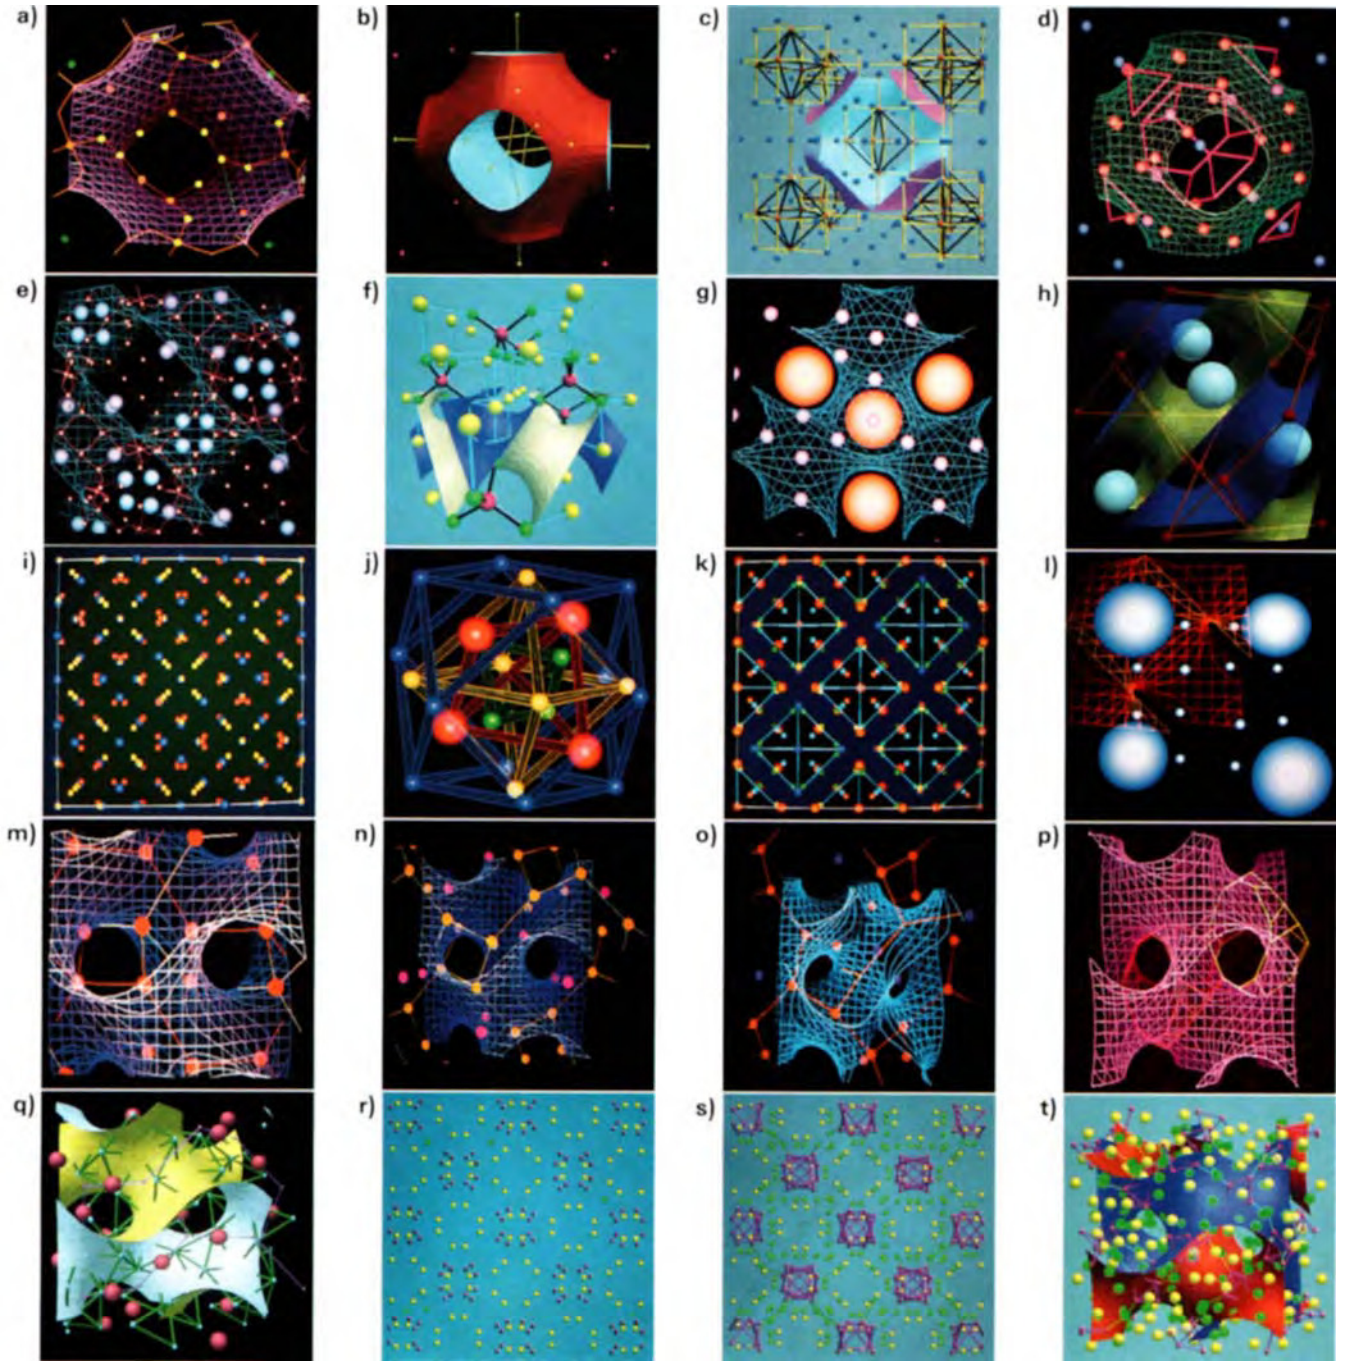

Fig. 2. Structures and POPS. a)–d) The surface P^*. a) In the sodalite structure (section of the cubic elementary cell) the aluminosilicate framework (yellow, red) lies on the P^* surface. Cl (green) and Na (not plotted, in the center of the cell) form a partial structure of the CsCl-type. b) CaB_6 is partitioned by P^* (red, light blue, transparent representation) into the boron framework (yellow, light-blue space) and the cation part (Ca, red). c) Nb_6F_{15} consists of two interpenetrating partial structures of $[Nb_6F_{12}]F_{6/2}$ clusters (Nb red, F blue) which are separated from each other by a "van der Waals skin". d) Partition of the α-Mn structure like in $Li_5Mg_{12}Al_{12}$ into Friauf polyhedra (Al pink, not complete at the corners of the cell), whose centers (Li blue) as well as the atoms (Mg orange) are located close to P^* (light blue).—e)–h) The surface D^*: e) In the zeolite faujasite the aluminosilicate network (red) reproduces the essential contours of D^* (blue). The large cations (e.g. $La^{3\oplus}$ light blue) fill the tunnels on both sides of D^*. f) Spinel in a perspective [110] projection. D^* separates the connected AlO_6-octahedra (blue, Al yellow, O green) from the partial structure of the MgO_4-tetrahedra (black, Mg red). g) The Laves phase $MgCu_2$ in [111] projection. D^* (blue) separates the Mg atoms (orange) from the Cu atoms (pink) that are connected to tetrahedra. h) $MgCu_2$ and D^* in another representation (Mg (light blue) in the green and Cu (red) in the dark blue space). i)–l) $Li_{21}Si_5$ and the surface D^*. i) $Li_{21}Si_5$; the projection of the elementary cell only reveals the $6\times6\times6$ superstructure of a cubic body-centered cell. j) The building unit of $Li_{21}Si_5$ is a 26-atom-cluster consisting of an inner tetrahedron (IT), outer tetrahedron (OT), octahedron (OH) and cuboctahedron (CO). k) Distribution of the clusters in the structure of $Li_{21}Si_5$ (half cell in the direction of viewing). l) The CO positions (small light-blue spheres) of all clusters are interlocked and lie on D^*, the cluster nuclei consisting of IT, OT, OH (large light-blue spheres) center the tunnels.—m)–t) The surface Y^{**}: m) Y^{**} (blue) partitions the γ-Si structure, a high-pressure modification of silicon, into helix-type systems (orange). n) In $SrSi_2$, one of the Si partial structures is missing and this part is replaced by the $Sr^{2\oplus}$ cations (red). The other Si partial structure remains virtually unchanged. o) A part of the β-Mn structure (red) exactly corresponds to the arrangement of the Si-atoms in $SrSi_2$. p) The Y^{**} surface (red) and a convex polyhedron (yellow) generated via the Dirichlet-construction. A dense packing of such polyhedra approaches the POPS (and PMS) in the form of facets [31]. q) The garnet structure (Ca red, O light blue, O octahedra and tetrahedra green, Al and Si center the O polyhedra on Y^{**}). The whole structure arranges itself in the form of non-euclidean layers around the graphs (violet) connecting the Ca cations (see also Fig. 6a). r) Projection of the complex structure of Ta_6Cl_{15} (Ta violet, Cl green, yellow) in which the separation into centers with clusters (Ta octahedra, red) and channels with van der Waals-packing of the Cl atoms already becomes perceptible. t) The centers of the Ta_6 octahedra lie on Y^{**}, while the Cl atoms form a dense non-euclidean packing on both sides of the surface.

the D^* surface, which acts as the topological space partitioner. The significance of this detail for the spatial distribution of the highest occupied orbitals is discussed in Section 8.

5.3. The Y^{**} Surface

From the highest cubic space group $Ia\bar{3}d$ originate two symmetry branches, the characteristic point configurations of which are Y^*, Y, V and S. The symmetry groups $Ia\bar{3}d$, $I4_132$, $Ia\bar{3}$, $I23$, $P4_132$, $P4_332$, P23 belong to the first group and only $Ia\bar{3}d$, $I\bar{4}3d$, $I2_13$, and $P2_13$ to the second. The combination $Y^*\{^{+}_{(8a)}\} \wedge Y^*\{^{-}_{(8b)}\}$ in $I4_132$ generates the POPS Y^{**} (Type 1, symmetry $Ia\bar{3}d$, see Figs. 2m–t), which is a surface of aesthetic beauty. Their counterpart is *Schoen*'s gyroid (gyros (Greek) = twisted) and was discovered stochastically about 20 years ago as one of the cubic PMS.[40] The particular difficulty for the derivation of this minimal surface is the absence of any euclidean frame (straight lines). The surface is exclusively spanned by flat points of $\bar{3}$ symmetry—that is an all-over open frame results, which lets any experiment with soap films fail! However the POPS Y^{**} is generated without special efforts; it can even be obtained in three different ways, namely by taking all three possible combinations of the PK's Y^* and V (cf. Table 1). It is true that the three generating potential spaces are different, but not the resulting POPS, and that again is a nice example for the minor influence of the splitting of a generating pole into a multipole (PK $Y^* \rightarrow$ PK V).

We would like to discuss a few structures in connection with the Y^{**} surface. Today, compounds with the garnet structure $Ca_3[Al_2Si_3O_{12}]$ ($Ia\bar{3}d$[56]) are important materials. Because of their extraordinary physical properties[57,58] they are used as opto-electronic color displays and as magnetic bubble memories for computers. The garnet structure seems to be complex and difficult to survey.[59] This is simply due to the fact that its topology is also subject to the complicated twists, which are characterized by the POPS Y^{**} and the gyroid respectively. In Figures 2q and 6a the garnet structure and the Y^{**} surface are mapped on top of each other. The immediate question arises, which divine principle distributes and orientates the AlO_6 octahedra in such a terrible-but-beautiful way. Guided visually by the space partitioning POPS, one recognizes at once that all atoms are arranged on concentric non-euclidean layers of increasing surface area (Ca < O < Al, Si). The $Ca^{2\oplus}$ cations can be connected via two interpenetrating Y shaped graphs. The first structure-chemical envelope of each graph is formed by the O atoms (or by their lone electron pairs) and the following envelope is the Y^{**} surface (with Al, Si) which already belongs to both Y graphs. Developing the curved POPS the coordination polyhedra of Al and Si (tetrahedra, octahedra) therefore form a non-euclidean double layer with more covalent bonds in the center and the lone electron pairs of the O atoms on the outer skin. One immediately gets the impression that the plastic insulation of a slightly angled copper wire with Y shaped knots could be a pattern for the POPS Y^{**}. In other words: One should be able to pack such plastic pieces to a space-filling cube!

Ta_6Cl_{15} is a fascinating example to demonstrate how in the space group $Ia\bar{3}d$, 336 atoms can be organized into a harmonic structure with a few positional parameters. In contrast to Nb_6F_{15} the $[Ta_6Cl^i_{12}]$ clusters form a single continuous 3D net $^3_\infty[Ta_6Cl^i_{12}]Cl^a_{6/2}{}^a$ (Figs. 2r, s), which follows the curvature of the Y^{**} surface (Fig. 2t). In both structures, the centers of the clusters are arranged according to a simple bcc structure.[59,60] A part of the Cl^i atoms lies on Y^{**}, almost desperately following its curvature in detail and therefore breaking the internal octahedral symmetry of the cluster. The other atoms envelop the surface and form a curved optimal non-euclidean sphere packing (Figs. 2t and 6d).

As further examples we mention γ-Si (Fig. 2m), $SrSi_2$ (Fig. 2n) and β-Mn (Fig. 2o), that is completely different materials. γ-Si is formed from a hexagonal high pressure modification of silicon by pressure release. Three of four Si–Si bonds either belong to one *or* to the other of the two 3D nets which exclusively extend in one *or* the other labyrinth of the Y^{**} surface. The fourth bond crosses the surface and connects both interpenetrating nets to the complete structure. Both threefold bonded partial nets are related to each other like left-handed and right-handed systems (Fig. 2m). In the $SrSi_2$ structure the Si atoms still form *one* of the partial nets of γ-Si, while the Sr atoms now lie in the second labyrinth (Fig. 2n). One might speculate whether the bonds crossing the Y^{**} surface are those which are most open to attack in the structure of γ-Si at all and consequently the most vulnerable in case of an electron transfer. However, this plausible assumption has to be proven by a quantum mechanical investigation. The structure is certainly highly strained, and only with great efforts can it be joined together from tetrahedral knots and flexible bonds (Prentice-Hall Model Kit, Minit Model System). However, the result can then be taken as that of an analogue computation (Structure Model Analogue Computer[61]). The three bonds in the labyrinths are extremely bent, and the intersecting bond is straight. Since the tension can *only* be released by lengthening of the least bent bond, the cleavage of just this bond seems to be necessary. It is noted that the transition of γ-Si to the polyanion $^3_\infty[Si^{\ominus}]$ refers to a special case in which a tetrahedral structure[62] develops a completely threefold bonded net by the removal of *half* of all atoms (3D net of neighboring defects[63]).

Nobody would assume that β-Mn has anything to do with γ-Si or $SrSi_2$. However, part of the Mn atoms (Fig. 2o) form a very similar partial structure to that of the Si atoms in $SrSi_2$. The others lie close to the Sr positions. It isn't misleading to assume a tendentiously similar polarization between both partial structures even for the β-Mn. Hence it follows that during the phase transition α-Mn ⇄ β-Mn, something like a disproportionation takes place (cf. Section 8).

5.4. The S^* Surface

Actually the S^* surface (Fig. 1d) was discovered at first as a POPS,[1] and just recently the corresponding PMS could also be established.[31] It is a surface of type 1 with

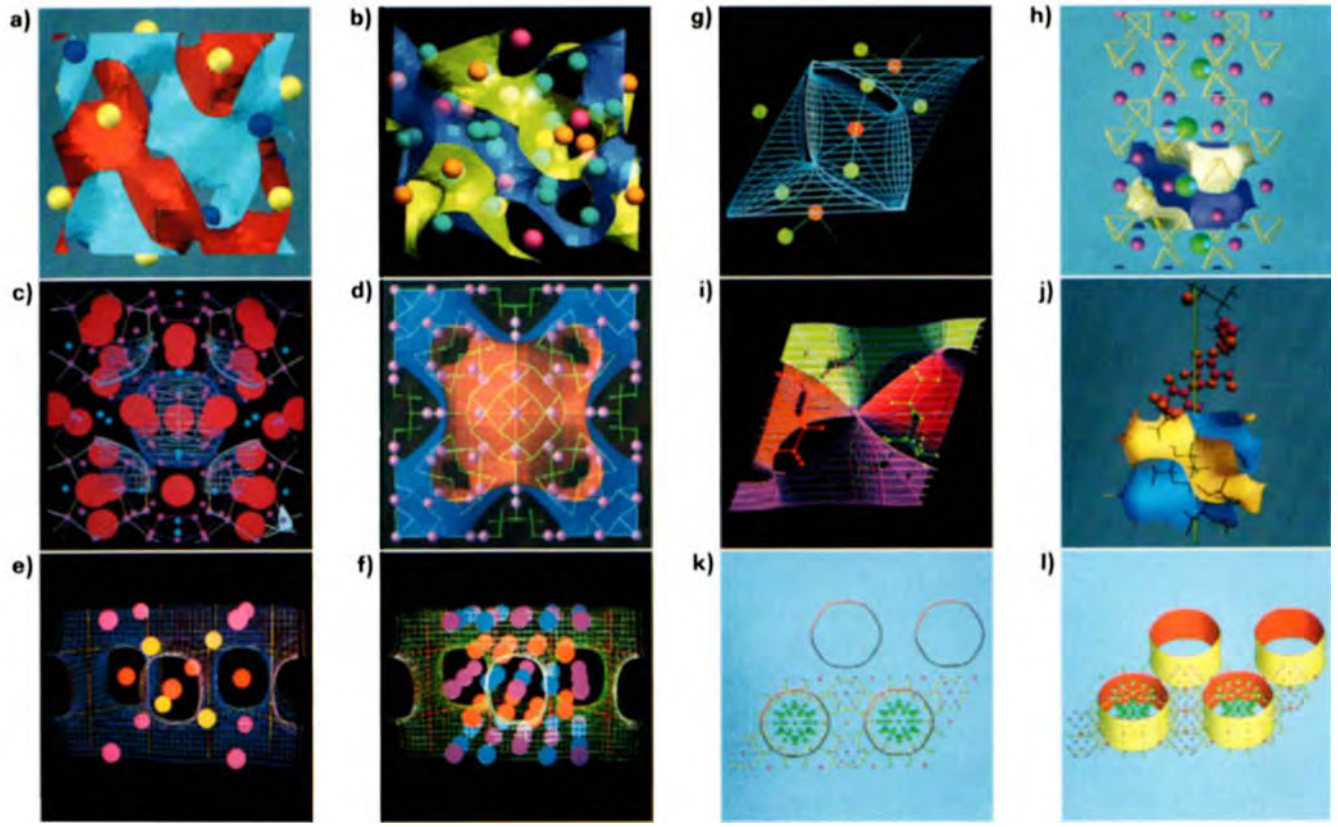

Fig. 3. Structures and POPS. a) The structure Th_3P_4 (Th yellow, P dark blue) and the surface S^* (light blue, red; only one half of unit cell is shown in direction of viewing). b) $Li_{14}MgSi_4$ (Li green-blue, Li/Mg orange, Si red; only one half of unit cell shown in direction of viewing). c) The clathrate-I structure (e.g. $K_8Ge_{44}\square_2$, K large red circles, Ge and □ small blue and violet circles, clathrate framework blue and violet lines) and the bubble surface *I-W* (blue). d) The complex structure of $BaCuO_2$ (Ba violet, Cu–O framework green) and the surface IP_2-J^*. e) $CdIn_2Se_4$ (Cd pink, In orange, Se yellow) and the surface $P_c^*I^*$ (blue, skew [100]-projection). f) $Cu_9Fe_9S_{16}$ (Cu blue, Fe violet, S orange) and the $P_c^*I^*$ surface (green, skew [100]-projection). g) Quartz structure (Si orange, O yellow-green, [001]-projection) and the surface Q^*. Si and O atoms center one of the tunnel systems, while the free electron pairs of the O atoms are directed through Q^* into the empty partial space. h) $CaSO_4(H_2O)_{0.5}$ (Ca violet, sulfate anion yellow tetrahedra) and the surface Q^* (light, dark blue, section around [00z] in the area of the double helix). Q^* separates the space of the $SO_4^{2\ominus}$ anions from the space of the $Ca^{2\oplus}$ cations, to which, the lone electron pairs are directed through Q^*. The H_2O molecules follow a wing of the helix (O green, H light blue). i) The double helix in the structure of α-amylose (red and green single helix) optimally follows the surface Q^* (violet and green wing); [001]-projection). The brown and the red wing mark the "van der Waals-skin" between the chains (see also Fig. 6b). j) The helix in α-amylose follows the different gradients on Q^* (yellow portion of the surface, black part of amylose, top: C red, O orange, H violet (small); [001]-projection). k) Zeolite L (Al,Si yellow, O green (small), H_2O green (large), cations red; [001]-projection) has large tubes containing the water molecules. The surface *P-G* (red hexagonal rings) distinctly changes its character (cf. Fig. 11) for the axial ratio $c/a = 0.408$ to a marked tubular topology. l) Oblique view of Zeolite L and *P-G* (red, yellow).

$Ia\bar{3}d$ symmetry and can be applied to structures of the symmetry $Ia\bar{3}d$, $I\bar{4}3d$, $I2_13$, and $P2_13$. It has the same flat points as Y^{**}, but in addition it also has straight lines (position 48g in $Ia\bar{3}d$; twofold axes). An important structure of suitable symmetry is the Th_3P_4 type (Fig. 3a). The eightfold coordinated Th atoms occupy a point configuration *S* and thus center one of the two tunnel systems, while the phosphorus atoms lie on the other side close to the POPS S^* and are coordinated from the direction of the thorium space. In this description the Th_3P_4 structure is a non-euclidean tube structure, in which two tunnel systems of Th atoms and of P atoms respectively interpenetrate without intersections. The S^* surface separates and connects both tunnel systems. The $Cu_{15}Si_4$ structure is a stuffed derivative of Th_3P_4 (Fig. 3a). It represents the basic structure type of a series of chemically unusual compounds, e.g. $Li_{15}Ge_4$, $Na_{15}Sn_4$ and $Na_{15}Pb_4$, for which one would actually expect the composition $A_{16}B_4$ with completely filled electron octet of the semi-metal. $H_{15}Th_4$ forms this structure, too, but now the B positions are occupied by the electropositive component.

The A atoms occupy two point configurations, namely the general position 48(e) and the position 12(b) in the space group $I\bar{4}3d$. The first one spans a multipole around one of the generating *S* PK's, the last one is the other PK of type *S* generating the S^* surface. On the other hand, the B atoms have the same PK as the P atoms of Th_3P_4 and therefore lie close to the S* surface which now separates both labyrinths of the A component. Whether this arrangement of the B component can "save" electrons, has to be studied in further detail. However, if additional electrons are offered to a phase like $Li_{15}Ge_4$, e.g. by replacing Li by Mg, salt-like Zintl phases of the same structure, like $Li_{14}MgSi_4$, are obtained[51] (see Figs. 3b and 6c). As expected, extended Hückel-calculations also show a distinct band gap at 16 electrons per formula unit.[54]

5.5. The Y^* Surface

This surface has $I4_132$ symmetry and was first discovered as a POPS. Recently, it was also shown that a corresponding and until now unknown PMS exists.[31] The Y^* surface has a remarkable property. It can be generated

from the two enantiomorphic space groups $P4_132$ and $P4_332$ and therefore exists in two enantiomeric forms ($^{-}Y^*$ and $^{+}Y^*$), but with the same symmetry. Only in the gyroid Y^{**} are both enantiomers united (non-euclidean mirror, cf. Section 5.3). Ag_3AuTe_2 is a structure with the Y^* surface as space separator. Due to the described symmetry conditions one can choose either to put the PK $^{-}Y^*$ *in the labyrinth* of a $^{-}Y^*$ surface or *on the enantiomeric* $^{+}Y^*$ surface. They both meet the symmetry, but more experience has to be gained to carefully consider the propositions of both representations. On the other hand, exactly such symmetry groups provide knowledge about "the Right in the Left" and vice versa.

5.6. The Surfaces IP_2-J^* and P^*J^*

Schoen's I-WP minimal surface[40] belongs to one of the very few surfaces discovered up to now which separate the space into two non-commutable and therefore different parts (type 2). The POPS IP_2-J^* corresponds to this surface (Figs. 1o, p). Both belong to the symmetry $Im\bar{3}m$ and separate the PK's I and J^* from each other (000, $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ and $\frac{1}{2}00$ cyc., $\frac{1}{2}\frac{1}{2}0$ cyc.). They can be used for the analysis of structures of the symmetry branches $Im\bar{3}m$, $I\bar{4}3m$, $I\bar{4}32$, and $Im\bar{3}$. As an example the complicated structure of $BaCuO_2$ might be named.[64] The cavities around the PK I are filled by large spherical clusters, in which a net of square-planar coordinated Cu atoms encompasses a single Ba atom. Eight characteristic tunnels—their bounds are the generating elements of the entire surface, a "Wendehals" (turn-neck) of $\bar{3}$ symmetry—are centered by the eight pairs of isolated Cu_6O_{12} crowns surrounded by Ba atoms which lie close to the surface. Both structure parts lie together in the larger labyrinth. The smaller labyrinth is a four-armed tunnel system with a square planar tunnel cross and with extended flat points as bounds. Located in this labyrinth is that part of the $CuO_2^{2\ominus}$ partial structure which is distinguished by disorder.

The POPS P^*J^* belongs to the type 1 but has a certain relationship to the POPS IP_2-J^*, because it is also generated by a combination of PK's with different point charges (Table 1, Fig. 1q). Generators here are two interpenetrating equivalent partial structures of the ReO_3 type. This surface also has $Im\bar{3}m$ symmetry, is generated in $Pm\bar{3}m$, and can be related to the so-called Neovius' surface.[65] The special property of this surface is the appearance of enveloped areas of completely different extension (Fig. 3q), a consequence of the different charges on both sides used for the generation of the POPS. Because both substructures are topologically identical, P^*J^* divides the space into two equal halves.

The larger cavities show twelve exits to the neighboring small cavities, and each of these has four tunnels in square planar arrangement to the large cavities. The surface P^*J^* (and the Neovius' PMS) is a complementary surface of P^* (*Schwarz*'s "P" surface), because the tunnels of P^* are closed by the extended flat points of P^*J^*, but for that twelve saddle points of P^* are opened. An example is the simple Mg_3NF_3 structure. Here P^*J^* separates the cations from the anions and therefore again describes an internal surface.

5.7. The Bubble Surface I-W

The surface I-W (Table 1) is discussed as an example of a non-connected POPS (general context cf. Section 3.3). It is generated by the distribution of charges onto the positions of the Cr_3Si structure (A15). Therefore, these positions are trivially located in both partial spaces with the minority component in the bubble (Fig. 1t). Apparently, bubble surfaces are typical for the generators $A^{n+} \wedge nB^{1-}$ with $n \geqq 3$. Surprising is the topological correspondence of these POPS I-W with the framework structure of the clathrates-I,[2] whose atoms, with one exception, lie on the surface. In defect clathrates (e.g. $K_8Ge_{44}\square_2$, Fig. 3c) the only position off the surface is exactly the location of deficiencies.[66]

5.8. The Surfaces F^*, W^* and E^*

These surfaces are distinguished by a complete enclosure *of all* generating points (Figs. 1g–i). The consequences for an understanding of very polar structures was already discussed previously.[2] The NaCl structure is the typical representative for F^*, while for W^* and E^* no simple examples are known. This is probably due to the coordination properties in these arrangements. However, there are filled-up derivatives in which there are polar centers as parts of a predominately non-polar structure separated by W^*.

5.9. The Quartz Surface Q^*

At this stage it should be pointed out again that the *generation* of POPS has *nothing* to do with real structures, which could possibly be assigned to the generating charge distribution. In particular, the "quartz surface" has nothing to do with the quartz structure except for the symmetry group and the axial ratio c/a, a free parameter. This remark is important, because we would like to show that the Q^* surface is an adequate space partitioner for SiO_2 as well as for α-amylose. Q^* is generated in $P6_222$ ($P6_422$), has the symmetry $P6_422$ ($P6_222$) with $c' = c/2$, and belongs to type 1. It was the first POPS of hexagonal symmetry,[1] and, during the calculation and representation, information about the general topology was obtained which later on allowed for the derivation of the extraordinarily important equivalent PMS,[67] because Q^* has a euclidean frame. This surface represents a novel variant, which in many respects exhibits special features. Q^* contains two surface regions which can serve as topological models for two different helical systems (Fig. 1j) and are centered by 3_1 axes and 6_2 axes in the ratio 2:1. The combination of these symmetry elements generates intersections, i.e. intersecting lines of surfaces, if the symmetry elements lie on the POPS (or PMS). Areas with 3_1 screw axes avoid the intersections, because the surface does not actually touch the helix axis, but winds around it—even if hardly noticeable. The corresponding region of the surface can, on the one hand, be understood as an equalizing (average) surface of a helix and, on the other, as the partitioning surface of two helices. In contrast to this, an intersection line lies in the center of the second screw type, coincident with the 6_2 axis. In

addition to this combination of a helical surface and double helix, the POPS Q^* has a further property of general meaning for structural chemistry. Q^* divides the space into two *four-armed* labyrinths, which is an unexpected feature for the hexagonal symmetry. However, it corresponds to the properties of the point configuration Q.[68]

In the structures of high-quartz (β) and low-quartz (α) the SiO_4 tetrahedra form a 3D network $^3_\infty[SiO_{4/2}]$ for which the four-armed feature of the Q^* labyrinths is tailor-made. At the same time, the tetrahedral network belongs to all three helical areas, which are in a certain way linked by the POPS Q^* as a common skin (Fig. 3g). All atoms lie *in one* of the partial spaces which are separated by the POPS. In $BaZnO_2$, a stuffed derivative of the α-quartz structure,[69] the corresponding atoms of the polymeric anions $^3_\infty[ZnO_2]^{2\ominus}$ lie in one labyrinth and the $Ba^{2\oplus}$ cations in the other. The O atoms are located exactly at the necks of the labyrinths, and concerning the scale of the interatomic distances it is clear that their lone electron pairs should almost lie on Q^*. Therefore, the free labyrinth in α-quartz is also a non-euclidean layer structure with exclusively van der Waals interactions. The $BaZnO_2$ structure contains cations intercalated in this labyrinth, and the surface Q^* now acts so to speak as a donor.

Calcium sulfate hemihydrate $CaSO_4(H_2O)_{0.5}$[70,71] does not have much in common with α-SiO_2 in a purely chemical sense. The two structures merely crystallize trigonally in the same space group with a similar c/a ratio. They become comparable through the POPS Q^* common for both structures. The $SO_4^{2\ominus}$ anions fill one partial space, whereby the modified orientation of the tetrahedra (90° compared to SiO_2) provides optimal distances between the O atoms of neighboring $SO_4^{2\ominus}$ groups. The O atoms now lie close to Q^*, and from Figure 3h there is hardly any doubt that their lone electron pairs are directed through Q^* towards the $Ca^{2\oplus}$ cations in the other partial space. Therefore Q^* divides the space in SiO_2, $BaZnO_2$ and in $CaSO_4(H_2O)_{0.5}$ into two parts of different interactions. The H_2O molecules finally squeeze themselves into the tight area of the intersections of Q^* (6_2 axis) and are therefore able to form hydrogen bonds for two parts of the $SO_4^{2\ominus}$ labyrinth and coordinate $Ca^{2\oplus}$ in two parts of the $Ca^{2\oplus}$ labyrinth (Fig. 3h).

From the structures treated so far, one continuously has the feeling that adequate things are combined with each other, e.g. P^* with CaB_6 and sodalite, or D^* with $MgCu_2$ and faujasite, or Q^* with quartz and gypsum. The compounds are inorganic, and the surfaces would more likely be assigned to the non-organic objects, just for once using common short terms for things of importance and unimportance—not to mention the bio-aspect.

With α-amylose Nature presents us a welcome interdisciplanary example for the extensive and obligate rules which symmetry imposes on all things that attempt to organize themselves in the solid state. The α-amylose impressively reveals the role of POPS and PMS as a continuous mediator between local and collective forms. This very large organic molecule crystallizes in three forms (α, β, γ), which are distinguished by their water content. The α-form crystallizes orthorhombically; however, the axial ratio and the presently known details of the structure[72–74] show a surprisingly close relationship to high quartz. In particular the amylose molecules follow the 6_2 axis as double helices (if idealized), and, in a natural way, through their quasi-hexagonal rod packing, generate intermediate areas with two 3_1 screws in which the unsettled (but presumably also helical) water structure is built up. In Figures 3i and 6b a part of the presently known partial structure of the α-amylose together with the POPS Q^* is shown. (Q^* was fitted to the dimension of the α-amylose by merely applying a minimal distortion of the mean hexagonal c/a ratio, namely a pseudo hexagonal angle $\gamma = 112.5°$ and by introducing *one single* scaling factor.) With surprising precision the surface area around the 6_2 axis characterizes the mean helical surface of the gigantic molecule intersecting the centers of the glycosidic six-membered rings. One should bear in mind that no uniformly curved helix is present, but rather that steep and flat parts alternate! Because of the polar screw axes, structures can be fitted into the Q^* surface in steps of $c/6$. Therefore the gigantic molecules of the α-amylose can either be centered *on* Q^* (as mentioned above) or they are centered *between* two successive subspaces (Fig. 3i). With this second equivalent representation Q^* forms approximately the "van der Waals skin" of the amylose chains.[72]

At some time in the course of the enzymatic construction of amylose chains, bifurcations develop on the primary helices, which then begin to wind up in the neighborhood of parallel secondary helices (in the present model neighboring 6_2 screws of the rod packing). Until now there is nothing known about the structure of these interconnections. However, we expect with the knowledge of the Q^* surface that the marked saddles of Q^*, which appear between the 6_2 screws, carry the connecting glycosidic unit (and/or are "enclosed" by them). In any case, a model structure yields an extraordinarily satisfying interconnected structure with respect to symmetry spatial expansion and orientation.

For biochemistry another aspect might still be of importance.[75] The Q^* surface gains its special features from the combination of double helices and simple screws in the ratio 1:2 (cf. above). Precisely this ratio is typical for the composition of muscular fibers with the building units myosin (large double helix) and actin (small helices). One might imagine that in the course of the contraction, these different helical structures move against each other, controlled and mediated by the suitable space partitioner Q^*.

Finally, there is another general aspect of this remarkable surface which essentially deals with the translational symmetry, through which certain symmetry elements are generated half-way to the translational identity quasi from nothing. In this way, all symmetry elements appear again after one half rotation (because of the double helix $\pi/2$), suited to wind a second double helix of the same kind or of a different kind (e.g. a helical water structure). A close packing of double helices comes close to a hexagonal rod packing, and again this arrangement produces by translation the above mentioned *two* additional helical areas in the interspace (centers of triangles), and it naturally also produces intersections of the space partitioning surfaces. In general the Q^* surface is, therefore, the space separator for "successful" rod packing of double helices. Not much is changed concerning the principal topological properties,

even if neighboring double helices are out of phase with regard to their windings.

5.10. The Hexagonal *P-G* Surface

The fundamental type of this POPS can be directly compared with the PMS *H'-T* (*Schoen*[40]). Especially in this case, with the help of POPS (Fig. 1k) the dominant influence of the axial ratio *c/a* can be studied. For $c/a \approx 0.5$ the POPS consists of modulated tubes along *c*. In the zeolite structure ($K_6Na_3Al_9Si_{27}O_{72}H_2O$[77]) with $c/a = 0.41$ the aluminosilicate framework fills the area between the tubes. In the tubes the water molecules (large tube) and the cations are distributed according to the modulation. At $c/a \approx 0.9$ the POPS *P-G* is very similar to the PMS *H'-T* and forms a 3D labyrinth with wide and narrow necks along *c* (ratio 1:2). With $c/a \geqq 1.05$ the necks tear off and the two-dimensional character now corresponds to the AlB_2 structure (cf. also BN).

This width of variation of the POPS *P-G* with *c/a* permits the modelling of completely different structure branches, a capability which the PMS do not have to that extent.

5.11. The Tetragonal Surfaces ${}^{v}D^*$ and $P_c{}^*I^*$

The two POPS apparently obtain their topological type independent of the axial ratio *c/a* — a very important property. For $c/a = 2.0$ and $1/\sqrt{2}$ they correspond to the already known PMS D_T and *CLP*, respectively (*Schoen*[40]). The POPS ${}^{v}D^*$ (Fig. 1n) separates at $c/a = 2\sqrt{3}$, inter alia, the substructures of α-$ThSi_2$. The Th atoms occupy the centers of one labyrinth, while the 3D net of the Si atoms fills the other. Two Si atoms form poles (PK ${}^{v}T$) around the PK ${}^{v}D$, which is equivalent to Th (Fig. 3b). ${}^{v}D^*$ is discussed in Section 8 in connection with the unusual electron density distribution of Cs-IV. With $c/a \approx 2$ the ${}^{v}D^*$ surface separates the partial structures of scheelite $CaWO_4$ into $Ca^{2\oplus}$ and $WO_4^{2\ominus}$, or those of anatase TiO_2 and $LiInO_2$.

Approximately 20 different crystal structures correspond to the POPS $P_c^*I^*$ (Fig. 1m, PMS *CLP*). In most cases the following holds true: 1) the anions always occupy the position of the largest curvature at the intersection point of twofold axes; 2) in complex structures, polyhedral splittings are found around the same positions, e.g. in $Cu_9Fe_9S_{16}$;[78] 3) the ratio *c/a* almost does not influence this arrangement of cations and anions; 4) the cations lie in both labyrinths, which are arranged in crosswise stacked tubes (Figs. 3e, 3f).

6. POPS and Dynamical Processes

After investigating numerous crystal structures, for which very close relationships between structure elements and zero-potential surfaces occur, we are encouraged to use this instrument to investigate other phenomena than pure structural phenomena. Even if the surfaces PEPS and POPS are used as relatively easily accessible substitutes for the PMS, they nevertheless represent definite physical quantities, which contain an important aspect of the kaleidoscope of all interactions in real structures. PEPS and POPS are based on quite a simple potential ansatz, however they are particularly suited for our purpose to demonstrate the general influence of the symmetry on the topology of structures. Just the really simple ansatz for the individual allows to demonstrate in an exceptionally clear way the influence of the collective—which no member of a structure can escape. Therefore, when interpreting physical properties we concentrate on the global topological links without forgetting that each substitution of an atom by another one or by a defect generates a local change in the structure. Only when such local changes are very large does one expect a phase transformation, i.e. another symmetry then optimally joins the units together.

Earlier we pointed out the fact that the $Ag^{\oplus}$ ions in the optimized ionic conductor α-AgI ($Pm\bar{3}m$,[76]) are located on the POPS P^*. It is noted that the silver ions apparently do not occupy the largest interstitial positions on the face centers of the cubic unit cell, but rather those indicated in Figure 4a. These are the locations of the highest probability density, which is depopulated with increasing temperatures for the benefit of other positions. So far we have not found exact information in the literature about the trace of the hopping paths, nevertheless we do not believe that these are straight lines, as is often suspected. Rather they should follow the POPS's curvature as in PbF_2 and β-eucryptite (cf. below). What relationship does the POPS P^* have to the hopping paths of the silver anions in a cubic body-centered partial structure of $I^{\ominus}$ ions? The largest gradients that are "felt" by a positively charged particle on a POPS, are always perpendicular to the surface and point in the direction of the anions. By definition, no potential changes and also no gradient occur along the POPS. However the occurrence of preferred positions for $Ag^{\oplus}$ means that gradients along the surface are present in β-AgI. The reason for this still needs to be clarified. But it is clear that the curvature of the POPS is maximal at the favored positions i.e. the neighboring equi-potential surfaces follow one another very closely.

At higher temperatures NaOH (NaOD) forms the CsCl structure, in which the $OH^{\ominus}$ ions apparently behave spherically symmetric. This high symmetry is produced by a dynamic orientational disorder. As far as the preferred orientations of the dipoles are concerned, it might be said, that the H atoms should rarely point in the direction of the space diagonal ($Na^{\oplus}$), but should prefer the orientation along the cubic axes. By means of neutron diffraction it was shown[79] that precisely this arrangement, which appears to be optimal, is completely avoided, and, instead, orientations of the D atoms follow a probability distribution which reproduces the basic features of the POPS P^* suitable for the symmetry of the CsCl structure.

Here, we again refer to the fast ionic-conductors PbF_2 ($F^{\ominus}$ conduction) and ZrO_2 ($O^{2\ominus}$ conduction)[80,81] both having the CaF_2 structure. Some time ago the controversy whether the hopping $F^{\ominus}$ ions in PbF_2 prefer to occupy the favorable vacancies of the structure ($\frac{1}{2}\frac{1}{2}\frac{1}{2}$ fcc) or not was settled with the experimental determination of the $F^{\ominus}$ hopping paths.[82] On their diffusion path they follow the topology of the POPS *F* (CaF_2; cf. Table 1 and Fig. 4e). This

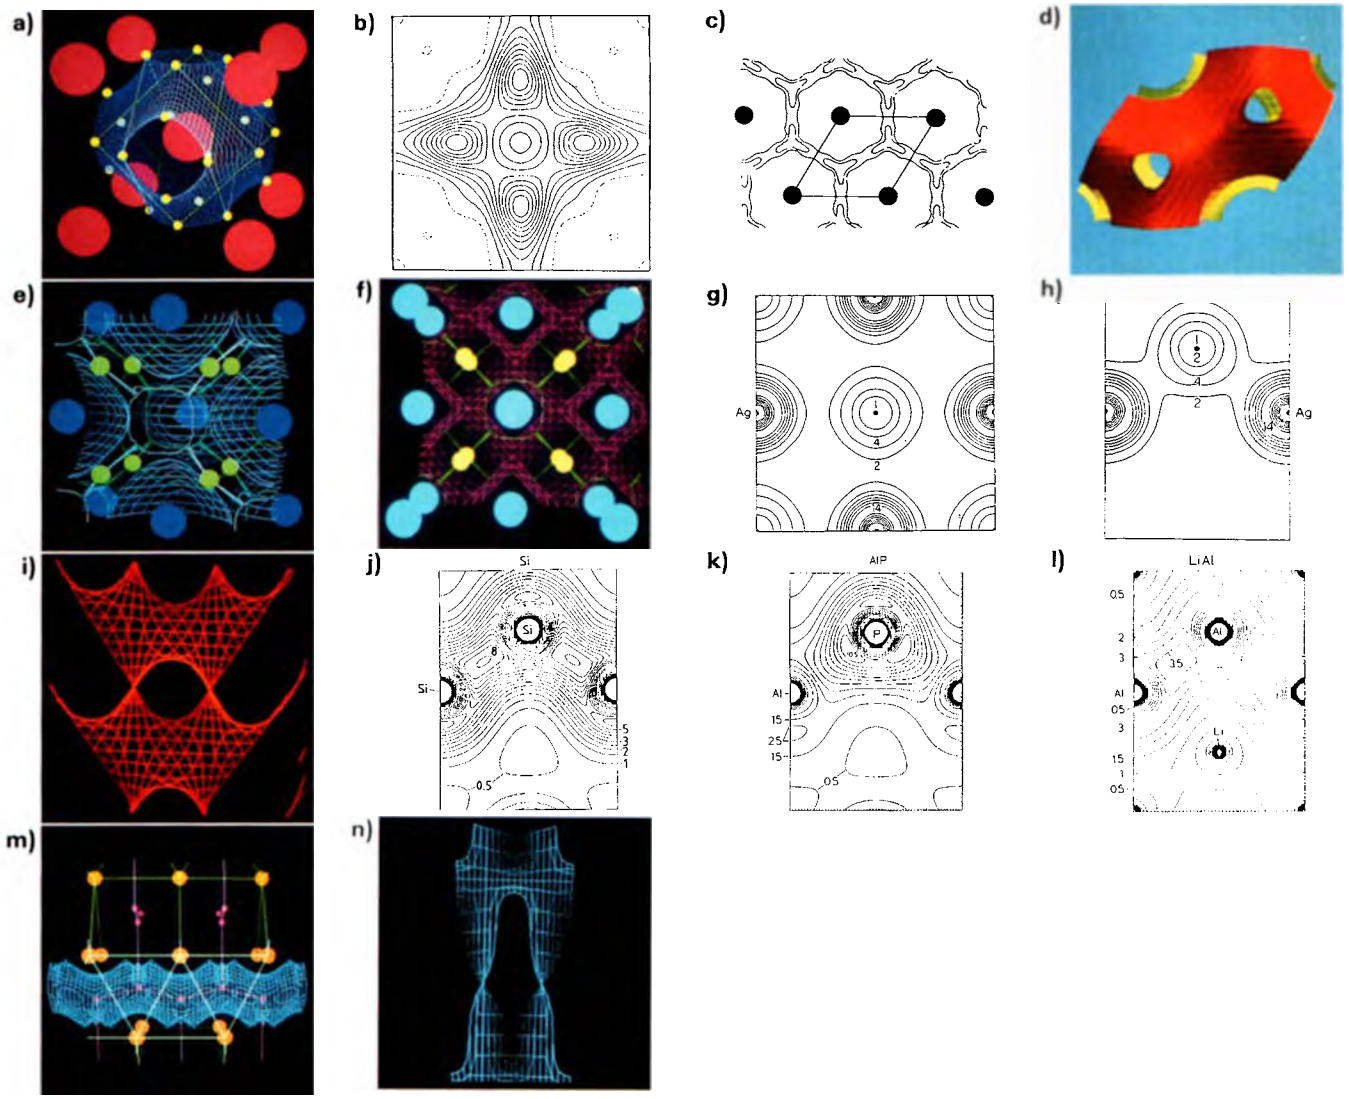

Fig. 4. Ionic conduction and electron density distribution. a) The $Ag^{\oplus}$ ions (yellow) in α-AgI ($I^{\ominus}$ red) lie on P^* (blue). b) Experimentally determined electron density for the surface $(x, y, 0)$ [76]. c) Electron density distribution of $Na^{\oplus}$ ions in (001) plane of β-eucryptite [83, 84]. d) The surface P-G partitioning the space of the cation partial structure (yellow) and of the O atoms (red). e) The bubble surface F-P_2 (blue) and the $F^{\ominus}$ ionic conductor PbF_2 (Pb dark blue, F light green, experimentally determined hopping paths [82] green). f) A negative PEPS (violet) which only leaves opened narrow tunnels between $F^{\ominus}$-$F^{\ominus}$ (yellow) and $Pb^{2\oplus}$-$Pb^{2\oplus}$ (light blue) through which the paths of the anion movement proceed. g, h) Calculated electron density distributions for AgI [95]. In the NaCl structure (g) only almost spherical densities appear; in the zinc blende structure (h), on the other hand, distinctly polarized densities occur. i) The surface D^* with a (110) section. j)-l) Calculated electron densities ((110) sections) for silicon [101], AlP [98] and LiAl [99] between the atoms the densities follow the local circumstances. In the interstitial range the equi-density lines follow D^*. m) Structure and calculated valence electron density (blue) for the high pressure modification Cs-IV (yellow) [105]. The positions of the Cs atoms correspond to the positions of the Th atoms in $ThSi_2$ (Si violet). The highest densities are found in the range where they are observed in $ThSi_2$ too, along the Si chains. n) A part of the "D^* surface with a tunnel structure corresponding to the density distribution.

zero-potential surface is not an interconnected unit, but forms isolated bubbles around the $M^{2\oplus}$ poles, whose outer shape has flat regions related to a formation of octahedra ($m\bar{3}m$). Only the following neighboring PEPS in the negative partial space form increasingly closed surfaces between the positive and negative poles. One of these surfaces finally comes close to the form of connected tetrahedra (around $F^{\ominus}$) and octahedra (around $Pb^{2\ominus}$). The topological development of the PEPS and the experimental $F^{\ominus}$ hopping paths are clearly correlated. Both correspond optimally where the largest distance to the neighboring ions is reached, e.g. in the area of the "neck" connecting the $Pb^{2\oplus}$ in the center of Figure 4f. Obviously the $F^{\ominus}$ ions try not to "descend", or also not to "ascend" in the potential of the neighborhood while hopping. In any case, they circle around the "favorable" potential holes at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ etc.! This example also follows the general trend, which we would like to demonstrate with the help of the POPS.

β-Eucryptite $Na_xAl_2O_3$ (Figs. 4c, d) is famous for its properties as a $Na^{\oplus}$ ionic conductor and has been studied extensively.[83, 84] Reliable information about the paths of the hopping $Na^{\oplus}$ ions come from diffraction experiments. *Schoen*'s H'-T surface[40] belongs to the matching symmetry branch and is topologically equivalent to the POPS P-G (Table 1). The POPS P-G is generated by a charge distribution of the AlB_2 structure type, and it partitions the space in non-commutable labyrinths. The $O^{2\ominus}$ partial structure of β-eucryptite lies in one part and the cations $Al^{3\oplus}$ and $Na^{\oplus}$ in the other, with the latter ones one upon the other along the c-axis (channels). With its tunnel system the sur-

face models the optimal paths of the hopping ions (the tunnels themselves are "blocked" by $Al^{3\oplus}$), and in this structure the POPS can be regarded as topological approximation of the inner surface of the $O^{2\ominus}$ anion in the crystal.

7. POPS and Phase Transitions

Second order phase transitions proceed continuously without activation and often have extended induction periods. Structural changes can be very easily observed, because the transformation takes place without destoying the crystals. The local motions of the atoms and especially their coordinative variations refer directly to the reaction paths in molecular reactions. With first order phase transitions the circumstances are complicated. On the one hand, at T_c, two separated and principally different solid phases are in equilibrium, and therefore there is no need for any structural relationships between the two. On the other hand, local structural changes are frequently observed in such transitions when approaching T_c, which show all the important synonyms of cooperative second order transformations. Only at T_c each reference is lost between the beginning- and end-states, because no symmetry relationships are necessary according to *Landau-Lifschitz*. For the phase transformations, the discussion can be limited to thermodynamic variables of state as a driving force; hence, one is always on the safe side. On the other hand, chemists show a preference for kinetic pictures. They "know" exactly when and why such bonds open and close, at least in molecules. While in the first case one retreats to the space of the observables—it is the reciprocal space—one acts in the second case freely and easily in the real space of the surrounding objects. Especially here the cooperative is not easily examinable, and therefore all efforts are concentrated on the local process. We believe that at least in the crystalline phases the POPS (and PMS) can bridge the gap, because they are a part of the real structure, however they describe the global characteristics of collective forms of organization. Thus, it is not surprising that the POPS reveal details during the process of phase transformations, which seem to be in obvious contradiction to the local variations at positions which are occupied by atoms.

First of all, we analyzed how the POPS react to changes of symmetry, and how they behave at phase transformations. Often principal topological changes in the POPS occur regarding the number of tunnels (genus of the POPS, cf. Section 3.4) and their position to each other. Even a complete break off of the continuous surface in one, two or three directions can occur, which leads to forms that are characteristic for layer structures, one-dimensional arrangements, and locally more or less closed systems.

For the transition between the CsCl and NaCl structure there are several models,[86,87] which we only partly have pursued with POPS. Even though it concerns a transition of first order, as discussed in the following, it can be regarded as a continuously proceeding mechanism, in which the interface between the phases moves through the structure. For this, both cubic structures are set up trigonally along the space diagonal. This has the advantage that the positional parameters do not change during the transition and the entire relative shift of all atoms can be described by one single parameter, namely by the axial ratio c/a: $CsCl \triangleq \sqrt{3/2} = 1.2247 \leqq c/a \leqq 2.4495 = \sqrt{6} \triangleq NaCl$. As c/a increases the symmetry groups $Pm\bar{3}m$, $R\bar{3}m$, $Fm\bar{3}m$ are passed through, i.e. only both terminal members are cubic, while the phase transition itself proceeds under rhombohedral symmetry. The calculations for this simple process show how differently the changes act *locally* and *globally*. Looking at the potentials on the positions of the point charges (via the Partial Madelung Factors[88,89] they supply the Madelung Part of Lattice Energy MAPLE according to *Hoppe*[90]), one immediately gets the impression that the NaCl structure is maintained for wide regions of c/a, before the CsCl structure almost appears as a singularity.[91] However, the topology of the affiliated POPS as a measure for the course of the potential *between* the ions behaves completely different. *All* rhombohedral intermediate stages belong to a six-armed tunnel system (genus = 3) which is *continuously* modelled from the P^* surface that is typical for CsCl (Figs. 5a-j[92]). Only the tunnel cross sections become increasingly narrow, and they change from almost circular to small slit-shaped graphs and finally close to cube edges, typical for the F^* surface (Table 1, Figs. 5g, h). Now the topology of the NaCl surface F^* is a singularity which can only be established accurately with the correct c/a ratio. If one looks again at the last step before reaching the NaCl structure it can be seen that each time six of the cube edges open the one partial space, and six edges open the other partial space. Close to the POPS, as 'inner surface', these atoms touch each other, and here the outer electron shells are located, which easily can be polarized. With minor distortions produced by lattice vibrations tunnels are opened in the NaCl structure, and thus polarization is induced which is able to drive the phase transition.

If c/a is increased and exceeds the value $\sqrt{6}$, then immediate neighboring cube edges open to form puckered layers perpendicular to the trigonal c axis, and a POPS with the characteristic topology of a layer structure develops. Indeed for $c/a > 2.45$ the typical layer structures are found, like e.g. α-$Zn(OH)_2$ (2.51), Bi (2.61), Sb (2.62), As (2.81), α-Ga_2O_3 (2.70) etc. The structure of bismuth together with the POPS R^* ($c/a = 2.61$) is shown in Figure 5j. The correlation between structure and surface requires no further comments.

By maintaining the cubic symmetry a continuous transition can be demonstrated for the POPS P^* and Y^{**}. For this one generates in the space group $P2_13$ with the PK $FY1xxx$ according to ($FY^{(+)}_{(4a)}[x]$, $FY^{(1+)}_{(4a)}[x+1/2] \wedge FY^{(1-)}_{(4a)}[x+1/4]$, $FY^{(1-)}_{(4a)}[x+3/4]$). The transition occurs by the selection of x. P^* develops for $x = 0$, the gyroid Y^{**} for $x = 1/8$. The point configurations change from a F-type into a Y-type, and at the same time the tunnel system of the resulting POPS continuously changes from a six-armed (P^*) into a three-armed (Y^{**}). In Figures 5k-p it can be seen clearly how the F^*Y^* surfaces change little by little and finally lock into the higher symmetric POPS. The generating operation by the way is a remarkable structural chemical procedure. By variation of x the components of an interpenetrating fourfold rod packing, that is non-crossing

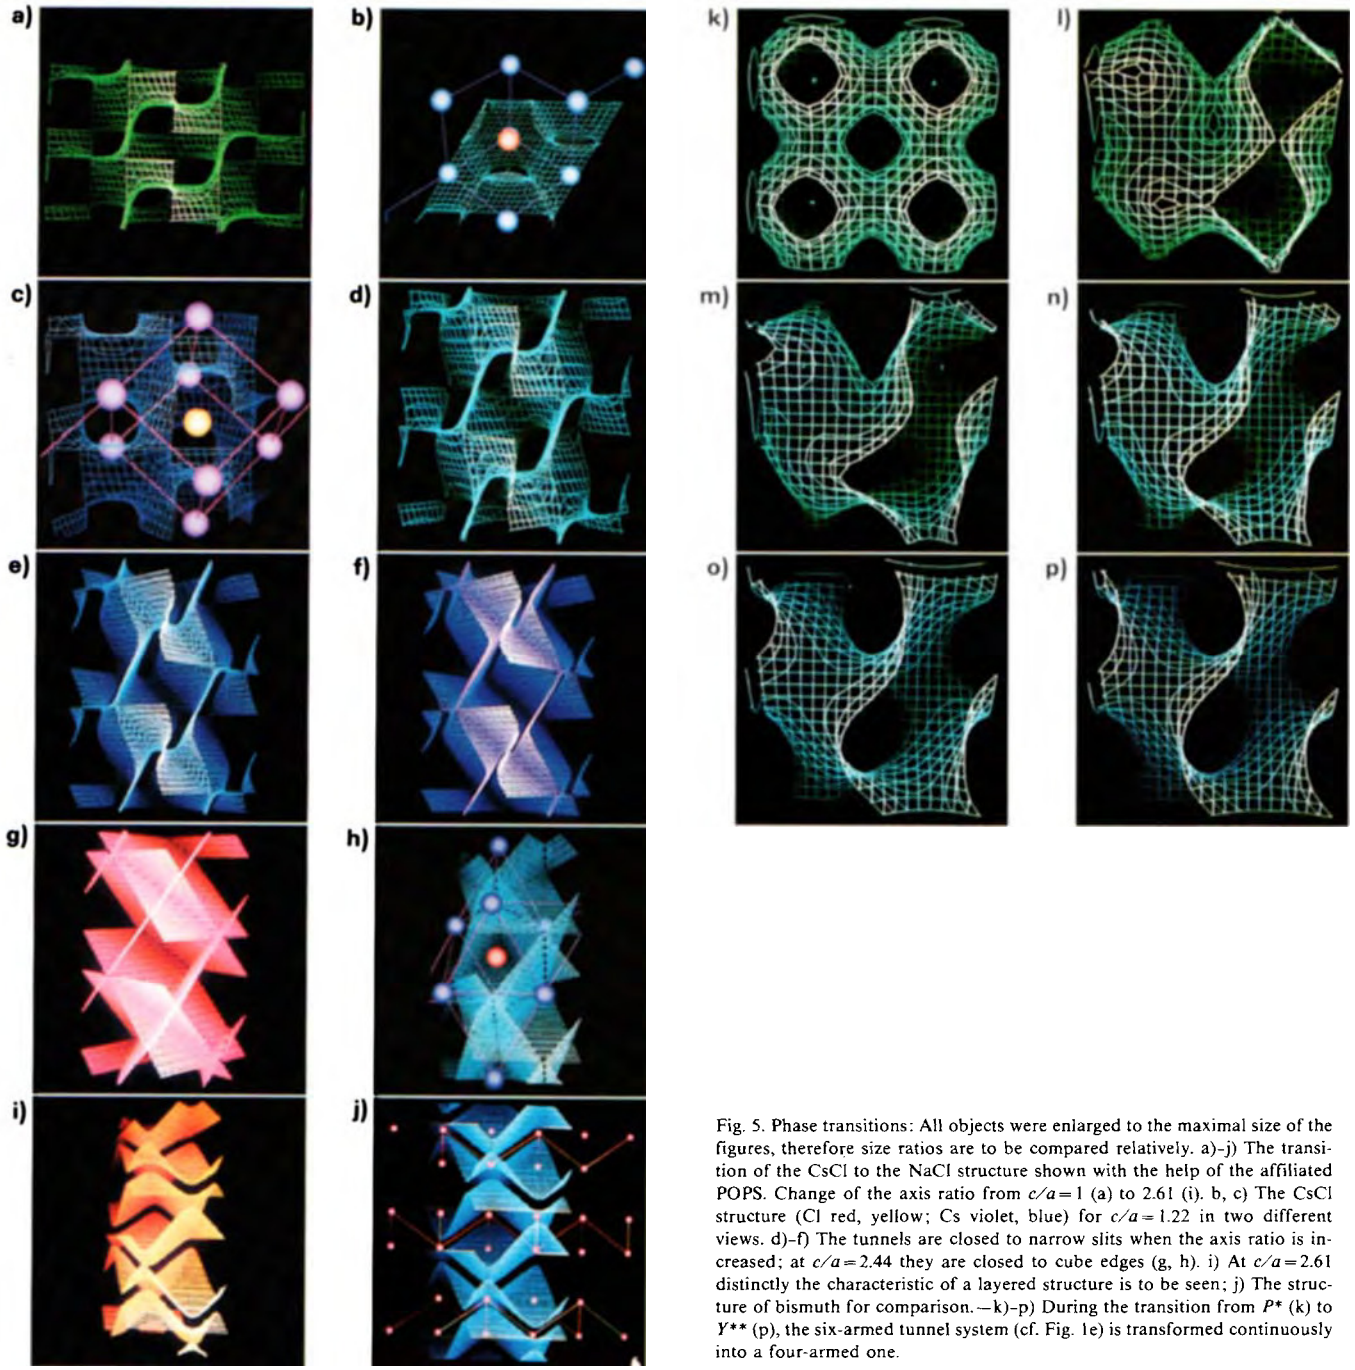

Fig. 5. Phase transitions: All objects were enlarged to the maximal size of the figures, therefore size ratios are to be compared relatively. a)–j) The transition of the CsCl to the NaCl structure shown with the help of the affiliated POPS. Change of the axis ratio from $c/a = 1$ (a) to 2.61 (i). b, c) The CsCl structure (Cl red, yellow; Cs violet, blue) for $c/a = 1.22$ in two different views. d)–f) The tunnels are closed to narrow slits when the axis ratio is increased; at $c/a = 2.44$ they are closed to cube edges (g, h). i) At $c/a = 2.61$ distinctly the characteristic of a layered structure is to be seen; j) The structure of bismuth for comparison.—k)–p) During the transition from P^* (k) to Y^{**} (p), the six-armed tunnel system (cf. Fig. 1e) is transformed continuously into a four-armed one.

stacks, are shifted.[9] The displacement of the rod shaped components is polar along the four cubic space diagonals. Only at $x = 0$ a *local* cubic symmetry is obtained. In the remaining range $0 < x \leqq 1/8$ only the *global* symmetry is cubic, but the local symmetry is at most trigonal! An interesting example for this transition would be the transformation of the Nb_6F_{15} structure into the Ta_6Cl_{15} structure (which unfortunately has not been observed yet). Although in both structures the M_6X_{12} clusters are linked to six other M_6X_{12} clusters, in Nb_6F_{15} a system of two interpenetrating nets is present, while in Ta_6Cl_{15} all clusters are connected directly or indirectly to a common net (cf. Sections 5.1 and 5.3). The transformation would have to be accompanied by a drastic change of the network but could topologically still be forseeable.

It should be mentioned that a continuous transition from Q^* to P^* is possible. A four-armed tunnel system is transferred into a six-armed one by removal of the intersections in the space partitioners. Both compounds $BaZnO_2$ and $CaTiO_3$ exemplarily show that there are important relations to be discovered between perovskites and defect perovskites with statistical defect distribution on the one hand and ordered and reorganized defect distribution on the other.

Such investigations could become important, if successive cooperative displacements of a large number of atoms (which lie e.g., on the POPS) are to be described by a few parameters, just as are needed for the generation of POPS. A nice example is the investigation of martensitic transformations with the help of D^* and Y^{**} as were carried out

by *Andersson* and *Hyde*.[22] The authors look at the PMS and not the POPS. For the PMS a mathematical transformation exists, the so-called Bonnet transformation,[94] in which no changes of lengths appear on the surfaces, but the angles do. One can think of it as a surface of chain links which doesn't allow compression and expansion (knight's chain mail). The Bonnet transformation is derived from a representation of the surface in the complex Gaussian plane, and consequently in certain cases a further reduction of the number of parameters is possible. In the present case therefore not even the definition of a fixed-point in real space is necessary. That is, during the transformation all the atoms shift at the same time and continuously against each other—apparently a very realistic description of the actual processes.

8. Electron Density and POPS

In structures with small unit cells there are only a few atoms, mostly at special positions. Direct relationships to the POPS and PMS can hardly be seen, because the atoms are often subjected to the high local symmetry and are not able to follow the global forces of the entire arrangement. On the other hand, exactly these structures present themselves for the investigation of very fine structural details, as, e.g., the formation of specific electron density contours of the different atoms under the influence of the symmetry (e.g., in homoemorphic series).

The surfaces F^* and D^* (Fig. 1, Table 1) differ drastically. F^* consists of a space-filling pack of closed cubes—each center of the cubes is therefore surrounded by a closed "cube skin"—while for D^* a four-armed "tetrahedral" tunnel system is typical. AgI and AgBr appear in two modifications, namely the NaCl structure and the ZnS structure.[95,96] How will the electron density distribution adapt to both of these crystal fields? 50 years ago, *Brill* et al. carried out directive experiments[97] and until now in principle nothing has changed in their statement. In the NaCl structure essentially spherical electron densities are found around the atoms (Fig. 4g) and this corresponds to the concept that the atoms are optimally shielded from each other and are surrounded by a closed POPS (F^*). In contrast to that the compounds having the ZnS structure (blende) clearly show a direction-dependent density distribution,[95] which as expected extends in the direction of the tunnel opening of the D^* surface. In this connection the inspection of the valence electron densities obtained in quantum mechanical calculations is impressive for such analogues of the diamond structure and its partial structures (Si (Fig. 4j), LiAl (Fig. 4l), LiAlSi,[98–101] LiZnAs).[102] In all cases the electron density on the short connection lines (chemical bond) is increased but very differently according to height and shape. This is to be expected because of the substantial differences between the investigated systems. However, the electron density is almost equal or at least more similar on the interstitial range for all the compounds (Fig. 4) and its progress is as if the electron density was modelled onto the D^*-surface in this range. Obviously there are areas in the structures in which the global overall symmetry gains the greater influence over the localized central forces of the atoms. How strong this collective effect finds its expression in different structures can't be estimated yet.

However, one thing seems to be well established, namely that structures with a trigonal-prismatic arrangement preferably 'house' d-electrons. We will illustrate this with the example Cs-IV, a high pressure modification of cesium. At a pressure of 44 kbar a tetragonal structure with the relative volume $V/V_0 = 0.39$ is formed,[103] in the picture of *Biltz*'s volume increments, this corresponds to $Cs^{\oplus}$.[104] Despite the enormous collapse in volume, none of the usual 'dense packings' are realized, but a packing of trigonal prisms directly comparable to the arrangement of the Th atoms in α-$ThSi_2$. In their publication the authors themselves recognized neither the trigonal prisms nor the connection to α-$ThSi_2$. An extensive quantum mechanical treatment shows that Cs with this curious structure has no electrons in s-states any more[105] but has transformed into a d^1 metal. The distribution of the valence electrons is really surprising (Fig. 4m): The areas with highest density are *not* located in the proximity of the Cs core but have the form of bent tubes (caterpillar shape) crossing the centers of the prisms. The highest accumulation is found on the square faces and at the centers of the prisms. This distribution shows a striking reference to the α-$ThSi_2$ structure, in which the electronegative Si atoms form a threefold bonded framework which exactly reproduces the topology of the electron density distribution of Cs-IV (Fig. 4m). Maximum densities are found at the centers of the Si–Si bonds in α-$ThSi_2$ and where the Si atoms are located. From this simple electronic system one gets the impression that trigonal-prismatic arrangements of atoms generate optimal positions for electrons, which are "localized" in the centers or on the square faces of the prisms respectively. Finally, the symmetry adapted POPS ${}^{c}D^*$ ($c/a = 3.73$) in addition presents the three-dimensional topological model for exactly this peculiar density distribution—it contains a three-armed tunnel system and separates the $Cs^{\oplus}$ ions from their valence electrons!

In a broader sense this description implies the concept of understanding this Cs modification as cesium electride $Cs^{\oplus}e^{\ominus}$. Perhaps one has to take into consideration that despite high pressure, no optimal packing of the atoms is reached, because additional quasi-particles need appropriate coordination polyhedra and therefore take part in determining the structure. Apparently the electrons are more strongly localized in Cs-IV than in α-Cs, an observation which demonstrates clearly that with increasing

Fig. 6. Stereo representations. a) The structure of garnet, $Ca_3[Al_2Si_{12}O_{12}]$ (Ca red, O light blue, Si inside the green octahedra, Al inside the green tetrahedra), consisting of two interpenetrating partial structures, which are centered by the Y shaped graph (violet) and which are separated by the surface Y^{**} (yellow and light blue side of the surface, respectively). b) One chain of the double helix in α-amylose (C pink, O orange, H small pink spheres) and a section of the Q^* surface (green, blue). c) The structure of $Li_{14}MgSi_4$ is partitioned by the S^* surface into a yellow and a blue labyrinth in which Li (green), Mg (orange) and Si (red) lie. The silicon atoms are located above the flat points of the surface. d) The structure of Ta_6Cl_{15} and the surface Y^{**}. The Ta atoms (red) form octahedra (black), which are linked by one type of the chlorine atoms (green) to a three-dimensional network. The other Cl atoms (dark blue) mold Y^{**} in the form of a non-euclidean sphere packing.

pressure not necessarily the stronger degenerate (metallic) state is favored.

As already mentioned from the adaption of certain structure fragments to the POPS it can be derived that in this area predominantly the highest occupied orbitals (HOMO) are located.[6] Once again we go back to the structure of $Li_{21}Si_5$ (cf. Section 5.2 and Figs. 2i-l[55]) which is fragmented by the D^* surface. By application of the Zintl-Klemm rule in the usual form, according to $[Li_{22}Si_4]^{4\oplus}$ and $[Li_{20}Si_6]^{4\ominus}$ two electrons remain in the first cluster, which can not be placed into Si states.[55] Because of these electrons metallic conductivity would be expected. Quantum mechanical cluster calculations have shown that these excess electrons are in fact (de-)localized on the surface of the cluster in a *cage orbital* over the outer Li atoms.[106, 107] Exactly these Li atoms lie on the correctly scaled D^* surface, which is the topological space partitioner. Therefore it is definitely proven that the weakest bonded electrons (the cage orbitals are highest in energy) essentially are localized around this surface. At this time it is emphasized again that the POPS of type 1 like D^* represent a higher symmetry than the overall structure actually has. In this respect one might as well think of a symmetry conditioned stabilization of the cage orbital.[6]

Band structure calculations for the structure of $Li_5Mg_{12}Al_{12}$ show (cf. Section 5.1) that the electrons essentially occupy the Al states and the highest occupied states substantially mediate the Mg-to-Al interactions and are therefore located between the Al and Mg atoms. This is again the interstitial area which topologically follows the P^* surface.[6]

Finally, another remark about CsCl and β-AgI (cf. Sections 5.1 and 6). For both structures imbedded in P^* it equally applies that the electrons feel the smallest potential and thus experience the weakest bond on or close to the POPS P^*. This means that the highest occupied states in CsCl as well as those in β-AgI are spatially to be expected where P^* partitions the space. In the first case this is caused by the balance of the attractive forces, $Cs^{\delta\oplus}$–$Cl^{\delta\ominus}$, in the second case by those of the repulsive $I^{\delta\ominus}$–$I^{\delta\ominus}$. We assume that the characteristic partition of the space in directions of symmetry conditioned different qualities, even for complicated realistic potential conditions, maintains the topological features of the POPS. This means directions distinguished by tunnels are different in their structural-chemical meaning, e.g., from such which are perpendicular to the POPS. Nature uses this discrimination of the different directions for an optimal arrangement of different interactions.

In any case it would be interesting to carry out an analysis of the spatial distribution of the HOMO's. Their result possibly gives preference to one or the other description.

9. Epilogue

The experiences in this relatively new field are still limited, and a systematic investigation of the structures of solids is out of the question. However even the kaleidoscopic glance into the world of collective forms of organization, which is gained from the investigation carried out up to now, already permits a few general statements.

1. Important knowledge is gained from the interplay between periodic potential surfaces and chemical structures namely the following: Apparently from the threefold infinite set of positional parameters *xyz* Nature chooses only this small subset, which lies in the close spatial area of the POPS, and only in a few special cases in the centers of the labyrinths. It still has to be examined if this phenomenon can be used for the derivation of phase relationships between structure factors. Relevant investigations are already under way.[108]

2. The importance of POPS (PMS) in structural chemistry results from the natural separation of different interactions in collective chemical structures. Such spatial separations are typical for molecules (intra-insular covalence, van der Waals skin) and can be recognized in cluster compounds, in which the covalent intra-cluster interactions can be distinctly spatially delimitated from the localized inter-cluster bonds or from the ionic inter-cluster interactions. Crystals of molecules and cluster-anions and cluster-cations have in common that the intra-insular interactions are based on non-directional ("delocalized") central forces of the van der Waals type or Coulomb type, respectively. In both cases the demarcations to the interstitial space are formed by the lone electron pairs of the substituents or the outer ligands, respectively. In metallic phases with the formation of clusters, there is reason to believe that the weakest bound electrons populate just these interstitial areas.[6]

3. One finds that distinguished regions are centered by the POPS, e.g. double layers, where either especially strong (covalent, ionic) or especially weak interactions (metallic, van der Waals) appear in the overall structure. Therefore POPS serve as topological concepts for structural basic models or even as concept for space partitioner of structures.

4. As a rule the majority component forms the inner surface (POPS, PMS) in a structure, where stoichiometry and space requirements play an important role. Therefore, for the formation of interpenetrating structures, it can be considered that even with suitable symmetry certain boundary conditions have to be fulfilled. The conservation of sufficient atomic distances between the interpenetrating partial structures is absolutely necessary. The more atoms take part in building the net-forming units (Nb_6F_{15}) the easier it is. In small structures this can only be achieved, if simultaneously the majority component provides the smaller atoms (Cu_2O, but not cristobalite SiO_2).

5. A few words about the curvature in structures: The question whether everything is curved will of course always be asked. A glance at the phenomena of Nature teaches us very quickly that the construction of curved structures is actually the norm, and for the formation of linear or plane arrangements considerable efforts are needed. A two-dimensional plane form needs exact relationships of radial and lateral extensions (growth rules). In the language of interatomic distances of a net this means exact relationships for all vectors. A plane NaCl net is only obtained for $q = d(\text{Cl-Cl})/d(\text{Na-Cl}) = \sqrt{2}$. However, in the free interplay of the forces deviations like $q < \sqrt{2}$ (surface of positive curvature; spherical cap) and $q > \sqrt{2}$ (surface of negative curvature, "pleated skirt"; PMS) are more likely. An in-

structive experiment is the pasting of five, six, seven etc. equilateral triangles around a common center. In crystalline compounds the translation period (elementary cell) forms the outer frame of a net. Only if this frame is small $q=\sqrt{2}$ can not be avoided. Therefore, only structures with very small translational periods are typical collectives: Here, the individual has no chance and even the electron density has to obey. In a natural way larger unit cells give space for free development to the variety of curved structures.

Chemistry is alive and essentially profits from the creative intuition as a successful strategy as well as from the pronounced feeling of a chemist for compounds and their structures, which even enables him to see electrons. Our contribution to this is the partition of structures by means of non-euclidean periodic curved surfaces, which separate fragments from each other and at the same time connect them. In view of their chemical meaning they can be analyzed as structure increments and therefore serve for a better understanding of the collective laws. These surfaces express the translational symmetry and play an important role in the hierarchy of the organization of organisms, comparable with the homoetic genes in biological systems. These determine, e.g., *where* legs grow, but have nothing to do with the growth of organs. Quite analogously, in crystalline phases the translational symmetry determines *where* building units lie and has nothing to do with the construction of the units. With the application of periodic potential surfaces to crystal structures we believe that we have found a new, strong strategy for an understanding of larger correlations in structures and for the interpretation of their properties. It helps and inspires us daily, hourly—may it be of use!

We would like to thank Dipl.-Chem. M. Oehme for the calculations of the phase transitions, Dr. R. Wedig and B. Koerner for extensive help in setting up the computational facilities and Mrs. C. Fowler for typing this manuscript. Special thanks are addressed to Prof. S. Andersson for numerous fruitful discussions on firm (diagonal support) and on uncertain grounds (not only around Öland) and to Prof. W. Jeitschko for sacrificing his kitchen for wet mathematics. The incomparable support of our work by the Fond der Chemischen Industrie is gratefully acknowledged.

Fluorides of Copper, Silver, Gold, and Palladium

By Bernd G. Müller*

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

Fluorine, by far the most reactive of the non-metals, is capable of forming a large number of compounds with nearly all other elements (exceptions (so far): He, Ne, and Ar), even under comparatively "mild" reaction conditions. These compounds usually differ markedly from those of the heavier halogens in composition, structure, and chemical and physical properties. Thus, for example, it is generally quite easy to prepare fluorides containing elements in high oxidation states (often their maximum), as in AgF_2, $CsAgF_4$, PdF_3, $CsAuF_6$ etc., whereas the corresponding chlorides, bromides or iodides are in many cases (still) unknown. Conversely, the synthesis of fluorides containing these elements in middle or low oxidation states often meets with considerable difficulty, even where it is possible at all, as, e.g., in the case of CuF, AuF, PtF_2, SeF_2. Finally, there are also some examples of compounds MX_n, which with X = F are stable, but with X = Cl are unstable or decompose easily (e.g. $CoF_3/CoCl_3$, VF_4/VCl_4, $PbF_4/PbCl_4$, $AsF_5/AsCl_5$). Consequently, fluorine compounds are of great general interest.

1. Introduction

The nineteen-fifties heralded a new phase of development in fluorine chemistry. It began, on the one hand, with the preparation of complex transition metal fluorides (and oxides) in high and in some cases previously unknown oxidation states (K_2NiF_6, K_3CuF_6, $CsAgF_4$ etc.),[1-3] first by *W. Klemm*, then later by *R. Hoppe* and co-workers, and, on the other, with the use of BrF_3 as a solvent and fluorinating agent (e.g. by *H. J. Emeléus* et al.). It culminated in the (independent) discovery of the first noble gas fluorides by *N. Bartlett* ("$XePtF_6$")[4] and *R. Hoppe* et al. (XeF_2)[5] in 1962. In the following years it became possible, using more sophisticated methods of fluorination (e.g. high pressure fluorination, or the use of KrF_2 as a fluorinating agent) to synthesize further compounds of unusual constitution, some likewise in previously unknown oxidation states, for example $Cl_6^+PtF_6^-$,[6], $KrF^+AuF_6^-$,[7] and Cs_2CuF_6,[8] (see also Refs. [9, 10]).

However, despite the remarkable progress that has been made regarding preparative methods, our knowledge of this area of inorganic fluorine chemistry, where single crystal X-ray diffraction measurements are essential for the unambiguous characterization of the constitution and structure of the compounds, is still only fragmentary. Up to now such investigations have mainly been restricted to thermally stable, involatile and, in most cases, ionic fluorides which are capable of being grown in the form of single crystals from the melt, with air and moisture excluded if necessary, and using flasks or crucibles of appropriate materials (the Bridgman/Czochralski technique and its variants).[11] Only seldom is it possible to prepare anhydrous monocrystalline fluorides without decomposition:

1. from concentrated HF solutions (e.g. Cs_2PtF_6, K_2MnF_6,[12, 13] or under hydrothermal conditions;[14]
2. by crystallization from anhydrous HF as solvent (e.g. $XeF_4 \cdot SbF_5$,[15] $H_3O^+TiF_5^-$,[16] $AgF_2 \cdot 2SbF_5$[17])—a method whose application is limited by the sparing solubility of many (ionic) fluorides in HF;
3. by growing crystals from the melt,[18] either by transport or by gel crystallization;[11]
4. by sublimation without decomposition, under an inert atmosphere (e.g. Ar), under fluorine, or in a high vacuum (e.g. RhF_5,[19] AuF_3,[20] $(XeF_5)_2^+PdF_6^{2-}$[21]).

Very few examples of the preparation of single crystals of fluorides which are easily decomposed thermally (especially in the absence of F_2) have thus far been reported in the literature.

As already known, the structures of many metal fluorides can be derived from those with the most densely packed anions, as a result of their essentially ionic bond character, with the cations distributed between the available sites (usually octahedral, less frequently tetrahedral) in a usually ordered manner corresponding to the molecular formula.

Following this simple building principle, many classes of compounds can be assigned to a small number of basic structural types. Thus, for example, in the VF_3 structure vanadium can be replaced by any of the similarly charged ions (Al^{3+}, Ga^{3+}, Ti^{3+}, Cr^{3+}, etc.), or by M^{II}/M^{IV} ($\triangleq M^{II}M^{IV}F_6$ with M^{II} = Zn, Ni, Co, ..., M^{IV} = Ti, Sn, Pd, Pt ...), or by M^{I}/M^{V} ($\triangleq M^{I}M^{V}F_6$ with M^{I} = Li, Na ..., M^{V} = Sb, Pt ...)[22] without altering any basic structural features.

The same holds true for complex fluorides, an example being the $RbNiCrF_6$-type structure derived from the pyrochlores.[23] Here substitution of other metals in place of Rb, Ni and Cr gives a remarkably large number of new quaternary fluorides with the same structure and arrangement of cations. With fluorides, therefore, one is often in

Heinrich-Buff-Ring 58, D-6300 Giessen (FRG)

the fortunate situation of being able to dispense with single crystal measurements and to limit oneself to interpreting the generally less informative powder diffraction data, providing an exact single crystal structure determination is already available for at least one example.

There are, nevertheless, certain exceptions which do not allow such simplified analogies and isostructural considerations. These are the cases where one or more of the cations involved in building up the structure require a less symmetrical arrangement of the ligands, owing to the existence of e_g states with odd-numbered occupancy (Jahn-Teller effect). Those which are relevant for fluorides include Cr^{2+} and Mn^{3+} ($3d^4$ "high spin" configuration: $t_{2g}^3e_g^1$), Cu^{2+} and Ag^{2+} ($3d^9/4d^9$ configuration: $t_{2g}^6e_g^3$), and Ni^{3+}, Cu^{4+}, and Pd^{3+} ($3d^7/4d^7$ "low spin" configuration: $t_{2g}^6e_g^1$).

Unusual structures are sometimes also found in the case of fluorine complexes of Cu^{3+}, Pd^{2+}, Ag^{3+}, and Au^{3+} (nd^8 configuration, where $n=3, 4, 5$), as a result of the rarely occurring coordination number C.N. $[M^{n+}]=4$ in relation to fluorine (with F^- ions in a square planar configuration around the central ion).

Because of these special structural characteristics, such fluorides have already been the subject of many of the early studies, but there are some further reasons why the fluorides of the coinage metals seem a particularly attractive subject for investigation:

1. The elements Cu, Ag, and Au lie on the border between transition metals and Main Group metals ("meta-metals"), but are "true" transition metals in the narrower sense insofar as, in contrast to the elements Zn, Cd, and Hg, d-electrons can still be involved in their bonding.
2. They are the only elements (apart from, in the widest sense, a few lanthanoids, e.g., Ce, Pr ...) which occur in oxidation states higher than that corresponding to their position in the Periodic System of the Elements, i.e. their outer electron shell configuration.
3. The individual physical and chemical properties of the elements differ more widely, and are less susceptible to extrapolation than in any other group of the Periodic System—one need only consider their chemistry in aqueous solution.
4. The fluorides are of particular importance insofar as they are the only compounds in which certain oxidation states can exist.

An interpretation of the, in some cases remarkable, physical properties (magnetism, spectra, conductivity etc.) of these compounds requires a detailed knowledge of the structures; consequently, careful single-crystal measurements are essential.

However, there are usually considerable difficulties in preparing pure microcrystalline samples of the fluorides of interest in this connection, and the production of suitable single crystals poses even greater problems. The following report describes some methods for synthesizing thermally less stable fluorides of the coinage metals and palladium, and outlines the associated problems (e.g. side reactions and decomposition of products) that are commonly met with; it also gives an overview, mainly in the form of tables, of our present state of knowledge of this area of chemistry.

2. Copper Compounds

Copper occurs in combination with fluorine in the oxidation states +1, +2, +3, and +4, with the +2 state as clearly the predominating one. Fluorine complexes of mono-, tri- and tetravalent copper are listed in Table 1. Because of the very large number of known copper(II) compounds, Tables 2 and 3 (p. 1084) list only a few representative examples chosen more or less arbitrarily, but limited to those whose structures have been determined on single crystals.

It is surprising that, apart from $CuAsF_6$,[24] fluorides of Cu^I (including CuF itself) are so far totally unknown, despite numerous attempts at producing them. This contrasts with copper(I) oxides, e.g. Cu_2O, $K_4[Cu_4O_4]$,[35] or chlorides such as CuCl and $KCuCl_2$. Copper differs markedly in this respect from the homologous element silver, in which it is well known that the +1 oxidation state predominates, and not only as regards its chemistry in aqueous solutions. Copper is also unique amongst the coinage metals (even though based on only a few examples) in its ability to form compounds having the +4 oxidation state, namely $M^I_2[CuF_6]$, where $M^I=$(K), Rb, Cs.[8,29,30,31] These are of particular interest from the structural chemistry standpoint in having (according to original powder diffraction data) a slightly distorted orthorhombic (and from more recent single-crystal data tetragonal) structure of the same type as K_2PtCl_6. Thus, single crystal studies are necessary in this case to determine the Cu^{4+} coordination sphere more exactly (d^7 "low spin/high spin" configuration), and to give a deeper understanding of other features, e.g. magnetic properties. Understandably, however, their preparation is by no means easy. This is related to the fact that pure samples of, for example, Cs_2CuF_6, can only be obtained by (in solid reaction terms) rapid conversion of, e.g., Cs_2CuF_4 using F_2. If one attempts prolonged annealing (in order to grow crystals), decomposition occurs by uncontrollable and incompletely understood mechanisms which are affected by pressure, temperature, and the material of the crucible. Some of the possible products from side-reactions or decomposition are indicated in Scheme 1.

One is therefore limited to either carrying out experiments over longer periods at relatively low temperatures, or to repeated annealing for short periods (at higher temperatures) on the same sample. This also applies for all other compounds which can only be prepared under similar conditions. Using the second (rather laborious) method, it has recently been possible to prepare single crystals even of Cs_2CuF_6, and to determine the structure in detail.

The basic problems involved in synthesizing single crystals of thermally sensitive, highly reactive fluoro-complexes of the transition metals (especially those containing alkali metals or alkaline earth metals) are already evident from the above discussion, namely the large number of possible side-products or decomposition products, and of reactions between one or more components (especially CsF) and the walls of the vessel during lengthy experi-

Table 1. Copper fluorides with oxidation states +1, +3, +4.

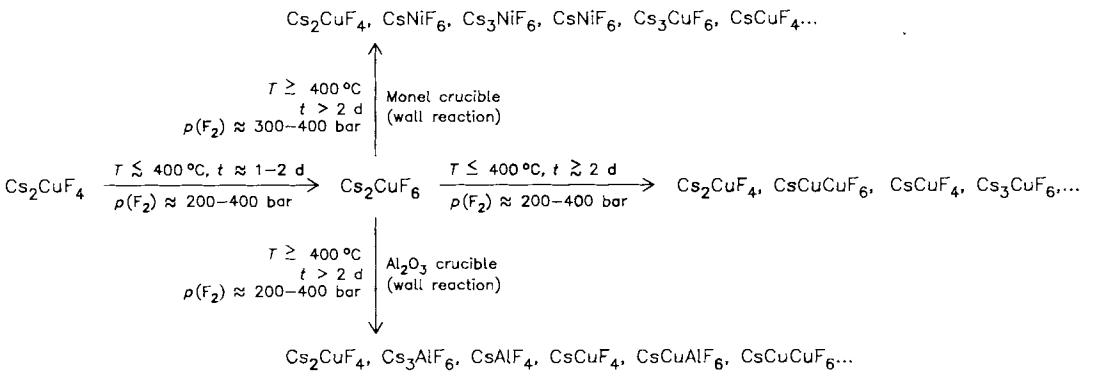
[a] Interatomic distances found from powder data, where these are given, are by their nature inaccurate (except in structures without F parameters, eg. AgF), and are often based on analogy considerations, or (occasionally) on MAPLE calculations. The same remarks apply to the rest of the tables. [b] The structures which have been postulated for these and other compounds of the form $M^I_3M^{III}F_6$ (M^I = K, Rb, Cs; M^{III} = Ga, Fe, Co ...) are in need of correction, as shown by a number of studies (see, for example, [26, 32-34]). [c] Isostructural type: $M^I_2M^ICuF_6$, light green to beige (M^I = K, Rb, Cs; M^I = Li, Na, K, Rb) [26]. [d] Single crystal data available for this compound.



Scheme 1. Side-reactions in attempts to prepare Cs_2CuF_6 single crystals.

ments. Further, a reduction in F_2 partial pressure (as a result of fluorine being lost through reaction with the autoclave material) can cause thermal decomposition of those compounds which are particularly sensitive.

Also, owing to the fact that practically all the fluorides of interest here are insoluble (without causing hydrolysis or decomposition) in the usual solvents, and that other more appropriate methods of purification such as distillation or sublimation are not available, it is impossible in principle to remove impurities from samples after preparing them.

The fluorine complexes of trivalent copper are generally much more stable, and have consequently been more thoroughly studied. A notable example is the successful preparation of single crystals of Cs_2KCuF_6 in closed copper crucibles (under argon!). In this case the basic elpasolite structure of the complex evidently permits an "optimal" arrangement of the individual ions (stable matrix with a high lattice energy) which gives exceptional thermal stability.[27] Other examples too support this conclusion.

In addition to these, copper(III) fluorides are known, namely $Cs[CuF_4]$[28] and $CsCuCuF_6$,[26] but these can only be made under more extreme conditions (F_2 pressures above 400 bar), and are correspondingly lacking in stability. The existence of $Cs[CuF_4]$ (isostructural with $K[BrF_4]$) is "reassuring", since in this respect copper follows the behavior of the two other coinage metals, which in their +3 oxidation states with fluorine show predominantly (for Ag^{3+}) or exclusively (for Au^{3+}) a coordination number of 4, with a square planar arrangement of F^- ions around M^{3+}.

$CsCuCuF_6$ is interesting as regards its structural chemistry, being a very sensitive compound of mixed valency Cu^{2+}/Cu^{3+}. According to powder diffraction data it is isostructural with $CsNiNiF_6$,[36] but the results do not allow one to determine either the positions of the Cu^{2+} ($3d^9$, Jahn-Teller effect) and Cu^{3+} ions or the F parameters (proximity to the strongly scattering Cs^+ ions) and thus to calculate reliable values for the distances $d[Cu^{n+}\text{-}F]$. Nor is it easy in such cases to propose plausible structural mod-

els, as the structures of $CsPdPdF_5$,[37] $RbCuPdF_5$,[38] and $CsAgFeF_6$[39] show, and single crystal data are therefore essential.

In general, a considerable amount of knowledge exists concerning the structure and constitution of copper(II) fluorides, which, as a result of their $3d^9$ configuration, differ markedly from compounds of similar formula (so far as these are known) formed by the adjacent elements nickel and zinc. The reason for this is that CuF_2 and fluorine complexes of Cu^{2+} (compared with Cr^{2+}, Mn^{3+}, or Ag^{2+} compounds) can usually be prepared without difficulty, even as single crystals, and there exists a correspondingly large amount of exact (single crystal) structural data—see Tables 2 and 3. Ternary and quaternary systems containing Cu^{2+} are usually obtained by annealing suitably chosen mixtures in copper bombs or Au/Pt tubes (welded under Ar). The only exceptions to this are compounds in which one or more of the cations involved (in polynary complexes) is thermally sensitive, that is decomposes with change of oxidation state upon heating, or can be readily split off in the form of a binary volatile fluoride. This is the case in the $CuMF_6$ series (M = Ti, Sn, Mn, Cr, Pt ...), for example, and as a result it has only recently been possible to determine the structure of $CuPtF_6$ single crystals.[38] The synthesis of $CuPtF_6$ must be carried out in a closed autoclave, because of the volatility of PtF_5 and PtF_6; however, for the same reason too high a pressure of F_2 must be avoided. Once made, however, $CuPtF_6$ has—apart from its

susceptibility to hydrolysis—surprisingly good thermal stability, and single crystals can be grown in welded platinum tubes (under Ar) at about 750 °C (!).

Generally speaking, the coordination sphere of Cu^{2+} is of most interest. Usually one expects this to occupy an elongated octahedral environment with a coordination number C.N.$[Cu^{2+}]=4+2$, but in the limiting case C.N.$[Cu^{2+}]=4$ (square planar). Here, though, it is to some extent a "philosophical" question as to whether one describes the environment as (still) octahedral or (already) square planar—the transition is a gradual one. Numerous examples are known—Tables 2 and 3 list just a few, with the corresponding interatomic distances. In addition, however, quite a few fluorides have been reported, mainly in recent work, in which Cu^{2+} has been found to be in an "abnormal" coordination state, or in which different coordination states occur alongside each other in the same compound. Abnormally coordinated are, e.g., $KCuAlF_6$[44a] and $KCuCrF_6$[44b] with C.N.$[Cu^{2+}]=2+4$, and $FCu[AuF_4]$[43] and $CuPtF_6$[38] with C.N.$[Cu^{2+}]=2+2+2$; mixed coordination is found in $Cs_7Cu_6F_{19}$[47b] with C.N.$[Cu^{2+}]\simeq 3+2+1$; $2+2+2$; $1+1+1+1+1+1$ (this assignment is, of course, arbitrary—but some evidence is obtainable from ECoN calculations[51, 52]). Other phases exist in the CsF/CuF_2 system besides $Cs_7Cu_6F_{19}$; in this case Cu^{2+} resembles its neighbor element nickel, which similarly forms numerous compounds with CsF (cf., e.g., Ref. [53]), rather than the homologous element silver, for which only $CsAgF_3$[54] and Cs_2AgF_4[44] are known up to now.

The copper fluorides, considered as a whole in comparison with those of the other coinage metals, remain the most thoroughly characterized, especially those of Cu^{2+}.

The surprising results that are occasionally found (especially concerning the stoichiometry and environment of Cu^{2+}, as for example in $Cs_7Cu_6F_{19}$ or $FCu[AuF_4]$) on the one hand, and some yet unsolved problems (e.g. regarding the existence of copper(I) fluorides, or the exact structures of Cs_2CuF_6 and $CsCuCuF_6$) on the other, show that it is certainly worthwhile to take a fresh look at problems regarded as already solved, or at systems believed to be fully understood.

3. Silver Compounds

Silver, like copper, shows valencies of +1, +2, +3 and (formally) +4 in its fluorides. In contrast to copper, however, compounds of Ag^+ are by far the most stable, while those in the remaining oxidation states are all very unstable thermally (in the absence of fluorine), and are accordingly difficult to prepare as pure samples or single crystals.

In addition to these "chemical" differences one also often finds, in comparable systems with the same oxidation states, differences in constitution and structure, and associated differences in the coordination geometry at the central ion.

Table 4 lists a few selected silver(I) compounds, together with all the known fluorides containing silver in the +3

Table 4. Silver fluorides with the oxidation states (+0.5), +1, +3, +4 (+3/+5).

[a] Single-crystal data measured for this compound. [b] Isostructural are $Ag_2M^{II}M^{III}F_7$, colorless (M^{II} = Mg, Co, Ni ...; M^{III} = Al, Ga, Sc, In ...) [60]. [c] Isostructural are M^IAgF_4, yellow (M^I = Na, Rb) [64].

and +4 (or +3/+5) oxidation states, insofar as these have already been described in detail.

Ag_2F is anomalous and is unique in its stoichiometry, being the only subfluoride so far known. Ag_2F can be prepared, for example, by reaction of AgF with finely divided silver, or by electrolysis of AgF in HF; it is obtained as bronze-colored platelet-like crystals,[56] and is an electrical conductor. The structure is of the same type as that of *anti*-CdI_2, and consists of alternating Ag double layers (metallic bonds) and intercalated fluorine (F^-) layers (ionic bonding). Ag_2F is thus one of the very few examples of cluster compounds (in the broadest sense) containing F^-. It is reminiscent—with a little imaginative licence—of the suboxides of Rb and Cs,[68] although in these cases $Rb_9O_2^{5+}$ or $Cs_{11}O_3^{5+}$ clusters are present (two Rb_6 or three Cs_6 face-sharing octahedra with an O^{2-} ion at the center of each octahedron).

Fluorides of Ag^+ are (mainly) ionic. As might be expected on comparing atomic radii (for C.N. = 6, $r[Ag^+] = 1.15$ Å and $r[Na^+] = 1.02$ Å[69]), they are often found to resemble the corresponding Na^+ compounds (this is true, for example, for the binary fluorides AgF and NaF). A detailed description of the Ag^+ fluorides in this respect is therefore unnecessary. Furthermore, their preparation does not usually call for any special precautions; they can be obtained (similarly to the copper(II) fluorides, which are entirely comparable in this respect) by heating intimately mixed samples of the corresponding binary fluorides under Ar in sealed Ag bombs or welded tubes. Only the preparation of dry AgF presents some difficulties; direct fluorination of finely divided silver at room temperature (using a 1:10 mixture of F_2 with N_2) has proved to be a suitable method. The presence of some AgF_2 here causes no problems; on the contrary, by evolving fluorine it inhibits the partial decomposition to elemental silver (probably caused by a reaction with the container walls) at high temperatures.

It can further be seen from Table 4 that fluorine complexes of silver in the +3 and +4 (+3/+5) oxidation states are rare; so far, only a few have been prepared as pure samples and studied in detail. Such complexes include, aside from Cs_2KAgF_6,[65] the species M^IAgF_4 (M^I = Na, K, Rb),[64] for all of which there exist X-ray powder data.[64] Also magnetic data are available for Cs_2KAgF_6,[65] and spectroscopic data for M^IAgF_4 (M^I = K, Rb[42]). Other compounds which have been reported[71] are $CsAgF_4$ and "$BaAgF_5$" (or "$Ba[AgF_4]_2$", which is analogous to $Ba[AuF_4]_2$[70]), but no further details of these are yet available.

The purple-red paramagnetic complex Cs_2KAgF_6 (with an elpasolite structure!) occupies a special position, being up to now the only confirmed example of a fluoroargentate(III) with Ag^{3+} being 6-coordinative with F^-. The rest of the silver(III) fluorides, which again are not many in number, contain silver in a square planar environment (C.N.$[Ag^{3+}] = 4$, with the possible exception of AgF_3); this certainly also holds true for $CsAgF_4$, "$BaAgF_5$" ($Ba[AgF_4]_2$), and the recently reported $XeF_6 \cdot AgF_3$ ($= XeF_5^+ AgF_4^-$),[67] all of which are yellow and diamagnetic, with still unknown structures.[*]

Little is known, at least with regard to structure, about the red-brown compound AgF_3, which is by far the most sensitive and most difficult of the trivalent silver compounds to isolate; it is prepared by the oxidation of AgF_2 with KrF_2 in HF (20 °C, 2 d), but the product may still contain some impurities. Its color and magnetic properties indicate an octahedral Ag^{3+} environment, comparable with the isoelectronic Pd^{2+} in PdF_2 (C.N.$[Pd^{2+}] = 6$[72]) rather than (as in the case of the mainly planar fluoroargentates(III)) with Au^{3+} in AuF_3 (C.N. $[Au^{3+}] = 4$[20]). The mixed valency formula $Ag^{2+}[Ag^{4+}F_6]^{2-}$ has also been proposed (somewhat analogous to $PdF_3 = Pd^{II}Pd^{IV}F_6$), although this to some extent conflicts with the findings for Cs_2AgF_6 (here the replacement of Ag^{4+} by Ag^{3+}/Ag^{5+} should explain some experimental results).

For Cs_2AgF_6[66] (obtained as an orange-colored, light-sensitive, and very unstable substance by high pressure fluorination of, for example, Cs_2AgF_4), the formula $Cs_2Ag^{III}_{0.5}Ag^{V}_{0.5}F_6$ appears entirely plausible (the isoelectronic PdF_3 too can be envisaged as a mixed valency compound $Pd^{II}Pd^{IV}F_6$,[73] and Ag^{3+} can also be replaced by Ga^{3+}, as in $Cs_2Ga^{III}_{0.5}Ag^{V}_{0.5}F_6$[66]), but the actual structure, as also in the case of AgF_3, can be clarified only by single crystal studies. It is surprising in this context that it has not yet been possible to obtain any pure Ag^V compounds (such as "$CsAgF_6$"), although $CsAuF_6$[74] and the (isoelectronic) Cs_2PdF_6[75] can be prepared without difficulty at normal pressure ($p_{F_2} \leq 1$ bar).

It is easy enough to emphasize on paper the importance of synthesizing single crystals of these very unstable substances, but putting this into practice may still be only a distant prospect, at least with the techniques currently available. It appears that for these compounds (and also for PrF_4,[76] Cs_2KNdF_7 and Cs_2KDyF_7[77,78] and others) a frontier has now been reached, with further progress hindered by the difficulties of synthesizing single crystals using existing methods. The decomposition (with release of F_2), which already commences at room temperature or slightly above leads one to suspect that the substances described here are already thermodynamically unstable toward decomposition to "low valency" fluorides and elemental fluorine in the temperature ranges specified.

Although AgF_2 was first described more than fifty years ago, and its magnetic properties were also investigated soon afterwards,[79,80] there was for a long time uncertainty about its true nature. At first it was envisaged, by analogy with AgO ($= Ag^IAg^{III}O_2$[81]) as a mixed valency compound ($= Ag^I[Ag^{III}F_4]$), and it was only later shown, by more precise magnetic measurements (combined with a thorough understanding of collective magnetic properties), and by a neutron diffraction structure determination (on powder samples),[82] that silver in AgF_2 is actually in the +2 oxidation state.

Surprisingly, fluorine complexes of Ag^{2+}—in contrast to those of Ag^{3+}[63]—were not synthesized until comparatively recently. Then, however, their intense colors (at least

[*] In the meantime the structure of $XeF_5^+AgF_4^-$ has been determined by a single-crystal structure analysis; as suspected Ag^{3+} has C.N. = 4 and resides in a square planar environment (*B. Zemva*, private communication).

for simple inorganic fluorides, and in comparison, e.g. with copper(II) fluorides), their widely varying magnetic properties, and their individual structural properties with sometimes unusual stoichiometry, stimulated the preparation of further silver(II) compounds in rapid succession (Table 5).

In a few cases it was possible to derive the crystal structures from powder diffraction data (based on isostructural types), while "plausibility" considerations and MAPLE calculations[51] led to "credible" interatomic distances $d[Ag^{2+}\text{-}F]$, and gave the first indications concerning the coordination behavior of divalent silver. As a rule, however, more exact information on structure could not be obtained, and spectroscopic data[83] or magnetic measurements[55] provided little further clarification.

Divalent silver is particularly interesting, at least from the structural chemistry standpoint, for several reasons:

1. Ag^{2+}, with its $4d^9$ outer electron configuration, is like Cu^{2+} a cation in which, owing to the Jahn-Teller effect, the ligands need to be less symmetrically arranged around the central ion (Ag^{2+}) than in other M^{2+} ions of comparable size.
2. In the series Pd^{2+}, Ag^{2+}, Cd^{2+} one finds, as a result of the increase in the radius $r_{M^{2+}}$ (or in the ratio $r_{M^{2+}}/r_{F^-}$), a transition from the rutile structure with C.N.$[M^{2+}]=6$ (PdF_2) to the fluorite structure with C.N.$[M^{2+}]=8$ (CdF_2). $CdPdF_4$,[90] which is (formally) "isoelectronic" with AgF_2, and the isostructural high pressure modifications of PdF_2[91,92] and of AgF_2[91] already crystallize in a CaF_2-type structure with C.N.$[M^{2+}]=6$ (+2), with a highly distorted octahedral arrangement of F^- around M^{2+}; for AgF_2 itself and for the corresponding fluoride complexes one therefore might expect to find (at the transition) an essentially singular structural behavior.
3. Neither binary nor simply constructed complexes (i.e. those in which there is no additional stabilization from organic ligands such as py, bpy etc.) of Ag^{2+} are yet known, and, as is shown by the high redox potential of Ag^{2+} ($\varepsilon_0(Ag^+/Ag^{2+})=1.98$ V in aqueous solution!), they are scarcely to be expected. The highly unstable

[i] Isostructural type: $Ag[NbF_6]_2$, light blue [88] and possibly $AgF_2\cdot 2SbF_5$, green [89].

oxides Ag_3O_4[89] and Ag_2O_3,[93] which have recently been prepared as single crystals by anodic oxidation at low temperatures (about 0°C), do show, however, that oxoargentate(II), or oxoargentate(III) complexes are conceivable. Consequently, if information about the spectroscopic, magnetic or structural chemical properties of Ag^{2+} is required, one has in principle to rely on studies of the corresponding fluorides.

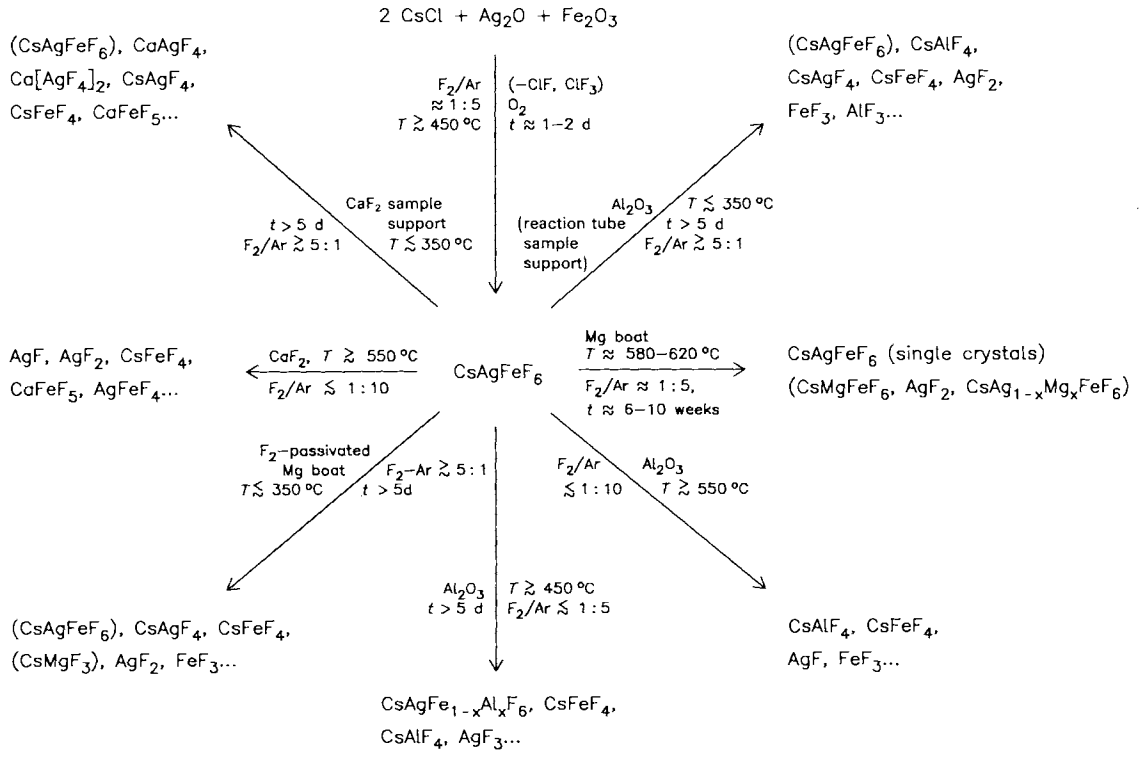
The synthesis of microcrystalline (powder) samples of AgF_2 and complex fluorides of Ag^{2+} is now relatively easy, by direct reaction of suitable starting mixtures with elemental fluorine ("Klemm/Hoppe fluorinations"[94]). Growing single crystals suitable for X-ray structure analysis, on the other hand, sometimes involves considerable difficulties. The reason for this is simple: fluorides of divalent silver decompose with loss of fluorine (in the absence of F_2) at temperatures between 150 and 200°C depending on the particular compound, and, if crystals are required, prolonged annealing (6–10 weeks or longer) at relatively high temperatures (above 580°C, say) under a partial pressure of F_2 (depending on the compound) is necessary. There is, of course, much corrosion of the vessel (with associated impurities and side-reactions) if common materials are used, and it is therefore not surprising that structure determinations from single crystal data have only been successfully achieved in recent times.

The first such success was achieved with silver(II) compounds of the composition $M^IAg^{II}M^{III}F_6$ (M^I = Cs, Rb; M^{III} = Al, Fe).[39] Owing to the high reactivity of MF (wall reactions) and the possibility of silver being oxidized further with the formation of $M[AgF_4]$, careful attention to maintaining correct reaction conditions (F_2 partial pressure, crucible material, temperature) was essential.

It was found that Mg boats "passivated" with fluorine (formation of MgF_2) were especially suitable as sample receptacles, since MgF_2 forms neither mixed crystals nor any kind of ternary compounds with AgF_2, and is also very stable towards other fluorides, especially those of the alkali metals (cf. Scheme 2).

In the first structure determinations carried out on $CsAgFeF_6$, Ag^{2+} was found to have a compressed octahedral environment (an unusual situation for a "Jahn-Teller ion"; cf. Table 5). In order to confirm this unexpected result, the investigations were repeated (with similar results in each case) on $CsAgAlF_6$ and $RbAgAl_{1-x}Fe_xF_6$ (Fe^{3+} being partially replaced in the latter case by Al^{3+} from the corundum boats used!). However, since in parallel with this the same structure was also found in the case of $NH_4Fe^{II}Fe^{III}F_6$[95] (same space group, same occupancy of the corresponding lattice positions, comparable interatomic distances), with no involvement of a cation with d^4 or d^9 configuration in this case, the compression of the octahedron around Ag^{2+} could well be mainly a structural effect. It appears that in both the elpasolites and the pyrochlores (and variants thereof), the Cu^{2+} ion (cf. Table 3) or Ag^{2+} ion adapts to the usually less favorable environment with C.N.$[M^{2+}] = 2+4$, so as to optimize the overall arrangement of the differently charged ions.

This rather vague notion is, however, substantiated to some extent by the existence and structure of $CsPd^{II}Pd^{II}F_5$ and $RbCu^{II}Pd^{II}F_5$. In both these compounds the distribution of all the atoms at the lattice positions corresponds exactly with that in $CsAgFeF_6$ and NH_4FeFeF_6, except that one F^- position remains unoccupied to preserve the electric charge balance. This leads to half the number of Pd^{2+} ions having a square planar configuration with



Scheme 2. Conditions needed for preparing $CsAgFeF_6$ single crystals, with side reactions.

C.N.$[Pd^{2+}]=4$ in relation to F^-, instead of being in a compressed octahedral environment (like Ag^{2+}, Fe^{2+}).[37,38] Figures 1a and 1b show the similarity of the two structures.

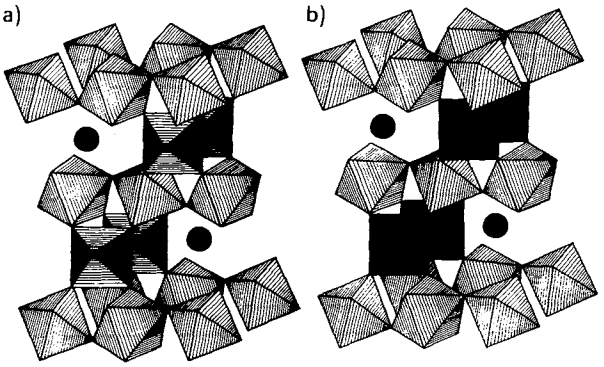


Fig. 1. a) Crystal structure of $CsAgFeF_6$ with chains of $[FeF_6]$ and $[AgF_6]$ octahedra; b) crystal structure of $CsPdPdF_5$ with chains of $[PdF_6]$ octahedra and planar $[PdF_4]$ units.

The synthesis of $Ag_3Hf_2F_{14}$ single crystals is somewhat more difficult, as we here have a phase which is comparatively rich in silver. Accordingly, the compound readily decomposes and annealing must therefore be performed under nearly pure fluorine (cf. Scheme 3). Any small variations in the fluorine concentration above the sample cause partial decomposition with the formation of Ag^+, and the sample melts and "creeps" over the edges of the boat.[87]

The existence of a compound with the composition $Ag_3Hf_2F_{14}$ is quite surprising, since in the case of Cu^{2+}, or the appreciably larger ions Sr^{2+}, Pb^{2+} and Ba^{2+}, under similar conditions one obtains only $M^{II}M^{IV}F_6$ (M^{II} = Cu, Sr, Pb, Ba; M^{IV} = Zr, Hf).[41,96] Its structure too is very unusual, as Ag^{2+} is found to have markedly different coordination numbers at adjacent sites (namely 4+2 and 4+2+2). Consequently, it is possible to selectively replace[87] the first of these two types of Ag^{2+} ions by Cu^{2+}, Ni^{2+}, Zn^{2+} or Mg^{2+} and the other type by Ca^{2+}, Cd^{2+} or Hg^{2+} (although not by Sr^{2+} or Ba^{2+}, which produce bright blue compounds of unknown structure).

This compound, whose structure at first sight appears so complicated, provides a further example of the stability of certain types of ionic structures, which, as was mentioned at the outset, remain essentially unchanged on substituting many different cations. It is therefore not surprising that this structural principle continues to hold true for other compounds of completely different stoichiometry. This is so, not only for $AgPdZr_2F_{11}$ (cf. Tables 5 and 8) and $NaM^{II}Zr_2F_{11}$ (M^{II} = Ag, Pd), formally derived from $Ag(1)Ag(2)_2Zr_2F_{14}$ by replacing $Ag^{2+}(1)$ by Na^+ and "eliminating" AgF_3), but also for $CaMnF_5$,[97] and for $NaMn_3F_{10}$,[98] as can be seen from Figures 2–5.

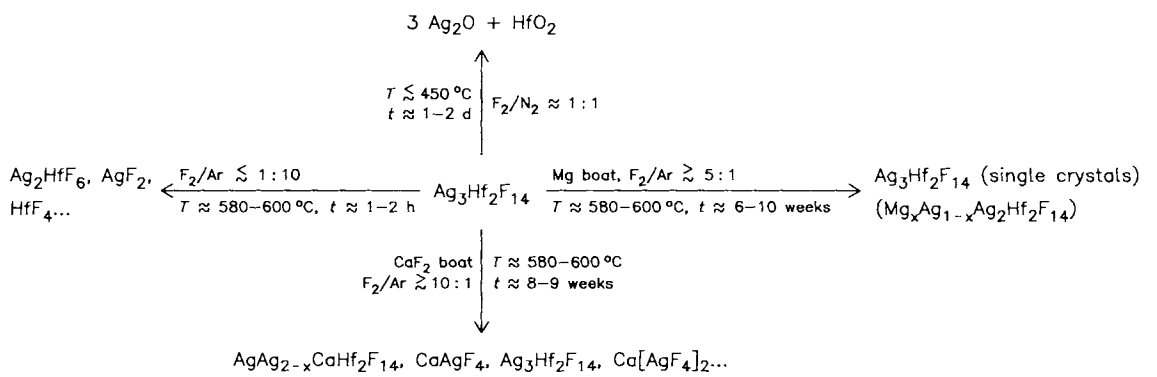
All these crystal structures are based on coordination polyhedra sharing edges or corners in the "equatorial plane" (i.e. octahedral, pentagonal and hexagonal bipyramids) and all have nearly planar layers, built up in a "base on peak" arrangement (i.e. they are linked through F^- ions in a *trans* position).

It can be seen from this description that loosely packed layers containing only F^- ions (e.g. with a shortest interatomic distance $d[F^-\text{-}F^-]=3.48$ Å in $AgPdZr_2F_{11}$ (Fig. 2)) alternate with layers which, in addition to F^-, contain all the cations (shortest fluorine-fluorine distance in the above compound: d[F-F] = 2.27 Å!). The individual structures differ only in the order of stacking, according to the various stoichiometries.

As a final example of the synthesis of single crystal samples containing Ag^{2+}, we consider $Ag[TaF_6]_2$. Owing to the ease of decomposition into the binary components (in a stream of fluorine gas at temperatures above 150 °C) and the volatility of TaF_5, one must in this case use a closed system (autoclave). The production of single crystals is briefly outlined in Scheme 4.

It is interesting here to note that single crystals of $Ag[TaF_6]_2$ are always found in the cooler, upper part of the autoclave. Since AgF_2 (m.p. $\gtrsim$ 620 °C, under F_2) certainly does not sublime under these conditions ($T \lesssim 400$ °C), TaF_5 must participate (with the formation of volatile complexes of unknown constitution that are stable only at high pressures) in the transport through the gaseous phase.

The layer structure is very simple: three AgF_6 octahedra (with approximate D_{4h} symmetry—see also Table 5) are attached in the *cis* position above a very obviously distorted TaF_6 octahedron (cf. Fig. 6). The remaining three F^- of the TaF_6 octahedron are terminal, i.e. no linkage via further cations takes place between each of the layers. Thus each AgF_6 octahedron has six different TaF_6 octahedra, each TaF_6 octahedron, however, only three different AgF_6 octahedra as ligands (for further details cf. Ref. [90]).



Scheme 3. Conditions for the synthesis of $Ag_3Hf_2F_{14}$ single crystals, with side reactions.

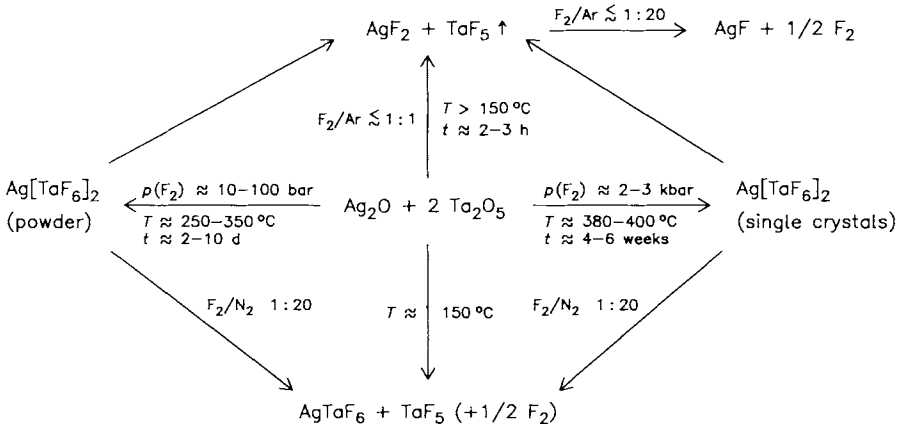

Scheme 4. Conditions for the synthesis of $Ag[TaF_6]_2$ single crystals, with side-reactions.

As we can see from the examples given here, silver(II) compounds are actually quite unpredictable in their structural chemical behavior. The conditions needed to prepare them—at least for single crystals—vary considerably and cannot be simply extended from one to another, so that one must treat each case individually and find the optimal conditions, sometimes through a tedious succession of experiments calling for much patience.

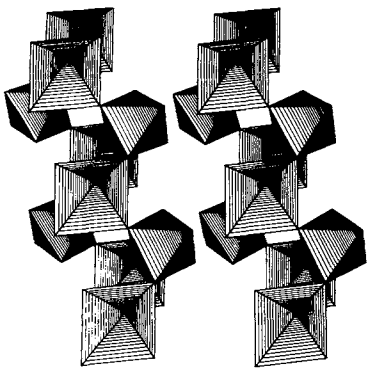

Fig. 6. The layer structure of $Ag[TaF_6]_2$, consisting of corner-sharing $[AgF_6]$ and $[TaF_6]$ octahedra.

4. Gold Compounds

In contrast to the rather "enigmatic" behavior of silver fluorides, and to a lesser extent that of copper fluorides, the chemistry and especially the structural chemistry of gold fluorides are remarkably lacking in surprises. This is largely due to the fact that neither gold(I), gold(II) nor (clearly defined) gold(IV) fluorides have thus far been described. Only fluoroaurates(III) and a few fluoroaurate(V) complexes are known. They are all yellow, the coordination number relative to fluorine being always $C.N.[Au^{3+}]=4$ for the trivalent gold compounds (square planar configuration), and $C.N.[Au^{5+}]=6$ for the pentavalent gold compounds (octahedral environment).

Further, all the compounds are diamagnetic, excepting where one of the other cations is paramagnetic. Their preparation too is generally comparatively easy, and is carried out under similar conditions for the different compounds.

In the case of the ternary gold(III) fluorides, the volatility of AuF_3 in the stream of fluorine ($T>350°C$) causes something of a problem; nevertheless it is possible[20] to obtain AuF_3 as orange-red needle-shaped crystals up to several mm in length. Single crystals of the ternary fluorides listed in Table 6 can be obtained (similarly to the Cu^{2+} and Ag^{2+} compounds) by annealing fine mixtures of the starting components in welded Au tubes (under dry Ar).

It is interesting from a crystallographic point of view that so many different structure types are found for the same empirical formula $M^{II}[AuF_4]_2$. It appears that here the structure is determined (in a subtly graded way) by the sizes (i.e. ionic radii) of the individual cations. Thus for $M^{II}[AuF_4]_2$ with different metals one finds different types of structures as follows: $M^{II}=Mg$, Ni or Zn (monoclinic), $M^{II}=Pd$ (orthorhombic), $M^{II}=Ca$ or Sr (monoclinic), $M^{II}=Cd$, Hg or Pb (tetragonal-P), $M^{II}=Ba$ (tetragonal-I), with coordination numbers ranging from $C.N.[M^{2+}]=6$ (e.g. Mg^{2+}) to $C.N.[M^{2+}]=12$ (Ba^{2+}).[42] Copper, instead of forming "$Cu[AuF_4]_2$", forms the compound $FCu[AuF_4]$, in which only one of the F^- ions in CuF_2 is formally replaced by $[AuF_4]^-$. The structure of this compound (see Fig. 7) is surprisingly simple: linear [-F-Cu-F-] chains lie along the [001] direction, around which, at the same "height" as Cu^{2+}, four isolated square planar $[AuF_4]$ units are so arranged that one F^- ion of each such unit completes the (highly distorted) octahedron around the Cu^{2+}.[43] In contrast the structures of $FM^{III}_2[AuF_4]_5$—in which we again see that the F^- ions of MF_3 are only partly formally replaced by $[AuF_4]^-$—are extraordinarily complicated. Remarkable is the occurrence of $[M^{III}_2F_{17}]$ units (two corner-sharing trebly capped trigonal prisms), which are linked by (isolated) $[AuF_4]^-$ units to form a three-dimensional structure (cf. Fig. 8).

Comparatively little is known about gold(V) fluorides; the first known gold(V) compound was described only quite recently.[102] This is rather surprising, since $CsAuF_6$ can be obtained by the direct conversion of $CsAuCl_4$ with elemental fluorine at about 300°C; to prepare homogeneous samples, however, increased fluorine pressures are recommended.[101] It appears that the surprisingly easy formation and the (relatively) good stability of $CsAuF_6$ (toward decomposition into $CsAuF_4+F_2$) were so unexpected that the results of early experiments led, at first, to wrong inter-

pretations ("$CsAuF_4 \cdot 1.5\,HF$"); the same also applies in the case of "$M[AuF_4] \cdot x\,HF$" (M = K, Rb; $x = 1.5$–2.0).[105]

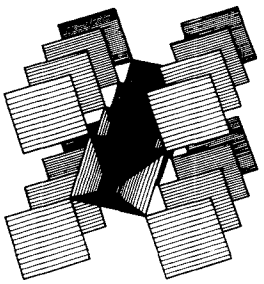

Fig. 7. Crystal structure of $FCu[AuF_4]$, with corner-sharing chains of $[CuF_6]$ octahedra and planar $[AuF_4]$ units.

Single crystal studies have so far only been carried out on $[Xe_2F_{11}]^+[AuF_6]^-$,[103] whose preparation under comparatively "mild" conditions ($T \approx 400$ °C, $p_{F_2} \approx 70$ bar, $t \approx 48$ h) is possibly made easier by the volatility (and high mobility) of XeF_6, or perhaps of both components (AuF_5, XeF_6).

In AuF_6^-, as in all other examples which have been studied in detail, Au^V is in an octahedral environment; the interatomic distances $d[Au^{5+}\text{-}F^-] = 1.85$–$1.90$ Å are of the expected order of magnitude. Other fluorine complexes of pentavalent gold, e.g. $M^{II}[AuF_6]_2$ (M^{II} = Ca, Sr) and "$FM_2^{III}[AuF_6]_5$" (M^{III} = La, Pr ...), can be prepared by high-pressure fluorination ($p_{F_2} > 3$ kbar) of $M^{II}[AuF_4]_2$ or $FM_2^{III}[AuF_4]_5$ respectively, but up to now they have only been obtained as microcrystalline powders, owing to increasing instability.[100]

Only sparse information exists as yet on gold pentafluoride, which is, as expected, the most unstable of the gold(v) compounds. It is obtained in the form of a dark orange-red, diamagnetic X-ray amorphous solid upon careful thermal decomposition of $O_2^+AuF_2^-$ (or $KrF^+AuF_6^-$). In the solid state (m.p. ≈ 75 °C) tetrameric units are probably present (as in RhF_5 and other pentafluorides[19]), and elec-

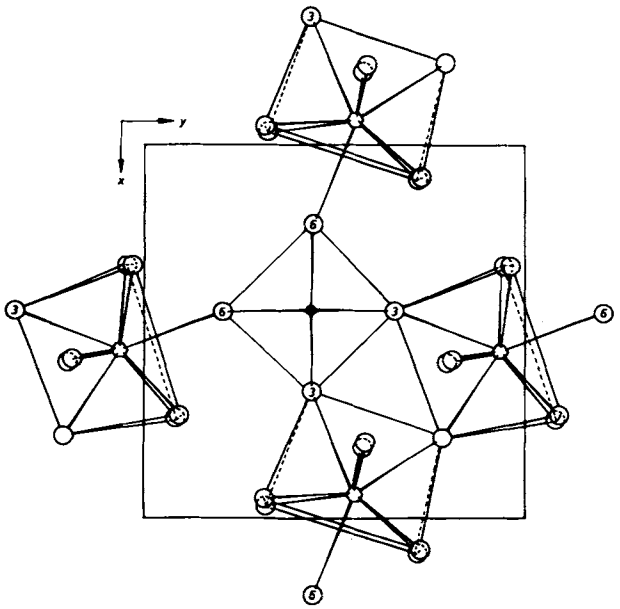

Fig. 8. The $[M_2^{II}F_{17}]/[AuF_4]$ units in $FM_2[AuF_4]_5$ (M = In, La-Tb) and their interlinkage. Filled circles: Au^{III}; open circles, F^-; hexagons, Mn^{III}.

tron diffraction studies (at 493 K) have provided evidence for the existence of $[AuF_5]_2$ and $[AuF_5]_3$ species.[106]

Viewed as a whole, the fluoroaurate(V) complexes are comparatively difficult to prepare, with increased fluorine pressures being generally necessary, but most of them (e.g. $MAuF_6$, where M = K, Rb, Cs) are appreciably more stable than, for example, Cs_2AgF_6 or Cs_2CuF_6.

In the interest of completeness it should also be mentioned here that in Raman spectroscopic measurements on a mixture of $NO^+AuF_4^-$ and $NO^+AuF_6^-$ also the yellow compound $[NO^+]_2[AuF_6]^{2-}$ was identified. However, in view of the comparatively small amount of information available, further more detailed studies are needed (especially magnetic measurements) to confirm the existence of this only known example of a gold(IV) compound.[107] The same applies to the recently reported compound "AuF_7" (prepared by the reaction of AuF_5 with F_2 in vacuum (!)), for which again there exists only spectroscopic evidence.[108]

5. Palladium Compounds

The existence of fluorides of di-, tri- and tetravalent palladium is firmly established (cf. Table 7). Results on $O_2^+PdF_6^-$ containing Pd^V (identified by Raman spectroscopy) need to be definitely substantiated, since under comparable reaction conditions ($p_{F_2} \gtrsim 4$ kbar, $T \approx 300$–400°C, $t \approx 2$ h–3 d) no evidence has so far been found for the formation of "$CsPdF_6$".

Further, the X-ray powder diffraction patterns of $O_2^+PdF_6^-$, containing many lines, are considerably different from those of the structurally related dioxygen(1+) compounds $O_2^+MF_6^-$ (M = Rh, Pt, Au ...) having the same general formula.[109]

There is little difficulty in synthesizing alkali metal and alkaline earth metal fluoropalladates(IV) (by conversion of the appropriate starting mixtures with dilute fluorine at temperatures of 300–500°C)[75,110] and the compounds $M^{II}PdF_6$ (with M^{II} = Ni, Mg, Zn ...),[111] including $Pd[PdF_6]$ itself.[73] The brick-red, diamagnetic, very unstable compound PdF_4 is, in contrast, obtainable only by high-pressure fluorination of PdF_3.[112] Its structure (determined by neutron diffraction on powder samples) is unusual, and consists—in contrast to SnF_4[113]—of $[PdF_6]$ octahedra linked at their corners with terminal F^- ions in the *cis* position.[114] The interatomic distances $d[M^{4+}\text{-}F^-]$ are comparable to those in SnF_4.

Up to now, single crystal studies have only been carried out on $[XeF_5^+]_2[PdF_6]^{2-}$, prepared under conditions identical to those for single crystals of $Xe_2F_{11}^+AuF_6^-$.[117] Like the isoelectronic Au^{5+} ion, Pd^{4+} here has an octahedral environment of fluorine ions; the interatomic distances have been found to be in the range $d[Pd^{4+}\text{-}F^-] = 1.86$–$1.92$ Å, as expected and previously estimated from known Pd^{IV} complexes.[75]

The constitution of PdF_3—similarly as in the case of AgF_2—was at first in doubt, but one can now regard the mixed valency formula $Pd^{II}[Pd^{IV}F_6]$ as proven, despite the lack of any single-crystal data. On the other hand, "true" palladium(III) fluorides are extraordinarily rare, having been reported for the first time only recently.[115,116] Their preparation is sometimes not easy, and in certain cases one needs to use high pressures (inert gas, e.g. Ar at about 4 kbar). The compounds $M_2^IM'^{II}PdF_6$ (elpasolites!), however, can be prepared by heating the binary fluorides under argon at atmospheric pressure.[115]

In view of the fact that Co^{2+} (with an identical arrangement of valence electrons) always has the $t_{2g}^5e_g^1$ ("high spin") configuration in fluorides, and that magnetic measurements on Ni^{3+} compounds (e.g. on Cs_2KNiF_6[119]) indicate a thermal equilibrium between "high spin" and "low spin" configurations (with the possibility of a Jahn-

Teller distortion involving Ni^{3+}), there is naturally great interest in the comparable palladium(III) fluorides. ESR and magnetic measurements indicate the existence of the "low spin" case ($t_{2g}^6 e_g^1$). If the arrangement of F^- ions around the Pd^{3+} ion could be determined, with exact values for the distances $d[Pd^{3+}\text{-}F^-]$, this would give information concerning the nature and magnitude of the Jahn-Teller distortion, which would be of considerable importance.[115]

Divalent palladium behaves in complex fluorides as an inorganic "chameleon", i.e. it adapts its coordination number, and accordingly the structure, color, and magnetic properties in the compounds concerned, to the situation imposed by the type and number of the accompanying cations.

In the alkali metal and alkaline earth metal fluoropalladate(II) complexes one generally finds a square planar environment (C.N.$[Pd^{2+}]=4$), e.g. in $M_2^IPdF_5$ (M^I = K, Rb, Cs) (yellow),[37] and in $M^{II}[PdF_4]$ (M^{II} = Ba (orange), Sr (red), Ca, Pb (purple)),[120] all of which are diamagnetic. In the compounds $M^IPd^{II}Pd^{III}F_5$ (M^I = K, Rb, Cs), which are orange-brown and antiferromagnetic, Pd^{2+} occupies a half octahedral and half square planar environment of F^- ions; the Pd^{2+} ions in octahedral positions can be selectively replaced by M^{2+}, [$M^{2+}=Mg^{2+}$ or Zn^{2+} (yellow, diamagnetic) and $M^{2+}=Ni^{2+}$ or Cu^{2+} (yellow and orange-brown respectively, antiferromagnetic)].[37,38]

Fluorides in which Pd^{2+} has regular octahedral coordination can be violet colored (PdF_2[72,120,121]), brown-violet ($RbPdF_3$[90]) (both antiferromagnetic), or blue ($NaPdZr_2F_{11}$, $AgPdZr_2F_{11}$, paramagnetic[61]). In addition, we have dark blue $CdPdF_4$, black $HgPdF_4$,[122] and HP-PdF_2[91,92] (antiferromagnetic) with a highly distorted octahedral arrangement of F^- around Pd^{2+}.

As a rule, the divalent palladium compounds listed in Table 8 are quite easy to prepare. If required, they can be obtained as single crystals by annealing mixtures of the appropriate binary fluorides under inert gas (Ar) in welded Pd tubes. The preparation of pure samples of PdF_2, however, presents something of a problem; PdF_3 (obtained by fluorination of, e.g., metallic Pd) is allowed to react with powdered palladium (which has previously had all traces of oxygen removed by heating in high vacuum), under inert gas (Ar) in welded Pd tubes at temperatures between 600 and 950 °C. By this method, using $T \gtrsim 950$ °C and $t \approx 4$-6 weeks, it has been possible to grow excellent millimeter-sized, amethyst-colored single crystals of PdF_2.[120]

Of the many palladium(II) fluorides which are now known, and which, in some cases, have been characterized by single crystal measurements, aside from those already mentioned, the compounds $CsPdPdF_5$, $M_3^IPdF_5$ (M^I = K, Rb, Cs), and $CdPdF_4$ are especially noteworthy. In Rb_3PdF_5, which is an "alkali-rich" phase, unusual amongst fluorometalate(II) complexes, two crystallogra-

[a] Single-crystal data measured for this compound. [b] Isostructural are $HgPdF_4$, black [90]. [c] Isostructural are $M^{II}PdF_4$, purple to orange (M^{II} = Sr, Ba, Pb) [120]. [d] Structurally related are M^IPdF_3, brown-violet (M^I = K, Tl) [90]. [e] Isostructural are $CsPdM^{III}F_6$ (M^{III} = Fe, Sc ...) [92]. [f] Isostructural are $M^IM^{II}PdF_5$, yellow to orange-brown (M^I = K, Rb, Cs, Tl; M^{II} = Pd, Mg, Ni) [37]. [g] Isostructural are $M_3^IPdF_5$ and $M^IM_2^{II}PdF_5$, yellow (M^I = K, Rb, Cs, Tl) [37]. [h] Isostructural are M^ICuPdF_5 (M^I = K, Cs) [100].

phically different types of Rb^+ and F^- ions are present. Those rubidium ions which occupy sufficiently large holes in the lattice can be specifically replaced by cesium (to give $CsRb_2PdF_5$), with no appreciable change in the lattice constants, but attempts to carry out a similar partial exchange of Cl^- for F^- have so far been unsuccessful. Most surprisingly, however, the same types of compounds and structures have recently been found in complex platinum hydrides, e.g. Rb_3PtH_5 or $CsRb_2PtH_5$.[124] Figure 9 shows a pictorial impression of the structure of the palladium compounds, consisting of channels with square and triangular cross sections.

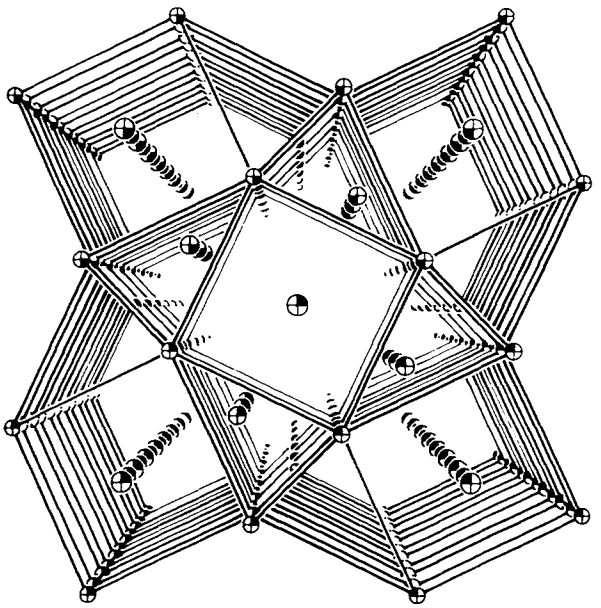

Fig. 9. Crystal structure of Rb_3PdF_5 and $CsRb_2PdF_5$ with tetragonal and trigonal channels.

Finally, $CdPdF_4$ (and also $HgPdF_4$) is of interest from a structural chemical standpoint, since it undergoes the transition from a $KBrF_4$-type structure, through a variant of the CaF_2 type ($CdPdF_4$), to the pure CaF_2 type (CdF_2), as has already been suggested in the case of $CdAgF_4$[84] (with $c/a \approx 1.99$). In view of this, it seems plausible that high pressure modifications of PdF_2 and AgF_2, metastable at normal pressure and isostructural with $CdPdF_4$, can exist.

6. Concluding Remarks

Despite the remarkable progress that has been made in this area of inorganic solid state chemistry the present state of our knowledge regarding the fluorides of copper, silver, gold and platinum, which has here been described only selectively, still leaves much to be desired. In the first place there is a shortage of available methods for preparing pure homogeneous samples (partly due to a lack of suitable methods of purification), and secondly the growing of single crystals (especially those of fluorides with poor thermal stability) is often hindered by severe problems in finding suitable materials, and by the occurrence of obscure or unpredictable side reactions.

It is possible in some cases that the presence of one or more volatile substances (even when one can only speculate about their existence as intermediate products or species of unknown composition) plays an important or even a crucial role. Two final examples will again serve to illustrate this.

1. When one tries to make single crystals of $Ba[AuF_6]_2$ (F_2 pressure >3 kbar) one obtains, in addition to crystals of that compound (of moderate quality), ruby-red single crystals of $BaNiF_6$ (formed by Ni from the monel-metal crucible!). This compound can normally be prepared (under comparable conditions, but without Au) only with difficulty, and always in microcrystalline form.[125, 126] A possible cause of this surprising occurrence of $BaNiF_6$ crystals is the formation of AuF_5 (as a "mobile phase" side-product) during the preparation. However, in the absence of firm evidence this remains mere speculation.
2. Single crystals of MnF_4 are only obtained (under an F_2 pressure of >3 kbar) if traces of O_2 are present (leading to formation of the volatile, structurally related compound $O_2^+Mn_2F_9^-$). In oxygen-free experiments under otherwise identical conditions, the samples produced are X-ray amorphous.[127, 128]

Finally, we are still far from having a deeper understanding of these structures, even in such simple systems which are formed predominantly by ionic bonding.

Thus, it remains unclear (and incomprehensible) why, in the system MF_2/ZrF_4 with both small (M^{II} = Ni, Co, Fe ... through to Cu) and large (M^{II} = Ca, Cd, Eu ...) cations, compounds of the type $M^{II}ZrF_6$ are formed (usually variants of the ReO_3 structure), whereas with Ag^{2+}, $Ag_3Zr_2F_{14}$ is formed (with a noticeably more complicated structure), and—even less comprehensible—why no compounds at all are formed with Pd^{2+}.

Simple models or concepts based on purely ionic bonding are inadequate to explain these results. Consequently, even in fluorides of metals in low oxidation states, there must be additional factors (apart from simple geometrical influences such as those of ionic radii or local distortions of the immediate environment due to the Jahn-Teller effect). For example, there could be a definite space requirement for occupied d orbitals (with a preferred orientation), as has been suggested for NbF_4,[129] or there may be significant contributions from covalent bonding (considering the volatility of AuF_3 and HgF_2!).

This is quite at variance with the view expressed by *Wilhelm Klemm* (on the occasion of a tribute in 1940 to the work of *O. Ruff* in fluorine chemistry): "*Ruff*'s work on the preparation of fluorides was so complete and thorough that little more remains to be done. In future research in this field the emphasis must increasingly be on determining their physical properties".[130] On the contrary, now as then we need new or more refined and sophisticated methods for preparing purer, well-characterized samples, including single crystals (as indeed *Klemm* himself shortly afterwards demonstrated when he introduced new fluorination techniques). The substances so prepared will then

lay down the basis for measuring their real physical properties and interpreting them correctly.

I wish to thank Herrn Dipl.-Chem. D. Kissel, Herrn Dr. M. Serafin, Herrn Dr. K. H. Wandner and, in particular, Frau W. Schmidt for their extremely valuable help in preparing this review.

Homoatomic d^{10}–d^{10} Interactions: Their Effects on Structure and Chemical and Physical Properties

By Martin Jansen*

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

The distinction between valence electrons and essentially inactive core electrons is the basis of many classifying concepts in chemistry. However, it has recently been recognized that this is an oversimplification and should, at least in some areas of chemistry, be modified. Many cases are known where cations with closed d^{10} configurations are subject to homoatomic interactions that influence structure and properties. A characteristic and surprisingly uniform structural feature (e.g., of a number of compounds containing monovalent coinage metals) is a clusterlike assembly of d^{10} cations that corresponds in geometry and bond lengths to fragments of the metal structures themselves. Further evidence for a special type of bonding in such compounds is provided by their physical properties; for example, the absorption in the UV/VIS region shows a drastic redshift and the compounds are often conductors or semiconductors. The d electrons in such cases have obviously lost their pure "core" nature. All bonding models so far proposed for such systems involve mixing of higher orbitals.

1. Introduction

The nature of chemical bonding was unclear until, after the proposal of *Bohr*'s atomic theory and before the development of wave mechanics, *W. Kossel* and *G. N. Lewis* published descriptions of the limiting cases of ionic[1] and covalent[2] bonding that were plausible and consistent with concepts of atomic structure. Some of the underlying assumptions of these bonding theories are still valid today. This is true in particular for the subdivision of the electron cloud into valence electrons, which largely determine the type, strength, and number of bonds formed by an atom, and core electrons, which do not contribute to the bonding. This simple concept has proved extraordinarily useful for teaching purposes and in descriptive chemistry for the classification and qualitative explanation of new experimental results. All the empirical rules that are based on the number of electrons in a bonding system should also be mentioned here; e.g., the noble gas rule in transition metal chemistry, the concepts derived from the $(8-N)$ rule by *Zintl–Klemm*[3] and *Grimm–Sommerfeld*,[4] the introduction of the "paraelement" concept[5] as a generalization of *Grimm*'s "hydride shift rules" (a special case of a "diagonal relationship"), and the role of "valence electron concentration" in the metallic state.

Core and valence electrons are also handled differently in quantum-chemical bonding calculations. The contributions of the core electrons are regarded as angle-independent in the form of a pseudopotential.[6] Similar considerations lie behind the experimental determination of bonding electron distribution ("deformation density") using diffraction methods: a spherically symmetrical contribution ("core") is subtracted at each atom from the total density.[7]

Although the precise treatment of a bonding system should involve the consideration of all states whose interaction integrals could, by symmetry, be nonzero under the given conditions, the more approximate treatment involving only the valence electrons in the ground state proves to be astonishingly good in practice. There are few experimental results (temperature-independent paramagnetism, for instance) that can only be interpreted when higher energy states are considered. It is also a commonly held view that an increase of the coordination number above four in covalent compounds requires an expansion of the valence shell.

Until recently there were no experimental results that needed a consideration of the core electrons for their interpretation. This situation changed, however, on the discovery of several curious features in compounds with d^{10} or $d^{10}s^2$ cations. In addition to the known bonding patterns, these species seem to involve homoatomic interactions that influence their structure and properties (cf. Ref. [8]), despite the fact that their electron configurations are generally regarded as closed-shell.

It often happens in chemistry, when modern developments generate principles of general validity, that a closer examination of the literature shows related evidence published long before. *A. Byström* and *L. Evers*, in a 1950 report on Ag_2PbO_2 and $Ag_5Pb_2O_6$, drew attention to the short Ag^+–Ag^+ contacts and discussed a form of "covalent" bonding.[9] In 1963, *G. A. Barclay* and *B. F. Hoskins* noted marked differences in the crystallochemical behavior of potassium and silver in $KAgCO_3$ and did not exclude the possibility of bonding between the d^{10} Ag^+ ions.[10] In 1973, *H.-L. Keller* and *Hk. Müller-Buschbaum* described assemblies of silver atoms in the novel compounds $SrAg_6O_4$ and $BaAg_6O_4$ as "metallic regions."[11]

Parallel to this development in solid-state chemistry, corresponding results from coordination chemistry became available. The most remarkable was certainly the synthesis and structure of $[Pt(PPh_3)_2]_2$.[12] The crystal structure of this compound shows a short platinum(0)–platinum(0) contact that, in the absence of bridging ligands, can only be interpreted as a metal–metal bond.

These observations, originally regarded as exceptions, have now attained significance both in number and in consistency[13] and are worthy of detailed classification. This article will review those results that provide evidence for the d^{10}–d^{10} interactions, present correlations between structure and properties, and discuss proposed bonding models. Most examples will be drawn from inorganic solid-state chemistry; it will not be possible to discuss more than isolated examples from the no less extensive and interesting field of related molecular systems.

2. Structural Chemistry

The structure of a solid is determined by the sum of the forces present in it and thus represents an observable property important for the characterization of chemical bonding. Unfortunately, it is in principle impossible to associate particular structural features (e.g., coordination polyhedra, bond lengths and angles) unambiguously or exclusively with a particular set of bonds. However, this is still possible to a good approximation in molecular crystals; the molecular structure is determined by the predominantly covalent bonding between the constituent atoms, whereas the molecular packing is determined by molecular shape and van der Waals forces.[14] Such distinctions, the limitations of which already become apparent on comparing crystal structures of small molecules such as Cl_2, Br_2, and I_2, become invalid for "collective" solids such as ionic crystals or intermetallic phases. This in turn places limitations on the significance of the following discussion of d^{10} systems in crystalline solids. To minimize these limitations, we shall present structural comparisons of compounds that differ only in one component.

2.1. Ternary Silver(I) Oxides

Monovalent silver is in many respects (e.g., transport properties in dilute aqueous solution, crystal chemistry in compounds such as elpasolites[15]) intermediate in properties between sodium and potassium. It thus seems worthwhile to compare ternary silver(I) oxides with their sodium and potassium analogues in order to discover any structural peculiarities of the silver compounds. Such comparisons reveal almost without exception drastic differences in the tertiary structure (the packing of the anionic and cationic components to form a three-dimensional framework), and sometimes even in the secondary and primary structure of the complex anions present in some of these oxides. Whereas crystal structures with cations of noble-gas configuration display (in addition to the usual tendency to form characteristic cation–anion contacts) a tendency to maximize the cation–cation distances and thus the lattice energy, the structures with Ag^+ are distinguished by a separation of the anionic and cationic components of the structure—an "aggregation" of the silver cations to form extended silver assemblies.[13] The peculiar resulting microheterogeneous structure and the special nature of monovalent silver become all the more apparent on comparison with alkali metal ions in formally similar environments; the crystal structure of $KAgCO_3$[10] fulfills this requirement ideally. The complete separation of potassium and silver "substructures" by layers of $CO_3^{2\ominus}$ ions (Fig. 1) is striking. The potassium ions achieve substantial interionic separations, but the silver ions aggregate to form two-dimensional, close-packed assemblies. The shortest K^+–K^+ distance is 404 pm, much longer than the shortest Ag^+–Ag^+ contact (297 pm).

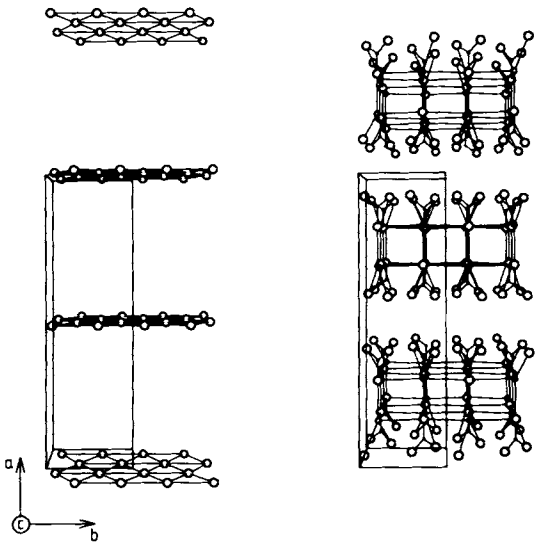

Fig. 1. Crystal structure of $KAgCO_3$; left, silver aggregate; right, KCO_3 grouping.

Further illustrations of this structural tendency are shown in Figures 2–4, where the silver and anion structures are presented separately. These examples ($Ag_6Si_2O_7$,[16] Ag_2CO_3,[17] and $LiAg_3O_2$[18]) show that the aggregation of silver ions is essentially independent of the particular coordination at silver and also of the "cationic" or "anionic" (oxoargentate) role of silver.

Although the general tendency of silver ions to form aggregates is noteworthy, the silver–silver distances within the aggregates are even more impressive; they are approximately constant, the shortest being ca. 280 pm (shorter than the 289 pm in metallic silver) and the longest not longer than 330 pm (i.e., less than the van der Waals diameter of 340 pm[19]). A more detailed examination of the crystal structures shows in addition that the silver aggregates are based on a uniform motif, namely, an approximately equilateral triangle of silver atoms. The triangles are then "condensed" to form ribbons, layers, and three-dimensional frameworks (cf. Figs. 5–8). The crystal structures of the ternary silver oxides known so far show a preference for two-dimensional aggregates (ribbon or layer structures). The silver substructures thus correspond to fragments of the structure of metallic silver, both in geom-

etry and in interatomic distances. Table 1 presents a summary of silver compounds in which the shortest Ag–Ag distance lies below 300 pm.

The formation of silver aggregates influences not only the packing of anions and cations but can also govern the secondary structure of condensed oxoanions. The first known example of the tetrasilicate ion in a crystalline solid was the silver salt $Ag_{10}Si_4O_{13}$;[20] $AgBO_2$ contains a polyanion with tetrahedral and trigonal-planar boron in the ratio 1 : 1,[21] previously known only in the high-pressure form of $Ca(BO_2)_2$; and $Ag_2Ge_2O_5$ involves a three-dimensional framework of a kind previously unknown for oxoanions of the composition $Ge_2O_5^{2-}$.[22]

Table 1. Shortest distances between d^{10} cations in compounds of monovalent copper, silver, and gold [pm].

2.2. Ternary Copper(I) and Gold(I) Oxides

In contrast to the considerable amount of information (mostly stemming from the last few years) on ternary silver oxides, few corresponding examples with similar structural features are known for monovalent copper and none for gold. This difference may simply be attributable to the more intensive preparative studies of ternary silver(I) oxides; even the more silver-rich species[*] are now accessible, thanks to developments in high-pressure oxygen technique that permit solid-state reactions involving Ag_2O.[8a]

Ternary oxides in which univalent gold would be cationic in nature have, to the best of our knowledge, not yet been systematically investigated. Our group has made extensive efforts to synthesize copper-rich species such as $Cu_6Si_2O_7$ or Cu_3BO_3—as yet without success, but our attempts are continuing. This lack of success is difficult to explain, particularly since a series of less metal-rich ternary oxides have been described (e.g., $Cu_6Mo_5O_{18}$[79] and $Cu_4Mo_5O_{17}$[80]), and new representatives of the type $CuMO_2$ (with the delafossite structure) have been obtained without great difficulty.[81] Furthermore, *R. Hoppe* and coworkers have synthesized numerous alkali metal oxocuprates(I), including the only known copper-rich ($Cu : O > 1$) species, $Rb_3Cu_5O_4$.[67] This compound, with a shortest Cu–Cu distance of 257 pm (cf. copper, 254 pm), is clearly related to the silver compounds described above. The assumption that copper(I) oxides could also form clusterlike metal aggregates is therefore not so unreasonable; however, it remains essential to confirm the assumption experimentally.

2.3. Halides and Further Chalcogenides of the Monovalent Coinage Metals

The current knowledge of ternary coinage-metal compounds involving other nonmetal components, such as the halogens or the higher homologues of oxygen, is limited and thus only isolated cases can be discussed here. *Bronger* and co-workers have described silver- and copper-rich sulfides and selenides such as $K_2Ag_4Se_3$,[82] $Cs_2Cu_5Se_4$,[83] and $K_3Cu_8S_6$,[71] in which the singly charged coinage-metal ions are again segregated from the rest of the structure. Figure 9 shows that the copper and silver substructures represent fragments of the cubic face-centered metal lattices. The structural relationship becomes even clearer through the transition to three-dimensional aggregates. The metal–metal distances in the cited compounds are approximately equal to those in the metals themselves, although generally somewhat longer. A comparison with smaller metal fragments (e.g., pairs or isolated groups of atoms) can give the impression that—as with ions of opposite charge—the M^+–M^+ distances increase with coordination number.

An examination of halide structures yields fewer examples of similar phenomena; however, they present some re-

[*] The silver compounds prepared at high oxygen pressure (6 kbar) are not quenched high-pressure phases; they were tested by tempering below their decomposition temperatures at normal pressure and did not revert to "normal-pressure" phases.

markable features. $SrAg_2I_4 \cdot 8H_2O$[38] displays chains of silver atoms with an unusually short Ag-Ag distance of 278 pm. The metal atoms are tetrahedrally coordinated by iodine, as is the case in some iodocuprates(I),[77] where the short Cu^+-Cu^+ distances (241 pm) arise from the linking of coordination polyhedra via common edges or faces. The AuI_2 "dumbbells" in $Rb_2AgAu_3I_8$[45] are not linear; the narrowing of the bond angle at Au^+ to 173° is associated with a short Au^+-Au^+ distance of 304 pm. Except for Au^+-Au^+ interactions, no other reasons for the distortion are detectable.

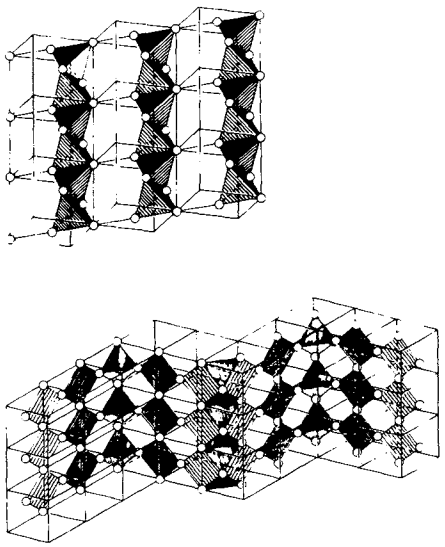

Fig. 9. Coinage-metal aggregates in $K_2Ag_4Se_3$ (above) and $Cs_2Cu_5Se_4$ (below).

2.4. The Structures of Zinc, Cadmium, and Silver Subvalent Compounds

A classical problem (still unsolved) from the structural chemistry of metals is that of the anomalous *c/a* ratios in the hexagonal close-packed crystal structures of zinc and cadmium. There are about 20 metals that crystallize, at least in one allotropic form, in close-packed hexagonal structures; all except zinc and cadmium display *c/a* ratios in the narrow range 1.57-1.64 (the ideal value is 1.63). The deviations for zinc (1.856) and cadmium (1.886) are extreme (over 15%).[84] The distances to the 12 nearest neighbors distort into six shorter ones within the layers and three longer ones both above and below the layers. Proposed explanations of this anomaly, such as the assumption of ellipsoidal Zn^{2+} and Cd^{2+} cores,[85] have not met with general acceptance.[86] Since the conduction band of these two metals can be shown to contain two electrons per atom, the cores must have d^{10} configurations; furthermore, the bonding interactions discussed in this article act preferentially in two dimensions. The zinc and cadmium anomalies therefore correspond perfectly to the structural results described in the preceding section. This is the first time that they have been classified in terms of a more general context.

Silver subfluoride, Ag_2F,[87] was also viewed very much as an exception. It was the only known subvalent compound of silver for a long time and is still the only known subfluoride. The compound is formed by electrochemical reduction of silver(I) fluoride and possesses the *anti*-CdI_2 structure. The distances between silver atoms in the layers are 290 pm, and those between silver atoms of different layers 285 pm. Ag_2F is no longer quite so unusual because Ag_3O, the first silver sub*oxide*, has also been described.[23] The structure is to a first approximation an *anti*-BiI_3 type. The influence of the remaining valence electrons (1/3 per silver atom) causes a deformation of the silver substructure to form Ag_6^{4+} octahedra. The bond lengths within the cluster are significantly shorter than those between clusters (275 and 285, compared with 297 pm). There is an interesting parallel here to the silver germanium phosphide $Ag_6Ge_{10}P_{12}$,[88] which also contains "isolated" Ag_6 groups; if the nonmetals germanium and phosphorus are allocated oxidation states corresponding to their chemical and structural roles, the Ag_6 cluster is also formally 4+, with a valence electron concentration of two per structural unit. The newest member of the small family of silver subvalent compounds, $Bi_4Ag_{18}O_{12}$,[89] also contains silver in the oxidation state 2/3 (a coincidence?). It possesses a three-dimensional silver framework in which, remarkably, no shortening of the silver-silver distances is observed, as compared to the ternary silver(I) oxides discussed in Section 2.1. The published crystal structure of $Ag_5Pb_2O_6$ describes it as a subvalent compound,[9] but the inadequate accuracy of the structure determination precludes an unambiguous assessment.

We believe that there is a connection between the existence of subvalent silver compounds and the tendency of univalent silver to engage in homoatomic interactions. The substructures thereby formed have empty s and p conduction bands, which can easily accommodate further electrons on reduction. The subvalent compounds thus represent a structural link with classical metal cluster compounds, which, however, lie outside the scope of this review.

2.5. Coordination Compounds

Numerous coordination compounds of copper(I), silver(I), and gold(I) have been prepared and structurally investigated.[90] Their crystal structures generally consist of "isolated" molecules, but they nevertheless show remarkable similarity to the compounds discussed above in terms of their cation substructures; the M^+-M^+ contacts are of similar length to the interatomic distances in the elements themselves, sometimes even shorter. Table 2 presents a summary of the shortest contacts so far observed. There are however significant differences between the coordination compounds and the more highly "polymeric" ternary oxides and sulfides. The d^{10} atoms are often held together in pairs by 1,3-bifunctional bidentate ligands; aggregates of more than two d^{10} centers are observed only in isolated cases, and extended two- or three-dimensional cation structures not at all.

The reservations mentioned in Section 2 with respect to structure-bonding relationships are therefore particularly serious. Possible metal-metal interactions cannot be distin-

Table 2. Shortest Cu-Cu, Ag-Ag, and Au-Au distances in coordination compounds [pm].

guished from the effects of the ligands. Even the deviations from 180° at the metal atom allow no unambiguous conclusions to be drawn; they are associated with both longer and shorter metal-metal contacts (compared with an ideal linear geometry), and no systematic relationship can be recognized at present. It is possible that crystal packing effects are important in view of the generally small deformation energy of linear systems, but such effects are generally ill-defined. The dimeric Pt^0 complex $[Pt(PPh_3)_2]_2$ is a key compound in this respect, since the two d^{10} metal atoms are only 276.5 pm apart despite the absence of bridging ligands.[12] The existence of this complex thus lends weight to the assumption that bonding interactions are present between d^{10} centers in complexes with bridging ligands, too.

2.6. Systematic Structural Comparisons

A structural comparison of related compounds, with systematic variation of anionic or cationic moieties, is more profitable than an amorphous presentation of isolated results. A sufficient number of structures have now been investigated to allow such comparisons for the following compounds:

1. isotypic compounds differing only in the nature of the complex anion (e.g., analogous silver(I) silicates and germanates)
2. salts of the same anion with differing coinage-metal content (e.g., silver(I) sulfamides)
3. compounds that retain the same structural type while allowing the metal-metal distance to vary over a wide range (e.g., copper delafossites)

For the silver silicates and germanates, the following compounds have been shown to be isotypic: $Ag_{10}X_4O_{13}$, $Ag_6X_2O_7$, and $[Ag_4XO_4]_2\cdot AgNO_3$, where X = Si or Ge.[122,44] However, quantitative structural data are available only for the ortho salts. Figure 10 shows the corresponding contacts in the silicate and germanate. Whereas the X-O bond lengths vary markedly and uniformly, the Ag-O bond lengths are not significantly different. Surprisingly, the latter is also true for the silver-silver contacts below 330 pm (within a margin of $\pm 3\sigma$); the average contacts are 308 (Ge) and 309 (Si) pm. The increase in volume in going from the silicate to the germanate is clearly not uniform over the whole crystal structure. Since the Ag-Ag contacts, like the Ag-O distances, are more or less constant, it is possible to speak of a silver-silver "bond length." Moreover, the average deviation (1.4 pm) from the mean value of the shortest Ag-Ag contact (<330 pm) is much lower than that of those contacts between 330 and 400 pm (8.2 pm). We regard these observations as evidence that the metal-metal interactions are indeed bonding.

The silver(I) salts of sulfamide, $O_2S(NH_2)_2$, and their structures are known for all possible stoichiometries (mono- to tetrasilver salts). Apart from the differing degree of protonation, the anions show no marked changes in this series, and a comparison of the silver substructures should therefore provide, to a first approximation, information about the silver-silver interactions. The comparison shows characteristic trends as regards both the extent of the silver aggregates (see Fig. 11) and the interatomic distances within them; for the mono-,[123] di-,[124] tri-,[64] and tetra-

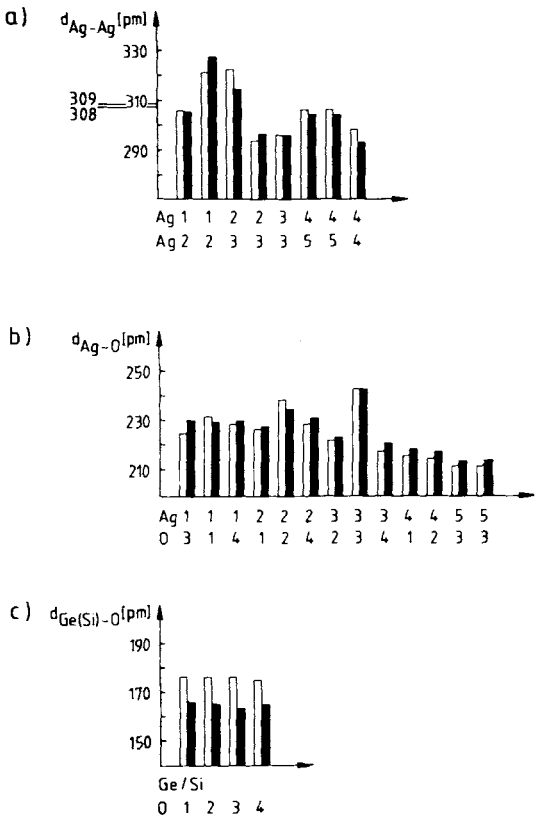

Fig. 10. Comparison of bond lengths in $[Ag_4XO_4]_2\cdot AgNO_3$ with X = Si (dark bars) and Ge.

silver sulfamides,[63] the silver atoms occur singly, in pairs, and in two- and three-dimensional infinite arrangements, respectively (taking 330 pm as the upper limit for an Ag–Ag contact). The variations in, and averages of, the Ag–Ag distances (Fig. 12) also indicate increasing Ag–Ag interactions in going from the mono- to the tetrasilver salt.

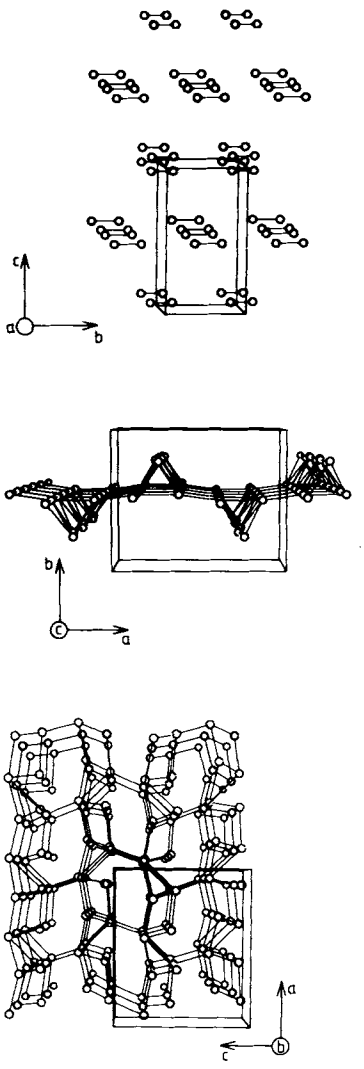

Fig. 11. Silver aggregates in (from above) di-, tri-, and tetrasilver sulfamide.

The delafossites (general formula $A^+B^{3+}O_2$) display two-dimensional infinite networks of d^{10} cations based on equilateral triangles. This can be readily explained in terms of the preferred coordination geometries of the constituent metal ions (octahedral and linear coordination by oxygen). In the context of this article, however, the aggregation phenomenon appears in a different light. The structure can accommodate different sizes of B^{3+} ions, thereby allowing systematic comparison of the ensuing variations; the A^+–A^+ distances are identical with the value of a for the hexagonal crystal system, which is in turn determined by the radius of B^{3+}. The known Cu(I) delafossites have a values of 280–380 pm and thus form a structural group in which the Cu^+–Cu^+ distances also vary over this wide range. If Cu^+–Cu^+ interactions are present, these should vary systematically with the Cu–Cu distance, and the physical properties dependent on the band structure should vary uniformly with the value of a.

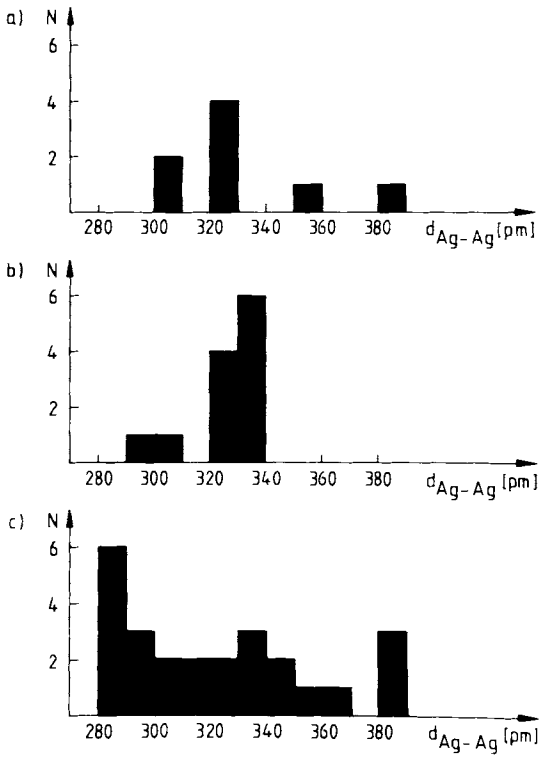

Fig. 12. Distribution of silver–silver distances in di- (a), tri- (b), and tetrasilver sulfamide (c).

A study of bond lengths in delafossite structures determined by single-crystal X-ray analysis reveals a previously unknown tendency: the Cu–O bond lengths decrease significantly with increasing radius of B^{3+}. The obvious assumption that the shortening of the Cu–O bonds occurs at the expense of the B^{3+}–O bonds can be shown to be invalid using the bond length/bond strength concept.[125] The contributions of the trivalent cations to the valence sum (s) of oxygen remain constant.[81] Accordingly, the expected valence sum of 2 for oxygen would constrain the contribution from copper to remain constant at 0.5. Copper would then display the expected valence sum of 1 for all compounds of the series. This conclusion is unfortunately not consistent with the experimental observation that the Cu–O bond lengths decrease with increasing radius of B^{3+}.

Table 3. Contributions of various bonds to the valence sum of copper in some copper delafossites.

	$2H\text{-}CuAlO_2$	$3R\text{-}CuGaO_2$	$2H\text{-}CuScO_2$	$3R\text{-}CuYO_2$
Cu-O[pm]	186.5	185.2	183.5	182.6
Cu-Cu [pm]	286.29	297.66	322.27	353.33
2·s(Cu-O)	0.796	0.850	0.927	0.970
6·s(Cu-Cu)	0.204	0.147	0.073	0.030

Since the valence s of the Cu–O bond in $CuYO_2$ has a higher value than in $CuAlO_2$ (according to the observed bond lengths), the question arises as to the origin of the additional valence needed to saturate the copper atom.

The only possibility is Cu–Cu interactions, since all other contacts outside the inner coordination sphere are too long. An estimate based on *Brown*'s work[125] is that the Cu–Cu interactions contribute 3% to the valence sum of copper in $CuYO_2$ but the impressive amount of more than 20% in $CuAlO_2$ (cf. Table 3).

3. Physical Properties as Indicators of d^{10}–d^{10} Interactions

As already stated, unambiguous conclusions regarding chemical bonding cannot always be drawn from structural data. This can be demonstrated clearly in the case of Na_3AgO_2, which, with a shortest Ag–Ag distance of 296 pm, can reasonably be classified with the compounds discussed in this article. However, the best description of the structure (as published by *R. Hoppe*[33]) is as a structural variant of Na_2O; the shortest distances between all cations (Na^+ and Ag^+) are practically equal and are determined by the matrix of oxide ions. Bond lengths alone are plainly unreliable indicators of bonding interactions between d^{10} cations and it becomes necessary to back up the structural data with evidence from additional sources. Suitable properties to study are clearly those that unambiguously demonstrate marked changes in the electronic structure of the d^{10} cations associated with the homoatomic interactions.

3.1. Absorption in the UV/VIS Region

One change in properties associated with the structural features discussed here is qualitatively apparent; intensely colored compounds are formed, even with anions that (like the "isolated" univalent coinage-metal cations) do not themselves absorb in the visible region. Figure 13 summarizes the known UV/VIS spectroscopic studies[126] and presents the reflection spectrum of Ag_2SO_4 for comparison. The spectra typically show absorption edges with relatively steep gradients (explaining the brilliant coloration of the compounds), the position of the absorption edge corresponding to the particular color. Compared with Ag_2SO_4, which has "isolated" Ag^+ ions, the absorption edges of the compounds described in Section 2.1 are shifted by up to 18000 cm^{-1} (!) to lower wavenumber. This represents a striking correlation between structure and properties, rendered even more significant by the increase in redshift with increasing silver content and with increasing metal aggregation (Table 4). A more rigorous quantitative treatment of this correlation is impossible because we do not yet understand the complicated mutual effects of metal–metal distances and extent of aggregation. A pressure increase also brings about a shift to lower wavenumber, which identifies the associated transitions as those between bands. The UV shift on cooling could then be attributed to a reduction of thermally induced band broadening.

Table 4. Silver content and energy of the absorption edge in selected silver compounds.

Compound	Color	Absorption edge ν [cm^{-1}]	Proportion of silver (per formula unit)
$Ag_2H_2N_2O_2S$	colorless	33300	0.22
Ag_2SO_4	colorless	33100	0.29
Ag_3PO_4	yellow	25600	0.38

Ag_3BO_3-(II)	yellow	23000	0.43
$Ag_6Si_2O_7$	red	17900	0.40
$Ag_4N_2O_2S$	red	17500	0.44
$Ag_{10}Si_4O_{13}$	red	17300	0.37
$LiAg_3O_2$	red	—	0.50
$Ag_{10}Ge_4O_{13}$	black	13500	0.37

3.2. Electrical Conductivity

Electrical conductivity is a physical property dependent on band structure. The conductivities of several compounds have been determined,[127] allowing for the effects of ionic conductivity, which can be appreciable for d^{10} univalent cations. In contrast to Ag_2SO_4, which is essentially a complete insulator, all compounds with d^{10} cation aggregates so far investigated have proved to be semiconductors. Figure 14 presents Arrhenius diagrams of the conduc-

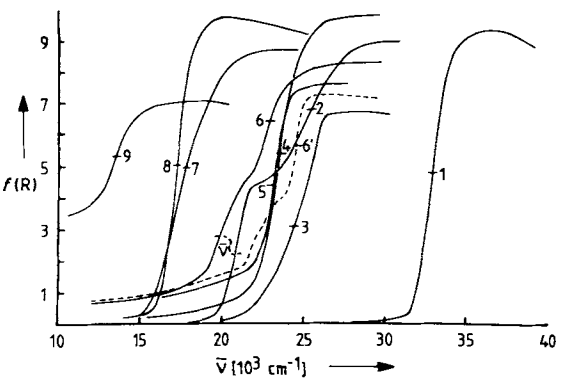

Fig. 13. Reflection spectra of oxoanionic silver(I) compounds: Ag_2SO_4 (1), Ag_3PO_4 (2), Ag_2CO_3 (3), $AgBO_2$ (4), $Ag_2Ge_2O_5$ (5), Ag_3BO_3 at room temperature and at 5 K (6 and 6'), $Ag_6Si_2O_7$ (7), $Ag_{10}Si_4O_{13}$ (8), $Ag_{10}Ge_4O_{13}$ (9).

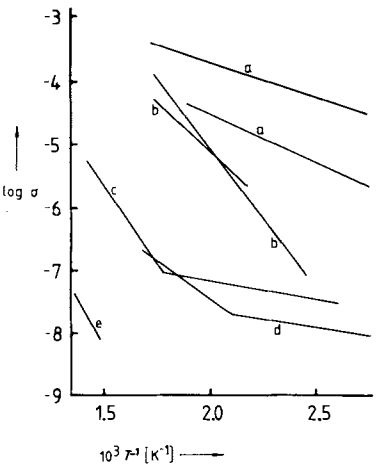

Fig. 14. Electrical conductivity of $Ag_6Ge_2O_7$ (a), Ag_3BO_3 (b), $Ag_2Ge_2O_5$ (c), $Ag_6Si_2O_7$ (d), and $AgBO_2$ (e).

tivity of some representative compounds. An analysis of the intrinsic conductivity curves gives the corresponding activation energy, which is compared in Figure 15 with the optical band gap. The relationship between spectroscopic band gaps and those determined by conductivity measurements is unmistakable. As would be expected, the agreement extends only to relative changes, not to absolute values; the optical transitions with the selection rule $\Delta k = 0$ and the induction of electrical conductivity are governed by different mechanisms.

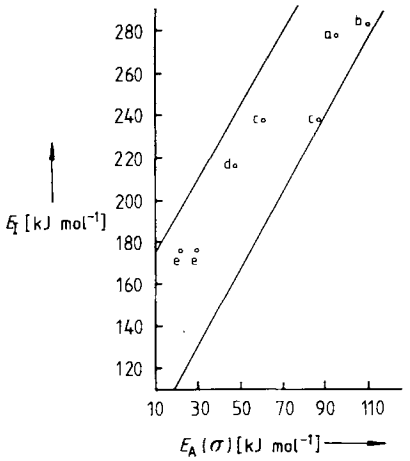

Fig. 15. Optical and conductivity-determined band separations in $Ag_2Ge_2O_5$ (a), $AgBO_2$ (b), Ag_3BO_3 (c), $Ag_6Si_2O_7$ (d), and $Ag_6Ge_2O_7$ (e). E_I = energy of the optical absorption edge; $E_A(\sigma)$ = activation energy of the electrical conductivity.

The silver substructures of the oxides investigated so far differ appreciably in structural detail and are thus difficult to compare quantitatively. Conductivity measurements were therefore carried out on a series of copper delafossites, in which the copper substructures remain qualitatively the same but the Cu-Cu distances vary. It was essential to prevent the formation of Cu^{2+} defects in order to obtain reliable results; this was to a large extent achieved by fixing the oxygen activity during the synthesis.[81] Samples prepared in this way show a very low ionic conductivity and give purely intrinsic electrical conductivity curves. The conductivities vary over the range $\sigma = 10^{-2}$–10^{-6} S cm^{-1} at 273 K. The plot of electrical conductivity against Cu-Cu distance (Fig. 16) shows a practically linear correlation. Since the conductivities of the constitutive sesquioxides are three orders of magnitude smaller, and the conductivity of the delafossites is thus almost entirely attributable to the Cu/O part of the structure, this is a further independent confirmation of interactions between centers with "closed" d^{10} configurations.

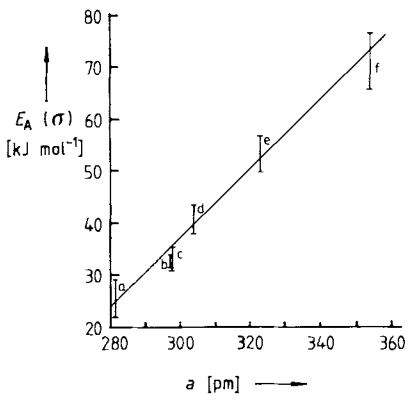

Fig. 16. Activation energy of the electrical conductivity, $E_A(\sigma)$, as a function of the cell constant a in copper(I) delafossites $CuAlO_2$ (a), $CuCrO_2$ (b), $CuGaO_2$ (c), $CuFeO_2$ (d), $CuScO_2$ (e), and $CuYO_2$ (f).

It should be possible to induce electrical conductivity optically as well as thermally; silver sulfamides indeed show a photoinduced rise in conductivity over several orders of magnitude when the wavelength of the irradiated light reaches a value corresponding to the position of the absorption edge (determined independently by reflection spectroscopy)[128,129] (Fig. 17). The observed reduction in the band gap with increasing silver content is consistent with the associated changes in the silver substructures (see above).

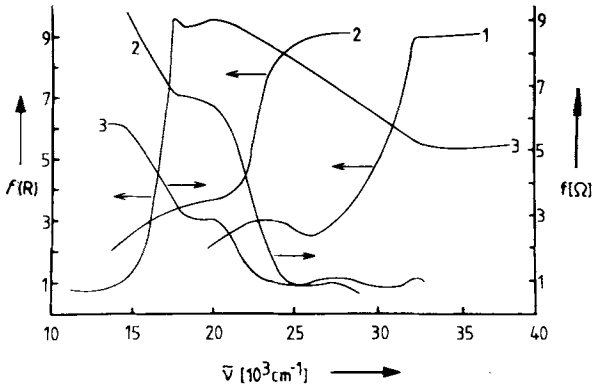

Fig. 17. UV/VIS absorption and photoinduced conductivity of $Ag_2H_2N_2O_2S$ (1), $(Ag_3HN_2O_2S)NH_3 \cdot H_2O$ (2), and $Ag_4N_2O_2S$ (3).

3.3. Other Physical Properties

The bistable switching of amorphous silver(I) silicates[130] and phosphates[131] may also be connected with their microheterogeneous structure and d^{10}–d^{10} interactions. Such materials can, after suitable pretreatment, be reversibly switched between high and low resistance by the application of short square-wave electrical pulses. This behavior is illustrated for a silver(I) silicate glass in Figure 18.

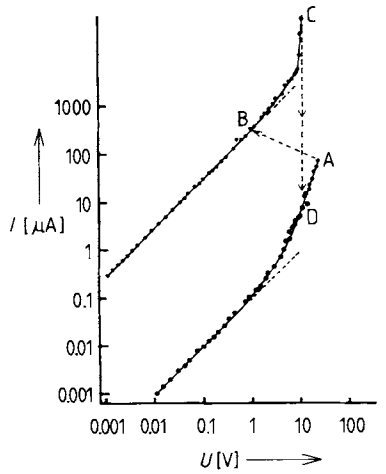

Fig. 18. Current/voltage characteristic of a silver(I) silicate glass after pretreatment. A–D = switching cycle.

Investigations using dielectric methods have given some indication of the presence of silver "clusters" in such glasses.[132]

Solid-state ^{109}Ag-NMR spectroscopy can also be a sensitive probe of changes in bonding; this is shown by the drastic changes in chemical shift between Ag_4RbI_5 and Ag_2F compared with AgF.[133] Our own preliminary studies of $Ag_{10}Si_4O_{13}$ with ^{109}Ag MAS NMR spectroscopy have shown a shift to low field of 320 ppm compared with solid $AgNO_3$.[134]

Anomalies in the dynamic behavior of Ag^+, manifested for example in the phonon spectra[135] of AgCl or AgBr, have been discussed for a long time. Although no unusual Ag^+-Ag^+ contacts are involved (NaCl structure), it is generally agreed that the difference between silver and alkali metal halides is due to attractive interactions between Ag^+ ions.[136]

Finally, it should be remembered that the dominant defect type in silver halides is the Frenkel defect, the formation of which requires the accommodation of short metal-metal contacts.

4. Correlations and Models

There is now enough empirical material to permit initial attempts to (1) establish conditions under which interactions between d^{10} electron systems, usually regarded as closed, become effective, (2) demonstrate correlations between structure and properties, and (3) set up preliminary bonding models.

4.1. Conditions for the Existence of d^{10}-d^{10} Interactions

The influence of homoatomic interactions is regarded as decisively less than that of classical bonding between "anions" and "cations." The tendency of d^{10} cations to undergo aggregation is only realized when their primary coordination requirements are satisfied. An analysis of available structural information shows that a high ratio of electropositive to electronegative species (e.g., the cation-to-oxygen ratio in the ternary silver oxides) is a necessary condition for the development of the characteristic collective bonding that essentially determines the tertiary structure. The excess of cations forces them into mutual proximity, which is clearly necessary in order that the attractive forces should become effective. A high proportion of d^{10} cations alone is not a necessary requirement, as is shown, for example, by the case of $KAgCO_3$. At present, the lowest known cation/oxygen ratio capable of producing d^{10} aggregation is 4/5 (in $Ag_2Ge_2O_5$).

The various classes of compounds are represented by widely varying numbers of known examples (a fact largely determined by the amount of preparative study invested in the individual systems); we believe that it is not yet possible to derive systematic correlations. General tendencies are already recognizable, however, in that the necessary cation/anion ratio is more difficult to attain with highly charged cations or with anions of low charge (halides)—a result of simple arithmetic. This could be the explanation for the readily formed metal aggregates involving the univalent coinage metals and the chalcogenides. For divalent cations, the mutual electrostatic repulsion would be highly disadvantageous; it is therefore not surprising that indications of bonding relationships between the core electrons of divalent atoms have only been obtained for zinc, cadmium, and mercury. Accordingly, the crystal structures of these elements are of key interest because they are ideally suited for studying pure d^{10}-d^{10} interactions. The influence of bonds to the anions on metal-metal distances, which could be critical, obviously plays no part in metallic zinc, cadmium, and mercury.

4.2. The Causes of Color and Conductivity

We have already shown that there are correlations between the structures of the compounds discussed here and their properties. However, the correlations alone provide no information on the nature of the electronic transitions involved. Classical ligand field transitions can be ruled out because of their localized nature, and, particularly, because the absorption phenomena in the visible and ultraviolet regions have proved to be independent of the ligand and of the coordination geometry. Another explanation[137] of the color of silver(I) compounds based on the covalent character of the Ag-X bond (as indicated by bond length) proved to be insupportable[138] because many compounds are now known that have equal Ag-X bond lengths but different colors. There remain two feasible explanations: (1) band transitions between a valence band of predominantly d character and a conduction band with predominantly s and p character within the silver substructure or (2) transitions between the highest occupied molecular orbital in the anionic part of the structure and the s or p band in the silver substructure, or in other words, a charge-transfer phenomenon. There are two main objections to the first explanation that are not easy to refute: first, it is improbable that the transition $^1S_0(4d^{10}5s^0) \rightarrow {}^3D_3(4d^95s^1)$ is lowered from 39000 cm^{-1} in the free silver ion[139] to 12000 cm^{-1} by band broadening induced by the Ag-Ag interactions, and, secondly, it is becoming clear that the position of the absorption edge also depends on the nature of the complex anion. In the isotypic silicates and germanates previously discussed, for example, the silver aggregates are the same, but there is an IR shift of the order of 1000-3800 cm^{-1} on going from a silicate to a germanate. On the other hand, there are drastic changes in groups of related compounds with differing cation content but similar anions—e.g., in the series $Ag_2Ge_2O_5$, $Ag_6Ge_2O_7$, $Ag_{10}Ge_4O_{13}$, and $[Ag_4GeO_4]_2 \cdot AgNO_3$. The absorption therefore clearly depends on the type of silver aggregates (its extent and bond lengths) and on the type of anions. Since the bonding between Ag^+ and silicate ions, for example, is mainly ionic (the irregular coordination of silver by oxygen and the similarity of the silicate dimensions to those in alkali metal silicates support this assumption), it seems easiest to explain the experimental observations in terms of charge-transfer transitions between the HOMOs of the complex anions and the acceptor levels of the metal aggregates, the latter being lowered in energy by the d^{10}-d^{10} interactions.

It should be pointed out, however, that this interpretation is in one respect in conflict with published views. According to *C. K. Jørgensen*, the energy of a charge-transfer process is dependent on the differences in the optical electronegativities of the electron donors and acceptors,[140] as described by the following equation: $\tilde{\nu}=30000\ \mathrm{cm}^{-1}\,(\chi_{opt}(A)-\chi_{opt}(D))$. This concept was modified by *J. A. Duffy*[141] for complex anions, χ_{opt} for oxygen in such anions being determined by the electronegativity of the central nonmetal atom. A comparison of isotypic silver silicates and germanates having the same electron acceptor (the Ag^+ aggregates) but different donors (silicate or germanate) should therefore show a lower energy absorption edge in the silicate because of the lower electronegativity of silicon.[142] The opposite is observed experimentally. This discrepancy should not be regarded too seriously, however, because the postulated transition involves the energy level of the highest occupied state with preponderantly "anionic" character, and this cannot be determined entirely by the electronegativity of the central nonmetal atom.

4.3. Bonding Models

L. E. Orgel[143] suggested a valence-bond model for bonding in compounds of d^{10} ions such as Cu^+, Ag^+, and Hg^{2+}. He postulated hybrid orbitals $1/\sqrt{2}(d_{z^2}-s)$ and $1/\sqrt{2}(d_{z^2}+s)$; the former occupies a position in the xy plane and contains two electrons, while the latter, directed along the z axis, can accept electrons from ligands and so stabilize the linear coordination that these ions generally display. According to *Jørgensen*, linear coordination is rendered more favorable by a small energy separation between the ground state ($^1S_0$) and the first excited state ($^3D_3$). *Rogers* et al.,[144] using the Orgel model as a basis, have stressed the importance of the increased electron density in the xy plane (associated with the d_{xy}, $d_{x^2-y^2}$, and $1/\sqrt{2}(d_{z^2}-s)$ orbitals) as regards the possibility of forming corresponding bands with preponderantly metallic character. A deformation electron density study of $CuAlO_2$ indeed showed the expected increased electron density in the xy plane[145] (Fig. 19); an unexpected feature of the study was that the maxima were located not on the Cu–Cu vectors but at the centers of the equilateral triangles of copper atoms. A detailed analysis of the results suggested the formation of a partially hybridized valence orbital $(0.97\,d_{z^2}-0.24\,s)$.

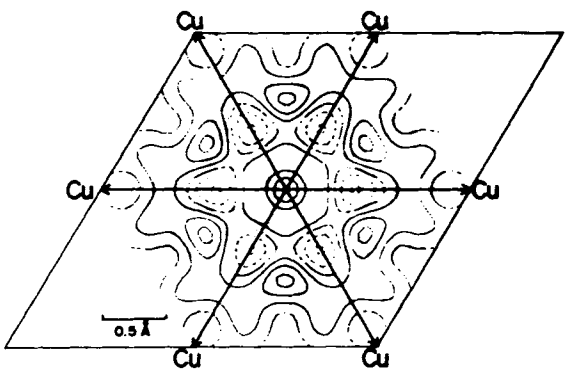

Fig. 19. Difference electron density in $CuAlO_2$, section at $z=0$.

This model seems, at least for the delafossite structures, to be self-consistent and to have been confirmed experimentally. However, it depends on the assumption that the Cu–O bonds are exactly perpendicular to the planes defined by the metal atoms, which is the case in very few compounds in which d^{10}–d^{10} interactions have been postulated. For example, the silver layers in $LiAg_3O_2$ are planar and the coordination at silver is exactly linear, but the angle between the AgO_2 units and the silver plane is only 32°.

Independently of such chemical considerations, and before the discovery of the numerous examples of the particular cation substructures, *H. Bilz* came to the conclusion that d^{10} ions with low-lying excited states—especially Ag^+—should be liable to attractive interactions.[8c] His considerations were prompted by differences in the phonon spectra of AgCl and AgBr compared with alkali metal halides.[135] The model involved polar interactions; it assumed the ready excitation of d valence electrons into s states of the conduction band associated with the formation of a quadrupole moment at the d^{10} centers. Although this model was intended to explain dynamic effects, it also seems suitable for the static phenomena observed; quadrupole–quadrupole interactions between several centers preferentially lead to two-dimensional assemblies, just as were found to predominate in the crystal structures. The shift in optical absorption would then be explicable in that the excited quadrupole state would be lowered in energy by the interactions. This concept reminds one qualitatively of dispersion interactions. Incidentally, it should be noted that *Bilz*'s quadrupole deformation model of d^{10} cations relates also to their marked mobility in ionic crystals.[146]

R. Hoffmann et al. have concerned themselves, in a series of publications, with an explanation of the bonding in the short metal–metal contacts frequently observed in bi- and polynuclear complexes of d^{10} species.[147] An EHMO analysis showed that, even when perturbations of the d^{10} systems by the ligands were neglected, bonding interactions between fully occupied d shells could arise if single-electron d functions were allowed to have partial s and p character. *R. Hoffmann* et al. and *J. K. Burdett* showed that such considerations of localized systems can also be extended to "collective" structures, e.g., the silver substructures in silver-rich oxides.[148]

Although the bonding models so far postulated differ greatly in detail, they all lead to the same conclusion: the presence of a low-lying excited state destroys the pure "core" nature of the "closed" d^{10} shell and also destroys its spherical symmetry. This is illustrated by the determination of deformation electron density at Zn^{2+} in a tetrachloro complex (Fig. 20);[149] the electron density distribution is easiest to reconcile with a configuration $(3d-e)^4(3d-t_2)^{6-x}(4s)^x$. Since the d–s separation is clearly of central importance, Ag^+ should assume a special position with respect to the effects discussed here (Table 5). This is consistent with our current state of knowledge: short Cu^+–Cu^+ and Au^+–Au^+ contacts have so far been observed mainly in the presence of strongly covalently bonded ligands and, in contrast to silver, have less ten-

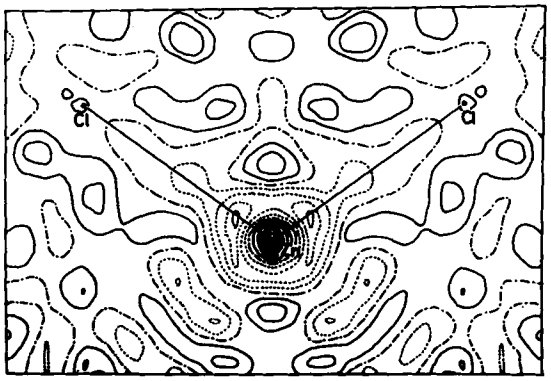

Fig. 20. Difference electron density in the region of the Zn^{2+} ion in $[NH_4]_3[(ZnCl_4)Cl]$.

Table 5. Some energy separations [cm^{-1}] in the free ions Cu^+, Ag^+, and Au^+.

	$^1S_0(d^{10}s^0) \rightarrow {}^3D_3(d^9s^1)$	$^1S_0(d^{10}s^0) \rightarrow {}^3P_2(d^9p^1)$
Cu^+	21928	66418
Ag^+	39163	80172
Au^+	15039	63052

dency to form extended, clusterlike aggregates. Isolable subvalent compounds of copper and gold analogous to those of silver (see Section 2.4) are unknown. The high ionic mobility associated with the unusual bonding interactions discussed here is also most marked for silver.

5. Conclusions

The empirical results presented in this article furnish convincing evidence that d^{10} cations can interact with each other in a way that influences both structure and physical properties. This capability is to a first approximation independent of the type of ligand and the geometry of the ligand field: it is unimportant whether the cations display linear coordination, with strongly covalent ligands, or an irregular geometry involving ionic bonds. The only precondition so far recognizable is that other influences (e.g., bridging ligands or an excess of cations) must first force the d^{10} ions into mutual proximity. "Isolated" d^{10} cations do not display the characteristic phenomena mentioned in this article.

It is not yet clear what causal role the interactions play in determining structure; do they "actively" lead to a weak bond or do the d^{10} species "tolerate" the short homoatomic contacts? It seems that no general answer can be given to this question and to others concerned with the type of bonding. The molecular systems (coordination compounds) will have to be treated differently from the more "collective" (polymeric) structures, and other treatments again will be necessary to describe dynamic effects such as the high mobility of such ions in a solid matrix in detail. Furthermore, it can be seen from the first excitation energies of the free ions Cu^+, Ag^+, and Au^+ (Table 5) that no uniform picture can be expected for the group of coinage metals because of their intrinsic heterogeneity. The only common feature to which the postulated interactions and their consequences can be attributed is the combination of a "closed" d^{10} ground state with low-lying excited states.

I would like to thank the co-workers and colleagues, listed in the references, who were involved with the individual contributions to this field. I am grateful to Dipl.-Chem. Konrad Heidebrecht, Berndt Ullrich Köhler MSc, and Dr. Hartmut Ehrhardt for helpful and fruitful discussions. The Deutsche Forschungsgemeinschaft supported this work financially.

Carbosilanes**

By Gerhard Fritz*

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

Carbosilanes are compounds in which the elements carbon and silicon occupy alternate positions in the molecular framework. Formal replacement of every second carbon atom in the diamond lattice by a silicon atom gives silicon carbide, which exists, however, in several modifications characterized by different stacking orders. The SiC lattice is the basis of most carbosilanes.[1] These are divided on the basis of structural differences into carborundanes, silascaphanes, and molecules that no longer contain elements of the silicon carbide structure. In the carborundanes the Si-C six-membered rings are arranged in the chair form, in the silascaphanes in the boat form. The molecular framework of the third group is derived from barrelane and asterane. The reactivity of the carbosilanes is determined mainly by the substituents on the skeletal atoms. The presence of SiH or Si-halogen groups leads to a high reactivity, while derivatives with organic groups on the silicon atoms and CH_2 or CH groups in the skeleton are much less reactive. However, even such CH_2 and CH groups permit certain characteristic reactions. Because of their structural features and the range of substituents that can be introduced, the carbosilanes are presently of considerable interest with respect to technological developments as precursors for ceramics.

1. Introduction

The first organosilicon compounds were obtained in the second half of the last century by reaction of chlorosilanes with alkylzinc or alkylmercury compounds and by Wurtz-Fittig syntheses (reaction of R_3SiCl with R'Cl and sodium). Their systematic study, however, only began after the discovery of Grignard reagents.[2] The "direct synthesis" of the methylchlorosilanes by reaction of silicon and methyl chloride in the presence of a copper catalyst in the 1940s led to the industrial preparation of Me_2SiCl_2 and thus to the development of the chemistry of silicones.[3] Compounds whose molecular framework consists of alternating silicon and carbon atoms have only been synthesized in the last 30 years;[4] the impetus for their study did not come from syntheses involving organosilicon compounds but through studies of the free radical reactions initiated by the thermal decomposition of silanes in the gas phase: e.g., the formation of H_3Si-PH_2 from SiH_4 and PH_3[5] or the reactions of ethylene with thermally produced silyl radicals.[5] The thermal decomposition of methylsilanes and methylchlorosilanes ($Me_{4-x}SiY_x$; Y = Cl, H) in the gas phase leads to the preferential formation of liquid, glassy, or crystalline compounds with an Si-C-Si skeleton.[6]

Another route to carbosilanes is provided by reactions of elemental silicon with CH_2Cl_2 or $CHCl_3$ or with *C*-chlorinated carbosilanes such as $(Cl_3Si)_2CCl_2$ in the presence of a copper catalyst.[7]

Routes involving organometallic synthesis can also be used for the construction of various carbosilanes.[8] Cyclization reactions of *Si*-methylated, linear or monocyclic carbosilanes under the influence of $AlBr_3$ provide a route to oligocyclic carbosilanes.[9]

The silicon and/or carbon atoms of the carbosilanes can be functionalized (e.g., as SiH, SiCl, or SiF, or as CCl, CF, or CLi). Such functionalizations open up further synthetic possibilities. Furthermore, they permit studies of the directing influence of the substituents on the reaction course.

2. Formation of Carbosilanes

2.1. Carbosilanes by Gas-Phase Pyrolysis of $SiMe_4$ and $Me_{4-x}SiCl_x$ (x = 1-3)

2.1.1. Experimental

The synthesis of carbosilanes on a preparative scale is carried out using an apparatus of the type shown in Figure 1. The pump P transfers $SiMe_4$ (b.p. = 26 °C), which evaporates from K into the (initially evacuated) apparatus, in the direction of the arrows through the reaction vessel (720 ± 5 °C) at such a rate that the contact time is ca. 1 min. Shortly after commencement of the reaction, white fumes exit from the reaction vessel and condense out at room temperature in the traps F_1-F_3. At a later stage, molten yellow products emerge from the reaction vessel and crystals are deposited on the walls of the vessel below the oven.[10] At the same time, H_2, CH_4, C_2H_4, and C_2H_6 are formed. Since the vapor pressure of $SiMe_4$ at 20 °C is ca. 720 torr, atmospheric pressure is built up in the apparatus after 2-3 h (excess pressure is released via a mercury valve). The vapor pressure of $SiMe_4$ remains constant in the system as long as liquid $SiMe_4$ is present in the reservoir, so that steady-state conditions are maintained in the apparatus. $SiMe_4$ and (in small amounts) product molecules such as H_2, CH_4, C_2H_4, C_2H_6, SiH-containing alkylsilanes, and some very low-boiling carbosilanes are continuously

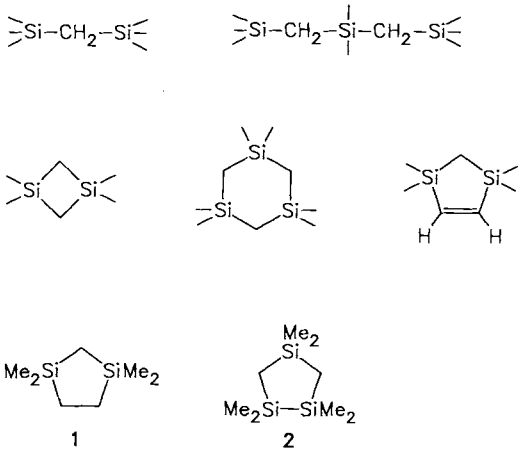
forced through the reaction vessel. The pyrolysis of other methylsilanes occurs in an analogous manner.

2.1.2. *Carbosilanes by Pyrolysis of $SiMe_4$*

The complex product mixtures obtained upon pyrolysis of $SiMe_4$ can be separated using chromatographic techniques.[11] The products containing two and three silicon atoms are both linear and cyclic (Scheme 1).

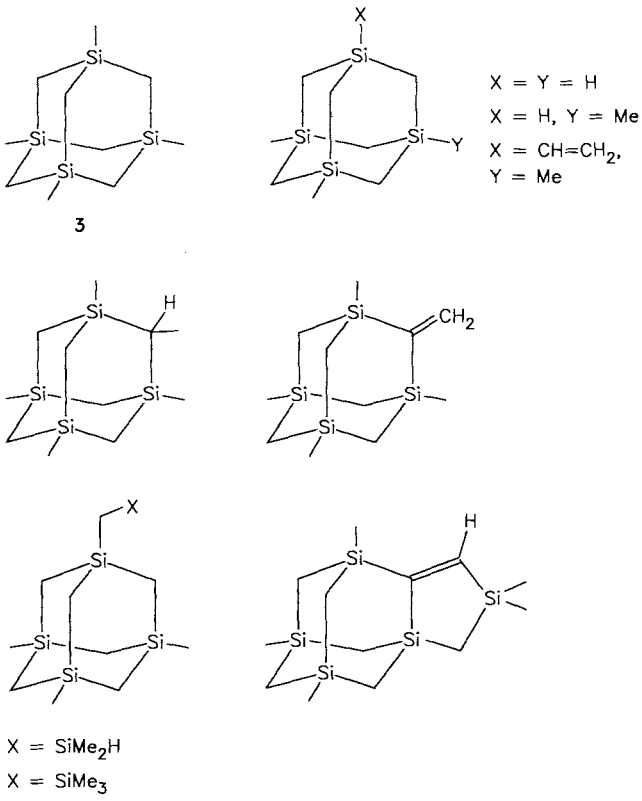


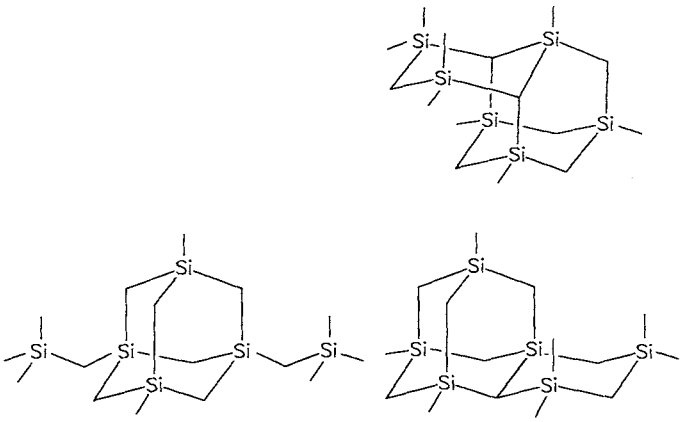
Scheme 1. — = Me or H.

Schemes 2–4 show characteristic silicon-richer compounds, the molecular skeletons of which contain the 1,3,5,7-tetrasilaadamantane unit; this unit can formally be derived from β-SiC (zinc blende type). Scheme 2 contains substituted 1,3,5,7-tetrasilaadamantanes,[12] some of which have an annelated Si–C ring, and Scheme 3 contains compounds in which such skeletons are linked by CH_2 bridges.

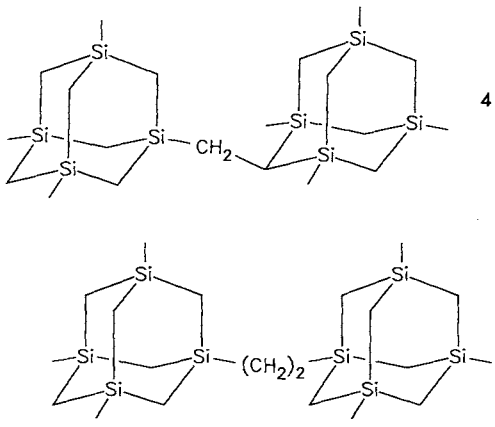
Scheme 4 contains the carborundanes, a group of compounds whose molecular skeletons contain two, three, and four annelated 1,3,5,7-tetrasilaadamantane units.[13]

The structural unit of α-SiC (wurtzite-type ZnS) appears in compounds **6** and **7**. Compound **6** contains the adamantane and wurtzitane units, **7** in addition the barrelane unit. Compound **7** represents all essential features of the

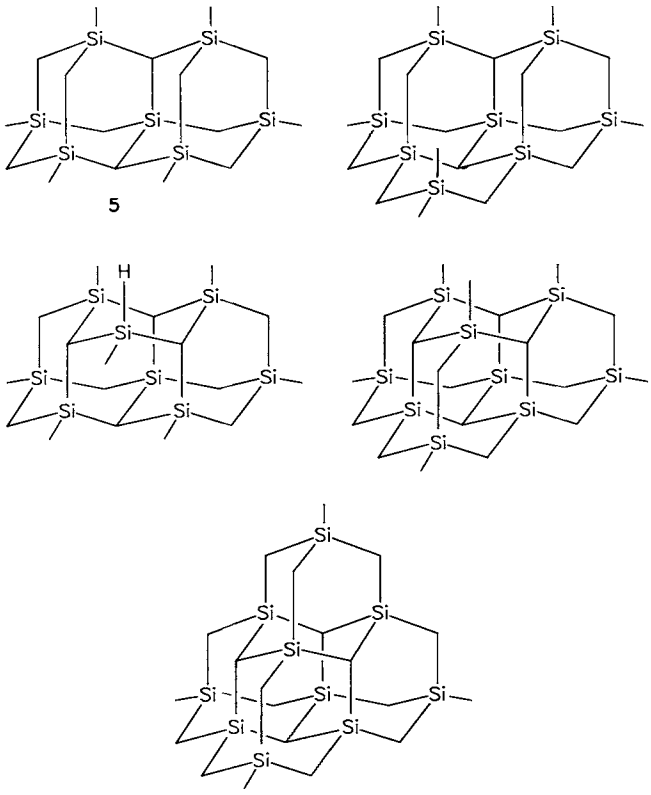




Scheme 2. — = Me.



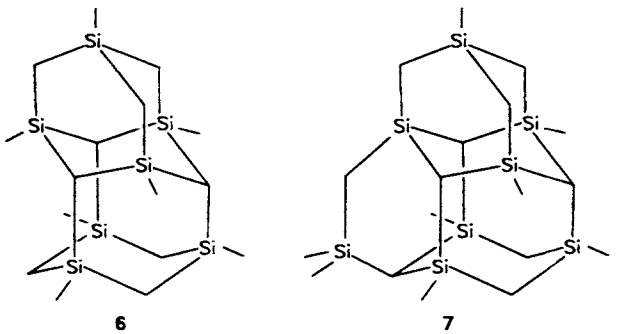
Scheme 3. — = Me.



5

Scheme 4. — = Me.

4H-SiC structure: the adamantane unit and the complete wurtzitane skeleton.[14]



6 7

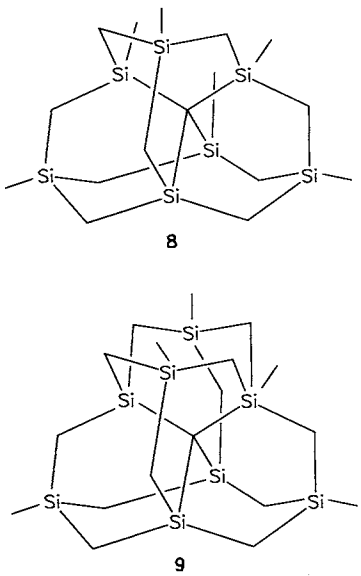
— = Me

While the carborundanes contain structural elements of silicon carbide, compounds **8** and **9** are members of the silascaphanes, a group whose Si-C six-membered rings are arranged in the boat form.[12, 15]

2.1.3. *Carbosilanes by Pyrolysis of Chloro(methyl)silanes*

The carbosilanes obtained by pyrolysis of tetramethylsilane are mostly unreactive, since (apart from SiH groups in a few cases) they are not functionalized. Carbosilanes containing SiCl functional groups can however be obtained by pyrolysis of the three methylchlorosilanes.[16]

The thermal decomposition of the methylchlorosilanes in the gas phase occurs with sufficient rapidity at ca. 700°C. 60 vol% of the pyrolysate obtained from Me_3SiCl consists of a fraction boiling between 160 and 200°C at atmospheric pressure, the remainder being oils and solids which are soluble in nonpolar solvents. $MeSiCl_3$ yields a pyrolysate of which 85% is liquid and colorless and 15% oily or solid (fusible).



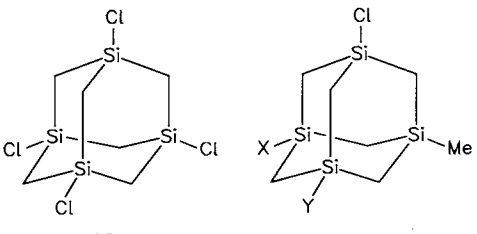
8 9

— = Me

The main products obtained from the methylchlorosilanes include partially methylated 1,3-disilapropanes. Their contribution to the total pyrolysate is 32% in the case of Me_3SiCl, 43% in the case of Me_2SiCl_2, and 60% in the case of $MeSiCl_3$. The pyrolysate from Me_3SiCl contains all the possible chloro- and methyl-substituted compounds with the basic structure $\geqslant Si-CH_2-Si\leqslant$. The main product from Me_3SiCl is **10**, while that from Me_2SiCl_2 and $MeSiCl_3$ is **11**. Isolation and identification of these products

$Me_3Si-CH_2-SiCl_3$ **10** $Cl_3Si-CH_2-SiCl_3$ **11**

was accomplished after reduction with $LiAlH_4$, whereby complete Cl/H exchange occurs without any change in molecular structure. This is also true for the silicon-richer compounds. In the latter case, the 1,3,5-trisilacyclohexane and 1,3,5,7-tetrasilaadamantane structures are increasingly favored when more methyl groups are present in the starting material. Thus, the 1,3,5,7-tetrasilaadamantanes **12**-**15** are formed from Me_3SiCl in the ratio 170 : 26 : 3 : 1.



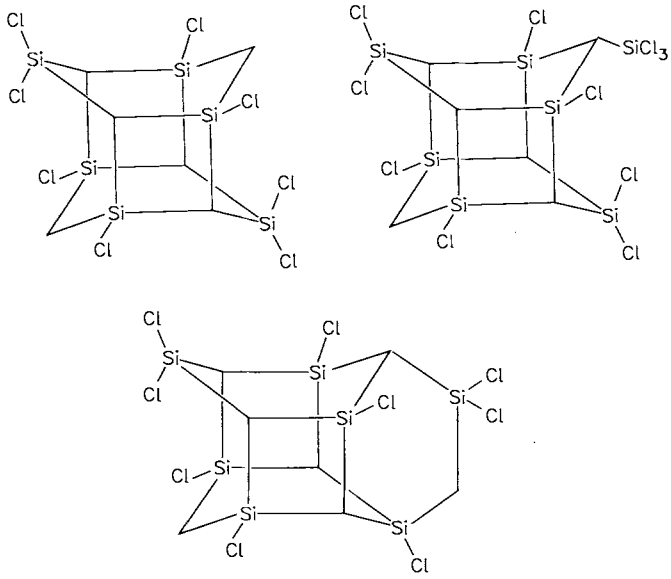
12

13, X = Y = Cl
14, X = Cl, Y = Me
15, X = Y = Me

The silicon-richer compounds formed upon pyrolysis of Me_3SiCl have not been studied in more detail. Those com-

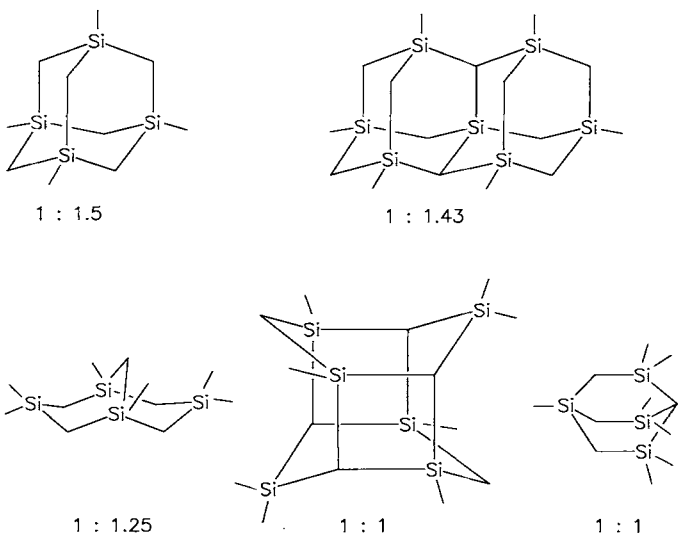
pounds formed upon pyrolysis of Me_2SiCl_2 or $MeSiCl_3$ that contain four to eight silicon atoms have been better characterized.[17] Separation of the products forming the pyrolysate of Me_2SiCl_2 yielded forty compounds containing five to seven silicon atoms; the separation was carried out by chromatography following the conversion of the SiCl groups to SiH groups, and the products were identified on the basis of NMR and MS studies[18]. Figure 2 shows the types of compound obtained, with some examples. Compound **22** is the first known carbosilane with carbon atoms forming the bridgeheads of an adamantane skeleton; i.e., a 2,4,6,8,9,10-hexasilaadamantane derivative.

The polycyclic products formed in the pyrolysis of $MeSiCl_3$ are mostly carbosilanes with the asterane structure[18, 19] (Scheme 5).



Scheme 5.

The Si:C ratio of the methylsilanes has a considerable influence on the structure of the pyrolysis products. As the number of methyl groups in the starting material is reduced in the series $SiMe_4$, $MeSiCl_3$, $MeCl_2Si-CH_2-SiCl_3$, the formation of carbosilanes with an Si:C ratio of 1:1 is increasingly favored. Carbosilanes with an adamantane structure are formed preferentially from $SiMe_4$, but never from $MeSiCl_3$; in support of this finding, no carbosilanes with the asterane structure are formed from $SiMe_4$. The Si:C ratios of some molecular skeletons are given in Scheme 6.



Scheme 6.

Fig. 2. 2.1.4. *Mechanism of the Formation of Carbosilanes in the Gas-Phase Pyrolysis of Methylsilanes*

Prior to the discussion of the mechanism we should note the following observations. The compounds formed from $SiMe_4$ contain methyl groups and, to a lesser extent, hydrogen atoms as the substituents on the silicon atoms: only in a few cases are structures with Si–Si bonds observed. The compounds derived from methylchlorosilanes bear methyl and chlorine substituents on the silicon atoms. Neither *C*-chlorinated carbosilanes nor carbon polymers are observed. The formation of the pyrolysate occurs via complex reaction sequences which have until now not been sufficiently clarified in detail. Clearly, the preparative method used permits low-molecular-weight reaction products to participate in the overall reaction, owing to the permanent circulation of volatile molecules through the apparatus. The formation of silicon-rich products of higher molecular weight is favored by a thermal aftertreatment. Taking into account the experimental facts, the discussion of the mechanism has to include the following considerations:

a) the primary reaction in the thermal decomposition of the methylsilanes in the gas phase;
b) the importance of insertion of the CH_2 group into the Si–Si bond;
c) the possible participation of initially produced, simple carbosilanes in the formation of higher-molecular-weight ones.

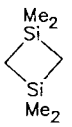
a) The first step in the thermolysis of $SiMe_4$ is described by reaction (1). In order to account for the formation of

$$SiMe_4 \longrightarrow Me_3Si + Me \qquad (1)$$

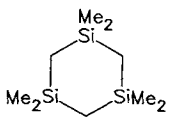
compounds with the $\geqslant Si-CH_2-Si\leqslant$ skeleton, reaction (2) also seems likely. Of particular importance is the isola-

$$Me_3Si-Me + Me \longrightarrow Me_3Si-CH_2 + CH_4 \qquad (2)$$

tion of the cyclic compounds **25** and **26**. These are also formed when the methylsilanes are decomposed in a cold plasma;[20] under these conditions, thermally induced sec-



25



26

ondary reactions cannot occur. These compounds are presumably formed via reaction (3), followed by dimerization and trimerization.

$$Me_3Si-CH_2 \longrightarrow Me_2Si-CH_2 + Me \qquad (3)$$

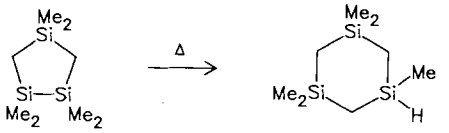
Helm and *Mack*[21a] and later *Davidson* et al.[21b] have suggested a primary reaction in which radicals or reactive intermediates with a silicon–carbon double bond are formed, respectively. The existence of radicals has not yet been proved, and species with Si–C double bonds formed at 700 °C in the gas phase should be regarded in a more general sense as reactive intermediates. However, it appears correct to define the primary reaction as one in which an Si–C bond undergoes homolysis to give a silyl and a methyl radical.

b) It is noteworthy that compounds with SiH groups are found among the pyrolysis products of $SiMe_4$. Since silyl radicals are formed in the pyrolysis of the methylsilanes, their recombination to give compounds with Si–Si bonds is to be expected. The formation of the SiH groups is due to the insertion of the CH_2 group into the Si–Si bond according to reaction (4). Examples are provided by hexamethyl-

$$\geqslant Si-Si\leqslant CH_3 \longrightarrow \geqslant Si-CH_2-Si\leqslant H \qquad (4)$$

disilane [reaction (5)][22] and trisilacyclopentane **2**[23,24] [reaction (6)].

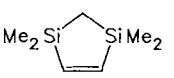
$$Me_3Si-SiMe_3 \longrightarrow Me_3-CH_2-SiMe_2H \qquad (5)$$



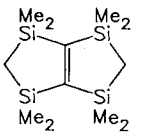
(6)

2

c) In order to obtain information pertinent to the participation of simple carbosilanes in the total pyrolysis reaction, the thermal behavior of the linear compounds $(Me_3Si)_2CH_2$, $(Me_3Si-CH_2)_2SiMe_2$, and $(Me_3Si-CH_2-SiMe_2)_2CH_2$ and the cyclic compounds **25**, **26**, and **27** was studied. Ther-



27



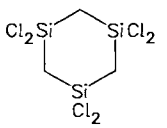
28

mally induced rearrangements are most likely to occur when the molecular framework of the compound is strained. The studies on the disilacyclobutane derivative **25** show the influence of temperature;[25] while at 300–320 °C polymeric Si–C–Si chains are formed, at 480–500 °C molecular structures are formed which correspond to those observed in the pyrolysis of $SiMe_4$. The six-membered ring compound **26**, in contrast, is much more stable. At 500 °C the disilacyclopentene **27** yields 1,3,5,7-tetrasilaadamantanes and the bicyclooctene **28** as well as further products of the $SiMe_4$ pyrolysis. Thus it appears that some of the compounds formed in the pyrolysis of $SiMe_4$ react further, under the reaction conditions, as intermediates in the construction of the silicon-richer compounds. The studies carried out until now have not permitted a complete characterization of the higher-molecular-weight carbosilanes in the methylsilane pyrolysates; they occur as solid, glasslike, fusible products.

2.2. Carbosilanes by Reaction of Silicon with CH_2Cl_2, $CHCl_3$, and CCl_4

2.2.1. *Reaction of CH_2Cl_2 with Silicon*

As early as 1945, following the direct synthesis of the methylchlorosilanes, a US patent reported the reaction of silicon with CH_2Cl_2 in the presence of copper;[26] the products were stated to include linear compounds, $X_3Si(CH_2)_nSiX_2Y$ (X = Cl, Y = H or Cl, n = 1–4) and cyclic compounds $(SiCl_2CH_2)_x$ (x = 3 and larger). We were later able to isolate the crystalline six-membered ring com-



29

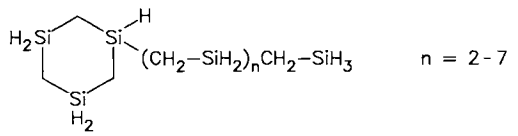
30

pound $(Cl_2Si{-}CH_2)_3$ **29** and the eight-membered ring compound $(Cl_2Si{-}CH_2)_4$ **30** from such reactions.[17,27] Apart from these and the linear compounds **11** and **31**, only viscous and nondistillable products are formed. The reaction of silicon with CH_2Cl_2 in a fluidized bed at 350 °C favors the formation of such substances. Since SiCl groups hinder chromatographic separation, they were first converted into SiH groups by reduction with $LiAlH_4$. The compounds obtained (see Fig. 3) were then separated by HPLC[7,11] (for further details see Refs. [4, 7]).

11 **31**

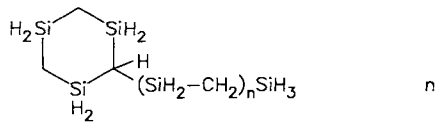
a) $Si_nC_{n-1}H_{4n}$ n = 4–12 (two terminal SiH_3 groups)
b) $Si_nC_nH_{4n+2}$ n = 4–9 (one terminal SiH_3 and one terminal CH_3 group)

c)



n = 2–7

d)



n = 3–8

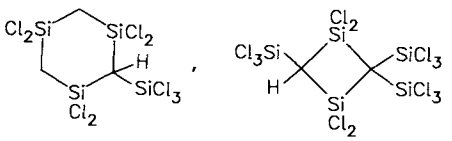
Fig. 3. Types of substances formed in the reaction of silicon with CH_2Cl_2 (Cu catalyst).

The products of the reaction of silicon with CH_2Cl_2 contain the corresponding *Si*-chlorinated compounds. Those of higher molecular weight are honeylike, tarry, or solid glassy substances. The proportion of such substances is ca. 20%. The viscosity of the SiH-containing compounds is considerably lower.

2.2.2. *Reaction of $CHCl_3$ and CCl_4 with Silicon*

R. Müller et al.[28] studied the reaction of silicon with $CHCl_3$ and were able to identify the compounds shown in Figure 4a. In this case, too, the reaction in a fluidized bed favors the formation of higher-molecular-weight products; these could be separated by chromatography and identified after transforming the SiCl groups into SiH groups (see Refs. [7, 4] and Fig. 4b–d).

a) $(Cl_3Si)_2CH_2$ **11**, $HCl_2Si{-}CH_2{-}SiCl_3$, $Cl_3Si{-}CHCl{-}SiCl_3$, $HCl_2Si{-}CH(SiCl_3)_2$, $(Cl_3Si)_3CH$, $(Cl_3Si{-}CH_2)_2SiCl_2$ **31**, $Cl_3Si{-}CHCl{-}SiCl_2{-}CH_2{-}SiCl_3$, $(Cl_3Si)_2CH{-}SiCl_2{-}CH_2{-}SiCl_3$, $(Cl_3Si{-}CH_2{-}SiCl_2)_2CH_2$,



b) Unbranched carbosilanes with terminal SiH_3 groups, e.g., $H_3Si(CH_2{-}SiH_2)_4CH_2{-}SiH_3$
c) Carbosilanes with one or two C branches, e.g.,
$H_3Si{-}CH_2{-}SiH_2{-}CH(SiH_3){-}SiH_2{-}CH_2{-}SiH_3$,
$H_3Si(CH_2{-}SiH_2)_2CH(SiH_3){-}SiH_2{-}CH_2{-}SiH_3$,
$H_3Si(CH_2{-}SiH_2)_3CH(SiH_3)_2$,
$(H_3Si)_2CH{-}SiH_2{-}CH(SiH_3)_2$,
$H_3Si{-}CH_2{-}SiH_2{-}CH(SiH_3){-}SiH_2{-}CH(SiH_3)_2$,
$H_3Si{-}CH_2{-}SiH_2{-}CH(SiH_3){-}SiH_2{-}CH(SiH_3){-}SiH_2{-}CH_2SiH_3$
d) 1,3,5-Trisilacyclohexanes with one, two, or three Si substituents at the C atoms, e.g.,

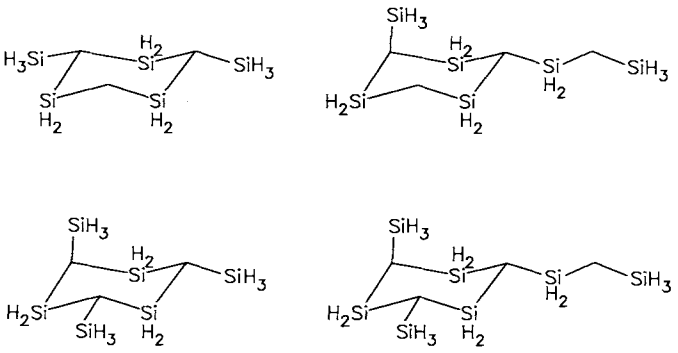


Fig. 4. Compounds formed in the reaction of $CHCl_3$ with silicon (Cu catalyst).

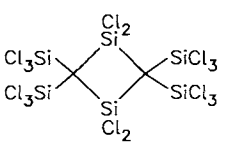
R. Müller and co-workers[29,30] also studied the reaction of silicon with CCl_4. In agreement with *Müller*'s results, the reaction in a fluidized bed[7] leads mainly to the following substituted methane, ethylene, and acetylene derivatives:

$Cl_3Si{-}C{\equiv}C{-}SiCl_3$, $(Cl_3Si)ClC{=}CCl(SiCl_3)$, $(Cl_3Si)_3CH$, $(Cl_3Si)_3CCl$, $(Cl_3Si)_4C$,



32

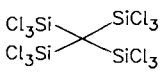
2.2.3. *Mechanism of the Reaction of CH_2Cl_2, $CHCl_3$, and CCl_4 with Silicon*

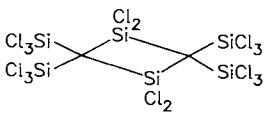
The reactions of silicon (Cu catalyst) with CH_2Cl_2 and $CHCl_3$ in a fluidized bed afford almost solely carbosilanes. With CH_2Cl_2, 70–80% of the products consist of non-branched carbosilanes, while with $CHCl_3$ similar amounts of *C*-branched carbosilanes and *C*-substituted trisilacyclohexanes are formed; no bi- and polycyclic carbosilanes are observed. An increase in the reaction temperature always leads to a decrease in the amounts of Si-richer carbosilanes. These results can be understood on the basis of the mechanism proposed by *Klebanskij* and *Fikhtengol'ts*[31,32] for the reaction of silicon (Cu catalyst) with MeCl. The adsorption of the CH_2Cl_2 molecules on the catalyst surface is a crucial step, the complete reaction occurring at this surface. The possibility that further reaction steps occur in the gas phase, leading finally to the observed products, can be excluded. This hypothesis is supported by the following observations: no further reaction occurs when isolated carbosilanes, such as $(Cl_3Si{-}CH_2{-}SiCl_2)_2CH_2$, are passed over activated silicon (Cu catalyst) at 350°C; changes occur only at 500°C after three days. Linear carbosilanes with four or more Si atoms undergo degradation to give the six-membered ring compound **29**, which is not formed from **31**.[33]

2.2.4. *C-Spirocyclic Carbosilanes from Perchlorinated Carbosilanes and Silicon (Cu Catalyst)*

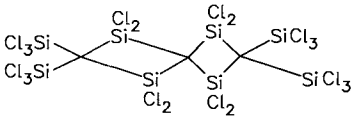
The reactions of chlorinated methanes with silicon described in Sections 2.2.1 and 2.2.2 can be applied to *C*-chlorinated carbosilanes. Thus, $(Cl_3Si)_2CCl_2$ **33** reacts at 300–350°C with silicon (Cu catalyst) to give the carbosilanes shown in Figure 5 (white crystals); the four-membered rings are joined in a spirocyclic manner via carbon atoms.[34]

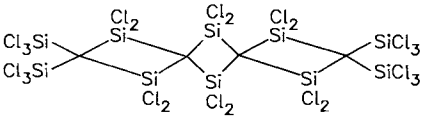
$(Cl_3Si)_2CCl_2$ **33**





32





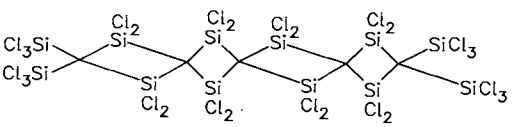


Fig. 5. Carbosilanes formed by reaction of **33** with silicon (Cu catalyst).

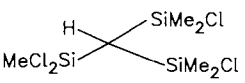
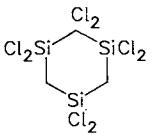
The replacement of the chlorines on silicon by methyl groups has a considerable effect on this reaction, as can be seen by the reaction of **34**

$(Me_3Si)_2CCl_2$ **34**

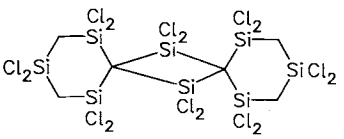
and of the partially methylated derivatives. A $\geqslant Si{-}CHCl{-}Si\leqslant$ unit is formed which prohibits the formation of cyclic compounds. Thus, $Me_3Si{-}CCl_2{-}SiMe_2Cl$ gives (among other compounds) isomers of composition $Si_3C_6H_{16}Cl_4$, e.g., compound **35**.[33] The formation of the spiro arrangement from perchlorinated carbosilanes appears to be favored; thus the products of the reaction of the octachloro derivative **36** with elemental silicon at



35



36



37

330°C include the spirocyclic compound **37** as well as further compounds such as those having the empirical formulas $Si_7C_6H_9Cl_3$ and $Si_{11}C_9H_{12}Cl_{20}$, whose structures are not completely clear.[35] These reactions, the mechanism of which is not known, lead to a new group of carbosilanes.

3. The Organometallic Synthesis of Carbosilanes

Functional substituents on silicon are of great importance for the synthesis and chemical behavior of the carbosilanes. Most substitution reactions with organometallic compounds occur via the Si–halogens, particularly via the SiCl group.[36] The cleavage of phenyl groups from silicon with HBr or HI has proved to be extremely useful for the synthesis of carbosilanes from organosilicon compounds and for the preparation of halosilanes with SiH groups (such as SiH_3Br)[37] [reaction (7)]. The cleavage of phenyl

$$\geqslant Si{-}Ph + HBr \longrightarrow \geqslant SiBr + C_6H_6 \qquad (7)$$

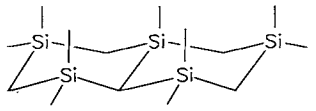
groups is slowed down, or even prevented, by the introduction of electronegative substituents on the Si atom.

3.1. The Synthesis of Oligocyclic Carbosilanes

The organometallic synthesis of cyclic and polycyclic carbosilanes has been reviewed.[8] It is made possible by

the introduction of Si-protecting groups (e.g., phenyl), which are transformed into functional groups in the step preceding the final one of ring formation. An example is the synthesis of *trans*- and *cis*-nonamethyl-1,3,5,7,9-pentasiladecalin **40**: construction of the linear, protected carbo-

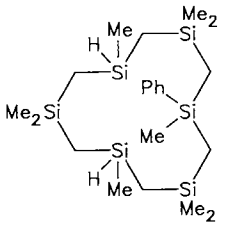
$(PhMe_2Si-CH_2-SiMe_2-CH_2)_2SiPhMe$ **38**
$(BrMe_2Si-CH_2-SiMe_2-CH_2)_2SiMeBr$ **39**



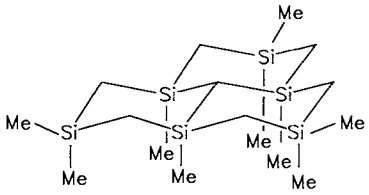
40, — = Me

silane **38**; cleavage of the Si-phenyl bonds with the formation of the bromo compound **39**; reaction of **39** with $CHBr_3$ and lithium to give the *trans* and *cis* compounds **40**.[38] A further example is the synthesis of the *trans-trans* and *cis-trans* perhydrophenalene derivatives **45** and **46**, respectively:[39] synthesis of the chain **41**; Br_2 cleavage of one phenyl group on each Si atom to give **42**; reduction with $LiAlH_4$ to give **43**; ring formation with lithium to yield **44**; once again, Si-Ph cleavage; bromination of the SiH groups and reaction with $CHBr_3$ and lithium to give a product mixture from which the isomers **45** and **46** are isolated.

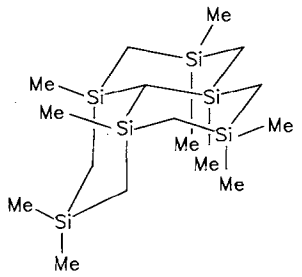
$XPhMeSi-CH_2(SiMe_2-CH_2-SiMeX-CH_2)_2SiMe_2-CH_2Br$
41, X = Ph; **42**, X = Br; **43**, X = H



44



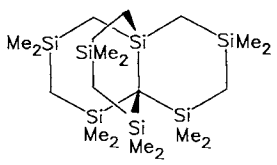
45



46

The synthesis of the heptasila[4.4.4]propellane **48**[40] was achieved in an analogous manner from **47** (after replacing the phenyl groups by bromine), CCl_4, and lithium.

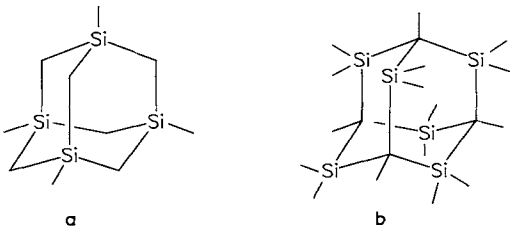
$PhSi(CH_2-SiMe_2-CH_2-SiMe_2Ph)_3$ **47**



48

3.2. Synthesis of C-Bridged Carbosilanes

So far, the syntheses of oligocyclic carbosilanes always make use of functional substituents at silicon and thus lead to bridging via silicon atoms. The pyrolysis of methylsilanes (Section 2.1) and the rearrangement reactions of carbosilanes induced by $AlCl_3$ (Section 4) also lead in general to similar Si-bridged carbosilanes. The situation is illustrated in Scheme 7.



a b

Scheme 7.

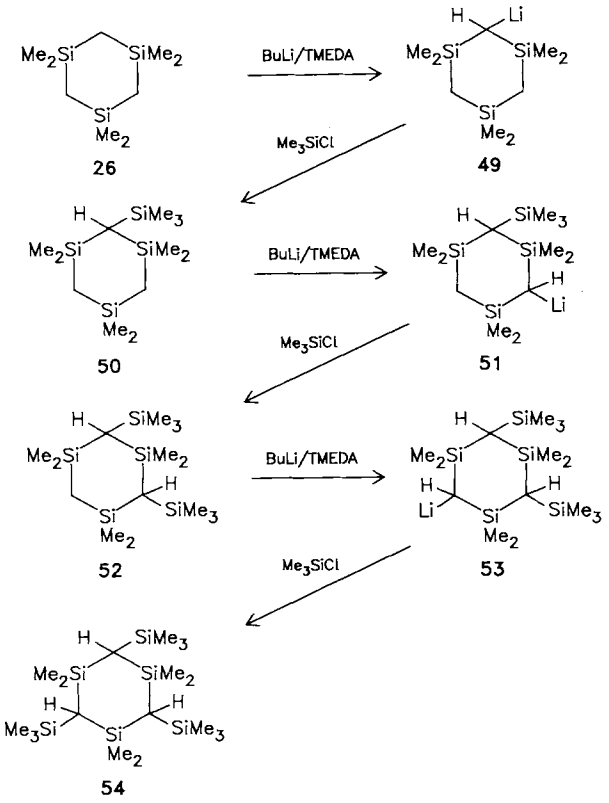
In the isolated carborundanes the Si atoms occupy bridgehead positions (a). The formation of compounds with carbon bridgeheads and the Si_6C_4 skeleton (b) is an exception[18] (cf. **22**). An approach to compounds of this type requires further progress in the syntheses of *C*-functional carbosilanes. In Sections 3.2.1 and 3.2.2 suitable reactions at the carbon atoms of the carbosilane skeleton will be described.

3.2.1. Lithiation at Skeletal Carbon Atoms of Si-Methylated Carbosilanes

In contrast to the possibilities for reactions involving the substituents on the Si atom, the CH_2 group in the carbosilanes appears unreactive. In order to expand the scope of carbosilane synthesis it is necessary to incorporate the latter group into the synthetic scheme. Reactions of perchlorinated carbosilanes with alkyllithium or alkylmagnesium compounds are not suitable, since the reactivity of the CCl_2 group is enhanced by its position between the two $SiCl_2$ groups: for example, reactions with MeMgCl lead to skeletal changes (see Section 5.1.3). However, one possibility lies in the selective acid-base reaction[41] according to reaction (8).

$$-Me_2Si-CH_2-SiMe_2- + LiR \longrightarrow -Me_2Si-CHLi-SiMe_2- + RH \quad (8)$$

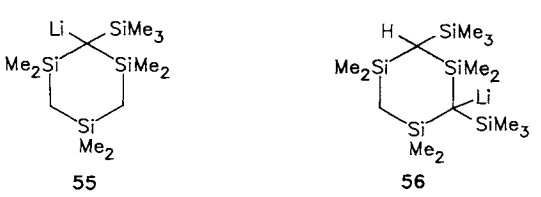
Reaction (8) requires a reagent that selectively lithiates $\geqslant Si-CH_2-Si\leqslant$ groups but does not react with either $(\geqslant Si)_3CH$, $\geqslant SiMe$, $>SiMe_2$, or $-SiMe_3$ groups. These criteria are satisfied by the complex between *n*BuLi and *N,N,N',N'*-tetramethylethylenediamine (TMEDA).[42] The model substance used for our studies was 1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane **26**, which can undergo several successive lithiations and silylations.[41] The reaction of **26** with *n*BuLi/TMEDA in hexane at 30°C gives the monolithiated compound **49** quantitatively in 2-3 h (Scheme 8).



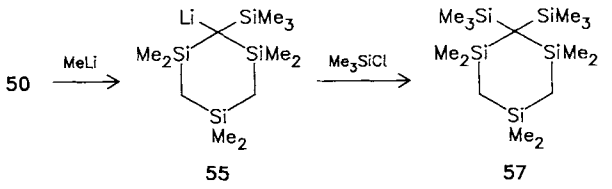
Scheme 8. Stepwise lithiation and silylation of compound **26** to give **54**.

The reaction is thermodynamically controlled, the carbanion formed being stabilized by two $SiMe_2$–CH_2 groups. No further metalation occurs with an excess of BuLi at 20 °C. Compound **49** is stable for several weeks; it undergoes quantitative silylation with Me_3SiCl to afford **50**. The treatment of **50** with BuLi can in principle lead to two products, the formation of either the thermodynamically more stable arrangement $(\geqslant Si)_3CLi$ (stabilization of the carbanion) or the kinetically preferred arrangement $\geqslant Si-CHLi-Si\leqslant$.

The use of *n*BuLi/TMEDA leads to compound **51**, owing to the large size of the reagent and the high shielding of the $(\geqslant Si)_3CH$ group. The reaction of **51** with Me_3SiCl gives compound **52**: the *cis* and *trans* isomers are formed in a ratio of 1 : 2.[43] The further reaction of **52** (80% *trans* and 20% *cis* isomer) with *n*BuLi/TMEDA at 20 °C confirms the selectivity of the lithiation; compound **53** is formed. Silylation of **53** gives compound **54** (94% *cis-trans* and 6% *cis*-is isomer[43]). The lithium compounds **51** and **53** are the kinetically controlled reaction products and are formed quantitatively. The thermodynamically favored lithium compounds are **55** and **56**, in which the anion is stabilized by three methylated silyl groups. The rearrangement of **51** to **55** or of **53** to **56** occurs in TMEDA/hexane at higher temperatures.



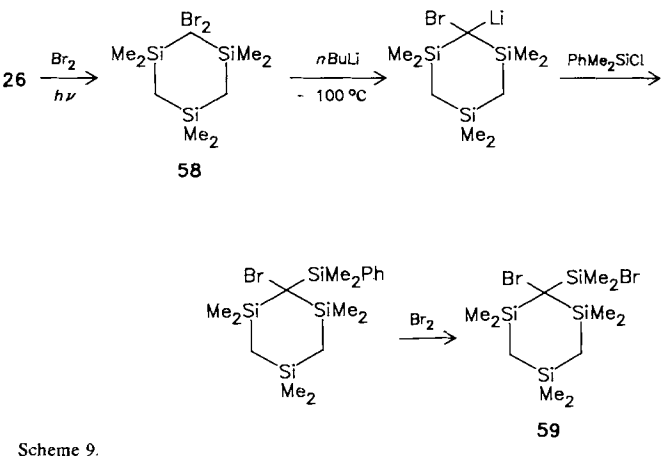
Compound **50** contains primary, secondary, and tertiary C atoms and is thus a model substance for studying the thermodynamic acidity of this class of compound: $(\geqslant Si)_3CH > \geqslant Si-CH_2-Si\leqslant > \geqslant SiMe$. Since MeLi in THF is a weaker base than BuLi in TMEDA, but sterically less demanding, the reaction with MeLi should be thermodynamically controlled. Indeed, the reaction of **50** with



MeLi in THF/ether (7 : 1) is complete in 24 h at 20 °C. Subsequent reaction with Me_3SiCl leads, as expected, to **57**. Further examples are provided by the lithiation of nonamethyl-1,3,5,7,9-pentasiladecalin **40** and of the silabarrelane **62**.[50]

3.2.2. *Metalation of the CBr_2 Group*

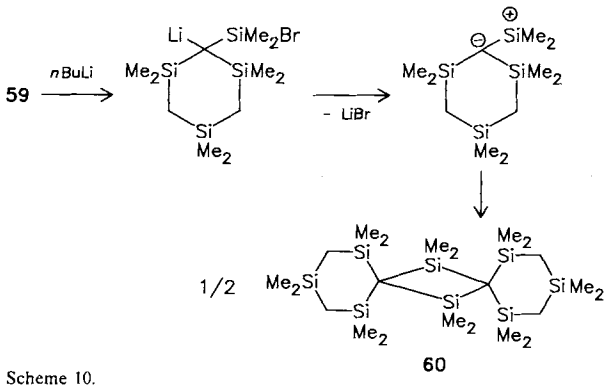
The photobromination of the trisilacyclohexane **26** permits the conversion of a CH_2 group into a CBr_2 group.[44] The product **58** can be metalated at −100 °C in a mixture of THF, ether, and pentane (4 : 1 : 1) according to Scheme 9.



Scheme 9.

This reaction principle leads to various synthetic possibilities, e.g., that shown in Scheme 10.[45] The spirocyclic compound **60** is formed extremely selectively (cf. Section 2.2.4).

As *N. Wiberg* and *G. Wagner* have shown,[46] *C*-lithiation at a position next to a Si-halogen group and subsequent elimination of LiX leads to the formation of a silaalkene when the necessary sterically demanding groups are pres-



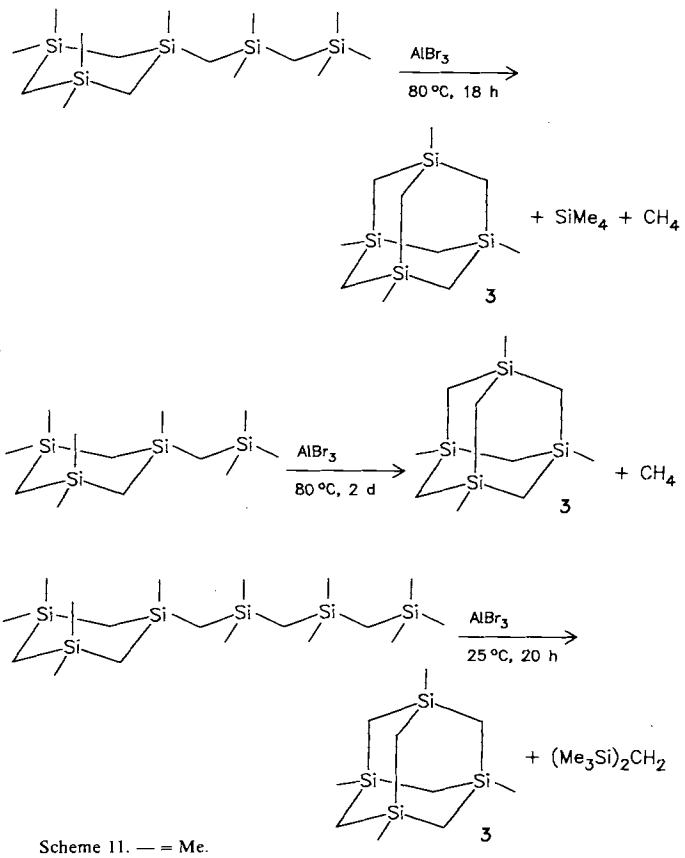
Scheme 10.

ent. They prepared compound **61**, which contains a SiC double bond.

$Me_2Si{=}C(SiMe_3)SiMe(tBu)_2$ **61**

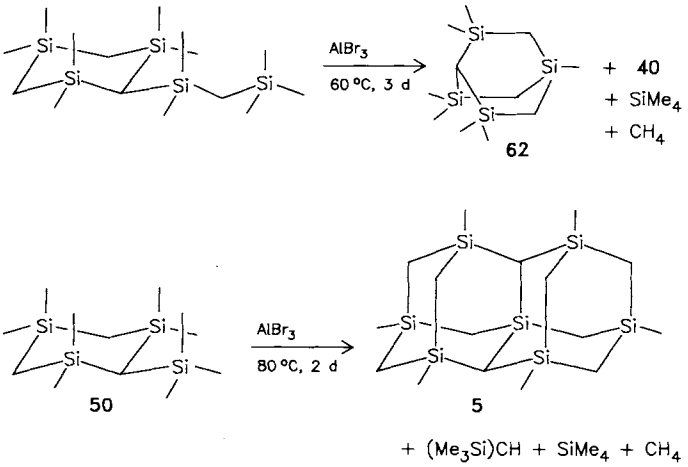
4. Polycyclic Carbosilanes via Rearrangement of *Si*-Methylated Linear and Monocyclic Carbosilanes with $AlBr_3$ or $AlCl_3$

The organometallic syntheses of carbosilanes have not yet opened a convenient route to the 1,3,5,7-tetrasilaadamantanes: thus cyclization reactions that proceed without pyrolysis are of interest. Such a reaction is that of $(Me_2Si{-}CH_2)_3$ **26** with $AlBr_3$ to give 1,3,5,7-tetrasilaadamantane **3** and $SiMe_4$.[47] Linear carbosilanes react under similar conditions with $AlBr_3$ to give **26** and thence **3**.[9] *Si*-methylated carbosilane chains as substituents at the tertiary C atom of a carbosilane form an additional six-membered ring with $AlBr_3$, as shown in Scheme 11. Both *cis* and *trans* isomers of pentasiladecalin **40** were formed.



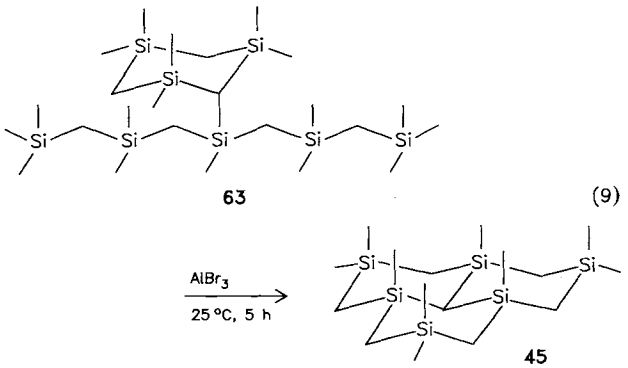
Scheme 11. — = Me.

In contrast, if the side chain is shortened so that ring closure to give a six-membered ring is no longer possible, carbosilanes with the barrelane (**62**), decalin (**40**, *cis* and *trans*), or diadamantane (**5**) skeleton are formed[9] (Scheme 12).



Scheme 12. — = Me.

According to this principle, compound **63** can be converted via a double ring closure into the all-*trans* compound **45** [reaction (9)].

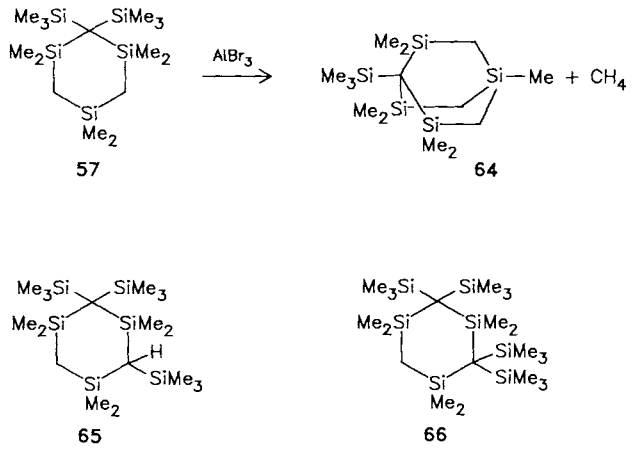


(9)

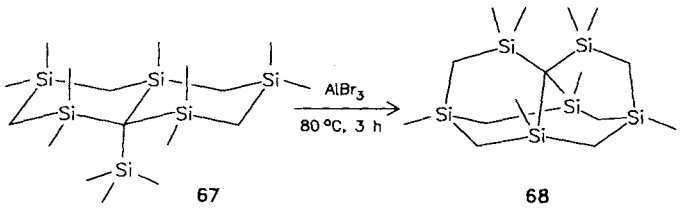
Compound **45** is a convex molecule (the cap of a sphere) in which all axial methyl groups point upwards, the axial CH_2 protons and the CH group downwards.[48]

Steric factors play an important part in these ring closure reactions. While the transformation of the *C*-substituted compound **57** into the carbosilane **64** occurs with elimination of CH_4 (Scheme 13),[9] a corresponding reaction of compounds **65** and **66** (with further $SiMe_3$ substituents on the skeletal carbon atoms) no longer occurs on steric grounds.[49] The sole reaction is a partial bromination with substitution of a methyl group.

This steric hindrance is not present in compound **67**, so that it can eliminate methane to give the silascaphane **68**[50] (Scheme 14).

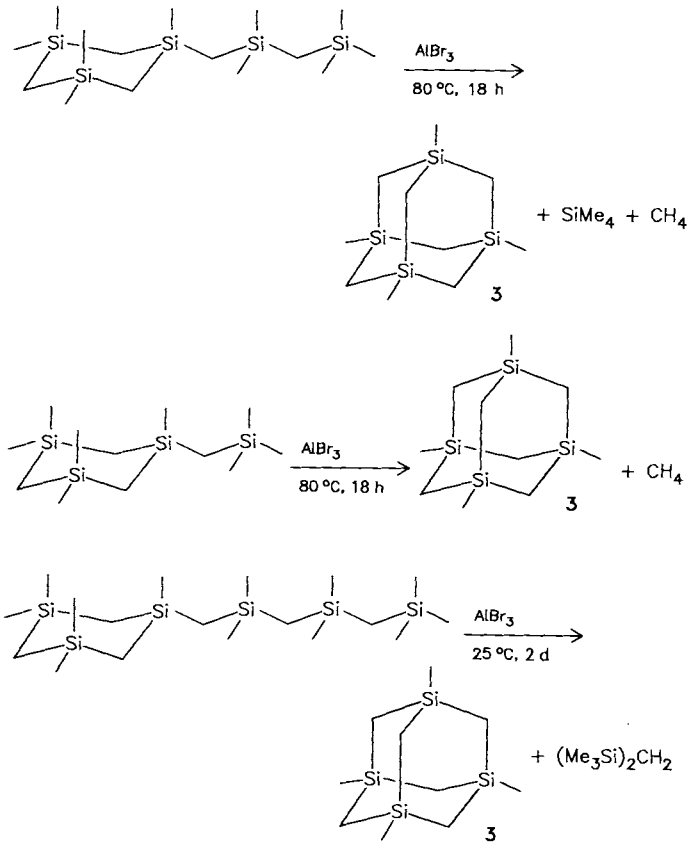


Scheme 13.



Scheme 14. — = Me.

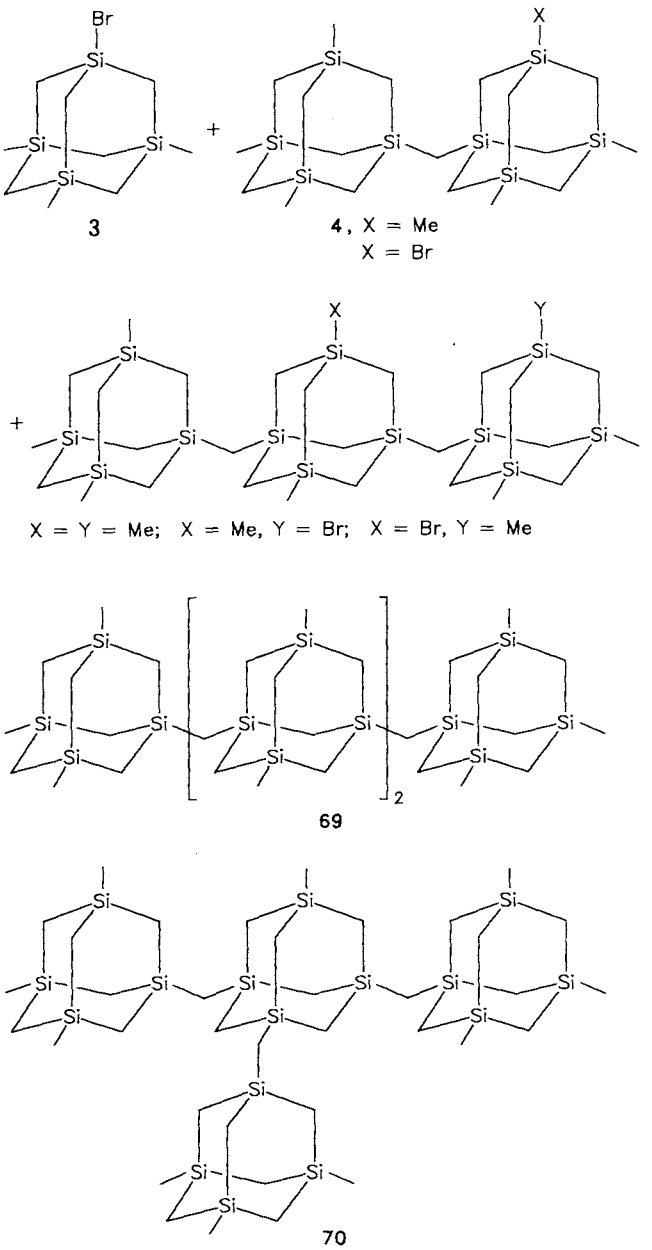
Ring formation accompanied by methane elimination also occurs when carbosilane chains of varying lengths are attached to a Si atom of a carbosilane ring (Scheme 15).



Scheme 15. — = Me.

This provides a relatively simple route to *Si*-methylated 1,3,5,7-tetrasilaadamantane **3**.[49]

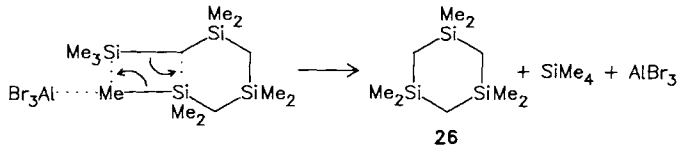
In many cases the compounds initially formed are further transformed when they are subjected to the influence of $AlBr_3$ for a longer time. Thus, compound **40**, which is formed in a yield of ca. 90% according to Scheme 11, reacts further in the reaction mixture to give derivatives of 1,3,5,7-tetrasilaadamantane, along with **26** and $SiMe_4$.[51] The barrelane derivative **62** rearranges under similar conditions to give derivatives of **3**.[52] The 1,3,5,7-tetrasilaadamantane structure element is stable towards $AlBr_3$. The reaction without solvent leads after 8 d at 80 °C to the compounds shown in Scheme 16.



Scheme 16. — = Me.

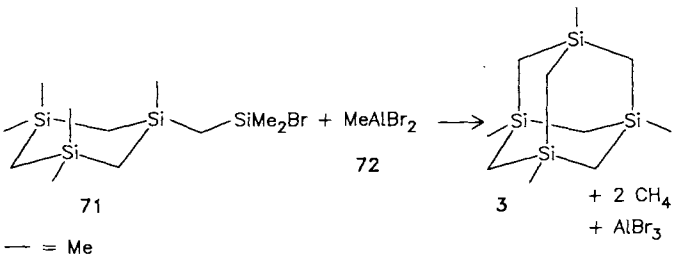
An increase in the reaction time leads to the formation of insoluble polycarbosilanes of this type. The reaction with $AlCl_3$ is slower, so that the isolation of the isomers **69** and **70** is possible.[52]

The ring formation of *Si*-methylated carbosilanes with concurrent elimination of $SiMe_4$ is induced by the polarization of the Si–C bond by $AlBr_3$ (Scheme 17), as has been shown for partially deuterated carbosilanes.[51]



Scheme 17.

The ring closure reaction with $SiMe_4$ elimination is sometimes accompanied by a ring closure with methane elimination; in some cases the latter is the sole reaction. It is due to an initial cleavage of a Si–Me bond by $AlBr_3$ to give $\geqslant$Si–Br and $MeAlBr_2$ **72**. Thus, the pure compounds **71** and **72**, synthesized independently, react in a molar ratio of 1 : 1 with the formation of almost no side products[53] to give the tetrasilaadamantane **3** and CH_4.



Very pure $AlBr_3$ and $AlCl_3$ do not induce the ring closure reaction; this only occurs when small amounts of Br_2 or HBr are added or with commercially available $AlBr_3$.

5. Reactions of Carbosilanes

The question arises as to whether the known reactions of functionalized silanes also occur for carbosilanes; in particular, what influence is exerted by groups such as CH_2, CCl_2, SiCl, SiF, and SiH. The following model compounds were chosen to give an answer to this question:

$(Cl_3Si)_2CH_2$ **11**, $(Cl_3Si{-}CH_2)_2SiCl_2$ **31**, $(Cl_2Si{-}CH_2)_3$ **29**, 1,3,5,7-tetrachloro-1,3,5,7-tetrasilaadamantane **12**.

5.1. Reactions of *Si*- and *C*-Chlorinated Carbosilanes with MeMgCl and RLi

The conversion of CH_2 groups into CCl_2 or CHCl groups in carbosilane skeletons can be carried out via photochlorination without cleavage of the Si–C–Si skeleton. The photochlorination can be controlled in such a way that intermediates with one and two CCl_2 groups can be preparatively isolated. Examples of such products are:

$(Cl_3Si)_2CCl_2$ **33**,[54] $(Cl_3Si{-}CCl_2)_2SiCl_2$ **73**, $SiCl_3{-}CCl_2{-}SiCl_2{-}CH_2{-}SiCl_3$ **74**,[55] $(Cl_2Si{-}CCl_2)_3$ **75**[56]

5.1.1. Reactions of $(Cl_3Si)_2CCl_2$ with MeMgCl and MeLi

The reactions of $(Cl_3Si)_2CCl_2$ **33**, the simplest member of this series, with MeMgCl or MeLi (excess with respect to the total number of Cl atoms) leads to the compounds shown in Scheme 18.[57]

$(Me_3Si)_2C{=}CH_2$ **76** (85%) {3%}, $(Me_3Si)_2CHMe$ **77** (2%) {23%}, $(Me_3Si)_2CMe_2$ (2%) {25%}, $(Me_3Si)_2CHCl$ (2%) {28%}

Scheme 18. Yields of the reactions with MeMgCl in parentheses; yields of the reactions with MeLi in curly brackets.

When **33** is treated with MeMgCl, a total of 55 different 1,3-disilapropanes can be detected depending on the molar ratio of the reactants. These products have varying chlorine content and can be divided into six groups according to changes in the carbon bridge (CCl_2, CHMe, C=CHMe, CHCl, CH_2, $C{=}CH_2$).[58]

The reaction with MeLi occurs in a more straightforward manner: it is initiated by the methylation of the CCl_2 group:

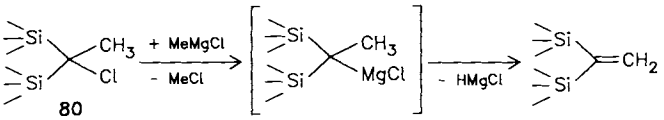
$$(Cl_3Si)_2CCl_2 + MeLi \longrightarrow (Cl_3Si)_2CMeCl + LiCl$$
33 **78**

Reaction of **33** with 1–1.5 molar equivalents of MeLi gives **78** in 93% yield, while reaction with 2 molar equivalents gives $(Cl_3Si)_2CMe_2$ in 90% yield. Only then does the methylation of the $SiCl_3$ groups occur, so that the reaction of **33** with 4 molar equivalents of MeLi gives $(ClMe_2Si)_2CMe_2$ in 86% yield.[58]

The study of the course of reaction was first concentrated on the formation of the methylidene group in the main product **76** of the reaction with MeMgCl. The formation of methylidene groups is always observed when an isolated Si–CCl_2–Si group is present in a carbosilane, as is shown for example by 2,2-dichlorohexamethyl-1,3,5-trisilacyclohexane and the carbosilane **79**.[67,68] The only pos-

$Me_3Si{-}CCl_2{-}SiCl_2{-}C{\equiv}C{-}SiMe_3$
79

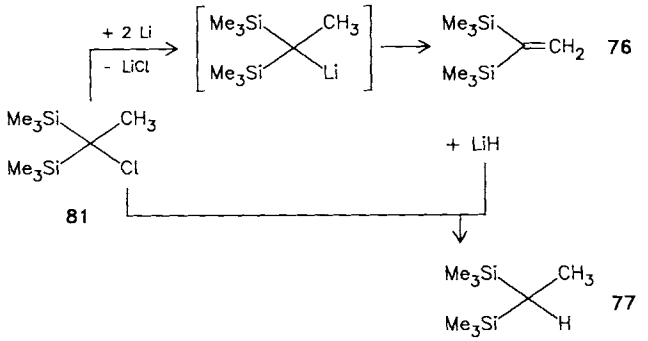
sible intermediates for their formation from **33** are derivatives with CCl_2 or CMeCl groups, as all others can be excluded because of their low reactivity. The study of the reaction mechanism was thus carried out using 2,2-dichloro-1,3-disilapropanes chlorinated and methylated at silicon to different degrees as well as 2-chloro-2-methyl-1,3-disilapropanes, which were available as pure compounds.[59,60] The compounds **80** are indeed precursors for the formation of $(\geqslant Si)_2C{=}CH_2$.



— = Me, Cl

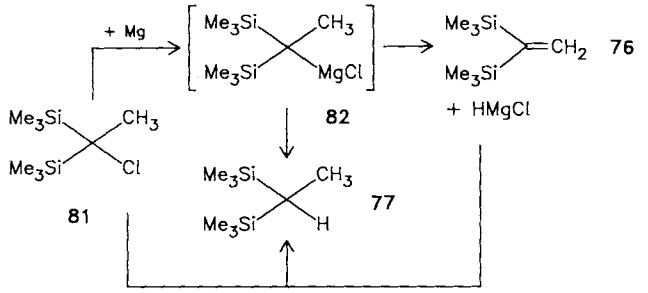
C-metalation of **81** does not occur with MeMgCl or MeLi, but can be carried out with magnesium or lithium.

Complete reaction of **81** with lithium in cyclohexane or benzene gives **76** and **77** in the ratio of 55 : 45 (see Scheme 19).



Scheme 19.

The reaction with magnesium in ether occurs in an analogous manner, but the compounds **76** and **77** are formed in the ratio of 43 : 57. This change in product ratio is explained by Scheme 20.

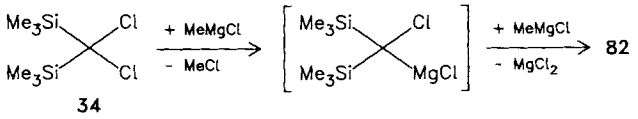


Scheme 20.

The intermediate **82** formed initially reacts further with elimination of HMgCl, which in turn reduces unreacted **81** to **77**; these reactions are accompanied by reaction of ether with the intermediate and subsequent ether cleavage, which also leads to **77**. This mechanism is confirmed by the reaction of $(Me_3Si)_2CCl(CD_3)$ with magnesium in ether: according to Scheme 20, this compound should split off DMgCl to give $(Me_3Si)_2C{=}CD_2$. The reaction of $(Me_3Si)_2CCl(CD_3)$ with DMgCl should give $(Me_3Si)_2CD(CD_3)$, while ether cleavage by the intermediate gives $(Me_3Si)_2CH(CD_3)$. The three compounds $(Me_3Si)_2C{=}CD_2$, $(Me_3Si)_2CD(CD_3)$, and $(Me_3Si)_2CH(CD_3)$ are indeed formed in the ratio of 3 : 3 : 1.[60]

Si-chlorinated derivatives of **81** form the methylidene group even with MeMgCl, since the intermediate is formed more readily when the partial negative charge on carbon is stabilized more strongly by electronegative substituents on silicon.

$(Me_3Si)_2CCl_2$ **34** reacts with MeMgCl about as fast as **81** with Mg to give the final product **76**. However, **34** reacts faster to give the intermediate **82** than does **81**. The reaction of **34** can thus not begin with a methylation at the CCl_2 group followed by a metalation, but must occur in the reverse manner (Scheme 21); this can also be understood in terms of the better stabilization of the carbanionic intermediate.



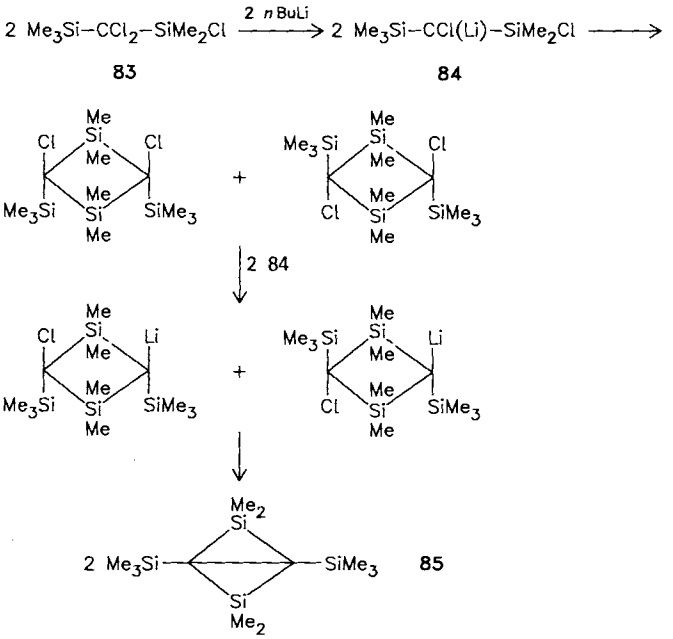
Scheme 21.

Either *Si*-methylation or *C*-metalation can occur upon reaction of the 2,2-dichloro-1,3-disilapropanes with MeMgCl. *C*-metalation dominates when the degree of chlorination at silicon is low, while *Si*-methylation is more important when it is high. Thus, for example, all products obtained from $Me_3Si{-}CCl_2{-}SiMe_2Cl$ are formed by attack at the bridging C atom, while ca. 40% of those from $MeCl_2Si{-}CCl_2{-}SiCl_3$ are due to *Si*-methylation. The metalation, and thus the formation of the methylidene and CHCl groups, however, is much faster if, besides methyl groups, chlorine substituents are still present on silicon.

5.1.2. *Formation and Reaction of $Me_3Si{-}CCl(Li){-}SiMe_2Cl$*

Great importance was attached to the proof of the *C*-lithiation of perchlorinated carbosilanes, which has been verified for $(Cl_3Si)_2CCl_2$ **33** and $(Cl_2Si{-}CCl_2)_3$ **75** by subsequent trapping reactions at $-100\,^{\circ}C$ with MeI or Me_3SiI. Thus, starting from **33**/*n*-BuLi, it is possible in this way to prepare $(Cl_3Si)_2C(Cl)Me$ **78** and $(Cl_3Si)_2C(Cl)SiMe_3$ preparatively (yield 80%). Compound **75** behaves in a corresponding manner.[61] Warming of $(Cl_3Si)_2CCl(Li)$ leads to the formation of LiCl, the chlorine atom of which is derived from one of the $SiCl_3$ groups. In this way, the disilabicyclo[1.1.0]butane **85** (white crystals, m.p. = 28 °C) is obtained as the end product of the *C*-lithiation.[62]

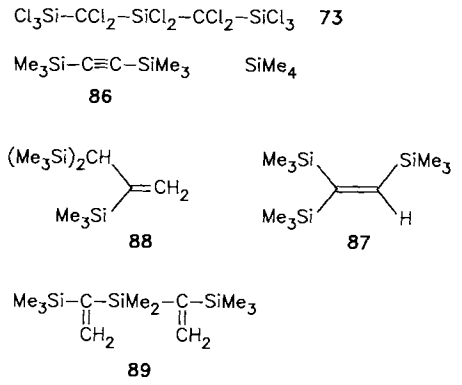
The precursors of **85** are two 1,3-disilacyclobutanes formed initially from the carbenoid **84**. They are lithiated by **84** in THF according to Scheme 22.[63]



Scheme 22.

5.1.3. *Reactions of $(Cl_3Si-CCl_2)_2SiCl_2$ with MeMgCl and MeLi*

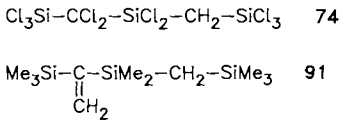
The reaction of the trisilapentane **73** with an excess of MeMgCl (molar ratio 1:18) in ether leads to the compounds shown in Scheme 23; the main products are **86** and $SiMe_4$.[64]



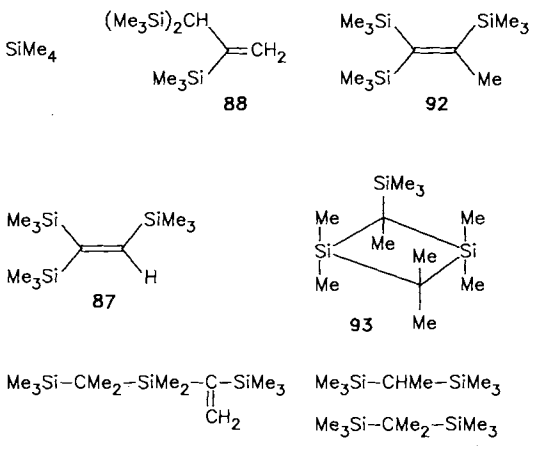
Scheme 23.

Reactions of **73** with lesser amounts of MeMgCl give less of the compounds shown in Scheme 23, and at a molar ratio of 1:1 the product is **90**.

The number of CCl_2 groups in the 1,3,5-trisilapentane determines the course of the reaction. Thus the reaction of **74** with MeMgCl leads to **91** (70%) and that of **90** to **87** as

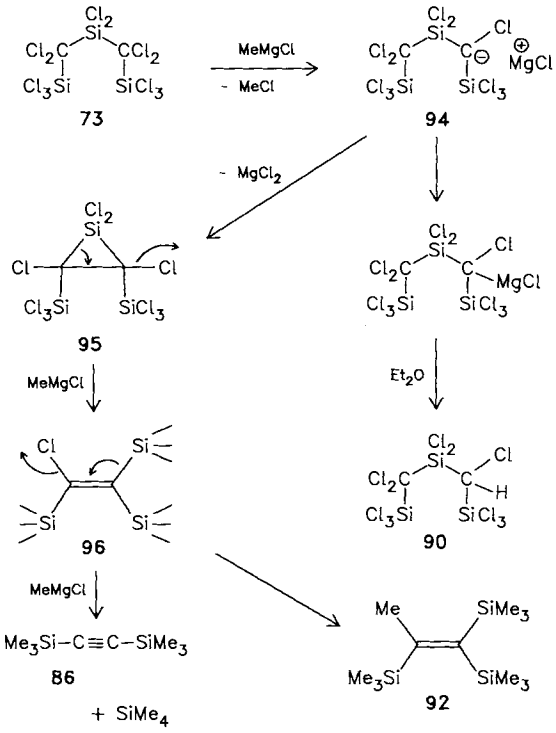


the major product. The reaction of **73** with an excess of MeLi[65] occurs in a similar manner to give $SiMe_4$, **87**, **88**, **92**, and **93** as the main products, which are shown along with the byproducts in Scheme 24.



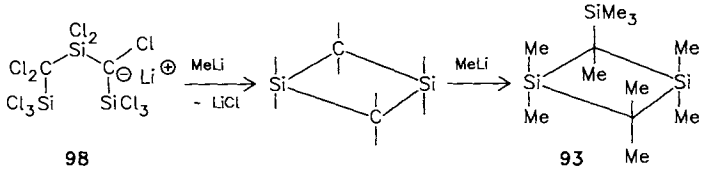
Scheme 24.

The reaction of **73** with MeMgCl can be explained by the mechanism in Scheme 25.



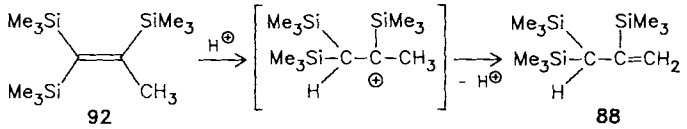
Scheme 25.

The first step is a metalation at a CCl_2 group to give **94**. It is followed by an intermolecular elimination of $MgCl_2$ to give **95**, which undergoes β-elimination and *Si*-methylation to give **86** and $SiMe_4$. The initial reaction of **73** with MeLi is analogous. Compound **86** reacts with an excess of MeLi according to reaction (10), as is shown by the formation of acetylene in the hydrolysis of the reaction product **97**. The vinylic Cl atom in the intermediate **96**, which is not isolated, can be methylated by MeLi to give **92** (Scheme 24), so that no further reaction occurs. The formation of **87** is due to the reaction of **90** (CCl_2-lithiation and subsequent ether cleavage). An important difference between the behavior of MeLi and MeMgCl with respect to **73** lies in the formation of **93**; it is formed via the *C*-lithiated intermediate **98** (Scheme 26).



Scheme 26. — = Me or Cl.

The carbanion of the Li compound **98** is much more reactive than the corresponding Mg derivative **94** and attacks not only at the CCl_2 group but also at the terminal Si atom with the formation of **93**. Compound **92** rearranges catalytically, undergoing 1,3-isomerization in the presence of traces of moisture or acids, to give **88** (Scheme 27).

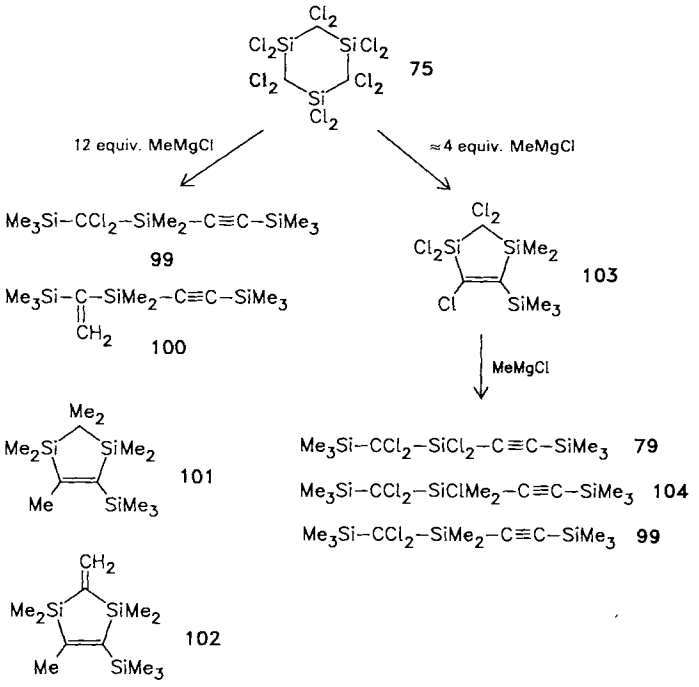


Scheme 27.

The product ratio is strongly influenced by the MeLi concentration during the reaction.

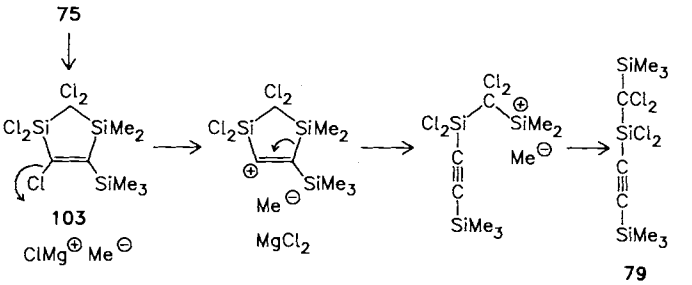
5.1.4. *Reactions of $(Cl_2Si-CCl_2)_3$ with MeMgCl*

The perchlorinated compound **75** reacts with MeMgCl to give the products of ring contraction and ring cleavage[66,67] shown in Scheme 28.



Scheme 28.

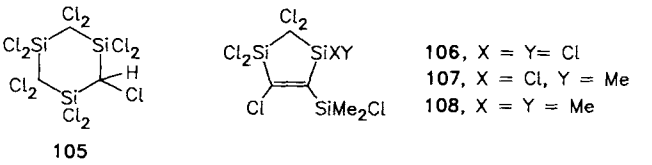
The linear derivatives **99** and **100** are formed preferentially when MeMgCl is used in excess (for the transformation of **99** to **100**, compare Scheme 20). The formation of the 1,3-disilacyclopentene **103** is the decisive step in the reaction sequence: **103** is formed as white crystals in ca. 98% yield when **75** is treated with MeMgCl (molar ratio 1:4) and reacts with further MeMgCl to give mainly the acetylene derivatives **79**, **104**, and **99**,[66] which are also formed directly when **75** is treated with an excess of MeMgCl. This reaction proceeds via **103** (Scheme 29; for the reaction **75** → **103**, see Scheme 30).



Scheme 29.

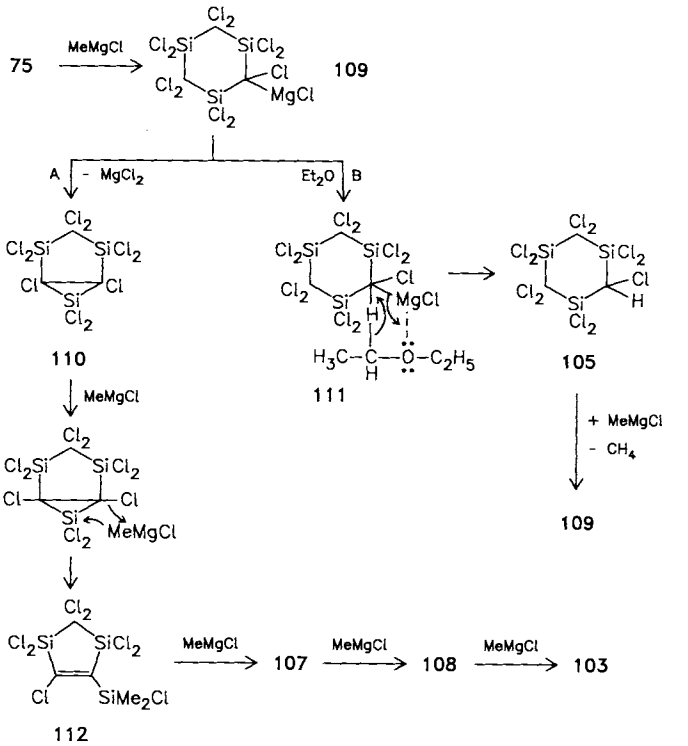
The initial step is the cleavage of the vinylic chlorine atom under the influence of MeMgCl: the cation thus formed rearranges to the energetically more favored C≡C linkage and then adds the nucleophilic anion $Me^{\ominus}$ with concomitant methylation at silicon to give **79**.

The experiment gives the following information regarding the ring contraction of **75** to **103**: the reaction begins



106, X = Y = Cl
107, X = Cl, Y = Me
108, X = Y = Me

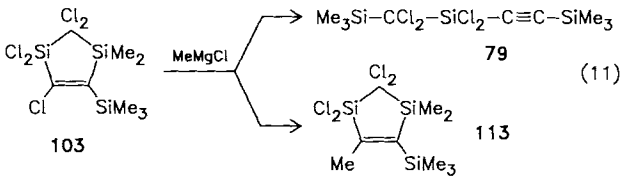
with a magnesium–halogen exchange at a skeletal carbon atom. The primary reaction products **105**–**108** have been detected.



Scheme 30.

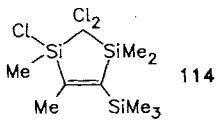
Scheme 30 describes the course of the reaction. The first step is the magnesium–halogen exchange of **75** to give **109**, which can react further by two routes. Route A results

in a rearrangement under the influence of MeMgCl of the bicyclic intermediate formed to give **112**; *Si*-methylation by further MeMgCl gives **103**. Route B leads from **109** via ether cleavage to **105**. The acidic CH proton of **105** reacts with MeMgCl to give CH_4 and **109**, provided that no metalation of a CCl_2 group in **105** by MeMgCl occurs. Whether route A or route B is preferentially followed depends on the concentration of MeMgCl; if it is low, **105** containing the CHCl group is formed, while if it is high the rearrangement via route A is favored. The complete course of the subsequent reactions is determined by the key compound **103**[68] [reaction (11)].



(11)

The cleavage reaction giving **79** (Scheme 29) starts from the vinylic chlorine substituent: if this position is methylated (here a side reaction), no cleavage takes place, and the disilacyclopentenes **114**, **101**, and **102** are formed. All

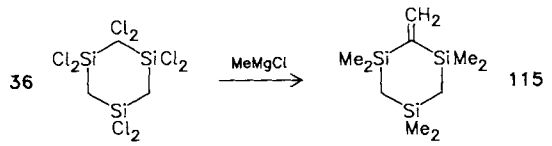


114

the linear reaction products can be explained by the reactions of the functional groups in **79**.

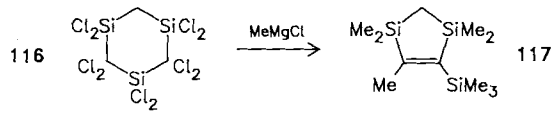
5.1.5. *Reactions of SiCl-Containing and Partially C-Chlorinated Carbosilanes with MeMgCl*

The reaction of $(Cl_2Si–CCl_2)_3$ **75** with MeMgCl to give the 1,3-disilacyclopentene skeleton (such as **103**) according to Scheme 30 requires the presence of at least two CCl_2 groups for the ring contraction: it should not occur when only one such group is present. Thus, the reaction of compound **36** with an excess of MeMgCl proceeds without any change in ring size to give **115** (Scheme 31). Compound **36** thus reacts like an acyclic compound containing an $–SiCl_2–CCl_2–SiCl_2–$ group.[59,60]



Scheme 31.

However, compound **116** (with two CCl_2 groups) undergoes ring contraction with an excess of MeMgCl to give **117** (Scheme 32) in ca. 80% yield. This reaction proceeds analogously to that shown in Scheme 30.[67] Rearrangement with formation of linear compounds according to



Scheme 32.

reaction (11) does not occur, apparently because of the favored methylation of the vinylic Cl atom.

5.2. Reactions of *C*-Chlorinated SiH-Containing Carbosilanes

The SiCl groups in CH_2-containing carbosilanes can be converted by $LiAlH_4$ into SiH groups without any change in the molecular structure.[69] Examples are provided by the transformations of **31** and **29**.

$$(Cl_3Si–CH_2)_2SiCl_2 \longrightarrow (H_3Si–CH_2)_2SiH_2$$
31

$$(Cl_2Si–CH_2)_3 \longrightarrow (H_2Si–CH_2)_3$$
29

This reaction also permits the formation of SiH- and CCl-containing derivatives from perchlorinated compounds, as shown below:

$$(Cl_3Si–CCl_2)_2SiCl_2 \longrightarrow (H_3Si–CCl_2)_2SiH_2$$
73 **118**

$$(Cl_2Si–CCl_2)_3 \longrightarrow (H_2Si–CCl_2)_3$$
75

However, side reactions such as cleavage of the Si–C bond and formation of CH groups are always observed. It must be noted that violent explosions will occur when pure SiH- and CCl-containing compounds (such as **118**) are heated above room temperature: however, their solutions in ether or hydrocarbons have shown themselves to be safe. Their reactivity is due to hydrogen–chlorine exchange [reaction (12)]. This reaction can be used for the formation

$$\geqslant SiH + \geqslant CCl \longrightarrow \geqslant SiCl + \geqslant CH \qquad (12)$$

of partially chlorinated SiH-containing compounds, as the example in Scheme 33 shows.[70]

$(Cl_2Si–CCl_2)_3$ **75** $(Cl_2Si–CH_2)_3$ **29**

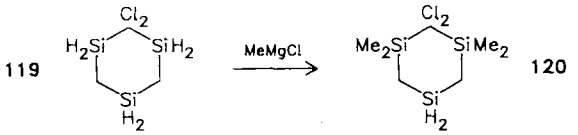
$3(H_3Si–CH_2)_2SiH_2$ $3H_2ClSi–CH_2–SiHCl–CH_2–SiH_3$

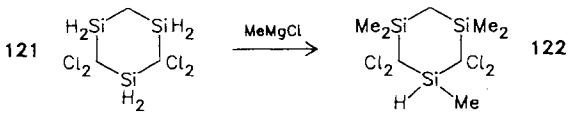
Scheme 33.

The influence of the CCl_2 group on the SiH bond is shown by the following comparison: while in $(H_2Si–CH_2)_3$ the SiH group can only be methylated with extreme difficulty by MeMgCl in Et_2O, such a methylation does occur

under analogous conditions for derivatives containing the CCl_2 group (e.g., formation of **120** from **119**).



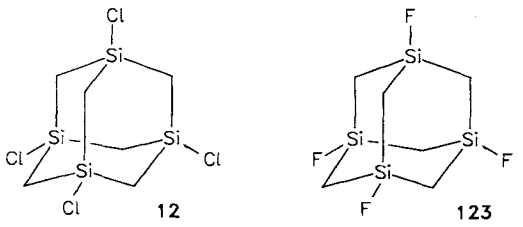
Derivatives containing SiHMe groups are also formed, but there is no formation of the $C{=}CH_2$ group (cf. Scheme 31). The reaction of the 1,3,5-trisilacyclohexane **121** (containing two CCl_2 groups) with MeMgCl gives **122**; thus the reactions shown in Schemes 31 or 32 do not occur.



The studies thus present the following picture: $(Cl_2Si{-}CH_2)_3$ reacts with MeMgCl to give $(Me_2Si{-}CH_2)_3$ **23**, while $(H_2Si{-}CH_2)_3$ does not react under these conditions. Methylation of the neighboring SiH_2 groups is only possible when a CCl_2 group is introduced; the latter does not undergo substitution. However, the route from $(H_2Si{-}CCl_2)_3$ to $(Me_2Si{-}CCl_2)_3$ with MeMgCl is not feasible, since the introduction of three CCl_2 groups favors cleavage of the Si–C–Si skeleton during the reaction with MeMgCl.

5.3. Reactions of *C*-Chlorinated SiF-Containing Carbosilanes

The fluorination of SiCl groups in carbosilanes can be carried out using ZnF_2; almost no Si–C bond cleavage is observed. The preparation of $(F_3Si{-}CH_2)_2SiF_2$ and $(F_3Si{-}CCl_2)_2SiF_2$ is most readily carried out by reaction of the corresponding chlorinated compounds with ZnF_2 in hexachlorobutadiene.[71] In a similar manner, $(F_2Si{-}CH_2)_3$ is formed from $(Cl_2Si{-}CH_2)_3$ **29** and the adamantane **123** from **12**.[72]



However, it is not possible to use perchlorinated carbosilanes and ZnF_2 to form cyclic SiF- and CCl-containing carbosilanes, since decomposition reactions occur which may even lead to the formation of SiF_4. Such carbosilanes can be formed via photochlorination of SiF-containing derivatives; e.g., reaction of $(F_2Si{-}CH_2)_3$ gives $(F_2Si{-}CCl_2)_3$.[72]

The SiF groups in *Si*-fluorinated, *C*-chlorinated carbosilanes determine the course of their reactions. Thus, **124** reacts with MeLi according to reaction (13).

$$(F_3Si)_2CCl_2 + MeLi \longrightarrow (Me_3Si)_2CCl_2 + LiF \quad (13)$$

124 **34**

$F_3Si{-}CCl_2{-}SiFMe_2$ **125** $Me_2FSi{-}CCl_2{-}SiFMe_2$ **126**

Additional products are **125** and **126** as well as further partially methylated derivatives.[71] Similarly, **127** reacts to give **128**.

$$F_3Si{-}CCl_2{-}SiF_2{-}CH_2{-}SiF_3 \longrightarrow$$

127

$Me_3Si{-}CCl_2{-}SiMe_2{-}CH_2{-}SiMe_3$

128

In contrast, **129**, which, unlike **127**, contains no CH_2 groups, behaves in a quite different manner; the products of three different methylation reactions are shown in Scheme 34.

$(F_3Si{-}CCl_2)_2SiF_2$ **129**

a) $F_3Si{-}CCl_2H$, $MeF_2Si{-}CCl_2{-}SiMeF_2$, $Me_2FSi{-}CCl_2{-}SiMeF_2$

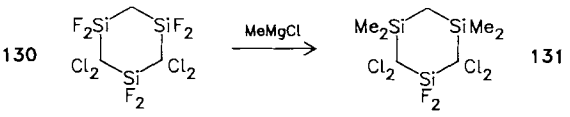
b) $Me_3Si{-}CCl_2{-}SiMe_3$ **34**, $Me_3Si{-}CCl_2{-}SiMe_2{-}CH_2{-}SiMe_3$, $(Me_3Si{-}CCl_2)_2SiMeF$, $Me_3Si{-}CH_2{-}SiMe_2{-}CCl_2H$, $Me_3Si{-}CCl_2{-}SiMeF{-}CH_2{-}SiMe_3$, $(Me_3Si{-}CCl_2)_2SiMe_2$

c) $Me_3Si{-}C{\equiv}C{-}SiMe_3$ **86**, **34**, $Me_3Si{-}C{\equiv}C{-}SiMe_2{-}C{\equiv}C{-}SiMe_3$, $Me_3Si{-}CCl_2{-}SiMe_2{-}C{\equiv}C{-}SiMe_3$ **99**, $SiMe_4$

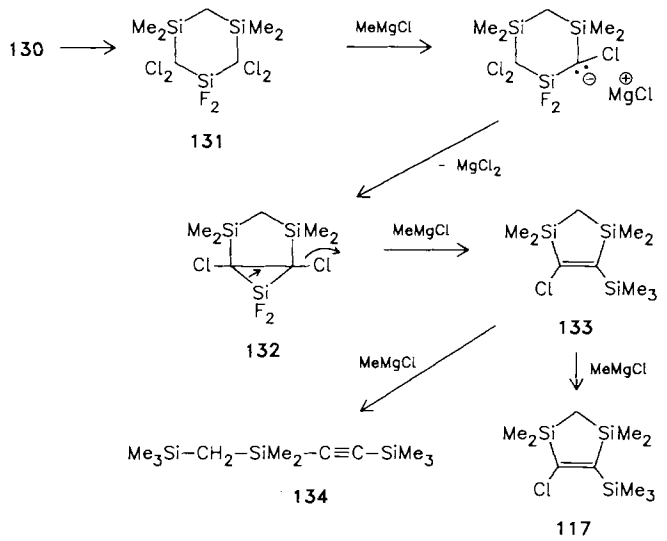
Scheme 34. Reaction of **129** in Et_2O with a) MeMgCl in a molar ratio of 1 : 1, b) excess MeMgCl, and c) MeLi in excess (1 : 10).

In this case the cleavage of the molecular skeleton is the predominant reaction; it is followed by *Si*-methylation. The reaction with MeLi leads to, among other compounds, **86** and shows that this stronger metalating agent is also capable of *C*-metalation and thus is able to induce the accompanying skeletal changes.[71]

The initial reaction of *Si*-fluorinated 1,3,5-trisilacyclohexanes (e.g., **130**) is also *Si*-methylation.[73] As with the linear derivatives, ring cleavage is favored by polar solvents (e.g., THF) and MeLi.



$(F_2Si{-}CCl_2)_3$ can be methylated by MeMgCl, affording $(MeFSi{-}CCl_2)_3$ in 86% yield. Further reaction with MeMgCl or MeLi leads to changes in the ring structure. The reaction of **130** with an excess of MeMgCl (Scheme 35) makes this clear. The initial reaction is the *Si*-methylation to give **131**. At this degree of methylation the metalation of the CCl_2 group occurs; it leads via ring contraction to **133**, which rearranges to give **117** and **134**. Thus, above a certain degree of *Si*-methylation, the reaction occurs according to Scheme 30 and reaction (11).



Scheme 35.

5.4. Reactions of CF_2-Containing Carbosilanes

Carbosilanes containing the $\geqslant Si-CF_2-Si\leqslant$ group can be prepared via the insertion of difluorocarbene into the Si–Si bond.[74]

$$FMe_2Si-SiMe_2F + CF_2 \longrightarrow FMe_2Si-CF_2-SiMe_2F$$
135 **136**

The carbene CF_2 is formed by thermolysis of Me_3SnCF_3.[75] Further examples are provided by the reactions of **137** and **138** and of the trisilane **139**.[74] This insertion into the Si–Si bond is only observed when the terminal Si atoms bear one or more $-I$ substituents

$$XMe_2Si-SiMe_3 \longrightarrow XMe_2Si-CF_2-SiMe_3$$
137 (X = F, Cl, Br, OMe)

$$F_2MeSi-SiMe_2F \longrightarrow F_2MeSi-CF_2-SiMe_2F$$
138

$$(FMe_2Si)_2SiMe_2 \longrightarrow$$
139
$$FMe_2Si-CF_2-SiMe_2-SiMe_2F + (FMe_2Si-CF_2)_2SiMe_2$$

(F, Cl, Br, OMe). These substituents weaken the Si–Si bonds and favor the CF_2 insertion. In the absence of such substituents (e.g., for Si_2Me_6) the CF_2 insertion does not occur, and more highly fluorinated disilanes (such as $F_2MeSi-SiMeF_2$ and Si_2F_6) decompose at temperatures below that required to generate CF_2 from $MeSnCF_3$.

In contrast to comparable *C*-chlorinated carbosilanes, **136** reacts with MeMgCl or MeLi even at lower temperatures not with *C*-metalation but with *Si*-alkylation, the products being **140** and **141**. Similarly, reaction with PhLi and PhMgBr gives **142** and **143**. Compound **136** and its derivatives react with $LiAlH_4$ with formation of SiH groups; e.g., $(HMe_2Si)_2CF_2$ is formed. Reaction with $LiPMe_2$ leads to substitution at the silicon atom: reaction of **136** gives $Me_2P-SiMe_2-CF_2-SiMe_2F$ and $(Me_2P-SiMe_2)_2CF_2$.[74]

$Me_3Si-CF_2-SiMe_2F$ $(Me_3Si)_2CF_2$
140 **141**

$PhMe_2Si-CF_2-SiMe_2F$ $(PhMe_2Si)_2CF_2$
142 **143**

5.5. The Cleavage of the Si–Me Bond in Carbosilanes

The clean cleavage of the Si–C bond and the influence of substituents on this reaction are of considerable interest. The alkaline cleavage is favored by the chlorination of the α-carbon atoms.[54,75] The Si–Ph bond is cleaved in aqueous HCl solution.[76] These reactions have the disadvantage that the SiOH groups thereby formed condense to form $\geqslant Si-O-Si\leqslant$ units and therefore the functionality at silicon is lost. The cleavage of the Si–Ph bond by pure HBr is a basic requirement for the organometallic synthesis of carbosilanes (see Section 3).[37] Under these conditions the Si–Me bond is stable. Its cleavage by Me_3SiCl or acetyl chloride with $AlCl_3$ as a catalyst has been described by *Kumada* and co-workers.[77] A cleavage reaction using $HSiCl_3$ and catalyzed by H_2PtCl_6 was described by *Benkeser* et al.[78] and extended by *Hengge* et al.[79] to the *Si*-chlorination of methylated silanes with Si–Si bonds. *Calas* et al.[80] reported the formation of Me_3SiCl from $SiMe_4$ and ICl (Scheme 36); *Eaborn* et al.[87] have reported similar reactions.

$$Me_3Si(CH_2)_nSiMe_3 + 2\,Me_3SiCl \xrightarrow{AlCl_3}$$
$$ClMe_2Si(CH_2)_nSiMe_2Cl + 2\,SiMe_4 \;(n = 1\text{–}4)$$

$$SiMe_4 + CH_3COCl \xrightarrow{AlCl_3} Me_3SiCl + CH_3COCH_3$$

$$R_3SiMe + HSiCl_3 \xrightarrow{Pt\ cat.} R_3SiCl + MeHSiCl_2$$

$$SiMe_4 + 2\,ICl \longrightarrow Me_3SiCl + MeCl + I_2$$

Scheme 36.

These reactions convert the unreactive SiMe group into a functional SiCl group. The reaction with ICl can be extended to numerous *Si*-methylated carbosilanes,[81] leading in each case to the replacement of at the most one methyl group at each silicon atom.[81] Thus, the end product of the reaction of $(Me_2Si-CH_2)_3$ **26** is $(ClMeSi-CH_2)_3$, while in 1,3,5,7-tetramethyl-1,3,5,7-tetrasilaadamantane **3** all SiMe groups are converted into SiCl groups. Further examples for the reaction with ICl are:

$$(Me_3Si-CH_2)_2SiMe_2 \longrightarrow (ClMe_2Si-CH_2)_2SiMeCl$$

$$HC(SiMe_3)_3 \longrightarrow HC(SiMe_2Cl)_3$$

A higher degree of chlorination is possible with ICl and catalytic amounts of $AlBr_3$:[81]

$(Me_2Si-CH_2)_3 \longrightarrow (Cl_2Si-CH_2)_3$

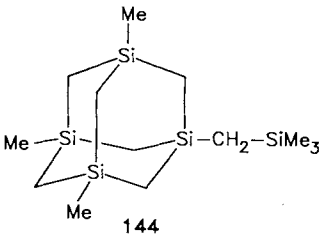
26 **29**

$(Me_3Si-CH_2)_2SiMe_2 \longrightarrow$

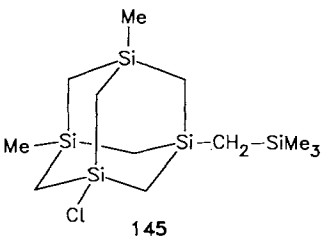
$(ClMe_2Si-CH_2)_2SiMeCl \longrightarrow (Cl_2MeSi-CH_2)_2SiCl_2$

$(Me_3Si)_2CH_2 \longrightarrow (Cl_2MeSi)_2CH_2$

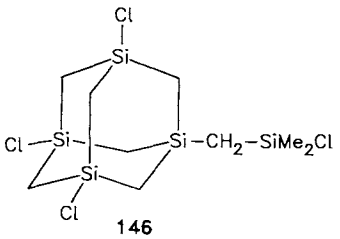
The CH_2-SiMe_3 group in compound **144** is not degraded by ICl; instead, one Cl atom is introduced at each Si atom. The initial reaction is the formation of **145**, which



144

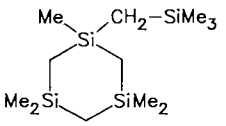


145

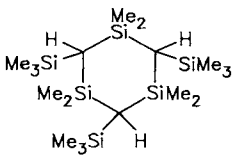


146

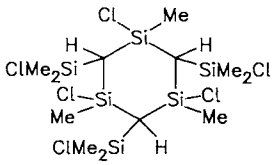
is then converted into the end product **146**. Compound **147** behaves similarly, though in a side reaction (8%) there is ring opening at the Si atom bearing the side chain. *C*-silylated derivatives behave similarly: for example, **54**



147



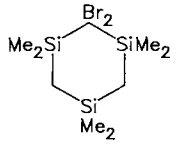
54



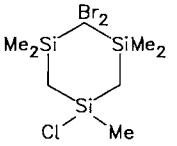
148

reacts with ICl to give **148**, and $(Me_2Si-CHMe)_3$ forms $(ClMeSi-CHMe)_3$.[81]

Not only Cl substituents at silicon atoms but also the CBr_2 group stabilizes the neighboring Si-Me bonds, as is



58



149

shown by the reaction of **58** to give **149**: ICl causes the selective cleavage of an Si-Me bond at the silicon atom in the position "*para*" to the CBr_2 group.[81]

6. The Influence of Substituents on Carbosilanes

The substituents on the Si and C atoms of carbosilanes have an effect on both the reactivity of the remaining groups and the stability of the molecular skeleton, as shown by the following examples:

a) The SiH group in carbosilanes such as $(H_2Si-CH_2)_3$ reacts only slowly with MeMgCl in Et_2O to give *Si*-methylated products. However, if the SiH group is in a position next to a CCl_2 group, it can be relatively easily substituted (with *Si*-methylation); the CCl_2 group is not attacked.

b) The SiCl group is normally much more readily alkylated by RLi or RMgCl than is the CCl_2 group. However, in the case of perchlorinated carbosilanes such as **73** or **75** the reaction with MeMgCl commences at the CCl_2 group; the primary reaction is followed by further characteristic reactions. At $-100\,^{\circ}C$ *n*BuLi lithiates the C atom of **33** without attacking the SiCl groups. The behavior of *C*-chlorinated carbosilanes containing either SiF or SiH groups towards MeMgCl is quite different: in these cases the initial reaction occurs at the SiF or SiH groups, and the CCl_2 group is at first not involved in the reaction (e.g., conversion of $(F_3Si)_2CCl_2$ into $(Me_3Si)_2CCl_2$ **34**).

$(Cl_3Si-CCl_2)_2SiCl_2$ $(Cl_2Si-CCl_2)_3$ $(Cl_3Si)_2CCl_2$

73 **75** **33**

c) In carbosilanes with CCl_2 groups the cleavage of an Si-C bond in the molecular skeleton occurs relatively readily, e.g., when one attempts to convert **33** into $(H_3Si)_2CCl_2$ or **75** into $(H_2Si-CCl_2)_3$ using an excess of $LiAlH_4$. Such cleavages of Si-C bonds are also observed in reactions of SiH- and CCl-containing carbosilanes with organometallic compounds, such as in the reaction of $(H_2Si-CCl_2)_3$ with MeMgCl.

d) *Si*-methylated linear carbosilanes or *Si*-methylated cyclic carbosilanes with *Si*-methylated side chains rearrange under the influence of $AlBr_3$ (formation of six-membered rings with elimination of $SiMe_4$). This cyclization reaction does not occur with the corresponding compounds that are partially chlorinated at silicon.

e) The reaction of linear and cyclic *Si*-methylated carbosilanes with ICl leads only to the substitution of one SiMe group at the Si atom concerned: thus $(ClMeSi-CH_2)_3$ is formed from $(Me_2Si-CH_2)_3$ **26**, while the reaction with $ICl/AlBr_3$ gives $(Cl_2Si-CH_2)_3$

29. Here the second Si–Me bond is also cleaved, but the Si–C–Si skeleton of the molecule is not attacked.

The behavior of the carbosilanes is mainly determined by the polarity of the Si–C bond, which is influenced by the substituents. Because of the electronegativities of the elements concerned, the bond polarizations in a carbosilane such as $(H_3Si-CH_2)_2SiH_2$ are as follows:

$\overset{\oplus}{Si}-\overset{\ominus}{H}$, $\overset{\ominus}{C}-\overset{\oplus}{H}$, $\overset{\oplus}{Si}-\overset{\ominus}{C}$

C-chlorination leads via the electron withdrawal by chlorine to a decrease in the shielding at the C atom and thus to a decrease in the shielding at the Si atom. This in turn causes an increase in the polarity of the Si–H bond. Thus the increased reactivity of the SiH group caused by *C*-chlorination is explained, as well as the fact that the Si–C bond in such compounds is more readily cleaved. Similarly, methylation at silicon must (since Me acts as an electron-donating substituent) decrease the reactivity of the H atoms on the silicon concerned and thus reduce the tendency for Si–C cleavage. The *Si*- and *C*-chlorinated derivatives differ from those that are SiH-containing and *C*-chlorinated in that the reactivity of the CCl_2 groups is increased. The reason for this is that with increased *C*-chlorination more electrons of the chlorines in SiCl groups are available for an increased shielding of the Si atom, so that the SiCl group becomes less polar and less reactive. The behavior of the SiF- and CCl-containing carbosilanes, such as **150**, more nearly approaches that of SiH- and CCl-containing carbosilanes (e.g., **118**) than that of SiCl- and CCl-containing derivatives (e.g., **73**). The reaction of **127** with MeMgCl commences with *Si*-methylation and not with the *C*-metalation observed in the corresponding *Si*- and *C*-chlorinated compounds.

$(F_3Si-CCl_2)_2SiF_2$ **150** $(H_3Si-CCl_2)_2SiH_2$ **118**

$(Cl_3Si-CCl_2)_2SiCl_2$ **73** $F_3Si-CCl_2-SiF_2-CH_2-SiF_3$ **127**

Polarity variations of the Si–C bond also determine the chemical behavior observed in the reactions of *Si*-methylated carbosilanes with ICl and $ICl/AlBr_3$. In the reaction with ICl, only one methyl group in the $SiMe_3$ group is substituted by Cl. The introduction of such an SiCl group decreases the polarity of the remaining Si–Me bonds, so that the possibility of a nucleophilic cleavage is decreased. This is also the reason that the ring closure reaction of methylated carbosilanes with elimination of $SiMe_4$ no longer occurs when an SiCl group is present. The generally lower bond polarity of the $Si-CH_2-Si$ bonds in comparison with that of the Si–Me bond explains the observed stability of the carbosilane skeleton with respect to cleavage. Aluminum halides polarize not only the Si–Me bond but also the ICl molecule and thus make possible further Si–Me cleavage and higher degrees of chlorination. These experimental results and their qualitative interpretation are in agreement with quantum-mechanical calculations for simple silicon-carbon compounds.[82]

7. Polycarbosilanes

The favorable properties of silicon carbide (chemical resistance, density 3.2 g cm^{-3}, hardness 9.5) for use in modern ceramics have also led to an increasing interest in polymeric carbosilanes. These substances are obtained either via pyrolysis of methylsilanes[4,6] or via prolonged thermal treatment of polysilanes.[83] *S. Yajima*[84] has reported the formation of SiC fibers by thermal treatment of methylpolysilanes. Polysilanes of the type $(Me_2Si)_n$ (n = 5–35) are formed from Me_2SiCl_2 and Na/K in THF; various cyclic and polycyclic polycarbosilanes are obtained by the cocondensation of Me_2SiCl_2 and $MeSiCl_3$ with Na/K.[83] On heating to ca. 450 °C these polysilanes rearrange: CH_2 derived from $SiCH_3$ groups inserts into Si–Si bonds with concomitant formation of SiH groups according to reactions (5) and (6). The polycarbosilanes so formed[85] are converted into β-SiC at 1300 °C. Because of the formation of volatile products, this stepwise procedure involves considerable material loss. The mechanism of the formation of these polycarbosilanes as well as their further structural variations are not yet well understood.

In the pyrolysis of $SiMe_4$ (Fig. 1, Section 2) the Si-poor carbosilanes initially formed are involved in the subsequent reactions to give the Si-richer products: an example is provided by $(Me_2Si-CH_2)_2$ **25** (Section 2.1.4). The studies showed that in a closed system **25** is converted at temperatures between 200 and 280 °C without gas evolution into linear polycarbosilanes of the type $Me_3Si(CH_2-SiMe_2)_n-CH_2-SiMe_3$ ($M_r \approx 250\,000$, temperature-dependent; colorless gel-like substances, still soluble in toluene).[25] When these are subjected to higher temperatures (650 °C, 4 h), a partial degradation to give low-molecular-weight carbosilanes is accompanied by the formation of insoluble products.

The polycarbosilanes obtained by the pyrolysis of methylsilanes are not linear (as revealed by their composition); however, their structures have not been unambiguously determined. Since the lower-molecular-weight carbosilanes formed from the various methylsilanes (varying Si : C ratios) have different structures, differences in the structures of the polymers are also to be expected. This becomes clear in the thermal treatment of the compounds in Figure 2 (Section 2.1.3) obtained from Me_2SiCl_2. Between 420 and 620 °C there is a marked increase in viscosity, accompanied by elimination of $SiCl_4$ and $MeSiCl_3$; low-molecular-weight carbosilanes are formed. Since most of the end groups of the compounds in Figure 2 are initially $SiCl_3$ groups, the formation of $SiCl_4$ indicates a condensation with formation of additional Si–C bonds which link these molecular skeletons: they thus become structural elements in the polymers.[18]

8. Summary and Outlook

An extremely large number of structurally different carbosilanes have now been synthesized in different ways. Be-

cause of their chemical behavior, the carbosilane frameworks can be described neither as "quasi-C-skeletons" nor as silicone-like systems (despite the fact that the Si–CH_2–Si grouping is isoelectronic with Si–O–Si). It is noteworthy that the chemical stability of the Si–C–Si molecular structures is higher than that of SiMe end groups and that their stability increases still further when electronegative substituents are introduced at the Si atoms. Numerous questions however remain to be answered. Thus the formation of Si-richer and high-molecular-weight carbosilanes in the pyrolysis of methylsilanes is still not sufficiently well understood. Further studies on the reaction of silicon with CH_2Cl_2 to give unbranched linear carbosilanes should serve to increase considerably our knowledge of catalytic processes at Si surfaces. The same is true for the catalyzed reactions of perchlorinated carbosilanes with silicon, which will provide routes to new carbosilane structures. Organometallic synthesis from organosilicon compounds alone appears to be of only limited use for the construction of polycyclic carbosilanes, though the possibilities provided by its combination with cyclization reactions induced by $AlBr_3$ are extremely interesting. In many ways a more quantitative physicochemical foundation for carbosilane chemistry is required; for example, calorimetric studies could provide valuable information.

Studies on the construction and structure of polymeric carbosilanes are at present mainly of only a qualitative nature. The use of carbosilanes in high-performance ceramics[86] requires not only the formation of polymers of different types and information on the structures of such polymers but also a complete understanding of the reactions that they undergo on further thermal treatment. This is a challenge for both the chemist and the materials scientist.

I thank my co-workers (whose names appear in the list of references) for their dedication. The work discussed here could not have been carried out without the support of the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. I feel myself particularly indebted to these institutions.

J.-M. Lehn	Supramolecular Chemistry—Molecules, Supermolecules, and Molecular Devices
H. Ringsdorf	Molecular Architecture and Function of Polymeric Oriented Systems
A. Simon	Clusters of Valence-Electron-Deficient Metals—Structure, Bonding, and Properties
G. Wilke	100 Years of Organonickel Chemistry

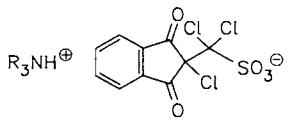
When submitting manuscripts, authors of articles intended for publication as "Communications" are requested to read the "Notice to Authors" reproduced in the January issue of the journal following the list of contents; upon request, a copy can be obtained from the editorial office.

A Sulfene Umpolung**

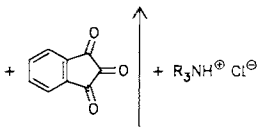
By *Rudolf Allmann, Wolfgang Hanefeld,* Magda Krestel,* and *Bernd Spangenberg*

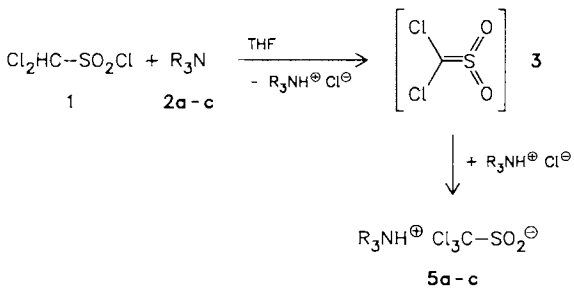
Sulfenes are very reactive intermediates which are usually generated from sulfonic acid chlorides such as **1**—which contain an α-hydrogen atom—and bases, and are trapped in situ. Stable sulfenes are unknown.[1]

We report here the first direct demonstration of a sulfene umpolung (charge reversion), which facilitates a nucleophilic attack at the sulfene C atom.



4a, b





2a, R_3N = $(C_2H_5)_3N$; 2b, R_3N = ; **2c, R_3N** = 1/2

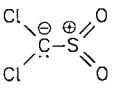
In connection with our studies on the preparation of novel β-sultones[2] we were able to trap **3** in a typical sulfene reaction with indanetrione to give **4**.[3] The intermediary dichlorosulfene **3** reacts in a manner typical for sulfenes, namely as a 1,2-dipole with a nucleophilic carbon atom (see **3A**).

If the reaction is carried out under the same conditions but in the absence of indanetrione,[4] the salt **5** containing a trichloromethanesulfinate ion is surprisingly formed almost quantitatively; this finding could be confirmed by an X-ray structure analysis of **5c**.[5] The spectroscopic data show that **5a** and **5b** also contain the trichloromethanesulfinate ion (Table 1).

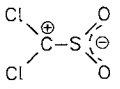
Table 1. Selected spectroscopic data of **4** and **5**. IR: **4a, 4b** (KBr), **5a** (NaCl platelets), **5b, 5c** (KBr), $\tilde{\nu}$ [cm^{-1}]; ^{13}C-NMR (25 MHz, $CDCl_3$; **5a, 5b**: solvent as standard; **5c**: in D_2O, dioxane ext.).

Cpd.	**4**: IR (SO_2^s) **5**: IR (SO_2^s)	^{13}C-NMR δ values
4a	1278, 1256, 1216, 1055	
4b	1282, 1255, 1214, 1190, 1050	
5a	1125, 1023	114.89
5b	1118, 1012, 997	113.83
5c	1098, 1005, 966	113.50

The reaction presented here, and described by *J. F. King* et al. as an "abnormal addition", has been postulated on several occasions for sulfenes,[6,7] but could never be conclusively demonstrated.[7,8] In particular, the reaction of camphorsulfonic acid chlorides with triethylamine[9] to give alkyl-substituted α-chlorosulfines (!), first reported as long ago as 1923, requires involvement of a sulfene umpolung.[10]



3A



3B

The proof that dichlorosulfene can react as a "normal" form **3A** and as a form **3B** with umpolung now supports, after 64 years, the presumption that the first sulfine was obtained via an intermediary sulfene.[9] The weakness of the explanation given at that time for the reaction—the formulation of an atypical sulfene reaction—no longer comes into question.

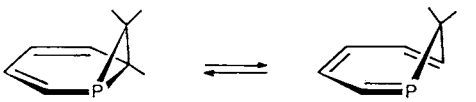
Valence Isomerization between 1-Phosphanorcaradienes and 1-Phospha-2*H*-tropylidenes (2*H*-Phosphepines)

By *Gottfried Märkl,* Hans J. Beckh, Manfred L. Ziegler,* and *Bernd Nuber*

In the case of the parent compounds the norcaradiene/tropylidene equilibrium lies on the side of the monocycle; electron-withdrawing substituents in the 7-position effect a shift in favor of the norcaradiene structure.[1] 1-Azanorcaradienes and thus also their valence isomerism with 1-azatropylidenes (2*H*-azepines) are still unknown.[2]

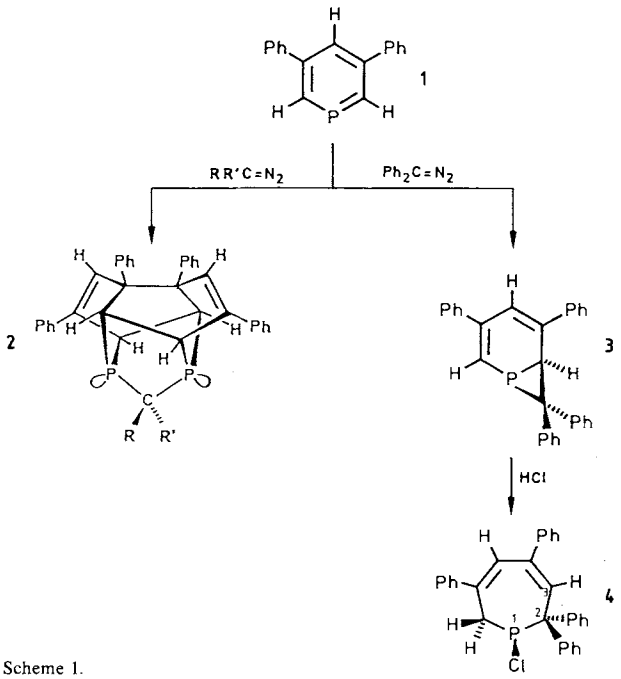
We describe here results which indicate a 1-phosphanorcaradiene/1-phospha-2*H*-tropylidene valence isomerization equilibrium [Eq. (a)].



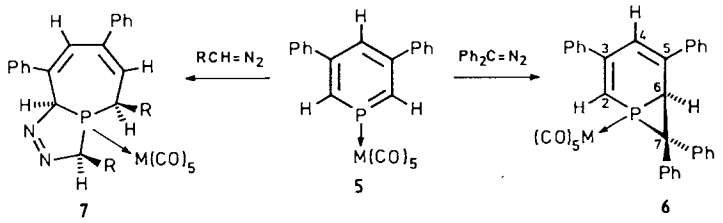
(a)

We recently reported that the pentacyclic phosphachiropteradienes **2** are formed in the reaction of 3,5-diphenyl-λ^3-phosphinine **1** with diazomethane, monosubstituted diazomethanes, and dialkyl-substituted diazomethanes.[3] In contrast, with diphenyldiazomethane, the 1-phosphanorcaradiene derivative **3** is formed (Scheme 1).

The $M(CO)_5$ complexes **5**[4] of **1** react with diphenyldiazomethane to give the 1-phosphanorcaradiene complexes **6**, corresponding to **3** (Table 1), but with diazomethane and monosubstituted diazomethanes to give the $M(CO)_5$ complexes of the [5.3.0]-bicycles **7**. Other than would appear to be the case, there is a causal relation between the formation of **6** and **7**. The chemistry of **6**, as well as the formation of **7**, affords arguments for the assumption that the reaction of **5** with diazoalkanes $RR'C{=}N_2$ generally first leads to the 1-phosphanorcaradienes **8**, which are in equilibrium with the valence isomeric 1-phosphatropylidene complexes **9**. This equilibrium must, however, lie so far on the side of the thermodynamically more stable phosphane **8** that a spectroscopic detection of **9** is impossible.

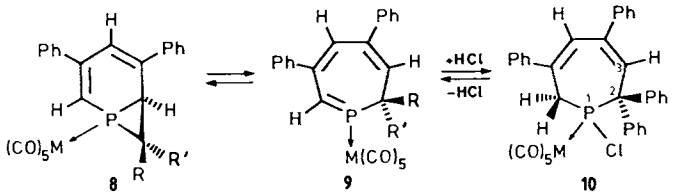


Scheme 1.



a, M = Cr; **b**, M = Mo; **c**, M = W; **7a**, **b**, R = H; **7c**, R = Me

An equilibrium between **8** and **9**, in which a reactive PC double bond with $\lambda^3\sigma^2$ phosphorus is present, is indicated by the fact that the 1-chlorodihydrophosphepine **10** is obtained upon addition of hydrogen chloride to **8** (Table 1).



The non-complexed bicycle **3** reacts analogously with hydrogen chloride to give **4** (Scheme 1, Table 1). Compound **10** can be quantitatively reconverted into **8** by base-induced (NEt_3) dehydrochlorination.

That the equilibrium **8**⇄**9** is actually established and the formation of **10** is not the result of a direct, ring-opening HCl-addition to **8**, underscores the result of the reaction of **5** with diazomethane and diazoethane: the 1-phosphanorcaradienes **8** formed with the first molecule of diazomethane with elimination of nitrogen can react further with a second molecule of diazoalkane only via the valence isomeric 1-phosphatropylidenes **9** in a 1,3-dipolar cycloaddition to give **7**. The cycloadducts **7** are not isolable as such; depending on R and the solvent from which they

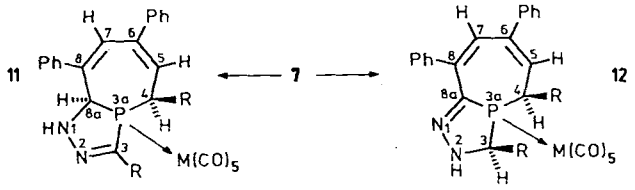
12c: 31%; m.p. 209–210 °C; ^1H-NMR: NH not observable, 4.76 (dq, J(P, H) = 6.93, $J(CH_3, H) = 6.86$; H-3), 1.63 (dd, J(P, H) = 15.97; CH_3-3), 3.69 (ddq, J(P, H) = 14.6, $J(CH_3, H) = 7.20$, J(H-4, H-5) = 4.59; H-4), 1.43 (dd, J(P, H) = 18.1; CH_3-4), 5.85 (dd, J(P, H) = 11.27; H-5), 6.42 (d, J(P, H) = 2.14; H-7)



are recrystallized, they undergo 1,3 H-shifts to give the isomeric hydrazones **11** and **12**.

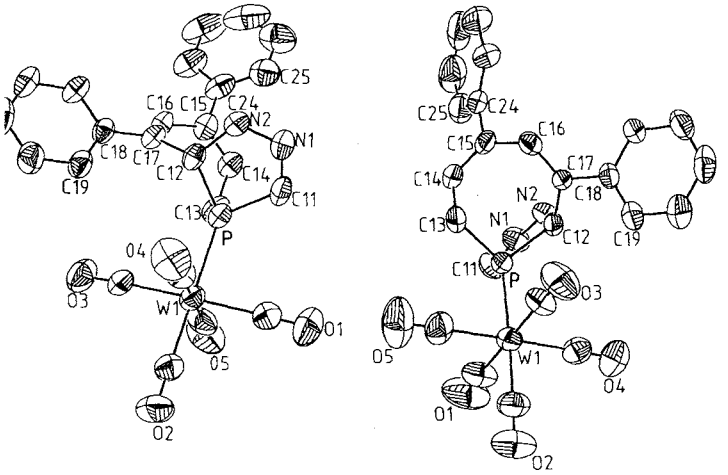


Fig. 1. Crystal structure of **11b** (two views). Selected bond lengths [Å] and angles [°] P-W1 2.492(2), P-C11 1.818(5), P-C12 1.863(7), P-C13 1.829(8), C11-N1 1.287(9), N1-N2 1.352(6), N2-C12 1.456(7); C11-P-C12 87.0(3), C11-P-C13 103.1(3), C12-P-C13 102.7(3).

Whereas both tautomers [**11b** from methanol (Table 1), **12b** from $CHCl_3$/petroleum ether (Table 1)] are obtained from **7b**, so far only the hydrazones **12a** and **12c** are formed from **7a** and **7c** (Table 1). The proposed structure is confirmed by spectroscopic data as well as the result of an X-ray structure analysis of **11b**[5] (Fig. 1).

The disrotatory, electrocyclic valence isomerization **8**⇆**9**, similarly as the Cope rearrangements of phospha-1,5-hexadienes[6] and the electrocyclic isomerization of 1,4-diphospha-1,3-butadienes in diphosphacyclobutenes,[7] demonstrates that the mutual conversion of $\lambda^3\sigma^3$- and $\lambda^3\sigma^2$-phosphorus in pericyclic reactions is possible (Scheme 2).

Scheme 2.

Stereoselective Synthesis of β-Amino Alcohols from Optically Active α-Amino Acids**

By *Manfred T. Reetz,* Mark W. Drewes,* and *Alfred Schmitz*

Optically active β-amino alcohols with two stereocenters not only occur as natural products[1] and are used as drugs,[2] but are also components of amino sugars[1] and of certain peptides and peptide analogues[3] which function as enzyme inhibitors. An attractive synthetic strategy con-

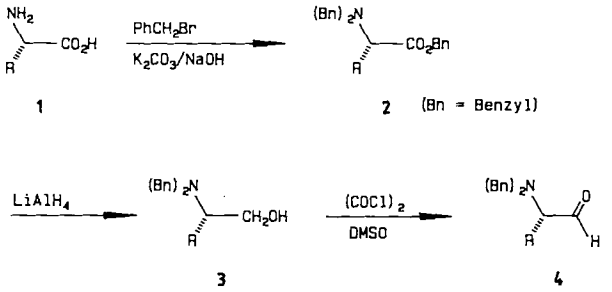
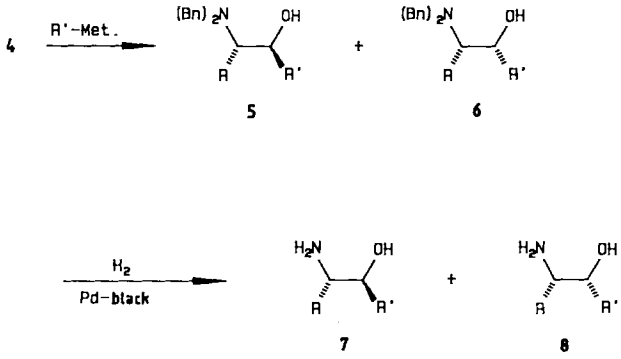
sists in the conversion of protected natural or unnatural α-amino acids into the α-amino aldehydes followed by stereoselective Grignard or aldol addition. The most frequently used protective group is *tert*-butoxycarbonyl (Boc), which, however, may lead to configurational lability at the stage of the aldehyde and only seldom allows a high degree of diastereoselectivity to be achieved.[4] The 9-phenyl-9-fluorenyl protective group guarantees configurational stability and thus the easy manipulation of the aldehyde, but Grignard and aldol additions afford only 1:1 and 1:3 mixtures, respectively.[5] We report here on a general solution of both problems using the benzyl protective group and suitable organometallic reagents.

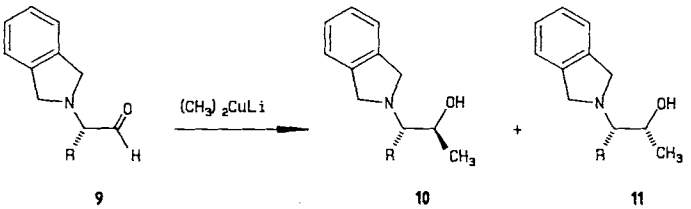
When the natural L-amino acids **1** are allowed to react with benzyl bromide in the presence of K_2CO_3/NaOH, the *N,N*-dibenzylamino benzyl esters **2** are formed (67–73%),[6] which can be reduced to the >99% optically active alcohols **3** (69–75%).[7] Swern oxidation affords the aldehydes **4** (88–92%), which are configurationally stable at room temperature.[8]



Surprisingly, Grignard and alkyllithium reagents react highly diastereoselectively with **4** with non-chelation control[9] to give the amino alcohols **6**[10] (Table 1). The degree of diastereoselectivity can even be further increased in some cases—by titanation of RMgX or RLi with $ClTi(OiPr)_3$ or $ClTi(NEt_2)_3$[11] (Entries 3, 12, 15, 20, 25, 27, 31, 34 in Table 1). In contrast, cuprates reduce the stereoselectivity (cf. Entry 10 in Table 1). Reversal of diastereoselectivity (cf. **5**) can be achieved with special Lewis acidic or chelating agents[9,11] of the type CH_3TiCl_3 or allyl-$SiMe_3/SnCl_4$ (Entries 9, 13, 21, 22, 28, 32, 35 in Table 1). Control experiments show that **5** and **6** are at least >99% enantiomerically pure, i.e. no racemization occurs during the reaction.[12] The protecting groups can be hydrogenolytically cleaved with H_2/Pd-black with formation of **7** and **8** (70–90%).[13]



Why do RMgX, RLi, and R_2CuLi[14] show *no* chelation effects, even though amino groups are known to have excellent donor properties? Perhaps "tieing up" the molecules by these metals to give a five-membered ring chelate is prevented on steric grounds, the *Cornforth* or *Felkin-Anh* model therefore being relevant.[9] Chelation is only possible by use of very strong Lewis acidic reagents. Remarkable is the finding that aldehydes such as **9**, which contain sterically less-demanding protective groups, undergo chelate-controlled reaction even with $(CH_3)_2CuLi$, thereby leading preferentially to **10** instead of **11** (75–78% yield).



R = CH_3	90	:	10
R = CH_2Ph	95	:	5

The addition of lithium enolates to **4** takes place under non-chelation control without any racemization (cf. **13**)[10] (Table 2). Here again, reversal of diastereoselectivity (formation of **12**) is the more difficult task. In the presence of Lewis acids such as $TiCl_4$, enolsilanes add with chelation control, but the yield of aldol is low (Entry 3 in Table 2).

The main product is formed by aldol condensation, i.e., under the reaction conditions water is eliminated.[15] Since the allyl residue represents a latent carbonyl unit,[16] the reaction of allyl$SiMe_3$/$SnCl_4$ provides a chelation-controlled aldol-analogous addition (Entries 13, 21, 28, 35 in Table 1).

[a] Conditions: −78→−40 °C, 3.5 h, in CH_2Cl_2.

Our results show that optically active *N,N*-dibenzylated α-amino aldehydes are readily accessible and that *optional* chelation or non-chelation-controlled Grignard and aldol additions free of racemization are possible for the first time. The potential of the natural L-amino acid chiral pool has thus been enlarged considerably.[17] Since many synthetic D-amino acids are also available, the mirror-image products are also accessible.

Experimental

Typical procedure for Grignard addition to **4**: the solution of (*S*)-α-(*N,N*-dibenzylamino)propionaldehyde **4**, R = CH_3, (1.0 g, 4 mmol) in ether (3 mL) was added dropwise under N_2 to a solution of methylmagnesium iodide (4.8 mmol) in ether (4 mL). After one hours' stirring the reaction mixture was hydrolyzed with 8 mL of saturated NH_4Cl solution; the organic phase was separated off and the aqueous phase was extracted with ether. The combined ether phases were washed with NaCl solution and dried over $MgSO_4$. After removal of ether the residue (**5**:**6** = 5:95 according to the ^{13}C-NMR spectrum) was purified by flash chromatography (silica gel/ethyl acetate, petroleum ether); yield 925 mg (87%) of pure (2*R*,3*S*)-3-(*N,N*-dibenzylamino)-2-butanol **6**, R = R′ = CH_3, white crystals of m.p. 76–77 °C.

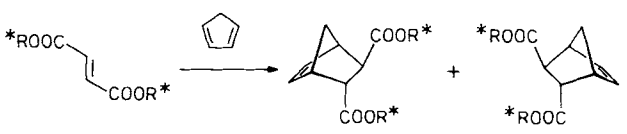
High Stereoselectivity in Lewis-Acid-Catalyzed and Uncatalyzed Diels-Alder Reactions of the Fumarate of (S)-Ethyl Lactate**

By *Horst Hartmann, Abdel Fattah Abdel Hady, Karina Sartor, John Weetman,* and *Günter Helmchen**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Asymmetric Diels-Alder reactions with α,β-unsaturated esters of chiral alcohols have been the subject of numerous studies.[1] Whereas a wide variety of excellent results have been reported for Lewis-acid-catalyzed reactions, very little has so far been achieved for the uncatalyzed variant. We have now found a dienophile, namely the title compound **1**, which exhibits both high stereoselectivity and inverse stereoselectivity for both variants.

The acrylate **3** of (*S*)-ethyl lactate reacts diastereoselectively (80:20) with cyclopentadiene at 0 °C in hexane to give the *endo*-adduct.[2] Under the same conditions, the fumarate **1** yields the adducts **2a** and **2b** in the ratio



1 **2a** **2b**

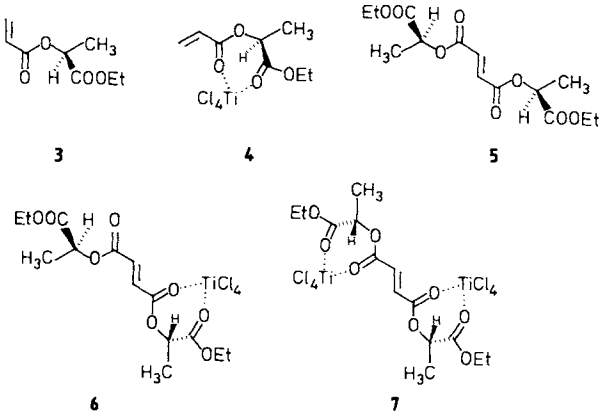
95.5 : 4.5, clearly indicating a cooperative effect[3] of the auxiliary groups. At −54 °C (cf. Table 1) the ratio **2a : 2b** is even 98 : 2.[4] To explain these results we assume that **1** reacts as C_2 symmetric species **5** with *anti*-enoate conformation[5] (cf. Formula), for which attack from the sterically more accessible back face is favored.

For $TiCl_4$-catalyzed additions of the acrylate **3**, which yield preferred products of opposite configuration compared to the uncatalyzed reactions, the complex **4** with *syn*-enoate conformation is postulated as reactive species.[6] On extending this mechanistic model to the fumarate **1** one would expect the 1 : 1 complex **6** with *syn*- and *anti*-enoate conformation as reactive species, and therefore antagonistic action of the auxiliary groups, and/or the 2 : 1 complex **7** with *syn*-planar enoate conformation on both



3 **4** **5**

6 **7**

R*−OH= (*S*)-ethyl lactate.

sides, and therefore synergistic action of the auxiliary groups. For differentiation of these complexes, **1** was allowed to react with cyclopentadiene using various $TiCl_4$: **1** ratios and the ratio **2a : 2b** was analyzed by HPLC. We interpret the results of this series of experiments (Fig. 1) as follows: at low $TiCl_4$: **1** ratios (A) **6** determines the course of reaction, hence the unselective reaction. In the range B, competition of the complex **7** becomes noticeable, which in range C finally dominates and gives the ester **2b** with 95 : 5 selectivity.

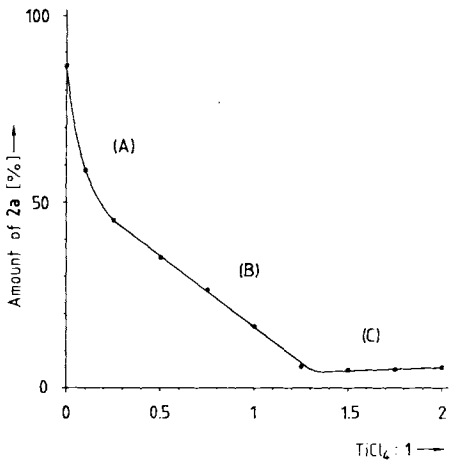


Fig. 1. Dependence of the diastereoselectivity (content of **2a** in product mixture) in the $TiCl_4$-catalyzed reaction of the fumarate **1** with cyclopentadiene on the molar ratio $TiCl_4$: **1** (solvent: CH_2Cl_2, $T = -40$ °C, concentration of 1 : 0.05 mol/L, ratio **1** : cyclopentadiene = 1 : 4).

Analogous results (Table 1) were obtained with cyclohexadiene, butadiene, and anthracene, although in uncatalyzed reactions these dienes require reaction temperatures above ca. 75 °C. Generally, high selectivity is achieved in the uncatalyzed reaction only with unpolar solvents, preferably hexane.[2] Increasing the pressure to 7 kbar allows the reaction temperature to be considerably lowered, leading to a significant increase in diastereoselectivity (Table 1).

[a] Reaction conditions: In the uncatalyzed reaction a solution of **1** (0.3 M) and diene in the given solvent was heated under reflux or in an autoclave at the given temperature until complete conversion was achieved (DC control). The molar ratio **1** : diene was 1 : 1.5 to 1 : 5. In the catalyzed variant a 1 M solution of $TiCl_4$ in CH_2Cl_2 was added at room temperature to a 0.05 M solution of **1** in CH_2Cl_2. 5 min later, at the given temperature, the diene was slowly added to the well stirred solution. The molar ratio of **1** : diene was 1 : 1.5 to 1 : 5. [b] Carried out in a high-pressure autoclave at 7 kbar. [c] Single recrystallization from *n*-hexane yielded diastereomerically pure **8a** in 84% yield. [d] At 140 °C the reaction was clearly reversible. [e] Diastereomerically pure **10a** was obtained in 50–60% yield by recrystallization from ethyl acetate/hexane. [f] Not determined.

Diels Alder reactions with the inexpensive fumarate **1** are of interest for preparative applications—e.g., the (2*S*,3*S*)-5-norbornene-2,3-dicarboxylic acid readily obtainable[4] from the adduct **2b** is a valuable starting material for the synthesis of prostaglandins.[7] It is advantageous for such applications that the diastereomeric adducts can generally be easily separated by liquid chromatography.[8] With **8** and **10**, in each case one of the diastereomers, **8a** and **10a**, respectively, is crystalline and can be obtained pure by recrystallization of the crude product.

[4] For the preparative utilization of the Diels-Alder adducts **2** and their analogues it is important to obtain enantiomerically pure secondary products with differentiated COOR groups. Both problems are solved by hydrolysis (LiOH in THF/water) to the dicarboxylic acid, preparation and recrystallization of the iodolactone, esterification or reduction of the COOH group, and reduction with zinc (cf. [1a]).
[5] The conformation of the chiral ester group was chosen on the basis of force-field calculations on **3**, which were carried out by Prof. *H.-J. Lindner*, Darmstadt.

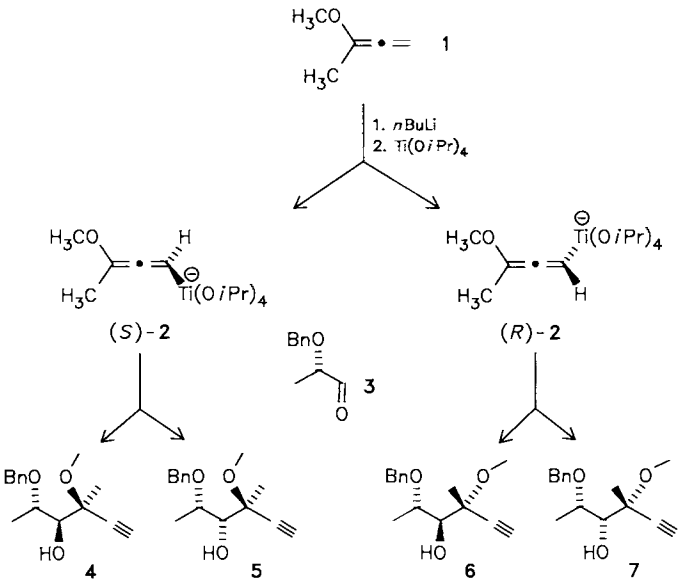
Estimation of the Configurational Stability of Chiral Organometallic Reagents**

By *Reinhard W. Hoffmann,* Joachim Lanz, Rainer Metternich, Gerhard Tarara,* and *Dieter Hoppe**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Information about the degree of configurational stability of organometallic compounds is of great importance for their use in stereoselective synthesis. Thus, the configurational stability of, e.g., vinyllithium[1] and (α-alkoxyalkyl)lithium compounds is well documented.[2,3] The configurational stability is frequently investigated by using a second stereogenic center in the organometallic compound as a reference point and observing the occurrence or absence of an epimerization by way of the secondary products.[2] We wish to present here another simple method for this purpose involving reaction of the organometallic compound in its racemic form with a chiral aldehyde.—This aldehyde is reacted once in enantiomerically pure form and once as a racemate with the organometallic reagent. Reaction of the allenyltitanium compound **2**[4] with α-benzyloxypropionaldehyde **3** serves as example. The reagent **2** was generated by metalation of 3-methoxy-1,2-butadiene **1**[5] with *n*-butyllithium at −30 °C and titanation with titanium tetraisopropoxide at −78 °C. The solution of **2** was then allowed to react at −78 °C with one equivalent of the aldehyde **3** [*rac*- or (*S*)-(−)-**3** (α_D^{20} = 66.35° neat, l = 1 dm], whereupon a mixture of the diastereomeric adducts **4**–**7**[6] was obtained in 70–90% yield.[7] The product ratios were determined by gas chromatography.

The inference that the establishment of equilibrium between the enantiomers of **2** is slow compared to addition of **2** to **3**, is based on the fact that the product ratios in the two experiments are different. Furthermore, one can recognize that the numbers in Experiment **A** can be combined pairwise, so that, within the accuracy of the determination (± 1%), the ratio 50 : 50 results (50 + 1 and 35 + 14).



A	(*S*)-(−)-**3**:	**4**		**5**		**6**		**7**
		50	:	1	:	35	:	14
B	*rac*-**3**:	*rac*-**4**		*rac*-**5**		*rac*-**6**		*rac*-**7**
		92	:	< 1	:	6	:	2

This is based on the fact that (*S*)-**2** leads to the products **4** and **5**, while the enantiomer (*R*)-**2** leads to the products **6** and **7**. Since the two enantiomers of **2** are present in the ratio 50 : 50, this must, after complete reaction of **2**, also be true for the products **4**+**5** and **6**+**7**. Experiment **A** thus represents the limiting case in which the enantiomer-equilibrium (racemization) of **2** is very much slower than the addition to **3**.

However, the combinations (*R*)-**2** + (*S*)-**3** and (*S*)-**2** + (*S*)-**3** react at different rates, as can be seen from Experiment **B**: Here, in the reaction of the racemates eleven times more of the product **4** (+**5**) was formed (92%) than of the products **6**+**7** (8%) by mutual kinetic resolution.[8] The combinations (*S*)-**2** + (*S*)-**3** and (*R*)-**2** + (*R*)-**3** thus reacted considerably more rapidly than the *R*/*S* pairs.

Returning to the question of the configurational stability of **2**: In the other limiting case—the enantiomer-equilibration of **2** be rapid compared to its addition of **3**—as also in the case of an achiral organometallic compound, in Experiment **A** the same number ratios ought to result as in Experiment **B**[9], because due to rapid enantiomer-equilibration of **2** the faster, reacting enantiomer would be immediately re-formed, i.e. it makes no difference whether the reaction partner (aldehyde) is racemic or enantiomerically pure. In the third case—the enantiomer-equilibration of the reagent and its addition to the aldehyde proceeding at a similar rate—in Experiment **A** a product ratio 92 : 8 > [**4**+**5**] : [**6**+**7**] > 50 : 50 should result.[10]

This method should be generally applicable for checking the configurational stability of chiral organometallic reagents. The example described here is comparatively complicated because four diastereomeric products are formed. The reason for this is the low *syn*/*anti* selectivity of **2** with respect to the relative configuration of the two new stereocenters. If this type of diastereoselectivity of the reagent is high, one has practically only to deal with two diastereo-

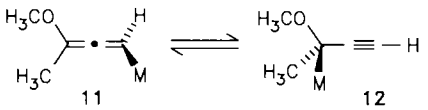
C	(*S*)-(−)-**3**:	53	:	47
D	*rac*-**3**:	68	:	32

meric products, which in the reaction of a configurationally stable racemic reagent with racemic aldehyde should be obtained as a mixture of two racemic diastereomers in a ratio ≠50:50, and with enantiomerically pure aldehyde[10] as a 50:50 pair of enantiomerically pure diastereomers. This was realized in the addition of the carbamoyltitanium compound **8**[3] to the aldehyde **3**. The product ratio **9**:**10** in Experiment **C** corresponds almost to the expected value of 50:50.

The enantiomers of **2**, probably allenylmetal compounds **11**, could equilibrate via a metallotropic shift[11] to give **12**. Such an isomerization is found in the case of the



lithium compound corresponding to **2**, which added with low regioselectivity to aliphatic aldehydes.[4, 12] The configurational stability of **2** at −78 °C reported here indicates that titanation presumably not only shifts the equilibrium in favor of **2** but also raises the isomerization threshold.[3]

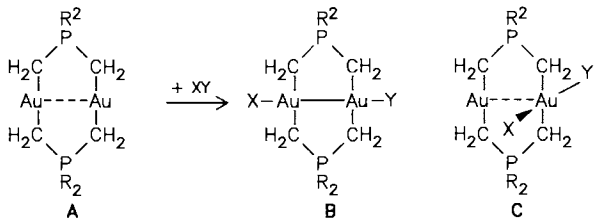
Isovalent and Mixed-Valent Ylide Complexes of Gold: The Synthesis of Trinuclear Compounds Having Double Paddlewheel Structure**

By *Hubert Schmidbaur,* Christoph Hartmann, Gabriele Reber,* and *Gerhard Müller*

Since their first synthesis,[1] gold complexes of phosphorus ylides have repeatedly been the subject of preparative, mechanistic, and theoretical studies,[2-5] because they are superbly suited as models for the investigation of the reactions of polynuclear coordination compounds. Of particular interest is the course of the oxidative additions to binuclear complexes of type **A**, since these reactions can lead to either isovalent Au^{II} compounds **B** having a Au–Au bond or mixed-valent Au^{I}–Au^{III} compounds **C**.[6-8] In favorable cases, reaction with XY may even lead to simultaneous formation of both isomers.



Herein we report on the reactions of **B** (R = phenyl; X = Y = halogen; ≙ **1**) with several phosphorus ylides R'_3PCH_2 ($R'_3 = Me_3$, Ph_3, and Ph_2Me), which result in the initial formation of mono- and disubstituted intermediates and which finally lead to the unexpected formation of novel, mixed-valent trinuclear complexes.

Reaction of the gold(II) complex **1b** with Ph_3PCH_2 in a 1:1 molar ratio affords **2b** as the main product. Likewise, reaction of the complex **1c** with Me_3PhCH_2[9] and with Ph_3PCH_2[10] affords **2a** and **2c**, respectively. The yellow, ionic products were obtained in high yields. Their structure was established by spectroscopic data as well as by

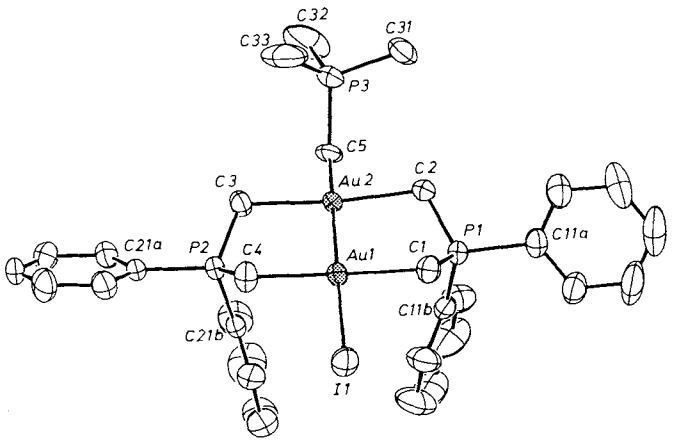

Fig. 1. Molecular structure of the cation of **2a** (ORTEP, thermal ellipsoids 50%, H atoms omitted). The eight-membered $Au_2C_4P_2$ heterocycle is in boat conformation with a nearly planar $C_2Au_2C_2$ moiety. The Ph_2P and PMe_3 groups point away from one another. Important distances [Å] and angles [°]: Au1-Au2 2.681(1), Au1-I1 2.822(1), Au1-C1 2.096(7), Au1-C4 2.100(7), Au2-C2 2.107(7), Au2-C3 2.106(7), Au2-C5 2.083(8); Au2-Au1-I1 172.4(1), C5-Au2-Au1 173.1(2), C1-Au1-C4 175.4(3), C2-Au2-C3 173.8(3) [11].

an X-ray structure analysis of **2a**.[11] Their diamagnetic character, the short Au–Au distance (Fig. 1), and the ^{197}Au Mössbauer spectrum[12] show unequivocally that the isovalent structure [$Au^{II}Au^{II}$] has been retained.

In contrast, reaction of **1c** with the ylides Me_3PCH_2, $MePh_2PCH_2$,[13] or Ph_3PCH_2 in a 1:2 molar ratio results in formation of the bright yellow, dicationic complexes **3a–c**, which have a $Au^{I}Au^{III}$ constitution, as shown, for example, by the Mössbauer spectra.[12] This result is in agreement with the finding that oxidative addition of CH_3I to **A** affords a product of type **B** (X = CH_3, Y = I), whereas attempts to carry out further alkylation with $LiCH_3$ afford only a mixed-valent isomer of type **C** (X = Y = CH_3).[1] Apparently, the strong *trans* influence of two alkyl groups on the Au–Au bond results in destabilization of this structural unit and induces disproportionation. The introduction of two onium charges—as in **3**—does not change this situation appreciably, and multiple fluorine substitution is necessary in order to generate dialkylated compounds of type **B**.[18]

	X		X	R'_3		R'_3
1a, 4a	Cl	**2a**	I	Me_3	**3a**	Me_3
1b, 4b	Br	**2b**	Br	Ph_3	**3b**	Ph_2Me
1c, 4c	I	**2c**	I	Ph_3	**3c**	Ph_3

Reaction of **1a–c** and **3b** with excess $MePh_2PCH_2$ leads, regardless of the nature of the halogen, to formation of the colorless, air-stable salts **4a–c** and **4c**, respectively, each of which contains the same trinuclear complex cation. For this reason, the NMR spectra of the solutions are nearly identical. The electrical conductivity corresponds to that of a 1:1 electrolyte. The ^{197}Au Mössbauer spectrum of **4c** shows that gold is present in two oxidation states.[12] The very simple NMR spectra, which exhibit, for example, only a single ^{31}P resonance and only two $^{13}CH_2$ resonances of equal intensity, indicate that the cation complex has a highly symmetrical structure. Indeed, the X-ray structure analysis of **4c**[11] (which crystallizes with four molecules of dichloromethane) shows a spirocyclic arrangement of two diauradiphosphacycles of type **A**, which are oriented at 90° relative to each other, resulting in a double paddlewheel with a Au···Au···Au shaft (Fig. 2). The spiro atom is a Au^{III} center coordinated in a square-planar fashion, whereas the other two gold atoms are present as linear doubly coordinated Au^{I} centers. The cation has no symmetry in the crystal. Its eight-membered rings are both present in boat conformation, as has already been observed for various examples of **A** and **B**. Moreover, the Au···Au···Au unit is not linear (Au1-Au2-Au3 163.6(1)°). In solution, however, the effective symmetry presumably corresponds to the point group D_2 owing to the flexibility of the skeleton.

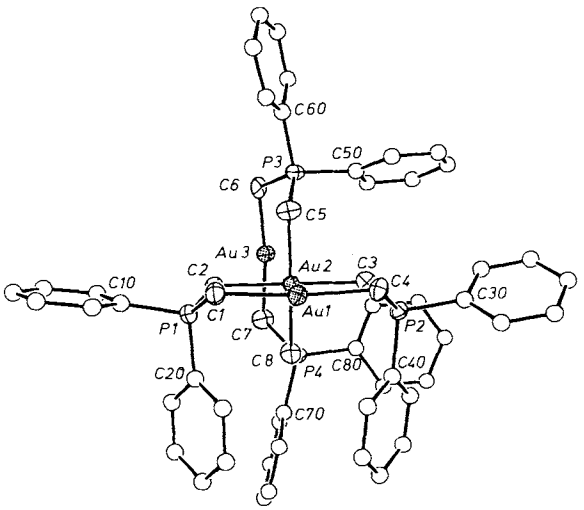

Fig. 2. Molecular structure of the cation of **4c** · $4CH_2Cl_2$ (ORTEP, phenyl C atoms with arbitrary radii). Two of the phosphorus centers (P1/P3) of the nearly perpendicularly oriented eight-membered rings point away from each other and the other two centers (P2/P4) point toward each other. Important distances [Å] and angles [°]: Au1-Au2 3.052(1), Au2-Au3 3.049(1), Au1-C1 2.10(2), Au1-C4 2.10(1), Au2-C2 2.12(1), Au2-C3 2.09(1), Au2-C5 2.13(1), Au2-C8 2.13(1), Au3-C6 2.09(1), Au3-C7 2.10(1); Au1-Au2-Au3 163.6(1), C1-Au1-C4 174.3(5), C2-Au2-C3 176.6(5), C5-Au2-C8 176.7(5), C6-Au3-C7 172.4(6) [11].

As side products of the reactions leading to **4**, ylide complexes of trivalent gold are formed, examples of which are already known:[2] [(ylide)$_2$AuX$_2$]X. Mass and redox balance, which require one Au^{III} equivalent for the transformation of two moles of **1** into one mole of **4**, is thereby

achieved. The structure of the side products, which may involve isomers, were not investigated further.

Experimental Procedure

Each type of complex is exemplified by one preparation.

2c: **1c** (220 mg, 0.21 mmol) was dissolved in THF (50 mL) and the resulting solution was treated at −35 °C with a solution of Ph_3PCH_2 (58 mg, 0.21 mmol) in the same solvent. After the reaction mixture had warmed to room temperature, the orange-yellow precipitate was filtered off, washed with diethyl ether, and dried under vacuum (yield 210 mg, 75%); m.p. = 174–177 °C (dec.), soluble in CH_2Cl_2, $CHCl_3/CH_3OH$; the solutions in $CHCl_3/CH_3OH$ are yellow at 20 °C, green at −30 °C.—^{31}P-NMR(CD_2Cl_2): δ = 44.5, 29.1 (each s, int. 2 : 1). ^{1}H-NMR (CD_2Cl_2): δ = 1.02, 1.76 (each virtual d, N = 10.99 and 9.89 Hz, ring CH_2), 3.18 (d, J = 11.4, CH_2PPh_3), 7.37–7.73 (m, Ph). ^{13}C-NMR (CD_2Cl_2): δ = 4.3, 4.5, 11.1 (all d, J = 51.3, 41.5, and 54.8 Hz, CH_2); 128.9, 130.4, 132.0, 133.5 (Ph_2); 121.7, 129.8, 133.8, 134.3 (Ph_3). ^{197}Au Mössbauer spectrum: *IS* 2.92 and 3.26 mm s^{-1}, *QS* 6.26 and 6.94 mm s^{-1} (4 K, int. 1 : 1).

2b: yield 81%, m.p. = 186–190 °C (dec.).

2a: yield 77%, m.p. = 170–173 °C (dec.) (see Fig. 1).

3a: **1c** (184 mg, 0.17 mmol) was dissolved in THF (50 mL) and the resulting solution was treated at −100 °C with a solution of Me_3PCH_2 (31 mg, 0.34 mmol) in THF. The color became lighter. At −90 °C, after further disappearance of the color, an almost colorless precipitate formed, which was filtered off, washed with ether, and recrystallized from CH_2Cl_2 (yield 146 mg (68%), m.p. = 166–174 °C (dec.), soluble in CH_2Cl_2, $CHCl_3$).—^{31}P-NMR ($CDCl_3$): δ = 26.9, 31.1 (each s, int. 1 : 1). ^{13}C-NMR ($CDCl_3$): δ = 11.34, 18.11, 18.82 (all "d," N = 56.2, 69.9 and 55.7 Hz, int. 1 : 1 : 1, CH_2); 14.65 (d, J = 54.8, CH_3); 129.0–134.6 (m, Ph). ^{1}H-NMR ($CDCl_3$): δ = 0.84, 1.34, 2.23 (all "d," N = 13.9, 12.9, and 14.6 Hz, CH_2); 1.95 (d, J = 13.3, CH_3); 7.2–8.1 (m, Ph). ^{197}Au Mössbauer spectrum: *IS* 3.59 and 3.69 mm s^{-1}, *QS* 6.49 and 9.40 mm s^{-1} (4 K, int.: 2 : 1).

3b: yield 82%, m.p. = 181–184 °C (dec.).

3c: yield 89%, m.p. = 173–176 °C (dec.).

4c: **1c** (464 mg, 0.432 mmol) was dissolved in THF (60 mL) and treated at −105 °C with a solution of $MePh_2PCH_2$ (643 mg, 3 mmol, large excess) in THF (5 mL). After the solution had warmed to room temperature, the colorless precipitate was filtered off, washed with ether, and dried under vacuum. Significant losses occurred upon recrystallization from CH_2Cl_2 (yield 165 mg (48%), m.p. = 195–197 °C (dec.), see Fig. 2)).—^{31}P-NMR ($CDCl_3$): δ = 31.4 (s). ^{13}C-NMR ($CDCl_3/CH_3OH$): δ = 7.45 and 11.37 ("d," N = 50.7 and 49.4 Hz, CH_2); 129.5, 132.1, 132.6, 133.1 (Ph). ^{1}H-NMR ($CDCl_3/CH_3OH$): δ = 1.26 and 1.33 (d, J = 12.2 and 12.7 Hz, CH_2); 7.36–7.57 (Ph). ^{197}Au Mössbauer spectrum: *IS* 3.43 and 3.79 mm s^{-1}, *QS* 5.61 and 9.67 mm s^{-1} (4 K; int. 1 : 1). Solutions in CH_2Cl_2 exhibit the electrical conductivity of a 1 : 1 electrolyte such as **2c**.

4b: decomposition temperature 198–204 °C.

4a: decomposition temperature 200–206 °C.

Satisfactory elemental analyses were obtained for all compounds.

The Recoil-Free Fraction of the γ Resonance in ^{197}Au Mössbauer Spectroscopy; Findings from Measurements of Polynuclear, Mixed-Valent Ylide Complexes**

By *Hubert Schmidbaur,* Christoph Hartmann,* and *Friedrich E. Wagner**

^{197}Au Mössbauer spectroscopy provides a useful method for elucidating the structure and bonding of gold compounds.[1] Progress in the interpretation of the spectra has resulted, in particular, from the availability of increasingly reliable correlations of the parameters for the isomeric shift *(IS)* and the quadrupole coupling *(QS)* with chemical characteristics such as the oxidation state and coordination number of gold as well as with the electronic influence of the ligands.[2–6] On the other hand, the interpretation of the absolute and relative intensities of the Mössbauer lines remains a problem, since—in contrast to NMR spectroscopy, for example—the intensities often do not agree with expectations based on stoichiometry. These discrepancies are ascribed to variations in the recoil-free fraction *(RFF)*[1,6] of the γ resonance, which depends on the "intermolecular" lattice vibrations as well as on the "intramolecular" vibrational motions of the gold atoms.[1,6,7]

Our investigations were prompted by the following observations:[8] The newly prepared trinuclear gold complex **1** exhibits two quadrupole doublets in its Mössbauer spec-

trum, each doublet being composed of two equal-intensity components (Fig. 1). In the binuclear complex **2**, in contrast, the components of the doublet appear in an intensity ratio of 1 : 2 (Fig. 2). Thus, there seems to be no relationship to the stoichiometry, an observation that resulted initially in the proposal of incorrect structures.

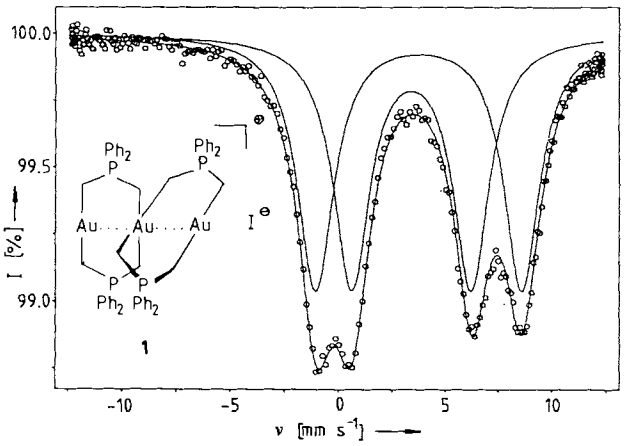

Fig. 1. ^{197}Au Mössbauer spectrum of the trigold compound **1** recorded at 4 K.

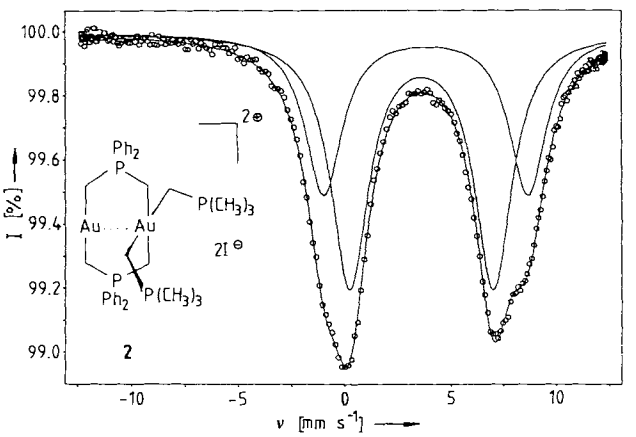

Fig. 2. ^{197}Au Mössbauer spectrum of the digold compound **2**.

Examination of the other measured values then showed that the ^{197}Au Mössbauer intensities are also strongly dependent on the oxidation state, and thus on the coordination number, since, at least for organogold compounds, an increase in the oxidation state is generally associated with an increase in the coordination number.[4]

This conclusion is established by a simple control experiment. The simultaneous measurement of exactly equimolar amounts of the crystalline reference compounds **3**[9] and **4**[10] affords a Mössbauer spectrum (Fig. 3) in which the components of the two doublets do not exhibit a 1 : 1 intensity ratio but rather a 1 : 1.25 ratio, the higher intensity being assigned to the gold(III) complex. With respect to the problem discussed above, this means that the *RFF* of the γ resonance of both **1** and **2** is larger for the Au^{III} centers than for the Au^{I} centers, so that the resonances of the Au^{I} centers are less intense. Otherwise, in the case of **1**, the Au^{I} resonance, which is assigned on the basis of the large *QS* value, should exhibit twice the intensity and, in the case of

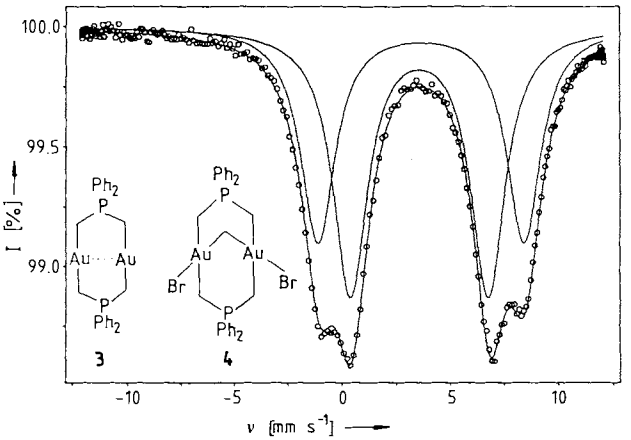

Fig. 3. ^{197}Au Mössbauer spectrum of a mixture of the digold compounds **3** and **4** in a molar ratio of 1 : 1.

2, it should exhibit the same intensity as the Au^{III} resonance.

In contrast, binuclear gold compounds in which the gold atoms are in similar (but not identical) environments, e.g., **5** and **6**,[11] give rise to two equal-area doublets (Fig. 4; the *IS* and *QS* values correspond to those of other di- and trivalent gold compounds[2-4]).

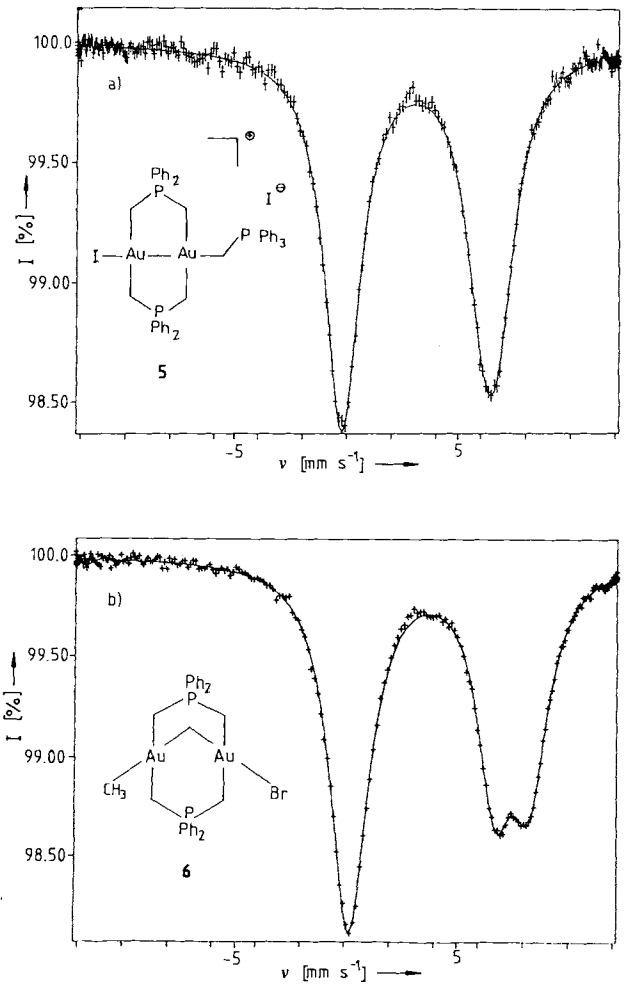

Fig. 4. ^{197}Au Mössbauer spectrum of the digold compounds a) **5** and b) **6**.

The significance of the new data for cations such as **1** and **2** lies in the fact that two gold atoms having different configurations are each present in a common structural unit. *RFF* values are usually broken down in a reasonable way into the aforementioned inter- and intramolecular components, provided that the solid is composed of larger individual structural units:[1]

$$f = f_L \cdot f_M$$

f_L and f_M are the Debye-Waller factors of the lattice and molecular effects, respectively.[1] In the mixed-valent gold compounds reported so far, Au^I and Au^{III} were present in separate species, for example in cation and anion, so that the two *RFF* terms for the individual units were not separable.[1] In the case of **1** and **2**, however, f_L can be assumed to be similar, to a good approximation, for each of the two types of gold atoms, particularly since **1** and **2** are loosely packed in the crystal without discrete interactions between the ions.[8] The dramatic increase in the *RFF* values of the gold atoms in the complexes under consideration on going to higher oxidation states/coordination numbers (C.N.) (Au^I/C.N. 2; Au^{III}/C.N. 4) is thus a direct consequence of the change in the immediate environment of the metal atoms and therefore of f_M.

These results clearly revealed that, in contrast to earlier assumptions,[12] f_L is not the dominant *RFF* term; instead, f_M is primarily responsible for determining the relative intensities of the Mössbauer lines.

The vibrational motions of simple organogold compounds have been the subject of numerous investigations.[12] Normal mode analyses show how the energies and amplitudes of the fundamental vibrations change on going from the one-dimensional (linear) to the two-dimensional (square) coordination. These changes differ particularly in their strong anisotropy from those observed on going to a tetrahedral or a pseudo trigonal-bipyramidal coordination. The situation in ylide complexes is complicated further in that the neighboring gold atoms appreciably approach each other perpendicular to the C-Au-C axis to within distances of under 3.00 Å,[4] resulting in a further increase in the effective coordination number at each gold atom. Although these interactions, indicated by dotted lines in the formulas, are weaker than normal coordinative bonds, they are sufficient, for example, to influence the conformations of complexes and their packing in the crystal.[4, 5] This phenomenon, which is the result of a relativistic effect,[13] presumably also affects the recoil behavior and thus enters into the *RFF* values.

These components are no longer present for **4** owing to the Au-CH_2-Au linkage, so that it is not surprising that the intensity ratio for **4/3** is smaller (Fig. 3) than for **1** or **2** (internal in each case).

It is noteworthy that the ellipsoids of thermal vibration of the gold atoms in **1**, determined by X-ray analysis, also directly reveal the stronger motion of the two Au^I atoms. Obviously, however, a quantitative evaluation is not possible.[9]

Overall, the data show that, in the case of **1** and **2**, the coordinative bonding of the gold atom in a square array of ligands with secondary bonding to further gold atoms causes the *RFF* parameter f_M to increase strongly and thereby results in considerable shifts in the intensities of the Mössbauer lines. Owing to the special geometries of **1** and **2**, these shifts are much larger than analogous effects in other complexes.

In one of the few reported studies in this area, the Debye-Waller factors f_{Au} were correlated with the molecular weight; however, satisfactory results were obtained for only some of the compounds studied.[1, 12] Apparently, the contribution of coordination number and coordination geometry[12] discussed above is still considerably underestimated.

Conformational Transitions between Enantiomeric 3_{10}-Helices

By *Rolf-Peter Hummel, Claudio Toniolo,* and *Günther Jung**

Dedicated to Professor Manfred Rothe on the occasion of his 60th birthday

In the following we report on the ^{13}C-NMR study of an enantiotopomerization of 3_{10}-helices. This conformational change of a peptide, which occurs rapidly at room temperature, has been detected by us on a decapeptide consisting of α-aminoisobutyric acid (Aib), $Me_2C(NH_2)CO_2H$ residues. Our results are of relevance for those engaged in conformational energy calculations, molecular modeling, or the dynamics of peptides or who, for example, wish to use enzyme-resistant, nontoxic α-amino acid residues such as Aib in drug design.

In proteins 3_{10}-helices are found rarely and usually as short segments at the end of α-helices.[1] On the other hand, partial sequences of the peptaibol antibiotics[2] from tri- to octapeptides containing L-amino acids and a large amount of α,α-dialkylated, achiral Aib residues strongly prefer the *right*-handed 3^r_{10}-helical conformation.[2a, 3a-e] When the *N*-terminal -X-Aib sequence is in the type-II β-bend conformation, the adjacent segment of the peptide

chain is forced to adopt the *left*-handed 3^{l}_{10}-helix even if it is formed partially by L-residues.[3a,d] The protected achiral -(Aib)$_n$- (n = 5, 8) homopeptides[3b,c,d] and poly(Aib)$_n$[3f] form enantiomeric 3_{10}-helices in the crystal (Fig. 1).

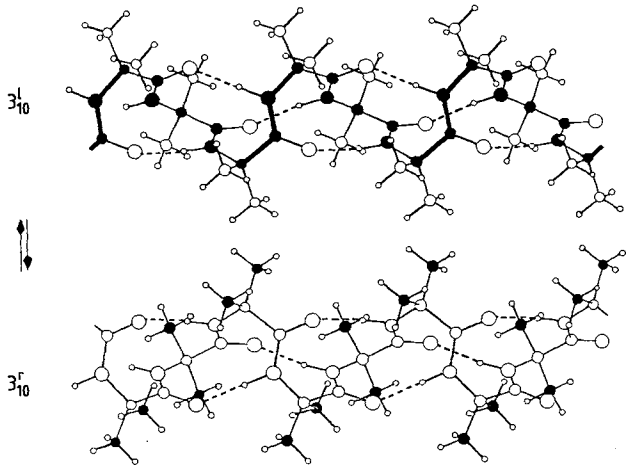

Fig. 1. Enantiomeric homopeptide 3_{10}-helices of Aib residues. In the 3^{l}_{10}-helix the backbone and in the 3^{r}_{10}-helix the α,α-dimethyl groups are emphasized (after [3f]).

In contrast to the short Aib peptides, the icosapeptide antibiotic alamethicin[4a] and three Aib-rich oligopeptides containing from nine to eleven residues[3a,4b,c] adopt mainly α-helical conformations. Solution studies revealed that the α-helical conformation[4b] is manifested at a chain length of about eight amino acids and is stabilized by Aib residues. In α-helices of comparable chain length this stabilizing effect is proportional to the Aib content (from 30 to 50%).[5] Thus, alamethicin and long model compounds possess α-helices of remarkable solvent and temperature stability,[6] which constitute the rigid macrodipole of peptaibols for voltage-dependent, ion-channel formation in membranes.[7] Obviously, at very high Aib content (more than 50%) and in particular in peptides with (Aib)$_n$ (n > 2) insertions, the helix-stabilizing effect is shifted in favor of the narrower 3_{10}-helix.

In a 3_{10}-helix the dipole vectors of the peptide bonds are not parallel to the helix axis and the 4→1 hydrogen bonds are not linear. The side chains of the amino acids are staggered in energetically unfavorable positions along the edges of the three-faced prism (Fig. 1). One of the diastereotopic, geminal Aib methyl groups is almost staggered with respect to the Aib CO group of the following peptide bond in contrast to the eclipsed position of the *pro-R* methyl group in the α-conformation (Fig. 2).[8]

On the NMR time scale conformationally stable, enantiomeric homopeptide 3_{10}-helices ($\Delta G^{\neq} \geqq 92$ kJ mol^{-1})[9] should exhibit a diastereotopic splitting of α-methyl signals,[8] because each methyl group is in a different chiral environment along the helix. Diastereotopicity should also be observable in samples of equal amounts of 3^{l}_{10}- and 3^{r}_{10}-helices, i.e., in a racemate that cannot be studied by chiroptical methods. In view of the strong steric restriction of Aib residues compared with protein amino acids, the question arises whether 3_{10}-helix⇄coil transitions can occur at all, or whether a $3^{l}_{10} \rightleftarrows 3^{r}_{10}$-helix interconversion (enantiotopomerization) occurs without intermediate states.

For the first time we have been able to prove a $3^{r}_{10} \rightleftarrows 3^{l}_{10}$ helix interconversion in the decapeptide **12** via temperature-dependent ^{13}C-NMR measurements between 200 and 300 K in dichloromethane (Fig. 3). At room temperature the conformationally uniform homopeptides **10**–**14**[10] show a sharp Aib-C$_\beta$ signal which broadens to $\Delta = 0.9$ ppm at maximum with increasing chain length (Fig. 2). Thus, the peak resulting from the 20 C$_\beta$ atoms of **12** exhibits a half-height width of only 0.7 ppm (Fig. 2). Its position at $\delta = 25.1$ is exactly halfway between the mean α-helical values of 26.8 and 23.2 ppm known for *pro-R*- and *pro-S*-C$_\beta$, respectively.[5,8]

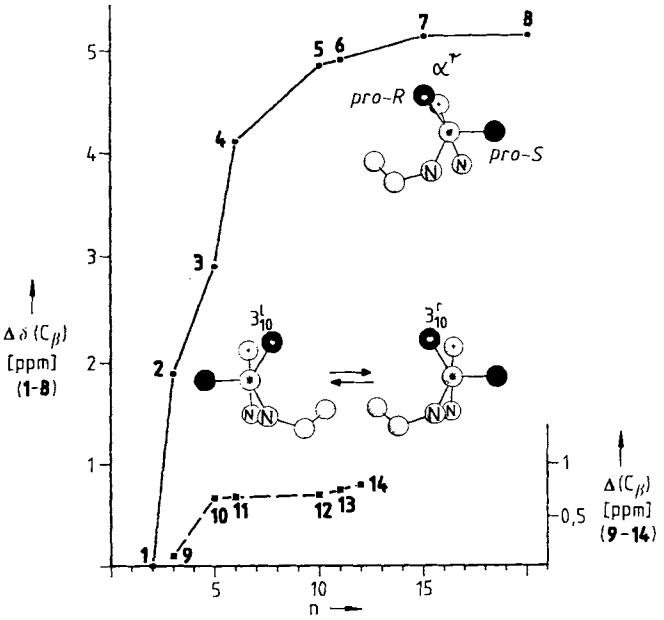

Fig. 2. Magnetic nonequivalence (Δδ) of the diastereotopic Aib C$_\beta$ atoms as a function of the main chain length in the ^{13}C-NMR spectra of the heteropeptides **1**–**8** with alternatingly positioned Aib residues between L-Ala or D-isovaline (Iva). **1**, Boc-Ala-Aib-OMe; **2**, Boc-Ala-Aib-Ala-OMe [8b]; **3**, Boc-Ala-Aib-Ala-Aib-Ala-OMe; **4**, Z-Iva-Ala-Aib-Ala-Aib-Ala-OMe; **5**, Boc-(L-Ala-Aib-Ala-Aib-Ala)$_2$-OMe; **6**, Boc-L-Ala-Aib-Ala-Aib-Ala-D-Iva-Ala-Aib-Ala-Aib-Ala-OMe; **7**, Boc-(L-Ala-Aib-Ala-Aib-Ala)$_3$OMe; **8**, Boc-(L-Ala-Aib-Ala-Aib-Ala)$_4$-OMe [5, 6a]. For comparison, the half-height widths Δ of the Aib C$_\beta$ signals of the homopeptides **9**–**14**, Z-(Aib)$_n$-OrBu (n = 3, 5, 6, 10–12) [70 mg/0.6 mL $CDCl_3/CD_3OD$ (1:1), 27 °C, 100.6 MHz, Bruker WM 400] are given. The inserts show a comparision of the positions of the methyl groups of an Aib residue (* = C$_\alpha$, + = carbonyl O) with respect to the carbonyl group of the following peptide bond.

Upon cooling of the decapeptide solution to 203 K, *two* distinct enantiomeric signal groups at $\delta = 26.7$ and 21.4 originate out of the 20 prochiral C$_\beta$ atoms of each enantiomeric 3_{10}-helix (Fig. 3), as found for the α^r-helices of alamethicin[8a,c] as well as **5**, **7** and **8**.[5] A marked increase in Δδ was seen with decreasing temperature and a maximum value of 5.3 ppm was measured at 203 K (Fig. 3). This finding agrees well with that for α-helical structures at room temperature with increasing chain length (Fig. 2).

At this point one could raise the question whether the decapeptide, known to fold into the 3_{10}-helical conformation in the *solid* state,[10] could eventually adopt the α-conformation in solution at very low temperature. Indeed $\alpha \rightleftarrows 3_{10}$ helix interconversions of alamethicin have been discussed in the context of the potential-dependent channel formation. However, besides vibrational data, several NMR spectroscopic results do not support the contention that Aib homopeptides form α-helices in *solution*. The strongly diverging T_1 relaxation time differences of gemi-

nal Aib C_β atoms between α-helical alamethicin ($\Delta T_1 = 250$–290 ms, 298 K)[8c] and **12** ($\Delta T_1 = 51$ ms, 240 K) at comparable $\Delta\delta$ values (4.5 and 4.6 ppm, respectively) are strongly in favor of the 3_{10}-helix for **12**. The exact evaluation would require additional α-helical T_1 data at 240 K. The energy barrier of the 3_{10}-helix interconversion of **12** at $T_c = 265$ K (Fig. 3) could be estimated rather accurately by the coalescence method.[9] The free energy of activation is $\Delta G^{\neq} = 46$ kJ mol^{-1}, i.e., 4.6 kJ mol^{-1} per Aib residue. This value is much lower than the mean values determined for α-helices.

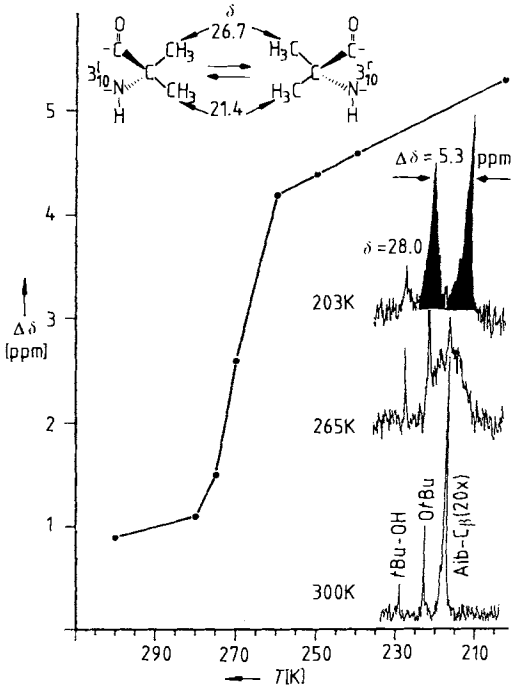

Fig. 3. Temperature dependence of the ^{13}C-NMR of **12** [70 mg/0.5 mL CD_2Cl_2; internal standards CD_2Cl_2 ($\delta = 53.8$) and *tert*-butyl alcohol (*t*Bu-OH) ($\delta = 30.0$) at room temperature; 50 MHz, Bruker MSL 200]. In the insert, spectrum in the region of the Aib-C_β signals at three temperatures: $T = 203$ K, $\delta = 21.4$, 26.7, $\Delta\delta = 5.3$ ppm, frozen 3_{10}-helix interconversion; $T_c(T_m) = 265$ K, broad coalescence signal (from which $\Delta G^{\neq} = 46$ kJ mol^{-1} is derived); $T = 300$ K, single Aib-C_β signal at $\delta = 25.1$ due to fast $3^l_{10} \rightleftarrows 3^r_{10}$ helix interconversion. The sharp signal at $\delta = 28.0$ corresponds to the methyl groups of the *tert*-butyl ester protecting group (O*t*Bu).

A corollary comparison between results from high-resolution and solid-state ^{13}C-NMR spectroscopy (CPMAS) gave further support to our interpretation. The effect of freezing the $3^l_{10} \rightleftarrows 3^r_{10}$ interconversion at very low temperature was found to be comparable to that of shorter Aib homopeptides in the solid state such as Z-(Aib)$_3$-OH ($\Delta\delta = 2.5$ ppm) and Z-(Aib)$_6$-OtBu (4.0 ppm). On the other hand, the Aib residues between the protein amino acid residues in the conformationally more stable α-helices show $\Delta\delta$ values of 3–5 ppm already *in solution at room temperature* (Fig. 2).

The 3_{10}-helix interconversion can be described as a fast monomolecular all-or-nothing process between enantiomeric P- and M-helical forms. A decision cannot be made so far whether measurable amounts of other conformations exist at and above the melting temperature T_m ($= T_c$). Our findings may be of relevance for short 3_{10}-helical segments of peptaibols particularly rich in Aib, e.g., trichotoxin,[11] which could be conformationally labile at room temperature. Inter alia, this could be one reason for the burstlike pore formation of trichotoxin in current/voltage experiments in lipid bilayer membranes,[11] in contrast to the stabile pore system of the α-helical and rigid alamethicin.[7] In addition, the surprising experimental results for this 3_{10}-helix enantiotopomerization, which indicate, e.g., 1200 interconversions per second at room temperature for **12**, appear to be of particular interest for conformational energy calculations.

A Novel Route to Cyclopentane Derivatives: A Radical Chain Reaction**

By *Klaus Weinges** and *Wolfgang Sipos*

Dedicated to Professor Hermann Schildknecht on the occasion of his 65th birthday

Dienes whose double bonds exhibit variable reactivity because of substituent effects can undergo an intramolecular cyclization when subjected to solvomercuration and subsequent reduction with complex boron or tin hydrides.[1-3] We have now found that a mixture of the cyclopentane derivatives *cis*-**4a** and *trans*-**4a** in the ratio 8 : 2 is

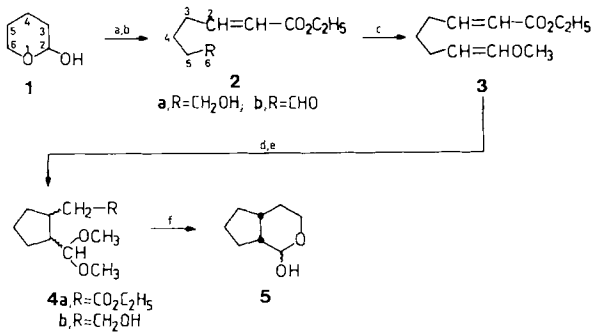
[**] This work was supported by the Land Baden-Württemberg (FRG) (Forschungsschwerpunkt No. 35).

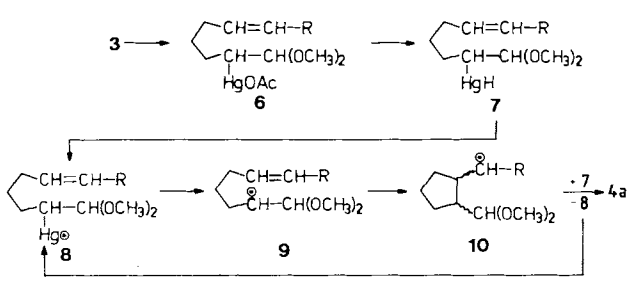
formed in 90% yield upon reaction of ethyl 8-methoxy-2,7-octadienoate **3** with mercury acetate in the presence of calcium oxide and methanol and subsequent reduction with $NaBH_4$ (Scheme 1).



Scheme 1. a) $(C_6H_5)_3P{=}CH{-}CO_2C_2H_5$ in DMF, 90 °C, 12 h; 65% **2a**. b) $pyH^{\oplus}ClCrO_3^{\ominus}$ in CH_2Cl_2, room temperature, 2 h; 95% **2b**. c) $[(C_6H_5)_3P{-}CH_2OCH_3]Cl$ with *t*BuOK in THF added dropwise to the solution of **2b** in THF, reflux, 1 h; 68% **3**. d) $Hg(OAc)_2$ and CaO in MeOH, room temperature, 2 h; $NaBH_4$, 0 °C, 5 min; 90% **4a**. e) $LiAlH_4$ in THF, reflux, 1 h; 72% **4b**. f) 2 N HCl, extraction with ether; 70% **5**.

As starting material for the preparation of **3** we used the commercially available 2-hydroxytetrahydropyran **1**, whose hemiacetal reacts with ethoxycarbonylmethylenetriphenylphosphorane in a Wittig reaction to give **2a**. Oxidation of the initially formed CH_2OH group of **2a** with pyridinium chlorochromate affords aldehyde **2b**. Reaction of **2b** with methoxymethylenetriphenylphosphorane in a second Wittig reaction affords **3** in good yield. Under identical conditions optically active, C-3, C-4- or C-5-substituted 2-hydroxytetrahydropyrans furnish optically active, substituted ethyl 8-methoxy-2,7-octadienoates. These are of special interest, since the chiral centers should influence the stereoselectivity of the subsequent cyclization.

Under the reaction conditions given for the cyclization in Scheme 1 the methanol attacks as intermolecular nucleophile during the mercuration step in such a way that the acetal **6** is formed (Scheme 2). Reaction of **6** with $NaBH_4$, in accord with previous studies on intermolecular C–C coupling,[4–7] affords the alkylmercury hydride **7**, which is converted by loss of a hydrogen atom into the reactive alkylmercury radical **8**. The radical **8** decomposes spontaneously into the carbon radical **9** and mercury. Intramolecular C–C coupling in **9** leads to formation of **10**. The function of the hydrogen donor, which traps the radical **10** as **4a** before a polymerization can take place, is assumed by the alkylmercury hydride **7**. The reactive alkylmercury radical **8** is thereby set free and a radical chain reaction takes place. It can be concluded from the ^1H-NMR spectrum of **4a** that the reaction proceeds with 80% *cis*-stereoselectivity.



Scheme 2. Mechanism of the radical chain reaction leading to the formation of **4a**. $R{=}CO_2C_2H_5$.

The cyclization reaction is of interest for many reasons. The *cis*-1-hydroxyoctahydrocyclopenta[c]pyran **5**, which represents the basic carbon skeleton of the natural iridoids, can be obtained directly from **4a** by $LiAlH_4$-reduction of the ester group to give **4b**, followed by acid hydrolysis in order to free the aldehyde group.[8] Accordingly, it should be possible to prepare enantiomerically pure iridoids from appropriate optically active starting compounds. Furthermore, **4a** contains already useful potentialities for the construction of a new diene by simple reactions. Further cyclizations would then lead to polycyclopentanes, a class of compounds to which naturally occurring di- and triquinanes belong.[9]

$$[(\eta^5\text{-}C_5Me_5)_2Ti(CO)_2] \xrightarrow[3\text{ h, ca. }150\,^\circ C]{P_4,\ \text{xylene}} [(\eta^5\text{-}C_5Me_5)_2Ti_2P_6] \qquad \text{(a)}$$

1 **2**

which were moderately soluble in pentane and readily soluble in benzene, toluene, and dichloromethane.

The ^{1}H-NMR spectrum (200 MHz, 293 K, C_6D_6, int. TMS) of **2** exhibits a singlet at $\delta = 2.60$, a region that differs significantly from that found for the triple-decker sandwich complexes **3** [δ **(3a)** = 0.47 (sept.),[2,3] δ **(3b)** = 0.54 (sept.),[3] δ **(3c)** = 1.32(s)[3]]. Even more striking are the differences in the ^{31}P{^{1}H}-NMR chemical shifts (80.82 MHz, CH_2Cl_2, 85% H_3PO_4 ext.): **2**: 386.7(s), **3a**: -315.6(s)[2,3], **3b**: -338.2(s)[3], **3c**: 164.9(s, $W_{1/2} = 540$ Hz[3]). P_2 elimination is observed in the mass spectrum [(EI-MS, 70 eV, 40 °C) *m/z* 552 $M^\oplus$, 89%), 490 ($M^\oplus - P_2$, 100%), 124 ($P_4^\oplus$, 10%), 62 ($P_2^\oplus$, 22%)] along with other lines.

$[(Cp^*M)_2(\mu,\eta^6\text{-}P_6)]$ **3** ($Cp^* = \eta^5\text{-}C_5Me_5$)

3a, M = Mo (28 valence electrons (VE))
3b, M = W (28 VE)
3c, M = V (26 VE)

The neutral 24-VE system **2** undergoes ready cyclovoltammetric oxidation[4] (irreversible, $E_{pa} = 0.70$ V) and reduction (ideally reversible one-electron reduction, $\Delta E = 60$ mV, $E_{red} = -1.31$ V). The redox potential difference (ca. 2.0 V) and the energy of the optical excitation (longest-wavelength band maximum observed as a shoulder at 430 nm ≙ 2.88 eV) exhibit significantly larger differences in this case than for the triple-decker complexes **3** having a planar middle deck (differences of 0.2–0.4 (e)V[3]). This observation is presumably due to a relatively large structural change on going from the crystallographically determined ground state to the first electronic excited state.

The 25-VE anion of **2** is well-characterizable by ESR spectroscopy. The *g* factor of the spectrum, which shows no splitting at room temperature, is 1.9967 and is thus in the range found for Ti^{III}.[5] By computer simulation it is possible to estimate an upper limit of 6 Gauss for the ^{47,49}Ti coupling, which is in agreement with the presence of a delocalized mixed-valent system (cf. **4**[6] and $[Cp_2Ti(\mu\text{-}H)_2TiCp_2]^\ominus$[5,7]). At low temperature, the solution ESR spectrum of the 25-VE anion of **2** exhibits coupling of the unpaired electron with six equivalent ^{31}P nuclei. The coupling of 3.8 Gauss, which is very small for a coupling to ^{31}P, is once again in agreement with the mainly metal character of the singly occupied molecular orbital; the parallels to the 27-VE complex **4** make it likely that the P_6 ring is at least flattened. The ESR results support a model containing high-valent titanium and a reduced P_6 ring. Reasonable alternatives to the 25-VE anion are: a planar $P_6^{4\ominus}$ ring (cf. M_4P_6[8]) and titanium in the oxidation states II and III or a puckered $P_6^{6\ominus}$ ring and Ti^{III}/Ti^{IV}.

$[(Cp^*Cr)_2(\mu,\eta^5\text{-}P_5)]$ **4**

The X-ray structure analysis[9] reveals the skeleton of **2** to consist of a distorted Ti_2P_6 cubane, which can be conceptually derived from a P_6 ring (chair conformation) and two Cp*Ti "caps" (Fig. 1). If **2** is regarded as a titanium–polyphosphide derivative with μ,η^3,η^3 coordination of the P_6 ring, then the following formal charges are obtained: *cyclo*-$P_6^{6\ominus}$ (isoelectronic with cyclo-S_6), $C_5Me_5^\ominus$, and $Ti^{4\oplus}$. This way of looking at the complex reveals an interesting analogy to the μ,η^3,η^3-*cyclo*-$P_6^{6\ominus}$ partial structure of the Th_2P_{11}.[10] The mean values of the P–P distances (2.23 Å) as well as the PPP angles (105.9°) in the P_6 ring of **2** differ by only small amounts from those in the *cyclo*-$P_6^{6\ominus}$ moiety of Th_2P_{11}.[10] They are also comparable with those in orthorhombic black phosphorus,[11] *cyclo*-$(PPh)_6$ (chair conformation),[12] the chair-like P_6 rings of Re_6P_{13} (partial structure),[13] and some MP_3 polyphosphides[14] (e.g., SnP_3[15]). A P–P distance of 2.26–2.31 Å was calculated for cubic P_8.[1] The Ti–P bonds (mean value 2.36 Å) are shorter in **2** than in titanium polyphosphides.[14]

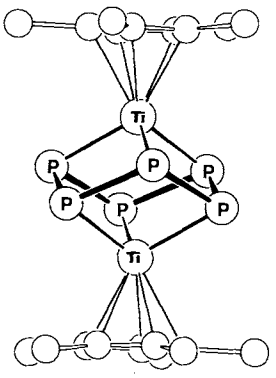

Fig. 1. Molecular structure of **2** (for simplicity, only one orientation is shown). Selected distances [Å] and angles [°]: P-P 2.217(17)-2.251(16), P-Ti 2.358(11)-2.375(13), Ti-Cp*$_{(centr.)}$ 2.00, P...Ti 2.867(12)-2.906(12), Ti...Ti 3.187(4); P-P-P 105.1(6)-106.9(7), Pi-Ti-P 97.3(4)-98.5(4), Ti-P-P 77.0(5)-78.5(5), Ti-Ti-Cp*$_{(centr.)}$ 179.1.

Although attempted generation of P_8 from **2** and two molar equivalents of PX_3 (X = Cl, Br) yielded Cp^*TiX_3 already at room temperature, ^{31}P-NMR spectroscopic analysis has so far only revealed small amounts of unreacted PX_3 in the soluble products.

Experimental Procedure

1 (700 mg, 1.9 mmol) [16] and P_4 (240 mg, 1.9 mmol) in xylene (40 mL) were heated at reflux for 3 h with stirring (monitored by IR; the ^{31}P-NMR spectrum showed only the signal of **2**). Subsequently, ca. 30 mL of xylene was distilled off and the remaining solution was allowed to stir with ca. 5 g of silica gel (Merck, 60, 0.063–0.200 mm; activity II) and then evaporated to dryness under an oil-pump vacuum until the resulting solid flowed freely. This mixture of substances was placed on a column filled with silica gel/pentane ($d = 2$ cm, $l = 40$ cm). Excess P_4 was eluted with pentane and a red-brown fraction was eluted with a 5 : 1 mixture of pentane/toluene. The latter fraction was evaporated to dryness (oil-pump vacuum) and the product was recrystallized from boiling toluene, which, upon cooling to -20 °C, afforded 98 mg of **2** (19%). A correct elemental analysis was obtained.

Reaction of Sn_9^{4-} with Single Crystal Au: Textured Fiber Epitaxial Growth of AuSn at Room Temperature

By *Robert C. Haushalter,* Michael M. J. Treacy,* and *Stephen B. Rice*

Since the report on the isolation of Sn_9^{4-},[1] and its decomposition reaction with large organic cations,[2] there have been few studies dealing with the chemical reactivity of these p-block polyanions. Recently, we have shown that many novel solid state materials can be obtained from these clusters such as surface metallized organic polymers[3] and inorganic solids,[4] and a new type of amorphous metallic spin glass.[5] When examining the reactivity of the more electronegative transition metals with the p-block polyanions, it was noted that Sn_9^{4-} or Pb_9^{4-} reacted instantly with clean metals like Au or Pt.[4] However, these reaction products were not completely characterized, so a study of the reaction of Sn_9^{4-} with single crystal Au foils was undertaken using transmission electron microscopy (TEM).

When single crystal gold foils, which were 20 nm thick and oriented with the Au[001] direction normal to the plane of the foil, were immersed in a solution of K_4Sn_9 in ethylenediamine (en), the characteristic gold color of the foil immediately turned to silver-gray. Examination of the reacted foils[6] in the TEM[7] gave the diffraction patterns shown in Figure 1. Even with very short residence times in dilute solutions, the diffraction patterns (Fig. 1b) show the presence of a new crystalline phase in which, except for unreacted Au and the very small spots sprinkled over the pattern which are due to β-tin, all of the spots and rings can be indexed as hexagonal AuSn.

At first glance the AuSn diffraction pattern appears puzzling as it shows rings, normally considered as arising from polycrystalline material, as well as sharp spots with a definite geometrical relationship to the underlying Au substrate indicative of epitaxial growth. The observation of both spots and rings could be explained simply as a mixture of epitaxial growth and polycrystalline deposition except that one of the AuSn reflections, the $[10\bar{1}0]$, has essentially no intense sharp spots, but spots do appear on this ring when the foil is tilted relative to the electron beam (Fig. 1d). To determine the cause of this mixture of spots and rings, the foils were examined by several additional electron microscopy techniques.

Normal bright field imaging immediately after reaction shows the Au to be covered by a thin layer of AuSn. Longer reaction time gives thicker films but eventually a passivating layer is formed as evidenced by the presence of Au reflections (Fig. 1c) even after prolonged exposure to saturated solutions of the Sn_9^{4-} anion. The microdiffraction patterns recorded from many individual AuSn crystallites revealed that none of them had exactly the same crystallographic orientation. The data suggested a form of textured fiber epitaxy[8] where the hexagonal c axis of the AuSn, $[0001]_{AuSn}$, is confined to lie in the plane defined by the $[001]_{Au}$ and $[110]_{Au}$ directions. This means that the $[1\bar{2}10]_{AuSn}$ axis tends to be colinear with the $[1\bar{1}0]_{Au}$ axis (or the other symmetry equivalent Au axes, [110], $[\bar{1}10]$ or $[1\bar{1}0]$) except when $[0001]_{AuSn}$ is parallel to $[001]_{Au}$. If this assumption is valid, then it should be possible to recreate the diffraction pattern using these criteria.

As shown in Figure 2 (top) diffraction vectors originating from each of the $[10\bar{1}1]$, $[10\bar{1}2]$, and $[20\bar{2}1]$ orientations are labelled as dots, squares, and hexagons respectively, and related diffraction spots arising from the fourfold symmetry imposed by the Au support are indicated by the hollow symbols. As the angle, θ, between the $[001]_{Au}$ axis and the $[0001]_{AuSn}$ axis of the various crystallites increases, these major AuSn crystallographic axes will become colinear with the incident beam and thus be brought into the proper condition for diffraction. In this way we can account for most of the sharp AuSn diffraction spots observed in Figures 1b and 1c, except for some of the faint satellites seen on the $(20\bar{2}1)$ ring, and for the rings themselves. The rings can be explained if one assumes that

[*] Dr. R. C. Haushalter, Dr. M. M. J. Treacy, Dr. S. B. Rice
Exxon Research and Engineering Company
Annandale, NJ 08801 (USA)

when the [0001] axis of AuSn is parallel to the [001] axis of Au, it can adopt any azimuthal angle without deviating from the Au [001]/[110] plane. In this unique orientation the constraint for $[1\bar{2}10]_{AuSn}$ to be parallel to $[1\bar{1}0]_{Au}$ disappears, thus producing rings for this reflection as shown in Figures 1b and 1c.

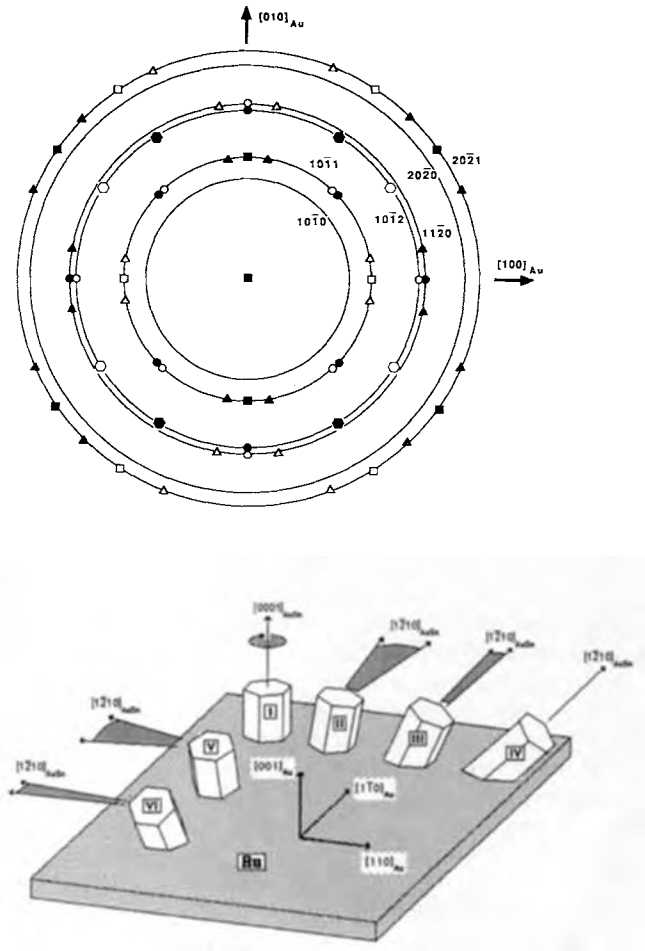

Fig. 2. Top: Reconstructed diffraction pattern based on the textured fiber epitaxy model. Diffraction vectors: ● $[10\bar{1}1]$, ■ $[10\bar{1}2]$, ● $[20\bar{2}1]$, ▲ $[10\bar{1}2]$, 10° misaligned. Note the excellent agreement with the experimental diffraction patterns in Figures 1b and 1c (see text). Bottom: The model for the textured fiber epitaxial growth of AuSn on Au (see text). Particles I–IV show one orientation of the $[1\bar{2}10]_{AuSn}$ to the Au substrate while particles V and VI show an orientation 90° away. The other two possible orientations are not shown.

The epitaxial model is sketched in Figure 2 (bottom). As the $[0001]_{AuSn}$ axis approaches being parallel to the $[001]_{Au}$ axis (i.e. $\theta = 0°$), such as the particle labelled I, the AuSn crystallites are free to adopt any azimuthal angular orientation. As the $[0001]_{AuSn}$ axis tilts within the plane defined by the $[001]/[110]_{Au}$ directions (particle II), or the $[001]/[1\bar{1}0]_{Au}$ directions (particle V), the $[1\bar{2}10]_{AuSn}$ is constrained to align with the $[1\bar{1}0]_{Au}$ or $[110]_{Au}$ directions, respectively. As the angle of declination increases the constraint strengthens (see particles III and IV). It is the weakening of the azimuthal constraint (i.e. that $[1\bar{2}10]_{AuSn}$ be parallel to $[1\bar{1}0]_{Au}$) as the angle of declination decreases that gives rise to the peculiar mixture of spots and rings in the diffraction patterns.

At this point, the precise mechanism for the formation of the epitaxial growth of the AuSn from the reaction of Sn_9^{4-} with Au is not clear, mainly due to our inability to determine the fate of the potassium. In our earlier studies of the reaction of the p-block polyanions with the surface of organic polymers,[3] the element from which the polyanion was composed was oxidized to the metallic state on the surface of the polymer while the polymer underwent concomitant reduction and was intercalated by the polyanion's countercation. If there is a potassium-containing phase present in the Au/AuSn system under consideration here, then it is either amorphous and thus not detectable in the diffraction experiments or it was destroyed by exposure to the air during the time it took to load the sample into the microscope (ca. 1 min). Another possibility is that the Au reacts with the Sn_9^{4-} and produces more reduced Sn clusters. Situations involving the production of transitory Au/Sn anions which rapidly decompose onto the substrate surface or the participation of the solvent in the reaction can be envisioned but all of these mechanisms remain speculative at this point. Furthermore, it is not known if the free metallic Sn found on the surface of the reacted foils is one of the reaction products or derives from the reaction of the highly reducing Sn_9^{4-} with the solvent or solvent impurities. The nature of the mechanism is further complicated by the fact that Sn and Au, and their intermetallic alloy phases, can undergo interdiffusion at relatively low temperatures[9] which could obscure the composition of the initially formed phases.

In summary, the polyanion Sn_9^{4-} reacts instantly with oriented single crystals foils of Au to give AuSn. The growth is such that $[0001]_{AuSn}$ always lies in the plane defined by $[110]_{Au}$ and $[001]_{Au}$ such that the $[1\bar{2}10]_{AuSn}$ is parallel to the $[1\bar{1}0]_{Au}$ (and its symmetry equivalent axes) within the plane of the foil. As the $[0001]_{AuSn}$ axis becomes closer to parallel to the $[001]_{Au}$ axis this restraint is weakened until it vanishes when the two axes are exactly parallel. At this point the AuSn axis is free to adopt any azimuthal angle with respect to the Au surface. This form of strong textured fiber epitaxial growth gives rise to a mixture of sharp spots and rings in selected area electron diffraction patterns.

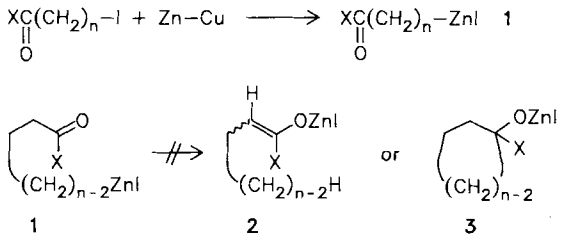
Generation of β-, γ-, δ-, ε-, and ζ-Zinc Ketones and Their Transition-Metal-Catalyzed Reactions with Carbon Electrophiles**

By *Yoshinao Tamaru,* Hirofumi Ochiai, Tatsuya Nakamura,* and *Zen-ichi Yoshida**

For organic chemistry, the behavior of compounds possessing both a nucleophilic and an electrophilic center has been a great concern, not only conceptually but also practically. Metallocarbonyl compounds are typical examples.[1] Recently, *Kuwajima*[2] and we[3] have shown that β- and γ-metalloesters (M = Ti, Zn) serve as carbon nucleophiles to form C–C bonds at the β and γ positions of the esters, respectively.[4] However, all β-metalloketones so far reported are either too unstable (forming cyclopropanolates **3** (n = 2))[5] or too unreactive[6] (M = Sn,[2d,7] Hg,[8] Mn),[9] to form C–C bonds with carbon electrophiles.[10] Some β-metalloketones (M = Pd,[11] Ni,[12] Cu,[13] Ag),[13] have been proposed as intermediates for carbonylation and oxidative dimerization.

Here we wish to report that β-zinc ketones and their higher homologues (**1**; X = alkyl, aryl; n = 2–6) are rather stable and undergo neither an intramolecular proton abstraction to form zinc enolates **2** nor nucleophilic attack at the keto carbonyl to form zinc cycloalkanolates **3**.[14] However, these zinc ketones **1** react with various carbon electrophiles by virtue of transition-metal catalysis, which serves either to activate the electrophiles [Eqs. (a)–(d)] or to activate **1** or to activate both species [Eq. (e)]. These zinc ketones **1** directly react with tri-*n*-butylchlorostannanes [Eq. (f)].[14]

In Table 1 are summarized the results of the reactions of **1** with saturated and unsaturated (aromatic and nonaromatic) acid chlorides, catalyzed by Pd^0 [Eq. (a)].[3a] For the generation of **1**, the use of HMPA as a co-solvent (HMPA : iodide = 1.67 : 1) is essential. In the absence of HMPA, no metalation took place. Dimethylformamide and dimethylacetamide (DMA) may serve as a co-solvent, but HMPA is by far the most satisfactory, since it not only greatly facilitates the metalation, which is therefore complete at lower temperatures, but also seems to stabilize **1** (compare reactions 9 and 10 in Table 1).[15] Generally, the larger the number n of CH_2 groups in the iodide, the higher the temperature required for the metalation. The low yields for the reactions 1 and 2 may partly be ascribed to an instability of the starting iodide.[16] Since use of an excess amount of acid chloride results in a complex reaction, a less than stoichiometric amount of acid chloride was routinely used.



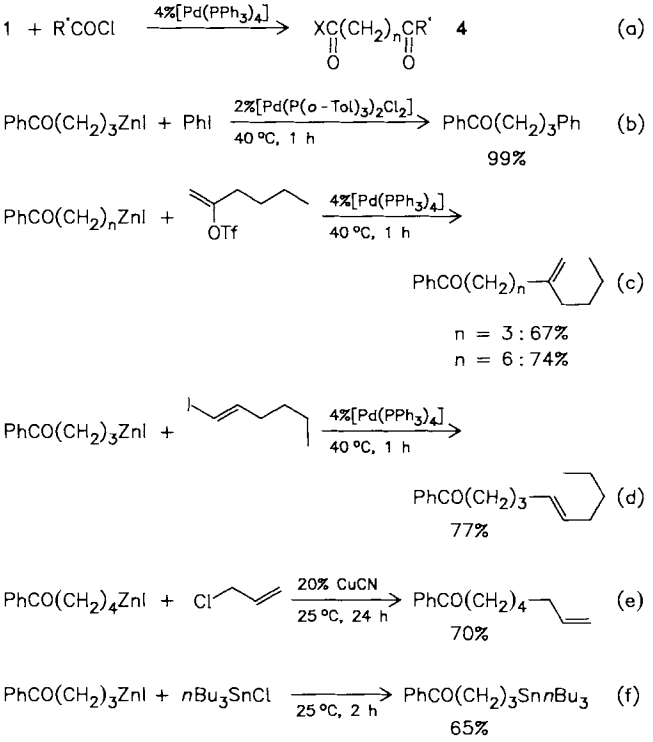


Table 1. Acylation of **1** catalyzed by Pd^0.

Reaction	1 n	1 X	Reaction conditions [a]	R' in R'COCl	γ [b]	Yield of 4 [%] [c]
1	2	Et	25 °C, 1 h, HMPA	Ph	1.3	53 (40)
2	2	Et	25 °C, 1 h, HMPA	C_7H_{15}	1.8	62 (34)
3	3	Ph	40 °C, 1 h, HMPA	C_7H_{15}	1.3	80 (61)
4	3	Ph	40 °C, 1 h, HMPA	*p*-MeO-C_6H_4	1.3	90 (69)
5	3	Me	25 °C, 2 h, HMPA	H_2C=CH	1.7	85 (50)
6	4	Ph	40 °C, 2 h, HMPA	Ph	1.3	76 (58)
7	4	Ph	40 °C, 2 h, HMPA	C_2H_5	1.3	77 (59)
8	4	Et	40 °C, 1 h, HMPA	CH_3	1.1	74 (67)
9	5	Ph	40 °C, 2 h, HMPA	C_2H_5	1.2	85 (71)
10	5	Ph	50 °C, 2 h, DMA	C_2H_5	1.2	63 (53)
11	6	Ph	50 °C, 2 h, HMPA	C_2H_5	1.1	91 (82)

[a] For the generation of **1**, all reaction mixtures were pretreated at 25 °C for 1 h. [b] The ratio of the starting iodide to carbon electrophile. [c] Yields based on acid chlorides. The figures in parentheses refer to the isolated yields based on the starting iodides.

Reactions (b), (c),[18] (d), and (e)[19] were performed according to a similar procedure.[20] Reaction (d) is stereospecific: *cis*- and *trans*-4-nonenyl phenyl ketone in 68% and 77% yield (≧95% purity each), respectively, were obtained from *cis*- (99% purity)[21] and *trans*-1-iodo-1-hexene (98% purity).[22]

The present zinc ketone methodology undoubtedly provides a short-cut for the synthesis of target compounds. The regio- and stereoselectivity for the Cu^I-catalyzed allylation [Eq. (e)] and reactions with other electrophiles are under extensive study.

Finally, the structure of **1** is worth mentioning.[15] The IR spectrum of **1** (n = 3, X = Ph) in benzene/HMPA showed one very strong CO absorption at $\tilde{\nu} = 1675\ cm^{-1}$, the same wavenumber as the starting iodoketone, while **1** (n = 2, X = Et) exhibited its CO absorption at a slightly lower wavenumber ($1690\ cm^{-1}$) compared with the starting iodoketone ($\tilde{\nu} = 1710\ cm^{-1}$). These data suggest that these zinc ketones do not form, or form very weakly, a chelating structure.[23]

Experimental Procedure

The generation of **1** and their reactions with acid chlorides were performed in one flask as typified in the following example (reaction 3 in Table 1).

A mixture of Zn-Cu couple [17] (110 mg, 1.7 mmol) and 3-iodopropyl phenyl ketone (356 mg, 1.3 mmol) in dry benzene (4 mL) and HMPA (0.5 mL) was stirred at room temperature for 1 h and then at 40 °C for 1 h under nitrogen. Then, solutions of $[Pd(PPh_3)_4]$ (46 mg, 0.04 mmol) in benzene (1 mL) and octanoyl chloride (163 mg, 1.0 mmol) in benzene (1 mL) were successively added at 40 °C and the mixture was stirred at the same temperature for 2 h. After dilution with ether, successive washing with 1N HCl and aqueous $NaHCO_3$, and drying over $MgSO_4$, followed by evaporation of the solvents, the residue was purified by column chromatography over silica gel (hexane-ethyl acetate gradient) to provide 1-phenyl-1,5-dodecanedione in 80% yield.

Anthracyclinone Ring C Synthesis via Chelate Carbene Complexes**

By *Karl Heinz Dötz** and *Michael Popall*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Anthracyclinones, the aglycone components of the antitumor-active anthracyclines,[2] usually feature neighboring central quinone and hydroquinone structures in their linear tetracyclic skeleton and are therefore potential targets of syntheses involving annelation of chromium carbonyl carbene complexes.[3] The most important anthracyclinone is daunomycinone **1**, whose B and C rings should be accessible in principle by a variety of routes—each starting from an unsaturated carbene ligand, a carbonyl ligand, and an alkyne (Scheme 1).

After the B ring had been constructed via routes (a) and (b),[4-6] we directed our attentions to the synthesis of the C ring.

The starting point was the carbene complex **2** [route (c)], which underwent decarbonylation in refluxing *tert*-butyl methyl ether to give quantitatively the chelate carbene complex **3**.[7] Crucial for the annelation of the carbene to the alkyne to afford the hydroquinone skeleton is the long chromium-oxygen bond,[8] which can be opened under mild conditions (ca. 40 °C). In the presence of the alkynes **4a** or **4b**, regiospecific annelation of the carbene ligand occurs to give the coordinated naphthols **5a** or **5b**, respectively. The metal carbonyl fragment is conveniently cleaved off under CO atmosphere, affording hexacarbonylchromium in practically quantitative yield. The latter, in turn, can be used again to generate the carbene complex **3**.

Functionalization of the ketone **6** to give the carboxylic acid **7** is necessary for the formation of ring B. It is achieved, following *O*-methylation, with isocyanomethyl(*p*-tolyl)sulfone.[10] Finally, the carboxylic acid is cyclized to the diketone **8** in acid (trifluoroacetic acid(TFA)/trifluoroacetic anhydride (TFAA)). This reaction was used earlier by *Sih* et al.[11] and by *Rao* et al.[12] as part of a longer route leading to intermediates in the synthesis of

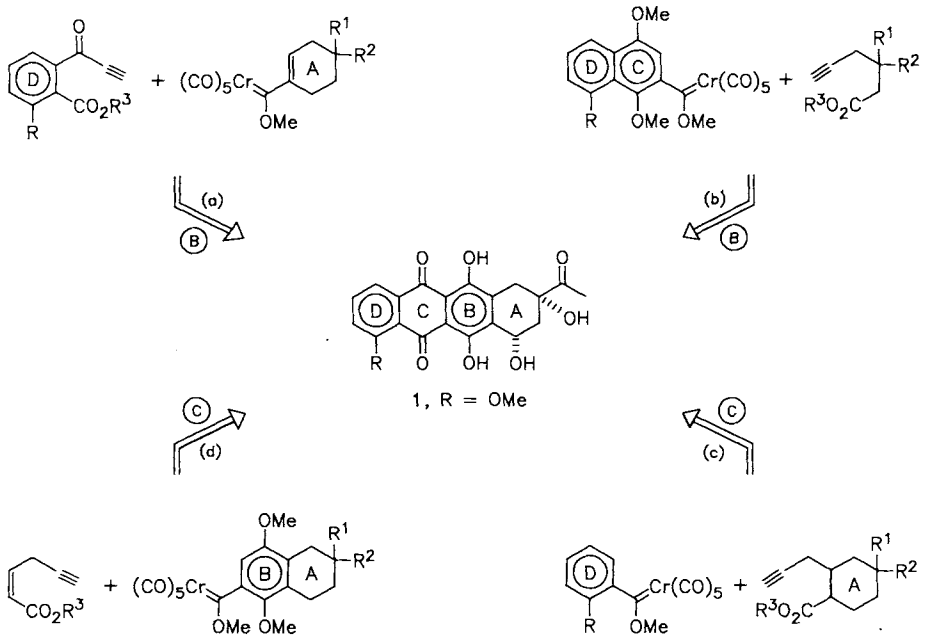
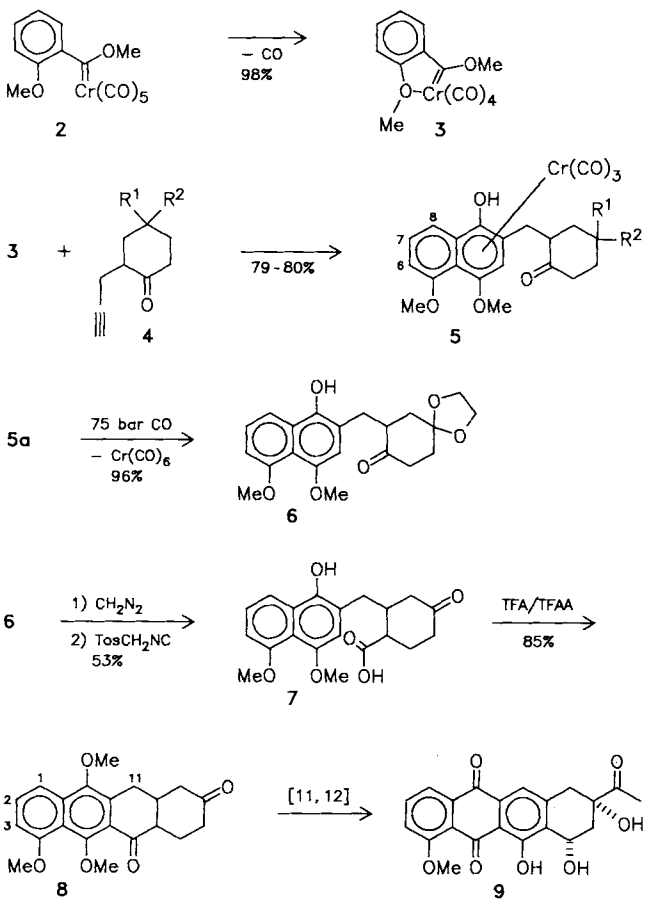
[**] Carbene Ligands as Anthracyclinone Synthons, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 4: [1].



Scheme 1. Synthesis of daunomycinone **1**, R = OMe, via carbene complexes.

11-deoxyanthracyclinones. Thus, the chromium-induced carbene annelation via the chelate carbene complex has been integrated into a formal total synthesis of 11-deoxydaunomycinone **9**; the synthetic route outlined here is overall appreciably shorter than the routes employed so far.



a: R^1, R^2 = OCH_2CH_2O; **b**: R^1, R^2 = O

Experimental Procedure

5a, b: The alkyne **4a** or **4b** [13] (7.5 mmol, 1.46 g or 1.13 g, respectively) was added to a solution of **3** (1.57 g, 5 mmol) [7] in *tert*-butyl methyl ether (50 mL). After stirring for 1 h at 40 °C, an orange-red suspension was obtained. Removal of the solvent and precipitation by addition of CH_2Cl_2/pentane yielded an orange-yellow crystalline powder. Yields: 2.02 g **5a** (79%) and 1.86 g **5b** (80%).—**5a**: IR (KBr): $\tilde{\nu}$(C=O) = 1952, 1864.—^{1}H-NMR (CD_3COCD_3): δ = 7.3–7.9 m, 6.6–7.2 m (3 H, H6-H8); 4.07 (s, 1 H, H3); 3.97 (s, 3 H, 4-OCH_3); 3.82 (s, 3 H, 5-OCH_3); 3.88 (s, 4 H, OCH_2); 3.37 (m, 2 H, CH_2); 1.4–2.9 (m, 7 H, H (cyclohexyl).—**5b**: IR (KBr): $\tilde{\nu}$(C=O) = 1947, 1866.—^{1}H-NMR (CD_3COCD_3): δ = 7.79 (d, 1 H, H8); 7.35 (m, 1 H, H7); 6.91 (m, 1 H, H6); 3.89 (s, 3 H, 4-OCH_3); 3.83 (s, 3 H, 5-OCH_3); 3.37 (m, 2 H, CH_2); 2.1–2.9 (m, 7 H, H (cyclohexyl)).

6: A solution containing **5a** (1.01 g, 2 mmol) in CH_2Cl_2 (100 mL) was heated to 70 °C in a steel autoclave equipped with a glass insert. CO (75 bar) was admitted and the solution was allowed to stir for 72 h. After cooling and careful release of pressure, the solvent was removed and the residue was dissolved in a small amount of ether. The $Cr(CO)_6$ formed was filtered off at −50 °C. Addition of CH_2Cl_2/pentane to the solution afforded a yellow crystalline powder. Yield: 0.82 g (96%).—^{1}H-NMR (CD_3COCD_3): δ = 7.74 (d, 1 H, H8); 7.33 (m, 1 H, H7); 6.91 (m, 1 H, H6); 6.63 (s, 1 H, H3); 3.95 (s, 3 H, 4-OCH_3); 3.88 (s, 4 H, OCH_2); 3.81 (s, 3 H, 5-OCH_3); 3.37 (m, 2 H, CH_2); 2.1–2.9 (m, 7 H, H (cyclohexyl)).—MS: *m/z* 372 ($M^{\oplus}$).

8: **6** (0.24 g, 0.65 mmol) was methylated with an excess of a 0.05 M diazomethane solution. The reaction product in THF was then added at −10 °C to a THF solution containing 0.65 mmol of both potassium *tert*-butoxide and isocyanomethyl(*p*-tolyl)sulfone. The mixture was stirred for 10 min and then treated with 0.4 g of glacial acetic acid. After removal of the solvent, the residue was dissolved in water and extracted with CH_2Cl_2. The crude product was deesterified with 2 N HCl. Extraction with CH_2Cl_2 at pH 1 afforded a yellow powder, which was treated carefully at 0 °C with 7.5 mL of TFA/TFAA (1:2). The red solution was worked up with $NaHCO_3$ and water; extraction with chloroform and evaporation of the solvent gave an orange-red powder, which was purified by preparative thin layer chromatography on silica gel with CH_2Cl_2/THF (2:1) and whose analytical and spectroscopic data are in agreement with those reported for the products described in Refs. [11] and [12]. Yield: 0.10 g (45%).—^{1}H-NMR ($CDCl_3$): δ = 7.72 (d, 1 H, H1); 7.43 (t, 1 H, H2); 6.83 (d, 1 H, H3); 3.98 (s, 3 H), 3.93 (s, 3 H), 3.89 (s, 3 H) (4-, 5-, 12-OCH_3); 3.6 (m, 2 H, CH_2); 2.0–2.9 (m, 8 H, CH_2, CH).—MS: *m/z* 354 ($M^{\oplus}$).

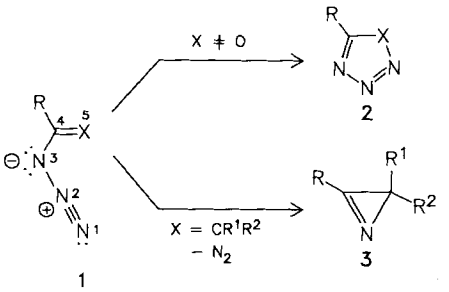
Methyl (*E*)-2-(1-Aryl-4,5-dihydro-1*H*-tetrazol-5-ylidene)-2-cyanoacetate from Methyl 3,3-Diazido-2-cyanoacrylate and Primary Aromatic Amines**

By *Rolf W. Saalfrank,* Michael Fischer, Uwe Wirth,* and *Helmuth Zimmermann**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Open-chain systems having the general structure **1**[***] can in principle undergo isomerization to give the corresponding cyclic systems **2**. Whether formula **1** or **2** represents the more stable structure depends on the substituents X and R.[2] For example, acyl azides **1**, X = O, exist exclusively in the open-chain form,[2,3] whereas thioacyl azides **1**, X = S, cyclize to give 1,2,3,4-thiatriazolones **2**, X = S.[2,4] In the case of imino azides **1**, $X=NR^1$, only electron-accepting substituents R^1 are capable of stabilizing the azide form, tetrazoles **2**, $X=NR^1$, being obtained otherwise.[2,5] Whereas this imino azide-tetrazole isomerization[6] is documented by numerous examples, there have been only a few reports on the vinyl azide-4*H*-triazole isomerization (**1**→**2** for $X=CR^1R^2$).[1,7]

Vinyl azides **1** [$R=NR^3R^4$, $X=CCN(CO_2CH_3)$] substituted with donor groups in the 4 position can undergo both 1,5 and 3,5 ring-closure reactions. Depending on the substituents R and the reaction conditions, either stable 1,2,3-triazoles are formed via the 4*H*-1,2,3-triazoles **2**, $R=NR^3R^4$, $X=CCN(CO_2CH_3)$, or 2*H*-azirines **3**, $R=NR^3R^4$, $R^1=CN$, $R^2=CO_2CH_3$, are formed with elimination of nitrogen.[1]

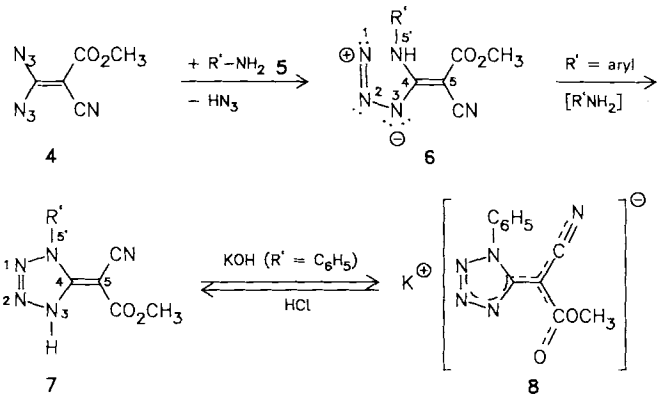


X = O, S, NR^1, CR^1R^2

The thermal transformation of vinyl azides **1** [$X=CR^1R^2$], with R, R^1, R^2 = H, alkyl, aryl, leads exclusively to 2*H*-azirines **3**. As the reaction mechanism, a 3,5 ring closure of **1** with concurrent elimination of nitrogen is favored over a pathway involving a free nitrene or one involving a 1,5 ring closure to give 4*H*-1,2,3-triazoles followed by elimination of nitrogen.[2a,8]

A detailed investigation of the vinyl azides **6**[***] [= **1** with $R=NHR'$, $X=CCN(CO_2CH_3)$] revealed that, for suitable substituents in the 4 position, these compounds could undergo novel, intermolecular reactions (1,5′ ring closure to give **7**,[***] nitrene addition to a C=C bond to give **9**).

Reaction of methyl 3,3-diazido-2-cyanoacrylate **4** with the primary arylamines **5a–c** at −25 °C leads initially to donor-substituted vinyl azides **6a–c** (for experimental data, see Table 1), which undergo base-catalyzed isomerization in dichloromethane to afford the methyl dihydrotetrazolylidenecyanoacetates **7a–c** (Table 1).[9,12]



5–7	a	b	c	d
R′	C_6H_5	4-H_3C–C_6H_4	4-H_3CO–C_6H_4	CH_2

Compound **7a** dissolves in aqueous potassium hydroxide as the salt **8** (yield 74%, m.p. = 263 °C (from water/acetone)), which can be converted back into **7a** by reaction with hydrochloric acid.

The constitution of the heterocycles **7** could not be established unequivocally from the spectroscopic data. These data would also be in agreement with the methyl *N*-aryl-*N*-(5-cyano-1*H*-1,2,3-triazol-4-yl) carbamidates iso-

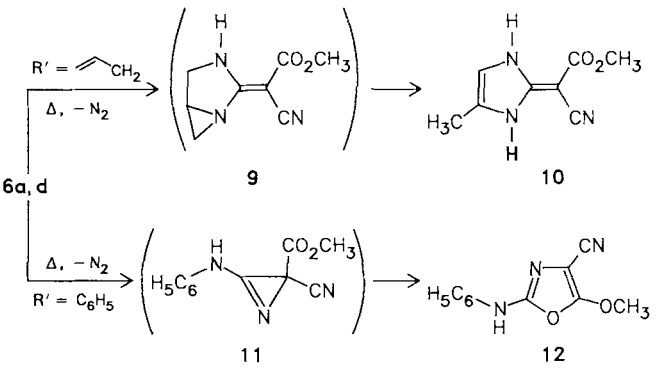
meric with **7**. For this reason, an X-ray structure analysis of **7a** was carried out (Table 2).[10]

Table 2. Structure data for the 1,4-dihydro-5-tetrazole skeleton of **7a**.

Bond lengths [pm]		Bond angles [°]	
N5′-N1	137.87 ± 14	N1-N5′-C4	110.1
N1-N2	126.59 ± 16	N2-N1-N5′	107.8
N2-N3	134.65 ± 14	N3-N2-N1	108.3
N3-C4	135.60 ± 15	C4-N3-N2	111.4
C4-N5′	135.47 ± 15	N5′-C4-N3	102.3

So far, it has not been possible to isomerize **6d** to **7d** using *base catalysis*. Upon *thermal* treatment (boiling toluene), **6d** undergoes nitrogen elimination. The nitrene thereby formed presumably reacts initially to give the bicyclic aziridine **9**, which, under the reaction conditions, undergoes spontaneous isomerization to give methyl (*E*)-2-(2,3-dihydro-4-methyl-1*H*-imidazolyidene)-2-cyanoacetate **10** (Table 1).[11, 12]



In contrast, thermolysis of **6a** affords the 2-anilino-5-methoxyoxazole-4-carbonitrile **12** (yield 78%, m.p. = 139 °C (from ethanol)), presumably via the azirine **11**.[8b, 13]

General Experimental Procedure

6a–d: The amine **5** (2.5 mmol) in dichloromethane (20 mL) was added under nitrogen to a solution of **4** (0.5 g, 2.6 mmol) [1,14] in dichloromethane (40 mL) at −25 °C. The resulting mixture was allowed to stir for 14 h at −25 °C and filtered. The solvent was then removed under vacuum.

7a–c: Vinyl azide **6** (2.0 mmol) and a catalytic amount of the arylamine **5** were allowed to stir together for 5–10 min at 40 °C in dichloromethane (50 mL). The solvent was then removed under water-aspirator vacuum.

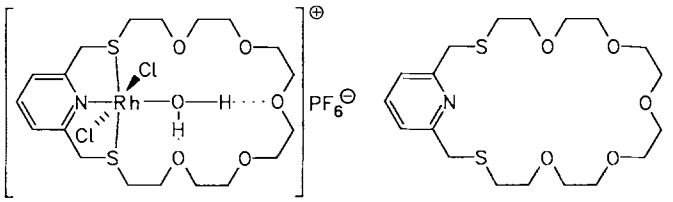
Simultaneous Primary and Secondary Coordination of a Neutral Guest within a Macrocyclic Complex of Rhodium(III)**

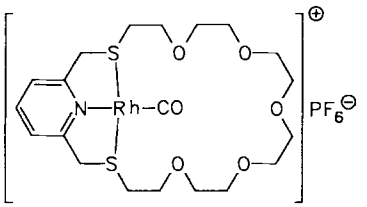
By *George Ferguson,* Karen E. Matthes,* and *David Parker**

The binding of a neutral ligand to a metal center within a macrocyclic complex is a common feature of the coordination chemistry of macrocyclic systems. However, there are very few examples[1] in which the complex is stabilized by secondary binding of the neutral ligand to the receptor molecule. During the course of studies directed towards an exploration of the receptor properties of heterotopic macrocyclic ligands,[2] we have characterized a remarkable Rh^{III} complex **1**, in which a water molecule is bound to the metal center and stabilized by intramolecular hydrogen bonding to the polyether chain.



1

2



3

Reaction of the ditopic macrocycle **2**[3] with rhodium trichloride in refluxing methanol followed by addition of NH_4PF_6 yielded an orange crystalline complex, **1**, whose fast atom bombardment mass spectrum (8 keV, Ar atoms, glycerol) revealed peaks at m/z 608 [$M^{\oplus}$], 573 [$M^{\oplus}-Cl$], 555 [$M^{\oplus}-Cl$, $-H_2O$], and 520 ($M^{\oplus}$ is the cation of **1** − H). The same complex could also be formed by aerial oxidation of the cationic rhodium(I) carbonyl complex **3** in chloride-saturated methanol. In the ^1H-NMR spectrum of **1** (298 K, CD_2Cl_2) the benzylic methylene protons were diastereotopic ($\delta = 4.92$, 4.70), consistent with stereogenic sulfur centers with a stable configuration. Such behavior was in contrast to the behavior of **3** in solution, which gave an exchange-broadened spectrum (CH_2S and CH_2O resonances) at 298 K (CD_2Cl_2) which sharpened on cooling ($\Delta G_c^{+} = 63.8$ kJ mol^{-1}). The inversion of sulfur may be attributed to a "ring-skip" of the polyether chain over the Rh–CO vector.

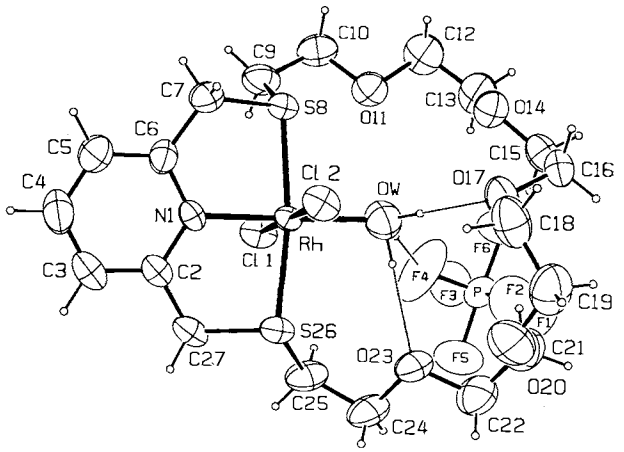

Fig. 1. Structure of **2** in the crystal. Monoclinic, $P2_1/n$, $a = 10.767(2)$, $b = 23.479(4)$, $c = 11.577(2)$ Å, $\beta = 95.04(1)°$, $V = 2915.4$ Å^3, $Z = 4$, $\rho_{calcd} = 1.72$ g cm^{-3}, $F(000) = 1528$, $\mu(Mo_{K\alpha}) = 10.3$ cm^{-1}; 4637 unique reflections were measured on a CAD4 diffractometer, $2\theta < 54°$. After correction for Lorentz polarization and absorption effects, 2103 were labeled "observed" and used in structure solution and refinement to give $R = 0.024$, $R_w = 0.032$. Selected bond lengths [Å] and bond angles [°]: Rh-N1 2.025(4), Rh-OW 2.070(4), Rh-Cl1 2.332(1), Rh-Cl2 2.330(1), Rh-S8 2.329(1), Rh-S26 2.327(1), OW...F4 3.133(6), OW...O17 2.986(6), OW...O23 3.128(6); S8-Rh-S26 166.76(5), OW-Rh-N1 178.2(2); Cl1-Rh-Cl2 179.50(5). Further details of the crystal structure investigation may be obtained from director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW (UK).

The crystal structure of **1** (Fig. 1) revealed an octahedral coordination for the Rh^{III} center, in which the main distortion arises from the S8–Rh–S26 bond angle of 166.76(5)° due to the intrinsically small bite angles of the two five-ring chelates. The coordinated water molecule is strongly bound to the Rh^{III} center[4] (Rh-OW: 2.070(4) Å), increasing the polarization of the O–H bonds which are directed towards the polyether chain. Electron-density difference-maps at $R = 0.025$ showed that the water hydrogens are disordered over three sites (occupancies from peak densities are 0.72, 0.80, and 0.48) and form three hydrogen bonds. Two of these are intramolecular bonds to O17 and O23 and the third is to a fluorine atom of the PF_6 counterion. This secondary binding is a consequence of the enhanced acidity of the coordinated water molecule.

Given that the Rh–Cl bonds may be easily cleaved by addition of $Ag^{\oplus}$ in solution, complex **1** (and its noble-metal analogues[5]) may afford access to some coordinatively unsaturated d^8 complexes, of potential catalytic activity, in which a neutral molecule (H_2O, NH_3, C_2H_4) or cationic guest ($Na^{\oplus}$, $K^{\oplus}$) may be closely bound within the macrocyclic ring.[6]

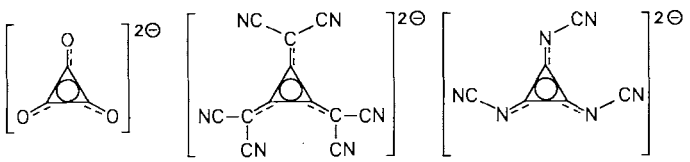
Trithiodeltate: a New, Aromatic Thioxocarbon Dianion**

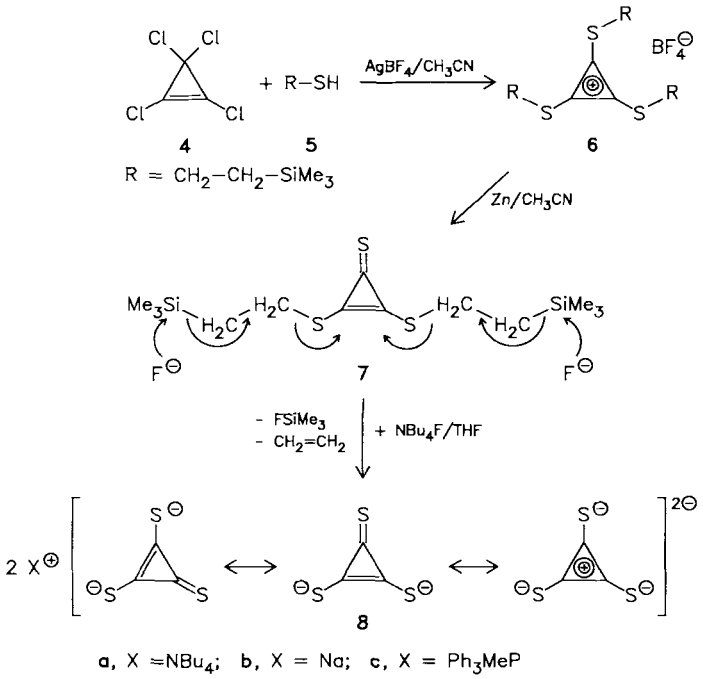
By *Gerhard Baum, Franz-Josef Kaiser, Werner Massa,* and *Gunther Seitz**

Replacement of the oxygen atoms in the dianion deltate **1**[1,2] with other functional groups leads to pseudooxocarbon dianions of the C_3 series,[3] e.g., **2**[4] and **3**,[5] which are



1 **2** **3**

novel, aromatic systems[6] having delocalized π electrons and exhibiting interesting properties. As part of our continuing studies, we have now succeeded in synthesizing the sulfur analogue, trithiodeltate, $C_3S_3^{2\ominus}$ **8**, which, along with tetrathiosquarate $C_4S_4^{2\ominus}$, is the first member of the series $C_nS_n^{2\ominus}$.[7]

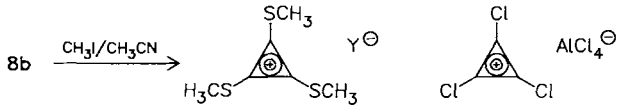


4 **5** **6** **7** **8**

R = CH_2–CH_2–$SiMe_3$

a, X = NBu_4; **b**, X = Na; **c**, X = Ph_3MeP

To introduce three sulfur functions into the deltic acid system,[8] tetrachlorocyclopropene **4** was allowed to react with 2-trimethylsilylethanethiol **5**[9] in the presence of silver ions. This results in formation of the triply thioalkyl-substituted cyclopropenylium salt **6** (yield 20%, m.p. = 114 °C), which contains sulfur functions capable of undergoing elimination reactions to form the dianion trithiodeltate. Before these elimination reactions are performed, however, **6** must be reduced to the thione **7**, which can be achieved with zinc powder in acetonitrile[10] (yield 54%, m.p. = 60 °C). Subsequent fluoride-promoted fragmentation of **7** results in elimination of fluorotrimethylsilane and ethylene to give the tetrabutylammonium salt **8a**, which, by addition of sodium perchlorate solution, is converted into the more readily isolated sodium salt **8b** (yield 62%). Dissolving **8b** in an aqueous methyltriphenylphosphonium bromide solution results in formation of the readily crystallizable salt **8c**. Chemical proof of the structure of **8b** was accomplished by treatment of **8b** with methyl iodide in acetonitrile in order to alkylate all three sulfur functions. The initially formed iodide **9a** reacts with sodium tetrafluoroborate to give the known salt **9b**.[8]



9 **10**

a, Y = I; **b**, Y = BF_4

The ^{13}C-NMR spectrum of **8b** in D_2O consists of a single signal at $\delta = 176.5$. The electronic absorption spectrum of an aqueous solution of **8b** exhibits a long-wavelength maximum at 268 nm (lg $\varepsilon = 4.32$).

The Raman and IR data[11] of the dianion of **8b** are similar to those of the isoelectronic cation of trichlorocyclopropenylium **10**[12] and are in agreement with a planar structure as well as with the expected D_{3h} symmetry.[13] This is also supported by the X-ray structure analysis[14] of **8c** (Fig. 1), which crystallizes along with three molecules

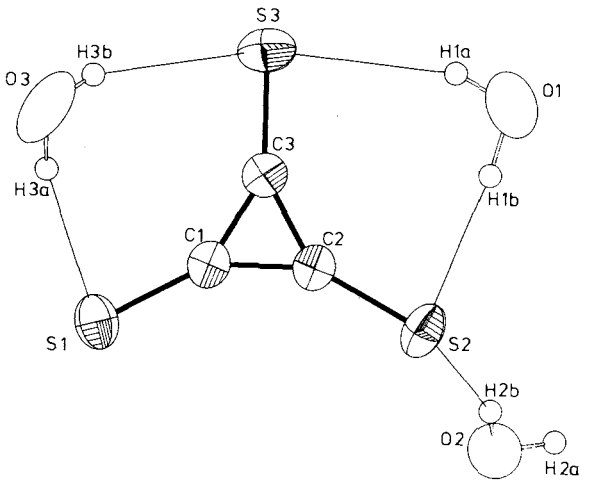


Fig. 1. ORTEP plot [19] of the molecular structure of the dianion of **8c** with surrounding molecules of water. The thermal ellipsoids are drawn at the 50% probability level. Important distances [Å] and angles [°] with vibrational correction in parentheses: C1-C2 1.402(3) [1.406], C1-C3 1.408(3) [1.413], C2-C3 1.406(4) [1.406], C1-S1 1.678(2) [1.684], C2-S2 1.680(3) [1.685], C3-S3 1.669(3) [1.674]; C2-C1-C3 60.0(5), C1-C2-C3 60.2(5), C1-C3-C2 59.8(5), S1-C1-C2 151.3(6), S1-C1-C3 148.7(6), C1-C2-S2 151.3(7), S2-C2-C3 148.5(7), C2-C3-S3 150.7(6), C1-C3-S3 149.6(6). H bonds: S2...O1 3.26, S2-H1b-O1 174; S3...O1 3.34, S3-H1a-O1 157; S3...O3 3.35, S3-H3b-O3 156; S1...O3 3.29, S1-H3a-O3 156; S2...O2 3.40, S2-H2b-O2 161.

of water. The bond lengths and bond angles of the crystallographically nonsymmetric dianion trithiodeltate exhibit only minor deviations from those expected for D_{3h} symmetry. The deviations of the "best" plane containing the six atoms of the dianion are all smaller than 0.015 (8) Å.

Trithiodeltate may therefore be regarded as virtually planar with the following mean distances and angles (with vibrational correction in parentheses): C-C 1.405 (1.408), C-S 1.676 (1.681) Å, C-C-C 60.0°, C-C-S 150.0°.

The C-C distances are equal within experimental error and similar to those in triphenylcyclopropenylium perchlorate[15] (1.373 Å) or 1,2,3-tris(dimethylamino)cyclopropenylium perchlorate[16] (1.363 Å). The C-S distance hardly differs from that in the next-highest homologue tetrathiosquarate (1.664 Å)[17] and corresponds to a partial double bond, such as that observed in thiocarboxylic acids and their derivatives.[18] It therefore seems reasonable to describe the ground state of the dianion trithiodeltate with resonance formulas containing cyclopropenylium and displaying C=S character.

Experimental Procedure

8b: A 1M solution (6 mL) of tetrabutylammonium fluoride in THF was added under a stream of nitrogen to a stirred solution of 7 (335 mg, 1 mmol) in $CHCl_3$ (1.5 mL) at 0 °C. After cessation of gas evolution, the cooling bath was removed and the solution was stirred for an additional 10 min under a stream of nitrogen and then for a further 12 h under nitrogen atmosphere. The dark solution was concentrated in a rotory evaporator. The residue was dissolved in $CHCl_3$ (7 mL) and washed six times with 4 mL of water. After drying over sodium sulfate, the organic phase was filtered; the solvent was removed under vacuum and the oily residue was taken up in acetonitrile (5 mL). Addition of a solution of $NaClO_4 \cdot H_2O$ (420 mg, 3 mmol) in acetonitrile (2 mL) resulted in precipitation of the sodium salt **8b** as a beige to grey solid. The grey impurity was removed by dissolving **8b** in water, filtering the resulting solution, and removing the solvent. Yield: 110 mg (62%) crude product; m.p. > 300 °C.

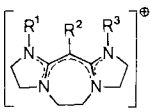
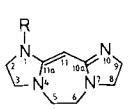
Tricyclic 2,4-Diaminovinamidines—Readily Accessible, Very Strong CHN Bases**

By *Reinhard Schwesinger**

Amidine bases such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and 1,4-diazabicyclo[4.3.0]non-5-ene[1] and guanidine bases such as tetramethylguanidine and 1,5,7-triazabicyclo[4.4.0]dec-5-ene[2] have so far been the strongest available neutral auxiliary bases. Because of the better charge distribution in the conjugate cation, the so far unknown, completely alkylated 2,4-diaminovinamidines would be expected to exhibit an even higher basicity. Owing to steric interactions, the corresponding open-chain cations,[3] however, exist in a twisted conformation, which is unfavorable for optimal conjugation.[4] The cations **1**, on the other hand, should be largely planar and the conjugate bases **2** should therefore be stronger bases.



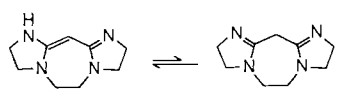
1a, $R^1 = R^2 = R^3 = H$
b, $R^1 = CH_3$, $R^2 = R^3 = H$
c, $R^1 = R^3 = CH_3$, $R^2 = H$
d, $R^1 = Ac$, $R^2 = H$, $R^3 = CH_3$



2a, R = H
b, $R = CH_3$
c, R = Ac

1a · Cl can be prepared on a large scale by the one-pot reaction of technical triethylenetetramine, malonodinitrile, and NH_4Cl. The free base **2a** is obtained by reaction of **1a** · Cl with NaOMe and is purified by crystallization (from dimethylformamide) or sublimation (130 °C/0.001 torr).

In contrast to the open-chain systems,[3] **2a** exists (largely) as 2,4-diaminovinamidine and not as malonodiamidine **2a'** according to ^{1}H-NMR analysis (Table 1, also in CD_3CN). This is presumably due to the more effective conjugation in **2a**.



2a ⇌ **2a'**

Monomethylation of **2a** to give **2b** is accomplished in good yield by monoacetylation (*N*-acetylimidazole/tetrahydrofuran/room temperature) to give **2c**, methylation (MeBr/acetonitrile) to give **1d** · Br, and deacetylation to

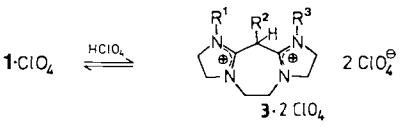
give **1b**·Br (Me_2NH/MeOH). The base **2b** (Table 1) is obtained by treatment of **1b**·Br with NaOMe and purified by distillation (b.p. = 172 °C/0.01 torr) or crystallization (from Et_2NH).

Table 1. Melting points and ^{1}H-NMR data for the compounds **1a,b**·ClO_4 and **2a,b** [5].

Compound	M.p. [°C]	250-MHz ^{1}H-NMR (δ in [D$_6$]dimethyl sulfoxide ([D$_6$]DMSO))
2a	137–139	3.25 (10 H, m), 3.47 (2 H, m; H-9), 4.07 (1 H, s; H-11), 5.3 (1 H, br.s; H-10)
1a·ClO_4	260–265	3.48 (4 H, s; H-2, H-9), 3.53 (8 H, m), 4.17 (1 H, s; H-11), 7.73 (2 H, br.s; H-1, H-10)
2b	102–104	2.61 (3 H, s; CH_3), 3.0–3.4 (12 H, m), 3.98 (1 H, s; H-11)
1b·ClO_4	145–147	2.79 (3 H, s; CH_3), 3.3–3.8 (12 H, m), 4.13 (1 H, s; H-11), 7.71 (1 H, br.s; H-10)

The extreme upfield shift (also compared with the open-chain permethyl compound[6]) of the NMR signal for the methine carbon atom in **1a** and **1c** ($\delta(^{13}C) = 61.1$ and 56.7, respectively) indicates the presence of a high charge density at C-11; the nucleophilicity of C-11 is supported by the identification of ca. 16% of **3e** ($R^1 = R^3 = H$, $R^2 = CH_3$) in the reaction of **1a** with methyl *p*-toluenesulfonate (in Me_2SO_2, 130 °C). The cations **1** (analogous to the open-chain cations[3]) are protonated by strong acids at C-11 to give **3**.[5]



The pK_a values of **2a** and **2b** in acetonitrile (26.22 and 26.95,[7] respectively; DBU, 24.32) are only slightly smaller than those of triaminomonophosphazene bases;[8] however, as dehydrohalogenation reagents and with respect to their (hydrolytic) stability, **2a** and **2b** are appreciably inferior to the latter.

Because of the sparing solubility and excellent crystallizability of the salts of **1a** and **1b**, the bases **2a** and **2b** are useful as proton trapping agents in aprotic medium. We are currently investigating to what extent the rigid skeleton of **2** is suitable for the construction of chiral, strong bases. Very strongly basic "proton sponges" structurally derived from **2** have already been synthesized and studied.[9]

Experimental Procedure

1a·Cl: NH_4Cl (185 g, 3.46 mol) was added in portions to a mixture of technical triethylenetetramine (235 g, ca. 1.13 mol of linear triethylenetetramine) in dry MeOH (330 mL) and anhydrous, peroxide-free diethylene glycol monomethyl ether (400 mL) at ca. 50 °C. A solution of malonodinitrile (66 g, 1 mol) in MeOH (170 mL) was then added over 2 h to the refluxing solution. At the end of the addition, a precipitate began to form. MeOH was distilled off under normal pressure. The residue was heated to 180 °C for 1.5 h (vigorous evolution of ammonia). A hot solution of butylamine (100 mL) in 2-propanol (1.7 L) was then added to the hot mixture (80–100 °C). After ca. 24 h at 0 °C, 176 g (82%) of **1a**·Cl, m.p. ≈ 290 °C (dec.), was isolated.

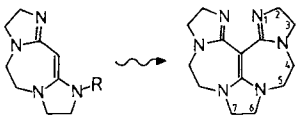
Novel, Very Strongly Basic, Pentacyclic "Proton Sponges" with Vinamidine Structure**

By *Reinhard Schwesinger,* Michael Mißfeldt, Karl Peters,* and *Hans Georg von Schnering*

The basicity of "proton sponges" is determined by the degree of repulsion between the lone pair electrons, the strength of the hydrogen bond in the conjugate cation, and the proton affinity of the chelating groups. X-ray structure analyses of bases containing two tertiary amino groups and of their cations[1,2] often provide insight into the first two factors and spectroscopic measurements afford information concerning the symmetry of the hydrogen bond.[3] In these systems a high thermodynamic basicity can only be achieved at the expense of a very low kinetic basicity;[4] presumably, it cannot be realized at all with sterically nondemanding, less basic groups.[5] Further extension of the strongly basic system **1**[6] by one dihydroimidazole unit offered a possible route to bases that would be both thermodynamically strong and kinetically active.



1a, R = H; **1b**, R = CH_3 **2**

Whereas **3** can be obtained directly from **4**[7] and diethylenetriamine, **2**, and its structural analogues **5** and **6** are readily accessible only by symmetrical construction from **4** via **7**, **8**, and **9** (Scheme 1). Compounds **9a–c** are products of "zip reactions";[8] their asymmetrical structures are confirmed by the ^{1}H- and ^{13}C-NMR data. The melting points and ^{1}H-NMR data of the new compounds **2**, **5**, and **6** are summarized in Table 1.

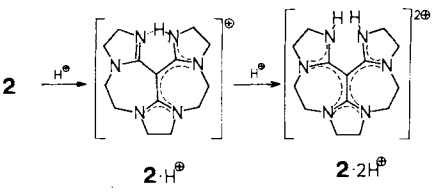
9b, n = 2, R = H
9c, n = 1, R = CH_3

Table 1. Melting points and ^{1}H-NMR data of **2**, **5**, and **6**.

Compound [9]	M.p. [°C]	250-MHz ^{1}H-NMR (δ in CD_3CN)
2	228–231	3.17(4 H; AA′ part of AA′BB′), 3.23–3.29 (8 H, m), 3.33 (4 H, s), 3.44 (4 H; BB′ part of AA′BB′)
5	255–258 (dec.)	1.71 (4 H, m), 3.13–3.18 (4 H, m), 3.21–3.31 (12 H, m), 3.28 (4 H, s), 3.36–3.43 (4 H, m)
6	192–194	1.07 (12 H, s), 2.94 (4 H, s), 3.21–3.24 (8 H, m), 3.31 (4 H, s)

The bases **2** and **5** are moderately stable and moderately soluble in aprotic solvents; **6** is stable and more soluble. With one equivalent of acid, they form monocations, e.g., **2**·H$^{\oplus}$; with two equivalents, dications, e.g., **2**·2H$^{\oplus}$.

In order to carry out an X-ray structure analysis (Fig. 1), crystals of **2**·2HClO$_4$ were obtained by precipitation from water and crystals of **2**·HBPh$_4$ by successive addition of 2-*tert*-butylimino-2-diethylamino-1,3-dimethyl-1,3,2-diaza-



phosphinane[10] and a solution of $NaBPh_4$ in acetonitrile to an acetonitrile solution of **2**·2HClO$_4$. We assumed that the conformation of **2**·2H$^{\oplus}$ might be similar to that of the (less easily handled) base **2**.

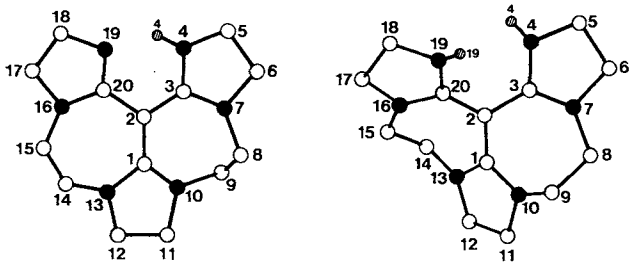


Fig. 1. Structures of **2**·HBPh$_4$ (left) and **2**·2HClO$_4$ (right), anions and *C*-bonded hydrogen atoms omitted (○ = C, ● = N, ⊘ = H) [11]. The numbering does not correspond to systematic nomenclature, but rather to computational parameters.

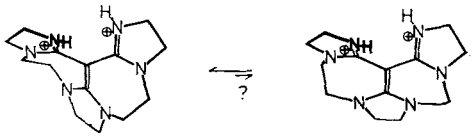
It was possible to localize approximately the chelate-bonded proton of **2**·H$^{\oplus}$ and to assign it unequivocally to N-4 (Fig. 1, left). Despite the extremely short N-4/N-19 distance (254.1 pm),[2] the hydrogen bond is asymmetric, presumably owing to the structurally imposed nonlinearity[12] ($\sphericalangle$ N-4/H-4/N-19 = 137.6°). This asymmetry also holds true for the chromophore system of **2**·H$^{\oplus}$. The part of the molecule delimited by N-4, C-2, and N-13 corresponds to a delocalized system with significant bond-length equalization; C-2/C-20, on the other hand, is unambiguously a single bond between two C_{sp^2} atoms and C-20/N-19 corresponds to a double bond (Table 2).

Table 2. Important bond lengths [pm] in **2**·HBPh$_4$ and **2**·2HClO$_4$.

Bond	**2**·HBPh$_4$	**2**·2HClO$_4$
C-20/N-19	127.0 (5)	132.6 (6)
C-3/N-4	131.0 (4)	133.6 (6)
C-3/N-7	133.7 (4)	132.2 (6)
C-1/N-10	133.6 (3)	132.3 (6)
C-1/N-13	133.5 (3)	130.6 (6)
C-20/N-16	133.5 (4)	134.6 (6)
C-2/C-20	146.9 (4)	141.2 (6)
C-2/C-3	143.1 (4)	143.0 (6)
C-1/C-2	141.5 (4)	143.9 (6)
N-4/H-4	92.0 (3)	86.0 (34)
N-19/H-4 and N-19/H-19	178 (1)	86.0 (49)

The conformations of the perimeters in **2**·H$^{\oplus}$ and **2**·2H$^{\oplus}$ can be described as sequences of sp^2 nitrogen atoms and ethylene units of planar dihydroimidazole rings (with the exception of the 1,10,11,12,13-ring of **2**·H$^{\oplus}$) and ethylene units of 2,3-dihydro-1,4-diazepinylium rings in the half-chair conformation.[13] Whereas a nearly planar six-membered ring (N-19/C-20/C-2/C-3/N-4/H-4) is present in **2**·H$^{\oplus}$, the C-2/C-20 and C-2/C-3 bonds in **2**·2H$^{\oplus}$ are twisted away from each other by ca. 26°. The N-4/N-19 distance is thereby 30.4 pm longer than that in

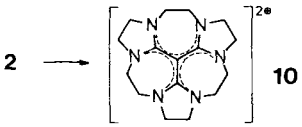


$2 \cdot 2H^{\oplus}$ $2 \cdot 2H^{\oplus\prime}$

$2 \cdot H^{\oplus}$. There is significant twisting around the C-1/C-2 bond in both $2 \cdot H^{\oplus}$ and $2 \cdot 2H^{\oplus}$ (26 and 39°, respectively). Since the C-1/C-2 bond in **2**, which is a pure double bond, should be largely planar—thus corresponding to the conformer $2 \cdot 2H^{\oplus\prime}$ (coupled, double inversion of the dihydrodiazepinylium half-chairs in $2 \cdot 2H^{\oplus}$) that had been expected for $2 \cdot 2H^{\oplus} - 2 \cdot 2H^{\oplus}$ cannot be viewed as a structural model for the free base **2**.

The pK_a values of the new bases in acetonitrile[14,15] (1,8-bis(dimethylamino)naphthalene: $pK_a = 18.18$[16]) allow the following conclusions to be drawn: an additional amidine function exerts a $-I$ effect [comparison of **1b** (26.95) with **3** (25.18)]; the chelate effect amounts to ca. four pK_a units [comparison of **3** with **2** (29.22)]; methyl groups have a $+I$ effect [comparison of **2** with **6** (30.03)]. The difference in the values for **2** and **5** (29.51) can only be interpreted when the structures are better understood.

Compounds **2** and **6** are kinetically active bases.[5] Only averaged signals are apparent in the ^{1}H-NMR spectrum of a mixture of **6** and $6 \cdot H^{\oplus}$ in CD_3CN at ca. 0 °C. Whereas only ca. 15% alkylation is observed by ^{1}H-NMR spectroscopy upon dehydrochlorination of β-phenylethyl chloride with **1b**, compound **2** surprisingly undergoes 43% alkylation in a reaction that is three times slower. Even isopropyl bromide alkylates **2** to a greater extent than **1b**. Compound **2** reacts with 1,2-dibromoethane to give **10** [$10 \cdot 2ClO_4$: m.p. = 323–325 °C; ^{1}H-NMR (CD_3CN): $\delta = 3.66$ (s), 3.75 (s)], which presumably exists in a D_3 conformation.



2 **10**

In a competition experiment, **6** is methylated three times faster than *N-tert*-butylpentakis(dimethylamino)diphosphazene[17] ($pK_a = 33.42$!). The relatively high nucleophilicity of **2** and **6** is presumably due to an interaction of the lone electron pairs on the chelate-forming nitrogen atoms (similar to the case of hydrazines). In their scope of application as auxiliary bases, **2** and **6** (and certainly **5**, as well) are thus far inferior to the phosphazene bases.

[15] The synthesis of the 6,7-didehydro compounds of **2** and **6** as the dications was also successful. The pK_a values of the thermally unstable bases were determined by generation of the free bases by treatment with a phosphazene base [17] in acetonitrile (31.94 and 32.88, respectively) [14]. These values are appreciably higher than those of **2** and **6**.

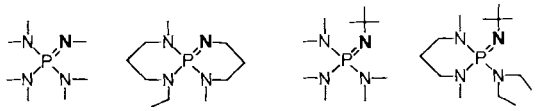
Peralkylated Polyaminophosphazenes—Extremely Strong, Neutral Nitrogen Bases**

By *Reinhard Schwesinger** and *Helmut Schlemper*

Neutral nitrogen bases such as sterically hindered tertiary amines[1] or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)[2] play an important role in synthesis; peralkylated, sterically hindered amidine[3] and guanidine bases[1b,4] have been described recently. It seemed of interest to us, therefore, to extend the collection of readily accessible, broadly applicable bases, which can be arranged in order of strength and steric hindrance, to higher pK_a values. The amino-substituted iminophosphoranes (monophosphazenes) **1**[5,6] and **2–4**[6] constituted the first step in this direction.



1 **2** **3** **4**

The question we posed was whether completely dialkylamino-substituted (with respect to the phosphazene chain),

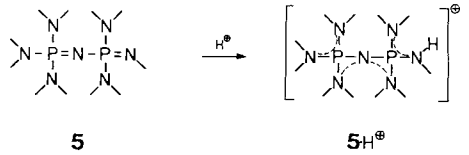
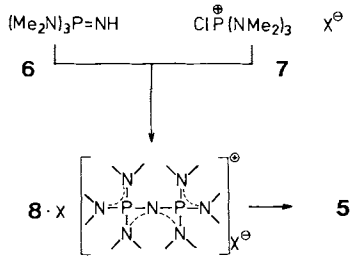
noncyclic *N*-alkyl oligophosphazenes,[7] such as the simplest example **5**, would be even stronger bases owing to the better charge delocalization in the conjugate cation[8] $5 \cdot H^{\oplus}$.



5 **5H$^{\oplus}$**

Compound **5** (Table 2) was easily obtained as a waxlike, distillable solid in 80–90% yield by reaction of **6**[9] with **7**[10] to give **8**·X [in MeCN, 40 °C, 2 h reflux; **8**·ClO_4,[11] m.p. = 280 °C (dec.), ^{1}H-NMR (CD_3CN): $\delta = 2.64$ (m)] followed by demethylation ($KSC_{12}H_{25}$, 180 °C, high vacuum).



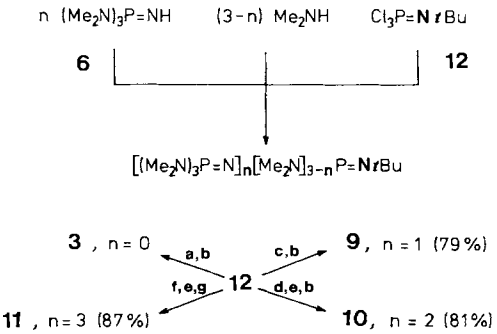
The increase in basicity on going from **1** to its "homologue" **5** is much greater than expected. Compound **5** is thus a very efficient dehydrohalogenation reagent of low nucleophilicity (Table 1).

Table 1. pK_a values of **5** and other bases and rate constants k for the reaction of β-phenylethyl chloride with these bases in MeCN at 25 °C and the percentage of alkylated bases formed upon reaction with excess isopropyl bromide.

Base	pK_a [12, 13]	$k \times 10^4$ [L mol^{-1} s^{-1}]	% Alkylation
4	27.58	0.011	0
NaOEt/EtOH		0.045 [14]	
DBU	24.32	0.047	21
1	27.53	2.2	13
2	28.27	15.5	49
$[Bu_4N]F$		38.9 [14]	
5	32.66	≈600	5

The cation **8** is suitable as a very stable phase-transfer catalyst, especially for strongly nucleophilic anions, as shown by the drastic demethylation conditions. However, salts of **8** are also more stable toward hydroxide ions than the corresponding tetrabutylammonium or tetrabutylphosphonium salts (and slightly more lipophilic):[15] the half-lives of the corresponding chlorides in 50% NaOH/chlorobenzene at 100 °C are 8 h, 20 min, and < 10 min, respectively. Alkylation of **5** results in the formation of more lipophilic cations.[16]

The sterically hindered bases **9–11**, which are "homologous" to **3**, can be prepared on a mole scale in a one-pot procedure from **6** and **12**[17] and isolated as the HBF_4 or $HClO_4$ salts, which are only sparingly soluble in water. Compounds **9** and **10** can be liberated by treatment of these salts with KOMe or NaOMe; **11** is best obtained using KNH_2 (Scheme 1). The most important physical and spectroscopic data for compounds **9–11** and for their $HClO_4$ salts are presented in Table 2.



Scheme 1. Synthesis of the bases **3** and **9–11** (data for **9–11**, see Table 2): a) 6 equiv. of Me_2NH(g) added at −15 °C, 24 h reflux. b) H_2O/NH_4BF_4; KOMe/MeOH (exactly 1 equiv.), filter, remove solvent, distill. c) MeCN/tetrahydrofuran (THF); 2.06 equiv. Me_2NH, 2.06 equiv. Et_3N at −60 °C, 24 h 20 °C; 3.03 equiv. **6** at 0 °C, 3 h reflux. d) 1 equiv. $Me_2NH \cdot HCl$, MeCN/THF; 2.06 equiv. Et_3N at −60 °C, 24 h 20 °C; 5.25 equiv. **6** at 0 °C, 2 d reflux. e) H_2O/NH_4BF_4; strongly basic anion exchanger, $Cl^{\ominus}$ form, MeOH; high vacuum 100 °C. f) 5.25 equiv. **6**, MeCN/THF, −60 °C; addition of **12**, 24 h 20 °C, 5 d reflux. g) THF,$KNH_2/NH_{3(l)}$, sublimation (130 °C/0.001 torr).

Table 2. Melting points (and boiling points) as well as ^{1}H-NMR data for the compounds **5** and **9–11** and for their $HClO_4$ salts [11].

Compound	M.p. [°C] (B.p. [°C])	250-MHz ^{1}H-NMR (δ, J[Hz])
5	42 (92 [a])	2.56 (12 H, d, J = 9.5), 2.61 (3 H, d, J = 24), 2.63 (18 H, d, J = 10) [b]
5 · $HClO_4$	> 235 (dec.)	2.50 (3 H, dd, J = 12.5, 6), 2.65 (18 H, d, J = 10.5), 2.65 (12 H, d, J = 10.5), 3.33 (1 H, br.s; NH) [b]
9	76 (83 [a])	1.13 (9 H, d, J = 0.8), 2.53 (12 H, d, J = 9.8), 2.55 (18 H, d, J = 9.8) [b]

11 · $HClO_4$	260–261	1.29 (9 H, d, J = 0.8), 2.07 (1 H, br.d; NH), 2.64 (54 H, d, J = 10.2) [b]

[a] At 0.001 torr. [b] In CD_3CN. [c] In C_6D_6.

The strongly hygroscopic, colorless, crystalline bases **9–11** are, like **1–5**, unusually stable and are very soluble in the conventional solvents. In 1 M D_2O solution, **10**, like **1–5**, undergoes hydrolysis only at about 160 °C ($t_{1/2} \approx 40$ h); even under these conditions, **9** and **11** remain unchanged over 20 h. However, aqueous mineral acids hydrolyze **9–11** readily.

Compound **11** is probably the strongest neutral nitrogen base known at present (Table 3); in THF solution, it is comparable to potassium bis(trimethylsilyl)amide, but less nucleophilic. It deprotonates acetone to a large extent and establishes a clear equilibrium with triphenylmethane. In acetonitrile (pK_a(MeCN) ≈ 44), **10** and **11** cannot be titrated, since they catalyze a rapid self-condensation with "self-buffering." Reaction of **9–11** with *n*-alkyl halides af-

Table 3. pK_a values of **9–11** and of other sterically hindered bases at 25 °C.

Compound	pK_a value	
	In MeCN [13]	In THF [a]
Pentaisopropylguanidine [1b, 4]	(23.2) [b]	
3	26.89 [12]	
4	27.58 [12]	
9	33.42 [12]	19.19 [c]
10	(38.35) [d]	24.18 [e]
11	(42.1) [f]	28.0 ± 0.2 [g]

[a] "Ion-pair pK_a value" [c], relative scale. [b] Estimated from the difference between the pK_a value of pentaisopropylguanidine and pentamethylguanidine in methoxyethanol [1b] and the value for the latter in MeCN [6, 12]. [c] Correlated with 9-phenylfluorene (PFH) [18] via the definition $pK_a = \lg[\mathbf{9}^- \cdot PFH] - \log[\mathbf{9}^-] - \log[PFH] + 18.59$. [d] By extrapolation of the difference of the "ion-pair pK_a values" of **9** and **10** in THF to the MeCN scale. [e] By titration of **9** and **10** in THF; the difference in the pK_a values of the two indicators used was extrapolated from the MeCN scale. [f] By extrapolation from the difference of the "ion-pair pK_a values" of **10** and **11** in THF to the MeCN scale. [g] Estimated by titration in THF against Ph_2NH, from the pK_a value of Ph_2NH in dimethyl sulfoxide (DMSO) [19], and by comparison of the heats of solution of Ph_2NH and Ph_2CH_2 in THF and DMSO in order to estimate the solvent correction factor.

fords 1-alkenes under exceptionally mild conditions (Table 4).

Table 4. Conditions and yields of 1-octenes in the reaction of *n*-octyl bromide (1 mmol) with **9** and **11** in comparison to a known procedure [20].

Base/solvent	Conditions	Yield [a] [%]	Alkylation of the base [%]
KO*t*Bu/[18]crown-6/petroleum ether [20]	60 °C/3 h	75	18
1.1 mmol **9**	70 °C/5 h	74	18
1.1 mmol **11**/0.5 mL THF	25 °C/6 h	96	3

[a] Determined by gas chromatography using a reference.

The extreme basicity of oligophosphazene bases such as **10**, **11**, and higher "homologues" and the high stability of the extremely soft phosphazenium ions should make it possible to modify in a specific manner the reactivity, stability, and selectivity of hard anions (obtainable so far only with hard counterions). Preliminary results have shown that the course of alkylation can indeed be influenced.[21]

[21] In the presence of **11** as base, benzothiazole was *C*-alkylated for the first time. With benzyl bromide in THF at −78 °C, ca. 50% of 2-(benzothiazol-2-yl)-1,2,3-triphenylpropane **13** is obtained. With potassium bis(trimethylsilyl)amide as base, on the other hand, little reaction occurs at −78 °C, possibly because of the poor solubility of the organopotassium compound. After thawing, **13** was isolated in ca. 2-3% yield along with ca. 12% of 1-(benzothiazol-2-yl)-1,2-diphenylethane. Presumably, 2-lithiobenzothiazole cannot be alkylated: H. Chikashita, K. Itho, *Heterocycles 23* (1985) 295.

The Synthesis and Catalytic Properties of Some Open-Sided Binuclear Complexes of Rh^I: The Structure of $[Rh_2(CO)_2(CH_3CN)_2\{CH(PPh_2)_3\}](CF_3SO_3)_2$

By *Hani El-Amouri, Ali A. Bahsoun, Jean Fischer,* and *John A. Osborn**

Binuclear rhodium(I) complexes have attracted attention of late in part because as hydrogenation catalysts they appear to differ in properties from the corresponding mononuclear species. For example, the complex $[Rh_2H_2\{P(OiPr)_3\}_4]$ has been reported to catalyze the *trans* addition of H_2 to diphenylacetylene, whereas monomeric Rh catalysts gave *cis* products.[1] Further, mechanistic studies on the transfer of hydrogen from $[Rh_2H_2(CO)_2(dppm)_2]$ (dppm = methylene(diphenylphosphane)) to acetylenes indicate the presence of a biradical mechanism which is not accessible to mononuclear analogues.[2] We report here on studies involving the synthesis and properties of some dirhodium(I) compounds assembled by the ligand $CH(PPh_2)_3$, and the X-ray determination of one such complex.

Treatment of **1**[3] with 0.5 equivalents of $CH(PPh_2)_3$ yields orange crystals of **2**. The IR spectrum (Nujol) shows

$[Rh(CO)_2S_2]CF_3SO_3$ **1**

$[Rh_2(CO)_3\{CH(PPh_2)_3\}](CF_3SO_3)_2$ **2**

terminal carbonyl absorptions at 2000(s), 2010(sh), 2015(s), and 2085(s) cm^{-1} as well as peaks at 1330 and 1250 cm^{-1}, suggesting the presence of coordinated triflate[4,5] in the solid state. The ^{31}P-NMR data (Table 1) indicate that, in solution, two equivalent phosphorus nuclei,

[*] Prof. J. A. Osborn, H. El-Amouri, Dr. A. A. Bahsoun, Prof. J. Fischer

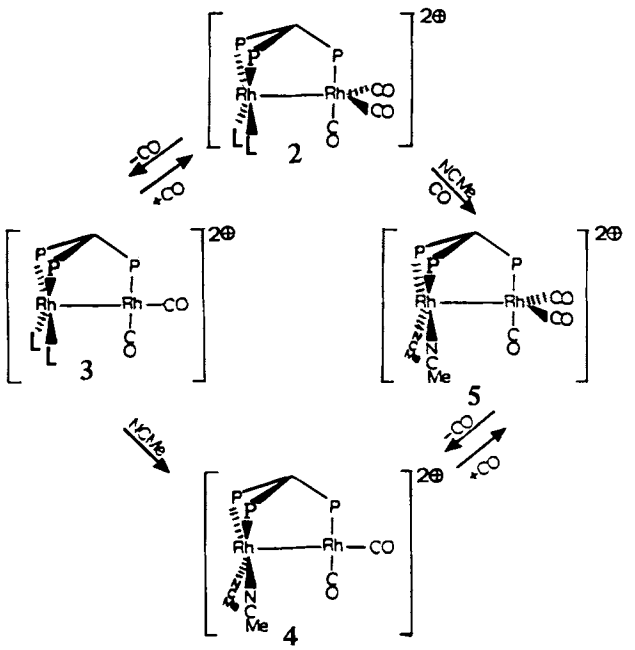
4 rue Blaise Pascal, F-67000 Strasbourg (France)

P_a, are bound to one rhodium atom, Rh_a, the other, P_b, being coordinated to the second rhodium atom, Rh_b. The ^{13}C-NMR data show three carbonyls binding solely to Rh_b,[6] the sites on Rh_a other than phosphorus being occupied by solvent molecules or weakly coordinated triflates. Further, we propose that a Rh-Rh bond is also present (vide infra). Complex **2** loses CO reversibly to produce **3** (Scheme 1), where the stereochemical change from trigonal bipyramidal to square planar about Rh_b is accompanied by a downfield shift of ca. 27 ppm in the ^{13}P-NMR spectrum of P_b (Table 1).



Scheme 1. L = solvent molecule.

Treatment of **3** (or **2** in the absence of CO) with CH_3CN yields **4**, which is spectroscopically very similar to **3**. Yellow crystals were subjected to an X-ray structural determination, which is presented in Figure 1.[7] Notably, the dimeric structure is confirmed, with a Rh–Rh distance of 2.745 Å (single bond), and with the $CH(PPh_2)_3$ ligand holding the two rhodium atoms in a clamplike fashion on one side of the molecule, leaving one side open for the coordination of reactant molecules. In **4**, this side is occupied by CH_3CN and CO ligands. The coordinating geometry about Rh_a is thus approximately square pyramidal, the Rh–Rh bond occupying the apical site on Rh_a and completing the square arrangement about Rh_b. The metal–metal bond appears to be of a strong donor–acceptor character, creating sufficient electron deficiency on Rh_a such that its affinity for π-acid ligands is greatly reduced despite the presence of electron-donating P_a groups. Accordingly, on treatment of **4** with CO, coordination to Rh_b and *not* to Rh_a occurs to form **5** (Scheme 1). This is shown by the similarity of the ^{31}P-NMR spectra of **5** and **2** (Table 1).

$[Rh_2(cod)\{CH(PPh_2)_3\}](CF_3SO_3)_2 \cdot (CH_3)_2CO$ **6**
(cod = 1,5-cyclooctadiene)

Analogously, the dirhodium diene complex **6** can be isolated as burgundy red crystals from acetone using two equivalents of $[Rh(cod)S_2]CF_3SO_3$[3] and one equivalent of

[a] Each dd. [b] Each dt.

$CH(PPh_2)_3$. ^{31}P-NMR data (Table 1) show **6** to be isostructural with **3**, the diene ligand replacing the two carbonyl groups. Complex **6** reacts with H_2 in acetone to liberate cyclooctane, and on addition of 1-hexene, catalytic hydrogenation proceeds (25°, 1 atm H_2). Complex **6** possesses two formally coordinatively unsaturated rhodium(I) atoms in close proximity, and interestingly the hydrogenation rate is increased about fivefold on addition of one equivalent of PPh_3. Investigations of the mechanistic details of this reaction are in progress.

Experimental Procedure

All reactions and operations including the distillation of the solvents were carried out under N_2.

2: A solution of $[Rh_2Cl_2(CO)_4]$ (389 mg, 1 mmol) in acetone (4 mL) was added to a solution of $AgCF_3SO_3$ (550 mg, 2.14 mmol) in acetone (3 mL). The white AgCl salt was filtered off, and to the clear yellow filtrate a solution containing $CH(PPh_2)_3$ (510 mg, 0.9 mmol) in benzene (6 mL) was added drop by drop until the solution turned orange-red. The solvent was removed under vacuum and the residue washed several times with benzene and ether. Recrystallization from acetone/ether; yield 550 mg (65%). ^{13}C-NMR ($(CD_3)_2CO$): δ = 188 (dd, *J* (C-Rh) = 70, *J* (C-P_{trans}) = 104 Hz), 170 (dd, *J* (C-Rh) = 66, *J* (C-P_{cis}) = 16 Hz).

4: **1** (50 mg, 0.043 mmol) was dissolved in acetone (4 mL) and to this orange solution acetonitrile (2 mL) was added to yield an immediate color change to

Mo^{II} and Mo^0 Complexes of 3,3,7,7,11,11,15,15-Octamethyl-1,5,9,13-tetrathiacyclohexadecane**

By *Toshikatsu Yoshida,* Tomohiro Adachi, Tatsuo Ueda, Megumi Watanabe, Manabu Kaminaka,* and *Taiichi Higuchi**

Recently, macrocyclic polythioethers as a ligand in transition-metal complexes have received considerable interest in view of the enormously high redox petentials found for the Cu^{II} [1] and Co^{II} [2,3] complexes and the ability to stabilize the metals in low oxidation states such as Rh^I.[4,5] The high nucleophilicity of the square-planar Rh^I cationic complexes of 1,4,8,11-tetrathiacyclotetradecane and its 6,6,13,13-tetramethyl analogue as proved by a facile oxidative addition of CH_2Cl_2 is also remarkable since $[RhCl(PPh_3)_3]$ and $[Rh(tBuNC)_4]^{\oplus}$ are inert toward CH_2Cl_2.[5] These salient features may promise a rich chemistry of macrocyclic polythioether complexes of transition metals, particularly in low oxidation states. In view of current interest in Mo complexes of sulfur ligands, we have prepared the novel monomeric Mo^{II} dihalo complexes **1** and **2** of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-

[*trans*-MoX_2L_A] **1**, X = Br; **2**, X = Cl

tetrathiacyclohexadecane, L_A. The Mo^{II} halo complexes of thioethers so far reported, e.g., $[Mo_2Cl_4(SEt_2)_4]$ and $[Mo_6Cl_{12}(dithiahexane)_2]$ are polymeric.[6]

L_A, R = Me
L_B, R = H

Cyclic voltammetry shows that both **1** and **2** exhibit extraordinarily high redox potentials for the Mo^{III}/Mo^{II} (ca. +1.2 V vs. SCE) and Mo^{II}/Mo^I (ca. −0.2 V) couples, which emphasizes the possibility that **1** and **2** might serve as potential precursors for syntheses of lower-valent molybdenum complexes containing the thioether as ligand. In fact, both chemical and electrochemical reductions of **1** under CO atmosphere afforded **3**. Complex **3** represents

[*trans*-$Mo(CO)_2L_A$] **3**

the first example of a Mo^0 *di*carbonyl complex of a thioether ligand, since all known complexes $[Mo(CO)_n(SR_2)_{6-n}]$ contain more than three CO ligands.[7] The dimeric complex $[Mo_2(SH)_2(L_B)_2]^{2\oplus}$ [8] is the only known Mo^{II} complex of a 16-membered cyclic tetrathioether. However, this complex cannot be a candidate for the starting material mentioned above.

The Mo^{II} dibromo complex **1** [9] was prepared by treating $[MoBr_2(CO)_4]_2$ with two molar equivalents of L_A [10] in toluene under reflux as paramagnetic, orange crystals (50% yield based on the ligand). Since the physical properties of **1**,[12] including magnetic, electronic spectral, and electrochemical data are similar to those of the dichloride **2**, a *trans* geometry was proposed for **1**. A similar reaction of $[MoCl_2(CO)_4]_2$ with L_A did not produce **2**; instead, **4** was obtained as paramagnetic, orange crystals (25% yield).[9,12] The formation of **4** is rather expected since the reaction of

[*fac*-$MoCl_3L_A$] **4**

$[MoCl_2(CO)_4]$ with a ligand of poor π-acceptor ability has been known to proceed via disproportionation of Mo^{II} to Mo^{III} and Mo^0 affording CO-free Mo^{III} complexes.[13] Alternatively, **4** was obtained in a higher yield (71%) by treating $[MoCl_4(MeCN)_2]$ with L_A in CH_2Cl_2 at room temperature. Reduction of **4** with Zn powder in CH_2Cl_2 took place readily at room temperature to give **2** as paramagnetic, yellow crystals (51% yield).[9,12] The observation of a single Mo-Cl stretching band ($\tilde{\nu}=306$ cm^{-1}) in the IR spectrum of **2** is consistent with a *trans* geometry.

The cyclic voltammogram of **1** and **2** measured in MeCN (0.1 M nBu_4NBF_4) at a scan rate of 100 mV s^{-1} shows two essentially reversible redox couples due to Mo^{II}/M^I ($E_{1/2}=-0.15$ V vs. SCE, $\Delta E=100$ mV, $I_{pa/pc}=0.92$ for **1** and $E_{1/2}=-0.28$ V, $\Delta E=75$ mV, $I_{pa/pc}=1.08$ for **2**) and Mo^{III}/Mo^{II} ($E_{1/2}=+1.21$ V vs. SCE, $\Delta E=120$ mV, $I_{pa/pc}=1.00$ for **1** and $E_{1/2}=+1.19$ V, $\Delta E=80$ mV, $I_{pa/pc}=1.22$ for **2**). The high redox potentials compared with those of [*trans*-$MoX_2(Ph_2PCH_2CH_2PPh_2)_2$] [$Mo^{II}/Mo^I$, $E_{1/2}=-1.51$ V vs. SCE for X = Br and −1.68 V for X = Cl; Mo^{III}/Mo^{II}, $E_{1/2}=+0.01$ V for X = Br and −0.05 V for X = Cl][14] are remarkable and probably due to the weak σ-donating property of thioethers.[6] In addition, the ring size of the thioether may be responsible for the high potentials as found for a series of the related Cu^{II} complexes.[1]

Reduction of **1** with Na/Hg in THF under CO atmosphere (1 atm CO) occurred at ambient temperature to give **3** as diamagnetic, red crystals quantitatively. Controlled-potential electrolysis of **1** at -2.2 V vs. SCE in MeCN under CO also afforded **3**. Despite the similar redox potentials of **1** and **2**, reduction of **2** under similar conditions employed for **1** gave only traces of **3**. The ^{1}H- and ^{13}C-NMR spectra of **3**[12] indicate a planar coordination of L_A with "all up" conformation, the four 6-membered $MoSCH_2CMe_2CH_2S$ rings assuming the chair form. This is confirmed by an X-ray structural study of **3** (Figure 1).[15]

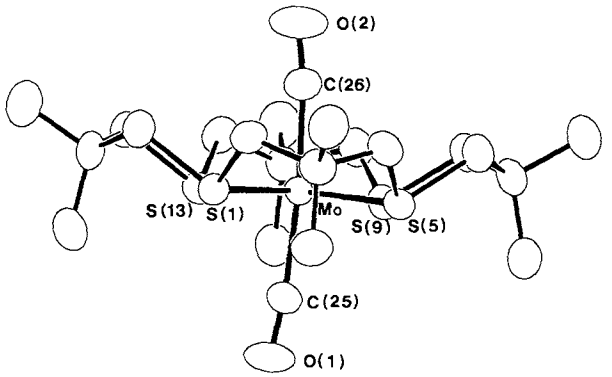

Fig. 1. Molecular structure of **3**. Selected bond distances [Å] and angles [°]: Mo-S(1) 2.434(2), Mo-S(5) 2.439(2), Mo-S(9) 2.432(2), Mo-S(13) 2.438(2); S(1)-Mo-S(5) 90.5(1), S(5)-Mo-S(9) 89.1(1), S(9)-Mo-S(13) 90.1(1), S(1)-Mo-S(13) 90.0(1), S(1)-MoS(9) 175.1(1), S(5)-Mo-S(13) 175.5(1), C(25)-Mo-C(26) 174.3(3), Mo-C(25)-O(1) 174.3(7), Mo-C(26)-O(2) 173.0(7).

The geometry around the Mo atom is slightly distorted octahedral with two CO ligands in the axial positions, and the molecule possesses approximately C_{4v} symmetry. The Mo atom is displaced toward the ring C atoms from the least-squares plane defined by the four S atoms by 0.093(2) Å. The plane defined by the four S atoms is strictly planar, the deviation of the S atoms from the plane being less than 0.002(2) Å. The two Mo–C (Mo-C(26) 1.979(8) and Mo-C(25) 2.002(8) Å) and C–O distances (C(26)-O(2) 1.161(10) and C(25)-O(1) 1.144(10) Å of two mutually trans CO ligands are not significantly different. The Mo–S distances (average 2.436(2) Å) are considerably shorter than those found in the Mo^0 complexes [*fac*-$Mo(CO)_3$(1,4,7-trithiacyclononane)] (mean 2.520(6) Å)[7] and [*trans*-$Mo(N_2)_2(Ph_2PCH_2CH_2SMe)(PMePh_2)_2$] (2.483(3) Å).[16] Furthermore, the short Mo–S distances in **3** compared with the corresponding lengths in $\{Mo_2(SH)_2(L_B)_2\}^{2\oplus}$ (mean 2.493(2) Å)[8] are consistent with the stronger d_π–d_π interaction in the Mo^0–S bond than in the Mo^{II}–S bond. It is to be noted that the *trans* geometry of **3** is stable at room temperature, while [*trans*-$Mo(CO)_2(Ph_2PCH_2CH_2PPh_2)_2$] is known to isomerize readily into the *cis* isomer.[17]

$[As_3Br_{12}]^{3-}$ and $[As_8I_{28}]^{4-}$ — Structurally Novel, Discrete Halogenoarsenate(III) Ions

By *William S. Sheldrick** and *Hans-Joachim Häusler*

The trihalides EX_3 of the elements E = P, As, Sb, Bi are capable of adding further halide ions X^- to give a variety of halogeno anions $[EX_{3+n}]^{n-}$ (in mononuclear anions with n = 1, 2, 3, in polynuclear anions with n = 1/4, 1/2, 2/3, 3/2 inter alia). In the case of the intensively studied halogenoantimonate(III) complexes,[1] both discrete anions[2] such as $[Sb_2Cl_9]^{3-}$ or $[Sb_4Cl_{16}]^{4-}$ as well as polymeric anions, for example $[Sb_2F_7^-]_n$ or $[Sb_3I_{10}^-]_n$,[3] are known. Characteristic of the stereochemistry of the individual Sb atoms is an octahedral coordination with three shorter and three considerably longer *trans*-sited (secondary) Sb-X bonds.

In contrast to the halogenoantimonate(III) complexes only a few of the analogous anions of trivalent arsenic have hitherto been characterized.[4] The data available for arsenic(III) indicate a lesser tendency for the coordination number to increase to six, as well as weaker secondary bonding. We now report on the structurally novel, discrete anions $[As_3Br_{12}]^{3-}$ and $[As_8I_{28}]^{4-}$.

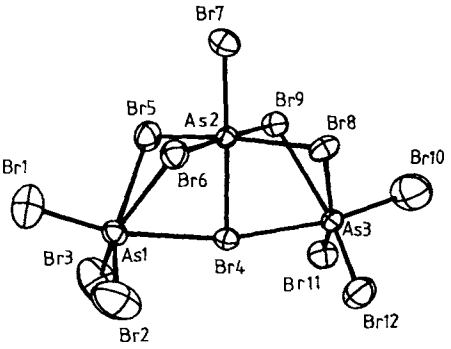

Fig. 1. Crystal structure of the anion of $[Et_3NH]_3[As_3Br_{12}]$. Bond lengths [pm]. As1-Br1 234.9(9), As1-Br2 233.6(9), As1-Br3 230.9(9), As1-Br4 313.8(8), As1-Br5 331.0(7), As1-Br6 312.6(9), As2-Br4 282.3(7), As2-Br5 248.3(7), As2-Br6 271.6(7), As2-Br7 252.2(7), As2-Br8 286.2(6), As2-Br9 258.2(7), As3-Br4 302.2(7), As3-Br8 317.0(7), As3-Br9 335.5(7), As3-Br10 236.1(9), As3-Br11 237.0(8), As3-Br12 236.4(7).

Both anions could be obtained as crystalline triethylammonium salts by cooling equimolar solutions of Et_3NHX and AsX_3 (X = Br, I) in CH_3NO_2 and CH_3CN, respectively.[5] The anion $[As_3Br_{12}]^{3-}$ consists of a central $AsBr_6$ octahedron which is connected via two faces with a common corner to two further $AsBr_6$ octahedra (Fig. 1).[6] The dimensions of the anion also allow the alternative description as a weak complex between a central $[AsBr_6]^{3-}$ ion and two attached $AsBr_3$ molecules. Thus, three very short bonds to terminal Br atoms (range 230.9–237.0 pm) as well as three very long bonds to bridging Br atoms (range 302.2–335.5 pm) are found in each case for the As1 and As3 octahedra. In the central, only slightly distorted As2 octahedron *trans* As-Br bonds expectedly show a characteristic interdependence, yet all bond lengths lie between 248.3 and 286.2 pm. Discrete $[AsX_6]^{3-}$ ions could hitherto not be unequivocally characterized.[4]

According to *Rundle*'s model the bonds of the *trans* X-E-X moieties in halogeno anions $[EX_{3+n}]^{n-}$ can be regarded as electron-rich three-center bonds. A bonding (σ_u^+), through participation of the s-valence orbital, a weak antibonding (σ_g^+), as well as a strongly antibonding (σ_u^+) molecular oribital are formed. The antibonding character of the σ_g^+ orbital can be reduced by asymmetrization of the X-E-X bond (2nd order Jahn-Teller effect); the bonding σ_u^+ interaction is concomitantly weakened. Such an X-E···X asymmetrization should be energetically more favorable for arsenic than for antimony, since an increasing relative s-participation at the σ_g^+ orbital with decreasing atomic number is to be expected for elements of the fifth main group of the Periodic System. However, the non-bonding electron pair does not seem to be stereochemically effective for the central $AsBr_6$ octahedron in the anion $[As_3Br_{12}]^{3-}$, as also in the known anion $[SbCl_6]^{3-}$.[7] All Br-As-Br angles for As2 lie between 87.1 and 93.8°, all angles between the three longer As-Br distances being smaller than 90°.

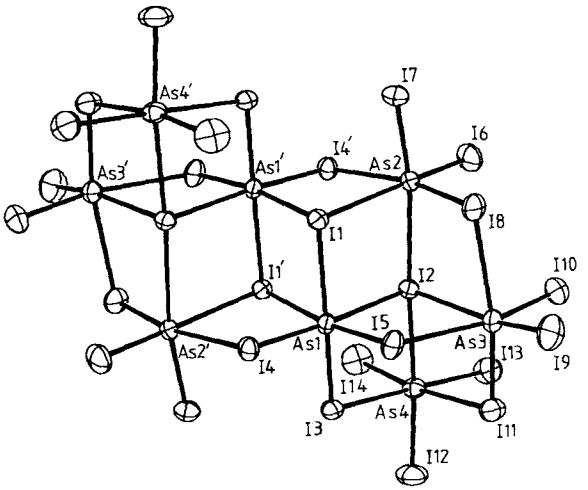

Fig. 2. Crystal structure of the anion of $[Et_3NH]_4[As_8I_{28}]$. Bond lengths [pm]. As1-I1 307.4(2), As1-I1' 306.8(2), As1-I2 316.3(2), As1-I3 272.3(2), As1-I4 269.0(2), As1-I5 273.6(2), As2-I1 320.4(2), As2-I2 334.9(2), As2-I4' 330.1(2), As2-I6 264.2(2), As2-I7 260.6(2), As2-I8 264.0(2), As3-I2 318.2(2), As3-I5 338.8(2), As3-I8 339.6(2), As3-I9 264.8(2), As3-I10 261.3(2), As3-I11 261.9(2), As4-I2 326.0(2), As4-I3 326.4(2), As4-I11 350.7(2), As4-I12 262.7(2), As4-I13 264.4(2), As4-I14 257.8(2).

The surprisingly large centrosymmetric anion $[As_8I_{28}]^{4-}$, which consists of eight edge-bridged AsI_6 octahedra, displays a close relationship with the recently characterized polymeric anion $[Sb_3I_{\bar{10}}]_n$.[3b] Both anions contain centrosymmetric E_6I_{22} units (the octahedra around As1-As3 and As1'-As3' in Fig. 2). In the $[Sb_3I_{\bar{10}}]_n$ anion (Fig. 3) the I atoms I9 and I10 are also related with each other by a symmetry center and thus bridge $[Sb_6I_{20}]^{2-}$ units to give an infinite chain. In contrast, in the discrete $[As_8I_{28}]^{4-}$ anion two further symmetry related AsI_3 units (octahedra As4 and As4') are attached in an edge-bridging fashion. The As-I distances to the μ_3- and μ_4-bridging I atoms I1 and I2 lie between 306.8 and 334.9 pm, whereas the individual As atoms each show three short As-I bonds in the range between 357.8 and 373.6 pm. The recently characterized $[As_8Cl_{28}]^{4-}$ has a completely different structure:[4g] four $AsCl_3$ molecules are very loosely attached to a central $[As_4Cl_{16}]^{4-}$ unit with cubane-like structure.

The common building principle in $[As_8I_{28}]^{4-}$ and $[Sb_3I_{\bar{10}}]_n$ would indicate that other, similarly built iodoar-

High-Pressure Synthesis and Crystal Structure of Neodymium(III) Oxide Peroxide, $Nd_2O_2(O_2)$**

By *Klaus-Jürgen Range,* Maximilian Stadler, Franz Rau,* and *Ulrich Klement*

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

Although the spectroscopically determined trend of the fourth ionization energies I_4[1a,b] in the lanthanoid series[1a,b] and the standard electrode potentials for the transition Ln^{III}-Ln^{IV} would make the existence of neodymium(IV) oxides appear possible, at least in the absence of water, all attempts to prepare binary neodymium-oxygen compounds with $O:Nd > 1.5:1$ have so far failed.[2] The stable oxide Nd_2O_3 is neither oxidized further by atomic oxygen[3] nor by $NaBrO_4$ or XeF_2.[4] In contrast, the stabilization of Nd^{IV} is possible by partial incorporation in perowskite host lattices such as $BaCeO_3$, $BaPrO_3$, $BaThO_3$, and $BaZrO_3$.[5] In (so far unsuccessful) attempts to prepare pure $BaNdO_3$ we have now obtained a compound of empirical composition NdO_2, which, however, according to the result of a structural analysis, is not a neodymium(IV) dioxide but a neodymium(III) oxide peroxide.

Nd_2O_3/BaO_2 mixtures react under high pressure/high temperature conditions only incompletely to give $Ba_2Nd_2O_5$. The formation of $Nd_2O_2(O_2)$ was first observed in the reaction of Nd_2O_3/BaO_2 mixtures to which KF had been added as flux. After the reaction at 40 kbar and 1500 °C (30 min, modified belt apparatus,[6] Pt crucible) it was found in the form of small, light-blue crystals in a partly white, partly dirty-violet matrix, albeit in a very low yield, which could not be noticeably increased even by drastic variation of the reaction conditions. Following the X-ray spectrographic detection of BaF_2 in the white matrix, it was immediately clear that an oxygen-rich potassium oxide formed from BaO_2 and KF in the melt, and not the relatively unreactive BaO_2, was the actual supplier of oxygen in the formation of $Nd_2O_2(O_2)$. This finding prompted us to react Nd_2O_3 with KO_2. Indeed, in this way it was possible to carry out the complete oxidation of Nd_2O_3 by reaction with KO_2 at 40 kbar and 1500 °C

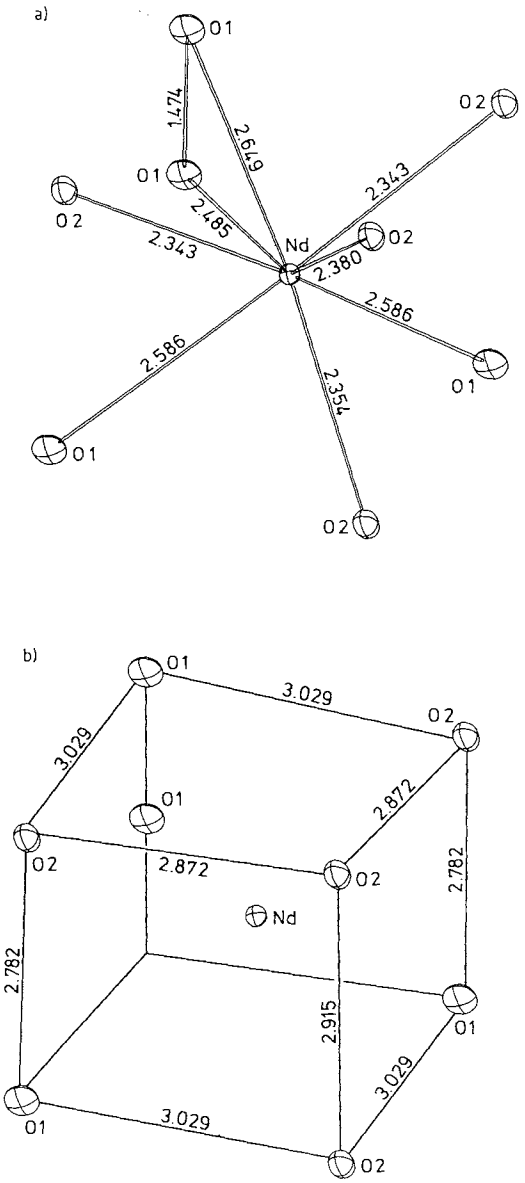

Fig. 1. Section of the crystal structure of $Nd_2O_2(O_2)$. a) Environment of Nd (bond lengths in Å); b) approximate cubic arrangement of O1 and O2 (O1 and O2 signify peroxidic and oxidic O atoms, respectively).

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/1111-1174 $ 02.50/0

(30 min, then finally slow cooling to 1000 °C). $Nd_2O_2(O_2)$, which can be easily isolated from the reaction product by treatment with water, forms pleochroic crystals which appear light blue or violet-pink depending on the direction of the incident light. The empirical composition NdO_2 was confirmed by EDX (Energy-Dispersive X-ray analysis) (no cations except Nd present) and chemical analysis (Nd: found 81.5%, calcd 81.8%). Remarkable is the stability of $Nd_2O_2(O_2)$ toward water and air. Upon heating to 420 °C (O_2 or argon atmosphere, 10 K/min) the compound is converted via elimination of oxygen into Nd_2O_3 (cubic C-form). 2 N H_2SO_4 attacks $Nd_2O_2(O_2)$ very slowly with formation of H_2O_2.

The crystal of $Nd_2O_2(O_2)$[7] contains O^{2-} ions and $(O_2)^{2-}$ ions (O-O distance in O_2^{2-}: 1.474(4) Å). Each neodymium ion is coordinated by four oxide (O2) and four peroxide (1) oxygen atoms (Fig. 1a), the peroxide groups assuming almost side-on positions (distances Nd-O: 2.485(3), 2.649(3) Å) and functioning as bridge ligands to other neodymium ions (Nd-O: $2 \times 2.586(2)$ Å). The distances Nd^{3+}-O^{2-} are significantly shorter ($2 \times 2.343(1)$, 2.354(2), 2.380(3) Å).

Figure 1b illustrates a crystallochemical peculiarity of the structure: seven of the eight oxygen neighbors of a neodymium ion are arranged at the corners of an almost regular cube, only the eighth ligand is shifted from a corner (with formation of the O_2^{2-} ion) in the direction of a cube edge. The close relationship to the fluorite structure, which is to be expected for a hypothetical neodymium(IV) dioxide is immediately apparent. The reduced volume for the latter, extrapolated from the ionic radii for Ce^{4+} and Pr^{4+},[8] is about 9.7% smaller than that of $Nd_2O_2(O_2)$. A conversion of $Nd_2O_2(O_2)$ into NdO_2 under still higher pressures than those used here also seems possible.

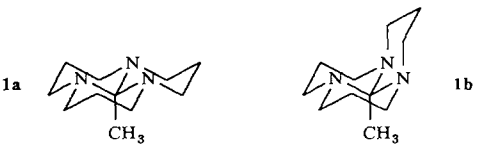
Observation of an Eclipsed C_{sp^3}-CH_3 Bond in a Tricyclic Orthoamide; Experimental and Theoretical Evidence for C–H ··· O Hydrogen Bonds**

By *Paul Seiler, Gary R. Weisman,* Eric D. Glendening, Frank Weinhold,* Van B. Johnson,* and *Jack D. Dunitz**

Although the conformations of many thousands of methyl groups have been determined in crystals by X-ray and neutron diffraction analyses, we do not know of a single example where the eclipsed arrangement has been established for a C_{sp^3}-CH_3 bond (in contrast to XC_{sp^2}-CH_3 bonds, where eclipsing of a C-H bond with the C=X double bond is the rule, as in propene,[1] acetaldehyde,[2] and numerous other examples). We now report the occurrence of a nearly eclipsed methyl group in the tricyclic orthoamide **1a**, as found by low-temperature (81 K) X-ray analysis



of its crystalline trihydrate,[3] where all H positions have been unambiguously determined. The tricyclic orthoamide molecule (Fig. 1) sits on a crystallographic threefold rotation axis and hence has the all-*trans* configuration with the three N lone pairs antiperiplanar (*app*) to C-CH_3 (with C-C bond distance lengthened to 1.561(1) Å). To our surprise, the conformation about this bond is nearly eclipsed, with N-C-C-H torsion angles of 8.0(9)°.

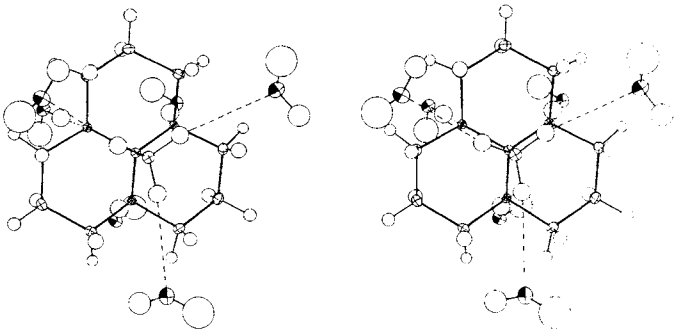


Fig. 1. Stereoview of the tricyclic orthoamide trihydrate in the cubic crystal modification, showing the three water molecules hydrogen-bonded to the nitrogen atoms (below) and the three water molecules hydrogen-bonded to the hydrogen atoms of the methyl group (above, dashed lines). The various atoms are represented by 50% probability ellipsoids (spheres for the hydrogen atoms).

Laube* for his help in obtaining the anhydrous material.

In the crystal structure, each N atom is involved in hydrogen bonding to a water molecule (N···O, 2.855 Å; N···H-O angle, 162°). The water molecules then make additional hydrogen bonds among themselves in such a way that the two triads related by the crystallographic inversion center form a chair-like $(H_2O)_6$ ring with O···O distances of 2.770 Å and O-H···O angles of 171°.[4] On the other side of the tricyclic orthoamide, we find that each C-H bond of the methyl group points nearly at an O atom of a neighboring triad (H···O, 2.67 Å; C-H···O angle, 170°). If the observed C-H distance of 1.00 Å is adjusted to correct for the characteristic X-ray shortening effect, the H···O distance in question decreases by about 0.1 Å. While the corrected distance is still somewhat on the long side for C-H···O hydrogen bonding,[7] the nearly linear angle is highly suggestive. Moreover, while the N-C-C-H torsion angle is 8.0° the N-C-C···O torsion angle is only 0.6°. All these features support the idea that C-H···O hydrogen bonding is largely responsible for the unusual methyl conformation.

In any case, we have good evidence that the nearly eclipsed methyl group is not an intrinsic property of the molecule. On the experimental side, after much effort, a solitary single crystal of the anhydrous material has been secured and its structure determined, also at 81 K.[8] Here the asymmetric crystal unit consists of two independent molecules of the tricyclic orthoamide. One has the same all-*trans* configuration as occurs in the trihydrate; the other has the *cis,cis,trans* configuration **1b** (Figure 2),

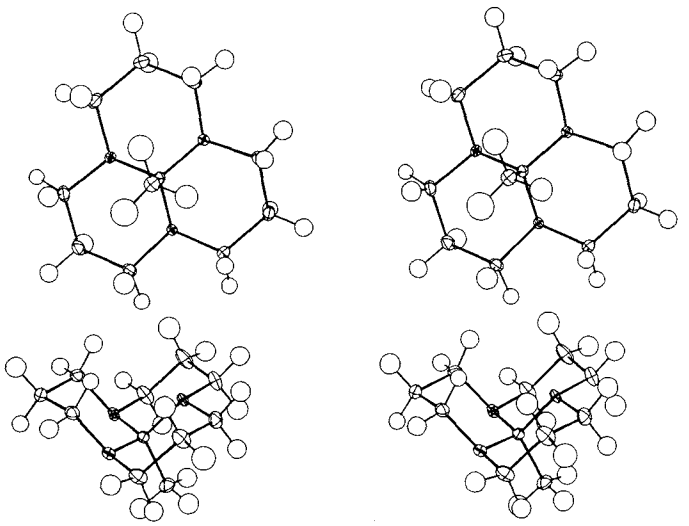

Fig. 2. Stereoview of the two independent cyclic orthoamide molecules **1a** and **1b** in the monoclinic crystal modification. The various atoms are represented by 50% probability ellipsoids (spheres for the hydrogen atoms).

known from NMR evidence[9] to be present in small amounts in dilute solution. In both molecules, the methyl groups are staggered.[10] The C-CH_3 bond distances are 1.555(1) Å in staggered **1a** and 1.539(1) Å in **1b**, both shorter than in eclipsed **1a**. Insofar as hydrogen bonding to the three *app* lone pairs in the trihydrate must surely weaken their stereoelectronic effect on the C-CH_3 bond, the slightly longer bond distance in the trihydrate has to be attributed to the effect of eclipsing.

These unexpected experimental results have prompted us to look into some calculated properties of suitable model systems. Ab initio 6-31G* SCF calculations for model 1,1,1-triaminoethane (N lone pairs *app* to C-C bond, crystal geometrical parameters) show the staggered conformation more stable than the eclipsed by 5.52 kcal mol^{-1}. If the torsion potential is approximated as $V=(V_{max}/2)(1+\cos 3\theta)$ where $V_{max}=5.52$ kcal mol^{-1} and $\theta=8°$, the minimum strength of each of the three C-H···O hydrogen bonds required to produce the eclipsed conformation is ca. 1.8 kcal mol^{-1}, far in excess of the reported $CH_4\cdots OH_2$ interaction strength (ca. 0.5 kcal mol^{-1}) calculated using similar basis sets.[11] Indeed, we calculate at 6-31G* an interaction energy of only −0.63 kcal mol^{-1} for the $CH_4\cdots OH_2$ supermolecule constrained to model the hydrate C-H···O geometry. This failure of the SCF calculations to account for the experimental structure led us to investigate the use of larger basis sets as well as the effect of electron correlation upon the C-H···O hydrogen bond in the $CH_4\cdots OH_2$ system. As can be seen from the results in Table 1, a correlation effect

Table 1. Calculated interaction energies of the $CH_4\cdots OH_2$ complex (kcal mol^{-1}). $E(\text{int})=E(\text{complex})-E(CH_4)-E(H_2O)$.

Basis	SCF	MP2	MP4
6-31G*	−0.634	−1.447	−1.359
6-311G**	−0.936	−1.872	−1.698
6-311G(2d,p)	−0.919	−1.935	−1.726

of unprecedented magnitude for hydrogen bonds significantly enhances the interaction strength (by 0.7–1.0 kcal mol^{-1}) at all levels of calculation. The physical reason for this effect is probably not typical dispersion attraction but rather the generalized contraction of electron density that reduces the effective van der Waals radius of the C-H group, thus allowing the ca. 2 kcal mol^{-1} hyperconjugative n_O-σ^*_{CH} interaction to fully assert itself.[12] We have also investigated the cooperative effect upon C-H···O hydrogen bonding in a model $CH_4\cdots O(H)H\cdots NH_3$ complex. At the MP2/6-31G* level, the C-H···O interaction energy was calculated to be −1.98 kcal mol^{-1}, more than 0.5 kcal mol^{-1} more negative than that of the $CH_4\cdots OH_2$ complex and in the range necessary to reverse the orthoamide methyl rotation barrier. Further extensions of the theoretical model lead to similar net values of C-H···O interaction strength.[13] We believe that the calculational results taken as a whole provide theoretical support for the notion of directed C-H···O hydrogen bonds of sufficient strength to qualitatively account for the anomalous methyl conformation in the orthoamide trihydrate crystal. Furthermore, we believe that the hydrogen bonding and methyl-eclipsing are not significantly dependent on stereoelectronic factors associated with orientation of nitrogen lone pairs (which affect mainly the C-CH_3 bond).

The fact that a suitable arrangement of water molecules can invert the rotation barrier of a methyl group through hydrogen bonding has obvious implications for interaction between "hydrophobic" regions of molecules and aqueous environments. The water molecule arrangements will, in general, be determined by the directional properties of the stronger O-H···O and N-H···O hydrogen bonds. This arrangement, in turn, may affect the conformation of aliphatic chains, etc., through the formation of weaker, but still direction specific, C-H···O hydrogen bonds. Hence, conformational regularities observed for aliphatic portions of molecules in non-aqueous environments may not be ap-

plicable without reservations when the molecules are embedded in a matrix of water molecules.

[10] Preliminary electron-density difference maps for the anhydrous crystal form show small diffuse residual density peaks (0.05–0.10 eÅ^{-3}) close to the positions expected for H atoms in the alternative eclipsed methyl conformation of the all-*trans* molecule. These could arise from the inadequacy of the isotropic temperature factor formalism used for the H atoms in the least-squares refinements.
[11] Several ab initio calculations of the methane-water system agree that C-H ··· O hydrogen bonding is significant but disagree about details. See for example, S. R. Ungemach, H. F. Schaefer III, *J. Amer. Chem. Soc. 96* (1974) 7898; H. Umeyama, K. Morokuma, *J. Am. Chem. Soc. 99* (1977) 1316; P. Ruelle, G. Leroy, G. Louterman-Leloup, *Bull. Soc. Chim. Belg. 87* (1978) 867.
[12] A. E. Reed, F. Weinhold, L. A. Curtiss, D. J. Pochatko, *J. Chem. Phys. 84* (1986) 5687.
[13] Two extensions are particularly important: Inclusions of diffuse ('+') functions reduces the C-H ··· O interaction by about 1 kcal mol^{-1}. Inclusion of higher-order cooperative effects [e.g., in the model complex $H_2NCH_2CH_3 \cdots O(H)H \cdots NH_3$] strengthens the interaction by an approximately compensating amount.
[14] Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52487, the names of the authors, and the journal citation.

Aromatic Nitration at the Encounter Rate in the Gas Phase

By *Marina Attinà,* Fulvio Cacace,* and *Giulia de Petris*

Despite the overwhelming amount of attention devoted to aromatic nitration in condensed media, important mechanistic aspects remain far from defined, largely owing to the complicating effects of the reaction environment, which prevent the construction of a unified mechanistic model.[1] This has stimulated extension of the study to the gas phase, where solvation, ion pairing, viscosity, and other complicating factors are largely absent, and the results are directly comparable with those of theoretical calculations. Recently, an integrated approach based on the combination of mass spectrometry with atmospheric-pressure radiolytic techniques allowed us to characterize reaction (a) as the first nitration by a gaseous cation whose

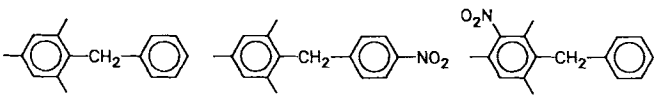
$$[RNO_3H]^{\oplus} + PhX \longrightarrow ROH + [PhXNO_2]^{\oplus} \quad (a)$$
1

substrate and positional selectivity conform to those of electrophilic substitution in solution.[2] A salient anomaly of the preliminary results, confirmed by the present, more detailed study,[3] is the unexpectedly low nitration rate of anisole, PhOMe, comparable to that of toluene, PhMe. It is tempting to ascribe this finding to competitive proton transfer (b) to strongly activated, hence highly basic, sub-

$$\mathbf{1} + PhX \longrightarrow RNO_3 + [PhXH]^{\oplus} \quad (b)$$

strates. This explanation, particularly fit for anisole, which contains an n-type nucleophilic center,[4] is less satisfactory when extended to pure π systems—e.g., polymethylbenzenes—which are characterized, as now we find, by the same behavior (Table 1). Such observations suggest an al-

Table 1. Relative reactivity and isomeric composition of products from the nitration of activated substrates with $[MeNO_3H]^{\oplus}$ and $[CF_3CH_2NO_3H]^{\oplus}$ ions in methane at 37.5 °C, 720 torr [a].



2 **3** **4**

		ortho	*meta*	*para*
Anisole [3]	7.6	41	–	57
Toluene [3]	5.1 (2.1)	59(50)	7(15)	34(35)
Diphenylmethane	5.7	41	4	55
Mesitylene	8.1			
Isodurene	7.7 (2.2)			
Pentamethylbenzene	7.8			
Benylmesitylene **2**	8 (2.4)	**3** < 5(8)	**4** > 95(92)	

[a] Values in parentheses refer to nitration by $[CF_3CH_2NO_3H]^{\oplus}$. Standard deviation of the data ca. 10%, except in the case of **2**, whose extremely low vapor pressure prevents accurate concentration measurements.

ternative explanation: namely, above a certain activation level all substrates undergo nitration at the encounter rate, kinetically controlled by the formation of an "early" ion-molecule complex [Eq. (c)].

$$\mathbf{1} + PhX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{early complex} \xrightarrow{k_2} \sigma \text{ complexes} \quad (c)$$

A decision between alternatives (b) and (c) cannot be made simply on the grounds that increasingly activated arenes, from toluene to pentamethylbenzene, are nitrated at comparable rates (Table 1), since the trend fits both hypotheses.

Crucial evidence was sought via a different approach, based on nitration of a suitable model molecule, benzylmesitylene **2**, where the activation of the aromatic rings is considerably different, roughly corresponding to that of toluene and isodurene (1,2,3,5-tetramethylbenzene), respectively. If the nitration rate is actually limited by incursion of process (b), one would expect a low isodurene/toluene intermolecular selectivity, and a correspondingly low intramolecular selectivity in the nitration of **2**, since the nitration rate of the more basic isodurene moiety should be limited by process (b) in both systems. On the other hand, if a limiting nitration rate is established by the kine-

tically determining formation of an early complex [Eq. (c)], a low isodurene/toluene intermolecular selectivity should be contrasted by the retention of intramolecular selectivity in the nitration of **2**. The latter has been studied, as in the case of the other substrates, by chemical ionization (CI) mass spectrometry (in CH_4, 0.5 torr, 160 °C) and by a radiolytic technique[5] (in CH_4, 720 torr, 37.5 °C). The nitrating reactant **1** (R=Me, CF_3CH_2) has been obtained in both cases by protonation of the corresponding alkyl nitrate with the $C_nH_5^{\oplus}$ (n=1,2) ions from the ionization of CH_4. The CI spectra reveal formation of the expected $[Arene\cdots NO_2]^{\oplus}$ adducts, of unknown structure. The radiolytic results provide clear-cut evidence for the rate-limiting formation of an early adduct [Eq. (c)] since the $k_{isodurene}:k_{toluene}$ ratio is as low as 1.5, while the intramolecular selectivity in the nitration of **2** is much higher, the activated ring reacting at least 20 times faster than the unsubstituted one, despite the unfavorable (2:5) statistical factor. Nor can such a result be traced to isomerization of primary arenium ions, i.e., to the energetically favored intramolecular migration of $NO_2^{\oplus}$ to the more activated ring. Convincing evidence against such a process is provided by control experiments based on metastable-ion kinetic energy (MIKE) and collisionally induced dissociation (CID) spectrometry of suitable model ions.[6]

In conclusion, the results show that in the nitration of sufficiently activated substrates by gaseous $[RNO_3H]^{\oplus}$ ions the rate-determining and the product-controlling steps are kinetically distinct, according to the scheme outlined in Equation (c).

Whenever k_2 exceeds k_{-1} (i.e., the activation barrier to Wheland intermediates is *lower* than that to dissociation of the complex), nitration occurs at the encounter rate and substrate selectivity is lost. Such a state of affairs is analogous to that prevailing in solution, where the reactants are confined within a solvent cage, forming an "encounter pair" whose separation requires overcoming a viscosity barrier. In the gas phase, formation of the early complex can be traced to the intense electrostatic forces between the free nitrating cation and the aromatic molecule.[7] In a dense gas (e.g., in CH_4 at 720 torr), the energy released in the formation of the complex is rapidly removed by thermalyzing collisions, and the reactants are trapped in a sort of "electrostatic cage," kinetically, if not physically, equivalent to the viscosity cage envisaged in solution.[8]

Experimental Procedure

CH_4 (720 torr), RNO_3 (5–10 torr), and the aromatic substrates (0.1–1 torr) were irradiated in a 220 Gammacell (Nuclear Canada Ltd.) to a dose of 2×10^3 Gy in the presence of O_2 (10 torr) and SF_6 (5 torr), the products being analyzed by GLC and GLC/MS. The ionic nature of the nitration is demonstrated by the negligible yields of nitrated products from irradiations where CH_4 was replaced by isobutane, whose $tBu^{\oplus}$ ions are unable to protonate RNO_3, and by the depression of the yields caused by the presence of ionic interceptors, such as NMe_3, apart from the direct observation of the charged intermediates by CIMS.

The CID experiments were carried out in a ZAB-2F mass spectrometer (VG Micromass Ltd.), whose source was operated in the CI mode, using He as the collision gas.

[1] K. Schofield: *Aromatic Nitration*, University Press, Cambridge 1980 and references cited therein.

[2] a) M. Attinà, F. Cacace, M. Yañez, *J. Am. Chem. Soc. 109* (1987) 5092; b) M. Attinà, F. Cacace, *ibid. 108* (1986) 318. Previous low-pressure mass spectrometric results where hardly consistent with solution-chemistry trends, e.g., pointing to the lack of nitrating ability of $NO_2^{\oplus}$ (S. A. Benezra, M. K. Hoffman, M. M. Bursey, *J. Am. Chem. Soc. 92* (1970) 7501) and to anomalous activating effects of substituents (P. Ausloos, S. G. Lias, *Int. J. Chem. Kinet. 10* (1978) 657).

[3] The irradiation conditions and the analytical techniques have considerably been improved over those reported in Ref. [2]. A sixfold decrease of the dose, aimed at evaluating *initial* nitration rates, and use of SF_6 as a thermal-electron scavenger have provided more accurate selectivity data for activated substrates and a significant decrease of the standard deviation. The changes, concerning in particular the k_A/k_{PhH} ratio for A=toluene and anisole (2.9 and 3.2 [2b]), do not significantly affect the overall selectivity pattern, nor the conclusions from this study.

[4] Most exothermic proton-transfer reactions between n-type nucleophilic centers occur at a collisional rate in the gas phase, T. Su, M. T. Bowers in M. T. Bowers (Ed.): *Gas Phase Ion Chemistry, Vol. 2*, Academic Press, New York 1979, p. 83.

[5] For a recent survey of the integrated mass spectrometric-radiolytic approach, see F. Cacace in P. Ausloos, S. G. Lias (Eds.): *Structure/Reactivity and Thermochemistry of Ions*, Reidel, Dordrecht 1987, p. 467.

[6] a) MIKE = metastable-ion kinetic energy; CID = collisionally induced dissociation; b) Protonated (*p*-nitrobenzyl)mesitylene **3** and protonated benzylnitromesitylene **4** obtained from the corresponding neutral precursors under methane-CI conditions give different MIKE and CID spectra. The fragment at *m/z* 133 (loss of $C_6H_5NO_2$) is detectable only in the MIKE and CID spectra of **3**, and that at *m/z* 178 (loss of C_6H_6) is significant only in the spectra of **4**. Furthermore, the fragments at *m/z* 119 and 241 are present only in the spectra of **3**, and those at *m/z* 160 and 226 in the spectra of **4**. Such conspicuous differences show that **3** fails to rearrange to **4**, despite conditions highly favorable to intramolecular isomerization, including the high exothermicity of the formation process, the high temperature (180 °C), the low pressure (0.5 torr), and the long delay (10^{-5} s) before structural assay.

[7] The stabilization energy of ion-molecule electrostatic complexes are of the order of 10 kcal mol^{-1}, or higher: a) D. K. Sen Sharma, P. Kebarle, *J. Am. Chem. Soc. 104* (1982) 19; b) P. Politzer, K. Jaysauriya, P. Sjoberg, P. R. Laurence, *ibid. 107* (1985) 1174; c) W. Bäther, H.-F. Grützmacher, *Int. J. Mass Spectrom. Ion Processes 64* (1985) 193.

[8] A reaction environment consisting of an inert gas at sufficiently high pressure, e.g., CH_4 at 720 torr, is essential for meaningful comparison with condensed-phase kinetics. At the low pressures typical of mass spectrometric approaches, the energy released in the formation of the ion-molecule complex, unaffected by thermalyzing collisions, often allows the reactants to overcome the barrier to products. This explains the apparent lack of activation energy and the negative temperature coefficient of many exothermic ion-molecule reactions in the low-pressure domain.

Photo- and Thermochromic Liquid Crystal Polysiloxanes**

By *Ivan Cabrera, Valeri Krongauz,** and *Helmut Ringsdorf**

Dedicated to Professor Ernst Fischer on the occasion of his 65th birthday

The combination of photochromic and liquid crystalline properties in one molecule might lead to an unusually versatile material for practical applications.[1] The attempts to synthesize such materials failed because the combination of photochromic and mesogenic moieties in one molecule led to impairment of one or both of the properties.[2,3]

Earlier[3–5] we reported "hybrid" low-molar-mass molecules containing spiropyran and mesogenic groups. The molecules are thermochromic and give a very peculiar metastable mesophase (we named them quasi-liquid crystals). However, they do not exhibit photochromism.

Recently we reported[6] structural transformations occurring in side-chain liquid crystal polyacrylates containing spiropyran side groups. The polymers were synthesized by copolymerization of vinyl monomers with spiropyran and

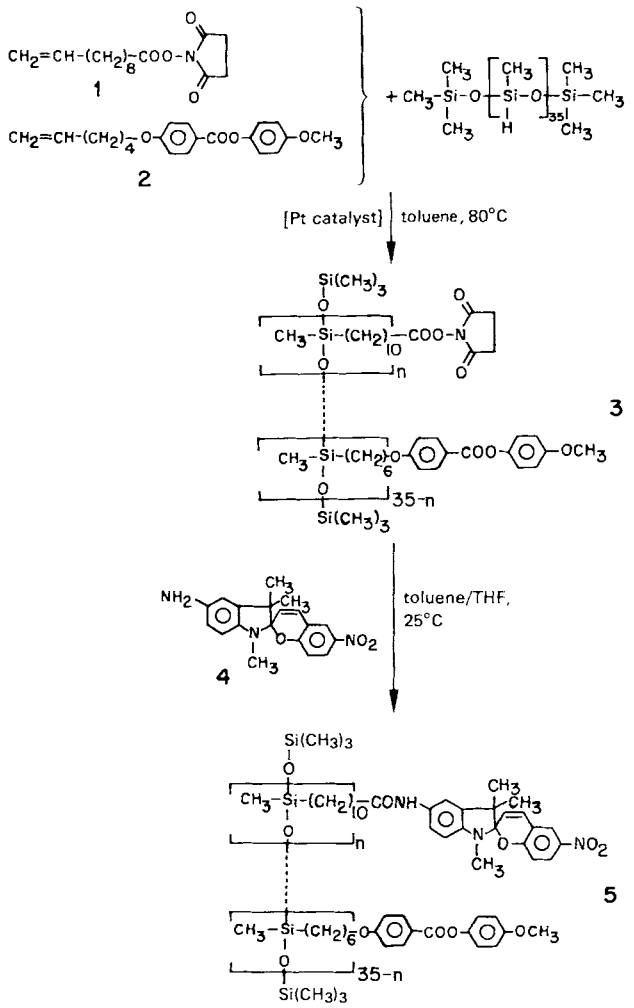
p-cyanophenylbenzoate groups. The thermochromic spiropyran-to-merocyanine dye conversion occurs on heating of the copolymers. The mesophase could be observed in the copolymers containing more than 20 mol% of spiropyran side groups. Cross-linking of the macromolecules due to aggregation of the dye moieties gives rise to formation of a network, which is responsible for the appearance of a new rheo-optical effect: strong dynamic birefringence, observed above the clearing point.



Scheme 1. Synthesis of photochromic polysiloxanes. 5'-amino-1',3',3'-trimethyl-6-nitro-2',3'-dihydrospiro[2*H*-chromen-2,2'-indene] **4** was synthesized according to Ref. [12]. 4-Methoxyphenyl-[4-(5-hexenyloxy)benzoate] ester **2** was prepared by standard methods published in the literature [8]. The *N*-hydroxysuccinimide ester of 10-undecenoic acid **1** was synthesized by the direct esterification of the acid with *N*-hydroxysuccinimide [13]. The product was purified by recrystallization from *n*-hexane (yield 72%, m.p. = 53–55 °C). All compounds were characterized by elemental analysis, ^{1}H-NMR, and mass spectrometry. The copolymers **3** were prepared by addition of the olefins **1** and **2** to polysiloxanes containing SiH groups [7, 8]. The copolymers with spiropyran groups, **5**, were obtained by reacting in situ the copolymers **3** with **4** at room temperature in toluene/THF. The polymers were isolated by preparative gel permeation or by repeated precipitation with methanol (yields 60–70%). The composition of the copolymers was determined by elemental analysis.

Here we report for the first time the photochromic behavior of similar hybrid materials, obtained by the synthesis of liquid crystal polysiloxanes containing spiropyran groups. Since the many organic functions of the spiropyran groups interfere in the hydrosilylation reaction by which the liquid crystal polysiloxanes are usually prepared,[7, 8] the spiropyran-containing polymers were synthesized via the active ester copolymers (Scheme 1). The synthesis through the active ester copolymers can be used in general as a way of preparing polyfunctional liquid crystal polysiloxanes. The phenylbenzoate copolymers with the spiropyran side chains give a mesophase whose clearing temperature decreases with increasing spiropyran content. The phase diagram is given in Figure 1.

The copolymer films cast from solution acquire a pink color at room temperature and exhibit strong birefringence. Irradiation with visible light ($\lambda > 500$ nm) brings about a pale yellow color (Fig. 2a, b), while irradiation of

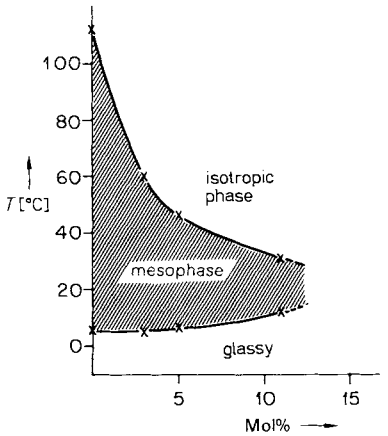


Fig. 1. Phase diagram of the polysiloxanes containing spiropyran. The composition of the copolymers is given as mol% of spiropyran groups.

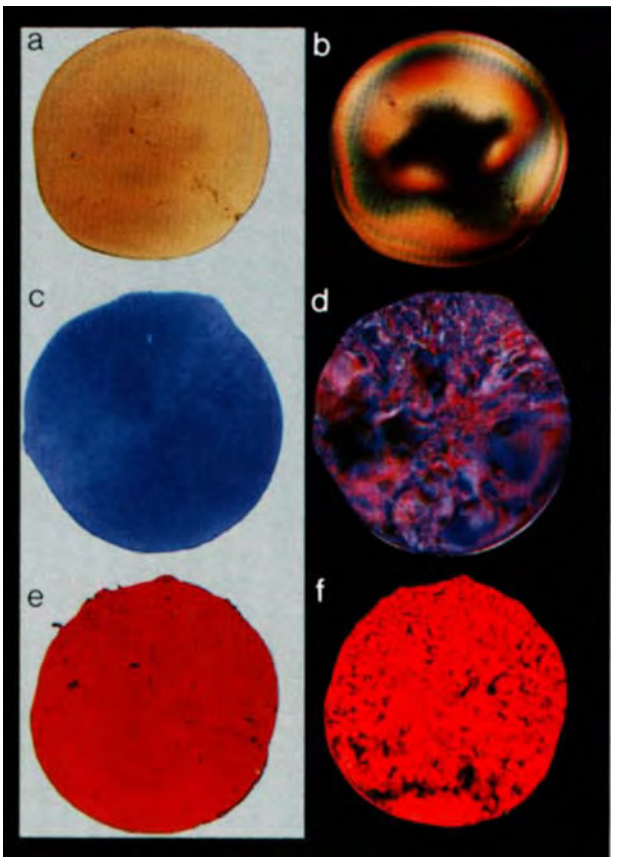

Fig. 2. Photocolored films of the copolymer with 11 mol% of spiropyran units observed without (a,c, e) and between (b, d, f) crossed polarizers (x18). a, b) After irradiation with visible light (> 500 nm) at 25 °C. c, d) After UV irradiation (365 nm) at −20 °C. e, f) After UV irradiation at 25 °C.

the yellow film with UV light ($\lambda = 365$ nm) results in a deep red color (Fig. 2e, f). A yellow film irradiated with UV light at $-20\,^{\circ}C$ turns blue (Fig. 2c, d), and can be converted back to yellow by irradiation with visible light. The blue film is stable in the dark at $-20\,^{\circ}C$ but turns red on heating above $-10\,^{\circ}C$. The red film is thermally stable below the glass transition temperature (see Fig. 1), but turns yellow on irradiation with visible light. Below $-10\,^{\circ}C$, however, the red film is not affected by irradiation with visible light. At room temperature the fading of the red color takes several days, but less than a minute above the clearing point.

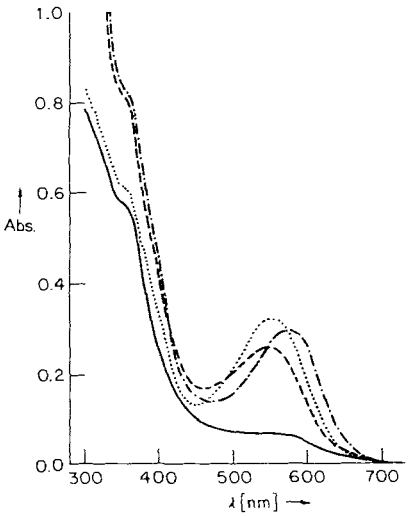

Fig. 3. Absorption spectra of films of the copolymer with 11 mol% of spiropyran units: (——) yellow film at 25 °C; (· · ·) red film at 25 °C; (— · —) blue film at −20 °C; (- - -) red film obtained by heating the blue film to 25 °C. Abs, absorption in arbitrary units.

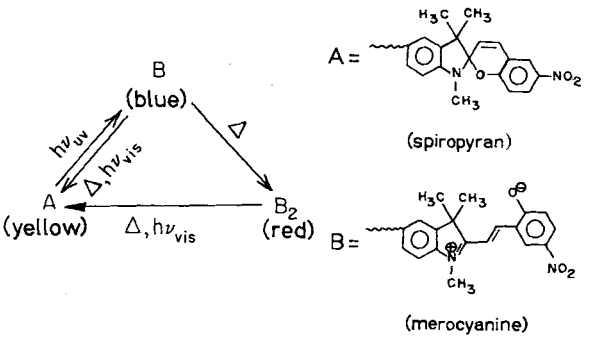
The electronic absorption spectra of the polymer films are shown in Figure 3. The maximum at 550 nm (red) corresponds to aggregated merocyanines, which cause physical cross-linking of the macromolecules, while the maximum at 580 nm (blue) has been ascribed to isolated merocyanine groups.[6,9] The yellow color ($\lambda_{max} \approx 370$ nm) corresponds to the spiropyran absorption (Scheme 2).



Scheme 2. Scheme for the conversion of the photochromic side groups.

Apparently at temperatures below $-10\,^{\circ}C$ the side chains are immobilized[10] and neither thermal dimerization of the merocyanine groups nor photochemical dissociation of their dimers occurs under these conditions.

The possibility of controlling with light and temperature the formation of the three primary colors may make it possible to tailor these liquid crystal polymers for new applications in imaging technologies.[11]

Structure and Color of Pentaphenylbismuth**

By *Arno Schmuck, Jürgen Buschmann, Joachim Fuchs,* and *Konrad Seppelt**

The pentaphenyl compounds of phosphorus, arsenic, antimony, and bismuth synthesized in quick succession by *Wittig* et al,[1] $P(C_6H_5)_5$, $As(C_6H_5)_5$, and $Sb(C_6H_5)_5$, whose crystal and molecular structures have in the meantime been characterized, are colorless, stable solids at room temperature. The phenyl groups of $P(C_6H_5)_5$ and $As(C_6H_5)_5$ in the crystalline state are almost ideally oriented towards the corners of a trigonal bipyramid with longer axial element-C bonds,[2] whereas the geometry of the $Sb(C_6H_5)_5$ molecule very much resembles a square pyramid with a particularly short axial Sb-C bond.[3] In contrast, $Bi(C_6H_5)_5$ is violet colored; because of its sensitivity to light, heat, and moisture, however, its crystal and molecular structures have thus far not been determined. The color is very unusual for a compound of a main-group element in its highest valence state and this prompted us to examine it in more detail.

We established that the violet color of $Bi(C_6H_5)_5$ is almost the same in the dissolved state as in the solid state and cannot be attributed to paramagnetism or impurities. The color is due to a weak, broad absorption in the green-yellow region ($\lambda_{max} = 532$ nm, $\log \varepsilon = 2.4$).

Blue needle-shaped crystals containing THF separate out from dilute THF solutions of $Bi(C_6H_5)_5$ at $-25\,^{\circ}C$; on warming to room temperature, however, they rapidly lose THF. Solvate-free $Bi(C_6H_5)_5$ can be isolated in the form of large, rhombic, violet crystals from concentrated THF solutions. Figure 1 shows the molecular structure of $Bi(C_6H_5)_5$ in the crystal at $-96\,^{\circ}C$. It can be seen that $Bi(C_6H_5)_5$ and $Sb(C_6H_5)_5$ have very similar triclinic unit cells ($P\bar{1}$, $Z = 2$). $P(C_6H_5)_5$ and $As(C_6H_5)_5$ also have similar unit cells;[2] they are monoclinic.

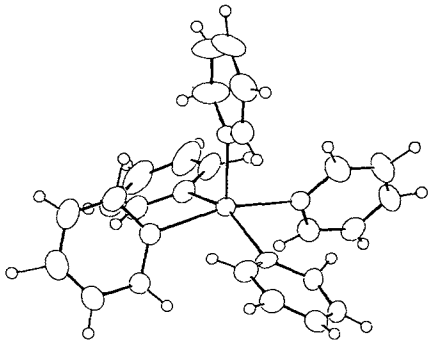

Fig. 1. Crystal structure of $Bi(C_6H_5)_5$ at $-96\,^{\circ}C$ [10]. Vibrational ellipsoids at the 50% probability level. Hydrogen atoms located by difference Fourier analysis. Bi-C_a: 222.1(9), Bi-C_e: 232.9, 232.4, 232.7, 232.2 (9–11) pm; C_a-Bi-C_e: 100.1, 96.4, 103.8, 105.9(4)°; C_e-Bi-C_e: adjacent C_e: 88.1, 87.3, 88.3, 87.8; opposite C_e: 163.5, 150.3(4)°. $P\bar{1}$, $a = 1020.2(2)$, $b = 1064.1(3)$, $c = 1352.5(5)$ pm, $\alpha = 67.54(3)$, $\beta = 78.19(3)$, $\gamma = 62.16(2)°$, $Z = 2$, $V = 1199 \times 10^6$ pm^3. 4650 reflections, 4225 observed with $I > 2\sigma(I)$, $R = R_w = 0.039$, after numerical absorption correction $R = R_w = 0.38$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52633, the names of the authors, and the journal citation.

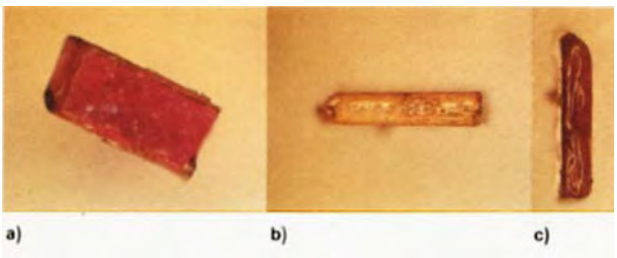

Fig. 2. A $1 \times 0.5 \times 0.2$ mm^3 crystal of $Bi(p\text{-}CH_3C_6H_4)_3(p\text{-}CH_3C_6H_4)_2$, which shows the optical phenoma described in the text better than the multifaceted $Bi(C_6H_5)_5$ crystals. Because of twinning, the exact structure of this compound is not known. a) Large face of crystal; b) same crystal seen from the edge; c) as b) but crystal rotated 90° against the plane of polarization of light. The increasing diffuseness of the surface is real and a result of hydrolytic decomposition within a period of ca. 20 min.

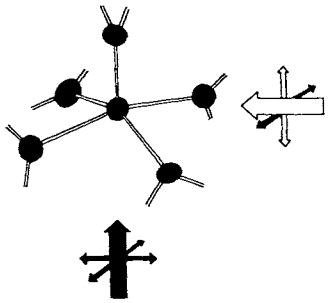

Fig. 3. Optical behavior of a $Bi(C_6H_5)_5$ crystal relative to the molecular orientation. The large arrows indicate the direction of light, the small arrows the vibration plane of the electric vector. Bold arrows: absorption; open arrows: no absorption. It can be seen that a beam of light is polarized after passing parallel to the basal plane of the square pyramid.

$Bi(C_6H_5)_5$ crystallizes in molecules—there is but little evidence of intermolecular interactions. The molecule has an almost regular square pyramidal geometry. The angles between opposite equatorial phenyl groups (163.5 and 150.3°) are quite similar, but deviate markedly from those of an ideal trigonal pyramid (120 and 180°). The four equatorial bonds are significantly longer (232 pm) than the axial bond (221 pm). The four equatorial phenyl groups are oriented propeller-like, that is equidirectionally *twisted*. The structure of $Sb(C_6H_5)_5$ is exactly the same,[3] yet it is colorless! After it had been established that the colorless $Sb(p\text{-}CH_3C_6H_4)_5$ has a trigonal-pyramidal structure[4] it was concluded beyond doubt that the different structures are to be attributed to a slightly different distribution of intermolecular forces in the crystal. In any case, the knowledge of the structure gives no indication of the origin of the color. Even the positions of the hydrogen atoms are completely normal (no agostic H atoms).

We came nearer to solving the color problem when a violet/colorless dichroism was observed with well-formed crystals. Despite the multifacetted surface of the crystals and the triclinic crystal system, we were able to study the phenomenon. Maximum absorption was found in the direction parallel to the axial Bi–C bond and maximum transmission in the plane perpendicular thereto. Light is apparently transmitted unhindered through the crystal in this plane; however, it is strongly polarized; when the electric vector vibrates parallel to this plane, the crystal appears violet, when perpendicular the crystal again appears colorless (see Fig. 2). In this orientation such a crystal is a very effective polarization filter! Since the electric vector always vibrates in the basal plane of the square pyramid in the case of absorption, it must be the excitation of the four long equatorial Bi–C bonds that causes the absorption (see Fig. 3).

So far, the nature of the chromophore is still a matter of speculation: We propose a charge-transfer transition from the phenyl ligand to the bismuth. The pentavalent state is energetically much more unfavorable in the case of bismuth than in the case of antimony, because of poorer shielding of the nucleus by the filled 4f shell (lanthanoid contraction), i.e. bismuth is strongly electronegative in this state. The long bonds are strongly polarized to the bismuth and hence closely approach the excited charge-transfer state:

$$(C_6H_5)_4\overset{\delta^{\ominus}}{Bi}\text{-}\overset{\delta^{\oplus}}{C_6H_5} \longrightarrow (C_6H_5)_4Bi^{\ominus}C_6H_5^{\oplus}$$

Model calculations with inclusion of relativistic effects could confirm both this and the difference from the bonding in $Sb(C_6H_5)_5$. Interestingly, $Bi(C_6H_5)_5$ can be used as an arylating reagent. Acidic hydrogen atoms are thereby replaced by phenyl groups.[5,6] The mechanism of this reaction is presumably not a radical one, but rather an aryl cation has been assumed to be involved in the transition state.[5] It is also remarkable that $Bi(C_6H_5)_5$ produces significant amounts of benzene on heating, whereas $Sb(C_6H_5)_5$ cleaves off only diphenyl.[1] This also indicates a heterolytic Bi–C bond fission.

Since the color of $Bi(C_6H_5)_5$ is in no way connected with the aggregate state, and since the molecule is certainly not rigid in solution and thus present in several different structures, one can predict that trigonal bipyramidal pentaarylbismuth compounds should also be colored. Structural investigations of this kind have hitherto not been described, but $Bi(C_6H_5)_3(p\text{-}ClC_6H_4)_2$[7] and $Bi(p\text{-}CH_3C_6H_4)_5$[8] are likewise violet. Strong electron-withdrawing groups on the ligand should render the charge-transfer transition more difficult. Consistent with this hypothesis, $Bi(C_6H_5)_3(C_6F_5)_2$[9] and $Bi(C_{12}H_8)(C_6H_5)_3$[7] are yellow to orange.

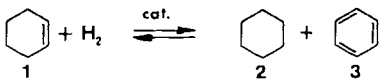
Catalytic Dehydrogenation of Cyclohexene on Silica Overlayer Films**

By *Jeffrey M. Cogen, Khosro Ezaz-Nikpay, Ronald H. Fleming, Scott M. Baumann,* and *Wilhelm F. Maier**

Heterogeneous dehydrogenation of cyclohexene **1** to benzene **3** has received attention as a model reaction for dehydrogenation processes.[1] This reaction is not stoichiometric (see temperature dependence of the product distribution in Fig. 3) and requires the presence of dihydrogen.



The reaction is not only catalyzed by noble metals, but also by spillover hydrogen[2] as well as on carbonaceous overlayers on Pt.[3,4] Chemically bound hydrogen atoms on Te were proposed as active sites for cyclohexene dehydrogenation in Te-NaX zeolites.[5] The reaction also occurs on gold covered Pt[6] and may be due to active spillover hydrogen on the Au surface.[7] These studies indicate that an exposed transition metal surface may not be necessary to catalyze this reaction.

To test the importance of an exposed transition metal surface the catalytic properties of Pt films supported on Si wafers with and without silica overlayers were compared (see Fig. 1). It was hoped that dihydrogen would diffuse readily through the overlayer to become activated (dissociated) at the underlayer. This activated hydrogen could then migrate back to the oxide surface and was expected to exhibit catalytic reactivity different from that of the exposed transition metal surface.

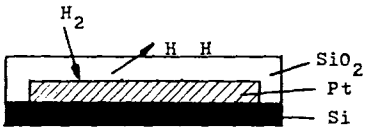


Fig. 1. Schematic representation of the overlayer catalysts.

The film catalysts were prepared by deposition of 10 ± 1.5 nm of Pt by electron beam evaporation at 10^{-7} torr onto polished silicon single-crystal wafers. Overlayers were deposited at a rate of 30–40 nm/min by electron beam evaporation of SiO_2 (from quartz) and the thickness was followed by a quartz crystal thickness monitor. The films were then transferred to a gas-phase flow reactor to test the catalytic activity at atmospheric pressure with dihydrogen or dideuterium as carrier gas. These SiO_2/Pt/Si films catalyze the hydrogenation and dehydrogenation of cyclohexene, while in control experiments SiO_2/Si proved to be catalytically inert.

The effect of the silica overlayer thickness on the rate of conversion of **1** to **2** and **3** at 250 °C was studied for SiO_2/Pt/Si.[8] The reaction rate per unit of geometric surface area drops exponentially with increasing overlayer thickness up to about 30 nm after which the rate stabilizes at about 1/100 (3 orders of magnitude above the background) of the activity of exposed metal and becomes nearly independent of thickness (overlayer thicknesses up to 2200 nm were investigated). During this study we noted that the activity decreases with decreasing deposition rate of the SiO_2 overlayer. Annealing of the overlayer catalyst prior to the reaction also results in a reduction of activity. These data suggest that catalytic activity requires defects in the overlayer film which can serve as carriers of the dissociated hydrogen and/or dihydrogen.

To exclude edge effects the Pt was deposited through a window leaving an outer frame (2 mm) of uncovered silicon so that the subsequent SiO_2 deposition completely covered the edges of the Pt film. On such films the masked (Pt-free) area showed no catalytic activity providing evidence against lateral Pt diffusion. As expected from the low concentration (based on simple geometrical estimates) of exposed edge platinum on unmasked films there was no detectable difference in the activity of masked and unmasked overlayer films. Scanning electron microscopy (SEM) of new and used overlayer catalysts gave no evidence for cracks or pores in the overlayer. Subsequent deposition of silica or gold onto used overlayer films (to fill any cracks or pores) did not decrease catalytic activity. Relative rates of deuteriation of *n*-hexane and *n*-octane (first order in hydrocarbon) on overlayer catalysts correlate with boiling point (as with Pt[9]) and not with hydrocarbon diffusion rates. These experiments are evidence against cracks or pores as carriers of catalytic activity.

The dependence of catalytic activity on SiO_2 overlayer thickness is most likely due to hydrogen recombination processes. However, due to analytical limitations we can not rule out partial accessibility of the Pt films with thin silica overlayers. For this reason subsequent experiments were conducted on thicker (>60 nm) SiO_2 overlayers for which possible exposure of Pt could be addressed.

Auger electron spectra (AES) and thickness profiles of such films are very clean and no transition metal diffusion into the overlayer or to the surface has been detected.[10]

However, the rather low sensitivity of AES (about 0.5% for Pt) is not suitable for trace analysis. The most sensitive method for trace analysis of such layered thin films is secondary ion mass spectrometry (SIMS, sensitivity limit <0.0005 atom-% for Pt),[11] which was used to analyze representative thin film catalysts before and after use. Rutherford back scattering spectrometry (RBS, sensitivity limit ≈ 0.005 atom-% for Pt)[12] was also used for chemical analysis and thickness measurements of the overlayer films. SIMS depth-profiling is based on sputtering which leads to unavoidable tailing of one layer into the next, while RBS is nondestructive and provides a much better depth resolution and accuracy. The RBS data confirmed film thicknesses in all cases. RBS and SIMS (see Figure 2) gave no evidence for Pt at or near the oxide surface. The RBS profiles show that the thickness of the films is homogeneous and that the surface of the SiO_2 is continuous and not rough. Although very close to exact stoichiometry, a slight oxygen deficiency in the silica overlayer was sometimes noted by RBS (33–36% Si : 67–64% O). Catalytic activity due to platinum on the silica surface at concentrations below the detection limit of our analytical techniques ($\approx 10^8$ Pt atoms/cm^2) was excluded by the lack of activity after impregnation and activation of SiO_2/Si films with readily detectable Pt concentrations of 10^8–10^{14} Pt/cm^2.[13]

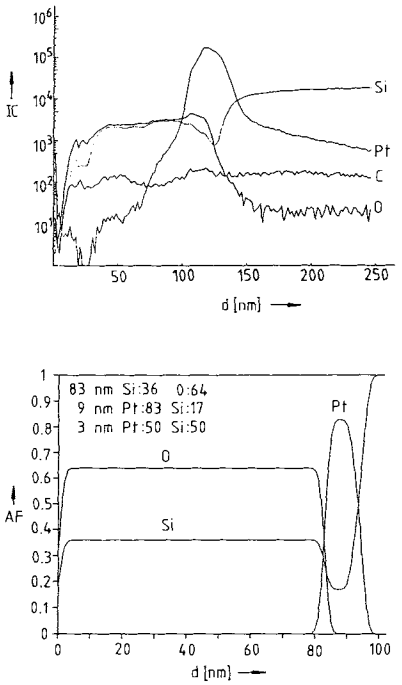

Fig. 2. Representative SIMS (left) and RBS (right) depth profiles of a used, active SiO_2/Pt/Si catalyst. Chemical composition of overlayers is given in atom-% in the upper left corner of the RBS profile. IC = ion counts, d = layer thickness, AF = atomic fraction.

Single crystal experiments have shown that prompt and extensive carbonation occurs on Pt during dehydrogenation of **1** while the reaction continues.[3] To test for sensitivity of SIMS for carbon at the SiO_2-Pt interface, we used a Pt/Si film for the catalytic reaction and then deposited the silica overlayer. The SIMS profile of this film indicated extensive carbonation at the SiO_2-Pt interface showing that SIMS can detect low carbon concentrations in these overlayers. Other overlayer films show no detectable increase of the carbonation below the SiO_2 surface upon use. This also serves as evidence against catalysis at the interface due to cracks or pores or diffusion of hydrocarbons through the silica layer.

Upon prolonged use of these films RBS and SIMS indicate sometimes that there is a slow diffusion of Pt into the silica overlayer (concentration 30 ppm Pt in SiO_2) which is currently under investigation. In this study each experiment was run on an unused film for time periods too short for significant Pt diffusion (confirmed by SIMS and RBS).

The effect of temperature on the rate (turnover frequency, N_f, molecules cm^{-2} sec^{-1}) and selectivity of a 72 nm SiO_2/Pt/Si was remarkably similar to that on a Pt/Si catalyst (Fig. 3). Over the temperature range studied the **3**/**2** ratio was slightly lower on the SiO_2/Pt/Si. The activation energies for the overall reaction of cyclohexene are: Pt/Si $= 2.09 \pm 5$ kJ/mol, SiO_2/Pt/Si $= 16.3 \pm 5$ kJ/mol; for formation of benzene: Pt/Si $= 82.8 \pm 14$ kJ/mol, SiO_2/Pt/Si $= 92.5 \pm 6$ kJ/mol. The differences between the exposed Pt and the overlayer films are not believed to be significant.

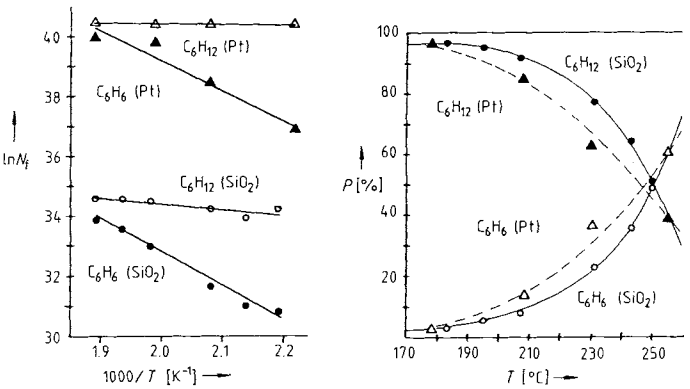

Fig. 3. Comparison of the Arrhenius plots (left) and the temperature dependence of the product composition (right) of cyclohexene conversion (low conversion conditions) on a 72 nm SiO_2/Pt/Si film with that on an exposed Pt/Si film.

Since isotopic product distributions have been useful as characteristic fingerprints for substrate catalyst interactions it was hoped to observe differences between the deuteriation patterns obtained on the oxide and on the Pt surface upon substitution of dideuterium for dihydrogen as carrier gas. However, the isotopic distributions of the products benzene and cyclohexane are very similar and show only a slightly higher deuterium content on Pt/Si relative to the products obtained on SiO_2/Pt/Si.

The similarity of the catalysis on the oxide overlayer to that on the Pt film suggests that this dissociated hydrogen[14] (whatever its nature on the surface) and not the exposed metal represents the active site for this catalytic reaction. The presence of active hydrogen on a surface may then be more important than the chemical nature of the surface. This conclusion is consistent with the wide variety of surfaces known to catalyze this reaction.[1–6]

In summary, inert silicon dioxide thin films become catalytically active in the presence of a platinum underlayer. Additional studies in our laboratory have shown that this phenomenon is not limited to SiO_2 on Pt, but has been observed with many other over-underlayer combinations. The most promising potential features of such catalysts—induction of catalytic activity on new surfaces and the resistance to poisoning due to protection of the transition metal by the overlayer—have now to be investigated.

[14] Artifacts due to Brønsted sites can safely be excluded due to the lack of activity of the oxide overlayer in the absence of transition metal underlayer and the lack of detectable rearrangement to methylcyclopentane or methylcyclopentene.

Transition State π-Solvation by Aromatic Rings: An Electronic Contribution to Diels-Alder Reaction Diastereoselectivity**

By *David A. Evans,* Kevin T. Chapman, Deborah Tan Hung,* and *Alan T. Kawaguchi*

"π-Stacking" interactions between aromatic rings and prochiral carbon atoms have been implicated as stereochemical control elements in a broad range of stereodifferentiating organic reactions.[1-8] In each of the cited cases, enhanced reaction diastereoselection *could* be attributed to the imposition of a transition state π-interaction between a resident aromatic ring and prochiral carbon(s). It has proven difficult, however, to unequivocally dissect such noncovalent interactions from the accompanying steric effects which together define reaction stereoselectivity. In the most comprehensive study reported to date for a given system, *Whitesell* et al. have established that the presence of a proximal phenyl group is essential for high diastereoselectivity in certain glyoxylate ene reactions.[3a-e] As was concluded in this study, however, these results do not demand the presence of an electronic effect, but imply that some property of the phenyl ring, be it size, shape, or electronic character, is essential for high stereoselectivity. In view of the tremendous potential utility of such π-stacking interactions in asymmetric synthesis design, we have attempted to define a protocol which might unequivocally demonstrate the presence of such a transition state electronic effect for a given reaction of interest. In the present study we have focused on the Diels-Alder reactions recently reported from this laboratory.

(a)

D_1 **D_2**

During the course of our investigations of the Diels-Alder cycloaddition reactions of α,β-unsaturated acyloxazolidinones **1** [Eq. (a)] we observed that oxazolidinone dienophile **1g** (R = benzyl) consistently provided diastereofacial discrimination superior to that of the closely related congener **1d** (R = isopropyl; cf. Table 1).[12m,n] Since we expected the steric requirements of an appended isopropyl group to exceed those of a benzyl group, we attributed the enhanced facial bias provided by **1g** to "π-tacking". In an effort to verify that we were observing an electronic interaction which was associated with the aromatic π-system, the reaction diastereoselectivity of the fully reduced cyclohexylmethyl derivative **1e** was also evaluated. We noted a significant decrease in the diastereoselectivity of this cycloaddition relative to that of **1g** despite the increased steric bulk of the appended side-chain (Table 1). Thus, some property of the phenyl ring of **1g** is important to the observed diastereofacial bias. It seemed reasonable to expect that a charge-transfer interaction between the aromatic ring and the electron deficient dienophilic moiety in **1g** should manifest itself not only in *increased* diastereoselectivity, but also in *decreased* reactivity. Accordingly, a relative rate comparison between **1e** and **1g** in the cycloaddition with isoprene was carried out. Contrary to expectation, it was found that the phenyl-substituted dienophile **1g** actually reacts slightly faster (rate ratio: 1.3) than does its fully saturated counterpart **1e**. This result suggests that little, if any, electronic reorganization accompanies the alleged π-stacking in the cycloaddition of **1g**. Addi-

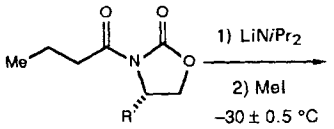
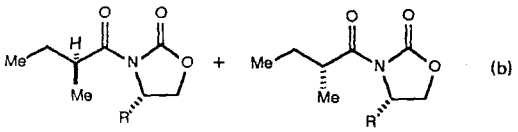
tional support for this assertion was derived from an examination of the reaction diastereoselectivities of dienophiles **1h–1j** containing electronically perturbed benzyl substituents. The observed reaction diastereoselectivities of these analogues were insignificantly different from that of the parent crotonate **1g** (Table 1). A similar observation has been made by *Oppolzer* et al. in the Diels-Alder reactions of 8-arylmenthyl acrylates.[2d]

In order to gain more insight into the origin of these substituent effects, a set of experiments was designed to unambiguously dissect the steric from the electronic contributions to reaction diastereoselectivity. We chose to compare the Diels-Alder reaction [Eq. (a)] to an unrelated process which possessed gross transition state topographical similarities but which would not be expected to benefit from π-stacking. In this regard we have previously reported the relevant diastereoselective alkylation reactions of the lithium enolates of *N*-acyl-2-oxazolidinones **2**.[9] Al-



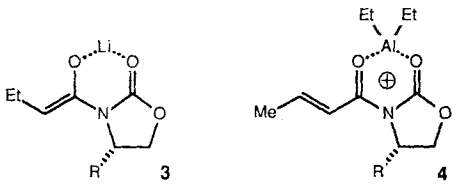
2 a-j



(b)

A$_1$ **A$_2$**

though lithium enolate **3** is topographically quite similar to Lewis acid complex **4**, the presumed reactive species in these Diels-Alder reactions, the electron rich nature of the enolate π-system was presumed to disfavor the π-stacking interaction. Direct comparison of the diastereoselectivities in analogous alkylation and Diels-Alder reactions should



3 **4**

expose any stereochemical control element not common to both sets of transition states. The illustrated enolate methylations [Eq. (b)] and isoprene Diels-Alder reactions of (*E*)-crotyloxazolidinones [Eq. (a)] were selected for comparison at a common reaction temperature (−30 °C). Product diastereomer ratios for these reactions are listed in Table 1 and are plotted against each other in Figure 1.[10] Oxazolidinone substituents which cannot π-solvate the Diels-Alder transition state (Ph, Me, Et, *i*-C_3H_7, CH_2(*c*-C_6H_{11})) lie on a line representing the purely steric contribution to diastereofacial differentiation in both reactions. The excellent linear correlation ($r = 0.997$) for this set of substituents validates this direct comparison. The *para*-substituted benzyl substituents (four cases) fall well off this line in the direction of higher Diels-Alder diastereoselectivity. As would be expected on purely steric grounds, the cyclohexylme-

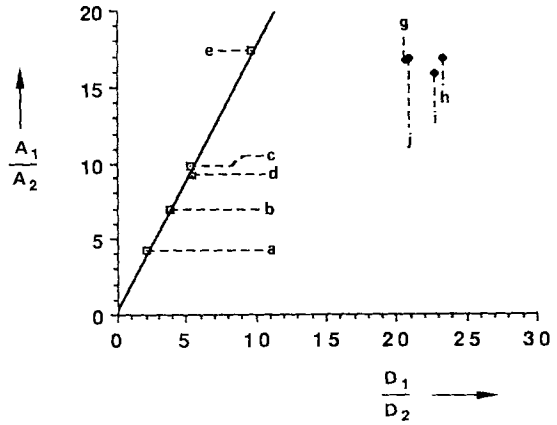


Fig. 1. Plot of crotonate oxazolidinone/isoprene Diels-Alder diastereomer ratio versus corresponding butyrate oxazolidinone/methyl iodide alkylation diastereomer ratio (see Table 1).

thyl- and benzyl-substituted oxazolidinones afford similar distereoselectivities in their butyrate alkylation reactions. They differ dramatically, however, in their corresponding crotonate Diels-Alder diastereoselectivities. *This direct alkylation/Diels-Alder comparision provides compelling evidence that π-facial differentiation, which is electronic in origin, occurs in these Diels-Alder transition states.* Alteration of the π-donor ability of the phenyl group has little effect on the stereselectivity of the Diels-Alder reaction and, as would be expected, has essentially no effect on the corresponding alkylation process. In view of these observations, we believe that the electronic contribution of the benzyl substituent associated with the cycloaddition process results largely from dipole-dipole and Van der Waals attractions and not from a charge-tansfer interaction. Similar conclusions have been reached by *Rebek* et al. with respect to π-π molecular recognition of aryl-substituted amino acids.[11]

In conclusion, we have unambiguously established that appropriately oriented aromatic rings contribute to the enhanced diastereoselectivity of Diels-Alder reactions of α,β-unsaturated *N*-acyloxazolidinones by processes having both steric *and* electronic components. The electronic component to diastereofacial shielding does not appear to have significant charge-transfer character. The method of analysis, which involves the comparison of corresponding alkylation and Diels-Alder reactions, directly provides information about the transition states themselves without recourse to ground state conformational arguments.

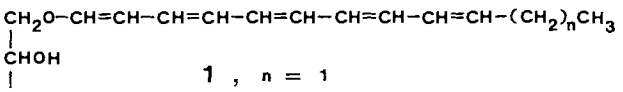
Natural Fecapentaene-14 and One Fecapentaene-12 Component are all-*trans* Stereoisomers**

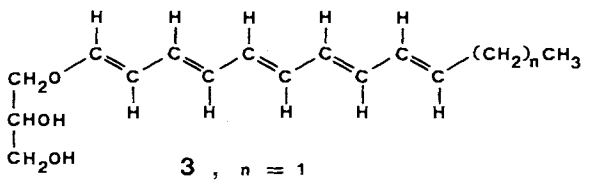
By *José Baptista, Jiri J. Krepinsky,** and *Hans Rudolf Pfaendler**

Fecapentaenes are very effective, directly acting mutagens present in the feces of a large section of European and North American communities, and are suspected of being colon carcinogens.[1] Their structures were elucidated recently as **1** and **2**.[2,3] The absolute configuration of the single chiral center has been determined to be *S*,[4] but the full geometry of the large, conjugated double bond system allowing 32 stereoisomers (excluding enantiomers) has thus far remained unclear. Only the *trans* configuration



1, n = 1

2, n = 3



3, n = 1

4, n = 3

[**] The synthetic part of this work was financially supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

of the CC double bond adjacent to the glyceryl moiety could be deduced from the H-NMR coupling constant (12 Hz) of the isolated O–C*H*=CH– signal ($\delta = 6.84$ in [D$_7$]DMF.[2,3]

Our investigation of many fecal samples by HPLC revealed the occurrence of three fecapentaene-12 isomers (cf. Fig. 1a, peaks **A**, **B**, and **C**). In contrast fecapentaene-14 exists in only one geometric form (Fig. 1a, peak **D**). The ratio of the components can vary considerably from sample to sample depending on the donors.

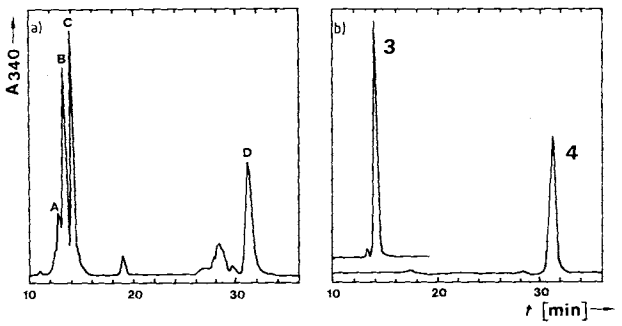

Fig. 1. a) HPLC profiles of fecapentaene fractions from human feces. **A**, **B**, **C**: fecapentaene-12 isomers; **D**: fecapentaene-14 isomer. b) HPLC profiles of the synthetic fecapentaenes **3** and **4**. A_{340}: absorption at 340 nm. Column: Ultrasphere ODS, 25 cm × 4.6 mm; mobile phase: $CH_3CN:CH_3OH:H_2O$:tetrahydrofuran 36.2:25.4:32.0:6.4; diode array detector LKB, model 2140.

The fecapentaenes are very unstable compounds; the mixture of fecapentaenes-12 could not be separated on a preparative scale. However, the three components, corresponding to the peaks **A**, **B**, and **C** in Figure 1a, were shown to have the same CI mass spectrum using a combined HPLC-mass spectrum unit. Thus, it became evident, that they were true stereoisomers. However, the exact identification of the isomers was not possible.

Fecapentaene-14 (peak **D** in Fig. 1a) is isomerically pure. Nevertheless, the geometry of its double bonds could not be defined because of the complexity of the olefin H signals in the ^{1}H-NMR spectrum.[2] Fecapentaene-14 is even less stable than the fecapentaenes-12 and the spectrum of the natural material was always adversely affected by decomposition products.

Through the total synthesis of crystalline, racemic all-*trans*-fecapentaene-12[5] and -14[6] it became possible for the first time to compare synthetic and natural materials and thus to clarify which natural products, if any, are all-*trans*. The HPLC system used for the separation of fecal samples was also suitable for making a comparison of these materials.

A mixture of fecapentaenes from feces was freshly prepared using a procedure previously described in the literature[2] (for HPL chromatogram, see Fig. 1a). Synthetic all-*trans*-fecapentaene-12 (**3**) (cf. Fig. 1b) showed exactly the same retention time as the component **C** of the fecapentaenes-12 and also co-eluted with it. The UV spectrum of the component **C** (recorded with the diode array detector) and the UV spectrum of **3** were likewise identical. This proves that the component **C** is all-*trans*-fecapentaene-12 (**3**).

Similarly, synthetic all-*trans*-fecapentaene-14 (**4**) (cf. HPL chromatogram, Fig. 1b) exhibited identical retention time as the component **D**, and both co-eluted. The H-

NMR spectra (in $[D]_7DMF$) of natural **D** and synthetic **4** were essentially identical, particularly in the region representing olefinic protons ($\delta = 5.6$–6.8). This, in turn, proves that the the component **D** is pure all-*trans*-fecapentaene-14 (**4**).

We have also established that the CI mass spectra of the natural and the synthetic compounds are identical. These spectra, however, show very little fragmentation, and thus are not sufficiently informative.

These investigations enable us for the first time to assign the complete structural formulas to two naturally occurring fecapentaenes. The geometry of the CC double bonds may play a role in the degree of mutagenicity exhibited by both types of fecapentaenes.[7,8] Interestingly, the two identified components, all-*trans*-fecapentaene-12 (**3**)[9] and all-*trans*-fecapentaene-14 (**4**)[7] belong to the most potent mutagens so far known. Their occurrence in human feces and their accessibility by chemical synthesis raise hopes that they might serve to answer the question whether the fecapentanes are carcinogens.

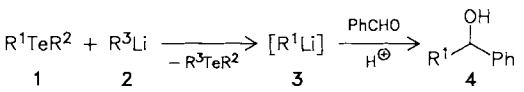
Lithium-Tellurium Exchange: A New Entry to Organolithium Compounds**

By *Tomoki Hiiro, Nobuaki Kambe,* Akiya Ogawa, Noritaka Miyoshi, Shinji Murai,* and *Noboru Sonoda**

Since organolithium compounds,[1] as well as Grignard reagents, are most commonly used for the introduction of carbon moiety into organic molecules, the development of efficient methods for the synthesis of organolithium compounds is of vital importance. Organolithium compounds can be prepared directly by hydrogen abstraction or lithium-halogen exchange reaction; when these reactions fail, however, metal-metal exchange is widely resorted to.

We report here on a new method providing access to organolithium compounds **3** from organic tellurides **1** via lithium-tellurium exchange. Alkyl-, benzyl- and allyllithium compounds can be synthesized in a one-pot operation from halides without isolation of the tellurides [see Reaction (c)].

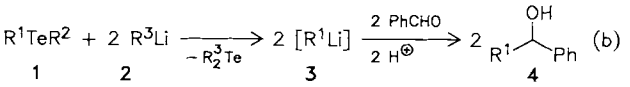
Diorganotellurides **1** react with butyllithium at $-78\,^{\circ}C$ in THF to give the more stable organolithium compounds **3**, which are subsequently trapped with benzaldehyde to give the alcohols **4**. In this way several types of organolithium compounds can be obtained in good yields [Reaction (a), see Table 1]. (*Z*)-Phenyl styryl telluride **1c** afforded exclusively the (*Z*)-olefin **4c**. It should be noted that benzyloxymethyllithium **3e** and trimethylsilylmethyllithium **3f** are synthetically useful as alkoxymethylating[2] and silylmethylating[3] reagents, respectively.



(a)

R^3 = *n*Bu

When the telluride **1** and the alkyllithium **2** are allowed to react in the ratio 1:2, both organic groups on the tellurium are converted into carbanions. For example, reaction of 1 mmol of dibutyl telluride **1h** with 2 mmol of *sec*-butyllithium affords 1.73 mmol of the adduct **4h** [Reaction (b), see Table 1]. This result suggests that the method described here is even suitable for the preparation of nonstabilized carbanions. Phenyllithium **3b** can be generated under identical conditions using *n*- or *tert*-butyllithium.



(b)

$R^1 = R^2$

Since alkyl aryl and dialkyl tellurides are readily accessible by reaction of lithium tellurolates **6**[4] with alkyl halides **5**, we then attempted a one-pot synthesis of the organolithium compounds **3** from the corresponding halides without isolation of the tellurides **1** [Reaction (c), see Table 1]. With benzyl, allyl and alkyl halides as starting materials, we obtained the products **4a**, **4i** and **4j** in good yields. When methyl vinyl ketone was used as an electro-

phile instead of benzaldehyde, reaction with butyllithium under identical conditions proceeded via 1,2-addition to the carbonyl group to give 2-methyl-1-phenyl-3-buten-2-ol (44% yield based on **5a**).

This one-pot procedure is operationally convenient and will be especially useful when direct lithium-halogen exchange cannot be resorted to—as in the preparation of benzyl- and allyllithium compounds.[5]

Although lithium-selenium exchange has been reported on several occasions,[6] examples of lithium-tellurium exchange were hitherto rare.[7] Studies on the scope and limitation of this reaction are currently in progress.

Experimental Procedure

Preparation of the telluride **1**, $R^1 \neq R^2$: **1a,e,f** from lithium butanetellurolate [4] and benzyl bromide, benzyloxymethyl chloride and trimethylsilylmethyl iodide, respectively, in THF; **1b** from lithium benzenetellurolate and propyl iodide in THF; **1c** from benzenetellurol and phenylacetylene [8]; **1d** by a similar method as described in the literature [9] from benzenetellurenyl iodide (PhTeI) [10] and lithium phenylacetylide.

Typical reaction starting from a diorganyl telluride **1**: A solution of **1f** (1 mmol, 272 mg) in THF (5 mL) was treated at −78 °C with a 1.6 M solution of butyllithium **2** (1 mmol, 0.63 mL), $R^3 = n$Bu, in hexane. After stirring for 15 min, benzaldehyde (1 mmol, 106 mg) was added by a syringe in one portion, and the reaction mixture then warmed to 25 °C over a period of 1 h. Et_2O (30 mL) and dil. aq. HCl (ca. 0.1 M, 50 mL) were added to the mixture, and the product was extracted with Et_2O (50 mL × 3). The ethereal solution was dried over $MgSO_4$ and the solvent removed by evaporation. Subsequent radial layer chromatography (silica gel, Et_2O/hexane) afforded 171 mg (0.89 mmol; 89%) of **4f** together with 238 mg (0.99 mmol) of dibutyl telluride.

Typical reaction starting from a halide **5**: To a solution of lithium benzenetellurolate **6**, $R^2 = Ph$ [4] (prepared in situ from tellurium (2 mmol) and phenyllithium (2 mmol, 1 mL 2.0 M solution in cyclohexane/Et_2O) in THF (5 mL) was added 342 mg (2 mmol) of benzyl bromide **5a** at −78 °C. The mixture was warmed to 25 °C and stirred for 30 min. At this stage, the conversion to the benzyl phenyl telluride **1a** is complete. Further conversion and work-up are the same as in the case of **1f**.

Control of the Superconducting Properties of $YBa_2Cu_3O_7$ by Topotactic Redox Reactions

By *Heinz Eickenbusch, Werner Paulus, Elmar Gocke, Joachim Friedrich March, Hans Koch,* and *Robert Schöllhorn**

Dedicated to Professor Rudolf Hoppe on the occasion of his 65th birthday

A series of ternary copper oxides with perovskite type structures have recently been shown to exhibit unusual superconducting properties with critical temperatures significantly higher than those measured so far for superconducting materials.[1,2] For the defect perovskite system $YBa_2Cu_3O_7$ with the highest confirmed transition temperature it has become obvious that the oxygen stoichiometry plays a major role with respect to the electronic behavior.[3-5] We report here on the modification of the superconducting properties of this compound by topotactic intercalation and deintercalation of oxygen which demonstrates that the temperature of the phase transition normal conductivity/superconductivity can be controlled reversibly in a continuous mode between 93 K and 30 K. Since solids characterized by electronic conductivity, vacant lattice sites, and redox active transition elements may undergo electron/cation transfer reactions,[6] we have, moreover, performed a study on the intercalation of small cations into the lattice of $YBa_2Cu_3O_7$ which shows that both hydrogen and lithium can be inserted.

The starting material $YBa_2Cu_3O_{7\pm0.05}$ **1** was prepared from the corresponding high purity binary oxides in oxygen atmosphere at 950 °C with subsequent controlled cooling and annealing; details of preparation and characterization have been described elsewhere.[5,7] Polycrystalline pressed samples of **1** were annealed under equilibrium conditions at defined temperatures between 25 °C and 900 °C in oxygen atmosphere (1 bar) for 24 h and subsequently quenched in liquid nitrogen. Analytical data (gravimetry, differential thermal gravimetry, reduction in H_2 atmosphere) reveal a continuous decrease of the oxygen content with increasing temperature [Eq. (a)] and a change in

$$YBa_2Cu_3O_7 \rightleftharpoons YBa_2Cu_3O_x + (7-x)/2\,O_2 \qquad (a)$$

stoichiometry from $YBa_2Cu_3O_7$ at 25 °C to $YBa_2Cu_3O_{6.5}$ at 750 °C (Fig. 1); equilibrium is observed after a few hours above 350 °C. The superconducting transition temperatures T_c were measured by ac susceptibility with lead sam-

ples of identical volume for evaluation of the volume susceptibility. Additional measurements of the resistivity were made for comparison reasons with the four probe *(van der Pauw)* technique. Figure 1 shows that the transition tem-

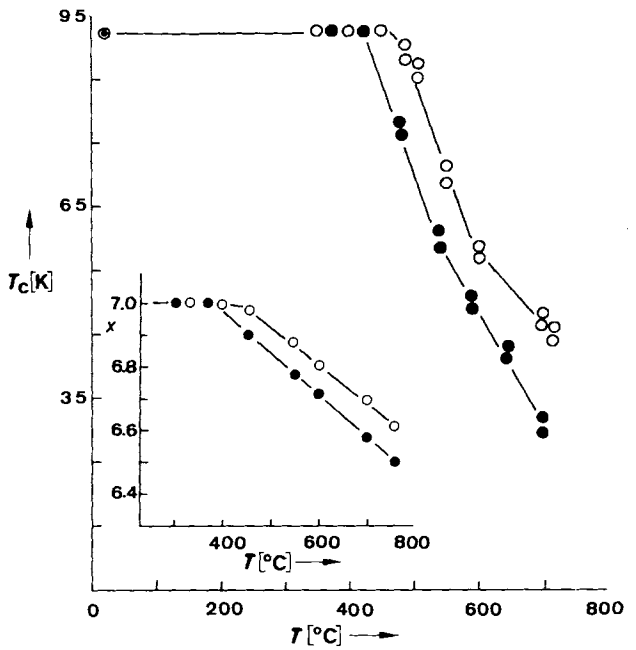

Fig. 1. Outer: Onset temperatures T_c (measured by susceptibility) of the transition normal conductivity/superconductivity for $YBa_2Cu_3O_x$ as a function of the annealing temperature T under oxygen atmosphere (○) and air (●). Inset: change in stoichiometry x with T. In the case of the samples at 760 °C, no phase transition was found up to 4.2 K.

perature can in fact be varied continuously between 93 K and 30 K. This effect is entirely reversible; on treatment of the samples with lower T_c in oxygen atmosphere at 400 °C the original value of $T_c = 93$ K is restored. Annealing at temperatures above 750 °C leads to samples which show semiconducting behavior down to 4 K. At higher temperatures the oxygen content decreases first down to $x \approx 6$, thereafter, non-topotactic processes occur with the appearance of several phases in agreement with earlier reports.[4] The transition width—defined as the temperature difference between 10% and 90% of the susceptibility signal—changes from 1 K at $x = 7.0$ to 3 K at $x = 6.58$. Similar results with slightly different stoichiometry and T_c values at equal annealing temperatures were obtained upon performing the reaction in air. The decrease of the volume susceptibility at $T > 580$ °C and X-ray measurements, however, indicate side reactions leading to increasing fractions of non-superconducting phases.

The change of the lattice parameters with x in $YBa_2Cu_3O_x$ is illustrated in Figure 2. With decreasing x the orthorhombic c axis increases linearly, while a and b change their magnitude such that they finally become identical for $x = 6.5$, where the symmetry of the system converts from orthorhombic to tetragonal. The entire unit cell volume change from $x = 7$ to $x = 6.5$ corresponds to a relatively small increase of 1%.

The orthorhombic distortion of **1** is related to an ordered arrangement of O^1 in the basal plane of the defect perovskite (Fig. 3).[8] Oxygen loss leads for $x = 6.5$ to tetragonal symmetry as a consequence of the selective removal of 50% of O^1 and a statistical distribution of the remaining

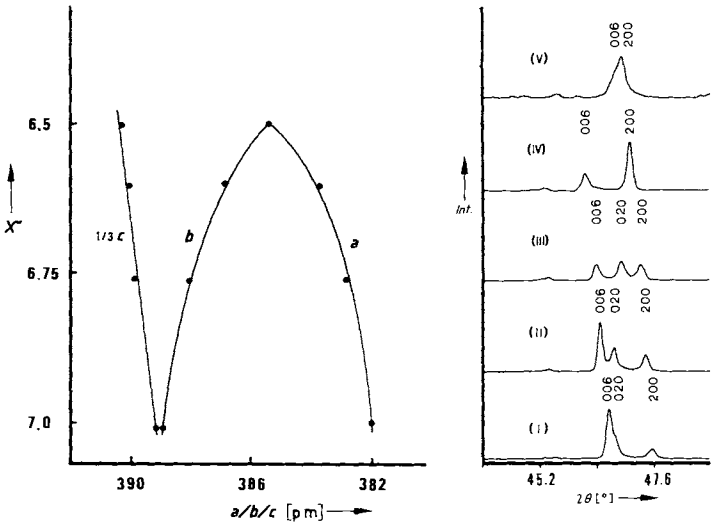

Fig. 2. Left: Change in lattice parameters of $YBa_2Cu_3O_x$ with the oxygen stoichiometry x. Right: X-ray diffractometer scans showing the transition from orthorhombic to tetragonal symmetry: (I) $x = 7.0$; (II) $x = 6.76$; (III) $x = 6.6$; (IV) $x = 6.5$; (V) pseudocubic metastable phase (c.f. text).

oxygen in this plane. The formal oxidation state of Cu in **1** is 2.33 or $YBa_2Cu_2^{2\oplus}Cu^{3\oplus}O_7$ in terms of integral valencies. It is reasonable to assume that $Cu^{3\oplus}$ is preferentially located on the Cu^1 positions (short Cu^1-O^2 distances) forming chains along the b axis, while $Cu^{2\oplus}$ is on sites with distorted pyramidal coordination close to the oxygen free $Y^{3\oplus}$ planes. The position of $Cu^{2\oplus}$ presents a favorable geometry for an interaction of the partially filled d_{z^2} orbitals across the central plane of the unit cell (Fig. 3) leading to distorted pseudooctahedral coordination of $Cu^{2\oplus}$ with a weakly coupled electron pair as the sixth ligand.

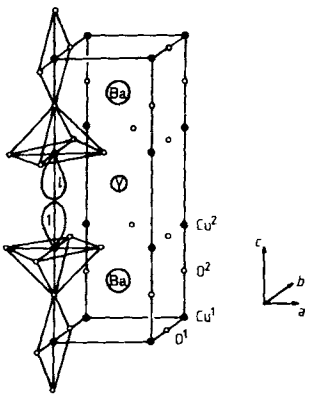

Fig. 3. Stucture model of $YBa_2Cu_3O_7$. Unit cell scheme indicating the coordination of Cu and partially filled d_{z^2} orbitals.

This model could actually explain recent observations on the absence of temperature-dependent magnetism in **1** in spite of the presence of $Cu^{2\oplus}$.[9] At the transition orthorhombic/tetragonal the stoichiometry corresponds formally to bivalent Cu only, i.e. $YBa_2Cu_3^{2\oplus}O_{6.5}$; the magnetic properties of this phase have not been studied in detail so far.

A most interesting phenomenon—also with respect to potential application in catalysis—is the high mobility of oxygen at relatively low temperatures in $YBa_2Cu_3O_x$. The quenched metastable phase $YBa_2Cu_3O_{6.5}$ may take up oxygen already at temperatures as low as 285 °C[5] and convert

to $YBa_2Cu_3O_7$. We now have observed the appearance of an intermediate "pseudocubic" phase under these conditions with $a=b=c/3=388$ pm, which demonstrates that the low temperature reaction mechanism is different from that under equilibrium conditions (Fig. 2), where this phase does not appear. This observation is most likely a consequence of the different positional selectivity of the oxygen anion mobility under the corresponding reaction conditions. Recently the existence of holes in the anion valence band of $YBa_2Cu_3O_x$ due to the equilibrium $Cu^{3\oplus}/O^{2\ominus} \rightleftharpoons Cu^{2\oplus}/O^{\odot\ominus}$ has been discussed.[5] We suggest here a model for the high oxygen mobility on grounds of the presence of monovalent $O^{\odot\ominus}$ ions which must have a considerably lower activation energy for site change as compared to bivalent $O^{2\ominus}$ anions.

Investigations on the intercalation of hydrogen were based on the assumption that $Cu^{3\oplus}$ in **1** can be reduced to $Cu^{2\oplus}$ in a topotactic process with formation of a hydrogen bronze [Eq. (b)]. The maximum value of x can be calculated according to Equation (c) as $x=1.0$.

$$xH^{\oplus} + xe^{\ominus} + YBa_2Cu_3O_7 \rightarrow H_x[YBa_2Cu_3O_7] \quad (b)$$

$$Cu_2^{2\oplus}Cu^{3\oplus} + e^{\ominus} \rightarrow Cu_3^{2\oplus} \quad (c)$$

The electrochemical reaction by galvanostatic cathodic reduction of pressed polycrystalline electrodes of **1** in a galvanic cell with aqueous electrolyte (pH = 6.5) was characterized by a continuous decrease in potential. After an electron transfer of $n=0.3\ e^{\ominus}/YBa_2Cu_3O_7$ the potential of hydrogen discharge was reached. The value for x obtained under these conditions is thus equivalent to $x=1/3$. Direct intercalation of hydrogen gas was performed in a closed system with activation of **1** by sputtering with platinum (1 wt.-% Pt, "overspill" technique[6]). Volumetric determination of the hydrogen taken up at 25 °C/1 bar corresponded in agreement with the electrochemical data to $x=1/3$. The lattice parameters of the resulting hydrogen bronze $H_{1/3}[YBa_2Cu_3O_7]$ (orthorhombic, $a=382.5$ pm, $b=388.5$ pm, $c=1169$ pm) were close to those of the starting phase **1**. Susceptibility measurements revealed that the hydrogen phase exhibits a broad transition with an onset temperature of 89 K. Further reduction with H_2 using extended reaction time or higher temperatures resulted in irreversible structural changes.

$$xLi + xe^{\ominus} + YBa_2Cu_3O_7 \longrightarrow Li_x[YBa_2Cu_3O_7] \quad (d)$$

The intercalation of lithium into **1** according to Equation (d) was carried out in a galvanic cell $Li//LiClO_4$, propylene carbonate$//YBa_2Cu_3O_7$ under galvanostatic and potentiostatic conditions. The reaction proceeds topotactically up to $x=1/3$, i.e. $Li_{0.33}[YBa_2Cu_3O_7]$ (tetragonal, $a=388.1$ pm, $c=1172.6$ pm); beyond a charge transfer of $n=1/3$ irreversible side reactions have been observed. The same phase could also be prepared by reaction of **1** with butyllithium (1.5 M solution in hexane) at ambient temperature. ^{7}Li-NMR line-width studies of $Li_{0.33}[YBa_2Cu_3O_7]$ showed a chemical shift of $\delta=-2$ vs $LiCl/H_2O$ at 300 K and a narrow line width (450 Hz) indicating a rather high lithium mobility comparable with that of Li in the framework lattice of molybdenum cluster chalcogenides $Li_xMo_6X_8$.[10] The electronic properties of the highly susceptible lithium phase are presently under investigation.

The results discussed demonstrate that the new oxide high-temperature superconductors are most interesting systems not only with respect to the correlation between electronic properties, structure and bonding but also in terms of their chemical reactivity as a means for controlling the physical properties of these systems.

Hexacarbonylzirconate(2−), $[Zr(CO)_6]^{2-}$: The First Binary Carbonyl Complex of Zirconium**

By *Kai Ming Chi, Scott R. Frerichs, Stephen B. Philson,* and *John E. Ellis**

Since the pioneering work of *Walter Hieber*,[1] mono- and/or polynuclear binary carbonylmetalates have been isolated for practically all d-block transition metals, except those of the 3rd, 4th and 11th triads, and have proven to be extremely important materials in chemical synthesis.[2] We now report on the synthesis, isolation and characterization of the first binary carbonylzirconium complex $[Zr(CO)_6]^{2-}$ as salt **1**, which contains zirconium in an unprecedented formal oxidation state of −2.[3] Except for important modifications (vide infra) this material was obtained by the alkali-metal naphthalenide method we originally developed for the reductive carbonylation of MCl_5 to $[M(CO)_6]^-$ (M = Nb and Ta) at atmospheric pressure.[4] The ready availability of $[Zr(CO)_6]^{2-}$ should facilitate general studies on the carbonyl chemistry of zirconium, which has been previously limited almost exclusively to cyclopentadienyl derivatives such as $[(C_5H_5)_2Zr(CO)_2]$[5] and $[(C_5H_5)Zr(CO)_4]^-$[6] and other related carbocyclic derivatives.

The reaction sequence for the preparation of **1** is given in Equation (1) (THF = tetrahydrofuran, $C_{10}H_8$ = naphthalene, 15-C-5 = [15]crown-5 = 1,4,7,10,13-pentaoxacyclopentadecane and DME = 1,2-dimethoxyethane). Further details are given under *Experimental procedure*.

$$ZrCl_4 \cdot 2THF + 6KC_{10}H_8 + 4\,15\text{-C-}5 + 6CO \longrightarrow$$
$$[K(15\text{-C-}5)_2]_2[Zr(CO)_6]\downarrow + 4KCl + 6C_{10}H_8 + 2THF \quad (1)$$

It is important to note that in the absence of an effective alkali-metal complexant such as a crown ether or a cryptand,[7] the carbonylation reaction step fails to provide any isolable $[Zr(CO)_6]^{2-}$. Although the formation of **1** is undoubtedly aided by its insolubility in this medium, the product dissolves in strongly polar aprotic solvents such as acetonitrile to provide fairly stable solutions at ambient temperature. The presence of weakly solvated alkali metal cations appears to either prevent formation or cause decomposition of $[Zr(CO)_6]^{2-}$ at low temperature. In contrast, effective alkali-metal complexants need not be present during the aforementioned synthesis of the isoelectronic $[Nb(CO)_6]^-$.[4]

Crystallization of **1** from acetonitrile/THF provides dark purple, extremely air-sensitive microcrystals which appear to be indefinitely stable under argon at room temperature (decomp. pt. ca. 140 °C). The spectroscopic properties of **1** are consistent with the proposed formula.[8] Thus **1** shows a single intense band in the IR spectrum at 1757 cm^{-1} (cf. $[Na_2Ru(CO)_4]$ in $(Me_2N)_3PO$, 1736 cm^{-1}), a single ^{13}C-NMR resonance at $\delta = 245.2$ (cf. $[HV(CO)_5]^{2-}$ in NH_3, $\delta = 250.3$[9] and $[W(CO)_5]^{2-}$ in THF, $\delta = 247.4$[10]), and an extremely narrow ($W_{1/2}$ = ca. 20 Hz) single ^{91}Zr-NMR resonance expected for a molecule of cubic or octahedral symmetry.[11] Although attempts to obtain single crystals of **1** for an X-ray structural determination have so far failed, the presence of octahedral $[Zr(CO)_6]^{2-}$ in **1** has been corroborated by the ^{91}Zr-NMR spectrum of 99% ^{13}C-enriched $[Zr(^{13}CO)_6]^{2-}$ (Fig. 1), which shows the binomial septet predicted for six equivalent carbonyl groups bound to a central zirconium atom.[12] To our knowledge this is the first example of a compound for which ^{91}Zr-^{13}C coupling has been resolved.

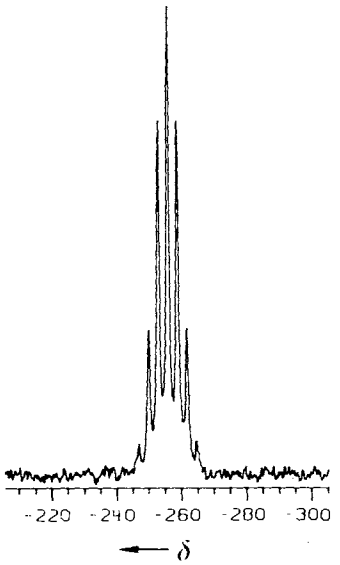

Fig. 1. The ^{91}Zr-NMR spectrum of $[K([15]\text{-Crown-5})_2]_2[Zr(^{13}CO)_6]$ (cf. [12]).

Experimental Procedure

1: A solution of $ZrCl_4 \cdot 2THF$ (2.0 g, 5.30 mmol) was prepared in 50 mL of cold DME at −70 °C and transferred under argon by cannula to a magnetically stirred solution/slurry of $KC_{10}H_8$ (5.35 g, 32.0 mmol) and $C_{10}H_8$ (1.28 g, 10 mmol) in 150 mL of DME at −70 °C. The red-brown solution containing presently uncharacterized intermediate(s) was allowed to slowly warm in a Dewar flask to near ambient temperature over a period of about 12 h. It was then filtered into a Morton flask, anaerobic [15]-Crown-5 was added (4.75 g, 21.6 mmol) and the resulting solution was mechanically stirred at ambient temperature for 2 h. After cooling to −60 °C, the argon atmosphere was removed by evacuation and replaced by ≥99.9% carbon monoxide (free of CO_2, O_2, H_2O). Stirring was continued for 40 h at −60 °C, during which time much purple solid precipitated. The slurry was then warmed to room temperature. After filtration, the solid was thoroughly washed with DME (2 × 20 mL), dried in vacuo, and recrystallized from CH_3CN-DME at 0 °C. In this way we obtained 2.15 g (1.77 mmol, 33% yield) of dark purple microcrystalline product which provided satisfactory elemental analyses (C, H and K). A very similar compound of the formula $[Cs([18]\text{Crown-6})_2]_2[Zr(CO)_6]$ (satisfactory C, H, Cs analysis, decomp. pt 130 °C) has been prepared by the same procedure. Syntheses of $[Zr(CO)_6]^{2-}$ in THF generally provide 10–15% lower yields than those conducted in DME.

Two-Dee or not to be*

In the seminar room at the Hotel Alem, which lies in an idyllic situation on the Jugoslavian Adriatic coast near Baska Polje, the Belgian physicist *J. Jeener* wrote on the small blackboard just a few lines in the abstract language of the density matrix. It was enough, however, to sketch out his idea for a two-dimensional NMR spectrum, whose spectral lines would stand out like the mountains in a relief map of the Alps, showing the couplings between the hydrogen nuclei of a molecule and allowing its structural formula to be directly determined. On that day, the 4th of September 1971, none of the 136 participants at the NMR Summer School realized that this idea was actually, in every sense, opening up a second dimension for NMR spectroscopy. It led to a new way of interpreting spectra, which 13 years later made it possible even to determine the tertiary structure of a protein molecule.

It must be remembered that in 1971 the pulsed FT method, nowadays used routinely, was bringing about a revolution in ^{13}C-NMR spectroscopy, which up to then had been withering away. In ^{1}H-NMR spectroscopy the FT method was at first seen by most practitioners as interesting but inappropriate for general use. One important reason for this was the inability with FT NMR spectroscopy to easily and independently change the resolution and spectral range. Another was the lack of adequate on-line data storage capacity, magnetic tapes and disks being not yet available. In these circumstances *Jeener*'s proposal seemed utopian. One had to use, instead of one r.f. pulse, two pulses separated by an interval t_1, to record the signal following the second pulse, and then to repeat the process with a new t_1 value. In this way one would record several hundred FID's, each with around 1000 data points, then carry out a 2D Fourier transformation on the entire data. According to *Jeener* the resulting 2D NMR spectrum would contain complete information on the coupled system of the molecule. However, it appeared that the same information could also be obtained with the double resonance techniques in common use at the time. Since these could be used to study single transitions and selected regions of the spectrum, it was thought that *Jeener*'s proposed method, owing to its heavy demands on data storage capacity and computing power, did not offer any improvement in chemical structure determination.

The Sleeping Beauty of 2D NMR was awakened by the kiss not of one prince, but of several, who finally helped *Jeener*'s idea to make its breakthrough. *Richard Ernst* in Zürich was the first to carry out the experiment. The chemical information yielded was small because of the inadequate computing power available, but nevertheless this experiment was of such fundamental importance that *Ernst*'s joint paper with *Aue* and *Bartholdi* (*J. Chem. Phys. 64* (1976) 2229) determined the course of research for many years to follow. The decisive point for chemistry, however, came with a joint paper by *Richard Ernst* and *Kurt Wüthrich* (*Biochem. Biophys. Res. Commun. 78* (1977) 99), in which they used 2D techniques to study a mixture of five amino acids. These results demonstrated the great potential of 2D NMR spectroscopy, and stimulated its accelerated development, helped by important contributions from *Ray Freeman*'s group in Oxford. During the years 1978 to 1982, many efforts were made to apply the technique to chemically important problems, in spite of the limitations of the available equipment. The phrase "Two Dee or not to be" eloquently summarizes the concerns which occupied many NMR spectroscopists at that time.

We can now recognize that two parallel developments during the last ten years have brought about enormous advances in NMR spectroscopy. Progress in hardware has come from the development of spectrometers with increased sensitivity and spectral dispersion, based on reliable high field cryomagnets and improved r.f. receivers, and of much more powerful on-line computers. Simultaneously, on the techniques side, many new and highly informative experimental procedures have grown out of a deeper understanding of spin dynamics, i.e. the behavior of spin systems under the influence of r.f. pulses. 2D NMR measurements occupy a particularly important position amongst these, the development of the methods and their early applications having been documented in around 1000 publications up to the beginning of 1986. Since then the number of applications has grown rapidly, and 2D NMR spectroscopy now belongs to the armoury of routinely used analytical techniques. However, these modern NMR techniques demand from the spectroscopist a level of knowledge far beyond that which was common in 1980, and one that cannot be gained from the older standard works on NMR spectroscopy. The need arising from this situation is taken into account in the books reviewed here, namely

together with a few more which have appeared in the past year*.

First, some general remarks relating to these books. The direction of rotation which corresponds to a positive angle

[*] Abbreviations used in this review: 1D—one-dimensional, 2D—two-dimensional, r.f.—radiofrequency, H,H-COSY and H,X-COSY—homonuclear and heteronuclear correlation spectroscopies, respectively, CT—coherence transfer, PT—polarization transfer, CP—cross-polarization, MAS—magic angle spinning, DCPL—decoupling, δ—chemical shift, J—coupling constant, T_1, T_2—relaxation times, FID—free induction decay, DQ—double quantum, MQ—multiple quantum, FT—Fourier transform, CW—continuous wave, NOE—nuclear Overhauser effect.

[*] W. R. Croasmun, R. M. K. Carlson: *Two-dimensional NMR Spectroscopy: Applications for Chemists and Biochemists*, VCH Publishers, New York 1987, DM 197.00; K. Wüthrich: *NMR Studies of Proteins*, Wiley, New York 1987, $ 49.95; J. K. Whitesell, M. A. Minton: *Stereochemical Analysis of Aliphatic Compounds by ^{13}C NMR*, Chapman & Hall, London 1987, £ 25.00; J. K. M. Saunders, B. K. Hunter: *Modern NMR. is not uniquely defined in the NMR literature. According to the "left hand rule" (LHR) which has been generally used up to now in the chemically-oriented NMR literature, an r.f. magnetic field vector along the positive x-axis causes the magnetization vector to turn from the positive z-axis to the positive y-axis (e.g. for a 90°_x pulse, the thumb is in the direction of the positive x-axis, and the direction of rotation is given by the bending of the fingers). The "right hand rule" (RHR) gives an opposite rotation, i.e. from the positive z-axis to the positive y-axis. Books (1) and (2) use the LHR, while books (3) and (4) use the RHR. Although the procedures in NMR experiments and the interpretation of results are unaffected by the direction of rotation, a universal convention is desirable. It may well be that the RHR convention will now become generally accepted, following the publication of the "Zürich" book (4).

Book (1) is intended as an introduction to modern NMR spectroscopy for students of chemistry and biochemistry. In its 358 pages it describes conventional techniques (Chapters 1-4, 200 pp.), 1D and 2D pulse sequences (Chapter 5, 104 pp.), together with exercises and solutions (26 on ^{1}H NMR, 13 on ^{13}C NMR). The index contains about 1700 entries, of which about half are chemical compounds; some important abbreviations do not appear in the index, even though they are mentioned in the text, i.e. CT, PT and DCPL. Literature references are occasionally included as footnotes, whilst a bibliography for further reading is given at the end of each chapter. It is baffling to find that Chapter 2 (H-H couplings, 53 pp., dealing with systems of two to five spins and giving J-values) cites only twelve references, of which the last seven have already been given in Chapter 1 (δ in ^{1}H NMR, principles, tables, 33 pp.). Of the preceding five references, four relate to ^{13}C NMR, and would therefore be expected to appear instead in Chapter 4 (δ and J in ^{13}C NMR, tables, CP/MAS, 60 pp.)—and indeed we do find them there too! Chapter 4 contains, rather oddly, half a page on NMR imaging, as a paragraph to CP/MAS. On page 89 of Chapter 3 we are told that both permanent and electromagnets are used, and that instruments for both CW and FT operation exist; cryomagnets are not mentioned.

Many of the spectra shown have been copied by hand, and consequently have a rather "sick" appearance. Some of the figures are already familiar to me, but the original papers are not cited. I have the impression that some have been redrawn so as to get around the copyright. There are also some inaccuracies, e.g. in the discussion of CP in liquids, which equates CP to PT and fails to explain the importance of the Hartmann-Hahn condition. The book certainly contains much useful information, and also one or two teaching points worthy of special note, e.g. the reference to geostationary satellites in the explanation of the rotating frame. All the modern pulse sequences are mentioned and explained with vector diagrams. Nevertheless, I felt dissatisfied with the book as a whole, and particularly with the way in which it relates traditional NMR knowledge to modern techniques. I cannot recommend it to my students, as better books are available.

Book (2) is addressed to chemists who are concerned with structure determination in organic and inorganic chemistry. Some knowledge of ^{1}H and ^{13}C NMR spectroscopy is assumed, with regard to the effects of the properties and environments of the molecules under observation on δ, J, T_1 and T_2; books of proven value are available covering these basic topics. However, it is not necessary to be a δ, J virtuoso to benefit from the book, since the modern NMR techniques actually make it easier to interpret spectra. The book therefore concentrates mainly on the practical aspects of the newer pulse methods, dealing with the setting up of the spectrometer conditions, the principles and execution of the experiments, illustrative examples, and even performance tests for a spectrometer, being either available or considered for purchase. The basic construction of the spectrometer is illustrated by photographs. The material is presented in a clear instructive way, with an attractive text written in a user-friendly "I/you/we" style. This is combined with vector diagrams for the rotating frame (to which a detailed introduction is given), and simple energy level diagrams. So as to keep the explanations simple, the author avoids using spin operators in describing the experiments. Consequently the book does not allow one to gain a deeper understanding of zero quantum and multiple quantum processes. The only fall from grace in the presentation of the theory occurs when the off-resonance case is discussed in terms of the Bloch equation without relaxation. The rest of the 61 equations given are all simple, and provide quantitative relationships between quantities to be measured or evaluated. Through the 275 pages, the reader willingly follows the author on his journey through the ideas involved. The ten chapters are as follows: Introduction (8 pp.), Pulsed and FT NMR (30 pp.), Basic experimental techniques—sample preparation, solution concentrations and sensitivity (30 pp.), Theoretical description of pulsed NMR—vector model, relaxation (34 pp.), NOE—mechanism calculations, measurements, applications (32 pp.), Polarization transfer and spectral editing—INEPT, DEPT (24 pp.), Other experimental techniques—pulse length and r.f. field strength in homo- and heteronuclear experiments, composite pulses, broad-band decoupling, T_1 measurements, quantitative measurements, selective excitation, suppression of signals (30 pp.), Homonuclear chemical shift correlations (62 pp.), Heteronuclear chemical shift correlations (14 pp.), Spin echoes and δ,J correlation spectroscopy (18 pp.). Each chapter ends with a short bibliography; a total of 130 references is a far from adequate coverage of the relevant literature, especially in Chapter 8 which contains only 29 references. The subject index contains 600 key words; important examples such as CT, PT and DCPL have adequate ranges of sub-headings. Regrettably there is no list of abbreviations, which would have been especially helpful to the reader in view of the author's tendency to employ some unusual ones (RuSH = *Rubens, States* and *Habekorn*, HSC = heteronuclear shift correlation, nOe = NOE, etc.). Also, of course, the misprint demon has been at work—for example, on p. 74 the legends for the figures have been interchanged. This is already a disaster page, since the author here associates the absorption and dispersion parts of the signal with the x and y components of the magnetization, rather than as arising from the decay of the individual x (or y) component of the FID signal.

Altogether this is a very commendable book in which the author has undoubtedly achieved his objective, and it should be available in every chemistry department. It can be most warmly recommended for anyone wishing to acquire a deeper knowledge of modern NMR spectroscopy, whether as an introduction to practical use of the techniques, or as preparatory reading before a study based on more theoretically oriented monographs. It seems especially suitable for use in research groups which have a considerable turnover of people, for providing newcomers with a minimum basis of NMR knowledge. The paperback is reasonably priced, and should be within the means even of students.

Book (3) is a good complement to Book (2), as it describes the basic pulse experiments in product operator formalism. The 380 pages contain 671 equations! Chapter 1 (18 pp.) briefly introduces the basic theory and relates it to the experiment. A particularly elegant derivation is given leading to the equations for the development of the spin system under the influence of r.f. pulses and the effects of δ and J, for spins of 1/2 and 1, using the Baker-Campbell-Hausdorff equation for exponential operators. Chapter 2 (34 pp.) deals with 1D experiments (transverse magnetization, echoes, J-spectroscopy, spectral editing, decoupling, NOE, J-scaling, selective excitation). The treatment in Chapter 3 of the various PT/CT methods, and of DQ/MQ/z filters, provides the NMR spectroscopist with a very useful account of these important techniques; here the authors' own research interests clearly show to advantage (see *J. Magn. Reson. 71* (1987) 322 and refs. cited therein). In Chapter 4, the longest in the book (102 pp.), the authors deal with the types of 2D experiments currently used for liquids (2D NMR spectra in general, δ,J-spectroscopy, H,H-COSY and H,X-COSY, MQ filtering, relayed COSY, NOESY). Even some quite exotic variations are discussed, such as SuperCOSY, COCONOESY and ACCORDION, but I was surprised to find no mention of such a useful experiment as COLOC. The neat formal description of 2D experiments, which is made possible by using product operators, shows to great advantage in the introduction to the COSY techniques on p. 154. Multiple quantum NMR for liquids and solids is treated succinctly in Chapter 5 (34 pp.), and includes multiplicity-selective excitation and MQ imaging. The final chapter on "Experimental Methods" (20 pp.) is not what one excpects from its title, as it deals mainly with the compensation of r.f. field inhomogeneities (using composite pulses), and—one reads with amazement—11 pages (!) on NMR imaging and in vivo NMR.

The content of the book, except for the last chapter, achieves its aims very well. The book should appeal especially to the physical chemistry oriented reader who needs a survey of the fundamentals of modern NMR spectroscopy. Nevertheless, it falls short of the ideal in some respects. For example, the list of contents tells one little more than one already expects from the title. Nor is it clear from the title itself that most of the book is concerned with the underlying theory of the experiments and techniques. The bibliography, which is divided into fundamentals, books and monographs, CT, 2D NMR in liquids, MQ spectroscopy, high resolution NMR in solids, composite pulses and NMR imaging, contains only 116 references, and therefore does not represent the current literature at all adequately. There are no literature citations at all in the text, apart from the sources given for most of the 259 figures. This means that one has to engage in detective work in trying to identify references, e.g. for interesting applications of ^{2}H NMR spectroscopy which are introduced on p. 226. The index, which for 380 pages of text contains only 140 key words, many of them acronyms, appears as a perfunctory duty to satisfy the publishers rather than as an aid to the reader. It soon fails one, e.g. in looking for "phase sensitive 2D spectrum", WALTZ-16, or MLEV-16, although all these are discussed in the text. Here again, as in Books (1) and (2), there is no list of abbreviations.

To summarize, the shortcomings mentioned here ought not to deter anyone from reading this informative book, which gives an outstandingly good introduction to modern pulse experiments, using the product operator formalism. One could profit greatly from working through it in the manner of a course of lectures; for liquids NMR only this amounts to about 260 pages. I can strongly recommend buying this book although it is not suitable as a reference source.

Finally, *Book (4)* can be regarded as *the* complete 2D NMR book, or even as several books combined into one. Whether or not it deserves to be regarded as the NMR spectroscopist's "New Testament"—the "Old Testament" being *Abragam*'s book—remains to be seen. At least it is almost identical in color, format, number of pages and weight (and also comes from the same publisher). The competence of the new apostles is beyond question, and their charisma is overwhelming, especially when they are shedding light on to spectral chaos (Chapter 7, Separation of the interactions, 42 pp.), reporting from the NMR tree of knowledge (Chapter 8, H,H-COSY and H,X-COSY, 90 pp.), or even offering the forbidden fruit of spectroscopy (Chapter 5, MQ transitions, 41 pp.). After an introductory chapter (9 pp.), Chapter 2 (60 pp.) relates the story of the dynamics of nuclear spin systems. Density matrix operators and superoperators within and outside Liouville space provide us with energy and relaxation. Chapter 3 (20 pp.) describes the manipulation of the Hamiltonian operator and stroboscopic observations. In Chapter 4 (152 pp.) we have the book of 1D FT NMR spectroscopy, including system theory, classical and quantum-mechanical descriptions, non-ideal pulses, sensitivity, heteronuclear PT and investigation of the dynamics of molecular processes, and double resonance. Chapter 6 (75 pp.) is a concise, but mathematically demanding, treatment of the principles of 2D FT NMR spectroscopy (coherence transfer mechanisms, 2D FT experiments, line shapes, and 2D data manipulation). Chapter 9 (50 pp.) deals with dynamic processes such as PT, cross-relaxation (NOE) and chemical exchange, and lastly Chapter 10 (26 pp.) describes NMR imaging techniques. Altogether there are 596 pages, containing 1260 equations. The literature references have been carefully checked and arranged according to chapters; there are 971 references in all. It must be mentioned, though, that two years elapsed between the writing of the preface (March 1985) and the publication of the book. Some of the most recent work, e.g. on fast NMR imaging (FLASH, for example) is therefore not covered. The index contains about 1500 entries; incredibly, though, "exponential operator" does not appear in the list of key words.

The Zürich book, what else would one expect, offers a comprehensive theoretical description of modern pulsed NMR spectroscopy, and includes the relaxation of MQ coherence. Although the principles set out are of quite general validity, the main emphasis of the treatment is on applications to liquids. The discussion of solid samples deals with the separation of δ effects from dipolar coupling effects, and of δ(isotropic) from δ(anisotropic). It may well be useful for chemists to make themselves familiar with exponential operator methods before working through the book, by using either Book (3) or Slichter: *Principles of Magnetic Resonance*, Harper & Row, New York (1963), just as it used to be necessary to first understand pages 22–24 of Abragam. However, the book has a lot to offer even to those less versed in the theoretical background, e.g. the discussions on signal optimization in 1D NMR (the Ernst angle, p. 125), spectral editing (p. 192), a review of methods for measuring T_1 (p. 202), chemical reactions occurring during recording of the FID (p. 211), spin filtering (p. 431) and the important "seven golden rules" for 2D NMR measurements (p. 357). There is a particularly instructive discussion on p. 468 of sensitivity in H,X-COSY

measurements for the case where an insensitive nucleus which is coupled to a proton is to be observed using 1D or 2D pulse sequences. For ^{15}N the relative signal to noise ratios vary in proportion to 1, 10, 30 and 300, depending on the pulse sequence used, requiring measurement times of 25 h, 15 min, 100 s or 1 s, respectively.

The book by *Ernst, Bodenhausen*, and *Wokaun* is undoubtedly to be regarded as the standard work on modern NMR spectroscopy, presenting the basic theory which underlies the newer pulse experiments used in structure elucidation. It will be indispensable for all scientists who wish to learn "at first hand" about these advanced techniques, and no departmental library should be without it. It is likely to become required reading for all physical chemistry oriented NMR spectroscopists.

What, then, is the overall impression? In the last ten years new methods have been introduced into NMR spectroscopy which allow quicker solutions to standard types of chemical problems, and make it possible for the first time to answer questions concerning the structures of such complex systems as proteins in solution. Up to now one has had to rely mainly on reading the original papers for the principles of these methods and examples of their applications. There has been a lack of monographs on the subject, apart from the doctoral thesis by *Ad Bax*, which was successfully published in book form. This situation is now changing rapidly, perhaps more so than people responsible for libraries would wish, in view of their limited budgets. In addition to the four books reviewed here, more are already on the way[*]. With the availability of these, the cost of updating the book stock in NMR alone could easily exceed DM 1000. With regard to the four books reviewed, however, the choice is not too difficult. The purchase of Book (1) is subject of personal preference. Book (2) is highly recommended to everyone who is engaged in the application of modern NMR techniques. No chemistry department should be without it. Book (3) will please anyone who already has NMR experience, and wishes to gain a deeper understanding of the theory of modern pulsed NMR methods using the product operator formalism. Finally, Book (4) is the standard work which belongs in every library and on the desk of the NMR specialist.

Zuckermans Compendium of Inorganic Chemistry—"timely, critical, comprehensive"?

For some time now it has been well known amongst those involved with the subject that VCH Verlagsgesellschaft was planning a multivolume work in which the wealth of experience in synthetic methods and experimental skills in inorganic chemistry would be brought together in an orderly presentation. At a very early stage well known inorganic chemists were invited to serve on an "Editorial Advisory Board", or as "Editorial Consultants to the Series", so as to take part in managing this truly monumental project under the direction of an experienced editor. Of course, authors were also needed, and some years had passed by the time these were found, and eventually the first contributions arrived and were assembled together in their appropriate individual volumes. Of the 18 volumes on "Reactions" which are planned (with a further six on "Methods" to follow), volumes 1 and 15 have now appeared, namely:

Inorganic Reactions and Methods. Edited by *J. J. Zuckerman*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, Deerfield Beach 1986. **Vol. 1: The Formation of Bonds to Hydrogen (Part 1).** xxv, 326 pp., bound, DM 275.00.—ISBN 3-527-26259-8/0-89573-251-3; **Vol. 15: Electron-Transfer and Electrochemical Reactions; Photochemical and Other Energized Reactions.** xxiii, 399 pp., bound, DM 298.00.—ISBN 3-527-26273-3/0-89573-250-5

This reviewer anticipated seeing the result of this long gestation with as much curiosity as must the many others who at various times have taken interest in the preparation of the volumes. How would those in charge cope with the almost impossible task which they had been given?

The first chapter of Vol. 1 ("How to Use this Book") begins with an explanation under the title "Organization of Subject Matter". We learn that reactions and techniques are grouped together under "Formation of Bonds" according to the elements involved. Thus we begin in Vol. 1 with "Formation of Bonds to Hydrogen", the elements of the halogen and chalcogen groups being the first bonding partners dealt with. Vol. 2 accordingly deals with hydrides formed by the remaining elements, and this is followed by "Formation of Bonds to Halogens", "Formation of Bonds to Chalcogens", and so on (Vols. 3–13). The material in these volumes is supplemented by special volumes (Vols. 14–18) on themes such as "Insertion Reactions and Their Reverse" (in Vol. 14), and "The Formation of Intercalation Compounds" (in Vol. 17). Vol. 15 deals with "Electron-Transfer and Electrochemical Reactions" and "Photochemical and Other Energized Reactions".

What, then are one's observations after using these "sample volumes"? Vol. 1 turned out to be largely unreadable: if one wishes to get an overview on methods for forming a particular type of bond or compound, one finds that the "iron discipline" which has been followed in the arrangement of the material severs all the usual connections. As an example, in a section which has the subtitles "1.2 The Formation of Hydrogen—1.2.2 By Reactions of Hydride Ions—1.2.2.2 With OH Groups and Acids in OH Systems", one finds on pages 5–11 descriptions of reactions which include that of NaH with water or carboxylic acids, the decomposition of methylberyllium hydride or $B_{20}H_{18}^{2-}$ by acids, the hydrolysis of UH_3 and Th_4H_{15}, the reaction of $Sn(OCH_3)_4$ with diborane, and the catalytic steam reforming reaction (production of hydrogen from alkanes and steam). Under each of these topics there are only a few lines and one equation, and only eight literature references *in total*, then we push on further with the systematic treatment! Again, under the series of headings "1.4 The Formation of Bonds between Hydrogen and Elements of Group VIB (O, S, Se, Te, Po)—1.4.5 By Reactions of Protonic Acids—1.4.5.2 With Sulfides—1.4.5.2.3 In Preparations of Anhydrous Acids of Sulfur", one finds the formation of $H_2S_2O_3$ from sodium thiosulfate and HCl, together with an (incorrect) formula. Would one have looked for it there?—and does it belong there anyway? The next reaction, which follows in the same section without a sentence to bridge the transition, is the formation of CF_3SH.

Since this first volume contains virtually no easily digestible sections which make for easy reading (such as are still found in "Houben-Weyl", for example), this part of the handbook is best treated as a work of reference. It is in fact ideally suited for this purpose, as the author, compound and subject indexes to the first volume occupy 90 of the

326 pages, and are excellent. The more specialized the subject on which one wants information, the better the book serves one as a reference source; for example, the information given on HSeD is faultless, while on the other hand to seek out a critical survey of essential facts about H_2O_2 is a time-consuming task which yields no satisfactory result. There is some compensation, however, in the convenient reading list given at the end of each chapter, even though it is not always fully up to date. This reflects the wide variation between the many individual authors as regards their competence and specialized knowledge in the topics covered.

Quite a different picture emerges in Vol. 15, which contains long reviews on specialized topics by only a few authors, with coverage of even very recent results. The test is enriched by the inclusion of many structural formulas, diagrams and numerical results, and the physical-chemical basis is also treated. The publishers' advertisement of the work as "timely, critical and comprehensive" is certainly true of this volume, while it is not of Vol. 1. The two parts entitled "Electron-Transfer and Electrochemical Reactions" (*N. Sutin, R. G. Linck, C. Creutz, W. E. Geiger, M. J. Weaver*) and "Photochemical and Other Energized Reactions" (*G. L. Geoffroy, P. C. Ford, H. B. Abrahamson, M. Z. Hoffman*) are concerned virtually exclusively with the chemistry of transition metals. Provided that one accepts this limitation, it can be said that the material has been put together in an exemplary way and presented in a very useful and readable form. Presumably in these "late" volumes the shortcomings which result from the rigidly systematic treatment of the d and f blocks elements in only one short volume (Vol. 14) must be remedied.

These first two samples of the new series are thus of very different quality. It is to be hoped that, in the volumes to come, it will still be possible to correct some negative aspects. The external appearance of the books is faultless.

Houben-Weyl - Controversial

"Houben-Weyl" is one of the central pillars of the chemical literature; it is an authoritative source book of the first rank—and not only in the German-speaking world. The blue cloth-bound volumes command respect, and provide comprehensive and clearly set out information about the methods of organic chemistry. They contain a wealth of treasures, with carefully prepared synopses edited for ease of use. Such, for example, are the volumes on organophosphorus and organoboron chemistry. It is a pleasure to extract information from these, just as much for the experienced specialist as for the newcomer in unfamiliar territory. Two new supplementary volumes have just appeared to join the series on the bookshelf.

Houben-Weyl. Methoden der Organischen Chemie. Vol. E 18/Parts 1 and 2. Organo-π-metall-Verbindungen als Hilfsmittel in der organischen Chemie. Edited by *J. Falbe*. Thieme, Stuttgart 1986. DM 1580.00 (subscription price DM 1422.00). Part 1: xxvii, pp. 1–749, bound, ISBN 3-13-218804-2; Part 2: xv, pp. 750–1428, bound, ISBN 3-13-218804-2

which deal with the use of organometallic π-complexes in organic chemistry. After well over thirty years of productive research in this field, it was high time that it should be thoroughly reviewed from the organic chemist's viewpoint. Because of the large number of topics to be covered, working systematically through all the material has been a laborious and time-consuming task and it is to the credit of the editor *Jürgen Falbe* that these two new volumes have been so rapidly written. The team of sixteen authors has covered all the material, each from has own specialist viewpoint, in 1234 pages (not counting the indexes). They offer the user well-informed summaries of the various aspects, and a mine of information on experimental methods. Amongst these the contributions on hydroformylation by *B. Cornils* and *L. Markó* are outstanding.

However, the volumes fall short of the objective of being a systematically ordered handbook, of the sort that we are accustomed to in "Houben-Weyl". This reviewer struggled on bravely and hopefully through the chapters, at first filled with curiosity, but then with teeth clenched, grim determination. This perseverance yielded only pages of notes containing errata, inconsistencies, and information which was sometimes incomprehensible. According to the jacket synopsis, Part 1 describes preparative methods "arranged according to the various hapto forms". From the outset, however, the book runs into trouble with the hapto nomenclature: as early as the contents list we find "η^2-carbene complexes", an incorrect hapto form which is surpassed on page 58 by "η^3-carbynes". This is definitely taking liberties with the system of nomenclature. Nowadays one expects such a handbook to use nomenclature which conforms to the Chemical Abstracts standards, but these two volumes pay no regard to that. Here alkenyl ligands are usually described by a dehydroolefin nomenclature which, in the absence of a structural formula, is understood by nobody—certainly not by the computer, judging by the "η^3-3-dehydro-cyclooctene" group (p. 1001). Elsewhere, though, we find the more generally accepted form "η^5-cyclopentadienyl-" rather than "dehydrocyclopentadiene". An amusing example found on page 850 is [η^5-cyclopentadienyl]-(η^3-3-dehydro-cyclopentene)-nickel. On page 182 a decision has even been made in favour of "η^5-dehydropyrrolyl-", whereas on page 228 the same ligand is called "dehydropyrrole". What is intended to be a guide through the literature thus instead becomes a labyrinth from the user's point of view.

Presumably it was pressure of time that allowed the misprint gremlin to create havoc by changing "thorium" into "thor", inventing on page 481 a "tris-η^6-pyridine-rhodium", transforming a η^6-phenylborinato ligand into a η^5-ligand, and showing $CO + D_2O$ in equilibrium with $CO_2 + H$ (p. 659). The pressures given in the preparative methods have mostly been converted to kPa, but sometimes incorrectly, as for example on page 1002. For variety, though, they are sometimes measured in bar or torr, while other obsolete units such as "Stde." and "Schmp." have been allowed to pass uncorrected. By referring to an addition as a "silanation" (German: "Silanierung") it becomes instead a substitution, and alongside silylation we find also "disilylation" (German: "Disilylierung"). As for the possible meanings of the (German) words "Carborierung" and "Hydrocarborierung" which have been coined in the list of contents, we can discover them only by studying the relevant chapter in Part 2.

Theophrastus Paracelsus, commenting in 1538 on the chemical literature of his day, wrote in his Labyrinthus Medicorum "Die Tintenbücher haben kein Kunst in ihnen, sondern Sudelns und Kudelns durch einander und machen dann Schwaderlappen, daß die Säu lieber Dreck fressen,

denn ihr Geköcht ..."—i.e. he complained the books were so full of meaningless squiggles and obfuscations that if they were stewed up and fed to the pigs the latter would leave them alone and go on eating filth. The present reviewer cannot express his disappointment in language of such baroque eloquence, but must instead sum up his verdict on these two volumes in just one short sad phrase: What a shame!

Helmut Bönnemann [NB 842 IE]
Max-Planck-Institut für Kohlenforschung,
Mülheim/R. (FRG)

Houben-Weyl: Methoden der Organischen Chemie. Vol. XIII/9a: Organometallverbindungen von Mn, Re, Fe, Ru, Os und Pt. Thieme, Stuttgart 1986. Approx. 1000 pp., bound, DM 1100.—ISBN 3-13-214804-0; **Vol. XIII/9b: Organometallverbindungen von Co, Rh, Ir, Ni und Pd.** 1984. lviii, 1057 pp., bound, DM 1190.—ISBN 3-13-215004-5

In Volumes XIII/9a and XIII/9b, and Volumes XIII/4 and XIII/7 which were published a short time earlier, "Houben-Weyl" steps into new territory, thereby earning praise and respect. Twenty years ago, organometallic compounds of transition metals still belonged in the curiosities cabinet for most preparative organic chemists, but their outlook has since changed (even if hesitantly for some), and now to an ever increasing extent one reads of new syntheses being carried out using transition metals. One need not be much of a prophet to forecast that this trend will intensify.

Volume XIII/9a is devoted to preparations and transformations of organomanganese, -rhenium, -iron, -ruthenium, -osmium and -platinum compounds containing at least one M–C σ-bond (insofar as these reactions are of interest to organic chemists), while Volume XIII/9b deals in a similar way with organometallic compounds of the cobalt series (Co, Rh, Ir) together with nickel and palladium. In both volumes the compounds are arranged under individual metals, first in order of increasing oxidation state of the metal atom, then further divided within these groups according to classes of substances, i.e. organometallic alkyls, ylides, 1-alkenyls, aryls, acyls, alkoxycarbonyls, and aminocarbonyls. The next method of classification is by method of preparation. The foremost of these is the principle of "double substitution" (e.g. in metal halides using Grignard reagents or organolithium compounds). After this π→σ transformations (e.g. of allyl-metal complexes), and methods of synthesis starting from other organometallic transition metal compounds are discussed. Each chapter includes information on the relative importance of the compounds discussed, their properties and relative stabilities, and the transformations which they can undergo. An additional noteworthy feature is the inclusion in Volume XIII/9b of information about the importance of intermediates containing Co–C, Rh–C and Pd–C σ-bonds in large-scale processes such as hydroformylation, the Monsanto acetic acid process, and the Wacker process. Potential applications to synthesizing natural products, e.g. by the use of organopalladium complexes, are also mentioned.

Apart from the use of some rather idiosyncratic expressions, which even most organometallic chemists will fail to understand (e.g. "σ-C→carbene rearrangement"), there is little to find fault with in these two volumes. The usual high standard of the Houben-Weyl series has been maintained, which is saying a great deal with regard to quality. The individual chapters are illustrated throughout with very good structural formulas, enabling the reader to quickly grasp the significance of the results given. The bibliography is remarkably up-to-date for a work of this scale (complete up to 1985 in some cases), indicating a very good degree of collaboration between authors and publisher.

It is difficult to understand why Volume XIII/9a includes platinum organometallic compounds. In spite of all attempts at rearranging the Periodic Table, platinum still remains in the nickel triad of elements, and the platinum compounds ought, therefore, to have been in Volume XIII/9b. It is true that this volume would then have been somewhat thicker than the first one, but that ought not to worry anyone. In any case, the cost of both volumes is—unfortunately—such that only libraries will be able to afford them, and nowadays they are surely groaning not only under the weight of thick volumes, but also under financial burdens such as this. One can only hope that, despite these difficulties, "Houben-Weyl" will maintain its high standards, and will continue to bring about a closer liaison between organometallic chemists of organic and inorganic color.

Structural Methods in Inorganic Chemistry. By *E. A. V. Ebsworth, D. W. H. Rankin* and *S. Cradock*. Blackwell Scientific Publications, Oxford 1987. xi, 456 pp., hardback, £ 13.50.—ISBN 0-632-01603-5

The authors have written this book with the aim of familiarizing advanced chemistry students in a selective way with the most important physical methods of structure investigation used in inorganic chemistry. An important part of this task is to enable the student to apply the most appropriate combination of techniques to a given structural problem. On the whole the authors fulfill this need, but shortcomings are apparent in some matters of detail.

Following an introductory chapter, which includes a nine page table reviewing the various physical methods, with notes on their use, the methods themselves are treated in eight chapters as follows: nuclear magnetic resonance spectroscopy, electron spin resonance spectroscopy, nuclear quadrupole resonance spectroscopy, rotational and vibrational spectroscopy, electronic spectroscopy and photoelectron spectroscopy, Mössbauer spectroscopy, diffraction methods, and mass spectrometry. A good balance is maintained in the importance accorded to the various methods; thus NMR and vibrational spectroscopies are treated in considerable detail, and mass spectrometry only briefly. It is notable, however, that there is no chapter on magnetochemistry. For each of the techniques covered there is a theoretical introduction; the impression is given in each case that this treatment is sufficient for understanding and using the technique, even though the preface certainly does not make such a claim. Anyone who has little previous knowledge of a technique will discover the limitations of the treatment as soon as he begins to apply what he has read. Thus, for example, in the chapter on vibrational spectroscopy the degeneracy of a vibrational mode is mentioned but not explained, and symmetry operations are treated in a very labored fashion. Again, in the section on diffraction methods, although one is told of the importance of determining the correct space group, the details of this are nowhere explained; reflection planes and

axes of rotation are not mentioned. Crucially important explanations are often dismissed too briefly, e.g. that of Miller indices. Occasionally there appears without warning an unexplained term such as "difference maps".

Yet despite all the criticisms of individual topics, the book is a considerable success, and a useful addition to the major resources available for the study of chemistry. A final, particularly impressive, chapter is entitled "Case Histories", and gives instructive examples of the practical application of what has been learned previously. The reader can also test how well he has learned the material by means of the problems that are set, with answers given at the end only for every second one; this contributes to a useful dialogue between student and teacher.

The Organic Chemistry of Nucleic Acids (Volume 24 in the series **Studies in Organic Chemistry**). By *Y. Mizuno*. Elsevier, Amsterdam 1986. 342 pp., bound, HFl 245.00.—ISBN 0-444-99521-8

The compactness of this book and its broadly worded title lead one to expect a standard reference work rather than an introduction. The preface restricts the scope implied by the title by stating that the length of the chapters is not related to their importance, and furthermore that the main emphasis is on Japanese papers.

The short introduction recalls the history of nucleic acids in chemistry and elaborates the important role which they play in nature. It culminates with a description of the synthesis of the gene for somatostatin, and its expression in *E. coli*. This topic is again taken up briefly in the chapter on "Genetic Engineering" at the end of the book.

The main emphasis of the book and at the same time its best chapters are those on synthesis and reactions of nucleosides, which is the author's speciality. Here also the outstanding contributions made by Japanese investigators become evident. Apart from the mainly historical considerations and those that are included for the sake of completeness, an especially useful feature is the evaluation of the various synthetic routes to purine and pyrimidine nucleosides. The advantages and disadvantages of the individual methods are given, together with the currently preferred method for each case. A great many compounds of pharmacological interest, which are obtained by isolation from microorganisms, by chemical synthesis, or by enzymatic or microbial processes, are listed.

Of the chapters on nucleic acid syntheses, that on the RNA synthesis is almost more instructive than that on the DNA synthesis, as the former is more elaborated on from a chemical point of view. The informative chapter on "DNA Drug Interaction", which provides the pharmaceutical chemist with a short review of the interaction mechanisms of both covalent and non-covalent intercalators, crosslinkers, and DNA splitting agents, deserves special mention. A weak point is the analytical section, which besides the sequencing of DNA and RNA includes only a brief mention of ^{13}C and ^{31}P NMR spectroscopy.

It is a pity that this book, which, according to the author, aims to provide students, lecturers and interested organic chemists in general with a readily comprehensible insight into nucleic acid chemistry, will probably fail to attain that objective because of its considerable cost. For the expert the book gives an overview of the extent of the Japanese contributions in this field. So far as the presentation of the book is concerned, I would have liked to see the many printing errors corrected, and a clear numbering system used for the formulae so that a non-specialist might follow the formulae charts more easily. This book can definitely be recommended for those pharmaceutical chemists who have an interest in what is going on in the area of nucleosides and nucleotides of pharmacological importance.

Chemistry and Structure at Interfaces: New Laser and Optical Techniques. Edited by *R. B. Hall* and *A. B. Ellis*. VCH Publishers, Deerfield Beach 1986. xiv, 351 pp., bound, DM 175.00.—ISBN 0-89573-311-0

The development of lasers and the availability of synchrotron radiation have had an enormous influence on all those fields of research in which electronic excitation can be used either to trigger physical or chemical processes, or to detect them. This book was stimulated by a three-day symposium held by the American Chemical Society in March 1983 on the theme "Photoprocesses at Solid Surfaces". It contains six seminar papers from this symposium, which have been updated by the authors to mid-1985.

"Examination of the Gas-Solid and Metal-Support Interfaces in Supported Catalysts by Near Edge X-ray Absorption Spectroscopy", by *J. A. Horsley* and *F. W. Lytle*, is a comparatively short contribution (23 pp.) dealing mainly with results obtained using synchrotron radiation on small clusters of platinum, iridium and rhodium. The interpretation of the results emphasizes the role played by the *d*-electrons of such clusters in their interaction with adsorbates.

In the next paper "Final-State-Resolved Studies on Molecule-Surface Interactions" (59 pp.), *D. S. King* and *R. R. Cavanagh* describe a very demanding, but highly informative technique, whereby one can get an insight into the distribution of energy between the different modes of excitation of a molecule following its interaction with a surface. For this purpose one makes use of either the fluorescence of the molecules following selective excitation by lasers, or the resonance ionization which generates ions with single or multiple charges, as determined by the absorption of the molecule. Up to now the molecule used as a model has in nearly all cases been NO, whose spectroscopic properties are especially well understood. In this article the authors describe studies of the energy distribution following thermal desorption or after scattering of a molecular beam at single crystal surfaces.

R. B. Hall and *S. J. Bares*, in their paper "Pulsed-Laser-Induced Desorption Studies of the Kinetics of Surface Reactions" (65 pp.), deal exclusively with the thermal desorption of adsorbed molecules by heating of the support. By using a laser beam the heating can be confined to a very small region, thus allowing one to sample small parts of surfaces and follow the progress of chemical reactions which take place during a gradual heating process. Using this technique one can also, by repeated irradiation of a small surface region, monitor the transport of material by surface diffusion.

Second order processes in non-linear optics can occur at boundary surfaces as a consequence of asymmetry. In the article "Applications of Optical Second-Harmonic Generation to Surface Science" by *Y. R. Shen* (56 pp.), some examples are given showing how this process can be used to

study adsorbed molecules, particularly with regard to their orientations. Since this effect depends on the strength of the local electromagnetic field at the surface, it can be used to measure the field, a capability which is important for the SERS effect discussed in the next paper.

Surface-enhanced Raman spectroscopy (SERS) has already been reviewed in numerous articles. *D. A. Weitz, M. Moskovits,* and *J. A. Creighton,* in their article "Surface-Enhanced Raman Spectroscopy with Emphasis on Liquid-Solid Interfaces" (51 pp.), support the view that the only significant factor in the SERS effect is the amplification of the electromagnetic field by resonance phenomena in small particles or at rough surfaces, which is highly controversial. There are many indications that a considerable contribution to the very high enhancement factors of 10^5–10^6 arises from specific chemical interactions between the adsorbate and the substrate. The SERS effect is of importance in its application to investigating problems of practical interest, some of which are briefly discussed here. An example is adsorption on small catalyst particles.

The luminescence observed from semiconductors, either following excitation by absorption of light or as a result of the injection of minority carriers, comes from the bulk material. However, its intensity is surface-dependent, since the radiation yield is determined essentially by the amount of radiationless recombination occurring at the surface. In his contribution "Luminescent Properties of Semiconductor Electrodes" (100 pp.), *A. B. Ellis* describes the experimental requirements for observing the phenomena that occur at semiconductor electrodes, and the theoretical models used to analyze the results. The main interest in such experiments is in evaluating semiconductors for energy conversion purposes, as the yield in photoelectrochemical cells is limited essentially by surface recombination.

All these articles provide interesting and stimulating ideas on the use of lasers and other optical techniques for the characterization of interfaces. The techniques that are proposed are still undergoing development, but undoubtedly have great potential for the future.

Molecular Structure and Energetics. Edited by *J. F. Liebman* and *A. Greenberg.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, Deerfield Beach, FL 1986. **Vol. 1: Chemical Bonding Models.** XIV, 360 pp., bound, DM 240.00 (subscription price DM 210.00).—ISBN 3-527-26344-6/0-89573-139-8; **Vol. 3: Studies of Organic Molecules.** XIV, 385 pp., bound, DM 240.00 (subscription price DM 210.00).—ISBN 3-527-26477-9/0-89573-141-X

A new "open-end" series has been started and the volumes 1 and 3 published first – in the meantime volumes 2 and 4 also appeared – contain 360 und 385 pages respectively; they have been published by the US subsidiary of VCH Verlagsgesellschaft, our old friend Verlag Chemie, in the same esthetic way to which we have become accustomed. (The binding is not to my taste but *de gustibus not est disputandum*).

Each of the two volumes has a general heading and the contributions chosen fit in reasonably well. Each author was given much latitude in the relative blending of theory and experiment and in style. This is perhaps most evident in the chapters written or co-authored by the editors themselves. The standard of the contents, almost without exception, is very high.

In comparing two similar series, published as beautifully as this one by a competing publisher ("Structure and Bonding" and "Topics in Current Chemistry"), one finds similar breadth and homo- or heterogeneity. It is evident that it is cheaper to print in East or even in West Germany per individual volume than in the U. S.

Not as a matter of modesty, but as a matter of fact, I have checked my opinions on chapters further from my realm of understanding with trusted expert colleagues. Though they remain unidentified, any misjudgements are solely my responsibility.

Volume 1 contains nine chapters, the first of which (15 pages) is by *L. Pauling* and *Z. S. Herman.* What a nice idea for the opening chapter of a book on chemical bonding! Although one can always learn from *Pauling*, I, of course, included (albeit Vitamin C is unmentioned), I must abjectly confess my disappointment. I was looking forward to a much greater treat upon reading the first half of the title: "Nature of the Chemical Bond Fifty Years Later:" I expected from the Master a deeper evaluation and perspective than actually touched. The purpose of sub-heading "The Relative Electronegativity of Atoms Seen in Perspective" is achieved. I expected a wider overview on the nature of the chemical bond, 50 years later, perhaps employing more of "the work of such investigators as *Roald Hoffmann*". Perhaps my judgement is clouded by the nature of the first chapter (by *D. J. Cram*) in a two-volume set on cyclophanes.

Chapter 2 by *H. A. Bent* on "Isoelectronic Molecules" treats the subject in an incredibly terse manner (30 pages!), as can be done only by a leading expert; it explains the concepts involved with well chosen examples. I was sorry when the beautifully written chapter ended. I should have been glad to see included the word isolobal.

Chapter 3 by *J. F. Liebman* and *J. Simons* discusses "Carbenes: A Study in Quantitative and Qualitative Theory" (49 pages). Since reviews of carbenes emphasizing the synthetic viewpoint are plentiful, this one is particularly valuable.

In Chapter 4, *M. S. Gordon* considers "Theoretical Studies of Multiple Bonding to Silicon" (22 pages). The author's first sentence makes the point of how rapidly this new field is developing. The length of the chapter is due to the novelty of the field and though coverage is very good Si=N bonding might have been added when Si=P is discussed. The author even manages to cite some 1985 references which were available to him, but much has already appeared in the interim. It is a pity that in this case there is no addendum (as in Vol. 3) to catch up a bit more. Nevertheless, here is the place to mention that publication has been relatively fast and many 1984 references are cited throughout.

In contradistinction, Chapter 5 by *R. B. King* on "Topological Relationships in Molecular Structures and Energetics" (26 pages) is disappointing. It not only skims the surface but its latest 1983 reference is to a chapter elsewhere by the same author on the same general theme. I should have thought that a chapter with this title ought to have contained a bit more about graph theory to simple planar organic compounds if not to those few that cannot be accommodated by a planar graph. Perhaps a more limiting title could not have led to great expectations.

Chapter 6 by *T. P. Fehlner* and *C. E. Housecroft* discusses "Boranes and Heteroboranes" (59 pages). It is a good introduction to the uninitiated as to structures of

cluster compounds, those of boron being perhaps the most versatile examples. Other clusters are mentioned in Chapter 5. This is a place where the editors might have had a bit more substantive inter-connection between the two rather than just placing them adjacently.

J. K. Burdett writes about "Structural-Electronic Relationships in the Solid State" in Chapter 7 (65 pages). It is here again unfortunate that other than two (self) citations from 1985. Nevertheless, this is an excellent review on the subject with examples from a variegated array of molecules. This chapter is one of the best in the Series.

Chapter 8 by two excellent authors, *L. J. Schaad* and *B. A. Hess, Jr.* on "A Detailed Derivation of the Schrödinger Equation" (42 pages) is out of place even in a book with such a broad subtitle, the explanation in its first paragraph notwithstanding. Nor do several theoreticians whom I consulted see any justification for its inclusion.

Chapter 9 by *J. E. Del Bene* on "Quantum Chemical Reaction Enthalpies" need not scare away any organic chemist. Added to the interesting discussion is a very helpful appendix regarding basis set and method notation.

Volume 3 contains seven chapters on almost entirely unrelated subjects. Though heterogeneous we have a collection of interesting discussions, some more specific, some more general. I have found the latter generally useful but I predict that readers will rate the more specific subjects in accord with their interests.

Chapter 1 is an authoritative review by *S. F. Nelsen* on "Hydrazine-Hydrazine Cation Electron Transfer Reactions" (56 pages), a field in which the author is the major contributor. It is a goldmine of information while explaining relative behavior principally by conformational means.

Chapter 2 by *G. R. Stevenson* on "Stabilization and Destabilization of Aromatic and Antiaromatic Compounds" (27 pages) is to me another in a long chain of books and chapters still flogging this creature. I say this seriously but the tongue-in-cheek statement by *E. Heilbronner* about "schizoaromaticity" (a compound believes itself aromatic by one criterion, not so by another) summarizes my feelings about this subject. Annulenes are emphasized and other than a handful of references to his own more recent work the citations are mainly from the 60's and 70's. I do not see the need for a chapter such as this.

Chapter 3 by *R. P. Johnson* on "Structural Limitations in Cyclic Alkenes, Alkynes, and Cumulenes" (56 pages) cites a great many from the late 70's and the 80's including some from 1985. Thus it is a useful up-to-date review nicely blending theory and experiment. I missed explicit citation of *Sondheimer*'s classic work. It ought, perhaps, to have been fitted into the discussion.

Chapter 4 by *B. F. Smart* on "Fluorinated Organic Molecules" (51 pages). (As an aged conservative I enjoyed the note explaining how to convert kcal/mol into SI units! This is dealt with in Chapter 6 in a more kosher manner.) The review is an excellent addition to another by the same author (Ref. 2). Troubles with experimental accuracy and problems in calculations are well illustrated.

Chapter 5 by *A. Greenberg* and *T. A. Stevenson* discusses "Structures and Energies of Substituted Strained Organic Molecules" (74 pages); it is an expectedly fitting sequel to the Liebman-Greenberg monograph on the same topic and a rich source of updated experimental and calculated data.

Chapter 6 by *J. F. Liebman* has relatively little to do with strain. It is entitled "Macroincrementation Reactions: A Holistic Estimation Approach for the Properties of Organic Compounds" (62 pages). Graduate students in chemistry as well as their teachers would do well to enjoy the well written story of heats of formation and their correct application, remembering not to compare apples with pears. They might even learn the meaning of some words in the title. Here again many recent citations are given. The use of comments bracketed by the symbol ≪ ≫ are an original way for emphasis.

Chapter 7 by *E. Ōsawa* and *K. Kanematsu* discusses "Generation of Long Carbon–Carbon Single Bonds in Strained Molecules by Through-Bond Interactions" (41 pages; the ≪ ≫ method employed). It is not surprising that such a fine theoretician-experimentalist team has produced such a valuable chapter. All in all: The Series is a must for every chemical library.

Chemistry of the Silicon–Silicon Double Bond

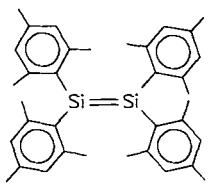
By Robert West*

Disilenes, compounds containing silicon–silicon double bonds, can be isolated as thermally stable, yellow- or orange-colored crystalline compounds; the substituent groups at silicon must be large (mesityl, *tert*-butyl, etc.) to prevent polymerization. Structural and spectroscopic studies indicate many similarities between the 3p–3p π bonding in disilenes and the 2p–2p π bonding in olefins, but disilenes are much more reactive than alkenes. The reactions of disilenes lead to many new classes of silicon compounds, including three- and four-membered rings which present novel problems in chemical bonding.

1. Introduction

Much of the richness and diversity of organic chemistry results from the ability of carbon to form multiple bonds, with itself or with other elements. Since silicon is the element most closely related to carbon, it seemed likely to early researchers that silicon should also form multiple bonds. However, all attempts to synthesize doubly bonded compounds of silicon early in this century proved unsuccessful, leading instead to cyclic oligomers or polymers containing only single covalent bonds.[1] Similar results were obtained for other second- and third-row elements, especially phosphorus and arsenic.[2] These findings led to the view that compounds containing multiple bonds involving silicon or other heavier main-group elements must be unstable: the so-called "double-bond rule."[3,4] According to this concept, weakness of multiple bonds between second-row elements was rationalized as resulting from the large radii of these atoms, leading to poor overlap between adjacent p orbitals.

Evidence for several transient species containing multiple bonds between second-row elements began however to accumulate in the late 1960s and 1970s. And in the single year 1981, the double-bond rule was decisively overthrown when the isolation of stable compounds containing P=P,[5] Si=C,[6] and Si=Si[7] bonds was announced.[*] The key to synthesis of these compounds was the use of sterically hindering substituent groups to block polymerization. Thus the first compound containing a Si=Si double bond to be prepared was tetramesityldisilene, **1**. The same principle has subsequently been used in the synthesis of several other new kinds of multiple bonds, including, inter alia, As=As,[8] Ge=Ge,[9] and for silicon, Si=N[10] and Si=P.[11]



1

This review deals with the disilenes (Si=Si compounds), concentrating on the stable compounds, whose chemistry has undergone considerable development in the last six

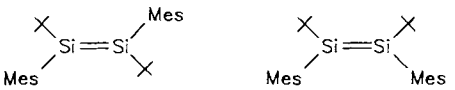
[*] Note added by the editorial staff: For a short comment on this area of research, see a letter from J. Goubeau (*Angew. Chem. 98* (1986) 944; *Angew. Chem. Int. Ed. Engl. 25* (1986) 1038).

years.[12] Some mention will be made also of the several marginally stable disilenes obtained only in solution.[13] In addition many other disilenes have been isolated in argon or hydrocarbon matrices.[14] The less stable disilenes, and multiple bonds to silicon generally, have been comprehensively reviewed elsewhere.[15] A valuable review of Si=C double bonds has also appeared recently.[16]

2. Si=Si and C=C Bonds: An Overview

Now that compounds containing Si=Si double bonds are readily available, it is fascinating to compare their properties with those of their carbon analogues, the alkenes, which are so well known and understood. In this section the differences and similarities between Si=Si and C=C double bonds will be summarized; details will be given in the sections following.

Structurally, the formation of Si=Si double bonds is accompanied by a marked shortening from the normal Si–Si single-bond distance; the decrease is quite similar to the bond shortening observed on going from C–C to C=C. However, the disilenes may exhibit deviation from the regular planar structure of olefins, because the Si=Si double bond is much more flexible toward distortion than C=C. Appropriately substituted disilenes such as the di-*tert*-butyldimesityl compound **2** exist as *Z* and *E* stereoisomers,



(*E*)-**2** (*Z*)-**2**

Mes = mesityl = 2,4,6-trimethylphenyl

which can be separated but undergo slow thermal isomerization. The barrier to rotation at Si=Si is about 70% as large as that for comparable alkenes. In sharp contrast to alkenes, the disilenes are yellow or orange, with electronic absorption bands between 400 and 470 nm. The visible spectra of disilenes are due to $3p\pi \rightarrow 3p\pi^*$ transitions, which have energies only about half as great as those for typical olefins, whose $2p\pi \rightarrow 2p\pi^*$ absorptions fall in the vacuum ultraviolet region. This difference is understandable in terms of a crude molecular orbital model. As shown in Figure 1, the π orbital for disilenes lies much higher than for alkenes, and the π^* level much lower.

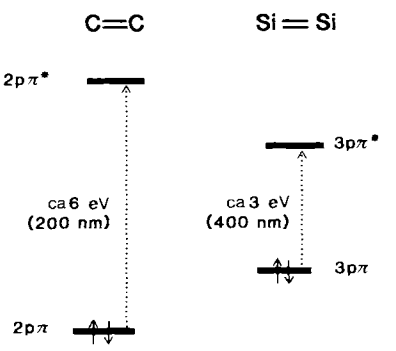


Fig. 1. Qualitative MO diagram showing relative energies of π and π^* levels for alkenes and disilenes.

From the MO diagram of Figure 1, it follows that disilenes should be both more electron-deficient *and* more electron-rich than alkenes. Indeed, the stable disilenes, in spite of their sterically hindering substituents, react readily with a variety of both nucleophilic and electrophilic reagents, and also take part in free-radical reactions. Disilenes undergo the typical addition reactions found for alkenes, but in addition take part in many reactions not normally observed for olefins.

Although the reactions of disilenes are known only very incompletely, they have led to a number of classes of compounds with previously unknown structures. Examples are shown in Figure 2. Some of these new compound types present unusual problems in chemical bonding theory.

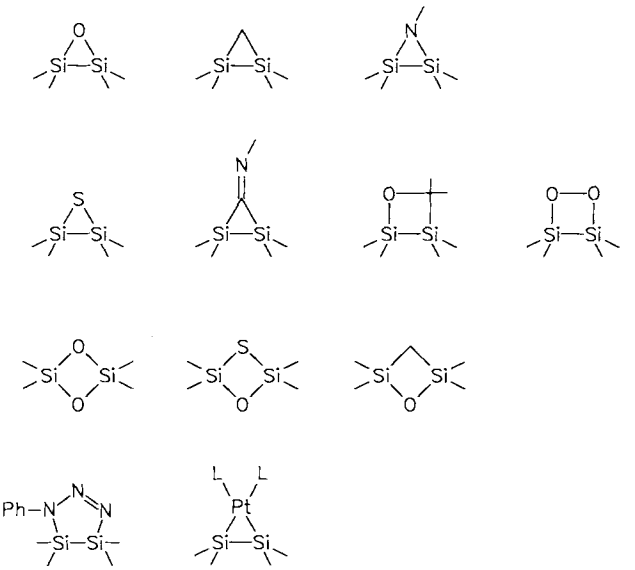

Fig. 2. New structural types obtained from disilenes.

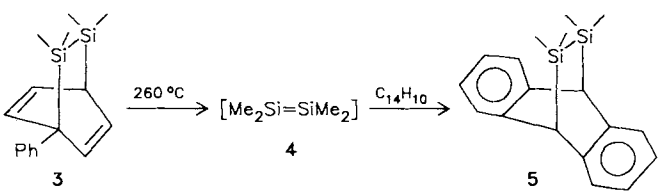
^{29}Si-NMR spectroscopy is of particular importance in the study and characterization of disilenes and their derivatives, just as ^{13}C-NMR spectroscopy has been important for alkenes and other hydrocarbons. Disilenes show ^{29}Si resonances which are strongly deshielded and (for **1**, the only case yet studied) highly anisotropic; also, the $^{1}J_{Si,Si}$ coupling constants are nearly twice as great for Si=Si as for Si–Si. All of these observations are closely paralleled in the ^{13}C-NMR spectra of olefins.

3. Historical: The Discovery of Stable Disilenes

The first evidence for transient disilenes was presented in 1972 by *Roark* and *Peddle*.[17] In a now-classic experiment they heated the $Me_2Si–SiMe_2$ bridged precursor molecule **3** with anthracene, obtaining a high yield of the

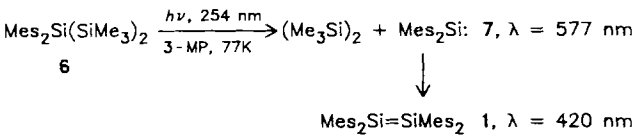


3 **4** **5**

adduct **5**. The result can be explained as due to a retro-Diels–Alder fragmentation of **3** leading to tetramethyldisilene **4**, which undergoes 9,10-addition to anthracene. Subsequently, important work on transient disilenes was carried out by *Barton* et al.,[18] *Gaspar* et al.,[19] and *Sakurai* et al.[20,21]

Our original experiments were also directed toward the synthesis of **4**, which we hoped to trap in an argon matrix for identification. However, these attempts, involving dehalogenation of $ClMe_2SiSiMe_2Cl$ or $BrMe_2SiSiMe_2SiMe_2Br$, were completely unsuccessful; if any disilene was formed, it did not survive long enough to be trapped in the matrix. We then turned our attention to matrix isolation of divalent silicon species (silanediyls or "silylenes"), beginning with Me_2Si generated photolytically from the six-membered ring $(Me_2Si)_6$.[22] This reaction proceeded smoothly at 10 K in argon, permitting a detailed study of the spectroscopy of dimethylsilanediyl.[22]

It soon became evident that photolysis of polysilicon compounds could be used for generation of many different silanediyls, and that these divalent silicon compounds are indefinitely stable not only in argon matrices near 10 K but also in hydrocarbon glasses at liquid nitrogen temperature.[14] Upon melting of the matrix or glass, most silanediyls polymerized, forming cyclic or linear polymeric polysilanes. Dimesitylsilanediyl, however, behaved abnormally. Photolysis of trisilane **6** in 3-methylpentane (3-MP) at 77 K led to the intensely blue-colored silylene **7**. When the hydrocarbon glass was melted a yellow solution was formed which gave reactions consistent with the presence of tetramesityldisilene, **1**, formed by dimerization of **7**. Ultimately, **1** was isolated as a bright yellow crystalline solid when the hydrocarbon was evaporated.[7] In practice, isolation of the silanediyl is not necessary. Simple photolysis of **6** in hydrocarbon solution at −60 °C leads directly to **1**, which crystallizes from solution as it is formed.[23]

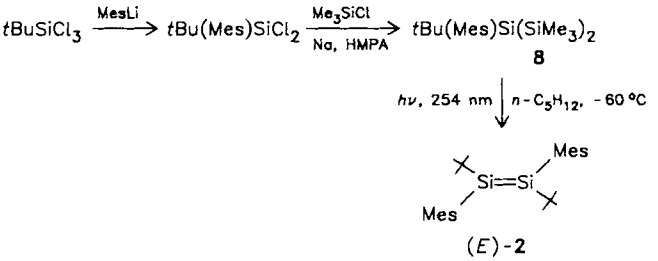


Later experiments have shown that when matrices containing silanediyls are annealed, dimerization to disilenes is the usual first step in polymerization.[14]

4. Synthesis and Properties of Stable Disilenes

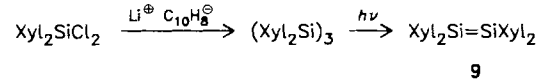
4.1. Photolysis of Linear Trisilanes (Method A)

Ultraviolet irradiation at 254 nm of precursors like **6** is a general method for the preparation of stable disilenes.[24] The required trisilanes can be made by standard coupling reactions, illustrated for the synthesis of tBu(Mes)Si($SiMe_3$)$_2$, **8**. Photolysis of **8** leads to the *E* isomer of 1,2-di-*tert*-butyl(dimesityl)disilene, (*E*)-**2** (HMPA = hexamethylphosphoramide).[23]



4.2. Photolysis of Cyclic Trisilanes (Method B)

A general method for the synthesis of trisilanes has been developed by *Masamune* et al.[25,26] Cyclic trisilanes are made from hindered diorganodihalosilanes and lithium naphthalide, then photolyzed to give the disilene. The first example was the synthesis of disilene **9**.[27] Presumably, photolysis of the cyclotrisilane produces disilene **9** and the corresponding silanediyl, with the latter undergoing dimerization to give more disilene. Both methods A and B have been used to make unstable as well as stable disilenes.



Xyl = 2,6-dimethylphenyl

[a] DEP = 2,6-diethylphenyl; 1-Ad = 1-adamantyl. [b] By UV irradiation of the *E* isomers. [c] By thermal isomerization of the *Z* isomer.

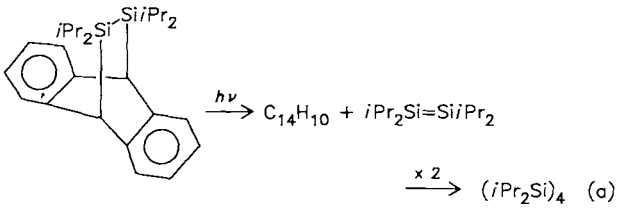
4.3. Dehalogenation of Dihalosilanes (Method C)

The preparation of **1** from the corresponding dichloride has been reported, using either controlled-potential electrochemical reduction or ultrasound-promoted dehalogenation with lithium metal.[28a] These syntheses, however, appear to produce rather impure disilene, and have not been widely used.[28b]

In Table 1 the known stable disilenes are listed with their ^{29}Si-NMR chemical shift values, UV/VIS absorption maxima, and where known, the Si=Si distances.

4.4. Photolytic [2+4] Cycloreversion

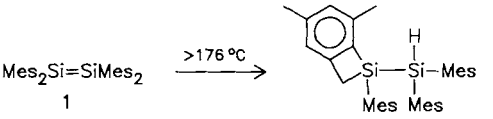
Recently it has been shown that irradiation of a disilabicyclo[2.2.2]octadiene precursor is a route to the nearly stable disilenes, tetra-*tert*-butyl-[29] and tetra-*iso*-propyldisilene.[30] The reaction used for the latter is illustrated in Equation (a). Probably the same method could be used to synthesize disilenes that are fully stable at room temperature.



(a)

4.5. Physical Properties of Disilenes

The stable disilenes are pale-yellow to orange-red crystalline solids with remarkable thermal stability. Some disilenes are strongly thermochromic. For example, when tetramesityldisilene (**1**) is heated as a solid, its color changes from bright yellow to orange to red; it melts to a red liquid at 176 °C.[23] The reason for the color changes is not known, but they probably result from temperature-dependent conformational changes affecting the Si=Si chromophore[33]. All of the color changes are reversible if the sample is cooled promptly, but molten **1** decomposes fairly rapidly according to Equation (b).[34]



(b)

Other disilenes are even more stable thermally. (*E*)-1,2-Bis(1-adamantyl)-1,2-dimesityldisilene, **11**, apparently survives brief heating to 275 °C.[46]

5. Molecular Structures

X-ray crystal structures have been determined for three disilenes, **1**[23] and (*E*)-**2**[23] (Fig. 3) as well as tetrakis(2,6-diethylphenyl)disilene, **10**.[25] The Si=Si distances in the three compounds fall between 214 and 216 pm (Table 1), about 20 pm less than the normal Si-Si single bond length. The decrease is slightly larger than that observed on going from C–C to C=C in the carbon series (ca. 18 pm).

Each of the three compounds has a slightly different structural arrangement at the Si=Si double bond. In (*E*)-**2**, the two silicon atoms and the four carbons attached to them are coplanar, just as in a normal olefin structure. For **10**, the arrangement at each silicon is coplanar, but the two halves of the molecule are twisted by 10°. In **1**, there is a slight (6°) twist of the double bond and, in addition, the two silicon atoms are pyramidal rather than planar, in an *anti* fashion to one another. The pyramidalization may be measured by the 18° angle formed between the C-Si-C planes and the Si-Si vector.

The slight distortions from planar geometry found for **1** and **10** are consistent with theoretical calculations on $H_2Si{=}SiH_2$[36a] and $(CH_3)_2Si{=}Si(CH_3)_2$,[36b] which indicate that the potential energy surface is quite flat for both *anti*-pyramidalization and for twisting about the Si-Si axis. Therefore, the small differences in structure around the double bond for **1**, (*E*)-**2**, and **10** may reflect preferences due to packing in the crystal lattice, as well as relief of steric strain.

In (*E*)-**2**, the two phenyl rings are inclined at angles of 88° to the plane of the silicon and attached carbon atoms. In this conformation little conjugation can occur between the aromatic rings and the Si=Si double bond. In **1**, two of the aromatic rings, *cis* to each other, are similarly rotated

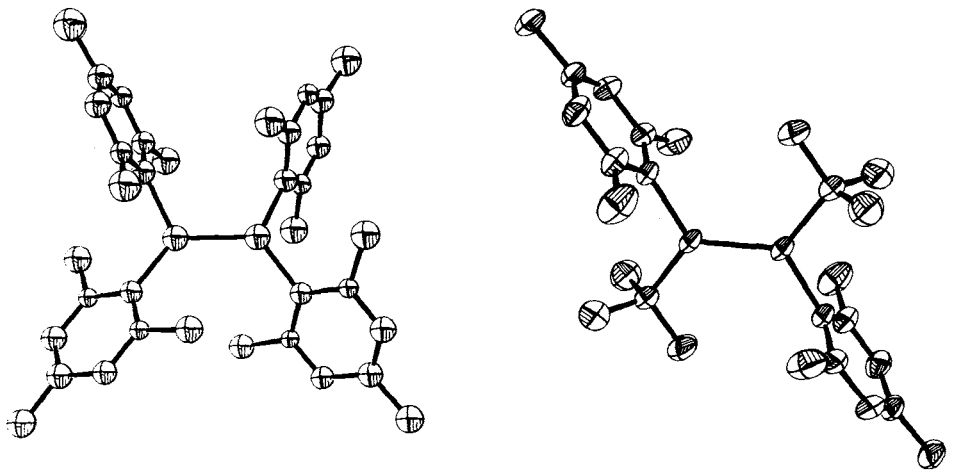


Fig. 3. ORTEP diagrams of X-ray crystal structures for tetramesityldisilene **1** (left) and (*E*)-1,2-di-*tert*-butyl(dimesityl)disilene (*E*)-**2** (right).

so that they are nearly orthogonal to the Si=Si double bond, but the other two rings are much more nearly coplanar with the mean plane of the silicon and attached carbon atoms so that conjugation with the Si=Si double bond is possible. In **10**, all of the aromatic rings are rotated relative to the respective C–Si–Si plane by 62–64°.

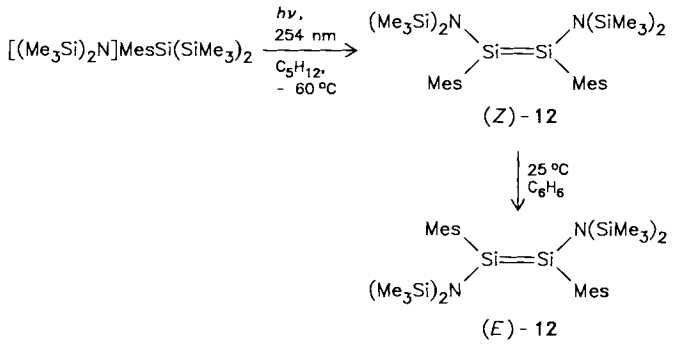
The conformations described are those present in the crystals, but of course other conformations are possible in solution. In fact, both the variable-temperature NMR spectra and the emission spectra of **1** suggest coexistence of more than one conformation.

6. Isomerism of Disilenes

6.1. *Z* and *E* Stereoisomers

The isolation of *Z* and *E* stereoisomers of disilenes has made possible studies of the rotational barrier at the silicon-silicon double bond, as well as permitted some beginning studies of reaction stereochemistry. Syntheses of disilenes sometimes produce mainly or exclusively one stereoisomer. For example, photolysis of the trisilane precursor **8** at −60°C produces the thermodynamically stable *E* isomer, (*E*)-**2**, which precipitates from solution almost isomerically pure. Irradiation of a solution of (*E*)-**2** at 350 nm converts it into a photostationary mixture of isomers (63:37 *E*:*Z*). When irradiation is ceased, interconversion of (*Z*)-**2** to (*E*)-**2** takes place slowly to give the equilibrium mixture of isomers (99:1 *E*:*Z*).[31]

For disilene **12**, irradiation of the trisilane precursor produces initially the *less* stable isomer (*Z*)-**12**, which can be crystallized from the photolysis solution in >97% isomeric purity. In solution (*Z*)-**12** slowly transforms to the equilibrium mixture (94:6 (*E*)-**12**:(*Z*)-**12**), from which the pure *E* isomer can be obtained by recrystallization.

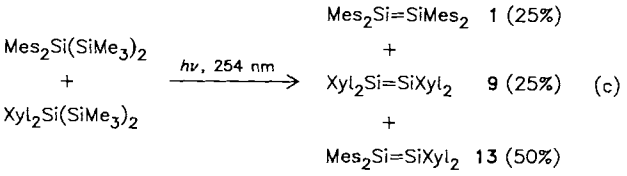


The *Z*/*E* interconversion of disilenes **2** and **12** has been followed using ^{1}H- and ^{29}Si-NMR spectroscopy. From rate measurements as a function of temperature, the rotational energy barriers E_A have been determined. For (*Z*)-**2**/(*E*)-**2**, the barrier is 131 kJ mol^{-1}.[31,35,36] It is of interest to compare this value with the corresponding barriers for C=C double bonds; however, rotational barriers for olefins depend greatly upon the substituent groups present. For DHC=CHD the barrier is 272 kJ mol^{-1}, but for some highly hindered olefins the value is even lower than that for **2**.[36] Perhaps a good molecule for comparison is (*Z*)-stilbene, for which E_A is 179 kJ mol^{-1}, about 30% greater than for (*Z*)-**2**.[37]

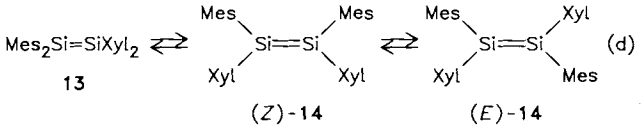
For (*Z*)-**12**, E_A for rotation is lower, 107 kJ mol^{-1}, perhaps because interactions of the nitrogen lone pair with the silicon π system reduce the Si–Si bond strength, or lower the energy of the transition state for rotation.[38] Additional data on rotational barriers in disilenes would clearly be desirable.

6.2. 1,2-Migration of Aryl Groups

The first disilene containing silicon atoms that are differently substituted, **13**, was recently synthesized. As shown in Equation (c), cophotolysis of two different trisilane precursors gave initially a 1:2:1 mixture of **1**, **13**, and **9**. It was surprising to find that the composition



changed with time; **1** and **9** remained constant but the amount of **13** slowly decreased, being replaced by its isomer Mes(Xyl)Si=Si(Xyl)Mes, **14**. As shown in Equation (d), the *Z* isomer of **14** is formed first, but eventually isomerizes to give a *Z*/*E* mixture. At equilibrium, approximately equal amounts of **13**, (*Z*)-**14**, and (*E*)-**14** are present.[30]



This unusual rearrangement appears to be dyotropic,[39] involving a concerted intramolecular migration of two σ-bonded aryl groups across the Si=Si double bond. Since 1,2-aryl migration is observed to be more rapid than *Z*/*E* interconversion, it must proceed through a different and lower-energy transition state. Presumably, similar rearrangements take place in all tetraaryldisilenes, but are unobservable except in special cases like **13** ⇌ (*Z*)-**14**. On the other hand, no such rearrangement occurs for **2** or **12**; apparently *t*Bu and $(Me_3Si)_2N$ groups do not undergo the 1,2-migration, at least under ordinary conditions.

7. Spectroscopy of Disilenes

7.1. UV/VIS Spectroscopy

The electronic absorption spectra for three disilenes are shown in Figure 4.[40] For (*E*)-**2**, which has no aryl groups in a position suitable for conjugation with the Si=Si bond, the lowest-energy absorption is found at 400 nm, identical to λ_{max} recorded for many tetraalkyldisilenes.[41] In the tetraaryldisilenes, where conjugation between aryl groups and Si=Si is possible, λ_{max} occurs near 420 nm, and in the

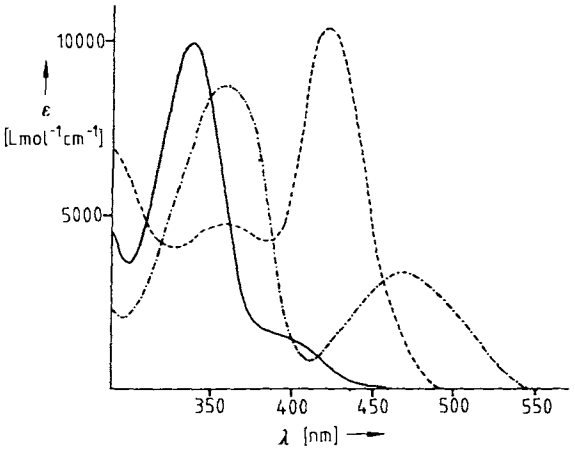


Fig. 4. Electronic absorption spectra for **1** (----), (*E*)-**2** (——), and (*E*)-**12** (—·—·—).

disilene isomers containing $(Me_3Si)_2N$ groups a much larger shift occurs to ca. 475 nm (Table 1).

The absorption and emission spectra of **1** have been investigated in somewhat greater detail.[33] At 77 K in a hydrocarbon glass, the additional absorptions shown in Figure 5 are found for **1**. Also displayed in Figure 5 are the

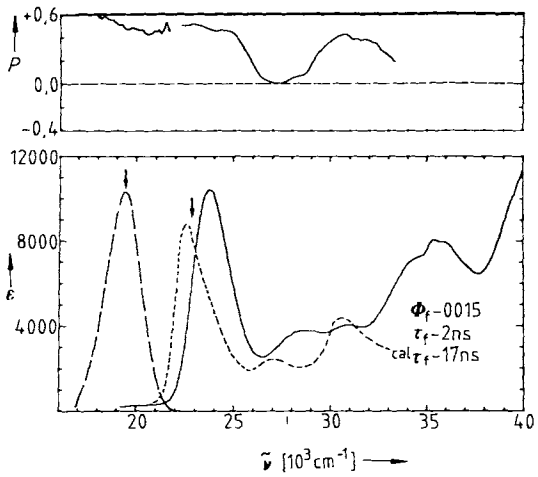

Fig. 5. Absorption (———), emission (— — —), and excitation (----) spectra for **1** in 3-methylpentane at 77 K. Above, polarization of the absorption and emission spectra.

emission and excitation spectra for **1**, as well as their polarizations. The identical value of 0.5 for the emission and excitation spectra indicates that a single electronic transition is involved. The curious feature of the spectra is that the excitation spectrum, although it follows the absorption spectrum closely, is shifted to longer wavelength. Moreover, the fluorescence lifetime of 2 ns is much shorter than the theoretical lifetime of 17 ns calculated from the integrated intensity of the long-wavelength absorption band. The likely explanation of these anomalies is that more than one conformer of **1** is present in solution; nonfluorescing conformer(s) are mainly responsible for the absorption spectrum, and the emission is due to a minor amount of a strongly fluorescent isomer. Similar effects have been observed for conformers of molecules related to stilbene.[42]

7.2. IR and Raman Spectroscopy

The vibrational spectra of disilenes have not been investigated in any detail, but resonance Raman experiments have established that lines at 539 cm^{-1} for **1** and at 525 cm^{-1} for (*Z*)-**2** are associated with Si=Si stretching vibrations.[43] These frequencies are about 30% higher than those for Si–Si single-bond stretching vibrations, consistent with increased Si–Si bond strength in the disilenes.

7.3. NMR Spectroscopy

^{29}Si-NMR spectra are particularly important in the characterization of disilenes. As seen in Table 1, ^{29}Si chemical shift values for disilenes are strongly deshielded, falling between $\delta = +49$ and $+95$. The ^{13}C chemical shift for olefins is similarly deshielded compared with that for alkanes. A study of the ^{29}Si-NMR spectrum of **1** in the solid state revealed a very large anisotropy of the ^{29}Si chemical shift tensor, due to the Si=Si π bond.[44] The ^{29}Si anisotropy for the corresponding disilane $Me_2HSiSiHMes_2$, lacking the π bond, is low. As shown in Table 2, similar effects are seen in the ^{13}C-NMR spectra of olefins versus alkanes.

Table 2. Principal values of chemical shift tensors.

Nucleus	Compound	σ_{11}	σ_{22}	σ_{33}
^{29}Si	$Mes_2Si{=}SiMes_2$	180	27	−15
^{29}Si	$Mes_2HSi{-}SiHMes_2$	−31	−56	−73
^{13}C	$H_2C{=}CH_2$	234	120	24
^{13}C	$H_3C{-}CH_3$	14	14	10

NMR coupling constants are also consistent with π-bonding in disilenes. The one-bond coupling constant, $^1J_{Si,Si}$, was recently measured as 155 Hz for **13**,[32] compared with ca. 85 Hz for typical aryldisilanes. The increase indicates much greater s character in the σ Si–Si bond in disilenes than in disilanes, consistent with approximate sp^2 hybridization of the Si atoms in the disilenes.[45]

^{1}H-NMR spectra of disilenes are normal at room temperature. For **1**[1] and **13**[25] splittings appear as the temperature is lowered, indicating the freezing-out of some motions and possibly also slow equilibration between conformers. Further study of the temperature dependence of the NMR spectra for disilenes seems warranted.

7.4. Cyclic Voltammetry and ESR Spectroscopy

The electrochemistry of several disilenes has recently been studied by cyclic voltammetry. In tetrahydrofuran, disilenes undergo irreversible one-electron oxidations and reductions; a typical voltammogram is shown in Figure 6, and half-wave potentials are listed in Table 3. As expected, both oxidation and reduction occur more easily than for alkenes.[46]

Radical anions or radical cations formed directly from disilenes have not been reported, but *Weidenbruch* et al. have published ESR spectra assigned to disilene radical anions obtained indirectly.[47] Reduction of tetra-*tert*-butyl-1,2-dichlorodisilane or the corresponding dibromo com-

pound with alkali metals gives an ESR signal assigned to the radical anion $[t\mathrm{Bu_2Si{=}Si}t\mathrm{Bu_2}]^{\odot\ominus}$. The main peak and ^{29}Si sidebands show hyperfine splitting corresponding to interaction with 36 equivalent protons, indicating delocalization of the unpaired electron over the entire molecule (Fig. 7). Similar reduction of 1,2-dichlorotetramesityldisi-

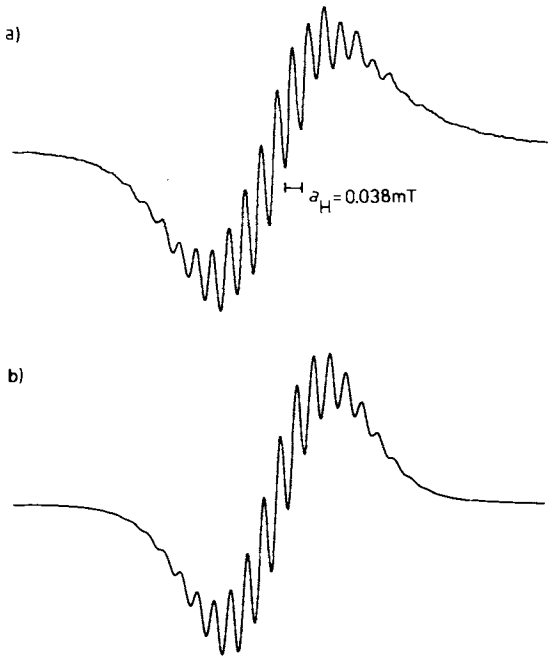

Fig. 7. a) Measured and b) simulated ESR spectrum of tetra-*tert*-butyldisilene radical anion.

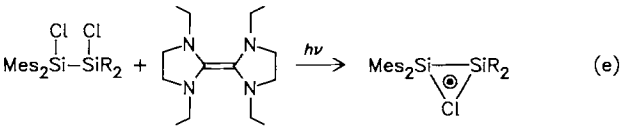
lane gave eventually a single-line ESR spectrum attributed to $[\mathrm{Mes_2Si{=}SiMes_2}]^{\odot\ominus}$. For both of these radical anions, the intensity of the ^{29}Si sidebands indicated interaction of the unpaired electron with two silicon atoms. Alkali metal reduction of $t\mathrm{Bu_2ClSi{-}SiClMes_2}$ produced a signal with no hyperfine structure and coupling to only one silicon, explained as due to a localized radical anion, $[t\mathrm{Bu_2Si{=}SiMes_2}]^{\odot\ominus}$.[48]

Reduction of dichlorodisilanes photolytically in the presence of an electron-rich amine produced ESR signals assigned to the chloro-bridged neutral radicals [Eq. (e)].

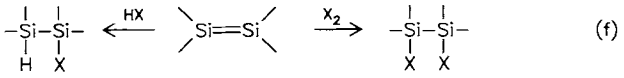


R = Mes, *t*Bu

8. Reactions of Disilenes

8.1. 1,2-Additions

Disilenes readily add hydrogen halides[34,49] and halogens,[27,49] just as olefins do. When these reactions were carried out with the stereoisomeric disilene (*E*)-**2**, HCl added to give a 2.5 : 1 mixture of *meso* and *R,S* diastereomers, indicating that Si–Si rotation takes place during the addition. Reaction with chlorine (in benzene), however, produced only one of the two possible stereoisomers, showing that no Si–Si rotation occurs [see Eq. (f)].[49] The

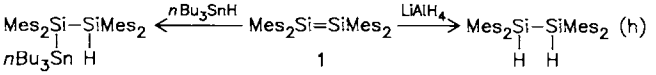


X = Cl, Br

results are consistent with a polar stepwise mechanism for addition of HCl, and a pathway involving a bridged radical or a chloronium ion for addition of Cl_2. However, further study of the mechanisms for these addition reactions is needed.

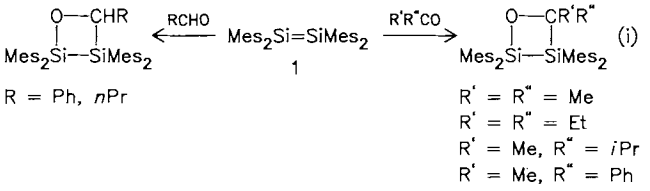
Addition of Cl_2 to **1** in alkanes takes a different course, producing $\mathrm{Mes_2HSi{-}SiClMes_2}$ as the major product along with products of free-radical chlorination of the alkane. Evidently the disilene catalyzes free-radical chlorination, and then reacts with the liberated HCl.

Unlike olefins, disilenes add OH compounds across the Si=Si bond, slowly at room temperature but rapidly at 60 °C [Eq. (g)].[29,34] Addition of alcohols to (*E*)-**2** produces a 1 : 1 mixture of stereoisomers, and so doubtlessly proceeds stepwise.[49] Additional 1,2-addition reactions reported for **1** include those with $n\mathrm{Bu_3SnH}$[49] and $LiAlH_4$ [Eq. (h)].



8.2. [2 + 2] Cycloadditions

Tetramesityldisilene reacts readily with aldehydes and ketones to give 1,2,3-oxadisiletanes [Eq. (i)].[28,34] As shown

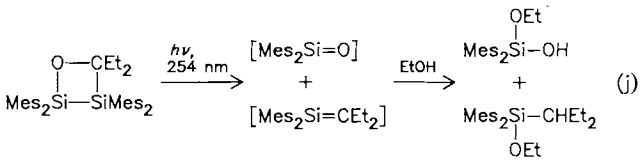


R = Ph, *n*Pr

R' = R'' = Me
R' = R'' = Et
R' = Me, R'' = *i*Pr
R' = Me, R'' = Ph

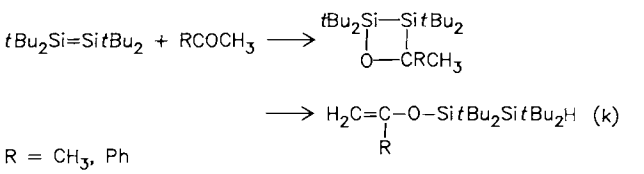
(i)

in Equation (j), photolysis of the 3-pentanone adduct of **1** in the presence of ethanol leads to cleavage products which suggest the intermediacy of silanone and silaethene species.[50]



(j)

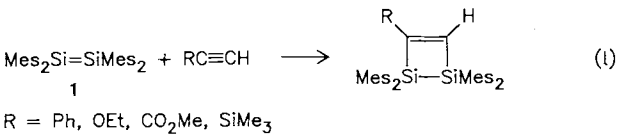
Tetra-*tert*-butyldisilene also adds to ketones to give 1,2,3-oxadisiletanes.[51] For the acetone and acetophenone adducts interesting further rearrangement reactions have been reported [Eq. (k)].



R = CH_3, Ph

(k)

Disilenes also undergo [2+2] cycloadditions with certain 1-alkynes [Eq. (l)].[49] Cycloaddition takes place slowly at room temperature and rapidly at 80°C in benzene. However, no reaction was observed between **1** and



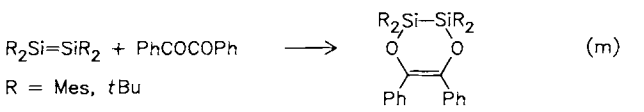
R = Ph, OEt, CO_2Me, $SiMe_3$

(l)

*n*BuC≡CH, $CH_3C{\equiv}CH$, PhC≡CPh, PhC≡CSiMe$_3$, or $MeO_2CC{\equiv}CCO_2Me$, even under forcing conditions. When phenylacetylene or ethynyl ethyl ether was added to (*E*)-**2**, the products were mixtures of equal amounts of diastereomers, indicating that the cycloaddition cannot be concerted.[52] An open-chain, diradical or dipolar intermediate seems likely.[53]

8.3. Other Cycloaddition Reactions

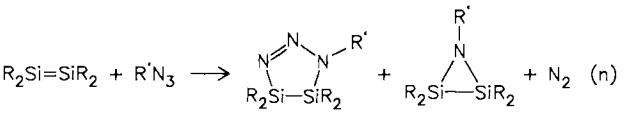
Diels–Alder cycloadditions between disilenes and 1,3-dienes have not been observed. In fact, with 1,3-cyclohexadiene, tetra-*tert*-butyldisilene is reported to react to give the [2+2] rather than the [2+4] cycloadduct.[51] However, both this disilene and **1**[28] react in a [2+4] fashion with benzil [Eq. (m)].



R = Mes, *t*Bu

(m)

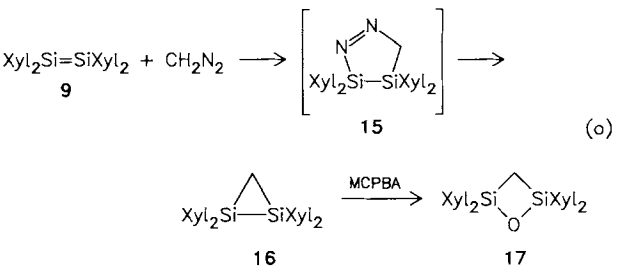
One clear example of [2+3] cycloaddition is known. Disilene reacts with aryl azides to give triazadihydrodisiloles along with azadisiliranes [Eq. (n)].[54] These com-



R' = Ph, Mes

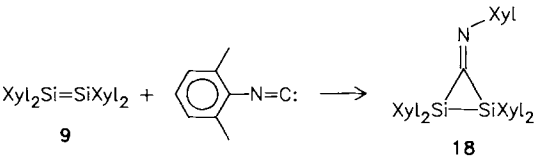
(n)

pounds, like other silyl diazenes, are deeply colored.[55] As shown in Equation (o), the reaction of **9** with diazomethane may also proceed through a [2+3]-cycloaddition intermediate, **15**. The isolated product is the disilacyclopropane **16**, which can be oxidized with *m*-chloroperbenzoic acid (MCPA) to give the 1,2,3-oxadisiletane **17**.[56]

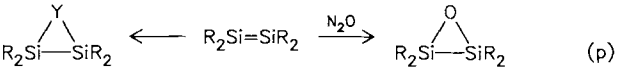


(o)

It is also possible that **16** arises from direct reaction of methylene with the Si=Si double bond. Recently, a [2+1] cycloaddition of a carbene-like molecule to a disilene was discovered. Reaction of **9** with 2,6-dimethylphenyl isocyanide yields the three-ring disilaketimine **18**, as a stable, bright red crystalline compound.[57]



Reactions of disilenes with sulfur[58] or selenium, or with the single-oxygen transfer agents N_2O or azoxybenzene,[59] give three-membered rings containing two silicons and a chalcogen atom [Eq. (p)]. The structure of the sulfur com-

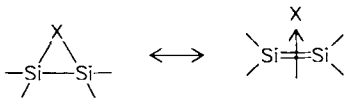


19a, Y = S
19b, Y = Se

(p)

pound, **19a**, has been determined by X-ray crystallography and is of unusual interest. The Si–Si bond is rather short (228.9 pm, compared with Si=Si 215, Si–Si 235 pm). Even more striking, the arrangement of the C, C, and Si atoms attached to each silicon is nearly planar, the sum of the bond angles at Si being 357.4°. The structure of disilacyclopropane **16** is similar, with Si–Si = 227.2 pm and angle sums between 357 and 358°. These features suggest that for both compounds, the σ-bond hybridization at silicon

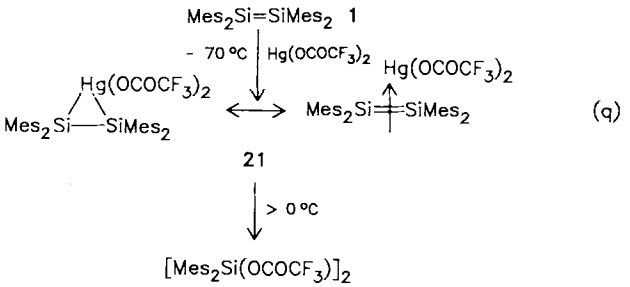
may be better represented as sp^2 than sp^3, and that partial π-bonding may persist between the silicon atoms. In other words, in compounds **16** and **19** the bonding may be intermediate between a normal three-membered ring and a π-complex (Scheme 1).[60]



Scheme 1. X = CH_2, S, Se.

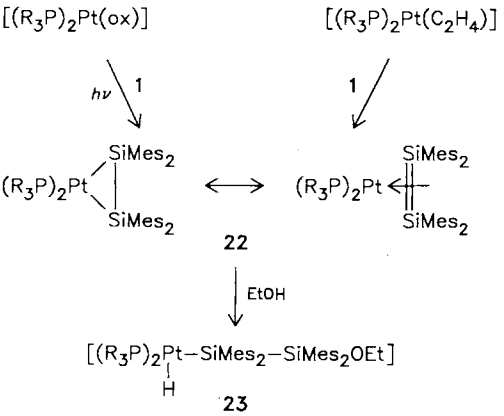
8.4. Metal Complexes of Disilenes

Olefin complexes of metals date back to the famous preparation of Zeiss' salt in 1827.[61] The first probable metal complex of a disilene was reported only in 1986.[62] At −70°C, **1** reacts with $Hg(OCOCF_3)_2$ to form a complex[26] observed by NMR and IR spectroscopy. The spectral data suggest a three-membered ring or π-complex structure for **21**. As shown in Equation (q), upon warming of the solution to room temperature, **21** decomposes to give a 1,2-bis(trifluoroacetoxy)disilane.



(q)

Very recently, metal complexes of **1** have been isolated at room temperature.[63] Photolysis of a bis(phosphane)platinum(II) oxalate in the presence of **1** produces an orange-yellow crystalline product, identified by its NMR and other spectroscopic properties as the disilene–platinum complex **22**. The same product is obtained by the reaction of ethylenebis(phosphane)platinum(0) with **1**. The characterization of **22** is provided by its reaction with ethanol, leading to the Pt–Si σ-bonded product **23** (Scheme 2).

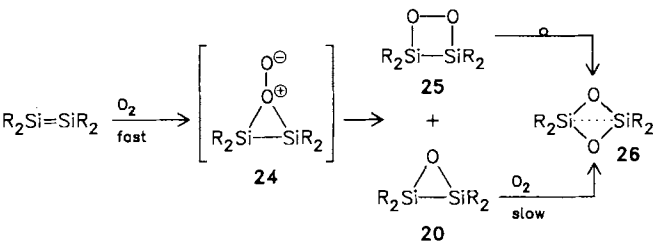


Scheme 2. R = Et, Ph; ox = oxalate.

8.5. Oxidation of Disilenes

Solid disilenes react with dioxygen of the air, rather rapidly for **1** and similar tetraaryldisilenes, but slowly for the more hindered disilenes **2** and especially **11**. The half-time for oxidation of **11**, exposed to the air, is many hours.[64] In all cases the principal products are the novel 1,3-cyclodisiloxanes[*] **26**.[34,65] Cyclic siloxanes are important materials of commerce, made in multiton quantities as intermediates in the silicone industry, but all previously known compounds have six-membered or larger rings.

In solution the oxidation reaction is more complex.[59] Initially two compounds are rapidly produced: A major (ca. 80%) amount of the 1,2-dioxetane **25**, and a minor quantity of the oxadisilirane **20**. The latter compound slowly undergoes further oxidation to the 1,3-cyclodisiloxane **26**, which is also produced by slow intramolecular rearrangement of **25**.[32,59] Both of the pathways to the end product **26** are stereospecific; oxidation of (*E*)-**2** gives, by either route, the *trans*-1,3-cyclodisiloxane.



Although 1,2-dioxetanes in the carbon series are formed from (hindered) olefins and singlet oxygen, the analogous silicon compounds **25** are produced from disilenes with triplet oxygen. Spin-pairing must occur at some point in the latter case. The rearrangement of **25** to **26** is unparalleled in carbon chemistry; organic 1,2-dioxetanes instead undergo cleavage to give carbonyl compounds in a photoluminescent reaction.[66] Conversion of **25** to **26** does not go through the silanone ($R_2Si{=}O$) species as an intermediate, because the identical rearrangement takes place in ethanol (which would be expected to trap silanone $R_2Si{=}O$ rapidly). Since both **20** and **25** are formed simultaneously in the initial oxidation, it is possible that they arise from a common intermediate such as the perepoxide **24**.

X-ray crystal structures have not yet been determined for **20** or **25**, but structures are known for three 1,3-cyclodisiloxanes and these are of unusual interest.[67] An ORTEP diagram for the *trans*-1,3-di-*tert*-butyl-1,3-dimesityl compound is shown in Figure 8. Within the nearly planar four-membered rings, the Si–O–Si angles are quite small, ranging from about 86 to 91°. As shown in Figure 9, the effect is to bring the silicon atoms very close to one another. The most extreme case is the tetramesityl compound, in which the Si–Si distance of 230.6 pm is substantially shorter than the normal single bond distance of ca. 235 pm.

[*] According to IUPAC rules, 1,3-cyclodisiloxanes are named 1,3-dioxa-2,4-disiletanes. The trivial name is used in this article.

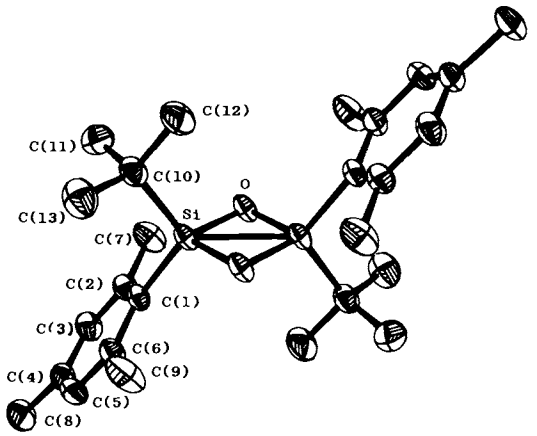


Fig. 8. ORTEP diagram of the X-ray crystal structure for *trans*-1,3-di-*tert*-butyl-1,3-dimesitylcyclodisiloxane.

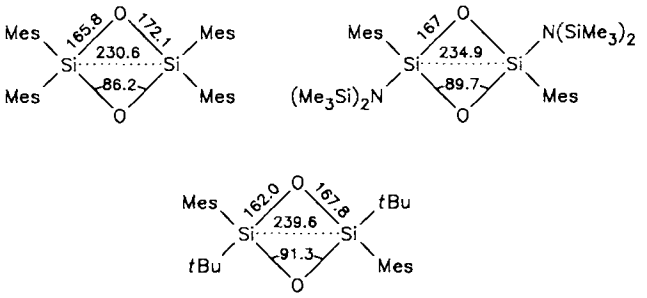

Fig. 9. Bond lengths [pm] and angles [°] in the central four-membered rings in 1,3-cyclodisiloxanes, **26**.

These remarkable structures raise serious questions concerning the chemical bonding in 1,3-cyclodisiloxanes. If there were actually a single covalent bond between the silicon atoms, the Si–O bonds would have to be partially electron-deficient. In fact the Si–O distances are slightly larger than normal siloxane bond lengths (161–165 pm). Another model would be that O–O lone-pair repulsions or other factors are dominant, determining the structure and forcing the silicon atoms close together without any Si–Si bonding.

Several theoretical papers have appeared on the structure and bonding in the (unknown) parent molecule, $(H_2SiO)_2$.[68–72] Most of these studies have concluded that there is no bonding between the silicons, but according to recent work by *Grev* and *Schaefer*,[72] the structure can also be accounted for in terms of an "unsupported pi-bond" with no σ component. The one item of evidence concerning the structure is the $J_{Si,Si}$ coupling constant determined recently in our laboratories for the 1,3-cyclodisiloxane $Mes_2Si(O)_2SiXyl_2$.[32] The observed coupling constant, 3.8 Hz, is about the same as the value of $^2J_{SiOSi}$ found for open-chain siloxanes (1–5 Hz). This result indicates that there is essentially no s-orbital component to the bonding between the silicon atoms in this cyclodisiloxane. It is therefore consistent with the model of *Grev* and *Schaefer* as well as with the other theoretical treatments which propose no bonding between the silicons.

9. Looking to the Future

Although significant progress has been made in the six years since the discovery of stable disilenes, much more remains to be done. The conformations of disilenes in solution are not understood, and the thermochromism of some disilenes is not yet explained. The structures and chemical bonding of many of the known reaction products of disilenes require further investigation. In addition, numerous potentially interesting reactions of disilenes remain to be tried, for example those with carbenes, carbanions, nitroso compounds, amines, imines, sulfoxides and sulfones, azo compounds, and various 1,3-dipolar reagents. Further reactions of the many new kinds of compounds made from disilenes have scarcely been looked at, and almost no work has yet been done on mechanisms of disilene reactions. The potentially large area of disilene–metal complexes has only just been opened up.

It seems clear that the chemistry of disilenes is just in its earliest stages, and that interesting new developments may be expected for many years to come.

Addendum

Since this article was written, several notable developments in disilene chemistry have been reported. The very stable compound tetrakis(2,4,6-triisopropylphenyl)disilene was obtained by the direct reaction of the corresponding dichloro compound with lithium naphthalenide.[73] The first stable tetra*alkyl*disilene, tetrakis[bis(trimethylsilyl)-methyl]disilene, was prepared by a similar lithium naphthalenide reduction of the dialkylsilyl diiodide.[74]

In addition, the crystal structure of oxadisilirane **20** has been determined; the structure resembles that of the sulfur compound **19a** but is even more extreme.[75] The Si–Si bond length is only 222.7 pm, and the arrangement of C, C, and Si atoms around each silicon is *coplanar*.

This work was supported by the Air Force Office of Scientific Research Air Force Systems Command, USAF, under contract No. F49620-86-0010 and by the National Science Foundation Grant No. CHE-8318820-02. I am most grateful to my able and industrious co-workers in our disilene investigations, to my collaborator Professor Josef Michl, now of the University of Texas at Austin, and to H. B. Yokelson for a critical reading of the manuscript.

Modern NMR Spectroscopy of Organolithium Compounds

By Harald Günther,* Detlef Moskau, Peter Bast, and Dietmar Schmalz

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

Modern methods of NMR spectroscopy, in particular the two-dimensional techniques, offer new chances for structure determinations in the field of organolithium compounds, where the combination of ^{1}H-, ^{13}C-, and $^{6(7)}Li$-NMR spectroscopy is an especially useful feature. Chemical shift correlations which also include the lithium nuclei allow a complete assignment of the ^{1}H-, ^{13}C-, and ^{6}Li-NMR spectra and thereby a better characterization of the various aggregates and complexes present in solution. Spatial proximities of ^{6}Li and ^{1}H can be detected by nuclear Overhauser experiments, and $^{6(7)}Li$-NMR exchange spectroscopy can provide new information with regard to the mechanisms and energetics of dynamic processes like aggregate interchange and complexation. After a short resumé of the experimental aspects of the NMR spectroscopy of organolithium compounds and a discussion of the NMR parameters of these systems, new experimental techniques are presented. Areas of application of these newly conceived one- and two-dimensional NMR experiments are illustrated with selected examples. The results show that even more detailed information about the structure and reactivity of organolithium compounds, which are so important for organic synthesis, can be expected in the future.

1. Introduction

In the last ten years a large number of new experimental techniques have been developed for nuclear magnetic resonance spectroscopy, the most important of which already belong to the standard repertoire of NMR investigations of molecular structure.[1] Structure determinations of dissolved organolithium compounds, which are valuable reagents for organic synthesis,[2] also profit from this development. Numerous X-ray structure investigations performed in recent years have shown that this class of compounds presents a fascinating variety of structures in the solid state.[3] The same is true even more in solution, where organolithium compounds of the type RLi usually do not exist as monomers but rather form oligomeric aggregates $(RLi)_n$. Association in hydrocarbon solvents leads to dimers, tetramers, hexamers, and even nonamers, which very often coexist in fast, reversible equilibria (Fig. 1). In basic solvents like ethers or upon the addition of complex-forming amines like tetramethylethylenediamine (TMEDA) oligomerization is repressed in favor of complex formation with the solvent or the amine. Much more complicated situations can be expected for polylithium compounds, where research on structures is only at its beginning.[4]

The reactivity of dissolved organolithium compounds[2c] also varies with the structure, consequently a knowledge of the structure is very important for planning synthetic strategies. NMR spectroscopy, as the most important physical method for the determination of molecular structures in solution, has therefore long occupied a dominating position in this field,[5] all the more so because various nuclei can be employed as probes. Besides the well-known nuclides ^{1}H and ^{13}C, which are used for the characterization of the organic ligands, two additional attractive magnetic nuclei are available with the isotopes ^{6}Li and ^{7}Li. Despite their quadrupole moment, both are well suited for NMR measurements.[6] Because of the above mentioned equilibrium reactions between aggregates, the dynamic NMR spectroscopy of organolithium compounds is likewise of great importance, since temperature-dependent NMR spectra enable the elucidation of the exchange mechanisms as well as the determination of the thermodynamic and kinetic parameters of the equilibria.

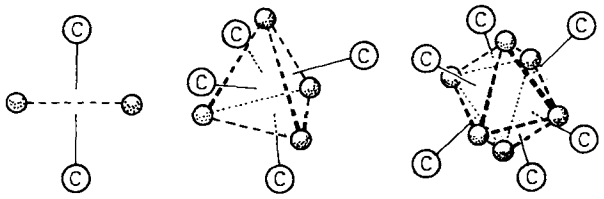

Fig. 1. Schematic representation of the structures of dimeric, tetrameric, and hexameric aggregates of organolithium compounds $(RLi)_n$ in solution [5].

Two-dimensional NMR spectroscopy (2D-NMR) will undoubtedly have a significant impact on further progress in the fields mentioned above. Thus, on the one hand, the ^{1}H- and ^{13}C-NMR spectra of the ligands may be assigned more precisely with the help of homo- and heteronuclear shift correlations, and, on the other, polarization transfer and multiple quantum spectroscopy enable the development of new measuring techniques incorporating the lithium isotopes. The detection of nuclear Overhauser effects between ^{6}Li and neighboring protons provides a new approach for the measurement of Li–H distances in solution and thus allows conclusions to be drawn about the regioselectivity during second metalation reactions. Finally,

[*] Prof. Dr. H. Günther, Dr. D. Moskau, Dipl.-Biol. P. Bast, Dipl.-Chem. D. Schmalz
Fachbereich 8, Organische Chemie II der Universität Gesamthochschule Postfach 10 12 40, D-5900 Siegen (FRG)

two-dimensional exchange spectroscopy should gain importance for the study of the dynamic processes of solute organolithium compounds. This progress report outlines and critically evaluates the potential of these new experimental techniques. Technical aspects are emphasized and a number of experiments are described for the first time.

2. Nuclear Properties

Table 1 lists the nuclear properties of the nuclides ^1H, ^{13}C, ^6Li and ^7Li which are most important for NMR spectroscopy. Those of ^1H and ^{13}C are well-known and serve here only for comparision.

Table 1. Nuclear properties of the lithium isotopes ^6Li and ^7Li in comparision to ^1H and ^{13}C [a].

Nucleus	N [%]	Spin I	γ	Q	ν_0	R (^{13}C)
^6Li	7.42	1	3.9366	-8×10^{-4}	14.72	3.58
^7Li	92.58	3/2	10.396	-4.5×10^{-2}	38.86	1.54×10^3
^1H	99.985	1/2	26.751	—	100.00	5.68×10^3
^{13}C	1.108	1/2	6.7263	—	25.15	1.00

[a] Abbreviations and symbols: N = natural abundance; γ = gyromagnetic ratio in 10^7 rad T^{-1} s^{-1}; Q = quadrupole moment in 10^{-28} m^2; ν_0 resonance frequency (MHz) at field strength B_0 of 2.35 T; $R(^{13}C)$ = signal strength (receptivity), $\gamma^3 N I(N+1)$, rel. to ^{13}C.

Both lithium nuclei have a nuclear spin $I > 1/2$ and therefore a quadrupole moment, which in the case of the isotope ^6Li, however, is so small that this nucleus behaves nearly like a spin-1/2 nucleus and thus is well suited for NMR investigations on organolithium compounds.[7] Line broadening, a disturbing feature often found in the case of nuclei with $I > 1/2$ because of fast quadrupole relaxation, is rarely observed in ^6Li-NMR spectra, and is also always within reasonable limits in ^7Li-NMR spectra. The resonance signals of both nuclei can easily be measured; however, scalar spin-spin couplings J to neighboring nuclei are usually better resolved in the case of ^6Li. This is especially true for low-temperature measurements, which are indispensable for investigations dealing with the dynamics of solute organolithium compounds, because faster ^7Li quadrupole relaxation leads to line broadening and thereby masks line splittings.[8] Thus, it is only ^6Li-labeling which in general paves the way for the measurement of the important structural parameter $^1J(C,Li)$, as the pioneering work of *Fraenkel* et al.[9] and *Seebach* et al.[10] has shown. If high sensitivity is important, additional ^{13}C-labeling is advisable, which then provides optimal NMR conditions for the spin system in question. Since ^6Li labeling can be achieved relatively easily—in the majority of the synthetic routes metallic lithium is used directly or indirectly through a practicable lithium reagent like *n*-butyllithium[2a]—and since this isotope is easily obtainable,[11] the reduced receptivity[6a] of ^6Li as compared to ^7Li presents no problems for the NMR experiment. Furthermore, ^6Li has the advantage that its resonance frequency is close to that of the deuteron (58.86 as compared to 61.40 MHz at a magnetic field strength of 9.4 T), so that with many spectrometers the ^2H-lock channel can be used for ^6Li-NMR experiments, as for instance $^{13}C\{^6Li\}$ decoupling.

2.1. Spin Lattice Relaxation Mechanisms

Because of its small quadrupole moment, other mechanisms besides the mechanism of quadrupole relaxation must contribute to a considerable extent to the spin lattice relaxation of ^6Li. This was first shown by *Wehrli*,[7] who found up to 35% dipolar relaxation through ^6Li-^1H interactions in the case of alkyllithium compounds and who was able to measure $^6Li\{^1H\}$ nuclear Overhauser effects (NOEs) for the first time. NOE measurements provide a valuable supplement to structural information obtained through spin-spin couplings. ^7Li relaxes almost completely via the quadrupole mechanism and exhibits much shorter spin lattice relaxation times T_1 than ^6Li, for which values of 125 s are possible[12] even in organolithium compounds. In case of solvated $^6Li^{\oplus}$ ions T_1 values of up to 1000 s have been measured![13] Therefore, for the determination of the 90° excitation pulse length, which is indispensible in FT-NMR spectroscopy, the steady-state method[14] is suitable in the case of ^6Li because it allows high repetition rates despite long T_1 values. The different contributions of ^6Li and ^7Li to the spin lattice relaxation of neighboring nuclei also provide a means for the determination of Li-C and Li-H distances in aggregates of solute organolithium compounds through the use of the isotopic substitution method,[16] as has been shown by *Jackman* et al. for phenyllithium.[15] If one replaces a nucleus ^nX (spin quantum number I) with strong dipole-dipole interaction by its isotope ^mX (spin quantum number S) with weak dipole-dipole interaction, the difference in the spin lattice relaxation rate R_1 of the neighboring ^{13}C nucleus is given by

$$R_1^{exp}(^nX) - R_1^{exp}(^mX) = R_1^{DD}(^nX)\left[1 - \frac{\gamma_{^mX}^2\, S(S+1)}{\gamma_{^nX}^2\, I(I+1)}\right] \qquad (a)$$

If the correlation time τ_c is known, the distance $r_{C\text{-}X}$ can be determined according to

$$r_{C\text{-}X} = \sqrt[6]{\hbar^2 \gamma_{^{13}C}^2 \gamma_{^nX}^2 \tau_c / R_1^{DD}(^nX)} \qquad (b)$$

τ_c is obtained from the dipolar relaxation rate R_1^{DD} of another ^{13}C nucleus in the same molecule measured under identical conditions and its respective C-H distance.

2.2. Chemical Shifts

The chemical shifts of the lithium nuclides have thus far been the subject of very few investigations. Calculations[17] and measurements on aryllithium compounds[18] have shown that the diamagnetic anisotropy effect of the organic ligands strongly influences the ^7Li resonance frequency in these systems. Since the chemical shift range is extremely small (ca. 2–3 ppm, i.e. ca. 65 Hz for ^6Li and ca. 120 Hz for ^7Li at 2.35 T according to Table 1) and since the resonance frequencies strongly depend on the medium and concentration effects owing to aggregate formation, chemical shifts are not very informative for structure investigations on organolithium compounds. Furthermore, measurements are usually made with external references, and, in addition, various reference compounds are used, thus causing further uncertainties. Nevertheless, a diamagnetic

ring current effect has been detected for the ^{6}Li resonance of lithium salts of charged π-electron systems.[19] In these cases the ^{7}Li shift can also be used for the study of ion pair structures.[20] The ^{1}H and ^{13}C shifts in the organic groups follow the well-known trends, where the charge density plays no major role in the case of aryllithium compounds RLi. Much more important are the anisotropy of the C–Li bond (for ^{1}H)[21] and the local paramagnetism caused by n→π* transitions (for ^{13}C).[22] Typically, the situation for phenyllithium is similar to that in pyridine.[23]

The ^{13}C resonance frequencies of alkyllithium compounds RLi have recently been analyzed in more detail.[24] Compared to the data for the corresponding hydrocarbons RH, low-field shifts of 5.3 ± 0.7 and 7.7 ± 0.5 ppm have been observed for the β- and γ-carbon atoms, respectively. Steric interactions in branched alkyl groups diminish the γ-effect and can even give rise to high-field shifts. The resonance of the δ-carbon atom is not influenced by the metalation, while the effects on the α-carbon atom vary strongly. For primary alkyl groups a shielding of 5.9 ± 0.9 ppm was found which increases on α branching, i.e. in the case of secondary and tertiary alkyllithium compounds. For secondary systems a relationship between $\delta(^{13}C_\alpha)$ and the degree of aggregation was found: the shielding is larger for tetramers than for hexamers.

2.3. Scalar Spin–Spin Coupling

The measurement of ^{13}C,$^{6(7)}$Li coupling constants[25] and the determination of ^{13}C-NMR signal multiplicities has in recent years considerably increased our knowledge of the structure of solute organolithium compounds.[9,10,26] An overview of the rules which have been established, based on the data collection published by *Seebach* et al.,[10a] is presented in Table 2. The values for the $^1J(^{13}C,^6Li)$ coupling constant range from 2 to 18 Hz, whereby the smaller values are a consequence of exchange processes within individual aggregates which are still fast on the NMR time scale even at low temperature. Under these conditions, on time average, each ^{13}C nucleus has contact with all lithium atoms of the aggregate in question so that the coupling with the ^{6}Li nuclei is averaged effectively over all positions. The magnitude of the ^{13}C,^{6}Li coupling constants measured and the multiplicity of the ^{13}C signal are directly related to the degree of aggregation, *n*.[10a] For such dynamic systems the empirical rule $|J| \approx 18/n$ holds true. In the case of fast exchange between different aggregates the line splitting disappears. At room temperature the $^{6(7)}$Li-NMR spectra of organolithium compounds therefore typically show a singlet, because the chemical shifts are averaged as well. "Static" spectra are obtained, on the other hand, if the exchange rates are so small that ^{13}C,$^{6(7)}$Li coupling is limited to next neighbors within one aggregate.

Scalar couplings to ^{7}Li are, according to the relation $\gamma(^7Li)/\gamma(^6Li)$, larger by a factor of 2.64 than coupling to ^{6}Li. Besides coupling to ^{13}C scalar interactions of the lithium nuclides with other nuclei have also been demonstrated; thus, for instance, $^1J(^7Li,^{31}P)$ (39–40 Hz),[27,28] $^1J(^{6(7)}Li,^{29}Si)$ (20–29, 51 Hz),[29] and for highly diluted solutions (0.01 M) of the complex **1**

$(C_5(CH_3)_5)IrHLi$-PMDETA **1**
PMDETA = pentamethyldiethylenetriamine

in the temperature range between 20 and −40°C even $J(^7Li,^1H)$ (8.4 Hz).[30]

3. Applications of New Measuring Techniques

For the NMR spectroscopy of the organic ligands in organolithium compounds the entire arsenal of one and two-dimensional pulse techniques[1] available for ^{1}H- and ^{13}C-NMR spectroscopy can be employed. This has already been demonstrated in a few cases for the important homo- and heteronuclear shift correlations.[31,32] Absolute assignments of ^{13}C resonances are obtained most reliably through the two-dimensional INADEQUATE experiment,[33] which, however, because of its insensitivity—the ^{13}C satellites in the ^{13}C NMR spectrum are detected—requires concentrated samples. The experiment fails if the relative chemical shift between neighboring ^{13}C resonances falls below a critical value which depends on the field strength and the resolution obtained.[33] In the case of organolithium compounds a further limit must be seen in the fact that it is difficult or even impossible to detect the

Table 2. Compilation of $^{13}C,^6Li_x$ spin systems for aggregates of organolithium compounds of the type $(RLi)_n$ with characteristic data for the dependence of the $^1J(^{13}C,^6Li)$ coupling constants on the degree of aggregation *n* (*n*-propyllithium [36, 26d], *tert*-butyllithium [70a], phenyllithium [10], trichloromethyllithium [10]).

Aggregate	$(RLi)_9$		$(RLi)_8$		$R(Li)_6$		$(RLi)_4$		$(RLi)_2$	RLi
Structure

[a] "Dynamic" implies interaction with all lithium atoms of the aggregate in the fast exchange region; "static" implies selective interactions with a reduced number of lithium atoms in the sense of a multicenter bond. The ^{13}C-multiplicity is given by $2x+1$ (x = number of lithium nuclei); for ^{7}Li by $3x+1$.

resonance of the metalated carbon atom which is broadened because of coupling to ^{6}Li,^{7}Li. If the assignment of this carbon is uncertain, the experiment should be repeated with ^{7}Li decoupling or, in the case of ^{6}Li-labeled samples, with ^{6}Li decoupling. The scope and the limits of the INADEQUATE method are demonstrated in Figure 2 with the ^{13}C-NMR spectrum of the 1-naphthyllithium-TMEDA complex.[34]

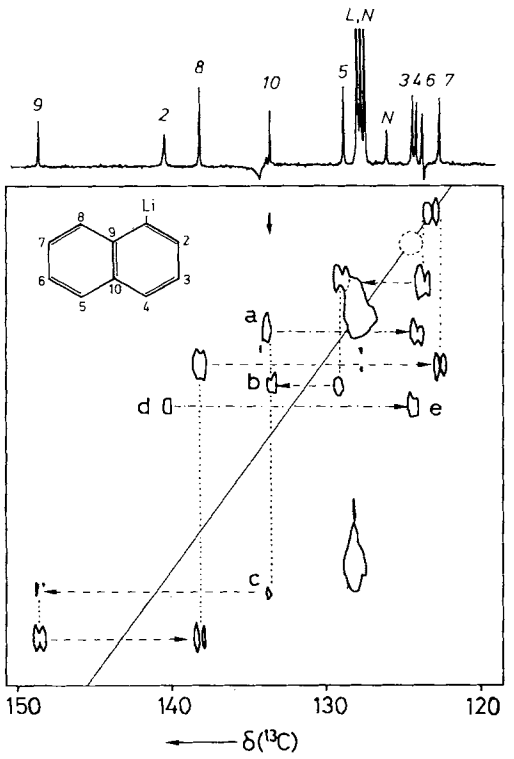

Fig. 2. Two-dimensional INADEQUATE-experiment [33] for 1-naphthyllithium-TMEDA in the region of the resonances of C-2 to C-10 (contour diagram; measuring frequency 100.61 MHz; reference TMS; ca. 1 M in C_6D_6 total experimental time 37 h; additional signals N = naphthalene, L = solvent). The resonances at $\delta = 148.6$ and 133.7 have been identified as those of quaternary carbons by a DEPT-experiment [35]. The assignment starts at C-10, since only this carbon can show three correlation signals with direct neighbors (a, b, c). The C,C connection proceeds from signal c via C-9 as the only quarternary neighbor to C-4. It is then interrupted, because the strongly coupled AB-system of C-3 and C-4 ($\Delta\delta$ 24.3 Hz, $J \approx 60$ Hz), degenerated to a singulet, cannot be detected [33]. The remaining pair of signals d, e must belong to C-2 and C-3 and the absolute assignment follows from the fact that only the signal at $\delta = 124.39$ can yield a strongly coupled AB system (B part at $\delta = 124.15$). The results of this experiment are in agreement with the results of a combined ^{1}H- and ^{13}C,^{1}H-shift correlation [31].

In the following we deal with experimental techniques which have been developed on the basis of the new pulse methods especially for the spectroscopy of the metalated carbon atom and the metal, that is for the spin systems ^{13}C,^{6}Li and ^{13}C,^{7}Li. Because of the far more favorable NMR properties of ^{6}Li the system ^{13}C,^{6}Li stands to the fore.

3.1. Multiplicity Selection and *J,δ* Spectroscopy

The signal multiplicity of scalar coupled $^{13}C_yLi_x$ spin systems can be determined best in the ^{13}C-NMR spectrum (determination of x) for ^{6}Li labeled compounds. If y is also to be determined, the ^{13}C satellite signals in the ^{6}Li-NMR spectrum have to be detected. This measurement is facilitated by ^{13}C labeling of the metalated position. In general, for aggregates of organolithium compounds with labeled α-carbon atom $y = 1$, since spin-spin coupling between individual organic groups in the aggregate is absent. In this case, therefore, the simple first order multiplet patterns for spectra of the $^{13}C^6Li_x$ type are observed for the ^{13}C resonances (Table 2). This situation is met with aggregates of monolithium compounds of type $(RLi)_n$, where the labeled carbon atom on time average can have contact with up to nine lithium atoms.[36] In the case of static spectra one finds coordination with up to three ^{6}Li nuclei. On the other hand, more complicated signal patterns result if different lithium neighbors are present, a situation encountered in the case of polylithium compounds (see Section 2.3). In contrast, in the ^{6}Li-NMR spectrum simple multiplets can always be expected, because homonuclear ^{6}Li,^{6}Li couplings are negligibly small (see Section 2.2) and the metalated carbon atoms have no homonuclear coupling partner if, as is usual, only this position in the molecule is ^{13}C-labeled.

For the recognition of spin multiplets the *J*-modulated spin echo techniques (attached proton test[37]) have proven of value in the case of ^{13}C-NMR spectroscopy. They yield for CX_n groups (X = spin-1/2 nucleus) signal phases of -1 (CH), $+1$ (CH_2), and -1 (CH_3). Through gated ^{13}C-decoupling a similar phase selection can be achieved for ^{6}Li signals which are coupled to ^{13}C, as is shown in Figure 3a with two signals from the ^{6}Li-NMR spectrum of dilithio(phenylsulfonyl)trimethylsilylmethane (**2**).[38]

$C_6H_5-SO_2-CLi_2-Si(CH_3)_3$ **2**

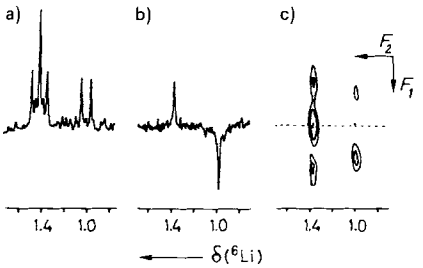

Fig. 3. a) Triplet ($J = 4.1$ Hz) and doublet ($J = 5.6$ Hz) for a $^{13}C_2{}^6Li$- and a $^{13}C^6Li$-spin system in the 58.86-MHz ^{6}Li-NMR spectrum of ^{6}Li- and ^{13}C-labeled dilithio(phenylsulfonyl)trimethylsilylmethane (**2**) (measuring frequency 58.86 MHz; ext. ref. 1 M LiBr/[D_8]THF). b) Phase selection with the technique of gated ^{13}C-decoupling (measuring time 1 h). c) Two-dimensional $^1J(^{13}C,^6Li)$-resolved ^{6}Li-NMR spectrum (measuring time 5.7 h).

If the ^{13}C,^{6}Li-coupling constants over one bond differ strongly, several experiments are necessary for optimal phase selection. If one carries out a two-dimensional *J,δ*-NMR experiment,[39] the $^1J(^{13}C,^6Li)$-resolved ^{6}Li-NMR spectrum shown in Figure 3c is obtained.

Phase selection in the ^{13}C-NMR spectrum through gated ^{6}Li decoupling corresponds to the spin echo methods developed for ^{13}C,^{2}H spin systems,[40] whereby the intensities of the CX_n signals (X = spin-1 nucleus) with an evolution time $t_1 = 1/2J$ are given by Equation (c):[40c]

$$I = I_0(-1/3)^n \qquad (c)$$

For practical applications this procedure is less well suited, since the signal intensity is strongly reduced already for $n=3$ and the ^{13}C signal disappears practically completely for $n>3$.

Besides the determination of multiplicity the two-dimensional J,δ spectroscopy allows a simplification of complicated spectra, because coupling to other nuclei only appears in the F_2 dimension.[41] In this way the $^{31}P,^{6}Li$-coupling constants have been seperated from the homonuclear $^{31}P,^{31}P$-coupling constants in the ^{31}P-NMR spectra of lithiated organophosphorus compounds.[28]

Since scalar spin-spin coupling constants—and only these can be measured in isotropic media—are transmitted in general through covalent bonds, it seems reasonable to ask whether the observation of $^{6(7)}Li,X$ coupling allows conclusions to be drawn about the nature of the corresponding Li-X bonds (ionic or covalent). In this connection *Streitwieser* et al.[42] pointed out for the first time that scalar spin-spin coupling between carbon and lithium does not necessarily imply covalent bonding. The mechanism which they termed spin polarization and which is known in NMR spectroscopy as through-space coupling[43] is believed to operate in several cases where ^{19}F nuclei are involved. In general it is more an exception than the rule. It requires non-bonded interactions of neighboring orbitals which are close in space. Also in the case of a purely ionic Li-X bond scalar Li,X coupling could therefore operate, if only the orbital contact is sufficient.

Several arguments can be cited in favor of this interpretation. It appears, that $^{13}C,^{6(7)}Li$ couplings over more than one bond have, to the best of our knowledge, so far not been observed. In case of a through-bond mechanism however, also geminal and vicinal $^{13}C,^{6(7)}Li$ couplings are to be expected. Furthermore, many well resolved ^{7}Li couplings are not compatable with a high covalent character of the carbon lithium bond, since the unsymmetrical charge distribution should increase the ^{7}Li quadrupole relaxation rate and broaden the ^{13}C-NMR lines.[44] Considering the mechanistic dichotomy for the scalar spin-spin interaction (through-bond or through-space) it cannot so far be decided if the experimentally measured scalar spin-spin couplings of the lithium nuclides are a consequence of a covalent contribution to the respective Li-X bonds or if they are transmitted by a pure through-space mechanism. In view of the dominancy of the through-bond mechanism with other nuclei the second possibility would certainly be unusual.

3.2. Homonuclear Shift Correlations

Shift correlations are without doubt the most important two-dimensional pulse techniques. One distinguishes between scalar and dipolar correlated spectra. The origin of the cross peaks observed in the 2D-NMR spectrum is scalar spin-spin coupling in the first case and the nuclear Overhauser effect in the second. That is, information is obtained, on the one hand about the bonding in the molecule under study, and, on the other, about the spatial surroundings.

Homonuclear δ,δ or COSY spectra[45] for ^{6}Li or ^{7}Li rest on corresponding homonuclear spin-spin coupling. So far this type of coupling has not been observed conventionally, that is by line splitting. Since most organolithium compounds, for reasons of symmetry, show only *one* ^{6}Li- or ^{7}Li-NMR signal for the individual aggregates, even at low temperature (see Fig. 1), such measurements had to be performed on systems with a $^{6}Li/^{7}Li$ isotope ratio of ca. 1:1. From the line width in the ^{7}Li-NMR spectrum of methyllithium, which forms a tetramer,[46] *Brown* et al.[47] concluded that in this case a $^{6}Li,^{7}Li$ coupling over one bond of about 0.3 Hz exists.

With the COSY experiment,[48] we were able to detect a homonuclear $^{6}Li,^{6}Li$ coupling for the first time for 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**3**).[49] The crystal structure of this compound (Fig. 4)[50] revealed two different Li

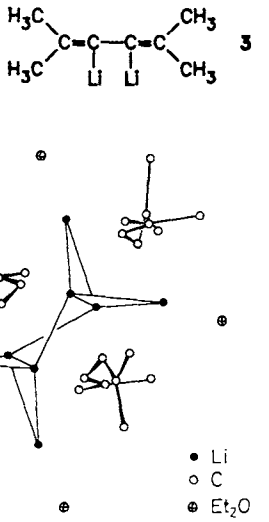

Fig. 4. Crystal structure of 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**3**) [50].

positions. In THF as solvent, **3** shows two ^{6}Li-NMR signals at $-78\,^{\circ}C$; the COSY experiment (Fig. 5) proves that a scalar spin-spin coupling exists between the two ^{6}Li signals. This suggests that **3** has the same structure in both the solid state and in solution. Both ^{6}Li-NMR signals must be assigned to the same aggregate, which, therefore, like the molecule in the crystal, must contain two types of lithium atoms. The $^{6}Li,^{6}Li$ coupling should be of the order of 0.1 Hz. This is in good agreement with the value estimated by *Brown* et al. for the $^{6}Li,^{7}Li$ coupling, if the corresponding γ factors are taken into account. So far, it is unknown if the coupling is a one-bond or a geminal interaction which includes the metalated carbon in the coupling path.

COSY experiments for quadrupole nuclei have so far been successfully performed for ^{11}B,[51] ^{51}V,[52] ^{2}H[53] and in a few cases for ^{14}N.[54] Broad lines and/or small scalar couplings have negative consequences and may prevent the detection of cross peaks. According to the product operator formalism[55] the dependency of the cross peak intensity, I_k, on the evolution time t_1 for COSY experiments with spin-1 nuclei is governed by the following equation:

$$I_k = I_o \sin 2\pi J t_1 \exp(-t_1/T_2) \qquad \text{(d)}$$

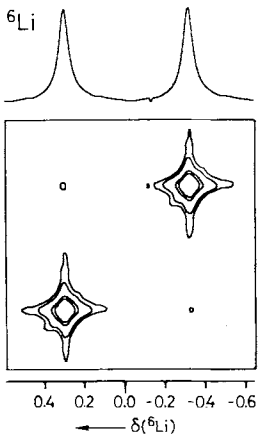

Fig. 5. ^{6}Li,^{6}Li COSY spectrum of 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**3**) [49], recorded with the pulse sequence proposed for emphasizing small couplings $90°_x - t_1 - \Delta$, $90°_x$, Δ, FID(t_2) [45] (measuring frequency 58.86 MHz; measuring time 1.2 h).

A plot of Equation (d) (Fig. 6) shows that for small couplings and short transverse relaxation times T_2 the cross peak intensity has a maximum if the condition $t_1 = T_2$ holds. Experiments with the quadrupole nucleus ^{2}H show good results with the pulse sequence (1),[45] which was developed in order to emphasize small couplings and to suppress diagonal signals.

$$90°_x - t_1 - \Delta, 45°_x, \Delta - \mathrm{FID}(t_2) \qquad (1)$$

where $t_1(\max) + \Delta = T_2$

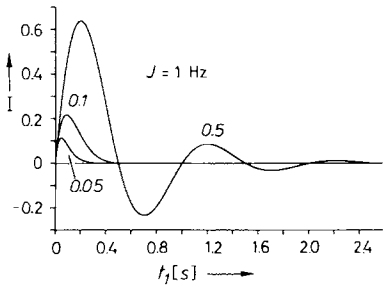

Fig.6. Cross-peak intensity for COSY experiments with nuclei of spin $I = 1$ and small couplings as a function of the transverse relaxation time T_2 (0.5, 0.1, 0.05 s) and the evolution time t_1.

As expected, the COSY experiment for ^{7}Li with the larger quadrupole moment is less favorable. Nevertheless, homonuclear ^{7}Li,^{7}Li couplings for **3** were also successfully detected, even if less clear then in the case of ^{6}Li.[54]

3.3. Heteronuclear Shift Correlations

In principle, there are two pulse sequences available today for the measurement of heteronuclear shift correlations: the standard technique, which is based on polarization transfer (Fig. 7a),[56] and a variant (Fig. 7b),[57] which uses the possibilities of multiple quantum coherences. In the case of organolithium compounds the ^{6}Li,^{13}C correlation is of primary interest, because the identification of ^{6}Li,^{13}C spin pairs via the multiplicities in the ^{13}C- or ^{6}Li-NMR spectra is no longer possible in more complicated cases. Only selective decoupling or one of the two-dimensional methods mentioned above, where one can choose between ^{6}Li or ^{13}C detection, are then applicable. Such experiments form the basis for a successful simulation of the respective ^{13}C,^{6}Li spin systems.

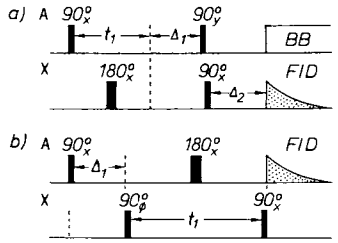

Fig. 7. Pulse sequences for two-dimensional heteronuclear shift correlations on the basis of polarization transfer (a) [56] and multiple quantum coherences (b) [57].

The dilithiosulfone **2** already mentioned above offered the possibility of testing the use of the ^{6}Li,^{13}C shift correlation, because the ^{13}C- as well as the ^{6}Li-NMR spectrum of this compound displays a number of simple as well as complicated multiplets (Fig. 8).[58] Considering the spectrometer configuration available, the two-dimensional experiments could be performed in either case (a) or (b) only with ^{6}Li detection. Method (a) failed, apparently because of fast transverse relaxation, and difficulties with the correct choice of the Δ_1 interval, while method (b) was successful (Fig. 8d). All correlations obtained were confirmed by selective ^{13}C decoupling. The double-resonance technique yielded two additional correlations which were not found in the 2D-NMR experiments, apparently because of small scalar couplings.

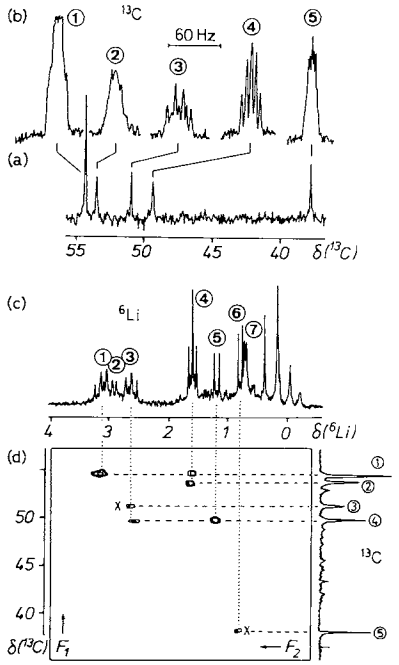

Fig. 8. a) ^{1}H,^{6}Li decoupled 100.61-MHz ^{13}C-NMR spectrum of the dilithiosulfone **2** (−103 °C in [D$_8$]THF); b) ^{13}C multiplets with ^{6}Li coupling; c) 58.86-MHz ^{6}Li-NMR spectrum of ^{13}C-labeled **2** with ^{13}C,^{6}Li coupling (ext. reference, see Fig. 3); d) Two-dimensional ^{6}Li,^{13}C-shift correlation for **2** with the pulse sequence of Figure 7b; the correlations X have been detected with selective ^{6}Li{^{13}C}-spin decoupling [58] (measuring time 4.7 h).

The potential of the $^6Li,^{13}C$-shift correlation experiment is also demonstrated by its application to the dilithium compound **3**.[59] Here, the ^{13}C-NMR spectrum shows all signals of the tetramethylbutadiene structure twice, and the task was to assign the individual resonance lines to the "inner" and "outer" ligands (Fig. 4). This was achieved through the finding that one of the metalated carbon atoms couples to two different lithium nuclei, namely to one of the "inner" and to one of the "outer" positions. The two-dimensional $^6Li,^{13}C$ double quantum spectrum (Fig. 9) shows two cross peaks for the high-field ^{13}C and for the high-field ^6Li signal. Considering the direction of the carbanion orbitals at C-3 and C-4 given by the geometry of the ligands as found in the crystal (Fig. 4), only the carbon of the "outer" ligand can take part in two different scalar interactions and thus show two correlation signals. The results of dynamic NMR spectroscopy, 2D-^1H exchange and 2D-$^{13}C,^1H$-δ,δ-NMR spectroscopy completed the assignment of the resonance signals.

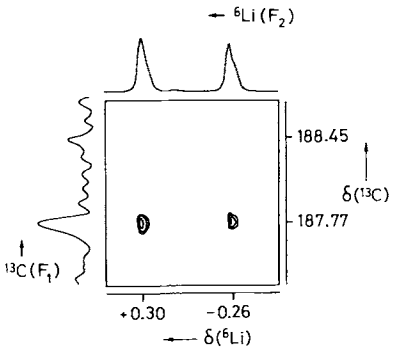

Fig. 9. Two-dimensional $^6Li,^{13}C$-shift correlation based on multiple quantum coherences for 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (**3**) [59] (measuring time 8.7 h).

3.4. Nuclear Overhauser Effects

The nuclear Overhauser enhancement (NOE)[60] is based on dipolar cross relaxation between closely spaced nuclei, which have no chemical bond in common. It is therefore an important supplement for the identification of chemical structures on the basis of scalar spin-spin coupling constants, which are transmitted nearly without exception through bonding pathways. Consequently, NMR spectroscopy is the only method which allows one to determine three-dimensional molecular structures in solution.

For the NMR spectroscopy of solute organolithium compounds it is important that neighboring protons can make a significant contribution to the relaxation of ^6Li through dipolar interactions[7] (see Section 2.1). The proximity of ^6Li and ^1H can, therefore, be detected by heteronuclear $^6Li\{^1H\}$-NOE spectroscopy, where a maximum signal enhancement of 340% would result for the ^6Li nucleus if no competing relaxation mechanisms were available. For ^7Li such experiments are impossible because of its different relaxation behavior.

Heteronuclear NOE experiments can be performed one-dimensionally (1D), best employing the method of difference spectroscopy[61] or, as was first shown by *Rinaldi*[62] for the pair $^{13}C,^1H$ and by *Yu* and *Levy*[63] for $^{31}P,^1H$ two-dimensionally with the pulse sequence (2) (HOESY[63]); ($I = ^1H, ^{19}F, ^{31}P$; $S = ^{13}C, ^{15}N, ^6Li$):

$$\begin{array}{ll} \text{I:} & 90^\circ_x - t_1 - 90^\circ_x - t_m - \text{BB} \\ \text{S:} & \text{——}\ 180^\circ_x\ \text{———}\ 90^\circ_x, \text{FID}(t_2) \end{array} \qquad (2)$$

In this way hydrogen bridges between lithium and boron as well as aluminum, indium or gallium in hydrido[tris(trimethylsilyl)methyl]metalates could be detected[64]. 2D-NMR experiments with the pulse sequence (2) and a 1:1 aggregate of methyl- and 1-naphthyllithium[31] as well as 2-lithio-1-phenylpyrrole[65] allowed the localization of spatially closely related ^6Li and ^1H nuclei (< ca. 350 nm). Since short ^6Li-^1H distances correlate with the activation of the respective CH bond for a second metalation, NOE spectroscopy also yields information about the reactivity of the organic ligands. Quantitative measurements of NOE build-up rates should here, as in the case of ^1H-NMR spectroscopy,[66] enable a more exact determination of nuclear distances. Figure 10 shows the result of a 1D-$^6Li\{^1H\}$-NOE difference experiment for the complex 1-naphthyllithium-TMEDA. Compared to the 2D-NMR experiment[31] the selective detection of ^6Li-^1H neighborhoods is simpler, because a better digital resolution can be achieved.

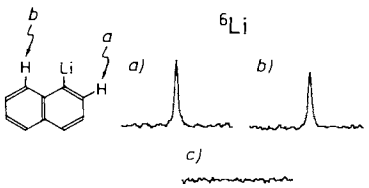

Fig. 10. Selective 58.86-MHz $^6Li\{^1H\}$ nuclear Overhauser difference spectrum for 1-naphthyllithium-TMEDA with natural ^6Li abundance; a) irradiation at 2-H, b) irradiation at 8-H, c) control experiment with off-resonance decoupling (measuring time 4 h each). The NOE effects are 8.5% and 7%, respectively. The decoupler power was calibrated with the SPI-experiment for chloroform[68]; for the assignment of the ^1H-resonances see Ref. [31].

3.5. 2D-$^6Li,^6Li$- and $^7Li,^7Li$-NMR Exchange Spectroscopy (EXSY)

Whether homonuclear NOE effects for $^6Li,^6Li$ nuclear pairs can be detected or not has so far not been investigated. However, *Wehrli* estimated only 6% for the dipolar contribution to the ^6Li relaxation in $^6Li,^7Li$ pairs in methyllithium.[7] For $^6Li,^6Li$ pairs this contribution reduces further to less then 1% and is thus practically negligible. On the other hand, 2D-$^6Li,^6Li$ and 2D-$^7Li,^7Li$-NMR exchange spectra for dynamic systems can be measured without difficulty in the region of slow exchange with the pulse sequence (3),[67]

$$90^\circ_x - t_1 - 90^\circ_x - t_m - 90^\circ_x, \text{FID}(t_2) \qquad (3)$$

as is shown in Figure 11a for ^6Li in the case of **3** and in Figure 11b for ^7Li in the case of an interaggregate exchange process. The investigation of dynamic processes of solute organolithium compounds by NMR line shape analysis[70] thus receives valuable support through 2D-NMR experiments, since not only can exchange mechanisms be

recognized, but, in addition, quantitative analysis of cross peak intensities allows the determination of rate constants.[71]

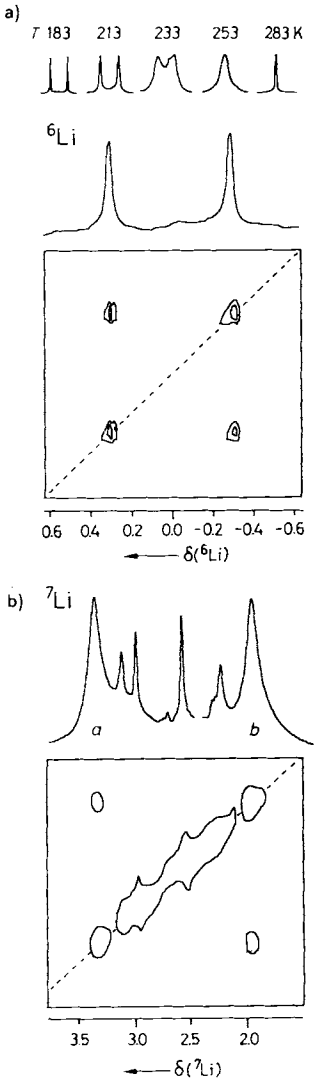

Fig. 11. a) 2 D-^{6}Li,^{6}Li-NMR exchange spectrum for the *intra*-aggregate ^{6}Li exchange in 3,4-dilithio-2,5-dimethyl-2,4-hexadiene (3) ([D$_8$]THF, −83 °C, measuring frequency 58.86 MHz, ext. reference, see Fig. 3, mixing time 1 s, measuring time 1 h); above, the 1D-NMR spectrum for comparision). b) Two-dimensional ^{7}Li,^{7}Li-NMR exchange spectrum for the *inter*-aggregate ^{7}Li exchange between the diethyl ether complex of the dimer of 8-dimethylamino-1-naphthyllithium (signal b) and the ether-free aggregate (signal a) ([D$_8$]toluene [69], −15 °C; measuring frequency 155.51 MHz; ext. reference 1 M LiCl/D$_2$O; mixing time 0.1 s; measuring time 45 min).

3.6. High Resolution Solid State NMR Spectroscopy

This timely and promising technique[72] is without doubt also of interest for the field of organolithium compounds, despite the fact that so far only one investigation has been reported.[73] The reason for this may be seen in the relatively large amount of material necessary for such measurements (200–300 mg) and in the more complicated sample preparation required for compounds that are sensitive to air and moisture. ^{13}C- as well as ^{6}Li-NMR measurements on solids should furnish important structural information bridging the gap between the results of crystal structure analysis on the one hand and NMR spectroscopy in solution on the other. The investigation of methyllithium and dilithiomethane[73] mentioned above shows that ^{6}Li decoupling is also possible in solid state NMR spectroscopy and that the quality of the ^{13}C-NMR spectra thereby increases considerably.

4. Outlook

The experiments discussed in the foregoing sections demonstrate how the structure of organolithium compounds in solution may be determined even more confidently and in more detail in the future. Our knowledge about the reactivity of this important class of compounds can thus be deepened and defined more exactly. More emphasis should be devoted to the elucidation and the quantitative investigation of the mechanisms of the dynamic processes present in solution. 2D-NMR methods can certainly yield new insights in this respect. From the standpoint of bonding theory further investigations of the mechanism of ^{13}C,$^{6(7)}$Li spin–spin coupling as well as the dependence of this parameter on structure are desirable. This is even more true for couplings between lithium nuclei. Finally, interesting results can be expected from the solid state NMR spectroscopy of organolithium compounds, especially since this method can also detect dynamic phenomena in the crystal.[74,75] Organolithium compounds will therefore remain exciting subjects for demanding NMR studies in the future.

We are indebted to Prof. Dr. A. Maercker, Siegen, for a number of important references. Our thanks are due to him and Prof. Dr. H.-J. Gais, Freiburg, as well as to their coworkers Dr. R. Dujardin and Dipl.-Chem. F. Brauers, Siegen, and Dipl.-Chem. J. Vollhardt, Freiburg, for gifts of valuable compounds and exciting collaboration. Generous support of our investigations by the Fonds der Chemischen Industrie, is gratefully acknowledged.

Molecular Dynamics of Elementary Chemical Reactions (Nobel Lecture)**

By Dudley R. Herschbach

Introduction

The vast field of chemical kinetics embraces three distinct levels of understanding or abstraction.[1] The broadest level is qualitative description. Here the emphasis is on *substances:* what products are obtained from what reagents under what conditions. The information gathered is encyclopedic, but quite feeble in predictive power. This is because the overall observed transformation in most reactions comprises a more or less complex sequence or network of elementary steps.

At the next level, the aim is to identify the distinct *elementary steps* and to determine quantitatively the rate factors of the Arrhenius equation, $k=A\exp(E_a/RT)$, a remarkably durable formula now nearly a century old! Some steps involve intermediate species that do not appear among the final products; whenever possible, these intermediates are also characterized by structural, spectral, and thermodynamic properties. Over about the past 70 years, immense effort has been devoted to compiling such quantitative data. It is of great practical value because predictions can be made for many reaction systems, on the usually reliable assumption that the rate parameters for each indivisible elementary step can be carried over from one system to another.

As well as mapping the cooperation and competition among elementary processes, kinetic studies at this level also gave rise to many key chemical ideas. These include such concepts as chain reactions carried by free radical intermediates, collisional energy transfer, and the time lag for energy flow within an excited molecule. Most fundamental was the idea introduced by *Henry Eyring* and *Michael Polanyi* of a transition state on a potential energy surface. This has guided qualitative reasoning about molecular mechanisms, and when augmented by resourceful semitheoretical approximations for potential parameters has enabled limited but useful estimates of rate factors. However, these valuable insights were won despite frustrating handicaps. The basic experimental variables of concentration and temperature are not incisive enough to allow further progress. Postulated elementary steps or intermediates often prove incomplete or illusory. The observable rate factors, which represent averages over myriad random collisions, are too remote from the molecular interactions.

Emergence of Chemical Dynamics

Over the past 30 years a new level has been attained by study of the intimate *molecular dynamics* of individual reactive collisions. One of the chief experimental approaches is molecular beam scattering. This involves forming the reagent molecules into two collimated beams, each so dilute that collisions within them are negligible. The two beams intersect in a vacuum and the direction and velocity of the product molecules emitted from the collision zone are measured. A host of reactions can now be studied readily in this way, by virtue of an extremely sensitive mass spectrometric detector and the use of supersonic nozzles which generate beams with greatly enhanced intensity and with collision energies much higher than provided by ordinary thermal sources. The coupling of spectroscopic techniques with molecular beams has provided further advances in selectivity and sensitivity, particularly by use of intense laser light sources.

The reaction properties now accessible include the disposal of energy among translation, rotation, and vibration of the product molecules; angles of product emission; angular momentum and its orientation in space; and variation of reaction yield and other attributes with impact energy, closeness of collision, rotational orientation or vibrational excitation of the target molecule. From the earliest stages these experiments have stimulated and responded to a vigorous outburst of theoretical developments. Especially helpful are computer simulations in which dynamical properties are predicted for various postulated forces by Monte Carlo sampling of huge numbers of calculated collision trajectories. Both the laboratory experiments and computer simulations have prompted a variety of insightful mechanical models as well as very useful diagnostic procedures based on information theory. Ab initio electronic structure calculations have also begun to contribute significantly to the exploration of reaction dynamics, although (except for $H+H_2$) satisfying overall accuracy has yet to be achieved for potential energy surfaces.

As urged by my students, on this occasion I want both to view our still youthful field of research from a wider perspective and to recount some favorite, instructive episodes from its infancy. I will also briefly discuss several prototype reactions that have served to develop heuristic models and to reveal how electronic structure governs the reaction dynamics. More technical and systematic surveys are abundant.[2] Particularly recommended are recent books by *Bernstein* and by *Levine* and *Bernstein*.[3] The latter, about to appear in its second edition, contains references to 500 review articles in the field of molecular reaction dynamics! Nobody has tried recently to count the research papers in this prolific field; these probably now exceed 5000. This

does not include kindred developments in the study of molecular dynamics in solution or the solid phase.

The emergence of chemical dynamics captivated many enterprising scientists and imbued them with a sense of historical imperative. Figure 1 indicates this in the wider context of physical chemistry. The subject began with thermochemistry, still its foundation. The thermochemical era can be considered to reach a pinnacle in 1923, with the publication of the classic text by *Lewis* and *Randall*. This was shortly before the discovery of quantum mechanics ushered in the new structural era (and spawned chemical physics). In turn, the grand pursuit of molecular structure and spectra reached a twin pinnacle in 1951 and 1953 with the monumental discoveries of the alpha-helix by *Pauling* and the DNA double helix by *Watson* and *Crick*. This was shortly before the early molecular beam and infrared chemiluminescence experiments appeared as harbingers of the dynamics era. It is striking that the prequantum models of *Lewis* and *Langmuir*, still valued today, came well before the onset of the structural era. Likewise, the potential surface and transition-state concepts of *Eyring* and *Polanyi* anticipated the dynamics era.

Not evident in Figure 1, and in contrast to the scientific continuity, are cultural chasms between the eras. *Linus Pauling* once told me of the gulf his students encountered in the late 1920s when, as candidates for an academic position, they presented seminars describing molecular structures they had determined by electron diffraction. All the faculty in the audience had done their Ph.D.'s in thermochemistry, and so imbibed a tradition which emphasized that it did not need to postulate the existence of molecules! Worse, interpretation of the diffraction rings then relied entirely on the so-called "visual method." A densitometer tracing showed only monotonically decreasing intensity curves; the rings could only be seen because the human eye can detect slight changes in intensity. The molecular structures obtained thus depended on an "optical illusion," incomprehensible and reprehensible to many professors of thermodynamics. Forty years later, my own students encountered a similar gulf when presenting seminars describing our early crude molecular-beam reactive-scattering studies. Almost all the incumbent faculty then had done their Ph.D.'s in structure or spectroscopy. They were dubious about work that depended on drawing velocity vector diagrams to interpret bumps on scattering curves.

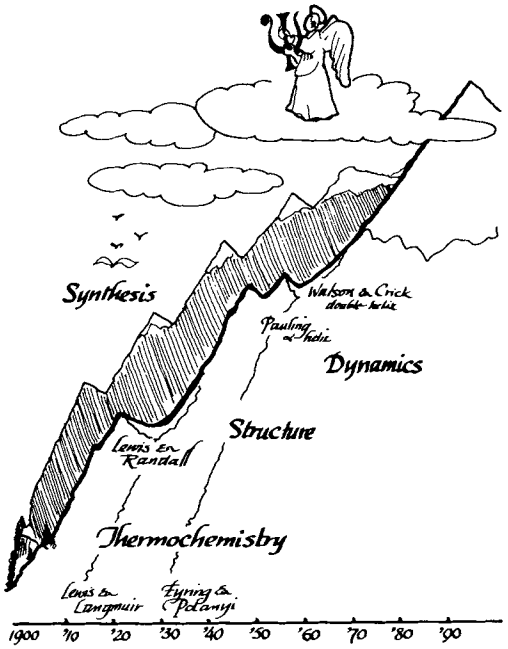

Fig. 1. Historical perspective. Ascending mountains represent three eras, since *thermochemistry* was prerequisite for the *structure* era and both underlie the *dynamics* era. All three connect to a vast range representing *synthetic* chemistry, which draws closest to dynamics as both disappear heavenwards into clouds symbolizing the ultimate triumph of *ab initio* quantum chemistry.

Molecular Beams before Chemical Dynamics

The first molecular beam experiments were carried out 75 years ago, immediately after the invention of the high-speed vacuum pump had made it possible to form directed "rays" of neutral molecules at sufficiently low pressures to prevent their disruption by collisions with background gas. Figure 2 indicates the historical progression. Systematic research began with *Otto Stern*, who developed many aspects of beam techniques. He had retired and was living in Berkeley when I arrived there in 1959. Occasionally, *Stern* attended seminars, and I had the opportunity to hear from him several memorable stories about his work. Two of these are pertinent here.

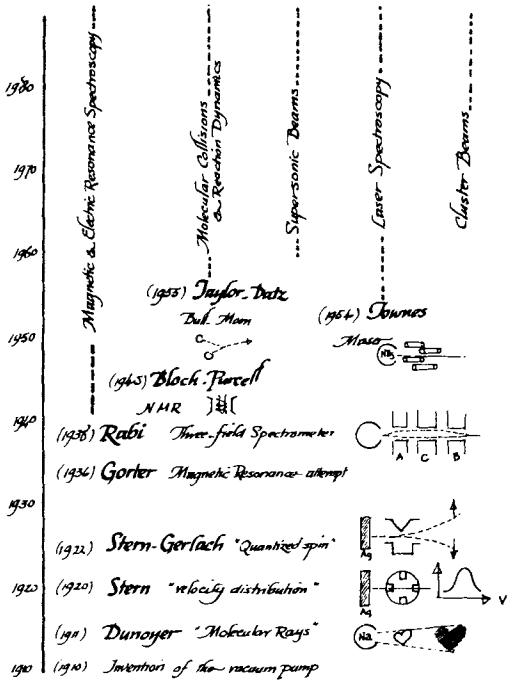

Fig. 2. Evolution of molecular beam and kindred methods.

In his first work, done at Frankfurt in 1920, *Stern* undertook to test the Maxwell-Boltzmann velocity distribution by analyzing the speeds of a silver atom beam with a rotating device. Gleefully, he described how the money to build the apparatus was supplied by *Max Born*; the great theoretical physicist was renowned as a public speaker and gave

a special lecture series to raise the funds. *Stern* found that his experimental results were in approximate agreement with the Maxwell-Boltzmann distribution, but deviated from it in a systematic way. He said:[4]

> After my paper was sent off, I received a letter pointing out that I had overlooked an extra factor of v (the velocity) which enters because the detected atoms must pass through a slit. When this factor was inserted, the agreement became quantitative. That letter came from *Albert Einstein*!

The "extra factor" represents the Jacobian for the transformation from number density (atoms cm^{-3}) to flux density (atoms $cm^{-2}\ s^{-1}$). That same factor and Jacobians for numerous other transformations often appear in chemical dynamics, so I've had reason to tell *Stern*'s story to many bedeviled students. As noted below, some striking effects in molecular collisions are due entirely to a Jacobian factor.

The other favorite story concerns the celebrated Stern-Gerlach experiment, in which a beam of silver atoms was sent through an inhomogeneous magnetic field and discovered to split into two, thereby revealing the space-quantization of the electron spin. This is how *Stern* told the story:[4]

> The question whether a gas might be magnetically birefringent (in the words we used in those days) was raised at a seminar. The next morning I awoke early, too early to go to the lab. As it was too cold to get out of bed, I lay there thinking about the seminar question and had the idea for the experiment. When I got to the lab, I recruited *Gerlach* as a collaborator. He was a skilful experimentalist, while I was not. In fact, each part of the apparatus that I constructed had to be remade by *Gerlach*.
>
> We were never able to get the apparatus to work before midnight. When finally all seemed to function properly, we had a strange experience. After venting to release the vacuum, *Gerlach* removed the detector flange. But he could see no trace of the silver atom beam and handed the flange to me. With *Gerlach* looking over my shoulder as I peered closely at the plate, we were surprised to see gradually emerge two distinct traces of the beam. Several times we repeated the experiment, with the same mysterious result. Finally we realized what it was. I was then the equivalent of an assistant professor. My salary was too low to afford good cigars, so I smoked bad cigars. These had a lot of sulfur in them, so my breath on the plate turned the silver into silver sulfide, which is jet black so easily visible. It was like developing a photographic film.

Although I've rarely tried a cigar, our first reactive scattering work also benefited from lucky contamination of the detector, as described later.

Soon *Stern* could afford good cigars, as he was appointed professor of physical chemistry at Hamburg. His Institute there conducted a series of remarkable molecular beam studies, including invention of the surface ionization detector that was to be so vital in the "alkali age" of chemical dynamics. This detector, derived from *Langmuir*'s studies of surface ionization, has since been used in thousands of experiments. It consists simply of a heated filament of a metal such as tungsten and will ionize with nearly 100% efficiency materials having ionization potentials lower than about 4 or 5 eV, such as alkali atoms. *Stern* had to abandon his splendid work at Hamburg in 1933 when *Hitler* took office.

Other epochal molecular beam contributions to physics came from *Isidor Rabi*. He had also been educated as a chemist and worked with *Stern* as a postdoctoral fellow before joining the physics faculty at Columbia. In 1938 he invented his magnetic resonance method. This followed a seminar by *Gorter* from Leiden describing his failed attempt to detect nuclear magnetic resonance in a crystal. It was then not obvious that the tiny nucleus, with dimensions of the order 10^{-13} cm, would interact appreciably with the external atomic electron distribution, with dimensions of the order 10^{-8} cm. If not, the different nuclear spin orientations (favorable "up" or unfavorable "down") would remain equally probable even when subjected to an external magnetic field. There would then be no net absorption of radiofrequency radiation in the magnetic resonance experiment. Spin flips induced by the radiation are equally likely up or down, so net absorption cannot occur unless interactions permit the spins to relax toward thermal equilibrium where more will be up than down.

Rabi immediately realized how to exploit beams to escape this constraint. He introduced two opposing Stern-Gerlach fields. A beam traversing the first field (denoted A) is split into its nuclear spin components, but on passing through the second field (denoted B) these are recombined. Between these fields, which act like diverging and converging lenses, *Rabi* introduced a third field (the C-field). This was homogeneous and so had no lens action, but it served the role of *Gorter*'s field in defining "up" and "down." Since there are no collisions in the beam, there is no means to relax the spin component populations. But now none is needed. Radiofrequency radiation in the C-field region will at resonance flip equal numbers of spins up or down; but now any spin changing its orientation after the A-field will not be refocused in the B-field. In this ingenious way, *Rabi* could detect which frequencies produced resonances. He thus created a versatile new spectroscopy with extremely high resolving power. It has provided a wealth of information about nuclear structure. An analogous electric resonance spectroscopy operates with rotational states of polar molecules. This has likewise been very fruitful for molecular structure. It has also been used to fully analyze the quantum states of products in some reactive scattering experiments.

Shortly before inventing his resonance spectroscopy, *Rabi* undertook some simple elastic scattering studies by observing the attenuation of an alkali atom beam sent through a gas-filled chamber and detected on a surface ionization filament. If *Gorter* had not come by, perhaps *Rabi* would have continued on to develop reactive scattering. Another quirk of fate was only revealed in 1945, when nuclear magnetic resonance was successfully done in li-

quids and solids by *Purcell* at Harvard and *Bloch* at Stanford. Only then did it become clear that *Gorter*'s original experiment would have worked if he had used a material with magnetic impurities which would have induced the necessary relaxation. Yet another epilogue, also of great portent, was the invention of the maser in 1954 by *Townes* at Columbia. In this device, the precursor of lasers, he sent a beam of ammonia molecules through an electric quadrupole focusing field which selected an energetically unfavorable state. When illuminated with microwave radiation, the molecule reverted to the energetically favorable state, emitting the excess energy as a photon. Thus was born molecular amplifiers and oscillators and the now vast industry of quantum electronics. The idea came to *Townes* on a sunny park bench, 33 years after *Stern* woke up early in his warm bed.

My First Encounters with Kinetics and Beams

Within days of my arrival at college, I first learned something of the challenging field of chemical kinetics from my freshman advisor, *Harold S. Johnston*. He was then a young assistant professor at Stanford University, applying new methods of his own devising to measure rates of fast gas-phase reactions in regimes previously inaccessible. In the summer after my sophomore year, and again after my junior year, *Hal* hired me as a lab assistant for his research group. One project involved weeks of glassblowing, silver soldering, and plastering with great quantities of asbestos paste (now outlawed!) to install a large-volume reaction vessel that could be maintained at a high and uniform temperature. I was greatly impressed with the care and attention to detail shown by *Hal* and his graduate students, and his emphasis on testing theory. He stressed that this could only be done with a reaction known to be an elementary step—and that we could never be entirely certain that all steps and intermediates had been correctly identified.

In my senior year, I took *Hal*'s excellent course in chemical kinetics, and the following year a study of transition-state theory begun there became my master's thesis. In this, we calculated the Arrhenius A factors for twelve well-characterized bimolecular reactions involving only four to six atoms. Necessary assumptions about the properties of the transition state were made uniform for the whole set and consistent with similar stable molecules. Internal rotations of the reaction complexes received special attention, thanks to the help of *Kenneth Pitzer* at Berkeley, who kindly showed me how to design a sensible approximation. Previous tests had been piecemeal and often capricious about internal rotations; *Hal* expected our test might prove embarassing for the theory. In fact, the agreement with experiment was good. This persuaded *Hal* that the theory deserved further development; over the next decade he carried this out and produced an exemplary book. Although *Hal*'s contagious enthusiasm had long since convinced me that I wanted to pursue kinetics, the thesis project made me decide to study first the dynamics of stable molecules. Thus I applied to the chemical physics program at Harvard in order to do Ph. D. research with *E. Bright Wilson, Jr.*

A few weeks before turning in the master's thesis, I first heard of molecular beams. In his course on statistical thermodynamics, *Walter Meyerhof* briefly described *Stern*'s test of the Maxwell-Boltzmann velocity distribution. It was love at first sight. I remember a flush of excitement at the thought that this was *the way* to study elementary reactions, the unequivocal way to know a reaction is elementary and to study directly its properties. This was the spring of 1955. I did not imagine that five years later my own first beam apparatus would be nearly complete at Berkeley and I would have met *Otto Stern* himself.

On arrival at Harvard in the fall, I was delighted to discover that *Norman Ramsey* was offering a seminar course based on the proof sheets of his book on molecular beams. *E. B. Wilson* was giving a course using his just published book on molecular vibrations. *Roy Glauber* provided a rigorous treatment of electromagnetic theory, working through all the mathematical derivations in class with no notes at all. The dessert course of this remarkable academic menu was entitled "Chemical Physics," and given by the legendary *Peter Debye*, a visitor that year. His course had 40 or more auditors, but only 3 of us took it for credit and thus had individual oral exams with *Debye*. I still relish the memory of his lucid lectures and the twinkle in his eye as he so often began, "Let me tell you a story ..." Early in *Ramsey*'s course, he too discussed *Stern*'s velocity analysis study and actually announced, in his booming voice: "This would be a wonderful way to do chemistry!" In the spring term I took among others *Kenneth Bainbridge*'s course on nuclear physics to learn something about nuclear reactions; this was indeed to prove very useful later.

Even more exhilarating that year and thereafter was my experience in *Bright Wilson*'s research group. With microwave spectroscopy, he and his students were developing an elegant new way to study internal rotation by exploiting the tunnel effect. Typical systems had a methyl group attached to an asymmetric molecular frame. The torsion or internal rotation of the methyl group about its axis is hindered by a sinusoidal potential barrier with three equivalent minima. If the barrier is very high, then essentially there are only small torsional oscillations in three separate potential wells, and to good approximation the microwave spectrum is that of a rigid rotor molecule. If the barrier is low enough, however, tunneling between the wells occurs and this causes the microwave rotational transitions to split into doublets. These splittings are very sensitive to the barrier height, so an approximate dynamical theory is adequate to extract an accurate value for the barrier. Since I already had seen how prevalent internal rotation is, not only in stable molecules but in transition states for reaction, I was very excited about this new method. It was such a fresh and powerful approach that almost every day some member of the group had an unanticipated result to report. Because the microwave spectra display a forest of transitions, there was ample need to work out variations on the basic theme and satisfying opportunity for definitive tests.

Although this research was entirely different in character from molecular collisions, I learned invaluable lessons from it and from working with *Bright* and his extremely

able group. A microwave spectroscopist simply must calculate as much as possible before plunging into the forest; for a molecular beamist, the need is less obvious but just as vital. *Bright*'s high standards and absolute integrity had great impact on his students. Thus he put strong emphasis on analyzing and clearly stating what is well-established and what is really based on unproven assumptions. He also gave strong emphasis to blocking out the big questions and on coupling theoretical investigations with experiments.

Microwaves soon led to my first work with beams, in collaboration with an ebullient young instructor, *Bill Klemperer*. He had developed a technique for high-temperature infrared spectroscopy and was using it to study alkali halides (later to become my favorite molecules). *Bill* invited me to help build a high-temperature microwave spectrometer, again a project requiring much asbestos paste. One day *Bill* came in with a paper just published by *Marple* and *Trischka* reporting an electric resonance study of lithium chloride. They had used the venerable tungsten surface ionization filament as a detector. Depending on resonance field settings, the apparatus could resolve four vibrational states. However, the vibrational frequency derived from the relative intensities was much lower than *Bill* had measured in the IR. We examined various possibilities and concluded that most likely was an increase in the efficiency of the surface reaction (dissociation of the salt molecule to ions) with vibrational excitation of the incident molecule.[5] This was near Christmas, 1956. Almost 15 years later, the vibrational excitation mechanism was confirmed and recently it has become a leading issue in surface chemistry.

We were eager to study the surface ionization process experimentally. Since an electric resonance apparatus was not available (at that time only three existed, none closer than 300 miles of Cambridge), we could not study alkali halide molecules. Hence we decided to study ionization of alkali atoms as a function of the surface temperature. *Ramsey* kindly lent us one of his machines over Christmas vacation and we quickly obtained a hundred pages or so of data from which we derived residence times and heats of adsorption for atoms on tungsten and platinum surfaces. Then we discovered that very similar data existed in the Russian literature, so did not publish our results. However, this was a key episode for both *Bill* and me. He too fell in love with molecular beams, and immediately undertook to build an electric resonance apparatus. *Bill* and his students have since turned this into a cornucopia for molecular spectroscopy, unprecedented in resolution and chemical scope. Especially revealing have been their studies in recent years of molecules held together by weak van der Waals forces. This work is building an understanding of these ubiquitous forces which may help elucidate the specificity and selectivity of interactions in biomolecules.

In studying the literature on surface ionization, I was elated to discover[6] a paper by *Taylor* and *Datz* from Oak Ridge describing an actual crossed-beam study of the reaction $K + HBr \rightarrow KBr + H$. Although the traditional tungsten surface ionization detector is about equally sensitive to K and KBr, *Taylor* and *Datz* found that a platinum alloy is much more effective for K than for KBr. From the difference in the signals read on the two detector filaments, they were able to distinguish the small amount of reactively scattered KBr from the large background of elastically scattered K atoms. Small as it was, the little difference bump was a joyful sight. In a series of classic studies in the 1920s, *Michael Polanyi* had shown that many alkali reactions proceeded at rates corresponding to "reaction at every collision." With this differential surface ionization detector, there was now prospect that crossed-beam studies of many of these reactions could be made with relatively simple apparatus.

Soon I found another intriguing crossed-beam study, published two years before by *Bull* and *Moon* at Birmingham. They bombarded a stream of Cs vapor with a pulsed accelerated beam of CCl_4 produced by swatting with a paddle attached to a high-speed rotor. The intense CCl_4 beam could be monitored with a simple ionization gauge and signal pulses due to scattered Cs or CsCl were detected by surface ionization on a tungsten filament. Although there was no direct means to distinguish between Cs and CsCl, the observed signal pulses appeared to come primarily from reactively scattered CsCl, on the basis of time-of-flight analysis and blank runs with the CCl_4 replaced by Hg vapor. Unjustly, these experiments were long discounted or ignored. This was due to the misconception that elastic scattering would always predominate. The high-speed rotor technique also intimidated other prospective experimenters; thus this fine early work did not have the impact it deserved.

During the spring of 1958, while completing my Ph. D. thesis, I visited several universities as a faculty candidate. My seminar about internal rotation was always well received, but my plans for beam experiments sometimes produced outright dismay. Yet the response was often enthusiastic from faculty young in either age or spirit. I was delighted to accept an assistant professorship at Berkeley, especially since *Hal Johnston* was now there and also *Bruce Mahan*, who had the year before completed his Ph. D. at Harvard in kinetics with *George Kistiakowsky*. My appointment was to take effect a year later; meanwhile I continued at Harvard as a Junior Fellow of the Society of Fellows. The intervening year was extremely useful. It gave me time to work out detailed calculations for design of the beam apparatus and a kinematic theory for interpreting crossed-beam experiments. Membership in the Society of Fellows was also a great pleasure because it brought together intense people from all academic disciplines. Monday night dinners included the two dozen Junior Fellows, ten Senior Fellows, and typically ten guests, in a "neo-Pickwickian atmosphere" with ample wine and cigars too good to have saved the *Stern-Gerlach* experiment.[7]

Just before departing to Berkeley, I went to say goodbye to *Kistiakowsky*. Like so many others, I revered him as a scientist and a sage as well as an awesome personality. He confirmed a legendary story about a molecular beam experiment he and *Slichter* had tried in 1951 to test early theoretical calculations on the properties of supersonic expansions.[8] Because of inadequate pumping speed, the experiment was inconclusive and a miserable struggle. Afterwards, *Kisty* destroyed the apparatus with an ax! He said to me, with his extra heavy Russian accent (conveying

whimsey—or so I hoped): "So you have been bitten by the molecular beam bug. Too bad! The trouble is that there are no collisions in one beam, and no collisions in the other beam, so when you cross them there are still no collisions!"

Early Alkali Age of Reactive Scattering

At Berkeley, I was soon joined by two graduate students, *George Kwei* and *Jim Norris*. Space was in short supply, and we were content with a corner (only 4 m × 6 m) of a lab in Lewis Hall. Our first task was to remove a large calorimeter that had long occupied that corner; this we viewed as a rite of passage, with the historical perspective of Figure 1 already in mind. The beam apparatus we installed (dubbed *Big Bertha*) was almost rudimentary. As shown in Figure 3, the beams were formed by thermal effusion from ovens mounted on a turntable which could be rotated to sweep the angular distribution of scattered atoms and molecules past the surface ionization detector. Typically, the distance from the scattering center to the alkali oven was 10 cm, to the other oven 1.5 cm, and to the detector 10 cm. Use of a double-chamber oven for the alkali allowed the temperature of the beam emerging from the upper chamber to be varied by about 300 degrees independently of the vapor pressure established in the lower chamber (about 0.1 torr), which governed the beam intensity. The oven for the reactant gas was connected to an external barostat by a supply tube which passed through the support column in the rotatable lid. Cold shields and collimating slits hid both ovens from the scattering center, and a cold shield also surrounded the detector. The entire scattering chamber was enclosed in a copper box attached to a large liquid nitrogen trap. Since the reactants are condensable, the cold shields and trap provided very high pumping speed. This kept the background vacuum in the scattering chamber low enough (of the order 10^{-7} torr) to ensure that collisions with background gas were negligible for both the reactant beams and the product molecules in flight to the detector.

In typical experiments, the concentration of alkali atoms within the volume defined by the intersection of the beams was about 10^{10} cm^{-3}, equivalent to a pressure of 10^{-6} torr, and that of the reactant gas molecules was about 100-fold

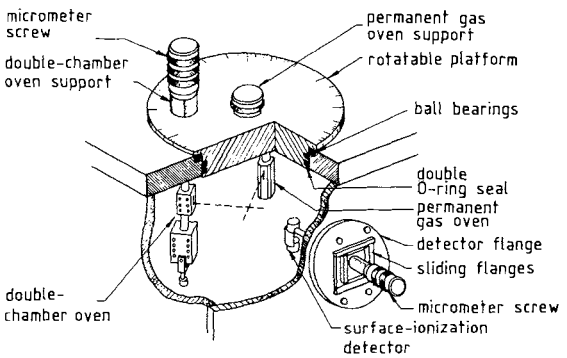

Fig. 3. Crossed-beam apparatus *Big Bertha* for study of alkali atom reactions. Cold shields, collimating slits, shutters to interrupt the beams, and other details omitted.

greater. About 10^{15} alkali atoms s^{-1} entered the reaction volume, of which roughly 0.1–1% reacted to form products while about 10% underwent elastic scattering. The steady-state concentration of products in the reaction volume was roughly 10^{7} to 10^{8} molecules cm^{-3}, the pressure about 10^{-9} to 10^{-10} torr. At the peak of the angular distribution of reactive scattering about 10^{10} to 10^{11} product molecules cm^{-2} s^{-1} arrive at the detector. Since conversion to ions on a hot tungsten or platinum surface is nearly 100% efficient for alkali species, such yields gave readily measurable signals of the order of 10^{-13} A. For many of the reactions studied more than a month would be required to deposit a monolayer of product molecules, so it was essential to have a detector far more sensitive than *Stern*'s cigar.

Experiments Revealing Product Recoil

Our first experiments were begun in the fall of 1960. On the basis of simple theoretical considerations, we decided to try reaction (a). From the angular distribution of the

$$K + CH_3I \longrightarrow KI + CH_3 \qquad (a)$$

reactively scattered KI we hoped to learn whether there was any preferred direction relating the reactant and product relative velocity vectors and also to get some idea how the reaction energy is partitioned between internal excitation of the product molecules and their relative translational motion. Our rationale was based on the CH_3/KI mass ratio. A simple kinematic calculation (see Fig. 5) showed that this ratio was large enough to permit the detected product KI to recoil sufficiently far away from the centroid to reveal any directional preference, but small enough to inhibit the KI from spraying out so widely that the reactive scattering became too weak to observe. Happily, even the first experiments worked nicely. Our kinematic rationale was vindicated, but it was not until three years later that we learned how lucky was this choice of reaction system; it turned out that CH_3I played the role of *Stern*'s cigar.

Figure 4 shows typical results. In Figure 4a, the parent K beam was attenuated 7% by the perpendicularly crossed

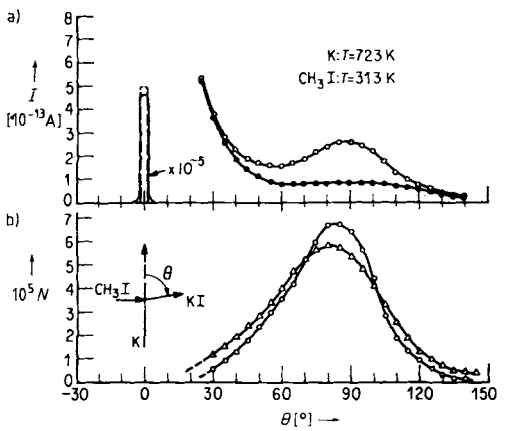

Fig. 4. Reactive scattering data: a) Parent K beam of 5×10^{-8} A attenuated 7% by crossed CH_3I beam. Readings on Pt detector (•) normalized to W (○) at parent beam peak. I = intensity. b) KI distributions; ○ derived from a), △ from a replicate experiment several months later. Area under curves gives collision yield. N = yield.

CH_3I beam; that represents chiefly elastic scattering. Readings on the platinum detector (solid points) were normalized to those on tungsten (open points) at the parent beam peak. In this case, the use of differential detection was not crucial, as the KI distribution (Fig. 4a, right) is displaced far enough from the K beam to appear as a pronounced bump in the signal from the tungsten detector. In Figure 4b, the KI distribution is normalized so that the area under the curve gives the collision yield (integrated intensity of KI divided by total K scattered out of the parent beam). This is about 5×10^{-4} and indicated the reaction cross section (or effective target area) is about 7 Å^2. Measurements at several temperatures of the incident beams indicated that the activation energy for reaction (a) is negligibly small, less than 0.3 kcal mol^{-1}. The new dynamical information we were after is contained in the location and shape of the product angular distribution, however. To extract that information we used a kinematic analysis derived from conservation laws that hold regardless of the forces governing the collision.

Kinematic Analysis Via Newton Diagrams

Velocity vector diagrams such as Figure 5 are a convenient aid in the kinematic analysis. The vectors pertain to the asymptotic initial and final states of the collision. By virtue of momentum conservation, the center-of-mass velocity vector $\boldsymbol{C}$ remains constant throughout; only motion relative to $\boldsymbol{C}$ involves chemical interactions. The recoil velocity vector $\boldsymbol{u}$, which carries the product KI away from $\boldsymbol{C}$, can have any direction, but energy conservation limits its magnitude. Thus, the possible spectrum of recoil vectors $\boldsymbol{u}$ is represented by a set of spheres, one for each accessible value of the final relative translational energy of the products. This energy ranges up to a maximum determined by the initial collision energy and the difference in dissociation energy of the new bond formed and the old bond broken.

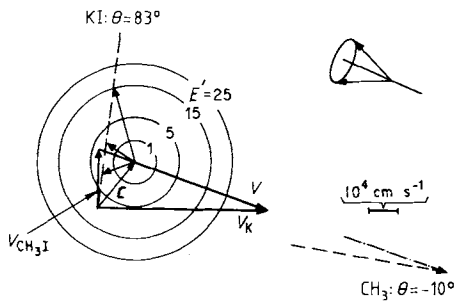

Fig. 5. Newton diagram corresponding to most probable velocities of reactants in Figure 4. Spheres indicate range of KI recoil vectors allowed by conservation of energy and linear momentum; each is labeled by value of E' [kcal mol^{-1}], the final relative translational kinetic energy. Distribution of recoil vectors must have cylindrical symmetry about initial relative velocity vector, by virtue of "dart board" randomness of collisions. Three sample recoil vectors are shown that correspond to the KI observed at the peak of the angular distribution. Also shown is estimate of most probable recoil vector for CH_3 product.

From the velocity vector diagram we see that the broad peak observed near 83° in the laboratory corresponds to reactive scattering in which an observer riding with the center of mass would see the product KI recoil into the backward hemisphere (and the CH_3 forwards) with respect to the incoming K beam. Markedly anisotropic scattering of this kind evidently corresponds to a "hard" collision dominated by repulsion, as the K atom, the CH_3 group, and the center of mass of KI must all reverse direction. We called this the *rebound* mechanism. It was later found for many other reactions dominated by repulsion.

Comparison with the velocity vector diagram also permits an estimate of the energy in product relative translation. This affects the displacement of the laboratory angular distribution from that of $\boldsymbol{C}$ as computed from the initial conditions. In assessing the displacement, it is necessary to take proper account of a Jacobian factor which enhances the intensity of the laboratory scattering at low recoil velocities. We failed to include this Jacobian in our early work (thereby unwittingly emulating *Otto Stern*) and hence underestimated the product translation. The correct analysis showed that for reaction (a) about half of the available energy appears in recoil of the products. This result, later confirmed by direct measurement of the KI velocity distributions, again exhibited the dominant role of repulsive forces in a *rebound* reaction.

For kinematic analysis, Newton's laws suffice. In the asymptotic translational states the beam molecules are too far apart to interact, hence need not be precisely localized in space and can be assigned definite momenta despite *Heisenberg*'s principle. Accordingly, we named our velocity vector constructions "Newton diagrams." These are still much used today, as kinematic analysis is an essential part of the design and interpretation of any collision experiment.

Frustrations and Preparations

We were very happy to find this clear evidence for a preferred range of product recoil angle and energy and were eager to study other alkali atom reactions to look for variations in the scattering patterns that might be correlated with electronic structure. However, we encountered frustrating difficulties with the surface ionization detector. Many reactant gases (other than alkyl halides) poisoned the Pt filament, inducing spurious and irreproducible responses that precluded measurement of reactive scattering. This difficulty stymied us until the fall of 1963, when we finally eliminated it by means of a procedure due to *Touw* and *Trischka*. They demonstrated that the Pt filament could be stabilized in either of two distinct modes. The Pt filament becomes essentially *nondetecting* for alkali compounds (but still detects alkali atoms) if it is preheated while doused with methane or another hydrocarbon. The Pt filament becomes *detecting* for alkali compounds and acts just like a W filament if it is instead preheated while doused with oxygen or merely operated in a sufficiently clean vacuum. The nondetecting mode evidently requires a stable carbon layer on the filament. Thus, the differential detection so useful for alkali reactive scattering results from a dirty surface. Before the preheating procedure was developed, the carbon deposit was a matter of luck, supplied either by pump-oil vapor if the vacuum were poor or

by hydrocarbon-rich reactant species such as methyl iodide; either acted like *Stern*'s cigar.

During the lean period of more than two years before rescue by a dirty detector, our only successful reactive scattering experiments dealt with variants of reaction (a), involving other alkali atoms and alkyl groups with up to seven carbon atoms. However, in this period our research group expanded rapidly and we constructed much new apparatus, experimental and theoretical, that was destined to bring a harvest of results. *Jim Kinsey, Ken Cashion, Mark Child,* and *Malcolm Fluendy* joined as postdoctoral fellows, and *Phil Brooks, Kent Wilson, John Birely, Ron Herm, Jim Cross,* and *Dick Zare* as graduate students. Figure 6 provides a succinct summary, indicating the chief projects pursued by this distinguished roster during our Berkeley era.

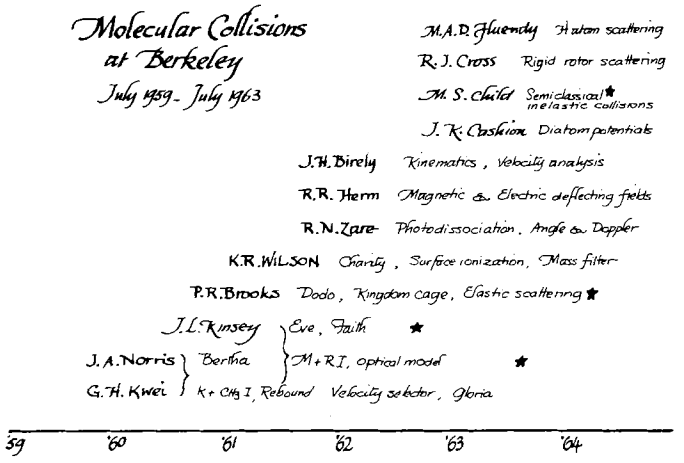

Fig. 6. Roster of graduate students and *postdoctoral fellows* with chief research projects during Berkeley era. Our first apparatus was a helium leak detector called Annie; hence our successive beam machines were named Bertha, Charity, Dodo, Eve, Faith, Gloria, etc. Stars indicate completion of Ph.D. theses or postdoctoral term.

In particular, we note among the apparatus construction projects three analyzing devices: rotating slotted-disk velocity selector, inhomogeneous magnetic deflecting field, and inhomogeneous electric deflecting field. These devices are quite similar to those used by *Otto Stern*; we liked to say that reactive scattering followed the evolutionary principle, "ontogeny recapitulates phylogeny." As seen already, velocity analysis was essential to obtain quantitative data for the recoil angle and translational energy distributions. Magnetic analysis provided, among other things, a definitive test of our detection technique, immune to poisoning of the filaments. By deflecting away most of the paramagnetic alkali atoms, we could measure directly the distribution of diamagnetic alkali halide molecules produced by reactive scattering. Electric deflection of these polar molecules enabled us to determine the rotational angular momentum. This had special appeal for me because of my background in rotational spectroscopy. Furthermore, since mass, velocity, and position all enter into angular momentum, it was clearly a key property for theoretical models of reaction dynamics.

Among our theoretical studies of this period was a treatment of the velocity vector distribution of fragments from molecular photodissociation. This was undertaken because already we had vague notions of a kinship between chemical reactions and photodissociation. In electronic excitation by photons, the angular dependence is determined simply by the dipole selection rule whereas the exit velocity of the photofragments is determined by the repulsive potential of the excited state. This "half-collision" model, worked out nicely by *Dick Zare*, provided rather general "form factors" for numerous properties.[9] Subsequently, this has served as the basis for extracting a lode of information about dissociative excited states by means of laser spectroscopy, and the suspected link with reaction dynamics did indeed emerge.

Our Berkeley days also included several memorable visits with others captivated by reaction dynamics. One of these occurred in the early summer of 1961, when I visited *Don Bunker* at Los Alamos. He had undertaken the first realistic Monte Carlo calculations of classical trajectories for chemical reactions, and his initial aim was to interpret our results for the $K+CH_3I$ system in terms of potential surface features. The scene in his office comes back vividly:[10]

> ... He was decorating the walls with strips of recorder chart paper several yards long, on which were plotted a series of undulating, intertwined curves. These were the first results of his Monte Carlo calculations. ... The room was bright with sunshine and the varicolored curves seemed to shimmer and dance about, as if choreographed to *Don*'s crisp and witty description. It was an exhilarating moment. Henceforth the mechanics of molecular collisions for any postulated force field could be computed, as he liked to say, "in instructive and entertaining detail."

Such classical trajectory calculations, as developed especially by *Martin Karplus* and *John Polanyi*, have indeed proven invaluable for interpreting data and testing concepts of reaction dynamics.

Other inspiring encounters came in April, 1962, at a Faraday Society Discussion held at Cambridge University, where I met many leading workers in chemical kinetics. Equally inspiring was a solo visit to Berkeley a few months later by *Michael Polanyi*. He witnessed an unsuccessful scattering experiment on the $K+Br_2$ reaction while he described to us his prescient speculations of 30 years before that it might proceed by a stripping mechanism with high vibrational excitation of the KBr product. He also mentioned that he liked to think that the attacking alkali atom used its valence electron to "harpoon" the halogen. Later I adopted this term to enliven numerous discussions of electron-transfer reactions.

From Rebound to Stripping with Rainbows Between

Within a few months my group was discussing an unanticipated transfer to Harvard. We had expected to relocate in a new lab about 100 m away in the basement of the nearly completed Latimer Hall, but in the late summer of 1963 instead moved 5000 km to the basement of Mallinckrodt Laboratory. I went even further that summer, as I'd agreed to present a lecture course on molecular collisions

at Göttingen University. There I strolled daily along the path atop the encircling medieval wall, the path taken by many of the pioneers of quantum mechanics during ambulatory debates. But only by communing with the charming little Goose Girl in the Rathaus fountain was I reconciled to the quantumlike dualities of the Harvard/Berkeley choice.

Our new lab was in nearly full swing by Halloween and soon we learned how to avoid poisoning our detector filaments. Thereafter results were rapidly obtained for a wide range of alkali reactions. As illustrated in Figure 7, many showed striking contrasts to reaction (a). We found that for reaction (b) and similar systems the reaction cross section

$$K + Br_2 \longrightarrow KBr + Br \qquad (b)$$

is remarkably large, ca. 200 Å^2, and most of the alkali halide product recoils into the forward hemisphere with respect to the incident alkali atom. These features indicate dominantly attractive interaction in which the bond exchange can occur for quite large impact parameters. This suggests a *stripping* mechanism of the type familiar in nuclear physics. In an independent study of reaction (b), *Minturn* and *Datz* obtained similar results and many other examples of *stripping* reactions were soon found.

Before long, we had examples for which the reaction cross section is of intermediate size and the product peaks sideways, giving a conical angular distribution about the direction of the initial relative velocity vector. Such a case is reaction (c) (see Fig. 7).

$$K + CCl_4 \longrightarrow KCl + CCl_3 \qquad (c)$$

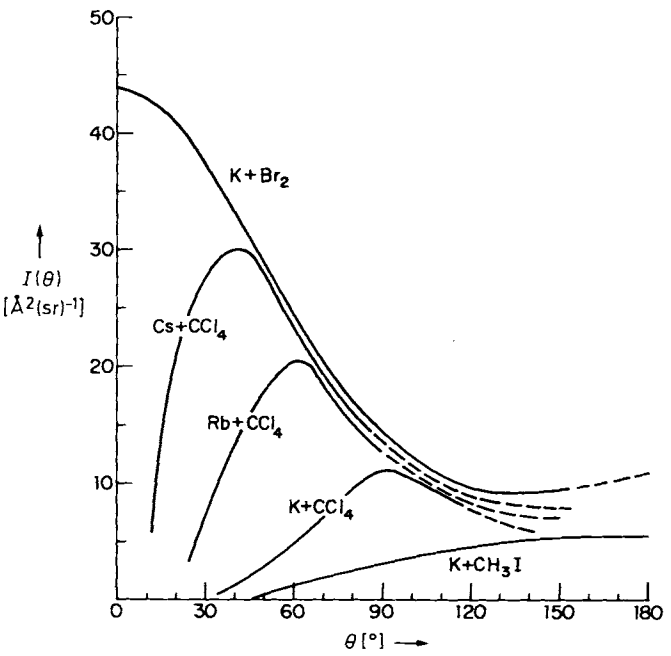

Fig. 7. Comparison of scattering angle distributions, $I(\theta)$, for reactions of alkali atoms with Br_2, CCl_4, and CH_3I, illustrating stripping, transitional, and rebound behavior. Ordinate scale indicates approximate normalization to total reaction cross sections. Distributions show angular variation that would be seen by a hypothetical observer traveling with the center of mass. Scattering angle, θ, indicates deviation of product relative velocity from reactant relative velocity; for $\theta = 0°$, the alkali halide emerges in same direction as incident alkali atom.

A strong correlation emerged: as the magnitude of the total reaction cross section increases, the preferred recoil direction of the alkali halide product shifts forwards. This is exemplified as K→Rb→Cs for the CCl_4 reaction (Fig. 7), whereas the angular distributions do not change much with the identity of the alkali atom for the CH_3I case or the Br_2 case. Velocity analysis experiments likewise show a nice contrast. The product translational energy is large for the CH_3I case and small for the Br_2 case, but the angular distributions do not change much with the exit energy. For the CCl_4 reaction, the preferred direction of the product moves forward rapidly as the translational recoil energy increases. The form of this strong angle–energy coupling resembles the *rainbows* familiar in elastic scattering of molecules and in sunny but moist skies.

The marked anisotropy of the product angular distributions for this family of reactions, ranging between rebound and stripping, indicates that all proceed by a *direct* or *impulsive* mechanism. The duration of the reactive collisions must be so short that most of the transient collision complexes decompose before rotating through 180°. Since the rotational velocities are quite high, roughly half or more of the complexes must decompose within about 5×10^{-13} s, a time not much longer than a vibrational period.

The dynamical properties and chemical variations found for these alkali reactions were well suited to the early Monte Carlo trajectory studies and also prompted several insightful heuristic models. Ironically, trajectory studies of product angular distributions suffered at first from an instructive malady akin to the poisoning problem that had held up our experiments. The calculations for atom exchange reactions, A+BC→AB+C, used plausible forms of potential energy surfaces with empirical parameters. These surfaces were constructed by adding up pairwise interactions modulated by switching functions to weaken each bond as the collision partner draws nigh. *Blais* and *Bunker* found that reactive trajectories for such surfaces gave chiefly backward scattering, in satisfying agreement with our first experiments. But this rebound behavior was unduly prevalent; for about two years after the discovery of stripping and rainbow-like reactive scattering, trajectory calculations remained unable to obtain anything but backward scattering. *Godfrey* and *Karplus* cured this affliction using potential surfaces derived from approximate quantum-mechanical secular equations. This ensured a smooth surface, free from spurious bumps and wrinkles that appeared in surfaces constructed by adding piecewise interactions. It was "contamination by such warts" that induced too much backward scattering. By varying the repulsive or attractive character of the wartless surfaces, the trajectory calculations nicely elucidated the various trends associated with transition from rebound to stripping. Likewise, trajectory studies by *John Polanyi* and his students mapped out the systematics of energy disposal among product translation, vibration, and rotation.

We now could also relate these general dynamical properties of alkali reactions to the electronic structure of the target molecules. All these reactions involve converting a covalent bond into an ionic bond, and in effect are gas-phase acid–base or ion–recombination processes, via reaction (d).

$$A + BC \longrightarrow A^{\oplus} + (BC)^{\ominus} \longrightarrow A^{\oplus}B^{\ominus} + C \qquad (d)$$

According to *Michael Polanyi*'s *harpooning* model, the attacking alkali atom tosses out its valence electron, hooks the halogen-containing molecule, and hauls it in with the Coulomb force. The basic features of the initial electron transfer had been examined as early as 1940 in an exemplary theoretical study by *Magee*. As pictured schematically in Figure 8, the transfer occurs in the vicinity of "curve crossing" between zeroth-order "purely covalent" and "ion-pair" potential surfaces. When the crossing radius r_c is large enough, Coulombic attraction is dominant there and this radius may be estimated from Equation (e),

$$e^2/r_c = IP(A) - EA(BC) \qquad (e)$$

the difference in the ionization potential of the alkali atom and the electron affinity of the target molecule. This relates the size of the reaction cross section to the energy required to create the ion pair.

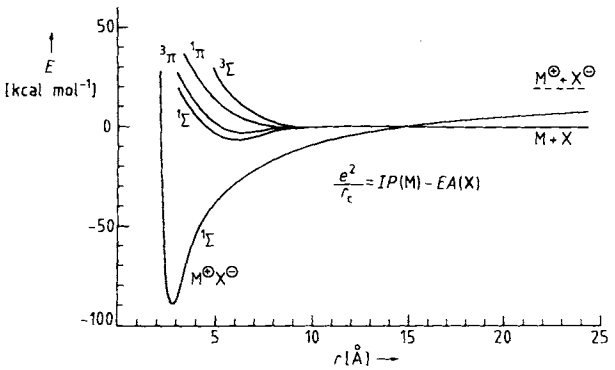

Fig. 8. Potential energy curves for an alkali halide molecule (drawn for KBr) showing the "zeroth-order" crossing of the ionic and covalent states.

However, the dynamical properties are also greatly influenced by the exit interaction as the $A^{\oplus}$ ion approaches the intermediate molecule-ion $BC^{\ominus}$, which is severely distorted by the strong electric field and dissociates [cf. reaction (d)]. Accordingly, many dynamical features will differ with the shape and particularly the location of the asymptote of the potential curve for the negative molecule ion. Often we could estimate the relevant potential curves for the $BC^{\ominus}$ ion from data obtained in electron impact experiments or by means of arguments developed by *Mulliken* for the analysis of charge-transfer spectra. Figure 9 classifies some of the possibilities.

For instance, the case designated $I^{\ominus}C$ pertains to the CH_3I reaction and many other examples of rebound reactions. The negative ion is then formed in a strongly repulsive state, because the harpooning electron enters a strongly antibonding molecular orbital with a node between the originally bonded atoms. This is usually the same orbital that governs photodissociation of the parent molecule, so we could derive the location and shape of the exit potential curve from its absorption spectrum.

In contrast, the case designated $I^{\oplus}A$ pertains to the Br_2 reaction and many of the prototype stripping systems. These involve exceptionally large electron affinities, which

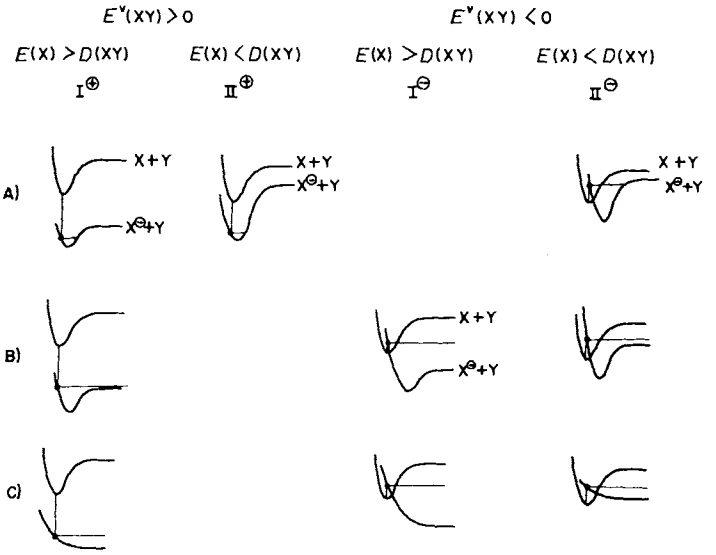

Fig. 9. Classification of electron attachment processes producing negative molecule ions ($XY + e \rightarrow XY^{\ominus}$). Here D denotes the bond dissociation energy, E the adiabatic and E^v the vertical electron affinity.

accounts for the very big reaction cross section and the long-range attraction that gives forward scattering. Here the intermediate negative molecule ion would be stable in the absence of the positive ion, although highly excited vibrationally. But when the ions are within the crossing radius of about 7 Å^2, the Coulomb field exceeds 3×10^9 V cm^{-1} and thus the negative ion will be pulled apart in a time comparable to a vibrational period, or ca. 10^{-13} s. This accounts for the direct character of the reaction. However, the transient attractive coupling between $B^{\ominus}$ and C in the exit channel has a major role in the energy disposal.

The harpooning model prompted treatments of many other properties, such as the mechanics of curve crossing and dissociative electron attachment, orientation dependence, and orbiting outside a centrifugal barrier at the crossing radius. But in terms of chemical perspective, the most striking aspect was the connection to charge-transfer spectra. In retrospect, the detection-imposed limitation of early beam studies was fortunate, as this alkali family was ideally suited for relating reaction dynamics to the electronic structure of reactant molecules.

Elucidating Polanyi Flame Reactions

As well as demonstrating very large reaction rates, the classic studies of alkali–halogen reactions by *Michael Polanyi* also revealed intense emission from electronically excited alkali atoms. This had a major role in early discussions about interaction of electronic and nuclear motions, as the Polanyi flames preceded by a few years the Born–Oppenheimer and Franck–Condon approximations, both found in 1925. Some central questions concerning the chemiluminescence remained unresolved 40 years later, however, when we undertook beam experiments to examine each of the postulated elementary steps in the flame mechanism. Again, the results exemplified prototypical aspects of electronic structure.

One of the key steps producing chemiluminescence involves *vibrational-to-electronic* energy transfer. This we studied by means of a "triple-beam" experiment. Vibrationally excited $KBr^{\dagger}$ was formed at the intersection of crossed beams of K and Br_2 and sent into a second scattering chamber containing a Na crossed beam, where fluorescence from K* was observed. The cross section found for this *reactive transfer* process [reaction (f)] is very large, 10–100 Å^2, whereas that for *nonreactive transfer* [reaction (g)]

$$Na + KBr^{\dagger} \longrightarrow NaBr + K^* \quad (f)$$

$$K + NaBr^{\dagger} \longrightarrow K^* + NaBr \quad (g)$$

is at least tenfold smaller. (The dagger denotes high vibrational energy, the asterisk denotes the lowest ^2P excited electronic state.) This result is interesting because the initial energy distributions of the reactants are nearly the same in the $Na + KBr^{\dagger}$ and the $K + NaBr^{\dagger}$ experiments and the same set of potential surfaces is accessible in both cases. On energetic or statistical grounds, both processes might have been expected to form $K^* + NaBr$ with the same probability. The interpretation becomes clear when the ionic character of the bonding is considered. If in the intermediate $(AB)^{\oplus}X^{\ominus}$ complex the $(AB)^{\oplus}$ ion decomposes rapidly and irreversibly in the field of the $X^{\ominus}$ ion, configurations in which both A and B are symmetrical with respect to both charge-sharing and interaction with $X^{\ominus}$ may seldom be traversed. The chemical exchange process ($A + B^{\oplus}X^{\ominus} \rightarrow A^{\oplus}X^{\ominus} + B^*$) is then more favorable for electronic excitation because it involves charge transfer ($B^{\oplus} + e \rightarrow B^*$), whereas the nonreactive process ($A + B^{\oplus}X^{\ominus} \rightarrow A^* + B^{\oplus}X^{\ominus}$) does not involve charge transfer. Later, we found *translational-to-electronic* energy transfer for these systems exhibits the same strong preference for reactive over nonreactive transfer, although the cross sections are a thousandfold smaller. Potential surface calculations indicate this preference appears to involve a "stereospecific" orientation dependence. The potential surfaces for the ground and excited states remain widely separated except for nearly collinear configurations with the halogen between the two alkali atoms.

In the other major chemiluminescent step, the same potential surface complex is reached via harpooning, $X + AB \rightarrow (AB)^{\oplus}X^{\ominus} \rightarrow A^{\oplus}X^{\ominus} + B^*$. This we studied by generating a beam of halogen atoms from thermal dissociation in a graphite oven and a beam of alkali dimers from a supersonic expansion. Contrary to previous indirect evidence, our beam experiments showed that this step occurs with a large cross section, ca. 10 Å^2. A "degeneracy-induced" excitation mechanism proposed long before by *Magee* was thereby vindicated. The reactant halogen atom has threefold orbital degeneracy, corresponding to location of its valence-shell "hole" in the p_x, p_y, or p_z orbital, whereas the reactant and product molecules are in nondegenerate electronic states. Thus the reactants give rise to three distinct potential energy surfaces but only one of these can lead to the nondegenerate ground state of the product alkali atom and the other two surfaces must lead to electronically excited states.

Many other aspects of the harpooning mechanism were revealed in subsequent studies of electronic excitation processes.[11] Particularly striking was evidence for an "internal reflection" mechanism. This is illustrated in Figure 10 for $K + SO_2$ collisions. Intense emission of $K^*(^2P)$ fluorescence is seen at collision energies above the endoergicity (1.6 eV) for this excitation. The emission increases strongly up to the threshold (3 eV) for formation of $K^{\oplus} + SO_2^{\ominus}$ ion pairs and then declines steeply. At energies above the $A^* + X$ asymptote but below the $A^{\oplus} + X^{\ominus}$ asymptote, trajectories that make the $A + X \rightarrow A^{\oplus}X^{\ominus}$ crossing and intend to exit via the ion-pair channel find it closed. This flux must be reflected back and redistributed at the $A^{\oplus}X^{\ominus} \rightarrow A^* + X$ and $A^{\oplus}X^{\ominus} \rightarrow A + X$ crossings until ultimately it escapes via either the excitation channel or the original entrance channel.

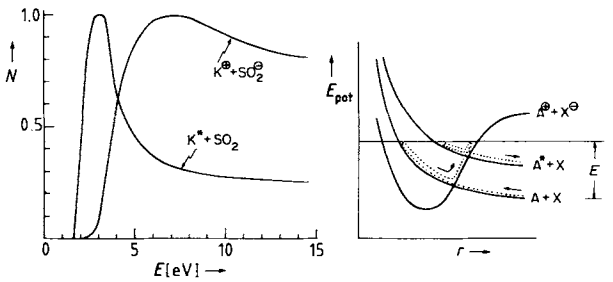

Fig. 10. Cross sections for electronic excitation and ion-pair formation on impact of K atoms with SO_2 molecules, as functions of initial relative kinetic energy E; N = normalized ion and light yields. Schematic potential curves at right show reaction path illustrating "internal reflection" mechanism.

Persistent Collision Complexes with Glorys Galore

Until late 1966, the alkali reactions studied in crossed beams or in Polanyi flames all converted a *covalent* bond into an *ionic* bond, and all appeared to involve abrupt, *impulsive* reaction dynamics. Likewise, by then trajectory calculations for A + BC reactions had explored a variety of "mountain-pass" and "ski-run" potential energy surfaces, and found that the lifetime of the transient A-B-C complex is usually too short for rotational or even vibrational motions; the products typically emerge within 10^{-13} s or less. However, we expected that suitable systems would form a lingering or *persistent* complex with lifetime long compared to rotational as well as vibrational periods. In this regime, the angle and energy distributions of the scattered products would give information about the *unimolecular* decomposition of the complex.

Among alkali reactions, likely candidates were the exchange reactions with alkali halides [reaction (h)] at ordi-

$$A + X^{\ominus}B^{\oplus} \longrightarrow A^{\oplus}X^{\ominus} + B \quad (h)$$

nary thermal energies, too low to permit electronic excitation. For these *ionic + ionic* reactions, since an ion pair is present throughout, electron transfer can enhance attraction rather than induce exit repulsion. Furthermore, the near equality of the $A^{\oplus}X^{\ominus}$ and $B^{\oplus}X^{\ominus}$ bond strengths and the exceptional stability of the diatomic alkali molecule ions (just then confirmed in the Ph. D. work of *Yuan Lee*

with *Bruce Mahan*) favor formation of an $(AB)^{\oplus}X^{\ominus}$ complex of appreciable lifetime. Electronic structure calculations subsequently demonstrated that the potential energy surfaces for dialkali halides indeed have a pronounced basin, corresponding at its minimum to a triangular complex stable by about 10 kcal mol^{-1} or more with respect to the separated products.

With the aim of studying these alkali atom + alkali halide reactions, before departing Berkeley we had begun constructing an apparatus with a mass spectrometer behind the surface ionization filament, to provide differential detection for both of the product species and both of the reactant species. *Walter Miller* and *Sanford Safron* completed the apparatus at Harvard and obtained lovely evidence for persistent collision complexes in more than a dozen of these exchange reactions. In each case, the angular distribution of products has symmetry about 90° and peaks very strongly near 0° and 180°. Furthermore, at wide angles the nonreactive scattering shows a "sticky collision bump" arising from breakup of the complex to reform the reactants rather than proceed to products.

We found the angular distributions could be nicely interpreted in terms of a statistical model adapted from the compound nucleus treatment of nuclear fission. The symmetry about 90° indicates that the complex persists for at least a few rotational periods and hence many vibrational periods. This permits a rough estimate of 5×10^{-12} s as a lower limit for the mean lifetime of the complex. The strong peaking at 0° and 180° indicates that the typical complex forms and dissociates with centrifugal angular momentum much larger than the rotational momenta of the reactant or product salt molecules. As illustrated in Figure 11, the products emerge with equal probability at all azimuthal angles about the total angular momentum vector J of the complex, like water from a lawn sprinkler. The complete angular distribution is obtained by averaging uniformly over all orientations of the sprinkler about the relative velocity vector V of the reactants. The result corresponds to the intersections of circles of latitude and longitude on a globe. The product intensity is low in the equatorial regions but becomes very high in the polar regions, near 0° and 180°. This prominent peaking forward or backward along V is called a "glory," after an analogous effect in light scattering from raindrops.

The glory peaks are rounded off when much of the angular momentum J appears in rotational tumbling of the reactant or product molecules rather than centrifugal motion. As seen in Figure 11, this tilts the spinning sprinkler away from the polar regions. The shape of the product angular distributions thus reveals the relative contribution of the centrifugal and tumbling motions. This is illustrated in Figure 12. In turn, the statistical model links the angular momentum disposal to the moments of inertia of the complex in the transition states for formation and decomposition. The arrangement of atoms and the rotational motions in the transition state thereby can leave its imprint in the product angular distribution, even though the complex may dissociate after only a few rotations.

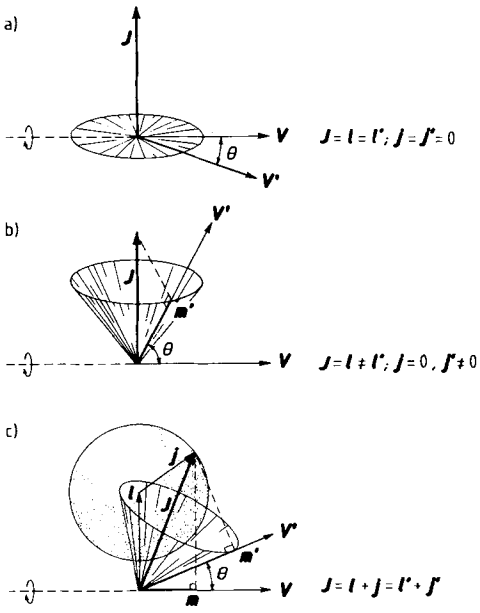

Fig. 11. Relationships among initial and final angular momenta and relative velocity vectors for a long-lived collision complex. In case a) there is no rotational momentum for either the reactant or product molecules; in b) it is present only for the products; in c) for both reactants and products. For fixed magnitudes of the total angular momentum J and the projections m and m' on the relative velocity vectors, the product angular distribution is generated by uniform precessions of V' about J and J about V.

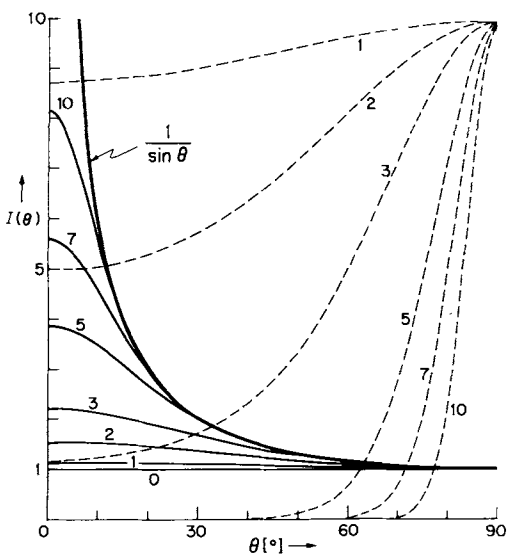

Fig. 12. Angular distributions for the statistical complex model, averaged over distributions of angular momenta appropriate to a prolate complex (solid curves) or an oblate complex (dashed curves), for case b) of Figure 11. All the curves are symmetric about 90°. The index gives the ratio of the maximum value of reactant orbital angular momentum l_{max} to the average value of the projection m' for the dissociating complex; thus the index indicates the relative contribution of centrifugal and tumbling motions.

The product energy distributions are more directly related to properties long familiar in the theory of unimolecular reaction rates. The main features are governed primarily by the statistical densities of rotational and vibrational states at the transition state, as in the Rice-Ramsberger-Kassel-Marcus (RRKM) treatment of unimolecular rates. Qualitative aspects are illustrated in Figure 13. In partitioning the available energy among relative translation, vibration, and rotation of the products, the statistically favored situation puts only a small part into transla-

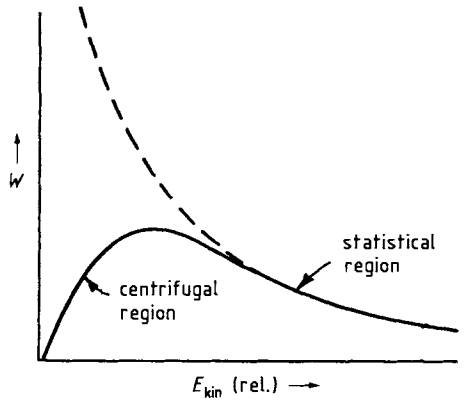

Fig. 13. Schematic distribution of product relative kinetic energy as predicted from statistical theory, without (dashed) and with (solid) the centrifugal contribution that enters for a rotating complex. W = probability.

tion, since the vibrational and rotational modes are more numerous. Thus, the probability distribution declines rather rapidly with increase in product translation energy. This decline becomes more rapid as the number of atoms in the complex increases and hence the number of vibrational modes increases. Another effect enters when the complex is rotating, however. The energy in centrifugal motion is not available for statistical distribution among the other modes. On decomposition of the complex this centrifugal energy is converted into relative motion of the emerging product molecules. This changes the shape of the product translational energy distribution. The low-energy region is determined by the centrifugal contribution, the high energy region by the statistical contribution.

As outlined here, the statistical model pertains to a "loose" complex defined by the exit and entrance centrifugal barriers associated with long-range attraction. Within these barriers, the energy disposal is assumed to be statistical; outside, the collision partners are assumed to rotate freely and travel like point masses subject to two-body forces. This simple model has worked well for many reactions, although various refinements are needed for quantitative analysis. Other basic factors enter for a "tight" complex. The transition state then occurs at a potential barrier rather than a centrifugal barrier, and bond deformations are required to surmount the barrier. This implies that energy can be exchanged between different degrees of freedom as the system moves from the transition state to the separated products. With allowance for such effects, statistical treatments akin to the RRKM theory usually prove adequate in the persistent complex realm.

A major, instructive discrepancy appeared for the dialkali halide systems, however. Despite its good agreement with the angle and energy distributions, the statistical model overestimated the ratio of reactive to nonreactive decay of the collision complex, often by a factor of 3 to 5 or more. This striking discrepancy is attributed to preferred reaction geometry. The potential energy surfaces predict that the preferred direction of approach is collinear, with the incoming alkali atom attacking the "wrong end" of the salt molecule. This corresponds to linear $(AB)^{\oplus}X^{\ominus}$ and reflects the stability of the dialkali ion. By virtue of the strong long-range attraction, most complexes are formed in collisions with large impact parameters and thus the centrifugal momentum often restrains the roughly collinear $(AB)^{\oplus}X^{\ominus}$ configurations from bending into the triangular configurations required for reaction. Later, we found many similar instances of preferred reaction geometry.

In search of another prototypical deviation from the statistical case, we looked for a collision complex with lifetime comparable to its mean rotational period. This is called an *osculating* complex, a term applied by *Wigner* to an analogous realm in nuclear reactions. As indicated in Figure 14, our model calculations for this case assume that during rotation about its total angular momentum J the complex is subject to decomposition with a random lifetime distribution, $\exp(-t/\tau)$. This gives an angle-dependent form factor governed by the ratio τ/τ_r of the mean lifetime to a typical rotational period. The angular distribution is approximated by multiplying that for a persistent complex by this factor. For $\tau \gtrsim 5\,\tau_r$, we thus expect the forward and backward glory peaks to be about equally strong, whereas for $\tau \approx \tau_r$ the backward peak should be attenuated by about 40%. Reactions of alkali atoms with thallium halides were examined as likely candidates. We expected the lifetime of the complex might be shortened by the higher ionization potential of the Tl atom, which inhibits the sharing of charge, and by the higher reaction exoergicity. Indeed, *George Fisk* and *Doug McDonald* found these systems show the glory peaks characteristic of a complex, but the backward peak is substantially weaker, by 30% to 50%. Again, similar behavior was later found for many other reactions. Attractive chemistry often yields not a persistent coupling but just a flirtatious whirl.

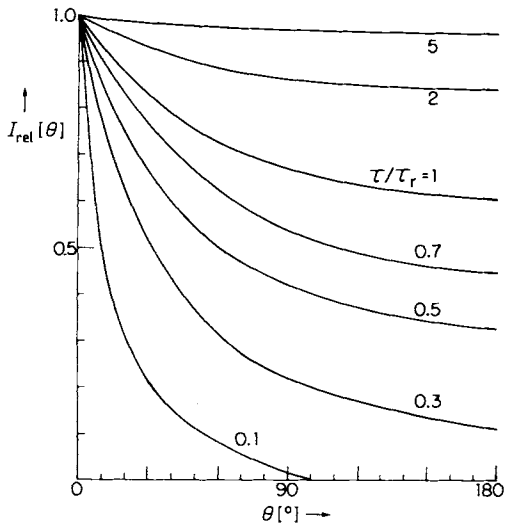

Fig. 14. Ratio of intensity, I_{rel}, appearing at angle θ to the peak intensity for forward scattering ($\theta = 0°$) as calculated for the *osculating model*. The corresponding angular distribution is obtained by multiplying this "falloff function" I_{rel} by the appropriate curve from Figure 12. The falloff curves are labeled by the ratio of the mean lifetime of the complex to a typical rotational period, τ/τ_r.

Another aspect of unimolecular kinetics explored with alkali reactions is the dependence on the number of degrees of freedom. Even some *covalent + ionic* reactions with sizable exoergicity proved to involve persistent or osculat-

ing complexes when six or eight atoms are involved. The most fully characterized example is the $Cs+SF_6$ reaction; in addition to angle and velocity distributions, we measured the CsF rotational excitation by electric deflection and the vibrational populations by electric resonance spectroscopy. Although the available energy is rather large, 40–50 kcal mol^{-1}, the reaction appears thoroughly statistical. It has symmetrical forward and backward glory peaks and the same effective temperatures for translation, rotation, and vibration, corresponding to equipartition of energy. In this study a miniature crossed-beams apparatus was joined with *Klemperer*'s electric resonance spectrometer. This enabled quantum states of the reactively scattered CsF to be completely identified with respect to vibrational level, rotational angular momentum, and space orientation of the angular momentum. It also completed another link with the saga of *Stern* and *Rabi*.

Beyond the Alkali Age

From the beginning, we spoke of the "early alkali age," a phrase both wistful and whimsical. It was intended to suggest that broader ages would inevitably follow, without predicting how soon. Skeptics discounted alkali reactions as an eccentric, unrepresentative family, but we gladly persisted because they revealed such instructive dynamical variety. Meanwhile, an unduly pessimistic view of prospects for beam studies of nonalkali reactions arose elsewhere. This came from attempts to use mass spectrometric detection which failed to reduce sufficiently the interfering background in the electron bombardment region. In March of 1967 we began designing a new apparatus, to be named *Hope*. Only nine months later it would take us "beyond the alkali age."

Universal Detector and Supersonic Nozzles

Hope was undertaken when *Yuan Lee* joined our group as a postdoctoral fellow. With *Bruce Mahan* at Berkeley, he had already built a major apparatus for beam studies of ion–molecule reactions. In this, as in *Hope*, he made elegant use of ion counting techniques adapted from nuclear physics. *Yuan* was teamed with two beginning graduate students, *Pierre LeBreton* and *Doug McDonald*, and several machinists in our Departmental Shop, headed by *George Pisiello*. It was a group of extraordinary skill and zeal, inspired by *Yuan*'s genius and fervent sense of mission. Blissfully, as each of the myriad design questions was settled, we all relished his verdict: "Should be all right."

The main features of *Hope* are shown in Figure 15. The entire detector unit is mounted on a rotatable lid and the beam sources are fixed, to facilitate changing the source modules and strong pumping of the source chambers. The key component of the detector, the electron bombardment ionizer, is located within three nested chambers, each differentially pumped by ion pumps and cryogenic traps. This fulfills two vital design criteria for the ionization region. (1) The background gas (at the mass of interest) that diffuses in from the scattering chamber must be reduced to a

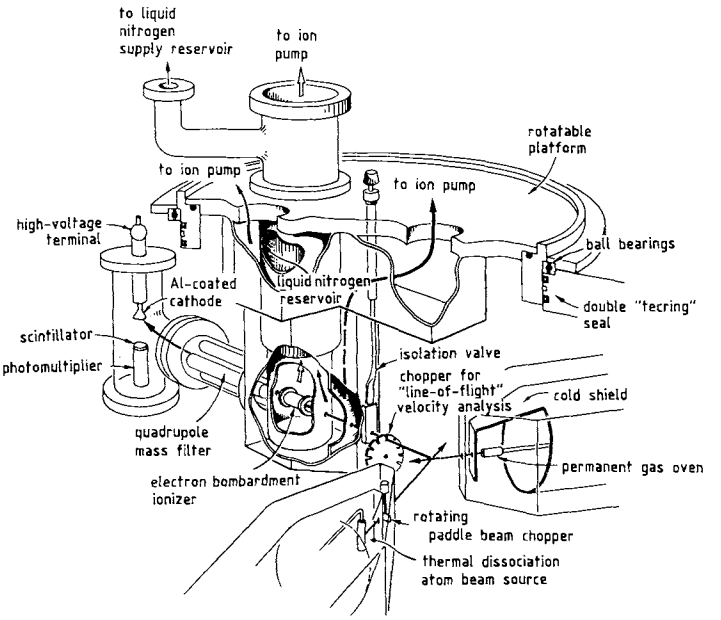

Fig. 15. Cutaway view of crossed-beam apparatus *Hope* with mass spectrometric detector, showing beam geometry and arrangement of differential pumping for detector and source chambers.

partial pressure comparable to or lower than the product species which enters in free flight. This partial pressure is typically ca. 10^{-14} torr, only tenfold above the vacuum in interstellar space. (2) Background from deposit of product molecules on surfaces near the ionizer must be avoided. This is accomplished by the nested design, which permits product molecules that pass through the ionizer without being ionized (the fate of 99.9%!) to fly on to another differentially pumped region before hitting a surface. In practice, *Hope* and its successors made accessible reactions with much smaller yields as well as greatly extending the chemical scope. Respectable reactive scattering data are now often obtained with product fluxes of only ca. 10^3 molecules s^{-1}.

Supersonic nozzles also greatly expanded the variety and scope of beam experiments. Beyond providing very high intensity (typically ca. 10^{18} molecules $(sr\ s)^{-1}$, beams generated from such nozzles can be aptly viewed as a "new state of matter," with special properties much different from the old trinity of gas, liquid, and solid. The collisions occurring in the high-pressure region of a supersonic nozzle organize the beam molecules to a remarkable extent. The exiting crowd of molecules may have mean separations of only 50 diameters, yet have nearly the same velocity and direction and hence suffer almost no collisions. Likewise, the temperatures associated with relative translation and rotation of molecules within the beam are typically very low (of the order of 1 K or less) whereas the vibrational temperature can be kept high or made low by choice of conditions. Another option is translational acceleration by "seeding." The reactant gas is mixed with a large excess (typically 100-fold) of light diluent gas such as helium or hydrogen. Collisions during the supersonic expansion then bring the seeded molecules to the same exit velocity as the diluent gas, and also concentrate the heavier species along the beam axis. Intense beams are thereby

obtained with kinetic energy readily variable over a wide range extending well above typical activation energies for chemical reactions.

Like many others since, our adoption of supersonic nozzles was spurred by *John Fenn* and *Jim Anderson*, ardent evangelists among the chemical engineers then exploring fluid flow in nozzles. Again, there was a cultural gap to be bridged; at a 1965 ecumenical meeting:[12]

> The engineers spoke only to one another and only about Reynolds numbers; the chemists likewise talked just to each other about harpooning electrons.

The *Kistiakowsky* ax story also prompted us to try nozzles and indeed we had already used them in a modest way in alkali studies. Later we extended the scope of the seeding technique by a nozzle design suitable for solid or liquid substances, and others have developed many variants that have found wide application in both collision and spectroscopic experiments. The splinters from *Kisty*'s ax sprouted into a bountiful garden.

Recognizing Covalent and Ionic Cousins

For our first experiments with Hope, we chose to study reaction (i) and other exchange reactions of halogen atoms

$$Cl + Br_2 \longrightarrow BrCl + Br \qquad (i)$$

and molecules. These were inviting because the reactant beams were easy to produce and all species could be very effectively pumped cryogenically. Furthermore, trihalogen complexes had long been postulated as intermediates in the mechanism of halogen atom recombination and other processes. Such complexes had not been detected in the gas phase, and the only rate constants available for the exchange reactions had been derived from the always equivocal analysis of multistep processes in photochemical systems.

Our first attempt to study reaction (i) gave data of excellent quality and revealed instructive dynamical features. Although the total reaction cross section is ca. 10 Å^2, smaller than the hard-sphere cross section, the BrCl angular distribution peaks strongly in the forward hemisphere. This indicates that the dominant interaction is short-range and yet attractive. In previous beam experiments and trajectory calculations, the reactive scattering had always peaked backwards when the cross section was smaller than the hard-sphere value. However, despite its much smaller reaction cross section, the $Cl + Br_2$ reaction gives product angle and translational energy distributions quite similar in form to the $K + Br_2$ reaction. We suggested this was evidence for an osculating complex mechanism.

Only a few months after our results for reaction (i) were announced, groups at Freiburg and Los Alamos had confirmed our study, using mass spectrometric apparatus of appreciably different design. This illustrates the value of choosing an amenable system to test new apparatus or to extend an experimental domain. Yet the reaction cross sections found in the beam studies indicated that the rate constants derived from the photochemical experiments were about 100-fold too low. Later the photochemical studies were repeated, with results in agreement with the beam work.

In studies of other trihalogen systems, we obtained further evidence for an osculating complex with preferred reaction geometry. The wide-angle reactive scattering indicates complexes containing iodine are more stable than those with only bromine or chlorine, in accord with simple electronic structure arguments. Likewise, for complexes containing different atoms, the most stable configuration has the least electronegative atom in the central position. One of the striking results attributed to this preferred geometry appeared in the Br + ClI case. The yield of BrCl is about fivefold smaller than otherwise expected and its angular distribution peaks backwards, indicating repulsive interaction. Subsequent studies, including variation of collision energy, brought out other dynamical features. Often these could also be interpreted by analogy to alkali reactions, despite the marked contrast in covalent and ionic bonding.

Next we pursued the reaction that *John Polanyi* had employed as the prototype in developing his IR chemiluminescence method [reaction (j)].

$$H + Cl_2 \longrightarrow HCl + Cl \qquad (j)$$

This system proved to have a gratifying kinship both to photodissociation of Cl_2 and to the $K + CH_3I$ reaction. Angle-velocity contour maps displaying this comparison are shown in Figure 16. For the Polanyi reaction, the product

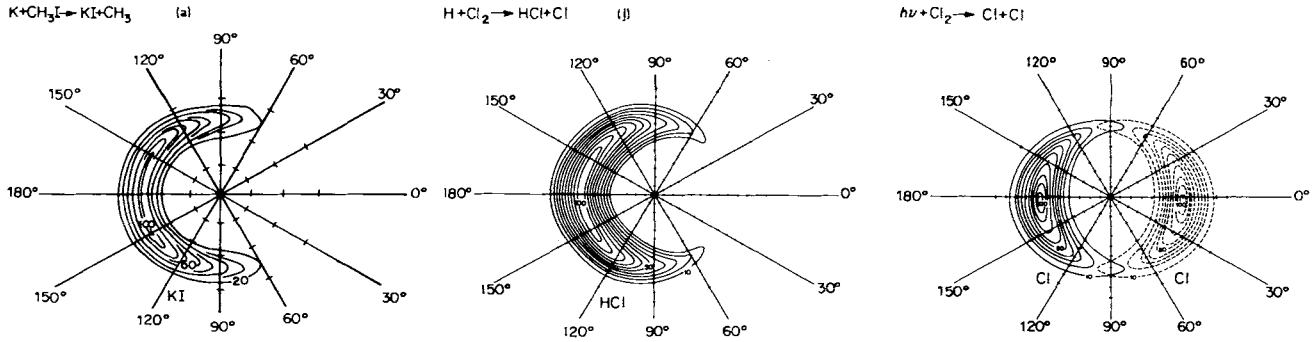

Fig. 16. Comparison of contour maps for photodissociation of the Cl_2 molecule and for reactions (a) and (j). Map for the latter case from work of *A. M. Rulis* and *R. B. Bernstein* [3]. For each map, origin is at center of mass and horizontal axis is along reactant relative velocity vector, with direction of incident atom or photon designated $\theta = 0°$. Tic marks along radial lines indicate velocity intervals of 200 m s^{-1}.

angular distribution is broad but quite anisotropic, with the HCl recoiling backwards and Cl forwards with respect to the incident H atom. The product velocity is very high, about 1600 m s^{-1} at the peak of the distribution. This corresponds to release of about half of the available energy (reaction exoergicity of ca. 45 kcal mol^{-1} plus initial collision energy of ca. 10 kcal mol^{-1}) in the translational recoil of HCl and Cl. The rest appears in vibrational and rotational excitation of HCl, which is observed in the IR luminescence. The form of the angular distribution indicates collinear H-Cl-Cl as the preferred reaction geometry and the high recoil energy shows that strong repulsive forces are abruptly released.

The contour map for photodissociation was constructed from the continuous absorption spectrum of Cl_2, which shows directly the distribution of relative translational energy of the fragment Cl atoms and hence the repulsive energy release. The spectrum can be closely approximated by simply "reflecting" the Gaussian vibrational distribution of the ground electronic state from the steep (ca. 7 eV $Å^{-1}$) repulsive wall of the dissociative excited electronic state. The angular distribution is governed by the dipole selection rule for absorption, which makes the transition probability vary as the square of the cosine of the angle between the Cl-Cl axis and the photon beam direction. We see that reaction (j) and $h\nu + Cl_2$ give remarkably similar angle-velocity maps.

More remarkable still is the close resemblance of reactions (j) and (a); except for a change of scale, the contour maps are almost congruent. In terms of electronic structure, as already noted, the analogy to photodissociation is obvious in the reaction (a) case because the harpooning electron enters the same strongly antibonding molecular orbital excited in photodissociation. In the reaction (j) case the analogy is not obvious, since the very high ionization potential of the H atom prohibits electron transfer. However, we found a molecular orbital rationale using the "frontier orbital" concept of *Fukui*. This is indicated in Figure 17. Collinear approach of the H atom generates three σ orbitals for the H-Cl-Cl complex. The middle one of these, 2σ, is expected to be the highest occupied orbital in the reaction complex. This frontier orbital has one node, resulting from the superposition of two components, one H-Cl antibonding and Cl-Cl bonding, the other vice versa. Simple calculations based on empirical data indicate the latter component is dominant. Thus, the frontier node lies roughly midway between the chlorine atoms, just as in the lowest-lying unoccupied orbital of Cl_2, the orbital excited during photodissociation. The similarity in the contour

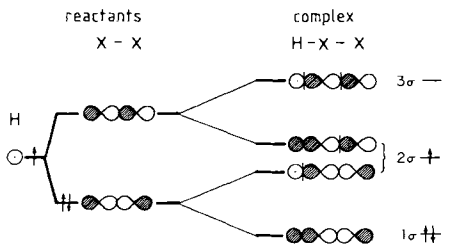

Fig. 17. Schematic construction of the three σ molecular orbitals of collinear H-X-X. The *frontier orbital*, 2σ, may be regarded as a superposition of two components, one H-X antibonding and X-X bonding, the other vice versa.

maps stems from the congruence in frontier nodes which govern the repulsive energy release in both reaction and photodissociation.

It is uncanny that reactions (j) and (a), seminal in developing the IR chemiluminescence and molecular beam methods, proved to be so closely related; not only are both rebound reactions, they are even "kissing cousins." The nineteenth century notation still used to write down chemical reactions gives no hint of such kinships, whereas electronic structure interpretations often bring out the underlying simplicity and broad scope of reaction dynamics.

Other hydrogen atom + halogen reactions provide instructive contrasts. As $Cl_2 \rightarrow Br_2 \rightarrow I_2$, the repulsive-energy release becomes a smaller fraction of that in photodissociation and the hydrogen halide angular distribution shifts from backwards to sideways with respect to the H-atom direction. These aspects are illustrated in Figure 18. The molecular orbital treatment relates both trends to the decrease in halogen electronegativity. This enhances the p character of hybrid orbitals involving the central atom and thereby favors a bent configuration. The frontier node also shifts from about midway between the halogen atoms in H-Cl-Cl to close to the central atom in H-I-I. Many analogous stable molecules are known which have one more or one less valence electron than these H-X-X systems. The molecules with one more electron are linear or nearly so; those having one less electron are strongly bent, with bond angles of 90° to 110°. The shift of the frontier node might be expected to make H-I-I resemble a case with one less electron. Thus it is plausible that decreasing the halogen electronegativity fosters bent reaction geometry and reduces the repulsive energy release.

The H + ICl reaction is especially interesting. On an energetic or statistical basis, reaction at the "Cl-end" would be more favorable than at the "I-end," since the H-Cl bond strength (102 kcal mol^{-1}) is much larger than H-I (70 kcal mol^{-1}). The molecular orbitals suggest the H atom should prefer to attack the I-end, however. As a consequence of the electronegativity difference, in ICl both the highest occupied orbital (π*) and the lowest unoccupied orbital (σ*) are predominantly I atom orbitals. The beam studies find the HI yield is at least comparable to HCl and probably substantially higher (although the effect of some experimental factors that discriminate against HCl remains unresolved). The angular distribution of HI peaks sideways, the HCl backwards. The IR chemiluminescence detects only HCl and not HI, but this is compatible with the beam results because the dipole derivative of HI is exceptionally small and hence the IR emission is very weak. The HCl energy distribution has a very unusual bimodal form. Comparison with trajectory calculations suggests that some of the HCl results from direct attack at the Cl-end but most comes from indirect reaction after initial attack at the I-end. These two reaction modes produce HCl in low and high rotation-vibration states, respectively. Analogous steric preferences for many other reactions can likewise be attributed to *orbital asymmetry* arising from differences in electronegativity.

Further aspects of this theme were examined by studying reactions of oxygen atoms with halogen molecules. We found that reaction (k) goes via a persistent com-

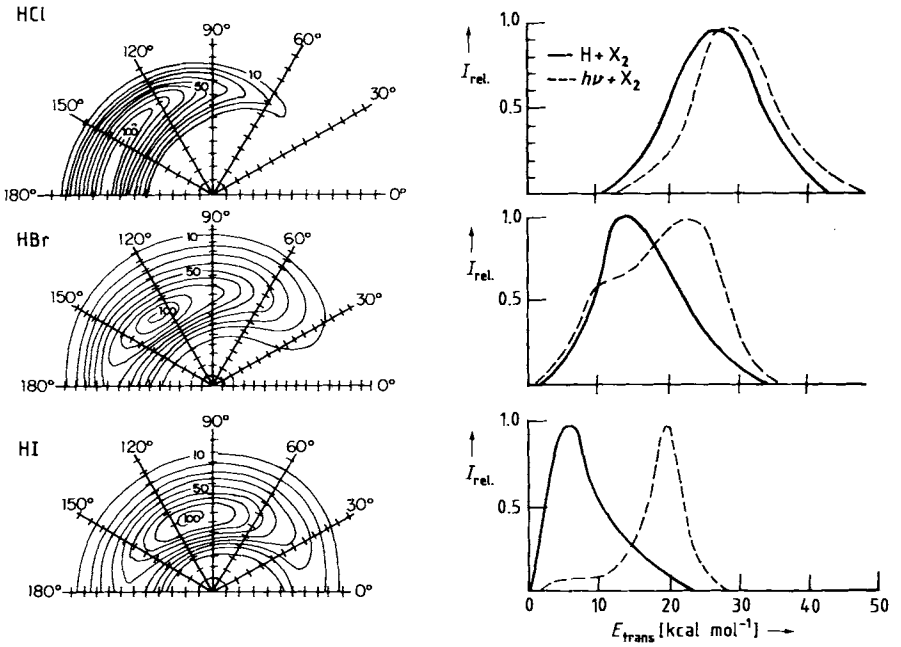

Fig. 18. Comparison of angle-velocity contour maps for reactions of H atoms with halogen molecules. Since maps must be symmetric with respect to the horizontal axis, only upper halves are shown. Tic marks along radial lines indicate velocity intervals of 200 m s^{-1} for Cl_2 case, 100 m s^{-1} for Br_2 and I_2. Panels at right compare distributions of product relative translational energy (solid curves) with continuous absorption spectra of halogen molecules (dashed curves). Abcissa scales for spectra are shifted to place origin at the dissociation asymptote, and thus show directly the repulsive energy release in photodissociation.

$$O + Br_2 \longrightarrow BrO + Br \qquad (k)$$

plex with large yield and no activation energy. The product contour map shows prominent glory peaks. For other reactions with such maps, the intermediate complex usually corresponds to a stable molecular species which correlates with the ground-state reactants and products. Here, however, different spin states are involved. The reactants approach on a triplet surface, whereas the products can depart on either a singlet or triplet surface. The known, stable OBr_2 molecule has a symmetric, strongly bent geometry and a singlet ground state. Qualitative electronic structure arguments suggest that the reaction goes predominantly via a less stable, triplet O-Br-Br potential surface without transition to the more stable, singlet Br-O-Br surface. Likewise, the O + ICl reaction would be expected to give primarily IO + Cl rather than ClO + I, although the latter path is much more exoergic. We indeed found a large yield of IO but no detectable ClO, nice evidence that the reaction involves end-on attack rather than insertion. These results led us to the unorthodox prediction that the $O + F_2$ reaction should prefer the F-O-F geometry rather than O-F-F, since oxygen is less electronegative than fluorine. This implies a relatively high activation energy, associated with the switch to an insertion mechanism, despite the large reaction exoergicity and the notorious chemical personalities of the reactants. Subsequent experiments[13] indeed confirmed that $O + F_2$ is inhibited by a large activation energy.

Migratory Atoms and Bonds

With the mass spectrometric detector, we could now also proceed to "the organic age" and thereby pursue many further aspects of reaction dynamics. Particularly inviting were unimolecular reactions involving isomerizations or rearrangements. Figure 19 shows the contour maps obtained for a favorite pair of examples, the displacement reactions of chlorine atoms with vinyl bromide and with allyl bromide. In these systems [reaction (l)], where R de-

$$Cl^{\odot} + RBr \longrightarrow ClRBr^{\odot} \longrightarrow RCl + Br^{\odot} \qquad (l)$$

notes CH_2=CH or CH_2=CH-CH_2, respectively, the intermediate bromochloroalkyl radical is a known, stable species. It is vibrationally excited by ca. 30 kcal mol^{-1}, the sum of the initial collision energy and thermal excitation of the reactant olefin, the loss in bond strength in converting the double bond into a single bond (ca. 57 kcal mol^{-1}), and the gain in forming the new C-Cl bond (80 kcal mol^{-1}). Under our single-collision conditions, the excited radical cannot be deactivated by a subsequent collision and thus must undergo unimolecular decomposition. The

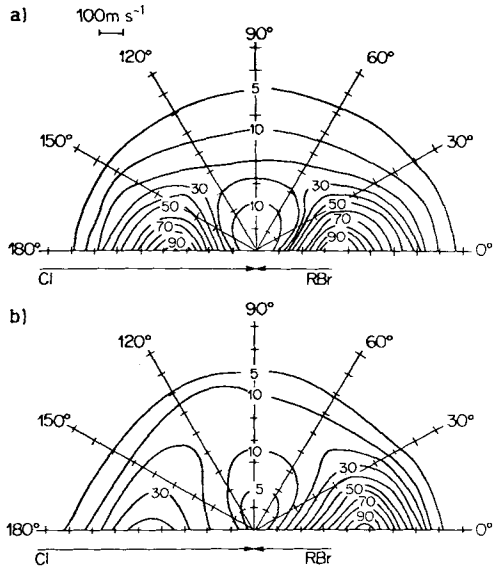

Fig. 19. Comparison of contour maps for chloroolefin products from reactions of chlorine atoms with a) vinyl bromide and b) allyl bromide. Tic marks along radial lines indicate velocity intervals of 100 m s^{-1}.

net energy available to the products on reforming the double bond and releasing the Br atom is ca. 19 kcal mol^{-1}. These energetic aspects are the same for the vinylic and the allylic reactions.

The customary theory of unimolecular processes predicts that the allylic reaction should proceed more slowly and hence show more nearly statistical behavior, since it involves more atoms and therefore the excitation energy shuffles among more vibrational modes than in the vinylic reaction. On the contrary, the contour map for the vinylic reaction indicates a persistent complex, that for the allylic reaction an osculating complex. Some special feature must intervene to make the vinylic reaction more nearly statistical than the allylic reaction. Indeed, this was anticipated in choosing these systems for study. According to a large body of work on organic reaction mechanisms, the initial stage in both reactions should involve addition of the Cl atom to the carbon atom "most distant" from that with the Br atom. As pictured in Figure 20, this implies that a "free valence" appears on the carbon linked to Br in the vinylic case, but not in the allylic case. Thus, the vinylic reaction seems likely to proceed via a 1,2 chlorine *atom migration*, whereas the allylic reaction can go via a 1,3 *bond migration*. Since the heavy atom migration would be much slower than the bond migration, this might provide a rate-limiting process which makes the vinylic reaction more statistical than the allylic one.

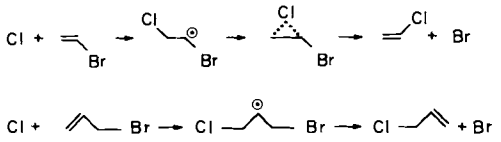

Fig. 20. Stereoselective mechanisms for 1,2 chlorine *atom migration* in vinylic reaction (above) and 1,3 *bond migration* in allylic reaction (below).

These mechanisms require the product chloroolefin to have Cl on the carbon to which Br was originally bonded in the vinylic case, but to remain on the "most distant" carbon in the allylic case. We verified this by analysis of the fragment-ion mass spectra of chloroolefins formed in corresponding reactions with a methyl group added to "label" one or another carbon atom. The methyl substitutions also produced revealing changes in the reactive scattering. For the vinylic cases, the angular distributions show variations which reflect changes in the rotational motions caused by the methyl group. For the allylic cases, the product translational energy distributions become statistical, as if the methyl group diverts the intramolecular energy flow and thereby makes it more random.

Further tests of the migration mechanisms were later obtained by *Rowland* using radioactive tracers.[114] In this work, the same vinylic and allylic reactions examined in the beam experiments were studied under "bulb" conditions. At low pressures, the products obtained were those expected for the atom- and bond-migration mechanisms, respectively. At high pressures, however, different products were obtained. These corresponded to the species expected from collisional stabilization of the intermediate bromochloroalkyl radicals, followed by standard reactions of those radicals.

A host of other organic reactions have now been studied by beam methods, especially by *Yuan Lee* and his students. Often the intermediates and initial elementary steps have proven to be quite different than those postulated in conventional mechanistic studies. The wide range of bonding and stereochemical situations in organic systems ensures vast scope for dynamical detective work in this domain.

Facile Molecular Reactions

The reaction systems discussed so far all involve attack by an open-shell atom or free radical. One of the chief criteria invoked in postulating elementary steps in reaction mechanisms is that only such processes have very low activation energies, less than 5 or 10 kcal mol^{-1}. The advent of the Woodward-Hoffmann rules focused attention on reactions of molecules with molecules, which involve the concerted making and breaking of two or three pairs of bonds. These processes typically have activation energies above 20 kcal mol^{-1} when fully "allowed" by the rules and above about 40 kcal mol^{-1} when "forbidden." In this context, we sought instructive examples of facile bimolecular and termolecular reactions of diatomic molecules.

The simplest case is the exchange reaction of two alkali halides [reaction (m)].

$$Cs^{\oplus}Cl^{\ominus} + K^{\ominus}I^{\ominus} \longrightarrow Cs^{\oplus}I^{\ominus} + K^{\ominus}Cl^{\ominus} \qquad (m)$$

This might be termed a "no-electron" reaction, since the salt molecules are essentially closed-shell ion pairs. Accordingly, no restraints are imposed by the molecular orbital correlations involved in the Woodward-Hoffmann rules. Yet a contemporary theoretical paper had concluded that even this alkali halide reaction would be subject to a high activation energy of ca. 50 kcal mol^{-1}. This seemed unlikely in view of the strong long-range dipole-dipole attraction. Since alkali halides form rhombic quadrupolar dimers with dissociation energy ca. 30–50 kcal mol^{-1}, the potential surface for the exchange reaction has a deep basin. Our beam experiments indeed found the reaction proceeds via a persistent complex. There is no activation energy and the reaction cross section is extremely large, corresponding to formation of the complex in collisions with impact parameters up to ca. 8–9 Å. We therefore spoke of a "vacuum cleaner" potential. The product angle and velocity distributions conform nicely to the usual statistical model, but the ratio of nonreactive to reactive decay of the complex was two or three times larger than statistical. As in the analogous atom + salt case, this can be attributed to geometrical isomerism. Ionic model calculations predict less stable, linear chain isomers exist in addition to the rhombic dimer. These linear chain isomers may often dissociate nonreactively rather than rearrange to the cyclic form required for the exchange process, especially when the centrifugal angular momentum in the collision keeps the chain "ends" apart. It is like two pairs of ice skaters playing "crack the whip." Extensive trajectory calculations by *Brumer* and *Karplus* confirmed this striking role of geometrical isomerism.

Since the four-center ionic + ionic reaction proved facile whereas the typical covalent + covalent case was for-

bidden according to *Hoffmann*'s orbital correlations, we examined several reactions involving ionic + covalent reactions. These also proved facile at thermal collision energies; for example, reaction (n). This reaction very likely

$$Cs^{\ominus}Br^{\circ} + ICl \longrightarrow Cs^{\oplus}Cl^{\ominus} + IBr \qquad (n)$$

involves formation of an alkali trihalide salt, $Cs^{\oplus}(BrICl)^{\ominus}$, and charge migration within the trihalide anion. Although apparently unknown in the gas phase, trihalides have been much studied in solution and in the solid state. In agreement with molecular orbital theory, the trihalide anions are linear or nearly linear, the middle atom is always the least electronegative (I, in this case) and it acquires a small positive charge whereas the end atoms share the negative charge. Clear evidence for this structure appears in the reactive scattering. There is no observable yield of $Cs^{\oplus}I^{\ominus} + BrCl$, even at collision energies more than 20 kcal mol^{-1} above the energetic threshold for this channel. Furthermore, as seen in Figure 21, the IBr angle-velocity contour map has a very unusual skewed shape. The lefthand product peak has distinctly higher intensity and velocity than the righthand peak. This shows that collisions from which IBr and CsCl rebound backwards with respect to the incident ICl and CsBr, respectively, are more probable and involve more repulsive energy release than collisions from which IBr and CsCl emerge in the same direction as the incident ICl and CsBr, respectively. These properties are consistent with the expectation that in $Cs^{\oplus}Br^{\ominus} + ICl$ reactive configurations, $Br^{\ominus}$ tends to be collinear with ICl while $Cs^{\ominus}$ is likely to collide with the central I atom. The positive charge acquired by I as the trihalide forms then repels $Cs^{\oplus}$, which picks up the emerging $Cl^{\ominus}$ and departs quickly in the direction opposite to the incident salt. Similar ionic + covalent reactions such as CsF + HCl and NaO + HCl[15] likewise go with near zero activation energy.

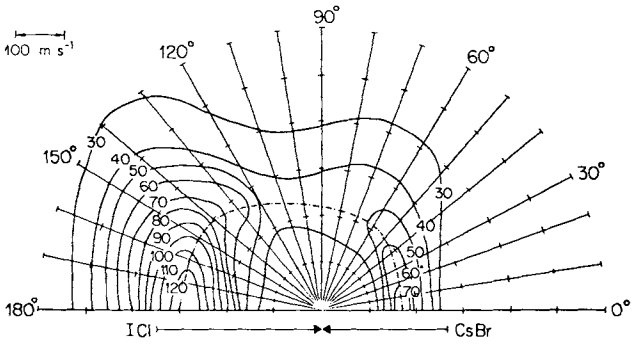

Fig. 21. Contour map of IBr product distribution from CsBr + ICl reaction at collision energy of 3.9 kcal mol^{-1}.

In the domain of four-center covalent + covalent reactions, the landmark is the classic work of Sullivan on the favorite "textbook" case, reaction (o).

$$H_2 + I_2 \longrightarrow 2\,HI \qquad (o)$$

In 1967 he showed reaction (o) does not occur as a four-center reaction but involves dissociation or near-dissociation of I_2 followed by $I + H_2 + I$. Soon after, *Jaffe* and *Anderson* studied HI + DI using the seeded supersonic beam technique and found no detectable HD yield at collision energies far above the empirical activation energy. This is certainly an allowed reaction, at least as the reverse of I + HD + I, but apparently vibrational rather than translational activation is required. Likewise, in our laboratory *David Dixon* and *David King* found no evidence for the four-center exchange reaction (p). Their experiment em-

$$Br_2 + Cl_2 \longrightarrow 2\,BrCl \qquad (p)$$

ployed two supersonic nozzles and scanned the collision energy up to ca. 25 kcal mol^{-1}. Formation of BrCl is readily observed on mixing the reactants in a bulb, and rate studies had indicated a relatively low activation energy, only ca. 15 kcal mol^{-1}. However, this was suspect because of "possible catalysis by moisture or surfaces," a traditional lament in kinetic studies. *Hoffmann*'s molecular orbital correlation diagram predicts a much larger activation barrier, comparable to the promotion energy of two electrons from a bonding to an antibonding orbital and thus above the dissociation energy of the weaker reactant bond (45 kcal mol^{-1}).

Since a six-center, termolecular reaction is allowed by the orbital correlations, we decided to look for reaction (q). Scattering experiments using three crossed beams are

$$Br_2 + Cl_2 \cdots Cl_2 \longrightarrow 2\,BrCl + Cl_2 \qquad (q)$$

utterly impractical, but appreciable fluxes of reactant dimer molecules, linked by a weak van der Waals bond, can readily be generated by a supersonic expansion. We were encouraged by tantalizing evidence obtained by *Noyes* for a third-order reaction of halogen molecules in solution. Yet analogy to other allowed six-center cases (such as Diels-Alder reactions) suggested that the activation barrier might well be ca. 20 kcal mol^{-1}, and it might also require chiefly vibrational rather than translational excitation. Thus, we were startled when *King* and *Dixon* found large yields of BrCl that appeared to come from the termolecular process even at thermal collision energies of only ca. 3 kcal mol^{-1}. However, velocity analysis data for this system and the analogous HI reaction provided several kinematic consistency tests which even indicated that three sequential bond scissions can be resolved in the termolecular exchange process. Soon another example of a facile molecular reaction fostered by a van der Waals dimer was provided by *Durana* and *McDonald*.[16] They found that $F_2 + (HI)_2$ yields intense HF infrared chemiluminescence whereas $F_2 + HI$ gives none. Whether or not these processes actually involve six-center transition states, the weak van der Waals link is remarkably effective in promoting a reaction that otherwise does not go.

Subsequently, we undertook potential surface calculations to examine termolecular, six-center bond exchange processes. For Cl_6 a traditional semiempirical treatment[17] indicates facile reaction but the approximations involved are dubious. For hexagonal H_6 ab initio calculations of high quality were carried out by *Dixon* and *Stevens*[18] and show that a termolecular path is indeed accessible without

breaking an H–H bond whereas there appears to be no such path for a bimolecular, four-center exchange. The results for H_4 and H_6 thus conform to the rule, amply demonstrated in organic chemistry, that cycloaddition reactions involving 4m electrons are forbidden as concerted processes while those involving 4m+2 electrons are allowed. But it turns out that H_6 obeys this rule only through configuration interaction, not by virtue of the usually invoked nodal properties.

The special role of H_6 was elucidated further by comparison with several previous calculations for larger H_n polygons, available for $n=4m+2$ extending from $n=14$ to 62. These calculations, pertinent to model treatments of metallic hydrogen, found the bond length and cohesive energy (binding per atom) to be nearly constant for the whole series. Since our values for H_6 proved to be practically the same, we can reliably estimate the stability of H_{10} and higher polygons by taking the cohesive energy as constant. This shows that H_6 is the only H_{4m+2} polygon that is stable with respect to dissociation of an H_2 bond and hence the only polygon that can serve as transition state for a concerted bond exchange. The customary orbital symmetry criterion thus fails for all the higher 4m+2 polygons; it must be supplemented by an energetic criterion in order to predict whether a reaction is concerted.

The unique stability of H_6 relative to dissociation of an H_2 bond also suggests that solid molecular hydrogen might undergo a high-pressure transition to form a new phase involving termolecular complexes before transition to the long-sought atomic or metallic phase (predicted in 1948 by *Wigner*). This possibility was examined by *Rich LeSar* by means of lattice-energy calculations employing approximate pair potentials.[19] Although uncertainties in the potentials prevent a definite conclusion, the results obtained for a range of parameters indicate that a phase comprising a "partly dissociated" form of the six-center transition state may be stable at pressures above a few hundred kilobars. As shown in Figure 22, repulsive forces from the neighboring units in the crystal prevent dissociation of this complex to diatoms. A marked drop in the H_2 stretching frequency observed at high pressure is qualitatively consistent with formation of molecular clusters but by no means a clear test. In any case, these calculations serve to illustrate how pursuit of reaction dynamics can lead to far distant domains!

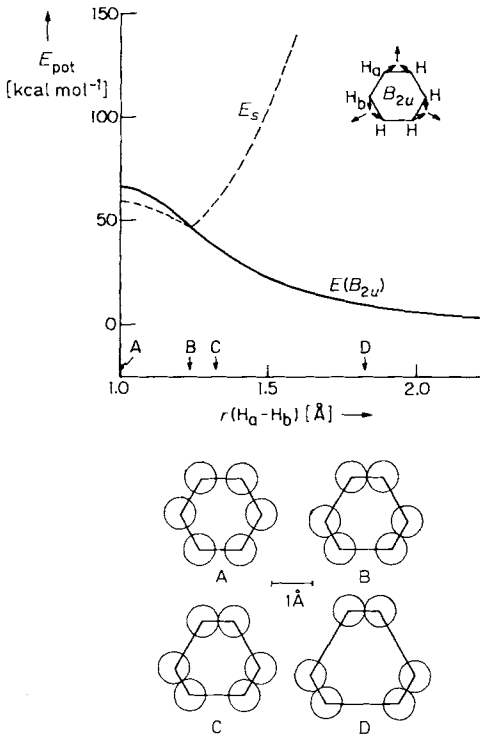

Fig. 22. Above: Potential energy profile for dissociation of a hexagonal H_6 complex in free space (solid curve) and in a hexagonal closest-packed crystal (dashed curve, computed for pressure of 400 kbar) in which repulsive interactions with neighbors prevent the dissociation. Below: Configurations of the termolecular complexes corresponding to positions marked along abcissa. The circles for each H atom have a radius of half of the free H_2 bond length.

Van der Waals Dimers and Clusters

Supersonic expansions make accessible a vast range of species and processes involving feeble bonds. In effect, the very low internal temperatures in supersonic beams circumvent the Second Law, since the entropy term in the free energy, $\Delta H - T\Delta S$, can be made negligible. Even a weakly favorable enthalpy term then suffices to produce large yields of dimers or bigger clusters. This permits studies involving "solvation" of reactant species and other interactions akin to condensed phase or surface chemistry. In the past few years such work has created a major new field, with particular emphasis on metal clusters.[20] Here we describe some of our experiments to illustrate a few favorite themes.

In solution kinetics, much attention has been devoted to photodissociation and recombination processes. These are usually interpreted in terms of "the cage effect," in which the solvent inhibits diffusive separation of the photofragments. A different perspective has now emerged from beam experiments.[21] Complexes of I_2 with various solvent species such as Ar, N_2, benzene, etc. were formed by supersonic expansion and excited with a laser in a spectral region above the dissociation threshold for the bare I_2 molecule. This produced intense fluorescence, showing that, instead of dissociating, much of the iodine relaxes into bound vibrational levels of the electronically excited B state. Energy balance is maintained by breaking the van der Waals bond(s) of the original solvent complex and releasing some repulsion into relative translation of the product fragments. In solution photodissociation must likewise be mollified by energy transfer to the solvent and the surviving excited iodine molecules may account for features previously attributed to recombination of caged atoms.

Another typical role of solvation is exemplified in reactions of ammonia clusters with hydrogen halides. For unclustered ammonia, proton transfer is endoergic to form the ionic salt, $NH_4^{\oplus}X^{\ominus}$, increasingly so for $X=I\rightarrow Br\rightarrow Cl$. In crossed-beam scattering with clustered ammonia, new mass peaks appear that correspond to $(NH_3)_nHX$ adducts with n as large as 15 or more. Fragmentation of these peaks appears to decrease markedly on completion of the first solvation shell. For sufficiently large clusters the complex formation probably involves proton transfer and is

driven by solvation of the resulting $NH_4^{\oplus}X^{\ominus}$ ion pair by the "extra" ammonia molecules in the reactant cluster.

Although solvated ions govern a host of solution phenomena, the individual molecular species and processes often cannot be resolved or characterized in condensed phases. Thus studies of molecular cluster ions in the gas phase have become another major field; for instance, the elusive hydrated electron has now been produced in beams of unfragmented water clusters.[22] In related work, we studied collisional electron transfer from alkali atoms to molecular clusters. Since the process is endoergic, fast atoms are generated from a seeded supersonic expansion. Because the electron transfer can only occur within the crossing radius for the ionic-covalent potential curves, the time scale becomes very short, typically ca. 0.3 ps. This limits use of the method for electron affinity studies but also provides a means to probe the size of cluster subunits involved in impulsive interactions.[23]

For small clusters, particularly dimers, it is feasible to study the exchange of van der Waals bonds by the same methods employed for chemical bonds. Figure 23 shows an angle-velocity contour map obtained by *Worsnop* and *Buelow*[24] for the $Xe + Ar_2$ reaction. Since thermal collision energies are typically several times larger than the dimer well depth, conservation of energy and momentum constrain the scattered diatom product to a narrow circular band centered on the center-of-mass velocity; only within that band can XeAr be formed with low enough internal excitation to hang together. However, several other features provide dynamical information. These include the pronounced "hole" in the reactive scattering in the forward direction, which is accompanied by strong peaking near 50°, and an even stronger backward scattering.

This pattern is remarkably similar to that found for some ion-molecule reactions, such as the $O^{\oplus} + HD \rightarrow OH^{\oplus} + D$ reaction, for which the collision energies and bond strengths are more than 100-fold higher. As illustrated in Figure 23, we find several properties are in nearly quantitative agreement with an impulsive model based on pairwise hard-sphere interactions. Two distinct collision modes give the chief contributions. In the mode that accounts for the forward pitched scattering, A + BC interact via *sequential* hard-sphere elastic collisions (A off B, then B off C); the exchange reaction occurs only when the final relative velocity of A and B corresponds to an energy less than the AB bond strength. For this mode, the angular distribution may be found from a geometric construction devised by *Mahan* et al. for high-energy ion-molecule reactions.[25] The other mode gives strong backward scattering by a process familiar in billiards; A *knocks out* B and thereby comes nearly to rest with respect to the C atom, so the resulting AC molecule moves briskly backward with respect to the center of mass. This study of an exchange of feeble bonds thus helped develop a more comprehensive asymptotic model applicable to any atom-transfer reaction when the ratio of collision energy to bond strength becomes large.

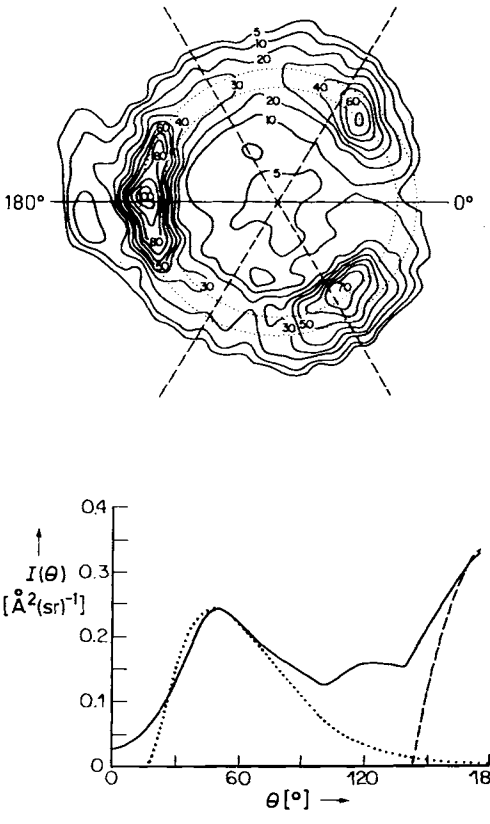

Fig. 23. Above: Contour map for XeAr from $Xe + Ar_2$ reaction at collision energy of 1.3 kcal mol^{-1}. The dotted circular band shows the kinematically allowed scattering region for nominal parent-beam velocities. Below: Angular distribution derived from experimental map (solid curve) is compared with predictions from the hard-sphere model, including *knock-out* (dashed curve) and *sequential impulse* (dotted curve) contributions.

Pursuit of Vector Correlations

In addition to the product angular distribution, many other directional or vector properties of reactions are now accessible in beam experiments, especially by means of laser-induced fluorescence techniques developed by *Zare* which exploit the orientation dependence of the dipole selection rule for electronic excitation.[26] These vector properties offer much information not provided by energetic or other scalar properties, and their study is now emerging as a vigorous field referred to as dynamical stereochemistry or *stereodynamics*. For instance, as indicated in Figure 24,

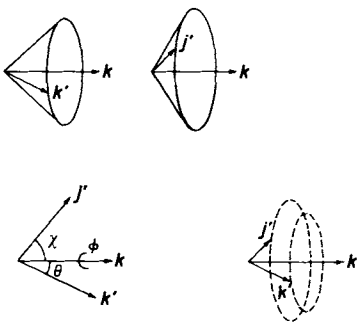

Fig. 24. Three-vector correlation among initial and final relative velocity vectors, here denoted by $\boldsymbol{k}$ and $\boldsymbol{k}'$, and product rotational angular momentum vector $\boldsymbol{j}'$. Upper pair of diagrams indicate the azimuthal symmetry about $\boldsymbol{k}$ of the $\boldsymbol{k}'$ and $\boldsymbol{j}'$ product vectors inherent when these are observed separately, as in the two-vector correlations $(\boldsymbol{k}, \boldsymbol{k}')$ and $(\boldsymbol{k}, \boldsymbol{j}')$. Lower pair of diagrams indicates how the three-vector correction $(\boldsymbol{k}, \boldsymbol{k}', \boldsymbol{j}')$ can give information about the dihedral angle ϕ, in effect undoing the azimuthal averaging about the initial relative velocity.

of special interest is the *triple-vector correlation* among the initial and final relative velocities and the product rotational angular momentum. In principle, this vector correlation offers a means to undo the "dart-board" averaging over the random azimuthal orientations of initial impact parameters. The distributions of both $\boldsymbol{k}'$ and $\boldsymbol{j}'$ must have azimuthal symmetry about $\boldsymbol{k}$, but when a subset is selected of $\boldsymbol{k}'$ vectors with particular $\boldsymbol{j}'$ (or vice versa), this subset in general will not have azimuthal symmetry about $\boldsymbol{k}$. Model calculations and an early electric deflection study by *Hsu* and *McClelland* of the $Cs+CH_3I$ reaction revealed marked asymmetry; as the freshly formed CsI recoils from the collision, its internuclear axis tends to rotate in or near the plane of the initial and final relative velocity vectors. Far more detailed information of this kind is in prospect from studies using laser-induced fluorescence, especially since the great sensitivity of the method may allow the alignment of individual rotation-vibration states to be measured as a function of the scattering angle.

We may even be optimistic about measuring some properties of the four-vector correlation involving both the velocity vectors and the reactant as well as product rotation. This correlation of course contains still more information than found in the six two-vector and four three-vector correlations involving pairs or triads of the four vectors. As exhibited in a model calculation,[27] such information includes the azimuthal asymmetry with respect to both $\boldsymbol{k}$ and $\boldsymbol{k}'$, the preferred rotational orientation of both the reactant and product molecules with respect to the $\boldsymbol{k},\boldsymbol{k}'$ plane, and even the relative sense of rotation (parallel or contrary). Several averages implicit in lower-order vector correlations are thus undone. The loss of information otherwise imposed by the random aspects of the initial conditions resembles the celebrated "phase problem" encountered in X-ray scattering. Thus the complications required to unravel phases for a molecular structure determination are heuristically analogous to undoing impact-parameter averaging by observing one or two "extra angles" in collision experiments. In such ways, a further level of molecular resolution awaits reaction dynamics.

This paper is a tour through a family album. The frequent mentions of work by "we" pertain to my colleagues listed in Table 1, a roster of 51 graduate students and 35 postdoctoral fellows (in italics) listed in order of their "graduation" from our research group. Their work totals about 250 years of research, 150 of that in reaction dynamics. The investment of human resources is far greater, however. Beyond the direct contributions by the machine shop and other staff, all of us received vital help along the way from our teachers, our relatives, and many friends and colleagues. Sustained financial support was likewise vital, including many scholarship and fellowship awards as well as research grants from several agencies, especially the National Science Foundation. To all who made our research possible, I am deeply grateful.

In revisiting the album, I have lingered fondly on the early episodes because, as in dynamics generally, the initial conditions are often as important as the force field. I hope that students and young researchers starting their own work might be encouraged to see how simple and naive were our first steps. I hope also that some research administrators and funding agencies might be encouraged to take a longer-range view of quixotic projects. In our work the essential impetus was the evangelical fervor of young scientists captivated by new vistas. But to pursue such distant vistas we had to have freedom and support. In many quarters this seems less forthcoming today. In expressing thanks for our good fortune, I must urge renewed efforts to foster enterprising work on fundamental problems.

The family album contains far more than shown here, including many intriguing chapters from other laboratories. Again I recommend an admirable pair of texts[3] which survey much work deserving of honor at this forum. Over 30 years of reaction dynamics, the fellowship of striving and joy of discovery have created an intense sense of community. Perhaps in emulation of our molecular friends, recruits to this field seem unusually excitable, zestful, and generous. Working in such a community in pursuit of new insights is a splendid prize, enhanced in the sharing. Thereby we offer thanks for the privilege of studying our ever mysterious atoms and molecules.

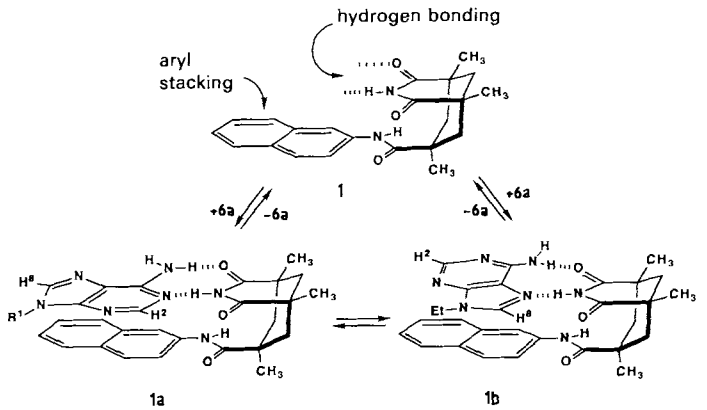
Molecular Recognition: Stacking Interactions Influence Watson-Crick vs. Hoogsteen Base-Pairing in a Model for Adenine Receptors

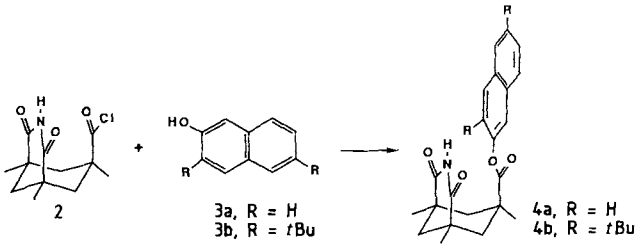
By *Julius Rebek, Jr.,* Kevin Williams, Kevin Parris, Pablo Ballester,* and *Kyu-Sung Jeong*

Hydrogen bonding and aromatic stacking interactions are the principal stabilizing forces of double-stranded nucleic acids. In recent disclosures[1] from this laboratory, we have shown how model systems can be used to assess the individual contributions of the two types of interactions. The new model systems consist of imides and aromatic surfaces which converge from perpendicular directions to provide a microenvironment complementary to adenine derivatives (Scheme 1). We have shown that **1a** and **1b** can form from **1** and 9-ethyladenine **6a**; thus the hydrogen bonding is a composite of Watson-Crick (**1a**) and Hoogsteen (**1b**) base-pairing[2] and bifurcated hydrogen bonds can also be involved. We describe here how refinements that influence the nature of base-pairing may be engineered into the model.

Condensation of the imide acid chloride **2** with either β-naphthol **3a** or the di-*tert*-butyl derivative[3] **3b** gave high yields of the corresponding esters **4a** and **4b**, respectively (Scheme 2). Crystallographic studies[4] revealed the conformation shown in which a nearly perpendicular arrangement exists between the planes of the naphthalene nucleus and the imide function in the solid state (Fig. 1; dihedral angle 70° for **4a** and 80° for **4b**). Intermolecular stacking is observed in the crystal structure of **4a** but not in that of **4b**. Apparently, the bulky *t*Bu groups prevent this form of self-association in **4b**.

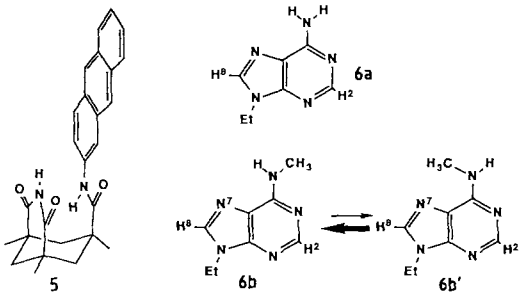


Scheme 1.



Scheme 2. Reaction conditions: NaH, THF, 25°C, 2 h.

Association constants for binding of 9-ethyladenine **6a** to **4a** and **4b** were measured in $CDCl_3$ using NMR titration; corresponding values for **1** and the anthracene **5** have been reported.[1] In addition, titrations were performed with the *N*-methyladenine derivative **6b**. Steric effects involving N^7 in such structures result in the preference of conformer **6b** over **6b'**,[5] and thus favor base-pairing in the Hoogsteen mode.[6]



The results are presented in Table 1, with intermolecular nuclear Overhauser enhancements (NOEs) obtained from irradiation of the imide N-H resonance in the various complexes;[7] the estimates of Hoogsteen vs. Watson-Crick base-pairing are calculated from the NOEs.

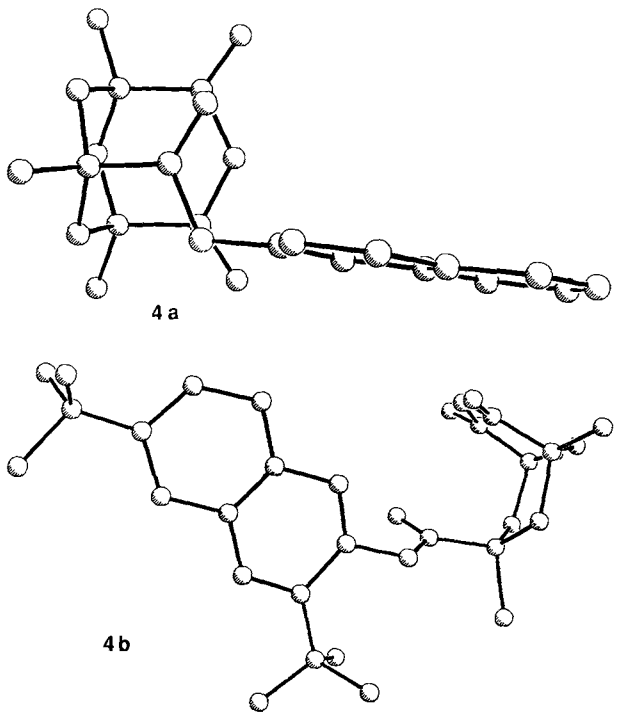


Fig. 1. Molecular structures of **4a** and **4b** [4].

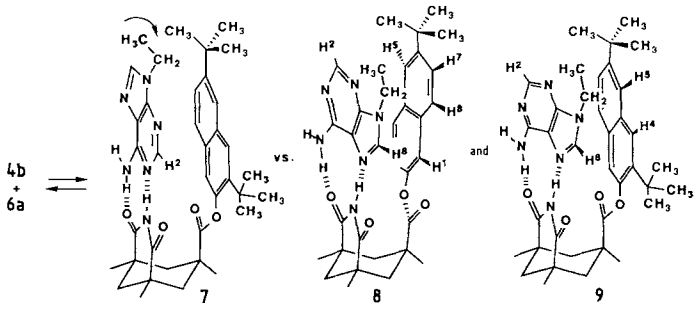

Scheme 3.

The relative sizes of the NOEs observed at H^2 and H^8 relate to the Watson–Crick (**1a**) and Hoogsteen (**1b**) base-pairing, respectively. Only the extended surface of the anthracene derivative **5** favors the Watson–Crick mode (Table 1, entry 7); the shorter naphthyl amide **1** or ester **4a** show comparable amounts of both types of base-pairing with **6a** (entries 1 and 3). Binding of the *N*-methyl derivative **6b** to either **1** or **4a** results in about a 50% diminution in K_a since the Watson–Crick component is largely removed (entries 2 and 4). Accordingly, the NOEs observed for H^2 in complexes with **6b** are much reduced compared with H^8. With the anthracene derivative **5** a larger fraction of the binding is lost with **6b** as the Watson–Crick component is reduced.

The di-*tert*-butyl derivative **4b** provides an example of remote steric effects on base-pairing. Molecular models (CPK) indicate that interactions between the ethyl side chain of the adenine derivative **6a** and the distal *tert*-butyl at C-6 of **4b** prevent close stacking in the Watson–Crick mode but not in the Hoogsteen mode (Scheme 3, **7** vs. **8**, and Fig. 2). Experimentally, two lines of evidence support this surmise. First, only a 30% reduction in K_a is observed for **4b** when the substituted **6b** is bound (instead of ca. 50% as observed for **1** and **4a**) even though the NOEs show most of the Watson–Crick component has been removed (entries 3 and 4). Second, 2D NOESY experiments indicate that H^8 of the adenine shows correlation only with H^1 of the naphthalene, while H^2 of the adenine shows correlation only with H^5 of the naphthalene; this is implicit in structure **8**. Therefore, bulky substituents on the naphthalene nucleus can orient hydrogen bonding elsewhere in the complex.

The model receptors **1**, **4a,b**, and **5** can be used to probe further details concerning multiple, weak intermolecular forces. The esters are intrinsically less attractive to adenine derivatives than amides (Table 1, entry 1 vs. 3 and 5) because bifurcation can be observed with the NH group of adenine and amides[1] but is not observed with the less basic ester carbonyls of **4a,b**. The enhanced binding of **4b** vs. **4a** is also significant. We suggest that the *t*Bu groups of **4b** render its structure more polarizable and result in greater π-stacking interactions.

Finally, the model receptor and NOE techniques reveal an additional subtlety concerning aryl–aryl interactions. *Petsko* et al.[8] have shown that perpendicular (edge-to-face) aryl–aryl interactions are common between aromatic side chains of phenylalanine and tyrosine residues in protein structures. Such interactions combine to provide a significant means of structural stabilization. The solid-state conformations of **4a** and **4b** are in an ideal geometry for such binding, yet irradiation of the CH_2 of 9-ethyladenine **6b** in contact with **4b** shows 1% enhancements in both H^4 and H^5 resonances of the naphthalene. Accordingly, **9** is a contributor to the complex, and face-to-face rather than edge-to-face interactions are indicated in these systems. This is presumably a result of the permanent dipoles featured by these heterocyclic compounds.[9]

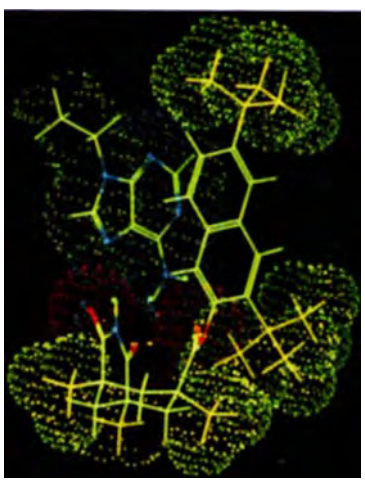

Fig. 2. Structure of the complex formed between **4b** and **6a**. Molecular modeling program: MACROMODEL (*W. C. Still*, Columbia University). Regions of high polarity are drawn in red (O) and blue (N), other regions in yellow [10].

2,3,9,10-Tetrakis(trimethylsilyl)[5]phenylene. Synthesis via Regiospecific Cobalt-Catalyzed Cocyclization of 1,6-Bis(triisopropylsilyl)-1,3,5-hexatriyne**

By *Luis Blanco, Harold E. Helson, Michael Hirthammer, Helene Mestdagh, Spyros Spyroudis,* and *K. Peter C. Vollhardt**

New developments in cobalt-mediated [2+2+2]cycloaddition methodology[1] have provided synthetic access to a series of novel benzenoid hydrocarbons, the [n]phenylenes.[2] In the linear members, electronic spectral data reveal a decreasing incremental bathochromic shift of the longest-wavelength absorption ($\Delta\lambda_{max}$([2]- to [3]phenylene) $\approx$ 75 nm, $\Delta\lambda_{max}$([3]- to [4]phenylene) $\approx$ 54 nm)[2a,c] in accord with MMP2 and MNDO calculations[3] predicting similarly attenuated HOMO–LUMO gaps and ionization potentials. On the other hand, and in contrast to trends expected based on the alternating π electron count between 4n and 4n+2, the ^{1}H-NMR spectra show equally sized upfield shifts ($\Delta\delta \cong 0.35$ ppm) of the inside benzenic hydrogens, whereas their peripheral counterparts resonate at approximately the same positions along the series. The preparation of the next higher "benzocyclobutadienolog" is imperative in order to corroborate these trends and to establish whether the inside benzene nuclei would become eventually olefinic, or more and more antiaromatic as reflected by their increasing paratropism. We report two syntheses of the title compound **6**, the second involving a considerable simplification of our iterative annelation scheme by the use of 1,6-bis(triisopropylsilyl)-1,3,5-hexatriyne as a regioselective cocyclization partner in cobalt-catalyzed alkyne cyclotrimerizations.

Scheme 1 depicts our first synthetic approach to the target, based on methodology employed successfully in the preparation of the [4]phenylene system,[2c] relying on the trimethylstannyl group as a masked halogen to gain access to the crucial cyclization intermediate **1**. Cocyclization with bis(trimethylsilyl)acetylene then gave[4] complex **2**, in addition to small amounts of **3** (<5%), only the second example of a seeming Diels–Alder adduct to a phenylene.[2c] Structural assignments rest on spectral data[4] and their comparison with those of model systems.[2]

Because the decomplexation of **2** proved difficult (treatment with CO[2c] was unsuccessful), a testament to the activated electronic nature of the ligand, a more expeditious route to **6** was sought, one that would also facilitate the synthesis of even higher linear phenylenes. This strategy had its cornerstone in triyne **5**, designed to furnish **1**, and hence **2**, much more rapidly (Scheme 2)[4] by exploiting the greater accessibility of the central triple bond in the cyclization with an *o*-diethynylarene unit, thus regenerating the latter directly in one step.

Demetalation of **2** required the mildest oxidative conditions, found by preliminary cyclic voltammetry experiments and necessitating the presence of eight equivalents of Et_3N to attenuate the oxidizing power of Cu^{II} ion (four

equivalents). The [5]phenylene derivative **6** is obtained as deep red, highly air-sensitive crystals, which decompose on attempted melting. The most significant spectral data are the positions of its UV and ^{1}H-NMR absorptions. The UV spectra, while exhibiting a pattern identical to that found in the electronic spectra of other linear phenylenes, reveal an even further attenuated bathochromic shift for the longest-wavelength band ($\Delta\lambda_{max}$([4]- to [5]phenylene) = 38 nm). The ^{1}H-NMR spectra, on the other hand, show an upfield shift for the central ring hydrogens ($\delta = 5.56$) by the same increment ($\Delta\delta = 0.33$ ppm) as that observed on going from

[2]- to [3]phenylenes and from [3]- to [4]phenylenes, and virtually unchanged chemical shifts for the other hydrogens.

The increasingly activated character of the [5]phenylene nucleus compared with the lower members is evident in its sensitivity to oxidizing agents, the tenacity with which it remains attached to $(C_5H_5)Co$, the relative facility with which it breaks through-conjugation by (formal) cycloaddition, as in **3**, and the profound aromatizing effect of metal complexation,[2c] which leads to dramatic downfield shifts of the ^{1}H-NMR absorptions of all the hydrogens, including those at considerable distances from the metal.

A strategy analogous to that depicted in Scheme 2 but starting with 2,3,6,7-tetraethynylbiphenylene[2c] has provided access to 2,3,8,9-tetraethynyl[4]phenylene (35%). So far, despite extensive experimentation, this molecule has failed to function as a precursor to [6]phenylene, perhaps signaling the limit of stability in this class of compounds.

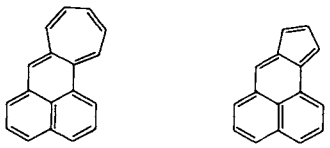
Cyclohepta[*a*]phenalene: A Highly Electron-Donating Nonalternant Hydrocarbon**

By *Yoshikazu Sugihara, Hiromasa Yamamoto, Kenji Mizoue,* and *Ichiro Murata**

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

Two nonalternant hydrocarbons, cyclohepta[*a*]phenalene, **1**, and cyclopenta[*a*]phenalene, **2**,[1] formally derived from azulene by replacing one of its two rings by phenalene, are known as *Reid*'s hydrocarbons, since he first suggested[2] that these two molecules could represent new, azulene-like, polar aromatic structures.[3] Based on Hückel MO treatment,[4] both molecules were predicted to be aromatic[5] with a high-energy HOMO (+0.1055 β) for **1** and a



1 **2**

low-energy LUMO (−0.1154 β) for **2**.[4b] Although some derivatives of **2** are known in the literature,[1,6] neither the parent molecule **1** nor any derivatives have been synthesized.[7] We present here the synthesis and some properties of **1** which reveal its high electron-donating ability.

The key step of the synthesis (Scheme 1) is based upon the benzene ring expansion by means of intramolecular ketocarbene reaction (**7**→**8**), which has been used for the synthesis of azulene by *Scott* et al.[8] Methyl 1-(8-phenyl)naphthyl ketone, **6**, easily prepared from 1,8-diiodonaphthalene, **3**,[9] via **4** and **5**, was converted into the diazoketone **7** utilizing a diazo group transfer reaction[10] with $TosN_3$. As expected, reaction of **7** with a catalytic amount of $Rh_2(OAc)_4$[11] in benzene afforded the desired ring-expanded ketone **8** (89% yield). Although transformation of

[**] This work was supported by a Grant-in-Aid for Special Project Research (60129030) from the Ministry of Education, Science and Culture, Japan.

8 into **1** could be accomplished by way of reduction with $NaBH_4$ and subsequent dehydration, considerable benzo[4,5]cyclohepta[1,2,3-*de*]naphthalene, **11**,[12] was formed along with **1** in a ratio of 1:1 to 1:5. To avoid a tedious purification of **1**, the ketone **8** was isomerized to the phenalenone **9**, which in turn was reduced with diisobutylaluminum hydride to a hydrocarbon mixture **10**. Without separation, **10** was oxidized with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) to afford **1**, which, in this case, could easily be purified by simple filtration through basic silica gel (eluant: hexane) followed by recrystallization from benzene/hexane (1:4).[13] Although compound **1**, as dark green needles (m.p. = 60.5 °C (dec.)), is fairly labile,[14] it could be stored under nitrogen in a refrigerator.

The UV/VIS spectrum of **1** exhibits a long-wavelength absorption up to approximately 850 nm. The ^{1}H-NMR resonances of **1** (Fig. 1) are fully consistent with the assigned structure and, at the same time, provide interesting insight into the bonding characteristics of this novel hydrocarbon, which, at first glance, seems to be a perturbed heptafulvene/naphthalene.

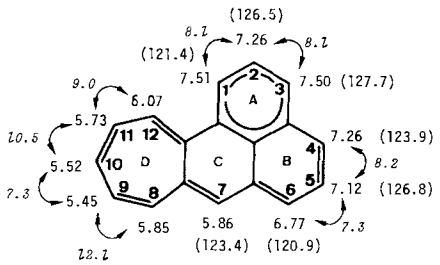

Fig. 1. ^{1}H- (CD_2Cl_2, 400-MHz, complete) and ^{13}C-NMR ($CDCl_3$, 100-MHz, selected, in parentheses) parameters of **1**. Chemical shifts in ppm downfield from internal TMS; *J* in Hz.

In comparison to the proton chemical shifts of naphthalene ($\delta = 7.46$ and 7.81), the signals of H-4, -5, and -6 (ring B) of **1** appear at higher magnetic field ($\delta = 6.77$–7.26) with H-6 being in the olefinic region. On the other hand, the chemical shifts of the ring-A protons might be regarded as appearing in a normal aromatic region. Furthermore, the vicinal proton coupling constants, $J_{4,5}$ and $J_{5,6}$, observed for the ring-B protons, are different by 0.9 Hz, whereas those for the ring-A protons are equivalent, indicating some bond alternation only in ring-B. As for the protons on the seven-membered ring-D, both the chemical shifts ($\delta = 5.45$–6.07) and the vicinal coupling constants ($J = 7.3$–12.1 Hz) are more similar to those of 8,8-diphenylheptafulvene ($\delta = 5.42$–6.10, $J = 7.3$–12.2 Hz)[15] than to those of the parent heptafulvene[16] and its derivatives having electron-withdrawing group(s) at C-8.[17] Based on these findings, the molecule **1** seems to represent a composite of an extended heptafulvene and a benzene ring (Fig. 1). The ^{13}C-NMR data (Table 1) also support this view.[18] Compound **1** is susceptible to protonation at C-7 in trifluoroacetic acid to give the conjugate acid **12**.

The most intriguing property of **1** is its electron-donating ability as borne out by cyclic voltammetry,[19] which reveals three oxidation waves at 0.39, 0.74, and 1.08 V (vs. SCE).[20] The first oxidation potential of **1** is far more negative than that of an alternant isomer, naphthacene (0.77 V),[21] and compares better with that of tetrathiafulvalene (0.34 V).[22] The small separation between E_1^{ox} and E_2^{ox} indicates a small coulombic repulsion that must be overcome in forming the dicationic species.[7] Interestingly,

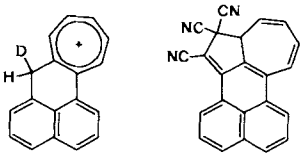
Table 1. Spectral data of compounds **1**, **12**, and **13**.

1: FD-MS: *m/z* 228 ($M^{\oplus}$); UV (acetonitrile): λ_{max} (lg ε) = 252 (4.46), 298 (3.96), 327 (3.93), 383 (sh, 3.75), 402 (sh, 3.81), 431 (sh, 3.92), 447 (3.93), 602 (3.16) nm, with long tailing up to 850 nm; 400-MHz-^{1}H-NMR (CD_2Cl_2): $\delta = 7.51$ (d, 1H, $J = 8.1$ Hz, H-1 or -3), 7.50 (d, 1H, $J = 8.1$ Hz, H-3 or -1), 7.26 (d, 1H, $J = 8.2$ Hz, H-4), 7.26 (t, 1H, $J = 8.1$ Hz, H-2), 7.12 (dd, 1H, $J = 8.2$, 7.3 Hz, H-5), 6.77 (d, 1H, $J = 7.3$ Hz, H-6), 6.07 (d, 1H, $J = 9.0$ Hz, H-12), 5.86 (s, 1H, H-7), 5.85 (d, 1H, $J = 12.1$ Hz, H-8), 5.73 (ddd, 1H, $J = 10.5$, 9.0, 1.3 Hz, H-11), 5.52 (dd, 1H, $J = 10.5$, 7.3 Hz, H-10), 5.45 (ddd, 1H, $J = 12.1$, 7.3, 1.3 Hz, H-9); 100-MHz-^{13}C-NMR ($CDCl_3$): $\delta = 140.5$, 132.6, 131.3, 128.8, 127.7 (seven-membered ring), 127.7 (C-3), 126.8 (C-5), 126.5 (C-2), 123.9 (C-4), 123.4 (C-7), 121.4 (C-1), 120.9 (C-6), 141.6, 139.8, 134.4, 134.1, 134.0, 131.7 (quaternary C atoms)

12: 400-MHz-^{1}H-NMR (CF_3COOD): $\delta = 9.40$ (d, 1H, $J = 9.2$ Hz, H-12), 8.70 (d, 1H, $J = 9.3$ Hz, H-8), 8.63 (t-like, 1H, H-11), 8.52–8.44 (m, 2H, H-9, -10), 8.40 (d, 1H, $J = 7.2$ Hz, H-1), 8.14 (d, 1H, $J = 8.3$ Hz, H-3), 7.75 (d, 1H, $J = 8.3$ Hz, H-4), 7.63 (dd, 1H, $J = 8.3$, 7.2 Hz, H-2), 7.53 (dd, 1H, $J = 8.3$, 6.4 Hz, H-5), 7.44 (d, 1H, $J = 6.4$ Hz, H-6), 5.00 (bs, 1H)

13: Orange prisms, m.p. = 210–212 °C; MS: *m/z* 329 ($M^{\oplus}$, 100%), 303 ($M^{\oplus} - CN$, 28%), 302 ($M^{\oplus} - HCN$, 10%); IR (KBr): $\tilde{\nu} = 2190$ cm^{-1}; UV-VIS (CH_2Cl_2): λ_{max} (lg ε) = 247 (sh, 4.17), 272 (4.36), 291 (sh, 3.90), 337 (3.99), 462 (4.28); 100-MHz-^{1}H-NMR (CD_2Cl_2): $\delta = 8.98$ (dd, 1H, $J = 1.0$, 7.5 Hz), 8.30–7.35 (m, 6H), 6.91 (dd, 1H, $J = 5.6$, 12.1 Hz), 6.40 (ddd, 1H, $J = 2.1$, 5.6, 10.1 Hz), 6.08 (dd, 1H, $J = 3.9$, 10.1 Hz), 4.06 (dd, 1H, $J = 3.9$, 2.1 Hz)

1 reacts with tetracyanoethylene (TCNE) by single electron transfer[23] to form an [8+2] cycloadduct **13**[13] in 21% yield.



12 **13**

This study provides insight on the bonding of a *peri*-condensed nonalternant molecule and it suggests a way to design novel hydrocarbons of high electron-donating ability.

The "Wheel of Mainz" as a Liquid Crystal?—Structural Variation and Mesophase Properties of Trimeric Discotic Compounds**

By *Willi Kreuder, Helmut Ringsdorf,** *Otto Herrmann-Schönherr,* and *Joachim H. Wendorff*

Liquid crystals—which are of great interest from both a theoretical and a practical point of view—are currently the subject of interdisciplinary research.[1] The reasons are the fascinating ability of anisotropic molecules to form supramolecular systems through self-organization and the resulting properties of such systems. The type and extent of this molecular order can be largely predetermined by the synthesis of molecules having appropriate molecular geometries. The first liquid crystals—discovered in 1888[2]—were formed from rodlike molecules (calamitic mesogens A, Fig. 1); the first discotic mesophases formed from disclike molecules were identified only ten years ago[3] (discogens B, Fig. 1). In both mesophase systems, the characteristic molecular axes are on average parallel (director): in the case of rods the long axes and in the case of discs the short axes.[4] If this is the only principle of organization, then there exists a nematic phase (*n* for calamitic-nematic phases formed from rodlike molecules, N_D for discotic-nematic phases formed from disclike molecules[5]). An additional positional order of the molecules gives rise to the different layer structures of the smectic phases in the calamitic system.[6] The analogues in the discotic system are the stack structures of the columnar phases.[4] These elementary geometries have been expanded recently: dimeric discogens[7] ("discotic twins"[8]) can form stable discotic phases; molecules with pyramid-shaped central moieties give rise to "pyramidal mesophases";[9] discogens with a small "hole" in the flat central moiety give rise to "tubular phases";[10] rodlike mesogens, the ends of which rigidly bear one or two half-discogens, form "phasmidic phases."[11]

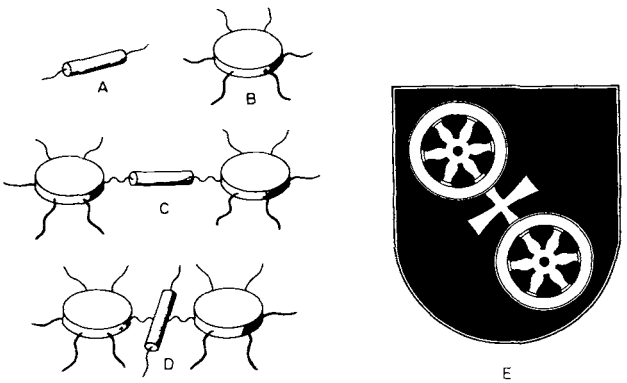

Fig. 1. Schematic representation of the geometry of liquid crystal molecules. A, rod-shaped mesogen (calamitic mesophases); B, disc-shaped mesogen = discogen (discotic mesophases); C, two discogens and a rodlike mesogen *terminally* linked; D, two discogens and a rodlike mesogen *laterally* linked; E, for comparison, the "Wheel of Mainz," the coat of arms of Mainz.

Structural variation of polymeric liquid crystals[12a] and, in particular, of discotic polymers bearing the discogens either as side groups[12b,c] or in the main chain[12c-e] led to the synthesis of monofunctional triphenylene derivatives. These derivatives provide access to compounds formed from disc- *and* rod-shaped mesogens. Such materials are of interest, for example, in integrated optics, since they might form macroscopically biaxial nematic phases. This state, which has been theoretically predicted[13] and recently discussed for polymers as well,[14] is characterized by the existence of a second director axis. Optical biaxiality has not been achieved so far in simple mixtures of an *n* phase and an N_D phase owing to their immiscibility.[5,15] Our goal, therefore, was to prevent phase separation by covalently combining one or more molecules having different geometric anisotropies.

We report here the syntheses and properties of compounds **4**, **5**, and **9**, each of which consists of one rodlike and two disclike mesogens (C and D in Fig. 1). However, none of the three substances fulfilled our expectations. The "trimesogen" **4** (structure C in Fig. 1) is amorphous; the homologous trimesogen **5** forms a novel, highly ordered mesophase; finally, **9**, which, owing to the similarity of its global geometry (structure D in Fig. 1) with the coat of arms of Mainz (E in Fig. 1), has been described as the chemical equivalent of the "Wheel of Mainz," is characterized by excellent crystallizability. Scheme 1 outlines the synthetic route leading to **4** and **5** and Scheme 2 that leading to **9**.

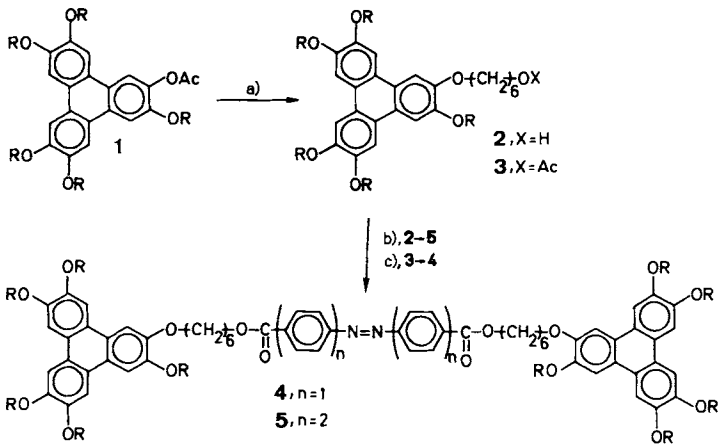
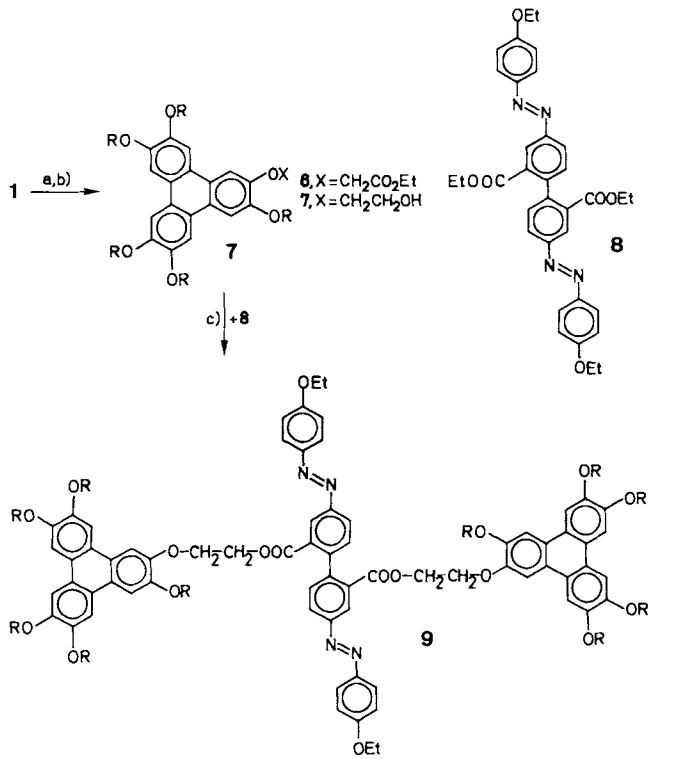


Scheme 1. R = C_5H_{11}. a) 6-Chlorohexanol (4 equiv.), K_2CO_3 (4 equiv.), KI (1 equiv.) in acetone, Ar, 5 d reflux, Ag_2O (wet) in THF, 20 h at room temperature; dissolve in ethyl acetate/water; lyophilized from benzene, chromatography (silica gel 60, CH_2Cl_2), R_f($CHCl_3$ + 6‰ EtOH): 0.2 (**2**) 0.5 (**3**); b) azobiphenyl-4′,4‴-bis(carbonylchloride) [16] (0.46 equiv.), 1,2-dichlorobenzene, pyridine, 60 h at room temperature, crystallization from $CHCl_3$/EtOH (2 + 5); chromatography ($CHCl_3$, ethanol-free) R_f ($CHCl_3$ + 6‰ EtOH) = 0.5–0.6 (owing to *cis-trans* isomerism); c) diethyl 4,4′-azobenzenedicarboxylate [17] (0.48 equiv.), (iPrO)$_4$Ti (0.4 equiv.) [18], Ar, 10 h 140 °C, 10 h 170 °C; repeated precipitation from THF/MeOH (1 + 1) in MeOH (4), flash chromatography (CH_2Cl_2/EtOH, 98 + 2), R_f = 0.7, precipitation from MeOH; flash chromatography (toluene/ethyl acetate, 49 + 1), R_f(*trans*) = 0.32, R_f(*cis*) = 0.2. Precipitation from THF/EtOH (1 + 1) in EtOH (4).



Scheme 2. R = C_5H_{11}. a) Ethyl bromoacetate (4 equiv.), K_2CO_3 (4 equiv.) in acetone, Ar, 5 h reflux. R_f(CH_2Cl_2): 0.4 (**1**), 0.2 (**6**). Dissolve in ethyl acetate + HOAc/water, crystallization from EtOH. Flash chromatography (CH_2Cl_2), crystallization from EtOH; b) $LiAlH_4$ (4 equiv.), THF, 3 h reflux, MeOH, ethyl acetate/1 N HCl/water; flash chromatography (first CH_2Cl_2, finally CH_2Cl_2/EtOH, 49 + 1), crystallization from EtOH; c) diethyl 4,4′-bis(*p*-ethoxyphenylazo)-2,2′-biphenyldicarboxylate **8** [19] (0.49 equiv.), (iPrO)$_4$Ti (0.1 equiv.), Ar, 2 h 130 °C, p = 0.5 mbar slow change to 180 °C, p = 0.005 mbar. Flash chromatography (toluene/ethyl acetate, first 99 + 1, finally 97 + 3). R_f(*trans*) = 0.55, R_f(*cis*) = 0.4. Recrystallization from THF/EtOH (1 + 17).

The yields and the liquid crystal properties obtained from polarization microscopic and differential calorimetric investigations of the new substances are listed in Table 1. The ^{1}H-NMR data are summarized in Table 2. Correct elemental analyses were obtained for all compounds. The monofunctional triphenylene derivatives **2**, **3**, **6**, and **7** display the columnar D_{ho} phase (cf. footnote [a] of Table 1). This corresponds to the observation[12b,d,21] that the high molecular symmetry of the reference compound 2,3,6,7,10,11-hexakis(pentyloxy)triphenylene—phase sequence: k 69 D_{ho} 122 i[22]—is not necessary for formation of the highly symmetric D_{ho} phase. In the case of **6**, the polar ethoxycarbonylmethyl side group, which may be regarded as a nearly isosteric replacement for a pentyl group, even results in enlargement of the mesophase region.[23] In contrast, the long acetoxyhexyl side group in **3**

9: δ = 8.52–6.64 (s and ms; arom., 26 H), 4.5 (m; CH_2OOC, 4 H), 4.3–4.0 (ms, ts (not resolved); CH_2O, 28 H), 2.0–1.8 (ms; CH_2CH_2O, 20 H), 1.6–1.2 (ms; $-(CH_2)_n-$, 40 H), 1.05–0.8 (ts; CH_3, 36 H)

[a] Correct ^{13}C-NMR spectra were obtained for all new compounds.

results in considerable reduction in the stability range of the mesophase.

The "Wheel of Mainz" **9** proved to be a spherolithic crystalline compound. The isotropic melt can be supercooled to 120 °C (m.p. = 167 °C). This rules out the existence of a monotropic, i.e., metastable, mesophase. Contact preparations[24] with typical liquid crystals of the *n* and D_{ho} type do not have any observable effect on the crystalline phase of **9**. It might be possible to prepare a liquid crystalline "Wheel of Mainz" by the introduction of lateral substituents on the molecular axis so as to hinder crystallization.

The most interesting compound proved to be **5**, in which two triphenylene moieties are joined via a mesogenic azobiphenyl moiety. It exhibits a highly viscous mesophase, which is reminiscent of an S_B texture as observed by polarization microscopy.[25] The relatively high enthalpy change at the clearing point (1c→i, 12 J g^{-1}) also points to the existence of an ordered mesophase structure. This was confirmed by X-ray structural analysis using flat camera diagrams of mechanically oriented samples (suppression of crystallization at room temperature) and goniometric diagrams of macroscopically nonoriented samples (Fig. 2).[26]

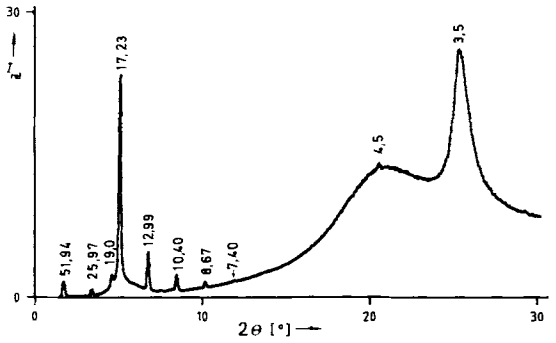

Fig. 2. X-ray goniometric diagram ($\lambda = 1.54$ Å) of **5** (nonoriented); the numbers give the corresponding Bragg distances in Å.

A diffuse halo ($d_{Bragg} = 4.5$ Å) appears in the wide-angle region; in the scattering diagrams of the oriented samples, it appears as a diffuse ring. This behavior is due to liquid-like arrangement of alkyl chains and is typical of discotic phases.[27] At small angles, reflections are observed corresponding to a one-dimensional lattice with a lattice constant of $a = 51.94$ Å. The Bragg distances correspond to 1 : 1/2 : 1/3 : 1/4 : 1/5 : 1/6 : 1/7. The intensities of the reflections indicate that, within a repeat unit *a* of the lattice, two triphenylene moieties are located at approximately 0 and 2/3 *a*. Two further reflections are observed perpendicular to the basis vectors of this lattice, corresponding to the distances $b = 19$ Å and $c = 3.5$ Å. These distances are comparable, respectively, with the diameter of a triphenylene mesogen and with the separations of regularly stacked triphenylene moieties in the D_{ho} phase of hexapentoxytriphenylene.[27] This novel liquid crystalline phase is characterized, on the one hand, by a layer structure typical for smectic phases.[6] On the other hand, the regular stacking of molecular discs observed for discotic phases is also found (similar to D_{ho}). The structure of the mesophase of **5** is shown schematically in Figure 3.

The amorphous substance **4** apparently cannot form a mesophase structure. The reason is presumably the reduction of the anisotropy of the linking azobenzene segment,

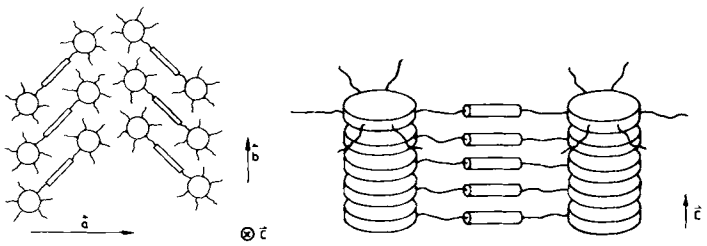

Fig. 3. Structure of the mesophase of **5**. Left: Layer structure of the trimesogens stacked regularly along the *c* axis ($\vec{a}$, layer vector). Right: Stack structure.

which, compared with that in **5**, is two phenylene moieties shorter. The azobenzene segment behaves almost the same as the usual flexible alkyl spacers. This axial mesogen in **4**, together with the two hexylene spacers, is too long, however, for the formation of a normal discotic phase. It is known for discotic main-chain polymers that a very long spacer segment is capable of preventing the formation of anisotropic long-range order.[12d]

Although no nematic phases, and, in particular, none with optical biaxiality, were obtained, we have been able to show that new and unexpected supramolecular structures can be generated by joining different structural elements in a single molecule. The substances discussed here are also model compounds for polymers consisting of alternating rod- and disc-shaped mesogens.

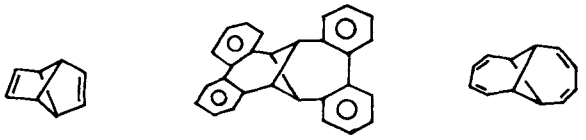
Relay Conjugation via Twisted Six- and Seven-Membered Rings**

By *Rolf Gleiter,** *Bernd Kissler*, and *Camille Ganter*

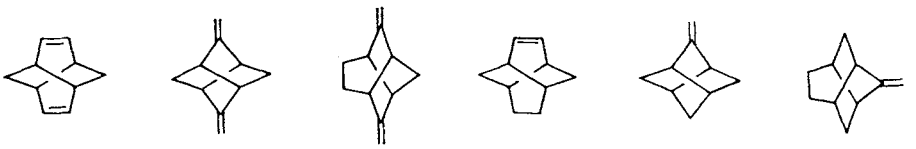
Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

Four-membered rings have been proposed to be good relays for the interaction between two perpendicular π systems.[1] Recent investigations on the tricyclic systems **1**–**3** have supported the concept of relay conjugation between remote π systems.[2,3]



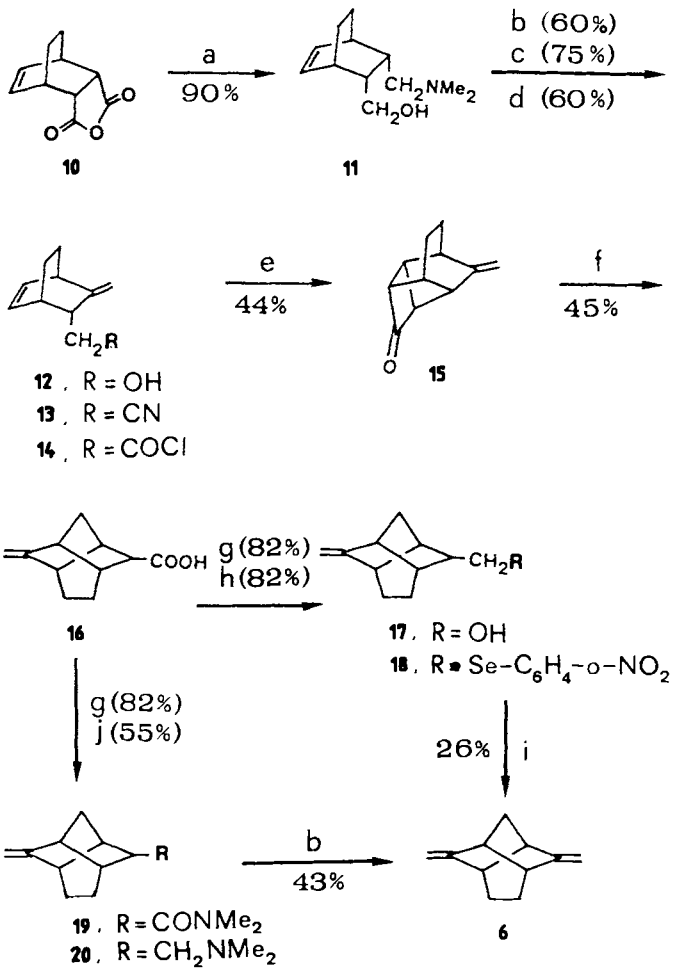
1 **2** **3**

To further extend these studies, we have investigated the spectroscopic properties of the compounds **4**–**6** in which two π moieties are separated by either a six- or seven-membered twisted ring.



4 **5** **6** **7** **8** **9**

Twistadiene, **4**, was first reported by *Ganter* et al.[4] The synthesis of **6**[6] has been carried out according to the one of **5**[5] (Scheme 1). Compound **14**, prepared from **10** via the intermediates **11**–**13**, was converted by a procedure analogous to that described by *Sauers* et al.[7] Intramolecular addition of the ketene yielded only the tetracyclic ketone **15**, which could be cleaved to the key intermediate **16**, the twistbrendane structure of which was proven by



Scheme 1. a) $HNMe_2$, $LiAlH_4$. b) H_2O_2. c) TosCl/pyridine, NaCN/DMF. d) KOH, $SOCl_2$. e) NEt_3/benzene. f) *t*BuOK. g) $LiAlH_4$. h) *o*-NO_2–C_6H_4–SeCN, *n*Bu_3P. i) H_2O_2/THF. j) $SOCl_2$, $HNMe_2$.

X-ray investigations on the dimethylamide **19**.[8] Diene **6**[6] could be prepared from **16** via two different routes; in both cases elimination proceeded without rearrangement as was observed in the corresponding synthesis of **5**.[5]

The method of choice to investigate the electronic interactions of the two C=C moieties is HeI_α photoelectron (PE) spectroscopy. In order to interpret the PE spectra of **4**–**6**, we also investigated the monoenes **7**–**9**.[9–11] In Table 1 the first ionization energies are compared to orbital ener-

gies obtained from ab-initio (4-31G[12]) and semiempirical SCF calculations (MINDO/3[13,14]), assuming the validity of *Koopmans*' theorem.[15]

Table 1. Comparison between the first vertical ionization energies, $I_{v,j}$, and the calculated orbital energies, ε_j, of **4**–**9**. Values in eV. j = 1-3 (**4**–**6**) and 1, 2 (**7**–**9**).

Compound	$I_{v,j}$	Assignment	$-\varepsilon_j$
4[a]	8.46	$7b_3(\pi)$	8.24
	9.8	$6b_2(\pi)$	9.54
	10.5	$6b_3(\sigma)$	10.52
5 [a]	8.49	$7b_3(\pi)$	8.87

	9.75	$12b(\sigma)$	9.73

[a] Orbital energies calculated with 4-31G. [b] Orbital energies calculated with MINDO/3.

The PE spectra of **4**–**6** reveal a strong splitting of the first two bands ($\Delta \approx 0.7$–1.3 eV). From the observation that the π-ionization energies of **7**–**9** lie between the first two bands of **4**–**6** and from the large separation between the π units in **4**–**6** (> 3 Å), we conclude that the splitting in **4**–**6** has its origin in strong electronic interactions between the central ring and both symmetry-adapted linear combinations of the π orbitals.

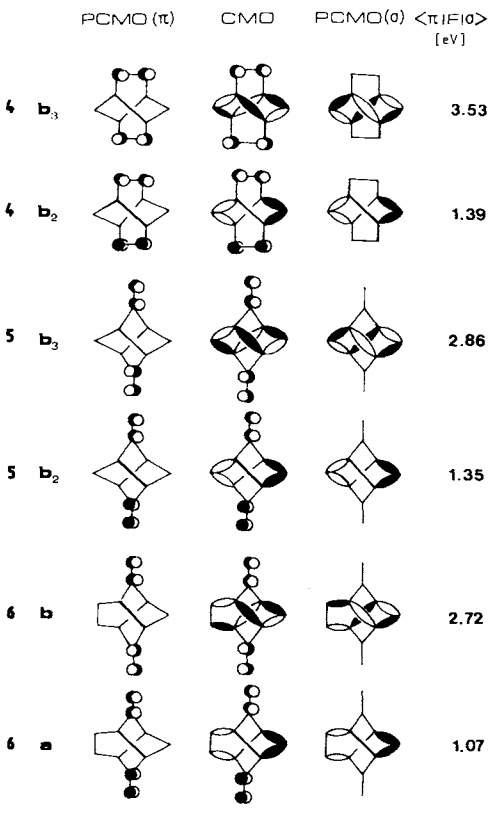

Fig. 1. Schematic representation of the symmetry-adapted precanonical π MOs and the precanonical σ MOs (PCMOs) of the twisted ring moiety together with the resulting two highest canonical MOs (CMOs). The symmetry assignments are given in the first column, the matrix elements $\langle\pi|F|\sigma\rangle$ between the PCMOs in the last column.

A quantitative analysis of this interaction was performed applying the procedure proposed by *Heilbronner* and *Schmelzer*.[16] In Figure 1 we show the precanonical orbitals (PCMOs) of the π and σ type, the resulting canonical MOs, and the matrix element $\langle\pi|F|\sigma\rangle$, the latter being a measure for the intensity of the π,σ mixing. This analysis reveals a strong interaction between the $b_3(\pi)$ (**4**,**5**) and the $b(\pi)$ (**6**) linear combination with the corresponding σ orbitals. Interestingly, the σ orbital that is responsible for the strong π/σ interaction does not belong to the set of ribbon orbitals[17] of the twisted six- or seven-membered ring.

Low-Temperature Photolysis of Peracetylated Dodecanoyl Peroxides of Tartaric Acid and D-Gluconic Acid in the Solid State— A Diastereoselective Radical Coupling

By *Rainer Lomölder* and *Hans J. Schäfer**

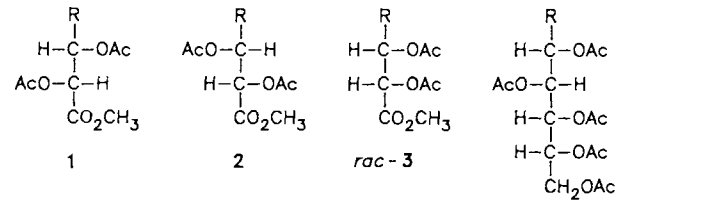
Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Kolbe electrolysis is an attractive method for CC coupling reactions, because it allows a large variety of compounds to be prepared easily and in high yields from inexpensive carboxylic acids.[1] A disadvantage, however, is the lack of selectivity for unsymmetrical products upon coelec-

[*] Prof. Dr. H. J. Schäfer, Dipl.-Chem. R. Lomölder
Organisch-chemisches Institut der Universität
Corrensstrasse 40, D-4400 Münster (FRG)

trolysis of two carboxylic acids and the loss of optical activity observed for carboxylic acids having an asymmetric center at the α-carbon atom. We recently showed that, by solid-state photolysis of unsymmetrical diacyl peroxides, it is possible to obtain unsymmetrical coupling products with high selectivity.[2] We have now found that the configuration at the α-C atom also remains largely unchanged when the optically active diacyl peroxides **1b**–**4b** are photolyzed in the crystal at low temperature.[3]

The peroxides **1b**, **2b**, and **4b** were synthesized, starting from the corresponding acid chlorides peroxydodecanoic acid, and pyridine, in yields of 83–95%. Compound **3b** was obtained, starting from the monomethyl ester of *rac*-bis-*O*-acetyltartaric acid (obtained from *meso*-tartaric acid),[4] peroxydodecanoic acid, and dicyclohexylcarbodiimide (DCC) in 73% yield. Photolysis of **1b**–**4b** afforded the acetates **1c**–**4c** (Table 1).



1 2 *rac*-3 4

a, R = COCl bzw. CO_2H (3); b, R = CO–OO–$COC_{11}H_{23}$; c, R = $C_{11}H_{23}$

Table 1. Diastereoselective synthesis of **1c**–**4c** by photolysis of the diacyl peroxides **1b**–**4b**.

No.	Diacyl peroxide	*T* [°C] (*t* [h]) [a]	Undecyl derivative	Yield [%]	Diastereoselectivity [b] [% *de*]
1	**1b**	−60 (4.5–7)	**1c** [c]	44–64	89–95.6
2	**1b**	−20 (3.5)	**1c**	25	35.7
3	**2b**	−60 (5.5)	**2c**	48	95.6
4	**2b**	5 (2)	**2c**	17	3.4
5	**3b**	−60 (7.5)	**3c** [d]	57	92.3
6	**4b**	−60 (5–7.5)	**4c**	34–41	81.6–87
7	**4b**	10 (2)	**4c**	22	6.6

[a] 2.6–8.9 mmol of the solid peroxide, as a suspension in petroleum ether (34–40°C), was irradiated with a medium-pressure Hg lamp in a circulation apparatus. [b] Determination of the diastereoselectivity: **1c**–**3c**, gas chromatography (FFAP, 50 m, 200°C); **4c**, gravimetrically after column chromatography. [c] After saponification, **1c** was converted into the 2,3-di-*O*-isopropylidene methyl ester, whose $J_{2,3} < 1.6$ Hz indicates the *threo* configuration according to the Karplus rule, i.e., the configuration at C3 remains unchanged. [d] **3c** was likewise converted into the 2,3-di-*O*-isopropylidene methyl ester, whose $J_{2,3} = 6.7$ Hz supports the existence of the *erythro* configuration, i.e., the configuration at C3 is presumably also retained in this case.

The high diastereoselectivity observed at −60°C is nearly completely lost at 5–10°C. Furthermore, the fair chemical yields obtained at low temperature decrease upon raising the temperature owing to competing disproportionation (undecane, 1-undecene), symmetrical coupling (docosane), and presumably ionic decomposition.[5]

Diacyl peroxides undergo photochemical decarboxylation to give radical pairs.[6] The cause of the diastereoselectivity, which is unusual for radical couplings, is presumably the restricted motion of the radicals in the solid state.[7] This would also explain the loss in stereoselectivity at higher temperatures. The reaction is mechanistically noteworthy because of the usually complete racemization observed for radical coupling in solution.[8] Furthermore, it permits the decarboxylative alkylation of carboxylic acids from the chiral pool in a simple way with retention of optical activity.

Experimental Procedure

4b: A solution of peroxydodecanoic acid (2.71 g, 12.5 mmol) and dry pyridine (1 mL) in anhydrous ether (70 mL) was treated dropwise at −30°C with a solution of **4a** (5.32 g, 12.6 mmol) in anhydrous ether (120 mL) and the resulting reaction mixture was allowed to stir for 3 h at −30°C. After filtering off the pyridinium hydrochloride, the ether solution was washed (3 × 30 mL 2N HCl, 3 × 20 mL saturated $NaHCO_3$, 3 × 20 mL H_2O) and dried over sodium sulfate. After removal of the solvent at ca. 5°C), the crude product was filtered at 5°C on silica gel (deactivated with 5% H_2O; eluent, ether with 0.1% triethylamine). After removal of the solvent, 6.63 g (11 mmol, 87%) of **4b** was obtained.—Photolysis of **4b** at −60°C: **4b** (2.2 g, 3.6 mmol), dissolved in ether (10 mL), was added to 300 mL of petroleum ether in a circulation apparatus at −60°C. The resulting suspension [9] was photolyzed with a medium-pressure Hg lamp (TQ 150, Hanau) in the well of a photolysis vessel made of quartz glass and equipped with a vacuum jacket. After removal of the petroleum ether, the crude product was dissolved in 300 mL of ether, washed (3 × 30 mL saturated $NaHCO_3$ solution, 3 × 20 mL H_2O), and dried over Na_2SO_4. Flash chromatography (silica gel deactivated with 5% H_2O, ether/petroleum ether (34–40°C) = 2 : 1, v/v) afforded 594 mg (1.2 mmol, 32%) of **4c** along with 41 mg (0.079 mmol, 2%) of the C5 epimer of **4c**.

[3] The corresponding peroxides of α-amino acids proved to be unsuitable. *N*-Boc-, *N*-trifluoroacetyl-, *N*-acetyl-, *N*-lauroyl-L-alanine, and *N*-Boc- and *N*-*p*-tosyl-L-proline were treated with DCC and peroxydodecanoic acid. However, the diacyl peroxides decomposed during the synthesis, presumably via an ionic pathway, to give unstable products that were not characterized further.
[4] The crude nonisolated diacetylated anhydride of *meso*-tartaric acid was treated with methanol; purification of the products by flash chromatography gave the monoester as a colorless oil (67% via two steps).
[5] GC/MS indicated the probable presence of 1-dodecanoyloxy derivatives of **1** and **2** ($R = C_{11}H_{23}CO_2$).
[6] R. A. Sheldon, J. K. Kochi, *J. Am. Chem. Soc. 92* (1970) 4395.
[7] The topochemical principle (reactions in the crystal proceed with a minimum of atomic and molecular motion (M. D. Cohen, *Angew. Chem. 87* (1975) 439; *Angew. Chem. Int. Ed. Engl. 14* (1975) 386)) is not always valid for photolyses of solid diacyl peroxides (J. M. McBride, B. E. Segmüller, M. D. Hollingsworth, D. E. Mills, B. A. Weber, *Science (Washington) 234* (1986) 830). However, the large degree of retention at −60°C indicates a restricted rotation around the C1–C2 bond in the radicals **1**–**4** ($R = \odot$). The diastereoselectivity of the coupling cannot be explained by an equilibrium between diastereomeric radicals, since, if this were the case, the same products or product mixtures would be obtained from **1b** and **3b** or from **2b** and **3b**. Moreover, the activation energies for attaining the diastereomeric transition states are probably not sufficiently different because the radical combination, which requires practically no activation energy, leads to early transition states.
[8] Another example of a diastereoselective radical coupling was described earlier: P. D. Bartlett, J. M. McBride, *Pure Appl. Chem. 15* (1967) 89.
[9] Crystalline **4b** (powder photograph at −58°C), suspended in petroleum ether, leads to the same diastereoselectivity and comparable yields. Compounds **1b**–**3b** were suspended in petroleum ether as solids and then photolyzed.

Polystannanes $Ph_3Sn\text{-}(tBu_2Sn)_n\text{-}SnPh_3$ (n = 1–4): A Route to Molecular Metals?**

By *Stefan Adams* and *Martin Dräger**

Two modifications of elemental tin exhibiting fundamentally different bonding exist, the semimetallic α form and the metallic β form. In the 4th main group of the periodic table, this dimorphism constitutes a stage between non- and semimetallic elements (C, Si, Ge) on the one hand and metallic lead on the other. In the inorganic chemistry of tin, Zintl phases and cluster anions with homonuclear Sn–Sn bonds reveal a continuous transition from metallic to covalent bonding.[1] The structural investigations of organopolystannanes[2a] carried out so far have shown a relationship between these compounds and alkanes; the structure of a distannene has also been described.[2b] Further linking of Sn centers, beyond that studied so far, should build a bridge between the organic and inorganic chemistry of tin.

$$2\,Ph_3SnLi + I\text{-}(tBu_2Sn)_n\text{-}I \xrightarrow[-2\,LiI]{} Ph_3Sn\text{-}(tBu_2Sn)_n\text{-}SnPh_3 \quad (a)$$

1 **2**, n = 2–4 **3**

a, n = 1; **b**, n = 2; **c**, n = 3; **d**, n = 4

With this goal in mind, we allowed the 1,n-diiodo compounds **2**[3] to react with Ph_3SnLi **1** [reaction (a)]. This chain-lengthening reaction is more complicated than the stoichiometry would at first lead one to expect. Variation of the molar ratio of the starting materials as well as of the solvent and the concentration (Table 1[4]) made it possible to isolate the tri- (**3a**), tetra- (**3b**), penta- (**3c**), and hexastannane (**3d**). The solutions of the iodine components react as equilibrium mixtures of different 1,n-diiodopolystannanes; only when nonpolar toluene is used in excess relative to added THF is **3d** obtained in good yield.

Table 1. Reactions and yields for the syntheses of **3a–d**.

1/THF [mmol]/[mL]	**2** n/[mmol]	Solvent ([mL])	Yields [mmol]/[%] [a] **3a** n = 1 [b]	**3b** n = 2 [b]	**3c** n = 3	**3d** n = 4
8.3/170	4/4.1	toluene (120)	1.36/33	0.68/16	—	—
6.0/ 50	4/3.0	THF (20)	0.51/17	0.26/9	0.63/21	
9.6/ 80	4/4.7	toluene (200)	—	—	—	2.1/45
16.0/100	3/8.0	THF (100)	1.52/19	0.76/10	3.7/47	—
12.0/110	2/6.0	THF (30)	—	2.2/37 [c]	—	—

[a] In addition, 2 to 3 mmol of $tBu_2Sn(OH)Cl$ from remaining tBu_2Sn units; yields based on **1**. [b] Mostly as a mixed phase **3a** · 0.5 **3b**. [c] In addition, 2.0/33 Ph_6Sn_2.

X-ray structure analyses[6] of **3a–d** revealed the molecular conformations, bond angles, and Sn–Sn distances shown in Figure 1. Bulky, electron-rich substituents on the Sn–Sn units generally effect an increase of the Sn–Sn bond length.[2a] This is confirmed by the series of *t*Bu-substituted compounds investigated here. The central bond in **3d** (296.6(3) pm; +15.6 ppm (5.6%) versus α-tin) is the longest Sn–Sn bond so far found in organopolystannanes. The same is true for *t*Bu-substituted polysilanes.[7a,b] In all compounds **3** as well as in $I\text{-}(tBu_2Sn)_4\text{-}I$[3a] the Sn_n unit exhibits the *trans* conformation. Intermolecular interactions are not present in the crystal.

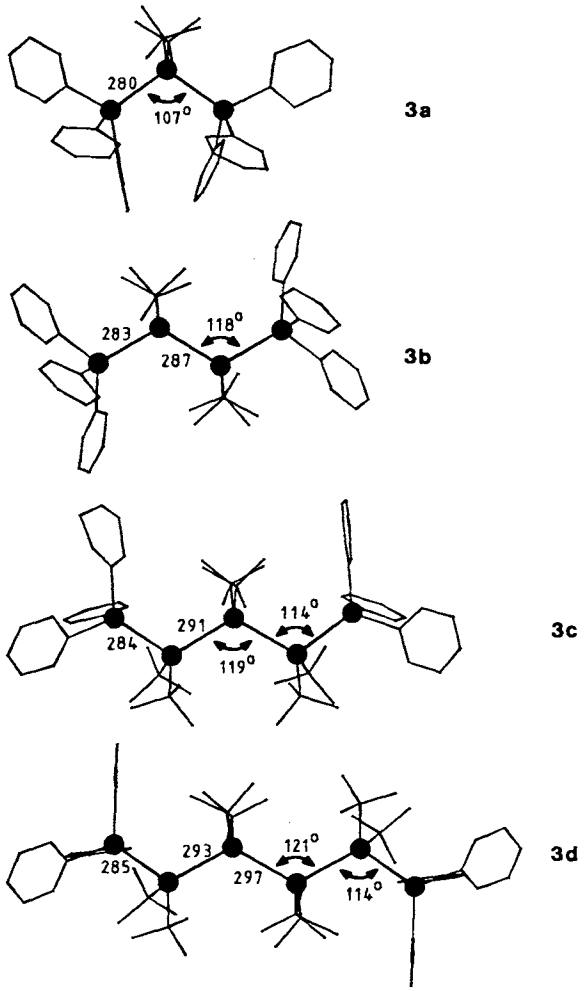

Fig. 1. Molecular structures of **3a–d** with average Sn–Sn bond lengths [pm] and Sn–Sn–Sn bond angles [6].

The polystannanes **3** are relatively soluble in $CDCl_3$; in the ^{119}Sn-NMR spectra, two (**3a**,**b**) or three (**3c**,**d**) major signals are surrounded by numerous well-resolved coupling satellites. Plotting of $^1J(^{119}Sn\text{-}^{119}Sn)$ versus d(Sn-Sn) (eight independent pairs of values) reveals a correlation that shows opposite signs for couplings via short (positive) or long (negative) bonds (change in sign at about 285 pm); data measured earlier by us (13 pairs of values[3a,5b]) and data from the literature (15 pairs of values[8]) fit this relation (Fig. 2). A linear relationship[5a] between $^2J(^{119}Sn\text{-}^{119}Sn)$ and the "nonbonding" distance $d(Sn\cdots Sn)$ was confirmed; in this case, too, the series **3a** to **3d** reveals a change in the sign of the coupling constants (at about 500 pm; 513 pm and −92 Hz for the central bonds in **3d**).

The UV spectra (Fig. 3) exhibit strong absorption maxima with marked redshift with increasing chain length.[7c] Parallels exist with conjugated polyenes, except that the HOMO in Sn_n chains is determined by σ Sn–Sn bonds. The HOMO/LUMO energy difference decreases with increasing chain length. We interpret this as the onset of formation of a metal-like electronic band and thus propose the term "molecular metals" for these compounds. In ad-

[**] Polystannanes, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 4: [5b].

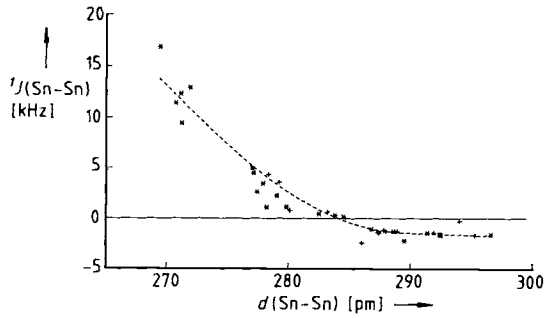

Fig. 2. Plot of the coupling constants $^1J(^{119}Sn\text{-}^{119}Sn)$ versus the bond lengths d(Sn-Sn); * pairs of values from our research, + literature data [8].

dition, Figure 3 shows a relationship between electronic excitation and ^{119}Sn-NMR chemical shift of the central Sn atom: an increase in the wavelength of the absorption is associated with a downfield shift of the NMR signals.

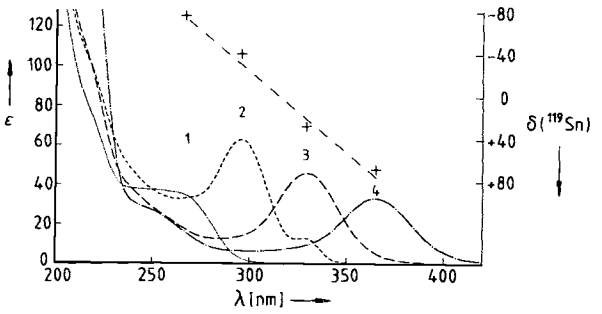

Fig. 3. UV spectra of the compounds **3a-d** (extinction coefficient ε for mol m^{-3}) and plot of the ^{119}Sn-NMR chemical shift [ppm] of the central Sn atom versus the corresponding excitation wavelength of the Sn_n chain (+).

The correlations described here and several empirical correlations for the series of compounds **3a** to **3d** point to a smooth transition between covalently bonded polystannanes and metallic tin. An analogous transition between molecular clusters and metallic microparticles of transition-metal elements has recently been the subject of frequent discussion.[9]

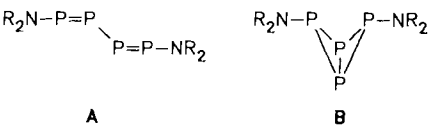
A 3,7-Diaza-1,2,4,5,6,8-hexaphosphatricyclo-[4.2.0.0^{2,5}]octane, a [2 + 2] Dimer of a 1,2-Dihydro-1-azatriphosphete containing a Planar P_4 Substructure**

By *Edgar Niecke,* Oliver Altmeyer, Martin Nieger,* and *Fritz Knoll*

$R_2N-PH-P(NR_2)-P(NR_2)-PH-NR_2$ ($R = SiMe_3$), a 1,2,3,4-tetrakisaminotetraphosphane, undergoes amine elimination to afford the tetraphosphabicyclobutane **B** instead of the tetraphosphabutadiene **A**.[1] In addition, calculations showed that **B** is the more stable isomer.[2]



A **B**

When we attempted to convert the diphosphene derivative **3**, obtained by reaction of the hydrazine derivative **1** with the diphosphene **2**, into the azatriphosphabicyclobutane **5** by elimination of chlorotrimethylsilane to give the azatriphosphabutadiene **4**, followed by isomerization,[3] we surprisingly obtained the tricyclic N_2P_6 system **7**.

We believe that electrocyclic ring closure of the azatriphosphabutadiene **4** leads to the intermediary formation of the 1,2-dihydro-1-azatriphosphete **6**, which, in turn, undergoes [2 + 2] cyclodimerization to give **7**.[4] In solution, **7** slowly decomposes to give the thermodynamically stable products P_4 and the iminophosphane **8**. The composition and constitution of compounds **1**, **2**, and **7** were established by elemental analysis, mass spectrometry, and NMR spectroscopy. The existence of the intermediate **3** is supported by the ^{31}P-NMR spectrum. The X-ray structure analysis of **7**[5] confirms the tricyclic structure of the compound (Fig. 1).

The molecule exhibits C_i symmetry in the solid. The bonding of the two azatriphosphetidine rings, which are present in a *trans* configuration and are arranged nearly orthogonally to the central P_4 framework, is in accord with expectations.[6] However, in comparison to other *cyclo*-P_4 compounds,[7] the planar arrangement of the central ring system is unusual. Noteworthy is also the relatively long P(2)–P(3) bond (228 pm), which provides an explanation for the retroreaction $7 \rightarrow 6 \rightarrow P_4 + 8$ occurring in solution. Experiments directed at stabilizing the azatriphosphete **6** as a complex ligand are currently in progress.

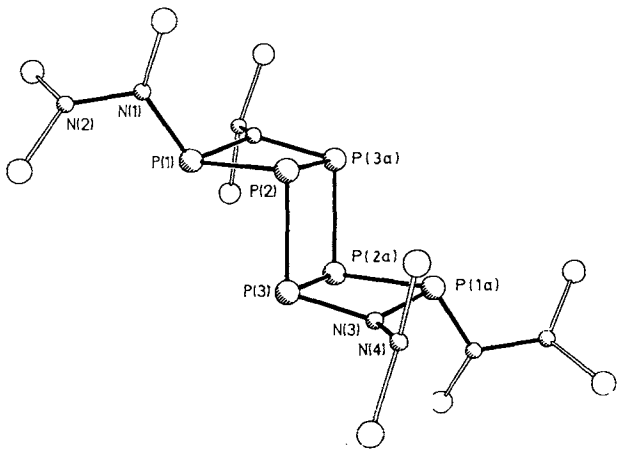

Fig. 1. Structure of **7** (without CH_3 groups). Important bond lengths [Å] and angles [°]: P(1)-P(2) 2.265(5), P(1)-N(3a) 1.745(8), P(2)-P(3) 2.281(6), P(2)-P(3a) 2.236(4), P(3)-N(3) 1.742(8); P(1)-P(2)-P(3) 93.5(2), P(2)-P(3)-N(3) 106.2(4), P(3)-P(2)-P(3a) 92.8(2), P(2)-P(3)-P(2a) 87.2(2), P(2)-P(1)-N(3a) 82.7(3), P(1)-P(2)-P(3a) 78.9(2), N(3)-P(3)-P(2a) 83.7(3), P(3)-N(3)-P(1a) 110.2(4).

Experimental Procedure

1: A solution of PCl_3 (6.0 g, 44 mmol) in ether (100 mL) was treated dropwise at −40 °C with a solution of lithium tris(trimethylsilyl)hydrazide (10.2 g, 40 mmol) in ether (200 mL). The resulting reaction mixture was then allowed to warm to room temperature with stirring. It was stirred for an additional 12 h, after which the solvent and unreacted PCl_3 were removed under vacuum, the residue was dissolved in 150 mL of pentane, and the precipitated LiCl was filtered out. Yield 12.0 g (92%); m.p. = 114–116 °C. MS: $m/z = 348$ $M^{\oplus}$ (5%), 333 $M^{\oplus}$ − Me (15%), 313 $M^{\oplus}$ − Cl (20%), 247 $M^{\oplus} - PCl_2$ (50%), 73 $SiMe_3^{\oplus}$ (100%). $^{31}P\{^1H\}$-NMR (pentane/C_6D_6): $\delta = 165$ (s); ^1H-NMR (C_6D_6): $\delta = 0.23$ (s, 18 H, $SiMe_3$), 0.4 (s, 9 H, $SiMe_3$); $^{29}Si\{^1H\}$-NMR (C_6D_6): $\delta = 13.4$ (d, $J = 6.6$ Hz, PNSi), 19.4 (s, NSi_2).

2: A solution of **1** (6.9 g, 20 mmol) in pentane (40 mL) was treated at −60 °C with a solution of $LiPR_2 \cdot 1.8\,THF$ (6.3 g, 20 mmol) in ether (30 mL) and the resulting reaction mixture was allowed to warm to room temperature. The diphosphane prepared in situ in this way, $R_2N-NR-PCl-PR_2$ (^{31}P-NMR: $\delta = 176$, −146.9, $J_{PP} = 288$ Hz) was stirred at room temperature until chlorosilane elimination was complete (ca. 3 h). Removal of the solvent and the chlorosilane afforded 3.5 g (91%) of **2** as a yellow oil. MS: m/z 382 $M^{\oplus}$ (9%), 367 $M^{\oplus}$ − Me (7%), 309 $M^{\oplus}$ − $SiMe_3$ (12%), 247 $M^{\oplus}$ − $PPSiMe_3$ (25%), 73 $SiMe_3^{\oplus}$ (100%). $^{31}P\{^1H\}$-NMR: $\delta = 542$ (d), 210.3 (d), $J_{PP} = 540$ Hz.

7: A solution of **2** (2 g, 5.2 mmol) in pentane (10 mL) was treated with a solution of **1** (1.8 g, 5.2 mmol) dissolved in pentane (20 mL). The resulting reaction mixture was allowed to stir at room temperature until **7** began to precipitate (ca. 24 h). ^{31}P-NMR spectroscopy, used to follow the reaction, indicated the intermediary formation of **3** ($-P_A=P_BP_C<$, ^{31}P-NMR: $\delta_A = 529.9$, $\delta_B = 292.2$, $\delta_C = 174$; $J_{AB} = 524$, $J_{AC} = 559$, $J_{BC} = 233$ Hz). Recrystallization twice from a small amount of hot toluene afforded **7** as a yellow crystalline solid, which underwent decomposition in solution to form P_4 ($^{31}P\{^1H\}$-NMR: $\delta = -520$) and **8** ($^{31}P\{^1H\}$-NMR: $\delta = 377$). Yield 0.9 g (16.8%), m.p. = 145–146 °C. MS: m/z 1028 $M^{\oplus}$ (< 0.1%), 708 $M^{\oplus} - 2NR_2$ (0.5%), 677 $M^{\oplus} - 2NR_2 - P$ (1%), 646 $M^{\oplus} - 2NR_2 - 2P$ (0.5%), 615 $M^{\oplus} - 2NR_2 - 3P$ (0.25%), 607 $M^{\oplus} - N_4R_5$ (5%), 576 $M^{\oplus} - PN_4R_5$ (2%), 545 $M^{\oplus} - P_2N_4R_5$ (5%), 514 $M^{\oplus}/2$ (30%), 483 $M^{\oplus}/2 - P$ (5%), 452 $M^{\oplus}/2 - 2P$ (20%), 309 $R_3N_2P_2^{\oplus}$ (5%), 205 $R_2N_2P^{\oplus}$ (100%). $^{31}P\{^1H\}$-NMR: $AA'B_2CC'$ spin system (numbering corresponds to Fig. 1) $\delta = 216.4$ (P(1)/(1a)), −48.8 (P(2)/(2a)), 108.4 (P(3)/(3a)); $J_{P(1),P(2)} = -162$ Hz, $J_{P(1),P(3)} = +172$ Hz, $J_{P(2),P(3)} = -100$ Hz, $J_{P(2),P(3a)} = -147$ Hz. Further couplings not observed owing to insufficient resolution.

The First 2*H*-Phosphirene**

By *Oliver Wagner, Gerhard Maas,* and *Manfred Regitz**

Unsaturated three-membered ring compounds are an attractive object of investigation for both theoretical and synthetic chemists. 1*H*-Azirines **1a** have proved to be transient, antiaromatic 4π-electron systems,[1] whereas the isomeric 2*H*-azirines **2a** are even of importance as synthetic building blocks.[2] The situation with the phosphorus analogues is completely different. Whereas 1*H*-phosphirenes **1b** may be regarded as well-studied, stable compounds,[3] nothing is known yet about 2*H*-phosphirenes **2b**. We re-

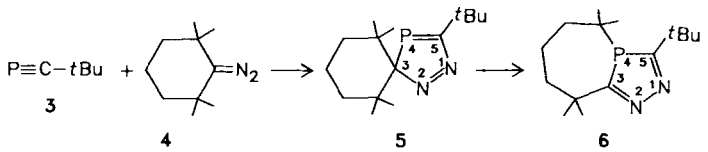
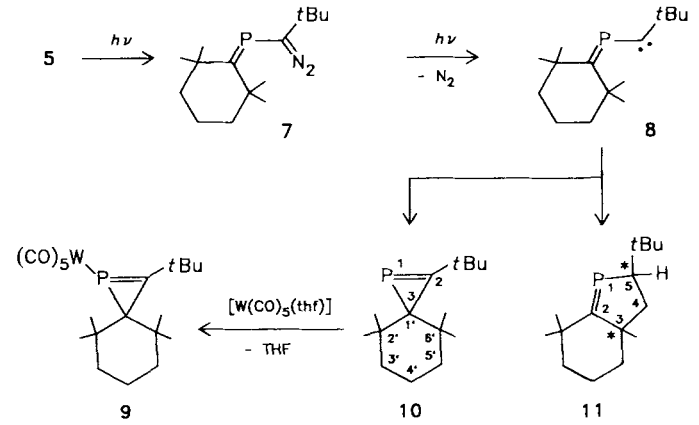
1b, X = PR **2b**, X = P

The phosphaalkyne **3**[4] undergoes [3+2] cycloaddition with the diazocyclohexane **4**[5] in pentane at −40 °C. After the reaction mixture loses its color, it was evaporated (20 °C, 15 mbar) to give the spirocyclic 3*H*-1,2,4-diazaphosphole **5** as an analytically pure, yellow oil (100%; ^{13}C-NMR (C_6D_6): $\delta = 129.3$ (C-3), 214.5 (d, $^1J(P,C) = 47.2$ Hz, C-5); ^{31}P-NMR (C_6D_6): $\delta = 269.9$).[6] The thermally unstable compound **5** undergoes [1,5]-sigmatropic migration at 20 °C in $CDCl_3$ (12 h) to afford the 4*H*-1,2,4-diazaphosphole **6**, also as an oil (86%; ^{13}C-NMR ($CDCl_3$): $\delta = 189.5$ (d, $^1J(P,C) = 26.0$ Hz, C-3), 186.5 (d, $^1J(P,C) = 39.8$ Hz, C-5)); as expected, the transition from $\lambda^3\sigma^2$ to $\lambda^3\sigma^3$ phosphorus is associated with a marked upfield shift of the ^{31}P-NMR signal (**6**: ^{31}P-NMR ($CDCl_3$), $\delta = 50.0$).



3 **4** **5** **6**

Photolysis of **5** at −40 °C in pentane (2 h, $\lambda \geq 280$ nm, Philips HPK 125 W)[7] affords, after distillative workup (kugelrohr, 130 °C oven temperature/10^{-2} mbar), a 5:1 mixture of the 1-phospha-1-cyclopentene **11** and the 2*H*-phosphirene **10** (Scheme 1). The two isomers were separated by medium-pressure column chromatography (silica gel (Merck, 15–25 μm), pentane, pressure ca. 20 bar); **11**, 54%;[8] **10**, 11%[9]). Compounds **10** and **11** are colorless liquids which can be readily handled in air.



5 **7** **8** **9** **10** **11**

Scheme 1. Arbitrary numbering of **10** and **11**.

Presumably, the photochemical ring opening **5** → **7**[10] is followed by the carbene formation **7** → **8**, at which stage the reaction branches to form **11** (C–H insertion) and **10** (1, 3 ring closure). Compared with the ^{31}P-NMR signals of **11**[8] and other cyclic phosphaalkenes containing four-[11] or six-membered[12] ring frameworks ($\delta \geq 225$), the signal of **10** ($\delta = 71.7$) is shifted far upfield. A comparable effect is observed for the ^{31}P-NMR resonances of cyclotriphosphanes relative to those of the open-chain triphosphanes and large-ring cyclophosphanes.[13] An X-ray crystal structure analysis should remove any remaining doubts concerning the constitution of **10**. The tungsten pentacarbonyl complex **9**[14] proved to be a suitable compound. It was formed from **10** and $[W(CO)_5(thf)]$[15] in tetrahydrofuran at room temperature (45%, yellow crystals, m.p. = 61 °C). The end-on coordination of the $(CO)_5W$ fragment results in an upfield shift of 23 ppm of the ^{31}P-NMR signal ($CDCl_3$). In the corresponding chromium complex (**9**, Cr instead of W),[16] on the other hand, a paramagnetic shift of 37 ppm is observed.[17]

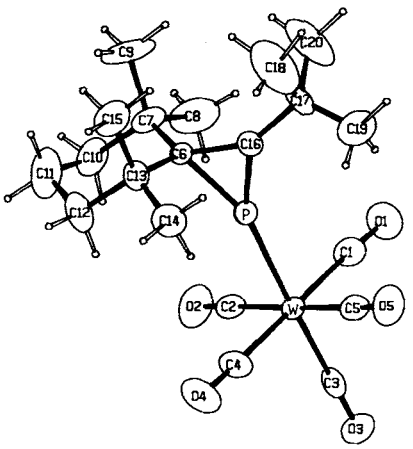


Fig. 1. Molecular structure of **9** (ORTEP). The thermal ellipsoids correspond to the 27% probability level. Selected bond lengths [Å] and angles [°]: W-P 2.458(1), W-C1 2.004(6), W-C2 1.997(6), W-C3 1.965(5), W-C4 2.029(6), W-C5 1.999(5), P-C6 1.881(4), P-C16 1.634(4), C6-C16 1.482(6); W-P-C6 157.7(2), W-P-C16 153.1(2), C6-P-C16 49.2(2), P-C6-C16 56.7(2), P-C16-C6 74.1(3), C7-C6-C13 116.4(4). The *t*Bu group is poorly defined owing to large thermal vibration amplitudes [18].

As revealed in Figure 1, the phosphirene ligand in **9**[18] occupies a site in the coordination octahedron around the tungsten atom. As found for other metal complexes of $\lambda^3\sigma^2$ phosphorus compounds (phosphaalkenes,[19,20] 1,2,3-σ^2-diazaphosphole[17]), the phosphorus atom exhibits nearly planar coordination (angle between P–W vector and the three-membered ring, 1.4°). In comparison to other free[11,21,22] and complexed[19,20] phosphaalkenes, the P=C bond (1.634(4) Å) is strikingly short; on the other hand, the P–C bond in the phosphirene three-membered ring is ca. 0.03 Å longer than the P–C_{sp^3} bond in a phosphaalkene.[21] The P–W distance is ca. 0.03 Å shorter than that in a 2*H*-phosphole, in which the P=C bond, however, functions as a four-electron donor.[23] The shortening of the W–C_{trans} bond (1.965 Å) compared with the W–C_{cis} bonds (mean 2.007 Å) is in accord with expectations.

$[\{(C_5H_5)Co\}_3(C_6H_5CH{=}CHCH_3)]$, an Organometallic Cluster with a Face-Bridging Arene Ligand**

By *Hubert Wadepohl,* Klaus Büchner,* and *Hans Pritzkow*

Molecular complexes in which an arene is bound to more than one metal atom are still rare.[1] Although numerous transition-metal clusters containing η^6-arene ligands are known,[1] the first complexes with a μ_3-η^2:η^2:η^2-benzene ligand attached to a M_3-face was reported only two years ago.[2] Herein we report the one-pot synthesis of the arene complex $[(CpCo)_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}trans\text{-}\beta\text{-methylstyrene})]$ **1** (Cp = C_5H_5), in the course of which the trinuclear metal cluster is assembled on the arene bearing an unsaturated side chain. The Jonas reagent $[CpCo(C_2H_4)_2]$[3] smoothly reacts with *trans*-β-methylstyrene at 20–60°C to give **1** in high yield;[4] allylbenzene, which is quantitatively rearranged in the course of the reaction, likewise affords **1** under similar conditions. With benzene or toluene no reaction takes place.

$$3[CpCo(C_2H_4)_2] + C_6H_5CH{=}CHCH_3 \xrightarrow{-6C_2H_4} \underset{\mathbf{1}}{[(CpCo)_3(C_6H_5CH{=}CHCH_3)]}$$

The constitution of **1** clearly follows from the spectra:[5] the absence of ^{1}H-NMR signals in the region typical of free arenes points to an arene complex. The mass spectrometrically determined composition [(CpCo)$_3$(methylstyrene)], however, is reconcilable with the NMR spectra only in terms of the arene ligand freely rotating on top of the triangular $(CpCo)_3$ moiety on the NMR time scale.[6] The ^{13}C-NMR signals of the arene are noticeably shifted upfield compared to the values found in η^6-arene complexes.[7] The *trans*-configuration of the side chain is unequivocally confirmed by the ^{1}H-^{1}H-coupling pattern of the olefinic protons H6 and H7. To obtain more detailed information about the bonding, an X-ray crystal structure analysis was carried out on **1**.[8]

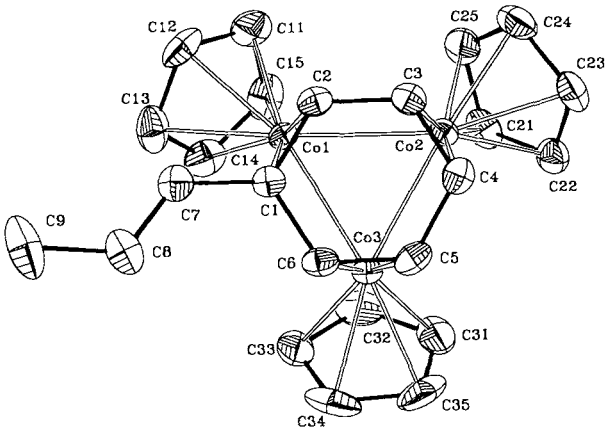

Fig. 1. Molecular structure of **1**. Selected bond lengths [Å] (standard derivations Co-C 0.002, C-C 0.005): Co1-Co2 2.501, Co1-Co3 2.503, Co2-Co3 2.496, Co1-C1 2.059, Co1-C2 2.019, Co2-C3 2.027, Co2-C4 2.027, Co3-C5 2.023, Co3-C6 2.017, C1-C2 1.432, C2-C3 1.435, C3-C4 1.412, C4-C5 1.438, C5-C6 1.415, C6-C1 1.466, C1-C7 1.461, C7-C8 1.317, C8-C9 1.512.

An equilateral triangle of Co atoms is bridged symmetrically by the planar (largest deviation 0.02 Å) arene; The Co_3-triangle and the C_6-ring are coplanar and staggered with respect to each other (Fig. 1). The plane of the 1-propenyl side chain is twisted by 17.4° with respect to the ring plane. Surprisingly, the C–C bond lengths in the aromatic ring show only slight, scarcely significant alternance (mean values 1.420(5) and 1.446(5) Å). The substituents on C1–C6 are displaced from the ring plane away from the Co atoms (C7 0.45 Å, H1 to H5 0.2 to 0.3 Å). In comparison the crystal structure analysis of **2**[2] does not allow an assessment of bond alternance in the benzene ring. However, alternat-

ing longer and shorter bonds (mean values 1.39(2) and 1.48(2) Å), corresponding to a cyclohexatriene, are present in the μ_3-bridging ligand of **3**.[2]

$[Os_3(CO)_9(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_6H_6)]$ **2**
$[Ru_6C(CO)_{11}(\mu_3\text{-}\eta^2:\eta^2:\eta^2\text{-}C_6H_6)(\eta^6\text{-}C_6H_6)]$ **3**

On metal single crystals benzene and other aromatic hydrocarbons are adsorbed molecularly parallel to the close-packed surfaces (e.g. Ni(111) or Rh(111)).[9] However, there is some uncertainty about the orientation relative to the surface metal atoms (C_6 centroid above a metal atom, a 2-fold (M_4) or 3-fold (M_3) metal site).[9, 10] According to LEED investigations (LEED = low energy electron diffraction) of coadsorbates C_6H_6/CO and C_6H_6/2CO on Rh(111) (planar benzene fixed in 3-fold coordination sites) benzene has, at least in these cases, the Kekulé structure with strongly alternating bond lengths.[11] In contrast, a planar arene with virtually equal bonding fixed in a 3-fold metal coordination site is present in **1** — a remarkable finding in view of the postulated analogy between metal surfaces and clusters.[12]

The unsaturated side chain on the benzene ring appears to be the prerequisite for the formation of **1**. We assume initial attack of a CpCo fragment at this site. Assembly of the metal cluster could then proceed (if necessary after shifting of the double bond into the α-position to the arene) via an intermediate with methylstyrene as a doubly η^4-coordinating diene (3-6-η, 1-2:7-8-η). Related structures, albeit with metal atoms coordinating the bridging ligands from opposite sides, were derived from NMR spectroscopic data for $[\{Fe(CO)_3\}_2]$-complexes of substituted styrenes[13] and $[\{(C_5Me_5)Co\}_3(\eta^4:\eta^4:\eta^4\text{-biphenyl})]$.[14] Reaction of the intermediate with a further CpCo fragment and rearomatization of the arene could then lead to **1**.

Reactions of 2,2,4,4-Tetramethyl-3-methylenecyclobutylidene; Thermal Rearrangements of a 2-Methylenebicyclo[2.1.0]pentane**

By *Udo H. Brinker** and *Wolfgang Erdle*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

Small ring carbenes are important reactive building blocks for the synthesis of highly strained, polycyclic compounds.[1] Cyclobutylidenes preferentially undergo ring contractions to give methylene cyclopropanes.[2] We have examined the extent to which possible interactions between carbene center and an *exo*-methylene group in the 2-[3] or 3-position influence the rearrangement behavior of 2,2,4,4-tetramethyl-3-methylenecyclobutylidene **4**. Besides ring contraction to give **7** there are further intramolecular reactions open to **4**, e.g. insertion into a C–H bond of the neighboring CH_3 groups with formation of the strained 2-methylenebicyclo[2.1.0]pentane **6**. A spectacular addition of the carbene **4** or of the diazo group in **3** to the *exo* double bond could result in formation of the tetramethyl-substituted [1.1.1]propellane **8** or the corresponding 4,5-dihydro-3*H*-pyrazole. That is, the highly-strained propellane skeleton[4] would either have to be formed directly via the structurally integrated allylcarbene[5] in **4** with concomitant formation of *three* cyclopropane rings or only after cleavage of N_2 from the dihydropyrazole.

The 3-methylenecyclobutanone **1**[6] required for the formation of the tosylhydrazone-sodium salt **2** was synthesized from commercially available 2,2,4,4-tetramethyl-1,3-cyclobutanedione.[6] The reaction of **1** with *p*-toluenesulfonylhydrazide afforded the corresponding tosylhydrazone in 92% yield, which on reaction with sodium hydride furnished the sodium salt **2** in almost quantitative yield (97%).

Upon flash pyrolysis[4] of **2** at 240–290°C (10^{-4}–10^{-5} torr) a pink-colored pyrolyzate was obtained whose IR spectrum (CCl_4) showed a strong band at 2020 cm^{-1} ($R_2C{=}N{=}N$ valence vibration). The diazo compound **3**

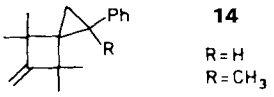
could be enriched if the decomposition of **2** took place between 120 and 130 °C ($<10^{-4}$ torr). The half-life of ca. 6700 s at 31.5 °C shows that **3** is kinetically highly stabilized in comparison to the diazocyclobutane, which is unstable at room temperature.[7] The "longevity" of **3** at 240–290 °C is also reflected in the relatively high yield of azine **5** (20–30%). At these temperatures in addition to some toluene (ca. 3%) seven hydrocarbons are formed in a total yield of 72% (isolated by preparative gas chromatography). 1-Isopropylidene-2,2-dimethyl-3-methylenecyclopropane **7**,[8] which could be formed by a cyclobutylidene-methylenecyclopropane rearrangement of **4**, is isolated in 35% (42% relative) yield. A 1,3-insertion of the carbene carbon into one of the C–H bonds of the four methyl groups results in formation of the strained 1,3,3-trimethyl-2-methylenebicyclo[2.1.0]pentane **6**[8] (27% relative, 15% isolated). As will be shown below, the methylenecyclopentenes **9** (10%, 8%)[8] and **10** (6%, 3%)[8] as well as the allene **11** (11%, 7%)[8] are secondary products of **6**. In addition, diisopropylidenecyclopropane **12**,[9] which could not be formed directly from the carbene **4**, was isolated in 2–3% (4% relative) yield.

Two possible routes come into consideration for the formation of **12** from **4**: 1. The intermediary tetramethyl[1.1.1]propellane **8** resulting from the intramolecular carbene addition (or a 1,3-dipolar cycloaddition of **3** via 4,5-dihydro-3*H*-pyrazole and subsequent N_2 cleavage) rearranges directly to **12**. The parent compound [1.1.1]propellane[5] yields exclusively dimethylenecyclopropane at 430 °C under flow pyrolysis conditions![10] 2. An isomerization of **7** takes place, and the geminal cyclopropane methyl groups are moved to the terminal carbon of the double bond via methylenecyclopropane rearrangement.[11] In the flow pyrolysis[12,13] of **7** at 550 °C (0.1 torr, quartz tube filled with quartz chips)[12] **12** is formed in 61% yield. This result suggests that 2–3% of **7** is also converted into **12**[14] under the conditions of the flash pyrolysis.[3,12]

In addition, 1,1-dimethyl-2-(2-methyl-1-propenylidene)cyclopropane **13**[13b,14] could be identified as a further product (<1%) of the pyrolysis. In the carbene **4** the 1,3-C–H insertion to give **6** (+**9**+**10**+**11**) dominates over the ring contraction to **7** (+**12**) in the ratio of ca. 1.2:1.

The photolysis (Pyrex, Philips HPK, 125W) of an ethereal suspension of **2** between 0 and 20 °C afforded the hydrocarbons **7** and **6** in 40 and 35% yield, respectively. In addition, ca. 5–10% azine **5**, 0.8% **12** and ca. 1% ketone **1** were isolated. **2** was decomposed thermally and photochemically also in the presence of styrene and α-methylstyrene. In the photolysis the spiro[2.3]hexanes **14** are formed in yields of 28–35%. The long lifetime of the diazo compound **3** suggests that spirohexane formation takes place by 1,3-dipolar cycloaddition of **3** via intermediary dihydropyrazoles.[15]



The thermolysis of **6** in the gas phase at 140–190 °C leads to formation of **9**, **10**, and **11**; their formation follows a first order rate law with the given activation parameters (see formula). This suggests formulating the formation of **9**, **10**, and **11**—as in the case of the unsubstituted bicyclo[2.1.0]pentane[16]—via a diradical **15**. Consistent with this interpretation the flow pyrolysis[13a] of the allene **11** affords, besides *p*-xylene, the isomers **9** and **10** (**9**:**10**:**11** = 7:4:89). The assumption of an intermediary diradical also makes the markedly lower activation energies compared to the parent system understandable. For the formation of **9** and **10** these are ca. 11 kcal mol^{-1} lower compared to the cyclopentene formation (E_a = 45.6 kcal mol^{-1}),[16] whereby the resonance stabilization of the allyl radical should make the greatest contribution.

[12] The results of the flow and the flash pyrolyses [3] cannot be compared with each other directly. Thus, the dry sodium salt of the tosylhydrazone is transferred in solid form into the reaction flask, where it decomposes on the hot glass surface. In contrast, the liquid hydrocarbons must be passed in the gas phase through a furnace-heated quartz tube.
[13] a) Under flow pyrolysis conditions (0.1 torr, quartz tube, $l = 30$ cm, $\varnothing = 1$ cm, packed with quartz chips) **12** first begins to convert into **7** above 400°C (575°C; **12** : **7** = 43 : 57); b) **3** rearranges completely to **12** at 300°C.

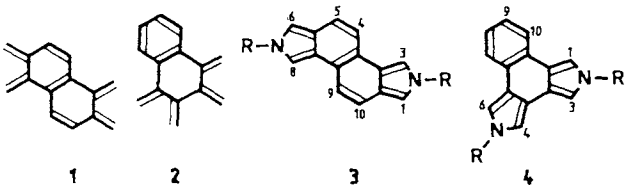
Annelated Isoindoles with an 18π-Electron System**

By *Richard P. Kreher** and *Thomas Hildebrand*

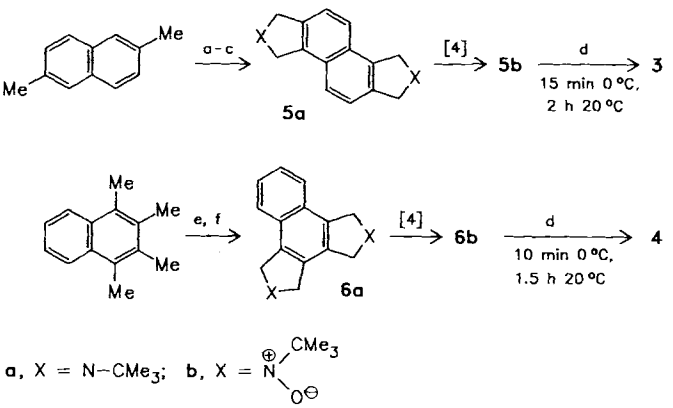
Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

The radialenes **1** and **2** of naphthalene[2] have been postulated as reactive intermediates and have been suggested as precursors for tetrahydrodicyclobuta[*a,f*]- and tetrahydrodicyclobuta[*a,c*]naphthalenes, respectively. By bridging with two alkylimino groups, it is possible to establish the labile radialene structure. The corresponding tetracyclic heteroarenes **3** and **4** are stabilized by cyclic conjugated 18π-electron systems. Noteworthy in the heteroarene **3** are the annelated 2*H*-isoindole moieties and the central triene system; the isoelectronic heteroarene **4**, on the other hand, is characterized by a "nonperturbed" peripheral benzenoid ring system.[3]



1 **2** **3** **4**

The convergent synthesis of the tetracyclic heteroarenes **3** and **4** makes use of the *N*-oxide route[4] for formation of the pyrrole rings. The preparative effort involved is mainly determined by the requirement of obtaining the corresponding tetrafunctional naphthalenes.



Scheme 1. Synthesis of **3** and **4**, R = CMe_3. a) HBr/formaldehyde in acetic acid/phosphoric acid, 6.5 h reflux. b) *N*-Bromosuccinimide in CCl_4, 45 min reflux. c) *tert*-Butylamine in benzene added over 3 d under reflux, 16 h room temperature. d) Acetic anhydride/triethylamine in $CHCl_3$; 15 min 0°C, 2 h room temperature. e) *N*-Bromosuccinimide in CCl_4, 1 h reflux. f) *tert*-Butylamine in $CHCl_3$ added over 3 d under reflux, 2 h reflux. **5b**: 98% yield, m.p. 163–164°C; **6b**: 71% yield, m.p. = 151°C.

The synthesis of the heteroarene **3**, R = CMe_3, starts from commercially available 2,6-dimethylnaphthalene (Scheme 1). An acceptable yield is obtained by halomethylation[5] of the reactive 1,5 positions. Radical bromination of the methyl groups in the 2,6 positions is followed by facile cyclization with *tert*-butylamine leading to **5a**. Acetolysis of the *N,N*-dioxide **5b**, which is likewise easily carried out, results in aromatization to form **3**.

In order to synthesize the heteroarene **4**, R = CMe_3, synthetically accessible 1,2,3,4-tetramethylnaphthalene[6] is substituted via radical bromination (Scheme 1). The subsequent ring closure occurs in spite of competing reactions with a satisfactory yield of **6a**. Compound **6a** is converted into the *N,N*-dioxide **6b**, which, in turn, is caused to undergo aromatization.

The structural differences in the isoelectronic heteroarenes **3** and **4** are manifested in their chemical behavior. Cycloaddition reactions, which are expected for **3**, are indeed observed. Treatment with *N*-methylmaleimide results, via addition to a pyrrole ring, in the formation of a 1 : 1 cycloadduct having the topology of 2*H*-benz[*e*]isoindole; the reactivity of this 14π-electron system is decreased by

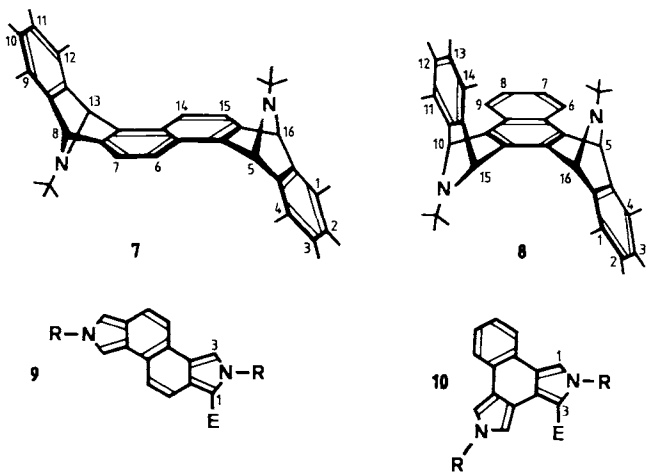
[**] Structure and Reactivity of Isoannelated Heterocyclic Systems with 4nπ and (4n+2)π Electrons, Part 13. This work was supported by the Fonds der Chemischen Industrie.

the *tert*-butyl groups,[7] so that dienophiles no longer react with the *o*-quinonoid diene system of the second pyrrole ring. On the other hand, **4** does not react with *N*-methylmaleimide, even though the 2*H*-benz[*e*]isoindole moiety should also be formed in the reaction with the diene system of a pyrrole ring. This behavior is presumably determined by the vicinal annelation of the pyrrole rings on the naphthalene framework and the resulting steric repulsion.

Chemical proof of the twofold *o*-quinonoid structure was achieved by reaction of the heteroarenes **3** and **4** with activated alkynes. Reaction of dimethyl acetylenedicarboxylate with **3** results in the formation of a crystallizable 2:1 cycloadduct. In this cooperative process, the *anti* arrangement predominates to the extent of ca. 80%. The reaction with the isoelectronic heteroarene **4**, on the other hand, does not occur in a uniform manner, presumably for steric reasons.

Both **3** and **4** react with 3,4,5,6-tetramethyl-1,2-dehydrobenzene, generated from 1,2-dibromo-3,4,5,6-tetramethylbenzene and methyllithium. No topological selectivity is observed in this cycloaddition, since the *o*-quinonoid 14π-electron system of the intermediate 2*H*-benz[*e*]isoindole also undergoes reaction. In the twofold cycloaddition yielding **7** and **8**, the *anti* arrangement of the annelated rings predominates; less than 3% of the *syn* product can be detected by ^{1}H-NMR spectroscopy in the case of the heteroarene **3**, which has isolated reactive centers. The constitution and configuration of the cycloadduct **8** were confirmed by X-ray structure analysis.[8]



E = N=N-C_6H_4-NO_2, R = CMe_3

4-Nitrobenzenediazonium tetrafluoroborate is a suitable reagent for S_E reactions. Monosubstitution of **3** and **4** leads to the heteroarenes **9** and **10**, respectively; the same regioselectivity is observed for 2*H*-benz[*e*]isoindole.[7] The disubstitution reaction in the case of **9** apparently depends on electronic factors, whereas in the case of **10** steric factors are important.

Selected data for the new compounds are listed in Table 1.

In summary, the tetracylic heteroarenes **3** and **4** behave like systems with localized isoindole structures;[9] the topology of the π system is the determining factor for the chemical reactivity and selectivity. Thermodynamic stabilization of radialene structures by the incorporation of alkylimino groups is obvious; this promising stabilization concept should be generalizable to other carbocylic intermediates.

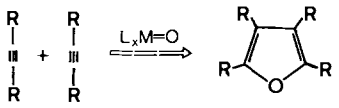
[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 51. This work was supported by the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, and the Fonds der Chemischen Industrie.—Part 50: [2].

tives.[1] A catalytic realization of this novel oxidative coupling of two alkynes, which is also possibly useful for the synthesis of thiophenes and pyrroles, has so far not been achieved due to a lack of detailed information about the mechanism involved. There are indications that formation of the two O-C bonds occurs before that of the C-C bond,[1] and apparently involves several reaction steps at rhenium centers in medium oxidation states. Since organorhenium oxides related to $[(\eta^5\text{-}C_5Me_5)ReO_3]$ have proven to be useful catalysts for the metathesis of open-chain alkenes as well as for the metathetical ring-opening polymerization of cycloalkenes to polyalkenamers with elastomeric properties,[2] we have concerned ourselves with gaining a better insight into the mechanisms involved in such catalytic reactions. We now report on the synthesis and structures of relevant model compounds.



Scheme 1. $L_xM{=}O$ = $(\eta^5\text{-}C_5Me_5)ReO_3/PPh_3/I_2$.

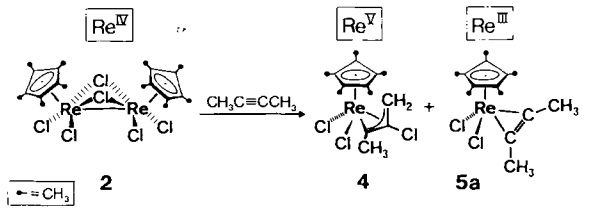
The organorhenium(V) halides

$[(\eta^5\text{-}C_5Me_5)ReX_4]$ **1a**, X = Cl; **1b**, X = Br

obtainable from the organorhenium(VII) oxide $[(\eta^5\text{-}C_5Me_5)ReO_3]$[3] by reductive halogenation can be reduced with HgX_2-activated aluminum powder in the presence of alkynes to rhenium(III) complexes of the type $[(\eta^5\text{-}C_5Me_5)ReX_2(\eta^2\text{-}RC{\equiv}CR)]$ **5**. In the absence of coordinating ligands, however, the reduction of **1a** first leads selectively to the dinuclear Re^{IV} complex **2**, which is further reduced to the chlorine-deficient Re^{III} derivative

$[(\eta^5\text{-}C_5Me_5)_2Re_2Cl_4]$ **3**

containing a ReRe double bond between two Cl bridges. The two diamagnetic compounds were characterized by X-ray structure analyses.[4] Whereas the complex **3** generally proved to be less reactive, the Re^{IV} derivative **2** was found to be a convenient source for a variety of mononuclear products. Thus, its reaction with 2-butyne in the absence of oxygen and moisture leads with disproportionation according to Scheme 2 to formation of the Re^{III} complex **5a** and the novel rhenium(V)-allenylidene complex **4** (each in 50% yield; Table 1); the unexpected constitution of **4** was established by an X-ray structure analysis (Fig. 1).[5]



Scheme 2.

The structure of the product **4**, which can be separated from the 2-butyne complex **5a** by column chromatography on silylated silica gel (−10 °C), consists of a $[(\eta^5\text{-}C_5Me_5)ReCl_2]$ moiety which forms a non-planar four-membered ring geometry with the ligand derived from 2-butyne (Fig. 1). Interesting here is that an H atom is cleaved from one of the two methyl groups. Moreover, a Cl atom originally attached to the metal migrates to C2 of the alkyne. The C_4-ligand resulting from the alkyne can best be described as a substituted allyl system, with a carbene/olefin resonance structure (C3 and C1, C2, respectively) contributing to its metal-fixation. The alternative metallacyclobutene structure[6] can be ruled out because of the

Table 1. IR and NMR data of some new compounds.

Cpd.	IR (KBr) [cm^{-1}]	^{1}H-NMR (270 MHz) [δ values]	^{13}C-NMR (68 MHz) [δ values]
4	ν(Re–Cl): 325, 290	4.31 (dq, 1H; ^2J = 3.29 Hz, ^5J = 0.32 Hz) 3.27 (dq, 1H; ^2J = 3.29 Hz, ^5J = 1.93 Hz) 2.76 (dd, 3H; ^5J = 1.93 Hz, ^5J = 0.32 Hz) 1.99 (s, 15H) [a]	265.2, 102.6, 102.4, 51.5, 27.1, 10.9 [c]

8c	ν(C≡C): 1780	3.52 (q, 2H), 3.43 (q, 2H), 3.21 (s, 3H), 2.86 (s, 3H), 1.96 (s, 15H), 1.43 (t, 3H), 1.07 (t, 3H) [d]	178.8, 176.9, 169.2, 166.7, 111.9, 26.7,23.8, 17.8, 15.2, 14.2, 13.9, 10.8 [d]

[a] 400 MHz, $CDCl_3$, 20 °C. [b] CD_2Cl_2, 30 °C. [c] $CDCl_3$, 20 °C. [d] $CDCl_3$, −20 °C; coalescence of the methyl group signals of the butyne ligands in **8b** observed at ca. 30 °C upon heating, $\Delta G^{\neq} = 60 \pm 5$ kJ/mol; further heating to 50 °C: δ = 3.06 (s, 6H), 1.99 (s, 15H); **8c** exhibits similar behavior.

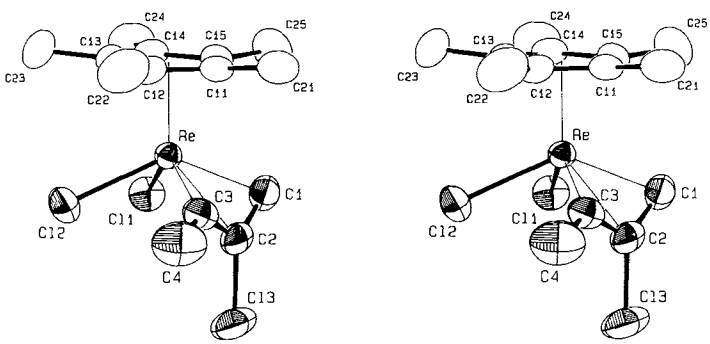

Fig. 1. Stereoview (ORTEP diagram) of the crystal structure of **4** (without H atoms). The vibration ellipsoids are at the 50% probability level.—Selected bond lengths [pm] and angles [°]: Re-C1 219.2(3), Re-C2 224.2(3), Re-C3 196.7(3), C1-C2 141.0(4), C2-C3 136.3(4), C3-C4 147.7(5), Cl3-C2 178.8(3), Re-Cl1 239.1(1); Re-Cl2 241.9(1); C1,C2,C3 117.3(3), C2,C3,C4 131.9(3), Cl3,C2,C1 121.7(3), Cl3,C2,C3 119.7(3), Cl1,Re,Cl2 82.27(3), C1,Re,C3 69.2(1). The C_5Me_5 ligand is decentrally coordinated to the metal (Re–C_{ring} 220.4–237.5 pm).—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52602, the names of the authors, and the journal citation.

non-planarity of the ReC_3 substructure (cf. Fig. 1). Thus, the Re-C1 and Re-C2 distances (219.2(3) and 224.2(3) pm, respectively) differ very little from the bond lengths in related allyl complexes such as the Re^{IV}-compound $[(\eta^5\text{-}C_5Me_5)ReBr_2(\eta^3\text{-}C_3H_5)]$.[7] The Re-C3 distance, on the other hand, is shorter (196.7(3) pm) and indicative of double bond character (Re-C distances in carbene complexes of rhenium are 192–197 pm). The system apparently chooses a compromise between the coordination geometry to be expected for a pure allyl and that for a pure carbene-ligand. This is reflected quite markedly in the angle and bond-length deformation in the corresponding structural units. The position of the rhenium atom, 130 pm above the plane through C1C2C3 and 70 pm above the plane through C2C3C4 (interplanar angle 21.0°) is also consistent with this concept.[7,8]

The π-bonded alkyne ligands, as 4e ligands with considerable multiple-bond character in the complexes **5a–5d**, are not easily cleaved from the metal atom, but the rhenium–halogen bonds permit a variety of secondary reactions. Thus, the corresponding diiodo derivatives are smoothly obtainable with sodium iodide in acetone, a typical example being the complex

$[(\eta^5\text{-}C_5Me_5)ReI_2(CH_3C{\equiv}CCH_3)]$ **5e**

Stepwise alkylation and hydrolysis reactions with formation of the complexes

$[(\eta^5\text{-}C_5Me_5)ReCl(CH_3)(CH_3C{\equiv}CCH_3)]$ **6a**
$[(\eta^5\text{-}C_5Me_5)Re(CH_3)_2(CH_3C{\equiv}CCH_3)]$ **6b**
$[(\eta^5\text{-}C_5Me_5)Re(=O)(CH_3C{\equiv}CCH_3)]$ **6c**

are also possible. Reaction of **5a–5d** with $Ag[SbF_6]$ according to Scheme 3 affords access to cationic species stabilized by σ or π ligands. The pyridine- and alkyne complexes **7** and **8**, respectively, which are not interconvertable exemplify the efficiency of this simple synthetic principle.

	5a	5b	5c	5d	5e	8a	8b	8c	8d
X	Cl	Cl	Br	Br	I	Cl	Br	Br	Br
R	Me	Et	Me	Et	Me	Et	Me	Me	Me
R'	–	–	–	–	–	Et	Me	Et	C_6H_5

Scheme 3.

The diamagnetism of the bis(π-alkyne) complexes **8** and the upfield shift of the ^{13}C-NMR signals of their alkyne C-atoms compared to the corresponding resonances of the mono(π-alkyne) complexes **5** can only be interpreted in terms of these two ligands contributing a total of six electrons to the bonds to the central metal. Temperature-dependent NMR investigations on the 3-hexyne and 2-butyne omplexes **8a** and **8b**, respectively, confirm the chemical equivalence of the alkyne ligands and rule out different bonding mechanisms or electron-balances. The especially easily accessible bis(π-alkyne) complexes **8** belong to the hitherto lesser known systems of this type[9] which serve as model compounds for intermediates of the rhenium-based furan synthesis of Scheme 1.

Experimental

4: A solution of **2** (410 mg, 0.5 mmol) in dichloromethane (10.0 mL) and dry 2-butyne (3.0 mL) was heated under reflux for 1 h. The volatile components were then removed in a vacuum and the green residue subjected to column-chromatography on silylated silica gel/*n*-hexane ($l = 40$ cm; $d = 1.5$ cm; −10°C). **4** was eluted as a lime-green broad zone with *n*-hexane/dichloromethane (10+1 parts by volume). **5a** was then eluted as a golden yellow zone with *n*-hexane/dichloromethane (10+3 parts volume). Yields after recrystallization from *n*-hexane/dichloromethane: 170 mg of **4** (decomp. at 145°C) and 140 mg of **5a** (decomp. at 75°C).—**5a** is more conveniently accessible in analogy to the procedure for **5c** (yield 90%).

5c: A suspension of **1b** (1.5 g, 2.3 mmol) in 12 mL of THF and 8.0 mL of 2-butyne was treated with 400 mg of granulated aluminum. After addition of a catalytic amount of $HgBr_2$ the mixture was vigorously stirred for 30 min at room temperature. After removal of unused aluminum by filtration, the reddish orange solution was evaporated to dryness in a vacuum. The residue was repeatedly extracted with 20 mL portions of *n*-hexane/dichloromethane (4+1 parts by volume). The combined extracts were evaporated down in a vacuum and the desired product **5c** allowed to crystallize out at −25°C. Yield 1.10 g (90%) (decomp. at 85°C).

8b: 110 mg (0.2 mmol) of **5c** and 0.5 mL of dry 2-butyne were dissolved in 5 mL of dichloromethane at −78°C and the mixture treated in the dark with a solution of 60 mg (0.18 mmol) of $Ag[SbF_6]$ in 1 mL of dichloromethane. Upon slowly heating to room temperature the color of the solution changed from reddish brown to brilliant orange. After removal of precipitated AgBr by filtration the solution was evaporated to dryness and the residue repeatedly washed with 10 mL portions of diethyl ether. Recrystallization from *n*-hexane/dichloromethane (1/1 parts by volume) furnished 120 mg (80%) of **8b** (decomp. at 165°C).

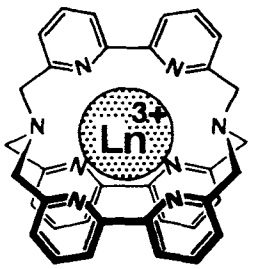
Luminescence Probes: The $Eu^{3\oplus}$- and $Tb^{3\oplus}$-Cryptates of Polypyridine Macrobicyclic Ligands

By *Béatrice Alpha, Vincenzo Balzani,* Jean-Marie Lehn,* Siglinda Perathoner,* and *Nanda Sabbatini*

There is currently a growing interest in the luminescence properties of lanthanoid complexes because of their importance as probe ion species,[1-6] especially for biological applications. Particularly promising are the cryptate complexes[7] where the luminescent lanthanoid ion is encapsulated into the ligand structure.[8-12] In this way, one may reach some important goals: (1) inertness of the complex;[8,12] (2) protection towards deactivating interactions between the luminescent lanthanoid ion and solvent (water);[9-11] (3) efficient energy transfer from the (strongly absorbing) ligand chromophore to the luminescent metal ion.[12,13] These three features are combined in the lanthanoid cryptates[12,14] of macrobicyclic ligands containing the 2,2′-bipyridine (bpy) or 1,10-phenanthroline chromophoric groups.[15]

We have carried out a systematic investigation on the photophysical properties of the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ complexes **1** and **2**[12] and we have found that these species are efficient molecular devices for the conversion of the UV light absorbed by the ligands into visible luminescence of the lanthanoid ions. In view of their interest, in particular as luminescent labels in aqueous solution, we briefly report here some results of our measurements.



1, Ln = Eu
2, Ln = Tb

Absorption and emission data for **1** and **2** in aqueous solution are shown in Table 1 where data for the corresponding aquo ions[16,17] are also reported for comparison purposes. The cryptate complexes exhibit strong ligand-centered (LC) absorption bands in the near UV region, 10^4-10^5 times more intense than the metal-centered (MC) f-f bands characteristic of the lanthanoid ions. The wavelength of the luminescence emission originating from the $^5D_0$ and $^5D_4$ levels of $Eu^{3\oplus}$ and $Tb^{3\oplus}$, respectively,[3] is almost unaffected by the coordinating environment (water or cryptand ligands), whereas the excited-state lifetimes and the luminescence quantum yields are strongly modified (Table 1). From the lifetime values in H_2O or D_2O solution it is possible to evaluate[2,3] the average number of coordinated water molecules (estimated error, ±0.5): **1**, 2.5; $Eu^{3\oplus}_{aq}$, 9.6; **2**, 3.0; $Tb^{3\oplus}_{aq}$, 9.0. These figures show the capability of the cryptand ligand to shield the metal ion from the solvent molecules.

Table 1. Absorption and emission data for $Eu^{3\oplus}$ and $Tb^{3\oplus}$ aquo ions and cryptates **1** and **2** in aqueous solution.

Complex	Absorption [a]		Emission [b]					
	λ_{max} [nm]	ε_{max} [M^{-1} cm^{-1}]	λ_{max} [nm]	$\tau^{300K}_{H_2O}$ [ms]	$\tau^{300K}_{D_2O}$ [ms]	$\tau^{77K}_{D_2O}$ [ms]	Φ [c]	η [d]
1	304 (LC)	25000	615 [e]	0.34	1.7	1.7	0.02	0.1
$Eu^{3\oplus}_{aq}$	393 (f-f)	3	616 [e]	0.11	3.2	3.3	0.006	—
2	304 (LC)	29000	542 [f]	0.33	0.43	3.8	0.03	0.3
$Tb^{3\oplus}_{aq}$	308 (f-f)	0.3	543 [f]	0.40	3.8	3.8	0.08 [g]	—

[a] Excitation wavelength; LC, ligand-centered band; f-f, metal-centered band. [b] Experimental uncertainties: lifetimes, < 10%; quantum yields, ca. 30%. [c] H_2O solution, room temperature. [d] Energy-transfer efficiency, given as the ratio between the emission quantum yield for LC excitation and excitation into the $^5D_0$ (for $Eu^{3\oplus}$) or $^5D_4$ (for $Tb^{3\oplus}$) emitting levels. The latter quantity has been evaluated from the ratio between the emission lifetime in H_2O at 300 K and the emission lifetime in D_2O at 77 K, taken as the radiative lifetime. [e] Assigned to the $^5D_0 \rightarrow {}^7F_2$ transition (most intense emission band). [f] Assigned to the $^5D_4 \rightarrow {}^7F_5$ transition (most intense emission band). [g] Excitation in the emitting $^5D_4$ level [17].

In H_2O solution at room temperature, the quantum yields of luminescence emission on excitation in the high-intensity ligand-centered band at ca. 300 nm are 0.02 for **1** and 0.03 for **2**. The reason for the lower than unity luminescence quantum yield is the competition between intraligand radiationless decay of ^3LC to the ground state and intramolecular $^3LC \rightarrow (MC)^5D_0$ (for $Eu^{3\oplus}$) or $^3LC \rightarrow (MC)^5D_4$ (for $Tb^{3\oplus}$) energy transfer (for details see Ref. [18]).

In conclusion, because of their very intense absorption bands, which collect incident light, and because of their reasonably high ligand-to-metal energy transfer and luminescence efficiencies, the cryptates **1** and **2** are excellent molecular devices to play the role of luminescence probes and luminescence concentrators (antenna effect). Even in very diluted *aqueous* solutions (ca. 10^{-5} M), they are able to convert about 1% of the *incident* UV photons into emitted visible photons, a quite interesting result for several applications, in particular for labeling of biological materials. Higher conversion efficiency may be attained if structural modifications are found which increase both the shielding of the enclosed ion and the yield of intramolecular energy transfer.

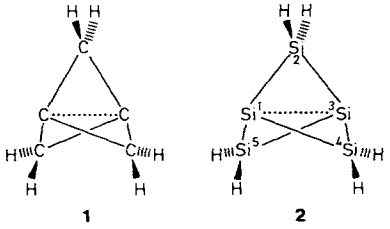
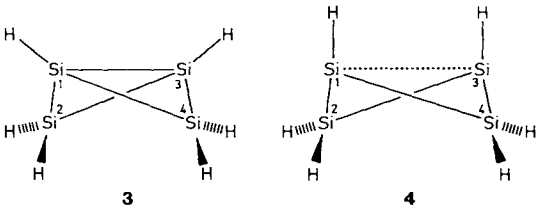
Pentasila[1.1.1]propellane. Predictions Concerning Structure, Bonding, and Strain Energy**

By *Paul von Ragué Schleyer** and *Rudolf Janoschek**

Because of its inverted carbons, high ring strain, the nature of the bonding between the bridgehead atoms, and, most certainly, its availability through synthesis, [1.1.1]propellane, **1**, is an exceptionally intriguing species.[1-4] Whether or not there is a central bond in **1**, or, if so, to what extent, is being hotly debated.[1-4] Similar questions pertain to pentasila[1.1.1]propellane (tricyclo[1.1.1.0]pentasilane, **2**), the silicon analogue of **1**. Small-ring silicon systems are providing instructive comparisons and contrasts with their carbocyclic analogues. In particular, we have predicted recently that two "bond stretch" isomers of bicyclo[1.1.0]tetrasilane, **3** and **4**, should be capable of existence.[5,6] One of these, **3**, with an essentially classical structure, has an experimental precedent,[6b] but derivatives of the more stable **4**, which can be regarded as a singlet diradical requiring a multiconfigurational description, are not yet known. As we mentioned,[5] similar structural possibilities exist for **2**. We now describe the nature of this species.



1 **2**



3 **4**

At all ab initio levels investigated, which include single-determinant optimizations with the 3-21G (sp), 3-21G* (spd), and pseudopotential-21G* (spd) basis sets, as well as multiconfigurational (MC-SCF) treatment with the latter method,[7] no minimum corresponding to a "classical" structure of **2** could be located. Like **3**, a classical geometry of **2** would be expected to have nearly equal Si1Si2 and Si1Si3 bond lengths. Instead, when these distances were set to 2.3 Å, optimization led automatically to extension of the central bond (see equilibrium values in Table 1). In order to rule out the possibility of a second minimum with a shorter Si–Si bridge distance, a series of two-configuration MC-SCF (spd) calculations were carried out with various fixed Si1Si3 distances, all other parameters being allowed to vary within the restriction of D_{3h} symmetry. As the results in Table 2 indicate, there was no second minimum. Thus, particularly with regard to the length of the central bond, the structure of **2** is similar to that of **4**, but not to **1** or to **3**. This conclusion is supported by the analysis of the two-configuration wave function:

Table 1. The geometry of **2** at various theoretical levels.

Method	*d*(Si1Si2) [Å]	*d*(Si1Si3) [Å]	Ref.
SCF-21G* (spd) [a]	2.325	2.686	
CEP-31G* [a]	2.347 [b]	2.729 [b]	[3]
MC-SCF (spd) [a]	2.330	2.735	
3-21G	2.443 [c]	2.885 [c]	
3-21G*	2.331 [d]	2.692 [d]	
6-31G*	2.347	2.719	[10]

[a] Pseudopotential method employed. [b] For comparison, the CEP-31G* values for **4** are 2.362 and 2.915 Å [3b]. [c] For comparison, the 3-21G values for **4** are 2.406 and 2.972 Å. [d] For comparison, the 3-21G* values for **4** are 2.305 and 2.731 Å [5].

$$\psi_{MC\text{-}2} = 0.97\,\psi_b(\sigma^2) - 0.25\,\psi_a(\sigma^{*2})$$

Table 2. Search for a second minimum of **2**, MC-SCF (spd).

d(Si1Si2) [Å]	*d*(Si1Si3) [Å]	E_{rel} [kcal mol^{-1}]
2.330	2.735	0.0 [a]
2.309 (opt.)	2.600 (fixed)	1.7
2.305 (opt.)	2.500 (fixed)	5.4
2.305 (opt.)	2.400 (fixed)	11.9

[a] From Table 1.

This wave function indicates substantial singlet diradical character.[8] Hence, it would be misleading to represent **2** by drawing a line between the bridgehead atoms. The 3-21G atom–atom overlap-weighted natural atomic orbital bond order[9] for the central Si1Si3 bond is only 0.176 vs. 0.677 for the Si1Si2 bonds. These are almost identical with the values for **4** (Si1Si3 = 0.173, Si1Si2 = 0.693) but contrast with those for **3** (0.600 and 0.765, respectively). The corresponding results for bicyclo[1.1.1]pentasilane, **5**, are 0.013 for Si1Si3 and 0.762 for Si1Si2.

As with **1**, the formally bonding σ-MO involving the central bond (HOMO) is higher-lying (but only by 0.02

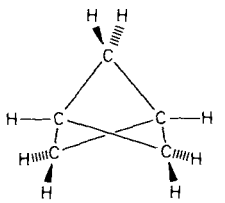
hartree), than the formally anti-bonding degenerate π^*-MOs. The latter are stabilized by interaction with the three peripheral silicon atoms. These are the "σ-bridged-π" interactions described and depicted by *Jackson, Allen* et al.,[3] the importance of which, however, has been discounted in some other analyses of the bonding in **1**.[4]

As we have pointed out in the case of **3** vs. **4**,[5] the difference in behavior of corresponding polycyclic carbon and silicon ring systems can be attributed to differences in strain contributions. While three-membered silicon ring systems are more strained than their carbon counterparts, the opposite is true for four-membered rings.[5] Thus, the ring-opening process, which, in effect, converts the three-membered rings in **3** into the four-membered ring in **4**, results in a higher relief of strain energy than would be possible with the corresponding carbocyclic system. Hence, bicyclobutane prefers a closed structure akin to **3**. The same situation pertains in **2** with its four-membered rings and roughly 100° Si1Si2Si3 bond angles. The geometry with a short Si1Si3 distance, which we find *not* to be minimum, would be higher in energy (see Table 2) due to the presence of three 3-membered silicon rings.

Despite the singlet diradical character of the bridgehead silicons and the weak Si1Si3 bonding, the strain energy in **2** (62.2 kcal mol^{-1} at pseudopotential MC-SCF-21G*)[10-12] is relatively low, particularly in comparison with the strain energy of [1.1.1]propellane **1** (102 kcal mol^{-1}).[2a,c] This difference also is apparent in the much higher strain energy of bicyclo[1.1.1]pentane **6** (67 kcal mol^{-1})[2c] than bicyclo[1.1.1]pentasilane **5** (37 kcal mol^{-1} at 3-21G*).[3b,11] While the bridgehead–bridgehead distance in **6** (1.88 Å) is much longer than that in **1** (1.60 Å),[2,3] the two separations are closer in **2** (ca. 2.73 Å) and in **5** (2.92 Å),[13] especially when the inherently larger silicon distances are taken into account.



6

In view of the relatively low strain energy predicted for **2** and the considerable recent experimental success in the preparation of **1**, **3**,[6b] and **5**,[13] as well as many small-ring silicon systems, the synthesis of appropriate derivatives of **4** affords an experimental challenge. Generally similar conclusions have been reached by *Allen* et al.[3b] and by *Nagase* et al.[10] who also have studied these systems.

[7] The standard HF calculations were carried out with the Gaussian 82 program; see W. J. Hehre, L. Radom, P. von R. Schleyer, J. A. Pople: *Ab Initio Molecular Orbital Theory*, Wiley, New York 1986. The MC-SCF treatment employed was similar to that described in Ref. [5].

[8] The MC-SCF wave-function obtained for **4** is quite similar, $\psi_{MC} = 0.95\,\psi_b - 0.30\,\psi_a$[5], ψ_b/ψ_a denotes that configuration in which the bonding/antibonding σ-MO of the Si1-Si3 bridge is doubly occupied.

[9] A. E. Reed, F. Weinhold, *J. Chem. Phys. 83* (1985) 1736; A. E. Reed, R. B. Weinstock, F. Weinhold, *ibid. 83* (1985) 735. These bond orders may vary somewhat at higher levels of theory (the 3-21G* bond orders for **2** are: Si1Si3 = 0.245, Si1Si2 = 0.834), but should be interpreted on a relative, rather than on an absolute basis.

[10] S. Nagase, T. Kudo (*Organometallics 6* (1987) 2456) give a strain energy of 70 kcal mol^{-1} for **2** (SCF/6-31G* calculations). These authors call attention to the negatively charged bridgehead silicon, Si1, in **2**. However, this is generally found when a silicon is bound to several SiH_3 or SiH_2 groups. For example, the 3-21G natural charges [9] on the central Si atoms are: −0.106 in **2** (−0.163 at 3-21G*) but −0.378 in $Si(SiH_3)_4$, +0.019 in **5**, +0.028 in **3**, +0.072 in **4**, and +0.19 in $HSi(SiH_3)_3$. In all these molecules, the SiH_2 silicons have charges $+0.34 \pm 0.1$ and the SiH_3 silicons $+0.55 \pm .02$.

[11] Ref. [3b] gives 71.3 and 37.4 kcal mol^{-1} for **2** and **5**, respectively, using a pseudopotential SCF-31G* (spd) basis. Our pseudopotential SCF-21G* value for **2** (72.4 kcal mol^{-1}) agrees well; also the SCF 69 kcal mol^{-1} estimate of *Nagase* [10]. However, an electron-correlation-corrected ring-strain energy was evaluated by "two-configuration (σ^2, σ^{*2})-per-SiSi-bond" wave functions. The decrease of total energy for a normal SiSi bond is 4.7 kcal mol^{-1} whereas that for the diradical central SiSi bond in **2** is 14.9 kcal mol^{-1}. Thus, SCF overestimates ring strain energies in **2**, and also in **4**, by more than 10 kcal mol^{-1}.

[12] All these strain energies are evaluated by the use of the unusual homodesmotic equations [3b, 5, 10].

[13] The first preparation of a derivative of **5** has been reported by *S. Masamune* et al. (*Fifth Int. Symp. Organosilicon Chem.*, St. Louis, MO, USA, June 1987).

Electrocyclic Opening of 2,3-Benzo- and 2,3;7,8-Dibenzobicyclo[4.2.0]octa-2,4,7-triene; Benzoannelated Transition States**

By *Wolfram Grimme,* Johann Lex,* and *Thomas Schmidt*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

The electrons participating in pericyclic reactions are aromatically stabilized in the transition state before they form new bonds in the product. When an electron pair of a benzene ring participates in a pericyclic reaction, the transition state is benzoannelated and "isoconjugate" with naphthalene, whereas the product has lost all aromaticity. Hence, energy-rich intermediates which rapidly undergo further reaction can be generated relatively easily by pericyclic reactions with benzenoid double bonds. Frequently, the reverse of their formation is the preferred reaction, and it requires special analytical methods in order to detect the occurrence of these processes.

An example of a hidden pericyclic reaction with participation of a benzene ring is the electrocyclic ring-opening of benzonorcaradiene **1** to give the bicyclo[5.4.0]undeca-

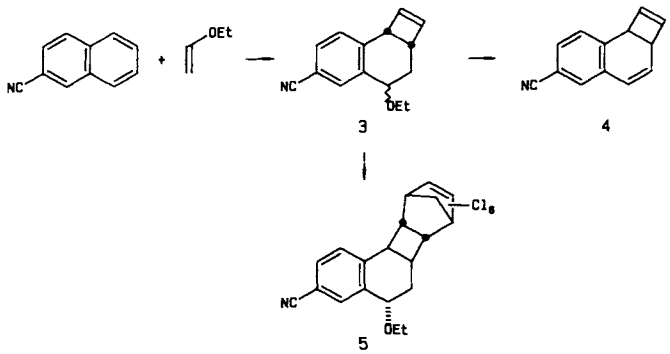
1,3,6,8,10-pentaene **2**.[1] The reaction already occurs at room temperature, but the product with the *o*-quinodimethane partial structure undergoes back reaction so rapidly that its detection is only possible via the racemization of the benzonorcaradiene, which is very rapid on the NMR time scale at 180°C.

1 2

We report here on the corresponding ring opening of benzo- and dibenzobicyclo[4.2.0]octa-2,4,7-triene. The synthesis of the 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene-2′-carbonitrile **4** was achieved starting from the photoproduct **3**[2] of β-naphthonitrile and ethyl vinyl ether; **3** was obtained in 63% yield as a 5:1 mixture of the *anti*- and *syn*-isomer. Since several steps are involved in the formation of **3** and another skeletal structure has been proposed for the product of the corresponding reaction with methyl vinyl ether,[3] we have confirmed the structure of **3** by an X-ray diffraction analysis of the Diels–Alder adduct **5**.[4] Compound **5** is formed upon heating a solution of **3** in hexachlorocyclopentadiene at 100°C for 14 h and can be isolated by chromatography ($CHCl_3$, silica gel) and purified by recrystallization from hexane. The ether **3** eliminates ethanol on heating to 105°C (3 h) in a mixture of glacial acetic acid, 85% phosphoric acid and water (5:2.75:1 parts by volume) and affords the benzobicyclo[4.2.0]octatriene derivative **4** (72%). Physical data of **4** and the other new compounds are given in Table 1.



3 4 5

Table 1. Some physical data of the compounds **4**, **5**, **7**, **8**-D, and **8′**-D. The NMR spectra were recorded at 90 MHz in CCl_4 (those of **4** and **5** at 300 MHz in $CDCl_3$ and $CCl_4+CD_2Cl_2$, respectively).

4, m.p. 64–66°C; ^{1}H-NMR: $\delta=7.28$ (AB, $\Delta\nu=71$ Hz, $J=7.8$ Hz; H-3′,4′), 7.27 (d, $J=1.9$ Hz; H-1′), 6.13 (AB, $\Delta\nu=64$ Hz, $J=9.9$ Hz; H-4, 5), 6.09 (AB, $\Delta\nu=50$ Hz, $J=2.7$ Hz; H-7, 8), 4.12 (d, $J=4.5$ Hz; H-1), 3.68 (t, $J=4.5$ Hz; H-6); ^{13}C-NMR: $\delta=140.82$ (C-3), 140.66 (C-7), 138.82 (C-8), 132.87 (C-2), 130.92 (C-3′), 130.47 (C-1′, 5), 128.46 (C-4′), 124.16 (C-4), 118.93 (CN), 110.22 (C-2′), 43.78 (C-1), 42.97 (C-6); UV (hexane): $\lambda_{max}=275$ nm ($\varepsilon=3930$), 285 (3360) sh, 302 (1330) sh, 313 (890) sh

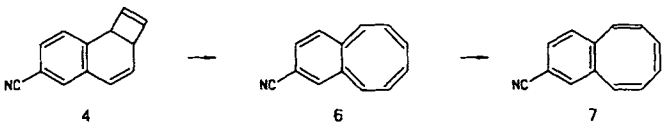
5, m.p. 173°C; ^{1}H-NMR: $\delta=7.65$ (d, $J=1.4$ Hz, 1H), 7.39 (AB, $\Delta\nu=114.5$ Hz, $J=7.9$ Hz, 2H), 4.38 (m, 1H), 3.52 (AB, $\Delta\nu=47$ Hz, $J=9$ Hz, 2H–Et), 3.18 (m, 1H), 3.06 (AB, $\Delta\nu=18$ Hz, $J=8.4$ Hz, 2H), 2.66 (m, 1H), 1.97 (AB, $\Delta\nu=51$ Hz, $J=13.4$ Hz, 2H), 1.22 (t, 3H–Et)

7, ^{1}H-NMR: $\delta=7.30$ (s, 1H), 7.28 (AB, $\Delta\nu=39.3$ Hz, $J=9$ Hz, 2H), 6.32 (AB, $\Delta\nu=37.5$ Hz, $J=12$ Hz, 4H), 5.90 (s, 2H); UV (hexane): $\lambda_{max}=275$ nm ($\varepsilon=2300$) sh

8-D, ^{1}H-NMR: $\delta=7.4$–6.8 (m, 8H), 6.02 (d, $J=4.7$ Hz, 1H), 4.51 (AB, $\Delta\nu=34$ Hz, $J=6$ Hz, 2H)

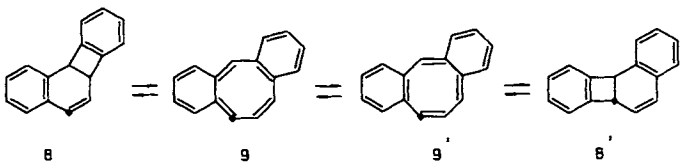
8′-D, ^{1}H-NMR: $\delta=7.4$–6.8 (m, 8H), 6.13 (AB, $\Delta\nu=15.6$ Hz, $J=9$ Hz, 2H), 4.73 (s, 1H)

Above 100°C, **4** rearranges uniformly in a first-order reaction into 2′-benzocyclooctatetraenecarbonitrile **7**; the NMR-spectroscopically measured rate constant in CD_3CN at 110.3°C is $k_i=(3.80\pm0.06)\times10^{-5}\,s^{-1}$. The energy-rich primary product **6** of the electrocyclic opening of the six-membered ring rapidly forms the arene by a double-bond shift in the eight-membered ring. To check whether recyclization to the starting compound is a competing process, **4** was resolved into the enantiomers by chromatography on microcrystalline triacetylcellulose.[5] The decrease in rotation of (−)-**4** ($[\alpha]_{575}=-360$, $c=0.44$) in CH_3CN at 110.3°C, too, is a first-order process with the rate constant $k_\alpha=(3.54\pm0.03)\times10^{-5}\,s^{-1}$. Since it is found, within the limits of error, that $k_i=k_\alpha$, it must be concluded that back reaction of **6** to racemic **4** does not take place. Likewise the intermolecular trapping reaction with reactive dienophiles cannot compete with the double-bond shift in **6**, so the occurrence of the mechanistically plausible intermediate **6** had to be substantiated in another way.



4 6 7

In 2,3;7,8-dibenzobicyclo[4.2.0]octa-2,4,7-triene **8**[6] the electrocyclic opening should occur analogously to that in **4** with participation of an electron pair of the benzene ring annelated to the six-membered ring. In the intermediate **9**, however, the double-bond shift in the eight-membered ring is degenerate and leads to **9′**; here a stabilization can only occur through recyclization. If the racemization of **8** or its automerization to **8′**, both of which are possible only via the *o*-quinoid intermediate, occurs under similar conditions as the rearrangement of **4**, the formation of such an intermediate can also be expected in the case of the latter.



8 9 9′ 8′

The position marked with a black dot is deuteriated.

We first investigated the automerization by means of the compound **8**-D deuteriated in position 4. This was obtained from 4-bromo-2,3;7,8-dibenzobicyclo[4.2.0]octa-2,4,7-triene[7] by metal–halogen exchange with *n*-butyllithium in THF at −70°C and subsequent hydrolysis with D_2O. NMR spectroscopic studies revealed that **8**-D is in equilibrium with its positional isomer **8′**-D at 100°C in CCl_4. The equilibrium constant is $K=1.13$ and the rate constant for the formation of the equilibrium was found to be $(k_a+k'_a)=(7.45\pm0.06)\times10^{-5}\,s^{-1}$ at 100.6°C. Thus the automerization of **8** takes place just as easily as the rearrangement of **4**, indicating the formation of an *o*-quinoid intermediate in both cases.

The question as to whether in the intermediate **9** the recyclization to **8** can compete with the energetically neutral double-bond shift to give **9′** was determined with help of enantiomerically enriched **8**. Partial hydroboration of racemic **8** with diisopinocampheylborane[8] (0.5 molar equivalents, prepared from (−)-α-pinene) in 1.5 M ethereal solu-

tion at °C furnished optically active (+)-**8** with $[\alpha]_{575} = 108.4$ ($c = 9.15$ in benzene). Its racemization in benzene at 100.6 °C is a reaction of first order with the rate constant $k_\alpha = (7.67 \pm 0.03) \times 10^{-5}\ s^{-1}$. Thus, the racemization is equally rapid as the establishment of the equilibrium between the labeled isomers, and the *o*-quinoid intermediate **9** preferentially undergoes a double bond shift to give **9'**.

The free enthalpies of activation for the electrocyclic ring opening of the benzoannelated cyclohexadienes in the compounds **1**, **4**, and **8** can be compared with those for the parent compounds. Table 2 shows that the participation of a benzenoid electron pair increases the free enthalpy of *activation* by 11 ± 1 kcal mol^{-1}. Incremental calculations,[12] on the other hand, indicate that the loss of aromaticity increases the free enthalpy of *reaction* of the benzoannelated compounds by 25 ± 1 kcal mol^{-1}. The introductory concept that benzoannelated transition states of pericyclic reactions are still aromatically stabilized is thus confirmed.

Table 2. Free enthalpies of activation for the ring-opening of cyclohexadienes and their benzoannelated derivatives.

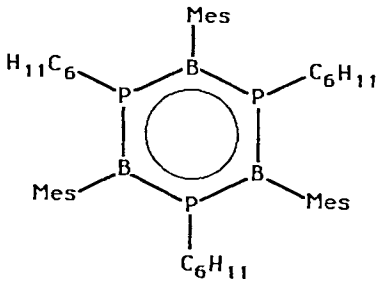
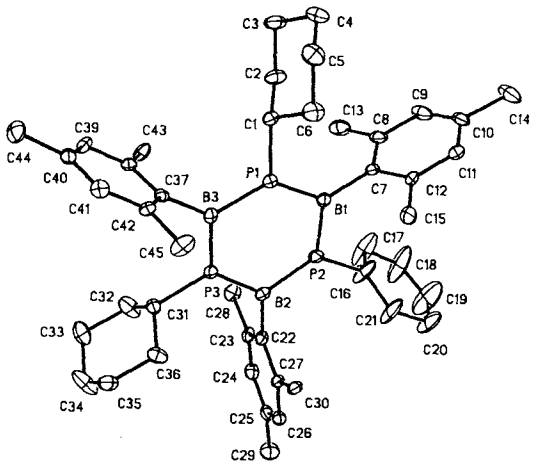
Synthesis and X-Ray Structure of $(2,4,6\text{-}Me_3C_6H_2BPC_6H_{11})_3$: A Boron-Phosphorus Analogue of Borazine**

By *H. V. Rasika Dias* and *Philip P. Power**

The isoelectronic nature of the BN and CC pairs has generated considerable interest in various boron-nitrogen compounds. Perhaps the best known species of this type are the borazines[1] and related derivatives. These have many of the characteristics of aromatic compounds exemplified by the close similarity in physical properties of borazine and benzene. In sharp contrast, boron-phosphorus compounds are not nearly as thoroughly studied and no stable boron-phosphorus analogue of borazine has been described. We have recently published the syntheses and structural studies of a monomeric phosphinoborane[2] and some phosphinideneborates[3] to gain some insight on the nature of BP single and multiple bonds. We now report a further addition to the known classes of BP compounds in the form of the first structurally characterized BP analogue of a borazine; this is the title compound $(MesBPC_6H_{11})_3$, **1** (Mes = 2,4,6-$Me_3C_6H_2$, C_6H_{11} = cyclohexyl), which has been characterized by X-ray crystallography, and ^{31}P- and ^{11}B-NMR spectroscopy.



The B_3P_3 compound **1** was formed as pale yellow crystals in moderate yield during the attempted synthesis of $MesB(PH{-}C_6H_{11})_2$. The X-ray crystal structure[4] is illustrated in Figure 1. It consists of a planar[5-7] $B_3P_3C_6$ array in which all the BP bonds are essentially equal, averaging 1.84 Å in length. This distance is considerably shorter than



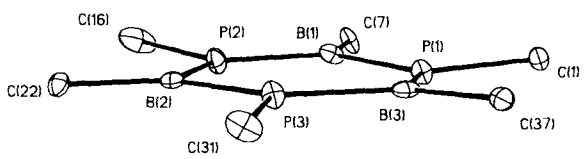


Fig. 1. Two views of the crystal structure of **1** (H atoms omitted for clarity). Selected bond distances [Å] and angles [°]: B1-P1 1.838(6), P1-B3 1.833(6), B3-P3 1.835(6), P3-B2 1.851(6), B2-P2 1.837(7), P2-B1 1.844(7), B1-C7 1.577(8), B2-C22 1.570(8), B3-C37 1.577(8), P1-C1 1.837(6), P2-C16 1.842(7), P3-C31 1.836(6); P1-B1-P2 114.8(3), P2-B2-P3 113.8(3), P1-B3-P3 116.0(3), B1-P1-B3 124.2(3), B1-P2-B2 126.0(3), B2-P3-B3 125.0(3).

the 1.92–1.96 Å range corresponding to a bond order of unity[8] and falls between the 1.859(3) Å seen in the monomeric phosphinoborane Mes_2BPPh_2, **2**,[2] and the 1.82–1.83 Å in the phosphinideneborate species $[Mes_2BPMes]^{\ominus}$, **3**, and $[Li(Et_2O)Mes_2BPR]$, **4** (R = Ph, C_6H_{11}, or Mes).[3] The monomer **2**, on the basis of its structure, has a significant interaction between the phosphorus lone pair and the empty boron p orbital, while the species **3** and **4** are thought to have a large amount of double-bond character. The B_3P_3 ring has thus at least three aromatic characteristics; (1) planarity, (2) equal BP bond lengths, (3) shortened BP bonds. It is also significant that the electronegativities of B and P are almost identical so that the B_3P_3 array should be much less polar than the corresponding B_3N_3 compound. Unfortunately, in the absence of comparative data, neither ^1H-, ^{13}C-, ^{11}B-, nor ^{31}P-NMR spectroscopy could provide evidence supporting the presence of a ring current.

^{31}P- and ^{11}B-NMR data are consistent with the X-ray structure. The ^{31}P-NMR shift ($\delta = 51.85$) of the singlet seen for **1** appears at much lower field than that of Mes_2BPPh_2 (**2**, $\delta = 30.2$) or $MesB(PPh_2)_2$,[9] ($\delta = -0.02$) suggesting less electron density at P, consistent with lone-pair delocalization. The broad singlet at $\delta = 52.6$ in the ^{11}B-NMR spectrum is very close to the value in **2** ($\delta = 51.7$). It is, however, further downfield than that found for $MesB(PPh_2)_2$ ($\delta = 30.1$), the closest compound available for comparison. In contrast, borazines generally absorb at higher ($\Delta\delta \approx 10$ ppm) field than monoaminoboranes whereas they absorb at similar fields to diaminoboranes.[10] Efforts to synthesize other derivatives related to **1** involving different substituents and heavier congeners are in progress.

Experimental Procedure

1: $MesBBr_2$ [11] (3.55 g, 12 mmol) in hexane (20 mL) was added to a solution of $C_6H_{11}PHLi$ (from $C_6H_{11}PH_2$ (2.86 g, 25 mmol) and *n*BuLi in hexane (15.5 mL of a 1.6 M solution)) in Et_2O (80 mL) at 0°C. Stirring for 12 h at ambient temperature afforded a yellow solution. Removal of volatiles under reduced pressure and extraction into hexane at 50°C gave, after filtration and concentration under reduced pressure and cooling to 0°C, pale yellow crystals of the title compound, **1**. Yield: 1.45 g, 48%; m.p. > 275°C. ^{31}P-NMR (THF/C_6D_6; H_3PO_4 ext.), $\delta = 51.85$; ^{11}B-NMR (THF/C_6D_6; $BF_3 \cdot OEt_2$ ext.), $\delta = 52.6$.

Proof of the (*S,S*) Configuration of (−)-Bissetone by Synthesis from D-Glucose**

By *Manfred Brehm, William G. Dauben, Peter Köhler,* and *Frieder W. Lichtenthaler**

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

The synthesis of enantiomerically pure non-carbohydrate natural products from readily available sugars is only of practical value if the reactions utilized and the number of steps lead to a high overall yield of product, if simple reagents and no complex separations are used, and if the reaction sequence can be transformed to a 10–100-g scale. Such practical criteria normally make it necessary to transform a sugar overfunctionalized with chirality and hydroxyl groups into an enantiomerically pure building block containing one or two chiral centers and suitable functional groups. The efficiency of the preparation of this building block is decisive for the practical utility of the planned total synthesis.

A building block meeting these criteria is the dihydropyranone **3**, which is available from D-glucose in six steps.[1] We report here a greatly improved procedure[2] which can be run on a 100-g scale and which reduces the former six-step reaction sequence to two one-pot reactions (Scheme 1): D-glucose → hydroxyglucal ester **1** (80%)[3] and hydroxylaminolysis → deoximation → elimination (84% for **1** → **2a** → **2b** → **3**).

Selective monooximation of dihydropyranone **3** liberates, without any side reactions, the second carbonyl group blocked as an enol ester and makes possible the synthesis of (*S,S*)-palythazine, **10**,[4,5] a compound isolated from the salt-water invertebrate *Palythoa tuberculosa*.[6] An isolated

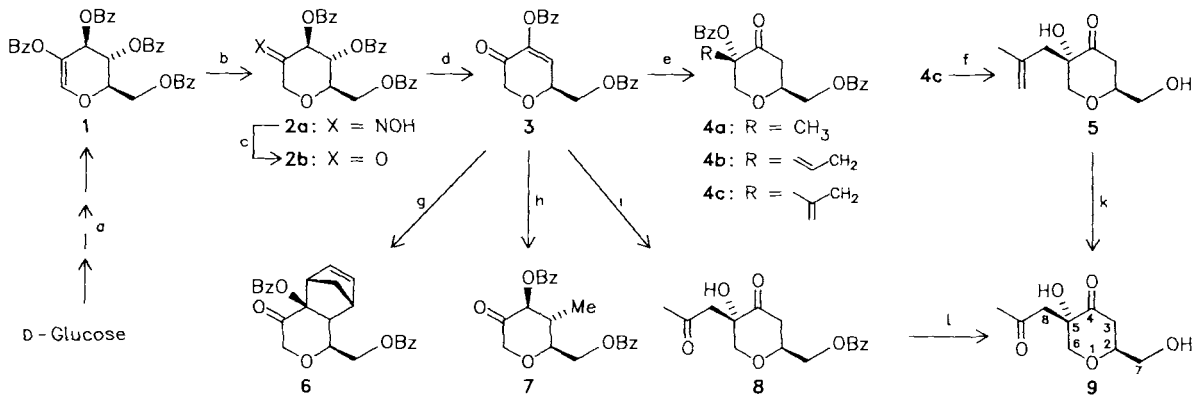

Scheme 1. Synthesis of (−)-bissetone, **9**, from D-glucose. a) Three steps, [3] (80%); b)→c)→d) [2] (84%); e) **3**→**4a**: MeMgI/Et_2O, −78°C, 15 min (69%); **3**→**4b**: $(CH_2{=}CH{-}CH_2)Ti(O\,iPr)_3$, CH_2Cl_2, 15 min, −78°C (85%); **3**→**4c**→**5**: $(CH_2{=}C(CH_3){-}CH_2)Ti(O\,iPr)_3$, CH_2Cl_2, −78°C, then f) NaOMe/MeOH, 15 min, 25°C (83%); g) cyclopentadiene, CH_2Cl_2, 15 kbar, 48 h, 25°C (53%); h) $Li_2Cu_3Me_5$, Et_2O, 30 min, −78°C (40%); i) $MeC(OLi){=}CH_2$, THF, −78°C, 10 min, then H_2O, 2 h, −20°C (60%); k) O_3/HOAc/Zn, 2 h, 25°C (84%); l) NaOMe/MeOH, 12 h, 0°C (92%).

study of the regio- and diastereoselectivities obtainable on **3** with C nucleophiles[7] now led to two different syntheses of (*S,S*)-bissetone, **9**, a constituent of the gorgonian soft coral *Briareum polyanthes*.[8]

The regioselectivities available in addition reactions of **3** naturally depend on the type of reagent and the reaction conditions employed. The steric course of these additions, however, is clearly determined by the envelope-conformation °E of **3**, five nearly coplanar carbon atoms with the ring oxygen above the plane.[9] The cycloaddition of cyclopentadiene to **3** under high-pressure conditions (15 kbar) occurs predominantly (4:1 selectivity) from the α side, i.e., opposite to the ring oxygen, to yield the α-*endo* product **6** (sirup, $[\alpha]_D^{20} = -103$ ($c = 1$, $CHCl_3$),[10] which is of importance for the synthesis of cyclopentanoid natural products by the facile cleavage of the olefinic double bond or by the opening of the pyranoid ring.[7b]

As expected, organocuprates give 1,4-addition products but the reaction leads to a variety of products. However, with $Li_2Cu_3Me_5$, a 40% yield of *C*-methyl-branched tetrahydropyranone **7** as the monohydrate (m.p. = 118–120°C, $[\alpha]_D^{20} = -38$, $CHCl_3$) can be obtained, thus indicating also a definite α selectivity.

With methyllithium or Grignard reagents, the addition to the carbonyl group of the enolone system clearly is the preferred reaction, the primary adduct rearranges by an $O^4 \rightarrow O^3$ benzoyl group migration, normally base-induced during workup,[12] to give a 4-tetrahydropyranone, e.g., **3**→**4a** (m.p. = 125–127°C, $[\alpha]_D^{20} = -89$, $CHCl_3$). The observed (^{1}H-NMR) 4:1 preference of nucleophilic attack from the β side strongly indicates a complexation of Mg in MeMgI with the ring oxygen and the carbonyl groups of **3** in the dominant °E conformation. The lithium enolate of acetone, a suitable C_3 synthon with regard to a synthesis of bissetone, adds with analogous stereoselectivity, affording after aqueous workup the 2-oxopropyl-branched tetrahydropyranone **8**[11] in crystalline form and in a 60% yield, together with 12% of its 5-epimer (syrup, $[\alpha]_D^{20} = -24$, $CHCl_3$). Distinctly higher selectivity of 10:1 in favor of the β-adducts **4b** and **4c** is found with allyl- and methylallyl titanium triisopropoxide, as expected,[13] due to the stronger complexation of the organotitanate with the ring and carbonyl oxygen of **3**. The allyl-branched adduct **4b** (m.p. = 105–106°C, $[\alpha]_D^{20} = 86$, $CHCl_3$) crystallizes from the reaction mixture (85%) whereas the syrupy methylallyl compound **4c**, as a result of its difficult separation from its 5-epimer, is better isolated after debenzoylation to **5**[11] (83% from **3**).

The diketone **8**, of which the configuration of the tertiary C-5 hydroxyl group was unequivocally established by an X-ray structure analysis,[14] constitutes the 7-*O*-benzoyl derivative of bissetone **9**, into which it is converted (92%) upon Zemplén saponification. The methylallyl derivative **5** is also converted into **9** via ozonation followed by reductive workup. The identity of the synthetic **9** with the product isolated from *Briareum polyanthes*[8] is proved by the identity of ^{1}H- and ^{13}C-NMR spectra and by the sign of the rotation. The considerably lower $[\alpha]_D^{20}$ value of the isolated product (oil, −43.6, $c = 4.25$, EtOH)[8] compared with synthetic **9** (sirup, −69.4, $c = 1$, EtOH) clearly indicates that the product isolated from the soft coral (73 mg from 31.3 g of water-soluble material via gel chromatography[8]) was not completely pure. Irrespective of the absolute value, the correspondence of the negative rotations of the synthetic and natural **9** now establishes the absolute configuration, until now unknown, to be (2*S*,5*S*), because the relative configuration was already established[8] and the only possible (*R,R*) alternative would have a positive rotation of at least 43°.

Since both soft-coral constituents palythazine **10** and bissetone **9** possess the (*S,S*) configuration, it is suggestive that the biosynthesis of both compounds proceeds from D-glucose via oxidation and elimination of water, together with transamination and C-branching, most likely through a biosynthetic equivalent of the building block **3**. In this case, the highly efficient syntheses of **9** and **10** from D-glucose (yields of 37% over eight and 26%[4] over nine steps, respectively) follow to a significant degree their biogeneses.

A New Mechanism For Superconductivity**

By *Michael J. S. Dewar**

The recent discovery[1,2] of high temperature superconductivity in certain mixed copper oxides has aroused much attention, not only because of possible practical applications but also because it cannot easily be explained in terms of the conventional Bardeen-Cooper-Schrieffer (BCS) mechanism.[3] Here, a radically different alternative is suggested, based on electron hopping between atoms of a metal in two different valence states under the control of two cooperating lattice vibrations. Other interpretations have involved variants of BCS theory, being likewise based on the conventional band theory of solids and electron–phonon coupling. The mechanism suggested here postulates a strong coupling between pairs of lattice vibrations and electron hopping, leading to a breakdown of the Born-Oppenheimer approximation in a manner reminiscent of that involved in the Jahn-Teller effect. Such a situation cannot be discussed in terms of conventional band theory because this rests on the Born-Oppenheimer approximation. While the possibility that electron hopping might be involved in these new materials has been recognized,[4,5] the essential feature of the mechanism suggested here is novel.

The basic idea will be illustrated by a specific example, i.e. a possible interpretation of superconduction in the species of greatest current interest, yttrium barium copper oxide (YBCO). Its optimum composition ($YBa_2Cu_3O_7$) corresponds to a situation where the copper atoms are in a mixed valence state, one-third trivalent (Cu^{III}) and two-thirds divalent (Cu^{II}). Recent studies[2,4] indicate that YBCO has a layer structure. Two layers (A) consist of square arrays of copper atoms linked by oxygen, while a third (B) contains parallel linear arrays of CuO_2 units linked by oxygen. The A layers are separated by the yttrium ions and the A and B layers by barium. The optimum composition and crystal symmetry suggests that either the copper atoms in the A layers are divalent and those in the B layer trivalent, or that the copper in the A layers is in a mixed valence state, half Cu^{II} and half Cu^{III}, while that in the B layer is Cu^{II}. We assume the latter. Each copper atom in each layer is linked to four oxygen atoms in an approximately square planar geometry, with longer spacings to the atoms (copper or oxygen) above and below. This is the geometry that would be expected for Cu^{II} or Cu^{III}, the d_{z^2} AO being doubly occupied while the $dCu_{x^2-y^2}$ AO is singly occupied (Cu^{II}) or empty (Cu^{III}).

Consider a linear array, $(-Cu-O-)_n$, of CuO units along the x direction in an A layer, with Cu^{II} and Cu^{III} alternating (Fig. 1). The valence states are expected to alternate because of the coulombic repulsions between the Cu^{III} ions. In situations of this kind, the distinction between different valence states is usually eliminated by resonance between them. Here, however, the two states differ in geometry, the CuO bonds being shorter for Cu^{III} than for Cu^{II}, and the coupling between the Cu atoms is small. It is therefore reasonable to suppose that Peierls-type distortion will lead to localization (Fig. 1a).

Consider the antisymmetric lattice vibration (ν_1) indicated by the full arrows in Figure 1a. In the phase indicated, the y-Cu^{II}–O bonds are shrinking while the y-Cu^{III}–O bonds are stretching. If the amplitude is sufficient to reverse the average CuO bond lengths round the two Cu atoms, electron transfer will occur, leading to an interchange of Cu^{II} and Cu^{III} with a parallel change in the lengths of the x-CuO bonds (see Fig. 1b). Furthermore, *all* the electron transfers in the array will take place in the same direction, leading to a net transfer of negative charge. If the amplitude of the corresponding zero point vibration is sufficient, the transfer of charge will take place spontaneously, without any need for external stimulus. Each half cycle of the vibration will lead to a similar transfer of charge between adjacent Cu atoms.

The direction in which charge transfer occurs will, however, be random because at the instant when the CuO distances are equal, the Cu atoms are equivalent. The direction of each electron transfer is not related to the previous one nor are the transfers in different arrays correlated. An applied electric field will bias the transfers and so lead to a flow of electrons—but only so long as the potential is ap-

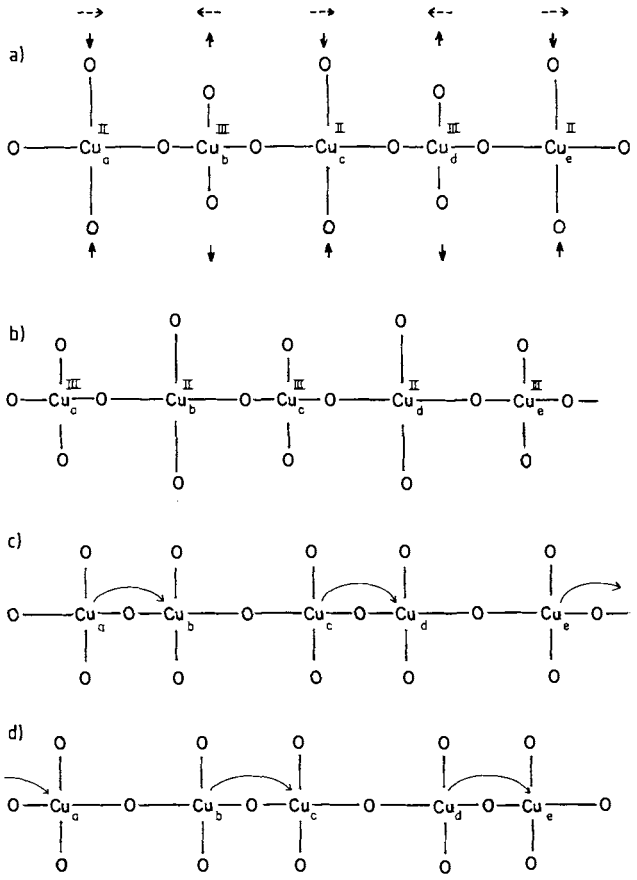

Fig. 1. Schematic representation of the proposed mechanism for superconductivity by application to a copper oxide chain. The differences between the CuO bond lengths are exaggerated, for clarity.

plied. Biassing each transfer involves a decrease in randomness and hence of entropy. For current to continue to flow, this must be continuously compensated. This mechanism, which is similar to that suggested by *Simon*,[3] thus provides a possible mode of conduction, not of superconduction.

Consider now the second lattice vibration (ν_2) indicated by broken arrows in Figure 1a. This leads to an alternate increase and decrease in the distance between pairs of adjacent Cu atoms. If these distances are unequal at the instant when ν_1 has made the Cu atoms equivalent, electron transfer will take place preferentially between pairs of Cu atoms that are closer together as indicated by the curved arrows in Figure 1c. If the two vibrations ν_1 and ν_2 have identical frequencies, the Cu-Cu distances will have inverted at the time of the next electron transfer, which will consequently tend to take place *in the same direction as the first* (see Fig. 1d). Cooperation of the two vibrations thus leads to a continuous unidirectional flow of electrons, which will continue as long as the vibrations remain synchronized. Establishing the flow of current will require energy both to compensate for the decrease in entropy involved in synchronizing the vibrations and to establish the corresponding magnetic field. Once the situation is established, the flow of current will continue without any need for further stimulus.

Consider one of the A (copper oxide) layers in YBCO. For reasons indicated above, alternate Cu atoms should be divalent (Cu^{II}) and trivalent (Cu^{III}) (see Fig. 2). The lattice vibration ν_1 (vertical arrows in Fig. 2) will lead to an oscillation of charge between adjacent Cu atoms along each x-$(CuO)_n$ array. The direction of transfer will be modulated by the lattice vibration ν_2 (horizontal arrows in Fig. 2). If the vibrations have similar frequencies and if the phase relation between them is appropriate, charge transfer will occur not only in the same direction at every vibration but also in the same direction for all the x-$(CuO)_n$ arrays in the crystal. Furthermore, once the vibrations have been synchronized, the flow of electrons will continue without any further stimulus. This clearly provides a mechanism for superconduction.

The situation considered here bears an obvious parallel to that involved in the Jahn-Teller effect. In both cases, a vibration, involving nuclear motion, leads to large changes in the electronic wave function and the Born-Oppenheimer approximation is therefore inapplicable. Neither of the two vibrations can be treated in conventional terms, involving separation of electronic and nuclear variables in the respective wave functions. The motions of electrons and atomic nuclei are strongly coupled in the superconducting state. For the proposed mechanism to operate, ν_1 and ν_2 have to be exactly synchronized. Since both involve similar kinds of vibration, their frequencies would be expected to be similar in a classical model, but not identical. The strong electron-phonon coupling should pull them into resonance. Note again that no work has to be done to maintain this relationship; only to establish it in the first place.

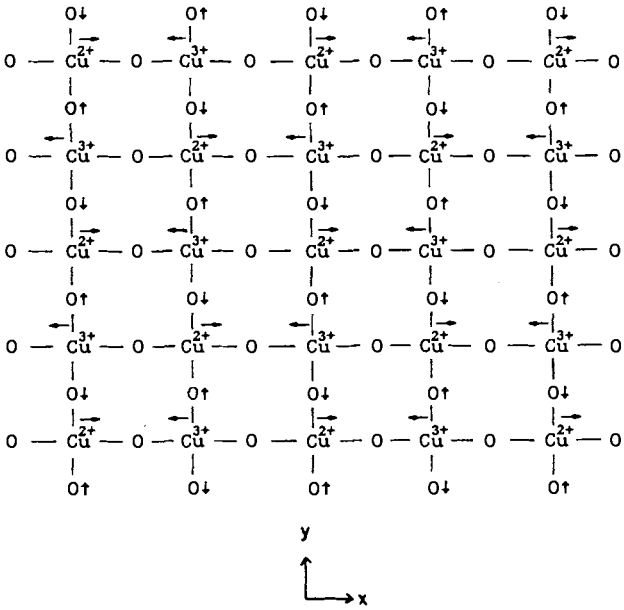

Fig. 2. Suggested mechanism for superconductivity in an A-type plane of YBCO (see text).

In this mechanism, superconduction involves the motion of single electrons along linear CuO arrays. It is possible that the electrons in adjacent A-type layers in YBCO may be coupled. If so, the electron transfers could be regarded as taking place in pairs, corresponding to conduction by a pair-hopping mechanism. However, there seems no advantage in this, particularly since, in the present model, *all* the migrating electrons in the whole crystal move in concert. Even if electron pairs are involved, these would in any case bear no relation to the Cooper pairs of BCS theory.

In the present model, superconduction can be interrupted only by the intervention of other lattice vibrations

that disrupt the phase relationship between ν_1 and ν_2. If this could be effected by other zero point lattice vibrations, the material in question would not be a superconductor in the first place. Higher vibrational modes must therefore be involved whose wavelengths resemble the short wavelength vibrations involved in superconduction (see Fig. 2). The energies of the corresponding quanta will be large, corresponding to frequencies near the top of the phonon band, and the temperature needed to excite them will be correspondingly high. The high transition temperature of YBCO, which has proved difficult to explain in terms of BCS theory, can thus be understood immediately in terms of the mechanism presented here. Indeed, superconduction by the present mechanism might well take place at higher temperatures than 90 K. The critical temperature will depend not only on the energies of interfering phonon quanta but also on the ease with which ν_1 and ν_2 can be uncoupled. This in turn should depend on the frequencies in the uncoupled state. Similar remarks apply to the remarkable insensitivity of YBCO to magnetic fields. Since a magnetic field does not alter the vibration frequencies of a crystal significantly, it should not easily interfere with superconduction by the present mechanism.

Note that above the critical temperature, where the electron-two-phonon coupling is disrupted, materials of this kind should show no unusual behavior. YBCO acts in fact as a poor metallic conductor at higher temperatures.

Another significant feature of YBCO is the insensitivity of its transition temperature to $^{16}O/^{18}O$-isotopic exchange. This finding is inconsistent with a BCS-type mechanism involving electron-phonon coupling. With the mechanism presented here, however, it would be expected, since such an exchange should affect the critical vibration frequencies to comparable extents. For superconduction to be possible, the frequencies only need to be similar. Their absolute values are irrelevant.

The present mechanism need not be confined to copper compounds. The only requirement is a crystal containing a linear array of a metal in two valence states where cooperation of two lattice vibrations leads to conduction by unidirectional electron-hopping. An analogous mechanism may operate in the case of bismuth oxide superconductors[6]—with participation of Bi^{III} and Bi^{V} centers.[5] There is also no need for the two valence states to alternate. The same mechanism could apply in YBCO if every third Cu atom in each A layer were trivalent. The wavelengths of the two relevant vibrations in the crystal would, however, be one-and-a-half times greater and the energies required to excite interfering vibrations should be correspondingly less. Samples of YBCO with compositions $YBa_2Cu_3O_{7-x}$ ($x > 0$) still superconduct, but less effectively, the larger x, i.e. the transition temperature decreases with increasing x.

In conclusion, one possible experimental test for the mechanism which I have presented here may be noted: Since the critical temperature is set by the point at which specific lattice vibrations are excited, superconductivity might be interrupted by irradiation with a tuned infrared laser at an appropriate frequency without heating the sample above its critical temperature.

Superconductivity—a New Classification of the Chemical Bonding in the Solid Allows to Understand Its Occurrence**

By *Werner Urland**

The chemical bonding in the solid state is traditionally divided into ionic, covalent, and metallic bonding. Compounds are classified according to these three types of bonding and their transitions,[1] a classification which is conveniently represented by a triangular plot corresponding to the phase diagrams of ternary systems.[2] The main aim of this communication is to present a new classification of the chemical bonding in the solid state which provides an insight into the occurrence of superconductivity.[3] The superiority of the new classification, which is *not* tied to the Periodic Table, lies in the fact that, in addition to the electric properties, also the magnetic properties of the solid as well as intermolecular forces are taken into consideration. The classification presented here represents a consequent further development of the ideas of *Anderson*[4] and *Woolley*.[5]

The bonding energy and therefore the chemical bonding in the solid is mainly determined by delocalization, correlation and localization of s, p, and d electrons with the respective energy contributions E_{Del}, E_{Cor}, and E_{Loc}.

E_{Del} means the sum of the energies of the electrons moving with a certain momentum $(h/2\pi)k$ (itinerant electrons with the energy $E(k)$) and arises theoretically as a one-electron problem from band theory. The width of the corresponding incompletely occupied band can be regarded as a measure of the magnitude of E_{Del} and increases with the overlap of the atoms. In the case of free electrons E_{Del} equals the kinetic energy of the electrons.

E_{Cor} is the energy of the spin-dependent electron-electron interaction. It takes into account that the equally-charged electrons avoid each other and favors, in accord with Hund's first rule, high-spin arrangements and therefore paramagnetism in isolated ions. Paramagnetism is theoretically treated by different versions of the formalism of ligand field theory, e.g. by the angular overlap model.[6,7] E_{Cor} leads in solid compounds with more or less strong overlapping of atomic orbitals—beginning delocalization and therefore increase of the ratio E_{Del}/E_{Cor}—to magnetic interaction and the appearance of cooperative magnetic phenomena, e.g. antiferromagnetism, ferromagnetism, as well as spin-density waves. Antiferromagnetism can be described in terms of the formalism of superexchange, which increases with increasing E_{Del}/E_{Cor}.[4] A large increase in the overlap of the atomic orbitals (large increase in E_{Del}/E_{Cor}) finally leads to such a large gain of kinetic energy of the electrons that the repulsion energy of the closely approaching electrons will be overcome and a complete delocalization will result.

E_{Loc} means the electron-phonon interaction energy (vibronic coupling energy). If E_{Loc} is larger than E_{Del} a localization of electrons will occur such that the delocalized (itinerant) electrons become electron pairs with antiparallel spins. If we imagine a hypothetical hydrogen metal with a half-filled 1s band (E_{Del}), strong electron-phonon interaction (E_{Loc}) will lead to a Peierls distortion with the formation of H↑↓H-molecules held together by intermolecular forces.[8] (The Peierls distortion corresponds to the known Jahn-Teller distortion in coordination chemistry.) The electron pairs formed by Peierls distortion are the well-known Lewis electron pairs of classical covalent bonding in molecular chemistry. The Peierls instability helps a great deal in undestanding the bonding and structure of elements and compounds like, e.g. P (black), As, Sb, Bi, β-Sn, C (diamond), NaCl and $(SN)_x$.[8,9] Besides the demonstrated localization of an electron pair by dimerization because of electron-phonon coupling in H_2 (E_{Loc}), a localization owing to inner disproportionation is possible in the case of linear metal-anion-metal groups, leading to mixed-valence compounds like, e.g. $(Ag^{I}Ag^{III})O_2$,[10,11] $Ba_2(Bi^{III}Bi^{V})O_6$,[12] or $Cs_2(Au^{I}Au^{III})Cl_6$.[13]

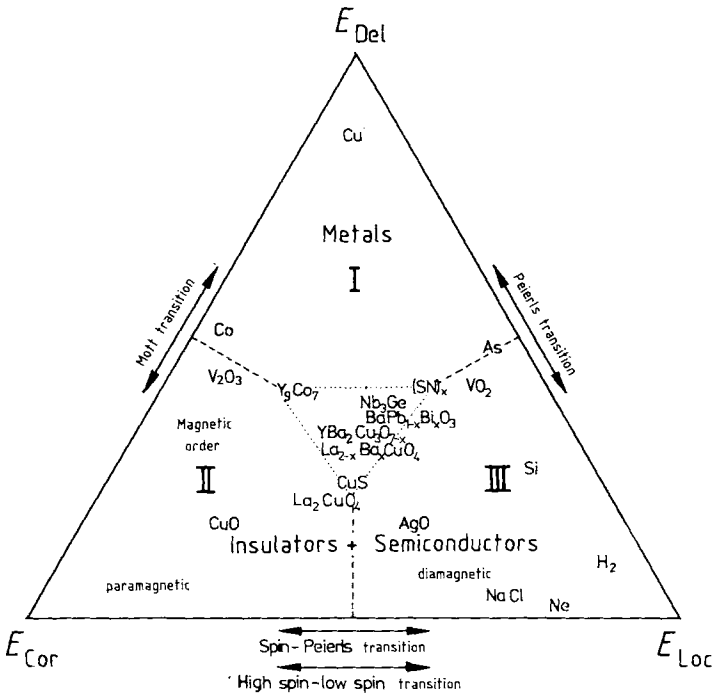

Fig. 1. "Phase diagram of chemical bonding in the solid state" providing an explanation for the occurrence of superconductivity. (Approximate values for x in the formulas are given in the text.)

The chemical bonding in the solid state will now be classified in a new fashion according to the energies E_{Del}, E_{Cor}, and E_{Loc} and their transitions. The classification is again conveniently represented by an equilateral triangle, with the vertices corresponding to the three energies (cf. Fig.1). Solid elements and compounds can now be classified in this "phase diagram" (for atmospheric pressure) according to respective magnitudes of E_{Del}, E_{Cor}, and E_{Loc}. One distinguishes between three 'phase regions':

I $E_{Del} > E_{Cor}, E_{Loc}$: metals, e.g. Cu, Ag

II $E_{Cor} > E_{Del}, E_{Loc}$: paramagnetic and magnetically ordered insulators (and semiconductors), e.g. complex compounds of transition metals; CuO, NiO[14]

III $E_{Loc} > E_{Cor}, E_{Del}$: diamagnetic insulators (and semiconductors), e.g. ionic crystals (NaCl), solid noble gases (Ne), molecular crystals (H_2), covalent crystals ($C_{diamond}$, Si), and mixed-valence compounds of class I[15] (AgO)

Solids with especially interesting physical properties are found to lie near to the broken 'boundary lines' (cf. Fig. 1), i.e. there, where the transitions between the 'phase regions' lie:

Transition I-II $E_{Cor} \approx E_{Del} > E_{Loc}$: compounds showing the Mott transition, e.g. V_2O_3[14]; magnetically ordered metals, e.g. α-Fe, Co, Ni, Cr[14]

Transition II-III $E_{Cor} \approx E_{Loc} > E_{Del}$: compounds showing high-spin (paramagnetic) -low-spin (diamagnetic) transition, e.g. complexes of $Fe^{2\oplus}$[16] or spin-Peierls transition, e.g. tetrathiafulvalene—$Au[S_2C_2(CF_3)_2]_2$[17]

Transition I-III $E_{Del} \approx E_{Loc} > E_{Cor}$: Peierls systems, e.g. semimetals: P (black), As, Sb, Bi[8]; VO_2[14] as well as substances exhibiting the phenomena of charge-density-waves[18] and bipolarons[19]

Solids which have to be classified near to the 'triple point' (cf. dotted triangle in Fig. 1) show superconductivity at low temperatures (transition temperature T_c):

$E_{Del} \approx E_{Cor} \approx E_{Loc}$: for example Y_9Co_7 ($T_c = 2.7$ K)[20], Nb_3Ge ($T_c = 23.2$ K)[3], CuS ($T_c = 1.35$ K)[15], $(SN)_x$ ($T_c = 0.26$ K)[3], $BaPb_{1-x}Bi_xO_3$ with $x \approx 0.3$ ($T_c = 13$ K)[21], $La_{2-x}Ba_xCuO_4$ with $x \approx 0.2$ ($T_c \approx 30$ K)[22], and $YBa_2Cu_3O_{7-x}$ with $x \approx 0.2$ ($T_c \gtrsim 90$ K)[23].

Thus, the occurrence of superconductivity in the solid would appear to be associated with the cooperative action of electron delocalization, localization and correlation with comparable energy contributions. High transition temperatures are found for solids where this cooperative action concerning the energy contributions is an optimum. The energy contributions can be roughly estimated from the chemical and physical properties as well as from theoretical and experimental work on the given or analogous compounds.[8,14,15,20,24-27] After what has been said the phenomenon of superconductivity can be understood in terms of the basis of the theory of *Bardeen*, *Cooper*, and *Schrieffer*—the formation of Cooper pairs[3]—as follows: localization leads to the pairing of electrons, delocalization to conduction, and correlation maintains the pairing of electrons in the superconducting state.

This may be exemplified more closely in the case of the high-temperature superconductors $La_{2-x}Ba_xCuO_4$ ($x \approx 0.2$)[22] and $YBa_2Cu_3O_{7-x}$ ($x \approx 0.2$).[23] Electron delocalization is given by the formation of a nearly half-filled Cu-$3d_{x^2-y^2}$-O 2p band. The bandwidth is maximal as the energies of the Cu 3d and O 2p orbitals practically agree.[28] Electron correlation can be assumed with reference to the compounds CuO and La_2CuO_4, where magnetic susceptibility measurements[25,26] indicate antiferromagnetism (Cu-O-Cu-superexchange). Electron localization can be understood as a Peierls distortion of a nearly half-filled band, as in the case of the above described hydrogen, or as an inner disproportionation if one compares $Cu^{II}O$ with homologous $(Ag^{I}Ag^{II})O_2$ (disproportionation in a linear metal-O-metal group). This all comes practically true also for La_2CuO_4 with copper in the oxidation state +2 which shows no superconductivity at the investigated temperatures.[26] Obviously in this case the influence of correlation is too large and that of delocalization is too small. Only the

increase in the ratio E_{Del}/E_{Cor} by the formation of mixed-valence systems with copper in the oxidation state $\approx +2.2$ bring the compounds discussed here near to the "triple point" (cf. Fig. 1).[29] But why does $YBa_2Cu_3O_{7-x}$ ($x \approx 0.2$) have a higher transition temperature than $La_{2-x}Ba_xCuO_4$ ($x \approx 0.2$)? An answer to this lies in the different structures of the two compounds. $YBa_2Cu_3O_{7-x}$ ($x \approx 0.2$) crystallizes in an orthorhombic structure which is characterized by stacked slabs separated by $Y^{3\oplus}$ ions. In turn the slabs consist of alternate Cu-O and Ba-O layers the Cu-O layers being about 4.2 Å apart.[30] $La_{2-x}Ba_xCuO_4$ ($x \approx 0.2$) crystallizes in the K_2NiF_4-structure, where Cu-O layers are separated by two La/Ba-O layers leading to a distance of about 6.6 Å from each other.[31] In the yttrium compound antiferromagnetic correlations (increase of E_{Del}/E_{Cor} by superexchange) between the Cu-O layers should be significantly larger than in the lanthanum compound; this would mean a closer approach to the "triple point" in Figure 1, and thus a higher transition temperature. Replacement of barium by the smaller strontium in this yttrium compound should therefore lead, as in the case of the lanthanum compound,[32] to a further increase in the transition temperature if no change of the structure occurs.

The concepts developed here embrace those of other authors,[33] e.g. the resonating-valence-bond model (cooperative action of correlation and delocalization),[34] the bipolaron model (localization and delocalization)[35] and the 'chemical model' (localization and delocalization).[36] The theoretical considerations outlined here do not allow the calculation of transition temperatures, but lay out the framework for a comprehensive theory of superconductivity.

A Facile, General Route to Bridge-Annelated [2.2]Paracyclophanedienes**

By *Oliver Reiser, Stefen Reichow,* and *Armin de Meijere**

Dedicated to Professor Klaus Hafner and to Professor Emanuel Vogel on the occasion of their 60th birthdays

The [2.2]paracyclophanediene **7a**,[1] benzoannelated at both bridges, contains two rigid, orthogonally oriented biphenyl moieties and thereby not only exhibits unusual structural features but can also be expected to have interesting chemical and physical properties. However, in the recently reported synthesis[2] **7a** was formed in such moderate yields as to make a detailed investigation of its chemical behavior rather cumbersome.[3] We report here on the first results of a new synthetic strategy which not only allows the parent compound **7a** but also a whole series of analogous bridge-annelated [2.2]paracyclophanedienes to be synthesized with little effort.

The *1,9- and 1,10-dibromodienes* **1**[5] were readily obtained from a mixture of the 1,1,9,9- and 1,1,10,10-tetrabromo[2.2]paracyclophanes[4,5] by dehydrobromination with potassium *tert*-butoxide (*t*BuOK) in *tert*-butyl methyl ether (MTBE). Subsequent addition of two Br_2 gave a mixture of the hexabromides **2**[6] (71% yield), which upon renewed dehydrobromination (*t*BuOK, MTBE) smoothly afforded (56%) 1,2,9,10-tetrabromo[2.2]paracyclophanediene **3** (Scheme 1). The four vinylic bromine substituents in **3** could be conveniently replaced by alkenyl substituents in a Heck-type[7] palladium-catalyzed reaction suitably modified as described by *T. Jeffery*[8] (see Table 1). Whereas the coupling with styrene **4c**, *p*-fluorostyrene **4d**, and methyl acrylate **4f** proceeds in good yields with potassium carbonate as base, sodium hydrogencarbonate was found to

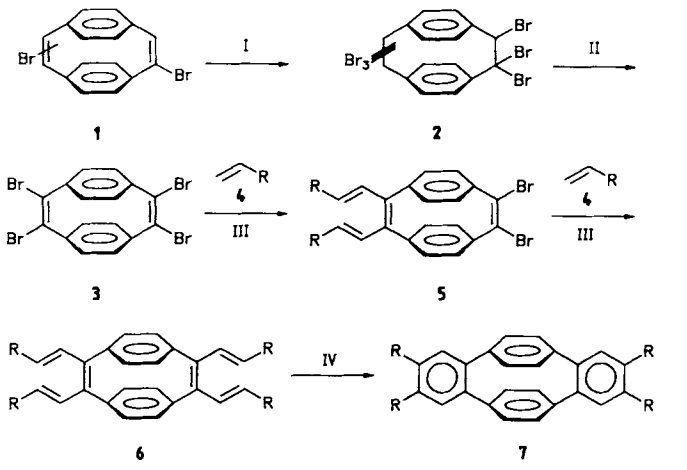
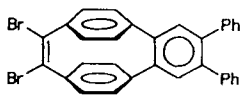
[**] This work was supported by the Stiftung Volkswagenwerk, by the Fonds der Chemischen Industrie, and by Hoechst AG, BASF AG, Hüls AG, and E. Merck GmbH (gifts of chemicals). *O. R.* thanks the Studienstiftung des Deutschen Volkes for a stipend. We thank Prof. Dr. *W. Lüttke*, Göttingen, for recording the UV spectra of **7c** and **9**.

be more suitable for the reaction with trimethylvinylsilane **4b** and the readily polymerizable acrolein **4e**. Nevertheless, under the reaction conditions (DMF, Bu_4NBR, $NaHCO_3$, $Pd(OAc)_2$, 40°C), the vinylic silyl groups in **6b**, and probably also in **4b**, were in most part split off. The main product formed thereby, the tetravinyl derivative **6a**, can also be obtained directly—albeit in poorer yield—by reaction of **3** with ethylene under 5 bar excess pressure in a glass autoclave.



Scheme 1. I: Br_2, $CHCl_3$, Δ. II: *t*BuOK, MTBE, 20°C. III, except for **a**, **b**, and **e**: $Pd(OAc)_2$, Bu_4NBr, K_2CO_3, dimethyl formamide (DMF). IV: Pd/C ($+O_2$) or S, xylene, Δ.

As has already been reported the Heck coupling proceeds in particularly good yields with acceptor-substituted olefins.[7,9] One may assume therefore that predominantly the 1,2-dialkenyl derivatives **5** occur as intermediates in the stepwise alkenylation of **3**: in a prematurely interrupted reaction with **4c**, exclusively the vicinal dibromide **8** was isolated after cyclization and aromatization (vide infra).



8

According to the ^{1}H-NMR spectra the double bonds in the side chains of **6c**–**f**, are, without exception, *trans*-configurated ($^3J = 15.2$–15.6 Hz). All the derivatives **6**, with exception of **6e**, smoothly underwent 6π-electrocyclization and aromatization to the benzoannelated products **7** upon heating with palladium/active charcoal in the presence of air or with sulfur (see Table 1).

The tetraphenyl derivative **7c** is particularly interesting in that it contains eight orthogonal biphenyl moieties. Four of these are rigidly fixed in the molecular framework, while the other four constitute units of the *o*-terphenyl moieties on both sides of the framework, with the *ortho* phenyl rings—as to be expected in *o*-terphenyls[10]—being perpendicular or almost perpendicular to the rings annelated to the phane skeleton. This is confirmed by the magnitude of the $^6J_{C,F}$ long-distance coupling[11] of the *p*-fluoro derivative **7d** of ≤0.5 Hz and by the UV spectrum of **7c**, in which the long wavelength maximum with $\lambda_{max}(\varepsilon_{max}) = 249$ nm (44200) is clearly hypsochromically shifted compared to that of the 4′,5″-diphenyl derivative[5] with $\lambda_{max}(\varepsilon_{max}) = 257$ (56600).

Table 1. Palladium-catalyzed fourfold coupling of **3** to give tetraalkenyl-[2.2]paracyclophanedienes **6** and their cyclization + dehydrogenation to **7** [6].

	R	6 Conditions	6 Yield [%]	7 Conditions	7 Yield [%]

High-Resolution CP-MAS ^{13}C-NMR Spectra of Allylzinc Compounds—Structural Similarities and Differences in the Solid State and in Solution

By *Reinhard Benn,* Hiltrud Grondey, Herbert Lehmkuhl, Hans Nehl, Klaus Angermund,* and *Carl Krüger*

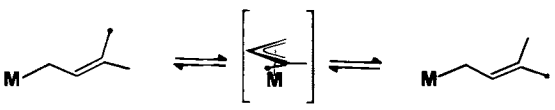
The structure of simple Li-, Mg-, and Zn-allyl compounds has been the subject of numerous NMR[1] and IR/Raman spectroscopic[2] investigations, X-ray analyses,[3] and theoretical calculations.[1f,4] We have now succeeded for the first time in obtaining high-resolution CP-MAS ^{13}C-NMR spectra of 3,3-dimethylallylzinc chloride **1**, bis(2-methylallyl)zinc **2**, bis(allyl)zinc **3**, and 2-methylallylzinc chloride **4**, and a crystal structure analysis of **2**, and in demonstrating that the organic ligand in **1** is bound in an η^1, in **2** in an η^1, η^2, and in **3** and **4** in an η^3 fashion. In contrast, in donor solvents the allyl groups in **1**–**4** are always bound η^1-like to zinc.

Table 1. ^{13}C-chemical shifts of **1**–**4** in the solid state and dissolved in THF (in brackets); cf. also Ref. [2].

Compound	C1	C2	C3	Me
[(3,3-dimethylallyl)ZnCl] **1** [a]	21.4 (14.6)	135.7 (129.1)	127.4 (117.1)	18.8, 28.5 (17.3, 26.0)
[(2-methylallyl)$_2$Zn] **2** [b]	31.0 (24.3)	174.4 (153.0)	91.8 (98.1)	30.0 (26.7)
[(allyl)$_2$Zn] **3** [c]	52 (20.0)	170 (145.4)	52 (99.8)	— —
[(2-methylallyl)ZnCl] **4** [d]	55 (21.2)	207 (152.5)	55 (100.1)	29 (26.6)

[a] At 300 K. [b] In THF at 173 K; in the solid state at 300 K. [c] At 183 K. [d] In THF at 173 K, in the solid state at 300 K.—Central $\delta(^{13}C)$ value in the CP-MAS ^{13}C-NMR spectra.

The ^{13}C-NMR data of **1**–**4** determined by the CP-MAS technique[5] and high power proton decoupling at 50.2 MHz are collected in Table 1. The ^{13}C chemical shifts for **1** in the solid state and in solution differ only slightly, i.e. in each case an η^1-allyl structure is present. According to two-dimensional NMR spectra[6] a slow chemical exchange of the methyl groups takes place in **1** in solution at 300 K, whereas such a process cannot be detected in the solid state at up to $T = 360$ K. Apparently the barrier for the σ-π rearrangement [Eq. (a)] is higher in the solid state



(a)

than in solution. This is also supported by the ^{13}C-NMR spectra of **2** (Fig. 1). In THF solution σ-π rearrangements prevent the typical signals for an η^1-allyl structure from being observed above 173 K, but in the solid state spectrum different signals are found for the terminal allyl C-atoms at 300 K. The halfwidths of these signals are unusually narrow for solid state NMR spectra. The differences between the positions of the signals in the solid state and the solution spectrum lie outside the usual tolerances and cannot be explained in terms of conformational changes. Significant in the CP-MAS spectrum of **2** are, in particular, the strong deshielding of the central allyl C-atom ($\Delta\delta(C2) = +21.4$) and the increased deshielding and shielding of the terminal allyl C-atoms ($\Delta\delta(C1) = +6.7$, $\Delta\delta(C3) = -6.3$).[7] We interpret this finding in terms of a complexation of the double bond to zinc, such that the allyl C-atoms in **2** are unsymmetrically bound in an η^1,η^2 fashion.[8,9] This is confirmed by the crystal structure analysis of **2** (Fig. 2).[10] In the single crystal each symmetry-equivalent methylallyl ligand is σ-bonded via the atom C1 to one Zn atom and is also π-complexed via the C2–C3 bond to another Zn atom. Whereas the two types of bonding can be distinguished at C1 and C3 by the very different

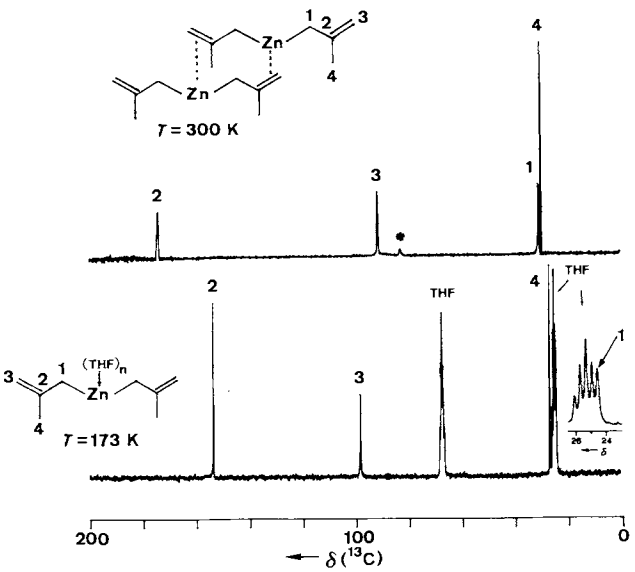


Fig. 1. 50.2-MHz ^{13}C-NMR spectra of bis(2-methylallyl)zinc **2** in THF (ca. 10%) at 173 K (bottom) and CP-MAS spectrum at 300 K (top). Spin frequency ca. 4600 Hz, 90°-^{1}H-pulse 5 μs, contact time 4000 μs. * denotes ^{13}C-signal of the rotor.

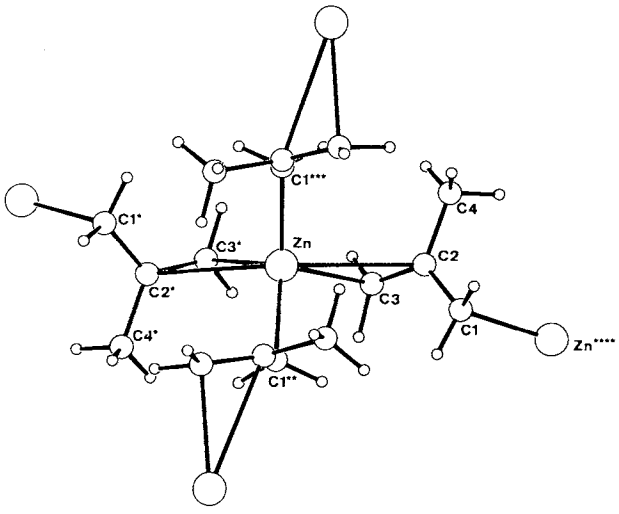

Fig. 2. Molecular structure of **2** in the crystal; space group $P3_221$, $a = b = 8.3452(4)$, $c = 10.565(1)$ Å, $V = 637.2$ Å^3, $Z = 3$, $T = 109$ K, $\mu(Mo_{K\alpha}) = 28.78$ cm^{-1}, $\rho_{calc} = 1.37$ g cm^{-3}, 19280 measured reflections ($\pm h$, $\pm k$, $+l$), averaged to 2602 independent reflections, 2374 observed ($I > 2\sigma(I)$), 70 refined parameters, $R = 0.025$, $R_w = 0.022$ ($w = 1/\sigma^2(F_o)$), residual electron density 0.62 eÅ^{-3}, H positions refined isotropically. Selected bond lengths [Å] and angles [°]: Zn-C1** 2.043(1), Zn-C2 2.919(1), Zn-C3 2.441(1), Zn****-C2 2.906(1), C1-C2 1.460(1), C2-C3 1.367(1), C2-C4 1.511(1); C1**-Zn-C1*** 139.4(1), Mp(C2*,C3*)-Zn-Mp(C2,C3) 113.9 (Mp = midpoint) [10].

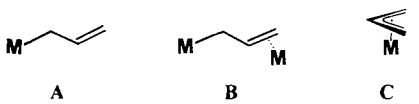
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim/Ruhr (FRG)

Zn-C distances and the differing deviations of the hydrogen atoms from the allyl plane, the *meso* C-atoms are practically equidistant from the two Zn atoms. (Difference 0.013 Å.) The Zn–C2 bond lengths are very long for a Zn–C π-bonding and can possibly be explained in terms of a very unsymmetric (distorted) π-complexation of the C2–C3 bond, caused by the simultaneous σ-bonding of C1 to a further Zn atom, or a frozen-in dynamic process, in the course of which C1 and C3 are each alternately π- and σ-coordinated. The Zn atoms themselves lie on twofold axes of rotation and are each surrounded pseudotetrahedrally by four methylallyl ligands. The overall result is a three-dimensional polymeric structure.

In the case of **3** and **4** the terminal C-atoms of the allyl moiety absorb at $\delta = 52$ and 55, respectively, in the solid-state ^{13}C-NMR spectrum. The spectra of **3** and **4** in THF solutions already show signals characteristic for an η^1-allyl structure at 200 K, whereas no changes in the ^{13}C-chemical shifts and signal halfwidths are observed up to 180 K ($B_0 = 7.0$ T) in the solid state spectrum of **3**. Since it is unreasonable to assume that the barrier for a π-σ allyl rearrangement (in **3** and **4** compared to **2**) is considerably lowered by the methyl group on C2 or the Cl-substituents on Zn, we conclude, in agreement with IR/Raman spectroscopic results,[2] that in the absence of donors the allyl groups of **3** and **4** are symmetrically η^3-complexed to zinc in the solid state.

The results show that in the solid state the simple allyl compounds of zinc can be of quite different structure types **A**, **B**, or **C**, depending upon the alkyl substituent attached to the allyl moiety and the ligand attached to the metal.



A B C

The differences in the ground state energies for **A**, **B** and **C** are obviously only small, so that upon dissolution in donor solvents exclusively the structure type **A** is found. Moreover, it is clear in the case of **2** that a classification of the allyl structure type merely on the position of the C=C valence vibrations is problematic.

[7] We have observed a similarly strong deshielding of C2 in the solid-state ^{13}C-NMR spectra of allylmagnesium halides. In contrast, no significant shift changes are observed between the solution and the solid-state spectrum for the central allyl carbon atom in $[(\eta^3\text{-allyl})_4\text{Mo}]$, $[(\eta^3\text{-2-methylallyl})_2\text{Pd}]$ or in ether-free $[(\eta^3\text{-allyl})\text{Li}]$. We tentatively attribute the strong deshielding of C2 in the CP-MAS NMR spectra (compared to in solution) to a change in the allyl-metal bonding in the solid state, as has been found for example in the case of **2**.

[8] The IR and Raman spectra of solid **2** and **3** [2] (**2**: IR 1540; Raman 1550; **3**: IR 1520; Raman 1535 cm^{-1}) have been interpreted as being consistent with symmetrically delocalized η^3-bound allyl groups. In the case of **2**, the CP-MAS ^{13}C-NMR spectra clearly contradict this interpretation, whereas in the case of **3** they support it.

Dipyrrolo[1,2-*a* : 2′,1′-*c*]quinoxalines: A Novel Heterocyclic System**

By *Gerd Kaupp,** *Heike Voss*, and *Herbert Frey*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Whereas open-chain nitrones are highly reactive partners for 1,3-dipolar cycloadditions to di- and tetrahydro oxazoles,[1] no cycloadditions have thus far been reported for the quinoxaline dioxides, which are currently the subject of intensive studies because of their wide-ranging biological activities.[2,3] In the reaction of 2,3-dimethylquinoxaline dioxides **1** with phenylpropiolate **2** we have now found a convenient method for the synthesis of the first derivatives of the new heterocycle dipyrrolo[1,2-*a* : 2′,1′-*c*]-quinoxaline.[4]

Reaction of **1**[5] with an excess of **2** for 3 d at 115 °C (Scheme 1) leads to elimination of water and regioselective formation of **3** (35% **3a**, 20% **3b**; no regioisomers). The structure of the reaction product was derived from the ^{1}H-NMR spectra of **3** and the derivative **4**, which was obtained by saponification and decarboxylation of **3a**. In particular the singlet at $\delta = 6.78$ ($\Delta\nu_{1/2} = 2$ Hz) in the spectrum of **4** is reconcilable only with a 2,4-relationship of the H atoms of the pyrrole ring.[6] By-products of the reaction include, inter alia, dimethyl-1-phenylnaphthalene-2,3-dicarboxylate, the dimer of **2** which presumably is formed by [4+2]-cycloaddition in conjunction with a 1,3 H-shift.

As expected this novel mode of reaction (eliminating cycloaddition) is not restricted to 2,3-dimethylquinoxaline dioxides. Thus, the monoxide **5** also reacts regioselectively with **2** to give **6** (115 °C, 4 d, 44%; no regioisomers).

The yellow compounds **3** and **4** containing the new heterocyclic ring system[4] are stable and exhibit the expected structured UV/VIS spectra, the molecular ions as the most intense signals in the mass spectra, and unequivocally as-

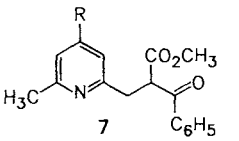
4: m.p. 222 °C; UV: $\lambda_{max}(\lg\varepsilon)=313.5$ (1.61), 287.5 (3.60), 264 (4.63), 249 nm (sh, 4.52).—^{1}H-NMR: $\delta=7.7$–7.15 (16H), 6.78 (2H, s).—MS: *m/z* 358 ($M^{\oplus}$, 100%), 332 (1), 330 (3), 328 (2), 282 (1), 280 (3), 254 (3), 179 (12), 178 (4), 140 (1), 102 (1), 77 (2)

6: m.p. 118 °C; UV: $\lambda_{max}(\lg\varepsilon)=334$ (3.96), 345 (sh, 3.90), 265 nm (4.54).—^{1}H-NMR: $\delta=7.95$–7.25 (9H), 6.85 (1H, s), 3.79 (3H, s), 2.67 (3H, s).—^{13}C-NMR: $\delta=163.6$ (C=O), 152.6, 136.5, 134.0, 133.6, 129.1, 128.5, 128.5, 127.8, 127.8, 127.4, 127.1, 126.7, 126.5, 125.2, 118.0, 116.0, 106.2, 51.8 (CH_3), 21.4 (CH_3).—MS: *m/z* 316 ($M^{\oplus}$, 100%), 285 (42), 258 (61), 257 (11), 242 (5), 158 (3), 128 (8), 77 (11)

Since compounds of the types **1** and **5** are accessible in a large variety of ways the reactions presented here may prove to be preparatively very productive. Care should be taken, however, that the heterocyclic α-alkyl *N*-oxides are not too nucleophilic, otherwise predominantly alternative products like **7**[7] (from 2,6-dimethyl- or 2,4,6-trimethylpyridine *N*-oxide and **2**) are formed, in which **2** is incorporated in reversed orientation.[8] The scope and mechanism of this condensation reaction involving ring closure is presently under investigation.



a, R = H; **b**, R = CH_3

Experimental

3a: A mixture of **1a** (1.0 g, 5.3 mmol) and **2** (8.5 g, 53 mmol) was heated in a flask fitted with a condenser for 3 d at 115 °C; the color of the liquid changed from yellow through green and red to greenish black. On cooling, **3a** crystallized out; it was recrystallized from 2-propanol: 0.77 g, m.p. 243 °C. From the mother liquor, a further 0.10 g of **3a** (total yield 35%) could be separated from **2**, its dimer, a green compound (80 mg, $M^{\oplus}=618$), by-products, 2,3-dimethylquinoxaline monoxide (24%), and 2,3-dimethylquinoxaline (24%) by chromatography on silica gel with dichloromethane and ethyl acetate.

Regioselective Protonation of Allylic Anions**

By *Siegfried Hünig,** *Norman Klaunzer,* and *Rüger Schlund*

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

Because of the great preparative importance of substituted allylic anions, numerous studies have appeared on the α/γ selectivity of their reaction with electrophiles such as alkylating agents and carbonyl compounds.[1] However, systematic investigations on the regioselectivity of protonation exist only with respect to substituent effects on allylic anions,[2] solvent effects,[3] and the use of various bases;[3] several allylmetal compounds have also been studied.[4] The influence of the proton source XH, on the other hand, has either not been studied at all or only examined within

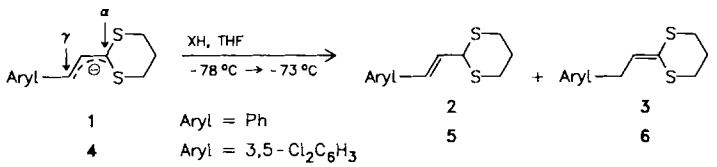
[**] This work was supported by the Deutsche Forschungsgemeinschaft (as part of the program on "Noncovalent Interactions").

narrow limits.[2,4,13] The goal of this investigation was therefore to determine the regioselectivity of protonation of a substituted allylic anion as a function of the proton source.

We chose the anions **1** and **4** as models—protonation of these anions leads to the isomer pairs **2/3** and **5/6**—for the following reasons: (1) The dithianes **2**[5] and **5** used as educts are smoothly deprotonated by *n*BuLi. This avoids the necessity of using LDA as base, the conjugate acid of which, diisopropylamine, can interfere in the protonation process after addition of a proton source—as has been shown for other examples.[6] (2) The anions **1** and **4** are so strongly basic[7] that they are protonated even by very weak bases. (3) Since water protonates the anion **1** exclusively in the α position,[5] the halogen-substituted derivative **4** was also included, since significant differences in the α/γ protonation ratio would be expected for waterlike proton sources XH.



Our results so far are collected in Table 1.[8] They reveal at first glance that the regioselectivity of electrophilic attack on allylic anions can be controlled in principle by the choice of proton source to the same extent as by the choice of alkylating agent.[5] Subsequent equilibration under the experimental conditions can be ruled out. The equilibrium was determined to be **2** : **3** = 35 : 65 and **5** : **6** = 20 : 80 (refluxing methanol/KOH).

Table 1. Product ratios in the protonation of the anions **1** and **4** (as 0.1 M solution in THF, generated by treatment of the conjugate bases with *n*BuLi) with XH at −78 °C to give the isomer pairs **2/3** [9] and **5/6** [10], respectively.

No.	XH	**2** : **3**	**5** : **6**
1	D_2O	> 99 : 1	95 : 5
2	H_2O	> 99 : 1	87 : 13
3	CD_3OD	> 99 : 1	95 : 5

12	Me−$CH(CO_2Me)_2$	66 : 34	
13	Me−$CH(CO_2Et)_2$	66 : 34	10 : 90
14	Me−$CH(CO_2Et)_2$	> 99 : 1 [b]	

[a] $C_2H_5CO_2H$ instead of CH_3CO_2H. [b] +4 equiv. HMPA.

The exclusive α protonation of **1** by H_2O to give **2** initially provides confirmation of the reported findings.[5] The α protonation of **1** is so strongly preferred that no differences were observed for all OH and OD acids employed (Nos. 1–6 in Table 1). On the other hand, differences are observed for **4**, if the electron density at the α position is reduced by the chlorine substituents.[11] Both deuterium effects (Nos. 1 and 2 as well as 3 and 4) and the effects of small structural differences for XH (Nos. 2 and 4) are now evident. It was surprising, therefore, that the stronger, quite different acids CH_3CO_2H and PhSH display roughly the same differentiation between α and γ protonation (Nos. 7 and 8).

Especially noteworthy are the effects obtained with malonic esters. The amount of γ-protonation product is only small in the case of malonic ester (No. 9); it increases for the monoalkyl malonic esters (with decreasing size of the alkyl group) to surprisingly large values (Nos. 10–12), whereas no difference is observed between methyl and ethyl esters (Nos. 12 and 13).

In the case of **4** the regioselectivity of the α/γ protonation can be forced to two extremes: from 90 : 10 (thiophenol, No. 8) to 10 : 90 (methylmalonic ester, No. 13). This corresponds to a difference of 7.9 kJ mol^{-1} in the energies of the transition states. For **1**, a difference of at least 6.4 kJ mol^{-1} is evident (> 99 : 1 to 66 : 34).

Thus, it is possible in principle to control the regioselectivity of α/γ protonation of allylic anions to an unprecedented extent merely by varying the proton source.

Since no concrete ideas exist concerning the structure of the transition states formed in the kinetically controlled protonation of ambident anions, a detailed interpretation of our results is premature. The counterion ($Li^{\oplus}$) plays an important role in α protonations, since addition of HMPA suppresses this protonation completely (No. 14). Thus, the complexation of the proton sources (e.g., malonic ester derivatives) by the ion pairs Li-**1** and Li-**4** is probable.

It remains to be shown whether the lower rate (by a factor of 10^5 to 10^{12}) of proton transfer from CH acids compared with that from OH acids[12] is also a reason for the increased rate of γ protonation.

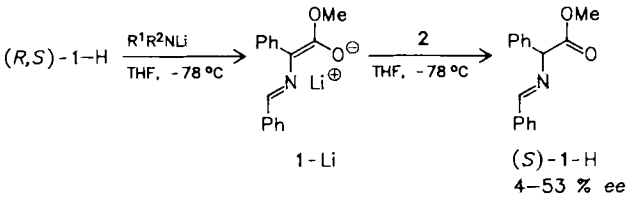
Enantioselective Protonation of Carbanions with Chiral Proton Sources**

By *Uwe Gerlach* and *Siegfried Hünig**

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

One of the most important routes for the enantioselective construction of carbon frameworks proceeds via carbanions having chiral auxiliary groups, which must be removed after diastereoselective reaction of the carbanion with alkylating agents or carbonyl compounds.[1] In contrast, only a few reactions of prochiral carbanions with electrophiles are known, in which the nucleofugal leaving group X* functions as a chiral auxiliary group. Examples are X*Me[2] and X*NMe$_2$.[3] An enantioselective protonation of broad scope would also be highly desirable, especially since it should be possible in most cases to recover the chiral proton source X*H. However, no experimental results are available at present in order to develop synthetic applications of such a protonation.

Systematic studies have only been reported by *Duhamel*'s group[4] for the Schiff bases of amino acid esters, e.g., (*R,S*)-**1**-H.[5] Their salts **1**-Li, accessible by reaction of the esters with secondary lithium amides R^{1}R^{2}NLi, react with (*R,R*)-diacyltartaric acids **2** to afford the *S* enantiomer with 4–53% *ee*, the reaction occurring with "deracemization"[4] and the enantiomeric selectivity depending on the lithium amide used and the acyl moiety selected. For example, **2a** protonates prochiral **1**-Li—generated by reaction of the ester with lithium diisopropylamide (LDA)—with 50% *ee* to give (*S*)-**1**-H; on the other hand, reaction with **2b** affords a product with 12% *ee*.[4]



We present here the first results of an extensive study on the enantioselective protonation of the synthetically important ester enolates of α-hydroxycarboxylic acids. As a model, we chose **3**-Li, the cyclic ester enolate of mandelic acid. In contrast to **1**-Li, **3**-Li is neither stabilized by an additional double bond nor by an atom capable of undergoing chelation, but its configuration is unambiguously fixed by its ring structure. (*R,S*)-**3**-H,[6] (*S*)-**3**-H,[7] and (*R*)-**3**-H are readily accessible from the corresponding mandelic acids and acetone. In addition, **3**-Li was prepared via the silyl enol ether **4**, in order to exclude the influence of amines, as well as directly from (*R,S*)-**3**-H by reaction with various amide bases R^{1}R^{2}NLi, in order to clarify the effect of the corresponding amine (Scheme 1). The results are collected in Table 1.

Only 5–7% *ee* was attained for (*R*)-**3**-H when the diacyltartaric acids **2a** and **2b** were employed. Although these acids had afforded good results with **1**-Li. On the other

hand, the tartaric esters **5a–d** are very effective, affording products with 29–46% *ee*, (*S*)-**3**-H predominating. The enantioselectivity increases slightly with increasing size of the alkoxy groups. As expected, the enantiomeric excess for **3**-H reverses by using (*R,R*)-**5c** instead of (*S,S*)-**5c**. To determine the effective structural elements of **5a–d**, other proton sources were employed. For malic ester (*S*)-**6**, the enantiomeric excess decreases to approximately one-half the value; for lactic esters **7a** and **7b**, approximately one sixth of the value is obtained. Replacement of the methyl group in **7** by a phenyl group (**8**), however, results in a ca. 50% *ee* of (*R*)-**3** for the mandelic esters (*S*)-**8a** and (*S*)-**8b**, thus exceeding even (*R,R*)-**5c**. On the other hand, the chiral induction is almost completely lost when the β-hydroxybutyric ester (*R*)-**9** is used as X*H. In addition, the absence of alkoxycarbonyl groups ((*R,R*)-**10** and (*S,S*)-**11**) lowers the *ee* value to less than 10%. The front runner in the present series of chiral proton sources is the pantolactone (*R*)-**12**,[9] which produces (*S*)-**3**-H with 53% *ee*. Carbohydrate derivatives, which are obvious candidates, have so far shown only moderate selectivity: diacetoneglucose D-**13**[10, 11] affords (*S*)-**3**-H with only 31% *ee* and the 4,6-*O*-benzylidene-α-D-glucopyranoside D-**14**[11] yields only half this value.

Evidently, chiral proton sources having the α-hydroxycarboxylic acid structural element are of particular importance. Since only (*S*)-**3**-H is formed with *R* proton sources (and vice versa), the (*R,S*) or (*S,R*) arrangement in the transition states formed from X* and **3**-Li is always preferred over the (*R,R*) or (*S,S*) configurations (**5–8**, **12**).

Moreover, Table 1 shows that, in the presence of the amine HMDS-H, the *ee* values are usually only slightly smaller and, in one reproducible case, even a little higher, so that several X*H were allowed to react only with **3**-Li generated from (*R,S*)-**3**-H by reaction with LiHMDS. Table 2 even confirms these results for the bases LDA and LiTMP.

Table 2. Generation of **3**-Li with various bases and its protonation or deuteration with the diisopropyl (*R,R*)-tartarates **5c** or [D]**5c**, respectively, in THF at −78°C.

Base	X*H(D)	% **3**-D	% *ee* of (*R*)-**3**-H
MeLi [a]	**5c**	—	47
MeLi [a]	[D]**5c**	>95	55
LiHMDS [b]	**5c**	—	42
LiHMDS [b]	[D]**5c**	>95	57
LDA [b]	**5c**	—	45
LDA [b]	[D]**5c**	41	51
LiTMP [b]	**5c**	—	41
LiTMP [b]	[D]**5c**	57	48

[a] Reaction with **4**. [b] Reaction with (*R,S*)-**3**-H.

This result is surprising, since it is not in agreement with the deuteration experiments on **3**-Li. In the reaction of **3**-Li (generated with LDA[12] or LiTMP) with [D]**5c**, only ca. 50% of **3**-D is formed (Table 2). Several examples of this effect are known.[13] In those cases, the results are ascribed to the rapid addition of $D^{\oplus}$ to the strong bases $i Pr_2NH$ ($pK_a = 35.7$[14]) and TMPH ($pK_a = 37.3$[14]), whose onium ions can then transfer either protons or deuterons. It is remarkable that this undesired reaction is already completely suppressed on going to HMDS-H ($pK_a = 25.8$[15]) when weak acids such as D_2O or ROD are used. We were also able to smoothly deuterate other compounds after deprotonation with LiHMDS.

On the basis of these results, one would have expected lower *ee* values for (*R*)-**3**-H in the reaction of **3**-Li (generated with LDA or LiTMP) with **5c** and [D]**5c**. As discussed above, however, that is not the case. Furthermore, a significant deuterium effect is observed (also for **3**-Li generated from **4**), presumably owing to the different transition states (distances!) for $H^{\oplus}$ and $D^{\oplus}$ transfer.[16]

According to Table 2, the amount of (*R*)-**3**-H increases, for complete deuteration (LiHMDS as base), from 42 to 57%; for ca. 50% deuteration, the *ee* difference is, as expected, only half as large. All these results support the conclusion that the secondary amine (actually the amount of ammonium ion) does not contribute to the protonation (deuteration) of **3**-Li. Instead, a rapid exchange reaction as shown in (a) presumably occurs. The reason for this course

$$[D]\mathbf{5c} + R_2NH \rightleftharpoons \mathbf{5c} + R_2NHD^{\oplus} \rightleftharpoons \mathbf{5c} + R_2ND \qquad (a)$$

of the enantioselective protonation of **3**-Li is presumably the better coordination (compared with secondary amines) of OH (or OD) acids **5c** to the lithium ion (see below).

As shown by protonations of **3**-Li with (*R,R*)-**5c**, the chiral induction is lower both in ether (27% *ee*) and in THF + 4 HMPA (11% *ee*), owing, in the latter case, to the generation of a solvent-separated ion pair. The necessity of forming a close ion pair with the lithium ion is evident from the decrease in the *ee* value to 2% with NaHMDS and KHMDS. The generation of an ate complex with $Ti(OiPr)_4$, on the other hand, results in an increase in the amount of (*S*)-**3**-H to even 61% *ee*, whereas with $Ti(NEt_2)_4$ only 31% is attained and the mixed titanyl ester expected from **3**-Li and $ClTi(OiPr)_3$ affords only 15% *ee* for (*S*)-**3**.

Thus, the decisive role of the cation is clearly revealed. Presumably, the cation complexes with the carbonyl group of the chiral α-hydroxycarboxylic ester. It is thereby possible for the proton of the α-hydroxyl group perpendicular to the double bond of the enolate to be transferred directly to its α-C atom, as has been shown for the ketonization of enols (enolates).[17] On the basis of this simplified working hypothesis, it should be possible to vary the enantioselectivity by specific structural changes in the proton source, resulting in values even larger than those obtained so far. However, rapid O-protonation, especially when solvent-separated ion pairs are present, might result in formation of the prochiral enol. Since this species can undergo ketonization only intermolecularly,[17, 19] it might itself act as an undesired proton source.

[5] Enantioselective reactions of Li enolates with chiral, nonprotic electrophiles in the presence of chiral secondary amines (D. Seebach, *Proc. Welch Foundation*, Houston 1984, p. 93) are not completely comparable because of the special role of the proton.
[6] M. Farines, J. Soulier, *Bull. Soc. Chim. Fr. 1970*, 332.
[7] The mild synthetic method according to [6] (reaction of (*S*)- or (*R*)-mandelic acid in acetone with $BF_3 \cdot OEt_2$, 4 h at room temperature, chromatographic workup) affords (*S*)-**3**-H with $[\alpha]_D^{20} = +52.7$ or (*R*)-**3**-H with $[\alpha]_D^{20} = -52.9$ ($c = 2$, CCl_4), m.p. = 74°C. For (*S*)-**3**-H, $[\alpha]_D^{20} = 41$ ($c = 2$, CCl_4), m.p. = 71°C (T. Polonski, *Tetrahedron 39* (1983) 3131). The enantiomeric purity was checked by gas chromatographic separation of the enantiomers. We thank Dr. *K. Günther*, Degussa AG, for performing these analyses.
[8] a) **3**-Li from (*R,S*)-**3**-H: (*R,S*)-**3**-H (1.0–1.3 mmol) in THF (4 mL) was added to a solution of LiHMDS (1.5–2.0 mmol, prepared from 1.8–2.1 mmol of HMDS-H and 1.5–2.0 mmol of *n*BuLi in hexane) in THF (4 mL) at −40°C. After the reaction mixture had stirred for 30 min, X*H (3.5–4.1 mmol) in THF (2 mL) was added at −78°C to −72°C. After 15 min, the resulting mixture was allowed to warm to room temperature and then treated with 10 mL of ether and 5 mL of saturated $NaHCO_3$ solution. The washed ether phase was dried over Na_2SO_4 and evaporated and the reaction product was purified by radial chromatography (eluent, petroleum ether/diethyl ether 9/1; yield, 70–90%). The enantiomeric excess was determined polarimetrically and, in certain cases, after addition of a chiral solvent ((*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol), by NMR spectroscopy [18]. b) **3**-Li from **4**: **4** (0.9–1.5 mmol) in THF (4 mL) was treated at −40°C with MeLi (1.1–2.0 mmol) in Et_2O and the reaction mixture was allowed to stir for 30 min at this temperature. The protonation, workup, and analysis were carried out as described in [8a]. The reported enantiomeric excesses are average values from two or three independent experiments (reproducibility ±1.5%).

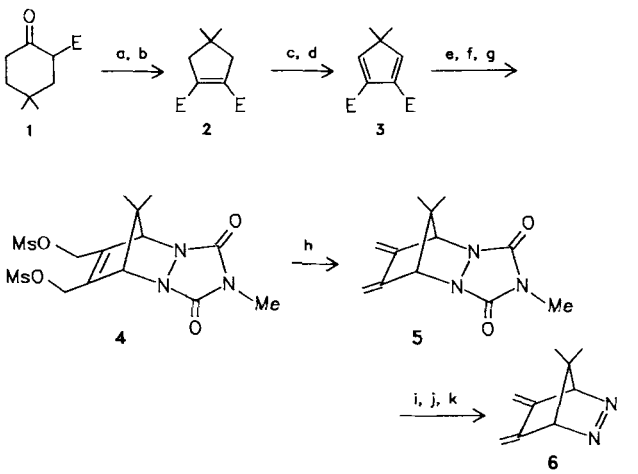
Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

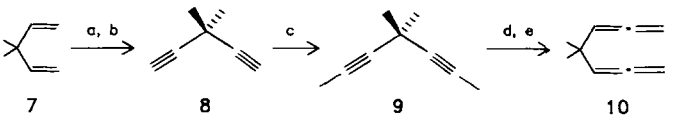
Theoretical calculations indicate that a singlet ground state can be expected for tetramethyleneethane in its planar as well as its energetically more favorable non-planar conformation.[1] Contrary to this prediction, *Dowd* et al.[2] have recently shown that the parent molecule does have a triplet ground state. If one assumes the orthogonal geometry to be expected for this molecule from calculations,[1] then there remains the question of the multiplicity of the planar system. The aim of the present study is to try to resolve this problem with 2,2-dimethyl-4,5-dimethylene-1,3-cyclopentanediyl **17** as model substrate.

Three precursors of **17** were prepared: 1. The ketoester **1** was converted by α-bromination and Favorskii ring contraction into the cyclopentene derivative **2**, which after bromination with *N*-bromosuccinimide (NBS) and elimination of HBr with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) furnished **3**. Reduction to the diol, mesylation and reaction with methyltriazolinedione (MTAD) afforded **4**. Subsequent 1,4-elimination with NaI/acetone furnished **5**, which was converted in the usual way into the diazo compound **6**[3]—a starting compound for **17**—in a total yield of ca. 15% (Scheme 1).



Scheme 1. E = COOMe; a) Br_2, ether, 0°C; b) Na, CH_3OH, room temperature; c) NBS, CCl_4; d) DBU, benzene, 0°C; e) $LiAlH_4$, ether; f) $MeSO_2Cl$, CH_2Cl_2, Et_3N, 0°C; g) MTAD, CH_2Cl_2, room temperature; h) NaI, acetone, room temperature; i) KOH, CH_3OH, 60°C; j) $CuCl_2$; k) NH_3.

2. Starting from 3,3-dimethyl-1,4-pentadiene **7** the **17**-precursor **10**[4] was obtained in a total yield of 27% via the diyne **8**, chain-lengthening to the diyne **9**, and subsequent hydrogen shift reactions (Scheme 2).



Scheme 2. a) Br_2, CCl_4; b) KOH, 180°C; c) BuLi, hexane, CH_3I; d) *t*BuLi, ether, *N,N,N',N'*-tetramethylethylenediamine (TMDA), Me_3SiCl [5]; e) CF_3COOH, CH_2Cl_2 [6].

3. Starting from the ketoester **11**, the diethynylcyclopropane derivative **13** was obtained via the diketone **12**. Thermolysis of **13** at 500°C led to the extremely labile triene

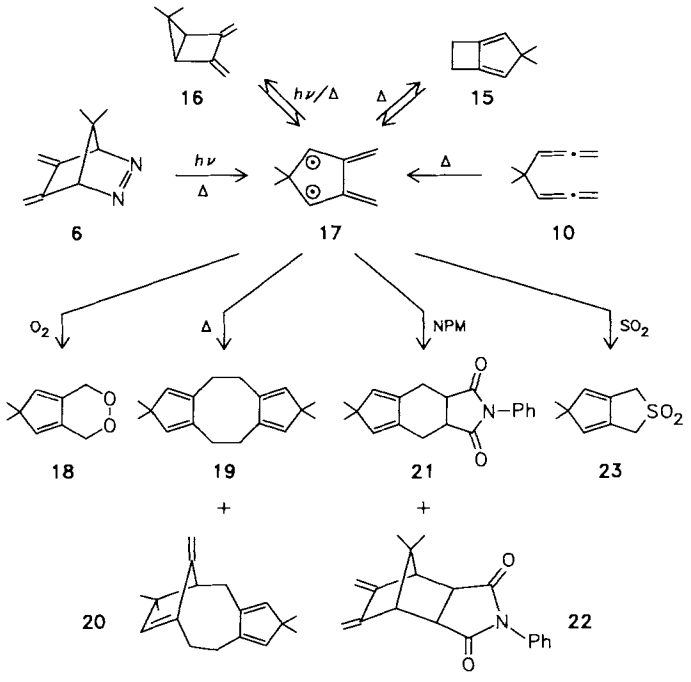
14, selective hydrogenation of which afforded **15**[7]—the third source of **17**—in a total yield of ca. 10% (Scheme 3).

The diradical **17** can be generated from all three precursors **6**, **10**, and **15** thermally, and from **6** also photochemically, whereby only the dimers **19** and **20** are formed as final products. The diazo compound **6** already decomposes at 40 °C, whereas the bisallene **10** requires temperatures of ca. 150 °C ($E_a = 26.3 \pm 0.1$ kcal mol^{-1}; $A = (1.2 \pm 0.1) \times 10^{11}$ s^{-1}) and the bicycle **15** of ca. 220 °C ($E_a = 40.1 \pm 0.8$ kcal · mol^{-1}; $A = (1.2 \pm 0.9) \times 10^{14}$ s^{-1}). When these reactions are carried out in the presence of oxygen, the peroxide **18** is formed as well as **19** and **20**. If **17** is generated in solution in the presence of *N*-phenylmaleimide (NPM) or SO_2, the trapping products **21**, **22**, and **23** are formed.

The diradical **17** establishes equilibrium with **15** at temperatures above 160 °C. The gas-phase thermolysis of **10** at 160 °C leads to the dimers **19** and **20** *and* to the bicycle **15**, which at temperatures in excess of 200 °C reacts further to give **19** and **20**. If the photolysis of **6** (directly or sensitized) is carried out at temperatures below −20 °C, not only **19** and **20** but also the bicycle **16**[10] is formed, which at temperatures above −20 °C decomposes again to the diradical **17**.

Upon irradiation of **6**[11] in an argon matrix ($\lambda = 350$ nm, $T = 10$ K), the formation of the diradical **17** can be demonstrated both UV and IR spectroscopically. In the UV spectrum an absorption band appears at 463 nm ($\varepsilon \approx 400$) with shoulders at 497 and 520 nm, whose position is comparable with that observed for the absorption band of 2,3-dimethylene-1,4-cyclohexanediyl ($\lambda_{max} = 427$ nm ($\varepsilon = 2400$), 480 (sh)).[15] The IR spectrum, with an intense out-of-plane CH vibration at 767 cm^{-1}, is also consistent with the structure of **17**.[12] The bands of **17** disappear on prolonged irradiation of the matrix (slowly at 350 nm, rapidly at 450 nm), and a new substance is formed which shows no absorption above 300 nm in the UV spectrum. The IR spectrum of this new substance shows two intense bands at 868 and 886 cm^{-1}, indicating the presence of *exo*-methylene groups and a cyclization of **17** to **16**.



Informative regarding the multiplicity of the diradical **17** is its ESR spectrum. Irradiation[13] of **6** in an argon matrix ($\lambda = 330$ nm, $T = 22$ K) furnished a triplet spectrum (Fig. 1, $\Delta m = 1$: 3387 G, $\Delta m = 2$: 1690 G), from which the

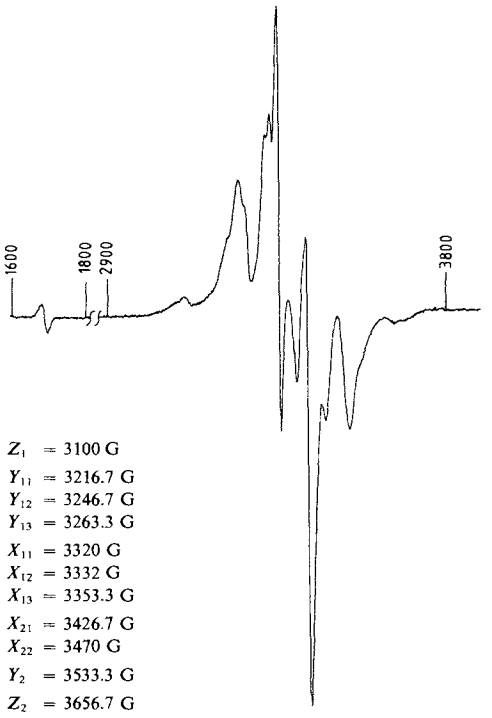


Fig. 1. ESR spectrum of **17** in an argon matrix at 22 K.

zero field parameters were found to be $|D|/(hc) = 0.0259$ and $|E|/(hc) < 0.001$ cm^{-1}. A linear dependence ($r = 0.988$) of the signal intensity on $1/T$ was observed between 15 and 115 K ([D_{16}]adamantane matrix). Thus, contrary to theoretical expectations the singlet and triplet states are either practically degenerated, or, what is more likely, the diradical has a triplet ground state.

Consistent with this interpretation is the observation of polarized ^{1}H-NMR spectra upon thermolysis of **6** (at 40 °C) and **16** (at 0 °C), with the polarized signals appearing exclusively in the emission. The direction of polarization together with the strong dependence of the intensity on the field (no polarization at field strengths above 80 MHz) is consistent with a $T_{\pm} \rightarrow S$ transition,[14] thus requiring thermally achievable triplet states.

The triplet ground state of **17** is also supported by the trapping experiments. Only very reactive dienophiles can compete with the dimerization of the triplet diradical.[15]

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/1212-1286 $ 02.50/0 Angew. Chem. Int. Ed. Engl. 26 (1987) No. 12

Thermal as well as photochemical decomposition of **6** in 1,2-dichloroethylene, styrene or fumarates (as solvent) leads exclusively to the dimers **19** and **20**, and even with *N*-phenylmaleimide the dimerization can only be suppressed with excess of the reagent. Since the ratio of trapping products to dimers is not changed in the sensitized photolysis of **6**, the trapping products most likely are formed from the singlet-species present in equilibrium with the triplet species. If one assumes that dimerization and trapping reaction are diffusion controlled, the singlet state must lie at least 4–5 kcal mol^{-1} above that of the triplet state; if the trapping reaction were slower the energy difference would be even greater.

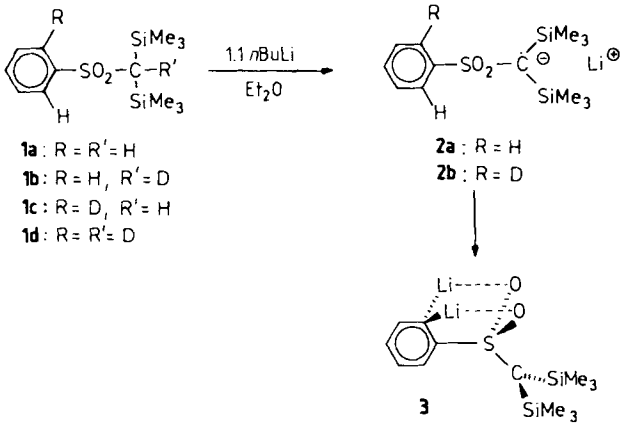
X-Ray Structure Analysis of the Li_2-Compound of Bis(trimethylsilyl)methyl Phenyl Sulfone; Structural Units of an α-Sulfonyl- and a Complex-Stabilized *ortho*-Sulfonyl-"Carbanion"**

By *Werner Hollstein, Klaus Harms, Michael Marsch,* and *Gernot Boche**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Regio- and stereo-control by complexation in reactions with organolithium compounds (directed lithiation) not only led to a "new arene chemistry"[1] (*ortho*-lithiation), but also to the selective preparation of other lithium compounds (complex-induced proximity effects).[2] Herein we report on the lithiation of bis(trimethylsilyl)methyl phenyl sulfone **1a**, which furnishes 1,*o*-dilithiobis(trimethylsilyl)methyl phenyl sulfone **3**. Compound **3** crystallizes as the dimer $[\mathbf{3}\cdot(OEt_2)_2]_2$, which contains the structural units of an α-sulfonyl "carbanion"[3] as well as those of an *ortho*-"carbanion" complex-stabilized by the sulfonyl group.[4,5]



A 1,*o*-dilithio compound of this kind was first characterized chemically and NMR spectroscopically by *Gais* et al. in 1985.[6]

The remarkable formation of the crystalline 1,*o*-dianion $[\mathbf{3}\cdot(OEt_2)_2]_2$ upon reaction of **1a** with 1.1 molar equivalents of *n*BuLi in ether[8] is not fully understood at the moment.[6,7] It can be shown that the sulfones **1a** and **1b** are first completely deprotonated to the dissolved monoanion **2a**,[9] but just how **2a** transforms into **3** and $[\mathbf{3}\cdot(OEt_2)_2]_2$ is still unclear. The dianion character of $[\mathbf{3}\cdot(OEt_2)_2]_2$ was confirmed by deuteriation to **1d**; its structure is reproduced in Figure 1.

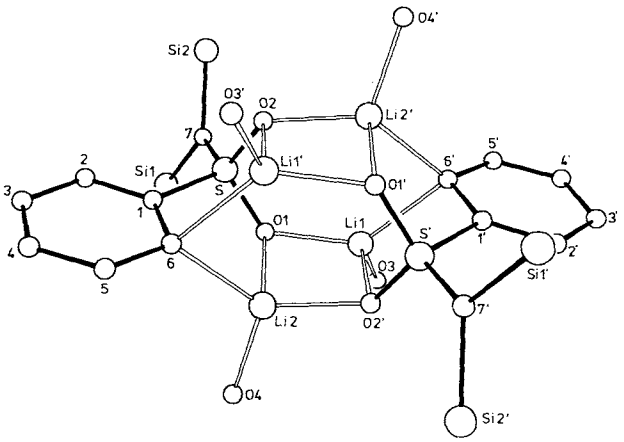


Fig. 1. Crystal structure of $[\mathbf{3}\cdot(OEt_2)_2]_2$. The atomic radii are arbitrary. For clarity, all H atoms, the CH_3 groups of the trimethylsilyl substituents and the CH_3CH_2 groups of the ether molecules are omitted. One CH_3 position of a diethyl ether ligand is disordered. $[\mathbf{3}\cdot(OEt_2)_2]_2$ has an inversion center; symmetry-dependent atoms are primed. Space group $P2_1/c$, $a=11.195(3)$, $b=21.374(5)$, $c=12.619(3)$ Å, $\beta=112.66(3)°$, $Z=4$ (referred to the monomer). Measurements on an Enraf-Nonius CAD4 four-circle diffractometer with graphite monochromated $Cu_{K\alpha}$ radiation at 210 K. 4328 measured reflections (2θ 4–100°); after Lp correction and averaging there remained 2061 observed reflections with $F_o > 3\sigma(F_o)$, which were used for the calculations. Solution by direct methods, refinement according to the least-squares method to $R=0.048$, non-hydrogen atoms anisotropic, hydrogen atoms isotropic [$B(H)=1.3\,B_{equ}(C)$] at calculated positions with a riding model. Some important bond lengths [pm] and angles [°]: C1-S 180.1(5), C7-S 163.7(5), S-O 149.4(3), C7-Si 183.9(4), C6-Li2 215.8(9), C6-Li1' 217.8(9), Li2-O1 204.8(8), Li2-O2' 199.3(8), Li2-O4 195.0(8), Li1-O1 193.8(8), Li1-O2' 214.2(8), Li1-O3 196.4(8); O1-S-O2 109.6(2), Li2-C6-Li1' 83.3(3); torsion angles: O1-S-C1-C6 −47.8(4), O2-S-C1-C6 65.4(4), O1-S-C7-Si1 −50.8(4), O2-S-C7-Si2 13.3(4), C1-S-C7-Si1 66.6(4), C1-S-C7-Si2 −103.1(3), C7-S-C1-C6 −171.8(4), S-C1-C6-Li2 37.8(5), S-C1-C6-Li1' −47.1(4).—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52656, the names of the authors, and the journal citation.

Coupling to the dimer takes place via two Li–O–Li–O four-membered rings. Each $Li^{\oplus}$ (e.g. Li2) is bound to an *ortho* C atom (C6), to two O atoms of two different sulfonyl groups (O1 and O2′) and to one diethyl ether O atom (O4). The sp^2 orbital at C6 is oriented almost centrally between Li2 and Li1′ (the torsion angles S-C1-C6-Li2 and S-C1-C6-Li1′ are 37.8(5) and −47.1(4)°, respectively). The two $Li^{\oplus}$ (e.g. Li2 and Li1′) which are coupled to an *ortho* C atom (C6) are complexed by the neighboring sulfone O atoms O1 and O2 such that five-membered rings are formed (e.g. C6-Li1′-O2-S-C1).[10] The ease of *ortho*-lithiation of arenes with an RSO_2 group[4] is thus understandable. The structure computed for $Li_2CHSO_2CH_3$ by *Streitwieser* et al.[11] is very similar to that of $[\mathbf{3}\cdot(OEt_2)_2]_2$ in one respect: the two $Li^{\oplus}$ are bound to the two sulfone O atoms and an "anionic" C (α-C).

The structural characteristics of the α-sulfonyl anion moiety of $[\mathbf{3}\cdot(OEt_2)_2]_2$ are not influenced to any great extent but, nevertheless, noticably so by the dianion formation: the C7–S bond is shortened from 174.7(5) pm in the sulfone **1a**[12] to 163.7(5) pm, and the S–O bonds are lengthened from 144.3(3) pm to 149.4(3) pm; hence, the S–O bonds here are ca. 3 pm longer than in the known α-sulfonyl "carbanions".[3] This could be due to the fact that each O atom in the "dianion" $[\mathbf{3}\cdot(OEt_2)_2]_2$ is coordinated to two $Li^{\oplus}$, but in the monoanions to only one $Li^{\oplus}$. The dihedral angles O1-S-C7-Si1 (−50.8(4)°) and O2-S-C7-Si2 (13.3(4)°) would indicate that the lone pair on C7 assumes a *gauche* conformation to the sulfone O atoms, which is rotated through ca. 18.5° from the ideal position; the same situation is found in monoanions.[3a] C7 is almost planar coordinated: the sum of the torsion angles C1-S-C7-Si1 and C1-S-C7-Si2 is 169.7°. Further, the eight-membered ring (e.g. S-O1-Li1-O2′-S′-O1′-Li1′-O2), which characterizes α-sulfonyl "carbanion" dimers, is also still present.

The X-ray structure analysis of $[\mathbf{3}\cdot(OEt_2)_2]_2$ thus confirms the structural characteristics found in α-sulfonyl "carbanions"; further, the five-membered ring complexation of $Li^{\oplus}$ by the O atoms of an RSO_2 group in an aromatic *ortho* anion is recognizable which contributes to its ease of formation.

[6] a) In the reaction of allyl phenyl sulfone with *two* molar equivalents of *n*BuLi in THF at low temperatures the initially formed α-sulfonyl "carbanion" reacts further to give the 1,*o*-dianion corresponding to **3**. Transprotonation to the 1,1-dianion takes place at 50°C [7]; see J. Vollhardt, H.-J. Gais, K. L. Lukas, *Angew. Chem. 97* (1985) 607; *Angew. Chem. Int. Ed. Engl. 24* (1985) 608; b) the second lithiation of (trimethylsilyl)methyl phenyl sulfone proceeds exclusively to the 1,1-dianion; see J. Vollhardt, H.-J. Gais, K. L. Lukas, *ibid. 97* (1985) 695 and *24* (1985) 696; c) the α-sulfonyl "carbanions" mentioned under [3a-d] are formed from the sulfone and one molar equivalent of *n*BuLi; nothing has been reported about a further reaction product. 2,*o*-Dilithio compounds are also known: J. E. Mulvaney, S. Groen, L. J. Carr, Z. G. Garlung, *J. Am. Chem. Soc. 91* (1969) 388; H. M. Walborsky, P. Ronman, *J. Org. Chem. 43* (1978) 731.

[7] 1,1-Dilithiosulfones have been known for some time: a) E. M. Kaiser, L. E. Solter, R. A. Schwarz, R. D. Beard, C. R. Hauser, *J. Am. Chem. Soc. 93* (1971) 4237; b) J. B. Evans, G. Marr, *J. Chem. Soc. Perkin Trans. 1 1972*, 2502; c) K. Kondo, D. Tunemoto, *Tetrahedron 1975*, 1397; d) A. Roggero, T. Salvatori, A. Proni, A. Mazzei, *J. Organomet. Chem. 177* (1979) 313; e) S. P. J. M. van Nispen, C. Mensink, A. M. van Leusen, *Tetrahedron Lett. 21* (1980) 3723; f) M. C. Mussatto, D. Savoia, C. Trombini, A. Umani Ronchi, *J. Org. Chem. 45* (1980) 4002; g) J. J. Eisch, S. K. Dua, M. Behrooz, *ibid. 50* (1985) 3674.

[8] *Procedure* for $[\mathbf{3}\cdot(OEt_2)_2]_2$: A solution of **1a** (90 mg, 0.30 mmol) in diethyl ether (1 mL) was treated at room temperature with 0.33 mmol of *n*BuLi in hexane. After 10 min the solution was evaporated down to about 0.5 mL in an oil-pump vacuum. Single crystals suitable enough for an X-ray analysis could be isolated from the solution after 1 hour. Yield: 44 mg (0.05 mmol), 30%.

[9] The exclusive formation of **2a** from **1b** additionally shows that the deprotonation of **1** does not initially lead to an *ortho* anion that is transprotonated in a second step to the α-anion **2**. Otherwise **2b** and, after protonation, **1c** would have to be formed; deuterium determinations were carried out mass spectrometrically. A corresponding experiment was carried out for the first time by *Gais* et al., see [6b]. A related problem has recently been investigated by other authors: A. I. Meyers, K. B. Kunnen, W. C. Still, *J. Am. Chem. Soc. 109* (1987) 4405. For the mechanism of the second lithiation in some other compounds see: W. Bauer, T. Clark, P. von R. Schleyer, *J. Am. Chem. Soc. 109* (1987) 970; W. Coupling of Two Ethyne Molecules at a Nickel Center to Form a Nickelacyclopentadiene Complex

By *Klaus-Richard Pörschke**

The nickel catalyzed cyclooligomerization reactions of acetylene discovered by *Reppe* presumably proceed stepwise by a mechanism involving a nickelacyclopentadiene intermediate.[1] Compounds of this type are already known for other metals,[2] whereas with nickel so far only substituted derivatives have been obtained.[3] Continuing our investigations on ethyne complexes of nickel(0)[4] we have now observed for the first time a coupling of two ethyne molecules on nickel(0) at −78°C (!), leading to formation

[*] Dr. K.-R. Pörschke

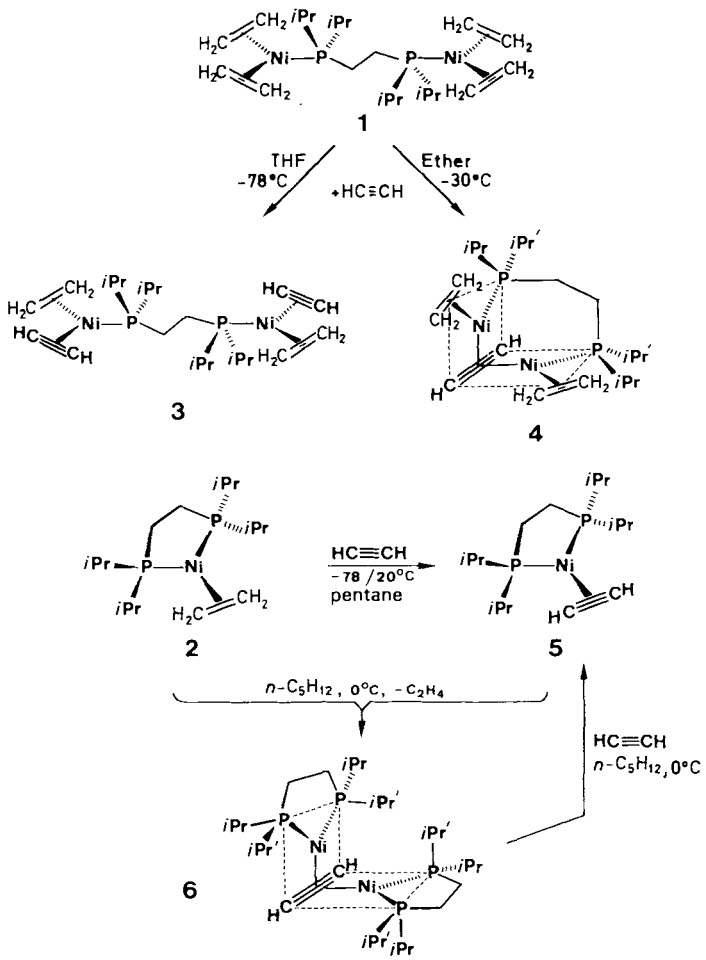
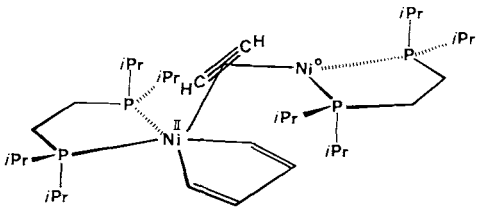
Postfach 101353, D-4330 Mülheim a. d. Ruhr 1 (FRG)

of a nickelacyclopentadiene complex with bis(diisopropylphosphino)ethane as stabilizing ligand.

When tris(ethene)nickel(0)[5] is treated with stoichiometric amounts of iPr$_2$PC$_2$H$_4$PiPr$_2$ in pentane the crystalline ethene complexes [(μ-iPr$_2$PC$_2$H$_4$PiPr$_2$){Ni(C$_2$H$_4$)$_2$}$_2$] (**1**) and (iPr$_2$PC$_2$H$_4$PiPr$_2$)Ni(C$_2$H$_4$) (**2**) can be isolated. **1** reacts with ethyne in THF at −78°C to yield the mixed ethene/ethyne dinuclear complex [(μ-iPr$_2$PC$_2$H$_4$PiPr$_2$)-{Ni(C$_2$H$_4$)(C$_2$H$_2$)}$_2$] (**3**)[6] as a colorless crystalline and rather sensitive compound. A similar reaction proceeds in ether at −30°C to afford yellow crystals of [(μ-iPr$_2$PC$_2$H$_4$PiPr$_2$){Ni(C$_2$H$_4$)}$_2$(μ-C$_2$H$_2$)] (**4**),[7] in which only one ethyne ligand is present, bridging the nickel atoms. From **2** and ethyne the complex [(iPr$_2$PC$_2$H$_4$PiPr$_2$)Ni(C$_2$H$_2$)] (**5**; C$_2$H$_2$: ν = 1598 cm^{-1}, δ_H = 7.29, δ_C = 123.8, ^1J(CH) = 202 Hz) is obtained, which, particularly in solution, is comparatively stable. **5** reacts with the ethene complex **2** at 0°C with liberation of ethene to afford [{(iPr$_2$PC$_2$H$_4$PiPr$_2$)Ni}$_2$(μ-C$_2$H$_2$)] (**6**; μ-C$_2$H$_2$: ν = 1315 cm^{-1}, δ_H = 5.52, δ_C = 86.3, ^1J(CH) = 188 Hz), in which the ethyne ligand bridges two bis(phosphane)nickel(0) moieties. **6** is cleaved by ethyne at 0°C into two molecules of **5**. Single crystal X-ray structure analyses have been carried out on **5** (d(C≡C) 1.287(7) Å) and **6** (d(C≡C) 1.335(7) Å).[8]



When iPr$_2$PC$_2$H$_4$PiPr$_2$ and excess ethyne are added to a pentane solution of **1** at −78°C, fine yellow crystals of the nickelacyclopentadiene complex **7** separate out in the course of 48 h. Apparently, **7** is formed via **3**: presumably the bridging iPr$_2$C$_2$H$_4$PiPr$_2$ ligand of **3** transforms under the influence of the added iPr$_2$PC$_2$H$_4$PiPr$_2$ into the chelating binding mode and in the course of this reorientation two of the ethyne molecules combine to form the nickelacyclopentadiene group, while a third ethyne molecule forms a bridging ligand between the formal nickel(II) ion and the nickel atom.



7

7 has been characterized by its ^{1}H-, ^{13}C-, ^{31}P-NMR, and IR spectra[9]. The C≡C stretching vibration of the bridging ethyne ligand of **7** occurs at the same wave number ν = 1315 cm^{-1} as that of **6**. The ^{1}H- and ^{13}C-NMR data of the ethyne ligand of **7** (δ_H = 5.96, δ_C = 98.8, ^1J(CH) = 190 Hz) are similar to those of **6** and also indicate a bridging ethyne ligand (cf. values of **5**). For the μ-C$_4$H$_4$ ligand the chemical shifts and coupling constants of δ_H = 5.09, 4.85 and δ_C = 115.6 (^1J(CH) = 151 Hz, NiCH=*C*H−), 110.8 (^1J(CH) = 143 Hz, Ni−*C*H=) are in the range expected for a metal alkenyl group. In the ^{31}P-NMR spectrum two singlets for the iPr$_2$PC$_2$H$_4$PiPr$_2$ ligands show that the P atoms of each ligand do not couple with those of the neighboring ligand. We are currently studying further reactions of **7**.

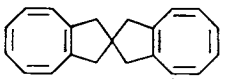
The Dependence of Intramolecular Electron Transfer on Structure in a Spiro Compound Containing Two Cyclooctatetraene Moieties**

By *Günter Krummel, Walter Huber,* and *Klaus Müllen**

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

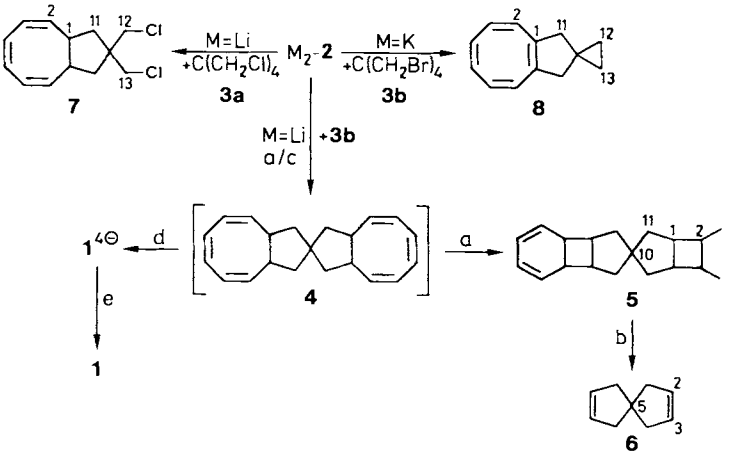
The rate constants of the intramolecular electron transfer between separate redox units[1] are not only dependent on the substrate and ion-pair structure[2] but also on the length and conformation of the bridging group.[3,4] We have generated extended redox sequences of several "bis-electrophoric" systems and have been able to alter the energy profiles of intramolecular electron transfers.[5,6]



1

The previously unknown compound **1**, 10,10′-spirobi(bicyclo[6.3.0]undeca-2,4,6,8-tetraene), offers the following advantages over already investigated model systems: 1) the subunits are fixed orthogonally to each other by the spiro coupling;[3,6] 2) both a direct π,π conjugation[7–9] as well as a through-space conjugation[6] between the subunits are ruled out; 3) because of the planarization of the cyclooctatetraene (COT) necessary for ion formation,[10] the reorganization energy required for an intramolecular electron transfer between the subunits should be increased.

We describe here the synthesis of **1** and structurally related compounds, the generation of $\mathbf{1}^{\odot\ominus}$, $\mathbf{1}^{2\ominus}$, and $\mathbf{1}^{4\ominus}$ and discuss the possibility of electron transfer between COT subunits of these anions. The method of choice for the preparation of **1** (Scheme 1) is that previously used by us on several occasions: cycloannelation by reaction of dianions with bifunctional electrophiles.[11] After alkylation of the cyclooctatetraene dianion Li_2-**2** (2 equiv.) with tetrabromoneopentane **3b** and aqueous work-up the polycycle **5** is isolated in 56% yield. Apparently a twofold cycloannelation takes place, but the primary product undergoes a valence isomerization under the reaction conditions. The ^{13}C-NMR spectrum of **5** (Table 1) shows that only one species of several conceivable configurational isomers exists. Photolysis of **5** leads via cleavage of benzene to formation of the previously unknown spiro[4.4]nona-2,7-diene **6** as sole product (Table 1).



Scheme 1. a) NH_3, −33°C; H_2O, 20°C. b) Pentane, 3×10^{-3} M, Pyrex lamp. c) NH_3, −60°C; d) NH_3, −60°C, KNH_2. e) $CdCl_2$.

The course of the cycloannelation reaction depends on the structure of the ion pair of the nucleophile and on the leaving group of the electrophile **3** (Scheme 1). Alkylation of Li_2-**2** with the chloride **3a** instead of with the bromide **3b** leads to formation of only the monoadduct **7** (Table 1). On the other hand, if the potassium salt K_2-**2** is allowed to react with **3b** only the polycycle **8** is obtained after dehydrogenation (cf. **4** → $\mathbf{1}^{4\ominus}$ → **1**) (Table 1), i.e., here a reductively induced three-membered ring formation follows the cycloannelation.

The conversion of **4** into **5** can be partially suppressed by working at lower temperatures (Scheme 1), and the target compound **1** is obtained via the tetraanion $\mathbf{1}^{4\ominus}$.[12]

Table 1. Melting points (**5**, 7) and ^{13}C-NMR data [a] of **5**–**8**.

5: 83°C; δ=127.6, 127.5, 120.6 (C3–C6, C3′–C6′), 57.6 (C10), 52.0, 51.1 (C2, C7, C2′, C7′), 47.4, 46.3 (C1, C8, C1′, C8′), 37.0, 36.8 (C9, C11, C9′, C11′)

6: δ=130.1 (C2, C3, C7, C8), 48.7 (C5), 47.5 (C1, C4, C6, C9)

7: 84–85°C; δ=134.8, 128.2, 127.7 (C2–C7), 51.5, 50.6 (C12, C13), 46.3 (C10), 43.0, 41.8 (C1, C8, C9, C11)

8: δ=140.2 (C1, C8), 132.5, 131.7, 131.2 (C2–C7), 47.3 (C9, C11), 19.0 (C10), 14.7 (C12, C13)

[a] $CDCl_3$; **5**, **6** 100 MHz; 7, **8** 50 MHz.

The spectroscopic characterization of **1** at room temperature (Table 2) indicates a structure with effective D_{2d} symmetry. Cooling leads to a line-broadening of the singlet signal of the methylene protons and finally at −60°C to the appearance of the signals of two AB systems. This dynamic behavior confirms that both rings are present in a tub conformation.

When a solution of **1** in [D$_8$]tetrahydrofuran is brought into contact with lithium the tetraanion $\mathbf{1}^{4\ominus}$ is formed again. The number and position of the NMR signals (Table 2) indicate a structure with D_{2d} symmetry which contains two planar $COT^{2\ominus}$ units. If one monitors the reduction of **1** NMR spectroscopically it is possible to detect the dianion $\mathbf{1}^{2\ominus}$ as intermediate. The number of the ^{1}H- and ^{13}C-NMR signals (Table 2) shows beyond doubt that the

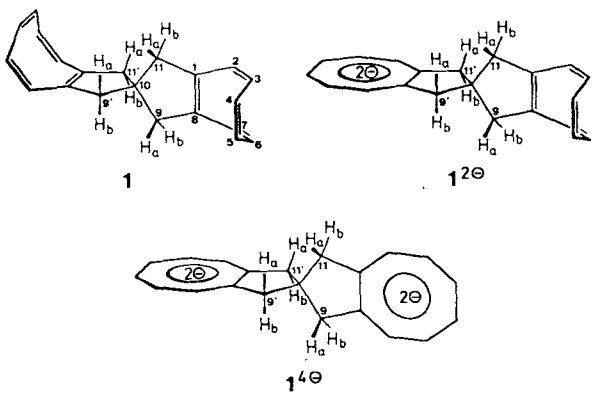
excess charge remains localized in a single eight-membered ring and, as a consequence, a charged and a neutral π-unit are present alongside each other. The equivalence of H9a and H11a and non-equivalence of H9a′ and H11a′ observable at −60°C points to planarity of the charged eight-membered ring and the tub conformation of the uncharged eight-membered ring (Scheme 2). Above 10°C, a rapid inversion of the uncharged ring, recognizable by the coalescence of the signals of H9a′ and H11a′, takes place. No change in the ^{13}C-NMR spectra is observed on heating to 40°C, so that an intramolecular electron transfer on the time scale accessible in the experiment can be ruled out.



Scheme 2. NMR spectroscopically derived structures of **1**, $\mathbf{1}^{2\ominus}$, and $\mathbf{1}^{4\ominus}$.

During the reduction of **1**, the NMR signals of **1** and $\mathbf{1}^{2\ominus}$ are observed alongside each other without significant line-broadening. This shows that no rapid intermolecular electron transfer takes place and that the intermediate radical anion $\mathbf{1}^{\odot\ominus}$ disproportionates. The ion $\mathbf{1}^{\odot\ominus}$, which apparently is present in only low concentration, cannot be detected ESR spectroscopically. Its characterization can only be achieved if it is generated from the dianion by photooxidation. The ESR coupling constants a_H (0.40 (6 H, COT-ring), 0.40 (2 H, CH_2), 0.88 mT (2 H, CH_2)) show that the unpaired electron is localized in one COT moiety.

Take-up of an electron by **1** forces, as also in COT **2**, a planarization of the eight-membered ring, which contains the additional electron. Such a change of conformation would have to occur alternately in the two eight-membered rings if an intramolecular charge fluctuation between the subunits were to take place in $\mathbf{1}^{\odot\ominus}$ or $\mathbf{1}^{2\ominus}$. As a result of the associated increased reorganization energy,[8–10] the excess charge of $\mathbf{1}^{\odot\ominus}$ and $\mathbf{1}^{2\ominus}$ therefore remains localized in one subunit. The activation energy for the ring inversion of the uncharged ring of $\mathbf{1}^{2\ominus}$, which we determined as 12 kcal mol^{-1}, should comply with the activation barrier of the charge fluctuation. This is also consistent with the fact that the spatial separation of COT subunits is not solely responsible for the charge localization, since rapid intramolecular electron transfer processes can take place in ion pairs with separate rigid subunits.[13]

Dibenzo[*fg,mn*]octalene and Cycloocta[*def*]phenanthrene. New Models for the Conformational Analysis of Biphenyl Systems**

By *Willi Heinz, Peter Langensee,* and *Klaus Müllen**

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

An important step in the conformational analysis of biphenyl systems is the bridging of the *ortho* positions.[1,2] The compounds **1**, **2**, and **3**[3,4] are particularly attractive

[*] Prof. Dr. K. Müllen, Dipl.-Chem. W. Heinz, Dr. P. Langensee

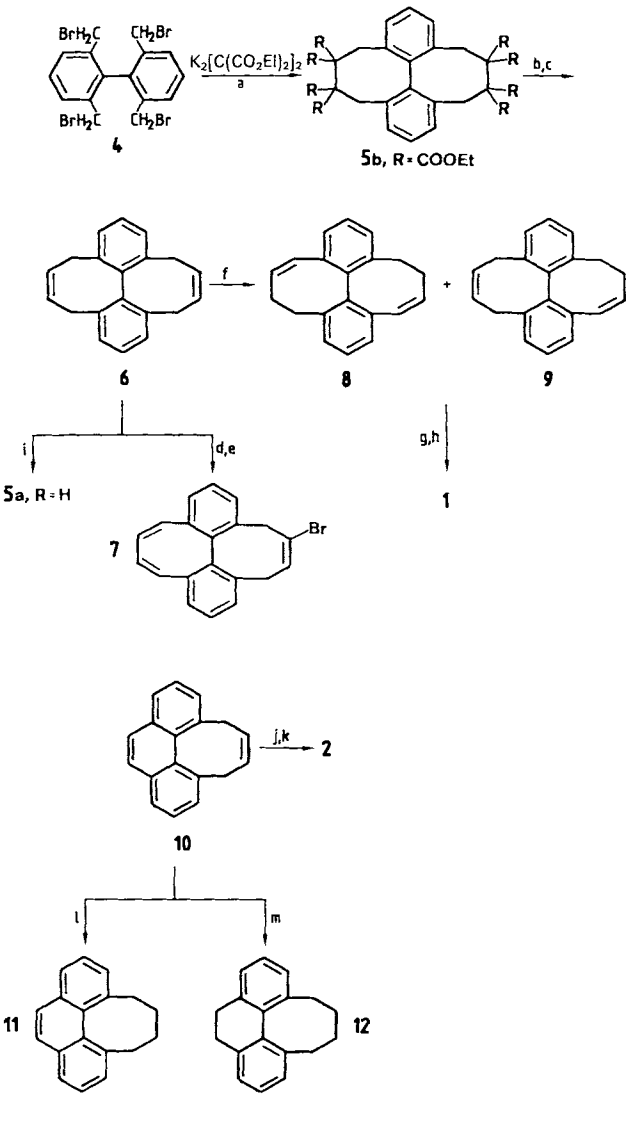
tional importance in view of the recently described finding that the energy profiles of conformational conversions can be influenced by electron transfer processes.[5–7] Herein we describe the synthesis, structure, and redox chemistry of the new compounds dibenzo[*fg,mn*]octalene **1** and cycloocta[*def*]phenanthrene **2** and the saturated analogues **5a**, **6** and **8**, and **10**–**12**, respectively, derived therefrom. In the case of the dianion of **1** it was possible to demonstrate a symmetry deformation by charge localization.

The key step of the synthesis of **1** is the reaction of 2,2′,6,6′-tetra(bromomethyl)biphenyl **4** with the dipotassium salt of ethyl ethanetetracarboxylate to give the octaester **5b**, in which two condensed eight-membered rings are formed in one step (Scheme 1). For transformation into **1** the diene **6** obtainable from **5b** by hydrolysis/decarboxylation and subsequent oxidative decarboxylation[4] was converted by bromine addition into a tetrabromide, dehydrobromination of which however, for conformational reasons, did not furnish **1** but only **7**. Therefore **6** was first subjected to a base-induced isomerization. The resulting 7:3 mixture of **8** (*syn/anti*) and **9** after bromination with *N*-bromosuccinimide (NBS) and dehydrobromination affords compound **1** [m.p. 188°C (hexane), colorless needles]. The cycloocta[*def*]phenanthrene **2** is synthesized analogously from 4,5-di(bromomethyl)phenanthrene via **10** (Scheme 1). The partially hydrogenated analogues **5a** as well as **11** and **12** are formed upon reduction of the precursors **6** and **10**, respectively, with H_2. Characteristic data of the new compounds are listed in Tables 1 and 2.



Scheme 1. a) Dimethoxyethane/toluene (1/1), 110°C; 25%. b) KOH, ethylene glycol, 200°C; 84%. c) Pb(OAc)$_4$, pyridine, 65°C; 23%. d) Br_2, CCl_4, 0°C. e) 1,5-diazabicyclo[4.3.0]non-5-ene, toluene, 110°C; 27% referred to **6**. f) *t*BuOK, THF, 65°C. g) NBS, CCl_4, 80°C. h) *t*BuOK, THF, 20°C; 40% referred to **6**. i) H_2 (2 equiv.), Pd/C (5%), ethyl acetate, 25°C; 81%. j) Br_2, CCl_4/hexane, −80°C; 90%. k) 1,8-Diazabicyclo[5.4.0]undec-7-ene, benzene, 80°C; 43%. l) Analogous to (i) (1 equiv. H_2); 80%. m) Analogous to (i); 91%.

Table 1. Melting points (apart for **15**) and ^{1}H-NMR spectroscopic data of the compounds **5a**, **6**, **10**–**13**, and **15**.

5a, m.p. 123°C; ^{1}H-NMR ($C_2D_2Cl_4$, 300 MHz, 110°C): δ=7.31 (t, 2H; *p*-$H_{arom.}$), 7.15 (d, 4H; *m*-$H_{arom.}$), 2.69 (m, 4H), 2.15–2.05 (m, 8H), 1.56 (m, 4H)

6, m.p. 204–205°C; ^{1}H-NMR ($CDCl_3$, 400 MHz): δ=7.29 (t, 2H; *p*-$H_{arom.}$), 7.05 (d, 4H; *m*-$H_{arom.}$), 5.81 (m, 4H; $H_{olef.}$), 3.09, 2.90 (AB system, 8H)

10, m.p. 86.5°C; ^{1}H-NMR (CD_2Cl_2, 300 MHz, 20°C): δ($H_{arom.}$)=7.68 (d, 2H), 7.55 (t, 2H), 7.51 (s, 2H), 7.38 (d, 2H), δ=6.32 (t, 2H; $H_{olef.}$), 3.22 (d, 4H)

11, m.p. 88.5°C; ^{1}H-NMR (CD_2Cl_2, 300 MHz, −30°C): δ($H_{arom.}$)=7.66 (d, 2H), 7.52 (s, 2H), 7.56–7.47 (m, 4H), δ($H_{aliph.}$)=2.91 (m, 2H), 2.33 (m, 2H), 2.21 (m, 2H), 1.99 (m, 2H)

12, m.p. 87°C; ^{1}H-NMR ($CDCl_3$, 300 MHz, 20°C): δ=7.30–7.16 (m, 6H; $H_{arom.}$), 2.89–2.66 (m, 6H), 2.23–2.15 (m, 4H), 1.80–1.73 (m, 2H)

13, m.p. 149–150°C; ^{1}H-NMR ($C_2D_2Cl_4$, 300 MHz, 120°C): δ=7.39–7.26 (m, 8H; $H_{arom.}$), 2.74 (m, 2H), 2.25–2.10 (m, 4H), 1.60 (m, 2H)

15, ^{1}H-NMR ($CDCl_3$, 200 MHz, 20°C): δ=7.27–6.90 (m, 6H; $H_{arom.}$), 6.73, 6.03 (AA′BB′ system, 4H; "butadiene" H), 5.84 (m, 2H; $H_{olef.}$), 3.57 (m, 2H; 2C*H*–CH_3), 0.47 (d, 6H; 2CH_3)

The twisting with respect to the C8–C8′ bond brought about by the tub conformation of the unsaturated eight-membered rings of **1** and **2** as well as the bond alternation are confirmed by the small value for the vicinal coupling constant ^3J(H8,H8′) (see Table 2). According to the X-ray structure analysis[8] the eight-membered ring subunit of **2** is more flattened than that of **3a**[9] (twist angles of the biphenyl moiety: 33.0 and 68.5°; of the butadiene moiety: 51.2 and 58.0°).

If one takes the position of the conjugation band of the respective biphenyl unit[1] in the UV spectrum as a measure of the twist [λ [nm] (ε): **1**, 217 (32000); **3a**, 230 (24000); **5a**, 220 (13000); **12**, 260 (12300); **13**, 235 (11800)], the interplanar angle of the biphenyl system should, firstly, be greater in **1** than in **3a**, secondly, remain unaltered in the transition from **1** and **3a** to **5a** and **13**, respectively, and, thirdly, be smallest in the dihydrophenanthrene system **12**.

Table 2. $^1H[\delta_H]$- and $^{13}C[\delta_C]$-NMR chemical shifts as well as the magnitudes of the vicinal couplings ^3J [Hz] of **1**, **2**, **3a** and K_2-**1**, Li_2-**2**, K_2-**3a** [a].

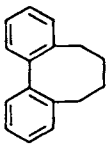
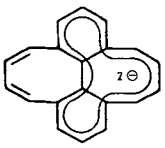
[b] Assignment not confirmed experimentally. [c] One of the signals between $\delta = 126.8$ and 128.2.



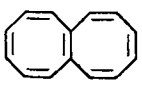
13

The synthesis of the salts M_2-**1** and M_2-**2** was achieved by treatment of **1** and **2**, respectively, with alkali metal (M = Li, K) in [D$_8$]THF. The NMR spectroscopic characterization of the ions (see Table 2) revealed the relationship of **2**$^{2\ominus}$ and **3a**$^{2\ominus}$.[10,11] Characteristic of both species are the distribution of the charge over the *whole* π-electron system (as derived from the chemical shifts), the diatropism of the ions, and the formation of *planarized* eight-membered rings with π-bond delocalization [see the adjustment of the vicinal H,H couplings ^3J(H7,H8) and ^3J(H8,H8')].

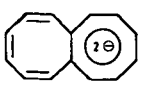
Whereas the number of the NMR signals is consistent with a D_2 symmetry for the neutral compound **1**, a lowering of the symmetry is observed in **1**$^{2\ominus}$. The number and position of the signals of **1**$^{2\ominus}$ can only be interpreted in terms of the excess charge of the dianion remaining localized in a dibenzocyclooctene moiety (see **1a**$^{2\ominus}$). Whereas the charged substructure becomes more planar, the uncharged butadiene bridge remains bent. The strain associated with a flattening of the whole molecule is apparently so great that it does not permit a symmetric structure with electrostatically preferred charge delocalization. Even at room temperature there is no fluctuation of charge between charged and uncharged subunits in **1**$^{2\ominus}$.



1a$^{2\ominus}$



14



14a$^{2\ominus}$

The conformationally determined charge localization in **1**$^{2\ominus}$ invites comparison with **3b**, **3c**, and **14**:

- ion formation in **3b** effects a flattening or drastically reduces the inversion barrier of the eight-membered ring;[6,7] only strong steric interactions as in **3c** lead to non-planar dianions;[7]
- the dianion of octalene **14** has D_{2h} symmetry even at −145°C; i.e. should structures with charge localization (**14a**$^{2\ominus}$) occur, then they rapidly interconvert.[12]

The charge localization in **1**$^{2\ominus}$ has characteristic chemical consequences. The kinetically controlled attack of electrophiles on dianion-intermediates[13] preferentially takes place at the site of highest charge density; in the case of a charge delocalization in **1**$^{2\ominus}$ (D_{2h}), this would, according to a simple MO consideration, be at C1 and C1'. These bridgehead centers are the centers of highest charge density in **14**$^{2\ominus}$, as has been shown by preparatively useful reductive transformations via Li_2-**14**.[14] That the charge distribution in **1**$^{2\ominus}$ corresponds to that in **3a**$^{2\ominus}$ but not to that in **14**$^{2\ominus}$, follows from the reaction of K_2-**1** with dimethyl sulfate: exclusively the dimethyl adduct **15** is formed.

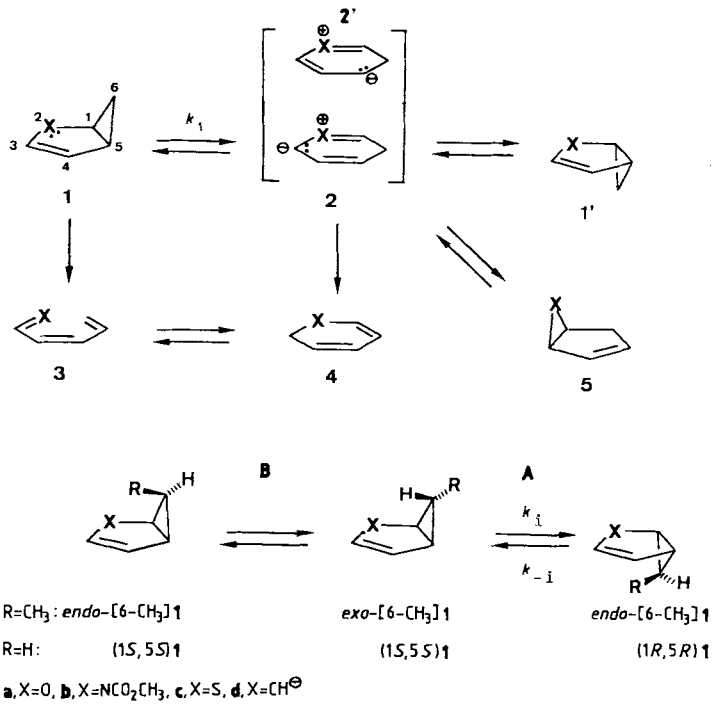
1,5-Electrocyclization in Homofuran, Homopyrrole, and Homothiophene**

By *Frank-Gerrit Klärner** and *Dietmar Schröer*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

Carbonyl ylides and azomethyne ylides—the products of oxirane and aziridine ring-opening, respectively—are presently attracting considerable interest (e.g. as reaction partners in 1,3-dipolar cycloadditions).[1] The 1,5-electrocyclic ring-opening[2] of the heterocycles homofuran **1a**,[3] homopyrrole **1b**,[4] and homothiophene **1c**[3]—isoelectronic with the bicyclo[3.1.0]hexenyl anion **1d**—should lead to ylide intermediates of the type **2**, which can also be regarded as vinylogous carbonyl ylides, azomethine ylides, and thiocarbonyl ylides **2'**, respectively.



Scheme 1. Valence tautomerizations starting from **1**.

Hitherto, only the epimerization of *exo*- and *endo*-6-methylhomofuran (Scheme 1, bottom) was known,[5] but it was not known whether it takes place, as required for the electrocyclic process, by cleavage of the central cyclopropane bond C^1–C^5 (Route **A**) or by cleavage of one of the peripheral cyclopropane bonds C^1–C^6 or C^5–C^6 (Route **B**). With optically active **1** it should be possible to establish which one of the two alternatives applies, since the epimerization via Route **A** should proceed with concomitant racemization, that via Route **B**, on the other hand, without racemization.

We partially separated racemic **1a** and **1b** into the enantiomers by medium-pressure chromatography on microcrystalline triacetylcellulose (with 95% ethanol as eluant, (−)-**1a** and (−)-**1b**, respectively, were obtained as first fraction and (+)-**1a** and (+)-**1b**, respectively, as second fraction).[6] The enantiomeric excess (*ee*) of (+)-**1a** ($[\alpha]_D^{20} = 194.5°$) could be determined ^{1}H-NMR spectroscopically using the chiral shift reagent Eu(hfc)$_3$ to be 34%.[7,8]

Optically active homofuran **1a** racemizes without side reactions at about 70°C. The temperature-dependence of the rate constants (in dioxane) determined from the decrease of $[\alpha]_D$ with time between 60 and 90°C can be described with the Arrhenius equation (a).

$$k_{rac} = (3.7 \pm 1.3) \times 10^{13} \exp[-(118.6 \pm 1.0)\,\mathrm{kJ\,mol^{-1}(RT)^{-1}}]\,\mathrm{s^{-1}} \quad \text{(a)}$$

Optically active homopyrrole **1b** already slowly racemizes at room temperature. The rate constants determined between 28 and 61°C fit the Arrhenius equation (b).

$$k_{rac} = (1.9 \pm 0.6) \times 10^{13} \exp[-(102.5 \pm 0.4)\,\mathrm{kJ\,mol^{-1}(RT)^{-1}}]\,\mathrm{s^{-1}} \quad \text{(b)}$$

In the case of the homothiophene system all attempts to separate racemic **1c** chromatographically or its methyl derivatives *exo*-[6-CH_3]**1c** and *endo*-[6-CH_3]**1c**, which are formed in the ratio 65 : 35[9] in the copper(I) chloride-catalyzed reaction of thiophene and diazomethane, gas chromatographically, met without success. An explanation for this is found in the ^{1}H-NMR spectra of **1c** recorded at several temperatures (Fig. 1). Above 80°C the exchange of the cyclopropane H atoms *exo*-6-H and *endo*-6-H is rapid on the NMR time scale. The signals of the olefinic H atoms 3-H and 4-H, however, remain unchanged over the whole temperature range, as to be expected for the epimerization process.[10] The rate of exchange of *endo*-6-H and *exo*-6-H at the coalescence temperature of 120°C is estimated with an approximation formula to be $k_{coal} = 205\ \mathrm{s^{-1}}$.[11]

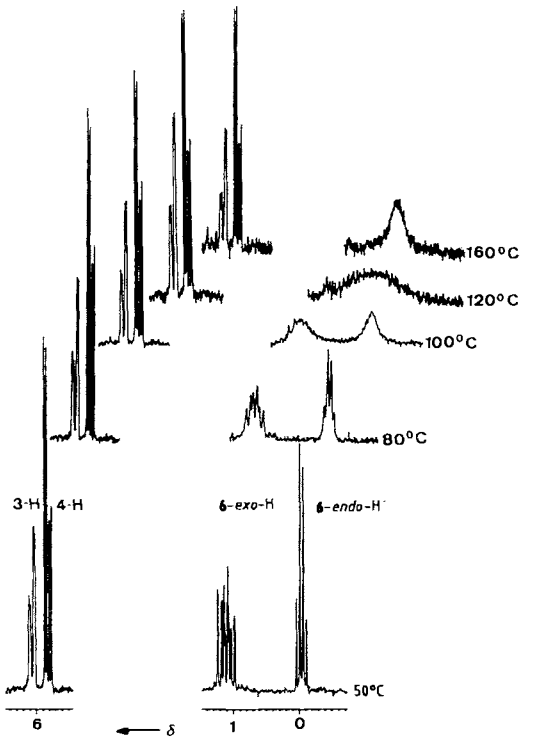


Fig. 1. Sections from the ^{1}H-NMR spectra of **1c** at temperatures between 50 and 160°C (80 MHz, [D_6]Me_2SO).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

That the racemization of optically active **1a** and the epimerization of *exo*-[6-CH_3]**1a** proceed at comparable rates (Table 1) affords evidence for the opening of the central cyclopropane bond (Route **A**) and rules out any significant participation of Route **B**.[12] The disrotatory course of the ring-opening is consistent with the Woodward–Hoffmann rules.[13] An electrocyclic process involving participation of a lone pair on the heteroatom leads to the formal dipolar intermediate of type **2**,[14] but its small dependence on the pressure and solvent polarity (Table 1) indicates

Table 1. Dependence of the racemization of optically active **1a** and the epimerization *exo*-[6-CH_3]**1a** ⇄ *endo*-[6-CH_3]**1a** on solvent and pressure.

	$k \times 10^5$ [s^{-1}] [a]	K [b]	Solvent	p [bar]
[c]	3.49 ± 0.12	1	benzene	1
[c]	2.97 ± 0.03	1	acetonitrile	1
[c]	2.88 ± 0.09	1	acetone	7000
[d]	6.67 ± 0.11	2.12	acetone	1
[d]	2.97 ± 0.05	1.42	acetone	7000

[a] $k = (k_i + k_{-i})$. [b] $K = k_{-i}/k_i$. [c] Racemization. [d] Epimerization.

that the transition state of the reaction **1** → **2** is isopolar with the ground state. Surprisingly, the nature of the heteroatom has a large influence on the rate. From the kinetic parameters it can be estimated by extrapolation that the ring-opening of homothiophene **1c** ($k_i = 2k_{coal}$) and of homopyrrole **1b** ($\Delta G^{\neq} = 77.4$ kJ mol^{-1} and 99.6 kJ mol^{-1}, respectively) occur 63 100 times and 72 times faster, respectively, than that of homofuran **1a** ($\Delta G^{\neq} = 113.4$ kJ mol^{-1}) ($k_i = k_{rac}$). These effects afford proof, for the first time, that the heteroatoms (O, N, and S) stabilize carbonyl-ylide-like intermediates very differently. The surprisingly strong influence of sulfur indicates that the stabilization in the case of **2c** is similar to that in the case of sulfur ylides.[15] However, a quantitative analysis is not possible without a knowledge of the influence which the heteroatom has on the stability of the ground state.

The heterocycles **1a–c** are thermally very stable and only begin to rearrange irreversibly into **3a**,[16] **4b** or **4c**[1] and their secondary products above 250 °C (in a static system) or 400 °C (in a flow system). With the aid of the C-6 labeled compounds [6-CH_3]**1a**,[5] [6,6-D_2]**1b**,[4] and [6-CH_3]**1c** it was established that **4b** is formed from **2b** by a sigmatropic 1,4-H shift, whereas in **1a** and **1c** the cleavage of the C^1–X and C^5–C^6 bonds competes with the H-shift in the ratio 4.8 : 1 and 4.4 : 1, respectively.[17] In no case has a rearrangement to the bicycle **5** been observed, for which an orbital symmetry-forbidden disrotatory ring closure of the intermediate **2** would be required. The rearrangement **1a** → **5a** (besides other reactions) was observed only in a shock tube at 700 °C and with a reaction time of 1.2 ms.[18] The Gibbs activation energy of the reaction **1a** → **5a** can be estimated thereby to be 209 kJ mol^{-1}. Thus, the activation barrier of the orbital symmetry-forbidden ring closure **2a** → **5a** could therefore be at least 96 kJ mol^{-1} higher than that of the allowed reaction **2a** → **1a**.

[7] Tris-[3-(heptafluoropropyl-hydroxymethylene)-(−)-camphorato]europium; H. L. Goering, J. N. Eikenberry, G. Koermer, S. Lattimer, *J. Am. Chem. Soc.* 96 (1974) 1493.

[8] The catalytic hydrogenation (Pd-C, isooctane) of (+)-**1a** (*ee* = 34%) furnished optically active 2- and 3-methyltetrahydrofuran and tetrahydropyran in the ratio 12 : 54 : 34. The analyses of the hydrogenation products carried out on a chiral GC column by Prof. Dr. *V. Schurig* and Frau *D. Wistuba* show that (*S*)-2-methyltetrahydrofuran (*ee* = 32%) is formed. Hence, the (1*S*,5*S*)-configuration can be assigned to the (+)-**1a** enantiomer; cf. W. Kirmse, P. V. Chiem, V. Schurig, *Tetrahedron Lett. 26* (1985) 197.

[9] ^{1}H-NMR (400 MHz, $CDCl_3$) of *exo*-[6-CH_3]**1c**: $\delta = 0.42$ (m; 6-H), 1.09 (d; CH_3), 2.16 (m, $J(1,5) = 7.5$, $J(5,6) = 3.0$ Hz; 5-H), 2.58 (m, $J(1,6) = 3.3$ Hz; 1-H), 5.75 (dd, $J(4,5) = 3.0$ Hz; 4-H), 5.90 (dd, $J(1,3) = 1.6$, $J(3,4) = 5.8$ Hz; 3-H); of *endo*-[6-CH_3]**1c**: $\delta = 0.79$ (d; CH_3), 0.90 (m; 6-H), 2.58 (m, $J(5,6) = 7.4$ Hz; 5-H), 3.00 (td, $J(1,5) = J(1,6) = 7.4$, $J(1,3) = 1.8$ Hz; 1-H), 5.50 (dd, $J(3,4) = 5.8$, $J(4,5) = 3.0$ Hz; 4-H), 6.02 (m; 3-H).

[10] This finding rules out that 1,3- or 1,4-shifts of C-6, leading to an exchange of 1-H and 3-H as well as of 4-H and 5-H, compete with the epimerization at C-6 observed here.

[11] H. Günther: *NMR-Spektroskopie*, 2nd Edit., Thieme, Stuttgart 1985, p. 229.

[12] The small difference in the racemization and epimerization barriers could be attributed to the effect of the methyl group at C-6.

[13] R. B. Woodward, R. Hoffmann, *Angew. Chem. 81* (1969) 797; *Angew. Chem. Int. Ed. Engl. 8* (1969) 781.

[14] Still further resonance structures can be formulated for **2**. According to quantum mechanical calculations [1b] a diradical structure participates up to more than 50% in the structure of the parent carbonyl ylide.

[15] The unusual stability of sulfur ylides is commonly attributed to a dπ–pπ interaction (for example, J. March: Advanced *Organic Chemistry*, 3rd edition, Wiley, New York 1985, p. 36); see also W. Kutzelnigg, *Angew. Chem. 96* (1984) 262; *Angew. Chem. Int. Ed. Engl. 23* (1984) 272.

[16] In the thermolysis of **1a** we obtained essentially the same products as are formed in the thermolysis of 3,4-epoxycyclopentene: P. Schiess, P. Radimerski, *Helv. Chim. Acta 57* (1974) 2583, and references cited therein.

[17] **1c** and [6-CH_3]**1c** were thermolyzed in a flow system (550 °C, 1 torr and 500 °C, 0.1 torr, respectively). Product ratios: **1c** : **4c** : unidentified products = 6 : 84 : 10; [6-CH_3]**1c**: [2-CH_3]**4c** : [3-CH_3]**4c** : unidentified products = 33 : 51 : 12 : 4. The spectroscopic data of the 2*H*-thiopyran derivatives **4c**, [2-CH_3]**4c** and [3-CH_3]**4c** agree with the values given in the literature (D. Schuijl-Laros, P. J. W. Schuijl, L. Brandsma, *Recl. Trav. Chim. Pays-Bas 91* (1972) 785).

[18] We thank Prof. Dr. *W. R. Roth* and Dr. *R. Schmidt*, Bochum, for carrying out the shock tube experiments.

Stereocontrolled Formation of Annelated Cyclopentanes by Intramolecular Hetero-Diels–Alder Reaction. Synthesis of Deoxyloganin from Citronellal**

By *Lutz F. Tietze,* Horst Denzer, Xenia Holdgrün,* and *Manfred Neumann*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Deoxyloganin, **4a**, is a member of the large class of iridoidglycoside natural products,[1] whose characteristic

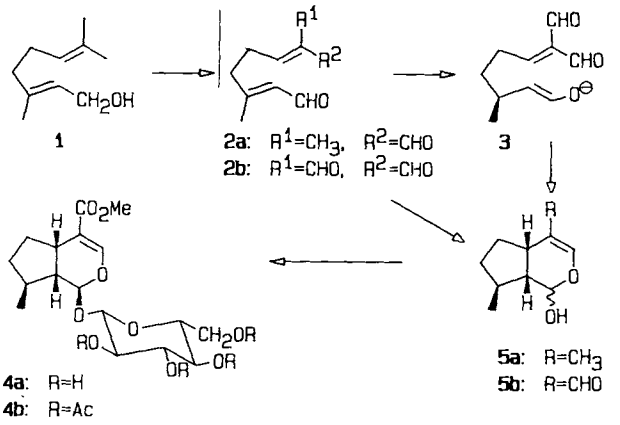
[**] Inter- and Intramolecular Hetero-Diels-Alder Reactions, Part 20. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We wish to thank Professor *Hiroyuki Inouye*, Kyoto, for an authentic sample of deoxyloganin for comparison. Part 19: [7].

structural feature is a cyclopenta[*c*]pyran framework having a β-glycosidically linked glucose at C1. In plants, **4a** is formed from the monoterpene geraniol, **1**, and is a biosynthetic precursor of secologanin, which is a key intermediate in the biosynthesis of a large variety of alkaloids. *Arigoni* et al.[2] postulated that **4a** is formed via the tricarbonyl compound **2b**. It was assumed that **2b** first undergoes a stereoselective hydrogenation to give **3**, which then reacts to yield **5b**. Recently, however, *Inouye* et al.[3] showed that the dialdehyde **2a**, identified by us as a biosynthetic precursor,[4] undergoes a direct cyclization to give **5a**, which, in turn, is transformed into **4** via **5b**.



We synthesized in situ compound **12**, as an analogue of **3**, by condensation of the aldehyde (*E*)-**8c** with meldrum's acid **9**. Compound **12** undergoes a hetero-Diels–Alder reaction[5] to give the cyclopenta[*c*]pyran derivatives **11a** and **11b** in 77% yield in a ratio of 10:1 (Scheme 1). The synthesis of (*E*)-**8c** was carried out by first converting (*S*)-citronellal **6a** (*ee* = 86%) via the dimethyl acetal **6b** into the aldehyde **7a**, which, without isolation, was reduced to the alcohol **7b** and subsequently acetylated to give **7c**. Acid-catalyzed elimination afforded a 1:1 mixture of the enol ethers (*E*)-**8a** and (*Z*)-**8a** in good yield, which can be separated by distillation. The (*E*)-enol ether was employed in the subsequent reactions, since the product of its condensation with **9** (**12**, *E*-dienophile moiety) underwent cycloaddition to give **11** with higher selectivity. (*Z*)-**8a** can be reconverted into a 5:4 mixture of (*E*)-**8a** and (*Z*)-**8a** by acid-catalyzed isomerization ($KHSO_4$, 30 min, 180–200 °C; 89%). Solvolysis of (*E*)-**8a** followed by Swern oxidation[6] gives the aldehyde **8c**, which, because of its relative instability, was not isolated but instead allowed to react directly with meldrum's acid **9**.

The *endo-E-syn* (**12**-KI) and *exo-E-anti* (**12**-KII) orientations of the heterodiene moiety of the Knoevenagel product **12** formed as an intermediate must be considered as possible transition states for the cycloaddition. An *exo-Z-syn* arrangement can also be taken into account, but it would lead to a product that was not detected. Moreover, it has been shown for other systems that this transition state is of minor importance.[7] The preferential formation of the *cis*-linked cyclopenta[*c*]pyran derivative **11a** (Table 1)[8] is surprising, since, for comparable compounds bearing two methyl groups on the dienophile moiety, the *trans*

cycloadduct was detected as the major product.[9] Also noteworthy is the high diastereoselective induction (*i-de*[10] > 98%).

To synthesize the deoxyloganin aglycone **10c**, compound **11a** was subjected to solvolysis to give the lactone

Table 1. NMR data for **10a** and **11a**. 200 MHz (^{1}H), 50.3 MHz (^{13}C), in $CDCl_3$.

10a: ^{1}H-NMR: $\delta = 1.10$ (d, $J = 6.0$ Hz, 3H; 7-CH_3), 1.16–1.36 (m, 2H; 5α-H, 6α-H), 1.73–1.90 (m, 2H; 6β-H, 7-H), 1.93 (m, 1H; 7a-H), 2.08 (m, 1H; 5β-H), 3.18 (m, 1H; 4a-H), 3.34 (d, $J = 4.8$ Hz, 0.7H; 4-H), 3.36 (d, $J = 7.5$ Hz, 0.3H; 4-H), 3.48 (s, 3H; OCH_3), 3.80 (s, 3H; CO_2CH_3), 5.03 (d, $J = 3.0$ Hz, 1H; 1-H)

11a: ^{1}H-NMR: $\delta = 1.09$ (d, $J = 6.0$ Hz, 3H; 3-CH_3), 1.1–1.3 (m, 1H; 2β-H), 1.50–1.70 (m, 1H; 1β-H), 1.71 (s, 6H; 2 × 7-CH_3), 1.78–1.98 (m, 3H; 3-H, 3a-H, 2α-H), 2.1–2.3 (m, 1H; 1α-H), 3.02 (m, 1H; 9b-H), 3.57 (s, 3H; OCH_3), 4.97 (d, $J = 3.6$ Hz, 1H; 4-H). — ^{13}C-NMR: $\delta = 20.31$ (3-CH_3), 23.97 (7-CH_3), 26.04 (7-CH_3), 31.21, 32.84 (C1, C2), 32.30, 34.91 (C9b, C3), 49.87 (C3a), 57.30 (OCH_3), 83.00 (C7), 104.69 (C4), 105.44 (C9a), 161.42 (C5a), 168.82 (C9)

ester **10a** (present in the keto form shown; Table 1). Subsequent reduction with two molar equivalents of diisobutylaluminum hydride (DIBAH) afforded the 1,3-diol **10b**, which was treated with acid to obtain **10c**. The unusual cleavage of the acetal moiety of **10a** is due to the fact that the ring of the cyclic hemiacetal (lactol) formed upon reduction undergoes opening between O2 and C3 to form an aluminum enolate and an acyclic hemiacetal moiety. Hydrolysis of the complex affords a dialdehyde, which, presumably as the monohydrate, cyclizes to give **10b**. This reaction course would also explain why two molar equivalents of DIBAH are required for the reduction of the lactone **10a**. Selective glycosidation of **10c** to give **4b** was accomplished using a method developed by us.[11] Compound **10c** was acetylated to give **10d**, which was then allowed to react with peracetylated β-D-trimethylsilylglucose and trimethylsilyl triflate. The peracetylated β-glycoside **4b** was obtained in 44% yield (based on conversion: 83%) and was subsequently converted by solvolysis into deoxyloganin **4a**.[12]

[8] Compound **11b** cannot be isolated in pure form by chromatography, since it readily undergoes isomerization to give **11a**, which is also a *cis*-annulated product. In this process, the C4–O5 bond is presumably cleaved, giving possibly an enol ether as intermediate. Such isomerizations, in which the meldrum's acid moiety remains unchanged, have also been observed for the products of the intermolecular hetero-Diels–Alder reaction of alkylidenemeldrum's acids and enol ethers (W. Holla, *Dissertation*, Universität Göttingen 1985): (3*S*,3a*S*,4*S*,9b*R*)-**11** (*cis*-annulated): $R_f = 0.43$ (silica gel, ether/petroleum ether = 1/1). — ^{1}H-NMR ($CDCl_3$): $\delta = 1.06$ (d, $J = 7.0$ Hz, 3H; 3-CH_3), 1.20–1.40 (m, 1H; 2-H), 1.50–1.65 (m, 2H; 1-H, 3-H), 1.71 (s, 6H; 2 × 7-CH_3), 1.65–2.22 (m, 2H; 1-H, 2-H), 2.22–2.42 (m, 1H; 3a-H), 3.06 (m, 1H; 9b-H), 3.54 (s, 3H; OCH_3), 5.05 (d, $J = 4.0$ Hz, 1H; 4-H). The *trans*-annulated cycloadduct analogous to **11b** can be obtained in pure form by reaction of **8c** with *N,N*-dimethylbarbituric acid: (3*S*,3a*R*,4*R*,9b*R*)-1,2,3,3a,4,6,7,8,9,9b-decahydro-4-methoxy-3,6,8-trimethyl-7,9-dioxacyclopenta[4,5]pyrano[2,3-*d*]pyrimidine: $R_f = 0.5$ (silica gel, diethyl ether). — M.p. = 76 °C (from *n*-pentane). — ^{1}H-NMR ($CDCl_3$): $\delta = 1.12$ (d, $J = 6.5$ Hz, 3H; 3-CH_3), 1.34–1.54 (m, 3H; 1α-H, 2-H, 3a-H), 1.76–2.00 (m, 2H; 3-H), 2.04–2.22 (m, 1H; 1β-H), 2.42–2.68 (m, 1H; 9b-H), 3.32 (s, 3H; N–CH_3), 3.38 (s, 3H; N–CH_3), 3.68 (s, 3H; OCH_3), 5.24 (d, $J = 9.1$ Hz, 1H; 4-H). The *trans* annulation is supported by the relatively high upfield shift of the 9b-H signal and a strong nuclear Overhauser effect between 4-H and 9b-H (*cis*-annulated cycloadduct: 3a-H, $\delta = 1.76$–1.98; 9b-H, $\delta = 3.10$).

[9] We assume that, in analogy to the formation of cyclohexanes, the *exo-E-anti* arrangement of an ω-disubstituted dienophile is preferred in the formation of cyclopentanes for steric and stereoelectronic reasons. However, for ω-monosubstituted dienophiles having the *E* configuration, the steric interactions are less in an *endo-E-syn* arrangement. This is supported by the fact that the corresponding dienophiles having the *Z* configuration afford more *trans*-annulated product and that a 1:1 mixture of *cis*- and *trans*-annulated cycloadducts was obtained upon reaction of **8c** with methyl 3-(trimethylsilyloxy)propenoate; cf. S. Takano, S. Satoh, K. Ogasawara, *Heterocycles 23* (1985) 41.

[10] For an explanation of *i-de* and *ni-de* see L. F. Tietze, U. Beifuss, *Angew. Chem. 97* (1985) 1067; *Angew. Chem. Int. Ed. Engl. 24* (1985) 1042.

[11] L. F. Tietze, R. Fischer, *Angew. Chem. 95* (1983) 902; *Angew. Chem. Int. Ed. Engl. 22* (1983) 888.

[12] Identity was shown by comparison of the NMR spectrum of synthetic **4a** with that of an authentic sample. Glycosidation of **10c** also afforded ca. 7% of a different, chromatographically separable β-glycoside, which is formed from *ent*-**10c**, present as an impurity. This is in accord with the amount of *ent*-**6a** present in the (*S*)-citronellal **6a** employed, which was obtained from commercially available citronellol (Fluka). The *ee* of citronellol was determined by oxidation to citronellic acid and gas chromatographic determination of the diastereomers obtained therefrom by reaction with (*S*)-1-phenylethylamine: E. J. Corey, G. Schmidt, *Tetrahedron Lett. 1979*, 399; K. Mori, S. Masuda, T. Suguro, *Tetrahedron 37* (1981) 1329; T. Kikukawa, M. Amaida, A. Tai, *Bull. Chem. Soc. Jpn. 57* (1984) 1954.

CORRESPONDENCE

Back to the Structure of Benzene

By *R. Janoschek**

In a communication entitled "On the Structure of Benzene", *Ermer*[1] recently demonstrated in an impressive way that still questionable properties of the benzene molecule trace back to seemingly well-founded fundaments such as the D_{6h} symmetry of the structure. In particular, neither our present experimental nor theoretical knowledge can precisely exclude a structure with CC bond alternation (D_{3h} symmetry), he notes.

The term "Back" in the above title should, however, be understood in another sense—namely as referring to a supplement to *Ermer*'s review. Obviously, certain much discussed topics make a periodical appearence, possibly reflecting a change of generation and a changing consciousness with time. For, in the mid-sixties, it was *Rogowski* whose papers and lectures[2] on the D_{6h}–D_{3h} problem were the subject of heated discussions, although the corresponding electron diffraction experiments or at least their assignments were widely unaccepted. At the time also *Rogowski* turned to quantum chemistry for help. Relevant computations were performed and published.[3] A D_{3h} structure could certainly not be found, but the smooth increase in energy of only 4.6 kcal·mol^{-1} on going from D_{6h} (1.39/1.39 Å) to D_{3h} symmetry (1.35/1.43 Å) was remarkable.

A renewed call for quantum chemical calculations on the structure of benzene is not unwarranted, for such calculations can nowadays be performed more accurately and, therefore, more reliably than 20 years ago. The new calculations have been investigated in the following way: starting from the optimized D_{6h} structure, geometries with CC bond alternation have been generated by choosing a fixed length for three short CC bonds and a complete optimization of all other structural parameters. This procedure yields the optimal energy curve for a $D_{6h} \rightarrow D_{3h}$ distortion which is much more informative than the calculation of the complete set of harmonic force constants,[4] in particular that of the B_{2u} vibration, which unequivocally indicates a D_{6h} structure, but cannot exclude a D_{3h} structure.

$C{=}C_{short}$ (fixed) [Å]	1.383	1.370	1.340	1.325
$C{-}C_{long}$ (optim.) [Å]	1.383	1.388	1.402	1.409
ΔE [kcal·mol^{-1}]	0.0	0.2	2.4	4.5

These ab initio calculations at the SCF level with the 3-21G* basis set (spd) indicate again no energy minimum with D_{3h} symmetry. The use of an ethylene C=C bond length (1.339 Å) and a butadiene C–C bond length (1.483 Å) for a D_{3h} structure causes a surprisingly slight destabilization of only 8 kcal·mol^{-1} relative to D_{6h} (1.396 Å).

CORRIGENDUM

The manuscript of the Nobel Lecture "Concepts in Reaction Dynamics" by *John C. Polanyi* (*Angew. Chem. Int. Ed. Engl. 26* (1987) 952) was inadvertently incomplete. The third full paragraph on p. 960 should read:

Turning to the experimental findings of Section 2.1, it was evident that the moderate mean fractional conversion of reaction energy into product vibration, $\langle f_{V'} \rangle$, could be explained either by a highly attractive interaction leading to secondary encounters, or by predominantly repulsive energy release. The first of these alternatives appeared implausible since it implied a substantially broader distribution over product vibrational and also rotational states than was observed.[16] Instead the evidence favored a strongly repulsive PES, with the light-atom anomaly explaining the markedly reduced $\langle f'_V \rangle$ for $H + X_2$ as compared with $X + H_2$ or $X + HY$, and the lower barrier leading to a slightly increased HA in $H + Br_2$ as compared with $H + Cl_2$ (cf. the correlation noted above) accounting for the greater $\langle f'_V \rangle$ observed for $H + Br_2$ than for $H + Cl_2$.[16]

The success of a strongly repulsive PES in accounting for the general form of the triangle plot for $Cl + HI \rightarrow HCl + I$ is illustrated, by way of an example, in Figure 15,[61] which should be compared with Figure 9 above. Similar success has been obtained for the reaction $F + H_2 \rightarrow HF + H$ (Fig. 8) using a strongly repulsive PES.[62-64] In this case there is now dependable evidence from ab initio variational treatments of FHH[65,66] that the energy release is indeed substantially repulsive. The success of a repulsive PES in describing **L + HH** dynamics will be demonstrated (for $H + F_2 \rightarrow HF + F$; cf. Fig. 7) in Section 3.2.

The discussion of the previous paragraphs as it relates to repulsive energy release is summarized pictorially in Figure 16. Though visualization of reaction dynamics is generally, and often adequately, based on the collinear PES to which the sliding-mass analysis applies, tests of the validity of PESs are made by 3D trajectories.

Product rotational excitation is eliminated from the picture in the collinear world. Though this is a minor constituent of the product energy, it is revealing of the dynamics. In the visualization of Figure 16, we have included the effect of repulsive energy release in bent configurations as one source of product rotation. The experimental data in the triangle plots of Figure 11 give persuasive evidence of the significance of this effect in the important reaction $F + H_2$. Product repulsion should be expected[47,67] on the basis of momentum conservation to give rise to decreasing $\langle f_{R'} \rangle$ in the series FH·D > FH·H > FD·D > FD·H (the dot indicated the locus of the repulsion); this is found theoretically in 3D trajectory studies, and also experimentally (see Fig. 15). The triangle plots in Figure 11 correspond to the extremes of this range of isotopic mass combinations; $\langle f_{R'} \rangle$ for the FH·D pathway substantially exceeds that for FD·H.

Volumes X and XI of this handbook[*] provide instructions for the enzymatic assay of antibodies and antigens. These two volumes provide a compendium of model enzyme-immunoassays for immunochemistry rather than attempting to cover the growing field completely. They will be useful for many years.

The five chapters of Volume X cover assay procedures for immunoglobulins and immune complexes, for antigens and antibodies in allergic and autoimmune diseases, and for antigens and antibodies in viral diseases. The first chapter discusses the problems of standardizing enzyme-immunoassays for antibodies, particularly with respect to the treatment and expression of data, much as Volume II discusses the interpretation of more classical assays. The chapter also discusses general methods for the assay of antibody- and antigen-secreting cells as well as an ELISA technique for screening monoclonal antibodies.

The remaining chapters of Volume X are a collection of working procedures for the determination of specific antigens and antibodies such as red blood cell autoantibodies, anti-DNA antibodies, and antibodies against herpes simplex virus, measles virus, or the HTLV III virus. A description of these sections appears below.

Volume XI, the companion handbook, treats antigens and antibodies in chlamydial and bacterial diseases, such as various *Clostridia* species or bacterial endotoxins, as well as antigens and antibodies in fungal and parasitic diseases, such as aflatoxins or *Pneumocystis carinii* antigen. The third and final section of this volume comprises a short section devoted to a related and emerging field: that is, the use of enzyme-immunoassays to identify plant viruses such as potato viruses or the soybean mosaic virus.

As in previous volumes, treatment of each antigen or antibody rigidly follows a standard format. This approach makes the two volumes and the entire twelve volume series a convenient and informative reference. One may locate the section covering the desired antigen or antibody using the index at the end of each volume; unfortunately these indices are not cross-referenced to each other or to other volumes. A typical section begins with a general introduction describing the purpose and applications of the assay, properties of the antigen or antibody relevant to the analysis, other methods of determination, and mention of international reference methods and standards, when available.

The assay forms the core of each section, and its documentation is detailed. In standardized format are listed the design of the method, the equipment required, where to obtain and how to prepare the reagents and solutions, and the complete assay procedure from collecting and preparing the sample to interpreting the results. The next unit explains how to validate the method and includes a discussion of sources of error in the assay. Appendices usually provide further detailed information regarding procedures such as how to prepare and purify monoclonal or enzyme-labeled antibodies or how to coat the assay plates.

Graphics illustrating the principle of each method are particularly valuable. Also useful are the graphs and illustrations providing information on optimization of procedures, such as well coating, or on the results of the methods described. Each section closes with a list of references.

These two volumes, containing assay procedures for over 75 substances, provide a solid reference to specific and illustrative methods useful for the analysis of antigens, antibodies and viruses. Clinicians and epidemiologists in particular will find them useful, although the wealth of information presented will assist those interested in using or designing enzyme-immunoassays in biochemistry and biology.

The final volume of "Methods of Enzymatic Analysis," Volume XII, describes the relatively recent applications of enzyme-immunoassays to the quantitative analysis of drugs and pesticides. The first two chapters focus on the determination of serum concentrations of therapeutic drugs and drugs of abuse. The final chapter on pesticides is meant "to stimulate analysts involved in environmental investigations to design simple enzyme-immunoassays".

The eighteen sections of chapter 1, "Drugs Monitored during Therapy", provide information and assay procedures for 25 drugs ranging from the bronchodialator, theophylline, to various aminoglycosides such as gentimycin or tobramycin. The next chapter, "Drugs of Abuse and of Toxicological Relevance," provides similar information for substances such as benzodiazepines or barbiturates in its 16 sections. The final chapter on pesticides, containing six sections of environmental applications of enzyme assays, mainly focusses on the determination of cholinesterase inhibitors such as organophosphorus compounds.

The organization of each of the three chapters is similar. Each opens with a brief, general introduction describing the importance of enzyme-immunoassays to the particular topic. As in previous volumes of the series, the bulk of each chapter is a collection of sections giving information for a particular drug or pesticide, one or more assay methods, and techniques to validate the method. Many sections also include an appendix giving additional information regarding the assay, such as how to prepare enzyme conjugates or antibodies or antigens for the assay. A typical section for a drug is described below; the sections on pesticides have the same format.

Information for a given drug usually includes its chemical structure, mention of the physiological affects and clinical use of the drug, some of its pharmacokinetic parameters, and the reasons for monitoring the drug. Also pro vided is a short summary of chemical properties relevant in analysis (FW, values of pK_a, solubility) and a listing and discussion of other methods of determination. The inclusion of references is helpful because, although the presentation of the information is clear and well organized, it does not attempt to replace descriptions found in more detailed clinical handbooks because the focus of the volume is not on drug description but on drug analysis; the collec-

[*] *Angew. Chem. Int. Ed. Engl. 26* (1987) 368.

tion of clearly explained and well-documented assays meets this goal.

The presentation of the assays is standardized as in previous volumes and typically includes the following information: the method design, equipment needed, how to make up the reagents and solutions, and the assay procedure. Information on the validation of the method is also given, including data on the specificity of the assay and therapeutic ranges of the drug.

This final volume should be a useful handbook for the biochemical, biomedical and clinical laboratory, and will be helpful to those involved in the measurement of drugs or pesticides.

The third edition of "Methods in Enzymatic Analysis"—comprising 6821 pages in twelve volumes—is greatly expanded from the the 2302 pages in the four volumes of the second English edition (1974). This change reflects the increasing importance of enzymatic analyses in the analytical laboratory. As various contributors mention, assays based on enzymes often supplement or replace more lengthly procedures requiring expensive equipment and a high level of technical expertise. The specificity of enzyme assays often means that sample purification can be simplified. In some cases no other reliable analytical method exists.

As with previous editions, this one is primarily designed for those who need to conduct analyses of biological substances, ranging from oxidoreductases to pesticides. The expanded coverage of this edition also collects important material on the theory, design, implementation and interpretation of enzymatic assays, thus making the series of useful reference for scientific and medical libraries as well as a handbook for the laboratory worker.

The great strength of the collection is its adherence to a standard format when presenting the assays. This organizes an immense amount of practical information. The clear and detailed explanations given for each assay allow the procedures to be followed easily and should stimulate the development of new assays, particularly in the rapidly expanding areas of determination of immunological, pharmacological and environmental analytes.

A weakness of the individual volumes of this edition is the lack of cross-referencing to other volumes or to previous editions. Fortunately, work on an index volume is in progress. Complete indexing of the series will make it an even more valuable reference. Overall, this series is a foundation of modern biological analysis. It will be used heavily by those conducting analyses of biological substances.

Modern Synthetic Methods 1986. Vol. 4. Edited by *R. Scheffold*. Springer, Berlin 1986. viii, 356 pp., paperback, DM 68.00.—ISBN 3-540-16526-6

"Modern Synthetic Methods 1986" contains the texts of the papers presented at the Fourth International Seminar on Modern Synthetic Methods, which was held at Interlaken in April 1986. The general themes of this seminar were "Sound and Light in Synthesis" and "Synthesis of Enantiomerically Pure Compounds". The book contains three papers on each of these two themes, as follows: first theme—"Ultrasound in Synthesis" by *K. S. Suslick* (University of Illinois, Urbana), "Photochemically Generated Building Blocks: Part I—The Tricyclooctanone Approach to Polyquinane Synthesis: The Underlying Photochemistry" by *K. Schaffner*; Part II—"The Tricyclooctane Approach: Photochemical Methods in Cyclopentanoid Natural Products Synthesis—A Comparison" by *M. Demuth* (both authors at Max-Planck Institut für Strahlenforschung, Mülheim); second theme—"EPC Synthesis with C,C-Bond Formation via Acetals and Enamines" by *D. Seebach* (ETH, Zürich), "Asymmetric Diels-Alder Reactions with Chiral Enoates as Dienophiles" by *G. Helmchen* (Heidelberg University), "Enantiomerically Pure Compounds via Chiral Organoboranes" by *H. C. Brown* (Purdue University, West Lafayette).

The papers are not so much review articles of the usual kind as progress reports on important developments in synthetic methods, by authors closely involved in the work; this applies even to the first paper, which reviews the applications of ultrasound in chemistry. In accordance with the "workshop" character of the conference, the book is without doubt mainly of value to the practical researcher; beginning with the basic principles and background and continuing through to the latest results, some still unpublished, it contains a wealth of practical information, and in some cases even a critical evaluation of alternative methods, with full experimental details for representative examples, some of which have not been generally available before. There are plentiful literature references (up to 365 citations), with a coverage which appears to extend to the end of 1985. This is without doubt where the book's greatest value lies. The authors are all leading exponents of their specialist fields, and direct reproduction of their typescripts has made it possible to publish the material rapidly, thereby disseminating it at first hand, as it were, even to those who did not participate in the conference. It would be difficult to find a more competent, topical and comprehensive survey of the themes treated here, emphasizing as they do some important current trends in organic synthesis. For this reason it is certain that the book, like the reports of the previous Interlaken meetings, will be frequently cited.

To summarize, this is an outstandingly informative book, which is a must for all chemists interested in the topics discussed, and it also makes stimulating reading. Working through it reinforces one's impression of the enthusiasm which characterizes these Interlaken conferences.

High Resolution NMR Spectroscopy of Synthetic Polymers in Bulk. Edited by *R. A. Komoroski*. VCH Publishers/VCH Verlagsgesellschaft, Deerfield Beach and Weinheim 1986. xi, 379 pp., bound, DM 185.00.—ISBN 0-89573-146-0, 3-527-26464-7

The macroscopic properties of polymers are closely connected with their molecular structure and dynamics. Therefore the behavior of the macromolecules in the solid state is of particular interest. In addition to rigid glassy polymers, elastomers, in which the polymer chains in network structures can have mobilities similar to those in liquids have to be considered.

Nuclear magnetic resonance (NMR) spectroscopy, which now plays such a prominent role in elucidating the chemical structures of liquids or solutions, has in the past

been severely limited in its application to solid polymers, because in *solids*, owing to dipolar coupling, one could only obtain poorly resolved spectra with broad signals. In the last ten years, however, techniques have been developed to overcome this deficiency and can now be used in various ways for polymer studies. The most important method is undoubtedly the CP-MAS procedure, in which cross-polarization (CP), proton decoupling, and rotation of the sample at the "magic angle" (magic angle spinning, MAS) enhance the sensitivity and resolution of ^{13}C-NMR spectroscopy sufficiently to justify the description "high resolution NMR spectroscopy of solids".

By this technique, for example, conformational changes can be studied. Furthermore, the anisotropic couplings which exist in the solid state offer various possibilities for using NMR spectroscopy to give information on the important questions of molecular ordering, e.g. alignment of the polymer chains in stretched fibers, and phase separation in block copolymers. One can also use these effects to study molecular dynamics, e.g. segmental mobility in crystalline and amorphous polymers, and in elastomers above the glass transition temperature.

This book edited by *R. A. Komoroski*, gives an outstandingly good review of the application of the newer NMR techniques to solid polymers. The authors of the individual chapters are experts in polymer NMR spectroscopy. Most of them are from the academic world, but others are from industrial research laboratories in the United States, which further underlines the importance of the above mentioned developments to polymer research. Following two introductory chapters, a detailed description is given of the study of chain conformation and mobility in rigid glassy polymers and partly crystalline polymers using ^{13}C-NMR methods. After a chapter on elastomers, the last four chapters of the book have a more physical emphasis, being concerned with local motions in the glassy state, oriented polymers, and two other important techniques, namely ^{1}H multi-pulse NMR spectroscopy and ^{2}H-NMR spectroscopy.

The book is intended mainly for polymer chemists who wish to obtain an overview of the capabilities of solid state NMR techniques for polymer research. It includes enough background information to enable one to understand the newer NMR techniques, and most importantly it contains a wealth of practical examples. It can therefore be highly recommended for all laboratories engaged in the study of the physical chemistry of polymers.

Mechanisms of Inorganic Reactions. By *D. Katakis* and *G. Gordon*. Wiley, New York 1987, 384 pp., hand cover, $ 53.15.—ISBN 0-471-84258-3

This book was written to serve as a basis for a one-semester course on this topic for advanced undergraduate and starting level graduate students. It was not intended as a comprehensive review of the current literature, but does contain a brief list of relevant books and review papers at the end of each chapter. In addition, appropriate problems are given such that students can check their ability to analyse kinetic data and to asign mechanisms.

The nine chapters of the book are devoted to: introduction, mechanisms, kinetics and equilibria; events at the molecular level—the activated complex; experimental methods and handling of the data; mechanism and structure; group transfer and atom-transfer reactions; electron-transfer reactions; catalysis; inorganic photochemistry. In general the authors treat more classical type inorganic complexes with little information on organometallic systems. In this respect the book nicely complements *Jim Atwood*'s "Inorganic and Organometallic Reaction Mechanisms" (Brooks/Cole 1985) which mainly concentrates on organometallic systems.

Some sections of this book are extremely well written and the reader will appreciate the authors' efforts. Other sections, for instance the introductory chapter, are rather unsatisfactory. In general the book presents a good course on inorganic reaction mechanisms. Interesting systems dealing with the reactions of dioxygen, antitumor activity and catalysis, demonstrate the applicability of the mechanistic information. A number of shortcomings are: too little information on the meaning of the transmission coefficient (p. 59); an organic example is used to demonstrate the effect of pressure on a rate constant (p. 67) where so many inorganic examples are available; important fast reaction techniques such as stopped-flow (p. 102) and *T*-jump (p. 104) are only treated in a few sentences.

After having read this book. I did experience the need for a comprehensive treatment of inorganic and organometallic reaction mechanisms, an update of the *Basolo* and *Pearson*, *Tobe* or *Wilkins* treatment of the subject. With all the activity in this field, such an undertaking will be a major task and hopefully this book will encourage an inorganic/organometallic kineticist to tackle this challenge in the near future.

Chemical Modification of Enzymes: Active Site Studies. Edited by *J. Eyzaguirre*. John Wiley, New York 1987. 187 pp., bound, £21.50.—ISBN 0-7458-0023-8

This book describes the classical methods of enzyme chemistry, with special reference to their use for modifying active sites; it consists of eleven chapters written by ten authors. The papers were presented at a conference held in Chile in 1984, and have been edited by *Jaime Eyzaguirre* and published here in book form. The conference report has thereby become a textbook-style description of known techniques with selected examples. In relation to the present state of the techniques it is, unfortunately, already out of date to some extent. For example, it fails to cover any of the DNA techniques for protein modification, in particular that of *in vitro* mutagenesis, and the analytical use of two-dimensional NMR spectroscopy is not included. The book thus suffers from a fault common to many conference publications, in being partly outdated by the time it has appeared.

The book can be recommended for advanced students of biochemistry and for newcomers to the proteins field. It is written in a comprehensible style, is well illustrated and edited, and the individual chapters contain literature references up to 1986. To summarize: easy reading for newcomers to protein chemistry, but containing nothing new for specialists in this field.

Hans Günter Gassen [NB 864 IE]

Principles of Electrochemistry. By *J. Koryta* and *J. Dvořák*. John Wiley, Chichester 1987. xi, 447 pp., bound, $ 84.40.—ISBN 0-471-91211-5

"Koryta" has long occupied an assured position amongst textbooks on electrochemistry. The authors have now thoroughly revised and updated their book to take account of the rapid progress made during the last 15 years in this area of physical chemistry. Once again, they have produced an excellent book which is easy to read and understand. However, the authors' claim in the preface that they have picked out and emphasized problems of modern electrochemistry, including materials, electrodes, electrochemistry in non-aqueous media, and relevant spectroscopic techniques, does not seem to me to be fully justified. Instead the first three chapters, which constitute almost half the book, mainly treat themes of classical thermodynamics which can be found in physical chemistry textbooks, though usually in significantly less detail.

The book starts with a detailed introduction to electrolyte equilibria. It includes the theory of strong (Debye-Hückel) and weak electrolytes, acids and bases, and models for polyelectrolytes and ionic association phenomena. Chapter 2 discusses transport processes in electrolyte solutions, including a skillful development of the central idea of the ionic flux from the thermodynamics of irreversible processes. It is noteworthy that, besides the phenomenology of mass transport, there is also a separate section discussing the dynamic causes of such processes. This is followed in Chapter 3 by a quite conventional treatment of the thermodynamic principles involved in mass transport at the interface between the electrode and electrolyte phases, including the concepts of EMF, Volta and Galvani potentials, and reversible electrodes with their numerous variations. Practical applications are also discussed, in relation to pH measurements and the determination of activity coefficients and dissociation constants.

In Chapter 4 the electrical double layer is described, together with all the essential thermodynamic and structural properties of this interface, which plays such an important part in electrochemistry. In addition to the familiar Gouy-Chapman theory, there is also a short section devoted to the "jellium" model developed in recent years. Non-metallic interfaces such as occur in semiconductors and immiscible electrolytes are treated in detail.

This is followed in Chapter 5 by a thorough treatment of the electrode reactions themselves, with detailed discussions both of the electrode kinetics in the narrower sense and of transport phenomena. The many different forms current overvoltage curves can take, depending on the type of transient signal are discussed. A welcome feature is the treatment of not only the phenomenological Butler-Volmer equation, the basic equation of electrochemical kinetics, but also the principles of the Marcus theory in relation to other topical problems; they thus present a modern view of elementary processes in charge transfer. Further sections provide information on dynamic electrochemical measurement techniques, including spectroscopic methods, and on coupled chemical reactions which can either precede or follow the charge transfer. Special electrode processes, such as occur in electrocrystallization or in photoelectrochemistry, are also included. The book concludes with a chapter on membrane electrochemistry and bioelectrochemistry. This is mainly concerned with the thermodynamics of charge transfer and transport phenomena in biological and synthetic membranes, and with a description of their applications in ion-selective electrodes. Topics in pure bioelectrochemistry, such as photosynthesis and redox reactions in enzymes, are touched on only in passing.

This textbook by its nature, provides a concise, but complete survey of the fundamentals of electrochemistry. Hence, there is little space for details; but this lack is alleviated by the bibliography at the end of each section, each expertly compiled with a view to topicality. All those who wish to embark on a study of electrochemistry via the classical thermodynamic route will find the new "Koryta" a dependable guide. For a textbook it is, however, expensive, and this will not help it to achieve the wide use which it deserves.

SUBJECT INDEX

(R) = Review Article (C) = Short Communication (B) = Book Review (L) = Correspondence

ABSOLUTE CONFIGURATION, The absolute configuration of the ant alarm pheromone manicone (C) 784

Acenaphthene, Cerium(IV)-catalyzed single electron transfer (SET) on acenaphthene and 1,4-dihydronaphtho-[1,8-*d,e*][1,2]diazepine: chemical evidence for distinct radical cations (C) 797

Active sites, Chemical modification of enzymes. Active site studies (B) 1301

Addition, Formation of diiridium(II) complexes by photoassisted oxidative-addition reactions: structure of a stable binuclear iodo(iodomethyl)iridium(II) complex (C) 444

Oxidative addition of hydrogen telluride to organometallic fragments (C) 132

Unsaturated molecules containing main group metals (R) 1

1,6-Addition, Unusual 1,6-addition of a carbenoid (C)72

Adenine receptors, Molecular recognition: stacking interactions influence Watson-Crick vs. Hoogsteen base-pairing in a model for adenine receptors (C) 1244

Adsorption and curvature in highly dealuminated zeolites (C) 1017

A-Frame cluster, New $AuPt_2$ A-frame cluster complexes (C) 86

Alcohols, Inversion of the configuration of secondary alcohols via isourea ethers prepared in situ (C) 773

Aldoketene dimers, Mycoloylpeptides and other lipopeptide adjuvants from higher aldoketene dimers (C) 336

Aldol reaction, Stereoselective aldol reactions with α-unsubstituted chiral enolates (R) 24

Alkali-metal cyclopentadienide, Structure of a crystalline alkali-metal cyclopentadienide (C) 583

Alkali metals, Ether cleavage with organoalkali-metal compounds and alkali metals (R) 972

Alkanoates, Reduction of 2-enoates and alkanoates with carbon monoxide or formate, viologens, and *clostridium thermoaceticum* to saturated acids and unsaturated and saturated alcohols (C) 785

Alkene complexes, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723

α-Alkoxyaldehydes, The first direct evidence for a Cram chelate (C) 477

α-Alkoxyketones, The first direct evidence for a Cram chelate (C) 477

Alkylaluminum cations: synthesis and structure of $[Al(2\text{-}C(SiMe_3)_2C_5H_4N)_2][AlCl_4]$ (C) 681

Alkylation, Control of the relative electrophilicity of alkylating agents by variation of the Lewis acid concentration (C) 1029

Alkylation of aromatic compounds, Stereoselective alkylation of aromatic compounds with threonine trifluoromethanesulfonates (C) 142

Alkyl complexes, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723

Alkyl radicals, The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770

Alkyne complexes, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723

Allenes, Generation and interception of 1-oxa-3,4-cyclohexadiene (C) 690

Trimethylenemethane complexes of Cr, Mo, and W by novel methylenation of allenes with carbene complexes; cyclopentanes by [3+2] cycloaddition of trimethylenemethane complexes to allenes (C) 357

Allenylidene ligands, Alkyne complexes of rhenium in medium oxidation states: synthesis and molecular structure of a rhenium(V)–allenylidene complex (C) 1263

Allylamines, Allylamine derivatives—a new class of active substances in antifungal chemotherapy (R) 320

Allylcyclopentadienylpalladium, Reactions of $(\eta^3\text{-allyl})(\eta^5\text{-cyclopentadienyl})$palladium with cyclopropabenzenes (C) 67

Allylic anions, Regioselective protonation of allylic anions (C) 1281

Allylic ethers, Unusual ligand directed regioselectivity in the iron catalyzed cross coupling of allylic ethers to 2-substituted 1,3-dienes (C) 1013

Allylmetal compounds, Crystal structure of the η^1-allyl-Grignard compound bis(allylmagnesium chloride-TMEDA) (C) 696

Allylzinc compounds, High-resolution CP-MAS ^{13}C-NMR spectra of allylzinc compounds—structural similarities and differences in the solid state and in solution (C) 1279

Aluminum compounds, Alkylaluminum cations: synthesis and structure of $[Al(2\text{-}C(SiMe_3)_2C_5H_4N)_2][AlCl_4]$ (C) 681

Stabilization of the $[AlMe_2]^{\oplus}$ cation by crown ethers (C) 485

Amalgams, Square Hg_4 clusters in the compound CsHg (C) 687

Amavadin, an example for selective binding of vanadium in nature: studies of its complexation chemistry and a new structural proposal (C) 545

α-Amino acids, Asymmetric synthesis of cyclic α-amino acids by the bislactim ether method (C) 143

α-Amino-γ-nitrocarboxylic esters, Asymmetric synthesis of α-amino-γ-nitrocarboxylic esters by the bislactim ether method (C) 480

Amino acids, Diastereoselective Strecker synthesis of α-aminonitriles on carbohydrate templates (C) 557

β-Amino alcohols, Stereoselective synthesis of β-amino alcohols from optically active α-amino acids (C) 1141

Amino(imino)phosphanes, $(Me_3Si)_2N\text{–}P{=}NSiMe_3$ as educt for electron-rich phosphorus-nitrogen ligands (C) 59

Analysis, ^{2}H,^{2}H-COSY and ^{2}H,^{2}H,^{13}C-RELAY NMR experiments for the analysis of deuteriated compounds (C) 156

Instrumentelle Multielementanalyse (B) 273

Analytical methods, Direct identification of the carbon skeleton of organic compounds using double quantum coherence ^{13}C-NMR spectroscopy. The INADEQUATE pulse sequence (R) 625

in human toxicology (B) 1051

Nuclear quadrupole interaction and time-resolved perturbed γ-γ-angular correlation spectroscopy: applications in chemistry, materials science, and biophysical chemistry (R) 110

The generation and characterization of molecules by neutralization-reionization mass spectrometry (NRMS) (R) 805

The practice of quantitative gel electrophoresis (B) 370

Angular correlation spectroscopy, Nuclear quadrupole interaction and time-resolved perturbed γ-γ-angular correlation spectroscopy: applications in chemistry, materials science, and biophysical chemistry (R) 110

Annulenes, A new class of organozirconium(IV) compounds: alkyl derivatives of tetramethyltetraazadibenzo[14]annulenatozirconium(IV) (C) 70

Anthracyclinone ring C synthesis via chelate carbene complexes (C) 1158

Antifungal chemotherapy, Allylamine derivatives—a new class of active substances in antifungal chemotherapy (R) 320

Antimony compounds, Nonaphenyltristiboxane-1,5-diyl disulfonates (C) 906

$[Ph_4P]_2[Sb_2I_8]$: weak interactions between phenyl groups of the cation and antimony atoms of the anion (C) 467

Antitumor agents, New cisplatin analogues — on the way to better antitumor agents (R) 615

Arene adducts, $[Ph_4P]_2[Sb_2I_8]$: weak interactions between phenyl groups of the cation and antimony atoms of the anion (C) 467

Arene complexes, Arene adducts with weak interactions: hexaethylbenzene–bis(tribromoarsane) (C) 234

Arene complexes with weak interactions: a macrocyclic tris(arene) complex of gallium(I) with ν^{18} coordination (C) 338

Azulene as unusual η^6-ligand and as $\eta^6{:}\eta^4$-bridge in Mo-complexes (C) 147

$[CH_3C_6H_5BiCl_2][AlCl_4]$ and $[(CH_3)_6C_6BiCl_2][AlCl_4]$—compounds containing η^6-arene-complexed $BiCl_2^{\oplus}$ units (C) 74

$[\{(C_5H_5)Co\}_3(C_6H_5CH{=}CHCH_3)]$, an organometallic cluster with a face-bridging arene ligand (C) 1259

Electron delocalization in diruthenium complexes of polycyclic arenes (C) 700

Arenes, Benzene and linearly annelated arenes as dienophiles in Diels–Alder reactions with inverse electron demand (C) 332

Deep-colored, through-conjugated multitriphenylmethylium ions (C) 794

Selective molecular recognition and separation of isomeric and partially hydrogenated arenes (C) 901

Arenium ions, Mono- and diarenium ions of [2.2]paracyclophanes (C) 564

Aromaticity, Annelated isoindoles with 18π electrons (C) 1262

Back to the structure of benzene (L) 1298

[2.2](1,4)Benzo[*g*]chrysenoparacyclophane dianion: a novel, paratropic, double-layered carbanion (C) 232

Concerning the structure of benzene (C) 782

Cyclohepta[*a*]phenalene: a highly electron—donating nonalternant hydrocarbon (C) 1247

2,6-Diaza-*s*-indacenes (C) 1037

Dicyclopropa[*a,c*]naphthalene: a compound capable of existence? (C) 577

Propellanes of the glycoluril series and bridged tetrazocines (C) 1039

Synthesis of tricyclo[5.2.0.0^{1,3}]nona-4,6,8-triene, a norcaradiene structure constrained by the antiaromaticity of cyclobutadiene (C) 559
Aromatic nitration at the encounter rate in the gas phase (C) 1177
Arsenic bromides, Arene adducts with weak interactions: hexaethylbenzene-bis(tribromoarsane) (C) 234
Arsenic compounds, $[As_3Br_{12}]^{3-}$ and $[As_8I_{28}]^{4-}$ — structurally novel, discrete halogenoarsenate(III) ions (C) 1172
Arsenic iodides, Structure of triphenylarsane diiodide, $[Ph_3As \cdot I_2]$, a compound formed in the thermal decomposition of $[Mn(OAsPh_3)_3I_2(SO_2)_2]$ (C) 264
Arsenic-titanium compounds, Synthesis of the four-membered metallacycle $[Cp_2Ti(AsPh)_3]$ via the in situ reduction of $[Cp_2TiCl_2]$ (C) 244
Arsinosulfur diimides, $As_4S_5N_{10}$—A diaminosulfane derivative with two bicyclic arsino sulfur diimides (C) 82
Arsoles, 1,1'-Diarsaferrocene (C) 229
α-Arylglycine esters, Optically active α-arylglycine esters by Friedel-Crafts alkylation with the chiral cation of the bislactim ether of *cyclo*-(L-Val-Gly) (C) 683
(+)-Aspicilin, Total synthesis of the enantiomerically pure lichen macrolide (+)-aspicilin (C) 362
Asteranes, Diasterane (tricyclo[3.1.1.1^{2,4}]octane) (C) 554
Nonacyclo[10.8.0.0^{2,11}.0^{4,9}.0^{4,19}.0^{6,17}.0^{7,16}.0^{9,14}.0^{14,19}]icosane, a double tetraasterane (C) 1006
Asymmetric Diels-Alder reactions, High stereoselectivity in Lewis-acid-catalyzed and uncatalyzed Diels-Alder reactions of the fumarate of (S)-ethyl lactate (C) 1143
Asymmetric synthesis of α-amino-γ-nitrocarboxylic esters by the bislactim ether method (C) 480
of cyclic α-amino acids by the bislactim ether method (C) 143
Optically active α-arylglycine esters by Friedel-Crafts alkylation with the chiral cation of the bislactim ether of *cyclo*-(L-Val-Gly) (C) 683
Azaalkenylidene complexes, A novel route to azaalkenylidene-metal complexes (C) 248
2-Azabut-1-en-3-ynes, First synthesis of *N*-methylene-ynamines (2-azabut-1-en-3-ynes) (C) 923
Azatriphosphete, A 3,7-diaza-1,2,4,5,6,8-hexaphosphatricyclo[4.2.0.0^{2,5}]octane, a [2+2] dimer of a 1,2-dihydro-1-azatriphosphete containing a P_4 structure (C) 1256
Azides, [4+2] Cycloadditions of 2,3-diazido-1,3-butadienes: a novel entry to vicinal vinyl diazides and 1,4-dicyano compounds (C) 879
The pyrolysis of azides in the gas phase (R) 504
Azoalkene-nitrene cleavage on an Fe_3-cluster (C) 355
Azo compounds, Azo cope rearrangements of nonstabilized azo compounds (C) 672
Azo cope rearrangements of nonstabilized azo compounds (C) 672
Azo coupling, Diazo coupling of nortricyclene(tricyclo[2.2.1.0^{2,6}]heptane)-1-diazonium ions (C) 570
Azo/nitrene addition, Unusually stable *cis,cis*-trialkyltriaziridines by azo/nitrene addition (C) 566
Azulene as unusual η^6-ligand and as η^6:η^4-bridge in Mo-complexes (C) 147

BACTERIORHODOPSIN, Regulation of the 6-s equilibrium conformation of retinal in bacteriorhodopsin by substitution at C-5; 5-methoxy- and 5-ethylretinalbacteriorhodopsin (C) 580
Base-pairing, Molecular recognition: stacking interactions influence Watson-Crick vs. Hoogsteen base-pairing in a model for adenine receptors (C) 1244
Bases, Novel, very strongly basic, pentacyclic "proton sponges" with vinamidine structure (C) 1165
Peralkylated polyaminophosphazenes—extremely strong, neutral nitrogen bases (C) 1167
Tricyclic 2,4-diaminovinamidines—readily accessible, very strong CHN bases (C) 1164
Belts, Molecular belts and collars in the making: a hexaepoxyoctacosahydro[12]-cyclacene derivative (C) 892
Benzene, Back to the structure of benzene (L) 1298
Concerning the structure of benzene (C) 782
Benzoborole, The first synthesis of a benzoborole (C) 665
Bergmeyer, Methods of enzymatic analysis. Vol. VIII. Metabolites 3: Lipids, amino acids, and relate compounds (B) 272
Vol. IX. Proteins and peptides (B) 368
Vol. X: Antigens and antibodies 1. Vol. XI: Antigens and antibodies 2. Vol. XII: Drugs and pesticides (B) 1299
Bicycloalkylcarboxylic acids, Anodic Grob fragmentation of bicycloalkylcarboxylic acids to specifically disubstituted cycloalkenes (C) 1026
Bicyclotetrasilanes, Bond stretch isomerism in bicyclo[1.1.0]tetrasilanes. Contrasts between strained silicon and carbon ring systems (C) 364
Bilayer membranes, Lactosylceramides with unsaturated fatty acids — synthesis and use in the generation of bilayer membranes (C) 793
Bimetallic macrocyclic polymer structures, Novel bimetallic macrocyclic polymer structures incorporating deprotonated 2-pyrrolidone bridges: the crystal structures of $[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ ($X = NO_3$ or ClO_4) (C) 1044
Binuclear complexes, The synthesis and catalytic properties of some open-sided binuclear complexes of Rh^1: the structure of $[Rh_2(CO)_2(CH_3CN)_2\{CH(PPh_2)_3\}](CF_3SO_3)_2$ (C) 1169
Biocatalysts, A biocatalyst for the preparation of (*R*)- and (*S*)-2-hydroxycarboxylic acids (C) 128
Biochemistry, High-performance liquid chromatography in biochemistry (B) 705
Bioglass ceramics, The development of bioglass ceramics for medical applications (R) 527
Bioinorganic chemistry, Frontiers in bioinorganic chemistry (B) 90
Biological macromolecules, Methods in enzymology. Vols 114 and 115. Diffraction methods for biological macromolecules (B) 367
Biological recognition, Synthesis of glycopeptides, partial structures of biological recognition components (R) 294
Biological reduction, Reduction of 2-enoates and alkanoates with carbon monoxide or formate, viologens, and *clostridium thermoaceticum* to saturated acids and unsaturated and saturated alcohols (C) 785
Biomimetic synthesis, Chemistry of pyrrocorphins: biomimetic regioselectivity of *C*-methylation at the ligand periphery of magnesium(II) uropyrrocorphinate(type I)-octanitriles (C) 261
of a twofold *N,N'*-bridged porphyrinogen (C) 64
Biotechnology. A comprehensive treatise in 8 volumes. Vol. 4: microbial products II (B) 1057
Comprehensive biotechnology. The principles, applications and regulations of biotechnology in industry, agriculture and medicine (B) 588
Mikrobiologische und biochemische Verfahrenstechnik; eine Einführung (B) 1055
Biphenylenes with strongly distorted trapezoidal four-membered ring (C) 470
Bipyridyl complexes, Photoisomerization of bis(bipyridyl)rhodium(III) complexes; synthesis of *trans*-$[Rh(bpy)_2YCl]^{n\oplus}$, Y = Cl, H_2O (C) 240
Bishomo-aromaticity, Propellanes of the glycoluril series and bridged tetrazocines (C) 1039
Bislactim ether method, Asymmetric synthesis of α-amino-γ-nitrocarboxylic esters by the bislactim ether method (C) 480
Optically active α-arylglycine esters by Friedel-Crafts alkylation with the chiral cation of the bislactim ether of *cyclo*-(L-Val-Gly) (C) 683
Bismuth(III) chlorides, $[CH_3C_6H_5BiCl_2][AlCl_4]$ and $[(CH_3)_6C_6BiCl_2][AlCl_4]$—compounds containing η^6-arene-complexed $BiCl_2^{\oplus}$ units (C) 74
Bismuth compounds, Structure and color of pentaphenylbismuth (C) 1180
Bissecododecahedradienes, One- and two-electron oxidations of pagodanes and bissecododecahedradienes: unusually persistent radical cations (C) 457
Bissecododecahedraenes, unusual hyperstable olefins (C) 455
Bissetone, Proof of the (*S,S*) configuration of (−)-bissetone by synthesis from D-glucose (C) 1271
Bis(trimethylsilyl)methyl phenyl sulfone, X-ray structure analysis of the Li_2-compound of bis(trimethylsilyl)methyl phenyl sulfone; structural units of an α-sulfonyl- and a complex-stabilized *ortho*-sulfonyl carbanion (C) 1287
Bond angles, Biphenylenes with strongly distorted trapezoidal four-membered ring (C) 470
Bonding concepts, Homoatomic d^{10}-d^{10} interactions: their effects on structure and chemical and physical properties (R) 1098
Bond stretch isomerism in bicyclo[1.1.0]tetrasilanes. Contrasts between strained silicon and carbon ring systems (C) 364
Borazine-analogue, Synthesis and X-ray structure of $(2,4,6\text{-}Me_3C_6H_2BPC_6H_{11})_3$: a boron-phosphorus analogue of borazine (C) 1270
Boron compounds, Synthesis and structure of a 2,5-dihydro-1*H*-1,2,5-phosphadiborole derivative (C) 781
The first synthesis of a benzoborole (C) 665
Boron-Oxygen compounds, Cooperative effects in the phase transformation of triethylcyclotriboroxane (C) 245
Boron-phosphorus compounds, Synthesis and X-ray structure of $(2,4,6\text{-}Me_3C_6H_2BPC_6H_{11})_3$: a boron-phosphorus analogue of borazine (C) 1270
Bridging ligands, A mixed-metal cluster with two quadruply-bridging carbonyl ligands (C) 685
$[\{(C_5H_5)Co\}_3(C_6H_5CH{=}CHCH_3)]$, an organometallic cluster with a face-bridging arene ligand (C) 1259
Dinuclear complexes of gold(I) containing bridging cyclometalated arylphosphane or arylarsane ligands (C) 258
1,8-Naphthalene-linked cofacial dimeric phthalocyanines (C) 1021
RP-Bridged metal carbonyl clusters: synthesis, properties, and reactions (R) 743
Sulfur oxides as ligands in coordination compounds (R) 98
Tetranuclear mixed-valence manganese complexes with reduced TCNE or TCNQ as η^4-bridging ligands (C) 251
Butterfly structure, Synthesis and structure of $[(PPh_3)_2N][Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$: a butterfly oxo cluster (C) 255
tert-Butylethynyllithium, Tetrameric and dodecameric *tert*-butylethynyllithium: a

novel aggregation principle in organolithium compounds (C) 587

CAGE COMPOUNDS, $[Ag_4(SCH_2C_6H_4CH_3S)_3]^{2-}$, a novel polynuclear silver thiolate with trigonal-planar coordination of all silver atoms and a central $[Ag_4S_6]$-cage (C) 145
Macrobicyclic polyethers as second sphere ligands for tetraammineplatinum(II) (C) 693
Nonacyclo[10.8.0.0^{2,11}.0^{4,9}.0^{4,19}.0^{6,17}.0^{7,16}.0^{9,14}.0^{14,19}]icosane, a double tetraasterane (C) 1006
Second sphere coordination of tetraammineplatinum(II) by a macropolycyclic crown ether bisamide receptor (C) 692
Selective molecular recognition and separation of isomeric and partially hydrogenated arenes (C) 901
Synthesis and chirality of sixfold-bridged triple-decker phanes (C) 777
Unsaturated molecules containing main group metals (R) 1

Calcium antagonists, Substituted α-pyrones as starting compounds for the synthesis of 4,4-disubstituted 1,4-dihydropyridines (C) 790

Captodative substitution, A test for synergetic captodative radical stabilization (C) 573

Carbanions, [2.2](1,4)Benzo[*g*]chrysenoparacyclophane dianion: a novel, paratropic, double-layered carbanion (C) 232
Enantioselective protonation of carbanions with chiral proton sources (C) 1283
New reductive transformations of unsaturated cyclic hydrocarbons (R) 204

Carbene additions, Apparently nonstereospecific dihalocarbene addition—an explanation (C) 329

Carbene complexes, Nitrogen heterocycles from carbene complexes and alkenyl isocyanides (C) 563
Trimethylenemethane complexes of Cr, Mo, and W by novel methylenation of allenes with carbene complexes; cyclopentanes by [3+2] cycloaddition of trimethylenemethane complexes to allenes (C) 357
Vanadium carbene complexes by reaction of (diene)metallocenes with $[CpV(CO)_4]$ (C) 666

Carbene-like chemistry, The development of a carbene-like chemistry with terminal phosphinidene complexes (R) 275

Carbenes, Conversion of η^4-bound cyclopentadiene into the complexed carbene cyclopentadienylidene (C) 127
Reactions of 2,2,4,4-tetramethyl-3-methylenecyclobutylidene; thermal rearrangements of a 2-methylenebicyclo[2.1.0]-pentane (C) 1260

Carbenium ions, Control of the relative electrophilicity of alkylating agents by variation of the Lewis acid concentration (C) 1029

Carbenoid, Unusual 1,6-addition of a carbenoid (C) 72

Carbocations, Carbocation chemistry (B) 274
Crystal structure analysis of the 1,2,4,7-*anti*-tetramethyl-2-norbornyl cation: an unsymmetrically bridged carbocation (C) 560

Carbohydrate matrices, Diastereoselective Diels-Alder reaction on carbohydrate matrices (C) 267

Carbon-carbon bond formation, CC-linkages of ethene with CO_2 on an iron(0) complex—synthesis and crystal structure analysis of $[(PEt_3)_2Fe(C_2H_4)_2]$ (C) 153
Coupling of cyclometalated phenylphosphanes in dinuclear gold(II)-complexes (C) 260
Generation of β-, γ-, δ-, ε-, and ζ-zinc ketones and their transition-metal-catalyzed reactions with carbon electrophiles (C) 1157
Low-temperature photolysis of peracetylated dodecanoyl peroxides of tartaric acid and D-gluconic acid in the solid state—a diastereoselective radical coupling (C) 1253
Radicals in organic synthesis: formation of carbon-carbon bonds (B) 369
Regio- and stereoselective carbosulfenylation of olefins (C) 1028
Shortened C–C bonds and antiplanar O=C–O–H torsion angles in 1,4-cubanedicarboxylic acid (C) 447
Stereoselective aldol reactions with α-unsubstituted chiral enolates (R) 24
Unusual ligand directed regioselectivity in the iron catalyzed cross coupling of allylic ethers to 2-substituted 1,3-dienes (C) 1013

Carbon dioxide, Formation of oxazolidinones and oxazinanones by reaction of allylamines and of homoallylamines with carbon dioxide and iodine via intramolecular cyclization (C) 334
Nickel(0)-catalyzed production of a functionalized cyclopentanecarboxylic acid from 1,3-butadiene and CO_2 (C) 571

Carbonic acid, Thermolysis of NH_4HCO_3—a simple route to the formation of free carbonic acid (H_2CO_3) in the gas phase (C) 354

Carbon-sulfur, Bond cleavage in a π-thiophene ruthenium complex (C) 909

Carbon-supported nickel catalysts, Decarbonylation on carbon-supported nickel catalysts (C) 461

Carbon-tin double bond, A stable stannaethene (C) 546

Carbonyl complexes, RP-Bridged metal carbonyl clusters: synthesis, properties, and reactions (R) 743

Carbosilanes (R) 1111

Carbosulfenylation, Regio- and stereoselective carbosulfenylation of olefins (C) 1028

Carboxylic acids, CC-linkages of ethene with CO_2 on an iron(0) complex—synthesis and crystal structure analysis of $[(PEt_3)_2Fe(C_2H_4)_2]$ (C) 153

Catalysis, A new 1,3-diphosphaallylnickel complex for the polymerization of ethene (C) 1012
A 1-oxa-2-nickela-5-cyclopentanone from ethene and carbon dioxide: preparation, structure, and reactivity (C) 771
Control of the molecular weight of polyethene in syntheses with bis(ylide)nickel catalysts (C) 63
Coupling of two ethyne molecules at a nickel center to form a nickelacyclopentadiene complex (C) 1288
C–S Bond cleavage in a π-thiophene ruthenium complex (C) 909
Directed homogeneous hydrogenation (R) 190
Homogeneous catalysis with compounds of rhodium and iridium (B) 271
Metal clusters (B) 1050
Metal clusters in catalysis (B) 1050
The synthesis and catalytic properties of some open-sided binuclear complexes of Rh^{I}: the structure of $[Rh_2(CO)_2(CH_3CN)_2\{CH(PPh_2)_3\}](CF_3SO_3)_2$ (C) 1169

Catalysts, A biocatalyst for the preparation of (*R*)- and (*S*)-2-hydroxycarboxylic acids (C) 128
A novel heterobimetallic asymmetric hydrogenation catalyst based upon a chiral rhenium template containing two phosphido substituents (C) 910
Catalytic dehydrogenation of cyclohexene on silica overlayer films (C) 1182
Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309
IR Emission analysis of temperature profiles in Pt/SiO_2 catalysts during exothermic reactions (C) 1042
Organometallic rhodium(III) complexes as catalysts for the photoreduction of protons to hydrogen on colloidal TiO_2 (C) 567

Catenates, Molecular structure of a [3]-catenate: curling up of the interlocked system by interaction between the two copper complex subunits (C) 661

Cations, Alkylaluminum cations: synthesis and structure of $[Al(2\text{-}C(SiMe_3)_2C_5H_4N)_2][AlCl_4]$ (C) 681

Ceramics, Science of ceramic chemical processing (B) 706
The development of bioglass ceramics for medical applications (R) 527
The importance of chemistry in the development of high-performance ceramics (R) 371

Ceramides, Lactosylceramides with unsaturated fatty acids — synthesis and use in the generation of bilayer membranes (C) 793

Cerium(IV)-catalysis, Cerium(IV)-catalyzed single electron transfer (SET) on acenaphthene and 1,4-dihydronaphtho-[1,8-*d,e*]-[1,2]diazepine: chemical evidence for distinct radical cations (C) 797

Charge transfer and radical ions in photochemistry (R) 825

Charge-transfer complexes, Control of the electronic structure of organic conductors as exemplified by [NMP][TCNQ] charge-transfer complexes (R) 287

Charge-transfer interaction, Noncovalent bonding interactions between tetraphenylborate anions and paraquat and diquat dications (C) 890

Chelate complexes, Novel rhenium(V) carbonato and sulfato chelate complexes: synthesis and investigation of molecular dynamics by ^{17}O-NMR spectroscopy (C) 464

Chemical bond, Homoatomic d^{10}–d^{10} interactions: their effects on structure and chemical and physical properties (R) 1098

Chemical bonding, Superconductivity—a new classification of the chemical bonding in the solid (C) 1275

Chemical evolution, Aspects of chemical evolution (B) 937

Chemical processing, Science of ceramic chemical processing (B) 706

Chiral auxiliaries, Diastereoselective Strecker synthesis of α-aminonitriles on carbohydrate templates (C) 557

Chiral complexes, The mechanism of substitution reactions at $[LRe(NO)(CO)(CH_3)]^{\oplus}$ in acid solution and the structure of $[\{LRe(NO)(CO)\}_2(\mu\text{-}CH_2OCH_2)]I_2$ (L = 1,4,7-triazacyclononane) (C) 924

Chiral recognition, Stereoelectronic effects and chiral recognition: a natural system of relationships between chiral compounds based on selectivities in the formation of acetals (C) 442

Chlorins, 2,3-Dihydroporphycene—an analogue of chlorin (C) 931

CHN bases, Tricyclic 2,4-diaminovinamidines—readily accessible, very strong CHN bases (C) 1164

C–H···O hydrogen bonds, Observation of an eclipsed C_{sp^3}–CH_3 bond in a tricyclic orthoamide; experimental and theoretical evidence for C–H···O hydrogen bonds (C) 1175

Chromatographic separation of higher polythionates $S_nO_6^{2\ominus}$ (n = 3 ... 22) and their detection in cultures of *Thiobacillus ferroxidans*; molecular composition of bacterial sulfur secretions (C) 151

Chromatography, Affinity chromatography: a practical approach (B) 1056

CIDNP, Photo-CIDNP in the vacuum-UV: di-*tert*-butyl ether and 2,2,5,5-tetramethyltetrahydrofuran in aqueous solution (C) 446

Cisplatin analogues, New cisplatin analogues — on the way to better antitumor agents (R) 615
α-Cleavage, MNDOC calculations of the potential surfaces for photochemical α-cleavage (C) 238
Cleavage of water, A new photosynthesis-like system for the light-induced reduction of water to molecular hydrogen (C) 241
Cluster chemistry, Isoelectronic relationships in cluster chemistry: nucleophilic addition to a vinylidene ligand (C) 572
Clusters, Azoalkane-nitrene cleavage on an Fe_3-cluster (C) 355
Cluster of clusters: structure of the 37-atom cluster $[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2\oplus}$ and a novel series of supraclusters based on vertex-sharing icosahedra (C) 897
Heterometallic polyhydride raft formation: a comparison of syntheses using alkoxides of copper and gold (C) 135
Metal clusters (B) 1050
Metal clusters in catalysis (B) 1050
Mixed-metal cluster formation by carbonylmetalate-induced Pt–P bond cleavage in $[PtCl_2(Ph_2PCH_2PPh_2]$ (C) 88
$[\{(C_5H_5)Co\}_3(C_6H_5CH{=}CHCH_3)]$, an organometallic cluster with a face-bridging arene ligand (C) 1259
New $AuPt_2$ A-frame cluster complexes (C) 86
Novel Ni-clusters with Se and PR_3 (R=Ph, Et) as ligands (C) 148
Reactions of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ with electrophilic complexes of copper and gold. Synthesis of the Pd_4 cluster $[Pd_4(\mu\text{-}Cl)_2(\mu\text{-dppm})_4](PF_6)_2\cdot 2(CH_3)_2CO$ (C) 768
RP-Bridged metal carbonyl clusters: synthesis, properties, and reactions (R) 743
Salicylate-mediated assembly of the discrete mixed-valence nonanuclear manganese complex $[Mn_9O_4(O_2CPh)_8(sal)_4(salH)_2(py)_4]$ ($salH_2$ = salicylic acid, py = pyridine) 915
Spherical mixed-valence $[V_{15}O_{36}]^{5\ominus}$, an example from an unusual cluster family (C) 1045
Square Hg_4 clusters in the compound CsHg (C) 687
Synthesis and structure of $[(PPh_3)_2N][Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$: a butterfly oxo cluster (C) 255
^{13}C-NMR spectroscopy, High-resolution CP-MAS ^{13}C-NMR spectra of allylzinc compounds—structural similarities and differences in the solid state and in solution (C) 1279
Cobalt clusters, A triple decker sandwich structure by reaction of cyclopentadienylbis(ethylene)cobalt with carbodiimides: an unusual cyclopentadienylcobalt oligomer (C) 68
"Two-electron reduction" of phosphane-substituted tricobalt clusters—evidence for a 17-electron intermediate in the dissociative ETC ligand substitution (C) 352
Cobalt compounds, Cobalt-mediated [2+2+2]cycloadditions of alkynes to the imidazole 4,5-double bond. First Synthesis of the 3*a*,7*a*-dihydrobenzimidazole nucleus and its preliminary chemistry including a novel quinoline construction (C) 1035
Conversion of η^4-bound cyclopentadiene into the complexed carbene cyclopentadienylidene (C) 127
1,8-Naphthalene-linked cofacial dimeric phthalocyanines (C) 1021
2,3,9,10-Tetrakis(trimethylsilyl)[5]phenylene. Synthesis via regiospecific cobalt-catalyzed cocyclization of 1,6-bis(triisopropylsilyl)-1,3,5-hexatriyne (C) 1246
Cobalt(II)-ions, Highly polarizing Co^{2+} ions from $[Co_2(CO)_8]$ and pyridine in hydrocarbons: synthesis and structure of $[\{Co_3(CO)_{10}\}_2\{Co(py)_4\}]$ and $[(Co)_4CoCo(py)_3][Co(CO)_4]$ (C) 680
Cobaltocenium, $[\{Co(Cp)_2\}\{CuI_2\}]_n$ (n = 3, 4), cobaltocenium iodocuprates(I) with unusual anion structures (C) 927
Cocyclization, 2,3,9,10-tetrakis(trimethylsilyl)[5]phenylene. Synthesis via regiospecific cobalt-catalyzed cocyclization of 1,6-bis(triisopropylsilyl)-1,3,5-hexatriyne (C) 1246
Coin-metal fluorides, Fluorides of copper, silver, gold, and palladium (R) 1081
Collagen fibers, Structural dynamics of collagen fibers cross-linked with isocyanates; application of synchrotron radiation in macromolecular chemistry (C) 551
Collars, Molecular belts and collars in the making: a hexaepoxyoctacosahydro[12]-cyclacene derivative (C) 892
Colloidal metals, Colloidal bimetallic catalysts: Pt-Au (C) 918
The morphology and microstructure of colloidal silver and gold (C) 676
Comprehensive biotechnology. The principles, applications and regulations of biotechnology in industry, agriculture and medicine (B) 588
Computer-assisted molecular design (CAMD)—an overview (R) 403
Conductivity, Control of the electronic structure of organic conductors as exemplified by [NMP][TCNQ] charge-transfer complexes (R) 287
Superconductivity—a chemical phenomenon? (C) 579
(+)-Confertin, Total synthesis of the pseudoguaianolide (+)-confertin (C) 61
Configuration, Inversion of the configuration of secondary alcohols via isourea ethers prepared in situ (C) 773
Proof of the (*S*,*S*) configuration of (−)-bissetone by synthesis from D-glucose (C) 1271
The absolute configuration of the ant alarm pheromone manicone (C) 784
Configurational stability, Estimation of the configurational stability of chiral organometallic reagents (C) 1145
Configuration analysis, Sequential configuration analysis of peptides (C) 331
Conformation, Observation of an eclipsed C_{sp^3}–CH_3 bond in a tricyclic orthoamide; experimental and theoretical evidence for C–H···O hydrogen bonds (C) 1175
Regulation of the 6-s equilibrium conformation of retinal in bacteriorhodopsin by substitution at C-5; 5-methoxy- and 5-ethylretinalbacteriorhodopsin (C) 580
Conformational Analysis, Dibenzo[*fg*,*mn*]-octalene and cycloocta[*def*]phenanthrene. New models for the conformational analysis of biphenyl systems (C) 1291
Conformational transitions between enantiomeric 3_{10}-helices (C) 1150
Conjugation, Deep-colored, through-conjugated multitriphenylmethylium ions (C) 794
Relay conjugation via twisted six- and seven-membered rings (C) 1252
The dependence of intramolecular electron transfer on structure in a spiro compound containing two cyclooctatetraene moieties (C) 1290
Coordination, Alkylaluminum cations: synthesis and structure of $[Al(2\text{-}C(SiMe_3)_2\text{-}C_5H_4N)_2][AlCl_4]$ (C) 681
Conversion of η^4-bound cyclopentadiene into the complexed carbene cyclopentadienylidene (C) 127
Fluorides of copper, silver, gold, and palladium (R) 1081
High-pressure LiGe with layers containing two- and four-coordinate germanium atoms (C) 76
Macrobicyclic polyethers as second sphere ligands for tetraammineplatinum(II) (C) 693
Novel bimetallic macrocyclic polymer structures incorporating deprotonated 2-pyrrolidone bridges: the crystal structures of $[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ (X = NO_3 or ClO_4) (C) 1044
Novel Ni-clusters with Se and PR_3 (R=Ph, Et) as ligands (C) 148
Second sphere coordination of tetraammineplatinum(II) by a macropolycyclic crown ether bisamide receptor (C) 692
Simultaneous primary and secondary coordination of a neutral guest within a macrocyclic complex of rhodium(III) (C) 1162
Structure of triphenylarsanediiodine, $[Ph_3As\cdot I_2]$, a compound formed in the thermal decomposition of $[Mn(OAsPh_3)_3\text{-}I_2(SO_2)_2]$ (C) 264
Sulfur oxides as ligands in coordination compounds (R) 98
Tetrameric and dodecameric *tert*-butylethynyllithium: a novel aggregation principle in organolithium compounds (C) 587
s-Tetrazine as ligand for monomeric and bridged macrocyclic metal complexes (C) 344
Cope rearrangements, Azo cope rearrangements of nonstabilized azo compounds (C) 672
Proton-controlled equilibration between $[4^+ + 2]$ and $[4 + 2^+]$ cycloadducts: a characteristic example for the aberrant Diels-Alder reactions between two 1,3-dienes (C) 670
Copolymer, The copolymer of 2,6-pyridinedimethanethiol and 1,4-benzenedimethanethiol (C) 137
Copper compounds, $FCu[AuF_4]$, an unusual copper(II) fluoroaurate(III) (C) 688
$[\{Co(Cp)_2\}\{CuI_2\}]_n$ (n = 3, 4), cobaltocenium iodocuprates(I) with unusual anion structures (C) 927
Reactions of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ with electrophilic complexes of copper and gold. Synthesis of the Pd_4 cluster $[Pd_4(\mu\text{-}Cl)_2(\mu\text{-dppm})_4](PF_6)_2\cdot 2(CH_3)_2CO$ (C) 768
Coronanes, Pentacyclo[11.3.0.0^{1,5}.0^{5,9}.0^{9,13}]-hexadecane ([4.5]coronane) (C) 1023
Heptacyclo[19.3.0.0^{1,5}.0^{5,9}.0^{9,13}.0^{13,17}.0^{17,21}]-tetracosane ([6.5]coronane) (C) 130
Correspondence, Questions of assignment (L) 703
CP-MAS ^{13}C-NMR spectroscopy, High-resolution CP-MAS ^{13}C-NMR spectra of allylzinc compounds—structural similarities and differences in the solid state and in solution (C) 1279
Cram chelate, The first direct evidence for a Cram chelate (C) 477
Cross-linking, Structural dynamics of collagen fibers cross-linked with isocyanates; application of synchrotron radiation in macromolecular chemistry (C) 551
Crown ethers, 1D and 2D NMR investigations of the jump mechanism of Co^{II} ions in [12]crown-4 stacks (C) 228
Noncovalent bonding interactions between tetraphenylborate anions and paraquat and diquat dications (C) 890
Stabilization of the $[AlMe_2]^{\oplus}$ cation by crown ethers (C) 485
Crown thioether complexes of Ag^I and Cu^I: the crystal structures of $[\{Ag_3L_2\}\{AgL_2\}](ClO_4)_4$ and [LCuI] (L = 1,4,7-Trithiacyclononane (C) 575
Cryptates, Energy transfer luminescence of europium(III) and terbium(III) cryptates of macrobicyclic polypyridine ligands (C) 266
Luminescence probes: the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ cryptates of polypyridine macrobicyclic ligands (C) 1266
1,4-Cubanedicarboxylic acid, Shortened C–C bonds and antiplanar O=C–O–H torsion angles in 1,4-cubanedicarboxylic acid (C) 447
Cubane-like frameworks, $[Fe_4Te_4(TePh)_4]^{3\ominus}$, the first telluride-tellurolate complex (C) 1009
$[(\eta^5\text{-}C_5Me_5)_2Ti_2P_6]$, a distorted dimetallaphosphacubane (C) 1153
$Cs_3Mo_5P_6O_{25}$: a novel molybdenum phosphate containing a cubane-like Mo_4O_4

cluster with six molybdenum–molybdenum bonds (C) 549
Cumulenes, Synthesis and properties of 1-cycloheptatrienylidene-2-cyclopentadienylideneethylene derivatives (C) 335
Cuprates, $[\{Co(Cp)_2\}\{CuI_2\}]_n$ (n = 3, 4), cobaltocenium iodocuprates(I) with unusual anion structures (C) 927
Curvature, Adsorption and curvature in highly dealuminated zeolites (C) 1017
How nature adapts chemical structures to curved surfaces (R) 1059
Cyanohydrin synthesis, Enzyme-catalyzed cyanohydrin synthesis in organic solvents (C) 458
Cyanotriphenylphosphoranylidenemethanide Synthesis of nitriles via the ylide anion of sodium cyanotriphenylphosphoranylidenemethanide (C) 79
Cyclization, Formation of oxazolidinones and oxazinanones by reaction of allylamines and of homoallylamines with carbon dioxide and iodine via intramolecular cyclization (C) 334
Methyl (*E*)-2-(1-aryl-4,5-dihydro-1*H*-tetrazol-5-ylidene)-2-cyanoacetate from methyl 3,3-diazido-2-cyanoacrylate and primary aromatic amines (C) 1160
Cycloadditions, Cobalt-mediated [2+2+2]-cycloadditions of alkynes to the imidazole 4,5-double bond. First Synthesis of the 3*a*, 7*a*-dihydrobenzimidazole nucleus and its preliminary chemistry including a novel quinoline construction (C) 1035
[1+4] Cycloaddition of a diphosphene to acrolein: synthesis and structure of a dihydro-1,2λ^5-oxaphosphole with an exocyclic P=P bond (C) 1010
[4+2] Cycloadditions of 2,3-diazido-1,3-butadienes: a novel entry to vicinal vinyl diazides and 1,4-dicyano compounds (C) 879
Proton-controlled equilibration between $[4^+ + 2]$ and $[4 + 2^+]$ cycloadducts: a characteristic example for the aberrant Diels–Alder reactions between two 1,3-dienes (C) 670
Trimethylenemethane complexes of Cr, Mo, and W by novel methylenation of allenes with carbene complexes; cyclopentanes by [3+2] cycloaddition of trimethylenemethane complexes to allenes (C) 357
Cycloalkenes, Anodic Grob fragmentation of bicycloalkylcarboxylic acids to specifically disubstituted cycloalkenes (C) 1026
Cycloannelation, New reductive transformations of unsaturated cyclic hydrocarbons (R) 204
Cyclobutafuran, Dihydrocyclobutafuran (C) 471
β-Cyclodextrin, Changes of stereoselectivity in Diels–Alder reactions by hydrophobic solvent effects and by β-cyclodextrin (C) 896
Cyclohepta[*a*]phenalene: a highly electron-donating nonalternant hydrocarbon (C) 1247
1-Cycloheptatrienylidene-2-cyclopentadienylideneethylenes, Synthesis and properties of 1-cycloheptatrienylidene-2-cyclopentadienylideneethylene derivatives (C) 335
1,2-Cyclohexadiene, 1,2,3,5,8,8a-Hexahydronaphthalene from 1,2-cyclohexadiene (C) 449
Cycloocta[*def*]phenanthrene, New models for the conformational analysis of biphenyl systems (C) 1291
Cyclooligomerization, Coupling of two ethyne molecules at a nickel center to form a nickelacyclopentadiene complex (C) 1288
Cyclopentadienides, Structure of a crystalline alkali-metal cyclopentadienide (C) 583
Cyclopentadienylidene, Conversion of η^4-bound cyclopentadiene into the complexed carbene cyclopentadienylidene (C) 127
Cyclopentanecarboxylic acid, Nickel(0)-catalyzed production of a functionalized cyclopentanecarboxylic acid from 1,3-butadiene and CO_2 (C) 571
Cyclopentanediyl, 2,2-Dimethyl-4,5-dimethylene-1,3-cyclopentanediyl (C) 1285
Cyclopentanes, A novel route to cyclopentane derivatives: a radical chain reaction (C) 1152
Stereocontrolled formation of annelated cyclopentanes by intramolecular hetero-Diels–Alder reaction. Synthesis of deoxyloganin from citronellal (C) 1295
Trimethylenemethane complexes of Cr, Mo, and W by novel methylenation of allenes with carbene complexes; cyclopentanes by [3+2] cycloaddition of trimethylenemethane complexes to allenes (C) 357
Cyclophosphanes, P_8iPr_4—the first tricyclo[3.2.1.0^{2,4}]octaphosphane (C) 347
Polyphosphorus compounds—new results and perspectives (R) 419
$P_8tBu_6O_6$—a highly oxidized cyclophosphane with intact P framework (C) 348
Cyclpropabenzenes, Reactions of (η^3-allyl)(η^5-cyclopentadienyl)palladium with cyclopropabenzenes (C) 67
Cyclopropapyridine, Synthesis and structure of a cyclopropapyridine (C) 668
Cyclotrimerization, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of a molybdenum-coordinated 1,3,5-triphosphabenzene (C) 907
Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
DEBYE SCREENING LENGTH, The role of Debye screening length in ordered arrays of cylindrical nickel dimethylglyoxime particles (C) 765
Decarbonylation on carbon-supported nickel catalysts (C) 461
1,3-Dehydro-5,7-adamantanediyl dication, Four-center two-electron bonding in a tetrahedral topology. Experimental realization of three-dimensional homoaromaticity in the 1,3-dehydro-5,7-adamantanediyl dication (C) 761
Dehydrogenation, Catalytic dehydrogenation of cyclohexene on silica overlayer films (C) 1182
Deltate, Trithiodeltate: a new, aromatic thioxocarbon dianion (C) 1163
Deoxyhexoses, Enantioselective synthesis of methylfuranosides of unnatural 3,6-dideoxy-3-methylaldohexoses from lactates by homoaldol reactions (C) 1034
Deoxyloganin, Stereocontrolled formation of annelated cyclopentanes by intramolecular hetero-Diels–Alder reaction. Synthesis of deoxyloganin from citronellal (C) 1295
2-Deoxy sugars, Synthesis of 2-deoxy sugars (C) 233
Deuteriated compounds, $^2H,^2H$-COSY and $^2H,^2H,^{13}C$-RELAY NMR experiments for the analysis of deuteriated compounds (C) 156
Dewar-Phosphinine, Isomerization reactions in the system Dewar-phosphinine/phosphaprismane/phosphabenzvalene/phosphinine (C) 85
Diaminosulfanes, $As_4S_5N_{10}$—A diaminosulfane derivative with two bicyclic arsinosulfur diimides (C) 82
2,4-Diaminovinamidines, Tricyclic 2,4-diaminovinamidines—readily accessible, very strong CHN bases (C) 1164
1,1'-Diarsaferrocene (C) 229
Diasterane (tricyclo[3.1.1.1^{2,4}]octane) (C) 554
Diastereoselective Diels–Alder reaction on carbohydrate matrices (C) 267
Diastereoselective radical coupling, Low-temperature photolysis of peracetylated dodecanoyl peroxides of tartaric acid and D-gluconic acid in the solid state—a diastereoselective radical coupling (C) 1253
Diastereoselectivity, Totally synthetic routes to the higher monosaccharides (R) 15
Transition state π-solvation by aromatic rings: an electronic contribution to Diels–Alder reaction diastereoselectivity (C) 1184
Diazahexaphosphatricyclooctane, A 3,7-diaza-1,2,4,5,6,8-hexaphosphatricyclo[4.2.0-0^{2,5}]octane, a [2+2] dimer of a 1,2-dihydro-1-azatriphosphete containing a P_4 structure (C) 1256
2,6-Diaza-*s*-indacenes (C) 1037
2,5-Diazapentalenes (C) 552
Diazido-2-cyanoacrylate, Methyl (*E*)-2-(1-aryl-4,5-dihydro-1*H*-tetrazol-5-ylidene)-2-cyanoacetate from methyl 3,3-diazido-2-cyanoacrylate and primary aromatic amines (C) 1160
Dibenzo[*fg,mn*]octalene and cycloocta[*def*]-phenanthrene. New models for the conformational analysis of biphenyl systems (C) 1291
Di-*tert*-butyl ether, Photo-CIDNP in the vacuum-UV: di-*tert*-butyl ether and 2,2,5,5-tetramethyltetrahydrofuran in aqueous solution (C) 446
Dichroism, Structure and color of pentaphenylbismuth (C) 1180
Dictionary, A dictionary of scientific units (B) 938
1,4-Dicyano compounds, [4+2] Cycloadditions of 2,3-diazido-1,3-butadienes: a novel entry to vicinal vinyl diazides and 1,4-dicyano compounds (C) 879
Dicyclopropa[*a,c*]naphthalene: a compound capable of existence? (C) 577
Diels-Alder reactions, A non-stereospecific Diels–Alder reaction (C) 1046
Benzene and linearly annelated arenes as dienophiles in Diels–Alder reactions with inverse electron demand (C) 332
Changes of stereoselectivity in Diels–Alder reactions by hydrophobic solvent effects and by β-cyclodextrin (C) 896
Diastereoselective Diels–Alder reaction on carbohydrate matrices (C) 267
High stereoselectivity in Lewis-acid-catalyzed and uncatalyzed Diels–Alder reactions of the fumarate of (S)-ethyl lactate (C) 1143
New lead structures by Diels–Alder reactions of streptazolin with naphthoquinones (C) 664
Proton-controlled equilibration between $[4^+ + 2]$ and $[4 + 2^+]$ cycloadducts: a characteristic example for the aberrant Diels–Alder reactions between two 1,3-dienes (C) 670
Transition state π-solvation by aromatic rings: an electronic contribution to Diels–Alder reaction diastereoselectivity (C) 1184
Diene complexes, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723
Dienes, Stereoselective synthesis of (*E*)-3-methylene-4-alken-2-ones from aldehydes and methyl vinyl ketone and their spontaneous dimerization (C) 1015
Unusual ligand directed regioselectivity in the iron catalyzed cross coupling of allylic ethers to 2-substituted 1,3-dienes (C) 1013
Dienophiles, Benzene and linearly annelated arenes as dienophiles in Diels–Alder reactions with inverse electron demand (C) 332
Di-*Grignard compounds and metallacycles* (R) 990
Dihalocarbene additions, Apparently non-

stereospecific dihalocarbene addition—an explanation (C) 329
3*a*,7*a*-Dihydrobenzimidazole, Cobalt-mediated [2+2+2] cycloadditions of alkynes to the imidazole 4,5-double bond. First Synthesis of the 3*a*,7*a*-dihydrobenzimidazole nucleus and its preliminary chemistry including a novel quinoline construction (C) 1035
Dihydrocyclobutafuran (C) 471
1,4-Dihydronaphtho-[1,8-*d*,*e*][1,2]diazepine, Cerium(IV)-catalyzed single electron transfer (SET) on acenaphthene and 1,4-dihydronaphtho-[1,8-*d*,*e*][1,2]diazepine: chemical evidence for distinct radical cations (C) 797
1,4-Dihydropyridines, Substituted α-pyrones as starting compounds for the synthesis of 4,4-disubstituted 1,4-dihydropyridines (C) 790
Dilithioethylene, *cis*- and *trans*-1,2-Dilithioethylene (C) 1032
Dimanganese heptoxide, The crystal structure of Mn_2O_7 (C) 139
for the selective oxidation of organic substrates (C) 1007
Dimerization, Macrocyclic dienes by metathetic dimerization of cycloheptene and cyclooctene on Re_2O_7/Al_2O_3 (C) 702
of 1,6-dithiacyclodeca-3,8-diyne in the presence of cobalt complexes. A simple synthesis of a [2.2](2,5)thiophenophane derivative (C) 763
Preparation and structure of $[Mo_4(OMe)_2(OiPr)_{10}]$; comments on why $[W_2(OiPr)_6]$ dimerizes, whereas $[Mo_2(OiPr)_6]$ does not (C) 904
Stereoselective synthesis of (*E*)-3-methylene-4-alken-2-ones from aldehydes and methyl vinyl ketone and their spontaneous dimerization (C) 1015
2,2-Dimethyl-4,5-dimethylene-1,3-cyclopentanediyl (C) 1285
Dioxetanes, A psoralen-substituted dioxetane as DNA intercalator for photogenotoxic studies (C) 796
Photooxidation of 2,5-dimethyl-2,3,4-hexatriene—matrix isolation of a trisdioxetane (C) 475
Diphosphaallylnickel complex, A new 1,3-diphosphaallylnickel complex for the polymerization of ethene (C) 1012
1,4-Diphospha-1,3-butadienes (C) 779
Diphosphene, [1+4] Cycloaddition of a diphosphene to acrolein: synthesis and structure of a dihydro-1,2λ^5-oxaphosphole with an exocyclic P=P bond (C) 1010
Diphosphetes, A new low-temperature synthesis of 1,2-dihydro-1,2-diphosphetes (C) 548
A new low-temperature synthesis of 1,2-dihydro-1,2-diphosphetes (C) 548 (804)
Dipyrrolo[1,2-*a*:2′,1′-*c*]quinoxalines: A novel heterocyclic system (C) 1280
Diquat, Noncovalent bonding interactions between tetraphenylborate anions and paraquat and diquat dications (C) 890
Diradicals, 2,2-Dimethyl-4,5-dimethylene-1,3-cyclopentanediyl (C) 1285
Neutral and charged biradicals, zwitterions, funnels in S_1, and proton translocation: their role in photochemistry, photophysics, and vision (R) 170
Reactions of 2,2,4,4-tetramethyl-3-methylenecyclobutylidene; thermal rearrangements of a 2-methylenebicicyclo[2.1.0]-pentane (C) 1260
The diradical 2,3,5,6-tetramethylene-1,4-cyclohexanediyl ("1,2,4,5-tetramethylenebenzene") (C) 256
Discotic compounds, The "Wheel of Mainz" as a liquid crystal?—Structural variation and mesophase properties of trimeric discotic compounds (C) 1249
1,2-Diselenete and 1,2-thiaselenete (C) 343
Disilenes, Chemistry of the silicon-silicon double bond (R) 1201
Synthesis and characterization of tetrakis[bis(trimethylsilyl)methyl]disilene (C) 584
Disproportionation, Highly polarizing Co^{2+} ions from $[Co_2(CO)_8]$ and pyridine in hydrocarbons: synthesis and structure of $[\{Co_3(CO)_{10}\}_2\{Co(py)_4\}]$ and $[(Co)_4CoCo(py)_3][Co(CO)_4]$ (C) 680
Redox disproportionation of Ge^{II} compounds: synthesis and structure of $[(Me_3Si)C(PMe_2)_2]_2GeCl_2$ and $[\mu\text{-}\{(Me_3Si)C(PMe_2)_2\}]_2Ge_2$ (C) 673
Distortion, Biphenylenes with strongly distorted trapezoidal four-membered ring (C) 470
Disulfur, 5,5-Dimethyl-1,2-dithia-3,7-diselenacycloheptane—a storable source of disulfur, S_2 (C) 887
1,6-Dithiacyclodeca-3,8-diyne, Dimerization of 1,6-dithiacyclodeca-3,8-diyne in the presence of cobalt complexes. A simple synthesis of a [2.2](2,5)thiophenophane derivative (C) 763
Dititanahexaphosphacubane, $[(\eta^5\text{-}C_5Me_5)_2Ti_2P_6]$, a distorted dimetallaphosphacubane (C) 1153
DNA intercalator, A psoralen-substituted dioxetane as DNA intercalator for photogenotoxic studies (C) 796
2D-NMR Spectroscopy, Modern NMR techniques for chemistry research (B) 1192
Modern techniques in high resolution FT NMR (B) 1192
Nuclear magnetic resonance. Basic principles (B) 1192
Principles of nuclear magnetic resonance in one and two dimensions (B) 1192
Dodecahedradienes, One- and two-electron oxidations of pagodanes and bissecododecahedradienes: unusually persistent radical cations (C) 457
Dodecahedraenes, Bissecododecahedraenes, unusual hyperstable olefins (C) 455
Dodecahedranes from [1.1.1.1]pagodanes (C) 452
The pagodane route to dodecahedranes—thermal, reductive, and oxidative transformations of pagodanes (C) 451
Donor-acceptor complexes, $[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2\}_2GeCl_2$, a germanediyl-donor germanediyl-acceptor complex containing a mixed-valent Ge_5 chain (C) 674
Double-bond localization, The influence of substituents on double-bond localization e.g. in *s*-indacene (C) 360
Double proton transfer, Kinetic ^{15}N-CPMAS-NMR study of a double proton transfer in a crystalline malonaldehyde diimine derivative (C) 247
Drugs, New cisplatin analogues — on the way to better antitumor agents (R) 615
New lead structures by Diels-Alder reactions of streptazolin with naphthoquinones (C) 664
Dynamics, Dynamic processes on the IR time scale: coalescence of CO stretching vibrational bands in $[(\eta^4\text{-diene})Fe(CO)_3]$ complexes (C) 885

EFFECT OF SOLVENT, The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770
Eicosapentaenoic acid, Stereocontrolled total synthesis of lipoxins A_5 and B_5 (C) 1019
Electrocatalysis, Electrocatalytic deposition of polypyrrole (C) 1031
Electrochemistry, Anodic Grob fragmentation of bicycloalkylcarboxylic acids to specifically disubstituted cycloalkenes (C) 1026
Geschichte der Elektrochemie (B) 160
1,8-Naphthalene-linked cofacial dimeric phthalocyanines (C) 1021
Principles of electrochemistry (B) 1302
Electrocyclization, 1,5-Electrocyclization in homofuran, homopyrrole, and homothiophene (C) 1294
Electrodes for potential measurements in aqueous systems at high temperatures and pressures (R) 161
Electron delocalization in diruthenium complexes of polycyclic arenes (C) 700
Electron donor, Cyclohepta[*a*]phenalene: a highly electron-donating nonalternant hydrocarbon (C) 1247
Electron microscopy, Imaging oxygen vacancies in superconducting $YBa_2Cu_3O_{7-\delta}$ by high resolution electron microscopy (C) 1048
Scanning tunneling microscopy - from birth to adolescence (Nobel lecture) (R) 606
The development of the electron microscope and of electron microscopy (Nobel lecture) (R) 595
Electron transfer, The dependence of intramolecular electron transfer on structure in a spiro compound containing two cyclooctatetraene moieties (C) 1290
Electron transport, Control of the electronic structure of organic conductors as exemplified by [NMP][TCNQ] charge-transfer complexes (R) 287
Electrophilicity, Control of the relative electrophilicity of alkylating agents by variation of the Lewis acid concentration (C) 1029
Elementary chemical processes, Molecular beam studies of elementary chemical processes (Nobel lecture) (R) 939
Molecular dynamics of elementary chemical reactions (Nobel Lecture) (R) 1221
Some concepts in reaction dynamics (Nobel lecture) (R) 952 (1302)
Element-element bonds, $[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2\}_2GeCl_2$, a germanediyl-donor germanediyl-acceptor complex containing a mixed-valent Ge_5 chain (C) 674
Pentabenzylcyclopentadienylthallium(I): synthesis and structure of a "dimeric" organothallium compound with Tl-Tl interaction (C) 789
Redox disproportionation of Ge^{II} compounds: synthesis and structure of $[(Me_3Si)C(PMe_2)_2]_2GeCl_2$ and $[\mu\text{-}\{(Me_3Si)C(PMe_2)_2\}]_2Ge_2$ (C) 673
Elimination, Glycolate and thioglycolate complexes of rhenium and their oxidative elimination of ethylene and of glycol (C) 462
Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309
Emission analysis, IR Emission analysis of temperature profiles in Pt/SiO_2 catalysts during exothermic reactions (C) 1042
Enantioselective protonation of carbanions with chiral proton sources (C) 1283
Enantioselectivity, Enantioselective synthesis of α-trialkylsilyl ketones and aldehydes (C) 351
Enantiotopomerization, Conformational transitions between enantiomeric 3_{10}-helices (C) 1150
ENDOR investigation, First ENDOR investigations of biologically relevant organic radicals in reversed micelles (C) 345
ENDOR spectroscopy, The spin distribution in ion pairs of 1-aminoanthraquinone radical anion and alkali-metal cations (C) 791
Energy transfer luminescence of europium(III) and terbium(III) cryptates of macrobicyclic polypyridine ligands (C) 266
Enoates, Reduction of 2-enoates and alkanoates with carbon monoxide or formate, viologens, and *clostridium thermoaceticum* to saturated acids and unsaturated and saturated alcohols (C) 785
Environmental chemistry, Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309

Enzymatic analysis, Methods of enzymatic analysis. Vol. VIII. Metabolites 3: lipids, amino acids, and related compounds (B) 272
Methods of enzymatic analysis. Vol. IX. Proteins and peptides (B) 368
Methods of enzymatic analysis. Vol. X: Antigens and antibodies 1. Vol. XI: Antigens and antibodies 2. Vol. XII: Drugs and pesticides. Cumulated subject index (B) 1299
Enzyme catalysis, Enzyme-Catalyzed cyanohydrin synthesis in organic solvents (C) 458
Enzymes, A biocatalyst for the preparation of (*R*)- and (*S*)-2-hydroxycarboxylic acids (C) 128
Chemical modification of enzymes. Active site studies (B) 1301
IR Spectroscopic determination of the enzyme content of carrier-fixed enzymes (C) 483
Molybdenum enzymes (B) 487
Organized multienzyme systems: catalytic properties (B) 488
Enzymology, Methods in enzymology. Vols. 114 and 115. Diffractin methods for biological macromolecules (B) 367
Epidermal growth factor (Nobel lecture) (R) 717
Epitaxicity, Reaction of Sn_9^{4-} with single crystal Au: textured fiber epitaxial growth of AuSn at room temperature (C) 1155
Ethene, A new 1,3-diphosphaallylnickel complex for the polymerization of ethene (C) 1012
Ether cleavage with organo-alkali-metal compounds and alkali metals (R) 972
Ethylene complexes, Olefinic C=C double bond coordination to a M≡M triple bond: bis(η^2-ethylene)hexakis(neopentyloxy)ditungsten (C) 903
Ethylene elimination, Glycolate and thioglycolate complexes of rhenium and their oxidative elimination of ethylene and of glycol (C) 462
Europium compounds, Energy transfer luminescence of europium(III) and terbium(III) cryptates of macrobicyclic polypyridine ligands (C) 266
EXAFS: basic principles and data analysis (B) 801

FECAPENTAENE-14, Natural fecapentaene-14 and one fecapentaene-12 component are all-*trans* stereoisomers (C) 1186
Fischer–Tropsch synthesis, Hydride abstraction from $[C_6H_6Os(CO)(CH_3)_2]$: does a metal-bound methyl group migrate preferentially to a CO or to a CH_2 ligand? (C) 686
Synthesis and structure of the formaldehyde complex $[(tmeda)Ni(C_2H_4)(H_2CO)]$ (C) 919
Fluorides of copper, silver, gold, and palladium (R) 1081
Fluoro compounds, $Ag[MF_6]_2$ (M = Nb, Ta), ternary fluorides of divalent silver (C) 689
$FCu[AuF_4]$, an unusual copper(II) fluoroaurate(III) (C) 688
Inorganic solid fluorides. Chemistry and physics (B) 803
Preparation of $F_4S=CH-COF$ by isomerization of $F_5S-CH=C=O$ (C) 799
Trifluoromethyl isocyanide as a synthetic building block—reaction with trifluoroacetic acid and with hexafluoroacetone (C) 921
Fluorometry, The fluorometric determination of thymine glycol as criterion of the treatment of foodstuffs (biological material) with ionizing radiation (C) 340
Fluoroorganic compounds, Syntheses of fluoroorganic compounds (B) 704
Fluorosulfur compounds, Sulfur pentafluoride cyanate, $F_5S-O-C\equiv N$ (C) 134
Foodstuffs, The fluorometric determination of thymine glycol as criterion of the treatment of foodstuffs (biological material) with ionizing radiation (C) 340
Formaldehyde complexes, Synthesis and structure of the formaldehyde complex $[(tmeda)Ni(C_2H_4)(H_2CO)]$ (C) 919
Fragmentation, Anodic Grob fragmentation of bicycloalkylcarboxylic acids to specifically disubstituted cycloalkenes (C) 1026
Friedel–Crafts alkylation, Optically active α-arylglycine esters by Friedel–Crafts alkylation with the chiral cation of the bislactim ether of *cyclo*-(L-Val-Gly) (C) 683
Frontier orbitals, How chemistry and physics meet in the solid state (R) 846
Fulvalene complexes, Dinuclear fulvalene complexes of tri- and tetravalent zirconium (C) 697
Fulvene complexes, Titanium hydride formation through hydrogen transfer from 2-methylpyridine to a titanium fulvene compound; the first structurally characterized terminal titanium hydride (C) 330

GADOLINIUM COMPOUNDS, Structure and magnetic properties of a gadolinium hexafluoroacetylacetonate adduct with the radical 4,4,5,5-tetramethyl-2-phenyl-4,5-dihydro-1*H*-imidazole 3-oxide 1-oxyl (C) 913
Gallium compounds, Arene complexes with weak interactions: a macrocyclic tris(arene) complex of gallium(I) with η^{18} coordination (C) 338
Gas-inclusion crystals of tetra-*tert*-butyltetrahedrane and its deformation density (C) 356
Gas-phase pyrolysis, 1,2-Diselenete and 1,2-thiaselenete (C) 343
The pyrolysis of azides in the gas phase (R) 504
Gel electrophoresis, The practice of quantitative gel electrophoresis (B) 370
Gene recognition, Transcription in eukaryotes—the role of transcription complexes and their components (R) 218
Genetic engineering with plants (R) 382
Genotoxic studies, A psoralen-substituted dioxetane as DNA intercalator for photogenotoxic studies (C) 796
Germaethenes, Stable germaethenes (C) 798
Germanides, High-pressure LiGe with layers containing two- and four-coordinate germanium atoms (C) 76
Germanium compounds, $[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2]_2GeCl_2$, a germanediyl-donor germanediyl-acceptor complex containing a mixed-valent Ge_5 chain (C) 674
Redox disproportionation of Ge^{II} compounds: synthesis and structure of $[(Me_3Si)C(PMe_2)_2]_2GeCl_2$ and $[\mu\text{-}\{(Me_3Si)C(PMe_2)_2\}]_2Ge_2$ (C) 673
Glycol, Glycolate and thioglycolate complexes of rhenium and their oxidative elimination of ethylene and of glycol (C) 462
Glycopeptides, Synthesis of glycopeptides, partial structures of biological recognition components (R) 294
O-(α-Glyco)peptides, Synthesis of *O*-(α-glyco)peptides by the *N*-iodosuccinimide procedure (C) 888
Glycosphingolipids, Lactosylceramides with unsaturated fatty acids — synthesis and use in the generation of bilayer membranes (C) 793
β-Glycosylation in 2-deoxysaccharides: convergent synthesis of the oligosaccharides of mithramycin (C) 555
Glycosyl isocyanide dichlorides—novel synthetic building blocks in sugar chemistry (C) 359
Gold, The morphology and microstructure of colloidal silver and gold (C) 676
Gold compounds, Cluster of clusters: structure of the 37-atom cluster $[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2\oplus}$ and a novel series of supraclusters based on vertex-sharing icosahedra (C) 897
Coupling of cyclometalated phenylphosphanes in dinuclear gold(II)-complexes (C) 260
Dinuclear complexes of gold(I) containing bridging cyclometalated arylphosphane or arylarsane ligands (C) 258
$FCu[AuF_4]$, an unusual copper(II) fluoroaurate(III) (C) 688
Gold-tin compounds, Reaction of Sn_9^{4-} with single crystal Au: textured fiber epitaxial growth of AuSn at room temperature (C) 1155
Isovalent and mixed-valent ylide complexes of gold: the synthesis of trinuclear compounds having double paddlewheel structure (C) 1146
New $AuPt_2$ A-frame cluster complexes (C) 86
Graphite, Two different intercalate structures in the intercalation compounds of graphite with perfluorobutanesulfonic acid (C) 253
Grignard compounds, Crystal structure of the η^1-allyl-Grignard compound bis(allylmagnesium chloride-TMEDA) (C) 696
Di-Grignard compounds and metallacycles (R) 990
9,10-(1′-Magnesiapropano)-9,10-dihydroanthracene, synthesis, structure, and reactivity (C) 1025
Grob fragmentation, Anodic Grob fragmentation of bicycloalkylcarboxylic acids to specifically disubstituted cycloalkenes (C) 1026
Growth factors, Epidermal growth factor (Nobel lecture) (R) 717
The nerve growth factor: 35 years later (Nobel lecture) (R) 707

HALOPHOSPHORANES, Iodophosphonium salts with unusual properties and a structural alternative for halophosphoranes (C) 912
β-Halothiophenes, Preparation of β-halothiophenes by isomerization of α-halothiophenes on zeolite catalysts (C) 468
3_{10}-Helices, Conformational transitions between enantiomeric 3_{10}-helices (C) 1150
Heptoses, Totally synthetic routes to the higher monosaccharides (R) 15
Heteroallenes, Metathesis of CS_2-like heteroallenes on 1,1-dithio complexes of rhodium(III) (C) 767
Heteroannulenes, The synthesis of 1,3- and 1,4-phenylene-linked bisquinone-substituted porphyrin dimers (C) 678
Heteroarenes, 2,3-Dihydroporphycene—an analogue of chlorin (C) 931
Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of a molybdenum-coordinated 1,3,5-triphosphabenzene (C) 907
Noncovalent bonding interactions between tetraphenylborate anions and paraquat and diquat dications (C) 890
Quino[7,8-*h*]quinoline, a new type of "proton sponge" (C) 460
Synthesis and structure of a cyclopropapyridine (C) 668
2,7,12,17-Tetrapropylporphycene—counterpart of octaethylporphyrin in the porphycene series (C) 928
The first synthesis of a benzoborole (C) 665
Heterocycles, Bis(η^5-cyclopentadienyl)-1,3-diphosphabicyclo[1.1.0]butane-2,4-diylzirconium: a simple synthesis of an unusual molecule (C) 764
1,4-Diphospha-1,3-butadienes (C) 779
Dipyrrolo[1,2-*a*:2′,1′-*c*]quinoxalines: A novel heterocyclic system (C) 1280
Nitrogen heterocycles from carbene complexes and alkenyl isocyanides (C) 563
Phosphasilirenes, three-membered rings containing PC double bonds (C) 776
Synthesis and structure of a 2,5-dihydro-

1*H*-1,2,5-phosphadiborole derivative (C) 781
Hetero-Dewar-benzenes, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
Hetero-Diels-Alder reaction, Stereocontrolled formation of annelated cyclopentanes by intramolecular hetero-Diels-Alder reaction. Synthesis of deoxyloganin from citronellal (C) 1295
Heterometallic clusters, Heterometallic polyhydride raft formation: a comparison of syntheses using alkoxides of copper and gold (C) 135
Mixed-metal cluster formation by carbonylmetalate-induced Pt-P bond cleavage in $[PtCl_2(Ph_2PCH_2PPh_2)]$ (C) 88
Synthesis and structure of $[(PPh_3)_2N][Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$: a butterfly oxo cluster (C) 255
Heteropolycycles, Reaction of phosphinines with diazoalkanes: diphosphachiropteradienes by intramolecular, ionic 5s+5s [6+4] cycloaddition (C) 236
Heteroprismanes, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
Hexacarbonylzirconate(2−), $[Zr(CO)_6]^{2-}$: the first binary carbonyl complex of zirconium (C) 1190
Hexafluoroacetone, Trifluoromethyl isocyanide as a synthetic building block—reaction with trifluoroacetic acid and with hexafluoroacetone (C) 921
1,2,3,5,8,8a-Hexahydronaphthalene from 1,2-cyclohexadiene (C) 449
Hexatriyne, 2,3,9,10-tetrakis(trimethylsilyl)-[5]phenylene. Synthesis via regiospecific cobalt-catalyzed cocyclization of 1,6-bis-(triisopropylsilyl)-1,3,5-hexatriyne (C) 1246
High-performance liquid chromatography in biochemistry (B) 705
Practice of high-performance liquid chromatography (B) 705
High pressure chemistry, Electrodes for potential measurements in aqueous systems at high temperatures and pressures (R) 161
High-pressure synthesis and crystal structure of neodymium(III) oxide peroxide, $Nd_2O_2(O_2)$ (C) 1174
Inorganic high pressure chemistry. Kinetics and mechanisms (B) 1053
High temperature chemistry, Electrodes for potential measurements in aqueous systems at high temperatures and pressures (R) 161
History of chemistry, Difficulties in the emergence of the polymer concept—an essay (R) 93
Geschichte der Elektrochemie (B) 160
Ostwalds Klassiker der exakten Wissenschaften 265. Jacobus Henricus van't Hoff: Studien zur chemischen Dynamik (études de dynamique chimique) 1884 (B) 936
Polymers. The origins and growth of a science (B) 270
The development of the electron microscope and of electron microscopy (Nobel lecture) (R) 595
Schrödinger. Centenary celebration of a polymath (B) 1052
Homoaldol reaction, Enantioselective synthesis of methylfuranosides of unnatural 3,6-dideoxy-3-methylaldohexoses from lactates by homoaldol reactions (C) 1034
Homoaromaticity, Four-center two-electron bonding in a tetrahedral topology. Experimental realization of three-dimensional homoaromaticity in the 1,3-dehydro-5,7-adamantanediyl dication (C) 761
Homofuran, 1,5-Electrocyclization in homofuran, homopyrrole, and homothiophene (C) 1294
Homogeneous catalysis with compounds of rhodium and iridium (B) 271
Homopyrrole, 1,5-Electrocyclization in homofuran, homopyrrole, and homothiophene (C) 1294
Homothiophene, 1,5-Electrocyclization in homofuran, homopyrrole, and homothiophene (C) 1294
Hopping conduction in solids (B) 92
Houben-Weyl, Methoden der Organischen Chemie. Vol. E 18/Parts 1 and 2; Vol. XIII/9a and XIII/9b (B) 1196
Hydride abstraction from $[C_6H_6Os(CO)(CH_3)_2]$: does a metal-bound methyl group migrate preferentially to a CO or to a CH_2 ligand? (C) 686
Hydrido complexes, Heterometallic polyhydride raft formation: a comparison of syntheses using alkoxides of copper and gold (C) 135
Hydrocarbon combustion, Chemistry of hydrocarbon combustion (B) 269
Hydrodesulfurization, C-S Bond cleavage in a π-thiophene ruthenium complex (C) 909
Hydrogenation, A novel heterobimetallic asymmetric hydrogenation catalyst based upon a chiral rhenium template containing two phosphido substituents (C) 910
Directed homogeneous hydrogenation (R) 190
Hydrogenation methods (B) 593
Hydrogen bonds, Observation of an eclipsed $C_{sp^3}\text{-}CH_3$ bond in a tricyclic orthoamide; experimental and theoretical evidence for C-H···O hydrogen bonds (C) 1175
Hydrogen production, Organometallic rhodium(III) complexes as catalysts for the photoreduction of protons to hydrogen on colloidal TiO_2 (C) 567
Hydrogen telluride, Oxidative addition of hydrogen telluride to organometallic fragments (C) 132
2-Hydroxycarboxylic acids, A biocatalyst for the preparation of (*R*)- and (*S*)-2-hydroxycarboxylic acids (C) 128
Hyperstable olefins, Bissecododecahedraenes, unusual hyperstable olefins (C) 455

ICOSAPEPTIDES, Structure elucidation of a new icosapeptide from human semen (C) 774
Iminophosphanes, Imino-, phosphoranylidene-, and sulfuranylidenephosphanes by 1,3-silyl migration (C) 83
Inadequate, Direct identification of the carbon skeleton of organic compounds using double quantum coherence ^{13}C-NMR spectroscopy. The INADEQUATE pulse sequence (R) 625
s-Indacenes, 2,6-Diaza-*s*-indacenes (C) 1037
The influence of substituents on double-bond localization e.g. in *s*-indacene (C) 360
Inorganic chemistry, Inorganic reactions and methods. Vol. 1: The formation of bonds to hydrogen (part 1), Vol. 15: Electron-transfer and electrochemical reactions (B) 1195
Mechanisms of inorganic reactions (B) 1301
Interactions, Homoatomic d^{10}–d^{10} interactions: their effects on structure and chemical and physical properties (R) 1098
Molecular recognition: stacking interactions influence Watson-Crick vs. Hoogsteen base-pairing in a model for adenine receptors (C) 1244
Relay conjugation via twisted six- and seven-membered rings (C) 1252
Intercalation compounds, Two different intercalate structures in the intercalation compounds of graphite with perfluorobutanesulfonic acid (C) 253
Interfaces, Chemistry and structure at interfaces: new laser and optical techniques (B) 1198
Inversion of the configuration of secondary alcohols via isourea ethers prepared in situ (C) 773
Iodocuprates, $[\{Co(Cp)_2\}\{CuI_2\}]_n$ (n = 3, 4), cobaltocenium iodocuprates(I) with unusual anion structures (C) 927
Iodophosphonium salts with unusual properties and a structural alternative for halophosphoranes (C) 912
Iodoselenides, Synthesis and structure of a stable iodoselenide (C) 780
N-Iodosuccinimide, Synthesis of *O*-(α-glyco)peptides by the *N*-iodosuccinimide procedure (C) 888
Ion pairs, The spin distribution in ion pairs of 1-aminoanthraquinone radical anion and alkali-metal cations (C) 791
Ion solvation (B) 486
IR emission analysis of temperature profiles in Pt/SiO_2 catalysts during exothermic reactions (C) 1042
Iridium compounds, Formation of diiridium(II) complexes by photoassisted oxidative-addition reactions: structure of a stable binuclear iodo(iodomethyl)iridium(II) complex (C) 444
Iron catalysts, CC-linkages of ethene with CO_2 on an iron(0) complex—synthesis and crystal structure analysis of $[(PEt_3)_2Fe(C_2H_4)_2]$ (C) 153
Iron compounds, Dynamic processes on the IR time scale: coalescence of CO stretching vibrational bands in $[(\eta^4\text{-diene})Fe(CO)_3]$ complexes (C) 885
Synthesis and structure of $[(OC)_4Fe{=}Si(OtBu)_2{\cdot}HMPT]$, a donor-stabilized silanediyl ("silylene") complex (C) 669
IR Spectroscopy, Dynamic processes on the IR time scale: coalescence of CO stretching vibrational bands in $[(\eta^4\text{-diene})Fe(CO)_3]$ complexes (C) 885
IR-Spectroscopic determination of the enzyme content of carrier-fixed enzymes (C) 483
Isocyanide dichlorides, Glycosyl isocyanide dichlorides—novel synthetic building blocks in sugar chemistry (C) 359
Isocyanides, Nitrogen heterocycles from carbene complexes and alkenyl isocyanides (C) 563
Trifluoromethyl isocyanide as a synthetic building block—reaction with trifluoroacetic acid and with hexafluoroacetone (C) 921
Isoindoles, Annelated isoindoles with 18π electrons (C) 1262
Isomerization, Isomerization reactions in the system Dewar-phosphinine/phosphaprismane/phosphabenzvalene/phosphinine (C) 85
Photoisomerization of stilbazolium chromophores with potential nonlinear optical applications (C) 341
Preparation of β-halothiophenes by isomerization of α-halothiophenes on zeolite catalysts (C) 468

KINETICS, Control of the relative electrophilicity of alkylating agents by variation of the Lewis acid concentration (C) 1029
1D and 2D NMR investigations of the jump mechanism of Co^{II} ions in [12]crown-4 stacks (C) 228
Kinetic ^{15}N-CPMAS-NMR study of a double proton transfer in a crystalline malonaldehyde diimine derivative (C) 247

LANTHANOID COMPOUNDS, Luminescence probes: the $Eu^{3\oplus}$- and $Tb^{3\oplus}$-cryptates of polypyridine macrobicyclic ligands (C) 1266
Laser chemistry—What is its current status? (R) 38

Lead structures, New lead structures by Diels-Alder reactions of streptazolin with naphthoquinones (C) 664
Ligands, Alkyne complexes of rhenium in medium oxidation states: synthesis and molecular structure of a rhenium(V)–allenylidene complex (C) 1263
Crown thioether complexes of Ag^{I} and Cu^{I}: the crystal structures of $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$ and [LCuI] (L = 1,4,7-trithiacyclononane) (C) 575
Mo^{II} and Mo^{0} complexes of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane (C) 1171
Lipoxins, Stereocontrolled total synthesis of lipoxins A_5 and B_5 (C) 1019
Liquid crystals, Liquid crystalline polymers (R) 816
Photo- and thermochromic liquid crystal polysiloxanes (C) 1178
The "Wheel of Mainz" as a liquid crystal?—Structural variation and mesophase properties of trimeric discotic compounds (C) 1249
Lithium compounds, *cis*- and *trans*-1,2-Dilithioethylene (C) 1032
Lithium germanide, High-pressure LiGe with layers containing two- and four-coordinate germanium atoms (C) 76
Tetrameric and dodecameric *tert*-butylethynyllithium: a novel aggregation principle in organolithium compounds (C) 587
X-ray structure analysis of the Li_2-compound of bis(trimethylsilyl)methyl phenyl sulfone; structural units of an α-sulfonyl- and a complex-stabilized *ortho*-sulfonyl carbanion (C) 1287
Lithium-tellurium exchange: a new entry to organolithium compounds (C) 1187
Loganin, Stereocontrolled formation of annelated cyclopentanes by intramolecular hetero-Diels-Alder reaction. Synthesis of deoxyloganin from citronellal (C) 1295
Low-temperature photolysis of peracetylated dodecanoyl peroxides of tartaric acid and D-gluconic acid in the solid state—a diastereoselective radical coupling (C) 1253
LSI mass spectrometry, Structure elucidation of a new icosapeptide from human semen (C) 774
Luminescence, Energy transfer luminescence of europium(III) and terbium(III) cryptates of macrobicyclic polypyridine ligands (C) 266
Luminescence probes: the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ cryptates of polypyridine macrobicyclic ligands (C) 1266
Lysine, Precipitates with β-pleated sheet structure by mixing aqueous solutions of helical poly(D-lysine) and poly(L-lysine) (C) 699

MACROBICYCLES, Luminescence probes: the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ cryptates of polypyridine macrobicyclic ligands (C) 1266
Macrobicyclic polyethers as second sphere ligands for tetraammineplatinum(II) (C) 693
Macrocycles, A new class of organozirconium(IV) compounds: alkyl derivatives of tetramethyltetraazadibenzo[14]annulenatozirconium(IV) (C) 70
Arene complexes with weak interactions: a macrocyclic tris(arene) complex of gallium(I) with η^{18} coordination (C) 338
Mo^{II} and Mo^{0} complexes of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane (C) 1171
Molecular structure of a [3]-catenate: curling up of the interlocked system by interaction between the two copper complex subunits (C) 661
Novel bimetallic macrocyclic polymer structures incorporating deprotonated 2-pyrrolidone bridges: the crystal structures of $[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ (X = NO_3 or ClO_4) (C) 1044
Simultaneous primary and secondary coordination of a neutral guest within a macrocyclic complex of rhodium(III) (C) 1162
Stabilization of the $[AlMe_2]^{\oplus}$ cation by crown ethers (C) 485
s-Tetrazine as ligand for monomeric and bridged macrocyclic metal complexes (C) 344
The synthesis of 1,3- and 1,4-phenylene-linked bisquinone-substituted porphyrin dimers (C) 678
Macrocyclic dienes by metathetic dimerization of cycloheptene and cyclooctene on Re_2O_7/Al_2O_3 (C) 702
Macrolides, Total synthesis of the enantiomerically pure lichen macrolide (+)-aspicilin (C) 362
Macropolycycles, Second sphere coordination of tetraammineplatinum(II) by a macropolycyclic crown ether bisamide receptor (C) 692
Selective molecular recognition and separation of isomeric and partially hydrogenated arenes (C) 901
Magnesium compounds, Chemistry of pyrrocorphins: biomimetic regioselectivity of *C*-methylation at the ligand periphery of magnesium(II) uropyrrocorphinate(type I)-octanitriles (C) 261
Crystal structure of the η^{1}-allyl-Grignard compound bis(allylmagnesium chloride-TMEDA) (C) 696
9,10-(1'-Magnesiapropano)-9,10-dihydroanthracene, synthesis, structure, and reactivity (C) 1025
Magnesium phosphides—Synthesis and structure of $[Mg(PHPh)_2(tmeda)]$ (C) 81
Main-group elements, Chemie der Hauptgruppenelemente - Stand und Erwartung (B) 802
Main-group metals, $[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2]_2GeCl_2$, a germanediyl-donor germanediyl-acceptor complex containing a mixed-valent Ge_5 chain (C) 674
Redox disproportionation of Ge^{II} compounds: synthesis and structure of $[(Me_3Si)C(PMe_2)_2]_2GeCl_2$ and $[\mu\text{-}\{(Me_3Si)C(PMe_2)_2\}]_2Ge_2$ (C) 673
Mainz Wheel, The "Wheel of Mainz" as a liquid crystal?—Structural variation and mesophase properties of trimeric discotic compounds (C) 1249
Manganese compounds, Dimanganese heptoxide for the selective oxidation of organic substrates (C) 1007
Salicylate-mediated assembly of the discrete mixed-valence nonanuclear manganese complex $[Mn_9O_4(O_2CPh)_8(sal)_4(salH)_2(py)_4]$ ($salH_2$ = salicylic acid, py = pyridine) 915
(2,2,8,8-Tetramethyl-5-oxa-4,6-diphospha-3,6-nonadiene)tetrakis[dicarbonyl(methylcyclopentadienyl)manganese], the first complexed bis(phosphavinyl)ether (C) 900
Tetranuclear mixed-valence manganese complexes with reduced TCNE or TCNQ as η^{4}-bridging ligands (C) 251
The crystal structure of Mn_2O_7 (C) 139
Manicone, The absolute configuration of the ant alarm pheromone manicone (C) 784
Mass spectrometry, Gaseous ion chemistry and mass spectrometry (B) 1055
Structure elucidation of a new icosapeptide from human semen (C) 774
The generation and characterization of molecules by neutralization-reionization mass spectrometry (NRMS) (R) 805
Materials science, Control of the electronic structure of organic conductors as exemplified by [NMP][TCNQ] charge-transfer complexes (R) 287
Nuclear quadrupole interaction and time-resolved perturbed γ-γ-angular correlation spectroscopy: applications in chemistry, materials science, and biophysical chemistry (R) 110
The development of bioglass ceramics for medical applications (R) 527
The importance of chemistry in the development of high-performance ceramics (R) 371
Medical applications, The development of bioglass ceramics for medical applications (R) 527
Medicinal chemistry research in India (B) 159
Membranes, Lactosylceramides with unsaturated fatty acids — synthesis and use in the generation of bilayer membranes (C) 793
Mercury compounds, Square Hg_4 clusters in the compound CsHg (C) 687
Mero-stabilization, The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770
Metabolite formation, Regulation of secondary metabolite formation. Proceedings of the sixteenth workshop conference, Hoechst, Gracht castle, May 12–16, 1985 (B) 367
Metallacycles, A 1-oxa-2-nickela-5-cyclopentanone from ethene and carbon dioxide: preparation, structure, and reactivity (C) 771
Di-Grignard compounds and metallacycles (R) 990
First four-membered metallacycles of Rhenium (C) 73
Reactions of (η^{3}-allyl)(η^{5}-cyclopentadienyl)palladium with cyclopropabenzenes (C) 67
Synthesis of the four-membered metallacycle $[Cp_2Ti(AsPh)_3]$ via the in situ reduction of $[Cp_2TiCl_2]$ (C) 244
Unsaturated molecules containing main group metals (R) 1
Metalloproteins, Pt. 1: Metal proteins with redox roles, Pt. 2: Metal proteins with non-redox roles (B) 91
Metathesis, Macrocyclic dienes by metathetic dimerization of cycloheptene and cyclooctene on Re_2O_7/Al_2O_3 (C) 702
of CS_2-like heteroallenes on 1,1-dithio complexes of rhodium(III) (C) 767
(*E*)-3-Methylene-4-alken-2-ones, Stereoselective synthesis of (*E*)-3-methylene-4-alken-2-ones from aldehydes and methyl vinyl ketone and their spontaneous dimerization (C) 1015
2-Methylenebicyclo[2.1.0]pentane, Reactions of 2,2,4,4-Tetramethyl-3-methylenecyclobutylidene; thermal rearrangements of a 2-methylenebicyclo[2.1.0]pentane (C) 1260
N-Methylene-ynamines, First synthesis of *N*-methylene-ynamines (2-azabut-1-en-3-ynes) (C) 923
Micelles, First ENDOR investigations of biologically relevant organic radicals in reversed micelles (C) 345
Microparticles, Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309
Mithramycin, β-Glycosylation in 2-deoxysaccharides: convergent synthesis of the oligosaccharides of mithramycin (C) 555
Mixed-metal clusters, A mixed-metal cluster with two quadruply-bridging carbonyl ligands (C) 685
Mixed-metal cluster formation by carbonylmetalate-induced Pt-P bond cleavage in $[PtCl_2(Ph_2PCH_2PPh_2]$ (C) 88
Mixed-valence compounds, Electron delocalization in diruthenium complexes of polycyclic arenes (C) 700
Isovalent and mixed-valent ylide complexes of gold: the synthesis of trinuclear compounds having double paddlewheel structure (C) 1146
$[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2]_2GeCl_2$, a germanediyl-donor germanediyl-acceptor complex containing a mixed-valent Ge_5 chain (C) 674

1,8-Naphthalene-linked cofacial dimeric phthalocyanines (C) 1021
Salicylate-mediated assembly of the discrete mixed-valence nonanuclear manganese complex $[Mn_9O_4(O_2CPh)_8(sal)_4(salH)_2(py)_4]$ ($salH_2$ = salicylic acid, py = pyridine) 915
Spherical mixed-valence $[V_{15}O_{36}]^{5\ominus}$, an example from an unusual cluster family (C) 1045
The recoil-free fraction of the γ resonance in ^{197}Au Mössbauer spectroscopy; findings from measurements of polynuclear, mixed-valent ylide complexes (C) 1148
MNDOC calculations of the potential surfaces for photochemical α-cleavage (C) 238
Molecular beam studies of elementary chemical processes (Nobel lecture) (R) 939
Molecular design, Computer-assisted molecular design (CAMD)—an overview (R) 403
Molecular dynamics, Novel rhenium(V) carbonato and sulfato chelate complexes: synthesis and investigation of molecular dynamics by ^{17}O-NMR spectroscopy (C) 464
Molecular dynamics of elementary chemical reactions (Nobel Lecture) (R) 1221
Molecular metals, Polystannanes $Ph_3Sn-(tBu_2Sn)_n-SnPh_3$ (n = 1–4): a route to molecular metals? (C) 1255
Molecular recognition, Selective molecular recognition and separation of isomeric and partially hydrogenated arenes (C) 901
Stacking interactions influence Watson-Crick vs. Hoogsteen base-pairing in a model for adenine receptors (C) 1244
Molecular structure and energetics. Vol. 1: Chemical bonding models; Vol. 3: Studies of organic molecules (B) 1199
Molybdenum compounds, A mixed-metal cluster with two quadruply-bridging carbonyl ligands (C) 685
$Cs_3Mo_5P_6O_{25}$: a novel molybdenum phosphate containing a cubane-like Mo_4O_4 cluster with six molybdenum–molybdenum bonds (C) 549
Mo^{II} and Mo^0 complexes of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane (C) 1171
Preparation and structure of $[Mo_4(OMe)_2(OiPr)_{10}]$: comments on why $[W_2(OiPr)_6]$ dimerizes, whereas $[Mo_2(OiPr)_6]$ does not (C) 904
Synthesis and structure of $[(C_5Me_5)_2Mo_2S_4 \cdot SO_3]$: concerning the oxidation of sulfur ligands in transition-metal complexes (C) 230
Monosaccharides, Totally synthetic routes to the higher monosaccharides (R) 15
Morphology, The morphology and microstructure of colloidal silver and gold (C) 676
The role of Debye screening length in ordered arrays of cylindrical nickel dimethylglyoxime particles (C) 765
Mössbauer spectroscopy, The recoil-free fraction of the γ resonance in ^{197}Au Mössbauer spectroscopy; findings from measurements of polynuclear, mixed-valent ylide complexes (C) 1148
Multicenter bonding, Four-center two-electron bonding in a tetrahedral topology. Experimental realization of three-dimensional homoaromaticity in the 1,3-dehydro-5,7-adamantanediyl dication (C) 761
Multienzyme systems, Organized multienzyme systems: catalytic properties (B) 488
Multitriphenylmethylium ions, Deep-colored, through-conjugated multitriphenylmethylium ions (C) 794
Mutagens, Natural fecapentaene-14 and one fecapentaene-12 component are all-*trans* stereoisomers (C) 1186
Mycoloylpeptides and other lipopeptide adjuvants from higher aldoketene dimers (C) 336
Mycoses, Allylamine derivatives—a new class of active substances in antifungal chemotherapy (R) 320

NAFTIFINE, Allylamine derivatives—a new class of active substances in antifungal chemotherapy (R) 320
Natural products, Amavadin, an example for selective binding of vanadium in nature: studies of its complexation chemistry and a new structural proposal (C) 545
Metalloproteins. Pt. 1: Metal proteins with redox roles. Pt. 2: Metal proteins with non-redox roles (B) 91
Mycoloylpeptides and other lipopeptide adjuvants from higher aldoketene dimers (C) 336
Natural fecapentaene-14 and one fecapentaene-12 component are all-*trans* stereoisomers (C) 1186
Proof of the (*S,S*) configuration of (−)-bissetone by synthesis from D-glucose (C) 1271
Stereocontrolled formation of annelated cyclopentanes by intramolecular hetero-Diels–Alder reaction. Synthesis of deoxyloganin from citronellal (C) 1295
Stereoselective syntheses of building blocks with three consecutive stereogenic centers: important precursors of polyketide natural products (R) 489
Synthesis of 2-deoxy sugars (C) 233
Synthesis of valienamine (C) 482
The chemistry of the plasmodial pigments of the slime mold *Fuligo septica* (myxomycetes) (C) 586
Totally synthetic routes to the higher monosaccharides (R) 15
Total synthesis of the pseudoguaianolide (+)-confertin (C) 61
^{15}N-CPMAS-NMR spectroscopy study of the problem of NH tautomerism in crystalline porphine and porphycene (C) 934
Neighboring group effects, Regio- and stereoselective carbosulfenylation of olefins (C) 1028
Neodymium(III) oxide peroxide, High-pressure synthesis and crystal structure of neodymium(III) oxide peroxide, $Nd_2O_2(O_2)$ (C) 1174
Nerve growth factor, The nerve growth factor: 35 years later (Nobel lecture) (R) 707
Neutralization-reionization mass spectrometry, The generation and characterization of molecules by neutralization-reionization mass spectrometry (NRMS) (R) 805
Nickelacyclopentadiene, Coupling of two ethyne molecules at a nickel center to form a nickelacyclopentadiene complex (C) 1288
Nickelatricyclo[4.1.1.$0^{1,6}$]octadienes, Nickel complexes with a propellane structure (C) 65
Nickel compounds, A 1-oxa-2-nickela-5-cyclopentanone from ethene and carbon dioxide: preparation, structure, and reactivity (C) 771
Novel Ni-clusters with Se and PR_3 (R = Ph, Et) as ligands (C) 148
Synthesis and structure of compounds containing ditellurium *side-on* bonded to nickel complex fragments (C) 916
Synthesis and structure of the formaldehyde complex $[(tmeda)Ni(C_2H_4)(H_2CO)]$ (C) 919
Nickel dimethylglyoxime, The role of Debye screening length in ordered arrays of cylindrical nickel dimethylglyoxime particles (C) 765
Niobium compounds, $Ag[MF_6]_2$ (M = Nb, Ta), ternary fluorides of divalent silver (C) 689
Nitration, Aromatic nitration at the encounter rate in the gas phase (C) 1177
Nitrenes, The pyrolysis of azides in the gas phase (R) 504
Unusually stable *cis,cis*-trialkyltriaziridines by azo/nitrene addition (C) 566
Nitrile oxides, Isolation and photoisomerization of simply substituted nitrile oxides (C) 155
Nitriles, Synthesis of nitriles via the ylide anion of sodium cyanotriphenylphosphoranylidenemethanide (C) 79
Nitrobenzyllithium·ethanol, Crystal structure of $[\alpha$-nitrobenzyllithium·ethanol$]_n$; a lithium nitronate–ethanol interaction (C) 78
Nitrogen bases, Peralkylated polyaminophosphazenes—extremely strong, neutral nitrogen bases (C) 1167
Nitrogen compounds, [4 + 2] Cycloadditions of 2,3-diazido-1,3-butadienes: a novel entry to vicinal vinyl diazides and 1,4-dicyano compounds (C) 879
Nitrogen heterocycles from carbene complexes and alkenyl isocyanides (C) 563
Nitrogen homocycles, Unusually stable *cis,cis*-trialkyltriaziridines by azo/nitrene addition (C) 566
Nitronate–ethanol interaction, Crystal structure of $[\alpha$-nitrobenzyllithium·ethanol$]_n$; a lithium nitronate–ethanol interaction (C) 78
Nitroxyl radicals, Structure and magnetic properties of a gadolinium hexafluoroacetylacetonate adduct with the radical 4,4,5,5-tetramethyl-2-phenyl-4,5-dihydro-1*H*-imidazole 3-oxide 1-oxyl (C) 913
NMR of solids, Transient techniques in NMR of solids. An introduction to theory and practice (B) 1053
NMR Spectroscopy, 1D and 2D NMR investigations of the jump mechanism of Co^{II} ions in [12]crown-4 stacks (C) 228
Direct identification of the carbon skeleton of organic compounds using double quantum coherence ^{13}C-NMR spectroscopy. The INADEQUATE pulse sequence (R) 625
^{2}H,^{2}H-COSY and ^{2}H,^{2}H,^{13}C-RELAY NMR experiments for the analysis of deuteriated compounds (C) 156
High resolution NMR spectroscopy of synthetic polymers in bulk (B) 1301
Kinetic ^{15}N-CPMAS-NMR study of a double proton transfer in a crystalline malonaldehyde diimine derivative (C) 247
Modern NMR spectroscopy of organolithium compounds (R) 1212
Modern NMR techniques for chemistry research (B) 1192
Modern techniques in high resolution FT NMR (B) 1192
^{15}N-CPMAS-NMR study of the problem of NH tautomerism in crystalline porphine and porphycene (C) 934
Nuclear magnetic resonance. Basic principles (B) 1192
Principles of nuclear magnetic resonance in one and two dimensions (B) 1192
Nobel lecture, Epidermal growth factor (Nobel lecture) (R) 717
Molecular beam studies of elementary chemical processes (Nobel lecture) (R) 939
Molecular dynamics of elementary chemical reactions (Nobel lecture) (R) 1221
Scanning tunneling microscopy – from birth to adolescence (Nobel lecture) (R) 606
Some concepts in reaction dynamics (Nobel lecture) (R) 952 (1302)
The development of the electron microscope and of electron microscopy (Nobel lecture) (R) 595
The nerve growth factor: 35 years later (Nobel lecture) (R) 707
Nonacyclo[10.8.0.0^{2,11}.0^{4,9}.0^{4,19}.0^{6,17}.0^{7,16}-0^{9,14}.0^{14,19}]icosane, a double tetraasterane (C) 1006
Nonbenzenoid aromatic compounds, Synthesis and properties of 1-cycloheptatrien-

ylidene-2-cyclopentadienylideneethylene derivatives (C) 335
Nonclassical carbocations, Crystal structure analysis of the 1,2,4,7-*anti*-tetramethyl-2-norbornyl cation: an unsymmetrically bridged carbocation (C) 560
Nonlinear optical properties, Photoisomerization of stilbazolium chromophores with potential nonlinear optical applications (C) 341
Norbornyl cation, Crystal structure analysis of the 1,2,4,7-*anti*-tetramethyl-2-norbornyl cation: an unsymmetrically bridged carbocation (C) 560
Norcaradiene, Synthesis of tricyclo[5.2.0.0^{1,3}]nona-4,6,8-triene, a norcaradiene structure constrained by the antiaromaticity of cyclobutadiene (C) 559
Norcaradiene/tropylidene equilibrium, Valence isomerization between 1-phosphanorcaradienes and 1-phospha-2*H*-tropylidenes (2*H*-phosphepines) (C) 1134
Nortricyclene-diazonium ions, Diazo coupling of nortricyclene(tricyclo[2.2.1.0^{2,6}]-heptane)-1-diazonium ions (C) 570
NRMS, The generation and characterization of molecules by neutralization-reionization mass spectrometry (NRMS) (R) 805
Nuclear quadrupole interaction and time-resolved perturbed γ-γ-angular correlation spectroscopy: applications in chemistry, materials science, and biophysical chemistry (R) 110
Nucleic acids, The organic chemistry of nucleic acids (B) 1198
Nucleophilic addition, Isoelectronic relationships in cluster chemistry: nucleophilic addition to a vinylidene ligand (C) 572

OLEFIN METATHESIS and ring-opening polymerization of cyclo-olefins (B) 270
Concerning the role of organotin compounds in olefin metathesis: synthesis, structure, and lewis acidity of [(η^5-C_5Me_5)CH_3ReCl_3] (C) 466
Oligosaccharides, β-Glycosylation in 2-deoxysaccharides: convergent synthesis of the oligosaccharides of mithramycin (C) 555
Opto-electronics, Liquid crystalline polymers (R) 816
Organic chemistry, Houben-Weyl, Methoden der Organischen Chemie. Vol. *E 18*/Parts 1 and 2; Vol. XIII/9a and Vol. XIII/9b (B) 1196
Organische Chemie (B) 271
Organic conductors, Control of the electronic structure of organic conductors as exemplified by [NMP][TCNQ] charge-transfer complexes (R) 287
Organo-alkali metal compounds, Ether cleavage with organo-alkali metal compounds and alkali metals (R) 972
Organo-hafnium compounds, Chemistry of organo-zirconium and -hafnium compounds (B) 592
Organolithium compounds, Lithium-tellurium exchange: a new entry to organolithium compounds (C) 1187
Modern NMR spectroscopy of organolithium compounds (R) 1212
Organometallic chemistry, An introduction to organometallic chemistry (B) 704
Organometallic compounds, Organometallic intramolecular-coordination compounds (B) 802
Organometallic oligomers, A triple decker sandwich structure by reaction of cyclopentadienylbis(ethylene)cobalt with carbodiimides: an unusual cyclopentadienylcobalt oligomer (C) 68
Organotitanium reagents in organic synthesis (B) 592
Organo-zirconium compounds, Chemistry of organo-zirconium and -hafnium compounds (B) 592
Osmium compounds, A novel route to azaalkenylidene-metal complexes (C) 248
Overlayer catalysts, Catalytic dehydrogenation of cyclohexene on silica overlayer films (C) 1182
1-Oxa-3,4-cyclohexadiene, Generation and interception of 1-oxa-3,4-cyclohexadiene (C) 690
Oxaphosphole, [1 + 4] Cycloaddition of a diphosphene to acrolein: synthesis and structure of a dihydro-1,2λ^5-oxaphosphole with an exocyclic P=P bond (C) 1010
Oxazinanones, Formation of oxazolidinones and oxazinanones by reaction of allylamines and of homoallylamines with carbon dioxide and iodine via intramolecular cyclization (C) 334
Oxazolidinones, Formation of oxazolidinones and oxazinanones by reaction of allylamines and of homoallylamines with carbon dioxide and iodine via intramolecular cyclization (C) 334
Oxidation, Dimanganese heptoxide for the selective oxidation of organic substrates (C) 1007
Methods for the oxidation of organic compounds. Alkanes, alkenes, alkynes, and arenes (B) 593
One- and two-electron oxidations of pagodanes and bissecododecahedradienes; unusually persistent radical cations (C) 457
Synthesis and structure of [$(C_5Me_5)_2$-$Mo_2S_4 \cdot SO_3$]: concerning the oxidation of sulfur ligands in transition-metal complexes (C) 230
Oxidative elimination, Glycolate and thioglycolate complexes of rhenium and their oxidative elimination of ethylene and of glycol (C) 462
Oxirene, CO_2 elimination from vinylene carbonate radical anions and charge reversal in $C_2H_2O^{\ominus\ominus}$: reactions involving the radical anion and cation of oxirene? (C) 140
Oxygen vacancies, Imaging oxygen vacancies in superconducting $YBa_2Cu_3O_{7-\delta}$ by high resolution electron microscopy (C) 1048

PAGODANES, Dodecahedranes from [1.1.1.1]pagodanes (C) 452
One- and two-electron oxidations of pagodanes and bissecododecahedradienes: unusually persistent radical cations (C) 457
The pagodane route to dodecahedranes—thermal, reductive, and oxidative transformations of pagodanes (C) 451
Palladium compounds, Reactions of [Pd_2(μ-dppm)$_2Cl_2$] with electrophilic complexes of copper and gold. Synthesis of the Pd_4 cluster [Pd_4(μ-Cl)$_2$(μ-dppm)$_4$]$(PF_6)_2 \cdot 2(CH_3)_2CO$ (C) 768
Palladium reagents in organic synthesis (B) 593
Paracyclophanedienes, A facile, general entry to bridge-annelated [2.2]paracyclophanedienes (C) 1277
Paracyclophanes, Mono- and diarenium ions from [2.2]paracyclophanes (C) 564
Paraquat, Noncovalent bonding interactions between tetraphenylborate anions and paraquat and diquat dications (C) 890
Pentacyclo[11.3.0.0^{1,5}.0^{5,9}.0^{9,13}]hexadecane, ([4.5]coronane) (C) 1023
Pentaphenylbismuth, Structure and color of pentaphenylbismuth (C) 1180
Pentaphosphaferrocenes, [(η^5-P_5)Fe(η^5-C_5Me_5)], a pentaphosphaferrocene derivative (C) 59
Pentasila[1.1.1]propellane. Predictions concerning structure, bonding, and strain energy (C) 1267
Peptides, Conformational transitions between enantiomeric 3_{10}-helices (C) 1150
Sequential configuration analysis of peptides (C) 331
Structure elucidation of a new icosapeptide from human semen (C) 774
Synthesis of *O*-(α-glyco)peptides by the *N*-iodosuccinimide procedure (C) 888
Pericyclic reactions, Electrocyclic opening of 2,3-benzo- and 2,3;7,8-dibenzobicyclo-[4.2.0]octa-2,4,7-triene; benzoannelated transition states (C) 1268
Periodic minimal surface, Adsorption and curvature in highly dealuminated zeolites (C) 1017
Periodic potential surfaces, How nature adapts chemical structures to curved surfaces (R) 1059
Persistency, One- and two-electron oxidations of pagodanes and bissecododecahedradienes: unusually persistent radical cations (C) 457
Phanes, A facile, general entry to bridge-annelated [2.2]paracyclophanedienes (C) 1277
[2.2](1,4)Benzo[*g*]chrysenoparacyclophane dianion: a novel, paratropic, double-layered carbanion (C) 232
Mono- and diarenium ions from [2.2]paracyclophanes (C) 564
Synthesis and chirality of sixfold-bridged triple-decker phanes (C) 777
Phase-transfer catalysis, Apparently nonstereospecific dihalocarbene addition—an explanation (C) 329
Phase transformation, Cooperative effects in the phase transformation of triethylcyclotriboroxane (C) 245
Pheromones, The absolute configuration of the ant alarm pheromone manicone (C) 784
Phosgene, Triphosgene, a crystalline phosgene substitute (C) 894
Phosphaalkyne complexes, First examples of complexes containing η^1-bonded phosphaalkynes - synthesis and crystal and molecular structure of *trans*-[Mo(AdC$\equiv$P)$_2$($Et_2PCH_2CH_2PEt_2$)$_2$] (Ad=adamantyl) (C) 474
Phosphaalkynes, Mono- and Diphosphatricyclo[3.2.1.0^{2,7}]oct-3-enes: synthesis from 1,3- and 1,4-dienes and a stable phosphaalkyne (C) 1011
(2,2,8,8-Tetramethyl-5-oxa-4,6-diphospha-3,6-nonadiene)tetrakis[dicarbonyl(methylcyclopentadienyl)manganese], the first complexed bis(phosphavinyl)ether (C) 900
λ^3-Phosphaalkynes, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne formation of a molybdenum-coordinated 1,3,5-triphosphabenzene (C) 907
Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
Phosphabenzvalene, Isomerization reactions in the system Dewar-phosphinine/phosphaprismane/phosphabenzvalene/phosphinine (C) 85
Phosphadiboroles, Synthesis and structure of a 2,5-dihydro-1*H*-1,2,5-phosphadiborole derivative (C) 781
Phosphanediyl complexes, The development of a carbene-like chemistry with terminal phosphinidene complexes (R) 275
Phosphanes, Imino-, phosphoranylidene-, and sulfuranylidenephosphanes by 1,3-silyl migration (C) 83
1-Phosphanorcaradienes, Valence isomerization between 1-phosphanorcaradienes and 1-phospha-2*H*-tropylidenes (2*H*-phosphepines) (C) 1134
Phosphaprismane, Isomerization reactions in the system Dewar-phosphinine/phosphaprismane/phosphabenzvalene/phosphinine (C) 85
Phosphasilirenes, three-membered rings containing PC double bonds (C) 776
Phosphatricyclooctenes, Mono- and Diphosphatricyclo[3.2.1.0^{2,7}]oct-3-enes: synthesis from 1,3- and 1,4-dienes and a stable phosphaalkyne (C) 1011

Phosphavinyl ethers, (2,2,8,8-Tetramethyl-5-oxa-4,6-diphospha-3,6-nonadiene)tetrakis[dicarbonyl(methylcyclopentadienyl)-manganese], the first complexed bis(phosphavinyl)ether (C) 900
Phosphazenes, Peralkylated polyaminophosphazenes—extremely strong, neutral nitrogen bases (C) 1167
2*H*-Phosphepines, Valence isomerization between 1-phosphanorcaradienes and 1-phospha-2*H*-tropylidenes (2*H*-phosphepines) (C) 1134
Phosphinidene complexes, The development of a carbene-like chemistry with terminal phosphinidene complexes (R) 275
Phosphinines, Isomerization reactions in the system Dewar-phosphinine/phosphaprismane/phosphabenzvalene/phosphinine (C) 85
Reaction of phosphinines with diazoalkanes: diphosphachiropteradienes by intramolecular, ionic 5s + 5s [6 + 4] cycloaddition (C) 236
Phosphirene, The first 2*H*-phosphirene (C) 1257
Phosphonium salts, Iodophosphonium salts with unusual properties and a structural alternative for halophosphoranes (C) 912
Phosphoranes, Iodophosphonium salts with unusual properties and a structural alternative for halophosphoranes (C) 912
Phosphoranylidenephosphanes, Imino-, phosphoranylidene-, and sulfuranylidenephosphanes by 1,3-silyl migration (C) 83
Phosphorus compounds, A new low-temperature synthesis of 1,2-dihydro-1,2-diphosphetes (C) 548
1,4-Diphospha-1,3-butadienes (C) 779
Polyphosphorus compounds—new results and perspectives (R) 419
Phosphorus homocycles, $[(\eta^5\text{-}P_5)Fe(\eta^5\text{-}C_5Me_5)]$, a pentaphosphaferrocene derivative (C) 59
P_8iPr_4—the first tricyclo[3.2.1.$0^{2,4}$]octaphosphane (C) 347
$P_8tBu_6O_6$—a highly oxidized cyclophosphane with intact P framework (C) 348
Phosphorus ligands, A novel heterobimetallic asymmetric hydrogenation catalyst based upon a chiral rhenium template containing two phosphido substituents (C) 910
Bis(η^5-cyclopentadienyl)-1,3-diphosphabicyclo[1.1.0]butane-2,4-diylzirconium: a simple synthesis of an unusual molecule (C) 764
RP-Bridged metal carbonyl clusters: synthesis, properties, and reactions (R) 743
Phosphorus-nitrogen compounds, A 3,7-diaza-1,2,4,5,6,8-hexaphosphatricyclo-[4.2.0.$0^{2,5}$]octane, a [2 + 2] dimer of a 1,2-dihydro-1-azatriphosphete containing a P_4 structure (C) 1256
Phosphorus-nitrogen ligands, $(Me_3Si)_2N\text{-}P{=}NSiMe_3$ as educt for electron-rich phosphorus-nitrogen ligands (C) 59
Phosphorus-phosphorus double bond, [1 + 4] Cycloaddition of a diphosphene to acrolein: synthesis and structure of a dihydro-1,2λ^5-oxaphosphole with an exocyclic P=P bond (C) 1010
Phosphorus-titanium compounds, $[(\eta^5\text{-}C_5Me_5)_2Ti_2P_6]$, a distorted dimetallaphosphacubane (C) 1153
Photochemistry, Charge transfer and radical ions in photochemistry (R) 825
Formation of diiridium(II) complexes by photoassisted oxidative-addition reactions: structure of a stable binuclear iodo(iodomethyl)iridium(II) complex (C) 444
Photochromic behavior, Photo- and thermochromic liquid crystal polysiloxanes (C) 1178
Photo-CIDNP in the vacuum-UV: di-*tert*-butyl ether and 2,2,5,5-tetramethyltetrahydrofuran in aqueous solution (C) 446
Photoelectron spectroscopy, Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309
Photoisomerization, Isolation and photoisomerization of simply substituted nitrile oxides (C) 155
of bis(bipyridyl)rhodium (III) complexes; synthesis of *trans*-$[Rh(bpy)_2YCl]^{n\oplus}$, Y = Cl, H_2O (C) 240
of stilbazolium chromophores with potential nonlinear optical applications (C) 341
Unusual photoisomerization of a cyclic sulfonamide (C) 146
Photolysis, Low-temperature photolysis of peracetylated dodecanoyl peroxides of tartaric acid and D-gluconic acid in the solid state—a diastereoselective radical coupling (C) 1253
Photooxidation of 2,5-dimethyl-2,3,4-hexatriene—matrix isolation of a trisdioxetane (C) 475
Photoreduction, Organometallic rhodium(III) complexes as catalysts for the photoreduction of protons to hydrogen on colloidal TiO_2 (C) 567
Photosynthesis, A new photosynthesis-like system for the light-induced reduction of water to molecular hydrogen (C) 241
The synthesis of 1,3- and 1,4-phenylene-linked bisquinone-substituted porphyrin dimers (C) 678
Phthalocyanine derivatives, 1,8-Naphthalene-linked cofacial dimeric phthalocyanines (C) 1021
Plant breeding, Genetic engineering with plants (R) 382
Platinum compounds, Macrobicyclic polyethers as second sphere ligands for tetraammineplatinum(II) (C) 693
Mixed-metal cluster formation by carbonylmetalate-induced Pt-P bond cleavage in $[PtCl_2(Ph_2PCH_2PPh_2)]$ (C) 88
New $AuPt_2$ A-frame cluster complexes (C) 86
New cisplatin analogues — on the way to better antitumor agents (R) 615
Second sphere coordination of tetraammineplatinum(II) by a macropolycyclic crown ether bisamide receptor (C) 692
Platinum-gold sols, Colloidal bimetallic catalysts: Pt-Au (C) 918
β-Pleated sheet structure, Precipitates with β-pleated sheet structure by mixing aqueous solutions of helical poly(D-lysine) and poly(L-lysine) (C) 699
Poisonous gas, The poisonous cloud, chemical warfare in the first world war (B) 90
Polyaminophosphazenes, Peralkylated polyaminophosphazenes—extremely strong, neutral nitrogen bases (C) 1167
Polycycles, [2.2](1,4)Benzo[*g*]chrysenoparacyclophane dianion: a novel, paratropic, double-layered carbanion (C) 232
Cyclohepta[*a*]phenalene: a highly electron-donating nonalternant hydrocarbon (C) 1247
2,3-Dihydroporphycene—an analogue of chlorin (C) 931
Dimerization of 1,6-dithiacyclodeca-3,8-diyne in the presence of cobalt complexes. A simple synthesis of a [2.2](2,5)thiophenophane derivative (C) 763
Electrocyclic opening of 2,3-benzo and 2,3;7,8-dibenzobicyclo[4.2.0]octa-2,4,7-triene; benzoannelated transition states (C) 1268
Heptacyclo[19.3.0.$0^{1,5}$.$0^{5,9}$.$0^{9,13}$.$0^{13,17}$.$0^{17,21}$]tetracosane ([6.5]coronane) (C) 130
Molecular belts and collars in the making: a hexaepoxyoctacosahydro[12]cyclacene derivative (C) 892
New reductive transformations of unsaturated cyclic hydrocarbons (R) 204
Reaction of phosphinines with diazoalkanes: diphosphachiropteradienes by intramolecular, ionic 5s + 5s [6 + 4] cycloaddition (C) 236
2,7,12,17-Tetrapropylporphycene—counterpart of octaethylporphyrin in the porphycene series (C) 928
The dependence of intramolecular electron transfer on structure in a spiro compound containing two cyclooctatetraene moieties (C) 1290
Polyethene, Control of the molecular weight of polyethene in syntheses with bis(ylide)nickel catalysts (C) 63
Polyketides, Stereoselective syntheses of building blocks with three consecutive stereogenic centers: important precursors of polyketide natural products (R) 489
Polylysine, Precipitates with β-pleated sheet structure by mixing aqueous solutions of helical poly(D-lysine) and poly(L-lysine) (C) 699
Polymer chemistry, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723
Polymer concept, Difficulties in the emergence of the polymer concept—an essay (R) 93
Polymer foams, Integral/Structural polymer foams. Technology, properties and applications (B) 369
Polymerization, Control of the molecular weight of polyethene in syntheses with bis(ylide)nickel catalysts (C) 63
Olefin metathesis and ring-opening polymerization of cyclo-olefins (B) 270
Plasma polymerization (B) 91
Polymerization of ethene, A new 1,3-diphosphaallylnickel complex for the polymerization of ethene (C) 1012
The copolymer of 2,6-pyridinedimethanethiol and 1,4-benzenedimethanethiol (C) 137
Polymers, High resolution NMR spectroscopy of synthetic polymers in bulk (B) 1301
Liquid crystalline polymers (R) 816
Polymer synthesis (B) 1056
Structural dynamic of collagen fibers cross-linked with isocyanates; application of synchrotron radiation in macromolecular chemistry (C) 551
The origins and growth of a science (B) 270
Polynuclear complexes, Novel bimetallic macrocyclic polymer structures incorporating deprotonated 2-pyrrolidone bridges: the crystal structures of $[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ (X = NO_3 or ClO_4) (C) 1044
Polyphosphorus compounds—new results and perspectives (R) 419
P_8iPr_4—the first tricyclo[3.2.1.$0^{2,4}$]octaphosphane (C) 347
$P_8tBu_6O_6$—a highly oxidized cyclophosphane with intact P framework (C) 348
Polypyridine ligands, Energy transfer luminescence of europium(III) and terbium(III) cryptates of macrobicyclic polypyridine ligands (C) 266
Luminescence probes: the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ cryptates of polypyridine macrobicyclic ligands (C) 1266
Polypyrrole, Electrocatalytic deposition of polypyrrole (C) 1031
Polysiloxanes, Photo- and thermochromic liquid crystal polysiloxanes (C) 1178
Polystannanes, $Ph_3Sn\text{-}(tBu_2Sn)_n\text{-}SnPh_3$ (n = 1–4): a route to molecular metals? (C) 1255
Polythioethers, Mo^{II} and Mo^0 complexes of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane (C) 1171
Polythionates, Chromatographic separation of higher polythionates $S_nO_6^{2\ominus}$ (n = 3...22) and their detection in cultures of *Thiobacillus ferrooxidans*; molecular composition of bacterial sulfur secretions (C) 151
Porphines, ^{15}N-CPMAS-NMR study of the problem of NH tautomerism in crystalline porphine and porphycene (C) 934
Porphycenes, 2,3-Dihydroporphycene—an analogue of chlorin (C) 931

^{15}N-CPMAS-NMR study of the problem of NH tautomerism in crystalline porphine and porphycene (C) 934
2,7,12,17-Tetrapropylporphycene—counterpart of octaethylporphyrin in the porphycene series (C) 928
Porphyrin dimers, The synthesis of 1,3- and 1,4-phenylene-linked bisquinone-substituted porphyrin dimers (C) 678
Porphyrins, A new photosynthesis-like system for the light-induced reduction of water to molecular hydrogen (C) 241
2,7,12,17-Tetrapropylporphycene—counterpart of octaethylporphyrin in the porphycene series (C) 928
Porphyrinogens, Biomimetic synthesis of a twofold *N,N'*-bridged porphyrinogen (C) 64
Precipitates with β-pleated sheet structure by mixing aqueous solutions of helical poly(D-lysine) and poly(L-lysine) (C) 699
Propellanes of the glycoluril series and bridged tetrazocines (C) 1039
Propellane Structure, Nickel complexes with a propellane structure (C) 65
Pentasila[1.1.1]propellane. Predictions concerning structure, bonding, and strain energy (C) 1267
Reactions of (η^3-allyl)(η^5-cyclopentadienyl)palladium with cyclopropabenzenes (C) 67
Protective group methods, Synthesis of glycopeptides, partial structures of biological recognition components (R) 294
Proteins, The nerve growth factor: 35 years later (Nobel lecture) (R) 707
Protonation, Enantioselective protonation of carbanions with chiral proton sources (C) 1283
Regioselective protonation of allylic anions (C) 1281
Proton sponges, Quino[7,8-*h*]quinoline, a new type of "proton sponge" (C) 460
Novel, very strongly basic, pentacyclic "proton sponges" with vinamidine structure (C) 1165
Proton transfer, Kinetic ^{15}N-CPMAS-NMR study of a double proton transfer in a crystalline malonaldehyde diimine derivative (C) 247
Pseudoguaianolide, Total synthesis of the pseudoguaianolide (+)-confertin (C) 61
Psoralen, A psoralen-substituted dioxetane as DNA intercalator for photogenotoxic studies (C) 796
Pyridinedimethanethiol, The copolymer of 2,6-pyridinedimethanethiol and 1,4-benzenedimethanethiol (C) 137
Pyrolysis, The pyrolysis of azides in the gas phase (R) 504
α-Pyrones, Substituted α-pyrones as starting compounds for the synthesis of 4,4-disubstituted 1,4-dihydropyridines (C) 790
Pyrrocorphins, Chemistry of pyrrocorphins: biomimetic regioselectivity of *C*-methylation at the ligand periphery of magnesium(II) uropyrrocorphinate(type I)octanitriles (C) 261

QUANTUM CHEMISTRY, A handbook of computational chemistry (B) 158
Back to the structure of benzene (L) 1298
Bond stretch isomerism in bicyclo[1.1.0]tetrasilanes. Contrasts between strained silicon and carbon ring systems (C) 364
Computer-assisted molecular design (CAMD)—an overview (R) 403
MNDOC calculations of the potential surfaces for photochemical α-cleavage (C) 238
Neutral and charged biradicals, zwitterions, funnels in S_1, and proton translocation: their role in photochemistry, photophysics, and vision (R) 170
Pentasila[1.1.1]propellane. Predictions concerning structure, bonding, and strain energy (C) 1267
Semi-empirical methods of quantum chemistry (B) 158
Quinoline derivatives, Cobalt-mediated [2+2+2]cycloadditions of alkynes to the imidazole 4,5-double bond. First Synthesis of the 3*a*,7*a*-dihydrobenzimidazole nucleus and its preliminary chemistry including a novel quinoline construction (C) 1035
Quino[7,8-*h*]quinoline, a new type of "proton sponge" (C) 460

RADICAL ANIONS, The spin distribution in ion pairs of 1-aminoanthraquinone radical anion and alkali-metal cations (C) 791
Radical cations, Cerium(IV)-catalyzed single electron transfer (SET) on acenaphthene and 1,4-dihydronaphtho-[1,8-*d*, *e*][1,2]diazepine: chemical evidence for distinct radical cations (C) 797
One- and two-electron oxidations of pagodanes and bissecododecahedradienes: unusually persistent radical cations (C) 457
Radical chain reaction, A novel route to cyclopentane derivatives: a radical chain reaction (C) 1152
Radical ions, Charge transfer and radical ions in photochemistry (R) 825
CO_2 elimination from vinylene carbonate radical anions and charge reversal in $C_2H_2O^{\ominus\ominus}$: reactions involving the radical anion and cation of oxirene? (C) 140
Radical reactions, Influence of H-donor and temperature on the stereoselectivity of radical reactions (C) 479
Radicals, A test for synergetic captodative radical stabilization (C) 573
First ENDOR investigations of biologically relevant organic radicals in reversed micelles (C) 345
Low-temperature photolysis of peracetylated dodecanoyl peroxides of tartaric acid and D-gluconic acid in the solid state—a diastereoselective radical coupling (C) 1253
Structure and magnetic properties of a gadolinium hexafluoroacetylacetonate adduct with the radical 4,4,5,5-tetramethyl-2-phenyl-4,5-dihydro-1*H*-imidazole 3-oxide 1-oxyl (C) 913
The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770
Radicals in organic synthesis: formation of carbon-carbon bonds (B) 369
Raft structure, Heterometallic polyhydride raft formation: a comparison of syntheses using alkoxides of copper and gold (C) 135
Raman spectrum of the tetrasilatetrahedrane anion Si_4^{4-} (C) 349
Reaction dynamics, Molecular beam studies of elementary chemical processes (Nobel lecture) (R) 939
Molecular dynamics of elementary chemical reactions (Nobel lecture) (R) 1221
Some concepts in reaction dynamics (Nobel lecture) (R) 952 (1302)
Reaction mechanisms, A non-stereospecific Diels–Alder reaction (C) 1046
Aromatic nitration at the encounter rate in the gas phase (C) 1177
Hydride abstraction from $[C_6H_6Os(CO)(CH_3)_2]$: does a metal-bound methyl group migrate preferentially to a CO or to a CH_2 ligand? (C) 686
Reactive intermediates, 1,2,3,5,8,8a-Hexahydronaphthalene from 1,2-cyclohexadiene (C) 449
Rearrangements, Electrocyclic opening of 2,3-benzo and 2,3;7,8-dibenzobicyclo-[4.2.0]octa-2,4,7-triene; benzoannelated transition states (C) 1268
Heptacyclo[19.3.0.0^{1,5}.0^{5,9}.0^{9,13}.0^{13,17}.0^{17,21}]-tetracosane ([6.5]coronane) (C) 130
Reactions of 2,2,4,4-tetramethyl-3-methylenecyclobutylidene; thermal rearrangements of a 2-methylenebicyclo[2.1.0]-pentane (C) 1260
Reduction, A new photosynthesis-like system for the light-induced reduction of water to molecular hydrogen (C) 241
New reductive transformations of unsaturated cyclic hydrocarbons (R) 204
of 2-enoates and alkanoates with carbon monoxide or formate, viologens, and *clostridium thermoaceticum* to saturated acids and unsaturated and saturated alcohols (C) 785
Regioselective protonation of allylic anions (C) 1281
Regioselectivity, Totally synthetic routes to the higher monosaccharides (R) 15
Unusual ligand directed regioselectivity in the iron catalyzed cross coupling of allylic ethers to 2-substituted 1,3-dienes (C) 1013
Relative electrophilicity, Control of the relative electrophilicity of alkylating agents by variation of the Lewis acid concentration (C) 1029
Relay conjugation via twisted six- and seven-membered rings (C) 1252
Retinal, Regulation of the 6-s equilibrium conformation of retinal in bacteriorhodopsin by substitution at C-5; 5-methoxy- and 5-ethylretinalbacteriorhodopsin (C) 580
Reversed micelles, First ENDOR investigations of biologically relevant organic radicals in reversed micelles (C) 345
Rhenium compounds, Alkyne complexes of rhenium in medium oxidation states: synthesis and molecular structure of a rhenium(V)—allenylidene complex (C) 1263
A novel heterobimetallic asymmetric hydrogenation catalyst based upon a chiral rhenium template containing two phosphido substituents (C) 910
Concerning the role of organotin compounds in olefin metathesis: synthesis, structure, and Lewis acidity of $[(\eta^5\text{-}C_5Me_5)CH_3ReCl_3]$ (C) 466
First four-membered metallacycles of rhenium (C) 73
Glycolate and thioglycolate complexes of rhenium and their oxidative elimination of ethylene and of glycol (C) 462
$[(\eta^5\text{-}C_5Me_5(Re(CH_3)_4]$, the first organorhenium(V) compound without heteroatom ligands (C) 787
Novel rhenium(V) carbonato and sulfato chelate complexes: synthesis and investigation of molecular dynamics by ^{17}O-NMR spectroscopy (C) 464
Oxidative addition of hydrogen telluride to organometallic fragments (C) 132
The mechanism of substitution reactions at $[LRe(NO)(CO)(CH_3)]^{\oplus}$ in acid solution and the structure of $[\{LRe(NO)(CO)\}_2(\mu\text{-}CH_2OCH_2)]I_2$ (L = 1,4,7-triazacyclononane) (C) 924
Rhodium compounds, Metathesis of CS_2-like heteroallenes on 1,1-dithio complexes of rhodium(III) (C) 767
Organometallic rhodium(III) complexes as catalysts for the photoreduction of protons to hydrogen on colloidal TiO_2 (C) 567
Photoisomerization of bis(bipyridyl)rhodium (III) complexes; synthesis of *trans*-$[Rh(bpy)_2YCl]^{n\oplus}$, Y = Cl, H_2O (C) 240
Simultaneous primary and secondary coordination of a neutral guest within a macrocyclic complex of rhodium(III) (C) 1162
The synthesis and catalytic properties of some open-sided binuclear complexes of Rh^I: the structure of $[Rh_2(CO)_2(CH_3CN)_2\{CH(PPh_2)_3\}](CF_3SO_3)_2$ (C) 1169
Ring opening, Electrocyclic opening of 2,3-benzo and 2,3;7,8-dibenzobicyclo[4.2.0]-octa-2,4,7-triene; benzoannelated transition states (C) 1268
Ruthenium compounds, A mixed-metal

cluster with two quadruply-bridging carbonyl ligands (C) 685
C–S bond cleavage in a π-thiophene ruthenium complex (C) 909
Electron delocalization in diruthenium complexes of polycyclic arenes (C) 700
Synthesis and crystal structure of the homoleptic thioether ruthenium complex [Ru(1,4,7-trithiacyclononane)$_2$]-(BPh$_4$)$_2$·2 Me$_2$SO (C) 250

SANDWICH COMPLEX, Structure of a crystalline alkali-metal cyclopentadienide (C) 583
Scanning tunneling microscopy, Scanning tunneling microscopy - from birth to adolescence (Nobel lecture) (R) 606
Schrödinger. Centenary celebration of a polymath (B) 1052
Scientific units, A dictionary of scientific units (B) 938
Selenide ligands, Novel Ni-clusters with Se and PR$_3$ (R=Ph, Et) as ligands (C) 148
Selenium compounds, 5,5-Dimethyl-1,2-dithia-3,7-diselenacycloheptane—a storable source of disulfur, S$_2$ (C) 887
1,2-Diselenete and 1,2-thiaselenete (C) 343
Synthesis and structure of a stable iodoselenide (C) 780
Shortened C–C bonds and antiplanar O=C–O–H torsion angles in 1,4-cubanedicarboxylic acid (C) 447
Side-on complexes, Synthesis and structure of compounds containing ditellurium side-on bonded to nickel complex fragments (C) 916
Silanediyl complexes, Synthesis and structure of [(OC)$_4$Fe=Si(O*t*Bu)$_2$·HMPT], a donor-stabilized silanediyl ("silylene") complex (C) 669
Silicides, Raman spectrum of the tetrasilatetrahedrane anion Si$_4^{4-}$ (C) 349
Silicon compounds, Bond stretch isomerism in bicyclo[1.1.0]tetrasilanes. Contrasts between strained silicon and carbon ring systems (C) 364
Carbosilanes (R) 1111
Phosphasilirenes, three-membered rings containing PC double bonds (C) 776
Silicon-silicon double bond, Chemistry of the silicon-silicon double bond (R) 1201
Synthesis and characterization of tetrakis[bis(trimethylsilyl)methyl]disilene (C) 584
Silver, The morphology and microstructure of colloidal silver and gold (C) 676
Silver compounds, Ag[MF$_6$]$_2$ (M=Nb, Ta), ternary fluorides of divalent silver (C) 689
[Ag$_4$(SCH$_2$C$_6$H$_4$CH$_2$S)$_3$]$^{2-}$, a novel polynuclear silver thiolate with trigonal-planar coordination of all silver atoms and a central [Ag$_4$S$_6$]-cage (C) 145
Cluster of clusters: structure of the 37-atom cluster [(*p*-Tol$_3$P)$_{12}$Au$_{18}$Ag$_{19}$Br$_{11}$]$^{2\oplus}$ and a novel series of supraclusters based on vertex-sharing icosahedra (C) 897
Silylene complexes, Synthesis and structure of [(OC)$_4$Fe=Si(O*t*Bu)$_2$·HMPT], a donor-stabilized silanediyl ("silylene") complex (C) 669
Single electron transfer, Cerium(IV)-catalyzed single electron transfer (SET) on acenaphthene and 1,4-dihydronaphtho-[1,8-*d*,*e*][1,2]diazepine: chemical evidence for distinct radical cations (C) 797
Slime mold, The chemistry of the plasmodial pigments of the slime mold *Fuligo septica* (myxomycetes) (C) 586
Solar energy, A new photosynthesis-like system for the light-induced reduction of water to molecular hydrogen (C) 241
Biological exploitation of solar energy by photosynthetic water splitting (R) 643
Solid-state chemistry, A new mechanism for superconductivity (C) 1273
Control of the superconducting properties of YBa$_2$Cu$_3$O$_7$ by topotactic redox reactions (C) 1188
Fluorides of copper, silver, gold, and palladium (R) 1081
Homoatomic d^{10}–d^{10} interactions: their effects on structure and chemical and physical properties (R) 1098
How chemistry and physics meet in the solid state (R) 846
How nature adapts chemical structures to curved surfaces (R) 1059
Superconductivity—a new classification of the chemical bonding in the solid (C) 1275
Solid-state physics, How chemistry and physics meet in the solid state (R) 846
π-Solvation, Transition state π-solvation by aromatic rings: an electronic contribution to Diels–Alder reaction diastereoselectivity (C) 1184
Solvent effects, Changes of stereoselectivity in Diels–Alder reactions by hydrophobic solvent effects and by β-cyclodextrin (C) 896
The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770
Solvophobicity, Changes of stereoselectivity in Diels–Alder reactions by hydrophobic solvent effects and by β-cyclodextrin (C) 896
Spectroscopy, EXAFS: basic principles and data analysis (B) 801
Nuclear quadrupole interaction and time-resolved perturbed γ-γ-angular correlation spectroscopy: applications in chemistry, materials science, and biophysical chemistry (R) 110
Spin distribution, The spin distribution in ion pairs of 1-aminoanthraquinone radical anion and alkali-metal cations (C) 791
Spirobi(bicyclo[6.3.0]undeca-2,4,6,8-tetraene), The dependence of intramolecular electron transfer on structure in a spiro compound containing two cyclooctatetraene moieties (C) 1290
Spiro compounds, Heptacyclo[19.3.0.0^{1,5}.0^{5,9}.0^{9,13}.0^{13,17}.0^{17,21}]tetracosane ([6.5]coronane) (C) 130
Stabilization, A test for synergetic captodative radical stabilization (C) 573
The effect of solvent on the stability of mero-substituted alkyl radicals (C) 770
Stacking interactions, Molecular recognition: stacking interactions influence Watson-Crick vs. Hoogsteen base-pairing in a model for adenine receptors (C) 1244
Stannaethenes, A stable stannaethene (C) 546
Stereoelectronic effects and chiral recognition: a natural system of relationships between chiral compounds based on selectivities in the formation of acetals (C) 442
Stereoselective aldol reaction, Stereoselective aldol reactions with α-unsubstituted chiral enolates (R) 24
Stereoselective alkylation of aromatic compounds with threonine trifluoromethanesulfonates (C) 142
Stereoselective synthesis, Estimation of the configurational stability of chiral organometallic reagents (C) 1145
of building blocks with three consecutive stereogenic centers: important precursors of polyketide natural products (R) 489
Stereoselective synthesis (B) 1053
Stereoselectivity, Changes of stereoselectivity in Diels–Alder reactions by hydrophobic solvent effects and by β-cyclodextrin (C) 896
Directed homogeneous hydrogenation (R) 190
Influence of H-donor and temperature on the stereoselectivity of radical reactions (C) 479
Stereospecificity, A non-stereospecific Diels–Alder reaction (C) 1046
Steroids, Interaction of steroid hormone receptors with DNA (B) 591
Stiboxanes, Nonaphenyltristiboxane-1,5-diyl disulfonates (C) 906
Stilbazolium chromophores, Photoisomerization of stilbazolium chromophores with potential nonlinear optical applications (C) 341
Strain, Dicyclopropa[*a*,*c*]naphthalene: a compound capable of existence? (C) 577
Strain energy, Pentasila[1.1.1]propellane. Predictions concerning structure, bonding, and strain energy (C) 1267
Strecker synthesis, Diastereoselective Strecker synthesis of α-aminonitriles on carbohydrate templates (C) 557
Streptazolin, New lead structures by Diels–Alder reactions of streptazolin with naphthoquinones (C) 664
Structural chemistry, How nature adapts chemical structures to curved surfaces (R) 1059
Structural methods in inorganic chemistry (B) 1197
Structure, Back to the structure of benzene (L) 1298
Concerning the structure of benzene (C) 782
Structure determination, Direct identification of the carbon skeleton of organic compounds using double quantum coherence ^{13}C-NMR spectroscopy. The INADEQUATE pulse sequence (R) 625
Structural dynamics of collagen fibers cross-linked with isocyanates; application of synchrotron radiation in macromolecular chemistry (C) 551
Substituent effects, A test for synergetic captodative radical stabilization (C) 573
Substitution, The mechanism of substitution reactions at [LRe(NO)(CO)(CH$_3$)]$^{\oplus}$ in acid solution and the structure of [{LRe(NO)(CO)}$_2$(μ-CH$_2$OCH$_2$)]I$_2$ (L = 1,4,7-triazacyclononane) (C) 924
Sugar chemistry, Glycosyl isocyanide dichlorides—novel synthetic building blocks in sugar chemistry (C) 359
Sulfenes, A sulfene umpolung (C) 1133
Sulfonamides, Unusual photoisomerization of a cyclic sulfonamide (C) 146
Sulfones, X-ray structure analysis of the Li$_2$-compound of bis(trimethylsilyl)methyl phenyl sulfone; structural units of an α-sulfonyl- and a complex-stabilized *ortho*-sulfonyl carbanion (C) 1287
Sulfonyl carbanions, X-ray structure analysis of the Li$_2$-compound of bis(trimethylsilyl)methyl phenyl sulfone; structural units of an α-sulfonyl- and a complex-stabilized *ortho*-sulfonyl carbanion (C) 1287
Sulfuranylidenephosphanes, Imino-, phosphoranylidene-, and sulfuranylidenephosphanes by 1,3-silyl migration (C) 83
Sulfur bacteria, Chromatographic separation of higher polythionates S$_n$O$_6^{2\ominus}$ (n=3...22) and their detection in cultures of *Thiobacillus ferrooxidans*; molecular composition of bacterial sulfur secretions (C) 151
Sulfur compounds, Chromatographic separation of higher polythionates S$_n$O$_6^{2\ominus}$ (n=3...22) and their detection in cultures of *Thiobacillus ferrooxidans*; molecular composition of bacterial sulfur secretions (C) 151
Dimerization of 1,6-dithiacyclodeca-3,8-diyne in the presence of cobalt complexes. A simple synthesis of a [2.2](2,5)thiophenophane derivative (C) 763
5,5-Dimethyl-1,2-dithia-3,7-diselenacycloheptane—a storable source of disulfur, S$_2$ (C) 887
The copolymer of 2,6-pyridinedimethanethiol and 1,4-benzenedimethanethiol (C) 137
Sulfur ligands, [Ag$_4$(SCH$_2$C$_6$H$_4$CH$_2$S)$_3$]$^{2-}$, a novel polynuclear silver thiolate with trig-

onal-planar coordination of all silver atoms and a central $[Ag_4S_6]$-cage (C) 145
Metathesis of CS_2-like heteroallenes on 1,1-dithio complexes of rhodium(III) (C) 767
Synthesis and structure of $[(C_5Me_5)_2Mo_2S_4 \cdot SO_3]$: concerning the oxidation of sulfur ligands in transition-metal complexes (C) 230
Sulfur oxides as ligands in coordination compounds (R) 98
Sulfur pentafluoride cyanate, $F_5S-O-C\equiv N$ (C) 134
Sulphur fluor compounds, Preparation of $F_4S=CH-COF$ by isomerization of $F_5S-CH=C=O$ (C) 799
Superconduction, Control of the superconducting properties of $YBa_2Cu_3O_7$ by topotactic redox reactions (C) 1188
Imaging oxygen vacancies in superconducting $YBa_2Cu_3O_{7-\delta}$ by high resolution electron microscopy (C) 1048
Superconductivity—a chemical phenomenon? (C) 579
—a new classification of the chemical bonding in the solid (C) 1275
A new mechanism for superconductivity (C) 1273
Supersandwich complex, Structure of a crystalline alkali-metal cyclopentadienide (C) 583
Supraclusters, Cluster of clusters: structure of the 37-atom cluster $[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2\oplus}$ and a novel series of supraclusters based on vertex-sharing icosahedra (C) 897
Surface chemistry, Low energy electrons and surface chemistry (B) 1054
Surface reactions, Decarbonylation on carbon-supported nickel catalysts (C) 461
Reaction of Sn_9^{4-} with single crystal Au: textured fiber epitaxial growth of AuSn at room temperature (C) 1155
Synthetic methods, Directed homogeneous hydrogenation (R) 190
Modern synthetic methods 1986. Vol. 4 (B) 1300
New reductive transformations of unsaturated cyclic hydrocarbons (R) 204
Stereoselective aldol reactions with α-unsubstituted chiral enolates (R) 24
Stereoselective syntheses of building blocks with three consecutive stereogenic centers: important precursors of polyketide natural products (R) 489
Synthesis of glycopeptides, partial structures of biological recognition components (R) 294
Totally synthetic routes to the higher monosaccharides (R) 15

TANTALUM COMPOUNDS, $Ag[MF_6]_2$ (M = Nb, Ta), ternary fluorides of divalent silver (C) 689
Tautomerism, ^{15}N-CPMAS-NMR study of the problem of NH tautomerism in crystalline porphine and porphycene (C) 934
Telluride-tellurolate complex, $[Fe_4Te_4(TePh)_4]^{3\ominus}$, the first telluride-tellurolate complex (C) 1009
Tellurium ligands, Synthesis and structure of compounds containing ditellurium *side-on* bonded to nickel complex fragments (C) 916
Temperature profiles, IR Emission analysis of temperature profiles in Pt/SiO_2 catalysts during exothermic reactions (C) 1042
Tetra-*tert*-butyltetrahedrane, Gas-inclusion crystals of tetra-*tert*-butyltetrahedrane and its deformation density (C) 356
Tetrahedrane, Gas-inclusion crystals of tetra-*tert*-butyltetrahedrane and its deformation density (C) 356
2,3,9,10-Tetrakis(trimethylsilyl)[5]phenylene. Synthesis via regiospecific cobalt-catalyzed cocyclization of 1,6-bis(triisopropylsilyl)-1,3,5-hexatriyne (C) 1246
Tetramethylene cyclohexanediyl, The diradical 2,3,5,6-tetramethylene-1,4-cyclohexanediyl ("1,2,4,5-tetramethylenebenzene") (C) 256
2,2,4,4-Tetramethyl-3-methylenecyclobutylidene, Reactions of 2,2,4,4-tetramethyl-3-methylenecyclobutylidene; thermal rearrangements of a 2-methylenebicyclo-[2.1.0]pentane (C) 1260
2,2,5,5-Tetramethyltetrahydrofuran, Photo-CIDNP in the vacuum-UV: di-*tert*-butyl ether and 2,2,5,5-tetramethyltetrahydrofuran in aqueous solution (C) 446
Tetrasilatetrahedrane anion, Raman spectrum of the tetrasilatetrahedrane anion Si_4^{4-} (C) 349
s-Tetrazine as ligand for monomeric and bridged macrocyclic metal complexes (C) 344
Tetrazocines, Propellanes of the glycoluril series and bridged tetrazocines (C) 1039
Tetrazole derivatives, Methyl (*E*)-2-(1-aryl-4,5-dihydro-1*H*-tetrazol-5-ylidene)-2-cyanoacetate from methyl 3,3-diazido-2-cyanoacrylate and primary aromatic amines (C) 1160
Thallium compounds, Pentabenzylcyclopentadienylthallium(I): synthesis and structure of a "dimeric" organothallium compound with Tl-Tl interaction (C) 789
Theoretical chemistry, Concerning the structure of benzene (C) 782
How chemistry and physics meet in the solid state (R) 846
Thermochromic behavior, Photo- and thermochromic liquid crystal polysiloxanes (C) 1178
Thermodynamics, Computer-aided chemical thermodynamics of gases and liquids—theory, models, programs (B) 1057
Thermolysis of NH_4HCO_3—a simple route to the formation of free carbonic acid (H_2CO_3) in the gas phase (C) 354
1,2-Thiaselenete, 1,2-Diselenete and 1,2-thiaselenete (C) 343
Thioether complexes, Synthesis and crystal structure of the homoleptic thioether ruthenium complex $[Ru(1,4,7\text{-trithiacyclononane})_2](BPh_4)_2 \cdot 2\,Me_2SO$ (C) 250
Thiophene complexes, C-S Bond cleavage in a π-thiophene ruthenium complex (C) 909
Thioxocarbon dianion, Trithiodeltate: a new, aromatic thioxocarbon dianion (C) 1163
Threonine trifluoromethanesulfonates, Stereoselective alkylation of aromatic compounds with threonine trifluoromethanesulfonates (C) 142
Thymine glycol, The fluorometric determination of thymine glycol as criterion of the treatment of foodstuffs (biological material) with ionizing radiation (C) 340
Tin compounds, Concerning the role of organotin compounds in olefin metathesis: synthesis, structure, and Lewis acidity of $[(\eta^5\text{-}C_5Me_5)CH_3ReCl_3]$ (C) 466
Polystannanes $Ph_3Sn-(tBu_2Sn)_n-SnPh_3$ (n = 1–4): a route to molecular metals? (C) 1255
Titanium hydride formation through hydrogen transfer from 2-methylpyridine to a titanium fulvene compound; the first structurally characterized terminal titanium hydride (C) 330
Topotactic redox reactions, Control of the superconducting properties of $YBa_2Cu_3O_7$ by topotactic redox reactions (C) 1188
Total synthesis of the enantiomerically pure lichen macrolide (+)-aspicilin (C) 362
Toxicology, Analytical methods in human toxicology (B) 1051
Trace analysis. Spectroscopic methods for molecules (B) 1052
Transcription in eukaryotes—the role of transcription complexes and their components (R) 218
Transition metal complexes, Diene, alkyne, alkene, and alkyl complexes of early transition metals: structures and synthetic applications in organic and polymer chemistry (R) 723
s-Tetrazine as ligand for monomeric and bridged macrocyclic metal complexes (C) 344
The development of a carbene-like chemistry with terminal phosphinidene complexes (R) 275
Transition states, Electrocyclic opening of 2,3-benzo and 2,3;7,8-dibenzobicyclo-[4.2.0]octa-2,4,7-triene; benzoannelated transition states (C) 1268
Transmission electron microscopy, Reaction of Sn_9^{4-} with single crystal Au: textured fiber epitaxial growth of AuSn at room temperature (C) 1155
α-Trialkylsilylaldehydes, Enantioselective synthesis of α-trialkylsilyl ketones and aldehydes (C) 351
α-Trialkylsilyl ketones, Enantioselective synthesis of α-trialkylsilyl ketones and aldehydes (C) 351
Triaziridines, Unusually stable *cis,cis*-trialkyltriaziridines by azo/nitrene addition (C) 566
Tricycloheptane-1-diazonium ions, Diazo coupling of nortricyclene(tricyclo-$[2.2.1.0^{2,6}]$heptane)-1-diazonium ions (C) 570
Tricyclononatriene, Synthesis of tricyclo-$[5.2.0.0^{1,3}]$nona-4,6,8-triene, a norcaradiene structure constrained by the antiaromaticity of cyclobutadiene (C) 559
Tricyclooctane, Diasterane (tricyclo-$[3.1.1.1^{2,4}]$octane) (C) 554
Tricyclooctaphosphane, P_8iPr_4—the first tricyclo$[3.2.1.0^{2,4}]$octaphosphane (C) 347
Trifluoroacetic acid, Trifluoromethyl isocyanide as a synthetic building block—reaction with trifluoroacetic acid and with hexafluoroacetone (C) 921
Trifluoromethyl isocyanide as a synthetic building block—reaction with trifluoroacetic acid and with hexafluoroacetone (C) 921
Trimethylenemethane complexes of Cr, Mo, and W by novel methylenation of allenes with carbene complexes; cyclopentanes by [3+2] cycloaddition of trimethylenemethane complexes to allenes (C) 357
Triphenylarsane diiodide, Structure of triphenylarsane diiodide, $[Ph_3As \cdot I_2]$, a compound formed in the thermal decomposition of $[Mn(OAsPh_3)_3I_2(SO_2)_2]$ (C) 264
Triphenylmethylium, Deep-colored, through-conjugated multitriphenylmethylium ions (C) 794
Triphosgene, a crystalline phosgene substitute (C) 894
1,3,5-Triphosphabenzene, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of a molybdenum-coordinated 1,3,5-triphosphabenzene (C) 907
Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne: formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
Triphosphatriborinane, Synthesis and X-ray structure of $(2,4,6\text{-}Me_3C_6H_2BPC_6H_{11})_3$: a boron-phosphorus analogue of borazine (C) 1270
Triple bond, Olefinic C=C double bond coordination to a M≡M triple bond: bis(η^2-ethylene)hexakis(neopentyloxy)ditungsten (C) 903
Triple-decker phanes, Synthesis and chirality of sixfold-bridged triple-decker phanes (C) 777
Triple decker sandwich structure, A triple decker sandwich structure by reaction of cyclopentadienylbis(ethylene)cobalt with carbodiimides: an unusual cyclopentadienylcobalt oligomer (C) 68
Trisdioxetane, Photooxidation of 2,5-dimethyl-2,3,4-hexatriene—matrix isolation of a trisdioxetane (C) 475

Trithiacyclononane, Crown thioether complexes of Ag^I and Cu^I: the crystal structures of $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$ and $[LCuI]$ (L = 1,4,7-Trithiacyclononane) (C) 575
Trithiodeltate: a new, aromatic thioxocarbon dianion (C) 1163
Tungsten compounds, Olefinic C=C double bond coordination to a M≡M triple bond: bis(η^2-ethylene)hexakis(neopentyloxy)ditungsten (C) 903
The first 2*H*-phosphirene (C) 1257
Two-electron reduction, "Two-electron reduction" of phosphane-substituted tricobalt clusters—evidence for a 17-electron intermediate in the dissociative ETC ligand substitution (C) 352

UMPOLUNG, A sulfene umpolung (C) 1133
Unsaturation, Molecular belts and collars in the making: a hexaepoxyoctacosahydro-[12]cyclacene derivative (C) 892
New reductive transformations of unsaturated cyclic hydrocarbons (R) 204
Unsaturated molecules containing main group metals (R) 1
Unstable compounds, Generation and interception of 1-oxa-3,4-cyclohexadiene (C) 690
The generation and characterization of molecules by neutralization-reionization mass spectrometry (NRMS) (R) 805

VALENCE ISOMERISM, Metal-promoted cyclotrimerization of a λ^3-phosphaalkyne formation of vanadium-complexed valence isomers of a 1,3,5-triphosphabenzene (C) 908
Valence isomerization between 1-phosphanorcaradienes and 1-phospha-2*H*-tropylidenes (2*H*-phosphepines) (C) 1134
Valienamine, Synthesis of valienamine (C) 482
Vanadium compounds, Amavadin, an example for selective binding of vanadium in nature: studies of its complexation chemistry and a new structural proposal (C) 545
Spherical mixed-valence $[V_{15}O_{36}]^{5\ominus}$, an example from an unusual cluster family (C) 1045
Vanadium carbene complexes by reaction of (diene)metallocenes with $[CpV(CO)_4]$ (C) 666
Vinamidines, Novel, very strongly basic, pentacyclic "proton sponges" with vinamidine structure (C) 1165
Tricyclic 2,4-diaminovinamidines—readily accessible, very strong CHN bases (C) 1164
Vinyl diazides, [4+2] Cycloadditions of 2,3-diazido-1,3-butadienes: a novel entry to vicinal vinyl diazides and 1,4-dicyano compounds (C) 879
Vinylene carbonate, CO_2 elimination from vinylene carbonate radical anions and charge reversal in $C_2H_2O^{\odot\ominus}$: reactions involving the radical anion and cation of oxirene? (C) 140
Vinylidene ligands, Isoelectronic relationships in cluster chemistry: nucleophilic addition to a vinylidene ligand (C) 572
Viologens, Reduction of 2-enoates and alkanoates with carbon monoxide or formate, viologens, and *clostridium thermoaceticum* to saturated acids and unsaturated and saturated alcohols (C) 785

WATER SPLITTING, Biological exploitation of solar energy by photosynthetic water splitting (R) 643

X-RAY PHOTOELECTRON SPECTROSCOPY, Emission of microparticles from automotive sources—X-ray photoelectron spectroscopy in environmental analysis (R) 309

YLIDE COMPLEXES, Isovalent and mixed-valent ylide complexes of gold: the synthesis of trinuclear compounds having double paddlewheel structure (C) 1146
The recoil-free fraction of the γ resonance in ^{197}Au Mössbauer spectroscopy; findings from measurements of polynuclear, mixed-valent ylide complexes (C) 1148
Ylides, 1,5-Electrocyclization in homofuran, homopyrrole, and homothiophene (C) 1294
Synthesis of nitriles via the ylide anion of sodium cyanotriphenylphosphoranylidenemethanide (C) 79
Ynamines, First synthesis of *N*-methyleneynamines (2-azabut-1-en-3-ynes) (C) 923

ZEOLITE CATALYSTS, Preparation of β-halothiophenes by isomerization of α-halothiophenes on zeolite catalysts (C) 468
Zeolites, Adsorption and curvature in highly dealuminated zeolites (C) 1017
Zinc compounds, High-resolution CP-MAS ^{13}C-NMR spectra of allylzinc compounds—structural similarities and differences in the solid state and in solution (C) 1279
Zinc ketones, Generation of β-, γ-, δ-, ε-, and ζ-zinc ketones and their transition-metal-catalyzed reactions with carbon electrophiles (C) 1157
Zirconium compounds, A new class of organozirconium(IV) compounds: alkyl derivatives of tetramethyltetraazadibenzo-[14]annulenatozirconium(IV) (C) 70
Bis(η^5-cyclopentadienyl)-1,3-diphosphabicyclo[1.1.0]butane-2,4-diylzirconium: a simple synthesis of an unusual molecule (C) 764
Dinuclear fulvalene complexes of tri- and tetravalent zirconium (C) 697
Hexacarbonylzirconate(2−), $[Zr(CO)_6]^{2-}$: the first binary carbonyl complex of zirconium (C) 1190
Zwitterions, Neutral and charged biradicals, zwitterions, funnels in S_1, and proton translocation: their role in photochemistry, photophysics, and vision (R) 170
