That phosphane is, in fact, eliminated during the reduction of **2** can be shown by measurements carried out in the presence of **1**, since **1** reacts with free phosphane ligands, PR_3, via an ETC-catalyzed reaction, to form clusters of the general composition $[(\mu_3\text{-MeC})Co_3(CO)_8(PR_3)]$.[2] Indeed, voltammetric experiments with solutions containing both **1** and **2** demonstrate the formation of **3**. Because the forward potential scan results in the reduction of **1** and since the phosphane ligand is only released after reduction of **2** to the radical anion, the substitution product **3**, formed from **1**, can only be detected in the reverse scan as well as during the second cathodic sweep. In control experiments in which only **1** was present in solution, there was no evidence in the voltammograms for the formation of subsequent products. Further evidence for the mechanism shown in Scheme 1 is provided by voltammetric experiments with **2** in the presence of a large excess of the corresponding phosphane ligands. The cathodic scan remained unchanged; however, in the reverse, anodic scan, the wave corresponding to $\mathbf{4}^{\odot\ominus} \rightarrow \mathbf{4}$ disappeared and the wave corresponding to the normally stable redox pair $\mathbf{4}^{2\ominus}/\mathbf{4}^{\odot\ominus}$ became irreversible. This strongly implies that, after the reoxidation of $\mathbf{4}^{2\ominus}$ to $\mathbf{4}^{\odot\ominus}$, the phosphane ligand adds to the 17-electron species $\mathbf{4}^{\odot\ominus}$ with re-formation of $\mathbf{2}^{\odot\ominus}$. Thus, when the potential is scanned positively to $E^0_{2/2^{\odot\ominus}}$, $[E(t) > E^0_{2/2^{\odot\ominus}}]$, $\mathbf{2}^{\odot\ominus}$ is immediately transformed into **2**. The backward reaction becomes dominant, because, after the reoxidation of $\mathbf{4}^{2\ominus}$ to $\mathbf{4}^{\odot\ominus}$, the reaction sequence $\mathbf{2} \rightarrow \mathbf{2}^{\odot\ominus} \rightarrow \mathbf{4}^{\odot\ominus}$ can no longer occur owing to an electrode potential greater than $E^0_{2/2^{\odot\ominus}}$ (see Fig. 1a).

The voltammograms of **2** reveal no evidence of other reaction channels for **4**, e.g., addition of solvent or fragmentation of the metal framework. In fact, the second cathodic scan (Fig. 1a) reveals that, after the oxidation of $\mathbf{4}^{\odot\ominus}$ to **4**, only the regenerated starting system **2** and the still present $\mathbf{4}^{\odot\ominus}$ are reduced.

The neutral species **4** corresponds to the classical 16-electron intermediate involved in thermal dissociative CO substitution. A 17-electron intermediate is of analogous significance for the ETC reaction scheme, which has been carried out with much success on clusters.[2,6] The existence of such a species, formed by one-electron reduction and ligand elimination, could only be demonstrated up to now indirectly on the basis of kinetic data or product distributions, owing to its high lability.[2,7] Its detection in the form of $\mathbf{4}^{\odot\ominus}$ is presumably due to the presence of several phosphane ligands, which relieve the electron deficiency by their donor ability and help to shield the unsaturated species by their steric bulk.

Two further observations support this interpretation. The clearly visible crossing effect suggests a homogeneous disproportionation reaction, which, in accordance with

Equation (a), takes place in the diffusion layer in front of the electrode, in addition to the heterogeneous ECE process.[8]

$$4^{2\ominus} + 2 \rightleftharpoons 4^{\odot\ominus} + 2^{\odot\ominus} \qquad (a)$$

Although it is not thermodynamically favored ($E^0_{4^{\odot\ominus}/4^{2\ominus}} > E^0_{2/2^{\odot\ominus}}$), reaction (a) proceeds from left to right, since, owing to the elimination of phosphane, $2^{\odot\ominus}$ is transformed to $4^{\odot\ominus}$. Therefore, the product of the concentrations of $4^{\odot\ominus}$ and $2^{\odot\ominus}$ becomes smaller than that allowed by the thermodynamic equilibrium conditions. The radical anion $4^{\odot\ominus}$, which continues to be formed by disproportionation in the diffusion layer after potential reversal in the potential range $E < E^0_{4^{\odot\ominus}/4^{2\ominus}}$, can once again be reduced to the dianion $4^{2\ominus}$ at the electrode.

Furthermore, multisweep experiments (Fig. 1b) reveal the existence of an isopotential point, which can be interpreted in complete analogy to an isosbestic point. It shows that the transformation of $2^{\odot\ominus}$ into $4^{\odot\ominus}$ occurs without side reactions and quantitatively.[5,9] Thus, the only redox system remaining in this potential range is the pair $4^{\odot\ominus}/4^{2\ominus}$. Thereby, the existence of the intermediate (in this case, $4^{\odot\ominus}$) that is essential for the dissociative, ETC ligand exchange and its stability in solution for a finite length of time have been demonstrated.

Thermolysis of NH_4HCO_3—A Simple Route to the Formation of Free Carbonic Acid (H_2CO_3) in the Gas Phase**

By *Johan K. Terlouw, Carlito B. Lebrilla,* and *Helmut Schwarz**

Dedicated to Professor Tilman J. De Boer

"Carbonic acid, $(HO)_2CO$, cannot exist in the free state."[1] A statement of this kind is warranted in so far as it has until now only been possible to prepare the ether adducts of carbonic acid $H_2CO_3 \cdot R_2O$ ($R = CH_3$, C_2H_5),[2] at temperatures below -30°C. In solution, the adducts decompose into H_2O, CO_2 and R_2O above 5°C. The hydration of CO_2 is one of the fundamental processes in many biological and ecological systems.[3] It is represented by equation (a), of which—at pH ~7—the first step is considered to be rate determining;[4] the formation of bicarbonate ions via step II is fast.[4,5]

$$CO_{2\,aq} + H_2O \overset{I}{\rightleftharpoons} H_2CO_{3\,aq} \overset{II}{\rightleftharpoons} HCO_3^{\ominus}{}_{aq} + H^{\oplus}_{aq} \qquad (a)$$

The reaction of CO_2 and H_2O in the gas phase [equation (b)] has been studied in detail by *ab initio*[6] and semiempirical (MNDO) MO calculations.[7] These predict that a sizeable activation energy (>40 kcal/mol) is involved in the formation and the dissociation of carbonic acid, **2**, and thus the *free* acid should exist as a stable molecule. The reaction pathway of minimum energy proceeds via **1**. This computational result provides a rationale in that this pathway is formally symmetry forbidden. In solution however, acid/base- and also solvent-catalysis occurs. This increases the rate of hydration of CO_2 and of the dissociation of carbonic acid to such an extent that **2** is inaccessible.

$$CO_2 + H_2O \rightleftharpoons \left[\; O{=}C\!\begin{array}{l}O\\ \diagup\\ \diagdown\\ O\end{array}\!H \;\right]^{\ddagger} \rightleftharpoons O{=}C\!\begin{array}{l}OH\\ \diagdown\\ \diagup\\ OH\end{array} \qquad (b)$$

1 **2**

We report here results of a simple experiment which unambiguously demonstrates that **2** and its radical cation $2^{\odot\oplus}$ can easily be generated as stable species in the gas phase.

Finely powdered NH_4HCO_3 decomposes upon heating, and its reaction products were analyzed using a vacuum generator (VG) analytical ZAB-2F mass spectrometer in the electron impact mode (70 eV ionizing electron energy, 50 μA emission current). The sample was introduced by the standard direct insertion probe and heated by the heat transfer of the ion source block ($T = 150$°C) to the quartz sample holder. Alternatively, the sample was put in an evacuated glass bulb—immersed in an oil bath at 120°C—which was connected to the ion source by a glass line of 30 cm. The mass spectra obtained from NH_4HCO_3 introduced by either method showed signals at *m/z* 17 ($NH_3^{\odot\oplus}$), *m/z* 18 ($H_2O^{\odot\oplus}$, $NH_4^{\odot\oplus}$) and also *m/z* 62. The signal to noise ratio for these *m/z* 62 ions was better than 100:1, although the peak is <1% of the base peak (*m/z* 44, $CO_2^{\odot\oplus}$), and irregular evaporation causes strong intensity fluctuations. An exact mass measurement was performed on the *m/z* 62 ions and the result, 62.00002 Daltons, is only compatible with the elemental composition CH_2O_3 (calculated 62.00039 Daltons); the next best combination, CH_4NO_2, has a calculated mass of 62.0241 Daltons. No signal was present at *m/z* 79 and a metastable transition for the reaction

$$m/z\ 79 \longrightarrow m/z\ 62 + NH_3$$

could not be detected. This strongly indicates that the $CH_2O_3^{\odot\oplus}$ ions must be generated by direct ionization of the

corresponding neutral molecule and not as fragment ions produced by loss of NH_3 from ionized NH_4HCO_3. As soon as the temperature used to evaporate the sample was lowered to ca. 100 °C the *m/z* 62 ions disappeared and the intensity of the other signals also became much lower.

Collision induced decomposition of the mass-selected *m/z* 62 ions (MS/MS experiments,[8]) yields the collisional activation[9] (CA) spectrum shown in Figure 1a. Both the pronounced loss of $OH^{\odot}$ by direct α-cleavage ($\rightarrow m/z$ 45) and the elimination of neutral H_2O ($\rightarrow m/z\ 44^{\odot\oplus}$) and CO_2 ($\rightarrow m/z\ 18^{\odot\oplus}$) are compatible with our proposal that the *m/z* 62 ions are carbonic acid radical cations, $\mathbf{2}^{\odot\oplus}$.

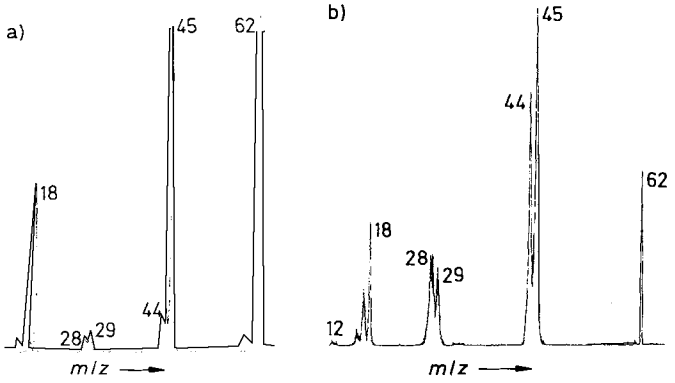

Fig. 1. a) CA mass spectrum (collision gas: He) of mass-selected $CH_2O_3^{\odot\oplus}$ ions (*m/z* 62) generated by electron impact ionization of NH_4HCO_3 followed by 70 eV ionization. b) NRMS spectrum of $CH_2O_3^{\odot\oplus}$ ions, using xenon for neutralization and oxygen for reionization.

Encouraged by our recent Neutralization-Reionization (NRMS[10]) experiments, which made it possible to generate exotic molecules like HC≡COH,[11a] HC≡CNH$_2$,[11b] and XC≡CY with X, Y = OH, NH$_2$[11c] by neutralizing the corresponding radical cations in the gas phase, we have also performed such an experiment with ions $\mathbf{2}^{\odot\oplus}$. The NRMS spectrum (Fig. 1b) leaves no doubt that a significant fraction of the *m/z* 62 $CH_2O_3^{\odot\oplus}$ ions remains intact upon neutralization followed by reionization.[12] We conclude that both $CH_2O_3^{\odot\oplus}$ *and* CH_2O_3 are stable species in the gas phase. It follows from the analysis of the potential energy surface of CH_2O_3[6] that the neutral *m/z* 62 molecule can only be the free carbonic acid, **2**.

Our MNDO calculations yield a value of −146.1 kcal/mol for the enthalpy of formation, ΔH_f^0, of **2** (*syn/anti* conformation of the OH groups). Use of *Benson*'s additivity scheme[13] yields the same value. The radical cation **2** is estimated to have a ΔH_f^0 of 110–115 kcal/mol using the Holmes/Lossing scheme[14] with an ionization energy of 10.8 eV[15] for $(CH_3O)_2C{=}O$.

[12] A complete analysis of the spectra in Figures 1a and b is not given. Note, however, that the half height width of the *m/z* 44 signal in Figure 1b is considerably smaller than that of *m/z* 45. This implies that the larger part of the *m/z* 44 ions results from direct ionization of neutral CO_2. The intense broad peak at *m/z* 45, however, can only correspond with fragment ions, produced by the collision induced dissociations of *m/z* 62 *ions* (i.e. *m/z* 62 → *m/z* 45 + $OH^{\odot}$); see also Ref. [10b].

Azoalkane–Nitrene Cleavage on an Fe_3-Cluster**

By *Edward J. Wucherer* and *Heinrich Vahrenkamp**

It has already been demonstrated on several occasions that unsaturated substrates are capable of undergoing some very unusual reactions upon multicenter attachment to clusters.[1] Among the simplest of such reactions are the facile, in some cases even reversible, formation and cleavage of C≡C- and C≡N bonds in the ligand sphere.[2] In the context of our studies in this area we have so far been able to demonstrate the cleavage of a *formal* P=P bond and the oxidative decarbonation of an acetylide ligand.[3] In continuation of these studies we have now succeeded in cleaving the *formal* N=N bond of an azoalkane on a cluster without altering the overall composition of the complex.

The study of azoalkane-bridged triiron clusters such as **1** calls for a high-yield synthesis, which we found in the reaction of azoethane with the labile complex $[(CO)_3Fe(cyclo\text{-}C_8H_{14})_2]$.[4] The reactivity of **1** was immediately evident on investigating its thermal behavior: when a solution of **1** in ligroin was heated to 120 °C for 11 hours, ca. 5% of a decomposition product was obtained together with ca. 75% of **2** as the sole newly formed compound, which could be separated from unchanged **1** (ca. 20%) by chromatography on silica gel. During the transformation of **1** into **2** the six-electron azoalkane ligand R_2N_2 is converted into two four-electron nitrene ligands. Since the number of CO-ligands remains the same during this conversion, opening of a metal–metal bond must take place for compensation: the closed Fe_3-triangle in **1** becomes the angular open Fe_3-arrangement in **2**, which is typical

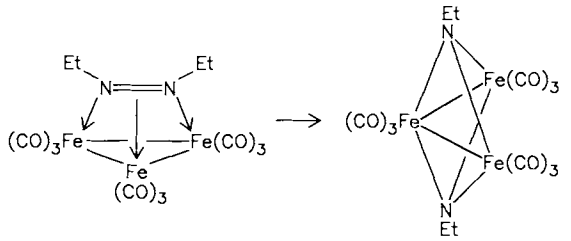
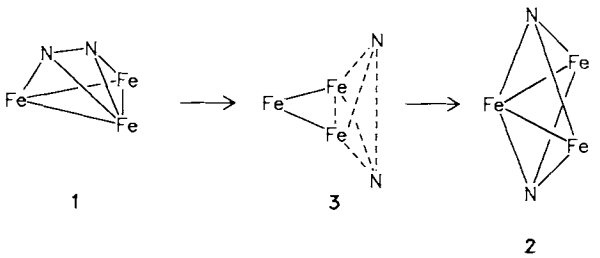
for $Fe_3(CO)_9$ complexes containing two four-electron μ_3-ligands.



1 2

The green complex **1** and the red complex **2** were characterized by elemental analyses and by their EI-mass spectra. Representatives of both types of complex have already been prepared via other routes, and their molecular structures are known.[5] The IR data of **1** and **2** establish their relation to them; the NMR data, which reveal the diastereotopy of the CH_2 groups in **1** and the equivalence of the ethyl groups in **2** lend support to the assignment.[6]

The mechanism of the transformation of **1** into **2** can be explained in terms of the arguments presented by *Shapley* and *Hoffmann*[2] for the transformation of a μ_3-R_2C_2-ligand into two μ_3-RC-ligands.[7] Accordingly, the R_2N_2-ligand in **1** could slide to an edge of the metal triangle that is not parallel to the NN bond. The new Fe–N bonds would then be formed via a transition state such as **3** with synchronous opening of the Fe–Fe and N–N bonds. However, from our experience with the ready fragmentation of cluster frameworks[8] a mechanism involving reactive fragments also cannot be ruled out.



1 3 2

The cleavage of N=N bonds in, e.g. azides, azo compounds etc., in reactions with carbonylmetal compounds is not unusual and leads to numerous types of products.[9] Obviously, the transformation **1** → **2** can be seen as the elementary step in such reactions. Moreover, analogous cleavages with chemical reagents should correspond to the spontaneous thermal N–N cleavage in **1**. We therefore expect that, besides the chemistry developed by *Kisch*[10] for the organic molecular moiety of iron complexes of cyclic azoalkanes, also a new derivative chemistry at the nitrogen via complexes such as **1** and **2** and their dinuclear analogues can be elaborated.

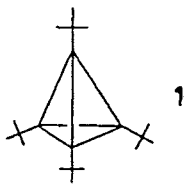
Gas-Inclusion Crystals of Tetra-*tert*-butyltetrahedrane and Its Deformation Density**

By *Hermann Irngartinger,* Reiner Jahn, Günther Maier,* and *Rolf Emrich*

Having elucidated the structure of tetra-*tert*-butyltetrahedrane, **1**,[1] we decided to determine the deformation density in **1** by low-temperature X-ray diffraction at 103 K according to the X–X method.[2] We found thereby that the hexagonal crystals grown at 213 K had entrapped nitrogen



1

molecules at lattice sites. The solvent used for the crystallization had been purged with a stream of nitrogen beforehand in order to remove dissolved oxygen. The nitrogen molecules were found to be disordered at the centers of the threefold rotoinversion axes. To avoid disorder effects during the determination of the deformation density we grew argon-clathrates at 213 K.[3] These gas-inclusion crystals are held together exclusively by van-der-Waals forces. Such clathrates were previously only known in crystals with hydrogen bonds.[4] Two sorts of octahedral holes are present in the ratio 1:2 in the hexagonal closest packed structure of **1** (Fig. 1). The octahedral holes, each of which is surrounded by only one of the four *tert*-butyl groups per tetrahedrane molecule, entrap the gas molecules or atoms. The remaining holes are too small. In the packing diagram (Fig. 1) the positions of the argon atoms are marked by

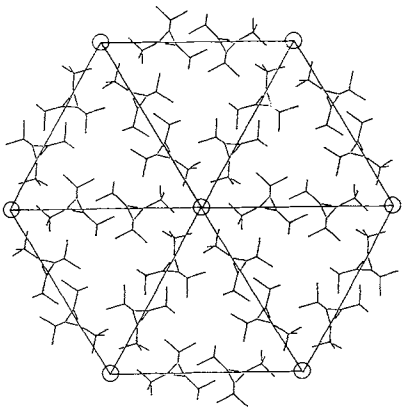

Fig. 1. Packing diagram of the argon inclusion crystal of **1** (projection along *c*); argon atoms marked by circles.

circles. The occupancy in the crystal used was 26%. On heating the crystals in the mother liquor to a temperature above 220 K under the microscope gas bubbles were observed escaping from the crystals and the solution. The crystals became cloudy; without the supporting gas-inclusions the lattice is destroyed. On the basis of low-temperature data, the two mirror-image torsional disorder sites of the *tert*-butyl groups, which extended into the holes occupied by argon atoms, could be refined separately. The torsional angle between the two disorder sites was found to be 26°. The thermal parameters yielded a torsional vibration of 9° for the *tert*-butyl groups, which can be explained in terms of dynamic libration or static disorder. In comparison to the measurement at 213 K[1] the bond lengths were essentially free of effects produced by the non-spherical electron density distribution in the bonds,[2] because of the refinement with reflections of high order.[3]

In all cases the deformation densities were calculated in sections (Fig. 2) along a tetrahedral bond and through the

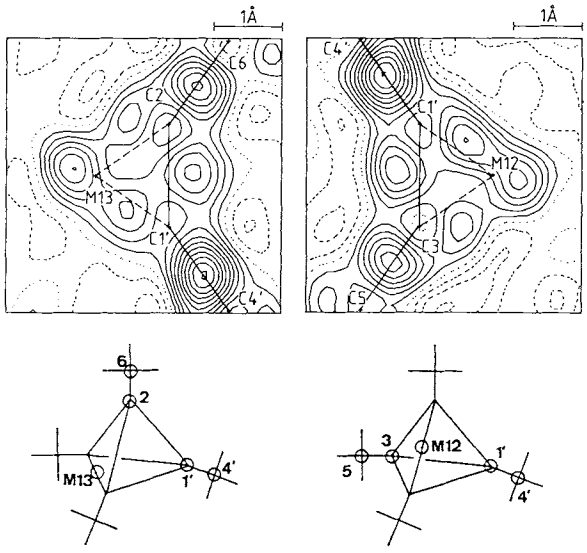

Fig. 2. Deformation densities of **1** [3]. All sections along a bond and perpendicular to the opposite bond of the tetrahedron. The atoms and midpoints of the bonds marked in the formulas with circles all lie in the plane of the section. Contour interval 0.05 e Å^{-3}.

midpoint of the opposite tetrahedral bond. Sections with maxima in special positions (mirror planes) have been ignored because of the high standard deviation ($\sigma(\rho)$ = 0.06 e Å^{-3} vs. 0.04 e Å^{-3} in general positions). The density maxima of the tetrahedral bonds are located 0.37 Å outwards from the bond axis. Therefore these bonds are bent by 26°. The tetrahedrane bond is thus one of the most strongly bent C–C bonds.[5] Theoretical calculations[6] give bends of the same order of magnitude. An arc over the density maximum between two tetrahedrane C-atoms is 1.7 Å long, whereas the distance between the atoms is 1.497 Å. The density maxima of the bonds between the tetrahedrane C-atoms and the quarternary C-atoms of the *tert*-butyl groups (Fig. 2) lie exactly on the connecting lines between the atoms. This is also the case for the C_{quart}–C_{methyl} bonds of the *tert*-butyl groups.

Trimethylenemethane Complexes of Cr, Mo, and W by Novel Methylenation of Allenes with Carbene Complexes; Cyclopentanes by [3 + 2] Cycloaddition of Trimethylenemethane Complexes to Allenes**

By *Rudolf Aumann** and *Jürgen Uphoff*

The development of versatile C_3 building blocks for the synthesis of functionalized cyclopentanes by [3 + 2] cycloaddition continues to be a challenge for many synthetic chemists. In addition to ionic C_3 components,[1] organometallic C_3 building blocks exhibiting 1,3-dipolar behavior[2,3] have been used so far.

We recently described the synthesis of cyclopentanes by [3 + 1 + 1] cycloaddition of vinylcarbene[4] or arylcarbene complexes (as C_3 components) and two equivalents of methyl isocyanide (as C_1 components).[5]

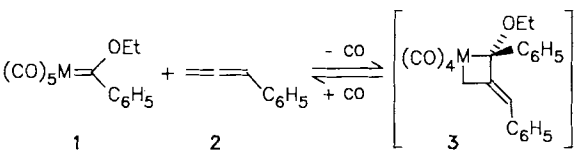
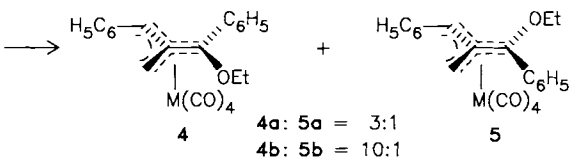
[**] Organic Syntheses with Transition-Metal Complexes, Part 22. This work was supported by the Fonds der Chemischen Industrie. — Part 21: [4].

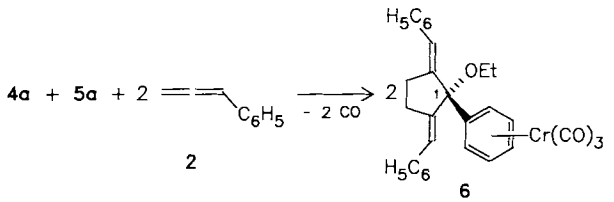
In the course of our studies of metal-promoted cycloadditions, we have now found a novel type of methylenation of allenes **2** with carbene complexes **1**, leading to the diastereomeric trimethylenemethane complexes **4** and **5**. Previous syntheses of such complexes always started from C_4 building blocks in which the carbon framework of the ligand was preformed.[6] In contrast, we were able to construct the trimethylenemethane ligand from a C_1 and a C_3 building block. In this respect, there exists a parallel between this approach and the synthesis of such ligands by template-directed olefination of aldehydes with allenes, which involves the loss of an aldehyde oxygen as CO_2 by reduction with CO.[7]

The reaction sequence, described here for the first time, presumably proceeds via the metallacyclobutane **3**, whose regiochemistry is controlled by the steric demands of the tetracarbonyl metal fragment and by the charge distribution in **1** and **2**; **3** isomerizes to the complexes **4** and **5**. The reaction can be initiated thermally or photochemically. It was investigated for carbene complexes of Cr, Mo, and W (order of reactivity Mo > Cr > W) as well as of Fe.[8] The products **4** and **5** were isolated by chromatography and characterized spectroscopically (Table 1).





4a: **5a** = 3:1
4b: **5b** = 10:1
4c: **5c** = 10:1



a: M = Cr, **b**: M = Mo, **c**: M = W

Table 1. Spectroscopic data for the complexes **4a–c**, **5a**, **6**, and **7**. The substituents and skeletal C atoms of **4** and **5** are numbered nonsystematically. The configurational assignment was based on the ^4J-"W" coupling and on the low-field shift of the resonance of the γ-H (in the *anti* position; cf. [7]).

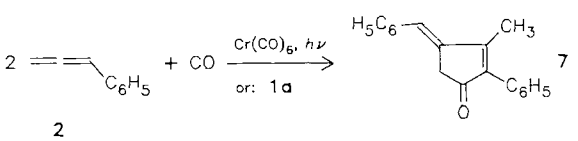
Apparently, an η^4-trimethylenemethane complex is formed from the metallacyclobutane **3** of a transition metal only when a vacant coordination site on the metal is available. Otherwise, as in the case of titanacyclobutanes,[9] metathesis-like reactions may subsequently occur. Taking into consideration the prerequisites discussed above, we assume that our procedure opens up a general route from allenes to new trimethylenemethane complexes.

The diastereomeric trimethylenemethane complexes **4a** and **5a** slowly react with allene **2**, already at 25 °C, to give the carbocyclic five-membered ring compound **6**. In this reaction, which involves a [3 + 2] cycloaddition and the loss of CO, the carbonylchromium fragment migrates to the phenyl group of the original carbene ligand. The addition occurs regiospecifically and leads, with loss of three centers of chirality (!) of the ligands of **4a** and **5a**, to the same product **6**, which no longer has centers of chirality but possesses a mirror plane, as shown by the ^{1}H-NMR (300 MHz) and ^{13}C-NMR (75 MHz) spectra (Table 1).

In the reaction sequence **1a** → (**4a** + **5a**) → **6**, the $(CO)_5Cr$ fragment loses a total of two equivalents of CO. Interestingly, these are then used in a parallel reaction in which two equivalents of **2** and one equivalent of CO undergo a template-directed [2 + 2 + 1] cycloaddition to give the 4-methylenecyclopentenone **7**. The carbene complex



1a appears to catalyze this reaction *thermally*. However, the formation of **7** from **2** can also be induced *photochemically* with $Cr(CO)_6$.

Experimental Procedures

Syntheses of **4a**, **5a**, **6**, and **7**: **1a** (326 mg, 1.00 mmol) and **2** (348 mg, 3 mmol) in 5 mL of dry toluene were heated at 45 °C under an inert atmosphere in a screw-cap vessel for 2 h. After **1a** had been consumed (TLC), the solvent was removed, and the residue was dissolved in 2 mL of toluene and chromatographed on silica gel. Elution with petroleum ether/dichloromethane (10:1) afforded a pale yellow band ($R_f = 0.7$) containing **4a** and **5a** (250 mg, 60% based on **1a**, product ratio 3:1). Recrystallization from petroleum ether at −78 °C gave **5a** as yellow crystals, m.p. = 93.5 °C. Subsequent elution with petroleum ether/dichloromethane (4:1) gave a yellow band ($R_f = 0.5$) containing **6** (80 mg, 16% based on **1a**, m.p. = 174 °C, from petroleum ether at −78 °C). Prolonged reaction resulted in the formation of **6** at the expense of **4a** and **5a**. Finally, a colorless fraction ($R_f = 0.5$) containing **7** (200 mg, 77% based on **1a**, m.p. = 154.5 °C, from ether) was eluted with dichloromethane.

1b and **1c** were allowed to react analogously for 8 h at 20 °C and for 6 h at 80 °C, respectively. For spectroscopic data see Table 1.

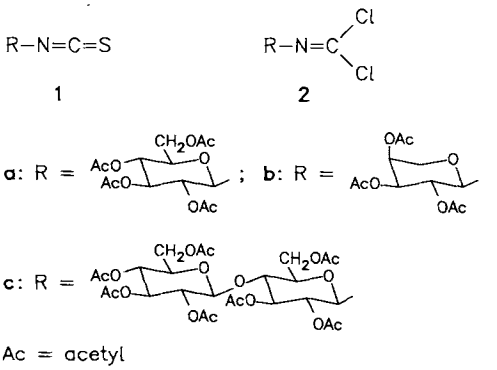
Glycosyl Isocyanide Dichlorides—Novel Synthetic Building Blocks in Sugar Chemistry**

By *Tillmann Hassel** and *Hanns Peter Müller*

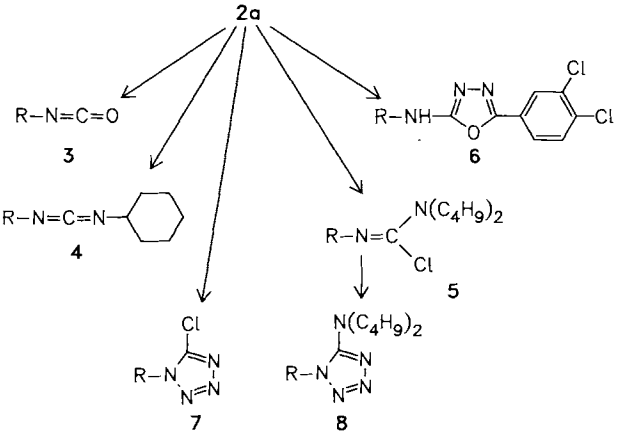
Dedicated to Professor Ernst Bayer on the occasion of his 60th birthday

Owing to their universal reactivity,[1] organoisocyanide dichlorides are of special interest as intermediates in the synthesis of heterocycles. These compounds can be prepared by reaction of organoisothiocyanates with chlorine. We report here on the synthesis of the glycosyl isocyanide dichlorides **2a**–**c** by chlorination of the readily accessible[2,3] glycosyl isothiocyanates **1a**–**c**. By a series of different reaction examples we demonstrate that the synthetic potential[1] of the isocyanide dichlorides can be exploited in carbohydrate chemistry, too.



Reaction of the glucose derivative **1a**[3] with chlorine in chloroform[4] affords the isocyanide dichloride **2a** (m.p. 125 °C) in 92% yield. Glycosyl isothiocyanates of pentoses react analogously; the L-arabino-derivative **1b** furnishes **2b** as an oil in 78% yield. As example for a disaccharide we used cellobiose; the known isothiocyanate **1c**[2] is converted quantitatively into the isocyanide dichloride **2c** (m.p. 200 °C).

The compound **2a** undergoes reactions typical for isocyanide dichlorides[1] without aminolysis or acidolysis of the protecting groups. On heating 0.2 mol of **2a** with 0.2 mol of methanesulfonic acid[5] in 400 mL of chlorobenzene to 110 °C for 40 min the isocyanate **3**, m.p. 115 °C,[6] is obtained in 73% yield. Reaction of 0.1 mol of **2a** with 0.1 mol of cyclohexylamine in the presence of 0.2 mol of triethylamine in 200 mL of toluene at −20 °C to 0 °C leads quantitatively within 12 h to the carbodiimide **4**, m.p. 80 °C;[7] from a solution of 0.03 mol/L each of **2a**, dibutylamine, and triethylamine in toluene, the chloroformamidine **5** (m.p. 92 °C) can be isolated in 70% yield after 12 h.



The synthesis of heterocycles is also possible with the glycosyl isocyanide dichlorides **2**. When a solution of 0.1 mol of 3,4-dichlorobenzoylhydrazine in 70 mL of dimethylformamide (DMF) is added dropwise to a solution of 0.1 mol of **2a** and 1.0 mol of triethylamine in 200 mL of DMF at 0 °C and the mixture then stirred for 15 min at room temperature, after work-up the oxadiazole **6** (m.p. 181 °C) can be isolated in 60% yield. Reaction of 0.05 mol

[**] This work was supported by the Bundesministerium für Forschung und Technologie (Project O3C 1439).

of **2a** with an equivalent amount of sodium azide in 150 mL of DMF at room temperature for 30 min affords the chlorotetrazole **7**, m.p. 172 °C, in 60% yield. The corresponding dibutylamino compound **8** can be prepared analogously from **2a** via **5** by reaction with sodium azide for 1 h. It melts at 87 °C and is isolated in 40% yield (based on **5**).

The structures of all the new compounds have been confirmed by elemental analysis and by IR, ^{1}H-NMR and ^{13}C-NMR spectroscopy.[8] The results reported here demonstrate that glycosyl isocyanide dichlorides are readily accessible, valuable intermediates for syntheses in carbohydrate chemistry.

[4] The isothiocyanate **1** is chlorinated in alcohol-free chloroform until disappearance of the IR band of the isothiocyanate group. Passage of chlorine is then continued for the same length of time again, the mixture heated to room temperature, and the solvent, excess chlorine, and dichlorosulfane removed in a cold trap. The residue consists of the product **2**, which can be purified by conventional methods.

[8] The isocyanide dichlorides **2a–c** show a characteristic IR band at 1660 cm^{-1}; in the ^{13}C-NMR spectra recorded in $CDCl_3$ the carbon signal of the functional group appears between $\delta = 131.4$ (**2b**) and 132.8 (**2a**).

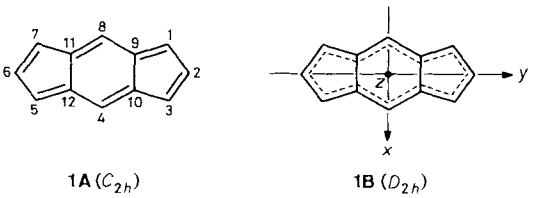
The Influence of Substituents on Double-Bond Localization, e.g. in *s*-Indacene**

By *Edgar Heilbronner** and *Zhong-Zhi Yang*

For Gerhard Quinkert, on the occasion of his 60th birthday

There exists an extensive literature concerning the theory of double-bond localization, beginning with the work of *H. C. Longuet-Higgins* and *L. Salem*[1] up to the detailed investigations of *T. Nakajima* et al.[2,3] In connection with work on *s*-indacene **1A**, **1B**,[4] *Hafner* et al.[5] have dealt with an important extension of the problem, namely the direction and extent by which the tendency towards double-bond localization is influenced by substituents, or in other words, how substitution affects the difference $\Delta_{loc}^{deloc}H_m^{\ominus} = \Delta_f H_m^{\ominus}(\mathbf{1B}) - \Delta_f H_m^{\ominus}(\mathbf{1A})$ of the molar enthalpies of formation of **1B** and **1A**. Using the MINDO/3 procedure, they obtained the values given in Table 1.

Although many-electron treatments are required for the computation of reasonably reliable $\Delta_{loc}^{deloc}H_m^{\ominus}$-values, such models prove rather unsatisfactory for the derivation of heuristic rules of thumb which can be used qualitatively



1A (C_{2h}) **1B** (D_{2h})

Table 1. Influence of substituents on double bond localization in *s*-indacene and *s*-indacene derivatives.

Substituents	$\Delta_{loc}^{deloc}H_m^{\ominus}$ [a] [kJ mol^{-1}]	λ_{max}	λ'_{max} [b]
1 (unsubstituted)	40	1.57	(1.57)
2 (1,3,5,7-tetraalkyl)	8	1.38 [c]	1.35
3 (2,4,6,8-tetraalkyl)	40	1.53 [c]	1.57
4 (4,8-diamino)	<0	1.03 [d]	
5 (2,6-dicyano)	25	1.44 [e]	

[a] From MINDO/3 calculations [5]. Note that the absolute values may be seriously in error; cf. D. F. V. Lewis, *Chem. Rev. 86* (1986) 1111. [b] According to equation (f) with $\delta h_\zeta = -0.3$ and taking multiple substitution into account. [c] For the inductive perturbation due to the alkyl groups, $\delta h_\zeta = -0.3$ has been used. [d] For the amino group: $\alpha_N = \alpha + \beta$, $\beta_{C-N} = \beta$. [e] For the nitrile group: $\alpha_N = \alpha + \beta$, $\beta_{C\equiv N} = 1.2\beta$, $\beta_{C-CN} = \beta/\sqrt{2}$.

when planning or rationalizing experiments. Taking *s*-indacene as an example, we wish to demonstrate how such rules may be obtained.

Some time ago an algorithm was presented[6] which allows one to answer the question of whether an unsubstituted π-system covering all n carbon centers of a hydrocarbon C_nH_m (e.g. $C_{12}H_8$ = *s*-indacene **1**) will prefer to localize its double bonds (e.g. **1A**) or not (e.g. **1B**). First one calculates the bond-bond-polarizability matrix $\boldsymbol{\pi} = (\pi_{\mu\nu,\rho\sigma})$ within the framework of a standard HMO treatment (i.e. all $\beta_{\mu\nu} = \beta$, all $\alpha_\mu = \alpha$, maximum symmetry) using, e.g., equation (a) for an even-centered, closed shell π system in

$$\pi_{\mu\nu,\rho\sigma} = 2\sum_{j=1}^{n/2}\sum_{k=\frac{n}{2}+1}^{n}\frac{(c_{\mu j}c_{\nu k} + c_{\mu k}c_{\nu j})(c_{\rho j}c_{\sigma k} + c_{\rho k}c_{\sigma j})}{x_j - x_k} \qquad (a)$$

its ground configuration ($c_{\mu j}$ is the coefficient of the p-orbital at the center μ in MO ψ_j; x_j is the jth eigenvalue of the Hückel matrix).[7] The second step consists in the computation of the eigenvalues λ_r and the eigenvectors $\mathbf{u}_r = (u_{\mu\nu,r})$ of matrix $\boldsymbol{\pi}$. If the largest eigenvalue, λ_{max}, exceeds a critical value λ_{crit}, then the π-system will localize its double bonds according to $\mathbf{u}_{max} = (u_{\mu\nu,max})$. The critical value λ_{crit} depends on the σ-force constant of the CC bonds, on the value β_0 of the resonance integral and on its derivative $\beta'_0 = (d\beta/dR)_0$ at distance R_0 between bonded centers. A rough estimate yields $\lambda_{crit} \approx 1.7$.[6] Application of the procedure to non-alternant π systems[8] yielded among other results: azulene, $\lambda_{max} = 1.3$; pentalene, $\lambda_{max} = 2.4$; *s*-indacene, $\lambda_{max} = 1.6$. It is known that azulene does not show double bond localization, in contrast to pentalene[9] which presents alternating single and double bonds (C_{2h} symmetry).

We limit our discussion to purely inductive perturbations by assuming that a substituent X in position ζ changes the local α-value by $\delta\alpha_\zeta = \beta \cdot \delta h_\zeta$. Under these conditions, the sign and absolute value of $\delta\lambda_{max}$ [Eq. (b)] yields the answers to the question if and how the substituent X will influence the tendency towards double bond localization of the π-system. Taking *s*-indacene as an ex-

ample, and substituting symmetry equivalent positions $\zeta = 1, 3, 5, 7$ or $\zeta = 2, 6$ or $\zeta = 4, 8$ (thus conserving the D_{2h} symmetry of molecule **1B**) one finds:

$$\delta\lambda_{max} = \left(\frac{\partial\lambda_{max}}{\partial\alpha_\zeta}\right)\delta\alpha_\zeta = \left(\frac{\partial\lambda_{max}}{\partial h_\zeta}\right)\delta h_\zeta \qquad \text{(b)}$$

$$\begin{aligned} \zeta = 1, 3, 5, 7 \quad \left(\frac{\partial\lambda_{max}}{\partial h_\zeta}\right) &= 0.95 \\ = 2, 6 &= -0.50 \\ = 4, 8 &= 0.63 \end{aligned} \qquad \text{(c)}$$

For alkyl groups X the value $\delta\alpha_\zeta \approx 1$ eV may be used[10] i.e. $\delta h_\zeta \approx -0.3$ if $\beta \approx -3$ eV. Substitution of the values (c) into (b) leads to $\delta\lambda_{max} = -0.28$ for 1,3,5,7-tetraalkyl-*s*-indacene **2** and to $\delta\lambda_{max} = -0.04$ for 2,4,6,8-tetraalkyl-*s*-indacene **3** (cf. Table 1). It follows that with respect to **1**, our treatment predicts a smaller tendency towards double bond localization for **2** and no significant change for **3** in agreement with the MINDO/3 calculations.[5]

In view of an analysis of these results, it is of advantage to rewrite λ_{max} in the form of equation (d), from which one obtains (e), according to first order perturbation theory.

$$\lambda_{max} = \mathbf{u}^T_{max}\,\boldsymbol{\pi}\,\mathbf{u}_{max} \qquad \text{(d)}$$

$$\delta\lambda_{max} = \mathbf{u}^T_{max}\left(\frac{\partial\pi_{\mu\nu,p\sigma}}{\partial h_\zeta}\right)\mathbf{u}_{max} \qquad \text{(e)}$$

The expansion of the right-hand side of equation (e) reveals that the leading terms contributing towards $\delta\lambda_{max}$ are those with $j = n/2 = \text{HOMO}$ and $k = 1 + n/2 = \text{LUMO}$ [cf. eq. (a)]. These terms increase (decrease) in first order, if the difference $x_{HOMO} - x_{LUMO}$ decreases (increases) under the influence of the substituent. Note that in this approximation the $c_{\mu j}$ do not change. A purely inductive perturbation by a substituent X in position ζ leads to $x'_j = x_j + c^2_{\zeta j}\,\delta h_\zeta$, from which one obtains as a rough approximation for the λ'_{max} value of the perturbed system (cf. Table 1) the expression (f). Although this expression should be used with caution,[11] some qualitatively useful rules can be deduced from it:

$$\lambda'_{max} \approx \lambda_{max}\left(1 + \frac{(c^2_{\zeta,HOMO} - c^2_{\zeta,LUMO})\,\delta h_\zeta}{x_{HOMO} - x_{LUMO}}\right)^{-1} \qquad \text{(f)}$$

1) Substitution-induced changes in double bond localization tendency are expected to be *large* only for systems with a *small* $x_{HOMO} - x_{LUMO}$ gap.

2) If a substituent decreases (increases) the difference $x_{HOMO} - x_{LUMO}$, then the tendency towards double bond localization increases (decreases).

Remarks:

1) Because a small gap $x_{HOMO} - x_{LUMO}$ implies in general a high value of λ_{max} of the unperturbed system, one expects large changes $\delta\lambda_{max} = \lambda'_{max} - \lambda_{max}$ in the tendency of double bond localization only for such systems. Of special interest are systems with $\lambda_{max} \approx \lambda_{crit}$ (e.g. *s*-indacene, **1**), because substitution will then allow to switch them from a delocalized (**1B**) to a localized (**1A**) ground state, and vice versa, depending on the position(s) of the substituent(s). The discriminating quantity is $c^2_{\zeta,HOMO} - c^2_{\zeta,LUMO}$, the sign of which determines the direction, and the absolute value of the size of the change λ_{max}. In neutral, alternant closed shell π-systems one has $c^2_{\zeta,HOMO} = c^2_{\zeta,LUMO}$, and it follows from (f) that no (or very little) change in the tendency of double bond localization can be induced by substitution.

2) For a given δh_ζ, the sign and absolute value of $\delta(x_{HOMO} - x_{LUMO})$ can be read off orbital diagrams, e.g. those of *s*-indacene (Fig. 1), which is a particular case because of the presence of two accidentally degenerate HOMOs.[12]

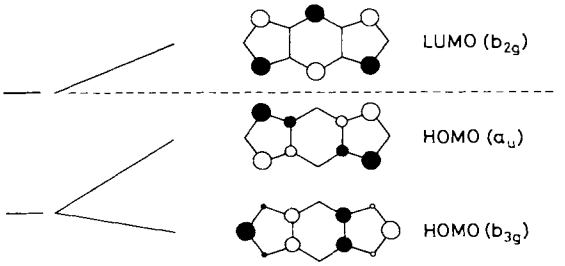

Fig. 1. HMO orbital diagram of the frontier orbitals of **1**.

Substituting, for example, the H atoms at centers 4 and 8 by alkylgroups ($\delta h_\zeta < 0$), leaves the HOMO energies unchanged, whereas the LUMO orbital will be raised. This increases the $x_{HOMO} - x_{LUMO}$ gap and consequently λ_{max} decreases, indicating a decreased tendency towards double bond localization. The above line of reasoning suggests the rule that inductive substituents which lead to a bathochromic (hypsochromic) shift of the LUMO←HOMO band in the UV/VIS spectrum of the molecule[13] will increase (decrease) the double bond localization tendency. In this connection the elegant treatment by *Nakajima* et al.[14] of double bond localization in terms of a pseudo Jahn-Teller effect should be mentioned. However, there are limitations to this attractive rule, which will be discussed elsewhere.[11]

3) The treatment outlined here can be extended to conjugative perturbations. Thus it is found that two amino groups in positions 4 and 8 of *s*-indacene lead to a completely delocalized molecule (**4** in Table) in agreement with the results of a MINDO/3 calculation[5] and the experimental findings.[15] Two nitrile groups in positions 2 and 6 should also reduce the double bond localization tendency in molecule **5**, however to a smaller extent than observed for **2**, as is also predicted by the MINDO/3 model.[5]

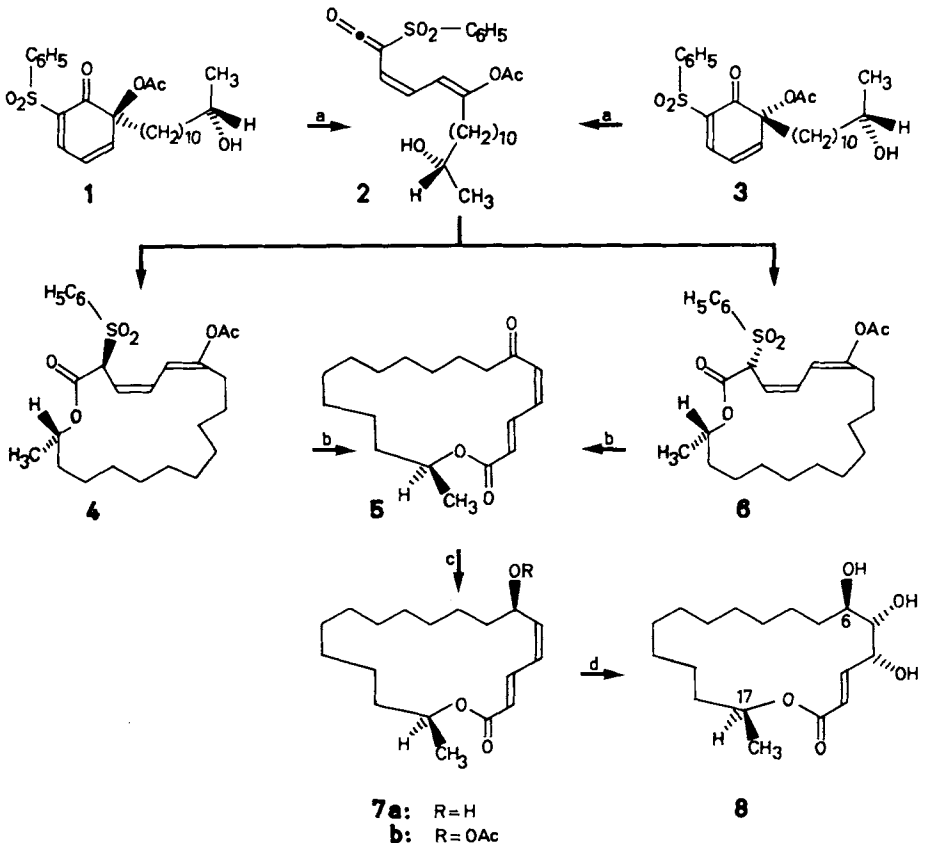
Total Synthesis of the Enantiomerically Pure Lichen Macrolide (+)-Aspicilin**

By *Gerhard Quinkert,* Nana Heim, Jürgen Glenneberg, Uta-Maria Billhardt, Volker Autze, Jan W. Bats,* and *Gerd Dürner*

After having established the absolute configuration of the title compound[1] and having opened up a new synthetic route to large ring sized lactones, we now report the total synthesis of the first isolated lichen macrolide.[2] The core of our total synthesis of (+)-aspicilin **8** is the photolactonization of the diastereomeric *o*-quinol acetates **1** and **3** (via the *seco*-isomeric diene ketene **2**[3]) to the diastereomeric macrolides **4** and **6** (69%, ratio 2.5 : 1;[4] see Scheme 1). The mixture of the photolactones **4** and **6** is converted, without the lactone ring ever being opened again, into the enantiomerically pure target compound **8** via the dienone lactone **5** and the dienol lactone **7a**.

Chemoselective azidolysis[6] of the enol acetate group of **4** and **6** and subsequent elimination of the benzenesulfinate anion, furnishes a 1 : 1 : 2 mixture of **5** and its (*E,E*)- and (*Z,E*)-stereoisomers. The (*E,Z*)-diastereomer **5** has been isolated in 72% overall yield (referred to the mixture of lactones **4** and **6**): 22% immediately after azidolytic elimination, the rest after photoisomerization of the (*E,E*)- and (*Z,E*)-stereoisomers of **5** with light of the wavelength region > 340 nm.[7]

Reduction of the keto group, at −90 °C in toluene, with *Yamamoto*'s reagent[8] converts the dienone lactone **5** with exceedingly high stereoselection almost exclusively into the dienol lactone **7a** (96%).[9] The relative and (as the (*S*)-chirality at C(17) is already known by use of **12**; see Scheme 2) absolute configuration of **7a** have been established by single-crystal X-ray analysis of *rac*-**7b**.[10] The center of chirality at C(17) already present prior to reduction, by the tendency of the CH_3 group to take up the pseudo equatorial position, determines the dominating conformation of the dienone lactone **5**. Due to the preferred approach of the reducing agent from the less occupied half space[11] C(17) finally controls the configuration of the dienol lactone **7a**.[12] Reaction of **7a** with OsO_4 in the presence of pyridine at room temperature in CH_2Cl_2 leads to formation of the target compound **8** in 40% yield. Table 1 lists some physical data of characteristic synthetic intermediates and substantiates, in particular, the identity of the macrolide isolated from *Aspicilia caesiocinerea* with the synthesized target compound **8**.



Scheme 1. a) *hv*, $\lambda > 340$ nm, *N*-methylimidazole (1.3 equiv.), CCl_4, 30 min; flash chromatography [5]. b) NaN_3 (11 equiv.), benzene/water (6 + 1), methyltrialkyl(C_8-C_{10})ammonium chloride (ADOGEN 464®, Janssen), RT, 120 h; separation of **5** by flash chromatography; *hv*, $\lambda > 340$ nm, hexane, 90 min; flash chromatography and threefold repetition of the irradiation-chromatography cycle [7]. c) Diisobutylaluminum hydride in toluene (14 equiv.), 2,6-di-*tert*-butyl-4-methylphenol (28 equiv.), 1 h, 0–4 °C; addition of **5** in toluene at −90 °C, 2 h at −90 °C, 2 h at −40 °C; 0.1 N HCl (aq.); Flash chromatography, crystallization. d) OsO_4 (1.25 equiv.) in CH_2Cl_2 at RT to **7a** (1 equiv.), pyridine (5 equiv.) in CH_2Cl_2, 30 min; methanol (15-fold amount), 15 min passage of H_2S, evaporation, dissolution of residue in ethyl acetate, filtration over Celite, semipreparative HPLC.

group in **14c** has been introduced for two reasons: firstly, for the later conversion of the photolactones **4** and **6** into the stereoisomeric dienone lactones and, secondly, to achieve regioselective Wessely acetoxylation. The oxidation of **14c** with $Pb(OAc)_4$, however, must then be catalyzed by Lewis acid: with BF_3·ether in a mixture of methanol and ethyl acetate[17] the *o*-quinol acetates **1** and **3** are isolated in 85% yield.

To sum up: the synthesis of **8** shows, for the first time, how useful photolactonization for the synthesis of macrolides really is and, once again, that in a cyclic system the information of a remote center of chirality can be transmitted to a high degree to a newly developing stereogenic center.

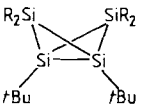
Bond Stretch Isomerism in Bicyclo[1.1.0]tetrasilanes. Contrasts Between Strained Silicon and Carbon Ring Systems**

By *Paul von Ragué Schleyer,* Alexander F. Sax, Josef Kalcher,* and *Rudolf Janoschek*

Dedicated to Professor Tilman J. De Boer, Amsterdam

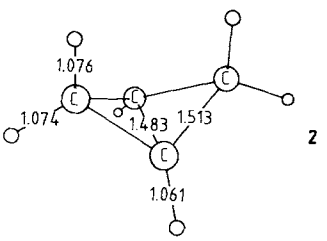
The strains in small ring silicon systems afford interesting contrasts with their carbon counterparts:[1] Three-membered silicon rings are more strained and four-membered silicon rings less strained than their carbocyclic analogs.[1,2] We now show how these differences may lead to *bond stretch isomerism*[3] in bicyclo[1.1.0]tetrasilanes. Although many such possibilities have been considered in carbon ring systems,[3,4] no example of isomers which differ principally in the length of a central bond has been demonstrated experimentally.

Masamune et al. have synthesized and determined the X-ray structure of a highly strained bicyclo[1.1.0]tetrasilane derivative, **1**.[5a,b] Although the ring inversion is extremely facile (barrier ca. 15 kcal/mol), the central bond length, 2.373(3) Å, is not very much longer than that found



1 R=2,6-$Et_2C_6H_3$

for the other Si–Si bonds, which average 2.322 Å.[5c] In this respect, bicyclotetrasilane is similar to bicyclobutane **2** (where the two types of CC bonds have the same, nearly normal lengths),[6] rather than to 2,4-disilabicyclo[1.1.0]butane **3**, where both experiment and calculations find the central C–C bond to be exceptionally long (ca. 1.78 Å).[7] Since other heteroatom substituted bicyclobutanes have abnormally long central bonds,[6a] we have examined the nature of Si_4H_6, the parent compound of **1**, calculationally.



2

The results are quite surprising: At all levels of theory employed, two distinctly different minima were found: **4**[1a] corresponds closely to *Masamune*'s experimental structure, and **5**, *which is lower in energy*, to a geometry

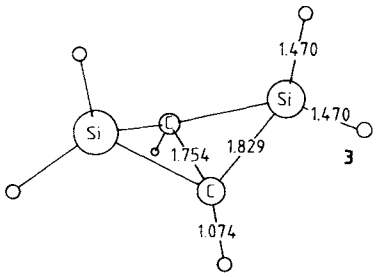
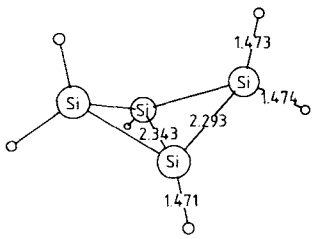
Schoeller*, Bielefeld, for information prior to publication and an unknown referee for suggestions.

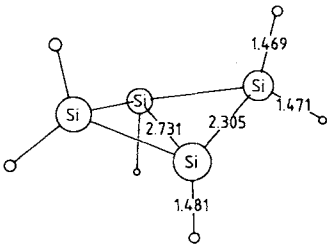


3

calculated recently for Si_4H_6 by *Dabisch* and *Schoeller*.[8] These are "bond stretch" isomers; the bridgehead Si–Si distance in **5** exceeds that in **4** by ca. 0.5 Å (Table 1).



4



5

The Si_4H_6 structures were optimized at the all electron level with the 3-21G (split valence) and d-orbital augmented 3-21G* (polarized) basis sets[9] as well as with the pseudopotential multiconfiguration-self consistent field (MC-SCF) method, using a triply split but unpolarized valence basis set.[10, 11] Of the five configurations employed for the MC-SCF treatment, only two proved to be of major importance, namely $\Psi_b = \ldots(5a_1)^2$ and $\Psi_a = \ldots(3b_1)^2$; whereby $5a_1$ is the bonding MO of the Si–Si bridge, and $3b_1$ is the corresponding antibonding MO.

At all three levels two optimized structures, **4** and **5**, were found. Both have C_{2v} symmetry; the main differences are not only in the Si–Si distances mentioned above, but also in the interflap angles between the three-membered ring moieties (ca. 120° vs. 140°) and in the Si–Si–H angles at the bridgehead positions (ca. 140° vs. 90°). The key geometrical parameters of **4** and **5** are compared in Table 1, along with the corresponding experimental values for **1**.[5b] When one considers that the latter involves heavy substitution and that polarized basis sets are needed for the best results with second row molecules,[9] the agreement between the X-ray geometry and the 3-21G* data for **4** is quite satisfactory.

However, our data indicates structure **5** to be *lower* in energy than **4**. The difference depends on the theoretical level, but is 2.6 kcal/mol with the 6-31G* basis set (3-21G* geometries) and increases to 8.4 kcal/mol with inclusion of electron correlation via perturbation theory (MP2/6-31G*//3-21G*). The multiconfiguration treatment (MC-SCF), which should be better suited for this purpose, gave similar geometric parameters (Table 1) and an even greater energy difference, 17 kcal/mol, favoring **5** over **4**. While part of this further increase may be due to the lack of d-orbitals in the MC-SCF basis set, **5** should be considerably more stable than **4**. Furthermore, the energy barrier separating **4** from **5** is calculated to be quite small, 1 kcal/mol or less. Hence, **4** is not likely to be a viable isomer for Si_4H_6 itself. The MC-SCF lowering of the relative energy of **5** occurs due to considerable admixture of Ψ_a into the total wave function, $\Psi_{tot}(\mathbf{5}) = 0.95\,\Psi_b(\mathbf{5}) - 0.30\,\Psi_a(\mathbf{5})$, which reflects its diradicaloid character. In contrast, the wave function of structure **4** is well represented by $\Psi_b(\mathbf{4})$ only, $\Psi_{tot}(\mathbf{4}) = 0.98\,\Psi_b(\mathbf{4}) - 0.12\,\Psi_a(\mathbf{4})$. Additional consideration of singly and doubly substituted configurations (CI-SD) does not change these results. Thus, the electronic structure of **4** is similar to that of bicyclobutane (**2**).[6b, c] The central Si_1Si_3 bond of **4** has considerable π character (as in **2**) and Mulliken populations indicate the Si_1Si_3 interaction to be antibonding. The bond stretch isomer, **5**, has greater Si_1Si_3 antibonding character, and can be regarded to be a singlet diradical. The nature of this species has been discussed by *Schoeller* and *Dabisch*.[8] As in $SiH_3^{\oplus}$, the bond angles at the bridgehead positions in **5** are close to 90°. This results in a rather close approach of the bridgehead hydrogens. Although **5** is lower in energy than **4** for Si_4H_6, this order will be reversed if bulky substituents, instead of hydrogens, are present at the bridgeheads. We have shown this calculationally by replacing the two bridgehead H atoms in **4** and **5** by methyl groups (but otherwise retaining the Si_4H_6 geometries); this reverses the relative stabilities. The even larger *t*Bu-bridgehead substituents in **1** cannot be accommodated in a structure of type **5** at all; the **4**-like geometry of **1**, in which the *t*Bu groups are separated due to the large RSiSi angles (Table 1), results as a consequence.

$$Si_4H_6 + 5\,Si_2H_6 \longrightarrow 2\,i\text{-}Si_4H_{10} + 2\,Si_3H_8 \quad (a)$$

$$(SiH_2)_n + n\,Si_2H_6 \longrightarrow n\,Si_3H_8 \quad (b)$$

The strain energy of bicyclobutane (**2**) is 66.5 kcal/mol.[12, 13b] A somewhat higher value (70.6 kcal/mol, 3-21G*)[1a] is estimated theoretically for **4** by means of homodesmotic[13] equation (a). This reflects the generally higher strain energy of three-membered silicon over the

[a] Unless indicated otherwise, see [1] for the silicon and [12] for the carbon data. Based on equation (b). [b] This work. Based on equation (a). [c] Other values: 39.6 (6-31G*//6-31G*); 38.2 (MP2/6-31G*//6-31G*); see [1a]. [d] Ref. [12]. Theoretical calculations (6-31G* basis set) give nearly identical values; see K. B. Wiberg, *J. Comput. Chem. 5* (1984) 197.

corresponding carbon ring systems (Table 2).[1,14] However, cyclotetrasilane is less strained than cyclobutane.[1,3] Hence, the opening of bicyclobutane (**2**) to a hypothetical four-membered ring diradical bond stretch isomer would involve less strain relief than the corresponding change from **4** to **5**: roughly 40 kcal/mol for **2** vs. 52 kcal/mol for **4** (this assumes that the four membered ring diradicals have the same strain energy as *cyclo*-Si_4H_8 and *cyclo*-C_4H_8, respectively). A similar treatment has been used by *Wiberg* et al. to analyze ring opening processes in strained polycyclic ring systems.[15] This difference in ring-opening thermodynamic driving force and the inherently lower Si–Si bond dissociation energy (74 kcal/mol in H_3Si–SiH_3 vs. 88 kcal/mol in H_3C–CH_3)[16] are responsible for the preference of Si_4H_6 for the "bond-stretch" structure (**5**) in contrast to C_4H_6 which favors a geometry with normal bond lengths (**2**). These two factors also contribute to the smaller inversion barrier observed for the bicyclotetrasilane (**1**)[5b] than for bicyclobutane (**2**).[17,18]

We conclude that **1** only adopts a structure of type **4** due to the spacial requirements of the bulky bridgehead substituents. If these can be replaced experimentally by hydrogens or by a bridging ring, we predict that a geometry corresponding to the "bond-stretch" isomer **5** will result. Indeed, our preliminary calculations indicate pentasila[1.1.1]propellane to have only a single minimum with a large (ca. 2.9 Å) separation between the bridgehead atoms.

Methods in Enzymology. Vol. 114 and 115. Edited by *H. W. Wyckoff, C. H. W. Hirs,* and *S. N. Timasheff.* Academic Press, New York 1985. Vol. 114: **Diffraction Methods for Biological Macromolecules,** Part A, xxiv, 588 pp., hardcover, $ 64.00;—ISBN 0-12-182014-9. Vol. 115: Part B, xxii, 485 pp., hardcover, $ 55.00;—ISBN 0-12-182015-7

Despite the impressive developments in NMR spectroscopy in recent years, which now allow the secondary and tertiary structures of small polypeptides (< 10000 daltons) to be determined in solution, X-ray crystallography will probably remain the only method capable of providing detailed structural information (namely, three-dimensional atomic coordinates) on larger, globular proteins. Whereas application of NMR techniques to the determination of protein structure is limited by the requirements that the protein be available in large amounts, be sufficiently soluble, and exhibit good stability, the use of protein crystallography primarily depends on the ability to crystallize the macromolecule. Once suitable crystals of the protein have been obtained, the elucidation of its structure can be accomplished within a reasonable length of time, provided that its amino acid sequence is known.

New techniques for the collection of diffraction data (area detectors) and for the interpretation of electron density (high-resolution vector graphics) have not only decreased the time required for protein structure determination, but, even more importantly, have improved the accuracy of the structures obtained. Crystallographic refinement has progressed to a point where the methods available, while still requiring considerable patience, often afford atomic coordinates with error limits of only 0.1 to 0.2 Å. Such highly refined protein structures are, in turn, essential for modeling the interaction of these proteins with small molecules, such as substrates and inhibitors, or for planning site-directed mutagenesis experiments. These applications, in particular, have made protein crystallography an interesting and potentially important tool for the pharmaceutical industry.

The rapid development of this field makes periodic reviews of protein crystallographic methods all the more urgent, but these have been lacking so far. The standard textbook on protein crystallography by *Blundell* and *Johnson* is now ten years old and therefore no longer up to date, although it remains an essential source of information. Thus, there has been a crucial need for a current description of the new methods of high-resolution protein crystallography. This gap has now been filled by Volumes 114 and 115 of the renowned series "Methods in Enzymology." Well-known experts have contributed a total of 63 articles, which provide a more or less comprehensive account of protein crystallography. The individual contributions have been organized into sections dealing with the historical development of the field, crystallization, data collection, phase determination, model building, and presentation of the results. This arrangement, however, is not always optimal. For example, the clearly written article by *R. Sparks* on least-squares refinement is included, less than ideally, in the chapter on phase determination.

The volumes are a gold mine for the specialist if only because of the nearly 700 references to the scientific literature, which cover developments up to 1982 and even include articles published in 1984. It is questionable, however, whether the volumes achieve the goal explicitly stated in the introduction, namely, to provide biochemists with an introduction to macromolecular diffraction methods. This goal is a priori unrealistic for a work consisting of differently arranged contributions from a number of individuals. An exception is the collection of well-written articles on the crystallization of biological macromolecules, which should provide many biochemists with useful insights.

Some of the contributions are more technical in nature or describe specific computer programs; others are comparable to well-planned review articles. Even unpublished material is to be found: The method of "iterative single isomorphous replacement" of *B. C. Wang*, which is best described by the term "electron density modification" (although the author specifically disapproves of this term—I trust he will forgive me), is described here in detail for the first time. This method has been used for the past three years by many protein crystallographers with considerable success—an indication of the excellent communication within this scientific community.

Only a few topics are not covered by these volumes. For example, the important technique of phase combination is not mentioned at all. On the other hand, the section on the systematics of protein structures is remarkably encompassing (with very instructive pictures by *Jane Richardson, Arthur Lesk,* and *Karl Hardman*!). For this reason, Volume 115, in particular, is recommended to all those interested in protein structures, namely, spectroscopists, gene technologists, and theoreticians. Both volumes, however, belong on the book shelf of every protein crystallographer.

Regulation of Secondary Metabolite Formation. Proceedings of the Sixteenth Workshop Conference, Hoechst, Gracht Castle, 12–16 May 1985. Edited by *H. Kleinkauf, H. von Döhren, H. Dornauer,* and *G. Nesemann.* VCH Verlagsgesellschaft, Weinheim 1986. xx, 402 pp., bound, DM 108.00.—ISBN 3-527-26475-2

The production of antibiotics using microorganisms is one of the standard tasks of biotechnology. Mutation and selection have been used to obtain strains giving the best production. This empirical procedure has been employed without knowing how the formation of secondary metabolites depends on the regulating processes. It is remarkable that, in spite of the great importance of antibiotics, the genetic instability of high performance strains is not yet understood, nor has an adequate bridge been established between our knowledge of the biosynthesis of antibiotics and that of the genetics of the organisms which produce them. The mutagenic mechanism for even such a technologically important group as the *Streptomycetes* is much less well understood than that for the classical model *Escherichia coli.*

It therefore seems very appropriate that the 16th Workshop conference arranged by Farbwerke Hoechst was on microbiology, being concerned with the topical theme of secondary metabolites. Twenty papers by acknowledged experts from throughout the world were presented.

Bu'Lock reported on genetic aspects of the production of mycotoxins. *Hopwood* reviewed his group's important and detailed studies on the genetics of the *Streptomycetes*. Problems concerning the genetics of eukaryotic cells were discussed by *Esser*. There were several papers dealing with the important topic of the production of penicillins and cephalosporins, e.g. *Demain* discussed the inhibition by ammonium salts of cephamycin formation in *Streptomyces clavuligerus*. There were contributions by *Luckner* and by *Keller* on alkaloid biosynthesis in molds. *Kleinkauf* and *von Döhren* discussed problems in the synthesis of peptide antibiotics using enzymatic systems. *Vining* reported on his group's researches on genetic and physiological control of chloramphenicol biosynthesis. *Gräfe* in his paper took a close look at the control of secondary metabolite formation in *Streptomyces* by the use of the A-factor (2-(6'-methylheptanoyl)-3-hydroxymethyl-4-butanolide) and its derivatives. *Behal* discussed the regulation of tetracycline biosynthesis, and, in a second paper, the control of formation and activity of secondary metabolic enzymes in general. Synthesis of these enzymes usually only begins after the readily available sources of carbon, nitrogen and phosphorus have been exhausted, and in some cases is inhibited by the end product. *Floss* reported on the biosyntheses of some polyketide antibiotics. *Omura* gave an interesting insight into tylosin biosynthesis and its control by ammonium salts and phosphates. There was also an opportunity to hear a representative of plant biochemistry, when *Grisebach* gave a contribution on the induction and regulation of phytoalexin synthesis in soya-beans. In a concluding discussion, summarized by *Hans von Döhren*, terms were defined and unresolved problems identified. A final summary by *Demain* led to a statement of the following desirable conditions to promote genetic studies aimed at resolving the puzzle of secondary metabolism: 1. that industry should develop genetic systems for technologically important organisms; 2. that there should be agreement in the academic world to use a suitable organism as a model; 3. that investigations on the control of secondary metabolism should be carried out on one particular organism, such as *Bacillus subtilis*, whose genetics are already well understood.

Those engaged in research on antibiotics or secondary metabolites will find this book stimulating. For others it makes interesting reading on an important interdisciplinary field of research, which is at the boundaries between biochemistry, organic chemistry, microbiology and genetics.

Methods of Enzymatic Analysis. Vol. 9. Proteins and Peptides. Edited by *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grassl.* 3rd Edition. VCH Verlagsgesellschaft, Weinheim 1986. xxv, 571 pp., bound. Series price: DM 270.00; individual volume price: DM 310.00.—ISBN 3-527-26049-8

Volume 9 is an entirely new volume devoted to methods for the determination of biologically important proteins lacking enzymic activity, and of hormonal proteins, peptides, and amino acids. The volume is devoted almost entirely to enzyme-immunoassay (EIA) methods. It is divided into five parts, and summarizes methods for 37 compounds or classes of compounds and antibodies.

The first, introductory, part of volume 9 emphasizes current limitations of EIA methods with respect to validation and standardization, and notes the advantages of EIA once a suitable method has been devised. The four chapters in part one—introduction, enzyme immunoassay as an important methodology in biology and medicine, practical considerations in enzyme-immunoassays illustrated by a model system, and problems in the standardization of enzyme-immunoassay for antigens—provide a concise survey of the problems encountered in the development of an EIA method. Some comparisons with alternative methods give the newcomer to EIA some idea as to whether this methodology is worth pursuing further.

Parts 2 through 5 present assay methods for six transport proteins, four carcinoembryonic and pregnancy proteins, twelve structural and regulatory proteins, and fifteen hormones (proteins, peptides and the iodoamino acids triiodothyronine and tetraiodothyronine), respectively. The chapter on calmodulin presents a method based on activation of cAMP phosphodiesterase in the presence of calcium ions and calmodulin and is the only assay in this volume not based on EIA. Of the remaining assays, most are of the heterogeneous double-antibody sandwich-type as used in enzyme-linked immunosorbent assay (ELISA). The other assays represent a small selection of different or modified strategies for using EIA. Reading through the descriptions of the principles of these different assays provides those unfamiliar with EIA some idea of the varied ways in which EIA can be used for analysis.

In a number of chapters a second assay method is included in several different manners. The collagen chapter includes methods for the determination of collagen types as well as a method for the determination of collagen antibodies. The thyroglobulin chapter is of the same form with assays for antigen and antibody. The chapters for α_1- and β_2-microglobulins both contain two methods for use with different concentration ranges of antigen in the sample. The thyroid-stimulating hormone chapter includes a semi-automated assay intended for mass screenings of newborns. The tetraiodothyronine chapter contains assays for both total and free hormone.

A typical assay chapter is composed of seven sub-sections followed by references and is comparable in layout to the metabolite assays in volumes 6 to 8. A general section gives a brief discussion of the compound being assayed and indication of the major application of the assay whether in the clinical or research laboratory; substance properties assayed by alternative methods; and reference and standard methods if available. The assay is then described in detail in the remainder of the chapter, which includes a schematic representation of the assay, conditions for the assay, a listing of required equipment, a list of reagents and solutions, the procedure for carrying out the assay, a section on validation of the assay, and an appendix that typically includes comments on topics such as preparation of antibody and enzyme-antibody conjugates. While considerable detail is provided in these methods chapters, they are not as complete as enzyme-based assays from previous volumes with regard to detailed instructions on the determination of an experimental value. A typical requirement for a calibration curve and variability in the biologically-derived materials used in immunoassays precludes the formulation of an exact procedure.

This volume provides a uniform and detailed single-source reference for EIA methods of use in the clinic and laboratory. It will be most immediately useful to those already familiar with EIA and in need of methods for the

specific compounds covered in the volume. For those developing a new EIA method, this volume provides a variety of approaches to immunoassay and may be a suitable starting point for the development of a new assay. Workers unfamiliar with immunochemistry may find this volume difficult to read and should see chapter 2.7 of volume 1, if not a general textbook description of the science involved in order to be familiar with some of the terminology used.

The appendix to this volume contains lists of symbols, quantities, units and constants; abbreviations for chemical and biological compounds; and formulae useful in spectrophotometry. It is not as extensive as in previous volumes.

Anyone regularly using immunoassay methods in their work should have this book. Those needing to understand the nature and application of EIA and the practical aspects involved would do well to read part or all of volume 9.

Integral/Structural Polymer Foams. Technology, Properties and Applications. Edited by *G. Henrici-Olivé* and *S. Olivé*. Springer, Berlin 1986. xxii, 295 pp., bound, DM 198.00.—ISBN 3-540-15038-2

Integral polymer foams, or structural polymer foams (these being the names used in Europe and in the USA respectively), have a cellular structure, with the density increasing outwards from the core to a rigid skin, thus imitating the structure of wood or bone. Integral polymer foams are often used as a wood substitute.

F. A. Shutov and many other authors from Germany, the USA and elsewhere were involved in putting together this very carefully written book. It deals with the basic relationships between the morphology and properties on the one hand, and the formulating, the equipment and its setting up, and the manufacturing variables on the other. The applications are discussed, together with a summary of the molding of the materials and marketing problems. An economic analysis of commercial processes for marketable materials is also included.

The book deals with the starting materials, the technology of integral polymer foams, and applications using polyurethanes, polystyrenes, polyvinyl chloride, polyolefins, ABS copolymers, polyphenylene oxides, polycarbonates, polyamides, polyesters, polyacetals, polyimides, epoxides, phenyl resins, and other starting materials. It ends with a chapter on rigidity calculations, molding techniques, and considerations affecting manufacturers and users.

Useful features are the numerous figures illustrating equipment, the engineering drawings, flow diagrams and schematic diagrams, together with detailed indexes of manufacturers, processes, products, abbreviations, a contents list, and an excellent subject index.

The book is suitable both for those concerned with the production of these materials and for users, and also for students of the science, technology and applications of polymers.

Radicals in Organic Synthesis: Formation of Carbon-Carbon Bonds. By *B. Giese*. Pergamon Press, Oxford 1986. XIII, 294 S., Paperback, $ 25.00.—ISBN 0-08-032494-0

During the last decade organic free-radical chemistry has undergone a remarkable metamorphosis from a rather prosaic area of limited utility for the construction of carbon-carbon bonds, except in polymers, to one of major synthetic importance with methods capable of providing chemo-, regio- and stereo-selectivity far beyond the most optimistic expectations of early workers in the field. Professor *Giese*, one of those who has played a significant role in bringing about these developments, now provides a timely account of the mechanistic basis and synthetic applications of free-radical methods, abundantly illustrated with examples from the recent literature.

The book opens with a short introduction in which well earned credit is rightfully accorded to those physical-organic chemists whose studies in this area laid that kinetic and mechanistic base upon which the present cornucopia of synthetically useful methods so firmly rests. The main substance of the book is contained in the following four long chapters, each of which deals with a major topic and is subdivided into a number of smaller sections.

In the first of these chapters (Basic Principles) the subsections cover general aspects of syntheses with radicals, elementary reaction steps between radicals and non-radicals, and the comparison of radicals and ions in synthesis. The Author wisely advises the reader to study this chapter carefully since an understanding of the factors which affect the relative reactivities of radicals is essential to the successful application of radical reactions in synthesis. This point is nicely exemplified by a thorough examination of the way in which a knowledge of the rate constants for the individual steps in the reaction of alkyl halides with activated olefins in the presence of trialkylstannane allows the choice of optimum experimental conditions. Another particularly useful topic in this chapter deals with the frontier-orbital approach to radical addition processes.

The next chapter provides a comprehensive account of the intermolecular formation of aliphatic carbon-carbon bonds. It is mainly devoted to addition processes subdivided according to the nature of the reagent (tin hydrides, mercury hydrides, etc.) which reacts with the adduct, but there is also a small section covering synthetic applications of radical-radical reactions. Pleasing features of this and following chapters are the diversity and number of illustrative examples, drawn for the most part from the very recent literature. Indeed dramatic evidence of the level of current activity in this area is provided by the fact that 55% of the 250 or so papers cited in this chapter have been published during the last six years.

The proportion of very recent papers cited is even higher in the next chapter which deals with intramolecular formation of aliphatic carbon-carbon bonds. The many examples in this chapter of the formation of bi- or tri-cyclic ring systems, often related to such important natural products as triquinanes, cephems, and pyrrolizidine alkaloids, clearly shows why this radical methodology is currently attracting so much interest. By comparison the formation of bonds to aromatic systems is somewhat neglected. However, chapter 5 which deals with this topic, indicates the potential synthetic utility of $S_{RN}1$ reactions, of additions involving aryl radicals, and of homolytic substitution in both aromatic and heteroaromatic systems.

The last chapter (Methods of Radical Formation) is quite different from those that precede it. It does not provide a full discussion of the ways in which radicals can be

generated; rather it is a summary index of all the various methods referred to in earlier chapters and as such provides a most useful way of rapidly finding illustrative examples of their use.

In summary, this is a splendid book. Inevitably it is stronger in some areas than in others; I personally would have welcomed a little more discussion of photochemical methods, of phenolic coupling, and of intramolecular aryl addition. But these are minor quibbles. Overall it gives not only a good account of the power and diversity of presently available methods, but also a feeling for the current state of intense activity in this area, and for the potential for new breakthroughs. Anyone who wishes to use the present methodology or to participate in the exciting developments that lie just around the corner should read this book from cover to cover.

Research School of Chemistry
Australian National University, Canberra (Australia)

The Practice of Quantitative Gel Electrophoresis. By *A. Chrambach*. VCH Verlagsgesellschaft, Weinheim 1985. xv, 265 pp., bound, DM 110.00.—ISBN 3-527-26039-0

It must be said at the outset that this is an extremely useful book. Those who have previously used polyacrylamide gel electrophoresis (PAGE) only as an analytical technique will have found the texts by *Weber* and *Osborn*, by *Laemmli* and by *O'Farrell*, sufficient for obtaining reproducible one- or two-dimensional protein patterns, or for determining "apparent" molecular weights. The present book treats sodium dodecyl sulfate PAGE (SDS-PAGE) as just one of the possible forms of gel electrophoresis; everyone who casts gels knows that PAGE did not begin with *Maizel* or *Laemmli*, but a glance at current issues of biochemical journals might lead one to think that most other forms of analytical gel electrophoresis are now being forgotten.

A. Chrambach sees gel electrophoresis as an integrated whole. Consequently, as is stressed in the preface, polyacrylamide gel and agarose gel electrophoresis, isotachophoresis and electrofocussing are treated in unity. The objective is to isolate specific proteins or protein complexes by an appropriate combination of these various methods for passing a protein mixture through a gel. In this connection the native macromolecules themselves are chiefly of interest, as distinct from the dissociated individual proteins that are studied in SDS-PAGE. The concept of "quantitative" gel electrophoresis results from the methodology now available; suitable conditions for achieving a separation are determined using computer programs, taking into account results from theoretical physical chemistry and from statistics. (Some programs are listed in the appendix, while for others a source from which they can be obtained is given in the text.) Experimental arrangements for quantitative electrophoresis are described in detail. In the author's opinion no manufacturer yet offers a system which comes near to meeting all the requirements, e.g. precise temperature control and efficient heat conduction; hence the advice is to build one's own. Following a precise account of the properties of polyacrylamide and agarose gels, the many different available buffer systems for running these gels are described. This leads to a detailed plan for determining the "happiness conditions" which apply to the protein to be isolated, i.e. those conditions under which the protein will retain its native form during its passage through the system. From the determination of the optimal concentration, degree of cross-linking of the separating gel, and pH value, the computer program is used to define conditions for fractionation by PAGE, electrofocussing or isotachophoresis.

The book is arranged in a clear way, and is provided with a carefully compiled index and an extensive appendix. Information on a specific application can be found without difficulty by using the detailed contents list, and the many cross-references give rapid and precise access to important additional information. This book will probably be too complicated for someone wishing to carry out a gel electrophoresis for the first time. For all others, though, who daily encounter problems of protein separation, and are not regular readers of *Electrophoresis*, it will certainly provide useful ideas for new experiments, and open up the possibility of using an advanced technique.

The Importance of Chemistry in the Development of High-Performance Ceramics

By Fritz Aldinger* and Hans-Jürgen Kalz

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Due to their mechanical, thermal and chemical stability, high-performance ceramics have a range of properties which makes it possible in many fields to go beyond the limits of use of the various classes of materials nowadays available. In spite of this favorable starting situation, the worldwide endeavors to introduce this new group of materials have suffered some setbacks in both conventional applications and in new technologies. The ultimate reason is that these materials are very brittle. After the introduction of fracture mechanics, designers in many fields have learned how to handle brittle materials and how to exploit the potential of their properties in components subject to extreme loadings. Materials scientists have also been very successful in developing ceramics with high strength and fracture toughness characteristics. Nevertheless, the field of use has hitherto been restricted, since, in many cases, the reliability of the components is inadequate. Small and very small defects, such as micropores and cracks, as well as any other chemical and physical inhomogeneity in the structure can cause catastrophic failure of the components due to the high brittleness. Since, on the one hand, these defects are as a rule caused by inadequate control of the process sequences and, on the other, the production processes comprise a large number of chemical process steps, it is to be hoped that consistent application of the way of thinking and procedures of a chemist will make an important contribution in overcoming these difficulties.

1. Introduction

Ceramics are nonmetallic inorganic materials. Conventional ceramics have been used from prehistoric times and, for example in the form of fired clay, stoneware and porcelain, are some of the most important materials in industrial development. A group of materials based on certain specific oxides, nitrides, borides and carbides has only recently gained technological importance or is even still at the development stage with regard to future possible applications.[1,2] Some of the most important representatives of this group of materials, which are frequently called high-performance ceramics, are listed in Figure 1. They are attractive because of their unique combination of properties. They share mechanical strength, hardness and wear resistance coupled with high thermal and chemical stability and low density. Most of them are electrical and thermal insulators—but some combine a high electrical resistance with a high (Al_2O_3, Si_3N_4) and in some cases even a very high (AlN, SiC, BeO) thermal conductivity. Some are distinguished by semiconductor properties (SiC) or ion conductivity (ZrO_2), and others exhibit ferromagnetism (ferrite) or piezoelectricity ($PbZr_xTi_{1-x}O_3$) and advantageous dielectric properties ($BaTiO_3$) or are even optically translucent under certain conditions (Al_2O_3).

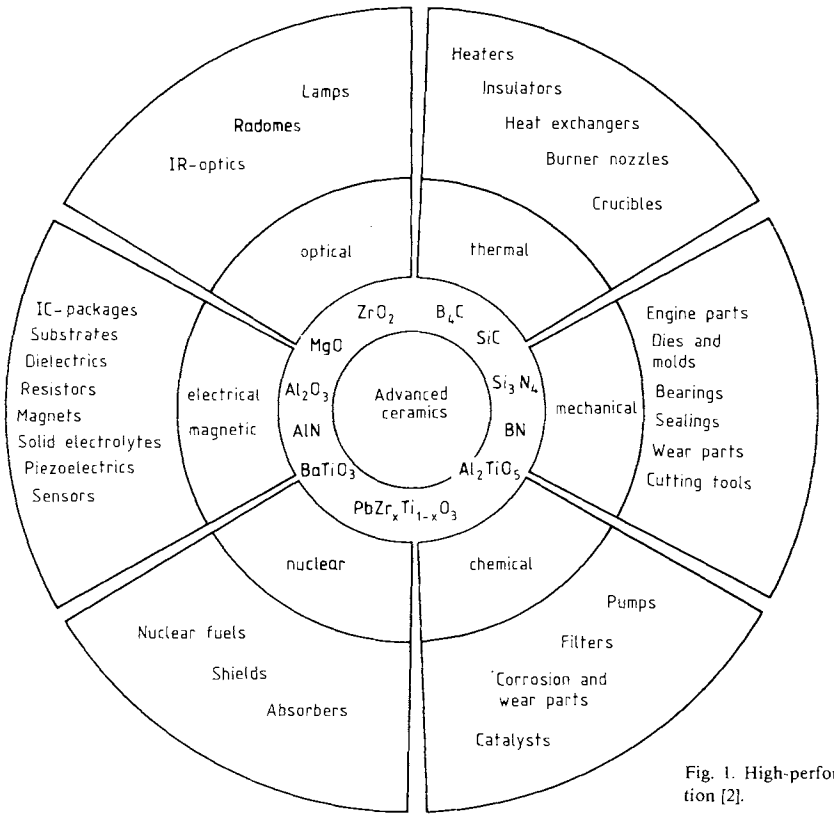

Fig. 1. High-performance (advanced) ceramics and some fields of application [2].

The possible applications, which are subdivided in Figure 1 according to various functions, are considerably diverse. The most important applications, apart from in a wide variety of electrical/magnetic components, are in the field of microelectronics as substrates for integrated circuits. A considerable increase in the use of these materials in engine and machine construction, in chemical process engineering, and in thermal engineering is expected in the future.

However, high-performance ceramics are not only novel with respect to their chemical composition and structure but, compared with conventional ceramics, impose completely new requirements in respect of absolute control of the preparation of the material. Only if starting powders of well defined composition and purity as well as controlled particle morphology are used, and only if all working steps for the preparation of parts (Fig. 2) are carried out under strictly controlled conditions is it possible to obtain the desired performance features in high-performance ceramics.

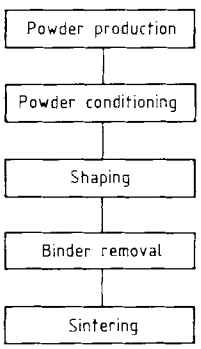

Fig. 2. Process diagram for the production of ceramics.

By contrast, imperfect production conditions lead as a rule to component faults and structural faults, i.e. to products of restricted quality and reliability.

Component faults such as, for example, unduly wide tolerances in the component dimensions, distortion, unevenness as well as surface defects and excessive roughness, cavities and scratches can be eliminated only by considerable subsequent effort or not at all. As a result, the use of such components is as a rule impossible or uneconomical.

Structural faults such as, for example, pores, microcracks, inclusions, i.e. any kind of chemical and physical inhomogeneities, can have adverse consequences when the component is subjected to mechanical stress.[3,4] Due to the extreme susceptibility of ceramics to brittle fracture, such faults lead as a rule to catastrophic failure by fracture even if they are very small (for example 20 to 50 μm) and even under low mechanical stresses. The reason is that stress intensities which are not degradable by plastic flow—as in the case of ductile materials—arise at the structural defects. Consequently, the fracture stress of the material can be reached locally, even if the total stress is far below the fracture strength of the undisturbed material. Since it is known that the stress intensities arising increase with the size of the structural defects, the largest defect present ultimately determines the strength. The strength of the ceramic component is therefore not a constant but a statistical parameter which depends on the type and population of defects (Fig. 3).

Reliable avoidance of defects in ceramics is no mean task in production. Table 1 shows the diversity of the defects which can arise during the most important process

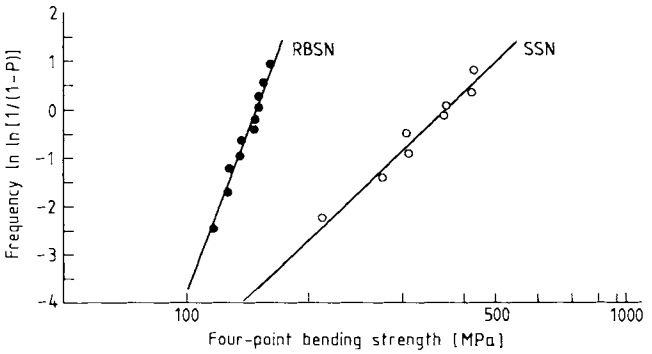

Fig. 3. Typical Weibull distribution of the flexural strength of reaction-sintered (RBSN) and normally sintered (SSN) silicon nitride [2]. P = population.

steps in ceramics production. Since many of the process steps are based on chemical process methods and procedures—as will be illustrated in detail below—avoidance of these defects and hence the economic production of ceramic components is highly dependent on the control of the chemical processes. Chemistry therefore plays a dominating role in solving the existing problems, i.e. its importance in implementing the possible applications of high-performance ceramics is substantially greater than, for example, in the case of the metallic materials which compete with ceramics.

Table 1. Defects in different stages of the processing of ceramics.

Powder	Conditioned powder	Green compact	Sintered parts
Unsuitable particle size distribution	Unsuitable agglomerate size distribution	Flows	Flows
Unsuitable mean particle size	Hard agglomerates	Void clusters	Voids
Nonuniform particle size	Hollow agglomerates	Cavities	Void clusters
Non-equiaxed particle shape	Regions of different density in agglomerates	Insufficient green density	Large voids
Deviations in the composition	Pores in agglomerates	Inhomogeneity in density	Cavities (cavity cracks)
Uncontrolled impurities	Unsuitable viscosity	Inhomogeneity in sintering additives	Circumferential cracks
Foreign particles	Insufficient inert phase suspension	Inhomogeneity in organic distribution	Unsuitable grain size distribution
Oversize particles	Inhomogeneity in additive distribution	Seggregations (inert phase, small particles etc)	Coarse grains
Hard agglomerates	Unstable suspension (sedimentation, flocculation)	Incomplete binder removal	Exaggerated grain growth
	Low inert phase content	Organic inclusions	Zones of different grain size
	Organic inclusions	Dirt	Unsuitable grain boundary phase distribution
		Texture due to particle shape	Second phases (free Si, free C, etc)
			Inclusions
			Surface roughness

Therefore, the chemical aspects in the individual process steps are analyzed below, and a few examples demonstrate the success which is expected or has already been achieved by the consistent application of chemical procedures.

2. Powder Preparation

The first step in the production of ceramics (Fig. 2) is the powder preparation. For ceramics, this is exclusively carried out by chemical processes. A well-known example is the Bayer process which converts bauxite to Al_2O_3. In the western world alone, about 25 million tonnes of Al_2O_3 is produced per year in this way, of which about 2% is processed further to give ceramic components (excluding refractory materials).[5]

2.1. Processes

The processes for the preparation of ceramic powders are very diverse. Depending on the type of starting components and on the requirements of the powders to be produced, different processes are used. Table 2 shows a few examples arranged according to the physical states of the starting compounds. More recent methods, for example powder preparation by the sol/gel process,[6] alkoxides,[7] organosilicon compounds[8] and hydrothermal synthesis[9] can also be included in this table. Supplementary process steps such as, for example, the calcination of intermediates or the processing of raw materials are not separately listed in the table.

Table 2. Preparation of ceramic powders.

Physical states [a] of the starting components	Example
Solid - Solid	Al_2TiO_5 from Al_2O_3 and TiO_2
Solid - Solid - Gaseous	AlN from Al_2O_3, C and N_2
Solid - Liquid	TiO_2 on Al_2O_3 from Al_2O_3 and $Ti(OR)_4$
Solid - Gaseous	Si_3N_4 from Si and N_2
Solid	MgO from $MgCO_3$
Liquid	Al_2O_3 by Bayer process
Gaseous	SiC from CH_3SiCl_3
Gaseous - Gaseous	SiC from SiH_4 and C_2H_4
Liquid - Liquid	Si_3N_4 from $SiCl_4$ and NH_3
Gaseous - Liquid	Si_3N_4 from $SiCl_4$ and NH_3

[a] Including multi-component systems, for example solutions.

The requirements to be met by the powders, and hence by the preparation processes, cannot be generalized. In each case, however, the process parameters of the diverse preparation processes must be controllable to the extent that powders of defined purity can be produced and specific requirements with regard to powder characteristics, for example particle shape and size distribution, can be met. In selecting the procedure, it is a fundamental condition that the economics, i.e. the acceptable cost of the manufacture of a product, must always be borne in mind. The procedure for the synthesis of specific powders therefore not only differs from one ceramic to another, but also from process to process. The chemist can, for example, control a process by way of the following parameters: by choice of starting components (anions of the metal salts, precipitants), of solvents, and of concentrations, and by the kinetics of hydrolyses, polymerizations (oligomerization) and crystallization.

As an example, the preparation of silicon nitride powders, which are intended especially for use in the engineering ceramics field, will be discussed. Such ceramics should exhibit very high strengths (for example 800 to 1200 MPa) at high temperatures (for example 1200 to 1400 °C). From experience gained so far this is best accomplished with powders which meet the following requirements:

mean particle size < 1 μm
narrow particle size distribution
equiaxed particles
95% α-modification
impurity contents for metals $< 0.1\%$, carbon $< 0.2\%$, oxygen $< 1.5\%$

In principle, four routes are presently available for the industrial production of silicon nitride powder:

Nitriding of silicon

$$3\,Si + 2\,N_2 \longrightarrow Si_3N_4 \quad (a)$$

Carbothermal nitriding

$$3\,SiO_2 + 6\,C + 2\,N_2 \longrightarrow Si_3N_4 + 6\,CO_2 \quad (b)$$

Gas phase reactions

$$3\,SiCl_4 + 4\,NH_3 \longrightarrow Si_3N_4 + 12\,HCl \quad (c)$$
$$3\,SiH_4 + 4\,NH_3 \longrightarrow Si_3N_4 + 12\,H_2 \quad (d)$$

Thermal decomposition of silicon diimide

$$3\,SiCl_4 + 6\,NH_3 \longrightarrow 3\,Si(NH)_2 + 12\,HCl$$
$$3\,Si(NH)_2 \longrightarrow Si_3N_4 + 2\,NH_3 \quad (e)$$

Each of these processes gives powders of special characteristics. The main impurities in each case are oxygen and carbon. In the direct nitriding of silicon [eq. (a)], the powders must be ground during the preparation. This could give rise to additional impurities. The same risk also exists in the carbothermal process [Eq. (b)]. Although the products obtained by the gas phase reaction [eqs. (c) and (d)] can exhibit high degrees of purity, there are problems with respect to the grain morphology. It is difficult to adjust the parameter profiles in the reaction zone—agglomerations, whisker formation and inhomogeneous particle size distributions are the consequences. Attempts have been made to overcome these problems, for example by decomposing the products in laser light.[10] The powders obtained in this way are very homogeneous and not agglomerated. However, production on a larger scale by this method has so far not been reported. In the synthesis according to equation (e), by-products are formed which can likewise lead to impurities (NH_4Cl).

2.2. Impurities

Aside from the overall purity, it is above all necessary in powder preparation that the impurities inherent in the preparation, namely oxygen, carbon, aluminum, calcium and iron, be generally controlled. Although a high oxygen content facilitates compaction on sintering, due to glass formation, an excessive glass content reduces the high-temperature strength of the sintered bodies. Moreover, a thick oxide layer on the particle surfaces reduces the sinter activity of a powder. Suitable powders have in general an oxygen content of $< 1.5\%$. Carbon makes compaction more difficult since, on sintering, it reduces the oxygen content or the content of sinter additives by the formation of CO. Residual carbon in a sintered sample increases the susceptibility of the latter to oxidation. For these reasons, the carbon content should be $< 0.2\%$. In the sintered structure, the metallic impurities are enriched in the grain boundary phase which is responsible, to a very large extent, for the mechanical properties. Total metal contents below 0.01% are nowadays reached in good commercial powders. Hitherto, there have been few investigations of the influence of non-metals on the sintering behavior and the properties of silicon nitride.

In the case of oxygen, apart from knowledge of the bulk analysis, it is of interest for the evaluation of the powders to have information on the location of the impurities in the powder particle and on their form of bonding. Figure 4

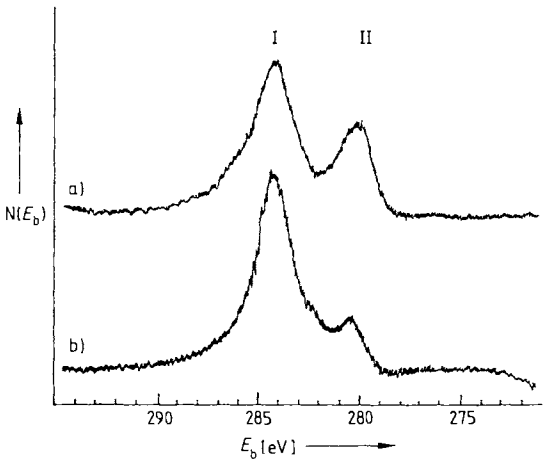

Fig. 4. C(1s)-XPS spectra of Si_3N_4 powders [11]. a) Anzon 1001. b) Ube E-10. I = graphitic carbon, II = carbidic carbon; E_b = binding energy.

shows the XPS signals of the 1s level of the carbon level in two silicon nitride powders.[11] The spectra clearly show that two different carbon species are present. One of these is graphitic carbon with a bond energy of 284–285 eV, and the other is carbide carbon (280–281 eV).

Graphitic carbon can be found on every surface exposed to the atmosphere. In general, it reacts with the residual

oxygen in the sintering atmosphere to give volatile carbon monoxide. In contrast, carbide carbon is firmly bound. As a rule, it remains in the product and has a very pronounced influence on the properties.

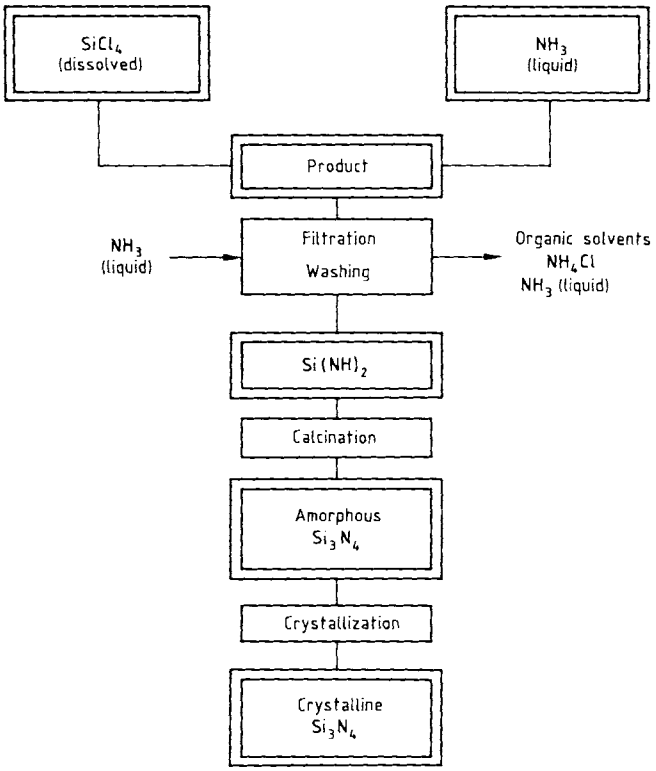

Fig. 5. Preparation of Si_3N_4 by decomposition of silicon diimide [12].

When comparing the qualities of the powders at present obtainable industrially, the impression gained is that powders prepared via direct nitriding and via the decomposition of the diimide (Fig. 5) best meet the aforementioned requirements. Table 3 shows the properties of commercially available powders which were prepared by these two processes. The particle characteristics are very homogeneous and, in particular, they are neither needle-shaped nor platelet-shaped particles, nor are there any extraneous particles visible (Fig. 6).

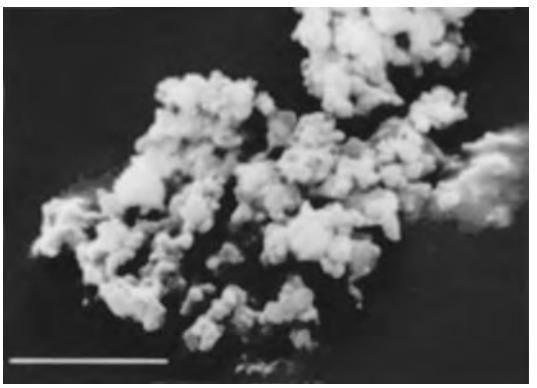

Fig. 6. Si_3N_4 powder (Ube E-10) of advantageous particle morphology. Scale mark = 2 μm.

Although, in the case of alumina ceramics, the sinter additives, frequently in the form of natural products such as kaolin, soapstone or wollastonite, can introduce impurities into the product, the alumina powder itself must also be carefully monitored, depending on the intended use. Impurities originating from the raw material or contaminations due to additives during production (for example calcining auxiliaries) can interfere with both the processing and the finished ceramics. The harmful effect of U and Th impurities is discussed in Section 3. Al_2O_3 ceramics are frequently used in the electronics sector. High insulation resistances and low dielectric constants then represent an essential part of the requirement profile. For example, sodium has an adverse effect on both these properties. In alumina ceramics of high Al_2O_3 content (>99%), impurities such as, for example, SiO_2, CaO, FeO and Na_2O, can reduce the quality of the material.

In the case of aluminum nitride, traces of oxygen (Fig. 7) and also magnesium, iron and silicon sharply reduce the high thermal conductivity of this material.[13]

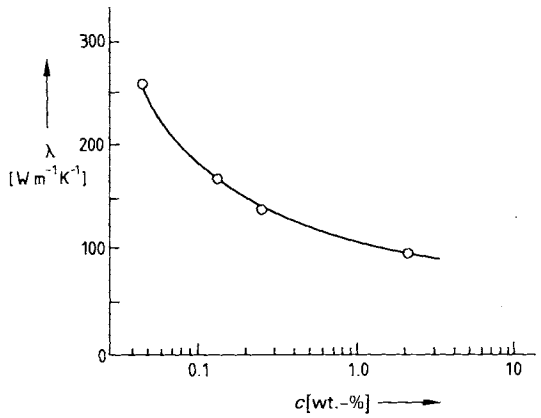

Fig. 7. Thermal conductivity λ of AlN ceramics as a function of the oxygen content c [13].

In the case of silicon carbide those impurities must above all be monitored, in addition to oxygen and carbon, which are introduced by the grinding processes during powder preparation (WC, CO, Ti, Fe). Free carbon has a deoxidizing action on the SiO_2 skins of the powder particles. Fairly large contents have a very disadvantageous effect on the high-temperature strength, particularly if they are present as lamellar graphite inclusions. Oxygen, water and oxides bind sinter additives (B, Al) and thus have an inhibiting effect on sintering. Alkali metal oxides and alkaline earth metal oxides (Na, K, Ca), which form low-melting silicates with SiO_2 and thus additionally impair the high-temperature strength, are particularly disadvantageous. Free silicon also has an inhibiting effect on sintering. Aluminum and iron, as impurities originating from the raw material, are not critical within certain limits. Iron has no substantial effect on sintering and on the strength properties. Aluminum has a getter action and is added as a sinter additive, in addition to boron. An excess of aluminum is disadvantageous, however, because it accelerates sub-critical crack growth at high temperatures.

2.3. Analysis

The composition of the powder is checked by chemical analysis. The analytical procedure for ceramic powders based on aluminum and silicon compounds will be briefly outlined.

The main constituents are analyzed as far as possible by classic wet-chemical methods. For silicon nitride and silicon carbide, the silicon is determined, for example gravimetrically,[14, 15] and aluminum in alumina is determined by complexometry (with *trans*-1,2-cyclohexylenediamine-*N*,*N*,*N'*,*N'*-tetraacetic acid (DCTE)[16]). Nitrogen is determined acidimetrically after a steam distillation, and the carbon and oxygen contents are determined by gas analysis using commercially available apparatus.[17, 18]

The accompanying metallic substances (for example B, Na, K, Mg, Ca, Al, Ti, Fe, Y, Zr) which are present in trace amounts or as secondary constituents are determined by optical methods such as, for example, atomic emission spectrometry with plasma excitation (ICP-AES) and atomic absorption spectrometry with flame excitation (FS-AAS). These methods enable the entire range of desired elements to be determined in a single sample solution. Acids or acid combinations matched as far as possible to the samples are used for digesting the samples in a bomb at elevated temperatures (250 to 320°C) under pressure and with stirring. Compared to alkalis or salts as the matrix for analysis solutions, acids always have the advantage of higher purity. This creates more favorable conditions for low determination limits, good reproducibility and a high degree of reliability of the measured data.

3. Powder Processing and Shaping

Even though powder processing and shaping are two separate working steps, they should be discussed together since they are closely interrelated. Ceramic parts are shaped by various processes (Fig. 8), depending on the form, size and required properties of the components. With a view to low manufacturing costs, the processes mainly of interest are those which involve the preparation of so-called green compacts. These are two-stage processes in which the powder is first compacted in the "cold" state, for example by tape-casting, slip-casting or dry pressing, to give a shape which is then sintered in a second step. In addition, there are processes, such as, for example, uniaxial hot-pressing or isostatic hot-pressing in capsules, where molding and sintering proceed simultaneously. However, these processes are economical only in certain cases. In particular, they appear to be inferior to the two-stage processes for the mass production of components of complicated shapes.

For every production process, the starting powders must be prepared in a suitable manner; in the narrower sense this involves the introduction of two types of additives. On the one hand, these are inorganic additives, i.e. so-called sinter additives, which promote sintering and/or are intended to vary the properties of the ceramic in a controlled manner. As a rule, these additives remain in the ceramic. In most cases they are likewise ceramic powders so that in principle the same conditions are applicable as for the matrix ceramic itself. On the other hand, substances are added which facilitate shaping or even make it possible. Aside from water, mainly organic substances are used which are highly volatile and/or combustible, so that they can be expelled again from the molding without leaving residues before the actual sintering.

3.1. Auxiliaries and Sinter Additives

The usual auxiliaries, as this group of additives is called, and their functions are listed in Table 4. The requirements

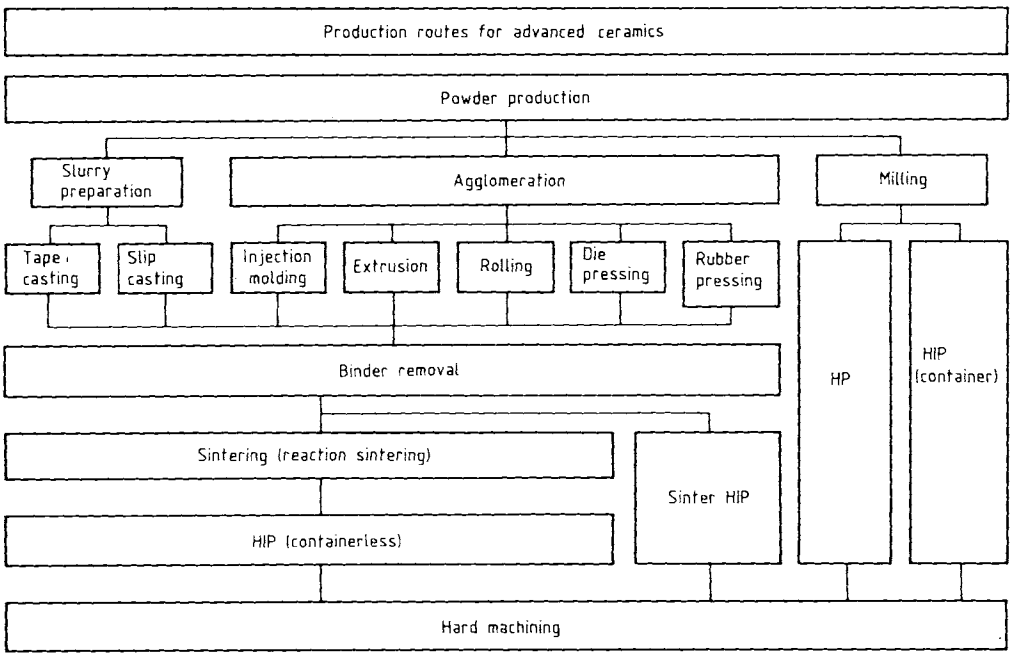

Fig. 8. Production routes for advanced (high-performance) ceramics [2].

to be met by the auxiliaries differ in the various molding processes. In dry pressing and isostatic pressing, they must essentially meet two requirements, firstly the formation of easily flowing and soft agglomerates which allow rapid and trouble-free filling of the press dies where they can be readily pressed, and secondly they must ensure good adhesion of the ceramic powder particles in the green compact, so that the strength of the latter suffices for trouble-free handling. In extrusion and injection-molding, the requirements to be met by the auxiliaries are very similar to those in dry pressing, except that substances to facilitate degassing are frequently also added in injection-molding, especially if the components are relatively large or have relatively thick walls. By contrast, slip-casting and tape-casting make completely different demands on the auxiliaries. For these molding processes, low-viscosity masses are required which dry rapidly after casting without the components distorting or cracking. In addition, easy separation from the tape carrier or the casting mold must be possible. In all cases, the green compacts should be easy to handle, i.e. they must have sufficient strength for further processing. This is in particular a major requirement whenever mechanical working of the green compacts is to be carried out, for example, by sawing, cutting, turning, milling or punching.

These general requirements to be met by the auxiliaries are very complex in individual cases, so that the demand for fault-free production presupposes a deep understanding of the interaction of the auxiliaries with one another, with the dispersed ceramic powders, and with the mold materials. Absolute control of molding and the production of perfect components is possible only with an exact knowledge of the composition of the molding masses and the influences of the processing parameters on their phase composition, structure, and rheological behavior.

These problems will be explained in more detail, taking tape-casting as an example. This forming process is nowadays used on a large scale throughout the world for the production of thin alumina plates as substrates for the mounting of electronic circuits (Fig. 9).

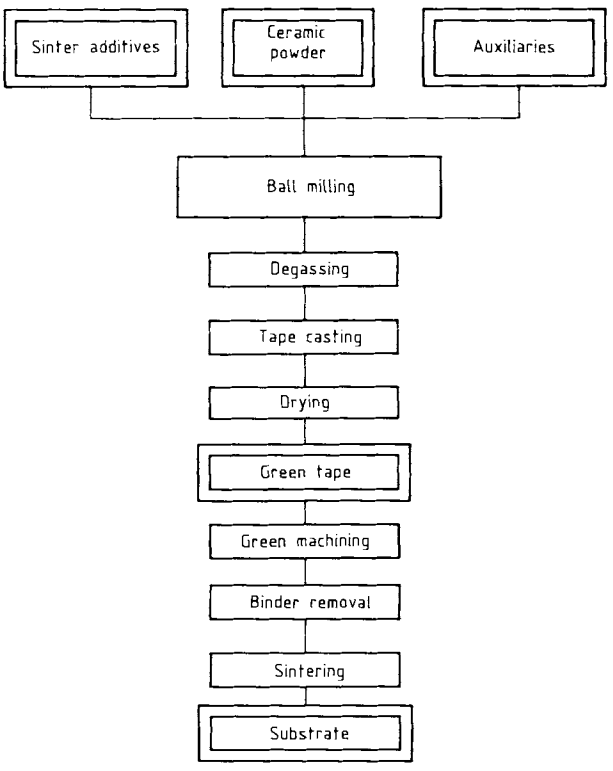

Fig. 9. Process diagram for the production of substrates for electronic circuits.

A low-viscosity casting mass (of about 5 to 20 Pa s) is prepared from the ceramic powders and the admixed sinter additives together with the auxiliaries; this can then be cast by the so-called doctor-blade process (Fig. 10) in which it is applied via the casting head to a tape carrier,

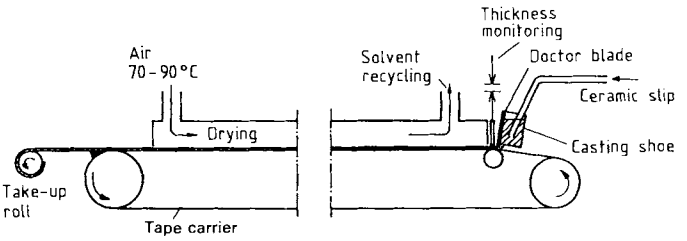

Fig. 10. Sketch of a production unit for ceramic green tapes.

i.e. an endless strip of steel or a polyester film. Between the casting head and the tape carrier, there is, in the direction of casting, a narrow gap (0.5 to 1 mm) which is adjustable by means of a blade (doctor blade) and by means of which the thickness of the tapes is controlled. After passing the doctor blade, the mass passes through a drying section where the solvent evaporates and a leathery sheet is formed. At the end of the drying section, the sheet is taken off the tape carrier and wound, for example on reels. The dimensions of such tape casting machines are about 20 to 25 m in length and about 1 m in width. Typical casting rates are about 0.5 to 2 cm s^{-1}.

The casting masses which can be processed by this method represent a very complex system. The starting point for a suitable formulation is in every case an alumina powder, with which the requirements to be met by the finished product can be fulfilled. In general, powder qualities of a mean particle size of 2 to 3 μm, a not unduly wide particle size distribution and a specific powder surface area of about 2 $m^2 g^{-1}$ are used. The purity is normally higher than 99.7%.

In spite of the high purity of the matrix powders, it is still usual to use natural products as the sinter additives. These are as a rule silicates such as kaolins, talcs, wollastonites and, for special applications, also zircon. Alternatives are carbonates and also basic carbonates. However, the natural substances have the disadvantage of impurities and of a composition which is not reliably constant from one charge supply to the next. Moreover, there are also problems with respect to the particle size properties as compared with the frequently very fine matrix powders.

The traces of uranium and thorium frequently present in kaolin, soapstone and zircon are very disadvantageous for applications in electronics. The α-radiation generated in the decay of these elements leads to the feared "soft er-

rors" in memory components.[19] A further problem in processing the natural layer silicates such as kaolin or talc is the loss of structural water in the temperature range from 600 to 900 °C. This is the range in which usually high rates of heating are used. There is therefore a fear of such effects damaging the microstructure of the ceramic components which are not very strong in this temperature range (at this point, there are no longer any "binding" organic constituents present), and this can later lead to defects in the ceramic product.

A sustained improvement can be achieved by using synthetic sinter additives such as oxides and silicates of calcium, magnesium, aluminum and zirconium. An advantage of the synthetic materials is that the release of water takes place at lower temperatures (<400 °C) than in the case of the natural sinter additives which contain structural water. Furthermore, with the synthetic additives a controlled surface treatment, e.g. a modification of the surface by means of auxiliary components such as dispersing groups is simpler. There are a number of classes of compounds which can be bonded, for example to silica surfaces, by chemical reactions, such as, for example, alcohols, esters, alkoxy compounds, and silanes.[20,21]

3.2. Examples of Auxiliaries and Their Uses

The conventional auxiliaries and their functions are listed in Table 4. Their nature and composition depends finally on the ceramic constituents. For casting masses for the production of a standardized material of 96% of alumina and further phases composed of SiO_2, MgO and CaO, the following composition has proved suitable (data in wt.-%):[22]

65% of ceramic substances
3% of binder (poly(vinyl butyral))
3% of plasticizer (dioctyl phthalate)
1% of dispersant (fish oil)
28% of dispersing agent (trichloroethylene/ethanol)

Table 4. Auxiliaries for the shaping of advanced ceramics.

Shaping	Auxiliaries	Function of the Auxiliaries
Dry pressing	Polyacrylates, huminates	Dispersants
	Polyvinyl alcohols, tylose, waxes	Binders
	Polyethylene glycols	Lubricants
Slip casting	Polyacrylates, fish oil	Dispersants
	Polyvinyl alcohols, mod. polysaccharids, polyvinyl butyrals	Binders
	Water, trichlorethylene, ethanol	Dispersing agents
Tape casting	Oleates, polyacrylates, phosphate esters	Dispersants
	Poly(vinyl butyrals), polyvinyl alkohols), polyacrylic resins, emulsions,	Binders
	Phthalates, polyethylene glycols, phosphate esters,	Plasticizers
	Toluene, trichlorethylene, methanol, methyl isobutyl ketone, water	Dispersing agents
Injection molding	Oleates, polyacrylates	Dispersants
	Polyethylene, polystyrene, waxes,	Binders (dispersing agents)
	Polyethylene glycols	Lubricants
	Caster oil	Baking aids
Extrusion	Polyacrylates	Dispersants
	Polyvinyl alcohols, tyloses	Binders
	Polyethylene glycols, glycerine	Lubricants

Initially, the ceramic constituents must be dispersed in a liquid phase. In the present example, an organic dispersing agent is chosen for this purpose. For absolute reproducibility of the processes, complete dispersing of the powders is absolutely necessary, and this is ensured by the use of dispersants, in addition to mechanical processing.

The choice of suitable *dispersants* is not easy and depends on both the nature of the powder surface and on the type of dispersing agent. There are particular problems when different powder species or sinter additives are used in a mass, where optimum dispersing of all the powders is not possible with a single dispersant. Should this be the case, and the use of several dispersants becomes necessary, there is a risk of mutual interaction of the dispersants, whereby the entire system may be destabilized. In this case, it is possible to use surface-modified powders (see Section 3.1) and thus to avoid these difficulties. Before choosing the dispersant, it is advisable to characterize the surfaces of the solids. In addition to the usual powder particle characteristics such as the BET surface area and the particle size distribution, a knowledge of the chemical properties of the powder surface is necessary.

Measurements of the potential in organic solvents are often difficult. Hence, microcalorimetric and potentiometric titrations in neutral solvents can provide supplementary information on the sign and quantity of charges on the powder surface. A further assessment of the ease with which, for example, surface-active substances carrying P=O, C=O, OH or NH groups (for selection of the dispersants) can be added to the powders can be obtained by measuring the band shift of those groups in FTIR spectra (measurement in diffuse reflection) as compared with the isolated substances.

Moreover, the effect of dispersants can also be evaluated via the sediment volumes by means of sedimentation tests on dispersions, which are easy to carry out. Rheological measurements of the dispersions give further indications. A dispersant which is very frequently used in the preparation of substrates is fish oil.[23]

The choice of *dispersing agent* depends above all on its dissolving capacity, on the binder, and on the temperature level in use. Other important aspects relate to safety, the environment, and the price.

A very frequently used dispersing agent is trichloroethylene in conjunction with ethanol. The addition of ethanol is necessary in order to raise the solubility of the organic binders used here. The mutual ratio of the two organic solvents is in the range of the azeotropic mixture (27% ethanol, 73% trichloroethylene, boiling point 72.9 °C).

Regarding the quality of the solvent, it goes without saying that the requirements in respect of purity are exacting.

In the case of ethanol, the composition (denaturant, water) must be carefully checked, since any change affects the rheology of the casting slurry and jeopardizes the reproducibility of the process. As a result of these requirements, for example, solvent recovery or solvent-reuse involve considerable difficulties.

Since, in addition, the solvents are either flammable and/or cause environmental problems, work is proceeding on the substitution of the organic solvents by water. Apart from the advantage of compatibility with the environment and the safety aspects, however, water has the disadvantage of lower volatility, so that drying takes longer. Of course, the use of water also involves different binder systems, which entails a large number of difficulties. For example, many of the available plastics dispersions have such a tendency to foam that complete removal of occluded air from the tape-casting mass raises problems. Cracks in the green tape are then the consequence. For these reasons, water-based systems for substrate preparation are not yet generally available.

To ensure adequate strength of the desired ceramic green tape—for example it must be workable by punching and notching steps—*binders* are added. Poly(vinyl butyral) has proven suitable for the preparation of ceramic Al_2O_3 substrates and IC packages. Poly(vinyl butyral) is produced from poly(vinyl alcohol) and butyraldehyde; the molecular weights of the products of interest are 30000—80000. Not all the OH groups of the poly(vinyl alcohol) are acetalized, and about 19% of the compound is in the form of poly(vinyl alcohol). Since these groups compete with other surface-active compounds (dispersants) and can undergo interactions with the ceramic particles, strict adherence to the chemical composition and molecular structure is here again necessary for reproducibility of the process. Small changes in the molecular structure can lead to changes in the density of the green tape, and these cause problems with the dimensional accuracy of the finished ceramic components.

The poly(vinyl butyrals) used have a glass transition temperature of 50°C. For this reason, *plasticizers* are added, which reduce the glass transition temperature down to the range of room temperature or even down to below 0°C. Easily workable tapes are obtained only in this way. Tape parameters such as, for example, the tear strength and extensibility can be controlled and adapted to the requirements of working the green product by means of an adroit combination of the quantities of binder and plasticizer and also the types of plasticizer. Usual plasticizers are dioctyl phthalate, dibutyl phthalate, benzyl butyl phthalate, and phosphate esters.

Other important parameters affecting the formulation of the casting mass are the drying and adhesion of the sheets to the tape carrier. Thus, for example, formation of a skin on the cast tape must be avoided, since it would impede the healing of casting defects and drying.[24] Sticking of the sheet to the tape carrier can be avoided by a suitable choice of the carrier material and/or by means of additives to the casting mass. Sticking to glass substrates can be reduced, for example, by the use of binders showing an acid reaction (after aging, the glass surface has an acid reaction).

Furthermore, apart from high flexibility, extensibility and tear strength, the sheet must have good storage stability, i.e. the structure of the binder phase should no longer change after drying. All these requirements make it clear that the tape-casting process gives products of constant quality only if detailed knowledge of the chemistry of casting masses has been exploited.

4. Finishing of Ceramics

The production of ceramics is concluded by a temperature treatment, in which essentially two processes take place. First, the auxiliaries added for molding must be "expelled" again from the green compact, i.e. they must be vaporized and/or burned. This process step—frequently called baking—takes place at moderately elevated temperatures and is in general complete at 600 to 700°C. In the second step, the so-called sintering which is carried out in the temperature range between 1200°C and 2300°C, the components are "fired". In this stage, the individual ceramic powder particles sinter together, and a more or less dense body having the known outstanding mechanical properties is formed.

4.1. Baking

The removal of the auxiliaries by *baking* must be carried out with great care, that is to say they must be removed quantitatively before the components undergo dense sintering, since even minute residues have as a rule a very detrimental effect on the mechanical properties of the materials. A forced procedure also involves the risk of an uncontrolled loss of mass or sudden melting of the binder phase causing irreparable damage (cracks) to the components, thus reducing the yield. If, on the other hand, baking is carried out too carefully, the process sometimes takes a long time, and this above all adversely affects the cost. The aim is therefore an optimized baking rate for obtaining components which are free of residues. This presupposes an exact knowledge of the reactions which occur during baking, and of their kinetics.

As explained in Section 3, the formulations for the individual forming processes involve a fair number of auxiliaries, some of which belong to very different classes of substances (Table 4). The reactions during baking and the time curve of the loss of mass as a function of temperature can be correspondingly complicated. Figure 11 shows the result of a thermogravimetric investigation, taking the example of a green tape composed of a mass system which is similar to that shown in Section 3.

The reaction starts at about 200°C and is complete at about 500°C. As can be seen from the diagram, the weight loss is not uniform at a given constant heating rate, but shows a maximum weight loss at about 220°C. In addition, the thermogravimetric investigation indicates the occurrence of several reactions.

The aim of every process development is uniform baking, i.e. a mass loss which is constant in time. There are two different possibilities for solving this problem. On the one hand, baking can be extended over a wider tempera-

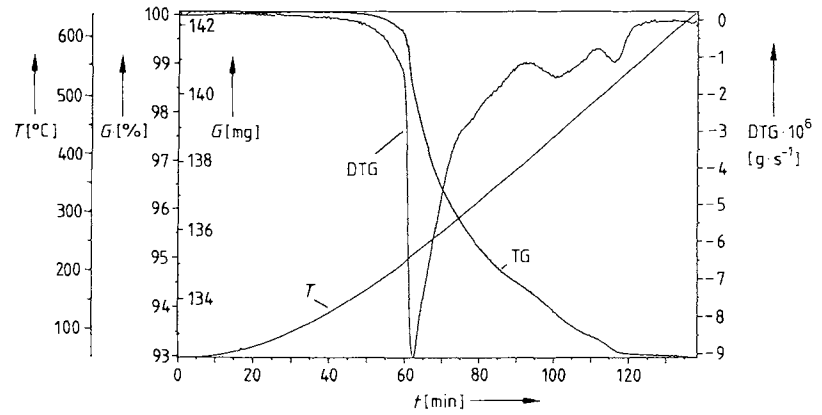

Fig. 11. Thermogravimetric (TG) investigation of an Al_2O_3 green sheet (heating rate 5 °C/minute in air). The result of the differential thermogravimetric analysis (DTG) is also shown. The absolute weight G of the sample and the weight relative to the initial weight are given.

ture range by means of a suitable blend of different types of binder and plasticizer. On the other hand, the temperature/time profile on heating up can be chosen such that the mass loss per unit time is constant over the entire reaction range. In general, this leads to temperature programs with widely fluctuating heating rates. In the case of highly exothermic reactions, temporary cooling phases may even be necessary.

Apart from the thermogravimetric and thermoanalytical investigations already mentioned, mass spectroscopic methods in particular are suitable for establishing optimized temperature programs for baking. Especially if carried out simultaneously, these investigations provide information on the reaction products and the type of reactions.

The ultimate technical and economic importance of knowledge of the processes during baking becomes clear from the example of the injection-molding of large and thick-walled components. For exhaust gas turbocharger wheels of, for example, silicon nitride, baking periods of several weeks or even months may become necessary because of high proportions of binder—particularly in the case of large wheels. The development of new mass systems with a chemical composition and reaction kinetics which allow rapid baking of the molded components without leaving any residues, is therefore of prime importance for ceramic high-performance materials. This problem can be solved only with the aid of a fundamental knowledge of the chemistry of these systems and their reaction kinetics.

4.2. Sintering

In the final high-temperature treatment—the actual sintering—the moldings are given their final properties. As already mentioned, the individual ceramic powder particles sinter together in this step. The driving force for this process is the reduction of the specific surface area of the compacted powder. The material transport occurring at this stage can proceed by very different mechanisms. In principle, these are diffusion processes, and the shares of surface diffusion, grain boundary diffusion and volume diffusion can differ widely for the individual types of ceramics. In addition, gas transport reactions may make an important contribution to the densification process. Since these are thermally activated transport processes in every case, the share of the individual mechanisms and hence the rate of densification are very highly dependent on the temperature.

The sinter additives, and especially those which form liquid, i.e. glassy phases, can be an important factor here. In many cases, sintering would be impossible without such additives. This is true, for example, in the case of silicon nitride, which has very low self-diffusion coefficients and the dissociation constant of which is relatively high. As a result, noticeable decomposition takes place before the temperatures are high enough for sufficient densification. This difficulty can be overcome only to a certain extent, even by working under high nitrogen pressures. The cause is the covalent structure of the silicon nitride, i.e. the strongly oriented bonds in conjunction with the extremely low self-diffusion coefficient make sintering more difficult. In general, only the simultaneous application of high mechanical pressures and temperatures, as in uniaxial or isostatic hot-pressing, is successful, that is to say processes which are economical only in exceptional cases. Information on sinter additives which noticeably reduce the diffusion coefficients is therefore indispensable.

So far, however, only additives are known with which a sufficiently fast densification takes place via the formation of glass phases. But, since the glass phases control the high-temperature resistance, i.e. greatly reduce the latter because of their limited viscosity, this approach is only sometimes successful with regard to high-temperature applications. It is not yet clear whether the current approaches to overcoming these difficulties represent a solution. For example, utilization of favorable phase equilibria is aimed at effecting dissolution of the glass phase in the matrix lattice or a devitrification, i.e. a transformation of the glass phase into crystalline phases.[25] Unfortunately, however, the results obtained so far represent only a partial success. The reason is the adverse change in the silicon nitride lattice, which accompanies the transformation of the glass phase, and/or adverse effects of the crystalline phases.

Hence the search for suitable additives which directly and significantly facilitate self-diffusion in silicon nitride still represents a major problem. For silicon carbide, boron and aluminum are known as additives which have this effect.[26] With a view to economical processes, however, the sintering temperatures of about 2300 °C are very high.

An interesting preparative variant for silicon carbide and in particular for silicon nitride is reaction-sintering. In the case of silicon nitride,[27] the starting material here is a molding of silicon powder which is nitrided at moderate temperatures (for example 1450°C) in a nitrogen atmosphere. However, the nitride being formed only partially fills the original pores so that, according to the present status, no dense samples can be prepared without additional process steps such as, for example, hot isostatic pressing.

For oxidic ceramics, which are predominantly of ionic character, sinter additives do not have this paramount importance. Here again, however, the choice of suitable sinter additives and especially their control is an important factor and, in many cases, they indirectly determine the quality of the product and the economics of the process.

5. Concluding Remarks

It is shown in this paper that, in the field of high-performance ceramics, the development of materials and the provision of reliable components crucially depend on the elucidation and control of the chemical relationships in the process steps including powder preparation. The great importance of these results is underlined by the fact that, for both the ceramic green compacts and for the fired products, no non-destructive test methods exist which would allow reliable detection of microscopically small but serious structural defects. It is therefore not always possible to pick out defective components and—if they are detected at all—these defects can be eliminated only in a limited number of cases. The emphasis of the measures to be taken is therefore on the prevention of defects, i.e. on a careful characterization of all precursors, intermediates, and finished products, combined with meticulously strict adherence to all working instructions and the particular production parameters.

A number of problems have here been discussed only briefly by reference to a few examples of selected ceramics. However, there are many fields in the high-performance ceramics sector, where a greater knowledge of chemistry is also highly desirable. Examples which may be mentioned here are questions relating to constitution and, in particular, compatibility. These are of great importance in connection with reinforcing mechanisms, i.e. the development of whisker-, fiber- or particle-reinforced ceramics. Many questions also remain with regard to the corrosion behavior in present and future applications of high-performance ceramics in engine construction and in chemical equipment manufacture. In the first place however, the raw material and process engineering aspects in the production of ceramic components are of predominant importance, and the feasibility of the numerous promising applications of high-performance ceramics crucially depends on the solution of these problems.

Genetic Engineering with Plants

By Peter Eckes, Günter Donn, and Friedrich Wengenmayer*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Today there are no longer any basic problems involved in isolating and characterizing plant genes. Our knowledge of the structure and function of the genes so far sequenced provides a beginning understanding of gene regulation in plants. In connection with the recently developed methods of gene transfer to plant cells, the most important application is the production of plants with new characteristics through genetic engineering. Since the genes can be transferred from any kind of plant—indeed even from any organism—completely new possibilities are opened up for plant breeding.

1. Introduction

Ten years ago molecular biologists succeeded in isolating the first structural gene of a plant enzyme.[1] Since then, developments in the field of plant molecular biology have opened up possibilities for practical applications that were previously inconceivable.

The first isolated gene, which is localized on the DNA of chloroplasts, encodes the large subunit of the enzyme ribulose-1,5-bisphosphate carboxylase (rubisco). This enzyme enables plants to bind CO_2 from the air. Indeed, the entire chloroplast DNA of tobacco has already been sequenced[2]—it consists of 155844 base pairs. Meanwhile, methods have become available for the stable transfer of foreign genes into plants; "transgenic plants" have already been obtained in numerous laboratories. In the USA, official approval has recently been given for the first field trials with plants that have been altered by genetic engineering.

The growing interest in the biochemistry and molecular biology of plants is also indicated by the increasing number of publications in this field. Industry, mainly in the United Kingdom, the United States, and Japan, has also begun to establish research groups in this area (Table 1).

Table 1. Number of companies involved in the application of biotechnology to agriculture (taken from [3]).

Country	Number
Italy	1
Federal Republic of Germany	2
France	5
Japan	12
United Kingdom	15
USA	73

Several factors are responsible for the recent successes and the growing interest in the biochemistry and molecular biology of plants. One of the most important is scientific interest in the gene structure and gene regulation of plants. Knowledge in this area lags far behind what is known about prokaryotic and animal cells.

A further reason for the great interest in the molecular biology of plants is the close relationship between the basic knowledge obtained and its possible applications in agriculture. In principle, genes that are responsible for the expression of an important trait can be isolated from any plant or other organism and transferred into crop plants. In this way, characteristics that were not previously accessible to the classical methods of plant breeding become transferable to plants. Thus, for example, resistance genes could be isolated from exotic plants and transferred to domestic crops. Previously, genes and the corresponding characteristics could only be transferred naturally from parent plants that already possessed them. These limitations are now being overcome with the help of genetic engineering.

Scientists are also becoming more actively engaged in the molecular biology of plants because of the possibility that the knowledge obtained might help in an important way to solve the problem of worldwide famine. According to the most recent calculations of the U. S. Bureau of Statistics, the world population by the year 2000 will have risen from the present level of 4.9 billion to 6.2 billion.

The following factors have accounted for the impressive increase in food production over the last few decades:

—the introduction of new, high-yield varieties of plants
—the use of fertilizers and crop protection chemicals
—the increasing mechanization of agriculture

Crop yields will continue to increase in the future, but exponential increases such as occur in the world population will not appear. The large agricultural surpluses in the EEC and the USA at present do not represent a solution for the 80% of the world population that will be living outside Europe, the United States, and the Soviet Union in the year 2000. Especially in tropical and subtropical countries, plants with genetically engineered resistance toward pests, diseases, or stress conditions could acquire great importance.

A further consideration is that, after genetically engineered plants have been produced in the laboratory, they still have to be incorporated into cultivation programs and tested. This process takes several years, so that such plants will not be available to farmers in sufficient quantities un-

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0505-0382 $ 02.50/0

til the mid-1990s. Consequently, an evaluation of the possibilities of genetic engineering for agriculture must be based not on present food requirements but on the requirements anticipated for the year 2000. Of course, the problem of worldwide famine cannot be resolved solely by genetic engineering; political and sociological factors are also of decisive importance. However, genetic engineering could provide the basis for an adequate food supply in the form of high-yield and resistant plants.

2. Plant Cell Biology

The development of procedures in cell biology to regenerate plants from individual cells and to transfer genes to plant cells provided the prerequisite for the practical use of genetic engineering. Specific objectives of plant breeding could be achieved, in many cases, through the methods of genetic engineering as well as by suitable cell-biological selection procedures. Hence, this section will examine a few aspects of cell biology that are important for obtaining plants with new characteristics or for the application of genetic engineering. The techniques of plant cell cultivation that have been the focus of interest for the past decade have been described in several review articles and monographs.[4-7]

2.1. Vegetative Plant Reproduction

Plants are characterized by a large regenerative capacity. If plant shoots or segments of shoots are cultivated under suitable conditions (high humidity and absence of pathogens), these shoot segments develop roots. This asexual reproductive process, which is familiar in horticultural practice, can be carried out particularly efficiently on synthetic culture media under sterile conditions. The simplest of these culture media contain a balanced mixture of the salts and trace elements essential to plant nutrition, plus several required vitamins and suchrose.[8]

In a medium that is free of phytohormones, shoots or shoot meristems grow to complete plants. If the culture medium contains phytohormones, however, the reaction of the explant depends on the ratio of the auxin to the cytokinin concentration in the medium.[9] If both phytohormones are present in adequate concentrations, undifferentiated tissue, named callus, typically grows at the cut surface of the explant. This is true regardless of whether the explant is a leaf fragment, a piece of stem, or a root. If such a primary callus is transferred to fresh medium at regular intervals, it can be propagated for an indefinite time.

If cytokinin predominates in the medium, the formation of buds is favored, both on primary explants and on pre-

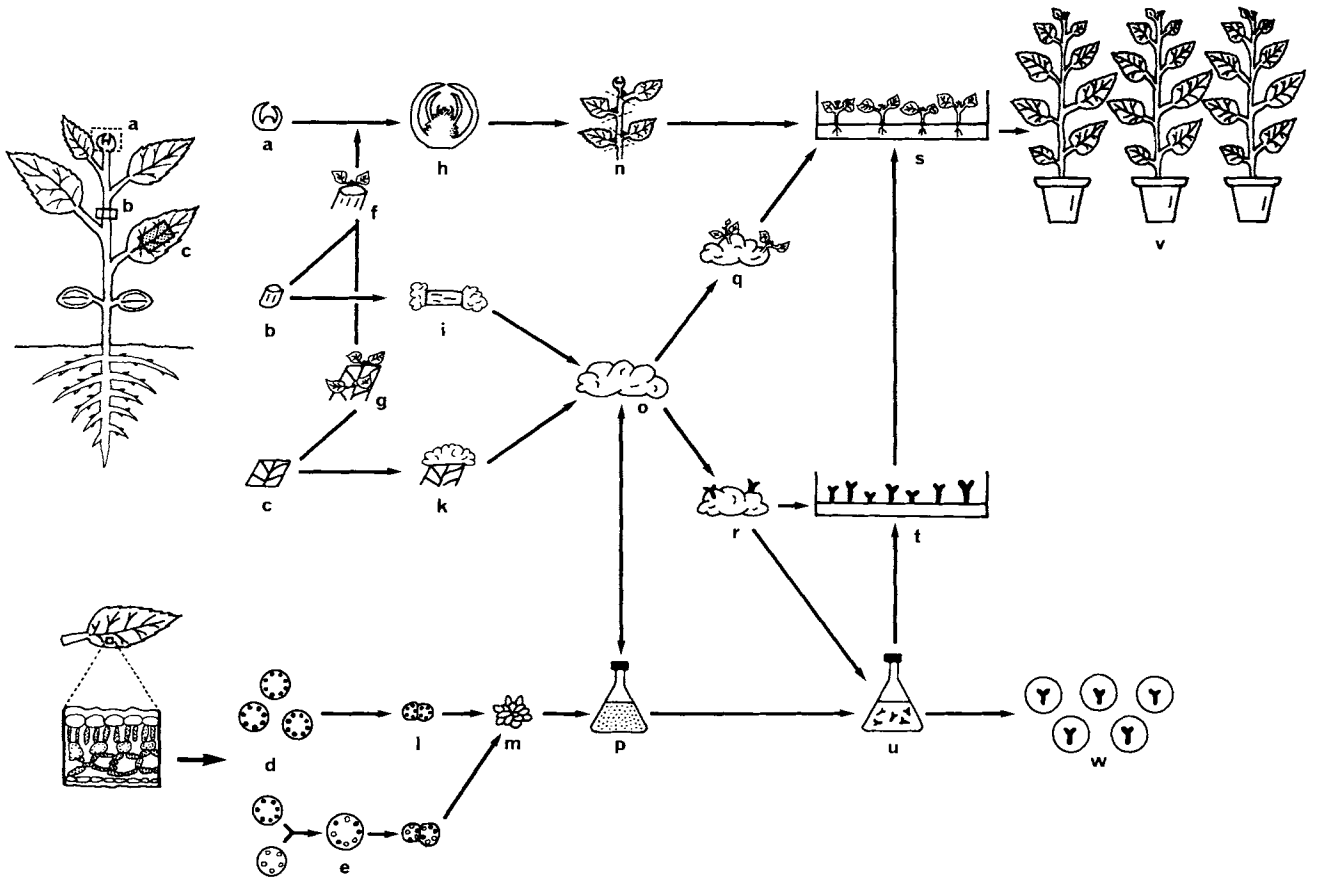

Fig. 1. Cell culture techniques used for mutant selection and production of transgenic plants. Shoot meristems (**a**), stem segments (**b**), leaf fragments (**c**), and mesophyll protoplasts (**d**) are used as explants both for the initiation of in vitro cultures and for gene-transfer methods. Through protoplast fusion, hybrid protoplasts (**e**) can be obtained. Plant regeneration may occur via shoot formation (**q**) either immediately at the explants (**f**-**h**) or at the callus stage (**i**, **k**, **o**). Alternatively, somatic embryos may develop (**r**). A cell wall is regenerated from protoplasts and cell division (**l**) begins, leading to cell clusters (microcalli) (**m**). They can be cultured as suspension cultures (**p**). In some species, the development of somatic embryos (**u**) can then be induced. On agar media, microcalli grow to form callus (**o**), which, as shown above, can undergo differentiation. If toxins, antibiotics, or herbicides are added to the media, resistant mutants or transformants can be selected preferentially at stages **f**-**p**. Shoot cultures (**n**), shoot-forming calli (**q**), and embryo cultures (**t**) are used for clonal propagation of genotypes (**s**, **v**). Under suitable conditions, somatic embryos may be converted into artificial seeds (**w**).

viously formed calli. However, the capability of a callus to differentiate depends strongly on its genotype. In some plant varieties (for example, tobacco) regeneration of a shoot, and hence of the plant, succeeds with practically every explant and even with callus that has already been cultivated for many years.[10] In other varieties (for example, soybeans), on the other hand, shoot regeneration from established callus cultures is not successful.

Regeneration from shoots is a prerequisite for the production of transgenic plants by the usual methods (Section 3). Alternative routes to shoot regeneration are shown in Figure 1. Shoots cultivated in vitro on culture media containing a cytokinin produce adventitious shoots, so that within a short time thousands of individuals of the same genotype can be produced from a single shoot. This method of vegetative propagation has so far proved economical for only a few types of plants (ornamental plants, potatoes[11]) because of the expensive manual labor required.

In a number of crop plants, including alfalfa,[12] soybean,[13] and rape,[14] the formation of somatic embryos can be induced in cell cultures. In contrast to the zygotic (sexual) embryos of seeds, somatic embryos arise from somatic cells (Figs. 1–3).

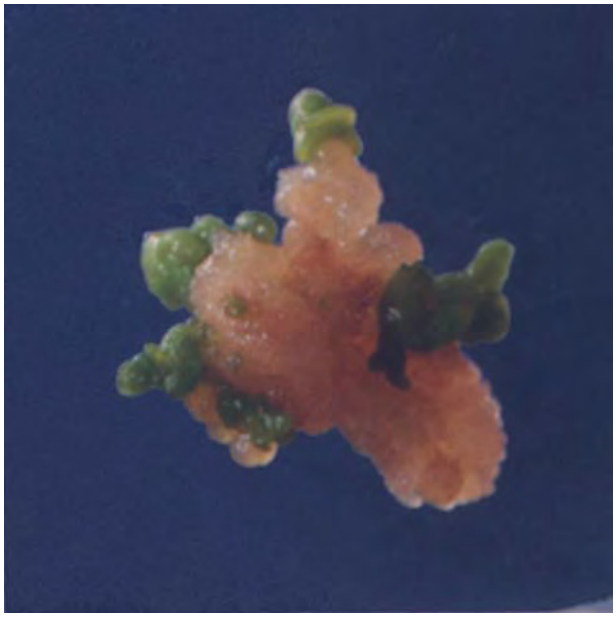

Fig. 2. Alfalfa callus (white) developing somatic embryos (green).

Somatic embryos can be cultivated in any desired number in synthetic media. On a laboratory scale it has already been shown that somatic embryos can be encapsulated together with a nutrient stock, stored for a short time, and then induced to germinate.[15] Such biotechnologically produced plant embryos that are enclosed in polymer capsules are called "artificial seeds." When this technology is further perfected it is conceivable that such artificial seeds could be sown like natural seed. This would make possible a productive and economical form of vegetative propagation of elite genotypes.

2.2. Protoplasts

Protoplasts are individual plant cells without cell walls which can be obtained from plant tissue by the digestion of the cell walls by hydrolytic enzymes (pectinases, hemicellulases, and cellulases). Several million mesophyll protoplasts can be obtained from 1 g of leaf tissue. In 1971, the first successful regeneration of plants[16] from mesophyll protoplasts was achieved with tobacco. Meanwhile, methods of plant regeneration have been worked out for a number of useful plants, including rape,[17] potatoes,[18] tomatoes,[19] alfalfa,[20] and rice.[21] Figure 3 shows the development of alfalfa protoplasts to complete plants. Protoplasts are especially interesting because they are able to take up macromolecules such as DNA[22] and even cell organelles[23] and chromosomes.[24] On the basis of these early observations, a method of direct DNA transfer to protoplasts has been developed in the last few years (see Section 3).

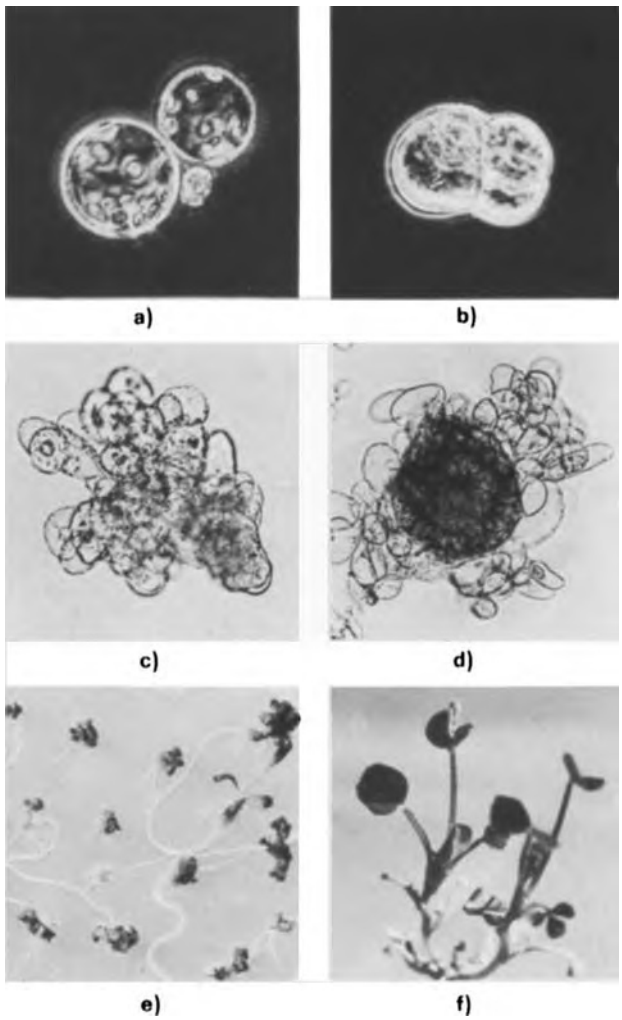

Fig. 3. Plant regeneration from protoplasts of alfalfa (*Medicago sativa*). a) Freshly isolated protoplasts (day 1); b) four-cell stage (day 4); c) microcallus (day 11); d) formation of embryogenic clusters (day 14); e) germinating somatic embryos (5 weeks after protoplast isolation); f) regenerated plant (8 weeks after protoplast isolation).

2.2.1. *Protoplast Fusion*

Plant protoplasts can fuse under various conditions, including the presence of Ca^{2+} ions at pH values over 9.5,[25] polyethylene glycol,[26] or dimethyl sulfoxide. Brief electric pulses[28] will also trigger protoplast fusion. The protoplasts of any plants can be fused, but, in general, the fusion products of protoplasts from different plant genera are difficult to regenerate. In only a few cases has it been possible so far to regenerate intergeneric hybrids, which, moreover, proved to be infertile.[29,30] A familiar example is the somatic hybrid from tomato and potato. This somatic hybrid is of theoretical importance, showing that, by means of protoplast fusion, hybrids can be produced that are not accessible via the sexual route. Fertile hybrid plants can be obtained by fusing the protoplasts of closely related plant species, even when these plants cannot be hybridized sexually.[31] If different selectable marker genes are present in the genomes of the two fusing protoplasts, the somatic hybrids can be sorted out easily in a selection medium. One method of protoplast fusion, which was already described in principle in 1980,[32] has excited much interest recently. Donor protoplasts whose genome has been fragmented by exposure to intense X-irradiation are fused with nonirradiated acceptor protoplasts. In some of the hybrid protoplasts, the fragments of the donor genome are integrated into the acceptor genome. If the donor genome contains genes that are responsible for the expression of resistances, it is possible to select out these recombinants. In this way, a chromosome fragment containing a gene for resistance against the antibiotic methotrexate could be transferred from carrots to tobacco protoplasts. The plants regenerated from these hybrid protoplasts resemble tobacco plants and, in addition to the transferred gene for methotrexate resistance, they possess some further carrot genes.[33] The plants are fertile (i.e., they produce seed) and transmit the methotrexate resistance to their progeny. This asymmetric protoplast fusion method could be a way of transferring several, even unknown, genes between species.

2.3. Mutant Selection in vitro

The isolation of protoplasts has enabled large populations of homogeneous, diploid, and totipotent cells to be obtained for many varieties of plants and to be regenerated to plants. Early in the development of protoplast techniques, attempts were made to use protoplast populations for mutant selection.[34] A single petri dish may contain 1–5 million protoplasts, all of which are potential plants. If mutations can be induced in this cell population and the mutants selected, it should be possible to regenerate plants with new characteristics.

Protoplasts are not a necessary condition for mutant selection, however; any readily regenerating plant cell culture may be used for this purpose. There are now a number of reports describing the successful selection of mutants from plant cell cultures, including pathogen-resistant (Table 2) and herbicide-resistant plants (cf. Table 5) as well as plants that overproduce specific amino acids. Most mutants and variants found in this way could already be selected and isolated at the cell level by means of a selection pressure—e.g., the addition to the culture medium of enzyme inhibitors, amino-acid analogues, pathogen toxins, or herbicides.[50] Strikingly, these variants were also found in experiments in which the mutation rate was not accelerated by chemical or physical mutagens.

Table 2. Pathogen-resistant crop plants obtained through tissue culture (taken in part from [35]).

Crop plant	Pathogen	Ref.
a) After in vitro selection for toxin resistance		
Tobacco	*Pseudomonas tabaci*	[34]
(Nicotiana tabacum)	*Alternaria solani*	[36]
Potato	*Phytophtora infestans*	[37]
(Solanum tuberosum)	*Fusarium oxysporum*	[38]
	Erwinia carotovora	[39]
Tomato	*Fusarium oxysporum*	[40]
(Lycopersicon esculentum)		
Rape	*Phoma lingam*	[41]
(Brassica napus)		
Alfalfa	*Fusarium oxysporum*	[42]
(Medicago sativa)	*Verticillium alboatrum*	[43]
Maize	*Helminthosporium maydis*	[44]
(Zea mays)		
b) Resistance observed without prior in vitro selection		
Potato	*Alternaria solani*	[45]
	Phytophtora infestans	[46]
	Potato Y virus	[47]
	Potato curling virus	[47]
Tobacco	Tobacco mosaic virus	[48]
Tomato	Tobacco mosaic virus	[49]

2.3.1. *Somaclonal Variation*

The high variability described above seems to arise spontaneously through the process of in vitro cultivation, especially when the cell cultures have been cultivated for a prolonged period as undifferentiated cells. Under such conditions, chromosome mutations can accumulate easily.[51] Only part of the observed variability, however, can be explained by the loss of individual chromosomes or by the presence of supernumerary chromosomes. The variability induced by cell cultivation is named "somaclonal variation."[52] An obvious application would be to use this source of variability for breeding programs.[53] Meanwhile, increasing evidence has appeared, indicating that, under the stress of in vitro cultivation, mechanisms are activated in plant cells that lead to reorganization of the genome.[54] In maize, for example, "jumping genes" can be activated by in vitro cultivation.[55]

2.4. Importance of Cell Biology for Genetic Engineering

The contribution of plant cell biology to genetic engineering consists in making competent (i.e., transformable) plant cells available, effecting DNA transfer, and regenerating plants from the transformed cells. These prerequisites have not been met to the required extent for important crop plants such as soybeans, cotton, and the cereals, with the exception of rice. The cell culture systems of species that are difficult to regenerate have to be improved further. It would be ideal to be able to regenerate proto-

plasts of these plants, too, since protoplasts are capable of taking up foreign DNA directly and integrating it into their genomes.

Hope that progress is also possible with the cereals has been inspired by the recent reports of three research groups that rice plants have been successfully regenerated from protoplasts.[21] This breakthrough was achieved by the use of embryogenic suspension cultures as starting material for the isolation of protoplasts.

3. Transfer of DNA

3.1. The *Agrobacterium tumefaciens* System

3.1.1. Tumor Formation

Until recently it was not possible to transfer foreign genes to plant cells. Although DNA could be isolated from plants and characterized, the function of certain DNA sequences was difficult to analyze because the possibility of transfer was lacking. Surprisingly, this dilemma was solved through studies of the formation of certain plant tumors, the so-called crown galls. These tumors are undifferentiated cell growths caused by the infection of a plant with gram-negative soil bacteria of the species *Agrobacterium tumefaciens* (Fig. 4). The formation of these tumors is caused by the introduction of bacterial DNA into plant cells.[56]

Agrobacterium tumefaciens is a soil bacterium that is capable of infecting a large number of dicotyledonous plants, such as tobacco, tomatoes, carrots, and potatoes, after an injury.[57] At the site of infection, strong undifferentiated cell growth begins, leading to the crown gall tumors. Once a tumor has formed, it can continue to grow even in the absence of agrobacteria.[58] Two properties of the tumor tissue should be especially emphasized: the tumor proliferates on sterile culture media of a defined composition without the addition of plant hormones (auxins and cytokinins), although these hormones are essential for the growth of normal cell tissue.[58] Furthermore, the tumor synthesizes specific metabolites, the so-called opines, that are not present in other plant tissues.[59] Opines are derivatives of amino acids and sugars; they can be used by agrobacteria but not by plants as sources of nitrogen and carbon.[59,60] The opines found in plants belong to four different classes: nopalines, octopines, agropines, and agrocinopines (Fig. 5).[61]

Fig. 4. Undifferentiated, growing tumor tissue (crown gall) on the stem of a tomato plant after infection of the wounded area with *Agrobacterium tumefaciens*.

A given strain of agrobacteria can, within certain limits, utilize only the class of opines whose synthesis it induces in the plant. Nopaline-inducing bacteria, for example, cannot metabolize octopine.[59] Corresponding to the opines, the agrobacteria have been divided into different classes,

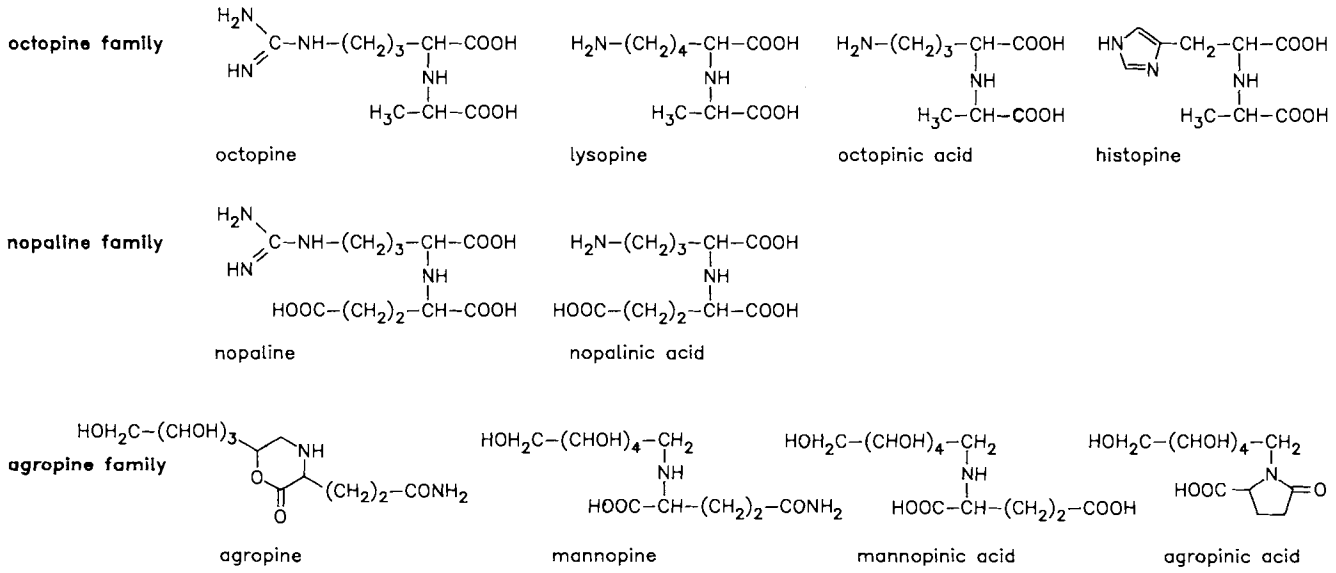

Fig. 5. Chemical structure of the opines (data from [61]). Agrocinopines are phosphorylated sugars of unknown structure.

of which the nopaline and octopine classes have been most thoroughly characterized.

3.1.2. The Ti Plasmid as the Tumor-inducing Principle

The hormone-independent growth of gall tumors in the absence of agrobacteria and the biosynthesis of opines led to the conclusion that agrobacteria must transmit a "tumor-inducing principle" to the plants.[62] Indeed, infectious bacteria were found to contain a megaplasmid, the Ti plasmid (Ti = tumor-inducing), which is approximately 200 kilobases (kb) long.[63] When the plasmid was removed from *Agrobacterium tumefaciens*, the bacterium lost its ability to induce plant tumors. Reintroduction of the plasmid restored the tumor-inducing capability. The plasmid was thus identified as the tumor-inducing principle being sought.[64] This Ti plasmid contains the genes that are responsible for hormone-independent growth of the tumor and those involved in opine formation and utilization (Fig. 6).[60,65-68]

Only a relatively small region of the overall Ti plasmid is integrated stably into the plant genome.[70-72] Hence, the transfer of DNA to plant cells is a natural process that has been practiced by *Agrobacterium tumefaciens* for ages. The integrated region of DNA, the so-called T-DNA, comprises about 20 kb. The genes responsible for opine biosynthesis and those causing tumor growth are localized on the T-DNA.[67,72,73]

Besides their striking similarities, the T-DNA regions of octopine and nopaline bacteria also exhibit several significant differences. Whereas nopaline T-DNA represents an approximately 23-kb-long DNA fragment on the Ti plasmid and is transmitted as such, octopine T-DNA is divided into two adjoining sections of about 14 kb (left T-DNA, TL) and about 7 kb (right T-DNA, TR).[74,75] TL and TR are integrated independently of each other into different sites on the plant genome.[75,76] TL-DNA and nopaline T-DNA possess a very homologous, approximately 9-kb-long nucleotide region, on which genes 5, 2, 1, 4, 6a, and 6b are localized (Fig. 6).[69] The functions of the known genes are compiled in Table 3. At least three of these genes (genes 1, 2, and 4) are responsible for tumor growth in infected plants. Since all three genes are active in wild-type agrobacteria, both auxins and cytokinins are formed, which leads to tumors with fully undifferentiated growth (cf. Fig. 4). Agrobacteria in which gene 4 is inactivated (much auxin, no cytokinin) induce root growth in the tumor, so that gene 4 (roi gene: root inhibition gene) prevents the differentiation of roots. Shoots are induced by inactivation of genes 1 and 2 (much cytokinin, no auxin). Thus, genes 1 and 2 (shi genes: shoot inhibition genes) prevent the formation of shoots.[83,85]

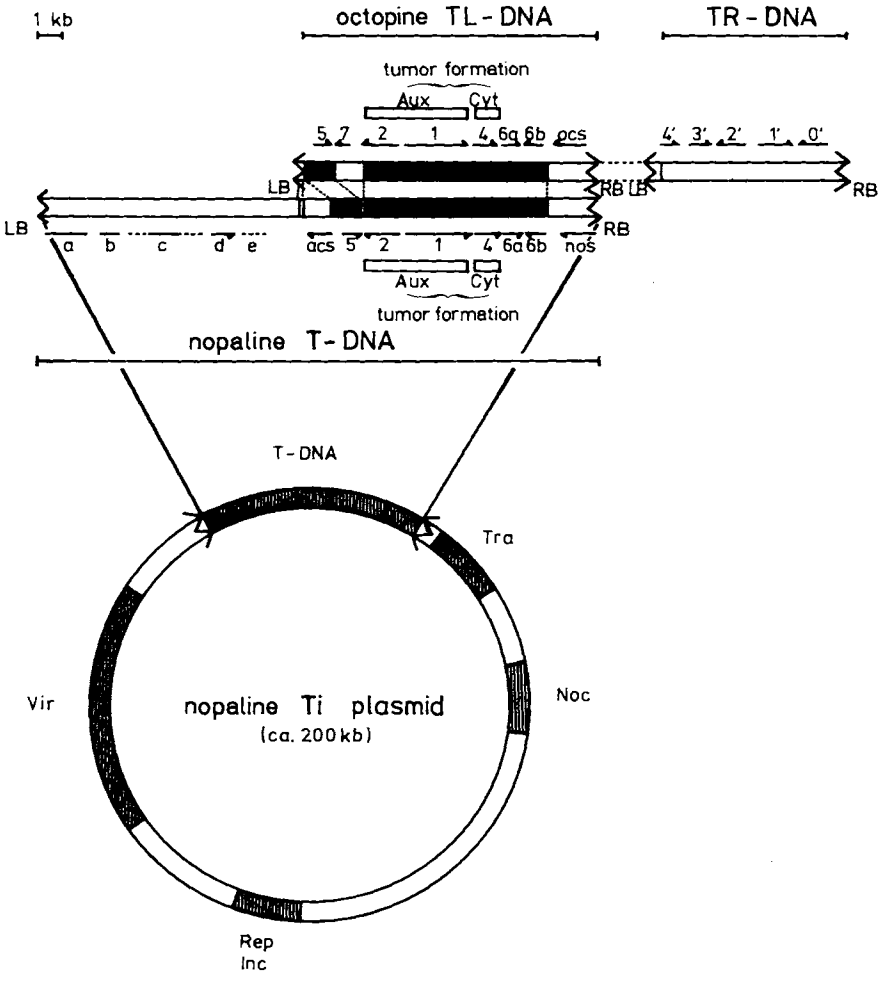

Fig. 6. Genetic organization of a Ti plasmid. Lower part: Functionally characterized regions of a nopaline Ti plasmid. Tra, functions for plasmid transfer between bacteria; Noc, nopaline catabolism; Rep, functions for plasmid replication in agrobacteria; Inc, functions that confer incompatibility of two different Ti plasmids in a single cell of *Agrobacterium tumefaciens* (i.e., nopaline and octopine Ti plasmids can't exist together in the same cell); Vir, virulence region; T-DNA, DNA region that becomes integrated in the plant genome. Upper part: Comparison of the T-DNAs of nopaline and octopine Ti plasmids. Polyadenylated transcripts are shown as either half-arrows or bars according to whether the direction of transcription is known or not. Nomenclature of transcripts is according to [69]. Black areas mark the regions of homology between the two T-DNAs. Nos, nopaline synthase gene; ocs, octopine synthase gene; acs, agrocinopine synthase gene; Aux, genes involved in auxin biosynthesis; Cyt, Gene involved in cytokinin biosynthesis; RB, right border sequence; LB, left border sequence.

Table 3. Functions of T-DNA genes. Functions of other genes included in Figure 6 are still unknown.

Gene	Function	Protein	Ref.
1	Auxin biosynthesis	Tryptophan 2-monooxygenase	[77]
2	Auxin biosynthesis	Indoleacetamide hydrolase	[78]
nos	Nopaline biosynthesis	Nopaline synthase	[79]
ocs	Octopine biosynthesis	Octopine synthase	[80]
4	Cytokinin biosynthesis	Isopentenyltransferase	[81]
5	Tumor growth		[78]
6a	Opine secretion		[82]
6b	Tumor growth		[83]
0′	Conversion of mannopine to agropine		[84]
1′	Mannopine biosynthesis		[84]
2′	Mannopine biosynthesis		[84]

Accordingly, T-DNA genes are responsible for tumor growth. They are not required, however, for the actual plant infection or for the integration of T-DNA into the plant genome.[86] Deletion of various regions of the Ti plasmid has shown that only two regions of the plasmid are essential for infection and integration. One of these is the virulence region ("vir") and the other the "border" regions of the T-DNA. These borders consist of two nearly identical nucleotide sequences,[87,88] which are 25 base pairs (bp) long and exhibit very strong conservation in all types of T-DNA (Fig. 7). Any DNA sequences up to 50 kb long that are inserted between these borders can be integrated into the plant genome.[6,89] The mechanism of this integration process has not yet been clarified. It has been shown, however, that during an infection the T-DNA is cut out of the Ti plasmid and circularized beyond these 25-bp-long border sequences to form unstable intermediate products.[90]

The DNA of the approximately 40-kb-long virulence region is not itself integrated into the plant genome,[75] but the virulence genes are responsible for the infectiousness of the agrobacteria.[91] The vir region consists of at least six different complementation groups.[91,92] To determine a complementation group, a mutation that leads to avirulence was inserted into the vir region. An attempt was then made to restore virulence by introducing into the bacteria a second vir region with a mutation at a different site. If both mutations are in the same complementation group, the bacteria remain avirulent, but if they lie in different groups, the two groups complement each other and the bacteria become virulent again. Each complementation group corresponds to a single transcription unit. Two of these transcripts are expressed constitutively; the remaining four transcripts are induced only in the presence of plant cells.[92] The exact mechanism of virulence induction is not yet fully understood. Since in nature agrobacteria infect only injured plant cells, it was suspected that certain substances are synthesized by these plant cells to which the bacteria "react." Two of these compounds, acetosyringone **1** and α-hydroxyacetosyringone **2**, have so far been isolated (Fig. 8). These phenolic compounds interact with the

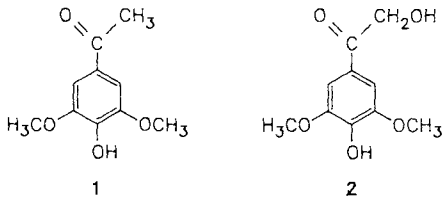

Fig. 8. The two compounds synthesized by wounded plant cells which activate the virulence region of *Agrobacterium tumefaciens*: acetosyringone **1** and α-hydroxyacetosyringone **2**.

products of the two constitutively expressed virulence genes and thus stimulate the activity of the other four vir loci.[93,94] In addition to the borders and the vir region of the Ti plasmid, agrobacteria contain at least two chromosomal loci that are responsible for the attachment of the bacteria to the plant cell walls.[95,96]

3.1.3. *Agrobacterium tumefaciens as a Gene Vector*

Knowledge of the basic processes involved in the infection of plant cells by *Agrobacterium tumefaciens* led to the development of two basically different methods of introducing foreign genetic material into a plant: the use of "integrative vectors" and the use of "binary vectors." In constructing the "integrative vectors," advantage is taken of the fact that the tumor-inducing genes are not required for the actual infection and that any DNA sequence that is inserted between the two borders will also be transmitted to the plant. In these integrative vectors, the tumor genes of T-DNA, for example, are replaced by sequences of the *E. coli* cloning vector pBR 322.[86] The foreign DNA that is to be integrated into the plant genome is simply cloned in a pBR vector in *E. coli* and then inserted by homologous recombination, via these pBR sequences, into the Ti plasmid (Fig. 9).

In the construction of the "binary vectors," the fact is utilized that the vir region and the "borders" can be localized on two separate plasmids without affecting the infectiousness of the agrobacteria.[97] Accordingly, the T-DNA borders are transferred to a plasmid that can be replicated in *E. coli* as well as in agrobacteria. These plasmids can be very much smaller than the Ti plasmid (about 10–20 kb),[98] and the different cloning steps can readily be carried out in *E. coli*. If the DNA to be transferred to plants has been cloned on such a plasmid, this plasmid is transferred to a strain of agrobacteria that already has a Ti plasmid, but which, although it still has a vir region, contains no further T-DNA. Agrobacteria with these two plasmids are also capable of stably integrating the DNA lying between the borders into the plant genome.

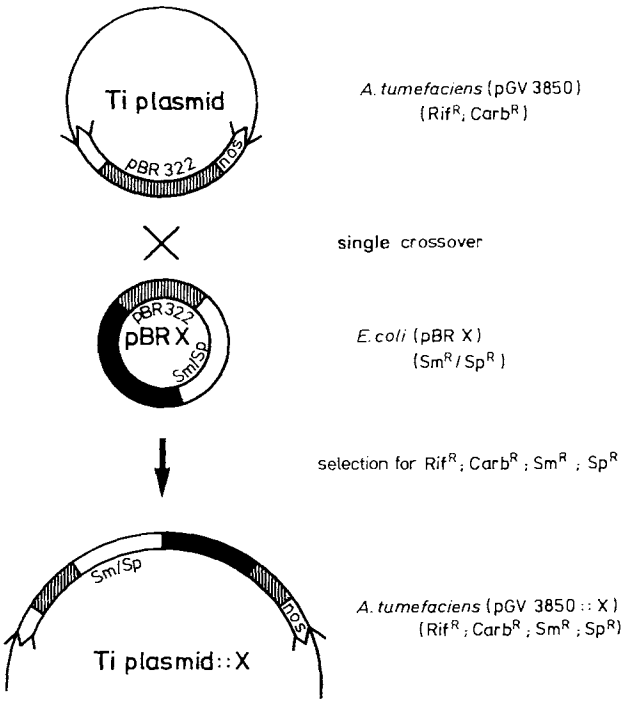

Fig. 9. Schematic drawing of the mobilization of a pBR vector of *E. coli* into a modified Ti plasmid of *Agrobacterium tumefaciens* (modified according to [86]). Production of a transgenic plant by transferring a gene, imparting resistance against the phytotoxic antibiotic kanamycin. a) Leaf pieces after transformation with *Agrobacterium tumefaciens*. Transformed (right) and nontransformed leaf fragments (left) are cultivated on media containing kanamycin. Only the transformed leaf pieces form shoots. b) Transgenic tobacco plant regenerated from a shoot (right) and nontransformed tobacco plant (left) on media containing kanamycin. Only transformed plants survive.

3.1.4. Methods of Gene Transfer with Agrobacterium tumefaciens

The prerequisite for the transfer of DNA by *Agrobacterium tumefaciens* in plants is the infection of plant cells by the bacterium. The techniques for infecting plant tissue with *Agrobacterium tumefaciens* are relatively easy to perform. In the simplest case, plants are injured mechanically, e.g., with a scalpel, and a suspension of agrobacteria is applied to the site of the wound.

Better transformation efficiencies are achieved by incubating parts of the tissue with agrobacteria and then cultivating the tissue on synthetic culture media. Thus, with the "leaf disc" method, small parts of leaves are dipped into a bacterial suspension and then cultivated.[99] If a selectable marker gene such as the resistance gene to the phytotoxic antibiotic kanamycin (see Sections 3.3 and 4.1), is transferred by means of the agrobacteria, new plants can be regenerated only from transformed cells of the leaf parts on kanamycin-containing media (Fig. 10).

The incubation of plant protoplasts with agrobacteria and the subsequent regeneration of the treated protoplasts to plant tissue or intact plants, which is known as coculture, also leads to good transformation results.[100]

However, the advantages of the agrobacteria system, for example, the simple transformation technique and good transformation frequency, must be weighed against a large disadvantage, namely, the limited host range of the agrobacterium. A large number of dicotyledonous and also some monocotyledonous plants of the Liliaceae family, for example, *Asparagus officinalis* (asparagus)[101a] and *Chlorophytum capense* (spider plant),[101b] are susceptible to infection. With the exception of maize,[102] however, no susceptibility to infection by *Agrobacterium tumefaciens* has yet been observed for the economically important Gramineae to which all other cereal species belong.

3.2. Direct Transformation of Plant Cells with Isolated DNA

Owing to the limited host range of the agrobacteria, other methods were also sought at the same time for introducing genetic material into plants. The most successful method so far has proved to be the transformation of plant protoplasts with isolated DNA,[103, 104] as had already been carried out with bacteria[105] and animal cells.[106] In this approach, the transfer of the foreign DNA into the plant cells is carried out without using a natural plant-infectious system such as *Agrobacterium tumefaciens*. The cells to be transformed are simply incubated together with the DNA in a suitable solution and subjected to certain procedures which have already been used in microbiological research to transfer foreign genetic material. These procedures include, in particular, treatment with polyethylene glycol,

heat shocks, and electrical shocks (electroporation). In electroporation, short electrical pulses are used to produce small pores in the cell membrane through which the DNA is able to pass into the cell.[104, 107] Although this method may appear to be easy, the detailed procedure presents difficulties since the individual experimental parameters have to be optimized for each plant species.

Direct transformation has the undisputed advantage that it can be used with all plants from which protoplasts can be obtained. These include some of the Gramineae as well as many dicotyledonous plants. So far it has been possible to introduce foreign DNA into protoplasts from rice *(Oryza sativa)*,[108] maize *(Zea mays)*,[109] and wheat *(Triticum monococum)*,[110] among others.

One disadvantage of the direct transformation of protoplasts compared with transformation with *Agrobacterium tumefaciens* is the fact that the regeneration of intact plants from protoplasts takes much longer than regeneration from tissue parts. However, the greatest disadvantage of direct transformation is that so far, despite extremely intensive research with cereals, only rice protoplasts could be regenerated to intact plants.[21]

3.3. Other Methods of Gene Transfer

Since there has been only limited success in transforming and regenerating the most important crop plants by using either the direct transformation of protoplasts or by means of agrobacteria, other transformation methods have also been investigated, including the introduction of genetic material via phytopathogenic viruses. Although most plant viruses belong to the group of RNA viruses, experiments have mostly been carried out with DNA viruses, since work with RNA on the molecular biological level is vastly more difficult than with DNA. Only two classes of phytopathogenic DNA viruses that can be used as DNA vectors are currently known, namely, the gemini viruses and the caulimoviruses.[111] By far the best characterized DNA virus, namely, cauliflower mosaic virus (CaMV), which belongs to the class of caulimoviruses, has already been used for transferring genetic material into plants.[112] However, with CaMV, owing to the special genome structure of the virus, only very small pieces of DNA up to 500 nucleotides long can be integrated into the virus genome. In addition, the narrow host range of CaMV (only plants of the Brassicaceae family) and the fact that virus DNA is not integrated stably into the plant genome prevent cauliflower mosaic virus from being suitable as a universal transformation system.

In order to avoid the difficulties in regenerating intact plants from the protoplasts of many species, attempts have been made to transfer DNA directly into certain tissues. Several authors have described how, after incubation of pollen with foreign DNA and subsequent dusting of plants with this pollen, transformed progeny were obtained.[113, 114] However, it has not yet been possible to reproduce these experiments.[115]

Microinjection of DNA into cell nuclei using a very fine cannula is a proven method for the genetic manipulation of animal cells.[116] Microinjection has also been used for transforming plant cells.[117] Owing to the very large plant cell vacuole and the small cell nucleus into which the DNA has to be injected, this method requires special equipment and is not very efficient.

The injection of DNA into reproductive plant organs is also carried out. A breakthrough seems to have been achieved here with the injection of DNA into young inflorescences of rye plants.[118] After the injection of a gene for resistance to the phytotoxic antibiotic kanamycin, it was possible, for the first time, to regenerate resistant, transformed rye plants.

4. Gene Expression in Plants

4.1. Regulatory Regions of Plant Genes

The first successful attempts to introduce foreign DNA into plants by means of the Ti plasmid were carried out with bacterial genes for resistance to the antibiotics streptomycin and kanamycin.[119, 83] These genes were inserted into the T-DNA and introduced in this way into the plant genome. However, no transcription could be detected. The same result was obtained for an alcohol dehydrogenase gene obtained from yeast[120] and a β-globin gene from mammalian cells.[121] These genes were integrated into the genome but were not active in the plant. It was therefore assumed that certain transcription signals specific to plants are necessary in order to activate the genes. From the study of animal systems, the general structure of functional eukaryotic genes was already known.[122] In principle, plant genes show the same structure.[123] A typical plant gene is illustrated in Figure 11. The promoter is located in the nontranscribed 5′ region of eukaryotic genes. The enzyme RNA polymerase II, which catalyzes the synthesis of messenger RNA, binds to the promoter sequences, in particular to a region approximately 10 bp long which is rich in adenine and thymine, the so-called TATA box.[125] Promoter sequences are therefore responsible for the correct initiation of the transcription process. The transcription is terminated at DNA sequences in the 3′ region, namely at the end of the gene. These terminator sequences are involved, in a way that is not yet exactly clear, in the termination of transcription and the attachment of the poly-A sequences to the RNA chains produced (polyadenylation).[126] In order to express foreign genes in plants, attempts were therefore made to use promoter and terminator sequences of genes known to be actively expressed in all plant tissues. The best gene for this purpose was the nopaline synthase gene from *Agrobacterium tumefaciens*, which was first isolated at that time.[79] It possessed eukaryotic promoter and terminator sequences and, as was known from transformation experiments with wild-type agrobacteria, it was also expressed in callus and other plant tissues. The fusion of the promoter and terminator regions of this gene to the bacterial gene for chloramphenicol acetyltransferase (resistance to chloramphenicol) resulted in the first chimeric gene that could be expressed in plant cells.[127] Thus, certain regulatory regions are necessary to express genes in plants (Fig. 11).

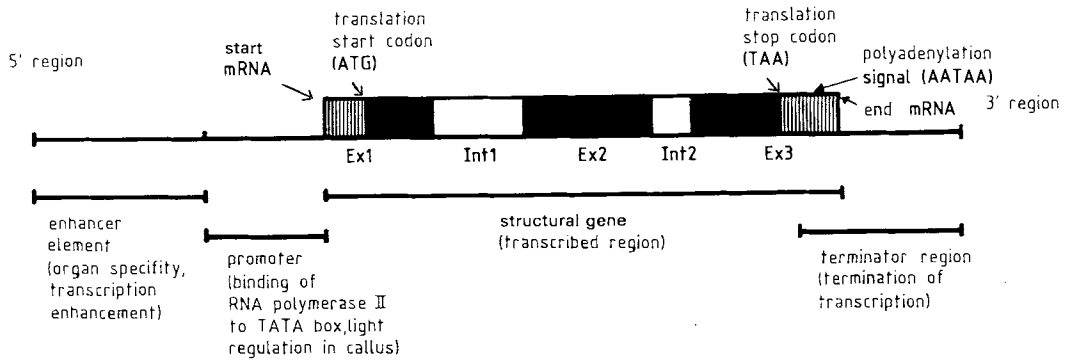

Fig. 11. General structure of a plant gene (ss-rubisco gene). Enhancer, promoter, and terminator elements regulate the expression of the structural gene. The whole structural gene is transcribed. After removal of introns (Int), the exons (Ex) are spliced to build up the mature m-RNA. ▥ = nontranslated regions of the m-RNA; ■ = translated regions of the m-RNA. Technical terms are explained in [124].

Most of the following research focused on achieving the expression of resistance genes to phytotoxic antibiotics in order to use these genes as selectable markers to differentiate transformed and nontransformed plant cells. Resistance to kanamycin **3**, hygromycin, and methotrexate could be expressed in plant cells.[128] Resistance to kanamycin, for example, is based on expression of the transferred gene for neomycin-kanamycin phosphotransferase, which catalyzes phosphorylation of the antibiotic and consequent inactivation.

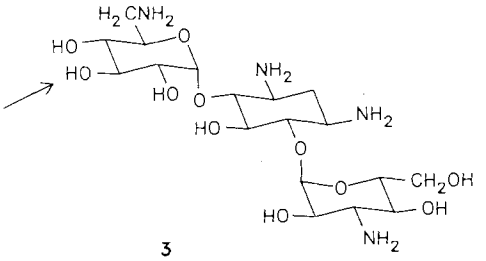

Fig. 12. Chemical structure of the phytotoxic antibiotic kanamycin **3** [129]. The hydroxyl group marked by an arrow is phosphorylated by the enzyme neomycin-kanamycin phosphotransferase, resulting in inactivation of the antibiotic.

4.2. Differential Gene Expression

Once evidence had been supplied that foreign genes can be introduced into the plant genome and expressed, more complex gene regulatory mechanisms in plants were investigated on the molecular level. The development of integrative and binary vector systems (see Section 3.1.3) was essential for this purpose. Using these systems it was possible for the first time to regenerate morphologically normal plants after the transformation.

Two phenomena of developmental biology are currently being investigated intensively, since their parameters can be defined quite easily: the light-specific and the organ-specific activation of certain genes.

The light-induced gene expression is being examined primarily in genes coding for the small subunit of ribulose-1,5-bisphosphate carboxylase (ss-rubisco) or for the chlorophyll a/b binding protein (CAB). Rubisco and CAB are key enzymes in CO_2 fixation and in plant photosynthesis.[130]

The organ-specific gene expression is also being investigated in the genes mentioned above, since, apart from their light-dependent expression, they are only activated in tissues containing chloroplasts (e.g., leaves and stems). Another important class of differentially expressed genes codes for the storage proteins, which are important from a nutritional and physiological point of view.[131] Thus, the zein genes of maize *(Zea mays)* or the legumin genes of pea *(Pisum sativum)*, for example, are active in seeds but not in other organs such as leaves or roots.

Below, we shall briefly describe a few attempts to elucidate gene regulatory mechanisms by the application of DNA transfer methods, as exemplified by ss-rubisco.

The enzyme ribulose-1,5-bisphosphate carboxylase is the most frequently occurring protein in the world, accounting for approximately 50% of all soluble plant protein. It is composed of eight identical large subunits (M_r 56000 daltons, LS-rubisco) and eight identical small subunits (M_r 14000 daltons, ss-rubisco). Whereas the gene of the large subunit is localized on the chloroplast genome, the small subunit is encoded by the nuclear DNA. The ss-rubisco subunits are formed in the cytosol and then transported to the stroma of the chloroplasts after proteolytic cleavage of a transit peptide of approximately 6000 daltons. Here, they combine with the LS-rubisco subunits formed in the chloroplasts to form the functional holoenzyme.

The enzyme rubisco can only be detected in the tissue of illuminated plants. In the dark, the synthesis of the enzyme stops after a short while.[132] Since no rubisco-specific mRNA can be detected once the plants have been put in the dark, the regulation of gene activity is effected on the level of transcription.[133] In order to transcribe a gene, RNA polymerase II has to bind to the corresponding promoter sequence. It was therefore assumed that a specific sequence exists in this promoter region which is somehow linked to light-dependent expression. Factors that enhance or inhibit polymerase binding to the DNA could bind to this sequence.[134] A possible way to investigate this hypothesis would be to isolate these DNA regions and fuse them with structural regions of suitable marker genes. The differential expression of these chimeric genes could then be investigated in transgenic plants. In order to achieve this, a region approximately 1000 nucleotides long that

was situated directly in front of the start site for transcription of an ss-rubisco gene was inserted into the corresponding position of the gene for the bacterial chloramphenicol acetyltransferase. This construction was light-regulated in transformed tobacco cells and therefore confirmed the above-mentioned hypothesis.[135] In the meantime, similar experiments showed that a 33-bp-long DNA region is sufficient for light-specific regulation of an ss-rubisco gene in callus tissue.[136] However, it was not possible to obtain strong expression of the gene with this region alone. A further "enhancer" (see Fig. 11) with a length of approximately 250 bp was discovered, which, independent of its orientation but dependent on light, enhanced the activity of an otherwise constitutively acting promoter.[130]

The plant-specific promoters that have been isolated to date can be divided into three categories: (1) the light-dependent promoters, (2) the tissue-specific regulated promoters, such as those from the seed storage protein genes in maize and wheat, and (3) the promoters of constitutively expressed genes. The degree of expression of transferred genes is usually lower in the transgenic (i.e., transformed) plants than in the plants from which the genes were isolated.[137] Therefore, promoters of highly expressed genes are of special interest. One of the strongest promoters so far used in plant transformation experiments is of viral origin. It is the constitutively acting promoter of the 35S transcripts of the phytopathogenic cauliflower mosaic virus and seems to be about 30 times as strong as the nopaline synthase promoter.[138] In the search for other inducible genes, gene sequences that are inducible by heat,[139] darkness,[140] and nitrate.[141] have been isolated.

Promoters of dicotyledonous plants appear to regulate the expression of genes in other dicotyledonous plants correctly. Thus, in addition to many other examples, an organ-specifically expressed seed-storage-protein gene from soybeans, after transfer into tobacco plants, was expressed in exactly the same time and tissue-specific pattern as in the soybean.[142]

There are contradictory reports, however, on the function of promoters of monocotyledonous plants in dicotyledonous species. For example, a CAB gene from wheat was correctly transcribed in tobacco plants,[143] whereas an ss-rubisco gene from wheat was not active in tobacco.[144]

In addition to the strength of a promoter, other factors play an important role in the level of expression of a transferred gene. Thus, often not just one gene copy is integrated into the plant genome when a gene is transferred. Indeed, more than five copies of a transferred gene have been detected in the genomes of transgenic plants.[137] But even when the different number of gene copies is taken into account, a large variability in expression is observed with different transgenic plants in a transformation experiment. This phenomenon is usually explained by what is called the position effect.[145] The integration loci of transferred DNA in the plant genome have so far shown no obvious similarities as regards the nucleotide sequence. The integration sites seem to be entirely coincidental.[146] Since the genes are presumably integrated into DNA regions that are transcribed to different extents, they are expressed to varying degrees. Owing to this variability in the degree of expression of a transferred gene, those plants that show the desired characteristics to the required extent have to be selected from a number of transgenic plants. However, once a gene is integrated in the plant genome, it will be stably maintained and transmitted to the progenies according to the Mendelian laws.[147]

5. Aims of Applied Genetic Engineering with Plants

Some of the most important aims of genetic engineering with plants are shown in Table 4. The aims mentioned only represent examples, which were selected to illustrate the many possibilities of genetic transfer to plants. This is therefore not a complete list.

Table 4. Genetic engineering with plants—some possible applications.

herbicides
viral diseases
fungal diseases
pests
microorganisms
stress conditions
2. Changes in the compositions of plant substances
Modification of amino-acid composition
Modification in the composition of vegetable oils, carbohydrates, or plant metabolites
Modification in the content and activity of enzymes important for processing, transportation, or storage of agricultural products
3. Changes in physiological processes
Photosynthesis/photorespiration
4. Improvement of nitrogen fixation
5. Genetic engineering as an aid to plant breeding
Diagnosis of plant diseases
Restriction fragment length polymorphism (RFLP)

5.1. The Production of Resistant Plants

5.1.1. Resistance to Herbicides

The cultivation of plants that show resistance to herbicides has long been part of agricultural practice, "selective herbicides" being in widespread use. These herbicides are metabolically transformed in certain cultivated plants (e.g., by hydroxylation, conjugation with carbohydrates or glutathione, demethylation) in such a way that herbicidal action is lost. Examples are maize with resistance to atrazine,[148] wheat with resistance to diclofop-methyl,[149] sugar beet with resistance to phenmedipham,[150] and cereal species with resistance to chlorsulphuron. Thus, these plants have a physiologically based, natural herbicide resistance, which is exploited by the farmer.

Often, several different herbicides have to be used, because this is the only way that all weeds that occur can be controlled. By introducing a resistance to a nonselective herbicide, the use of several herbicides may no longer be necessary.

Plants with resistance to nonselective herbicides will be one of the first results of genetic engineering with plants to have an application in agriculture. The site of action of most modern herbicides is known and biochemically characterized. This knowledge is the prerequisite for the development of strategies for producing herbicide-resistant

plants with the aid of genetic engineering. This aim seems to be achievable in several cases by transferring only one or a few genes. Further reasons for intensive work on herbicide resistance are the advantages that resistant plants offer to the farmer.

The cultivation of resistant cultures makes the preventative use of herbicides superfluous. The farmer now has to use the herbicide only when it is needed, that is, only if the weeds exceed a tolerable level. This is contrary to usual practice today, where a preventative application of herbicides is commonly made.

Soil erosion can also be reduced by using herbicide-resistant plants, since the later application of herbicides makes it possible to avoid the occurrence of exposed areas. Herbicide-resistant cultures are also particularly well suited to the no-till (or "slot" planting) method.[151]

The possible use of herbicides according to the damage threshold concept and the replacement of several different herbicides by a single nonselective herbicide should result in decreased overall use of herbicides as herbicide-resistant cultures are introduced. In addition to simplified use, the economic advantage for the farmer is obvious.

The methods of classical cell biology (see Section 2.3) can also be used to obtain herbicide-resistant plants. The addition of a herbicide to the plant-cell culture medium enables the selection of resistant calli from which herbicide-resistant plants can later be obtained.[152, 153] The various possibilities for obtaining herbicide-resistant plants by means of cell biology and genetic engineering will be exemplified here for several newer herbicides (Table 5).

Relatively new herbicides have been obtained from the compound classes of sulfonylureas and dihydroimidazolones. These herbicides inhibit the enzyme acetolactate synthase, which is involved in the biosynthesis of the branched amino acids leucine, isoleucine, and valine in plants.[154, 155] With the sulfonylureas chlorsulfuron and sulfometuron-methyl, resistant plants were obtained by using selection against these herbicides.[156] The selection of plants resistant to dihydroimidazolones was also successful.[157] These plants show cross-resistance to sulfonylureas owing to the common site of action.

In both cases, the cause of the resistance seems to lie either in excess production of the enzyme or in a mutation of the gene. Both possibilities can easily be checked and reproduced with the aid of genetic engineering after isolation of the gene for acetolactate synthase.

Genetic engineering may be used to obtain herbicide-resistant plants via the following paths (the site of action refers to enzymes in these cases):

- —change in the site of action through mutation (e.g., glyphosate[158])
- —increase in the concentration of the site of action (e.g., glyphosate,[159] phosphinotricine[160])
- —introduction of metabolizing enzymes

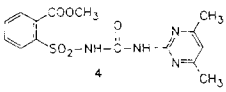
In order to choose the most favorable strategy, exact knowledge of the site of action and the degradation pathway of the herbicide is necessary. Usually, several of the paths indicated are successful for producing herbicide resistance.

The herbicide glyphosate prevents the synthesis of aromatic amino acids in plant cells by inhibiting the enzyme 5-enolpyruvylshikimate 3-phosphate synthase (EPSP synthase).[161] Glyphosate is one of the most widespread nonselective herbicides. Resistant plant cell cultures were obtained by selection in the presence of glyphosate. The resistance was found to be due to an increase in the concentration of EPSP synthase, which, in turn, was caused by an increase in the number of genes (gene amplification).[159] For the production of tolerant plants by means of genetic engineering, a similar strategy was followed. The gene for EPSP synthase was first isolated from cell cultures of *Petunia hybrida*. Overproduction of the enzyme in plants was then achieved by exchanging the promoter of the EPSP synthase gene for the constitutively acting 35S promoter of the cauliflower mosaic virus (Section 4.2). After reintroducing this hybrid gene into petunia cells, a 40-fold increase in enzyme activity was detected in calli and is presumably responsible for the observed tolerance.[163] Tolerant plants were obtained from these calli.

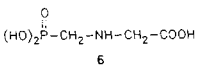
Tolerant plants may also be obtained by means of mutants that have an altered site of action for the herbicide glyphosate. After mutagenesis of *Salmonella typhimurium*, a strain was obtained whose EPSP synthase was insensitive to glyphosate. The resistance was based on replacement of one of the 421 amino acids of the *Salmonella* enzyme.[158] The mutated structural gene was isolated, fused with regulatory elements that are recognized in plants, and then integrated into the genome of tobacco plants. With this bacterial resistance gene, it was thus possible to obtain plants that are tolerant to glyphosate.[164]

A final example is provided by the herbicide phosphinotricine,[162] which, by inhibiting the enzyme glutamine synthetase, prevents ammonium ions from being metabolized

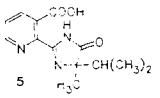
Table 5. Examples of herbicide resistance in plants.



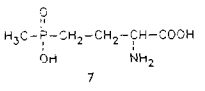
4



6



5



7

	Herbicide	Class	Mode of action	Ref.
4	Sulfometuron-methyl	Sulfonyl-urea	Inhibition of acetolactate synthase, thereby blocking biosynthesis of branched amino acids	[154, 156]
5	Imazapyr	Dihydro-imidazolone	Same as for 4	[155, 157]
6	Glyphosate	Amino-acid derivative	Inhibition of 5-enolpyruvylshikimate 3-phosphate synthase, thereby blocking biosynthesis of aromatic amino acids	[153, 159, 161]
7	Phosphinothricine (glufosinate)	Amino-acid derivative	Inhibition of glutamine synthetase, thereby increasing the intracellular concentration of ammonia and blocking biosynthesis of glutamine	[160, 162]

in plant cells. This enzyme catalyzes the following reaction:

$$\text{glutamate} + NH_4^{\oplus} + ATP \longrightarrow \text{glutamine} + H_2O + ADP + P_i$$

Resistant cell cultures were also obtained in this case. Gene amplification and a correspondingly increased concentration of the enzyme glutamine synthetase was determined as the cause of this resistance.[160] Owing to the increased number of copies of the glutamine synthetase gene, this cell line proved suitable for the isolation of the gene.[165]

Recently, the gene of a plant glutamine synthetase was expressed in an *E. coli* mutant that no longer had any glutamine synthetase of its own.[166]

5.1.2. Resistance to Viruses

In the production of virus-resistant plants by genetic engineering, considerable successes have recently been achieved. It was known for a long time, that, after an infection with a weakly pathogenic virus, plants do not develop any more symptoms when they are subsequently infected with a virulent strain. This property is used in the cultivation of tomatoes and potatoes. The molecular mechanism of this type of "cross resistance" has not yet been clarified. Different theories, some of them conflicting, are still waiting for experimental confirmation. Based on the consideration that cross-resistance could possibly be produced by the expression of specific genes of a virus, *Beachy* et al.[167] transferred the gene for the coat protein of the tobacco mosaic virus (TMV) by means of *Agrobacterium tumefaciens* to tobacco plants. Indeed, a high percentage of the transformed plants, which now form the coat protein of the virus, showed no symptoms after artificial infection with TMV. By contrast, a clear infection was observed in all the control plants after three to four days.

This very important success in producing virus-resistant plants enables specific investigations to be carried out into the phenomenon of cross-resistance, since only the expression of a single gene is required. This approach thus opens up the possibility of producing virus-resistant seed.

Induced resistance is possibly also linked to the formation of "pathogen-related proteins" (PR proteins). Several plants, after infection with viruses, viroids, bacteria, or fungi, form specific proteins whose occurrence can be correlated with resistance to further infections.[168] The concentration of PR proteins increases at the beginning of an infection to up to 100 times the initial value.[169, 170] They usually occur extracellularly and are frequently resistant to proteases. By crossing tobacco cultivars that form the same PR protein after induction with a pathogen, hybrids were obtained which form this PR protein constitutively and showed much greater resistance to virus infections.[171] Further investigations into the still unknown functions of these proteins promise to provide a better understanding of the resistance mechanism of plants.

Since gene sequences of some of these proteins have already been cloned,[170] the practical use of these resistance mechanisms may become possible in the foreseeable future. Investigation of the promoters of the PR protein genes may lead to numerous scientific and practical applications, since these genes are induced by infection and the genes for the PR proteins (about ten have been identified to date) may have different promoters. The overexpression of some of these proteins could activate specific protective mechanisms.

5.1.3. Resistance to Fungal Diseases and Microorganisms

In spite of the use of crop protection agents, damage caused by plant diseases continues to be very high. For 1976, worldwide crop losses due to disease, mainly of fungal origin, were estimated at 50 billion U.S. dollars.[172] Similarly to most of the previous examples mentioned, the genetic expression of resistances to diseases can be based on the utilization of natural resistance mechanisms, which are either intensified or transferred by genetic engineering between plants that were previously not capable of being crossed. As is the case with virus infections, an induced resistance also occurs in fungal and bacterial infections. It has not yet been possible, however, to explain its cause.[173] Plants possess a number of different defense mechanisms against infections:

- Increased lignin formation at the cell wall and thus greater protection against invaders
- Formation of hydrolases, whose function may be to degrade polysaccharides in the cell wall of invading fungi
- Formation of low-molecular-weight, secondary metabolites, which can have a toxic effect on infectious organisms
- Formation of "hydroxyproline-rich proteins" of unknown function, which occur in the cell wall of plants and whose concentration rises appreciably following an infection
- Formation of infection-specific proteins whose function has not yet been clarified, but which probably are an important factor in the defense against infections[174]

There are a number of possible approaches to producing resistance mechanisms against fungi or microorganisms by genetic engineering methods:

1. Clarification of the inducers and the mechanisms necessary for the expression of defense reactions in plants is necessary. Several triggers of defense mechanisms (elicitors) have already been identified. In addition, the genes of several important proteins whose expression rises sharply when infection occurs have been characterized.[175, 176]
2. Numerous plants contain the enzyme chitinase, whose activity increases considerably after fungal attack.[177] Chitin (poly-*N*-acetyl-D-glucosamine) is not found in plant cells, but is an important constituent of the cell wall of fungi. Therefore, the function of the chitinase formed during an infection is presumably to hydrolyze the fungal cell walls and thus defend the plant against fungal attack. Several chitinase genes have already been isolated.[178] The next step would be to use genetic engineering methods to achieve an increase in the formation of chitinase when fungal attack occurs.

3. Undomesticated relatives of our crops often possess important resistance genes. It has not in all cases been possible, however, to transfer these resistance genes to crops by means of crossing experiments. Here, genetic engineering could develop into an important tool for the breeder. One example is the occurrence of rust in soybeans *(Glycine max)*, which is caused by *Phakospora pachyrhizi* and can result in heavy crop losses. Although resistance genes have not been found in corresponding breeding plants, they are present in species of the genus *Glycine*. Their transfer to soybeans by genetic engineering methods would yield considerable economic benefits.[179]

4. Strains closely related to some plant-pathogenic organisms are often no longer able to cause infection in plants. Since it is often easier to carry out molecular biology studies in microorganisms than in plants, an attempt is frequently made to characterize the genes responsible for "recognizing" the susceptible host plants and for initiating the plant-pathogenic reaction.[180, 181] Once these mechanisms are understood, genetic engineering strategies can be devised to produce a resistance to these pathogens.

5.1.4. Resistance to Pests

As in the case of the examples discussed above, plants have presumably also developed defense mechanisms against insects. Fragments of the cell wall (oligosaccharides) are probably the inducing factors in some cases.[176, 182] One possible defense mechanism against animal pests is the formation of protease inhibitors as a reaction to plant lesions.[182] These are proteins that act as potent inhibitors of serine proteases, which are involved in the digestive process of insects.[183] The inhibitors can therefore act as feeding suppressants. Since the substances in question are proteins, genetic engineering should make it possible through overexpression of the corresponding genes to obtain increased formation of these inhibitors, perhaps specifically in leaves or fruits. The gene structure and sequence of an inhibitor of this type was published recently.[184]

The transfer of genes for proteins toxic to insects represents a further possibility for the creation of insect-resistant plants by genetic engineering methods. One example of such a protein is the toxin of *Bacillus thuringiensis*. The bacteria producing this toxin have already been used for decades in the biological control of certain species of caterpillars. However, because of their slow action compared with chemical crop protection agents, they have not been employed on a wide scale. Recently, the corresponding gene could be isolated and incorporated into tobacco plants.[185] Information is not yet available, however, on the insect resistance of a plant changed by this means. Another effective defense may consist in the formation of low-molecular-weight substances whose concentration rises considerably in the event of mechanical damage or insect attack and which at least suppress feeding.[175, 186, 187] These compounds can belong to a wide range of different chemical classes and are often secondary metabolites: phytoalexins, tannins, and even substances that function as hormones or signals (ecdysone, pheromones, and analogues of the juvenile hormone of insects). The utilization of this defense strategy for genetic engineering purposes appears problematic at present, since, on the one hand, numerous enzymes (and genes) are involved in the biosynthesis of the compounds mentioned, and on the other, these compounds frequently have unpleasant side effects on humans.

5.1.5. Stress Resistance

Many environmental factors produce stress conditions for plants: heat, aridness, excess moisture, high salt content of the soil, etc. As defense against these stress conditions, various counterreactions are initiated by the plant, the importance of which is not yet understood. In response to heat shock, for example, various proteins are synthesized whose precise function is not yet known. They are, however, certainly involved in a protective mechanism and are partly transported to the chloroplasts[188] and incorporated there.

Under other stress conditions, the formation of the same heat shock proteins frequently occurs, but on a smaller scale.[189] Stress-related fluctuations in the amino-acid content also occur; for example, a sharp increase in the proline content of plants is often observed.[190]

The genetic engineering approach to increasing stress resistance could lie in the identification and isolation of the most important genes involved in protection against stress conditions and the subsequent transfer of them from resistant to sensitive plants.

5.2. Changes in the Composition of Plant Substances

Several of the examples discussed in Section 5.1 in relation to the creation of resistance in plants already entailed the increased formation of specific plant substances. Further possibilities, which result in an "improvement" in the characteristics of a specific crop, will now be mentioned. This approach can be used, for instance, to influence both the production and processing of foodstuffs as well as plant raw materials used in industry.

Because of their high protein and amino-acid content, the seeds of cereals and vegetables constitute an important nutritional factor for humans and animals. However, the composition of the substances contained in this important food source does not always conform to requirements, since essential amino acids are often not present in the necessary amounts. Maize, for example, only has a low lysine and tryptophan content. For this reason, soybean flour is generally added when using maize as animal feed. Soya flour, however, is deficient in the amino acid methionine. A long-term goal of genetic engineering might be to change the amino-acid content of the storage proteins of important plants in such a way that a balanced composition is obtained. Using conventional breeding methods it has already been possible to develop maize varieties with a higher lysine content. However, this also resulted in undesirable features such as lower crop yields, lower protein content, and susceptibility to disease.[191] The genetic engineering approach to such a project is not simple, since large gene families are generally responsible for the forma-

tion of storage proteins. The increased expression of a single gene therefore does not appreciably affect the amino-acid content. Genetic engineering can be used, however, either to influence the metabolism in the seed in such a way that the content of a specific free amino acid is greatly increased or to introduce several, suitably altered genes. Other possibilities of improving the quality of plant seeds have been discussed.[192]

Apart from genetic changes in plant products used as food, the increased formation of substances of medicinal or industrial importance is doubtless also important.[193] An example is the genetic engineering of oil plants (e.g., soybean, rape, sunflower) with the aim of achieving a change in the oil composition. In principle, by transferring specific genes, it should be possible to obtain, within certain limits, uniform oil fractions which could be tailor-made for industrial application. For this purpose, however, much intensive basic research in the fields of biochemistry and molecular biology is still required. The new possibilities opened up for both agriculture and industry certainly appear to justify this kind of commitment.

5.3. Influencing Physiological Processes in Plants

Ribulose-1,5-bisphosphate carboxylase (rubisco) is a key enzyme in photosynthesis, since it is responsible for the fixation of carbon dioxide from the air (see Section 4.2). In addition to carbon dioxide, this enzyme also transfers oxygen to ribulose-1,5-bisphosphate and thus gives rise to the formation of undesirable side products. This reaction, known as photorespiration, diminishes the efficiency of photosynthesis.

Because of the fundamental importance of photosynthesis and photorespiration to all plants, there have been numerous attempts to use mutagenesis to create enzymes that exhibit a lower degree of photorespiration. Up to now, however, no commercially utilizable results have been obtained. The chances of reducing photorespiration have recently improved considerably, since the genes for the two subunits of rubisco have been isolated from photosynthetic bacteria and transferred to *E. coli*. An active enzyme was then formed in *E. coli*.[194] Furthermore, the three-dimensional structure of the enzymes from the photosynthetic bacteria *Rhodospirillum rubrum*[195a] and *Alcaligenes eutrophus*[195b] were recently published.

Moreover, gene transfer in *E. coli* has been used to create a hybrid, active enzyme of rubisco consisting of the large subunit from cyano bacteria and the small subunit from wheat.[196] It should now be possible, by means of site-directed mutagenesis with synthetic genes, to change almost any amino acid and subsequently study the effect on enzymatic activity. The great importance of an enzyme that, by means of an increased rate of fixation of carbon dioxide, gives rise to more efficient photosynthesis doubtless does not need to be emphasized.

5.4. Influencing Nitrogen Fixation

It should first be noted that nitrogen-fixing plants are unlikely to be produced before the turn of the millennium.

Table 6. Some applications of genetic engineering to nitrogen fixation.

a)	Fixation by free-living microorganisms
	Improvement of fixation reactions
b)	Fixation by symbiotic microorganisms
	Increase of efficiency (number of nodules, regulation)
	Host-range extension of rhizobia among leguminous plants
	Transfer of the capability to undergo symbiosis with other plants
c)	Nitrogen fixation in plants

However, this represents the "maximum requirement." A number of smaller steps could certainly be achieved in the next few years. Various possibilities for influencing nitrogen fixation are listed in Table 6. Numerous microorganisms in the soil, such as *Azotobacter*, *Azospirillum*, *Klebsiella*, and *Rhizobium*, are capable of fixing nitrogen from the air and forming ammonia. As a result of their metabolism, these bacteria contribute to nitrogen fertilization. The quantity of nitrogen bound by this biological fixation process is considerable. Worldwide, it amounts to many times the quantity of industrially produced ammonia.[179]

Nitrogen-fixing microorganisms can be divided into two large groups: free-living fixers and symbiontic fixers. Only in partnership with plants, frequently a leguminous crop, are the latter able to fix nitrogen. In this partnership, the microorganisms supply the product of their nitrogen fixation to the plant and in exchange receive from the plant assimilation products of photosynthesis. The proportion of symbiotically fixed nitrogen is far higher than the nitrogen combined by free-living microorganisms.

Structure and function of the genes involved in nitrogen fixation have up to now been investigated most thoroughly for *Klebsiella pneumoniae*, a free-living fixer, and *Rhizobium meliloti*, which forms a symbiosis with alfalfa.[198, 199]

In *K. pneumoniae*, the enzymes specifically involved in nitrogen fixation are coded by a block of 17 adjacent genes. The large number of genes involved in this process is one of the difficulties that has to be overcome for their transfer to plants. The control regions (promoters) of all these genes have to be changed and adapted to the conditions in the plant. Additional difficulties arise owing to the oxygen sensitivity of nitrogenase, the enzyme that reduces nitrogen, and the high energy requirement of the whole process of nitrogen fixation and assimilation.

When sufficient ammonium ions are present in the surrounding environment, the energy-consuming process of nitrogen fixation by free-living fixers is discontinued, since the requirement can now be met by uptake of ammonium ions. This regulation is achieved by specific genes, which, in the presence of ammonium ion, prevent the formation of the nitrogen-fixing enzymes. For agricultural application, strains in which this regulation is no longer operative can represent an important contribution toward improving the nitrogen supply.

The symbiotic nitrogen fixation of rhizobia takes place after formation of typical root nodules (Fig. 13). Development of a symbiosis depends on numerous complex steps: mutual recognition between microorganism and plant, infection of the root, formation of nodules, and finally the actual nitrogen fixation and exchange of molecules between plant and microorganism. About 40 genes of the plant are involved in the formation and functioning of the nodules.[200] In principle, each of the steps mentioned op-

Fig. 13. Symbiotic nodules on the roots of a broad bean plant as a consequence of infection with rhizobia. Fixation of nitrogen takes place in these nodules.

ens up a number of possibilities for influencing the overall process by means of genetic engineering. In the mutual recognition and formation of nodules, for instance, low-molecular-weight substances (flavones), which are excreted by the plant, are involved.[201] By influencing the type and quantity of the flavones that are biosynthesized and distributed, it may be possible to influence the number of nodules formed and thereby to achieve an increase in nitrogen fixation. The discovery of soybean plants that in comparison to the wild variety, possess a higher number of nodules, supports this possibility.[202]

The various symbiotic rhizobium strains exhibit a pronounced specificity for certain host plants. Marked differences arise in this regard in the growth behavior and fixation rates of the various bacterial strains. A realistic goal would be to widen the host spectrum of the rhizobia involved. This could result in a marked improvement in the supply of nitrogen to leguminous plants that up to now have only been capable of forming a symbiosis with slow-growing rhizobia.

Several of the plant gene products that are involved in the formation and functioning of nodules also occur in plants not able to form a symbiosis. It may be easier to use genetic engineering methods to enable these plants to form a symbiosis with bacteria than to transfer to them the ability to fix the nitrogen themselves.

5.5. Genetic Engineering as an Aid to Plant Breeding

Molecular biology methods can be used to supply precise information on the presence of specific genes in plants. The sensitivity of these techniques has been increased to the extent that they can be carried out with fewer than ten plant cells.[203] There are numerous possible applications of this technique in plant breeding: rapid examination of the progeny of crosses and of unknown genotypes for the presence of specific genes, characterization of certain varieties by identifying characteristic DNA restriction patterns (RFLP: restriction fragment length polymorphism),[204] information on the relationship between specific varieties, and tests for the presence of viruses in seed or breeding material. A comparison between such tests and the corresponding serological tests revealed that the results obtained by hybridization with DNA are more reliable and informative in determining the presence of viruses.[205]

6. Problems and Risks

The objectives of genetic engineering with plants, described in Section 5, are unlikely to cause any risk. Serious objections can hardly be raised against the development of resistant or high-yield varieties, since this has been the aim of conventional plant breeding methods for many decades. In the case of herbicide resistance, however, a discussion would appear to be useful in order to prevent misunderstandings. In addition to the hypothetical risks that might arise as a result of modifying plants by genetic engineering methods, herbicide resistance will also be discussed here.

6.1. Risks Resulting from Plants Modified by Genetic Engineering

Genetic engineering permits the isolation of genes from widely differing organisms and their incorporation in plants. With present methods it is only possible to transfer specific genes whose function is generally known. The following hypothetical sources of risk exist:

1. Development of rampant-growing plants with uncontrolled propagation (weeds);
2. Transmission of the transferred genes from crops to weeds by cross-fertilization;
3. Formation of toxic substances in plants modified by genetic engineering.

First, the release of plants modified by genetic engineering is far less problematic than the release of modified microorganisms or animals. Undesired plant growth can after all be controlled by various means (herbicides, mechanical weed control), which belong to the daily activities of the farmer.

Second, prior to a field experiment, plants modified by genetic engineering are first tested under laboratory conditions and in greenhouses. During this phase, any undesirable or harmful characteristics in a plant can be identified.

Third, plant breeders have for centuries achieved good results with widely differing crosses, including some that would never have come about without human assistance. In such experiments, tens of thousands of different genes are recombined. This has not up to now resulted in any serious problems. The methods of cell biology have also been used to create gene combinations in new plants,

which would never have resulted under natural conditions. Here one may call to mind the protoplast fusions between tomato and potato (cf. Section 2.2.1).[30] Even a critical examination gave no indication here of any possible risks. It is therefore inconceivable that the transfer of a few genes by genetic engineering methods might give rise to a dangerous situation.

Fourth, characteristics such as rapid, uncontrolled growth (weed formation) can be obtained only by means of a large number of genes which must be suitably adapted to one another. For this reason, it is also inconceivable that new weeds could be created unintentionally through genetic engineering with plants.

Fifth, characteristics unintentionally transferred to other plants (e.g., weeds) can only be preserved and dispersed if the necessary selection pressure is present. If the customary rules of good agricultural practice are observed (e.g., rotation of crops and herbicides), this is unlikely to occur when an unintentional transfer of individual genes takes place. Moreover, only in a few instances can crops cross with closely related weeds.

Sixth, in conventional breeding methods the possibility cannot be entirely ruled out that the concentrations of toxic substances peculiar to plants will be greater after a crossing experiment. One example of this is the development of varieties of potato possessing an unpleasant, burning taste due to an increased concentration of glycoalkaloids.[206] This was not a very surprising result, since many wild varieties of potato, which are frequently used in the development of new varieties, already contain high concentrations of these glycoalkaloids. Here, too, similar effects are unlikely to be obtained by selective transfer of a few genes. Moreover, toxic side effects can be easily identified by appropriate analyses and test methods.

In summary, it is difficult to recognize any specific or potential risk due to plants modified by genetic engineering.

6.2. Release of Plants Modified by Genetic Engineering

In the Federal Republic of Germany, organisms modified by genetic engineering may not be tested or released under field conditions. On request and after a hearing of the "Central Committee for Biological Safety," the Federal Health Department can, in agreement with the responsible federal biological institutes, allow exceptions.[207] As far as we know, no such experiments have hitherto been carried out.

It was recently reported in the press that in the USA two field experiments with tobacco plants modified by genetic engineering were approved by the responsible authorities. In one case, the plants contain an additional gene from yeast (the alcohol dehydrogenase gene) and, in the other case, they contain the toxin gene from *Bacillus thuringiensis*. The aim of the experiments now being conducted is to show that under field conditions an additional gene does not cause a change in growth behavior. In the latter case, resistance to caterpillars is also being tested under field conditions.

Within Europe, the preconditions and rules for carrying out field experiments on organisms modified by genetic engineering still vary considerably. From the viewpoint of both safety and competitiveness of the companies and research institutes involved, a uniform ruling, at least within Europe, would be extremely desirable.

6.3. Herbicide Resistance

The most important advantages resulting from the cultivation of herbicide-resistant crops are again summarized below:

- Use of herbicides only when required, and thus no further need for preventive application
- Increased economic efficiency for the farmer
- Increased use of ecologically favorable (more rapidly degradable) herbicides in place of older products
- Reduced soil erosion by preventing the appearance of exposed areas
- Replacement of herbicide mixtures by a single nonselective herbicide

These advantages are opposed by a number of potential disadvantages and apprehensions:

- Creation of ecological problems owing to increased use of herbicides when herbicide-resistant crops are grown
- Emergence of herbicide-resistant weeds
- Further decrease in the number of different varieties

The discussion on herbicide-resistant plants[208] should not overlook the fact that many years of experience have already been acquired in the use of selective herbicides in agriculture. The resistant crops possess metabolic pathways that render individual herbicides ineffective. A natural herbicide resistance thus exists, which applies only to the individual crop. The use of these selective herbicides on crops with natural resistance does not differ from the application of nonselective herbicides and the corresponding herbicide-resistant crops created by genetic engineering.

Because of the possibility of using herbicides only when required, i.e., not until weed infestation has gone beyond an acceptable level, and because of the replacement of several selective herbicides by a single nonselective one, the use of herbicide-resistant plants should result in less use of herbicides.

In the development of resistances to herbicides with long-lasting action, it cannot be ruled out that over a period of years the herbicide will accumulate in the soil and thus cause ecological problems. The trend observed at all research institutes toward the development of resistances only against ecologically favorable herbicides is therefore to be welcomed. This shows that the specific properties of the respective herbicide are the decisive factors in the discussion on herbicide resistance (degradation, environmental behavior, toxicity, possibility of accumulation, etc.). A separate discussion on each herbicide is therefore necessary.

The possible formation of herbicide-resistant weeds is probably not a major problem in the use of nonselective herbicides. For example, in spite of the fact that the herbi-

cide glyphosate has been used for over twelve years, no problems have yet arisen as a result of the development of resistances. In the event that herbicide-resistant weeds do indeed emerge, these can be controlled at any time by herbicides with other sites of action.

Herbicide resistance in a specific plant variety will probably be as important a characteristic, as, for example, resistance to disease, hardiness, or high yield. None of these characteristics alone, however, is a decisive factor in seriously eliminating other varieties of crops. Therefore, herbicide resistance is unlikely to reduce the existing number of varieties to a greater extent than the other breeding objectives mentioned. In this connection, it should also be emphasized that, as regards the modification of plants by genetic engineering, the preservation of as many different varieties as possible is of very considerable importance, since only in this way is a wide range of natural genes accessible.

Herbicide resistance is probably one of the most easily attainable objectives in genetic engineering with plants. The experience gained here can subsequently be utilized in solving more complex problems, such as the creation of resistances to virus infections, animal pests, or fungal diseases.

7. Summary and Prospects

A number of crop plants can be regenerated from single cells or protoplasts in any desired quantity by means of cell culture techniques. Such regenerating cell cultures are used both for selection of mutants and for DNA transformation experiments. DNA transfer by means of engineered Ti plasmids and *Agrobacterium tumefaciens* has become an established technique for a rapidly growing number of dicotyledonous plants.

Proof of general transformability by agrobacteria is still lacking in cereals. Alternative methods of DNA transfer are thus being developed. Direct gene transfer in protoplasts has proved to have universal applicability. Transformed cereal cell cultures are accessible from DNA-treated protoplasts by routine methods. The dogma that cereal protoplasts are incapable of being regenerated has been refuted by the successful plant regeneration from rice protoplasts.

Major efforts are being undertaken to render gene transfer independent of cell culture methods. For example, an attempt is being made to transfer foreign DNA into reproductive cells both by pollen transformation and by direct DNA injection into young inflorescences.

The number of isolated plant genes is rapidly increasing. By analysis of the regulation sequences of these genes, DNA segments are becoming accessible that are responsible for tissue-specific or environmentally stimulated expression of genes in plants.

The first genes that may be of economic importance to plant breeding and crop protection have already been transferred to plants. These include genes that impart to the transformants resistance against viruses, insects, or herbicides.

The further development of the biochemistry and molecular biology of plants will result in the elucidation of the molecular mechanisms of previously unexplained plant diseases, for example, fungal and viroid diseases. Although the complete sequence of the infectious RNA of a number of viroids has been determined,[209] there is still no explanation for the mechanism and causes of plant damage.

The efforts being made in the genetic engineering field will result in more resistant and productive plants. These plants will be available to the farmer in the 1990s. On the one hand, this will enable an important contribution to be made toward solving the problem of world famine; on the other hand, the production of tailor-made raw materials for industrial application will open up additional markets for agricultural products in industrialized countries. It may even be possible to use wild plants to create new types of crops with advantageous characteristics (e.g., salt tolerance, high biomass production, good protein quality in the harvested crop) by employing breeding and genetic engineering methods.[210]

Close cooperation between biochemists, cell biologists, molecular biologists, plant pathologists, and plant breeders is urgently necessary in order to obtain more productive crops with high adaptability and less susceptibility to disease.

Our thanks are due to H. Dräger for preparation of the light-optical micrographs. We wish to thank B. Diehls and R. Stehr for typing the manuscript and P. Spönemann for drawing the figures.

Computer-Assisted Molecular Design (CAMD)—An Overview

By Horst Frühbeis,* Robert Klein, and Holger Wallmeier

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

A new instrument, long established as CAD in engineering, is beginning to make its presence felt in chemical research laboratories: Computer-Assisted Molecular Design (CAMD). The combined use of computer graphics and theoretical chemistry is opening up new perspectives in molecular research. Structures and properties of molecules such as spacefilling, charge distribution, or dynamic behavior can be determined and used for comparison. For research on complex systems like biomolecules (protein engineering), this new approach turns out to be indispensable.

1. Introduction

Computer-assisted molecular design is a new approach to molecular research using methods from theoretical chemistry. The essential feature is the use of models and their realization on a computer. This may be regarded as the continuation of an old tradition. Many important concepts of chemistry have been worked out using models.[1] As an example take *van't Hoff* and *Le Bel*'s tetrahedron model of the carbon atom, which gave rise to the terms valency and isomerism in organic chemistry. With his model of the benzene molecule, *Kékulé* likewise prepared the way for the concepts of delocalization, conjugation, and resonance. In developing the model of the DNA double helix, *Watson* and *Crick*[2] opened up a new dimension in the understanding of specificity.[3]

Concomitant with the increasing interest in large systems more and more detailed problems are being encountered, and there is a growing tendency to transfer molecular models from the chemist's desk to the computer. This offers the possibility of providing models with well-defined properties and boundary conditions, and thus obtaining quantitative information. The mathematical instruments of theoretical chemistry and many-particle physics can be used. Computer graphics as a tool for handling models has played a decisive role in this development.

The interest of industrial research in computer-assisted molecular design stems from the desire to make the search for new drugs and plant protection agents more efficient. Theoretical methods can help to keep research costs within limits and are therefore being used to an increasingly greater extent. At present, there are two complementary strategies. The one which is based on structure/activity relationships takes an indirect route by comparing known active compounds. For the large number of cases where site and mechanism of action are not known, comparative methods are indispensable. In contrast, the other strategy requires knowledge of the target of action. Active compound and receptor are both included in the model. The computer becomes the locus of an experiment.

From a large number of different applications it has become obvious that both strategies can be used for more than just drug design. In the present review, we therefore try to outline the spectrum of theoretical, molecular research by presenting a representative selection of the large variety of methods used and their possibilities. We regard computer-assisted molecular design as a new *additional* tool for research—combination with experiment still remains an essential precondition for successful molecular design.

2. Interactive Modeling

Computer-assisted molecular design (CAMD) was introduced into chemistry only a relatively short time ago, whereas computer-assisted design in engineering (CAD) has been well established for several years. One of the reasons for this is that interactive work with three-dimensional structures—a typical operation in molecular design—requires highly developed computer graphics systems, which have become available only in the last few years. They generally consist of a minicomputer, a graphics system, and very extensive software. Their development began with the MAC project at the Massachusetts Institute of Technology. Probably the first computer graphics system for molecular modeling was developed in the course of this project. *Cyrus Levinthal*, director of this project, also published the first papers on computer-assisted molecular graphics.[4] Since then a large number of modeling systems have been developed at universities and industrial research institutes,[5-7] but almost exclusively in the USA and Great Britain, only one important contribution coming from Germany.[8] For this reason, the major part of commercially available software now comes from the Anglo-Saxon countries.[9-13] This also applies to the hardware. A good review of the development of molecular graphics is given in Ref. [14]. Molecular graphics systems have now become a useful instrument in molecular research. They make it possible to employ substantially more complicated models than has been possible in the past. At the beginning, computer graphics was predominantly used in pro-

tein crystallography. As a consequence, the molecular modeling program, which is probably the one most widely used, was developed by a crystallographer.[8] Other areas followed, including drug and plant protection research.

The modeling systems mentioned above have more or less convenient user interfaces in their current versions and differ considerably in the number of features available. Some have been designed primarily for modeling large biopolymers,[11] while others are more suitable for medium-sized organic molecules.[10, 13] However, there are also program systems for handling any type of molecule.[6]

The important features of computer-assisted molecular design, to be found in most of the modeling systems, will be described in the following. To start modeling, chemical structures can be generated either by building them up from atoms and/or molecular fragments or by altering an existing structure, for example one taken from a data base.

Molecules can be displayed e.g. as vectors, which correspond to the bonds (Dreiding models), as overlapping spheres (space-filling CPK models), or as vectors together with a transparent space-filling representation, consisting of a dotted surface or a polygonal network (chicken wire model). The object displaced on the screen can be rotated, zoomed, and clipped (3D clipping). All operations work in real time. Furthermore, a number of techniques are available which give a three-dimensional impression of the object, for example by rotation and wagging, perspective representation, and depth cueing (the intensity of the vectors represented decreases with increasing distance between the object and the observer). The most elegant solution, however, is provided by the liquid crystal 3D viewer.[15] A detailed description of virtually all the techniques available is given in Ref. [16].

To visualize properties of three-dimensional structures, it is often helpful to superimpose them. Thus, for example, the space occupied, or atomic charge patterns can be compared (see Section 4.1). A typical problem in modeling is the analysis of the conformational space of a molecule. All the possible geometrical arrangements for a given structure at a specified level of energy have to be determined. This is performed interactively by connecting the relevant torsion angles to dials and rotating them, and monitoring the energy in real time. Such an analysis can also be carried out systematically by means of special algorithms (see Section 5). Conformation analysis was one of the first applications of computer modeling.[17]

The docking of substrate and inhibitor molecules into enzymes is used to determine whether or not a proposed structure will fit into the active site cavity of a particular enzyme. Some stages of such a docking manoeuvre are shown in Figure 1. One of the first programs for carrying out interactive docking was developed by a crystallography group.[18] Docking programs were generally designed so that enzyme and substrate can be subjected to rotations or translations, both together and separately. Moreover, any desired conformation of the substrate can be generated by rotation through the appropriate torsion angle. In the simplest case, it is possible to check by inspection whether or not an arrangement produced in this way is physically realizable. Overlap of van der Waals radii of the enzyme and inhibitor should be avoided. This can be checked easily with the above mentioned graphics facilities of a modern modeling system. In addition, the energy of the complex under consideration can be calculated. It has to be minimized in the course of the docking manoeuvre.

A more elegant tool for interactive docking is the display of 'hot spots' (Fig. 1b), which indicate sites of strong repulsion between enzyme and substrate. Such sites must be eliminated by means of the usual geometrical operations on the substrate. Interactive docking is very time-consuming and requires a lot of intuition; nowadays it should only be used for relatively rigid inhibitor or substrate molecules. For flexible molecules, automatic docking is the method of choice (see Section 5.5).

Apart from these basic functions of CAMD, the structure data banks at Cambridge (Cambridge Crystallographic Data File) and Brookhaven (Brookhaven Protein Data Bank) play a very important role. They provide a vast number of experimentally determined chemical structures which can be used for modeling directly, or in the form of

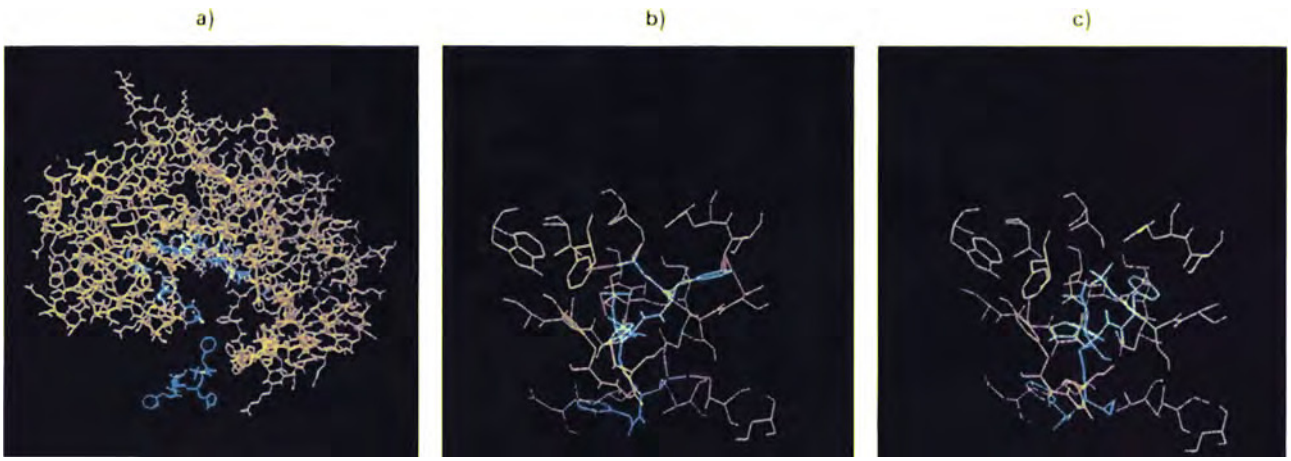

Fig. 1. a) Skeleton model of the enzyme renin (yellow) with a view into the active site (blue) and a model inhibitor (blue) in the lower part of the picture. b) Cavity of the active site (yellow) with poorly docked inhibitor (blue). The red vectors indicate 'hot spots'. The complex has an energy of 14220.53 kcal/mol. c) Optimally docked inhibitor. The energy is markedly less than in b) (180.61 kcal/mol).

templates. It is for this reason that virtually all CAMD program systems include interfaces to these data banks. A description how to exploit the Cambridge Data Bank in a skilful fashion is found in Ref. [19], for example, and in the literature cited therein.

3. Analytical Studies on Models—the Deductive Route

3.1. Basic Principles

To estimate the stability of molecules a number of quite different criteria are considered in chemistry. One may, for example, look at the lifetime of a molecule, i.e. the probability and conditions for decomposition or transformation. The behavior against various reagents is another aspect of stability. Frequently, molecular models are used to interpret the findings in terms of steric hindrance, ring strain, bond strengths, and polarities.[20] For computer models it is very useful that all those aspects of stability can be correlated with the total energies or energy changes of a system. Energy is thus the most important property of a computer model.

Quantum mechanics enables the calculation of the energy of atoms and molecules and therefore forms the basis of most computer models of chemical systems. The characteristic feature of a quantum mechanical model is the wave function, which, as a solution of the Schrödinger equation, contains all the information for a particular state of the system. An important simplification in calculating molecular wave functions is the Born-Oppenheimer approximation.[21] It allows the motions of nuclei and electrons to be considered separately. One obtains the electronic Schrödinger equation,[22] which describes the motion of electrons in the field of stationary nuclei. The electronic wave function is generally represented by orbitals, i.e. solutions for one-electron atoms. In the case of molecules, orbitals are combined according to their symmetry in the molecular orbital (MO) formalism, and according to the bonds between atoms in the valence bond (VB) formalism.[23]

Among the quantum mechanical methods used today, the ab initio methods are those which are closest to solving the electronic Schrödinger equation. The Hartree-Fock self-consistent field (SCF) method[24] is the most important method in practice, particularly in conjunction with basis set expansions, like the Roothaan SCF scheme.[26,27] It represents the lowest level at which the interaction between electrons can be described completely. The computational effort is proportional to the 4th power of the number of electrons, so that meaningful application is restricted to systems of, say 30 second-row atoms, even when supercomputers are used.

Approximations at a somewhat higher level are the method of configuration interaction (CI),[28] the multiconfiguration SCF (MCSCF),[29] and methods based on perturbation theory, such as the Møller-Plesset formalism (MP).[30] Usually they are based on the SCF scheme and provide an improved description of the electron interaction (electron correlation). When used correctly, these methods give substantially more reliable results than simple SCF calculations. Unfortunately, the computational effort for these methods increases with the 5th power of the number of electrons, so that possible applications are even further restricted.

An almost complete parametrization of electron interaction is the key feature of the so-called semiempirical methods.[31] As a consequence, the computational effort is at most proportional to the 3rd power of the number of electrons. The proper choice of parameters is crucial for the usefulness of the results. Hence, these methods can only be used to investigate phenomena, which the parameters chosen are able to describe. A considerable advantage, however, is that one can study quantum effects on systems which are not just trivial fragments of the systems one actually is interested in.

In the Born-Oppenheimer approximation, the energy E of the electronic Schrödinger equation is the potential for the motion of the N nuclei. The gradient of the energy hypersurface (energy as a function of the nuclear coordinates, $E=E(\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_N)$) can be used to determine the forces which act on the nuclei. Minima in the hypersurface correspond to force-free arrangements of the atoms and are referred to as equilibrium geometries or conformations. For determining conformations, it is advantageous if the hypersurface is given as an analytical function (see Section 5.1). This can be achieved, at least locally, by approximation with suitably simple functions. One starts off from a representation in terms of interatomic distances, valence angles, and torsion angles, which correspond to the internal degrees of freedom of molecules.[32] Potential functions with adjustable parameters are used to represent the energy of the internal degrees of freedom.[33-35] In the harmonic approximation, harmonic oscillator potentials are used for bonds and valence angles, while trigonometric functions of proper periodicity are employed for the torsion angles (Fig. 2). In addition, long-range interactions

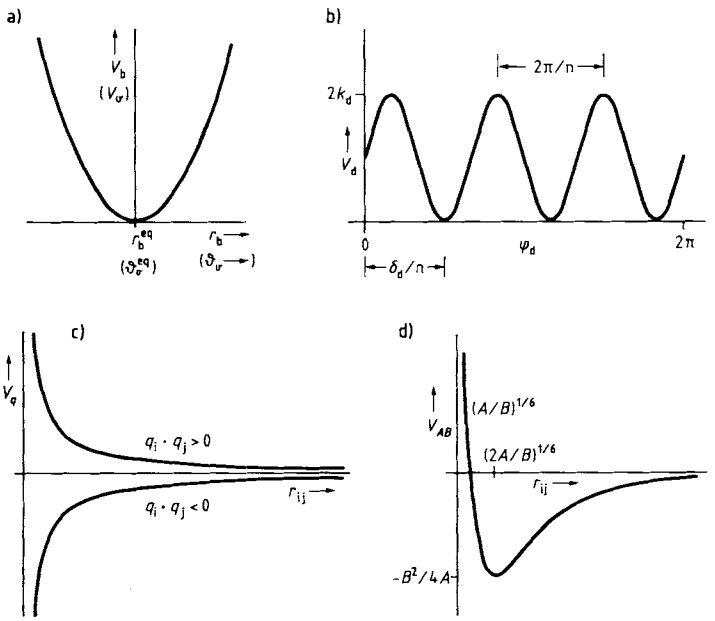

Fig. 2. Potential functions for valence force fields. a) Potential of the harmonic oscillator. b) Potential for torsion angle. c) Potential for Coulomb interaction. d) 12/6 Lennard-Jones Potential for van der Waals interaction.

are represented by Coulomb potentials for the effective charges and by Lennard-Jones potentials for the van der Waals interactions. In the valence force field, all coupling terms between the internal degrees of freedom are neglected, so that

$$
\begin{aligned}
E \approx V = & \sum_{b} k_b (r_b - r_b^{eq})^2 && \text{bond lengths} \\
& + \sum_{\nu} k_\nu (\vartheta_\nu - \vartheta_\nu^{eq})^2 && \text{valence angles} \\
& + \sum_{d} k_d (1 - \cos(n_d \varphi_d - \delta_d)) && \text{torsion angles} \\
& + \sum_{i,j} q_i \cdot q_j / (4\pi\varepsilon r_{ij}) && \text{effective charges} \\
& + \sum_{i,j} A_{ij}/r_{ij}^{12} - B_{ij}/r_{ij}^{6} && \text{van der Waals interactions}
\end{aligned} \qquad \text{(a)}
$$

'eq' denotes equilibrium values which fix the position of the particular potential minimum, and ε is the dielectric constant. The parameters k_b, k_ν, k_d, r_b^{eq}, ϑ_ν^{eq}, n_d, δ_d, q_i, A_{ij} and B_{ij} permit fitting to the energy hypersurface. In molecular models they serve to distinguish between different types of atoms and bonds, and thus determine the properties of the model. The term 'force field' usually refers to a set of such parameters in conjunction with the corresponding potential functions. The term is based on the relationship (b).

$$\vec{F} = -\text{grad}(V). \qquad \text{(b)}$$

The type of force field described above (valence force field) has been implemented in various program systems,[33,36,37] which are also used to study biomolecules. It constitutes the simplest form in which the most important interactions can be described and is also suitable as a basis for computer simulation (see Section 5). All contributions to the energy can be readily formulated in computer programs. The computational effort is proportional only to the square of the number of atoms.

Concerning the potential functions, a number of variants exist: for example, bonds are described by some authors in terms of anharmonic potentials;[38,39] linear combinations of trigonometric functions of different periodicities (Fourier expansions)[40] are used for torsion angles; and modified potentials for the van der Waals interaction are employed to describe hydrogen bonds.[37,40]

The extended valence force fields[39,41] contain a few of the coupling terms between the internal degrees of freedom, which is particularly advantageous for strained molecules[42] but makes calculation of the energy and determination of the parameters more complicated (see below). Models of large systems require force fields which are optimized with respect to the balance between computational effort and 'physical content'. This is most readily achieved with the valence force fields.

A common drawback of force fields is the treatment of Coulomb interaction in terms of effective charges. Due to the polarizability of the atoms, the charges have a mutual effect on one another and change with the conformation of the molecule. Distance-dependent as well as scaled dielectric constants have been used as a remedy.[40] The situation is critical because Coulomb interaction often accounts for the major part of the total energy of a conformation.

Given a set of potential functions, the number of force field parameters is determined by the number of atom types g to be distinguished. For example, in a valence force field of the form (a), $g(g+1)/2$ equilibrium distances and force constants are required for the bonds. For the valence angles, as many as $g^2(g+1)/2$ equilibrium angles and force constants are needed, and in principle $(g(g+1)/2)^2$ force constants, phase angles and periodicity factors are necessary to distinguish between all possible types of torsion angles. The nonbonding interactions can be described by g effective atomic charges and $g(g+1)/2$ Lennard-Jones coefficients. In order to keep their number as small as possible, atom types and parameters should be chosen such that there is maximum transferability. However, this imparts an artificial, internal symmetry to the force field, which becomes a property of the model, as well.

As indicated above, force field parameters can be determined by fitting the potential functions to quantum mechanical energy hypersurfaces. Furthermore, quantum mechanical calculations are the most important source of the effective charges of atoms (see Section 3.2).

In general, force field parameters are determined from experimental data.[35,42,43] A very widely used method is the so-called consistent force field procedure,[33] in which force field parameters are varied iteratively until given experimental data are reproduced. The most important sources of data are IR and Raman spectroscopy for force constants, and X-ray crystallography and microwave spectroscopy for equilibrium geometries. The parameters of the van der Waals interaction are frequently derived from thermodynamical data, such as heats of fusion and vaporization, as well as volume/temperature diagrams.

3.2. Calculation of Molecular Properties

Quantum mechanical models are necessary for the investigation of electronic properties. A population analysis, i.e. the summation of the moduli of orbital, atomic, or bond contributions to the wave function, permits the electron and charge distribution to be characterized in terms of effective charges and hybridizations.[44] The moments of the charge distribution (dipole moment, quadrupole moment, etc.)[26] and, using test charges, the entire electric field of the system can be determined.

Preferred positions for electrophilic or nucleophilic attack can be identified as regions of enhanced or reduced electron density.[45] The corresponding structuring of the electric field is very important for the initial phase (molecular recognition) of reactions.[3]

Optical properties of molecules are generally related to transitions between different states.[46] The chrominance, i.e. the ability to absorb light of certain wavelengths, is attributable to the energy difference between two states having a sufficiently high transition probability, the latter being a measure of intensity.[46]

Energy differences, regardless of whether they relate to conformational changes, rearrangements or reactions, can often be read off directly from the energy hypersurface as level differences. In some cases, however, structuring of the hypersurface is an indication of nonadiabatic phenomena, for which the Born-Oppenheimer approximation no longer holds.[47] This applies very frequently to transition states of reactions, if there is a competition between homolytic and ionic dissociation of a bond. In such critical cases, it is appropriate to use the more elaborate methods, such as CI or MCSCF, for determining both energy barriers and geometry.

Like the electric field, the geometry of a molecule is one of the important factors determining affinity and activity of molecules. Optimizing the geometry is equivalent to locating the deepest minimum of the energy hypersurface. If the initial geometry is not too far away from the minimum, it is sufficient to relax the structure, i.e. to vary the coordinates of the atoms so that the energy cannot be lowered further. Several methods[48,49] are available for carrying out optimizations of this type, which will not be discussed here in detail.

One aspect of the geometry is spacefilling, which brings into play the concept of molecular surface. From the quantum mechanical point of view, the surface of a molecule is a fractal, i.e. a geometric object with a dimensionality between two and three,[50] which can neither be readily represented nor easily handled. However, the concept of fractals makes it possible to quantify roughness and structuring, which is certain to become important with regard to the understanding of processes on solid surfaces and membranes.

A somewhat more pragmatic concept of spacefilling and surface can be derived from the van der Waals radii of the atoms. A molecule is taken as an arrangement of overlapping spheres (CPK spacefilling model). If the overlap of the spheres is taken into account, the volume and surface area of a molecule can be calculated[51-54] (also see Section 2).

Spacefilling by molecules is generally used to assess steric similarity of molecules (see Section 4). The surface area of a molecule provides information about the behavior towards solvents.[54,55] In addition to the effective charges of the atoms, the curvature of the surface is regarded as a measure for the ease of solvation, i.e. the accessibility of the particular atoms to solvent molecules. For this purpose, an imaginary sphere is allowed to roll on the surface of the spacefilling model, and the appropriate parameters are read from its path.

4. Comparative Methods

With the aid of so-called comparative methods, an attempt is made to extrapolate experimental data, i.e. to transfer the data which are available for a number of compounds to other molecules taking into account structural similarities and differences. In general, these data are reactivities or biological activities which, if they could be obtained prior to synthesis, would help to select the most promising compounds. A study of the relationships of structure and reactivity/activity is based on the experience that molecules which have similar structure also exhibit similar chemical and biological behavior.

Unlike the approaches described in Section 5 the comparative methods do not necessarily require experimental information about the site where the molecule finally acts or reacts. Thus, e.g. quantitative structure-activity relationships can be set up for a number of enzyme inhibitors without knowing anything about the enzyme itself.

4.1. Superposition Methods

In medicinal chemistry, activity of a low molecular weight substance is often equivalent to a specific receptor interaction. This correlation is attributed to a molecular recognition mechanism.[56] Consequently, all compounds which form a stable complex with the same receptor should exhibit a common structure-dependent feature which is referred to as a pharmacophore. In this context, a pharmacophore is not restricted to a certain substitution pattern as is generally done, since it has been found that a recognition pattern can, for example, also be realized by the charge distribution in a molecule.[57] The comparison of molecules by superposition with the aid of one of the methods discussed below is used to set up, confirm or discard a pharmacophore model for a particular biological action and to design new molecular structures which also carry the pharmacophoric pattern. A three-dimensional superposition is necessary because not only the presence of obvious common features like functional groups are responsible for the recognition by the receptor but the three-dimensional orientation of the pharmacophore as well.

In the simplest case of a structural comparison, the centers of functional groups in a set of structurally analogous molecules are considered. Using a least squares fit procedure, the sum of the distances between corresponding centers is minimized by displacing and rotating the rigid molecular skeletons. However, in general the initial conformations of the molecules under investigation do not correspond to those that allow a truly optimal fit. Therefore, it may also be necessary to perform rotations about single bonds or even to allow all atoms to move freely in space. In order to exclude unreasonable conformations or geometries the energy required for the geometry change or another suitable parameter (e.g. bump check) is calculated simultaneously. The remaining differences—possibly together with the energy required for the fit—provide qualitative information about the closeness of the fit of the basic pharmacophore model and the structural properties of the molecules investigated.

The van der Waals volumes too are suitable for testing steric correspondence.[51,52,58] For example, the degrees of freedom are varied so as to achieve a minimum of the united volume of all molecules. A pharmacophore model restricted to these space-filling properties is shown in Figure 3. The fungicides shown there inhibit the enzyme cytochrome P450 monooxidase which is vital to fungi.

The discovery of suitable evaluation functions for the matching of charge patterns by varying the degrees of freedom of the molecules is not a completely trivial matter.

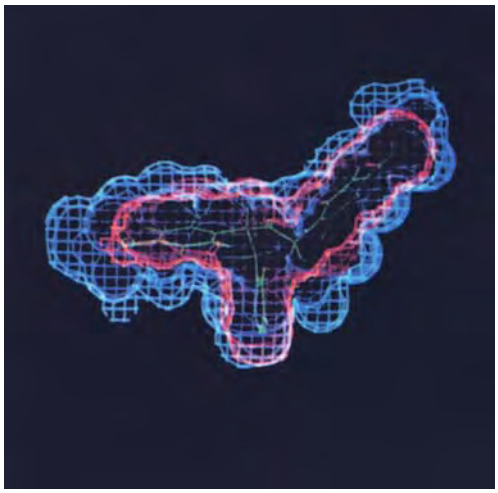

Fig. 3. Chickenwire representation of the van der Waals volumes of the natural substrate (blue) of cytochrome P450 and miconazole (red). The molecular skeleton of miconazole is shown in green.

Namasivayam and *Dean*[59] have described a statistical method for matching charge patterns on molecular surfaces. A least squares fit procedure can also be used to fit the electrostatic potentials of several molecules on an arbitrary surface which is resolved into grid points.[60] In Figure 4, the potential differences are projected on a section

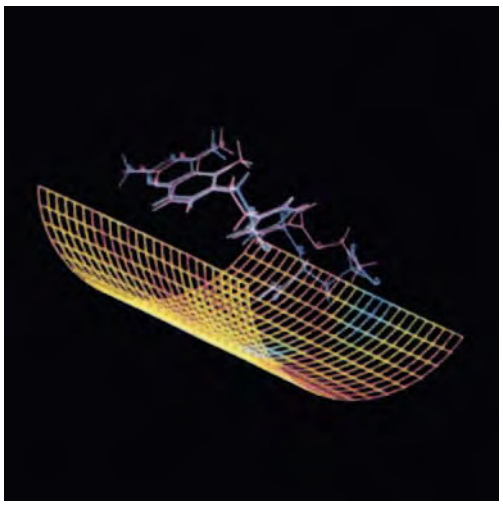

Fig. 4. Projection of the electrostatic potential difference of two quinazoline derivatives (dihydrofolate reductase (DHFR) inhibitors) onto a surface (red: small differences, blue: large differences).

of the curved surface of a cylinder which surrounds the molecules to be compared. By appropriately coloring the vectors between the grid points the differences in the charge patterns before and after the fit can conveniently be analyzed visually. *Broto* and *Moreau*[61] use a so-called intercorrelation function to superimpose structures with respect to the effective atomic charges (as well as other atomic properties). Here, they translated their concept of the autocorrelation function[62] for describing the "property distribution" within a molecule into the problem of making similarities in this distribution quantifiable. *G. Naray-Szabo*[63] uses an electrostatic lock-and-key model to investigate common features of trypsin inhibitors.

A very elegant method which makes it possible to confirm or reject a pharmacophore model is called the active analog approach developed by *Marshall* et al.[64] A pharmacophore hypothesis is first proposed by defining several functional groups or hetero atoms to be essential for activity. A systematic conformational search (torsion or rotatable bonds) in all molecules is supposed to give that three-dimensional arrangement of the pharmacophore which at least can be realized by all active compounds. If there is no such arrangement the initial hypothesis is rejected. If the search has been successful the three-dimensional pharmacophore found this way serves as an initial criterion for the classification of novel compounds. In a second step the volume provided by the receptor—the so-called excluded volume—is determined as the united volume of all active molecules in their active conformations. In spite of having the correctly oriented pharmacophore, inactive molecules should not be capable of being fitted into this volume. Otherwise, there will once again be a reason for doubting the correctness of the proposed pharmacophore.

The so-called distance geometry method developed by *Crippen*[65] for describing molecular geometry can also be applied to the problem of extracting common steric features from a set of molecules.[66,67] The flexibility of a molecule is represented by a minimum and a maximum distance matrix, i.e. by a range of validity of the interactomic distances. For the distance between two atoms (or representative points) of the pharmacophore, the only values allowed are those which lie within the range of validity for all active molecules. This considerably reduces the number of conformations which can be calculated from the distance matrices.

Frequently, the structure of the transition state of the natural substrate rather than a number of active compounds is used as a template for the design of novel drugs (transition state analogs)[68] (also see Section 3.2). Since the properties of transition states are in general difficult to determine experimentally, as a rule, extensive quantum-mechanical calculations (ab initio, MNDO, MINDO etc., also see Section 3.2) of the reaction path from the substrate to the product have to be carried out.

A pharmacophore model which has been derived by one or more of the methods described above provides, with certain restrictions, information about the structure and properties of the receptor. In the literature, the procedure for obtaining such a qualitative image of the receptor is often referred to as receptor (site) mapping.[58,67,69-71] Thereby, it is possible to design novel drugs which do not necessarily exhibit the same structural features as the active molecules compared or the lead compound, and yet to estimate the activity of the novel compound, even if purely qualitatively.

4.2. Qualitative Structure-Activity Relationships (SAR)

The methods described so far are suitable only for a relatively small number of compounds to be compared. Furthermore, they are based on the assumption that there is

essentially only one mechanism responsible for the biological activity, namely the formation of a receptor-ligand complex. The use of so-called pattern recognition (PR) methods[72] does not depend on any of these conditions. PR is based on structure-dependent molecular properties, so-called descriptors (e.g. number of oxygen atoms in the molecule, molecular diameter, etc.). Depending on the individual values of the descriptors each molecule has a particular descriptor pattern. Using artificial intelligence methods and mathematical procedures such as cluster analysis, principal component analysis and discriminant analysis these patterns serve to assign a compound to activity classes. PR is used in particular where a large number of structural inhomogeneous compounds is encountered, for example in studies on carcinogenicity and genotoxicity.[73]

In the approach of *Broto* et al.[62] a so-called autocorrelation vector is calculated for each molecule from atom-related parameters or properties (e.g. heteroatom/non-heteroatom, atomic log P increment etc.). These vectors can be considered to represent the property distribution within the molecules and are used to classify the compounds according to their activities.

The so-called CASE algorithm[74] (computer automated structure evaluation) breaks up the molecules under investigation into fragments and searches for those substructures which contribute to activity or those which lead to inactivity. Thus, this method immediately provides a pharmacophore model. A similar approach, which also permits the derivation of quantitative structure-activity relationships, has been reported by *Streich* and *Franke*.[75]

4.3. Quantitative Structure-Activity Relationships (QSAR)

In a study of quantitative structure-activity relationships an attempt is made to describe the activity or reactivity within a set of compounds by means of a mathematical formalism which incorporates structure-dependent parameters (descriptors).[76] Although the classical QSAR approaches were introduced purely empirically they can be derived in terms of an extrathermodynamic approximation[77] (additivity of substituent effects, separability of different effects etc.).

The first quantitative structure-activity relationship was developed as early as 1937 by *Hammett*.[78] He correlated the hydrolysis rate of *meta*-substituted and *para*-substituted benzoates with the so-called Hammett σ which is calculated from the dissociation constants of the corresponding benzoic acids. In order to obtain a relationship which could be applied to *ortho*-substitutions as well, *Taft*[79] added a steric parameter E_s to the Hammett equation.

In addition to electronic substituent effects, which were to be described by the Hammett σ, hydrophilic/hydrophobic properties were also considered responsible for biological activity. Therefore, *Hansch* et al.[80] introduced a further parameter, π, [eg. (c)] which is based on studies by *Meyer* et al.[81] and *Overton*[82] and is calculated from the octanol-water partition coefficient (log P value).

$$\log(1/C) = a \cdot \sigma + b \cdot \pi + c \qquad (c)$$

C is the (theoretical) activity; the coefficients a, b and c are determined by a least squares procedure so that equation (c) optimally reproduces the measured biological data of a selected set of molecules (regression analysis). Many systems, however, cannot adequately be described by this approach. *Hansch*[83] attributed these deficiencies to transport mechanisms which also manifested themselves in the in vivo activity data and therefore assumed a parabolic dependence of the activity on π [eq. (d)].

$$\log(1/C) = a \cdot \sigma + b \cdot \pi^2 + c \cdot \pi + d \qquad (d)$$

Probably the most frequently used form of the classical QSAR approach, based on a linear combination of descriptors, also takes into account steric effects with the aid of *Taft*'s E_s [eq. (e)].

$$\log(1/C) = a \cdot \sigma + b \cdot \pi^2 + c \cdot \pi + d \cdot E_s + e \qquad (e)$$

Extensive efforts are still being made to improve the substituent parameters, replace them by others or add new ones. *Hammett*[84] himself differentiated between σ_m for *meta*-substituents and σ_p for *para*-substituents. The knowledge that electronic effects comprise an inductive part and a resonant part led to a splitting of σ into σ_i and σ_r.[85]

In addition to the Hansch π, other substituent parameters which can be derived from measurable molecular properties, have been proposed for modeling hydrophobic interactions: the parachor which is related to the surface tension,[86] the Hildebrand-Scott solubility factor[87] and parameters obtained from chromatography.[88] An empirical hydrophobicity parameter can be calculated by the HIBIS method.[89] The classical QSAR approach employs only scalar descriptors. However, steric properties of substituents are based on three-dimensional orientation. It is therefore difficult to model steric effects by means of parameters such as *Taft*'s E_s or *Charton*'s U,[90] which is calculated from van der Waals radii. By separating the steric descriptor into components *Verloop* et al.[91,92] was nevertheless successful in introducing relative orientation into the so-called STERIMOL parameter. Further steric parameters, all of which are based on the superposition of molecular volumes, are the MSD,[93] MTD,[94] SIBIS,[70,95] and 3D-MSD[52,96] descriptors.

The typical PR descriptors and the components of autocorrelation vectors in *Broto*'s approach[97] are QSAR descriptors of a very special type. There have also been many attempts to correlate the biological activity with other computable parameters which describe the molecule or a substituent effect. For example, parameters derived from semi-empirical quantum mechanical calculations[98] and electron densities from Hückel and CNDO/2 calculations[99] have been used as QSAR descriptors.

Apart from (multiple) regression analysis[100] as the standard method, principal component analysis,[102] discriminant analysis[103] and cluster analysis[104] are also used for the statistical exploitation[101] of a Hansch or a similar QSAR approach. Several statistical parameters, such as the RMS deviation and the correlation coefficient, provide means to check the reliability of a regression analysis.[100]

The significance of a descriptor can be determined approximately by performing two QSAR procedures with and without the descriptor and by comparing the respective correlation coefficients. However, even satisfactory statistics cannot exclude random correlations.[105] The probability of chance correlations clearly grows when the number of descriptors becomes large compared with the number of structures used.[106]

In the QSAR approach by *Free* and *Wilson*,[107] structure-activity relationships are set up without physicochemical parameters. It is assumed that the substituents contribute additively to the activity. The activity value of a compound is taken to be the sum of a basic activity and the contributions of the substituents. The contribution of a substituent depends both on its type and its position in the molecule. If the equation is set up for all tested compounds a system of linear equations is obtained. By solving the equations using a least squares fit procedure the individual substituent contributions can be determined. The effect of substituents other than those present in the compounds tested cannot be calculated; only the effect of different combinations of substituents can be estimated by this approach.

It is possible to combine the Hansch and Free-Wilson methods.[76] In general however, they are used exclusively, since the application of the Hansch method is limited by the availability of physicochemical parameters whereas the Free-Wilson method needs large variations in the substitution pattern. Thus, the two approaches complement each other.

An approach similar to that of the Free-Wilson method has been described by *Crippen*,[108] who used the distance geometry algorithm to set up quantitative structure-activity relationships. This method too is based on substituent constants, which additively contribute to the activity and depend on the position within the receptor binding site. In general, receptor binding energies are used to quantify the activities. In contrast to the classical Free-Wilson method several (generally two) three-dimensional orientations of the pharmacophore are determined. The compounds investigated are assumed to bind to the receptor with different pharmacophore orientations. By taking these different "binding modes" into account the poor correlation between substituent contributions and activity when using only one orientation should be improved.

Some recent publications have been concerned with the combination of QSAR and superposition or receptor mapping methods in order to obtain a model of the receptor which also provides quantitative information.[92, 109, 110] A procedure,[111] which allows generation of a receptor model by means of pseudo atoms, will be described in Section 5.6. The method predicts activities without being based upon an extrathermodynamic approximation as are the classical QSAR approaches.

5. Inductive Modeling: Computer Simulation

The optimization of molecular geometries, as discussed in Section 3, generally gives only information about a single conformation. For molecules with many internal degrees of freedom, however, there may be a large number of minima in the energy hypersurface. Therefore, the most stable conformation can only be identified if all the minima are known. There are several methods of searching systematically for the most stable conformation. Unfortunately, these methods reach their limits very quickly. A molecule with only 50 atoms, for example an open-chain hydrocarbon with the formula $C_{16}H_{34}$, can already have several million local minima. Such a molecule does not remain in a single conformation but fluctuates between several conformations. In view of this, it seems more reasonable to depart from the concept of the most stable conformation and instead to model the dynamic properties of the molecule. All methods for this purpose, which are presented here, are based on force field energies.

5.1. Conformation Search

The systematic scanning of a conformation space in order to find the conformation with the lowest energy (global minimum of the hypersurface) is referred to as conformation search. Usually, advantage is taken of the fact that conformations can virtually always be distinguished by torsion angles. In principle, therefore, all conformations can be found by varying the torsion angles in all possible combinations. One selects a sufficiently large number of initial geometries[112] and relaxes them (see Section 3.2). The conformations thus determined are of course 'close' to the initial geometries. To become more independent of the critical choice of initial geometries, a grid can be placed over the space of torsion angles (grid search).[113]

The energy calculations necessary for the conformation search can be carried out using quantum mechanical methods, whenever high accuracy is required.[114] In general, however, force fields are used. The complexity of this type of conformation search increases exponentially with the number of bonds, so that it is reserved for small molecules.

In the case of large molecules, the search has to be simplified by means of additional restrictions. Frequently, it is possible to reduce the number of variable torsion angles by making use of local symmetry.[113, 115] The most favorable conformations of small subunits are determined and included as fixed blocks in the total molecule, or are used to define grid points for the global search. An important example is the prediction of secondary structure elements in polypeptides and proteins.[116] Introducing pleated sheets, turns, and helices constitutes a preselection of possible values for the main chain torsion angles.[117]

5.2. Molecular Dynamics

The huge number of internal degrees of freedom of biomolecules and polymers, and the coupling of degrees of freedom in cyclic molecules, suggest that use should be made of the dynamic properties of models in the conformation search. Conformation search is performed as a computer experiment in which the behavior of the model is observed, when subjected to external perturbations. This corresponds to the idea that a real molecule in thermal equilibrium finds its most favorable conformation in a se-

quence of reversible geometry changes. To transfer this to a mechanical model, one has to observe the time evolution of geometry ($\vec{x}=\vec{x}(t)$, trajectory). From the expansions for $t+\mathrm{d}t$ and $t-\mathrm{d}t$ one obtains equation (f).[118,119]

$$\vec{x}(t+\mathrm{d}t)=2\vec{x}(t)-\vec{x}(t-\mathrm{d}t)+\frac{\mathrm{d}^2\vec{x}}{\mathrm{d}t^2}(\mathrm{d}t)^2+0((\mathrm{d}t)^4) \quad \text{(f)}$$

According to *Newton*, for each atom i equation (g) holds and the force field [see Section 3.1, eq. (b)] provides the relationship (h).

$$\frac{\mathrm{d}^2\vec{x}_i}{\mathrm{d}t^2}=\vec{a}_i=\frac{\vec{F}_i}{m_i} \quad \text{(g)}$$

$$\vec{F}_i=-\mathrm{grad}_i(V) \quad \text{(h)}$$

Newtons equations of motion are solved by discrete integration over a very large number of finite time steps ($\mathrm{d}t\rightarrow\Delta t$). The size of the first change in geometry (perturbation of the system) defines the level of kinetic energy, which, according to statistical mechanics, corresponds to a temperature T [eq. (i)].

$$\frac{3}{2}NkT=\frac{1}{2}\sum_i^N m_i v_i^2. \quad \text{(i)}$$

The time evolution can also be formulated in terms of the velocities of the atoms [eq. (j)].

$$\vec{v}(t+\mathrm{d}t/2)=\vec{v}(t-\mathrm{d}t/2)+\frac{\mathrm{d}^2\vec{x}(t)}{\mathrm{d}t^2}(\mathrm{d}t)^2+0(\mathrm{d}t)^4 \quad \text{(j)}$$

whereby the model temperature can be kept constant by scaling the velocities. This corresponds to coupling the system to a heat bath.[119,120]

Molecular dynamics (MD) simulations can be carried out either with individual molecules or with entire ensembles of molecules. The molecules are arranged with the desired density in a cell of appropriate volume. In the case of liquids, a cube is generally used; for crystal structures, the form used corresponds to that of the unit cell. By means of so-called periodic boundary conditions, surface artefacts are eliminated and a quasi-infinite number of particles is generated by surrounding the cell with its own images in all directions of space[121] (Fig. 5). By scaling the cell volume, the pressure can be kept constant.[119,120]

The optimum time step Δt for the simulation of molecules with many internal degrees of freedom is 10^{-15} to 10^{-14} seconds. This roughly corresponds to the time scale of molecular vibrations. With supercomputers, it is possible to carry out simulations over 10^6 time steps[122] so that processes such as internal rotations and aggregations can be studied. The dynamics of molecules containing 500 atoms can be investigated very thoroughly, even including a few hundred solvent molecules. Rapid, periodic movements and slow, nonperiodic movements can be read off from the trajectory of the system. The latter are particularly interesting since they lead to conformational changes. In this way, the stability of a hypothetical conformation of a large molecule can be assessed directly. Transitions of the system to other conformations can be accelerated by means of high temperatures. However, the degree of aggregation may change, so that a completely different area of conformation space is entered. It is therefore possible to study phase transitions.

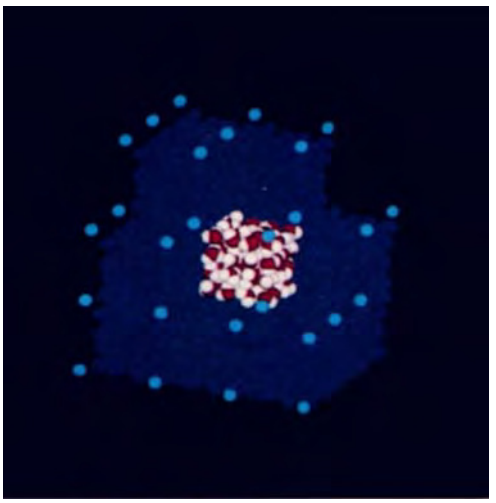

Fig. 5. Periodic boundary conditions for MD and Monte Carlo (MC) simulations (see text).

Correlation and averages play an important role in the evaluation of MD simulations. One considers correlations in time and in space which are represented by so-called correlation functions.[123,124] The different types of motions[125] (periodic, nonperiodic) and in particular coupling between different parts of the molecule can be read off from the time correlation functions. In the case of time-independent correlations, time averages are considered. Preferred local and global conformations can be identified, thereby. This procedure is often used to analyze the structure of solvation shells in the simulation of dissolved molecules to estimate hydrophilic or hydrophobic behavior.[126]

The above statements on the possibilities of MD simulations apply in principle to all types of systems, provided the necessary force field parameters are available. Most applications are found for fluid systems,[127] but solids and surfaces[128] as well as polymers[129] have also been simulated. Biomolecules such as nucleic acids,[130] peptides,[125,131,132] poteins[133] and membranes[134] have been studied. However, all types of systems are subject to the restriction that, with the computers available today,[122,135] it is impossible to consider any process which takes substantially longer than 10^{-9} seconds. Thus, for example, it is impossible to model the folding of proteins solely by means of MD simulation. The same applies to most biological transport processes. Nonetheless, the transport of ions through membrane channels [136] just constitutes the limit of meaningful investigations.

5.3. Monte Carlo Methods

Another type of computer experiments is based on statistical variations of the model. The Monte Carlo proce-

dure is a method for calculating properties of fluctuating systems as so-called ensemble averages.[123, 137] Integrals of the form (k) are made discrete in accordance with eq. (l).

$$\langle A \rangle = \frac{\int f(\vec{x}) \cdot A(\vec{x}) \cdot d\vec{x}_1 d\vec{x}_2 \ldots d\vec{x}_N}{\int f(\vec{x}) \cdot d\vec{x}_1 d\vec{x}_2 \ldots d\vec{x}_N} \quad (k)$$

$$\langle A \rangle \approx \frac{\sum_k^M f(\vec{x}^{(k)}) \cdot A(\vec{x}^{(k)})}{\sum_k^M f(\vec{x}^{(k)})} \quad (l)$$

Random numbers are used to generate M local variations of the system (displacement of an atom, change in a torsion angle), which lead to new states. If the energy of a new state is lower than that of the previous one, the new state is accepted, i.e. the next variation will start from this new state. On the other hand, if the energy is higher, the Boltzmann factor f [eq. (m)] is calculated, and compared

$$f = \exp(-E^{new} - E^{old})/kT \quad (m)$$

with another random number. If the random number is smaller than f, the new state is after all accepted; otherwise, the previous state is retained. f is thus the transition probability for a state of higher energy, and depends only on the directly preceding state. This type of random walk through the conformation space of the system is called a Markov chain.[138] In this way, the system is allowed to fluctuate (Fig. 6) according to a Boltzmann distribution for

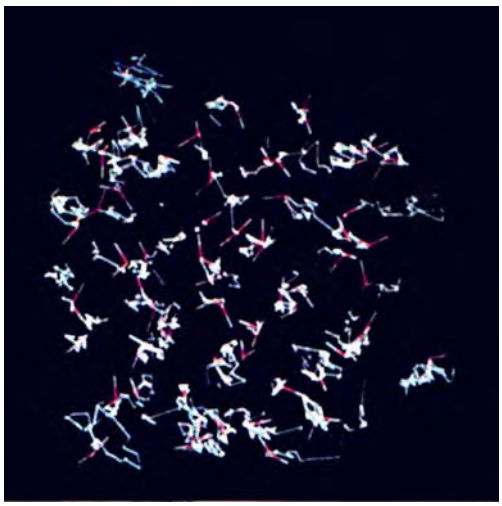

Fig. 6. Brownian motion of H_2O molecules simulated by a MC method.

temperature T. Using the Boltzmann factor as a transition probability is the essential feature of the metropolis sampling method.[139] As in molecular dynamics, it is customary to provide periodic boundary conditions for many-particle systems (see Fig. 5).

Calculation of averages is of course affected by statistical errors, showing up in the root mean square deviation of the values [eq. (n)]. Since s(A) is proportional to $1/\sqrt{M}$, the number of sample points M must be increased by a factor of a hundred to obtain a result which is more precise by one decimal place. In practice, M is of the order of magnitude of 10^6.

$$s(A) = \sqrt{\sum_k^M (A^{(k)} - \bar{A})^2 / M} \quad (n)$$

The Monte Carlo method (MC) too, has so far mainly been used for studying the properties of liquids.[137] The solvation of biomolecules has also been investigated by the MC method.[140] In addition, there are a number of studies on polymers which are primarily concerned with determining conformations.[141] Because of the statistical choice of variations, the MC method is very suitable for conformation search. A very important aspect of MC simulations is the calculation of thermodynamic entities, especially the entropy, which will be discussed in the next section.

5.4. Calculation of Entropy Contributions

The energy balance of a process is not determined solely by the differences in internal energies or enthalpies of the subsystems involved. The 'usable' free energy ΔG [eq. (o)]

$$\Delta G = \Delta H - T\Delta S \quad (o)$$

also has a contribution from the change in entropy, which is temperature-dependent. This may be taken as an indication that the dynamics of molecules play a role here. According to the third law of thermodynamics entropy is related to the probability of a state or a conformation of a system [eq. (p)]. This forms the basis for the calculation of entropy by means of computer models.

$$S = k \cdot \ln(W) \quad (p)$$

There are various contributions to the entropy. The external ones arise from the translational motion of particles, the rotational motion of particles, and the number of particles (solvation, aggregation), while the internal contributions are due to molecular vitrations and internal rotations.

The individual contributions can be calculated from the partition functions Z_{trans}, Z_{vib}, Z_{rot} of statistical mechanics [eq. (q)].[142]

$$S = Nk\left[T\frac{\partial \ln(Z)}{\partial T} + \ln(Z)\right] \quad (q)$$

Thus, in the approximation of the harmonic oscillator and the rigid rotator even quantum effects are taken into account. The contributions from the number of particles primarily manifest themselves as 'stoichiometric' factors but also have an indirect effect on the other contributions. They represent, for example, the main contribution to the entropic part of the hydrophobic interaction.[143]

For very large systems, the direct calculation of entropy via partition functions is too inexact owing to the approxi-

mations involved. Instead, MC[144] or MD simulations[145] can be used to calculate the entropy from the fluctuations of the internal coordinates. This is equivalent to determining the probability W. Unfortunately, only periodic motions can be taken into account. However, this is a viable method for determining the entropy contributions to the energy differences between different conformations of a molecule.

5.5. Docking

The interaction between a receptor molecule (R) and possible ligands decides whether a particular type of ligand is preferred, and can thus repress others. An example of this is the competitive inhibition of enzymes, the natural substrate (S) being displaced by an inhibitor (I). If entropy contributions are neglected, the relevant energy balances (r) apply.

$$\begin{aligned}\Delta E(\mathrm{S}) &= E(\mathrm{RS}) - E(\mathrm{R}) - E(\mathrm{S}) \\ \Delta E(\mathrm{I}) &= E(\mathrm{RI}) - E(\mathrm{R}) - E(\mathrm{I})\end{aligned} \qquad (\mathrm{r})$$

For a complex to be formed at all, ΔE must be negative. $|\Delta E(\mathrm{I})| > |\Delta E(\mathrm{S})|$ is then a necessary condition for I to have an inhibitory effect. In order to calculate ΔE, one has to know the optimum conformations of the R, S, and I molecules, and the conformations of the complexes RS and RI. For the free R molecule, the X-ray structure is generally used, while the methods described in Sections 3.1 and 5.1. can be employed for substrate and inhibitor molecules. Determining the conformations of the complexes, however, is a special problem since two molecules are involved. The search for the conformations of the complexes, generally referred to as docking, has three aspects:[146]

a) relative orientation of S/I with respect to R
b) optimum conformation of S/I in contact with R
c) optimum conformation of R in contact with S/I

In the docking of rigid ligands with rigid receptors, only (a) is important. In such cases, interactive docking (see Section 2) is the method of choice. However, if the ligands are not rigid, the problem of multiple minima is encountered immediately (b). Interactive docking can very easily give misleading results if the global minimum is not found. In such cases, a special form of MC simulation has proved useful.[147] This method uses an evolution algorithm[49] to search for several conformations simultaneously, and optimizes and accommodates them. Conformation changes in the receptor (c) can be taken into account by subsequent optimization of the entire receptor-ligand complex by MD or MC simulation, provided the changes in geometry of the receptor are small. At the same time, entropy contributions to complex formation can be determined.

5.6. Receptor Modeling

As already mentioned in Section 4 the comparative methods may also be used to produce receptor models.[58,67,69-71] Only when combined with classical QSAR methods (Free-Wilson or Hansch) do these models also provide quantitative information about the activity of analogs.[92,109,110]

The method described below makes direct use of the experimental activity data of a number of structurally analogous molecules in order to determine a receptor model[111]. But unlike classical QSAR methods it is not based on physicochemical parameters *(Hansch)* or empirically determined substituent contributions *(Free-Wilson)*. The method gives the active conformations of the active molecules and a model receptor, which makes it possible to calculate activities of untested compounds. Thus, receptor modeling provides information of both an active analog approach (see Section 4.1) and a QSAR procedure, but still is not a hybrid of the two methods. The essential feature is the calculation of the binding energy between each molecule investigated and a pseudomolecule, the model receptor. This pseudo-binding energy comprises the electrostatic and van der Waals interaction between a molecule and the model receptor and the conformational energy of the molecule. The energy terms used correspond exactly to the force field contributions described in Section 3 [eq. (a)]. The receptor consists of pseudoatoms which differ from "normal" atoms in that they are capable of varying their van der Waals radii and their effective charges during the calculation.

By an iterative procedure, the geometry of the molecules and of the model receptor and the effective charges and the van der Waals radii of the pseudoatoms are varied so as to achieve an optimal fit of the pseudo-binding energies and the experimentally determined enthalpies (calculated from the activity data). A further requirement is that the molecule/model receptor complexes are stable, i.e. are located in an energy minimum—as far as possible a global one. The method makes use of two approximations: a) the receptor is identical for all molecules and b) entropy and solvation effects are not taken into account explicitly. Figure 7 shows a model receptor which was calculated from six quinazoline derivatives which inhibit dihydrofolate reductase (DHFR) (also see Section 6.1).

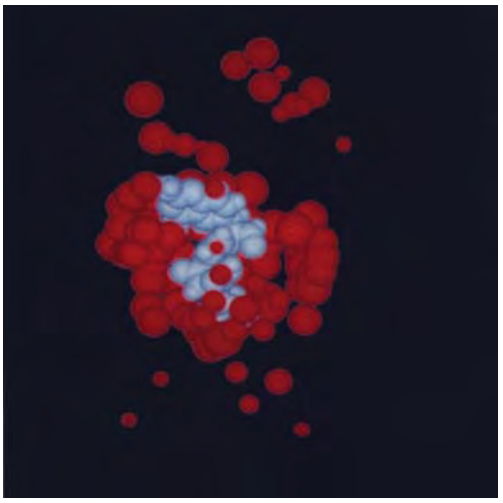

Fig. 7. Space-filling CPK representation of a model receptor (red) for DHFR inhibitors with a docked quinazoline derivative (blue).

In order to check the model receptor, further experimentally investigated molecules (so-called test molecules) are docked into the pseudomolecule. Comparison of the resulting pseudo-binding energies with the experimental binding energies of the test molecules gives information about the predictive power of the model receptor.

Novel untested compounds can now be docked into the model receptor. The calculated pseudo-binding energy allows the activity to be predicted, the reliability of which clearly depends on the predictive power of the model as determined by the test substances.

6. Applications

CAMD is already very widely used today. It will be quite impossible to list all areas of application here. We have therefore chosen three examples, which will illustrate the function and importance of this new instrument. So to speak for historic reasons, our first example is DHFR, which is both of great pharmacological interest and probably one of the enzymes which has been investigated the longest and the most thoroughly by computer-assisted methods. The same applies to renin. In the section on modeling for enzyme engineering, it is intended to demonstrate that this promising area is inconceivable without computer graphics.

6.1. Studies on Dihydrofolate Reductase

Interest in the structure and function of dihydrofolate reductase (DHFR) has grown very rapidly over the past few years and, consequently, so has the volume of relevant literature.

DHFR catalyzes the NADPH-dependent reduction of 7,8-dihydrofolate to 5,6,7,8-tetrahydrofolate and thus plays a key role in the metabolism of a large number of organisms. It is the target enzyme of the cytostatic methotrexate and the bactericide trimethoprim. Since the three-dimensional structures of DHFR from chicken liver,[148] *Lactobacillus casei*[149] and *Escherichia coli*[149] and the structure of a complex of methotrexate, cofactor and enzyme were available at about the same time as powerful molecular graphics, dihydrofolate reductase became a preferred research object for molecular design. A number of groups in industrial research[150] worked very intensively on the design of improved, more specifically acting analogs of the bactericide trimethoprim and on the development of new inhibitors with antimalarial activity.[151] At the universities, *Hansch* et al. and *Langridge* et al.[152] attempted to design more effective inhibitors for DHFR by combining QSAR and molecular modeling (also see Section 4.3), while *Höltje* et al. and *Richards* et al. tried to obtain better inhibitors using semiempirical[153] and ab initio quantum mechanical methods[154] (see Section 3). The work by *Cody*,[155] *North* et al.,[156] and *Ghose* and *Crippen*[109] on the modeling of DHFR inhibitors should also be mentioned. Extensive NMR studies of inhibitor-enzyme complexes were carried out as well.[157]

Recently, *Kraut*, *Matthews*[158] and co-workers succeeded in determining the structure of at least ten enzyme-inhibitor complexes of DHFR from chicken and *E. coli*. Analysis of these structures helped to explain why trimethoprim had a greater inhibitory effect on bacterial DHFR than on vertebrate DHFR. Those amino acids which are on opposite sides of the cavity of the active site are 1.5 to 2 Å further apart in chicken DHFR than in DHFR from *E. coli*, leading to different arrangements of the inhibitors in the enzyme-inhibitor complexes of the two enzymes and different levels of inhibition. These results give rise to the expectation that, after isolation and crystallographic analysis of a target protein, it may be possible in the future, to use the methods described in Section 5 to design selective inhibitors which do not intervene in the metabolism of the host organism. Drug development would thus become much more efficient.

6.2. Studies on Renin

Inhibitors of the enzyme renin are potential therapeutics against hypertension. No X-ray structure of the enzyme itself has so far been determined. However, some aspartyl proteinases, such as pepsin, *Rhizopus chinensis* pepsin, penicillopepsin and endothiapepsin are closely related to renin. Thus, when the high-resolution 3D-structures of these related enzymes[159-162] and the sequences of mouse renin[163-166] and subsequently also of human renin[164] became available, it was possible to develop three-dimensional models of mouse renin[165] and human renin[166, 167] with the aid of CAMD. On the basis of these computer models and the structures of the enzyme-substrate complexes of pepstatin in *Rhizopus chinensis* pepsin and penicillopepsin,[159, 160, 162] several research groups attempted to design renin inhibitors.[168] This was done in a number of steps:

1) The cavity in which the active site of the enzyme is located was investigated with regard to the available space and the possible sites of binding between the enzyme and the substrate or inhibitor molecule (structural elements which form hydrogen bonds, hydrophobic pockets, etc.).
2) Further important information was obtained from the arrangement of the inhibitor in the enzyme-inhibitor complex. Potential inhibitors should be capable of assuming the same geometry in certain parts of their structure and occupy the same enzyme-binding sites as the model inhibitor. The proposed structures were therefore subjected to special fitting algorithms (see Section 4).
3) Once a structure fulfilled these conditions at low conformation energy it was then introduced interactively into the cavity of the human renin model. If a subsequent relaxation procedure, carried out by means of a molecular mechanics calculation, led to an energetically favorable arrangement, a novel active structure had fortunately been designed. However, definitive information about the inhibitory activity which may have been achieved can only be obtained by experiment. More careful consideration of the transition state of the enzymatic reaction of renin led to novel, highly active compounds,[169] the so-called transition state analogs, and to a deeper understanding of the enzymatic mechanism.[160]

6.3. Protein Engineering

Protein engineering is a relatively new, promising field whose impact on other areas is difficult to assess. Protein engineering can be used to discover structure–activity relationships in enzymes and, based on this, to produce proteins with selectively altered, i.e. novel or improved, properties.[170, 171] These properties include thermal stability, substrate specificity and kinetic behavior of enzymes, as well as therapeutic properties of proteins. For example, the effect of disulfide bridges on the in vitro stability of T4 lysozyme derivatives has been very thoroughly investigated.[172] Extensive studies led among other things to the determination of the structure–activity relationships for subtilisin[171, 173] and for tyrosyl-tRNA synthetase.[174] This requires that one or more amino acids in a protein can be replaced selectively by a genetic engineering method (site-directed mutagenesis) and that the three-dimensional structures of the proteins are made available by crystallography or NMR. These structures are represented, modeled, and exploited by molecular modeling methods. In the simplest case, modeling is carried out interactively.[175] Starting from the structure of the wild type enzyme, the amino acids of interest are replaced. The backbone conformation of the original enzyme is retained and each of the side chains is oriented so that no forbidden steric interactions occur. This can be carried out completely visually, as described in Section 2, or by means of molecular dynamics calculations. The interaction between the protein and the substrate can be estimated by docking procedures (see Section 2). There are also sophisticated methods which include homologous substructures from the Brookhaven protein data bank.[176] To what extent replacement of certain amino acids is accompanied by a change in the tertiary structure of the protein cannot be readily predicted up to now.

Docking of the substrate into the active site of the mutated enzyme investigated can of course also be carried out using an automatic docking program (see Section 5.5). This will certainly give more objective results than interactive docking.

Other objects of interest in the field of enzyme engineering have been the peptide cleavage by thermolysin[177] and electrostatic effects in enzyme catalysis.[178]

7. Conclusions and Prospects

In this review, very different approaches have been described, all of which have a single goal: the design of molecular structures with very specific properties taking into account all available information. Consequently, CAMD is not restricted to one standard procedure; efficient molecular design, as described for the practical examples in Section 6, is based on the availability of several methods side by side and the awareness of the strengths and weaknesses of these methods.

CAMD has now become an indispensable tool in very different areas of molecular research. Apart from more "classic" applications, such as the drug design described in Section 6, CAMD is certain to be used extensively in protein research in the future. Thus, it may be speculated[179] whether, once the structures of the coat proteins of rhinovirus and poliovirus[180] have been solved, it will be possible to use computer-assisted methods to discover new drugs against these viruses.

In the industrial sector, the search for novel biologically active compounds is characterized by an increasing research expenditure. This trend may be reversed by reinforcing industrial research efforts in molecular biology and the use of computer-assisted molecular design to explain the biochemical mechanisms. CAMD will therefore be applied to an even greater extent to the development of new drugs and plant protection agents.

New perspectives are also expected to open up with regard to chemical reactions on solid surfaces (heterogeneous catalysis) and the elucidation of solid state properties.[181]

Further development of CAMD certainly depends on the extent to which supercomputers will be available in the future for calculations for molecular simulation, and on the progress made in the development of new methods and software, possibly involving artificial intelligence.

Polyphosphorus Compounds—New Results and Perspectives**

By Marianne Baudler*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

In contrast to the numerous known and often technically important mono- and diphosphorus compounds with phosphorus in its maximum oxidation state, polyphosphorus compounds led only a shadowy existence up to about twenty years ago. One of the reasons for this was the properties of such compounds, which made their handling and structural characterization difficult. This problem was solved by the development of modern preparative techniques and, especially, by the further methodological development of nuclear magnetic resonance spectroscopy. Thus, a fascinating new branch of phosphorus chemistry has been opened up in recent years. The first comprehensive review on this subject was published five years ago. Since then, research on this "element-near" chemistry of phosphorus has produced further impressive advances with the result that a surprisingly large variety of compounds with skeletons consisting of chains or rings of phosphorus atoms is known today. However, the recent observation of the spontaneous formation of the "aromatic" pentaphosphacyclopentadienide ion, P_5^-, during the synthesis of phosphorus-richer polyphosphides from phosphorus-poorer compounds in solution and the discovery of the inversion of phosphorus in tetra- and pentacyclic organophosphanes demonstrate that this field is still capable of producing surprises.

1. Introduction

The chemistry of polyphosphorus compounds has undergone impressive developments in the past two decades. Whereas up to the 1970s compounds with a skeleton of directly linked phosphorus atoms were still considered as laboratory curiosities, phosphorus, after carbon, now appears to be the element with the most pronounced ability to form homonuclear element–element bonds. The fact that this "carbon-like" aspect of phosphorus chemistry was overlooked for so long is certainly related to the enormous technical importance of many "classical" phosphorus compounds of the oxidation state +5 and the resultant focus of interest on these classes of compounds. However, in recent years, the discovery of a surprising variety of "low-valent" phosphorus compounds with differing structural types has opened up a new chapter in the chemistry of this element, the extent and significance of which can hardly be estimated at the moment. This "element-near" chemistry covers a wide range, from small molecules through medium-sized ensembles of atoms up to high-molecular solids, and thus represents an important link between inorganic molecular chemistry and solid-state chemistry.

Developments in the field of polyphosphorus compounds up to 1982 have already been reviewed.[1] The present article is thus limited to recently obtained results. Research in the last few years has focused mainly on extension of the phenomenological basis in order to (1) obtain a comprehensive structural understanding and (2) explore the reaction behavior of chain- and ring-type polyphosphorus compounds.

2. Phosphorus Hydrides and Partially Organosubstituted Phosphanes

Compounds containing skeletons of trivalent phosphorus atoms may have open-chain or cyclic structures. They are derivatives of the corresponding phosphorus hydrides or phosphanes.

2.1. Existence, Properties, and Structural Elucidation

The number of known hydrides of phosphorus is only exceeded by that of carbon. The present state of knowledge is summarized in Table 1. In the last few years alone, 31 new phosphorus–hydrogen compounds with up to 22 phosphorus atoms in the molecule have been identified in the thermolyzates of diphosphane and other phosphorus-poorer hydrides by mass spectrometry. Thus, most of the gaps in an earlier systematic classification[1] have now been filled, and representatives of two further series of phosphanes with the compositions P_nH_{n-16} and P_nH_{n-18} have been discovered.

Without doubt, however, all possible types of compounds have not yet been verified experimentally. Thus, neither the hydride $P_{18}H_2$ nor the "triphosphirene" P_3H have yet been detected and, also, the maximum possible size of a phosphorus skeleton has by no means been attained. On the whole, however, the "scenary" has not changed in principle since the previous reviews:[2] with increasing number of phosphorus atoms, the stability of the open-chain phosphanes P_nH_{n+2} decreases significantly in favor of the formation of the monocyclic and polycyclic

Table 1. Phosphorus hydrides (phosphanes).

Phosphane series	Known compounds
P_nH_{n+2}	PH_3, P_2H_4, P_3H_5, P_4H_6, P_5H_7, P_6H_8, P_7H_9, P_8H_{10}, P_9H_{11}
P_nH_n	P_3H_3, P_4H_4, P_5H_5, P_6H_6, P_7H_7, P_8H_8, P_9H_9, $P_{10}H_{10}$
P_nH_{n-2}	P_4H_2, P_5H_3, P_6H_4, P_7H_5, P_8H_6, P_9H_7, $P_{10}H_8$, $P_{11}H_9$, $P_{12}H_{10}$
P_nH_{n-4}	P_5H, P_6H_2, P_7H_3, P_8H_4, P_9H_5, $P_{10}H_6$, $P_{11}H_7$, $P_{12}H_8$, $P_{13}H_9$
P_nH_{n-6}	P_7H, P_8H_2, P_9H_3, $P_{10}H_4$, $P_{11}H_5$, $P_{12}H_6$, $P_{13}H_7$, $P_{14}H_8$, $P_{15}H_9$
P_nH_{n-8}	$P_{10}H_2$, $P_{11}H_3$, $P_{12}H_4$, $P_{13}H_5$, $P_{14}H_6$, $P_{15}H_7$, $P_{16}H_8$, $P_{17}H_9$
P_nH_{n-10}	$P_{12}H_2$, $P_{13}H_3$, $P_{14}H_4$, $P_{15}H_5$, $P_{16}H_6$, $P_{17}H_7$, $P_{18}H_8$, $P_{19}H_9$, $P_{20}H_{10}$
P_nH_{n-12}	$P_{13}H$, $P_{14}H_2$, $P_{15}H_3$, $P_{16}H_4$, $P_{17}H_5$, $P_{18}H_6$, $P_{19}H_7$, $P_{20}H_8$
P_nH_{n-14}	$P_{15}H$, $P_{16}H_2$, $P_{17}H_3$, $P_{18}H_4$, $P_{19}H_5$, $P_{20}H_6$, $P_{21}H_7$
P_nH_{n-16}	$P_{17}H$, $P_{19}H_3$, $P_{20}H_4$, $P_{21}H_5$, $P_{22}H_6$
P_nH_{n-18}	$P_{19}H$, $P_{20}H_2$, $P_{21}H_3$, $P_{22}H_4$

phosphorus hydrides P_nH_n and P_nH_{n-2m} ($m = 1$-9), respectively.

In addition to the characterization of individual phosphanes by their mass spectra,[1] detailed information on the structures of a series of compounds has been obtained from their phosphorus nuclear magnetic resonance spectra (see Sections 2.2 to 2.5). The constitution, configuration, and conformation can be determined on the basis of the spin systems and the ^{31}P-NMR parameters, especially the coupling constants. However, for technical reasons, this method of structural determination can be applied at present only to liquid phosphanes and to solid phosphanes in solution. Since compounds with high phosphorus and low hydrogen contents are usually only very poorly soluble and, in addition, amorphous to X-rays, most of the polycyclic phosphorus hydrides are not as yet amenable to direct nuclear magnetic resonance spectroscopic or X-ray structural investigations.

1 P_7H_3 $(Me_3Si)_3P_7$ **2**

The only exception is the heptaphosphane(3) **1**,[4] which is obtainable by the mild methanolysis of the silyl compound **2**[3,4] in pure form.[4] The substance is amorphous to X-rays and insoluble in hydrocarbons, alcohols, ethers, chloroform, carbon disulfide, acetonitrile, cyclohexanone, dimethylformamide, dimethyl sulfoxide, hexamethylphosphoric triamide, diphosphane, and 1,2-di-*tert*-butyldiphosphane, as well as in molten white phosphorus. A solubility sufficient for nuclear magnetic resonance studies, however, can be achieved when **1** is prepared directly in benzene, 1-methylnaphthalene, or 1-methylnaphthalene/phenanthrene, which are particularly good solvents for higher phosphanes of the series P_nH_{n+2} and P_nH_n, and the nuclear magnetic resonance spectrum is recorded shortly thereafter.[5] The ^{31}P{^{1}H}-NMR spectrum of **1** (Fig. 1) shows nine complex signal groups, which, on the basis of their intensity ratios and splitting patterns, can be assigned to the two diastereomers **1a** and **1b** with symmetrically and unsymmetrically arranged hydrogen atoms, respectively. All the available data, in particular the results of a complete analysis of the partial spectrum of **1a** confirm that **1**, like the starting compound **2**, possesses a P_7 framework analogous to that of nortricyclene; however, in the case of **2**, only the symmetrical isomer could be detected by X-ray methods.[6]

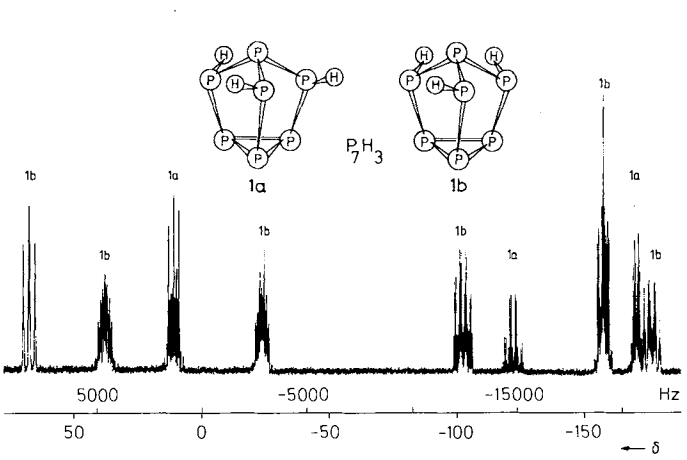

Fig. 1. ^{31}P{^{1}H}-NMR spectrum of P_7H_3, **1** (mixture of isomers), in 1-methylnaphthalene at 27 °C (121.497 MHz).

2.2. Open-Chain Triphosphanes

Open-chain phosphorus hydrides generally exhibit a pronounced tendency to undergo disproportionation, so that only the first members of the homologous series P_nH_{n+2} (up to $n = 3$) can be isolated in pure form. Triphosphane(5) **3** decomposes rapidly even at room temperature under diffuse daylight, thereby turning yellow.[1] In contrast, partially organosubstituted triphosphanes of the types **4** and **5** are more stable, especially when the phosphorus chain is protected toward intermolecular dispro-

5b: $R^1=SiMe_3$, $R^2=Me$ [9]

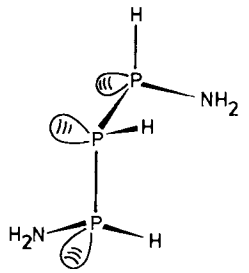
5c: $R^1=SiMe_3$, $R^2=tBu$ [9]

5d: $R^1=R^2=tBu$ [9]

5e: $R^1=Me$, $R^2=tBu$ [9]

portionation reactions by the presence of bulky substituents. Unlike **3**, these triphosphane derivatives—with the exception of **5a**—each contain phosphorus atoms as chiral centers, so that diastereomers exist.[7-9] Their populations depend on the respective molecular conformations, which, in turn, are governed by the tendency for *gauche* orientations of neighboring lone electron pairs[10] and by steric interactions of the substituents.

1,3-Diaminotriphosphane(5) **6**[11] is an "inorganic" derivative of **3** and, as such, a representative of the "mixed" non-metal hydrides. It is formed, together with $NaPH_2$,



6

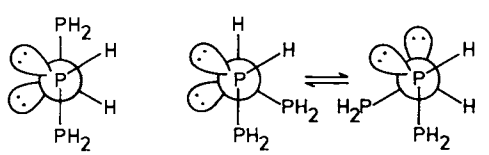
Na_2HP_7, and phosphorus-richer phosphides, in the reaction of white phosphorus with sodium in liquid ammonia (P : Na = 2 : 1 or 1.5 : 1). The composition and structure of **6**, which is only stable in liquid ammonia, were deduced from the phosphorus nuclear magnetic resonance spectrum. Of the three possible diastereomers, only the *erythro,erythro* isomer is formed and is probably stabilized energetically by hydrogen bonds between the central phosphorus atom and the transoid NH_2 groups.

2.3. Open-Chain Tetraphosphanes

Tetraphosphane(6) is always obtained as a mixture of the constitutional isomers *n*-P_4H_6 (*d,l* and *meso* forms) **7a** and iso-P_4H_6 **7b**.[1] According to the most recent ^{31}P-NMR

n-P_4H_6: $H_2P-PH-PH-PH_2$; iso-P_4H_6: $P(PH_2)_3$

7a **7b**

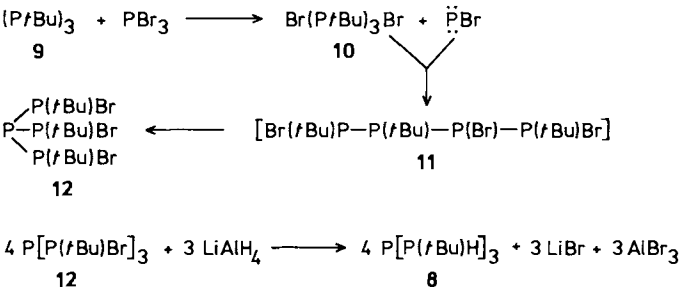


d,l-*n*-P_4H_6 *meso*-*n*-P_4H_6

spectroscopic results[12] on the *n*-P_4H_6 diastereomers, the AA'BB' spin system at higher field corresponds to the "bent" *meso* isomer and that at lower field to the "extended" *d,l* isomer.

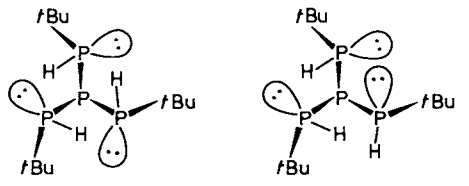
The separation of *n*-P_4H_6 and iso-P_4H_6 has not yet been achieved owing to the hyperreactivity of these two compounds. However, tris(*tert*-butylphosphino)phosphane **8**, the first partially substituted derivative of iso-P_4H_6, has been prepared.[13]

The starting material for this synthesis is the three-membered ring compound **9**. Halogenative ring-opening of **9** with phosphorus(III) bromide initially produces the open-chain triphosphane **10**. The bromophosphanediyl (bromophosphinidene), formed as an intermediate, then inserts into the phosphorus chain with formation of the mixed substituted tetraphosphane **11**. As expected, the latter is unstable and rearranges spontaneously to furnish the constitutional isomer **12**.



Compound **12**, which is stable at room temperature, can form two diastereomers; however, only the symmetrical isomer with (*R,R,R*) and (*S,S,S*) configuration can be detected by ^{31}P-NMR spectroscopy. On reaction with lithium aluminum hydride, smooth substitution of the bromine atoms by hydrogen atoms and formation of **8** occur.

Compound **8** is not stable at room temperature but can be isolated, below −30 °C, in the form of colorless crystals. Immediately after preparation, only the signals of the symmetrical isomer **8a** (A_3X spin system) can be observed in the $^{31}P\{^1H\}$-NMR spectrum, indicating that the hydrogenation of **12** proceeds stereoselectively. Subsequently, however, even at −78 °C, formation of the asymmetrical isomer **8b** (ABCX system) with (*R,R,S*) and (*S,S,R*) configuration proceeds until the statistical distribution of **8a** : **8b** = 1 : 3 is attained at equilibrium (the (*R,R,R*) enantiomer of **8a** and the (*R,R,S*) enantiomer of **8b** are shown). The rate of isomerization is strongly solvent-dependent; in *n*-pentane at −78 °C, equilibrium is attained after about 300 h.[13]



8a **8b**

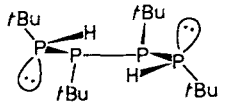
Of the class of partially organosubstituted *n*-tetraphosphanes, only the compounds **13a** and **13b** are as yet known. They are prepared by the mild alcoholysis of the corresponding silyl compounds, which, in turn, are accessible from α,ω-dimetalated organophosphanes by reaction with chlorotrimethylsilane.[14,16] A particularly suitable method for the preparation of **13b** is the reaction of the dipotassium salt **14**[17] with *tert*-butyl chloride, which proceeds with elimination of isobutene.[15]

$H(R)P-(PR)_2-P(R)H$ **13a**: R = Ph[14]
13b: R = *t*Bu[15]

$K(t\mathrm{Bu})P-(Pt\mathrm{Bu})_2-P(t\mathrm{Bu})K + 2\,t\mathrm{BuCl} \longrightarrow$
14

13b + $2\,H_2C{=}CMe_2$ + 2 KCl

With increasing bulk of the substituents R, the configurations and conformations of the existing isomers are governed to an increasing extent by steric factors in addition to the tendency for *gauche* orientation of neighboring lone electron pairs. This is clearly seen in the case of **13b**; of the six possible configurational isomers, only the three diastereomeric forms *threo/d,l/threo, erythro/threo/threo,* and *erythro/d,l/erythro* are formed in solution in a ratio of 10:5:1, which deviates from statistical expectations.[15] Accordingly, only *d,l* and *threo* configurations, referred to the central P–P bond, occur in which both an all-*trans* arrangement of the *tert*-butyl substituents and a *gauche* orientation of the lone electron pairs of the phosphorus atoms of the middle bond are realized. This situation leads to a spiral-like structure of the P_4 chain, as exemplified for the dominating *threo/d,l/threo* isomer. The relative amounts of the observed isomers are governed by the orientations of the lone electron pairs on the outer P–P bonds (*gauche,gauche, trans,gauche,* or *trans,trans*).[15]



13b

threo/d,l/threo isomer

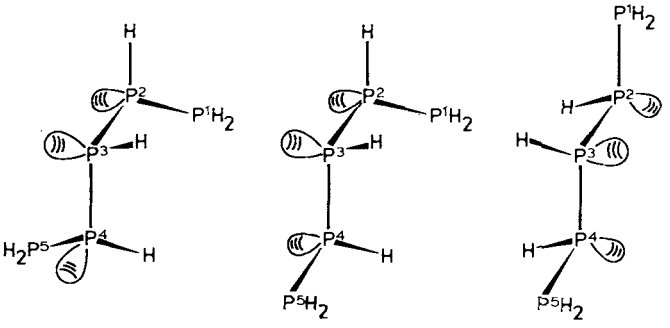
The three diastereomers of **13b** exist in a dynamic equilibrium at room temperature in solution,[15] whereas the triphosphane **4b** is configurationally stable under the same conditions.[8] As expected, the barriers to inversion of the phosphorus atoms decrease markedly with increasing length of the phosphorus chain.[18]

2.4. Phosphorus Hydrides P_nH_{n+2} with n > 4

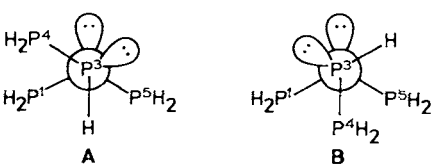
To date, no methods are known for the synthesis of open-chain organophosphanes containing more than four phosphorus atoms. Thus, in order to obtain information on compounds with longer phosphorus chains, phosphorus hydride mixtures must be studied. These are obtained by the mild thermolysis of diphosphane[1] or as distillation residues from the purification of larger amounts of crude diphosphane[19] and, according to mass spectroscopic studies, contain varying amounts of the higher homologues. The unequivocal characterization of the individual species present in such mixtures is possible with the help of ^{31}P-NMR spectroscopy.

The procedure will be exemplified for the isomers of pentaphosphane(7) **15**.[1,20] Phosphane mixtures of the above-mentioned origin contain phosphorus-poorer members of the phosphane series P_nH_{n+2} with n = 2–4[1] as the major components. An enrichment of the higher homologues with n > 4 presents inherent difficulties as a result of the pronounced tendency of longer-chain compounds to undergo disproportionation. Thus, identification of the individual isomers of **15** by direct analysis of the appropriate ^{31}P spin systems is not possible since the corresponding partial spectra are partly masked by the intense signal groups of the P_4H_6 isomers and of P_3H_5. As can be seen from the $^{31}P\{^1H\}$-NMR spectra of such phosphane mixtures, however, the resonance signal of at least one phosphorus atom of each of the various isomers is clearly shifted to lower field into a signal-poorer region of the spectrum with increasing chain length. This opens up the possibility for a "spectroscopic separation" of the individual spin systems by application of double resonance experiments and, in particular, of homonuclear ^{31}P-selective population transfer (SPT) experiments.[21,22]

In SPT experiments, a selective pulse is applied to a specific line of a spin system, resulting in a change in the population difference of the corresponding energy levels and thus a change in the intensity of the lines associated with these levels. This is particularly clear after subtraction of the "unperturbed" spectrum from the SPT spectrum. Only the perturbed line and the progressively or regressively associated transitions (the latter being characterized by positive or negative line intensities, respectively) can be observed in the corresponding difference spectrum. In this way, masked or weak resonances of a spin system can be identified and, in combination with a simulation of the spectrum, questions of assignment can be answered unequivocally.



15a **15b** **15c**



A **B**

15d

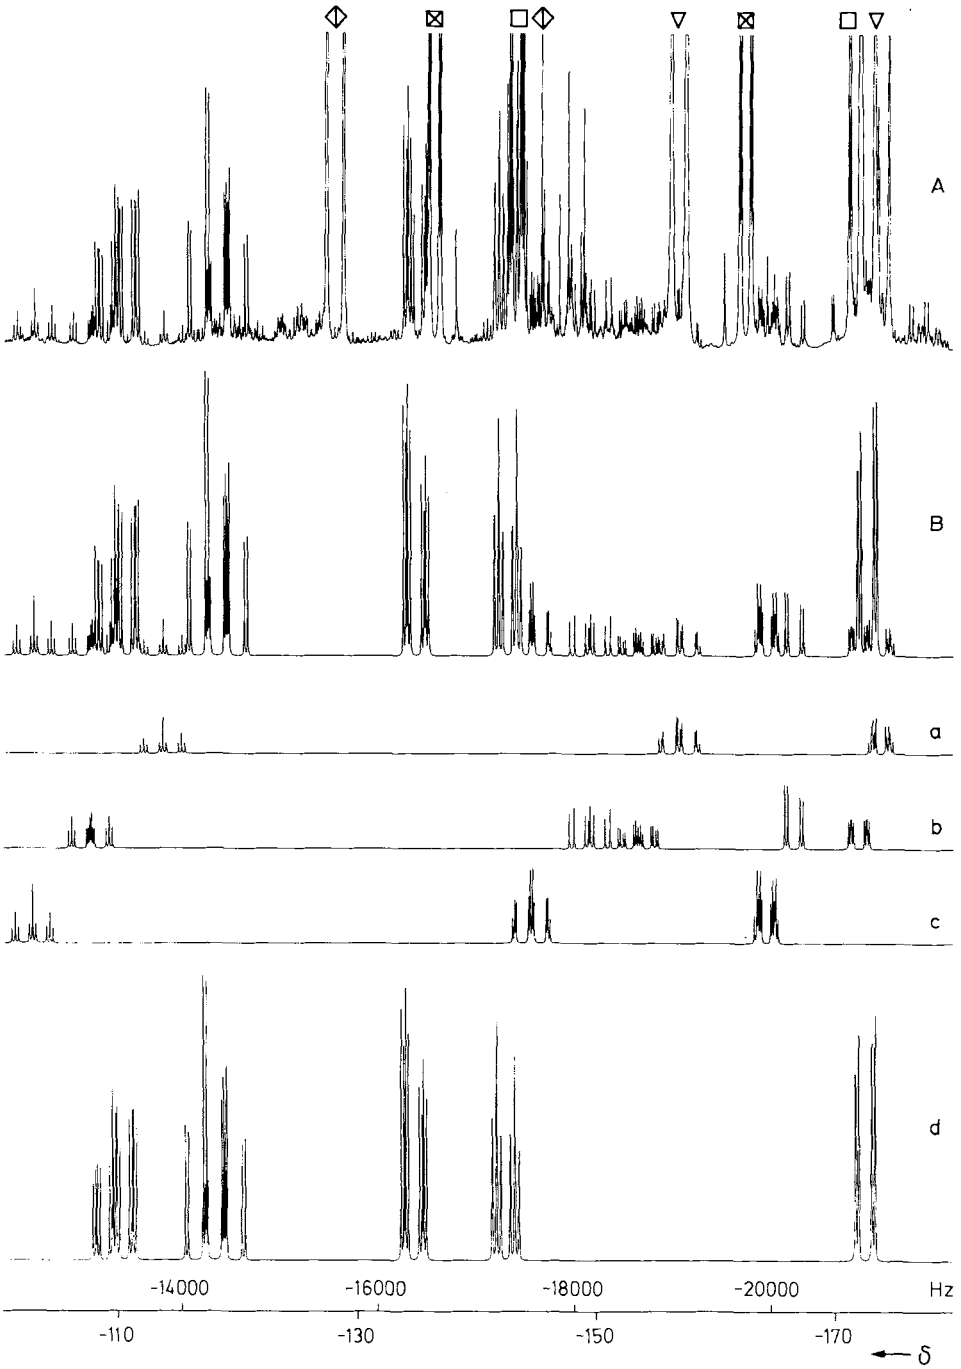


Fig. 2. Observed (A) and simulated (B) $^{31}P\{^1H\}$-NMR spectrum of pentaphosphane(7) in a phosphane mixture with 15 P-% P_5H_7 ($\nabla = P_3H_5$, $\square$ = *meso-n*-P_4H_6, $\boxtimes$ = *d,l-n*-P_4H_6, $\diamondsuit$ = iso-P_4H_6) at $-30°C$ (121.497 MHz); a, b, c, d: simulated spectra of the individual P_5H_7 isomers **15a**, **b**, **c**, **d**.

The sets of starting parameters obtained from a series of SPT experiments for the isomers of **15** were optimized by systematic variation of the values until an assignment of the calculated lines with the experimentally observed lines was possible. Since the NMR parameters are far overdetermined as a result of the large number of lines, it is sufficient to assign only those lines that are not influenced by neighboring signals. The final data sets are obtained by subsequent iteration. The superimposition of the individual simulated spectra reproduces the experimentally observed $^{31}P\{^1H\}$-NMR spectrum of **15** very satisfactorily (Fig. 2).

Accordingly, pentaphosphane(7) exists as a mixture of the three diastereomers of *n*-P_5H_7 (**15a**, *erythro,erythro*; **15b**, *erythro,threo*; **15c**, *threo,threo*) and the constitutionally isomeric 2-phosphinotetraphosphane (iso-P_5H_7) **15d**. The branched isomer is present in the largest relative abundance. From the determined ^{31}P-NMR parameters,[20] the three-dimensional structures of **15a–d** can be deduced directly. The isomer **15d** can occur in two conformations, **A** and **B**, of which **A** is probably favored for steric reasons.

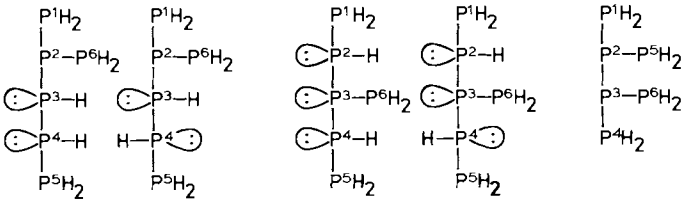
With the complete sets of ^{31}P-NMR parameters for **15a–d**,[20] the general equations, formulated previously[1] on the basis of incomplete data for **15**, for the dependence of the chemical shifts δ and the coupling constants $^1J(PP)$ for open-chain phosphanes on the structural parameters (*a*, *b*,

c; number of phosphorus atoms in α, β, and γ positions) were optimized. The following equations were obtained for $t = -30\,^{\circ}C$:

$$\delta(^{31}P) = -214.9 + 21.7a + 31.8b - 7.3c\ (\pm 4.4)$$
$$^{1}J(PP) = -112.5 - 31.7a - 15.3b\ (\pm 4.7)\ Hz$$

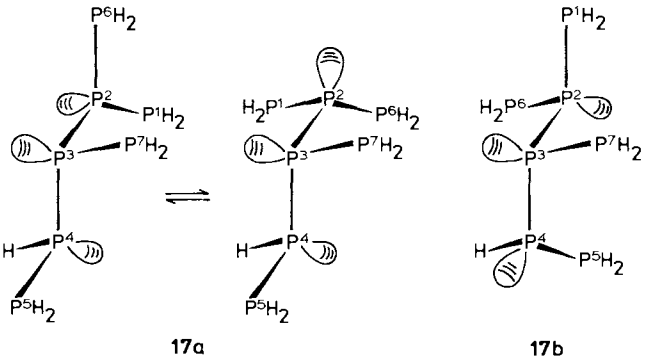
The increasing low-field shift of the higher phosphanes in comparison with PH_3 is mainly a result of the increase in the bonding angles on replacement of a hydrogen atom by a more bulky PH_2, $P(H)PH_2$, or $P(PH_2)_2$ group (increase in the amount of p character in the hybrid orbital of the lone electron pair). Both equations are valuable tests in determining the constitutions of the phosphorus-richer homologues in the phosphane series P_nH_{n+2} with $n > 5$ by ^{31}P-NMR spectroscopy. The calculated $\delta(^{31}P)$ values, however, correspond only to the averaged positions of the resonances for the diastereomers, since their chemical shifts exhibit a "conformation effect" in the sense that molecules with extended P_n chains (such as **15c**) give rise to signals at lower field than those with bent structural elements (such as **15a** and **15b**; see Fig. 2). An analogous conformation dependence also exists for the $\delta(^{13}C)$ values of alkanes.[23]

In the case of hexaphosphane(8), **16**, because of the tendency to preferentially form branched compounds, only isomers with branched P_6 chains have so far been identified and their structures elucidated; none of the six diastereomers of *n*-P_6H_8 have been observed.[24] The isomers so far characterized are the two diastereomers of 2-phosphinopentaphosphane (**16a**, *erythro*; **16b**, *threo*), two of the three diastereomers of 3-phosphinopentaphosphane (**16c**, *erythro,erythro*; **16d**, *erythro,threo*), and the highly symmetrical 2,3-diphosphinotetraphosphane **16e**.



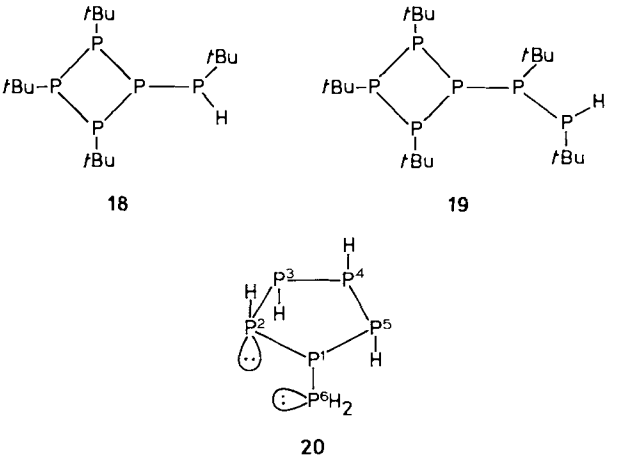
The trend for the formation of molecules with branched phosphorus skeletons is also continued by heptaphosphane(9) **17**. Of the six possible constitutional isomers, as yet only one of the two with maximum chain branching, namely, 2,3-diphosphinopentaphosphane, has been detected and its structure elucidated.[25] The diastereomers (**17a**, *erythro*; **17b**, *threo*) exist in comparable amounts, since the steric interactions between the phosphino groups in the two species are similar.

The pronounced tendency for the formation of tertiary phosphorus atoms in the synthesis of longer-chain phosphanes gives an insight into the route of formation of these compounds. The disproportionation of phosphorus-poorer homologues apparently proceeds preferentially by intermolecular elimination of PH_3 from a PH middle group and a PH_2 end group, thus resulting in chain branching.



2.5. Monocyclic Phosphanes with Side Chains

Phosphanes with the compositions P_nH_n and $P_nR_{n-1}H$ where $n > 3$ do not necessarily consist of monocyclic skeletons of n phosphorus atoms, but may also be smaller monocycles with P_m side chains ($m = 1, 2$). Examples are the partially organosubstituted compounds **18**[26] and **19**[27] as well as the phosphorus hydride **20**.[28]



Compounds **18** and **19** are formed in the thermolysis of the diphosphane **21**[29] via the intermediacy of the triphosphane **4b**. After about 20 h at 170 °C, the proportion of **18** reaches a maximum and then decreases again on further thermolysis in favor of the formation of **19**. A further lengthening of the phosphorus side chain by reaction of **19** with **21** does not occur; instead, a retroreaction to give **18** and **4b** takes place at higher concentrations of **21**.

$$\underset{\mathbf{21}}{2\,H_2(PtBu)_2} \longrightarrow \underset{\mathbf{4b}}{H_2(PtBu)_3} + \underset{\mathbf{22}}{tBuPH_2}$$

$$\underset{\mathbf{4b}}{2\,H_2(PtBu)_3} \longrightarrow \underset{\mathbf{18}}{P_5tBu_4H} + \underset{\mathbf{22}}{tBuPH_2} + tBuH$$

$$\underset{\mathbf{18}}{P_5tBu_4H} + \underset{\mathbf{21}}{H_2(PtBu)_2} \longrightarrow \underset{\mathbf{19}}{P_6tBu_5H} + \underset{\mathbf{22}}{tBuPH_2}$$

$$\underset{\mathbf{18}}{P_5tBu_4H} + \underset{\mathbf{4b}}{H_2(PtBu)_3} \rightleftharpoons \underset{\mathbf{19}}{P_6tBu_5H} + \underset{\mathbf{21}}{H_2(PtBu)_2}$$

The four-membered ring structures for **18** and **19** have been confirmed by ^{31}P-NMR spectroscopy; accordingly, the compounds are 1-(*tert*-butylphosphino)- and 1-(1,2-di-*tert*-butyldiphosphino)-2,3,4-tri-*tert*-butylcyclotetraphosphane, respectively. Compound **18** is thus a constitutional isomer of 1,2,3,4-tetra-*tert*-butylcyclopentaphosphane,[30] which is formed on hydrolysis of $K(t\text{Bu})_4P_5$ and, like the starting material, possesses a five-membered ring of phosphorus atoms. Since the formation of four-membered ring structural elements is generally favored with *tert*-butyl-substituted cyclophosphanes,[1] compound **18**, as expected, possesses the higher thermodynamic stability of the two isomers.[30]

Hexaphosphane(6) **20** was detected by mass spectrometry among the thermolysis products of higher open-chain phosphanes already twenty years ago.[31] At temperatures up to +35 °C, pentaphosphane(5)[1] is the main product; in addition, small amounts of **20** (5–10 P-%) and other cyclic phosphorus hydrides are formed.

The structure elucidation of **20** was achieved only recently by complete analysis of the corresponding ^{31}P spin system on the basis of SPT experiments (see Section 2.4).[28] According to the data obtained, **20** has the constitution of a 1-phosphinocyclopentaphosphane in the configuration shown. Particularly informative in this respect is the large, positive, long-range coupling $^2J(P^2P^6)$ as an indication that the lone electron pairs of these phosphorus atoms are directed toward each other.[13, 15, 16, 32] The *cis* arrangement of the substituents at P^1 and P^5 was confirmed by the magnitude of the absolute value of the corresponding $^1J(PP)$ coupling. Evidence for the existence of the constitutional isomer with a six-membered ring of phosphorus atoms and an all-*trans* arrangement of the hydrogen atoms or lone electron pairs was not found.

The presently available results indicate that, on formation of the monocyclic phosphanes P_nH_n and $P_nR_{n-1}H$ under thermodynamically controlled conditions, the ring size (H, n = 5; *t*Bu, n = 4) is determined by the dominating substituent (H, R). Furthermore, in cases with sufficient kinetic stabilization, constitutional isomers with other ring sizes may be capable of existence and may be preparatively accessible by special synthetic routes.

3. Hydrogen Polyphosphides and Polyphosphides with Isolated Anions

In this section, only polyphosphides and hydrogen polyphosphides with isolated anions, P_n^{m-} and $H_xP_n^{(m-x)-}$, obtainable from solutions, and their reactions will be discussed.

3.1. New Hydrogen Polyphosphides by Metalation of Diphosphane

As reported previously,[1, 33] diphosphane **23** reacts with *n*-butyllithium or lithium dihydrogen phosphide in tetrahydrofuran (THF) or 1,2-dimethoxyethane with disproportionation, forming trilithium heptaphosphide **24** and phosphane.

$$9\,P_2H_4 + 3\,n\text{-}C_4H_9Li \xrightarrow[-20\,^\circ C]{THF} Li_3P_7 + 11\,PH_3 + 3\,n\text{-}C_4H_{10}$$

23 **24**

Recently, a series of new metal hydrogen polyphosphides (partially metalated higher phosphanes) were detected as intermediates in this metalation reaction and some of them were isolated in pure form at lower temperatures.[34–37] From the formation and degradation of the intermediates, the following detailed picture of the reaction of **23** with *n*-butyllithium has emerged.

The primary step is the formation of lithium trihydrogen diphosphide **25**, which, however, is not stable in the presence of diphosphane. In a rapid series of disproportionation and transmetalation reactions, **25** is initially converted into the highly reactive, monolithiated, phosphorus-richer, open-chain phosphanes $LiH_{n+1}P_n$ and then into cyclic compounds, until phosphides having insufficient nucleophilicity for attack on diphosphane are formed. Since the reaction temporarily comes to a standstill at this point, these phosphides are the first reaction products that can be identified.

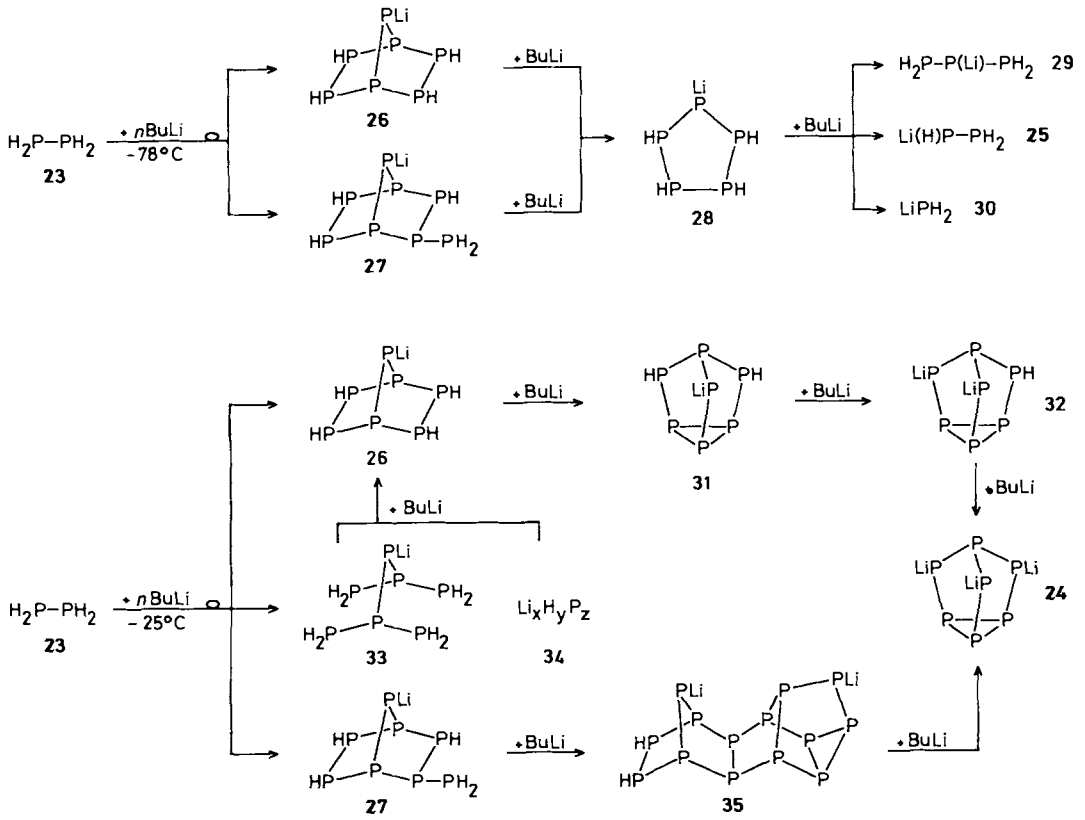
$$P_2H_4 + n\text{-}C_4H_9Li \longrightarrow LiH_3P_2 + n\text{-}C_4H_{10}$$

23 **25**

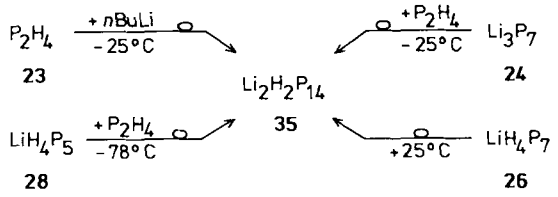
When the metalation is performed at −78 °C, these products are mainly lithium tetrahydrogen heptaphosphide **26** and lithium pentahydrogen octaphosphide **27**, whereas at −25 °C two potential precursors of **26** additionally occur, namely, lithium octahydrogen heptaphosphide **33** and a not yet identified phosphide **34**. On the whole, a noticeable tendency for the formation of a $P_7(5)^-$ skeleton, which is analogous to that of norbornane and which apparently exhibits a relatively low nucleophilicity, is observed.

The reaction continues only after renewed addition of the metalating agent. At −78 °C, mainly further **26** is initially formed. This reacts further—as does **27**—to furnish the monocyclic lithium tetrahydrogen cyclopentaphosphide **28**, which, in turn, undergoes degradation to give the open-chain phosphides **29**, **25**, and **30**. The tricyclic heptaphosphide **24** is not formed at this temperature; however, above −30 °C, **28** does disproportionate to form dilithium hydrogen heptaphosphide **32**, PH_3, and P_2H_4, a reaction that is attributable to the particular stability of the $P_7(3)$ skeleton.

At −25 °C further **26** is initially formed from the precursors **33** and **34**. Whereas **26** remains unchanged until a **23** : *n*BuLi ratio of 8 : 1 has been reached, **27** is converted into the polycyclic compound **35**, which is insoluble in tetrahydrofuran and precipitates as an orange-red solid. Subsequently, **26** also reacts further to give lithium dihydrogen heptaphosphide **31**, which already exhibits the tricyclic $P_7(3)$ skeleton. Further metalation leads first to **32** and then to the final product **24**, which is also formed during the last step in the reaction by degradation of **35**. The differing courses of the reaction at −25 and −78 °C are attributed to the increasing solubility of PH_3 in tetrahydrofuran with decreasing temperature, so that, at −78 °C, PH_3 can also participate to an increasing extent in the reaction.



The compositions and structures of the new hydrogen polyphosphides were confirmed by complete analyses of their $^{31}P\{^1H\}$-NMR spectra or by their two-dimensional $^{31}P\{^1H\}$-NMR spectra. Of particular interest is the dilithium dihydrogen tetradecaphosphide **35**, whose polycyclic molecular skeleton is formed in the course of the transformation of a bicyclic P_7 skeleton with a side chain (**27**) to a tricyclic P_7 skeleton (**24**). The same compound is also accessible by a type of retroreaction starting from **24** and diphosphane **23** and is formed additionally in the reaction of **28** with diphosphane and on disproportionation of **26**.[36] Since difficultly separable by-products are formed in all cases, $Li_2H_2P_{14}\cdot 6THF$ can only be obtained in 80–90% purity. The $H_2P_{14}^{2-}$ ion is a typical conjuncto-phosphane, which is made up of a $P_7(5)$ partial structure analogous to that of norbornane and a $P_9(3)$ partial structure analogous to that of deltacyclane joined through a common two-atom bridge; thus, a $P_8(6)$ partial structure analogous to that of pentalane is formed.

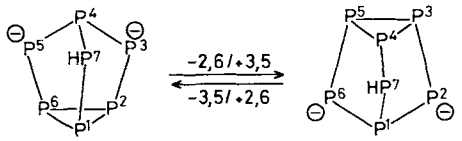


The dilithium hydrogen heptaphosphide **32**, a further intermediate, is also formed by the partial metalation of P_7H_3 **1** with $LiPH_2$ or **24** as well as by the partial protolysis of **24**. The best preparative route, however, is the reaction of **23** with **24**.[35]

$$9\,P_2H_4 + 2\,Li_3P_7 \xrightarrow[-25\,^\circ C]{THF} 3\,Li_2HP_7 + 11\,PH_3$$

23 **24** **32**

The special structural feature of the anion of **32** is—as in the case of **24**[1,33]—its fluxional behavior. As a result of its similarity to the hydrocarbon dihydrobullvalene,[38] the HP_7^{2-} ion is capable of a degenerate Cope rearrangement[39] and can be described at room temperature by two structurally equivalent valence tautomeric forms.[35] As can be seen, opening of the bond between P^2 and P^6 in the three-membered ring and formation of a bond between the

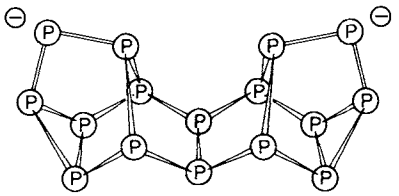


bridging atoms P^3 and P^5 with concomitant migration of the negative charges to the atoms P^2 and P^6 leaves the HP_7^{2-} ion unchanged. On the other hand, metal/hydrogen exchange in **32** occurs neither *intra-* nor *inter*molecularly.

3.2. Polyphosphides with Conjuncto-Phosphane Skeletons

Hydrogen-free polyphosphides with a larger number of phosphorus atoms generally possess conjuncto-phosphane skeletons, the partial structures of which are known from phosphorus-poorer phosphides or organophosphanes (see Section 4).

The hydrogen heptaphosphide **32** is not stable at room temperature but decomposes in a complex disproportionation reaction in which, among other products, dilithium hexadecaphosphide **36** is formed.[1,35,40] Compound **36** can be prepared more simply and in greater yield by the nucleophilic cleavage of white phosphorus with **30** in a molar ratio of 1.92 : 1.[41] The corresponding sodium salt **37** can be obtained in an analogous manner using sodium powder in the presence of [18]crown-6.[42] The formation of **36** was also observed by *Fritz* et al.[43] in the reaction of white phosphorus with $LiP(SiMe_3)_2$. In each case, **36** and **37** are formed as solvent adducts, which, on drying or warming, lose part of the bound solvent with a deepening of the color and a decrease in solubility. According to ^{31}P-NMR spectroscopic observations, isolated P_{16}^{2-} ions exist in solution in each case and have the same constitution as that found by *von Schnering* et al.[44,45] for solid $(Ph_4P)_2P_{16}$



P_{16}^{2-}

by means of X-ray structural analysis. Thus, the $P_{16}(2)$ skeleton represents a conjuncto-phosphane made up of two $P_9(3)$ structural elements, analogous to that of deltacyclane, joined through a common two-atom bridge.

$$\underset{\mathbf{32}}{Li_2HP_7} \xrightarrow{-\Omega} \underset{\mathbf{36}}{Li_2P_{16}} + \cdots$$

$$23\,P_4 + 12\,LiPH_2 \longrightarrow \underset{\mathbf{36}}{6\,Li_2P_{16}} + 8\,PH_3$$
$$\mathbf{30}$$

Na_2P_{16} **37**

As a result of their reactive phosphidic phosphorus atoms, compounds **36** and **37** are suitable for the preparation of other compounds having $P_{16}(2)$ skeletons. However, it must be considered that covalent, higher phosphanes are readily attacked by nucleophiles with concomitant changes in the phosphorus skeleton upon alkylation according to the following equation:

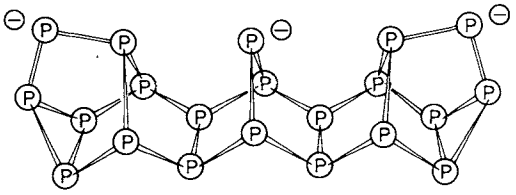
$$\underset{\mathbf{36}}{Li_2P_{16}} + 2\,RBr \longrightarrow \underset{\mathbf{38}}{P_{16}R_2} + 2\,LiBr$$

a, R = Me; **b**, R = Et

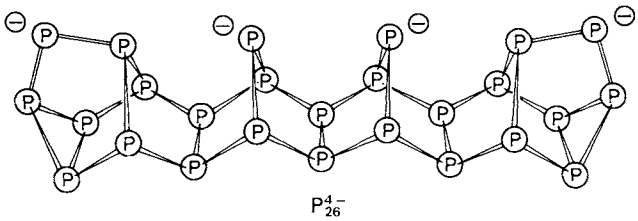
If, by the choice of a suitable method for carrying out the reaction, the reaction of the basic phosphide with the already formed diorganohexadecaphosphane is suppressed, then **38a** and **38b** can be obtained in high yields and in pure form.[46] Their constitutions were confirmed by the similarity of their molecular vibration spectra with those of **36** and by the fragmentation patterns in their mass spectra.

39 $Na_3P_{21}\cdot 15\,THF$ $Li_4P_{26}\cdot 16\,THF$ **40**

Likewise, both the room temperature decomposition of **32** and the cleavage of white phosphorus with $LiPH_2$ or sodium under different stoichiometric conditions give rise to the henicosaphosphides $M_3^1P_{21}$ and the hexacosaphosphides $M_4^1P_{26}$ (M^1 = Li, Na, K). Of these products, the compounds **39** and **40** have been isolated in pure form.[47,48] According to ^{31}P-NMR spectroscopic investigations, they contain the isolated anions P_{21}^{3-} and P_{26}^{4-}, which



P_{21}^{3-}



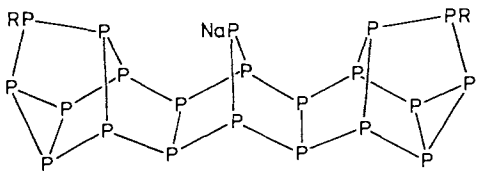
P_{26}^{4-}

are made up of two $P_9(3)$ terminal groups, analogous to that of deltacyclane, and one or two, respectively, $P_7(5)$ middle groups, analogous to that of norbornane. In K_4IP_{21}, synthesized by *von Schnering* et al.,[49] these P_{21}^{3-} groups are linked to form a polymeric $^2_\infty[P^-_7]$ structure by opening of their three-membered rings.

Noteworthy of the phosphorus-rich phosphides with conjuncto-phosphane skeletons is the preference for $P_9(3)$ terminal groups analogous to that of deltacyclane, whereas covalent, polycyclic organophosphanes P_nR_m ($m < n$) usually contain terminal, two-atom bridges with *trans*-oriented substituents (see Section 4). Apparently, two-atom bridges with negative charges on neighboring phosphorus atoms (in addition to the lone electron pairs) are energetically so unfavorable in phosphides that the system spontaneously stabilizes itself by closure of a zero bridge to form the three-membered ring of the partial structure analogous to deltacyclane. This explains why the corresponding polyphosphides with isolated P_n^{m-} ions do not exist for all covalent phosphanes P_nR_m (R = H, alkyl, aryl). In spite of intensive efforts, therefore, it was not possible to prepare nonaphosphides of the type $M_3^1P_9$ with constitutions analogous to that of deltacyclane.[50]

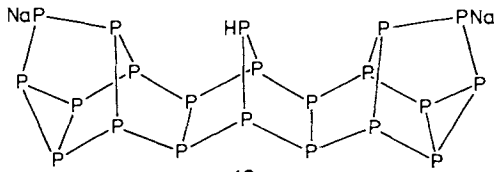
Investigations of the reaction behavior of **39** have shown[51] that, on treatment with alkyl halides or chloro(trimethyl)silane, smooth substitution occurs at the phos-

phidic phosphorus atoms of the $P_9(3)$ terminal groups but not at the phosphidic phosphorus atom of the $P_7(5)$ middle group for steric reasons. Partially substituted henicosaphosphides $NaP_{21}R_2$ **41a-d** with the substituents R on the



41a, R = Me; **41b**, R = Et; **41c**, R = *i*Pr; **41d**, R = $SiMe_3$

terminal groups in a *trans* arrangement are obtained in this way. Protonating agents such as acetylacetone, in contrast, attack primarily at the central phosphidic phosphorus atom, the site of greatest nucleophilicity, so that the hydrogen henicosaphosphide **42** is accessible in this man-

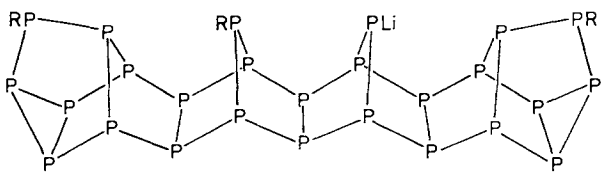


42

ner.[52] The basicity of the anion HP_{21}^{2-} toward acetylacetone or glacial acetic acid is not sufficient for the formation of $P_{21}H_3$. However, the partially organosubstituted henicosaphosphane(3) **43** can be obtained from **41a** and can, in turn, be quantitatively metalated by butyllithium to give $LiP_{21}Me_2$.[53]

$$\underset{\textbf{41a}}{NaP_{21}Me_2} \xrightarrow[-Na^+]{+H^+} \underset{\textbf{43}}{P_{21}HMe_2}$$

On alkylation, the hexacosaphosphide **40** gives the triorganohexacosaphosphides $LiP_{26}R_3$, **44a,b**, as the end products.[54] Primary attack here takes place also at the phosphidic phosphorus atoms of the $P_9(3)$ end groups, as confirmed by the ^{31}P-NMR identification and the structural



44a, R = Me; **44b**, R = Et

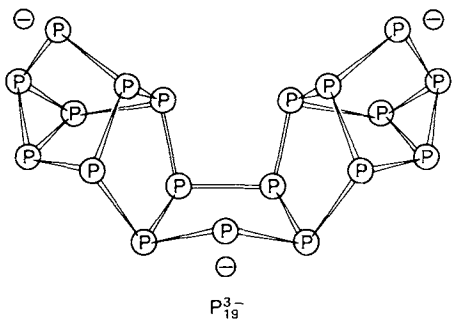
characterization of the intermediate products 45a,b. Since, compared with **39**, compound **40** contains an additional $P_7(5)$ middle group, the steric prerequisites for an alkylation in the middle part of the phosphorus skeleton are more favorable. By contrast, solely a rearrangement of the $P_{26}(4)$ skeleton takes place on reaction with protonating agents.[53]

45a $Li_2P_{26}Me_2$ $Li_2P_{26}Et_2$ **45b**

In addition to the already mentioned compounds, the nonadecaphosphides **46a-c** are also formed on nucleophilic cleavage of white phosphorus with $LiPH_2$ or an alkali metal.[55] They cannot be isolated in pure form and are only capable of existence in equilibrium with other polyphosphides up to a maximum of 16 P-% in the reaction mixture. Compound **46a** is also formed on degradation of the hexadecaphosphide **36** with $LiPH_2$ as well as in the reaction of the heptaphosphide **24** with white phosphorus or iodine or 1,2-dibromoethane.

Li_3P_{19} Na_3P_{19} K_3P_{19}
46a **46b** **46c**

As can be deduced from the two-dimensional ^{31}P-NMR spectrum and SPT experiments,[55] the P_{19}^{3-} ion has a conjuncto-phosphane skeleton with a five-membered ring middle group. The resultant, relatively "open" total structure is the reason for the high reactivity of this polyphosphide ion.



P_{19}^{3-}

The nonadecaphosphides **46** are further intermediates in the complex subsequent reactions of the nucleophilic cleavage of the P_4 molecule in which phosphorus-richer partial structures of Hittorf's phosphorus[56] are built up. Compounds **46a-c** are formed over a relatively wide range of reactant ratios $P_4 : M^IPH_2(M^I)$, which is limited on the phosphorus-poorer side by the stoichiometry required for the formation of $M_3^IP_7$[57] and which extends on the phosphorus-richer side beyond that necessary for the formation of $M_2^IP_{16}$.[41] As can also be seen from the other preparative routes (see above), the nonadecaphosphides represent important intermediates in the transformation of the heptaphosphides $M_3^IP_7$ to the hexadecaphosphides $M_2^IP_{16}$. As can be deduced from the compositions of known polyphosphides with conjuncto-phosphane skeletons (Table 2), the compounds **46** are direct "precursors" of the polyphosphides $M_4^IP_{26}$ and $M_3^IP_{21}$, whose $P_7(5)$ middle groups,

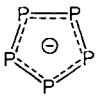
Table 2. Composition of polyphosphides of the general formula $M_m^IP_n$ with conjuncto-phosphane skeletons.

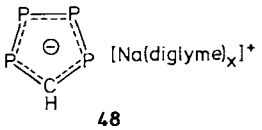
Compound type		Example	M^I : P ratio
$M_3^IP_7$	**24**	Li_3P_7	1 : 2.3
$M_3^IP_{19}$	**46a**	Li_3P_{19}	1 : 6.3
$M_4^IP_{26}$	**40**	$Li_4P_{26} \cdot 16THF$	1 : 6.5
$M_3^IP_{21}$	**39**	$Na_3P_{21} \cdot 15THF$	1 : 7.0
$M_2^IP_{16}$	**36**	Li_2P_{16}	1 : 8.0

analogous to that of norbornane, are apparently formed from the five-membered ring structural moiety of **46**. Furthermore, the synthesis of phosphorus-richer polyphosphides from phosphorus-poorer polyphosphides surprisingly does not proceed with a continuous increase in the size of the phosphorus skeleton. Instead, the conversion of $M_3^IP_{19}$ to $M_2^IP_{16}$ reveals that, in the case of the conjuncto-phosphanes, relatively large, "open," skeletal structures are first formed; the smaller and more "closed" phosphorus skeletons of the phosphorus-richer polyphosphides then take shape by successive elimination of the phosphidic middle groups (see Section 3.3).[55]

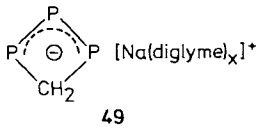
3.3. Polyphosphides with Phosphorus of Coordination Number 2

In the reaction of white phosphorus with sodium powder (P : Na = 3 : 1) in boiling diethylene glycol dimethyl ether (diglyme), small amounts of the compounds **47a**, **48**, and **49**[58] are formed in addition to those polyphosphides obtained when the reaction is performed in tetrahydrofuran or 1,2-dimethoxyethane.[55] These products are characterized by ^{31}P-NMR signals at low field in the region typical for diphosphenes[59-62] and phosphaalkenes.[63] With $LiPH_2$ in tetrahydrofuran, only **47b** is formed and, after separation of the other polyphosphides, it can be obtained as a pure solution in tetrahydrofuran.[58] The formation of **48** and **49** in the reaction with sodium is indicative of the participation of the solvent diglyme in the course of the reaction. Compounds **47**, **48**, and **49** are remarkably stable in solution; neither at room temperature nor after short-heating can the start of decomposition be detected by ^{31}P-NMR spectroscopy. In contrast, a partial conversion to phosphorus-richer polyphosphides, especially $M_2^IP_{16}$ and $M_3^IP_{21}$, takes place on complete removal of the solvent.





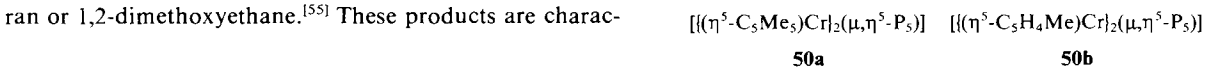
48



49

The compositions and structures of **47**–**49** were deduced from their ^{31}P-NMR spectra and, in the cases of **47a,b** also from the ^{23}Na- and ^{7}Li-NMR spectra, respectively. Compounds **47** each exhibit a sharp singlet in their ^{31}P-NMR spectra (**47a**, $\delta = +470.2$; **47b**, $\delta = +468.2$), which undergoes neither broadening nor splitting between -60 and $+30$ °C. A substitution at phosphorus by an organic group can thus be excluded with certainty. That the species responsible for the singlet exists as an anion can be deduced from the cation NMR spectra of **47a,b**. About two years ago, *von Schnering* et al.[64,65] observed, among other signals, a sharp singlet at $\delta = +473$ in the ^{31}P-NMR spectrum of the reaction mixture of K_4P_6 and Me_3SnCl in 1,2-dimethoxyethane and attributed it to the fluxional P_6^{4-} ion (10π-electron system). However, it seems difficult to correlate the strongly low-field position with a P_6 ring having four negative charges and only one PP double bond. Now that the same species has also been formed by the cleavage of white phosphorus (see above), the postulation of a P_6 ring structure is no longer imperative. Rather, the NMR spectroscopic data can be readily correlated with a resonance stabilized P_5^- ion, analogous to the cyclopentadienide ion (6π-electron system), in which the distribution of the negative charge over five phosphorus atoms somewhat reduces the strong deshielding effect of the sp^2 hybridization. Confirmation that the compounds **47** are actually salts with the pentaphosphacyclopentadienide ion is provided by the analytically determined Na : P ratio of 1 : 5 for solutions of **47a**.[58]

To date, the P_5^- species has only been observed in the negative ion mass spectrum of red phosphorus at 325 °C[66] and in the triple-decker complexes **50a,b** recently prepared by *Scherer* et al.[67] The formation of this ion in the



50a **50b**

subsequent reactions of the nucleophilic cleavage of white phosphorus under conditions that favor the formation of polyphosphides with conjuncto-phosphane skeletons is indicative of its direct participation in the complex reactions involved in the synthesis of phosphorus-richer from phosphorus-poorer polyphosphides (see Section 3.2). Its formation is apparently closely related with the transformation of $M_3^IP_{19}$ to $M_2^IP_{16}$ via successive elimination of small phosphidic middle groups from larger, "open," conjuncto-phosphane skeletons. The spontaneous formation and thermal stability of **47a,b** are in accord with the most recent MNDO calculations,[68] which predict a significant stability for the P_5^- ion. Studies on the reaction behavior of **47a,b** from various points of view are in progress.

The constitutional assignments for **48** and **49** are based on the analysis of the AA'BB' or AB_2 spin systems appearing at low field in the ^{31}P{^{1}H}-NMR spectra as well as on the splittings observed on ^{1}H-coupling.[58] Compound **48** is thus a salt with the tetraphosphacyclopentadienide ion, whereas **49** contains the triphosphacyclobutenide ion, for which no carbon analogue exists to date.

Common structural features of the ions P_5^-, P_4CH^-, and $P_3CH_2^-$ are resonance-stabilized rings of unsubstituted phosphorus atoms of coordination number 2. The existence of the "aromatic" anions P_5^- and P_4CH^- again documents the close relationship between phosphorus and carbon chemistry.[1] The phosphorus hydride P_5H,[1] first detected by mass spectroscopy several years ago, should thus have a structure analogous to that of cyclopentadiene and exhibit a high acidity. The latter has already been confirmed in preliminary experiments.[69]

4. Organopolycyclophosphanes

A branch of the chemistry of polyphosphorus compounds presently undergoing intensive further develop-

ment is that of the polycyclic organophosphanes. Since an unexpected variety of polycyclic phosphorus hydrides P_nH_m ($m < n$) had been detected earlier by mass spectrometry in the hydrolysis products of calcium phosphide and in the thermolyzates of diphosphane[1,2,3] (Table 1), particular interest has been placed on the structural elucidation of these compounds. As a result of their pronounced tendency to undergo disproportionation as well as their insolubility and lacking tendency to crystallize, polycyclic phosphorus hydrides are, in general, not amenable to nuclear magnetic resonance spectroscopic or X-ray structural investigations. Thus, a strategy involving the synthesis and structural elucidation of the corresponding *derivatives* is followed in which substitution of hydrogen atoms by alkyl groups is utilized to obtain structural information about the parent compounds.[1] *Organophosphanes* P_nR_m of this type generally have a higher kinetic stability toward disproportionation reactions and are considerably simpler to isolate on a preparative scale than the corresponding *phosphorus hydrides*. Since the initial preparation of a series of organopolycyclophosphanes (Table 3) and the elucidation

Table 3. Polycyclic organophosphanes with six to nine phosphorus atoms (structures of the phosphorus skeletons) [1].

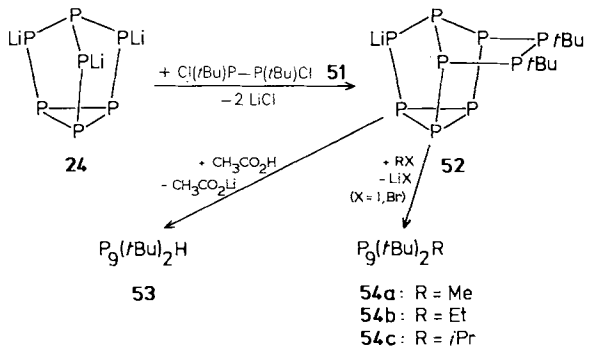
*t*Bu						

of their structures in the course of these investigations,[70] many further representatives of the various classes of compounds with 4–13 phosphorus atoms in the molecule have been prepared and their structures characterized unequivocally during the last few years. Furthermore, alkyl derivatives of all known phosphorus hydrides (Table 1) have been detected by mass spectroscopy in the crude reaction mixtures or in the thermolyzates of phosphorus-poorer organophosphanes. The organopolycyclophosphane with the largest phosphorus skeleton so far identified is the compound $P_{24}iPr_4$ of as yet unknown structure.

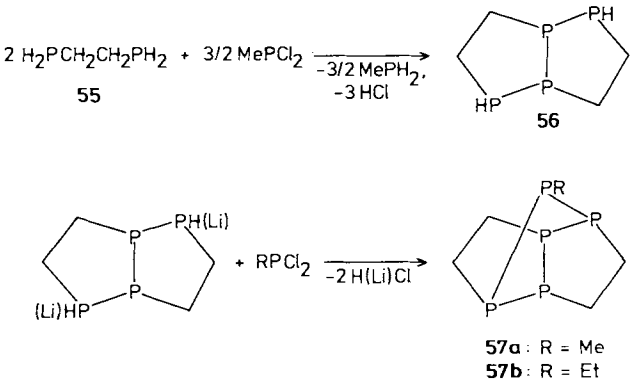
4.1. Synthetic Routes

As can be seen from Section 3.2, some of the polycyclic organophosphanes are accessible by direct alkylation of the corresponding polyphosphides. The tricycloheptaphosphanes P_7Me_3[71] and P_7iPr_3,[72] the octacyclohexadecaphosphanes $P_{16}R_2$, **38a,b**,[46] and the partially organosubstituted decacyclohenicosaphosphane $P_{21}HMe_2$, **43**,[53] have been obtained in this way. However, since polyphosphides with isolated P_n^{m-} ions corresponding to all covalent phosphanes P_nR_m ($R = H$, alkyl, aryl) (see Section 3.2) by no means exist, this route does not represent a generally applicable synthetic method.

The $P_n(m)$ skeleton of an organopolycyclophosphane, for which a saltlike starting material of analogous structure is not available, can sometimes be built up specifically from a phosphorus-poorer phosphide. Thus, starting from the tricyclic heptaphosphide **24**, the partially organosubstituted, tetracyclic nonaphosphide **52** was prepared by cyclocondensation with the diphosphane derivative **51**. The product can be isolated as the black-red, highly viscous solvent adduct $LiP_9tBu_2 \cdot 3$ monoglyme.[73,74] On reaction with protonating agents, **52** is converted into the partially substituted phosphorus hydride **53**; with alkyl halides, the mixed alkylated nonaphosphanes(3) **54a–c** are formed. According to their ^{31}P-NMR spectra, **53** and **54** are each present as mixtures of two configurational isomers, which differ in the spatial arrangements of the substituents at P^5 (see Section 4.4).



In some cases, *hetero*polycyclophosphanes in which the number of phosphorus atoms in the ring skeleton is equal to or larger than the number of heteroatoms can also be built up specifically by suitable reactions. Thus, 1,2-ethylenebisphosphane **55** reacts with dichloro(methyl)phosphane to give the bicyclic, disecondary phosphane **56**,[75] which, on treatment with $RPCl_2$, furnishes heterotricyclophosphanes of the type **57**.[76]



The successful preparation of the first organosubstituted bicyclotetraphosphane, **58**, reported very recently by *Fluck*

et al.,[77] represents a special case; previously, only the "inorganic"-substituted $P_4[N(SiMe_3)_2]_2$ was known.[78] Compound **58** is formed together with the diphosphene **59** by the reaction of 2,4,6-tri-*tert*-butylphenyllithium and 1-bromo-2,4,6-tri-*tert*-butylbenzene with white phosphorus; the reaction proceeds with elimination of lithium bromide.

$$4\,RLi + 4\,RBr + 3\,P_4 \longrightarrow \underset{\mathbf{58}}{2\,P_4R_2} + \underset{\mathbf{59}}{2\,P_2R_2} + 4\,LiBr$$

$R = 2,4,6\text{-}tBu_3C_6H_2$

According to the X-ray structural analysis (Fig. 3), the molecule exists as the sterically favorable *exo,exo* isomer with a folding angle of the P_4 bicyclic ring of 95.5°.[77]

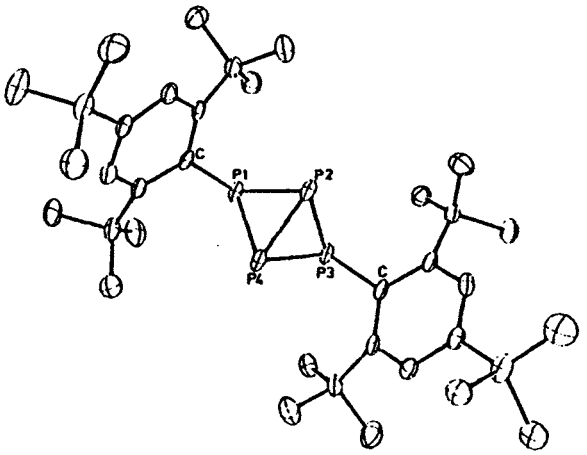


Fig. 3. Molecular structure of **58** in the crystal [77].

Whereas the synthetic routes described up to now have each been limited to only a few organopolycyclophosphanes, the synthetic methods described below have wide scopes of application. As has been repeatedly demonstrated by numerous results published in the last few years (see Section 4.2), substances of the general composition $P_{x+y}R_x$ (x, y = the number of organosubstituted or exclusively P-substituted phosphorus atoms, respectively) can generally be prepared by four different routes.[1,79-81] The first is the dehalogenation of a mixture of a dichloro(organo)phosphane and phosphorus(III) chloride. As can be seen from the following two synthetic sequences, the organosubstituted phosphorus atoms can also be introduced into the reaction in the form of the monocyclic compounds $(PR)_n$ and the unsubstituted phosphorus atoms in the form of white phosphorus. Other dehalogenating agents, such as

$$x\,RPCl_2 + y\,PCl_3 + \frac{2x+3y}{2}\,Mg \longrightarrow P_{x+y}R_x + \frac{2x+3y}{2}\,MgCl_2$$

$$\frac{x}{n}\,(PR)_n + y\,PCl_3 + \frac{3y}{2}\,Mg \longrightarrow P_{x+y}R_x + \frac{3y}{2}\,MgCl_2$$

$$x\,RPCl_2 + \frac{y}{4}\,P_4 + x\,Mg \longrightarrow P_{x+y}R_x + x\,MgCl_2$$

$$\frac{2x+3y}{2n}\,(PR)_n + y\,PCl_3 \longrightarrow P_{x+y}R_x + \frac{3y}{2}\,RPCl_2$$

alkali metals or lithium hydride, may also be used in place of magnesium. The last reaction route shown essentially represents a ring transformation of a monocyclic organophosphane by phosphorus(III) chloride in the absence of magnesium. In every case, the overall composition of the reaction product can be defined by the molar proportions of the two phosphorus-containing starting materials. However, since the P:R ratios of different organopolycyclophosphanes can be rather similar, a product mixture consisting of several compounds is always formed. Decisive for the product spectrum, furthermore, is whether the reaction is thermodynamically or kinetically controlled; this can be governed by the reaction conditions.

Thus, it is hardly possible to obtain compounds with more than nine phosphorus atoms by the first two synthetic routes, even with a large excess of phosphorus(III) chloride, when the reaction is performed rapidly in boiling tetrahydrofuran. The main products are always the organophosphanes P_nR_m with n = 5–9 and m = 3–5, in particular the thermodynamically favored compounds of the types P_9R_3 and P_7R_3. In contrast, the third synthetic method, based on white phosphorus, at moderate temperatures (10–35 °C) and high stationary concentrations of the reactants, favors the formation of phosphorus-rich compounds with up to 24 phosphorus atoms in the molecule. The degree of substitution is thereby influenced not only by the temperature but also by the steric bulk of the group R. On going from R = Me to R = *i*Pr, the proportion of phosphorus-rich, highly alkylated compounds increases markedly, as the corresponding $P_n(m)$ skeletons are increasingly stabilized kinetically. Thus, for each individual organopolycyclophosphane, the synthetic reaction must be optimized by changing the reaction conditions in order to maximize the proportion of the target molecule in the product mixture and thus to make its enrichment or isolation possible.

The same is true for another general method for the preparation of polycyclophosphanes: the thermolysis of the corresponding phosphorus-poorer compounds. As shown by systematic investigations,[81] open-chain and monocyclic phosphane derivatives always give only low yields of polycyclic compounds. Relatively high proportions of phosphorus-rich polycycles are obtained from bi- and tricyclic *methyl*phosphanes such as P_7Me_5, P_7Me_3, or P_9Me_5; however, the thermolyzates of the tricycles are generally insoluble and thus preparatively not useful.

Meanwhile, we have been able to perform the thermolysis reaction in such a way that it may be applied specifically for the preparative formation of phosphorus-rich polycyclic organophosphanes.[81] Generally, bicyclic heptaphosphanes, P_7R_5, are the most suitable starting materials since, with R = Me to R = *t*Bu, they give rise to soluble thermolyzates. The solubility increases with increasing number of carbon atoms in the substituents so that, with larger alkyl moieties, an admixture with higher cyclic—especially tricyclic—phosphane derivatives is possible. In the case of smaller alkyl groups, the solubility of the thermolyzate can be increased by addition of the monocyclic compound, $(PR)_5$, corresponding to the heptaphosphane(5) employed. The most suitable thermolysis temperature (within the range 180–230 °C) is dependent on the alkyl substituent. The duration of the thermolysis, which in-

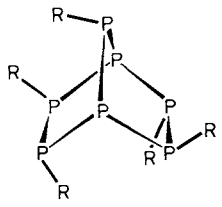
creases with increasing size of the substituents and also with increasing amount of added monocycle $(PR)_n$, is in the range 7 to 150 h.

The thermolyzates contain as main products the compounds $(PR)_n$ (n = 4 or 5, depending on R) and P_9R_3, in addition to considerable proportions of P_7R_5, P_8R_6, P_9R_5, $P_{10}R_4$, $P_{11}R_5$, $P_{12}R_4$, and $P_{13}R_5$; furthermore, $(PR)_n$ (n = 3–6, depending on R) as well as preparatively interesting amounts of the polycyclophosphanes P_nR_{n-2} (n = 4–6, 9), P_nR_{n-4} (n = 6–8, 10, 12), P_nR_{n-6} (n = 8, 12), P_nR_{n-8} (n = 10, 11, 14–16), P_nR_{n-10} (n = 14–18), P_nR_{n-12} (n = 16, 18), and P_nR_{n-14} (n = 18) are also present. The quantitative product distribution depends on the substituent R and on the detailed thermolysis conditions. Generally, the proportion of lower alkylated compounds dominates so that the thermolysis provides a meaningful supplement to the previously described synthetic reactions.

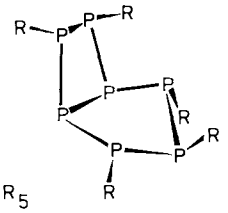
The strategy of a combined application of fractional crystallization, column chromatography, high-pressure liquid chromatography, and sublimation has proved useful for the enrichment or isolation of the individual organopolycyclophosphanes.[81]

4.2. New Polycyclic Organophosphanes

As reported previously,[1,79] the dehalogenation of dichloro(organo)phosphanes or monocyclic organophosphanes in admixture with phosphorus(III) chloride leads, in the case of small alkyl groups, to the 2,3,5,6,7-pentaorganobicyclo[2.2.1]heptaphosphanes **60a–c**.



60a: R = Me
60b: R = Et
60c: R = *i*Pr

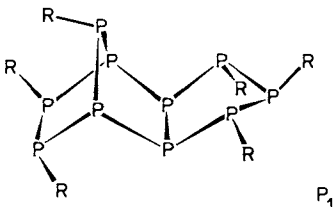


P_7R_5

61: R = *t*Bu

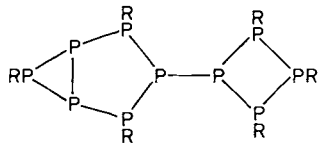
Surprisingly, the recently prepared P_7 *tert*-butyl compound **61** contains a completely different phosphorus skeleton, consisting of a five-membered ring and an annelated four-membered ring.[82] The structure of **61**, a 2,3,4,6,7-penta-*tert*-butylbicyclo[3.2.0]heptaphosphane, is apparently the result of a destabilization of the structural type **60** owing to increasing steric interactions with increasing steric bulk of the substituents at P^6 and P^7. Differing skeletal structures for R = Me, Et, *i*Pr, and R = *t*Bu have previously been found for the compound class P_8R_6[83,84] (see Table 3). In the case of **61**, a molecular, polycyclic phosphane has been forced, for steric reasons, to form an annelated four-membered ring as a structural element for the first time.

In the case of the hexaorganotricyclodecaphosphanes, the earlier reported assumption that the compounds $P_{10}R_6$ (R = *i*Pr, H), identified by mass spectroscopy, do not possess a phosphorus skeleton analogous to that of adamantane[11] has, in the meantime, been unequivocally confirmed. The compound **62b**, formed to 0.7 mol-% in the reaction of $EtPCl_2$, P_4, and magnesium, has now been enriched to 38% and definitely characterized as 3,4,5,8,9,10-hexaethyltricyclo[5.2.1.$0^{2,6}$]decaphosphane by ^{31}P-NMR spectroscopy.[81] Compound **62c** (present enrichment: 11%) has the same conjuncto-phosphane structure also assumed to be present in **62a** (as yet only identified by mass spectroscopy).



$P_{10}R_6$

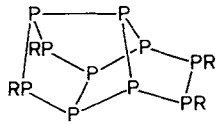
62a: R = Me
62b: R = Et
62c: R = *i*Pr



63: R = *t*Bu

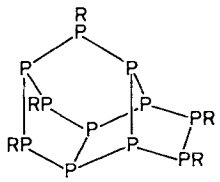
On going to the *tert*-butyl compound (present enrichment: about 50%), a significant structural change occurs again: compound **63** is a 2,4,6-tri-*tert*-butyl-3-(2,3,4-tri-*tert*-butylcyclotetraphosphanyl)bicyclo[3.1.0]hexaphosphane.[85] The obvious close structural relationship with the bicyclic compounds P_6tBu_4[86] and P_8tBu_6[84] (see Table 3) helps to explain the unusual constitution. The spatial arrangement of the substituents of the two partial skeletons with respect to each other, however, remains to be clarified.

During the preparation of the low-temperature form of the tricyclooctaphosphanes P_8R_4 (see Section 4.3), small amounts of the corresponding tetracyclodecaphosphanes, of which **64c** has been enriched up to about 15%,[81] are always formed as well. The structure, a 4,5,9,10-tetraisopropyltetracyclo[5.2.1.$0^{2,6}$.$0^{3,8}$]decaphosphane, confirmed by ^{31}P-NMR spectroscopy, is derived from that of the P_8iPr_4 isomer, which is analogous to bisnoradamantane, by condensation of a two-atom bridge with formation of a new five-membered ring.



$P_{10}R_4$

64a: R = Me
64b: R = Et
64c: R = *i*Pr



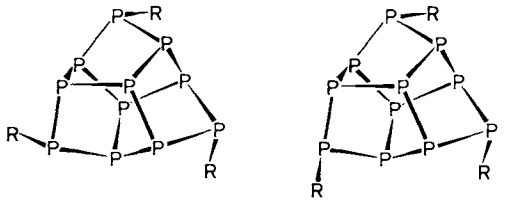
$P_{11}R_5$

65a: R = Me
65b: R = Et
65c: R = *i*Pr

An analogous state of affairs is valid for the tetracycloundecaphosphanes **65a–c** with respect to their structural relationship with the P_9R_5 isomers analogous to noradamantane (see Section 4.3), together with which they are usually formed. Thus, they are 3,4,7,9,11-pentaorganotetracyclo[6.2.1.$0^{2,6}$.$0^{5,10}$]undecaphosphanes. Compound **65b** has been isolated in 85% purity as an intense yellow,

highly viscous liquid.[81] According to the complex $^{31}P\{^1H\}$-NMR spectrum, several configurational isomers in comparable abundance and, possibly, an additional constitutional isomer with analogous structural elements are present.

Although the pentacyclic undecaphosphane **66** is built up exclusively of five-membered ring units and thus exhibits a relatively high thermodynamic stability, it is only formed to about 0.2 mol-% in the reaction of iPrPCl$_2$, P_4, and magnesium. Its abundance can be increased to about 1% by thermolysis of the crude product and, after stepwise separation, **66** can be isolated in pure form as intense yellow needles.[87] The $^{31}P\{^1H\}$-NMR spectrum shows twelve

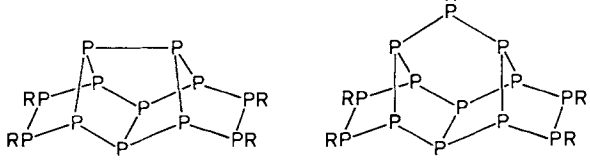


66a $P_{11}R_3$ **66b**

R = iPr

signal groups in the region from $\delta = +133$ to -38 (121.5 MHz), which, on the basis of their intensity ratios and splitting patterns, correspond to the two diastereomers **66a** and **66b** with symmetrically and unsymmetrically arranged isopropyl substituents in the statistical distribution of 1:3. According to an X-ray structural analysis,[88] the crystals consist solely of the unsymmetrical isomer, as had also been found for the only previously known "inorganic"-substituted species, $P_{11}(SiMe_3)_3$,[89] which has a phosphorus skeleton identical to that of **66**.

The phosphorus-richer pentacyclophosphanes **67** and **68** are also formed preferentially by the "thermolysis route"; of these, **67c** and **68c** have been isolated in pure form as pale yellow platelets or needles, respectively.[90]



$P_{12}R_4$ $P_{13}R_5$

67a: R = Me
67b: R = Et
67c: R = iPr
67d: R = tBu

68a: R = Me
68b: R = Et
68c: R = iPr
68d: R = tBu

They are characterized by an exceptionally high thermal stability such that they can be heated up to 250°C without decomposition. According to the X-ray analysis of **67c** (Fig. 4), the P_{12} skeleton is made up of two P_7 moieties, which are analogous to that of norbornane and which are joined by a common two-atom bridge and a zero bridge. Compound **67c** is thus 3,4,9,10-tetraisopropylpentacyclo[6.4.0.0^{2,6}.0^{5,12}.0^{7,11}]dodecaphosphane. As can be seen

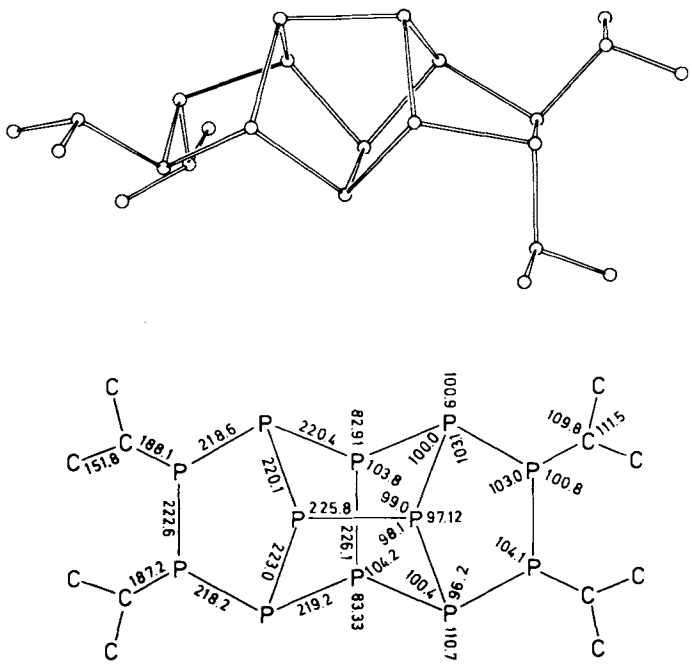


Fig. 4. Molecular structure of **67c** in the crystal. Above: ORTEP plot. Below: projection of the molecule parallel to the C_2 axis with averaged bond lengths in pm ($\sigma \leq 0.7$ pm) and selected, averaged bond angles in degrees ($\sigma \leq 0.6°$; exceptions: $110.7 \pm 1.2°$ and $96.2 \pm 1.4°$).

from a comparison of the P-P bond lengths, the zero bridges of the middle P_8 unit are markedly lengthened.

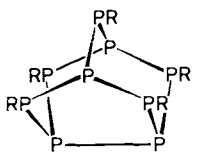
In the case of **68c**, the crystalline needles obtained so far have always been too thin for an X-ray structural determination. On the basis of the common route of formation of **68c** and of **67c** and **65c** as well as the analogy of the $^{31}P\{^1H\}$-NMR spectrum with those of **67c** and **65b**, however, **68c** should be a 3,4,7,10,11-pentaisopropylpentacyclo[7.4.0.0^{2,6}.0^{5,13}.0^{8,12}]tridecaphosphane. The P_{13} skeleton is again derived from the tetracyclic $P_{11}(5)$ partial skeleton by an additional two-atom bridge as part of a new five-membered ring.

The structures of the $P_{12}(4)$ and $P_{13}(5)$ skeletons are by no means unusual since both occur as important building units of Hittorf's phosphorus in which they are alternatingly joined through common two-atom bridges to form five-cornered tubes.[56] Thus, the existence of **67** and **68** shows that unchanged, phosphorus-rich partial structures of the element can exist as discrete molecules.

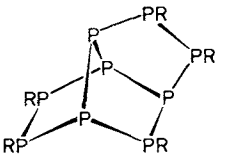
4.3. Constitutional Isomers of Organopolycyclophosphanes

The increasing information available on the polycyclic organophosphanes indicates that the formation of constitutional isomers is probably as common as it is with the polycycloalkanes. Whereas in Section 4.2 only those cases were discussed where the increasing steric demands of the substituents cause significant changes in the structural skeletons characteristic of the individual classes of compounds, the formation of different phosphorus skeletons for one and the same compound will be discussed in this section. "Actual" constitutional isomers in this sense apparently occur when several skeletons with comparable stabilities are possible for a single compound.

As reported previously,[1,79] on dehalogenation of a mixture of $RPCl_2$ or $(PR)_n$ and PCl_3 under suitable conditions, the tricyclononaphosphanes **69a-c**, with P_9 skeletons analogous to that of noradamantane (a-P_9R_5), are formed (see Table 3). In contrast, the synthesis with white phosphorus



a-P_9R_5



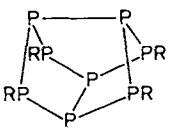
b-P_9R_5

69a: R = Me
69b: R = Et
69c: R = *i*Pr

70a: R = Me
70b: R = Et
70c: R = *i*Pr

gives rise to a mixture of **69** and a further constitutional isomer of lower relative abundance (b-P_9R_5), which, in the case of **70b**, has been isolated as a pale yellow, oily liquid and, in the cases of **70a** and **70c**, has been highly enriched.[81,91] As confirmed by a complete analysis of its $^{31}P\{^1H\}$-NMR spectrum, **70b** has a constitution analogous to that of the hydrocarbon brexane; thus **70a-c** are 2,4,5,8,9-pentaorganotricyclo[4.3.0.$0^{3,7}$]nonaphosphanes.
On the basis of an MNDO calculation of the ΔH_f° values of a-P_9H_5 and b-P_9H_5 (−54.5 and −58.7 kcal/mol, respectively) by *Gleiter* et al.,[92] the isomer with the structure analogous to that of brexane has the higher relative stability, in contrast to the carbocyclic analogues.[93] In accord with this, evidence for a rearrangement of **69b** to **70b** was found.[91] The isomers **69** and **70** are each formed as mixtures of several configurational isomers and this is the reason for the lacking tendency of the pure compounds to crystallize.

The tricyclic octaphosphanes **71** only show a low tendency for formation in the synthetic reactions given in Section 4.1, so that to date only **71c** has been enriched up to about 30 mol-%.[81,94] The constitution, a 2,4,6,8-tetraisopropyltricyclo[3.3.0.$0^{3,7}$]octaphosphane with a P_8 skeleton analogous to that of bisnoradamantane (a-P_8R_4), has been confirmed by ^{31}P-NMR spectroscopy.



a-P_8R_4

71a: R = Me
71b: R = Et
71c: R = *i*Pr

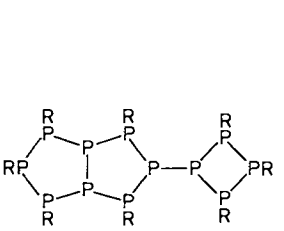
72a: R = Me
72b: R = Et
72c: R = *i*Pr

In attempts to increase the proportion of **71c** by thermolysis of the crude product at 230 °C, an increase in the yield was indeed detected by mass spectroscopy. However, as was found already in the course of separation and again on complete analysis of the $^{31}P\{^1H\}$-NMR spectrum of the compound isolated in 95% purity, the constitutional isomer **72c** is formed by the "thermolysis route."[95] Compound **72c** contains a framework analogous to that of homonorbornene (b-P_8R_4) and is thus a 3,6,7,8-tetraisopropyltricyclo[3.2.1.$0^{2,4}$]octaphosphane. The compounds **72a** and **72b**, also identified by mass spectroscopy after thermolysis are assumed to have the same constitutions. According to a MNDO calculation, **72a** ($\Delta H_f^\circ = -120.1$ kcal/mol) is somewhat more stable than **71a** ($\Delta H_f^\circ = -115.8$ kcal/mol). Consequently, on slight warming, **71c** rearranges to **72c** with simultaneous partial disproportionation. By inclusion in larger P_n skeletons, like those of **64** and **67** or Hittorf's phosphorus,[56] the $P_8(4)$ unit of **71** apparently gains in stability.

Constitutional isomers of *conjuncto*-phosphanes can also vary by different linkage of the same partial skeletons. One example of this is the highly alkylated dodecaphosphane **74**, which is formed by thermolytic "dimerization" of the bicyclohexaphosphane **73**[86] (cf. Table 3) and can be isolated as colorless crystals.[96,97] It is produced as a mixture of the isomers **74a** and **74b** of comparable abundance, which can be separated by chromatography. According to

$$2\,P_6tBu_4 \xrightarrow{\Delta} P_{12}tBu_8$$

73 **74**



74a R = *t*Bu **74b**

the 2D $^{31}P\{^1H\}$-NMR spectrum, **74a** is 2,4,6,7,8-penta-*tert*-butyl-3-(2,3,4-tri-*tert*-butylcyclotetraphosphanyl)bicyclo-[3.3.0]octaphosphane and **74b** is the isomer with the large substituent in the 2 position. Both compounds have similar stabilities.

4.4. Inversion of Phosphorus in Organopolycyclophosphanes—First Examples

The tetracyclononaphosphanes **75** constitute a particularly interesting class of compounds on account of their exceptional thermal stability and pronounced tendency for formation. Following the initial preparation of **75b** in pure and **75c** in highly enriched form,[80] the preparation of **75a** and **75c** in pure form was also achieved recently.[98] Thus, the prerequisites for further intensive studies, especially of the most soluble compound, **75c**, are now provided.

P_9Et_3 **75a** P_9iPr_3 **75b** P_9tBu_3 **75c**

First, the deltacyclane-like constitution of the $P_9(3)$ skeleton, previously deduced from a qualitative interpretation

of the NMR spectra,[1,80] was confirmed by a complete analysis of the $^{31}P\{^1H\}$-NMR spectra of **75c** (Fig. 5) and **75a**. The results additionally show that, for each compound, two configurational isomers of varying abundance exist in solution and differ in the spatial arrangement of the substituents.

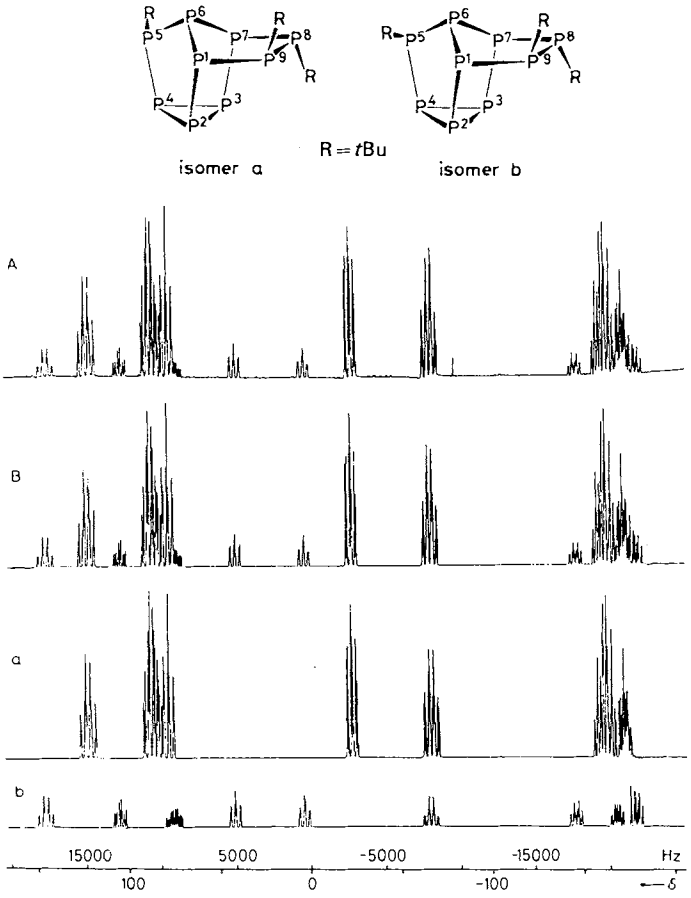


Fig. 5. Observed (A) and simulated (B) $^{31}P\{^1H\}$-NMR spectrum of P_9tBu_3 **75c** (mixture of isomers) in [D_6]benzene at 22°C (121.497 MHz); a, b: simulated spectra of the isomers a and b, respectively.

After completion of the nuclear magnetic resonance structural investigation, single crystals of **75c** suitable for an X-ray structural analysis were obtained.[98] As shown by the result (Fig. 6)[99] and confirmed for the whole solid substance by cold dissolution (−40°C) of a larger number of crystals under NMR spectroscopic control, the main isomer a separates out exclusively under suitable conditions.

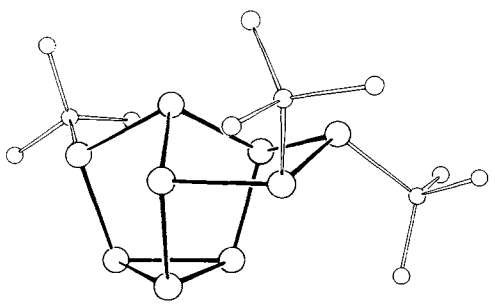

Fig. 6. Molecular structure of P_9tBu_3 **75c** (without hydrogen atoms) in the crystal [99].

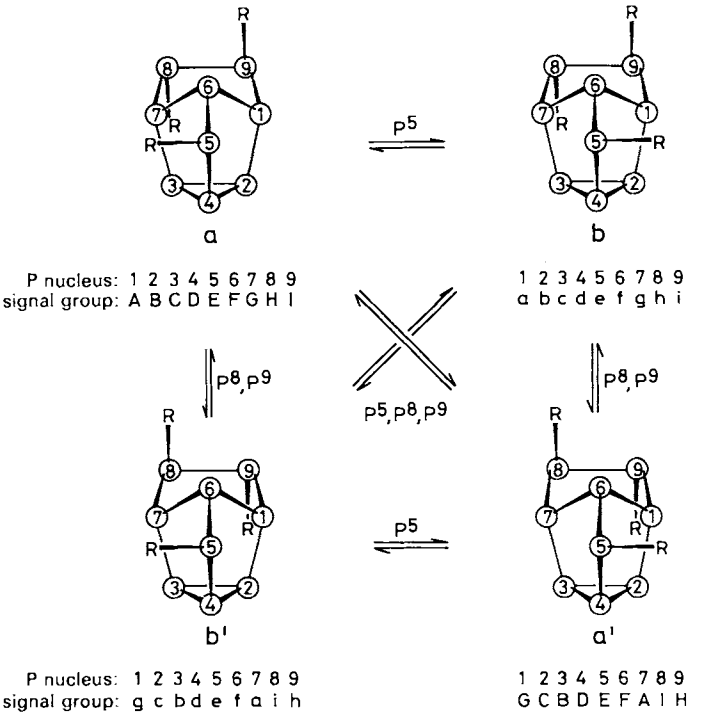
After the solution of pure isomer a, prepared at −40°C, has been allowed to stand at 25°C for about 30 min, the isomer distribution characteristic of **75c** (a:b = 4:1, see Fig. 5) can be observed again in the $^{31}P\{^1H\}$-NMR spectrum.[98] This result is a clear indication that the transformation of isomer a into isomer b, which can only occur through inversion, takes place at a noticeable rate already at room temperature.

The inversion processes that must be taken into consideration for the transformations between the four different molecules of the enantiomer pairs a, a′ and b, b′ are summarized in Scheme I. The signal groups A–I (for the molecules a and a′) and a–i (for the molecules b and b′) corresponding to the phosphorus nuclei 1–9 are given below the individual configurational isomers.



Scheme I. Possible inversion processes for the configurational isomers of P_9R_3 **75**.

As can be seen, the observed transformation of isomer a into isomer b can occur by inversion at P^5 or by simultaneous inversions at P^8 and P^9, whereby the molecules formed are mirror images of each other. Since enantiomers exhibit identical NMR spectra, a differentiation between these two possibilities can only be achieved with the help of dynamic NMR methods. This is also valid for a proof of the simultaneous inversion of all three organosubstituted phosphorus atoms (P^5, P^8, P^9), which transforms each of the molecules into its corresponding enantiomer. As can be seen from Scheme 1, the inversion at P^5 in isomer a causes a shift of the resonance of the nucleus P^1 from A to a. The associated magnetization transfer is visible in a two-dimensional exchange spectrum[100] as two cross peaks Aa between the respective groups. All possible inversion processes are given with the associated cross peaks in the upper part of Figure 7; the cross peaks emphasized by underlining are particularly characteristic of the respective process.

Inversion process	Cross-peaks
P^5	Aa, Bb, Cc, Dd, Ee, Ff, Gg, Hh, Ii
P^8, P^9	Ag, Bc, Cb, Dd, Ee, Ff, Ga, Hi, Ih
P^5, P^8, P^9	AG, BC, HI, ag, bc, hi

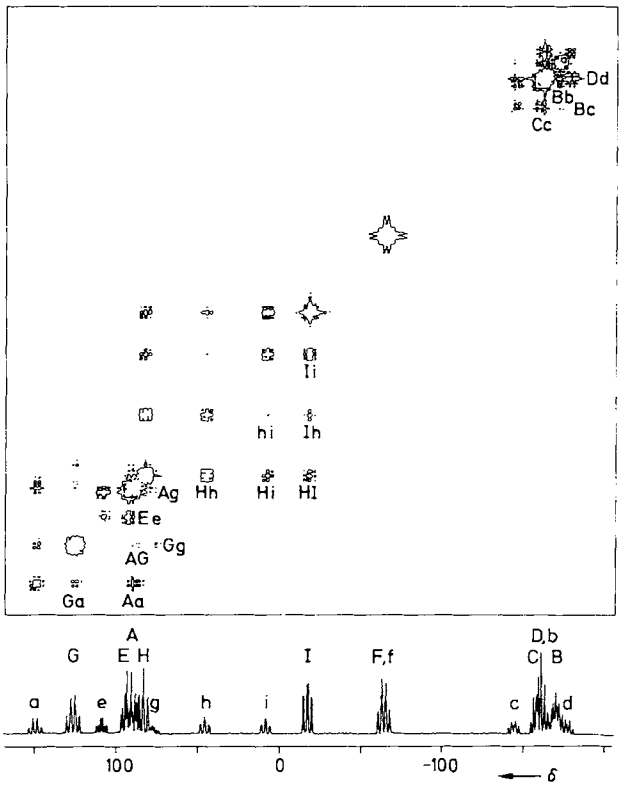


Fig. 7. Above: 2D exchange NMR spectrum of P_9tBu_3 **75c**; cross peaks for the possible inversion processes. Middle: 2D $^{31}P\{^1H\}$-NMR spectrum (pulse sequence: 90°, t_1, 90°, t_m, 90°, t_2), mixing time for magnetization transfer $t_m = 0.2\ s \pm 30\%$, measuring temperature 100°C, measuring frequency 121.497 MHz. Below: corresponding 1D $^{31}P\{^1H\}$-NMR spectrum.

The expected magnetization transfer is clearly observable in the two-dimensional nuclear magnetic resonance spectra recorded above 70°C.[98] As shown by the 2D $^{31}P\{^1H\}$ exchange spectrum recorded at 100°C (Fig. 7, middle), the cross peaks for the inversion process at P^5 have the highest relative intensity, so that this is, without doubt, the dominating process. In addition, however, configuration inversions take place at P^8 and P^9, and also possibly at P^5, P^8, and P^9, as can be seen from the occurrence of the corresponding cross peaks of lower intensity.[101] The activation parameters for the first two processes were determined by line-shape analysis of the ^1H-NMR spectra of **75c**; the third process could not be determined for methodological reasons.[102]

Inversion at P^5: $\Delta H^{\neq} = 18.5 \pm 2$ kcal/mol
$\Delta S^{\neq} = -9.3 \pm 0.5$ cal K^{-1} mol^{-1}
Inversion at P^8, P^9: $\Delta H^{\neq} = 30.1 \pm 2$ kcal/mol

As expected, the enthalpy of activation for the second process is considerably larger than that for the first, since steric interactions between the two *tert*-butyl groups inevitably occur during inversion at the two neighboring phosphorus atoms.[103] The value for the first process is about half as large as that for PH_3,[104] in confirmation of the analogous trends found for open-chain phosphanes (see Section 2.3).

The observation that the ethyl compound **75a**, independent of its method of preparation, always exhibits the same isomer distribution (a : b = 66 : 34) in solution at room temperature already indicates that, in this case also, a thermodynamic equilibrium exists between the two isomers. Indeed, the same inversion processes as for **75c** were demonstrated for **75a** by 1D and 2D NMR investigations. However, under the same conditions, the measured magnetization transfer is markedly lower than that for **75c**, in accord with the general rule that the presence of bulky substituents lowers the barrier to inversion.[18]

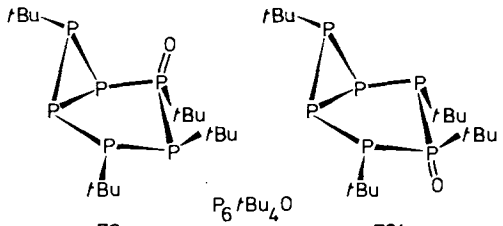
Very recently, it was shown that the configuration of the pentacycloundecaphosphane **66** also undergoes change in solution even under mild conditions.[87] After at most 2 h at room temperature, a solution of the pure, asymmetrical isomer **66b** (see Section 4.2), prepared by cold (−30°C) dissolution of its crystals, exhibits the statistical isomer distribution (**66a** : **66b** = 1 : 3). As can be seen from a comparison of the conditions for the isomerization of **66** and **75c**, the inversion barrier for **66** is markedly higher.

Before reliable statements on the mechanism of inversion of phosphorus in organopolycyclophosphanes can be made, further work is required.

4.5. Polycyclophosphane Oxides

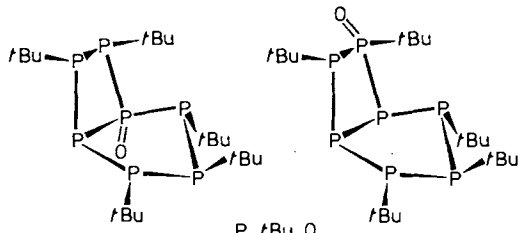
Like all other compounds of trivalent phosphorus, organopolycyclophosphanes P_nR_m ($m < n$) readily undergo oxidative attack at the lone electron pairs on the phosphorus atoms. Although the resistance toward atmospheric oxygen increases with increasing phosphorus content and increasing bulk of the substituents, rapid oxidation generally takes place in solution. Until recently, nothing was known about the polycyclophosphane oxides thus formed. Of particular interest is whether oxygen reacts with insertion into the P_n skeleton, as in the formation of P_4O_6 from P_4, or by exocyclic addition to the intact polycyclophosphane. We have found conditions under which the latter reaction takes place exclusively.

The bicyclophosphanes P_6tBu_4 **73** and P_7tBu_5 **61** react with dry air in solution at room temperature to form the corresponding monoxides **76** and **77**, respectively, which can be isolated as pale yellow solids.[105] Both compounds are produced as a mixture of two constitutional isomers (abundance ratios **76a** : **76b** = 4.5 : 1; **77a** : **77b** ≈ 1 : 1). Their structures have been confirmed by complete analyses of their $^{31}P\{^1H\}$-NMR spectra. Accordingly, in each case, the oxygen atom is bonded exocyclically to the P_n skeleton of the parent compound. The product formation is apparently governed mainly by steric factors. Thus, for **76** the observed isomer distribution is an indication that the five-membered ring atom P^3 is more strongly shielded by the *tert*-butyl groups than the neighboring atoms P^2 and P^4 (statistical isomer abundance 2 : 1). In the case of **61**, the exocyclic bonding of oxygen to P^1 and P^7 is apparently



P_6tBu_4O

76a 76b

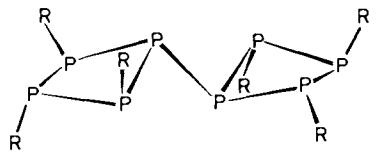


P_7tBu_5O

77a 77b

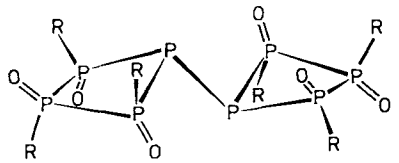
equally favorable, but at P^2 or P^4, in contrast, it is hindered by the *endo* position of the substituent at P^7. The fact that no isomers of **76** are formed with the oxygen bonded to the three-membered ring is presumably attributable to the predominant s character of the lone electron pairs on the corresponding phosphorus atoms of **73**.

The 1,1′-bicyclotetraphosphane **78**[84] (see Table 3) is more resistant to oxidation and only reacts in solution with pure oxygen at higher temperatures and then with cleavage of the P-P bonds and formation of 1,2-di-*tert*-butyldiphosphane dioxide. In contrast, it can be converted smoothly into the hexaoxide **79** with hydrogen peroxide, peracetic acid, or—particularly selectively—cumene hydroperoxide at room temperature,[106] whereas, above 30 °C, decomposi-



P_8tBu_6 **78**

R = *t*Bu



$P_8tBu_6O_6$ **79**

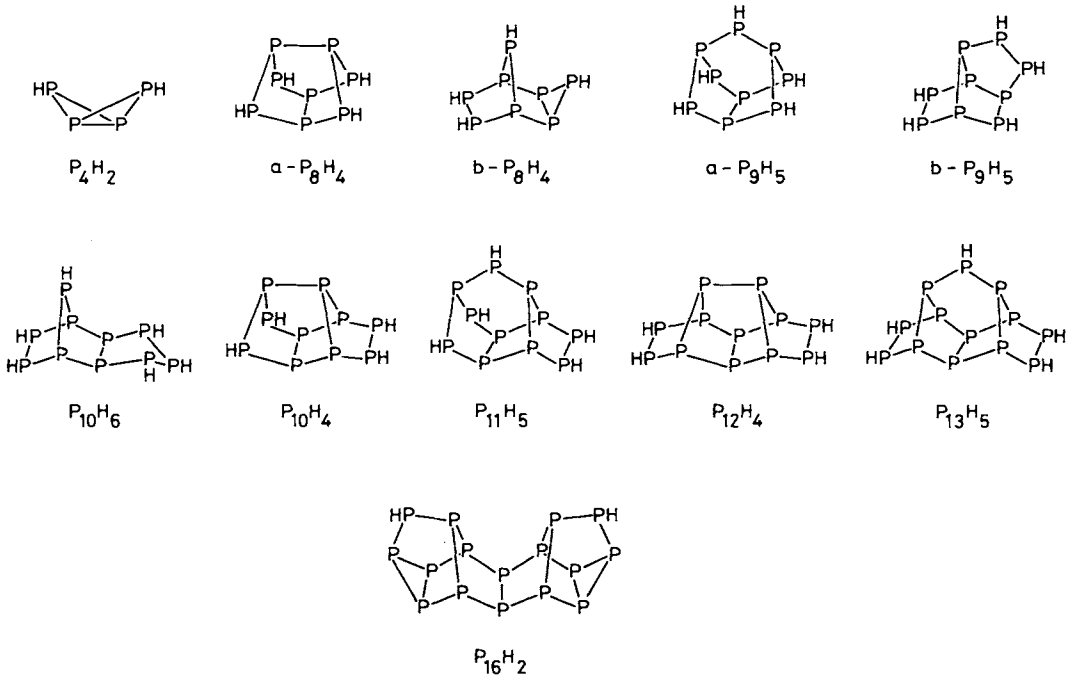
tion to P_2 units also takes place. Compound **79** is characterized by an exceptional tendency for formation and can be detected, along with oxygen-poorer oxides, by ^{31}P-NMR spectroscopy, even at a reactant ratio of 1 : 1. It can be isolated as a colorless, finely crystalline solid, which is hardly soluble in organic solvents and which, on warming, only dissolves with decomposition. The constitution was deduced from the $^{31}P\{^1H\}$-NMR spectrum, which shows three multiplets of an $AA'B_2B_2'CC'$ spin system with resonance positions, intensity ratios, and splitting patterns that are only compatible with an exocyclic bonding of oxygen to the organosubstituted phosphorus atoms. Compound **79** is thus 2,2′,3,3′,4,4′-hexa-*tert*-butyl-1,1′-bicyclotetraphosphane 2,2′,3,3′,4,4′-hexaoxide. The fact that **78** cannot be converted into an octaoxide even with a large excess of cumene hydroperoxide is presumably a result of the relatively small bonding angles at the exocyclic bridge ($\bar{\varphi}$(P-P-P) = 96.6°[84]) and the related, mainly s character of the lone electron pairs at the "bridgehead" atoms.

5. On the Structure of Polycyclic Phosphorus Hydrides and the Formation of Polycyclic P_n Skeletons

The new organopolycyclophosphanes mentioned in Section 4 open up possibilities for experimentally based statements concerning the structures of a series of polycyclic phosphorus hydrides. The structures of the compounds P_7H_5, P_7H_3, P_8H_6, P_9H_3,[1] and $P_{11}H_3$[107] have already been clarified. Since, in the individual classes of compounds P_nR_m, variation of the substituents within the range of relatively small alkyl groups (Me to *i*Pr) in no case is accompanied by a change in the phosphorus skeleton (see also Table 3), a structural change on replacement of these organic groups by hydrogen atoms can also be excluded with certainty. Thus, the molecular structures determined for the organopolycyclophosphanes are also representative of the corresponding phosphorus hydrides. The structures thus derived for a series of polycyclic phosphorus hydrides that have been identified by mass spectroscopy are shown in Scheme 2.

Tetraphosphane(2), P_4H_2, is bicyclo[1.1.0]tetraphosphane; octaphosphane(4), P_8H_4, exists as two constitutional isomers, namely, tricyclo[3.3.0.$0^{3,7}$]octaphosphane (a-P_8H_4) and tricyclo[3.2.1.$0^{2,4}$]octaphosphane (b-P_8H_4); nonaphosphane(5), P_9H_5, also occurs as two constitutionally isomeric forms, namely, tricyclo[3.3.1.$0^{3,7}$]nonaphosphane (a-P_9H_5)[1] and tricyclo[4.3.0.$0^{3,7}$]nonaphosphane (b-P_9H_5); decaphosphane(6), $P_{10}H_6$, is tricyclo[5.2.1.$0^{2,6}$]decaphosphane; decaphosphane(4), $P_{10}H_4$, is tetracyclo[5.2.1.$0^{2,6}$.$0^{3,8}$]decaphosphane; undecaphosphane(5), $P_{11}H_5$, is tetracyclo[6.2.1.$0^{2,6}$.$0^{5,10}$]undecaphosphane; dodecaphosphane(4), $P_{12}H_4$, is pentacyclo[6.4.0.$0^{2,6}$.$0^{5,12}$.$0^{7,11}$]dodecaphosphane; tridecaphosphane(5), $P_{13}H_5$, is pentacyclo[7.4.0.$0^{2,6}$.$0^{5,13}$.$0^{8,12}$]tridecaphosphane; hexadecaphosphane (2), $P_{16}H_2$, is octacyclo[7.7.0.$0^{2,6}$.$0^{3,8}$.$0^{5,7}$.$0^{10,14}$.$0^{11,16}$.$0^{13,15}$]-hexadecaphosphane.

The previously formulated[1] general structural principles for polycyclic phosphanes and their sterically unperturbed derivatives have proved their general validity in the course of the further expansion of this field. In particular, the outstanding significance of five-membered ring structural elements in the construction of mono- and polycyclic phosphane skeletons has been confirmed again and again in numerous examples. However, with the increasing annelation of five-membered rings in the formation of higher cyclic compounds, increasing strain energies are appar-



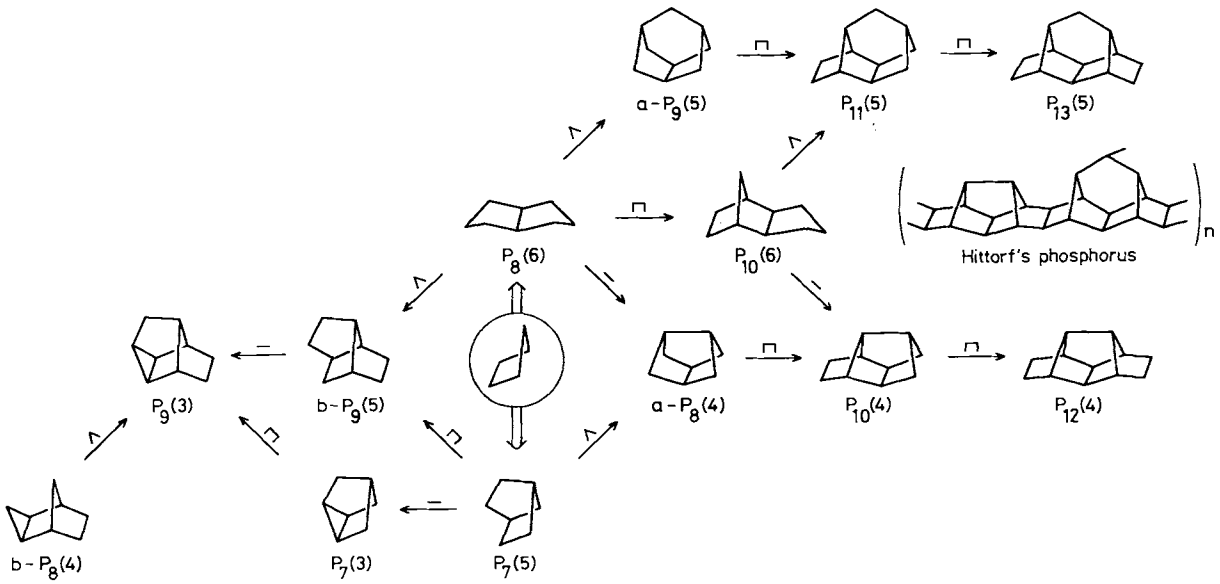
Scheme 2. Structures of polycyclic phosphorus hydrides.

ently built up, as can be seen, for example, in the stability order a-P_8Me_4 < b-P_8Me_4.[95]

Next to the five-membered ring units, three-membered ring units play a larger role than was initially assumed. This is now understandable since the strain energy of the P_3 ring as opposed to the nonstrained P_5 ring has been recently found to be 7.8 kcal/mol.[108] When this value is compared with *von Schleyer*'s[109] estimated value of 26.8 kcal/mol for the ring strain in cyclopropane compared with cyclohexane, it becomes clear that the deformations of the bonding angles at trivalent phosphorus result in considerably lower strain energies than do deformations of those at carbon. Accordingly, P_3 rings often occur as partial structures in polyphosphides and organopolycyclophosphanes.

On the other hand, according to *Ahlrichs*,[110] the fact that no sterically unperturbed $P_n(m)$ skeletons with four-membered ring partial structures exist is attributable to the general skeletal destabilization caused by parallel σ bonds at a separation corresponding to a single-bond distance. The first example in which a molecular polycyclic phosphane is forced to adopt an annelated four-membered ring as a structural element as the result of special steric relationships is the compound P_7tBu_5 **61**.

With increasing numbers of phosphorus atoms, the formation of conjuncto-phosphane structures in which lower-



Scheme 3. Principles for the formation of sterically unperturbed, polycyclic phosphanes; the numbers in parentheses each represent the number of substituents at the positions in the phosphorus frameworks where only two bonds join together. ⊓ = two-atom bridge; ∧ = one-atom bridge; — = zero bridge.

cyclic partial skeletons are linked by single bonds or through two common phosphorus atoms dominates increasingly.

The polycyclic $P_n(m)$ skeletons show, on the whole, closely related features (Scheme 3). The dominating structural element is the five-membered ring. Either the $P_7(5)$ structural group analogous to that of norbornane or the $P_8(6)$ structural group analogous to that of pentalane is formed on condensation of two phosphorus five-membered rings. Both are major partial structures of the phosphorus-richer, polycyclic phosphanes. All sterically unperturbed polycyclophosphanes with up to thirteen phosphorus atoms can formally be interconverted, according to the construction principles shown in Scheme 3, by the use of three basic operations:

1. On condensation of a two-atom bridge to give a new five-membered ring, the next-higher cyclic and two-P-atom-richer phosphane is formed:[1]

$$P_n(m) \longrightarrow P_{n+2}(m)$$

2. On condensation of a one-atom bridge, the number of phosphorus atoms increases by one while the number of substituents is simultaneously reduced by one; this leads to a change from even- to odd-numbered phosphanes:

$$P_n(m) \longrightarrow P_{n+1}(m-1)$$

3. On intramolecular formation of a zero bridge, the next-higher cyclic phosphane with the same number of phosphorus atoms and a substituent number reduced by two is formed:

$$P_n(m) \longrightarrow P_n(m-2)$$

Furthermore, two identical or different phosphorus skeletons can be linked intermolecularly to form a bicyclo[3.3.0]octaphosphane structure; the resulting phosphorus-richer phosphane contains two five-membered rings with a common two-atom bridge,[1] e.g.,

$$2\,P_5(5) \longrightarrow P_8(6); \quad P_7(5) + P_5(5) \longrightarrow P_{10}(6)$$

On the whole, increasingly larger building units of Hittorf's phosphorus[56] whose free valencies are satisfied by hydrogen atoms or organic groups are formed with increasing numbers of phosphorus atoms.

Since the construction principles mentioned have retained their general validity up to now, they can be used to derive the most probable structural skeletons for phosphanes whose structures have not yet been clarified.

6. Perspectives

The investigations of the last five years have demonstrated that the field of open-chain and cyclic polyphosphorus compounds has undergone a remarkable development in this short time. A surprising variety of new compounds, some with unexpected structures, could be found and studied by application of generalizable synthetic routes and modern nuclear magnetic resonance spectroscopic methods. During this process, the close relationship between phosphorus and carbon chemistry[1] has become apparent to an extent that would hardly have been considered possible earlier. Who would have ever thought in their wildest chemical speculations that, in the course of the synthesis of phosphorus-richer from phosphorus-poorer polyphosphides, a resonance-stabilized pentaphosphacyclopentadienide ion with unsubstituted phosphorus atoms of coordination number 2 would form spontaneously? Just as surprising, however, is the "detour" that nature follows in this complex redox process: from relatively small, "compact" P_n^{m-} skeletons such as P_7^{3-}, relatively large, "open" structures such as P_{26}^{4-} are initially formed which then transform to medium-sized, more "closed" phosphorus skeletons of the phosphorus-richer polyphosphides, such as $M_2^I P_{16}$, with separation of individual building units. And finally, we were rather intrigued by the (not completely unexpected) inversion of phosphorus in the tetra- and pentacyclic organophosphanes P_9R_3 and $P_{11}R_3$.

What remains to be done? The structures of a considerable number of polycyclic phosphorus hydrides and the corresponding organopolycyclophosphanes remain to be elucidated. Although the most probable structures can be predicted with the help of the general principles given, the example of the constitutionally isomeric compounds P_8R_4 shows that surprises can still be expected and that the definitive elucidation of the skeletal structure of a compound can only be achieved by experimental methods. The syntheses of the corresponding molecules should, in principle, be only a question of the experimental effort and the chemist's patience. For structural studies on phosphorus-richer, higher-cyclic compounds, a major contribution may be expected from solid-state, multinuclear magnetic resonance spectroscopy.

All classes of compounds—the lower, homologous, open-chain phosphorus hydrides as well as the polyphosphides with isolated anions and also the organopolycyclophosphanes—promise a rich chemistry, on which research is just beginning. The expectations for the further development of *the chemistry* of polyphosphorus compounds can hardly be set high enough.

Ultimately, the perspectives reach beyond the limits of this topic. The question arises whether the heavier elements of the 5th main group also possess a comparable ability to form compounds with homonuclear molecular skeletons. On the basis of our present knowledge, the answer is, at least for arsenic, a definite yes. Table 4 lists the presently known polycyclic *tert*-butylarsanes.[111] These compounds have been identified unequivocally by spectroscopic methods, but most have not yet been prepared on a preparative scale or characterized structurally.

The question of the structures of these compounds is in no way trivial, even with knowledge of the corresponding phosphorus compounds. For example, As_8tBu_6 and P_8tBu_6[84] as well as the compound pair $As_{12}tBu_8$[112] and $P_{12}tBu_8$[96] have been found to have completely different skeletal structures. Thus, a further, extensive field of research is open for the future.

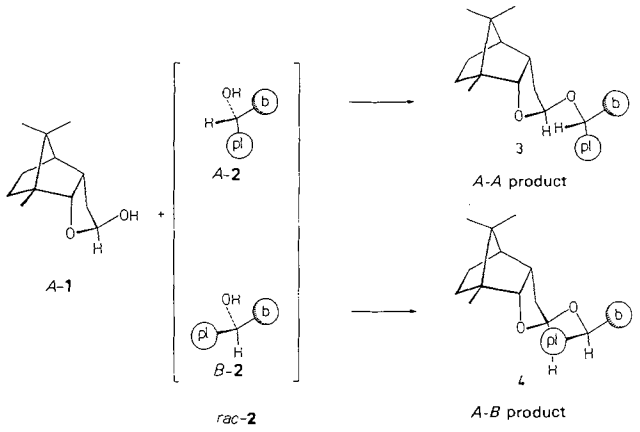
Stereoelectronic Effects and Chiral Recognition: A Natural System of Relationships between Chiral Compounds based on Selectivities in the Formation of Acetals

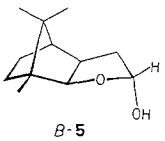
By *Christian R. Noe,* Max Knollmüller, Georg Göstl, Berndt Oberhauser,* and *Horst Völlenkle*

Stereoelectronic effects of the same type as the anomeric effect have been extensively investigated since the formulation of the latter by *R. U. Lemieux* et al.,[1] and their fundamental importance in carbohydrate chemistry is unquestionable.[2] In our studies using terpenoids of type **1** as models of carbohydrates, we have been especially concerned with the phenomenon of enantiomeric selectivity,[3,4] and, among other things, we have developed a rule that—based on this selectivity—allows a simple determination of the absolute configuration by means of the characteristic positions of the signals in the nuclear magnetic resonance spectra. The rule was derived, in particular, for secondary alcohols of type **2** (Scheme 1) having a bulky group (b) and a planar or linear group (pl), by analysis of numerous examples.[4–6] However, the rule is also generally applicable to compounds containing an amino or a thio group bonded to a secondary C atom.[4]

A compound has the absolute configuration *A* when, upon viewing the center of chirality in the direction of the heteroatom bound to this center—the exocyclic heteroatom in the case of lactol derivatives (acetals, thioacetals, aminals)—the groups b and pl and the H atom are arranged clockwise. Configuration *B* is present if they are arranged counterclockwise. Owing to enantiomeric selectivity, only a compound of the *A* type reacts preferentially with the lactol **1**, which was prepared from D-(+)-camphor. The designation *A* for the configuration of the isomer of **2** that reacts preferentially with **1** was chosen because the semiacetalic center of **1** exhibits the same configuration as α-D-glucose.[7]

By viewing the semiacetalic center of **1** in the direction of the OH group, it can be seen that this center also has a b ligand (CH_2), a pl ligand (O), and a hydrogen atom arranged in a clockwise sense. Thus, **1** is also a compound of type *A*. The enantiomer selectivity leading to preferential formation of the diastereomer **3** can therefore be formulated more generally: The reaction of two compounds of the same type is preferred over the reaction of a type-*A* compound with a type-*B* compound.





Scheme 1.

To test this assumption, the type-*A* lactol **1** was allowed to react with the type-*B* lactol **5**[9] in a 1 : 1 ratio under acid catalysis. Under these conditions, lactols generally condense to form acetals.[10] Indeed, the self-condensation products **6** (*A*-*A* type)[10] and **7** (*B*-*B* type)[9] were formed

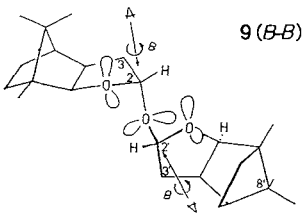
preferentially (Scheme 2). The proportion of the mixed condensation product **8** (*A*-*B* type)[11] was only 15%.[12] Treatment of the condensation product **8**, isolated from the reaction mixture, with a catalytic amount of acid resulted in rapid equilibration. Compounds **6**, **7**, and **8** were thereby formed in the same ratio as obtained for the reaction of **1** with **5**. A similar result was obtained for the condensation of the racemic mixture of **1** and *ent*-**1**,[13] which is a 1 : 1 mixture of *A*-**1** and *B*-**1**. The main products were **6** (*A*-*A* reaction) and *ent*-**6** (*B*-*B* reaction) as a racemic mixture. The proportion of condensation products formed by reaction of *A*-**1** with *B*-**1** was only about 15% in this case. In a final experiment, *B*-**1** was synthesized from L-borneol,[14] and allowed to react with the type-*B* lactol **5**. In addition to the self-condensation products *B*-*B*-**6** and **7**, formed by *B*-*B* reaction, the mixed product **9**,[15] also formed by *B*-*B* reaction, was isolated as the main product (ratio of products according to ^{1}H-NMR: *B*-*B*-**6** : **7** : **9** ≈ 1 : 1 : 2).



9 (*B*-*B*)

Although the b-pl-H rule appears to hold, at first glance, for geometric reasons, the type of chiral recognition described here is based, above all, on stereoelectronic anomeric effects. Only the preferentially formed diastereomer (*A*-*A* and *B*-*B* reaction) can assume a non-sterically hindered conformation in which one of the two lone electron pairs on the bridging oxygen atom can be involved in an *exo*-anomeric effect, while the second electron pair is oriented in an antiperiplanar fashion with respect to the pl ligand. In the diastereomer formed by the *A*-*B* reaction, such a conformation is strongly hindered sterically. The spectroscopic data that support the assumption of a preferred (in the *A*-*A* case) and a nonstabilized (in the *A*-*B* case) conformation are further supported by several X-ray structure analyses.[3,4,16]

The pl ligands investigated (CN, C≡C, aryl, O, CHO) are indeed substituents that—in the antiperiplanar position to a lone electron pair—can favor the stabilizing n-σ* interaction. In order to determine whether the relatively restricted spatial extension of the planar ligand (in comparison to the bulky ligand) is responsible for the conformation of the preferentially formed diastereomer in each case, the X-ray structure analysis of compound **10**[17] was performed (Fig. 1); in **10**, the bulky residue at C-2 (≙C12) is replaced by hydrogen.

Figure 1 shows that **10** indeed adopts a conformation in which one of the lone electron pairs on the exocyclic oxygen atom can be stabilized in an *exo*-anomeric fashion by interaction with the σ* orbital of the C-O bond in the ring. Moreover, the cyano group is arranged in such a way that a further anomeric stabilization is possible by n-σ* interaction of the second lone electron pair on the exocyclic oxygen atom with the σ* orbital of the C-CN bond. The conformational position of the cyano group is in excellent agreement with that of the pl ligand in the preferentially

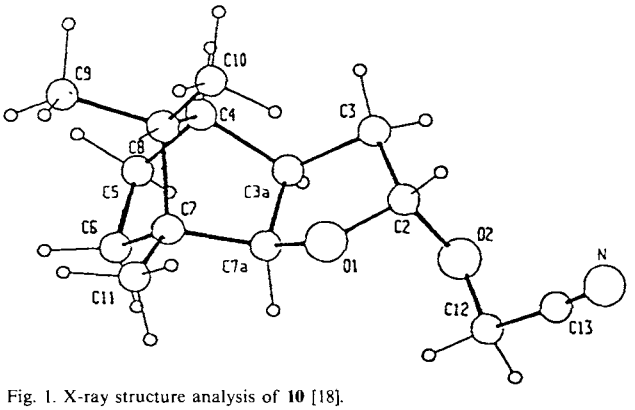


Fig. 1. X-ray structure analysis of **10** [18].

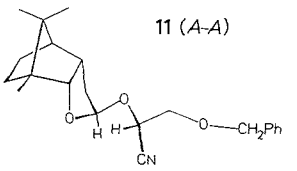
formed *A*-*A* and *B*-*B* products.[19] It can thus be assumed that, for b-pl-H compounds, the whole acetal group is stabilized by the interaction of three stereoelectronic effects (anomeric, *exo*-anomeric effect, n-σ* (C-pl) effect).

We believe that this type of chiral recognition, which we would like to refer to as family selectivity, is of fundamental importance in biological processes and that many chiral compounds that are naturally occurring in nature may be assigned to an *A* family or to a *B* family on the basis of the criteria mentioned here.

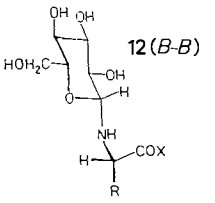
For instance, the reaction of racemic, benzyl-protected glyceronitrile with *A*-**1** (corresponding to α-D-glucose) results in preferential formation of the acetal **11**,[5,20] which corresponds to an α-glycoside of D-glyceronitrile—which, like D-glyceraldehyde, is a type-*A* compound. The observed enantiomeric selectivity could indicate that this mechanism played a prebiotic role in the spread of carbohydrate chirality[21] (type-*A* compound propagates type-*A* compound).



11 (*A*-*A*)

The small number of results that have been obtained so far for amines[4] indicate that this class of compounds behaves analogously. Since the natural α-amino acids (with the exception of glycine) are compounds containing b-pl-H ligands (L-amino acids are type-*B* compounds like β-D-glucose when viewed in the direction of the C-N bond, cf. *B*-*B* product **12** from an L-amino acid and β-D-glucose), it may be possible to develop an all-encompassing stereochemical picture of carbohydrates and amino acids.

We recommend the system of relationships described here above all on account of its simplicity and straightfor-



12 (*B*-*B*)

ward way of viewing glycosidic centers. For example, an analysis of the configuration of iridoid glucosides reveals that, in general, they contain a glycosidic center of the *B*-*B* type (*B* family). The b-pl-H rule can also explain the criteria established for this class of compounds for the configuration preferred by the glycosidic center,[22,23] as well as those worked out for the cyanogenic glycosides.[24]

[7] The *B* form exhibits the same arrangement of the ligands as α-L-glucose. β-D-Glucose also exhibits this configuration and is therefore a type-*B* compound. It is necessary, however, to take into consideration the lack of anomeric stabilization of the equatorial lactolic hydroxyl group in these compounds.

[8] The conformations of the acetalic centers shown in the formulas are idealized (cf. [2a], p. 78f). The actual conformations, determined by nuclear magnetic resonance spectroscopy and X-ray crystallography, are very similar to those shown (only a slight outward rotation of the alkoxy residue in a clockwise sense; cf. [4, 5]) in the case of the stabilized *A*-*A*-type compounds. In the case of the *A*-*B*-type compounds **8**, a conformation is expected in which the alkoxy group is strongly rotated outward in the clockwise sense (cf. structure data in [3, 16]).

[9] Compound **5** was synthesized analogously by reduction of the corresponding lactone with diisobutyl aluminum hydride. Likewise, **7** and **6** were synthesized in an analogous fashion from **5** and **1**, respectively: C. R. Noe, M. Knollmüller, G. Steinbauer, unpublished results.

Formation of Diiridium(II) Complexes by Photoassisted Oxidative-Addition Reactions: Structure of a Stable Binuclear Iodo(iodomethyl)iridium(II) Complex**

By *Miguel A. Ciriano, Fernando Viguri, Luis A. Oro,* Antonio Tiripicchio,** and *Marisa Tiripicchio-Camellini*

Double oxidative-addition of dihaloalkanes to anionic[1] or neutral[2] binuclear complexes is only a restricted route to the syntheses of the unique and intensively studied class of alkylidene-bridged complexes.[3] In studies of the mechanism of this reaction, the highly reactive intermediate **1** which is involved in the formation of methylene-bridged digold(II) complexes,[2a] was recently isolated[4] and some pyrazolato-bridged halo(halomethyl)diiridium(II) complexes have been prepared.[2d, 5]

$[\{Au(CH_2)_2PPh_2\}_2(CH_2Cl)Br]$ **1**

Binuclear alkylmetal compounds, M-M-CH_2X, having a functional group X in the α position could be key reagents in organic synthesis, as are their mononuclear counterparts.[6] Some have been proposed as intermediates in reactions between coordinated ligands.[7] In addition, knowledge of their chemistry is basic to the understanding of some metal-promoted catalytic processes.[8]

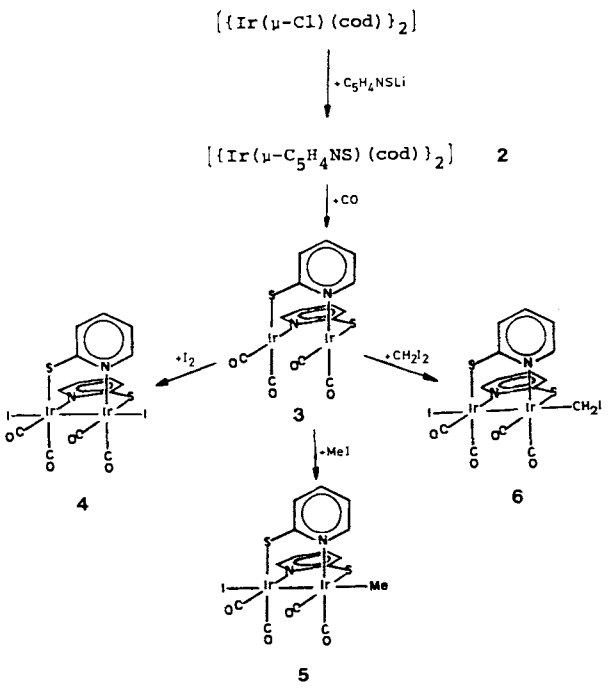
[**] This work was supported by C.A.I.C.Y.T. (Spain).

Herein we report the preparation, by photosensitive transannular oxidative-addition reactions, of a new family of binuclear iridium(II) complexes. In particular, the unusual complex **6**, which is stable toward a thermal intramolecular oxidative-addition (to give a methylene-bridged complex), has been fully characterized by X-ray methods and offers the possibility of studying its chemistry.

Reaction of lithium 2-pyridinethiolate with $[\{Ir(\mu\text{-}Cl)(cod)\}_2]$ (cod = 1,5-cyclooctadiene) in diethyl ether gives the complex **2** as a dark red air-stable crystalline solid in good yield. Carbon monoxide replaces the diolefin in **2** at atmospheric pressure in toluene to give a deep purple, very air-sensitive solution of **3**, from which **3** can be isolated as black-violet crystals having metallic luster. The IR and ^{1}H-NMR spectra of **3** (Table 1) are in accordance with a binuclear structure of C_2 symmetry in which the two carbonyl groups on each iridium are in *cis* positions and the two planes formed by the square-planar arrangement of the ligands are parallel.[6]



Complex **3**, prepared in situ in toluene, undergoes transannular oxidative-addition reactions, at room temperature upon exposure to direct sunlight or irradiation with a 150-W incandescent lamp, with an excess of iodine, methyl iodide, or diiodomethane to give the air-stable iridium(II) complexes **4** (red, 64% yield), **5** (orange-brown, 73%), and **6** (orange, 66%), respectively. These reactions are complete within a few minutes under these conditions but take about one day in the dark in accordance with the photoreductive properties of d^8–d^8 binuclear iridium(I) complexes.[5]

The structure of the complex **6**, determined by X-ray diffraction methods, is shown in the Figure 1.[9] It consists of two iridium atoms, at a distance of 2.695(2) Å, corresponding to a metal–metal bond, bridged by two 2-pyridinethiolate ligands through their N and S atoms and bonded to two terminal carbonyl groups. The Ir atoms are in different octahedral arrangements, Ir1 completing its coordination through two terminal carbonyls and one iodine atom, Ir2 through two terminal carbonyls and the CH_2I group. The Ir atoms have different environments, the sixth ligand being I in one case and CH_2I in the other.

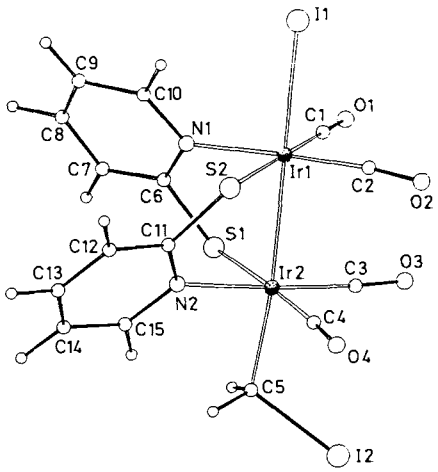


Fig. 1. Crystal structure of **6**. Selected bond lengths [Å] and angles [°]: Ir1-Ir2 2.695(2), Ir1-I1 2.833(2), Ir1-S2 2.360(4), Ir1-N1 2.112(12), Ir1-C1 1.878(17), Ir1-C2 1.826(17), Ir2-S1 2.361(4), Ir2-N2 2.109(11), Ir2-C3 1.874(14), Ir2-C4 1.906(13), Ir2-C5 2.173(15), I2-C5 2.133(15), S1-C6 1.761(12), S2-C11 1.742(16); Ir2-Ir1-I1 173.7(1), I1-Ir1-N1 96.8(3), I1-Ir1-S2 90.3(1), N1-Ir1-S2 88.0(3), Ir1-Ir2-C5 172.6(4), C5-Ir2-S1 88.4(4), C5-Ir2-N2 91.0(5), S1-Ir2-N2 87.3(3), Ir2-C5-I2 115.0(7).

Remarkably, no formation of the expected complex **7** occurs upon refluxing **6** in toluene, in contrast with previous observations.[4, 5a] Comparison of the structures of **1** and **6** shows a markedly different position of the halogen in the halomethyl group with respect to the nearest metal atom.

$[\{Ir(\mu\text{-}C_5H_4NS)I(CO)_2\}_2(\mu\text{-}CH_2)]$ **7**

The photosensitivity of the reactions of **3** described above and the their solvent dependence suggest that a radical mechanism might be involved.[11] On the other hand, if

[a] ^{1}H-NMR spectra at 200 MHz with TMS as internal standard.

the reaction of **3** with diiodomethane is carried out in the presence of a large amount of $[Bu_4N]Cl$ in dichloromethane, the main product is **8**. Moreover, complete replacement of the iodo ligand of **6** by chlorine takes place at room temperature or upon refluxing **6** and $[Bu_4N]Cl$ in dichloromethane for 1 h. If the reaction of diiodomethane with complex **3** is carried out in the presence of $[Bu_4N]Br$ in dichloromethane, a 20 : 10 : 70 mixture of **6**, **8**, and **9** (as analyzed by ^{1}H-NMR spectroscopy) is isolated. The formation of **8** shows that the chlorinated solvent can participate in the reaction.

$[\{Ir(\mu\text{-}C_5H_4NS)(CO)_2\}_2(CH_2I)Cl]$ **8**

$[\{Ir(\mu\text{-}C_5H_4NS)(CO)_2\}_2(CH_2I)Br]$ **9**

Satisfactory elemental analyses were obtained for all new compounds; selected spectroscopic data are collected in Table 1.

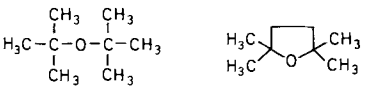
Photo-CIDNP in the Vacuum-UV: Di-*tert*-butyl Ether and 2,2,5,5-Tetramethyltetrahydrofuran in Aqueous Solution**

By *Knut Hildenbrand, Heinz-Peter Schuchmann,* and *Clemens von Sonntag**

In the vacuum-UV photolysis of saturated ethers, homolytic cleavage processes are common (for a review see Ref. [1]). In particular, the 185-nm photolysis of the title compounds **1a** and **1b** has been studied in the neat liquid



1a **1b**

state.[2,3] Alongside the homolytic cleavage processes leading to free-radical formation, molecular elimination reactions are thought to occur, which, however, cannot be distinguished from cage recombination reactions in these product studies. The photolysis of 1,4-dioxane[4,5] and dimethyl ether[6] has been studied also in aqueous solutions, with clear indications not only of cleavage to free radicals,[6] but also photoionization. So far, the UV photolysis of ditertiary ethers has not been studied in aqueous solutions; in this case, however, photoionization is expected to play an important part. Estimates indicate that the gas-phase ionization potential of di-*tert*-butyl ether lies below that of primary ethers by more than 0.5 eV.[7] In order to follow the photochemistry of aliphatic ethers by spectroscopic means, photo-CIDNP experiments (ArF excimer laser excitation, $\lambda=193$ nm) were carried out. Nonaqueous solutions (ether undiluted or dissolved in *cyclo*-C_6D_{12}), as well as aqueous solutions of primary, secondary, and monotertiary ethers, did not yield polarized NMR signals upon illumination. Only in solutions of di-*tert*-butyl ether, **1a**, and 2,2,5,5-tetramethyltetrahydrofuran, **1b**, in oxygen-free D_2O (concentration ≈0.01 M) was enhanced absorption observed ($\delta=0.23$) with a 1 : 1 : 1 triplet splitting of 1.9 Hz, which is assigned to CH_3D, and a singlet emission signal ($\delta=0.9$; C_2H_6) (Fig. 1).

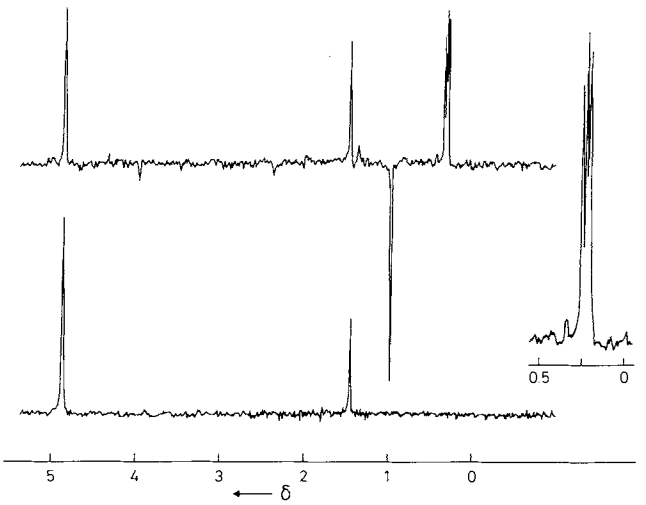


Fig. 1. Top: ^{1}H-NMR spectrum of a solution of di-*tert*-butyl ether, **1a**, in D_2O (0.01 M, deoxygenated) recorded directly after illumination with 20 laser pulses ($\lambda=193$ nm, frequency = 1 Hz). An expansion of the polarized CH_3D signal is shown on the right side. Bottom: ^{1}H-NMR spectrum of the same solution recorded 2 min after the end of the CIDNP experiment. In both experiments, five free induction decays were accumulated.

In the presence of H_2O a singlet at $\delta=0.25$ (CH_4) was superimposed on the triplet of CH_3D. The relative intensity of the signals of CH_4 and CH_3D was directly correlated to the ratio $H_2O:D_2O$, which supports the involvement of the aqueous environment in the photoreaction. These assignments were confirmed by the results of a product analysis.[8]

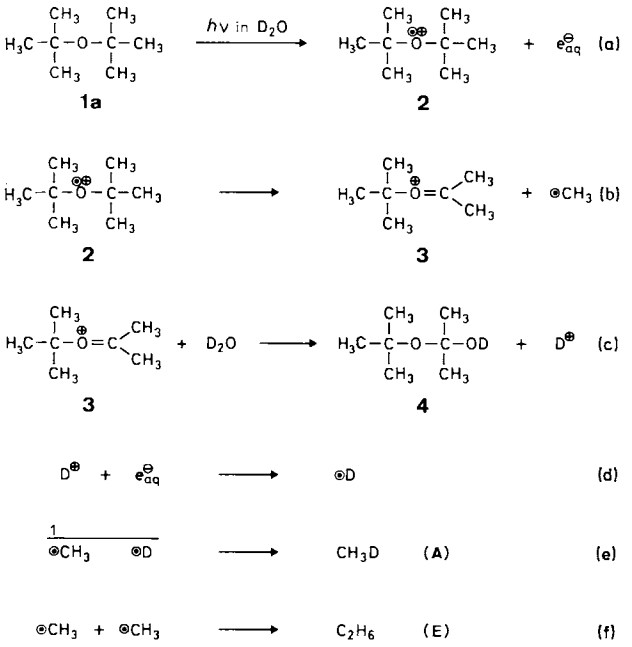
[**] We would like to thank Professor *H. Fischer* for helpful discussions, and Dr. *H. Görner* for his kind assistance with the laser experiments.

At first sight, the participation of water seems surprising because the concentration of the ethers is such that practically no light is absorbed by the solvent. Here, it is helpful to recall that in aqueous medium the ionization threshold of a solute is lowered by about 3 eV relative to its gas-phase ionization potential.[9] The title compounds are expected to have a gas-phase ionization potential below 9.2 eV,[7, 10] and photoionization with 193-nm light (~6.4 eV) appears likely in an aqueous medium.[11] With this assumption, the experimental observations can be explained by reactions (a)–(f).



Upon photoionization, the ether **1a** gives rise to the radical cation **2** and a solvated electron [reaction (a)]. The radical cation **2** loses a methyl radical [reaction (b)]. The oxonium ion **3** thus formed reacts rapidly with water yielding the hemiacetal **4** and a deuteron [reaction (c)]. If this sequence of events is sufficiently fast, D atoms will be formed with a high probability from the solvated electron and the deuteron [reaction (d)]. The cage product would then be CH_3D [reaction (e)], the escape products ethane [reaction (f)] and D_2. The products CH_3D and C_2H_6 have been observed. D_2 is not detected by this ^{1}H-NMR experiment. (A) and (E) in reactions (e) and (f), respectively, mean enhanced absorption and emission.

Using Kaptein's rules[12] and $g(^{\odot}CH_3) = 2.0025$,[13] $g(^{\odot}D) = 2.00223$,[13] and $A(^{\odot}CH_3) = -23.04$ Gauss,[13] the signs of the polarizations can be explained by assuming that the $\overline{^{\odot}CH_3\ ^{\odot}D}$ radical pair is originally in a correlated singlet state before $S\text{-}T_0$ mixing and escape of $^{\odot}CH_3$ and $^{\odot}D$ radicals takes place.

Since photo-CIDNP studies carried out in the vacuum-UV have not been reported previously, the experimental requirements are reported here in somewhat more detail.

Experimental Procedure

The NMR experiments were performed with a Bruker WH 90 FT NMR spectrometer. The samples were irradiated in situ with an excimer laser (EMG 200, Lambda-Physik). The light entered the sample through a hole at the rear of the probe head. The insert consisted of a single-wall Suprasil cylinder. It is essential for the vacuum-UV experiment that the coil should not be densely wound and should only be fastened with glue at the side opposite the light beam. Wilmad 5-mm quartz tubes were used. A sequence of 20 laser pulses (100 mJ/pulse laser output; 20 mJ/pulse input into the sample, pulse frequency = 1 Hz) was applied and then the NMR experiment was started (rf pulse ≈ 25°, 8-K data memory). In order to improve the signal-to-noise ratio, the experiment was repeated five times with a delay in between of 2 min. For assignment of the polarized signals, the samples were saturated with CH_4 and C_2H_6 after the end of the CIDNP experiments. Chemical shifts were measured relative to sodium 3-trimethylsilylpropionate ($\delta = 0$).

Shortened C–C Bonds and Antiplanar O=C–O–H Torsion Angles in 1,4-Cubanedicarboxylic Acid**

By *Otto Ermer** and *Johann Lex*

Whereas the structures of many molecules with considerably lengthened C–C single bonds have been determined (more than 50 cases with C–C distances > 1.60 Å), relatively little is known about shortened C–C bonds.[1] Generally, CC shortenings may be expected if the bond of interest is involved in bond angles widened beyond their normal values. This can be explained in terms of hybridization as well as by an analysis of the influence of stretch-bend cross terms or 1,3-repulsions in molecular force fields.[1, 2] On the other hand, CC bonds adjacent to compressed angles should be lengthened.[2] We report here on the crystal structure analysis of 1,4-cubanedicarboxylic acid **1**,[3]

[**] This work was supported by the Fonds der Chemischen Industrie.

which exhibits shortened $C(sp^3)$-$C(sp^2)$ bonds between the cubane and carboxyl C atoms, since the endocyclic C-C-C angles in the rigid cubane framework are compressed to about 90° and the exocyclic angles correspondingly widened to about 125°.

Important findings of the X-ray analysis are summarized in Figures 1 and 2.[4] The density of **1** is 1.643 g cm^{-3} and thus rather high, which may partly be due to the compression of the cubane C atoms ensuing from the small bond angles. Two conformationally different centrosymmetric molecules are present in the crystals of **1**. In both cases, the $C(sp^3)$-$C(sp^2)$ bond lengths are 1.480(1) Å (1.481 Å corrected for libration). For comparison, the corresponding C-C bonds of **2** and **3** that are not involved in widened bond angles have lengths of 1.513(4) and 1.523(4),[5] and 1.518(2) Å,[6] respectively. Thus, the $C(sp^3)$-$C(sp^2)$ bonds in **1** are shortened by about 0.04 Å. The angular deformations at the bridgehead C atoms of bicyclo[1.1.1]pentane are comparable to those in cubane.[7] Accordingly, the X-ray structure analysis of 3-phenylbicyclo[1.1.1]pentane-1-carboxylic acid **4** reveals similarly shortened $C(sp^3)$-$C(sp^2)$ bond lengths of 1.47(1) and 1.46(1) Å for the exocyclic bonds from the atoms C1 and C3, respectively.[8] The central C-C bond in 1,1'-binorbornyl is also slightly shortened (1.515(5) Å), which is ascribable to moderate widening of the exocyclic bond angles at the bridgehead C atoms.[9]

Model calculations on methylcubane, carried out with our consistent force field,[10a] gave a shortening of the exocyclic C-C bond approximately twice the amount observed in **1**. Similarly, this force field also overestimates bond lengthening due to bond angle compression.[10b] This originates from the relatively large stretch-bend cross terms of the potential, which are required for a good reproduction of vibrational frequencies. The MM2 force field[11] yields better bond length effects,[2b] since here these cross terms are smaller and since vibrational data are regarded as unimportant. The cubane C-C bonds of **1** are each involved in four compressed and two widened bond angles, resulting in an average lengthening to 1.566 Å (1.570 Å corrected for libration); for comparison, values of cubane are 1.575(1),[12a] 1.565(4),[12b] and 1.551(3) Å[12c] (1.566 Å corrected for libration).

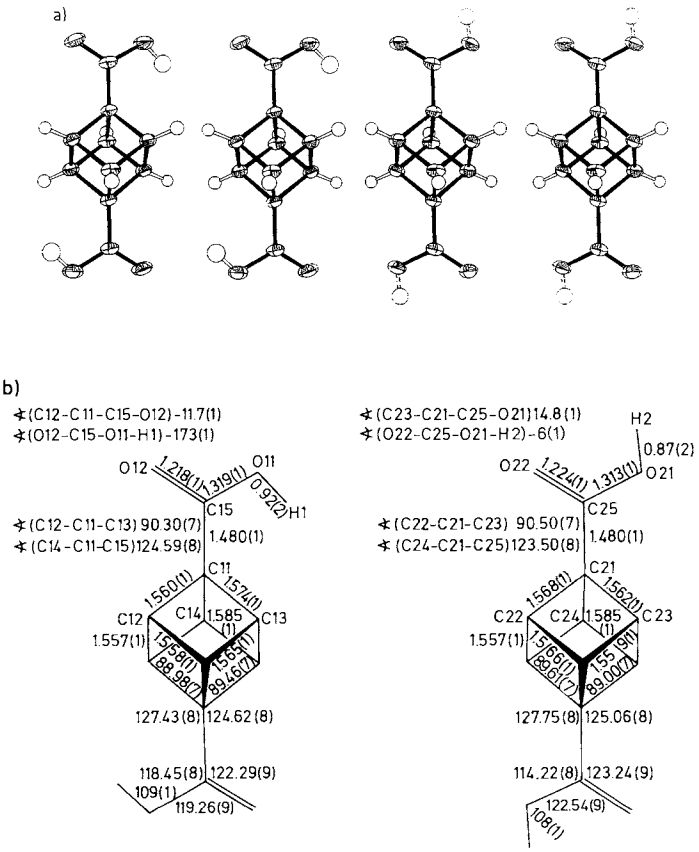

Fig. 1. a) Stereoview of the two conformers of **1** in the crystal with thermal ellipsoids (50% probability); temperature factors of the H atoms halved. b) Important bond lengths [Å], bond and torsion angles [°], and atomic numbering.

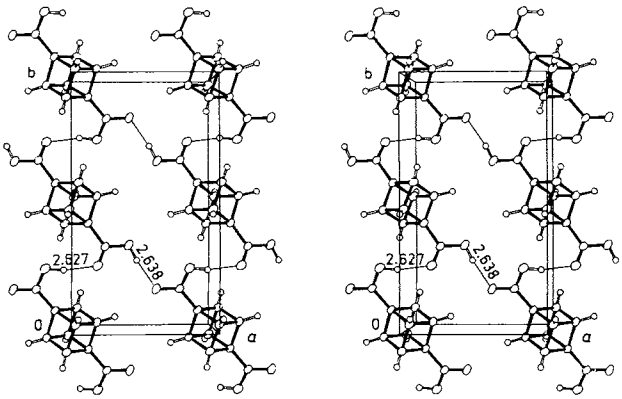

Fig. 2. Crystal structure of **1** with O···O distances of the hydrogen bonds ([Å], standard deviations 0.001 Å).

Two carboxyl conformations are observed in the crystals of 1,4-cubanedicarboxylic acid **1** (Figs. 1 and 2). The O=C-O-H torsion angle is synplanar for one-half of the molecules, yet antiplanar for the other half. This latter observation is very rare: Only one other crystal structure has been reported for a carboxylic acid without intramolecular hydrogen bonds that prefers an antiplanar O=C-O-H partial conformation.[13] Apparently, this unusual geometry is supported in **1** by the molecular packing, which also deviates from the usual pattern. Whereas dicarboxylic acids, e.g., **2**,[5] are normally linked in the crystal by hydrogen bonds to form chains,[14] the molecules of **1** join to set up layers (Fig. 2). Possibly, another crystal modification of **1** exists with an "ordinary" chain structure and exclusively synplanar O=C-O-H torsion angles; crystal force field calculations would be instructive.

The 14 strongest residual density maxima of a difference Fourier map of **1** may be assigned to electron densities in

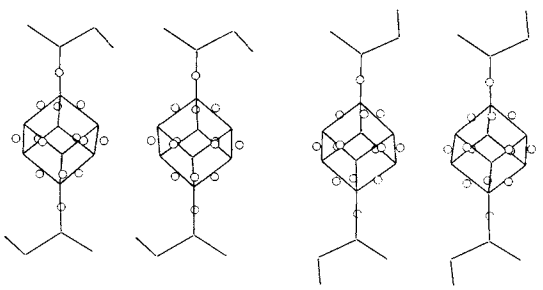

Fig. 3. Strongest 14 residual electron density maxima (empty spheres) from a difference Fourier synthesis of **1** (1213 reflection intensities with $\theta_{Mo} \leq 25°$; C and O atomic parameters from a refinement with 1423 reflections with $25° < \theta_{Mo} < 35°$; H parameters from a normal refinement [4]); residual electron density maxima between 0.22 and 0.34 eÅ^{-3}; stereoview as in Figure 1.

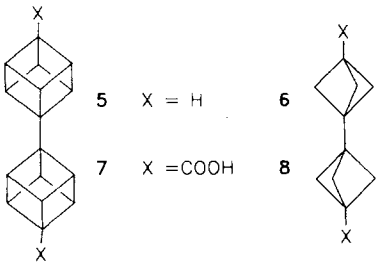
the 14 independent C–C bonds (Fig. 3). The cubane C–C bonds appear to be bent and the endocyclic interorbital angles at the C atoms amount to 105° on the average (maximum 112, minimum 96°); i.e., they are considerably larger than 90°.



Extreme shortenings of up to 0.08 Å may be expected for the central C–C bonds of the hypothetical bicubyl **5** and 1,1′-bibicyclo[1.1.1]pentyl **6**, since they participate in six significantly widened C–C–C angles (compared with only three in the case of the $C(sp^3)$–$C(sp^2)$ bonds of **1**). Of interest are also the torsional barriers around these bonds in **5** and **6**, which presumably are unusually low. Preparative and structural work on **5**–**8** is in progress.

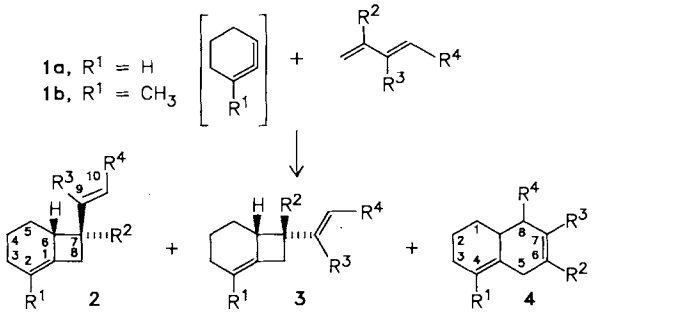
1,2,3,5,8,8a-Hexahydronaphthalene from 1,2-Cyclohexadiene**

By *Manfred Christl** and *Michael Schreck*

Although the reactive intermediate 1,2-cyclohexadiene **1a** has been characterized very well both experimentally and theoretically,[1] applications of **1a** in synthesis have not yet been reported. Prompted by the rearrangement[2a] of the [2+2] cycloadduct of 1,3-butadiene with tricyclo[4.1.0.0^{2,7}]hepta-3,4-diene,[2b] which occurs under mild conditions, we have now studied the reactions of 1,3-butadiene and some of its methyl derivatives with **1a** and 1-methyl-1,2-cyclohexadiene **1b**,[3] as well as the rearrangement of the [2+2] cycloadducts **2** and **3** to the unknown 1,2,3,5,8,8a-hexahydronaphthalene **4a** and some of its methyl derivatives.

Bottini et al.[4] obtained 7-vinylbicyclo[4.2.0]oct-1(2)-enes of the type **2,3** by reaction of **1a** with *cis*-1,3-pentadiene, *trans,trans*-2,4-hexadiene and 2,3-dimethylbutadiene but they did not report the configurations of the products. We have now generated **1a** likewise by treatment of 6,6-dibromobicyclo[3.1.0]hexane with methyllithium,[5] and allowed it to react at −20 to −15 °C with 1,3-butadiene, *trans*-1,3-pentadiene, isoprene, and 2,3-dimethylbutadiene, each of which served as solvent, and obtained the [2+2] cycloadducts **2** and **3** and, in several cases, the [4+2] cycloadducts **4** (Scheme 1). Analogously, **1b**[3] reacted with 1,3-butadiene to afford the products **2f**, **4f**, and **5**.



a, $R^1=R^2=R^3=R^4=H$; **b**, $R^1=R^3=R^4=H$, $R^2=CH_3$;
c, $R^1=R^2=R^4=H$, $R^3=CH_3$; **d**, $R^1=R^2=R^3=H$, $R^4=CH_3$;
e, $R^1=R^4=H$, $R^2=R^3=CH_3$; **f**, $R^1=CH_3$, $R^2=R^3=R^4=H$

Scheme 1 [6].

All the compounds **2**–**5** were purified by preparative gas chromatography (column: ethylene glycol adipate, ca. 100 °C). The yields are listed in Table 1. Table 2 contains selected NMR spectroscopic data.

We have investigated the reactions of **1a** with 1,3-butadiene and isoprene with special thoroughness. Compound

[*] Prof. Dr. M. Christl, Dr. M. Schreck
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

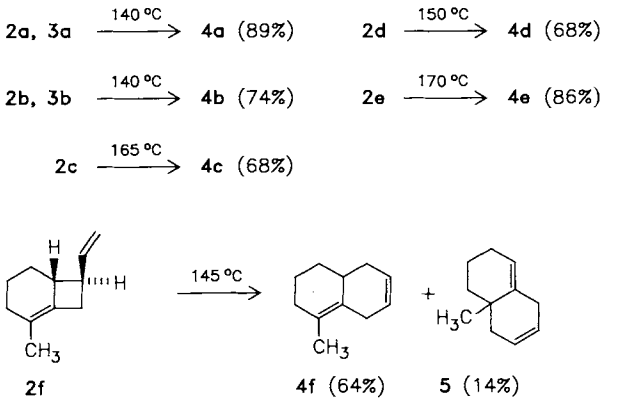
[**] This work was supported by the Fonds der Chemischen Industrie.

Table 1. Yields [%] of **2**–**4** and **5** after purification by gas chromatography.

	a	b	c	d	e	f
2	31	27	5	17	42	29
3	4	5				
4	8	3	3			1 + **5** (2)

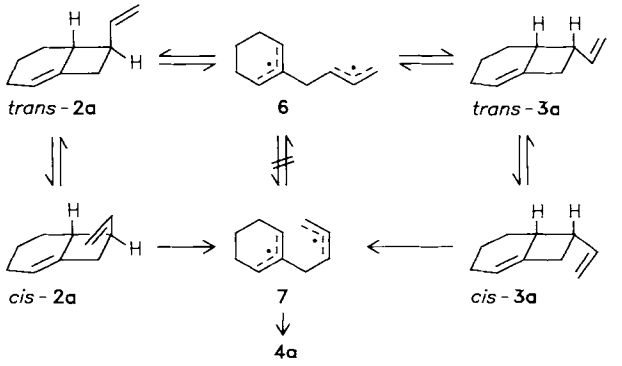
4a was found to be a primary adduct and not derived from **2** or **3** (see below). The same should be valid for the methyl derivatives of **4a**. The ratio (**2b** + **3b**) : **2c** = 6.4 shows that **1a** preferentially attacks the more highly substituted double bond of isoprene. By means of a competition experiment, we determined a value of 1.9 for the ratio of the rate constants for the reactions of 1,3-butadiene and 2,3-dimethylbutadiene with **1a**; thus, 1,3-butadiene is one of the more reactive trapping reagents for **1a**.[4]

Most probably, the mechanism of formation of **2** and **3** is a two-step process, similar to that proved for the addition of styrene to **1a**.[3, 7] Compound **1a** presumably reacts with 1,3-butadiene to give the diradical **6** having a *trans*-configurated allyl group in the side chain. Intermediate **6** then cyclizes to form **2a** or **3a**. The diradical 7 having a *cis*-configurated allyl group could be involved as an intermediate in the formation of the [4 + 2] cycloadduct **4a**, if 7 arose directly from **1a** and 1,3-butadiene.



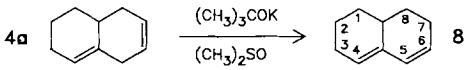
Scheme 2 [6].

Despite the formation of product mixtures, the addition of 1,3-butadienes to **1a** is of preparative interest, since the diastereomeric bicyclo[4.2.0]oct-1(2)-enes **2**, **3** undergo rearrangement to a single 1,2,3,5,8,8a-hexahydronaphthalene **4** upon thermolysis in C_6D_6. At 140 °C, the half-life of **2a** is about 2 h and that of **3a** about 18 min. These reactions and the yields isolated are summarized in Scheme 2. Thus, the previously unknown **4a** and some of its methyl derivatives are now readily accessible.



Scheme 3.

The formation of **4f** from **2f** rules out a Cope rearrangement in this case and makes one unlikely for the other ring expansions (**2**, **3** → **4**; **2f** → **5**). In analogy to the results obtained for the thermolysis of 3-vinylmethylenecyclobutane and some of its derivatives,[8] we propose the diradical 7 as a precursor of **4a**; the allyl group in the side chain of 7 has the *cis* configuration. Because of the rotation barrier of about 15 kcal/mol in the allyl radical,[9] 7 cannot arise directly from **6** but only from *cis*-**2a** and *cis*-**3a** (Scheme 3). A detailed study of the rearrangement of **2a** ($\Delta H^{\neq} \approx 33$ kcal mol^{-1}, $\Delta S^{\neq} = 1$ cal mol^{-1} K^{-1}) and **3a** showed that the isomerization **2a** ⇌ **3a** proceeds parallel to the ring expansion and that, starting from **2a**, the amount of **3a** was maximally 1%, whereas, starting from **3a**, that of **2a** was maximally 7%.



The base-induced isomerization of **4a** is also of preparative value. We isolated 1,2,3,7,8,8a-hexahydronaphthalene **8** in 49% yield, a compound that had been obtained previously, in a multistep synthesis, only as a mixture containing one other isomer.[10]

Table 2. ^{1}H- and ^{13}C-NMR data for **2a**, **3a**, **4a**, and **8** ($CDCl_3$, δ values, coupling constants in Hz).

8: ^{1}H-NMR: δ = 1.00–2.30 (m, strong maxima at 1.82 and 2.14; 11H), 5.43 (m; 4-H), 5.65 (ddm, J = 9.9, 5.0; 6-H), 5.98 (dd, J = 9.9, 2.0; 5-H). — ^{13}C-NMR: δ = 22.68 (C-2), 25.89 and 26.09 (C-3, C-7), 30.50 and 30.73 (C-1, C-8), 35.70 (C-8a), 123.51 (C-4), 127.12 and 129.59 (C-5, C-6), 137.52 (C-4a)

[a] The coupling constants between the protons at the bicyclo[4.2.0]oct-1(2)-ene skeleton are as large as those in the 7-aryl derivatives [3]. [b] The assignment was assisted by the off-resonance decoupled or proton-coupled spectra as well as by the methyl substituent effects of the methyl derivatives.

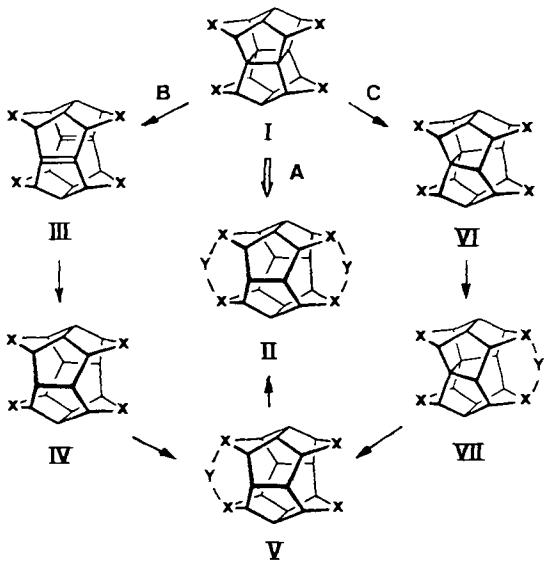
The Pagodane Route to Dodecahedranes—Thermal, Reductive, and Oxidative Transformations of Pagodanes**

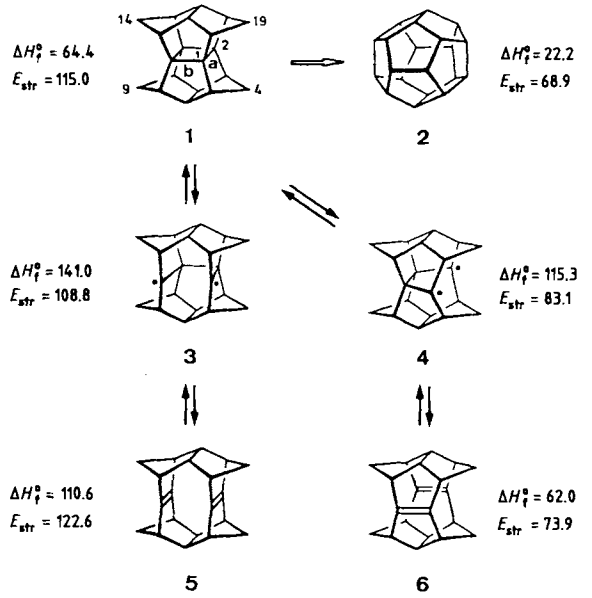
By *Wolf-Dieter Fessner, Bulusu A. R. C. Murty,* and *Horst Prinzbach**

"Pagodanes" are compounds having structures of type **I**, which we are synthesizing primarily as precursors of dodecahedranes **II**.[1] Variation of the X,Y bridges should allow diverse patterns of substitution and/or skeletal modifications in **II** as well as various methodologies for the transformation **I** → **II**.[2] The required cleavage of two cyclobutane bonds and the linking of opposing X positions are being attempted, depending on the nature of X, either catalytically (pathway A) or directly via a multistep sequence of reactions (**I** → **III** → **IV** → **V** → **II**, pathway B, or **I** → **VI** → **VII** → **V** → **II**, pathway C; Scheme 1).[3,4]

The prototypes of the series **I** and **II**, [1.1.1.1]pagodane **1** (**I**, X = CH_2)[1] and dodecahedrane **2** (**II**, X-Y-X = CH-CH),[5] are $C_{20}H_{20}$ isomers having high-symmetry (D_{2h} and I_h, respectively) undecacyclic skeletons, each containing twelve cyclopentane units. According to MM2 calculations,[6] the transformation **1** → **2** involves a considerable reduction in energy (enthalpy of formation difference: $\Delta\Delta H_f^\circ = -42.2$ kcal/mol; strain energy difference $\Delta E_{str} = -46.1$ kcal/mol).[7] Of primary interest was the possibility of specifically opening the four-membered ring of **1**, in particular a $2\sigma \rightarrow 2\pi$ cleavage with formation of the bissecododecahedradiene **6**[4] (Scheme 2). According to MM2 force-field calculations, the cleavage of the a bonds in **1** (to give **6** via **4**) is significantly favored both kinetically and thermodynamically over that of the b bonds (to give **5** via **3**). The findings reported here exemplify the thermal, reductive, and oxidative cyclobutane cleavage in **1**.

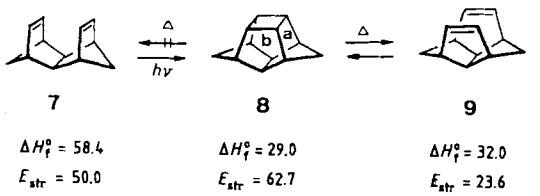


Scheme 1.



Scheme 2. ΔH_f° and E_{str} in kcal/mol.

Thermolysis of the "pagodane moiety" **8**,[8] which is accessible photochemically from **7**, provided a model for the thermal isomerization **1** → **6** (Scheme 3). According to recent measurements[9] and in good agreement with the results of force-field calculations, thermolysis of **8** above 400 °C results in selective cleavage of the a bonds with formation of the diene **9** ($\Delta H^\neq$ (430 °C) ca. 59 kcal/mol); the opening **8** ⇄ **9** is reversible.



Scheme 3. ΔH_f° and E_{str} in kcal/mol.

Upon thermolysis in a vertical pyrolysis tube (in order to achieve longer contact times; benzene and ethanol solutions), **1** remained unchanged up to 500 °C; at 600–620 °C/700–720 °C/750 °C, the pyrolysates still contained at least 80%/< 10%/< 2% educt. The only product isolated (in yields of up to 60%) was naphthalene **12** (along with "polymeric" material)! Because of the rigidity of the molecular skeleton ("corset effect"), the backward reaction **4**(**6**) → **1** is apparently efficient, and product formation occurs via the kinetically and thermodynamically less favorable reaction channel **1** → **3** → **5**, from which the diene **5** can be removed by fragmentation. Consecutive [4 + 2] cycloreversions presumably lead to formation of the known $C_{10}H_{10}$ triene **10**,[10] which is transformed, probably via azulene **11**, to **12**. In control experiments at 650 °C (under the

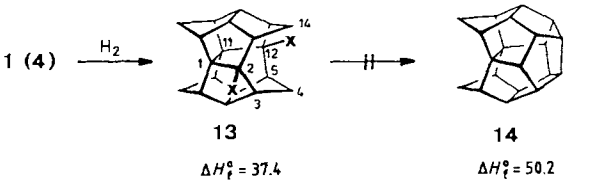
same conditions, the conversion of **1** was ca. 60%), **12** was formed nearly quantitatively from both **10** and **11**.

The cleavage of one of the two a bonds in **1** could be achieved, however, by hydrogenolysis. Heating of a 4% mixture of **1** on Pd/C (10%) in an autoclave under H_2 (10 atm H_2, 300°C, 14 h) resulted in nearly quantitative formation (95% isolated yield) of the high-melting (m.p. = 330 ± 5°C), C_{2v}-symmetric $C_{20}H_{22}$ decacycle **13a** (decacyclo[9.9.0.0^{1,8}.0^{2,15}.0^{3,7}.0^{5,12}.0^{6,10}.0^{11,18}.0^{13,17}.0^{16,20}]eicosane), the formal trapping product of the diradical **4**[11] (Scheme 4). Characteristic of the skeletal changes connected with the opening **1** → **13a** is, among other things, the increase in the vicinal H,H coupling constants in the ^{1}H-NMR spectrum (with decreasing torsional angle; **1**, H-C3-C7-H = 41.8°; **13a**, H-C2-C3-H = 27.8°, H-C3-C7-H = 20.9°; **2**, H-C-C-H = 0°). The low-field position of the 2(12) H signal (δ = 2.39, $CDCl_3$) reflects the trend, which culminates in δ = 3.38 for the perfect eclipsed orientation of the vicinal C–H bonds in **2**. The X-ray structure analysis of **13a**, also carried out as a control of the MM2 data, failed (as also was the case for the dibromide **13d**; cf., however, **13e**[12]) on account of crystallographic disorder. A structure simulating that of the diene **6** was obtained with oversized ellipsoids of thermal vibration for the "unsaturated" C atoms.[13] In agreement with the results of the force-field calculations, **13a** is remarkably stable. Even under drastic hydrogenolysis conditions, selective C–C bond cleavage, in particular of C1–C11 to give the saturated D_{2h} bissecododecahedrane,[4] could not be achieved. Drastic dehydrogenation conditions, moreover, did not result in (considerably endothermic) C–C bond formation between C4 and C14 to give the "isododecahedrane" **14** (cf. **VI** → **VII**, pathway C, Scheme 1), which it was hoped would occur because of the spatial proximity of the 4*syn*/14*syn* hydrogen atoms and the 4/14 carbon atoms (d = 1.926 and 3.1 Å, respectively) (Scheme 4).

2σ → 2π cleavages have been achieved in highly strained cyclobutane compounds under metal catalysis. That **1** remains unchanged up to 200°C in the presence of $AgClO_4$ and $[Rh_2(CO)_4Cl_2]$ is possibly explained by the weakly exothermic course of the opening **1** → **6** ($\Delta\Delta H_f^\circ = -2.4$ kcal/mol) and the steric shielding of the cyclobutane C–C bonds. In such situations, the symmetry-allowed cleavage via radical cations presents itself as a possibility.[14] Compound **1** reacted slowly with tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate (ionization at 1.05 V versus the saturated calomel electrode) in chloroform at 20°C. A single product was obtained (only) if an equimolar amount of the radical cation salt was used; however, this product is not the diene **6** but the dichloride **13b** (Scheme 4). Heating of a $CHCl_3$ solution of **13b** in the presence of water or methanol results in formation of solely the crystalline diol **13c** (m.p. = 193°C, 86%) or the dimethoxy compound **13e**,[12] respectively. Compound **13b** is presumably formed via the (opened) radical cation of **1**,[15] which was detected by ESR spectroscopy and by electrochemical methods.



a, X = H; **b**, X = Cl; **c**, X = OH; **d**, X = Br; **e**, X = OCH_3

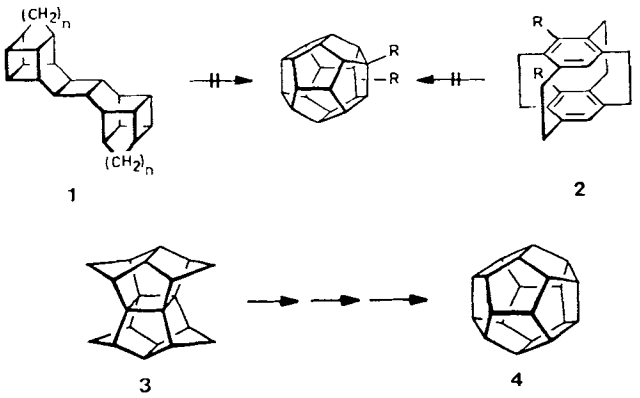
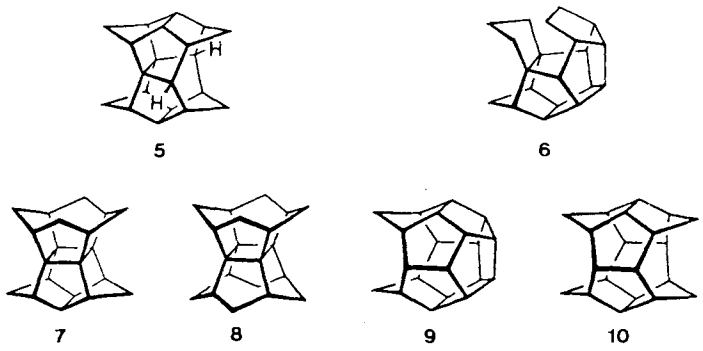
route A (see preceding communication[3]) seemed promising because a considerable reduction in energy should result.[3] With increasing spherical geometry, however, complications might result from the increasing difficulty in forming carbocationic[4] intermediates and the hyperstability and transannular reactivity of olefinic intermediates.[5]

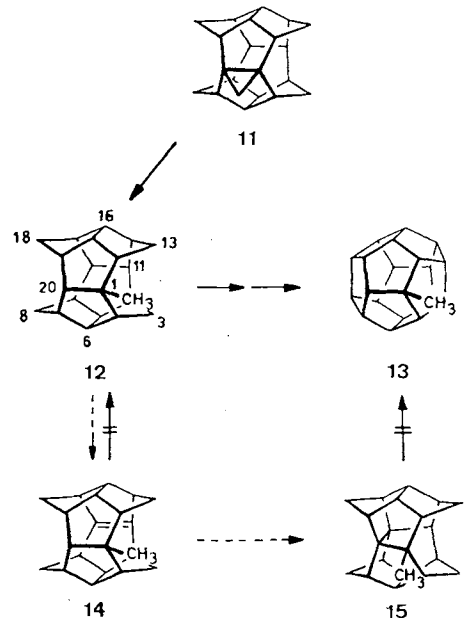


Encouraged by the preparation of adamantane and other cage hydrocarbons by isomerization,[6] there have been earlier attempts to obtain dodecahedrane **4** and its methylated derivatives from precursors like the basketene dimer **1** (n = 1) or homobasketene dimer **1** (n = 2)[7] or from cyclophanes like **2**.[8] However, no success was achieved under various isomerization conditions. Attempted acid-catalyzed isomerizations of **3** also failed. Treatment with CF_3SO_3H (CH_2Cl_2) led to rapid decomposition; this also occurred, but more slowly, with H_2SO_4.[9] Under *Olah*'s stable ion conditions (e.g., FSO_3H/SbF_5, SO_2ClF, −78°C), **3** was oxidized to a dication.[10] With diverse AlX_3 Lewis acids, **3** was converted slowly into undefined products.

In initial gas-phase isomerization experiments (flow apparatus;[11] $Pt/Re/Al_2O_3$, Pd/C, Rh/C, Pd/Al_2O_3 supported catalysts; 250–450°C), complicated mixtures of products (70–95%) were isolated and analyzed by GC/MS. Eventually after enrichment through crystallization, six main components could be separated in the following order by gas chromatography:[12] 4–12% $C_{20}H_{22}$ (unsymmetrical, 4 CH_2, 14 CH, 2 C); 19–47% $C_{20}H_{22}$ (**5**); 4–25% $C_{20}H_{24}$, (6 CH_2, 12 CH, 2 C(?)); 0.2–8% $C_{20}H_{24}$ (C_s, 6 CH_2, 12 CH, 2 C (?)), 1–5% $C_{20}H_{26}$ (unsymmetrical, 1 CH_3, 11 CH, 6 CH_2, 2 C), and 0.1–2.5% $C_{20}H_{20}$. This last product proved to be dodecahedrane **4**! Of the catalysts optimized for the conversion of cyclooctane to bicyclo[3.3.0]octane, Pd, Rh, and Ni on various supports, as well as modified Pd–Ti[13] and Pt–Ti catalysts, gave only very modest results, whereas Pt/Al_2O_3 brought about nearly quantitative conversion. By variation of the dispersion (D) of the platinum (Pt foil (0% D), 25% Pt/Al_2O_3 (2.7% D), 5% Pt/SiO_2 (40% D), 0.1% Pt/Al_2O_3 (80% D)), the reaction temperature, the flow rate, and the composition of the carrier gas (hydrogen–helium mixtures), the yield of **4** could be increased to 8% (0.1% Pt/Al_2O_3, reduced with H_2 at 360° for 1 h; reaction conditions: 315°C, H_2 flow rate 0.75 mL/min, He flow rate 2.25 mL/min, substrate temperature 250°C). Because of its long gas-chromatographic retention time and the remarkably downfield ^{1}H-NMR signal ($\delta = 3.38$, $CDCl_3$), dodecahedrane **4** can readily be identified even in mixtures. The ^{1}H-/^{13}C-NMR analysis of the other main components leads to the conclusion that the expected symmetrical [4]peristylanes **7/8**, which might have resulted from the hydrogenolysis of the longest C–C bond in **3**, or the secododecahedranes **9/10** were not formed. For the $C_{20}H_{24}$ compound with C_s symmetry, structure **6** seems likely, which could be helpful in the evaluation of route C.[3] Numerous experiments in condensed phases (treatment with Pd/C, 70 h, 300°C, ca. 1 atm H_2) only lead to 1–2% of **4** from **3**. Control reactions with the main product **5** gave a similarly complex product mixture, but no **4** could be detected in the gas-phase experiments and only 1–2% under solution conditions.

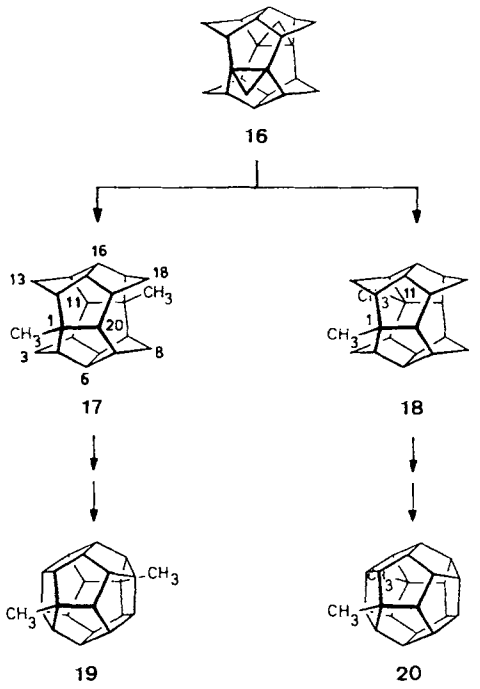


Schemes 1 and 2 summarize the first preliminary results from the B route.[3] The desired saturated bissecododecahedranes,[5] which could not be obtained through hydrogenation of the bisseco-dienes, became available by hydrogenolytic cleavage of appropriate cyclopropa derivatives, **11** (m.p. = 295–300°C) and **16** (m.p. > 340°C). These could be prepared by conventional reduction (Na/*t*BuOH, tetrahydrofuran (THF); 95–100°C) from their dichlorocyclopropa precursors.[5] Heating (150°C) a mixture of **11** with a tenfold quantity of Pd/C (10%) under 50 atm hydrogen pressure leads to complete conversion after 90 minutes. A mixture of 70–75% **12** and 5–10% each of **14** and **15** could be isolated and separated by gas chromatography (along with numerous minor components). Longer reaction times lead to the formation of more **14/15** at the ex-



Scheme 1.

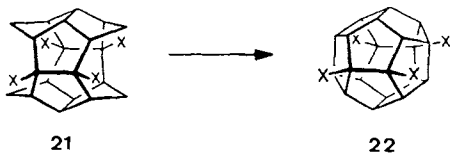
pense of **12**. Apparently, the dehydrogenation of **12** to give the "hyperstable" bisseco-olefin **14**, which isomerizes to **15**, is efficient even under hydrogenation conditions. Under similar conditions (20 mg **16**, 2 g Pd/C (10%), 150 °C, 20 atm H_2, total conversion in 6 h), **16** gives a 2:3 mixture (>90%) of the 1,10- and 1,11-dimethylbissecododecahedranes (C_{2h} and C_{2v} symmetry) **17** and **18**, respectively.



Scheme 2.

After careful drying and degassing, 40 mg of **11** and 4 g of Pd/C (ca. 1:10) were heated slowly (30 min) to 100 °C under 50 atm H_2 pressure and maintained at this temperature for ca. 2.5 h. The reaction mixture was cooled, the H_2 pressure was reduced to 5 atm, and the reaction mixture was then heated slowly to 250 °C and maintained for 5 h (3 h) at this temperature. After thorough extraction, an 80% isolated yield of a product mixture containing six components was obtained (GC/MS): $m/z = 276$ (21 (20)%), $m/z = 278$ (5 (3)%), $m/z = 278$ (9 (8)%), $m/z = 280$ (3 (0)%), $m/z = 274$ (31 (30)%), and $m/z = 260$ (9 (10)%). The last two products to be eluted could be obtained nearly pure by fractional sublimation (80 °C, 1 torr). Complete ^1H-/^{13}C-NMR data[14] permitted their definite identification as the dodecahedranes **4** and **13**.[15] Heating 40 mg of **16** with 4 g of Pd/C (10%) first under 20 atm H_2 pressure at 150 °C (5 h), then under 5 atm H_2 pressure at 300 °C (6 h) gave, after extraction and filtration over silica gel, 30–34 mg (75–85%) of a mixture with the following main components: $m/z = 276$ (29%), $m/z = 290$ (28%), $m/z = 288$ (29%), $m/z = 274$ (1%), and $m/z = 288$ (1%). Comparison of the spectra showed the first component to be **15**, the third and fifth to be the known dimethyldodecahedranes **19** and **20**,[13] and the fourth to be **13**. Under various conditions, **20** was formed in much lower yields than **19**. This suggests that dealkylation[13,16] (e.g., to **14** and **15**) is relatively rapid on the route from **18** to **20**.

The maximal 8% yield of dodecahedrane **4** in the gas-phase isomerization of **3** constitutes a remarkable improvement of the present situation in view of the availability of **3**. The limitation in the formation of **4** from **3** can be attributed to the irreversible formation of **5**, which effectively diverts the reaction from the desired course. By substitution of the presumed bisseco intermediates **2/3** (as described in the following communication[5]) in positions C-1,10,11,20, this competition, which is caused by transannular bond formation, can be hindered or precluded. The formation of ca. 25% of **13** (along with 8% of **4**) and ca. 25% of **19** (along with a little **4** and **20**) supports this assumption.



It is hoped that various saturated bisseco precursors **21** (X = OR, NHR, CO_2R, etc.), with modified catalysts and under milder conditions, will be dehydrogenated without loss of functional groups, to give **22**. Alternatively, C–C bond formation in the bisseco precursors might be achieved, e.g., via carbenoid intermediates or photochemical processes or by functionalization of all four methylene positions in the pagodane skeleton.

Bissecododecahedraenes, Unusual Hyperstable Olefins**

By *Paul R. Spurr, Bulusu A. R. C. Murty, Wolf-Dieter Fessner, Hans Fritz*, and *Horst Prinzbach**

As an alternative to the catalytic procedure,[1] directed multistep pagodane→dodecahedrane transformations (routes A and/or B/C in Ref. [2]) are a current goal: for example, via the intermediates **2**–**5** (Fig. 1) in the case of the basic skeletons **1**/**6**. At intermediate **5**, this route converges with *Paquette*'s dodecahedrane synthesis, which was recently considerably improved for step **5**→**6**, which involves dehydrogenation and simultaneous C–C bond formation.[3] The calculated (MM2)[4] molecular structures (Fig. 1) clearly reveal how, with increasing expansion of the "waist" of **1** (1.55 Å) to 3.49 Å in **4**, the distance between the opposing methylene C atoms (which are eventually to undergo direct C–C bond formation) and their *syn* hydrogen atoms becomes increasingly small. The enthalpies of formation, ΔH_f°, decrease continuously on going from **1** to the "stabilomer"[5] **6**, while the strain energies, E_{str}, decrease discontinuously (Fig. 1). The increase of E_{str} in going from **2** via **3** to **4**, which is primarily a consequence of the increasing transannular and vicinal H/H interactions, necessarily implies considerably reduced "olefinic strain (*OS*)"[4,5] for **2**/**3** (*OS* = −11.4/−13.9 kcal/mol). The diene **2** is of further structural interest because the C=C bonds, held in an overall very rigid molecular skeleton, have an unusually small transannular distance, with ideal colinear orientation of the π orbitals;[6] the calculated value of 2.62 Å, however, is probably at least 0.1 Å too small.[7] The (transannular) strain inherent in **2** and **3** is manifested in a pyramidalization of the olefinic centers by about 10° and 5°, respectively. Comparable energetic and structural relationships were calculated for the reaction sequence starting from the diketone **7** and proceeding via the intermediates **10**–**12**.

After initial model studies,[8] a preparatively efficient entry into the reaction sequence **1**→**6** was made possible by the finding that [1.1.1.1]pagodane **1** reacts with bromine (in very large excess) regiospecifically and quantitatively to give the crystalline, moisture-sensitive dibromide **8** (m.p. = 240–241 °C (dec.)); the reaction occurs thermally within days and upon irradiation (300-W Osram Vitalux lamp, pyrex filter) within minutes. Under standard conditions (Zn, dimethylformamide, 160 °C, 3 h), **8** is converted in high yield (89%) into the crystalline bissecododecahedradiene **2** (m.p. = 260 °C (dec.)), which, especially in solution, is sensitive toward oxidation. Analogously, the pagodanedione **7** is transformed, via the dibromide **9** (m.p. = 294–295 °C (dec.), 100%), into the dienedione **10** (m.p. = 322–323 °C, 85%).[9] Heating or irradiation of the dibromides **8**/**9** results in loss of bromine with re-formation of **1**/**7**; this finding explains why a large excess of reagent is necessary in their preparation.

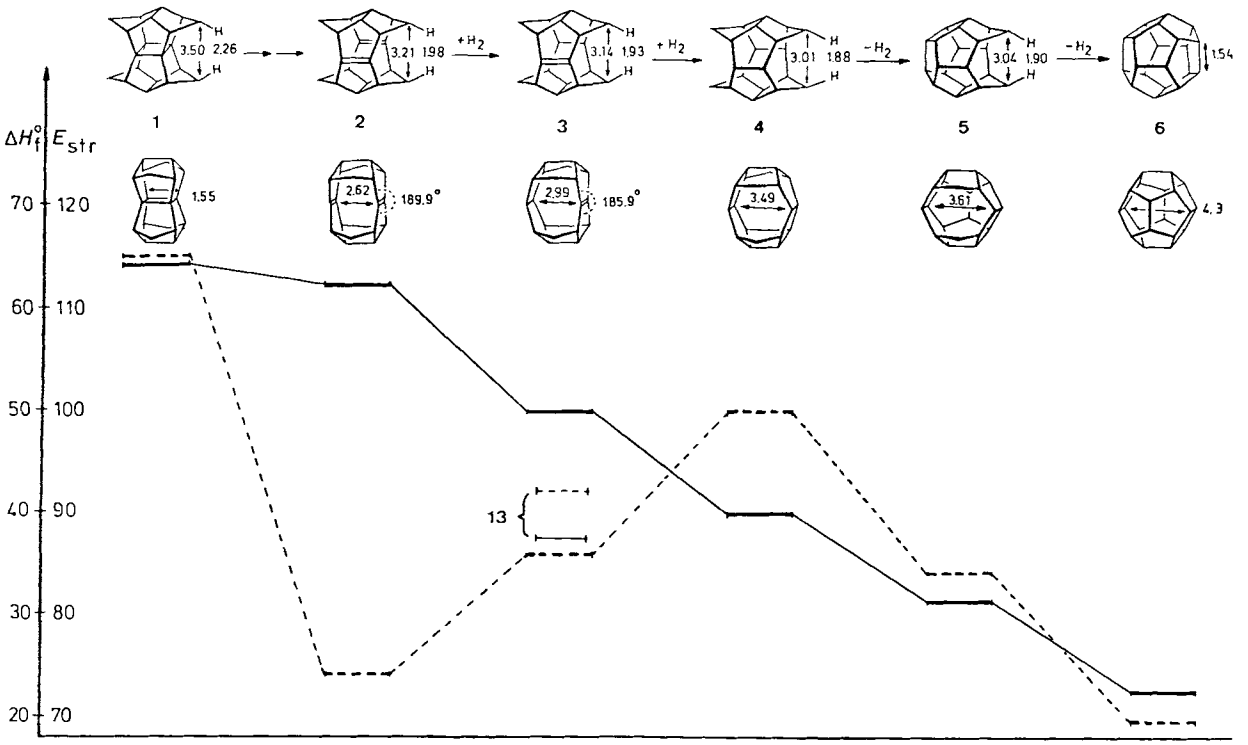

Fig. 1. Enthalpies of formation, ΔH_f° (——), and strain energies, E_{str} (----), of **1**–**6** in kcal/mol. Distances [Å].

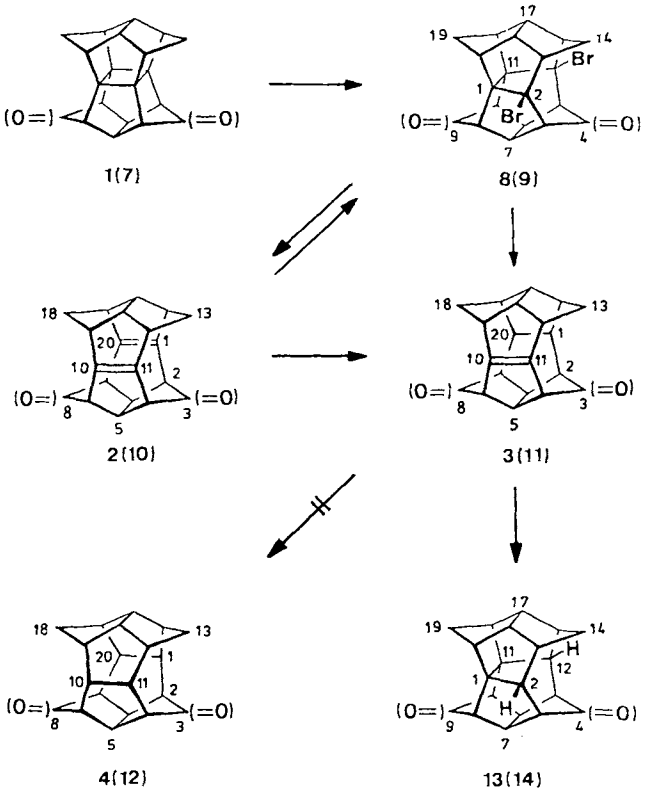
The unique orientation of the C–C double-bond π orbitals in the bissecododecahedradiene skeleton of **2** and **10** gives rise, according to PE spectroscopic analysis, to an unusually strong through-space π,π homoconjugation (ca. 2 eV),[10] which is presumably also responsible for the relatively long-wavelength UV absorption of **2** (isooctane, $\lambda = 270$ (sh, 180)), 250 nm (sh, $\varepsilon = 450$) and **10** (CH_3CN, $\lambda = 320$ nm (sh, $\varepsilon = 115$), 280 (sh, 170), 250 (190)). Acetone-

sensitized excitation of **2** and **10** results in rapid cycloaddition to give **1** and **7**, respectively.[11] Bromine adds regiospecifically to give **8** and **9**.



The predicted hyperstability of **2** and **3** has adverse consequences for our approach. Reaction of the dienes **2** and **10** with diimine, which has proved useful for the reduction of highly substituted olefins, only results in hydrogenation to the monoenes **3** and **11**, respectively; not even trace amounts (< 1%), even under forced conditions, of the tetrahydro derivatives can be detected. The greater reactivity of the dienes **2/10** compared with the enes **3/11** presumably reflects a partial compensation of the hyperstability by the destabilizing transannular π/π repulsion. Diverse noble metal catalysts (Pd, Pt, Rh) were also unable to effect the hydrogenations **3**→**4** and **11**→**12**; under the drastic conditions that are already necessary for steric reasons, varying amounts of **1** and **13**, in addition to **3**, are formed from **2**. Compounds **13** and **14**, respectively, are formed in nearly quantitative yields upon short heating of the enes **3** and **11** to 300 °C, which demonstrates the efficient transannular stabilization of the intermediate homoallyl radical (or cation) and an efficient competition with the catalytic route.[11]

As observed in similar cases, the hyperstability of the enes **3/11** can be overcome by the use of reagents having greater "driving force." They are oxidized quantitatively to the epoxides **15a/16a** with *m*-chloroperbenzoic acid ($CHCl_3$, NaOAc, 20 °C); under these conditions, the dienes **2/10** are oxidized to the epoxides **19a/20a** and the diepoxides **21a/22a**.[12] Under phase-transfer conditions, dichlorocarbene also adds to **3/11** (to give **15b/16b**) and to **2/10** (to give **19b/20b** and **21b/22b**). In these reactions, the second addition is usually so much slower that it is possible to obtain **19a,b** and **20a,b**, respectively, thereby allowing further functionalization of the molecular skeleton by reactions at the remaining C=C bond. For **15b/16b**, the quantitative C–H insertion of chlorocarbene (to give **17b/18b**), obtained with an excess of reagent, is so slow that **15b/16b** can be selectively prepared.

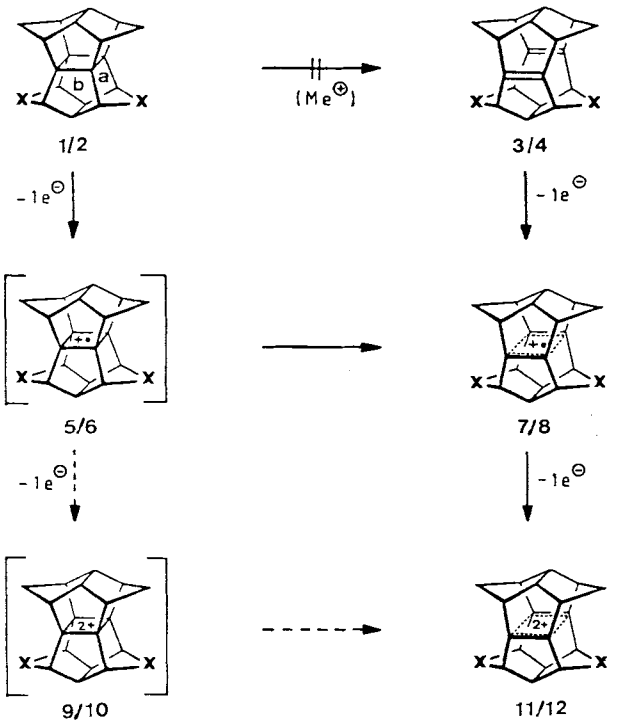
One- and Two-Electron Oxidations of Pagodanes and Bissecododecahedradienes: Unusually Persistent Radical Cations**

By *Horst Prinzbach,* Bulusu A. R. C. Murty, Wolf-Dieter Fessner, John Mortensen, Jürgen Heinze,* Georg Gescheidt,* and *Fabian Gerson**

[1.1.1.1]Pagodane **1** (D_{2h}) and the valence-isomeric diene **3** (D_{2h}) undergo oxidation in super acid solution to give the same, novel 2π-aromatic dication **11** (D_{2h}). Its surprising stability is closely connected with its special structure; the dication **12**, generated from [2.2.1.1]pagodane **2**, is significantly less stable.[1] The preparatively important cleavage of the cyclobutane a bonds in **1** is made selectively possible by the use of radical cation salts.[2] Further insight into the course of this process should be provided by cyclovoltammetric and ESR spectroscopic measurements.[3]



1,3,5,7,9,11, X=CH_2 ; **2,4,6,8,10,12**, X=$(CH_2)_2$

The oxidation of pagodane **1** and the diene **3** was investigated voltammetrically in CH_2Cl_2 and SO_2[4] in the presence of tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$) as supporting electrolyte. Because of their low nucleophilicity, both solvents are ideal for the generation of reactive cations.[5] In the case of **1** (Fig. 1a), an irreversible wave is observed at +1.2 V vs. Ag/AgCl in both solvents, which indicates that a rapid chemical reaction (cycloreversion **5**→**7**) occurs following formation of the radical cation. The shape and height of this wave support the assumption that a further charge transfer (**7**→**11**) occurs subsequently to this chemical reaction and is possibly followed by another chemical step. An ECE process is further supported by the observation of a reversible wave at +0.65 V during the reverse scan, which is due to the reduction of the radical cation **7** to **3**. The presumed oxidation to a dication (**11**?) around +1.2 V cannot be confirmed under the experimental conditions owing to rapid reaction with nucleophilic partners (residual H_2O in SO_2; $Cl^\ominus$ in CH_2Cl_2). The diene **3** is reversibly oxidized to **7** in CH_2Cl_2 and SO_2 at +0.66 V vs. Ag/AgCl (Fig. 1b). The radical cation **7** is very stable in SO_2 but undergoes slow subsequent reactions in CH_2Cl_2. The oxidation to **11** occurs at +1.2 V. The dication **11** is appreciably less stable than the radical cation **7**; it reacts with $Cl^\ominus$ in CH_2Cl_2 and with residual H_2O in SO_2 so rapidly to give the known quenching products (cf. **13b,c** in Ref. [1, 2]) that its reduction can no longer be observed by cyclic voltammetry. From measurements with scan rates between 10 and 50 V/s it is possible to estimate a lifetime of ca. 0.05 s.

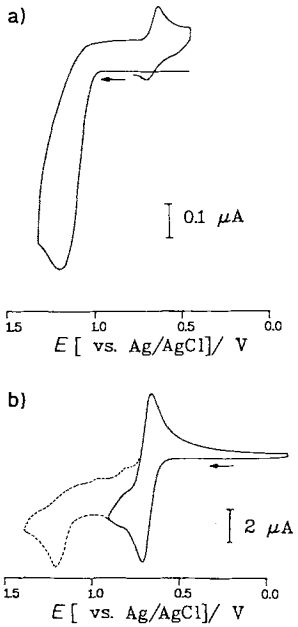


Fig. 1. a) Cyclic voltammogram of **1** (SO_2/0.1 M $TBAPF_6$, −20 °C, v = 100 mV/s); b) cyclic voltammogram of **3** (SO_2/0.1 M $TBAPF_6$, −20 °C, v = 50 mV/s).

For ESR studies, **1** was oxidized in CH_2Cl_2 both electrolytically on a helical Au anode[6] ($TBAClO_4$ as the supporting salt) and chemically with $AlCl_3$ or tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate. The deeply colored radical cation ($\lambda_{max} \approx 610$ nm) thus generated is very persistent, having in vacuo a lifetime of ca. ten and two days at −70 and +20 °C, respectively. Its temperature-independent ESR spectrum ($g = 2.0031 \pm 0.0001$), shown in Figure 2, extends over 13 mT; the nine groups of lines, each group separated by 1.544 mT, are indicative of a hyperfine interaction with eight equivalent protons. The splittings within the groups arise from three sets of four equivalent protons each, with coupling constants of 0.117, 0.065, and 0.051 mT (±0.001 mT), as well as from a second-order interaction associated with the large coupling

constant of 1.544 mT. By the use of the general TRIPLE resonance technique,[7] the values of 1.544 and 0.051 mT are found to have the same sign, which is opposite to that of 0.117 and 0.065 mT.

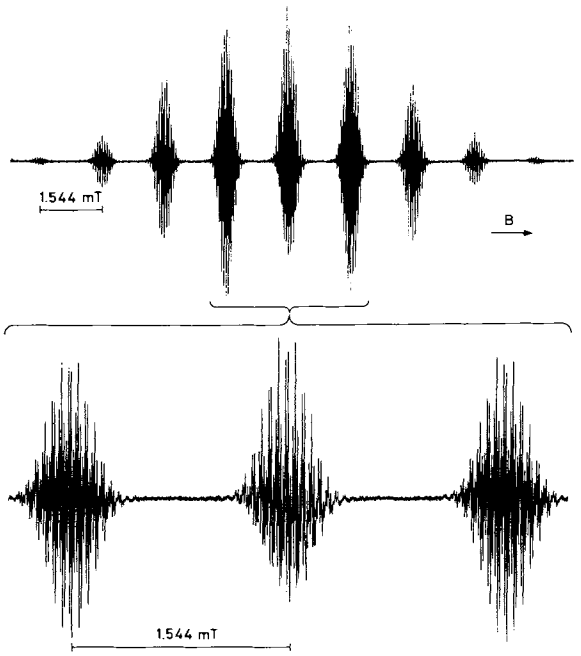

Fig. 2. ESR spectrum of the radical cation **7** generated from **1** or **3** (CH_2Cl_2, $-40°C$). Top: complete spectrum. Bottom: part of the spectrum including the three central groups of lines at an expanded magnetic field scale.

An identical ESR spectrum is observed for the diene **3** subjected to the same treatment; in line with the lower oxidation potential, the appearance voltage in the electrolysis is substantially lower than for **1**. The results of the ESR studies are thus fully consistent with the postulated cycloreversion **5**→**7**, so that the structure of the radical cation should be properly described by formula **7**.

Assignment of the large coupling constant (1.544 mT) to the eight equivalent β protons, i.e., to those that are separated by one C–C bond from the π system of **7**, is straightforward, considering the D_{2h} symmetry. The coupling constants, a_{H^β}, of β protons arise from hyperconjugation and obey the relationship[8] $a_{H^\beta} = \mathbf{B} \cdot \rho^\pi \cdot \cos^2\theta$, where ρ^π is the spin population at the adjacent π center and θ stands for the dihedral angle between the $2p_z$ axis at this center and the C–H^β bond. Since the total π-spin population in **7** is evenly distributed among the four π centers, ρ^π amounts to 0.25. Taking +6 mT as the proportionality factor B appropriate for radical cations and setting $\theta \approx 10°$ on the basis of structural data for **3**,[9] one obtains $a_{H^\beta} = +1.5$ mT. According to the evidence from TRIPLE, the positive sign thus predicted for 1.544 mT also holds for 0.051 mT, whence 0.117 and 0.065 mT must be negative. Assignments of the three last-mentioned coupling constants to the three sets of four equivalent γ protons in specific positions of **7** are hardly feasible without further information.

The colored radical cation ($\lambda_{max} \approx 610$ nm) generated under similar conditions from [2.2.1.1]pagodane **2** is also rather persistent; however, it decays faster than **7**. By analogy to **7**, its structure should be described by formula **8**. The ESR spectrum ($g = 2.0040 \pm 0.0001$) reflects the lower C_{2v} symmetry of **8** by exhibiting two large coupling constants, 1.76 ± 0.01 and 0.96 ± 0.01 mT, each due to a set of four equivalent β protons. The hyperfine splittings of the sixteen γ protons belonging to six different sets are not resolved in the ESR spectrum; they do not exceed 0.1 mT, as indicated by the ENDOR spectrum.[10]

The persistence of the radical cations **7/8** is closely connected with their polycyclic skeletons. Under a variety of oxidation conditions, it was not possible, by ESR spectroscopy, to detect radical cations generated from the "molecular moieties" of **1/3** (**8/9** in Ref. [2]). The opening of the four-membered ring, which occurs upon formation of the dications **11/12** from the pagodanes **1/2**, presumably also occurs in **5/6** (ECE) but not in **9/10** (EEC). Owing to the small exothermicity of the opening **1**→**3** ($\Delta\Delta H_f^\circ = -2.4$ kcal/mol),[11] and presumably also of **5**→**7**, and owing to the rigidity of the [1.1.1.1]pagodane **1**, there is a good chance that **5** might be identified directly at low temperature[12] and that **5** and **7** as well as **9** and **11** might be differentiated in the gas-phase oxidation ("charge stripping").[13]

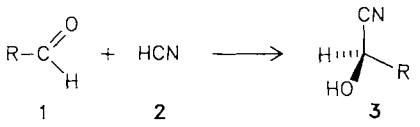
Enzyme-Catalyzed Cyanohydrin Synthesis in Organic Solvents

By *Franz Effenberger,* Thomas Ziegler,* and *Siegfried Förster*

Pfeil et al. have described the enantioselective addition of hydrogen cyanide **2** to benzaldehyde and numerous other aldehydes **1** in the presence of the enzyme mandelonitrile lyase ("(*R*)-oxynitrilase") to give optically active (*R*)-cyanohydrins **3**.[1] However, in the aqueous and aqueous alcoholic systems exclusively used so far, the chemical reaction, leading to the formation of racemates, occurs in

[*] Prof. Dr. F. Effenberger, Dr. T. Ziegler, Dr. S. Förster
Institut für Organische Chemie der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (FRG)

addition to the enzyme-catalyzed reaction, so that only moderate optical yields are often obtained in this reaction.[1c]



1 2 3

The ready accessibility[2] of mandelonitrile lyase (E.C. 4.1.2.10) from bitter almonds *(Prunus amygdalus)* and the great importance of optically active cyanohydrins for the preparation of optically active amino alcohols,[1c] α-hydroxy carboxylic acids, pyrethroid insecticides,[3a] imidazoles, and heterocycles,[3b] prompted us to investigate this reaction in more detail. Our goal was the preparative synthesis of cyanohydrins having the highest possible enantiomeric purity.

Variation of the reaction conditions (pH value, temperature, concentration) in water/ethanol led to no appreciable improvements.[1] The use of organic solvents that are not miscible with water but in which the enzyme-catalyzed reaction can take place,[4] however, resulted in suppression of the chemical reaction to a significant extent, whereas the enzymatic formation of cyanohydrin was only slightly slower (Fig. 1). The enantiomeric purity of the cyanohydrins is thereby considerably increased.

Of the organic solvents we tested, ethyl acetate proved to be the most suitable; the enantiomeric purity thereby achieved is higher than in H_2O/EtOH. The enzyme can be bound to a fixed support and consequently reisolated and used again. Of the supports tested, ECTEOLA cellulose, DEAE cellulose, glass beads, and cellulose, cellulose proved to be the best.

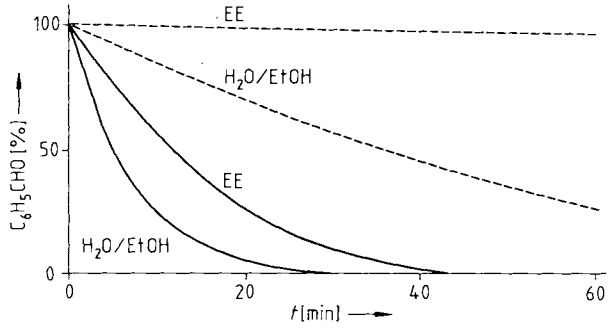


Fig. 1. Rate of the chemical (- - -) and enzymatic additions (——) of HCN to benzaldehyde (initial concentration 5×10^{-3} M) in H_2O/EtOH and in ethyl acetate (EE)/cellulose.

In the earlier investigations,[1] the optical yields were solely determined from the optical rotation of the products obtained. However, because only mandelonitrile was available in pure form, only the reaction of benzaldehyde with hydrogen cyanide allowed a statement to be made about the optical purity of the product; in general, precise statements as to the optical purity of a compound cannot be made from the optical rotation values. Furthermore, cyanohydrins undergo ready isomerization by means of the equilibrium reaction. We therefore converted the cyanohydrins so obtained into diastereomeric esters by reaction with (*R*)-α-methoxy-α-trifluoromethylphenylacetoyl chloride [*R*(+)-MTPA chloride][5] and determined their optical purity by gas chromatography. The results of the enzymatic cyanohydrin syntheses carried out by us, on the one hand, in H_2O/EtOH (according to Ref. [1]) and, on the other hand, in ethyl acetate, are compared in Table 1.

Table 1. Enzymatic formation of cyanohydrins **3** in H_2O/EtOH (see Experimental Procedure A) and in ethyl acetate (EE)/cellulose (see Experimental Procedure B).

Aldehyde **1**	**3** in H_2O/EtOH			**3** in EE/cellulose		
	Reaction time [h]	Yield [%]	*ee* [a] [%]	Reaction time [h]	Yield [%]	*ee* [a] [%]
Benzaldehyde	1	99	86	2.5	95	99
3-Phenoxybenzaldehyde	5	99	10.5	192	99	98
Furfural	2	86	69	4	88	98.5
Nicotinaldehyde	2.5	78	6.7	4.5	89	14
Crotonaldehyde	1.5	68	76	3	68	97
Phenylacetaldehyde	4	82	27	4.5	95	40
3-Methylthiopropionaldehyde	3	87	60	6.5	97	80
Pivalaldehyde	2.5	56	45	4.5	78	73
Butyraldehyde	2	75	69	4.5	75	96

[a] As (*R*)-(+)-MTPA derivatives.

The comparison shows that, although the synthesis in ethyl acetate requires longer reaction times, the enantiomeric purity is appreciably better than it is for the reaction in EtOH/H_2O.

More recent investigations into the preparation of *O*-acylated cyanohydrins by reaction of optically active cyanohydrins with dipeptide catalysts[6] or by enzymatic ester cleavage[7] were less satisfactory with respect to optical and preparative yields.

Experimental Procedure

A) Mandelonitrile lyase solution (150 μL, 700 Units/mL, A_{sp} = 65 Units/mg, in 0.02 M acetate buffer, pH 5.4) was added by pipette to 10 mL of 0.05 M acetate buffer (pH 5.4, 50% ethanol). The aldehyde **1** (5 mmol) and **2** (250 μL, 6.5 mmol) were then added. The mixture was shaken until a clear solution had formed, allowed to stand for the allotted length of time (Table 1), and extracted with chloroform. The extract was dried and the organic phase was removed in a rotary evaporator.

B) The support (2 g, AVICEL cellulose) was allowed to swell in 20 mL of 0.01 M acetate buffer (pH 5.4) for 1–2 h. The support was then filtered off, pressed, and transferred to a one-necked flask, and 150 μL of mandelonitrile lyase solution (see A) was added followed by 20 mL of ethyl acetate (saturated with 0.01 M acetate buffer, pH 5.4), 5.0 mmol of **1** and 250 μL (6.5 mmol) of **2**. The mixture was allowed to stand at room temperature for the allotted length of time (Table 1) and filtered. The filter cake was pressed and washed with ethyl acetate. The combined solutions were dried and the organic phase was removed in a rotary evaporator.

For example, 0.53 g of benzaldehyde **1**, R = Ph, gave, according to A in 1-h reaction time, 0.66 g (99%) of benzaldehydecyanohydrin **3**, R = Ph, $[\alpha]_D^{20} = +45°$ (c = 5, $CHCl_3$), *ee* = 86%. According to B in 2.5 h, 0.63 g (95%) of **3**, R = Ph, $[\alpha]_D^{20} = +49°$ (c = 5, $CHCl_3$), *ee* = 99.3%, was obtained.

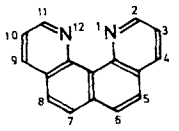
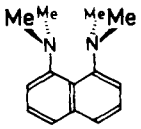
Quino[7,8-*h*]quinoline, a New Type of "Proton Sponge"**

By *Michael A. Zirnstein* and *Heinz A. Staab**

So far, "proton sponges" have been defined as bis(dialkylamino)arenes whose dialkylamino groups are in close spatial proximity.[1] The unusual basicity of these compounds is ascribed to the destabilizing overlap of the lone electron pairs on the nitrogen atoms, to the formation of especially strong hydrogen bonds in the monoprotonated diamines, and to the hydrophobic shielding of these hydrogen bonds. In order to differentiate and assess the relative importance of these factors, we were interested in quino[7,8-*h*]quinoline **1**, whose nitrogen atoms exhibit a mutual orientation similar to that in 1,8-bis(dimethylamino)naphthalene **2** ("proton sponge"). In contrast to **2**, however, **1** lacks the hydrophobic shielding of the hydrogen bonds of its monoprotonated derivative. This shielding is considered to be responsible for the low rates of proton transfer, which make the "proton sponges" reported so far unsuitable as auxiliary bases in chemical reactions.



1

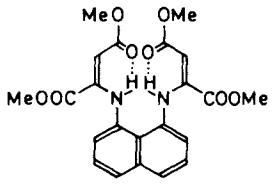


2

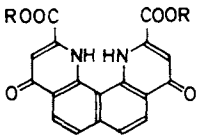
The synthesis and properties of **1** have been reported by several groups.[2] In all cases, however, these claims proved to be incorrect,[3] so that, to the best of our knowledge, **1** was unknown until now.

Our synthesis of **1** started from tetramethyl 2,2'-(1,8-naphthylenediimino)difumarate **3**, which was obtained, by a modified procedure of *Honda* et al.,[4] from 1,8-diaminonaphthalene and dimethyl acetylenedicarboxylate (molar ratio 1:2, methanol; m.p. = 142–143 °C; 71% yield).[5] Thermal cyclization of **3** (diphenyl ether, 240 °C) gave dimethyl 4,9-dioxo-1,4,9,12-tetrahydroquino[7,8-*h*]quinoline-2,11-dicarboxylate **4** (m.p. = 276–278 °C; 64% yield).[5,6]

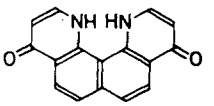
Alkaline hydrolysis of **4** afforded the corresponding dicarboxylic acid **5** (m.p. = 314–315 °C, dec.; 93% yield),[5] which underwent decarboxylation at 335 to 370 °C/10^{-5} torr in a sublimation apparatus to give quino[7,8-*h*]quinoline-4,9-(1*H*,12*H*)-dione **6** (m.p. = 375–377 °C, dec.; 76% yield).[5] Short heating of **6** at reflux with phosphoryl chloride gave 4,9-dichloroquino[7,8-*h*]quinoline **7** (m.p. = 234–235 °C; 81% yield),[5] which was converted into **1** (m.p. = 196–197 °C, 39%)[5] by catalytic hydrogenation (Pd/C, glacial acetic acid, sodium acetate).



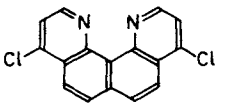
3



4: R = Me, 5: R = H



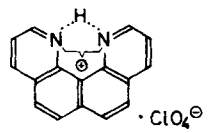
6



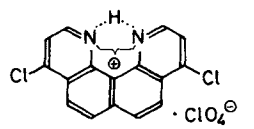
7

The compound thereby obtained gave the correct elemental analysis and spectroscopic data for the structure of **1**. In the mass spectrum, besides *m/z* 230 ($M^{\oplus}$, 100%), 229 (25%), and 115 ($M^{2\oplus}$, 13%), no other fragment ions with $I_{rel} > 5\%$ appear. Comparison of the ^{1}H-NMR spectrum ($CDCl_3$, 360 MHz) with that of quinoline leads to the following assignments: $\delta = 7.60$ (dd, $J = 4.3$ Hz, 8.1 Hz, 2H; 3,10-H), 7.98 ('s,' 4H; 5,8-H and 6,7-H), 8.32 (dd, $J = 1.9$ Hz, 8.1 Hz, 2H; 4,9-H), 9.43 (dd, $J = 1.9$ Hz, 4.5 Hz, 2H; 2,11-H).

Like other "proton sponges," **1** reacts with perchloric acid in excess to form only a *mono*perchlorate (colorless needles, m.p. = 282–285 °C).[5] The structure **8**, containing a very strong N···H···N hydrogen bond, was established from the ^{1}H-NMR spectrum,[7] which exhibits a broadened singlet at $\delta = 19.38$, the most strongly downfield-shifted proton resonance observed so far for an N···H···N hydrogen bond (in dimethyl sulfoxide (DMSO)). Analogously, the monoperchlorate **9** (m.p. = 317–318 °C, dec.)[5] is obtained from **7**. The hydrogen-bonded proton of **9** absorbs at $\delta = 19.34$.



8



9

On the basis of transprotonation experiments of **1** with protonated **2** and of **2** with **8**, the pK_a value of **1** was estimated to be 12.8 by ^{1}H-NMR spectroscopy (500 MHz, [D$_6$]DMSO). Accordingly, the basicity of **1** compared with quinoline ($pK_a = 4.91$) is increased by nearly eight orders of magnitude, which roughly corresponds to the increase of basicity of **2** compared with *N,N*-dimethylaniline.[1] Whereas the hydrophobic shielding of the N···H···N hydrogen bond plays only a minor role in the basicity of "proton sponges," it has a great effect on the rate of proton transfer: the ^{1}H-NMR spectra of mixtures of **1** and **8** in [D$_6$]dimethyl sulfoxide at 30 °C exhibit coalesced signals

[**] New "Proton Sponges," Part 4.—Part 3: [1c].

for each of the various groups of protons at averaged δ values corresponding to the respective **1/8** ratio. Thus, in contrast to the "proton sponges" reported so far,[1] a rapid proton exchange obviously exists between **1** and **8**. Quantitative investigations of the equilibrium and the kinetics of proton transfer in the system **1/8** have been initiated. The preliminary results have already shown that not only strong, but also kinetically active bases are accessible according to the "proton sponge" concept.

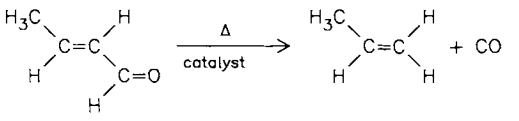
Decarbonylation on Carbon-Supported Nickel Catalysts**

By *Hans Bock** and *Olaf Breuer*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Surface reactions of gases on[1a-c,f,g] and with[1d,e] solids can be detected and optimized most readily by PE-spectroscopic real-time analysis[2] of the gas mixture after it has flowed through the reaction zone (compare Fig. 1). As a model reaction for the heterogeneously catalyzed decarbonylation,[3a] we have investigated the cleavage of crotonaldehyde[3c] to CO and propene at 10 Pa on quartz wool, on metal powders, and on supported catalysts (Scheme 1). A carbon-supported nickel catalyst proved to be the most suitable,[4] lowering the decarbonylation temperature by more than 500 K relative to that for quartz wool.[5]



catalyst	[SiO$_2$]	[Cu]	[Ni]	[Ni/SiO$_2$]	[Rh/C]	[CO/C]	[Ni/C]
T[K]	870	770	670	570	520	470	360

Scheme 1.

The selective cleavage of CO from furfurylaldehyde at 400 K shows that the reaction is catalyzed by nickel clusters[4] that are presumably present in the pores of the carbon, which has a large surface area. The uncatalyzed decomposition of furfurylaldehyde requires a 700-K higher temperature, resulting mainly in the formation of propyne and CO (Fig. 1).[3b]

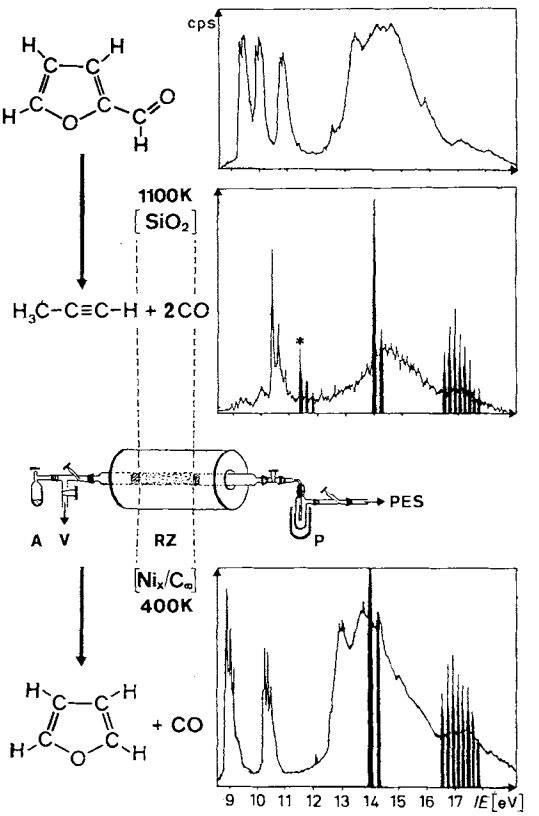


Fig. 1. Thermal decomposition of furfurylaldehyde on quartz wool (above) and selective decarbonylation on a carbon-supported nickel catalyst (below). He(I) PE spectra and experimental apparatus (A, starting material; V, vacuum-pump connection; RZ, heated reaction zone; P, product cold trap for GC analysis; PES, connection to PE spectrometer). In the uncatalyzed decomposition, a small amount of acetylene (*) was observed as a side product. The black bands in the middle and lower spectra are due to CO [9]. The PE spectrum of pure furan is known [9]. The absence of an acetylene band in the lower spectrum proves that no side products are formed in the Ni$_x$/C$_\infty$-catalyzed decarbonylation of furfurylaldehyde.

Numerous other organic compounds can be decarbonylated, on carbon-supported nickel catalysts[4] at low temperatures on a preparative scale and largely selectively (according to the gas chromatograms):[5] aldehydes, acid chlorides, and acyl cyanides (Scheme 2, R = CH_3, C_6H_5). The uncatalyzed reactions require temperatures that are up to 700 K higher.

[**] Surface Reactions, Part 8. This work was supported by Hoechst AG, the Fonds der Chemischen Industrie, and the Max-Buchner Stiftung.—Earlier Parts: cf. [1].

An unexpected course was observed for the reaction of alkyl isocyanates on carbon-supported nickel catalysts.[4] For example, isopropyl isocyanate undergoes noncatalyzed decomposition above 920 K with the formation of propene and HNCO; the reaction is suitable for the synthesis of pure isocyanic acid.[6] In contrast, reaction on Ni_x/C_∞ catalysts occurs at 500 K, yielding CO, methane, and acetonitrile as the main products (Fig. 2). Since CO cleavage already takes place above 400 K, presumably a chemisorbed isopropyl nitrene is involved as a surface-bound intermediate. It possibly stabilizes by eliminating CH_4 to a presumably π-bound[7] acetonitrile, which, under the reaction conditions, begins to desorb only after about one hour and at a 50-K higher temperature. The

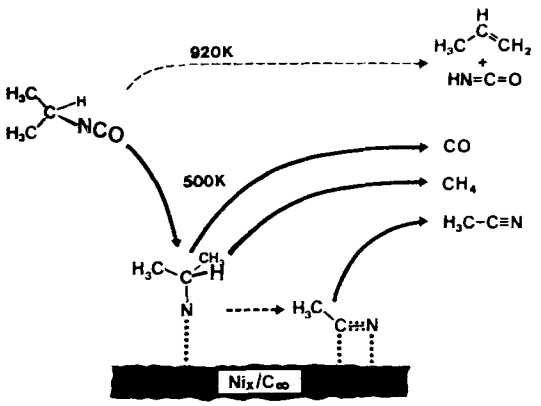

Fig. 2. Possible mechanism for the decomposition of isopropyl isocyanate.

uncatalyzed thermal decomposition of *tert*-butyl isocyanate requires a temperature of 900 K and affords HNCO and isobutene. In contrast, on the carbon-supported nickel catalyst, isobutene and CO already form at temperatures above 500 K, as well as NH_3 and N_2—possibly by disproportionation of NH species bound to the surface.[8]

[3] a) In contrast to the extensive literature on homogeneously catalyzed carbonylation equilibria, e.g., in the oxo synthesis (cf. K. Weissermel, H. J. Arpe: *Industrielle Organische Chemie*, 2nd ed., Verlag Chemie, Weinheim 1978), there are only a few publications on heterogeneously catalyzed decarbonylations (cf., e.g., *Houben-Weyl: Methoden der Organischen Chemie, Band VII, Teil 1*, Thieme, Stuttgart (1954), p. 494f). b) For CO elimination from furfurylaldehyde on nickel or cobalt catalysts cf. A. P. Dunlop, W. J. McKillip, S. Winderl in *Ullmanns Encyklopädie der technischen Chemie, Bd. 12*, Verlag Chemie, Weinheim 1976, p. 15, especially p. 19, on $[Cr_2O_3/ZnO/Mn_2O_3]$ contact catalysts, for example, O. W. Can, *Ind. Eng. Chem. 40* (1948) 216 or S. A. Hiller, A. Y. Karmilchik, U. U. Stonkus, B. S. Kalayew, S. Shymanska in B. Delmon, P. A. Jacobs, G. Poncelet (Eds.): *Preparation of Catalysts*, Elsevier, Amsterdam 1976, p. 579f. c) For the decarbonylation of crotonaldehyde on nickel powder, cf. P. Sabatier, J. W. Senderens, *Ann. Chim. Paris 4* (1905) 433.

[4] Active carbon (20 g, Strem, 4021-s 06-005, particle size 2 mm, surface area 1000 m^2/g) was degassed to a final pressure of 1 Pa in a 250-mL round-bottom flask fitted with a dropping funnel and then subjected to ultrasonication in a solution containing $Ni(NO_3)_2 \cdot 6H_2O$ (40 g) in 50 mL of H_2O for approximately 1 h until gas evolution had ceased. After decantation of the liquid layer, the product was dried for 12 h at 370 K. In each experiment, 5 g of the catalyst was placed in the reaction tube (Fig. 1) between quartz-wool plugs; the tube was flushed for 15 min each with N_2 and H_2; reduction was then carried out in a stream of H_2 (10 L/h) for 30 min at 320 K, 1 h at 520 K, and 3 h at 720 K; finally, the water formed was removed at 1 Pa and 720 K. The carbon-supported nickel catalyst so formed contains 7% Ni; further characterization by means of the X-ray powder diagrams is being carried out in collaboration with Prof. *M. Trömel*, Universität Frankfurt. In general, the diameters of metal particles of supported catalysts prepared by adsorption of metal nitrates from solution, thermal decomposition, and subsequent reduction with H_2 are in the nm range (cf. J. R. Anderson: *Structure of Metallic Catalysts*, Academic Press, London 1975, Chapter 4 (Dispersed Metal Catalysts), p. 163ff).

[5] For decarbonylation of crotonaldehyde at 530 K and a flow rate LHSV $\approx$ 1/h, the conversion amounts to 80% and the propene selectivity amounts to 89%. Control experiments using undoped active carbon confirm that no CO cleavage is observed up to 750 K.

[6] Usually, HNCO is synthesized by depolymerization of cyanuric acid above 970 K with formation of CO_2, HCN, and H_2O as side products (*Gmelins Handbuch der Anorganischen Chemie, Bd. Kohlenstoff D1*, 8th ed., Verlag Chemie, Weinheim 1971, p. 327f). In contrast, the pyrolysis of isopropyl isocyanate for short contact times results solely in the formation of readily separated propene (b.p. (760 torr) = 226 K; HNCO, b.p. (760 torr) = 297 K); for the kinetics, cf. P. G. Blake, S. Ijadi-Maghsoodi, *Int. J. Chem. Kinet. 15* (1983) 609.

[7] The π coordination of alkyl cyanides on copper surfaces could be detected by, among other methods, IR spectroscopy (A. M. Bradshaw, Fritz-Haber-Institut, Berlin, private communication).

[8] For the detection of $NH_{(ads)}$ as intermediate in the synthesis of NH_3 on $Fe/K/Al_2O_3$ supported catalysts by physical methods of surface analysis, cf. G. Ertl, *Catal. Rev. 21* (1980) 201.

Glycolate and Thioglycolate Complexes of Rhenium and Their Oxidative Elimination of Ethylene and of Glycol**

By *Wolfgang A. Herrmann,* Dieter Marz, Eberhardt Herdtweck, Adolf Schäfer, Werner Wagner,* and *Heinz-Josef Kneuper*

Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

Selenium dioxide and osmium tetroxide are effective reagents and catalysts for olefin oxidation, although, owing to their toxicity, reservations remain as to their applicability.[1] We are therefore seeking more easily handled metal oxides that are soluble in organic solvents and that are as effective as osmium tetroxide in carrying out stereospecific *cis* hydroxylation of olefins. The rhenium(VII) oxide **1**, which has meanwhile become readily accessible, is a favorable candidate.[2]

Complex **1** reacts with germanium dichloride (as the dioxane adduct) in a clean redox reaction, according to

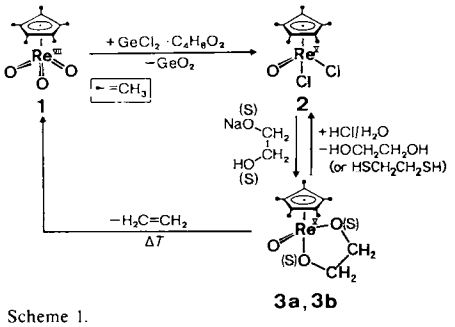
[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 40. This work was supported by Hoechst AG, Degussa AG, the Fonds der Chemischen Industrie, and the Bundesministerium für Forschung und Technologie.—Part 39: W. A. Herrmann, B. Koumbouris, E. Herdtweck, M. L. Ziegler, T. Zahn, *Chem. Ber.*, in press.

Scheme 1, to give the oxo dichloride **2**,[3] which, upon treatment with glycolate or dithioglycolate solutions (sodium salts), is converted nearly quantitatively into the novel metallacycles **3a** or **3b**, respectively.[4]



Scheme 1.

A single-crystal X-ray structure analysis of the parent glycolate complex **3a** (Fig. 1) gave the following results: In addition to an acentrically π-coordinated five-membered ring ligand and a double-bonded oxo group (Re-O3 169.6(2) pm), the molecule contains a puckered ReO_2C_2 five-membered ring (*twist* conformation) in which the interatomic distances correspond to those of single bonds. In the metallacycle, the planes defined by the atoms O1/Re/O2 and C1/Re/C2 form an angle of 23.6°.

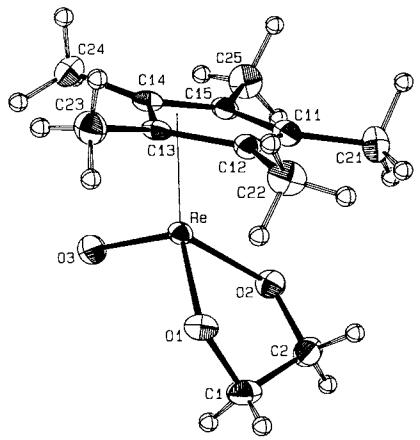


Fig. 1. ORTEP of the molecular crystal structure of the glycolate complex **3a**. The hydrogen atoms were localized by X-ray structure analysis. The ellipsoids of thermal vibration are drawn at the 50% probability level, except for the H atoms, where they are arbitrary.—**3a** forms orthorhombic crystals (*n*-hexane, −30°C) in the space group $P2_12_12_1$. $a=788.0(1)$, $b=1258.0(1)$, $c=1278.6(1)$ pm, $\alpha=\beta=\gamma=90°$, $Z=4$, $V=1267\times10^7$ pm^3, $\rho_{calcd}=2.083$ g cm^{-3}. 2496 measured reflections of which 2145 were unique, 221 parameters, $R=0.016$, $R_w=0.017$, GOF = 2.314. Selected distances [pm] and angles [°]: Re-O(1) 196.6(2), Re-O(2) 196.3(2), Re-O(3) 169.6(2), C(1)-C(2) 149.8(5), C(1)-O(1) 143.7(4), C(2)-O(2) 143.0(4); O(1)-Re-O(2) 80.2(1), O(1)-Re-O(3) 108.3(1), O(2)-Re-O(3) 110.9(1) [5].

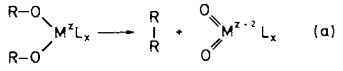
Of particular interest is the thermal behavior of the glycolate complex **3a**: Heating of the solid at 150°C (15 min, vacuum) or refluxing of a toluene solution in the absence of oxygen results in *quantitative* elimination of ethylene with regeneration of the trioxorhenium(VII) educt **1** (Scheme 1). This special case of cycloreversion, which has not before been encountered in organometallic chemistry,[9] may be regarded as an oxidative elimination of type (a), since the oxidation state is formally changed from Re^V

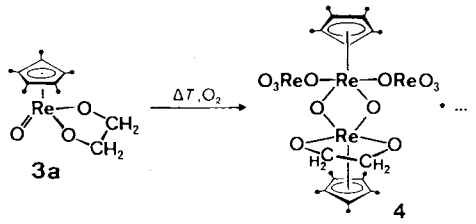


to Re^{VII}. This cleavage reaction can also be followed by NMR spectroscopy; when **3a** is heated in [D_8]toluene at 100°C with strict exclusion of O_2, the signals for **1** ($\delta=1.98$) and ethylene ($\delta=5.28$) are observed.

The dithioglycolate complex **3b** is thermally more stable than **3a**; however, heating of **3b** at 200°C over 30 min likewise results in quantitative loss of ethylene. The 2,3-butanediolato complex **3c** (synthesized from (2*R*,3*R*)-2,3-butanediol; red-violet crystals), corresponding to **3a**, eliminates *trans*-butene (100%) above 150°C to form **1** once again. The 1,3-propanediolate derivative **3d** (violet oil),

$[(\eta^5\text{-}C_5Me_5)(O)\overline{ReOCH_2CH_2CH_2O}]$ **3d**

which was synthesized analogously, behaves similarly; it eliminates propene already at room temperature (!) and can therefore be handled without decomposition only below 0°C.



Scheme 2.

In the presence of air, **3a** is transformed, according to Scheme 2, into the more complex oxidation product **4**,[6] which, according to a single-crystal X-ray structure analysis, is related constitutionally to the known complex [(η^5-$C_5Me_5)_2Re_2O_4$][7] (Fig. 2). The two nonidentical Re(v) fragments are joined through oxo bridges; one fragment (Re1) still contains the bidentate glycolate ligand, whereas the

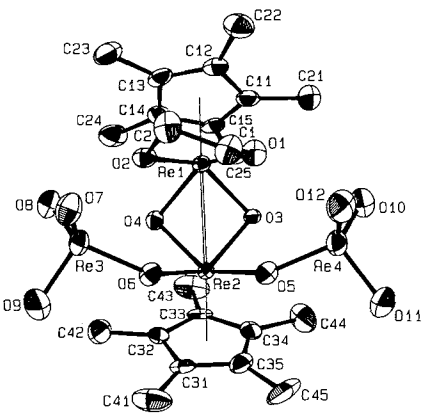


Fig. 2. ORTEP of the molecular crystal structure of the tetranuclear glycolate complex **4** (without hydrogen atoms).—**4** forms triclinic crystals (toluene), containing two molecules of the solvent, in the space group $P\bar{1}$. $a=938.2(1)$, $b=1452.3(1)$, $c=1543.7(1)$ pm, $\alpha=81.42(1)$, $\beta=82.60(1)$, $\gamma=72.88(1)°$, $Z=2$, $V=1980\times10^6$ pm^3, $\rho_{calcd}=2.381$ g cm^{-3}. 7005 measured reflections, of which 6008 were independent, 469 parameters, $R=0.028$, $R_w=0.031$, GOF = 3.934. Selected distances [pm] and angles [°]: Re(1)-Re(2) 260.2(<1), Re(1)-O(1) 199.6(3), Re(1)-O(2) 203.0(3), O(1)-C(1) 143.2(5), C(1)-C(2) 148.8(6), C(2)-O(2) 143.2(5), Re(1)-O(3) 193.4(2), Re(1)-O(4) 192.1(3), Re(2)-O(3) 192.7(2), Re(2)-O(4) 193.7(2), Re(2)-O(5) 208.1(3), Re(2)-O(6) 204.0(3); Re(1)-O(3)-Re(2) 84.7(1), Re(1)-O(4)-Re(2) 84.8(1), Re(2)-O(5)-Re(4) 139.7(2), Re(2)-O(6)-Re(3) 134.6(2), Re(1)-O(1)-C(1) 116.2(3), Re(1)-O(2)-C(2) 112.0(2) [5].

other (Re2) has two perrhenate groups (Re3/4). Thus, air oxygen effects both partial elimination of glycolate and oxidation of $[(C_5Me_5)Re^{V}O_x]$ fragments with loss of the ring ligand. The ReO_2C_2 metallacycle still present in **4** no longer decomposes with elimination of ethylene (monitored by GC), even at temperatures as high as 250 °C (vacuum).

The glycolate ligand in **3a** may also be split off intact, however. Thus, on the one hand, treatment of **3a** with dilute aqueous hydrochloric acid results in rapid formation of the oxo dichloride **2** (IR and MS detection) with quantitative formation of glycol (GC detection, Scheme 1); this reaction is the reversal of the route of formation leading to **3a**. On the other hand, treatment with HCl/ether results in formation of the complex $[(\eta^5\text{-}C_5Me_5)ReCl_4]$.[2] Furthermore, oxidative cleavage of the ReO bonds in **3a** may be achieved with hydrogen peroxide; in addition to glycol, the rhenium(VII) oxide **1** is cleanly formed under such conditions.

The mechanisms of decomposition of the oxidic glycolate complexes of rhenium presented here support, on the one hand, the supposition that structurally analogous intermediates are involved in the permanganate and osmium tetroxide systems (Criegee and Sharpless reactions) used in practice for the oxidation of olefins;[1,8] on the other hand, they suggest novel applications of the organometallic oxide **1**. However, the direct addition of **1** to CC double bonds must be accomplished in the next step of research.

[8] Oxyamination and -diamination reactions at Os^{VIII} complexes also appear to follow this mechanism; cf. A. O. Chong, K. Oshima, K. B. Sharpless, *J. Am. Chem. Soc. 99* (1977) 3420; the corresponding reactions may also be possible for rhenium-containing systems in view of the availability of complexes such as $[(\eta^5\text{-}C_5Me_5)ReCl_2(=N-R)]$ [2b].

[9] One example in tungsten chemistry is known but requires the presence of a further reagent: R. R. Schrock, S. F. Petersen, M. R. Churchill, J. W. Ziller, *Organometallics 3* (1984) 1574.

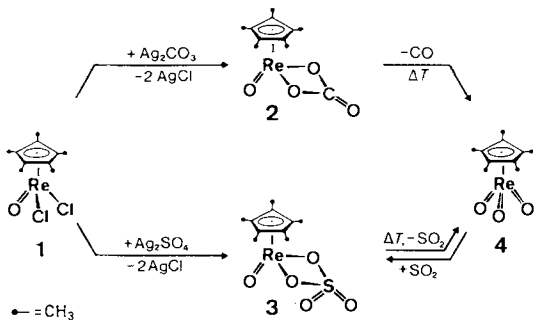
Novel Rhenium(v) Carbonato and Sulfato Chelate Complexes: Synthesis and Investigation of Molecular Dynamics by ^{17}O-NMR Spectroscopy**

By *Wolfgang A. Herrmann,* Karin A. Jung, Adolf Schäfer,* and *Heinz-Josef Kneuper*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Oxidic rhenacycles with four-, five-, and six-membered rings have recently become accessible, either by substitution of halogen accompanied by cyclization in the rhenium(V) complex **1** or by (reductive) cycloaddition to the rhenium(VII) oxide **4**.[1] The pronounced stability of ReO bonds prompted us to investigate the tendency of carbonate and sulfate ions to react at Lewis-acidic d^2-configurated rhenium centers to give cyclic products.

The oxo dichloride **1** reacts with the anhydrous silver salts of mono- and polybasic oxo acids in organic solvents with precipitation of silver chloride. Thus, reaction with silver carbonate affords the carbonato complex **2** and reaction with silver sulfate gives the sulfato complex **3** (Scheme 1).[2]



Scheme 1.

The two new metallacycles **2** and **3** are not only sensitive to moisture but also decompose upon heating with elimination of carbon monoxide and sulfur dioxide, respectively (GC and MS detection), as well as quantitative formation of the rhenium(VII) oxide **4**. Other cleavage products are not observed.[3] The sulfato complex **3** can also be prepared from the oxide **4** by treating it with dry SO_2 in hot toluene (80 °C) for several hours. The structures of **2** and **3** are presumably similar to that of the related complex $[(\eta^5\text{-}C_5Me_5)(O)Re(\mu\text{-}O)_2ReCl_2(\eta^5\text{-}C_5Me_5)]$,[4]

which is folded along the O···O vector at the central oxygen bridges.

During the ^{17}O-NMR spectroscopic characterization, we observed a previously unknown exchange phenomenon for the metallacycle **3**. In order to carry out this study, the starting complex **1** was $^{17}O/^{18}O$-labeled to about 10% and 40%, respectively, by subjecting the tetrachloride $[(\eta^5\text{-}C_5Me_5)ReCl_4]$ to partial hydrolysis with exactly one equivalent of $^{17}O/^{18}O$-labeled water[5] and then allowing the isotopomeric mixture [*O]-**1**, isolated as crystals, to react with *nonlabeled* silver sulfate according to Scheme 1. The ^{17}O-NMR spectrum of the product [*O]-**3**, shown in Figure 1,

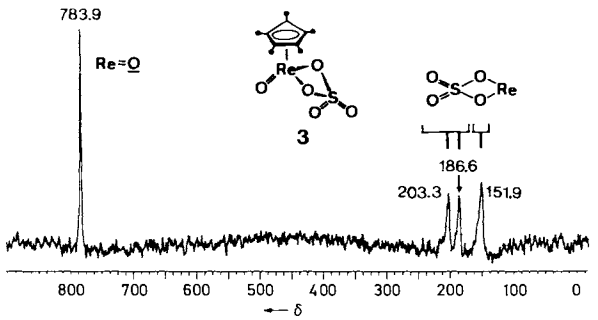

Fig. 1. ^{17}O-NMR spectrum of the complex [*O]-**3** (ca. 10% overall ^{17}O plus 40% ^{18}O enrichment; MS determination), prepared from $[(\eta^5\text{-}C_5Me_5)Re(*O)Cl_2]$ and *nonlabeled* Ag_2SO_4.—Recording parameters: 36.634 MHz, CD_2Cl_2, 27°C, 10000 scans, acquisition time 0.041 s, pulse delay 0.010 s, 90° pulse; δ values with respect to external H_2O ($\delta = 0.00$ ppm).

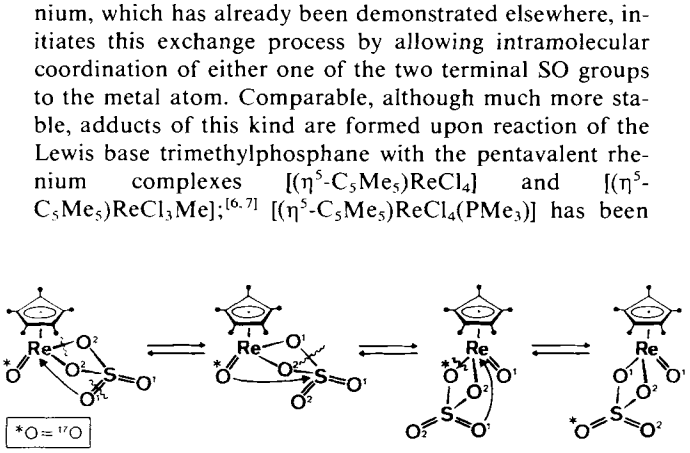
proves that, in agreement with the infrared[2] and mass spectra, the oxygen label is by no means found only in the ReO group (as was expected) but is *distributed statistically over all possible five positions* in the molecule. This means that an exchange of oxygen atoms bound to rhenium and sulfur occurs and must therefore be due to a dynamic process. Opening of the rhenium-oxygen bonds of the ReO_2S metallacycle alone is not sufficient, since this would only lead to exchange of the oxygen atoms bound to rhenium. The sulfur-oxygen bonds must also be involved in bond breaking and bond formation. The exchange mechanism proposed in Scheme 2 can explain these findings. Apparently, the Lewis acidity of d^2-configurated rhenium, which has already been demonstrated elsewhere, initiates this exchange process by allowing intramolecular coordination of either one of the two terminal SO groups to the metal atom. Comparable, although much more stable, adducts of this kind are formed upon reaction of the Lewis base trimethylphosphane with the pentavalent rhenium complexes $[(\eta^5\text{-}C_5Me_5)ReCl_4]$ and $[(\eta^5\text{-}C_5Me_5)ReCl_3Me]$;[6,7] $[(\eta^5\text{-}C_5Me_5)ReCl_4(PMe_3)]$ has been



Scheme 2. Proposed mechanism for complete oxygen exchange in the rhenium(v) metallacycle **3**, assuming an intramolecular exchange process. The bond cleavages shown correspond, in each case, to the formation of the following isotopomer.

characterized by means of X-ray structure analysis (distorted octahedral coordination) and contains a phosphane group in the *trans* position to the π-bonded ring ligand.[6]

Increasing the temperature does not result in an appreciable change of the spectrum. The comparably short time scale of ^{17}O-NMR spectroscopy in this case, due to the large line separation, does not allow coalescence to be observed, within the realm of experimental possibility. A related exchange phenomenon at a η^2-sulfato ligand has previously been detected only by IR spectroscopy.[8]

We have thus been able to show that oxidic organorhenium complex fragments react with simple oxo anions to form stable chelate complexes, the surprising molecular dynamics of which are due to the Lewis acidity of the d^2-configurated Re^V centers. Furthermore, reactions of the type in Scheme 1 offer the possibility of constructing extended metal oxide structures by complexation of oxometallates (e.g., di- and polychromates) in which different metal atoms are linked to one another through oxo bridges.

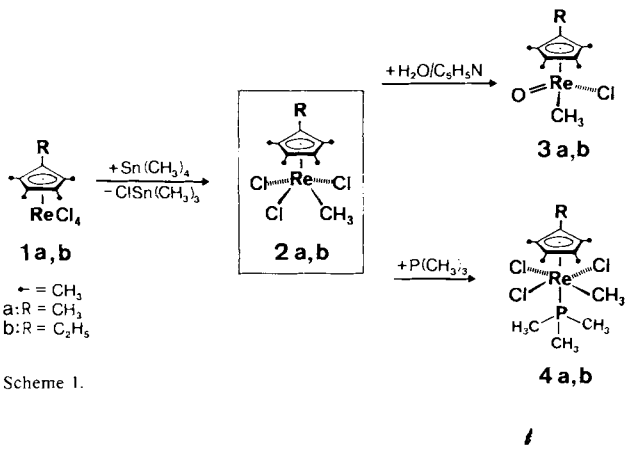
Concerning the Role of Organotin Compounds in Olefin Metathesis: Synthesis, Structure, and Lewis Acidity of $[(\eta^5\text{-}C_5Me_5)CH_3ReCl_3]$**

By *Wolfgang A. Herrmann,* Josef K. Felixberger, Eberhardt Herdtweck, Adolf Schäfer,* and *Jun Okuda*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Tetraorganotin compounds are the most effective cocatalysts for olefin metathesis. Rhenium, after molybdenum and tungsten, is the most active metal present in catalysts for this reaction.[1] A soluble reaction product formed from $ReCl_5$ and $Sn(n\text{-}C_4H_9)_4$ (molar ratio 2:3), which was not further characterized, was found in 1971 to be the first rhenium-containing system for olefin metathesis in homogeneous catalysis.[2] The related heterogeneous system $Re_2O_7/Al_2O_3/Sn(CH_3)_4$ even effects the metathesis of functionalized olefins.[3,4] Although the actual mechanism of metathesis[1] may be regarded as having been established at least for soluble catalysts (olefin cycloaddition to metal carbene species), this statement does not apply to the mode of activation of such catalysts by the tetraorganotin compounds (alkylation vs. reduction).[5] We have therefore attempted, by means of the readily accessible, simple organorhenium(v) complexes **1a,b**, to determine the elementary steps involved in the reaction of tin-containing cocatalysts with higher-valent, soluble rhenium compounds and report herein the synthesis, characterization, and reactivity of novel alkylrhenium complexes.



Scheme 1.

Treatment of a CH_2Cl_2 solution of **1a** at room temperature with 1.1 equivalents of tetramethylstannane results in smooth transmethylation, according to Scheme 1, to give, in addition to trimethyltin chloride (^{1}H-NMR detection), the new Re^V complex **2a** as brown, slightly air-sensitive, and strongly moisture-sensitive crystals. According to elemental analysis and the FD mass spectrum, this substance, which dissolves in polar organic solvents without undergoing decomposition, has the formula $[(C_5Me_5)CH_3ReCl_3]$. The IR spectrum exhibits, in addition to the band pattern for the $(C_5Me_5)Re$ fragment, characteristic bands for the ReCl and CH_3Re groups.[6] The complex $[(\eta^5\text{-}C_5Me_5)CD_3ReCl_3]$ ($[CD_3]$-**2a**, 99.5% labeling), which is obtained analogously from **1a** and $Sn(CD_3)_4$, allows the assignment of all CH and CD vibrations, respectively.[6] A single-crystal X-ray structure analysis of the better crystallizing derivative **2b** (Fig. 1), despite the disorder of a Cl atom with the CH_3 group, confirms the expected structure, namely, a half-sandwich complex with square-pyramidal coordination;[7] the analogously synthesized derivative $[(\eta^5\text{-}C_5Me_4Et)CH_3ReBr_3]$ has the same geometry in the crystal but exhibits no disorder.

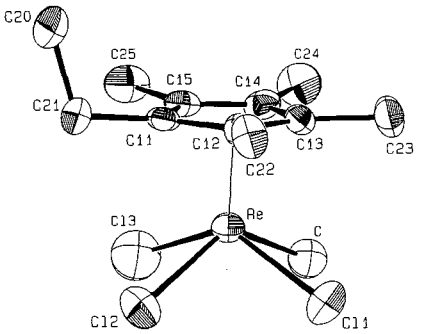


Fig. 1. Molecular crystal structure of **2b**. The complex forms orthorhombic crystals (dichloromethane/*n*-pentane, −30°C) in the space group *Pbca* (I.T. No. 61) [7]. The atoms Cl3 and C are disordered (75:25).—Selected distances [pm] and angles [°]: Re-Cl1 235.4(1), Re-Cl2 236.6(1), Re-Cl3 233.0(2), Re-C 229.7(3); Cl1,Re,Cl2 80.8(1).—Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52335, the names of the authors, and the journal citation.

In contrast to the oxidic d^2-Re^V complexes of the type $[(\eta^5\text{-}C_5Me_5)ReOX_2]$ (X = alkyl, halogen),[8] the aromatic π ligand of **2b** is nearly symmetrically bound to the metal. As shown by MO analysis of the d^2-complexes $[(\pi\text{-}C_5Me_5)ReX_4]$ (X = anionic ligand), these complexes can form singlet/triplet equilibria.[9] As a consequence, the metal-bound CH_3 group of **2a** exhibits a strongly temperature-dependent paramagnetic shift in the ^{1}H-NMR spectrum. Whereas the resonance absorption appears at $\delta = +36.5$ (!) at +50°C, it is shifted to higher field with decreasing temperature and appears at $\delta = +13.5$ at −50°C.

Because of the pronounced flattening of the $ReCl_3C$ pyramid in **2** (sum of angles of $ReCl_3C$ in **2b** 325°; Fig. 1), complexes of type **2** should allow an additional ligand to add at the *trans* position to the π-bonded ring system when the rhenium(v) centers act as Lewis acids. This is indeed the case (see Scheme 1): for example, **2a** reacts with water in the presence of two equivalents of pyridine to give the oxo derivative **3a** (*four* different ligands!),[10] and with trimethylphosphane to give the stable adducts **4a,b**,[11] which presumably have octahedral structures in analogy to the complex $[(\eta^5\text{-}C_5Me_5)ReCl_4(PMe_3)]$,[12] which has been characterized by X-ray structure analysis.

When higher alkyltin compounds are allowed to react with the tetrachloride **1a** under otherwise identical conditions, one obtains, in the case of $Sn(C_2H_5)_4$ and $Sn(n\text{-}C_4H_9)_4$, in addition to the corresponding trialkyltin chlorides, a rhenium(IV) complex, which does *not* contain the ethyl or *n*-butyl groups expected according to Scheme 1. Instead, the product, which is soluble in CH_2Cl_2, has the

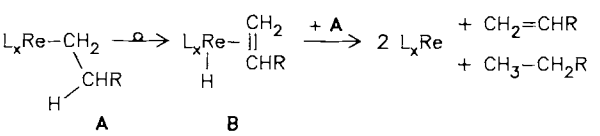
[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 42. This work was supported by Hoechst AG and the Bundesministerium für Forschung und Technologie.—Part 41: W. A. Herrmann, K. A. Jung, A. Schäfer, H.-J. Kneuper, *Angew. Chem.* 99 (1987) 464; *Angew. Chem. Int. Ed. Engl.* 26 (1987) 464.

$[\{(\eta^5\text{-}C_5Me_5)ReCl_3\}_2]$ **5a** $[(\eta^5\text{-}C_5Me_5)ReCl_3(PMe_3)]$ **6a**

formula **5a**.[13] Its binuclear constitution follows from the diamagnetism, which requires a direct metal-metal interaction, and from the reaction with trimethylphosphane leading to formation of the paramagnetic Re^{IV} complex **6a**.[14] Taking into consideration the liberation of ethylene/ethane and 1-butene/*n*-butane, respectively (detected by gas chromatography), the formation of **5a**, which involves reduction ($Re^V \rightarrow Re^{IV}$), may be explained by a β-hydride shift and its consequences (Scheme 2): the alkyl intermediate **A** rearranges to give the hydrido(olefin) isomer **B**, which then undergoes reductive decomposition with olefin elimination and intermolecular alkane formation; elemental hydrogen does *not* appear during the formation of **5a**. These findings show that alkyltin compounds of higher-valent metal halide systems, although alkylating initially in a redox-neutral reaction, can subsequently lead to reduction of the transition metal when, sterically and electronically (Lewis acids), the metal allows alkyl rearrangement processes such as the β-hydride shift to occur. It is interesting that even an excess of $Sn(CH_3)_4$ does not lead to multiple methylation of the tetrachloro complexes **1a,b**; the compound $[(\eta^5\text{-}C_5Me_5)Re(CH_3)_4]$ is obtainable, however, from **1a** via the Grignard route.[15]



Scheme 2.

Experimental Procedure

2a: A suspension of **1** (463 mg, 1.00 mmol) in 20 mL of CH_2Cl_2 was treated at room temperature with $Sn(CH_3)_4$ (0.15 mL, 1.08 mmol) and then allowed to stir for 2 h (N_2 atmosphere). The violet suspension was thereby transformed into a red-brown solution. After removal of the solvent, the crude product was washed three times with 10 mL of *n*-pentane and finally recrystallized from CH_2Cl_2/*n*-pentane at −30°C. Yield 375 mg (85%) red-brown, analytically pure crystals; no m.p. up to 250°C.—**2b** was synthesized analogously; brown-red crystals; m.p. = 135°C (dec.).

3a: A suspension of **2a** (160 mg, 0.36 mmol) in 10 mL of toluene was allowed to react at 25°C with a solution of H_2O (6.5 μL, 0.36 mmol) and pyridine (58 μL, 0.72 mmol) in 1 mL of tetrahydrofuran (THF). After stirring for 2 h under N_2, the brown reaction solution was filtered to separate the precipitated pyridinium hydrochloride and then concentrated. Addition of a layer of *n*-pentane resulted in the precipitation at −30°C of 84 mg (60%) of black crystals; m.p. = 174°C.

$[Ph_4P]_2[Sb_2I_8]$: Weak Interactions between Phenyl Groups of the Cation and Antimony Atoms of the Anion**

By *Siegfried Pohl,** *Wolfgang Saak*, and *Detlev Haase*

Arene-$SbCl_3$ adducts have already been well documented.[1,2] In the last few years numerous comparable complexes of gallium(I),[3] tin(II), and lead(II),[4] as well as of halides of trivalent elements of the fifth main group[5–7] with neutral arenes have also been synthesized or characterized for the first time. We report here on the complex

$[Ph_4P]_2[Sb_2I_8] \cdot 2CH_3CN$ **1**

in which we found similar interactions characteristically revealing that the phenyl groups of the cation function as

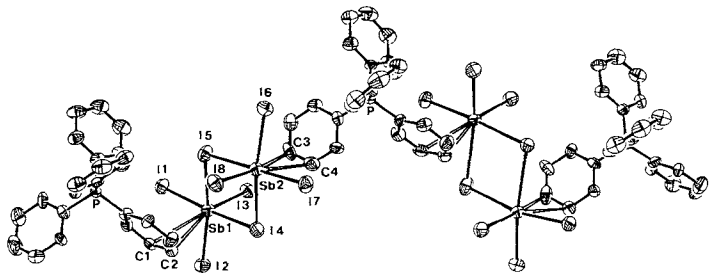

Fig. 1. Section of the structure of **1** [8]. The unit shown has crystallographic symmetry C_2. The fourth cation is not shown (see text). Selected bond lengths [pm]: Sb1-I1 286.4, Sb1-I2 288.3, Sb1-I3 277.3, Sb1-I4 324.7, Sb1-I5 328.8, Sb2-I4 335.3, Sb2-I5 318.7, Sb2-I6 287.3, Sb2-I7 287.2, Sb2-I8 276.7 (standard error 0.2 pm in each case); Sb1-C1 350, Sb1-C2 358, Sb2-C3 345, Sb2-C4 343 (standard error 2 pm in each case); angle between the normals to the planes through Sb1,C1,C2 and the phenyl ring: 114.7°; Sb2,C3,C4—phenyl ring: 115.3°.

donors towards the metal in the anion. The complex **1** is obtained in quantitative yield upon reaction of equimolar amounts of tetraphenylphosphonium iodide and antimony triiodide in acetonitrile at 81 °C; on evaporation of the solution to dryness, the compound crystallizes in the form of orange-red, prismatic crystals.

Figure 1 shows a section of the structure of **1** which was determined by an X-ray structure analysis.[8] The group shown is singly negatively charged per formula unit. The fourth, omitted tetraphenylphosphonium ion does not interact with the anion. The acetonitrile molecules are highly disorded. The antimony atoms in the $[Sb_2I_8]^{2\ominus}$ ions are square-pyramidally coordinated by iodine; $[As_2Cl_8]^{2\ominus}$, $[As_2Br_8]^{2\ominus}$, and $[Sb_2Br_8]^{2\ominus}$ ions have a comparable structure.[9] However, in these cases the non-bonding electron pairs each occupy the sixth coordination site, whereas in **1** η^2-bonded phenyl rings of the cations complement the coordination polyhedron around antimony(III). Hence, the non-bonding electron pair should, in this case, be largely stereochemically inactive.

Although a soft ligand such as iodine lowers the Lewis acidity of antimony on the one hand, on the other it probably favors the inert-pair effect and thus the observed phenyl–antimony interaction. As a result of the low acidity, the acceptor properties of Sb in $[Sb_2I_8]^{2\ominus}$ are not very pronounced. The Sb–C distances of between 343 and 358 pm, are somewhat larger than in $C_6H_6 \cdot 2SbCl_3$, where distances of 336 to 343 pm have been measured.[6] The bond lengths in the $[Sb_2I_8]^{2\ominus}$ ion correspond to those in other iodoantimonates.[10, 11] That the distances between antimony and the iodine atoms *trans* to the phenyl–antimony contacts are shortest indicates that the π-system of the phenyl group is here a weaker donor than iodine. The C–C distances are, within the limits of error, equal.

Preparation of β-Halothiophenes by Isomerization of α-Halothiophenes on Zeolite Catalysts

By *Udo Dettmeier, Klaus Eichler, Klaus Kühlein, Ernst Ingo Leupold,* and *Heinz Litterer**

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Halothiophenes and their secondary products are intermediate compounds in the synthesis of drugs and plant protection agents. Whereas predominantly α-thienyl compounds were prepared in the past,[1] β-halo derivatives[2] are increasingly being resorted to nowadays for the synthesis of active substances. However, the tediousness of the methods so far available for access to these derivatives has been a drawback to their general use in such syntheses.

Thus, for example, 3-bromo and 3,4-dibromothiophenes are obtained by exhaustive bromination of thiophene to give 2,3,5-tribromo- and 2,3,4,5-tetrabromothiophene and subsequent treatment of these with Grignard reagents,[3] organolithium compounds[4] or zinc dust in acetic acid.[5] The synthesis of the β-chlorothiophene derivatives is likewise time-consuming. According to a current method by *Conde*[6] 3-chlorothiophene is obtained by reaction of 3-bromothiophene with CuCl. Treatment of 2,3,4,5-Tetrachlorotetrahydrothiophene with ethanolic potassium hydroxide[7] furnishes approximately equal amounts of 2,4- and 3,4-dichlorothiophene, whereas thermolysis of this chlorothiolane furnishes 2,3- and 2,4-dichlorothiophene.

We have now found that β-halothiophenes can be obtained in good yields in a simple way by isomerization of α-halothiophenes on silicon-rich zeolites.[8]

Zeolites of the pentasil type[9] have proven especially suitable for such syntheses. Depending on the reactivity of the α-halothiophenes, the proton-forms of these zeolites are used in the gas phase or the liquid phase. Thus, 2-chlorothiophene is converted with high selectivity into 3-chlorothiophene on an H-ZSM-5 fixed-bed catalyst at 300–450 °C and atmospheric pressure (Fig. 1). With increasing residence time, the equilibrium amount of 3-chlorothiophene of ca. 85 mol-% is established. The secondary reactions of thiophene and its derivatives normally observed with other acid catalysts, e.g. oligomerization and sulfur-elimination,[10] do not occur; the only by-product formed in any mentionable amount is thiophene.

An analogous selectivity is observed in the isomerizations of 2-bromo- and 2-iodothiophene at 150 and 100 °C, respectively, in the liquid phase.

[*] Dr. H. Litterer, Dr. U. Dettmeier, Dr. K. Eichler, Prof. Dr. K. Kühlein, Dr. E. I. Leupold
Hoechst Aktiengesellschaft
Postfach 800320, D-6230 Frankfurt am Main 80 (FRG)

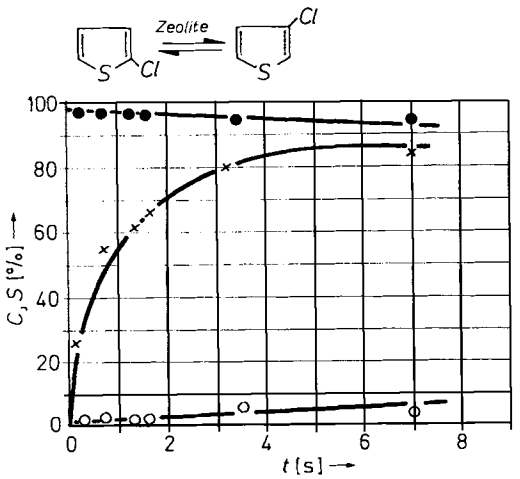

Fig. 1. Isomerization of 2-chlorothiophene with zeolites of the pentasil type [9]. C and S: conversion and selectivity. ×——×: conversion of 2-chlorothiophene; •——•: selectivity for 3-chlorothiophene; o——o: selectivity for thiophene. t = residence time. $T = 350°C$, $p_{tot} = 1$ atm.

Of special importance for carrying out such isomerizations is a well-balanced relationship between catalyst activity and catalyst life. As has been shown in exploratory experiments with a large number of ZSM-5 zeolites with varying aluminum content, ZSM-5 zeolites with ca. 0.5–0.9 wt-% Al are especially suitable for the isomerization of halothiophenes (Fig. 2).

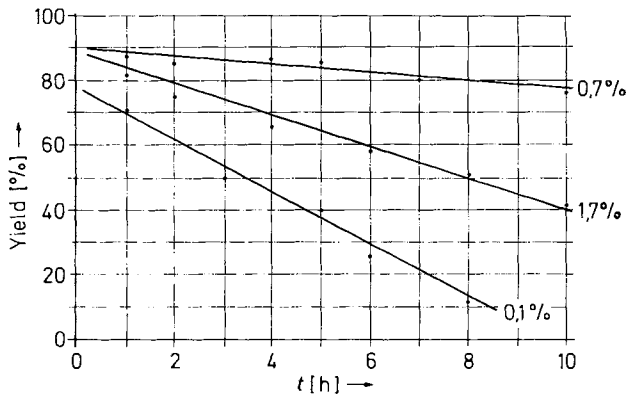

Fig. 2. Relationship of aluminum content and catalyst deactivation in the isomerization of 2- to 3-chlorothiophene. Catalyst: zeolite H-ZSM-5. The numerical data relate to the aluminum content (wt-%). t = duration of isomerization in hours.

By using these zeolites in combination with chlorination steps it has now been possible for the first time to obtain all the dichlorothiophene isomers in good yields via an industrially practicable route (Fig. 3).

A further interesting aspect of this new method is that mixed di- or trihalothiophenes can be isomerized selectively. Thus, the bromine atom in the α-position of 5-bromo-2-chlorothiophene migrates at 180–190°C in the liquid phase to the thermodynamically more favorable β-position with formation of 4-bromo-2-chlorothiophene. The migration of the less reactive chlorine is largely suppressed under these experimental conditions. In the gas phase above 300°C, however, the usual 3 mol-% of 4-bromo-3-chlorothiophene and 5-bromo-3-chlorothiophene increases to about 20 mol-% (Table 1).

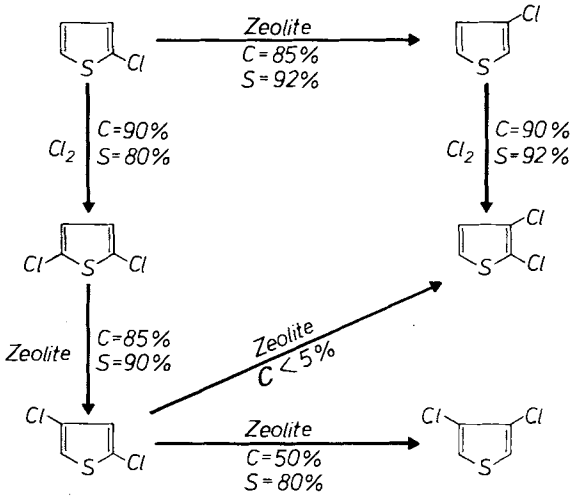

Fig. 3. New synthetic routes to 3-chlorothiophene and the dichlorothiophenes. C, S = conversion and selectivity, respectively.

Table 1. Distribution of the isomeric bromochlorothiophenes and influence of temperature on the conversion of 5-bromo-2-chlorothiophene in the presence of zeolite ZSM-5 containing 0.6 wt-% Al (see text).

T [°C]	5-Br, 2-Cl [%]	4-Br, 2-Cl [%]	4-Br, 3-Cl [%]	5-Br, 3-Cl [%]
190	15	82	2.5	0.5
300	10	70.5	17.3	2.2

The zeolite-catalyzed isomerization method provides a novel entry to a larger number of halothiophenes. The simplicity of the reaction is clearly evident from the following experimental procedure.

Experimental

1500 g of 5-bromo-2-chlorothiophene and 30 g of H-ZSM-5 zeolite powder are transferred to a 2 L four-necked flask fitted with a stirrer, reflux condenser and thermometer and the mixture heated under reflux for 7 h with vigorous stirring. The reaction mixture is then separated from the catalyst. On rectification with an efficient column, 880 g of 4-bromo-2-chlorothiophene (b.p. 192°C) and 590 g of a first fraction consisting of 4-bromo-2-chloro- and 5-bromo-2-chlorothiophene are obtained. The first fraction can be recycled for renewed isomerization.

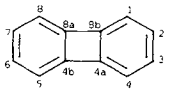
Biphenylenes with Strongly Distorted Trapezoidal Four-Membered Ring**

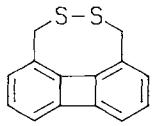
By *Fritz Vögtle,* Klaus Saitmacher, Sigrid Peyerimhoff, Dorothee Hippe, Heinrich Puff,* and *Petra Büllesbach*

The skeleton of biphenylene **1** has hitherto only been described in terms of a four-membered rectangular ring with bond dimensions 151 pm (C4a-C4b) and 143 pm (C4a-C8b).[1] We have now examined how biphenylene might evade any additional strain[2] imposed by attachment of as short as possible a bracket at the 1,8-position.[3] The problem is that distortion becomes all the more extensive and consequential, and the synthesis all the more difficult the shorter the length of the bridge.

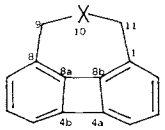
In exploratory experiments we therefore tried to attach a four-membered bridge, which, according to molecular models exhibited little strain,[3] to **1** to give the disulfide **2**, whose new ring ought to contract upon desulfurization.



1



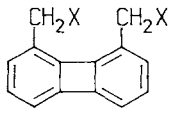
2



3 : X = S

4 : X = SO_2

5 : X = –

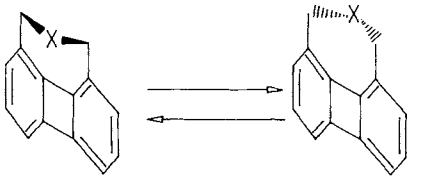


6 : X = Br

7 : X = SH

Reaction of the dibromo compound **6** with thiourea and subsequent oxidation of the dithiol **7** with H_2O_2 suffers from the low stability of **7**. In the mass spectrum of the crude product of the synthesis, however, we surprisingly observed signs of the existence of the monosulfide **3** with a shorter bridge. Studies on molecular models on the other hand, had indicated that **3** was so strained that its direct formation in a single step was not to be expected. Encouraged by the observed formation of **3** as by-product of **2**, we allowed the dibromo compound **6** (or more simply the mixture of 1,8- (**6**) and 1,5-isomer formed in its preparation[3]) to react with sodium sulfide in the presence of Cs_2CO_3 according to the dilution principle.[4] The strained sulfide **3** was obtained in 24% yield. Oxidation with H_2O_2 afforded the sulfone **4** in more than 90% yield.

At room temperature the 90-MHz ^{1}H-NMR spectra of **3** and **4** show a sharp singlet for the CH_2-protons ($\delta = 3.78$ and 4.56, respectively, in $CDCl_3$), which is considerably broadened in the 400-MHz ^{1}H-NMR spectrum of **4**. The CH_2 signals of both compounds split on lowering the temperature to give an AB system ($\Delta\nu = 31$ Hz, $J_{AB} = 17$ Hz and $\Delta\nu = 61$ Hz, $J_{AB} = 16$ Hz, respectively; coalescence temperatures $-34°$ and $-10°$C, respectively). The ring inversion barriers (flip-flopping of the C-S-C group from one side of the biphenylene system to the other; cf. Scheme 1) of **3** and **4** are thus calculated to be 49 and 53 kJ/mol, respectively.[5] The small difference in the barriers of sulfide **3** and sulfone **4** is remarkable considering a possible additional inversion of lone pairs on the sulfide sulfur, which is not possible in the case of sulfone sulfur.



3a **3b** : X = S

4a **4b** : X = SO_2

Scheme 1.

The mass spectrum of the sulfone **4** shows, in addition to the $M^{\oplus}$ peak, a significant $[M^{\oplus} - SO_2]$ peak. This could be an indication of the existence of the extremely strained, hitherto unknown hydrocarbon **5**. We therefore tried to obtain it by photolysis of the sulfide **3** in triethyl phosphite at 230 nm, but neither this reaction nor the pyrolysis of the sulfone **4** at 650°C/10^{-3} torr in a quartz tube afforded the product **5**.

The result of an X-ray structure analysis[6] of the sulfide **3** is reproduced in Figure 1 (an X-ray structure analysis was also carried out on **4**): In both compounds the ring strain gives rise to very different bond lengths in the four-membered ring. In the trapezoidally distorted four-membered ring of **4**, similarly as in the case of **3**, the C8a-C8b bond (144.4 pm) is shortened and the C4a-C4b bond (154.6 pm) is stretched; this bond is thus longer than an isolated single bond. Remarkably, dispite this distortion the entire biphenylene framework remains practically planar. However, the bond angles in the two benzene rings are markedly altered by the bracketing: the ideal angle of 120° for C8b-C1-C2 is reduced to 114.5° in **4** (and even to 113.2° in **3**) and that for C4a-C8b-C1 is increased to 128°.

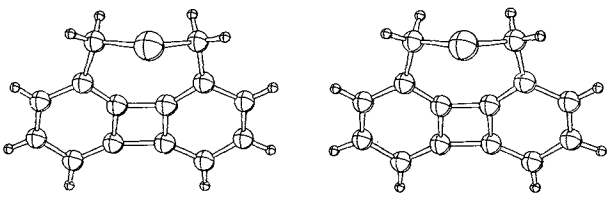


Fig. 1. Crystal structure of **3** (stereodiagram) [6].

The UV spectra of **3** ($\lambda_{max} = 359$, 258 nm; $\varepsilon = 2720$ and 28550, resp.) and **4** ($\lambda_{max} = 363$, 257 nm; $\varepsilon = 1780$ and 15390, resp.) show measurable red shifts and significant decreases in intensity of the long-wave bands (in ethanol)

[**] We thank Dr. *F. Knoch* for carrying out the X-ray structure analysis of **3**.—Thanks are also due to Prof. Dr. *W. Thiel* for supplying us with the computer program MNDOC (correlated semiempirical calculations with geometry optimization). The computations were carried out at the Regionales Hochschulrechenzentrum der Universität Bonn.

compared to biphenylene (λ_{max} = 278, 248 nm)[7] and dimethylbiphenylene (1,5-/1,8-mixture, λ_{max} = 357, 254 nm). This is an indication of perturbation of the π-electron system; analogous perturbations were observed in the transition from naphthalene to 1,8-methanonaphthalene.[8,9]

It has been shown by MNDO calculations[10] that the spatial structure of the molecule **3** is consistent with the results of the X-ray crystal structure analysis. To ensure reaching as near as possible the absolute energy minimum, the structure was optimized in three ways: a) simultaneous optimization of all bond lengths and angles, using approximate standard values for bond lengths and angles as starting values; b) simultaneous optimization of all bond lengths and angles using the structural data determined by an X-ray structure analysis as starting values; c) stepwise optimization, involving successive optimization of the carbon skeleton of the benzene ring, then the sulfur bridge, and then the H atoms, and repeating this procedure in the same succession after each individual optimization. In addition, optimization was begun with a U-shaped biphenylene skeleton, to make certain that the optimization led to a planar carbon skeleton. All three complete optimizations afforded the values listed in Table 1. Good agreement is found between experimental and calculated values.

Table 1. Calculated bond lengths [pm] and angles [°] of **3** and **5** and, for comparison, the values obtained by an X-ray structure analysis of **3** [a].

[a] Deviations between the values calculated: 1 pm and 1-3°, resp.; mean deviations of the experimental values: 1-3 pm and 1-2°, resp.

The hypothetical hydrocarbon skeleton **5** was also calculated in this way (Table 1). A further shortening of the C8a-C8b bond and a further lengthening of the C4a-C4b bond are accompanied by an even greater distortion of the benzene ring (angles between 107 and 139°). According to calculations, the bond between the two "bracket" carbon atoms C9 and C11 is unusually long (161 pm).

If the enthalpy of formation ΔH_0 is used as a measure of the stability (or the ring strain), it follows from the calculated values ΔH_0 = 395 kJ/mol for biphenylene **1**[2] and 431 kJ/mol for **3** that **5** (with 586 kJ/mol) is a considerably less stable system. On the basis of these data it is easy to comprehend that all previous attempts to prepare **5** met without success.

From the calculated atomic charges of the molecules **1**, **3** and **5** it follows that the charge distribution does not essentially alter upon bracketing **1** to give **3**.

3 and **4** are the shortest bracketed biphenylene derivatives known so far. The comparatively slight additional ring strain introduced thereby results in a surprisingly large distortion of the four-membered ring. From the existence of **3** and **4** it can be safely predicted that further three-membered bridged biphenylenes such as **3** (X = O, NR, CR_2) with even higher ring strain and larger distortions could be synthesized.

Experimental

2-Thia[3](1,8)biphenylenophane **3**: A mixture of benzene (1.6 L), ethanol (1.2 L) and cesium carbonate (3.00 g, 9.20 mmol) [4] contained in a 4 L three-necked flask was heated to boiling and treated dropwise and synchronously under N_2 for 13 h with solutions of the 56:44 mixture (formed during the preparation [3]) of 1,8- and 1,5-bis(bromomethyl)biphenylene (2.88 g, 8.59 mmol) [corresponding to ca. 1.60 g (4.80 mmol of pure (**6**)] in benzene (250 mL) and $Na_2S \cdot 9H_2O$ (1.91 g, 8.60 mmol) in ethanol (250 mL). After cooling, the yellow solution was evaporated down and the insoluble cesium compounds removed by filtration through a frit. The crude product was separated by column chromatography (SiO_2, cyclohexane/chloroform). Aside from unchanged starting compound, a dimeric product ($C_{28}H_{20}S_2$) and the disulfide compound **2** could be detected mass spectrometrically. The desired monosulfide **3** (240 mg, 24%) was obtained as yellow crystals, m.p. 142-144°C (from *n*-hexane/chloroform 2:1). — 90-MHz ^{1}H-NMR ($CDCl_3$, TMS int.): δ = 3.78 (s, 4H, CH_2), 6.5-6.7 (m, 6H, aromatic H).

4: M.p. 233°C (from acetone/cyclohexane 1:1); M_r = 242.0402, high resolution MS: 242.0396.

[**] Theory and Application of Photoelectron Spectroscopy, Part 111. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 110: F. Diehl, A. Schweig, *Angew. Chem. 99* (1987) 348; *Angew. Chem. Int. Ed. Engl. 26* (1987) 343.

drocyclobutabenzene **2** have already been the subject of detailed studies.[1,2] The measured data[3] suggest that **1** can be observed together with **2** either thermally at high temperatures in equilibrium [equilibrium constants $K_{581\,°C} = 20.8$ (measured[2,3]) and $K_{800\,°C} \approx 4$ (estimated[4])] or much more efficiently at low temperatures as intermediate after the decomposition of a suitable starting compound in a thermal flow reactor [rate constant (**1**→**2**) $k_{\rightarrow,225\,°C} \approx 3.3\ s^{-1}$; this corresponds to a half-life $t_{1/2}$ of ca. 0.2 s (estimated); reaction time t_R in the reactor, e.g. in combination with a UV photoelectron spectrometer, ca. 0.1 s[5]]. The latter strategy[6,7] made it possible for the first time to measure the photoelectron spectrum of **1**.[6]

In contrast, nothing is known about the analogous equilibrium reaction (b) between 2,3-dimethylene-2,3-dihydrofuran **3** and dihydrocyclobutafuran **4**, apart from the de-

(b)

3 **4**

tection of **3** by trapping reactions, and MS and NMR spectra;[8,9] **4**, in particular, has remained unknown.

According to MNDO calculations, the standard reaction enthalpy $\Delta_r H^{\ominus}$ of the reaction **1**→**2** is -82.8 kJ mol^{-1}, about 24.2 kJ mol^{-1} below the experimental value[3] (mainly a result of the overestimated stability of the closed form **2** compared to the open form **1** by the MNDO method). For the reaction **3**→**4** the MNDO method gives $\Delta_r H^{\ominus} = 75.3$ kJ mol^{-1} and, corrected by the same deviation as for **1**→**2** (-24.2 kJ mol^{-1}), ca. 99.5 kJ mol^{-1}. According to these results the reaction **3**→**4** is about twice as endothermic as the reaction **1**→**2** is exothermic. The standard reaction entropy $\Delta_r S^{\ominus}$ of the reaction **1**→**2** is negative[3] (ring closure unfavorable). Using the same value for the similar reaction **3**→**4** leads to an estimated value of ca. 10^{-13} at 200 °C to 10^{-7} at 800 °C for the equilibrium constant of this unknown gas-phase reaction. It thus follows from these data that it can hardly be possible to observe the thermodynamically "unfavorable" compound **4** in equilibrium with **3** at high temperatures in the same way as the thermodynamically "unfavorable" compound **1** in the equilibrium **1**⇄**2**.

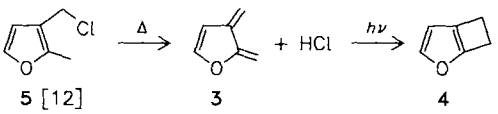
1 could be generated thermally and observed as an adequately long-lived intermediate for the following gas-phase secondary reaction

suitable starting compound → **1** → **2**

after completion of the first step in a thermal flow reactor at low temperature. An analogous procedure for the generation of **4** is less likely to succeed, since the reaction **4**→**3** will probably be much more rapid than the reaction **1**→**2** (pre-exponential factor A presumably of the same order of magnitude as for the reaction **2**→**1**,[3] activation energy E_a presumably lower than for the reaction **1**→**2**[3]), the ratio of the rates of forward and reverse reaction for (b) is much more unfavorable than for (a) [$k_{4\rightarrow3}/k_{4\leftarrow3} \approx 10^{13}$ for (b) at 200 °C, $k_{1\rightarrow2}/k_{1\leftarrow2} \approx 10^{4}$ for (a) at a comparable temperature], and, not least, since a suitable starting compound, i.e. one which first reacts to give **4** and only then to give **3**, is not in the offing.

For these reasons, dihydrocyclobutafuran—other than dihydrocyclobutabenzene—can very probably not be generated thermally. This is consistent with the hitherto unsuccessful attempts[9,11] to obtain **4** thermally.

We have therefore explored a photochemical route [eq. (c)]. The first (thermal) reaction step, unlike in other methods already described in the literature,[8,9a] proceeds without formation of interfering by-products and is quantitative at pressures in the region of ca. 10^{-2} mbar.[13] The subsequent ring closure reaction **3**→**4** was then accomplished photochemically in the consensed phase (argon-matrix).



(c)

5 [12] **3** **4**

First of all, the reaction **5**→**3** was carried out in a thermal flow reactor,[13] which was installed as close as possible to the ionizing region of a UV photoelectron spectrometer. As a result of a product optimization under the conditions dictated by the photoelectron spectrometer, only **3** as well as HCl can be detected photoelectron spectroscopically, even at 550 °C (Fig. 1). The structure of **3** is substantiated by comparison with the photoelectron spectrum of **1**[6] and by comparison of the measured ionization energies with those calculated by the MNDO[10]-PERTCI,[14] CNDO/S[15]-PERTCI, LNDO/S[16]-PERTCI (Fig. 1b), and HAM/3[17] methods. Especially characteristic is the band system of reduced intensity in the region of 10–11.5 eV as a result of an unusually strong interaction of two Koopmans configurations via the HOMO-LUMO configuration (cf. Ref. [6]). The PE spectrum (Fig. 1a) remains unchanged, even at very high pyrolysis temperatures. Thus, in contrast to **1**, **3** proves to be a thermally very stable compound showing no tendency to undergo a thermally induced ring-closure reaction in the gas phase [according to the photoelectron spectra[18] of 2,3-dimethylfuran and 4,5,6,7-tetrahydrobenzofuran as well as the calculated ionization energies (Fig. 1c), the photoelectron spectrum of **4** should differ considerably from the photoelectron spectrum of **3**].

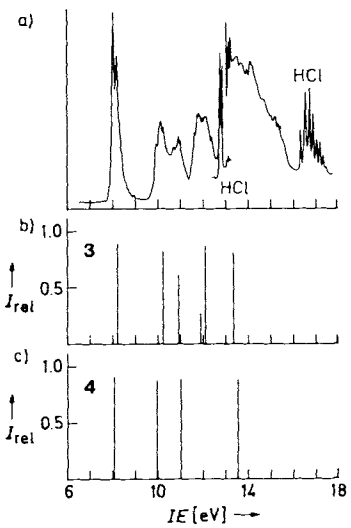


Fig. 1. a) HeI photoelectron spectrum (count rate vs ionization energy IE [eV]) of **3**; for the first three bands: assignment, measured vertical ionization energies [eV]: $^2A''(\pi)$, 8.00 (vibrational structure: $\Delta\tilde{\nu} = 1450 \pm 150$ cm^{-1}); $^2A''(\pi)$, 10.09, $^2A''(\pi)$, 10.93. b) LNDO/S-PERTCI ionization spectrum of **3** (relative intensity I_{rel} vs IE [eV]): for the first six ionizations: assignment, calculated vertical IE [eV] (I_{rel}): $^2A''(\pi)$, 8.21 (0.89); $^2A''(\pi)$, 10.23 (0.82); $^2A''(\pi)$, 10.92 (0.61); $^2A''(\pi)$, 11.89 (0.27); $^2A'(\sigma)$, 12.04 (0.87); $^2A'(\sigma)$, 13.35 (0.86). c) LNDO/S-PERTCI ionization spectrum of **4**; for the first four ionizations: $^2A(\pi)$, 8.07 (0.91); $^2A(\pi)$, 9.96 (0.88); $^2A(\sigma)$, 11.02 (0.89); $^2A(\sigma)$, 13.54 (0.89).

The reaction **5** → **3** was then carried out at the same temperature (optimized at the photoelectron spectrometer), but at a lower pressure (by about a power of ten as a result of the experimental set-up) in a reactor of the same construction,[13] which was installed as close as possible to the matrix carrier of a low-temperature cryostat. The gaseous reaction mixture was condensed together with a large excess of argon onto a NaCl-carrier at 16 K. Figure 2a shows the low-temperature IR spectrum of the reaction mixture in the solid solution (argon matrix) thus prepared, while Figure 2c shows the UV/VIS absorption spectrum of the same low-temperature matrix. From Figure 2a it can be seen that **5** does not react completely to give **3** under the reaction conditions. However, this is of no importance for the investigation described here. The UV/VIS spectrum (Fig. 2c) with a well-resolved vibrational structure of the long-wave band at $\lambda = 318$ nm is unequivocally shown, by its similarity with the UV/VIS absorption spectrum of **1**[19] and by the agreement with calculated CNDO/S-SECI,[15] LNDO/S-PERTCI and HAM/3 excitation energies (Fig. 2c) and oscillator strengths, to be the (previously unknown) spectrum of **3**.

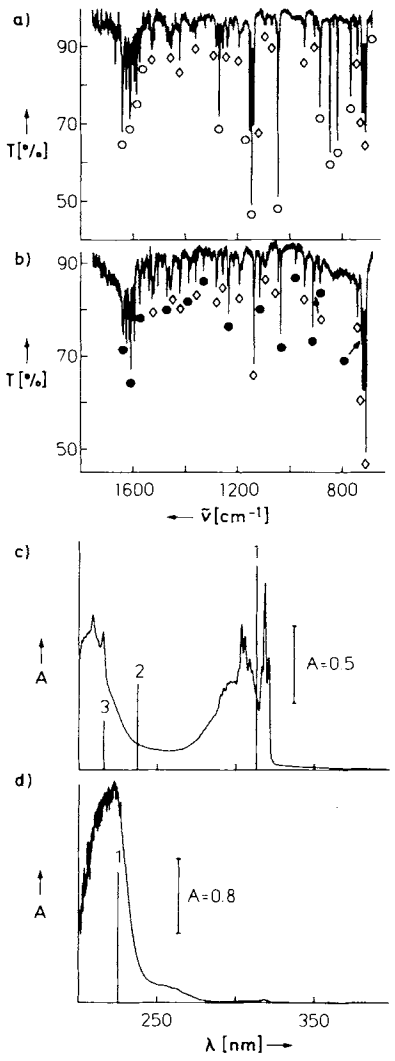

Fig. 2. a) IR spectrum (background subtracted) of the reaction mixture in argon matrix at 16 K after pyrolysis of 2-methyl-3-chloromethylfuran in a thermal reactor, T = transmission; bands of **5** and **3** are indicated by ◇ and ○, respectively; the five most intense absorptions ($\tilde{\nu}$ [cm^{-1}]) of **5**: 1421.6 (m), 1137.2 (s), 723.0 (vs), 717.4 (vs), 709.8 (vs); of **3**: 1639.6 (s), 1145.6 (vs), 1044.8 (vs), 845.6(s), 816.8 (s). b) IR spectrum (background subtracted) of the matrix of a) irradiated with UV-light of wavelength $\lambda = 300$ nm with the five most intense bands of **4** (indicated by ●): 1608.8 (s), 1234.2 (s), 1115.4 (m), 1034.6 (s), 912.4 (s). c) UV/VIS absorption spectrum (background subtracted) of the reaction mixture isolated as described in a) and HAM/3 electron excitation spectrum of **3**, A = absorbance; wavelength [nm] (oscillator strength): 1: 313.2 (0.661); 2: 237.4 (0.282); 3: 216.0 (0.163). d) UV/VIS absorption spectrum (background subtracted of the matrix of b) (i.e. after irradiation) and HAM/3 electron excitation spectrum of **4**: 1: 225.3 (0.357).

If the argon matrix containing **3** is irradiated with UV-light of wavelength $\lambda = 300$ nm for 13.5 h,[13] the absorption bands in the IR spectrum of **3** completely disappear (Fig. 2b), and the band system located at $\lambda = 318$ nm in the UV/VIS spectrum of **3** is likewise no longer observed (Fig. 2d). The new spectra unambiguously identify **4** as photoproduct: The IR spectrum (Fig. 2b) is in full agreement with the theoretical spectrum of **4** calculated according to the AM1 method,[20] both as far as the number of observed IR bands as well as their frequency and intensity are concerned. The new UV/VIS absorption band at $\lambda = 223$ nm (Fig. 2d) is best interpreted by the results of theoretical studies as a HOMO-LUMO($\pi \rightarrow \pi^*$) excitation of **4**. Moreover, the UV/VIS spectrum of **4** excellently agrees with the spectra of other 2,3-alkyl-substituted furans, whose longest wave $\pi \rightarrow \pi^*$ transition is observed at $\lambda \approx 220$ nm.[21]

The results impressively show how a thermodynamically unfavorable (because of restricted mobility, high ring strain, and lack of resonance stability) and thus thermally inaccessible compound can be generated photochemically from its thermodynamically more favorable isomeric form.

First Examples of Complexes Containing η^1-Bonded Phosphaalkynes—Synthesis and Crystal and Molecular Structure of *trans*-[Mo(AdC≡P)$_2$(Et$_2$PCH$_2$CH$_2$PEt$_2$)$_2$] (Ad = adamantyl)**

By *Peter B. Hitchcock, Mohd Jamil Maah, John F. Nixon,* Jalal A. Zora, G. Jeffery Leigh,* and *Mohamad Abu Bakar*

In a series of papers[1-2] we have described the wide variety of ligating behavior exhibited by phosphaalkynes RC≡P (R = *t*Bu or adamantyl (Ad)). UV photoelectron spectroscopic studies on RC≡P (R = H, F, Me, Ph, or *t*Bu) establish that the HOMO is of the π-type with the orbital of the lone pair on the P atom significantly lower in energy. It is therefore not surprising that only η^2-type coordination has hitherto been found for the coordination of phosphaalkynes to transition metals.[3] We had previously[2a] attempted to facilitate η^1-coordination of a phosphaalkyne to a metal by treating [Pt(triphos)(PPh$_3$)] (triphos = (Ph$_2$PCH$_2$)$_3$CMe) with *t*BuC≡P but obtained instead the η^2-phosphaalkyne complex **1** (Scheme 1).

We now report the synthesis of **2**–**7**, the first η^1-phosphaalkyne complexes (Scheme 2). They are readily obtained by displacement of dinitrogen from appropriate *trans*-[M(N$_2$)$_2$(R$'_2$PCH$_2$CH$_2$PR$'_2$)$_2$] (M = Mo or W) complexes[4,5] (Scheme 2).

	M	R	R'

4	Mo	*t*Bu	Ph
5	Mo	*t*Bu	*p*-Tolyl
6	Mo	Ad	Et
7	W	*t*Bu	Ph

Scheme 2.

2

3-7

The formulation of complexes **2**–**7** is supported by their solution $^{31}P\{^1H\}$-NMR spectra which give typical patterns expected for [AA'BB'X] or [A$_4$X$_2$] spin systems,[6] and the magnitude of $^2J_{PMP'}$ is typical for this type of pseudooctahedral MP$_6$-complex (P = phosphorus ligand). Much smaller values of $^2J_{PMP'}$ would be expected for an η^2-bonded phosphaalkyne complex.

Confirmation of the proposed η^1-bonding mode comes from a single crystal X-ray diffraction study on **6**;[7] the molecular structure is shown in Figure 1. As expected, the complex contains the linear seven-atom CCPMoPCC framework involving the two *trans*-η^1-coordinated phosphaalkynes. Other features of interest in **6** are:

1) The short Mo–P$_{alkyne}$ distance (2.305(3) Å) compared with the Mo–P$_{phosphane}$ length (ca. 2.433(4) Å), reflecting the smaller sp radius of phosphorus (0.94 Å) compared with the sp^3 radius (1.07 Å).
2) The short P≡C bond distance (1.520(12) Å) compared with an average value of 1.540(4) Å observed in the free RC≡P ligands (R = H, F, Me, or *t*Bu)[8] and 1.672(17) Å in the η^2-complex [Pt(PPh$_3$)$_2$(*t*BuC≡P)].[2b]
3) The metal-phosphorus network exploited here is such that only ligands which are long and thin can approach the metal to bind in the axial position. Examples include N$_2$, CO, and MeNC. The network is also particularly robust, and consequently side-on coordination of AdC≡P is excluded on steric grounds.

Studies to investigate whether the P≡C bonds in **6** will undergo further η^2-interaction with other metals are underway.

Experimental

An evacuated sealed tube containing a mixture of $[Mo(N_2)_2(Et_2PCH_2CH_2PEt_2)_2]$, (0.0436 g, 0.082 mmol), and AdC≡P, (0.0292 g, 0.164 mmol), in dry degassed toluene was slowly warmed from −196 °C to room temperature. After agitating the solution with ultrasound for 8 h the color changed from yellow to deep-red and on standing dark red crystals of **6** formed (yield 0.067 g, 94%; satisfactory elemental analysis).

Photooxidation of 2,5-Dimethyl-2,3,4-hexatriene—Matrix Isolation of a Trisdioxetane**

By *Wolfram Sander** and *Andreas Patyk*

Photooxidations of reactive double bonds via singlet oxygen to give dioxetanes or ene-type products are well known,[1] but evidence for the direct photoreaction of olefins with triplet oxygen is still rare.[2] Although most unsaturated compounds are only slowly oxidized when exposed to air and light (autoxidation), some cumulenes are extremely reactive. For example 2,5-dimethyl-2,3,4-hexatriene (tetramethylbutatriene **1**) is reported to react rapidly to form an oxygen containing polymer if exposed to air.[3] We therefore used **1** as a model to study the photooxidation of reactive olefins. To investigate the primary reaction steps and to avoid radical chain and other intermolecular reactions, all operations were carried out at cryogenic temperatures (10–40 K) in oxygen/argon matrices.

1,[4] matrix-isolated in Ar at 10 K, showed two UV absorptions at $\lambda=256$ and 278 nm and no absorption in the visible part of the spectrum. Prolonged irradiation of the argon matrix with a mercury arc lamp and quartz optics ($\lambda>230$ nm) did not give any photoproducts observable in the UV/VIS or IR spectra.

In O_2-containing matrices (1–100% O_2), oxidation products were readily formed even on visible light irradiation (interference filter, $\lambda=543\pm10$ nm). The UV/VIS spectrum of **1** in solid O_2 showed a broad maximum at $\lambda\approx250$ nm with a long tail extending into the visible region. The photooxidation of **1** at $\lambda=543$ nm can be explained either by the excitation of a contact charge-transfer (CCT) complex $^3[\mathbf{1}^{\oplus}\cdots O_2^{\ominus}]$[2b] or by the direct excitation of a singlet-triplet transition of **1**.[5] These transitions are weakly allowed in O_2 matrices by the magnetic perturbation of triplet O_2.[5] Direct singlet-triplet transitions of organic compounds in solid O_2 have been spectroscopically observed at very high compound/O_2 ratios (>1/

10).[5] For matrix isolation, a ratio $< 1/500$ is necessary; thus it was not possible to observe these transitions spectroscopically. A similar photooxidation of an olefin (2,3-dimethyl-2-butene) by visible light irradiation in solid O_2 was reported recently and was explained by excitation of a CCT complex.[2b]

The products formed in the photooxidation of **1** depended on the O_2 content of the matrix and on the wavelength used for irradiation. At O_2 concentrations between 10% and 100%, 543-nm irradiation led to a single photoproduct **4** almost exclusively (Fig. 1). **4** was very labile and fragmented to acetone and CO_2 upon irradiation (slowly at $\lambda > 500$ nm and rapidly at $\lambda > 300$ nm) or by warming the matrix from 10 K to 45 K and evaporating the argon (see Scheme 1).

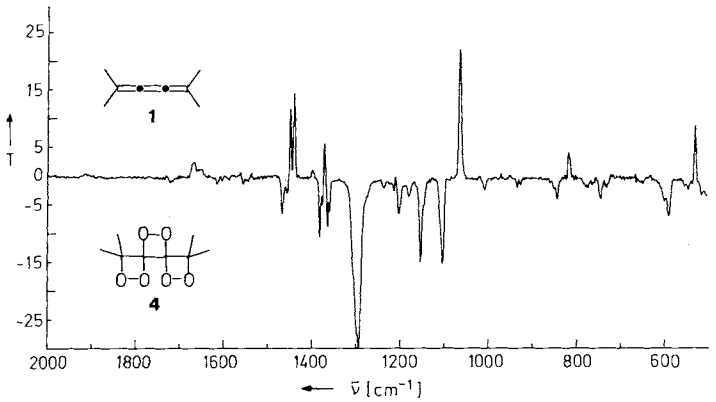

Fig. 1. Difference IR spectrum of the photooxidation of **1** in Ar/O_2 (20% O_2) at 10 K. The matrix was irradiated with the 543-nm Hg line (interference filter, Osram HBO 200W high-pressure mercury arc lamp). Top: IR-bands of **1** vanishing after irradiation. Bottom: newly occurring bands of the trisdioxetane **4**. T = transmission.

The most intense band in the IR spectrum of **4** (Fig. 1) was a broad band at $\tilde{\nu} = 1292\ cm^{-1}$.[6] This band showed an isotopic shift of approximately 2-5 cm^{-1} if the experiments were repeated in $^{18}O_2/Ar$ matrices.[7] The frequency of the band and the magnitude of the isotopic shift is typical for C-O stretching vibrations.[8] Other bands exhibiting pronounced isotopic shifts were found at $\tilde{\nu} = 1154\ cm^{-1}$ (20 cm^{-1} shift) and 1103 cm^{-1} (48 cm^{-1} shift). The latter band can be assigned to an O-C-O stretching vibration of the skeleton of **4**.[9] No bands were found in the carbonyl- (1650-1800 cm^{-1}) or cumulene- (1800-2200 cm^{-1}) regions of the spectrum.

On the basis of the observed fragmentation pattern and the IR data, we conclude that compound **4** has the structure of a trisdioxetane.[10] More evidence for this assignment came from the observation of the isotopic pattern in the CO_2 formed by the fragmentation of partially ^{18}O-labeled **4**. If a 1:1 mixture of $^{16}O_2$ and $^{18}O_2$ in argon was used to generate **4**, $C^{16}O_2$, $C^{16}O^{18}O$ and $C^{18}O_2$ were formed in a 1:2:1 ratio after short-wavelength irradiation ($\lambda > 300$ nm). This proves that the oxygen atoms in CO_2 come from two different O_2 molecules. Other possible products of the fragmentation of the trisdioxetane **4** such as peroxylactones[12] can be excluded by the IR data.

Attempts to observe chemiluminescence during the thermal fragmentation of **4** failed. In control experiments with various ketones, it was found that the high O_2 content (> 5%), required to generate **4** was sufficient to quench completely the phosphorescence of the ketones.

At lower O_2 concentrations (1-10%) a second photoproduct was formed on long-wavelength irradiation (slowly at $\lambda = 543$ nm and rapidly at $\lambda > 500$ nm). This photoproduct showed a very intense IR band at $\tilde{\nu} = 2100\ cm^{-1}$ and was identified as methyl-1,2-butadien-1-one (dimethylpropadienone **6**) by comparison with an authentic matrix-isolated sample.[13] The most likely precursor of **6** is dioxetane **2** (Scheme 1). This dioxetane, with a vinylidene side chain, is expected to show an allene band in the IR at $\tilde{\nu} \approx 1900\ cm^{-1}$ which was not observed under any conditions used in our experiments. Short-wavelength irradiation ($\lambda >$ 300 nm) of **6** gave CO, traces of carbon suboxide, and other, unidentified photooxidation products. Dimethylketene, the expected final product of the fragmentation of the isomeric dioxetane **5**, was not observed. From that we conclude that the first O_2 molecule attacks a terminal double bond in **1** to give **2** rather than the central double bond to give **5** (Scheme 1).

The second O_2 molecule can attack **2** either at the double bond adjacent to the dioxetane ring or at the terminal double bond. In the first case, a bisdioxetane is formed, which should fragment to acetone, CO_2, and to dimethylketene (which was not found). In the latter case bisdioxetane **3** is formed which should fragment to acetone and CO (Scheme 1). The only hint for the formation of **3** came from the observation of small amounts of CO upon short-wavelength irradiation ($\lambda > 300$ nm) under conditions (> 10% O_2) where only traces of **6** were formed. Although **3** is a likely source of CO, it was not possible to identify it spectroscopically in the presence of a large excess of **4**.

Interestingly, even prolonged irradiation ($\lambda > 500$ nm) in pure O_2 matrices did not lead to complete consumption of **1**. After a fast initial reaction step (ca. 30 min), the rate of photooxidation slowed down and finally stopped after several hours. Annealing the matrix at 40 K and cooling back to 10 K led to further photoreactivity. This shows that the formation of dioxetanes **2**, **3**, or **4** requires a well-defined orientation of O_2 molecules relative to **1**.

[5] A. J. Rest, K. Salisbury, J. R. Sodeau, *J. Chem. Soc. Faraday Trans. 2* (1977) 265, 1396.
[6] Infrared spectra were recorded on an Perkin Elmer PE580 spectrometer. The resolution was generally 1.7 cm^{-1}. Some bands assigned to **4** showed matrix effects up to $\Delta\tilde{\nu} = 5\ cm^{-1}$ on changing from 5% to 100% O_2. On annealing the matrix at 40 K and recooling to 10 K, the broad band at 1293 cm^{-3} was split into two bands at 1304 and 1291 cm^{-1}. This can be explained best by a thermal reorientation of the matrix cage to give the thermodynamically most stable arrangement. **4**: IR (90% Ar, 10% O_2, 10 K): $\tilde{\nu}$ [cm^{-1}] = 2998 s, 1468 m, 1383 m, 1293 s, 1154 m, 1110 m, 1103 m, 746 w, 589 w, 547 w.
[7] [^{18}O]-**4**: IR (90% Ar, 10% $^{18}O_2$, 10 K): $\tilde{\nu}$ [cm^{-1}] = 2998 s, 1462 m, 1380 m, 1289 br s, 1134 m, 1055 m, 718 w, 580 w.
[8] S. Pinchas, I. Laulicht: *Infrared Spectra of Labelled Compounds*, Academic Press, New York 1971, p. 238 ff.
[9] The assignment of the band at $\tilde{\nu} = 1103\ cm^{-1}$ to an acetal group is based on the following considerations: The large isotopic shift of 48 cm^{-1} can only be explained if at least two ^{18}O atoms are involved in this vibration (maximum $\Delta\tilde{\nu}$ for a diatomic C-O oscillator at 1103 cm^{-1}: 27 cm^{-1}). Acetals show a series of strong absorptions in the region 1070-1190 cm^{-1}: E. D. Bergman, S. Pinchas, *Recl. Trav. Chim. Pays-Bas 71* (1952) 161.

[10] Three stereoisomers are possible for **4**: two enantiomers with C_2 symmetry and one isomer with C_s symmetry. Owing to nonbonding interactions of two methyl groups, the C_s isomer is calculated by the MNDO [11] method to be 8 kcal/mol less stable than the C_2 isomer.

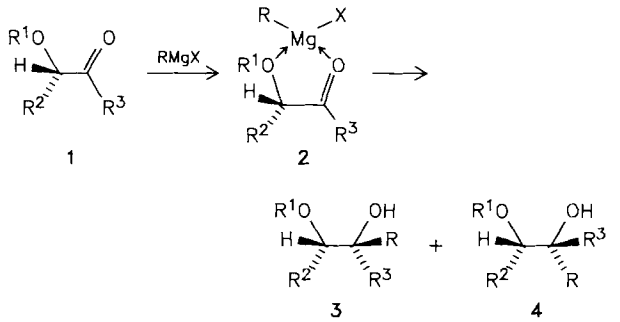
The First Direct Evidence for a Cram Chelate**

By *Manfred T. Reetz,* Michael Hüllmann,* and *Thomas Seitz*

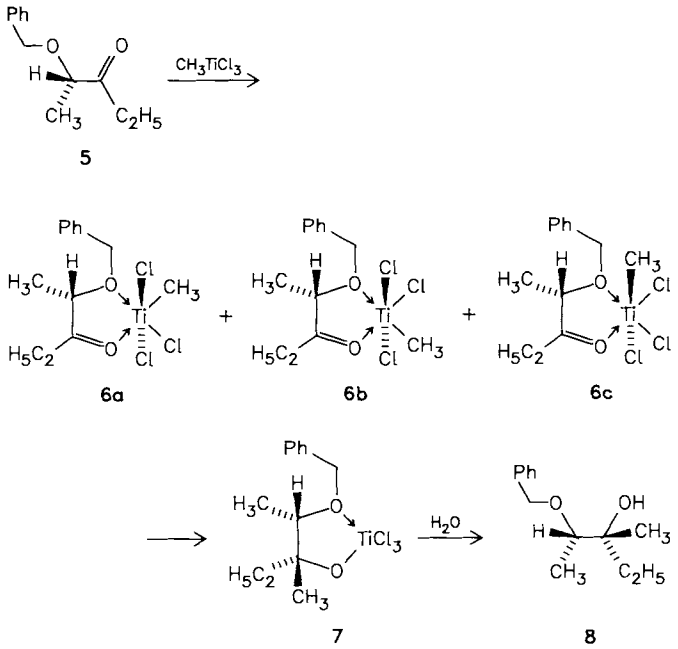
The reaction of alkyllithium and Grignard reagents with α-chiral α-alkoxyketones **1**, first investigated systematically by *Cram*, preferentially affords the "chelation controlled" diastereomer **3**.[1,2] Since the more reactive α-alkoxyaldehydes usually react unselectively,[2] other organometallic reagents were examined, of which Lewis acidic and/or chelate-forming titanium compounds such as CH_3TiCl_3 lead to excellent diastereoselectivities.[3] *Cram*'s postulate that short-lived chelates of type **2** are formed and react preferentially at the sterically less hindered side



has been used as a model for 30 years.[3] However, it is based solely on the stereochemical outcome of the CC coupling.

We now report on the first direct evidence for an intermediate Cram chelate. When CH_3TiCl_3 or the more reactive reagents CH_3MgCl and CH_3Li are allowed to react with the ketone **5**, the sole product is the "chelation controlled" diastereomer **8**.[4] In the case of the monomeric organotitanium compound CH_3TiCl_3[5] we were able to monitor the reaction at −45 °C in CD_2Cl_2 by ^{13}C-NMR spectroscopy.

The spectrum recorded immediately after addition of CH_3TiCl_3 to the ketone **5** (Fig. 1) shows two signals in the carbonyl region at $\delta = 225.1$ and 225.9 in the ratio 60 : 40.[6] This means a downfield shift of about 11 ppm relative to the noncomplexed ketone **5** ($\delta = 214.2$) and corresponds to the change that is observed on complexation with $TiCl_4$ ($\delta = 227.4$).[7] A double set of signals is also observed in the other part of the ligand system (some signals overlap): $\delta = 7.5$ (slight splitting recognizable in the original spectrum; methyl group of the ethyl moiety), 15.0, 16.1, 32.4, 32.5, 75.1, 81.0, 82.4, 89.0 (arene signals appear in the δ-range 129–133). The complexation of the ether function



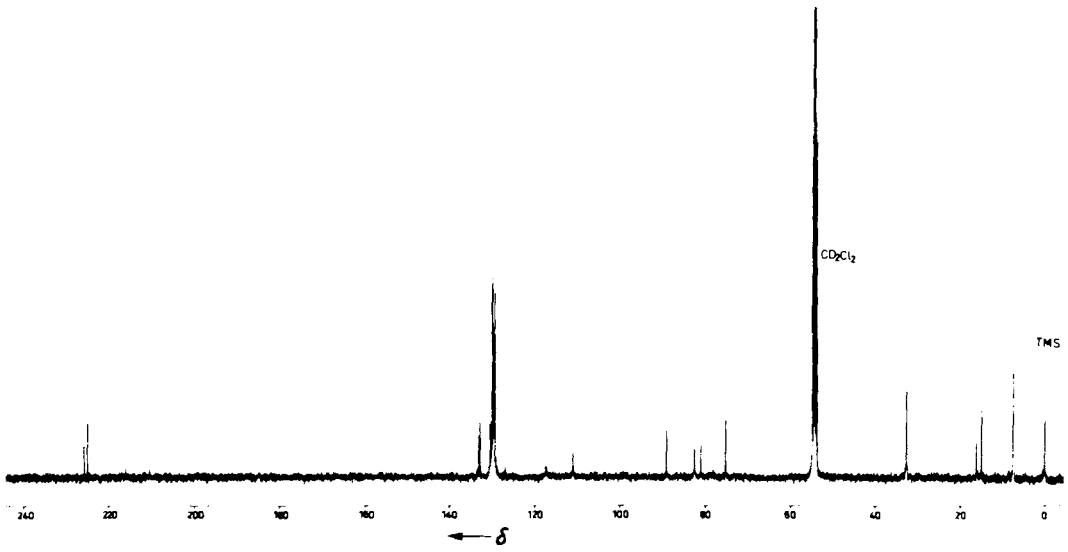


Fig. 1. ^{13}C-NMR spectrum of the freshly prepared reaction mixture CH_3TiCl_3/**5** (400 MHz instrument, −45 °C, CD_2Cl_2, after 30 min).

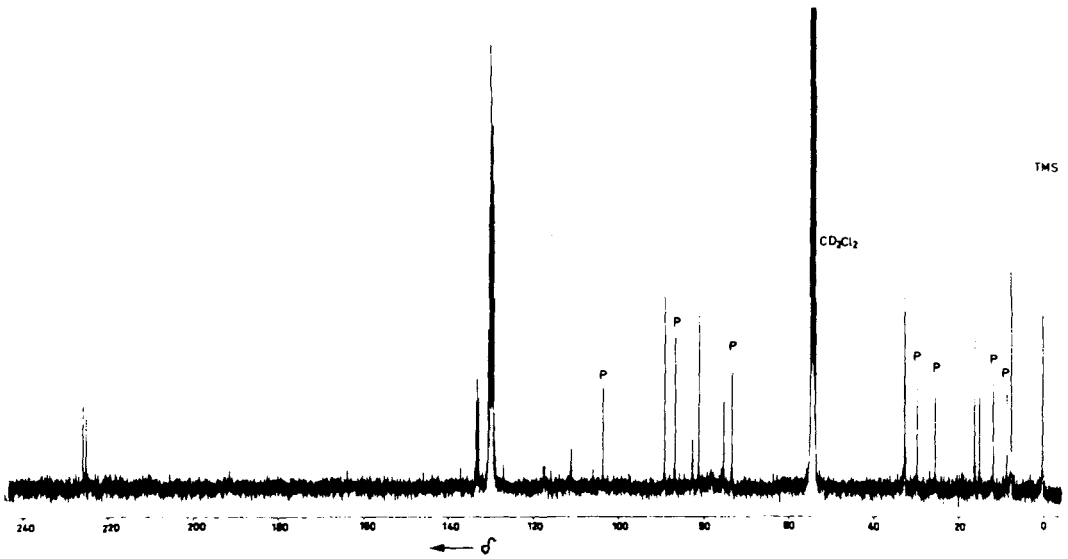

Fig. 2. ^{13}C-NMR spectrum of the reaction mixture CH_3TiCl_3/**5** after 1 h. Conditions: see Fig. 1.

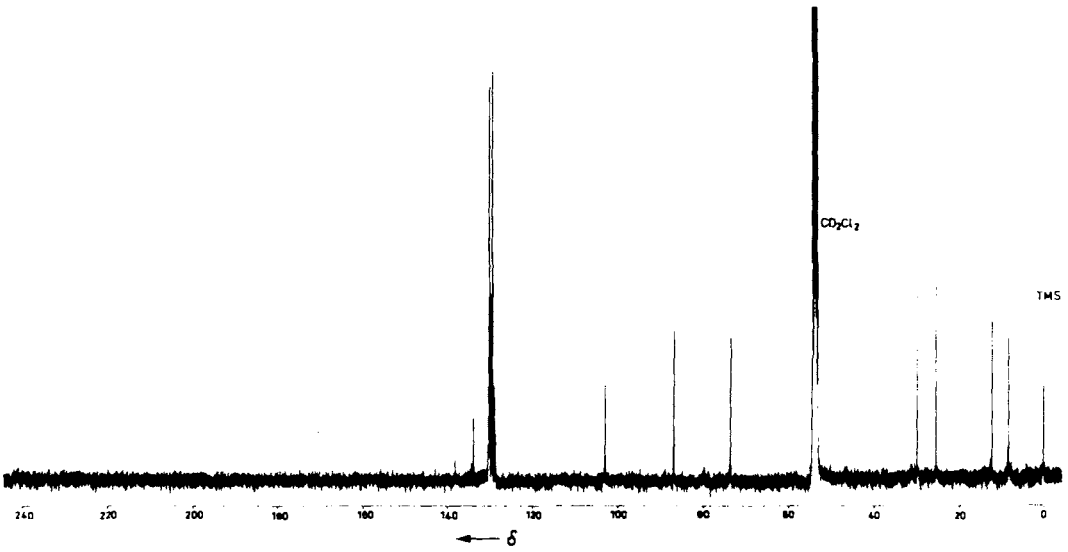

Fig. 3. ^{13}C-NMR spectrum of the reaction mixture CH_3TiCl_3/**5** after 4 h. Conditions: see Fig. 1.

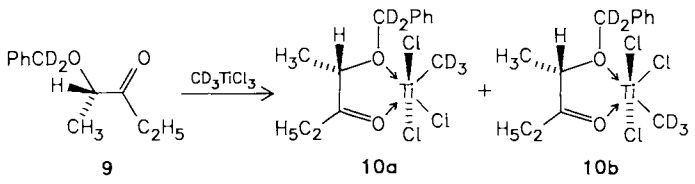

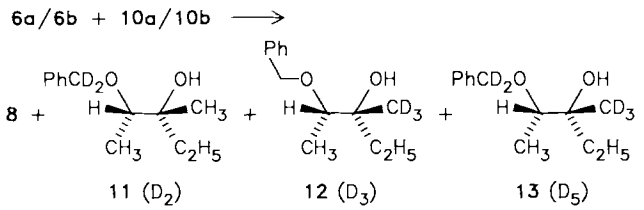

ligand exchange reactions between **6a/6b** and **10a/10b** are conceivable, which would simulate an intermolecular CC bond formation.

To check this ambiguity, kinetic experiments were performed. In the case of a purely intramolecular CC coupling step **6a/6b** → **7** a first order reaction with respect to the complex is expected, whereas in case of an intermolecular reaction, second order kinetics should pertain. Experimentally, we observed the latter ($k = 3.29 \times 10^{-3}$ L mol^{-1} s^{-1} at -15 °C). Hence an intramolecular methyl transfer can be ruled out.

Our investigations thus show[13] that *Cram*'s chelate model has a real basis and that a seemingly simple and stereochemically clean reaction can proceed in a complex manner (multistep).

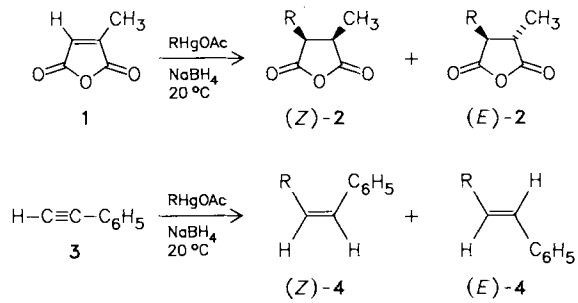
[5] Distilled CH_3TiCl_3 was used. Review of organotitanium reagents in organic synthesis: M. T. Reetz: *Organotitanium Reagents in Organic Synthesis*, Springer, Berlin 1986.
[6] Racemic **5** was used; only one enantiomer is shown.—When CH_3TiCl_3 is mixed with **5** at -78 °C virtually only the diastereomer with the carbonyl absorption at higher field is formed in a kinetically controlled reaction. On warming to -45 °C, isomerization to give a mixture of the diastereomers takes place first, followed by CC coupling.
[7] Chiral α- and β-alkoxycarbonyl compounds react with $TiCl_4$ to give characteristic 1 : 1 complexes, which have been investigated ^{1}H- and ^{13}C-NMR spectroscopically: M. T. Reetz, K. Kesseler, S. Schmidtberger, B. Wenderoth, R. Steinbach, *Angew. Chem.* *95* (1983) 1007; *Angew. Chem. Int. Ed. Engl.* *22* (1983) 989; *Angew. Chem. Suppl.* *1983*, 1511; G. E. Keck, S. Castellino, *J. Am. Chem. Soc.* *108* (1986) 3847; K. Kesseler, *Dissertation*, Universität Marburg 1986; see also [5].
[8] R. J. H. Clark, A. J. McAlees, *Inorg. Chem.* *11* (1972) 342.
[9] J. Dawoodi, M. L. H. Green, V. S. B. Mtetwa, K. Prout, *J. Chem. Soc. Chem. Commun.* *1982*, 1410.
[10] In contrast, the position of the benzyl groups (arrangement around the oxygen of the ether function) is unclear; NOE experiments do not allow any reliable conclusions to be drawn.
[11] Some additional but very weak signals are observed in the original spectrum; they probably arise from a product of ether cleavage. The titanium alkoxide **7** is likely to have the chelate structure shown, since the ^{13}C-NMR signals of the α,α'-C-atoms of the ether function are shifted markedly downfield compared to the absorptions of the titanium-free product (M. Hüllmann, *Dissertation*, Universität Marburg 1986). Normal titanium alkoxides of the type $ROTiCl_3$ are monomeric compounds which do not display any additional coordination: R. L. Martin, G. Winter, *J. Chem. Soc.* *1961*, 2947.
[12] After 2 h reaction time the ratio of the unreacted diastereomeric complexes is 27 : 73 in favor of the compound with the carbonyl signal at $\delta = 225.9$.
[13] We have also been able to monitor the reaction described here by ^{1}H-NMR spectroscopy: M. Hüllmann, *Dissertation*, Universität Marburg 1986.

Influence of H-Donor and Temperature on the Stereoselectivity of Radical Reactions**

By *Bernd Giese*,* *Juan Antonio González-Gómez*, *Stephen Lachhein*, and *Jürgen O. Metzger**

Radical reactions are finding increasing use in organic synthesis, whereby a knowledge of the reactivities and selectivities is of decisive importance. Stereoselectivity plays a crucial role, for it is dependent not so much on the product stability but rather on the shielding of the radical center because of the early transition states of rapid radical reactions. This is important in the case of H-abstraction reactions because the transfer of the small H-atoms from the less shielded side leads to the thermodynamically less stable product. Thus the addition of alkyl radicals to methylmaleic anhydride **1** and to phenylacetylene **3** in the subsequent H-abstraction step by cyclohexylmercury hydride preferentially affords the isomers (*Z*)-**2** and (*Z*)-**4**, respectively, whereby the selectivity increases with increasing size of the substituent R.[2]



R	**a** *n*-C_6H_{13}	**b** *c*-C_6H_{11}	**c** *t*-C_4H_9
(*Z*)-**2** : (*E*)-**2**	62 : 38	89 : 11	94 : 6
(*Z*)-**4** : (*E*)-**4**		74 : 26	97 : 3

In the case of the π-vinyl radical **5b**,[3] formed by addition of cyclohexyl radicals to phenylacetylene, we have now observed that the (*Z*)/(*E*) ratio can also be influenced, and even reversed, by variation of the H-donor and the reaction temperature. Measurements between -20 °C and 260 °C show that (*Z*)-**4b** is formed with less activation enthalpy then (*E*)-**4b** (Table 1).

The approach of the H-donor from the *anti* side of the vinyl radical **5b** (away from the cyclohexyl group), for instance, requires less activation enthalpy than the attack from the *syn* side. The energy difference $\Delta H^{\neq}$((*E*)-**4b**) $-$ $\Delta H^{\neq}$((*Z*)-**4b**) thereby increases with decreasing

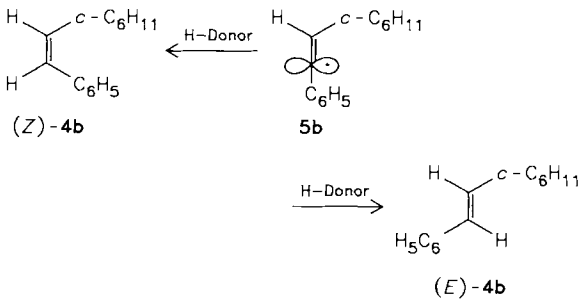
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Table 1. Activation parameters for the stereoselectivity of H-transfer to the vinyl radical **5b**.

H-Donor	$\Delta H^{\neq}((E)\text{-}\mathbf{4b}) - \Delta H^{\neq}((Z)\text{-}\mathbf{4b})$ [kJ/mol]	$\Delta S^{\neq}((E)\text{-}\mathbf{4b}) - \Delta S^{\neq}((Z)\text{-}\mathbf{4b})$ [J mol^{-1} K^{-1}]	Temperature [°C]
c-C_6H_{11}HgH	2.5 ± 0.2	1.2 ± 0.5	−20–80
Bu_3SnH	4.6 ± 1.5	7 ± 5	0–84
c-C_6H_{12}	11.7 ± 1.0	28 ± 1.3	120–260

reactivity of the H-donor. It increases from 2.5 (cyclohexylmercury hydride) to 4.6 (tributyltin hydride) to 11.7 kJ/mol (cyclohexane). At the same time, the rate of H-transfer in this series decreases by about a factor of 10^7.[4]



Apparently, the differences in the steric shielding have greater influence on the activation enthalpies the less reactive the H-donor is, because the distance between the reactants is smaller in the later transition states.[5] Since the difference in the activation entropies in the same series also increases from 1.2 to 7 to 28 J/mol^{-1} K^{-1}, the compensation of the activation enthalpies and activation entropies leads to an isoselective temperature,[6] which lies between 60 and 80°C (Fig. 1). In this temperature range the H-donors mentioned here react with the same selectivity. In the case of cyclohexane the entropy effects are so large that above 140°C the isomer (*E*)-**4b** is the major product. Thus, at 0°C the ratio (*Z*)-**4b**:(*E*)-**4b** is 78:22 with Bu_3SnH as donor, whereas at 260°C with cyclohexane as H-donor the selectivity (29:71) is reversed.[7]

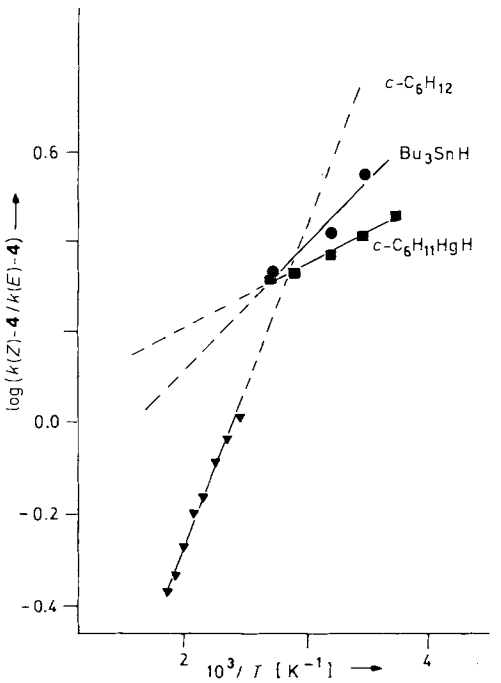


Fig. 1. Temperature dependence of the stereoselectivity for H-transfer to the vinyl radical **5b** by c-C_6H_{12}, Bu_3SnH, and c-$C_6H_{11}HgH$ as H-donors.

These investigations on the vinyl radical **5b** show how the stereoselectivities of radical reactions can be steered by varying the H-donors (radical trapping agents) and the reaction temperature.

Asymmetric Synthesis of α-Amino-γ-nitrocarboxylic Esters by the Bislactim Ether Method**

By *Ulrich Schöllkopf,* Wulf Kühnle, Ernst Egert,** and *Michael Dyrbusch*

Dedicated to Professor Hans Paulsen on the occasion of his 65th birthday

Optically active γ-nitro-α-amino acids are attracting attention lately because of their potential biological activity and there usefulness as building blocks for modified oligopeptides. Moreover, they are suitable as starting compounds for the synthesis of further unusual amino acids, since the nitro group can be reduced to an amino group[1,2] or converted into a carbonyl group by the Nef reaction.[1,3] So far, however, no method for the asymmetric synthesis of this class of compounds has been reported in the literature. We now describe here an asymmetric synthesis for the methyl α-amino-γ-nitrocarboxylates **7** starting from the titanium derivative **3** of the (commercially available[4]) bislactim ether **1** of cyclo(-L-Val-Gly) and the nitroolefins **4**. Intermediates of the synthesis are the adducts **5**, which, in the case of the (*E*)-nitroolefins **4a–c**, are formed with high asymmetric induction with respect to the two stereocenters (C-2 and C-1') (Table 1). Surprising is not only the

Table 1. Synthesis of the diastereomeric compounds **5**.

5	R^1	R^2	B.p. [b] [°C/ 0.01 torr]	Yield [%]; diastereomers [a] with **3** [c]	with **2** [d]
a	CH_3	H	80	51; 97.4 : 0.8 : 1 : 0.8	81; 86 : — : 10 : 4
b	C_6H_5	H	140	57; 94 : 2.7 : 3.3 : —	78; 45 : 38 : 11 : 6
c	[e]	H	94–95 [f]	60; 99 : — : 1 : —	52; 49 : 41 : 6 : 4
d	CH_3	CH_3	80	—	80; 98 : 2 [g]

[a] The ratio (2*R*,1'*S*):(2*R*,1'*R*):(2*S*,1'*S*):(2*S*,1'*R*) is given; the 1'-configuration in the case of (2*S*)-isomers is arbitrary. A dash means no longer clearly recognizable. [b] (Kugelrohr). [c] GC Capillary. [d] Mean value of a capillary GC analysis and a ^{13}C-NMR analysis. [e] R^1 = 3,4-methylenedioxyphenyl. [f] M.p.: purified by low-pressure chromatography [silica gel, ether/petroleum ether (1 : 5)]. [g] (2*R*):(2*S*).

high stereoselectivity with which the two stereocenters are simultaneously formed, but also the finding that nitroolefins **4** react in satisfactory yields with the azaenolate **3** (or **2**). SET processes between the nitro group and the azaenolate were to be expected, because **3** affords a relatively stable "diazapentadienyl radical". The 2,2-dimethyl-substituted nitroolefin **4d** does not react with **3** however, but does so—and with high induction—with the lithium compound **2**.[5]

The C-2/C-5-*trans* configuration of the main components of **5** follows from the (in the bislactim ether system typical) *trans*-$^5J_{H\text{-}5/H\text{-}2}$-NMR coupling constants of ca. 4 Hz, and from the fact that 1'-aryl compounds show a high-field shift of the *cis*-H-5, which is attributed to the "aryl-inside" preferred conformation ("folded" conformation). The (1'*S*)-configuration was determined, by way of example on **5c**, by an X-ray structure analysis (Fig. 1), which concomitantly confirmed the NMR-spectroscopically identified "folded" conformation. The diastereomeric ratio (Table 1) was determined by capillary gas-chromatography[6] (with and without combined GC/MS) and/or by ^{1}H- and ^{13}C-NMR spectroscopy (Table 2).

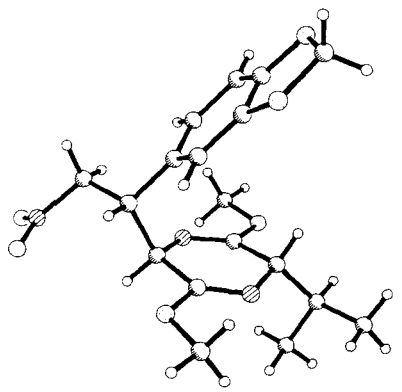

Fig. 1. Crystal structure of (5*S*,2*R*,1'*S*)-**5c** [11]. Remarkable is the "aryl-inside" conformation ("folded" conformation). O atoms dotted, N atoms hatched.

Hydrolysis of the adducts **5** to methyl L-valinate **6** and the methyl (2*R*,3*S*)-2-amino-4-nitrobutanoates **7** (Table 2), the target compounds, was accomplished under such mild conditions (0.1 N HCl, room temperature, tetrahydrofuran (THF) as cosolvent) that the nitro group remained intact. However, on attempting to hydrolyze the ester **7a** to the amino acid under acidic conditions (4 N HCl) a Nef reaction took place. An example has been described in the literature[2] for an alkaline ester hydrolysis (1 N NaOH) in which the nitro group remained intact. As shown by an ex-

ploratory hydrogenation experiment (Pd/C) with **7a**—here, as usual[1,2]—the nitro group of **7** can be reduced to an amino group. Hence, the bislactim ether method also affords access to optically active α,γ-diamino acids (NH_2 instead of NO_2 in compounds of type 7), which, as analogues of GABA, are of interest as potential enzyme inhibitors.[7]

Experimental

Compounds **5**: The bislactim ether **1** [4, 8] was lithiated to **2** [8] (1.1 equivalents of butyllithium, −78 °C, 10 min, 8 mL of THF per mmol of **1**).—Experiments with **2**: The solution of **2** was treated at −78 °C with the solution of one equivalent of **4** in THF (10 mL per mmol of **4**). After 12 hours' stirring the mixture was treated with 1.1 equivalents of acetic acid and allowed to warm to room temperature. Water (30 mL per mmol of **4**) was then added and the mixture extracted with ether. The ether extract (containing **5**) was dried over $MgSO_4$ and the ether removed under vacuum. **5** was isolated from the residue by Kugelrohr distillation (Table 1).—Experiments with **3** : **1** (0.42 g, 3.0 mmol) was lithiated to **2**. The solution of $ClTi[N(C_2H_5)_2]_3$ [9] (3.15 mmol) in hexane (ca. 3.5 mL) was then added to **2** and, after 45 min, the mixture was forced under pressure (with argon) into a solution of **4** (3.0 mmol) in THF (30 mL). After 12 hours' stirring the mixture was treated with 3.2 mmol of acetic acid and then worked-up as described above [10].

Compounds **7**: The solution of **5** (3.0 mmol) in THF (2 mL) was treated with 60 mL of 0.1 N HCl and the resulting suspension stirred at room temperature until complete dissolution (ca. 24–80 h). After saturation with NaCl and subsequent addition of 20 mL of ether, concentrated ammonia was added to the stirred mixture until a pH of 9 was reached. The phases were then separated; the aqueous phase was extracted with 4 × 20 mL of ether and, after drying the extract over $MgSO_4$ the solvent was removed under vacuum. Methyl L-valinate **6** was then removed by evaporation at 30 °C/0.01 torr in a Kugelrohr apparatus and **7** isolated from the resulting residue by Kugelrohr distillation (0.01 torr); **7c** was purified by low-pressure chromatography (silica gel, ether, $R_F = 0.16$). When prepared via **3** the crude compounds **7** were isomerically pure (^{13}C-NMR, CGC and CGC/MS; ^{1}H-NMR with Eu(hfc)$_3$ [10]).

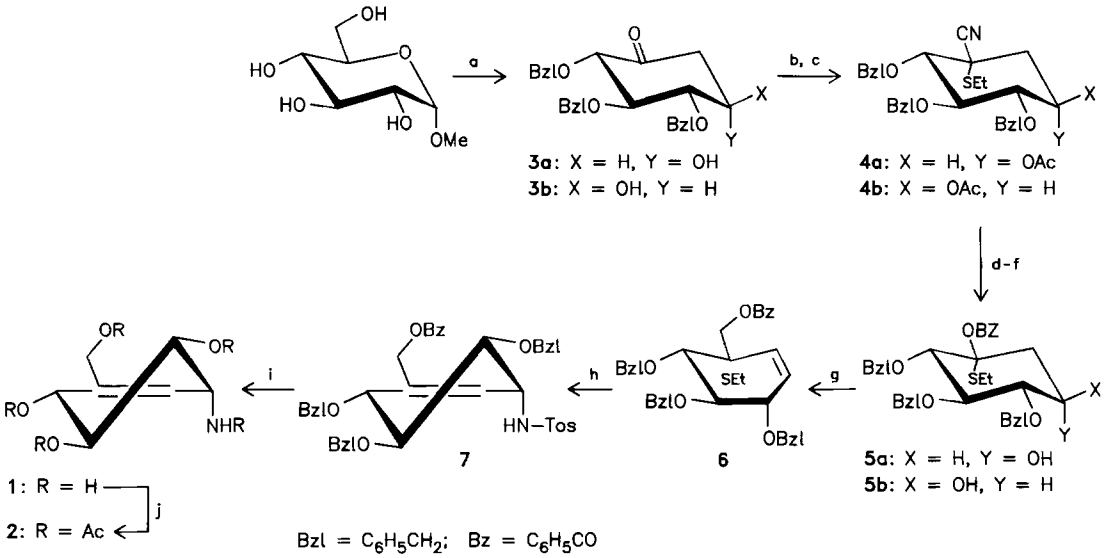
Synthesis of Valienamine**

By *Richard R. Schmidt** and *Arnim Köhn*

Valienamine **1** has interesting biological properties. Aside from its inhibitory action towards α-glucosides[1,2] it exhibits antibiotic activity.[2] Much more important, however, is its occurrence as central building block of several complex aminoglycoside antibiotics, such as, e.g., the validamycins,[3] and a series of pseudooligosaccharidic α-glucosidase inhibitors, including acarbose.[1,4]



Scheme 1. Synthesis of valienamine, **1**, from methyl α-D-glucopyranoside. a) Six steps, see text and [10]; b) EtSH/MeOH, HCl; Ac_2O, pyridine (86%); c) Me_3Si–CN, $SnCl_4$, CH_2Cl_2, 0 °C (85%); d) DIBAH, CH_2Cl_2/petroleum ether, −70 °C to room temperature (RT) (78%); e) $LiAlH_4$, tetrahydrofuran, 0 °C to RT (85%); f) BzCN, CH_3CN/NEt_3, −15 °C (73%); g) PPh_3, DEAD, toluene, RT (79%); h) chloramine T, BTAC, CH_2Cl_2, RT (78%); i) NH_3(liq.), Na, −70 °C (58%); j) Ac_2O, pyridine (quantitative).

However, in its synthesis described by *Paulsen* and *Heiker* leads from (+)-quebrachitol via several steps to op-

[**] α-Glucosidase Inhibitors, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 3: [4].

tically active valienamine.[5] Other syntheses described in the literature afford either the racemate[6] or (with **3a** as starting compound) a diastereoisomeric mixture.[7] For the decisive diastereospecific allylic amination of an alkoxy-substituted cyclohexene we chose the [2,3]-sigmatropic shift of a sulfimide group[8] as reaction step[9] (see Scheme 1). The starting compound is the cyclitol derivative **3a**, **b**, which can be obtained via Ferrier rearrangement as a 4:1 diastereomeric mixture in an overall yield of 40% in six simple steps from the commercially available methyl α-D-glucopyranoside.[7, 10] For introduction of the C_1 side-chain, and preparatory to the sigmatropic shift, the 4:1 diastereomeric mixture was converted (without separation) in an HCl-catalyzed reaction with ethanethiol into the thioketal derivative, which on reaction with trimethylsilyl cyanide and tin(IV) chloride as catalyst according to a method described by *Reetz* and *Müller-Starke*[11] afforded **4a**,**b** (4:1 diastereomeric mixture). Reduction of the nitrile group with diisobutylaluminum hydride (DIBAH) led directly to the corresponding aldehyde, which on further reduction with $LiAlH_4$ and selective benzoylation with benzoyl cyanide (BzCN)[5] furnished the cyclitol derivative **5a**,**b** (1:4 diastereomeric mixture) in good yield. This product mixture was regiospecifically dehydrated by treatment with triphenylphosphane/diethyl azodicarboxylate (DEAD) to compound **6**. Imination of the thioether group with chloramine T in a two-phase process with benzyltriethylammonium chloride (BTAC) in dichloromethane afforded directly and diastereospecifically the valienamine derivative **7** in good yields. The protecting groups on **7** were removed with sodium in liquid ammonia[12] to give valienamine, **1**, which was characterized by peracetylation to the known compound **2**.[6]

IR Spectroscopic Determination of the Enzyme Content of Carrier-fixed Enzymes

By *Willi Herzog, Reinhold Keller,* Erhart Neukum,* and *Dieter Wullbrandt*

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

Enzymes are attracting increasing attention as catalysts for organic syntheses.[1] They are employed both in hydrolyses on an industrial scale as well as for the preparation of reagents for analyses and syntheses on a laboratory scale. Improvements in the preparation of the enzymes and in their stabilization and manipulation by immobilization continually make these catalysts all the more attractive.

In order to find optimal conditions for the immobilization of the enzymes it is necessary to determine not only the activity but also the enzyme content and then to calculate the specific activity. In this way one obtains activities based on the amounts of enzyme used, thus enabling a comparison of the catalysts. We now show with the enzyme α-chymotrypsin as example that the enzyme content can be determined by IR spectroscopy. α-Chymotrypsin is an endoprotease and catalyzes, inter alia, the enantiospecific ester cleavage of L-phenylalanine methyl ester.[2] α-Chymotrypsin is preferentially immobilized on inorganic substances such as silica gels. The support is first aminated on the surface and then coupled via glutaric dialdehyde with the enzyme (Fig. 1).

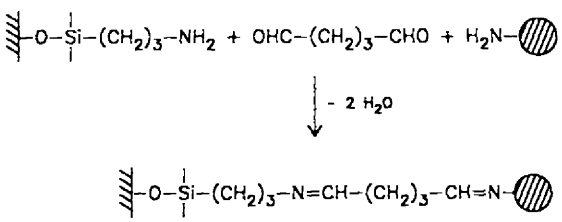

Fig. 1. Coupling of an aminated silicate support via glutaric dialdehyde with an enzyme (schematic).

The IR measurements were carried out with a Perkin-Elmer grating spectrometer 580B coupled to a computer (Perkin-Elmer PC-7300 with CDS-IR software). First of all, it was demonstrated by recording the IR spectra of self-supporting targets of ca. 10 mg weight (diameter: 13 mm, thickness < 0.1 mm), prepared from the carrier material, the carrier material treated with glutaric dialdehyde and carrier-fixed α-chymotrypsin (Fig. 2) with a pressure of 100 kN, that there is no band overlap.

The spectrum of the catalyst shows a broad band at $\tilde{\nu} = 3350\ cm^{-1}$, which is mainly due to the NH_2- and NH-groups of the enzyme. Besides the absorption bands of the CH_3- and CH_2-valence vibration in the region of 2970–2880 cm^{-1} and those of the lattice overtone vibrations of the carrier material at 2000–1850 cm^{-1}, the amide-I and amide-II bands of the enzyme are clearly observable at 1650 and 1540 cm^{-1}, respectively. The integral of these two amide bands is a valid measure of the enzyme content. After recording the IR spectrum the target was weighed and the spectrum normalized to 10 mg initial weight. Be-

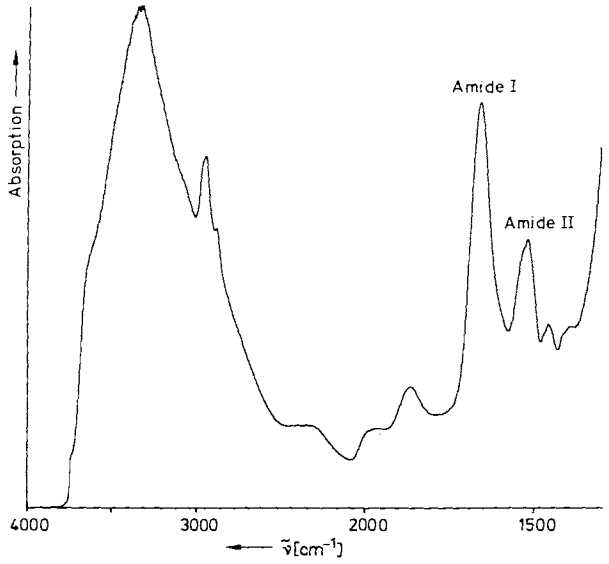

Fig. 2. IR spectrum of the fresh catalyst of propylamine-silica gel, glutaric dialdehyde and α-chymotrypsin (see text).

cause of the relatively strong absorption of water at 1650 cm^{-1} the sample had to be carefully dried before being pressed. This was carried out using a pump equipment with (forepump) backing pump and diffusion pump, first to a pressure of 1 mbar and then, after pulverization of the catalyst, to a pressure of less than 5×10^{-3} mbar.

For constructing the calibration curve a stock mixture of 880 mg propylamine-silica gel and 120 mg α-chymotrypsin was prepared; this was moistened to improve mixing, and finally dried. From this stock mixture, containing 12 wt-% α-chymotrypsin, further aliquoted mixtures ranging down to a content of 2 wt-% α-chymotrypsin were prepared by addition of propylamine-silica gel (Fig. 3). In order to determine the scatter, the spectra of four pressed disks from each mixture were recorded.

Finally an integration was carried out in the region of the amide bands from 1736 to 1426 cm^{-1}. The calibration curve was then plotted after subtraction of the background (absorption of the propylamine-silica gel in the same region (Fig. 4).

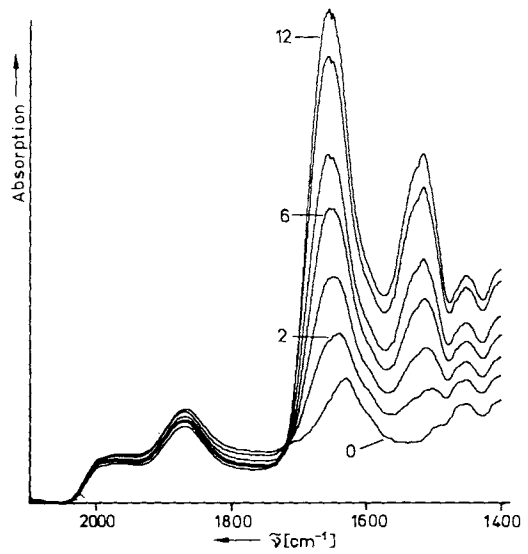

Fig. 3. IR spectra of fresh catalysts (cf. Fig. 2) as a function of the α-chymotrypsin content (data in wt-%).

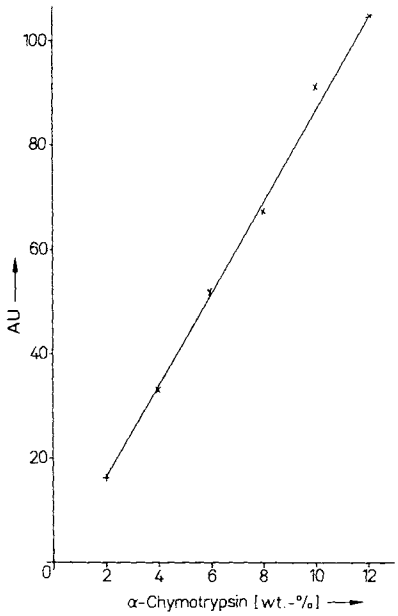

Fig. 4. Calibration curve for the IR spectroscopic determination of the α-chymotrypsin content of support catalysts (cf. Fig. 2). AU denotes arbitrary units.

On completion of the calibration curve, the α-chymotrypsin contents of five fresh contact catalysts containing varying amounts of enzyme were determined IR spectroscopically (lower limit of measurement ca. 1 wt-%, relative error 3%). As shown in Table 1, α-chymotrypsin is completely bound to the silica gel during the catalyst preparation.

8	7.7
10	9.9
15	14.5

Since the catalytic activity of freshly prepared catalysts increases during the reaction it was necessary to check whether this is due to loss of enzyme or deactivation of the enzyme. The enzyme contents of the fresh and the used contact catalysts determined from Figure 5 are listed together with other values in Table 2.

These results clearly show that a loss of enzyme occurs during the use of the catalyst. From measurements on used catalysts it follows that the catalytic activity decreases proportionally with the enzyme content; accordingly, the loss in activity must in the first place be attributed to a loss of enzyme and not to a deactivation. The catalyst was used in a continuously operating fixed bed reactor with flow rates of $SV \geq 400\ h^{-1}$. The large initial drop in activity is most

Stabilization of the $[AlMe_2]^{\oplus}$ Cation by Crown Ethers**

By *Simon G. Bott, Abbas Alvanipour, S. David Morley, David A. Atwood, C. Mitchell Means, Anthony W. Coleman,* and *Jerry L. Atwood**

Although alkylaluminum compounds have played a commanding role in many areas of chemistry for more than 30 years, the simple species $[AlMe_2]^{\oplus}$ has not been structurally characterized in the presence of neutral donor ligands.[1] We now report that crown ethers stabilize this cation and show the interesting features of its coordination to [18]crown-6 and to [15]crown-5.

We have recently shown that the $[AlCl_2]^{\oplus}$ cation is generated in the reaction of $AlCl_3$,[2] $EtAlCl_2$,[3,4] and Et_2AlCl[5] with such crown ethers as [15]crown-5 and [18]crown-6.[6] Indeed, crown ethers are not necessary: the $[AlCl_2]^{\oplus}$ cation results from the reaction of $EtAlCl_2$ with two equivalents of dimethoxyethane,[7] or from the reaction of $AlCl_3$ with four equivalents of tetrahydrofuran in toluene.[8] The cationic species are of two structural types: those in which the chlorine atoms are *cis* and those in which they are *trans*. In $[AlCl_2 \cdot [18]crown\text{-}6]^{\oplus}$, the aluminum atom exists in an octahedral environment with *cis* chlorine ligands,[4] whereas in $[AlCl_2 \cdot [15]crown\text{-}5]^{\oplus}$ the aluminum atom is in a pentagonal bipyramidal array with *trans* chlorine ligands.

The $[AlMe_2]^{\oplus}$ cation has been seen often in our attempts to trap species related to Ziegler/Natta catalysis with crown ethers. In a typical experiment, one equivalent of Cp_2TiCl_2 is allowed to react with two equivalents of $AlMe_3$ in toluene in the presence of one equivalent of [18]crown-6.[9] Mass balance indicates the reaction as shown in equation (1).

$$Cp_2TiCl_2 + 2\,AlMe_3 + [18]crown\text{-}6 \xrightarrow{\text{toluene}} [AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}[AlMe_2Cl_2]^{\ominus} + Cp_2TiMe_2 \quad (1)$$

$Cp = \eta^5\text{-}C_5H_5$

Related reactions may be written for Cp_2ZrCl_2 and $CpTiCl_3$, and $[AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}$ has been obtained from each of these.[10] $[AlMe_2 \cdot [15]crown\text{-}5]^{\oplus}$ has also been isolated in accord with equation (1) with [15]crown-5 and from the reaction of $CoCl_2$ with $AlMe_3$ and [15]crown-5 (in toluene, molar ratio 1 : 4 : 1).[11]

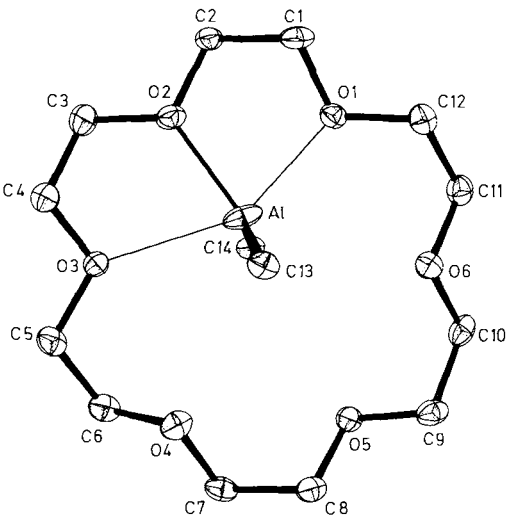

Fig. 1. Crystal structure of the cation of $[AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}[AlMe_2Cl_2]^{\ominus}$ in the crystal [12, 13].

The structure of the $[AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}$ cation is shown in Figure 1.[12,13] The visually most surprising feature is that the crown ether exhibits its full symmetry configuration. (The six oxygen atoms are planar to within 0.29 Å.) The aluminum atom is strongly coordinated to O(2) at a distance of 1.929(5) Å, but also interacts with O(1) at 2.181(5) Å, and with O(3) at 2.435(5) Å. The latter is

[*] Prof. Dr. J. L. Atwood, Dr. S. G. Bott, Dr. A. Alvanipour, S. D. Morley, D. A. Atwood, C. M. Means, Dr. A. W. Coleman

Tuscaloosa, AL 35487 (USA)

[**] This work was supported by the U. S. National Science Foundation.

the longest Al-O length to be referred to as a bond in the literature,[14] but the interaction is further substantiated by the Me-Al-Me angle of 140.6(3)°. Indeed, a comparison of van der Waals radii shows that even O(6) interacts to a small extent with the aluminum (Al···O = 3.093(5) Å). O(4) and O(5) are outside the contact distance with the aluminum atom (Al···O = 3.460(5) and 3.800(5) Å, respectively), and, significantly, the two methyl groups incline toward O(5). However, the aluminum atom should be regarded as 5-coordinate. The two Al-$C_{(methyl)}$ distances in the cation are short, Al-C(13) = 1.915(6) Å and Al-C(14) = 1.939(7) Å, compared to those in the anion of 2.005(7) and 2.053(6) Å.

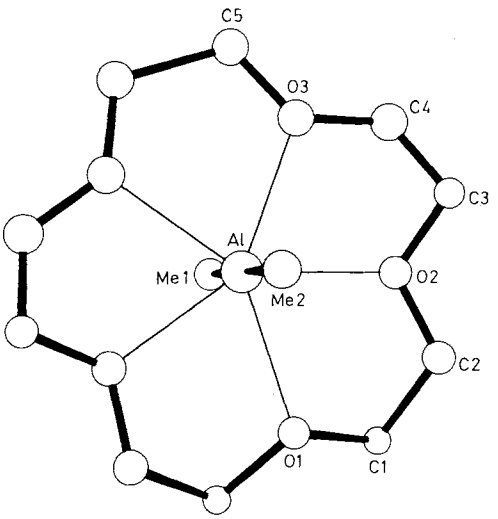

Fig. 2. Crystal structure of the cation of $[AlMe_2 \cdot [15]crown\text{-}5]^{\oplus}[AlMe_2Cl_2]^{\ominus}$. Al-O1 = 2.26(1), Al-O2 = 2.18(2), Al-O3 = 2.13(1) Å [13, 15].

The structure of $[AlMe_2 \cdot [15]crown\text{-}5]^{\oplus}$ is shown in Figure 2.[13, 15] It has a similar configuration to that found for the $[AlCl_2 \cdot [15]crown\text{-}5]^{\oplus}$ cation.[3] The Al-C distances are 1.99(1) and 2.01(1) Å, and the Me-Al-Me angle is 178(1)°.

These studies indicate that $[AlR_2]^{\oplus}$ species may be important in the reaction chemistry of Ziegler/Natta systems with donor ligands.

[8] N. C. Means, C. M. Means, S. G. Bott, J. L. Atwood, *Inorg. Chem.*, in press.
[9] In a typical experiment 2.50 g (0.01 mol) of $[Cp_2TiCl_2]$ and 2.65 g (0.01 mol) of [18]crown-6 were mixed together in toluene (ca. 50 ml). $AlMe_3$ (2.0 ml, 0.02 mol) was slowly added. The reaction began immediately and from the red solution ca. 2.64 g (62%) of colorless crystalline material was deposited. The latter was shown by an X-ray crystallographic analysis to be $[AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}[AlMe_2Cl_2]^{\ominus}$.
[10] In each case signals due to M-Me (M = Ti, Zr) resonances have been recorded in the NMR. It is likely that the $[Cp_2M(Cl)Me]$ species is formed rather than $[Cp_2MMe_2]$. Other products which apparently contain M-crown linkages have been found in low yield. It is reasonable to assume that the $[AlMe_2 \cdot [18]crown\text{-}6]^{\oplus}$ species comes from the attack of $AlMe_2Cl$ on the crown after the $AlMe_3$ alkylates the transition metal. The formation of $AlMe_2Cl$ in the reaction of $AlMe_3$ with $[Cp_2TiCl_2]$ has been reported: K. Claus, H. Bestian, *Justus Liebigs Ann. Chem. 654* (1962) 8; F. N. Tebbe, G. W. Parshall, G. S. Reddy, *J. Am. Chem. Soc. 100* (1978) 3611.
[11] $CoCl_2$ (0.65 g, 0.005 mol) was slurried with [15]crown-5 (1.0 ml, 1.1 g, 0.005 mol) in toluene (ca. 50 ml). $AlMe_3$ (2.0 ml, 0.02 mol) was slowly added. A vigorous reaction ensued, and a black liquid clathrate was immediately noted. Colorless, air-sensitive crystals of $[AlMe_2 \cdot [15]crown\text{-}5][AlMe_2Cl_2]$ grew from the liquid clathrate.
[12] $P2_1/n$, $a = 11.397(4)$, $b = 12.670(4)$, $c = 17.075(6)$ Å, $\beta = 93.08(4)°$, $V = 2462$ Å^3, $Z = 4$. CAD-4 diffractometer, $Mo_{K\alpha}$, $2.0 \leq 2\theta \leq 46°$, 1326 measured reflections with $I \geq 3\sigma(I)$, MULTAN and difference Fourier methods, hydrogen atoms located and refined, all non-hydrogen atoms refined with anisotropic thermal parameters, $R = 0.044$.
[13] Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Data Centre, Cambridge CB2 1EW, England, on quoting the names of the authors, and the journal citation.
[14] In $[AlCl_2 \cdot$ benzo[15]crown-5$][AlEtCl_3]$ [3], the five Al-O lengths range from 2.03(1) to 2.30(1) Å. The latter is the longest previously reported as a formal bond.
[15] *Pnma*, $a = 11.184(3)$, $b = 10.928(8)$, $c = 17.717(9)$ Å, $V = 215$ Å^3, $Z = 4$. CAD-4 diffractometer, $Mo_{K\alpha}$, $2 \leq 2\theta \leq 44°$, 1104 measured reflections with $I \geq 3\sigma(I)$. MULTAN and difference Fourier methods. The crown was badly disordered. This problem has been discussed: P. C. Stark, M. Huff, E. A. Babaian, L. M. Barden, D. C. Hrncir, S. G. Bott, J. L. Atwood, *J. Incl. Phenom. 5*, in press. $R = 0.152$.

BOOK REVIEWS

Ion Solvation. By *Y. Marcus*. John Wiley, Chichester 1985. viii, 306 pp., bound, £ 42.00.—ISBN 0-471-90756-1

Chemical reactions are usually carried out in solution, and often involve ions as reactants. A knowledge of the interactions between solvent molecules and dissolved ions is therefore of great importance for understanding and thereby influencing such reactions.

The better-known books on this topic are already rather outdated, and Prof. *Yizhak Marcus* of the Hebrew University of Jerusalem has therefore taken on the task of bringing the subject up to date, and treating some parts of it in a completely new way. It must be said at the outset that he appears to have succeeded very well. The nine chapters cover every important aspect of the solvation of ions in aqueous and nonaqueous media.

Following a brief introductory chapter (Significance and Phenomenology of Ion Solvation), the simple case of an interaction between a single ion and a single solvent mole-

cule in the gas phase is first discussed (Ion Solvation in the Gas Phase). This is followed by a treatment of the solvation of a single ion by many solvent molecules, as in a dilute solution, dealing with structural, spectrochemical, and kinetic aspects. Chapter 3 (Interaction Models for Ion Solvation) describes various theoretical models based on statistical thermodynamics considerations. Chapter 4 (Structural and Kinetic Aspects) deals with changes in the dynamic behavior of the solvent molecules caused by ion solvation. Concepts such as first and second solvation shells, primary and secondary solvation, and coordination and solvation numbers, are here put into an up-to-date context. Chapter 5 (Ion Hydration) deals with the special position occupied by water as a solvent for electrolytes, being concerned exclusively with the thermodynamic and structural aspects of the ion/water interaction. The growing importance of ions in nonaqueous organic solvents is recognised in the following chapter (Ion Solvation in Nonaqueous Solvents). Detailed tables listing relevant properties of nonaqueous solvents (including empirical parameters of solvent polarity), and of Gibbs transfer energies ΔG_t^0 (X, $H_2O \rightarrow S$)/kJ·mol^{-1}) for single ions, make this chapter one of the most useful in the book. Here the reader benefits from the knowledge which the author gathered in compiling (for IUPAC) critical tables of Gibbs transfer energies, enthalpies, and entropies for the transfer of single ions from water into nonaqueous solvents [Y. Marcus, *Pure & Appl. Chem. 55* (1983) 977; *ibid. 57* (1985) 1103]. Attempts at correlating such Gibbs transfer energies with intrinsic solvent properties using multiparameter equations are also described.

Chapter 7 is devoted to the selective solvation of ions in binary solvent mixtures. Chapter 8 deals with solvation of ion pairs, with particular attention to molten hydrated salts, perhaps as a result of the author's laboratory being near the Dead Sea (Dead Sea Water contains a 8.8 mol ions/liter!). In the final chapter (Some Applications of Ion Solvation) many different applications in the fields of electrochemistry, hydrometallurgy, solvent extraction, and organic synthesis are discussed.

The book excels in having a lucid, readable style, and the detailed author and subject indexes make it easy to use. Lists of references at the end of each chapter (more than 310 references altogether) enable the reader to gain easy access to original papers—although that should often be unnecessary, since the 64 tables and 36 figures provide a wealth of useful information. The book should be included in every library, and anyone who can afford to (at the price of DM 175.00!) should have the book on his desk—he will certainly get a lot of use from it.

Molybdenum Enzymes. Edited by *T. G. Spiro*. Wiley, Chichester, England 1985. x, 611 pp., hardcover, $ 125.00.—ISBN 0-471-88542-8

This book collects some excellent reviews on the inorganic chemistry and biochemistry of molybdenum, molybdenum-containing enzymes, and the molybdenum-containing cofactors. As noted by *P. J. Stephens* in his chapter, the general area of molybdenum enzymes, especially as related to nitrogen fixation, has been extensively reviewed in comparison to research productivity. These reviews are, however, a significant new contribution because of the emphasis on the chemical aspects as opposed to the agricultural and genetic aspects. The authors are well chosen, critical, and careful to avoid oversimplification or overinterpretation. The literature is completely covered through 1983 with some references to 1984. The ten chapters overlap some in their scope; thus, there is some redundancy that would not occur in a monograph by a single author. However, to carry on the editor's analogy, although some of the same territory is being explored, it is being seen through different eyes and to different purposes.

Chapter 1, by *R. H. Holm* and *E. Simhon*, is a thorough survey of molybdenum- and tungsten-containing iron-sulfur clusters, their structure, physical properties, reactivity, especially with respect to substitution and electrochemistry, and synthesis. These results are then discussed by comparison to the properties of the iron-molybdenum cofactor from nitrogenase. The second chapter, by *E. Stiefel* and *S. Cramer*, concerns the isolation, composition, physical and chemical properties, assay, and biosynthesis of the iron-molybdenum cofactor. The same authors discuss the molybdenum cofactor (the molybdenum center of enzymes other than nitrogenase) in Chapter 8.

Chapter 3, by *P. J. Stephens*, reviews structures of the iron and iron-molybdenum proteins that compose the nitrogenase enzyme. This review is organized by presenting the "Dominant Hypothesis" concerning each protein, and then presenting the experimental data. Conflicts between the "Dominant Hypothesis" and the data are pointed out in a stimulating presentation. For example, there are problems with the hypotheses about the types and number of clusters in light of the cysteine analysis of the proteins.

The next two chapters concern the reactions of nitrogenase. *B. Burgess* presents a discussion of the varied substrates of nitrogenase and describes the steady-state kinetics results. Emphasis is put on the importance of considering electron flow through the enzyme, careful product analysis, and the problems of controlling the "inputs" to the enzyme (reducing equivalents, MgATP, substrate, medium). There is also some discussion of substrate interaction, the evidence for interacting sites on the enzyme, and the problem of the competition between hydrogen evolution and substrate reduction.

Chapter 5, by *R. Thorneley* and *D. Lowe*, is the most detailed discussion of the mechanism of nitrogenase. The authors attempt to fit a mechanism and individual rate constants particularly to the reactions of the *Klebsiella pneumoniae* proteins. The work especially involves the authors' pre-steady-state kinetics measurements, but also encompasses the steady-state measurements. This type of detailed analysis is necessary in order to get a real understanding of this complex system, and in order to avoid errors from too facile interpretation of individual experiments, but the details will appeal more to committed kineticists. The next chapter, by *M. Hidai*, reviews the diverse work on the inorganic and organometallic chemistry of complexes of dinitrogen and their reactivity. Unfortunately, there still remains little connection between these studies and advances in the understanding of nitrogenase.

The remaining four chapters concern molybdenum-containing proteins other than nitrogenase. Chapter 7 by *D. Garner* and *S. Bristow* presents the inorganic background through a discussion of oxomolybdenum chemistry. This long presentation also demonstrates the relevance of the measurements on the inorganic complexes to the study of the enzymes. Chapter 8 on the molybdenum cofactor is next, followed by a detailed discussion by *R. Hille* and *V. Massey* primarily on xanthine oxidase. Here the emphasis

is properly on the molybdenum chemistry, but the flavin chemistry is presented as necessary. A good discussion is presented of the problem of the oxidation-reduction potentials of the centers and whether they are in equilibrium with each other. The last chapter, by *M. Adams* and *L. Mortenson*, discusses nitrate reductase and formate dehydrogenase. Here, there is less physical information on the proteins and the sites and more discussion on physiology, purification, and characterization.

The book is well printed, with only a few errors in layout, such as misplaced figures in Chapter 2 and some missing compound numbers in Chapter 1. This is a solid addition to any library for those interested in the chemistry of molybdenum in biological systems and related inorganic chemistry.

Organized Multienzyme Systems: Catalytic Properties. (Biotechnology and applied Biochemistry Series.) Edited by *G. R. Welch*. Academic Press, New York 1985. xiii, 458 pp., bound, $ 75.00.—ISBN 0-12-744040-2

This monograph summarizes, mainly from a biochemical and biological viewpoint, the extraordinary wealth of information which exists on organized multienzyme systems. In each of the nine chapters an expert in the relevant topic outlines its most important features, with examples. The topics discussed include the fundamentals of protein organisation in mitochondria, catalytic processes and energy transfer in membranes, dynamic compartmentalization of multienzyme complexes in the cytoplasm, questions concerning the flexibility and co-operativity of enzyme molecules in the kinetics and regulatory mechanism of allosteric enzymes, and reversible adsorption as a modulator of enzymatic activity. Mechanistic models for sequential enzymatic pathways are also proposed and discussed, and detailed analyses of the kinetics of multienzyme systems are given. The monograph concludes with a chapter on long-range energy continua, and their role in the transfer and conservation of chemical energy in multienzyme sequences, and thus in the regulation of metabolism.

Chapters on naturally occurring multienzyme sequences are especially appropriate to the aims of this monograph, in showing the mode of action and structural features of organized multienzyme systems and the role of the microenvironment, together with a critical discussion of current theoretical models. On the other hand, Chapter 7, on the kinetic analysis of multienzyme systems in homogeneous solutions, falls outside the proper scope of the book. Kinetic models for sequential reactions, some of which are already well-known, are laboriously presented here in a complicated and unconventional notation. The inclusion of a lengthy and not very useful 13-page digression into the use of the Laplace-Carson transformation to solve ordinary differential equations is quite incomprehensible. Apart from the availability of numerical computation methods nowadays, there is no obvious advantage in using such laborious integral transformations rather than conventional integration methods. Furthermore, the literature referred to is not always truly representative; for example the book by *Ayres* (1952) on the theory of differential equations is now hardly the most appropriate source on the trivial solution of the differential equations for a first-order reaction. However, readers who are engaged in theoretical work or interested in these aspects will be compensated by the discussion in Chapter 8 on the behaviour of immobilized multienzyme systems, particularly in membranes. Here we find a successful combined presentation of experimental studies of diffusion-limited enzymic reactions together with the relevant theoretical models, using mathematical techniques of a practical nature which are described in a comprehensible way. Especially noteworthy is the elegant theoretical modelling of the highly nonlinear diffusion-limited reaction effects in multienzyme systems with complex control mechanisms. A reading of this chapter will also be of value to all process-oriented biotechnologists. Elsewhere in the monograph, however, there are many places where, although it is assumed that the knowledge presented will be of interest to biotechnologists, no relevant cross-reference is included. Consequently those involved in the practice of biotechnology may have difficulty in making use of the abundant fundamental knowledge displayed. The one chapter whose title mentions practical applications (Chapter 6—Models of organized multienzyme systems: use in microenvironmental characterization and in practical application) is comparatively vague, and deals with the practical aspects in a mere five pages. The main emphasis is on coenzyme regeneration, but the discussion of coupled equilibria does not, unfortunately, include the latest developments which have been reported, e.g. for the enzyme membrane reactor.

The monograph thus demonstrates the importance and the difficulties of communication in interdisciplinary fields of knowledge. The book can be recommended to all who are concerned with setting up immobilized cells for bioconversions, as the results, concepts and theoretical models presented here are of considerable importance for them. Because of the comparatively high price, only highly specialized readers and those with theoretical interests will wish to buy it for their private libraries.

Stereoselective Syntheses of Building Blocks with Three Consecutive Stereogenic Centers: Important Precursors of Polyketide Natural Products

New Synthetic Methods (68)

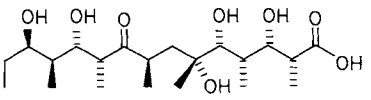
By Reinhard W. Hoffmann*

Sequences of directly adjacent stereogenic centers were first discovered for the monosaccharides, which therefore constituted the first focus of interest in stereoselective synthesis. The structures of many polyketide-derived natural products that have been elucidated in recent years often exhibit longer sequences of stereogenic centers in which hydroxy-substituted secondary carbon atoms alternate with tertiary carbon atoms. This finding inspired the development of methods allowing the specific construction of first two and then—more importantly—three neighboring stereogenic centers. The diverse methodologies that have thereby emerged reveal common principles and stress the variety of approaches possible in stereoselective synthesis.

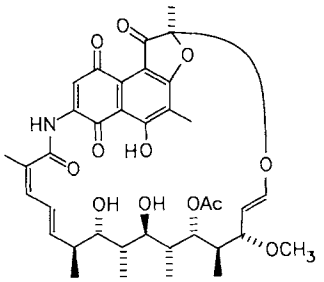
1. Introduction

Each era of preparative organic chemistry has its own target molecules. Those of the 1980s include polyketide-derived natural products such as erythronolide and rifamycin (Scheme 1). The synthetic challenge thereby results from the large number of directly adjacent stereogenic centers (in this article, the term "stereogenic center" will be shortened to "stereocenter").

Although synthetic chemists have been interested in this class of compounds for a long time,[1] attempts at their syntheses were not practical as long as analytical methods were not available by which the many stereoisomers that could be formed during synthesis could be detected separately, characterized individually, and identified. These prerequisites were fulfilled at the end of the 1970s with the development of high-field ^{1}H- and ^{13}C-NMR spectroscopy and the new HPLC techniques. As a logical consequence, the first complicated polyketide natural products were then synthesized in impressive pioneering work.[2] Since then, many reports concerning the syntheses of polyketide-derived natural products have been published.[3] The increasing interest in this class of compounds soon led to the development of general principles for their elaboration. One limitation, however, was the state of development of methods for the specific construction of stereocenters in



seco acid of erythronolide B



rifamycin S

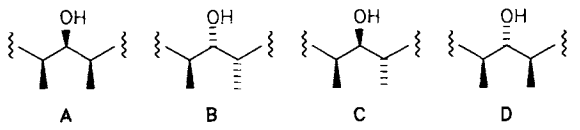
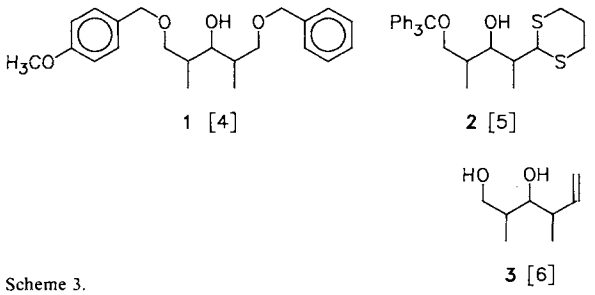
open-chain systems ("acyclic stereocontrol"). The renaissance of stereoselective synthesis has also led, therefore, to the rapid development of such methods during the last few years. Thus, it seems to me that the time has come for a review and critical evaluation of the achievements to date.

Long sequences of stereocenters have been most conveniently analyzed in terms of subunits of three stereocenters each. These, in turn, can be classified into four triads of stereogenic centers (for short, stereotriads) **A** to **D** (Scheme 2). Only the relative and not the absolute configu-



Scheme 2.

ration will be considered at first (i.e., if the end groups differ, an enantiomer exists for each of the triads). One of the strategies for the synthesis of polyketide-derived natural products consists in the preparation of individual building blocks containing the stereotriads **A**–**D** in order to incorporate them as units into the target molecule. Thus, for example, all four diastereomers of **1**[4] and **2**[5] as well as three of the four possible diastereomers of **3**[6] have been obtained in enantiomerically pure form from, for instance, D-glucose or D-mannitol (Scheme 3).

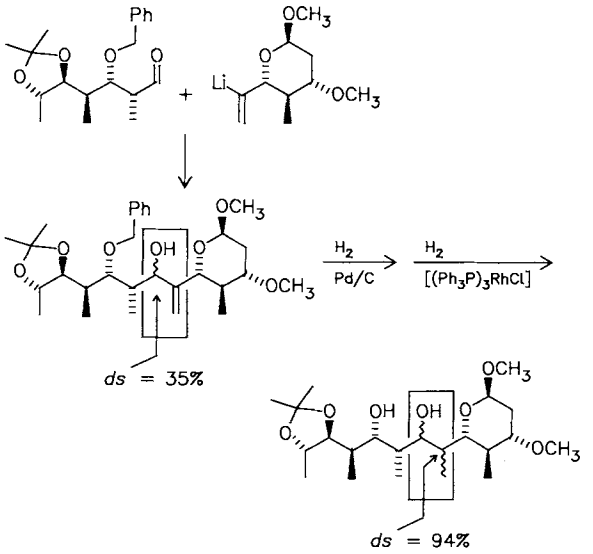


1 [4] 2 [5] 3 [6]

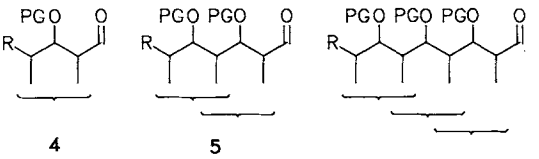
Scheme 3.

The Achilles' heel of this strategy becomes apparent, however, when the individual blocks have to be linked to form longer sequences of directly adjacent stereocenters. While the stereocenters in the linkage region must be constructed with the correct configurations, external stereocontrol of the C–C coupling step is no longer possible, since the chirality of *both* reaction partners is predetermined by the synthetic objective. Part of the synthesis of rifamycin S by *Kinoshita* et al.[7] exemplifies this problem (Scheme 4).

For this class of compounds, therefore, the useful principle of convergent synthesis meets with inherent difficulties for which no generally valid solutions are in sight. Thus, linear synthesis strategies must be employed instead. These include iterative chain lengthening in which each new stereotriad is constructed by adding two new stereocenters to an existing stereotriad (e.g., transformation of **4** to **5**, Scheme 5).



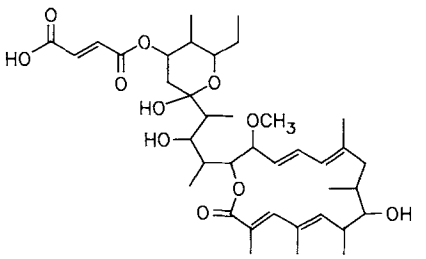
Scheme 4. Part of the synthesis of rifamycin S by *Kinoshita* et al. [7]. The linkage region is shown in the box.



4 5

Scheme 5. PG = protecting group.

Once these transformations can be performed in a small number of steps, in high yields, and with high stereoselectivity, it becomes possible to construct all imaginable sequences of stereocenters with the desired flexibility. The importance of this approach is increased still further by the fact that the exact configurations of the stereocenters of many polyketide-derived natural products are not known with sufficient certainty or, as in the case of hygrolidin (Scheme 6),[8] for example, are only partially known. In such cases the only alternative at present is to synthesize all of the stereoisomers in order to determine the configuration of the natural product.[8]



Scheme 6. Hygrolidin.

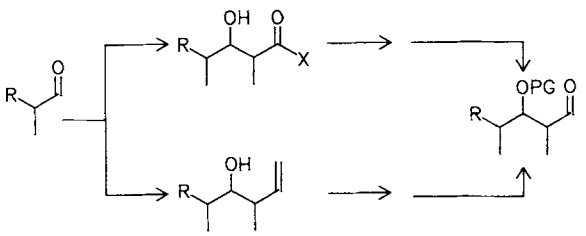
A further reason for this, at first surprising, preference for linear synthesis strategies is, in principle, the possibility of using an iterative procedure, which is amenable to automatization. Following on the development of automatic synthesizers for oligonucleotides and oligopeptides, the development of an automated, highly stereoselective syn-

thesis of polyketide-derived natural products no longer seems utopian. However, reliable procedures for the specific construction of the stereotriads **A** to **D** are first required. The present status of this development is the topic of this review.

The chain lengthening of **4** to **5** requires at least one C–C coupling step to build up the skeleton, resulting in the formation of two new stereocenters. At first, procedures in which both new stereocenters can be defined in one stroke appear most favorable. Those methods that involve simultaneous C–C coupling would be particularly efficient. Ideally, a one-step, repeatable chain lengthening could be achieved in this manner. In practice, any number of steps larger than one is the result of the as yet unavoidable refunctionalization steps.

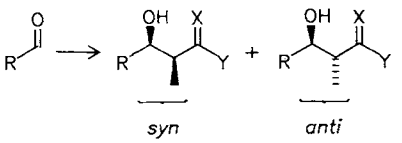
2. C–C Coupling and Construction of Both Stereocenters in One Step

Aldol additions[9] and aldol-like C–C coupling reactions[10] already come close to the above-postulated, ideal process for an iterative chain lengthening (Scheme 7).



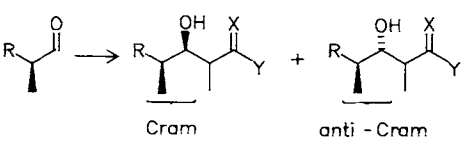
Scheme 7. X = H or a substituent that can be transformed into X = H.

Here, two stereochemical problems need to be solved. The first is the "simple" diastereoselectivity,[9, 10] which concerns the relative configuration at the two newly formed stereocenters (Scheme 8). The second is the 1,2-asymmetric



Scheme 8. Relative configuration at the newly formed stereocenters. X, Y = substituents that permit the ultimate generation of an aldehyde function.

induction, the Cram/anti-Cram selectivity, which concerns the configuration at the newly formed stereocenters relative to the resident stereocenter introduced with the aldehyde (Scheme 9).[11]

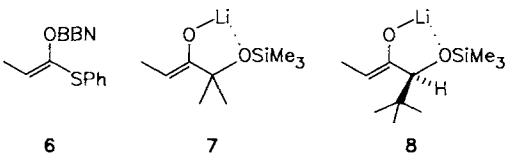


Scheme 9. Relative configuration at newly formed and previously present stereocenters. For X and Y see Scheme 8.

Whereas the problem of simple diastereoselectivity had already been more or less solved at the beginning of the 1980s, the solution of the Cram/anti-Cram problem required and continues to require greater efforts. Only the solution of both problems will open up specific routes to each of the desired stereotriads.

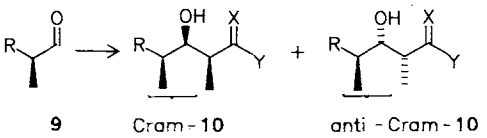
2.1. Aldol Additions

Enolates of acid derivatives, such as **6** (Scheme 10), are often employed in order to make the reaction sequence repetitive (cf. Scheme 5), since a new aldehyde function can be generated after the C–C coupling. Alternatively, enolates **7** of α-siloxy ketones can be used (Scheme 10). In this case, a new aldehyde function can be obtained after the C–C coupling by oxidative glycol cleavage.



Scheme 10. BBN = 9-borabicyclo[3.3.1]nonan-9-yl.

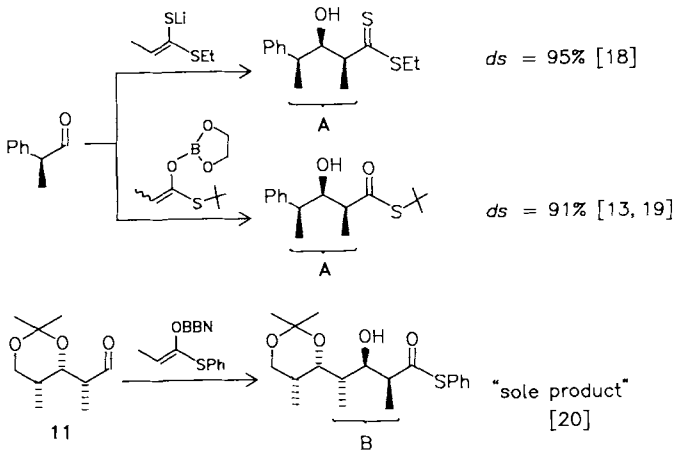
These enolates are obtained with uniform "*Z*" configuration of the double bond by deprotonation of the corresponding carbonyl compounds. They undergo addition to aldehydes to give *syn*-aldols with very high simple diastereoselectivities. The Cram/anti-Cram selectivities of additions to chiral aldehydes, however, exhibit a wide range of values.[12, 13] Thus, an extensive study by *S. Masamune*[14] showed that, depending on the aldehyde **9** employed (steric demands of the group R, presence or absence of other functional groups, and centers of chirality in R which could eventually make chelation control[11] possible), the Cram-**10** : anti-Cram-**10** selectivity was scattered[14] over a range from 15 : 1[9] to 1 : 27 (Scheme 11).[15]



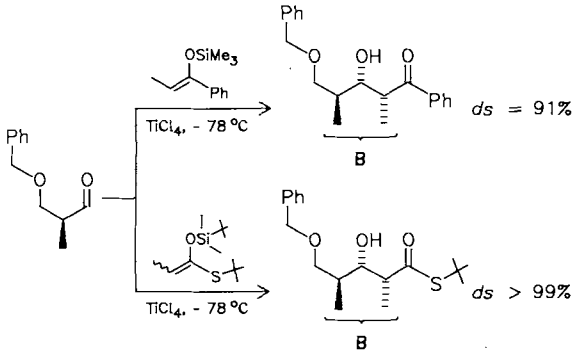
Scheme 11. For X and Y see Scheme 8.

The boron enolate **6** and the lithium enolate **7** did not differ principally in this respect. Hence, only in a few lucky cases is it possible to obtain a homogeneous diastereomer having the stereotriad **A** or **B** with high selectivity (Scheme 12).

The Mukaiyama variant of the aldol addition, the Lewis acid-catalyzed reaction of aldehydes with silyl enol ethers, also shows a good selectivity in favor of the Cram-diastereomer.[21] This is also valid, of course, when an alkoxy-substituted aldehyde exhibits a high diastereofacial differentiation as a result of chelation control (Scheme 13).[11, 19]

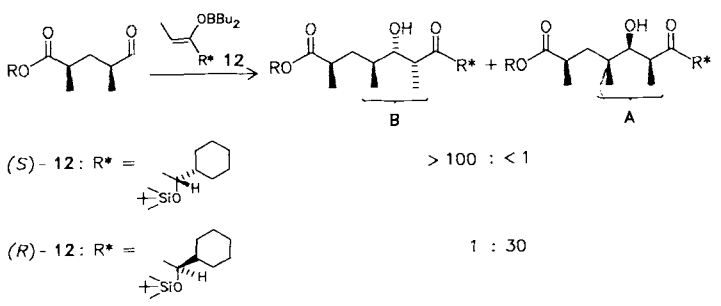


Scheme 12.



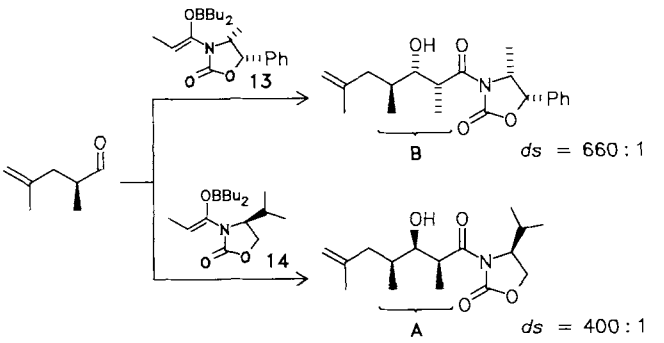
Scheme 13.

In view of the arbitrary factors governing the extent and direction of the diastereoselectivity in the aldol addition, reliable access to the stereotriad **A** or **B** (for **C** and **D**, see the last paragraph of this section) is not guaranteed. For this reason, chiral enolates (e.g., **8**, Scheme 10) were developed so that an insufficient asymmetric induction of the aldehyde can be increased by a reagent-controlled asymmetric induction (double stereodifferentiation).[22] The logical further development focused on chiral enolates with such high asymmetric inductions that they could override the asymmetric induction of the aldehyde. This effect is known as "reagent control of stereoselectivity."[23] This principle is clearly illustrated by the reaction shown in Scheme 14,[23] in which (*R*)- and (*S*)-**12** must be employed in order to obtain the stereotriads **A** and **B**, respectively.



Scheme 14.

Alternatively, stereochemically complementary reagents (e.g., **13** and **14**, Scheme 15) can also be utilized.[24] Compounds **13** and **14** are particularly versatile reagents since the parent chiral compounds norephedrine and valine are readily accessible and the acyloxazolidinone group in the product can be converted very simply into an ester, a carboxylic acid, or a primary alcohol.



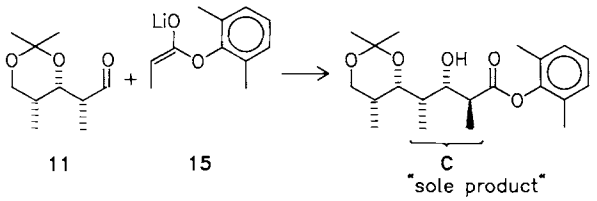
Scheme 15.

Higher asymmetric inductions were achieved with boron enolates such as **6** (or with zirconium[25] and tin enolates,[26]) than with lithium enolates. Presumably, the transition states are more compact[27] in the former cases so that the steric interactions mainly responsible for the asymmetric induction are more pronounced.

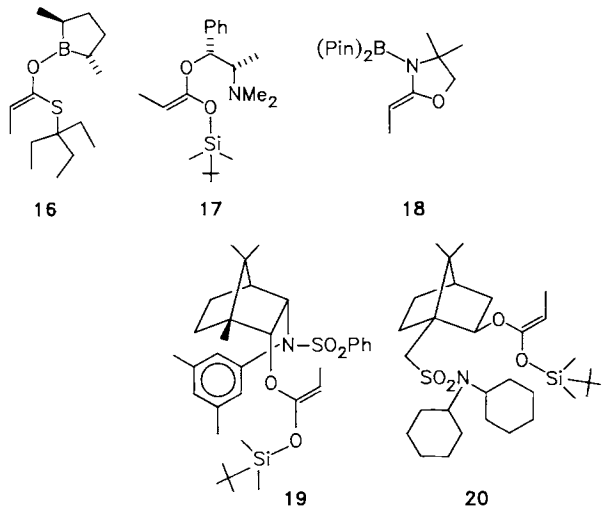
In order to override the inherent 1,2-induction of a chiral aldehyde, the diastereofacial selectivity of the reagent should be greater than 100 : 1. This is the case for the reagents **12**–**14**. A further important point, however, must be emphasized. Reagent control of stereoselectivity in the reaction of a chiral aldehyde can only be applied when this aldehyde is enantiomerically pure. Racemates cannot be utilized! Since the configurations of the new stereocenters are defined by the reagent, use of a racemic substrate would result in the formation of two diastereomers in a 1 : 1 ratio. Of course, recourse to reagent control of stereoselectivity will only then be taken when the reaction with achiral reagents is unsuccessful.

Whereas the problem of obtaining the stereotriads **A** and **B** can thus be considered as firmly solved in principle, the lack of general, *anti*-selective aldol additions necessitated for a long time the use of other routes or the acceptance of tedious refunctionalizations[28,29] in order to obtain the stereotriads **C** and **D**. However, even after the discovery of a series of *anti*-selective aldol additions,[30,31] it was found that, e.g., for the addition of the lithium enolate **15**, the Cram/anti-Cram selectivity is again dependent on the nature of the chiral aldehyde.[32] In a favorable case, such as that of the aldehyde **11**, which exhibits a high asymmetric induction, a single diastereomer could be obtained (Scheme 16)[33] (for further examples, see Refs. [19, 34]).

In this situation as well, only reagent control of stereoselectivity will help in the long term. New chiral, *anti*-selective enol derivatives such as **16**,[35] **17**,[36] **18**,[37] **19**,[38] and **20**[39] can be considered as promising starting points (Scheme 17).

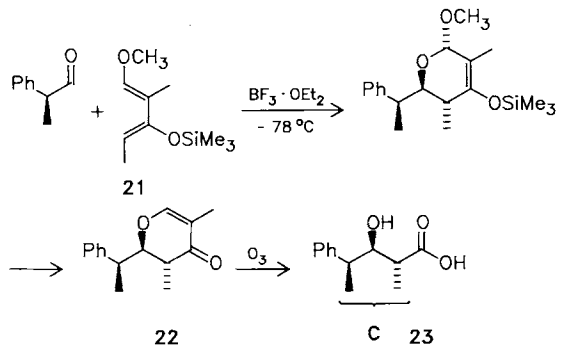


Scheme 16.



Scheme 17. New chiral, *anti*-selective enol derivatives. Pin = isopinocamphenyl.

As far as the final result is concerned, the cycloaddition of Danishefsky's diene to aldehydes corresponds to an aldol addition. Here, the Cram product **22** (Scheme 18) was formed with a normal diastereoselectivity of 4.3 : 1 and,



Scheme 18.

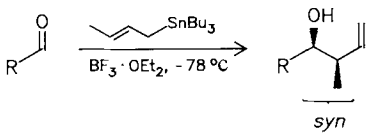
after refunctionalization, gave the carboxylic acid **23** (stereotriad **C**).[40] By changing the solvent, a structure with the stereotriad **A** could be obtained with a selectivity of up to 10 : 1.[41] It remains to be clarified whether or not high diastereoselectivities can be obtained generally with the reagent **21** on addition to chiral aldehydes.

2.2. Crotyl-Metal Compounds

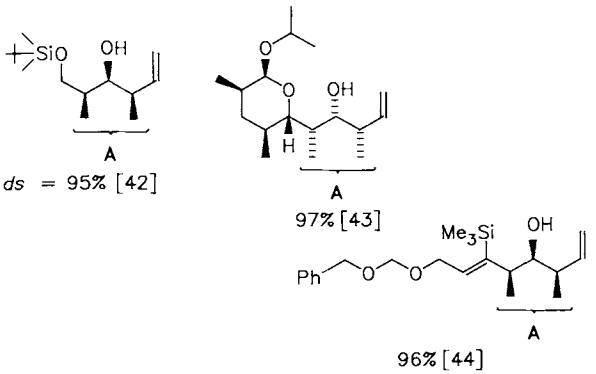
The problem of simple diastereoselectivity can also be considered as solved for the additions of crotyl-metal compounds to aldehydes.[10] Again, the Cram/anti-Cram selectivity of the addition to chiral aldehydes remains a problem.

2.2.1. Crotyl-Tin Compounds

The additions of crotyltributylstannane to aldehydes, which proceed under Lewis acid catalysis and result in good *syn*-selectivities, will be mentioned first (Scheme 19). In many cases of additions to chiral aldehydes, high diastereoselectivities in favor of the formation of the triad **A** have been reported (Scheme 20).

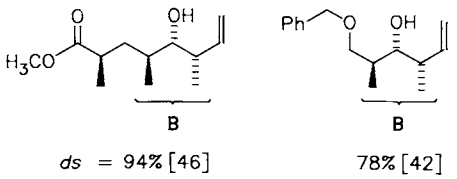


Scheme 19.



Scheme 20.

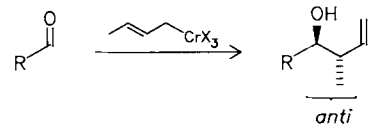
Furthermore, recent results[45] suggest that changing the Lewis acid and the reaction conditions could make other stereotriads accessible. In any case, however, it is the nature of the aldehyde that governs the extent of the diastereoselectivity.[46, 47] In cases in which it is possible to fix the aldehyde in a different conformation by chelation with a multidentate Lewis acid, products with the stereotriad **B** also become accessible (Scheme 21).



Scheme 21.

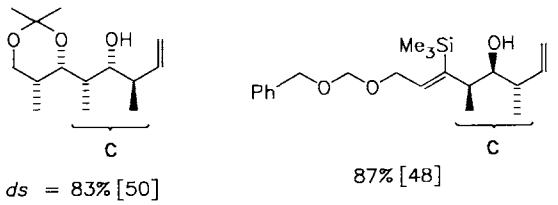
2.2.2. Crotyl-Chromium Compounds

There are many reports on the addition of crotyl-chromium compounds to aldehydes proceeding with high *anti*-selectivity (Scheme 22).



Scheme 22.

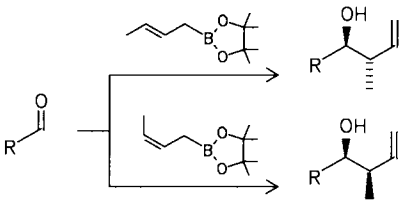
For reactions with α-chiral aldehydes, the reagent should be prepared from pure $CrCl_2$ instead of from $CrCl_3 + LiAlH_4$ in order to avoid an epimerization (racemization) of the aldehyde.[48] The Cram diastereomer (stereotriad **C**) predominates in the addition to α-chiral aldehydes.[49–51] Here again, the selectivity varies over a wide range: the examples in Scheme 23 represent exceptionally good selectivities.



Scheme 23.

2.2.3. *Crotylboronate Esters*

In the case of crotylboronate esters, both the *Z* and the *E* isomers are accessible. They undergo addition to aldehydes with high simple diastereoselectivities (Scheme 24).[10, 52, 53] In additions to α-chiral aldehydes, *E*-crotylboronate esters gave a higher Cram selectivity in comparison to the reactions of allylboronate esters, whereas *Z*-crotylboronate esters generally led to preferential formation of the anti-Cram diastereomers, albeit often in only small excess.[54] Since boronate esters are monodentate Lewis acids, the aldehyde conformation is not fixed by chelation in any of the cases.



Scheme 24.

The results in Table 1 show unequivocally for the first time that, in the case of a given chiral aldehyde, not only the extent but also the *direction* of the asymmetric induction can be determined by the nature of the achiral reaction partner. This situation occurs when the steric interactions across the forming partial bond are energetically similar to the steric interactions responsible for the 1,2-asymmetric induction, owing to a late, compact transition state—such as that transversed in the addition of an allylboronate ester to an aldehyde. In principle, this signifies a reagent control of the stereoselectivity by *achiral* reagents! On the basis of these data, it was possible for the first time to probe experimentally the conformation of the aldehyde side chain responsible for the asymmetric induction in the transition state of the allylboronate ester addition.[54] The most favorable transition states are shown in Scheme 25.

Table 1. Cram/anti-Cram selectivities of additions of boronate esters to chiral aldehydes.

Aldehyde \ Boronate ester				49 : 51	95 : 5	9 : 91
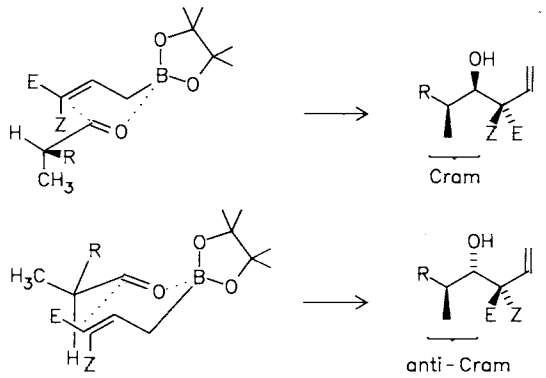
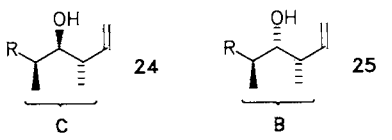
	61 : 39	89 : 11	22 : 78
	79 : 21	98 : 2	40 : 60
	79 : 21	94 : 6	41 : 59
	62 : 38	83 : 17	30 : 70



Scheme 25. E and Z indicate the positions of the substituents for a double bond having an E and Z configuration, respectively.

With respect to the synthesis of stereotriads, one can summarize that *E*-crotylboronate esters give frequently good to very good selectivities in favor of **24**. With *Z*-crotylboronate esters, however, usually only modest selectivities in favor of **25** result (Scheme 26).

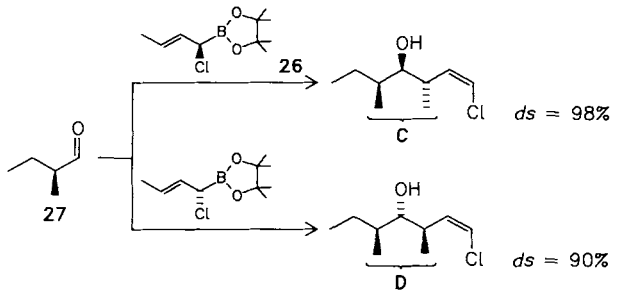


Scheme 26.

In order to obtain stereotriads other than the stereotriad **C** by this methodology, it is thus again necessary, as in the case of the aldol addition, to employ chiral reagents. Chiral, α-substituted crotylboronate esters, such as **26**, have been developed for this purpose.[55]

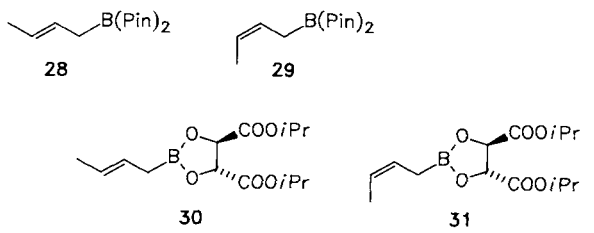
In this way, the principle of reagent-controlled stereoselectivity was demonstrated again, for example, in the case

of the aldehyde **27** (Scheme 27). However, the approximately 30:1 asymmetric induction originating from reagent **26** did not reach the desired range of >100:1. Thus, other α-chiral *E*-crotylboronate esters are at present being tested for their suitability.



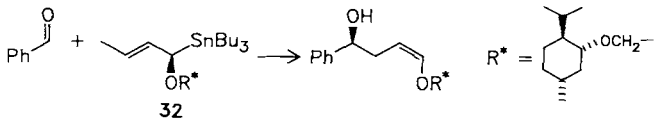
Scheme 27.

Further crotylboron compounds that have given encouraging results are the crotylboranes **28** and **29** reported by *H. C. Brown* et al.[56] and the chirally modified crotylboronate esters **30** and **31** reported by *W. R. Roush* et al.,[52,53] all of which are available in both enantiomeric forms (Scheme 28).



Scheme 28.

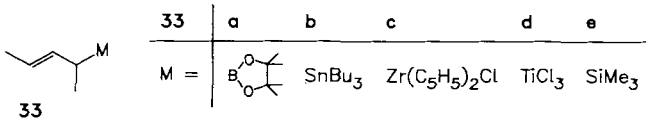
Here also, it remains to be seen how near these reagents approach the desired selectivity of >100:1. The utility of α-chiral crotyl-metal reagents has also been demonstrated for the tin compound **32**, which undergoes thermal addition at 130°C to benzaldehyde with formation of a homogeneous, *anti*-configurated product (Scheme 29).[57]



Scheme 29.

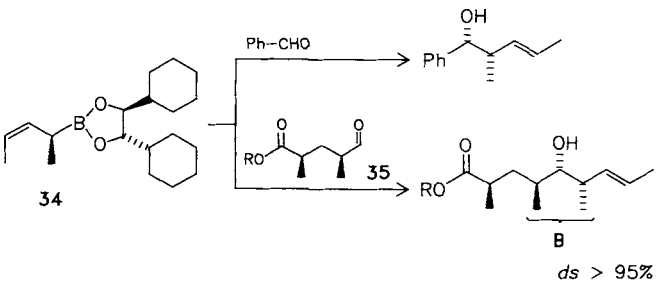
2.3. Pentenyl-Metal Compounds

Pentenyl-metal compounds of the type **33** (Scheme 30) already have a center of chirality at the α-position to the metal, which may be employed for control of the addition



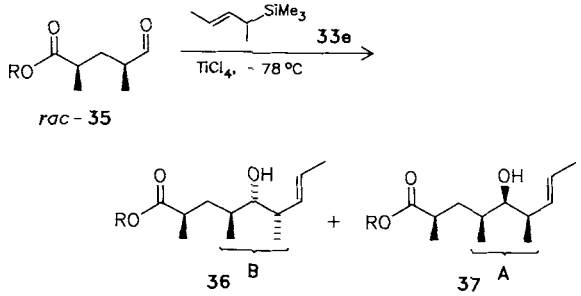
Scheme 30.

to aldehydes. This has also been realized in the case of the *Z*-pentenylboronate ester **34**, which, on addition to benzaldehyde, resulted in an asymmetric induction of 99% *ee* (Scheme 31).[58] Correspondingly, the aldehyde **35** was converted specifically into the compound with the stereotriad **B**. Experiments in the racemic series, however, indicated that the asymmetric induction of the *E*-pentenylboronate ester **33a**, corresponding to **34**, is low.



Scheme 31.

Moreover, the reactions of *rac*-**35** with racemic **33b-d** under Lewis acid catalysis exhibited a wide range of diastereoselectivity in favor of individual stereotriads (Scheme 32).[59] For the reaction of racemic **33e**, a high selectivity in favor of **36** (stereotriad **B**) has been reported.[60] The same reaction using the enantiomerically pure aldehyde **35** gave both stereoisomers **36** and **37** in a ratio of 1:1.[58]

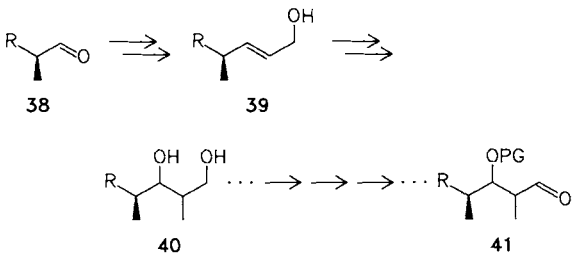


Scheme 32.

This shows that each enantiomer of **35** leads specifically to one of the products; the diastereoselectivity of the reaction is therefore subject to reagent control. This is not surprising in light of the reactions of other α-chiral crotylsilanes with aldehydes.[61]

3. Construction of the Skeleton and the Stereocenters in Separate Steps

Procedures will first be discussed in the first step of which the carbon skeleton is extended by chain lengthening introducing a prochiral C=C bond. In a subsequent step, the diastereotopic sides of the C=C bond are functionalized in such a way that only one of the desired stereotriads results. In principle, these procedures are also designed so that they can be performed repetitively (Scheme 33, **41** can be used again as educt **38**).

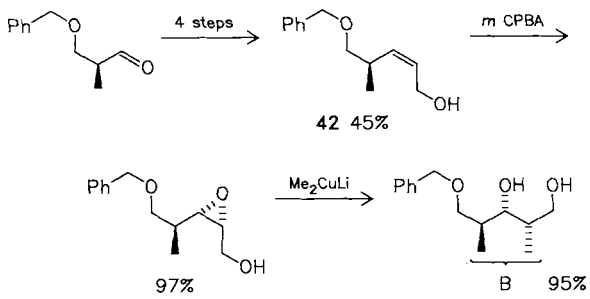


Scheme 33. The exclusive formation of an olefin having either a *Z* or an *E* configuration is decisive for this synthetic sequence.

However, since the chain lengthening and the construction of the stereocenters are now performed in two separate steps, longer reaction sequences than those described in Section 2 are inevitable. In the first, chain-lengthening step a double bond with uniform prochirality (i.e., homogeneous *E* or *Z* configuration) must be formed initially. Effective methods, such as the Wittig reaction or analogous procedures, are available for this.[62,63]

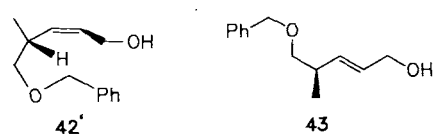
3.1. Epoxidation

The isomerically uniform olefins thus obtained (e.g., **39** from **38**) can be functionalized, e.g., epoxidized, utilizing the asymmetric induction from the resident center of chirality. The epoxide can then be opened regioselectively with inversion at C-2 by means of cuprates to give compounds **40**. A typical sequence[64] is shown in Scheme 34.



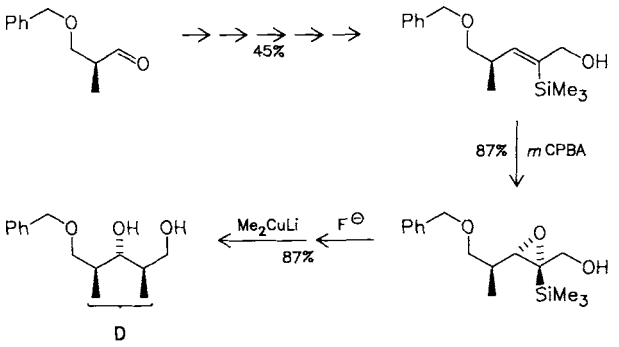
Scheme 34. *m*CPBA = *m*-chloroperbenzoic acid.

The key to the high diastereoselectivity observed in the epoxidation of the olefins lies in the *Z* conformation of the double bond. This practically allows only one configuration for **42**, namely, **42'** (Scheme 35), in which the benzyloxy group is fixed on one side of the double bond. Since *m*-chloroperbenzoic acid reacts by coordination with the benzyloxy group, the epoxidation of **42** occurs selectively from this side. When the *E*-allyl alcohol **43** is the starting material, the situation is less favorable since the position of the benzyloxy group relative to the double bond is not fixed by a preferred conformation. For this reason, the epoxidation of **43** proceeds unselectively.[64]



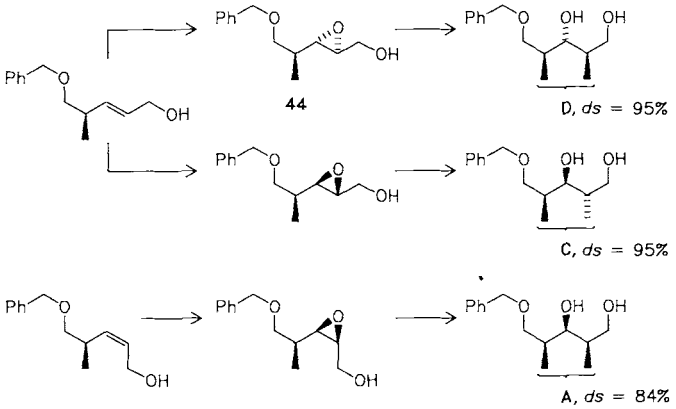
Scheme 35.

This situation can be corrected by temporary introduction of an auxiliary substituent (e.g., Me_3Si) into the *Z* position of the olefin. The epoxidation then takes place once again with high diastereoselectivity (Scheme 36).[65] However, the number of reaction steps is increased.



Scheme 36.

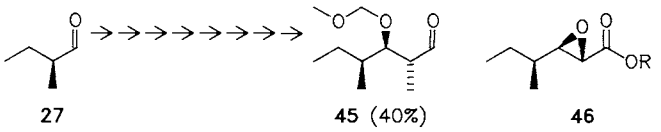
It might therefore be more favorable to epoxidize the double bond under reagent control of stereoselectivity, i.e., an asymmetric induction resulting from the reagent (e.g., Sharpless epoxidation[23]). In this way, three (**A**, **C**, and **D**) of the four stereotriads were obtained in yields of about 80% (Scheme 37).[66]



Scheme 37.

The fourth stereotriad (**B**) is accessible utilizing the asymmetric induction resulting from the educt (see Scheme 34). Furthermore, a method has been developed by which a compound of the type **44** has been converted into the stereotriad **B**. This has been realized by reductive conversion of the CH_2OH group into a methyl group followed by introduction, via cuprate, of the C_1 unit at the oxidation level of an aldehyde.

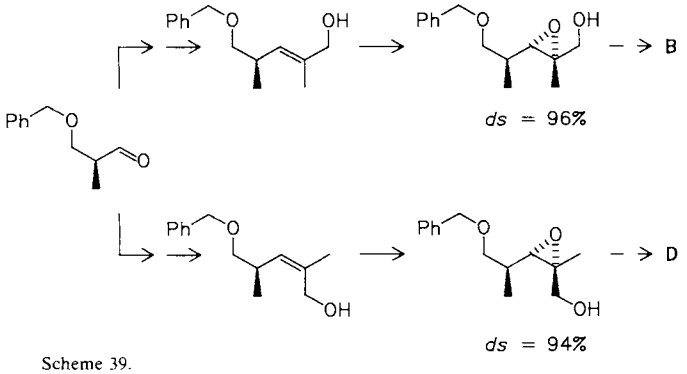
The repetitive chain lengthening of **38** to **41** allows access to all four stereotriads with high diastereoselectivities and thus is the most flexible strategy. However, it requires many steps.[68] This also arises from the fact that the OH groups on the primary and secondary carbon atoms in the intermediate products **40** must be differentiated. In a synthesis of avermectin, eight steps were required for the "simple" lengthening of **27** to **45**, which, nevertheless, was achieved in 40% yield (Scheme 38).[69]



Scheme 38.

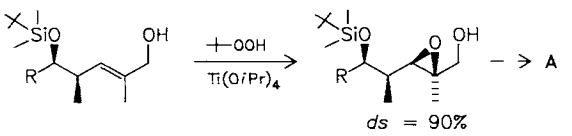
The differentiation of the hydroxyl groups would be easier if the epoxide opening were performed on the epoxycarboxylic acid or the epoxy ester **46** rather than on the epoxy alcohol.[70]

Instead of introducing the methyl group by means of dimethylcuprate (see Scheme 36), it can be introduced in the chain-lengthening step (Scheme 39).[65] Since a substituent



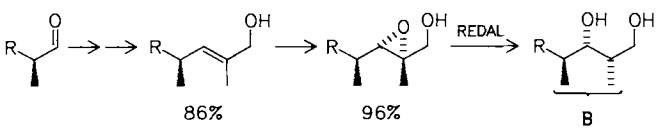
Scheme 39.

is now present at the double bond in the *Z* position with respect to the chiral moiety, the asymmetric induction from the resident center of chirality in the epoxidation step is high; once again, the benzyloxy group directs the peracid onto only one side of the double bond. If, instead of the benzyl group, a sterically more demanding protecting group (tBuMe$_2$Si) is used, this group shields this particular side of the double bond so that, with the same starting configuration and a different epoxidizing agent, the other side of the double bond can now be epoxidized (Scheme 40).[71]



Scheme 40.

In order to obtain the stereotriads **A**, **B**, or **D** from the trisubstituted epoxides, the latter must be hydrogenolytically opened in a regioselective manner. Sodium hydridobis(2-methoxyethoxy)aluminate (REDAL) has proved useful for this purpose (for the use of AlH_3, see Ref. [72]). This sequence (Scheme 41) has been used, for example, in a synthesis of protomycinolide,[73] in which the regioselectivity of epoxide opening was 9 : 1.

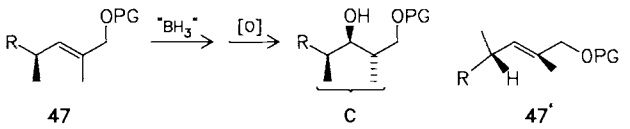


Scheme 41.

In summary, the routes involving epoxidation of prochiral olefins are reliable and versatile with respect to stereochemical control but require a large number of steps.

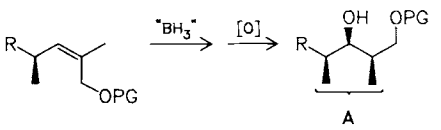
3.2. Hydroboration or Hydrosilylation

Epoxidation of a double bond followed by a REDAL reduction is, however, only one possibility for the regioselective addition of water to a double bond. The standard method for anti-Markownikoff addition is hydroboration. It was thus of interest to determine whether hydroboration of substrates of the type **47** (Scheme 42) could be achieved with sufficient asymmetric induction from the resident centers of chirality.



Scheme 42.

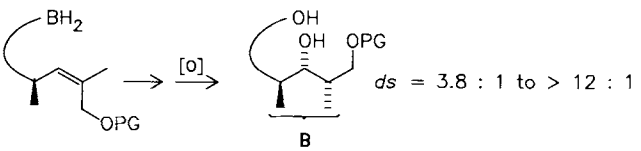
It is the difference in spatial requirements of the groups R and CH_3 (cf. **47'**) that governs the extent of the asymmetric induction, which varied from 3 : 1 to 8 : 1.[17,64,66,74] This reaction sequence was developed by *Kishi* et al. and then used in the synthesis of rifamycin S.[2] By changing the prochirality—*Z* configuration of the double bond—the stereotriad **A** could be obtained with a selectivity ranging from 2.5 : 1 to 12 : 1 (Scheme 43).[17,64]



Scheme 43.

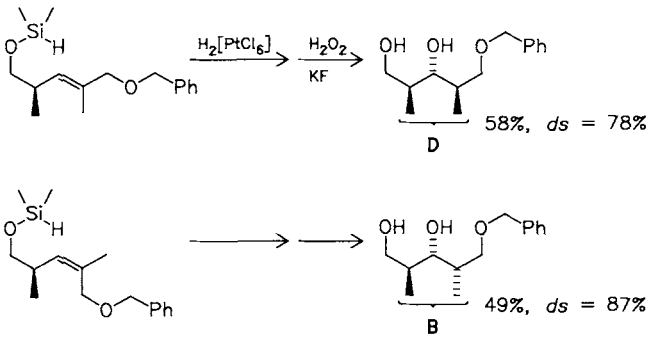
Generally, higher diastereoselectivities in the hydroboration would be desirable in most cases. It is therefore surprising that the possibility of double stereodifferentiation by means of chiral hydroborating agents[75] has not been utilized in these cases.

The diastereoselectivity can also be increased, however, by performing the hydroboration intramolecularly instead of intermolecularly (Scheme 44). In addition, since the hydroborating agent is linked to the group R, the other side of the double bond is now attacked.[76,77]



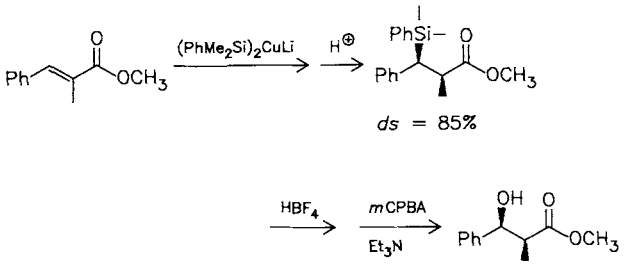
Scheme 44.

The same is true for the intramolecular hydrosilylation (Scheme 45). Depending on the prochirality of the double bond used, the stereotriad **D** or **B** is thereby accessible after oxidative cleavage of the C–Si bond.[78] Here, good to very good (20 : 1) selectivities have been achieved.



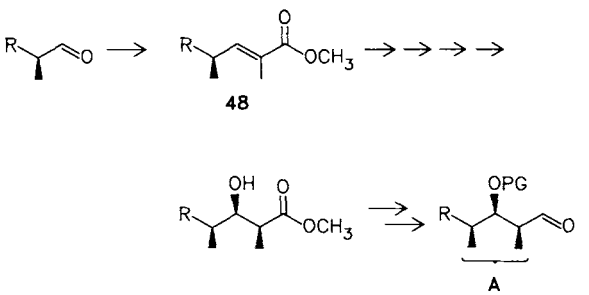
Scheme 45.

While hydrosilylation results in simultaneous introduction of the C–Si and C–H bonds, it is also possible to form these two bonds sequentially. The acceptable diastereoselectivities of the reaction sequence shown in Scheme 46[79] could serve as the basis for an iterative chain lengthening with formation of the stereotriad **A**. In this case, the ste-



Scheme 46.

reocenters would be formed in a series of asymmetric induction steps, in the first of which the differences in size of the R and CH_3 groups in **48**, for a fixed conformation (cf. **47'** in Scheme 42), are again assumed to be responsible (Scheme 47).



Scheme 47. The four steps required for addition of water to the C=C bond of **48** correspond to those of Scheme 46.

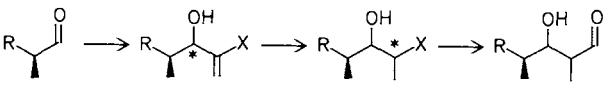
The procedures described in this section for the iterative construction of stereotriads require as well a large number of steps, because of the frequently necessary protecting group manipulations.

4. Stepwise Construction of Both New Stereocenters

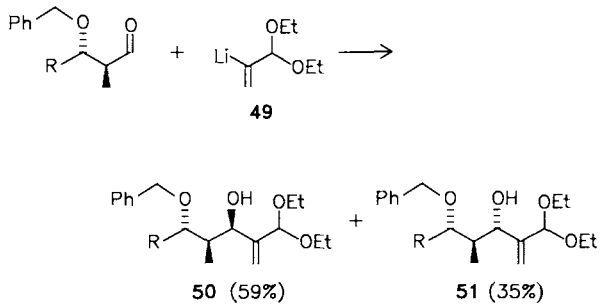
The last example in Section 3.2 already demonstrated a stepwise construction of the two new stereocenters. Since the problem of asymmetric induction must be solved in each step, this approach appears at first to be inherently unfavorable. The following examples, however, demonstrate that this is not necessarily the case and that even relatively short reaction sequences for the iterative construction of stereotriads can be realized.

4.1. Vinylation/Hydrogenation

If this stepwise route is selected, it is logical to construct neighboring, not distal, stereocenters utilizing 1,2-asymmetric induction (Scheme 48). This route has already been realized several times using **49**[80] as an acrolein d^2 synthon (Scheme 49).[81]

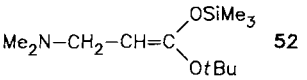


Scheme 48. X = a protected or latent aldehyde function.



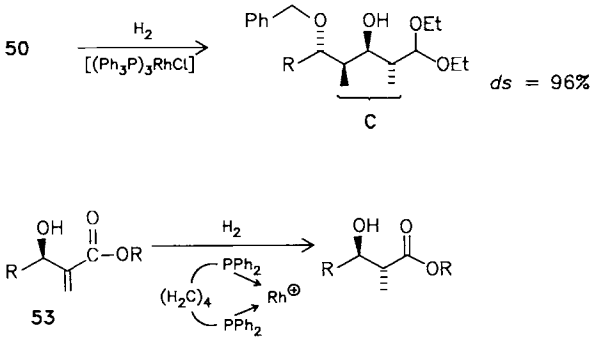
Scheme 49.

Unfortunately, the Cram selectivity in the first step is unsatisfactory. However, an extensive arsenal of acrolein and acrylate d^2 building blocks[82] is available, some of which should most certainly result in a high Cram/anti-Cram selectivity (see, e.g., Ref. [83]). This could also be achieved by the use of the corresponding ketene acetals, such as **52** (Scheme 50), under Mukaiyama conditions.[84] Since the above-mentioned synthons are all achiral, the stereoselectivity is solely dependent on the magnitude of the inherent asymmetric induction of the chiral aldehydes.[11]



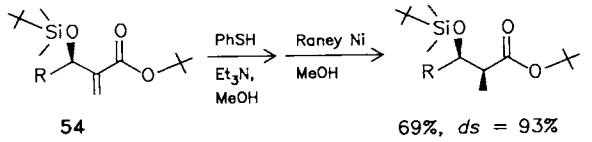
Scheme 50.

In the second step, the last stereocenter of the stereotriad must be constructed by hydrogenation of the double bond (e.g., of **50** or **51**). Here, it has been shown that in the case of the Cram diastereomer **50**, a rhodium-catalyzed hydrogenation takes place with very high *anti*-selectivity (Scheme 51),[81] whereas with the anti-Cram diastereomer **51** the stereoselectivity varied widely.[85] The rhodium-catalyzed hydrogenation of acrylates of the type **53** also generally proceeds with high *anti*-selectivity (Scheme 51). If necessary, the selectivity can be increased by employing chiral catalysts or by utilizing menthyl esters.[86] In cases with a high stereoselectivity in the first step, stereotriads of



Scheme 51.

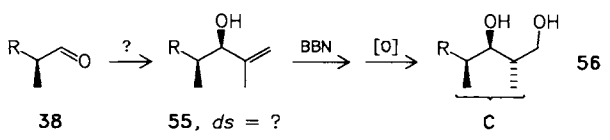
the type **C** are generally accessible in this manner. Of interest is the observation by *Scolastico* et al.[83] that addition of thiophenol to an acrylate of the type **54** followed by desulfurization gave just the other isomer (Scheme 52). In connection with the chain lengthening described in this section, this method should make possible the selective construction of the stereotriad **A**.



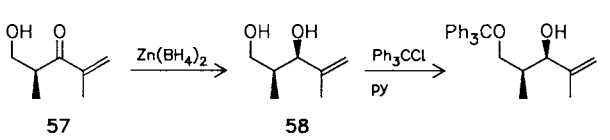
Scheme 52.

4.2. Vinylation/Hydroboration

A related reaction sequence consists in a diastereoselective propenylation[87] of the chiral aldehyde **38** to form **55** (Scheme 53); however, no direct information on the magnitude of the achievable diastereoselectivity is available. The second step, the hydroboration to give **56**[88] proceeds, in contrast, with very high diastereoselectivity to yield the stereotriad **C**.[89,90] Protection of the OH group in **55** reduces the diastereoselectivity.[72] All the other stereotriads have also been prepared, albeit in multistep sequences, from a starting compound of the type **55**.[5] This led to the recognition that the $ZnBH_4$ reduction of **57** to **58**[5] represents a further method to convert an α-chiral β-hydroxycarboxylic acid into intermediate products of the type **55** (Scheme 54).



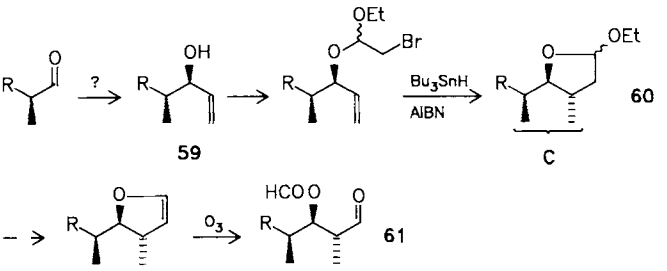
Scheme 53.



Scheme 54.

4.3. Vinylation/Cyclization

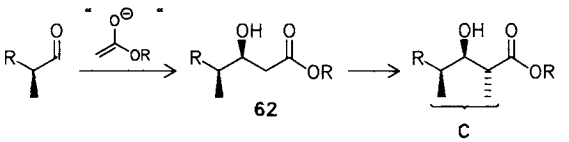
The reaction sequence in Scheme 55 represents a completely different approach which has not yet been employed for the iterative construction of the stereotriad **C**. In the first step, a Cram-selective vinylation[87,91] of the starting aldehyde to give **59** must be realized. The further transformation to **60** by radical cyclization proceeds with high (*ds* > 95%) *anti*-selectivity.[89,92] Subsequent refunctionalizations should result in the formation of the desired aldehyde **61** having the stereotriad **C**.



Scheme 55. AIBN = azobisisobutyronitrile.

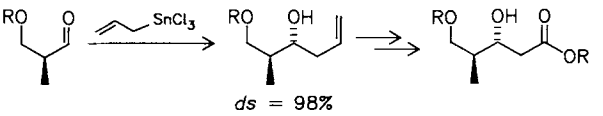
4.4. Acetate-Enolate Addition/Frater Alkylation

In the procedure discussed in Section 4.3, the second step consisted in a stereoselective C–C coupling with formation of the main chain. A C–C coupling with introduction of the methyl group is just as feasible (Scheme 56).



Scheme 56.

However, the first step in this case poses difficulties since easily controlled achiral[18] or chiral[93] acetate-enolate equivalents are rare. The first step must, if necessary, be achieved by other routes.[94,95] For example, a chelation-controlled allylation of β-alkoxyaldehydes is a possibility (Scheme 57)[45] (for non-chelation control, see Ref. [96]).



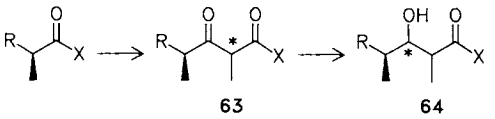
Scheme 57.

The second part of the reaction sequence, in contrast, is well substantiated. The methylation of the β-hydroxy ester **62**, after conversion to the dianion according to the method of *Frater* et al.,[94,97] is successful with good (*ds* ≥ 90%) *anti*-selectivity. *Oppolzer* et al.[95] have described an analogous sequence that is of interest here.

Although the procedures described in Sections 4.3 and 4.4 are mainly limited to the formation of the stereotriad **C**, they require only four to five steps for an iterative chain lengthening.

4.5. Acylation/Reduction

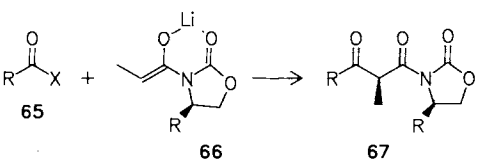
The reverse order for the stepwise construction of the stereocenters remains to be discussed (Scheme 58). In this case, the more distant stereocenter (* in **63**) is defined in the first step and the now central center (* in **64**) is constructed in the second step. This procedure at first seems to



Scheme 58. For example, X = an oxazolidinane residue.

be of little value since a high 1,3-asymmetric induction from the stereocenter present in the starting material can hardly be expected. Just this fact, however, demands and allows the use of reagent control of the stereoselectivity, thereby making all four stereotriads possibly accessible. Furthermore, since the stereocenter marked with an asterisk in **63** is flanked by two carbonyl groups, a rapid epimerization appears unavoidable. Fortunately, groups X exist that are capable of hindering an enolization in **63** for stereoelectronic reasons. Finally, this sequence is also involved in the natural biogenesis of the polyketide-derived natural products, whereby the *S*-coenzyme A moiety serves as the group X. This iterative chain lengthening is short and, furthermore, takes place at the oxidation state of the acid derivative (not that of the aldehyde as in the preceding sections), thus bringing further advantages. In short, on closer consideration, the approach shown in Scheme 58 could be one of the more attractive routes to obtain the desired stereotriads simply and specifically.

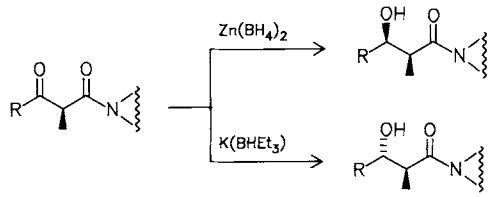
What does the reality look like? The lithium enolates **66** are cleanly acylated by acid chlorides (**65**, X = Cl) to give the products **67** with an asymmetric induction of about 95% (Scheme 59).[99] Depending on the configuration of



Scheme 59. For example, X = Cl.

the controlling oxazolidinone group in **66**, either configuration at the new stereocenter in **63** can be attained. The special β-dicarbonyl system withstands weakly basic and weakly acidic conditions without epimerization.[100] Application of this method to iterative chain lengthening requires acylating agents **65** that do not undergo epimerization of the α center of chirality during preparation, handling, and reaction. Perhaps, among other derivatives, the *N*-methoxyamides, **65** (X = $N(CH_3)OCH_3$), introduced by *Weinreb* et al.[101] could be suitable.[102]

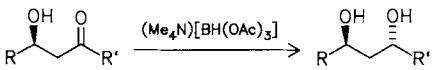
The α-methyl-β-oxo carboxylic acid derivatives **63** thus obtained can be stereoselectively reduced with $Zn(BH_4)_2$ in the second step of the reaction sequence (Scheme 60).[103]



Scheme 60.

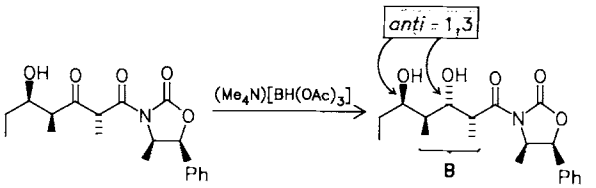
In this way, *syn*-configurated β-hydroxy-α-methylcarboxylic acid derivatives are obtained under chelation control. Starting from the intermediate products **63**, this leads to the stereotriads **A** and **B**, the ones which are also accessible by the aldol addition (see Section 2.1) under reagent control of stereoselectivity. In this respect, an *anti*-selective reduction of α-methyl-β-oxo esters would be much more valuable. This was recently realized by the use of potassium triethylhydridoborate.[104] Thus, the construction of the stereotriads **C** and **D** should also be possible by this method.

Another type of control is based on the observation that, in the reduction of β-hydroxy ketones, a 1,3-induction from the stereocenter bearing the hydroxyl group is possible. Thus, reduction with triacetoxyhydridoborate leads to *anti*-1,3-diols (Scheme 61).[105] A hydroxyl group in the δ-



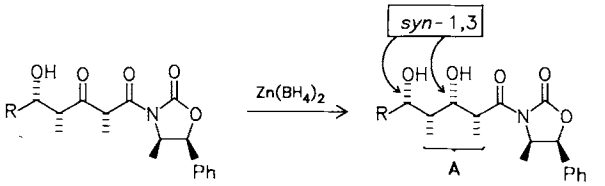
Scheme 61.

position of a β-dicarbonyl system can thus take over the stereochemical control in the reduction (Scheme 62).[105, 106]



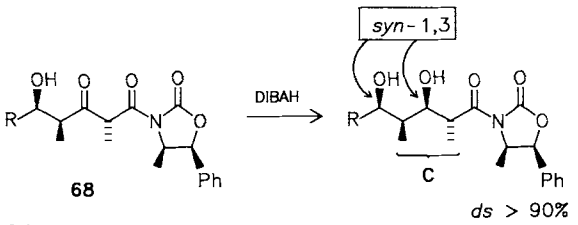
Scheme 62.

Use of $Zn(BH_4)_2$ or diisobutylaluminum hydride (DIBAH) to reduce β-hydroxy ketones,[107] in contrast, should lead to *syn*-1,3-diols. The example shown in Scheme 63[100]



Scheme 63.

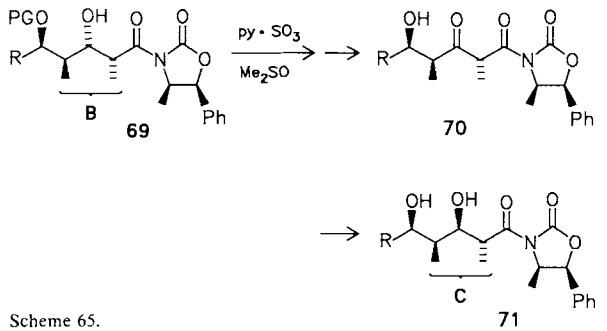
does not answer the question whether the control results from the β-hydroxy ketone moiety or from the methyl group of the β-dicarbonyl unit. The reduction of **68** with DIBAH (Scheme 64)[100] demonstrates that the former method of control dominates over the latter. Thus, not only the stereotriad **C** but probably also the stereotriad **D** should be accessible by exploiting the 1,3-induction from a hydroxyl group in the δ-position.



Scheme 64.

5. Interconversion of Stereotriads

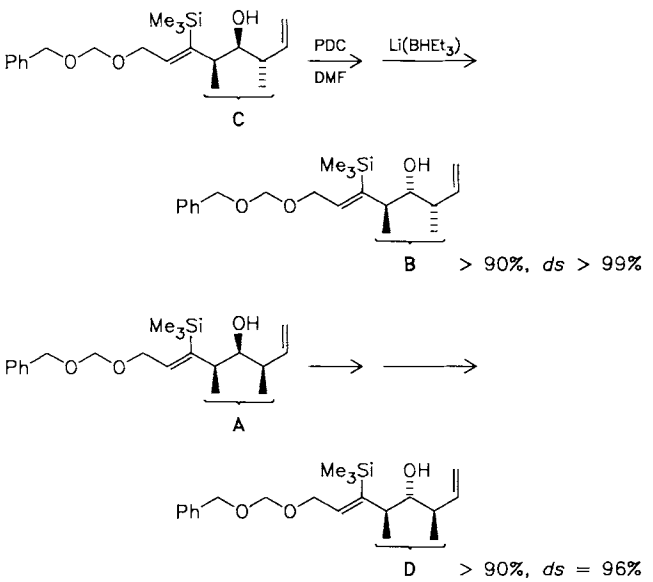
The reduction of **68** with DIBAH opens up the possibility of converting, for example, compound **69** with the stereotriad **B**, accessible by direct aldol addition (see Section 2.1), into **70** by oxidation; **70** could then be converted into



Scheme 65.

71 having the stereotriad **C** (Scheme 65). Indeed, oxidation of such (β-hydroxyacyl)oxazolidinones to the corresponding β-dicarbonyl compounds without epimerization of the central stereocenter is possible.[98]

In another case, the conversion of the stereotriad **C** to **B** or **A** to **D** has been realized by an oxidation-reduction sequence (Scheme 66).[44]



Scheme 66. PDC = pyridinium dichromate, DMF = dimethylformamide.

The presence of the bulky (but removable[48, 108]) Me_3Si group is most certainly favorable[109, 110] but not absolutely necessary[109] for the high diastereoselectivity in the reduction. Whereas the above-mentioned interconversions can be realized in only one direction, the Mitsunobu reaction[111] offers, in principle, bidirectional interconversions of the stereotriads **C** and **B** or **A** and **D**. However, to the best of my knowledge, this possibility has not yet been exploited. Application of this method may be necessary when, for example, an aldehyde with high asymmetric induction is employed in an aldol addition and where one would have to override this by reagent control of stereoselectivity. In this situation, the aldol addition will inevitably be very slow so that side reactions could dominate. In this case, it would be more favorable to build up another stereotriad, which is epimeric at the OH group, in a process that utilizes the high asymmetric induction of the aldehyde and then to invert the configuration of the carbon atom bearing the OH group in a second step.

6. Summary and Outlook

The extent of the results reported here clearly shows that this field of stereoselective synthesis has been widely developed in only a few years. Thus, a sufficient arsenal of methods is now available for the chemist interested in the synthesis of polyketide-derived natural products. The summary in Table 2 shows, however, that not all stereotriads are equally well accessible.

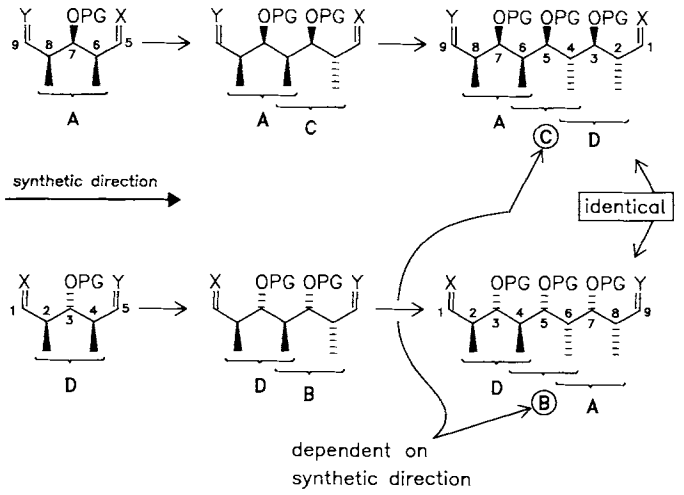
Table 2. Survey of methods for the preparation of the stereotriads **A**–**D**.

Methods	OH A	OH B	OH C	OH D
2.1	+	+	[a]	
2.2.1	+	[a]		
2.2.2			+	
2.2.3		[a]	+	[a]
2.3	[a]	+		
3.1	+	+	+	+
3.2	+	+ [b]	+	+ [b]
4.1	[a]		+	
4.2, 4.3, 4.4			+	
4.5	+	+	+	
5		+	[a]	[a]

[a] Few examples or frequently low diastereoselectivity. [b] Only with certain structural features in the substrate.

In this respect, it is important to know that, in the synthesis of polyketide-derived natural products by such repetitive procedures, the nature of the stereotriads to be constructed also depends on the direction of the synthesis (Scheme 67). Whereas the symmetrical stereotriads **A** and **D** are obtained irrespective of whether the chain is built up from left to right or from right to left, the stereotriads **B** and **C** are dependent on the direction of construction of the molecule.

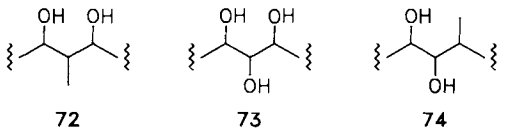
The large number of methods available for the construction of the triad **C** could hence be of importance for choosing the direction of synthesis. The methods described here are not all equal. The most mature are the methods described in Section 2.1, for the preparation of the stereotriads **A** and **B** by means of aldol additions with chiral enolates. In other cases, the choice must be made between



Scheme 67. C=X, C=Y = real or latent aldehyde functions.

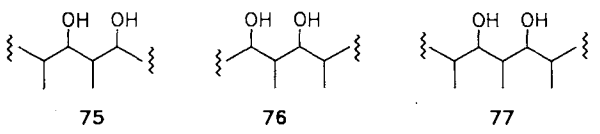
high stereoselectivity and versatility but a large number of steps (epoxidation of prochiral olefins, Section 3.1), on the one hand, and moderate to good stereoselectivity with a lower number of steps, on the other hand.

Further development of methods for stereoselective syntheses is in full progress. Therefore, it can be safely predicted that the unsatisfactory results in Table 2 will eventually be improved and that the gaps will be filled. More important, however, is the elucidation of the principles by which the synthesis of molecules with long sequences of stereocenters can be approached. The emphasis on the stereotriads **A**–**D** is completely arbitrary. A review of the newly developed methods for the synthesis of the four diastereomers of the type **72**,[88, 112–114] **73**,[23, 115] or **74**[6, 11, 116] would be equally possible (Scheme 68).



Scheme 68.

Even the limitation of this review to the synthesis of stereo*triads* as steps in the synthesis of larger molecules was only opportune initially; it is by no means binding. For example, the eight stereotetrads, e.g., with the structures **75** and **76** (Scheme 69), are still waiting for the development of specific methods for their synthesis. Impressive routes of access to specific representatives have already been developed.[117] Moreover, the direct approach to some of the sixteen stereopentads of type **77** (Scheme 69) has already begun.[100, 106, 117, 118] In this decade a new continent of stereoselective synthesis will be opened up to exploration.



Scheme 69.

The Pyrolysis of Azides in the Gas Phase**

By Hans Bock* and Ralph Dammel

*In memoriam Wilhelm Klemm****

*Dedicated to Professor Friedrich Hund on the occasion of his 90th birthday****

The chemistry of the non-metallic elements has in recent years passed through a period of rapid development, often referred to as its "renaissance". To emphasize just one of the key facets: numerous short-lived molecules containing multiple bonds to elements of the third and higher periods have been discovered, often accompanied by the planned synthesis of derivatives which are sterically shielded by bulky groups and thus kinetically stabilized. Thus today molecules such as silabenzenes $H_6C_{6-n}Si_n$ and silaethenes $H_2Si{=}CH_2$ or $R_2Si{=}CR_2$, disilenes $R_2Si{=}SiR_2$ and diphosphenes $RP{=}PR$, silaphenylisonitrile $H_5C_6{-}N{\equiv}Si$, or methylidyne-phosphanes $R{-}C{\equiv}P$, are all well-known species. Sandwich compounds with P_6 rings or silicon centers demonstrate that there are now hardly any barriers to impede the imagination of the non-metal chemist. In sharp contrast is our lack of knowledge regarding the "microscopic" pathways of chemical reactions: thus apart from information provided for example by molecular beam experiments, or from exact numerical calculations involving species consisting of only a few atoms, it remains largely unknown from which directions medium-sized molecules must approach each other to successfully collide and form a "reaction complex", in which way their structures are changed in such a process or which role is played by molecular dynamics in the energy transfer.—The pyrolysis of azides $X{-}N_3$, i.e. compounds which tend to explode violently when ignited in the condensed phase but can be heated in low-pressure gas flow systems without much risk, illustrates that studies of reactive intermediates are of interest not only because novel molecules may be discovered and isolated, and thereby possibilities for synthesis expanded. Moreover, some aspects of the "microscopic" pathways of these azide pyrolyses can be described satisfactorily on the basis of calculated energy hypersurfaces, and the influence of molecular dynamics becomes experimentally visible in the "chemical activation" of intermediates which leads to their "thermal explosion".

"Despite all that is known about reaction behavior, understanding of it is rather shallow ..."

(George C. Pimentel[1])

1. Azides and Imines—Prototypes for Reactive Nitrogen Compounds

The pyrolysis of methyl azide[2] can be carried out to advantage by passing an undiluted stream of gas at a pressure of 10^{-2} mbar through an externally heated quartz tube filled with quartz wool and following the decomposition by PE-spectroscopic gas analysis[3] (Figs. 1 and 3). At red heat, the cleavage of molecular nitrogen begins and methanimine is formed.

The nitrogen compounds of interest here, i.e. covalent azides $X{-}N_3$, the molecule N_2 and the readily polymerizing alkanimines $R_2C{=}NH$ as well as their most important properties will be presented first by way of introduction:

Covalent azides $X{-}N_3$ have been known for more than 120 years;[4] nitrogen is one of the few elements which form polyatomic homonuclear, unsaturated and linear

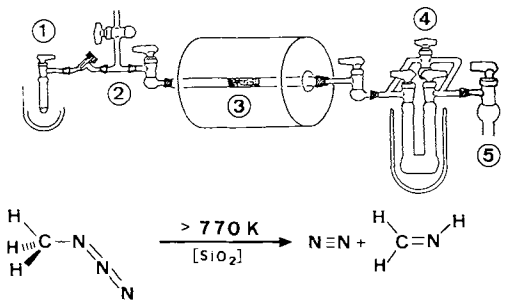

Fig. 1. The gas-phase pyrolysis of methyl azide: modular apparatus consisting of ① substance container, ② connector for evacuation, ③ reaction tube filled with quartz wool in a temperature-regulated oven, ④ cold trap with closable bypass and ⑤ connection to the PE-spectrometer.

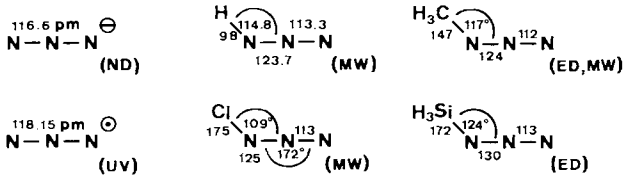
[**] 15th essay on "Molecular Properties and Models".—14th essay: H. Bock "How Do Medium-Sized Molecules React?", Akademie der Wissenschaften und der Literatur Mainz, 1986/2, Verlag F. Steiner, Wiesbaden. Also Gas Phase Reactions, Part 66.—Part 65: R. Dammel, H. Bock, *Z. Naturforsch. B*, in press.

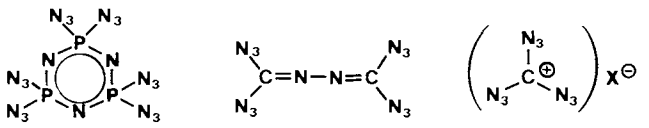
[***] A report on gas phase pyrolyses of methyl azide and vinyl azide and on the corresponding energy hypersurface calculations was given on the occasion of the First Hund/Klemm Lecture (November 14, 1983) at the Max-Planck-Institut für Festkörperforschung Stuttgart, in the presence of both honoured scientists.

substituent groups such as =N=N or –N=N=N. The structures of numerous azides have been determined using various methods (Scheme 1a. ND: neutron diffraction, UV: ultraviolet spectroscopy, MW: microwave spectroscopy, ED: electron diffraction; for further information see [4a, 5]). In general the NNN unit is linear; substituent effects may cause small deviations from linearity.[5]



Scheme 1a.

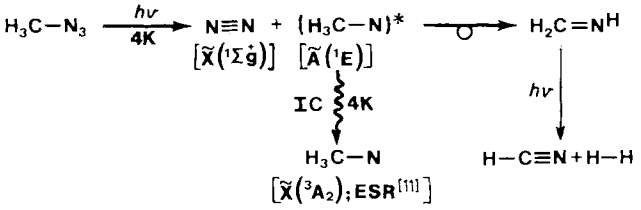
Compounds containing a high proportion of azide nitrogen can be prepared;[4] Scheme 1b shows as examples P_3N_{21}, C_2N_{14} (with 89.1% one of the most nitrogen-rich organic molecules) and the salt $(CN_9)^{\oplus}X^{\ominus}$. It has been suggested that the empirical lower limit for explosivity of covalent azides corresponds to 25% by weight of azide nitrogen.[6]



Scheme 1b.

In spite of the danger of explosion when they are improperly handled (cf. Section 2), the chemistry of covalent azides $X-N_3$ is attractive because of their multifarious reactivity: thus for the period 1967–1985 Chemical Abstracts has registered 10859 (!) publications dealing with them.[7] The subject areas listed range from the preparation of new azides via their preparative use, in particular in the synthesis of heterocycles, to the study of rearrangement and degradation reactions and their photochemical decomposition. Thermolyses of azides of small molecular size are, however, underrepresented,[8, 9] one particular difficulty being the detection of the unstable imines which are usually formed (see Section 3.10), since these require suitable real-time gas analysis procedures such as PE-spectroscopy.[2, 3]

The few alkyl azide pyrolyses in the gas phase which have so far been studied[8, 9] show first-order decay[9a] and yield complex product mixtures consisting of N_2, H_2, HN_3, NH_3, alkanes, alkenes and $H_2C=NH$ polymers such as urotropine.[9b] In mechanistic speculations, nitrene intermediates have often been postulated to be the primary products:[10] according to ESR studies[11] and quantum chemical calculations[12] alkyl nitrenes RN have a triplet ground state $\tilde{X}(^3A_2)$. However, in thermolysis or non-sensitized photolysis the alkyl nitrenes are formed in the excited singlet state $\tilde{A}(^1E)$ because of spin conservation; the singlet $\tilde{X}(^1\Sigma_g^+) \rightarrow$ triplet $\tilde{A}(^3\Sigma_u^+)$ excitation of the nitrogen molecule would require 590 kJ/mol (!)[13] (Scheme 2).



Scheme 2.

Excited singlet alkyl nitrenes (RN)* have only short lifetimes: thus an intersystem crossing (IC) to the ESR-active[11] triplet ground state ($\tilde{X}(^3A_2)$) occurs only under the extreme conditions of an inert gas matrix at 4 K.[10, 11] None of the typical intermolecular nitrene reactions such as insertion into σ-bonds or stereospecific addition to π-double bonds have been observed for the short-lived primary products (RN)*.[10] Instead, H- or R-migration to give open-chain imines or ring closure to N-heterocycles takes place. When our studies commenced, virtually no direct information on these unimolecular routes for stabilization of (RN)* was available, only indirect conclusions on the basis of the compounds formed on acid hydrolysis of the pyrolysis products.[9b, 10, 14] Direct detection of the rapidly polymerizing imine secondary products[14] had not been achieved at that time.

Dinitrogen N_2, the most stable modification of the element[15] is, because of its extremely high dissociation energy ($D_{298}^0 = 945.33 \pm 059$ kJ/mol[16]), one of the thermodynamically most favorable leaving groups.

Alkanimines, as simple and reactive nitrogen compounds,[17] probably play a part in the formation of bioorganic compounds in "primeval soup" experiments.[18] Radioastronomers have shown[19] that the simplest homologue methanimine $H_2C=NH$ is present in large quantities in hydrogen-rich nebulae such as Sagittarius B2. In contrast to the isoelectronic formaldehyde, which has been known since prehistoric times, it was first detected in a matrix experiment in 1961[13] and in the gas phase in 1965 by microwave spectroscopy of the reaction

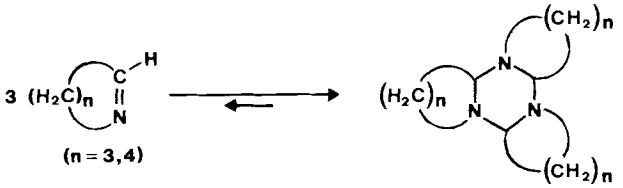
$$H_3C-NH_2 + 2F^{\ominus} \rightarrow H_2C=NH + 2HF^{[20]}$$

There followed PE-spectroscopic detection in the mixtures formed by pyrolysis of methylamine[21] and as the main product of the thermal decomposition of methyl azide[2] (Figs. 1 and 4), and finally in 1982 its isolation as a pure substance.[22, 23]

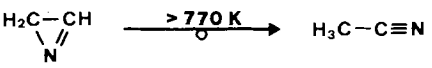
The gaps in our knowledge of simple alkanimines are due entirely to their extreme reactivity under normal conditions (300 K, 1 bar, air): these cause immediate polymerization, oxidation or hydrolysis to occur. The azomethine[*] $(CH_3)CH=NCH_3$, the simplest alkanimine derivative, prepared in 1947 by condensation of acetaldehyde and methylamine, is a water-clear liquid, which, however, rapidly undergoes further reaction.[24] The smallest cyclic imine, the three-membered ring 2*H*-azirine, was first isolated in 1981 as the lowest-temperature decomposition product in the pyrolysis of vinyl azide[3, 25] (see Fig. 2). Even larger cyclic

[*] According to IUPAC rule C-185.3 only compounds of the type $>C=NH$ may be referred to as imines. Compounds of the type $R^1R^2C=NR^3$ form the class of compounds known as the azomethines.

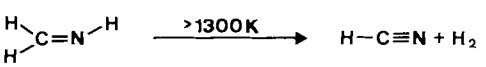
imines such as 3,4-dihydro-2*H*-pyrrole or 2,3,4,5-tetrahydropyridine, which are important building blocks for alkaloid biosyntheses, could not until now be prepared in a pure form because of their tendency to trimerization.[26]



Even as monomers, cyclic azomethines are not always the thermodynamically most favorable constitutional isomers of the formula $C_nH_{2n-1}N$: thus 2*H*-azirine rearranges to acetonitrile on heating to 770 K.[3,25]



Imines can split off H_2 or hydrocarbons RH in order to form cyanides as thermodynamically favored end products; for example, the parent compound $H_2C{=}NH$ is dehydrogenated at yellow heat to $HC{\equiv}N$.[23]



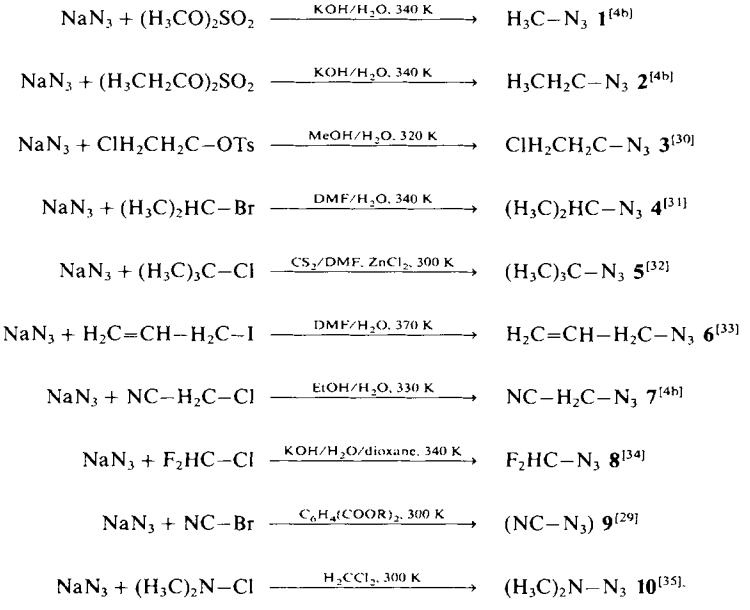
As this short survey illustrates, indeed, azides, imines, and simple azomethines are from "*a*ddition reactions to zero stability" prototypes for reactive nitrogen compounds. From the multitude of possible reactions we shall here select and report on their fascinating and largely unknown behavior in the gas phase, which is of preparative interest, and, moreover, offers some insight into the "no man's-land" of the reaction pathways of medium-sized molecules.

2. Synthesis and Handling of Covalent Azides

The preparation and properties of covalent azides $X{-}N_3$, including their pyrolysis in the gas phase, have been studied by us since 1980.[2,3] Because of the extreme care and meticulousness in handling this malicious class of compounds and the use of newly-developed measurement techniques,[3] we have so far experienced neither an explosion nor a case of poisoning.[27] The literature contains a number of explicit warnings in this respect; the following example is an excerpt from an original text reporting studies on bromine azide:[28]

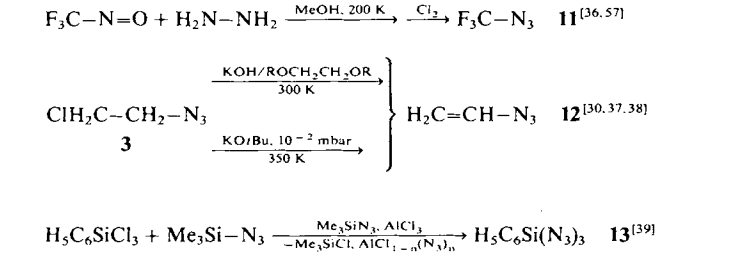
> **Solid, liquid, and vapour are as sensitive to shock as iodoazoimide, the explosion (often apparently spontaneous) being accompanied by a flash of vivid blue light. Some idea of the instability of the compound, even at −200°, may be gathered from the fact that, of twenty-four attempts at freezing the compound and determining its melting point, only six were completed without explosion. Fortunately, in the majority of cases, the sphere of action was limited to a radius of about 3 feet. Within this radius, all glass apparatus was reduced to powder; beyond it, a reinforced glass screen proved a sufficient protection.**

The syntheses of the azides studied, which apart from $NC{-}N_3$[29] have all been isolated as pure compounds, follow standard literature procedures,[4b,29-39] though these were never used uncritically and wherever possible improved.[23] Starting from sodium azide (activated when necessary[29]), the azides **1** to **10** could be obtained in generally satisfactory yield and purity[23] from substitution reactions with dialkyl sulfates, alkyl tosylates and *C*- or *N*-halogen derivatives (Scheme 3a).



Scheme 3a.

Other azides are best prepared by special methods; e.g. trifluoromethyl azide **11**, vinyl azide **12**, or triazido(phenyl)silane **13** (Scheme 3b).



Scheme 3b.

The last-mentioned compound, triazido(phenyl)silane (**13**), can be distilled at a bath temperature of 600 K without decomposition and on ignition in a spatula burns quietly in air with formation of soot.[23] Nevertheless, the following warning should be heeded: the decomposition of covalent azides, accompanied by highly exothermal nitrogen formation, leads to a "heat explosion"[4a] due to reaction multiplication when the energy set free in a single step cannot be dissipated via an extended molecular skeleton with less than 25% by weight azide nitrogen[6] or via the surrounding solvent.[27] Since the extrusion of nitrogen

may be initiated not only thermally but also mechanically, photolytically or chemically,[27] even azides which have been handled several times without incident can detonate with considerable explosive power[8] for no apparent reason. Therefore, besides using the standard explosion protection methods (shatterproof glass shields, fencing masks, leather gloves), we have for example in all reactions of sodium azide with dialkyl sulfates (see Scheme 3a) always kept the pH above 10 in order to diminish the danger of HN_3 formation.[27] The metal azide-containing deposits precipitating during the syntheses of *tert*-butyl azide (**5**) or triazido(phenyl)silane (**13**) in the presence of metal halide Lewis acids were filtered off immediately and hydrolyzed in a fume cupboard using protic organic solvents. Only glass vessels with unscratched and unetched surfaces were used, in particular for distillation; if necessary, active centers can be deactivated by treatment with a refluxing mixture of R_3SiCl and R_2SiCl_2. All operations were carried out on a millimolar scale, and the covalent azides prepared were as far as possible only cooled within the range at which they remain liquid, since when for example solid samples of vinyl azide are allowed to thaw, an explosion can occur, probably due to a tribomechanical shock.[40]

The example of the particularly dangerous vinyl azide **12**[23,25,37,38,40] will be chosen to demonstrate the advantages of handling and decomposing explosive compounds such as S_4N_4[41] or $X-N_3$[2,3,23,25,34,42] under reduced pressure in the gas phase with the help of photoelectron-spectroscopic real-time analysis.[3] Thus the dehydrochlorination of β-chloroethyl azide **3** can advantageously be carried out as a heterogeneous gas phase reaction on solid potassium *tert*-butoxide,[37,38] avoiding the isolation of the explosive vinyl azide (Fig. 2).

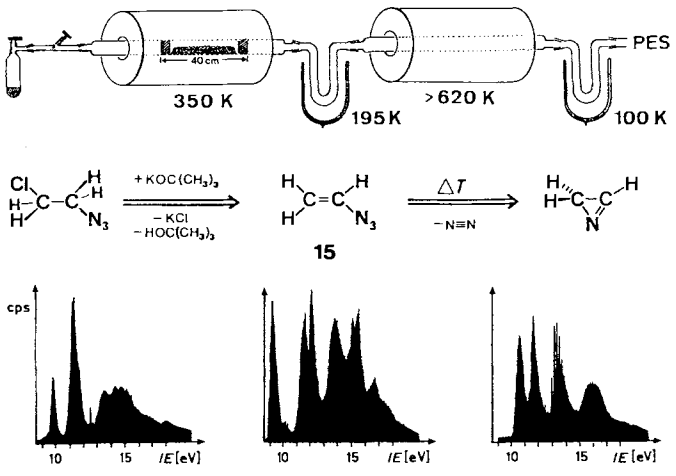


Fig. 2. The heterogeneous gas phase dehydrochlorination of β-chloroethyl azide on solid potassium *tert*-butoxide yielding vinyl azide **12**, and the subsequent thermal decomposition of the latter to 2*H*-azirine: double-oven apparatus with cold traps for the by-product *tert*-butyl alcohol and the end product 2*H*-azirine. The PE-spectroscopic ionization patterns of the pure compounds were used for optimization of the reaction conditions (see text).

The gaseous vinyl azide **12** formed is then pyrolyzed in a second oven to give 2*H*-azirine;[25] and at any one time only a few milligrams of the explosive **12** are present in the double-oven flow apparatus (Fig. 2). To collect the 2*H*-azirine on a preparative scale, cold traps are inserted between the second oven and the PE-spectrometer,[3] the vacuum pump system of which is used to sustain substance flow at a pressure of ca. 10^{-2} mbar. The PES real-time gas analysis has proved itself to be well-suited for the optimization of the reaction conditions, such as the length of the KOR zone necessary for the complete elimination of HCl, and the vinyl azide pyrolysis temperature:[3] with increasing conversion, the ionization "fingerprints" of the starting materials are increasingly replaced by those of the reaction products (Fig. 2).

The handling of covalent azides $X-N_3$ in a flow apparatus at reduced pressure, i.e. in most cases under virtually unimolecular conditions outside their explosion limits,[4a] was the indispensable precondition for their safe pyrolysis in the gas phase and for the identification of their decomposition products.

3. Gas Phase Pyrolysis of Covalent Azides

3.1. Experimental Procedure

Millimolar amounts of the azide $X-N_3$ are vaporized at ca. 10^{-2} mbar and are drawn by the vacuum pump system of the attached spectrometer through the heatable reaction tube (see Fig. 1) at the relatively high velocity of ~ 1 m/s, in the boundary region between laminar *(Newton)* and molecular *(Knudsen)* flow.[43] Depending on the volatility and thermolability of the starting material and in particular on the lifetime of the desired product, the decomposition can be performed either externally in a thermolysis tube, which is up to 40 cm long and if necessary is filled with quartz wool in order to increase the contact time (Figs. 1 and 2), or internally using a short-path pyrolysis oven built into the PE spectrometer. The molybdenum tube of the latter is heated both resistively and in addition by electron impact (Fig. 3: $U_{1,2}$), and the distance between the end of the oven zone and the PES ionization chamber amounts to only 3 cm (Fig. 3).[44] The use of the short-path pyrolysis technique permits the detection of decomposition products with lifetimes in the millisecond range.[45]

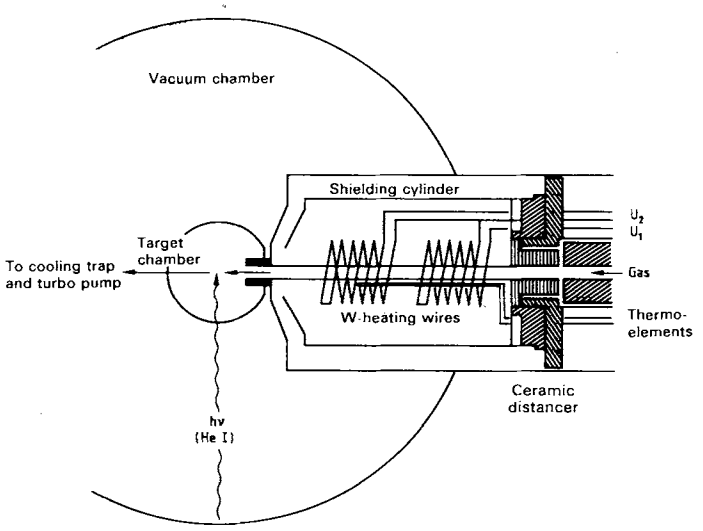

Fig. 3. Outline of the short-path pyrolysis apparatus integrated into the PE spectrometer (U_1 = resistive heating; U_2 = electron impact heating; for details see ref. [44]).

The temperature-dependence of the azide decomposition is monitored using the ionization pattern (see Fig. 4) continually recorded by the attached PE spectrometer.[3] Since there are no restrictive selection rules for the photoionization (in contrast e.g. to rotational and vibrational spectroscopy), all molecules leaving the heated zone in concentrations greater than ca. 5% may be identified from their unmistakable ionization "fingerprints".[52] In particular the "azide leaving group" N_2 is so clearly recognizable from the appearance of its needle-like bands above 15.5 eV (Fig. 4) that the decomposition temperature of the azide $X-N_3$ can be easily determined within the continuously heated flow system. Advantageously, the N_2 ionization pattern leaves blank a broad "observation window" in the low-energy range between 8 and 15.5 eV. On the other hand, covalent azides $X-N_3$ also generally exhibit a needle-like first band (at ca. 9.8 eV), corresponding to the ionization to the radical cation ground state $\tilde{X}(\pi^{*}_{N_3})$ (cf. Section 3.2); the disappearance of this band signals complete decomposition (Fig. 4: -----›).

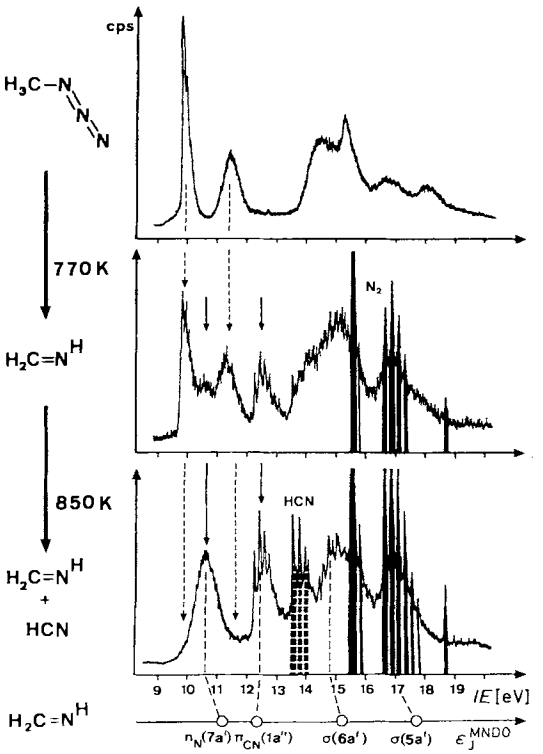

Fig. 4. He(I) PE spectra of methyl azide **1** and its decomposition products at 770 and 850 K. The start of the pyrolysis is recognized by the appearance of the unmistakable N_2 ionization needles (black) between 15.5 and 18.7 eV, and complete decomposition by the disappearance of the characteristic azide bands (-----›). At 770 K, the characteristic bands of $H_2C{=}NH$ (—›), here assigned by Koopmans-correlation [50] with MNDO calculations, are first observed. The second thermal reaction pathway to $H-C{\equiv}N$ (PE bands between 13.6 and 14.21 eV) and H_2 is populated at temperatures above 820 K (due to its low ionization cross-section, H_2 becomes visible only after PE spectrum subtraction [46, 47] or after freezing out the remaining products in a 77 K cold trap [47]).

When the azide pyrolysis is carried out at the optimal decomposition temperature as determined by PE spectroscopic gas analysis, a number of further measurements become possible: thus the externally heated reaction tube may also be attached to the inlet system of a mass spectrometer or, in the case of short-lived molecules, flanged directly onto its measurement chamber.[48] A 10 K argon matrix[49] or a cold finger incorporated between the heated zone and the PE spectrometer are suitable for the isolation of reactive decomposition products: in the latter case the cold condensate may for example be thawed to drop into a precooled NMR tube. After cocondensing $CDCl_3$ and sealing the tube, 2*H*-azirine from the pyrolysis of vinyl azide (Fig. 2) can thus be additionally characterized by its ^{1}H-NMR spectrum (Fig. 5).[23]

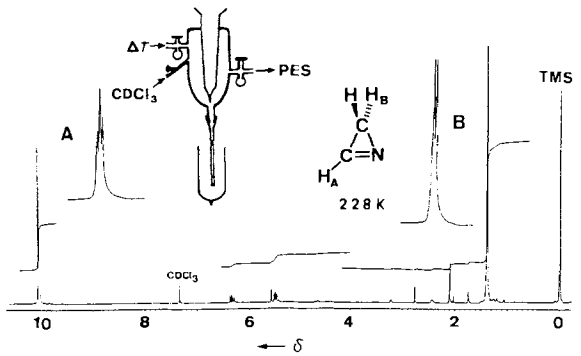

Fig. 5. Condensation apparatus for NMR sampling and 270-MHz ^{1}H-NMR spectrum ($CDCl_3$, 228 K) of 2*H*-azirine, which was obtained by vinyl azide pyrolysis.

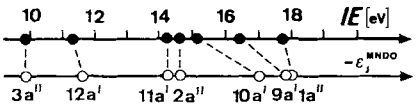
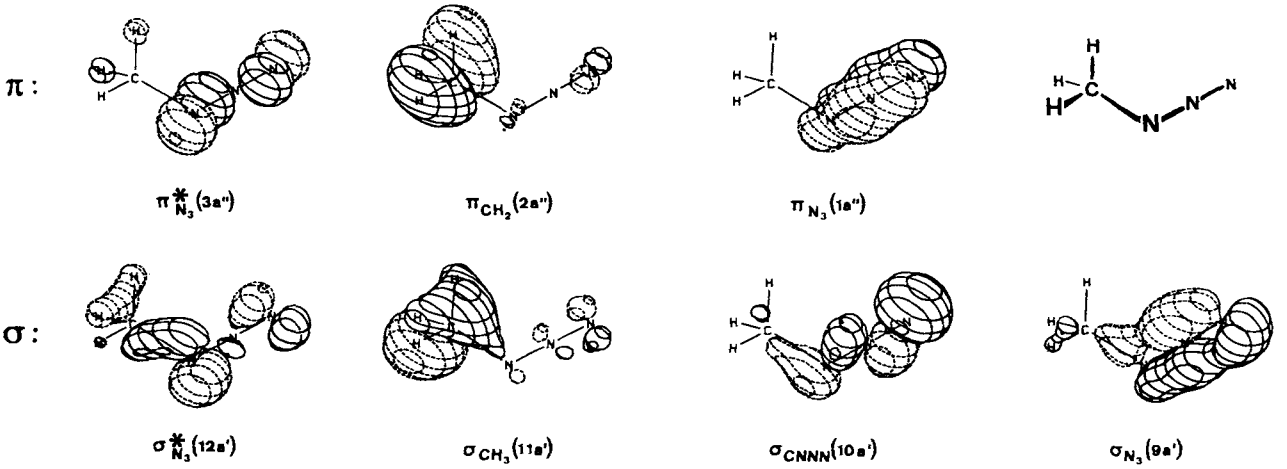
3.2. Ionization Pattern of Azides $X-N_3$

When a He(I) photon of energy 21.21 eV hits a molecule M in its neutral ground state $\tilde{X}(M)$, an electron is ejected within 10^{-15} s, leaving behind a radical cation $M^{\oplus\ominus}$ in either its ground state $\tilde{X}(M^{\oplus\ominus})$ or in one of its singly excited states $\tilde{A}, \tilde{B}, \tilde{C}\ldots$ These rapid electron ejection processes IE_n^v are described as "vertical", since the vibrations in the molecular cation $M^{\oplus\ominus}$ only start after about 10^{-13} s and thus the coordinates of the neutral molecule initially remain "frozen". The vertical processes may be correlated with the SCF eigenvalues $-\varepsilon_j^{SCF}$ calculated for the neutral molecule in a generally satisfactory approximation[50] using *Koopmans*' theorem ($IE_n^v = -\varepsilon_j^{SCF}$). This forms the basis for other important advantages of PE-spectroscopic gas analysis: the ionization band patterns of unknown molecules can be precalculated to a degree of accuracy sufficient to facilitate the spectroscopic search for unknown and possibly short-lived compounds, which may be identified vice versa by the assignment of their PE spectra via Koopmans' correlation. Moreover, the comparison of equivalent radical cation states of chemically related compounds on the basis of perturbation arguments[51] provides the chemist with a multitude of information on the series of compounds which he is investigating.

The PE spectrum of methyl azide **1** in the He(I) measurement range (Fig. 4) shows, as expected,[52] seven ionization bands[2, 53] which can be correlated using *Koopmans*' theorem ($IE_n^v = -\varepsilon_j^{MNDO}$) with MNDO eigenvalues[2, 54, 55] (see Scheme 4, top). For a C_s conformation of the almost freely rotating[56] methyl group relative to the CNNN plane, the radical cation states may be subdivided into π- and σ-like ones, and their respective charge distributions



fifth band at 15.4 eV, which corresponds to the $D(^2A')$ state with a dominant σ_{CNNN} distribution.[2,54] When the three typical azide radical cation states, assigned via Koopmans' correlation with MNDO eigenvalues, are compared along



Scheme 4.

characterized qualitatively by the corresponding MNDO orbital diagrams (see Scheme 4, bottom).

Because of the nodes through the CNNN plane and the central nitrogen center, the radical cation ground state $\tilde{X}(^2A'')$ is often denoted in the short form $\pi^*_{N_3}$. The two other $\pi(a'')$ states of H_3C-N_3 at 14.7 and 18 eV with dominant H_2C- and NNN-contributions appear less prominently in the PE spectrum. More characteristic are the second band at 11.4 eV, which is assigned to the first excited radical cation state $\tilde{A}(^2A')$ and denoted as $\sigma^*_{N_3}$ because of its $\pi^*_{N_3}$-analogous node distribution rotated by 90°, and the the series of molecules $X-N_3$ (Fig. 6), a considerable amount of information on the effects of substituents X on the NNN unit becomes available.

The characteristic ionizations $\pi^*_{N_3}$, $\sigma^*_{N_3}$, and σ_{XN_3} of the azides $X-N_3$ studied (Fig. 6), in all of which the radical cation charge is predominantly localized in the NNN-unit[23], exhibit a marked dependence on the substituent X: the exchange of $C(CH_3)_3$ for CF_3 causes the ionization energies to fall by about 2 eV. This indicates that π- and σ-perturbations generally run parallel, so that acceptor or donor substituent effects may be defined relative to X = H

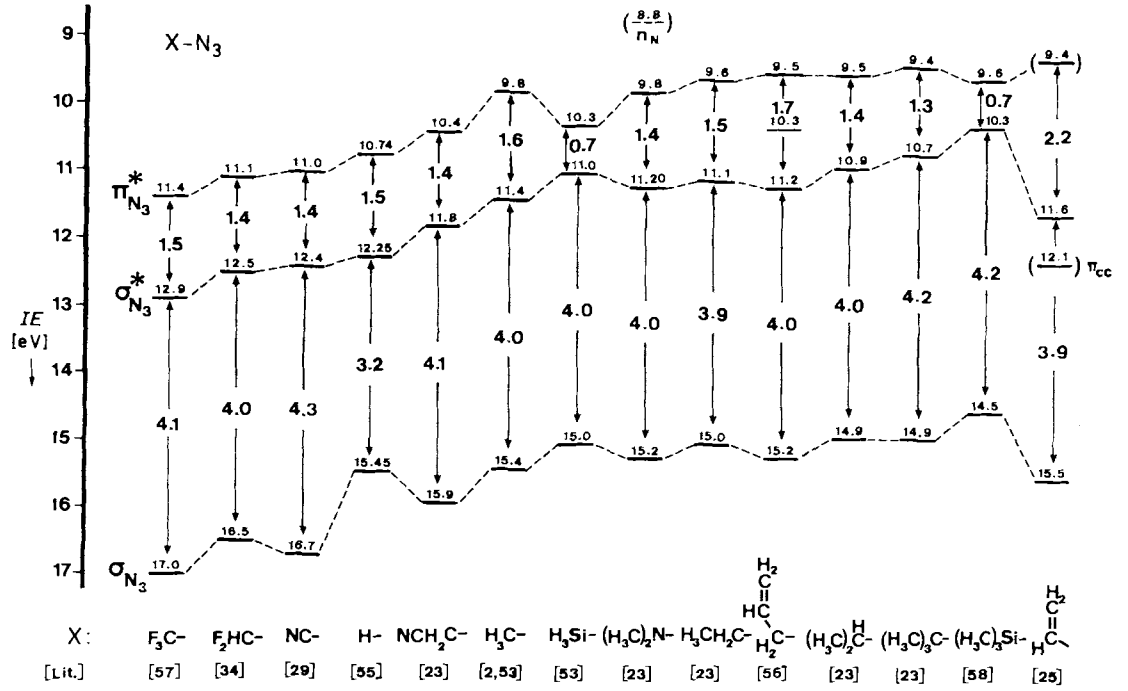


Fig. 6. Correlation diagram of the characteristic vertical ionization energies of azides $X-N_3$ (see text and Scheme 4).

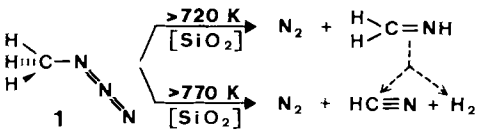
or CH_3. The deviations in the cases of the parent compound, HN_3, of the silicon derivatives and of vinyl azide can be rationalized in a simplified manner as follows: the small difference of only 3.2 eV between $\sigma^*_{N_3}$ and σ_{XN_3} in HN_3[55] is due to the fact that inserted radical cation states with a large contribution in the substituent group X are lacking. In comparison with the alkyl substituents, the iso(valence)electronic R_3Si groups function as weaker π- and stronger σ-donors,[58] i.e. π-type states of $M^{\oplus\oplus}$ are less well stabilized than σ-type states, so that the ionization energies $\pi^*_{N_3}$ increase, whereas $\sigma^*_{N_3}$ and σ_{XN_3} decrease[53,58] (Fig. 6). In vinyl azide, strong $(\pi^*_{N_3}+\pi_{CC})$ conjugation and weak $\sigma^*_{N_3}$-stabilization by the $H_2C{=}CH$-group lead to an unusually large difference between the $\pi^*_{N_3}$ and $\sigma^*_{N_3}$ ionization energies.[25] In contrast, in allyl azide[56] the vinyl and azide groups are isolated from one another by the CH_2 bridge and all characteristic ionizations lie within the narrow regions typical for the alkyl azides from H_3C-N_3 to $(H_3C)_3C-N_3$. The donor effect of the $(H_3C)_2N$ substituent on the NNN unit is unexpectedly small,[59] and comparable to that of an ethyl group (Fig. 6). Finally one may note that the PE spectrum of $NC-N_3$[29] can be constructed from the ionization patterns of $NC-H$[60] and $H-N_3$[55] using a "molecules in a molecule" approximation with only small second order perturbations;[23] the π-interaction is thus considerably smaller than in vinyl azide (Fig. 6).

Naturally, neither the characteristic radical cation state patterns of azides $X-N_3$ nor the MO calculations for their assignments allow any conclusions regarding their thermal stabilities and the decomposition products formed after nitrogen extrusion. Since for example the thermal stability of many organosilyl azides (cf. Section 3.9) is repeatedly and erroneously attributed to $(p\rightarrow d)\pi$-bond contributions in the literature,[61] the considerably more complex nature of the nitrogen extrusion (cf. Section 4) will be emphasized here. On the other hand, comparison of radical cation states (Fig. 6) provide a valuable tool for assigning the PE-spectra and thus permit a critical check of the MO calculations, which for azides $X-N_3$ tend to somewhat larger deviations from *Koopmans'* theorem:[23,54] A correct assignment of the $X-N_3$ ionization patterns is an indispensable prerequisite for the use of PE spectroscopy to monitor azide pyrolyses (Fig. 4).

3.3. Pyrolysis of Methyl Azide

The thermal decomposition of methyl azide **1**[2,9b] (cf. Fig. 1) at 10^{-2} mbar begins at 720 K; concomitantly, the first PE bands of the decomposition and rearrangement product methanimine are clearly observed in the PE spectrum at 10.63 and 12.48 eV (Fig. 4: —). At the same time a further reaction channel is accessible in which HCN and H_2 are formed. At 850 K H_3C-N_3 is pyrolyzed completely: its characteristic ionization pattern has vanished (Fig. 4: - - -) and the two other bands of methanimine become visible at 15.1 and 17.0 eV, partially overlapped by the nitrogen ionization needles. The band between 13.6 and 14.21 eV (Fig. 4: dashed) exhibiting vibrational fine structure proves $H-CN$[60] to be an additional product.

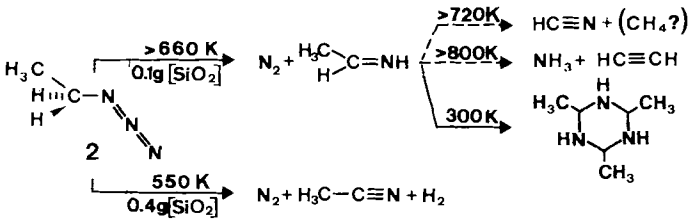


The formation of $H_2C{=}NH$ during the thermal decomposition of H_3C-N_3 can be confirmed as follows: On pyrolysis in a mass spectrometer, the H_3C-N_3 molecular ion parent peak at $m/z = 57$ vanishes at 870 K, while the intensity of the H_3CN peak at $m/z = 29$ has increased.[23] Methanimine can be prepared independently from *N*-chloromethylamine by elimination of HCl on solid KOR (Fig. 16) and isolated at a temperatures below 150 K.[22,62] The PE spectrum recorded on revaporization[62] contains no bands due to N_2 or HCN, and is identical with that recording during methyl azide pyrolysis at 850 K after electronic subtraction of the N_2 and HCN ionization bands.[21,62] Moreover, the $H_2C{=}NH$ ionization pattern and calculated SCF eigenvalues agree satisfactorily; energy hypersurface and gradient norm calculations for the reaction pathway of lowest energy (cf. Section 4.2) in the extrusion of N_2 from H_3C-N_3 also exclude the formation of other decomposition products.[23]

The temperature of 800 K[2] at which methyl azide splits off nitrogen under approximately unimolecular conditions is unexpectedly high, but agrees with the estimated energy (170 kJ/mol) for the dissociation of the H_3CN-N_2 bond.[10a,10e]

3.4. Pyrolysis of Higher Alkyl Azides

Ethyl azide **2** begins to split off nitrogen at 660 K; its thermolysis is complete above 770 K.[23] The main product is a mixture of *cis/trans* ethanimines. The by-products observed after condensation of the latter in an interposed 250 K cold trap are HCN, NH_3 and $HC{\equiv}CH$, all of which are probably formed from a "chemically activated" imine (see Section 4.3). When $H_3C-HC{=}NH$ is revaporized, crystals of the trimeric 2,4,6-trimethylhexahydro-*s*-triazine remain behind in the cold trap (Scheme 5).

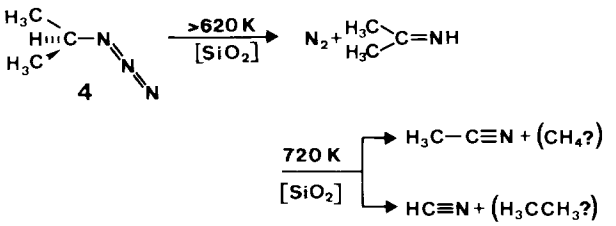


Scheme 5.

The increase in the contact time brought about by filling the tube more tightly with four times the original amount of quartz wool leads to abrupt decomposition of ethyl azide already at 550 K, yielding N_2, H_2 and acetonitrile; presumably under these conditions the explosion limit of $H_5C_2N_3$[9a] is reached.

Isopropyl azide **4** begins to decompose above 620 K, N_2 being completely cleaved off at 770 K.[23] The main prod-

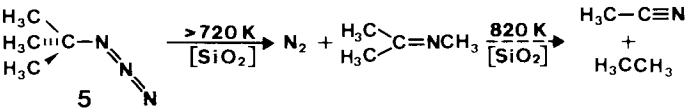
uct is 2-propanimine, as can again be demonstrated by a PE-spectroscopic comparison with a sample prepared by dehydrochlorination of the respective *N*-chloroamine (Section 3.10).[62] Both H_3C-CN and H−CN are identified as by-products by their characteristic ionization needles (see Figs. 4 and 7 and Scheme 6).



Scheme 6.

The stoichiometrically required decomposition products CH_4 and C_2H_6 from a "chemically activated" 2-propanimine cannot be identified with certainty due to their rather contourless PE spectra (see Fig. 7).

tert-Butyl azide **5** requires temperatures of at least 720 K before nitrogen is eliminated.[23] According to the PE spectra (Fig. 7), which are shown here as an example, acetonitrile and ethane are formed at 820 K as well as *N*-isopropylidenemethylamine (Scheme 7).



Scheme 7.

The PE spectroscopically determined temperatures for initial (Fig. 8: ●) and complete (Fig. 8: ▲) decomposition of alkyl azides $(H_3C)_nH_{3-n}C-N_3$ run parallel to one another.

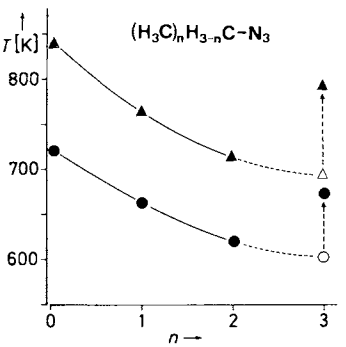


Fig. 8. Temperature dependence of initial (●) and complete (▲) decomposition in the pyrolysis of the alkyl azides $(H_3C)_nH_{3-n}C-N_3$.

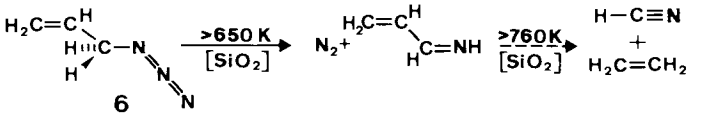
Extrapolation of the parabolas for the 1,2-H shift (each defined by 3 points) to n = 3 for *tert*-butyl azide **5** results in temperatures (Fig. 8: ○, △) approximately 70 K below those measured, and thus confirms literature reports[9c, 10a, 10b] that 1,2-alkyl migrations require higher activation energies.

Allyl azide **6** is monomeric and planar in the gas phase.[23, 33, 56] Above 600 K it decomposes into N_2 and 1-azabutadiene ("acroleinimine"), which can be isolated by condensation in a cold trap (Fig. 1: ④).[62] At 760 K, a second reaction pathway to ethene and hydrogen cyanide opens up, presumably via "chemical activation" of 1-azabutadiene ("acroleinimine") (Scheme 8).



Scheme 8.

In summary, the alkyl azides $R-N_3$ with $R=CH_3$, $CH_{3-n}(CH_3)_n$ (n = 1-3) and $CH_2(HC=CH_2)$ exhibit rather similar thermolysis behavior: extrusion of nitrogen begins within a relatively narrow temperature range between 620 K for isopropyl azide **4** and 720 K for methyl azide **1** (Fig. 8). The primary products, alkanimines and azomethines formed via 1,2-H shifts or 1,2-CH_3 migration, are both detected by PE spectroscopy and isolated.[62] At temperatures 50 to 100 K higher or on prolonged contact time,[15] cleavage of H_2, alkanes or alkenes and formation of the cyanogen compounds HCN or H_3CCN takes place.

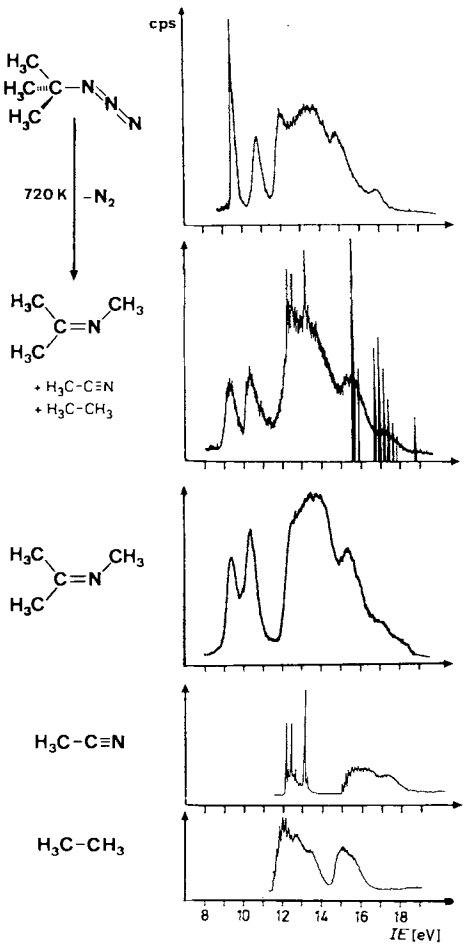


Fig. 7. He(I) PE spectra of *tert*-butyl azide **5** and the product mixture formed on its pyrolysis at 770 K (N_2 ionization needles are shown in black). For comparison, the PES band patterns of *N*-isopropylidenemethylamine (prepared by condensation of acetone with methylamine), of acetonitrile, and of ethane are shown.

3.5. Pyrolysis of Vinyl Azide

Substituted vinyl azides $R_2C=CR'-N_3$ (R, R'=alkyl, aryl or H), which contain two conjugated functional groups, are widely used in organic synthesis:[63] thermolysis and selective photolysis afford derivatives of 2*H*-azirine besides small amounts of substituted ketimines $R_2C=C=NR'$.[63]

The PE-spectroscopically monitored gas phase pyrolysis of the highly explosive parent compound vinyl azide **12**[3,25,37,38] (Figs. 2 and 9) already sets in above 620 K, i.e. 100 K lower than for H_3C-N_3 **1** (Fig. 4): the characteristic N_2 ionization needles (Fig. 9 (middle): black) appear, and at an oven temperature only 30 K higher the PE bands of **12** (Fig. 9: ----›) have disappeared. The main thermolysis product is 2*H*-azirine (Fig. 9 (middle): hatched), which can be isolated as a pure compound after the by-product acetonitrile (Fig. 9: dotted) has been frozen out in a U-tube cooled to 180 K (Fig. 2). The purity of the 2*H*-azirine so obtained may be checked either NMR-spectroscopically (Fig. 5) or from the PE spectrum assigned on the basis of $\Delta E^{SCF/CI}$ calculations (Fig. 9, bottom). When a stream of purified 2*H*-azirine is heated in a third oven to temperatures above 750 K, the unmistakable ionization pattern of H_3C-CN appears, and at 1000 K 2*H*-azirine rearranges quantitatively to acetonitrile.

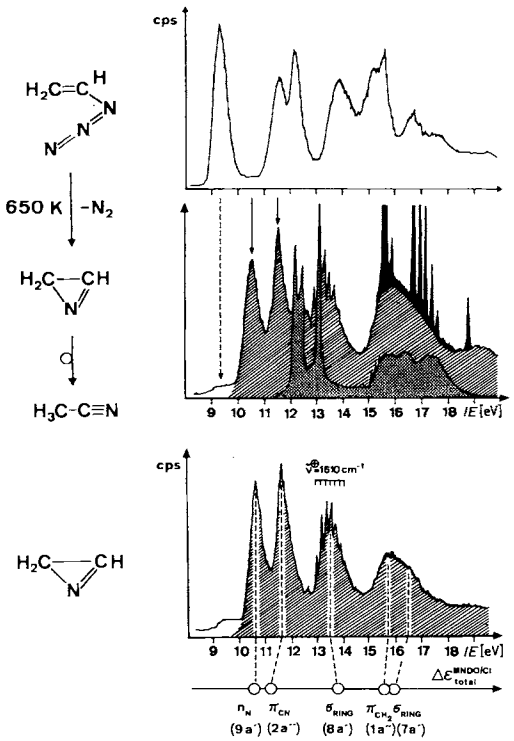

Fig. 9. He(I) PE spectra of vinyl azide **12** (for assignment see [25] and Fig. 6), of the mixture obtained from its thermolysis at 650 K (2*H*-azirine (hatched), acetonitrile (dotted, cf. Fig. 7) and nitrogen (black)) and of pure 2*H*-azirine with its $\Delta E^{SCF/CI}$ assignment (see text).

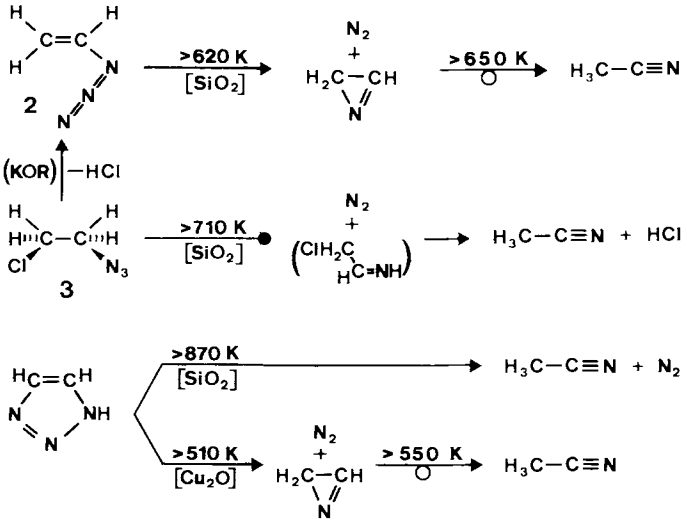
The PE spectroscopic pyrolysis studies have been extended to include the starting material for vinyl azide preparation, β-chloroethyl azide **3** (Fig. 2[37]), and the $C_2H_3N_3$ isomer 1*H*-1,2,3-triazole[25,64] (Scheme 9).



Scheme 9.

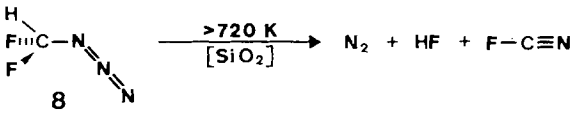
Above 710 K, β-chloroethyl azide **3** simultaneously splits off N_2 and HCl; its complete decomposition at 870 K yields acetonitrile and small amounts of HCN.[37] No unequivocal PE-spectroscopic evidence is obtained for the intermediate formation of 2-chloroethanimine or iminoethene ("ketenimine") $H_2C=C=NH$, another C_2H_3N isomer. Probably the excess energy from the azide pyrolysis initiates a rapid rearrangement to H_3C-CN, the most stable molecule in the C_2H_3N ensemble (see also Fig. 19). H_3C-CN is also formed as the sole product of nitrogen extrusion from 1*H*-1,2,3-triazole:[25] here the decomposition temperature of 870 K exceeds that at which 2*H*-azirine rearranges under similar conditions. When the pyrolysis of the electron-rich triazole is catalyzed by the "electron-poor" p-semiconductor copper(I) oxide, the decomposition temperature is reduced by 360 K (!) and the main product obtained is 2*H*-azirine. The amount of H_3C-CN in the thermolysis mixture, however, rises rapidly with increasing temperature.

The probable course of the pyrolysis of vinyl azide will be discussed in Section 4.2 on the basis of calculated energy hypersurfaces.[25,65]

3.6. Pyrolysis of Acceptor-substituted Methyl Azides

Alkyl azides R_3C-N_3 (R=H, CH_3) rearrange with thermal extrusion of nitrogen via 1,2-H shift or 1,2-CH_3 migration to methanimines or azomethines (cf. Sections 3.3 and 3.4). However, the pyrolysis of β-chloroethyl azide **3** proceeds with elimination not only of N_2 but also of HCl as another thermodynamically favorable leaving molecule, and H_3C-CN is formed. The PE spectra recorded at different temperatures provide no evidence for the intermediate formation of $ClH_2C-HC=NH$. The thermolysis of acceptor-substituted methyl azides such as F_2HC-N_3, F_3C-N_3 or $NC-H_2C-N_3$ should provide an answer to the question as to whether N_2-extrusion may also be accompanied by 1,2-X shifts (X=H, F, CN).

Difluoromethyl azide **8** starts to split off N_2 *and* HF above 720 K (Fig. 10); at 930 K complete reaction to F–CN can be demonstrated PE spectroscopically.[34]



Difluoromethanimine $F_2C{=}NH$ is not observed as an intermediate.[34] An explanation of this unexpected result is that under unimolecular conditions the considerable activation energy for the decomposition of $F_2HC{-}N_3$ cannot be dissipated efficiently, so that the "chemically activated" (cf. Section 4.3) reaction complex apparently "bursts" to give the thermodynamically favored final products N_2, HF and F–CN. When carried out carefully,[68] the selective thermolysis may be suitable for the preparation of pure FCN,[23] the boiling point of which lies 60 K below that of the other product HF.

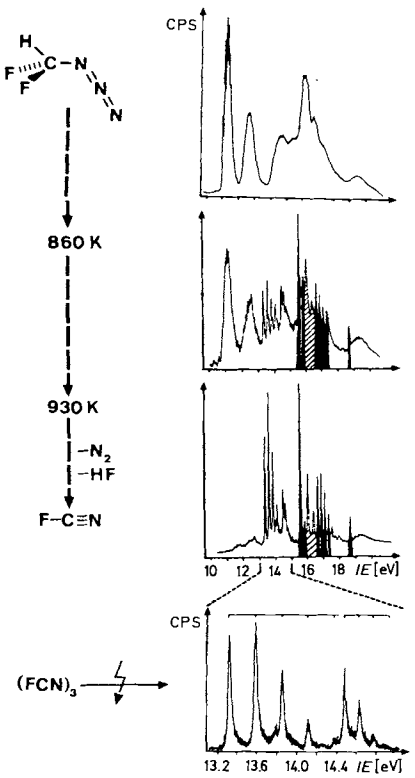


Fig. 10. He(I) PE spectra of difluoromethyl azide **8** at 300 K, 860 K and 930 K (N_2, black; HF [66], hatched) and of cyanogen fluoride [67], prepared from cyanuric fluoride by electrical discharge.

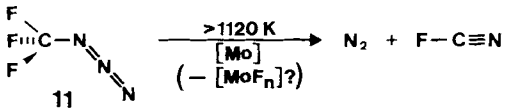
Trifluoromethyl azide **11** was studied because $F_2C{=}NF$, if produced on nitrogen extrusion,[69] could only react further via the thermodynamically unfavorable elimination of F_2 to give F–CN. The pyrolysis, which, because quartz is readily fluorinated by F_3CX compounds,[70] has been carried out in a molybdenum tube,[10] begins only above 1120 K, i.e. at a temperature 400 K higher than that observed for $F_2HC{-}N_3$ **8**, and proceeds quantitatively at 1270 K.[57]

The reaction partner for the fluorine molecule, which cannot be detected PE spectroscopically, is presumably the



wall of the molybdenum tube. $F_2C{=}NF$, the PE spectrum of which was recorded for comparison,[57] is only produced in trace amounts, if at all. The formation of $F_3C{-}CF_3$ can also not be demonstrated with certainty. Hexafluoroazomethane, which decomposes completely at 870 K to N_2 and hexafluoroethane, can be excluded as a pyrolysis product of **11**.

Azidoacetonitrile **7** should afford one of the HCN dimers (Fig. 11)[71,72] on elimination of N_2. *Trans*- and *cis*-iminoacetonitrile NC–CH=NH have been predicted[71] to be the most stable isomers, followed by the linear dipole complex HCN···HCN and *N*-cyanomethanimine $H_2C{=}N{-}CN$.

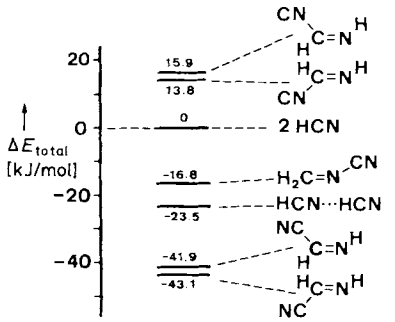


Fig. 11. Relative energies of $C_2H_2N_2$ isomers ("HCN dimers") [71].

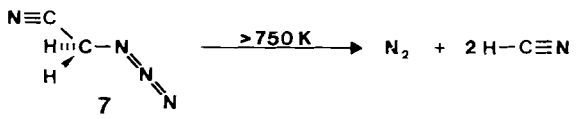
Photolysis of $NC{-}H_2C{-}N_3$ **7** in a 12 K argon matrix yields via cleavage of N_2 and a 1,2-H shift the expected $NC{-}HC{=}NH$[73]; prolonged irradiation leads to HCN.[72] The HCN dimer NC–HC=NH has been suggested to be involved in the chemistry of the formation of life on earth as a precursor for HCN oligomers and polymers,[72] the hydrolysis of which can lead to the formation of amino acids and polypeptides.[74] Since a PE-spectroscopically optimized gas phase production of iminoacetonitrile is thus of interest, the pyrolysis of $NC{-}H_2C{-}N_3$ has been studied under various experimental conditions: when passed through a quartz tube of 1.5 cm internal diameter loosely filled with quartz wool (Fig. 1), the N_2 extrusion starts already at 750 K, but in the narrower and shorter molybdenum tube of the short-path pyrolysis apparatus (Fig. 3) a temperature of more than 900 K is needed.[23] In both experiments, the PE spectrum of a N_2/HCN mixture is recorded. On tenfold amplification of the region between 10 and 13.5 eV, however, weak band contours emerge out of the noise level; if these are due to one of the HCN dimers, its concentration in the pyrolysis mixture must be less than 1%.

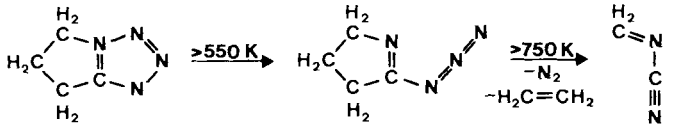


The gas phase pyrolyses of the acceptor-substituted methyl azides $X_nH_{3-n}C{-}N_3$ show the following parallels: in each case apart from N_2 a further "leaving molecule" HX or X_2 (F_2 as $[MoF_n]$) is eliminated under the experimental conditions chosen, and cyanogen compounds X–CN are formed as stable end products. The intermediate formation of methanimine derivatives $X_nH_{2-n}C{=}NH$ or $X_2C{=}NX$ cannot be detected by PE spectroscopy.[23]

3.7. Pyrolysis of Tetrazoles

In contrast to the thermally labile HCN dimer iminoacetonitrile NC–HC=NH, the isomeric *N*-cyanomethanimine $H_2C{=}N{-}CN$ is readily prepared by flash vacuum pyrolysis of trimethylenetetrazole, which opens above 550 K to its valence tautomeric azide (Scheme 10).[72,73]

N-Cyanomethanimine is also formed on heating dimethylcyanamide to 1270 K.[75] Since it contains two of the most frequently detected structural features in interstellar molecules, the cyano group and the methanimine skeleton,[76] it has been characterized by its microwave and millimeterwave spectra[72] for the purpose of facilitating radioastronomic search.



Scheme 10.

On heating trimethylenetetrazole in the short-path pyrolysis apparatus (Fig. 3), the N_2 ionization needles appear in the PE spectrum above 730 K; at 880 K the pyrolysis proceeds quantitatively.[77] The ionization pattern of *N*-cyanomethanimine can be obtained from the on-line PE spectra of the pyrolysis mixture by computer subtraction of the previously stored PE spectra of N_2 and ethene (Fig. 12).

The assignment of the seven radical cation states of $H_2C{=}N{-}CN$ observed in the He(I) range (Fig. 12), which leads to the expected sequence $n_N < \pi_{C=N} < n_{(C)N} < \pi_{C\equiv N}$,[60] is further corroborated by band shapes and by comparison with the ionization patterns of the isoelectronic molecules acrylonitrile $H_2C{=}CH{-}CN$[60] and nitrosyl cyanide $O{=}N{-}CN$.[78]

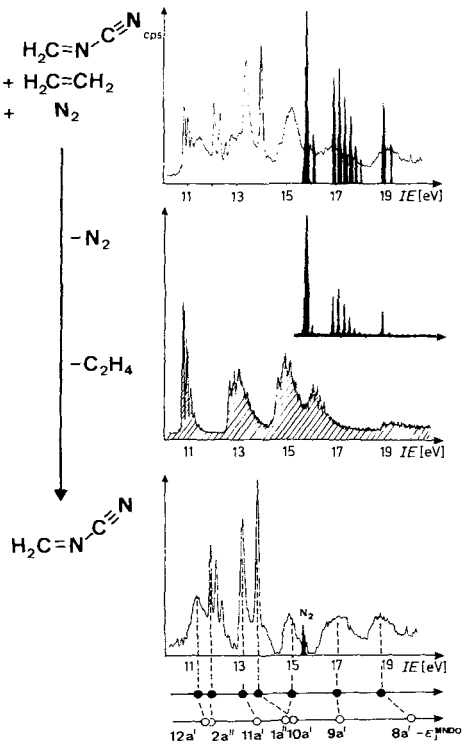


Fig. 12. He(I) PE spectra of the trimethylenetetrazole pyrolysis product mixture at 880 K, of N_2 (black) and of ethene (hatched) as well as the spectrum of $H_2C{=}N{-}CN$ obtained by computer subtraction, together with its Koopmans assignment based on MNDO eigenvalues (see text).

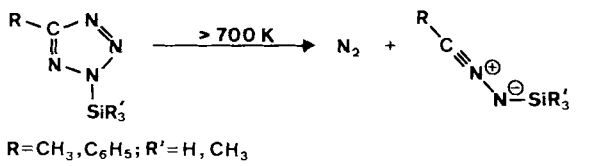
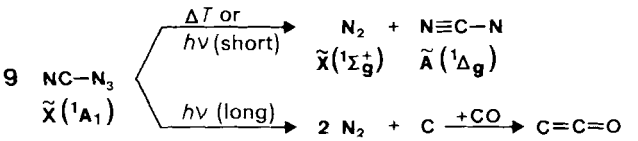


2,5-Disubstituted tetrazoles also cleave off nitrogen selectively during short-path pyrolysis at comparable temperatures. The products are gaseous nitrile imines,[77] which in solution are known as reactive intermediates in 1,3-dipolar cycloadditions.[79] In the low-energy range their PE spectra exhibit characteristic bands with ionization energies of ca. 8.0 (π_1), 8.6 (n_N), and 10.5 eV (π_2).

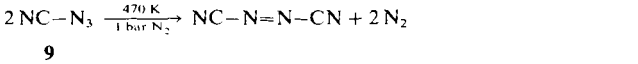
3.8. Pyrolysis of Cyanogen Azide and Azidodimethylamine

$NC{-}N_3$ **9** and $(CH_3)_2N{-}N_3$ **10**, whose typical ionization energies are found in the expected range and differ by ca. 1.3 eV (Fig. 6), in gas phase pyrolysis at reduced pressure lose nitrogen at relatively low temperatures; however, neither imines nor nitriles can be detected PE-spectroscopically as decomposition products.

Cyanogen azide, **9**, is a colorless, oily liquid which detonates when subjected to mechanical shock or on warming[29] and, therefore, should preferentially be handled as a dilute solution in an aprotic solvent.[29,80] The structurally[81] and spectroscopically[82] well-characterized molecule decomposes in a unimolecular manner on low pressure gas phase thermolysis or photolysis to linear cyanonitrile in its excited singlet state.[83]



Prolonged irradiation of cyanogen azide **9** in a low-temperature matrix produces cyanonitrene in its triplet ground state[83] and then atomic carbon, which subsequently reacts, e.g., with co-condensed CO to give C_2O.[83] In contrast, pyrolysis at atmospheric pressure in a stream of nitrogen carrier gas at above 470 K proceeds via N_2 elimination and substantial deposition of a polymer to azodicarbonitrile.[84]



9

The orange-red $NC{-}N{=}N{-}CN$ is an explosive, volatile solid[84] with a melting point of 308 K. It reacts with stop-

cock grease as well as with a number of organic solvents;[84] its half-wave oxidation potential of +0.40 V (vs SCE) lies 0.25 V above that of tetracyanoethylene,[84] and its vertical first ionization energy amounts to 11.9 eV.[23]

We have examined the decomposition of NC–N_3 **9** and NC–N=N–CN in the gas phase under various conditions. Cyanogen azide[29] may be safely evaporated into the short-path pyrolysis apparatus from a ca. 3% solution in diethyl phthalate (b.p. 571 K) at 10^{-2} mbar. The evolution of N_2 begins at an oven temperature of 700 K, and at 860 K the complex ionization pattern of the pyrolysis mixture has changed: spectral comparison shows that neither NC–N=N–CN nor NC–CN are present. Other possible decomposition products such as NCN can however neither be completely excluded nor clearly identified.[23] Above 1000 K the PE spectrum consists only of the N_2 ionization needles (see, e.g., Fig. 12), and the deposition of carbon becomes visible if the decomposition is carried out in a quartz tube (Scheme 11, top). The intermediate formation of azodicarbonitrile may also be excluded by studying its pyrolysis, which starts at temperatures above 1280 K, i.e. 480 K above that for NC–N_3, and proceeds in a uniform manner yielding dicyanogen (Scheme 11, bottom).

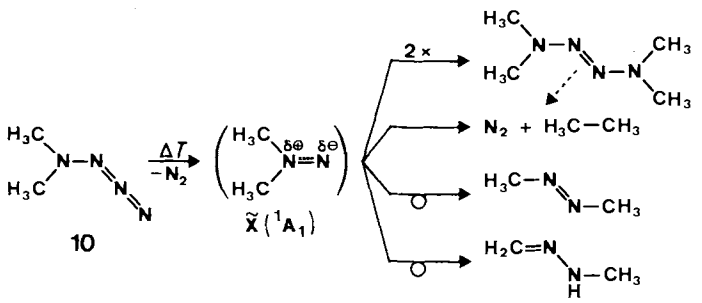
$$\underset{\mathbf{9}}{NC-N_3} \xrightarrow[10^{-2}\ mbar]{>1000\ K} 2\,N_2 + (C)_\infty$$

$$NC-N=N-CN \xrightarrow[10^{-2}\ mbar]{>1280\ K} N_2 + NC-CN$$

Scheme 11.

The remarkable stability of NC–N=N–CN under unimolecular conditions is surprising, since in the condensed phase nitrogen is evolved even at room temperature. The PE spectra registered continuously during heating give no indication of a *trans→cis* isomerization of azodicarbonitrile in the gas phase even above 1000 K.[85]

Azidodimethylamine, **10**, the first 1,1-tetrazine,[35] might on elimination of nitrogen in the gas phase yield dimethylaminonitrene, which, according to the known reactions of this class of compounds in their singlet ground state,[86] could possibly stabilize itself as shown in Scheme 12.



Scheme 12.

Sterically crowded dialkylaminonitrenes $(R_3C)_2NN$ can be handled in solution at 200 K,[87a] and it has even been possible to photolytically generate the blue parent compound H_2NN from carbamoyl azide $H_2N-CO-N_3$ in an 80 K matrix.[87b]

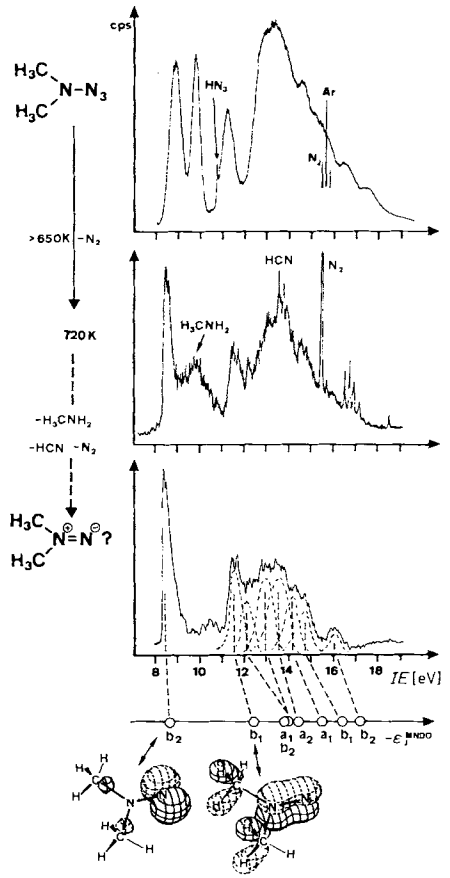


Fig. 13. He(I) PE spectra of $(H_3C)_2N-N_3$ **10** and its pyrolysis mixture at 720 K. The ionization pattern resulting from digital subtraction of H_3CNH_2, HCN and N_2, has tentatively been assigned to the nitrene $(H_3C)_2N-N$ on the basis of MNDO calculations (see text).

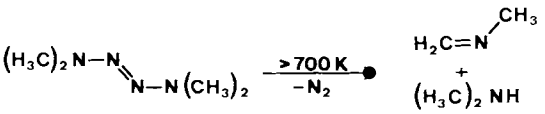
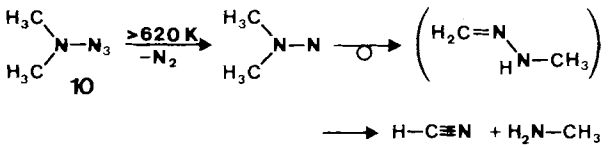
The decomposition of $(H_3C)_2N-N_3$ **10** begins at 620 K (loss of N_2) and is complete at 720 K. The PE spectrum of the pyrolysis mixture (Fig. 13) shows characteristic bands due to H_3CNH_2, HCN and N_2. Digital subtraction of their computer-stored PE spectra (see Fig. 12) leaves an ionization pattern which can be deconvoluted into eight partially overlapping bands (Fig. 13). For dimethylaminonitrene $(H_3C)_2N-N$, eight ionizations are expected in the He(I) range according to the reliable "electron counting" rule,[52] and Koopmans comparison with the calculated MNDO eigenvalue pattern (Fig. 13) would support such an assignment, allocating in particular the dominant sharp band at 8.22 eV to the radical cation ground state of the singlet dimethylaminonitrene with a preponderant contribution from the terminal nitrogen center. Moreover, from a comparison of the PE spectra the known R_2NN stabilization products (Scheme 12) can be ruled out:[86] thus tetramethyltetrazene decomposes only at temperatures above 700 K, forming *N*-methylenemethylamine and dimethylamine.[23]



The ionization pattern of ethane only features bands above 12 eV, and $H_3C-N=N-CH_3$, which might result from $(H_3C)_2N-N$ via methyl migration (Scheme 12),

would show an ionization band at 9 eV.[88] The hydrazone $H_2C{=}N{-}NH{-}CH_3$ should have two characteristic bands at 8.9 and 10.2 eV.[23] Since no other likely nitrogen compound with about 20 valence electrons[52] has a first ionization energy of only 8.22 eV, we suggest that the decomposition of **10** proceeds as shown in Scheme 13. The validity of this suggestion must be checked by other experiments such as matrix isolation of dimethylaminonitrene produced in the gas phase. Both final products, hydrogen cyanide and methylamine, are detected PE-spectroscopically in the pyrolysis of **10** (Fig. 13).



Scheme 13.

Altogether the results obtained thus indicate: in contrast to triplet alkyl nitrenes RN[10–12] but analogous to singlet phosphanitrenes $(R_2N)_2PN$,[4d] the singlet dialkylaminonitrenes R_2NN,[87a] known to be stable in solution at low temperatures, should also be observable in the gas phase.

3.9. Pyrolysis of Triazido(phenyl)silane

Almost 100 years after the preparation of $H_5C_6{-}N_3$, the first C-azide,[89] the unexpected formation of $(H_3C)_3Si{-}N_3$ in the pyrolysis of a silatetrazole[90] laid the foundation for the rather complex chemistry of the covalent silyl azides $R_{4-n}Si(N_3)_n$ (n = 1, 2, 3).[91] With only few exceptions,[92a] these exhibit higher thermal stability than their C-homologues,[92b] an experimental fact, which should by no means be explained in an oversimplifying way referring to fictitious (p→d)π-bond contributions $\geqslant Si{=}N_3$.[61,93] In fact, because of the lower effective nuclear charge at silicon, silyl substituents $R_{4-n}Si$- act predominantly as σ-donors with respect to the −NNN group (see Section 3.2) and thus increase the barrier for the kinetically important nitrogen extrusion $\geqslant SiN{-}N_2$. In addition, the Si substituent effect will reverse the relative thermodynamic stabilities of azides $R_3X{-}N_3$ and the corresponding imines or azomethines $R_2X{=}NR$, which for C azides are frequently the products of N_2 extrusion followed by 1,2-R migration.[4d,94] For analogous reasons, silyl azides may also decompose via a rearrangement to form isonitriles; the photolysis of $H_3Si{-}N_3$ in an argon matrix at 4 K yields the silaisocyanide $H{-}N{\equiv}Si$[95a] which, as confirmed by quantum chemical calculations,[95b,c] is stable with respect to a rearrangement to the isomeric hydrogen silacyanide $H{-}Si{\equiv}N$.

Triazido(phenyl)silane **13** can be prepared from trichloro(phenyl)silane by $AlCl_3$-catalyzed transazidation with trimethylsilyl azide (Scheme 3b) and, after careful decantation from the explosive $AlCl_x(N_3)_{3-x}$ flakes precipitated on the walls of the apparatus, it is purified by distillation. Its "controlled explosion" may be performed without risk if only small amounts are heated in the short-path pyrolysis apparatus (Fig. 3) using PE-spectroscopic real-time analysis (Fig. 14).[42]

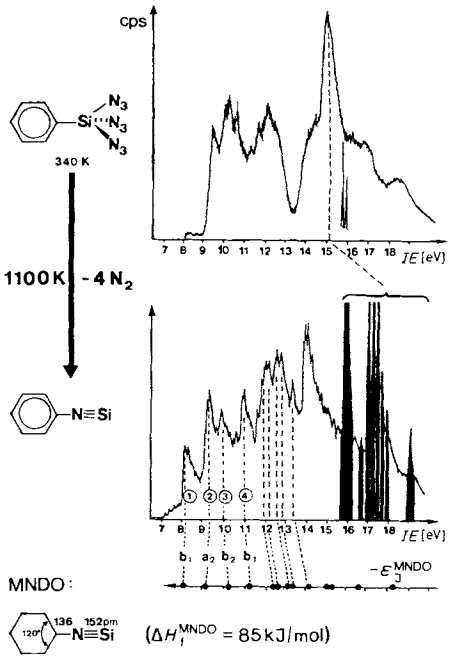


Fig. 14. He(I) PE spectra of triazido(phenyl)silane **13** at 340 K and of its pyrolysis products at 1100 K (N_2: black). The Koopmans' assignment of the ionization pattern of phenylsilaisocyanide is based on eigenvalues from a geometry-optimized MNDO calculation (see text).

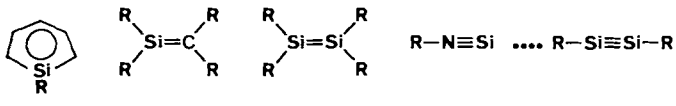
According to the continuously recorded PE spectra **13** is completely decomposed at 1100 K: its strong (σ_{N_3})-band between 15 and 16 eV (cf. Fig. 6) has been replaced by the intense N_2 ionization needles. The ionization pattern consisting of 11 largely resolved bands between 8 and 14.5 eV is assigned on the basis of comprehensive calculations to the pyrolysis product phenylsilaisocyanide (Fig. 14). The calculations also predict $H_5C_6{-}N{\equiv}Si$ to be more stable than $H_5C_6Si{\equiv}N$ by ca. 400 kJ/mol, paralleling the behavior of the isomers HNSi,[95] and the optimized bond length $d^{MNDO}_{N-Si} = 152$ pm agrees well with the 154 pm determined IR-spectroscopically[95a] and from highly correlated calculations[95b] for $H{-}N{\equiv}Si$. As for the valence-isoelectronic phenylisocyanide,[96] a linear arrangement (C)−N≡Si with NSi triple bond character is calculated. In the meantime the PE-spectroscopic results[42] have been further supported by the matrix isolation of phenylsilaisocyanide.[97]



Scheme 14.

The pyrolysis of triazido(phenyl)silane **13**, driven by the energy-producing elimination of 4 molecules of N≡N (cf. Section 1), leads to the formation of a polar triple bond −N≡Si with a silicon atom of coordination number 1. In the series of organosilicon compounds with multiple bonds to silicon (Scheme 14), which since 1979 have either been identified in the gas phase by PE spectroscopy[98] or kinetically stabilized, and thus rendered isolable, by wrapping with bulky hydrocarbon residues, the present result represents a further step towards an as yet unknown mole-

cule with an Si≡Si triple bond.[98f] At present, we are trying to obtain such a species from the pyrolysis of tetraazidodisilanes $R(N_3)_2Si-Si(N_3)_2R$. However, quantum chemical calculations for the ensemble Si_2H_2 predict the energy minimum to correspond to the isomeric $Si(H_2)Si$.[99]

3.10. Preparation and Properties of Reactive Imines and Azomethines

Cyclic or acyclic imines RR'C=NH or azomethines RR'C=NR'' are detected PE-spectroscopically as intermediates in the gas phase pyrolyses of alkyl azides and of other organic compounds with unsaturated NNN groups such as 1,2,3-triazoles, tetrazenes or tetrazoles (Figs. 3, 5, 6 and 8). They can be isolated at low temperatures and characterized, for example, by their NMR spectra.

Imines of low molecular weight, which have been discovered in interstellar space[19,76] and some of which are considered to be of prebiotic importance,[18,72] are so short-lived in the condensed phase (see Section 1) that relatively little was known about these reactive substances at the beginning of our investigations.[2,3] Their handling in the gas phase and in particular the optimization of their syntheses and reactions is made easier by the fact that they exhibit characteristic n_N and π_{CN} ionization bands at relatively low energy (Figs. 4, 7, 9, 12 and 15), and thus can be detected in gas mixtures by means of PE-spectroscopic real-time analysis.[3]

The n_N and π_{CN} ionization energies of simple imines $X_2C=NX$ are greatly influenced by the substituents H, F, CF_3, CH_3, $(CH_2)_n$, and $CH=CH_2$ (Fig. 15: Δn_N up to 4 eV, $\Delta\pi_{CN}$ 3.4 eV). The normal sequence $n_N > \pi_{CN}$ may be reversed: perfluorosubstitution of $H_2C=NH$ expectedly changes π_{CN} only slightly,[102] but n_N is considerably shifted. CF_3 substitution at N lowers n_N more than π_{CN}, leading to an approximately equal energy; two CF_3 groups on carbon both lower n_N and π_{CN} relative to $H_2C=NH$ by 1.3 eV! Methyl substituents function as donors; the hyperconjugative interaction with π_{CN} is of comparable magnitude for both *C*- and *N*-substitution, while n_N is raised more by *N*-substitution. The n_N ionization energy of cyclopropanimine is comparable to that of $(H_3C)_2C=NH$.[23] In 2*H*-azirine only one CH_2 group exerts a hyperconjugative effect on π_{CN}, while the n_N ionization is comparable to that of $H_2C=NH$ (Fig. 11). Both n_N and π_{CN} increase with increasing ring size in the cyclic azomethinimines; vibrational fine structure analysis of the n_N band indicates that dihydroazete ("1-azetine") is distorted on ionization to the radical cation ground state.[101] The comparison between 1- and 2-azabutadienes again confirms the stronger π-interaction due to *N*-substitution. The comparison of the n_N and π_{CN} radical cation states outlined here for selected derivatives[100] leads in detail[23] to numerous correlations and thus to extensive information on the >C=N< bond system.[23]

PE-spectroscopic gas analysis makes possible not only the detection of reactive imines and azomethines as intermediates in azide pyrolysis but also the optimization of new procedures for their preparation: thus 2*H*-azirine is best prepared by elimination of HCl and N_2 from the stable β-chloroethyl azide[37,38] (Fig. 2). For other imines and azomethines, the method developed by *Denis* et al.[22,101,103] and optimized PE-spectroscopically by us[23,37,101,104] has proven suitable: it involves the successive chlorination of gaseous alkylamines on solid *N*-chlorosuccinimide and dehydrochlorination of the *N*-chloroamines so formed with solid potassium *tert*-butanolate or adamantolate (Scheme 15).[39] Imine syntheses in the gas phase are best carried out in a double-oven apparatus consisting of modules which are fitted together and varied as required (Fig. 16, see also Fig. 2), with the PE-spectroscopic optimization of the reaction parameters in two stages.[105]

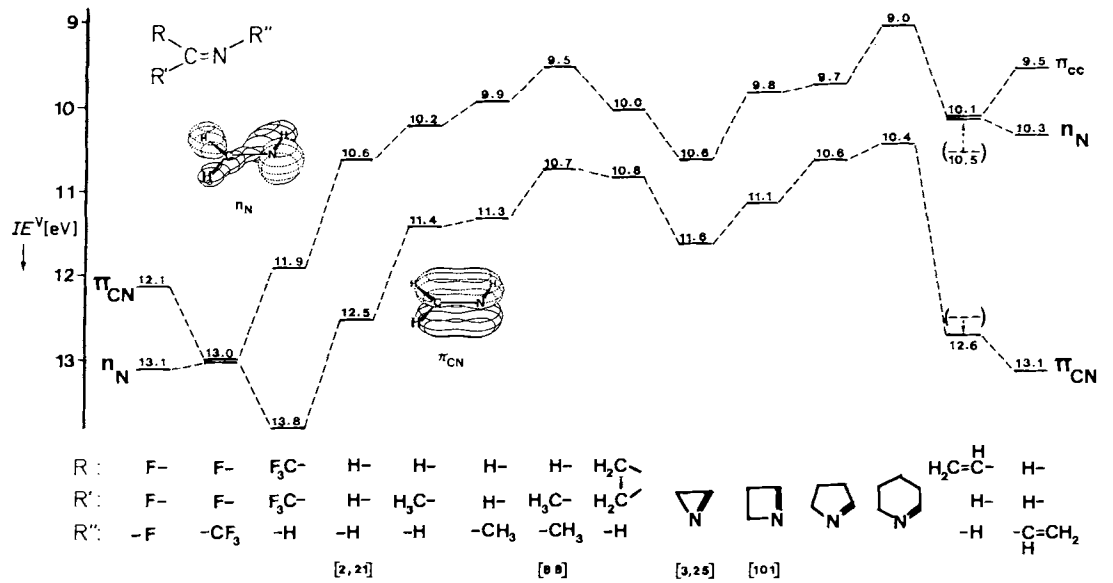


Fig. 15. Vertical n_N and π_{CN} ionization energies of selected [23, 100] imines and azomethines with various substituents and of cyclic azomethines with three- to six-membered rings (see text).

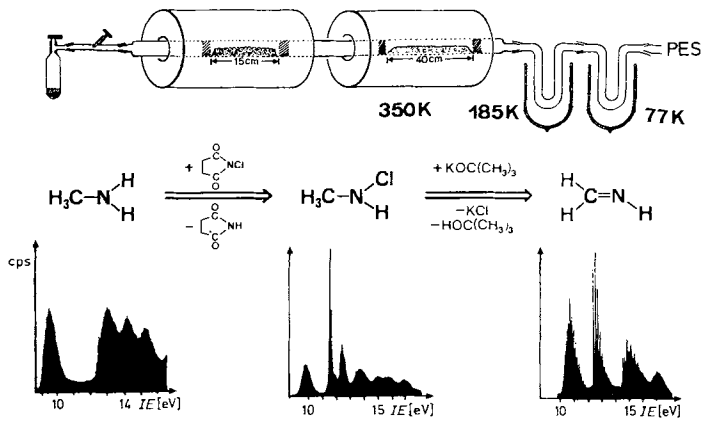

Fig. 16. Preparation of methanimine by successive chlorination of gaseous methylamine using solid *N*-chlorosuccinimide and dehydrochlorination of the *N*-chloromethylamine formed with potassium *tert*-butanolate (see Fig. 2). The PE-spectroscopic ionization patterns of the pure compounds used in the optimization of the reaction conditions are shown below (see text).

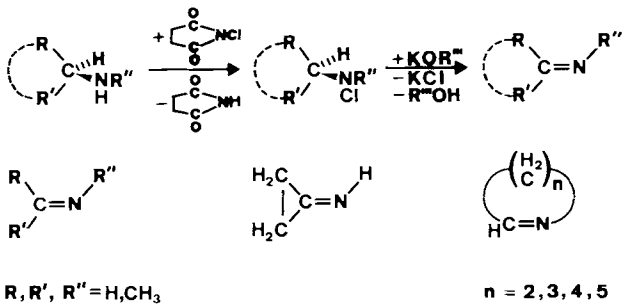
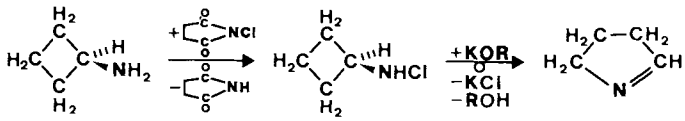
The imines and azomethines shown in Scheme 15 have been prepared (in some cases for the first time, see [103]) by consecutive chlorination of gaseous amines and dehydrochlorination of the resulting *N*-chloro derivatives.[39]



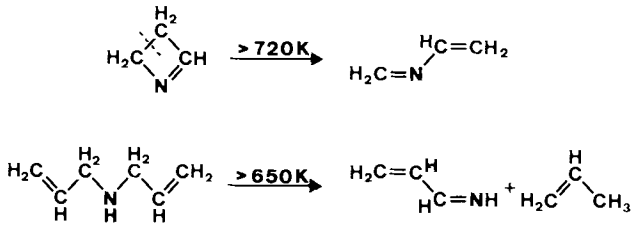
Scheme 15.

From N-chloroethylamine, the thermodynamically less stable[106] *E*-isomer is preferentially formed (70%).[103] During the chlorination of cyclopropylamine, the *N*-chlorosuccinimide layer atypically turns yellow while heat is evolved, and PE spectroscopy shows that among other products HCN is formed; pure cyclopropanimine is obtained only after the gas stream has passed through the KOR zone (Fig. 16). The cyclic imine 2*H*-azirine (Scheme 15: n = 1) cannot be prepared by HCl-elimination from *N*-chloroaziridine, since the three-membered ring opens under base catalysis to yield acetonitrile;[23] however, the two-step synthesis starting from β-chloroethyl azide offers convenient synthetic access[37,38] (Fig. 2). Imines with larger rings cannot pass through the 185 K cold trap (Fig. 16) because of their lower volatility and, therefore, potassium adamantanolate, the salt of a high-boiling alcohol, has to be used for the dehydrochlorination. 3,4-Dihydro-2*H*-pyrrole may also be prepared by thermal retro-trimerization of hexahydro-*s*-triazine[107] or by gas phase dehydrochlorination of *N*-chlorocyclobutylamine (Scheme 16).[23]

2-Azabutadiene is formed in quantitative yield in the gas phase pyrolysis of 2,3-dihydroazete (Scheme 17, top).[23, 103a] 1-Azabutadiene can be obtained either from gas phase pyrolysis of allyl azide or by thermal elimination of propene from diallylamine (Scheme 17, bottom).[56]

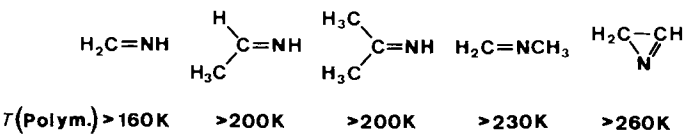


Scheme 16.



Scheme 17.

The synthetic methods discussed here, which have mainly been developed since 1980, provide a convenient access to simple methanimine derivatives $X_2C{=}NY$ with a variety of substituents X and Y such as H, CH_3, $(CH_2)_n$, $CH{=}CH_2$, F and CF_3.[2, 3, 23, 69, 103, 108] In spite of comparable structural data,[108] some of their molecular properties, are greatly influenced by the substituents. This is true not only for their ionization energies[100] (Fig. 15), IR stretching vibrations[103, 108] or ^{1}H-NMR signals[103, 108] (see Fig. 5), but in particular also for their tendency to polymerize. While acceptor-substituted imines such as $F_2C{=}NF$[69] or $Cl_2C{=}NCl$,[109] peralkylated[24] and F_3C-substituted[108] imines can be stored at least for a limited time at room temperature, others polymerize even in dilute solutions at temperatures below 273 K to give cyclic or linear[108] amines; this holds in particular for the NH-derivatives, but also for $H_2C{=}NCH_3$ and 2*H*-azirine (see Scheme 18: polymerization temperatures *T* (Polym.)).[23, 103]



Scheme 18.

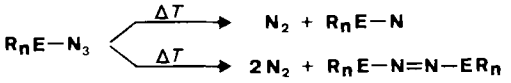
The parent compound $H_2C{=}NH$ is even converted in part into hexamethylenetetramine.[100] The behavior of many simple methanimine derivatives on heating in the gas phase emphasizes their nature as reactive intermediates. Thus $H_2C{=}NH$ eliminates hydrogen to form HCN under nearly unimolecular conditions[2] (cf. Fig. 4), 1-azetine opens to 2-azabutadiene (Scheme 17),[103a] and 2*H*-azirine rearranges to the thermodynamically stable end product acetonitrile[3, 25] (cf. Fig. 9). The PE-spectroscopic detection of the imine intermediates in the gas phase pyrolysis of alkyl azides provides the key information on the course of the N_2-extrusion.

4. Discussion of the Course of Azide Pyrolyses

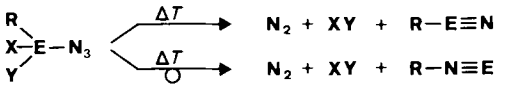
4.1. Reaction Channels of Azides Involving N_2 Extrusion

A total of 16 covalent azides R_nE-N_3 with central elements E = C, N, and Si has been pyrolyzed under comparable and approximately unimolecular conditions in a gas flow system at a pressure of ca. 10^{-2} mbar.[23] Upon thermal elimination of N_2, the following reaction channels are accessible:

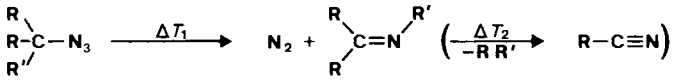
— formation of nitrenes or their dimerization products:

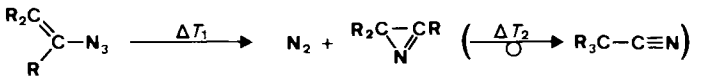


— elimination of further leaving molecules such as H_2, CH_4 or C_2H_6, $H_2C=CH_2$, HCl, HF, F_2, HCN, or N_2 to yield nitriles (E = C) or to rearrange to isocyanides (E = Si):



— rearrangement to methanimines (1,2-hydrogen shift) or azomethines (1,2-methyl migration) and ring closure to cyclic azomethines:





— at higher temperatures (ΔT_2), methanimine derivatives split off H_2[7, 14] or alkanes[16, 17] and form nitriles, while 2*H*-azirine rearranges with ring opening to acetonitrile.

The various reaction channels for azide pyrolysis may be commented on as follows: N_2 extrusion leading to stable singlet nitrenes is unusual (cf. Section 3.8); nitrene dimers are only observed at higher pressure. The elimination of additional leaving molecules may either occur simultaneously or be due to a "chemical activation" of the imines formed in the azide pyrolysis (cf. Section 4.3). In particular, no imine intermediates can be detected PE-spectroscopically during the decomposition of acceptor-substituted azides such as $ClH_2C-H_2C-N_3$ **3**, F_2HC-N_3 **8** or $NC-H_2C-N_3$ **7**. Corroborating evidence for "chemical activation" is provided by the fact that the imines and azomethines isolated in azide pyrolyses on revaporization are only converted into nitriles at considerably higher temperatures (see Section 4.3).

4.2. The N_2 Elimination: Substituent Effects and Energy Hypersurfaces

The temperatures of beginning nitrogen extrusion, which have been determined PE-spectroscopically under similar low-pressure conditions, range from 550 K for trimethylenetetrazole (Section 3.7) to 1100 K for trifluoromethyl azide (Section 3.6) and exhibit the following substituent effects:

— for methyl azide derivatives $(XYZ)C-N_3$, the decomposition point increases non-linearly with increasing acceptor perturbation by the substituents X, Y, Z (cf. Fig. 6): $(H_3C)_2HC-N_3$ shows the lowest nitrogen extrusion temperature of only 620 K, and F_3C-N_3 the highest with 1120 K. This observation parallels the sequence of their explosivity in the condensed phase;[4] trifluoromethyl azide cannot be caused to detonate even by heating to the softening point of the glassware used.[109]

— *tert*-butyl azide $(H_3C)_3C-N_3$ decomposes at a temperature 100 K higher than that of isopropyl azide $(H_3C)_2HC-N_3$ (Fig. 8) and thus confirms earlier observations[9c, 10a, 62] that barriers for 1,2-methyl migrations exceed those for 1,2-hydrogen shifts.

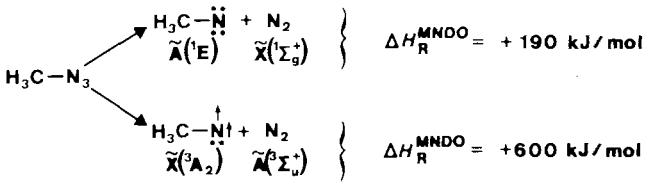
— the decomposition temperatures of silyl azides[91-95] ($(H_3C)_3Si-N_3$ 950 K, $(H_5C_6)_3Si-N_3$ 1170 K, cf. ref.[23]) are considerably higher than those of comparable carbon azides; based on the ionization energies (Fig. 6), this observation may be discussed as being due to a stronger σ-donor effect of the Si-substituent on the azide group (cf. Section 3.9).

— all azides, in which N_2 extrusion is assisted by neighboring groups, expectedly decompose at lower temperatures: notable examples are vinyl azide (620 K) and trimethylenetetrazole (550 K).

Altogether, the thermal N_2 elimination from the various azides is a complex process, which, even when the individual molecular dynamics (i.e. the vibratory and rotatory states of the molecules) are disregarded, raises numerous questions: Are short-lived nitrenes formed initially and if so, in their excited singlet or in their triplet ground states? Do nitrenes rearrange rapidly to the imines or azomethines isolated in a number of azide pyrolyses, or are the latter formed in an energetically favored synchronous process via a 1,2-substituent shift coupled to the N_2-extrusion? Are imines and azomethines actually intermediates even in cases where they cannot be detected by PE spectroscopy? For a discussion of the experimental results presented in Sections 3.2 to 3.9, extensive calculations[2, 3, 23, 25, 65] have been carried out using the semiempirical MNDO method[110] without explicit consideration of electron correlation.[111] As examples for the calculated MNDO energy hypersurfaces,[65] those of the simplest saturated and unsaturated organic azides, H_3C-N_3[2] and $H_2C=CH-N_3$,[3, 25] are presented.

For methyl azide, the N_2 extrusion temperature under approximately unimolecular conditions has been determined by PE spectroscopy to be 720 K, in agreement with the estimated H_3CN-N_2 dissociation energy of ca. 170 kJ/

mol.[10a,c] For the dissociation product methylnitrene, "double-zeta" SCF calculations[12] predict a triplet ground state $\tilde{X}(^3A_2)$, whereas the excited singlet state $\tilde{A}(^1E)$ should lie higher by 170 kJ/mol.[12, 13] However, the spin conservation principle would require that singlet methylene should be formed preferentially, because of the extremely large energy difference of 590 kJ/mol between the singlet ground state $\tilde{X}(^1\Sigma_g^+)$ of N_2 and its lowest excited triplet state $\tilde{A}(^3\Sigma_u^+)$ (Scheme 19).



Scheme 19.

This, together with experimental observations (Sections 1 and 3),[112] suggests that both thermal formation and subsequent reactions of methylnitrene occur on singlet energy hypersurfaces. The asynchronous N_2-extrusion with formation of singlet methylnitrene can be described to a first approximation using a one-dimensional reaction coordinate (Fig. 17a) if, starting from the known structure of methyl azide,[113] the CH_3N-N_2 distance is increased in steps of 20 pm, and the remaining bond distances and angles are optimized by the MNDO procedure.[65, 111] The calculation[23] predicts an activation energy of ca. 220 kJ/mol and an elongated H_3CN-N_2 bond length of 202 pm in the product-like transition state.[114]

The subsequent 1,2-H shift starting from one of the Jahn-Teller minima of the methylnitrene singlet state $\tilde{A}(^1E)$ is predicted to be highly exothermic ($\Delta H_R^{MNDO} = -390$ kJ/mol).[23] This 1,2-H shift in the five-atom species H_3C-N, which possesses $3\times5-6=9$ degrees of freedom, can be visualized on a two-dimensional energy hypersurface projected out of the 9-dimensional hyperspace, if the bond angle $\sphericalangle HNC$ and the torsional angle $\omega(HNCH)$ are chosen as the reaction coordinates[65] and varied stepwise, optimizing the remaining structural parameters by MNDO calculations. Inspection of the resulting hypersurface (Fig.

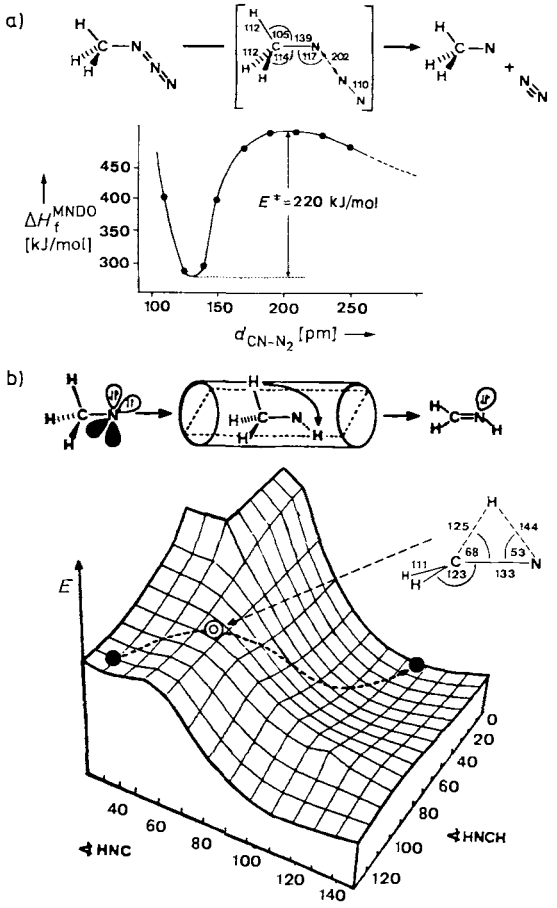


Fig. 17. MNDO energy hypersurfaces for asynchronous methyl azide decomposition: (a) barrier for the N_2 extrusion to singlet methylnitrene and (b) the rearrangement of the latter to methanimine (see text). Angles in degrees, bond lengths in pm.

17b) shows the potential well for singlet methylnitrene to be extremely flat; the barrier to the 1,2-H shift is estimated to be less than 20 kJ/mol, and the systematic search for a saddle point[115] leads to a three-membered ring transition state (Fig. 17b).

It is however more probable that the decomposition of methyl azide proceeds in a synchronous manner, since the different activation energies for the asynchronous partial

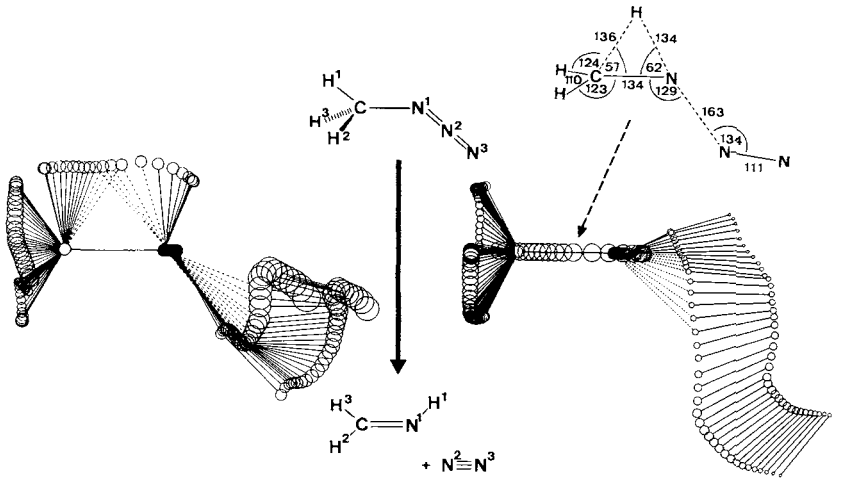

Fig. 18. Stroboscopic representation of geometry changes in synchronous methyl azide decomposition, as calculated by the MNDO method. Left: view onto the H^1CN^1 plane; right: view in the $^1HCN^1$ plane (---› position of H^1 at the saddle point; see text). Angles in degrees and bond lengths in pm.

steps lead one to expect a lower barrier for a concerted reaction. A stroboscopic representation of the calculated geometry changes along the reaction path (Fig. 18) shows a curved trajectory for the extruded N_2 molecule which appears to be coupled to the flattening and rotation of the H_2C fragment.

A further saddle point search[115] provides a structure for the transition state of the synchronous methyl azide decomposition, in which the H_3CN-N_3 distance is shorter by 40 pm (Fig. 18, top right) relative to that for asynchronous N_2-extrusion (Fig. 17a). A MNDO calculation of the barrier for simultaneous N_2-extrusion and 1,2-H shift predicts (within the error limits of the semiempirical approach with neglect of electron correlation and molecular dynamics) an activation energy which is comparable to that estimated for asynchronous methylnitrene formation. However, a synchronous process is supported by the temperature-dependence of the decomposition of alkyl azides $(H_3C)_nH_{3-n}C-N_3$ (Fig. 8): since the activation energies for the breaking of the $RN-N_2$ bond are largely substituent-independent[10c] and those for nitrene rearrangement negligibly small in comparison, the difference of more than 100 K in the decomposition temperatures indicates that the methyl azide pyrolysis occurs with coupled N_2-extrusion and 1,2-H shift.

Vinyl azide $H_2C=CH-N_3$ contains only one carbon atom more than the seven-atom molecule methyl azide; however, its different molecular topology requires consideration of the formation of several potential elimination products. MNDO calculations for the "normal" valence isomers of the ensemble C_2H_3N predict the enthalpies of formation shown in Figure 19.[25]

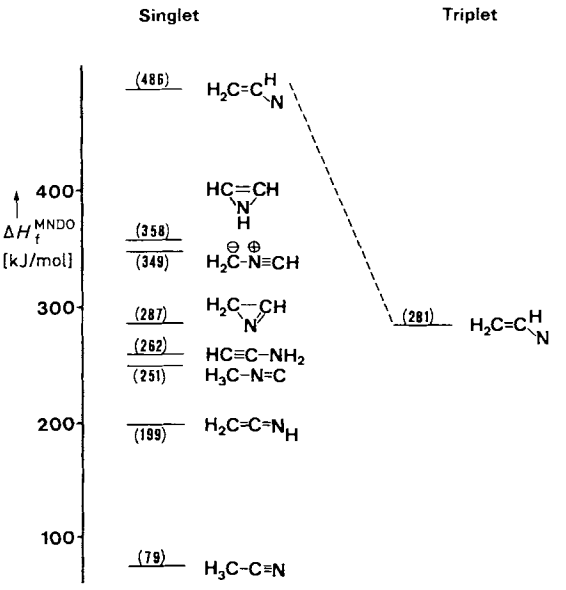

Fig. 19. MNDO calculated enthalpies of formation of low-energy C_2H_3N isomers.

Obviously, acetonitrile is by far the most stable isomer, followed by ketenimine, methyl isonitrile, aminoacetylene and 2*H*-azirine. Nitrile ylide and 1*H*-azirine are predicted to be relatively unstable, in agreement with chemical experience. The singlet ground state of vinylnitrene is estimated to lie ca. 205 kJ/mol above its triplet ground state.[25, 116] As for the decomposition of methyl azide, an energetically favored elimination of singlet N_2 should lead (with conservation of spin) to singlet vinylnitrene (Fig. 20).

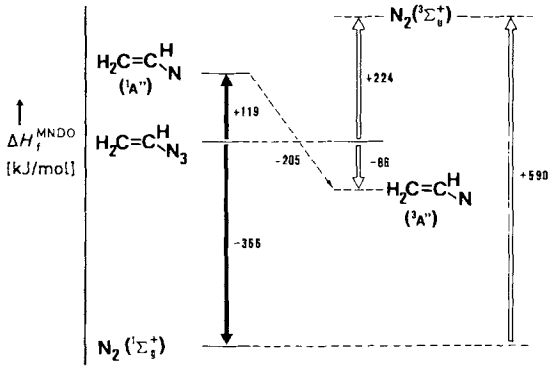

Fig. 20. Relative MNDO enthalpies of formation of vinyl azide and possible products of its thermal decomposition, N_2 and vinylnitrene, in their singlet and triplet ground states (see text).

Several of the C_2H_3N isomers (Fig. 19) can be formed from vinylnitrene only via multiple rearrangement steps. Thus two hydrogen atoms would have to migrate to produce $HC\equiv C-NH_2$, while for H_3C-NC even the molecular skeleton would have to be reorganized. Simpler processes such as ring closure or 1,2-H shift lead to 2*H*-azirine, acetonitrile or ketenimine. These three products can be projected onto favorable positions of a common singlet energy hypersurface, if the angles $\sphericalangle$HCN and $\sphericalangle$CCH are chosen from the possible $\binom{12}{2}=66$ pair combinations of the $(3\times 6-6)=12$ reaction coordinates (Fig. 21a).

The MNDO energy hypersurface for asynchronous vinyl azide decomposition shows that the resulting singlet vinylnitrene (Fig. 21a) would be located like H_3CN (Fig. 17b) in an extremely shallow potential minimum. The activation barrier for ring closure to 2*H*-azirine amounts to only a few kJ/mol, while that for the 1,2-H shift to acetonitrile is predicted to be ca. 40 kJ/mol. Ketenimine, which has been detected by microwave spectroscopy as a by-product of vinyl azide pyrolysis,[117] is separated by a hypersurface ridge over 70 kJ/mol high (Fig. 21a). The energy hypersurface for singlet vinylnitrene reproduces the observed decomposition products with the correct temperature dependence and relative concentrations. Additional MNDO calculations for the N_2 extrusion from $H_2C=CH-N_3$, however, predict, as for H_3C-N_3, an activation energy of ca. 240 kJ/mol.[23] This large barrier disagrees both with the observed decomposition temperature of vinyl azide in the gas phase, which is lower by 100 K, and with experimentally determined activation parameters in solution.[118] A refined energy hypersurface for synchronous N_2 extrusion and ring closure (Fig. 21b) can be calculated by choosing the torsional angle (HCCN) as the second reaction coordinate, thus allowing a twisting of the CH_2 group. This results in opening a trough through the activation barrier and in lowering the calculated enthalpy of activation by ca. 100 kJ/mol to 140 kJ/mol.

For substituted vinyl azides, the following decomposition routes have been discussed in the literature:[25, 63] the

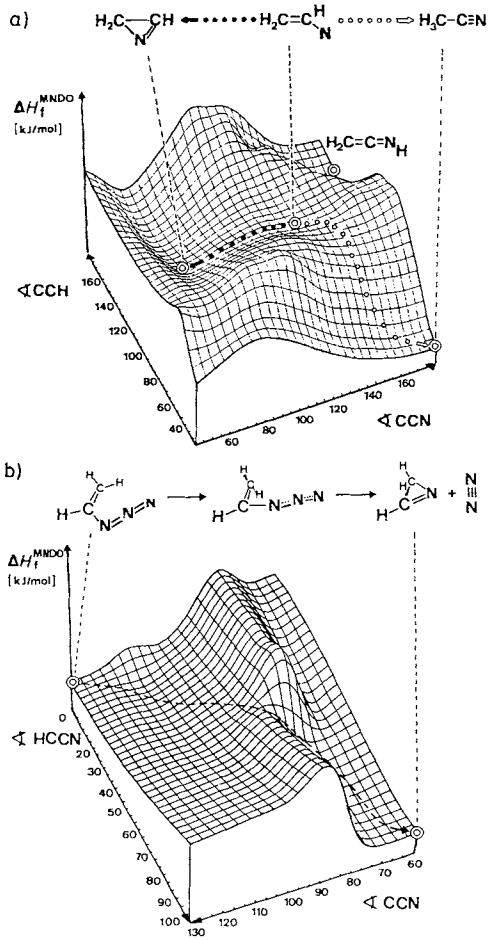

Fig. 21. MNDO singlet energy hypersurfaces for (a) vinylnitrene products accessible via ring closure (●●●●➡) or 1,2-H shift (○○○○⇨) in asynchronous vinyl azide decomposition and (b) synchronous N_2 extrusion and formation of the three-membered ring (see text).

asynchronous one via free vinylnitrene, the synchronous ring closure to 2*H*-azirine, and the intermediate formation of 4*H*-1,2,3-triazoles.[119] However, the parent molecule $H_2C=CH-N_3$ decomposes already at 620 K and thus ca. 100 K lower than methyl azide, while 1*H*-1,2,3-triazole does not decompose below 870 K. This is in agreement with the energy hypersurface calculations,[25, 116, 119] according to which N_2-extrusion and ring closure to the isolated 2*H*-azirine are the dominating mechanisms for vinyl azide decomposition.

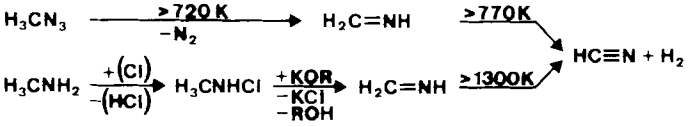
4.3. "Chemical Activation" of Imine and Azomethine Intermediates

Imines or azomethines have been detected PE-spectroscopically as intermediates in the low-pressure gas phase pyrolyses of the following C-azides:

- alkyl azides $R_2R'C-N_3$, whose α-carbon carries a group R′ capable of undergoing a 1,2-shift, on N_2-elimination form derivatives $R_2C=N-R'$; R′=H migrates in the case of methyl, ethyl, isopropyl or allyl azide (formation of imines), while $R'=CH_3$ migrates in the case of *tert*-butyl azide (formation of an azomethine).
- trimethylenetetrazole (Scheme 10) simultaneously splits off both N_2 and its $-H_2CCH_2-$ bridge as ethene, forming the *N*-cyano derivative $H_2C=N-CN$.
- vinyl azide decomposes preferentially via ring closure to 2*H*-azirine.

In exothermic reactions in solution, the reaction enthalpy stored as vibrational, rotational and translational energy in the resulting molecules is generally quickly dissipated by frequent collisions. In the gas phase, however, the collision frequency is low, particularly at low pressures, and the heat of reaction contained in the products can induce further reactions; a phenomenon, called "chemical activation."[120, 121]

For the consecutive reactions of imines to nitriles considerable temperature differences are observed depending on whether the gas stream from azide pyrolysis is heated further or whether the "cold" imine isolated in a cooling trap is thermally decomposed after revaporation. The difference is particularly drastic for methanimine: for methanimine generated by pyrolysis of methyl azide a temperature of only 770 K is required for H_2-cleavage, while the isolated compound has to be heated to 1300 K (Scheme 20). The temperature difference amounts to over 500 K (!).[23] The rearrangement of 2*H*-azirine to acetonitrile also requires a temperature ca. 120 K higher than that necessary for its formation in the pyrolysis of vinyl azide[20].



Scheme 20.

For the unimolecular thermal decomposition of methyl azide, it has been estimated from literature bond enthalpy data and from the activation energy for the N_2-extrusion[10a, d] that the methanimine molecule formed should be "chemically activated" by approximately 340 kJ/mol[23, 121] (Fig. 22).

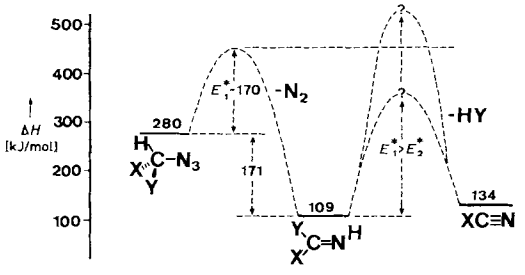


Fig. 22. Enthalpy diagram of methyl azide decomposition and methanimine dehydrogenation.

In satisfactory agreement, MNDO calculations predict for the N_2-extrusion from H_3C-N_3 an activation energy E_1^*(MNDO) of about 220 kJ/mol and for the strongly

exothermic formation of methanimine a reaction enthalpy ΔH_R^{MNDO} of about 170 kJ/mol. Since the "excess" energy stored in the molecule cannot be "dissipated" under the nearly unimolecular conditions in the gas stream,[12,1] a small increase in temperature leads to the additional elimination of H_2 and formation of HCN (Fig. 22: X, Y = H). In contrast, the thermal dehydrogenation of isolated methanimine requires that the full activation energy be supplied, i.e. a temperature higher by more than 500 K.

According to the PE-spectroscopic observations, the "chemically activated" imine and azomethine intermediates generated in alkyl azide pyrolyses can eliminate not only H_2 but also CH_4, H_3C-CH_3 or $H_2C=CH_2$, forming nitriles in an entropy-controlled reaction. Referring to the enthalpy diagram of Figure 22, all azides $(HYX)C-N_3$ for which the second activation barrier E_2^+ is relatively low should split off a further molecule fragment HY together with N_2. The experimental result that in gas phase pyrolyses of acceptor-substituted azides (cf. Section 3.6), the corresponding imines or azomethines are not observed PE-spectroscopically in spite of their demonstrated stability in some cases,[34,36] is thus readily explained: the N_2-extrusion from $ClH_2C-H_2C-N_3$, F_2HC-N_3 or $NC-H_2C-N_3$, which only commences at relatively high temperatures, leads to an "intramolecular explosion" of the "chemically activated" imine intermediate. The considerable reaction enthalpies which are stored in the molecular fragment remaining after N_2-extrusion also help to answer questions as to why for example tetramethylenetetrazole (Scheme 10) also eliminates $H_2C=CH_2$ with the formation of $H_2C=N-CN$, which under the reaction conditions is stable towards further decomposition to HCN, or why phenylsilyl triazide $H_5C_6Si(N_3)_3$ in its 1000 K gas-phase pyrolysis "suddenly" splits off four equivalents of N_2 and rearranges to the thermodynamically more stable isomer phenylsilaisocyanide $H_5C_6-N\equiv Si$ (Fig. 14).

5. "To What End Does One Study the Gas-phase Pyrolysis of Azides?"

An important precondition for our studies[23] has been the advantages offered by PE-spectroscopic real-time analysis[3] for gases flowing under reduced pressure (Sections 2 and 3.1). Using this technique we were able to safely pyrolyze azides and other nitrogen-rich substances and to determine their decomposition temperatures (Sections 3.2–3.9), to detect (in part for the first time) or to isolate imines and other short-lived intermediates, and to optimize synthetic routes to a number of nitrogen compounds which had previously either been unobtainable or obtainable only with difficulty (cf. Section 3.10). MNDO calculations have proven valuable in the assignment of unknown ionization patterns (Section 3.2) and thus in the identification of decomposition products (Section 3.10); calculated energy hypersurfaces (Section 4.2) agree with many experimental results and in addition permit some insight into the complex microscopic pathway of the apparently so simple azide decomposition, in which "chemically activated" intermediates (Section 4.3) have been detected.[23]

The decomposition of azides under unimolecular conditions, i.e. outside their explosion limits, requires unexpectedly high temperatures. Three substituent-dependent decomposition pathways to (singlet) nitrenes, to imines and to nitriles or isocyanides are observed. A comparison between experimental and calculated data suggests that in azide pyrolyses singlet nitrogen elimination and rearrangement to observed intermediates proceed in a synchronous manner. A number of imines have been detected as intermediates; their decomposition, studied in part using independently prepared samples, occurs only at high temperatures and provides evidence that they are formed "chemically activated" in azide pyrolyses. A series of new compounds such as phenylsilaisonitrile $H_5C_6N\equiv Si$ with a formally triply-bonded silicon atom of coordination number 1 (Section 3.9) extend the chemistry of the main group elements.

The title question may also be answered as follows: the gas-phase pyrolysis of azides—provided that necessary precautions are taken!—is not only a useful method for the preparation of compounds which are otherwise difficult to obtain as well as an illustration of the advantages of PE-spectroscopic gas analysis, but in addition is particularly suitable for studying the still largely unknown reaction paths of medium-size molecules with numerous degrees of freedom. The compounds discussed, which are often "malicious" in the condensed phase, and their demonstrated safe handling under reduced pressure in the gas phase, the thermodynamically favorable elimination of singlet N_2, or the proven formation of "chemically activated" intermediates should be of interest to other research groups with, for example, access to more time-resolved measurement techniques. We hope that in the future also the gas phase pyrolysis of azides, as a many-faceted model reaction, will contribute to improving our currently fragmentary knowledge of microscopic reaction pathways, a hope, which closes the circle to the quotation from *George C. Pimentel* at the beginning of this article.[1]

The "detours to the formation of elementary nitrogen" described here have been generously supported by the Deutsche Forschungsgemeinschaft within the special program "short-lived molecules", by the Fonds der Chemischen Industrie and by the Federal State of Hessen; R. D. thanks the Studienstiftung des Deutschen Volkes for a doctoral stipendium. Parts of this study were carried out in cooperation with Dr. J.-M. Denis (Rennes), Prof. Dr. W. A. Herrmann (München, formerly Frankfurt) and Prof. Dr. C. Wentrup (Brisbane (Australia), formerly Marburg); samples of other compounds were provided by Prof. Dr. H. Bürger (Wuppertal), Dr. K. O. Christie (Rocketdyne Corp., Canoga Park, California), Dr. D. Lentz (Berlin) and Prof. Dr. D. D. DesMarteau (Clemson, South Carolina).

[46] PE spectra can be digitally recorded on-line and stored in a computer. The so-called "spectrum stripping", in which the PE spectra of pure single components previously stored in a data bank are electronically subtracted, has often proved useful in PE-spectroscopic analysis. Cf. also, e.g., $SiCl_2$/naphthalene: H. Bock, B. Solouki, G. Maier, *Angew. Chem. 97* (1985) 205; *Angew. Chem. Int. Ed. Engl. 24* (1985) 205; or SPCl/PCl_3: M. Binnewies, B. Solouki, H. Bock, R. Becherer, R. Ahlrichs, *ibid. 96* (1984) 704 and *23* (1984) 731.

[47] It is advisable to first condense out less volatile decomposition products in a 77 K trap; cf., e.g., H. Bock, H. P. Wolf, *Angew. Chem. 97* (1985) 411; *Angew. Chem. Int. Ed. Engl. 24* (1985) 418.

[48] See, e.g., H. Bock, T. Hirabayashi, S. Mohmand, *Chem. Ber. 114* (1981) 2595, 2609; *115* (1982) 492.

[49] See, e.g., H. Bock, S. Mohmand, T. Hirabayashi, G. Maier, H. P. Reisenauer, *Chem. Ber. 116* (1983) 273.

[50] In particular, it is assumed that the electron relaxation energy stabilizing the radical cation and the correlation energy contribution of the expelled electron are comparable in magnitude and due to their opposing signs approximately cancel (cf. H. Bock, *Angew. Chem. 89* (1977) 631; *Angew. Chem. Int. Ed. Engl. 16* (1977) 613). Moreover the vibronic coupling between the various $M^{\oplus\oplus}$ states must be negligibly small (cf. H. Köppel, L. S. Cederbaum, W. Dancke, S. S. Shaik, *ibid. 95* (1983) 221 and *12* (1983) 210).

[51] Selected examples of molecular state comparisons for chemically related compounds according to topological considerations and pertur-

bational arguments are collected in H. Bock, *Angew. Chem. 89* (1977) 631; *Angew. Chem. Int. Ed. Engl. 16* (1977) 613 ("Molecular States and Molecular Orbitals").

[52] According to a useful rule of thumb (cf. H. Bock, B. G. Ramsey, *Angew. Chem. 85* (1973) 773; *Angew. Chem. Int. Ed. Engl. 12* (1973) 734) the ionizations of all $np_{element}$ and $1s_H$ electrons should be observable in the He(I) measurement range. Thus, taking into account the Pauli principle, we expect $(3+1\times2+3\times3)/2=7$ PES bands for methyl azide, with those at 14.4 and 14.8 eV overlapping considerably.

[53] S. Cradock, E. A. V. Ebsworth, J. D. Murdoch, *J. Chem. Soc. Faraday Trans. 67* (1971) 86.

[54] In particular, the higher-energy radical cation states of azides, in which the positive charge is mainly localized in the NNN group as for example in the $\tilde{D}$(10a) state of H_3C-N_3 [11], are generally reproduced only with considerable "Koopmans' defects" even by SCF calculations with large basis sets: the corresponding SCF eigenvalues differ by up to several eV from the experimental ionization energies, since electron reorganization and correlation effects no longer cancel [50]. Thus SCF calculations for the third ionization energy of HN_3 (Fig. 6: $IE_3^v=15.45$ eV [55]) deviate as follows: MNDO 16.80 eV [23], ab initio STO-3G 16.19 eV [55c], ab initio "double zeta" 18.51 eV (J. F. Wyatt, I. H. Hillier, V. R. Saunders, J. A. Connor, M. Barber, *J. Chem. Phys. 54* (1971) 5311).

[90] L. Birkofer, A. Ritter, P. Richter, *Angew. Chem. 74* (1962) 293; *Chem. Ber. 96* (1963) 2750.

[91] See the reviews: R. M. Pike, N. Sobinski, P. J. McManus, *J. Organomet. Chem. 253* (1983) or those in [4d] and in the references cited therein.

[92] a) For example, $H_3CSi(N_3)_3$ explodes on attempted distillation (see [39] and W. T. Reichle, *Inorg. Chem. 3* (1964) 402); H_3SiN_3 decomposes below room temperature with the formation of SiH_4 (cf. W. R. Peterson Jr., *Rev. Silicon, Germanium, Tin, Lead Compd. 1* (1974) 206); see also [95a]. b) For closely related compounds the decomposition point determined under comparable conditions can differ by more than 200 K: thus N_2-extrusion from $(H_3C)_3SiN_3$ in the gas phase starts at 950 K [23], that from $(H_3C)_3CN_3$ at 720 K (Fig. 7).

[93] In spite of the relatively short SiN bond distance, which is 147 pm in $(H_3C)_3SiN_3$ (M. Dakkouri, H. Obernhammer, *Z. Naturforsch. A 27* (1972) 1331), the SiN stretch force constant of the SiN bond is not increased (H. Bürger, *Monatsh. Chem. 96* (1965) 1710). Furthermore, $(H_3C)_3SiN_3$ shows a bond angle $\sphericalangle$SiNN of 128° and, in contrast to H_3SiNCO, also H_3SiN_3 is non-linear (E. A. V. Ebsworth, M. J. Mays, *J. Chem. Soc. 1964*, 3450).

[94] Using the MNDO approximation, the following reaction enthalpies ΔH_{MNDO} (kJ/mol) for the reaction $R_3X-N_3 \rightarrow N_2+R_2X=NR$ [23] are estimated: R=H, X=C, −173; R=H, X=Si: +8; $R=CH_3$, X=C: −194; $R=CH_3$, X=Si: +91.

[95] a) *J. F. Ogilvie* and *S. Cradock* (*Chem. Commun. 1966*, 364) obtained the following structural data from IR spectroscopy $d_{NSi}=154$ pm, $d_{HN}=100$ pm and HNSi=180°. b) *J. N. Murrell, H. W. Kroto*, and *M. F. Guest* (*J. Chem. Soc. Chem. Commun. 1977*, 619; cf. also H. W. Kroto, J. N. Murrell, A. Al-Derzi, M. F. Guest, *Astrophys. J. 219* (1978) 886)

calculated HNSi to be 372 kJ/mol more stable than the isomer HSiN. c) On the basis of CI calculations, *R. Preuss, R. J. Buenker,* and *S. D. Peyerimhoff (J. Mol. Struct. 49* (1978) 171) predict the barrier for the rearrangement HSiN→HNSi to be only 55 kJ/mol.

[96] The CNC skeleton in the iso(valence) electronic phenyl isocyanide is linear according to microwave-spectroscopic studies (B. Bak, B. P. van Eijck, C. Kierkegaard, *J. Mol. Struct. 18* (1973) 429); the N=C bond length is only 114.2 pm.

[105] The PE-spectroscopic optimisation of the gas phase synthesis of imines shall be exemplified here for the parent compound H_2C=NH; details are given in [23]: H_3CNH_2 is drawn at 10^{-2} mbar by the pump of the spectrometer into the horizontal reaction tube, the first part of which is half-filled with *N*-chlorosuccinimide (Fig. 16). The resulting H_3CNH_2/H_3CNCl_2 mixture is analyzed using the known ionization patterns (cf. E. Nagy-Felsobuki, J. B. Peel, *J. Chem. Soc. Faraday Trans. 2 74* (1978) 1927). After extensive optimization of the reaction parameters we obtained, at room temperature and with 18 cm length of *N*-chlorosuccinimide-filling, almost exclusively H_3CNHCl. This compound, which may explode on liquefaction, should therefore preferably not be isolated in a pure form. Next, the second part of the tube, which can be heated separately, is half-filled under argon with $KOC(CH_3)_3$. On starting the methylamine gas flow, the oven temperature is increased continuously until the band pattern of pure methanimine is recorded: optimal conditions are 350 K and a KOR zone 40 cm in length. After the removal of *tert*-butanol at 185 K, H_2C=NH may be frozen out in a 77 K cold trap; it contains PE-spectroscopically detectable traces of NH_3. Cf. also [62].

[112] Singlet methylnitrene rearranges rather rapidly even in a 4 K inert gas matrix [11, 13], and H_3CN-insertion into other bonds is neither observed during thermal nor during photolytic methyl azide decomposition [10a, d]. If the rearrangement H_3CN→H_2C=NH were to occur on a triplet energy hypersurface, singlet methylnitrene should have such a long lifetime because of the spin-forbidden transition $\tilde{A}(^1E)$→$\tilde{X}(^3A_2)$ that it ought to be chemically detectable. In addition, a triplet rearrangement would lead to triplet methanimine, the ground state of which lies above that of methylnitrene [12].

[114] According to the Hammond criteria (H. S. Hammond, *J. Am. Chem. Soc. 77* (1955) 1288); cf. the transition states of exothermic reactions should be similar to the starting materials and those of endothermic reactions product-like.

[115] See also: K. M. Müller, *Angew. Chem. 92* (1980) 1; *Angew. Chem. Int. Ed. Engl. 19* (1980) 1. We thank Dr. Müller for his help in the preparation of the SPLOC programme developed in cooperation with Dr. *B. Roth* (*Dissertation,* Universität Frankfurt 1983) using his saddle point location algorithm.

[116] On the basis of our studies [25], *L. L. Lohr* and *K. Morokama* (*J. Am. Chem. Soc. 105* (1983) 5541) have carried out ab initio SCF calculations with a "double zeta + polarization functions" basis set; in the main their results confirm the conclusions from the MNDO energy hypersurfaces. In addition, they suggested H_3C–NC as a further intermediate, which, however, cannot be detected PE spectroscopically during the gas phase pyrolysis of vinyl azide [23, 25].

[117] R. G. Ford, *J. Am. Chem. Soc. 99* (1977) 2389.

[118] The following activation parameters have been measured for the decomposition of substituted vinyl azides in solution: $\Delta H^{\neq}$ = 100–200 kJ/mol and $\Delta S^{\neq}$ = −12 to −30 J mol^{-1} K^{-1} [63]. Higher values for $\Delta H^{\neq}$ (see, e.g., Fig. 19) and in particular positive entropies of activation are to be expected for reactions involving free nitrenes. The negative $\Delta S^{\neq}$-values observed are commensurable with a sterically demanding transition state involving synchronous N_2-elimination and 1,2-R migration.

[119] The formation of 4*H*-1,2,3-triazoles observed when substituted vinyl azides undergo base-catalyzed decomposition in solution (J. S. Meek, J. S. Fowler, *J. Org. Chem. 33* (1968) 985, cf. also [63] and L. A. Burke, G. Leroy, M. T. Nguyen, M. Sana, *J. Am. Chem. Soc. 100* (1978) 3668) is less probable for a gas-phase reaction: according to MNDO calculations [23], the bending of an NNN group requires a considerable amount of energy; in addition, 4*H*-1,2,3-triazole lacks the stabilization by cyclic 6-electron delocalization of the 1*H*-tautomer.

The Development of Bioglass Ceramics for Medical Applications

By Werner Vogel* and Wolfram Höland

The enormous progress made in the field of medicine over the past few decades has been partly due to the introduction of new instruments but also a result of the use of new materials. It is impossible to imagine modern medicine without metals, alloys, sintered corundum, organic high polymers (also as composite materials), glassy carbon, etc. Bioglass ceramics open up new possibilities for medical treatment and constitute a new area of research in the natural sciences and medicine. Owing to their widely variable combinations of properties, bioglass ceramics can be more easily adapted to suit medical requirements than can customary implants. Two properties of bioglass ceramics are of primary importance: their biocompatibility, i.e., acceptance of the material by the tissues of the human body without irritation, rejection reactions, or toxic effects; and their bioactivity, i.e., the ability to establish firm intergrowths with tissues of the human body. This property is not shared by any of the classical biomaterials. A wide range of applications is envisaged for the bioglass ceramics that have so far been developed; some are still undergoing animal tests while others are being clinically tested in humans. Possible applications are the replacement of vertebrae and use in the middle ear, throat, nose, and eye, in the entire head region, in the shoulder and leg, and in dental prosthetics, in particular the replacement of dental roots (a hard tissue substitute in the broadest sense of the word). The question as to the behavior of a bone/bioglass ceramic contact or bond on a long-term scale and on being exposed to varying mechanical stress has still not been satisfactorily answered, because interdisciplinary research in this field is still immature. All observations made so far indicate, however, that the materials do not cause any adverse effects.

1. Introduction

The development of new materials for bone implants and substitutes in man has gained major importance over the past five to ten years. In addition to metals, sintered corundum, and organic polymers, bioglasses and bioglass ceramics have come especially to the fore. These new implant materials are not only biocompatible, like the other customary materials, but are also bioactive. They are not regarded as foreign bodies and encapsulated by living bone tissue; instead, direct intergrowth takes place. The special combinations of properties required by medicine can be more easily adjusted and varied in bioglasses and bioglass ceramics than in metals, sintered corundum, or organic polymers. Moreover, bioglasses and bioglass ceramics can be more easily adapted to the natural composition of bone, which obviously adds greatly to their bioactivity and their compatibility with living human tissue. It should be mentioned at this point that some of the uses of these new materials in medicine extend considerably beyond mere bone replacement.

2. Conditions for Controlled Crystallization in Glass as the Basis for the Systematic Development of Glass Ceramics

A review article was published in this journal in 1965 concerning the "Structure and Crystallization Behavior of Glasses."[1] Subsequent studies, which considerably extended these earlier findings, have since been reviewed.[2, 3] They have provided a reliable basis for the development of a large number of new optical and technical glasses, for overcoming disturbances in glass production, and for the development of several families of new glass ceramics with widely differing properties and combinations of properties.

It can be demonstrated experimentally that most phase separations that occur when glass melts solidify to form a solid body produce a microheterogeneous structure. In the simplest case, a droplet-shaped microglass phase is incorporated in a matrix glass phase with a different composition. The resultant microglass phases are not the product of statistical variations in composition; they tend instead to assume a composition corresponding to that of defined, stable chemical compounds—the extent to which this is achieved depends on the degree of undercooling of the melt. Phase separation can be controlled in a multitude of ways and represents the key to the developments cited above. Figure 1a shows a typical example of a phase-separated glass with a microheterogeneous structure.

The reason for phase separation is presumably the presence of at least two different building groups with extremely different volume requirements. This phase separation entails considerable consequences for the crystallization behavior of a glass. (For a theoretical treatment of phase-separation phenomena in glasses, see Ref. [3].)

The theoretical basis for homogeneous nucleation is given by Volmer's equation [Eq. (1)], which states that the nucleation rate I depends primarily on the enthalpy of activation required to attain the critical nuclear size.

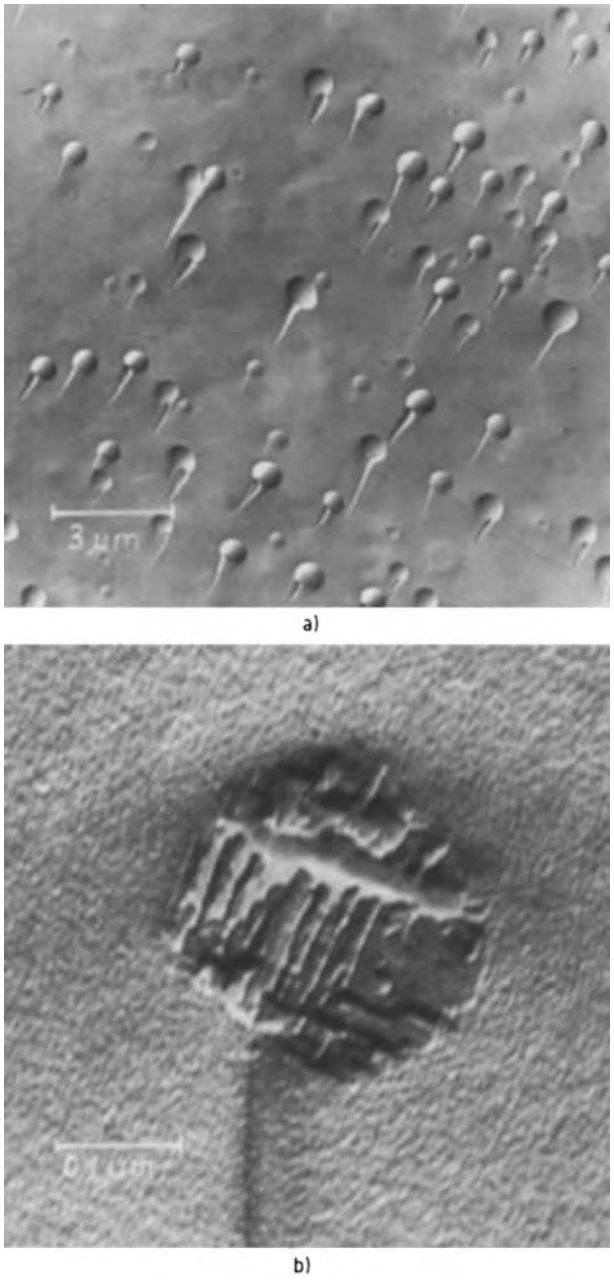

Fig. 1. a) Typical immiscibility phenomena in a silicate glass. Replica electron micrograph of a glass fracture surface prepared in a high vacuum. The droplets with their "fracture flags" are incorporated in a matrix glass phase of different composition. b) The start of nucleation within the droplet region (replica electron micrograph).

$$I = A \cdot e^{-\frac{(\Delta G^* + \Delta G_D)}{k \cdot T}} \quad (1)$$

A = constant
ΔG^* = enthalpy of activation for reaching the critical nuclear size
ΔG_D = enthalpy of diffusion
k = Boltzmann's constant
T = temperature

The enthalpy of activation consists of two terms ($\Delta G^* + \Delta G_D$). The total activation energy decreases by the amount ΔG_D if the building blocks of the nucleus are already present at the nucleation site. This is the case when phase-separated base glasses are induced to nucleate and crystallize (Fig. 1b). Since the composition of the droplet regions closely approaches that of defined, stable chemical compounds, nucleation begins simultaneously in all of the droplets. The number and size of the resulting crystals can accordingly be varied by controlling phase-separation phenomena in the glass. As is shown in Figure 1b, growth of the crystallite front is stopped when it reaches the droplet phase boundary; i.e., even if nucleation happens to be delayed in one or other of the droplets, the sizes of the crystals will be comparable because growth of the nuclei stops at the droplet boundary. The following main criteria must be satisfied for controlled crystallization in glass: the starting conditions for nucleation should be uniform at an infinite number of equally distributed sites within the total volume of glass and the final product should contain equal-sized crystallites with very small dimensions (usually only a few micrometers).

Heterogeneous nucleation (i.e., nucleation in the presence of a foreign nucleus) is described by Turnbull's relation [Eq. (2)]. Foreign nuclei can be produced in glass in a

$$I = A' \cdot e^{-\frac{(\Delta G^* \cdot f(\theta) + \Delta G_D)}{k \cdot T}} \quad (2)$$

variety of ways. If at least two of their lattice constants do not differ from those of the desired crystalline phase by more than $\pm 15\%$ (or a multiple of the lattice constants of the desired crystalline phase), epitaxial interactions can occur. In other words, the foreign nucleus that has become capable of growth can continue to grow with an unrelated substance, i.e., with the molecular building groups of the desired crystalline phase, which, for example, may be located in the droplets. This also accounts for the fact that it is often very difficult or even impossible to demonstrate and unequivocally identify the heteronuclei in cases of epitaxial interaction. Epitaxy further decreases the necessary critical enthalpy of activation for nucleation, ΔG^*, by a function of θ, $f(\theta)$. It is a function of the measurable contact angle θ between the foreign nucleus and the melt from which the main crystalline phase is to be formed. The contact angle reflects the strength of the epitaxial interaction. If deposition occurs, this function is always less than 1, which means that nucleation and crystallization proceed much more quickly than without a foreign nucleus. The action of foreign nuclei can to some extent be compared with that of initiators.

3. Development of Bioglass Ceramics—Present Status, Requirements, and Our Own Goals

Important advances have been made in the field of medicine as a result of developments generally involving the use of phosphosilicate glasses (which are closely related to the apatite-rich bone substance) to form coatings and thin films on implant materials such as metals and sintered corundum.[4–6] Thin glass films have also been employed which, in some cases, have been converted into crystalline apatite by tempering. These bone-related glasses and glassy crystalline films exhibit relatively good bioactivities and bonding with the bone tissue. As a rule, however, thin films ultimately dissolve and thus become useless. This behavior has been exploited for different purposes to de-

velop completely reabsorbable glasses and glass ceramics.[7-9] Another approach was to develop sintered ceramics as solid materials, usually sintered products consisting of crystalline apatite.[10] Powdered phosphate glasses in which crystalline apatite is formed by tempering have also been used as sintered products.[11, 12] The resulting properties were then further modified by sintering mixtures of a phosphate glass powder and a silicate glass powder in which crystalline silicates such as wollastonite or devitrite separate out.[13, 14] The products obtained are porous and of variable bioactivity, depending on their apatite content, and can be worked to a limited extent with tools made of hard metals. Their porosity and relatively poor mechanical strength, however, often prove to be serious disadvantages.

An important advance was made when glassy crystalline products were obtained by tempering solid glasses.

The first important step toward the formation of a solid bond between inorganic materials and bone was taken by *Hench* et al. with the preparation of glass films and partially crystalline glasses.[15, 16] Their base glass had the following composition [wt%]:

SiO_2	45	CaO	24.5
Na_2O	24.5	P_2O_5	6.0

In the 1970s, the development of the so-called ceravital material (which is based on the base glass system SiO_2-Na_2O-CaO-$Ca_3(PO_3)_2$-MgO-K_2O-CaF_2) led to a significant improvement in chemical stability and thus opened up the way for new applications.[17, 18] More recent developments, which are essentially all based on the above base glass system, have brought about further advances.[19-21] Extensive studies, especially on different possible applications, revealed that the bioactivity of these materials was good but that the bonding zone between the bone (or other tissue) and the glassy crystalline material broadened owing to the relatively high solubility of the latter; moreover, this process did not come to a standstill on prolonged contact of the material with the bone. This means that there is a risk that the implant will become loose if the bonding zone is subjected to mechanical stress. The bonding is adequate, however, for other types of applications. The main crystalline phases of the new materials cited are apatite ($Ca_5[F/(PO_4)_3]$), wollastonite ($Ca_3[Si_3O_9]$), and/or devitrite ($Na_2O \cdot 3\,CaO \cdot 6\,SiO_2$).

The authors' own aim has been to develop bioglass ceramics with novel properties by using available knowledge about the microprocesses occurring on solidification of a glass melt and during conversion of a glass to a glass ceramic by means of controlled crystallization. The requirements of our meanwhile large number of medical collaborators vary widely; it thus seems likely that a series of bioglass materials will be developed that is to a certain degree comparable with the range of stainless steels now available for various applications. The properties primarily required are:

- complete biocompatibility or
- maximum bioactivity with maximum mechanical strength,

a high degree of chemical resistance, especially against body fluids, and
good machinability, ideally carried out by the surgeon.

Good biocompatibility means, for example, that cell compatibility tests, both in vitro and in vivo, do not indicate the occurrence of defense reactions or toxic effects and that direct contact is established with the bone without the formation of connective tissue. Bioactivity is understood to be the ability of the implant to stimulate the tissue to form a true biochemical bond with it after a limited period of dissolution and ion exchange.

4. Development of Biocompatible, Machinable Glass Ceramics

4.1. Machinable Glass Ceramics from the System Na_2O-MgO-Al_2O_3-SiO_2-F with Flat, Flake-Shaped Mica Crystals[22]

A glass ceramic is defined as being machinable if it can be turned, milled, drilled, or threaded with metal-working tools (primarily those made of hard metals) without causing the workpiece to fracture as is the case with ordinary ceramics. The test devised to compare machinability involves measuring the time required for a hard-metal drill to penetrate to a specified depth under otherwise identical conditions.

The development made by *Beall* and *Grossmann* et al.[23-25] in the early 1970s entails the controlled separation of mica crystals in a given base glass. In order to ensure good machinability the crystals should be of optimal size, should be in mutual contact, and should account for about two-thirds of the total volume of the ceramic.[3]

Figure 2 shows a typical example of this type of material developed by our group. A standard base glass (15.5 mol%

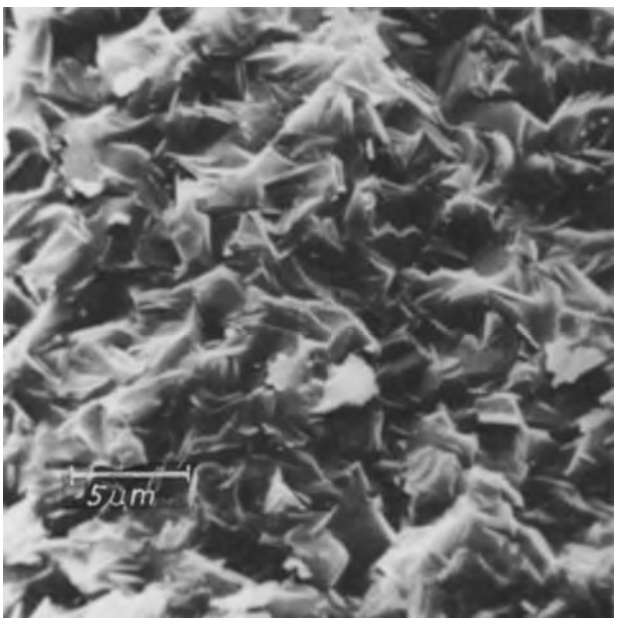

Fig. 2. Flat sodium phlogopite mica crystals arranged like a "card house" in a machinable glass ceramic (scanning electron micrograph).

MgO, 12.6 mol% Al_2O_3, and 71.9 mol% SiO_2) was used in which 11.2 mol% of the oxygen ions were replaced by fluoride ions and which was additionally doped with 5.2 mol% sodium oxide. By controlled phase separation of the base glass, sodium phlogopite crystals ($Na_{0.5-1}Mg_3[AlSi_3O_{10}F_2]$), a type of mica, were made to separate out in a specific fashion in accordance with the given requirements.[26,27]

The machinability is based on the fact that the microfractures produced by machining occur preferentially along the (001) plane of the mica crystals (see Fig. 3). Since the crystals are in mutual contact, the microfractures readily propagate to neighboring crystals. The material can thus be worked without shattering. The (001) plane of the mica crystal is the preferred direction of fracture owing to the presence of alkali ions (see Fig. 4), which loosely connect two triple-layer packets.

This ceramic, developed for special applications in scientific instruments and mechanical engineering, is also biocompatible and can be used in a variety of ways in medicine. Its physical properties are listed in Table 1.

Table 1. Properties of the machinable glass ceramic containing flat fluorophlogopite mica crystals. Composition [mol%]: Na_2O 3–15, MgO 7–23, Al_2O_3 10–30, SiO_2 45–70, F 3–6 [22].

Densitiy	2.5 g/cm³
Linear coefficient of thermal expansion (20–400 °C)	75×10^{-7} K^{-1}
Mechanical flex-cracking resistance	90 MPa
Modulus of elasticity	50 GPa
Pressure resistance	450 MPa
Shock resistance	2.0 kN/m
Hydrolytic class	1–2
Acid class	3
Alkali class	1–3
Roughness height after polishing	0.15 μm
Machinability	Very good

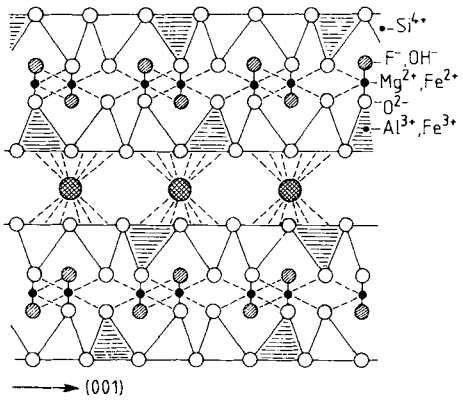

Fig. 3. Schematic representation of the structure of phlogopite. Triangles, $[SiO_4]$ tetrahedra; hatched triangles, $[AlO_4]$ tetrahedra; ⊗, K^+ or Na^+; ○, O^{2-}; ◎, F^-; ●, Mg^{2+}. F^- can be replaced by OH^-, Mg^{2+} by Fe^{2+}, Al^{3+} by Fe^{3+}, and K^+ by Na^+.

4.2. Glass Ceramic with Maximum Machinability from the System Na_2O/K_2O-MgO-Al_2O_3-SiO_2-F with Curved Mica Crystals[28,29]

A previously unknown mica phase could be induced to separate in a different standard base glass (21.2 mol% MgO, 19.5 mol% Al_2O_3, 59.3 mol% SiO_2) after doping with 11.2 mol% F^- and 6.4 mol% Na_2O/K_2O. Here, the mica crystals do not occur as flat flakes but as cabbagelike aggregations of curved "leaves" (see Fig. 4). Comparison of the Mg and Al peaks in the X-ray spectra obtained by energy-dispersive electron-beam microanalysis (EDAX)[30] (see Fig. 5) revealed that the Al concentration in the curved mica crystals is higher than that in the flat crystals. Increasing the total (Al_2O_3 + MgO) content of the glass relative to the SiO_2 content results in replacement of part of the Mg^{2+} ions by Al^{3+} ions (1.5 Mg^{2+} correspond to 1 Al^{3+}) in the new mica crystal. As a result, stresses develop

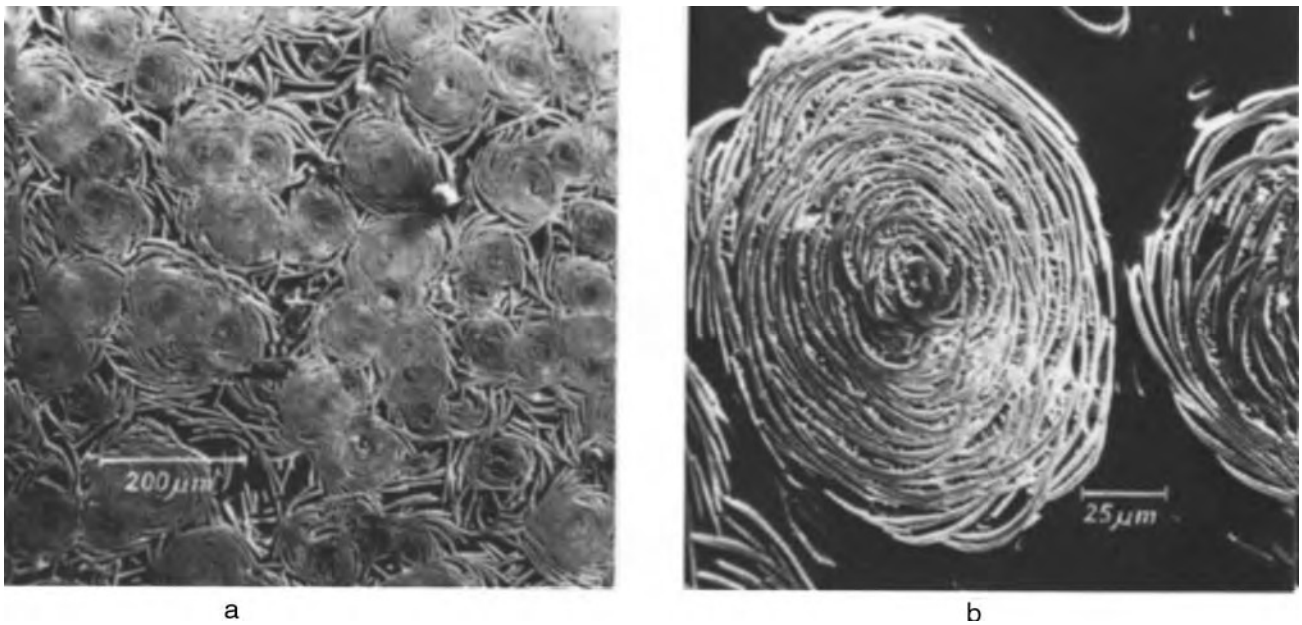

Fig. 4. a) Fluorophlogopite mica crystals in a new configuration. The mica flakes occur in the form of spherically arranged lamellae (cabbagelike). b) A single spherical aggregate (scanning electron micrograph).

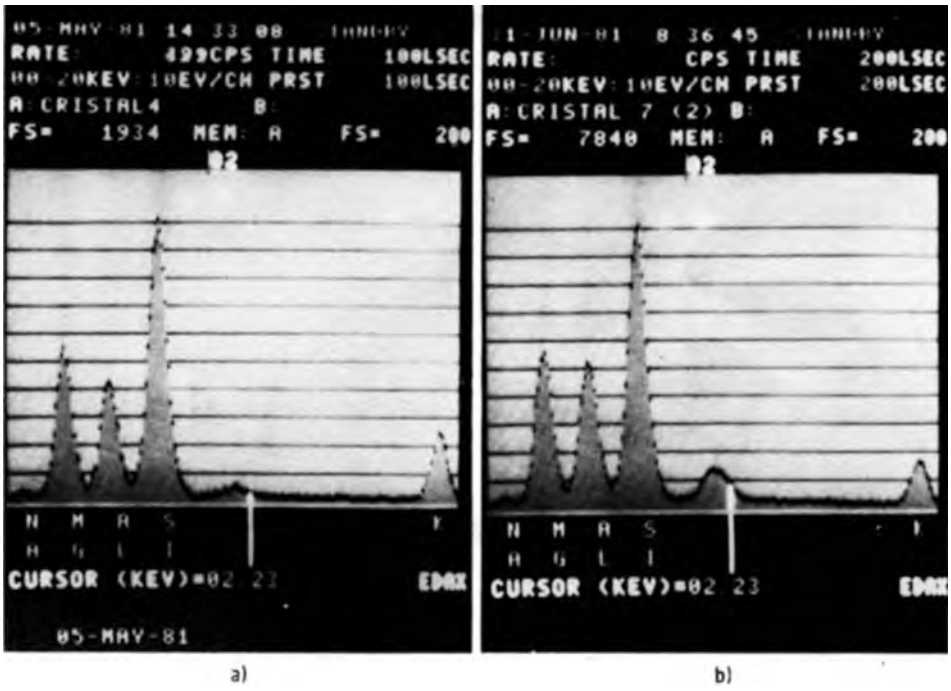

a) b)

Fig. 5. a) EDAX spectra of flat fluorophlogopite mica crystals. Mass ratio Al/Si = 0.43, Mg/Si = 0.71. b) EDAX spectra of curved fluorophlogopite mica crystals. Mass ratio Al/Si = 0.51, Mg/Si = 0.63.

in the octahedron layer of the mica structure, which cause the crystal to bend. This state is also reflected in the change of the dioctahedron–trioctahedron character of the crystals as shown by X-ray diffraction. If the $(MgO + Al_2O_3)$ concentration of the base glass were further increased, cordierite crystals ($Mg_2Al_3[AlSi_5O_{18}]$) would be formed. The $[AlO_{4/2}]$ groups of cordierite are stabilized by Mg^{2+} ions. The machinability of the glass ceramic containing curved mica crystals is four to five times better[28,29] than that of the glass ceramic with flat mica flakes described in Section 4.1.

This machinable glass ceramic is once again biocompatible and is suitable for many medical applications. Its main properties are compiled in Table 2.

Table 2. Properties of the best machinable glass ceramic containing curved fluorophlogopite mica crystals. Composition [mol%]: M_2O 5-12 (Na_2O 0-8, K_2O 0-6), MgO 8-17, Al_2O_3 21-36, SiO_2 34-60, F 1-7 [29].

Linear coefficient of thermal expansion (20-400 °C)	$50-75 \times 10^{-7}\ K^{-1}$
Mechanical flex-cracking resistance	Up to 110 MPa
Hydrolytic class	1-2
Alkali class	1-3
Machinability	Excellent

4.3. Machinable Glass Ceramic from the System Na_2O/K_2O-MgO-Al_2O_3-SiO_2-F with both Mica and Cordierite Crystals[31]

Machinable glass ceramics that only contain mica crystals have already been described. Glass ceramics containing solely cordierite crystals ($Mg_2Al_3[AlSi_5O_{18}]$) are also known.[26] The mechanical strength and fracture toughness of these materials are particularly high. Mica and cordierite crystals can be made to separate out simultaneously in specifically modified base glasses by means of controlled phase separation as described in Section 4.2. Glasses of the following composition were used [wt%]:

SiO_2	43-50	F^-	3.3-4.8
Al_2O_3	26-30	Cl^-	0.01-0.6
MgO	11-15	CaO	0.1-3
Na_2O/K_2O	7-10.5	P_2O_5	0.1-5

The glass ceramics thus obtained exhibited a combination of advantageous properties—good machinability, high mechanical strength, and high fracture toughess. This material is suitable for a wide range of uses in dentistry owing to these properties and because it is totally biocompatible, can readily be polished, has a very low roughness height, can be colored, etc.

Figure 6a shows a typical cordierite crystallite in a technical glass as a glass defect; cordierite-mica crystallization in the new glass ceramic described above is shown in Figure 6b for comparison. The close correlations (transition from the curved phlogopite crystal to the cordierite crystal) are clearly revealed in the figure.

The most outstanding properties of the biocompatible, machinable mica-cordierite glass ceramic are compiled in Table 3.

The three types of glass ceramics described above (see Tables 1-3) and other subtypes that satisfy special requirements can be used as biocompatible materials in science, technology, and medicine.

Table 3. Properties of the machinable mica (phlogopite)/cordierte glass ceramic.

Density	2.5 g/cm^3
Linear coefficient of thermal expansion (20-400°C)	75-125 × 10^{-7} K^{-1}
Mechanical flex-cracking resistance	90-140 MPa
Modulus of elasticity	70 GPa
Pressure resistance	450 MPa
Fracture toughness K_{Ic}	Up to 1.9 Pa·m$^{1/2}$
Vicker's hardness	Up to 8000 MPa
Hydrolytic class	1-2
Acid class	3
Alkali class	1
Roughness height after polishing	0.1 µm
Machinability	Good to very good

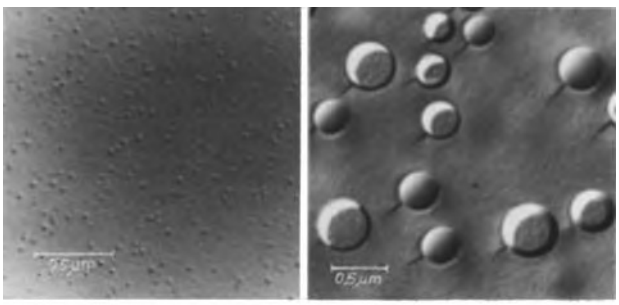
5. Development of Bioactive Glass Ceramics

5.1. Machinable, Bioactive Glass Ceramics and the Kinetic Processes Involved in Their Production[32,33]

The glass ceramics described in Section 4 have proved to be biocompatible and do not disturb living cells. An implant material is generally bioactive if it contains apatite crystals, i.e., the natural building substance of bone.[17,18,34] The next logical step, therefore, was to use controlled crystallization to simultaneously segregate both mica (phlogopite) and apatite crystals from a glass melt in variable proportions. In order to understand the procedures used, it should be remembered that controlled phase separation is both the basis of and a prerequisite for almost every controlled crystallization in glass. Phase separation occurs as a result of the formation of stable molecular structural groups and their enrichment in specific regions. As a rule, this considerably facilitates nucleation in the droplet phase since the full amount of the activation energy necessary for a base glass of homogeneous structure is not needed to attain the critical nuclear size. The phase-separation structure of the base glasses in the types of machinable glass ceramics already dealt with has been established. What subsequent steps are required for bioactivity?

5.1.1. CaO and P_2O_5 Doping of the Base Glass from which Fluorophlogopite Mica Crystals Separate Out

When the base glass from which phlogopite crystals separate out is doped with small proportions of CaO/P_2O_5, its phase-separation structure does not change. Figure 7a shows a silicate droplet phase in which Mg, Al, alkali metal, and fluoride ions along with silicic acid are enriched;



a) b)

Fig. 7. a) Phase-separation structure of the low CaO/P_2O_5-doped base glass after rapid undercooling. Small silicate droplets. b) Phase-separation structure of the high CaO/P_2O_5-doped base glass. Large phosphate droplets. The small silicate droplets have disappeared (replica electron micrograph).

the matrix phase, on the other hand, is very rich in SiO_2. Doping the same base glass with high proportions of CaO/P_2O_5 changes its phase separation behavior fundamentally. The silicate droplet phase disappears. Instead, relatively large droplet regions rich in P_2O_5 are formed in the silicate matrix phase (see Fig. 7b). If the two CaO/P_2O_5-doped base glasses are subjected to specific thermal treatment, only the familiar flat phlogopite crystal flakes and not apatite will separate out from the low CaO/P_2O_5-doped glass.

On the other hand, only apatite separates out from the high CaO/P_2O_5-doped glass; phlogopite crystals do not separate out simultaneously. This apparently negative result is due to the different phase-separation kinetics of the two doped base glasses (see Fig. 8).

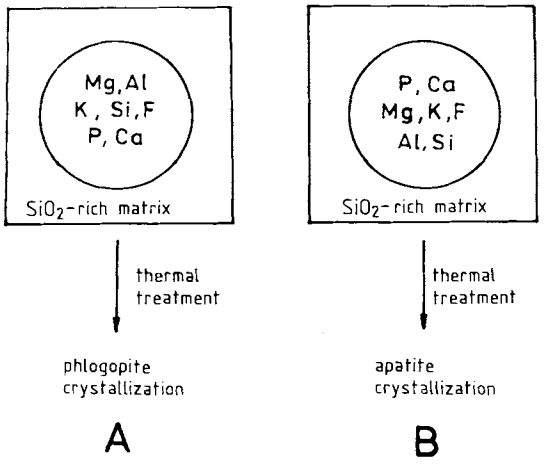


Fig. 8. Schematic representation of phase separation and crystallization kinetics in the glasses shown in Fig. 7.

In case A, most of the low CaO/P_2O_5 content is taken up homogeneously by the droplet phase without fundamental alteration of the familiar crystallization behavior. In case B, where CaO/P_2O_5 doping is high, a pure phosphate droplet phase enriched with Ca^{2+}, Mg^{2+}, Al^{3+}, K^+/Na^+, and F^- is formed in the solidified base glass. The P^{5+} ion has a higher field strength (z/a^2, where z is the valency and a is the distance between the anion and the cation) than the Si^{4+} ion (2.1 and 1.57, respectively); the P^{5+} ion therefore has a greater shielding tendency. A large proportion of the Mg^{2+}, Al^{3+}, and alkali-metal ions are consequently removed from the original silicatic droplet phase so that it disappears in favor of the phosphate droplet phase.

This process is promoted by increasing the fluorine content of the base glass because of a pronounced reduction of viscosity. If this base glass is tempered, only apatite crystallizes. The conditions required for simultaneous separation of phlogopite have been lost.

5.1.2. CaO (10–19 mol%) and P_2O_5 (2–9 mol%) Doping of the Base Glass from which Spherical, Lamellar Aggregates of Phlogopite Crystals Separate Out

Doping a base glass having a high Mg^{2+} and Al^{3+} ion content (see Section 4.2) with CaO and P_2O_5 primarily yields a three-phase glass (see Fig. 9a). Two droplet phases with different dimensions and compositions are embedded in a matrix glass phase that is very rich in SiO_2.

The large droplets constitute a phosphate phase that is enriched with MgO, Al_2O_3, K_2O/Na_2O, and F^-. The small droplets are also rich in MgO, Al_2O_3, Na_2O/K_2O, and F^- and represent the original silicate separation phase, which thus still coexists with the phosphate droplet phase.

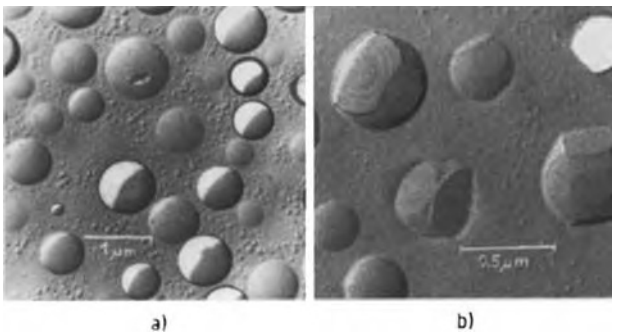

Fig. 9. a) Three-phase base glass. Large phosphate droplets and small silicate droplets coexist. b) The large phosphate droplets start to become transformed into apatite crystals (scanning electron micrograph).

In a standard base glass from which flat mica flakes separate out, the addition of phosphorus causes the formation of a new phosphate droplet phase and the distribution ratio for the Mg^{2+}, Al^{3+}, Ca^{2+}, fluoride, and alkali-metal ions is shifted considerably toward the phosphate phase. The silicate droplet phase disappears.

In the case of a base glass with a high MgO and Al_2O_3 content that separates out spherical, lamellar aggregates of phlogopite mica flakes, the basic aim of doping with CaO/P_2O_5 is to obtain the same change in the distribution of Mg^{2+}, Al^{3+}, fluoride, and alkali-metal ions as is found in the standard base glass. The ratio does not, however, favor the phosphate droplet phase so extremely. Owing to the high MgO and Al_2O_3 content of the base glass, sufficient Mg^{2+}, Al^{3+}, F^-, and alkali-metal ions remain in the original silicate droplet phase so that now both droplet phases can exist side by side (see Fig. 9a).

When this type of three-phase glass is tempered, fluoroapatite is formed in the large phosphate droplets. The small silicate droplets still contain enough Mg^{2+}, Al^{3+}, fluoride, and alkali-metal ions to permit formation of phlogopite mica crystals by reaction with the matrix phase. Since, however, the higher field strength of the P^{5+} ions compared with that of the Si^{4+} ions withdraws Mg^{2+}, Al^{3+}, fluoride, and alkali-metal ions from the silicate droplet phase, the mica crystals no longer separate out as lamellar spheres—they revert to the flat flake form. In Figure 9b, the large P_2O_5-rich droplets are beginning to be transformed into apatite crystals whose faces can already be discerned. Figure 10 shows apatite crystals together with fluorophlogopite crystals. The ratio of apatite to phlogopite crystals and the ratio between the residual glass phase and the crystalline phases can be varied. Although the machinability of the glass ceramic is reduced by the simultaneous formation of apatite crystals along with mica crystals, it is still adequate. A major part of the goal outlined at the outset has thus been successfully accomplished in the form of a base glass with the following composition [mol%]:

SiO_2	19–54	F^-	3–23
Al_2O_3	8–15	CaO	10–34
MgO	2–21	P_2O_5	2–10
Na_2O/K_2O	3–8		

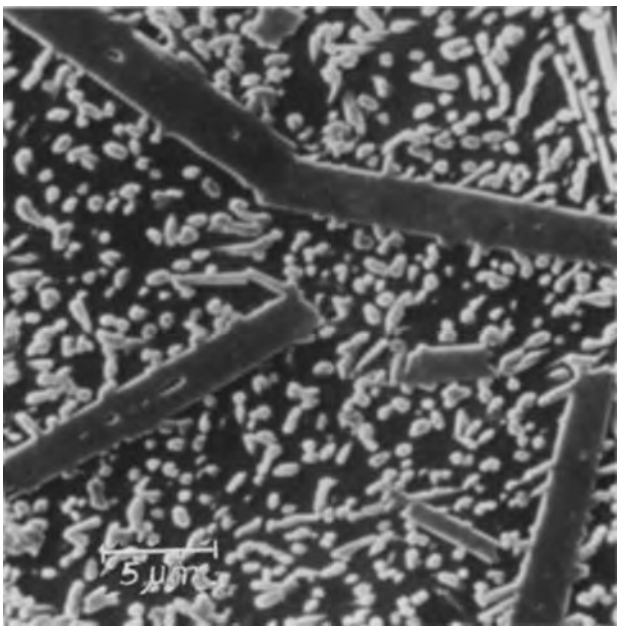

Fig. 10. Bioactive, machinable glass ceramic. Apatite and fluorophlogopite crystals occur side by side in a matrix glass phase (scanning electron micrograph).

5.1.3. Chemical and Mechanical Properties

The behavior of the surfaces of bioglass ceramics toward chemical agents is of particular interest with regard to their possible uses. In the standard water resistance test,[35] the bioglass ceramic optimized for medical applications was found to belong to the "hydrolytic class" 1–2. Machinable glass ceramics with a high apatite content belong to the "hydrolytic class" 2, whereas those with a high phosphate content and a low apatite content are classified in class 3. For comparison, the values for two internationally well-known bioglass ceramics (which are not machinable, however) belong to the "hydrolytic class" 5. The alkali class, determined by standard tests, is 1 and the acid class 3. These two properties are of little significance as far as medicine is concerned, however, because the test conditions are not comparable to those existing in the human body.

"Ringer's solution"[18] is a model liquid that resembles human physiological body fluid; it is an aqueous solution containing Na^+, Ca^{2+}, Cl^-, and CO_3^{2-} ions. Samples of the new machinable bioglass ceramic boiled in Ringer's solution for 40 h had a roughness height of only 0.5 µm. Tests to detect possible increases in the Na^+ and K^+ ion concentrations of the "Ringer solution" due to leaching proved to be negative.

Another highly informative method for determining the release of ions from an implant under quasi-physiological conditions consists in treating the powdered bioglass ceramic with "Tris" buffer solution (2-amino-2-hydroxymethyl-1,3-propanediol–HCl–H_2O mixture). The results of these tests are given in Table 4.

Further studies showed that the release of Na^+ and K^+ ions had almost stopped after 14 days and practically came to a standstill after 4 weeks. As has already been mentioned in Section 5.1.2, the properties of machinable glass ceramics containing apatite crystals can be varied within wide limits by changing the ratio of apatite to mica crystals. The machinability grades determined by a drilling test ranged from "machinable" to "excellently machinable." Mechanical flex-cracking resistance was measured using samples resting on three points; values ranged from 140 MPa for glass ceramics with a low apatite content to 220 MPa for samples with a high apatite content. In order to minimize scattering of the measured values, the surface of the sample under test was systematically damaged prior to measurement; this was done by exposing it to the action of SiC granules in a rotating drum. (For mechanical properties see Table 5.)

Table 4. Ion release in bioactive, machinable glass ceramics during treatment with Tris buffer solutions. Experimental conditions: pH of the buffer solution, 7.4; temperature, 37 °C; 3 g of glass ceramic powder with a particle size of 0.16–0.315 mm; 100 mL of solution; sample was agitated constantly. t = reaction time; the measured ion concentration is given.

Bioglass ceramic	t [h]	Ion concentration [mg/L]		
		Na^+	K^+	Al^{3+}
High apatite content	168	1.0	0.7	—
(apatite 40 vol. %,	336	1.1	0.7	—
phlogopite 20 vol. %)	672	1.8	0.7	—
High phlogopite content	168	1.8	2.1	—
(apatite 20 vol. %,	336	1.9	2.1	—
phlogopite 70 vol. %)	672	2.1	2.1	0.08

Table 5. Mechanical properties of the machinable, bioactive glass ceramic. For composition see Section 5.1.2.

Density	2.8 g/cm³
Linear coefficient of thermal expansion (20–300 °C)	$80–120 \times 10^{-7}\ K^{-1}$
Mechanical flex-cracking resistance	140–220 MPa
Modulus of elasticity	77–88 GPa
Pressure resistance	500 MPa
Fracture toughness K_{Ic}	0.5–1.0 MPa $m^{+1/2}$
Vicker's hardness	Up to 5000 MPa (500 H V 10)

5.1.4. Biocompatibility and Bioactivity

The results of laboratory tests commonly used in medicine such as the INT reduction test, the LDH release test, and, in particular, cell culture experiments were extremely favorable. In the latter case, the materials were added to the cell cultures in the form of a dust at a concentration of 0.4–3.2 mg/mL. Neither the glass ceramic nor the sintered corundum reference substance was found to have any effect on cell multiplication; the glass ceramic must thus be regarded as being completely biocompatible.

The animal experiments performed by *J. Gummel* and *K.-J. Schulze*[32] yielded further results of critical importance. Double implants of a glass ceramic and sintered corundum were made in each experiment; sintered corundum is known to be absolutely biocompatible.

To assess bioactivity, a series of implants were introduced into the tibial heads of guinea pigs. The animals were sacrificed 8, 12, or 16 weeks later or after up to two years, and the tibial heads were removed and subsequently subjected to special tests.

The shearing strength of the implant–bone boundary was determined by measuring the mechanical force necessary to push out the implant cubes. The values found for glass ceramic implants were on average eight times greater than those for the sintered corundum implants. The maximum values were 5 N/mm^2. Moreover, electron microscopic examination revealed that residues of bone adhered to the forcibly removed glass ceramic implants.

Optical and electron micrographs of the ceramic–bone bond provided further interesting insights. Figure 11 shows an optical photomicrograph revealing the direct bond between the bone and the glass ceramic. It can be seen that the alizarin-stained bone substance grows directly into the glass ceramic implant after only eight weeks. Furthermore, bone cells and a blood vessel are found in the immediate vicinity of the implant. Optimal bioactivity has thus been achieved.

Figure 12 shows an optical photomicrograph of the bone–sintered-corundum contact zone that has also been stained with alizarin for comparison. Even 16 weeks after implantation, no direct bonding with the bone is visible. A gap between the bone and the implant has become filled with a layer of connective tissue. The implant could consequently be pulled out like a cork from a bottle. Sintered corundum is therefore biocompatible but not bioactive.

Figure 13 shows a scanning electron micrograph of the boundary layer between the glass ceramic and the bone.

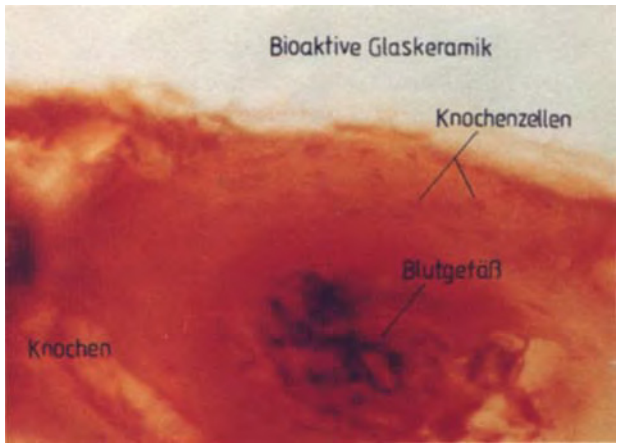

Fig. 11. Intergrowth between bone and glass ceramic eight weeks after implantation in an animal experiment. There is true intergrowth between the bioactive glass ceramic and the bone (optical photomicrograph taken by Dr. *J. Gummel* after alizarin staining [32]). Translation: Bioaktive Glaskeramik = bioactive glass ceramic; Knochen = bone; Knochenzellen = bone cells; Blutgefäß = blood vessel.

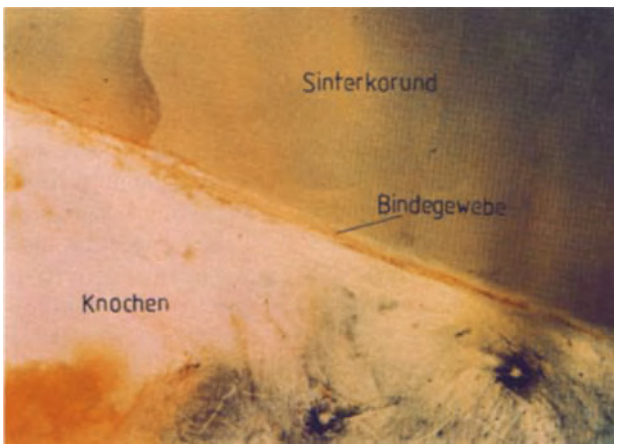

Fig. 12. Bone-sintered-corundum contact zone 16 weeks after implantation in an animal experiment. The implant is encapsulated by a layer of connective tissue (collagen). There is no intergrowth between the biocompatible implant and the bone (optical photomicrograph taken by Dr. *J. Gummel* after alizarin staining [32]). Translation: Sinterkorund = sintered corundum; Knochen = bone; Bindegewebe = connective tissue.

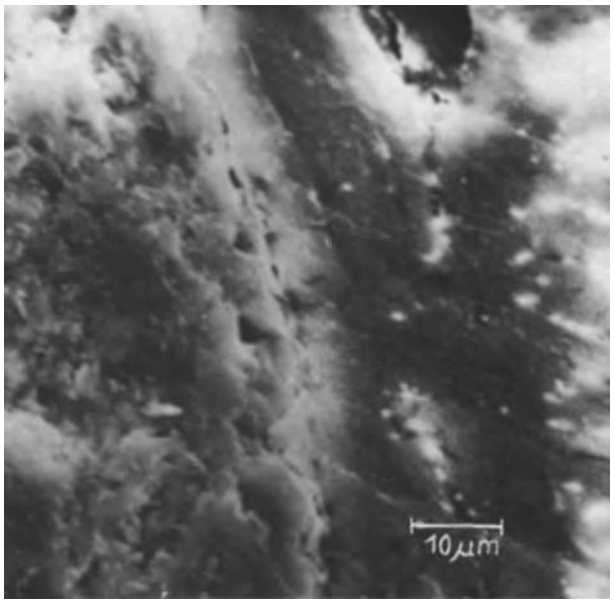

Fig. 13. Intergrowth zone between bioactive glass ceramic and bone in an animal experiment. The maximum thickness of the boundary layer is 5–10 µm (scanning electron micrograph).

Specific dissolution and ion diffusion processes must occur at the surface of the implant under the action of the cell fluid if a firm bond is to be formed between the bone and the implant and new crystals of apatite are to be produced. This dissolution must, however, be brought to a halt at not too great a depth, since the reaction zone will otherwise become too wide which may lead to loosening of the implant if it is subjected to continuous stress later on. Implantation experiments with the new machinable bioactive glass ceramic show that the reaction zone does not exceed 5–10 µm (see Fig. 13). In the case of other foreign bioactive implant materials, the corresponding zone was 100–150 µm and it was not even certain whether the reaction process had completely stopped at the time of examination.

Figure 14 shows an electron-beam microprobe analysis of the boundary layer between the bone and the implant. The X-ray intensity profiles for $Si_{K\alpha}$, $Ca_{K\alpha}$, $P_{K\alpha}$, and $K_{K\alpha}$ radiation suggest the following:

- There is slight leaching of the glass matrix from the surface of the glass ceramic; however, diffusion of SiO_2 into the bone does not occur.
- Leaching of potassium ions from the implant surface is almost quantitative up to a depth of 5 µm. This confirms the previous statement made concerning the width of the reaction zone.

The Ca and P content is higher in the reaction zone than in the glass ceramic. This indicates that new apatite is formed which results in a firm bond between the bioceramic and the bone. The possibility of further bone crystal growth using substances dissolved from the surface of the implant is not excluded.

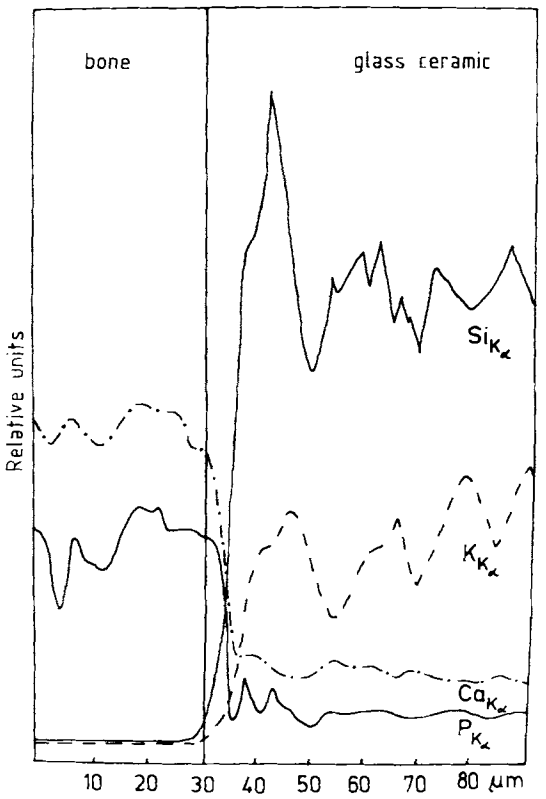

Fig. 14. Electron-beam microprobe investigation of the intergrowth zone shown in Fig. 13. X-ray intensity profiles for $Si_{K\alpha}$, $K_{K\alpha}$, $Ca_{K\alpha}$, and $P_{K\alpha}$ radiation in the boundary layer.

Figures 15a and b show the ceramic-bone bond after 54 and 71 weeks, respectively. The original zone of contact is hardly recognizable, particularly in Figure 15b.

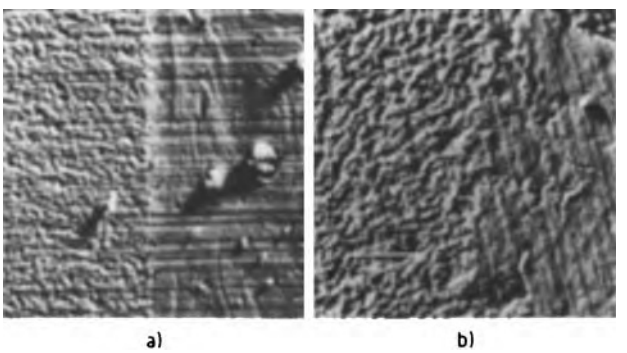

Fig. 15. Scanning electron micrograph of the glass ceramic-bone bond in an animal experiment: a) after 54 weeks; b) after 71 weeks. The contact zone does not broaden as a result of dissolution of the glass ceramic; instead, there is intimate intergrowth.

5.1.5. Interim Assessment and Evaluation of Results

Laboratory and animal experiments designed to test the suitability of the machinable, highly bioactive glass ceramic for bone implants and artificial bones have almost been completed. Experiments on several special applications are still in progress.

The first stage of clinical testing on humans has so far yielded solely positive results. The machinable, highly bioactive glass ceramics provide the surgeon with an implant material that can not only be subjected to the normal procedures used for machining metals but can also be fabricated into complex forms. The surgeon himself will be able to make special corrections and changes during an operation.

5.2. Bioactive, Piezoelectric Phosphate Glass Ceramic Devoid of Silicic Acid

5.2.1. Developmental Trends in Phosphate Glass Ceramics

The successful development of biocompatible and bioactive silicate bioglass ceramics and their medical uses have resulted in medical advances and new possibilities for medical treatment.

It is still not totally certain, however, whether prolonged contact of silicate compounds with the human body will produce undesirable reactions or negative interactions. It would thus be much better to replace bone with a pure biophosphate glass ceramic whose chemical composition corresponds more closely to that of bone than do those of all the bioglass ceramics so far developed. Preliminary efforts in this direction have been made.[38, 39]

The preparation of such a material has not yet been fully accomplished, however, because almost all phosphate glasses have a relatively homogeneous base glass structure and do not display the phase separation that is a prerequisite for controlled crystallization. Only "wild" crystallization is thus possible within or at the surface of the material and does not produce the distinctive properties of a "vitroceramic."

In some cases attempts have been made to overcome the natural structural barriers standing in the way of the development of phosphate glass ceramics by using the glass-powder sinter method.[11] This method consists in tempering, sintering, and crystallizing a phosphate glass powder of suitable composition whose particle sizes approximately correspond to the dimensions of the droplet-shaped immiscibility regions in silicate glasses. Crystallization starts mainly from the surfaces of the particles and proceeds inward toward the center of each glass granule. Uniform crystallization with equal-sized crystallites can thus be achieved in the sintered product by selecting a suitable particle size. The product is porous, however, and its mechanical resistance is lower than that of solid glass ceramics. These materials are therefore only of limited use for medicine; the same also holds for the sintered products of pure crystalline apatite.[10]

The main aim of our studies was to find a way of converting a pure phosphate glass into a glass ceramic by

means of controlled crystallization; one crystalline phase had to be composed of apatite, because existing evidence indicated that this material would be bioactive.

5.2.2. *Structure and Crystallization Behavior of Phosphate Glasses*

Silicate glasses are generally composed of a three-dimensional network of $[SiO_4]$ tetrahedra. The introduction of network-modifying oxides leads to the breaking of oxygen bridges in the $[SiO_4]$ tetrahedron network and results in the incorporation of the large network-modifying ions in the large network cavities consequently formed (see Fig. 16a).

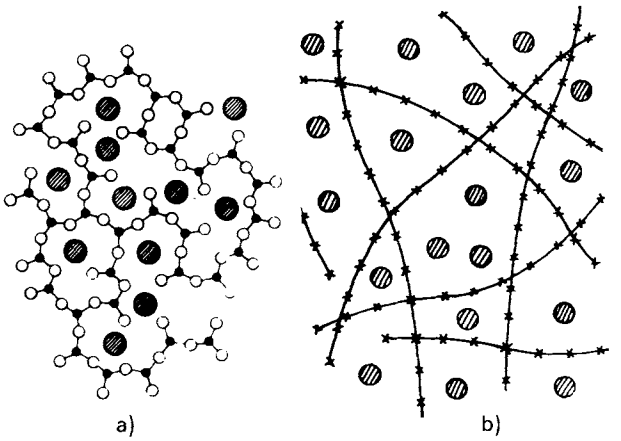

Fig. 16. Hypothetical models for the structure of a) a silicate glass having a network structure; ● = Si, O = O, ◎ = Na (according to *Zachariasen* and *Warren* [3]) and b) a basic phosphate glass having a chain structure; × — ×, PO_4–PO_4, ◎ = Na.

In many cases, however, the network-modifying ions are not distributed statistically within the three-dimensional network. Phase separation occurs owing to the different volume requirements of two different molecular building units, one of which tends to concentrate in one microphase and the other in another such phase.[3]

To some extent, the above phenomena can be compared, on the one hand, with mixed crystal formation in analogy with a homogeneous glass and, on the other hand, with a eutectic crystal mixture in analogy with a glass undergoing microphase separation. As has already been discussed in Section 2, however, microphase separation of a glass is of critical importance for controlled crystallization. The structure and thus the crystallization behavior of phosphate glasses differ from those of silicate glasses. Acidic phosphate glasses also consist of a network, but only three corners of each $[PO_4]$ tetrahedron are linked with neighboring tetrahedra. Basic phosphate glasses, especially those with a network-modifying oxide : P_2O_5 ratio > 1 have a chain structure[40–42] (see Fig. 16b). The cavities between tangled chains are so large, however, that they can easily accommodate a different molecular building block of the glass. A tendency to undergo phase separation is therefore not observed. It is thus impossible to use the customary approach to satisfy the criteria for controlled crystallization in these glasses. Other ways must be found.

5.2.3. *Development of Pure Biophosphate Glass Ceramics*[36, 37]

Glasses of the system CaO-Al_2O_3-P_2O_5: Melts of the ternary system CaO-Al_2O_3-P_2O_5[43] can solidify to form a glass within limited ranges of composition. The ^{31}P-NMR studies of *Haubenreisser* et al.[44], in particular, have clearly demonstrated the chain structure of these glasses. Tempering brings about surface or wild crystallization in which the $AlPO_4$, $Ca(PO_3)_2$, and $Ca_2P_2O_7$ crystalline phase is formed. Apatite does not separate out.

Glasses of the System Na_2O-CaO-Al_2O_3-P_2O_5 and Na_2O-CaO-Al_2O_3-P_2O_5-F: The chain structures of the system CaO-Al_2O_3-P_2O_5 can be specifically degraded by adding increasing amounts of Na_2O; this must improve the chances for the subsequent separation of apatite.

That all of these glasses are "invert glasses" with a P_2O_5 content of less than 50 mol% can be seen from the compositions of the melts [mol%]:

Na_2O	11.0–32.0	Al_2O_3	8.3–16.0
CaO	21.0–37.5	P_2O_5	29.9–42.0

The structural groups determined in the ^{31}P-NMR studies of *Haubenreisser* et al.[44] are solely mono- and diphosphate groups.

In 1959 *Trapp* and *Stevels* were the first to demonstrate the tendency of silicate melts with less than 50 mol% of SiO_2 to form glasses without a three-dimensional network, which they referred to as "invert glasses."[45] The results discussed here indicate that a similar situation may exist in phosphate glass melts. Hypothetical models for the structures of these glasses are presented in Figure 17.

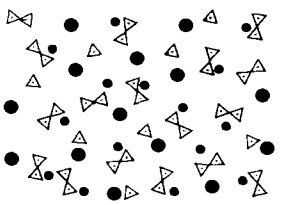

Fig. 17. Hypothetical model for the structure of a phosphate invert glass. Triangles, $[PO_4]$ tetrahedra; black circles, cations (Na^+, Ca^{2+}, Al^{3+}).

Invert glasses, i.e., glasses that are composed exclusively of very small molecular structural groups, tend to crystallize much more rapidly. It was hoped that this would perhaps provide a new way of achieving controlled crystallization in phosphate glasses.

After special thermal treatment, the following crystalline phases can be induced to separate from the above-mentioned glasses: the cristobalite-isotype $AlPO_4$ modification, the tridymite-isotype $AlPO_4$ modification, β-$Ca_2P_2O_7$, an unknown "complex phosphate," a diphosphate, and apatite. However, the crystallization is wild. Most important, a modified hydroxylapatite phase has been made to separate for the first time.

Considerable changes in the crystallization process are observed on addition of fluoride components to melts of the system Na_2O-CaO-Al_2O_3-P_2O_5 [mol%]:

Na_2O	24.1-26.1	P_2O_5	31.6-33.6
CaO	21.7-25.5	F	6.1-10.9
Al_2O_3	11.0-12.2		

Wild crystallization now produces the following crystalline phases: fluoroapatite, the lowquartz-isotype $AlPO_4$ ("berlinite"),[46] which displays piezoelectric properties, and the "complex phosphate phase." ^{27}Al-NMR studies conducted by *Haubenreisser* et al.[44] revealed that the ratio of fourfold- to sixfold-coordinated Al^{3+} was 3:1. This fact, together with the results of the ^{31}P-NMR studies and chemical analyses of the glasses, has been used to deduce a structural model for the "complex phosphate" (see Fig. 18). Such a structural model can indeed be constructed without any strain whatsoever. The precise structure still has to be determined, however. Although controlled crystallization has not yet been achieved in this base glass, attention should be drawn to the special importance of the fluoroapatite and piezoelectric berlinite crystalline phases that have been produced.

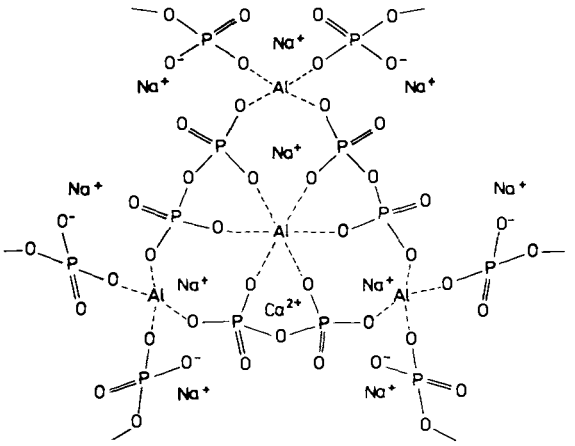

Fig. 18. Hypothetical structure of the crystalline "complex phosphate."

Glasses of the System Na_2O-CaO-Al_2O_3-P_2O_5-FeO/Fe_2O_3 and Na_2O-CaO-Al_2O_3-P_2O_5-F-FeO/Fe_2O_3: Controlled crystallization is not possible in glasses with phosphate chain structures. Phosphate glasses with an invert glass structure (i.e., which contain exclusively mono- or diphosphate structural groups) tend to undergo rapid nucleation and crystallization on tempering. In the corresponding melting diagram, they are located extremely close to the boundary of glass formation. Supersaturation of such melts belonging to the system Na_2O-CaO-Al_2O_3-P_2O_5 with FeO/Fe_2O_3 and cooling or subsequent tempering triggers an effect that resembles phase separation but has nothing at all to do with it.

The selected compositions of the base glasses are [mol%]:

Na_2O	24.1-25.7	P_2O_5	30.7-33.1
CaO	24.9-31.2	FeO/Fe_2O_3	1.2-6.2
Al_2O_3	9.9-14.5		

Figure 19a shows a replica electron micrograph of a selected glass belonging to the system Na_2O-CaO-Al_2O_3-

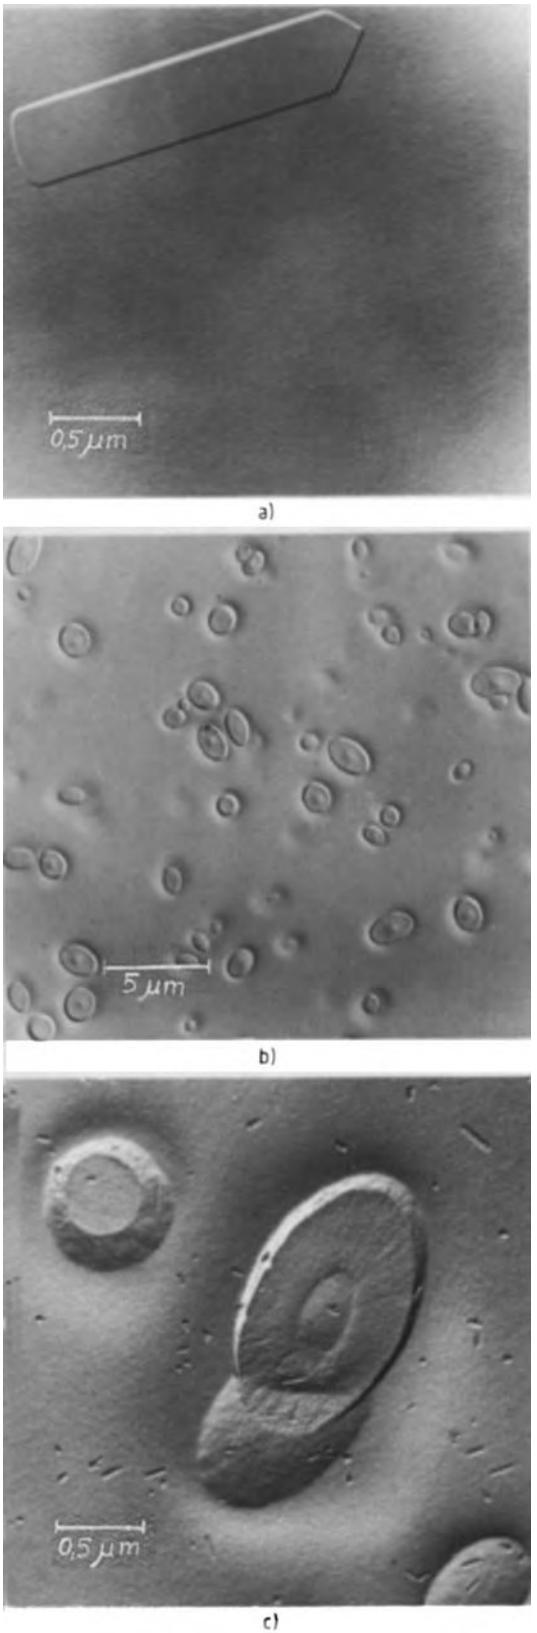

Fig. 19. Replica electron micrograph of a selected glass of the system Na_2O-CaO-Al_2O_3-P_2O_5-FeO/Fe_2O_3. a) After rapid undercooling, the glass displays a homogeneous structure. b) On tempering, supersaturation phenomena disappear; spontaneous nucleation and crystallization occur uniformly throughout the whole glass. c) A single crystallite; a primary iron phosphate nucleus apparently continues to grow by means of epitaxial interaction with the apatite building substance.

P_2O_5-FeO/Fe_2O_3. Comparison of the fractured surface with a MoO_3 crystal test plane clearly demonstrates the homogeneous structure of the glass.

Figure 19b shows a micrograph taken after subjecting the same glass to thermal treatment. Numerous, equal-sized, mostly ellipsoid structures can be seen throughout the glass and are of the kind produced by phase separation. Each ellipsoid region also contains a clearly defined nucleus (see particularly Fig. 19c). The textured structure in Figures 19b and c is a result of the termination of the supersaturation effects because of iron oxides in the base glass.

The nucleus of the ellipsoid region consists of crystalline iron phosphate which has not yet been fully identified. As soon as this primary nucleus has reached a critical size, it apparently continues to grow by means of epitaxial interaction with the hydroxylapatite building substance. Comparison of the lattice constants of apatite with those of various iron phosphates reveals that at least two constants of iron phosphate correspond with two constants of apatite or do not differ by more than ±15% (see Table 6). In principle, epitaxial interactions are therefore possible; the intermediary formation of iron apatites does not appear to be totally inconceivable either.

Table 6. Comparsion of the lattice parameters of some iron-containing phosphates with those of fluoro- and hydroxylapatite.

Crystalline phase	Lattice parameter [Å]	Difference with respect to apatite [%]
Fluoroapatite $Ca_5[F/(PO_4)_3]$	$a = 9.37$ $c = 6.88$	
Hydroxylapatite $Ca_5[OH/(PO_4)_3]$	$a = 9.43$ $c = 6.88$	
$Fe_3(PO_4)_2$	$a = 8.80$ $b = 11.50$ $c = 6.25$	-6.1 to -6.7 (1 × apatite a) -16.4 (2 × apatite c) -9.2 (1 × apatite c)
$NaFeP_2O_7$ I	$a = 7.11$ $b = 10.03$ $c = 8.09$	$+3.3$ (1 × apatite c) $+6.3$ bis 7.8 (1 × apatite a) -13.7 bis -14.3 (1 × apatite a)
$NaFeP_2O_7$ II	$a = 7.33$ $b = 7.90$ $c = 9.57$	$+6.5$ (1 × apatite c) $+14.8$ (1 × apatite c) $+1.5$ bis $+2.1$ (1 × apatite a)
$Ca_xFe_y(PO_4)_6O_z$ [a]	$a = 9.39$ $c = 6.90$	$+0.2$ bis -0.5 (1 × apatite a) $+0.3$ (1 × apatite c)

[a] $x \approx 9.5$, $y \approx 0.5$, $z \approx 1.25$.

An X-ray scanning micrograph taken using $Ca_{K\alpha}$ radiation demonstrates the enrichment of Ca in the ellipsoids (see Fig. 20). X-ray diffraction micrographs clearly indicate that the ellipsoids consist of crystalline hydroxylapatite. Further tempering of such glasses leads to the separation of the crystalline "complex phosphate phase" and the tridymite- or cristobalite-like $AlPO_4$ crystalline phase. Figure 21 shows the tridymite-like $AlPO_4$ crystalline phase; interestingly, this phase is extremely similar to the tridymite shape found in silicate glasses. It can also be seen, however, that as the temperature increases, the axes of the star-shaped crystals rearrange to give the cristobalite-like modification of $AlPO_4$ in which the axes intersect at right angles. Equally surprising are the identical appearances of the original cristobalite in silicate glasses and the cristobalite-like modification of $AlPO_4$.

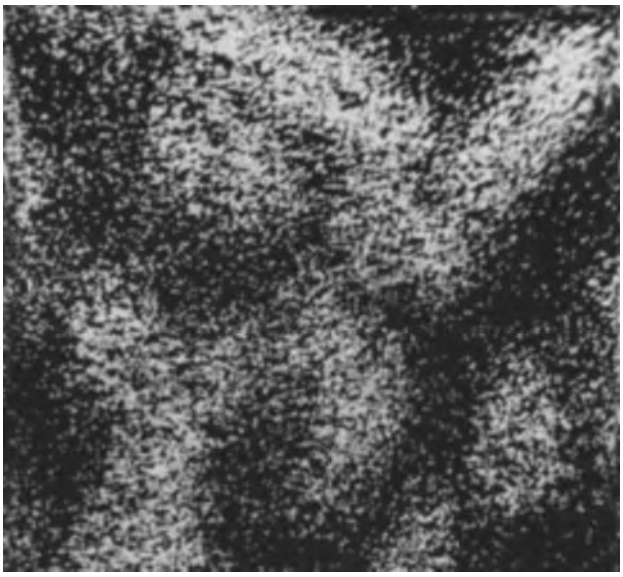

Fig. 20. $Ca_{K\alpha}$ X-ray scanning micrograph of the glass shown in Fig. 19b. Aggregation of Ca^{2+} ions (white dots) in the ellipsoid regions can clearly be seen.

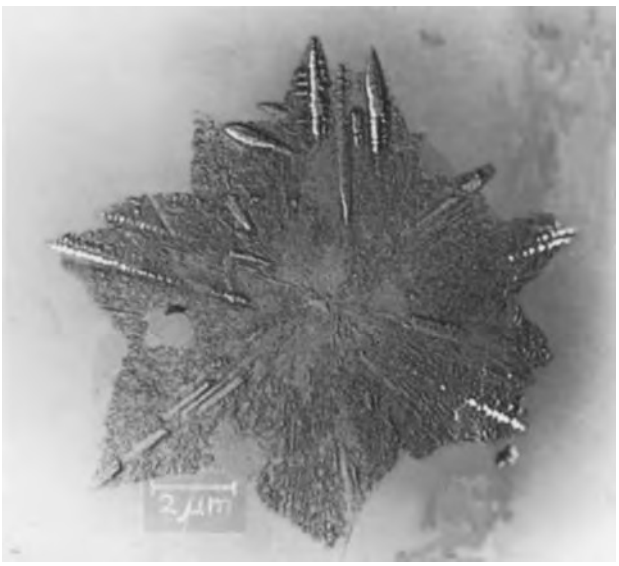

Fig. 21. Formation of the tridymite-like modification of the $AlPO_4$ crystal in the glass matrix obtained after further tempering of the glass shown in Fig. 19b. Transitions to the cristobalite-like $AlPO_4$ modification can be recognized at the ends of the main growth axes of the star-shaped crystal where the axes intersect at right angles (scanning electron micrograph).

A more important advance in attaining optimal bioactivity in phosphate glass ceramics would be achieved if, instead of the cristobalite- or tridymite-like modification of $AlPO_4$, the lowquartz-like $AlPO_4$ modification "berlinite," which exhibits piezoelectric properties,[46] would separate out. In modern medical practice, microcurrents are known to dramatically promote healing of bone fractures.[47,48] Crystallization of apatite and formation of a piezoelectric "berlinite" phase would complement each other very fa-

vorably as regards developing a bioactive pure phosphate glass ceramic.

Separation of "berlinite" can also occur, depending on the fluoride content, in the crystallization of melts belonging to the system Na_2O-CaO-Al_2O_3-P_2O_5-F. It thus seemed logical to add fluoride to melts of the system Na_2O-CaO-Al_2O_3-P_2O_5-FeO/Fe_2O_3 in order to produce the same effect. Separation of "berlinite" has indeed been obtained by adding 2.4–9.4 mol% of fluoride to base glasses of the system Na_2O-CaO-Al_2O_3-P_2O_5-FeO/Fe_2O_3.[36,37]

The complete crystallization sequence occurring during the tempering of certain glasses belonging to the system Na_2O-CaO-Al_2O_3-P_2O_5-F-FeO/Fe_2O_3 is shown in Figure 22. At low temperatures, an iron diphosphate phase and fluoroapatite are formed in addition to the tridymite-like

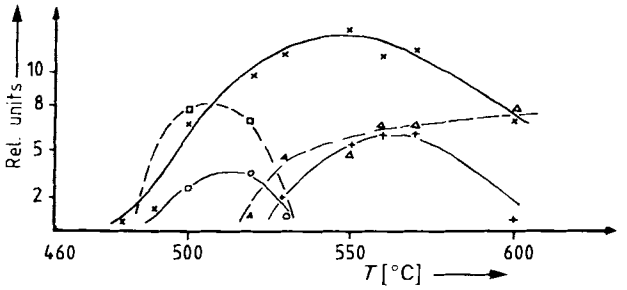

Fig. 22. The temperature dependence of the crystallization sequence of a glass from the system Na_2O-CaO-Al_2O_3-P_2O_5-F-FeO/Fe_2O_3. × — ×, apatite (211); ○—○, tridymite-like $AlPO_4$ ($10\bar{1}0$); +—+, berlinite (102), □—□, iron diphosphate phase; △—△, complex phosphate.

$AlPO_4$ modification; the latter decomposes at higher temperatures, however, to form "berlinite." At about 525°C, the crystalline "complex phosphate phase" is formed as well. Figure 22 also shows that an optimal apatite and berlinite content can be obtained at a temperature of approximately 560°C. Thus, a pure phosphate glass with an invert glass structure has been subjected to controlled crystallization (i.e., volume crystallization) by supersaturating it with iron oxides. Fluoroapatite and the piezoelectric lowquartz form of $AlPO_4$ particularly improve the bioactivity of the bioglass ceramic. It is not yet totally clear, however, whether the other crystalline phosphates also contribute to the increase in bioactivity.

5.2.4. Animal Experiments on the Bonding of Phosphate Glass Ceramics and Bone at the Medizinische Akademie Dresden

The first implantation experiments performed in the tibial heads of guinea pigs demonstrated that the bone substance grows into the phosphate glass ceramic without the formation of connective tissue (see Fig. 23). Moreover, microprobe investigations (see Fig. 24) reveal that the bonding zone is only about 10 μm wide and that the dissolution process, which is a prerequisite for intergrowth, stops after about 12 weeks (cf. Fig. 14). The width of the bonding zone in the glass ceramic was taken as being the distance

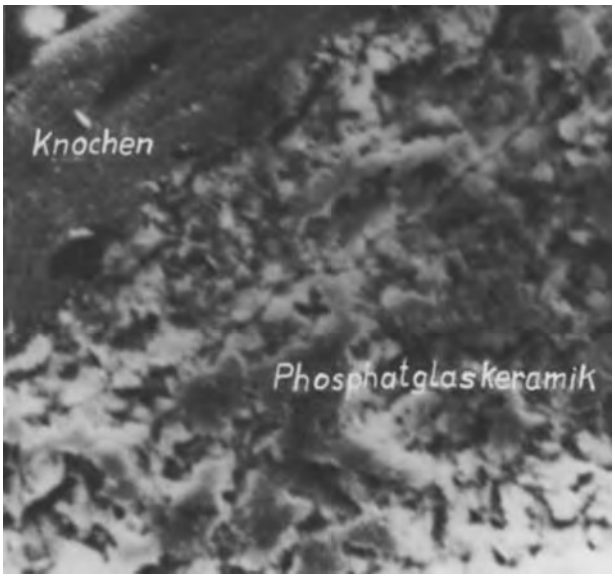

Fig. 23. Intergrowth of pure phosphate glass ceramic and bone in an animal experiment without the formation of connective tissue (scanning electron micrograph). Translation: Knochen = bone; Phosphatglaskeramik = phosphate glass ceramic.

between the point in Figure 24 where the $Ca_{K\alpha}$ intensity suddenly drops and the $Al_{K\alpha}$ intensity simultaneously increases and the point where the $Ca_{K\alpha}$ and $Al_{K\alpha}$ intensities again reach steady levels. If intergrowth is poor or a gap is formed between the glass ceramic and the bone tissue, a totally different microprobe profile is obtained.

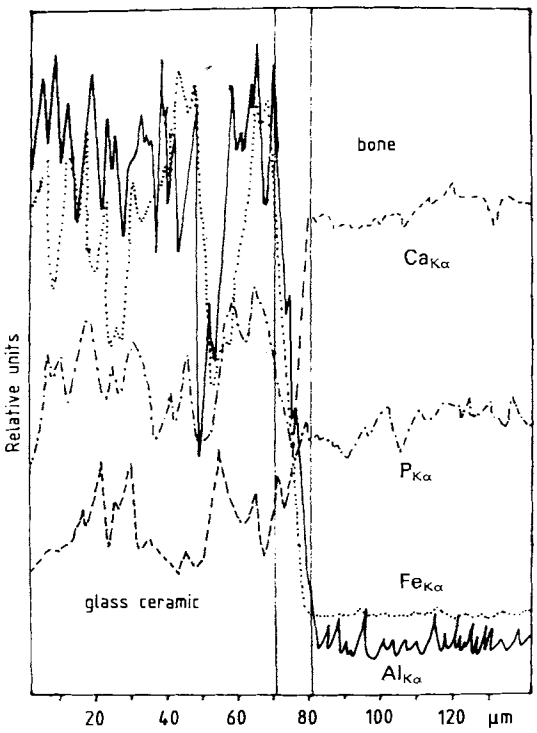

Fig. 24. Electron-beam microprobe profile of the bonding zone in Fig. 23. The zone is not significantly wider than that observed with silicate glass ceramics (cf. Fig. 14).

6. Development of an Inorganic-Organic Bonding Material as a Substitute for Hard Tissue

"Bone cement" is often required in medicine (e.g., to embed endoprostheses or for filling teeth) and usually consists of low-molecular-weight organic compounds that quickly polymerize and harden. Inorganic additives are often mixed with the organic components yielding composite materials. In keeping with more recent applications (e.g., for filling cavities in bones formed during operations), the term "bone cement" should be replaced by the more fitting term "moldable hard-tissue substitute."

If the organic compounds used (e.g., methyl methacrylates, polyurethanes, polyamides, epoxide resins) are applied to a fresh wound as monomers or oligomers, however, they may be removed by the blood during the initial phase prior to polymerization. They may then accumulate at other sites where they can have detrimental effects, including a pronounced drop in blood pressure, fat embolisms,[49] and blood clots.[50] Furthermore, non-reacted isocyanate groups or oligomers can react with body fluid, body tissues, blood corpuscles, or individual proteins, undergoing hydrolysis to give metabolites containing amino groups. Aromatic diamines, in particular, are potential carcinogens.[51]

In all cases, the biocompatible or bioactive glass ceramics or other inorganic materials added to the organic compounds were used exclusively as fillers. The optimal particle size for the inorganic filling materials is 40–60 μm. The reaction zone of many known bioactive glass ceramics reaches 150 μm or more during intergrowth; i.e., any bonding of bone to the mixture of filling material and bioceramic particles occurring in the initial phase is virtually cancelled out by complete dissolution of the particles.

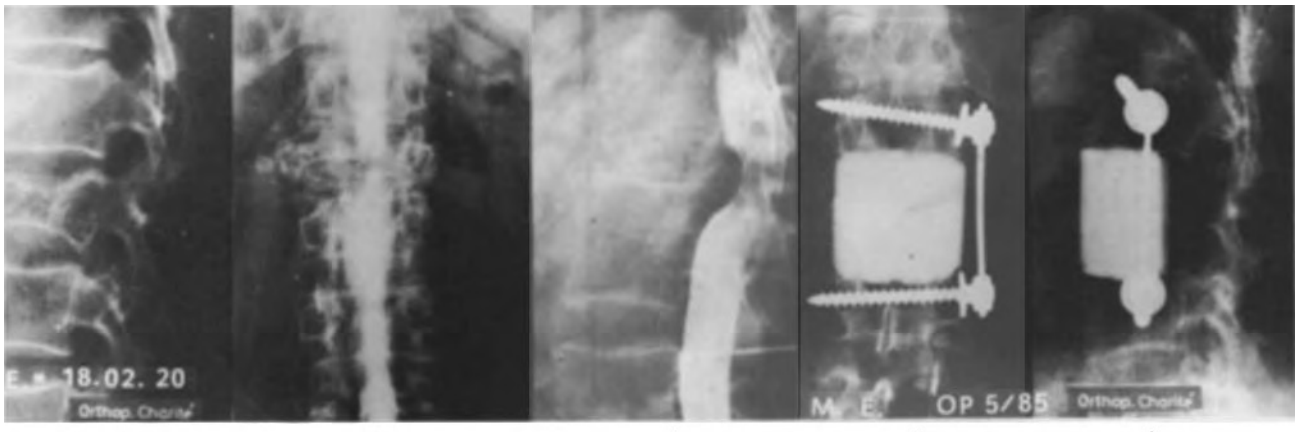
A completely new solution to this problem has now been found.[52] A biocompatible, monomer-free, epoxidated, polymeric hydrocarbon is used which consists solely of C, H, and O. It has a mean molecular weight of 2000 to 6000 with 50 to 500 g of epoxide equivalents. After special surface treatment of the bioactive glass ceramic powders or other additives, they are mixed with the highly polymeric compound to form a chemically bonded substance. Since the surface reaction zones formed during intergrowth with the bone only become 5–12 μm wide (see Section 5.1.4), a sufficient amount of the 40–60-μm bioglass ceramic granule remains to allow firm intergrowth. It is possible to control hardening and the resulting properties of the product, which may vary from cartilage-like to bone-hard. There is no limit so far to the range of applications of these new composite materials.

7. Clinical Testing of the New Bioglass Ceramics in Man

A number of the bioglass ceramics described above have been successfully tested in animals by our medical collaborators. Other bioglass ceramics that are intended for more special applications (e.g., in the eye) are still undergoing tests in animals. Four clinics have been given the go-ahead to perform the first level of clinical tests in humans in special cases.

- At the Orthopädische Klinik (orthopedic clinic) of Charité der Humboldt-Universität Berlin, Prof. H. *Zippel*, in collaboration with Dr. *J. Gummel* and Dr. *H. Hähnel*, has supervised the replacement of single vertebrae in several tumor patients with a bioactive, machinable glass ceramic. Figures 25a–c show several views of a destroyed vertebra before the operation. Figures 25d and e show the substitute vertebra immediately after the operation; it is held in place with a Zielke bridge. The first patient was able to walk without pain after six months.
- At the Hals-, Nasen- und Ohrenklinik (throat, nose, and ear clinic) of the Friedrich-Schiller-Universität Jena, a large range of machinable, biocompatible, and bioactive glass ceramics have been successfully implanted in the middle ear, the nose, the jaw, and the entire skull region (operations performed by Dr. *E. Beleites* under the supervision of Prof. *K.-H. Gramowski*).

  The following operations have been performed as part of the first level of clinical tests:
  - collumellization in tympanoplasty
  - augmentation of the stapes



a) b) c) d) e)

Fig. 25. Replacement of a vertebra in a tumor patient with a machinable bioactive glass ceramic (Dr. *J. Gummel*, Charité der Humboldt-Universität Berlin). a)–c) Different views of the destroyed vertebra; d), e) The vertebral prosthesis (X-ray picture). See text.

- reconstruction of the posterior wall of the auditory canal
- reconstruction of the skull base
- maintenance of the base of the orbit
- construction of the anterior wall of the frontal sinus
- rhinoplasty

Figure 26 shows middle-ear implants made by the surgeon. They allowed the patient to hear normally. Animal experiments have demonstrated that intergrowth occurs without causing any adverse reactions and that the biocompatible implant is covered with epithelium. Intergrowth takes place as if the implant were part of the body (see Fig. 27).

Fig. 26. Middle-ear implants made of machinable biocompatible or bioactive glass that were shaped by the surgeon (Dr. *E. Beleites*, HNO-Klinik der Friedrich-Schiller-Universität Jena). Scale in cm.

Fig. 27. Intergrowth of an implant made of biocompatible, machinable glass ceramic in an animal experiment. Intergrowth proceeds without causing any irritation and the implant is covered with a layer of epithelium (optical photomicrograph, Dr. *E. Beleites*, HNO-Klinik der Friedrich-Schiller Universität Jena).

— At the Orthopädische Klinik (orthopedic clinic) of the Medizinische Akademie Dresden, machinable bioactive implants have been used for a wide range of applications. The following operations have been performed as part of the first level of clinical tests under the supervision of Prof. *K.-J. Schulze* in collaboration with Dr. *W. Purath* and Dr. *T. Schubert*:

- reconstruction of the root of the acetabulum in a dislocated hip at the dysplasic stage (pericapsular iliumosteotomy according to *Pemberton*)
- ligament fixation in capsule-ligament plastic surgery of the knee joint
- osteotomy of the tibial head and augmentation of the tibial plateau
- operation according to *Bandi*
- partial replacement of vertebrae in the dorsal part of the spine
- ventral spondylodesis in the cervical vertebra according to *Robinson*
- plastic surgery of the shoulder joint according to *Eden-Hybinette*
- distraction osteotomy for keeping of distance
- filling of large bone cysts (glass ceramic as filler)

— Figures 28 and 29 shows two examples for the broad application of machinable, bioactive glass ceramics at the Orthopädischen Klinik der Medizinischen Akademie Dresden.

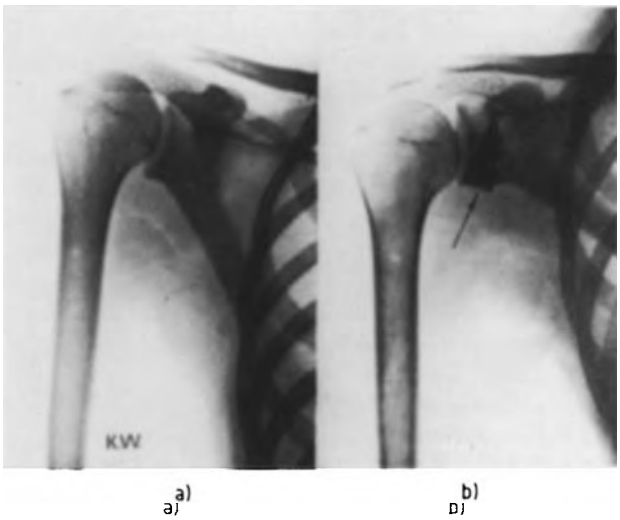


Fig. 28. Use of a wedge-shaped implant made of machinable, bioactive glass ceramic for treating recurrent dislocation of the shoulder by an *Eden-Hybinette* operation. a) Preoperative; b) eight months after the operation. Integration into the bone with good clinical results (Prof. *K.-J. Schulze*, Dr. *W. Purath*, Dr. *T. Schubert*, Medizinische Akademie Dresden).

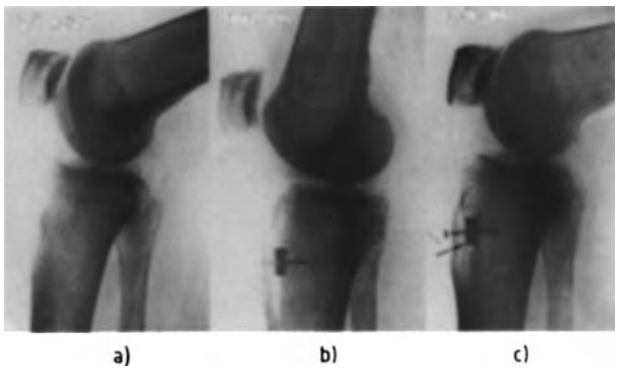

Fig. 29. Use of an oblique, cube-shaped implant made of machinable, bioactive glass ceramic with a central hole and a fixation pin for treating patellofemoral arthrosis by means of ventralization of the tubercle of the tibia according to *Bandi*. a) Preoperative; b) one week and c) eight months after the operation. Integration of the implant into the bone without loss due to correction (Prof. *K.-J. Schulze*, Dr. *W. Purath*, Dr. *T. Schubert*, Medizinische Akademie Dresden).

At the Klinik und Poliklinik für Kiefer-Gesichts-Chirurgie und Chirurgische Stomatologie (clinic and polyclinic for oral and facial surgery and surgical stomatology) of the Sektion Stomatologie of the Medizinische Akademie Dresden, dental roots have been replaced with machinable, highly bioactive glass ceramics following the successful completion of experiments on pigs performed by Doz. Dr. *R. Pinkert*. The preliminary results are extremely encouraging. Figure 30 shows some of these crude dental root implants; they are made from liquid glass by using a centrifugation technique and are later ceramicized. They were made from an impression of the original after preparing a ceramic mold by means of the centrifugation technique.

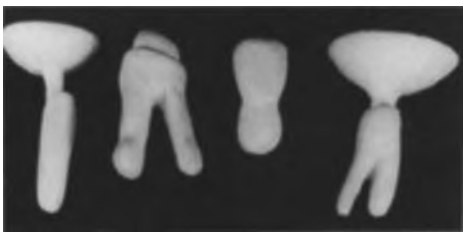

Fig. 30. Crude dental root implants made of machinable, highly bioactive glass ceramic. The implants were prepared by a centrifugation technique (Doz. Dr. *R. Pinkert*, Medizinische Akademie Dresden).

8. Summary and Outlook

Considerable progress has been made in this young, interdisciplinary area of science. Not just one but a whole spectrum of bioglass ceramics are now available for medical uses. The properties of these materials can be varied and adjusted within wide limits to suit special medical requirements and different types of applications. However, many questions have not yet been satisfactorily answered: What happens to a bioglass ceramic/bone contact and intergrowth on the long-term scale or when subjected to heavy, variable mechanical loads? How does the gum covering the jaw bone react to dental root implants? As far as prolonged contact is concerned, positive results have been obtained in animal tests extending over several years.

New, unpredictable problems sometimes arise during animal or clinical tests. It can be concluded, however, that the materials have not so far failed in any of their clinical applications. This has encouraged us to pursue further the current direction of development.

One of the advantages of the machinable bioglass ceramics in medicine that is repeatedly stressed is that an implant can be modified and fitted by the surgeon with his own instruments during the course of an operation. This is very important, for instance, in emergency surgery, oral surgery, and stomatology. One of our major aims is to increase the mechanical and shearing resistance of bioglass ceramics either directly or indirectly so that hip joint prostheses can be constructed. It is not yet possible to say whether this goal can be realized. It is evident, however, that the new opportunities for medical treatment that are offered by the development and utilization of new inorganic biomaterials in medicine are by no means exhausted.

The authors would finally like to thank their many coworkers and collaborators for their active and constructive cooperation. It is impossible to mention them all here but several at the Friedrich-Schiller-Universität Jena deserve special mention for their work on the development of biomaterials: Dr. K. Naumann, Dr. J. Vogel, Dr. G. Carl, Dipl.-Chem. P. Wange, Doz. Dr. habil. W. Götz (X-ray crystallography), Dr. G. Völksch and Ing. L. Horn (electron microscopy), Dr. sc. nat. Haubenreisser (nuclear magnetic resonance studies), Prof. Dr. habil. G. Heublein and Dipl.-Chem. M. Böse (organic polymer development). The numerous animal experiments and clinical tests performed by the following medical colleagues have made a decisive contribution to the present status of development: Dr. sc. med. J. Gummel (Humboldt-Universität Berlin), Dr. med. E. Beleites (Friedrich-Schiller-Universität Jena), Prof. Dr. sc. med. K.-J. Schulze (Medizinische Akademie Dresden), Dr. med. T. Schubert (Medizinische Akademie Dresden), Dr. med. W. Purath (Medizinische Akademie Dresden), Doz. Dr. Dr. sc. med. R. Pinkert (Medizinische Akademie Dresden). Our thanks also go to many other medical colleagues whose studies are still at the stage of laboratory and animal tests. Many of our own co-workers—research students, laboratory assistants, and technicians—have also made considerable contributions to the success of the work presented here.

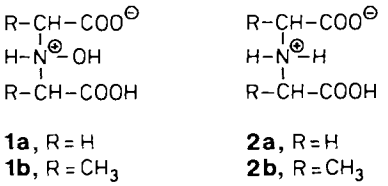
Amavadin, an Example for Selective Binding of Vanadium in Nature: Studies of Its Complexation Chemistry and a New Structural Proposal

By *Ernst Bayer,* Eckhard Koch,* and *Giorgio Anderegg*

The selective enrichment of metals in nature is of great interest.[1] For example, the concentration of vanadium in the blood of tunicates is a millionfold higher than in sea water.[2-4] Fly agaric *(Amanita muscaria)* also concentrates vanadium.[5,6] The structure of the vanadium compound of tunicates has not yet been elucidated.[7,8] However, a structure (**3**) has been proposed[9] for the vanadium compound of fly agaric, amavadin.[9-11] The structural elucidation and synthesis of the organic ligand **1b**[9b] allows, for the first time, the specificity of a naturally occurring vanadium ligand to be investigated. Amavadin can be prepared from $V^{IV}O$ salts and synthetic **1b**.[9b] Since the ligand **1b** was previously unknown and since all attempts to obtain crystals of amavadin suitable for an X-ray structure analysis failed, a detailed investigation of the complex formation of **1b** should also provide an answer to the question of the arrangement of the ligands around the central atom in amavadin.



1a, R = H **2a**, R = H
1b, R = CH_3 **2b**, R = CH_3

The stability constants of the complexes of the amavadin ligand *N*-hydroxy-2,2′-iminodipropionic acid **1b** and the parent compound *N*-hydroxyiminodiacetic acid **1a** were determined for a variety of metals and are listed in Table 1 for the 1 : 1 (K_1) and 1 : 2 complexes (K_2). Most of the constants were determined potentiometrically by using the computer program of *Anderegg*.[12,13] The stability constants of the 1 : 1 copper complexes CuL were determined by ligand exchange with tris(β-aminoethyl)amine.[14] Potentiometric titration is not suitable, however, for measuring the stability of the vanadium(IV) complexes, since the formation of amavadin, namely, a 1 : 2 complex, is already complete before the start of the titration. For this reason, earlier attempts to determine the stability by means of potentiometric titration also led to false results.[15] Investigations by ESR and UV spectroscopy have also shown that, even for a less than stoichiometric amount of ligand, the 1 : 2 complex is formed so fast that no 1 : 1 complex can be detected. Monitoring of the dissociation of the complex at very low pH values by UV spectroscopy gave a value of $\lg\beta_2 = 23.0 \pm 1.0$ for the overall complex formation constant β_2. This value is eleven orders of magnitude larger than that for the copper complex and confirms the exceptional selectivity of the bonding of vanadium(IV) by the ligands of amavadin. This finding clearly reveals how nature selectively binds vanadium in fly agaric by providing a selective ligand.

Table 1. Logarithms of the stability constants K_n ($[ML_n]/([ML_{n-1}][L])$) for various metal ions. The threefold standard deviation in the last digit(s) is shown in parentheses. Measurements at 25°C (**1a**, **1b**, **2b**) and 20°C (**2a**) and ionic strength $I = 0.1$ (KNO_3).

Metal ion		Ligand **1a**	**1b**	**2a**	**2b**
$Ca^{2\oplus}$	$\lg K_1$	3.0(1)	2.7(1)	2.6 [a]	2.0(1)
$Ni^{2\oplus}$	$\lg K_1$	6.4(1)	5.7(1)	8.19 [a]	7.6(1)
	$\lg K_2$	4.65(10)	5.0(1)	6.11 [a]	5.9(1)
$Cu^{2\oplus}$	$\lg K_1$	8.45(10)	9.2(1)	10.63 [a]	10.6(2)
	$\lg K_2$	4.10(5)	3.45(10)	6.05 [a]	4.4(1)
$Zn^{2\oplus}$	$\lg K_1$	5.5(1)	5.05(10)	7.27 [a]	6.6(1)
	$\lg K_2$	3.96(1)	4.05(10)	5.33 [a]	4.5(1)
$VO^{2\oplus}$	$\lg K_1$	—	—	9.00 [b]	9.54 [b]
	$\lg\beta_2$ [c]	21.9 ± 1.0	23.0 ± 1.0		

[a] From [22]. [b] From [15], $T = 25$°C. [c] $\beta_2 = [VL_2^{2\oplus}]/[VO^{2\oplus}][L^{2\ominus}]^2$.

Comparison of the stability of complexes with *N*-hydroxyimino ligands **1a,b** with those with imino ligands **2a,b** is of particular interest. Whereas the *N*-hydroxy ligand **1b** was unknown prior to its discovery in amavadin, iminodiacetic acid **2a** and iminodipropionic acid **2b** belong to the same group of ligands as ethylenediaminetetraacetic acid (EDTA).

By slightly changing the structure of a ligand—namely, by insertion of an oxygen into the analogous imino compound—nature has achieved an effective selectivity for vanadium. The analogous imino compounds form only 1 : 1 complexes with $VO^{2\oplus}$, the stability of which is one to two orders of magnitude smaller than that of the corresponding copper complexes. With the exception of the vanadium complexes, all other metal complexes of the imino ligand **2** are more stable than those of the corresponding *N*-hydroxy compounds. This is expected because of the larger basicity of the NH group in comparison with the NOH group.

Why is such a dramatic increase in complex stability observed in the case of vanadium? This selectivity must be connected with the special arrangement of the ligands around the vanadium. However, the structure assumed so far, **3**, cannot provide an explanation.

Table 2. Complex formation constants K_n ($[ML_n]/[ML_{n-1}][L]$) for various amino and *N*-hydroxyamino acid metal complexes ($T = 25°C$, $I = 0.1$ (KNO_3)).

Ligand	$VO^{2\oplus}$			$Cu^{2\oplus}$	
	$\lg K_1$	$\lg K_2$	$\lg K_3$	$\lg K_1$	$\lg K_2$
$H_2N-O-CH_2-COOH$	$\bar{n}_{max} < 0.15$			5.02 [a]	
$H_2N-CH_2-CH_2-COOH$	< 7.5			7.10 [b]	5.40 [b]
$HO-NH-CH_2-COOH$	6.4	6.2	5.1	$Cu^{2\oplus}$ reduction	
H_2N-CH_2-COOH	< 6.6			8.46 [b]	6.83 [b]
$HO-N(CH_3)-CH_2-COOH$	6	5	4	$Cu^{2\oplus}$ reduction	
$H_3C-NH-CH_2-COOH$	< 7.5			7.94 [c]	6.65 [c]
$HOOC-CH_2-CH(NHOH)-COOH$	7.24	5.4		6.54	4.3
$HOOC-CH_2-CH(NH_2)-COOH$	9.2			8.57 [d]	6.78 [d]
$HON(CH_2CH_2COOH)_2$	5.8	4.2		7.3	

[a] From [23]. [b] From [24]. [c] From [25]. [d] From [26].

Synthesis of substances for comparison and investigation of their complex formation with $VO^{2\oplus}$ were used to establish which elements of structure are essential for the vanadium selectivity. These compounds, together with the stability constants for the $VO^{2\oplus}$ and $Cu^{2\oplus}$ complexes, are collected in Table 2. The complex stability of amavadin is not even approached with any of these ligands. We therefore conclude that, in addition to the NOH group, the two carboxyl groups are also necessary for the vanadium selectivity. On the basis of our results, we propose the new, symmetrical structure **4** as the true structure of amavadin. The absence of a VO group, as found in structure **3**, can be concluded from the following observations. The ESR spectra provide no evidence for the binding of additional ligands,[16] as is often observed to be the case for vanadyl complexes.[17] The IR band at 980 cm^{-1} exhibited by amavadin and assigned to the VO vibration is not observed for the vanadium(IV) complex of *N*-hydroxyiminodiacetic acid, even though this complex exhibits a stability similar to that of amavadin. Therefore, the band at 980 cm^{-1} cannot be assigned to the vanadyl group. Furthermore, recently performed large-angle X-ray scattering (LAXS) experiments show that the shortest metal-ligand distance is probably larger than 1.9 Å.[18] The V-O distance of a vanadyl group is 1.57–1.65 Å. The acidity of amavadin, $pK_a \approx 0$, moreover, does not support the presence of free carboxyl groups. A side-on binding of the anion of the NOH group, as postulated in structure **4**, has been observed for vanadium(V) hydroxylamine complexes.[19,20]

The vanadium compound of fly agaric, amavadin, represents the most stable vanadium(IV) complex known to date. Nitrogen-containing ligands in naturally occurring vanadium complexes are of growing interest because of the recent report of a vanadium nitrogenase.[21]

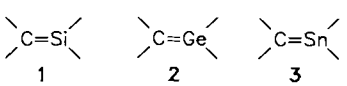
A Stable Stannaethene**

By *Harald Meyer, Gerhard Baum, Werner Massa, Stefan Berger,* and *Armin Berndt**

Silaethenes **1** have been completely characterized[1,2] and germaethenes **2** have been identified by trapping reactions;[3] 1,1-dimethylstannaethene **3a** has been generated in the gas phase.[4] Calculations have been carried out for the basic structures **1**–**3**.[5] We now describe the synthesis, spectroscopic characterization, and crystal structure of the stable stannaethene **3b**.



1 **2** **3**

The boranediylborirane **4**, which, according to calculations,[6] has the nonclassical structure shown in Scheme 1,

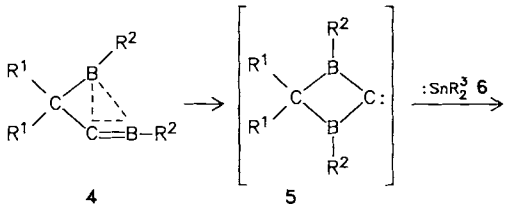
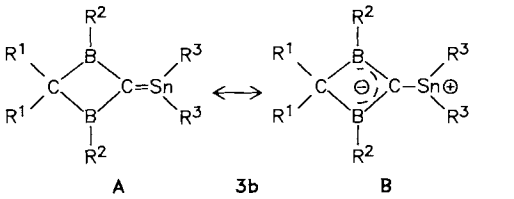
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

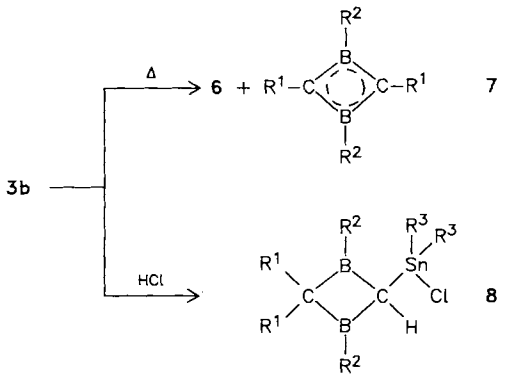
behaves toward suitable reagents as if it were the carbene **5**.[7,8] This observation prompted us to carry out the reaction of **4** with the stannanediyl **6**.[9] Reaction in pentane at room temperature led to formation of the stannaethene **3b** in quantitative yield as shown by ^{13}C-NMR spectroscopy.



4 5



A 3b B

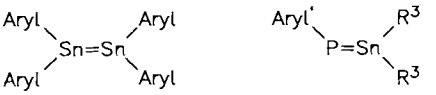


$R^1 = Si(CH_3)_3$; $R^2 = C(CH_3)_3$; $R^3 = CHR^1_2$

Scheme 1.

Compound **3b** crystallizes from pentane at −30 °C as Indian red cubes, which slowly lose their color (over 2 h) upon exposure to air. They melt at 133 °C, undergoing partial decomposition to give **6** and the 1,3-dihydro-1,3-diboretete **7**.[7] Compound **3b** reacts with HCl to give the colorless 1,3-diboretane **8** (m.p. = 178 °C) in quantitative yield according to ^{13}C-NMR spectroscopy.

The structures of **3b** and **8** were established from the ^{1}H-, ^{13}C-, ^{11}B-, and ^{119}Sn-NMR spectra (Table 1). Decisive proof for the presence of tricoordinated tin in **3b** is provided by the very high-frequency position of the ^{119}Sn-NMR signal at $\delta = 835$ (cf. $\delta = 75$ for **8**, both values relative to $\delta(Sn(CH_3)_4) = 0$). Chemical shifts of $\delta(^{119}Sn) = 427.3$[10] and 658.3[11] were found for the tricoordinated Sn atoms in **9** and **10**, respectively.



9 **10**

Aryl = 2, 4, 6-triisopropylphenyl

Aryl' = 2, 4, 6-tri-*tert*-butylphenyl

$R^3 = CH(Si(CH_3)_3)_2$

A typical chemical shift ($\delta(^{13}C) = 142$) for a tricoordinated C atom is observed for the C atom of the C=Sn bond. The shift of the ^{11}B-NMR signal of **3b** to lower frequencies ($\delta(^{11}B) = 64$) compared with the signals of **8** ($\delta(^{11}B) = 83$) reveals negative π charge on the B atoms and therefore a strong polarization of the C=Sn bond corresponding to the ylide form **B**.

An X-ray structure analysis[12] of **3b** gave a length of 2.025(4) Å for the bond between the Sn atom and the tricoordinated C2 atom and lengths of 2.152(5) and 2.172(4) Å for the bonds to the tetracoordinated C atoms C19 and C20 (Fig. 1). The torsion angles B1-C2-Sn-C19 and B3-C2-Sn-C20 (Fig. 2) are 40 and 82°, respectively;

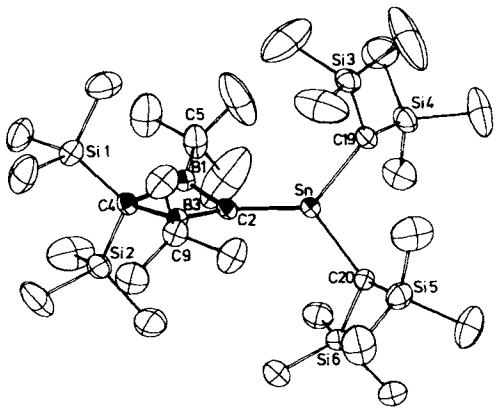


Fig. 1. ORTEP plot of a molecule of **3b** in the crystal (ellipsoids of thermal vibration at 30% probability level; view onto the plane C2,C19,C20; H atoms not shown). Important bond lengths [Å], bond angles and torsion angles [°]: Sn-C2 2.025(4), Sn-C19 2.152(5), Sn-C20 2.172(4), B1-C2 1.510(6), B1-C4 1.624(8), B1-C5 1.601(9), B3-C2 1.494(7), B3-C4 1.653(6), B3-C9 1.603(8), C4-Si1 1.868(4), C4-Si2 1.872(5), B1···B3 1.994(8), C3···C4 2.393(5); C2-Sn-C19 129.2(2), C2-Sn-C20 125.6(2), C19-Sn-C20 104.8(2), Sn-C2-B1 139.2(4), Sn-C2-B3 132.9(4), B1-C2-B3 83.2(4), C2-B1-C4 99.5, B1-C4-B3 75.0(3), C4-B3-C2 98.9(4), Si1-C4-Si2 113.3(3); B1-C2-Sn-C19 40.2(6), B1-C2-Sn-C20 −132.2(4), B3-C2-Sn-C19 −106.1(5), B3-C2-Sn-C20 81.5(5), Sn-C2-B1-C4 −170.5(4), Sn-C2-B3-C4 172.9(4).

the average twist angle around the C=Sn bond is therefore 61°. The angles between the line joining C2 and Sn and the planes C19,Sn,C20 and B1,C2,B3 are 5 and 16°, respectively; i.e., the Sn atom is slightly pyramidalized and the

Table 1. NMR spectroscopic data for **3b** and **8** [a].

3b: ^{1}H-NMR: $\delta = 1.40$ (s, 2H; SnCH), 1.27 (s, 18H; $BC(CH_3)_3$), 0.20 (s, 18H; $BCSi(CH_3)_3$), 0.0 (s, 36H; $HCSi(CH_3)_3$); ^{13}C-NMR: $\delta = 142.0$ (br. s, 1C; C=Sn), 34.9 (d, 2C; SnCH), 32.4 (q, 6C; $BC(CH_3)_3$), 29.1 (br. s, 1C; BCSi), 24.2 (br. s, 2C; $BC(CH_3)_3$), 5.8 (q, 6C; $BCSi(CH_3)_3$), 4.5 (q, 12C; $SnCSi(CH_3)_3$); ^{11}B-NMR: $\delta = 64$; ^{119}Sn-NMR: $\delta = 835$

8: ^{1}H-NMR: $\delta = 1.36$ (s, 1H; BCHSn), 1.28 (s, 18H; $BC(CH_3)_3$, 0.51 (s, 2H; SnCHSi), 0.39 and 0.35 (s, each 18H; $SnCSi(CH_3)_3$), 0.29 and 0.21 (s, each 9H; $BCSi(CH_3)_3$); ^{13}C-NMR: $\delta = 56.7$ (br. s, 1C; BCSi), 53.1 (br. d, 1C; BCSn), 30.5 (q, 6C; $BC(CH_3)_3$), 27.5 (br. s, 2C; $BC(CH_3)_3$), 16.2 (d, $^1J(^{13}C^{119}Sn) = 183$ Hz, 2C; SnCSi), 7.1 and 5.6 (q, each 3C; $BCSi(CH_3)_3$), 5.2 and 5.1 (q, each 6C; $SnCSi(CH_3)_3$); ^{11}B-NMR: $\delta = 83$; ^{119}Sn-NMR: $\delta = 75$

[a] Solvent C_6D_6.

C2 atom is significantly pyramidalized. Despite these distortions, the C=Sn distance (2.025 Å) is in good agreement with that calculated for $H_2C{=}SnH_2$ (1.982 Å).[5] The short distances B1-C2 (1.510(6)) and B3-C2 (1.494(7) Å)—which are practically identical with the corresponding distances in the 1,3-dihydro-1,3-diborete (7 with $R^2 = N(CH_3)_2$) synthesized by *Siebert* et al.[13]—confirm the importance of the ylide resonance form **B**, which was concluded from the ^{11}B-NMR chemical shift data. This resonance form also helps to explain the extremely high-frequency ^{119}Sn-NMR signal.

A New Low-Temperature Synthesis of 1,2-Dihydro-1,2-diphosphetes

By *Louis Ricard, Nicole Maigrot, Claude Charrier,* and *François Mathey**

Among carbon-phosphorus heterocycles, 1,2-dihydro-1,2-diphosphetes **5** deserve special attention. In some instances, their chemistry can be controlled by their potentially aromatic π-electron sextet.[1,2] On the other hand, the cyclic strain within the ring varies widely according to the substitution pattern,[2,3] thus inducing significant differences in their chemical behavior. Finally, in some cases, compounds **5** may act as masked 1,4-diphosphabutadienes.[4] In spite of these interesting aspects, however, the chemistry of 1,2-dihydro-1,2-diphosphetes **5** is presently very poorly developed, undoubtedly because of the lack of a simple and general synthesis of this ring. The initial high-temperature route [$(RP)_n + R'C{\equiv}CR''$][2,3,5,6] yields complicated mixtures of products and can only provide an access to thermally stable 1,2-dihydro-1,2-diphosphetes **5**. The only other practical route [$RP(SiMe_3)_2 + ClCO{-}COCl$][4] has a limited generality since the two carbons of the ring necessarily bear Me_3SiO substituents.

Fortunately, the recent discovery in our laboratory of a new and simple access to tervalent phosphirenes[7] has allowed us to conceive a new and versatile synthesis of the title compounds. It relies on the formal insertion of a phosphanediyl into a phosphirene C-P bond.

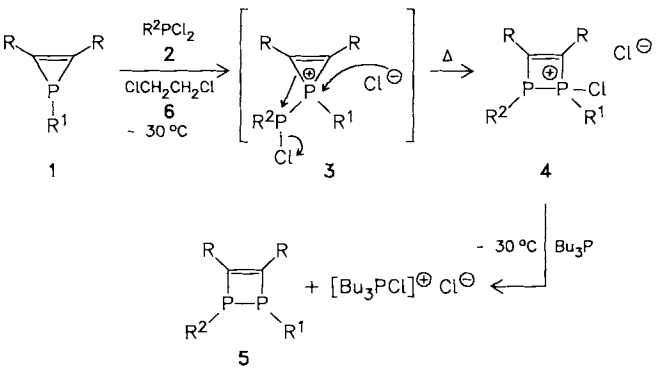

Table 1. Substituents of **1** and **3**–**5**; yields [%] of **5**.

	1		3–5			5

h			Et	*t*Bu	Me	30

[a] Unsatisfactory yields.

In the first step, a dichlorophosphane, **2**, is allowed to react with a phosphirene, **1**. The reaction probably proceeds through a transient phosphirenium salt, **3**. In the presence of $AlCl_3$, **3a** has been characterized by ^{31}P-NMR spectroscopy: AB system with $\delta(^{31}P) = -102.9$ ($P^{\oplus}$) and +67.6 ppm (PCl), $^1J(PP) = 503$ Hz. Without $AlCl_3$, **3** immediately rearranges to give a dihydrodiphosphetium salt, **4**, which is reduced in situ by Bu_3P to give **5** (for yields see Table 1).

The rearrangement to **4** probably involves the nucleophilic attack of $Cl^{\ominus}$ on $P^{\oplus}$ inducing the opening of the ring. The carbanion thus formed reacts with the P-Cl bond of the exocyclic phosphino group. Except for **5a** and **5e**,[3] all the 1,2-dihydro-1,2-diphosphetes **5** thus produced are new and have been fully characterized (Table 2). The ring expansion sometimes fails when bulky R^1 or R^2 groups are used (**5c**, **g**, **g′**).

[a] NMR spectrum in $CDCl_3$ and 20-eV EI mass spectra unless noted otherwise. [b] Synthesized according to [7]; used in situ without further purification.

Experimental Procedure

Two typical experimental procedures are described. All reactions were carried out under argon. The synthesis of the dihydrodiphosphetes **5** relies on the insertion of a dichlorophosphane into the C–P bond of preformed phosphirenes **1**. Depending on the stability of **1**, they may or may not be isolated prior to conducting the insertion reaction [8].

5b: To **1** (2.86 g, 10 mmol) was added $MePCl_2$ (1.17 g, 10 mmol) in **6** at -30°C. After 10 min, the reaction mixture was added to a cold solution of Bu_3P (2.02 g, 10 mmol). The mixture was then concentrated and the residue extracted with hexane. The hexane extract was chromatographed as fast as possible on silica gel (70–230 mesh, Riedel de Haën) with hexane/toluene (80/20). Compound **5b** (2 g, 60%) was thereby obtained as a colorless oil.

5e: A phosphirenium adduct was formed from 3-hexyne (0.86 g, 10 mmol), $AlCl_3$ (1.7 g, 11.5 mmol), and $PhPCl_2$ (1.79 g, 10 mmol) at -30°C in **6** [9]. The reduction leading to **1d** was performed by pouring the adduct onto a solution of Bu_3P (2.02 g, 10 mmol) in 5 mL of **6** at -30°C. A stoichiometric amount of $PhPCl_2$ (as determined from ^{31}P-NMR spectroscopy, usually 70–80% of the initial amount of $PhPCl_2$) in 3 mL of **6** at -30°C. Reduction of **4e** to **5e** was carried out by pouring the solution onto a molar-equivalent solution of Bu_3P in 5 mL of **6** at -30°C. After addition of *N*-methylimidazole in excess, the reaction mixture was extracted with hexane. The extract was chromatographed on a well-degassed silica gel column with hexane. Yield: 2 g (70%) **5e**.

$Cs_3Mo_5P_6O_{25}$: a Novel Molybdenum Phosphate Containing a Cubane-like Mo_4O_4 Cluster with Six Molybdenum–Molybdenum Bonds

By *Kwang-Hwa Lii*,* *Robert C. Haushalter*, and *Charles J. O'Connor*

Several different structure types have been discovered in the quaternary system M–Mo–P–O (M = metal cation) which contain molybdenum in oxidation states less than +6. For example, $K_4Mo_8P_{12}O_{52}$,[1] $TlMo_2P_3O_{12}$,[2] $Cs_4Mo_8P_{12}O_{52}$,[3] and $AgMo_5P_8O_{33}$[4] have tunnel structures with various pore sizes in which the metal cations M^+ reside. Interestingly, $Cs_2Mo_4P_6O_{26}$,[3] which has the same chemical composition as $Cs_4Mo_8P_{12}O_{52}$, adopts a layer structure. The formal oxidation state of the Mo atom in $TlMo_2P_3O_{12}$ is +4, and that in the other compounds is +5. In the Mo^V-containing compounds, the MoO_6 octahedra are "diluted" with either PO_4 or P_2O_7 groups, but corner-sharing MoO_6 octahedra exist in the Mo^{IV}-containing phosphate. As the formal oxidation state of the molybdenum atom is further reduced, one might expect the formation of metal–metal bonds. We report here a novel molybdenum phosphate, **1**, which contains tetrahedral Mo_4 clusters with six Mo–Mo bonds. Although tetrahedral Mo_4 cluster units have been found in $GaMo_4S_8$[5] and $Mo_4S_4Br_4$,[6] and in the organomolybdenum compounds containing cubane-like Mo_4S_4 units, e.g., $[\{(\eta^5\text{-}C_5H_5)Mo(\mu_3\text{-}S)\}_4]$,[7] the structure of **1** is unprecedented among metal phosphate systems.

$Cs_3Mo_5P_6O_{25}$ **1**

Black chunky crystals of **1** were obtained by heating an intimate mixture of Cs_2MoO_4, MoO_2, Mo, and P_2O_5 (mole ratio of 3:4:3:6) in a sealed quartz tube at 900°C for two days and its single crystal structure was determined.[8] Although the compound is pure by X-ray diffraction measurements, visual microscopic examination always showed the product was contaminated with a small amount of a pale green material.

The structure of **1**, viewed approximately parallel to the trigonal *c* axis, is shown in Figure 1 and contains tunnels where the Cs^+ ions are located. Figure 2a is a projection of the structure of **1** onto the (110) plane and shows the arrangement of the tetrahedral Mo_4 clusters and $Mo(2)O_6$ octahedra, which are connected by pyrophosphate groups, in the unit cell. The Mo_4 tetrahedra all point in the $+z$ direction with the apex atoms, Mo1, at the 2b special positions. The unique molybdenum atom, Mo2, is at the 2a special position and exhibits regular Mo2–O bond distances (2.067(6) Å (3×) and 2.090(5) Å (3×)), which excludes the possibilities of Mo^{6+} and Mo^{5+} for Mo2 (which would involve very asymmetrical configurations of Mo).

As shown in Figure 2b, which is a view approximately parallel to the threefold axis, each face of the Mo_4 tetrahe-

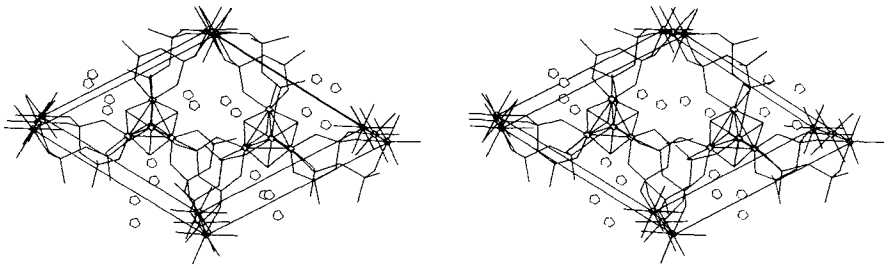

Fig. 1. A stereoscopic view of the crystal structure of **1** in a direction approximately parallel to the threefold axis. The Cs and Mo atoms are represented by large and small polygons, respectively. For clarity, the radii for P and O atoms are set equal to zero.

dron is capped with a μ_3-oxygen atom, three corners of the tetrahedron base are each coordinated by a bidentate P_2O_7 ligand, and the three slant edges (Mo1–Mo3) are each bridged by a P_2O_7 group. The four Mo atoms and four μ_3-O atoms form a distorted cube with edge lengths from 1.992 to 2.051 Å and angles from 95.2 to 102.7°. Each Mo atom of the cluster is coordinated by six oxygen atoms in a distorted octahedral geometry; the O–O distance is 2.84–3.15 Å for the $Mo(1)O_6$ unit and 2.68–3.15 Å for the $Mo(3)O_6$ unit. The cluster consists of four MoO_6 octahedra each sharing its three common edges such that each cluster unit is bound to 16 oxygen atoms. Alternatively, the Mo_4O_{16} cluster can be described as a cubic close-packed array of oxygen atoms with the molybdenum atoms at octahedral sites (AcBaC). The Mo_4 tetrahedron, which resides on a crystallographic site of 3 symmetry, is compressed along the threefold axis (Mo3–Mo3 2.697(1) Å, Mo1–Mo3 2.558(1) Å). Cluster **1** contains three P_2O_7 groups, each of which is coordinated to a corner of the Mo_4 tetrahedron as a bidentate ligand, bridges an edge of a neighboring Mo_4 cluster, and also forms a bridge between two neighboring Mo2 atoms. Both the configuration and the P1–O8–P2 bond angle of the pyrophosphate group in **1** are similar to those found in $Cs_4Mo_8P_{12}O_{52}$.[3] The Cs atom is surrounded by 11 oxygen atoms at distances ranging from 3.041 to 3.582 Å.

An assessment of the oxidation state of the Mo atoms using the bond-length bond-strength formula for the Mo–O bond $[s=(d_{Mo-O}/1.882)^{-6.0}]$[9] yields the following puzzling results: Mo1 +3.32, Mo2 +3.31, Mo3 +3.44 (2.69 e/Mo2, 10.36 e/Mo_4 cluster). However, the summation of the assessed oxidation states over the five Mo atoms of **1** is equal to 16.95, which is in excellent agreement with the value of 17 based on the stoichiometry.

The Mo_4 cluster in **1** has a pronounced distortion similar to that of the 10-electron cluster in $[Mo_4S_4(NCS)_{12}]^{6-}$,[10] which undergoes a Jahn–Teller distortion. However, the distortion in **1** could also be due to a geometric effect because the three Mo1–Mo3 bonds are bridged by P_2O_7 ligands. In order to determine the charge distribution between the Mo_4 cluster and the unique Mo2 atom in **1** magnetization data were obtained, using a SQUID magnetometer from 400 K to 2.3 K, on a crushed sample of manually selected crystals. Figure 3 displays the

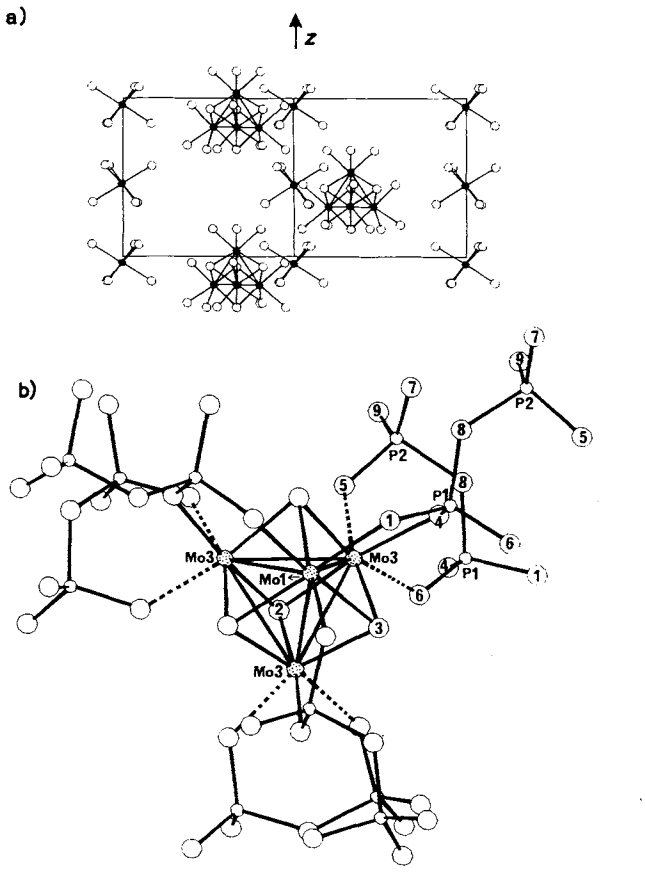

Fig. 2. a) A projection of the structure of **1** onto the (110) plane showing $Mo(2)O_6$ octahedra and Mo_4O_{16} clusters. The P, O8, and Cs atoms have been omitted for clarity. b) Ball-and-stick drawing of a Mo_4O_4 cluster with the pyrophosphate ligands.

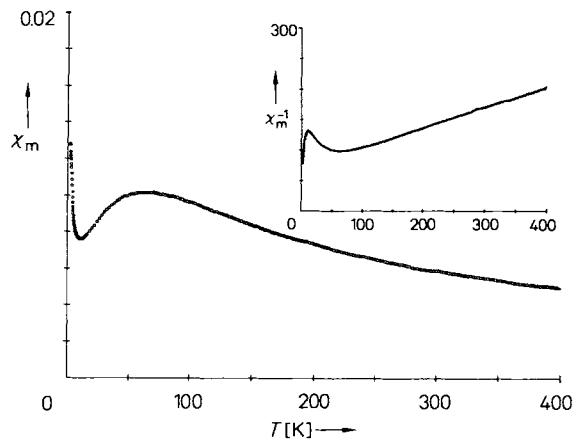

Fig. 3. Molar magnetic susceptibility (χ_m) of **1** vs. T and inverse molar magnetic susceptibility (χ_m^{-1}) vs. T (inset).

plots of molar magnetic susceptibility (χ_m) vs. T and inverse molar magnetic susceptibility vs. T (inset). A least-squares fit to the Curie–Weiss law ($\chi_m = C/(T-\theta)$) in the high-temperature interval gave $\chi_m = 2.91/(T+205)$. The effective magnetic moment (μ_{eff}) calculated from $\mu_{eff} = 2.828\sqrt{C}$, is 4.82 μ_B, which is in excellent agreement with the spin-only value (4.80 μ_B) for noninteracting S = 1

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0606-0550 $ 02.50/0

for the Mo_4 cluster and $S = 3/2$ for the unique Mo atom. The Curie tail below 10 K is due to the presence of a small amount ($< 1\%$) of magnetic impurity. However, the exact nature of the broad maximum around 60 K in the plot of χ_m vs. T is still not clear to us. The assumption of an unusual oxidation state ($+3$) for the unique Mo atom (Mo2) in **1** is supported by our recent discovery of $CsMoP_2O_7$,[11] which is isostructural with $KAlP_2O_7$[12] and contains isolated Mo^{3+} ions in the oxygen lattice.

Structural Dynamic of Collagen Fibers Cross-Linked with Isocyanates; Application of Synchrotron Radiation in Macromolecular Chemistry**

By *Erika Mosler, Hans Dieringer, Peter P. Fietzek, Waltraud Folkhard, Ernst Knörzer, Michel H. J. Koch,* and *Theobald Nemetschek**

Dedicated to Professor Klaus Kühn on the occasion of his 60th birthday

The reaction of collagen with mono- and dialdehydes[1] as well as with bifunctional reactive tannins[2] results in an increase in the thermal stability (shrinkage temperature T_m), the mechanical strength, and the enzymatic resistance of fibrillar-organized macromolecules, because of the additional cross-linking. However, so far it has been difficult to differentiate between intermolecular and interfibrillar cross-links by either chemical or structural analysis. In principle, structural analytical studies of modifications connected with cross-linking should be possible on the basis of dynamically induced intensity changes in the small-angle meridional X-ray diffraction spectra of fibers, since these changes are related to the sliding of parallel-aggregated collagen molecules relative to each other, a process that can be experimentally influenced.[3,4] However, such analyses proved difficult, because cross-linking with aldehydes already led to intensity changes in the spectra of the fibers.[5]

Diisocyanates,[6] such as hexamethylene diisocyanate (HMDI), can also be used to cross-link collagen.[7] The small-angle meridional X-ray diffraction spectra of HMDI cross-linked samples (Figures 1a and b) show reflections with intensities I and a periodicity identical to those observed for native fibers although the samples were otherwise comparable to fibers cross-linked with aldehydes. This initially unexpected finding can be ascribed to the practically identical electron density of HMDI and structure water of native fibers. The absent effect of HMDI on the small-angle meridional X-ray diffraction spectra of fibers thus provides, for the first time, an experimental way of quantifying the structural dynamics[9] of artificially cross-linked collagen fibers.[10]

The shrinkage temperature T_m shown in the box in Figure 2 reveals a time dependence of the cross-linking reaction; this finding leads to the expectation that the ability of parallel-aggregated collagen molecules to slide relative to

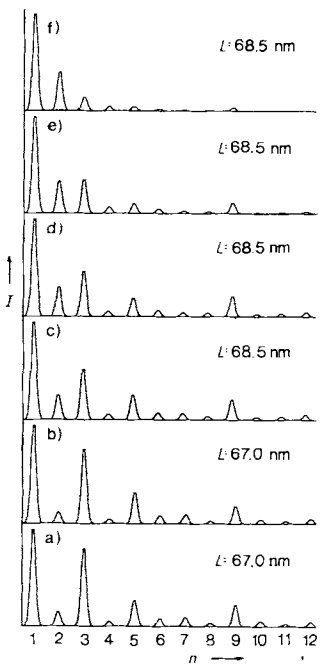

Fig. 1. Small-angle meridional X-ray diffraction spectra of unstretched (a, b) and stretched (c–f) collagen fibers (CF). "Molecular stretching" ΔL in c–f: 2.24%. a) Native CF, $\sigma = 0$; $I_2/I_3 = 0.2$. b) CF cross-linked for 60 min with HMDI, $\sigma = 0$; $I_2/I_3 = 0.15$. c) CF cross-linked for 60 min with HMDI, $\sigma > 0$; $I_2/I_3 = 0.48$. d) CF cross-linked for 30 min with HMDI, $\sigma > 0$; $I_2/I_3 = 0.65$. e) CF cross-linked for 15 min with HMDI, $\sigma > 0$; $I_2/I_3 = 0.95$. f) Native CF, $\sigma > 0$: $I_2/I_3 = 2.8$. The fibers (from rat tail tendon) were washed with Ringer's solution after cross-linking and the measurements were carried out in Ringer's solution. I = intensity; n = order; L = long period; σ = fiber tension; the first-order intensity is shown reduced by a factor of 10; measuring time, 3 s for each spectrum; fitting of the maxima and subtraction of the background by nonlinear regression analysis [8]; the intensity of the second- and third-order reflections (I_2 and I_3) should be noticed.

each other is reduced. Indeed, a reduced sliding ability of the molecules, dependent on T_m, and thus an increase in *intermolecular* cross-linkage is demonstrated by the delayed increase in I_2/I_3 shown in Figure 2.

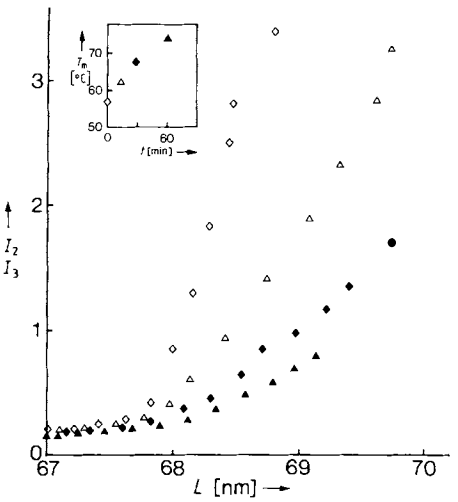

Fig. 2. Inset: Shrinkage temperature T_m of tendon fibers (from rat tail tendon) in Ringer's solution; native (◇) and as a function of the length of the cross-linking reaction t (△, 15 min; ◆, 30 min; ▲, 60 min). The figure shows stretching-induced changes in the ratio of the second- and third-order intensities (I_2/I_3) as a function of the long period L and the shrinkage temperature T_m as determined from the small-angle meridional X-ray diffraction spectra; for the meaning of ◇, △, ◆, and ▲, see above.

Comparison of the short-time diffraction spectra shown in Figure 1c–f reveals the possibility of carrying out, by measuring the I_2/I_3 value in comparison to ΔL, a differential analysis of the degree of cross-linkage as a function of the reaction time for the collagen fibers treated for varying times with HMDI.

These findings are important not only for collagen fibers but also for other fibrous biopolymers and high polymers that are accessible to analysis of the structural dynamic by X-ray diffraction.

[4] Only the use of synchrotron radiation made possible the study of this molecular sliding process by diffraction analysis (on account of the reduction in the exposure time by a factor of 10^5), since relaxation of the fibers, which is equivalent to a return of the molecules to their original position, starts within seconds. This is indicated by a reflection at ca. 67 nm in the X-ray diffraction spectrum as well as its higher orders, which point to a dynamically modifiable axial long period due to a staggered parallel arrangement of the ca. 300-nm-long collagen molecules. Recording of the small-angle spectra was carried out with the EMBL camera X 33 in combination with a linear, position-sensitive detector [3].

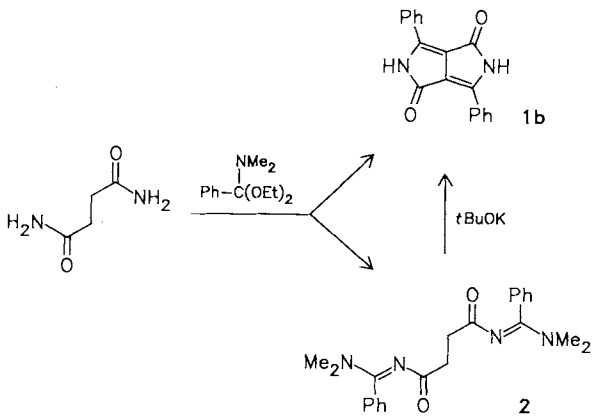
2,5-Diazapentalenes**

By *Fritz Closs* and *Rudolf Gompper**

Pentalene is a thermally unstable compound belonging to the class of destabilized, antiaromatic π-systems.[1-3] Stabilization of the pentalene system can be achieved by steric shielding (e.g., by *tert*-butyl groups[4]) or by the introduction of donor groups in the 1(3,4,6) position and acceptor groups in the 2(5) position.[5-9]

According to MO calculations,[3,10] 2,5-diazapentalene (pyrrolo[3,4-*c*]pyrrole) (cf. **7** and **8**) is expected to be nonaromatic, whereas 2-azapentalene is expected to be antiaromatic, although less antiaromatic than pentalene. 2,5-Diazapentalene-1,4(2*H*,5*H*)-diones **1**,[11] which exhibit interesting pigment properties[12] and are readily accessible by reaction of esters of succinic acid with aryl cyanides, open up a new route to 2,5-diazapentalenes. We have found another simple synthesis of compounds of the type **1** as exemplified by **1b**, namely, the reaction of succindiamides with *N*,*N*-dimethylbenzamide diethyl acetal. Heating of the two components results in the formation of **1b** in 30% yield. The succinylbenzamidine **2** (35%,



m.p. = 160–161 °C) can be isolated from the mother liquor and converted into **1b** in nearly quantitative yield by reaction with potassium *tert*-butoxide in tetrahydrofuran (THF) (overall yield ca. 60%; see Table 1 for UV/VIS data).

Treatment of the poorly soluble red diones **1** with tetraphosphorus decasulfide results in formation of the blue dithiones **3** (see Table 1). An alternative route to **3** consists in alkylation of **1** to give **4** (cf. Ref. [13]) followed by sulfurization of these more soluble compounds with Lawesson reagent to give the violet monothiones **5** (see Table 1) and the dithiones **6** (see Table 1). The preparation of **3** and **6** by reaction of compounds of the type **1** with sulfurization reagents has been independently described by a research group at Ciba-Geigy AG.[14] Debenzylation of **6be** with sodium in liquid ammonia also affords **3b**, although in varying yields (up to 35%).

The transformation of **1** and **3** into stable donor-acceptor-substituted 2,5-diazapentalenes **7** and **8** was achieved with chlorosilanes and with alkylation agents, respectively. 2,5-Diazapentalenes were previously unknown. Thus, reaction of the disodium salt of **1b** with *tert*-butyldimethylchlorosilane afforded the brown-red 1,4-bis(*tert*-butyldime-

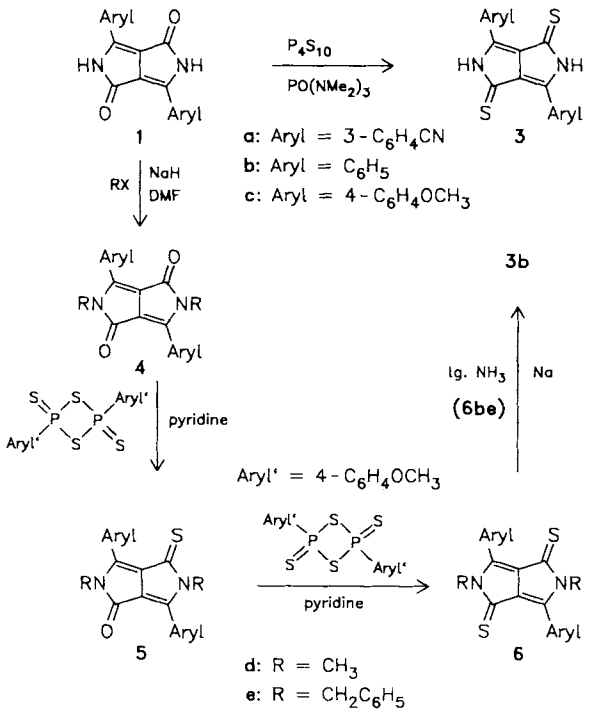
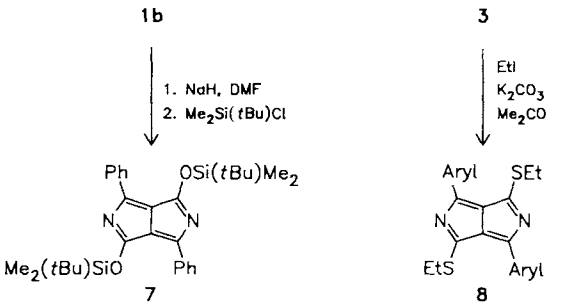
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (FRG)

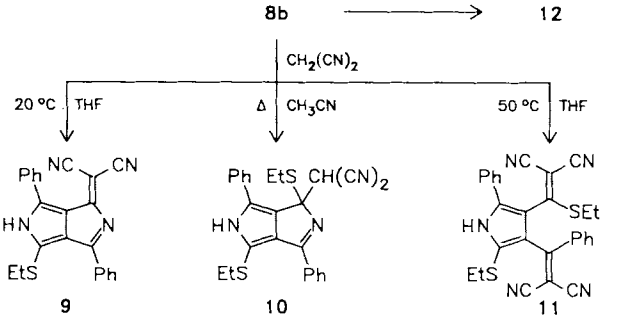
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.





goes decomposition upon treatment with acids or upon heating in polar solvents, **8c** can be protonated with tetrafluoroboric acid–ether and ethylated with triethyloxonium tetrafluoroborate. The substituents in the aryl moiety of **8** have little effect on the absorption spectra.

Although, as esters of thioimidic acid, the diazapentalenes **8** undergo nucleophilic substitution, their reactivity is not very great. Reaction of **8b** with sodium malonodinitrile at room temperature affords the yellow monosubstitution product **9**. Heating of **8b** with malonodinitrile in acetonitrile only leads to formation of the orange adduct **10**. When **8b** is heated to ca. 50 °C with sodium malonodinitrile, partial ring opening occurs, leading to formation of the pyrrole derivative **11** (orange needles, m.p. = 338 °C).



When **8b** is allowed to react in the melt with 2-aminobenzothiazole, the bright yellow compound **12** (see Table 1) is obtained, which exhibits yellow fluorescence in solution. This compound is presumably a pyrrolo[2′,3′:4,5]pyrimido[2,1-*b*]benzothiazole.

Ring opening, such as that observed in the formation of **11**, is also observed when **1b** is heated with a mixture of phosphorus oxychloride and phosphorus pentachloride in the presence of diethylaniline. Instead of the expected

thylsiloxy)-3,6-diphenylpyrrolo[3,4-*c*]pyrrole **7** (see Table 1) and reaction of **3** with ethyl iodide in potassium carbonate/acetone afforded the violet 1,4-diaryl-3,6-bis(ethylthio) derivative **8** (see Table 1). The stability of **8** is influenced by the substituents in the aryl moiety. Whereas **8a** under-

dichlorodiazapentalene, the violet azafulvene derivative **14** (see Table 1) is obtained, the formation of which can be formulated as shown. Nucleophilic substitution of the chlorine by pyrrolidine leads to formation of the green azafulvene **13** (85%).

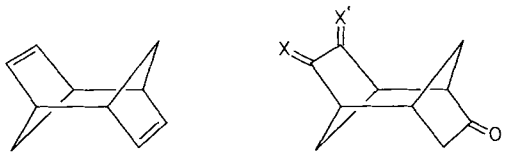
Diasterane (Tricyclo[3.1.1.1^{2,4}]octane)**

By *Andreas Otterbach* and *Hans Musso**

Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

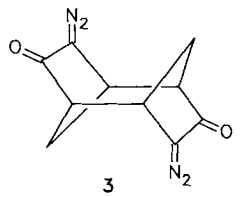
Diasterane **I**, the first member of the series of asteranes **I**, **II**,[1a] and **III**,[1b] has not been reported so far. In the asteranes, the axial hydrogen atoms at the bow and the stern of the boat-form cyclohexane structural moieties ("*endo*-1,4 H atoms") are in close proximity. Diasterane **I** should have a strain energy of 94 kcal/mol according to force-field calculations (MM 1).[2] The repulsion of ca. 5 kcal/mol of the *endo*-1,4 H atoms, forced by geometry to a distance of only 1.98 Å, is not sufficient to twist the molecule out of D_{2h} symmetry. The synthesis of **I** has been approached via various routes[3,4] in order to prove, among other things, that it is not formed upon hydrogenation of cubane **16**.[5] We have now succeeded in preparing diasterane **I** from tricyclo[4.2.1.1^{2,5}]decane **5** by two ring contractions.

I II III

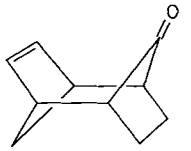


1

2a, X = O; X' = H, H
2b, X = H, H; X' = O



3



4

To do this twice in one step, the *anti*-diolefin **1**[6] was hydroborated. The two isomeric *exo*-3,7- and *exo*-3,8-diols were separated and oxidized with chromium trioxide in pyridine to the 3,7- and 3,8-diones **2**. However, the desired bis-diazoketone **3** could not be obtained. The deformylative diazo-group transfer reaction resulted only in the formation of a monodiazodiketone from **2** in poor yield. Other attempts to obtain the required bis-diazoketone **3** also failed. Furthermore, the diolefin **1** is not readily accessible in gram amounts by the method of *Grimme* et al.[6]

Therefore, the contraction of both rings was undertaken in two successive steps (Scheme 1). The tricyclic monoolefin **7** and the saturated hydrocarbon **5** were first synthesized by *Paquette* et al.[7] and *Ganter* et al.;[8] we have now prepared **5** by hydrogenation and Wolff-Kishner reduction of the unsaturated ketone **4**, obtained via the convenient route of *Zimmermann* and *Linder*.[9] The bromination of such hydrocarbons is unsatisfactory even under forced conditions.[7] However, the *exo*-bromide **6** could be obtained in 71% yield when **5** was photobrominated with deficient bromine in CCl_4 at 140°C and recycled. The direct Kornblum oxidation of **6** yielded at best 33% of ketone **9**. The main product was the olefin **7**, which could be obtained in better yield (87%) by elimination of HBr from **6** with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in dimethylformamide (DMF) at 150°C. Hydroboration of **7** to the *exo*-alcohol **8** (88%) and oxidation of **8** with dimethyl sulfoxide (DMSO) and oxalyl chloride provided ketone **9** in higher yield (97%). The conversion of **9** to the α-formyl derivative and subsequent reaction with tosyl azide yielded the diazoketone **10** (60%); photolysis and Wolff rearrangement at −150°C in methanol afforded the methyl ester of tricyclo[3.2.1.1^{2,4}]nonane-*endo*-3-carboxylic acid **11** in 51% yield, alkaline hydrolysis of which gave the *exo*-carboxylic acid **12** (90%). Decarboxylation of **12** to tricyclo[3.2.1.1^{2,4}]nonane **14**[10] was best achieved (82%) in one step by the method of *Barton* et al.[11] via free radical decarboxylation of the ester **13** in the presence of *t*BuSH as the source of hydrogen (82% yield, colorless crystals, m.p. = 109°C).

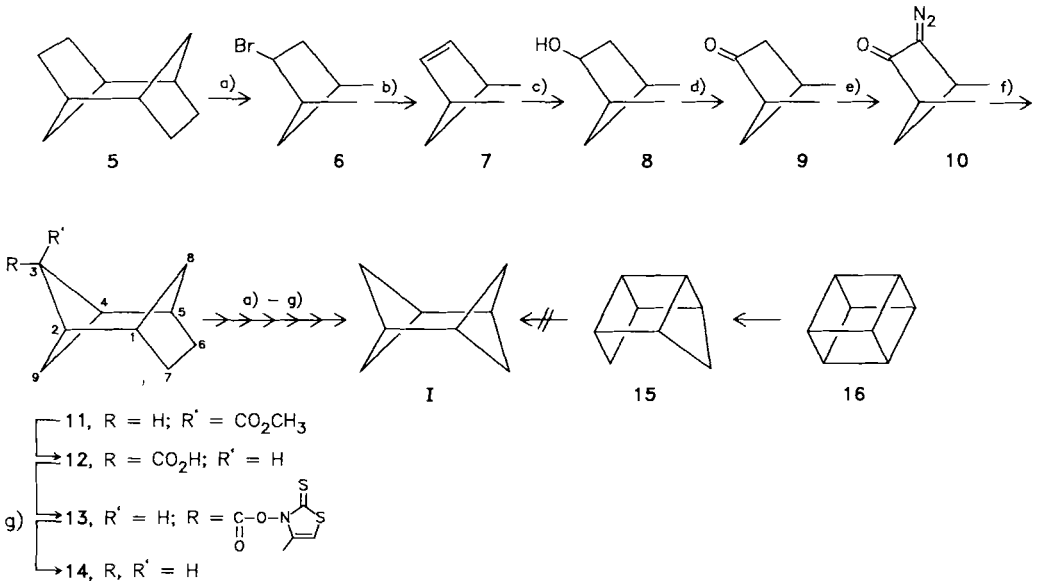
[**] Asteranes, Part 18. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank *A. Kuiper*, *P. Lang*, *I. Maier*, *I. Rossnagel*, *I. Süss*, and *U. Tanger* for numerous spectra, gas chromatograms, and elemental analyses and *U. Kasten* for experimental work.—Part 17: G. Kaiser, H. Musso, *Chem. Ber. 118* (1985) 2266.



Scheme 1. a) Br_2 in CCl_4, irradiated in glass ampoules at 140°C for 1 h with a Philips HPK 125-W Hg lamp; 71% **6** after GC separation and recycling of the recovered **5**. b) DBU in DMF, 150°C, 16 h, 87% **7**; same physical data as reported in [7]. c) B_2H_6 in tetrahydrofuran (THF), 0°C, 1 h, room temperature, 12 h, then NaOH and 30% H_2O_2, 35–40°C, 4 h, 88% **8**, m.p. = 108°C. d) **8** was added to oxalyl chloride in DMSO at −50°C; triethylamine was then added and the reaction mixture was warmed to room temperature. 97% **9**, m.p. = 158°C. e) Sodium hydride in THF, then ethyl formate, 14 h, room temperature, formylketone in THF with tosyl azide and triethylamine, 24 h room temperature, 60% **10** after chromatography. Yellow crystals, m.p. = 58°C (dec.). f) **10** → **12**: irradiated in methanol at −50°C with a medium-pressure Hg lamp (HPK, 125 W) for 5 h, 51% *endo*-ester **11**; in ethanol, KOH, 12 h, 80°C, 90% *exo*-acid **12**, m.p. = 131°C; irradiation in dioxane/water (4:1) at 5°C gave 44% of the *endo*-acid **11** (R' = CO_2H), m.p. = 164°C. g) **12** → **14**: 3-hydroxy-4-methylthiazole-2(3*H*)thione, 4-dimethylaminopyridine and dicyclohexyl carbodiimide (DCC) in CH_2Cl_2, quant. *exo*-ester **13**, m.p. = 109–110°C; *endo*-ester **13** (R, R' reversed), m.p. = 101°C. Reaction of both esters with *t*BuSH in refluxing benzene for 7 h followed by flash chromatography and GC gave 82% of **14**, m.p. = 109°C.

This reaction sequence was repeated starting with **14**: bromide (78%), olefin (77%), alcohol (84%), ketone (84%), diazoketone (ca. 14%). The diazoketone was photolyzed in aqueous dioxane at 0°C. The *endo*-acid, thereby obtained in 45% yield, was degraded analogously to **12** via the corresponding thiohydroxamate. Diasterane **I** could be isolated by preparative gas chromatography: 23%, colorless, readily sublimable crystals (m.p. = 96–97°C, sealed capillary).[10]

The repulsive interaction of the *endo*-1,4 H atoms mentioned in the beginning is revealed in the ^{1}H-NMR signal at $\delta = 2.55$, which is shifted downfield beyond the signal of the bridgehead protons ($\delta = 2.45$). The corresponding signals of the hydrocarbons **5** ($\delta = 1.80$) and **14** ($\delta = 2.27$) exhibit significantly smaller downfield shifts. The long retention time upon gas-chromatographic separation is unexpected: $R_r = 1.065$ relative to cubane **16** ($R_r = 1.00$), whose hydrogenation products all come faster than seco cubane **15** ($R_r = 0.763$) on a 1G20 column at 40°C.

β-Glycosylation in 2-Deoxysaccharides: Convergent Syntheses of the Oligosaccharides of Mithramycin**

By *Joachim Thiem** and *Bernhard Schöttmer*

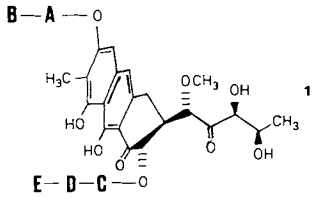
Dedicated to Professor Hans Paulsen on the occasion of his 65th birthday

The cytostatic agent mithramycin **1**, which belongs to the class of aureolic acids and is highly glycosylated with oligosaccharides,[1] exhibits exclusively β-glycosidic bonds between the D-arabino and D-lyxo sugar components **A** and **B**, respectively, and between the sugars in the trisaccharide **E**–**D**–**C**, which have D-ribo, D-arabino, and D-ara-

[*] Prof. Dr. J. Thiem, Dipl.-Chem. B. Schöttmer
Organisch-Chemisches Institut der Universität
Wilhelm-Klemm-Strasse 4, D-4400 Münster (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

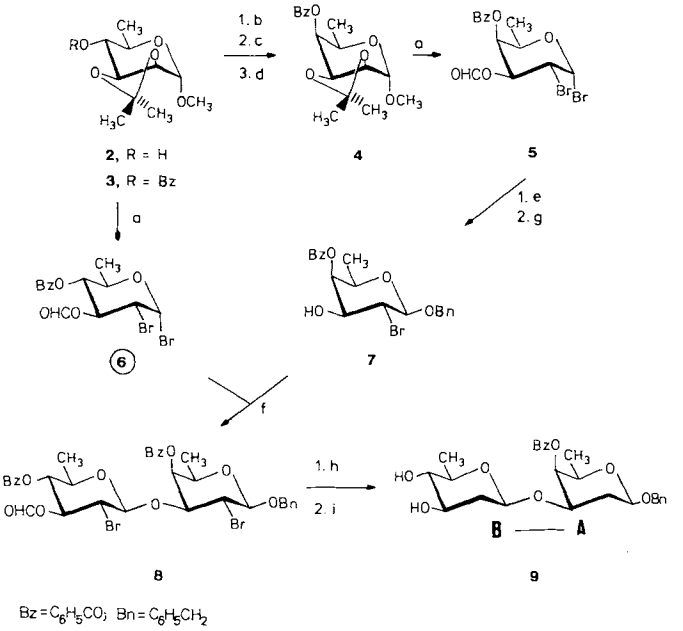
bino configurations, respectively, as well as between the sugar components and the aglycone.[2]



Whereas the α-glycosylated deoxyoligosaccharides are conveniently synthesized according to the *N*-iodosuccinimide (NIS) procedure,[3] and the problem of their synthesis may thus be regarded as having been solved,[4] this method has been applied with only moderate success to the β anomers.[5] In contrast, 2-bromo-2-deoxyglycosyl bromides, which are readily accessible according to the dibromomethyl methyl ether (DBE) procedure, can be favorably used for the β-glycosylation of even complex aglycones.[6]

The methyl rhamnoside **2**, which is accessible in only a few steps from mannose, can be oxidized to the 4-uloside with pyridinium dichromate (b, 62%). The product is stereospecifically reduced (c, 82%) and then benzoylated (d, 82%) to give the pure, crystalline D-talo compound **4**.[7] Reaction with dibromomethyl methyl ether and zinc bromide as catalyst (a, 70%) affords the highly reactive 2-bromo-2-deoxygalactosyl bromide **5**,[7] which can be selectively glycosylated to give the β-galactoside by reaction with benzyl alcohol in the presence of silver carbonate as catalyst at −20°C (e, 58%). Acid cleavage of the 3-formyloxy group (g, 80%) in the following step gives the alcohol component **7**.[7] Similarly, the benzoate **3** can be converted into the gluco-configurated bromide **6**[6c] by reaction with DBE (a, 89%), glycosylated (e, 72%), and selectively transformed into the partially esterified alcohol derivative **10**[6b] (g, 91%) (see Scheme 2).

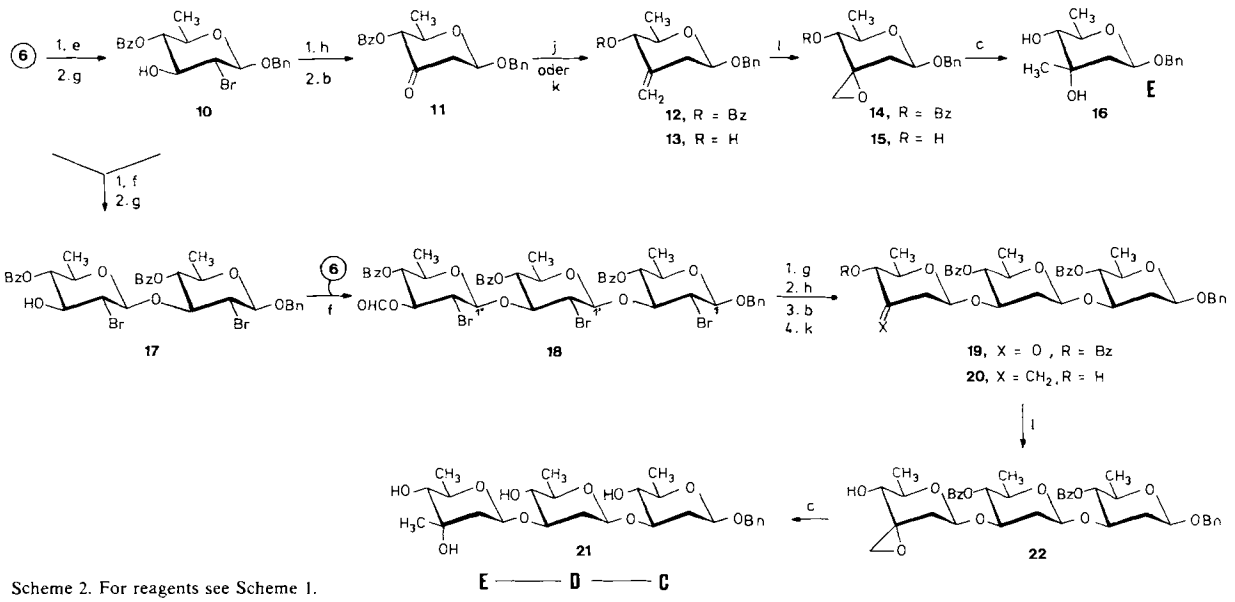
Silver triflate can be used for the glycosylation of the gluco bromide **6** with the galacto alcohol **7** (f, 56%); mainly the (1→3) β-linked disaccharide **8**[7] is formed (β:α = 3:1). Reductive dehalogenation with tributyltin hydride (h, 76%) followed by alkaline treatment with sodium methoxide (i, 78%) results in formation of the **B**-**A** disaccharide fragment of **1** as the glycoside **9**.[7]



Bz = C_6H_5CO; Bn = $C_6H_5CH_2$

Scheme 1. a) $Br_2CHOCH_3/ZnBr_2$; b) $(C_5H_6N)_2Cr_2O_7/CH_3CO_2H/CH_2Cl_2$; c) $LiAlH_4$; d) C_6H_5COCl/C_5H_5N; e) $C_6H_5CH_2OH/Ag_2CO_3$; f) $AgOSO_2CF_3$; g) H_3COH/HCl; h) $(C_4H_9)_3SnH$; i) H_3CONa; j) $(C_6H_5)_3P{=}CH_2$; k) $(H_3C)_3SiCH_2MgCl$; l) *m*-Cl–C_6H_4–CO_3H.

A novel approach to the synthesis of the **E**-**D**-**C** trisaccharide with only (1→3) β-interglycosidic bonds was elaborated starting from the glycosyl bromide building block **6**. Condensation of **6** with the alcohol component **10** (f, 92%) gives a (1→3) β-linked disaccharide,[6c] which reacts, under acid catalysis (g, 90%) to give the crystalline derivative **17**.[8] Silver triflate-promoted glycosylation (f, 69%) with **6** then leads to the protected trisaccharide **18**[8] with a β:α ratio of 10:1. After selective deblocking (g, 80%) at the 3″ position, complete reductive debromination at the 2, 2′ and 2″ positions (h, 92%), and oxidation (b, 75%), the



Scheme 2. For reagents see Scheme 1.

trisaccharide-3″-uloside **19**[8] is obtained, which, upon normal methyl branching reactions (MeLi, MeMgCl), gives the wrong, namely the D-arabino-configurated, terminal component (cf. [8]).

Thus, a controlled branching reaction was necessary, which was first worked out for the monosaccharide. Reductive debromination (h, 91%) of **10** and subsequent oxidation (b, 75%) affords the deoxygenated 3-uloside **11**.[8b] The methylene group can be introduced either by Wittig reaction (j, 64%) to give **12**[7] or by Peterson olefination (k, 46%) to give the derivative **13**.[7] All attempts to carry out a Sharpless epoxidation[9a] of the exocyclic allylic alcohol system of **13** were unsuccessful.[9b] Apparently, the chiral elements in the saccharide derivatives **12** and **13** already direct the epoxidation with *m*-chloroperbenzoic acid (l, 83%) completely stereospecifically to give the (3*R*)-configurated epoxides **14**[7] and **15**, respectively. Reductive opening of the epoxide results (c, 75%) in exclusive formation of the 3-*C*-methyl-branched and D-ribo-configurated glycoside **16**,[8] the *E* building block.

Whereas the Wittig olefination was unsuccessful in the case of the trisaccharide-uloside **19**, the Peterson reaction (k, 25%) gave a moderate yield of the exocyclic 3″ olefin **20**.[7] Reaction of **20** with peracid (l, 65%) leads to exclusive, stereospecific formation of the epoxide **22**,[7] which, after reductive opening (c, 68%), gives the **E**–**D**–**C** trisaccharide component **21**[7] of **1**. Comparison of the ^{1}H-NMR spectra of **21** and the trisaccharide having a terminal 3-*C*-methyl-branched D-arabino building block,[8] as well as NOE measurements, confirms the structure of **21**.

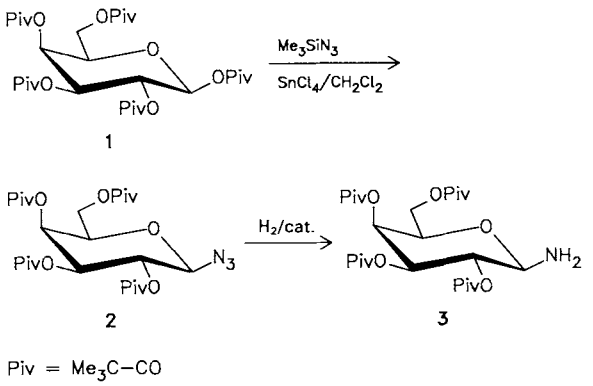
Diastereoselective Strecker Synthesis of α-Aminonitriles on Carbohydrate Templates**

By *Horst Kunz** and *Wilfried Sager*

Dedicated to Professor Hans Paulsen on the occasion of his 65th birthday

Chiral amino acids are of great biological and economic importance. This is also true of the nonproteogenic (*R*) enantiomers, which are found as components of many microbial products, in particular antibiotics. The diastereoselective syntheses of amino acids[1] are usually carried out via organometallic intermediates: for example, the approach via metalated bislactim ethers of cyclic dipeptides.[2] Besides the isolation from protein hydrolysates and the enzymatic reactions,[3] the Strecker synthesis is interesting from an economic viewpoint and has already been performed diastereoselectively with 1-phenylethylamine[4–6] and with (4*S*,5*S*)-5-amino-2,2-dimethyl-4-phenyl-1,3-dioxane.[7] Optical inductions of 50–75% were achieved.[5] The very high inductions (98% *de*) obtained in one case[8] proved to be a consequence of fractionations.[4] Highly enriched or even pure diastereomers are obtained only when one of the diastereomers precipitates out.[9, 10] This applies to the *N*-4-phenyl-1,3-dioxan-5-yl-substituted α-methyl-α-aminonitriles.[7]

Using the concept that the chirality of the carbohydrates can be exploited for diastereoselective reactions,[11] we have now developed a Strecker synthesis with glycosyl amines as chiral auxiliaries.[12] The 2,3,4,6-tetra-*O*-pivaloyl-β-D-galactopyranosylamine **3** proved to be especially effective. It can be obtained from penta-*O*-pivaloyl-β-D-galactopyranose **1** by reaction with trimethylsilyl azide/tin tetrachloride[13] to give the galactosyl azide **2** followed by its hydrogenation.[12, 14]



N-Glycosylaminonitriles are formed in high yields from aldehydes, sodium cyanide, and glacial acetic acid in 2-propanol, the (α*R*) diastereomers[15] being favored in a ratio of 5:1. However, reaction times of two weeks are necessary. This results in partial anomerization, presumably at the stage of the Schiff base intermediate, giving up to 20% of the α-configurated glycosylaminonitriles. The long reaction times can be avoided and the anomerization largely suppressed by first synthesizing the Schiff bases **4** from **3** and the respective aldehyde in 2-propanol or heptane in the presence of acetic acid. The aldimines **4**, formed in

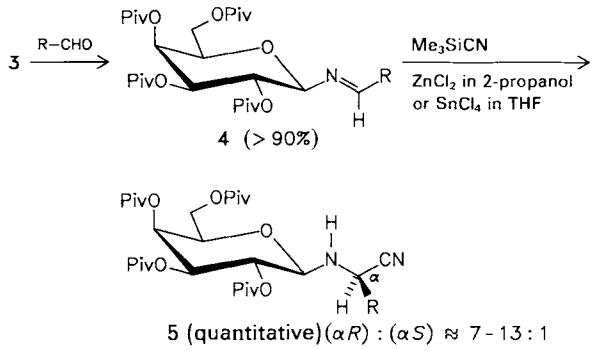
[**] This work was supported by the Fonds der Chemischen Industrie.

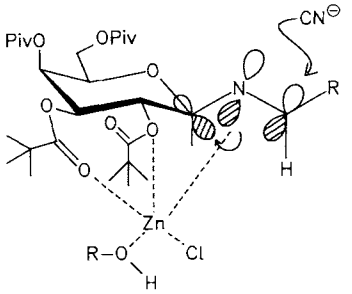
high yields, react with trimethylsilyl cyanide[5, 16, 17] in the presence of zinc chloride in 2-propanol or tin tetrachloride in tetrahydrofuran (THF) to give nearly quantitative yields of the corresponding *N*-glycosyl-α-aminonitriles **5** (Scheme 1).



Scheme 1.

The reactions are complete after only a few minutes at room temperature and in the presence of equimolar amounts of Lewis acids as catalysts. At lower concentrations of catalyst (5 mol%), they require about 12 h. The (α*R*) diastereomers **5** are preferentially formed in a ratio of about 7 : 1. At lower temperatures and corresponding longer reaction times, the diastereoselectivity can be increased to more than 10 : 1. The ratios of diastereomers were determined by analytical HPLC (diode array detector 190–370 nm) and 400-MHz ^{1}H-NMR spectroscopy for the quantitatively produced mixture of products obtained by hydrolysis. The results of the two methods are in agreement. The HPLC chromatograms reveal that the α-anomeric α-aminonitriles are only formed in trace amounts or at most in amounts of up to 5%. The results of the diastereoselective Strecker synthesis are shown in Table 1. Recrystallizing once from heptane affords the (α*R*) diastereomers of the *N*-glycosyl-α-aminonitriles **5**, which are pure by elemental analysis and NMR spectroscopy, in yields of between 75 and 90%.

We ascribe the high selectivity of this Strecker reaction to steric and stereoelectronic effects arising from the carbohydrate. Charge transfer from the C=N π orbital into the σ* orbital of the ring C–O bond favors the conformation **A** for the Schiff base **4**. Conformation **A** is confirmed by a strong NOE in the ^{1}H-NMR spectrum between H-1 and the proton introduced by the aldehyde. Because of the large axial substituent at C-4, the Lewis acids presumably complex and attack the aldimines **4** in the conformation **A** from below. This is revealed in the ^{1}H-NMR spectrum of the complex by a pronounced broadening of the signals of the axial protons H-1, H-3, and H-5, which project below the ring. The cyanide generated from the silyl cyanide in the polar solution can then approach from the opposite, free side, i.e., from the side of the ring oxygen, resulting in preferential formation of the (α*R*) diastereomer. We conclude from this hypothesis that it should be possible, by suitably changing the reaction conditions, to reverse the sense of induction. Preliminary experiments substantiate this conclusion.[18]



A

Interesting chiral products can be prepared from the (α*R*)-*N*-glycosyl-α-aminonitriles **5**, which are thereby selectively formed in high yields. For example, acid hydrolysis yields D-amino acids such as **6**. These do not contain the L enantiomers according to thin layer chromatography on "Chiral plate."[19] The measured optical rotations are also in agreement with reported values.[20] After hydrolysis, the pivaloylated galactose moieties can be recovered to a large extent (70–90%) by extraction with dichloromethane.

According to the procedure described here, enantiomerically pure D-amino acids and their derivatives are thus available by using inexpensive carbohydrate templates to

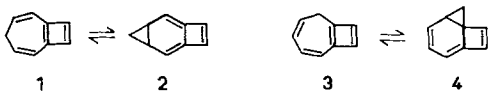
Synthesis of Tricyclo[5.2.0.0^{1,3}]nona-4,6,8-triene, a Norcaradiene Structure Constrained by the Antiaromaticity of Cyclobutadiene

By *Takeshi Kawase, Masahiko Iyoda,* and *Masaji Oda**

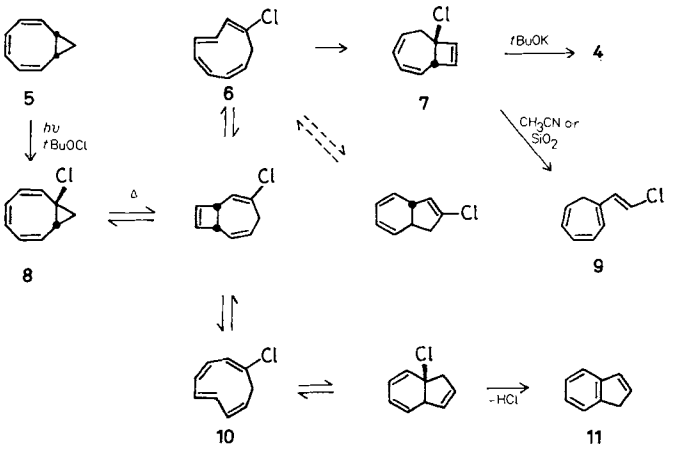
Cycloheptatriene–norcaradiene tautomerism has long attracted the attention of organic chemists.[1] Although cycloheptatriene itself is thermodynamically more stable than norcaradiene by about 4 kcal mol^{-1},[2] the tautomeric equilibrium is sensitive to the steric and electronic effects of substituents. *Klärner* and co-workers have shown that the derivatives of 5*H*-cyclobutacycloheptene **1** exist exclusively in the norcaradiene form **2** owing to the strong antiaromaticity of cyclobutadiene.[3] However, no synthesis of the 3*H*-isomer **3** or its tautomer **4** has been described.

[*] Prof. Dr. M. Oda, Dr. M. Iyoda, Dr. T. Kawase
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

We wish to report here the synthesis of tricyclo[5.2.0.0^{1,3}]nona-4,6,8-triene **4**, involving a novel thermal rearrangement of 1-chlorobicyclo[6.1.0]nona-2,4,6-triene **8**.



Photochemical chlorination of *cis*-bicyclo[6.1.0]nona-2,4,6-triene **5** with *tert*-butyl hypochlorite (1.5 equivalents) in rather concentrated CCl_4 solution (ca. 0.8 M) at −30 °C gave **8** in 50–70% yield after chromatographic purification (SiO_2, pentane, 0 °C). Although **8** (Table 1) is fairly stable below 0 °C, it underwent thermal rearrangement around and above room temperature in nonpolar solvents to give *cis*-7-chlorobicyclo[5.2.0]nona-2,4,8-triene **7** and indene **11** in an almost constant ratio of 7:3.[4] In a polar solvent (CH_3CN) or on adsorption to silica gel, **7** further rearranged to 1-[(*E*)-2-chlorovinyl]cycloheptatriene **9**.[5,6] Scheme 1 explains these rearrangements based on the results of trapping experiments and reported mechanistic pathways.[7,8] Notably, **7**, although its formation is symmetry allowed, is a new type of product that has not been previously observed in the extensively studied thermal rearrangement of bicyclo[6.1.0]nona-2,4,6-trienes.[8] The chlorine atom seems to play a role in changing the thermodynamics of these rearrangements.



Scheme 1.

Having **7** in hand, we expected it to be a good precursor for **3** or **4**, even though the lability of **7** made its isolation in pure form difficult. Treatment of a mixture of **7** and **11** with *t*BuOK (1.5 equivalents) in tetrahydrofuran under air at room temperature gave **4** as sole hydrocarbon product in about 50% yield (from **8**). The presence of oxygen is advantageous for destroying indene through oxidation of the indenide ion. Compound **4** can be formed in principle either by direct 1,7-elimination of hydrogen chloride or by 1,2-elimination followed by valence isomerization; however, the former process seems more likely since the reluctant 1,2-elimination would result in the formation of a cyclobutadiene.[9]

The norcaradiene **4** tended to decompose giving oligomeric substances on removal of solvents. A fairly clean solution for NMR spectra could be obtained, however, by

column chromatography on silica gel at $-20°C$ (pentane elution) followed by careful replacement of the solvent with CCl_4 or C_6D_6. ^1H- and ^{13}C-NMR spectra (Table 1) of the solutions thus obtained are in accord with the norcaradiene structure of **4** without any indication of equilibration with the cycloheptatriene **3**.

Table 1. Physical data for the compounds **4**, **7**, **8**, **12**, and **13**. *J* in Hz.

4: ^1H-NMR (100 MHz, C_6D_6, 4°C): $\delta = 0.91$ (t, $J = 3.5$; H-2_{endo}), 1.32 (dd, $J = 8.5, 3.5$; H-2_{exo}), 1.82 (ddd, $J = 8.5, 4.0, 3.5$; H-3), 5.20 (d, $J = 5.5$; H-6), 5.53 (dd, $J = 9.5, 5.5$; H-5), 5.92 (dd, $J = 9.5, 4.0$; H-4), 6.21 (d, $J = 2.5$; H-9), 6.73 (d, $J = 2.5$; H-8); ^{13}C-NMR ($CDCl_3$): $\delta = 13.8$ (C-2), 21.6 (C-3), 42.8 (C-1), 104.5 (C-6), 121.7, 124.1 (C-4, 5), 132.6, 138.6 (C-8, 9), 152.6 (C-7)

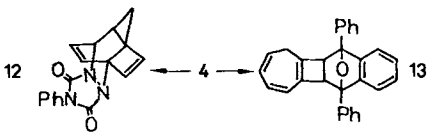
7: ^1H-NMR ($CDCl_3$): $\delta = 2.60$ (2H, m), 3.67 (1H, m), 5.8–6.2 (6H, m); Diels–Alder adduct with 4-phenyl-1,2,4-triazole-3,5-dione: m.p. = 146°C; ^1H-NMR (C_6D_6): $\delta = 2.11$ (1H, dd, $J = 15.5, 3.3$), 2.62 (1H, dd, $J = 15.5, 3.9$), 3.09 (1H, d, $J = 4.5$), 4.52 (2H, m), 5.55 (2H, m), 5.72 (1H, dd, $J = 2.7, 1.0$), 5.81 (1H, dd, $J = 2.7, 1.0$), 6.9–7.3 (3H, m), 7.70 (2H, m)

8: ^1H-NMR ($CDCl_3$, $-30°C$): $\delta = 0.78$ (1H, dd, $J = 7.5, 5.5$), 1.45 (1H, dd, $J = 10.5, 5.5$), 2.09 (1H, br. dd, $J = 10.5, 7.5$), 5.73 (1H, dd, $J = 11.0, 1.5$), 5.8–6.4 (5H, m); MS: *m/z* 153, 151 ($M^{\oplus}$), 117 (46%), 115 (100%); UV (cyclohexane): $\lambda_{max} = 245$ nm ($\varepsilon = 3200$)

12: m.p. = 150°C (dec.); ^1H-NMR ($CDCl_3$): $\delta = 0.48$ (1H, dd, $J = 6.1, 2.2$), 0.84 (1H, dd, $J = 7.2, 6.1$), 2.40 (1H, ddd, $J = 7.2, 4.5, 2.2$), 5.14 (1H, ddd, $J = 6.0, 4.5, 1.0$), 6.00 (1H, dd, $J = 7.9, 6.0$), 6.38 (1H, dd, $J = 7.9, 1.0$), 6.68 (1H, d, $J = 2.4$), 6.86 (1H, d, $J = 2.4$), 7.1–7.5 (5H, m)

13: m.p. = 195°C; ^1H-NMR ($CDCl_3$): $\delta = 2.48$ (2H, d, $J = 5.5$), 3.37 (2H, m), 4.97 (1H, dt, $J = 10.0, 5.5$), 5.6–6.0 (3H, m), 7.0–7.8 (14H, m); UV (cyclohexane): $\lambda_{max} = 269$ nm ($\varepsilon = 4350$), 275 (4800), 298 (4000)

Reaction of **4** with 4-phenyl-1,2,4-triazole-3,5-dione gave the Diels–Alder adduct **12** (yield 60%),[10] whereas reaction with 1,3-diphenylisobenzofuran gave the adduct **13** (33%) (both at room temperature). The adduct **13** can be formed through either an addition–tautomerization or a tautomerization–addition (i.e., via **3**) process. Since no dimers of **3** were detected during decomposition of **4**, the addition–tautomerization process is more likely.



Thus, the large antiaromatic destabilization of cyclobutadiene forces **3**, like **1**,[3] to tautomerize to **4** despite the accompanying increase in strain.

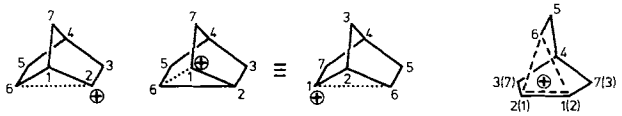
Crystal Structure Analysis of the 1,2,4,7-*anti*-Tetramethyl-2-norbornyl Cation: an Unsymmetrically Bridged Carbocation**

By *Thomas Laube**

Since the discovery by *Meerwein* and *van Emster*[1] that carbocations can occur as intermediates in solvolysis reactions, these ions have been the subject of many investigations because of the numerous, usually very rapid rearrangements they undergo. The 2-norbornyl cation **1** has come to occupy a position of central importance in physical and organic chemistry; the question whether this ion, even at very low temperatures, exists as a pair of rapidly equilibrating, unsymmetrical ions, **1** and **1'** (both of which



are unsymmetrically bridged according to the present state of knowledge; i.e., they exhibit weak C2–C6 and C1–C6 bonding, respectively) or as a symmetrically bridged ion **1''** having a plane of symmetry is extremely difficult to answer and has been approached by many methods[2] (NMR spectroscopy in liquid[2b] and solid[2c] phase, mass spectrometry,[2d] and ESCA,[2e] as well as solvolytic,[2f] thermochemical,[2g] and theoretical[2h] investigations). Of the more than 100 known substituted 2-norbornyl cations, the 1,2-dimethyl-substituted derivative **2** is particularly important[3] owing to its structural similarity to **1** and has been used as a model ("minimal perturbation introduced by the methyl groups"[4a]), even though **2** unquestionably exists as a pair of equilibrating, unsymmetrical ions.[4] Up to now, no crystal structure analysis of a 2-norbornyl cation or indeed of any bridged carbocation has been reported; there are only two reports providing evidence for the existence of crystalline 2-norbornyl salts.[2c,5] The reasons are the low thermal stability of many 2-norbornyl salts and their pronounced tendency to form plastic crystals.[6] After many unsuccessful attempts,[7] we have now succeeded in determining the crystal structure of the 1,2,4,7-*anti*-tetramethyl-2-norbornyl cation **3** (as the salt **3**-Sb_2F_{11}).

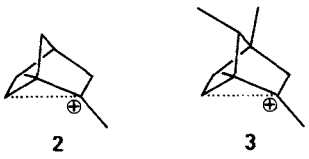
[**] I thank Prof. Dr. *D. Seebach* for financial support, Prof. Dr. *J. D. Dunitz* for providing me with measuring time, and Prof. Dr. *P. von R. Schleyer* (Universität Erlangen-Nürnberg) for numerous suggestions in the discussion of the results. I would like to especially thank *Thomas Blatter* for carrying out numerous syntheses and *Paul Seiler* for assistance in carrying out the measurements.



2 3

In order to synthesize this salt, isofenchone **4**[8] was converted into the fluoronorbornane **5**,[9] which, upon treatment with antimony pentafluoride,[10] underwent fluoride abstraction. The intention was to use a salt of the 1,2,5,5-tetramethyl-2-norbornyl cation **6**, which has a plane of symmetry in the transition state of the Wagner-Meerwein rearrangement, for the structure elucidation; the crystal structure analysis established,[11] however, that the crystalline compound was **3**-Sb_2F_{11}.[12]

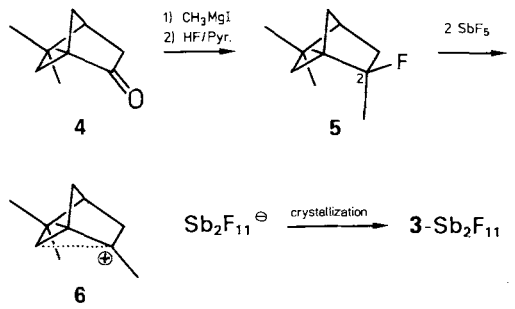


Figure 1 shows that the crystal consists of discrete cations and anions, neither of which exhibit symmetry. The shortest $C^{\delta+}\cdots F$ distances (C1···F15 3.28(1), C2···F15 3.27(1) Å) are probably longer than those in the trimethyladamantyl cation because of the (unsymmetrical) delocalization of the positive charge over C1 and C2 and because of several F···H van der Waals contacts.[13,14] A case of unsymmetrical σ-participation is evident in cation **3** (see Table 1). The formerly single bond C1-C6 is weakened by donating electron density to the electron-deficient center C2 and thereby lengthened to 1.74(2) Å. This increases the electron density in the bond C1-C2, which is thereby shortened to 1.44(2) Å. The angle C2-C1-C6 (81.6(8)°) and the distance C2-C6 (2.09(2) Å) also reflect the bridging between C2 and C6 (for comparison, in norbornane (see also Fig. 2) the distances C1-C6 and C1-C2 are 1.544 Å, the angle C2-C1-C6 is 108.2°, and the distance C2-C6 is 2.501 Å). The atom C2 exhibits nearly planar coordination, whereas C1 exhibits a pyramidalization of 0.23 Å (the partial bonds to C6 being ignored in each case); this finding is also in agreement with the assumption that the larger partial charge is on C2 and the smaller on C1 (the partial charge on C6 should be considerably smaller since a primary cationic center at C6 appears in the corresponding resonance formula). The Wagner-Meerwein rearrangement (analogous to **1** → **1'**) is thus indicated in the structure. The conformation of **3** is, at the same time, also stereoelectronically optimal for the two other rearrangements in 2-norbornyl cations, the 6,2-*endo*- and the 3,2-*exo*-hydride shift.[15] The bond of the *endo*-proton H62 to C6 forms a torsion angle of ca. +26° with the upward pointing part of the symmetry axis of the "empty" p orbital[16] at C2, and the bond of the *exo*-proton H31 to C3 forms a torsion angle of ca. +14° with the downward pointing part of the p symmetry axis at C2 (these torsion angles are only approximate values since they refer to calculated hydrogen positions).

The geometry of the skeleton of **3**, which significantly differs from the geometry of the norbornane skeleton (see

Table 1. The most important structure data of **3**-Sb_2F_{11} (distances in Å, angles and torsion angles in °; standard deviations (in parentheses) refer to the last decimal place given). The planes P*i* are formed by the following atoms: P*1*, C2,C7,C*11*; P2, C*1*,C3,C*21*; *P3*, C*1*,C2,C3,C7,C*11*,C*21*. pC*i* is a point on the direction vector of the p-like orbital on the threefold coordinated atom C*i* [16]; ′ means the symmetry operations 1−x, −0.5+y, 1.5−z.

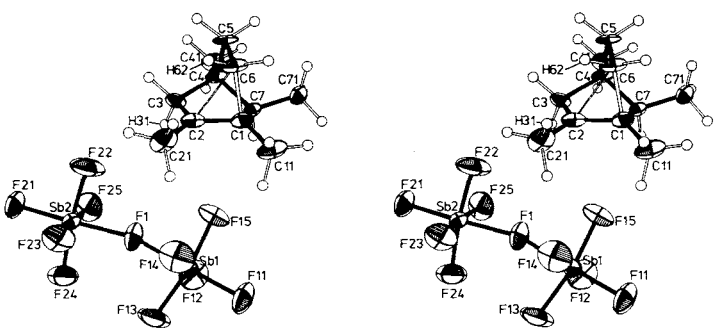

Fig. 1. Stereodrawing (ORTEP) of the crystal structure of 3-Sb_2F_{11}. The ellipsoids of thermal vibration are drawn at the 50% level. The ion pair shown forms the asymmetric unit.

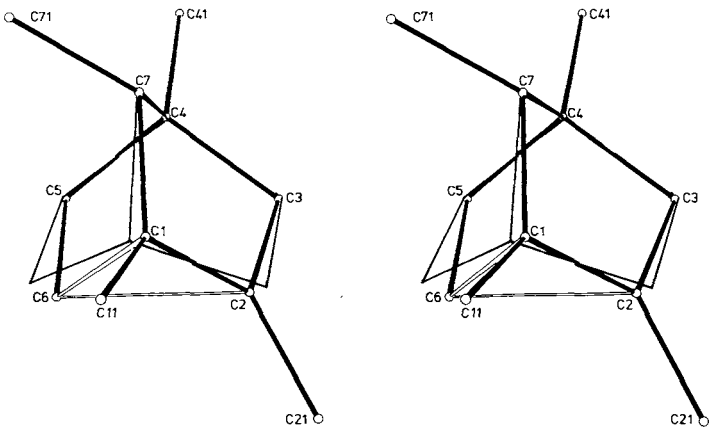

Fig. 2. Stereodrawing of superimposed skeletons of the cation **3** (atoms drawn as spheres; bonds drawn as thick lines) and norbornane [17] (bonds drawn as thin lines). The atoms C3, C4, C5, and C7 were fitted with a hundredfold weighting compared with C1, C2, and C6.

Fig. 2), is more similar to the geometry[18] calculated for the symmetrical 2-norbornyl cation **1''** (although significant differences still exist[19]). This is an unexpected finding, since a tertiary cation is transformed into a tertiary cation in the Wagner–Meerwein rearrangement of **3** (or **2**), both of which are much more stable than secondary cations and therefore should not exhibit the same tendency as the latter to engage in charge delocalization through bridging. Thus, the structural data establish that the skeleton of 2-norbornyl cations generally favors bridging.[20]

Overall, the results of the crystal structure analysis of **3** are in agreement with the results obtained earlier by other methods[4] for the rapidly equilibrating, partially σ-delocalized ion **2**.

[7] The following salts were prepared, but they proved to be noncrystalline, microcrystalline, plastically crystalline, or twinned (nb = 2-norbornyl): nb-Sb_2F_{11}, 2-methyl-nb-Sb_2F_{11}, 2-methyl-nb-$SbCl_6$, 2-phenyl-nb-Sb_2F_{11}, 2-phenyl-nb-$SbCl_6$, 2-phenyl-nb-SbF_6, 1,2-dimethyl-nb-Sb_2F_{11}, 1-methyl-2-ethyl-nb-Sb_2F_{11}, 1-methyl-2-propyl-nb-Sb_2F_{11}, 1,2,4-trimethyl-nb-Sb_2F_{11}, 1,2,4-trimethyl-nb-SbF_6.

[8] Synthesized as a (−)-fenchone/(+)-isofenchone mixture (≈1:1; J. M. Coxon, P. J. Steel, *Aust. J. Chem. 32* (1979) 2441) from (+)-fenchol (FLUKA) by tosylation, formolysis, and oxidation and isolated as a ca. 1°-higher-boiling component of the mixture by using a Spaltrohr® column (Fischer Labor- und Verfahrenstechnik AG; reflux ratio 250:1 to 500:1, ca. 90 theoretical plates) (**4**, 56% *ee*; isolated fenchone, 71% *ee*). For reasons of simplicity, **4** is drawn as (−)-isofenchone; racemization begins at the very latest after the generation of **6**.

[9] Mixture of the C2 epimers. Synthesized from **4** by reaction twice with CH_3MgI (in order to drive the reaction to completion) followed by fluorination with HF/pyridine at 0°C (G. A. Olah, J. T. Welch, Y. D. Vankar, M. Nojima, I. Kerekes, J. A. Olah, *J. Org. Chem. 44* (1979) 3872). The thermally labile product **5** was isolated as a colorless oil after quick aqueous workup at 0°C and distillation under high vacuum at room temperature (cold trap to cold trap) and stored under argon on dry ice. The 300-MHz ^{1}H-NMR spectrum already indicates the presence of small amounts of isomers.

[10] In a Freon mixture at −80°C. After 30 min of reaction, the salt was separated from the yellow suspension by filtration and then dried under high vacuum at −60°C. In order to carry out the recrystallization, a solution of the crude product in CH_2Cl_2 was allowed to stand for ca. 24 h at −78°C. After removal of the mother liquor and washing, the yellow crystals were dried under high vacuum. Suitable crystals were selected under the microscope and mounted in glass capillaries, which, after sealing, were immediately mounted in the diffractometer. (At no point were the crystals warmer than −60°C.)

[11] Enraf-Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, measuring temperature −80°C; space group $P2_1/c$, $a = 11.369(9)$, $b = 10.662(9)$, $c = 15.023(7)$ Å, $\beta = 94.88(5)°$, $V = 1814.4$ Å^3, $\rho_{calcd} = 2.210$ g·cm^{-3}, $\mu = 30.9$ cm^{-1} (no absorption correction), $Z = 4$, 3940 measured reflections ($\theta < 27°$), 2419 of which with $I > 3\cdot\sigma(I)$. Because of difficulties in fixing the crystal in the glass capillaries, the orientation had to be checked with four control reflections after every 50 reflections; during the measurement, 20 reorientations were carried out. Position of the Sb atom determined with the Patterson option of SHELX84, all other atoms except for hydrogen by subsequent difference Fourier synthesis with SHELX76. After anisotropic refinement of the non-hydrogen atoms, some of the H atoms could be localized by difference Fourier synthesis; for further refinement, however, the H-atom positions were calculated and the H temperature factors were refined using a riding model. The non-hydrogen atoms were refined once again in the XRAY system, first with unit weights, and finally with $w = 1/\sigma(I)^2$: $R = 8.0\%$, $R_w = 9.4\%$. Further details of the crystal structure investigation are available on request from the director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), on quoting the name of the author and the journal citation.

[12] The course of the isomerization **6** → **3** was not investigated in more detail. It is known, however, that the 2,5,5-trimethyl-2-norbornyl cation mainly undergoes rearrangement in superacid medium at −92°C to give an equilibrium mixture consisting of the 1,2,3-*endo*- and the 1,2,7-*anti*-trimethyl-2-norbornyl cation (a "Wagner–Meerwein pair"), which undergoes further rearrangement at −15°C to give the 1,2,4-trimethyl-2-norbornyl cation before it can react further at higher temperatures to give a substituted cyclohexenyl cation by ring opening (E. Huang, K. Ranganayakulu, T. S. Sorensen, *J. Am. Chem. Soc. 94* (1972) 1779). The formation of **3** from the 1,2,3,3- or the 1,2,7,7-tetramethyl-2-norbornyl cation is discussed in: L. Huang, K. Ranganayakulu, T. S. Sorensen, *ibid. 95* (1973) 1936. The shortest possible route of isomerization **6** → **3** was determined by means of a computer program and consists of five steps: 6,2-*endo*-H shift/3,2-*exo*-CH_3 shift/Wagner–Meerwein rearrangement/6,2-*endo*-H shift/3,2-*exo*-H shift. A similar program is described in: C. K. Johnson, C. J. Collins, *ibid. 96* (1974) 2514. (The ion **6** can racemize via a Wagner–Meerwein rearrangement, the ion **3** via the sequence Wagner–Meerwein rearrangement/3,2-*exo*-H shift/Wagner–Meerwein rearrangement.)

[14] Noteworthy is the practically symmetrical orientation of F15 with respect to the partial double bond C1–C2. The next smallest distance $C^{\delta+}\cdots F$ ($C2\cdots F21'$; see Table 1) is 3.64(1) Å. The contacts from F15 to C1 and C2 and from F21' to C2 reflect the situation for an *exo* and an *endo* attack, respectively, of a nucleophile on a 2-norbornyl cation. Only *exo* attack is observed (see discussion in W. F. Erman: *Chemistry of the Monoterpenes, Vol. B*. Marcel Dekker, New York 1985, p. 1067, 1083); *endo* attack on **3** would be strongly hindered sterically and stereoelectronically.

[15] T. Laube et al., unpublished results.

[16] R. C. Haddon, *J. Am. Chem. Soc. 108* (1986) 2837.

[17] The structure of norbornane has not yet been determined by X-ray diffraction because of the formation of plastically crystalline phases. R. L. Jackson, J. H. Strange, *Acta Crystallogr. Sect. B 28* (1972) 1645). Electron diffraction in the gas phase in connection with other spectroscopic data does not afford all inner coordinates with sufficient precision (L. Doms, L. Van den Enden, H. J. Geise, C. Van Alsenoy, *J. Am. Chem. Soc. 105* (1983) 158). The coordinates of norbornane used here were determined by nonlinear optimization of a force-field-like function (maintaining the C_{2v} symmetry) from the average values of the inner coordinates of substituted norbornanes (L. Doms, D. Van Hemelrijk, W. Van de Mieroop, A. T. H. Lenstra, H. J. Geise, *Acta Crystallogr. Sect. B 41* (1985) 270).

[18] It is probably only a coincidence that the skeletal geometry of **3** in the crystal is practically identical with the skeletal geometry of the unsymmetrical 2-norbornyl cation **1** calculated by ab initio methods (calculation of **1** and **1''**: J. D. Goddard, Y. Osamura, H. F. Schaefer III, *J. Am. Chem. Soc. 104* (1982) 3258). Calculations reported later [2h], however, showed that **1** did not correspond to a minimum and therefore that the symmetrically bridged ion **1''** is the only minimum on the potential surface.

[19] Average and maximal deviations of the corresponding skeletal atoms upon adjustment with the same weights in each case: **3**/norbornane [17]: $\bar{d} = 0.13$ Å, $d_{max} = 0.25$ Å; **3**/**1''** [18]: $\bar{d} = 0.08$ Å, $d_{max} = 0.15$ Å.

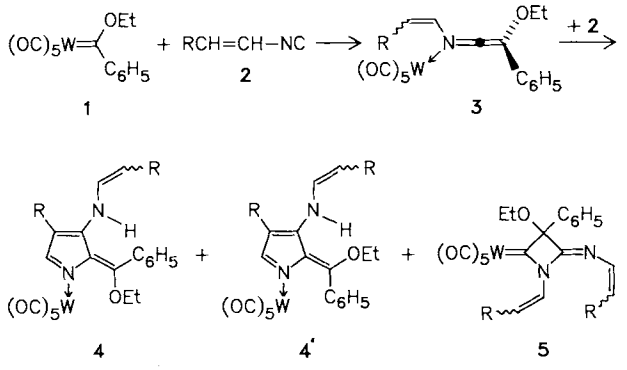
[20] Other bicycloalkyl cations are less stable compared with the hydrocarbons than are 2-norbornyl cations compared with the corresponding norbornanes: N. E. Okazawa, T. S. Sorensen, *Can. J. Chem. 60* (1982) 2180.

Nitrogen Heterocycles from Carbene Complexes and Alkenyl Isocyanides**

By *Rudolf Aumann,* Eberhard Kuckert, Carl Krüger,* and *Klaus Angermund*

Ketenimine complexes are readily accessible in good yields by the addition of isocyanides to carbene complexes.[1] They may be used, after isolation or in situ, for further transformations. Their reactivity patterns are completely different from those of ketenimines free of metals. Herein we describe novel template syntheses of four-, five-, and six-membered N-heterocycles by means of such complexes.

Complex **1** reacts rapidly with alkenyl isocyanides **2** at 0°C in hexane to form the 1:1 adducts (3-aza-1,2,4-pentatriene complexes) **3**. These can be trapped as aminocarbene complexes with protic nucleophiles.[1] In the absence of a suitable reactant, **3** adds a second molecule of **2**. The 1-azafulvene complexes **4** and **4'** and the azetidin-2-ylidene complexes **5** are thereby formed competitively by [4+1] and [3+1] cycloaddition, respectively.

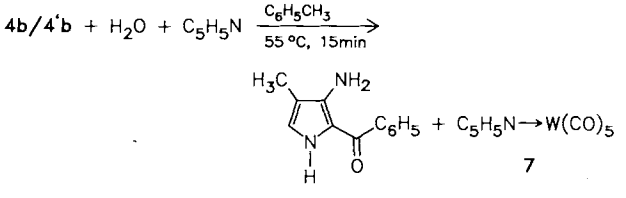


a, R = H; **b**, R = CH_3

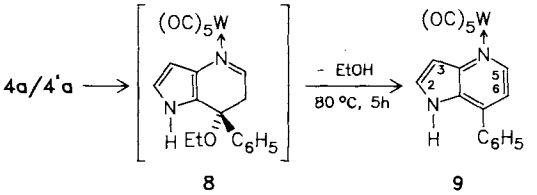
4a : **4'a** : **5a** = 5 : 1 : 2 (80%); **4b** : **4'b** : **5b** = 5 : 1 : 3 (93%)

Complexes **4/4'** precipitate directly from the reaction mixture as red crystals. They are by far more stable than metal-free 1-azafulvenes.[2] However, **4/4'** cannot be separated, because they undergo interconversion in solution. The structures of the complexes were established on the basis of spectroscopic data (Table 1).

Upon hydrolysis in the presence of pyridine, **4b/4'b** afford 3-amino-2-benzoyl-4-methylpyrrole **6** in 90% yield and pentacarbonyl(pyridine)tungsten **7**.



Thermolysis of **4a/4'a** gives the pyrrolo[3,2-*b*]pyridine complex **9** by a metal-promoted cyclization. The reaction presumably proceeds via **8** as an intermediate.



The formation of **4/4'** from **1** and **2** corresponds to the synthesis of indoles from carbene complexes and aromatic isocyanides.[1] The formation of azetidin-2-ylidene complexes **5**, on the other hand, must be regarded as a prototype of a novel [3+1] cycloaddition of a ketenimine ligand to an isocyanide. The reaction is favored by the migration of the $W(CO)_5$ group from the N atom to the central C atom of the C=C=N moiety, since this results in the formation of an especially stable aminocarbene structure.

Complexes **5** can be easily isolated by chromatography of the mother liquor after separation of the **4/4'** crystals. Complex **5b** was synthesized starting from a ca. 10:1 mixture of *cis*- and *trans*-**2b**.[3] A 15:1:1 mixture of three stereoisomers, which differ in the relative configurations of the C=C bonds, was obtained. As expected, the main product has a *cis* configuration at both C=C bonds [**5b**(*cis/cis*): R_f(petroleum ether) = 0.14, m.p. = 107°C; **5b**(*cis/trans*): R_f(petroleum ether) = 0.42, m.p. = 101°C; **5b**(*trans/cis*): R_f(petroleum ether/ether = 50/1) = 0.7, m.p. = 80°C].

The structure of the 3-methyl-3-ethoxyazetidin-2-ylidene-$W(CO)_5$ **5c**, which is analogous to **5a** (CH_3 instead of C_6H_5 in **5a**), was determined by an X-ray crystal structure analysis (Fig. 1).

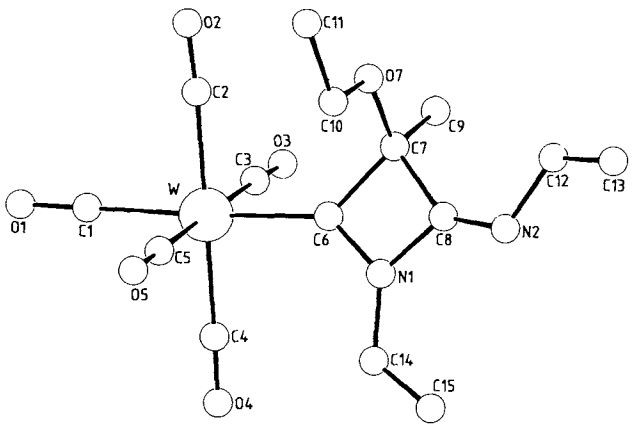


Fig. 1. Crystal structure of **5c** [4]. Important bond lengths [Å] and angles [°]: C1-W 2.044(6), W-C6 2.137(5), C6-C7 1.558(7), C6-N1 1.360(6), C7-C8 1.546(7), N1-C14 1.408(7), C14-C15 1.295(9), N1-C8 1.430(7), C8-N2 1.260(7), N2-C12 1.408(8), C12-C13 1.299(9); W-C6-C7 133.0(3), W-C6-N1 137.0(4), C7-C6-N1 89.9(4).

Oxidation of **5a** with pyridine *N*-oxide **10** in toluene leads to the β-lactam **11** in 88% yield.

In contrast to **1**, $[(OC)_4Fe{=}C(OEt)C_6H_5]$ reacts with both aliphatic and aromatic isocyanides to give the $(OC)_4$Fe-azetidin-2-ylidene complexes corresponding to **5** as the only products. These are again readily oxidized to β-lactams.[5]

Table 1. Spectroscopic data for the compounds **4a**, **4'a**, **5a**, **6**, **9**, and **11** [a].

4a: ^{1}H-NMR: δ = 7.95 and 5.52 (each 1H, each d, AX system, ^3J = 1.9 Hz; H2 and H3), 7.73 and 7.49 (2H and 3H, each m; C_6H_5), 6.14 (1H, ddd, ^3J = 15.0, 11.0, and 8.2 Hz; NH–C*H*=CH$_2$), 4.69 (1H, br. d, ^3J = 11.0 Hz; NH, shifted to lower frequency owing to the anisotropy effect of C_6H_5), 4.03 (1H, d, ^3J = 8.2 Hz; NH–CH=C*H*$_{cis}$), 3.63 (1H, d, ^3J = 15.0 Hz; NH–CH=C*H*$_{trans}$), 4.08 and 1.48 (2H and 3H; C_2H_5).—^{13}C-NMR: δ = 199.76 and 203.00 (1:4; *cis* and *trans*-CO), 166.95 (d; C2), 162.03 (*C*–OEt), 153.40, 132.02, and 130.16 (C4, C5, and *i*-C of C_6H_5), 131.72 and 93.24 (N–CH=CH$_2$); 98.05 (d; C3), 131.94, 130.69, and 128.88 (1:2:2; C_6H_5), 67.65 and 15.23 (C_2H_5).—IR (hexane; ν(C≡O)): $\tilde{\nu}$ = 2060 (10), 1920 (100), 1898 (70) cm^{-1}.

4'a: ^{1}H-NMR: δ = 8.59 (1H, br. d, ^3J = 11.4 Hz; NH), 7.90 and 5.73 (each 1H, each d, AX system, ^3J = 1.9 Hz; H2 and H3), 7.6–7.4 (5H, m; C_6H_5), 6.64 (1H, ddd, ^3J = 15.2, 11.4, and 8.0 Hz; NH–C*H*=CH$_2$), 4.60 (1H, d, ^3J = 15.2 Hz; NH–CH=C*H*$_{trans}$), 4.45 (1H, d, ^3J = 8.0 Hz; NH–CH=C*H*$_{cis}$), 3.95 and 1.39 (2H and 3H; C_2H_5).

[a] ^{1}H- and ^{13}C-NMR spectra in $CDCl_3$; 70-eV mass spectra.

Experimental Procedure

4a, **4'a**, and **5a** from **1** and **2a**: **2a** (106 mg, 2.00 mmol) was added to a stirred solution of **1** (458 mg, 1.00 mmol) in 20 mL of hexane at 0°C under inert gas. Dark red crystals of **4a/4'a** (338 mg, 60%, dec. above 66°C) precipitated at −15°C. Chromatography of the mother liquor (silica gel, 20 × 2 cm column, petroleum ether/ether = 50/1) afforded **5a** (113 mg, 20%), R_f = 0.7, m.p. = 97°C. **4** and **4'** are present in solution in a 5:1 equilibrium and were analyzed spectroscopically without attempting resolution.

6 by hydrolysis of **4b/4'b**: **4b/4'b** (300 mg, 0.51 mmol) were heated in 3 mL of toluene/pyridine/water (1/1/1) with stirring (15 min, 55°C). The pale red solution was then evaporated. The residue was dissolved in dichloromethane and chromatographed on silica gel (30 × 2 cm column, petroleum ether/ether = 1/1). After a yellow band containing **7** (170 mg, 83%), a pale yellow fraction containing **6** (92 mg, 90%, R_f = 0.15, m.p. = 135°C) was obtained.

9 by thermolysis of **4a/4'a**: **4a/4'a** was heated in toluene (5 h, 80°C); workup by chromatography on silica gel (ether/petroleum ether = 1/1), yellow crystals from petroleum ether/ether = 4/1, m.p. = 150°C (dec.).

11 by oxidative decomposition of **5a**: **5a** was heated with one equivalent of pyridine *N*-oxide in toluene (15 min, 80°C). Workup by chromatography afforded colorless crystals of **11**, m.p. = 37°C, in addition to yellow **7**.

Mono- and Diarenium Ions from [2.2]Paracyclophanes**

By *Henning Hopf,** *Jung-Hyu Shin,** and *Heinrich Volz**

[2.2]Paracyclophanes **1a** contain two aromatic moieties, which, upon protonation, can be transformed into σ complexes. We reported earlier on the preparation of several new *dianions* of paracyclophane derivatives.[1] We have now studied the possibility of forming *dications* from **1a**. *Cram* and *Hefelfinger* have already reported on the observation of **2a**, a monoarenium ion of **1a**, but no mention was made of a second protonation.[2] The intermediate formation of σ complexes has been postulated for numerous substitution and rearrangement reactions[3,4] of phanes; however, few structural details of these unusual arenium ions are presently known. In investigations of the protonation of [2.2]cyclophanes with super acids (FSO_3H) and magic acid (FSO_3H–SbF_5), we have now been able to prepare both monoarenium ions and, for the first time, diarenium ions of these bridged hydrocarbons and to characterize them by NMR spectroscopy. The parent system **1a** was also reinvestigated since nuclear magnetic resonance spectroscopy has undergone dramatic advances in the meantime.

Owing to the angle deformations and the π–π repulsion between the two benzene rings, [2.2]paracyclophane **1a** has a strain energy of 31 kcal/mol.[5] Protonation of one of the benzene rings of **1a** leads to formation of the monoarenium ion **2a**, and the π–π repulsion is transformed into an

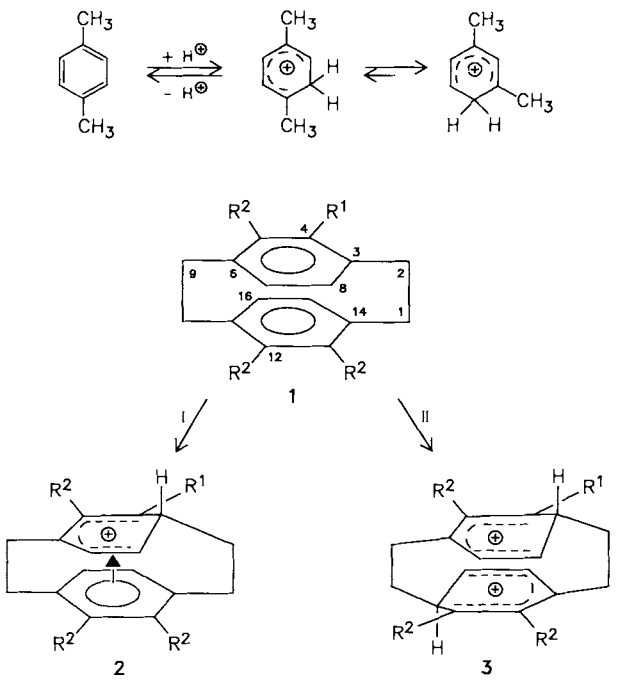
[**] Stable Carbenium Ions, Part 32. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *J.-H. S.* thanks the DAAD for a fellowship.—Part 31: H. Volz, J.-H. Shin, H. Hettel, *Liebigs Ann. Chem. 1982*, 480.

energetically more favorable charge-transfer interaction. The reduction in energy should be at least as large as the bonding energy of 11 kcal/mol found for the cluster formed from protonated benzene and unprotonated benzene.[6] In contrast to methyl-substituted benzenes, which are always protonated at the unsubstituted position—see *p*-xylene, for example[7]—exclusive protonation of the *ipso* carbon atom occurs in the case of [2.2]paracyclophanes, resulting in a reduction in angle strain (Scheme 1).[2]



Scheme 1. Generation of the monocations **2** with FSO_3H-SO_2ClF (I) and the dications **3** with FSO_3H-SbF_5-SO_2ClF (II). **a**, $R^1=R^2=H$; **b**, $R^1=CH_3$, $R^2=H$; **c**, $R^1=R^2=CH_3$.

The monoarenium ions **2** are generated from the cyclophanes **1** in FSO_3H-SO_2ClF at $-80°C$ (**2a**,**2b**) and $-110°C$ (**2c**). All three cations exhibit a bright red color owing to the charge transfer from the unprotonated ring to the arenium ion. In the ^{1}H-NMR spectrum, the protons of the protonated ring absorb at higher field than the protons of similarly substituted methylbenzenium ions, and the protons of the unprotonated ring absorb at lower field than those of the parent compounds **1**. The cause is, on the one hand, the charge transfer and, on the other, the changed magnetic anisotropy effect of the ring system (Table 1).

Reaction of the [2.2]paracyclophane **1** with magic acid (FSO_3H-SbF_5-SO_2ClF) at $-100°C$ results in double protonation and formation of the pale yellow diarenium ions **3**. The angle strain in these species is further decreased compared with that in the monoarenium ions by protonation at two *ipso* carbon atoms. The spatial proximity of the two complexes should result in a certain degree of charge repulsion. For this reason, it is reasonable to assume that the positions of highest positive charge density in the diarenium ions **3** are separated as far as possible from one another. In the ^{1}H-NMR spectrum, the protons of the diarenium ions exhibit chemical shifts that are approximately the same as those found for the protons of similarly substituted monoarenium ions. Instead of the *ipso* protonation at C-3 and C-11 shown in the scheme, attack could in principle also occur at C-3 and C-14. The dications formed in this way, however, would be considerably more strained, according to molecular models, than the isomers **3** proposed by us. Protonation of the methyl-substituted ring of the unsymmetrical educt **1b** can lead to the formation of two isomeric monoarenium ions. However, there is no evidence in the nuclear magnetic resonance spectrum for the presence of isomers. If the cyclophane **1b** were also protonated in position 6, then, as shown by comparison of the spectra of the 4*H*-*o*-, the 4*H*-*m*-, and the 2*H*-*p*-xylenium ions,[7] the signals of the protons in the *ortho* and *meta* positions to the site of protonation (H-5,H-7 and H-8) should be found about 0.2 ppm downfield and the signal of the methyl protons about 0.3 ppm upfield compared with the corresponding signals of **2b**. No signals are observed in this region, however. The ions formulated as **2b** and **3b** are therefore the energetically more favorable alternatives.

Table 1. ^{1}H-NMR data for the monoarenium ions **2a**-**c** and the diarenium ions **3a**-**c** [a].

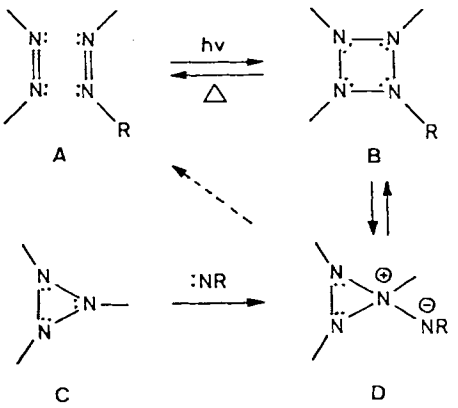
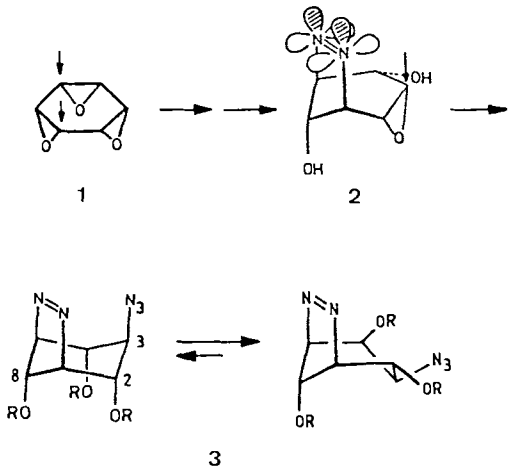
Unusually Stable *cis,cis*-Trialkyltriaziridines by Azo/Nitrene Addition**

By *Otmar Klingler* and *Horst Prinzbach**

All attempts to obtain tetrazetidines **B** by azo/azo photocycloaddition (**A** → **B**) have so far been unsuccessful; only in the case of an azoxy/azo substrate was a tetrazetidine oxide a likely intermediate in the photochemical metathesis reaction.[1] As an alternative route to kinetically stabilized tetrazetidines **B**, we are investigating the ring expansion of ylides **D**, whose synthesis is being approached through nitrene addition to triaziridines **C**. Here we report on the preparation of *cis,cis*-trialkyltriaziridines.

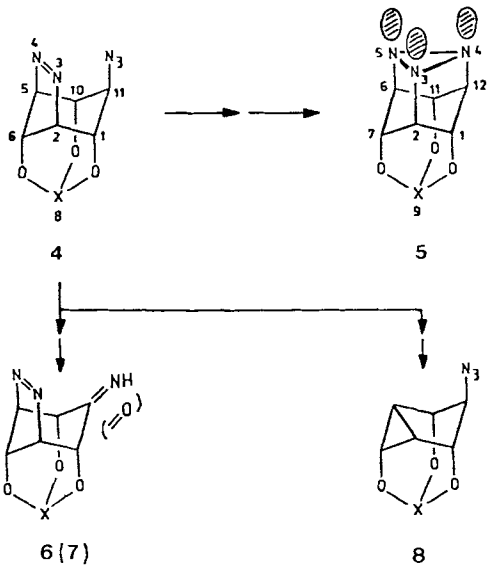


The thermally labile triaziridines described by *Dreiding* et al.,[2] as well as subsequent examples,[3] were obtained by photocyclization of acceptor-substituted azimines. Earlier attempts to achieve the intra- or intermolecular azo/nitrene addition resulted at best in the isolation of azimines.[2,4] In our approach,[5] the lability of the triaziridine ring, which is partly responsible for these earlier results, was counteracted by incorporation of the N_3 ring into a rigid molecular skeleton. This also guarantees a high degree of proximity of the azo/azide chromophore and the fixing of the potential nitrene in the N=N π plane.



a, R = H; **b**, R = Ac

The azoepoxydiol **2** is accessible[6] starting from *cis*-benzene trioxide **1** via an intermediate of the streptamine synthesis.[7] The opening of the epoxide ring in **2** by $N_3^{\ominus}$ (NaN_3, Al_2O_3, CH_3OH/H_2O, room temperature) proceeds slowly, even under catalysis, but sufficiently selectively at C-4 to give the crystalline C_s-symmetric triol **3a** (50–60%, $J_{1,8}=5.3$, $J_{2,3}=8.8$ Hz), which, like the triacetate **3b** ($\lambda_{max}(CH_3CN)=346$ nm ($\varepsilon=150$); $J_{1,8}=5.3$, $J_{2,3}=7.0$ Hz), favors a flattened boat conformation with a quasi-equatorial azide group. Reaction of **3a** with trimethyl orthoformate gives the trioxaadamantane **4a** (m.p. = 174°C, 70%), with trimethyl orthoacetate the product **4b** (m.p. = 135°C, 66%), with $POCl_3$ the product **4c** (m.p. = 211°C (dec.), 60%), and with $P(OC_6H_5)_3$ the product **4d** (m.p. = 175°C (dec.), 70%).[8] The fixed axial position of the azide group in **4a–d**, and hence its spatial proximity to the azo group, is confirmed, inter alia, by the small $J_{1,11}$ and $J_{10,11}$ coupling constants (ca. 3 Hz) as well as by the relatively long-wavelength UV absorptions (e.g., **4a**: $\lambda_{max}(CH_3CN)=$ 361 nm ($\varepsilon=530$)).



a, X = CH; **b**, X = CCH_3; **c**, X = PO; **d**, X = P

Direct irradiation of **4a** in a ca. 10^{-3} M degassed CH_3CN solution with monochromatic light (254 or 350 nm, Rayonet reactor, quartz photolysis vessel, room temperature), after 85–90% conversion, produces, in addition to a small amount of polymer, a mixture containing 45–50% or 50–65%, respectively, of triaziridine **5a** (m.p. = 233°C (dec.)), 15–20% or 10–20%, respectively, of azoimine **6a**, and 5–10% or < 2%, respectively, of azide **8a**. Compounds **5a** and **8a** can be isolated in pure form by chromatography; the imine **6a** is transformed, upon chromatography, into the ketone **7a**. Under the same conditions (350 nm), **4b** gives ca. 40% of **5b** (m.p. = 220°C (dec.)) and ca. 10% of **6b**; **4c** gives ca. 25% of **5c** (m.p. = 245°C (dec.)) and ca. 20% of **6c**, and **4d** gives ca. 20% of **5d** (m.p. = 230°C (dec.)) and ca. 20% of **6d**. The importance of the fixed proximity of the azo/azide chromophores in **4a–d** for the formation of the triaziridines **5a–d** is shown by control photolyses with **3b**. Under the same conditions (CH_3CN, 254 nm (350 nm), 85–90% conversion), along with a considerable (prevailing) amount of (mainly) polymeric material, ca. 35% (5%) of a 1:2 mixture

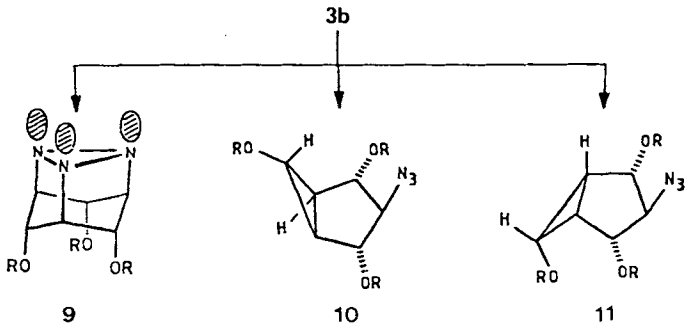
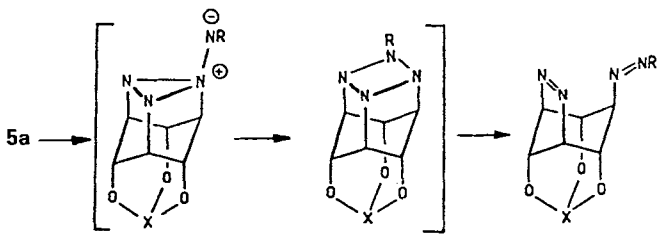
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

of the epimeric bicyclic azides **10b/11b**, ca. 5% (5%) of aniline derivatives, and only ca. 5% (5%) of triaziridine **9b** ("triazatriaxane"; [3]triazaperistylane)[9] are formed.[10]



The C_{3v} symmetry of the triaziridines **5a-d** is revealed in the ^{1}H- and ^{13}C-NMR data. Characteristic for the triaziridine moiety are a short-wavelength UV absorption (**5a** (CH_3CN): $\varepsilon_{220}=250$), the ^{15}N-NMR shift (**5a** ([D$_6$]dimethyl sulfoxide): $\delta=180.6$), the photoelectron (PE) spectra,[11] and the expected weak basicity (**5a** is not protonated in CF_3CO_2H/CH_3CN). The kinetic stabilization of the triaziridine ring in **5a-d** by the trioxaadamantane "corset" is impressively manifested in the unusual thermal stability. For example, upon heating in a ca. 10^{-2} M degassed solution in CD_3CN at 200°C, **5a** remains unchanged over several hours. In the mass spectrum of **5a** (chemical ionization, isobutane), the $M^{\oplus}+1$ peak (*m/z* 182) is the base peak (100%). Accordingly, the triaziridines **5a-d** should be able to withstand the thermolysis temperatures (150-200°C) necessary for the generation of nitrenes from alkyl azides such as **4a-d**. Indeed, heating of **4a** at 200°C (in the melt or in degassed benzonitrile solution) results in the formation of **5a/6a** mixtures similar to those formed by photolysis. This result also supports the assumption that the photoreaction **4a** → **5a** occurs via a nitrene and not via a [4+2] azo/azide adduct (pentazoline). The question of energy transfer to the azide group, especially upon 350-nm excitation (N=N, n→π*), however, remains unanswered.



R = CO_2CH_3

In view of the project mentioned at the beginning, the following preliminary result is noteworthy: upon irradiation (254 nm) of a CH_2Cl_2 solution of **5a** (10^{-3} M, room temperature) and methyl azidoformate, the bisazo compound **14a** is formed selectively (via **12a/13a** ?).[6]

Organometallic Rhodium(III) Complexes as Catalysts for the Photoreduction of Protons to Hydrogen on Colloidal TiO_2**

By *Ulrich Kölle** and *Michael Grützel*

The reduction of protons to hydrogen by transition metal complexes functioning as electron relays is currently under active research by a number of laboratories throughout the world.[1-4] Apart from the development of an efficient sensitizer **S** which should be excitable by sunlight and may be a molecule or semiconductor particle, the transfer of the electrons from its excited state **S*** to the proton to be reduced is the key step of any light-driven hydrogen cycle. Recently developed relay systems **R** exhibit remarkable quantum yields for hydrogen production[2c] and also have enabled mechanistic studies of the relay function.[5] The essential steps of such a cycle are outlined in Scheme 1.

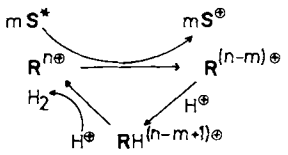

Scheme 1.

The relay $\mathbf{R}^{n\oplus}$ must be reducible by S* and the hydrogen atom in the protonated form $RH^{(n-m+1)\oplus}$ must be sufficiently hydridic in order to generate H_2 in, e.g., a subsequent proton-hydride reaction [see eq. (b)]. For m = 2, the initial form of the relay is regenerated directly. The redox potential of S* necessary for the generation of a sufficiently reducing species $\mathbf{R}^{(n-m)\oplus}$ is furnished for Co^{II}- and Rh^{III}-complexes as relays[1-3] by, e.g., $[Ru(bpy)_3]^{2\oplus *}$ (bpy = 2,2'-bipyridyl; $E_{1/2}([Ru(bpy)_3]^{2\oplus *}/[Ru(bpy)_3]^{3\oplus}) = -0.87$ V vs. NHE[6]) and — albeit only in strongly alkaline solution — by the conduction band (CB) of TiO_2 ($E_{1/2}(CB) = (-0.11 - 0.059\ pH)$ V vs. NHE[7]).

With the novel [Cp*Rh^{III}(ppy)] complexes, **1**, (Cp* = η^5-C_5Me_5; ppy = oligopyridine ligand) we have found a relay system capable of using the weakly reducing electrons of a TiO_2 colloid for hydrogen evolution without participation of colloidal Pt.

The complexes of constitution $[Cp^*Rh(ppy)L]^{n\oplus}$ (n = 1, 2; **1a**, ppy = 2,2'-bipyridyl; **1b**, ppy = [2,2'-bipyridyl]-4,4'-dicarboxylic acid; **1c**, ppy = 4,4'-diacetyl-2,2'-bipyridyl; **1d**, ppy = 1,10-phenanthroline; **1e**, ppy = 2,2'-bipyrazinyl; $L = H_2O$, $OH^\ominus$, $Cl^\ominus$, $I^\ominus$) are formed in 1–30 min at room temperature upon reacting a suspension of $[\{Cp^*RhCl(\mu\text{-}Cl)\}_2]$ in methanol with one equivalent of the oligopyridine ligand. They are stable in air and soluble in water. Their constitutions have been established by ^{1}H-NMR spectroscopy (Table 1) and by correct elemental analyses. Salts containing the cation $[Cp^*Rh(ppy)H_2O]^{2\oplus}$ crystallize from water or aqueous methanol, as has been confirmed for **1a** by a crystal structure analysis.[8] The neutral Rh^I-complexes [Cp*Rh(ppy)], **2**, can be obtained chemically by reduction of **1** with, e.g., Na-amalgam or $[Cp_2Co]$.[9]

Table 1. ^{1}H-NMR spectra of **1a**, **d**, **e** in $CDCl_3$, **1b** in D_2O and **1c** in $(CD_3)_2CO$ at 80 MHz. δ values in ppm.

1a (L = Cl): 1.68 (s, 15H; Cp*), 3.04 (s, 3H; CH_3OH), 8.85 (d, $J(3,4) = 4.7$ Hz, 2H; H^3, $H^{3'}$), 8.18 (ψt, $J(4,5) = 5.2$ Hz, 2H; H^4, $H^{4'}$), 7.81 (dd, $J(5,6) = 6.2$ Hz, 2H; H^5, $H^{5'}$), 8.93 (d, 2H; H^6, $H^{6'}$)

1b: 1.60 (s, 15H; Cp*), 8.87 (s, 2H; H^3, $H^{3'}$), 8.08 (d, 2H; H^5, $H^{5'}$), 9.02 (d, $J(5,6) = 4.7$ Hz, 2H; H^6, $H^{6'}$)

1c (L = Cl): 1.81 (s, Cp*), 2.97 (s, 6H; CH_3CO), 9.74 (d, $J(3,5) = 1.4$ Hz, 2H; H^3, $H^{3'}$), 8.30 (dd, $J(5,6) = 5.8$ Hz, 2H; H^5, $H^{5'}$), 9.31 (d, 2H; H^6, $H^{6'}$)

1d (L = Cl): 1.82 (s, 15H; Cp*), 8.06 (2H; H^5, H^6), 9.04 (d, 2H; H^2, H^9), 8.9 (dd, $J(3,4) = 7.6$ Hz, 2H; H^3, H^8), 8.72 (d, 2H; H^4, H^7)

1e (L = H_2O): 2.16 (s, 15H; Cp*), 9.52 (s, 4H; H^5, $H^{5'}$, H^6, $H^{6'}$), 10.21 (s, 2H; H^3, $H^{3'}$)

The reduction of Rh^{III} to Rh^I can be monitored electroanalytically in aqueous solution; this is especially easy in the case of the dicarboxylic acid **1b** where also the Rh^I-form is water soluble:

In alkaline solution, a single reduction wave is observed at $E_{1/2} = -0.75$ V (SCE); the cyclovoltammogram corresponds to an electrochemically irreversible (non-nernstian) but chemically reversible (peak current ratio = 1) two-electron reduction ($\Delta E_p = 40$ mV) $Rh^{III} \rightarrow Rh^I$. The observed half-wave potential is 0.2 V more positive than the redox potential of the pair $[Rh(bpy)_3]^{3\oplus}/[Rh(bpy)_3]^{2\oplus}$.[2b]

In acid solution (pH < 7.5) the reduction of Rh^{III} to Rh^I is also chemically irreversible (peak current ratio < 1). Polarograms recorded between pH 7.5 and pH 2 exhibit two waves changing in position ($E_{1/2}$) and height (i_g) with pH. In analogy with observations on related $Co\text{-}d^8/Co\text{-}d^6$ systems[5] we assign the more positive wave to the catalytic sequence [eqs. (a)–(c)], where only unprotonated Rh^{III} is reduced. The second wave, where also a protonated species, $(Rh^{III}H)^\oplus$, is reduced, could comprise the reactions (a), (b), and (d)–(f). (Here Rh^I, Rh^{II}, Rh^{III} designate complexes in their respective oxidation states.)

$$(Rh^{III}L)^{2\oplus} + 2e^\ominus \longrightarrow Rh^I + L \quad (a)$$
$$Rh^I + H^\oplus \longrightarrow (Rh^{III}H)^\oplus \quad (b)$$
$$(Rh^{III}H)^\oplus + H^\oplus + L \longrightarrow (Rh^{III}L)^{2\oplus} + H_2 \quad (c)$$
$$(Rh^{III}H)^\oplus + e^\ominus \longrightarrow Rh^{II}H \quad (d)$$
$$Rh^{II}H + H^\oplus \longrightarrow (Rh^{II})^\oplus + H_2 \quad (e)$$
$$(Rh^{II})^\oplus + e^\ominus \longrightarrow Rh^I \quad (f)$$

When complexes **1a**–**1e** (10^{-4} M) are irradiated in the presence of a TiO_2 colloid[10] at pH 10 (Suntest lamp, Hanau, or direct sunlight), the intense violet (**2a**) or green (**2d**) color of the respective Rh^I-complex develops.[11]

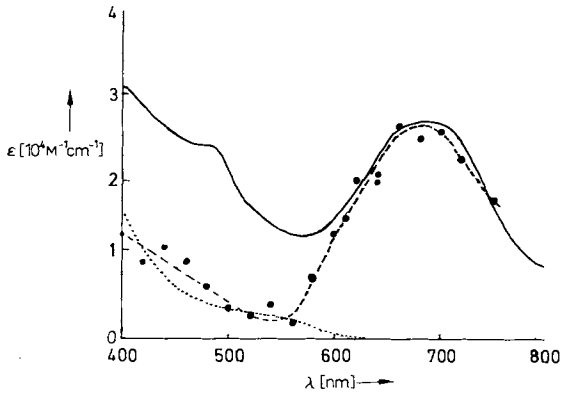

Fig. 1. Absorption spectra: **2d**, obtained by reduction of **1d** with Na/Hg in MeOH (——); transient spectrum 500 μs after triggering a laser flash at a solution of **1d** (2.8×10^{-4} M, 1 g/L TiO_2, pH 8.7 (---•---•-); **1d** (·····).

On laser-flash excitation[12] the absorption of **2** appears (transient spectrum after 500 μs, Fig. 1[13]) with a time constant of ca. 2×10^{-6} s^{-1} (Fig. 2a). The complex kinetics for the buildup of the Rh^I-absorption suggests a multistep reaction. Below pH 7.5, **2** becomes protonated, as evidenced from the absorption decay between 480 and 600 nm (Fig. 2b) followed by a further, much slower, proton-dependent reaction at acidic pH (< 2), assigned as the proton–hydride reaction [eq. (c), (Fig. 2c)]. Continuous irradiation at a pH < 7 does not change the color of the sample but causes hydrogen evolution. Thus, 20 mL of a solution containing 25 mg of TiO_2, 5 μmol of **1a** and 0.05% poly(vinyl alcohol), irradiated for three hours with direct sunlight yielded 0.5 mL H_2, corresponding to 4.5 turnovers.

The reduction and protonation steps via a Rh^{II} intermediate could be followed by means of pulse radiolysis.[14] The reduction of **1a** or **1b** with $e_{aq}^\ominus$ (G = 2.3) or $Me_2\dot{C}(OH)$ (G = 3.2 at pH 10) produces the absorption spectrum of the Rh^{II} complex shown in Figure 3 for **1b** in less than 1 μs.[13]

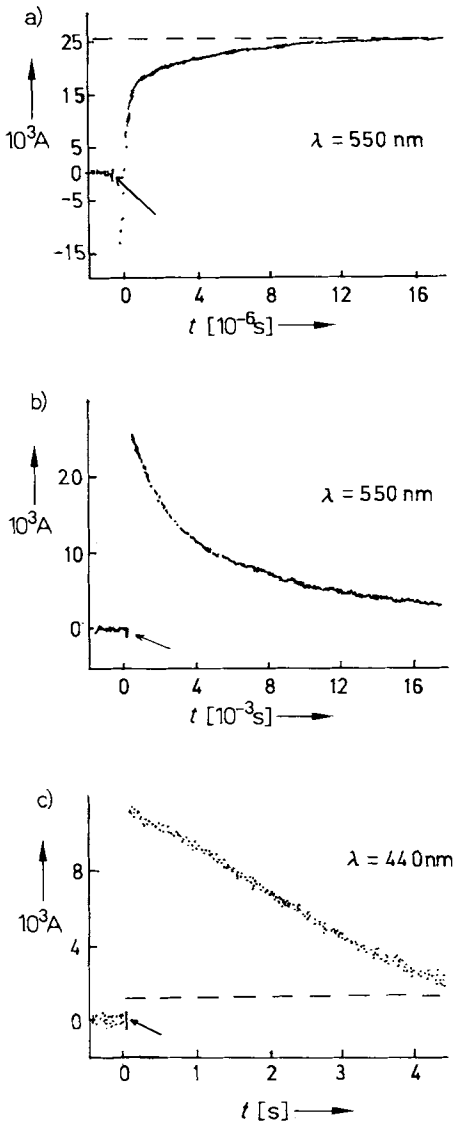

Fig. 2. Change in absorption of **2b** with time (2×10^{-4} M, 0.9 g/L TiO_2, pH 2.5, $\lambda_{exc} = 347$ nm): a) directly after the laser pulse, $\lambda_{obs} = 550$ nm, synthesis of the Rh^I species **2b**. b) $\lambda_{obs} = 550$ nm, decay of **2b** by protonation. c) $\lambda_{obs} = 440$ nm, back reaction of protonated **2b** ($+H^{\oplus}$) to give the starting complex **1b**. The arrow marks the time of triggering of the laser pulse.

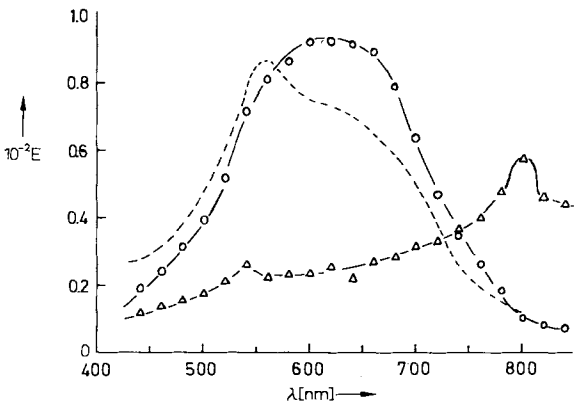

Fig. 3. Absorption spectra of the reduction products of **1b** (2×10^{-4} M, pH 10) obtained by pulse radiolysis: (Δ--Δ--Δ-) = Rh^{II}-complex, 2 μs after the pulse; (O--O--O-) = **2b**, 200 μs after the pulse; (------) spectrum of the reduced alkaline solution.

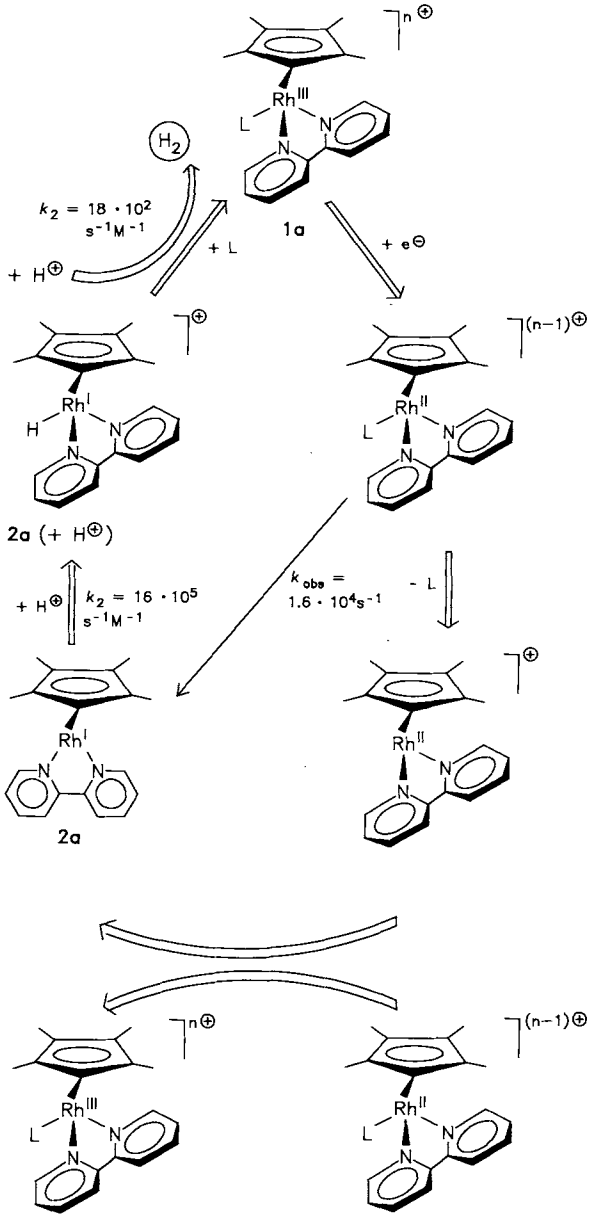
After ca. 200 μs, the spectrum of the Rh^I complex **2b**, identical to the one obtained by laser-flash excitation, is formed in a reaction between 1st and 2nd order, dependent on the pH and on L. Again, in acid solution the protonation of **2** (see rate constants in Scheme 2) and, at pH < 2, also the reaction of protonated **2** to reform the starting compound can be monitored. A reduction-protonation-oxidation cycle based on these results is depicted in Scheme 2.



Scheme 2. Reduction-protonation-oxidation cycle for **1a** with rate constants measured by pulse radiolysis. k_{obs} for $L = OH^{\ominus}$; for $L = I^{\ominus}$ $k_{obs} = 1.6 \times 10^3$ s^{-1}.

In contrast to the complex $[Rh(bipy)_3]^{3\oplus}$, in the present case the conduction band potential of TiO_2 suffices for a reduction of Rh^{III} to Rh^I in *acid* solution. Also at variance with the $[Rh(bpy)_3]^{3\oplus}$ system, where the Rh^I species $[Rh(bpy)_2]^{\oplus}$ does not give hydrogen with protons,[15] complexes **2** react, as has been shown independently, with protonic acids (trifluoroacetic acid in tetrahydrofuran) with formation of hydrogen and regeneration of the starting complex. Intervening dimerization of the Rh^{II} and Rh^I intermediates is prevented in this case by the quasi fivefold

coordination of the metal. Moreover, concomitant with the change in oxidation state from Rh^{III} to Rh^{II} and Rh^{I} only one monodentate ligand L, in aqueous solution preferentially water, is lost, a fact that greatly facilitates the disproportionation of intermediary Rh^{II}. The combined effects now make the reactions with protons as shown in Scheme 2 rate determining in the overall cycle.

Experimental

A suspension of $[\{Cp^*RhCl(\mu\text{-}Cl)\}_2]$ (0.31 g = 0.5 mmol) in MeOH (10 mL) was treated with 1.2 mmol of the oligopyridine ligand and the mixture stirred for 10 min (in the case of the sparingly soluble ligand [2,2′-bipyridyl]-4,4′-dicarboxylic acid an ultrasonic bath was used). The resulting clear orange-yellow solution was evaporated to 2 mL and the complexes **1** were either precipitated by addition of ether or crystallized on diffusion of ether into the concentrated methanolic solution. The yields were almost quantitative.

[12] JK-2000 ruby laser, $\lambda = 347$ nm, pulse width 15 ns.
[13] The difference in the wavelength region <600 nm of the spectrum obtained by chemical reduction (——) and after laser flash excitation (—•—•) in Figure 1 can be explained by the bleaching of the Rh^{III} complex accompanying the formation of **2d**. The somewhat different spectrum of **2b** in Figure 3 is also obtained by laser flash excitation at pH 4. It is traced back to the carboxylate groups of the Rh^{I} complex being protonated under these conditions. (If pulse radiolysis is carried out at pH 10 in unbuffered solution, the pH value drops and the protonated dicarboxylic acid can be present.)

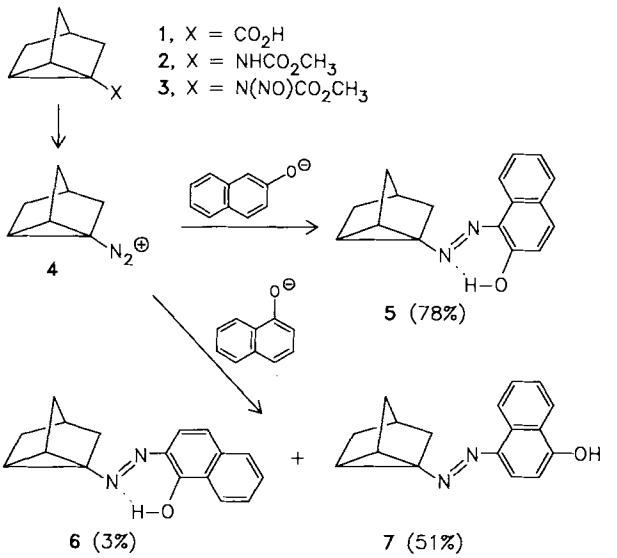
Diazo Coupling of Nortricyclene-(Tricyclo[2.2.1.$0^{2,6}$]heptane)-1-diazonium Ions

By *Georg Feldmann* and *Wolfgang Kirmse**

Cyclopropanediazonium ions react with azide ions[1,2] and with amines[1,3] by way of diazo coupling, but fail to couple with phenols (phenoxides). The "classical" diazo coupling reaction with phenoxides has now been achieved with nortricyclene-1-diazonium ions **4** to which the competitive pathways of ring opening[1,4] and inverting displacement[1,4] are not available.



Curtius degradation of nortricyclene-1-carboxylic acid **1**[5] to give the carbamate **2** (61%) was followed by nitrosation, yielding the nitrosocarbamate **3** (90%). Deacylation of **3** with a mixture of potassium carbonate, 2-naphthol, and methanol afforded the azo compound **5** [m.p. 98 °C, intense yellow crystals from pentane]. The analogous reaction of **3** with 1-naphthol led to the azo compounds **6** and **7**. The isomers were separated by means of HPLC, but were not obtained crystalline. In contrast to **5** [δ(OH) = 13.7] and **6** [δ(OH) = 13.6], **7** [δ(OH) = 5.6] does not form an intramolecular hydrogen bond and deteriorates in the presence of air (see Table 1).

Table 1. Selected spectral data of the azo compounds **5**–**7**. ^{1}H-NMR spectra: 80 MHz, $CDCl_3$. UV/VIS spectra: *n*-heptane.

5: ^{1}H-NMR: $\delta = 1.45$–1.85 (m, 4H), 1.95 (d, 2H, $J = 1.4$ Hz, 7-H), 2.3 (m, 1H, 4-H), 2.37 (s, 2H, 2-H, 6-H), 7.1–8.05 (m, 5 aryl-H), 8.73 (d, 1H, $J = 8$ Hz, aryl-3-H), 13.7 (s, 1H, OH); UV/VIS: $\lambda_{max} = 250$ nm ($\varepsilon = 17600$), 335 (9700), 375 (10400)

6: ^{1}H-NMR: $\delta = 1.2$–1.65 (m, 4H), 1.85 (d, 2H, $J = 2$ Hz, 7-H), 2.25 (s, br, 3H, 2-H, 4-H, 6-H), 7.2–7.8 (m, 5 aryl-H), 8.3 (m, aryl-8-H), 13.6 (s, 1H, OH); UV/VIS: $\lambda_{max} = 285$ nm ($\varepsilon = 39800$), 315 (14550), 385 (9000)

7: ^{1}H-NMR: $\delta = 1.45$–1.75 (m, 4H), 1.90 (d, 2H, $J = 2$ Hz, 7-H), 2.26 (m, 1H, 4-H), 2.40 (s, br, 2H, 2-H, 6-H), 5.6 (s, br, 1H, OH), 6.79 (d, 1H, $J = 8$ Hz, aryl-2-H), 7.43 (d, 1H, $J = 8$ Hz, aryl-3-H), 7.5–7.7 (m, 2H, aryl-6-H, aryl-7-H), 8.19 (m, 1H, aryl-5-H), 8.78 (m, 1H, aryl-8-H); UV/VIS: $\lambda_{max} = 240$ nm ($\varepsilon = 17150$), 348 (10050)

The behavior of the diazonium ion **4** in alcohols is also remarkable. Instead of the expected ethers we obtained the hydrocarbon nortricyclene **8** (90%) by way of reductive deamination.[6] With isopropanol, an equivalent amount of acetone (88%) was formed, suggesting hydride abstraction from the α-position of the alcohol. Deuterium incorporation into nortricyclene from CH_3OD increased with increasing concentration of base (K_2CO_3/CH_3OD: 0.15 D/mol; 2 M $NaOCH_3/CH_3OD$: 0.54 D/mol). In the presence of sodium borohydride, similar results were obtained. The

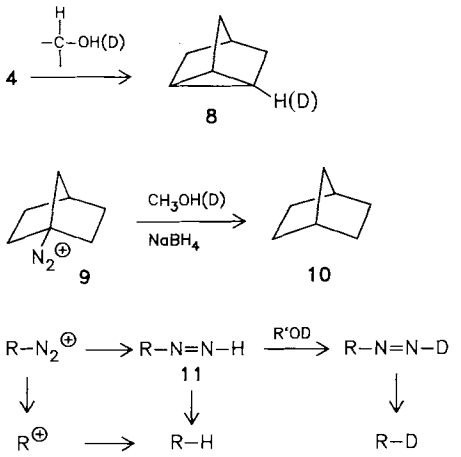
analogous behavior of arenediazonium ions[7,8] has been taken as evidence for a diazene (diimide) intermediate **11**. Regardless of the mechanism of diazene decomposition (*via* carbanions or free radicals),[9] the intervention of **11** will allow for (partial) exchange of hydrogen for deuterium. Hydride transfer at the carbocation stage cannot lead to incorporation of protons from the solvent.



Under identical conditions, norbornane(bicyclo[2.1.1]heptane)-1-diazonium ions **9**[2] afforded undeuterated norbornane **10** exclusively. It appears that **9** is not sufficiently persistent to act as a hydride acceptor; accordingly, all attempted azo coupling reactions of **9** failed. The behavior of **9** is characteristic of aliphatic diazonium ions, whereas azo coupling and reductive deamination of **4** are reminiscent of arenediazonium ions. The comparison with **9** reveals that the arene-like reactivity of **4** is not due to the bridgehead position of the diazonium group but may be attributed to the special electron distribution (σ delocalization)[10] of the cyclopropane ring.

Experimental

A mixture of potassium carbonate (0.5 g, 3.6 mmol), 2-naphthol (1.50 g, 10.4 mmol) and anhydrous methanol (2 mL) was stirred for 15 min and then treated dropwise with a solution of **3** (208 mg, 1.06 mmol) in methanol (0.5 mL). After 1.5 h the mixture was diluted with 5 mL of methanol and extracted with pentane (2 × 5 mL). The combined pentane extracts were washed with water, dried over magnesium sulfate, evaporated down under vacuum, and chromatographed on Polygosil 60-5 (25 × 3 cm column, hexane/ether 9:1). 220 mg (78%) of **5** (m.p. 95 °C) could be separated from the excess 2-naphthol. **5** was recrystallized from pentane, m.p. 89 °C.

The reaction mixture consisting of **3** and 1-naphthol was worked up under nitrogen and the components eluted with pentane/ether (5:1) in the sequence **6** (10 mg), 1-naphthol, **7** (150 mg).

Nickel(0)-Catalyzed Production of a Functionalized Cyclopentanecarboxylic Acid from 1,3-Butadiene and CO_2

By *Heinz Hoberg,* Sabine Gross,* and *Armin Milchereit*

The C_1 building block CO_2 is gaining increasing significance in preparative chemistry.[1] Stoichiometric reactions of alkenes or alkadienes with CO_2 on Ni^0-,[2] W^0-, or Mo^0-complexes[3] can be regarded as model reactions for the catalytic production of carboxylic acids. The catalytic formation of linear carboxylic acids from 1,3-butadiene and CO_2 has already been achieved on Pd-compounds.[4] A knowledge of how various types of ligands L (mono- or multidentate ligands with various electronic and/or steric effects) influence CC coupling reactions to transition-metal complexes is of central importance in organometallic chemistry. We have investigated the influence of ligands and solvents on the reaction of 1,3-butadiene **1** with CO_2 **2** on a nickel(0) system[5] with the aim of obtaining carboxylic acids catalytically. A series of monodentate phosphanes were examined, since multidentate ligands (chelate formers) lead only to stoichiometric reactions.[6]

When a mixture of **1**, **2** and **3**, L = PPh_3 (molar ratio 3:3:1) in tetrahydrofuran (THF) is prepared in a steel autoclave at −20 °C and the stirred mixture is allowed to warm to 20 °C, subsequent hydrolysis of the reaction solution affords the two cyclopentanecarboxylic acids **7**[7] and **9** (molar ratio ca. 9:1). On heating the reaction mixture to 40 °C the molar ratio changes to 1:1. If, on the other hand, the reaction is not carried out in the presence of PPh_3, but in the presence of a less basic ligand, e.g. triisopropyl phosphite $P(OiPr)_3$, **7** is formed only in traces (detected gas-chromatically as methyl ester) whereas **9** is formed in ca. 95% yield (based on Ni^0). Since the carboxylic acid **9** is composed of two molecules of **1** and one molecule of CO_2, it was to be expected that it should also be preparable catalytically. This assumption could be realized when the following general conditions were maintained: 1) Use of polar solvent, e.g. dimethylformamide, dimethylacetamide, tetramethylurea and, though less effective, THF. 2) A reaction time of ca. 30 h at ca. 60 °C and a partial pressure P_{CO_2} of ca. 20 bar. 3) A concentration of ca. 0.3 mmol Ni^0/100 mL of solvent[8] at a molar ratio L:Ni^0 of ca. 3:1. Under these conditions the carboxylic acid **9** can be prepared in ca. 30 catalytic cycles per Ni atom.

We suggest the following reaction course for the catalytic formation of the carboxylic acid (Scheme 1). The catalysis is initiated by the well-known dimerization of 1,3-butadiene on the (L)Ni^0 system **3** to give **4**.[9] The CC coupling with CO_2 then takes place by insertion into an Ni-C σ-bond; because of the reactivity differential $Ni\text{-}C_{prim} < Ni\text{-}C_{sec}$ this step takes place in the case of **4a**, but not in

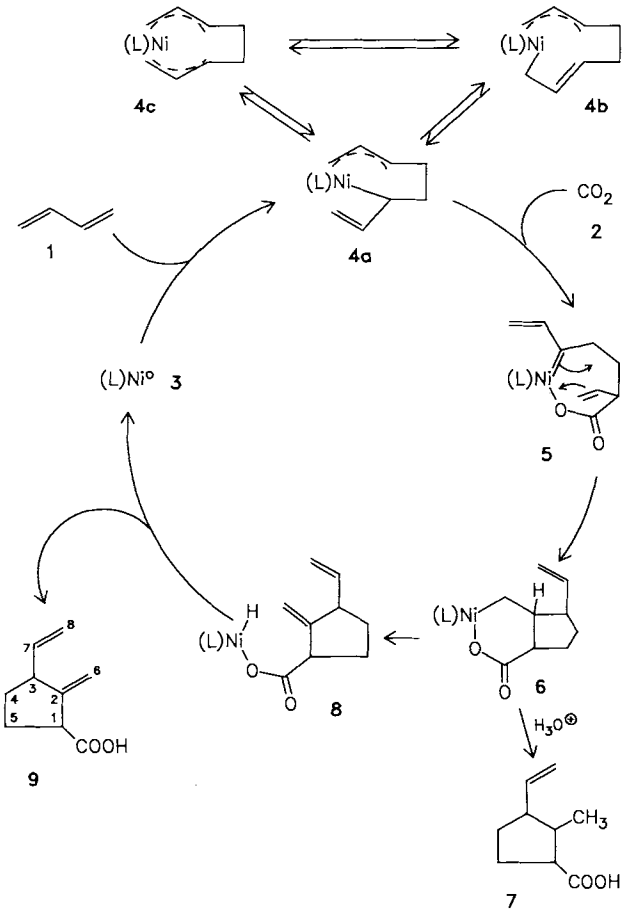
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)



Scheme 1. L = PPh_3 or $P(OiPr)_3$.

the case of **4b**. The carboxylate **5** is formed, which likewise contains a reactive Ni–C_{sec} bond. The CC double bond of the allylcarboxylate moiety inserts intramolecularly into the latter. This novel CC coupling reaction is made possible by the formation of the carbocyclic five-membered ring in the bicyclic nickela-complex **6** (the hydrolysis of **6** affords **7**[10]). A subsequent β-H elimination now affords **8** initially, from which the carboxylic acid **9** is liberated by reductive elimination and the (L)Ni^0 starting complex **3** is regenerated.

Experimental

2-Methylene-3-vinylcyclopentanecarboxylic acid **9** (catalytic): A cold mixture of $[(cod)_2Ni]$ (0.055 g, 0.20 mmol), triisopropyl phosphite (0.14 g, 0.66 mmol), and 1,3-butadiene (9 g, 166 mmol) in 70 mL of dimethylformamide was transferred to a 200-mL steel autoclave cooled to −20 °C. CO_2 (ca. 20 bar) was then passed into the autoclave and the stirred mixture heated within ca. 3 h to 60 °C and kept at this temperature for approximately a further 20 h. The solvent was removed from the cold reaction solution by vacuum distillation. The residue was hydrolyzed with ca. 20 mL of 2 N H_2SO_4 and then extracted several times with diethyl ether. The organic phase was now extracted several times with 1 N NaOH solution. The aqueous phase was then rendered acidic with dilute H_2SO_4, re-extracted with diethyl ether and the etheral phase dried over $MgSO_4$. Removal of the ether by distillation furnished **9** as a colorless, viscous liquid. Yield: 0.89 g (5.86 mmol), which corresponds to 29.3 catalytic cycles per Ni atom.—IR (KBr): $\tilde{\nu}$ = 1705 (C=O), 1648 (C=C) cm^{-1}; δ = 910, 990 (C–H) cm^{-1}.—^{1}H-NMR ([D_8]THF, 20 °C, 200 MHz): δ = 5.67 (ddd, 1 H; 7-H), 5.24 (s, 1 H; 6 *E*-H), 5.03 (d, 1 H; 8 *E*-H), 5.00 (d, 1 H; 8 *Z*-H), 4.91 (s, 1 H; 6 *Z*-H), 3.35 (m, 1 H; 1-H), 3.01 (s, 1 H; 3-H), 1.7–2.1 (m, 4 H; 4-, 5-H).—^{13}C-NMR ([D_8]THF, 20 °C, 75.47 MHz): δ = 174.9 (s; CO_2H), 153.8 (s; C-2), 141.6 (d, J_{CH} = 153 ± 2 Hz; C-7), 115.1 (t, J_{CH} = 156 ± 1 Hz; C-8), 109.4 (t, J_{CH} = 158 ± 1 Hz; C-6), 50.8 and 49.2 (d; C-1,3), 33.2 (t, J_{CH} = 132 ± 1 Hz; C-4), 29.9 (t, J_{CH} = 133 ± 1 Hz; C-5).

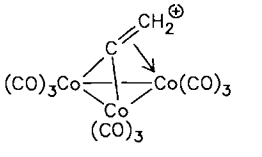
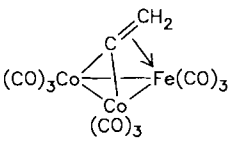
Isoelectronic Relationships in Cluster Chemistry: Nucleophilic Addition to a Vinylidene Ligand

By *Thomas Albiez* and *Heinrich Vahrenkamp**

The vinylidene group $=C=CH_2$ attracts interest in complex chemistry because it is one of the conceivable intermediates in the elementary processes for the production of petrochemical raw products. It is multifunctional, which means, e.g., that it can be bound to up to four metal atoms in complexes or on surfaces. Whereas this property is immediately apparent in the preparation of organometal-vinylidene complexes,[1] the associated consequences thereof, in the form of variable reactivity, have hitherto only been studied superficially.[1b,2] Thus, it is substantiated by experiment and theory that mononuclear vinylidene complexes are mostly electrophilic at the α-C atom;[3] this also seems to be true, to a limited extent, in the case of dinuclear complexes containing a bridging $=C=CH_2$ moiety.[1] Neutral trinuclear clusters containing a μ_3-vinylidene moiety have not as yet been studied theoretically with respect to their electron density distribution.[4] In the case of their cationic analogues such as **1**, however, which can be regarded as complex-stabilized carbenium ions,[5] it has long been known that they exhibit high electrophilicity at the β-C-atom.[6] It thus appears that their reactivity reverses with increasing number of the metal atoms bound to the vinylidene ligand.



1

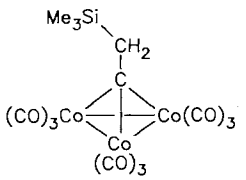


2

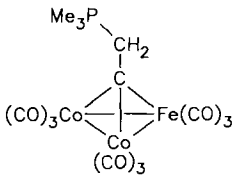
For the investigation of neutral vinylidene-trimetal complexes we chose the cluster **2**, for which we have devel-

[*] Prof. Dr. H. Vahrenkamp, Dipl.-Chem. T. Albiez
Institut für Anorganische und Analytische Chemie der Universität
Albertstr. 21, D-7800 Freiburg (FRG)

oped a convenient synthesis.[7] Although it is only moderately reactive towards nucleophiles and electrophiles, it undergoes reactions with basic phosphane ligands consistent with its isosteric relationship with **1**. Thus, **2** reacts with PMe_3 below 0°C practically quantitatively, undergoing addition to give the black, readily crystallizable cluster **4**, which is soluble only in polar solvents. **4** can be regarded as a zwitterion with positive charge on the phosphorus and negative charge on the iron. It is in turn isosteric with the cluster **3**,[8] which derives from **1**.



3



4

Spectroscopic characterization and structural analysis[9] confirm this isoelectronic relationship. The bond lengths in the $CFeCo_2$ nucleus of **4** (cf. Fig. 1) resemble very closely those in the $[(\mu_3\text{-}RC)Co_3(CO)_9]$-clusters;[6] the orientation of the vinylidene C–C axis at 82° to the $FeCo_2$-plane removes the outer C-atom of the $=C=CH_2$ unit from the bonding sphere of the metal atoms; the C–C distance of 153 pm is that of a single bond; and the phosphorus atom is surrounded by four P–C bonds of equal length (178.5 ± 1 pm). A further conceivable formulation even allows **4** to be considered as an ylide complex of the cluster $[CFeCo_2(CO)_9]$, drawing attention to its relationship with the "carbonyl complex" $[Fe_2Co(CO)_9(\mu_3\text{-}C\text{-}CO)]^{\ominus}$.[10]

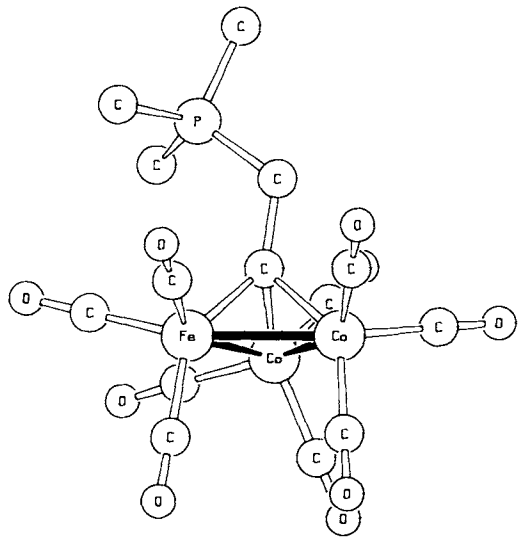


Fig. 1. Molecular structure of **4**. Central bond lengths [pm]: Fe-Co 250.9(1) and 251.7(1), Co-Co 248.4(1), Fe-C 188.0(7), Co-C 192.0(7) and 196.0(7).

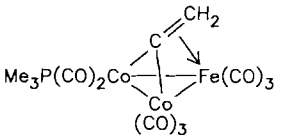
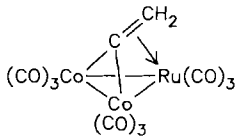
The addition of the phosphane to the vinylidene ligands of **2** competes with CO-substitution at the Co atoms. The latter reaction predominates on increasing the temperature, and **4** is also converted into the substitution product **5** on heating. A decrease in the basicity or an increase in the bulkiness of the phosphane ligand has the same effect. Thus, with PMe_2Ph and $PMePh_2$ the increasingly more labile addition products are still obtainable, whereas with PPh_3 only the substitution product is formed. Finally, the ruthenium cluster **6** which is analogous to **2** reacts with phosphane ligands only with CO-substitution. A structure determination and comparison of the spectra have enabled an assignment of the constitution of **5**.[11]



5



6

As a consequence of the formation and structure of the cluster **4** it could follow, to a limited extent, that an organic derivative chemistry of **2** analogous to that of **1** should be possible. It remains to be checked whether bonding of the vinylidene ligand to four metal atoms further increases the umpolung that is observed on going from a mono- to a multinuclear complex.

A Test for Synergetic Captodative Radical Stabilization**

By *Hermann Birkhofer, Johannes Hädrich, Hans-Dieter Beckhaus*, and *Christoph Rüchardt**

Some years ago it was suggested that pairs of substituents of opposite polarity (captodative substitution) act synergetically in the stabilization of radicals, i.e. their sta-

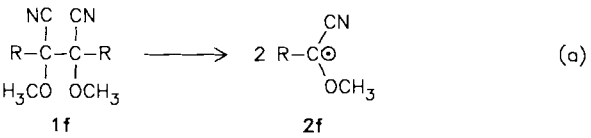
[*] Prof. Dr. C. Rüchardt, Dr. H. Birkhofer, Dipl.-Chem. J. Hädrich, Dr. H. Beckhaus
Institut für Organische Chemie und Biochemie der Universität Albertstrasse 21, D-7800 Freiburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, by the Land Baden-Württemberg, and by the Fonds der Chemischen Industrie.

bilizing effect is more than additive, while pairs of identical electron withdrawing (capto) or electron donating (dative) substituents act in a conflicting, i.e. less than additive, manner.[1, 2] This suggestion has been supported by qualitative arguments from synthetic work,[1a, b] by qualitative FMO theory,[3] by enhanced spin delocalization in ESR spectra of captodative substituted radicals,[4] by the influence of cd-substitution on rotational barriers of radicals,[5] and by kinetics.[1b, c, 6] It has been concluded, that the mutual interaction of cd-substituents causes enhanced delocalization of the unpaired spin by polarization[1] leading to an additional stabilization of the radical.

This simple model is based on the assumption that the stabilities of these radicals (relative to non-radical precursors) are predominantly determined by spin delocalization. However, it is well known that two geminal substituents at a *tetracoordinated* carbon may also interact and, accordingly, not contribute to the stability of molecules in an additive manner.[7] Any change of this mutual interaction of two groups by σ-type interaction in going from the radical to the parent saturated compound would cause the simple relationship between spin delocalization and thermodynamic stability of a radical to be misleading.

In the meantime, experiments have been performed which do not support a kinetic stabilization of cd-substituted radicals.[8, 9] Furthermore, an additive and not a synergetic effect of cd-substituents in the thermodynamic stabilization of CH_3O- and CN-substituted radicals was found. This was deduced from the rates of dissociation of several 2,3-dimethoxysuccinonitriles **1f**[9, 10, 11a] [Reaction



(a)

1f **2f**

R = C_6H_5[9], t-C_4H_9[11a], i-C_3H_7[11b]

(a)] and the known independent effects of α-cyano and α-methoxy substituents on the CC-bond strength in substituted ethanes.[10] These reactions are not susceptible to polar effects[12] and methods have been developed to account separately for steric effects in CC-cleavage reactions.[10] Furthermore, we could demonstrate that no measurable interaction of the geminal methoxy and cyano groups exists in ethanes **1f**, i.e. the group increments of ΔH_f° are additive.[9]

We have now exposed the claim stated in the first sentence of this note to an experimental test by comparing the activation parameters for the thermal cleavage reactions of the substituted ethanes **1d** and **1g**[13] with those of **1f** (see Table 1).[9, 11a] In all examples product analyses confirmed the homolytic cleavage [Reaction (b)] of the central CC-bond in the rate determining step.[10]

While the substitution of one OCH_3 group for a CH_3 group on each carbon of the ethane skeleton **1** (cf. **1c** vs. **1b**) results in a decrease of ΔH^+ by 4.4 kcal·mol^{-1}, the introduction of two further OCH_3 groups in **1d**[15]) (cf. **1c** vs. **1d**) leads to a 7.4 kcal·mol^{-1} *increase* in ΔH^+. This is a clear experimental proof that σ-type interactions of two geminal methoxy groups differ significantly between species with paired (**1**) and unpaired electrons (**2**). According to ab initio calculations by *Leroy* et al.,[16] **1d** is stabilized by the anomeric effect,[7, 17] but this stabilizing interaction of geminal methoxy groups is not present in **2d**. The thermal cleavage reactions of the series **1b**–**1d** are believed to be independent of steric effects, because the strain enthalpies of the three compounds are apparently comparable.[10]

Cpd.	X	Y	H_s [a] [kcal mol^{-1}]	ΔG^+ (300°C) [kcal mol^{-1}]	ΔH^+ [kcal mol^{-1}]	ΔS^+ [cal mol^{-1} K^{-1}]	a_H [b] [mT]
1a [10]	CH_3	CH_3	12.0	39.9	46.0	14.2	0.567 [19]
1b [10]	C_2H_5	CH_3 [c]	15.1	34.3	48.4	24.3	
1c [11b]	C_2H_5	OCH_3 [c]	15.6	34.5	44.0	16.6	0.625 [d]
1d	OCH_3	OCH_3	16 [e]	43.6	51.4	13.7	0.603
1e [14]	CN	CH_3 [c]	11.4	30.9	36.1	9.2	0.470
1f [9, 11a]	CN	OCH_3 [c]	12.8	27.9	36.6	15.1	0.409
1g [13]	CN	CN		18 [f]	26 [f]	14 [f]	0.503

[a] Strain enthalpy H_s as defined in [10]. [b] ESR hyperfine coupling constant of *p*-H of **2** in C_6H_5 from [4b]. [c] *meso*-Configuration. [d] For X = CH_3. [e] Preliminary value. [f] For 4-CH_3–C_6H_4 instead of C_6H_5 from [13].

From a comparison of ΔH^+ for the compounds **1a**, **1e**, **1f**, and **1g**, which again are similarly strained, one recognizes that introducing two cyano substituents for two methyls in **1** (cf. **1a** vs. **1e**) results in a decrease of ΔH^+ by almost 10 kcal·mol^{-1}. Exchanging the remaining methyl groups in **1e** by methoxy groups (cf. **1e** vs. **1f**) results in *no change* in ΔH^+ and causes only a 3 kcal·mol^{-1} decrease in ΔG^+.[18] On the other hand, by the substitution of cyano for methyl in **1e** (cf. **1e** vs. **1g**) a further decrease in ΔH^+ by approx. 10 kcal·mol^{-1} is observed.

We conclude that, in this series of compounds, pairs of captodative substituents stabilize a radical center in an additive way, in contrast to geminal dimethoxy substitution, which increases the C–C-bond strength of **1d** in comparison to monomethoxy substitution into **1b**, where the trend of monosubstitution (**1c**) is *reversed* by the introduction of a second methoxy group (**1d**). The fact that the first (**1a**/**1e**) and the second (**1e**/**1g**) substitution of methyl by cyano results in the same 10 kcal/mol^{-1} decrease in ΔH^+ is probably fortuitous. Neither the strain enthalpy of **1g**, H_s (**1g**), which is probably smaller than H_s (**1e**), is known nor is it possible to estimate the change of interaction energy between the geminal dicyano groups[16] on going from **1g** to the radical **2g**.

The *p*-H coupling constants a_H in the benzyl type radicals **2** are decreased in the series **2c** > **2d** ≫ **2g** > **2e** > **2f** (Table 1), indicating an increase of delocalization via the substituents X and Y in this order. It is clear that a_H responds to the substitution pattern X, Y in a different manner than the thermal stability of **1** does. It seems possible that a_H responds primarily to the SOMO and not to the total radical stability, expressed, for example, by $\Delta H_f^\circ(R^\odot)$.

Crown Thioether Complexes of Ag^{I} and Cu^{I}: The Crystal Structures of $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$ and [LCuI] (L = 1,4,7-Trithiacyclononane)**

By *Heinz-Josef Küppers, Karl Wieghardt,* Yi-Hung Tsay, Carl Krüger, Bernhard Nuber,* and *Johannes Weiss*

The coordination chemistry of the macrocycle 1,4,7-trithiacyclononane (**L**), a crown thioether, is currently the subject of intensive investigations. It forms very stable 2 : 1 complexes with a variety of transition-metal ions (Fe^{II}, Fe^{III}, Co^{II}, Co^{III}, Ni^{II}, Pd^{II}, Pt^{II}, Cu^{II}, Ru^{II})[1] and can stabilize the metal centers in unusual oxidation states, e.g. Pd^{III} and Pt^{III} in $[PdL_2]^{3\oplus}$ and $[PtL_2]^{3\oplus}$, respectively.[2]

We report here on complexes of this ligand with Ag^{I} and Cu^{I}. Both metal centers, as soft Lewis acids, form stable coordination compounds with the soft S-atoms of the ligand. Of particular interest are the 1 : 1 complexes between the metal centers that preferentially coordinate tetrahedrally and the potentially tridentate ligand. The structure of such compounds $[ML]^{\oplus}$ ($M = Cu^{I}$, Ag^{I}) is dependent upon the hardness/softness of the anion used. In this work we show that when $X = I^{\ominus}$ (soft anion) a distorted tetrahedral structure is formed in which **L** functions as tridentate ligand and the fourth coordination site is occupied by $I^{\ominus}$. In contrast, with hard anions ($X = ClO_4^{\ominus}$, $NO_3^{\ominus}$), $[ML]_n^{n\oplus}$-oligomers are formed in which **L** is a bridging ligand, so that a distorted tetrahedral MS_4 coordination results.

Upon reaction of $AgNO_3$ in CH_3CN or CH_3OH with **L** in the ratio Ag : **L** = 1 : 1, a colorless solid of the composition $[AgL]NO_3$ is obtained. According to IR spectroscopic findings the anion $NO_3^{\ominus}$ is not bound coordinatively to the Ag^{I} ($\tilde{\nu}(N\text{-}O) = 1390\ cm^{-1}$). When $AgClO_4 \cdot H_2O$ is allowed to react with **L** in the ratio 1 : 3 or 1 : 1.7, colorless crystals of the composition $[AgL_2]ClO_4$ and $[Ag_4L_5](ClO_4)_4$ are formed. Also in this case the anion is not bound coordinatively, as shown by the crystal structure analysis.[3]

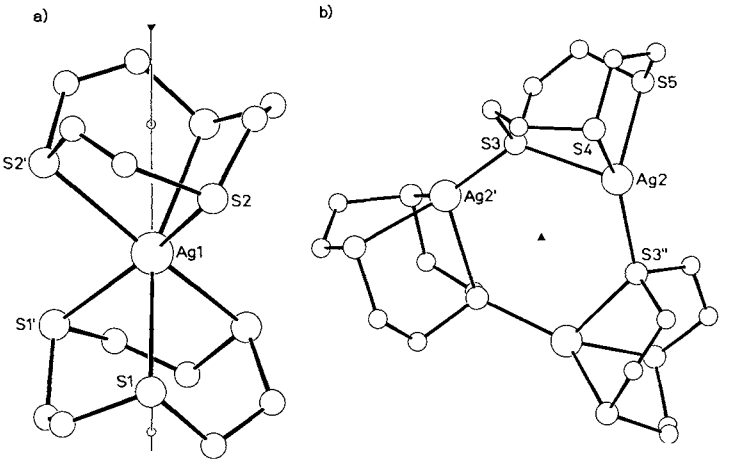

Fig. 1. a) Structure of the cation $[AgL_2]^{\oplus}$ in the crystal of $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$. Selected bond lengths [Å] and angles [°]: Ag1-S1 2.753(4), Ag1-S2 2.697(5); S2-Ag-S1 90.1(1), S2'-Ag1-S2 79.6(2), S2'-Ag1-S1 116.0(2), S1'-Ag1-S2 159.7(2), S1'-Ag1-S1 78.6(1). b) Structure of the trimeric cation $[Ag_3L_3]^{3\oplus}$ in the crystal of $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$. Selected bond lengths [Å] and angles [°]: Ag2-S3 2.724(2), Ag2-S4 2.595(4), Ag2-S5 2.613(4), Ag2'-S3 2.480(2); S3''-Ag2-S5 133.8(1), S3''-Ag2-S4 138.5(1), S3''-Ag2-S3 114.0(1), S5-Ag2-S4 84.9(1), S5-Ag2-S3 80.8(1), S4-Ag2-S3 81.7(1), Ag2'-S3-Ag2 126.0(1). ▲ denotes a crystallographic threefold axis.

Interestingly, the unit cell of $[Ag_4L_5](ClO_4)_4$ contains two different cations: the monomeric $[AgL_2]^{\oplus}$ (Fig. 1a) and a trimeric $[Ag_3L_3]^{3\oplus}$ (Fig. 1b), so that the salt can be formulated as $[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$. Like the metal centers in other ML_2 complexes, the Ag^{I} center in the $[AgL_2]^{\oplus}$ ion is surrounded by a distorted octahedral array of six S atoms from two ligands **L**. In contrast, in the trimeric cation $[Ag_3L_3]^{3\oplus}$ the Ag^{I} ions are coordinated to a highly distorted tetrahedral array of four S atoms; one S atom of each nine-membered macrocycle is bound to two Ag^{I} centers. This is the first example of a bridging crown thioether. The Ag_3S_3 six-membered ring is, within the limit of error, planar.[8] We therefore assume that octahedral $[AgL_2]^{\oplus}$ ions are present in $[AgL_2]ClO_4$ and that $[AgL](NO_3)$ con-

sists of oligomeric $[AgL]_n^{n\oplus}$ units with bridging thioether ligands and fourfold coordinated Ag^I ions. Possibly $n=3$ here also, but other values for n are conceivable.

To obtain information about the structures of these compounds in solution, the ^{1}H-NMR spectra of $[AgL]NO_3$, $[Ag_4L_5](ClO_4)_4$ and $[AgL_2]ClO_4$ in CD_3CN or [D$_6$]dimethyl sulfoxide were recorded. In all three cases only one broad singlet was observed. Therefore it could not be unequivocally established whether the structures of these salts in the solid state and in solution are identical.

The reaction of $[Cu(CH_3CN)_4](ClO_4)$ with **L** in CH_3CN in the ratio 1 : 1 under anaerobic conditions yields colorless crystals of $[CuL](ClO_4)$. In contrast to many coordinatively unsaturated Cu^I complexes, solutions of this salt in CH_3CN do not react with CO at $T=293$ K. The solid, on the other hand, is stable toward oxygen and water. We therefore assume that $[CuL]_n^{n\oplus}$-oligomers ($n\geq 3$) with bridging thioether ligands and Cu^IS_4 coordination polyhedra are likewise present in $[CuL](ClO_4)$.

Interesting in this context are the works of *Schröder* et al.[4] and *Cooper* et al.,[5] in which it is shown that the potentially hexadentate ligand hexathia[18]crown-6 $\mathbf{L}^1$ (1,4,7,10,13,16-hexathiacyclooctadecane) reacts with Cu^I to form the complexes $[CuL^1](BF_4)$ with distorted tetrahedral Cu^IS_4 polyhedra or the complexes $[Cu_2L^1(CH_3CN)_2](ClO_4)_2$ with two Cu^IS_3N polyhedra. That is, the coordination number six of Cu^I, other than in the case of Ag^I in the $[AgL_2]^{\oplus}$ cation described here, is not reached.

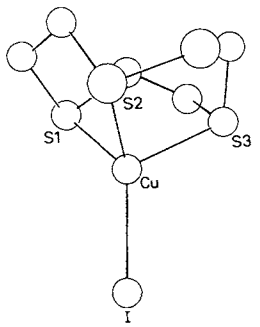

Fig. 2. Structure of [LCuI]. Selected bond lengths [Å] and angles [°]: Cu-I 2.490(1), Cu-S1 2.331(1), Cu-S2 2.343(1), Cu-S3 2.329(1); S1-Cu-I 128.6(1), S2-Cu-I 121.3(1), S3-Cu-I 118.7(1), S1-Cu-S2 92.6(1), S2-Cu-S3 93.9(1), S1-Cu-S3 93.1(1).

Upon reaction of a suspension of CuI in methanol with **L** in the ratio 1 : 1 we obtained the colorless solid [LCu^{I}I], which was recrystallized from CH_3CN. The crystal structure analysis of this compound,[6] was consistent with the monomeric neutral complex [LCuI] (Fig. 2). The Cu^I ion exhibits strongly distorted tetrahedral coordination; three S atoms of the macrocycle and a coordinatively bound $I^{\ominus}$ form the first coordination sphere. Unusual is the high stability of this complex toward oxygen in solution, as in the solid state.

Experimental

$[AgL](NO_3)$: A solution of **L** (0.1 g; 1 mmol) in CH_3CN (20 mL) was added to a solution of $AgNO_3$ (0.17 g, 1 mmol) in CH_3CN (10 mL) (298 K). After a few minutes a colorless precipitate formed, which was recrystallized from CH_3CN. Yield: 60-70%. IR spectrum (KBr): $\tilde{\nu}(NO_3)=1390$ cm^{-1} (s) and a weak band at $\tilde{\nu}=1760$ cm^{-1}. ^{1}H-NMR (80 MHz, CD_3CN, $T=298$ K): $\delta=2.94$ (broadened singlet).

$[\{Ag_3L_3\}\{AgL_2\}](ClO_4)_4$: A solution of $AgClO_4\cdot H_2O$ (0.13 g, 0.57 mmol) in CH_3OH (10 mL) was added to a solution of **L** (0.18 g, 1 mmol) in CH_3OH (30 mL). A colorless precipitate immediately separated; this was recrystallized from CH_3CN. Yield: 50-60%. ^{1}H-NMR (80 MHz, CD_3CN, $T=298$ K): $\delta=2.82$ (broadened signal).

$[AgL_2](ClO_4)$: A solution of $AgClO_4$ (0.10 g, 0.45 mmol) in CH_3OH (10 mL) was added to a solution of **L** (0.26 g, 1.4 mmol) in CH_3OH (30 mL). A colorless precipitate immediately separated out which, upon continued stirring (298 K) of the suspension, redissolved within 1 h. Upon concentration of the solution by evaporation, a colorless precipitate separated. Yield ca. 60%. ^{1}H-NMR (80 MHz, [D$_6$]dimethyl sulfoxide, $T=298$ K): $\delta=2.95$ (broadened singlet).

$[CuL](ClO_4)$: A solution of $[Cu(CH_3CN)_4](ClO_4)$ (0.33 g, 1 mmol) in oxygen-free CH_3CN (20 mL) was treated with 0.19 g (1.1 mmol) of **L** and the resulting mixture stirred for 3 h at 293 K. On evaporating down the solution, a colorless precipitate separated. Yield 30%.

[LCuI]: A suspension of CuI (0.13 g, 0.7 mmol) and **L** (0.12 g, 0.67 mmol) in CH_3OH (20 mL) was heated under reflux for 2 h. A colorless solid formed, which was insoluble in CH_3OH and H_2O but could be recrystallized from CH_3CN. Yield: 95%.

All the complexes gave correct analyses (C,H,S,I). The ligand 1,4,7-trithiacyclononane was prepared according to a procedure given in the literature [7].

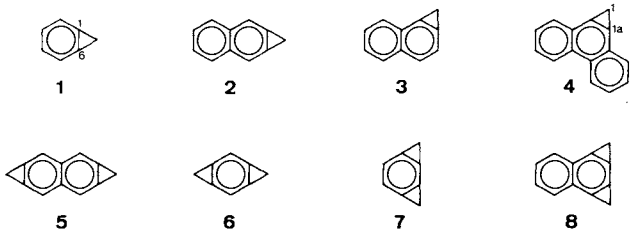
Dicyclopropa[*a,c*]naphthalene: a Compound Capable of Existence?**

By *Udo H. Brinker,* Hartmut Wüster,* and *Gerhard Maas*

Cycloproparenes have been the subject of intensive study for almost 25 years,[1] yet dicycloproparenes, which have *two* three-membered rings fused to the *same* aromatic ring, are thus far unknown. All cycloproparenes have a high strain energy; nevertheless, their kinetic stability strongly depends on their structure. *Linearly* coupled cycloproparenes such as **1**[2a-d] and **2**[2e] are generally more stable and also easier to prepare than, e.g., the *angular* species **3**[3] and **4**.[4] Thus, **3** explodes on melting,[3,4a] while solutions of **4** decompose on prolonged standing, even at −60 °C.



1 **2** **3** **4**

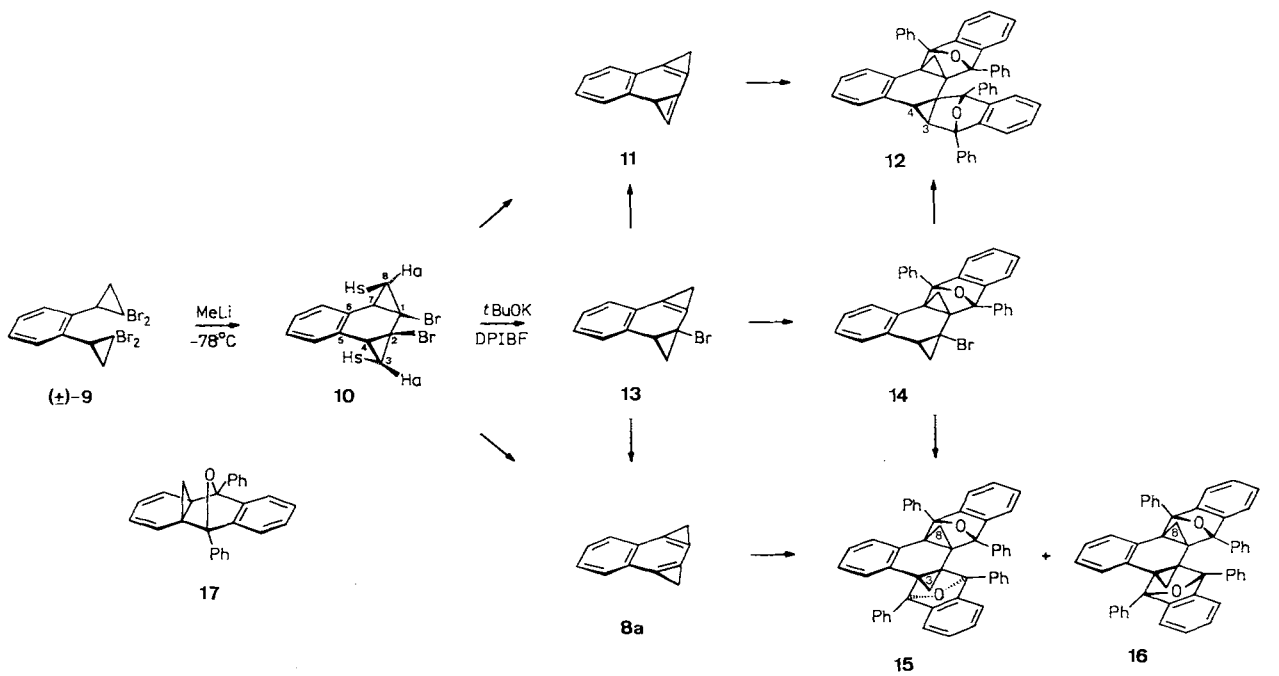
5 **6** **7** **8**

The dicyclopropa[*b,g*]naphthalene **5**[5] synthesized by *Vogel* et al. is the only dicycloproparene to have been isolated so far. Its strain energy has been determined as 166 kcal·mol^{-1} (lower limit);[6] it is sensitive to shock and explodes on melting.

Despite this there has been no lack of effort in attempting to prepare the more highly strained dicycloproparenes, in which *one* aromatic ring and *two* three-membered rings are annelated. Attempts to generate the parent compounds, the dicyclopropa[*a,d*]benzene **6**[7a] and dicyclopropa[*a,c*]benzene **7**,[7] have thus far failed. The species **8**, benzoannelated **7**, is expected to have a higher strain energy than **5**, in which the three-membered rings are located at the maximum distance from each other. We report here on the preliminary results of our attempts to generate and trap the species **8**.

An ideal starting compound for the generation of **8** is the benzoannelated *r*-1,*t*-2-dibromotricyclo[5.1.0.0^{2,4}]oct-5-ene **10**[8], which is obtained by 1,6-dehalogenation[8a] of the (±)-bisdibromocarbene adduct **9** with methyllithium at −78 °C (yield 60%). The dicycloproparene **8a** could be formed by twofold HBr-elimination from **10**, whereby the benzylic, tertiary protons (H-4 and H-7) should be attacked by a suitable base. Besides this there is the possibility of a competing 1,2-elimination taking place,[4] initiated by cleavage of one of the geminal cyclopropane ring protons. This process leads to an "exocyclic" double bond in the three-membered ring, which is not conjugatively bonded to the benzene ring (see **11**).

Upon reaction with potassium *tert*-butoxide (2.4 mol. equiv.) at 20 °C in THF/DMSO (1:1), **10** is already no longer detectable by gas chromatography after a few minutes. No significant signals could be observed in the temperature range from +20 to −70 °C during the ^{1}H-NMR and ^{13}C-NMR spectroscopic monitoring of the reaction of



10 (2.4 mol. equiv. KO*t*Bu, 2.4 mol. equiv. 18-crown[6], [D$_8$]THF).

Of the two possible Kekulé forms of **8**, only **8a** can be formed directly from **10** by twofold 1,2-elimination. **8a** could be the energetically more stable form, since it contains an intact benzene ring and two cyclopropene units.[9] Attempts to trap the diene unit in **8a** with 4-phenyl-1,2,4-

[**] This work was supported by the Fonds der Chemischen Industrie and by Degussa AG. We thank Dr. *W. Dietrich* and Dipl.-Chem. *H. Kühne* for the NMR spectra of **12**, **15**, and **16** and Herr *K. Gomann* for assistance with the synthesis of **10**.

triazol-3,5-dione (PTAD) as dienophile met without success, since KO*t*Bu destroys the trapping agent.[10]

In view of the expected instability of **8** it was considered advisable from the very start to use the reactive 1,3-diphenylisobenzofuran (DPIBF) as diene.[11] Reaction of **10** with DPIBF in the molar ratio 1:9 (2.4 mol. equiv. KO*t*-Bu, THF:DMSO = 1:1, 20°C) led to the formation of three crystalline bisadducts (yield 81%), which could be separated by HPLC (silica gel Si 60-5, pentane: CH_2Cl_2 = 6:4). The bisadduct **12** (yield 28%) is formed via twofold Diels-Alder addition of DPIBF to **11** or one addition to **13** with formation of **14**, which after HBr-abstraction and creation of an "exocyclic" double bond (cf. **11**) is attacked again by DPIBF. The chemical shifts of H-3 and H-4 in **12** are in good agreement with those of the corresponding protons of the adduct of furan to C-1 and C-1a of **4**.[4, 12] The crystal structure analysis[13] can explain the observed high-field shift of two aromatic protons at $\delta = 5.25$ and 5.6.

Since the number of ^{13}C-resonance lines is only half as many as the maximum possible lines, the main product **15** (yield 44%) must be a symmetrical compound. The three-membered rings are oriented in the *anti*-position,[14] whereas the cyclopropane ring and O-atom of a five-membered ring are each *syn*-oriented. The signals of the protons on C-3 and C-8 ($\delta = -0.5$), which point towards the benzene ring, are shifted upfield. In contrast, the protons oriented in the direction of the oxygen atoms ($\delta = 2.75$) are shifted markedly downfield. The overall result is that **15** is formed by twofold *endo*-addition of the trapping agent.

In contrast, **16** (yield 9%) can be formed by an *endo*- and an *exo*-oriented [4+2]-cycloaddition. The characteristically large difference in the chemical shifts of the protons on C-8 observed in the case of **12** and **15** is not found in **16**. As indicated by the X-ray structure analysis,[13] *both* protons on C-8 are similarly shifted noticeably downfield by the O-atoms. Altogether, the Diels-Alder reactions of DPIBF with the double bonds generated from **10** or **13** and **14** with KO*t*Bu with formation of the bisadducts **12**, **15**, and **16** proceed with strongly preferred *endo*-attack (94%).

The crucial question is, whether dicyclopropa[*a,c*]naphthalene **8** is in fact formed as an intermediate in the reaction of **10** with KO*t*Bu, or whether or not two cyclopropene systems generated by consecutive 1,2-eliminations are each trapped directly by DPIBF as bisadducts **15** and **16**. A concerted twofold HBr-elimination in **10**, on the other hand, seems unlikely.

As evidenced by the formation of **12** in 28% yield, not only is a conjugated "endocyclic" double bond formed but also, to the extent of ca. 17% (based on all 1,2-eliminations), the strained "exocyclic" double bond of the cyclopropenes.[15] The fact that ca. 83% of the DPIBF adducts **12**, **15**, and **16** result from additions to the double bonds generated between C-1 and C-7 and/or between C-2 and C-4, proves the strongly preferred direction of elimination with cleavage of benzylic hydrogen atoms and formation of conjugated double bonds.[15] Under the standard conditions with 2.4 mol. equiv. of base, formation of the monoadduct **14**, as is expected in the addition of DPIBF to the monoelimination product **13**, could not be detected. When only 1.1 mol. equiv. of the base was used, 45% of the monoadduct **14** could be isolated along with 9% of the bisadducts **12**, **15**, and **16** (ratio ca. 1:2.5:1). In the reaction of **14** with 1.2 mol. equiv. of base and DPIBF under the conditions employed for the reaction of **10**, three bisadducts (24% of **12**, 48% of **15**, and 10% of **16**) were isolated (ratio 2.4:4.8:1). The comparable ratios of the bisadducts on starting from **10** and **14** suggests that the monoadduct **14** should also be formed as intermediate in the reaction of **10** with 2.4 mol. equiv. of base.

The annelation of a cyclopropane ring to the benzene nucleus effects a strain increment of ca. 14 kcal·mol^{-1} in excess of the sum of the E_s of the structural units benzene and cyclopropene [difference of the strain energies E_s of **1** (68 kcal·mol^{-1})[16] and of cyclopropene (53.7 kcal·mol^{-1})]. Accordingly, for dicyclopropa[*a,c*]naphthalene **8** an increase in strain is expected which exceeds the strain energies of the two cyclopropene units contained in **8** by at least 28 kcal·mol^{-1}. This large increase in strain energy obviously cannot be compensated by the gain in aromatization energy. When starting from **10** in the presence of KO*t*Bu, instead of the formation of **8a** or of the aromatic system **8**, stepwise 1,2-eliminations and additions of DPIBF apparently take place.

[9] Concerning bond fixation in cyclopropabenzene see: Y. Apeloig, D. Arad, *J. Am. Chem. Soc. 108* (1986) 3241.

[10] The addition of the dienophile PTAD to the diene moiety in **8a** should lead to a markedly nonplanar double bond between the three-membered rings.

[11] In order to check to what extent cycloproparenes actually undergo cycloadditions with DPIBF at 20°C and normal pressure we have used **1** as a model species. Whereas **1** does not react with the less reactive 1,4-diphenyl-1,3-butadiene under these conditions (B. Halton, unpublished results, cited in [1a]), with DPIBF it forms the *endo*-adduct **17**. The stereochemical assignment is based on the deshielding of the proton in the *anti*-position to the norcaradiene unit by the oxygen atom ($\delta = 3.15$). Accordingly a [2+4]- or [6+4]-cycloaddition to C-1 and C-6 in **1** could have taken place.

[12] T. T. Coburn, W. M. Jones, *J. Am. Chem. Soc. 96* (1974) 5218.

[13] The structures of **12** and **16** have been confirmed by X-ray structure analyses.

[14] On the basis of the spectroscopic data it cannot be completely ruled out that the cyclopropane rings in **15** are in the *syn*-position. The reaction of **13** with DPIBF to give **14** is an *endo*-addition. However, a second *endo*-addition of DPIBF—to the "conjugated" cyclopropene resulting from reaction of **14** with the base—requires a sterically unfavored transition state. This is not the case in the formation of **15** with *anti*-oriented three-membered rings.

[15] DPIBF-adducts, derived from a compound with *two* strained "exocyclic" double bonds, were not found.

Superconductivity—a Chemical Phenomenon?**

By *Arndt Simon**

The accepted theory of superconductivity by *Bardeen*, *Cooper*, and *Schrieffer*[1] is based on the assumption that electrons pair (Cooper pairs) via special interactions with the lattice. The Coulomb repulsion between electrons is overcome indirectly by electron-phonon coupling. The interaction of an ion in the crystal and a passing electron changes the vibrations of the ion. The interaction of the ion with a second electron finally leads to attraction between both electrons. In other terms, a virtual phonon is exchanged between both electrons. The superconducting ground state corresponds to pairs of electrons with opposite spin and wave vectors of equal length but opposite sign ($+k\uparrow$, $-k\downarrow$). All pairs have the same energy. An energy gap separates ground and excited states, so no continuous change in momentum can occur.

This abstract model, as also the nature of the "classical" superconductors—as a rule these are intermetallic phases—does not make it easy to correlate the phenomenon of superconductivity with the electronic properties of certain elements and the specific features of their chemical bonding. Moreover, it does not add to the descriptive value of the model that the electrons of a Cooper pair can be thousands of angstroms apart.

The discovery of high-temperature superconductivity in oxides[2,3] has not yet forseeable practical applications, but, to the chemist, in addition it opens up insights into the relationships between the phenomenon of superconductivity and such concepts as, e.g., oxidation number, change of coordination with oxidation state etc.

$BaPb_{1-x}Bi_xO_3$ ($x \approx 0.3$) **1** crystallizes in the simple (deformed) perowskite structure, i.e. $(Pb,Bi)O_6$ octahedra are linked via all apices. The compound is metallic and becomes superconducting at $T_c = 13$ K.[2] Bismuth has the unusual oxidation state +4 and exhibits the tendency to delocalize one electron in the conduction band ($Bi^{5+} + e^-$) or to localize one electron to form a lone pair (Bi^{3+}). Regular octahedra and tetragonal pyramids are common coordination polyhedra for Bi^{5+} and the lone-pair ion Bi^{3+}, respectively.

Lattice vibrations which lead to a deformation of the coordination octahedron around the Bi-atoms in **1** (longitudinal optical (LO) phonons in the direction of one of the main axes), "switch" the tendency to localize (off-center position with Bi^{3+}, lone pair with antiparallel spin) and delocalize (Bi^{5+} in the center of the octahedron, delocalized electron pair) electrons with the characteristic frequency of this vibration (cf. Fig. 1) and correlated for all atoms in the crystal. The coupling of electrons and phonons hereby corresponds to an oscillating change in the oxidation state of bismuth ("valence fluctuation") by *two*. The aforementioned characteristics of the Cooper pairs, e.g. antiparallel spin, $+k\uparrow$, $-k\downarrow$, same energy of all pairs, large correlation lengths, immediately follow from such a tendency of the conduction electrons to localize pairwise at the Bi atoms. Of course, the oxygen atoms are vitally important for this process. *Bilz* et al.[4,5] pointed out that O^{2-} exhibits a very unusual increase of its polarizability with increasing cation–anion separation, enhanced by anisotropy and covalency effects which make the strong coupling of the electronic states of the cation to the vibrations of the oxygen atoms (and vice versa) plausible.

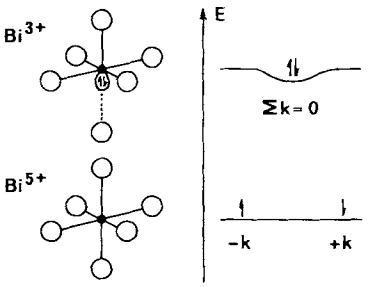

Fig. 1. Model of the pairing of electrons due to a change in the valence of the Bi atoms in **1**.

In $La_{1.8}Ba_{0.2}CuO_4$ **2** (K_2NiF_4 type), Cu has the oxidation state +2.2. The transition temperature of ca. 30 K[3] increases upon substitution of Ba by Sr to ca. 36 K.[6] Apparently, La, Ba and Sr merely determine the correct coordination dimensions and electron balance with Cu. Elongated CuO_6 octahedra (d^9, Jahn-Teller distorted, 4×190 and 2×240 pm) are linked according to $CuO_{4/2}O_2$ via the basal O atoms.[7] To a first approximation, networks of Cu-atoms square-planar coordinated to O-atoms are formed in layers (Fig. 2, top) and the indicated quadrupole mode

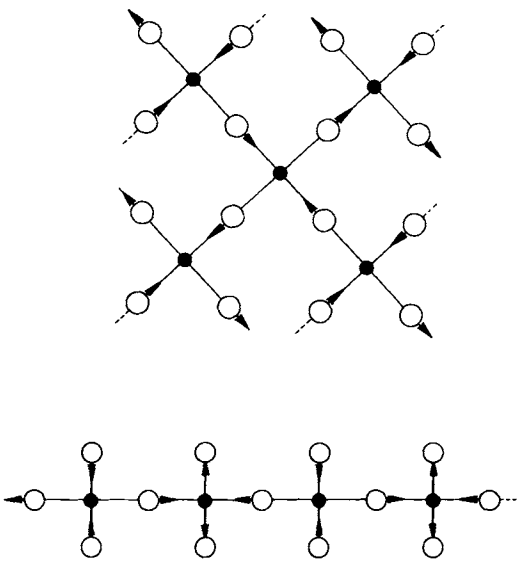

Fig. 2. Top: Cu atoms surrounded by a square-planar array of O-atoms. Bottom: CuO_2 units linked via bridging O-atoms.

leads to an oscillation between the coordination numbers 4 and 2 (+2). The deformation of the square-planar coordination, characteristic for Cu^{3+} (d^8, delocalized electron

Heisenbergstrasse 1, D-7000 Stuttgart 80 (FRG)

[**] Discussed in part at the International Conference on Lanthanides and Actinides (IGLA), Lisbon (Portugal), April 5-10, 1987.

pair) could again result in a tendency to localize *two* electrons with antiparallel spin (Cu^+, d^{10}).[*]

The explanation given for the superconductivity in **2** is supported by the results of investigations with $YBa_2Cu_3O_{7-x}$ ($x \approx 0.1$) **3**, which contains Cu in a mixed valence state +2.27 and which exhibits the highest transition temperature, $T_c \approx 93$ K reported so far.[8] Neutron diffraction studies on powders revealed an orthorhombic structure[9, 10] containing Cu2 in slightly buckled layers $CuO_{4/2}$ (Fig. 2, top) which enclose the Y atoms. Superconductivity should not arise from this part of the structure as substitution of Y by magnetic 4f elements does not destroy the superconductivity. In contrast, the other Cu atoms (Cu1) form parallel ribbons $CuO_{2/2}O_2$ (Fig. 2, bottom), which can be described as linear CuO_2 units (d(Cu-O) = 183 pm) linked via bridging O-atoms (194 pm). The square-planar environment of the Cu atoms is strongly deformed in these ribbons and therefore the tendency to localize an electron pair (Cu^+, d^{10}) in the CuO_2 unit should be even more pronounced than in **2**.

This tendency can be switched on and off periodically for each atomic site via the indicated zone edge mode. Of course, such an ionic model is a crude approximation. The covalency of the Cu-O bonds and its dynamic variation is essential.

The explanation given for the pair-wise attraction of electrons at the Fermi level seems closely related to the model of the Peierls-instability and in particular the model of the "bipolaron".[13, 14] But the latter is distinctly different as it is based on electronic interactions without involving specific atomic properties. Unspecific local lattice distortions lead to a pairing of electrons in the bipolaron model. Here, it is intended to draw attention to the specific bonding of certain elements which might lead to the formation of "itinerant" electron pairs on the basis of the familiar chemistry of these elements.

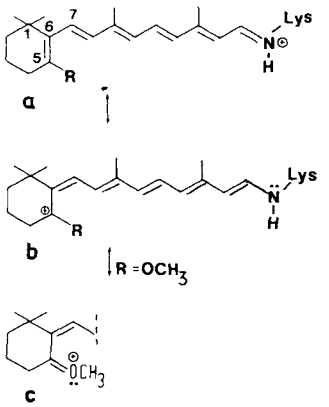
[*] In this context the structures of $KCuO_2$ [11] and $SrCu_2O_2$ [12] are instructive. In $KCuO_2$ the Cu^{3+} ion has square coordination (4 × 184 pm). Other than in **3**, $CuO_{4/2}$ ribbons are formed by edge-sharing. In contrast, $SrCu_2O_2$ contains (interconnected) linear CuO_2 units (2 × 184 pm).

Regulation of the 6-s Equilibrium Conformation of Retinal in Bacteriorhodopsin by Substitution at C-5; 5-Methoxy- and 5-Ethylretinalbacteriorhodopsin**

By *Elisabeth Kölling,* Dieter Oesterhelt, Henning Hopf,* and *Norbert Krause*

Retinal proteins, which contain retinal as protonated Schiff base (**1** in Scheme 1), absorb visible light. This involves, on the one hand, the triggering of sensory processes, e.g., vision in vertebrates by the rhodopsins and photophobic/photoattractive reactions by membrane proteins of *Halobacterium halobium*. On the other hand, energy conversion takes place, which in bacteriorhodopsin[1] leads to proton translocation and in halorhodopsin[2] to chloride translocation. The absorption of the protonated Schiff base in solution is shifted bathochromically in these proteins. This is brought about by the charged environment in the protein and the specific conformation of the retinal formed by interaction with the protein. Contributing factors are: a) the distance between a negative charge in the protein and the positively charged nitrogen center of lysine 216[3] of the protonated Schiff base,[4] b) a further negative charge[5] or a dipole[6] above (below) the cyclohexene ring, and c) the planarization of ring and chain at the C-6–C-7 bond (6-s bond).[7–9] The steric and electronic interaction of the retinal with the protein part can be analyzed by use of retinal analogues and isosteric compounds as controls. Especially interesting in this respect are substitutions at the cyclohexene ring, which can influence the torsion angle C5-C6-C7-C8 of the 6-s bond ("6,7-torsion angle"). Therefore 5-methoxyretinal and 5-ethylretinal[10] were synthesized and their influence on the absorption of the corresponding bacteriorhodopsins was investigated.



1, R = CH_3; **2**, R = CH_2CH_3; **3**, R = OCH_3

Scheme 1. The electron delocalization in the protonated Schiff base of retinal is illustrated by the resonance structures **a** and **b**. A methoxy group of C-5 additionally stabilizes the positive charge by a lone pair (resonance structure **c**).

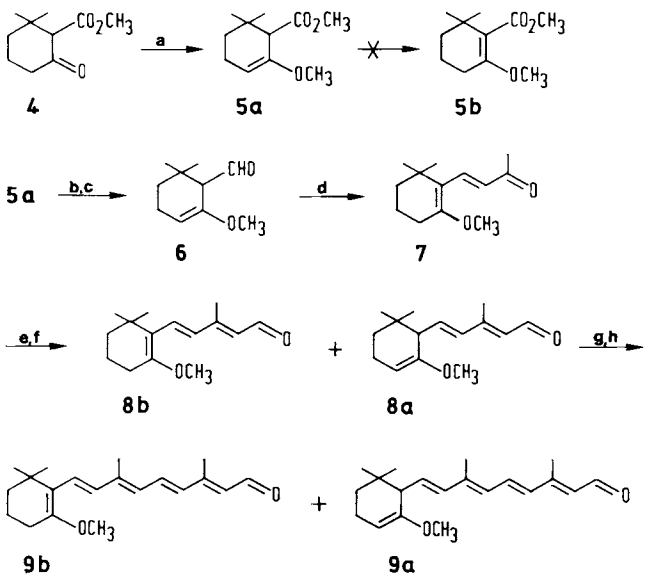
[**] Retinoids, Part 9.—Part 8: H. Hopf, N. Krause, *Tetrahedron Lett. 27* (1986) 6177.

For the synthesis of 5-methoxyretinal **9b** (Scheme 2), we used methyl 5,5-dimethyl-2-oxocyclohexanecarboxylate **4**[11] as key compound; the keto group is a masked enol ether function, and the ester group can serve for the coupling of the chain. The reaction of **4** with trimethyl orthoformate led exclusively to methyl 2-methoxy-5,5-dimethyl-2-cyclohexenecarboxylate **5a**. An isomerization to **5b**



Scheme 2. Synthesis of 5-methoxyretinal **9b**. a) $HC(OCH_3)_3$, *p*-toluenesulfonic acid, reflux (83%). b) $LiAlH_4$, 0.2 equiv. ethanol, diethyl ether, reflux (95%). c) PDC/CH_2Cl_2 (35%). d) Acetone KO*t*Bu, toluene 12 h (17%). e) $PO(OEt)_2CH_2CN$, NaH, THF (36%). f) DIBAH, toluene (95%). g) $PO(OEt)_2CH_2C(CH_3)CHCN$, NaH, THF (36%). h) As for f) (70%).

could not be accomplished, even under basic conditions (sodium ethoxide, 24 h, room temperature). Reduction of **5a** with $LiAlH_4$ afforded the corresponding hydroxymethyl derivative, which was oxidized to 5-methoxy-α-cyclocitral **6**. This could be converted quantitatively into 5-methoxy-β-cyclocitral only on treatment with a base (aluminum oxide). The aldol condensation of **6** with acetone and potassium *tert*-butoxide in toluene afforded the ketone **7**, exclusively as the β-isomer. For further chain elongation Wittig–Horner reactions were carried out with phosphononitriles and subsequent reduction with diisobutylaluminum hydride (DIBAH). The Wittig-Horner reaction of **7** with diethylphosphonoacetonitrile led, according to ^{1}H-NMR-analysis, to the formation of 5-methoxy-C_{15}-nitrile, 66% of which as the all-*trans*-isomer and 33% as the 9-*cis*-isomer. Even after reduction to the 5-methoxy-C_{15}-aldehyde **8**, only the β-isomer **8b** was present. However, in the reaction leading to 5-methoxyretinic acid nitrile the α- and β-forms were formed in about an equimolar ratio. Upon reduction the amount of α-isomer **9a** was increased. The mixture of 5-methoxyretinal **9a** and **9b** was separated by HPLC, whereby the pure α-isomer and fractions containing β-isomer contaminated with α-isomer were obtained. The β-isomer proved to be labile under the conditions used for its isolation and also at low temperature under an inert gas.

Bacterio-opsin was isolated from the retinal-negative mutants JW5 of *H. halobium*.[12] Upon incubation with retinal or suitable analogues, bacteriorhodopsin (BR) and analogue-bacteriorhodopsins, respectively, are reconstituted. Figure 1a shows the absorption spectra of α-5-methoxyretinal-BR (Spectrum 1, $\lambda_{max} = 460$ nm, cf. α-retinal-BR; $\lambda_{max} = 482$ nm) and a mixture of α- and β-5-methoxyretinal-BR (Spectrum 2). The difference spectrum from the spectra of **1** and **2** with a weighting of Spectrum 2 by a factor of 0.4 (not shown) corresponds to the absorption spectrum of β-5-methoxyretinal-BR ($\lambda_{max} = 570$ nm, shoulder in the short wavelength region). Cell vesicles from JW 5, which were incubated with α/β-5-methoxyretinal, showed ca. 20% of the proton transport activity of the bacteriorhodopsin. 13-*cis*- and all-*trans*-5-ethylretinal[10] were incubated with bacterio-opsin and absorption spectra were recorded at intervals between 10 and 144 s after incubation (Fig. 1b). Already after 10 s an intermediate was formed with an absorption maximum at 420 nm; the subtle fine structure of this spectrum points to restricted conformational mobility[7] of the 5-ethylretinal.

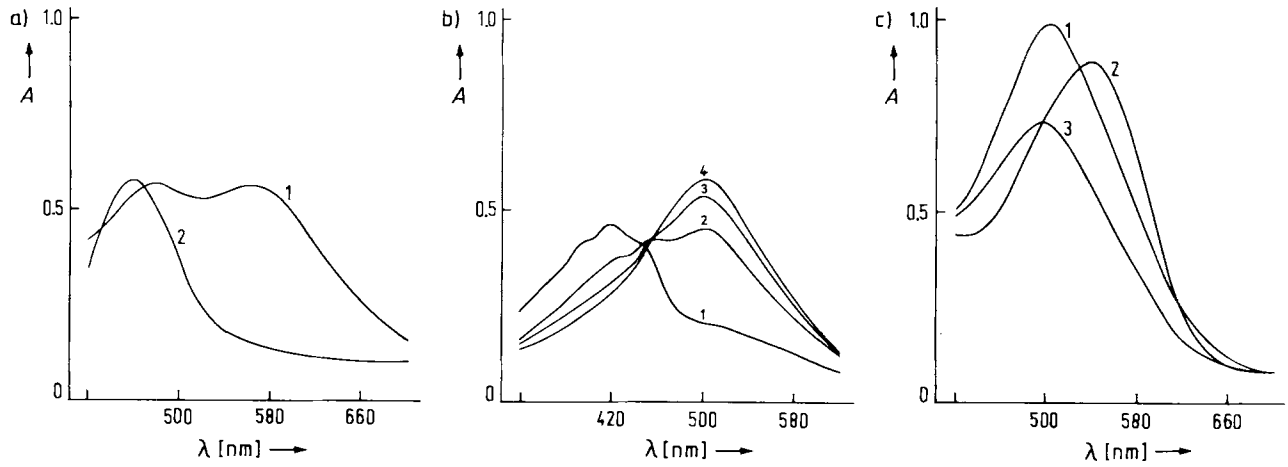


Fig. 1. a) Absorption spectra of bacterio-opsin in H_2O, incubated with α-5-methoxyretinal (Spectrum 1) and with a mixture of α- and β-methoxyretinal (Spectrum 2). b) Absorption spectra of bacterio-opsin in H_2O, incubated with all-*trans*-5-ethylretinal, after 10 s (Spectrum 1), 72 s (Spectrum 2), 108 s (spectrum 3), and 144 s (Spectrum 4); $\lambda_{max} = 504$ nm, $\varepsilon = 50000$. The time-dependent measurement at constant wavelength yields 3.2 mol/min for the rate of reconstitution of the chromophore with 13-*cis*-5-ethylretinal, 7 mmol/min with all-*trans*-5-ethylretinal, and 11 nmol/min with all-*trans*-retinal (not shown). c) Absorption spectra of 5-ethylretinal with bacterio-opsin in H_2O (Spectrum 1), with bacterio-opsin in 4M NaCl (Spectrum 2), and after dialysis against H_2O (Spectrum 3); cf. text.

The absorption spectra of 5-ethylretinal-BR in water ($\lambda_{max} = 505$ nm, Spectra 2–4 in Fig. 1b and Spectrum 1 in Fig. 1c) slope away unusually flatly at longer wavelengths for a retinal chromophore, thus indicating a mixture of chromophores. Indeed, addition of sodium chloride (final concentration 4 M) shifts the absorption maximum of the chromophore to $\lambda = 545$ nm (Fig. 1c, Spectrum 2). Removal of NaCl by dialysis again yielded the chromophore with a maximum at $\lambda = 504$ nm (Fig. 1c, Spectrum 3).

Table 1. Absorption maxima of retinal and 5- and 13-ethyl- and methoxyretinal and of the corresponding bacteriorhodopsins, and the proton transport activity measured on cell vesicles.

	λ_{max} [nm]		
	Retinal or analogue [a]	Bacterio-rhodopsin [b]	Proton transport activity [%]
Retinal	380	570	100
		(570) [e]	100

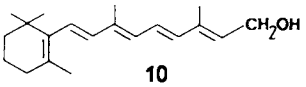
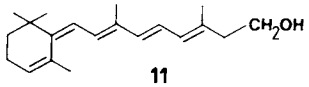
Both 5-ethylretinal-BR forms exhibit proton translocation activities; these are listed in Table 1 together with the absorption data and are compared with the data for the corresponding C-13 substituted compounds. To better understand the interpretation of the results it is important to remember the following facts.

Assumption of the planar conformation of the retinal in the bacteriorhodopsin with respect to the 6,7 single bond is based on the following findings: a) Retinol **10** contains the spectroscopic properties of retroretinol **11** at the binding



10



11

site of the bacterio-opsin and can be converted into retroretinal only photochemically in the binding site but not in free solution. Apart from retinol, only molecules which contain the cyclohexene ring bearing the side chain up to the C-13 atom of retinal exhibit this property.[7] b) In the reconstitution of the bacteriorhodopsin from bacterio-opsin and retinal an intermediate with an absorption shifted to the red region (BR_{400}) is formed in the first step without coupling of a covalent bond between retinal and protein.[13] This intermediate exhibits a fine structure in its absorption band.

Whether the planar conformation (6,7-torsion angle = 0°) is an s-*cis* or s-*trans*-conformation, is still uncertain. Analogous bacteriorhodopsins, in which these conformations are fixed by insertion of a second ring, which couples C-5 with C-8 and C-16 with C-8, respectively, have been studied.[8] In the case of the "*trans*-compound" the corresponding analogue-BR is formed more readily, is more active, and shows the absorption spectrum of bacteriorhodopsin; the *cis*-compound shows a strong red-shifted absorption maximum.[8] This effect is to be expected for *cis*-compounds but not for *trans*-compounds, and a very much smaller difference is predicted for open-chain, conjugated systems such as retinal itself.[7] There is no doubt, however, that a deviation of the 6,7-torsion angle from 0° must in each case effect a blue shift of the absorption maximum. On this basis the data in Table 1 can be interpreted in terms of different 6,7-torsion angles. The replacement of a methyl group at C-13 of retinal by an ethyl group gives rise to a blue shift of the absorption maximum of the corresponding bacteriorhodopsin of about 11 nm; neither large electronic nor steric effects are observed. The absorption maximum of all-*trans*-13-methoxyretinal-BR lies at about 550 nm,[14] i.e. even the methoxy group isosteric with ethyl does not have a very strong influence on the absorption maximum. In contrast, the introduction of the ethyl group in the 5-position causes a drastic blue shift of the absorption maximum from 570 nm to 506 nm. This cannot be determined by electronic effects; we assume that the 6,7-torsion angle is different, due to an alteration in steric interaction. NaCl obviously brings about a decrease in this angle, so that the absorption maximum is shifted to 545 nm and is once again similar to that exhibited by retinal-BR. This could be interpreted in terms of the forces which lead to a planarization of the cyclohexene ring of retinal in the binding site being overcompensated by steric hindrance of the ethyl group. Salt strengthens these forces, and thus reduces the 6,7-torsion angle again. Consistent with this, bacteriorhodopsin itself shows no dependence of its absorption maximum on the salt concentration. The absorption of the 5-methoxyretinal-BR (β-form) can also be understood on this basis. Due to the ethyl/methoxy isosteric relationship, the same steric repulsion was to be expected, but the stronger electronic interactions and the increased conjugation due to the donor property of the methoxy group (cf. the resonance structure **c** in Scheme 1) appear to lead to the planar conformation, and thus to the absorption maximum of the retinal remaining the same. For technical reasons the effect of salt on the absorption maximum could not be monitored. It is predicted that no change takes place on addition of salt.

The blue shift caused by an ethyl group in the C-13 position is smaller (11 nm) than that caused by such a group in the C-5 position (25 nm). Whether this is determined by electronic effects, different for both substitutions, or by incompletely compensated steric repulsion, cannot be established. With and without salt, 5-ethylretinal-BR shows proton translocation activity, even if reduced compared to BR, and hence substantiates that the position of the cyclohexene ring can reduce but not completely eliminate the activity.

Summarizing, it can be established that steric and electronic interactions of the cyclohexene ring with the protein environment determine the 6,7-torsional angle. It is 0° in retinal (6-*trans* or 6-*cis*), and, on suitable substitution, e.g. with an ethyl group in the C-5 position, it differs from 0°; however, it is then salt-dependent. These findings suggest a competition between electronic and steric interactions of the retinal with its environment. The 6,7-torsional angle has an influence on the activity of the proton pump, but only in quantitative form.

Structure of a Crystalline Alkali-Metal Cyclopentadienide

By *Peter Jutzi,* Wilhelm Leffers, Bernd Hampel* (dec.), *Siegfried Pohl,** and *Wolfgang Saak*

Due to the rapid development of metallocene chemistry in the fifties, alkali metal salts of cyclopentadiene—already known since the turn of the century[1]—have become indispensable agents for the transfer of cyclopentadienyl groups. In spite of the obvious importance of these compounds there is still hardly any information available on their solid-state structure. Base-free alkali-metal cyclopentadienides are nearly insoluble in non-donating solvents; to our knowledge,[2] they hitherto have always been obtained as X-ray amorphous substances, and, accordingly, have not been further investigated.

We recently reported that the solubility of cyclopentadienyllithium compounds in nonpolar solvents can be increased significantly by incorporation of trimethylsilyl groups; thus, for example, tris(trimethylsilyl)cyclopentadienyllithium even dissolves in hexane.[3,4] Crystalline adducts of this compound with amines[3] and ethers[5] are likewise readily soluble and monomeric in the solid state, in solution, and in the gas phase. In systematic studies on silylated alkali-metal cyclopentadienides we now succeeded for the first time in preparing a base-free compound in crystalline form. Upon reaction of trimethylsilylcyclopentadiene with potassium or potassium hydride in toluene as solvent we obtained potassium trimethylsilylcyclopentadienide **1** as colorless, extremely air-sensitive platelets which can be shredded into very fine fibers.[6]

$$(Me_3Si)C_5H_5 \xrightarrow[-1/2H_2]{+K} (Me_3Si)C_5H_4K$$

1

A structure with parallel oriented one-dimensional infinite units, presumed for **1** alone on the basis of this property, is confirmed by an X-ray structure analysis[7] (see Fig. 1). Each of these units contains a "supersandwich complex," which is made up of a repeating sequence of potassium atoms and (on both sides) pentahapto bonded cyclopentadienyl rings. The trimethylsilyl groups attached to the cyclopentadienyl moieties are arranged "in gaps".

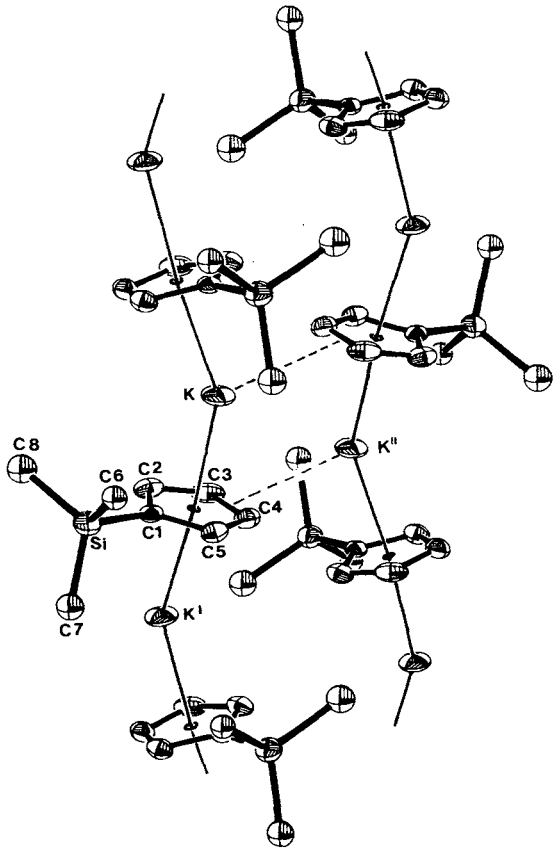

Fig. 1. Crystal structure of **1**; bond lengths [Å] and angles [°]: K-C1 3.006 (0.010), K-C2 2.988, K-C3 3.049, K-C4 3.079, K-C5 3.036, K'-C1 3.022, K'-C2 3.001, K'-C3 3.011, K'-C4 3.074, K'-C5 3.006, K''-C3 3.666, K''-C4 3.678, average CC distance in the C_5 ring 1.408, Si-C1 1.820; C5-C1-Si 126.3, Si-C1-C2 128.1.

The average distance between the potassium atoms and the carbon atoms of the cyclopentadienyl units is about 3.0 Å; this corresponds to a distance between potassium and ring center of about 2.78 Å. Considering the corresponding values for the tris(trimethylsilyl)cyclopentadienyllithium-quinuclidine adduct[3] (2.16 and 1.79 Å) and the increase in the ionic radius[8] of 0.73 Å on going from lithium to potassium, the distances found for **1** are exceptionally large, thus indicating an electrostatic interaction between anionic π-systems and potassium ions.[9]

Interestingly, an additional weak bonding relationship between potassium atoms and cyclopentadienyl units from neighboring strands (K–C distance about 3.7 Å) is observed in the structure of **1**. This interaction leads to a distortion of the geometry around each of the potassium atoms, resulting in a zig-zag chain structure for the polymeric potassium trimethylsilylcyclopentadienide **1**; the angle between the normals to the cyclopentadienyl rings (at

the potassium atom) is 150.7°. We presume that the weak interactions between the strands in **1** are responsible for the tendency to crystallize.[10]

Due to the sensitivity of **1**, molecular weight determinations in benzene solution are poorly reproducible; however, they clearly confirm the degradation of the polymer to low molecular units. According to mass spectrometric investigations, **1** becomes monomeric in the gas phase. Addition of tetrahydrofuran to a solution of **1** in toluene leads to the formation of $(Me_3Si)C_5H_4K \cdot THF$, a crystalline 1:1 adduct, whose structure has not yet been elucidated.

[4] At higher concentrations of tris(trimethylsilyl)cyclopentadienyllithium, a hexane solution solidifies to a gel.
[5] P. Jutzi, W. Leffers, unpublished.
[6] *Procedure*: Trimethylsilylcyclopentadiene (7.25 g, 52.4 mmol) was added dropwise to an ice-cooled suspension of potassium (2.00 g, 51.2 mmol) in toluene (150 mL). After the evolution of gas finished, the reaction mixture was filtered, concentrated, and cooled. Subsequent repeated recrystallization of the crude product afforded colorless needles of **1**; m.p. 203°C.—^{1}H-NMR (C_6D_6): $\delta(SiMe_3)=0.31$ (s, 9H), $\delta(C_5H_4)=5.85$ (AA'BB', 4H); ^{13}C-NMR (C_6D_6): $\delta(SiMe_3)=1.16$, $\delta(C_5H_4)=108.9$, 112.7, 110.1; ^{29}Si-NMR (C_6D_6): $\delta(SiMe_3)=-13.9$; MS (70 eV): *m/z* 176 ($M^{\oplus}$, 6%), 73 ($SiMe_3^{\oplus}$, 17%); 39 ($K^{\oplus}$, 100%).
[7] **1** crystallizes orthorhombically, space group *Pbca*, $a=7.967(1)$, $b=10.776(1)$, $c=24.661(1)$ Å, $V=2117.2$ Å^3, $Z=8$; 1261 symmetry independent reflections, 518 observed ($I>2\sigma(I)$); $R_w=0.057$ (measurements: Siemens AED 2; solution: SHELX 76). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-52381, the names of the authors, and the journal citation.
[8] Ionic radii for the coordination number 6 according to Pauling.
[9] Presumably lithium is also predominantly electrostatically bonded in tris(trimethylsilyl)cyclopentadienyllithium; it has not been possible so far to detect any covalent bonding. This also holds for other π-complexes of lithium (see: D. Seebach, R. Hässig, J. Gabriel, *Helv. Chim. Acta 66* (1983) 308).
[10] In potassium tris(trimethylsilyl)cyclopentadienide such an interaction is impossible for steric reasons. This explains why we could not obtain any crystals of this compound.

Synthesis and Characterization of Tetrakis[bis(trimethylsilyl)methyl]disilene**

By *Satoru Masamune,* Yuichi Eriyama,* and *Takeshi Kawase*

In recent years several ethene analogues **I** of elements of the fourth main group (E = Si, Ge, and Sn) have been synthesized.[1] Among the many unique physical and chemical properties that these compounds exhibit, the significant influence of the substituents R on the relative stability of **I** and **Ia** has attracted our attention. For instance, the digermene **1** and the distannene **2** dissociate in solution into the corresponding (monomeric) germanediyl **1a** and stannanediyl **2a**, respectively,[1j-m,2] whereas the tetraaryl compounds **3** and **4** retain their structural integrity both in solution and in the vapor phase.[1n-p] These facts naturally led to the query of how the stability of the hitherto unknown disilene **5** compares with that of **1** and **2** and with that of the known counterpart **6**.[1f]

$R_2E=ER_2$ **I** R_2E: **Ia**

1, 1a: E=Ge, R=$(Me_3Si)_2CH$
2, 2a: E=Sn, R=$(Me_3Si)_2CH$
3: E=Ge, R=2,6-diethylphenyl
4: E=Sn, R=2,4,6-triisopropylphenyl
5, 5a: E=Si, R=$(Me_3Si)_2CH$
6: E=Si, R=2,6-diethylphenyl

We describe here the synthesis of **5**, the first tetraalkyldisilene derivative isolated in pure, crystalline form, and present our answer to the above query.

$$SiH_2Cl_2 \xrightarrow{RLi} \underset{\mathbf{7}}{R_2SiH_2} \xrightarrow{I_2} \underset{\mathbf{8}}{R_2SiI_2} \xrightarrow{C_{10}H_8Li} \underset{\mathbf{5}}{R_2Si{=}SiR_2}$$

Scheme 1. R = $(Me_3Si)_2CH$.

The target compound **5** has defied many attempts at its synthesis both in our laboratory and in other laboratories, but a short and direct route has now turned out to be successful with the *proper* selection of intermediates (Scheme 1). Thus, reaction of dichlorosilane (3.4 M) in diethyl ether and pentane with 2.4 equivalents of $(Me_3Si)_2CHLi$[1j,3] (0.25 M) in ether (30 min at −78°C and then 5 h at 20°C) furnished **7** in 66% yield.[4] Subsequent reaction of **7** with 2.3 equivalents of iodine (2 h at 20°C and then 24 h at 100°C) afforded the corresponding diiodo compound **8**[4] (yield after recrystallization: 37%).

For the final step of reductive coupling the procedure used by *Weidenbruch* et al. for the synthesis of hexa-*tert*-butylcyclotrisilane was adopted,[5] but during the entire operation (including workup) contact of the product **5** with air and moisture had to be avoided. A 0.42 M solution of **7** in THF was added to a 0.5 M solution of lithium naphthalenide (2 equivalents) at −78°C; the mixture was stirred for 1 h at −78°C, for 2 h at −45°C, and finally for 1 h at 0°C. After dilution with hexane the mixture was filtered, the filtrate concentrated in vacuo, and naphthalene removed by sublimation at 10^{-4} torr. The resulting solid residue was dissolved in benzene and filtered in a glovebox. The residue remaining after evaporation of solvent from the filtrate was recrystallized from methylcyclohexane. Bright yellow crystals of **5** were obtained [yield: 40%, m.p. 224–226°C (decomp.)]. Occasionally **5** was contaminated with trace amounts of LiI, which was removed by washing with methanol (see below).

The physical and chemical properties of **5** are fully consistent with its formulation as the disilene structure:

1. Mass spectrum (EI, 70 eV), *m/z* calcd. for $C_{28}H_{76}Si_{10}$ 692.3698; found 692.36415; major fragments: *m/z* 692 ($M^{\oplus}$, 4.04%), 347 ($M^{\oplus}/2+1$, 100), 346 ($M^{\oplus}/2$, 38.87), 273 ($M^{\oplus}/2-Me_3Si$, 15.67). No fragment was registered with $m/z=1038$, which corresponds to the cyclotrimeric structure.[6]

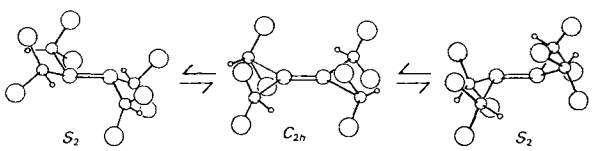
Department of Chemistry, Massachusetts Institute of Technology
Cambridge, MA 02139 (USA)

[**] This work was supported by the National Science Foundation (USA) and Kao Corporation (Japan). The authors thank Professor *S. Collins*, University of Waterloo, Canada, for constructive discussions.

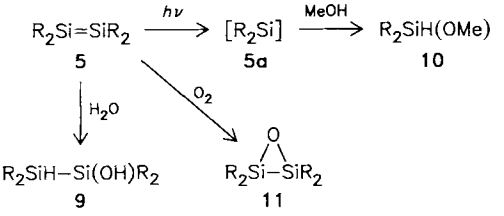
2. Electronic spectrum (methylcyclohexane, 20°C): $\lambda_{max}(\varepsilon)=393$ (12600), 357 (8600), 311 sh (2800), 224 nm (8300). The extinction coefficients remains constant with samples whose concentrations vary within the range 5×10^{-3} to 5×10^{-5} M. In comparison with the spectra reported for all known disilenes, the 393 nm absorption maximum and intensity of **5** is in the region expected for this disilene chromophore.[1a-i]

3. ^{1}H-NMR spectrum (250 MHz, C_6D_6, 20°C): $\delta=0.18$ (s, 2H; CH), 0.26 (s, 2H; CH), 0.37 (s, 36H; MeSi), 0.39 (s, 36H; MeSi). Although the chemical shifts of these signals are slightly temperature-dependent over the range -50 to 100°C, all spectra show only one set of signals, indicating that the sample solution contains a single species. While the appearance of more than one signal for the MeSi groups rules out the possibility of this species being (monomeric) $[(Me_3Si)_2CH]_2Si$ **5a**,[7] the presence of two signals for the CH groups and also for the MeSi groups in the spectra is consistent with the interpretation that **5** is undergoing rapid inversion between the two *trans*-bent conformers (S_2) via the planar conformer (C_{2h}) (Scheme 2)[8,9] or **5** might be frozen in the C_{2h} conformation.



Scheme 2. The size of the circles symbolizes the different-sized groups/atoms $Me_3Si>Si>C>H$.

5 reacts with water (THF/H_2O 10:1) to give in 95% yield the corresponding hydrate **9** (half-life of **5** at 25°C, 18 h; at 80°C, 20 min).[10] In contrast, **5** is unexpectedly stable toward methanol and remains unchanged even when heated in a MeOH/THF solution for 24 h at 80°C. (Therefore LiI can be removed with MeOH.) However, photolysis (Hanovia medium pressure, Pyrex filter, MeOH/methylcyclohexane solution) immediately caused dissociation of **5** into **5a**, which subsequently reacted with MeOH to afford **10**[4] in 87% yield.[11] Bubbling O_2 through a methylcyclohexane solution of **5** produced in an estimated yield of 60–70% the epoxide **11**[4] as major product.[12]



A preliminary characterization of **5** having been completed, a few comments and a brief summary are justified: 1. **5** is the first disilene derivative that has been prepared under reductive conditions. 2. The Si,Si double bond is well shielded by the substituents, as manifested in the inertness of **5** toward MeOH. 3. Unlike its Ge and Sn counterparts **1** and **2**, compound **5** shows no indication of dissociation into **5a** in solution to a detectable extent. This is obviously due to the expected high thermodynamic stability of the Si,Si double bond compared to the formal Ge,Ge and Sn,Sn double bonds.[13] This stability should also be reflected in the length of the Si=Si bond and in the size of the bent angle. For this reason, the crystal structure of **5** attracts special interest, and an X-ray analysis is currently under way.

[2] The ^{119}Sn{^{1}H}-NMR spectrum of **2** (149 MHz, [D$_{14}$]methylcyclohexane, Me_4Sn as reference) taken at -90.7°C shows the appearance of two signals, A and B, at $\delta_A=735$ and $\delta_B=750$, each with its own pair of ^{119}Sn-^{117}Sn coupling satellites. [$^1J_A(^{119}Sn-^{117}Sn)=3317$ Hz and $^1J_B(^{119}Sn-^{117}Sn)=1784$Hz]. The satellite intensities relative to the main resonances are roughly 3.5% for each satellite [1p]. These results suggest that **2** exists, at least partially, in a dimeric form in solution at cold temperatures (L. R. Sita, S. Masamune, unpublished results); cf. [1j-m].

The Chemistry of the Plasmodial Pigments of the Slime Mold *Fuligo septica* (Myxomycetes)**

By *Ingrid Casser, Bert Steffan,* and *Wolfgang Steglich**

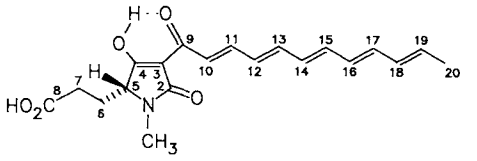
The flowers of tan, *Fuligo septica* (L.) Wiggers, form yellow slime masses (plasmodia), which are often to be found in woods after damp weather. For reproduction, the plasmodium transforms into a sessile flat crust (aethalium) which contains the blackish spore mass. Light plays an important role in the complex life cycle of the slime mold.[2] Consequently, attempts have already been made on several occasions to isolate substances from the plasmodia, for they could be potential photoreceptors. Thus, it was assumed that the yellow pigments were flavins, flavones, polyenes, pteridines or phenolic compounds.[3] In the following communication it will be shown that the yellow color of the plasmodia of *Fuligo septica*[4] is due to the occurrence of tetramic acids with a polyene chromophore.

Extraction of the plasmodia or aethalia with methanol yields a yellow solution which turns orange on acidification with hydrochloric acid. Apparently a greater part of the pigments is present in the form of salts,[5] from which the free pigments are obtained on acidification. Evaporation of the methanolic solution to dryness and partition of the residue between ethyl acetate and water affords an organic phase, which after removal of the solvent and digestion with *n*-hexane, furnishes a red powder. According to the thin-layer chromatogram this consists in the main part of colorless components together with two main pigments and several minor pigments. The mixture can be separated by chromatography on Sephadex-LH-20 with methanol; the separation must be carried out in the absence of light using a cooled column. After re-chromatography on Sephadex-LH-20 (eluent: acetone/methanol 4/1) one of the two main pigments, fuligorubin A, is obtained in pure form.

It follows from the mass spectrum that fuligorubin A has the empirical formula $C_{20}H_{23}NO_5$, and that the fragments $C_{12}H_{12}O$, $C_{11}H_{13}$ and $C_9H_{10}NO_5$ indicate coupling of a polyene unit $C_{11}H_{13}CO$ with a nitrogen-containing residue $C_8H_{10}NO_4$. The UV spectrum (MeOH) shows absorption maxima at $\lambda = 243$ and 425 nm. On addition of sodium hydroxide the long wavelength absorption shifts hypsochromically to $\lambda = 377$ nm, and a color change from orange to lemon-yellow occurs.

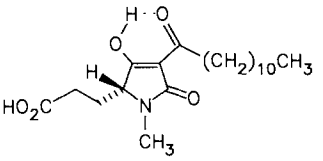
In the ^{1}H-NMR spectrum ([D$_6$]acetone) signals for an all-*trans*-2,4,6,8,10-undecapentaene chain and a structural unit $-CH_2CH_2\underset{|}{C}HN(CH_3)-$ were observed, which could be assigned by a 2D-H-H-COSY (90°)-NMR experiment. Two further protons are observed at $\delta = 11.85$ and 14.10 at low temperature ($T = 180$ K).

The ^{13}C-NMR spectrum confirms the two partial structures; the five additional signals can be assigned to a carbonyl group ($\delta = 172.5$), an acid amide group ($\delta = 174.1$), and a $-C(OH)=C-CO-$ moiety, to which the polyene residue must be coupled via the carbonyl group. Taking into consideration the results of selective ^{1}H- decoupled ^{13}C-NMR spectra, fuligorubin A must have the structure **1**.[6] The spectroscopic data are in agreement with those of other tetramic acids, for which the hypsochromic shift of the long wavelength absorption on addition of NaOH is also characteristic.[7]

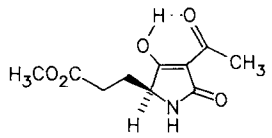


1

For determination of the absolute configuration, the chiroptic properties of decahydrofuligorubin A **2**[8] and the tetramic acid derivative **3**,[9] prepared from L-glutamic acid dimethyl ester and diketene, were compared. Since the CD curves are mirror-image-like, fuligorubin A must be 5*R*-configurated.



2



3

The isolation of a tetramic acid derivative from *Fuligo septica* is remarkable, since compounds of this type are known as mycotoxins, antibiotics and antitumor agents.[10] Whether the ability of **1** to form chelates with magnesium and calcium ions plays a role for the metabolism of *Fuligo* still has to be investigated.

Tetrameric and Dodecameric *tert*-Butylethynyllithium; A Novel Aggregation Principle in Organolithium Compounds

By *Maren Geissler, Jürgen Kopf, Bernd Schubert, Erwin Weiss,* Wolfgang Neugebauer,* and *Paul von Ragué Schleyer*

Dedicated to Professor Hans-Ludwig Krauss on the occasion of his 60th birthday

Organolithium compounds almost always exist in the form of associates, e.g., as $[(MeLi)_4]$, $[(EtLi)_4]$, $[(C_6H_{11}Li)_6]$.[1] In the presence of donor ligands (amines, ethers) one also regularly finds associates, frequently as doubly or fourfold associated species. The structure can be decisively influenced by the nature of the solvent. For example, phenyllithium forms monomeric, dimeric, and tetrameric solvates.[2]

The structure of phenylethynyllithium also depends on the nature of the solvent molecule: with *N,N,N',N'*-tetramethyl-1,3-propanediamine (= TMPDA) the dimer $[\{PhC{\equiv}CLi(tmpda)\}_2]$ is present in the crystal,[3a] with the longer chain *N,N,N',N'*-tetramethyl-1,6-hexanediamine (= TMHDA) on the other hand, the polymer $[\{(PhC{\equiv}CLi)_4(tmhda)_2\}_n]$ with cubane-like Li_4C_4 structural units .[3b] Dimeric phenylethynyllithium has also been detected in tetrahydrofuran (THF) as solvent (low-temperature ^{13}C-NMR investigations[4a] and cryoscopic measurements[4b]).

In the case of *tert*-butylethynyllithium, which crystallizes from THF-containing solutions, we have now been able to demonstrate that both tetramers as well as dodecamers having the compositions $[(t\text{BuC}{\equiv}\text{CLi})_4(\text{thf})_4]$ **1** and $[(t\text{BuC}{\equiv}\text{CLi})_{12}(\text{thf})_4]$ **2**, respectively, can occur.[5]

Crystals of **1** were obtained from a hexane/THF solution at −78°C. An X-ray structure analysis revealed the structure depicted in Figure 1, with the cubane skeleton characteristic for tetrameric organolithium compounds. The THF molecules are bound as expected to the Li atoms. *Fraenkel* and *Pramanik*[6] had already deduced such a structure in THF solution from low-temperature ^{13}C-NMR measurements. According to cryoscopic investigations by *Bauer* and *Seebach*[4b] a dimer/tetramer equilibrium exists at −108°C.

With our equipment we were only able to carry out the X-ray structure analysis at room temperature, and observed a slow cleavage of the THF molecule. The structural data could not be significantly improved even after repeated sample preparation and additional measurements. Although an *R*-value of only 0.17 was finally achieved, acceptable bond lengths were nevertheless obtained for the Li-C skeleton, so that there can be no doubt of the fundamental "correctness" of the structure.

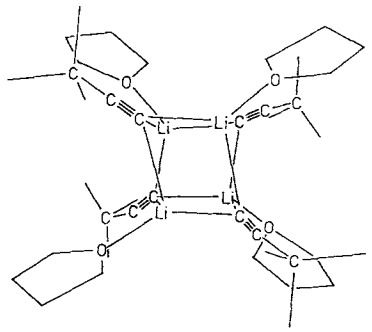

Fig. 1. Crystal structure of **1**. The center of the molecule lies on a twofold axis perpendicular to the plane of projection [7]. Important bond lengths [pm]: Li-C 219 (mean value; min. 217, max. 229); Li-O 192, 199; C≡C 120, 120; C-*t*Bu 145, 148; Li-Li 269 (mean value; min. 259, max. 278).

In further attempts to grow crystals under slightly modified conditions we unexpectedly obtained the dodecamer **2** with the structure shown in Figure 2. This indicates that the two structures are only slightly different energetically. Structure **2** results by linear coupling of three cubane-like subunits and can therefore only accomodate a total of four solvent molecules at the molecule terminals. Understandably, the crystals of **2** also effloresce very readily, and, consequently, the same problems are encountered as in the case of **1** in the X-ray structure analysis. Therefore, despite numerous repeated measurements, the structural data we present here are still inaccurate.

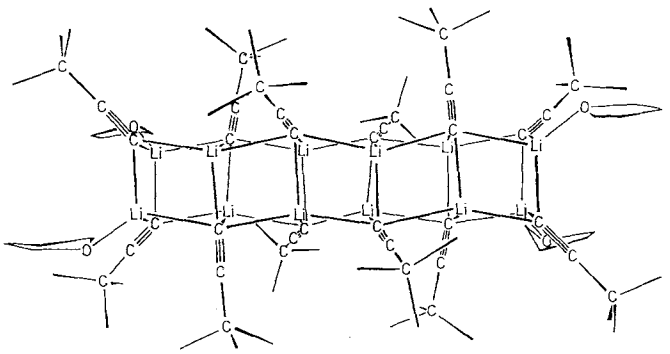

Fig. 2. Crystal structure of **2**. The center of the molecule lies on a twofold axis perpendicular to the plane of projection [10]. Some bond lengths [pm]: Li-C 222 (mean value; min. 207, max. 242); Li-O 206, 210; C≡C 115 (mean value; min. 111, max. 120); C-*t*Bu 146 (mean value; min. 140, max. 153); Li-Li 277 (mean value, min. 250, max. 302).

Disregarding polymeric compounds, **2** is the largest characterized associate of an organolithium compound reported so far. At the same time it represents a novel structural principle, according to which even still larger aggregates are conceivable, as well as smaller units such as decamers, octamers or hexamers: The cyclic, basic unit $[R_2Li_2]$ is stacked into aggregates $[(R_2Li_2)]_n$ (n = 1, 2, 3 ...). This structural principle is also taken into consideration in a theoretical study on the possible structures of LiH-oligomers.[11] Such structures are possibly also present in many solution equilibria of organolithium compounds.

[**] Alkyl- and Arylmetal Compounds, Part 34. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 33: [2].

For example, according to molecular weight determinations, allyllithium is associated to the extent of twelvefold in diethyl ether depending on the concentration of the solution,[12] the degree of association increasing with increasing concentration. Other structures are also conceivable, especially cyclic structures, as was recently demonstrated in the case of crystalline $[\{(PhCH_2)Na(tmeda)\}_4]$ (tmeda = *N,N,N',N'*-tetramethylethylenediamine).[13]

Experimental

Preparation of **1** and crystal growing: A solution of butyllithium (16.4 mmol) in hexane (10 mL) was treated at −78 °C firstly with THF (1.42 g, 19.7 mmol; 20% excess) and then with 3,3-dimethyl-1-butyne (1.39 g, 17.0 mmol). After 30 min at −78 °C the crystals that had formed were recovered by suction filtration and dried under vacuum until they no longer appeared moist. Yield ca. 1.8 g (70%). In order to avoid efflorescence, the crystals were treated with two drops of THF and prepared in a THF-saturated argon atmosphere.

Preparation of **2** and crystal growing: A solution of 3,3-dimethyl-1-butyne (1.7 g, 20.7 mmol) in cyclohexane (10 mL) was treated dropwise at room temperature with a 1.6 M solution of *n*-butyllithium in hexane until the initially precipitated *tert*-butylethynyllithium had re-dissolved (ca. 18 mL, 29 mmol). The solution was then evaporated down to 6 mL and treated with 1 mL of THF. After storage for several days at room temperature crystals of **2** separated out. Yield ca. 0.8 g (35%). To avoid cleavage of THF they were prepared in a THF-saturated argon atmosphere.

The THF content of **1** and **2** after hydrolytic decomposition was determined gas-chromatographically.

BOOK REVIEWS

Comprehensive Biotechnology. The Principles, Applications and Regulations of Biotechnology in Industry, Agriculture and Medicine. Editor-in-chief: *M. Moo-Young*. Pergamon Press, Oxford 1985. £695.00.

"Comprehensive Biotechnology" is yet another reference work, published in four volumes, on the subject of biotechnology. The executive editor claims that the publication of this work of reference has set a new standard in specialist literature on this multidisciplinary subject. The work is stated to be addressed to a broad readership including students, teachers, researchers, administrators and others in academia, industry and government. This ambitious claim imposes correspondingly high demands on the topicality, nature and scope of the contributions, and on facilitation of the use of the complete work.

A positive feature of the work worthy of first mention is that the four volumes comprising the set have been published simultaneously, lending to topicality of all the contributions. A guarantee of the quality of the contributions ought to be the choice of authors. The list of their names reads like an extract from Who's Who in Biotechnology. Regarding facilitation of the use of the reference work, it should however be mentioned, that only the last of the four volumes contains a cumulative subject index.

Volume 1. **The Principles of Biotechnology: Scientific Fundamentals.** Volume editors: *A. T. Bull* and *H. Dalton*. xxv, 688 pp., bound.—ISBN 0-08-032509-2

The first volume of the set attempts to outline the scientific fundamentals of biotechnology, a complex multidisciplinary field intersecting at some points with biological, chemical and engineering sciences.

The volume is organized in two main sections, viz. genetic and biological fundamentals (15 contributions), and chemical and biochemical fundamentals (16 contributions). The literature cited relates mainly to the period up to 1983, in some instances however up to 1985. The average length of the contributions is 20 pages.

The first section begins with an overview of the organisms of biotechnology, namely viruses, prokaryotes, eukaryotes represented by algae, protozoa and fungi, and animal and plant tissue cultures. In view of the wealth of the subject matter involved, it is understandable that only the most important distinguishing properties can be considered. For more detailed information, readers are referred to cited bibliography, in particular to certain handbooks. However, mention of the new edition of "*Bergey's Manual*", a standard work on microbiology, would have been desirable. The following contributions are devoted to the

isolation and preservation of microorganisms. The discussion of methods for genetic modification of microorganisms and in vitro recombination of DNA relates mainly to prokaryotes. Eukaryotic cloning systems for mammalian cells (SV 40), yeasts (ars system) and plants (Ti plasmid, cauliflower mosaic virus) are briefly mentioned. It is perhaps appropriate that very little space is devoted to the secretion of proteins at this juncture since this topic is discussed in detail in the second section of the volume in association with extracellular enzymes. Most of the first section is taken up by ten contributions on the subject of microbial growth. Aspects addressed include nutritional requirements of microorganisms, nutrient uptake, nutrient media, modes of growth of microorganisms, growth kinetics and mixed cultures, with special reference to prokaryotes. Animal and plant cell culture technologies are discussed and compared.

In the second section of Volume 1, particular emphasis is on the subject of microbial metabolism. Examples discussed include aerobic and anaerobic metabolism of glucose, and metabolism of C_1 compounds like methane, methanol and carbon dioxide. In the chapter that follows attention is drawn to the biotechnological importance of microorganisms that function as biocatalysts in methanogenesis.

A discussion of the different pathways involved in the microbial metabolism of aromatic compounds leads up to the question concerning microbial degradation of environmental chemicals. Readers wishing to have a comprehensive overview of this subject would have been still better served if the cited literature had included publications from a still wider circle of leading research workers.

The metabolism of polymeric substrates is illustrated by a description of the biosynthesis and degradation of fatty acids and lipids. Autotrophic metabolic pathways are treated by the presentation of a comparative description of patterns of microbial photosynthesis. Other pathways of electron transfer are also discussed, with bacterial respiratory chains and their regulation serving as an example. Principles of enzyme technology are explored in chapters on enzyme kinetics, mechanisms of enzyme catalysis, enzyme evolution and extracellular enzymes. In a contribution on the overproduction of microbial metabolites, the effects of nutrient limitation, pH and temperature are discussed. The final contribution presented in volume 1 is devoted to a description of the mechanisms of regulation relevant to metabolite synthesis, in particular prokaryotic biosynthesis of amino acids.

Olga Salcher
Bayer AG, Wuppertal (FRG)

Volume 2. **The Principles of Biotechnology: Engineering Considerations.** Volume editors: *C. L. Cooney* and *A. E. Humphrey*. xv, 632 pp., bound.—ISBN 0-08-032510-6

The material in Volume 2 addresses the state of technology in biochemical synthesis and processing. The division of the 37 chapters contributed by 44 authors into two sections (1. Bioreactor design, operation and control. 2. Upstream and downstream processing) is somewhat unusual in its organization. Whereas the fermenters, particularly the more recent developments in instrumentation and systems for fermentation process control, are dealt with in the first section, discussions on valves and pumps, gas compression, filtration systems, media sterilization, and problems associated with heat management are left until the second section.

The quality of individual chapters varies greatly. In Chapter 3, treatment of the very important areas of fermenter design and scale-up is completely inadequate. Criticism must be levelled at this particular contribution for its repetition of problems that have been described better elsewhere. The problem of asepsis is dismissed in eleven lines containing only two literature references in fact dating back to 1969 (!) and 1976 (!), and that of foam in as few as four lines including just one reference dated 1969 (!). By comparison, an excellent review of both the principles and practical applications of aqueous two-phase systems for liquid-liquid extraction of biopolymers is presented in chapter 28.

Bioreactor systems for plant and animal cells are addressed in two contributions but not discussed in any depth. There is not a single diagrammatic representation of a bioreactor shown fully equipped with valves, piping systems and sensors. On the other hand, a number of chapters describe the principles and state of the art of some downstream processing unit operations. But just as in the chapters on fermentation, the problems of asepsis are almost completely neglected in the discussions of the processing operations.

Each of the subjects addressed in the different chapters of this volume will now be reviewed briefly:

The first two chapters deal with the basics of transport phenomena in bioprocesses—oxygen transfer and heat transfer. Following an elaboration of the physical aspects, correlations with the oxygen consumption of the growing organisms are discussed. Purely biological problems like the critical oxygen concentration are examined, likewise questions relating to the structures of pellets and their supply with oxygen. As already indicated, it is considered that the chapter on fermenter design and scale-up is to all intents and purposes a nonentity. Fragments of this topic are discussed in other contributions.

Chapter 4 describes imperfectly mixed bioreactor systems, and examines the effects of micromixing and macromixing on bioprocesses. This is followed in Chapter 5 by a discussion of different types of nonmechanically agitated bioreactor systems some of which have been adopted for industrial applications; this chapter concludes with a comparison of the oxygen transfer efficiencies of different bioreactors. The next five chapters focus on dynamic modelling of fermentation systems, instrumentation for monitoring and controlling bioreactors, instrumentation for fermentation process control, use of computers for the control of fermentation processes, and computerized data analysis for on-line process applications. Here, too, accord among the authors would have been desirable to avoid duplication of material and to include instead more information on recent trends in measurement and control technologies.

The next three chapters (11 to 13) are devoted to techniques for immobilizing enzymes and cells. Based on comprehensive coverage of the latest literature data, these chapters not only describe the very large number of methods that have been developed but also explain why, in spite of the high potential of immobilized enzyme and cell technology, only relatively few of these elegant techniques have found industrial application.

The second section of Volume 2 begins with a chapter on transport and handling of bioprocess liquids and solids and on technologies for the mixing of these materials. Different types of pumps, valves (rather old data), piping systems and mixing equipment are discussed in detail. This is followed by two chapters on gas compression and filtra-

tion systems, including coverage of test procedures for air filtration. The next chapter discusses problems associated with media sterilization. The treatment of heat management in fermentation processes in the chapter that follows is considered to be inadequate.

The discussion of the unit operations of downstream processing begins with the disruption of microbial cells. It is considered that industrial use of disruption techniques could have been given greater coverage. The chapter on centrifugation reflects the state of technology in this area; it even addresses sterility and containment problems and puts forward suggestions for their solution.

Filtration processes are discussed in five chapters. Since crossflow filtration is the process generally used today, it is accorded considerable space. The discussion of membrane types and membrane methods is also vivified by examples of industrial applications. Ultrafiltration is dealt with in two large chapters in which the theory of the process, its economics and its biotechnological applications are discussed. The literature references on this fast growing technique are up to date.

Liquid-liquid extractions are discussed in two chapters. The first one in which examples relating to the production of antibiotics are given, is not of a particularly satisfactory standard because apart from the discussion of penicillin extraction processes, it does not present any recent data on extraction with organic solvents. The second of these two chapters reviews the latest developments in aqueous phase systems, contains a large number of tables giving examples of applications and listing methods, and discusses scale-up of the technology for the isolation of biopolymers.

The use of ion exchangers for the recovery of antibiotics and proteins is addressed in two relatively short chapters. The contributions on the unit operations of chromatography discuss methodologies and the constraints on their use at industrial level.

The section on upstream and downstream processing concludes with a discussion of the distillation system as a critical cost factor in the recovery of ethanol, a chapter on supercritical fluid extraction, and a contribution on the state of technology in electrodialysis.

It is considered that this volume, in its treatment of fermentation technology, fails to match the quality of comparable standard works. On the other hand, some of the unit operations addressed in the chapters on downstream processing are described in an excellent manner.

Wulf Crueger
Bayer AG, Wuppertal (FRG)

Volume 3. **The Practice of Biotechnology: Current Commodity Products.** Volume editors: *H. W. Blanch, S. Drew,* and *D. I. C. Wang.* xxv, 1136 pp., bound.—ISBN 0-08-032511-4

Following the discussion of the biological and engineering fundamentals of biotechnology in the first two volumes, Volume 3 provides a comprehensive overview of the products manufactured by biotechnological processes.

The book consists of fifty chapters organized in three sections. The first section describes the processes employed for manufacturing healthcare products. As one might expect, the largest amount of space in this section is devoted to processes for the production of antibiotics. Subjects addressed in other contributions include production and purification technologies for the development of anticancer agents; functions, production and uses of siderophores; bioconversions of steroids; microbial production of human proteins by recombinant DNA technology. The inclusion in this section of additional chapters on the production of vitamins, vaccines and immune globulins would have completed the spectrum of products in the healthcare sector.

In the second section of volume 3, processes are presented for the production of food and beverage products. The main emphasis is on descriptions of the classical technologies for the production of alcoholic beverages, cheese, fermented dairy products, bakers' yeast, and amino acids. Other topics addressed are biomass production and the processes employed in the Far East for the production of traditional fermented soybean foods.

The third and last section is devoted to those products which, in terms of quantity, play a key role as starting materials for the production of industrial chemicals (organic acids), biochemicals (hydrolytic enzymes) and fuels (ethanol).

Each of the three sections begins with a chapter dealing with the current market situation and the general problems of project selection and development in the particular product category. The following chapters furnish information on development and optimization of processes for the manufacture of individual products. Readers are provided, inter alia, with data on the biology and physiology of the microorganisms, on biosynthetic pathways, on production processes and product recovery (usually illustrated by diagrams), on production costs, and on the limitations of the different processes. These aspects are treated at varying depth by the respective authors. Notwithstanding, in its entirety the presented information provides a most useful overview of the state of research for anyone wishing to acquire a general insight into one of the areas covered. To obtain knowledge of much greater depth, readers are provided at the end of each chapter with a comprehensive bibliography generally containing references also to recent publications.

The authors of the third volume have succeeded convincingly in demonstrating how biological and engineering principles are translated into industrial processes so that this volume usefully complements the first two of the set. In view of the wealth of information it contains and the manner in which it is presented, it is considered that this volume compares most favorably with other standard works on industrial microbiology, and it can be recommended to anyone seeking a reference work on this field.

Wolfram Andersch
Bayer AG, Leverkusen (FRG)

Volume 4. **The Practice of Biotechnology: Speciality Products and Service Activities.** Volume editors: *C. W. Robinson* and *J. A. Howell.* xxix, 1308 pp., bound.—ISBN 0-08-032512-2

In contrast to the preceding volumes, the fourth volume of the set is very heterogeneous in its coverage of subject matter. Section 1 (Specialized Activities and Potential Applications) presents diverse new biotechnologies and bioprocesses considered to show promise of finding widespread applications in biomedicine, agriculture, process engineering and analysis. Section 2 addresses legal aspects of biotechnology, and Section 3 examines problems associated with waste management and pollution control.

The reviewer's curiosity was focussed first and foremostly on the contributions in Section 1 since some of the areas covered are witnessing such a rapid pace of new developments that the quality of a book devoted to these subjects obviously must be judged by the topicality of the information it contains and the manner in which it is presented. It is, however, generally concluded that the standard of these contributions by no means fully satisfies the claims formulated in the foreword. It is considered that this is mainly due, on the one hand, to the failure of most of the authors to relate their subject matter to the potentialities of technologies for product development, and, on the other hand, to the fact that the deadline set for receipt of most of the publications was 1982 yet they were not printed until three years later. Consequently, many of the biotechnological developments on which current interest is focussed, are not given adequate coverage.

The acknowledged authority *G. S. Eisenbarth*, in his contribution entitled "Monoclonal Antibodies", devotes only three sentences to the potential of monoclonal antibodies to replace conventional antibodies in assays. This fails to take consideration of the multiple development of new diagnostic agents; the use of monoclonal antibodies in downstream processing is not mentioned at all.

G. Gregoriadis discusses liposomes only in relation to their use as a drug delivery system, giving no regard to their use in bioprocess technology.

In the chapter by *K. Kano* on the rapidly developing field of Transplantation Immunology, the most recent literature reference cited by this author dates back to 1980!

In some of the articles, the literature references leave much to be desired not only in their up-to-dateness but also in balance of emphasis. *T. M. S. Chang* in his article on "Artificial Cells" gives more than 100 references to his own work (a few selected review articles would have sufficed), and the authors of the chapter "Surface Thermodynamics of Cellular and Protein Interactions" cite only their own work or that of their research group.

The relationship between biotechnology and agriculture is not adequately established. In fact, only one example is given to illustrate the potentialities of genetic engineering for the transfer of herbicide resistance.

The anthelmintic 22,23-dihydroavermectin B_{1a}, a biotechnological product for agriculture, which has a large sales volume, is not even mentioned.

However, Sections 2 and 3 of the fourth volume ("Governmental Regulations and Concerns" and "Waste Management and Pollution Control") both provide a good insight into the topics covered. Here too, though, it has to be pointed out that, especially in the discussion on risk-benefit assessment, information is wanting on the latest state of legislation and regulations.

Axel Kretschmer
Bayer AG, Wuppertal (FRG)

Summary

The detailed reviews of the four volumes indicate that the first three conform with the self-set high standards in both form and content. Conceptionally, these volumes constitute a logical unit although they can be recommended unreservedly for use as individual reference works. However, it is considered that the fourth volume is already in need of revision to update its contributions.

[NB 786 IE]

Interaction of Steroid Hormone Receptors with DNA. Edited by *M. Sluyser*. VCH Verlagsgesellschaft, Weinheim 1985. 242 pp., bound, DM 115.00.—ISBN 3-527-26221-0

The book is informative and extremely readable. The opening chapter provides an excellent overview of biochemical and histochemical studies in the steroid receptor field. It is thorough in both its historical perspective and its discussion of more recent findings concerning the intra- rather than extra-nuclear localization of unfilled receptors. The different views on receptor transformation are also well addressed and it is notable that opinions regarding activation not necessarily being associated with a change in sedimentation coefficient from 4 to 5S are discussed.

In the second chapter the philosophical question of why the steroid molecule should have been selected as the structure to control many diverse functions is raised. The role of nuclear ploidy and cell cycle on receptor binding is discussed. The significance of the similarities between receptor binding DNA regions and viral enhancer elements is also presented in this chapter as is the possibility of DNA helix destabilization resulting from interactions of the D ring of the steroid with specific DNA sequences.

The third chapter presents steroid-receptor interactions as they are viewed by an X-ray crystallographer. For example, the types of modification to the steroid molecule determine receptor binding potential and those modifications which determine function as an agonist or antagonist are discussed. It is argued that the conformation of the A-ring of the steroid determines the specificity of the receptor to which it binds and that the D-ring regulates its actual degree of activity.

Other chapters address the binding of activated estrogen receptor to specific DNA sequences and provide detailed specific discussions of the chick oviduct progesterone receptor and glucocorticoid receptor structure and function. The chapters on progesterone and glucocorticoid receptors essentially describe the state of the art (at publication date) regarding our understanding of steroid receptor structure and receptor mediated mechanisms. The chick oviduct system is an invaluable model for the study of progesterone receptor function since the egg white protein genes which are expressed in response to progesterone have been cloned and sequenced. The availability of antibodies to this receptor has also allowed careful studies to be made of the sub-unit structure of the receptor and its association with a non-steroid binding protein. This latter aspect is discussed in depth.

Studies with the glucocorticoid receptor are clearly presented and details are given of how, by the use of polyclonal and monoclonal antibodies the receptor can be divided into three functional domains. This chapter also provides a lucid summary of the use of the long terminal repeat (LTR) DNA sequences from the mouse mammary tumor virus to study the direct involvement of the receptor, which binds to these sequences, in determining glucocorticoid responsiveness. A brief description is also given of the significance of DNAse hypersensitive sites corresponding to the receptor binding region within the LTR.

Two chapters are devoted to the role of androgen receptors. One stresses the possible role of receptor-RNA binding which may modulate DNA binding, it also discusses the possible role of divalent cations on androgen-receptor interactions. The other chapter reviews the significance of receptor binding to the nuclear matrix and describes receptor binding to specific sequences adjacent to a prostatic binding protein (PBP) androgen induced gene in the pros-

tate. Associated with the nuclear matrix are specific DNA and RNA sequences involving actively transcribed genes, thus interactions of receptors with the matrix implies a role for their receptors on transcriptional events. The discussion of PBP gene receptor binding studies will be of particular interest to the reader because of the specific binding that has been observed within the first intron.

The final chapter provides an interesting discussion of the mechanism by which 20-hydroxyecdysone induces puffs in drosophila polytene chromosomes. The hypothesis is presented whereby the hormone-receptor complex is required to induce early puffing and that gene products of the early puffs lead to a removal of this complex and induce binding to late puff sites. The arguments supporting this hypothesis are well presented.

In summary, the topics are presented clearly, the book at time of printing is up to date, the choice of topics is good, and most commendably the book makes pleasurable reading because of its excellent balance in subject matter.

Roy G. Smith [NB 811 IE]

Houston, Texas (USA)

Organotitanium Reagents in Organic Synthesis (Volume 24 in the series **Reactivity and Structure, Concepts in Organic Chemistry**). By *M. T. Reetz*. Springer, Berlin 1986. x, 236 pp., bound, DM 168.00.—ISBN 3-540-15784-0

In the first half of the 1980's the early transition metals, especially titanium, have taken on a markedly increased importance in organic synthesis. The appearance of a progress report which collects together information on the important and topical theme of the use of organotitanium reagents in organic synthesis, written by *M. T. Reetz*, a prominent investigator in this field, is therefore to be welcomed.

A short general introduction to the use of organotitanium compounds in organic chemistry is followed by two chapters describing the preparation and the chemical and physical properties of some simple organotitanium reagents. The enhancement of selectivity in reactions involving carbanions, primarily by the introduction of titanium, a dominant aspect, is explained in the third chapter, which deals with the chemical selectivity of organotitanium reagents. The considerable amount of information is presented clearly to the reader, with a convenient subdivision into topics.

The brief fourth chapter deals with investigations into reaction kinetics. As a focal point the fifth chapter deals with the stereoselectivity of the addition of organotitanium reagents to carbonyl compounds; topics discussed in detail include diastereofacial selectivity, both with and without chelate control effects, diastereoselectivity in the addition of prochiral titanium-containing anions, and enantioselective additions. A short sixth chapter on Michael addition reactions is followed by a more important seventh chapter on nucleophilic substitutions using organotitanium reagents. The book ends with a comparatively brief eighth chapter on methylenation of carbonyl groups.

Apart from the synthesis and stability of the reagents discussed, the main emphasis in this book is on the chapters that deal with the selectivity of the reactions of organotitanium reagents. This is to be welcomed, since organotitanium reagents have a particular advantage over others with respect to selectivity, which is especially important in the chemistry of natural products. This is made very clear here by the frequent comparisons with organolithium, organomagnesium and organocopper compounds. It is gratifying to find that the bewildering mass of information contained in the original papers is collected here in an orderly fashion and presented clearly and comprehensibly. In most cases reaction mechanisms are discussed, and the selectivity of product formation is explained on the basis of the transition states likely to be involved. The reader is also told how the stereochemical and electronic behavior is affected by the choice of organotitanium reagent.

The seventh chapter, on substitution reactions, describes another important application of organotitanium reagents, whereby the use of titanium enolates gives, for the first time, a general method for the α-alkylation of carbonyl compounds when the alkyl group is tertiary. A similar situation occurs in the use of alkyltitanium compounds for the alkylation of tertiary halides. The eight chapter, on methylenation of carbonyl groups, seems at first sight to be rather short; however, this reflects the state of research at the time when it was written. All the chapters have comprehensive lists of literature references (up to the beginning of 1985). I was, however, a little disturbed to find that sources such as diploma theses, which are not easily accessible, are also included.

The book provides a full, well arranged, and readable description of the present state of research in this field. It can be recommended both for the instruction of advanced students and for use by those engaged in research. The price will deter many from buying it privately, which makes the volume all the more indispensable for chemically orientated libraries.

Holger Butenschön [NB 800 IE]
Max-Planck-Institut für Kohlenforschung,
Mülheim a. d. Ruhr (FRG)

Chemistry of Organo-Zirconium and -Hafnium Compounds. By *D. J. Cardin, M. F. Lappert,* and *C. L. Raston*. Ellis Horwood, Chichester 1986. 451 pp., bound, £ 59.50.—ISBN 0-85312-475-2

The book "Organometallic Chemistry of Titanium, Zirconium, and Hafnium", by *P. C. Wailes, R. S. P. Coutts,* and *H. Weigold*, published twelve years ago, portrayed the quite rapidly growing interest at that time in the chemistry of the early transition metals. The further rapid developments in the organometallic chemistry of Group IV transition elements in particular have now made a new review of this topic desirable. *Cardin, Lappert,* and *Raston* have produced an excellent monograph surveying results for the two heavier elements. They have provided a very careful and virtually complete coverage of the literature published up to and including 1982, and have set out the material in twenty chapters dealing with different structural and chemical aspects. Each chapter is supplemented by an appendix detailing those papers from the period 1983/84 which the authors regard as most important.

An introductory chapter includes thermodynamic data and general information on bonding properties and stereochemistry, together with a section on "Developments and Perspectives". This is followed by a treatment of mono(cyclopentadienyl) complexes of zirconium and hafnium in which the metal is in the +4 or +3 oxidation states. The chapters on compounds of the bent metallocenes zirconocene and hafnocene take up considerable space, beginning with a general discussion of the structure and stereochemistry of Cp_2M compounds. These are followed by very ex-

tensive compilations on $[Cp_2ML_2]$ complexes containing ligands whose donor atoms are elements of main Groups V, VI and VII. Particular attention is given to the corresponding compounds containing metal-carbon σ bonds. Three separate chapters deal with the synthesis and reactions of σ-alkyl, σ-alkenyl and σ-alkynyl complexes of the type $[Cp_2MR_2]$. Many users of this book will find the richly illustrated chapter on the molecular structures of $[Cp_2M^{IV}R_2]$ compounds especially useful. The treatment of Cp_2M chemistry is continued with short chapters on metallocene-silyl, -germyl, and -stannyl compounds and on hydride complexes.

There is also much valuable information on metallocene(IV) compounds in the chapters which follow on Cp_2Zr^{III} and Cp_2Hf^{III} compounds and adducts of Cp_2M^{II} groups with neutral donor ligands. Cp_3M and Cp_4M compounds have a chapter to themselves, as also do complexes of zirconium and hafnium with anionic π ligands other than C_5H_5, and metal complexes with neutral π ligands. Two chapters on homoleptic and heteroleptic alkyl compounds complete the treatment of the inorganic chemistry and the special characteristics of the organometallic chemistry of zirconium and hafnium compounds.

The book ends with a chapter on organo-zirconium and organo-hafnium complexes in organic synthesis and catalysis, which unfortunately is too brief. Here, if not earlier in the book, it becomes apparent that restricting one's attention to the organometallic chemistry of the two heavier Group IV transition elements. leaving out titanium, is a marked disadvantage when comparisons with the corresponding titanium compounds need to be introduced for a better understanding of chemical properties.

The strength of the book lies in its wealth of well-presented factual information, which is mostly arranged in the form of clear tables, each with a list of literature references. It is definitely not a work of reference, if only because of its limited index (a subject index of eleven pages), but it is made for reading. The book is a must for libraries. For everyone actively concerned with the organometallic chemistry of zirconium or hafnium, it will be a welcome aid for many years to come. One only hopes that a similar review on the organometallic chemistry of titanium will soon be available.

Gerhard Erker [NB 802 IE]
Institut für Organische Chemie
der Universität Würzburg (FRG)

Three volumes in the series "Best Synthetic Methods": Hydrogenation Methods. By *P. N. Rylander*. Academic Press, New York 1985. xv, 193 pp., bound, $ 48.00.—ISBN 0-12-605365-0

Methods for the Oxidation of Organic Compounds. Alkanes, Alkenes, Alkynes, and Arenes. By *A. H. Haines*. Academic Press, New York 1985. xix, 388 pp., bound, $ 83.00.—ISBN 0-12-315501-0

Palladium Reagents in Organic Synthesis. By *R. F. Heck*. Academic Press, New York 1985. xx, 461 pp., bound, $ 99.00.—ISBN 0-12-336140-0

For some time now the original literature in organic chemistry has been producing a flood of new synthetic methods and reagents, most of which are implicitly claimed to be better than the established procedures. The synthetic chemist has the task of making a choice, and relies more on instinct than on rational evaluation. The series of books under review is designed to eliminate this unsatisfactory state of affairs by a direct assault, enabling the user to find, under such circumstances, not merely a suitable recipe, but quite simply the best one available. The claim of this series to provide a critical evaluation obviously goes beyond the information which has long been available from other highly regarded works such as "Organic Synthesis", "Organic Reactions", "Reagents for Organic Synthesis", or "Houben, Weyl and Müller". Consequently, one is keen to discover how successfully the "best" method for each case has been chosen from the hundreds of possibilities.

Rylander's "Hydrogenation Methods" seems to have an especially easy task in that respect, since the catalytic hydrogenation reaction discovered as long ago as 1899 is virtually an ideal example of a perfectly controlled method. The book begins with a general description of the variations of catalyst, solvent and apparatus, which is quite long (28 pp.) in relation to the book as a whole, but does not go beyond non-committal statements and well established knowledge. The second chapter (23 pp.) is devoted to hydrogenation of CC double bonds, and this again contains little that is new; the problem of double bond migrations is discussed in detail, but the much more troublesome one of racemization during the hydrogenation of α-chiral olefins is ignored. All stereochemical aspects are dismissed in a mere four pages. From the detailed chapter on acetylenes one concludes essentially that there is nothing better than the good old Lindlar catalyst, and the lengthy discussion on the hydrogenation of multiple bonds involving heteroelements (50 pp.) needs to be more selective in this age of complex hydrides. Arene hydrogenation reactions are of more significance in industrial practice than as laboratory methods. The three concluding chapters contain exhaustive treatments of the hydrogenolysis reactions of carbon-halogen bonds and of heteroatom single bonds in rings and in acyclic protecting groups (breaking of *O*-benzyl and *N*-benzyl bonds), and they offer much that is of interest to all readers. Altogether *Rylander*'s book contains much valuable and detailed information and many useful hints, but lacks a sufficiently clear and systematic organization of the material. One soon gets the impression that here is an expert who has dipped into his well-filled, but no longer completely up-to-date, card index, and has thereby produced only a few ideas which could help the reader over his immediate difficulty.

The book by *Haines*, in contrast, is very clearly set out, dealing in a lucid and exemplary way with the standard methods for oxidizing CH, C=C, and C≡C bonds. The many examples of reactions which are collected together in the form of tables, and the experimental details given (both of which are absent from *Rylander*'s book) make this a true laboratory handbook. Well-tried methods predominate on the whole, e.g. in the field of CH oxidations, those given prominence are dehydrogenation with DDQ and selenium, or allylic oxidations by the *Kharash-Sosnovski* method, and with selenium dioxide. Special techniques such as "remote functionalization" of the steroid ring system by the *Breslow* or *Barton* methods are, however, unduly stressed, whereas the equally important Vedejs reagent (MoO_5-pyridine-HMPT) for the α-hydroxylation of carbonyl compounds is not mentioned. The chapter on C=C oxidation without bond breakage describes the *syn*-glycolysis method with iodine/silver acetate, as given by *Woodward*, or with osmium tetraoxide, in all the possible variations. Detailed attention is also given to epoxidation using peracids, or using peroxides with transition metal cat-

alysts, and also to the Sharpless reaction; no reference is made, though, to the possibilities for diastereofacial control in the peracid epoxidation reaction. In the section on oxidative cleavage of C=C bonds, one finds a wealth of information on ozonolysis and the Lemieux variants. The chapter on alkynes confines its attention to the oxidation to 1,2-diketones, the scission of terminal acetylenic bonds to give carboxylic acids, and the Glaser coupling. In the final chapter the author gives a detailed discussion of such aspects of the oxidation of arenes as hydroxylation with peracids, peroxides or lead tetraacetate, the formation of quinones with cerium ammonium sulfate or thallium trifluoroacetate, oxidative ring cleavage by ozone, permanganate, peracetic acid or ruthenium tetraoxide, and oxidative phenol coupling with iron(III) salts. One quickly learns to find one's way around *Haine*'s book, helped considerably by the terse presentation, liberal use of structural formulas, and descriptive chapter titles.

The most up-to-date of the three volumes as regards content is undoubtedly *Heck*'s "*Palladium in Organic Synthesis*". Whereas in the two volumes already described, literature citations for the last ten years tend to be the exception, they are instead the rule in this one. A comparison with slightly older monographs on the same topic (e.g. Tsuji: *Organic Synthesis with Palladium Compounds*, Springer 1980) does, however, show that progress during the most recent years has not been quite so fast. The book starts with a brief summary of methods for preparing the most important of the catalytically active palladium complexes, and deals also with the recovery of this expensive noble metal. The subsequent chapters describe the areas of application of palladium catalysis. Thus, for example, Cope and Claisen rearrangements can be carried out under very mild conditions; acetate shifts or rearrangements of vinyl epoxides or of α,β-epoxyketones proceed readily even in neutral media. Again, many variations of the Wacker process have been developed. α-Olefins can be oxidized to give methyl ketones, and α,β-unsaturated esters to give β-keto-esters. The intramolecular version of the Wacker oxidation leads to tetrahydrofurans, or in the case of *o*-allylphenols to benzofurans, while the analogous *o*-allylanilines undergo cyclization to indoles. An extensive chapter (62 pp.) is devoted to substitutions which proceed via π-allylpalladium intermediates. These allow one to introduce dialkylamines and well-stabilized carbanions of the acetoacetic ester and malonic ester types into allyl esters and allyl ethers under mild conditions. An interesting variation of this type of reaction is the Diels-Alder-like [3+2] cycloaddition of trimethylenemethane complexes to electron-deficient olefins, as discovered by *Trost*. About half the book is concerned with variations on the theme of the palladium-catalyzed CC bond, which leads readily to biarylenes, 1,3-dienes or styrene derivatives. The carbonylation of unsaturated halogen derivatives gives a wide range of carboxylic acid derivatives, while the cyclopropanation of CC double bonds with diazomethane/palladium acetate gives a high yield only in the presence of electron-withdrawing substituents. Hydrogen transfer reactions using cyclohexene or sodium tetrahydroborate as the hydrogen donor, as described in the final chapter, offer a mild alternative in many cases to the classical method of catalytic hydrogenation. The usefulness of the *Heck* volume, like that of the *Haines*, benefits from the inclusion of many tables and working rules. In some places the author unfortunately gives way to his encyclopedic tendencies, where it would have been more useful to confine the discussion to the most advantageous applications of palladium catalysis.

Altogether "Best Synthetic Methods" is undoubtedly a very welcome work. Whether or not one really is given the best method is, however, debatable. To achieve that, the authors ought to have included many more critical comparisons with alternative methods. Some important volumes have yet to appear; one needs only to think of the possibilities of boron, silicon, titanium or selenium reagents. Whether it is worth buying the whole series is something that one must decide for oneself; the high prices of the individual volumes mean that one could quickly get into large figures. It is certainly worth having one or another single volume. Perhaps organic synthesis, influenced by practical monographs such as this, will become reorientated again towards practical realizability and good sense, which would be a desirable outcome. There have been many sins in this respect in the past, when one considers the tiny scale of the reactions described, the poor standard of reproducibility, and the exaggerated yield figures that are often given. Instead of setting oneself the task of preparing unduly complicated compounds, which are usually more easily made by microbiological methods, one should again concentrate attention more on that which is feasible and sensible. Only in this way will it be possible to mend the gulf between academic synthetic work and industrial practice which is now deplored on all sides.

The Development of the Electron Microscope and of Electron Microscopy (Nobel Lecture)**

By Ernst Ruska*

1. Parents' House, Family

A month ago, the Nobel Foundation sent me its yearbook of 1985. From it I learnt that many Nobel lectures are downright scientific lectures, interspersed with curves, synoptic tables and quotations. I am somewhat reluctant to give here such a lecture on something that can be looked up in any modern schoolbook on physics. I will therefore not so much report here on physical and technical details and their connections but rather on human experiences—some joyful events and many disappointments which had not been spared me and my colleagues on our way to the final breakthrough. This is not meant to be a complaint though; I rather feel that such experiences of scientists in quest of new approaches are absolutely understandable, or even normal.

In such a representation I must, of course, consider the influence of my environment, in particular of my family. There have already been some scientists in my family: My father, *Julius Ruska*, was a historian of sciences in Heidelberg and Berlin; my uncle, *Max Wolf*, astronomer in Heidelberg; his assistant, a former pupil of my father and my godfather, *August Kopff*, Director of the Institute for astronomical calculation of the former Friedrich-Wilhelm University in Berlin. A cousin of my mother, *Alfred Hoche*, was Professor for Psychiatry in Freiburg/Breisgau; my grandfather from my mother's side, *Adalbert Merx*, theologian in Giessen and Heidelberg.

My parents lived in Heidelberg and had seven children. I was the fifth, my brother Helmut the sixth. To him I had particularly close and friendly relations as long as I can remember. Early, optical instruments made a strong impression on us. Several times uncle Max had shown us the telescopes at the observatory under his direction on the Königstuhl near Heidelberg. With the light microscope as well we soon had impressive, yet contradictory, relations. In the second floor of our house, my father had two study rooms connected by a broad sliding door which usually was open. One room he used for his scientific historical studies relating to classical philology, the other for his scientific interests, in particular mineralogy, botany and zoology. When our games with neighbours' kids in front of the house became too noisy, he would knock at the window panes. This usually only having a brief effect, he soon knocked a second time, this time considerably louder. At the third knock, Helmut and I had to come to his room and sit still on a low wooden stool, dos-à-dos, up to one hour at 2 meters distance from his desk. While doing so we would see on a table in the other room the pretty yellowish wooden box that housed my father's big Zeiss microscope, which we were strictly forbidden to touch. He sometimes demonstrated to us interesting objects under the microscope, it is true; for good reasons, however, he feared that childrens' hands would damage the objective or the specimen by clumsy manipulation of the coarse and fine drive.

Thus, our first relation to the value of microscopy was not solely positive.

2. School, Vocational Choice

Much more positive was, several years later, the excellent biology instruction my brother had through his teacher *Adolf Leiber* and the very thorough physics teaching I received through my teacher *Karl Reinig*. To my great pleasure I recently read an impressive report on *Reinig*'s personality in the Memoirs of a two-years-older student at my school, the later theoretical physicist *Walter Elsasser*. Even today I remember the profound impression *Reinig*'s comments made upon me when he explained that the movement of electrons in an electrostatic field followed the same laws as the movement of inert mass in gravitational fields. He even tried to explain to us the limitation of microscopical resolution due to the wavelength of light. I certainly did not clearly understand all this then, because soon after that on one of our many walks through the woods around Heidelberg I had a long discussion on that subject with my brother Helmut, who already showed an inclination to medicine, and my classmate *Karl Deissler*, who later studied medicine as well.

In our college (Humanistisches Gymnasium), we had up to 17 hours of Latin, Greek and French per week. In contrast to my father, who was extremely gifted for languages, I produced only very poor results in this field. My father, at that time teacher at the same school, learnt daily about my minus efforts from his colleagues and blamed me for being too lazy—so I had some sorrowful school years. My Greek teacher, a fellow student of my father, had a more realistic view of things: He gave me for my confirmation the book "Hinter Pflug und Schraubstock" (Behind plow and vise) by the Swabian "poet" engineer *Max Eyth* (1836–1906). I had always been fascinated by technical progress; in particular, I was later interested in the development of aeronautics and the construction of airships and airplanes. The impressive book by *Max Eyth* definitely prompted me to study engineering. My father, having studied sciences at the universities of Strassbourg, Berlin and Heidelberg, obviously regarded study at a Technical High School as not being adequate and offered me one physics semester at a university. I had, however, the strong feeling that engineering was more to my liking and refused.

3. The Cathode-Ray Oscillograph and the Short Coil

After I had studied two years electrotechnical engineering in Munich, my father received a call to become head of a newly founded Institute for the History of Sciences in Berlin in 1927. Thus, after my pre-examination in Munich I came to Berlin for the second half of my studies. Here I specialized in high-voltage techniques and electrical plants and heard, among others, the lectures of Professor *Adolf Matthias*. At the end of the summer term in 1928 he told us about his plan of setting up a small group of people to develop from the Braun tube an efficient cathode-ray oscillograph for the measurement of very fast electrical processes in power stations and on open-air high-voltage transmission lines. Perhaps with the memory of my physics school lesson in the back of my head, I immediately volunteered for this task and became the youngest collaborator of the group, which was headed by Dr.-Ing. *Max Knoll*. My first attempts with experimental work had been made in the practical physics course at the Technical High school in Munich under Professor *Jonathan Zenneck*, and now in the group of *Max Knoll*. As a newcomer I was first entrusted with some vacuum-technical problems which were important to all of us. Through the personality of *Max Knoll*, there was a companionable relationship in the group, and at our communal afternoon coffee with him the scientific day-to-day problems of each member of the group were openly discussed. As I did not dislike calculations, and our common aim was the development of cathode-ray oscillographs for a desired measuring capability, I wanted to devise a suitable method of dimensioning such cathode-ray oscillographs in my "Studienarbeit"—a prerequisite for being allowed to proceed to the Diploma examination.

The most important parameters for accuracy of measurement and writing speed of cathode-ray oscillographs are the diameter of the writing spot and its energy density. To produce small and bright writing spots, the electron beams emerging divergently from the cathode had to be concentrated in a small writing spot on the fluorescent screen of the cathode-ray oscillograph. For this, already *Rankin* in 1905[1] used a short dc-fed coil, as had been used by earlier experimentalists with electron beams (formerly called "glow" or "cathode rays"). Even before that, *Hittorf* (1869) and *Birkeland* (1896) used the rotationally symmetric field lying in front of a cylindrical magnet pole for focussing cathode rays. A more precise idea of the effect of the axially symmetric, i.e. inhomogeneous magnet field of such poles or coils on the electron bundle alongside of their axes had long been unclear.

Therefore, *Hans Busch*[3] at Jena calculated the electron trajectories in such an electron ray bundle and found that the magnetic field of the short coil has the same effect on the electron bundle as has the convex glass lens with a defined focal length on a light bundle. The focal length of this "magnetic electron lens" can be changed continuously by means of the coil current. *Busch* wanted to check experimentally his theory, but for reasons of time he could not carry out new experiments. He made use of the experimental results he had already obtained sixteen years previously in Göttingen. These were, however, in extremely unsatisfactory agreement with the theory. Perhaps this was the reason that *Busch* did not draw at least the practical conclusion from his lens theory to image some object with such a coil.

In order to account more precisely for the properties of the writing spot of a cathode-ray oscillograph produced by the short coil, I checked *Busch*'s lens theory with a simple experimental arrangement under better, yet sill inadequate, experimental conditions (Fig. 1) and thereby found a better but still not entirely satisfactory agreement of the imaging scale with *Busch*'s theoretical expectations. The main

reason was that I had used a coil of the dimensions of *Busch*'s coil whose field distribution along the axis was much too wide. My Studienarbeit,[4] submitted to the Faculty for Electrotechnical Engineering in 1929, contained numerous sharp images with different magnifications of an electron-irradiated anode aperture of 0.3 mm diameter which had been taken by means of the short coil ("magnetic electron lens")—i.e. the first recorded electron-optical images.

Busch's equation for the focal length of the magnetic field of a short coil implied that a desired focal length could be produced by the fewer Ampere turns the more the coil field was limited to a short region alongside the axis,

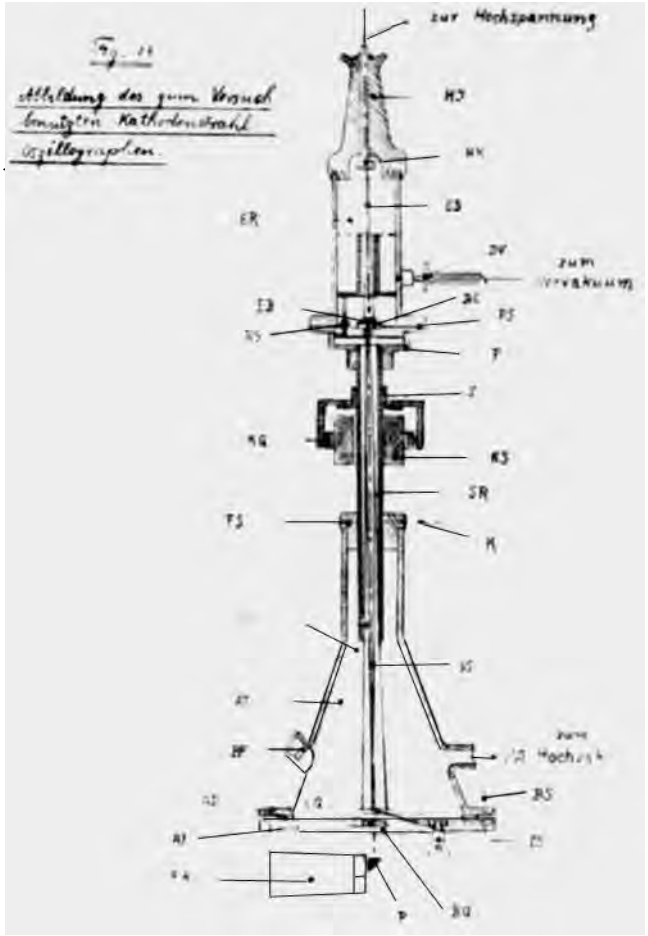

Fig. 1. Sketch by the author (1929) of the cathode ray tube for testing the imaging properties of the non-uniform magnetic field of a short coil [4, 5].

because in that case the field maximum is increased. It was therefore logical for me as a prospective electrotechnical engineer to suitably envelop the coil with an iron coating, with a ring-shaped gap in the inner tube. Measurements at such a coil immediately showed that the same focal length had been reached with markedly fewer Ampere turns.[4, 5] Vice versa, in this manner a shorter focal length can, of course, also be obtained by an equal number of Ampere turns.

4. Why I Pursued the Magnetic Electron Lens for the Electron Microscope

In my Diploma Thesis (1930) I was to search for an electrostatic replacement for the magnetic concentration of the divergent electron ray bundle, which would probably be easier and cheaper. To this end, *Knoll* suggested experimental investigation of an arrangement of hole electrodes with different electrical potential for which he had taken out a patent a year before.[6] We discussed the shape of the electric field between these electrodes, and I suggested that because of the mirror-like symmetry of the electrostatic field of the electrodes on either side of the lens center, a concentrating effect of the curved equipotential planes in the hole area could not take place. I only had the field geometry in mind then. But this conclusion was wrong. I overlooked that as a consequence of the considerably varying electron velocity on passage through such a field arrangement, a concentration of the divergent electron bundle must, in fact, occur. *Knoll* did not notice this error either. Therefore I pursued another approach in my Diploma Thesis.[7] I made the electron bundle pass through a bored-out spherical condenser with fine-meshed spherically shaped grids fixed over each end of the bore. With this arrangement I obtained laterally inverted images in the correct imaging scale. Somewhat later I found a solution which was unfortunately only theoretically correct. In analogy to the refraction of light rays at the surfaces ("Grenzflächen") on passage through optical lenses, I wanted to use, for the electrical lens, the potential steps at corresponding surfaces, which are shaped like glass lenses[8]. Thus, the energy of the electron beams is temporarily changed - just like light beams on passage through optical lenses. For the realization of this idea, on each side of the lens two closely neighbored fine-meshed grids of the shape of optical lenses are required which must be kept at electrical potentials different from each other. First attempts confirmed the rightness of this idea, but at the same time also the practical inaptness of such grid lenses because of the too-strong an absorption of the electron beam at the four grids and due to the field distribution by the wires. As a consequence of my false reasoning and the experimental disappointment I decided to continue with the magnetic lens. I only report this in so much detail to show that occasionally it can be more a matter of luck than of superior intellectual vigor to find a better—or perhaps the only acceptable way. The approach of the transmission electron microscope with electron lenses of electrostatic hole electrodes was later pursued by outstanding experimentalists in other places and led to considerable initial success. It had to be abandoned, however, because the electrostatic lens was, for physical reasons, inferior to the magnetic electron lens.

5. The Invention of the Electron Microscope

After obtaining my Degree (early 1931), the economic situation had become very difficult in Germany and it seemed impossible to find a satisfactory position at a University or in industry. Therefore I was glad that I could at

least continue my unpaid position as doctorand in the high-voltage institute. After having shown in my Studienarbeit of 1929 that sharp and magnified images of electron-irradiated hole apertures could be obtained with the short coil, I was now interested in finding out if such images—as in light optics—could be further magnified by arranging a second imaging stage behind the first stage. Such an apparatus with two short coils was easily put together (Fig. 2) and in April 1931 I obtained the definite proof that it was possible (Fig. 3). This apparatus is justifiably regarded today as the first electron microscope, even though its total magnification of about $3.6 \times 4.8 = 17.4$ was extremely modest.

The first proof had thus been given that—apart from light and glass lenses—images of irradiated specimens could be obtained also by electron beams and magnetic fields, and this in even more than one imaging stage. But what was the use of such images if even grids of platinum or molybdenum were burnt to cinders at the irradiation level needed for a magnification of only $17\times$? Not wishing to be accused of showmanship, *Max Knoll* and I agreed to avoid the term electron microscope in the lecture *Knoll* gave in June 1931 on the progress in the construction of cathode-ray oscillographs where he also, for the first time, described in detail my electron-optical investigations.[9, 10] But, of course, our thoughts were circling around a more efficient microscopy. The resolution limit of the light microscope due to the length of the light wave which had been recognized 50 years before by *Ernst Abbe* and others could not be important at such magnifications, since light was not used. *Knoll* and I simply hoped for extremely low dimensions for the electrons. As engineers we did not yet know about the thesis on the "material wave" by the French physicist de Broglie[11] that had been put forward several years earlier (1925). Even physicists only reluctantly accepted this new thesis. When I first heard of it in summer 1931, I was very much disappointed that the resolution should now be limited again by a wavelength (of the "Materiestrahlung") even in the case of the electron microscope. I was immediately heartened, though, when with the aid of the de Broglie equation I became satisfied that these waves must be around five orders of magnitude shorter in length than light waves. Thus, there was no reason to abandon the aim of electron microscopy surpassing the resolution of light microscopy.

In 1932 *Knoll* and I dared to make a prognosis of the resolution limit of the electron microscope.[12] Assuming that the equation for the resolution limit of the light microscope is valid also for the material wave of the electrons, we replaced the wavelength of the light by the wavelength of electrons at an accelerating voltage of 75 kV and inserted into the Abbe relation the imaging aperture of 2×10^{-2} rad which is what we had used previously. This imaging aperture is still used today. Thereby, even at that early date we came up with a resolution limit of $2.2\ \text{Å} = 2.2 \times 10^{-10}$ m, a value that was in fact obtained experimentally 40 years later.

Of course, at that time our approach was not taken seriously by most of the experts. They rather regarded it as a pipe-dream. I myself felt that it would be very hard to overcome the efforts still needed—mainly for solving the problem of specimen heating. In April 1932, *M. Knoll* had taken up a position with Telefunken (Berlin) involving developmental work in the field of television.

In contrast to many biologists and medical scientists, my brother Helmut, who had almost completed his medical

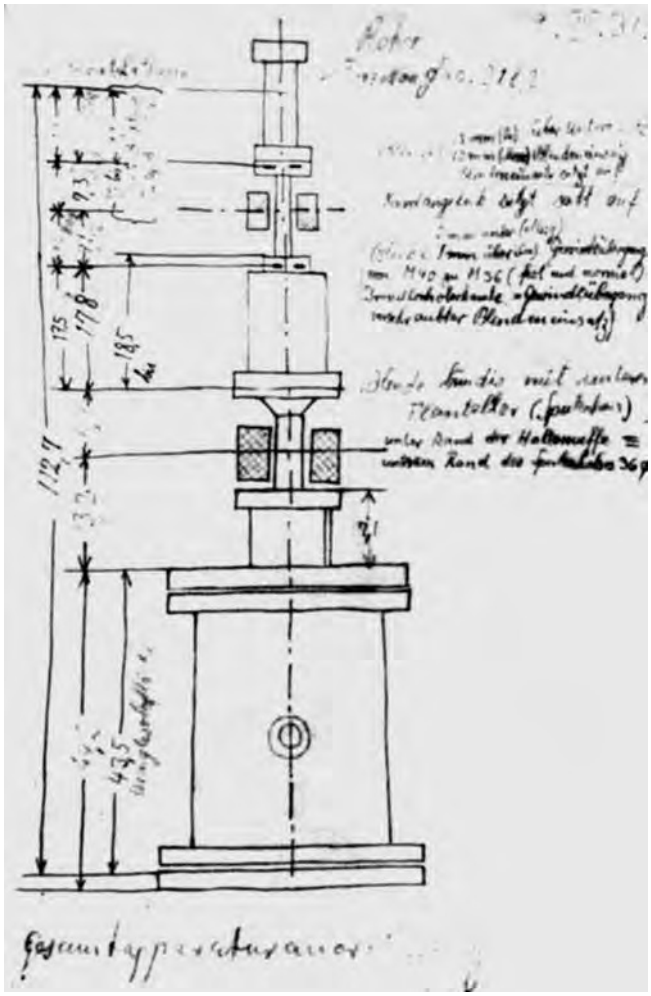

Fig. 2. Sketch by the author (March 9, 1931) of the cathode-ray tube for testing one-stage and two-stage electron-optical imaging by means of two magnetic electron lenses (electron microscope) [8].

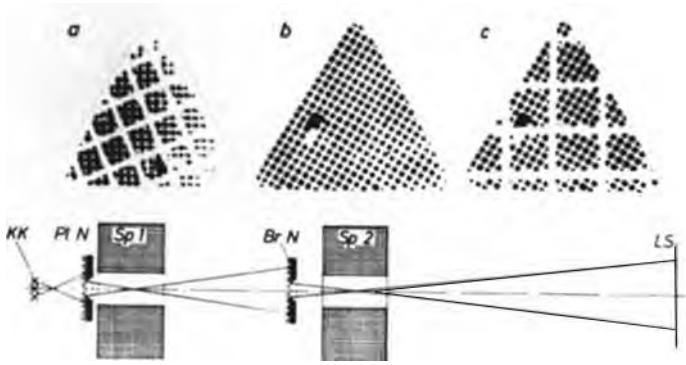

Fig. 3. First experimental proof (April 7, 1931) that specimens (aperture grids) irradiated by electrons can be imaged in magnified form not only in one but also in more than one stage by means of (magnetic) electron lenses ($U = 50$ kV) [8]. a) One-stage image of the platinum grid in front of coil 1 by coil 1; $M_{el} = 13:1$. b) One-stage image of the bronze grid in front of coil 2 by coil 2; $M_{el} = 4.8:1$. c) Two-stage image of the platinum grid in front of coil 1 and coil 2; $M_{el} = 17.4:1$ together with the one-stage image of the bronze grid in front of coil 2; $M_{el} = 4.8:1$; kk: cold cathode; Pt N: platinum grid; Sp. 1: coil 1; Br N: bronze grid; Sp 2: coil 2; LS: fluorescent screen.

studies, foresaw considerable progress in these disciplines should we be successful. With his confidence in a successful outcome he encouraged me to overcome the expected difficulties. In a next step I had to show that it was possible to obtain sufficiently high magnifications to prove a better-than-light-microscope resolution. To this effect a coil shape had to be developed whose magnetic field was compressed to a length that small in relation to the coil axis so as to allow short focal lengths as are needed for highly magnified images at not too great a distance behind the coil. The technical solution for this I had already given in my Studienarbeit of 1929 with the iron-clad coil. In 1932 I applied—together with my friend and co-doctorand *Bodo von Borries*—for a patent on the optimization of this solution,[13] the "Polschuhlinse", which is used in all magnetic electron microscopes today. Its realization and the measuring of the focal lengths which could be verified with it were the subject of my thesis.[14] It was completed in August 1933, and in my measurements I obtained focal lengths of 3 mm for electron rays of 75 kV acceleration (Fig. 4).

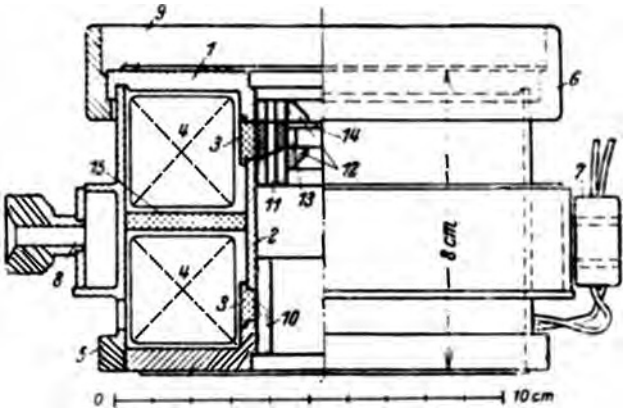

Fig. 4. Cross-section of the first polepiece lens [14, 15].

Of course, with these lenses I now immediately wanted to design a second electron microscope with much higher resolving power. To carry out this task I obtained, through the good offices of *Max von Laue*, a stipend of 100 Reichsmarks per month for the second half year of 1933 from the Notgemeinschaft der Deutschen Wissenschaft to defray running costs and personal expenses. Since I had completed the new instrument by the end of November (Fig. 5), I felt I ought to return my payment for December. To my great joy, however, I was allowed to keep the money "as an exception". Nevertheless, this certainly was the cheapest electron microscope ever paid for by a German Organization for the Promotion of Science.

For the reasons given at the beginning of the next chapter, I accepted a position in industry on December 1, 1933. Therefore I could only make a few images with this instrument which magnified 12000 × [15], but I noticed a decisive fact which gave me hope for the future: Even very thin specimens yielded sufficient contrast, yet no longer by absorption but solely by diffraction of the electrons, whereby—as is known—the specimens are heated up considerably less.

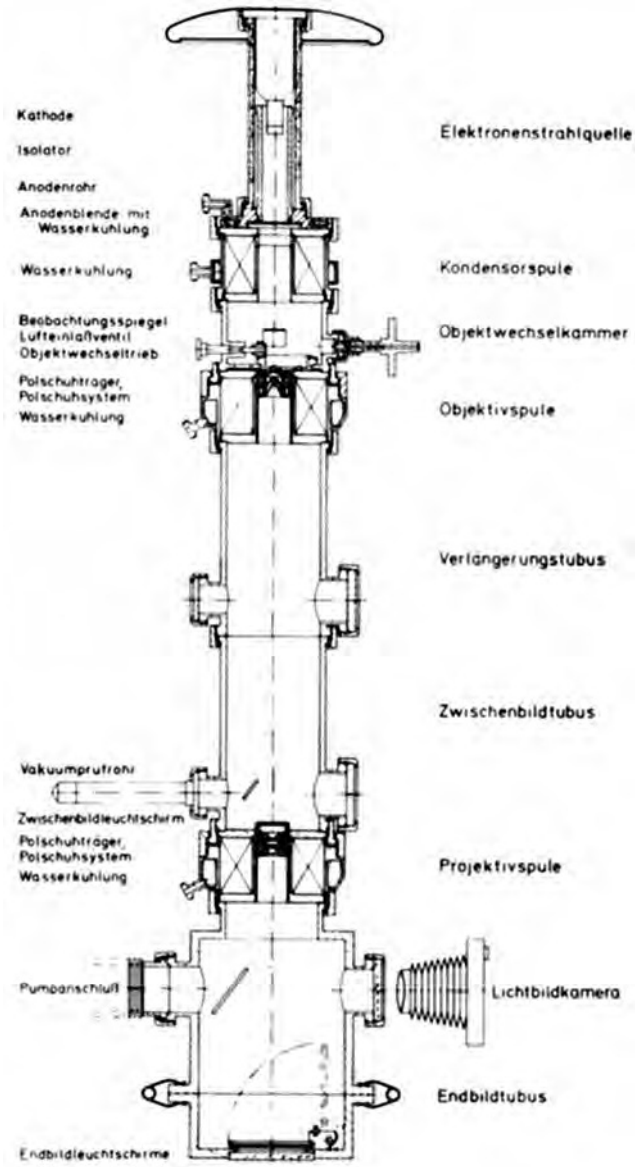

Fig. 5. First (two-stage) electron microscope magnifying higher than the light microscope. Cross-section of the microscope column [15] (redrawn 1976).

6. How the Industrial Production of Electron Microscopes Materialized

I also realized, however, that the further development of a practically useful instrument with better resolution would require a longer period of time and enormous costs. In view of the results achieved there was little hope of obtaining financial support from any side for the time being. I was prepared for a longer dry spell and decided to approach the goal of a commercial instrument later, together with *Bodo von Borries* and my brother Helmut. Therefore, I accepted a position with the Fernseh AG in Berlin-Zehlendorf where I was engaged in the development of Braun tubes for image pick-up and display tubes. In order to better coordinate our efforts to obtain financial support for the production of commercial electron microscopes, I con-

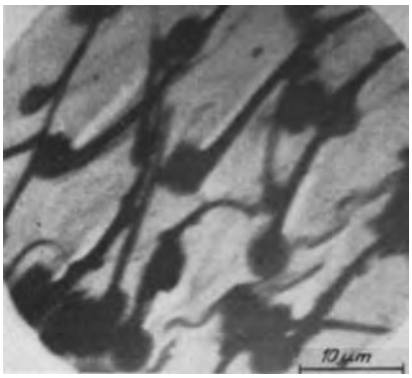

Fig. 6. Wing surface of the house fly. (First internal photography, $U = 60$ kV, $M_{el} = 2200\times$) (E. Driest, H. O. Müller: *Z. Wiss. Mikrosk. Mikrosk. Tech. 52* (1936) 53–57).

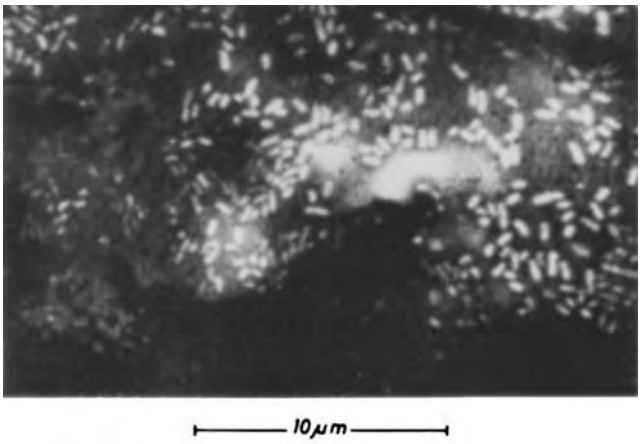

Fig. 8. Bacteria (culture infusion), fixed with formalin and embedded in a supporting film stained with a heavy metal salt ($U = 73.5$ kV, $M_{el} = 2000\times$) (F. Krause: *Naturwissenschaften 25* (1937) 817–825).

Fig. 7. Diatoms *Amphipleura pellucida* ($U = 53$ kV, $M_{el} = 3500\times$, $\delta'' = 130$ nm) (F. Krause in H. Busch and E. Brüche (Eds.): *Beiträge zur Elektronenoptik*, Johann Ambrosius Barth, Leipzig 1937, p. 55–61.

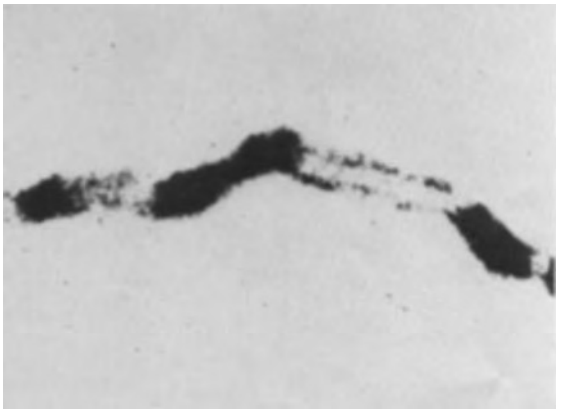

Fig. 9. Iron whisker ($U = 79$ kV, $M_{el} = 3100\times$) (D. Beischer, F. Krause: *Naturwissenschaften 25* (1937) 825–829).

vinced *Bodo von Borries* to give up his position at the Rheinisch-Westfälische Elektrizitätswerke at Essen and return to Berlin. Here, he found a position at Siemens-Schuckert in 1934. We approached many governmental and industrial research facilities for financial help.[16]

During this period, electron micrographs of biological specimens first appeared. *Heinz Otto Müller* (student in electrotechnical engineering) and *Friedrich Krause* (medical student) worked at the instrument I had built in 1933, and they published increasingly better results (Figs. 6 to 9). Unfortunately these two very gifted young scientists did not survive World War II.

At the University of Brussels *Ladislaus Marton* had built his first horizontal microscope and obtained relatively low magnifications of biological specimens.[17] In 1936 he built a second instrument, this time with a vertical column.[18]

In spite of these more recent publications, it took us three years to be successful in our quest for financial support through the professional assessment of *Helmut Ruska*'s former "clinical" teacher, Professor Dr. *Richard Siebeck*, Director of the I. Medical Clinic of the Berlin Charité. I quote two paragraphs of his assessment of October 2, 1936:[19]

"If these things were to be realized it hardly needs to be emphasised that the advances in the field of research into the causes of disease would be of immediate practical interest to the doctor. It would deeply affect real problems concerned to a large extent with diseases of growing clinical significance and thus of great importance for public health.

Should the possibilities of microscopical resolution exceed the assumed values by a factor of a hundred, the scientific consequences would be incalculable. What seems attainable now, I consider to be so important, and success seems to me so close that I am ready and willing to advise on medical research work and to collaborate by making available the resources of my Institute."

This expertise impressed Siemens in Berlin and Carl Zeiss in Jena, and they were both ready to further the development of industrial electron microscopes. We suggested the setting up of a common development facility in order to make use of the electrotechnical expertise of

Siemens and the know-how in precision engineering of Zeiss, but unfortunately the suggestion was refused and so we decided in favor of Siemens. As first collaborators we secured *Heinz Otto Müller* for the practical development and *Walter Glaser* from Prague as theorist. We started in 1937, and in 1938 we had completed two prototypes with condenser and polepieces for objective and projective as well as airlocks for specimens and photoplates. The maximum magnification was 30000×.[20] One of these instruments was immediately used for first biological investigations by *Helmut Ruska* and several medical collaborators. (*H. Ruska* was released from Professor *Siebeck* for our work at Siemens.) Unfortunately, for reasons of time I cannot give here a survey of this fruitful publication period.

In 1940, upon our proposal Siemens set up a guest laboratory, headed by *Helmut Ruska*, with four electron microscopes for visiting scientists. *Helmut Ruska* was able to show the first images of bacteriophages in 1940. An image taken somewhat later (Fig. 10) clearly shows the shape of these tiny hostile bacteria. This laboratory was destroyed during an air raid in the autumn of 1944.

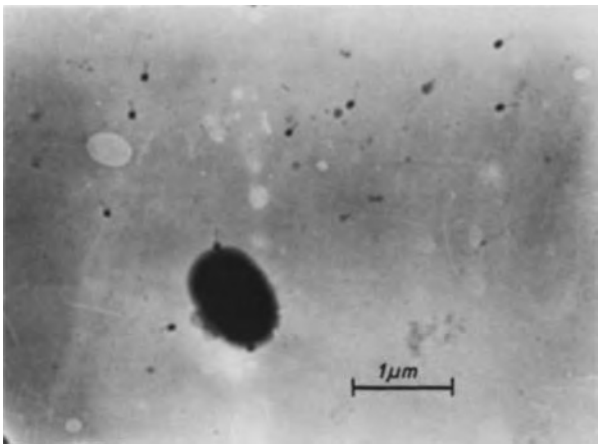

Fig. 10. Bacteriophages (M_{el} = 10000×) (H. Ruska: *Naturwissenschaften 29* (1941) 367-368 and *Arch. Ges. Virusforschung 2* (1942) 345-387).

Very gradually, interest in electron microscopy was now growing. A first sales success for Siemens was achieved in 1938 when the chemical industry which was represented largely by IG Farbenindustrie placed orders for an instrument in each of their works in Hoechst, Leverkusen Bitterfeld, and Wolfen. The instrument, however, was still only at the planning stage at the time, and not yet built or even tested. By the end of 1939 the first serially produced Siemens instrument[21] had been delivered to Hoechst (Fig. 11). The instrument No. 26 was, by the way, delivered to Professor *Arne Tiselius* in Uppsala in autumn 1943. By February 1945 more than 30 electron microscopes had been built in Berlin and delivered. Thus, now also independent representatives of various medical and biological disciplines could form their own opinions about the future prospects of electron microscopy. The choice of specimens was still limited though, since sufficiently thin sections were not yet available. The end of the war terminated the close cooperation with my brother and *Bodo von Borries*.

Fig. 11. The first serially produced electron microscope (Siemens). General view [21].

7. Development of Electron Microscopy after 1945

Our laboratory had to be reconstructed completely. I could start working with mainly new co-workers as early as June 1945. In spite of difficult conditions in Berlin and Germany, newly developed electron microscopes[22] could be delivered by the end of 1949. In 1954 Siemens had regained its former leading position with the "Elmiskop"[23] (Fig. 12). This instrument had, for the first time, two condenser lenses allowing thermal protection of the specimen by irradiating only the small region that is required for the desired final magnification. Since now, for a final magnification of 100000×, a specimen field of only 1 µm must be irradiated for an image of 10 cm diameter (in contrast to earlier irradiation areas of about 1 mm diameter), the power of the electron beam converted into heat in the object can be reduced down to the millionth part. The specimens are heated up just to the extent that the heat power produced can be radiated into the entire region around the object. If the heat power is low, a lower temperature rise with respect to the environment results.

The new instrument was, however, a big disappointment at first when we realized that at this "small region radiation" the image of the specimen field, which was now no longer hot, became so dark within seconds that all initially visible details disappeared. Investigations then showed that minor residual gases in the evacuated instrument, par-

ticularly hydrocarbons, condensed on the cold inner surfaces of the instrument, i.e. they now even condensed on the specimen itself. The image of the resulting carbon layer in the irradiated specimen field becomes darker with increasing thickness of the layer. Happily, also this hurdle could, after some time, be surmounted by relatively simple means: The entire environment of the specimen was cooled by liquid air so that the specimen was still markedly warmer than its environment, even without being heated by the beam. Thus, the residual gases of hydrocarbons condensed on the low-cooled surfaces and no longer on the specimen.

Along with the successful solution of this problem, another difficulty, that of specimen thickness, had also surprisingly been overcome by newly developed "ultramicrotomes". Instead of the ground steel knives whose blades were not sufficiently smooth due to crystallization, glass fracture edges were used which had no crystalline unevenness. The usual mechanical translation of the material perpendicular to the knife is—because of mechanical backlash or even oil layers—not sufficiently precise for the desired very small displacements of ca. 10^{-5} mm. Smallest displacements free of flaws were obtained by thermal extension of a rod at whose ends the specimen to be cut was fastened. In order to keep the extremely thin sections smooth, they were dropped into an alcoholic solution immediately after being cut so that they remained entirely flat. Moreover, more suitable fixing agents had been found for the new cutting techniques. The development of these new ultramicrotomes considerably reduced the limitation in the choice of specimens for electron microscopy. For 25 years now, almost all disciplines furthered by light microscopy have also been able to benefit from electron microscopy.

During the last decades, electron microscopy has been advanced in many countries by numerous leading scientists and engineers through new ideas and procedures. I can here only give a few examples: Figure 13 shows a cross-section through an electron microscope with single-field condenser objective, the specimen being in the field maximum of a magnetic polepiece lens.[24] Thereby, the region of increasing magnetic field in front of the specimen behaves like a condenser of short focal length and the decreasing field region behind the specimen as an objective of equal focal length. With this arrangement both lenses have a particularly small spherical aberration. Figure 14 gives an overall view of the same instrument. Figure 15

shows an image obtained with this instrument of a platelet of a gold crystal. One can clearly see lattice planes separated by a distance of 1.4 Å. Two such instruments have

ments, whose development was mainly promoted by Gaston Dupouy (1900–1985), apart from extremely high costs, special problems occur in the stabilization of the accelera-

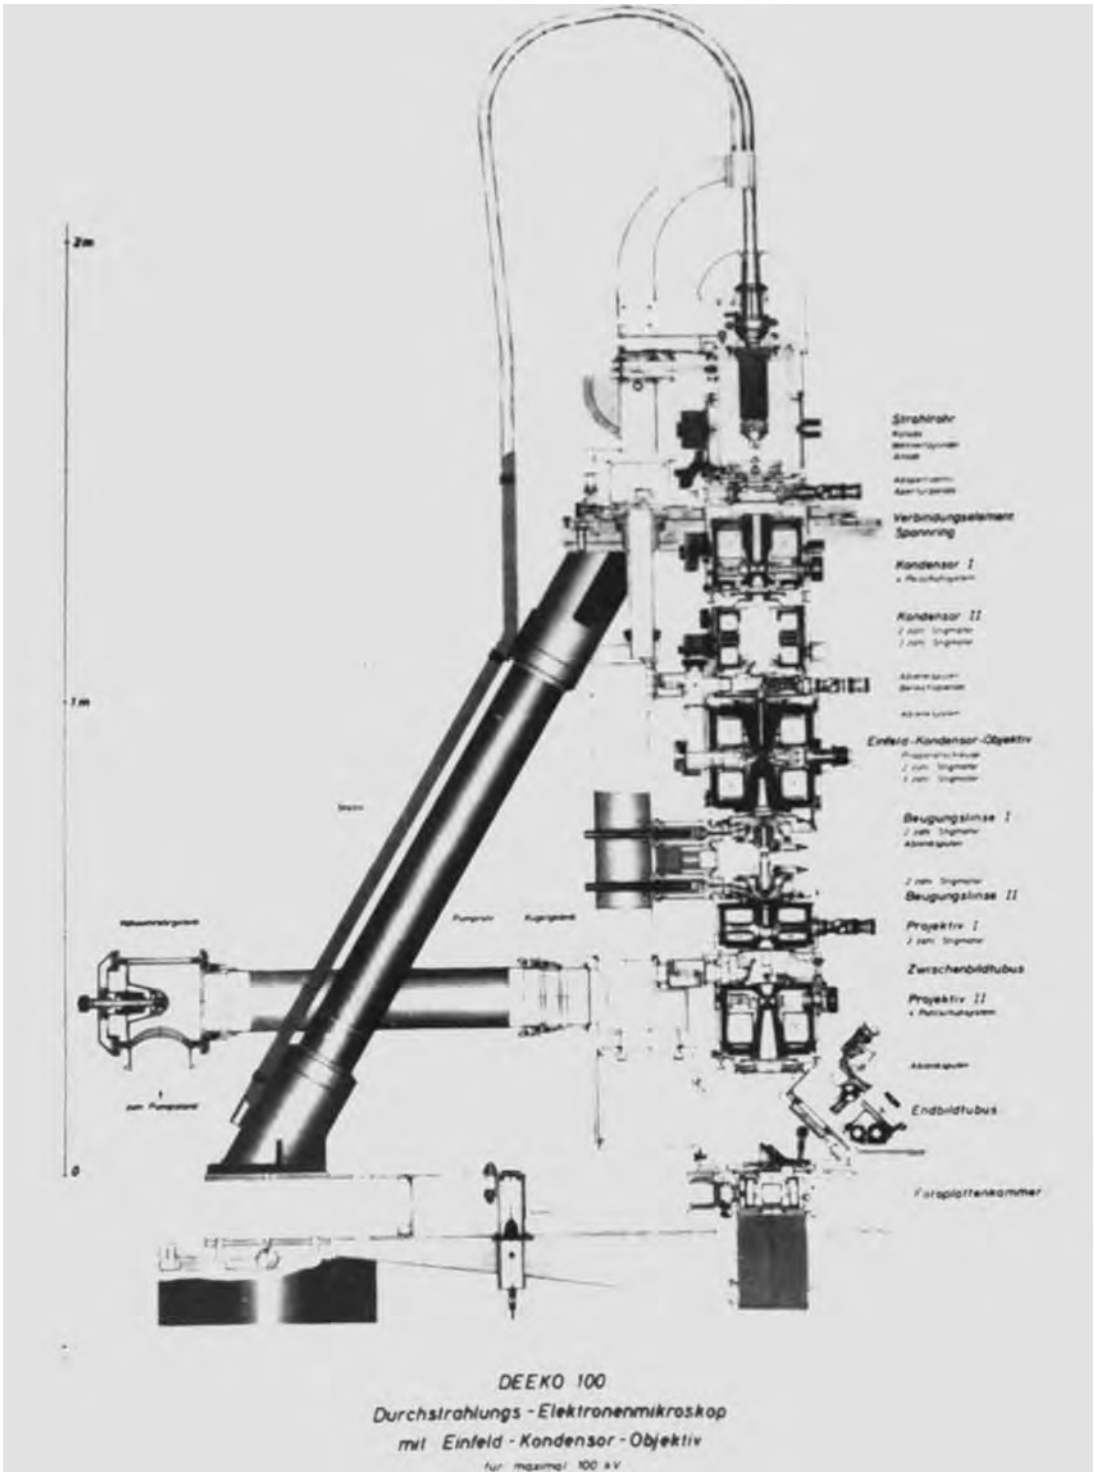

Fig. 13. 100 kV-Electron microscope with single-field condenser objective (cross-section) [24].

been further developed in the Institute for Electron Microscopy, which had been set up for me in 1957 by the Max-Planck-Gesellschaft after I had left Siemens. Figure 16 shows a 1 MV high-voltage instrument developed by Japan Electron Optics Laboratory Co. Ltd. With such instru-

tion voltage and with the protection of the operators against X-rays. The aim of the development of these instruments was the investigation of thicker specimens, but now that the problem of stabilizing the high voltages has been overcome, also the resolution has been improved by

Fig. 14. General view of the instrument shown in cross-section in Figure 13 [24].

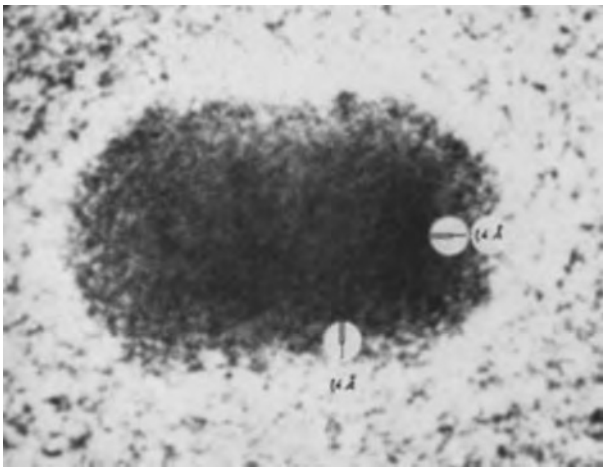

Fig. 15. Plate-like gold crystal, lattice planes with a separation of 0.14 nm, taken with axial illumination ($U = 100$ kV, $M_{el} = 800000\times$); taken in 1976 by *K. Weiss* and *F. Zemlin* with the 100-kV transmission electron microscope with single-field condenser objective at the Fritz-Haber-Institut of the Max-Planck-Gesellschaft.

the shorter material wavelength of particularly highly accelerated electrons, so that thinner specimens can also be investigated. For quite some time now, the cryotechnique—put forward mainly by *Fernandez-Moran* in the USA—has been of increasing importance. With this technique specimens cooled down to very low temperatures can be studied, because they are more resistant to higher electron doses, i.e. the mobility inside the specimen is very much reduced compared to that at room temperature. Thus, even after unavoidable ionization, the molecules keep their structure for a longer time. In the last few years it has been possible to image very beam-sensitive crystals with a resolution of 2.5 Å in a cryomicroscope[25,26] (Fig.

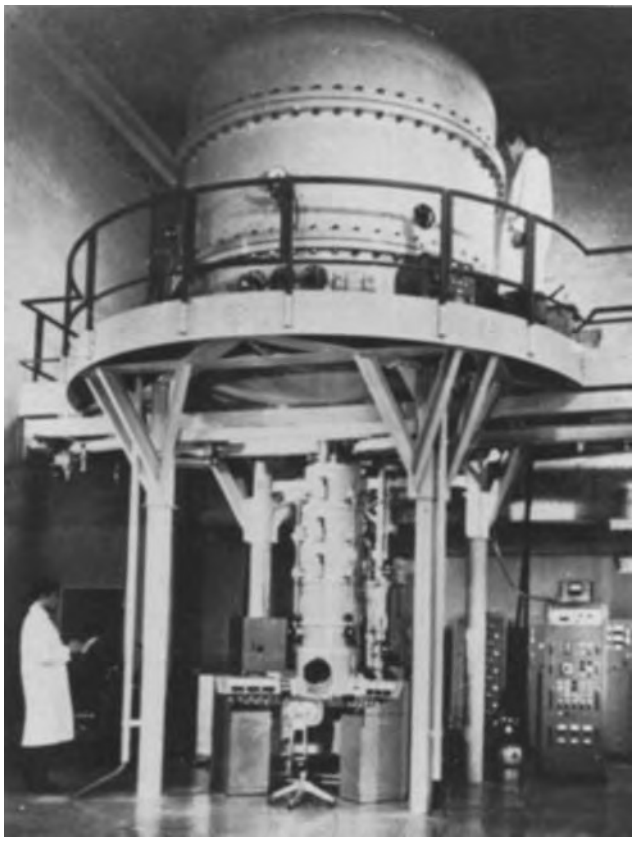

Fig. 16. 1 MV Electron Microscope (Japan Electron Optics Laboratory Co. Ltd.).

17).[27] The specimens were cooled down to a temperature of -269 °C. Direct imaging with sufficient contrast is not possible because the specimen is destroyed at the beam dose needed for normal exposure. Therefore, many very low-dose images are recorded and averaged. Such a single

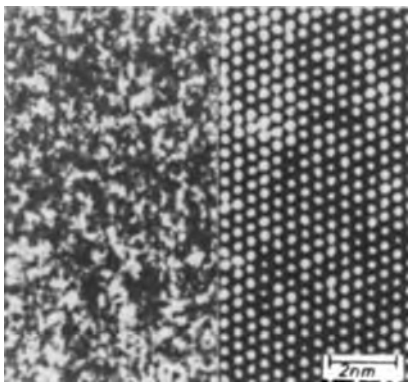

Fig. 17. Paraffin crystal (left: image taken with minimum dose, right: superposition of 400 sub-regions of the left image by means of the computer [25].

image is very noisy but still contains sufficient periodical information. The evaluation procedure is as follows: First, the micrograph is digitized using the densitometer so that each image point is given a number which describes the optical density. The underexposed image of the whole crystal is divided like a checker-board by the computer and then a large number—in our case 400—of these

image sub-regions is cross-correlated and summed up by the computer. The resulting image corresponds to a sufficiently exposed micrograph. On the left in Figure 17 the initial noisy image of a paraffin crystal is seen; the right side shows the averaged image. Each white point is the image of a paraffin molecule. The long paraffin molecules $C_{44}H_{90}$ are vertical to the image plane. With this procedure electron micrographical images can be processed by the computer. It is even possible to image three-dimensional protein crystals with very high resolution. The computer is a powerful tool in modern electron microscopy.

I cannot go into detail concerning the transmission electron microscopes with electrostatic lenses, the scanning electron microscopes which are widely used mainly for the study of surfaces as well as transparent specimens, the great importance of various image processing methods carried out partly by the computer, the field-electron microscope and the ion microscope.

The development of the electron microscopes of today was mainly a battle against the undesired consequences of the same properties of electron rays which paved the way for sub-light-microscopical resolution. Thus, for instance, the short material wavelength—prerequisite for good resolution—is coupled with the undesired high electron energy which causes specimen damage. The deflectability in the magnetic field, a precondition for lens imaging, can also limit the resolution if the alternating magnetic fields in the environment of the microscope are not sufficiently shielded by the electron microscope. We should not, therefore, blame those scientists today who did not believe in electron microscopy at its beginning. It is a miracle that by now the difficulties have been solved to such an extent that so many scientific disciplines today can reap its benefits.

Scanning Tunneling Microscopy—from Birth to Adolescence (Nobel Lecture)**

By Gerd Binnig* and Heinrich Rohrer*

We present here the historic development of scanning tunneling microscopy (STM); the physical and technical aspects have already been covered in a few recent reviews and two conference proceedings[1] and many others are expected to follow in the near future. A technical summary is given by the sequence of figures which stands alone. Our narrative is by no means a recommendation of how research should be done; it simply reflects what we thought, how we acted, and what we felt. However, it would certainly be gratifying if it encouraged a more relaxed attitude towards doing science.

Perhaps we were fortunate in having common training in superconductivity, a field which radiates beauty and elegance. For scanning tunneling microscopy, we brought along some experience in tunneling[2] and angstroms,[3] but none in microscopy or surface science. This probably gave us the courage and light-heartedness to start something which should "not have worked in principle" as we were so often told.

"After having worked a couple of years in the area of phase transitions and critical phenomena, and many, many years with magnetic fields, I [*H.R.*] was ready for a change. Tunneling, in one form or another, had intrigued me for quite some time. Years back, I had become interested in an idea of *John Slonczewski* to read magnetic bubbles with tunneling; on another occasion, I had been involved for a short time with tunneling between very small metallic grains in bistable resistors, and later I watched my colleagues struggle with tolerance problems in the fabrication of Josephson junctions. So the local study of growth and electrical properties of thin insulating layers appeared to me an interesting problem, and I was given the opportunity to hire a new research staff member, *Gerd Binnig*, who found it interesting, too, and accepted the offer. Incidentally, *Gerd* and I would have missed each other, had it not been for *K. Alex Müller*, then head of Physics, who made the first contacts."[1a]

The original idea then was not to build a microscope but rather to perform spectroscopy locally on an area less than 100 Å in diameter.

"On a house-hunting expedition, three months before my [*G. B.*] actual start at IBM, *Heini Rohrer* discussed with me in more detail his thoughts on inhomogeneities on surfaces, especially those of thin oxide layers grown on metal surfaces. Our discussion revolved around the idea of how to study these films locally, but we realized that an appropriate tool was lacking. We were also puzzling over whether arranging tunneling contacts in a specific manner would give more insight on the subject. As a result of that discussion, and quite out of the blue at the LT15 Conference in Grenoble—still some weeks before I actually started at IBM—an old dream of mine stirred at the back of my mind, namely, that of vacuum tunneling. I did not learn until several years later that I had shared this dream with many other scientists, who, like myself, were working on tunneling spectroscopy. Strangely enough, none of us had ever talked about it, although the idea was old in principle." Actually, it was 20 years old, dating back to the very beginning of tunneling spectroscopy.[4] Apparently, it had mostly remained an idea and only shortly after we had started, did *Seymour Keller*, then a member of the IBM Research Division's Technical Review Board and an early advocate of tunneling as a new research area in our laboratory, draw our attention to *W. A. Thompson*'s attempting vacuum tunneling with a positionable tip.[5]

We became very excited about this experimental challenge and the opening up of new possibilities. Astonishingly, it took us a couple of weeks to realize that not only would we have a local spectroscopic probe, but that scanning would deliver spectroscopic and even topographic images, i.e., a new type of microscope. The operating mode mostly resembled that of stylus profilometry,[6] but instead of scanning a tip in mechanical contact over a surface, a small gap of a few angstroms between tip and sample is maintained and controlled by the tunnel current flowing between them. Roughly two years later and shortly before getting our first images, we learned about a paper by *R. Young* et al.[7] where they described a type of field-emission microscope they called a "topografiner." It had much in common with our basic principle of operating the scanning tunneling microscope (STM), except that the tip had to be rather far away from the surface, thus, on high voltage, producing a field-emission current rather than a tunneling current and resulting in a lateral resolution roughly that of an optical microscope. They suggested to improve the resolution by using sharper field-emission tips, even attempted vacuum tunneling, and discussed some of its exciting prospects in spectroscopy. Had they, even if only in their minds, combined vacuum tunneling with scanning, and estimated *that* resolution, they would probably have ended up with the new concept, scanning tunneling microscopy. They came closer than anyone else.

In mid-January 1979, we submitted our first patent disclosure on the STM. *Eric Courtens*, then deputy manager of physics at the IBM Rüschlikon Laboratory, pushed the disclosure to a patent application with "thousands of future STM's." He was the first believer in our cause. Shortly afterwards, following an in-house seminar on our STM ideas, *Hans-Jörg Scheel* became the third.

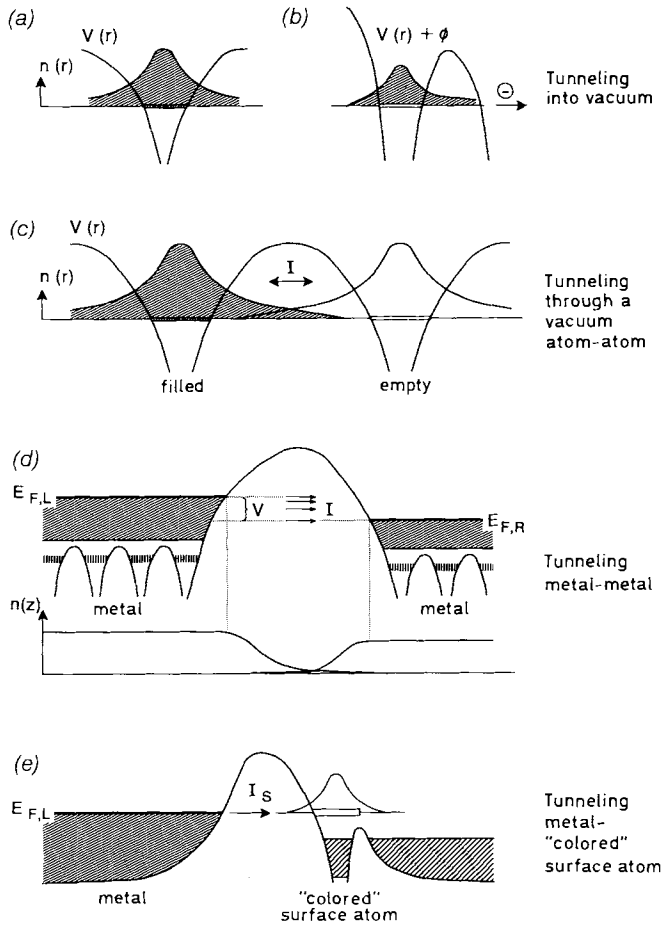

Fig. 1. Tunneling. (a) The wave function of a valence electron in the Coulomb potential well of the atom core plus other valence electrons extends into the vacuum; it "tunnels" into the vacuum. (b) Exposed to an electric field, the electron can tunnel through the potential barrier and leaves the atom. (c) If two atoms come sufficiently close, then an electron can tunnel back and forth through the vacuum or potential barrier between them. (d) In a metal, the potential barriers between the atoms in the interior are quenched and electrons move freely in energy bands, the conduction bands. At the surface, however, the potential rises on the vacuum side forming the tunnel barrier through which an electron can tunnel to the surface atom of another metal close by. The voltage V applied between the two metals produces a difference between the Fermi levels $E_{F,L}$ and $E_{F,R}$, thus providing empty states on the right for the electrons tunneling from the left side. The resulting tunnel current is roughly of the form $I = f(V) \cdot \exp(-\sqrt{\phi} \cdot s)$. $f(V)$ contains a weighted joint local density of states of tip and object; the exponential gives the transmittivity with ϕ the averaged tunnel barrier height in eV and s the separation of the two metals in Å. $f(V)$ and $\sqrt{\phi}$ are material properties obtained by measuring $d \ln I / d V$ and $d \ln I / d s$. (e) A simple case of local spectroscopy. A characteristic state, the "color," of a surface species is observed by the onset of the tunnel-current contribution I_s [see N. D. Lang, *Phys. Rev. Lett.* *58* (1987) 45, and references cited therein].

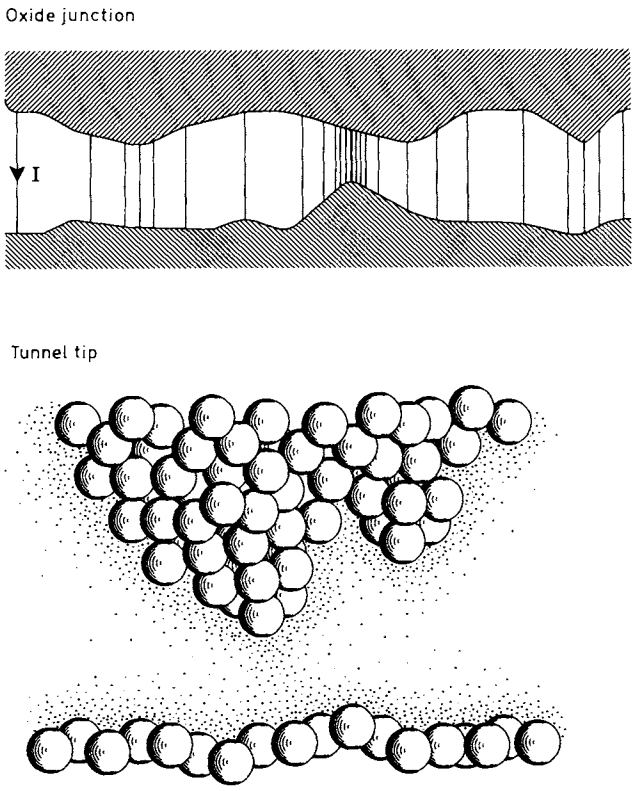

Fig. 2. The principle. The tunneling transmittivity decreases exponentially with the tunneling distance, in vacuum about a factor 10 for every Å. In an oxide tunnel junction, most of the current flows through narrow channels of small electrode separation. With one electrode shaped into a tip, the current flows practically only from the front atoms of the tip, in the best case from a specific orbital of the apex atom. This gives a tunnel current filament width and thus a lateral resolution of atomic dimensions. The second tip shown is recessed by about two atoms and carries about a million times less current.

For the technical realization of our project, we were fortunate in securing the craftsmanship of *Christoph Gerber*. "Since his joining IBM in 1966, *Christoph* had worked with me [*H. R.*] on pulsed high-magnetic fields, on phase diagrams, and on critical phenomena. By the end of 1978, we were quite excited about our first experimental results on the random-field problem, but when asked to participate in the new venture, *Christoph* did not hesitate an instant. He always liked things which were out of the ordinary, and, incidentally, was the second believer. This left me and the random-field problem without his diligent technical support. About a year later, *Edi Weibel* was the next one to join in, which left another project without technical support. Finally, I completed the team, leaving the random-field problem to others."

During the first few months of our work on the STM, we concentrated on the main instrumental problems and their solutions.[8] How to avoid mechanical vibrations that move tip and sample against each other? Protection against vibrations and acoustical noise by soft suspension of the microscope within a vacuum chamber. How strong are the forces between tip and sample? This seemed to be no problem in most cases. How to move a tip on such a fine scale? With piezoelectric material, the link between electronics and mechanics, avoiding friction. The continuous deformation of piezomaterial in the angstrom and subangstrom range was established only later by the tunneling experiments themselves. How to move the sample on a fine scale over long distances from the position of surface treatment to within reach of the tip? The "louse." How to avoid strong thermally excited length fluctuations of the sample and especially the tip? Avoid whiskers with small spring constants. This led to a more general question, and the most important one: What should be the shape of the tip and how to achieve it? At the very beginning, we viewed the tip as a kind of continuous matter with some radius of curvature. However, we very soon realized that a tip is never smooth, because of the finite size of atoms and be-

cause tips are quite rough unless treated in a special way. This roughness implies the existence of minitips as we called them, and the extreme sensitivity of the tunnel current on tip-sample separation then selects the minitip reaching closest to the sample.

Immediately after having obtained the first stable STM images showing remarkably sharp monoatomic steps, we focused our attention onto atomic resolution. Our hopes of achieving this goal were raised by the fact that vacuum tunneling itself provides a new tool for fabricating extremely sharp tips: The very local, high fields obtainable with vacuum tunneling at only a few volts can be used to shape the tip by field migration or by field evaporation. Gently touching the surface is another possibility. All this is not such a controlled procedure as tip sharpening in field-ion microscopy, but it appeared to us to be too complicated to combine STM with field-ion microscopy at this stage. We hardly knew what field-ion microscopy was, to say nothing of working with it. We had no means of controlling exactly the detailed shape of the tip. We repeated

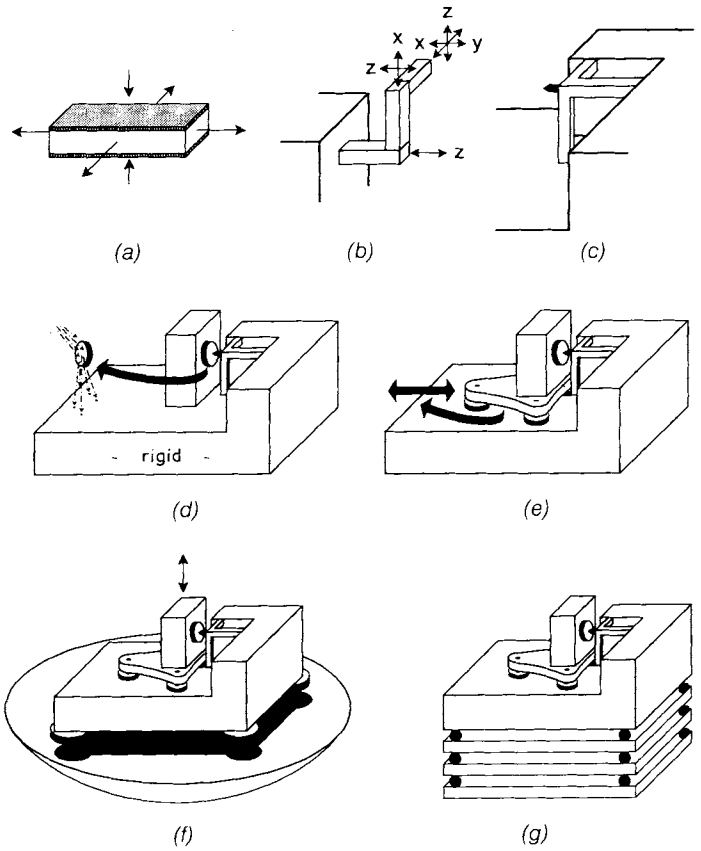

Fig. 3. The instrument. (a) A voltage applied to two electrodes contracts or expands the piezoelectric material in between. The practical total excursion of a piezo is usually in the region of micrometers. (b) A frictionless x-y-z piezodrive, which is quite vibration sensitive. (c) A rigid tripod is at present the piezodrive most used apart from the single-tube scanner. (d) Tripod and sample holder are installed on a rigid frame. The sample has to be cleared from the tip for preparation and sample transfer. (e) Positioning of the sample to within reach of the piezodrive was originally achieved with a piezoelectric "louse" with electrostatically clampable feet. Magnetic-driven positioners and differential screws are also now in use. (f) In the first vibration-isolation system, the tunnel unit with permanent magnets levitated on a superconducting lead bowl. (g) The simple and presently widely used vibration protection with a stack of metal plates separated by viton—a UHV-compatible rubber spacer.

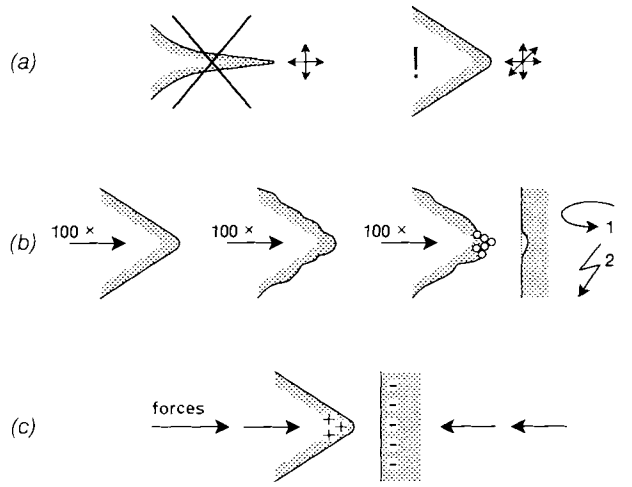

Fig. 4. Tips. (a) Long and narrow tips, or whiskers, are vibration-sensitive and thermally excited. (b) A mechanically ground or etched tip shows sharp minitips, only one of which usually carries the tunnel current. Further sharpening was initially achieved with gentle contact (1), later with field evaporation (2). (c) Electrostatic and interatomic forces between tip and sample do not deform a blunt tip, or a rigid sample, but they make the tunnel gap mechanically unstable when the tip carries a whisker. The response of soft sample materials like graphite or organic matter to such forces, however, can be appreciable and has to be taken into account.

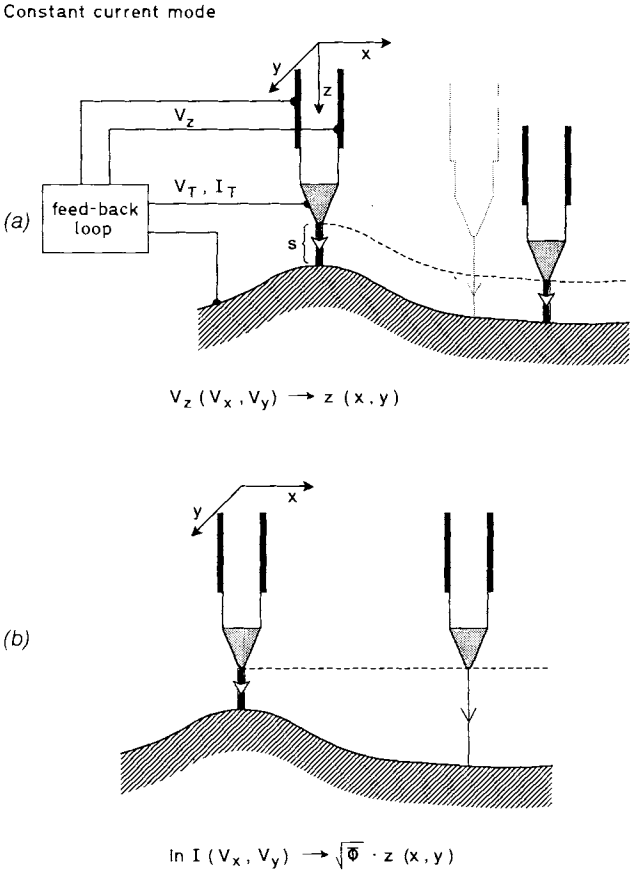

Fig. 5. Imaging. (a) In the constant current mode, the tip is scanned across the surface at constant tunnel current, maintained at a preset value by continuously adjusting the vertical tip position with the feedback voltage V_z. In the case of an electronically homogeneous surface, constant current essentially means constant s. (b) On surface portions with denivellations less than a few Å—corresponding to the dynamic range of the current measurement—the tip can be rapidly scanned at constant average z-position. Such "current images" allow much faster scanning than in (a) but require a separate determination of $\sqrt{\varphi}$ to calibrate z. In both cases, the tunnel voltage and/or the z-position can be modulated to obtain in addition, $d \ln I/dV$ and/or $d \ln I/ds$, respectively.

our trial and error procedures until the structures we observed became sharper and sharper. Sometimes it worked, other times it did not.

But first we had to demonstrate vacuum tunneling. In this endeavor, apart from the occurrence of whiskers, the most severe problem was building vibrations. To protect the STM unit also against acoustical noise, we installed the vibration-isolation system within the vacuum chamber. Our first set-up was designed to work at low temperatures and in ultrahigh vacuum (UHV). Low temperatures guaranteed low thermal drifts and low thermal length fluctuations, but we had opted for them mainly because our thoughts were fixed on spectroscopy. And tunneling spectroscopy was a low-temperature domain for both of us with a Ph.D. education in superconductivity. The UHV would allow preparation and retention of well-defined surfaces. The instrument was beautifully designed with sample and tip accessible for surface treatments and superconducting levitation of the tunneling unit for vibration isolation. Construction and first low-temperature and UHV tests took a year, but the instrument was so complicated, we never used it. We had been too ambitious, and it was only seven years later that the principal problems of a low-temperature and UHV instrument were solved.[9] Instead, we used an exsiccator as vacuum chamber, lots of Scotch tape, and a primitive version of superconducting levitation wasting about 20 L of liquid helium per hour. *Emil Haupt*, our expert glassblower, helped with lots of glassware and, in his enthusiasm, even made the lead bowl for the levitation. Measuring at night and hardly daring to breathe from excitement, but mainly to avoid vibrations, we obtained our first clear-cut exponential dependence of the tunnel current I on tip-sample separation s characteristic for tunneling. It was the portentous night of March 16, 1981.

So, 27 months after its conception the scanning tunneling microscope was born. During this development period, we created and were granted the necessary elbowroom to dream, to explore, and to make and correct mistakes. We did not require extra manpower or funding, and our side activities produced acceptable and publishable results. The first document on STM was the March/April 1981 in-house Activity Report.

A logarithmic dependence of the tunnel current I on tip–sample separation s alone was not yet proof of vacuum tunneling. The slope of $\ln I$ versus s should correspond to a tunnel-barrier height of $\phi \approx 5$ eV, characteristic of the average work functions of tip and sample. We hardly arrived at 1 eV, indicating tunneling through some insulating material rather than through vacuum. Fortunately, the calibration of the piezosensitivity for small and fast voltage changes gave values only half of those quoted by the manufacturers. This yielded a tunnel-barrier height of more than 4 eV and thus established vacuum tunneling. This reduced piezosensitivity was later confirmed by careful calibration with *H. R. Ott* from the ETH Zurich, and by *S. Vieira* of the Universidad Autónoma, Madrid.[10]

U. Poppe had reported vacuum tunneling some months earlier,[11] but his interest was tunneling spectroscopy on exotic superconductors. He was quite successful at that but did not measure $I(s)$. Eighteen months later, we were informed that *E. C. Teague*, in his Ph.D. thesis, had already observed similar $I(s)$ curves which at that time were not commonly available in the open literature.[12]

Our excitement after that March night was quite considerable. *Hirsh Cohen*, then Deputy Director of our laboratory, immediately asked us "What do you need?", a simple and obvious question people only rarely dare to ask. "*Gerd* immediately wanted to submit a post-deadline contribution[13] to the LT16 Conference to be held in Los Angeles in September. He was going there anyway with his superconducting strontium titanate, and I [*H. R.*] was sure we would have some topographic STM images by then. And indeed we had. I arranged an extended colloquium tour through the USA for *Gerd*, but about three weeks before his departure, a friend warned him, that once the news became public, hundreds of scientists would immediately jump onto the STM bandwagon. They did—a couple of years later. After two extended discussions on a weekend hike, he nevertheless became convinced that it was time for the STM to make its public appearance."[13] Our first attempt to publish a letter failed. "That's a good sign," *Nico Garcia*, a Visiting Professor from the Universidad Autónoma de Madrid, consoled us.

After this first important step with a complete STM set-up, it took us only three months, partly spent waiting for the high-voltage power supplies for the piezos, to obtain the first images of monosteps[14] on a $CaIrSn_4$ single crystal grown by *R. Gambino*. Here, the main problem was getting rid of the whiskers we continually created by bumping the tip into the surface. Now we were ready to turn to surface science, first to resolve surface reconstructions. We built a UHV-compatible STM (no longer with Scotch tape!) and, as a quick trial, operated it in vacuum suspended from a rubber band. The results indicated that superconducting levitation might be unnecessary.

That was the state of the art for the publicity tour through the USA in September 1981. Most reactions were benevolent, some enthusiastic, and two even anticipated the Nobel prize, but the STM was apparently still too exotic for any active outside engagement.

Next, we protected the STM from vibrations by a double-stage spring system with eddy-current damping,[8] and incorporated it in a UHV chamber not in use at that moment. We added sputtering and annealing for sample treatment, but no other surface tool to characterize and monitor the state of the sample or tip could yet be combined with that STM. Although the superconducting levitation served for three months only, it was cited for years. It would appear that something complicated is much easier to remember!

A most intriguing and challenging surface-science problem existed, namely, the 7×7 reconstruction of the Si(111) surface. A class of fashionable models contained rather rough features which should be resolvable by the STM. So we started to chase after the 7×7 structure, and succumbed to its magic. At first, with no success. The STM would function well, sometimes with resolutions clearly around 5 Å, but not our surface preparation. We occasionally found quite nice patterns with monolayer step lines[8] but usually the surface always looked rough and disordered on an atomic scale. One image even foreshadowed the 7×7 by a regular pattern of depressions, the precursors of the characteristic corner holes. However, a single event

is too risky to make a case for a new structure obtained with a new method. But it boosted our confidence.

By spring 1982, STM was already a subject talked about. Supposedly, an image of a vicinal surface expertly prepared with a regular step sequence would have eased the somewhat reserved attitude of the surface-science community. We, however, thought that the mono-, double-, and triple-steps of the $CaIrSn_4$ with atomically flat terraces[14] and the step lines of Si(111)[8] were convincing and promising enough. And instead of wasting further time on uninteresting step lines, we preferred to attack surface reconstructions with known periodicities and with a reasonable chance of learning and contributing something new.

For easier sample preparation and because the demand on resolution was only 8 Å, we changed to a gold single crystal, namely, the (110) surface known to produce a 1×2 reconstruction. This seemed to be well within reach of the STM resolution from what we had learned from the silicon step lines. Although some time earlier, we had returned to *Karl-Heinz Rieder*, the Laboratory's surface-science expert, his Si single crystal in a kind of droplet form, it did not deter him from proposing this gold experiment which meant lending us his Au crystal, and some weeks later we added another droplet to his collection! But in between, with his advice on surface preparation, we succeeded in resolving the 1×2 structure.[15] Contrary to expectations, we also had to struggle with resolution, because Au transferred from the surface even if we only touched it gently with our tip. The mobility of Au at room temperature is so high that rough surfaces smooth out after a while, i.e., really sharp Au-coated tips cease to exist. We should like to mention here that later, for measurements on Au(100), we formed sharp Au tips by field evaporation of Au atoms from sample to tip, and could stabilize them by a relatively high field resulting from a 0.8-V tunnel voltage.

In the case of the Au(110) surface, the atomic resolution was rather a matter of good luck and perseverance. It jumped from high to low in an unpredictable manner, which was probably caused by migrating adatoms on the tip finding a stable position at the apex for a while. We also observed an appreciable disorder leading to long but narrow ribbons of the 1×2 reconstruction mixed with ribbons of 1×3 and 1×4 reconstructions and step lines. Nevertheless, these experiments were the first STM images showing atomic rows with atomic resolution perpendicular to the rows. The disorder, intrinsic on this surface, but in its extent criticized from the surface-science point of view, demonstrated very nicely the power of STM as a local method and about a year later played an important role in testing the first microscopic theories of scanning tunneling microscopy.

With gold, we also performed the first spectroscopy experiment with an STM. We wanted to test a prediction regarding the rectifying I-V characteristic of a sample-tip tunnel junction induced by the geometric asymmetry.[16] Unfortunately, the sample surface became unstable at around 5 V, the sample being positive, and the small asymmetry observed in this voltage range could also have been due to other reasons. But with reversed polarity, the voltage could be swept up to 20 V, producing a whole series of marked resonant surface states.[8] We consider the gold exercise during spring and early summer of 1982 a most important step in the development of the method, and the STM had already exceeded our initial expectations. We had also won our first believers outside the Laboratory, *Cal Quate* from Stanford University[17] and *Paul Hansma* from the University of California at Santa Barbara.[18] We gave numerous talks on the Au work, and it attracted some attention, but, all in all, there was little action. We did not even take the time to write a paper—the 7×7 was waiting!

Meanwhile, we had also made the first attempts at chemical imaging: small Au islands on silicon. The islands were visible as smooth, flat hills on a rough surface in the topography, but they were also clearly recognizable as regions with enhanced tunnel-barrier height.[8] Thus, the Au islands were imaged thanks to their different surface electronic properties. It would certainly have been interesting to pursue this line, but we knew that, in principle, it worked—and the 7×7 was still waiting!

We started the second 7×7 attempt in autumn 1982 taking into consideration the advice of *Franz Himpsel* not to sputter the surface. This immediately worked and we observed the 7×7 wherever the surface was flat. We were absolutely enchanted by the beauty of the pattern.

"I [*G.B.*] could not stop looking at the images. It was like entering a new world. This appeared to me as the unsurpassable highlight of my scientific career and therefore in a way its end. *Heini* realized my mood and whisked me away for some days to St. Antönien, a charming village high up in the Swiss mountains, where we wrote the paper on the 7×7."

We returned convinced that this would attract the attention of our colleagues, even of those not involved with surface science. We helped by presenting both an unprocessed relief model assembled from the original recorder traces with scissors, Plexiglass, and nails, and a processed top view; the former for credibility, the latter for analysis and discussion.[19] It certainly did help, with the result that we practically stopped doing research for a while. We were inundated with requests for talks, and innumerable visitors to our Laboratory were curious to know how to build an STM. However, the number of groups that seriously got started remained small. It seemed there was still a conflict between the very appealing, conceptual easiness of displaying individual atoms in three-dimensional real space direct by recorder traces, and the intuitive reservation that, after all, it just could not be that simple.

Our result excluded all the numerous models that existed and, strangely enough, also some that followed. Only one came very close: The adatom model by *W. Harrison*[20] with just the number of adatoms not quite right. Nowadays, a variation of the adatom model where deeper layers are also reconstructed besides the characteristic 7×7 adatom pattern[21] is generally accepted and compatible with most results obtained by various experimental methods like ion channeling,[22] transmission electron diffraction,[23] and more detailed STM results from other groups.[24]

The 7×7 experiments also accelerated the first theoretical efforts of STM on a microscopic level. *Tersoff* and *Hamman* as well as *Baratoff*[25] applied *Bardeen*'s transfer Hamiltonian formalism to the small geometries of tip and

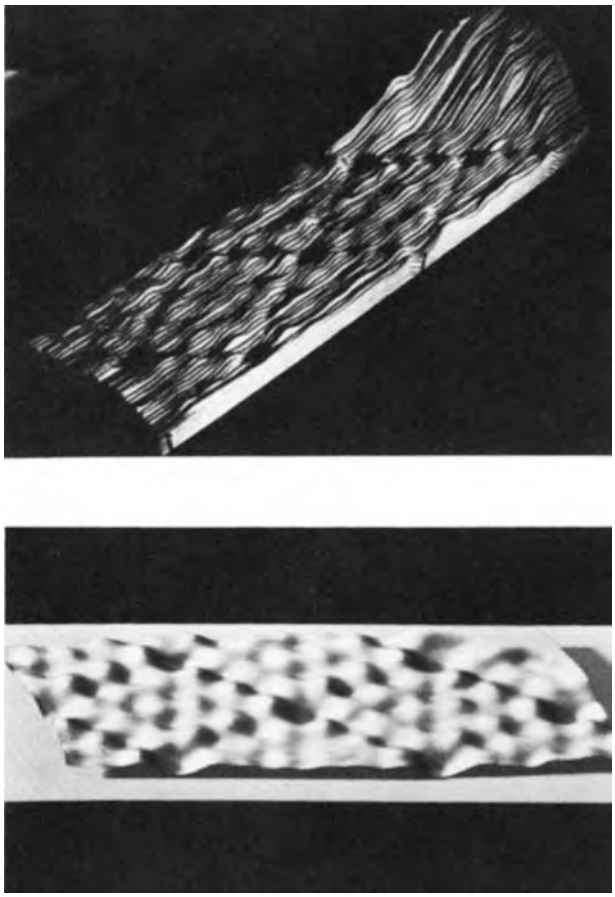

Fig. 6. 7 × 7 reconstruction of Si(111). (a) Relief assembled from the original recorder traces (from Ref. [19], © 1983 The American Physical Society) and (b) processed image of the 7 × 7 reconstruction of Si(111). Characteristic of the rhombohedral surface unit cell are the corner hole and the 12 maxima, the adatoms. In the processed image, the six adatoms in the right half of the rhombi appear higher. This is an electronic inequivalence on the surface owing to a structural left-right inequivalence in the underlying layers. The reconstruction extends undisturbed to the immediate vicinity of the large "atom hill" on the right.

an atomically corrugated surface. *Garcia, Ocal,* and *Flores* as well as *Stoll, Baratoff, Selloni,* and *Carnevali* worked out a scattering approach.[26] The two approaches converged; they consoled us by roughly confirming our intuitive view on tunneling in small geometries by simply scaling down planar tunneling, and they certainly improved the acceptance of STM in physics circles. The theoretical treatments concentrated on the nonplanar aspect of tunneling of free electrons, and the STM results on Au(110), still unpublished, served as a testing ground. They remained unpublished for quite some time, since the flashy images of the 7 × 7 silicon surface somehow overshadowed the earlier Au(110) experiments. One reaction to the first attempt to publish them was: "... The paper is virtually devoid of conceptual discussion let alone conceptual novelty ... I am interested in the behaviour of the surface structure of gold and the other metals in the paper. Why should I be excited about the results in this paper? ..." It was certainly bad publication management on our part, but we were not sufficiently familiar with a type of refereeing which searches for weak points, innocently ignoring the essence.

The gold and silicon experiments showed that STM in surface science would benefit greatly from additional, in-situ surface characterization, in particular low-energy electron diffraction (LEED). We had already learned that surfaces, even elaborately prepared, were frequently not as uniform and flat as generally assumed. The in-situ combination of LEED with STM proved extremely helpful, avoiding searching when there was nothing to be searched, and it gave us the opportunity to learn about and work with LEED and Auger electron spectroscopy (AES). The combination of STM with other established surface-science techniques also settled a concern frequently mentioned: How much did our STM images really have in common with surfaces characterized otherwise? We did not share this concern to such a degree, as we had also learned that reconstructions extended unchanged to the immediate vicinity of defect areas, and because we could detect most contaminants or defects individually. Thus, for us, the combined instrumentation was more a practical than a scientific issue.

After a short but interesting excursion with the new STM/LEED/AES combination into resolving and understanding the (100) surface of Au,[27] we proceeded into the realms of chemistry. Together with *A. Baró*, a Visiting Professor from Universidad Autónoma de Madrid, who also wanted to familiarize himself with the technique, we observed the oxygen-induced 2 × 1 reconstruction of Ni(110),[28] interpreting the pronounced and regularly arranged protrusions we saw as individual oxygen atoms. We had seen atomic-scale features before, which could be interpreted as adsorbates or adsorbate clusters, but they were more a nuisance than a matter of interest. The oxygen on Ni experiments demonstrated that the oxygen overlayer was not irreversibly changed by the imaging tunnel tip. This was a most significant result in regard to observing, studying, and performing surface chemistry with an STM tip. About a year later, when studying the oxygen-induced 2 × 2 reconstructed Ni(100) surface, we observed characteristic current spikes, which we could attribute to oxygen diffusing along the surface underneath the tip.[29] We noted that the same type of spikes had already been present in our earlier images of oxygen-covered Ni(110), but had been discarded at that time. Not only could diffusing atoms be observed individually, but their migration could be correlated to specific surface features like step lines or bound oxygen atoms, imaged simultaneously. Towards the end of 1983, we also started to probe the possibilities of STM in biology together with *H. Gross* from the ETH Zurich. We could follow DNA chains lying on a carbon film deposited on a Ag-coated Si wafer.[30]

That year ended with a most pleasant surprise: On Friday, December 9, we received a telegram from the secretary of the King Faisal Foundation, followed on Monday by a phone call from the secretary of the European Physical Society announcing the King Faisal Prize of Science and the Hewlett Packard Europhysics Prize, respectively. "The day the telegram arrived, *Gerd* was in Berlin delivering the Otto Klung Prize lecture. It was also my twentieth anniversary with IBM." This was an encouraging sign that scanning tunneling microscopy was going to make it. It also brought a new flood of requests.

In the summer of 1984, we were finally ready to assume what we had set out to do in autumn 1978, before the notion of microscopy had ever evolved, namely, performing local spectroscopy. Together with *H. Fuchs* and *F. Salvan*, we investigated the clean 7×7[1,31] and the $\sqrt{3}\times\sqrt{3}$ Au reconstructions on Si(111),[31] and—right back to the heart of the matter—a thin oxide film on Ni.[1,32] We could see that surfaces are electronically structured, as known, for example, from photoemission experiments, and that we could resolve these electronic structures in space on an atomic scale. We called this (and still do) the color of the atoms. Indeed, the oxide layers were inhomogeneous and most clearly visible in scanning tunneling spectroscopy (STS) images. On the 7×7, we could see by STS down to the second layer and observe individual dangling bonds between the adatoms.[1] At that time, *C. Quate* and his group already had an STM running, and they had performed local spectroscopy, not yet with atomic resolution but at low temperature.[33] They had measured the energy gap of a superconductor and later even plotted its spatial dependence. Spectroscopic imaging was not really surprising, yet it was an important development. We now had the tools to fully characterize a surface in terms of topographic and electronic structure. Although it is usually quite an involved problem to separate the property of interest from a set of STM and STS measurements, our vision of the scanning tunneling microscope had become true. But nevertheless, we heard that this view was not generally shared. Rumors reached us that scientists would bet cases of champagne that our results were mere computer simulations! The bets were probably based on the fact the STM was already three years old, and atomic resolution was still our exclusive property. This was also our concern, but in another way. In late summer 1983, *Herb Budd*, promoter of the IBM Europe Institute and an enthusiastic STM supporter, had asked us to run an STM Seminar in summer 1984 within the framework of the Institute. This meant one week with 23 lectures in front of a selected audience of the European academia. At that time, there was no way whatsoever of filling 23 hours, let alone of committing 23 speakers. A year later, we agreed, full of optimism for summer 1985. In December 1984, on *Cal Quate*'s initiative, nine representatives of the most advanced STM groups came together for a miniworkshop in a hotel room in Cancun. It was a most refreshing exchange of ideas, but there was still no other atomic resolution, and thus not a sufficient number of lectures in sight for the Seminar.

In the following few months, the situation changed drastically. *R. Feenstra* and co-workers came up first with cleaved GaAs,[34] *C. F. Quate*'s group with the 1×1 structure on Pt(100),[35] and *J. Behm*, *W. Hoesler*, and *E. Ritter* with the hexagonal phase on Pt(100).[36] At the American Physical Society March Meeting in 1985, *P. Hansma* presented STM images of graphite structures of atomic dimensions,[37] and when *J. Golovchenko* unveiled the beautiful results on the various reconstructions of Ge films deposited on Si(111),[38] one could have heard a pin drop in the audience. The atomic resolution was official and scanning tunneling microscopy accepted. The IBM Europe Institute Seminar in July turned into an exclusive workshop for STM'ers, and comprised some 35 original contributions, not all of them on atomic resolution, but already more than in March.[39] "A watershed of ideas" as *Cal Quate* expressed it.

Our story so far has dealt mainly with the striving for structural and electronic imaging in a surface-science environment with atomic resolution. Individual atoms had been seen before with field-ion microscopy and dealt with individually by the atom-probe technique.[40] The beauty of these techniques is relativized by the restriction to distinct atom sites on fine tips made from a rather limited selection of materials. Similarly, electron microscopy, the main source of present-day knowledge on submicron structures in practically all areas of science, technology, and industry, has advanced to the atomic level. Imaging of individual atoms or atomic structures, however, is still reserved for specific problems, expertise, and extraordinary equipment. The appeal and the impact of STM lie not only in the observation of surfaces atom by atom, but also in its widespread applicability, its conceptual and instrumental simplicity, and its affordability, all of which have resulted in a relaxed and almost casual perception of atoms and atomic structures.

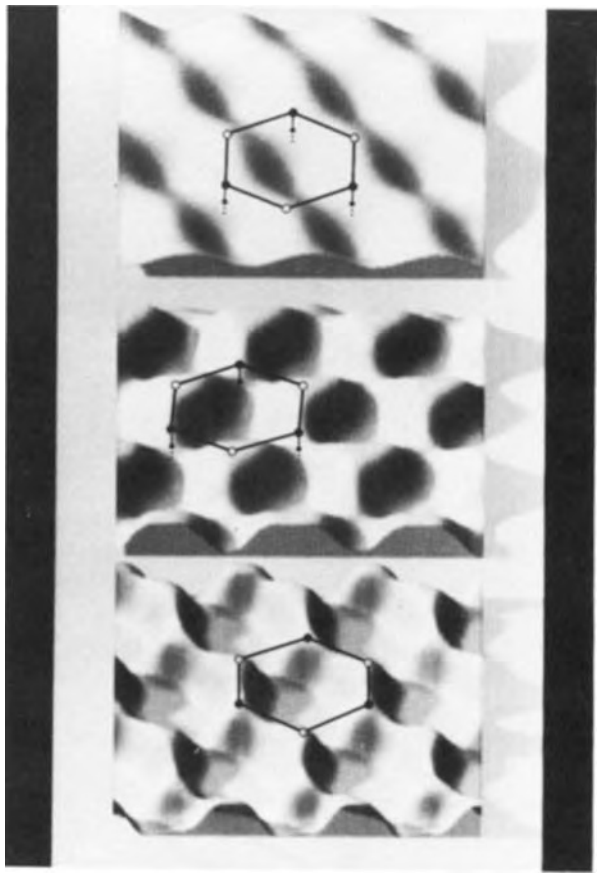

Fig. 7. STM image of cleaved graphite. The top image was taken at a constant tunnel current of 1 nA and at 50 mV. The corrugation traced by the tip reflects the local density of states (LDOS) at the Fermi level and *not* the positions of atoms, which form a flat honeycomb lattice as indicated. The LDOS at the atoms bound to the neighbors in the second layer (open circles) is lower than at the "free" atoms. The image is thus rather a spectroscopic than a topographic one. The middle image is a "current image" showing essentially the same pattern. In the bottom current image, taken closer to the surface, the two inequivalent atoms appear practically identical. This peculiar behavior is compatible with a different local elastic response of the two types of carbon atoms to the interatomic force exerted by the tip compensating for their different LDOS. A local perturbation of the electronic structure might also be important.

But there are many other aspects, maybe less spectacular but nonetheless significant, which have made STM an accepted and viable method now pursued in many areas of science and technology.

The instruments themselves have become simpler and smaller. Their greatly reduced size allows easy incorporation into other systems, for instance into a scanning electron microscope.[41] One type of instrument retains accurate sample positioning but is sufficiently rigid for in-situ sample and tip exchange. Other instruments are so rigid they are even insensitive to vibrations when immersed in liquid nitrogen[42] and even small enough to fit through the neck of a liquid-helium storage vessel.[43] These hummingbirds of STM, some concepts of which reach back to the squeezable tunnel junctions,[18] can also operate at television speed on relatively flat surfaces using single-tube scanners.[43, 44] Also, tip preparation has advanced to a level where well-defined pyramidal tips ending with one[45] or more[46] atoms can be fabricated in a UHV environment. Such tips are particularly important for investigations of nonperiodic structures, disordered systems, and rough surfaces. They are also interesting in their own right, for example, as low-energy electron and ion point sources.

Outside the physics and surface-science communities, the various imaging environments and imaging capabilities seem as appealing as atomic resolution. Images obtained at ambient-air pressure were first reported in 1984,[47] followed by imaging in cryogenic liquids,[42] under distilled water,[48] in saline solutions,[48] and in electrolytes.[49] Scanning tunneling potentiometry appears to have become an interesting technique to study the potential distribution on an atomic scale of current-carrying microstructures.[50] More recent advances include interatomic-force imaging with the atomic-force microscope,[51] with which the structure and elastic properties of conductors and insulators are obtained, and combined imaging of electronic and elastic properties of soft materials.[52] Also, the use of spin-polarized electron tunneling to resolve magnetic surface structures is being explored.

Finally, we revert to the point where the STM originated: The performance of a local experiment, at a preselected position and on a very small spatial scale down to atomic dimensions. Besides imaging, it opens, quite generally, new possibilities for experimenting, whether to study nondestructively or to modify locally: Local high electric fields, extreme current densities, local deformations, measurements of small forces down to those between individual atoms, just to name a few, ultimately to handle atoms[53] and to modify individual molecules, in short, to use the STM as a Feynman Machine.[54] This area has not yet reached adolescence.

The STM's "Years of Apprenticeship" have come to an end, the fundamentals have been laid, and the "Years of Travel" begin. We should not like to speculate where it will finally lead, but we sincerely trust that the beauty of atomic structures might be an inducement to apply the technique to those problems where it will be of greatest service solely to the benefit of mankind. *Alfred Nobel*'s hope, our hope, everybody's hope.

Fig. 8. Artist's conception of spheres. Art and Science are both products of the creativity of Man, and the beauty of nature is reflected in both. *Ruedi Rempfler*, the sculptor, found his interpretation in the deformation of a surface. It was the tension of the sphere in its environment which fascinated him, more than the mere portrayal of its shape. An independent creation, its visual and conceptual similarity with Fig. 6 is astounding. Original sculpture by *Ruedi Rempfler*, photograph courtesy of *Thomas P. Frey*.

We should like to thank all those who have supported us in one way or another and those who have contributed to the development of scanning tunneling microscopy, and express our appreciation of the pleasant and collegial atmosphere existing in the STM community. Thanks are also due to Dilys Brüllmann for her diligent handling of our manuscripts from the start and for her careful reading of this manuscript, and to Erich Stoll for processing Figures 6 and 7 using ideas of R. Voss.

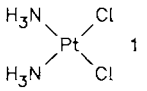
New Cisplatin Analogues— On the Way to Better Antitumor Agents

By Alessandro Pasini* and Franco Zunino*

The clinical success of cisplatin (*cis*-diamminedichloroplatinum(II)) in antitumor chemotherapy has encouraged an all-out search for analogues with lower toxicity, improved therapeutic index and increased activity. Literally thousands of analogues, obtained by replacement of the ammine- and chloro-ligands by other amines and anionic ligands, respectively, have been systematically screened for activity in experimental tumor models. Some of these analogues have been selected for clinical evaluation, but only very few of them appear to be promising antitumor agents. More recently, cisplatin analogues have been designed and synthesized on the basis of, inter alia, the following considerations: 1) platinum complexes with carrier molecules as ligands should prove useful for achieving increasing drug concentration in tumor tissues; 2) platinum complexes with chemotherapeutic agents as ligands could afford polyfunctional drugs with synergistic action; 3) complexes containing more than one platinum atom might be more effective than complexes containing only one platinum atom; 4) platinum complexes could be used as sensitizers in radiation therapy. In this paper, we shall give a brief account of the "traditional" analogues, and then critically discuss what we believe could be the new trends in the design of cisplatin analogues.

1. Introduction

Although some established antitumor agents (e.g. bleomycins) are expected to react as metal complexes with their biological targets,[1] and although a variety of compounds designed to interact with transition metals (e.g. thiosemicarbazones[2]), have been proposed as potential antitumor agents, the only metal complex currently used in the chemotherapy of neoplastic diseases is *cis*-diamminedichloroplatinum(II) ("cisplatin"), **1**.[3] This complex, of a non-essential heavy metal, exhibits a remarkable antitumor effectiveness and a broad spectrum of activity.[4]



1

Cisplatin has proven very successful in the treatment of a variety of human solid tumors such as genito-urinary and gynecologic tumors as well as head, neck, and lung tumors, and it is currently one of the most important compounds used in the treatment of solid tumors.[5]

The increasing therapeutic interest in this drug, after its introduction into clinical trials in 1972,[6] and the early recognition of its limited use because of severe toxic effects, have stimulated a widespread effort to: a) optimize cisplatin treatment regimens and alleviate toxic side effects (particularly nephro- and gastrointestinal toxicities) and b) find alternative platinum complexes having more favorable properties.

The dose-response curve for the treatment of sensitive human cancers with cisplatin is rather steep,[7] therefore high efficacy of the drug can be expected only by aggressive regimens, mainly in the treatment of advanced cancer. Several useful protective measures, such as hydration and the use of hypertonic saline, have successfully been adopted in the clinics to improve the therapeutic index of cisplatin,[8] but the use of high doses remains limited by other dose-related toxicities, especially myelosuppression and oto- and neurotoxicity.[9] Improved efficacy could however derive from the development of less toxic cisplatin analogues possessing the same or even higher antitumor activity. The goals in the search for new analogues include: a) decreased organ-specific and/or systemic toxicity, b) increased effectiveness against tumors characterized by natural or acquired resistance to cisplatin (lack of cross-resistance to cisplatin), c) more favorable physico-chemical properties such as solubility (cisplatin is only sparingly soluble) and stability in aqueous solution.

This paper is devoted to a critical discussion on present and possible future cisplatin analogues. For sake of simplicity we have deliberately avoided any reference to complexes of other metals, although some of them (those of tin, gallium, copper, gold, titanium, etc.) appear rather promising.[10]

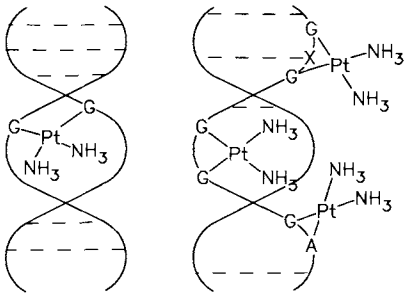
2. The Design of a Cisplatin Analogue

2.1. A Brief Account of the Mechanism of Action of Cisplatin

A rational development of a more effective analogue of a drug requires a detailed knowledge of the drugs mechanism of action at the cellular level.

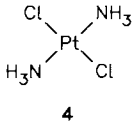
Chromosomal DNA has been proposed as the primary target of platinum antitumor agents,[11,12] but evidence that

this is the only site of attack is still a matter of debate.[13-15] For instance, if this hypothesis is correct, it remains to be explained why cisplatin, which reacts in a nonselective way with critical macromolecules of both tumor and normal cells, is so effective against some human neoplastic diseases. It is known that cisplatin reacts with a wide variety of cellular constituents, including (but not only) DNA. For example recent studies reported selective inhibitory effects of cisplatin on the amino acid transport system, thus indicating a drug-membrane interaction.[16] It is possible that these events may contribute to (selective?) lethal effects of the drug, since membranes play a critical role in the control of cell physiology.



2

3



4

According to the generally accepted mechanism, cisplatin binds preferentially, but not exclusively, at the N(7) position of the guanine of DNA,[17] replacing the two Cl ligands, usually called leaving groups, and thereby forming inter- (**2**)[18] and intrastrand (**3**)[19] cross-links, the latter probably being the critical lesion.[19] Recent results suggest that the cisplatin-DNA adduct can be accomodated in the double helix, causing only such a small localized disruption of the helix that cannot be recognized by any repair enzymes.[20] In contrast, the disruptions caused by the inactive (see Section 2.2) *trans*-isomer **4** are more profound, and are easily recognized and repaired.[20]

The reaction with DNA may involve an intermediate aquation step,[21] especially when **1** enters the cell with its low chloride concentration; aqua or—in neutral solution—aqua-hydroxo compounds are formed, which can give rise to, most likely highly toxic,[23] μ-hydroxo oligomers.[22]

$$\underset{\mathbf{1}}{cis\text{-}[PtCl_2(NH_3)_2]} \longrightarrow cis\text{-}[PtCl(NH_3)_2(H_2O)]^{\oplus} \longrightarrow$$

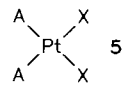
$$cis\text{-}[Pt(NH_3)_2(H_2O)_2]^{2\oplus} \longrightarrow cis\text{-}[Pt(NH_3)_2(OH)(H_2O)]^{\oplus} \longrightarrow$$

$$\longrightarrow \text{polymeric } \mu\text{-OH species.}$$

2.2. Structure-Activity Relationships

A cisplatin analogue can be described in terms of structure **5**, where X is a leaving group and A is an amine or other firmly bound ligand (for cisplatin X = Cl and A = NH_3). It must be remembered that no ligand is completely inert to substitution; thus, examples of the replacement of ammonia in cisplatin during its reaction with nucleobases have been reported.[24] The terms "leaving" and "non-leaving groups", therefore, refer only to relative reactivity.

At a very early stage it was found that the *trans*- isomer **4** is inactive;[11,25] therefore, the following discussion will be based solely upon variations of the basic structure **5** with *cis*-configuration.

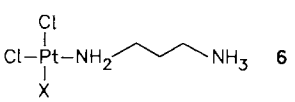


5

Several studies on structure–activity relationships for this basic structure have been reported, but simple relationships have seldom been found. Most of these studies have been carried out on different experimental models (murine L1210 and P388 ascitic leukemias, S180 sarcoma and ADJ/PC6 A plasmocytoma, etc.) using different treatment schedules, so a comparison of the relative efficacy is not easy. A further problem is presented by the structure-activity inconsistencies when the effects of the same compound are compared in different tumor systems. These observations underscore the importance of using a broad range of experimental models for preclinical evaluations, because of the predictive uncertainties of transplantable tumor systems.[26] The use of human tumors (e.g. ovarian adenocarcinoma) transplanted and grown in nude mice has recently been proposed as a useful strategy for acquiring models that overcome these drawbacks.[27]

2.2.1. *The Role of the Leaving Groups X*

The solubility of cisplatin in water is rather low (the Merck index quotes 0.253 g/100 g). To overcome this problem, other leaving groups, mainly carboxylates, were originally proposed. However, when A is kept unchanged, the nature of X determines the rate of its substitution, and thus also the antitumor effectiveness of an analogue.[28,29] Useful antitumor properties are generally associated with intermediate lability of the Pt-X bonds. Complexes with highly labile groups are very toxic and cannot be used as antitumor agents, because the compound can react with almost any nucleophile in the body. On the other hand, strongly bound ligands give rise to kinetically inert complexes. An exception to this generalization is found in the bidentate dicarboxylate ligands. It has been suggested that complexes with these leaving groups most likely require metabolic activation in order to exert their cytotoxic effects.[30]

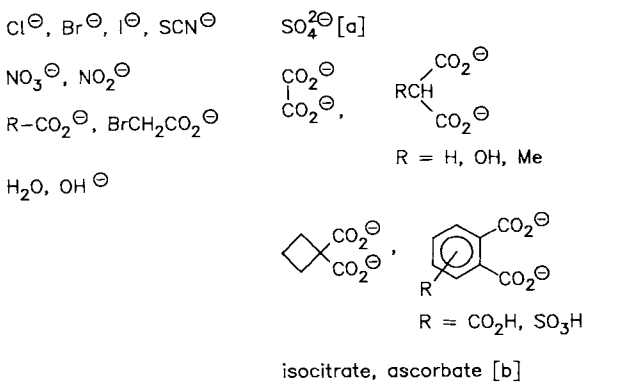


6

The lability of a particular leaving group X depends, inter alia, on the nature of the ligand *trans* to it ("*trans* effect"). For example, the cytotoxicity of compounds of the type **6** (which contain monoprotonated diamines to ensure charge neutralization, see Section 2.2.4) is determined by the nature of X (Cl, NO_2, SCN, etc.)[31]

Some typical leaving groups are listed in Table 1.[28,32-39]

Table 1. Some typical leaving groups X for *cis*-[PtA_2X_2] **5** [28, 32-39].



[a] The sulfate ion has been found to be monodentate both in the solid state [35] and in aqueous solution [36]. In these cases the other ligand is water. [b] A Pt-C bond has been reported in the case of a diaminocyclohexane complex [39].

2.2.2. *The Role of the Non-leaving Groups A*

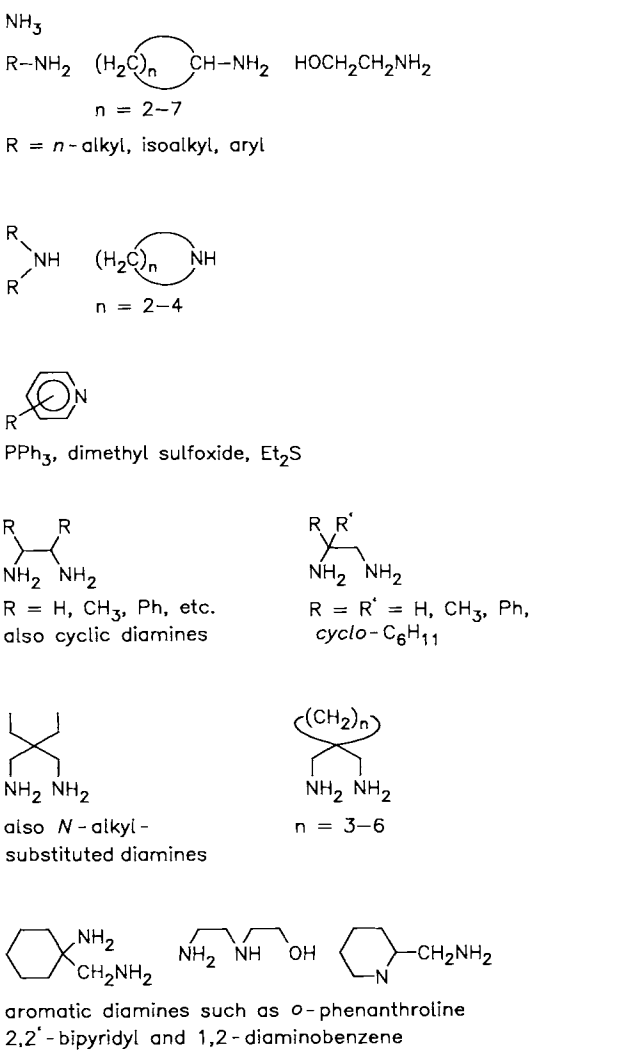
A number of non-leaving groups have been proposed, mainly amines, from the simplest one, ammonia, to linear, branched, or cyclic aliphatic amines, bidentate chelating amines (including diamino acids), and diaminocycloalkanes; in fact almost any ligand is possible (see Table 2[28,32-34,40-43]).

The role of these ligands is less clear, but since they are relatively difficult to replace (see Section 2.2), it is assumed that they accompany the platinum atom to the target macromolecules inside the cell, thus representing a major factor in governing the pharmacokinetic behavior, penetration into the cells, and interaction with DNA. In conclusion, therefore, these groups should modulate cytotoxicity and antitumor effects.[29]

Ligands with polar substituents reduce the activity of an analogue.[28] Ammonia and primary amines give rise to the more active compounds, while complexes with tertiary amines are inactive.[28] It has been suggested that hydrogen bonds between the amine and polar groups of DNA may play a role in the interaction with this macromolecule.[44] Recent molecular mechanics calculations are in agreement with this hypothesis.[45]

Complexes with the chelating 1,2-diaminocyclohexane **8**[46] (cf. Table 3) and 1,3-diaminopropane, substituted in position 2[47] (cf. Tables 2 and 3), are of special interest since these ligands are responsible for lack of cross-resistance to cisplatin, at least in experimental models. The complex with 1,2-diaminocyclohexane **9** appears to be particularly active when the (*R,R*)- rather than the (*S,S*)- or the *meso*-stereoisomer is used.[48] However, we were not able to detect any significant difference in the activity against murine tumors, of cisplatin analogues with diastereoisomeric diamines as ligands.[49] Furthermore, these complexes were found to lack any chiral recognition in the

Table 2. Some typical non-leaving groups A for *cis*-[PtA_2X_2] **5** [25, 29-34].



reaction with DNA,[50,51] but not so upon reaction with a dinucleotide.[52] We believe this matter is rather important and should be investigated in more detail.

2.2.3. *The Role of the Oxidation State of Platinum*

Studies have also been extended to platinum(IV) complexes.[28] These compounds are usually less potent than the corresponding platinum(II) complexes: They are most likely reduced in vivo, probably by cysteine,[53] to active Pt^{II} derivatives, since they neither form radical species[54] nor interfere with DNA in the absence of reducing agents.[55] Their utility resides mainly in their high solubility in water.

The so called "platinum blues" may be cited in this context. These are paramagnetic oligomers in which mixed-valence platinum is coordinated to nucleobases such as uracil.[56] Although some derivatives have been found to be rather active they are no longer used, mainly because of their toxicity and poor chemical characterization.[57]

2.2.4. The Role of the Charge of the Complex

Neutrality is generally regarded as a prerequisite for antitumor activity,[28] presumably on the grounds that neutral complexes can cross the cell membrane more easily. However, both cationic (e.g. *cis*-$[Pt(NH_3)_2(guanosine)_2]^{2\oplus}$[58]) and anionic complexes (e.g. $[PtCl_3A]^{\ominus}$; $A = NH_3$,[29] *tert*-butylamine[59]), show some low but significant activity. Clearly too little is known about the mechanism by which these molecules enter the cells. For cisplatin itself, an active transport has been proposed which is probably mediated by an amino acid transport system;[60] but different mechanisms could be operative for different analogues. Moreover, compounds of the type $[PtCl_3A]^{\ominus}$ can interact with endogenous low molecular weight amines and form neutral complexes.

3. Cisplatin Analogues in Clinical Trials

Most of the clinical studies with cisplatin analogues are still only at an exploratory stage, so only some general aspects of the clinical evaluation of new platinum complexes can be dealt with here.

Table 3 lists some cisplatin analogues which have recently been introduced into clinical trials in rapid succession.[61-66] As with other classes of antitumor agents, improvement in tumor selectivity remains the greatest challenge in the development of new analogues. The design of selective drugs is at present a difficult task, mainly because we ignore the factors determining the selectivity, if any, of the parent compound.

The criteria for selecting promising cisplatin analogues to be evaluated in clinical trials are favorable physicochemical properties (solubility and stability) and possible therapeutic advantages, as inferred from preclinical studies (high efficacy, favorable spectrum of activity, high therapeutic index and low toxicity). There are great expectations for derivatives which could prove to be effective against human cancers refractory to cisplatin; for instance, complexes with 1,2-diaminocyclohexane **8** reflect this expectation, since they lack cross-resistance to cisplatin.[34] This property is also shared by the derivatives of 1,1-bis(aminomethyl)cyclohexane **10** such as TNO6.[34] The clinical development of this compound has, however, been discouraged because it is inferior to cisplatin and exhibits unpredictable severe toxicity.[35,62,67] Other analogues have substantially inert leaving groups, e.g. **7** in JM8 and malonate in JM40, which could contribute to a reduced nephrotoxicity.

With few exceptions (e.g. JM8) insufficient experience has been gained with any of the analogues to be confident that they will have established therapeutic utility.

In general the pattern of toxicity predicted by preclinical evaluations has been confirmed. These analogues (with few exceptions) do not exhibit any nephrotoxic activity, but myelosuppression remains a general toxic property.

The widely divergent properties exhibited by some of these compounds were expected to lead to specific clinical indications not necessarily replacing those of cisplatin. Their therapeutic potential and clinical advantages over the parent drug remain, however, to be documented.

Table 3. Some cisplatin analogues *cis*-$[PtA_2X_2]$ **5** in clinical trials [51-56].

4. New Concepts in the Development of Cisplatin Analogues

A close look at Tables 1-3 reveals that most of the compounds derive from a somewhat empirical rationale: a change in the *cis*-$[PtA_2X_2]$ scheme with different A- and X-ligands, in the hope of finding superior analogues, the only guidelines being the results of structure-activity studies (see the cases of 1,2-diaminocyclohexane and of the lability of the Pt-X bond). However approaches based on different rationales have been attempted and realized. In this section we shall critically review some of the results obtained in these studies.

The antitumor activities of some selected compounds and platinum complexes are listed in Table 4. Since some variability is common in dealing with experimental tumor models in vivo, caution is required in comparing the antitumor activity data reported by different authors. Whenever possible the data of Table 4 contain a schematic description of the experiment and the activity of cisplatin itself, as a reference compound, when reported in the same paper and determined under the same conditions. The data of Table 4 must be examined taking into account that the evaluation parameters depend critically on tumor model, tumor burden, and treatment schedule. The compounds so far tested are discussed in the following sections.

Table 4. Antitumor activities of some representative cisplatin analogues. (for discussion see Sections 4.1 to 4.3).

Compound	Model	Schedule [a]	T/C% [b]	Dose	Ref.

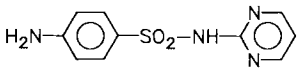
[a] Treatment was started on day one after tumor transplantation. s.d., single dose; for other schedules, for instance q4d × 3 means three administrations every four days. [b] T/C%: ratio between the median survival time of treated and untreated (control) animals × 100. Activity is considered to be significant for T/C% > 125. [c] Evaluted from the data reported by the authors. [d] L1210/DDP, L1210 leukemia resistant to cisplatin. [e] en = ethylenediamine; ox = oxalate; mal = malonate.

4.1. Low Molecular Weight Carriers as Ligands

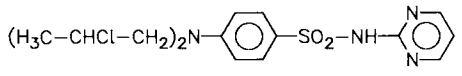
Known anticancer drugs are substances which are cytotoxic to any cell. Their antitumor activity and selectivity, if any, is mainly due to a kinetic factor, i.e. they preferentially kill rapidly growing cancer tissues, but of course normal proliferating tissues may also be affected. An ideal antitumor agent should therefore be a compound which is selectively accumulated in the cancer tissues, thus displaying its action only towards cancer cells. This can be achieved by binding the antitumor agent to carrier molecules. Some attempts have already been made at designing drugs of this sort and we shall briefly discuss this point with regard to cisplatin analogues.

4.1.1. Sulfadiazine

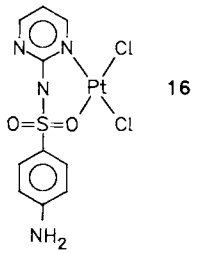
Sulfadiazine, **14**, accumulates in some cancer tissues, and sulfadiazine-substituted alkylating agents (e.g. **15**) have been proposed.[68] Compound **15**, however, exhibits a pharmacokinetic behavior different from that of **14** and accumulates preferentially in the liver.[68] We have synthesized some sulfadiazine-platinum complexes and one of



14



15



16

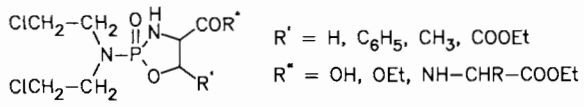
them, **16**, was found to be more active in vivo against some murine tumor models than expected on the grounds of its in vitro cytotoxicity.[69]

4.1.2. Nutrients and Metabolic Precursors

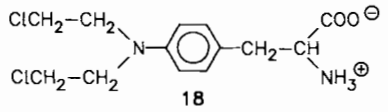
Rapidly growing tumor tissues have a high requirement for nutrients and metabolic precursors that are needed for cell proliferation. These substances (for instance amino acids) can be used as low molecular weight carriers. Incidentally, this observation has been exploited to produce cytotoxic effects in certain tumor tissues by depriving cells of a supply of amino acids, for instance by the use of depleting enzymes[70] like L-asparaginase, a well established antileukemic agent. Amino acid derivatives of alkylating agents such as **17** have been reported, and some of them possess significant activity.[71] Compound **18** (phenylalanine mustard, melphalan) is particularly active and routinely used in the clinics. Note that **18**, quite unlike **17**, still has the essential structural features of an amino acid. In fact **18** is likely to be actively transported into L1210 leukemia cells by an amino acid transport system.[72]

Some cisplatin analogues like **19**–**21** contain amino acids or peptides (aa-aaOEt = *N*-coordinated dipeptide ethyl ester). Some marginal activity against L1210 leukemia in mice[73] (but not against sarcoma 180[28]) is displayed by **19** (R = H, CH_2OH) and by **20** (aa-aa = glycylglycine), for which a preferential accumulation in cancer tissues has been demonstrated.[74] **21** is inactive.[40]

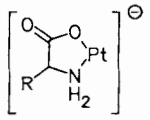
We have synthesized compound **22** in which *tert*-butylamine was chosen to increase liposolubility, whereas the *N*-coordinated amino acid moiety should act as a carrier. The glycine, serine and alanine derivatives did show some activity against murine leukemias, but they proved to be far less effective than cisplatin.[59] Such a low activity could



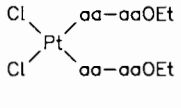
17



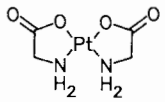
18



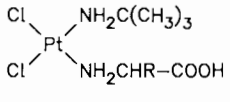
19



20



21



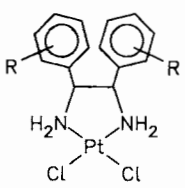
22

be due, inter alia, to some steric hindrance in the reaction with DNA.[75] Interestingly, however, we have found that the in vitro cytotoxicity of **22** against cisplatin-resistant L1210 cells is of the same order of magnitude as that for cisplatin-sensitive cells.[76] The reason for such a lack of cross-resistance is currently under investigation.

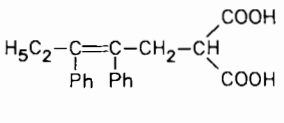
4.1.3. Non-Protein Hormones

The *cis*-PtX_2 moiety has been bound to estrogen-receptor binding molecules as in some derivatives of **23** with substituents in the ring. Thus, e.g., **23**, R = 4-OH, is an effective estrogen; since the hormone effect is retained upon complexation with platinum, it can be used as a carrier in the treatment of hormone-dependent mammary carcinomas.[77]

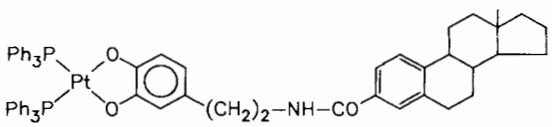
A similar recognizing moiety has also been bound to the leaving group as in **24**, where the leaving group malonic acid bears, as a substituent, ethylmethylstilbene, a compound with an estrogen-like activity.[78] The diammineplatinum derivative of **24** is active, but it has been shown that it does not bind to uterine estrogen receptors of the rat.[78] A *cis*-PtA_2 group (A = triphenylphosphane) has been bound via an *o*-catecholate to hormonally active steroids



23



24



25

(e.g. compound **25**). The cytotoxicity in vitro is acceptable,[79] but the selectivity must still be documented.

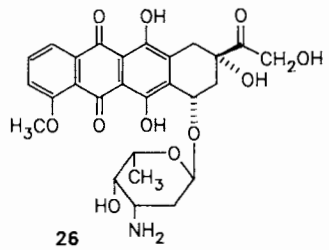
In conclusion the above discussed examples stress the general difficulty of using low molecular weight carriers, since small variations in their structure may lead to substantial changes in their biological properties, e.g. their interaction with receptors.

4.2. Multifunctional Drugs

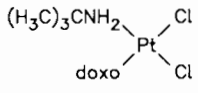
The success of combination chemotherapy is attributed to the fact that the development of resistant cell lines is prevented and that synergistic interactions between cytotoxic agents with different mechanisms of action occur.[80] Observations of this kind led to the idea of binding two different cytotoxic moieties within the same molecule.[81] Since synergism between cisplatin and other cytotoxic agents is well documented,[82] this approach would seem very promising.

4.2.1. Cytotoxic Drugs as Ligands

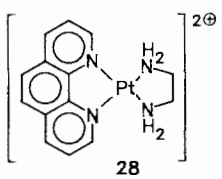
Some platinum complexes of the antitumor agent doxorubicin **26** have been described in the literature, however their activities are not higher than those of **1** or **26**.[83,84] The complex **27**, in which doxorubicin is coordinated to platinum via the amino group, is active against cisplatin- and doxorubicin-resistant murine tumors.[84] Doxorubicin probably owes its antitumor activity to intercalation in DNA[85] (although the base-sequence specificity is still a matter of debate[86]). Simple intercalating platinum complexes with no leaving groups (e.g. the complex **28**, which intercalates in the G-C regions[87]), are inactive, as expected, whereas it has been shown that compound **29** causes additive effects on the unwinding of superhelical DNA, i.e. through covalent binding of platinum and intercalation.[88] Moreover, the intercalating moiety of **29** influences the regioselectivity of the binding of platinum to DNA.[89] **29** has been reported to be active against cisplatin-resistant tumors.[90]



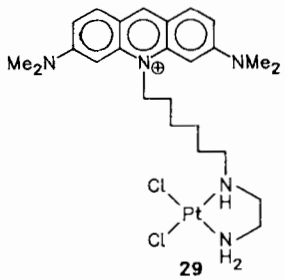
26
("doxo")



27



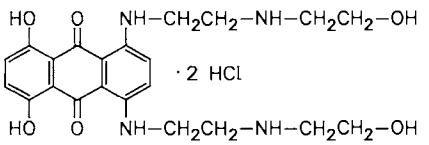
28



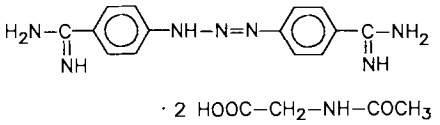
29

Further examples of complexes in which intercalating groups are bound to *cis*-$PtCl_2$, are $[PtCl_2(NH_3)$(acridine orange)] and the interesting $[\{PtCl_2(NH_3)\}_2$(proflavine)] (with two Pt atoms bound to proflavine). These complexes are less toxic than the parent ligands and are cytotoxic against L1210 cells.[91]

The antitumor activity of mitoxantrone, **30**, is also ascribed to DNA intercalation[92]—probably in the G-C rich regions[93]—and a patent has been registered claiming a very high activity of some platinum complexes of **30**.[94] These compounds were, however, poorly characterized.

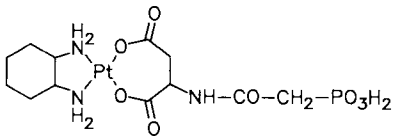


30



31

· 2 $HOOC–CH_2–NH–COCH_3$



32

Other examples of these multifunctional compounds are some complexes of triazenes (alkylating agents)[95] and complexes of mitomycin, which, however, are less active than mitomycin itself.[96]

A platinum complex of berenil, **31** (a trypanocide drug), has been prepared[97] on the grounds that there are certain parallels in the pharmacological activity of antitumor agents and drugs active against *Trypanosoma Rhodosiense* (the agent that causes sleeping sickness in man).[98,99] It has, in fact, been shown that cisplatin itself is active against this microbial agent.[97,99]

Here again the alternative approach is to use the pharmacologically active molecule, or some derivative of it, as the leaving group(s). One example is the use of melphalan, **18**, as the leaving group.[100] In the complex **32** the leaving group is *N*-(phosphonoacetyl)-L-aspartate (PALA), which is an antitumor agent in clinical evaluation.[101] This complex is rather active toward a number of experimental murine tumors, and is not cross-resistant to cisplatin.[102]

4.2.2. Repair Inhibitors

Trichloro(caffeine)platinate(1−) has been reported to possess some low, but significant, antitumor activity.[103] This complex has been synthesized because caffeine is an inhibitor of DNA repair and should enhance the lethal effect on cancer cells by the $PtCl_2$ moiety.

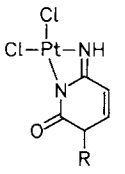
4.2.3. Polar Solvents

Some polar solvents, such as dimethyl sulfoxide (DMSO) and methylformamide induce differentiation of malignant cells and have been proposed as a class of antineoplastic agents.[104] DMSO has been bound to platinum both as non-leaving[28] and leaving group. In this case active compounds, less toxic than cisplatin, have been obtained.[99,105] Note that DMSO exercises a strong *trans* effect; hence, complexes of type **5** (X = DMSO) are less stable if A is a monodentate amine. To avoid extensive solvolysis, complexes of the type $[Pt(en)(DMSO)_2]^{2\oplus}$ (en = ethylenediamine) must be used.[106]

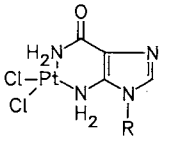
4.2.4. Antimetabolites

Antimetabolites are another important class of antitumor drugs. The rationale is that these agents should compete with normal metabolites, with increased cytotoxic action against rapidly growing cells. Long before the original paper by *Rosenberg* et al.,[3] which describes the antitumor properties of cisplatin, *Kirschner* et al. reported that platinum(IV) complexes of the antimetabolite 6-mercaptopurine were effective against murine tumors.[107] Similar results were obtained in the USSR.[33] More recently thio- and selenoguanine-platinum complexes have been reported.[108] However, with the probable exception of the selenoguanine–platinum complex, the antitumor activity of these complexes seems to be due to a slow release of the ligands, rather than to the action of the complexes as such.[109]

In the case of the complexes **33** and **34** the activity is again due to the *cis*-$PtCl_2$ moiety.[110] Compound **34** is interesting because the $PtCl_2$ group is part of a purine-like structure and could itself behave as an antimetabolite. In contrast, in **33** the platinum is bound to the antimetabolite. Some complexes of the type **33** and **34** (R = deoxyribosyl,



33



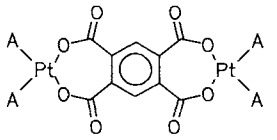
34

ribofuranosyl, or arabinofuranosyl) are active against murine L1210 leukemia, cause inhibition of DNA synthesis, and are not nephrotoxic in mice.[110] $PtCl_2$-complexes of 6-(aminoethyl)aminopurine[111] and 3′,5′-diaminodeoxythymidine[112] have also been reported. Relevant to this approach is the well known synergistic interaction between cisplatin and purine- and pyrimidine-analogues in the treatment of experimental and human tumors.[113]

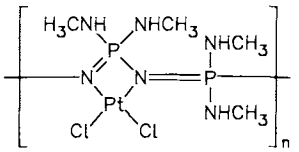
The tumor growth inhibition by glucosamine may arise, inter alia, from an alteration of multiple metabolic pathways.[114] Complexes of amino sugars have been reported as being active against some experimental model tumors.[115]

4.3. Dimeric and Polymeric Derivatives

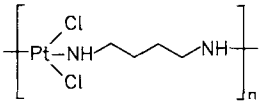
One way of increasing the effectiveness of an antitumor agent is to incorporate it in a molecule able to modify the pharmacokinetics in a favorable way. The complex **35** is probably an example of this approach.[116,117] It may be that these types of compounds act as depot systems releasing *cis*-PtA_2Y_2 species (Y = H_2O, OH). Another example may be the aforementioned proflavine–Pt_2 compound (see Section 4.2.1).[91]



35



36



37

The idea of binding antineoplastic drugs to polymers is not new.[118,119] There are many reasons for doing so. Some tumor cells display a preferential uptake of macromolecules;[120] in addition, certain natural and synthetic macromolecules display intrinsic antitumor activity.[118–120] The antitumor activities of polymeric cisplatin analogues **36** and **37** have been reported.[119,121] We have prepared some *cis*-$PtCl_2$(poly-L-lysine) derivatives which were more cytotoxic than the polymer itself; however, the toxicity of the latter precluded in vivo experiments. Finally, an adduct of polylactic acid and cisplatin slowly releases the drug. The life-span of tumor-bearing mice, has been reported to be prolonged to a greater extent by this adduct than by cisplatin.[122]

Other polymer derivatives of platinum have been reviewed.[123]

4.4. Natural Polymers as Carriers

There are a series of natural macromolecules which, at least on paper, should be the carriers of choice because of their specificity: namely, the antibodies. Binding of antitumor agents to these macromolecules should in fact yield highly selective drugs, providing such a binding does not occur at the recognition sites of the protein. Indeed, platinum complexes with tumor-directed immunoglobulins specifically inhibit DNA synthesis in tumor cells.[124] More recently, the activity of diaminoplatinum complexes with malonate or succinate ions bound to monoclonal antibodies has been reported.[125]

This area is rather exciting, but problems are encountered regarding the identity of the active moiety and how it can leave the protein and enter the cell; moreover, it is not known how many protein-bound platinum atoms are needed to kill a cell (i.e. whether the number of antibody proteins which can bind to a tumor cell multiplied by the number of platinum atoms bound to the antibody suffices to kill a cell).

4.5. Platinum Complexes as Radiation Sensitizers

Cisplatin and its congeners enhance the effect of radiation therapy, the enhancement being more than additive.[126] Analogues characterized by low toxicity also have this property.[127] This is interesting since a high local concentration of the sensitizer is needed, and compounds with low toxicity are therefore desirable. Many complexes have been proposed and some of them were designed specifically for this purpose; as examples we might mention the platinum complexes of nitroimidazole, which is itself a radiation sensitizer.[128,129] These compounds sensitize hypoxic tumor cells (i.e. cells receiving insufficient oxygen) which are not sensitive to radiation. The overall mechanism must be different from that of the cytotoxicity of cisplatin, since *trans* isomers also share this property.[127]

5. Conclusions

Extensive structure-activity studies have played a key role in attempts at optimizing the structure of cisplatin analogues. These studies have led to some important guidelines for the design of new complexes. In particular they have stressed the possibility of dissociating antitumor activity from some organ-specific toxic manifestations.[130] Thus, a number of analogues no longer appear to be nephrotoxic. However, since the toxicity toward rapidly proliferating cells (e.g. myelosuppression) becomes dose limiting in second generation cisplatin analogues, it is likely that changes in the therapeutic index of these drugs are associated with a reduction in the systemic toxicity, rather than due to an unexpected biochemical selectivity for tumor cells.[131]

Therapy with cisplatin is limited not only by its toxicity for a variety of normal tissues, but also by a resistance, which may be present initially in the treatment of less sensitive tumors, or which may emerge during the therapy of sensitive tumors. It is now generally agreed that future progress in the therapy of human cancer will be improved by the development of analogues with a wider spectrum of activity. In this respect promising derivatives are the platinum complexes with 1,2-diaminocyclohexane **8** because of their peculiar biological properties.[46]

New strategies have recently been developed. In our opinion the more interesting analogues will be compounds in which some biologically relevant molecules are complexed to platinum either as the inert or the leaving group. The biologically relevant molecules proposed are nutrients, recognizing entities such as steroids, and specific proteins (carrier approach), and substances with an intrinsic pharmacological activity, such as antimetabolites or other anticancer drugs (multifunctional approach). Other recent strategies included the preparation of "polyplatinum drugs" and of complexes which are suitable as sensitizers in radiation therapy.

Although it is difficult to predict whether these new types of complexes could be selective towards tumor cells, or possess therapeutic advantages over the second generation analogues, they are structural novelties worthy of biological evaluation.

In the authors' opinion, a rational development of new analogues requires a detailed knowledge of the mechanism of action of cisplatin itself. For instance very little is known on how cisplatin reaches certain organs, how it enters the cells, and why it ultimately reaches the chromosomal DNA, despite the fact that thousands of potential ligand groups, with high affinity for platinum, can be encountered before the medicament reaches its primary target. Thus, for example, it has been proposed that cisplatin enters the cells through an active membrane transport system.[60] Alteration of this system may be the cellular basis of natural and acquired resistance to a drug[132] and there are indications that this may be the case also for cisplatin,[76] although other mechanisms may also be involved.[133] The question therefore arises whether such a transport system can be characterized and eventually exploited to increase intracellular drug accumulation thus improving drug effectiveness, and to design analogues which use different cell membrane transport mechanisms to overcome the problems of resistance to cisplatin.

The discovery that cisplatin is an effective anticancer drug was, however, a fortuitous one.[3] Although at times we wonder whether only mere chance will bring us a really advanced cisplatin analogue, we believe that at the present stage more basic research is needed in order to elucidate many aspects of the cisplatin mode of action before new analogues with a really improved effectiveness can be designed.

We thank the CNR (Rome) and the Italian Ministry of Education for support of this work.

Direct Identification of the Carbon Skeleton of Organic Compounds using Double Quantum Coherence ^{13}C-NMR Spectroscopy. The INADEQUATE Pulse Sequence

New Analytical Methods (32)

By Joachim Buddrus* and Hans Bauer

NMR spectroscopy plays an important part in the determination of the structures of organic compounds. The parameters of importance here are the chemical shifts of the ^{1}H and ^{13}C nuclei and the spin-spin interactions both between ^{1}H nuclei and between ^{1}H and ^{13}C nuclei. Couplings between ^{13}C nuclei were almost completely neglected until a few years ago, since they were extremely difficult to observe because of the low natural abundance of ^{13}C. However, it is these couplings which afford information directly on the carbon–carbon connectivities in the molecule. It is now possible to use a special NMR pulse sequence to make these couplings more readily visible: the result of using this sequence is a ^{13}C-NMR spectrum from which the carbon skeleton concerned can be directly read off. Two-dimensional spectra in particular are very easy to evaluate. The pulse sequence involved, which bears the somewhat puzzling name INADEQUATE, produces double-quantum coherences from which the NMR signals of the coupled carbon nuclei can be obtained. In this article the principle of double-quantum coherence is described and a number of examples for the application of the INADEQUATE pulse sequences to problems in synthetic organic chemistry, biosynthesis and natural products chemistry are presented; in addition, the possibility of applying the INADEQUATE method to other nuclei is considered.

1. Introduction

It is not uncommon to come across carbon compounds which do not reveal the secret of their structure or of a detail of that structure: examples are provided by polycyclic hydrocarbons, compounds with several neighboring non-hydrogen-bearing carbon atoms or polyhalogen compounds. In such cases ^{1}H-, ^{13}C and if possible ^{15}N-NMR spectra have already been obtained, but to no avail. X-ray structural analysis, the last possibility, is not feasible, either because the compound of interest does not crystallize or because the crystals obtained exhibit unfavorable properties. If enough of the substance is available ($\geqslant$200 mg for a molecular weight of ca. 300), the technique of ^{13}C-NMR spectroscopy should again be applied; however, in this case spectra must be accumulated until molecules containing two neighboring ^{13}C nuclei can be observed (only one molecule in 10000 contains two such directly bonded nuclei). This can be done either using conventional techniques or, much more readily, using the INADEQUATE pulse sequence, since the latter eliminates the unwanted signals of isolated ^{13}C nuclei by subtraction. A comparison of the ^{13}C,^{13}C spin-spin coupling constants shows which molecular fragments (CH_3, CH_2, CH, C, CX, C=O etc.) are bonded together, and thus the exact nature of the carbon skeleton present.

2. Isotopomeric Carbon Compounds

The element carbon contains 98.9% of the isotope ^{12}C (spin quantum number I = 0) and 1.1% of the isotope ^{13}C (I = 1/2). Almost all carbon compounds thus consist of a number of isotopomers. Thus for example even the simple three-carbon molecule 1-propanol exists as a mixture of the following eight isotopomers (when hydrogen and oxygen are considered to be isotopically pure):

$H_3C-CH_2-CH_2-OH$ 96.73%	$H_3{}^{13}C-{}^{13}CH_2-CH_2-OH$ 0.01%
$H_3{}^{13}C-CH_2-CH_2-OH$ 1.08%	$H_3{}^{13}C-CH_2-{}^{13}CH_2-OH$ 0.01%
$H_3C-{}^{13}CH_2-CH_2-OH$ 1.08%	$H_3C-{}^{13}CH_2-{}^{13}CH_2-OH$ 0.01%
$H_3C-CH_2-{}^{13}CH_2-OH$ 1.08%	$H_3{}^{13}C-{}^{13}CH_2-{}^{13}CH_2-OH$ 0.0001%

The proportion of an isotopomer with a ^{13}C atom in a certain position is $0.011^{1} \times 0.989^{n-1}$ (n is the number of carbon atoms in the molecule), that of an isotopomer with two ^{13}C atoms in defined positions (whether these are directly neighboring or not) is $0.011^{2} \times 0.989^{n-2}$, and so on. This means that only one single molecule in 10000 has two neighboring ^{13}C atoms in a certain position.

Broad-band decoupling of the attached protons converts isotopomers with only a single ^{13}C nucleus to spin systems of type A, so that singlet signals are observed (this is the conventional ^{13}C-NMR spectrum). Isotopomers with two ^{13}C nuclei behave just like those with only a single ^{13}C

Table 1. $^1J(C,C)$ coupling constants as a function of carbon hybridization and of the substituent X in the fragment ^{13}C-^{13}C-X (substituent effects in brackets [a]).

Compound	Hybridization	X = H	X = CH_3	X = Cl	X = O-Alkyl
H_3C-CH_2-X	sp^3-C, sp^3-C	34.6	34.6 (0)	36.1 (1.5)	38.9 (4.3)
$H_2C=CH-CH_2X$	sp^2-C, sp^3-C	41.9	41.8 (0)	45.2 (3.3)	46.7 (4.3)
$H_2C=CX-CH_3$	sp^2-C, sp^3-C	41.9	41.9 (0)	48.5 (6.6)	51.8 (9.9)
H_5C_6-X	sp^2-C, sp^2-C	56.0 [b]	57.1 (1.1) [b]	65.2 (9.2) [b]	67.0 (11.0) [b]
$H_2C=CH-X$	sp^2-C, sp^2-C	67.6	70.0 (2.4)	77.6 (10.0)	78.1 (10.5)
$HC\equiv C-X$	sp-C, sp-C	171.5	175.0 (3.5)	207 [c] (35.5)	216.5 (45.0) [5]
$H_3C-CO-X$	sp^3-C, sp^2-C	39.7	40.1 (0.7)	56.1 (16.7)	58.8 (19.4)
$HCO-CH_2X$	sp^3-C, sp^2-C	39.7	38.3 (−1.4)		

[a] Values taken in part from Ref. [1] and in part determined by us. [b] $^1J(C_1,C_2)$. [c] Calculated [5].

nucleus if the ^{13}C nuclei are separated by several bonds. If however the ^{13}C nuclei are separated by only a few bonds (generally one to three), they couple and thus, unless they are isochronous, they form AB or AX spin systems whose spectra consist of two doublets. $^1J_{C,C}$, the coupling constant over one bond, depends on the hybridization of the carbon orbitals and on the substituent X in the fragment $^{13}C,^{13}C$-X and varies between ca. 35 and 220 Hz (Table 1).[1-4] Coupling constants over 2 or 3 bonds are much smaller, typically between 0 and 5 Hz. Isotopomers with three (and more) ^{13}C nuclei are present in vanishingly small amounts and cannot be detected by NMR spectroscopy at the present time unless their ^{13}C content is artificially increased.[6,7]

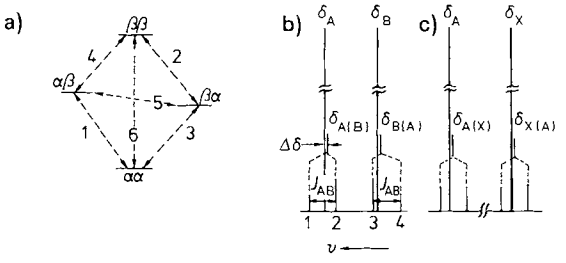

Fig. 1. Term scheme and NMR spectrum of a ^{13}C-^{13}C fragment. (a) Term scheme: 1, 2, 3, and 4 are allowed single-quantum transitions, 5 and 6 forbidden zero- and double-quantum transitions respectively. (b) and (c): NMR spectra of an AB and an AX spin system. The chemical shifts of the coupled ^{13}C nuclei are shifted to higher field by between 0 and 0.03 ppm (isotope effect on the chemical shift).

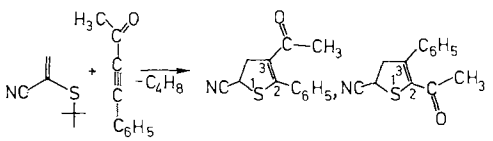
In ^{13}C-NMR spectra with a sufficient signal-to-noise ratio (> 500 : 1) the weak signals of the coupled nuclei can be seen on either side of the strong singlet signals of the isolated ^{13}C nuclei (see Fig. 1). The intensity ratio of the singlet signal to one of the four signals of the coupled nuclei is ca. 200 : 1. If the various coupling constants have different values, a comparison of the coupling constants of all ^{13}C nuclei in a molecule shows which atom is bonded to which and thus the exact structure of the carbon skeleton present.

3. Conventional ^{13}C-NMR Spectroscopy

The conventional ^{13}C-NMR procedure, by which we mean the sequence pulse-data acquisition, has been used several times to determine the coupling constants between two neighboring ^{13}C nuclei.[8-10] The coupling constants were used in part for an unequivocal assignment of ^{13}C-NMR signals and in part for the determination of biosynthetic pathways (starting from ^{13}C-labeled compounds).

We observed that the $^1J_{C,C}$ values in a conventional spectrum can also be used to determine the constitution of unknown compounds; this will be demonstrated below.



1 2 3 4

When the unsaturated compounds **1** and **2** are heated, isobutene is split off to give the dihydrothiophene **3** or its isomer **4**.[11] The use of conventional spectroscopic techniques to distinguish between these two possibilities is problematic, one reason being that in **2** the reacting carbon atoms bear no hydrogens. The distinction is however simple when $^{13}C,^{13}C$ spin-spin couplings are used (Fig. 2); the singlet at 154 ppm, which because of its position must be assigned to the olefinic carbon atom β to the carbonyl group, has only two pairs of satellites in the ratio 1 : 1. It can thus only be the C-2 signal in **3**. Further C,C couplings, which for reasons of clarity are not shown in Figure 2, confirm the suggested constitution.[12]

This example shows that the evaluation of the satellite signals of just one single ^{13}C signal can suffice to distinguish between alternative constitutions. However, in the case of completely unknown constitutions it is necessary to take into account the satellites of a large number of signals. Such a process is often difficult, since a) spinning side bands or signals due to impurities can be incorrectly identified as satellite signals or b) satellite signals can be hidden (by other satellite signals or by signals due to isolated ^{13}C nuclei).

Many of these difficulties can be avoided when instead of the conventional recording technique the pulse sequence INADEQUATE (*I*ncredible *N*atural *A*bundance *D*oubl*E* *QUA*ntum *T*ransfer *E*xperiment) is used; this sequence was first suggested by *Freeman* et al.[13] The basis for this particular pulse sequence is the technique of multi-

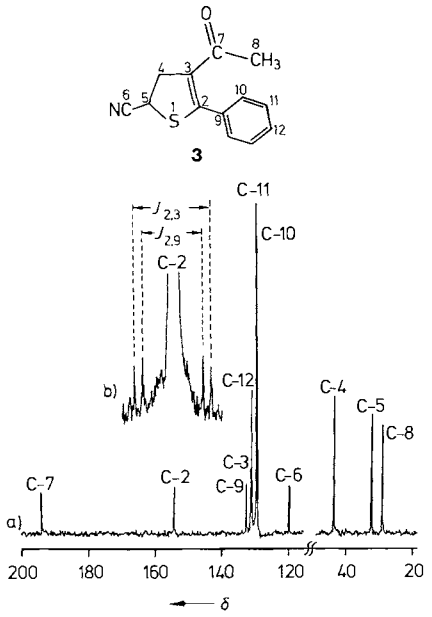


Fig. 2. 25-MHz $^{13}C\{^1H\}$-NMR spectrum of **3** (0.5 g) + [Cr(acac)$_3$] (acac = acetylacetonate) (ca. 10 mg) in $CDCl_3$ (1.5 mL). Digital resolution: 0.5 Hz/data point. a) Single transient. b) 60000 transients, repetition interval 4 s (partial spectrum). $J_{2,3} = 72.9$, $J_{2,9} = 57.7$ Hz.

quantum NMR spectroscopy developed by *Ernst* et al.[14, 15] (for reviews see Refs. [16, 17]).

Three methods are used to describe the influence of high-frequency pulses on spin systems: the vector model method, density matrix formalism, or product operator formalism. Vector models are simple to understand, but cannot generally be used to describe systems other than those containing only isolated nuclei. The density matrix formalism reproduces the behavior of isolated spins or of coupled spins correctly, but becomes cumbersome for systems containing a number of coupled nuclei. The latter systems are most conveniently described by the product operator formalism,[18] which is based on density matrix formalism. We shall use density matrix formalism (for details see Appendix), which is still easy to follow for two-spin systems; the results of the calculations will be represented by vector diagrams.

4. One-Dimensional INADEQUATE ^{13}C-NMR Spectroscopy

The INADEQUATE method consists of a pulse sequence which in the simplest version is executed twice (the "two-step cycle"), whereby the direction (phase) of the last 90° pulse and of the detector (data acquisition system) differ in the two steps. Two FIDs are thus obtained, and the co-addition of these leads to the elimination of the strong signals due to the isolated ^{13}C nuclei.

$90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_x$ - data acquisition (x) step 1
$90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \Delta - 90^\circ_y$ - data acquisition $(-y)$ step 2

The effect on a C_2 fragment is shown in Figure 3. The first part of the INADEQUATE pulse sequence ($90^\circ_x - \tau - 180^\circ_y - \tau$) is identical to a homonuclear spin-echo experiment (for a review of modern pulse sequences and their

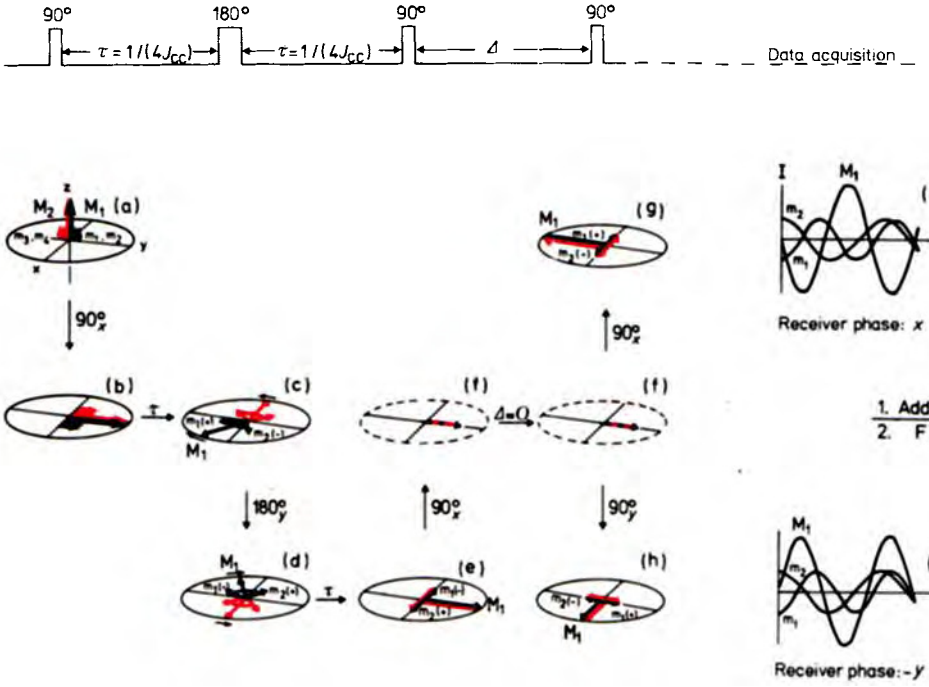

Fig. 3. The INADEQUATE pulse sequence and its effect on a C_2 fragment. M_1, M_2 and m_1 to m_4 are the magnetizations of the isotopomeric fragments ^{13}C-^{12}C, ^{12}C-^{13}C and ^{13}C-^{13}C. The delay time τ and the switching time Δ (ca. 10 μs) are not shown to scale. M_1, $m_1(+)$, $m_2(-)$: the Larmor frequency of m_1 is larger, that of m_2 smaller than that of M_1. The coordinate systems for single- and double-quantum transitions are denoted by full and dotted perimeters respectively. For clarity there have been omitted: the notations M_2, m_3 and m_4 in (b)–(e) and (h), and their Fourier components in (i) and (j). For the same reason the magnetizations M_1 and M_2 after the third and before the fourth pulse are not shown, since this would require a separate coordinate system (for single-quantum coherence). It can however readily be seen that M_1 and M_2 are transferred by the third and fourth pulses into the $-y$-direction ($90^\circ_x + 90^\circ_x$) and x-direction ($90^\circ_x + 90^\circ_y$) respectively, as shown in (g) and (h).

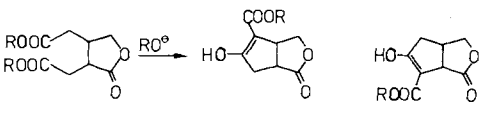
effects see [19]); when the total time $2\tau = 1/(2J_{C,C})$, the magnetization of the isolated ^{13}C nuclei (M_1 and M_2) is separated from that of the coupled nuclei (m_1 to m_4) so that the magnetizations lie on orthogonal axes of the rotating coordinate system (rotating frame) (Fig. 3e). The subsequent $90°_x$ pulse shifts the magnetizations M_1 and M_2 from the y-direction to the $-z$-direction, while the magnetizations m_1 to m_4 are transferred from the $\pm x$-direction into the so-called double-quantum coherence and directed along the y-axis of the rotating double-quantum coordinate system (Fig. 3f). In contrast to the single-quantum coherence (M_1, M_2), the double-quantum coherence does not represent observable magnetization. Thus it cannot be accommodated in the coordinate system for rotating single-quantum coherences and requires a separate rotating frame (Fig. 3f). The rotation of M_1 and M_2 is of the classical type. The conversion of m_1 to m_4 into double-quantum coherence and the phase direction of the latter follows from the density matrix formalism (see Appendix).

The last pulse (the "read pulse") is in the x-direction in the first step and in the y-direction in the second. It converts the double-quantum coherence into single-quantum coherence, whereby M_1 and M_2, and m_1 to m_4, are directed as shown in Figures 3g and 3 h respectively. The phase of the detectors is then switched in such a way that it follows only the magnetizations m_1 to m_4 of interest: in the first step in the x-direction and in the second in the $-y$-direction. Two free-induction decays are recorded; these contain the Fourier components of the magnetizations M_1, M_2 and m_1 to m_4 shown in Figures 3i and 3j. Addition of the FIDs leads to addition of m_1–m_4 and, if the high-frequency pulses are perfect, to the simultaneous *elimination of M_1 and M_2*. Finally, Fourier transformation affords the frequency spectrum (Fig. 3k), which only contains the two doublets (in antiphase in each case) of the AX spin system.

A one-dimensional INADEQUATE ^{13}C-NMR spectrum consists in theory only of signals from coupled nuclei: the unwanted signals due to isolated ^{13}C nuclei (whether from the main component or from impurities) as well as the spinning sidebands from these signals are not present.

The power of the one-dimensional INADEQUATE method is demonstrated by the following example: Dieckmann condensation of the diester **5** affords a compound which according to its 300-MHz ^1H-NMR spectrum is either **6** or **7**.[20]



5 **6** **7**

A decision as to which compound is present is made possible by the $^{13}C,^{13}C$ couplings (Fig. 4). The connectivity $O{=}C{-}CH{-}CH_2$ is demonstrated by the observed couplings, so that the structure must be **6**; further connectivities support this structure.[12] A distinction on the basis of the satellite signals in a normal ^{13}C-NMR spectrum would be difficult: **6** contains an impurity, the NMR signals of which overlap the all-important satellites of the signal of

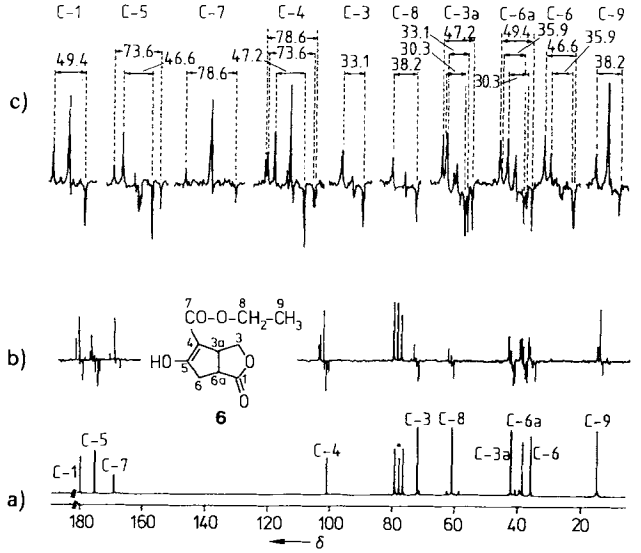


Fig. 4. 25-MHz ^{13}C-NMR spectrum of **6** (1.2 g) + [Cr(acac)$_3$] (20 mg) in $CDCl_3$ (1.0 mL). a) Conventional spectrum, 1000 transients. b) One-dimensional INADEQUATE spectrum; $\tau = 1/(4J)$ ($J = 50$ Hz); 122000 transients, repetition interval 4 s (total measuring time 135 h); digital resolution 0.5 Hz/data point. c) Expanded INADEQUATE spectrum. * Solvent signals.

C-6a. In general, the presence of up to 20% of impurities can be tolerated when structures are to be determined by the INADEQUATE method.

The determination of the carbon skeleton from $^{13}C,^{13}C$ coupling constants can also be carried out using a computer program. The frequencies of the satellite signals are first read off (automatization of this process is prevented by signal overlap) and stored: the program then searches for coupling constant values which appear twice.[21]

5. Two-Dimensional INADEQUATE ^{13}C-NMR Spectroscopy

If the $^{13}C,^{13}C$ coupling constants differ only slightly from one another, overlap of satellite signals (for AX spectra) or ambiguities in recognizing the coupling partner may occur. Difficulties of this type can be avoided when the INADEQUATE sequence is made two-dimensional.

The pulse sequence for the two-dimensional experiment is almost exactly the same as that in one dimension: the change is that the short switching time Δ in Figure 3 is replaced by the time t_1, which is incremented stepwise.

When $t_1 = 0$, the non-observable double-quantum coherence is directed along the y'-axis of the double-quantum coordinate system (Fig. 5a). It then rotates at the double-quantum frequency ν_{DQ} in the x', y'-plane of this coordinate system; after the evolution times $t_1 = n/(4\nu_{DQ})$,

$\nu_{DQ} = \nu_A + \nu_X - 2\nu_0$

ν_A, ν_X: resonance frequency of the nuclei A and X;
ν_0: exciting frequency

$n = 1$–4 in the directions shown in Figure 5. Conversion to single-quantum coherence by means of the 90° read pulse, followed by Fourier transformation, gives the satellite signals, the intensity of which is now modulated by ν_{DQ}.

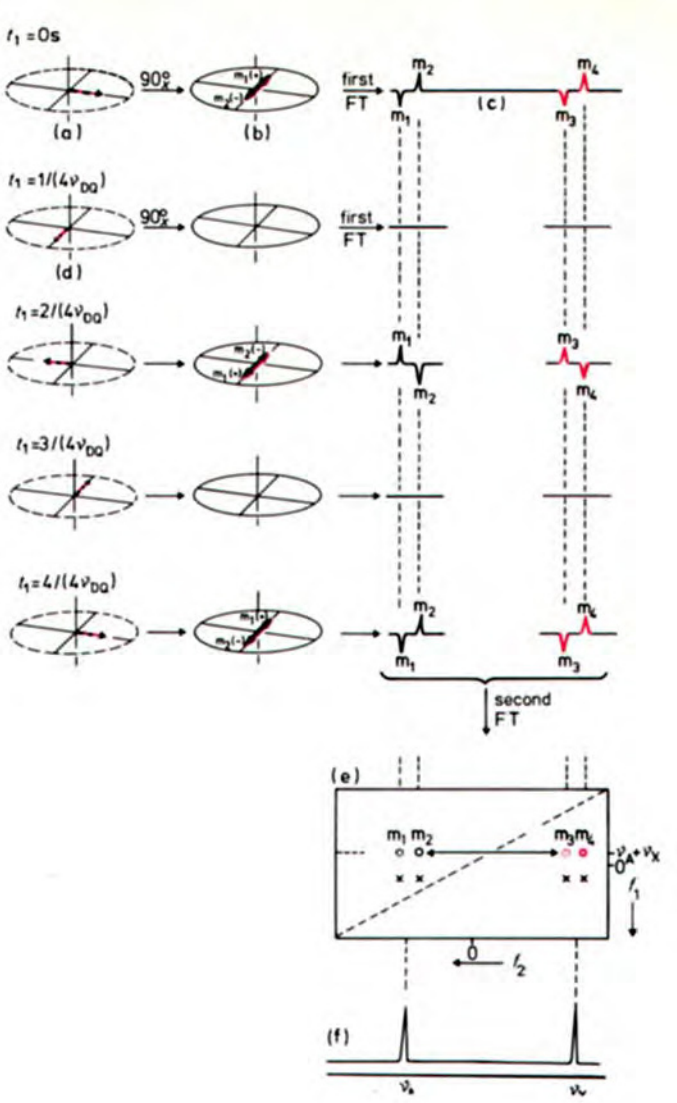

Fig. 5. Influence of the evolution time t_1 (which replaces Δ in Fig. 3) on the magnetization of a C_2 fragment. For clarity only the effect of the read pulse 90°$_x$ (step 1 in Section 4) on the magnetizations m_1 to m_4 is shown and the notations m_3 and m_4 are omitted. One should note the general agreement between (a), (b), and (c) and 3f, 3g and 3k. (e) shows the contours (full and dotted circles: above and below the plane of the paper respectively) of the four signals m_1 to m_4 of an AX spin system. The mid-points of those contours which belong together lie on the frequency diagonal $f_1 = 2f_2$ (f_1, f_2: double- and single-quantum frequencies respectively). The positions marked by an "×" are those of the mirror frequencies (see Section 7.3). (f) = conventional ^{13}C-NMR spectrum of the C_2 fragment.

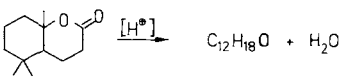
A second Fourier transformation—in this case applied on the intensity variation of the satellite signals—gives the double-quantum frequency ν_{DQ} of the AX spin system. Since this frequency is equal for all four signals of an AX spin system, the satellite signals appear in the same row (f_1 = constant) of the two-dimensional spectrum, though with differing phase. The situation is analogous for each further AX spin system.

The projection of the contours of a two-dimensional INADEQUATE spectrum onto the x-axis of a coordinate system (f_2) gives the chemical shifts of the satellite signals, that onto the y-axis the double-quantum frequencies of the different AX spin systems. The advantage over a one-dimensional spectrum is that no overlap can occur, even when $^1J_{C,C}$ values are equal, since the double doublets of each of the different AX spin systems occur in different rows.[22]

An application of the two-dimensional INADEQUATE method is shown in the following example: the acid-catalyzed elimination of water from the bicyclic lactone **8** gives a tricyclic ketone of the formula $C_{12}H_{18}O$, the constitution of which could not be established using the standard spectroscopic techniques.



8

Figure 6b shows the two-dimensional INADEQUATE spectrum, which to obtain better digital resolution in f_2 was recorded only for the aliphatic carbons. In order to identify the carbon skeleton, the signals are numbered from left to right, the corresponding numbers are joined up as in **9a**, and finally the numbers are replaced by the corresponding CH_n fragments (which have previously been obtained from another experiment, e.g. via off-resonance decoupling). The result is **9b**; after the keto group (δ = 229.5 ppm) has been added, the final structure **10** is obtained.[23]

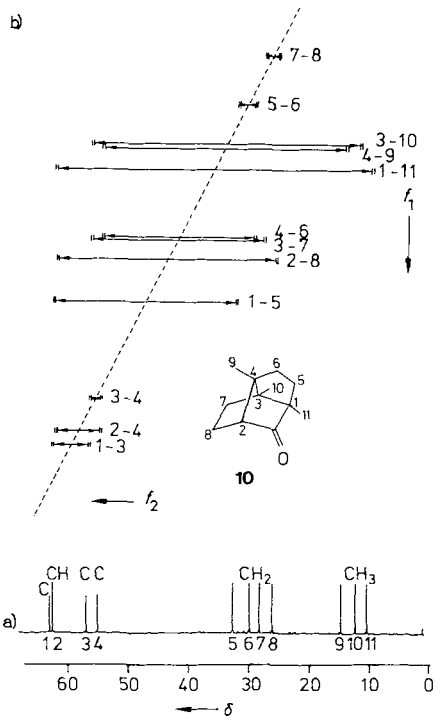


Fig. 6. 100-MHz ^{13}C-NMR spectrum (aliphatic part) of **10** (1.2 g) + [Cr(acac)$_3$] (10 mg) in $CDCl_3$ (1.5 mL). a) Conventional spectrum. b) Two-dimensional INADEQUATE spectrum, $\tau = 1/(4J)$ (J = 35 Hz). f_2 = 8771 Hz (8 K data points), f_1 = 8771 Hz/(512 data points). 113 rows were recorded, each with 128 transients; repetition interval 4 s; measuring time 16 h. The data matrix was zero-filled to 16 K · 512 and Fourier transformed after Gaussian multiplication in f_1 and f_2.

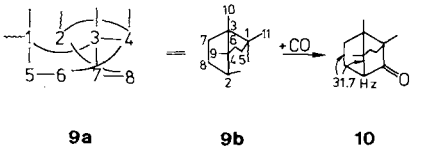

9a **9b** **10**

A conventional or one-dimensional INADEQUATE ^{13}C-NMR spectrum would not have provided the answer here, since several coupling constants are equal or very similar. Thus the coupling constant of 31.7 Hz would have suggested the connectivities C-7–C-2 and C-8–C-4 as well as the correct ones C-4–C-2 and C-7–C-8.

If all the contours in a 2D-INADEQUATE spectrum are visible, its interpretation requires little time and can be carried out without any particular spectroscopic or chemical experience.

6. Other NMR Methods for the Determination of the Carbon Skeleton

The carbon skeleton of an organic molecule can also be determined by using the method of zero-quantum coherence. The pulse sequence used is as follows:

$90°_{\phi_1}$-τ-$180°_{\phi_2}$-τ-$45°_{\phi_3}$-t_1-$90°_{\phi_4}$-data acquisition (ϕ_5)

For details of the phases ϕ_1–ϕ_5 see Ref. [24a]. The y-axis of the two-dimensional spectrum now contains the zero-quantum frequencies $\nu_{DQ}=\nu_A-\nu_B-2\nu_0$, the x-axis the chemical shifts of satellite signals. The signal intensities in the zero-quantum NMR spectrum are however reduced by a half compared with those in the INADEQUATE NMR spectra.[24b]

Apart from the direct methods of determining the carbon skeleton via coupling between ^{13}C nuclei, there are also indirect methods which use the coupling between ^{1}H nuclei or between ^{1}H and ^{13}C nuclei (Table 2). H,H-COSY (*CO*rrelation *S*pectroscop*Y*),[14] the most sensitive technique, detects relationships between hydrogen atoms, while an H,C-COSY experiment[25] (which uses polarization transfer) shows which H-atom is bonded to which C-atom. In suitable cases, an H-relayed H,C-COSY experiment[26] permits the construction of a connection pattern involving CH_n or CH_n–XH_m groups. An H,C-correlation via small coupling constants ($^3J_{C,H}$, $^2J_{C,H}$) using the pulse sequence H,C-COLOC (*CO*rrelation spectroscopy via *LO*ng-range *C*oupling)[27] permits relationships to quaternary carbon atoms to be established. The number of bonds between the coupling nuclei cannot however be extracted from spectra of this type. Unambiguous conclusions regarding connections between quaternary carbon atoms and CH_n-groups can be obtained with the help of a C-relayed H,C-COSY experiment,[28] in which the information on the chemical shift of the hydrogen atom is transferred via $^1J_{C,H}$ and $^1J_{C,C}$ to the quaternary C-atom. The latter method has been used to distinguish between regioisomers.[28]

As can be seen from Table 2, the INADEQUATE method is the least sensitive of those mentioned. Because of the resulting long measurement time, this method should be used only when the others are unsuccessful.

7. Practical INADEQUATE NMR Spectroscopy

7.1. The Intensity of the Residual Signal

In practice, the two-step cycle described above affords only an incomplete elimination of the signals of isolated ^{13}C nuclei. The reasons for this are firstly the non-ideal spectrometer conditions such as pulse angle errors and phase errors, and secondly differences between the two recording channels (receiver systems), each of which has its own analog-digital converter and amplifier. However, the residual signals can be reduced further by using extended phase cycles (Table 3).

The double-quantum coherence produced by the pulse sequence $90°_x$-τ-$180°_y$-τ-$90°_x$ can be read by a $90°_{-x}$ or $90°_{-y}$ pulse as well as by a $90°_x$ or $90°_y$ pulse. This 4-step cycle[13] compensates for the inequality of the recording channels with respect to the satellite signals, but not with respect to the main signals, since the subtraction of the latter still requires the use of both recording channels. A phase cycle for the excitation of the double-quantum coherence (i.e. equal phase changes for *all* pulses and of the receiver) leads to a 16-step cycle in which the inequality of the recording channels now also has no influence on the

Table 2. Two-dimensional NMR techniques for the direct and indirect determination of carbon skeletons.

Puls sequence	Skeleton	Correlation	Relevant couplings	Sensitivity with respect to INADEQUATE pulse sequence
INADEQUATE	C^1-C^2	δ(C-1) with δ(C-2)	^1J(C,C)	1
C-relayed H,C-COSY		e.g. δ(C-1) with δ(H-2)	^1J(C-1,C-2), ^1J(C-2,H-2)	2 for CH–$C_{quart.}$
H-relayed H,C-COSY		e.g. δ(C-1) with δ(H-2)	^1J(C-1,H-1), ^3J(H-1,H-2)	20–200, according to J(H,H)
H,C-COLOC		e.g. δ(C-2) with δ(H-1)	^nJ(C-2,H-1) ($n \geq 2$)	20–200
H,C-COSY		e.g. δ(C-1) with δ(H-1)	^1J(C-1,H-1)	~200
H,H-COSY		e.g. δ(H-1) with δ(H-2)	^nJ(H,H)	1000–10000

Table 3. Phase cycles in INADEQUATE NMR measurements with the pulse sequence $90°_x - \tau - 180°_y - \tau - 90°_\varphi - \Delta - 90°_\varphi$, data acquisition (*e*).

Step [a]	*a*	*b*	*c*	*d*	*e*
1	x	y	x	x	x

12	$-x$	$-y$	$-x$	y	$-y$
13	$-y$	x	$-y$	$-y$	$-y$
14	$-y$	x	$-y$	x	$-x$
15	$-y$	x	$-y$	y	y
16	$-y$	x	$-y$	$-x$	x

[a] Steps 1–2: 2-step cycle; Steps 1–4: 4-step cycle; Steps 1–16: 16-step cycle.

main signals. This cycle is the smallest which should be used in practice. The influence of pulse angle and pulse phase errors on the height of the residual signal can be reduced by further *separate* phase cycles for the various pulses. The 180° pulse has the largest effect on the height of the residual signal. Inversion of this pulse leads to a 32-step cycle, which in most cases affords good signal suppression; this phase cycle is contained in the software provided by most instrument manufacturers for INADEQUATE measurements. The residual signal can be reduced to practically zero by variation of the phase of the 180° pulse in all 4 possible directions (64-step cycle), inversion of the phase of the first pulse (128-step cycle)[29] and inversion of the phase of the third pulse (256-step cycle). Elimination of the residual signal however is possible only with sufficiently large repetition intervals (establishment of equilibrium of the longitudinal magnetization). This must be taken into account in particular when determining $^{13}C,^{13}C$ long-distance couplings.

7.2. The Intensity of the Satellite Signals

The only magnetizations observable after the application of an INADEQUATE pulse sequence are those resulting from a double quantum coherence. Thus the intensity of the satellite signals is determined by the effectiveness of the generation of double-quantum coherence.

The *delay time* has the greatest effect. Optimum generation of double-quantum coherence only occurs when τ and the coupling constant $^1J_{C,C}$ are related by Equation (a).

$$\tau = \frac{2n+1}{4 \times {}^1J_{C,C}} \quad (n = 0, 1, 2, 3, \ldots) \qquad (a)$$

The value to be used for the order n depends on the spin system.[30] In the AX case ($\delta/J > 3$), n has no influence on the intensity, and in practice $n = 0$ is used because of the influence of the transverse relaxation (time constant T_2^*); in the AB-case ($\delta/J < 3$), $n = 1$ or 2 is better (Fig. 7). In some cases only the conventional NMR method affords

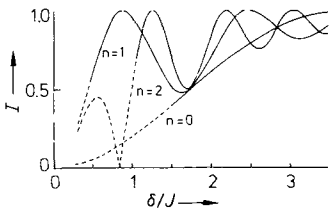

Fig. 7. Calculated total intensity of the four signals of a $^{13}C,^{13}C$ fragment as a function of the coupling strength δ/J. $\tau = 1/(4J)$ is an optimum for weak coupling, while for strong coupling ($\delta/J < 2.8$) $\tau = 3/(4J)$ or $5/(4J)$ is better. The dotted lines show the areas in which only low satellite intensities are observed in spite of an optimally chosen τ-value [30].

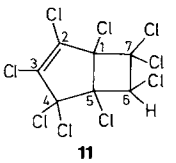
the satellite signals. The two techniques are compared in Figure 8 using example **11**[12]. The INADEQUATE experiment gives no satellite signals for C-1–C-5, since the order $n = 0$ set without knowledge of the δ/J ratio is unfavorable for C-1, C-5 coupling (the signals would have become visible with $n = 2$). In the conventional ^{13}C-NMR spectrum,



11

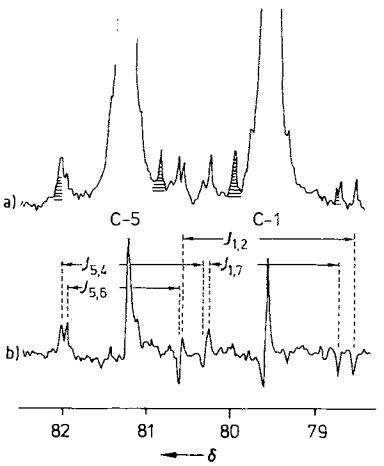


Fig. 8. 25-MHz ^{13}C-NMR spectrum (part only) of **11** in $CDCl_3$. a) Conventional spectrum. The shaded signals are due to $^1J_{1,5}$. b) One-dimensional INADEQUATE spectrum. $^1J_{5,4} = 42.4$, $^1J_{5,6} = 33.8$, $^1J_{1,2} = 51.2$, $^1J_{1,7} = 38.1$, $^1J_{1,5} = 30.4$ Hz.

the signals (shaded) are readily apparent. It is generally the case that only the conventional technique affords the maximum intensity for the satellite signals (for the calculation of strongly coupled AB spin systems ($\delta/J < 1$) from the inner lines see Ref. [8a]).

If the actual coupling constant (J_a) differs from the value J used in Equation (a), the intensity I will be decreased in the AX case according to Equation (b), since

$$I = I_{max} \sin(2\pi J_a \tau) \qquad (b)$$

the magnetization is no longer directed exactly along the $\pm$-axis (Fig. 3e). However, the results of this deviation

from ideality are not serious: 50% or more of the maximum intensity I_{max} is still observed when

$1/3J \leqslant J_a \leqslant 5/3J$ [for n = 0, Eq. (a)]

Thus, the satellite signals due to the coupling C-1–C-6a (49.4 Hz) in **6** have a greater intensity than those due to the coupling C-4–C-7 (78.6 Hz) if, as was the case, the NMR experiment is set up for $J = 50$ Hz (Fig. 4). (For the intensity decrease observed in the AB case see [30].)

Pulse imperfections, such as inhomogeneity of the high-frequency field within the measuring volume (pulse angles not constant) or "off-resonance" effects (when the effective high-frequency field is not constant across the chemical shift range), will also reduce the intensity of the satellite signals. Off-resonance effects can become particularly important at very high magnetic field and can lead to inversion of the phase of the satellite signals or even to a disappearance of the latter. The imperfections mentioned cannot be avoided by the use of a phase cycle, but may be removed by the use of composite pulses.[31-33]

The *linewidth* of the satellite signals in a 1D-INADEQUATE NMR spectrum is the same as that in a conventional spectrum. However, the linewidth of 2D-INADEQUATE spectra on the double-quantum frequency axis is increased on instrumental grounds by a factor of two.[29b]

All the factors discussed so far cause the signal-to-noise ratio (S/N) of the satellite signals to decrease as follows (assuming equal measurement time for all methods):

$$S/N_{normal} > S/N_{1D\text{-}INADEQUATE} > S/N_{2D\text{-}INADEQUATE}$$

In a conventional ^{13}C-NMR spectrum the two satellite pairs of an AX spin system have different intensities, since they are subject to differing influences such as the NOE (Nuclear Overhauser Effect) and T_1 (the longitudinal relaxation time). In the INADEQUATE experiment the magnetizations are distributed via the double-quantum coherence between the two nuclei, and equal intensities are observed for the satellite signals even in extreme cases such as $C_{quat.}$–CH_3.

When a carbon atom couples with several other C-atoms, the satellite pairs for this atom also have different intensities if the T_1-values for the coupling partners differ. Coupling between quaternary C-atoms is often only observed when either a long repetition interval is used (the optimal repetition interval for 90° observation pulses is $1.3\,T_1$[34]) or when relaxation reagents such as [Cr(acac)$_3$] are added to reduce the measurement time.

7.3. Modification of the INADEQUATE Pulse Sequence

The INADEQUATE pulse sequence has undergone a number of modifications which increase the information content of the spectra; both the one- and the two-dimensional versions have been varied.

In the one-dimensional version, signal cancellation can occur if two satellite signals lie very close together and are in antiphase. Such cancellations can be avoided by incorporating a delay time $\tau = 1/(2J_{C,C})$, which causes a refocussing of the phase directions of the satellite signals.[13] (For intensity distortions in AB spin systems see Ref. [35].) During the refocussing time, the methods applied in conventional ^{13}C-NMR spectroscopy for spectral editing according to the CH multiplicity can also be incorporated.[36,37] A further technique for the determination of multiplicities, SEMINA (*S*ubspectral *E*diting using a *M*ultiple quantum trap for *INA*DEQUATE) divides the spectra according to the sum of the H-atoms in the CH_n–CH_m-fragment: all satellite signals for C_2-fragments with this sum even (e.g. $C_{quat.}$–CH_2 or CH–CH) appear in one spectrum, while those for which the sum is odd appear in a second spectrum.[38]

One-dimensional INADEQUATE spectra can also be simplified by variation of the time period Δ in the INADEQUATE pulse sequence. If the signals of a certain AX spin system are to be eliminated, Δ is set to the corresponding double-quantum coherence according to $\Delta = 1/(4\nu_{DQ})$[39] (see Fig. 5d). If on the contrary only the signals of a particular AX spin system are to be recorded, the transmitter frequency is set at exactly the mid-point between the single frequencies ν_A and ν_B, and Δ is varied in a random manner. This method, known as DOUBTFUL (*DOUB*le quantum *T*ransition for *F*inding *U*nresolved *L*ines)[40-42] eliminates all signals which have a non-zero double-quantum frequency.

As shown by Figure 5, the 90° read pulse in the two-dimensional version results in an *amplitude* modulation: the Fourier transformation of the FIDs gives not only the required signals (echos) with double-quantum frequency ν_{DQ}, but also the unrequired reflected signals (antiechos) whose frequency is ν_{-DQ} (marked in Fig. 5e by crosses). The latter can be eliminated by a *phase* modulation, which is realized by adding to the two-step cycle ($\Delta = t_1$) the following sequence:[43]

$90°_x$ - τ - $180°_y$ - τ - $90°_x$ - $45°_{\bar{z}}$ - t_1 - $90°_x$ - acquisition (y)
$90°_x$ - τ - $180°_y$ - t - $90°_x$ - $45°_{\bar{z}}$ - t_1 - $90°_y$ - acquisition (x)

The $45°_{\bar{z}}$ pulse, which is in practice replaced by the combination $90°_{-x}$ - $45°_{-y}$ - $90°_x$, rotates the double-quantum coherence by 90°; its imaginary part is then converted by the read pulse into observable magnetization. Phase shifting the receiver by 90° allows these magnetizations to be added as imaginary parts to the real parts obtained from the pulse sequence without the $45°_{\bar{z}}$ pulse, which have already been stored. In this way quadrature detection with respect to the f_1-axis is also achieved.

A partial phase modulation can also be achieved by setting the read pulse angle to 135°:[44]

$90°_x$ - τ - $180°_y$ - τ - $90°_x$ - t_1 - $135°_x$ - data acquisition (x)
$90°_x$ - τ - $180°_y$ - t - $90°_x$ - t_1 - $135°_y$ - data acquisition ($-y$)

The result is a good suppression of the antiecho and at the same time an increase in the intensity of the echo. The ratio of echo to antiecho is now ca. 6 : 1 (instead of 1 : 1 for a read pulse angle of 90°). A further improvement (to 9 : 1) is obtained by setting the third and fourth pulses of the INADEQUATE pulse sequence to 120°.[45]

When the read pulse occurs in the middle of the evolution time t_1 as follows[46]

$$90^\circ_x - \tau - 180^\circ_y - \tau - 90^\circ_x - \frac{t_1}{2} - 135^\circ - \frac{t_1}{2} - \text{data acquisition}$$

the intensities of the satellite signals are modulated by half the frequency of the coupling partner, $(\nu+J/2)/2$, instead of by the double-quantum frequency.[47] The resulting two-dimensional spectrum resembles a COSY spectrum and can thus also be symmetrized. There is disagreement as to whether this variation leads to a worthwhile improvement in the signal-to-noise ratio.[47,48]

The relative insensitivity of the INADEQUATE method has been mentioned several times (Table 2). An increase in the sensitivity can be achieved by using the combined pulse sequences INEPT-INADEQUATE (INEPT: *IN*sensitive *E*nhancement by *P*olarization *T*ransfer)[49] and DEPT-INADEQUATE (DEPT: *D*istortionless *E*nhancement by *P*olarization *T*ransfer).[50] In these cases, the intensity of the satellite signals can be increased by polarization transfer from protons to carbon-13 (by a factor $\geq 4/3$); in addition the repetition interval can be decreased (as long as the relaxation times T_1 of the protons are shorter than those of the ^{13}C nuclei). A sensitivity increase is also provided by the sequence INSIPID (*IN*ADEQUATE *S*ensitivity *I*mprovement by *P*roton *I*ndirect *D*etection).[51a] The INSIPID sequence transfers ^{13}C coherence modulated by $^1J_{C,C}$ to proton coherence and thus takes advantage of the higher sensitivity of ^1H- relative to ^{13}C-NMR spectroscopy. The theoretical gain in sensitivity of $(\gamma_H/\gamma_C)^3 = 64$ is however not reached because of the inverse polarization transfer (from C to H) and because of signal splitting due to $^nJ_{H,H}$ and $^2J_{C,H}$. The authors estimate a tenfold gain in sensitivity to be more realistic. However, INSIPID experiments are not easy to carry out, since spectrometer modifications are necessary (pulses on the ^{13}C nuclei via the decoupler channel; recording of the ^1H-magnetization via the decoupler channel). (For the problem of suppressing the ca. 10^4-fold more intense H signals in the H-^{12}C-^{12}C fragments see Ref. [51b].)

7.4. Problems Due to Overlapping Signals from Isolated ^{13}C Nuclei

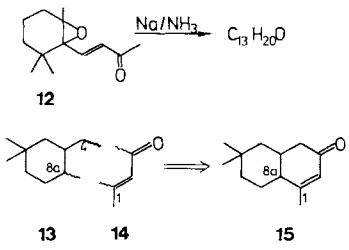
When the ^{13}C-NMR signals from two (or more) CH_2, CH or $C_{quat.}$ fragments lie on top of one another, the determination of the constitution of the molecule by means of INADEQUATE is not possible. Thus when the signals from two CH_2 groups overlap there are three possible connectivities, and one cannot establish which are correct. The situation is not quite so hopeless if the signals of a CH_n fragment and a quaternary carbon are superimposed: the addition of a delay time $t = 1/(2J_{C,H})$ to the INADEQUATE pulse sequence, during which the proton decoupler is switched off, causes the satellite signals of all protonated carbon atoms to be removed while those of the quaternary carbons remain (see **26** in Table 4).[36]

If two ^{13}C signals do not lie on top of each other but only very close together, another problem is encountered. The two-dimensional experiment now requires a very high digital resolution in f_2, which is often not compatible with the limited computer memory available. The one-dimensional experiment can fail when the $^1J_{C,C}$ values are similar. Two selective experiments which are not subject to these limitations will be described below. The first one is not an INADEQUATE experiment.

Selective irradiation at the resonance frequency of a certain ^{13}C nucleus using a field strength B_2, where $\gamma \cdot B_2/2\pi = 0.5\,{}^1J_{C,C}$, followed by a non-selective observing pulse leads to the observation of satellite signals only for those ^{13}C nuclei which are connected to that which is irradiated.[52a] It is necessary for the selective and unselective pulses to differ in phase by 90°.

$135^\circ_{x,\text{selective}} - 90^\circ_y$ - data acquisition (x)	step 1
$135^\circ_{x,\text{selective}} - 90^\circ_{-y}$ - data acquisition (x)	step 2

An application of this technique is shown in the following example. When compound **12** is reduced, one of the products is a compound of molecular formula $C_{13}H_{20}O$; the investigation of this molecule using INADEQUATE affords the fragments **13** and **14** but not the manner in which they are linked, since the signals of C-4 and C-8a which can provide the necessary information lie very close together.



Selective excitation at the frequency of C-1 gives a satellite pair (Fig. 9) which must be assigned to the signal C-8a; its assignment to C-4 would imply an unrealistically large isotope effect of -0.08 ppm on the chemical shift (see also Fig. 1): isotopic effects of $^{13}C/^{12}C$ on ^{13}C are between 0 and -0.03 ppm.[52b] Thus the compound has structure **15**.[53]

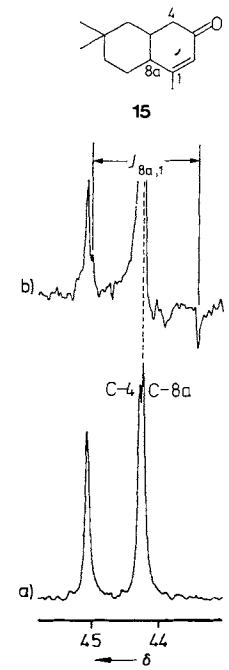


Fig. 9. 25-MHz ^{13}C-NMR spectrum of **15** (part only). Sample concentration: 1.9 g in 0.8 mL of $CDCl_3$. a) Conventional spectrum. b) Spectrum obtained using the pulse sequence described in Ref. [52a] with selective irradiation of C-1, power (corresponding to $0.5J_{C,C} = 20$ Hz) and phase adjusted using a "spin-lock" unit. 14000 transients with 6s repetition interval (total measuring time 23 h). Digital resolution: 0.4 Hz/data point. $J_{8a,1} = 40.5$ Hz.

The satellite spectrum is also simplified when the one-dimensional INADEQUATE experiment is carried out with selective ^{13}C saturation. In contrast to the experiment described above, all satellite signals in which the selectively saturated ^{13}C nucleus is involved are now removed.[54]

7.5. Hints on Carrying Out INADEQUATE NMR Measurements

The following points should be taken into account when INADEQUATE measurements are carried out:

1) The solution should be so concentrated that a single 90° pulse affords a ^{13}C-NMR spectrum with $S/N \geq 25$ (for a definition of S/N see Ref. [55]). 40000 scans then give an INADEQUATE NMR spectrum with a similar S/N ratio (neglecting saturation effects).
2) The T_1-values for the isolated ^{13}C nuclei should be determined prior to the INADEQUATE measurement and if necessary reduced with the help of relaxation reagents so that the longest T_1-values are only 2–3 s (pulse repetition time $1.3\,T_1$).
3) The 90° and 180° pulses should be determined using the solution to be investigated.
4) The delay time τ should be set to ca. 5.5 ms for molecules containing aliphatic and olefinic carbon atoms; from Equation (a) this corresponds to a J-value of about 45 Hz (cf. Table 1).
5) In a two-dimensional INADEQUATE experiment, the S/N ratio for each row should be at least 5, and the number of time increments (and thus rows) should be so chosen that all double-quantum frequencies are sufficiently separated. In practice, resolutions of 50–200 Hz per data point have proven adequate.

8. Applications

$^{13}C,^{13}C$ spin-spin coupling constants can be used for the determination of the constitution of the following types of carbon compound, the structures of which can either not be determined or can be determined only with difficulty using other NMR methods (including two-dimensional techniques):

- Hydrocarbons or hydrocarbon-like compounds (referred to below as "hydrogen-rich carbon compounds"): their ^1H-NMR spectra are complex, while normal ^{13}C-NMR spectra do not afford much information.
- Compounds in which those carbon atoms which are important for determining their constitution carry further carbon atoms or heteroatoms and few if any hydrogens. These will be referred to below as "hydrogen-poor carbon compounds", even when they contain groups such as methyl or phenyl at their periphery. In such cases ^1H-NMR is unsuccessful because of the lack of hydrogen atoms, while normal ^{13}C spectra can often not be interpreted with certainty.
- Compounds with particular symmetry properties, independent of whether they are hydrogen-rich or hydrogen-poor in the sense discussed above.

8.1. Hydrogen-Rich Carbon Compounds

Polycyclic hydrocarbons with but a few functional groups provide a challenge to the structural chemist. Thus the structures of several tricyclic triquinanes could not be determined;[56–58] only X-ray structural analysis of derivatives of some others provided the required structural information.[59,60] As the examples **15**–**20**, **21a**–**c**, **25**, **26** (Table 4) and further triterpenes[61] show, the determination of the carbon skeletons of hydrogen-rich compounds is readily possible, even when some (often redundant) connectivities are missing in their INADEQUATE spectra. In the case of ketones, the satellite signals due to coupling between the carbonyl carbon and the two α-carbon atoms are often not visible because only the aliphatic carbon range is measured; in such cases it is possible to determine the coupling between these two α-carbons over *two* bonds (**10**, **19**, **20**, **22b**). The aggregation state of the hydrocarbon is unimportant: non-polar, oily terpenes can also be studied. Because of the similar $^1J_{C,C}$-values observed for hydrocarbons, the two-dimensional INADEQUATE technique is required.

8.2. Hydrogen-Poor Carbon Compounds

The structural analysis of hydrogen-poor compounds using INADEQUATE will be demonstrated below for two types of compound, namely for certain types of cycloaddition products and for highly chlorinated hydrocarbons.

Products of cycloaddition reactions normally carry sufficient hydrogen atoms to make the determination of their structures by ^1H-NMR spectroscopy unproblematic. However, when hydrogen atoms are not present on the carbons which contain the necessary information, INADEQUATE ^{13}C-NMR spectroscopy can be successfully used. In this way it was possible to determine the structures of the products **27**, **28** and **30** of [3+2]-cycloadditions and of the product **11** of a [2+2]-cycloaddition directly (i.e. without using data from reference compounds). In the case of **29** the structure was also unambiguous, even though the one-dimensional experiment carried out afforded only three connectivities, since these were the decisive ones (the other signals were overlapped). INADEQUATE ^{13}C-NMR spectroscopy is the method of choice when the regiochemistry of cycloadditions is to be determined: the wavy lines in formulas **11** and **26**–**30** indicate the starting materials used and thus make clear the regiochemical problem.

The chemistry of highly-chlorinated hydrocarbons went through a period of vigorous development in the 1950s and 1960s, although not all the structures of the compounds formed were determined.[77] The determination of the constitution of such compounds is readily carried out using INADEQUATE ^{13}C-NMR spectroscopy, as is demonstrated for the examples of the compounds **31**,[75b] **32**–**34**,[76] and **11**[12] (Table 4).

Table 4. Compounds whose structures have been determined by means of INADEQUATE-^{13}C-NMR spectroscopy (boldlines: measured C,C connectivities)

 **18**	100 MHz, 1D und 2D [63] Aliphatic carbon range; 470 mg substance C-10–C-20 not detected, since, a) ^1J larger than the value set according to Eq. (a), b) T_1-values relatively large, c) off-resonance effects (140 ppm) are present Configuration at C-13 from δ-value for C-17
 **19** Velloziolone	100 MHz, 1D and 2D [64] 850 mg substance $T > 60$ °C to shorten T_1 C-11–C-9–C-8 from $^2J_{11,8} \approx 9.3$ Hz Configuration from δ-values
 **20**	100 MHz, 1D and 2D [65] Aliphatic carbon range, 1.2 g substance C-2–C-3–C-4 from $^2J_{2,4} = 11.3$ Hz C-13–C-17–C-16 from $^2J_{13,16} = 15.2$ Hz Configuration from δ-values
 **21** Velloziolide	100 MHz, 1D [66] 500 mg substance $T = 95$ °C (for solubility reasons) Some CC-connectivities not detected because of presence of large ^1J(C,C)-values or strongly coupled AB spin systems.
22a	50 MHz, 2D [67] 30% solution in $CDCl_3$
 **22b**	100 MHz, 2D [68] 360 mg substance in 2.5 mL $CDCl_3$ C-2–C-1–C-6 from $^2J_{2,6} = 9.7$ Hz Compound has mirror plane.
 **22c** Neviotine	90 MHz, 2D [69] 2.5 g substance Two spectra recorded ($\delta = 12$–217 and $\delta = 12$–89) C-12–C-13 and C-20–C-21 not detected (strongly coupled AB-spin systems) C-12–C-13 follows from correlations 12-H–C-14, C-20–C-21 from a relay experiment C-2–O–C-7 follows from correlations 7-H–C-2 Crystals not suitable for X-ray structural analysis
 **22d** Marmelerin	75 MHz, 2D [70] 250 mg substance and a few mg [Cr(acac)$_3$] in 1 mL $CDCl_3$ Sample prepared in 10 mm NMR tube; vortex plug used. C-1–C-2 not detected
 **23**, Amphimedine	75 MHz, 2D [71] 300 mg substance Reason for non-detection of certain correlations: long T_1's of non-protonated C-atoms
 **24**	50 MHz, 1D [72] Configuration determined using NOESY
 **25** Panamine	50 MHz, 2D [73] 950 mg substance C-3–C-4 and C-15–C-16 not detected, since strongly coupled AB spin systems present($\Delta\delta = 0.33$ and 0.17 ppm respectively) Crystal structure determined previously
 **26**	50 MHz, 2D [36] 840 mg substance Other C,C bonds apart from those emphasized were detected. In order to make the bonding partners of C-c better visible, the satellite signals of the proton-carrying C-atom d, which was fortuitously isochronous with C-c, were eliminated by incorporation of an additional delay time $\tau = 1/(2J(C,H))$ and appropriate switching of the decoupler X-ray structural analysis was not possible.
 **27**	25 MHz, 1D [74] 900 mg substance plus 10 mg [Cr(acac)$_3$] in 1.5 mL $CDCl_3$ Two experiments with τ corresponding to 38 and 76 Hz ($J\tau = 1/4$) were carried out in order to obtain all connectivities The *endo*-configuration was assigned on the basis of ^3J(C-9, 2-H) = 5.9 Hz
 **28**	25 MHz, 1D [74] 900 mg substance plus 10 mg [Cr(acac)$_3$] in 1.5 mL $CDCl_3$ Not all connectivities in benzene ring determined because of the presence of strongly coupled AB spin systems The *endo*-configuration was assigned on the basis of ^3J(C-2,6-H) = 7.9 Hz
 **29**	25 MHz, 1D [75a] 1 g substance plus 10 mg [Cr(acac)$_3$] in 1.5 mL $CDCl_3$ Further connectivities could not be determined because of signal overlap and long-range fluorine coupling
 **30**	25 MHz, 1D and 2D [75b] 1 g substance plus 10 mg [Cr(acac)$_3$] in 1.5 mL $CDCl_3$ The coupling in the "broken" bond was only observed for one C-atom C-2–C-2a not observed, since coupling about twice as large as $J = 45$ Hz used for Equation (a) (n = o)
 **31**  **32**  **33**	25 MHz, 1D and/or 2D [12, 75b, 76] 0.5–2 g substance, in each case with ca. 10 mg [Cr(acac)$_3$] and 1.5 mL $CDCl_3$ * = Connectivities determined from the inner signals of the strongly coupled AB spin systems
 **11**	**11**: C-1–C-5 ($\Delta\delta = 1.7$ ppm) determined from conventional ^{13}C NMR spectroscopy (Fig. 8) Configuration at C-6: determined from ^3J(C,C) and ^3J(C,H)
 **34**	**34**: C-1–C-2 not visible, since $\Delta\delta = 0.8$ ppm

8.3. Symmetrically Substituted Carbocyclic Compounds

Symmetrically substituted carbocycles are often not easily distinguished from one another. Molecules with a center of symmetry can be recognized fairly easily because of the different band positions in their IR and Raman spectra (the "exclusion rule"; see however Ref. [78]). When the molecule contains sufficient hydrogens at the informative positions the structure can be determined by simulation of the ^{1}H-NMR spectrum,[79] though the results so obtained are not always unambiguous.[80] We shall demonstrate below that certain symmetry properties can be read off directly from the intensity ratios of the ^{13}C,^{13}C satellite signals.[12]

When a ^{13}C atom is bonded to a second which has the same chemical shift, no satellite signals are observed; if it is bonded to two others which both have the same chemical shift, satellite signals of double intensity occur. Figure 10 shows how structures can be distinguished on the basis of such intensity ratios. The method will be demonstrated for two cyclobutanes, one planar and the other non-planar; no information is presently available on larger rings.

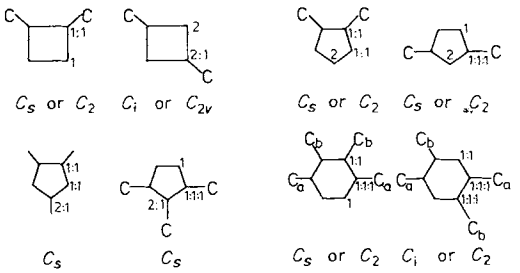

Fig. 10. Derivation of the constitution of symmetrically substituted hydrocarbons from the relative intensities of the ^{13}C,^{13}C-satellite signals.

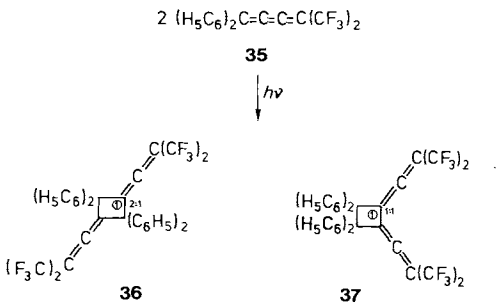
The photochemical dimerization of **35** leads to a product which according to its normal ^{13}C-NMR spectrum can be either **36** (head-to-tail adduct) or **37** (head-to-head adduct).[81]



These two structures can be distinguished on the basis of an evaluation of the ^{13}C,^{13}C satellite signals (Fig. 11). The signal at $\delta = 123.7$, which because of the lack of long-range couplings to H or F is assigned to C-1, exhibits two pairs of satellites in the ratio 2 : 1. Thus the correct structure is **36**, since for **37** the ratio would be 1 : 1. The satellite signals for the C-2 signal at $\delta = 68$ should afford the same result, but these are not visible due to broadening caused by long-range proton coupling. The Raman and IR spectra also agree with the suggested structure **36**.[12]

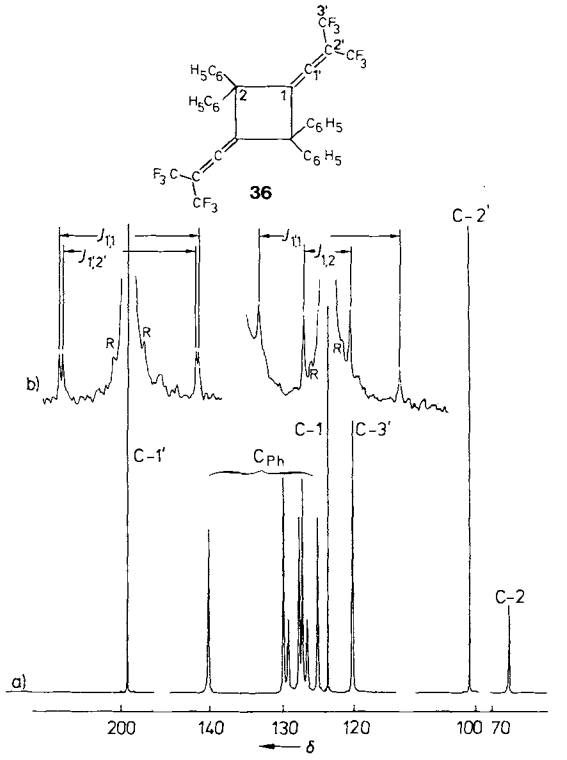


Fig. 11. a) Proton-coupled 62.5-MHz ^{13}C{^{19}F}-NMR spectrum of **36** (0.6 g) + [Cr(acac)$_3$] (10 mg) in $CDCl_3$ (1.5 mL). 35200 transients. Repetition interval 1.6 s. Digital resolution 0.6 Hz/data point. b) Expansion of the signals due to C-1 and C-1'. $J_{1,2} = 38.2$, $J_{1,1'} \approx 116.0$, $J_{1',2'} = 111.1$ Hz. R = spinning side bands.

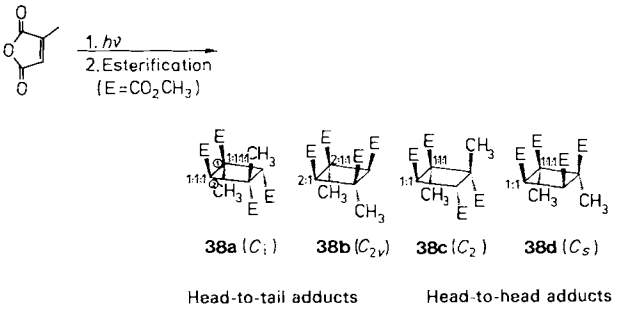
The photochemical dimerization of methylmaleic anhydride gives a product whose structure could initially not be determined; the same is true for the ester derived from the product (one of the structures **38a–d**).[82]



The C-2 signal of the ester shows three pairs of satellites in the ratio 1 : 1 : 1. Thus the product is the *anti* head-to-tail adduct **38a**. The pairs of satellites at C-1 are less informative because of partial overlapping. For confirmation the ^{1}H-NMR spectrum was recorded using the optically active shift reagent Eu(hfbc)$_3$. The splitting of each of the two methoxy signals into doublets proves them to be enantiotopic, as is expected for **38a** (in **38b** the methoxy groups are pairwise homotopic). This result agrees with that of the X-ray structure determination.[83,84]

These two examples show that it is possible to distinguish between head-to-head and head-to-tail products with

the help of $^{13}C,^{13}C$ satellite signals, independent of the substituents which are attached to the cyclobutane ring. When satellite signals are overlapped by signals of isolated ^{13}C nuclei the INADEQUATE method is recommended. However, deviations from the postulated intensity ratios can occur by incorrectly chosen τ-values or off-resonance effects (Section 7.2).

8.4. Assignment of ^{13}C-NMR Signals

Assignments of the ^{13}C-NMR signals of known compounds are of considerable importance for the determination of the structures of unknown compounds. When the chemical shifts of the carbon atoms of a parent substance are known, changes carried out on it can readily be localized.[85] In addition, correctly assigned signals are an important precondition for certain biosynthesic studies.[86]

Assignments on the basis of chemical shifts and CH-couplings are not free of uncertainties, particularly for complex structures. Evaluation of the $^{13}C,^{13}C$-couplings can remove such uncertainties, the two-dimensional INADEQUATE pulse sequence giving the most unambiguous results. In this manner the ^{13}C-NMR signals of several compounds were either assigned for the first time[87-92] or reassigned with the correction of previous errors.[86,93-96]

8.5. Electron Distribution in Carbon Compounds

$^{13}C,^{13}C$ coupling constants are often determined in order to obtain an insight into the bonding situation in a molecule. A detailed discussion of this topic is not possible in the present article, so that only the most important results will be presented. As mentioned initially, the $^1J_{C,C}$ values increase a) with increasing s-character of the carbon orbitals involved in the C–C bond,[97] b) with increasing electronegativity of the substituents at the two carbon atoms[98,99] (see Table 1), and c) with increasing π-bond order in aromatic compounds[100,101] (cf. however Ref. [102]). Multipath coupling can occur in cyclic compounds, which thus often exhibit large ^nJ-values.[103,104] The isotopic perturbation method for distinguishing between classical and non-classical electron arrangements can be used not only for deuterated compounds, but also for compounds which are not isotopically enriched: it then involves the comparison of the chemical shifts for isotopomers with one and two ^{13}C nuclei.[105]

8.6. Biosynthetic Studies

^{13}C-labeled precursors have long been used in the determination of biosynthetic pathways.[106] One important precursor is sodium acetate, which is labeled either in the 1- or the 2-position or in both. Its addition to nutrient solutions for bacterial or fungal cultures or its introduction into the transport channels of plants results in the formation of polyketides which ideally exhibit the ^{13}C distribution shown in Figure 12. If it is assumed that no dilution with unlabeled acetate occurs, singly labeled acetate gives a polyketide in which the ^{13}C nuclei are geminal to one another (Fig. 12a, b). When a 1 : 1 mixture of 1- and 2-^{13}C-acetate is used, the result (assuming no dilution) is an isotopomer mixture in which the ^{13}C nuclei are either neighboring (Fig. 12d), geminal (Fig. 12c, e) or vicinal (Fig. 12f). Doubly labeled acetate gives a polyketide whose carbon skeleton (again assuming no dilution) consists only of ^{13}C atoms (Fig. 12h); if it is diluted with unlabeled acetate the result is an isotopomer mixture containing fragments with two neighboring ^{13}C atoms (Fig. 12j, k).

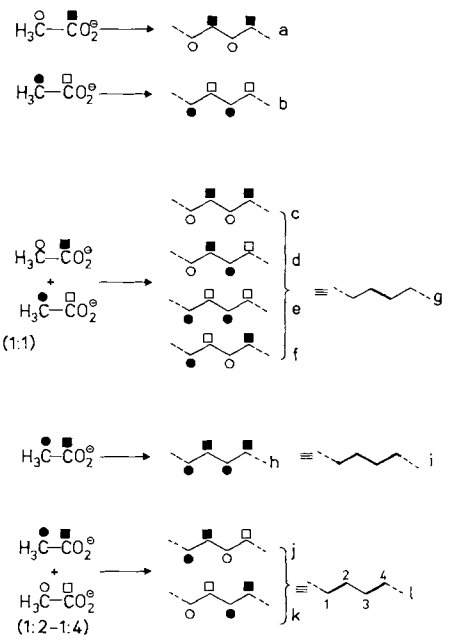


Fig. 12. Distribution of ^{13}C nuclei in polyketide chains: sections of chain after the incorporation of differently labeled acetates. For explanation see text. ^{12}C is denoted by O or □, ^{13}C by ● or ■.

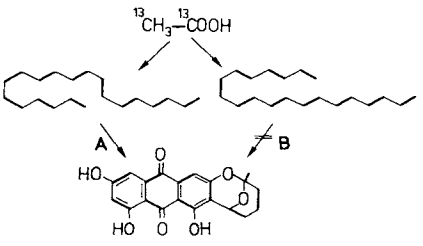
Isotopomers which contain neighboring ^{13}C nuclei in increased abundance are also indicated by bold lines at the appropriate positions (Fig. 12g, i, l). The structure fragment shown in Figure 12l indicates that double labeling occurs at C-1 and C-2 *or* C-3 and C-4: thus $^{13}C,^{13}C$ satellite signals of increased intensity are observed due to the couplings between C-1 and C-2 and between C-3 and C-4, but not between C-2 and C-3.

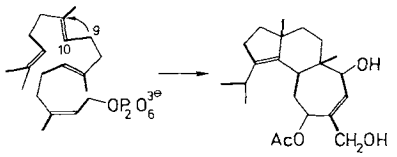
Double labeling with [1,2-$^{13}C_2$] acetate gives information on how polyketide chains are folded prior to cyclization and on whether rearrangements occur. The following two examples should make this clear. The conventional ^{13}C spectrum of labeled **39** contains corresponding satellite pairs: it thus follows that the C_{20}-precursor is folded as shown in **A** and not as in **B**.[107]

The conventional ^{13}C spectrum of labeled **41** shows satellite signals of increased intensity only for the seven C_2



39

fragments.[108] It follows that the cyclization of **40** occurs with 1,2-rearrangement in which ^{13}C-9 and ^{13}C-10 are separated and subsequently each bonded to a ^{12}C nucleus.



40 **41**

Not only biosynthetic pathways have been determined using ^{13}C-labeled acetate, but also the constitution of natural products. Because of the artificially increased ^{13}C-content, relatively small amounts of substance (ca. 50 mg) are sufficient. However, two feeding steps must be carried out, as shown by the elegant studies of *Seto* et al.[109] A mixture of doubly labeled and unlabeled acetate is used in the first feeding step. The conventional ^{13}C-NMR spectrum of the natural product so formed gives the C–C connectivities *within* the C_2 building blocks (see Fig. 12l). The second step consists of feeding with a 1:1 mixture of the two singly labeled acetates. The NMR analysis now affords C–C connectivities *between* the C_2 building blocks (see Fig. 12g). In this manner the complete carbon skeleton of the pigment **42**, as far as it is built up from acetate, has been determined[110] (see also Ref. [111]).

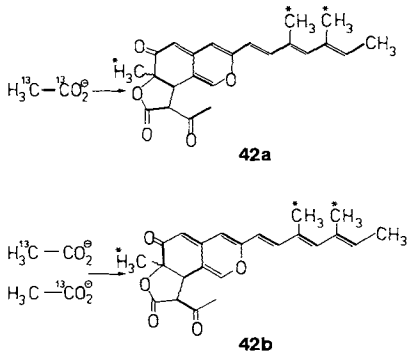


Fig. 13. Elucidation of the structure of **42**. The CH_3 groups marked with an * are formed from methionine. The connectivities indicated by wavy lines were obtained using other spectroscopic techniques.

The investigations described above were carried out in the 1970's with the help of conventional ^{13}C-NMR spectroscopy. Difficulties of the type described initially had to be accepted. Since the beginning of the 1980's the INADEQUATE pulse sequence[4] has been used increasingly for solving such problems. Its one- or two-dimensional versions have been used to study the biosynthesis of the following compounds (^{13}C-labeled precursor in brackets): mevinoline ([1,2-$^{13}C_2$]acetate),[112] lignin ($^{13}CO_2$),[113] the antibiotic ICI 139603 ([1,2-$^{13}C_2$]acetate),[114] cationomycin ([1,2-$^{13}C_2$]acetate),[115] 24-methylsterine ([1,2-$^{13}C_2$]acetate),[116] various compounds in the cells of *E. coli* (U-^{13}C glucose),[117] riboflavin (U-^{13}C glucose, [2,3-$^{13}C_2$]succinate),[118] ravidomycin ([1,2-$^{13}C_2$]acetate),[119a] brevitoxin B (*inter alia* [1,2-$^{13}C_2$]acetate).[119b] The study of the latter compound was performed using only 1.5 mg, although its molecular formula is $C_{50}H_{70}O_{14}$.

9. INADEQUATE-NMR Spectroscopy of Other Nuclei

The INADEQUATE pulse sequence can also be used to investigate inorganic compounds containing elements with a spin-1/2 isotope of *low natural abundance* (< 15%): examples are provided by the elements silicon (4.7% ^{29}Si), tin (7.6% ^{117}Sn, 8.6% ^{119}Sn) and tungsten (14.3% ^{183}W). The INADEQUATE-NMR spectra contain only signals due to AX spin systems, so that atomic frameworks can easily be recognized. Thus the two-dimensional ^{183}W-INADEQUATE-NMR spectra of polytungstates, obtained by using a delay time set for $^2J(^{183}W\text{-}O\text{-}^{183}W)$, permit not only an unambiguous assignment of the ^{183}W-NMR signals (in compounds whose structures are known) but also the recognition of the way in which the W-O-W-O building blocks are linked together.[120, 121]

When an element consists mainly or entirely of only one spin-1/2 isotope (the latter is the case for H, P and F) several double-quantum transitions are generally possible (for a survey see Ref. [17]). The term scheme of an AMX spin system (Fig. 14) contains a total of six double-quantum coherences:

$$\nu_{DQ} = \nu_A + \nu_M \pm (J_{AX} + J_{MX})/2 - 2\nu_0$$
$$\nu_{DQ} = \nu_A + \nu_X \pm (J_{AM} + J_{MX})/2 - 2\nu_0$$
$$\nu_{DQ} = \nu_M + \nu_X \pm (J_{AM} + J_{AX})/2 - 2\nu_0$$

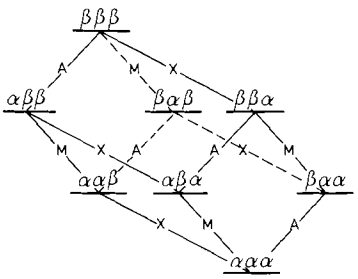

Fig. 14. Term scheme for an AMX spin system with six zero-quantum transitions (two each for AM, MX and AX), twelve single-quantum transitions (four each for A, M and X), six double-quantum transitions (two each for AM, AX and MX) and a triple-quantum transition AMX).

The two-dimensional INADEQUATE-NMR spectrum thus consists of six rows, each row containing all the twelve signals of the AMX spin system. Eight of the twelve signals are arranged symmetrically about a frequency diagonal: these signals are due to the "active spins", i.e. spins which determine the double-quantum frequency (e.g. AM). The remaining four signals are due to the "passive spin" (e.g. X). A simplification is achieved when a 135° read pulse is used instead of a 90° pulse. Each row then contains basically only eight signals; these are arranged symmetrically about a diagonal, so that the interpretation is made easier. Figure 15 shows two-dimensional proton INADEQUATE-NMR spectra of 2,3-dibromopropionic acid, recorded with read pulse angles of 90° and 135° respectively.[122]

Several proton spin systems have been studied using INADEQUATE as a tool for spectral assignment. The advantages and disadvantages with respect to COSY have been

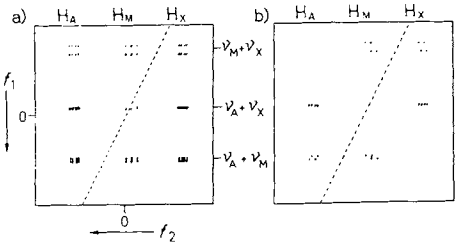

Fig. 15. Two-dimensional INADEQUATE ^{1}H-NMR spectrum of 2,3-dibromopropionic acid $BrH_MH_XC-CH_ABr-COOH$ (OH-signal not shown; quadrature detection in f_1). Read pulse angle 90°. (b) Read pulse angle 135°. Comparison of the two spectra shows that no appreciable coherence transfer to the passive spins has occurred [122].

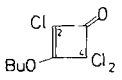
discussed.[123, 124] Two-dimensional proton INADEQUATE-NMR spectroscopy has also been used to determine the constitution of a natural product.[125]

10. Summary and Outlook

The determination of $^{13}C,^{13}C$ coupling constants makes possible the direct determination of the carbon skeleton of organic compounds. The interpretation of the spectra, particularly of those from two-dimensional experiments, is simple. The use of reference compounds, which is of paramount importance in conventional spectroscopic structural analysis, is not necessary. The reliability of the method is due to the fact that $^{13}C,^{13}C$ coupling constants larger than 35 Hz are virtually always due to neighboring carbon atoms: exceptions are provided by certain substituted cyclobutanone derivatives (e.g. **43**), in which incorrect C,C-connectivities are suggested by extremely large geminal couplings.[126]



43 $^2J_{2,4}=64.1$ Hz

If strongly coupled AB systems are present one must reckon with a loss in intensity of the satellite signals due to poorly chosen delay times. Ambiguities with regard to connectivities occur if NMR signals due to isolated ^{13}C nuclei overlap.[127] In both cases the limits of the method have been reached.

If heteroatoms are present in the form of structural fragments C–X–C (X = O, S, N), gaps occur in the carbon skeleton: sometimes these can be "closed" by taking the chemical shifts of the ^{13}C nuclei into account.

The determination of *configurations* with the help of the Karplus equation is only possible in exceptional cases.[128a] However, when the *constitution* is known and the proton NMR signals can be correctly assigned (via a C,H-correlation), the configuration can generally also be determined by using trusted methods such as proton–proton coupling and nuclear Overhauser effects.

The low sensitivity of INADEQUATE ^{13}C-NMR spectroscopy at present limits its broad application: several hundred milligrams of substance (for a molecular weight of ca. 300) and measurement times of between 10 and 50 h (according to the field strength of the magnet) are required. In the case of natural products formed from ^{13}C-labeled precursors, however, the amount of compound needed for an NMR investigation is drastically reduced: at an incorporation rate of 1%, only a few milligrams are needed to permit the detection of selected C,C-connectivities.[109, 119b, 128b] Combined pulse sequences for increasing signal intensity (such as INEPT- and DEPT-INADEQUATE, C-relayed H,C-COSY or INSIPID) require the presence of sufficient hydrogens on the carbons concerned, and have in some cases not as yet proved themselves in practical structural analysis. In addition, a number of the compounds listed in Table 4 contain several *hydrogen-free* carbon atoms in a chain. It remains to be seen what sort of improvement in the S/N ratio results from the mathematical treatment of the NMR signals of two-dimensional spectra. A decrease in the noise signals of 2D-INADEQUATE NMR spectra, which improves the S/N ratio by a factor of three to four, was recently reported.[51b] A better S/N ratio for a given measuring time was obtained in each case when the measurements were carried out in the presence of relaxation reagents.

If $^{13}C,^{13}C$ couplings are to be used for the structure determination, a conventional ^{13}C-NMR spectrum should first be recorded using only a *single* transient: if all the ^{13}C signals are visible, the necessary precondition for the use of $^{13}C,^{13}C$ coupling constants for the structure determination is fulfilled. If the NMR signals are well-separated and free from unwanted signals (impurities), the conventional ^{13}C-NMR technique should be used, as it is the most sensitive and because in addition all the $^{13}C,^{13}C$ satellite signals are of optimum intensity (see Figs. 2 and 11). If the latter preconditions are not fulfilled, the INADEQUATE pulse sequence should be used. The two-dimensional version of INADEQUATE represents a great achievement in the use of spectroscopic techniques for determining the constitution of carbon compounds: the conclusions it provides can hardly be surpassed for simplicity and logic.

Appendix: Density Matrix Formalism

Modern multipulse NMR experiments can be described quantitatively with the help of the density matrix formalism.[14, 29c, 129] The basis of this formalism and its application to the INADEQUATE pulse sequence have been described.[29c]

A homonuclear AX spin system can be described with the help of a complex 4×4 matrix σ. For thermal equilibrium this matrix is as given by (A1).

$$\sigma=\frac{p}{4}\begin{pmatrix}1&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&0&-1\end{pmatrix} \qquad (A1)$$

The diagonal elements correspond to the populations of the four energy levels of the spin system (with p equal to the excess population of the niveau of lowest energy), while the off-diagonal elements describe the interactions between the niveaus, the so-called "coherences". If the value of a matrix element is zero, the corresponding coher-

ence is not excited. The four elements σ_{12}, σ_{13}, σ_{24} and σ_{34} represent the observable magnetizations (single-quantum coherence; $\Delta m = 1$), the elements σ_{23} and σ_{14} the non-observable zero- and double-quantum coherences ($\Delta m = 0$ and 2 respectively). The intensity of a coherence is described by a complex number, the real part of which corresponds to the component in the x-direction and the imaginary part to that in the y-direction of the rotating frame. The observation of an NMR experiment is carried out in the coordinate system of the single-quantum coherence; separate coordinate systems exist for the zero- and double-quantum coherences.[130] The temporal change of a coherence and the effect of non-selective pulses on the spin system can be described with the help of two simple mathematical rules.

The temporal variation of a coherence (e.g. the rotation of a magnetization during a delay time) corresponds to the multiplication of the matrix elements by a time-dependent function [Eq. (A2)].

$$\sigma_{kl}(t) = e^{i\omega_{kl}t} \cdot \sigma_{kl} \quad (t=0)$$
$$e^{i\omega_{kl}t} = \cos\omega_{kl}t + i\sin\omega_{kl}t \tag{A2}$$

The angle velocity ω_{kl} is given by the difference of the two energy niveaus E_k and E_l. Relaxation effects are not taken into account. The absolute values of the matrix elements are not changed by the multiplication (which corresponds to a rotation in an orthogonal coordinate system).

The effect of a non-selective pulse (of angle α) on the spin system is obtained by multiplication of the matrix by the rotation matrix R and its inverse matrix R^{-1} [Eq. (A3)].

$$\sigma(\alpha) = R^{-1}(\alpha) \cdot \sigma \cdot R(\alpha) \tag{A3}$$

For a 90° pulse in the four directions of the rotating coordinate system (x, y, $-x$, $-y$) these rotation matrices are as follows:

$$R_x^{-1} = R_{-x} = \frac{1}{2}\begin{pmatrix} 1 & -i & -i & -1 \\ -i & 1 & -1 & -i \\ -i & -1 & 1 & -i \\ -1 & -i & -i & 1 \end{pmatrix}$$

$$R_x = R_{-x}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & i & i & -1 \\ i & 1 & -1 & i \\ i & -1 & 1 & i \\ -1 & i & i & 1 \end{pmatrix}$$

$$R_y^{-1} = R_{-y} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 1 & 1 \\ -1 & 1 & -1 & 1 \\ -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 \end{pmatrix} \tag{A4}$$

$$R_y = R_{-y}^{-1} = \frac{1}{2}\begin{pmatrix} 1 & -1 & -1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & 1 & 1 \end{pmatrix}$$

The corresponding matrices for a $180°_{-y}$ pulse ($= R_y(90) \cdot R_y(90)$) are as follows:

$$R_y^{-1} = R_y = \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \\ 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \tag{A5}$$

The variation of the density matrix during the INADEQUATE pulse sequence can be followed with the help of these two mathematical rules (time dependence, effect of pulse).

The first part of the sequence ($90°_x - \tau - 180°_y - \tau$; see Figs. 3a–e) corresponds to a spin-echo experiment. When the delay time $\tau = 1/(4J)$, the following density matrix results at the end of this sequence:

$$\sigma = \frac{1}{2}\begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & -1 \\ 1 & 0 & 0 & -1 \\ 0 & -1 & -1 & 0 \end{pmatrix} \tag{A6}$$

Only those matrix elements which correspond to the single-quantum coherences are now non-zero (e.g. nucleus A: $\sigma_{12} = 1$, $\sigma_{34} = -1$) and their values show that these coherences are, as shown in Figure 3e with the help of the vector model, oriented along the $\pm x$-axis of the rotating frame; they show a phase difference of 180°. A 90° pulse in the x-direction then gives:

$$\sigma = \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & i \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -i & 0 & 0 & 0 \end{pmatrix} \tag{A7}$$

All observable magnetizations are now no longer present ($\sigma_{12} = \sigma_{13} = \sigma_{24} = \sigma_{34} = 0$), as they have been transferred into the double-quantum coherence (σ_{14}). The numerical value of the matrix element σ_{14} shows that the corresponding vector is oriented along the y-axis of the double-quantum coordinate system (Fig. 3f). During a delay time t_1 in Fig. 3, $t_1 = \Delta = 0$) the density matrix changes to:

$$\sigma = \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & ia \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ ia^* & 0 & 0 & 0 \end{pmatrix} \tag{A8}$$

with $a = e^{i\omega_{14}t_1}$; $a^* = e^{i\omega_{41}t_1} = e^{-i\omega_{14}t_1}$

There now follows the 90° "read pulse": the resultant density matrices are dependent on the direction of this pulse and are given in Table 5. The orientations of the observable magnetizations can be derived from these matrices. The single-quantum coherences which result from the double-quantum coherence are always oriented along the axis in which the read pulse is applied. If the phase of this pulse is changed by a certain amount, the phase of the resulting single-quantum coherences is changed by double this amount. (It should be noted that the phases of $m_2(-)$ in Figures 3g and 3h are opposite with respect to the direction of the read pulse.) This description is equivalent to the statement that a phase change in the single-quantum coordinate system corresponds to double this phase change in the double-quantum coordinate system.

When the detector phase is switched in such a way that it follows the phase of the magnetization resulting from the double-quantum coherence, these coherences are added,

Table 5. Density matrices with orientation of the single-quantum coherences subsequent to read pulses of different phase.

Phase of read pulse	Density matrix σ after the variable time t_1 and the 90° read pulse		Orientation of the magnetization at $t_1=0$ according to the coherences	
	t_1 [a]	$t_1=0$	σ_{24}, σ_{34}	σ_{12}, σ_{13}
x	$\frac{1}{2}\begin{pmatrix} s & -c & -c & -s \\ -c & -s & -s & c \\ -c & -s & -s & c \\ -s & c & c & s \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 0 & -1 & -1 & 0 \\ -1 & 0 & 0 & 1 \\ -1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix}$	x	$-x$
y	$\frac{1}{2}\begin{pmatrix} -s & ic & ic & -s \\ -ic & s & s & -ic \\ -ic & s & s & -ic \\ -s & ic & ic & -s \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 0 & i & i & 0 \\ -i & 0 & 0 & -i \\ -i & 0 & 0 & -i \\ 0 & i & i & 0 \end{pmatrix}$	$-y$	y
$-x$	$\frac{1}{2}\begin{pmatrix} s & c & c & -s \\ c & -s & -s & -c \\ c & -s & -s & -c \\ -s & -c & -c & s \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & -1 \\ 1 & -1 & -1 & 0 \end{pmatrix}$	$-x$	x
$-y$	$\frac{1}{2}\begin{pmatrix} -s & -ic & -ic & -s \\ ic & s & s & ic \\ ic & s & s & ic \\ -s & -ic & -ic & -s \end{pmatrix}$	$\frac{1}{2}\begin{pmatrix} 0 & -i & -i & 0 \\ i & 0 & 0 & i \\ i & 0 & 0 & i \\ 0 & -i & -i & 0 \end{pmatrix}$	y	$-y$

[a] $c=\cos\omega_{14}t_1$; $s=\sin\omega_{14}t_1$.

while the single-quantum coherences resulting from the isolated nuclei are eliminated even after only two steps (the "two-step cycle") since in the second step the phases of the detector and the read pulse differ by 180°.

We thank Prof. Dr. G. Bodenhausen (Lausanne), Dr. W. E. Hull (Heidelberg), Prof. Dr. H. Kessler (Frankfurt), Dr. T. Kämpchen (Marburg), Dr. J. Lambert (Dortmund), and Priv.-Doz. Dr. H. Uzar (Siegen) for valuable comments.

Biological Exploitation of Solar Energy by Photosynthetic Water Splitting

By Gernot Renger*

The cleavage of water by solar radiation into dioxygen and metabolically bound hydrogen during photosynthesis is of central importance for the existence of higher forms of life on earth. The realization of this process in biological organisms made possible the use of the earth's huge water reservoir for the exploitation of solar energy and, at the same time, led to the creation of an aerobic atmosphere. The dioxygen thereby formed is a powerful oxidant which permits an energetically highly efficient nutrient turnover. In recent years considerable progress has been made in understanding the functional and structural organization of photosynthetic water splitting. This article attempts to give a review of our current state of knowledge with special emphasis on the oxidation of water to O_2 in biological systems.

1. Introduction

The relevance of solar energy as the prerequisite for the existence of the biosphere was already recognized in 1845 by *R. J. Maier* and was interpreted and formulated correctly by *L. Boltzmann* in thermodynamic terms in 1886:[1]

> The common fight for life is therefore neither a struggle for the basic elements nor for energy, present in every body in the form of heat—plentiful yet unfortunately nontransformable—but a fight for the entropy that becomes disposable during the transfer from the hot sun to the cold earth. Using this transfer to the utmost, plants spread the immense area of their leaves and, in still unexplained ways, force the energy of the sun, before it is reduced to the temperature level of the earth's surface, to perform chemical syntheses which are still unknown to our laboratories.

The second part of *Boltzmann*'s statement can now be considerably modified because remarkable progress has been made during the last 100 years in understanding the principles of biological solar energy exploitation.

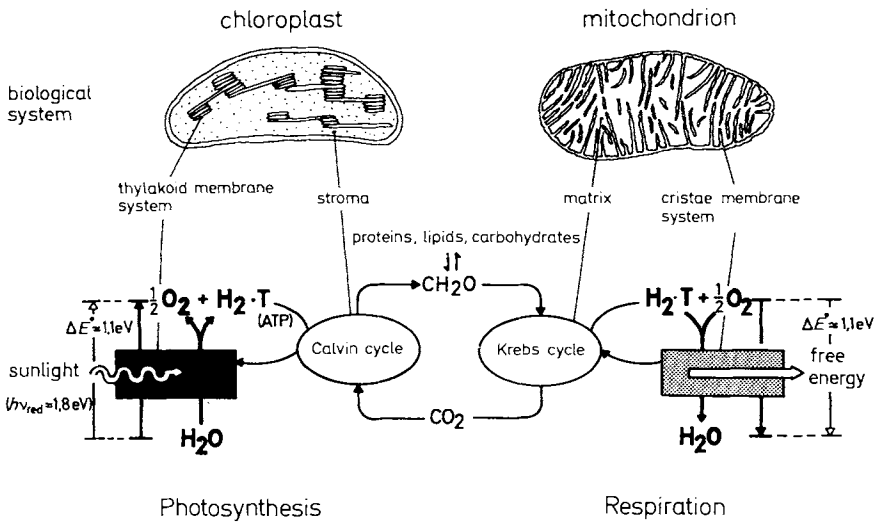

Fig. 1. Overall organization scheme of bioenergetics in higher organisms (for the sake of simplicity the energy differences are shown arbitrarily scaled). Bioenergetically important processes are symbolized as black (primary processes of photosynthesis) or grey (respiration chain) boxes. The complex anabolic and catabolic processes, which are responsible for the metabolism of the great variety of biological materials (proteins, lipids, carbohydrates), are only shown by arrows, since they do not possess the same bioenergetic importance as the primary processes of photosynthesis and respiration (for a review see Ref. [4]). Abbreviations: T = metabolite with chemically bound hydrogen; in the case of chloroplasts, T is NADP® (nicotinamide adenine dinucleotide phosphate); in the case of mitochondria, $H_2 \cdot T$ represents various kinds of bound hydrogen (e.g., NADH, succinate). CH_2O symbolizes a carbohydrate unit.

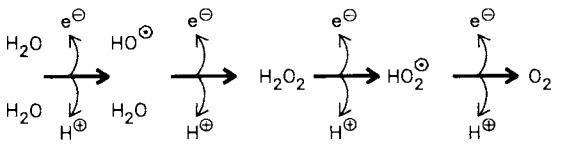
The basic principle of the functional and structural organization of the bioenergetic processes in all higher organisms is illustrated in Figure 1. The crucial phylogenetic

step in the biological exploitation of solar energy was the "invention" of photolytic water splitting, which took place two to three billion years ago on the level of cyanobacteria. This made the huge water reservoir of the earth's surface available as a raw material for the complex chemistry of metabolically bound hydrogen and simultaneously led to O_2 enrichment of the previously anaerobic atmosphere of the earth.[2] The availability of O_2 resulted in a tenfold increase in the exploitation of the free energy content of nutrients, thereby satisfying the bioenergetic prerequisite for the development of higher-organized heterotrophic organisms (for a review see Ref. [3]). From a bioenergetic point of view (based on a unit of bound hydrogen), the complex variety of enzyme-catalyzed reaction sequences, leading to the diverse forms of biological organization, is much less important than the light-driven water cleavage and its reversal (water production) in the dark in heterotrophic organisms. The differentiation of cells in higher organisms permitted a spatial separation of all reaction sequences by compartmentation, special organelles being developed for specific functions. The bioenergetically crucial processes take place in highly organized membrane systems:

1. The photosynthetic water splitting caused by visible light occurs in the thylakoid membrane of chloroplasts (Fig. 1);
2. The oxidative reaction of bound hydrogen ($H_2 \cdot T$) with O_2 takes place in the inner membrane of mitochondria (Fig. 1), the free energy thereby released being stored in the form of ATP.

Figure 1 shows that the initial and the terminal stage of the global chemical processes in all higher organisms are reactions of the redox chain $H_2 \cdot T/H_2O/O_2$, whereby the "management" of the redox system H_2O/O_2 is of crucial importance for the realization of the entire reaction. The four-step redox reaction sequence leading directly from two H_2O molecules to O_2 [Eq. (1)] involves intermediates that could lead to rapid destruction of biological material.



(1)

Therefore, nature had to evolve special catalysts (enzymes) which assure a "safe" course of reaction. Water cleavage requires a suitable source of free energy, whereas the reverse reaction produces free energy. Hence, different catalysts were evolved by nature. The oxidation of water with sufficiently strong oxidizing redox equivalents generated by a light reaction with consumption of free energy is catalyzed by the water-oxidizing enzyme system, whereas the reverse reaction takes place in a complex called cytochrome oxidase. For clarity it should be noted that "water splitting" refers to the overall process by which water is decomposed by light in photosynthesis. This reaction produces O_2 and bound hydrogen. "Water oxidation" refers to one step in the water splitting process, namely, the transformation of $2\,H_2O$ into O_2, $4\,H^{\oplus}$, and $4\,e^{\ominus}$.

In a time of intensive research activities directed at solving the energy crisis caused by our civilization, it is certainly worthwhile to analyze the mechanistic principles selected by nature, during a long evolutionary process, for efficient solar energy exploitation. Accordingly, in this review article only those reactions will be discussed that permit the storage of solar energy through water cleavage.

2. Organization Scheme of Photosynthetic Water Splitting

Water cleavage takes place via a sequence of redox steps coupled with protolytic reactions and is energetically driven by two light reactions. The redox groups participating in this process are anisotropically arranged in the thylakoid membrane (for a review see Ref. [4]). The essential steps of water cleavage take place in photosystem II (PS II) and can be summarized by Equation (2), whereby PQ stands for a plastoquinone and PQH_2 for a plastohydroquinone.

$$2\,PQ + 2\,H_2O \xrightarrow{4\,h\nu\,(II)} 2\,PQH_2 + O_2 \qquad (2)$$

In the subsequent light reaction of photosystem I (PS I), the hydrogen is formally transferred from PQH_2 to oxidized nicotinamide adenine dinucleotide phosphate ($NADP^{\oplus}$) and thereby reaches almost the same reduction potential (to within 0.1 V) as free H_2.[4] The reaction sequence of photosystem I can be summarized by Equation (3).

$$2\,PQH_2 + 2\,NADP^{\oplus} \xrightarrow{4\,h\nu\,(I)} 2\,PQ + 2\,NADP^{\oplus} \cdot H_2 \qquad (3)$$

Because of the central relevance of the reaction sequence summarized in Equation (2) for the overall bioenergetics, the discussion in this article is restricted to the realization of this sequence in algae and higher plants. Owing to limited space, other processes are not discussed (see Ref. [4]).

Photosynthetic water cleavage takes place via light-induced redox reactions, whereby PQ reduction and H_2O oxidation are spatially separated processes. Correspondingly, three functionally distinguishable types of reactions are involved in the overall process [Eqs. (4)–(6)]:

1. The transformation of an electronically excited state (generated by absorption of light) into an electron–hole pair with sufficient stability and redox power (P and A stand for a photochemically active pigment and an electron acceptor, respectively; see Fig. 2):

$$PA \xrightarrow{h\nu} P^*A \longrightarrow P^{\oplus}A^{\ominus} \qquad (4)$$

2. The cooperative reaction of four holes ($\oplus$) with H_2O:

$$4\oplus + 2\,H_2O \longrightarrow O_2 + 4\,H^{\oplus} \qquad (5)$$

3. The cooperative reaction of two electrons with PQ and H_2O:

$$2e^{\ominus} + PQ + 2H_2O \longrightarrow PQH_2 + 2OH^{\ominus} \quad (6)$$

Because of the anisotropic arrangement of the redox groups, the overall process consists of vectorial subprocesses. Accordingly, the protolytic reactions, which are coupled to the redox processes, lead to the formation of a transmembrane electrochemical potential difference for protons, which is utilized for ATP synthesis (for a discussion of the latter process, see, e.g., Refs. [3, 4]).

The mechanism of chemical reactions is not only determined by the participating functional groups but also by their environment. Biological systems have a unique tool for the regulation of reactions by the environment, namely, proteins. Their great variability enables them to adapt to the circumstances, so that practically every degree of specificity, efficiency, and regulatory control can be achieved that is required for carrying out specific biological functions. In order to understand the process of water cleavage it is therefore necessary to analyze the reactive properties of the redox components in situ and to view the prosthetic groups together with their protein matrices as operational units. Thus, the cooperation of three functional units is required for the process of water cleavage: (1) a photogenerator for light-induced charge separation, (2) the water-oxidizing enzyme system, and (3) the plastoquinone-reducing enzyme. Figure 2 shows the overall organization scheme of photosystem II, which is based on a stoichiometry of one H_2O molecule.

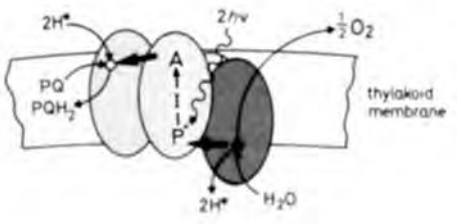


Fig. 2. Basic organization scheme of photosynthetic water cleavage in the thylakoid membrane. The functional units, described more fully in the text, are characterized as follows: reaction center (dotted), water-oxidizing enzyme system (dark grey), and plastoquinone-reducing enzyme (light grey). Thick arrows symbolize the electron-transfer route of photosystem II; white and black circles characterize the catalytic sites for PQ reduction [see Eq. (6)] and H_2O oxidation [see Eq. (5)], respectively. The excitation energy transfer from antenna pigment proteins to the reaction center is not shown (see Fig. 3). Abbreviations: P* = photochemically active pigment in the electronically excited singlet state [P = P680, see text and Eq. (4)]; I = intermediary redox component(s) (I contains Pheo, see text); A = electron acceptor responsible for the "stable" charge separation (primary plastoquinone acceptor Q_A, see text).

The functional principles of the reaction center and of the plastoquinone-reducing enzyme were already evolved at early stages of evolution, i.e., at the level of photosynthetic bacteria, which use easily oxidizable compounds as substrates (for a review see Ref. [5]). Therefore, two steps were of crucial importance for the realization of biological solar energy exploitation through water cleavage: (1) an appropriate modification of the reaction center in order to permit the generation of sufficiently strong oxidizing redox equivalents and (2) the "invention" of a water-oxidizing enzyme system. Accordingly, the focus of this review article is the mechanism of water oxidation and especially the "manageability" of the redox couple H_2O/O_2 in photosynthesis; the formation of bound hydrogen (in the form of PQH_2) is only briefly outlined.

3. The Reaction Center Complex of Photosystem II

In all photosynthetic organisms, the transformation of light into electrochemical free energy takes place in special pigment protein complexes, which are referred to as reaction center complexes. Only the reaction center complex of photosystem II is essential for water cleavage (this operational unit will be abbreviated as RC II in the following discussion).

For optimal adaptation to different light conditions, the reaction centers are coupled with pigment protein complexes that act as antennas, thereby increasing the optical cross section of the photoactive chromophore P [Eq. (4)] by more than two orders of magnitude (for a review see Refs. [6, 7]). In addition, the incorporation of carotinoids, which act as triplet quenchers, largely eliminates the probability of photodynamic destruction by O_2 at high light intensities.[8, 9]

3.1. Organization Scheme of Reaction Center Complexes of Photosystem II

According to Equation (4), each photogenerator has to include at least two functional groups: (1) a chromophore P, which forms the electronically excited state P*, which, in turn, gives rise to the photochemical reaction, and (2) an acceptor system A, which readily accepts the electron ejected from P* in a photoredox process and simultaneously permits a sufficient stabilization of the charge separation.

The functional scheme of RC II is shown in Figure 3. The photoactive pigment P in RC II is a specially bound chlorophyll a molecule,[10] which, in accordance with its red absorption band at around 680 nm, is referred to as pigment 680 (P680). It is still not yet clarified whether P680 is a monomeric chlorophyll a (Chl) or a special dimer complex, but comparison with other reaction centers (see below) makes a dimer structure more likely.[11, 12] P680 becomes photooxidized from its first singlet state ^{1}P680* in ≤ 1 ps (as estimated indirectly by fluorescence measurements, see Ref. [13]). A pheophytin a molecule (Pheo) is probably the primary electron acceptor I.[14] The initially formed $P680^{\oplus}Pheo^{\ominus}$ radical-ion pair is very unstable.[15, 16] A sufficient stabilization of the primary charge separation, which can be used for water oxidation,[17] can only be achieved if the electron from $I^{\ominus}$ (i.e., presumably $Pheo^{\ominus}$) is transferred to a specially bound plastoquinone molecule, symbolized as Q_A. Whether the intermediate electron car-

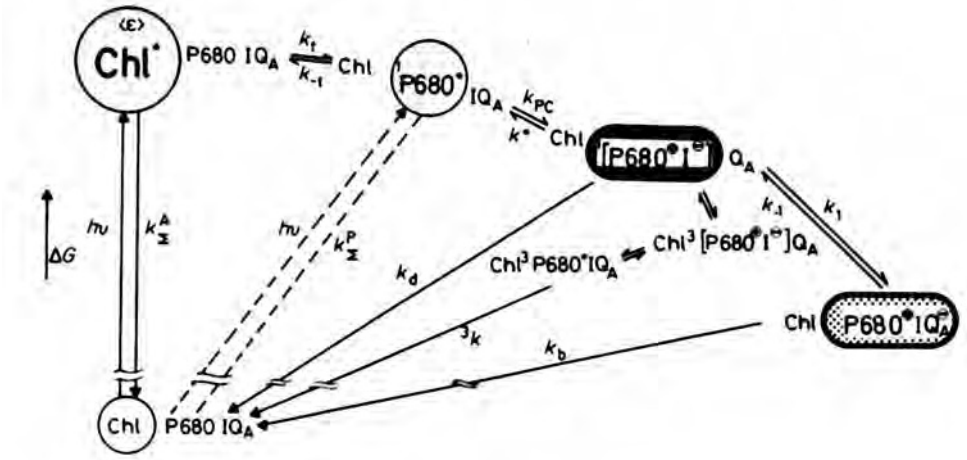

Fig. 3. Functional scheme of the light-induced charge separation of photosystem II. After light absorption, a singlet exciton (ε) is formed in chlorophyll a (Chl), an antenna pigment (the grey circle symbolizes an electronically excited antenna). This electronically excited state transfers its energy to the reaction center (see Refs. [6, 7]), thereby generating the first excited singlet of the photoredox active pigment P680, a specially bound chlorophyll a (dotted circle). Oxidation of ^{1}P680* leads to formation of the primary radical-ion pair ^{1}[P680$^\oplus$I$^\ominus$] (black oval), which is converted into the "stable" radical-ion pair P680$^\oplus$IQ$_A^\ominus$ (dotted oval) by electron transfer from the intermediary component I$^\ominus$ to the plastoquinone acceptor Q_A (component A of Fig. 2). Q_A is a specially bound plastoquinone. The rate constants describe the following processes: excitation energy transfer to the reaction center (k_1) and back to the antenna (k_{-1}), electron-transfer processes (k_{PC}, k^*, k_t, k_{-t}), radiationless decay processes of excited states within the antenna (k_Σ^A) or in P680* (k_Σ^P), dissipative recombination reactions (k_b, k_d), and decay of the triplet state of ^{3}P680* (^3k), which is created by a radical-ion pair mechanism (the rate constants of these processes are not explicitly given). The energy scale is interrupted because the energy difference between Chl* and Chl is much larger (1.83 eV) than that between Chl* and P680$^\oplus$IQ$_A^\ominus$ (0.5–0.6 eV).

rier(s), symbolized as I in Figure 3, is (are) identical with Pheo or whether further redox groups participate in the electron transfer between P680 and Q_A[18–20] is still a matter of debate. Q_A is complexed with $Fe^{2\oplus}$ (high spin)[21,22] and can only act as a one-electron acceptor[23] (the chemically interesting possibility of stabilizing semiquinones will be discussed in more detail in Sections 4 and 5). The functional role of $Fe^{2\oplus}$ is not yet understood, but investigations of the reaction centers of purple bacteria (removal of $Fe^{2\oplus}$ and replacement by $Zn^{2\oplus}$ or other bivalent cations) indicate that the electrostatic charge of $Fe^{2\oplus}$ and not its special 3d-electron configuration is important for the stabilization of the primary charge separation by Q_A.[24]

According to our current state of knowledge, only π electrons participate in the redox reactions of RC II. An analogous functional principle was already realized in the phylogenetically more ancient reaction centers of purple bacteria.[25] In this case, the photoactive pigment is a bacteriochlorophyll dimer, which transfers its electron from the excited singlet state via bacteriopheophytin to ubiquinone *(Rhodopseudomonas sphaeroides)* or menaquinone *(Rhodopseudomonas viridis)*, which is also complexed with $Fe^{2\oplus}$ (high spin).

The essential functional difference between the two types of "π-electron" reaction centers in RC II and purple bacteria is the oxidizing power of the holes generated at the photoactive pigment. In contrast to P680$^\oplus$, the bacteriochlorophyll radical cation is incapable of water oxidation for thermodynamic reasons. Therefore, the "invention" of P680 was the indispensable prerequisite for the development of O_2-evolving photosynthetic organisms. It could be speculated that this problem was simply solved by exchanging chlorophyll a (Chl) for the bacteriochlorophyll dimer, because the first excited singlet state of Chl is energetically higher by about 0.4 eV than that of bacteriochlorophyll (BChl) and because there is no large difference between the redox potential for the reduction of bacteriopheophytin (BPheo) and pheophytin (Pheo).[25] However, the utilization of Chl a was a necessary but not a sufficient condition, as is shown by the example of Chl a (P700) in reaction centers of photosystem I. The P700$^\oplus$ radical cation cannot support water oxidation because the redox potential of P700/P700$^\oplus$ is around +0.5 V (for a review see Ref. [25]). Therefore, the nature of the protein matrix is of central functional relevance for the redox potential of P680$^\oplus$/P680. The large influence of the apoprotein is clearly exemplified by the cytochromes. The redox potentials of their functional heme groups span a range of nearly 800 mV.[26,27] Based on model calculations, the effect of the protein matrix in cytochromes mainly consists in the establishment of an environment with a low dielectric constant around the heme group.[28]

Besides its thermodynamic role in controlling the redox potential of P680$^\oplus$/P680, the protein matrix possesses another essential function. It determines the rate constants of the elementary processes, which take place via vibronically coupled electron tunneling.[29,30] This "fine tuning" of the rate constants of the individual elementary electron-transfer processes in the reaction center is crucial for ensuring a high quantum yield for the entire reaction sequence;[31] the quantum yield is almost 1 for RC II.[32] Thus, the matrix protein has to be regarded as an apoenzyme of RC II, which determines the π-electron redox chemistry of this operational unit.[32] Therefore, the nature of this matrix is of great mechanistic importance and a topic of current research activities (see Section 3.2). How the individual reactions are regulated in detail by the protein matrix is still an open question.

3.2. Structural Arrangement of Reaction Center Complexes of Photosystem II

The decisive breakthrough in understanding the structure of the reaction centers of photosynthetic organisms was achieved by *Michel* and *Deisenhofer* et al. with the crystallization and X-ray analysis of this operational unit from *Rhodopseudomonas viridis* (for a review see Ref. [34]). Both the arrangement of the prosthetic groups and the essential details of the structure of the apoprotein were thereby unraveled. The apoprotein consists of two polypeptides, which are designated as the L and M subunits, each containing five transmembrane helices.[34] The basic arrangement of these bacterial reaction centers is shown schematically in Figure 4. Purple bacteria are not able to oxidize H_2O to O_2. This raises the crucial question whether further phylogenetic evolution of the L and M subunits of purple bacteria and replacement of bacteriochlorophylls (or bacteriopheophytins) by chlorophyll a (or pheophytin a) were sufficient to create the PS II reaction center complex coupled with a water-oxidizing enzyme system or whether new polypeptides had to be evolved.[35] There are striking analogies between purple bacteria and PS II in the organization scheme of reaction-center electron transport from the photochemically active pigment to the quinone acceptors.[36] Moreover, the photosystem II of water-splitting photosynthetic organisms contains two polypeptides with relative molecular masses of 32–34 kDa (designated D-1 and D-2), which show striking sequence homologies with the L and M subunits of bacterial reaction centers.[37] Both D-1 and the L subunit are essential for binding hydroquinones; both polypeptides also possess specific binding sites for herbicides.[38,39] Furthermore, the hydrophobic properties of the protein sequences indicate that[40] D-1 and D-2 contain five transmembrane helices similar to those of the L and M subunits.[34,41] These striking analogies led to the conclusion that D-1 and D-2 constitute the RC II apoprotein. If this is true, then these polypeptides ohould also bind chlorophyll a. Recently, we succeeded in the identification of two Chl-containing polypeptides in the range of 30–34 kDa from PS II preparations from spinach,[42] but it is still a matter of question whether these are really identical with D-1 and D-2.

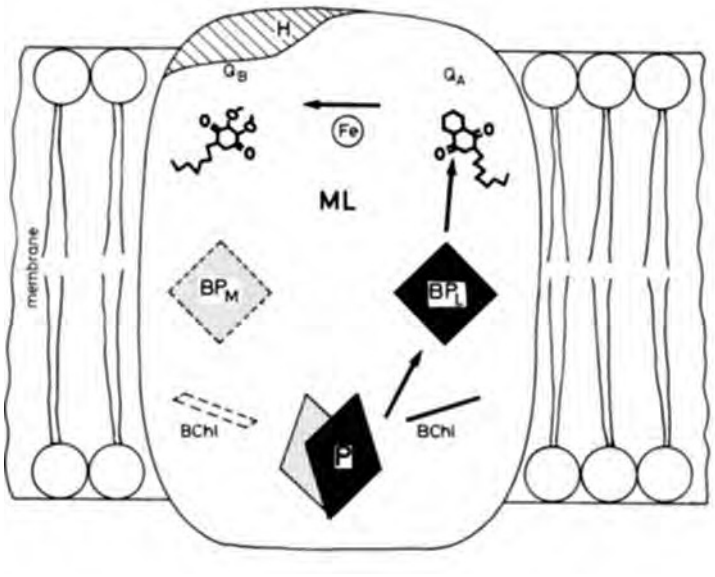

Fig. 4. Structural organization scheme of the reaction center complexes (RC) in photosynthetic purple bacteria *(Rhodopseudomonas viridis)* according to *Michel* and *Deisenhofer* et al. (see Ref. [34]). The bacteriochlorophylls of the photoactive dimer P and bacteriopheophytin (BP) are shown as parallelepipeds and squares, respectively; the monomeric bacteriochlorophylls (BChl) are symbolized as a small parallelepiped and a bar. The two functional quinones of the reaction center are menaquinone (Q_A) and ubiquinone (Q_B). A high-spin $Fe^{2\oplus}$ is located between these two quinones. The apoprotein, which consists of L and M subunits, is not shown; the regulatory H subunit is shown as a stripe pattern and the structures of the quinones are indicated.

The results mentioned above support the hypothesis that the structure of the PS II reaction centers of O_2-evolving organisms is basically similar to that of purple bacteria.[34,41] In all PS II RC preparations, however, a Chl-containing, 47-kDa polypeptide (CP47) exists, which is closely associated with D-1 and D-2. This raises the question of the functional role of CP47. Originally, CP47 itself was thought to be the RC II apoprotein.[43–45] According to the D-1/D-2 hypothesis, on the other hand, CP47 is assumed to be merely a special antenna for P680.[34,41] In an alternative model, the possibility is discussed that D-1, D-2, and CP47 act as subunits of the RC II apoprotein.[35] Recently, Chl-containing complexes were isolated which did not include either CP47 or polypeptides in the range of 30–34 kDa.[46a] Functional studies with these preparations have not yet led to definite conclusions.

The most recent studies, however, showed that a complex containing only D-1, D-2, cytochrome b 559, Chl, and Pheo (as well as β-carotene) exhibits the characteristic features (light-induced changes in absorption) for the formation of radical-ion pairs ($P680^{\oplus}Phe^{\ominus}$).[46b–c] These findings support the D-1/D-2 reaction center model of PS II.

In the next few years the structural elucidation of the PS II reaction center will be an important goal of basic photosynthesis research.

The reaction center complex RC II is anisotropically incorporated into the thylakoid membrane, whereby P680 is located on the inner side (lumen) and Q_A on the outer side (stroma) (see Fig. 2). Light-induced electron transfer from P680 to Q_A thus leads to the formation of an electrical potential difference across the thylakoid membrane[47] (the other reaction center complexes are also anisotropically integrated within the membrane, see Fig. 4).

4. The Water-Oxidizing Enzyme System

4.1. Organization Scheme of Photosynthetic Water Oxidation

A milestone for understanding the functional organization of photosynthetic water oxidation was the fundamental work of *Joliot* and *Kok* and their co-workers.[48–50] They found that the O_2 evolution after illumination of dark-adapted algae and chloroplasts with a sequence of short flashes shows a characteristic oscillation pattern, which has a periodicity of four. A typical trace is shown in Figure 5. The results clearly show that practically each reaction center is functionally connected with only one water-oxidizing enzyme system (for a review see Ref. [51]). The wa-

ter oxidation therefore occurs via a sequence of one-electron redox reactions, which can be described by the

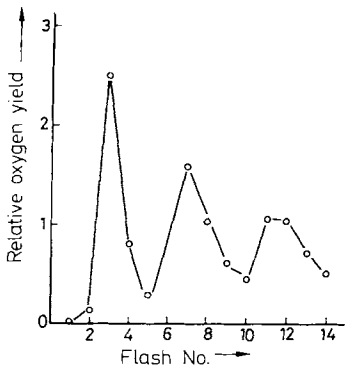

Fig. 5. Relative oxygen yield of dark-adapted chloroplasts as a function of the flash number in a sequence of short (10-μs) saturating flashes. The values are taken from the Thesis of *G. Dohnt* (Technische Universität Berlin 1984).

scheme depicted in Figure 6. Here, S_i (i = 0–4) symbolizes the redox state of the water-oxidizing enzyme system (i = 0 corresponds to the redox state of water, i = 4 to that of molecular oxygen). The coupling between P680 of RC II and the water-oxidizing enzyme system Y is symbolized by the dotted ovals in Figure 6. The nature of this coupling will be described in the following section.

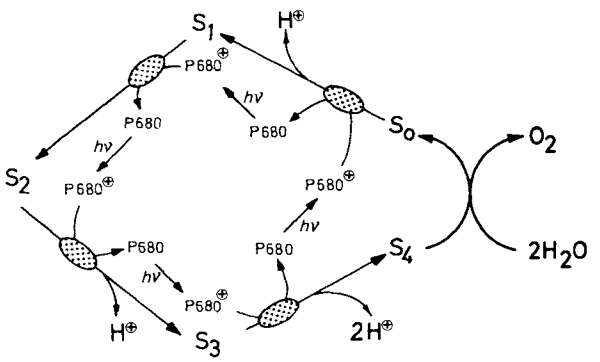

Fig. 6. Functional organization scheme of photosynthetic water oxidation as a sequence of a four one-electron redox reactions. S_i (i = 0–4) symbolizes the redox states of the catalytic site of the water-oxidizing enzyme system; P680 represents the photoactive chlorophyll a component of the reaction center (see Figs. 2, 3); the acceptor components are not shown. The functional coupling of the reaction center to the water-oxidizing enzyme system is symbolized by dotted ovals.

4.2. The Coupling between the Reaction Center and the Water-Oxidizing Enzyme System

Since $P680^{\oplus}$ reduction is much faster (ns to μs range[52–55]) than the redox transitions within the water-oxidizing enzyme system Y,[56,57] the functional connection to RC II presumably involves at least one redox component,[51] which is usually referred to as Z. This raises questions about the nature of Z and the possible participation of further redox components. Z was first detected by EPR spectroscopy.[58] An EPR signal at $g = 2.0046$ (called signal II_{vf}[*]) was observed after excitation of dark-adapted chloroplasts with a series of short flashes. The relaxation kinetics of signal II_{vf} depend on the redox state S_i of the water-oxidizing enzyme system.[59] Signal II_{vf} is ascribed to the oxidized form Z^{ox}. Destruction of system Y changes the kinetics of the EPR signal[60] significantly (this signal is thus called II_f[*]) as well as its microwave-power saturation.[61] Concomitantly, the $P680^{\oplus}$ reduction slows down. In this case, the kinetics of signal II_f formation and of $P680^{\oplus}$ reduction coincide. Both processes exhibit a characteristic pH dependence and have half-lives in the range of 2–40 μs.[62–64] If only Z^{ox} is present, $P680^{\oplus}$ is reduced via a back reaction with $Q_A^{\ominus}$ characterized by a half-life of 100–200 μs.[65,66]

A detailed analysis of the EPR spectrum of signal II_f and a comparison of this spectrum with those of corresponding in vitro model systems led to the conclusion that the redox-active group in the oxidized form Z^{ox} is a plastosemiquinone radical cation, whose ring plane is perpendicularly oriented with respect to the membrane.[67,68] Spectroscopic investigations in the UV/VIS range do not contradict this assumption.[69–72] Figure 7 shows the UV difference spectra of Z^{ox}/Z, which were obtained from analyses of flash-induced absorption changes.[69] The measurements were carried out with PS II membrane fragments (the contamination with photosystem I was ≤5%), where the water-oxidizing enzyme system Y was functionally intact in one case and totally destroyed in the other.

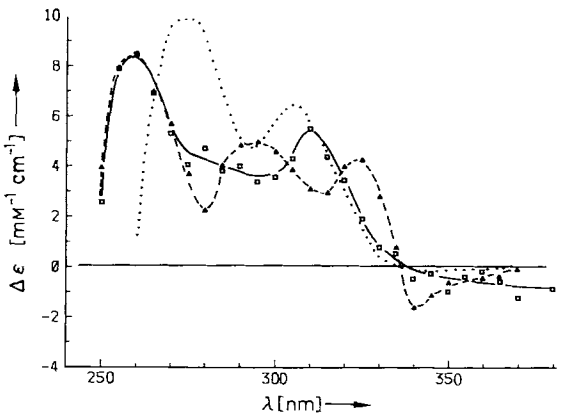

Fig. 7. Difference spectra of the redox components Z^{ox} and Z in PS II membrane fragments with intact (dashed curve) and inactivated (full curve) water-oxidizing enzyme system (for experimental details, see Ref. [69]) and of $PQH_2^{\oplus}/PQH_2$ in 9 M H_2SO_4 and 1 M CH_3OH (see Ref. [73]) (dotted curve).

A comparison with the system durosemiquinone/durohydroquinone in 9 M H_2SO_4 and 1 M methanol[73] shows that in the UV range the difference spectra of the durosemiquinone radical cation in solution and of Z^{ox} in photosystem II are similar. The hypsochromic shift of the 275-nm band to 260 nm and the slight bathochromic shift of the 305-nm band (to 310 nm) can be explained by the binding of the plastohydroquinone to the protein matrix. It should be emphasized, however, that an unambiguous identification of the prosthetic group of Z as PQH_2 has not

[*] The indices "vf" (very fast) and "f" (fast) are related to the different rates of relaxation.

yet been achieved, so that alternative assignments cannot be totally excluded (e.g., flavins, see Ref. [74], or tyrosine residues). Confirmation of the plastohydroquinone model for Z would have two interesting mechanistic consequences:

1. In solution, semiquinone radical cations can only exist in a strong acidic medium because of their negative pK values.[75] Therefore, the formation of a relatively stable plastosemiquinone radical cation in biomembranes requires its integration into a special protein matrix that prevents its rapid deprotonation[69,72] and thus plays an essential functional role. An experimental indication for the very strong isolation of the functional group of Z is the failure to observe deuterium exchange with the microenvironment of the prosthetic group when PS II membrane fragments are incubated in D_2O.[76a] Recent labeling experiments with ^{125}I suggest that the binding site of the functional group of Z is located in D-1 or in close proximity to this polypeptide.[76b,c]
2. Since the primary acceptor is a specially bound plastoquinone molecule associated with $Fe^{2\oplus}$ (high spin) (see Section 3), the generation of the [$P680^{\oplus}Pheo^{\ominus}$] radical-ion pair by the primary light reaction would eventually lead to the formation of a radical-ion pair consisting of spatially separated and fixed semiquinones,[77] which contain at least 60% of the free energy of the first excited singlet state of P680*. This implies that, for the intermediary storage (in the μs range) of solar energy, a system was evolved that maintains a relatively high electrochemical potential difference of approximately 1 V by using the same prosthetic groups (plastosemiquinones) and by controlling their microenvironments in order to achieve dramatic differences in the degree of protonation.

In addition, it is mechanistically interesting that, in contrast to the usual two-electron redox chemistry of quinoid systems, both prosthetic plastoquinone (or hydroquinone) groups act only as one-electron redox systems.[*] The oxidation of the functional plastohydroquinone in Z to the quinone stage is probably prevented by an efficient protonation (the formation of a doubly protonated quinone requires a very high oxidation potential, see Ref. [75]). The redox properties of the plastoquinone on the acceptor side are probably regulated by interaction with the $Fe^{2\oplus}$ center, but this process is mechanistically still unclear (see Section 5).

There are distinct differences between the difference spectra (Fig. 7) of Z^{ox}/Z for PS II membrane fragments whose water-oxidizing enzyme system Y is functionally intact and for those whose enzyme system Y is inactivated by selective treatments. These differences are typical for shifts caused by electrochromic effects. Therefore, the additional electrochromic band shifts might be caused by the electrostatic interaction between charged groups in the water-oxidizing enzyme system Y and the reaction center of photosystem II.[69] To what extent these interactions also affect the EPR spectra of the signals II_{vf} and II_f remains to be clarified.

Kinetic analyses of $P680^{\oplus}$ reduction led indirectly to the conclusion that two redox components participate in the functional coupling between RC II and the water-oxidizing enzyme system.[79,80] Since the kinetics of the signal II_{vf} relaxation[59] is in good agreement with that of the redox transitions $S_i \rightarrow S_{i-1}$,[56,57] Z is presumably associated directly with the water-oxidizing enzyme system. Therefore, if a further redox component D_x does exist, it should be located between Z and P680. Direct experimental evidence for the existence of D_x is still lacking (for a detailed discussion see Ref. [69]).

An interesting question with respect to the coupling mechanism between RC II and system Y is if and to what extent the redox state S_i in system Y influences the kinetics of $P680^{\oplus}$ reduction. If there is no interdependence between the two functional units, the electron-transport kinetics should be characterized only by the electronic and vibronic coupling between P680 and Z and therefore would be independent of S_i. Based on measurements of absorption changes at 690 nm, which reflect the turnover of P680, the kinetics of $P680^{\oplus}$ reduction was found to depend on the redox state of the water-oxidizing enzyme system.[79] Recent measurements with markedly higher time-resolution have confirmed this conclusion.[80] The regulation of the kinetics of electron transfer between $P680^{\oplus}$ and Z was attributed entirely to simple electrostatic interactions between the functional groups.[80] The possible influence of changes in the protein structure due to redox transitions of the prosthetic group was ignored. Such effects are well known for redox enzymes; e.g., the structure of the apoprotein of cytochrome c is significantly changed during oxidation of the functional heme group.[26] Recently, it was also shown for plastocyanin that the oxidation of the functional cation $Cu^{\oplus}$ to $Cu^{2\oplus}$ induces conformational changes, which are probably responsible for fine tuning of the electron transfer.[81] Therefore, it remains to be clarified whether or not the observed dependence of the kinetics of $P680^{\oplus}$ reduction on the redox state S_i of the water-oxidizing enzyme system is primarily caused by effects of the polypeptide structure on the electron transfer.

4.3. Functional Mechanism and Structural Composition of the Water-Oxidizing Enzyme System

A consideration of the formal sequence of one-electron reactions leading from two H_2O molecules to O_2 and $4H^{\oplus}$ (Fig. 8) readily reveals that the central problem of water oxidation in biological membrane systems is the mechanistic stabilization of the intermediary redox states.[82] The free energies of the oxidation products formed by a stepwise abstraction of electrons from water molecules ($HO^{\odot}$, H_2O_2, $HO_2^{\odot}$) immediately reveal that these intermediates cannot be involved as free species in photosynthetic water oxidation.[83,84] Furthermore, owing to the reactive properties of these compounds, a rapid oxidative degradation of sensitive biomolecules would occur. Accordingly, appropriate functional groups have to participate directly in the redox reaction sequence of photosynthetic water oxidation. The overall reaction consists in the cleavage of the

[*] Under nonphysiological experimental conditions in the presence of $Na_2S_2O_4$, reduction of Q_A to the hydroquinone stage [78] can be achieved.

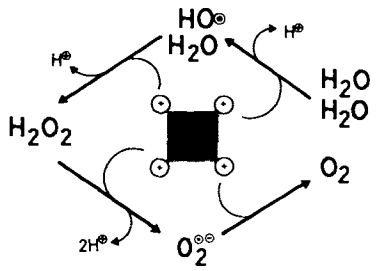

Fig. 8. Reaction scheme for the oxidation of two H_2O molecules to O_2 and $4H^{\oplus}$ by a sequence of four one-electron redox reactions. The grey area symbolizes a source of holes, which is not characterized in detail. With respect to the coupled protolytic reactions, it is assumed that the reaction takes place at a pH that is large compared with the pK value of HO_2.

bonds between the O and H atoms and the formation of σ and π bonds between two O atoms. Therefore, presumably systems with π orbitals and/or transition metals with incompletely filled d orbitals are especially suitable as functional groups. Investigations of O_2 enzymology[85] indicate that such systems (flavins, quinones; Fe, Cu, Mn, Mo) play an essential role as functional groups. Manganese is well known as an indispensable cofactor in photosynthetic water cleavage (for reviews see Refs. [51, 86–88]). Therefore, it seems plausible and logical to view the water-oxidizing enzyme system as a manganese protein, where the metal centers with their specific ligand shells act as the redox-active functional groups of the enzyme.[89, 90] From this basic postulate and from a comparison with the reaction schemes depicted in Figures 6 and 8, several important questions emerge regarding the mechanism of photosynthetic water oxidation:

1. What is the structure of the active site where the formation of O_2 from two H_2O molecules takes place?
2. What are the electronic structure and the nuclear configuration of the prosthetic groups that constitute the redox states S_i (see Fig. 6)?
3. Why does the water-oxidizing enzyme system almost completely attain the redox state S_1 after sufficient dark-adaptation?[51, 91]
4. What deprotonation reactions are coupled with the redox transitions $S_i \rightarrow S_{i+1}$?
5. How is the apoenzyme structurally arranged and how does it functionally influence the redox transitions?
6. What regulatory subunits are additionally involved in the function of the water-oxidizing enzyme system?

4.4. The Catalytic Site and the Functional Role of Manganese

The mechanistically crucial step for the formation of O_2 from two water molecules is the formation of an oxygen–oxygen bond. This requires a suitable geometric arrangement of the reactants, which can be achieved if the catalytic active site contains at least two centers. Moreover, the formation of a peroxidic precursor is thereby made possible. If the essential redox transitions are assumed to take place at these centers, then they constitute, together with their associated ligand shells, the prosthetic group of the water-oxidizing enzyme system. Redox-active groups that are required only for the electronic coupling with RC II (via component Z, see Section 4.2), or molecules and amino-acid residues that participate exclusively in deprotonation reactions (e.g., by the formation of hydrogen bonds) that are not directly involved in the reactive center, should not be considered as a part of the prosthetic group itself.

Based on these considerations, the prosthetic group of the water-oxidizing enzyme system Y is postulated to be a binuclear manganese complex. Stoichiometric analyses show that there are four Mn per system Y.[92, 93] These four Mn are assumed, however, to serve different functions. Indeed, even a structurally symmetric tetranuclear manganese complex can act as a functional binuclear group if it is incorporated into an asymmetric protein matrix (for a detailed discussion see Ref. [94]). Several reports suggest that the four Mn in system Y are not equivalent. They are distinguishable by (1) the magnetic interaction with Z^{ox},[61] (2) the interaction with $Cl^{\ominus}$,[95] (3) the binding strength after dissociation of the regulatory 33-kDa subunit (see Section 4.6.2),[96] and (4) the mechanism of the photoactivation of system Y.[97] After partial depletion of Mn, moreover, a reactivation of O_2 evolution without addition of Mn seems to be possible.[98] Furthermore, there are indications that two of the four manganese ions are replaceable by other bivalent metal cations.[99]

A binuclear manganese complex as the prosthetic group involved in water oxidation was already proposed in earlier models.[100, 101] This assumption is supported by the fact that, although enzyme systems catalyzing the reduction of O_2 to H_2O (cytochrome oxidase, laccase, etc.; for a review see Ref. [85]) also contain four metal centers, only two of them constitute the catalytic active site. Inorganic complexes containing binuclear metal centers have also been found to catalyze the oxidation of water.[102, 103]

If one assumes that the prosthetic group of the water-oxidizing enzyme system is a binuclear manganese complex, three questions arise: (1) What are the valence states of the two manganese centers in the redox states S_i? (2) How are the manganese centers coordinatively arranged in the protein and in what state of protonation will the substrate (H_2O) be bound? (3) Are further redox-active components (e.g., in the ligand sphere) involved in the electron-transfer processes of the catalytic center?

A variety of spectroscopic methods are available in order to characterize the electronic states of functional groups containing transition metals as redox-active species: NMR, EPR, UV/VIS, IR, EXAFS,[*] and XAES[*] spectroscopy. However, investigations of complex biological systems are confronted, in principle, with two difficulties. First, the difference spectra may overlap with those of components that do not participate in the reaction sequence in question. Secondly, even if good separation of the difference spectra can be achieved, tremendous problems arise for the interpretation of the data if neither the structure nor the chemical nature of the ligand shell is known. Both problems complicate the analysis of the reaction sequence in the water-oxidizing enzyme system so

[*] EXAFS = extended X-ray absorption fine structure; XAES = X-ray absorption edge structure.

strongly that a satisfactory answer to the above questions has not yet been possible. Therefore, we can only describe pieces of the puzzle formed by today's fragmentary state of information; these findings were obtained by the use of several spectroscopic methods. An attempt is then made to put together the pieces of the puzzle in order to draw a tentative picture of the whole mechanism. Since the isolation of the water-oxidizing enzyme system in a functionally intact state has not yet been achieved, the experiments have to be carried out with systems in which at least the processes occurring in RC II and the electron transfer to exogenous acceptors concomitantly take place. Therefore, the assignment of measured spectral properties to specific redox states S_i in the water-oxidizing enzyme system is based on the use of the characteristic oscillation pattern (see Fig. 5) as a "label" of the S_i states and their redox transitions $S_i \rightarrow S_{i+1}$.

4.4.1. NMR Spectroscopic Investigations

Strongly relaxing paramagnetic metal centers with suitable electron configuration (singlet orbital states with a low static zero-field splitting) influence the relaxation kinetics of water protons.[104] A change in the valence state of the manganese centers at the catalytic active site should therefore result in a change in the spin-lattice or spin-spin relaxation kinetics, which, in turn, should permit conclusions to be drawn about the redox states of the individual S_i states of the water-oxidizing enzyme system. Illumination of dark-adapted chloroplasts with a series of short flashes results in an oscillation pattern in the relaxation kinetics, which can be used to identify the S_i states.[105] This method requires the selection of suitable experimental conditions in order to exclude secondary effects caused by nonfunctional centers (for a review see Ref. [106]). Recent measurements unambiguously show that changes in the relaxation kinetics are associated with redox changes in the S_i states.[107] The results led to the preliminary conclusion that the transition $S_1 \rightarrow S_2$ is probably associated with an oxidation of Mn^{III} to Mn^{IV}, whereas the reaction $S_2 \rightarrow S_3$ might not involve a valence change in the manganese centers. The oxidation of S_0 to S_1 could be a $Mn^{II} \rightarrow Mn^{III}$ transition.[108] However the NMR results reported so far do not allow an unambiguous conclusion to be drawn about the redox state of manganese in the catalytic site.

4.4.2. EPR Spectroscopic Investigations

The bound manganese in photosystem II is EPR-inactive at room temperature (for a review see Refs. [87, 88]). Inactivation of the water-oxidizing enzyme system results in the appearance of a typical hyperfine EPR signal for $[Mn(H_2O)_6]^{2\oplus}$. Therefore, an attempt was made to release the manganese by sufficiently fast destruction of the enzyme system after occupation of specific S_i states and then to draw conclusions about the valence state of manganese from the amplitude of the measured EPR signal.[109] The results obtained by this indirect method suggested that the manganese is present as Mn^{II} and Mn^{III} during the redox cycle, whereby Mn^{IV} is also formed as an intermediate (during the transition $S_1 \rightarrow S_2 \rightarrow S_3$).[109]

Crucial for the applicability of EPR methods for analyses of the catalytic site of water oxidation was the discovery of a low-temperature EPR signal, which appears upon formation of the S_2 state.[110] The spectral simulation of the characteristic hyperfine structure led to the conclusion that the S_2 multiline signal is due to the mixed valence state of a bi- or tetranuclear manganese complex, whereby either a Mn^{II}–Mn^{III} or a Mn^{III}–Mn^{IV} configuration is possible.[110–116] Investigations on model complexes do not exclude the existence of a peroxo-bridged $[Mn^{II} \cdots O_2 \cdots Mn^{III}]$ state.[117] The influence of $H_2{}^{17}O$ on the hyperfine lines led to the conclusion that H_2O is associated directly with the catalytic manganese during the formation of S_2.[118] The S_2 multiline signal disappears when the water-oxidizing enzyme system is destroyed, as shown in Figure 9.[119] Besides the multiline signal, a further EPR

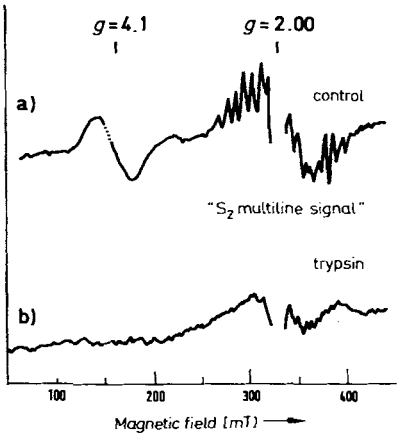

Fig. 9. Light-induced EPR signals of a) untreated and b) trypsin-treated PS II membrane fragments at pH = 7.5. The characteristic S_2 multiline signal (see text) is clearly resolved for untreated chloroplasts (the narrow range around $g = 2.0$ is not shown because of the superposition of very intense signals due to other radicals) (for experimental details see Ref. [119]).

signal exists at $g = 4.1$,[115, 120] which also belongs to S_2.[121, 122] The properties of these EPR signals suggest that the $g = 4.1$ signal arises from S_2 in the ground spin state ($S = 3/2$), and that the S_2 multiline signal is due to the excited spin state ($S = 1/2$) of an antiferromagnetic exchange-coupled binuclear Mn^n–Mn^{n+1} group, which is ferromagnetically coupled with a second ($S = 1$) center (possibly the second Mn dimer of a distorted Mn tetramer).[116, 121] In a recent model, a distorted cubane-like Mn_4O_4 structure is discussed.[122a] However, direct experimental evidence is still lacking. The analysis of the spin states alone does not permit a definite interpretation of the Mn valence state n. At present a value of $n = 3$ is most likely, [115, 116] whereby in the "cubane" model a Mn^{III}–Mn_3^{IV} configuration is assumed for S_2.[122a]

Structural information about the ligand sphere of the functional manganese centers, especially the distribution of the electron density, has not yet been obtained. In this connection a general problem of low-temperature EPR spectroscopy should be discussed. Measurements with manganese model complexes containing redox-active ligands[123, 124] do not exclude the possibility that the distribution of the electron density between ligands and central atoms depends on the temperature. If this phenomenon

also occurs in the water-oxidizing enzyme system, then low-temperature EPR measurements cannot provide any information, in principle, about the electronic configuration and hence the actual redox state of the manganese centers at the catalytic site at room temperature.

4.4.3. UV/VIS Spectroscopic Investigations

In principle, it should be possible to determine the UV/VIS difference spectra for the redox transitions $S_i \rightarrow S_{i+1}$ from flash-induced absorption changes because of the characteristic oscillation pattern (cf. Fig. 5). However, serious difficulties arise because of the superposition with binary oscillations, which are due to PQ reduction (see Section 5) (for a discussion see Refs. [94, 125]). By means of a proper modification of the apoprotein (mild trypsin treatment at $pH \leq 6.5$), it was possible to suppress PQH_2 production in thylakoids; simultaneously, $Q_A^{\ominus}$ becomes easily oxidizable with $K_3[Fe(CN)_6]$.[126-128] Illumination of dark-adapted trypsin-treated thylakoids with a sequence of short flashes in the presence of $K_3[Fe(CN)_6]$ gives rise to the absorption changes at 320 nm shown in Figure 10.[129]

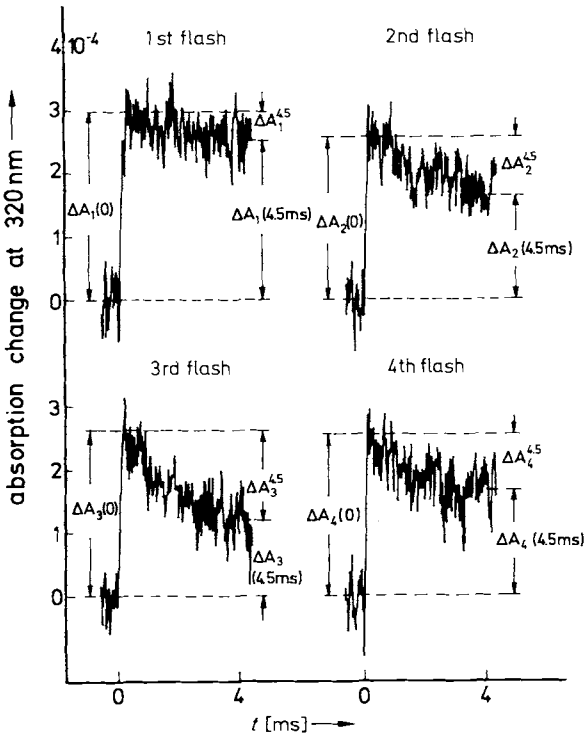

Fig. 10. Absorption changes at 320 nm as a function of the flash number in a sequence of short (10-μs) saturating flashes in dark-adapted and trypsin-treated thylakoids. $\Delta A_n(0)$ describes the initial amplitude of the n-th flash, ΔA_n (4.5 ms) represents the corresponding amplitude 4.5 ms after the excitation flash, and $\Delta A_n = \Delta A_n(0) - \Delta A_n(4.5\ ms)$ is the difference between the two values, which is a measure for the relative contribution of the 1-ms relaxation to the total relaxation (for experimental details see Ref. [129]).

Clearly revealed is a 1-ms relaxation, whose amplitude oscillates characteristically depending on the number of the flash. The half-life of about 1 ms corresponds to the time required for the rate-limiting step of O_2 production as derived from polarographic measurements.[130] Figure 11 shows that the amplitude of the 1-ms relaxation and the O_2 yield per flash of dark-adapted thylakoids exhibit practically the same oscillation pattern. Based on kinetic considerations, the amplitude of the 1-ms relaxation in trypsin-treated thylakoids corresponds to the following reaction:[53]

$$Z^{ox}S_3 + 2\,H_2O \longrightarrow ZS_0 + O_2 + 2\,H^{\oplus}$$

Thus, the difference spectrum of this reaction (Fig. 11, inset) can be obtained. A separation of the difference spectra for each individual redox transition $S_i \rightarrow S_{i+1}$ could not be achieved because of the poor optical properties of the thylakoid suspensions.

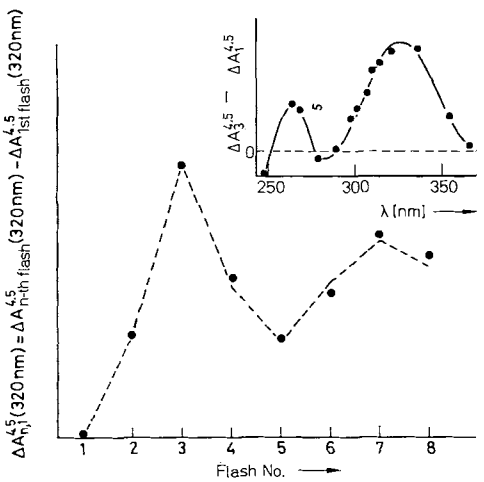

Fig. 11. Amplitude difference (●) of the 1-ms relaxation between the n-th and the first flash ($\Delta A_{n,1}^{4.5}$) and relative oxygen yield (----) as a function of the flash number in a sequence of short (10-μs) saturating flashes in dark-adapted trypsin-treated thylakoids. The inset shows the amplitude difference (●) of the 1-ms relaxation between the third and first flash as a function of wavelength (for further details see Ref. [53]).

Significant progress in all spectroscopic investigations of photosystem II was achieved by the development of preparative methods for the isolation of membrane fragments that contain almost no photosystem I, exhibit full O_2-evolving activity, and have convenient optical properties (low dispersion, small particle size).[131, 132] Measurements of flash-induced absorption changes with PS II particles and analyses of the results on the basis of the Kok scheme (see Section 4.2) were performed by several groups.[125, 133, 134] Different conclusions were drawn from these studies, the details of which will not be discussed here. However, it has to be emphasized that even the basic question is still open whether each redox transition $S_i \rightarrow S_{i+1}$ leads practically to the same difference spectrum for $i = 0$, 1, and 2[133] or whether significant differences appear.[125, 134] The most recent theoretical considerations reveal that, even in the ideal case of the absence of any interferring processes, the absorption changes per se do not permit an unambiguous deconvolution into the difference spectra $\Delta\varepsilon_{i+1,i}(\lambda)$.[135]

An attempt was also made to use the difference spectra obtained in these investigations to derive information about the nature of the participating redox groups. A comparison with the spectra of manganese gluconate complexes led to the conclusion that each $S_i \rightarrow S_{i+1}$ transition

for i = 0, 1, and 2 corresponds to an oxidation from Mn^{III} to Mn^{IV}.[133] This assignment remains equivocal, however, because, regardless of possible differences between various redox transitions,[125,134] the difference spectra by themselves do not permit a definite interpretation of the electron configuration of the manganese centers in the S_i states; the UV spectra of manganese complexes are primarily determined by the structure of the ligands[136a] rather than by the manganese centers. Recent investigations[136b] confirm these conclusions.

4.4.4. *IR Spectroscopic Investigations*

After illumination of dark-adapted PS II membrane fragments with a series of laser flashes, absorption changes were observed with a maximum at 820 nm ($\Delta\varepsilon$ on the order of 100 M^{-1} cm^{-1}), which reveal a characteristic dependence on the flash number.[137] The absorption changes show typical properties of an intervalence transition in binuclear manganese complexes. It was concluded that in the transition $S_1 \rightarrow S_2$ a Mn^{III}-Mn^{IV} configuration is formed, which disappears in the $S_3 \rightarrow (S_4) \rightarrow S_0$ transition. This assignment implies that the redox transitions $S_0 \rightarrow S_1$ and $S_2 \rightarrow S_3$ probably do not involve a valence change of the manganese centers at the catalytic site.

4.4.5. *EXAFS and XAES Spectroscopic Investigations*

The first attempts to measure the K edge of manganese (XAES measurements) in thylakoids led to the conclusion that S_1 is a mixed-valence $Mn^{II,III}$ state.[138] Later investigations with PS II membrane fragments showed that dramatic changes occur in the edge properties of the sample (a shift of 2.5 eV as well as a broadening of the main absorption peak) during the transition $S_1 \rightarrow S_2$.[139] In contrast, only marginal changes in the transition $S_2 \rightarrow S_3$ were observed. From these results it was inferred that manganese in the binuclear catalytic center exists only in the states Mn^{II}-Mn^{III} and Mn^{III}-Mn^{IV} and that the $S_1 \rightarrow S_2$ transition is a two electron transition with respect to the redox states of the manganese; moreover, a further redox-active component was assumed to be involved in this process.[139] EXAFS analyses revealed that a binuclear manganese complex with a Mn–Mn distance of 270 pm exists in S_1 and S_2.[140] Recent EXAFS investigations confirm this value. They also show that the manganese in the binuclear cluster is located in a special noncentrosymmetric environment, where each Mn has 3 ± 1 terminal ligands (N or O atoms) at a distance of 198 pm and 2 ± 1 bridge ligands (also N or O atoms) at a distance of 175 pm. Possibly, a μ-oxo-bridge structure is involved. An additional binuclear Mn cluster or a monomeric Mn atom is probably also present in the environment.[141]

4.5. Proposed Models for the Molecular Mechanism of Photosynthetic Water Oxidation

The results discussed in Section 4 permit two initial conclusions to be drawn. First, a mixed-valence configuration $Mn^n \cdots Mn^{n+1}$ probably exists in the state S_2. Second, water is directly bound in the first coordination sphere of the functional manganese.

Furthermore, no significant valence change appears to take place at the manganese centers of the catalytic site during the redox transition $S_2 \rightarrow S_3$, i.e., in this redox step the oxidation presumably occurs within the ligand sphere or at an additional redox component. Additionally, thermodynamic considerations led to the conclusion that a redox-active component (symbolized by M) with a relatively low redox potential participates in the redox transition $S_0 \rightarrow S_1$.[100,101] Whether M is a redox-active ligand[53] or a special redox state of the manganese itself[142] still remains to be clarified. A proposed mechanism, which takes these findings into account, is presented schematically in Figure 12.[142]

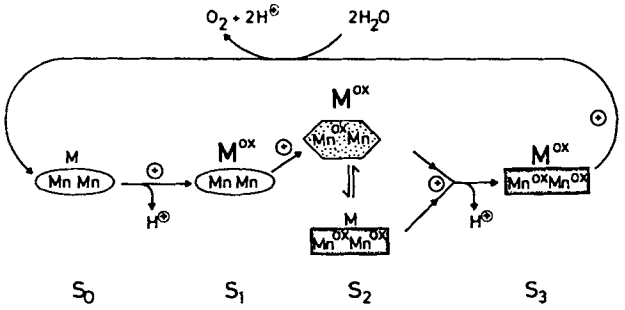

Fig. 12. Reaction scheme for the oxidation of two H_2O molecules to O_2 and $4H^{\oplus}$ at a binuclear manganese center containing an additional redox-active component M (see text). ⊕ symbolizes a hole.

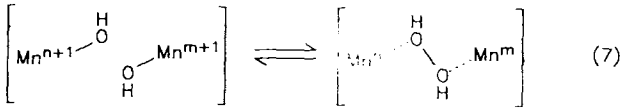
The symbols MnMn, $Mn^{ox}Mn$, and $Mn^{ox}Mn^{ox}$ in Figure 12 represent the functional binuclear manganese center in different oxidation states, whereby the different symbols refer to conformational changes possibly taking place in the apoenzyme during the redox transitions. The existence of two fundamentally different conformations (S_0 and S_1 are markedly different from S_2 and S_3) was recently inferred on the basis of $Cl^{\ominus}$ affinity measurements (see Section 4.6.1).[143a] This conclusion is further supported by measurements of the temperature dependence of the individual redox transitions $S_i \rightarrow S_{i+1}$ ($i = 1, 2, 3$),[143a] which provided information about the activation enthalpies and entropies.[143b] It remains to be shown whether or not these structural differences also influence the kinetics of $P680^{\oplus}$ reduction (see Section 4.2).

The distribution of electron density between the central atoms and the ligand sphere is not explicitly taken into consideration in Figure 12 (see following discussion).

In Figure 12, the "upper" reaction route corresponds to our previously proposed scheme,[100,101] while the "lower" reaction path better describes results obtained more recently.[108,125,139] It still remains to be confirmed whether the postulated S_2 equilibrium exists in the form shown. The existence of this equilibrium would imply the possibility of a shift of the equilibrium constant, so that the measured difference spectra for the redox transitions $S_1 \rightarrow S_2$ and $S_2 \rightarrow S_3$ might depend on experimental conditions.[142]

Until now, we have excluded the possible participation of water as a reactant in the different redox transitions

$S_i \rightarrow S_{i+1}$. Water can undergo protolytic as well as redox reactions. Of central mechanistic relevance for the O_2 production is the following question: At which redox stage S_i is the O–O bond formed? Based on possible analogies with the mechanism of the reverse reaction (namely, the reduction of O_2 to H_2O) in biological systems (for a review see Ref. [85]), it was concluded that the O–O bond is formed at the level of a binuclearly bridged peroxide at the redox stage S_3.[100, 101] Taking into consideration the equilibrium for S_2 formulated in Figure 12, peroxide formation is already possible in S_2. This is also true if $M \rightarrow M^{ox} + e^{\ominus}$ is a special valence-state transition at the catalytic Mn itself. Generally, O–O bond formation at the redox stage of a peroxide can be described by an equilibrium reaction of the type shown in Equation (7).



(7)

In this context it is interesting to note that in cytochrome oxidase the cleavage of the O–O bond takes place at the level of a three-electron reduction of the binuclearly complexed oxygen. This reaction is highly entropy-driven.[144] Analogously, O–O bond formation could occur at the redox stage of two or three holes (S_2 or S_3) in the water-oxidizing enzyme system. This raises the following question: Which redox state S_i satisfies the enthalpic and entropic prerequisites for a significant population of an electronic and nuclear configuration corresponding to the peroxidic form described in Equation (7)? This problem is still unsolved. There are experimental results that support the existence of a μ-peroxo bridge in S_2.[117, 118] Furthermore, the increase in the light-induced production of H_2O_2 after depletion of the regulatory subunits of the water-oxidizing enzyme system (see Section 4.6.2) could be ascribed to a destabilization of peroxide-like intermediary states in S_2 and/or S_3.[145]

In contrast, mass spectroscopic analyses of flash-induced O_2 production after incubation with $H_2{}^{18}O$ were interpreted to exclude the possible formation of peroxidic intermediates at the level of S_3 (or S_2).[146] For kinetic reasons, however, the interpretation of these data is not unequivocal (for a detailed discussion see Ref. [94, 125]). Furthermore, it was recently shown that a very stable S_3 state exists, whose O atoms do not undergo exchange.[147] Unequivocal results as to the possible existence of peroxidic intermediary stages can only be expected if either the time resolution of mass spectroscopic methods can be improved considerably or other spectroscopic methods (IR vibrational spectroscopy, Raman spectroscopy) become available for a selective detection of OH and O–O vibrations in the water-oxidizing enzyme system for the redox states S_i. The electronic configuration of the catalytic site in the different redox states is determined by the actual distribution of the electron density between the binuclear manganese center, the postulated component M, and the substrate ligand. In model systems many examples are known for an electron-density distribution between ligand and central atoms after binding of O_2 to transition-metal centers with only partly occupied d orbitals. The actual distribution can vary between that of O_2 and that of a peroxidic configuration depending on the nature of the entire ligand sphere.[148–152]

Analogous phenomena can appear in enzymatic systems. In a plant cytochrome oxidase, for example, a partial distribution of the charge density of the following form was found ($\delta_1 + \delta_2 \approx 1$, $\delta_1 > 0.5$, and $\delta_2 < 0.5$):[153]

$$Cu_B^{(1+\delta_1)} \cdots O^{\ominus(\delta_1+\delta_2)} O^{\ominus} \cdots Fe^{(2+\delta_2)} Cyt\, a_3$$

The formation of hydrogen bonds could play an essential role in determining the actual charge distribution, as shown by quantum-mechanical model calculations for a Zn–Cu superoxide dismutase.[154]

The possible role of a charge delocalization between ligands and the central atom for the stabilization of the intermediary redox stages of the water oxidation was discussed in detail in earlier proposed models.[100, 101] These considerations led to the conclusion that, in photosynthetic water oxidation, the redox transitions $S_1 \rightarrow S_2$, $S_2 \rightarrow S_3$, and $S_3 \rightarrow S_0$ have almost the same redox potential difference ($\Delta E \approx 1$ V), whereas the transition $S_0 \rightarrow S_1$ has a significantly lower redox potential difference (see Fig. 13).

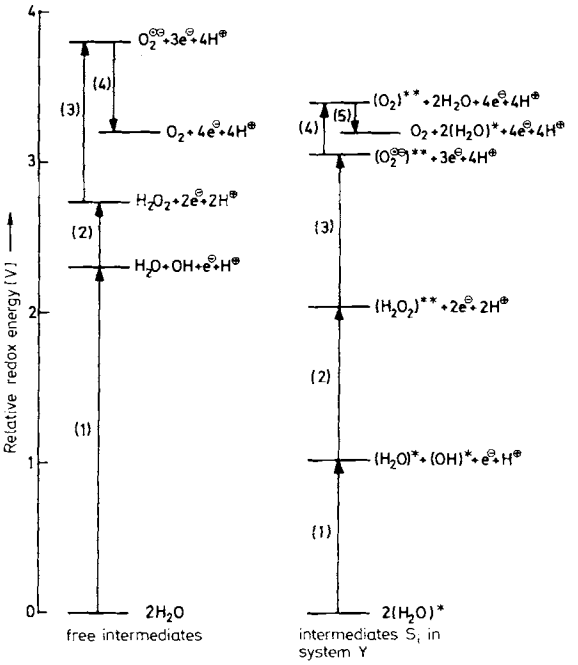


Fig. 13. Redox energy scheme for the oxidation of two H_2O molecules to O_2 and $4H^{\oplus}$ by a sequence of four one-electron redox reactions in vitro (left side) and in the water-oxidizing enzyme system (right side). For the sake of simplicity, the energy of the H_2O molecules in vitro and their energy in the catalytic center of the water-oxidizing enzyme system are shown at the same level, although the absolute values are considerably different. $(OH)^*$, $(H_2O_2)^{**}$, and $(O_2^{\ominus\ominus})^{**}$ represent the formal intermediates of photosynthetic water oxidation relative to the same zero level. These species describe the state of the entire catalytic site. The transitions (1), (2), (3), and (4) (right side) correspond to the transitions $S_1 \rightarrow S_2$, $S_2 \rightarrow S_3$, $S_3 \rightarrow S_4$, and $S_0 \rightarrow S_1$, respectively. The formal analogy does not correspond to the real reaction sequence. The comparison only serves to indicate that the oxidation state S_1 (M^{ox}) acts as an oxidant in the last step of the sequence: $(S_1) \cdot S_0' \rightarrow (S_0) \cdot S_4$. Theoretically, M^{ox} can also enter the redox sequence at S_3 or even at S_2 (see Eq. (12)). It is still unclear at what stage the formation of the O–O bond actually occurs (see text). In this scheme, the possibility is not explicitly considered that a μ-peroxo bridge may already be formed in S_2 [see Fig. 12 and Eq. (7)] (for further details see Refs. [94, 101]).

Similar values were estimated from the results of delayed fluorescence measurements.[155] Measurements of thermoluminescence confirm that the transitions $S_1 \rightarrow S_2$ and $S_2 \rightarrow S_3$ require practically the same redox energy.[156] This implies that, for a significant occupation of state $M(Mn^{ox}Mn^{ox})$ in S_2, the redox potential of the M/M^{ox} couple is strongly shifted for the transition $S_2 \rightarrow S_3$ compared with the reaction $S_0 \rightarrow S_1$. This can be plausibly explained by strong electrostatic interactions. Additionally, it is mechanistically interesting that the life-time of S_2 and S_3 is dramatically shortened by so-called ADRY substances,[157-159][*] while S_1 remains unaffected. Furthermore, thermodynamic considerations led to the conclusion that, at the catalytic center, the educt–product exchange

$$2\,H_2O + (O_2)\cdot X \longrightarrow O_2 + 2(H_2O)\cdot X$$

(X symbolizes a product (O_2) or educt (H_2O) that is coordinated to Mn) is an exergonic process.[100, 101] Hydrogen bonds could play a crucial function in this reaction, because they were shown to be decisive in determining the strength of O_2 bonding in hemoglobins and model systems where considerable changes can occur in the binding geometry of O_2 to the metal center.[160]

The use of highly sensitive glass electrodes or suitable pH indicators to study the protolytic reactions coupled with H_2O oxidation have shown that $H^{\oplus}$ release is not synchronous with O_2 production.[161-163] A deprotonation pattern of 1, 0, 1, 2 $H^{\oplus}$ per PS II appears to be linked with the redox transitions $S_i \rightarrow S_{i+1}$ ($i = 0$–3).[162-168] However, it has to be emphasized that this pattern does not necessarily indicate the actual deprotonation reactions of the water molecules bound to the manganese centers (or of other redox states of the substrate), because pK_a shifts of groups in the protein matrix that can undergo deprotonation also result in a release of protons. Therefore, the intrinsic deprotonation pattern of the ligand sphere of the catalytic manganese must be distinguished from the measured proton-release pattern.[101] This consideration also implies the possibility of an apparent stoichiometry with nonintegral values for the $H^{\oplus}$ release coupled with redox transitions $S_i \rightarrow S_{i+1}$ in the water-oxidizing enzyme system. In this case, a pH dependence for the $H^{\oplus}$ release pattern should be expected. This was not observed in measurements between pH = 6.0 and 8.0 using different preparations.[166-168] At pH < 6.0, the extrinsic proton release pattern seems to shift toward a 1:1:1:1 stoichiometry.[167b] So far, no method has been found to measure directly the intrinsic deprotonation pattern (for a detailed discussion see Ref. [94]).

4.6. Polypeptide Structure and Additional Cofactors in the Water-Oxidizing Enzyme System

The discussion so far has been limited to the nature of the redox-active manganese centers (including the postulated component M) and the bound water. In redox enzymes, however, one can hardly overemphasize the functional role of the surrounding protein matrix and of additional cofactors, which influence the redox processes and, in particular, the thermodynamics of the individual $S_i \rightarrow S_{i+1}$ transitions. The mechanism of this "fine tuning" of the four-step oxidation reaction sequence leading from H_2O to O_2 is still not understood. Therefore, only a short summary of some experimental results will be given.

4.6.1. The Role of $Cl^{\ominus}$ and $Ca^{2\oplus}$ as Cofactors

$Cl^{\ominus}$ has long been known to play an important role in photosynthetic H_2O oxidation (for reviews see Refs. [169–171]). In contrast to the absolute specificity for manganese, $Cl^{\ominus}$ can be replaced by other anions (e.g., $Br^{\ominus}$, $I^{\ominus}$). ^{35}Cl-NMR measurements indicate that reversible $Cl^{\ominus}$ binding occurs with an average exchange rate of $> 3 \times 10^4\ s^{-1}$ (25 °C).[172] The affinity for $Cl^{\ominus}$ depends on the redox state of the water-oxidizing enzyme system; it is low in S_0 and S_1, but high in S_2 and S_3.[174] Binding studies with the radioisotope $^{36}Cl^{\ominus}$ led to the conclusion that four $Cl^{\ominus}$ per PS II are required for the reactivation of the O_2 production of $Cl^{\ominus}$-"free" thylakoids.[173] Two specific binding sites exist for $Cl^{\ominus}$,[175, 176] the affinities of which differ from each other by approximately one order of magnitude.[176] In $Cl^{\ominus}$-depleted PS II membrane fragments, certain $S_i \rightarrow S_{i+1}$ transitions are blocked.[177-180] In the case of $Cl^{\ominus}$ deficiency, a light-induced S_2^* state with unusual properties is formed.[181] This S_2^* state does not exhibit a multiline EPR signal but rather the signal at $g = 4.1$. After addition of $Cl^{\ominus}$ in the dark, S_2^* is converted into S_2 with a normal multiline signal.

$Cl^{\ominus}$ probably plays a functional role in charge compensation during redox transitions in the water-oxidizing enzyme system and may be involved in protonation/deprotonation reactions coupled with H_2O oxidation.[170, 182, 183] In addition, reversible $Cl^{\ominus}$ binding to the redox states S_i possibly influences their thermodynamic properties.[181, 184] EXAFS measurements practically exclude the participation of $Cl^{\ominus}$ as a bridging ligand between the manganese centers[183, 185]—a function similar to that involved in inner-sphere electron-transfer processes between complexed transition-metal ions in solution (for a review see Ref. [186]). The EXAFS data show that the distance between bound $Cl^{\ominus}$ and Mn is at least 3–4 Å.[141] Furthermore, the superhyperfine splitting of the multiline EPR signal indicates that $Cl^{\ominus}$ is not very likely to be directly associated with the Mn of the functional group.[187]

The first evidence for a possible function of $Ca^{2\oplus}$ came from measurements of O_2 production in cyanobacteria.[188, 189] After depletion of regulatory subunits (see Section 4.6.2) from PS II membrane fragments of higher plants (e.g., by salt treatment, see Refs. [190, 191]), a restoration of the O_2-evolving activity can be achieved solely by the addition of $CaCl_2$.[192, 193] It was concluded that the lack of $Ca^{2\oplus}$ blocks the following reaction:[194]

$$Z^{ox}S_3 + 2\,H_2O \longrightarrow ZS_0 + O_2 + 2\,H^{\oplus}$$

Recently, a partial restoration of the ns-kinetics of $P680^{\oplus}$ reduction, which is specific for $Ca^{2\oplus}$, was found for

[*] Examples of ADRY substances: derivatives of carbonylcyanida and α-acyl-α-cyanocarbonylphenylhydrazones, of 2-anilino-3,5-dinitrothiophenes [158b] and of dipicryle-mine [158c].

PS II membrane fragments that had been modified by mild proteolysis.[195] Thus, $Ca^{2\oplus}$ appears to be essential for the functional coupling of the catalytic site with the reaction center.[195, 196] Depletion of $Ca^{2\oplus}$ from its native binding site probably leads to a total blockage of the water-oxidizing enzyme system.[197] $Ca^{2\oplus}$ is bound to an intrinsic membrane protein, whose conformation is influenced by an extrinsically bound 24-kDa protein (see Section 4.6.2).[198] The nature of the $Ca^{2\oplus}$-binding protein and the function of $Ca^{2\oplus}$ are still unclear. Probably structural effects in the environment of the catalytic active site are essential.[195]

4.6.2. *Polypeptide Structure of the Water-Oxidizing Enzyme System*

Generally, the processes at the catalytic center of an enzyme are directly affected by the nature of the apoprotein. Additional polypeptides, which are not functional parts of the catalytic site, can act as regulatory subunits to influence indirectly the reaction sequence via structural changes. This was clearly demonstrated for the cytochrome oxidase enzyme system, which catalyzes the reverse reaction, i.e., the reduction of O_2 to H_2O (for reviews see Refs. [199, 200]). Interestingly the nature of the polypeptides constituting the catalytic center of cytochrome oxidase (Cu_B, $Cyt\,a_3$) has changed comparatively little during the course of phylogenetic evolution, while the number of regulatory subunits has increased markedly.[201] Therefore, it was thought that an analogous phenomenon might have also occurred for the water-oxidizing enzyme system.[51] These considerations led to questions about the nature of both the polypeptides (or polypeptide) that contain(s) the catalytic, binuclear manganese center and the proteins that act as regulatory subunits.

The apoprotein of the functional manganese group has not yet been identified. Possible candidates include CP47[196, 202] and an integral 34-kDa polypeptide,[203] which could be D-1[204] (or D-2) (see Section 3.2).

The stability of the manganese binding is enhanced by a lysine-rich extrinsic 33-kDa protein, which is attached to the membrane surface and is not related to the integral 34-kDa protein (the 34-kDa protein is encoded in the plastid DNA, the 33-kDa protein in the nuclear DNA[205]). Several lines of evidence indicate that the 33-kDa polypeptide does not directly participate in manganese binding: (1) Mn incorporation into the catalytic site during photoactivation takes place even in the absence of this polypeptide.[206] (2) The polypeptide does not contain histidine,[207] which plays an important role in the complexation of metal centers.[208] (3) Selective depletion of the 33-kDa protein leads to a marked decrease in the O_2-evolving activity but not to loss of manganese;[96] however, Mn binding does become destabilized.

Surface enhanced Raman-scattering spectroscopy (SERS) measurements led to the conclusion that the binuclear Mn group of the catalytic center is arranged at the surface of the binding protein that is in contact with the associated 33-kDa polypeptide. The measured Raman frequency of 225 cm^{-1} can be assigned to either a Mn–O or a Mn–N as well as to a Mn–Cl vibration.[209] Investigations with NH_2OH and NH_2NH_2 led to the conclusion that the H_2O binding site at the functional group has a dimension of $4 \times 2.5 \times 1.5$ Å.[210] However, recent investigations show that cooperative binding of two NH_2NH_2 molecules takes place at or near the catalytic center.[211, 212] This means that either the H_2O binding site is flexible in dimension or the above-mentioned calculation has to be modified.

The 33-kDa polypeptide is an essential regulatory subunit, which appears in all O_2-evolving, photosynthetic organisms so far analyzed. The close relationship of this subunit between different species is shown by immunological cross-reactions with appropriate antibodies[213] and by reconstitution experiments.[214] Besides this universal regulatory subunit of the water-oxidizing enzyme system, there are additional polypeptides possessing regulatory functions. Like the corresponding subunits of cytochrome oxidase,[201] these polypeptide subunits have undergone marked variation during the course of phylogenetic development. This appears to be a general phenomenon of enzyme systems that can make the redox system H_2O/O_2 biologically "available" for the processes of photosynthesis and respiration. In higher plants a 17-kDa and a 24-kDa polypeptide, which do not appear in cyanobacteria,[215] are well characterized.[216] The 24-kDa polypeptide influences the effect of $Ca^{2\oplus}$[198] and simultaneously increases the effective concentration of $Cl^{\ominus}$.[217] After depletion of the 24-kDa polypeptide (by NaCl treatment), part of the water-oxidizing enzyme system is functionally disconnected from the reaction center; rebinding of the polypeptide leads to restoration of the ability to produce O_2.[218, 219] To what extent this effect correlates with a change in $Ca^{2\oplus}$ affinity has yet to be shown quantitatively. The 17-kDa polypeptide binds specifically to the 24-kDa subunit[220] and also leads to an increase in the effective $Cl^{\ominus}$ concentration in the water-oxidizing enzyme system. Recently, several other polypeptides were discovered in the range of 4–6 kDa[221] whose functions in photosystem II are still unclear.

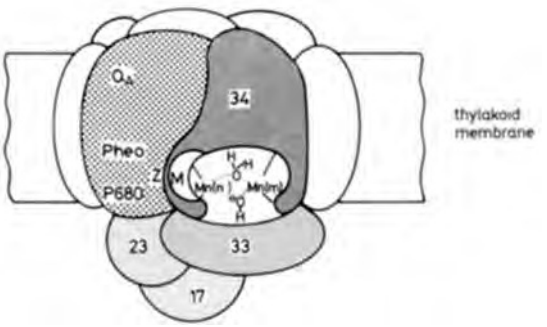

Fig. 14. Scheme of the structural organization of the water-oxidizing enzyme systems in higher plants. In contrast to Fig. 2, the catalytic active site of the water oxidation (black circle in Fig. 2) is specified and the three well-characterized regulatory polypeptides (17, 23, and 33 kDa) are explicitly shown. Further polypeptides with unknown functions are not shown; $Ca^{2\oplus}$ and $Cl^{\ominus}$ are also omitted, because only little is known about their binding sites (see text). The components P, I, and A of Fig. 2 are shown in their identified form (P680, Pheo, Q_A). The different shading of the polypeptide complexes in the membrane only corresponds to their function (reaction center, dotted; water-oxidizing enzyme system, dark grey; PQ-reducing enzyme, white). These differences do not stringently imply different polypeptides (e.g., the whole 34-kDa polypeptide may participate in binding of reaction center components and the catalytic active site of water oxidation; see Sections 3.2 and 4.6.2).

Summarizing the results outlined above leads to the highly simplified scheme for the structural organization of the water-oxidizing enzyme system shown in Figure 14. Only the binuclear Mn center where the water oxidation takes place is shown. The other two manganese atoms, which are also of importance for the H_2O oxidation,[94] are not shown because their role and exact structural arrangement have not yet been fully determined. Analogously to laccase[222] or cytochrome oxidase,[85] both of these Mn centers could participate in the electron transport from the catalytic site to the reaction center[51] or constitute the component M[125] or contribute to the stabilization of the geometry at the catalytic site via hydrogen bonding of H_2O molecules of the coordination sphere.[223] For the sake of simplicity in Figure 14, only the well-characterized 17-, 24-, and 33-kDa polypeptides are shown as regulatory subunits.

4.6.3. Possible Function of Lipids in the Water-Oxidizing Enzyme System

A comparison of the structural and functional organization of the water-oxidizing enzyme system with that of cytochrome oxidase leads directly to a further general question: What role do lipids play as essential and specific components for the function of these enzyme complexes? The negatively charged lipid cardiolipin is associated via a comparatively strong noncovalent bond with cytochrome oxidase and is crucial for its catalytic activity.[224,225] An analogous effect may also exist for the water-oxidizing enzyme system, because the negatively charged lipid sulfoquinovosyldiacylglycerol is relatively tightly bound to PS II protein complexes.[226] The O_2-evolving rate of PS II membrane fragments whose lipid content was decreased by detergent treatment during the preparation was stimulated up to 80% by the addition of lipids.[227] Therefore, lipids may also be of functional significance for the activity of the water-oxidizing enzyme system. Interestingly, in contrast to most of the lipids of the thylakoid membrane, sulfoquinovosyldiacylglycerol contains a high percentage of saturated fatty acids. This could suggest that the acidic lipid is bound to protein. However, the possible functional role of lipids in enzyme systems and especially in the water-oxidizing enzyme system is still totally unknown. Therefore, lipids were not included in Figure 14.

5. The PQ-Reducing Enzyme

The reductive formation of plastohydroquinone (PQH_2) from plastoquinone (PQ) requires the cooperation of two electrons. Analogously to water oxidation, the reduction of PQ to PQH_2 takes place via a sequence of one-electron redox steps.[228,229] In this process, one PQ molecule of the pool is statistically associated with a special binding site. After accepting one electron from $Q_A^{\ominus}$ of the reaction center (see Section 3.1), the newly formed semiquinone, which is designated $Q_B^{\ominus}$, is highly stabilized at the binding site.[*] A second electron transfer from $Q_A^{\ominus}$ leads to the formation of the redox state of a plastohydroquinone. The plastohydroquinone, formed by protonation, is bound relatively weakly and is replaced by another oxidized PQ molecule of the pool (for a review see Ref. [230]). The binding site of Q_B is located within a 32-kDa polypeptide, called D-1 (see Section 3.2). A high-spin $Fe^{2\oplus}$, which is probably coordinatively bound to four histidine residues of the polypeptides D-1 and D-2, is located between Q_A and Q_B (for a review see Ref. [231]). It has been proposed that this $Fe^{2\oplus}$ undergoes transient valence change to $Fe^{3\oplus}$ via a so-called "push-pull" mechanism, thereby participating directly in the electron transport from $Q_A^{\ominus}$ to Q_B (or $Q_B^{\ominus}$).[232] Recent investigations of the isolated reaction centers of photosynthetic purple bacteria have shown, however, that the kinetics of electron transfer are practically unaffected by depletion of $Fe^{2\oplus}$.[233] Interestingly, after depletion of $Fe^{2\oplus}$, the photochemical quantum yield of $Q_A^{\ominus}$ formation in the reaction center decreases significantly. This effect is caused by a 20–50-fold retardation of the electron transfer from bacteriopheophytin to $Q_A^{\ominus}$.[24] The incorporation of other bivalent cations ($Mn^{2\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$, $Cu^{2\oplus}$, $Zn^{2\oplus}$, but not $Mg^{2\oplus}$ or $Ca^{2\oplus}$) into the $Fe^{2\oplus}$ binding site leads to the restoration of the electron transport rate and the high quantum yield.[233] The results show that neither $Fe^{2\oplus}$ itself nor another bivalent cation is required for the fast electron transfer from $Q_A^{\ominus}$ to Q_B (or $Q_B^{\ominus}$). Instead, the $Fe^{2\oplus}$ is necessary in situ in order to establish the special functional properties of Q_A.

Recently, it was shown that the properties of the PQ-reducing enzyme are changed after detergent treatment.[234–236] This could suggest that the interaction with specific lipids is of functional significance for this polypeptide.

6. Reaction Scheme of the Photosynthetic Water Splitting

A summary of the results and models discussed in this review article for the mechanism of photosynthetic water splitting is given by the reaction sequence depicted in Figure 15.

7. Future Aspects

This short review has attempted to show what functional and structural principles are used by biological systems in order to exploit solar energy by water cleavage, leading to the formation of a biological "hydrogen-oxygen chain" involving bound hydrogen. The intensive research activities of the last two decades have led to important insights into the organization pattern of the entire process. However, essential mechanistic aspects are still not understood. Moreover, the significance of protein dynamics for the regulation of the individual reaction steps and for their coupling to the entire process is still unclear. Hopefully, new knowledge, especially in the field of protein physics and the fast developing area of molecular dynamics, will lead to a deeper mechanistic understanding of photosynthetic water

[*] In Figure 4, Q_A and Q_B refer to two different quinones.

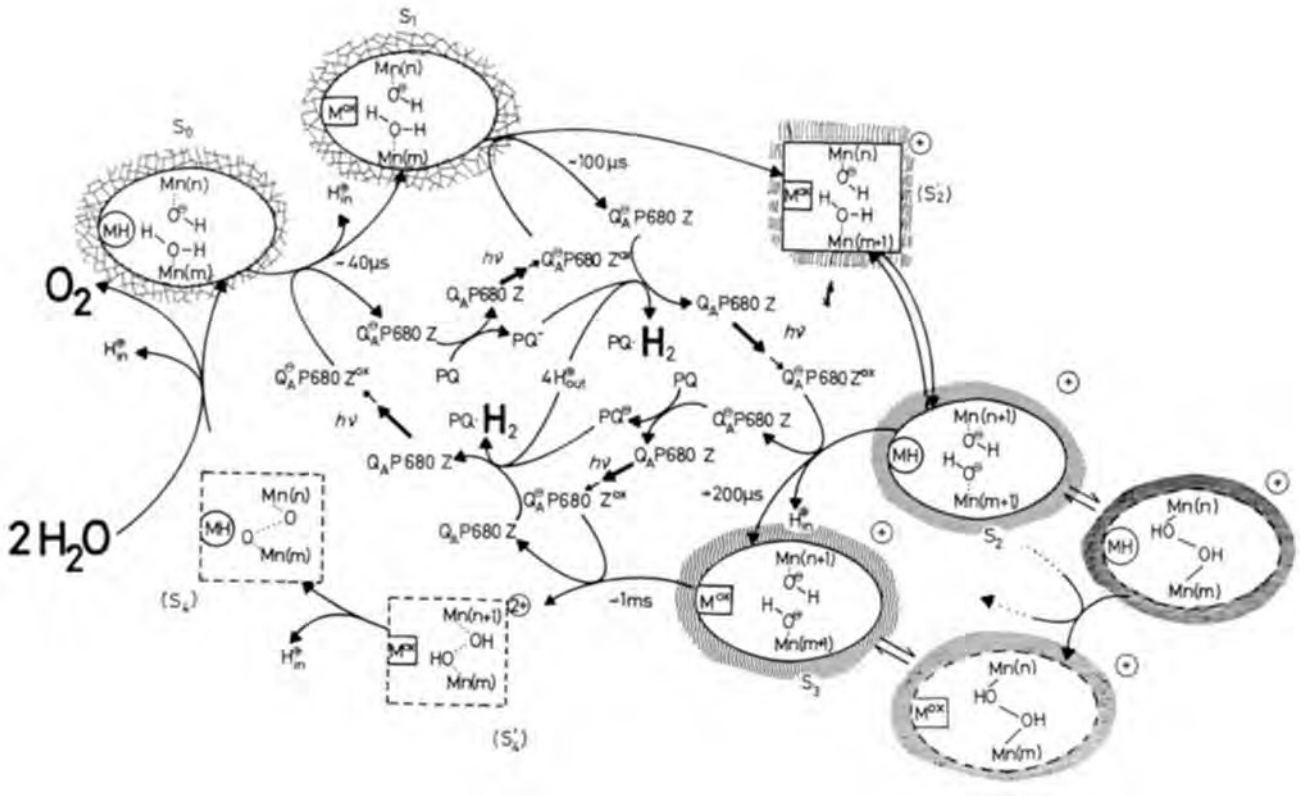

Fig. 15. Reaction scheme of photosynthetic water cleavage in photosystem II. The reaction sequences of the functional units are indicated by different shades of grey: (1) The grey circle in the middle symbolizes the reaction sequence in the reaction center, but the oxidation of Z by $P680^{\oplus}$ is not explicitly shown. (2) The outer circle represents the reaction sequence in the catalytic site of the water-oxidizing enzyme system and the inner white area shows the reaction sequence of the PQ-reducing enzyme. The catalytic site of the water oxidation is only symbolically shown because neither the ligand sphere nor the nature of M is known; n and m characterize the valence state of manganese (see text). The protein environment is indicated by hatched areas. For different conformational states in S_0, S_1 and S_2, S_3, different symbols are used (see Section 4.5 and Ref. [143]). The other symbols are described in the text. Supposedly, S_2 and S_3 are positively charged (in contrast to the other redox states), but it has so far been impossible to localize these charges. With respect to the deprotonation pattern, m and n are assumed to be different, so that deprotonation takes place at higher valence states of manganese ($n > m$) during $O_2/2H_2O$ ligand exchange. If the oxidation $M \rightarrow M^{ox}$ only corresponds to a special redox transition at the catalytic manganese with a small redox potential difference (see Section 4.5), then n should be equal to m and, in S_0, the binuclear manganese site would attain the redox state n and $n-1$. The possibility of a charge transfer from the substrate ligands to the central atoms accompanied by the formation of a µ-peroxo bridge [see Eq. (7)] is considered in the scheme. In accordance with the extrinsic deprotonation pattern, M presumably releases one $H^{\oplus}$ during oxidation.

cleavage as the central process of biological solar energy exploitation.

I would like to thank all my collaborators for their enormous efforts, their enthusiasm, and their excellent teamwork. Without their engagement, much of the work reported in the cited papers would have been impossible. I am very grateful to my colleagues from abroad for international collaboration, especially to the members of the solar energy group headed by Dr. Inoue (RIKEN, Japan) and to Dr. A. W. Rutherford (Saclay, France). For their special contributions, critical reading of the manuscript, and useful hints, I would like to thank H. J. Eckert, P. Gräber, B. Hanssum, K.-D. Irrgang, and M. Völker. I also thank A. Bowe-Gräber for drawing the figures. The financial support of our research by the Deutsche Forschungsgemeinschaft (Einzelprojekte und Sfb 312), the Fonds der Chemischen Industrie, the Bundesministerium für Forschung und Technologie, and the EPR-Sondervermögen is gratefully acknowledged.

Molecular Structure of a [3]-Catenate: Curling Up of the Interlocked System by Interaction between the Two Copper Complex Subunits**

By *Christiane O. Dietrich-Buchecker, Jean Guilhem, Abdel Kader Khemiss, Jean-Pierre Kintzinger, Claudine Pascard,* and *Jean-Pierre Sauvage**

Interlocked macrocyclic systems have appeared as fascinating molecules for many years.[1, 2] The templating properties of transition metals have recently been taken advantage of for interlocking coordinating acyclic molecules,[3] leading to catenands after demetalation of the corresponding catenates. [3]-Catenanes, consisting of three interlocked rings, have been synthesized by *Schill* et al.[4] [3]-Catenates have been prepared very recently[5] by using a surprisingly efficient synthetic procedure based on the oxidative coupling of terminal diynes.[5b] We now report both the crystallographic study and an NMR solution study of $1^{2\oplus}$. Both methods demonstrate that $1^{2\oplus}$ has a geometry dramatically different from that implied by Figure 1.

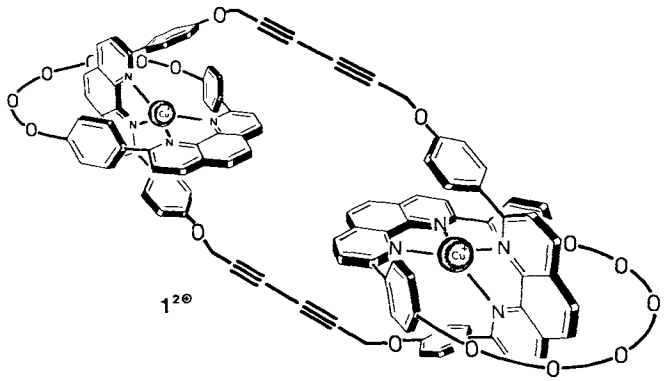

Fig. 1. Formula of the [3]-catenate $1^{2\oplus}$. The curved linkages joining the oxygen atoms correspond to CH_2CH_2 units.

[**] This work was supported by the Centre National de la Recherche Scientifique (CNRS). We would like to thank *P. Maltese* for his contribution to the NMR study.

The dicopper(I) complex $1^{2\oplus}$ contains two peripheral 30-membered rings separately interlocked with a central 44-membered ring. The molecular structure of $1^{2\oplus}$, as determined by X-ray diffraction, is shown in Figure 2. Owing to the large size of $1^{2\oplus}$, a tight packing is not possible; channels are formed, parallel to the *b* axis, in which solvent molecules and anions can be located. A clearly distinguishable CH_2Cl_2 molecule was localized halfway between the 1,10-phenanthroline (phen) nuclei B and B′ of the large ring.

Previous crystallographic studies of a [2]-catenate and its corresponding [2]-catenand clearly showed that the molecular shapes are dramatically different for both systems, a complete conformational change of the molecule taking place upon complexation.[6] The molecular structure of $1^{2\oplus}$ is strikingly different from the structure shown in Figure 1, which was drawn before any conformation or crystallographic study. The globular shape of $1^{2\oplus}$ is obvious from the view given on the cover of this issue. Figure 2 represents another view of $1^{2\oplus}$. The bottom half of Figure 2 clearly shows the folding up of the large central ring B, whose phen subunits are almost parallel (dihedral angle 7°) and 7.7 Å apart. The diacetylenic chains are also parallel to one another and located 10.5 Å apart. The four oxygen atoms of the 44-membered ring B form a 10.5-Å × 8.0-Å rectangle and the phenyl rings consist of two pairs of nearly parallel nuclei (dihedral angles φ1B, φ1B′ 6° and φ2B, φ2B′ 14°).

The 30-membered rings A and C are placed as bracelets in an approximately parallel fashion, their respective phen nuclei being similarly tilted with respect to the two corresponding phen subunits of the central ring (dihedral angle phen A, phen B 57°8 and phen C, phen B′ 58°2). The copper(I) centers are only 8.0 Å apart.

Some important structural features are collected in Table 1. Each aromatic ring is in close contact with another

Table 1. Some important distances between nuclei [Å] and angles [°] between aromatic rings [a] and the interatomic distances between the oxygen atoms of a 2,9-diphenyl-1,10-phenanthroline (dpp) fragment. The standard deviations values are 0.1 Å and 1°, respectively.

Aromatic nuclei		Distance			Dihedral angle

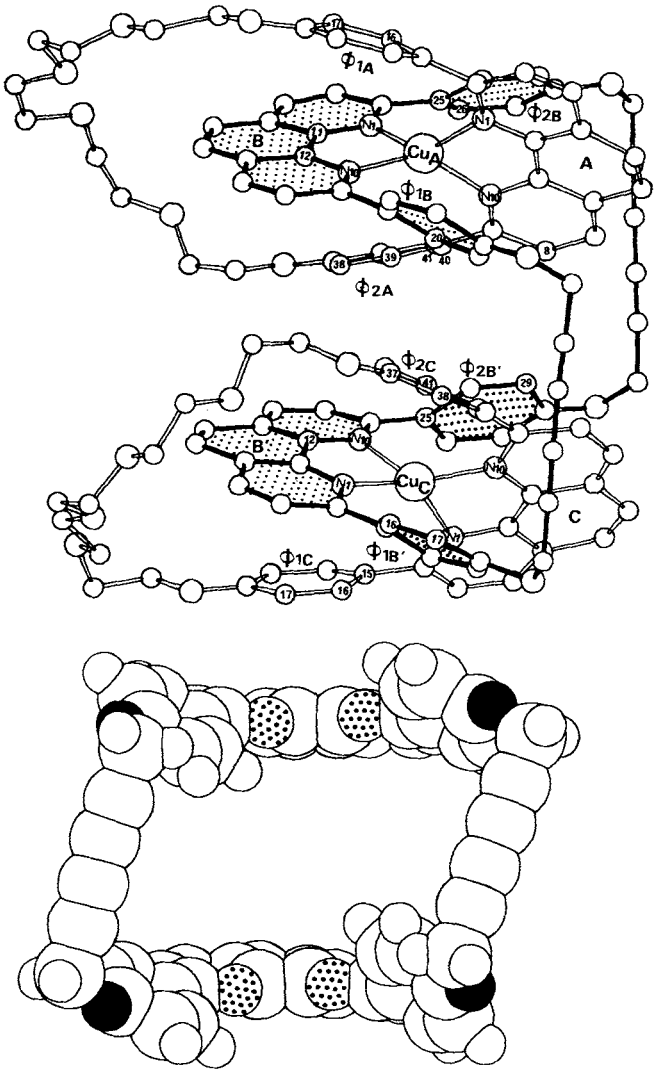

Fig. 2. Top: Computer drawing of the crystal structure of $1^{2\oplus}$. The carbon atoms of the 44-membered ring are yellow, those of the two 30-membered rings are green and light brown. The copper (I) centers are purple; the nitrogen and oxygen atoms are blue and dark red, respectively. Middle: Crystal structure of $1^{2\oplus}$. Bottom: Conformation of the central ring B of $1^{2\oplus}$ in the solid state showing the folding up of B and its boatlike shape. N atoms, dotted; O atoms, black.

one (distance less than 3.5 Å), a rough parallelism being observed (dihedral angles range between 9° and 35°; average value 20°). All the phenyl rings are rotated around their link to their respective phen nucleus, the average torsion angle being 43° (35° to 51°).

The geometry of the 2,9-diphenyl-1,10-phenanthroline (dpp) subunits is different for both types of rings. In B, no distortion is observed, whereas in the peripheral rings A and C, the phen nucleus is nonplanar and the dpp fragment undergoes a noticeable pinching. The closure of the angle between the phenoxy moieties (from 60° to 50°) is evidenced by the shortening of the oxygen–oxygen distance, the latter being normal in the large ring B.

As shown by the data collected in Table 2, the coordination polyhedra around the copper atoms are not equivalent: around Cu_A, the two phen nuclei are symmetrically disposed, but around Cu_C, phen C slides so that one of its N atoms lies in the phen B′/Cu_C plane, leading to a geometry similar to that of the copper(I) [2]-catenate previously studied.[6]

Table 2. Structure details of the coordination polyhedra around the Cu centers.

The curling up of $1^{2\oplus}$ and the close proximity of the two copper(I) complex subunits could be detected, independently of the crystallographic study, by ^{1}H-NMR solution measurements. The ^{1}H-NMR spectrum of $1^{2\oplus}$ and an NOE difference spectrum are presented in Figure 3. The ^{1}H-NMR spectrum and the ^{13}C-NMR spectrum[8] are as expected for a molecule containing (1) two dpp fragments entwined around a copper(I) center, (2) a $CH_2(CH_2OCH_2)_4CH_2$ link, and (3) a propargylic group. The assignment of all the hydrogen atoms was obtained by a dipolar correlation 2D NMR[9] experiment, allowing the unambiguous distinction between the signals corresponding to the 30-membered rings A and C (starting from $OCH_{2\alpha}$) and those of the central ring B (starting from the propargylic CH_2 group).

The signals of all the hydrogen atoms belonging to the dpp moiety of $1^{2\oplus}$ are shifted upfield compared with the corresponding signals of the same fragment in the [2]-catenate consisting of two 30-membered rings.[1, 10] This shielding indicates that the phenyl–phenyl and phenyl–phen stackings between the two complex subunits are retained in solution. The analogy between the molecular shapes in the solid state and in solution is also confirmed by the observation of a nuclear Overhauser effect (NOE) between H_{m} of the 44-membered ring and $H_{3,8}$ of the pe-

ripheral rings (Fig. 3, top). Indeed, such an NOE would be very difficult to explain without a curled-up conformation of the central ring. In fact, a particularly short distance is found in the solid state (Table 1): H8A and H29B′ (corresponding respectively to an $H_{3,8}$ of ring A and an H_m of ring B) are 2.30 Å apart.

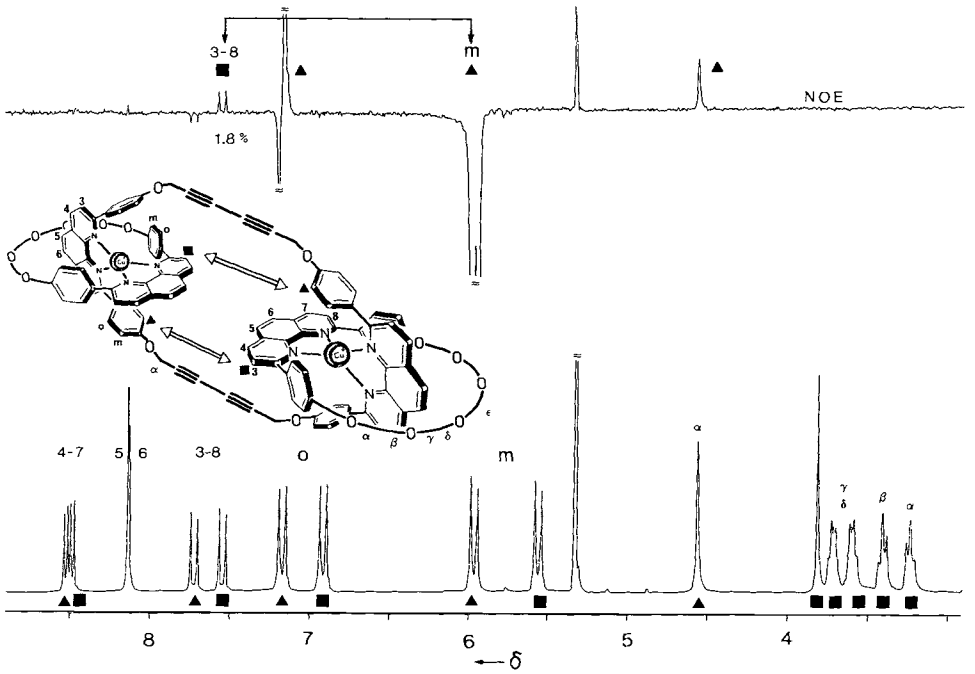

Fig. 3. ^{1}H-NMR spectrum of $\mathbf{1}^{2\oplus}$ (200 MHz) in CD_2Cl_2 (top). The signals indicated by a solid square belong to rings A and C whereas those marked by a solid triangle correspond to the large ring B. The difference spectrum (bottom) obtained by partial saturation of H_m (ring B) shows a clear Overhauser effect [7] on the propargylic OCH_2, a multiplet effect on H_o, a slight and negative three-spin effect on $H_{3,8}$ (ring B) and an effect amounting to 1.8% on $H_{3,8}$ (rings A and C). The H_m (ring B)-$H_{3,8}$ (ring A and C) interaction is indicated by a double arrow. In the solid state the interfragment contacts between H_m (ring B) and $H_{3,8}$ (rings A and C) are clear (see Table 1 and Fig. 2).

The folding up of the 44-membered ring and the subsequent globular shape of the molecule might be explained by a stabilizing π–π interaction between the aromatic rings belonging to the two copper complex subunits. It is noteworthy that the "ternary structure" of $\mathbf{1}^{2\oplus}$ (by analogy to proteins) is stable enough to be maintained in solution. The curled-up geometry of $\mathbf{1}^{2\oplus}$ and the internal stacking observed are reminiscent of recently reported systems consisting of a cationic noble-metal complex linked to a large macrocyclic polyether (second-sphere coordination) which has to fold up in order to adjust its geometry to the shape of the bound transition-metal complex.[11]

Experimental Procedure

Crystallographic study: Crystals of $\mathbf{1}^{2\oplus}[BF_4]_2$ (0.5 mm × 0.3 mm × 0.1 mm) were grown from CH_2Cl_2/C_6H_6 and sealed in a capillary tube. Intensity data collected at 1.1-Å resolution ($\theta_{max} = 45°$) with an automatic Philips PW 1100 diffractometer. Wavelength 1.5418 Å; graphite monochromator. From 10472 measured reflexions, 5561 ($I < 3\sigma(I)$) were used in the computations. Final R value: 14% for 181 identified atoms in the asymmetric unit. $[C_{128}H_{104}N_8O_{16}Cu_2][BF_4]_2$: $M_r = 2309$; monoclinic, $P2_1/a$; $a = 28.355(16)$, $b = 31.262(18)$, $c = 15.115(10)$ Å, $\beta = 103.9(2)°$, $V = 12980$ Å^3, $Z = 4$, $\rho_{calcd} = 1.18$ (12% solvent, CH_2Cl_2 and benzene). Further details of the crystal structure investigation are available on request from the director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), on quoting the name of the author and the journal citation.

NMR study: Spectra were run either on a Bruker WP 200 SY or on a Bruker AN 400 spectrometer with standard software. They were obtained from a degassed and sealed 5-mm sample tube containing about 2.5 mg of $\mathbf{1}^{2\oplus}$ in 0.5 mL of CD_2Cl_2.

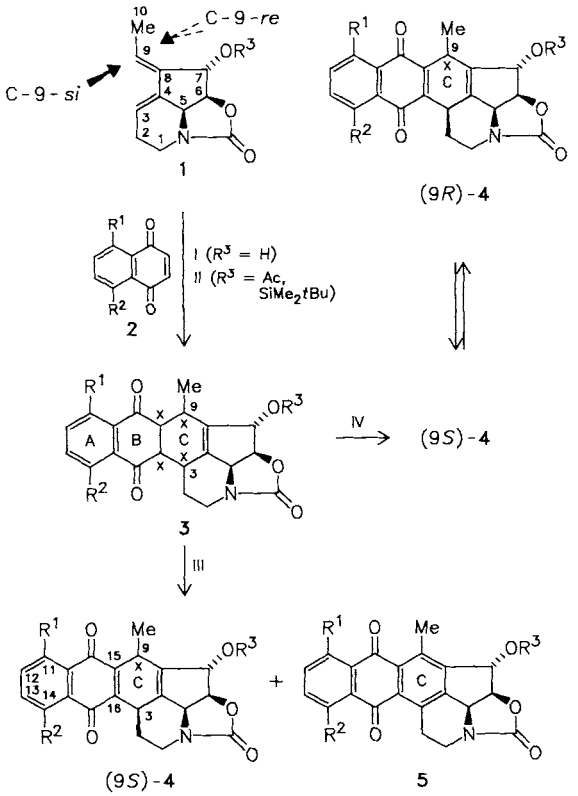
New Lead Structures by Diels-Alder Reactions of Streptazolin with Naphthoquinones**

By *Susanne Grabley, Heinz Kluge*, and *Hans-Ullrich Hoppe**

Dedicated to Professor Heinz Harnisch on the occasion of his 60th birthday

An important current goal of screening natural products[1] is the discovery of novel lead structures, which, possibly after derivatization, exhibit interesting pharmacological properties. Diels-Alder reactions of naphthoquinones **2** with streptazolin **1**,[2,3] which was reported for the first time in 1981 and has been isolated from various strains of *Streptomyces luteogriseus* in our natural-products screening program, have enabled us to attain this goal.

The metabolite **1** can be obtained in yields of more than 300 mg/mL from culture filtrates by centrifugation, extraction with ethyl acetate, and subsequent chromatography on silica gel, thereby affording adequate amounts of this chiral diene. In contrast to streptazolin **1**, the new compounds **3**, **4**, and **5** have striking antibiotic and cytotoxic properties.



Scheme 1. Diels-Alder reactions: I: toluene, 100°C, 4 h. II: $AlCl_3$ or $TiCl_4$, −20 to 0°C, 30 min. Oxidation: III: aqueous sodium hydroxide, air, room temperature, 15 min. IV: pyridine, oxygen, water-free, room temperature, 4 h. **a**, $R^1=R^2=H$; **b**, $R^1=R^2=OH$; **c**, $R^1=R^2=OAc$; **d**, $R^1=OH$, $R^2=H$; $R^3=H$, Ac, $SiMe_2tBu$. In addition, the reactions of derivatives with R^1, $R^2=OMe$, OCH_2Ph, $R^3=SiMe_3$, Glu, Glu-Ac_4 were investigated. x designates the newly formed center of chirality. The (unsystematic) numbering is intended for assignment of the NMR signals.

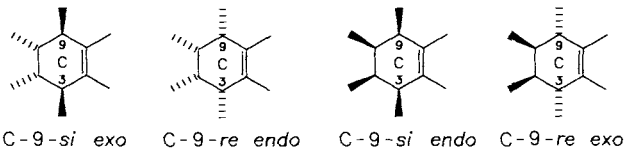
[**] This work was supported by the Bundesministerium für Forschung und Technologie. We thank Dr. *Kraemer* (Behringwerke), Dr. *Raether*, and Prof. *Siebert* (Hoechst) for carrying out the tests for cytotoxicity as well as antibiotic and other effects, Dr. *Voelskow* (Hoechst) for the microbiological work, and Professor *Laatsch* (Universität Göttingen) for helpful discussions.

The thermal cycloaddition of **1** to **2** can be carried out either at elevated temperatures (I in Scheme 1) or, if the hydroxyl groups are protected as acetates or silyl ethers, under Lewis acid catalysis (II). The yields by either route are over 90%. Mixtures of Diels-Alder adducts **3** are obtained, which can be only partly separated on silica gel but can be completely separated by analytical HPLC on RP18. Assuming a concerted mechanism for the Diels-Alder reaction, the symmetrical dienophiles **2a**-**2c** could yield, in principle, four stereoisomers (Scheme 2), whereas the unsymmetrical juglone **2d** could yield eight isomers owing to the possible regioisomers.[4]



Scheme 2. The four possible configurations of the ring C of **3** assuming a concerted Diels-Alder reaction.

The reactions of **2a**, **2b**, and **2d** with **1** do not exhibit pronounced *endo/exo* or diastereofacial selectivity. Three Diels-Alder adducts (five in the case of **2d**) are obtained, one of which predominates in each case depending on the dienophile used, as shown by the ^{1}H-NMR spectra of the reaction mixtures.[5]

This variety of products is welcome in terms of our search for new lead structures. However, despite the practically identical electronic substitution of the diene, the cycloaddition can also be carried out in a more controlled fashion. In the case of **2c**, the π-facial or *endo/exo* selectivity is significantly higher, the amounts of the two side products being reduced to less than 10%. Since we were able to determine the configuration at C-3 of **4b** (the oxidation product of **3c** after deacetylation) by ^{1}H-NOE measurements, we think that the main component of **3c** has the *endo* configuration as a result of attack of the dienophile from the C-9 *si* side of **1** (C-9 *si endo* in Scheme 2).

The oxidation of compounds **3** leads to both the more highly oxidized anthraquinones **5** and the 1,4-dihydroanthraquinones **4**, which can be differentiated unequivocably by NMR spectroscopy (Table 1) and can be separated on silica gel. Since, under the same conditions, **4** cannot be oxidized further to give **5**, compound **5** is not a subsequent product of **4**, but rather **4** and **5** are formed from different adducts.

Procedure III (Scheme 1) has been used to oxidize quantitatively all compounds **3** investigated so far; the ratio **4** : **5** varies depending on the pattern of substitution. In addition, epimerization at C-9 may be induced by control of the pH value. The two epimers (9*S*)-**4** and (9*R*)-**4** can be differentiated by ^{1}H-NMR spectroscopy and separated on silica gel. Comparison of the configurations of the 1,4-dihydroquinones **4** (see above for **4b**) with the theoretically possible configurations of the ring C (Scheme 2) leads us to conclude that compounds of type **4** are formed only from those isomers of **3** that arise by attack of the dienophiles from the C-9 *si* side of **1**. Procedure IV was developed for the oxidation of compounds **3** containing hydrolysis-sensitive substituents (R^1, R^2, R^3=OAc) and has so far afforded—although not quantitatively—exclusively 1,4-dihydroanthraquinones **4**.

Table 1. ^{1}H-NMR data for the compounds **3a**, **4b**, and **5a** (400 MHz, $CDCl_3$/TMS, dilute solutions, $T = 300$ K); (*) = assignment questionable.

3a, R^1 = H: $\delta = 1.160$ (d, 3H, $J(9,10) = 7.1$ Hz; H-10), 1.358 (tdd, 1H, $J(1a,2a) = 12$, $J(1b,2a) = 4.5$, $J(2a,2b) = -13$ Hz; H-2a), 1.957 (d, 1H, $J(15,16) = 7.0$ Hz; H-15), 2.03 (br., m, 1H, $J(1b,2b) = 1.5$ Hz; H-2b), 2.78 (br., 1H; 7-OH), 3.06 (m, 1H, $J(1a,1b) = -14.5$ Hz; H-1a), 3.06 (m, 1H, $J(3,16) = 4.5$ Hz; H-3), 3.09 (dd, 1H; H-16), 3.17 (br., 1H; H-9), 3.895 (ddd, 1H; H-1b), 4.419 (br. d, 1H, $J(5,6) = 6.0$ Hz; H-5), 4.708 (d, 1H; H-6), 4.74 (br., 1H; H-7), 7.771 (m, 1H, $J(11,12) = 8.0$, $J(12,13) = 7.4$, $J(12,14) = 1.5$ Hz; H-12 (*)), 7.779 (m, 1H, $J(11,13) = 1.1$, $J(13,14) = 7.6$ Hz; H-13 (*)), 8.014 (m, 1H, $J(11,14) = -0.6$ Hz; H-14 (*)), 8.091 (m, 1H; H-11)

4b, R^1 = H: $\delta = 1.307$ (tdd, 1H, $J(1a,2a) = 12.8$, $J(2a,2b) = -12.6$, $J(2a,3) = 11.2$, $J(1b,2a) = 4.5$ Hz; H-2a), 1.353 (d, 3H, $J(9,10) = 7.0$ Hz; H-10), 2.09 (br., 1H; 7-OH), 2.532 (dddd, 1H, $J(2b,3) = 4.4$, $J(1a,2b) = 2.9$, $J(1b,2b) = 1.7$ Hz; H-2b), 3.356 (ddd, 1H, $J(1a,1b) = -14.5$ Hz; H-1b), 3.780 (dtd, 1H, $J(3,9) = 4.5$, $J(3,5) = 0.9$ Hz; H-3), 3.918 (qdd, 1H, $J(5,9) = 2.2$ Hz; H-9), 4.015 (ddd, 1H; H-1a), 4.669 (ddt, 1H, $J(5,6) = 6.0$, $J(5,7) = 1.0$ Hz; H-5), 4.834 (d, 1H; H-6), 4.930 (br., 1H; H-7), 7.240 (d, 1H, $J(12,13) = 9.5$ Hz; H-12 (*)), 7.248 (d, 1H; H-13 (*)), 12.556 (s, 1H; OH), 12.640 (s, 1H; OH). The absolute configuration at C-9 is currently being determined by X-ray crystallography.

5a, R^1 = H: $\delta = 2.60$ (br., 1H; 7-OH), 2.845 (d, 3H, $J(2a,10) = 0.6$ Hz; H-10), 2.934 (dddd, 1H, $J(2a,2b) = -16.4$, $J(1a,2a) = 11.8$, $J(1b,2a) = 8.5$ Hz; H-2a), 3.370 (td, 1H, $J(1a,1b) = -12.1$, $J(1a,2b) = 6.2$ Hz; H-1a), 3.750 (ddt, 1H, $J(1b,2b) = 1.0$, $J(1b,5) = 0.8$ Hz; H-1b), 4.479 (ddd, 1H; H-2b), 4.960 (br. d, 1H, $J(5,6) = 6.1$ Hz; H-5), 5.108 (d, 1H; H-6), 5.436 (br., 1H; H-7), 7.771 (m, 1H, $J(11,13) = 1.3$, $J(12,13) = 7.4$, $J(13,14) = 7.8$ Hz; H-13 (*)), 7.781 (m, 1Hk $J(11,12) = 7.8$, $J(12,14) = 1.3$ Hz; H-12 (*)), 8.171 (m, 1Z, $J(11,14) = 0.6$ Hz; H-14 (*)), 8.191 (m, 1H; H-11)

Nearly all compounds **3**, **4**, and **5** are active against Gram-positive bacteria and yeast and some are even active against protozoa. Cytotoxicity was tested in vitro on leukemia cells of the type L 1210. Many compounds proved to be as effective as the standard compound adriamycin and were comparably less acutely toxic to mice. In those cases that afforded mixtures of stereo- and regioisomers in the syntheses, the mixtures themselves were initially tested. Only in very promising cases was subsequent separation carried out by HPLC on RP18 in methanol/water.

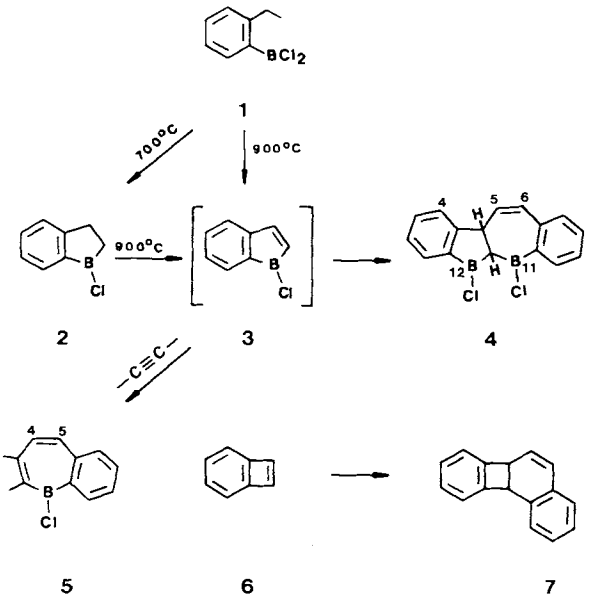
[5] The different Diels-Alder adducts **3** can be differentiated on the basis of the resonances of the methyl group at C-9 or the hydroxyl groups in the dienophile portion; e.g., for **3b**: $\delta(\text{C9-CH}_3) = 0.85$, 1.1, 1.16 (each d, $J = 7.1$ Hz); $\delta(\text{OH}) = 11.4$–12.2 (6 × s); intensities of each ca. 1 : 2 : 1.

The First Synthesis of a Benzoborole**

By *Wolfgang Schacht* and *Dieter Kaufmann**

Since the calculation of the geometries and resonance energies of boron-containing small-ring systems by *P. von R. Schleyer* et al.,[1] this field has also proven to be experimentally productive. So far, however, only highly substituted, sterically[2] or electronically[3] stabilized derivatives of antiaromatic boroles have been reported. Benzocyclobutadiene[4] **6**, which is related to the benzoborole **3**, has only been isolated at low temperatures. Since flash vacuum pyrolysis has already been used successfully for the generation of benzoannulated boracycloalkenes,[5] we have attempted to open up the first approach to benzoboroles via the pyrolysis of boraindanes. Matrix isolation appeared to offer a suitable way of isolating the borole derivatives, which, since they were substituted on only one side, were expected to exhibit very high reactivity.

1-Chloro-1-boraindane **2**[6] could be obtained in good yields (81%) by flash vacuum pyrolysis of dichloro(2-ethylphenyl)borane **1** at 700 °C/10^{-3} torr, without the formation of side products.[7] Dehydrogenation occurred at a pyrolysis temperature of 900 °C. At 77 K, the pyrolysate was intense yellow. The color largely disappeared upon warming to room temperature. Workup of the pyrolysate afforded colorless crystals of a dimer of **3** in a yield of 56%. According to ^{1}H-, ^{13}C-, and ^{11}B-NMR and mass spectroscopic data, this product is *cis*-11,12-dichloro-4b,11,11a,12-tetrahydro-11,12-diboradibenzo[*a*,*f*]azulene **4**.



The exclusive formation of the dimer **4** is also interesting in view of the similar reactivities of the benzoborole **3** and the related benzocyclobutadiene **6**, since, depending on the reaction conditions, **6** can react to give two different kinds of dimers, namely, the [2 + 2]cycloadduct dibenzotricyclooctadiene[8] and the product of a formal insertion reaction, the dibenzobicyclo[4.2.0]octatriene **7**.[9] Compound **7** corresponds structurally to the benzoborole dimer **4**, whose formation can be explained in terms of a regiospecific *syn*-vinylboration of a borole double bond with the B–C_{vinyl} bond of a second molecule of **3** upon warming of the matrix.

The yellow color of the cooled pyrolysate of **2** was a further indication for the initial formation of **3** since the crystals of *B*-chlorodibenzoborole are also yellow.[3a] ^{1}H-NMR spectroscopic identification of the monomer could not even be achieved at −90 °C. Apparently, **3** is very reactive, since, even at this temperature, it undergoes complete dimerization to **4**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Photoelectron spectroscopy (PES) allows the characterization of reactive molecules in high vacuum. Upon pyrolytic dehydrogenation (925 °C) of the boraindane **2** in the photoelectron spectrometer (He(I)), a new absorption band at lower ionization energy (8.53 eV) was observed, which can be assigned to the π ionization of a benzoborole.[10] Complete assignment of all the bands has not yet been possible, however, since, even at this temperature, the conversion is too low to separate all the bands of **2** and **3**.

Trapping reactions in the matrix further establish the formation of **3**. Whereas **3** could not be trapped with alkenes such as *Z*-butene or cyclopentadiene (dimerization is more rapid), it reacts smoothly with 2-butyne to give 1-chloro-2,3-dimethyl-1-benzoborepin **5**. This reaction opens up the first approach to the 10π-aromatic 1-benzoborepins; 3-benzoborepins are known.[11]

Reaction with electrophilic reagents such as DCl led to exclusive B–C_{vinyl} bond cleavage and formation of a 1:1 mixture of the *Z*- and *E*-[2-(β-deuteriovinyl)phenyl]boranes **8** and **9**, respectively. Their formation can be explained in terms of initial addition of $D^{\oplus}$ to the 2,3 double bond of **3**, followed by addition of the chloride ion to the boron atom and opening of the B–C2 bond.

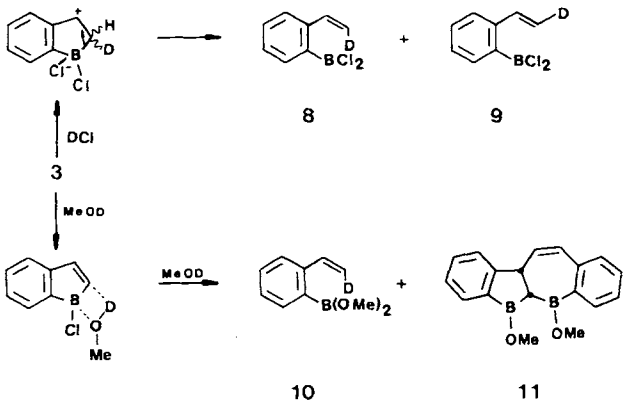

Table 1. Physical data for the compounds **4**, **5**, **8**–**10**, and **11**. NMR spectra: δ values, J in Hz, ^{1}H-NMR at 270 MHz.

4: yield 56%, colorless crystals, m.p. (sealed tube) = 78 °C. — ^{1}H-NMR (C_6D_6): 3.60 (d, $^3J_{4b,11a}$ = 5.6, 1 H, 11a-H), 3.66 (dd, $^3J_{4b,5}$ = 8.4, 1 H, 4b-H), 6.03 (dd, $^3J_{5,6}$ = 11.6, 1 H, 5-H), 6.31 (d, 1 H, 6-H), 6.64 (m, 2 H), 6.78 (m, 2 H), 7.06 (t, 1 H), 7.14 (d, 1 H), 7.52 (d, 1 H), 7.61 (d, 1 H). — ^{13}C-NMR (C_6D_6): 47.6, 68.5 (br.), 124.7, 126.5, 126.7, 129.4, 131.1, 132.0, 133.6, 134.3, 134.7, 135.0, 138.4 (br.), 140.6, 140.9 (br.), 166.5. — ^{11}B-NMR (toluene): 67.4. — MS (70 eV): *m/z* (%): 296 ($M^{\oplus}$, 92), 260 (100), 214 (96), 148 (38), 71 (27)

8 and **9**: yield 50%, colorless, very sensitive liquid, which could not be purified by distillation. — ^{1}H-NMR (C_6D_6): 5.09 (–CH=C*H*$D_{(trans)}$, $^3J_{trans}$ = 17.4, 1 H), 5.34 (–CH=C*H*$D_{(cis)}$, $^3J_{cis}$ = 10.9, 1 H) and 7.15 (–C*H*=CHD, 2 H, AB systems), 6.79 (t, 2 H), 7.70 (d, 2 H), 8.02 (d, 2 H), 8.10 (t, 2 H). — ^{11}B-NMR (C_6H_6): 49.8

10: yield 35%, colorless liquid. — ^{1}H-NMR (C_6D_6): 5.10 (–CH=C*H*$D_{(cis)}$) and 6.85 (–C*H*=CHD, AB system, 2 H), 7.10 (t, 1 H), 7.15 (t, 1 H), 7.28 (d, 1 H), 7.88 (d, 1 H)

11: yield 15%, colorless crystals, m.p. (sealed tube) = 55 °C. — ^{1}H-NMR (C_6D_6): 2.82 (d, 1 H, 11a-H), 3.64 and 3.73 (br. s, each 3 H, OCH_3), 3.85 (dd, 1 H, 4b-H), 6.37 (dd, 1 H, 5-H), 6.57 (d, 1 H, 6-H), 6.75–6.95 (m, 4 H), 7.10 (t, 1 H), 7.33 (m, 2 H), 7.48 (d, 1 H). — ^{11}B-NMR (*n*-hexane): 49.3. — MS (70 eV): *m/z* (%): 288 ($M^{\oplus}$, 88), 273 (54), 245 (25), 213 (78), 144 (44), 73 (100)

Cocondensation with the significantly more weakly acidic [D_1]methanol at 77 K, on the other hand, led, after warming of the matrix, to a mixture of the *Z*-[2-(β-deuteriovinyl)phenyl]borane **10** (73%) and the doubly methoxylated dimer **11** (27%). The stereospecific formation of **10** can be explained in terms of the cleavage of the B–C2 bond of **3**. Compound **11**, which was obtained independently by methanolysis of **4** at 0 °C, is presumably formed this way in the matrix as well, since no *E*-[2-(β-deuteriovinyl)phenyl]dimethoxyborane could be detected. Physical data for the new compounds are collected in Table 1.

The pyrolytic dehydrogenation of 2-chloro-2-boraindane[7] to the corresponding 2-benzoborole, on the other hand, was unsuccessful.

Vanadium Carbene Complexes by Reaction of (Diene)metallocenes with [CpV(CO)$_4$]**

By *Gerhard Erker,* Rainer Lecht, Rüger Schlund, Klaus Angermund,* and *Carl Krüger*

A large number of carbene complexes of nearly all the d elements have become accessible[1] by varying the reaction sequence developed by *E. O. Fischer* et al.[2] for the transformation of a carbonyl complex into a carbene complex. There are only a few transition metals that are not well represented with examples of this important class of ligand. One such transition metal is vanadium. To the best of our knowledge, only two special routes to simple Fischer-type vanadium carbene complexes have been described so far and supported by examples (Scheme 1).[3]

Carbene complexes may play an important role in vanadium-catalyzed olefin metathesis and polymerization reactions. Their availability could open up new routes to the

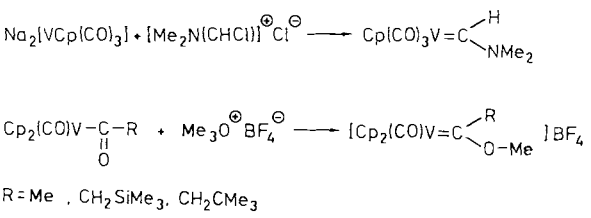
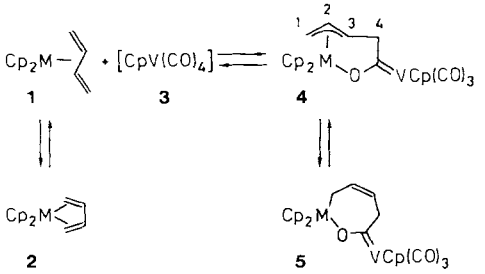


Scheme 1. Reported vanadium carbene complexes, Cp = η^5-C_5H_5.

preparation of proposed intermediates in vanadium-promoted oxidations.[4] The development of simple syntheses of vanadium carbene complexes is therefore of interest.

We recently described a new approach to the formation of heteroatom-stabilized carbene complexes from carbonyl complexes. In the key step, a metallacyclic oxycarbene complex is formed by C–C bond formation between an olefinic C atom of a reactive (η^2-olefin)metallocene complex and the C atom of an M–CO group.[5] Suitable reagents for this reaction are (*s-trans*-η^4-butadiene)zirconocene and -hafnocene.

The readily accessible equilibrium mixture of the *s-cis* and *s-trans* isomers **2a** and **1a**, respectively (**2a** : **1a** = 55 : 45)[6] reacts rapidly with $[CpV(CO)_4]$ **3** in toluene at room temperature, resulting in C–C bond formation between the zirconium-bound diene ligand and a V–CO unit (Scheme 2). The red oxycarbene complex **4a** precipitates from the reaction solution at room temperature.[7a]



a, M = Zr; **b**, M = Hf

Scheme 2. The (unsystematic) numbering of **4** is intended for the assignment of the NMR signals.

The X-ray structure analysis of **4a**[7b] reveals a binuclear Zr–V complex having the arrangement of ligands (Fig. 1) expected for a bent metallocene and a $CpVL_4$ group. Three of the C atoms derived from the butadiene ligand are bound to the zirconium center as a distorted π-allyl moiety.[8] The fourth C atom is coupled to a CO ligand which is bound to the vanadium center. Noteworthy features of the structure of **4a** are the short C1–O1 bond[5] (for comparison, see Ref. [2]) and the significantly lengthened V–C1 bond (compared with the other V–CO bonds).[9]

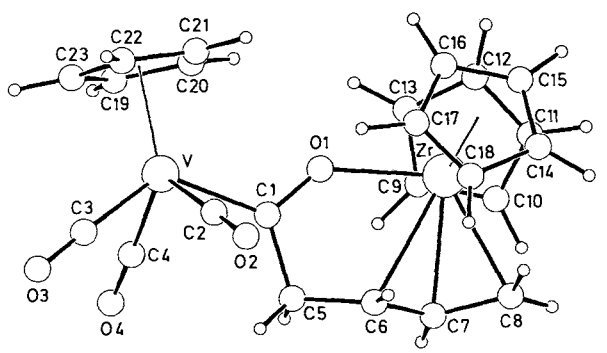


Fig. 1. Crystal structure of **4a**. Selected bond lengths [Å] and bond angles [°]: V-C1 2.102(3), V-C2 1.889(4), V-C3 1.899(4), V-C4 1.921(4), V-C19 2.302(4), V-C20 2.293(4), V-C21 2.268(4), V-C22 2.261(5), V-C23 2.286(4), C1-O1 1.270(4), C1-C5 1.545(5), C5-C6 1.505(5), O1-Zr 2.188(2), C6-Zr 2.653(4), C7-Zr 2.514(4), C8-Zr 2.443(4); V-C1-O1 120.7(2), O1-C1-C5 112.4(3).

The formation of the carbene complex is reversible in solution. When crystalline **4a** is dissolved in $[D_8]$toluene at room temperature, the educts **1a** and **3**, in addition to **4a** (ca. 1 : 1 : 1), can be detected almost immediately by ^{1}H-NMR spectroscopy. A subsequent equilibrium is then established between **1a** and the isomer **2a**. In order to use the carbene complex synthesis shown in Scheme 2, it is important that the position of the **1** + **3** ⇌ **4** equilibrium be easily controlled to give preferentially the vanadium carbene complex. Thus, reaction of **3** and the (η^4-butadiene)hafnocene system **1b**/**2b** gives the complex **4b** [65%, m.p. = 140 °C (dec.)],[10] which is not in equilibrium with the educts in solution at room temperature but rather with the seven-membered-ring σ-allyl isomer **5b** (which does not affect the preparative use of the carbene moiety).[10]

Experimental procedure

4a: (η^4-butadiene)zirconocene (0.82 g, 3 mmol), as an equilibrium mixture of **1a** and **2a**, and **3** (0.68 g, 3 mmol) were dissolved in 100 mL of toluene at 0 °C. The reaction mixture was allowed to warm to room temperature and then stirred for 4 h; the carbene complex **4a** thereby precipitated as an orange-red solid. After filtration and washing with petroleum ether, 1.06 g (71%) of **4a** was obtained. Suitable crystals for X-ray structure analysis were obtained by recrystallization from benzene. M.p. = 132 °C (dec.), correct elemental analysis (C,H).

[10] Spectroscopic data: **4b**: IR (KBr): $\tilde{\nu}$(CO) = 1925, 1840, 1820 cm^{-1}.—^{1}H-NMR (C_6D_6, 400 MHz): $\delta = 5.30$, 5.20 (Cp_2Hf), 4.90 (CpV), 1.35 (2H1), 4.65 (H3), 4.2 and 2.8 (H4 and H4'), H2 overlapped; **5b**: ^{1}H-NMR (C_6D_6, 400 MHz, room temperature): $\delta = 5.53$ (Cp_2Hf), 4.93 (CpV), 5.9, 4.8 (pseudo q, −CH=CH−), CH_2 groups not localized (for the dynamic behavior of similar oxametallacycloheptene compounds, see [8e]).

broad-band filter permitted selective excitation of the N=N π electrons ($\lambda_{max} \approx 350$ nm) without excitation of the aromatic π electrons of **1**, **3**, or **4**.

The formation of **3** and **4** is best explained by assuming the occurrence of the short-lived diradical intermediate **2**[2] after the photoinduced expulsion of a nitrogen molecule. Depending on its conformation, this diradical may undergo either ring-closure to give **3** or hydrogen transfer to give **4** (Scheme 1).

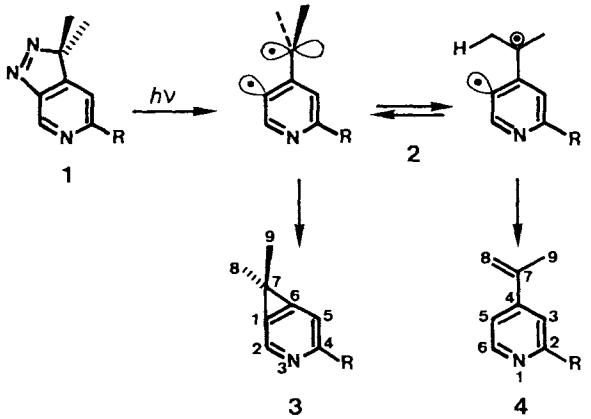
Synthesis and Structure of a Cyclopropapyridine**

By *Ramesh Bambal, Hans Fritz, Grety Rihs, Théophile Tschamber,* and *Jacques Streith**

Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

Ultraviolet photolysis (CH_2Cl_2/pentane, 10°C, MTO-A365b broad-band filter, medium-pressure mercury vapor lamp) of the known pyrazolopyridine **1**[1] led to the formation of the corresponding cyclopropapyridine **3** and the isomeric isopropenylpyridine **4** in moderate yields. The



Scheme 1. R = NH−COPh.

An X-ray structure analysis of **3** (Fig. 1) showed that the geometric parameters of the cyclopropene moiety and of its immediate surroundings were very similar to those that had been measured previously for a cyclopropabenzene derivative[3] and for a cyclopropanaphthalene.[4] The pyridine ring of **3** appears to have a normal geometry, an observation that is reminiscent of the structural similarity between benzene and cyclopropabenzene, or between naphthalene and cyclopropanaphthalene. It is worthy of note, however, that there is a lengthening of the C2–N3 bond (1.367 Å, instead of the normal bondlength of 1.335 Å for the C4–N3 bond), a result that is most likely the consequence of the shortening of the C1–C6 bond (1.344 Å).[5]

Compound **3** is the first cyclopropapyridine to have been synthesized.[6]

Experimental Procedure

In a typical experiment, a stirred solution of **1** (100 mg, 0.38 mmol) in CH_2Cl_2 (20 mL) and pentane (135 mL), which was kept under argon atmosphere at 10°C, was irradiated with a Philips HPK125 lamp for 5 h. The photolysis was stopped before consumption of **1** was complete. The reaction products were separated at 5°C by preparative thin-layer chromatography (TLC) (ethyl acetate/cyclohexane 1/9; Merck type E alumina). The following products were isolated in the order given (decreasing R_f values): **3** (24 mg, 27%), **4** (23 mg, 26%), and **1** (16 mg, 16%). As expected, **3** is sensitive toward acids and could not be purified by TLC on silica gel. In its crystalline state, it is quite stable when kept under argon at room temperature.

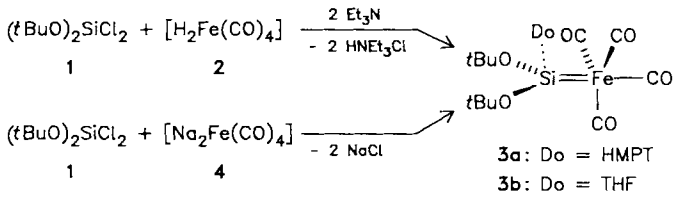
Synthesis and Structure of [(OC)$_4$Fe=Si(O*t*Bu)$_2$·HMPT], a Donor-Stabilized Silanediyl ("Silylene") Complex**

By *Christian Zybill** and *Gerhard Müller*

The existence of stable, monomeric silanediyl ("silylene") complexes was long in question.[1] A coordination of free silanediyls[2] to transition metals was previously assumed to occur only for reactive intermediates (for example, in platinum-catalyzed Si–Si coupling reactions[3]) or was observed in the gas phase by means of molecular beam experiments.[4] In contrast, the chemistry of the heavier homologues[5] of the carbene complexes is well established; particularly in the case of Sn, both donor-stabilized[6] and donor-free stannanediyl ("stannylene") complexes have been prepared.[7] We have now found that silylene complexes can be stabilized, both thermodynamically and kinetically, by bulky heteroatom substituents.



Starting from di(*tert*-butoxy)dichlorosilane **1**, the silylene complexes **3a**,**b** (THF = tetrahydrofuran) are accessible in two ways, each of which involves the use of the tetracarbonylferrate ion as the key reagent.[8,9] The colorless compounds **3a**,**b**, which sublime in high vacuum, are monomeric both in the solid state and in solution. In each case, the iron atom exhibits rigid trigonal-bipyramidal (tbp) coordination. According to the ^{13}C-NMR data, the FeSi bond undergoes unhindered rotation down to -30°C. Investigations at lower temperatures are difficult owing to the low solubility of **3a**,**b**.[10]

The X-ray structure analysis of **3a**[11] (Fig. 1) confirms this structural assignment. The silylene ligand occupies an apical position of the tbp-coordinated Fe fragment, which is a direct indication of its strong σ-donor properties.[12] The HMPT O atom is coordinated to the "unsaturated" Si atom and completes its distorted tetrahedral coordination sphere. The Si–O3 distance (1.730(3) Å) is significantly longer than the Si–O1 and Si–O2 distances (1.610(3) and 1.636(4) Å, respectively). The Fe–Si distance is 2.289(2) Å. A comparison with normal Fe–Si single bonds is difficult owing to the absence of reference compounds in which the Fe atom has a similar coordination number and oxidation state.[13]

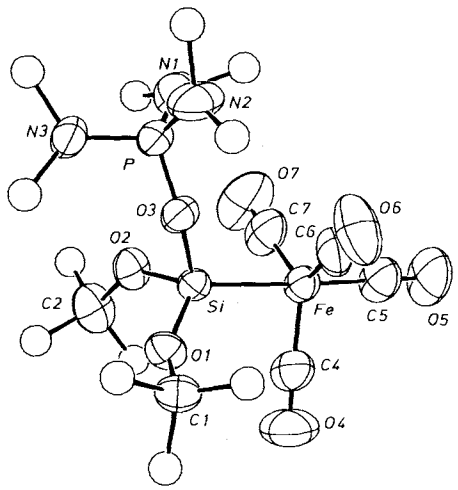


Fig. 1. Crystal structure of **3a** (ORTEP, thermal ellipsoids at the 50% probability level, methyl C atoms with arbitrary radii, without H atoms). Important distances [Å] and angles [°]: Fe-Si 2.289(2), Si-O1 1.610(3), Si-O2 1.636(4), Si-O3 1.730(3), P-O3 1.524(3), Fe-C4 1.754(7), Fe-C5 1.758(6), Fe-C6 1.769(7), Fe-C7 1.761(7); Fe-Si-O1 120.5(1), Fe-Si-O2 117.6(1), O1-Si-O2 104.0(2), O3-Si-Fe 112.1(1), O3-Si-O1 101.8(2), O3-Si-O2 97.5(2).

The deviations of the Si bond angles from the tetrahedral standard exhibit remarkable parallels to those of the donor adducts of silaethenes and silaketimines, which also form long bonds to the donor atoms.[14] As in those cases, the donor stabilization of **3a** presumably leads to a significantly lengthened Si–Fe bond in comparison with a "free" silylene complex. In **3a**, furthermore, the *t*BuO substituents also are expected to contribute to a lengthening of the Fe–Si bond.

Our results are in agreement with theoretical studies: According to ab initio SCF MO calculations, increased acceptor ability is predicted for nucleophilic attack on the Si atom of [(OC)$_5$Cr=SiH(OH)] in comparison with the carbene complex.[1] This explains the greater stability of the adducts **3a** and **3b**, which are presumably formed by nucleophilic attack on the donor-free system **3**.

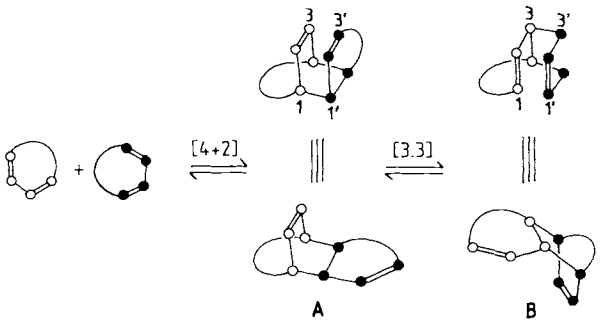
Proton-Controlled Equilibration between [4$^+$ + 2] and [4 + 2$^+$] Cycloadducts: A Characteristic Example for the Aberrant Diels–Alder Reactions between Two 1,3-Dienes**

By *Karin Beck* and *Siegfried Hünig**

The cleavage of *endo*-dicyclopentadiene to cyclopentadiene at ca. 200 °C is often cited as an example for the thermal reversibility of Diels–Alder reactions.[1] In just this case, however, *Woodward* and *Katz*[2] already showed unequivocally in 1959 that a degenerate Cope rearrangement occurs at 140 °C before the cycloreversion. Since *endo*-type [4 + 2] cycloadducts formed from two 1,3-dienes necessarily contain two double bonds in ideal positions for [3.3] rearrangements, this finding is of fundamental importance: An endo cycloadduct formed from two identical or different (hetero)-1,3-dienes can be formed either by a Diels–Alder reaction (**A**) or by a Diels–Alder reaction followed by a Cope rearrangement (**B**).[3]



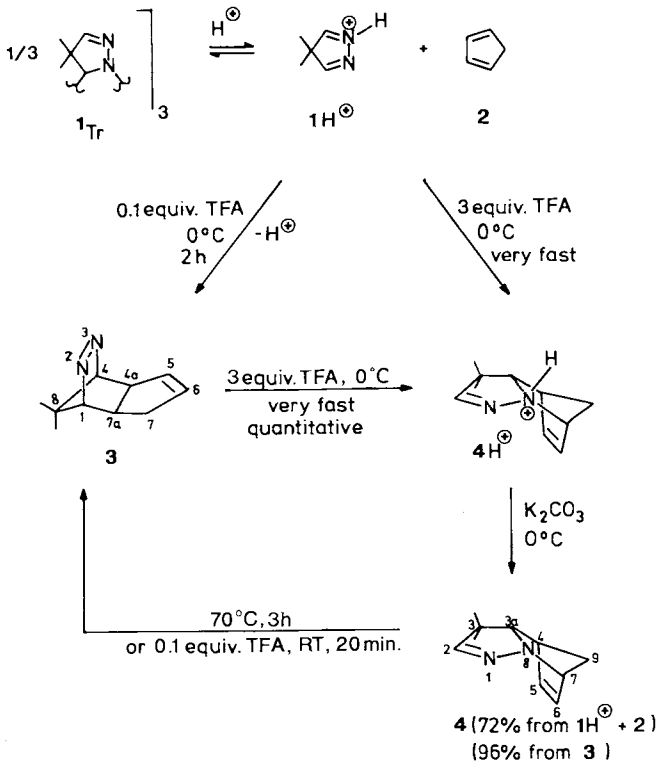
To the best of our knowledge, this obvious conclusion has not been explicitly stated previously. Furthermore, the isomerization of a series of cycloadducts has been described as a Cope rearrangement, even though the intramolecular course of the reaction has been established in only a few cases.[4] We present here a novel example in which the problem discussed above becomes readily apparent owing to the high mobility of the system.

In the presence of traces of acids, cyclic five- and six-membered azines, acting as electron-deficient 2,3-diaza-1,3-dienes, undergo addition to olefins in a Diels–Alder reaction with inverse electron demand to give polycycles containing azo bridges.[5] Cyclopentadiene (**2**) proved to be a particularly reactive dienophile in these [4 + 2] cycloadditions. For example, **2** adds to protonated 4,4-dimethyl-4*H*-pyrazole **1**-H$^{\oplus}$—generated in situ from the trimer $\mathbf{1}_{tr}$—to form the azo compound **3** (Scheme 1).[5c] Under optimized conditions,[6] reaction between $\mathbf{1}_{tr}$ and **2** in the presence of trifluoroacetic acid (TFA) (molar ratio 0.33 : 1.1 : 0.1) in chloroform is complete after 2 h (76% **3**, isolated). The ^{1}H-NMR spectrum of the reaction solution reveals, besides **3**, traces of a second product, which was identified as the dihydropyrazole **4**-H$^{\oplus}$.[7] The species **4**-H$^{\oplus}$ is formed immediately and quantitatively upon treatment of a solution of **3** with three equivalents of TFA. Neutralization of the reaction mixture containing **4**-H$^{\oplus}$ with an aqueous solution of sodium hydroxide at room temperature followed by the conventional workup, however, affords not the expected **4** but rather **3** in 70% yield! The free pyrazole derivative **4** can only be obtained by the slow addition of an acidic solution of **4**-H$^{\oplus}$ to an ice-cold, aqueous, saturated solution of potassium carbonate (Scheme 1).[8]

The rapid rearrangement of **4** to **3** is easily confirmed. Upon heating (70 °C, 3 h) or, appreciably faster, under acid catalysis (0.1 equivalents of TFA, $CDCl_3$, room temperature, 20 min), **4** undergoes a quantitative rearrangement to **3**. Thus, this system represents an unusual case of a proton-controlled equilibrium between **3** and **4** having high mobility. In acidic medium, the higher basicity of **4** is apparently decisive, whereas, as a free base, **3** is thermodynamically more stable.[9]

[*] Prof. Dr. S. Hünig, Dr. K. Beck
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and BASF AG, Ludwigshafen.



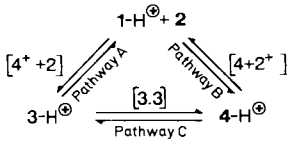
Scheme 1.

In light of these findings, it is not surprising that reaction of $\mathbf{1}_{tr}$ and **2** in the presence of 3 equivalents of TFA in chloroform at 0°C immediately yields **4**-H$^{\oplus}$ as the sole product, from which **4** can be isolated in 72% yield.

Interpretation of these confusing results requires the consideration of the following three hypotheses:

I. The isomers **3**-H$^{\oplus}$ and **4**-H$^{\oplus}$ are formed by competing [4$^+$ + 2] and [4 + 2$^+$] cycloaddition (Diels–Alder reaction with inverse electron demand[10]). The transformation of **3**-H$^{\oplus}$ to **4**-H$^{\oplus}$ takes place via cycloreversion (Scheme 2, pathway A and B).

II. The species **3**-H$^{\oplus}$ and **4**-H$^{\oplus}$ are formed as formulated under I. However, their interconversion involves a [3.3] rearrangement (Scheme 2, pathway C appreciably faster that the back reactions A and B).

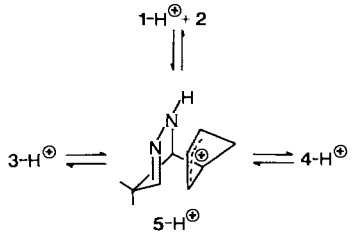


Scheme 2.

III. The formation of both **3**-H$^{\oplus}$ and **4**-H$^{\oplus}$ and their interconversion occur via a common intermediate, **5**-H$^{\oplus}$, which undergoes either further reaction to give the cycloadducts **3**-H$^{\oplus}$ and **4**-H$^{\oplus}$ or reverse cleavage to give the educts **1**-H$^{\oplus}$ and **2** (Scheme 3).

These mechanistic possibilities can be in part differentiated by experiment:

1. A 1:2 mixture of **4** and maleic anhydride (MA) was allowed to react with 0.1 equivalents of TFA in $CDCl_3$ at 0°C. Within 60 min, the ^{1}H-NMR signals of **4** had disappeared and those of **3** had appeared, with only traces of the cycloadduct between **2** and MA being detected. The latter was formed as the main product after 2 weeks.
2. Compounds **3** and **4** were replaced by the derivatives [D$_6$]-**3** and [D$_6$]-**4**, deuterated in the five-membered ring.[11] The rearrangement of [D$_6$]-**4** in $CDCl_3$ in the presence of five equivalents of undeuterated **2** was initiated by the addition of 0.05 equivalents of TFA.[12] After 2 h, [D$_6$]-**4** had undergone rearrangement to [D$_6$]-**3**, without the apparent formation of undeuterated **3**. This occurred only after 1–2 d upon addition of a further 0.25 equivalents of TFA.



Scheme 3.

According to these experiments, the rapid rearrangement of **4**-H$^{\oplus}$ to **3**-H$^{\oplus}$ occurs *intramolecularly* as a [3.3] rearrangement, with the retro Diels–Alder reaction proceeding much more slowly. The same is true for the thermal rearrangement **4** → **3**, since the reaction [D$_6$]-**4** → [D$_6$]-**3** in the presence of undeuterated **2** (5 equivalents) proceeds without incorporation of the latter. Hypothesis I is thus ruled out. It is not possible, however, to distinguish between hypotheses II and III. Although Diels–Alder reactions and Cope rearrangements normally proceed in a concerted fashion,[13] the reaction can occur via an intermediate under certain conditions.[4a, 14–16] A large difference in the π-MO energies of the reactants can lead to a strong reduction in the HOMO–LUMO interaction, so that there is no longer a compensation for the large negative entropy of the concerted transition states.

This situation could readily apply to the very different dienes **1**-H$^{\oplus}$ and **2**. Thus, in accordance with hypothesis III, an intermediate of the type **5**-H$^{\oplus}$[17] could be involved as the key species connecting the Diels–Alder and Cope products (see Scheme 3).

The rearrangement **3**-H$^{\oplus}$ → **4**-H$^{\oplus}$ is the first example of a Cope rearrangement involving a nonstabilized azo group without loss of nitrogen. This rearrangement can be extended to other systems.[18]

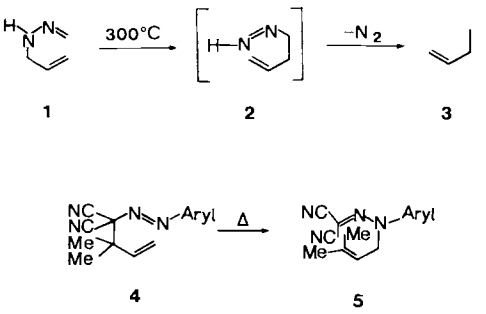
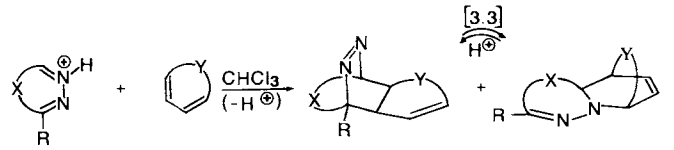
Azo Cope Rearrangements of Nonstabilized Azo Compounds**

By *Karin Beck, Harald Burghard, Gabriele Fischer, Siegfried Hünig,** and *Petra Reinold*

The numerous hetero-1,5-dienes for which Cope rearrangements are known include 3,4-diaza- and 2,5-diaza derivatives. In the first case, the N–N bond is broken during the rearrangement; in the second case, the azomethine function is merely shifted.[1] To the best of our knowledge, only one 2,3-diaza Cope rearrangement is known, namely, **1**→**2**. This rearrangement, which is expected to form an azo compound, leads to loss of nitrogen and the formation of 1-butene **3**.[2] Recently, the system **4**, which is stabilized by an aryl group, was shown to undergo an azo Cope rearrangement, resulting in the formation of the expected hydrazone **5**.[3]



We now report the first azo Cope rearrangement of the type **4**⇆**5** that, despite the absence of an aryl-group-stabilized azo group, proceeds without loss of nitrogen and, depending on the pattern of substitution, affords either the azo or the hydrazone isomer (partially reversible). In this reaction, the known charge acceleration of the rearrangement[1] is exploited by protonation of the N atom. The starting point of this reaction sequence is the cycloaddition of the isopyrazole **6a** to the cyclopentadiene **7d**, which, depending on the acid concentration, leads to a mobile equilibrium between the azo compound **8ad** and the hydrazone **9ad** (as **9ad**-H$^{\oplus}$). It was established that the transformation **8ad**-H$^{\oplus}$→**9ad**-H$^{\oplus}$ proceeds via an intramolecular [3.3] Cope-type rearrangement and not via the appreciably slower retro Diels–Alder reaction.[4] A series of further cycloadducts **8** and **9** that were also capable of undergoing isomerization were correspondingly obtained according to Scheme 1.[5] The structural dependence of the rearrangement was determined for five examples (Scheme 2).[6]



6	R	X
a	H	$C(CH_3)_2$
b	CH_3	$C(CH_3)_2$

ad	ad
bd	bd
ae	ae
cd	cd

Scheme 1.

As shown in Scheme 2, the reversibility of the rearrangement **8ad**⇆**9ad** is completely maintained upon introduction of a methyl group (**8bd**⇆**9bd**), although the reaction rate is markedly decreased. The cycloadducts obtained from isopyrazole **6a** and 1,3-cyclohexadiene **7e** or isoprene **7f**, namely, **8ae** or **8af**, respectively, undergo only irreversible isomerization to the dihydropyrazoles **9ae** and **9af**. In the case of the cycloadducts obtained from dihydropyridazine **6c** and cyclopentadiene **7d**, only rearrangement of **9cd** to the azo compound **8cd** occurs!

Calculations performed using the SCRIPT force-field program[7] revealed that, for the systems U1 and U4, the azo compounds are 3.0 kcal/mol and 6.8 kcal/mol, respectively, more stable, whereas, for U2 and U3, the hydrazones are 2.4 kcal/mol and 21.4 kcal/mol, respectively, lower in energy (Scheme 2). Indeed, treatment with 0.1

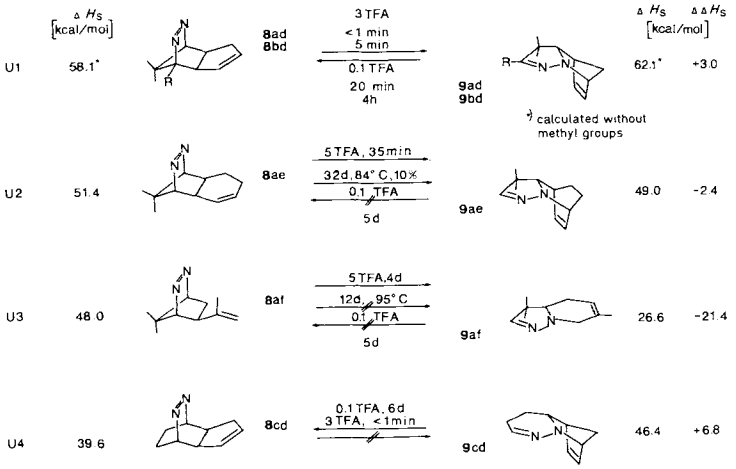

Scheme 2. Acid-catalyzed diaza Cope rearrangements in $CDCl_3$, at room temperature if not stated otherwise (the hydrazones **9** are protonated if an excess of acid is present).

equivalent of TFA results in the smooth isomerization of **9ad**, **9bd**, and **9cd** into the isomeric azo compounds; however, despite the larger difference in energy, **9cd** rearranges significantly more slowly. The influence of structure on the energy barrier for the isomerization is so large in the case of U2 and U3 that the calculated differences in energy can no longer be confirmed. The rearrangements carried out in the presence of a large excess of acid proceed in the appropriate direction but are not conclusive owing to the appreciably stronger basicity of the hydrazone form. With 0.1 equivalent of TFA, the conversion of **8ae** to **9ae** asymptotically approaches the limiting value of 10% after 32 d at 84°C, because **9ae**-$H^{\oplus}$ is such a poor protonating agent. An isomerization of **8af** to **9af** with 0.1 equivalent of TFA cannot be detected even after 12 d at 95°C. The reaction of **6a** with isoprene **7f** establishes that the regioselective rearrangement driven by an excess of TFA proceeds intramolecularly. In three competing reactions (monitored by GC), **8af**, **9af**, and the isomer **9'af** are simultaneously formed. Therefore, **9af**, which is formed exclusively according to U3, is not formed by cycloreversion, since **9'af** is absent. Accordingly, all isomerizations presumably involve a one- or two-step, intramolecular [3.3] rearrangement.[4]

Redox Disproportionation of Ge^{II} Compounds: Synthesis and Structure of $[(Me_3Si)C(PMe_2)_2]_2GeCl_2$ and $[\mu\text{-}\{(Me_3Si)C(PMe_2)_2\}]_2Ge_2$**

By *Hans H. Karsch,* Brigitte Deubelly, Jürgen Riede,* and *Gerhard Müller*

Low-valent, monomeric germanium compounds are known; to the best of our knowledge, however, there are no reports concerning spontaneous redox reactions of germanium(II) compounds under normal conditions. We have already shown that the stabilization of phosphane complexes of main-group elements can be extended to low-valent elements (e.g., Ge^{II}, Sn^{II}, Pb^{II})[1] if *anionic* phosphane ligands, such as phosphinomethanides **1**, are employed.

$[R_2P\text{–}CXY]^{\ominus}$ **1**, X, Y = H, PMe_2, $SiMe_3$; R = alkyl, aryl

We show here, by way of germanium as example, that such ligands can also be used to initiate redox reactions of low-valent element-phosphane complexes, leading to the formation of novel products having element-element bonds.

$SnCl_2$ smoothly reacts with $Li[(Me_2P)_2CX]$ (**1a**, X = PMe_2; **1b**, X = $SiMe_3$) to give Sn^{II}-phosphane complexes having pseudo trigonal-bipyramidal configurations.[2] An analogous reaction can also be carried out with $GeCl_2 \cdot$dioxane [Eq. (a)]; the germanium complexes **2**, corresponding to the tin complexes, are formed. The colorless crystals[3] of **2a**,**b** are stable indefinitely at room temperature. However, when the phosphinomethanide **1b** is used in less than the required stoichiometric amount, a redox process occurs, which presumably proceeds via the intermediate $[(Me_3Si)C(PMe_2)_2]GeCl$. For optimized stoichiometry, the reaction can be formulated as Equation (b).[4]

$$GeCl_2 \cdot \text{dioxane} + 2\,Li[(PMe_2)_2CX] \xrightarrow{-2\,LiCl} Ge[(PMe_2)_2CX]_2 \quad \text{(a)}$$
1a, b **2a, b**

$$3\,Ge^{II}Cl_2 \cdot \text{dioxane} + 4\,\mathbf{1b} \xrightarrow{-4\,LiCl} \begin{matrix}[(Me_3Si)C(PMe_2)_2]_2Ge^{IV}Cl_2\ \mathbf{3b} \\ + \\ [(Me_3Si)C(PMe_2)_2]_2Ge_2^{I}\ \mathbf{4b}\end{matrix} \quad \text{(b)}$$

The *oxidation* product **3b** can also be synthesized from $GeCl_4$ and **1b** [Eq. (c)], which confirms its formulation as a

$$GeCl_4 + 2\,\mathbf{1b} \xrightarrow{-2\,LiCl} \mathbf{3b} \quad \text{(c)}$$

Ge^{IV} complex.[5] Complex **3b** is the first example of a *trans*-octahedral structure (Fig. 1)[6] having 4 P and 2 Cl donors at a germanium center.[7]

[**] Complexes with Phosphinomethane and -methanide Ligands, Part 12.—Part 11: H. H. Karsch, A. Appelt, B. Deubelly, G. Müller, *J. Chem. Soc. Chem. Commun.*, in press.

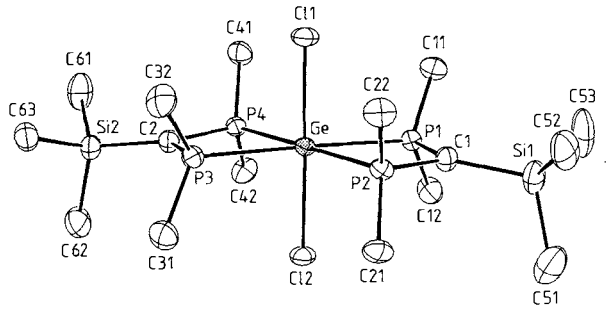

Fig. 1. Molecular structure of **3b** (ORTEP, thermal ellipsoids at the 50% probability level, without H atoms). Important bond lengths [Å] and angles [°]: Ge-Cl1 2.386(1), Ge-Cl2 2.434(1), Ge-P1 2.410(1), Ge-P2 2.412(1), Ge-P3 2.415(1), Ge-P4 2.411(1), C1-P1 1.727(5), C1-P2 1.725(4), C1-Si1 1.838(5), C2-P3 1.722(4), C2-P4 1.734(4), C2-Si2 1.829(4); Cl1-Ge-Cl2 178.7(1), P1-Ge-P2 69.9(1), P3-Ge-P4 69.8(1), P1-Ge-P4 109.5(1), P2-Ge-P3 110.7(1).

Searching for the *reduction* product, we investigated more closely the second fraction of crystals, likewise yellow, obtained according to Equation (b). The shift of their ^{31}P-NMR resonances to lower frequencies compared with those of **3a,b** indicates the presence of a reduced species.[5] Under reductive conditions, **4b** is obtained nearly quantitatively in pure form according to Equation (d)

$$GeCl_2\cdot\text{dioxane} + \mathbf{1b} \xrightarrow[THF]{Mg\ (excess)} \mathbf{4b} \qquad (d)$$

(THF = tetrahydrofuran). The X-ray structure analysis[6] of crystals obtained from pentane reveals a doubly phosphinomethanide-bridged $[Ge^{I}\text{-}Ge^{I}]^{2\oplus}$ structural unit (Fig. 2). The Ge atoms are each surrounded in a pseudo-tetrahedral fashion by one electron pair, two P atoms, and a Ge atom; this results in a nonplanar eight-membered ring perimeter having approximate $C_2(2)$ symmetry. The Ge-P distances, which are significantly shorter than, for example, those in $(Ph_3P)GeCl_2$ (2.51(1) Å[8]) and the nearly planar environment of the carbanionoid C atoms of the ligands are in agreement with the findings for **3b** (Fig. 1). The central Ge-Ge bond (2.540(1) Å), is ca. 0.1 Å *longer* than those in polygermanes.[9] This also means that the "bisgermanediyl" **4b** clearly differs from the digermenes having formal Ge-Ge double bonds, which are obtained by dimerization of germanediyls.[10]

Complex **4b** thus represents a new class of low-valent main-group-element compounds with element-element bonds. Its high stability (dec. at $T > 190$ °C) and formation tendency are supported by the novel redox reaction of Equation (b) and are undoubtedly based in part on the bridging function of the diphosphinomethanide ligands, which has not yet been observed for main-group elements. The phosphane donors should effect activation of the lone pairs at the germanium centers, which, together with the reactive Ge-Ge bond, should lead to interesting reactivity.

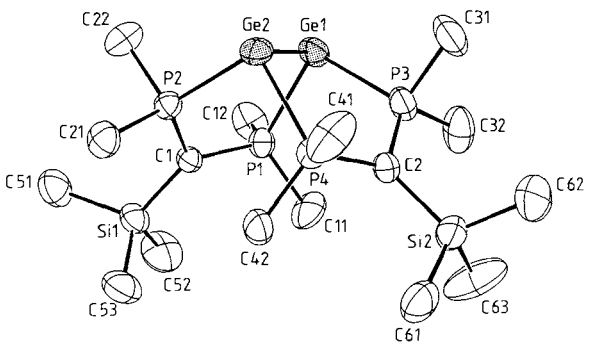

Fig. 2. Molecular structure of **4b**. Important bond lengths [Å] and angles [°]: Ge1-Ge2 2.540(1), Ge1-P1 2.420(1), Ge1-P3 2.370(1), Ge2-P2 2.368(1), Ge2-P4 2.420(1), C1-P1 1.734(3), C1-P2 1.741(3), C1-Si1 1.840(4), C2-P3 1.740(4), C2-P4 1.731(4), C2-Si2 1.845(4); Ge2-Ge1-P1 95.1(1), Ge2-Ge1-P3 86.7(1), P1-Ge1-P3 96.9(1), Ge1-Ge2-P2 87.6(1), Ge1-Ge2-P4 95.0(1), P2-Ge2-P4 96.1(1).

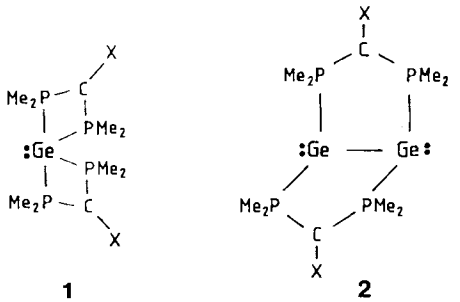
[**] Complexes with Phosphinomethane and -methanide Ligands, Part 13.—Part 12: [4].

Lewis acids or Lewis bases. As Lewis acids, they react with bases to form adducts ("ylides") which, as strong donors for transition metals, lead to the formation of interesting complexes.[1] However, the reactivity of the lone pair toward main-group acceptors appears to be low.[2] Structurally confirmed examples are limited to only a few donor-stabilized stannanediyl complexes.[3] Compounds of elements of the fourth main group acting as mutual donor and acceptor and thus being capable of forming complexes with homonuclear element-element bonds were unknown until now.

According to X-ray structure analyses, the "germanediyls" **1** and "bisgermanediyls" **2** (**a**, $X=PMe_2$; **b**, $X=SiMe_3$),[4,5] recently prepared by us, contain stereochemically active lone pairs. We have now attempted to



1 **2**

exploit the strongly increased donor ability of **1** and **2**, caused by the (anionic) phosphane ligands, to synthesize homonuclear complexes with $GeCl_2$ as acceptor. The complexes **1b** and $GeCl_2$·dioxane **3** do not form such donor–acceptor complexes. In contrast, **2b** reacts with **3** to give the 2:1 adduct **4b** [Eq. (a)]. This adduct can also be obtained by means of an "in situ" reaction [Eq. (b)] (cf. Ref. [4]).

$$2\,\mathbf{2b} + \underset{\mathbf{3}}{GeCl_2\cdot\text{dioxane}} \longrightarrow \underset{\mathbf{4b}}{[\{\mu\text{-}[(Me_3Si)C(PMe_2)_2]\}_2Ge_2]_2GeCl_2} \quad (a)$$

$$7\,\mathbf{3} + 8\,Li[(Me_3Si)C(PMe_2)_2] \xrightarrow[-8\,LiCl]{} \mathbf{4b} + 2[(Me_3Si)C(PMe_2)_2]_2GeCl_2 \quad (b)$$

Complex **4b**, obtained as pale yellow crystals from ether/pentane, is apparently the first homonuclear adduct of a divalent donor/acceptor pair of elements of the fourth main group. In solution, however, **4b** undergoes nearly complete dissociation: the $\delta(^{31}P)$ value of **4b** in solution at room temperature is identical with that of **2b**.[4] At $-100\,^{\circ}C$, on the other hand, the signals of an incompletely resolved ABCD spin system (four nonequivalent phosphorus atoms) are observed, as is expected for undissociated **4b**.

The X-ray structure analysis[6] (Fig. 1) confirms the presence of a mixed-valent donor–acceptor complex containing two equatorial bisgermanediyl ligands **2b** bound to a nearly linear $GeCl_2$. This results in a pseudo trigonal-bipyramidal environment for the central Ge3 atom (with the lone pair in the third equatorial position). To the best of our knowledge, the coordinative bonds Ge3-Ge2 (2.554(1) Å) and Ge3-Ge4 (2.562(1) Å) are the longest Ge–Ge bonds reported yet[7] and indicate weak coordination of the bisgermanediyl moieties; the Ge–Ge bonds of the bisgermanediyl ligands (2.485(1) and 2.492(1) Å), on the other hand, are noticeably shorter (by ca. 0.07 Å). Interestingly, they are also significantly shorter than those in uncomplexed **2b** (2.540(1) Å).[4] The P–Ge–P angles at Ge2/Ge4 (101.5(1)/99.7(1)°), whose electron pairs function as donors to Ge3, are significantly larger than those at Ge1/Ge5 (95.3(1)/96.3(1)°). The latter are in good agreement with those in **2b**.[4] The bond shortening and angle expansion thus appear to be analogous to those observed upon complexation of phosphanes R_3P. Equally revealing is a comparison of **4b** with the coordination polymer $GeCl_2$·dioxane **3**, which contains linear $C_4H_8O_2$–Ge–$C_4H_8O_2$ chains.[8] The angle Cl-Ge-Cl in **3** is about as small as the angle Ge2-Ge3-Ge4 in **4b**. In agreement with expectations, therefore, the more electronegative donor atoms (**3**, O; **4b**, Cl) in both complexes occupy the axial positions of the pseudo trigonal bipyramid and the Ge–Cl bonds in **3** are correspondingly shorter than in **4b**.

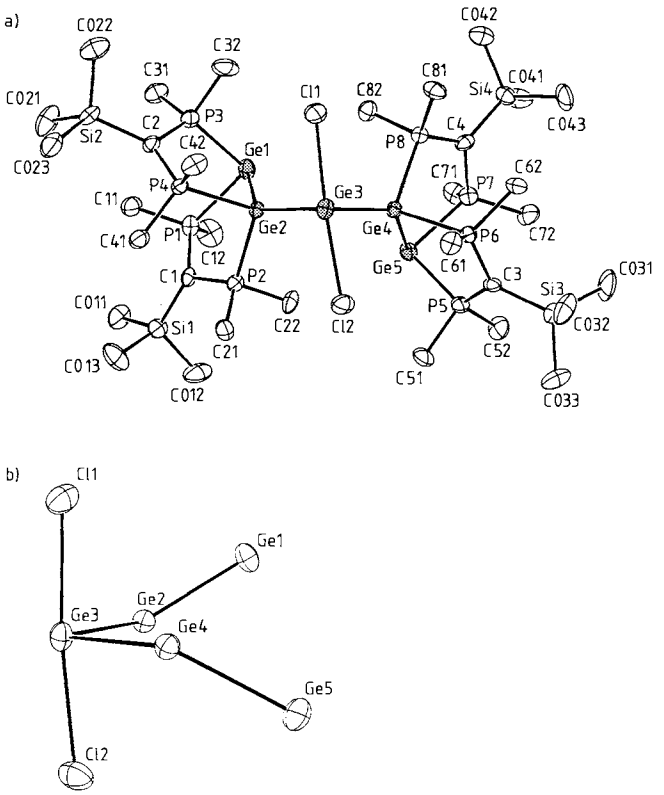


Fig. 1. a) Crystal structure of **4b**. b) $GeCl_2(Ge_2)_2$ partial structure in **4b** (ORTEP, thermal ellipsoids at the 50% probability level; H atoms omitted). Important bond lengths [Å] and angles [°]: Ge3-Cl1 2.596(2), Ge3-Cl2 2.644(2), Ge3-Ge2 2.554(1), Ge3-Ge4 2.562(1), Ge1-Ge2 2.492(1), Ge4-Ge5 2.485(1), Ge1-P1 2.433(2), Ge1-P3 2.378(2), Ge5-P5 2.389(2), Ge5-P7 2.435(2), Ge2-P2 2.351(2), Ge2-P4 2.391(2), Ge4-P6 2.401(2), Ge4-P8 2.367(2); Cl1-Ge3-Cl2 172.3(1), Ge2-Ge3-Ge4 94.8(1), Ge1-Ge2-Ge3 133.7(1), Ge3-Ge4-Ge5 136.3(1).

Overall, the structure of **4b** is characterized by a bent Ge_5 chain; taking into consideration the (formal) oxidation states, it may thus be viewed as a mixed-valent compound (Ge^{I}-Ge^{I}-Ge^{II}-Ge^{I}-Ge^{I}). A "chain lengthening" to form a coordination polymer with Ge–Ge chains appears favorable, since the terminal Ge atoms of the bisgermanediyl ligands should in principle also be able to act as donor atoms to $GeCl_2$.

The Morphology and Microstructure of Colloidal Silver and Gold**

By *D. G. Duff, A. C. Curtis, Peter P. Edwards,* D. A. Jefferson, Brian F. G. Johnson, A. I. Kirkland,* and *D. E. Logan*

The brilliant colors characteristic of colloidal gold and silver have been known for over a millennium.[1-3] Although the technique of electron microscopy has been applied previously to study the nucleation, growth, and topology of colloidal particles,[3,4] it is only recently that the resolution of the microscopes has been improved to such an extent[5,6] as to yield reliable images which may reflect the atomic microstructure of these divided metals.[2-7] Here we demonstrate how direct structural imaging by high-resolution electron microscopy (HREM), coupled with appropriate *chemical* routes to ultrafine particles, can indeed yield important information on the morphology and atomic structure of individual colloidal metal particles. Thus, the atomic imaging of a 35-Å-diameter silver particle by HREM enables a direct observation of the packing of individual silver atoms around a dodecahedral core. This observation is supported by computer-simulated images for an entire particle; the silver particle exhibits a perfect pentagonal symmetry in its atomic arrangement around the central C_5 axis.

All HREM examinations were carried out in a modified JEOL-200CX operating at 200 kV, with a new type of side-entry specimen stage utilizing an objective lens with characteristics $C_s = 0.6$ mm, $C_c = 1.05$ mm, and focal length $(f) = 1.6$ mm. Full details of this modification are given elsewhere.[8] The interpretable point resolution of the modified instrument at optimum defocus, as defined by the first zero of the phase-contrast transfer function[9] was 2.03 Å, as compared with 2.41 Å for the standard instrument. For gold, therefore, both {111} and {200} diffracted beams (corresponding to spacings of 2.35 and 2.04 Å, respectively) could be recombined into the image with the same relative phase shift at optimum defocus, and the atoms appeared as black dots in images viewed down the {110} directions. With silver, however, the most useful images were recorded at a defocus setting considerably greater than optimum with the atoms being resolved as white dots.

Owing to the extremely small size of the colloidal metal particles, no attempt was made to orient them with respect to the electron beam and particles were examined by systematic screening of the grid. Micrographs were recorded at ca. 490 000 ×, a series of pictures for each group of particles being taken, with a variation of objective lens defocus of ca. 300 Å between successive exposures. Astigmatism was corrected by observing the granularity of the amorphous support film, and diffraction patterns were obtained when required by means of optical diffraction from the recorded images.

The gold particles could be classified into two categories:

1. The first type includes multiply twinned particles (MTPs) similar to those previously described for gold samples prepared by evaporation of the bulk metal.[10,11] These particles gave very similar HREM images and varied in size from ca. 100 to 400 Å in diameter. A typical example of a decahedral particle being illustrated in Figure 1a. Strong diffraction contrast at the twin boundaries between the individual regions within these MTPs suggested that either considerable strain or defects were present at the boundaries. In all cases, however, the individual sub-

units within the MTPs examined were of roughly equal size.

2. The second type of gold particle is shown in Figure 1b. Tilting experiments on a lower-resolution instrument confirmed the flat nature of these particles. Although some were of irregular outline, most were clearly triangular, generally with truncated corners (Fig. 1b). Surface steps were visible at the corners, as shown in the inset. The lateral dimensions of these particles showed a wide variation, but were rarely less than 200 Å and frequently extended to greater than 1000 Å. Smaller particles without twinning were observed (Fig. 1c). Although not of triangular outline, they were definitely *not* of the icosahedral or decahedral type, and were possibly representative of the first stages of triangular particle formation, before the characteristic shape had developed.

Colloidal silver was prepared by the reduction of a solution of silver nitrate in acetonitrile by poly(ethylene imine) $(-H_2CCH_2NH-)_n$ (PEI). The use of PEI as a protecting agent for stabilizing gold sols against particle aggregation was first investigated by *Thiele* and *von Levern*.[12] Later work by *Thiele* ahd *Kowallik*[13] demonstrated that PEI could be used as a reducing agent in the preparation of colloidal gold from chloroauric acid, this method producing stabilized sols of extremely small particle size. In these reactions the polymer has the twin function of reducing and protecting agent.

In the present study we adapted this method for the production of colloidal silver in acetonitrile. This reaction mixture was treated in two ways. Immediate preparation of a sample for electron microscopy (involving dessication of the polymer–metal ion adduct onto a carbon film) produced a myriad of particles of diameter less than 50 Å. Allowing the mixture to stand in daylight caused the development, over the course of several weeks, of a rather unstable silver sol and the appearance of larger particles (ca. 100–500 Å diameter), as determined by transmission electron microscopy (TEM). If the sol was kept in the dark, this nucleation process was slowed down considerably. A partially reacted sol yielded a bimodal size distribution of particles on the electron microscope grid; the number of smaller particles decreased and the number of larger particles increased as the reaction proceeded. The samples under examination here were exposed to daylight for three days; this procedure yielded a good number of large and small particles for examination.

For the silver samples, no flat plates were observed, but again the particles could be classified into two categories:

1. MTPs were the predominant type, generally of lateral dimensions less than 500 Å and, by contrast with those observed in the gold samples, typically showed an arrangement of individual subunits that was far from perfect. A typical particle is shown in Figure 2a, where, although at first sight the particle appears to be of the decahedral type, closer examination reveals the existence of six component units. At least one of the boundaries within this particle is not along a crystallographic direction, and this may possibly be the method by which the metal adapts the bulk face-centered cubic structure to the developed morphology of the MTP. Also in contrast to the gold samples, no major strain contrast was observed at the boundaries within the MTPs, indicating that the manner in which the lattice adapts to strain might differ between these two colloidal samples.

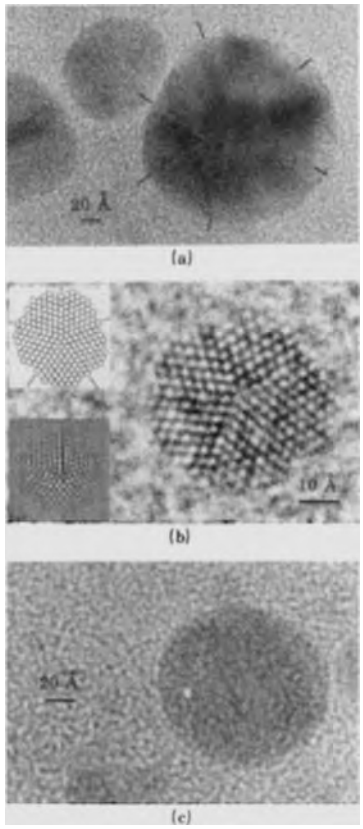

Fig. 2. a) Typical MTP in colloidal silver, viewed down {110}. The positions of the boundaries are indicated. b) Almost perfect decahedral particle of silver, with no visible strain at the boundaries. The inset shows the structural model deduced from the image and the simulated image at an objective lens defocus of ca. 650 Å. c) Agglomerate-like particle of silver, with no clear indication of distinct subunits or boundaries between them. The detail of the amorphous support film suggests that the objective lens defocus of this image is similar to that of Figure 2b.

When the particle dimensions become very small (<40 Å), they appeared to adopt only the decahedral form (Fig. 2b). Although faceting leading to truncation of the edges of the particles was noted, the atomic arrangement appeared to be a perfect decahedral one, and no strain contrast or zigzagging of boundaries was noted. Computer-simulated images of the particle of Figure 2b were calculated using the multislice method[14] as previously applied to image calculations of very small particles by *Gai* et al.,[15] although in the present investigation a simplified version was adopted; i.e., no account was taken of the atomic structure of the amorphous carbon background. This simplification is appropriate since the particles studied here are much larger, and the corresponding percentage contrast is much greater, than those in the studies carried out by *Gai* et al.[15]

The structural model employed and a simulated image are shown in the inset in Figure 2b. The model used contained 1427 silver atoms and, if a homogeneous strain[16, 17] was employed, necessitated a maximum expansion of 2.75% in the metal–metal bond length parallel to the edges of the decahedron. At the position where the notches at the boundaries occurred, the metal–metal distance in this direction was allowed to relax back to its ideal position, and this appeared to correspond to the actual arrangement within the particle. Given the small size of particle, it was found to be impossible to incorporate any type of dislocation to eliminate this strain without it being immediately visible in the simulated image; this would have not been in agreement with the experimental image (Fig. 2b). In addition, the image simulation indicated that the particle was elongated parallel to the fivefold symmetry axis, this again being as predicted by the theory of *Marks*.[18] Consequently, the homogeneous strain appeared to be most appro-

priate in these very small particles and their real structure did not therefore correspond exactly to the bulk face-centered-cubic structure.

2. The second type of silver particle (Fig. 2c) observed was much more enigmatic. These particles were approximately spherical, and initially were assumed to consist of small icosahedral units. However, the number of distinct individuals was in many cases much too large for a single icosahedral MTP; it is possible, however, that these particles are "polyparticles" as observed by *Smith* and *Marks* for evaporated samples. These particles varied considerably in size, although most were less than 100 Å. When they were of very small dimensions (<25 Å), they gave every indication of being quasiamorphous, in that no lattice rows were discernable, and it was often quite difficult to distinguish them from the background of the amorphous support film. Although it is tempting to consider such poorly structured particles as a type of large cluster, the number of atoms contained is still relatively high (from density calculations, 479 atoms in a 25-Å sphere) and little can be said about their structure until further image simulations are performed. It is possible, however, to consider that this second type of particle may actually form at a later stage than the MTPs, possibly in the final stages of evaporation of the sol. Although this would in turn imply that they were an essentially nonequilibrium phenomena, continued annealing in the electron beam did not appear to produce atomic rearrangement, unlike the case of gold particles on a silicon support, as observed recently.[6]

In this work we hope to have demonstrated that, in conjunction with appropriate chemical synthetic routes, direct imaging by HREM provides much detailed information about the atomic structure of colloidal metal particles on a nanometer scale. Perhaps the most striking results are the observations that certain small particles of colloidal silver exhibit a fivefold symmetry axis (Fig. 2b) and that metal particles grown from colloidal solutions show marked similarities to those produced by evaporation methods. The relative ease of experimental control on both the particle dimensions and morphology is considerably more straightforward in the case of colloidal preparations.

Experimental Procedure

Stringent conditions of experimental cleanliness were followed throughout for both the gold and silver preparations—glassware was washed variously with aqua regia, nitric acid, or chromic acid and then rinsed copiously with water, the last few times with doubly distilled water. The sols were initially characterized by low-resolution TEM (JEOL 200-CX) with scanning electron microscope facility. Optical spectra were obtained using a Pye-Unicam SP8800 UV-VIS spectrophotometer, the samples being contained in quartz cells.

Colloidal gold was prepared by citric acid reduction of chloroauric acid using the method of *Turkevich* et al. [4]: 5 mL of a 1% aqueous solution of citric acid (AR grade, monohydrated salt) was added to 95 mL of a refluxing 0.01% aqueous solution of chloroauric acid (49.42% Au) with stirring and the mixture was boiled for one hour (all water was doubly distilled before use).

Silver sol: The silver nitrate used was in the form of analytical reagent grade crystals (99.99% pure). Acetonitrile (HPLC grade) was distilled over calcium hydride before use. PEI was used as received as a very viscous liquid ($M = 1800$ g/mol). The concentrations of reagents used were so as to yield a sol containing 10^{-3} M silver nitrate. The starting mixture consisted of a 5.4 : 1 molar ratio of imine residues to silver ions: 0.120 g of PEI was dissolved in 100 mL of freshly distilled acetonitrile. A 20 mL aliquot of this solution was added to a further 70 mL of acetonitrile and then 10 mL of a 0.01 M solution of silver nitrate in acetonitrile was added with stirring. For subsequent procedure, see text.

The Synthesis of 1,3- and 1,4-Phenylene-Linked Bisquinone-Substituted Porphyrin Dimers**

By *Jonathan L. Sessler** and *Martin R. Johnson*

A key feature of photosynthesis in both green plants and bacteria is light-induced electron transfer from a "special pair" dimeric chlorophyll (or bacteriochlorophyll) donor (P), via a series of intermediate prosthetic groups, to a quinone acceptor (Q). Recent X-ray structural studies of the bacterial photosynthetic reaction center (RC) from *Rhodopseudomonas viridis* have revealed a well-defined orientation of six tetrapyrrolic macrocycles at the active site: The dimeric bacteriochlorophyll special pair (P) is flanked on two sides, at a distance of 13 Å and interplane angle of 70°, by two monomeric bacteriochlorophylls (Bchls), each of which is in turn in contact with a bacteriopheophytin (Bph). The Bchl and Bph are separated by an interplane angle of 65° and a center-to-center distance of 11 Å.[1] These structural results suggest that both donor–acceptor distances and intermacrocycle orientations play a crucial role in mediating the photosynthetic charge separation process. In recent years a number of photosynthetic model systems have been synthesized and studied in an effort to understand the first of these factors.[2] Intermacrocycle orientation effects, however, have not been thoroughly addressed in model systems.[3] We report here the synthesis of the quinone-substituted 1,3-phenylene-linked "gable"-type[4] porphyrin dimer **1** and its more open 1,4-phenylene-bridged analogue **2**. System **1** was specifically designed so as to constrain the two porphyrin subunits to a

The porphyrin precursors, **11** and **13**, of the quinone-substituted dimers **1** and **2** were prepared by the coupling of dipyrrylmethanes[5] using a procedure similar to that employed earlier to synthesize the "gable"-type porphyrin **3**.[6] The key dipyrrolic intermediate **6** was prepared in two steps. An acid-catalyzed condensation of dimethoxybenzaldehyde with ethyl 3-ethyl-4-methyl-2-pyrrolecarboxylate[7] in warm ethanol was followed directly by saponification and decarboxylation in boiling basic ethylene glycol to give **5** as a yellow powder (m.p. = 128–130 °C, 97% yield).[8] Vilsmeier formylation[9] then gave **6** in 68% yield as off-white crystals (m.p. = 208–209 °C). The *para*-phenylene-linked α-unsubstituted bis(dipyrrylmethane) **10** (m.p. = 162–163 °C, 90% yield) was prepared, via **9** (m.p. = 237 °C), from terephthalaldehyde and ethyl 3-ethyl-4-methyl-2-pyrrolecarboxylate[7] by the procedure used to produce **8** (via **7**).[6] Acid-catalyzed condensation of a 2 : 1 molar ratio of **6** and **8**, or **6** and **10**, for 12 h at room temperature in degassed methanol containing 1% $HClO_4$, followed by basification with triethylamine and oxidation with *o*-chloranil, gave **11** and **13** along with polymeric by-products. Chromatographic purification of the copper complexes[5d] (silica gel, $CHCl_3/CCl_4$ 1 : 1) followed by demetalation and recrystallization from $CHCl_3$/hexane gave **11** ($\lambda_{max}(CHCl_3) = 419$, 512, 545, 579, 630 nm) and **13** ($\lambda_{max}(CHCl_3) = 418$, 510, 543, 576, 626 nm) in 8% and 12% yields, respectively.[8] Compound **10** was also coupled with bis(4-ethyl-5-formyl-3-methyl-2-pyrryl)methane,[8] in a straightforward manner,[6] to give the unsubstituted, *para*-phenylene-linked reference dimer **4** (12%, $\lambda_{max}(CHCl_3) = 410$, 507, 540, 576, 627 nm).[3c,8]

Treating **11** with an excess of BBr_3 in dry CH_2Cl_2 and neutralizing the reaction solution with aqueous sodium bicarbonate gave **12** ($\lambda_{max}(CHCl_3) = 415$, 511, 545, 578, 628 nm) in 67% yield following chromatography on silica gel (1% MeOH in $CHCl_3$) and recrystallization from $CHCl_3$/EtOH.[8] The bishydroquinone **12** was oxidized to **1** in $CHCl_3$/MeOH (10 : 1) by treatment with a slight excess of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). Following chromatographic purification (silica gel, 0.1% triethylamine in $CHCl_3$) and recrystallization from $CHCl_3$/hexane, **1** was obtained in 93% yield as blue-violet crystals ($\lambda_{max}(CHCl_3) = 417$, 510, 543, 578, 628 nm).[8] An insoluble precipitate, assumed to have structure **14**,[8] was obtained when **13** was reacted with BBr_3. Following treatment with DDQ (as a slurry in $CHCl_3$/MeOH/pyridine 3 : 1 : 1), chromatographic purification (silica gel, 0.1% triethylamine in $CHCl_3$), and recrystallization from $CHCl_3$/hexane, the bisquinone **2** was isolated as blue-violet crystals in 72% yield based on **13** ($\lambda_{max}(CHCl_3) = 416$, 508, 541, 575, 626 nm).[8] The ^{13}C-NMR spectra of compounds **1** and **2** shows, in addition to the expected peaks in the alkyl and aromatic regions, a pair of signals at $\delta = 187.0$, 188.8 and 187.3, 188.9, respectively, corresponding to carbons 1 and 4 of the quinone ring.

Evidence for the dimeric nature of the porphyrins **1**, **2**, **11**, **12**, and **13** came from fast-atom-bombardment mass spectrometry (FAB, glycerol/oxalic acid matrix, 8-keV accelerating voltage). Only peaks corresponding to the expected $M^{\oplus} + nH$ (n = 1–5) ions were observed. Further support for the assigned dimeric structures came from ^1H-NMR spectroscopy. As expected for a porphyrin substituted in the 5 and 15 positions, the spectra of compounds **1**, **2**, **11**, **12**, and **13** in $CDCl_3$ show only one peak at $\delta \approx 10$, integrating for four protons and assignable to the *meso* protons. Signals, integrating for six and four protons, respectively, and assignable to both the hydroquinone/quinone and bridging phenylene rings were also resolved in the 360-MHz ^1H-NMR spectrum. For the *m*-phenylene-linked dimers **1**, **11**, and **12**, three signals are observed for the aromatic spacer. In the case of the *p*-phenylene-linked dimers **2** and **13**, the corresponding set of peaks appears as a doublet of doublets centered at $\delta \approx 8.6$. This splitting may indicate that even in the *para*-substituted series the two porphyrin macrocycles are not entirely coplanar.

The *p*-phenylene- and *m*-phenylene-linked free-base porphyrin dimers all show absorbance bands that are broadened and redshifted with respect to the reference monomer 2,8,13,17-tetraethyl-3,7,12,18-tetramethyl-5-phenylporphine ($\lambda_{max} = 402$, 501, 534, 559, 626 nm),[10] with the degree of broadening (but not shift) being greater in the *meta* series. Not surprisingly, the substituted dimers **1**, **2**, **10**, **11**, and **13** all showed larger bathochromic shifts than the unsubstituted dimers **3** and **4**; similar observations had been made earlier in the case of simple quinone-substituted monomeric porphyrins.[11] Dramatic differences

between the two isomeric sets of phenylene-linked dimers are seen in the case of the bis-zinc(II) complexes. The bis-zinc complexes of the *p*-phenylene-linked compounds **2**, **13**, and **14** all display one strong Soret band at ca. 420–425 nm with only a faint shoulder appearing at higher energy. The bis-zinc(II) complexes of the "gable"-type porphyrins **1**, **11**, and **12**, on the other hand, all display a Soret band that is split into two peaks of nearly equal intensity (at ca. 412 and 428 nm). This splitting of the Soret band, arising by virtue of dipole–dipole coupling, is indicative of interaction between the two porphyrin chromophores.[4] The observation of fluorescence quantum yields for the *meta*-linked dimers **3** and **11** that are both lower by ca. 25% than those of the corresponding *p*-phenylene-linked analogues (**4** and **13**) further confirms that a greater level of excitonic interaction pertains in the "gable" series of dimers.

As was expected on the basis of earlier work with quinone-substituted monomeric porphyrins,[11] neither **1** nor **2**, as ca. 10^{-6} M solutions in toluene, showed detectable fluorescence when irradiated at $\lambda = 418$ nm ($\Phi_f < 10^{-5}$). This suggests that rapid photoinduced intermolecular electron transfer is occurring from the porphyrins to the quinone acceptors. Compounds **1** and **2** thus appear to be suitable systems with which to model the primary events of photosynthetic charge separation.

Highly Polarizing Co^{2+} Ions from $[Co_2(CO)_8]$ and Pyridine in Hydrocarbons: Synthesis and Structure of $[\{Co_3(CO)_{10}\}_2\{Co(py)_4\}]$ and $[(CO)_4CoCo(py)_3][Co(CO)_4]$**

By *Giuseppe Fachinetti,* Giovanni Fochi, Tiziana Funaioli,* and *Pier Francesco Zanazzi**

Large excesses of Lewis bases promote metal carbonyl disproportionation,[1] with base-encapsulated cations and carbonylmetalate anions being formed. However, when relatively weak bases or only moderate amounts of strong bases in solvents having low dielectric constants are used, the disproportionation of neutral metal carbonyls yields complex cations and carbonylmetalate anions associated in homonuclear ion pairs (HNIP).[2] The reactivity of the anions is affected by ion pairing with acidic countercations;[3] therefore, HNIP phenomena are likely to yield a better understanding of metal carbonyl chemistry. Firm evidence for such behavior was obtained in the case of $[V(CO)_6]$ **1** and $[Fe(CO)_5]$ **2**. The reaction of **1** with tetrahydrofuran (THF) gave the structurally characterized complex $[(OC)_5VCOV(thf)_4OCV(CO)_5]$;[5] similarly, **2** reacts with pyridine (py) to yield the tetranuclear HNIP $[(py)_2FeFe(CO)_4]_2$.[6] The molecular structure shows cation–anion association through direct metal–metal interactions. Upon addition of moderate amounts of py to $[Co_2(CO)_8]$ **3** in THF solution, we obtained spectroscopic evidence for a $Co^{2+}/[Co(CO)_4]^-$ HNIP,[7] which led to the formation of both isocarbonyl compounds and species showing direct metal–metal interactions. We now report that, in hydrocarbon solutions containing moderate amounts of py with respect to the cobalt, HNIP formation from **3** occurs; two compounds of this class have been isolated and their molecular structures solved.

The addition of an equimolar amount of py to **3** in *n*-hexane results in gas evolution and the formation of a carmine solid in 60% yield analyzing as $[Co_7(CO)_{20}(py)_4]$ **4**.[8] The IR spectrum (Nujol mull) in the CO stretching region (2078 (w), 2016 (vs), 1995 (sh), 1980 (m), 1964 (m), 1520 (m) cm^{-1}) resembles the pattern for the $[Co_3(CO)_{10}]^-$ cluster in ether solvents.[4] Crystals suitable for X-ray diffraction grew from the mother liquor.[9]

Complex **4** (Fig. 1) contains an approximately octahedrally coordinated Co^{2+} ion bound to four py nitrogen atoms in the equatorial plane; the axial positions are occupied by the carbonyl oxygen atoms of the μ_3-CO groups

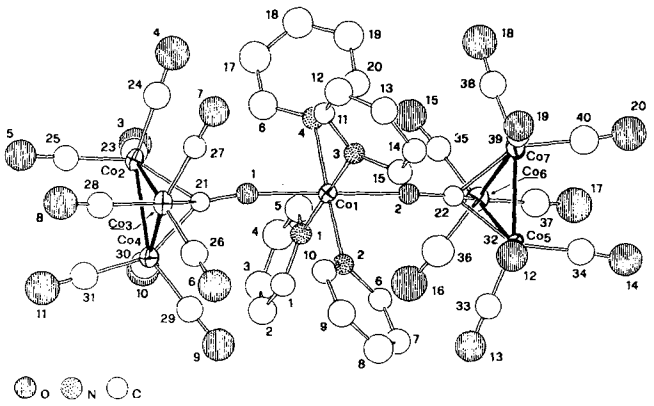

Fig. 1. Molecular crystal structure of $[\{Co_3(CO)_{10}\}_2\{Co(py)_4\}]$ **4**. Important distances [Å] and angles [°]: Co-Co (in the $[Co_3(CO)_{10}]^-$ units) 2.502 (average); C-O (terminal) 1.16 (average); C21-O1 1.233(12), C22-O2 1.239(13), Co1-O1 2.154(7), Co1-O2 2.146(7), Co1-N 2.144; C21-O1-Co1 168.7(6), C22-O2-Co1 173.0(6) (average).

belonging to two $[Co_3(CO)_{10}]^-$ units. The interatomic distances and angles in the two $[Co_3(CO)_{10}]^-$ clusters are comparable to those reported for other oxymethylidyne $Co_3(CO)_9$ clusters.[4]

Complex **4** is indefinitely stable in the solid state but decomposes quickly in THF or toluene, dark green solutions being obtained. In both these solvents, the IR spectra show the complex pattern already observed[2] for THF solutions of **3** containing moderate amounts of py, thus indicating the formation of other types of $Co^{2+}/[Co(CO)_4]^-$ HNIPs from **4**. Slow diffusion of *n*-hexane vapor into a toluene solution of **4** resulted in the formation of large black-green crystals having the composition $[Co_3(CO)_8(py)_3]$ **5** in low yield.[10] The IR spectrum of **5** (Nujol mull) shows absorptions at 2050 (m), 1992 (m), 1947 (s), 1933 (s), 1887 (m), and 1867 (s) cm^{-1}. Complex **5** can be obtained in 90% yield directly from **3** and py in toluene/*n*-hexane mixtures.[11] The X-ray crystal structure analysis of **5** showed that it consists of nearly regular tetrahedral $[Co(CO)_4]^-$ anions and dinuclear $[(OC)_4CoCo(py)_3]^+$ cations (Fig. 2). The geometry around the cobalt carrying the carbonyl groups is a distorted trigonal bipyramid, while that around the cobalt carrying the py groups is a distorted tetrahedron. The Co-Co distance is short (2.490(2) Å) compared with that in **3** (2.52 Å). The isolation of **5** from solutions containing both **3** and py suggests that electron transfer in disproportionation and

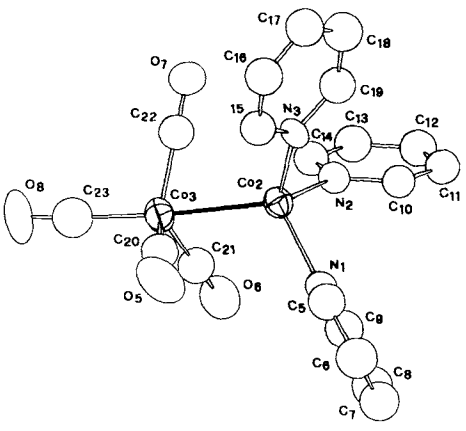

Fig. 2. Molecular crystal structure of $[(OC)_4CoCo(py)_3]^+$. Important distances [Å] and angles [°]: Co2-Co3 2.490(2), C-O 1.14 (average), Co3-C23 1.816(13), Co3-C_{eq} 1.74 (average), Co2-N 2.035 (average); Co2-Co3-C23 175.7(4), Co2-Co3-C_{eq} 77.9 (average), Co3-Co2-N 112.8 (average), Co3-C_{eq}-O 176.7 (average).

synproportionation of metal carbonyls can occur with[12] or without the intermediacy of isocarbonyl compounds.

These findings show that, through a base-promoted disproportionation reaction, $[Co_2(CO)_8]$ **3** can be the source of highly polarizing Co^{2+} ions when only moderate amounts of bases are employed.

[8] Pyridine (1.5 mL, 18.6 mmol) in 100 mL of *n*-hexane was added dropwise to a stirred solution of **3** (6.6 g, 19.3 mmol) in 500 mL of *n*-hexane. Simultaneously with gas evolution, **4** starts to precipitate immediately as a carmine microcrystalline solid. At the end of the addition, the solid was collected and washed with 25 mL of *n*-hexane. Yield: 4.25 g (60%).
[9] **4**: triclinic crystals, $P\bar{1}$, $a=16.910(3)$, $b=13.171(3)$, $c=12.125(3)$ Å, $\alpha=104.80(2)$, $\beta=97.45(2)$, $\gamma=108.95(2)°$, $V=2401.7$ Å^3, $Z=2$. The structure was solved by direct methods using the SIR package (G. Cascarano, C. Giacovazzo, M. C. Burla, A. Nunzi, G. Polidori, M. Camalli, R. Spagna, D. Viterbo, IXth European Crystallographic Meeting, Torino 1985, Abstracts 1-046) and refined by the full-matrix least-squares method with the SHELX-76 program. To avoid a too high number of parameters, the pyridine rings were constrained to perfect hexagons with an edge of 1.395 Å and refined as rigid groups. The hydrogen atoms were included at the calculated positions (C-H = 1.08 Å, $U=0.16$ Å^2). Anisotropic thermal parameters were assigned to the Co atoms only. $R=0.059$, $R_w=(\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}=0.064$ ($1/w=\sigma^2(F_o)+0.0039F_o^2$) for 2837 unique reflections ($I\geq 3\sigma(I)$); Philips PW1100 single-crystal diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator).
[10] **5**: monoclinic crystals, $P2_1/n$, $a=22.699(3)$, $b=13.340(3)$, $c=9.050(3)$ Å, $\beta=98.79(2)°$, $V=2708.2$ Å^3, $Z=4$). The structure was solved and refined with the procedure described in [9]. The contribution of H atoms at the calculated positions was included, with an overall isotropic thermal parameter (U) that refined to 0.15 Å^2. Anisotropic thermal parameters were refined only for Co, O, and N atoms. $R=0.048$; $R_w=(\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}=0.051$ ($1/w=\sigma^2(F_o)+0.0003F_o^2$) for 2172 unique reflections ($I\geq 3\sigma(I)$). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52384, the names of the authors, and the journal citation.
[11] To 3.8 g (11.1 mmol) of **3** dissolved in 100 mL of a mixture of toluene and *n*-hexane, 1.85 mL (22.9 mmol) of py was added. The solution was kept under reduced pressure and stirred for 4 hours. Complex **5** was obtained as an emerald-green microcrystalline solid. Yield: 4.1 g (87%).

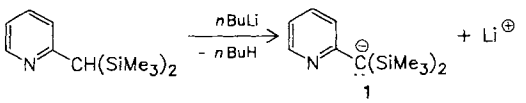
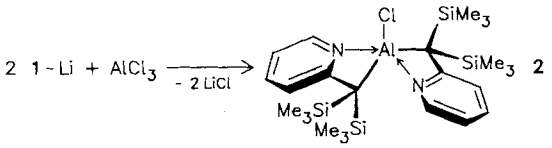
lution, having low electrical conductivities.[1] In the presence of neutral donor ligands such as pyridine and 2,2'-bipyridyl, however, their conductivities increase dramatically, presumably as a consequence of autoionization to $[AlR_2L_2]^{\oplus}$ and $[AlR_4]^{\ominus}$ or $[AlR_2Cl_2]^{\ominus}$ (L = Lewis base).[2] While anionic aluminate species are well known from other studies, there are no authenticated alkylaluminum cations.[***] Such cationic species for the heavier congeners of the Group III elements, in contrast, have been substantiated.[3] As part of a systematic study of the coordination chemistry of the bulky *N*-functionalized alkyl ligand **1**, we have prepared and structurally characterized a complex containing an alkylaluminum cation.

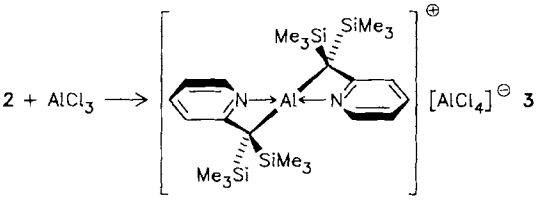


1

Solutions of $[(Li\,\mathbf{1})_2]$[4,5] in Et_2O/hexane react with $AlCl_3$ in Et_2O to yield $[Al\,\mathbf{1}_2Cl]$, **2**, in modest yield.[6] The corresponding gallium complex has a five-coordinate metal center, the alkyl ligands generating four-membered chelate rings,[7] as in the corresponding Mg, Zn, and Cd (but not Hg) complexes.[8] Complex **2** is also likely to have a five-coordinate metal center, a novelty for alkylaluminum sys-



tems devoid of multicenter bonding. The nonequivalence of the $SiMe_3$ groups on the ^{1}H-NMR time scale is in agreement with this structure in solution.



Compound **2** rapidly underwent metal-halogen cleavage with $AlCl_3$ in benzene yielding $[Al\,\mathbf{1}_2][AlCl_4]$, **3**,[9] which was isolated initially as a liquid clathrate of composition $\mathbf{3}\cdot(C_6H_6)_{14}$ (^{1}H-NMR). Despite the nonequivalence of the $SiMe_3$ groups in the cation as shown by an X-ray crystal structure determination,[10] the dynamic equivalence of these groups was evident in benzene on the ^{1}H-NMR time scale. Compound **3** was also isolated as a minor product in the above synthesis of **2**.

Overall, the environment about the metal in the cation of **3** is a distorted tetrahedron, which relates to the small "bite" of the bidentate ligand. The Al-C distances (mean 1.99 Å) are typical of terminal Al-C bonds; e.g., 1.995(8) Å in $[Al(2,4,6\text{-}Me_3C_6H_2)_3]$[11] and 1.982(6)-1.997(6) Å in $[Al(CH_2C_6H_4)_3]$.[12] The Al-N distances (mean 1.92 Å) are well below those for other N-centered Lewis base adducts of organoaluminum complexes. These distances are, however, for sp^3 rather than sp^2 nitrogen donors (e.g., Al-N is 2.02 Å in $[AlIMe_2(NMe_3)]$[13]) and therefore reflect a large polarization of the N electron cloud by electropositive aluminum in $[Al\,\mathbf{1}_2]^{\oplus}$. The geometry of the anion $[AlCl_4]^{\ominus}$ is unexceptional.

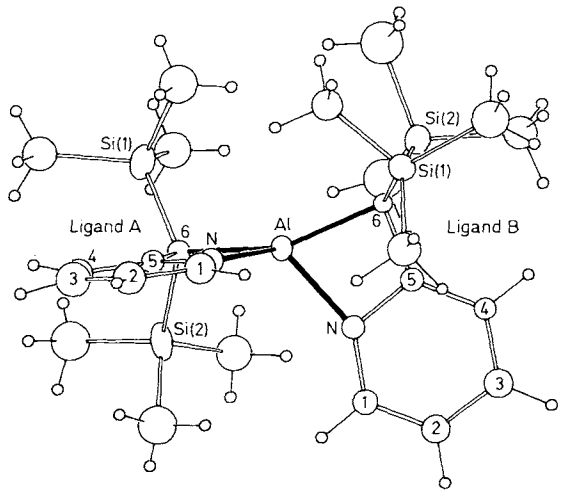


Fig. 1. Crystal structure of the cation in **3** (thermal ellipsoids at the 20% probability level). The hydrogen atoms have arbitrary radii of 0.1 Å. Selected bond distances [Å] and angles [°]: Al-N(A) 1.91(2), Al-C(A6) 1.98(2), Al-N(B) 1.93(2), Al-C(B6) 2.01(2), N(A)-Al-C(A6) 72.7(9), N(A)-Al-N(B) 114.6(10), C(A6)-Al-N(B) 123.9(6), N(A)-Al-C(B6) 123.2(8), C(A6)-Al-C(B6) 152.2(10), N(B)-Al-C(B6) 73.2(7).

Experimental Procedure

The syntheses were carried out with exclusion of air and water. To 20 mL of *n*BuLi in hexane (1.71 M, 34.2 mmol) was added 20 mL of Et_2O, then 7.3 g (30.0 mmol) of **1**-H. After stirring the resulting orange solution for 1 h, 2.0 g (14.7 mmol) of freshly sublimed $AlCl_3$ in 40 mL of Et_2O was added over 1 h. The mixture was stirred at room temperature overnight, then filtered and cooled to −30 °C, affording **2**. Complex **2** was recrystallized from benzene as colorless needles (4.3 g, 54%).

3: To **2** (0.81 g, 1.40 mmol) in 10 mL of benzene was added 0.25 g (1.87 mmol) of $AlCl_3$. Two liquid phases immediately separated. The solvent was then removed in vacuo and the product, **3**, recrystallized as colorless plates from 5 mL of tetrahydrofuran (0.74 g, 83%).

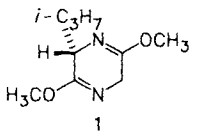
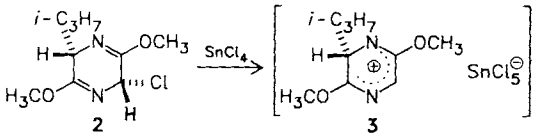
Optically Active α-Arylglycine Esters by Friedel-Crafts Alkylation with the Chiral Cation of the Bislactim Ether of *cyclo*-(L-Val-Gly)**

By *Ulrich Schöllkopf,** *Sabine Grüttner, Ralf Anderskewitz, Ernst Egert,** and *Michael Dyrbusch*

During the past few years, we have developed an asymmetric synthesis of nonproteinogenic amino acids, which makes use of metalated (anionic) bislactim ethers of 2,5-piperazinediones and has come to be called the bislactim ether method.[1] Its scope of application would be increased if it were possible to generate the bislactim ether cation **3**—a chiral, nonracemic glycine-cation equivalent[2]—and to allow this cation to react with olefins or arenes in a Friedel-Crafts (FC) reaction. Reaction with arenes would afford optically active α-arylglycines, which are of pharmacological interest on account of their potential biological activity and as components of drugs.[3] Although asymmetric syntheses of α-arylglycines according to the Strecker method have already been described,[4] there has been no report of their syntheses by asymmetric FC reactions.



1



2 **3**

We report here on the asymmetric synthesis of alkoxy-substituted α-arylglycine methyl esters of the type **9**. This synthesis starts from the chloride **2**[5] of the bislactim ether **1**;[6] compound **2** is allowed to react with alkoxy-substituted arenes **4** or **5** in the presence of tin tetrachloride as Lewis acid. The ion pair **3**, which is formed as an intermediate, reacts with **4** or **5** in an FC reaction[7] to give the compounds **6** or **7**, respectively (Table 1). In addition, small amounts of the pyrazine derivatives **8a** or **8b** are formed. Reaction with anisole **4c** is plagued—as is the case for other FC alkylations—by the problem of regioselectivity. However, the regioisomers **6c** and **6d** could be separated by gas chromatography.[8]

The *trans* arrangement of the substituents at C2 and C5 in **6** and **7** was confirmed (1) by the $^5J_{H\text{-}5/H\text{-}2}$ values of ca. 4 Hz, which are typical for the *trans* configuration in the bislactim ether system, (2) by the X-ray structure analysis of an FC adduct (**6c** with OiC_3H_7 instead of OCH_3, Fig. 1),[10] and (3) by hydrolysis of **9c** (cf. below) to (*R*)-(−)-*p*-anisylglycine.

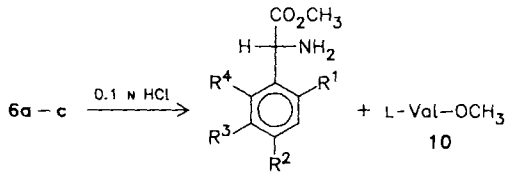
[**] Asymmetric Syntheses via Heterocyclic Intermediates, Part 35.—Part 34: U. Schöllkopf, W. Kühnle, E. Egert, M. Dyrbusch, *Angew. Chem. 99* (1987) 480; *Angew. Chem. Int. Ed. Engl. 26* (1987) 480.

Because of the danger of epimerization or racemization, the FC adducts **6a–c** have to be hydrolyzed, under the mildest conditions possible (0.1 N HCl, 2 equivalents, room temperature), to the previously unknown (*R*)-α-arylglycine methyl esters **9a–c** and L-valine methyl ester **10**.[11] As for **6c**, even under these conditions, 5–10% epimerization/racemization took place. The L-valine methyl ester that is formed along with the desired compound **9** could be removed under vacuum. Since the configuration of *p*-anisylglycine is known,[12] we hydrolyzed **9c** with 6 N HCl



9a – c

a, $R^1 = R^3 = OC_2H_5$, $R^2 = R^4 = H$
b, $R^1 = R^2 = R^4 = OCH_3$, $R^3 = H$
c, $R^1 = R^3 = R^4 = H$, $R^2 = OCH_3$

and obtained (*R*)-(−)-*p*-anisylglycine even though partial racemization occurred under the relatively drastic reaction conditions.

Experimental Procedure

Correct elemental analyses of all compounds. $[\alpha]_D^{20}$ values for $c \approx 1.3$ g/100 mL ethanol; 100-MHz ^{1}H-NMR spectra in $CDCl_3$.

6a: To the solution of **4a** (3.32 g, 20.0 mmol) in 40 mL of dichloromethane, $SnCl_4$ (1.30 g, 5.0 mmol) was injected at −78°C, the resulting solution was stirred for a short period, and the chloride **2** (as a solution in dichloromethane [5]), prepared from 0.92 g (5.0 mmol) of **1** according to [5], was then injected. After 6 h at −78°C, 50 mL of phosphate buffer (pH = 7) and 20 mL of dichloromethane were added, the phases were separated, and the aqueous phase was extracted three times with 30 mL of chloroform [13]. After drying of the organic phase with $MgSO_4$ and removal of the solvent under reduced pressure (12 torr), a residue was obtained which contained excess **4a**, **6a**, and a small amount of **8a**; the latter was removed at 25°C/10^{-3} torr. Distillation of the residue at 10^{-2} torr in a kugelrohr apparatus gave **4a** as forerun. Yield of **6a**: 1.14 g (65%), b.p. = 150°C/10^{-2} torr. Addition of a small amount of cyclohexane eventually resulted in the crystallization of (2*R*,5*S*)-**6a** (m.p. = 66–67°C).

6b: Synthesized analogously to **6a** from **4b** (0.84 g, 5.0 mmol), $SnCl_4$ (1.04 g, 4.0 mmol), and **1** (0.74 g, 4.0 mmol). Excess **4b** was removed from the final residue at 60°C/10^{-4} torr. Yield of **6b**: 0.94 g (67%), mixture of diastereomers. Crystallization from cyclohexane/dichloromethane at 4°C gave (2*R*,5*S*)-**6b**, m.p. ≈ 172–174°C.

6c/d: Synthesized analogously to **6a** from **4c** (0.43 g, 4.0 mmol), $SnCl_4$ (0.52 g, 2.0 mmol), and **1** (0.37 g, 2.0 mmol). Excess **4c** was removed from the residue at 20°C/10^{-3} torr. Yield of **6c/d**: 0.36 g (62%), contaminated with a small amount of **8a,b** [14]. **6c** and **6d** had to be separated by gas chromatography [8].

7: Synthesized analogously to **6a** from **5** (0.55 g, 3.5 mmol), $SnCl_4$ (0.78 g, 3.0 mmol), and **1** (0.55 g, 3.0 mmol). Most of the excess **5** was removed from the residue at 20°C/10^{-4} torr. Crude yield of **7**: 0.32 g (71%). Recrystallization from pentane gave (2*R*,5*S*)-**7**, m.p. = 96–97°C.

9a: **6a** (0.32 g, 1.0 mmol) was allowed to stir for 12 h at room temperature with 20 mL (2.0 mmol) of 0.1 N HCl and ca. 5 mL of tetrahydrofuran. The reaction mixture was extracted with ca. 20 mL of ether (which was discarded) and then saturated with NaCl. Approximately 15 mL of ether was added followed by conc. NH_3 (with vigorous stirring) until the pH was 9–10. The ether phase was separated and the aqueous phase was extracted three times with 15 mL of ether. The combined ether extracts were dried with $MgSO_4$. Removal of the ether under vacuum and of **10** at 50°C/10^{-3} torr (kugelrohr) gave 0.26 g (89%) of **9a**, *ee* > 95% [15], $[\alpha]_D^{20} = -94.4°$. Partial racemization of **9a** occurred upon distillation (100°C/10^{-2} torr). ^{1}H-NMR: $\delta = 1.34$ (t, $J = 7$ Hz, 6H; OCH_2CH_3), 1.97 (s, 2H; NH_2), 3.68 (s, 3H; CO_2CH_3), 3.96 (q, $J = 7$ Hz, 4H; OCH_2CH_3), 4.64 (s, 1H; CH–CO–), 6.65–6.90 (3H; aryl-H).

9b: Synthesized analogously to **9a** from (2*R*,5*S*)-**6b** (0.35 g, 1.0 mmol); **9b** (0.135 g, 60%), *ee* > 95% [15], $[\alpha]_D^{20} = -77.6°$, m.p. ≈ 75–77°C. ^{1}H-NMR: $\delta = 1.93$ (br. s, 2H; NH_2), 3.66 (s, 3H; CO_2CH_3), 3.80 (s, 6H; *o*-OCH_3), 3.81 (s, 3H; *p*-OCH_3), 4.93 (s, 1H; CH–CO–), 6.13 (2H; aryl-H).

9c: Synthesized analogously to **9a** from (2*R*,5*S*)-**6c** (0.43 g, 1.5 mmol) (*de* ≈ 89%, separated from **6d** by GC [8]), 2 h hydrolysis; **9c** (0.20 g, 69%), *ee* ≈ 84% [15], $[\alpha]_D^{20} = -117.3°$, m.p. = 64–65°C. ^{1}H-NMR: $\delta = 1.90$ (s, 2H; NH_2), 3.66 (s, 3H; *p*-OCH_3), 3.77 (s, 3H; CO_2CH_3), 4.52 (s, 1H; CH–CO–), 6.81–7.22 (4H; aryl-H).

[11] It is surprising that the compounds **6a–c**, which contain an aryl ring at C2 capable of undergoing conjugation, do not rapidly tautomerize in acidic medium to enamines and thus undergo epimerization at C2. As shown by the X-ray structure analysis (Fig. 1), the aryl ring is orthogonal to the heterocycle. This conformation is presumably strongly fixed by the *o*-substituted aryl rings (**6a,b**, 7). Thus, no π conjugation is possible between the aryl ring and the potential enamine double bond.

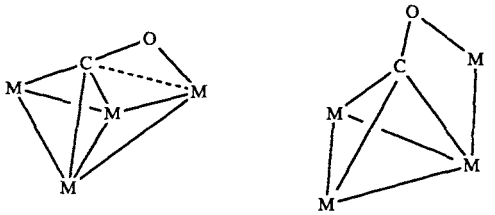
[13] The use of chloroform instead of dichloromethane results in better separation of the phases upon extraction.
[14] If necessary, **8a** can be separated by low-pressure chromatography (silica gel, ether/petroleum ether = 1/3). However, **6c/d** thereby epimerize to a small extent.
[15] Determined with 40-mol% Eu(tfc)$_3$ at the ^{1}H-NMR signal of the ester OCH_3 group ($CDCl_3$); >95% was assumed when the signals were shifted but no splitting occurred.

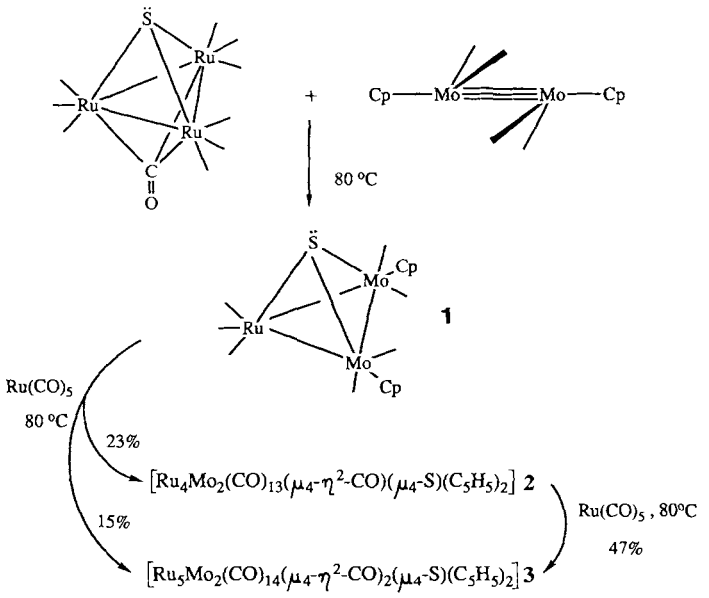
A Mixed-Metal Cluster with Two Quadruply-Bridging Carbonyl Ligands**

By *Richard D. Adams,* James E. Babin,* and *Miklos Tasi*

Although complexes containing quadruply bridging (μ_4) carbonyl ligands have been known for over ten years,[1] the number of examples of these bonding modes is still very small.[2,3] Sideways coordination and CO bond order reduction[3,4] are believed to be prerequisites for the C–O bond cleavage reactions that occur on metal surfaces.[5] We now wish to report the first example of a transition metal cluster compound that contains two quadruply bridging carbonyl ligands.



A B



Scheme 1. The lines from the metal atoms represent CO-ligands.

The products **1** (49%),[6] **2** (3%), and **3** (9%) were isolated by thin-layer chromatography from the reaction of $[Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$ with $[CpMo(CO)_2]_2$ in benzene at 80 °C (Scheme 1). All three compounds were characterized by IR and ^{1}H-NMR spectroscopy and X-ray crystallographic analyses.[7,8] The molecular structures of **2** and **3** are shown in Figure 1. Both compounds contain square-pyramidal Ru_3Mo_2-clusters. The molybdenum atoms occupy the apical and one basal position of the pyramid. The base is bridged by a μ_4-sulfido ligand. Compound **3** contains two μ_4-carbonyl ligands and has a crystallographically imposed plane of symmetry that passes through the two molybdenum atoms, Ru1 and the sulfur atom. In **2**, one Ru–Ru basal edge is bridged by a $Ru(CO)_3$ group, while in **3** both Ru–Ru basal edges are bridged by $Ru(CO)_3$ groups. Both compounds contain π-bonded μ_4-carbonyl groups arranged such that the carbon atoms bridge Ru_2Mo triangular faces of the cluster and the oxygen atoms are bonded to the bridging $Ru(CO)_3$ groups. The C–O distances in these ligands are large; they are 1.262(8) Å in **2** and 1.25(1) Å in **3**, and indicate a significant reduction in the CO bond order. This is further supported by the IR spectra, which show very low frequencies for the C–O stretching vibrations in **2** (1457 cm^{-1}) and **3** (1453 and 1419 cm^{-1}).[2] The observation of two IR absorptions for the μ_4-CO ligands in **3** indicates that vibrational coupling is important even for quadruply bridging carbonyl ligands. Compounds **2** and **3** can also be obtained from the reaction of **1** with $[Ru(CO)_5]$ at 80 °C (Scheme 1).

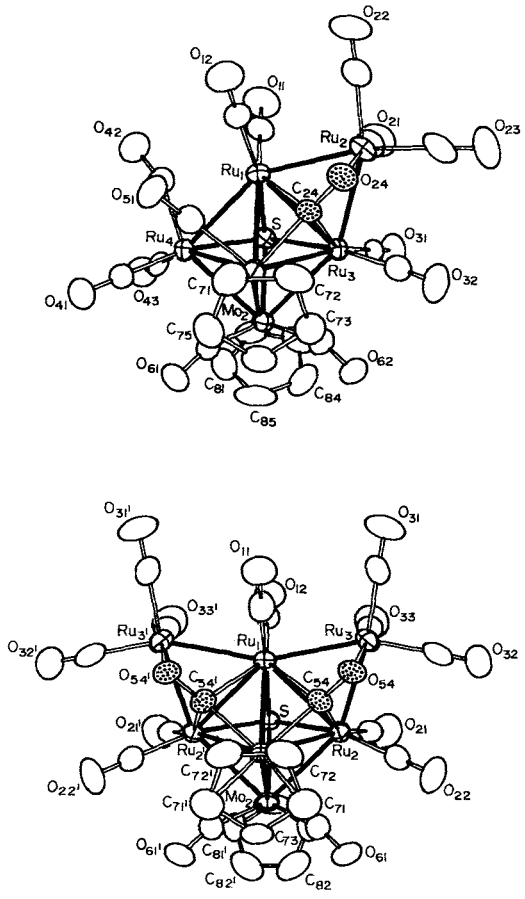


Fig. 1. Top: Crystal structure of **2**. Selected bond distances [Å] and angles [°]: Ru1-Ru3 2.864(1), Ru1-Ru4 2.841(1), Mo1-Ru1 3.022(1), Mo1-Ru3 2.887(1), Mo1-Ru4 2.937(1), Mo1-Mo2 3.117(1), Mo1-C24 1.940(8), Ru1-C24 2.315(7), Ru3-C24 2.259(8), Ru2-O24 2.136(5), C24-O24 1.262(8), Mo1-C24-O24 149.1(6).—Bottom: Crystal structure of **3**. Selected bond distances [Å] and angles [°]: Ru1-Ru2 2.867(1), Mo1-Ru1 2.918(2), Mo1-Ru2 2.897(1), Mo1-Mo2 3.049(2), Mo2-Ru2 2.887(1), Mo1-C54 1.98(1), Ru1-C54 2.36(1), Ru2-C54 2.18(1), Ru3-O54 2.125(7), C54-O54 1.25(1), Mo1-C54-O54 148.0(8).

A flurry of interest has greeted the growing study of mixed metal compounds.[9] An understanding of the heterosite-coordination and -reactivity[10] that occurs in

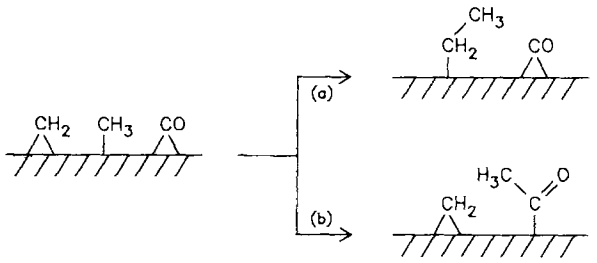
Hydride Abstraction From $[C_6H_6Os(CO)(CH_3)_2]$: Does a Metal-bound Methyl Group Migrate Preferentially to a CO or to a CH_2 Ligand?**

By *Karin Roder* and *Helmut Werner**

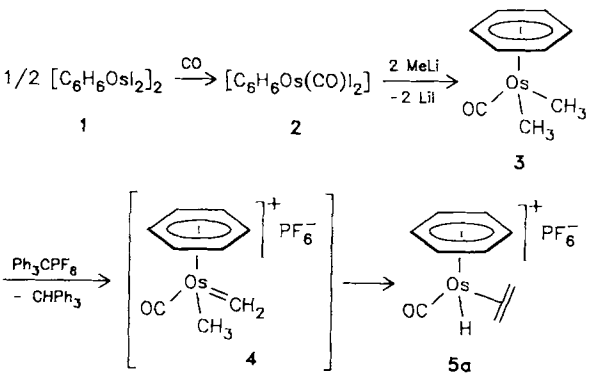
Dedicated to Dr. Reinhard Schliebs on the occasion of his 60th birthday

The concepts regarding the mechanism of the Fischer–Tropsch process include the assumption that primary C–C bond formation on the surface of the catalyst occurs by combination of a CH_3 with a CO group or with a CH_2 group formed in a hydrogenation step.[1] Model examples for both of these processes are known using both mono- and dinuclear metal complexes as starting materials.[2,3] However, a remaining question is whether the C–C bond forming step (a) or (b) of Scheme 1 is preferred, i.e., which of the competing ligands CH_2 or CO couples with the CH_3 group.



Scheme 1.

To answer this question, we have prepared compound **3** from **1** and studied its reaction with Ph_3CPF_6. Besides $CHPh_3$ (detected by ^{1}H-NMR and MS), only the ethylene hydrido complex **5a** is formed. In accord with the results of previous investigations,[4] we propose that the trityl cation abstracts a hydride ion from one of the CH_3 groups. The intermediate **4** can then rearrange by CH_3 migration (probably not by CH_2 insertion![3e]) to give the corresponding ethylmetal compound, from which complex **5a** is formed by β-hydride elimination. There is no evidence that radical species (which have been observed during the formation of $[(C_5H_5)_2WH(C_2H_4)]^+$ from $[(C_5H_5)_2W(CH_3)_2]$ and Ph_3CPF_6[5]) are involved in this process.



The properties (color, thermal stability, conductivity) and spectroscopic data of **5a**[6] are similar to those of the analogous complex $[C_6H_6OsH(C_2H_4)PMe_3][PF_6]$,[7] which has recently been prepared by a completely different route. For neither $OsH(C_2H_4)$ complex has an equilibrium with the corresponding alkyl isomer been detected by NMR spectroscopy.

Deprotonation of the cation of **5a** with NaH in tetrahydrofuran (THF) leads to the formation of **6**, which is the first example of a half-sandwich type complex $[C_6H_6OsLL']$ which contains *two monodentate* π-acceptor ligands. Although the electron density at the metal atom in **6** is lower than that in the analogous complexes **7**[7] and **8**,[8] compound **6** can be protonated by strong acids. With HBF_4 (in ether) **5b** is obtained; however, NH_4PF_6 does not react with **6** to give **5a**. Therefore, complex **6**, like **7**, **8** and the compounds $[C_6H_6OsL_2]$ ($L = PPh_3$, $P(OMe)_3$)[8] behaves as a *metal base*. The metal basicity of compound **6** is comparable to that of $[C_6H_6Ru(C_2H_4)PMe_3]$ and $[C_6Me_6Ru(CO)PMe_3]$.[9]

5a $\xrightarrow[-NaPF_6,\ -H_2]{NaH}$ $[C_6H_6Os(C_2H_4)CO]$ (**6**) $\xrightarrow{HBF_4}$ $[C_6H_6OsH(C_2H_4)CO][BF_4]$ (**5b**)

$[C_6H_6Os(C_2H_4)PMe_3]$ (**7**) $[C_6H_6Os(CO)PMe_3]$ (**8**)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and Degussa AG. We highly appreciate the active collaboration of Miss *I. Keupp* in this project.

Using the bis(ethylene) complexes $[C_5H_5M(C_2H_4)_2]$ (M = Rh, Ir) as starting materials, *Perutz* and *Haddleton* et al.[10] have recently generated in low-temperature matrices the compounds $[C_5H_5M(C_2H_4)CO]$, which are structurally similar to **6**. These $[C_5H_5M(C_2H_4)CO]$ complexes activate C–H bonds (including methane!). Since $[C_6H_6Os(C_2H_4)_2]$ is as yet unknown, compound **6** is not accessible via this route. Furthermore, it has not been possible to prepare **6** by the same method which leads to **7**, **8** and the complexes $[C_6H_6OsL_2]$[7,8] (reduction of the corresponding haloosmium(II) cation with $NaC_{10}H_8$). The transformation of **3** into **6** by stepwise abstraction of a hydride ion and a proton represents a valuable alternative to previous synthetic routes and promises further possible applications. The observation made in this study, that a CH_3 group prefers to migrate to a CH_2 instead of a CO group, can also be regarded as indirectly supporting the "polymerization of methylene groups" mechanism first proposed by *Fischer* and *Tropsch* as long ago as 1926.[11]

Experimental

2: A suspension of **1** (1.00 g, 0.96 mmol) in CH_2Cl_2 (60 mL) was saturated with CO in a Schlenk tube fitted with N_2 inlet. After stirring for 20 h at room temperature under a CO atmosphere, the solution was concentrated to ca. 5 mL and the product precipitated with hexane. The precipitate was separated from the solution, repeatedly washed with hexane, and finally dried in vacuo; m.p. 197 °C (decomp.); yield quantitative.

3: A suspension of **2** (276 mg, 0.50 mmol) in benzene (5 mL) was treated slowly at room temperature with 3.3 mL of a 0.6 N solution of methyllithium in ether (2.0 mmol). An orange-brown solution immediately formed which was stirred for 10 min and then evaporated to dryness in vacuo. The residue was treated with a few mL of benzene/hexane (1 : 1), and excess of methyllithium was destroyed by careful addition of deactivated Al_2O_3 (activity grade V). After chromatography of the benzene/hexane solution on Al_2O_3 (activity grade III), a yellow fraction containing **3** was eluted with benzene/hexane (1 : 1). Removal of the solvent furnished **3** as a yellow microcrystalline powder; m.p. 130 °C (decomp.); yield 63%.

5a: A solution of **3** (75 mg, 0.23 mmol) in ether (3 mL) was treated dropwise at −78 °C with a solution of Ph_3CPF_6 (89 mg, 0.23 mmol) in CH_2Cl_2 (3 mL). After slow warming, the reaction mixture was stirred for 1 h at room temperature. The precipitation of a light-brown solid was completed by addition of 15 mL of ether. The precipitate was separated from the solution, washed with ether and hexane, and dried in vacuo; yield 91%.

6: A suspension of **5a** (107 mg, 0.23 mmol) in THF (3 mL) was treated at −78 °C with NaH (ca. tenfold excess). After warming to room temperature, the solution was stirred for 30 min (evolution of gas occurs), and the golden-brown suspension was then reduced to dryness. The residue was extracted in small portions with 20 mL of benzene/hexane (1 : 1), the solution filtered, and the solvent removed in vacuo. A yellow microcrystalline powder was obtained; m.p. 98 °C (dec.); yield 77%. The protonation of **6** with HBF_4 in ether to give **5b** proceeds quantitatively.

Square Hg_4 Clusters in the Compound CsHg

By *Hans-Jörg Deiseroth** and *Axel Strunck*

It is astounding that all the studies reported thus far on the phase diagrams and magnetic properties of such apparently uncomplicated substances as the binary rubidium- and cesium-amalgams were carried out exclusively in the first half of the century.[1–3] And, with the exception of $RbHg_{11}$,[4] nothing has hitherto been reported about the structures of these experimentally problematical compounds, which are of special interest in view of the possibility of weak bonding interactions between the electronically saturated mercury atoms. Extremely air-sensitive, lustrous single crystals and microcrystalline samples of the compounds $RbHg_2$, $CsHg_2$, RbHg[5] and CsHg[6] have now been prepared and structurally characterized for the first time.[7] Only CsHg will be reported upon in this communication.

The peritectically melting CsHg, probably the most mercury-deficient compound in the cesium-mercury system, is characterized by isolated, square-planar Hg_4 clusters with metallic Hg-Hg contacts ($d_{Hg\text{-}Hg} \approx 300$ pm) corresponding to a formulation Cs_4Hg_4 (Fig. 1). CsHg is thus the second example of a structure type which was previously only found in the isotypic KHg investigated in an older and lesser known work.[8] Cs_4Hg_4 and K_4Hg_4, however, differ in a remarkable way: whereas the distances between the square Hg-clusters in K_4Hg_4 (336 pm) resemble those between the nearest neighbors in α-Hg (300–340 pm), in Cs_4Hg_4 they are so large (419 pm) that there can be no direct Hg-interaction between neighboring clusters.

The crystal structure of CsHg depicted in Figure 1a clearly reveals a columnar stacking of the Hg_4 clusters, which are surrounded by larger rectangular stacks of Cs atoms. The plane of the Hg_4 square is so strongly inclined to the stacking axis [001] that there would appear to be the possibility of there being shorter Hg–Hg distances within the stacks. These distances are, however, considerably longer than the shortest Hg–Hg distances between neighboring stacks.

Fachbereich 8—Anorganische Chemie der
Universität-Gesamthochschule
Postfach 1012 40, D-5900 Siegen (FRG)

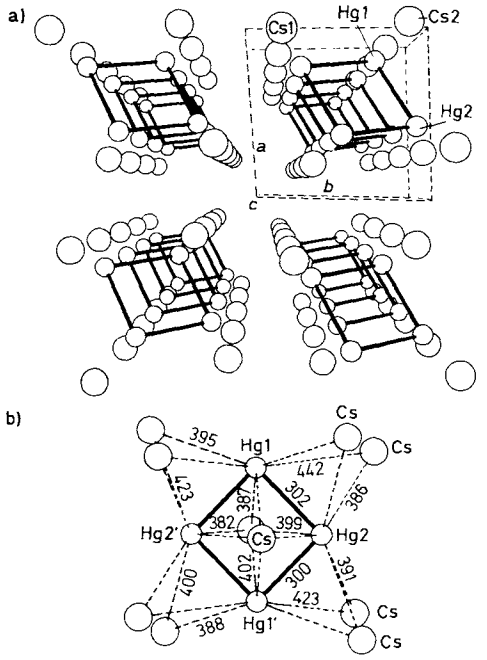

Fig. 1. a) Central perspective projection of the crystal structure of CsHg along [001]. b) Section from the crystal structure of CsHg with a Hg_4-cluster in the plane of the projection (all distances in pm, standard deviations smaller than 1 pm, distances not quoted can be completed by way of the symmetry center (midpoint of the Hg_4 square). The direction of viewing roughtly corresponds to the [111] direction of the triclinic unit cell. Angles [°]: Hg2-Hg1-Hg2' 88.2, Hg1-Hg2-Hg1 91.8.

The special role of the almost exactly square-planar Hg_4 units also follows from Figure 1b: the Hg atoms together with the Cs atoms in the immediate neighborhood form a characteristically distorted, almost cubic-face-centered unit with the Hg atoms located at four opposite face centers, but drastically shifted in the direction of the center of the cube. This immediately gives the impression of a bonding interaction between the Hg atoms.

So far, the only example of a compound containing similarly isolated square-planar Hg_4 clusters was the alkali-metal rich compound Na_3Hg_2 ($= Na_6Hg_4$).[9, 10] The structural data of the Hg_4 units in the three compounds Cs_4Hg_4, K_4Hg_4, and Na_6Hg_4 are almost identical. A square-planar Hg_4-unit as part of a Mn_4Hg_4 eight-membered ring is also present in the compound $[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)_2Hg]_4$.[11]

The chemical bonding in Cs_4Hg_4 could correspond to a state between the two extremes $(Cs^{\oplus})_4(Hg_4)^{4\ominus}$ (mercuride, saltlike) and $(Cs^{\oplus})_4(Hg_4)^0 4e^{\ominus}$ (metallic with four free electrons). Measurements of the temperature-dependence of the electrical resistivity[12] clearly show that Cs_4Hg_4 and the other amalgams newly prepared by us are metals. The formulation $(Cs^{\oplus})_4(Hg_4)^0 4e^{\ominus}$ must therefore be regarded as being the more appropriate. Our assumption of isolated $(Hg_4)^0$ in Cs_4Hg_4 is also supported by the results of a relativistic MO calculation for free $(Hg_4)^0$.[13] Accordingly, the Hg-Hg bonds in $(Hg_4)^0$ have a bond order of 0.5, so that the cluster can be expected to be stable—even if only slightly so.

Photoionization spectroscopic studies of Hg_n clusters in the gas phase[14] do indeed confirm the presence of Hg_4 units, but do not permit any conclusions to be drawn about their structure and abundance.

FCu[AuF_4], an Unusual Copper(II) Fluoroaurate(III)**

By *Bernd G. Müller**

Complex fluorides containing Cu^{2+} and Au^{3+} are of special interest because of their unusual structural chemistry: on the one hand, copper(II) fluorides with $3d^9$ configurated Cu^{2+} exhibit a structural behavior (Jahn-Teller effect) different from that of formally analogous compounds (such as those of the neighboring elements Ni, Zn), and, on the other, Au^{3+} is the only transition metal ion which exhibits exclusively coordination number four with square-planar arrangement toward fluorine. Furthermore, in the system CuF_2/AuF_3 the expected compound with the composition $Cu[AuF_4]_2$ (comparable to $M^{II}[AuF_4]_2$, $M^{II}=Mg$, Ni, Pd etc., up to Ba[1]) does not occur, instead (formally) only one F^- in CuF_2 is replaced by $[AuF_4]^-$.

The crystal structure of FCu[AuF_4] is remarkably simple:[2] in the center of the (triclinic) unit cell, linear $^1_\infty[-F(1)-Cu-F(1)-]$ chains (bond angle 180.0°) run parallel to [001]; four uncoupled $[AuF_4]^-$ groups are so arranged around each Cu^{2+} that the coordination number for Cu^{2+} is increased to C.N. = 6 (2+2+2). The structure of FCu[AuF_4] is reproduced in Figure 1: $[AuF_4]^-$ anions are stacked one above the other parallel to [001], each being so shifted (as a result of $\beta=98.7°$) that F(3) of one lies above Au^{3+} of the next $[AuF_4]^-$ unit at a distance $d_{Au-F(3)}=286.8$ pm. The $[AuF_4]^-$ group deviates only slightly from D_{4h} symmetry (all the F-Au-F angles are ap-

proximately 90° or 180°; only the distances (cf. Table 1) d_{Au-F} are slightly different), while the octahedral array around Cu^{2+} is noticeably distorted, especially with re-

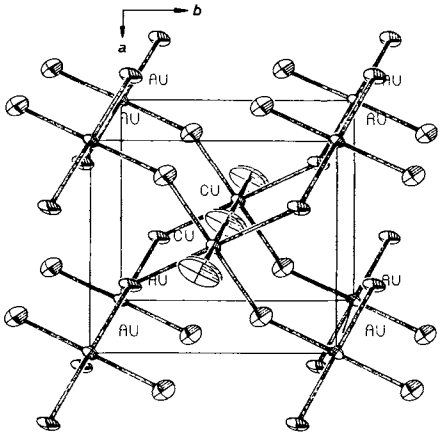

Fig. 1. Crystal structure of $FCu[AuF_4]$, view along [001].

spect to the distances d_{Cu-F} (cf. Table 1, the F(2)-Cu-F(3) angles are 87° (93°), all other angles are 180°). The interatomic distances are listed in Table 1, together with the motifs of mutual adjunction,[3] which provide information about the coupling and coordination sphere of the individual ions.

Table 1. Motifs of mutual adjunction, interatomic distances [pm], and coordination numbers.

	F(1)	F(2)	F(3)	C.N.
Cu^{2+}	2/2	2/1	2/1	6
d(Cu-F)	2×185.4(0)	2×221.6(1)	2×202.1(1)	(2+2+2)
Au^{3+}	—	2/1	2/1	4
d(Au-F)		2×193.0(1)	2×190.7(1)	
C.N. (F^-)	2	2	2	

As shown by the interatomic distances, $FCu[AuF_4]$ is an example of a structure with a d^9-configurated cation, in which this shows neither the "usual" environment with C.N. = 4+2 (elongated octahedron) nor the rarily observed C.N. = 2+4 (compressed octahedron), but assumes a special position with C.N. $[Cu^{2+}] = 2+2+2$. This is comparable with the situation found in $Ag_3Hf_2F_4$, in which isoelectronic Ag^{2+} ions with the coordination numbers C.N. = 4+2 as well as C.N. = 4+4 (more exactly: 4+2+2) are present.[4]

Magnetic measurements on $FCu[AuF_4]$ (μ_{eff}(251 K) = 1.32 B.M., μ_{eff}(13 K) = 0.32 B.M.) point to strong antiferromagnetic interaction along the linear [Cu-F(1)-Cu]-chains, which are shielded by diamagnetic $[AuF_4]^-$ groups. The ordering temperature, at which the (one-dimensional) antiferromagnetic coupling along these chains occurs, is $T_N \approx 85$ K.

Experimental

A mixture of equimolar amounts of CuO (Merck AR) and Au powder (prepared from 99.999% Au sheet (Degussa) by dissolution in HNO_3/HCl, repeated fuming-off with HCl and precipitation with SO_2) was treated with an F_2/N_2 mixture ($\approx 1:10$) at $T \leq 320$°C (AuF_3 sublimes from the reaction mixture at $T > 350$°C) ($t \approx 3$ d). The bright-yellow, microcrystalline samples were transferred under inert gas (dry Ar) to an annealed gold tube, which was then seal-welded and annealed at $T = 580$°C for ca. 4–5 weeks. The bright-yellow, transparent, irregular crystals could be selected and isolated under anhydrous petroleum (Na wire).

$Ag[MF_6]_2$ (M = Nb, Ta), Ternary fluorides of Divalent Silber**

By *Bernd G. Müller**

Ternary silver(II) fluorides are compounds of general interest, yet very little is known about their structures and properties. Thus, the structures of complex fluorides of divalent silver (just like the structure of AgF_2 itself) differ noticeably from those of formally analogous compounds of other elements—so far as they exist—due to the $4d^9$-configuration of Ag^{2+} (Jahn-Teller effect). Because of different ionic radii this also holds for corresponding fluorides containing isoelectronic $Cu^{2+}(3d^9)$. Furthermore, as a result of the frequently changing coordination numbers (C.N.) of Ag^{2+} toward F^- (e.g. $BaAgF_4$, C.N. = 4;[1] $CsAgFeF_6$, C.N. = 2+4;[2] $NaAgZr_2F_{11}$, C.N. = 2+2+2;[3] $Ag_3Hf_2F_{14}$, C.N. = 4+2 as well as 4+4[4]) predictions of the type and extent of Jahn-Teller deformation to be expected is not possible, particularly in the case of silver(II) compounds; detailed single-crystal investigations are therefore necessary in each of these cases. In addition, due to the high redox potential of Ag^{2+}, the number of compounds of simple composition (i.e. those compounds without additional stabilization by organic ligands such as py, bpy etc.) remains limited to fluorides and a few oxides (cf. e.g. ref. [5]), and, moreover, these are relatively difficultly accessible and readily decomposable.

The synthesis of $Ag[MF_6]_2$ (M = Nb, Ta), especially in the form of single crystals, is not simple because of the volatility of MF_5 and the thermal instability of $Ag[MF_6]_2$ (decomposition to $AgMF_6$, MF_5, F_2 as well as AgF and MF_5); the brilliant bright-blue samples are extremely sensitive to hydrolysis and attack the walls of the glass ampules on prolonged storage. The synthesis must therefore be carried out in autoclaves ($p_{F_2} \approx 3$ kbar) and the samples are usually inhomogeneous as a result of partial decomposition. Remarkably, in such experiments (360°C < $T \leq 400$°C) the needle-like, frequently clustered and twinned crystals separate out on the upper (colder) part of the autoclave (m.p. $(AgF_2) > 620$°C!).

Table 1. Motifs of mutual adjunction, interatomic distances [pm], and coordination numbers (C.N.).

	F(1)	F(2)	F(3)	F(4)	F(5)	F(6)	C.N.
Ag^{2+}	—	—	—	2/1	2/1	2/1	4+2
d(Ag-F)	—	—	—	2×236.7(7)	2×206.7(7)	2×203.0(6)	
Ta^{5+}	1/1	1/1	1/1	1/1	1/1	1/1	6
d(Ta-F)	181.7(7)	186.5(7)	183.4(6)	191.0(7)	197.6(6)	200.0(6)	
C.N.(F^-)	1	1	1	2	2	2	

The structure of $Ag[TaF_6]_2$ is best described in terms of a layer structure (Fig. 1):[6] Three $[AgF_6]$-octahedra are each coupled alternately "above and below" the (100) plane by three *cis* F^- forming a triangular face of a markedly distorted $[TaF_6]$-octahedron; cf. motifs of mutual adjunction[7] in Table 1.

No further coupling via cations takes place between these (two-dimensional) "layer packets".

$$[Ag(\overset{4}{F}_{1/2})_2\,(\overset{5}{F}_{1/2})_2\,(\overset{6}{F}_{1/2})_2]\,[\overset{4}{F}_{1/2}\,\overset{5}{F}_{1/2}\,\overset{6}{F}_{1/2}\,Ta\,\overset{1}{F}_{1/1}\,\overset{2}{F}_{1/1}\,\overset{3}{F}_{1/1}]_{6/3}$$

As follows from the interatomic distances (Table 1), Ag^{2+} in this type of compound shows the expected and favored elongated octahedral coordination for d^9-configurated cations. This, as mentioned at the outset, is certainly not the rule but rather an exception in the case of divalent silver. According to the crystal data ($a=906.1$, $b=560.7$, $c=520.7$ pm, $\alpha=118.7$, $\beta=91.61$, $\gamma=102.3°$) (four-circle diffractomer measurement) $Ag[NbF_6]_2$ is isotypic.

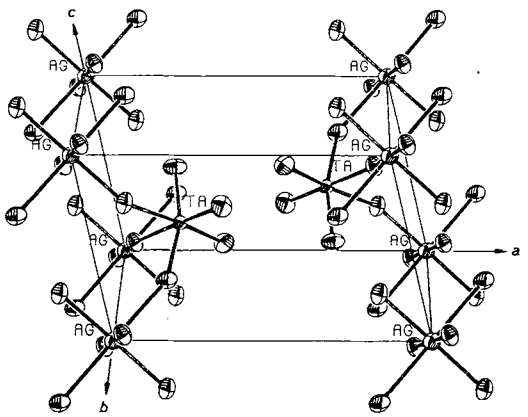

Fig. 1. Crystal structure of $Ag[TaF_6]_2$.

$Ag[TaF_6]_2$ is paramagnetic, the Curie or Curie-Weiss law is obeyed down to ca. 13 K ($\mu_{eff}(251\,K)=1.95$ B.M.; $\mu_{eff}(13\,K)=1.90$ B.M., $\theta_{calc}=3.1$ (± 1.1) K). This finding is understandable, because the AgF_6 octahedra are isolated from each other and consequently a magnetic interaction via F^- bridges is not possible.

Experimental

About 200–300 mg of an equimolar amount of Ag_2O (Merck p.a.) and M_2O_5 (pure, Merck) was transferred to an open Monel cylinder and inserted into a stainless-steel autoclave furnished with a Monel inlet. The autoclave (total volume: ca. 6 mL) was then cooled (with $(N_2)_{liq}$) to $-196°C$ and filled with ca. 4.5 mL $(F_2)_{liq}$ (the fluorine was taken from a steel bomb (Kali Chemie), passed over NaF to remove HF, condensed into a calibrated cold finger (Duran glass), and finally distilled into the autoclave). The (still) cold autoclave was placed in a furnace preheated to ca. 300°C; the furnace was then brought to 380–400°C ($p_{F_2}=3.4$ kbar) and kept at this temperature for 5–6 weeks (formation of single crystals). After slow cooling to room temperature the F_2/O_2 mixture still remaining was removed by distillation at $-196°C$ and the autoclave (again at room temperature and still under residual fluorine) finally opened. The samples were transferred into carefully baked out glass vessels under dry argon and worked up or stored at $-20°C$ in a refrigerator.

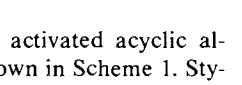
Generation and Interception of 1-Oxa-3,4-cyclohexadiene**

By *Michael Schreck* and *Manfred Christl**

The short-lived 1,2-cyclohexadiene **1**, the most highly strained of the previously known monocyclic allenes, is regarded as well characterized.[1] Very little is known, however, about hetero derivatives of this reactive intermediate; we therefore searched for an access to the title compound **2**. Allene **1** is best generated by treatment of 6,6-dibromobicyclo[3.1.0]hexane with methyllithium.[2] Hence, 6,6-dichloro- **3a**[3] and 6,6-dibromo-3-oxabicyclo[3.1.0]hexane **3b**[3a,4] are potential precursors for **2**. The reactions of **3a**[5] and **3b**[4] with *n*-butyllithium have already been investigated, but products derived from **2** were neither sought for nor found.[6] Utilizing well-established reaction partners[7] of **1** as solvents, we have now repeated such experiments at -40 to $-20°C$ and obtained trapping products of **2**.



The results of the reactions with activated acyclic alkenes and the yields obtained are shown in Scheme 1. Styrene yielded a 10 : 1 mixture of the *exo*- and *endo*-8-phenyl-

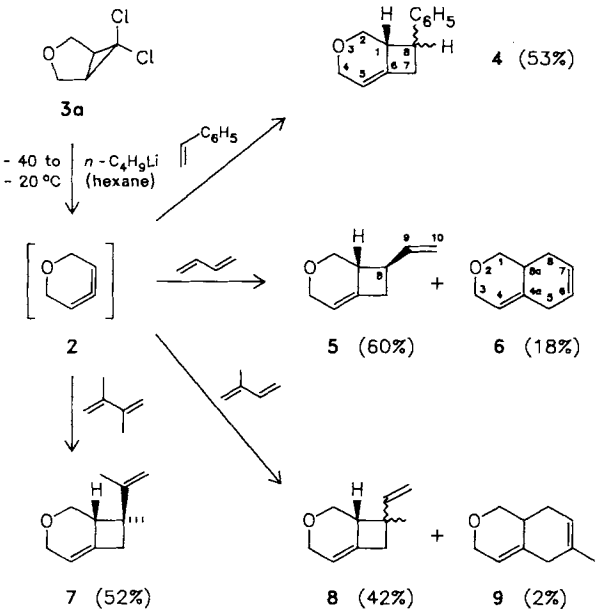
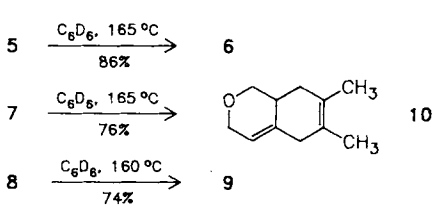
3-oxabicyclo[4.2.0]oct-5-enes **4**. 1,3-Butadiene gave rise to the [2+2]-cycloadduct **5** and the [4+2]-cycloadduct **6**. Isoprene afforded a 10:1 mixture of the diastereomeric [2+2]-cycloadducts **8** and a small amount of the [4+2]-cycloadduct **9**, while 2,3-dimethyl-1,3-butadiene furnished only the [2+2]-cycloadduct **7** (for selected physical data see Table 1).



Scheme 1. [8]

As shown in Scheme 2, the 8-vinyl-3-oxabicyclo[4.2.0]-oct-5-enes **5**, **7**, and **8** could be converted into the 3,5,8,8a-tetrahydro-1*H*-2-benzopyrans **6**, **10**, and **9**, respectively, in good yields by heating at 160–165°C. With regard to the mechanisms of all these processes, the same concepts may be applied which have been outlined for the formation of the corresponding adducts of **1**[7,9] and their rearrangement.[7c]



Scheme 2. [8]

The reaction of *n*-butyllithium with **3a** in furan, which counts among the less reactive trapping agents for **1**,[7b] did not produce an adduct of the heteroarene but gave the butylpentadienol **11**[8] in 49% yield[6] (Scheme 3). We also obtained **11** when using petroleum ether as solvent. *n*-Butyllithium probably attacks the central C-atom of the allene moiety of **2** and initiates ring-opening in an S_N2' reaction, in which the oxygen atom, possibly complexed by a lithium ion, serves as leaving group. Since furan is obviously not reactive enough to compete with *n*-butyllithium for **2** we generated **2** from **3b**[3] in furan by the less nucleophilic

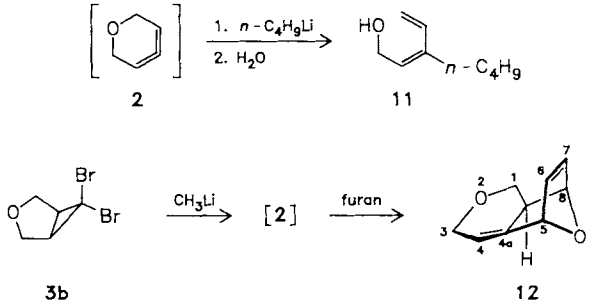
methyllithium and isolated the [4+2]-cycloadduct **12**[8] in 21% yield (Scheme 3).

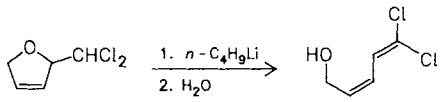
Because of the smaller covalent radius of the oxygen atom, the oxa derivative **2** should have a more bent allene moiety in comparison to 1,2-cyclohexadiene **1** and, as a



Scheme 3.

consequence, should exhibit a higher strain energy. Despite this, **2** can be generated in an analogous way as **1**, and cycloaddition products with activated alkenes are formed in similar yields as in the case of **1**. A specific feature of **2** is the addition of the nucleophile *n*-butyllithium to give **11**.

The majority of the above reactions of **3a** were not carried out with the pure substance but in the presence of the insertion product **13** of dichlorocarbene and 2,5-dihydrofuran which is also formed in the synthesis of **3a**.[3] *n*-Bu-



13 14

tyllithium converts **13** by ring-opening β-elimination into (*Z*)-5,5-dichlorpenta-2,4-dienol **14**,[10] which could, however, be readily separated from the cycloadducts.

Second Sphere Coordination of Tetraammineplatinum(II) by a Macropolycyclic Crown Ether Bisamide Receptor**

By *David R. Alston, Alexandra M. Z. Slawin, J. Fraser Stoddart,* David J. Williams,* and *Ryszard Zarzycki*

In our quest to find a molecular receptor more highly designed than [18]crown-6 (18C6)[1] for the antitumour drug cisplatin, [*cis*-$Pt(NH_3)_2Cl_2$], we decided to modify chemically those macrobicyclic polyethers with the demonstrated ability[2] to form adducts with cationic *cis*-diamminerhodium complexes. Since preliminary experiments indicated that **1** does not form adducts in a variety of organic solvents with cisplatin, it was decided, in view of our observation[1] of the inter-adduct hydrogen bonding interactions (a) between ammine and chlorine ligands and (b) between ammine ligands and solvating dimethylacetamide (dma) molecules in [{*cis*-$[Pt(NH_3)_2Cl_2]\cdot dma\}_2$-18C6], to incorporate between the two trisubstituted benzene rings a fourth chain containing two amide linkages as potential hydrogen bonding donors to the chlorine ligands. Here, we describe the preparation[3] in eight steps (→**2**→**3**→**4**→**5**→**6**→**7**→**8**→**9**) of the macropolycyclic bisamide **9** starting from 4-bromo-2,6-dimethylphenol and the X-ray crystal structures[4] of both the free receptor and its 2:1 adduct with $[Pt(NH_3)_4][PF_6]_2$.

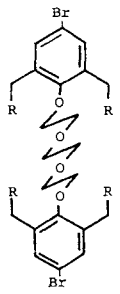
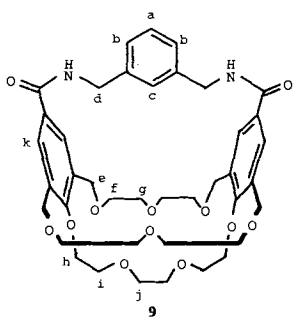
7, X = CO_2H
8, X = COCl



2, R = H
3, R = Br



9

The structure (Fig. 1, top) of **9**, when viewed from **A**[5] shows (Fig. 1, bottom) the existence of a shallow elongated cavity bounded at the bottom by the bisamide bridge, at the top by the three adjacently-located polyether chains and, on either side, by the two slightly inclined (33° between their mean planes) tetrasubstituted benzene rings (centroid-centroid distance, 4.9 Å). Of particular note is the directing of the two amide N–H bonds towards mouth **A** of the receptor cleft.

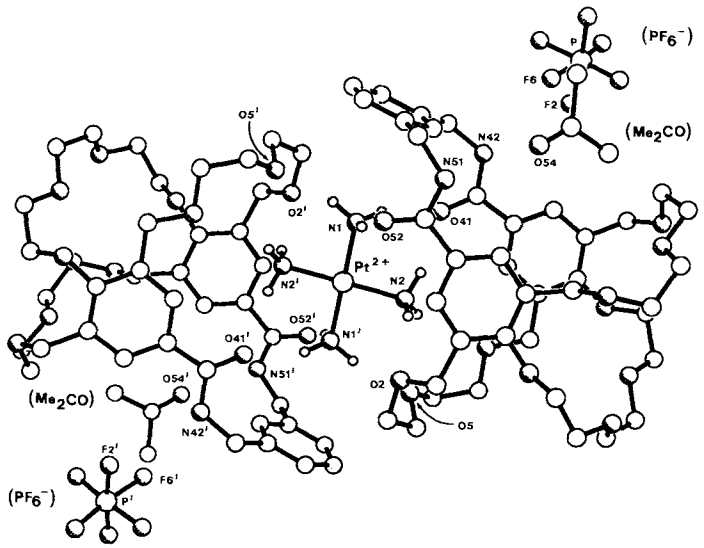

Fig. 2. Structure of $[Pt(NH_3)_4 \cdot (\mathbf{9})_2][PF_6]_2[Me_2CO]_2$ in the crystal. Distances for N1 to O5′, O41, and O52: 3.01, 2.90, and 2.90 Å, respectively. Those for N2 to O2, O5, and O41: 3.14, 3.08, and 3.18 Å, respectively. Contacts to $PF_6^{\ominus}$ and Me_2CO: N42···F2 3.20, N42···F6 3.29, N51···O54 2.83 Å.

Despite these favorable features, cisplatin is not solubilized[6] in halocarbon solvents containing **9**. On the other hand, $[Pt(NH_3)_4][PF_6]_2$ dissolves in $CH_2Cl_2/Me_2CO/MeOH$ (1 : 1 : 1, v/v) in the presence of 1 molar equivalent of **9**. However, a 2 : 1 crystalline adduct with m.p. 216–218 °C is formed[7] (see Fig. 2 for X-ray structure) as an acetone solvate[4] upon covering this solution with *n*-pentane. The reason for the formation of a 2 : 1 adduct can be rationalized by $[Pt(NH_3)_4]^{2\oplus}$ seeking a hydrogen bonding acceptor surface such as that provided by the two amide carbonyl oxygen atoms (O41 and O52) and two ethereal oxygen atoms (O2 and O5) which dominate the surface of the **B**-face. We surmise that this prevents[6] insertion of the tetraammine into the receptor cleft of **9** and so results in the approach of a second symmetry related receptor molecule. The **B** mouth is more open than in free **9**, the two tetrasubstituted benzene rings being nearly parallel (3° between their mean planes) with their centroid-centroid distance increased to 5.2 Å. The two N–H amide bonds emanating from N42 and N51 at the **A** mouth provide hydrogen bond donor sites for $PF_6^{\ominus}$ and Me_2CO, respectively.

Although we still have to improve[8] the design of **9** to induce it to form a 1 : 1 adduct with cisplatin, two novel features have emerged from this investigation: (i) the formation of a discrete adduct in which *two* receptor molecules serve simultaneously as outer sphere ligands for a transition metal complex, and (ii) the involvement of amide linkages in molecular receptors as hydrogen bond acceptors, pointing to a role for cyclic peptides as alternative second sphere coordinators to crown ethers.

[3] *Experimental:* Reaction (NaH, THF) of 4-bromo-2,6-dimethylphenol with triethylene glycol bistosylate afforded the acyclic polyether **2** (78%, m.p. 74.5–75.5 °C). Photochemical bromination (NBS, CCl_4) gave the hexabromide **3** (20%, m.p. 143.5–144.5 °C). Reaction (NaH, THF, high dil.) of **3** with diethylene glycol in the molar ratio 1 : 2 afforded **4** (20%, m.p. 126–127 °C). Treatment (CuCN, DMF) of **4** generated the dinitrile **5** (72%, m.p. 160–161 °C). Reaction (H_2O_2, KOH, EtOH, H_2O) of the dinitrile **5** yielded the diamide **6** (77%, m.p. 230–232 °C). Hydrolysis (KOH, EtOH, H_2O) of the amide functions in **6** produced the dicarboxylic acid **7** (99%, m.p. 213–214 °C). Reaction ($SOCl_2$, CH_2Cl_2) of **7** generated the diacid chloride **8**, which was allowed to react (Na_2CO_3, CH_2Cl_2, high dil.) *in situ* with *m*-xylylenediamine to afford the polycycle **9** [73%, m.p. 249–250 °C, single crystals suitable for an X-ray structure analysis from EtOH; ^{1}H-NMR (CD_2Cl_2): δ = 3.55–3.69 (8 H^f + 8 H^g, m), 3.70 (4 H^j, s), 3.78 (4 H^i, t), 4.06 (4 H^h, t), 4.25 and 4.66 (8 H^c, AB system), 4.54 (4 H^d, d), 6.57 (2 H, t, N*H*), 7.18–7.33 (H^a + 2 H^b + H^e, m), 7.57 (4 H^k, s)]. All new compounds gave satisfactory elemental analyses and spectroscopic data.

[4] Crystal data for **9**: monoclinic, a = 15.136(5), b = 16.032(5), c = 16.839(6) Å, β = 111.50(3)°, V = 3802 Å^3, space group, $P2_1/n$, Z = 4, ρ_{calc} = 1.31 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 7.6 cm^{-1}, 3285 independent observed reflections with [$|F_0| > 3\sigma(|F_0|)$, $\theta \leq 50°$], R = 0.090, R_w = 0.103. The high R factor is a consequence of severe disorder in one of the bridging polyether chains and in other portions of the molecule.—Crystal data for $[Pt(NH_3)_4 \cdot (\mathbf{9})_2][PF_6]_2[Me_2CO]_2$: triclinic, a = 12.218(2), b = 13.989(2), c = 16.133(3) Å, α = 69.82(1), β = 71.55(1), γ = 79.00(1)°, V = 2445 Å^3, space group $P\bar{1}$, Z = 1, ρ_{calc} = 1.47 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 39 cm^{-1}, 5017 independent observed reflections with [$|F_0| > 3\sigma(|F_0|)$, $\theta \leq 50°$], R = 0.033, R_w = 0.038. The NH_3 hydrogen atoms were obtained from a ΔF map and these groups were refined as rigid bodies. The $PF_6^{\ominus}$ ions are disordered. Data were measured on a Nicolet R3m diffractometer using the ω-scan routine with graphite-monochromated $Cu_{K\alpha}$ radiation. In the case of the free receptor **9** no absorption correction was applied. However, a numerical absorption correction for a face-indexed crystal was applied in the case of the adduct. The structure of the adduct was solved by the heavy atom method and that of the free receptor by direct methods. Both structures were refined anisotropically. Further details of the crystal structure investigations can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[5] Although there is the possibility of the existence of a similar cleft when **9** is viewed from **B** (Fig. 1, top), the inclination of the two tetrasubstituted benzene rings and their coplanar carbonyl substituents, together with the relative spatial disposition of the *meta*-disubstituted benzene ring within the bisamide chain, effectively bars the approach by substrates from this direction. The amide nitrogen atoms both form intermolecular hydrogen bonds, one (2.88 Å) to an amide carbonyl oxygen atom and the other (2.87 Å) to an ether oxygen atom.

[6] Although $[Rh(cod)(NH_3)_2][PF_6]$ (cod = 1,5-cyclooctadiene) dissolves in CD_2Cl_2 in the presence of equimolar amounts of **9**, the fact that there are no significant changes in the ^{1}H-NMR chemical shifts of the resonances for the complex or receptor protons indicates that the rhodium complex does not enter the receptor cleft: however, steric factors could be responsible for this observation. Addition of an equimolar amount of $[Pt(NH_3)_4][PF_6]_2$ to **9** dissolved in either CD_2Cl_2 or CD_3COCD_3 gives rise to only small (i.e. $< +0.1$ ppm) ^{1}H-NMR chemical shift changes to higher frequencies of the resonances for the aromatic protons (H^a/H^b/H^c/H^k). These results are in contrast with the considerably larger ^{1}H-NMR chemical shift changes (+0.23 and +0.26 ppm) observed (D. R. Alston, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, R. Zarzycki, *Angew. Chem.* 99 (1987) 698; *Angew. Chem. Int. Ed. Engl.* 26 (1987) 693) on addition of an equimolar amount of $[Pt(NH_3)_4][PF_6]_2$ to a solution of **1** in CD_3COCD_3.

[7] There is a crystallographic center of symmetry at the center of the 2 : 1 adduct which is coincident with the platinum atom of $[Pt(NH_3)_4]^{2\oplus}$.

[8] To date, all attempts to reduce the two –CONH– groups in **9** to $-CH_2NH-$ units have been unsuccessful.

Macrobicyclic Polyethers as Second Sphere Ligands for Tetraammineplatinum(II)**
